Location. Most osteosarcomas arising de novo arise in the metaphyseal area of long bones, particularly the distal femur, the proximal tibia, and the proximal humerus. A few cases arise in the diaphyses and an even smaller number in the epiphyses. Less commonly, osteosarcomas are found in flat bones (such as craniofacial bones, pelvis, and scapula),[121] spine,[122] and short tubular bones.[123] Occasionally, osteosarcomas are multicentric, in either a synchronous or a metachronous fashion: most of these multicentric cases occur in children and tend to be densely sclerotic radiographically and extremely aggressive.[124,125]

Radiographic features. Conventional osteosarcoma causes destruction of both the medullary cavity and cortical bone, often resulting in an aggressive pattern of periosteal reaction, such as a

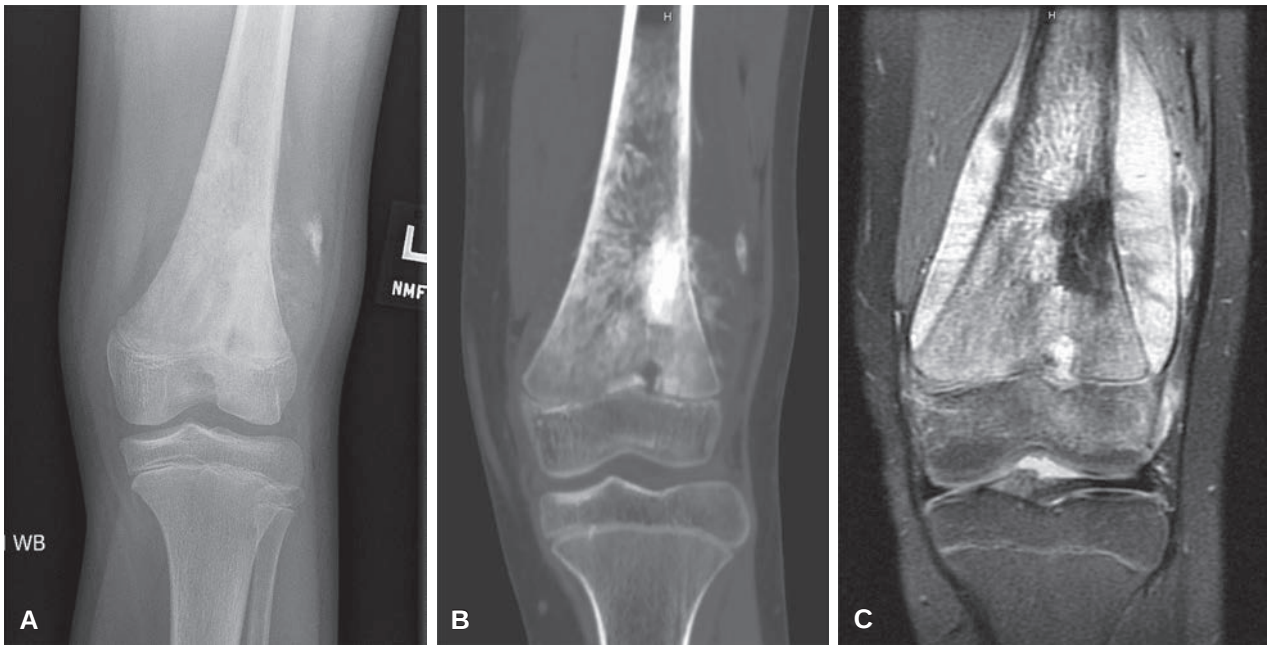

Figure 40.15 Radiographic Features of Conventional Osteosarcoma of the Distal Femur. A, Radiograph, **B,** coronal CT, and **C,** coronal MRI show a highly destructive bone-forming mass arising in the metaphysis and involving adjacent soft tissue.

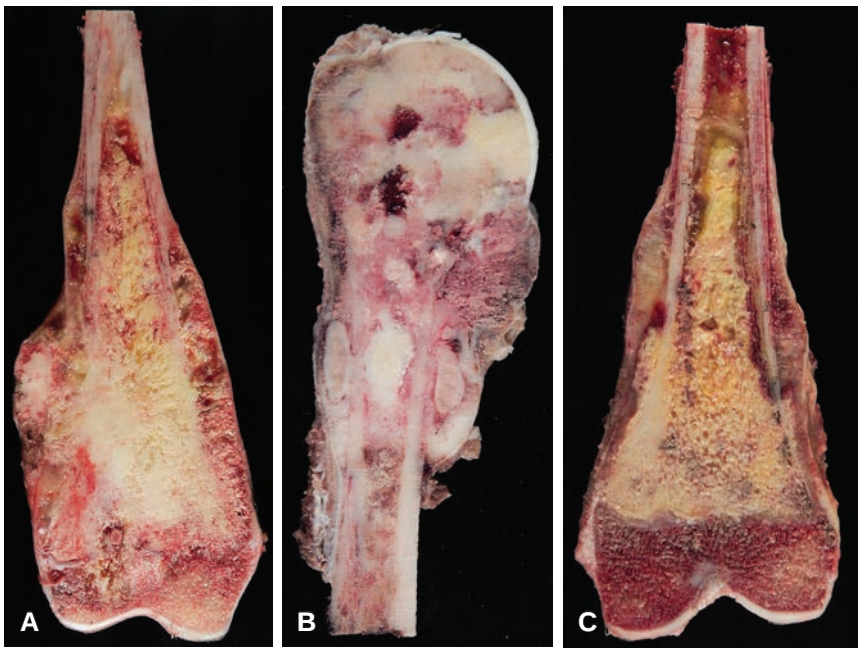

Figure 40.16 Gross appearance of osteosarcoma of the **A,** distal femur, **B,** proximal humerus, and **C,** distal femur. All three lesions extend into soft tissue and cause elevation of the periosteum.

Codman triangle or a sunburst appearance (Fig. 40.15). The degree and appearance of the mineralization within the tumor depends on the histologic subtype of osteosarcoma and the amount of matrix produced; however, most tumors contain a mixture of radiolucent and matrix-forming foci.[126] MRI is an excellent modality for determining the extent of the tumor in the medullary cavity and soft tissue, and is the study of choice for surgical planning.[127]

Gross appearance and spread. The gross appearance of the cut surface of an osteosarcoma is highly variable, depending on the histologic subtype and response to neoadjuvant chemotherapy (Fig. 40.16). The range extends from bony hard to cystic, friable, and hemorrhagic.

Osteosarcomas typically arise in the metaphysis and spread longitudinally in the medullary cavity. While the growth plate often acts as a barrier to tumor spread, occasionally osteosarcomas breach the physis and extend into the epiphysis.[128] They invade through the cortex by either directly destroying cortical bone or by invading through the vascular channels in the cortex. When the overlying

periosteum becomes irritated, it responds by forming reactive bone, or a periosteal reaction. This typically results in the formation of a Codman triangle, a "hair-on-end" or "sunburst" appearance, or less commonly a lamellated appearance, all of which are visible grossly. The bone underneath a Codman triangle is reactive and does not contain tumor. Osteosarcomas may also extend through the periosteum and into adjacent soft tissues, a feature sometimes seen in the setting of a suboptimal response to chemotherapy. Finally, on rare occasions osteosarcomas may involve the joint or extend across the joint via ligamentous connections such as the anterior cruciate ligament.[129]

Discontinuous foci of tumor within the same bone are defined as a "satellite lesion" when the separate focus occurs within reactive changes around the main mass, and a "skip metastasis" when it occurs outside reactive changes in normal bone and hematopoietic marrow.[130,131] The prognosis for patients with skip metastases is poor.

Osteosarcomas metastasize through the bloodstream to distant sites, particularly the lung, but they may also metastasize to other bones, the pleura, or other visceral sites. Metastases to regional lymph nodes are extremely uncommon.

Microscopic features. Microscopically, osteosarcoma is defined by the direct production of immature bone or osteoid by neoplastic cells. The most common histologic subtypes of conventional osteosarcoma are osteoblastic, chondroblastic, and fibroblastic, and less common subtypes include giant cell-rich, osteoblastoma-like, epithelioid, clear cell, and chondroblastoma-like.[76] In each of the various subtypes of osteosarcoma, osteoid may be abundant, as in the case of an osteoblastic osteosarcoma, or focal, which is often the case in fibroblastic osteosarcoma. The pattern of osteoid deposition is highly variable, ranging from fine to extremely dense, or "sclerosing."[132] Osteoid is recognized by its glassy, eosinophilic appearance following decalcification and may be difficult to distinguish from hyalinized collagen. A homogeneous rather than fibrillary appearance, punctate calcification, and a plump appearance of the cells around it are more in keeping with osteoid. The SATB2 immunostain can also be useful in this setting.[6] Occasionally the tumor osteoid appears as thin, tubular, anastomosing "microtrabeculae," which are very basophilic and vaguely reminiscent of the appearance of fungal hyphae (Fig. 40.17).

Conventional osteosarcomas are often composed of a mixture of osteoblastic, fibroblastic, and chondroblastic foci, the relative proportions among these three components varying a great deal from case to case. While the predominant component determines which histologic subtype is diagnosed, there is no prognostic significance to this division. The important fact to remember is that a malignant bone tumor should be designated as osteosarcoma whenever osteoid is formed directly by the tumor cells regardless of the predominate stromal cell type.

Morphologic variations in conventional osteosarcoma are plentiful.[133,134] The osteoid may be sparse or massive, surrounded by pleomorphic, bizarre cells, or relatively acellular and surrounded by tumor cells in a rosettelike configuration (the latter allegedly being a more aggressive variant).[135] The tumor cells may grow in diffuse, nested, or pseudopapillary arrangements. The vessels may be scanty or numerous, sometimes with a dilated or hemangiopericytomatous appearance. The tumor cells may be spindled, oval, or round, and their size may range from small to giant; exceptionally, they have a distinctly epithelial-like appearance.[136,137] Osteoclast-like multinucleated giant cells are present in many cases and may be so numerous as to simulate a giant cell tumor (so-called giant cell-rich osteosarcoma); the cartilage may be immature, mineralized, or highly myxoid. In the latter instance, the tumor may simulate a chondromyxoid fibroma.[138]

Depending on which one of the previously mentioned microscopic patterns happens to be present, the differential diagnosis of osteosarcoma may include a remarkably high number of benign and malignant lesions, such as fracture callus, fibrous dysplasia, osteoblastoma, "fibrosarcoma," chondrosarcoma, giant cell tumor, or even metastatic carcinoma. Exuberant fracture callus is particularly likely to be misdiagnosed as osteosarcoma by the unwary, with disastrous consequences for the patient. This callus may be secondary to a pathologic fracture in a benign lesion (such as a metaphyseal fibrous defect or aneurysmal bone cyst), in a metastatic carcinoma, or in osteogenesis imperfecta (where it may be particularly exuberant).[139,140] Other entities that need to be considered in the differential diagnosis are discussed in connection with the osteosarcoma variants described in the following section.

Histochemical and immunohistochemical features. Osteosarcoma cells usually exhibit strong alkaline phosphatase activity, regardless of their appearance (osteoblastic or other), but the use of histochemistry to detect alkaline phosphatase as a diagnostic tool is highly nonspecific. Likewise, immunohistochemistry has proven to be of limited value in the diagnosis of osteosarcoma due to lack of specificity; however, SATB2 may be useful in establishing osteoblastic lineage in osteosarcoma.[6] An important pitfall in the diagnosis of osteosarcoma is cytokeratin expression.[141]

Molecular genetic features. Osteosarcoma typically shows complex karyotypes, with structural alterations (including translocations) and numerical alterations (gain and loss) involving multiple chromosomes.[142,143] At the molecular level, alterations of both the *TP53* gene and retinoblastoma gene pathways are found in many cases, not unexpectedly since germline mutations in these genes are known to predispose to development of osteosarcoma.[144] The *TP53* pathway is altered through loss-of-function mutation in *TP53* (50%) and *MDM2* amplification (14%–27%).[145] Alterations in other cell cycle genes, such as *CDK4* and *CDKN2A*, are also detected in some osteosarcomas.[146] Deletions and amplifications of chromosomes 3, 6, and 8 result in gene alterations that may have prognostic significance, including *LSAMP*, *RUNX2*, and *MYC*.[76]

Microscopic variants and special types. In addition to conventional osteosarcoma, the WHO also recognizes other specific variants with characteristics that justify their own category.[76] Many of these osteosarcoma variants simulate other bone processes radiographically and microscopically, and some of them carry distinctive prognostic connotations.

Telangiectatic osteosarcoma. This variant has low-magnification architectural features resulting in an appearance similar to that of aneurysmal bone cyst radiographically and pathologically. Pathologic fractures are very frequent.[147] Telangiectatic osteosarcoma is characterized histologically by numerous blood-filled spaces separated by septa containing highly pleomorphic mononuclear and multinucleated giant cells accompanied by abundant mitotic activity (Fig. 40.18).[148] Telangiectatic osteosarcoma is treated with the same neoadjuvant chemotherapy and surgery as other high-grade osteosarcomas and appears to have a similar prognosis as other conventional osteosarcomas.[149]

Small cell osteosarcoma. This rare variant of osteosarcoma is composed of small, uniform, round or spindled cells closely simulating the appearance of Ewing sarcoma and malignant lymphoma.[150,151] The identification of osteoid and the exclusion of other round cell neoplasms with immunohistochemistry or molecular diagnostic testing is necessary for diagnosis. Small cell osteosarcomas are immunoreactive for SATB2 but negative for CD99. Furthermore, small cell osteosarcomas lack any of the Ewing or Ewing-like sarcoma gene fusions.[152] Nevertheless, care must be taken to distinguish this lesion from Ewing sarcoma or related lesions, lymphoma, and mesenchymal chondrosarcoma.

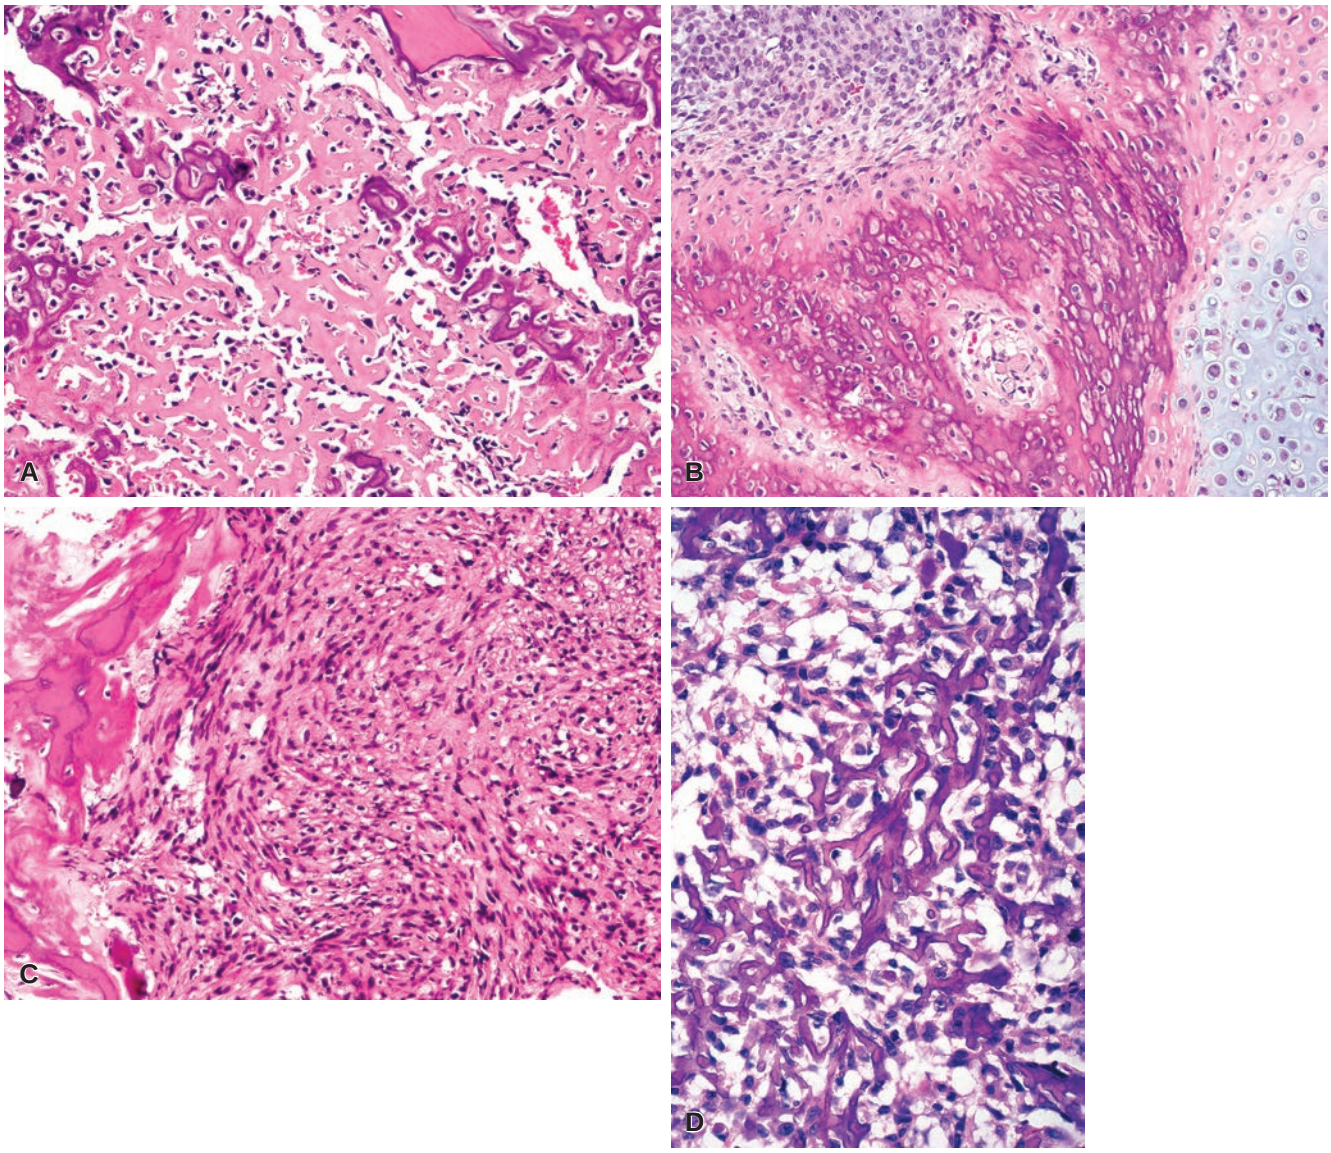

Figure 40.17 Main Histologic Variants of Conventional Osteosarcoma. A, Osteoblastic osteosarcoma. **B**, Chondroblastic osteosarcoma. **C,** High-grade fibroblastic osteosarcoma. In each instance, osteoid deposition is identified. **D,** Microscopic appearance of osteosarcoma showing characteristic basophilic osteoid with an appearance that is reminiscent of fungal hyphae.

Low-grade central osteosarcoma (Fig. 40.19). This osteosarcoma variant is historically difficult to recognize because of its deceptively bland microscopic appearance and is often underdiagnosed as a benign lesion such as fibrous dysplasia or desmoplastic fibroma. It closely resembles parosteal osteosarcoma.[153] Most patients are adults, and the femur and tibia are the most commonly involved sites; however, other sites, such as the gnathic bones, may be involved. Histologically, low-grade central osteosarcoma is a fibroblastic osteosarcoma with minimal cytologic atypia and minimal mitotic activity. The bone within the lesion may resemble fibrous dysplasia or have a Pagetic appearance. Recurrences are common with inadequate treatment, but metastases are very rare unless the tumor "dedifferentiates."[154,155] In contrast to fibrous dysplasia, this tumor shows radiographic evidence of cortical destruction.[154] This feature and the infiltrative growth pattern are helpful in distinguishing this tumor from fibrous dysplasia.

The *GNAS1* gene mutation consistently found in fibrous dysplasia is generally absent in low-grade central osteosarcoma, pointing to a different pathogenesis for each of the two processes and providing a tool for their differential diagnosis.[156,157] Low-grade central osteosarcomas frequently show gain or amplification of *MDM2* and12q13-15.[158] Gene amplification can be detected by molecular diagnostic techniques, or MDM2 or CDK4 protein can be detected by immunohistochemistry if only decalcified tissue is available.[159,160]

Other variants of osteosarcoma are defined on the basis of topographic, clinical, or radiographic features or a combination of them:

Parosteal osteosarcoma. This is the most common surface variant of osteosarcoma. It occurs in a slightly older age group than the

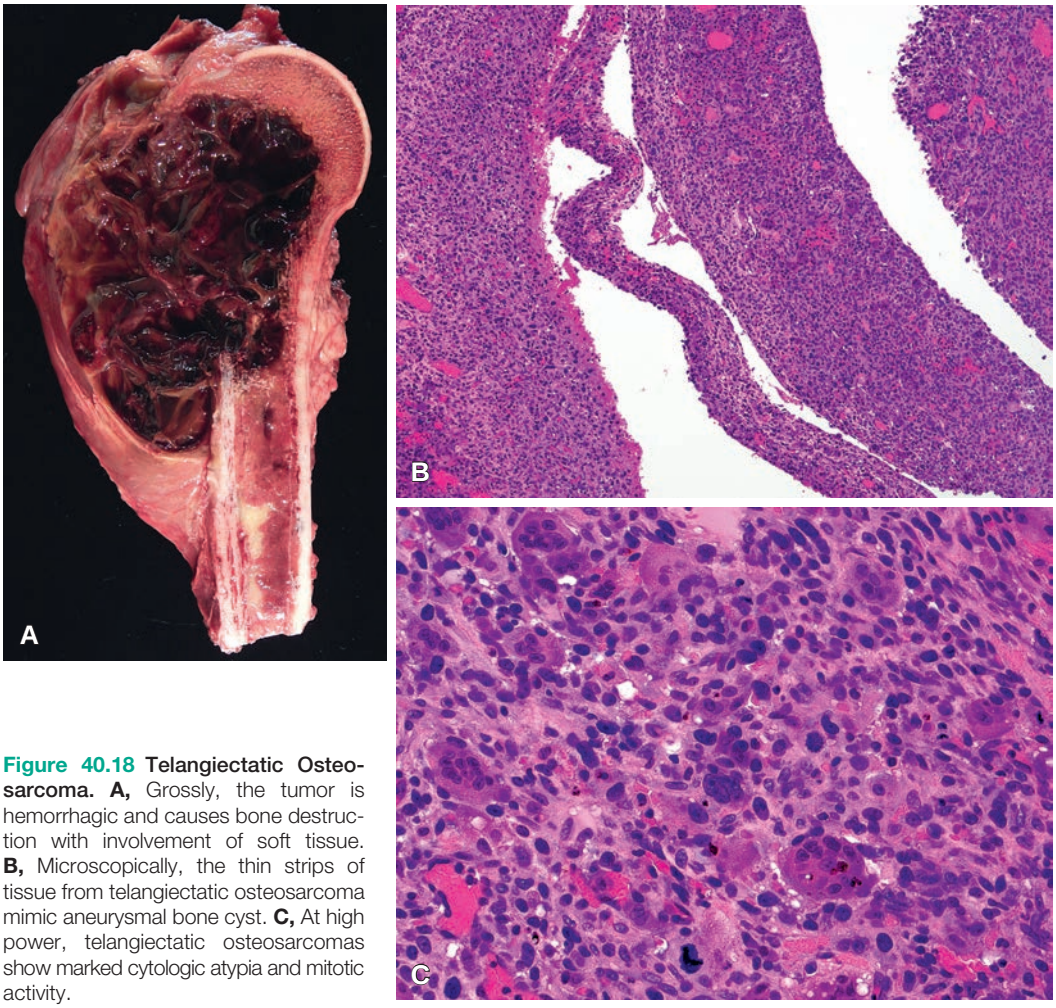

Figure 40.18 Telangiectatic Osteosarcoma. A, Grossly, the tumor is hemorrhagic and causes bone destruction with involvement of soft tissue. **B,** Microscopically, the thin strips of tissue from telangiectatic osteosarcoma mimic aneurysmal bone cyst. **C,** At high power, telangiectatic osteosarcomas show marked cytologic atypia and mitotic activity.

conventional variety.[161] It usually arises from the metaphyseal surface of long bones (usually the posterior aspect of the distal femur) and grows very slowly. Eventually, it forms a large lobulated mass with a tendency to encircle the bone (Fig. 40.20) and may penetrate into the medullary cavity, a feature sometimes associated with dedifferentitation.[162] Satellite nodules may be present. Rare cases have been described at other sites, such as the craniofacial bones. The radiographic appearance is highly characteristic.[163]

Microscopically, parosteal osteosarcoma closely resembles low-grade central osteosarcoma and is composed of bland fibrous stroma containing disorganized, immature bone (Fig. 40.21). Cartilage may be present on the periphery of the tumor or embedded deep within it. The cytologic signs of malignancy in the fibrous stroma are often subtle, thus accounting for the great frequency of misdiagnoses made in this tumor. Parosteal osteosarcomas are characterized genetically by supernumerary ring chromosomes which contain amplified material from 12q13-15, corresponding to the *CDK4* and *MDM2* genes, among others. The evaluation of these gene amplifications or detection of their protein products by immunohistochemistry may be useful in distinguishing parosteal osteosarcoma from benign mimics.[159,164]

The prognosis for parosteal osteosarcoma is very good, even with segmental excision. It should be emphasized that not all osteosarcomas originating from the bone surface belong to this variety. Those having morphologic features equivalent to those of the conventional intramedullary osteosarcoma are referred to as *high-grade surface*

Figure 40.20 Parosteal Osteosarcoma. A, On lateral plain radiograph and **B,** lateral CT scan, a lobulated, dense mass arises from the surface of the posterior femoral metaphysis and encompasses the bone. **C,** The gross appearance of the lesion closely reflects its radiographic features.

osteosarcomas and behave as aggressively as the former.[165,166] Sometimes, features of high-grade osteosarcoma are seen focally in what is otherwise a typical parosteal osteosarcoma, either initially or—more commonly—following repeated tumor recurrences; this phenomenon, which is referred to as "dedifferentiation," is associated with a markedly decreased survival rate.[161,167,168]

Periosteal osteosarcoma. This variant of osteosarcoma, which is very different from parosteal osteosarcoma despite the similarities in the nomenclature, also arises from the surface of long bones.[169] Most of the reported cases have been located in the tibial or femoral diaphysis and have presented as small lenticular lesions on the bone surface accompanied by reactive bone arranged perpendicular to the surface. The lesions are limited to the cortex and only rarely invade the medullary cavity (Fig. 40.22).[170,171] Microscopically, periosteal osteosarcomas are largely chondroblastic in appearance. The prognosis is better than for conventional osteosarcoma.[169]

Osteosarcoma of the jaw. Although not technically recognized as an entity in the WHO classification of osteosarcomas, gnathic osteosarcoma is distinctive enough to be discussed individually.[172] Patients affected are slightly older (average age, 34 years), and most lesions show a prominent chondroblastic component (Fig. 40.23). The most common sites of involvement are the body of the mandible

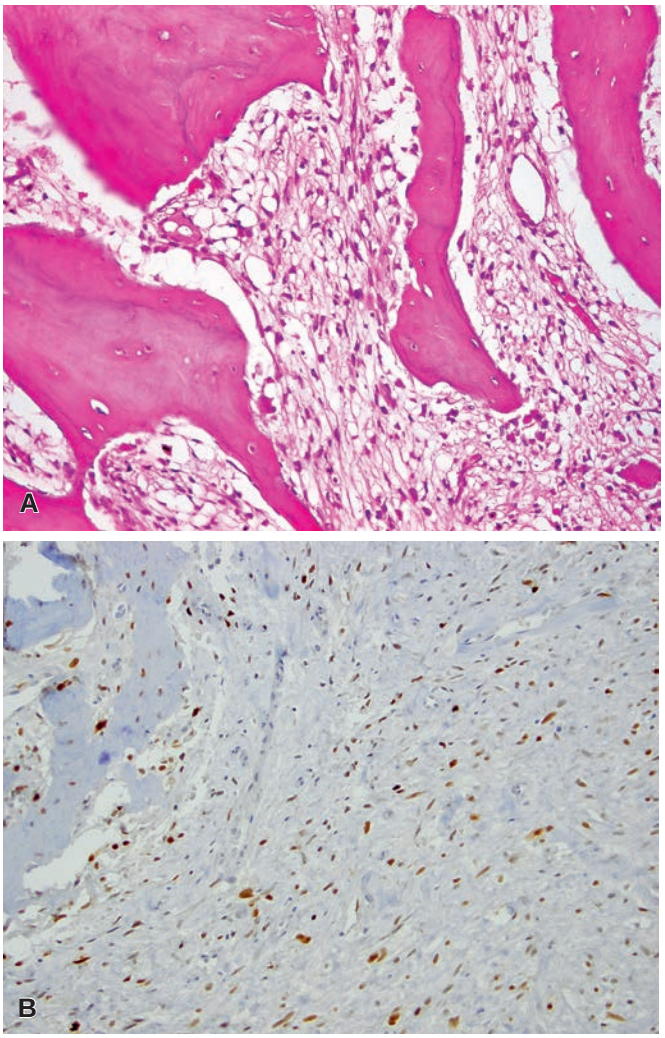

Figure 40.21 Parosteal Osteosarcoma. A, Mildly atypical spindle cells grow between irregularly shaped woven bone trabeculae. **B,** An immunostain for MDM2 is positive in the majority of the spindled cells in parosteal osteosarcoma.

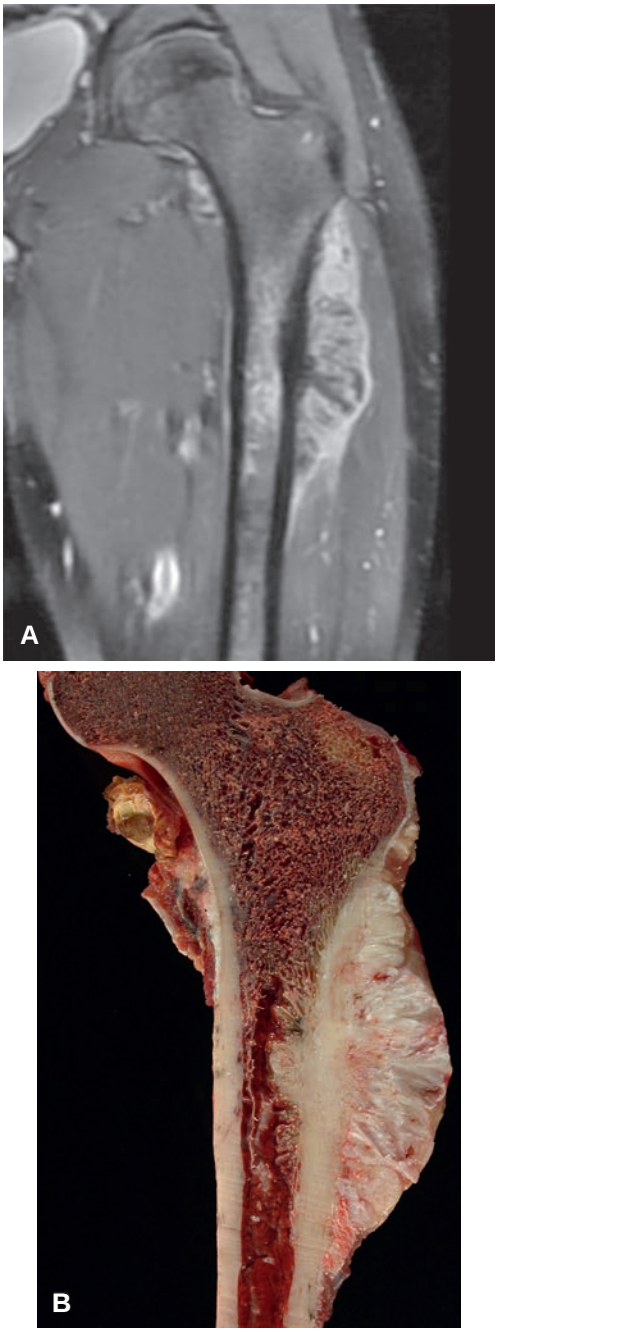

Figure 40.22 A, MRI and **B,** gross features of periosteal osteosarcoma. The lesion arises from the surface of the proximal femoral metadiaphysis, and the cut surface is cartilaginous and contains reactive bone oriented perpendicular to the femoral surface.

and the alveolar ridge of the maxilla. The prognosis is relatively good.

Osteosarcoma in Paget disease. Most cases of Paget osteosarcoma arise in the setting of polyostotic Paget disease. The most common locations are the pelvis, humerus, femur, tibia, and skull.[173–175] Their prognosis is extremely poor.

Therapy. Formerly, the therapy for osteosarcoma of the extremities typically consisted of amputation or disarticulation, depending on the location of the tumor, and overall survival was less than 20%. Current treatment protocols include neoadjuvant chemotherapy, followed by limb salvage surgery when feasible, and further chemotherapy following resection.

Microscopic studies of the tumor successfully treated with chemotherapy show extensive areas of necrosis and hemorrhage[176]; sites where viable tumor is more likely to persist are the soft tissue, adjacent to the cortex, and adjacent to the growth plate (Fig. 40.24).[177] The presence of extensive tumor necrosis following chemotherapy constitutes a good prognostic sign[178,179] (see next section).

Prognosis. The overall prognosis for osteosarcoma has significantly improved. For many years, the 5-year survival rate fluctuated very little from the figure of 20% in most series. Recently, many reports listing 5-year disease-free rates of 60% or better have appeared.[180] The routine use of multiagent neoadjuvant chemotherapy has had a dramatic positive effect on prognosis; patients with greater than 90% necrosis following chemotherapy generally have a better prognosis than those with less than 90% necrosis.[181]

A variety of other factors, including age, tumor size, stage, location, and surgical margins, have been examined with respect to prognosis.[178,182,183] However, the plateau in prognosis has led investigators to look beyond clinical parameters in the hope of discovering

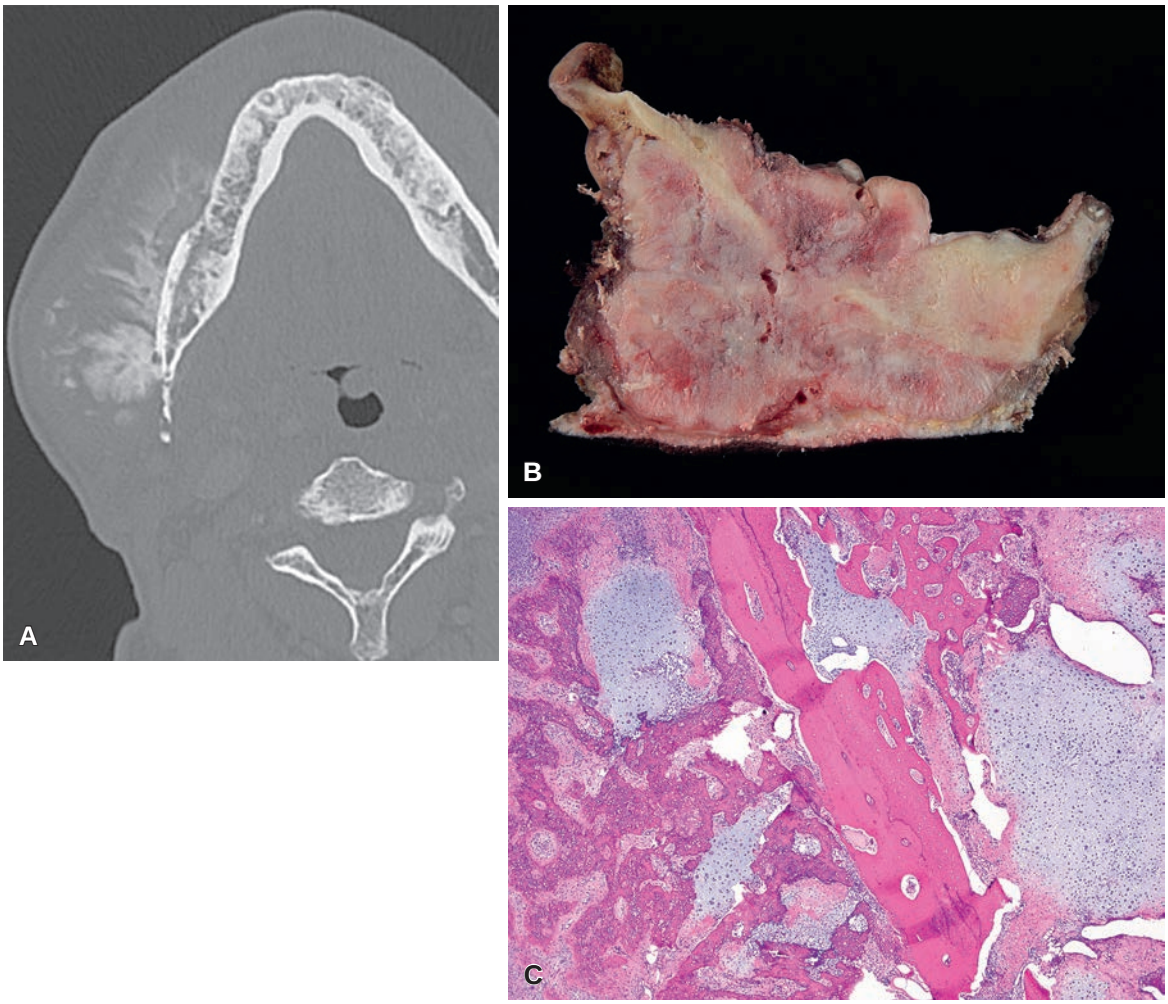

Figure 40.23 **A,** CT and **B,** gross features of osteosarcoma of the jaw. **C,** Most gnathic osteosarcomas are of the chondroblastic variety.

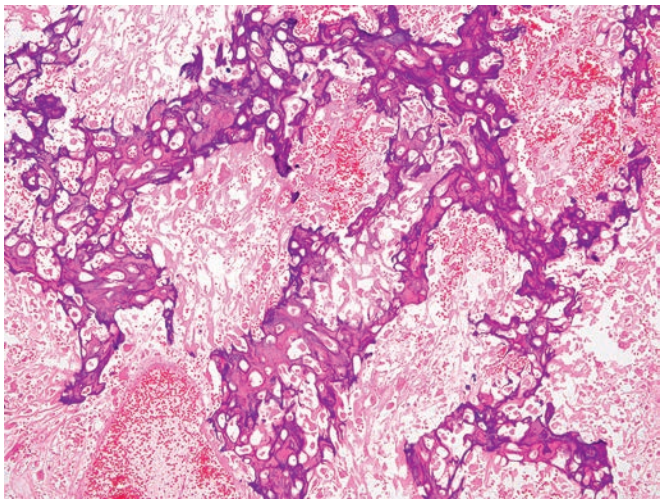

Figure 40.24 When treated with neoadjuvant chemotherapy, susceptible osteosarcomas show dropout of viable tumor cells ("necrosis"), but the osteoid matrix persists.

improved treatment regimens. Historically, the significance of P-glycoprotein and HER2/neu expression was heavily studied but highly controversial.[184–186] More recently, expression of p16, the product of the *CDKN2A* gene, has been shown to correlate with response to chemotherapy and outcome in high-grade localized osteosarcoma.[187–189]

Cartilage-Forming Tumors

Enchondroma

Enchondromas are relatively common neoplasms that occur over a wide age range. The most common site of origin is the small bones of the hands and feet, and enchondromas are extremely uncommon in flat bones. Enchondromas are non-growing lesions that are asymptomatic and often discovered incidentally during the work-up of other conditions such as arthritis, internal derangement of the knee, rotator cuff tears, or in the evaluation of a patient for metastatic disease.[190]

Enchondromas are composed of lobules of hyaline cartilage, often separated by normal cancellous bone or marrow. The lobules are often bounded by bone (so-called encasement pattern), and endochondral ossification may be present at the periphery of individual lobules (Fig. 40.25). Enchondromas lack invasive properties, differentiating them from low-grade chondrosarcomas.

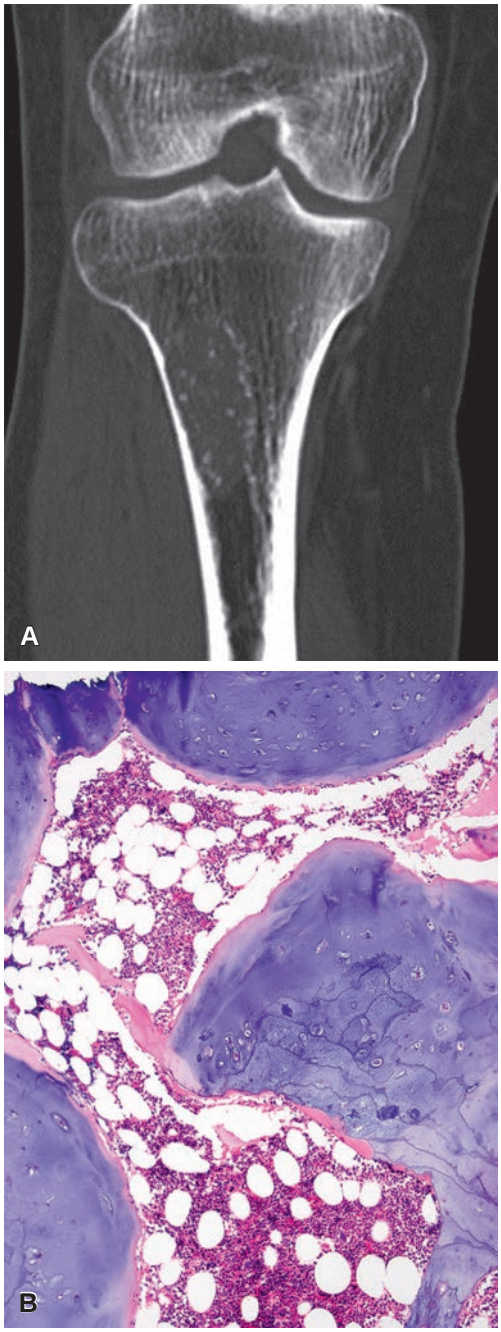

Figure 40.25 **A,** Coronal-plane CT shows a circumscribed metaphyseal enchondroma with stippled calcifications. **B,** Histologically, enchondromas are composed of lobules of mature hyaline cartilage which are partially or complete encompassed by bone.

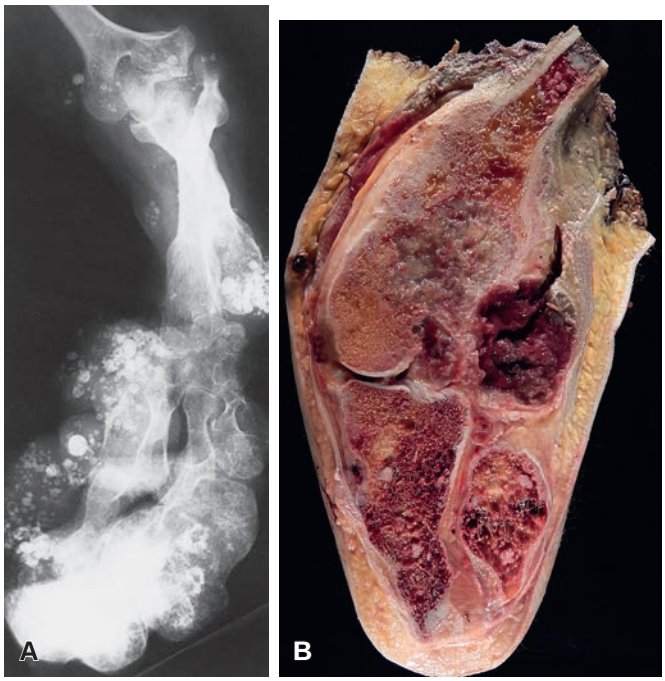

Figure 40.26 **A,** Arm of a patient affected by Maffucci syndrome. Innumerable chondromas are seen concentrated in the distal aspect of the extremity, and calcified phleboliths indicate hemangiomas in the soft tissue. **B,** Above-knee amputation specimen from a patient with Maffucci syndrome who developed a chondrosarcoma of the distal femur. Nodules of enchondroma can also be seen in the tibial and fibular stumps.

Cytologically, there is significant overlap between enchondromas and low-grade chondrosarcomas, and high-magnification evaluation cannot reliably separate these two entities. Nonetheless, most enchondromas are paucicellular and contain small, pyknotic chondrocyte nuclei. Lesions arising in the small bones of the hands and feet, those occurring in the setting of enchondromatosis, and those in children may appear somewhat more cellular.[191]

The differentiation of enchondroma from low-grade chondrosarcoma cannot be reliably achieved without radiographic (and clinical) correlation. Enchondromas are typically radiolucent with areas of mineralization that vary from punctate to ring-like. Endosteal scalloping may be seen with both enchondromas and low-grade chondrosarcomas (see later); however, endosteal scalloping associated with cortical thickening is an ominous feature. The most important radiographic features of enchondromas are those that are not present, including extensive bone destruction, cortical destruction, periosteal reaction, and the formation of a soft tissue mass.[191–194] It is important to understand that the radiographic features that help distinguish enchondromas from low-grade chondrosarcomas in the long bones are not applicable to lesions in the small bones of the hands and feet, in the setting of enchondromatosis, or in skeletally immature patients.

Enchondromas of long bones may be managed by observation alone, whereas those in the hands or feet may require curettage. Biopsy of well-differentiated cartilage tumors is of limited utility, and sampling issues often preclude reliably distinguishing enchondromas and low-grade chondrosarcomas. It should be emphasized that radiographic and clinical features are extremely valuable in separating enchondroma from low-grade chondrosarcoma.

Multiple enchondromas having a predominantly unilateral distribution are referred to as *Ollier disease*. The association of multiple enchondromas with soft tissue hemangiomas (including spindle cell hemangiomas) is known as *Maffucci syndrome* (Fig. 40.26).[195,196] In both of these nonheritable conditions, there is a significant risk of malignant transformation, usually in the form of chondrosarcoma.[197–200]

Periosteal (juxtacortical) chondromas are much less common than enchondromas. They arise from the periosteal region of a long bone, often the humerus, or a small bone of the hand or foot.[201,202] They characteristically erode and induce reactive changes in the underlying cortex. Radiographically, periosteal chondromas are small,

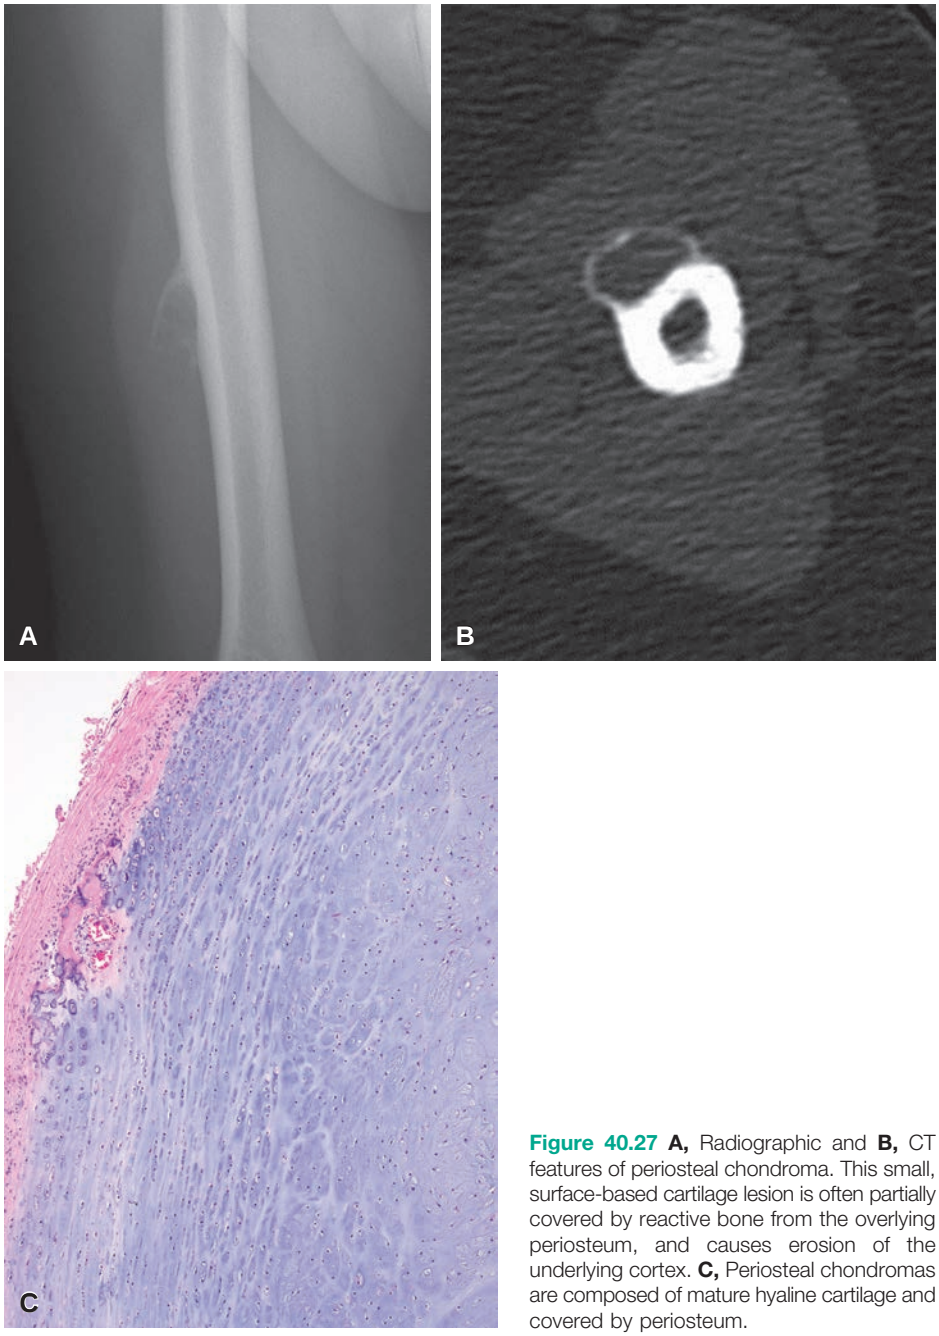

Figure 40.27 **A,** Radiographic and **B,** CT features of periosteal chondroma. This small, surface-based cartilage lesion is often partially covered by reactive bone from the overlying periosteum, and causes erosion of the underlying cortex. **C,** Periosteal chondromas are composed of mature hyaline cartilage and covered by periosteum.

circumscribed surface lesions that scallop the underlying cortex and are often accompanied by a buttress of reactive bone at the advancing edges of the lesion.[203]

Microscopically, periosteal chondroma tends to be more cellular than its medullary counterpart and may contain mild atypia (Fig. 40.27).[201]

Solitary enchondromas, periosteal chondromas, and the enchondromas of Ollier and Maffucci syndrome have heterozygous mutations in the *IDH1*/*IDH2* genes.[204]

Although not strictly a chondroma, the peculiar chest wall lesion of infancy known as **vascular and cartilaginous hamartoma (chest wall hamartoma, mesenchymal hamartoma)** is discussed here because of its benign nature and predominant cartilaginous composition.[205,206] These chondroid areas, which often exhibit endochondral ossification, are mixed with spindled cells forming vascular channels, hemangioma-like foci, and aneurysmal bone cyst-like foci. Most of the cases are already present at birth, and the behavior is benign.

Osteochondroma and Related Lesions

Osteochondroma is one of the most frequently encountered benign bone tumors in surgical pathology. The average age of the patient at onset is approximately 10 years; in the large majority of the cases, the tumor appears before the patient is 20 years old. It is usually asymptomatic, but it may become symptomatic if the stalk fractures, an overlying bursa develops, or if the mass impinges on adjacent neurovascular structures.[207] The most common locations are the metaphyses of the distal femur, proximal tibia, proximal humerus, and pelvis.

Radiographically, osteochondromas have a very characteristic appearance. These exophytic osteocartilaginous lesions can be

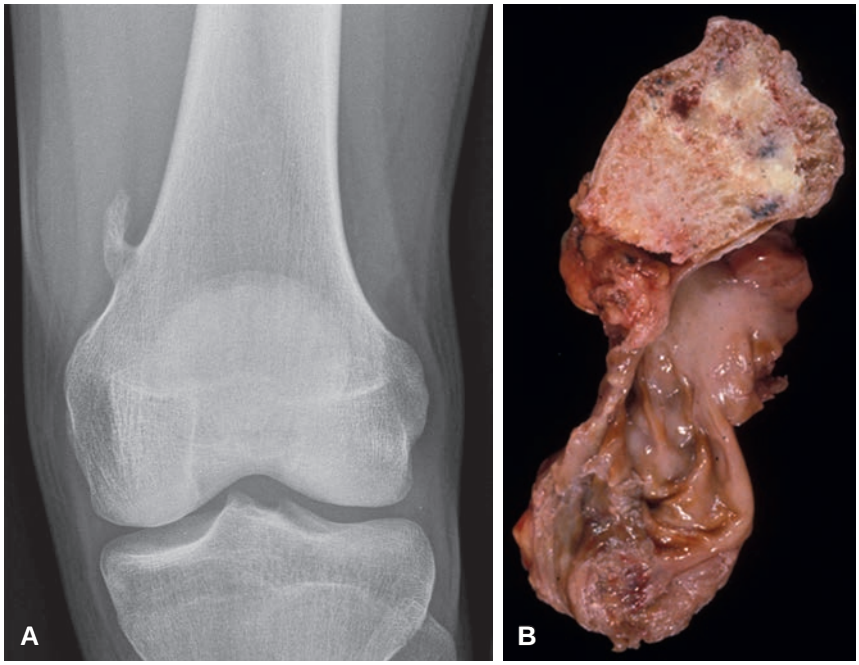

Figure 40.28 **A,** Radiograph showing a pedunculated osteochondroma arising from the distal femoral metaphysis and pointing away from the knee joint. **B,** Grossly, this osteochondroma was covered by only a thin cartilage cap and was complicated by the formation of a bursa.

pedunculated (with a thin stalk) or sessile (with a broad base). The cortical and medullary portions of the osteochondroma stalk merge with the same structures in the underlying bone (Fig. 40.28). These features are easily demonstrated on computed tomography (CT). The cartilage cap of the osteochondroma, best assessed with MRI, seldom exceeds 1 cm, is typically thinner than that, and diminishes as the patient's skeleton matures.[208]

Grossly, the surface of an osteochondroma is covered by a thin layer of fibrous tissue that represents a continuation of the periosteum. The measurable hyaline cartilage cap ranges from a few millimeters to a centimeter in thickness and is often thicker in skeletally immature patients. The surface may appear bosselated in larger sessile osteochondromas. The junction of the cartilage cap and underlying stalk contains calcified cartilage, and the stalk itself is composed of cortical and cancellous bone.

Microscopically, the cartilage cap is composed of hyaline cartilage, and endochondral ossification is evident at the junction of the cap and underlying stalk. The stalk is composed of cortical and cancellous bone (Fig. 40.29). The cap of the osteochondroma actively proliferates until the patient reaches skeletal maturity. In older patients, an osteochondroma may lack a cartilage cap altogether. A bursa may develop around the head of a longstanding osteochondroma; in turn, this bursa may develop complications such as osteocartilaginous loose bodies or synovial (bursal) chondromatosis.

Multiple hereditary exostoses (MHE) is an autosomal dominant condition characterized by multiple osteochondromas that are identical to sporadic osteochondromas. Because there is variable penetrance and expression in this disorder, the number of osteochondromas may vary considerably. In addition to multiple osteochondromas, patients often have modeling defects at the ends of bones and other bone deformities.

MHE is caused by germline mutation in the *EXT1* (at 8q24) or *EXT2* (at 11p11–12) genes.[209] These genes have been implicated in the formation of both sporadic and hereditary osteochondromas; defects in *EXT1* are roughly twice as common as defects in *EXT2*.[210–212]

Secondary chondrosarcomas arise in a very small proportion of solitary osteochondromas, but the incidence reaches 10% in the patients with MHE. The cells in secondary chondrosarcoma are frequently wild type for *EXT* genes, suggesting that separate genetic alterations are responsible for the malignant conversion.[213–216]

Osteochondroma should be distinguished from the **bizarre parosteal osteochondromatous proliferation (Nora lesion)**, which usually involves the small bones of the hands and feet[217,218] and occasionally in other long and flat bones.[219,220] These lesions are radiographically distinctive but can simulate chondrosarcoma microscopically because of the presence of enlarged, bizarre, and binucleated chondrocytes.[218,221] Recurrent chromosomal alterations have been found, suggesting that this condition is of neoplastic nature.[222]

Subungual exostosis (Dupuytren exostosis) is an osteochondroma-like lesion involving the distal phalanx, most commonly located on the great toe. This lesion is histologically similar to bizarre parosteal osteochondromatous proliferation and contains a proliferating cartilaginous cap that merges into relatively mature cancellous bone at its base. These exostoses may recur but are invariably benign.[223,224] Similar to bizarre parosteal osteochondromatous proliferation, cytogenetic studies have demonstrated a recurrent t(X;6), suggesting this is likely a neoplastic process.[225–227]

Dysplasia epiphysealis hemimelica (Trevor disease), a rare developmental disorder of childhood characterized by asymmetric enlargement of the epiphyseal cartilage of long bones, is yet another condition that can mimic osteochondroma.[228]

Osteochondromyxoma is a rare recently described congenital neoplasm associated with lentigines and other extraskeletal disorders; the syndrome seems to represent a variation of the Carney complex.[229]

Chondroblastoma

Chondroblastoma occurs predominantly in skeletally immature patients under 20 years of age and can be quite painful.[230] It usually arises in the epiphysis or apophysis of long bones prior to skeletal

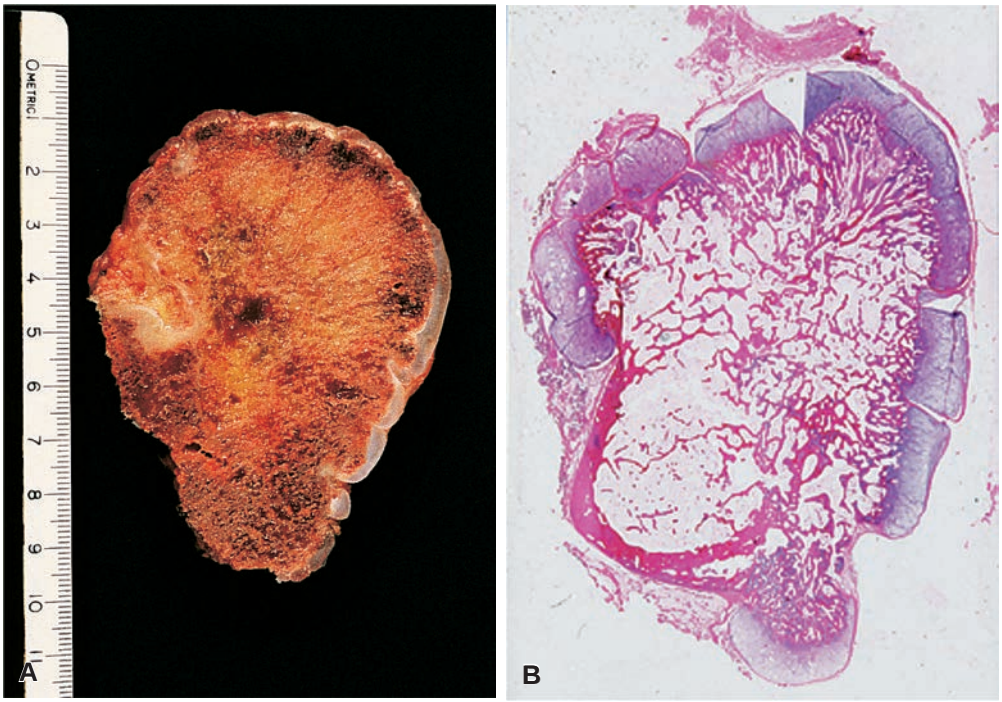

Figure 40.29 **A** and **B,** Gross and whole-mount appearance of osteochondroma. Mature bone is covered by a well-differentiated cartilaginous cap.

maturity, particularly in the distal femur, proximal humerus, and proximal tibia.

Radiographically, chondroblastoma usually appears as a sharply circumscribed radiolucent lesion and may contain small foci of mineralization. MRI typically shows extensive perilesional edema.[231] From the epiphysis, it may extend into the metaphyseal area or the joint space. Rarely, it is found entirely in a metaphyseal location or in a small bone.[232,233]

Microscopically, this lesion may be confusing because of its extreme cellularity and variability.[234] The occasional scattered collections of giant cells may lead to an erroneous diagnosis of giant cell tumor (Fig. 40.30). The basic tumor cell is the chondroblast with only a limited capacity for the production of a cartilaginous matrix. The shape of this cell is usually epithelioid, although spindle elements can also be present. Chondroblasts have sharply circumscribed cytoplasmic borders, and the nuclei vary in shape from round to indented and lobulated; some resemble those of Langerhans cells with a prominent longitudinal nuclear groove. Mitoses are not prominent. Recurrent lesions may show some degree of atypia, a feature that should not be interpreted as a sign of malignant transformation. A distinctive microscopic change is the presence of small zones of calcification. The calcifications range from a network of thin lines ("chicken wire") to obvious deposits surrounded by giant cells. The cartilaginous matrix in chondroblastoma often has an immature, eosinophilic appearance, and hyaline cartilage is uncommon. Secondary aneurysmal bone cyst is present in a significant number of chondroblastomas.

Immunohistochemically, the cells of chondroblastoma coexpress vimentin and S-100 protein. They may also be immunoreactive for SOX9, low-molecular-weight cytokeratins, p63, neuron-specific enolase, and muscle-specific actin.[235,236]

Recently, it has been shown that chondroblastomas have distinctive driver mutations in the genes that encode histone H3.3. Chondroblastomas harbor mutations in the *H3F3B* gene far more commonly than the *H3F3A* gene.[237] An antibody directed against the H3F3 K36M mutation has been found to be specific for chondroblastoma.[238]

The diagnosis is possible on the basis of fine-needle aspiration material, which in a typical case will consist of neoplastic chondroblasts, multinucleated osteoclast-like giant cells, and chondroid matrix fragments.[239] Curetting with bone grafting, which is the preferred treatment, provides local control in over 80% of the cases. Local recurrences can be treated similarly.[240]

Several cases of chondroblastoma, microscopically indistinguishable from the rest, have behaved locally in an aggressive fashion, invading the soft tissues and developing tumor thrombi in angiolymphatic channels. Most of these aggressive tumors have been located in the pelvis.[241] A few others have given rise to distant metastases, usually to the lungs.[242–245] In nearly all of the reported cases of this phenomenon, the metastases have occurred after surgical manipulation of the primary tumor.[246]

Chondromyxoid Fibroma

Chondromyxoid fibroma of bone is a rare benign tumor of cartilaginous nature.[247] It usually occurs in the long bones of young adults, but it has also been reported in the small bones of the hands and feet, pelvis, ribs, vertebrae, and skull base. In the skull base or flat bones, chondromyxoid fibroma may be misdiagnosed as myxoid chondrosarcoma or chordoma.[248]

Radiographically, it is sharply defined and often has a pronounced shell of surrounding reactive bone (Fig. 40.31). It is usually located in the medullary portion of the bone, but a juxtacortical variant arising on the bone surface has been described.[249] Grossly, it is solid and yellowish white or tan, replaces bone, and thins the cortex.

Microscopically, chondromyxoid fibroma is distinctly lobular, with individual lobules composed of paucicellular myxochondroid matrix separated by intersecting bands of highly cellular tissue composed of fibroblast-like spindle cells and osteoclasts (Fig. 40.32).[250]

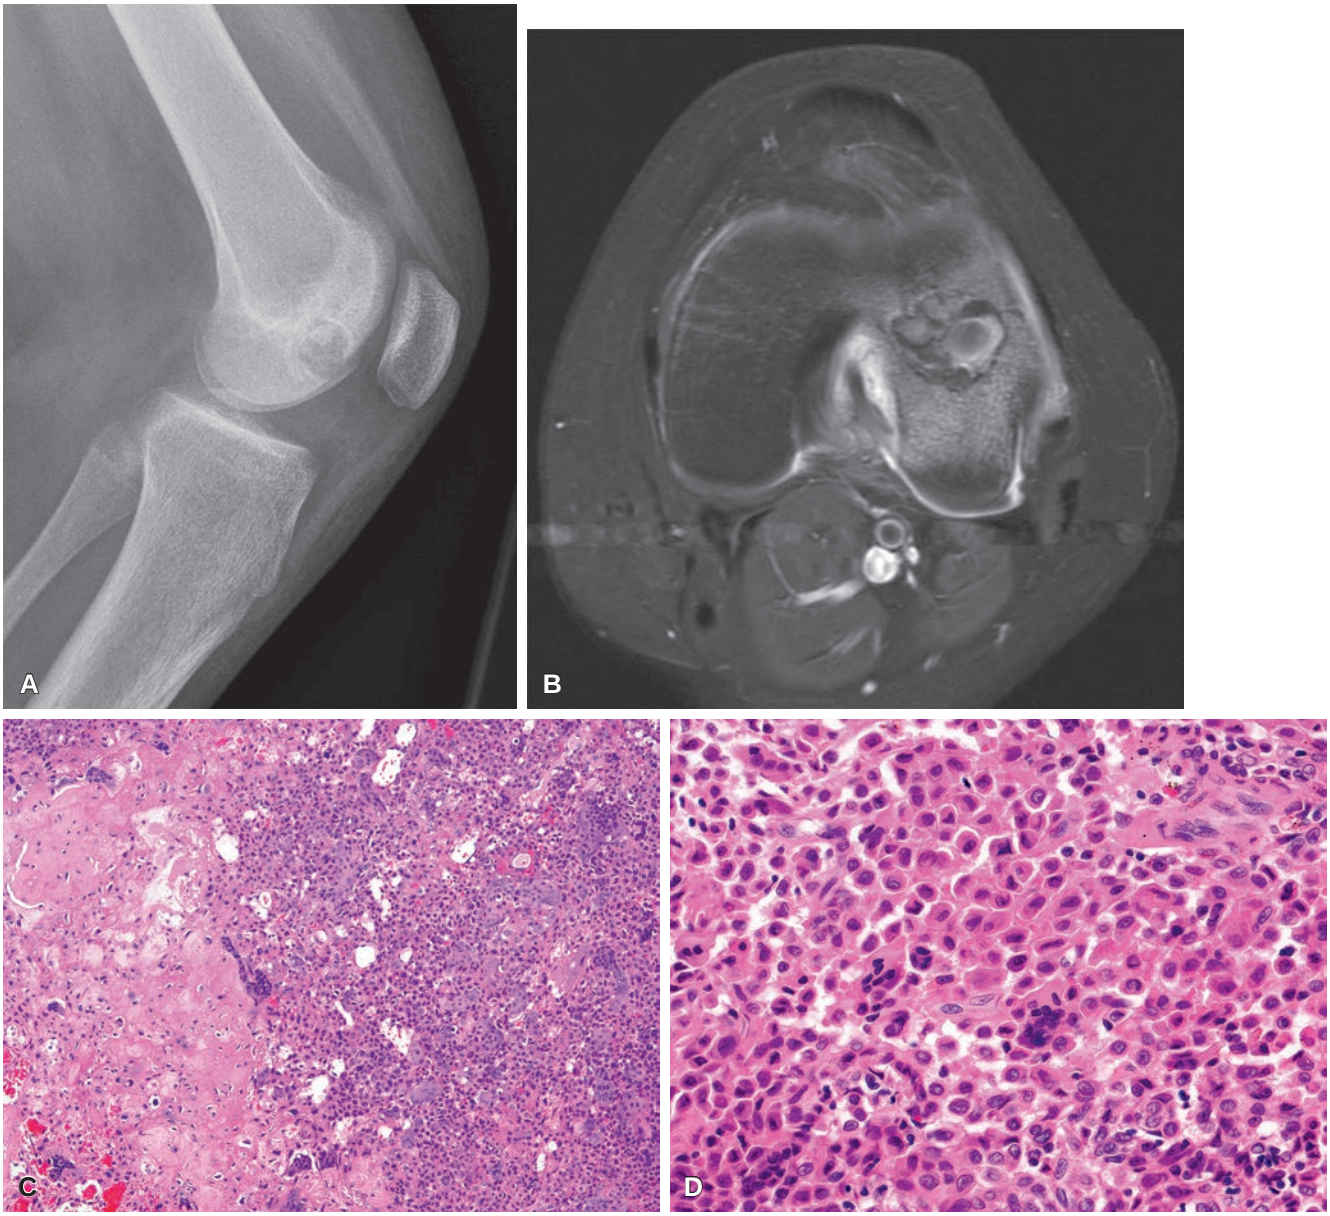

Figure 40.30 Chondroblastoma. A, Lateral radiograph of the knee shows a well-circumscribed radiolucent lesion arising in the epiphysis. **B,** MRI shows the circumscribed chondroblastoma with intense surrounding edema, a characteristic imaging feature. **C,** On low magnification, chondroblastomas are composed of islands of immature cartilage, mononuclear chondroblasts, and multinucleated giant cells. **D,** Chondroblasts have characteristic features, including well-defined cytoplasmic borders and longitudinal nuclear grooves.

Calcification may occur, particularly in the juxtacortical variant.[249] The occasional presence of large pleomorphic cells may result in an erroneous diagnosis of chondrosarcoma, particularly in recurrent lesions.[251,252] However, mitotic figures are exceptional. Some tumors show a combination of the features of chondroblastoma and chondromyxoid fibroma, and in such cases radiographic information must be incorporated for accurate diagnosis.

Immunohistochemical reactivity for S-100 protein is the rule, in keeping with its presumed cartilaginous nature,[253] but there are also cells with myofibroblastic and myochondroblastic features.[254] The basic cartilaginous nature of this tumor has been demonstrated through its immunoreactivity for SOX9 (an essential regulator of chondrogenesis) and further supported by the presence of type II collagen. In contrast to chondroblastoma, it is consistently negative for keratin.

Cytogenetically, chondromyxoid fibroma is characterized by rearrangements of chromosome 6 at band q13 or q25.[255,256] Aberrations in 6q13 map to the *COL12A1* locus.[257]

Local recurrence follows curettage of chondromyxoid fibroma in about 25% of cases, sometimes after an interval as long as 30 years.[258] Soft tissue extension or implantation may occur,[259] but distant metastases have not been reported.

Chondrosarcoma

Chondrosarcoma, a malignant tumor with chondroid differentiation, is divided into two broad categories on the basis of microscopic

Figure 40.31 Radiograph of chondromyxoid fibroma, which appears as a well-defined metaphyseal radiolucency with surrounding reactive bone. The overlying cortex may be absent in larger lesions.

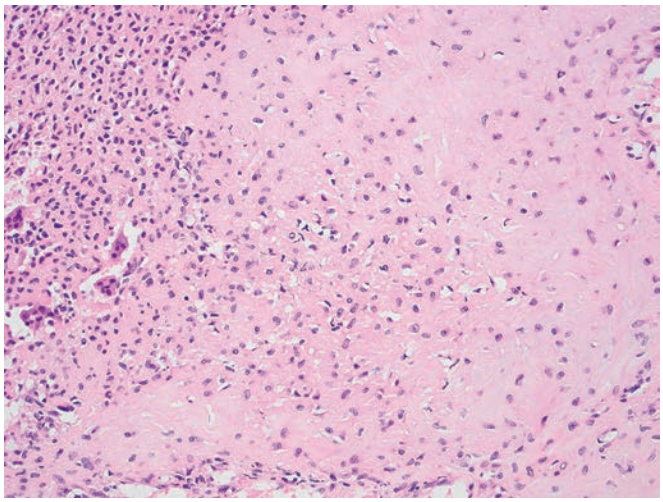

Figure 40.32 Microscopic appearance of chondromyxoid fibroma. Peripheral hypercellularity is common, and giant cells are encountered at the periphery of lobules.

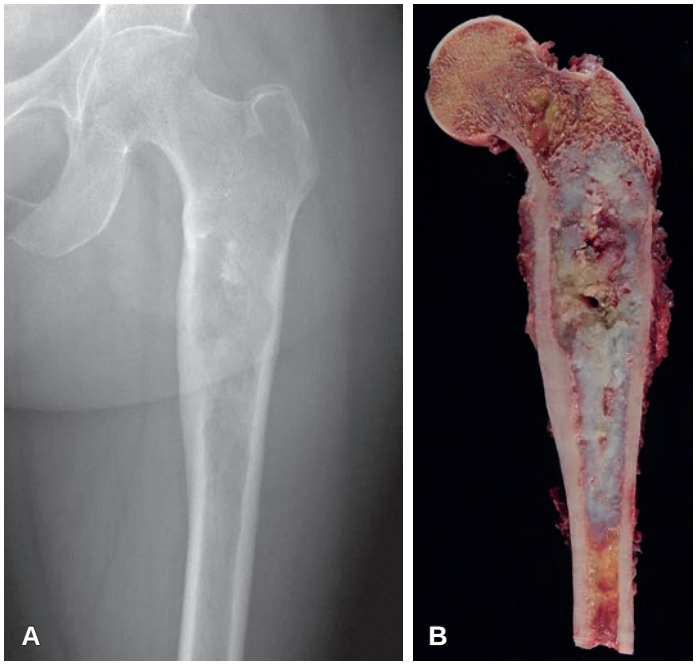

Figure 40.33 A, Radiographic and **B,** gross appearance of central chondrosarcoma. The lesion consists of gray hyaline cartilage which causes deep endosteal scalloping accompanied by cortical thickening.

criteria: conventional chondrosarcoma and chondrosarcoma variants. Each of these categories comprises several distinct types, some defined on microscopic grounds and others on the basis of location within the affected bone.

Conventional chondrosarcoma. The majority of patients with conventional chondrosarcoma are adults, usually aged 50 or more. Chondrosarcoma in childhood is distinctly uncommon,[260–262] and most malignant bone tumors in this age group exhibiting cartilage formation are actually osteosarcomas with a predominant cartilaginous component.

Chondrosarcomas are divided according to location into central (in the medullary cavity) or peripheral (on the surface of the bone), and can be primary (without an associated benign lesion) or secondary (associated with a benign precursor lesion) in either site.[76] **Central chondrosarcomas** are located in the medullary cavity, usually of a flat or long bone.[263] Although the radiographic features can vary depending on the grade, most central chondrosarcomas are radiolucent with areas of calcification (Fig. 40.33). Ill-defined margins, fusiform, expansile remodeling of bone with endosteal scalloping, and cortical destruction with a soft tissue mass are three important diagnostic signs.[191] The pelvic bones, ribs (usually at the costochondral junction), shoulder girdle, and femur are the most common locations. Chondrosarcomas of the small bones of the hands and feet are exceptional but have been described by several authors.[264–266] Chondrosarcoma can also involve the bones of the skull, especially the temporal bone and base of the skull, where the differential diagnosis also includes primarily chordoma.[267,268]

Peripheral chondrosarcomas may arise from the cartilaginous cap of a preexisting osteochondroma or far less commonly de novo (Fig. 40.34). Patients with MHE are particularly prone to this complication, as already indicated. The risk of malignant transformation in a solitary osteochondroma is between 1% and 2%. The signs of malignant progression in an osteochondroma include increased growth after skeletal maturity, or irregularity and thickening of the cartilage cap or destruction of the stalk radiographically.[269]

Juxtacortical (periosteal) chondrosarcoma is a rare tumor that commonly involves the diaphysis of a long bone (most often the femur) and is characterized by a cartilaginous lobular pattern with areas of spotty calcification and endochondral ossification.[270] These tumors are usually low grade and should be separated from the periosteal variant of osteosarcoma.[271]

Microscopically, conventional chondrosarcomas—whether central or peripheral—show a remarkably wide range of differentiation, the common denominator being the production of a cartilaginous matrix and the lack of direct bone formation by the tumor cells (see discussion later). The differential diagnosis between well-differentiated

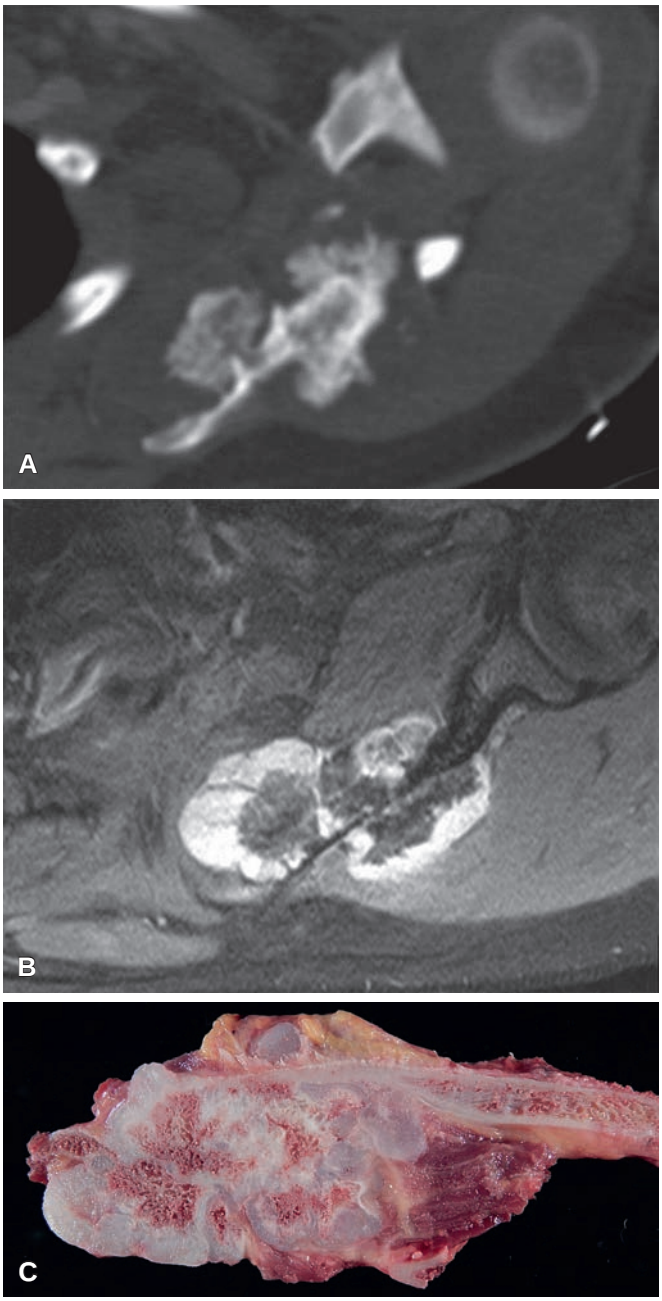

Figure 40.34 **A,** CT, **B,** MRI, and **C,** gross appearance of a secondary peripheral chondrosarcoma arising from an osteochondroma of the scapula. The cartilage cap is thick and highly irregular, and the lesion surrounds the scapula.

chondrosarcoma and enchondroma rests on a combination of clinical, radiographic, and architectural findings.[191] This differentiation can be very difficult and is subject to a distressingly high degree of interobserver variability.[272] Chondrosarcomas of all grades are characterized histologically by permeation and invasion. Mirra et al.[273] emphasized permeation of the bone marrow and cancellous bone with entrapment of host lamellar bone on all sides in well-differentiated chondrosarcoma as an important sign in the differential diagnosis with enchondroma. It cannot be overstated that correlation of the microscopic features with the clinical and especially the radiographic findings is essential in distinguishing benign and malignant hyaline cartilage tumors.

Peripheral chondrosarcomas are usually of low histologic grade. These tumors are characterized by thickening of the cartilage cap (often >3 cm) and the development of satellite nodules resulting in an irregular cartilage cap. Higher-grade chondrosarcoma is distinguished from osteosarcoma by the lack of direct osteoid or bone formation by the tumor cells. Bone can be present in a bona fide chondrosarcoma, but this is non-neoplastic and often represents either entrapped lamellar bone from the medullary cavity or results from endochondral ossification.

Cytogenetically, there is considerable heterogeneity among chondrosarcomas depending on grade, but also evidence that some of the karyotypic anomalies are not random.[274–276] *IDH1* and *IDH2* mutations are common in central chondrosarcoma,[204] and higher-grade chondrosarcomas can be distinguished from chondroblastic osteosarcomas on the basis of *IDH* mutation analysis.[277]

The management of chondrosarcoma is entirely surgical, and adjuvant therapies are of limited benefit. Higher-grade chondrosarcomas are treated with en bloc resection; conservative management of low-grade chondrosarcoma is used by some, while others also use resection techniques for these tumors.[278,279] Soft tissue implantation following biopsy is a well-known complication of chondrosarcoma. Therefore, biopsy tracts should be excised with the tumor.

The microscopic grade of chondrosarcomas is an important prognostic factor. Chondrosarcomas are divided into three grades based on cytologic features, cellularity, and mitotic activity.[280] Grade 1 tumors have similar cytologic features as enchondromas but show infiltrative properties. Grade 2 tumors often have abundant myxoid stroma and are more cellular and mitotically active than grade 1 tumors. Grade 3 tumors show high cellularity, marked cytologic atypia, and abundant mitotic activity and may be difficult to distinguish from chondroblastic osteosarcoma (Fig. 40.35). Survival is excellent for grade 1 tumors but steadily decreases with increasing grade.[280–282] Recurrences may be higher in microscopic grade than the original tumor.[283] Equally important prognostically is the adequacy of initial therapy.[284,285] An association between 6q13–21 chromosome aberrations and locally aggressive behavior has been described.[286] High-grade chondrosarcomas metastasize early, particularly to the lungs, but lymph node metastases are practically nonexistent.

Chondrosarcoma Variants

Clear Cell Chondrosarcoma. Clear cell chondrosarcoma is a rare variant of chondrosarcoma characterized by tumor cells with an abundant clear or ground glass cytoplasm and sharply defined borders, often interspersed with small trabeculae of woven bone, numerous multinucleated giant cells, and foci of cartilage.[287,288] It has overlapping clinical and radiographic features with chondroblastoma, and some have proposed that it may represent its malignant counterpart (Fig. 40.36).[289] Most patients are older than those affected by chondroblastoma.[290] Radiographically, the lesion is usually entirely radiolucent, often sharply circumscribed, and may be complicated by pathologic fracture. Most cases involve the proximal femoral or humeral epiphysis, and the behavior is generally that of a low-grade malignancy, with some outstanding exceptions.[291] In addition—and like conventional chondrosarcoma—it can undergo dedifferentiation.[292]

Cytogenetic analysis of clear cell chondrosarcoma has shown recurrent chromosome 9 and 20 abnormalities[293]; *IDH* mutations are absent.

Myxoid Chondrosarcoma (Chordoid Sarcoma). This variant of chondrosarcoma can occur in bone but is much more common in the soft tissues (see Chapter 41).[294,295] It is morphologically reminiscent of chordoma because of the rows of round to spindled cells separated by a myxoid background. Demmico et al. reported

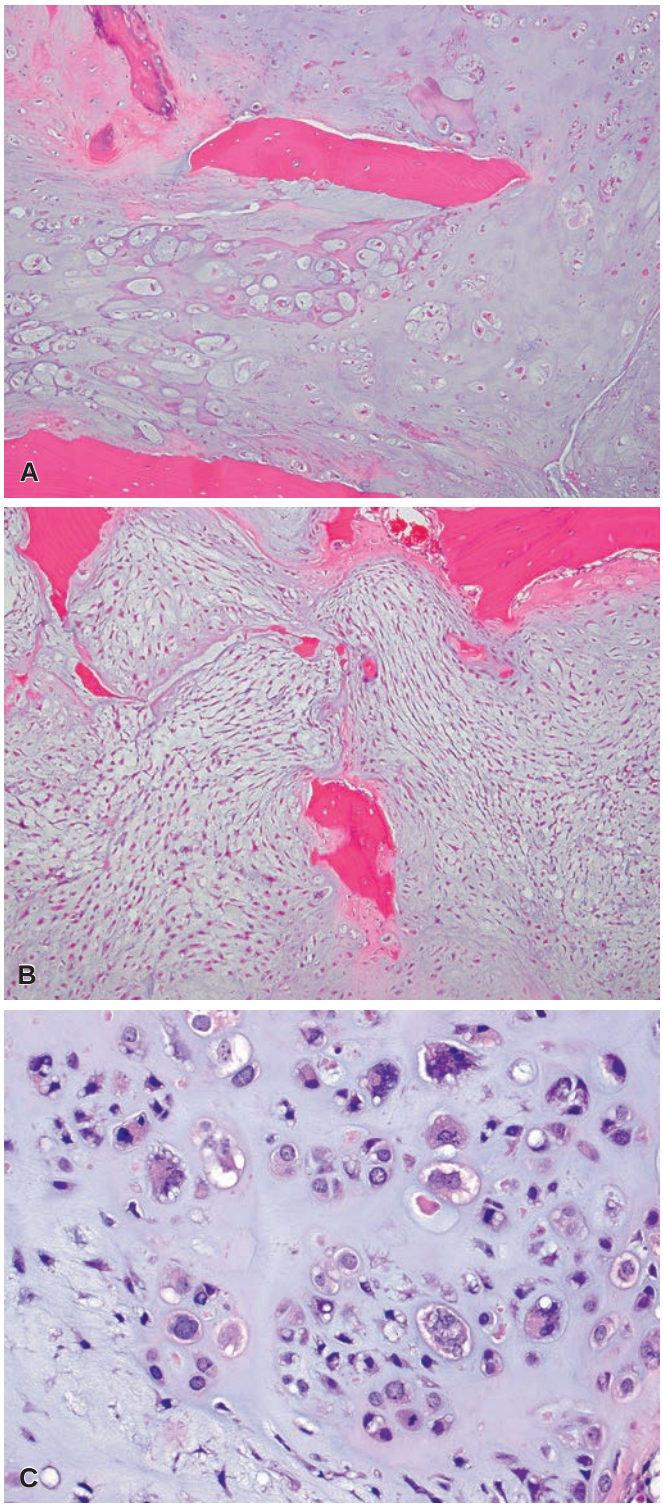

Figure 40.35 Microscopic features of **A,** grade 1, **B,** grade 2, and **C,** grade 3 chondrosarcoma.

five cases of osseous myxoid chondrosarcoma and demonstrated *EWSR1* and *NR4A3* gene rearrangements in all cases.[296]

Dedifferentiated Chondrosarcoma. The term dedifferentiated chondrosarcoma refers to the combination of low-grade chondrosarcoma with an intermixed high-grade sarcomatous component.[297–299] This phenomenon occurs most commonly in central chondrosarcoma but can occasionally be encountered in peripheral chondrosarcoma as well.[300,301] The dedifferentiation can be encountered in the initial lesion or in a locally recurrent tumor. The microscopic appearance of the high-grade component may resemble osteosarcoma, undifferentiated pleomorphic sarcoma, rhabdomyosarcoma, or other sarcomatous phenotypes, and there is typically a sharp transition between the low-grade and high-grade components (Fig. 40.37).[302,303] Simultaneous cytogenetic and immunophenotyping studies, as well as the finding that both components harbor *IDH1/2* mutations, suggest that both the differentiated and the "dedifferentiated" components originate from a common primitive mesenchymal cell progenitor, and that the term "dedifferentiated" may be an inaccurate designation.[304,305] At the molecular level, the process of anaplastic transformation is accompanied by overexpression of *TP53* and *HRAS* mutation.[306]

Regardless of terminology, the development of this component in chondrosarcoma is accompanied by a marked acceleration of the clinical course and a decidedly worsened prognosis.[307,308] The overall 5-year survival rate is around 10%.

Mesenchymal Chondrosarcoma. Mesenchymal chondrosarcoma is a relatively rare variant of chondrosarcoma that arises in females more commonly than males, most in the second or third decade of life. A high percentage of these neoplasms involve extraosseous sites and arise in the orbit, paraspinal region, meninges, or somatic soft tissue of the extremities. The bones most commonly affected are those of the axial skeleton and craniofacial bones, including the jaw, pelvis, ribs, and spine; however, bones of the extremities can also give rise to mesenchymal chondrosarcoma. The radiographic appearance resembles that of conventional chondrosarcomas in that most lesions contain foci of mineralization.[309,310] The prognosis is generally poor, although there is great variability in the clinical course.

Mesenchymal chondrosarcoma is characterized microscopically by a biphasic pattern in which areas of cellular cartilage are dispersed among a population of small, undifferentiated, round to spindled cells, often with staghorn-shaped blood vessels (Fig. 40.38).[309,310] The undifferentiated component can resemble malignant lymphoma or Ewing sarcoma. Small foci of osteoid matrix may be identified.

Immunohistochemically, the small cell component is positive for CD99 but not for S-100 protein; the latter is found instead in the chondroid areas. There is also nuclear immunoreactivity for Sox9 (a master regulator of chondrogenesis) and for osteocalcin.[311–315] Surprisingly, immunoreactivity for desmin and myogenin has been found in exceptional instances.[316]

Mesenchymal chondrosarcomas have a recurrent *HEY1-NCOA2* fusion, the detection of which may be useful in excluding other round cell neoplasms; *IDH* gene mutations are absent.[317]

Giant Cell Tumor

Giant cell tumor is usually seen in skeletally mature patients over 20 years of age.[318] It is more common in women than in men and seems to occur more frequently in China than in Western countries.[319] Giant cell tumors involve the epiphysis of a long bone, from which they may spread into the metaphyseal area, extend through the cortex, or even cross a joint space via structures such as the anterior cruciate ligament or ligamentum teres. The sites most commonly affected (in order of frequency) are the distal femur, the proximal tibia, and the distal radius.[318] It also occurs in the humerus, fibula, and skull, particularly the sphenoid bone. Occasionally, a giant cell tumor will be seen in a child[320] and/or in a metaphyseal or diaphyseal location.[321] Involvement of the bones of the hands and feet, jaw,

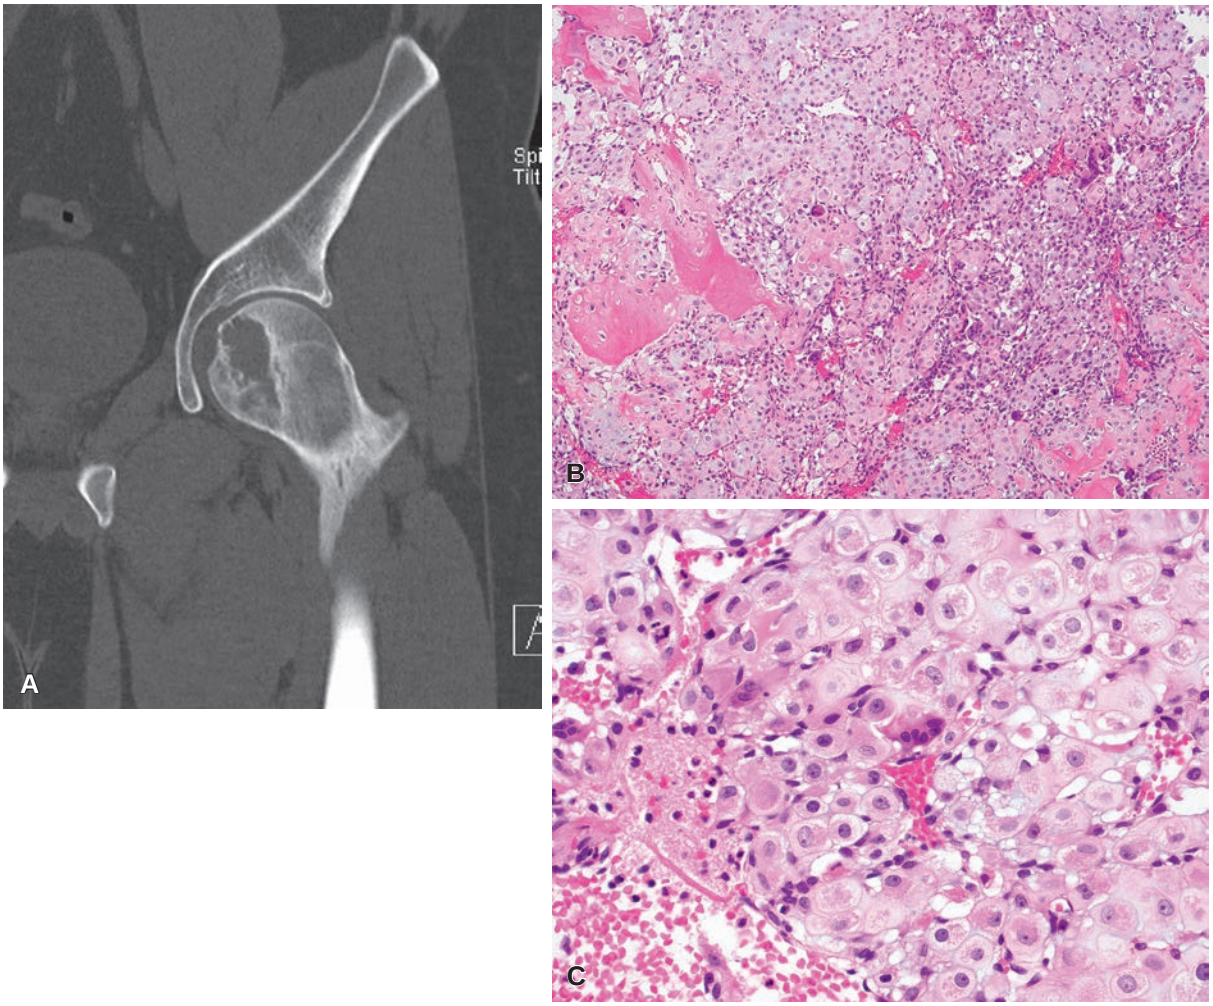

Figure 40.36 Clear Cell Chondrosarcoma. A, CT shows a deceptively circumscribed epiphyseal lesion, suggesting the possibility of a benign lesion. **B,** On low magnification, clear cell chondrosarcomas often contain large areas of woven bone and numerous multinucleated giant cells. **C,** The defining cells are large and contain either eosinophilic or clear cytoplasm, large nuclei, and a prominent central nucleolus.

and vertebrae (other than sacrum) is unusual. Although giant cell tumor has been documented at all of these sites, the occurrence of a giant cell–containing lesion in any of these locations should suggest an alternative diagnosis. Multicentricity has been reported, particularly in young patients and in the small bones of hands and feet.[322]

Radiographically, the typical appearance of a giant cell tumor is that of a radiolucent lesion involving the epiphysis and metaphysis. The lesion is usually well circumscribed, but lacks surrounding reactive bone. Giant cell tumor may be confined to the bone or extend into adjacent soft tissue.[323] Secondary aneurysmal bone cyst formation is better appreciated with CT or MRI (Fig. 40.39).

Grossly, the cut surface is solid or friable and has a variegated red–brown and yellow appearance. Hemorrhage and necrosis may be prominent. (Fig. 40.40). When the cortex is thinned or destroyed, a thin rim of reactive bone may surround the tumor.

Microscopically, the two main components of giant cell tumor are the so-called stromal cells and giant cells (Fig. 40.41). The giant cells are usually large and have over 20 or 30 nuclei. The giant cells are evenly dispersed among a population of mononuclear stromal cells, which are round to oval, and the nuclei of the two components frequently resemble one another. Mitoses can be prominent in the mononuclear stromal cells. Secondary changes, including hemorrhage, necrosis, fibrohistiocytic changes, or aneurysmal bone cyst may obscure the classic histologic features of giant cell tumor. In such cases, correlation of the histologic features with the radiographic findings is necessary for diagnosis. Symplastic or pseudoanaplastic changes are present in some giant cell tumors.[324]

Although the prominence of the giant cells gives this tumor its name, the principle tumor cells are a subset of the mononuclear cell component, while the remainder of the mononuclear cells are likely osteoclast precursors. The neoplastic stromal cells are osteoblast-like and express RANKL, which stimulates the formation of osteoclasts via the RANK-RANKL mechanism.[325] The giant cells resemble osteoclasts morphologically, ultrastructurally, histochemically, and immunohistochemically.[326–328]

Several important mutations have been identified in the neoplastic stromal cells of giant cell tumor. Kato Kaneko et al. recently identified *IDH2-R172S* mutations in 80% of the giant cell tumors they evaluated.[329] More recently, Behjati et al. identified driver mutations exclusive to the *H3F3A* gene in giant cell tumor.[237] A follow-up study by Presneau confirmed this finding but was not able to reproduce any *IDH2* mutations in their group of giant cell tumors.[330]

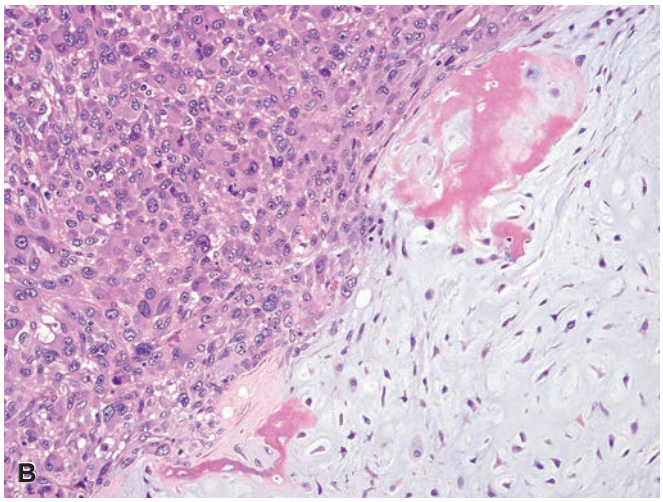

Figure 40.37 **A,** Gross and **B,** microscopic features of dedifferentiated chondrosarcoma. The low-grade chondroid component can be seen in the medullary cavity, and the high-grade component is present in the soft tissue.

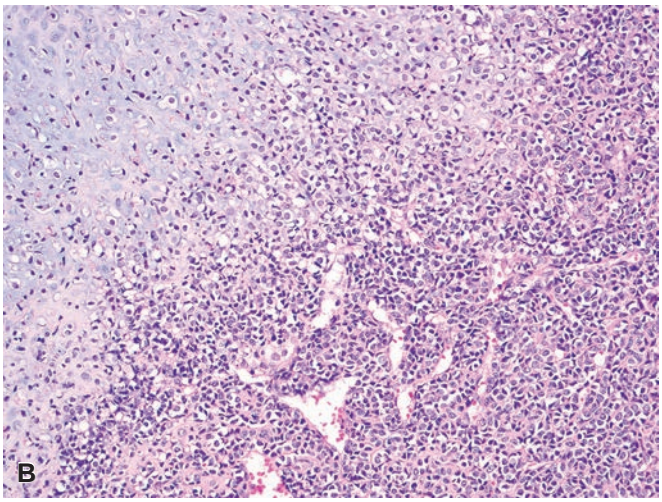

Figure 40.38 **A,** Gross photograph of a mesenchymal chondrosarcoma involving the bones of the midfoot. **B,** Mesenchymal chondrosarcomas contain areas of immature cartilage that alternate with primitive, round cell foci with prominent branching blood vessels.

Many benign lesions with giant cells have been confused with giant cell tumor in the past. A plethora of bone lesions—including fibrous cortical defect/nonossifying fibroma, chondromyxoid fibroma, chondroblastoma, Langerhans cell histiocytosis, brown tumor of hyperparathyroidism, giant cell reparative granuloma, and aneurysmal bone cyst—contain numerous giant cells. So-called giant cell tumors of tendon sheath are also unrelated to giant cell tumors of bone. One of the main microscopic differences between true giant cell tumor and these mimics resides in the spatial relationship between the giant and stromal cells. Giant cells tend to be distributed regularly and uniformly in giant cell tumor (except in areas showing secondary changes such as hemorrhage, fibrosis or fibrohistiocytic reaction), whereas in the lesions that simulate it, foci containing numerous, clumped giant cells alternate with large areas completely lacking this component. Additionally, most of these lesions are distinguishable with careful radiographic correlation as well. Although exceptions to all of the following statements have been recorded, a diagnosis of a lesion *other than* giant cell tumor should be favored if: (1) the patient is a child; (2) the lesion is located in the metaphysis or diaphysis of a long bone rather than the epiphysis; (3) the lesion is multiple (except if a patient has Goltz syndrome)[331]; and (4) the lesion is located in the vertebrae (other than sacrum), jaw (except for patients with Paget disease), or bones of the hands or feet. The distinction is of clinical importance because of the better prognosis associated with most of the giant cell–containing lesions that simulate giant cell tumor.

The treatment of giant cell tumor is usually surgical for tumors in most sites and consists of extended curettage with adjuvants and cementation with or without bone grafting.[332] En bloc excision is utilized less frequently. The use of radiation therapy should be reserved

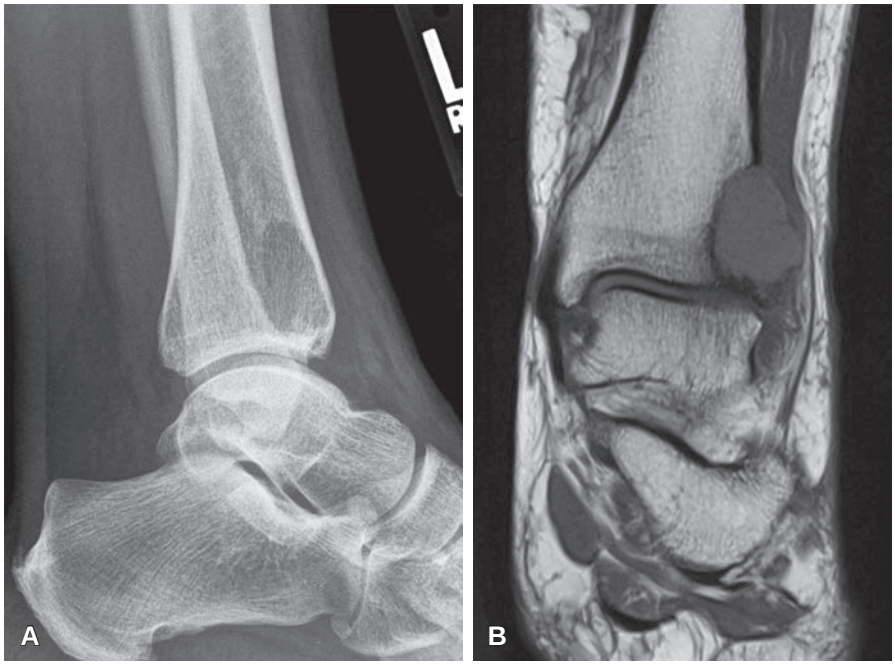

Figure 40.39 Radiographic Features of Giant Cell Tumor. A, Radiograph, **B,** MRI. Giant cell tumors involve the epiphysis and metaphysis of skeletally mature patients.

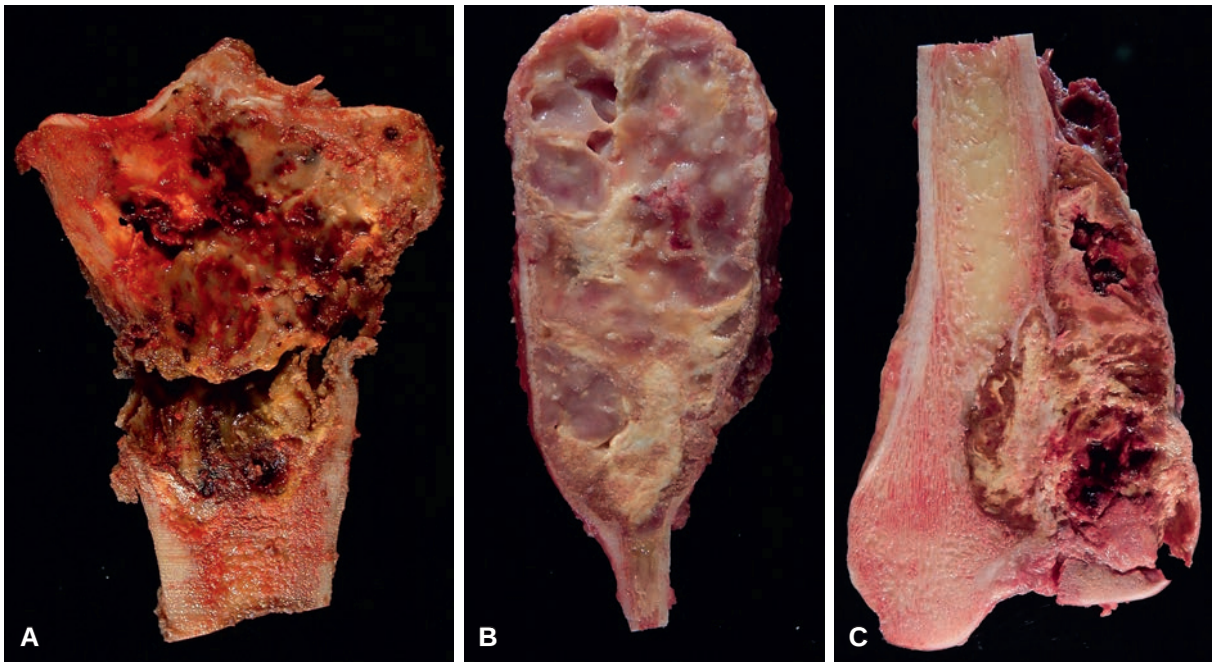

Figure 40.40 Gross Appearance of Giant Cell Tumor of Bone. This tumor can vary from red-brown and hemorrhagic, as in this example in the proximal tibia complicated by a pathologic fracture **(A)**, to yellow, as seen in this lesion in the fibula **(B)**. **C,** Giant cell tumor can aggressively destroy bone and involve soft tissue.

only for cases in which surgical removal is impossible, in view of the relatively high number of reported cases of malignant transformation following this therapeutic modality.[333] As a matter of fact, review of series of postradiation sarcomas of bone shows that in a disproportionate number of cases the initial lesion was a giant cell tumor. Giant cell tumors of the spine have been traditionally treated with radiation therapy, but they are also amenable to surgical excision.

There is growing experience with the treatment of giant cell tumors with denosumab, a monoclonal antibody antagonist of RANKL.[334] This drug offers an alternative to radiotherapy for lesions arising in locations not amenable to surgery or for local recurrences and is a highly effective adjuvant for local control. Histologically, denosumab-treated giant cell tumors show a marked diminution in the number of giant cells and an abundance of bone formation or calcification,

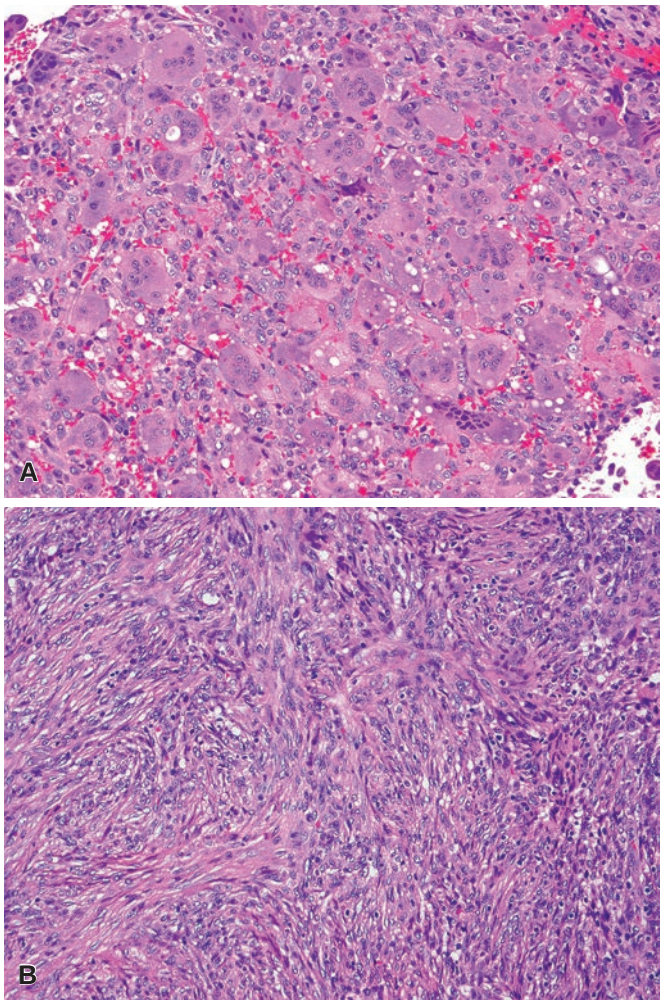

Figure 40.41 Giant Cell Tumor. A, The "typical" giant cell tumor contains numerous giant cells arranged diffusely and evenly, with mononuclear stromal cells in between. **B,** Some lesions may contain prominent fibrous or fibrohistiocytic areas devoid of giant cells.

resulting in an appearance resembling osteosarcoma. Lack of cytologic atypia, mitotic activity, and infiltrative borders are features that help to separate denosumab-treated giant cell tumor from true osteosarcoma.[335,336]

The natural history of giant cell tumor is that of a low-grade malignancy. A small number of giant cell tumors (1%–2%) metastasize, almost always following surgical manipulation. No relationship has been found between metastases and the presence of giant cell tumor invasion of blood vessels. Metastases are more likely in younger patients, from tumors located in the axial skeleton, following local recurrences, and in lesions that present with extraosseous extension.[337] Giant cell tumor metastases have a benign histologic appearance and do not ultimately cause death. Nevertheless, all patients with giant cell tumor are staged with imaging of the chest. Local recurrences follow curettage more often than resection.[338] Most cases of giant cell tumor exhibit chromosomal abnormalities, usually in the form of telomeric association that can involve a variety of chromosomes, such as 11p, 13p, 14p, 15p, 19q, 20q, and 21p.[339,340] Telomeric association is a rare form of cytogenetic abnormality characterized by end-to-end fusion of intact chromosomes. Clonal structural abnormalities may be present in addition.[341] There is no clear association between chromosomal aberrations and clinical outcome.

Malignant Giant Cell Tumor

As already mentioned, all giant cell tumors of bone should be regarded as potentially low-grade malignancies because of their tendency to recur and their occasional capacity to metastasize regardless of histologic appearance. The terminology related to malignant giant cell tumor is both confusing and controversial. "Primary" malignant giant cell tumor refers to a tumor that contains foci of typical giant cell tumor and pleomorphic sarcoma at first diagnosis (also sometimes referred to as "dedifferentiated giant cell tumor").[342,343] However, most malignant giant cell tumors are secondary malignant giant cell tumors in which the initial tumor has the appearance of classic giant cell tumor and sarcomatous transformation occurs after local recurrence or following radiotherapy.[344–346] A contentious issue is the existence of a cytologically malignant giant cell tumor (i.e., a lesion that retains the clinical, topographic, and general microscopic features of giant cell tumor that exhibits clear-cut evidence of malignancy in the mononuclear stromal component). As such, it is equivalent to a grade 3 giant cell tumor. It represents a most unusual process, part of the reason being the conceptual and practical difficulties in separating it from other malignant tumors, particularly so-called giant cell–rich osteosarcoma (when osteoid production is present) and other pleomorphic sarcomas (when osteoid production is absent).

Marrow Tumors

Ewing Sarcoma Family of Tumors

Ewing sarcoma was first described by James Ewing in the 1920s and represents the prototypic small, round cell sarcoma of bone.[347] Although Ewing sarcoma has been linked with primitive neuroectodermal tumor (PNET) and Askin tumor, it is now clear that all of these tumors are linked by common genetic features and should collectively be referred to as the "Ewing sarcoma family of tumors."[348] Tumors such as neuroblastoma and related sympathetic nervous system tumors, as well as esthesioneuroblastoma, are distinct from the Ewing sarcoma family of tumors.[349]

Ewing sarcoma of bone is the second most common bone sarcoma in children and is usually seen in patients between the ages of 5 and 20 years,[350] with only a minority of the cases presenting in infancy or adulthood.[351,352] Clinically, Ewing sarcoma may simulate osteomyelitis because of pain, fever, and leukocytosis. It can arise in virtually any bone in the body but occurs most often in long bones (femur, tibia, humerus, and fibula) and in bones of the pelvis, ribs, vertebrae, and clavicle.[76] It generally arises in the medullary canal of the metaphysis or diaphysis, from which it permeates the cortex and invades the soft tissues. Rarely, it is predominantly periosteal in location.[353] Ewing sarcoma may also arise in a wide variety of sites, including skin and viscera[354,355]; these are discussed in the respective chapters.

Radiographically, Ewing sarcoma causes permeative destruction of bone, usually accompanied by an aggressive periosteal reaction ("onion skinning"). There is intense uptake on scintigraphy, and CT and MRI typically show extensive soft tissue involvement that is often underappreciated on plain radiographs. The differential diagnosis for these changes includes lymphoma, osteomyelitis, Langerhans cell histiocytosis, and even osteosarcoma (Fig. 40.42).

Microscopically, the typical Ewing sarcoma consists of solid sheets of cells divided into irregular nests by fibrovascular septa (Fig. 40.43). Individual cells are primitive, small, and uniform. The cell outlines are indistinct, resulting in a "syncytial" appearance. The nuclei are round, with frequent indentations, small nucleoli, and variable mitotic activity. There is a well-developed vascular network. Some of the tumor cells may arrange themselves around the vessels in a pseudorosette fashion. Exceptionally, a few true rosettes

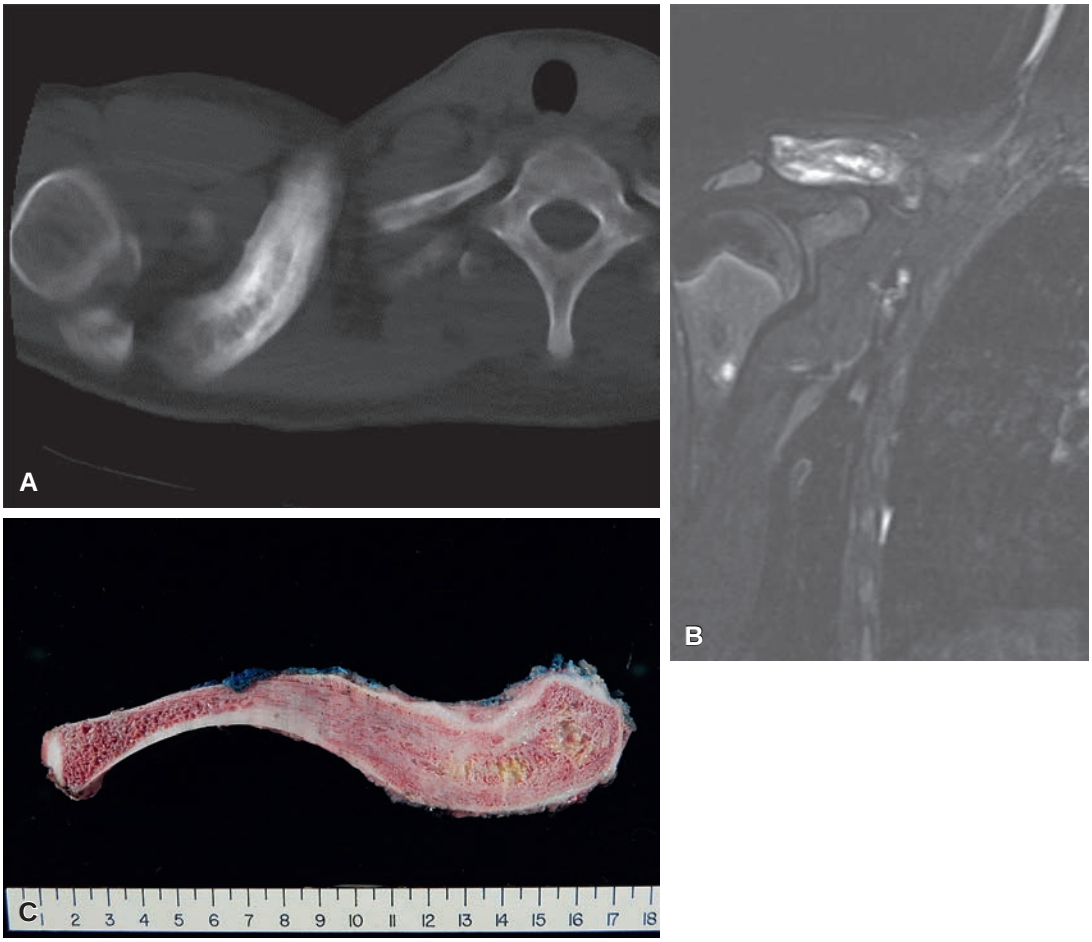

Figure 40.42 Ewing Sarcoma of the Clavicle. A and **B,** CT and MRI show an aggressive lesion with associated periosteal reaction. **C,** The resection specimen shows enlargement of the clavicle, but the tumor is extensively necrotic following neoadjuvant chemotherapy.

(without a central lumen) are formed, these having provided some of the earlier evidence for neuroepithelial differentiation in these neoplasms.[356] Necrosis is common and may dominate the microscopic picture. A fair degree of histologic heterogeneity exists.[357,358] Some tumors are composed of larger and more pleomorphic cells exhibiting conspicuous nucleoli (so-called large cell or atypical Ewing sarcoma).[359] The differential diagnosis of Ewing sarcoma includes practically all other "small round cell tumors," particularly lymphoblastic lymphoma, small cell osteosarcoma, and mesenchymal chondrosarcoma.[360,361] Immunohistochemical and molecular genetic features (described later) are necessary to definitively diagnose Ewing sarcoma.[357]

A most peculiar morphologic variation in the theme is the lesion combining features of Ewing sarcoma/PNET and adamantinoma, and variously called adamantinoma-like Ewing sarcoma and Ewing sarcoma-like adamantinoma.[362,363] The fact that these cases display the t(11;22) would seem to indicate that they represent a subtype of Ewing sarcoma family of tumors resembling adamantinoma rather than the reverse.[364] Cases of adamantinoma-like Ewing sarcoma of the head and neck may be challenging to differentiate from carcinomas.[365] Cases of Ewing family of tumors exhibiting complex epithelial differentiation (including expression of high-molecular-weight keratin) are probably an expression of the same theme.[366]

Histochemical and immunohistochemical features. Historically, histochemical stains and electron microscopy were used to help distinguish between the various small, round cell tumors. Currently, a combination of immunohistochemistry and molecular diagnostic techniques are necessary for diagnosis.

Immunohistochemically, detection of the *MIC2* gene product CD99 is important in establishing a diagnosis of Ewing sarcoma.[367] CD99 is a cell-surface glycoprotein encoded by the *MIC2* gene located on the short arms of the X and Y chromosomes that is consistently expressed by the cells of ES/PNET.[367,368] It is not specific for the Ewing family of tumors, inasmuch as expression of this antigen has been documented in many other tumors, including lymphoblastic lymphoma.[369–373] Antibodies to FLI1 and ERG may also be immunoreactive in Ewing sarcoma, given the *EWSR1–FLI1* (and less common) *EWSR1-ERG* fusions.[374–376] Further immunohistochemical work-up is useful to exclude entities such as lymphoblastic lymphoma, and CD3, CD20, CD34, and TDT are negative in Ewing sarcoma.

Molecular genetic features. About 95% of cases of Ewing family of tumors show on cytogenetic examination the reciprocal translocation t(11;22)(q24;q12) or t(21;22)(q22;q12), which results in the fusion of the *EWSR1* gene at 22q12 with the *FLI1* or *ERG* genes, respectively.[377,378] The most common fusion is the one that results in "in frame linking" of *EWSR1* exon 7 with *FLI1* exon 6. In the remaining cases, *EWSR1* or *FUS* fuses with other ETS and non-ETS family genes, such as *ETV1*, *ETV4*, *ERG*, *NFATC2*, *SMARCA*, *or SP3*.[379,380] These translocations are useful diagnostically and can be

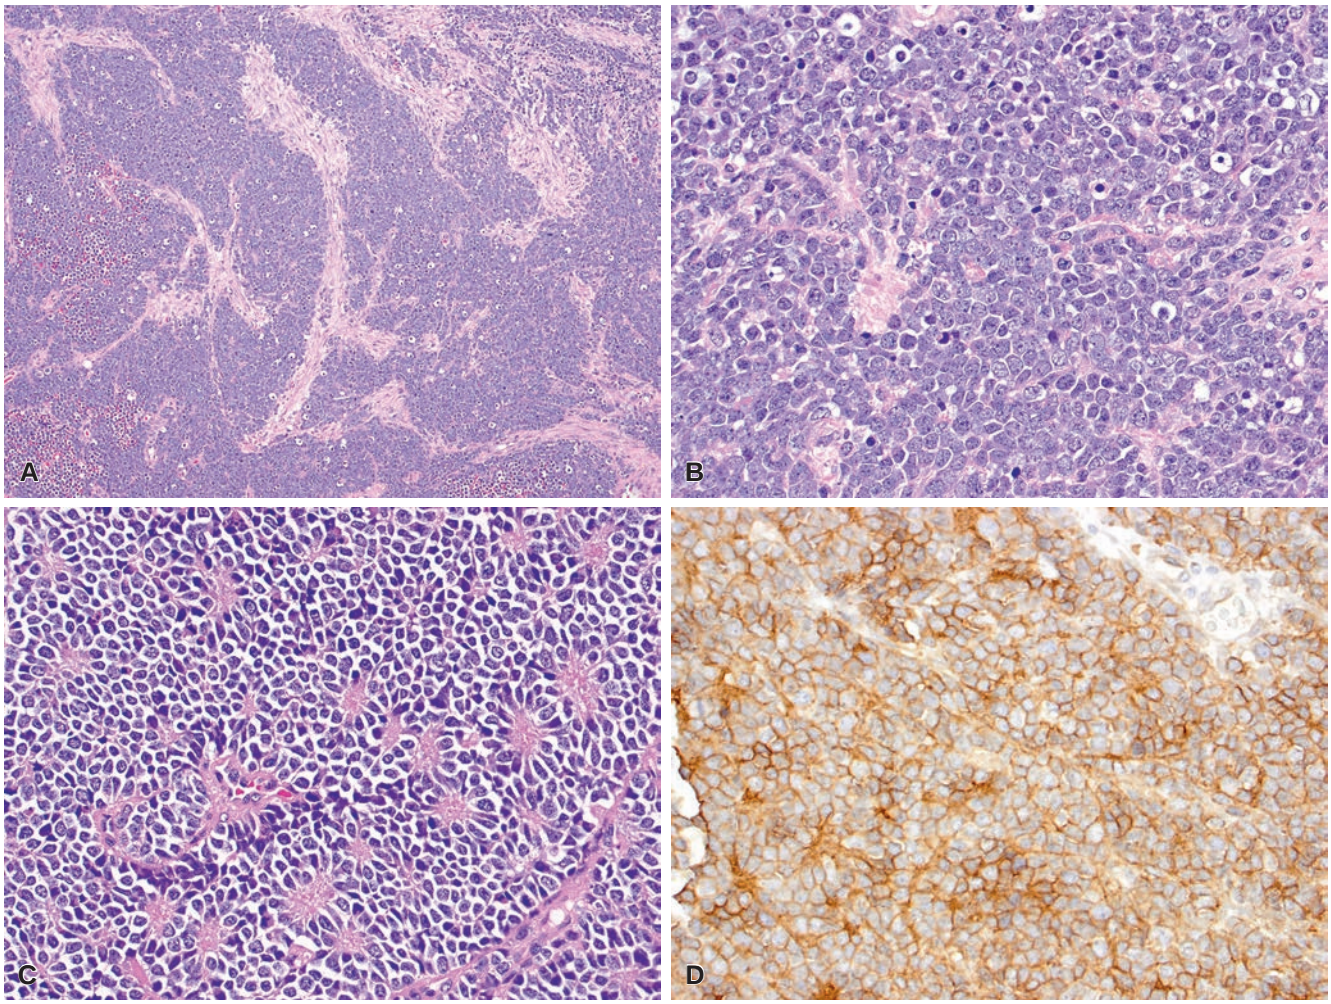

Figure 40.43 Microscopic Features of Ewing Sarcoma. A and **B,** Sheets of primitive, small, round cells are separated by fibrous septa. **C,** Some lesions contain rosettes. **D,** Ewing sarcoma shows strong immunoreactivity for CD99 in a membranous pattern.

detected by RT-PCR[381–387] The *EWSR1* and *FUS* rearrangements can also be detected by molecular cytogenetic analysis (FISH).[388–390] It has been demonstrated that those tumors harboring *ERG* abnormalities are frequently negative for *EWSR1* and *FUS* abnormalities when studied with FISH and suggest the need for additional molecular evaluation in this specific setting.[391] Two other "Ewing-like" sarcomas have been identified. *CIC-DUX4* tumors closely resemble Ewing sarcoma histologically and immunohistochemically but are frequently positive for WT1 and harbor the t(4;19)(q35;q13.1).[392] These tumors appear to be even more clinically aggressive than Ewing sarcoma.[393] The other recently discovered Ewing-like tumor is characterized by the *BCOR-CCNB3* gene fusion. These tumors contain both round cell and spindled cell elements and often lack the diffuse membranous CD99 immunoreactivity seen in Ewing sarcoma.[394]

Spread and metastases. The metastatic spread of ES/PNET is to the lungs and pleura, other bones (particularly the skull), central nervous system, and (rarely) regional lymph nodes. About 25% of patients have multiple bone and/or visceral lesions at the time of presentation.[395,396]

Treatment. The mainstay of treatment for Ewing family of tumors is chemotherapy, which has improved survival dramatically. In addition to chemotherapy, either radiotherapy or surgery—depending on the location of the tumor—is used for local control. Local control is achieved in over 85% of cases, and the actuarial 5-year disease-free survival is 75%. Assessment of the effect of chemotherapy is an important aspect of the patient's prognosis. A system similar to that used for osteosarcoma may be used, but it does not take into account the volume changes that occur in treated Ewing sarcoma. The alternative system is the so-called "Picci system," in which poor response (grade 1) is dictated by finding macroscopic evidence of viable residual tumor (or one nodule of tumor or multiple foci of viable tumor measuring greater than one 10× field) following chemotherapy; a grade 2 response, characterized by isolated foci of viable tumor measuring less than one 10× field in aggregate; or grade 3 response (no viable tumor).[397,398] Other poor prognostic factors include high stage, large tumor size, and pelvic location.

Malignant Lymphoma and Related Lesions

Malignant lymphomas can involve the skeletal system primarily or as a manifestation of systemic disease.[399,400]

Large B-cell lymphoma is the most common type of primary bone lymphoma in adults, 60% of the cases occurring in patients over the age of 30 years.[401] However, they can also affect children.[402] There is no gender predilection. Most cases are solitary, but there are also polyostotic examples limited to the skeletal system, without visceral or lymph node involvement.[403]

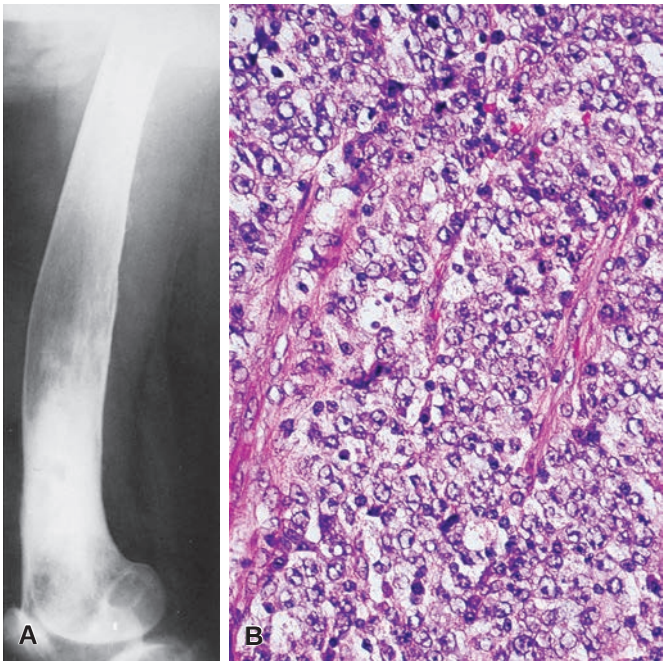

Figure 40.44 **A,** Malignant lymphoma involving the distal femur associated with bone destruction and bone production. These lesions may be erroneously diagnosed as chronic osteomyelitis. **B,** The tumor is of large cell type and is associated with some fibrosis.

Radiographically, large cell lymphomas have an aggressive pattern of bone destruction and often elicit a pronounced periosteal reaction. Less commonly, large cell lymphomas are associated with a sclerotic reaction. CT and MRI are useful in visualizing highly aggressive lesions and assessing the extent of bony involvement.[404,405] The differential diagnosis for these findings includes osteomyelitis and Ewing sarcoma.

Microscopically, the appearance is similar to that of large cell lymphomas in nodal and other extranodal sites.[406] Some cases are accompanied by prominent fibrosis or coagulative necrosis, compromising the morphology or resulting in an appearance that simulates a sarcoma. The cells of large cell lymphoma infiltrate the marrow space, leaving the cancellous bone intact. The tumor cells are large, and their nuclei are somewhat pleomorphic, with many indented, multilobulated, or horseshoe-shaped forms. They usually have prominent nucleoli, unlike the fine nucleoli of Ewing sarcoma (Fig. 40.44). Immunohistochemically, large cell lymphomas have the same pattern of immunoreactivity as their nodal counterparts. They are positive for CD45, the B-cell markers CD20, CD79a, and PAX5, and germinal center or non-germinal center markers CD10, BCL6, and MUM 1.[348]

The 5-year survival rate for localized large B-cell lymphomas of bone has now reached nearly 95%[407] with combination of radiotherapy and chemotherapy.[408]

Hodgkin lymphoma produces radiographically detectable bone lesions in approximately 15% of patients. The involvement is multifocal in about 60% of cases, the most frequent sites being vertebrae, pelvis, ribs, sternum, and femur.[409] The osseous lesions of Hodgkin lymphoma are often asymptomatic and in half of the cases are not demonstrable radiographically. When they become apparent radiographically, the foci may be osteolytic, mixed, or purely osteoblastic. The latter appearance is particularly common in vertebrae. Exceptionally, Hodgkin lymphoma will present initially as a bone mass,[410] with or without associated involvement of the adjacent soft tissues.[411–413]

Anaplastic large cell lymphoma of bone is extremely rare. The tumor cells are immunoreactive for CD30, EMA, CD3, CD4, and anaplastic lymphoma kinase (ALK1).[414–416]

Burkitt lymphoma, as originally reported from Africa, typically presents with massive jawbone involvement. It can also result in tumor masses in the long bones and pelvis.[417]

Lymphoblastic lymphoma of precursor B-cell type can present as a solitary bone tumor and very closely simulates Ewing sarcoma histologically and immunohistochemically.[418] The tumor cells are positive for CD99 but also positive for terminal deoxynucleotidyl transferase (TdT), PAX5, CD43, CD34, CD79a, and variably positive for CD20.

Acute leukemia of childhood is frequently associated with radiographic abnormalities in the skeletal system.[419] In the large majority of instances, the changes are widespread and therefore unlikely to be confused with a primary bone neoplasm. In contrast, destructive bone lesions are extremely rare in the chronic leukemias.

Plasma cell myeloma and **plasmacytoma** are discussed in Chapter 39. *Amyloidoma* of bone is regarded as a manifestation of plasma cell neoplasm and is also addressed in that same chapter.[420]

Vascular Tumors

Hemangiomas of bone are commonly seen in the vertebrae as incidental findings on radiographs. These lesions should probably be regarded as vascular malformations rather than true neoplasms. Radiographically, hemangiomas in the spine result in thick linear striations causing a "honeycomb" or "corduroy" pattern.

The most common location of clinically significant osseous hemangiomas is the craniofacial skeleton.[421] Hemangiomas in the long bones are uncommon. When a lesion involves the flat bones (particularly the skull), sunburst trabeculation occurs because of elevation of the periosteum. Grossly, the cut section of these tumors often has a currant jelly appearance. Microscopically, osseous hemangiomas are composed of thin-walled vessels and are usually cavernous in appearance (Fig. 40.45).

Multiple hemangiomas are mainly seen in children and are associated in about half of the cases with cutaneous, soft tissue, or visceral hemangiomas ("angiomatosis").[422]

Lymphangiomas of bone are exceptional.[426] Most cases are multiple and associated with soft tissue tumors of similar appearance; variations on the theme have been termed *cystic angiomatosis*.[427]

Glomus tumor of the subungual soft tissues may erode the underlying bone. Much rarer is the occurrence of a purely intraosseous glomus tumor involving the terminal phalanx.[428]

Cases previously diagnosed as "**hemangiopericytoma**" of bone are likely a combination of solitary fibrous tumors and synovial sarcomas.[429]

Epithelioid hemangioma is a distinctive hemangioma variant composed of well-formed vessels lined by epithelioid endothelial cells; alternatively, the endothelial cells may also grow in solid sheets. The stroma of these lesions contains loose fibrovascular tissue, and an inflammatory infiltrate rich in eosinophils may be prominent (Fig. 40.46). The myxohyaline stroma that characterizes epithelioid hemangioendothelioma is absent in epithelioid hemangioma.[430]

Epithelioid hemangiomas are usually solitary, but a small percentage can be multifocal. Most are circumscribed radiographically, but lesions arising in small bones can extend into adjacent soft tissue. Local recurrences following curettage are uncommon. Rarely, patients can have involvement of regional lymph nodes or present with epithelioid hemangiomas involving the skin.[430]

FOS gene rearrangements have been described in epithelioid hemangiomas in most locations but appear to be most common in skeletal lesions.[431,432]

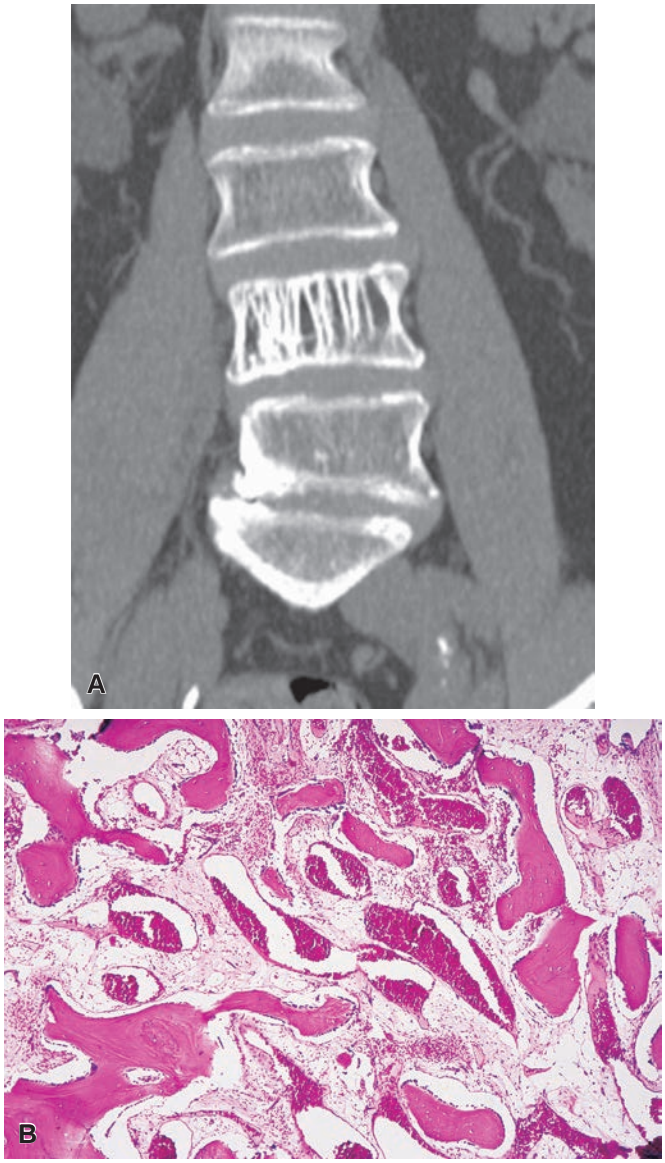

Figure 40.45 Vertebral Hemangioma. A, CT scan showing the typical corduroy pattern associated with hemangiomas in this site. **B,** Histologic features of a cavernous hemangioma of bone.

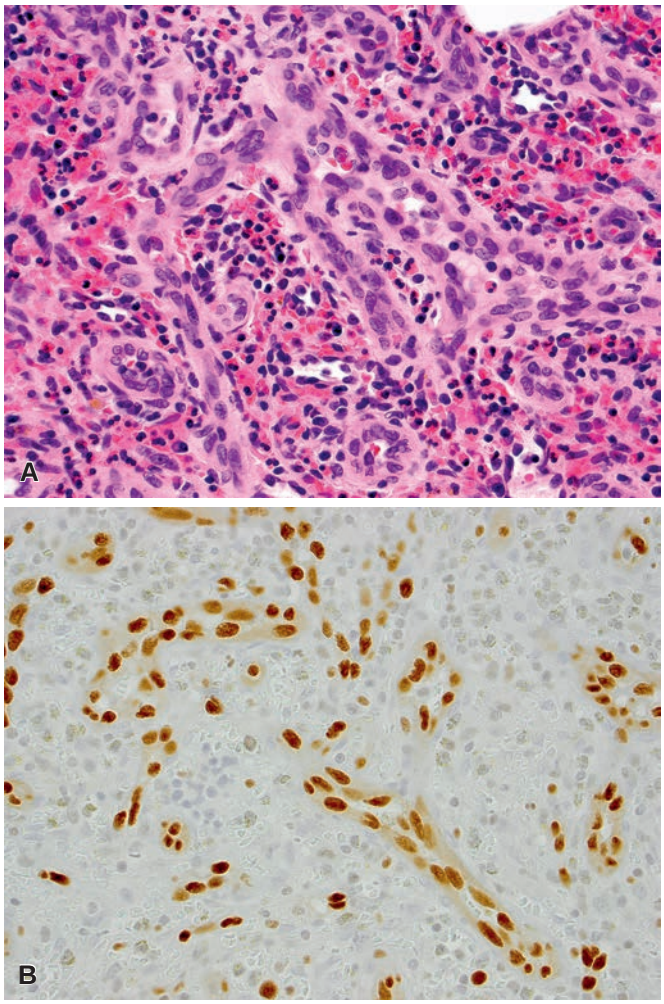

Figure 40.46 Epithelioid Hemangioma of Bone. A, Epithelioid hemangioma is composed of well-formed vessels lined by prominent epithelioid endothelial cells. The vessels are separated by an inflammatory infiltrate rich in eosinophils. **B,** An immunostain for ERG highlights the endothelial cells.

Gorham disease (Gorham–Stout syndrome, massive osteolysis, disappearing bone disease) is a florid vascular proliferation that causes resorption of large segments of bone. It is unclear whether this represents a neoplastic process or not. Involved bones, which may include the humerus or femur, pelvis, thorax, or jaw, are progressively resorbed as a result of the proliferation.[423–425]

Epithelioid hemangioendothelioma of bone is the most common and distinctive member of the family of epithelioid vascular neoplasms.[433,434] The WHO considers epithelioid hemangioendothelioma to be a malignant neoplasm of low to intermediate grade.[76]

Epithelioid hemangioendothelioma of bone is often multifocal[435] and may be associated with similar lesions in the skin, soft tissue, liver, or lung (Fig. 40.47). The clinical course is highly variable, but multifocal bone involvement, regardless of the presence or absence of visceral involvement, is associated with a worse prognosis.[436] Resection or radiotherapy are both effective in the treatment of this tumor.[437]

Microscopically, epithelioid hemangioendothelioma is characterized by the presence of epithelioid endothelial cells with abundant eosinophilic and often vacuolated cytoplasm, large vesicular nuclei (sometimes with prominent grooves), and inconspicuous or absent anastomosing channels (Fig. 40.48). A myxoid or hyalinized stroma is characteristic of this tumor.[438] **Pseudomyogenic hemangioendothelioma** has also been described in bone.[439]

Immunohistochemically, the cells of epithelioid vascular neoplasms display endothelial cell markers, including ERG, CD31, CD34, FLI1, and factor VIII. Keratin immunoreactivity is also quite common, and the aforementioned markers are useful in the distinction of epithelioid hemangioendothelioma and metastatic carcinoma in bone.[440,441]

YAP1-TFE3 (10%) and *WWTR1-CAMTA1* (90%) gene fusions have been described in epithelioid hemangioendothelioma,[442,443] and an antibody directed against the protein product of CAMTA1 appears to be useful in distinguishing epithelioid hemangioendothelioma from other epithelioid vascular and nonvascular mesenchymal neoplasms.[444]

Angiosarcoma exhibits obvious atypia of the tumor cells, formation of solid areas alternating with others with anastomosing vascular channels, and foci of necrosis and hemorrhage (Fig. 40.49).[445] A

Figure 40.47 Gross appearance of multicentric epithelioid hemangioendothelioma involving femur and tibia.

wide range of differentiation exists from tumor to tumor and sometimes within the same case. In some cases the cells have an epithelioid appearance (epithelioid angiosarcoma).[446] Similar to the other vascular neoplasms, angiosarcomas express ERG, CD31, FLI1, and CD34. Multicentric examples occur but are rare.[447] Distant metastases are common, particularly to the lungs. Before a diagnosis of angiosarcoma in a bone lesion is made, other more common lesions such as metastatic carcinoma should be excluded.[433]

Other Mesenchymal Tumors

Fibrous and Related Tumors

Desmoplastic fibroma is a rare neoplasm formed by long fascicles of mature fibroblasts separated by abundant collagen.[448,449] Pleomorphism, necrosis, and mitotic activity are lacking (Fig. 40.50), and the lesion closely resembles soft tissue fibromatosis histologically. However, immunohistochemical and molecular genetic studies have not shown the type of β-catenin pathway alterations that are typical of the latter.[450] Desmoplastic fibroma should also be distinguished from low-grade central osteosarcoma and fibrocartilaginous mesenchymoma.

Desmoplastic fibroma occurs most often in the long bones and jaw. There is a male predominance, and three-fourths of the patients are below the age of 30 years.[451] Radiographically, it has a destructive, purely lytic, honeycombed appearance. It is destructive locally and often recurs following incomplete excision, but metastases do not occur.[452]

Infantile myofibromatosis can present as a solitary lesion in bone. Most of the cases occur in patients 2 years or younger, and they almost always involve the craniofacial bones.[453,454] The microscopic appearance is the same as for its more common soft tissue counterpart.

Solitary fibrous tumor has been described as a pedunculated periosteal mass,[455] as well as an intraosseous lesion.[429]

Most examples of **fibrosarcoma** of bone likely represent other histologic entities, including dedifferentiated chondrosarcoma and fibroblastic osteosarcoma. In one study of fibrosarcomas arising in soft tissue, the majority were reclassifiable as other entities based on modern diagnostic methods.[456] Primary sclerosing epithelioid fibrosarcoma of bone has been well documented.[457,458]

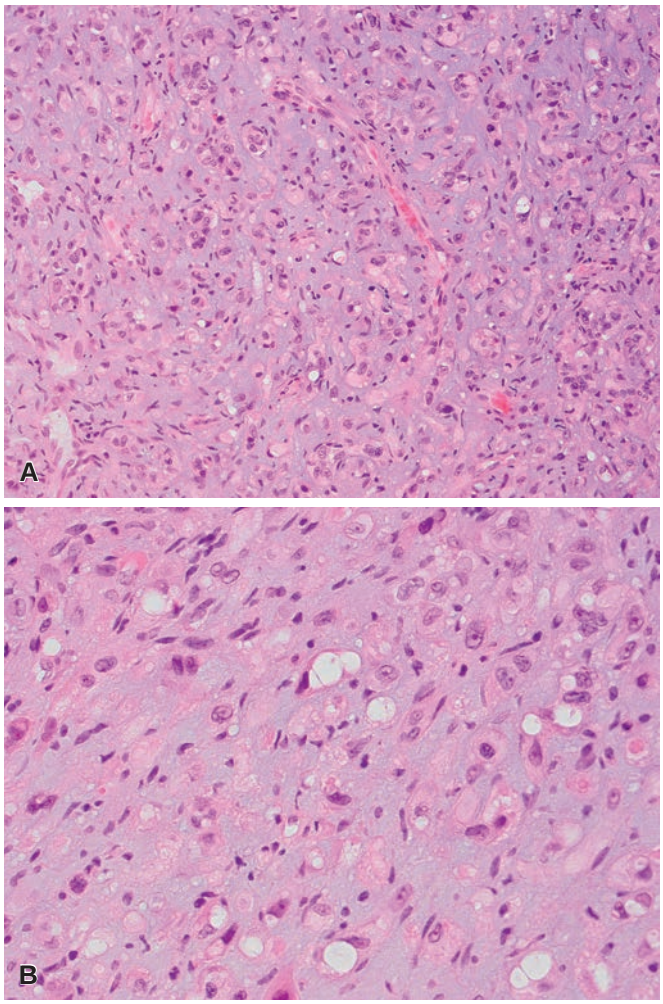

Figure 40.48 **A** and **B,** Microscopic appearance of epithelioid hemangioendothelioma of bone. Cords and nests of epithelioid endothelial cells are deposited in a prominent matrix. Occasional tumor cells contain intracytoplasmic vacuoles or blisters.

Undifferentiated high-grade pleomorphic sarcoma has a histologic appearance identical to its soft tissue counterpart (Fig. 40.51).[459–461] The most common sites of involvement include the long bones, especially the knee region, and the pelvis.[462] Close to 30% of these tumors arise in bone infarcts[48,463,464] around foreign bodies,[465,466] following irradiation,[467] in Paget disease,[66] or as expression of "dedifferentiation" in tumors such as chondrosarcoma. Most patients present at age 40 or older.[459]

Thorough sampling, careful correlation of radiographs, and extensive immunohistochemical work-up is necessary to exclude the possibilities of metastatic sarcomatoid carcinoma, osteosarcoma, and dedifferentiated chondrosarcoma.

Muscle Tumors

Leiomyomas of bone are practically nonexistent. **Leiomyosarcomas** are very rare, most of the reported cases being located in the jaw and in long bones, particularly the femur.[468–472] The morphologic and immunohistochemical features are analogous to those of its soft tissue counterpart.[470] Specifically, the tumor cells are immunoreactive for common and smooth muscle actin, desmin, and h-caldesmon,

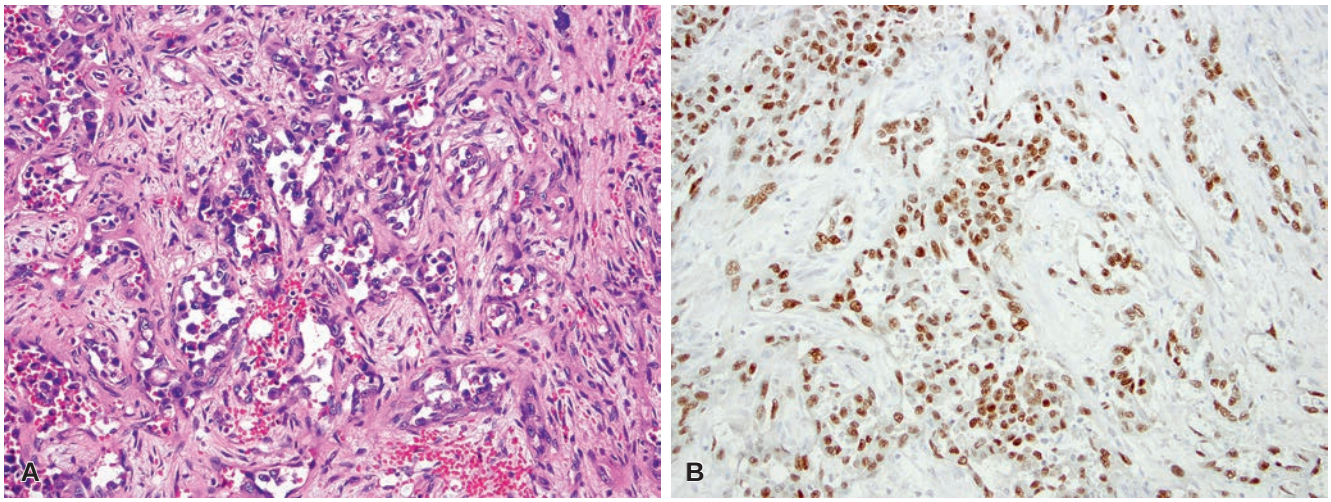

Figure 40.49 Angiosarcoma of Bone. A, Highly atypical endothelial cells line irregular vascular spaces. **B,** Tumor cells are strongly positive for ERG.

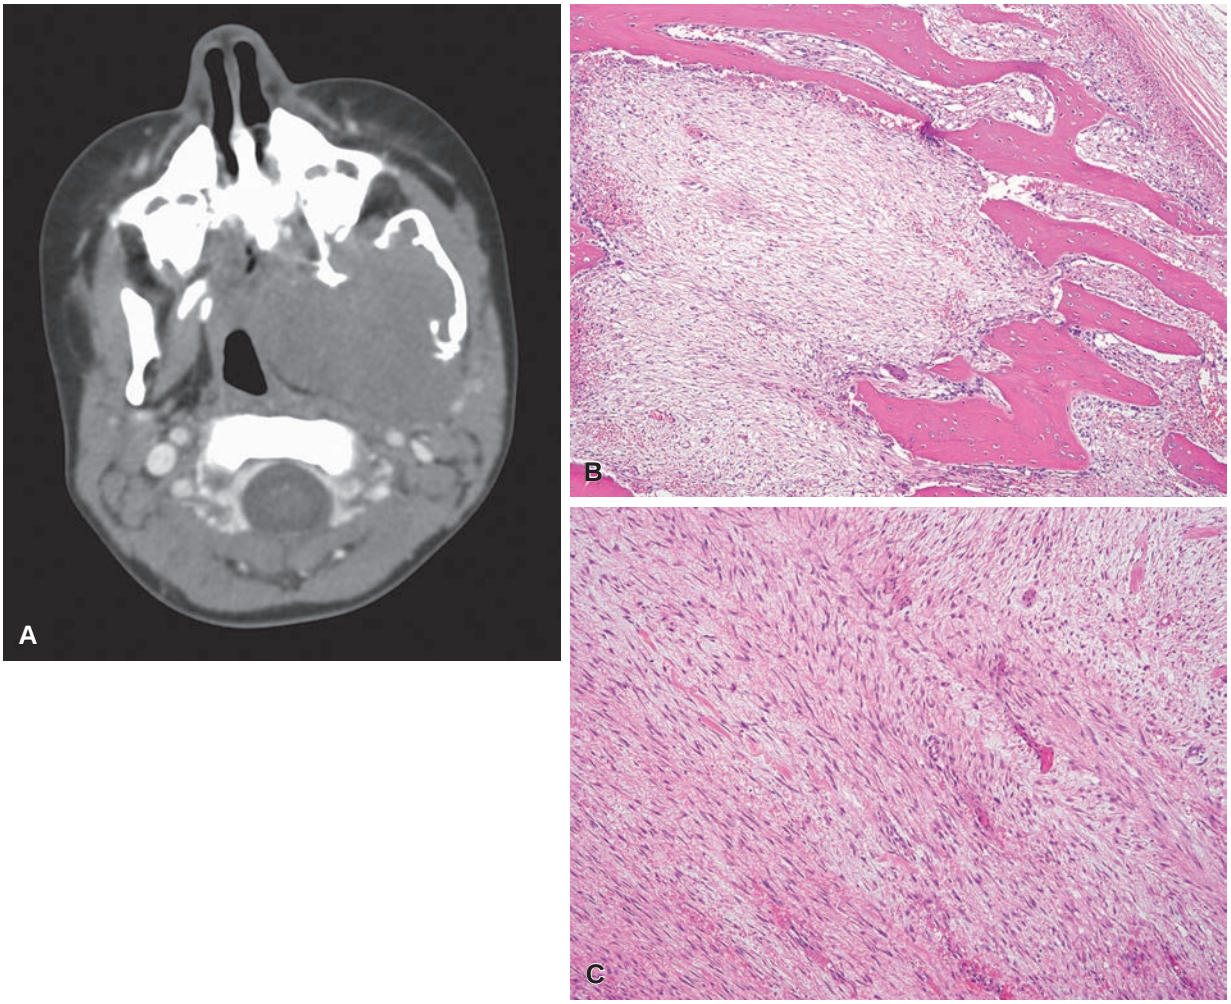

Figure 40.50 Desmoplastic Fibroma. A, CT highlights a large, destructive mass arising in the jaw. **B** and **C,** Desmoplastic fibroma is poorly circumscribed and composed of fascicles of bland fibroblasts, similar to soft tissue fibromatosis.

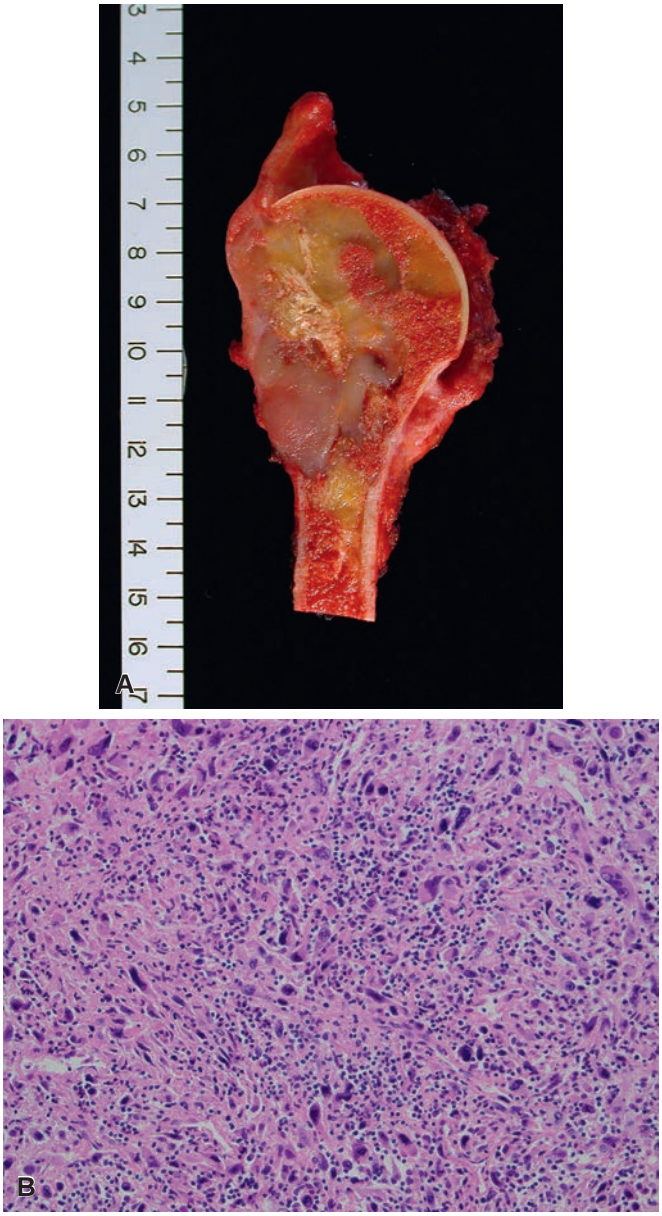

Figure 40.51 A, An infarct-associated undifferentiated pleomorphic sarcoma of the proximal humerus. The serpiginous infarct appears yellowish and calcified, while the sarcoma is gray and fleshy. **B,** Undifferentiated pleomorphic sarcoma of bone is histologically identical to its soft tissue counterpart.

and they are enveloped by type IV collagen.[470,473] They may also be positive for keratin and S-100 protein.[474,475] Exceptional cases have been seen of the epithelioid variety.[476] About half of the patients present with metastatic disease or develop metastases within 1 year of diagnosis.[477]

Isolated examples of primary **rhabdomyosarcomas** of bone are on record.[478,479] Some have been of the pleomorphic type and others had embryonal features.[480,481]

Adipose Tissue Tumors

Lipoma of bone is a very rare tumor. The few reported cases have occurred in the long bones of adults and have presented radiographically as sharply outlined lytic lesions with sclerotic margins.[482,483] Some may arise from the surface of the bone ("parosteal lipoma"). Microscopically, they are composed of mature adipose tissue devoid of hematopoietic elements; dystrophic calcification, fat necrosis, and hemorrhage may be present.[484,485]

Liposarcoma of bone is even more exceptional,[486] and metastatic liposarcoma to bone is more common than primary liposarcoma of bone.

Chordoma and Other Notochordal Lesions

The notochord is a phylogenetic structure representing a primitive spine, which in higher organisms is replaced by the vertebrae and sacrum. **Notochordal remnants** are found in humans within the vertebral bodies and intervertebral disks.[487] *Ecchordosis physaliphora* is the name given to a grossly visible notochordal remnant found incidentally at autopsy as a discrete gelatinous nodule attached to the clivus or overlying the anterior surface of the pons.[488] Other sites where ectopic notochordal tissues can be found are the odontoid process of the axis, the nasopharynx, and the coccyx and adjacent presacral soft tissues.[489]

According to the WHO, the term **benign notochordal cell tumor** encompasses giant notochordal rest and notochordal hamartoma.[76] When located in the vertebrae, these lesions can be easily overdiagnosed as chordoma, from which it is distinguished by a combination of clinical, radiographic, and microscopic features.[490] Radiographically, benign notochordal cell tumors are confined to the vertebra and may show varying degrees of sclerosis. They are easily identified on MRI, but there is no uptake on scintigraphy.[491] Histologically, these tumors are composed of sheets of vacuolated, lipoblast-like cells or physaliferous cells with bland cytologic features. The intervening cancellous bone is intact, and there is no myxoid matrix or necrosis.[492] Although benign, they are regarded by some authors as precursors of chordomas.[493,494]

Chordoma is most frequent in the fifth and sixth decades but occurs in all ages and in both sexes. Chordomas grow slowly, the duration of the symptoms before diagnosis usually being over 5 years. About 50% arise in the sacrococcygeal area, 35% in the spheno-occipital area, and the remainder along the cervico-thoraco-lumbar ("mobile") spine.[495] The sacrococcygeal tumors are more common in the fifth and sixth decades of life, whereas many of the spheno-occipital neoplasms occur in children and adolescents.[496,497] If the tumor encroaches on the spine, symptoms of spinal cord compression arise. The retroperitoneal space is often involved by direct extension, and the tumor may grow large enough to compress the rectum or bladder. Spheno-occipital chordomas may present with a nasal, paranasal, or nasopharyngeal mass, multiple cranial nerve involvement and/or destruction of bone.[498]

Radiographically, chordomas are destructive, midline lesions that may be extremely difficult to identify on plain radiographs. However, they are readily evident on CT or MRI. In the sacrum and coccyx, chordomas form lobular masses that extend anteriorly toward the rectum and bladder.[499] Lesions arising in the skull base arise in the midline, destroy surrounding bone, and may encroach on the brainstem or optic nerves.

Grossly, chordoma is lobulated, gelatinous, and soft and contains areas of hemorrhage. Microscopically, chordoma contains cohesive cords and nests of epithelioid cells deposited in an abundant myxoid stroma organized into distinct lobules by fibrous septa. Individual tumor cells have eosinophilic cytoplasm, and those with prominent vacuoles are referred to as "physaliphorous" cells (Fig. 40.52). Tumor cells are variable in size and may have prominent nucleoli, but cytologic atypia may be pronounced. Mitotic figures are generally scanty or absent. The microscopic differential diagnosis includes mainly metastatic carcinoma and chondrosarcoma, but myxopapillary ependymoma and chordoid meningioma may also enter the differential diagnosis.[500]

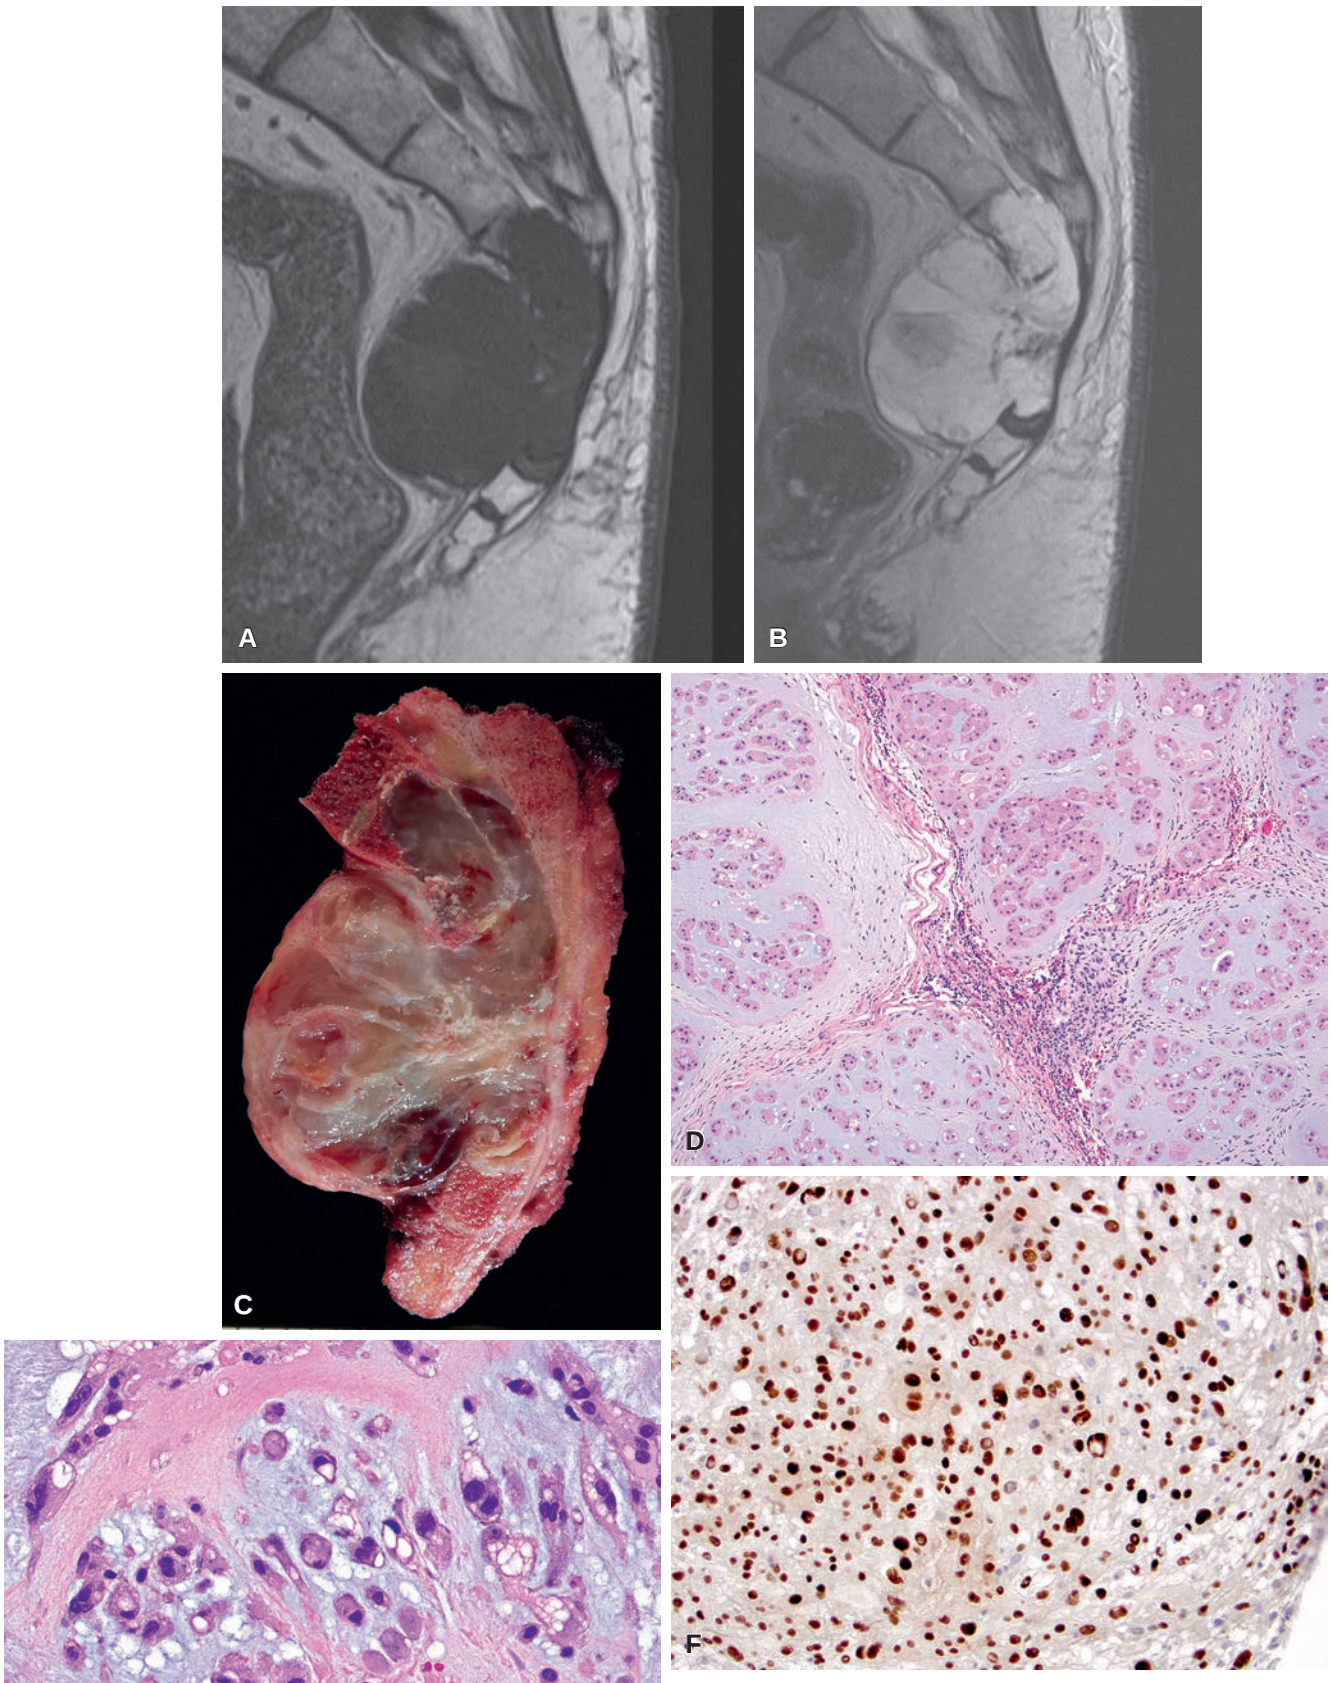

Figure 40.52 Sacral Chordoma. A, T1- and **B,** T2-weighted MRI shows the chordoma destroying the distal sacrum and involving anterior soft tissue. **C,** The gross appearance of chordoma is lobulated and gelatinous. **D** and **E,** Chordomas are lobulated and composed of cords and nests of epithelioid cells deposited in a myxoid stroma. Individual tumor cells may contain cytoplasmic vacuoles. **F,** An immunostain for brachyury confirms the diagnosis of chordoma.

Immunohistochemically, chordoma shows reactivity for S-100 protein, keratin, epithelial membrane antigen (EMA), and SOX9.[501–504] Among the keratins, those regularly expressed are cytokeratin 8, cytokeratin 19, and (less consistently) cytokeratin 5; they are usually negative for cytokeratin 7 and cytokeratin 20.[505] Glial fibrillary acidic protein (GFAP) reactivity is commonly encountered with the use of polyclonal antibodies, less so with their monoclonal counterparts.[506] The introduction of the brachyury antibody has simplified the work-up of chordoma.[504,507] This transcription factor—the product of the T gene—is necessary for notochord formation and is a highly sensitive and specific marker for chordoma. It is immunoreactive in only a limited selection of other neoplasms, most of which do not resemble chordoma histologically.[508–510]

The characteristic features of chordoma can be identified in material from fine-needle aspiration, which is also amenable to histochemical and immunohistochemical evaluation.[511]

Chordomas commonly show hypodiploid karyotype, frequently with loss of chromosomes 3 (especially 3p), 4, 10, and 13.[512–514] Comparative genomic hybridization shows that the most frequent changes are: −1p, −3p, +5q, +7q, +12q, and +20.[515] The candidate region for sporadic and inherited chordoma development has been mapped to 1p36.13.[516]

The natural history of chordoma is characterized by repeated episodes of local recurrence and an often fatal outcome. Recurrences may develop 10 years or longer after the initial therapy.[517] Distant metastases may also develop late in the evolution of the disease, and approximately 30% of patients develop metastatic disease.[518] The most common sites are the skin and subcutis (where they can simulate a sweat gland tumor) and bone, but they can occur in many other places, including rare sites such as the ovary.[519]

Treatment is in the form of surgical excision, radiation therapy, or a combination of both modalities.[520,521] Proton therapy, in particular, has proven to be an effective means for local control.[522] The recurrence rate is very high following surgery, particularly when the tumor is entered during the procedure. Adverse prognostic factors are represented by large tumor size, positive surgical margins, tumor necrosis, and high proliferative activity.[523–527]

"Dedifferentiated chordoma" is characterized by foci of high-grade spindle cell and/or pleomorphic sarcoma in conjunction with areas of typical chordoma, either in the primary tumor or in the recurrences.[528,529] This phenomenon is analogous to that of "dedifferentiated" chondrosarcoma and carries an equally ominous prognostic significance. Like in the latter, these foci may exhibit "divergent differentiation" in the form of rhabdomyoblasts or other cell types.[530] The high-grade foci exhibit a high proliferative index and are not immunoreactive for brachyury, in stark contrast to that of the conventional chordomatous component.[531] Indeed, dedifferentiation is a very poor prognostic factor in chordomas.[532]

Chondroid chordoma is a histologic variant that contains hyaline cartilage matrix, whether focal or extensive.[533] This entity has been controversial throughout the years, particularly with regard to the clinical significance of the chondroid foci in the tumor. However, at present, there is no definitive evidence that these tumors behave differently than conventional chordomas.

Adamantinoma of Long Bones

Classic adamantinoma is an extremely rare primary bone tumor of long bones that characteristically arises in the tibia but has been reported in other long bones, such as the femur, ulna, and fibula.[534,535] Occasionally, adamantinoma may involve the tibia and fibula simultaneously.[536]

Radiographically, classic adamantinomas typically arise in the anterior metaphyseal or diaphyseal cortex and may extend into the medullary cavity or adjacent soft tissue. Multiple foci of radiolucency are present, the margins of which may be sharply or poorly defined. An anterior bowing defect may be present.[537]

Grossly, classic adamantinoma can appear fleshy or contain gritty areas with the consistency of a fibro-osseous lesion. It is poorly defined and may extend into the overlying soft tissues. Microscopically, classic adamantinomas are dominated by an epithelial component that can appear basaloid, tubular, squamous, or spindled. The basaloid pattern is the most common and consists of solid nests of basaloid cells with palisading at the periphery and sometimes a stellate configuration in the center. The tubular pattern simulates closely the appearance of a vascular neoplasm (Fig. 40.53).[538] The keratins expressed by adamantinoma are mainly 14 and 19, with lesser representation of keratins 5, 17, 7, and 13. In contrast to other bone and soft tissue tumors with epithelial phenotypes—such as synovial sarcoma, chordoma, and epithelioid sarcoma—it lacks immunoreactivity for keratins 8 and 18.[539] Adamantinomas commonly show recurrent numerical chromosomal abnormalities, mainly gain of chromosomes 7, 8, 12, 19, and 21.[540]

Adamantinoma of bone is a low-grade malignant tumor characterized by a tendency for local recurrence and the occasional development of lymph node and distant metastases, particularly to lung. En bloc excision and amputation are the therapeutic choices, depending on the circumstances of the case.[534] A unique case has been described with complete sarcomatoid dedifferentiation.[541]

Differentiated (osteofibrous dysplasia-like) adamantinoma is a variant of adamantinoma that occurs in a younger age group than classic adamantinoma, frequently involves both the tibia and fibula, remains confined to the cortex, and is composed predominately of an osteofibrous dysplasia-like fibro-osseous component.[537,542] The epithelial nests in this variant can be sparse and difficult to identify and may only be recognized by cytokeratin immunostains. The behavior of differentiated adamantinoma is closer to that of osteofibrous dysplasia (see later) than classic adamantinoma, and Dorfman and Czerniak have proposed that the histologic features of this variant may reflect healing or regression of a classic adamantinoma.[543] The location, histologic features, and cytokeratin expression in classic and differentiated adamantinoma and osteofibrous dysplasia certainly suggest that these lesions are related.[544,545]

Peripheral Nerve Tumors

Schwannoma rarely presents as an intraosseous mass.[546] Although a strong predilection for the mandible has been noted, schwannomas also occur in the appendicular skeleton. Schwannomas of the sacrum can reach huge dimensions and present as retrorectal masses; they may simulate a malignant tumor on radiographic grounds (particularly chordoma) and present great technical difficulties for their surgical removal.[547] While most osseous schwannomas have conventional histologic features, a few of the reported cases of intraosseous schwannoma have been of the *melanotic* or *cellular* variety.[548]

Neurofibromatosis may be complicated by several types of skeletal abnormalities, including scoliosis, bowing, pseudoarthrosis, and other disorders of growth and may be accompanied by malignant bone tumors[549,550]; however, intraosseous neurofibromas are extremely rare.

Malignant peripheral nerve sheath tumor has been rarely seen in bone in patients with or without neurofibromatosis; several of the cases have involved jawbones.[551,552]

Xanthoma of bone presents in patients over the age of 20 years and has a male-to-female ratio of 2:1. It is almost always solitary, and the flat bones (pelvis, ribs, skull) are the most frequent sites. Radiographically, it presents as a well-defined, sometimes expansile lytic lesion, often with a sclerotic margin. Microscopically, an admixture of foamy cells, multinucleated giant cells, cholesterol clefts, and fibrosis is seen. The differential diagnosis includes Rosai–Dorfman disease

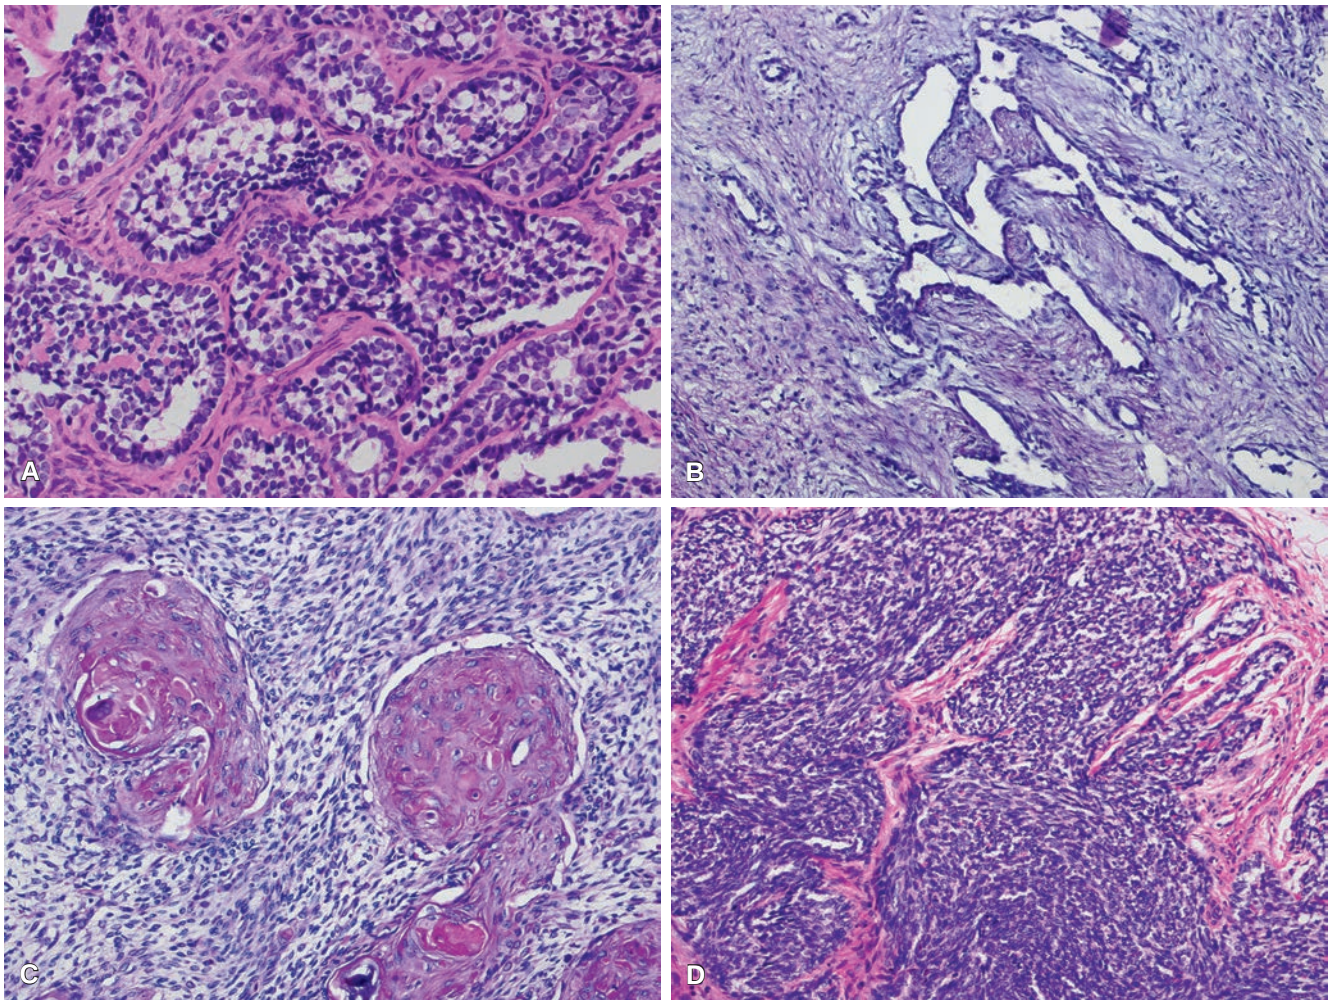

Figure 40.53 Microscopic Patterns of Adamantinoma. A, Basaloid, **B,** Tubular, **C,** Squamoid, and **D,** Spindled.

and secondary xanthomatous changes in other bone lesions, such as Langerhans cell histiocytosis or fibrous dysplasia.[553]

Fibrocartilaginous mesenchymoma is a term that has been applied to a rare benign neoplasm affecting the metaphysis of long bones, characterized microscopically by an admixture of spindle cells, bone trabeculae, and islands of cartilage. Some of the cartilage is in the form of structures resembling growth plates.[554,555] Fibrocartilaginous mesenchymoma may mimic desmoplastic fibroma and low-grade central osteosarcoma. Recurrences may supervene, but metastases have not been reported.[556]

Phosphaturic mesenchymal tumor is an unusual neoplasm often responsible for tumor-induced osteomalacia, a rare paraneoplastic syndrome due to phosphate wasting. This tumor may occur as a primary bone tumor but is far more common in soft tissue.[22] This entity is discussed in more detail in the following chapter.

Other types of mesenchymal neoplasms that have exceptionally presented as primary bone lesions include clear cell sarcoma,[557] alveolar soft part sarcoma,[558] desmoplastic small round cell tumor,[559] and perivascular epithelioid cell tumor (PEComa).[560]

Metastatic Tumors

Metastases are the most commonly diagnosed malignant neoplasms in bone. Multiple lesions are one of the hallmarks of metastases, and in most cases the presence of a tumor elsewhere is known, so the diagnosis is obvious. However, solitary metastases from occult primaries can be confused with primary bone tumors. More than 80% of all bone metastases originate in the breast, lung, prostate, thyroid, or kidney. Soft tissue sarcomas rarely metastasize to the skeletal system,[561] the outstanding exception being embryonal rhabdomyosarcoma of the soft tissues in children.[562]

About 70% of bone metastases affect the axial skeleton (cranium, ribs, spine, sacrum), and the remaining involve the appendicular skeleton (long bones) or both compartments. In all bones, metastases are preferentially situated in the red bone marrow.[563] When located in long bones, the area usually involved is the metaphysis.

Metastatic bone lesions are usually osteolytic but may be osteoblastic or mixed. Tumors with a tendency to produce pure osteoblastic metastases are prostatic carcinoma, carcinoid tumor and other neuroendocrine neoplasms, and breast carcinoma (Fig. 40.54).[564,565] The mechanism for blastic metastases is thought to involve both systemic and local factors that induce osteoblast proliferation, including TGF-β, fibroblast growth factor, and bone morphogenetic proteins.[566] Likewise, the mechanism of bone resorption is thought to be related to the stimulation of osteoclast formation via PTH, vitamin D_3, interleukins, and other factors activating the RANK-RANKL pathway.

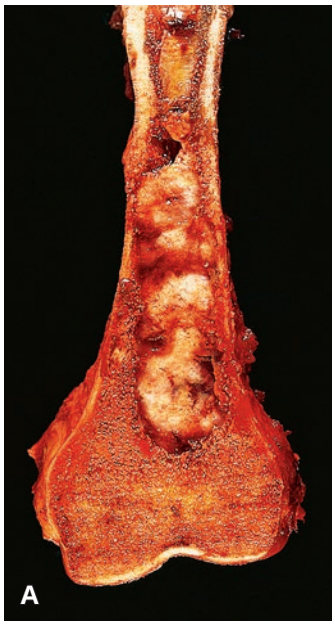

Figure 40.54 Ill-defined lytic lesion in midshaft of fibula produced by metastasis of lung carcinoma.

Figure 40.55 Radiograph of a metastatic pulmonary carcinoma involving the metacarpal.

The bone(s) involved and the character of the changes seen radiographically are helpful in predicting the site of the primary neoplasm. Thyroid carcinoma often metastasizes to the bones of the shoulder girdle, skull, ribs, and sternum, whereas carcinoma of the kidney tends to involve the skull, sternum, flat bones of the pelvis, humerus, and scapula.[567] Bone metastases peripheral to the knees or elbows are rare, but they certainly occur, as distally as the terminal phalanges, which may occur with pulmonary carcinomas (Fig. 40.55).[568]

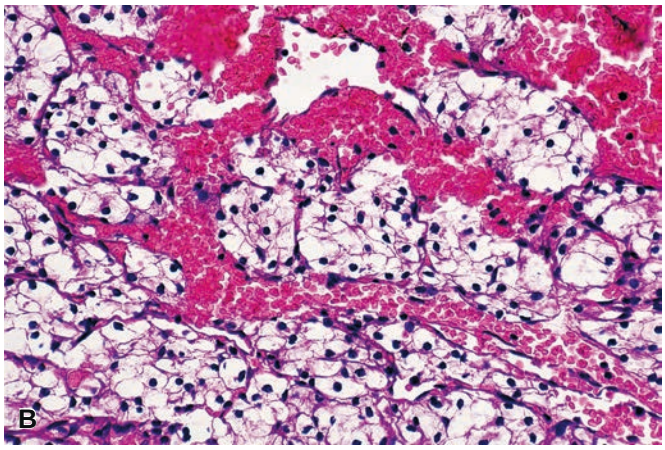

Figure 40.56 **A,** Gross appearance of femur with medullary involvement by metastatic renal cell carcinoma. **B,** Microscopic appearance. The optically clear appearance of the cytoplasm and the extensive hemorrhage are characteristic features.

Periosteal bone proliferation may rarely accompany a metastatic lesion. This is more likely to occur in certain blastic metastases such as those caused by prostate carcinoma. Exuberant new bone formation can also occur because of a pathologic fracture associated with metastatic carcinoma and lead to diagnostic confusion with osteosarcoma.[140] Metastatic malignant tumors—including carcinoma and melanoma—can be accompanied by a prominent population of osteoclasts and simulate a giant cell tumor.[569] Any tumor metastatic to bone, if extensive enough, may lead to hypercalcemia and elevation of serum acid phosphatase.

The work-up of metastatic tumors in bone, particularly when the primary site is unknown, includes the use of antibodies to the cytokeratin subsets—particularly cytokeratins 7 and 20—and antibodies more specific to specific organs, such as TTF-1, PSA, PAX8, GATA3, CDX2, and others (Fig. 40.56).

The treatment of metastatic carcinomas in bone involves providing analgesia and fracture fixation through a combination of surgery, radiotherapy, and the use of medications which reduce osteoclastic resorption, such as bisphosphonates.

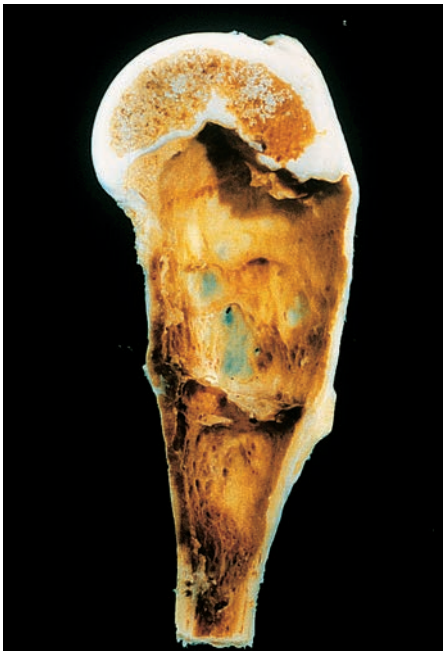

Figure 40.58 Gross appearance of solitary bone cyst. A large lesion located in the upper metaphysis of the humerus.

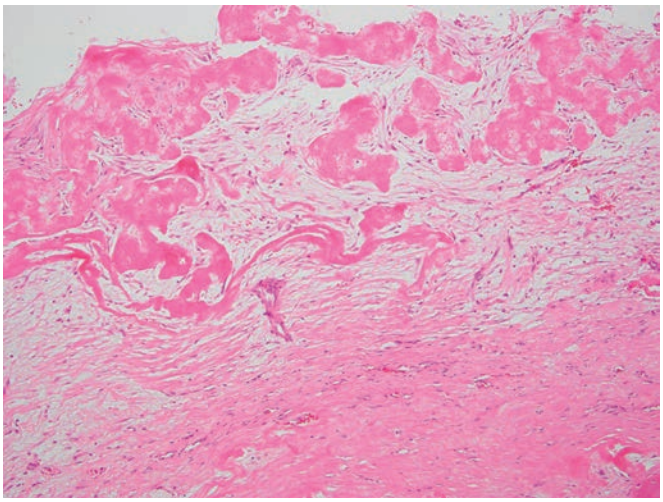

Figure 40.59 Microscopically, unicameral bone cyst contains a fibrous wall with adherent fibrin-like material that may incorporate into the wall.

Tumorlike Lesions

Unicameral Bone Cyst

Unicameral (solitary, simple) bone cysts usually occur in long bones, most often in the proximal humerus and femur (Fig. 40.57). They also may be seen in short bones, particularly the calcaneus.[570] Most cases are seen in males, and almost all occur in patients under 20 years of age.

Unicameral bone cysts arise in the metaphysis adjacent to the growth plate, but the growth plate grows away from the lesion resulting in the appearance that the cyst has "migrated." The cortex is thinned, but periosteal bone proliferation does not take place except in areas of fracture. Bones affected by these lesions often fracture, usually in the proximal portion of the cystic area, and a portion of cortical bone often drops to the bottom of the cyst, a feature referred to as a "fallen fragment sign."[571]

The unicameral bone cyst contains a clear or yellow fluid and is lined by a smooth fibrous membrane that may be brown (Fig. 40.58). The fluid may be hemorrhagic if a previous fracture has occurred. Microscopically, the cyst is lined by a thin fibrous membrane and well-vascularized connective tissue containing hemosiderin (often within macrophages), and cholesterol clefts are frequent. Fibrin deposits may become incorporated within the wall and calcify, at which point they resemble cementum-like material (Fig. 40.59).[572–574] Lesions with pathologic fracture often have areas resembling aneurysmal bone cyst.

Unicameral bone cysts can be treated with a variety injectables, decompression techniques, or curettage.[575]

Aneurysmal Bone Cyst

Aneurysmal bone cyst is seen usually in patients between 10 and 20 years of age[576] and is slightly more common in females. It occurs mainly in the vertebrae and flat bones but can also arise in long bones.[577] Vertebral lesions often involve the posterior elements of multiple spinal levels. Exceptionally, a lesion with the features of an osseous aneurysmal bone cyst is seen in a soft tissue location.[578,579]

Radiographically, aneurysmal bone cysts arise in the metaphysis (of long bones) and appear as a radiolucent lesion that thins the cortex, covered only by a thin shell of reactive periosteal bone. CT and MRI highlight the multiloculated nature of aneurysmal bone cysts; the characteristic fluid-fluid levels are best appreciated on MRI (Fig. 40.60).[580] Occasional lesions arise in subperiosteal locations.

Grossly, it forms a spongy, hemorrhagic mass covered by a thin shell of reactive bone, which may extend into the soft tissue; frequently

Figure 40.60 **Radiographic Features of Aneurysmal Bone Cyst. A,** Radiograph, **B,** MRI. Prominent fluid-fluid levels are seen on MRI.

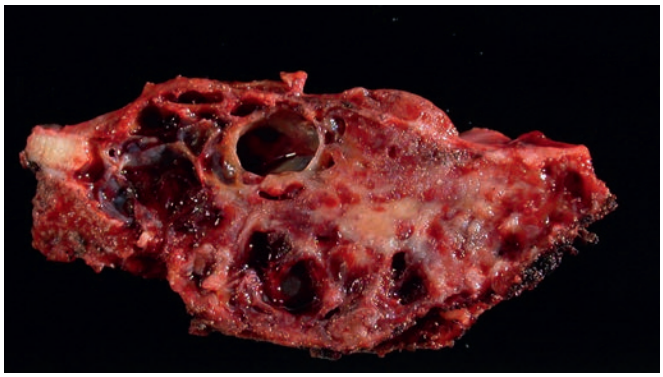

Figure 40.61 Gross appearance of an aneurysmal bone cyst, which contains multiple blood-filled cystic structures.

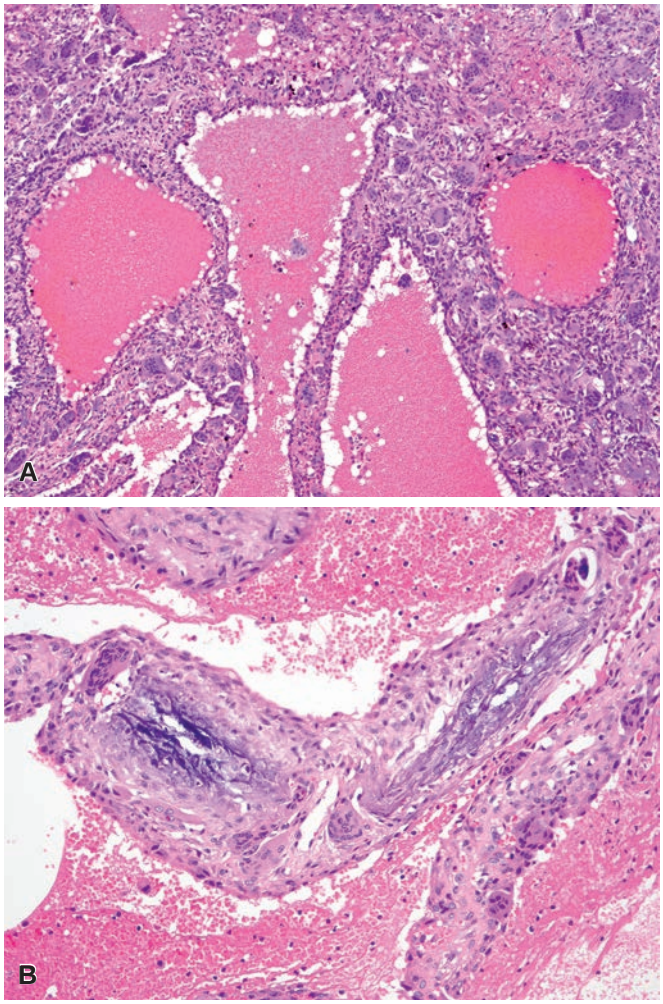

Figure 40.62 **Microscopic Features of Aneurysmal Bone Cyst. A,** Multiple blood lakes are surrounded by a giant cell–rich fibroblastic proliferation. **B,** Amorphous, calcified material is commonly identified in the walls of aneurysmal bone cyst and is a diagnostically useful finding.

aneurysmal bone cysts contain primarily blood with only small bits of tissue (Fig. 40.61). Microscopically, large spaces filled with blood are seen, separated by cellular septa containing fibrovascular tissue, inflammatory cells, and giant cells (Fig. 40.62). These septa do not have a true endothelial lining but are rather delimited by cells with the morphologic, ultrastructural, and immunohistochemical features of fibroblasts, myofibroblasts, and histiocytes.[581] Osteoclast-like giant cells may be prominent and often align along the bloody spaces. The septa also contain foci of osteoid and bone, and an additional feature of great diagnostic significance is the deposition of a peculiar degenerated calcifying fibromyxoid tissue.[582]

The differential diagnosis includes solitary bone cyst, giant cell tumor, hemangioma, telangiectatic osteosarcoma, and—especially for the lesions located in the jaw—central giant cell granuloma.

Once regarded as reactive lesions, current evidence suggests that primary aneurysmal bone cysts are likely neoplastic.[583] Approximately

70% of primary aneurysmal bone cysts have rearrangements of the *USP6* gene, located on chromosome 17. The most common translocation is t(16;17)(q22;p13), fusing *USP6* with *CDH11*.[584] Other partner genes include *TRAP-150* (chromosome 1), *OMD* (chromosome 9), *ANF9* (chromosome 3), and *COL1A1* (chromosome 17).[585] Secondary aneurysmal bone cysts may be associated with a variety of benign and malignant primary lesions, including chondroblastoma, giant cell tumor, osteoblastoma, and osteosarcoma; however, these secondary aneurysmal bone cysts lack *USP6* rearrangements. It has been suggested that insulin-like growth factor-1, which has been consistently found in this lesion, may play a role in its pathogenesis.[586]

Aneurysmal bone cysts recur approximately one-fourth of the time when treated by curettage alone because of incompleteness of surgical excision.[576,586]

A few cases of reasonably convincing malignant transformation of aneurysmal bone cyst into osteosarcoma have been described; this exceptionally rare phenomenon should be distinguished from telangiectatic osteosarcoma and osteosarcoma with aneurysmal cyst-like areas.[587,588]

Sometimes lesions with the features of aneurysmal bone cysts are seen in association with solid areas composed of an admixture of fibrous tissue, woven bone formation, and osteoclasts. In other instances, solid areas with this mixed appearance are seen in the absence of typical aneurysmal bone cyst features. Depending on the location of the lesion, variation in microscopic appearance, and the pathologist's bias, these lesions have been variously referred to as *giant cell reaction*, *(extragnathic) giant cell reparative granuloma*, *giant cell lesion of small bones*, and *solid variant of aneurysmal bone cyst*.[589–595] Locations include the small bones of the hand and feet, vertebrae, sacrum, and—less commonly—long bones. In the latter locations, they tend to have a metaphyseal location.

Other Cysts

Ganglion cysts morphologically indistinguishable from those commonly seen in the periarticular soft tissue are occasionally found in an intraosseous location, always close to a joint space (Fig. 40.63).[596,597] The cyst is surrounded by a zone of condensed bone, is often multiloculated, and has a gelatinous content and a wall of attenuated fibrous tissue. The bones of the ankle, particularly the tibia, are those most commonly affected.[598] Intraosseous ganglia are similar to the geodes those seen in association with degenerative joint disease.

Subpubic cartilaginous cyst is the name given to a fibrocartilaginous mass with extensive degenerative cystic changes that has been observed in the proximity of the symphysis pubis.[599]

Non-ossifying Fibroma (Fibrous Cortical Defect)

Non-ossifying fibromas are extremely common and distinctive lesions of bone that occur in adolescents, most often in long tubular bones, particularly the proximal and distal tibia or the distal femur.[600] Radiographically, they appear as eccentric, sharply delimited radiolucent lesions that arise in the metaphyseal cortex (Fig. 40.64). Smaller, completely intracortical lesions are typically referred to as fibrous cortical defects, whereas larger lesions that encroach on the medullary cavity are designated as non-ossifying fibromas. It is unclear whether these are neoplastic lesions or developmental aberrations.

Grossly, the lesion is granular and brown or dark red and may contain yellowish areas as well. Microscopically, it consists of cellular masses of fibrous tissue, often arranged in a storiform pattern (Fig. 40.65). Scattered osteoclasts and collections of foamy and hemosiderin-laden macrophages are frequent. The microscopic appearance is very reminiscent of a benign fibrous histiocytoma and is designated as such by some authors, especially when it occurs in adult patients in places other than metaphyses of long bones.[601]

Clinically, there are few or no symptoms except pain. The lesion is usually found incidentally on x-ray examination. Fractures can occur through the thinned cortex,[602] at which point surgical intervention is necessary. Most non-ossifying fibromas will spontaneously heal and do not require surgery.

Figure 40.63 MRI shows a well-circumscribed intraosseous ganglion cyst of the medial malleolus of the ankle.

Figure 40.64 Radiograph of a non-ossifying fibroma. This radiolucent lesion arises in the metaphysis of the distal tibial cortex and is surrounded by prominent reactive bone.

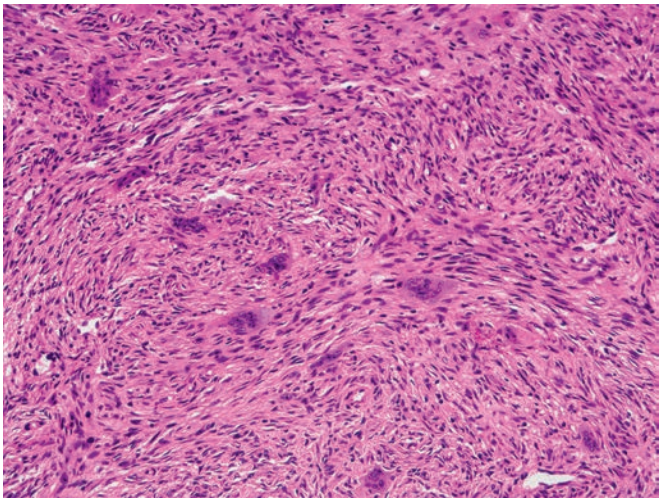

Figure 40.65 Non-ossifying fibromas are composed of bland spindled cells, often arranged in a vague storiform pattern, and contain scattered giant cells.

Figure 40.66 Fibrous Dysplasia. This lesion, located in the femoral neck, is well defined, radiolucent, and surrounded by reactive bone. A pathologic fracture extends through the lesion.

Fibrous Dysplasia and Osteofibrous Dysplasia

Fibrous dysplasia can present in two forms: monostotic and polyostotic. The monostotic variety is usually seen in older children and young adults and most commonly affects the rib, femur, tibia, and craniofacial bones. The less common polyostotic type may be unilateral or have widespread skeletal involvement. Patients with widespread skeletal involvement may also have associated endocrine dysfunction, precocious puberty in female individuals, and areas of cutaneous hyperpigmentation (McCune–Albright syndrome). Monostotic fibrous dysplasia, polyostotic fibrous dysplasia, and McCune–Albright syndrome all occur sporadically and are caused by activating mutations in the *GNAS1* gene (located in 20q13, encoding the α-stimulatory subunit of heterotrimeric G proteins) that occur postzygotically in a somatic cell.[603–605] The differences in clinical manifestations relate to the time in which the mutation takes place, with mutation occurring during embryonic life being more likely to result in McCune–Albright syndrome, and mutation occurring in postnatal life more likely to cause monostotic disease. The bone lesions of fibrous dysplasia have been found to be clonal, in keeping with a neoplastic process.[606]

Radiographically, fibrous dysplasia arises within the medullary cavity and may cause expansile remodeling of the bone. The lesions are usually well circumscribed and may have surrounding reactive bone. The appearance of the lesion on plain radiography and CT depends on the relative proportion of bone and fibrous tissue within the lesion but is often described as having "ground-glass opacity" (Fig. 40.66). Punctate areas of calcification may be seen in fibrocartilaginous dysplasia (see later). Lesions in craniofacial bones may appear radiodense. Occasionally the lesion protrudes far beyond the normal bone contour ("fibrous dysplasia protuberans").[607]

Grossly, the tissue cuts with a gritty consistency and is grayish white (Fig. 40.67). The cortical bone often is thinned and expanded. Microscopically, fibrous dysplasia is composed of irregularly shaped trabeculae of woven bone deposited in a fibrous stroma of variable cellularity. The bone trabeculae may have a "C" or "S" shape or can appear round (Fig. 40.68). These bone trabeculae are woven when viewed with polarized light and lack the accompanying osteoblastic rimming that would be expected given the immaturity of the bone. Older lesions may become cystic or develop a histiocytic infiltrate. Stromal hemorrhage may elicit a giant cell reaction.

Figure 40.67 Gross appearance of fibrous dysplasia of the rib. The lesion forms a fusiform, expanded mass that is grayish white.

Occasionally, lesions of fibrous dysplasia show calcified spherules similar to those seen in cementifying fibromas.[608,609] Other cases show highly cellular areas that may be diagnosed incorrectly as sarcoma. Focal areas of hyaline cartilage and cystic areas may also be present.[610] The former are more common in the polyostotic variety and can dominate the microscopic picture to such a degree that a mistaken diagnosis of a cartilaginous tumor can be made.

It has been suggested that some rib lesions resembling fibrous dysplasia but showing progressive maturation of the bone toward the periphery are secondary to trauma ("post-traumatic dysplasia or lesion").[611,612] Some of these lesions are bilateral and strikingly symmetrical.[613] A conceptually related issue is the so-called *liposclerosing myxofibrous tumor*, which some authors have hypothesized represents a form of fibrous dysplasia with secondary trauma-induced changes.[614,615] However, several authors have carefully

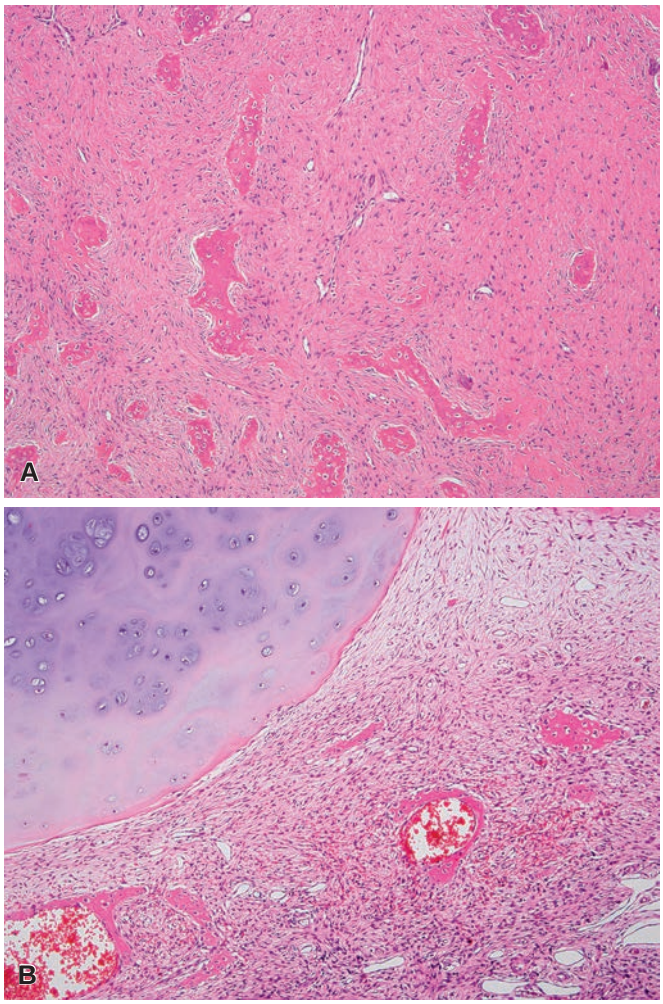

Figure 40.68 Histologic Features of Fibrous Dysplasia. A, Irregularly shaped woven bone spicules are surrounded by fibrous stroma. The surfaces of the trabeculae are devoid of osteoblasts. **B,** Chondroid nodules may be prominent.

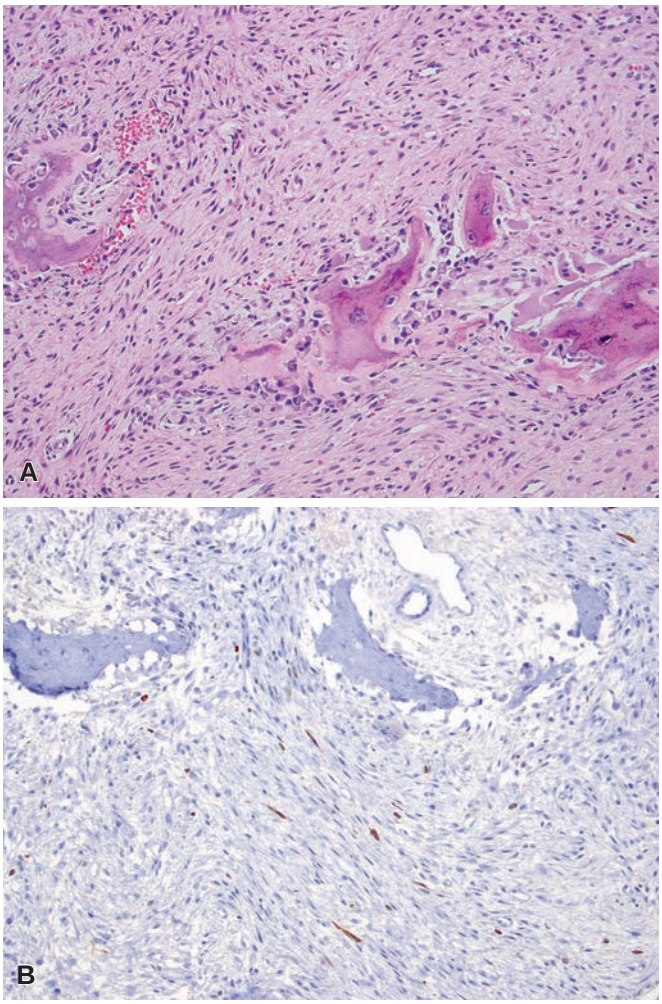

Figure 40.69 Osteofibrous Dysplasia. A, Osteoblastic rimming is a prominent feature of osteofibrous dysplasia. **B,** Individual keratin-positive spindled stromal cells are seen, but nests of epithelial cells are absent.

reviewed the histologic features in cohorts of patients with this condition and concluded that most cases are examples of fibrous dysplasia; others have shown that the lesions harbor an activating Gs alpha mutation, again suggesting these are examples of fibrous dysplasia.[616,617]

Fibrous dysplasia may be accompanied by intramuscular myxoma of the same extremity (Mazabraud syndrome).[618] In addition, fibrous dysplasia of either monostotic or polyostotic type can be complicated not only by the development of a primary bone sarcoma, particularly osteosarcoma,[619] but also chondrosarcoma and undifferentiated pleomorphic sarcoma.[620,621]

Resection cures fibrous dysplasia in bones such as the rib. Curettage is adequate in long bones such as the tibia. In the maxilla, where some deformity may exist, partial removal of the lesion is all that is necessary.

Osteofibrous dysplasia (ossifying fibroma, Campanacci lesion) is a benign fibro-osseous lesion more closely related to adamantinoma than fibrous dysplasia. It is distinguished microscopically from fibrous dysplasia by the cortical location of the process, prominent osteoblastic rimming of the bone trabeculae, and the presence of keratin-immunoreactive stromal cells (Fig. 40.69).[622,623] The tibia and fibula are affected almost exclusively, the lesions typically located in the anterior cortex.[622,624]

Clonal chromosomal abnormalities have been identified in this lesion, suggesting a neoplastic nature.[625,626] Immunohistochemically, reactivity for keratin, neurofibromin, S-100 protein, and Leu7 are commonly found in osteofibrous dysplasia.[627–629] In contrast to fibrous dysplasia, there are no activating mutations of *GNAS1*, suggesting that the two disorders are not pathogenetically related, despite their morphologic and some phenotypic similarities.[630]

Langerhans Cell Histiocytosis

This disorder is a histiocytic/dendritic cell proliferation characterized by the accumulation of dendritic cells and other inflammatory cells, including eosinophils, giant cells, neutrophils, foamy histiocytes, and often accompanied by areas of fibrosis (Fig. 40.70). Langerhans cells have a characteristic morphologic appearance. Their nuclei often are lobulated or indented, sometimes with a longitudinal groove; their cytoplasm is, for the most part, distinctly eosinophilic. A specific intracytoplasmic organelle, known as Langerhans or Birbeck granule, can be identified on electron microscopic examination. Diagnostic immunohistochemical markers include S-100 protein, CD1a, and langerin (CD207).[631]

Langerhans cell histiocytosis of bone can be divided into three major categories on the basis of type and extent of the organ

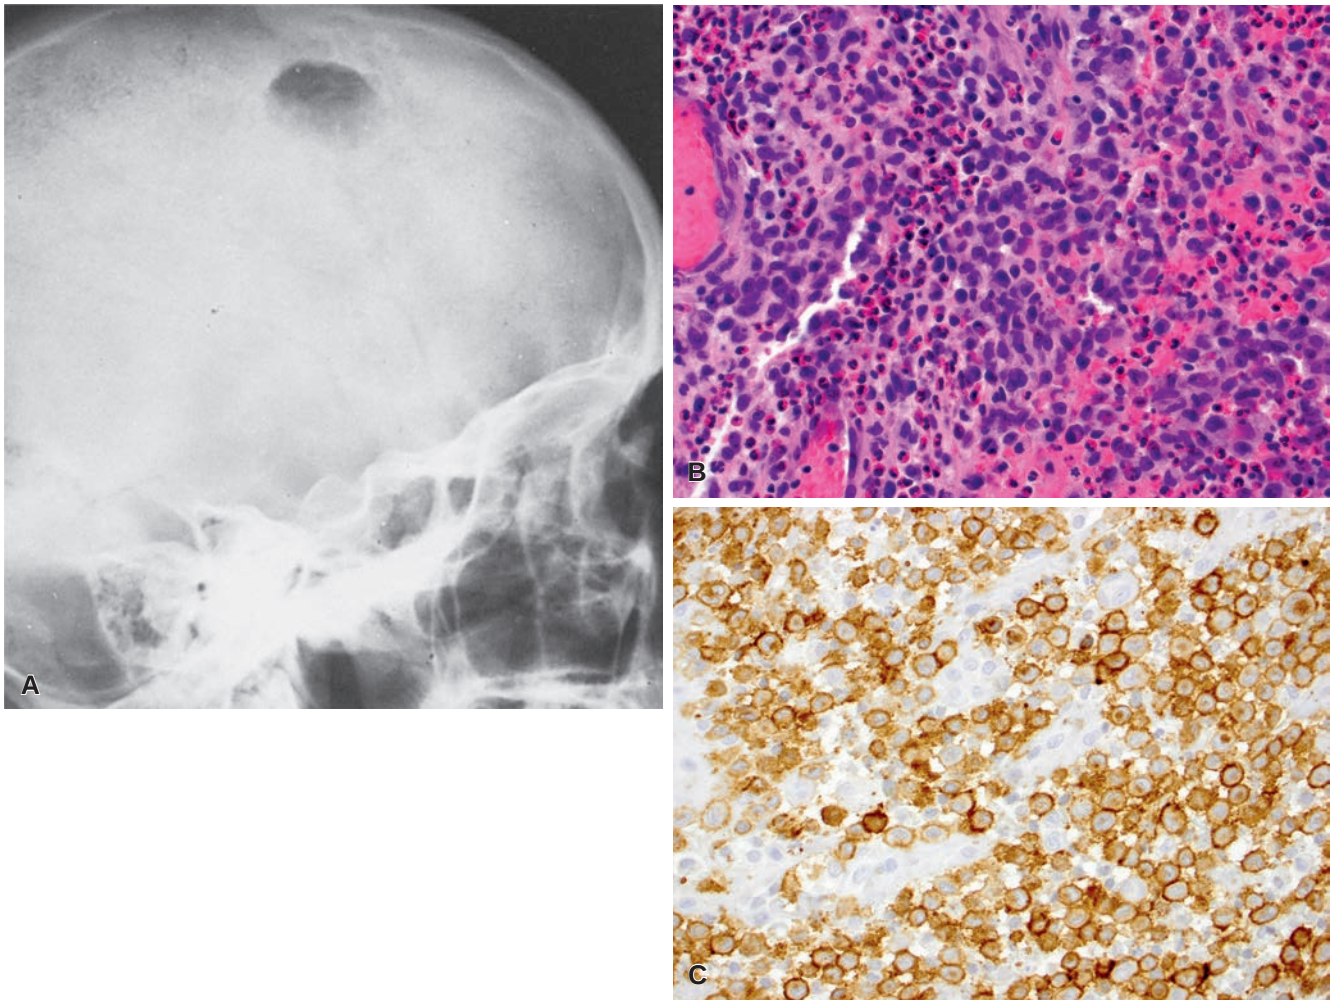

Figure 40.70 Langerhans Cell Histiocytosis. A, Punched out lesion of the skull. **B,** Histologic features of Langerhans cell histiocytosis include large, ovoid Langerhans cells with surrounding inflammation rich in eosinophils. **C,** An immunostain for CD1a highlights Langerhans cells.

involvement. Solitary bone involvement, multiple bone involvement (with or without skin involvement), or multiple organ involvement (bone, liver, spleen, and others).

The cases with solitary bone involvement, which represent the most common variety, have been traditionally referred to as eosinophilic granuloma. Young adults are most commonly affected. Any bone can be involved, with the possible exception of the hands and feet. The most common sites are the cranial vault, jaw, humerus, rib, and femur.[632,633] Radiographically, Langerhans cell histiocytosis is "the great imitator." Most lesions appear as well-circumscribed, punched out radiolucent lesions. In flat bones, Langerhans cell histiocytosis can have an aggressive pattern of bone destruction reminiscent of Ewing sarcoma or lymphoma. In the spine, this lesion causes vertebra plana.

The treatment may include observation, surgery, radiotherapy, or chemotherapy, depending on the extent of the disease. Many solitary lesions regress following biopsy. The long-term prognosis, particularly for solitary lesions, is excellent.[634] It is exceptional for these patients to develop other bone lesions or involvement of other organs.

Multiple bone lesions can be accompanied by proptosis, diabetes insipidus, chronic otitis media, or a combination of these conditions, historically referred to as Hand–Schüller–Christian disease. This form is characterized by a prolonged clinical course, often marked by alternating episodes of regressions and recrudescences, although the eventual outcome is favorable in most cases. By contrast, Letterer–Siwe disease—the development of Langerhans cell histiocytosis in multiple organ systems—follows a more aggressive clinical course.[632]

Langerhans cell histiocytosis should be regarded as a neoplastic disease. Recently, it has been shown that a relatively high percentage of cases of Langerhans cell histiocytosis harbor *BRAF* V600E mutations, resulting in activation of the MAPK pathway. A smaller percentage of lesions have mutations in the *MAP2K1* gene; these mutations are mutually exclusive.[635]

The differential diagnosis of Langerhans cell histiocytosis of bone at the microscopic level includes osteomyelitis and the osseous manifestations of Rosai–Dorfman disease.[636]

Other Histiocytic Lesions

Rosai–Dorfman disease (sinus histiocytosis with massive lymphadenopathy) can involve the skeletal system either as a manifestation of multisystem disease or, less commonly, as a mass limited to this site.[637] The morphologic features are similar to those seen at other extranodal sites, in the sense that secondary xanthomatous changes

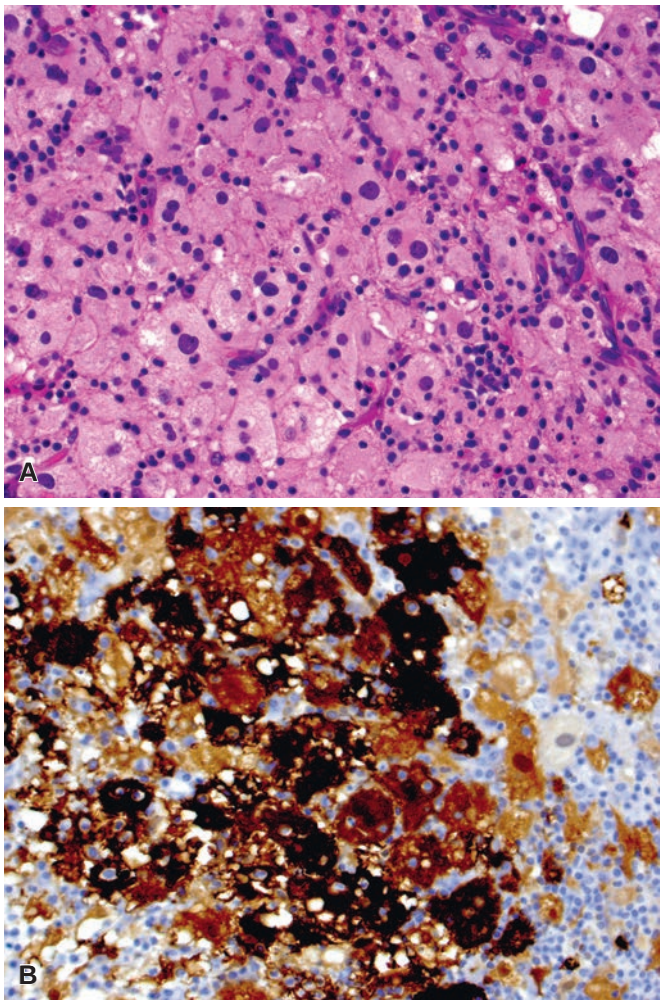

Figure 40.71 **Rosai–Dorfman Disease. A,** Large histiocytes admixed with acute and chronic inflammatory cells. The histiocytes engulf other inflammatory cells ("emperipolesis"). **B,** The histiocytes in Rosai–Dorfman disease are strongly immunoreactive for S-100 protein.

and fibrosis are common. These features, plus the paucity of emperipolesis, can render its recognition difficult (Fig. 40.71).[636]

Erdheim–Chester disease is a lipid-storing histiocytosis of non-Langerhans cell type which may be restricted to the bones or involve multiple organ systems, including lung and central nervous system. The foamy histiocytes that accumulate in this disease are CD68 positive and CD1a negative. The radiographic findings are virtually diagnostic and include mixed radiolucent and osteoblastic foci in the metaphyses and diaphysis of long bones. In the lung the involvement is primarily septal, a fact of diagnostic significance both radiographically and morphologically. As in the case of Langerhans cell histiocytosis, there is controversy as to whether the disease is reactive or neoplastic.[638–640]

Joints and Related Structures

Normal Anatomy

Joints that permit free movement of the bone, referred to as *diarthroses*, are covered by hyaline cartilage and enclosed in a capsule. This capsule is composed of an outer fibrous layer of dense connective tissues, which is continuous with the periosteum of the bones, and

Figure 40.72 Gross appearance of ganglion cyst. (Courtesy of Dr RA Cooke, Brisbane, Australia; from Cooke RA, Stewart B. *Colour Atlas of Anatomical Pathology*. Edinburgh: Churchill Livingstone; 2004).

an inner synovial layer.[1] The latter, also referred to as *synovial membrane*, contains fibroblast-like cells (synoviocytes, type B cells) and macrophage-like cells (type A cells).[641] Synoviocytes secrete proteoglycan, and the synovial membrane is organized such that cells and proteins move easily between joint fluid and synovium. A layer of loose connective tissue or adipose tissue is present in some regions of the joint between the synovial and the fibrous layers, resulting in the formation of folds or "villi," which protrude into the joint cavity.

Tendons are composed of closely packed parallel type I collagen fibers. They are surrounded by a layer of connective tissue known as the *tendon sheath*. In long tendons, this sheath is composed of an inner layer adjacent to the collagen and an outer layer that is loosely bound to the tissues surrounding the tendon. The space between these two layers is somewhat reminiscent of a joint cavity.

Non-neoplastic Diseases

Ganglion and Meniscal Cysts

Ganglion cysts occur around joints and—less commonly—around tendon sheaths. They are annoying deformities that may cause pain, weakness, partial disability of the joint, and bone changes. Individuals overusing the wrist and fingers (pianists, computer operators) are prone to this condition. A history of injury preceding ganglion formation may exist.

Ganglia develop by myxoid degeneration and cystic softening of the connective tissue of the joint capsule or tendon sheath. The most common location of ganglia is on the dorsal carpal area of the hand, where the cystic lesion pushes its way toward the surface between the tendons of the extensor indicis proprius and the extensor carpi radialis (Fig. 40.72). The second most frequent location is

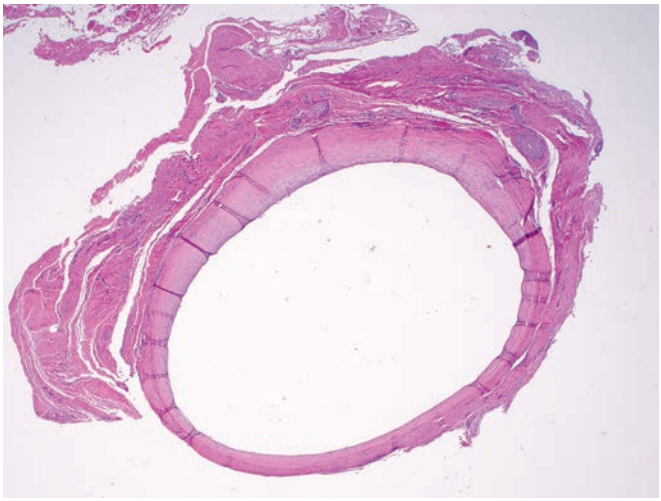

Figure 40.73 Microscopic appearance of ganglion cyst. The wall is composed of dense fibrous tissue, and there is no synovial lining.

the volar surface of the wrist, superficial and medial to the radial artery. Ganglia also arise on the volar surfaces of the fingers just distal to the metacarpophalangeal joints, in the dorsum of the foot, around the ankle and knee, and in the various articular and ligamentous areas of the spine. Ganglia are not lined by synovium and do not communicate with the joint cavity, two features distinguishing them from synovial (Baker) cysts (see next section; Fig. 40.73).

A lesion microscopically similar to soft tissue ganglion may occur in the menisci of the knee and is referred to simply as *meniscal cyst*. The most common site is the peripheral portion of the middle third of the lateral meniscus.[642,643] It may remain confined to the meniscus or extend extracapsularly. A traumatic etiology is favored.

Bursae and Baker Cyst

Bursae are found where muscles, tendons, and skin glide over bony prominences. They are composed of a fibrohyaline wall with no inner lining. Bursae are subject to all the diseases that occur in large joint spaces. Inflammation may be associated with the formation of cysts, fluid accumulation, and rice bodies (Fig. 40.74).

Baker cyst occurs in the popliteal space from herniation of the synovial membrane through the posterior part of the capsule or from escape of joint fluid through normal anatomic connections of the knee joint with the semimembranous bursa (Fig. 40.75). The cyst is lined by true synovium and may have cartilage in its wall. Any joint disease leading to increased intra-articular pressure, such as degenerative joint disease, neuropathic arthropathy, and rheumatoid arthritis, may result in the formation of Baker cysts.[644]

An unusual form of tenosynovitis characterized by the formation of psammoma bodies has been described that seems to result from repetitive motion or injury at the affected site.[645]

Carpal Tunnel Syndrome

The carpal tunnel is the space between the flexor retinaculum or transverse carpal ligament and the carpal bones. The median nerve courses through this tunnel, and its compression in this location by a variety of causes produces the symptoms of carpal tunnel syndrome.[646] These include bony deformity following trauma, masses within the canal (i.e., hemangiomas, lipomas, ganglia), rheumatoid

Figure 40.74 Gross appearance of prepatellar bursa with chronic inflammation.

Figure 40.75 Gross appearance of Baker cyst.

arthritis, and amyloidosis.[647] Often, no specific etiology can be demonstrated.[648]

Arthritis

Biopsies of the synovium or other articular structures may aid in the assessment of synovial inflammatory conditions, particularly when accompanied by synovial fluid evaluation.[649] Specimens can be obtained by blind needle biopsy, by minimally invasive arthroscopy, or under ultrasound guidance.[650] It is indicated for inflammatory joint diseases when the etiology remains in doubt, particularly when only one joint is affected. While it may not be possible to provide a definitive diagnosis in the case of chronic synovitis, other findings, such as acute synovitis, crystal deposits, or granulomas may point to a specific etiology.[649–651] Unfortunately, the histologic findings in

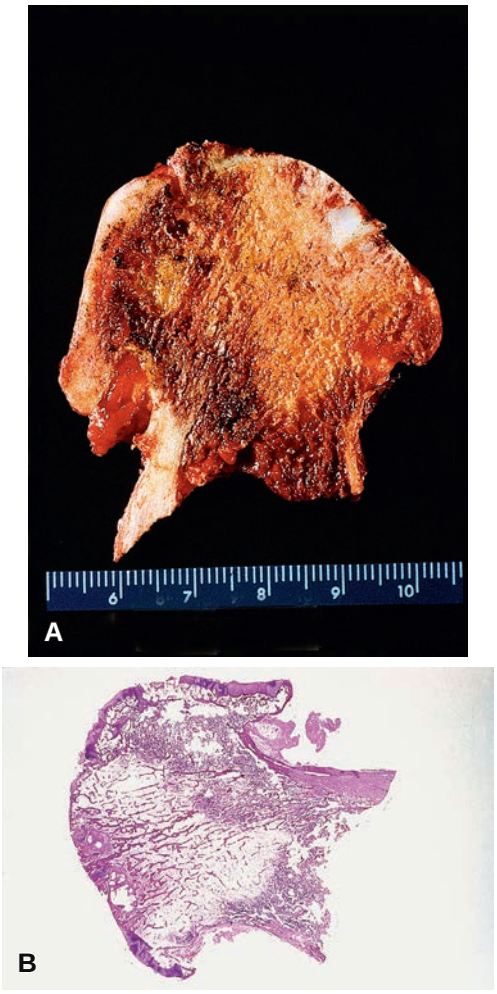

Figure 40.76 Advanced osteoarthritis of femoral head: **A,** gross appearance, showing near-total disappearance of articular cartilage; **B,** whole mount of the same case.

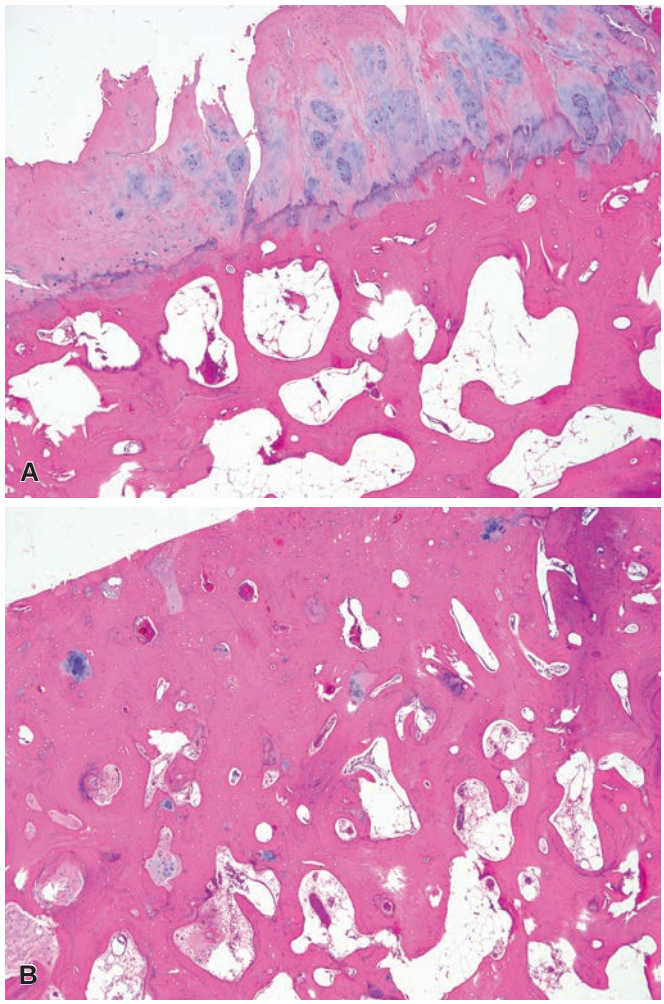

Figure 40.77 Early changes in osteoarthritis include cracking of the articular cartilage and cloning of chondrocytes **(A)**. **B,** Later, the cartilage is completely eroded, resulting in thickened subchondral bone.

the most common rheumatic diseases are often nonspecific[651]; however, the combination of prominent lymphoid follicles and marked hyperplasia of synovial cells is highly suggestive of rheumatoid arthritis or another inflammatory arthropathy.

Osteoarthritis (Degenerative Joint Disease)

Osteoarthritis is somewhat of a misnomer because this type of joint disease is degenerative and not inflammatory in nature. It may occur as a primary process as the result of repeated injury to the cartilage, or secondary to a variety of other conditions such as hip dysplasia, post-traumatically, or as the result of underlying conditions such as Paget disease or avascular necrosis. The earliest changes occur in the superficial hyaline articular cartilage, where the first detectable degenerative changes include fibrillation of the cartilaginous matrix at a right angle to the surface, and eventually resulting in a "papillary" appearance and sometimes in the freeing of fragments of cartilage. Initially, the chondrocytes clone in an attempt to repair the degenerative damage. Ultimately, the cartilage is completely worn, resulting in the articulation of two opposing subchondral bone surfaces (Fig. 40.76). The thickened, polished-appearing bone is referred to as "eburnated" (Fig. 40.77). Osteophytes, which are reactive osteocartilaginous projections, form at the peripheral margin of the joint. Subchondral cysts ("geodes") may form in the subchondral bone. The synovium may remain normal or undergo thickening, with formation of villous structures and chronic inflammation.[652]

In some cases of severe osteoarthritis, there are foci of subchondral acute inflammation resembling osteomyelitis, but these are probably of a noninfectious nature.[653]

It should be emphasized that the changes of degenerative joint disease are centered in the cartilage, a type of tissue notorious for its poor capacity for repair.[654] These changes are more prominent on the joint surface exposed to friction, weight bearing, or movement, but they also occur in areas of the joint not subject to these mechanical forces. The biology of osteoarthritis is highly complex but involves degradation of extracellular matrix, proteinases, cytokines, and inherent properties of the chondrocytes.[655]

Neuropathic arthropathy (Charcot joint) is a particularly destructive variant of degenerative joint disease that occurs as the result of neuropathy secondary to a variety of underlying causes, including diabetes, neurologic disorders, syringomyelia, or tertiary syphilis (Fig. 40.78). The underlying cause correlates with which joint is involved.[656] The process is usually progressive, and on occasion it may have an extremely rapid evolution. Particles of dead bone and cartilage often are seen in large amounts embedded in the synovial membrane ("detritic synovitis"). However, this is not specific for this condition.

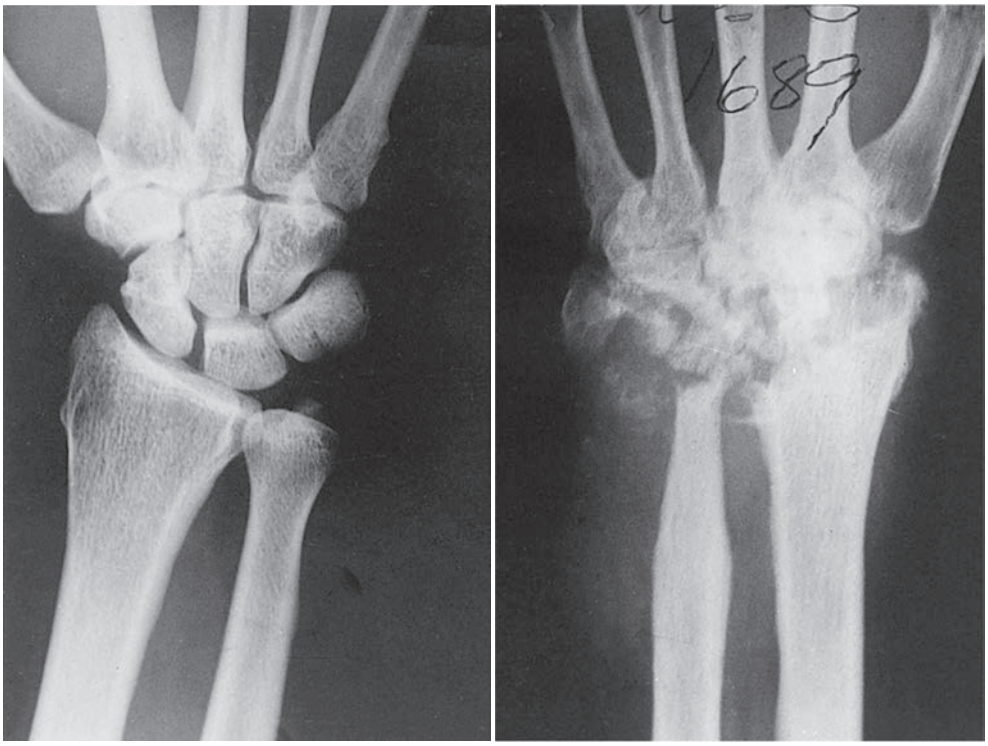

Figure 40.78 Neuropathic changes in wrist secondary to syringomyelia.

Chondromalacia patellae is the name given to a condition of obscure etiology characterized by softening, fibrillation, fissuring, and erosion of the articular cartilage of the patella.[657] Microscopically, the changes are indistinguishable from those of degenerative joint disease.

Rheumatoid arthritis is the most common inflammatory arthropathy and is an immune-complex disease that manifests as a chronic, polyarticular arthritis. It is mostly seen in women during the second and third decades of life. The joints of the feet and hands are nearly always involved. Other joints frequently affected are the elbows, knees, wrists, ankles, hips, spine, and temporomandibular articulations.[658]

The pathogenesis of rheumatoid arthritis starts with genetic susceptibility, and HLA-DRB1 plays a prominent role.[659] Autoantibodies against citrullinated peptides combine with IgG autoantibodies (rheumatoid factor) to form complexes that activate the complement system.[660,661] A T lymphocyte–mediated tissue response causes the marked joint inflammation seen in rheumatoid arthritis, and synovial fibroblasts and several key cytokines play a key role in tissue injury.[662] It has been suggested that a viral trigger may play a role in rheumatoid arthritis.[663]

The earliest morphologic changes occur in the synovial membrane. Hyperemia of the synovium is followed by proliferation of the synovial lining cells and infiltration by plasma cells and lymphocytes (Fig. 40.79).[664] Lymphoid follicles are often present. The small synovial blood vessels are lined by plump endothelial cells, and fibrin deposits often are seen close to the synovial lining or within the stroma. Two additional microscopic features, which are also nonspecific, include the presence of synovial giant cells and bone and cartilage fragments within the actual synovial membrane. The detritic cartilage and bone fragments tend to occur in joints with advanced disease and are likely the result of the erosive, destructive process of the articular surface.

As the process progresses, a granulation tissue pannus grows over the articular surface and erodes into the subchondral bone at the margin of the joint, resulting in osteopenic areas in the bone. The ensuing destruction of the articular cartilage (Fig. 40.80) may be followed by fibrous ankylosis and eventually bony ankylosis, or joint fusion. The pronounced tissue destruction not only involves the articular cartilage but the subchondral bone (leading to cysts) and the joint structures (leading to Baker cysts and synovial cysts) as well.[665] End-stage rheumatoid arthritis resembles osteoarthritis.

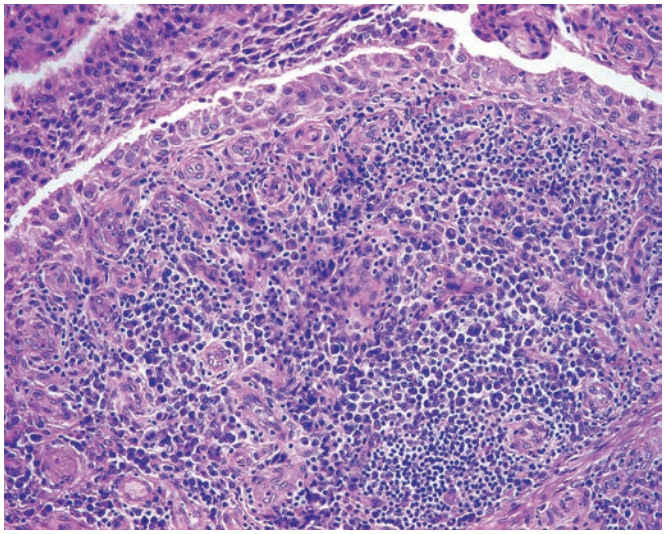

Figure 40.79 Synovial hyperplasia and heavy lymphoplasmacytic infiltrate in rheumatoid arthritis.

Tenosynovitis and "rheumatoid nodules" are the two most common extra-articular manifestations of rheumatoid arthritis. The changes seen in the former are indistinguishable from those seen in the joint membrane.[666] Rheumatoid nodules, which are seen in

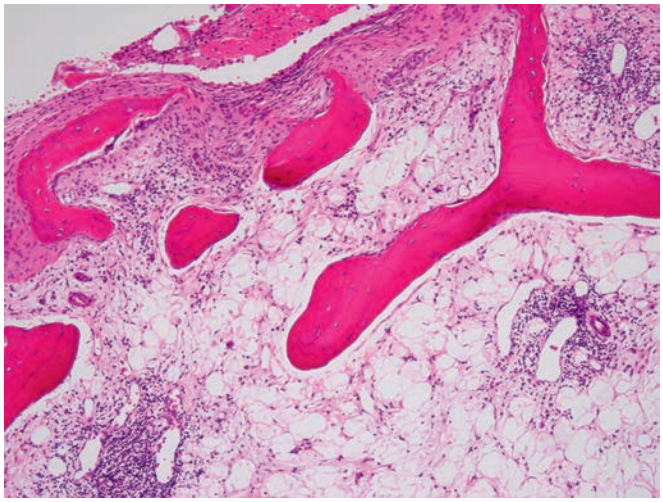

Figure 40.80 Examination of the bone in rheumatoid arthritis shows destruction of the articular surface by pannus, as well as lymphoid aggregates in the subchondral bone.

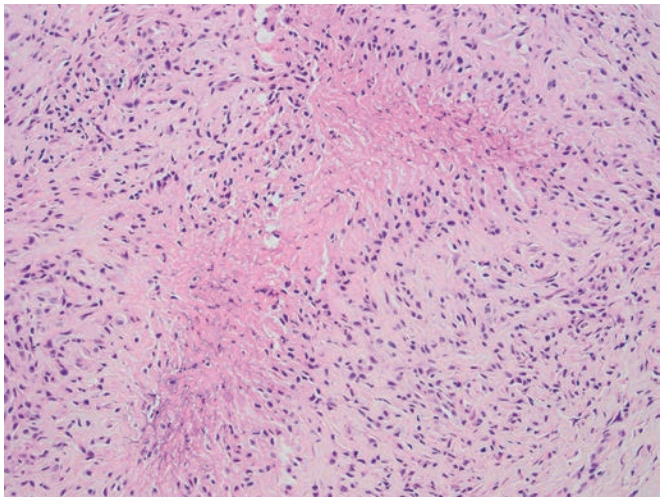

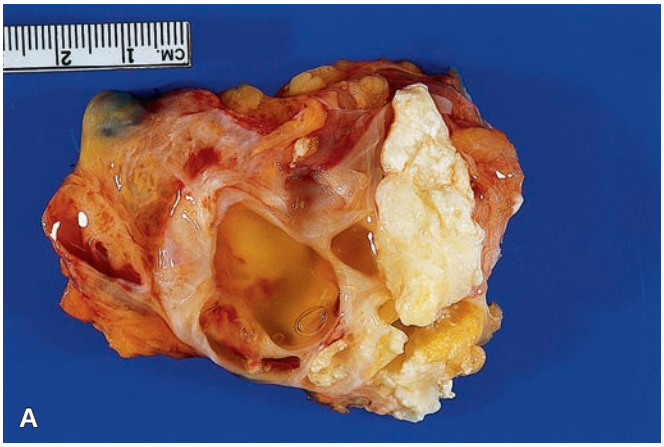

Figure 40.81 Rheumatoid nodule with early cystic change of the "necrobiotic" center. Note the peripheral palisading of histiocytes.

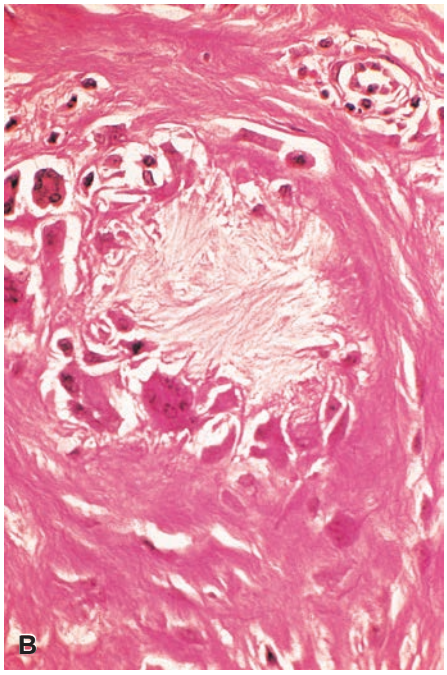

Figure 40.82 **Gout. A,** Gross appearance of large gouty deposit in the posterior knee. **B,** A lesion of periarticular gout showing a foreign body–type giant cell reaction to the deposited crystals. The crystalline nature of this material is not obvious in this formalin-fixed specimen.

approximately 20% of the patients, occur most often in tendons and tendon sheaths and periarticular subcutaneous tissue but also have been seen in the heart and large vessels, lung and pleura, kidney, meninges, and synovial membrane itself.[667] Microscopically, they are composed of a necrotic center containing fibrin, surrounded by a predominantly histiocytic inflammatory reaction, often arranged in a palisading fashion (Fig. 40.81). Rheumatoid nodules need to be distinguished from other palisading granulomatous processes, infectious granulomas, and on occasion epithelioid sarcoma.

Infectious Arthritis

Bacterial, fungal, and parasitic infections can reach the joints either by hematogenous spread or by contiguous extension from a neighboring osteomyelitis. A form of infectious arthritis that has risen dramatically in recognition and frequency in recent years is *Lyme disease*, an arthropod-transmitted infection caused by *Borrelia* species that can also involve skin, heart, and nervous system.[668–670] Erythema migrans occurs at the site of the initiating tick bite. The microscopic changes in the synovium are those of a nonspecific chronic synovitis, and serologic testing is typically used to establish the diagnosis.[671]

Gout and Pseudogout

Calcium pyrophosphate and monosodium urate crystal deposits are among the most common articular/periarticular deposits. About 2%–5% of chronic joint disease is caused by gout (caused by monosodium urate crystal deposits). The metatarsophalangeal joints are often the first to be involved, but other joints of the hands and feet are also frequently involved. The disease may also involve the joints of the long bones (Fig. 40.82). Uric acid deposits elicit a severe inflammatory reaction and progressively destroy the cartilage and may cause osteolytic, irregular destruction of subchondral bone. These deposits may extend out from a joint into the soft tissue and cause destruction of the ligaments. This destruction eventually leads to subcutaneous deposits that may erode through the skin. The

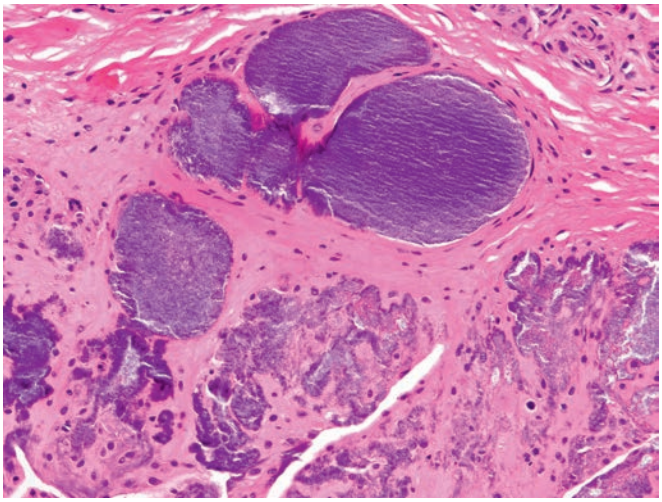

Figure 40.83 Aggregates of calcium pyrophosphate crystals appear bluish and lack a significant inflammatory response. Examination with polarized light will highlight the typical diamond or rhomboid shape of the crystals.

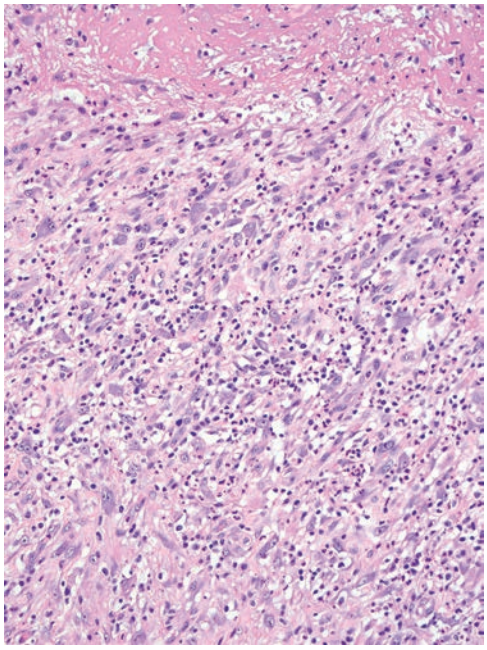

Figure 40.84 Periprosthetic joint infection. Tissue beneath the fibrin surface showing marked acute inflammation (greater than five neutrophils in five high-power fields, suggesting infection).

microscopic pattern of gout is unmistakable. The crystals appear as needle-like structures by polarized light examination. The crystals dissolve readily in water-based solutions; however, fixation in alcohol will help preserve the crystals, and alternatively thickly sectioned, unstained and coverslipped sections may allow the crystal to be visualized. Furthermore, the negative birefringence of these crystals can still be demonstrated after staining with nonaqueous alcoholic eosin.[672] Histiocytes and foreign body giant cells predominate in the inflammatory infiltrate.

Monosodium urate crystals should be distinguished from calcium pyrophosphate crystals *(pseudogout, "chondrocalcinosis")*. Calcium pyrophosphate crystals are commonly identified in articular cartilage, meniscal cartilage, and synovium. Calcium pyrophosphate crystals are recognizable as polarizable crystals that have a rhomboid or diamond shape, and the crystals do not elicit the same inflammatory response as urate crystals (Fig. 40.83). Tophaceous pseudogout, or the accumulation of calcium pyrophosphate crystal in a manner similar to tophaceous gout, is a much rarer condition.[673] Chondroid metaplasia can be prominent in this condition, resulting in a mistaken diagnosis of chondrosarcoma. Many of these cases involve the temporomandibular joint, but tophaceous pseudogout has been identified in many different sites.

Intervertebral disc prolapse is a complication of mechanical overload-induced degeneration of the disc. This process seems to be mediated through the mitochondrial apoptotic pathway.[674] Material curetted from an intervertebral disc because of prolapse is a very common surgical specimen. Features such as fibrillation, clustering of chondrocytes, and degenerative changes are generally regarded as indicators of degeneration related to prolapse.[675] Weidner and Rice[676] found instead that the feature that better correlated with prolapse was neovascularization occurring at the edges of the fibrocartilaginous fragments.

Other Articular and Periarticular Diseases

Hemophilia is characterized by the accumulation of hemosiderin in the synovium (hemosiderotic synovitis). In contrast to pigmented villonodular synovitis (PVNS), the iron pigment is deposited in superficial layers of the synovium and is accompanied by a chronic synovitis rather than a giant cell–rich histiocytic infiltrate with foamy histiocytes. The morphologic features of hemophilic arthropathy are those of a degenerative rather than an inflammatory process.[677]

Scleroderma (progressive systemic sclerosis) is often accompanied by arthralgia or arthritis, and sometimes these dominate the clinical picture. The main microscopic changes in the synovial membrane are superficial deposition of fibrin, mild mononuclear infiltrate, minimal hyperplasia of synovial lining cells, proliferation of collagen fibers, and focal obliteration of small vessels.[678]

Lupus erythematosus may be accompanied by microscopic changes in the synovium that are indistinguishable from those of rheumatoid arthritis. As a rule, however, there is a more intense surface fibrin deposition and less degree of proliferation of synovial cells.[651]

Amyloid can deposit in the synovium, articular cartilage, menisci, periarticular tissue, and intervertebral disk in old age, apparently unrelated to osteoarthritis and in the absence of systemic amyloidosis.[679–683] Heavier amounts can be seen as an expression of primary amyloidosis or multiple myeloma.[420] Amyloidosis is one of the causes of the carpal tunnel syndrome.[684]

SAPHO is a peculiar syndrome in which synovitis is seen in combination with acne, pustulosis, hyperostosis, and osteitis.[685]

The Pathology of Prostheses

A comprehensive review of joint implant pathology is beyond the scope of this text. However, surgical pathologists are often asked to review biopsies from tissue surrounding a prosthesis to assess for the possibility of infection. In the appropriate context, five or more neutrophils per high-power field in at least five fields suggests infection (Fig. 40.84). Care must be taken not to evaluate surface fibrin for neutrophils. The presence of foamy histiocytes, foreign body granulomas, and opaque particles or polyethylene suggests the possibility of aseptic loosening.[686] The histologic findings, particularly at the time of intraoperative consultation, are more reliably interpreted with knowledge of C-reactive protein levels, erythrocyte sedimentation rate, or alpha defensin results.

Tumors and Tumorlike Conditions

Tenosynovial Giant Cell Tumor and Pigmented Villonodular Synovitis

Localized tenosynovial giant cell tumor (giant cell tumor of tendon sheath, nodular tenosynovitis) and diffuse tenosynovial giant cell tumor (PVNS) are essentially the same lesion, differing mainly in their clinical features. Localized tenosynovial giant cell tumor is a common lesion that occurs more frequently in women than men, usually appearing in young and middle-aged patients. Most cases are located in the hands and fingers, followed by the feet. Other sites can be affected, including the vertebral column.

Grossly, these tumors are small (1–3 cm in diameter), circumscribed, and vary in color from brown to yellowish (Fig. 40.85). Microscopically, localized tenosynovial giant cell tumors are composed of mononuclear cells, foamy histiocytes, and multinucleated giant cells containing hemosiderin (Fig. 40.86). Mitoses may be prominent, and zones of hyalinization may constitute a variable proportion of the mass. Immunohistochemically, the mononuclear stromal cells express clusterin,[687] and some cells express desmin as well.[688] The multinucleated giant cells have the phenotypic features of osteoclasts.[689] Despite the similarities in the anatomic sites of origin, the lesion referred to as fibroma of tendon sheath appears to be a distinct entity. We suspect that the cases reported as *tendon sheath fibromas* are histogenetically related to tenosynovial giant cell tumor.[690] Their location, clinical presentation, and recurrence rate are certainly comparable.

The great cellularity of this tumor, its variable pattern, and the presence of mitotic figures may lead to an erroneous diagnosis of sarcoma. However, these tumors are nearly always benign. They may erode contiguous bone by pressure. If incompletely removed, they may recur locally.

Both localized and diffuse tenosynovial giant cell tumor share similar genetic features suggesting they are neoplastic.[691] Both lesions harbor a chromosomal translocation involving the *CSF1* gene (located at 1p13 and encoding ligand of the tyrosine kinase receptor).[692,693] Interestingly, the translocation is present in only a small percentage of the lesional cells.[693] There is high expression of *CSF1* mRNA and protein, even in tumors lacking demonstrable *CSF1* translocation.

A very rare malignant counterpart of this lesion has been described in both the localized and diffuse forms.[694,695] Features that should suggest malignancy are a high number of mitotic figures, marked nuclear hyperchromasia, and lack or paucity of multinucleated giant cells. The main differential diagnosis of tenosynovial giant cell tumor is epithelioid sarcoma. The presence of granuloma-like formations, necrosis, invasiveness, epithelioid features, and keratin immunoreactivity favors the latter.

Figure 40.85 **A,** Gross appearance of tenosynovial giant cell tumor. The lesion is small, well circumscribed, solid, and with a brownish cast. **B,** Whole-mount appearance of the cross section of a lesion located in the finger. Note the lobulated quality.

Pigmented Villonodular Synovitis and Bursitis

PVNS, or diffuse intra-articular tenosynovial giant cell tumor, is closely related to its localized counterpart. The diffuse variant occurs in young adults.[696,697] Although the knee joint is the usual site, the process may also involve the ankle, hip, shoulder, or even the elbow joint.[698] Usually only one joint is affected, instances of bilateral disease being exceptional. Occasionally, the lesion may cause cystic lesions in the bone adjacent to the involved joint.

The process diffusely involves the synovium of the affected joint. The lesion imparts a villous pattern in the synovium, which has a brown or yellowish appearance; the synovial fluid may be hemorrhagic. Microscopically and immunohistochemically, the cellular component is similar to that of localized tenosynovial giant cell tumor, but rather than having a circumscribed appearance, it is diffuse

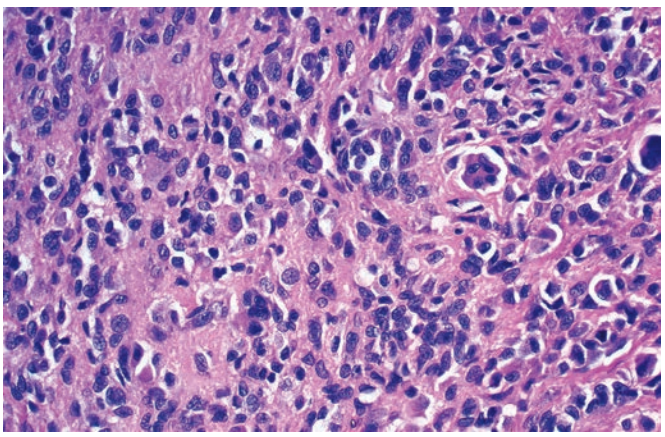

Figure 40.86 Microscopic appearance of tenosynovial giant cell tumor. A polymorphic infiltrate of small histiocytes and multinucleated giant cells is embedded in dense fibrous tissue.

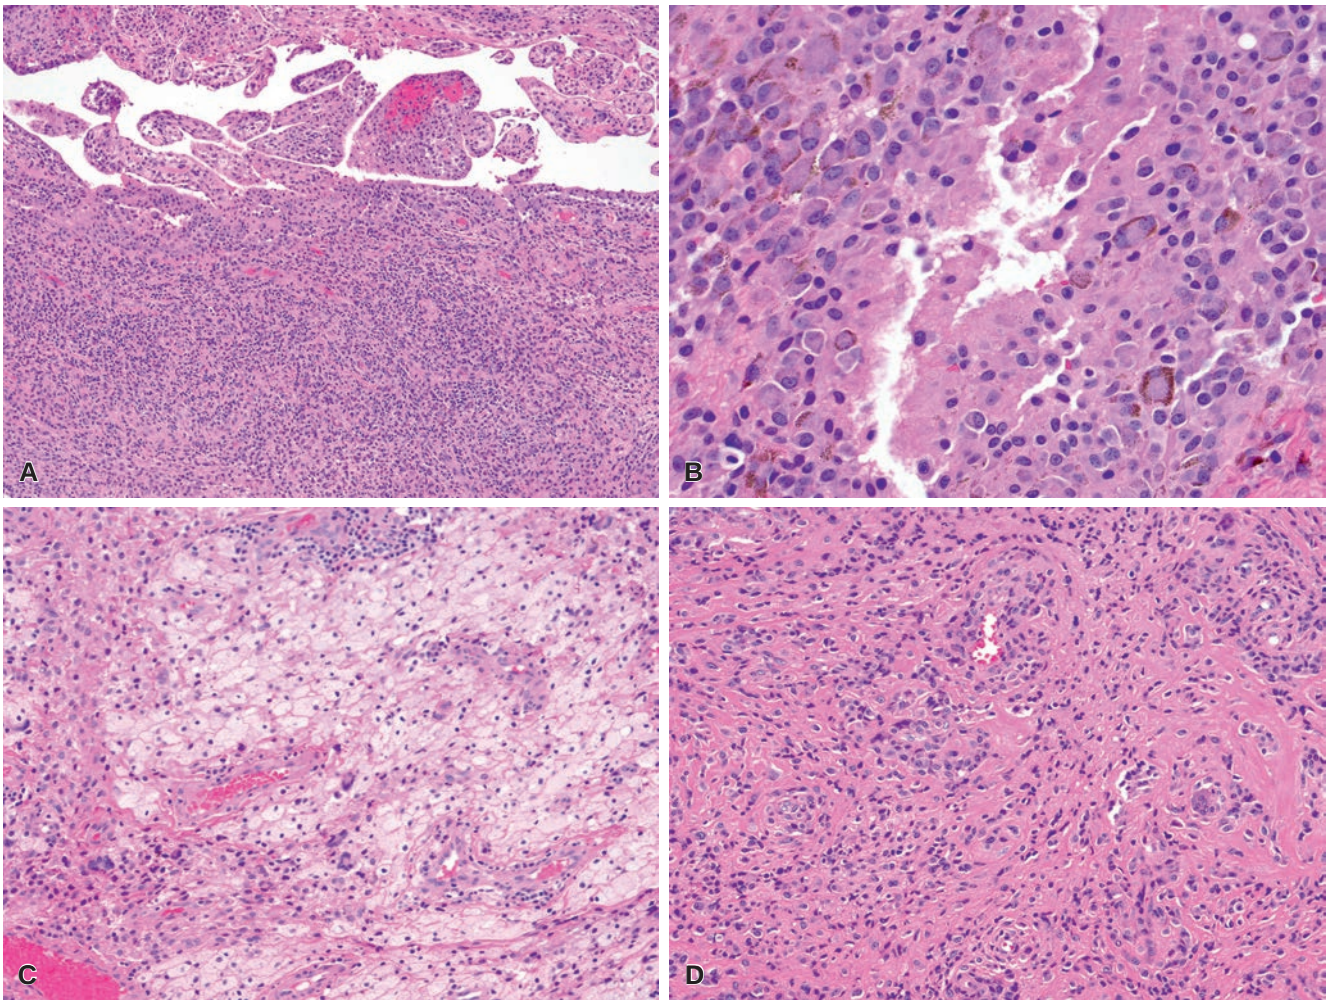

Figure 40.87 Pigmented Villonodular Synovitis. A, The villous architecture is evident on the surface of the lesion. **B,** Giant cells and histiocyte-like cells contain rings of iron in their cytoplasm. **C,** Foamy histiocytes may be prominent. **D,** Hyalinization may be striking.

and contains papillary projections (Fig. 40.87). Large clefts and pseudoglandular or alveolar spaces lined by synovial cells are also present. Occasionally, foci of chondroid metaplasia resembling osseous chondroblastoma are found.[699]

Clonal chromosomal aberrations similar to those of localized tenosynovial giant cell tumor have been found in PVNS, supporting a pathogenetic link between the two conditions and the neoplastic nature of both.[693]

This disease is treated by synovectomy, and local recurrences are common. Radiotherapy may be effective for local control for incompletely excised or recurrent tumors.[700] As for localized tenosynovial giant cell tumors, isolated examples of malignant PVNS have been described.[701]

Synovial Chondromatosis and Chondrosarcoma

Synovial chondromatosis is characterized by the formation of cartilaginous nodules in the synovial membrane.[702] This condition most often is monoarticular, affecting the knee or hip and communicating bursae, but it can also occur in extra-articular, tenosynovial sites.[703] The etiology is unknown, but the presence of clonal chromosomal aberrations suggests that it represents a neoplastic condition.[704] *IDH* mutations are not present in synovial chondromatosis.

Grossly, the osteocartilaginous bodies may remain confined to the synovium or be extruded into the joint cavity. They usually are partially calcified (Fig. 40.88). Innumerable small bodies can be seen grossly in the resected lesion.

Histologically, the nodules of synovial chondromatosis are composed of hyaline cartilage in which the chondrocytes are arranged in a characteristic clustered manner. Some nuclear atypia may be present. It is important to distinguish primary synovial chondromatosis from secondary forms, in which osteocartilaginous loose bodies are seen. The distinction is important because primary synovial chondromatosis is treated with synovectomy, whereas the secondary form is treated by simple removal of loose bodies and correction of the underlying cause.[705] Rare cases of malignant transformation to chondrosarcoma have been reported,[706] as have primary synovial chondrosarcomas.[707]

Other Tumors and Tumorlike Conditions

Most tumors involving the joint space represent direct extension from neoplasms initially located in the adjacent bones.

The only primary tumor of the joints that is seen with any frequency in addition to those already mentioned is **synovial hemangioma**. Most patients are young adults, and there is a predominance

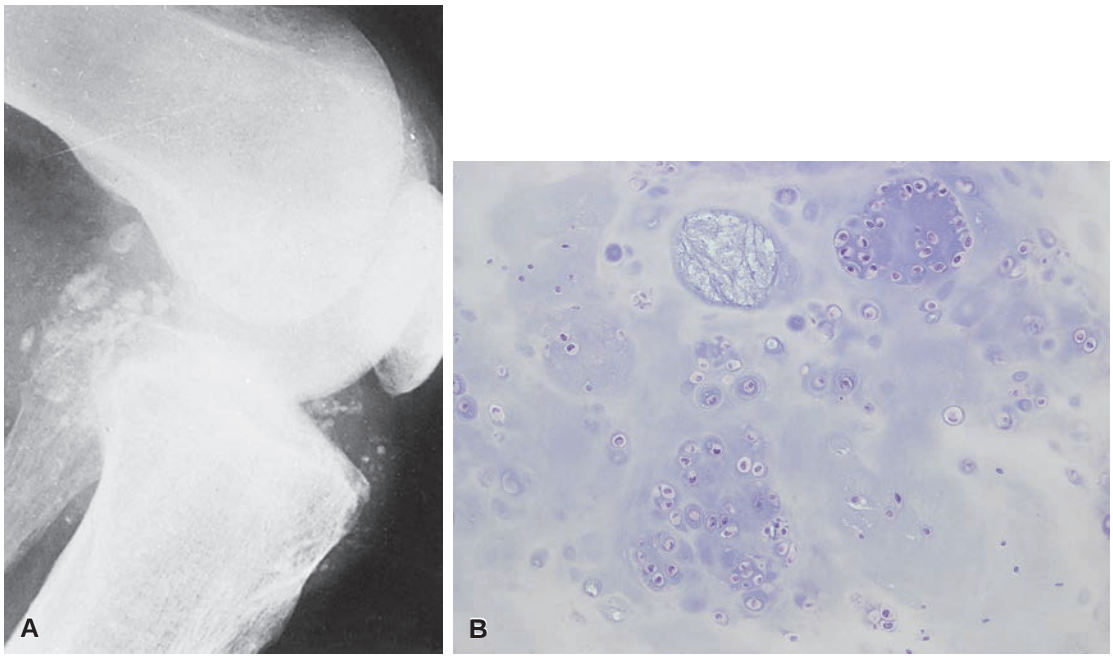

Figure 40.88 **A,** Synovial chondromatosis. Nodules can be seen clearly in the joint space on radiographic examination. **B,** Microscopically, the chondrocytes in synovial chondromatosis maintain a characteristic nested appearance.

for the male sex. The knee is the most common site, followed by the elbow and finger. In most cases the tumor is confined to the intra-articular synovium, but sometimes it is located in a bursa adjacent to a joint. The most common microscopic pattern is cavernous hemangioma, followed by lobular capillary hemangioma, arteriovenous hemangioma, and venous hemangioma.[708]

Isolated cases of *intra-articular synovial sarcoma* and other unusual neoplasms have been reported.

Nodular fasciitis can be seen in an intra-articular location. It is microscopically similar to its more common soft tissue counterpart, except for a greater tendency for stromal hyalinization and adjacent hemosiderin deposition.[709]

Normal Anatomy

Soft tissue is loosely defined as the complex of nonepithelial extraskeletal structures of the body exclusive of the supportive tissue of the various organs and the hematopoietic/lymphoid tissue. It is composed of fibrous (connective) tissue, adipose tissue, skeletal muscle, blood and lymph vessels, and peripheral nervous system.

Fibrous tissue consists primarily of fibroblasts and an extracellular matrix that contains fibrillary structures (collagen and elastin) and nonfibrillary extracellular matrix ("ground substance"). Fibrous tissue is classified according to its texture into loose (most locations) and dense (tendons, aponeuroses, and ligaments). *Fibroblasts* are responsible for the production of the various extracellular materials, including the many types of collagen. Their shape varies from spindle (especially when stretched along bundles of collagen fibers) to stellate (in myxoid areas). Immunohistochemically, they stain for actin, including smooth muscle actin (SMA), but are negative for h-caldesmon and often desmin as well. *Fibrocytes* represent the quiescent stage of fibroblasts. *Myofibroblasts* are modified fibroblasts that show features intermediate between fibroblasts and smooth muscle cells.[1,2]

Adipose tissue is divided into two major types: *white fat*, mainly located in the subcutaneous tissue, mediastinum, abdomen, and retroperitoneum; and *brown fat*, which is concentrated in the interscapular region, neck, mediastinum, axillae, and retroperitoneum (especially perirenal region).[3] Brown fat, whose main function is heat production, is much more conspicuous in infants and children. White fat consists of round or oval cells having most of the cytoplasm occupied by a single large lipid droplet that pushes the crescent-shaped nucleus to the periphery. *Brown fat cells* are smaller, with an acidophilic multivacuolated cytoplasm and a centrally located nucleus showing fine indentations; mitochondria are numerous at the ultrastructural level.

Skeletal muscle is mainly derived from within myotomes through the formation of myoblasts and eventually of myotubes (muscle fibers). The most distinguishing feature of these fibers is the presence of myofibrils, which are composed of two types of microfilament: thin (made of actin) and thick (made of myosin). The periodic arrangement and interdigitation of thin and thick filaments results in the cross-banding seen at the light microscopic level. The I (isotropic) band is made only of thin filaments, the adjacent A (anisotropic) band is a zone of overlapping thin and thick filaments, and the H band is made up only of thick myofilaments. The I band is divided in its center by the Z line or disc, which is thought to serve as an attachment site for the *sarcomere*, the repeating individual unit of the muscle fiber.

Vessels are divided into blood vessels and lymph vessels. *Blood vessels* are further subdivided into arterial and venous compartments joined by a network of capillaries. Blood vessels have two major

Abstract

Soft tissue tumors (and tumor-like lesions) are some of the most difficult diagnostic issues faced by practicing pathologists. The wide array of reactive and neoplastic soft tissue lesions can be overwhelming, and this chapter provides a comprehensive discussion of these entities, including some of the more recently described soft tissue tumors and their molecular genetic alterations. A thorough discussion of useful ancillary diagnostic techniques is also provided.

Keywords

fat,
fibroma,

lipoma,
hibernoma,
liposarcoma,
hemangioma,
glomus,
hemangioendothelioma,
smooth muscle tumors,
striated muscle tumors

cell types: endothelial cells (located toward the lumen) and a closely related group of cells including pericytes, smooth muscle cells, and glomus cells (located toward the outside). Ultrastructurally, endothelial cells exhibit numerous pinocytotic vesicles, cytoplasmic microfilaments, specialized cell junctions, microvilli, continuous basal lamina, and—most important—the Weibel–Palade body, a membrane-bound organelle thought to be specific to this cell type and shown to contain the von Willebrand factor (factor VIII-related antigen).[4]

Immunohistochemically, endothelial cells express a number of antigens including factor VIII-related antigen (FVIII-RA), CD34, CD31, FLI-1, and ERG.[5–7] CD31 is both highly sensitive and specific, although histiocytes and plasma cells are also positive. FVIII-RA is also very specific (the only other positive cell type being the megakaryocyte), but the labile nature of this antigen and its tendency to diffuse out in the tissues limit its utility. FLI-1 (a nuclear transcription factor involved in the pathogenesis of Ewing sarcoma/primitive neuroectodermal tumor [PNET]) is also a sensitive vascular marker. Perhaps most useful is ERG, given its strong nuclear positivity in virtually all benign, intermediate, and malignant vascular tumors, although it too is not completely specific.

The cells of the pericyte–smooth muscle–glomus family are characterized ultrastructurally by cytoplasmic microfilaments exhibiting focal condensations, numerous pinocytotic vesicles, and a thick continuous basal lamina. Immunohistochemically, they show reactivity for actin and myosin; positivity for desmin is largely restricted to smooth muscle cells.

Lymph vessels are lined by endothelial cells exhibiting a much weaker staining for FVIII-RA than endothelial cells from blood vessels. They also stain for Lyve-1 and podoplanin (D2-40).[8]

Peripheral nerves are formed by axons, Schwann cells, perineurial cells, and fibroblasts. Most of the fibroblasts are located in the *epineurium*, which is the outer sheath of fully developed nerves. Each nerve fascicle is surrounded by the *perineurium*, a structure continuous with the pia arachnoid of the central nervous system (CNS); unlike Schwann cells, *perineurial cells* are immunoreactive for epithelial membrane antigen (EMA) and GLUT-1 and negative for S-100 protein.[9] *Schwann cells* look somewhat similar to fibroblasts at the light microscopic level but are easily distinguished from them immunohistochemically because of their strong immunoreactivity for S-100 protein and ultrastructurally by an intimate relationship to axons (with the formation of mesoaxons) and the presence of a continuous basal lamina that coats the surface of the cell facing the endoneurium.

Infections and Hematomas

Soft tissue involvement by infectious processes usually is the result of direct extension from cutaneous, visceral, or osseous foci or the complication of trauma or surgery. Rarely, the process has a hematogenous source.

The severity of the inflammatory reaction and the type of tissue response observed pathologically depend on the type, dose, and virulence of the infecting organism, the resistance of the host tissues, the presence or absence of necrotic tissue, hematoma, or foreign body, and the anatomic features of the infected area.

Clinical types of infectious processes such as hemolytic streptococcal gangrene and necrotizing fasciitis must be diagnosed by clinical appearance and bacteriologic study. N**ecrotizing fasciitis** is accompanied by severe systemic toxicity and is usually caused by group A streptococci.[10] All of the pyogenic and necrotizing infections result in acute inflammatory tissue reactions that are indistinguishable microscopically. **Granulomatous inflammation** of soft tissue can be caused by *tuberculosis*, *atypical mycobacteriosis*, *actinomycosis*, *blastomycosis*, *coccidioidomycosis*, *sporotrichosis*, *cryptococcosis*, and *dirofilariasis*. A proper search for microorganisms should be made with appropriate special stains and cultures.

Hematoma, if deep and encysted, can simulate a sarcoma both clinically and radiographically. They occur most commonly in and around the tensor fasciae latae and have been variously referred to as ancient hematoma, calcifying myonecrosis, chronic expanding hematoma, and post-traumatic cyst of soft tissues.[11,12]

Tumors

Classification

Soft tissue tumors constitute a large and heterogeneous group of neoplasms. This chapter deals primarily with tumors located in the somatic soft tissues; it excludes those arising from the soft tissues of the mediastinum, retroperitoneum, and visceral organs and those primarily involving the dermis, such as Kaposi sarcoma and dermatofibrosarcoma protuberans (DFSP).

Traditionally, soft tissue sarcomas have been classified according to a histogenetic concept (e.g., fibrosarcoma as a tumor arising from fibroblasts, osteosarcoma as a tumor arising from osteoblasts). However, it seems clear that most if not all sarcomas arise from primitive multipotential mesenchymal cells, which in the course of neoplastic transformation undergo differentiation along one or more lines.[13] The acceptance of this alternative scheme does not require a change in terminology: a liposarcoma remains as such but is now viewed not as a tumor arising from a lipoblast but as a tumor exhibiting lipoblastic differentiation.

Clinical Features

A definite relationship exists between soft tissue tumor type and the age of presentation.[14] For instance, embryonal rhabdomyosarcoma is typically a tumor of infants and children, synovial sarcoma mainly affects adolescents and young adults, and liposarcomas and undifferentiated pleomorphic sarcomas (UPSs) are usually seen in middle-aged and elderly patients. Most soft tissue sarcomas are solitary; synchronous or metachronous multiple sarcomas are exceedingly rare.[15]

Diagnosis and Special Techniques

For any large soft tissue tumor in which the possibility of malignancy exists, the proper initial diagnostic procedure is to obtain material through excisional or incisional biopsy, core needle biopsy, or percutaneous fine-needle aspiration. The latter technique is being used with increasing frequency in the United States, with rates of accuracy equivalent to those obtainable with frozen section.[16] Excisional or incisional biopsy has the advantage of providing more tissue for diagnosis but, given the risk of bleeding and infection, should be performed only when a definitive diagnosis cannot be made by less invasive techniques. Importantly, site of biopsy or aspiration should be excised in continuity with the tumor at the time of definitive surgery.

Performance of frozen sections is useful in determining the type of neoplasm, the degree of malignancy, and the adequacy of surgical margins, but margins are often best assessed grossly at the time the specimen comes to surgical pathology, often done most effectively when the surgeon and pathologist examine the specimen simultaneously.

Light microscopic evaluation of hematoxylin–eosin-stained sections remains the standard technique for the initial diagnostic approach to these tumors and is sufficient in the majority of the cases. However, a significant percentage of cases require ancillary

diagnostic techniques including immunohistochemistry, molecular genetic methods, and rarely electron microscopy. Occasionally, histochemical stains may be used (e.g., PAS for assessing for intracytoplasmic crystals in alveolar soft part sarcoma), but many of these stains have been supplanted by other techniques.

The systematic use of cytogenetics has shown the existence of nonrandom chromosomal alterations (mainly translocations) in association with many types of soft tissue tumor.[17] The findings have validated the morphologic approach to classification of soft tissue tumors, helped to refine the boundaries of some entities (such as broadening morphology and location of desmoplastic small cell tumor, merging of spindle cell lipoma with pleomorphic lipoma, and merging of round cell liposarcoma with myxoid liposarcoma), and offered insight into the genesis of the tumors. Furthermore, the molecular alterations (gene fusions) that result from the chromosomal translocations can now be readily demonstrated in routine paraffin-embedded tissues by reverse transcription-polymerase chain reaction (RT-PCR) or fluorescence in situ hybridization (FISH). Such studies can be extremely helpful in the diagnosis of these tumors, especially in small biopsies, tumors with unusual morphology, or tumors in unusual sites.[18] A break-apart FISH probe for *EWSR1* is particularly helpful since this gene is implicated in many different soft tissue tumor types, including Ewing sarcoma/PNET, angiomatoid fibrous histiocytoma, extraskeletal myxoid chondrosarcoma, myxoid liposarcoma, clear cell sarcoma, and desmoplastic small cell tumor. Similarly, a break-apart FISH probe for *FUS* can aid in the diagnosis of low-grade fibromyxoid sarcoma (LGFMS), myxoid liposarcoma, and angiomatoid fibrous histiocytoma. FISH may be a particularly useful technique when evaluating cytologic preparations. As in other fields of oncology, gene expression profiling has significantly contributed to our understanding of the molecular underpinnings of many types of soft tissue tumors.[19–21] The specific applications of these various methods are described under the respective tumor types.

Grading and Staging

Some degree of microscopic grading of soft tissue tumors is already built into the conventional microscopic classification of these tumors. For example, DFSP is by definition a low-grade neoplasm, whereas all alveolar rhabdomyosarcomas are high-grade tumors. In addition, several attempts have been made to establish general guidelines for the grading of soft tissue sarcomas independent of their histologic type.[22–24] The number of grades has varied including two (low grade and high grade), three (I, II, and III, or low grade, intermediate grade, and high grade), and four (I, II, III, and IV) grade systems.

The criteria used to grade sarcomas have included degree of cellularity, pleomorphism, mitotic activity, and necrosis, and these features have been found to be of definite prognostic value for both adult and pediatric soft tissue tumors. However, there are some limitations to grading, including the inherently subjective nature of the evaluation, limited sampling in biopsy material, and the confounding effect of preoperative therapy.[25] Despite these limitations, grading (within the various histotypes and whenever applicable) remains one of the most powerful and inexpensive ways of assessing prognosis in a soft tissue sarcoma. The system devised by the French Federation of Cancer Centers Sarcoma Groups (also known as the FNCLCC grading system) is a three-grade system that is most widely used to grade sarcomas and is based on the evaluation of three separate parameters: tumor differentiation, mitotic rate, and extent of tumor necrosis.[22,24]

The most widely used staging system is that proposed by the American Joint Committee on Cancer (AJCC), which is largely based on the TNM system, in that it uses the size of the primary tumor (T), the status of lymph nodes (N), the presence of distant metastasis (M), and the tumor's histologic grade (G) (Tables 41.1–41.4).[26]

Table 41.1 Differentiation score in sarcomas as component of FNCLCC

HISTOLOGIC TYPE	DIFFERENTIATION SCORE
Atypical lipomatous tumor	1

Prognosis

The prognosis of soft tissue tumors depends on a variety of parameters, many of which are interrelated.

1. **Tumor size.** There is a definite relationship between tumor size and outcome. This is true for practically all tumor types in which this parameter has been analyzed.[27,28]
2. **Depth.** Superficially located tumors (dermis and subcutaneous tissue) have a much better prognosis than deep-seated ones (intermuscular or intramuscular, retroperitoneal) of similar microscopic type.[29,30] The difference is largely due to the fact that superficial lesions tend to be considerably smaller at the time of excision and are generally more amenable to complete excision.
3. **Location.** Tumors of the retroperitoneum do much worse than microscopically similar lesions located in the extremities.[28,31] Among the latter, local recurrence has been found to be more frequent with those of the upper extremity than those of the lower extremity.[30]

Table 41.2 Details of FNCLCC grading system

PARAMETER		DEFINITION
Tumor differentiation	Score 1:	Closely resembles normal adult mesenchymal tissue; potentially difficult to distinguish from counterpart benign tumor
	Score 2:	Sarcomas for which histologic type is certain (e.g., myxoid liposarcoma)
	Score 3:	Embryonal and undifferentiated sarcoma, synovial sarcoma, sarcomas of uncertain type
Mitotic count	Score 1:	0–9/10 HPF
	Score 2:	10–19/10 HPF
	Score 3:	>19/10 HPF
Tumor necrosis	Score 0:	No necrosis
	Score 1:	<50% tumor necrosis
	Score 2:	≥50% tumor necrosis
Histologic grade	Grade 1:	Total score 2, 3
	Grade 2:	Total score 4, 5
	Grade 3:	Total score 6, 7, 8

Data from Amin M, Edge S, Greene F, et al., eds. *AJCC Cancer Staging Manual*. Vol. 8. New York: Springer; 2017.

4. **Microscopic type.** Some soft tissue neoplasms (such as atypical lipomatous tumors [ALTs]) are low-grade lesions with no capacity to metastasize, whereas other neoplasms of similar cell type (such as pleomorphic liposarcoma) are highly aggressive and prone to spread distantly.
5. **Vascular invasion.** This has been shown to be the strongest predictor of distant metastases in several series.[32]
6. **Surgical margins.** Not surprisingly, adequacy of surgical margins is statistically associated with local relapse.[33–35] The relationship between local recurrence and subsequent risk of metastasis is less clear.
7. **Histologic grade.** As already indicated, a relationship has been found between various microscopic grading systems and outcome (see discussion on grading).
8. **Clinical stage.** As for most other tumors, this determination—which incorporates several of the previously mentioned parameters, as well as the presence or absence of metastases—is the most powerful prognostic determinator.
9. **Other factors.** A number of other prognostic factors have been implicated including DNA ploidy,[36] cell proliferation (MIB-1),[37] and specific genetic alterations such as mutations of *TP53*.[38] Along similar lines, claims have been made of a relationship between the type of gene fusion in the sarcomas associated with chromosomal translocations and prognosis (as in alveolar rhabdomyosarcoma and synovial sarcoma; these are discussed in the respective sections).

Therapy

Soft tissue tumors that are relatively small and/or clearly benign on clinical grounds (such as superficially located lipomas, schwannomas, hemangiomas, and tenosynovial giant cell tumors) can be removed without prior manipulation, but in most others the excision should be preceded by a biopsy or fine-needle aspiration. A few tumors (such as schwannomas) can be safely enucleated, but for most others—even if benign—a rim of uninvolved normal tissue should be excised in continuity with the neoplasm to prevent recurrence. Many soft tissue sarcomas, such as fibrosarcoma, myxoid liposarcoma, and leiomyosarcoma, may appear grossly encapsulated, but microscopic examination will often show tumor cells beyond the apparent capsule; therefore enucleation will usually fail. A wide local excision is particularly important for infiltrative lesions such as desmoid-type fibromatosis and DFSP.

Full-fledged soft tissue sarcomas in children are currently treated, for the most part, by a combination of surgery, radiation therapy, and multidrug chemotherapy, with results that are vastly superior to those obtained in the prechemotherapy era.[39]

The treatment of high-grade soft tissue sarcomas in adults has undergone radical changes. It has been thought for many years that amputation or disarticulation offered the best chances of cure for sarcomas involving an extremity. However, many studies have shown wide local excision with adjuvant therapy to have survival rates similar to those for amputation. Details of therapeutic options go beyond this discussion, but superb reviews on this topic can be found in the recent literature.[40,41] Similar to other types of neoplasms, increased emphasis has been placed on identifying targeted therapies for patients with recurrent or metastatic soft tissue sarcoma.[42,43]

Pathogenesis

The pathogenesis of most soft tissue tumors remains unknown. Environmental, oncogenic, immunologic, and genetic factors have all been implicated and, in fact, several of these factors may be involved in the development of a given tumor.

Trauma is frequently implicated in the development of sarcomas, but trauma often seems to merely call attention to the presence of a tumor which antedated the trauma.[44] Other environmental factors implicated in the pathogenesis of sarcomas include phenoxyacetic acid herbicides,[45] vinyl chloride (which is clearly associated with hepatic angiosarcoma)[46] and radiation exposure.[47] Although dioxin, a contaminant of the defoliant Agent Orange, which was used in Vietnam, has been implicated in sarcomagenesis, case control studies have found no increased risk of sarcomas.[48]

Oncogenic viruses play a role in the development of a small group of sarcomas. The human herpesvirus 8 (HHV8) is clearly the causative agent of Kaposi sarcoma.[49] Epstein-Barr virus (EBV) also seems to play a central role in the development of smooth muscle tumors in patients with immunodeficiencies or immunosuppression.[50]

A number of genetic diseases are associated with soft tissue tumors, including neurofibromatosis type 1 (malignant peripheral nerve sheath tumors [MPNSTs]), familial adenomatous polyposis/Gardner syndrome (Gardner-associated fibroma and fibromatosis), Li-Fraumeni syndrome (germline mutations of *TP53* associated with a number of sarcoma types), Carney complex (psammomatous melanotic schwannoma, cutaneous myxoma), and tuberous sclerosis (perivascular epithelioid cell tumor/PEComa).

It should be noted that most soft tissue sarcomas arise de novo rather than from malignant transformation of a preexisting benign tumor, an exception being transformation of neurofibroma into an MPNST. In most cases in which a benign tumor has been thought to become malignant, review of the original material shows the tumor to be malignant from its inception.

Figure 41.1 Gross appearance of calcifying aponeurotic fibroma. The mass is unencapsulated and ill defined.

Tumors and Tumorlike Conditions of Fibroblasts and Myofibroblasts

Calcifying Aponeurotic Fibroma

Calcifying aponeurotic fibroma is a distinctive lesion originally described as juvenile aponeurotic fibroma, typically presenting as a soft tissue mass in the hand or wrist of a child or adolescent (peak 8–14 years of age) but sometimes also occurring in the proximal extremities or trunk.[51] At surgery, it may appear as a nodule or as an ill-defined infiltrating mass in the subcutaneous tissue or attached to a tendon (Fig. 41.1). Sometimes, foci of calcification may be detected on gross inspection.

Microscopically, the lesion is characterized by an infiltrative proliferation of cells associated with spotty calcification (Figs. 41.2 and 41.3). Infiltration of fat and skeletal muscle is often seen at the periphery. Mitoses are scarce, and atypical cytologic features are absent. Scattered osteoclast-like giant cells are frequently seen. Cellularity varies from region to region; the cells are plump with ovoid nuclei and indistinct cytoplasm separated by dense fibrous stroma. There may be a cartwheel, linear, or whorled growth pattern. Calcifications vary from fine granules to larger areas with cells radiating out from them in linear columns. Immunohistochemically, the proliferating cells stain variably for actins, CD68, S-100 protein, and even CD99.[51]

Calcifying aponeurotic fibroma can be confused with rheumatoid nodule, schwannoma, soft tissue chondroma, and fibromatosis,

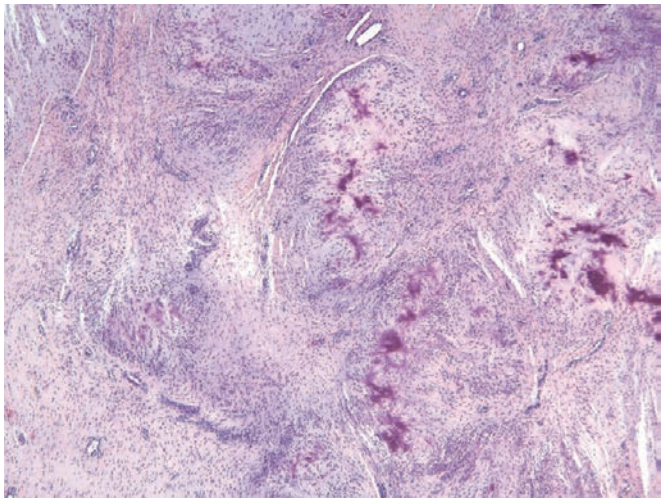

Figure 41.2 Low-power appearance of calcifying aponeurotic fibroma.

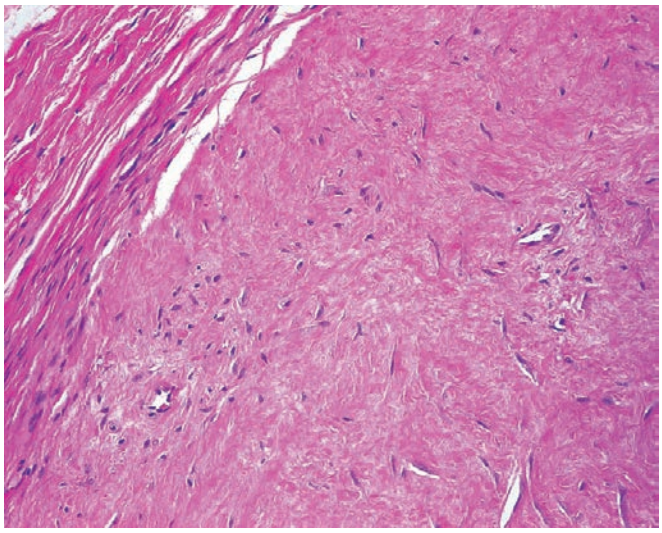

Figure 41.4 Fibroma of Tendon Sheath. The lesion is hypocellular and contains abundant collagen.

including infantile fibromatosis. Local recurrence is common, especially in young children (less than 5 years of age). However, distant metastases do not occur.[51,52]

Fibroma of Tendon Sheath

Fibroma of tendon sheath is a well-circumscribed, often lobulated tumor found attached to tendon or tendon sheath.[53] Microscopically, it is composed of dense fibrous tissue containing spindle and sometimes stellate mesenchymal cells deposited in a collagenous stroma (Fig. 41.4), although myxoid foci may be seen. Frequently, there are dilated or slit-like channels, particularly at the periphery of lobules.[54–56] Occasionally, a component of bizarre tumor cells unaccompanied by mitoses is seen (so-called pleomorphic fibroma of tendon sheath).[57] Ultrastructurally, most of the cells have features of myofibroblasts and, by immunohistochemistry, the cells express actins but not desmin.[58] The translocation t(2;11)(q31–32;q12) has been identified in rare cases.[59] More recently, some cases of fibroma of tendon sheath, particularly those that are highly cellular, have been shown to harbor rearrangements of *USP6*, suggesting a relationship to nodular fasciitis in these cases. Interestingly, however, these alterations were not identified in any classic cases of fibroma of tendon sheath.[59a] This suggests that lesions previously identified as cellular fibromas of tendon sheath are probably underrecognized examples of tenosynovial fasciitis.[60,61] The lesion is benign and only very rarely recurs.

Collagenous Fibroma

Collagenous fibroma (desmoplastic fibroblastoma) is a benign lesion usually centered in the subcutaneous tissue and with a wide anatomic distribution, usually arising in adults. A subset of these lesions may occur in deeper locations including intramuscular examples. The most distinctive microscopic feature is the presence of stellate fibroblasts (together with ordinary spindle-shaped fibroblasts) separated by a collagenous matrix with or without myxoid features (Fig. 41.5).[62–64] By immunohistochemistry, most cases show staining for SMA but are negative for desmin, consistent with myofibroblastic differentiation.[65] Some have suggested this lesion could represent the end stage of a reactive process. However, aberrations of 11q12 suggest a neoplastic process, as well as a possible link to fibroma of tendon sheath.[66–69] Interestingly, a recent study found consistent expression of FOSL1 in

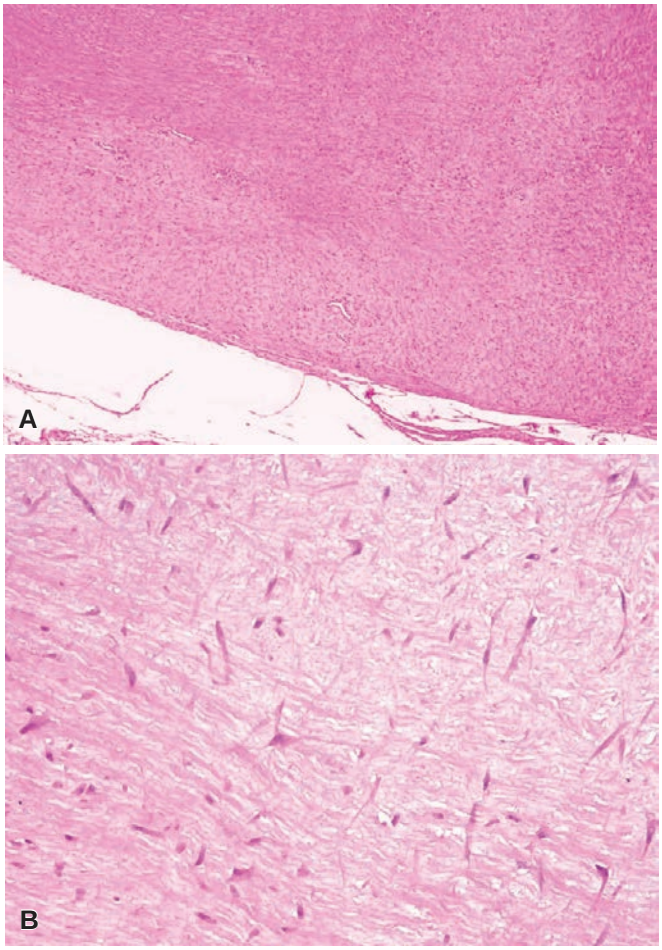

Figure 41.5 Collagenous Fibroma. A, The lesion is well circumscribed and hypocellular. **B,** The cells are spindle to stellate shaped.

collagenous fibroma, while none of the cases of fibroma of tendon sheath showed expression of this antigen, suggesting these are distinct lesions.[69a]

Nuchal-Type Fibroma

Nuchal-type fibroma is a benign lesion typically found in the posterior aspect of the neck and characterized microscopically by hypocellular bundles of thick collagen fibers, with entrapped adipose tissue and traumatic neuroma-like structures.[70] A high percentage of the patients are diabetic.[71] However, up to 30% occur in other soft tissue sites (buttocks, extremities, among others), and hence the reason the term nuchal-type fibroma is preferred over nuchal fibroma.

Gardner-associated fibroma has overlapping features with nuchal-type fibroma but seems distinct given its close association with Gardner syndrome/familial adenomatous polyposis.[72–74] These patients tend to be younger than those with nuchal-type fibroma, with most patients presenting in the first decade of life. Most arise in the back and paraspinal region, and histologically there is close resemblance to nuchal-type fibroma, although entrapped nerves are not conspicuous. The majority of cells express CD34, CD99, and nuclear β-catenin staining.[72,75] This lesion is benign, but it may recur if incompletely excised, and rare cases transform into a full-blown fibromatosis.[76] This process is probably distinct from **nuchal fibrocartilaginous pseudotumor**, which is characteristically located in the deep soft tissue overlying the posterior aspect of the lower cervical vertebrae and thought to be due to fibrocartilaginous metaplasia of the nuchal ligament, probably trauma induced.[77]

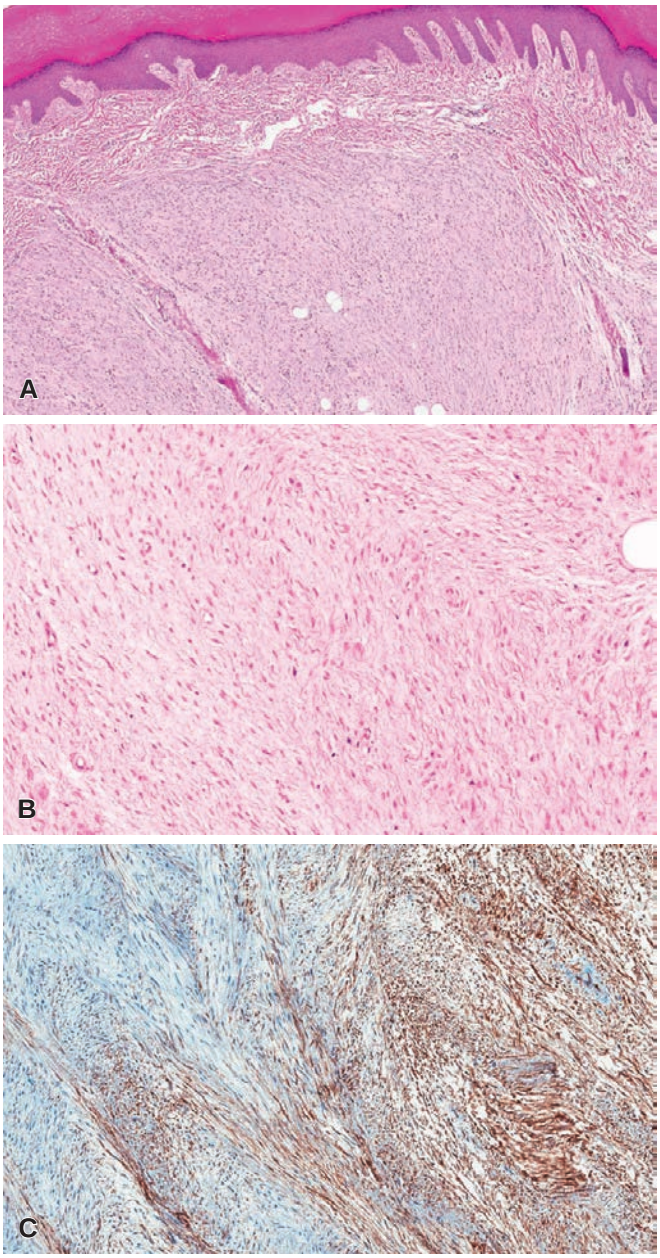

Figure 41.6 Superficial Acral Fibromyxoma. A, The dermis is expanded by a nodular proliferation of bland spindle cells deposited in a fibromyxoid matrix. **B,** Bland spindle cells are arranged in a vaguely whorled growth pattern. **C,** Strong CD34 staining in the neoplastic cells.

Superficial Acral Fibromyxoma

Superficial acral fibromyxoma (also referred to as *digital fibromyxoma*) is a soft tissue tumor with a predilection for the fingers and toes and composed of spindle- to stellate-shaped usually CD34-positive tumor cells arranged in a nondescript, storiform, or fascicular pattern of growth, embedded in a myxoid, fibromyxoid, or collagenous stroma (Fig. 41.6).[78,79] A cellular variant has also been described.[80] Some believe this lesion may be related to *cellular digital fibroma*,[81] but a recent study detected frequent RB-1 loss or deletions, suggesting a relationship to

other members of the RB-1 deleted tumor family (spindle cell lipoma, mammary-type myofibroblastoma, and cellular angiofibroma).[81a] The tumor arises in patients of all ages, with a 2:1 male to female ratio.[82,83] Although most are cured by local excision, up to 25% recur.[82]

Angiofibroma of Soft Tissue

Angiofibroma of soft tissue is a recently described fibrovascular tumor which most commonly arises in the soft tissues of the extremities. The tumor shows a proliferation of bland spindled cells in a myxocollagenous matrix with a distinct network of thin, finely branched blood vessels.[84–86] The cells variably express EMA, desmin, SMA, and CD34, but they characteristically show aberrations of the *NCOA2* gene on 8q13, which can be detected by FISH.[85,87,88] The lesion is benign and only rarely recurs following local excision.

Fibrous Hamartoma of Infancy

Fibrous hamartoma of infancy is a tumorlike condition seen almost exclusively during the first 2 years of life and sometimes present at birth.[89] It predominates in boys, and the most common locations are the region of the axilla, shoulder, and upper arm.[89a] It is almost always solitary. Grossly, it is poorly circumscribed and composed of white fibrous tissue intermixed with islands of fat.

Microscopically, the distinctive feature of this lesion is an organoid pattern with three distinct types of tissue being present: (1) well-differentiated spindle cells of fibroblastic/myofibroblastic appearance accompanied by deposition of collagen; (2) mature adipose tissue; and (3) immature cellular areas arranged in a whorling pattern and resembling primitive mesenchyme (Fig. 41.7). Very rare cases with overt sarcomatous-appearing foci have been reported, characterized

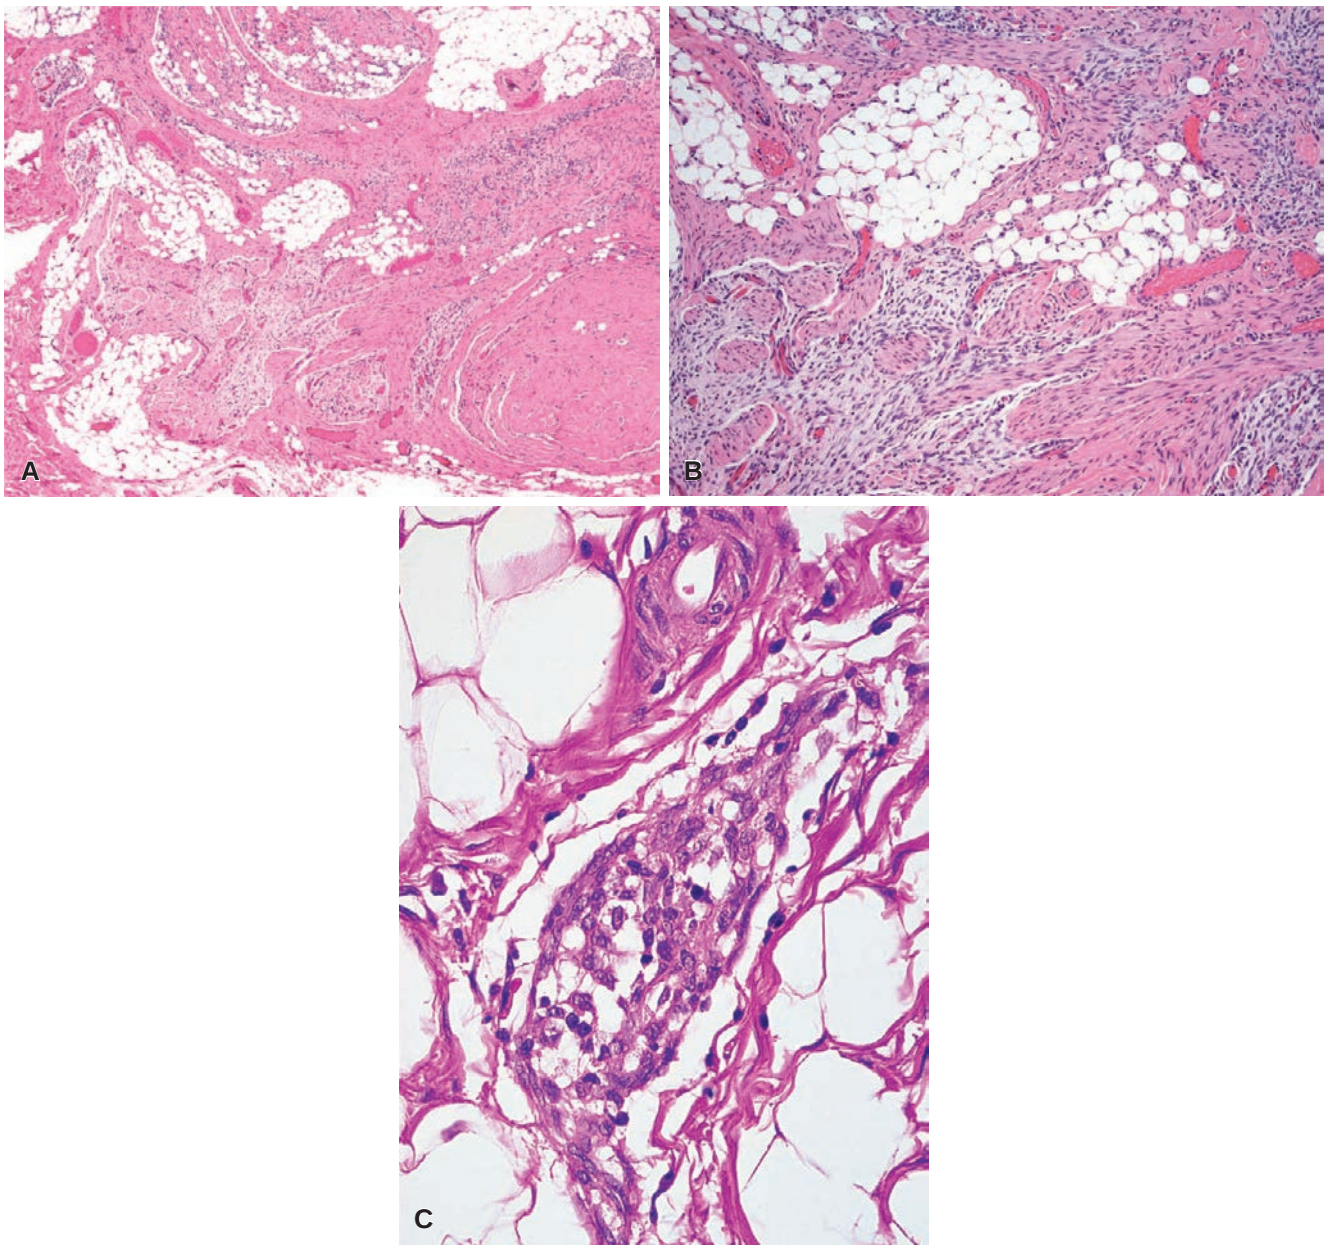

Figure 41.7 Fibrous Hamartoma of Infancy. A, An admixture of cellular fibrous foci and mature adipose tissue. **B,** A cellular spindle cell focus is seen surrounding mature adipose tissue. **C,** High-power view showing an oval cluster of plump mesenchymal cells.

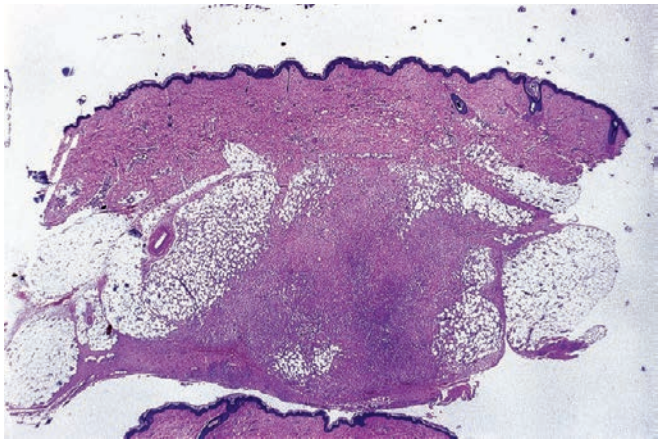

Figure 41.8 Panoramic View of Nodular Fasciitis. The lesion is small, ill defined, and centered in the subcutaneous tissue.

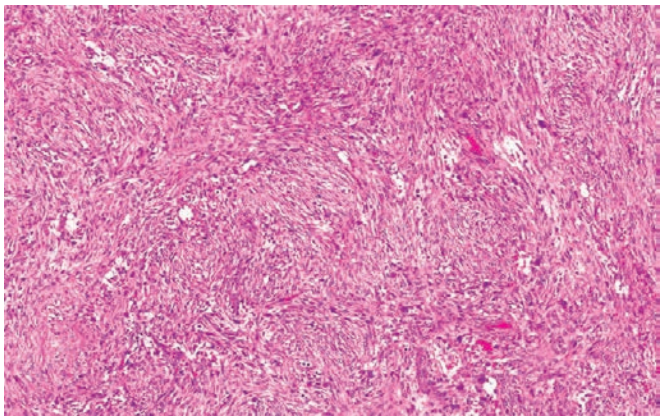

Figure 41.9 Strikingly cellular zone in nodular fasciitis.

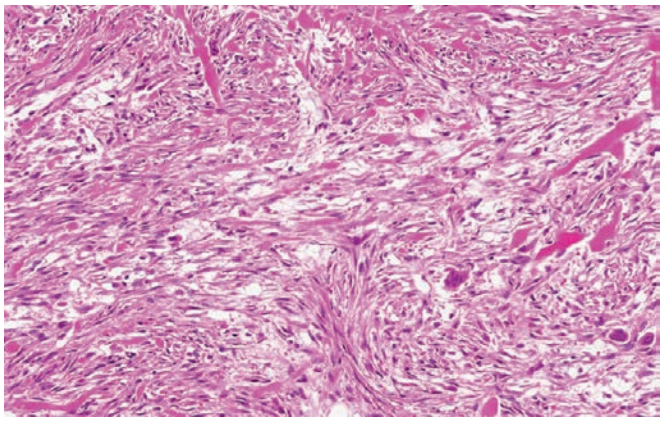

Figure 41.10 Nodular fasciitis with prominent collagen deposition and scattered giant cells.

by high cellularity, high nuclear grade, and brisk mitotic activity.[89a] Immunoreactivity for actin (and sometimes desmin) is found mainly in the spindle cell areas, suggesting myofibroblastic differentiation.[90–92] Recently a case of fibrous hamartoma of infancy with an EGFR exon 20 insertion/duplication mutation was reported.[92a] Although there may be local recurrence, the clinical course is benign.

Nodular Fasciitis and Related Lesions

Nodular fasciitis is a distinctive pseudosarcomatous myofibroblastic proliferation that is important because of its ability to simulate a malignant process.[93–95] It can affect patients of all ages but is most prevalent in young adults, with a peak between 20 and 40 years of age.

The most common locations are the upper extremities (particularly the flexor aspect of the forearms), trunk, and neck, but this lesion has been described in virtually every anatomic location. It presents as a rapidly growing mass of short duration, sometimes following known trauma. It usually extends above the fascia into the subcutis, but it may grow beneath it into skeletal muscle, remain within the fascia as a fusiform expansion, or even be centered in the dermis.[96,97]

Microscopically, the lesion is characterized by a cellular spindle cell growth set in a loosely textured myxoid matrix. Microcystic change, red blood cell extravasation, and lymphocytic infiltration are also often present (Figs. 41.8 to 41.11). A feature of diagnostic significance is the presence of undulating wide bands of collagen lined on the sides by spindle cells. Some areas have a storiform growth pattern. Focal metaplastic bone formation may be present, establishing a link between nodular fasciitis and myositis ossificans. The high cellularity of the lesion and the presence of numerous mitotic figures are responsible for the frequent confusion of this lesion with a sarcoma. However, the constituent cells lack nuclear hyperchromasia, a critical feature in distinguishing a reactive process from a sarcoma.

Ultrastructurally and immunohistochemically, many of the proliferating spindle cells have features of myofibroblasts with strong expression of SMA.[98,99] This lesion is completely benign and often resolves spontaneously. If a lesion originally diagnosed as nodular fasciitis recurs, it is wise to re-review the original pathology since recurrence is so uncommon. Interestingly, there are a number of reports of clonal chromosomal rearrangements involving *USP6* on 17p13 and *MYH9* on 22q13, which has led some authors to favor the interpretation that it is a neoplastic process.[100–102]

Cranial fasciitis is a distinct variant of nodular fasciitis generally seen in infants and characterized by involvement of the skull with erosion of the outer table of the cranium.[103] It shows histologic and immunohistochemical features identical to nodular fasciitis, including strong expression of SMA. Birth trauma has been implicated as causative in at least some cases.[103,104]

Intravascular fasciitis is another morphologic variant of fasciitis in which involvement of the wall and lumen of medium-sized veins and arteries occurs.[97,105] This is an exaggerated expression of a phenomenon seen frequently in ordinary nodular fasciitis and which constitutes a useful diagnostic sign, that is, the fact that, at the periphery of the lesion, the walls of small to medium-sized vessels are involved by the reactive mesenchymal process.

In ***proliferative fasciitis*** the location of the lesion, rapidity of growth, and self-limited nature are the same as those of nodular fasciitis, but the presence of large basophilic cells resembling ganglion cells indicates a link with proliferative myositis (see subsequent discussion) (Fig. 41.12). It usually affects adults, although it can also be seen in children.[106,107] As in the other conditions described in this section, myofibroblasts are the cells that predominate in this proliferation. It should be mentioned here that the presence of ganglion-like cells in a soft tissue lesion does not guarantee that the condition is of a reactive nature. Indeed, we have seen several cases of soft tissue sarcoma containing similar-appearing cells.

Nodular fasciitis and the variants described previously are characteristically located in the somatic soft tissues, but reactive fasciitis-like lesions with a somewhat different morphologic

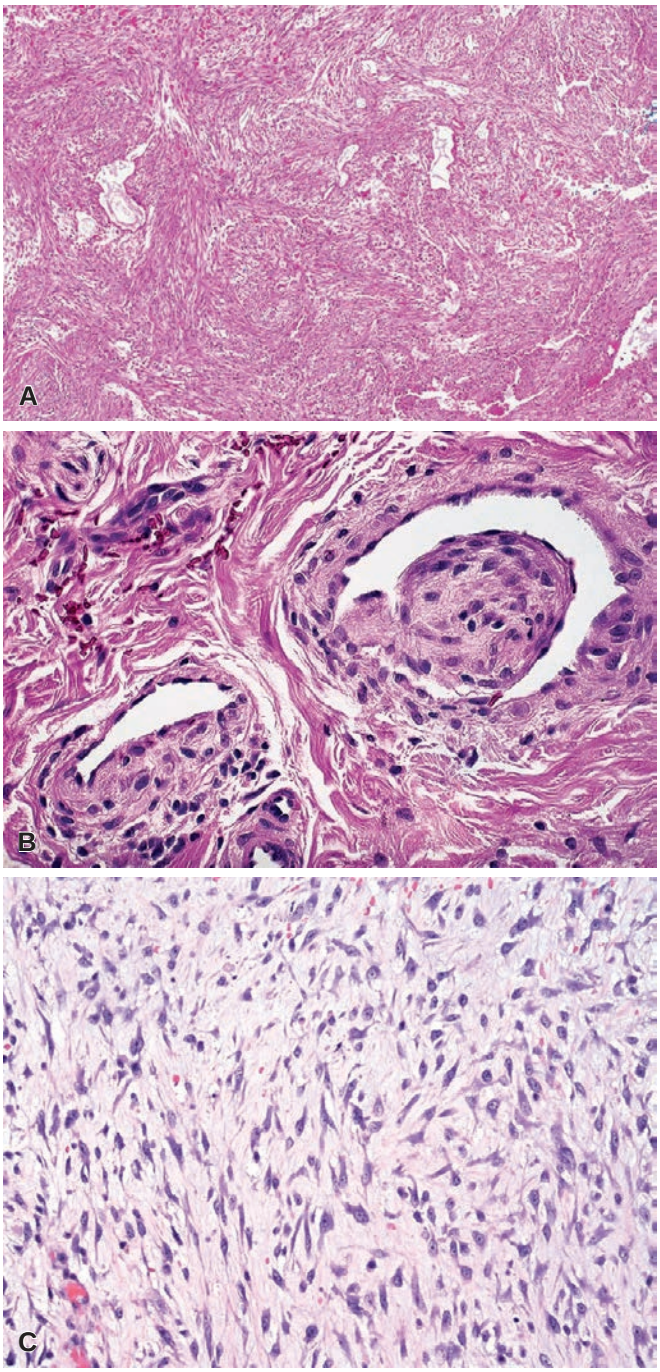

Figure 41.11 Nodular Fasciitis. A, Area of myxoid degeneration in nodular fasciitis. **B,** The proliferation involves the wall and lumen of blood vessels. **C,** High-power view of reactive myofibroblasts in nodular fasciitis.

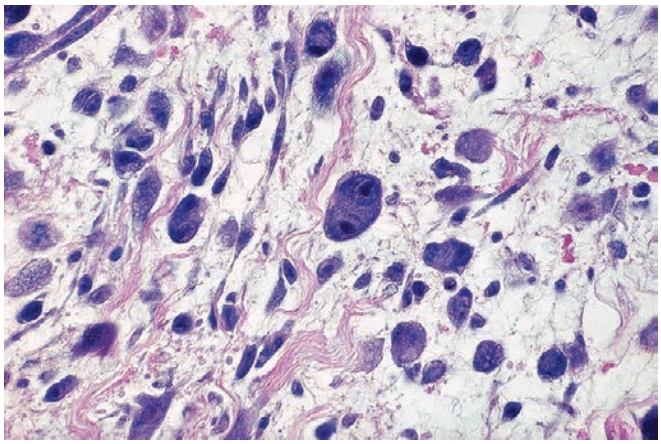

Figure 41.12 Ganglion-like cells in proliferative fasciitis.

Figure 41.13 Gross Appearance of Proliferative Myositis. There is ill-defined whitish material in between the skeletal muscle fibers.

appearance (even more sarcomatoid) can develop from the stromal tissue of a variety of organs, such as the bladder, prostate, vulva, vagina, and cervix (see respective chapters).

Proliferative myositis can be confused with sarcoma not only clinically but also microscopically.[108] The skeletal muscles of the shoulder, thorax, and thigh are most commonly affected. Most patients are over the age of 45 years, but it can also present in children.[106] Grossly, there is typically induration of muscle with an ill-defined scar-like lesion (Fig. 41.13). Microscopically, a cellular proliferation rich in fibroblasts and myofibroblasts is seen surrounding individual muscle fibers, creating a checkerboard pattern (Fig. 41.14). The hallmark of the lesion is the presence of large basophilic cells with vesicular nuclei and prominent nucleoli, resembling ganglion cells or rhabdomyoblasts (Fig. 41.15). Conservative surgery is curative.[109]

Other pseudoneoplastic myofibroblastic proliferations pathogenetically related to nodular fasciitis and representing an exaggerated reaction to injury include *proliferative funiculitis* (involving the spermatic cord and probably secondary to ischemia or torsion)[110] and ***atypical decubital fibroplasia***, otherwise known as ***ischemic fasciitis***.[111–113] This is a myofibroblastic proliferation that predominantly involves soft tissue overlying bony prominences, often occurring in debilitated or immobilized patients. Most of those affected are elderly (peak incidence in eighth or ninth decade), but this lesion rarely affects young patients as well.[111] The soft tissues of the shoulder, chest wall, and hip or sacrococcygeal region are most commonly affected. Microscopically, a zonal pattern best appreciated at low magnification is seen with a

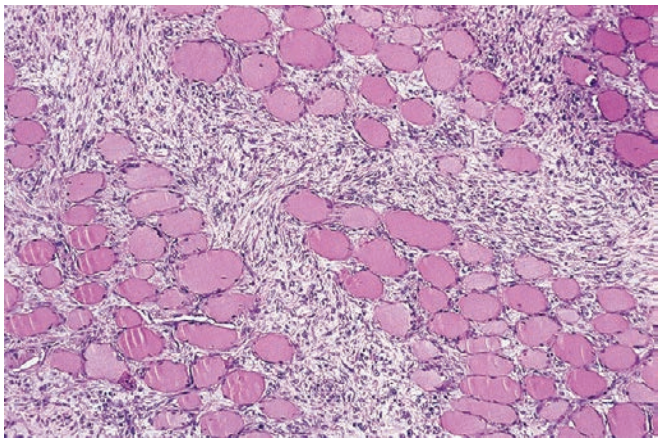

Figure 41.14 Low-power checkerboard appearance of proliferative myositis.

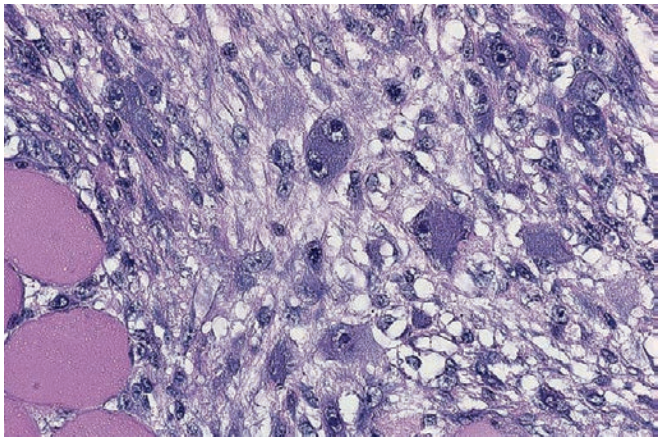

Figure 41.15 On high-power, the ganglion-like cells of proliferative myositis look similar to those of proliferative fasciitis (see Fig. 41.12).

central liquefactive zone surrounded by proliferating vessels and myofibroblasts, some of which have smudgy chromatin or resemble the ganglion-like cells in proliferative fasciitis/myositis (Fig. 41.16). The lesion is benign but can recur if the patient remains debilitated.

Myositis Ossificans

Myositis ossificans and related conditions such as *fibro-osseous pseudotumor of the digits* are located in the soft tissue and are pathogenetically and histologically linked to the previous entities (Fig. 41.17). They are more fully discussed in Chapter 40.

Intranodal Palisaded Myofibroblastoma

This is a distinctive benign neoplasm that arises in lymph nodes, most commonly in the groin, usually in middle-aged adults.[114–117] Microscopically, the tumor is well circumscribed with residual nodal tissue at the periphery and is composed of bland spindle cells arranged in short fascicles with vague nuclear palisading. The most distinctive feature is the presence of thick densely eosinophilic collagen (so-called amianthoid fibers) that is variably found throughout the tumor (Fig. 41.18). The cells have myofibroblastic features, as they express actins but not desmin.[118–120] Recently, mutations of *CTNNB1* (β-catenin gene) have been described.[121] The tumor does not recur or metastasize.

Figure 41.16 **Ischemic Fasciitis. Mammary-Type Myofibroblastoma

Mammary-type myofibroblastoma arises in both males and females with a slight male predominance. Although initially described to occur in the breast, the inguinal region is actually the most common location (45% of cases), followed by the lower extremities, trunk, breast, and intraabdominal/retroperitoneum,[121a] although many extra-mammary sites have been described.[122–126] Patients present with a slowly growing, well-circumscribed mass. The tumor is composed of a haphazard arrangement of slender spindle cells separated by collagen bundles (Fig. 41.19). The cells may be arranged in short fascicles or packets, and they have bland chromatin, inconspicuous nucleoli, and occasional intracytoplasmic inclusions.[124] Some cases

have extensive amounts of mature adipose tissue, and others have focal thick-walled blood vessels. Extensive hyalinization and myxoid stroma may also be seen. Tumors composed predominantly of epithelioid cells have also been described.[127] By immunohistochemistry, the cells typically coexpress CD34 and desmin, with variable expression of SMA. The tumor consistently shows rearrangements or deletions of 13q14, resulting in loss of Rb-1 expression by immunohistochemistry.[121a,128–130] Given overlapping morphology with spindle cell lipoma and cellular angiofibroma, and the fact that these all show loss of Rb-1, it is now believed these lesions are a family of closely related tumors. Mammary-type myofibroblastoma is benign and is generally cured by local excision, with very rare local recurrences.

Figure 41.20 Gross appearance of elastofibroma.

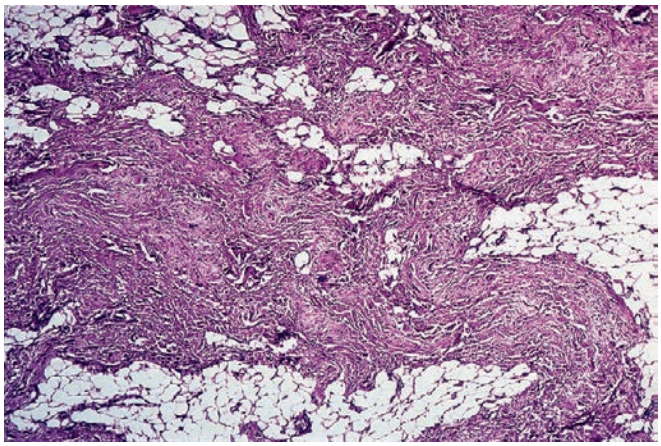

Figure 41.21 Low-power view of elastofibroma with an irregularly shaped fibrohyaline mass within adipose tissue.

Elastofibroma

Elastofibroma is a benign, poorly circumscribed process involving almost exclusively the subscapular region of elderly individuals, although isolated cases have been seen in a number of other locations including the gastrointestinal tract.[131] Multicentric and familial cases have also been described.[132] There is often a history of strenuous, repetitive manual labor. At surgery, the lesion is usually found at the apex of the scapula, beneath the rhomboid and latissimus dorsi muscles.

Microscopically, collagen bundles alternate with numerous acidophilic, refractive cylinders often containing a central dense core, both of which stain strongly with elastic stains (Figs. 41.20 and 41.22). Occasionally, adipose tissue is found intermingled with the collagen and elastic fibers, a variation in the theme that has been dignified with the name *elastofibrolipoma*.[133]

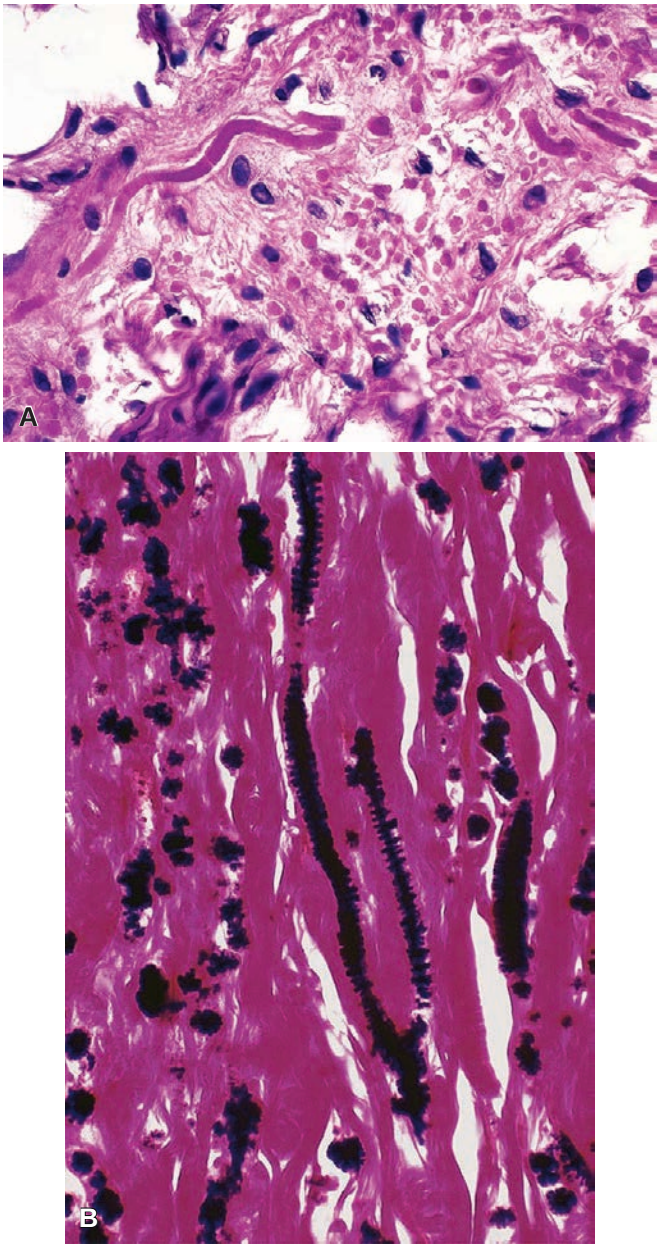

Figure 41.22 High-power view of elastofibroma showing **(A)** diagnostic rods of elastic tissue (**B,** elastic tissue stain).

The biochemical composition of the fibers is that of elastin but with an amino acid composition slightly different from that of normal elastic tissue.[134] The collagen deposited in the lesion is a mixture of types I, II, and III; the presence of type II collagen is perplexing because this is normally present only in articular cartilage and some ocular structures.[135] Traditionally, this lesion has not been regarded as a true neoplasm but rather a reactive hyperplasia involving abnormal elastogenesis[136]; however, several recent reports have found cytogenetic alterations of various types.[137,138]

Solitary Fibrous Tumor

This neoplasm is ubiquitous in soft tissues and has been described in virtually every anatomic site, although it is most common in the

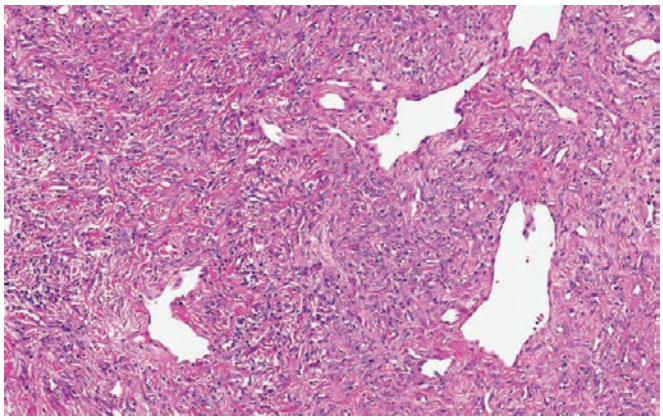

Figure 41.23 Solitary fibrous tumor showing a prominent hemangiopericytoma-like vascular pattern and variable cellularity.

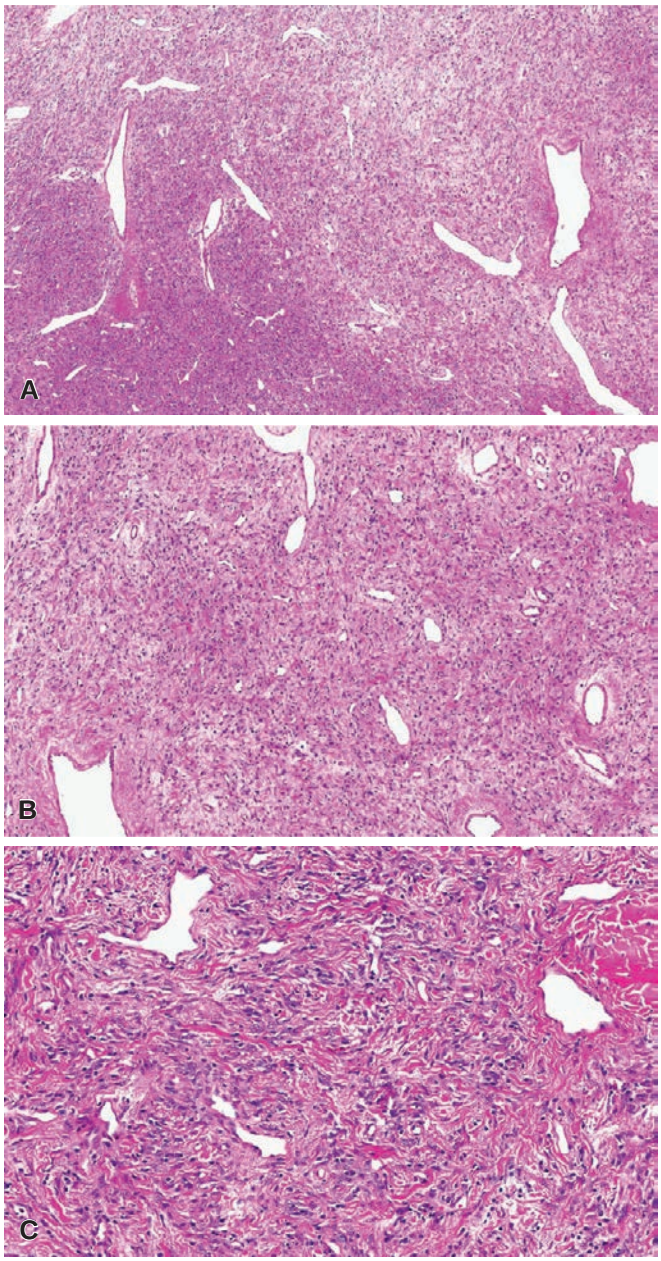

Figure 41.24 **Solitary Fibrous Tumor. A,** Prominent hemangiopericytoma-like vascular pattern. **B,** Hypocellular zone. **C,** Wire-like collagen in solitary fibrous tumor.

pleura. The tumor is composed of fibroblastic spindle cells arranged in a patternless pattern and associated with wire-like collagen and often a staghorn or hemangiopericytoma-like vascular pattern (Figs. 41.23 and 41.24).[139] Other features may include myxoid change, mature adipose tissue, floret-like giant cells (formerly referred to as giant cell angiofibroma),[140,141] and even dedifferentiation.[142–144] Although CD34 is virtually always expressed, this marker lacks specificity. More recently, STAT6 has been found to be a more sensitive and specific marker,[145–147] which is not unexpected given the identification of *NAB2-STAT6* gene fusions in a significant subset of these tumors.[148–152] Although most cases are clinically benign, some are both histologically and clinically malignant, particularly those with areas of high cellularity, necrosis, and greater than four mitotic figures per 10 high power field (HPF).[153–157]

Desmoid-Type Fibromatosis

The generic term **desmoid-type fibromatosis** was originally proposed by Stout[158] for a group of related conditions having in common the following features:

1. Proliferation of well-differentiated fibroblasts and myofibroblasts
2. Infiltrative pattern of growth
3. Presence of a variable (but usually abundant) amount of collagen between the proliferating cells
4. Lack of cytologic features of malignancy
5. Low or absent mitotic activity
6. Aggressive clinical behavior characterized by repeated local recurrences but lack of capacity to metastasize distantly

Grossly, these lesions are often large, firm, and white, with ill-defined outlines and an irregularly whorled cut surface (Fig. 41.25).[159] Microscopically, most of the proliferating cells have features of fibroblasts or myofibroblasts (Figs. 41.26 and 41.27).[1,160] Other light microscopic features commonly encountered in fibromatosis are a perivascular lymphocytic infiltrate located at the advancing edge of the lesion, and thick-walled often ectatic vessels sharply outlined from the surrounding tissue.

Clonal chromosomal aberrations are present in approximately half of the deep-seated fibromatoses but only in 10% of those located superficially. Trisomies 8 and 20 and loss of 5q material represent the recurring cytogenetic changes.[161,162] At the molecular level, there are activating mutations of *CTNNB1* (encoding β-catenin), leading to frequent nuclear expression of β-catenin.[163,164] For cases associated with Gardner syndrome, there is germline mutation of the *APC* gene (5q22), together with loss of heterozygosity at the locus.[165] The end result is similar, since both APC and β-catenin are components of the Wnt signaling pathway. The cells of fibromatosis are also immunoreactive for SMA and desmin, with variable staining for calponin, and estrogen receptor-beta (but not estrogen receptor-alpha or CD34).[166]

Some pathologists add the adjective *aggressive* to some forms of fibromatosis to emphasize its potential behavior. We do not use the term, since we regard it as redundant, being that all deep-seated fibromatoses are potentially aggressive. Other authors have gone even further and have used *well-differentiated fibrosarcoma* as a synonym for the histologically more cellular or clinically more aggressive types of fibromatosis. We are opposed to this terminology because the designation of sarcoma endows this lesion in the mind of many surgeons with a metastasizing potential that it simply does not possess.

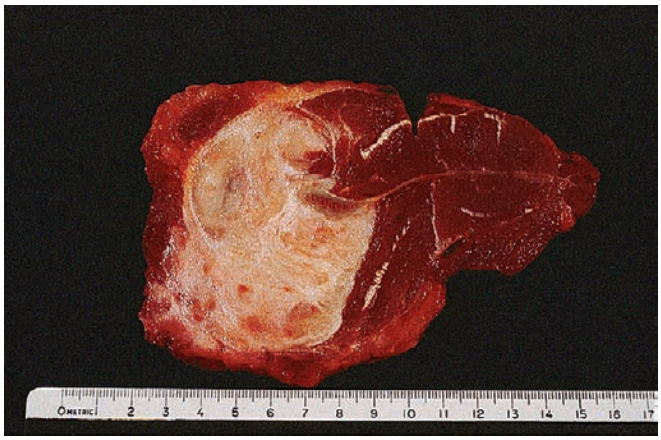

Figure 41.25 Deep-seated fibromatosis embedded within major skeletal muscle.

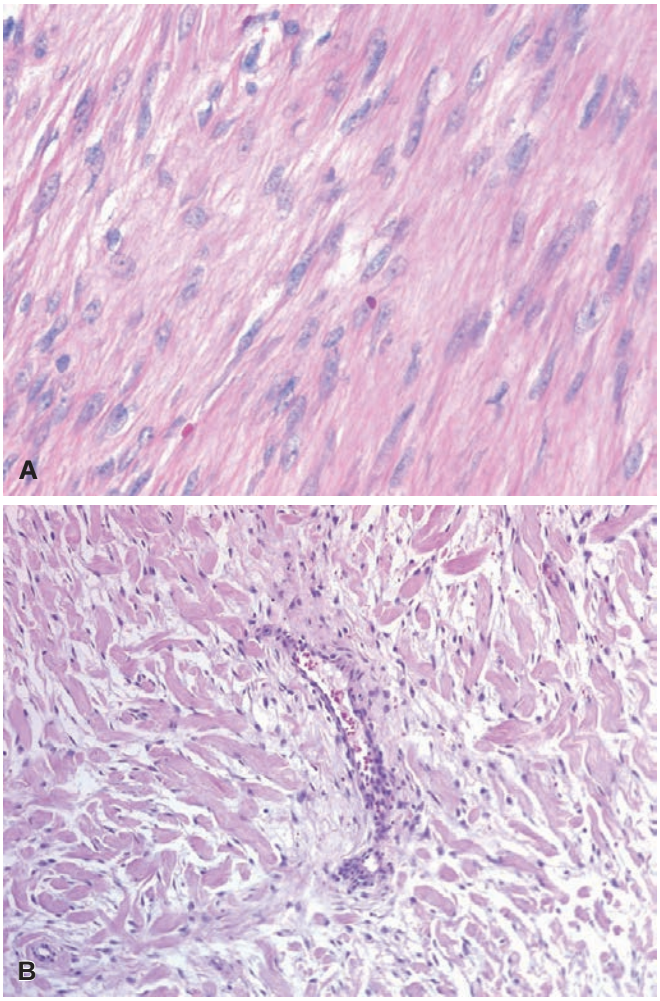

Figure 41.27 Abdominal Wall Fibromatosis. A, High-power view of cells in fibromatosis. **B,** Keloid-like collagen is often seen.

Although some cases are challenging, we always attempt to distinguish between fibromatosis and well-differentiated fibrosarcoma, reserving the latter term for tumors showing atypical cytologic features.

Most soft tissue fibromatoses are in intimate contact with skeletal muscles and their aponeuroses—hence their designation as *musculoaponeurotic fibromatosis*,[167] although the WHO refers to these lesions as desmoid-type fibromatosis. Although such lesions often arise in the abdominal wall in women during or following pregnancy, in our experience, this lesion is almost as common in men and in other locations, such as the shoulder girdle, head and neck area, and thigh.[168,169] It can also occur in the mediastinum, pleural cavity (with lung invasion), retroperitoneum, abdominal cavity (see subsequent discussion), and breast, among many other sites.

The treatment of deep fibromatoses should be individualized, and, in fact, a number of modalities can be utilized, including surgery alone or in conjunction with radiation and cytotoxic and noncytotoxic drugs (tamoxifen, Gleevec, and nonsteroidal anti-inflammatory drugs including sulindac). The tumor does have a strong propensity for local recurrence, but some authors have advised against the re-excision of a recurrent lesion that does not appear to be growing.[169] In the study by Gronchi et al., 76% of tumors locally recurred by 10 years.[170] Tumor size was associated with recurrence risk, but surprisingly, microscopic deposits of surgical margins were not predictive of recurrence. Recently, Colombo and colleagues found that sporadic tumors with mutations in codon 45 in the β-catenin gene *(CTNNB1)* have a greater tendency to locally recur.[163]

Juvenile fibromatosis is an antiquated term that has been applied to fibromatoses occurring in children and adolescents.[171] There is very little either on clinical or microscopic grounds that differentiates fibromatosis in children from that occurring in other age groups. There are, however, three variants of fibromatosis that predominantly occur in childhood that present a distinctive clinicopathologic picture: fibromatosis colli (congenital torticollis), inclusion body fibromatosis (infantile digital fibromatosis), and infantile myofibroma/myofibromatosis.

Fibromatosis colli (congenital torticollis) is a type of fibromatosis affecting the lower third of the sternocleidomastoid muscle and appearing at birth or shortly thereafter, sometimes bilaterally.[172] It is frequently associated with various congenital anomalies including rib cage anomalies and congenital hip dysplasia.[173,174] An association between complicated deliveries (particularly breech deliveries) and fibromatosis colli has been established.[175] Although some instances of spontaneous regression have been recorded, this condition usually necessitates resection of the muscle. Microscopically, there is partial replacement of the sternocleidomastoid muscle by a fibroblastic

proliferation of varying cellularity admixed with atrophic skeletal muscle fibers.

Inclusion body fibromatosis (infantile digital fibromatosis) is a form of fibromatosis usually restricted to childhood.[176] The typical location is on the exterior surface of the end phalanges of the fingers and toes, but it may also occur outside the digits and at sites such as the oral cavity and breast.[177,178] The lesions can be solitary or multiple and either present at birth or appear during the first 2 years of life. However, morphologically identical lesions in adults are on record.[179] A distinctive microscopic feature, generally not observed in other forms of fibromatosis, is the presence of peculiar eosinophilic cytoplasmic inclusions, often situated close to the nucleus and separated by a narrow clear zone (Fig. 41.28). A trichrome stain can highlight these inclusions. Ultrastructural findings suggest they represent bundles of microfilaments.[180,181] The spindle cells stain for SMA, desmin, calponin, and CD99.[182] Inclusion body fibromatosis has a high tendency for local recurrence.[182]

Very rare cases of inclusion body fibromatosis lacking inclusion bodies may be a component (and sometimes the first clinical manifestation) of the syndrome known as *terminal osseous dysplasia with pigmentary defects*.[183]

Infantile myofibroma/myofibromatosis presents as solitary (myofibroma)[184] or multiple (myofibromatosis)[185] nodules in the skin, soft tissues, or bone, either limited to these sites or associated with internal organ involvement.[186] A large majority of the cases occur before the age of 2 years, and approximately 60% are congenital.[184] However, this lesion can also occur in adults.[187] Solitary forms are more common in males, and multicentric forms are more common in females.[186] A familial incidence has been suggested, and evidence for both an autosomal dominant and recessive pattern of transmission has been proposed.[185,188] Microscopically, peripheral areas that resemble smooth muscle alternate with hemangiopericytoma-like areas and foci having a more typical fibroblastic appearance (Fig. 41.29). Central necrosis and intravascular growth may be present.[184] Both immunohistochemical and ultrastructural studies suggest the lesion is largely composed of myofibroblasts. However, a whole range of differentiation exists between fibroblasts and fully developed, desmin-positive smooth muscle cells.[187] Indeed, myofibromatosis seems to be a member of a family of tumors showing vessel-related myoid differentiation, which also includes glomangiopericytoma and myopericytoma[189,190] given that tumors with overlapping features exist. Solitary and multicentric lesions confined to the bone and soft tissues carry an excellent prognosis, with frequent spontaneous regression.[184,186] The prognosis is far less favorable in patients with multiple visceral lesions.

Interestingly, recurrent somatic *PDGFRB* mutations have been identified in sporadic infantile and solitary adult myofibromas, but these mutations were not identified in cases of angioleiomyoma and myopericytoma.[190a] However, recurrent *PDGFRB* alterations were identified in myopericytomatosis, suggesting a relationship between myopericytomatosis and infantile myofibroma/myofibromatosis. Alterations in *PDGFRB* also suggest the possible utility of tyrosine kinase inhibitors as a potential therapy for these lesions.[190b] A recurrent *SRF-RELA* fusion was recently found in highly cellular variants of myofibroma and myopericytoma, but cases of typical myofibroma and myopericytoma lack this fusion.[190c]

Lipofibromatosis is a minor variation on the theme of infantile fibromatosis, in which a spindle cell component of fibroblastic appearance (mainly located in septa and skeletal muscle) is admixed with mature adipose tissue.[191] This lesion affects children from birth to up to 10 years of age, usually arising in the muscles of the extremities, trunk, or head and neck. Like other forms of fibromatosis, this lesion frequently recurs but does not metastasize.

Recently, a series of locally aggressive lipofibromatosis-like neural tumors with recurrent *NTRK1* gene fusions were identified.[191a] These lesions occurred in children and young adults with an infiltrative growth pattern similar to that seen in lipofibromatosis, but with variable cytologic atypia and immunoreactivity for S-100 protein and CD34 suggesting neural differentiation.

Juvenile hyaline fibromatosis/infantile systemic hyalinosis is a distinctive group of lesions affecting children and characterized microscopically by cords of spindle cells embedded in an eosinophilic hyalinized matrix within the connective tissue of the skin, oral cavity, articular capsule, and bone.[192,193] Several studies have found mutations of the capillary morphogenesis genes 2 *(CMG2)* on 4q21 in both diseases, confirming these are part of a disease spectrum.[194,195] Inheritance is in an autosomal recessive manner, and there is a distinct predilection for patients of Middle Eastern descent.[196,197]

The superficial fibromatoses derive their names from their particular location. **Penile fibromatosis** (Peyronie disease) will be discussed in greater detail elsewhere. **Palmar fibromatosis** (Fig. 41.30) is also known as Dupuytren contracture and **plantar fibromatosis** as Ledderhose disease.[198] These conditions occur predominantly in adults but can also be seen in children and adolescents. Contracture of the fingers or toes is the leading clinical manifestation. The lesions can be multiple and bilateral and may coexist in the upper and lower extremities. The plantar form tends to be more localized than its palmar counterpart.

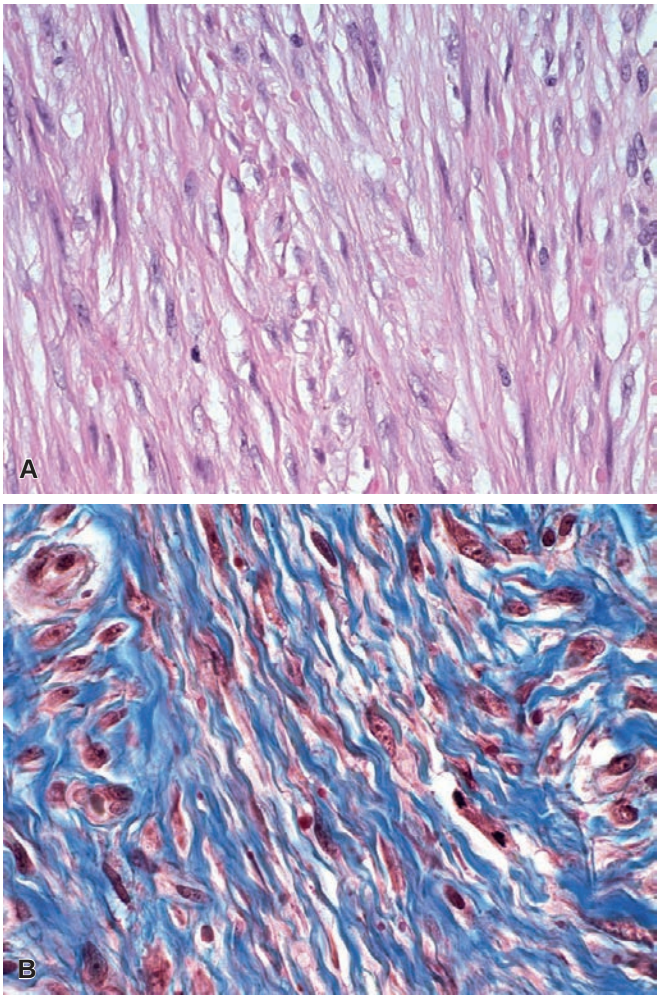

Figure 41.28 Inclusion Body Fibromatosis. A, Spindle cells with eosinophilic inclusions are seen. **B,** Trichrome stain revealing rare eosinophilic inclusions.

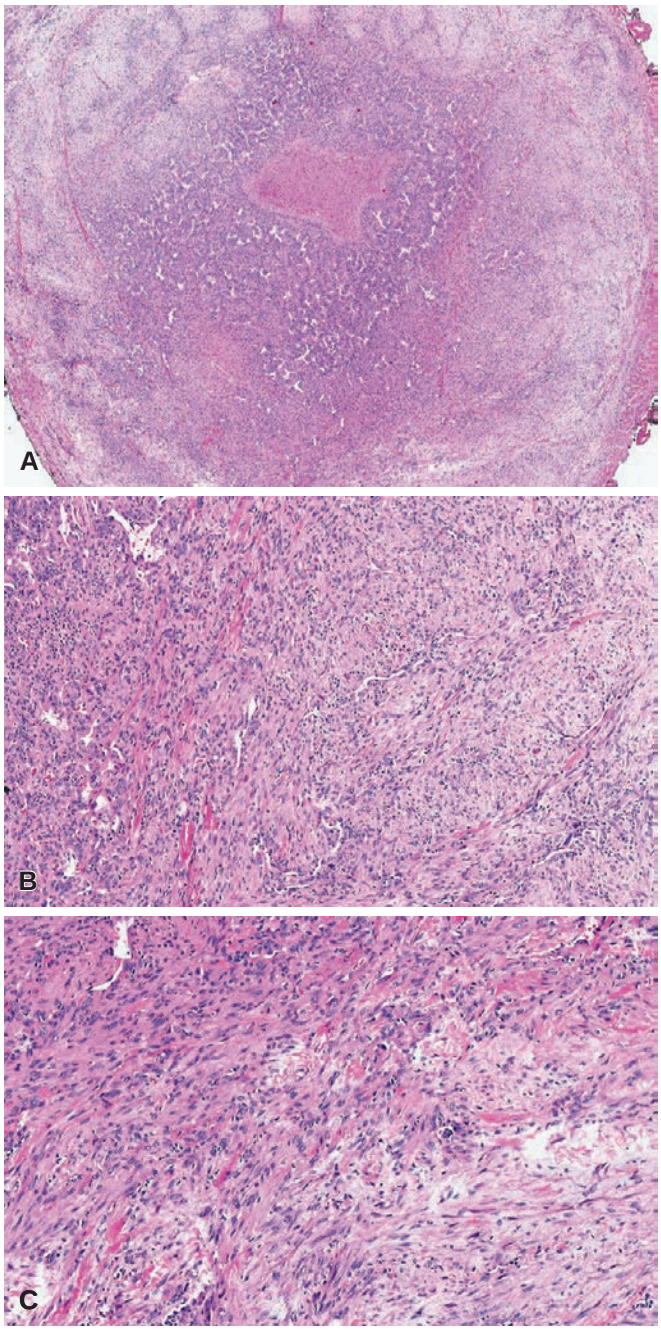

Figure 41.29 Infantile Myofibroma. A, Low-power view with central cellular zone with a hemangiopericytoma-like pattern and a peripheral myoid zone. **B,** Junction of hemangiopericytoma-like zone and myoid zone. **C,** High-power view of myoid zone in infantile myofibroma.

Microscopically, both often show a cellular proliferative phase (especially for the plantar lesions), which may lead to a mistaken diagnosis of fibrosarcoma. It is well to remember that fibrosarcoma of the palmar and plantar areas is exceptional and that the differential diagnosis of a cellular spindle cell tumor of the sole is usually between fibromatosis, synovial sarcoma, malignant melanoma, and Kaposi sarcoma. The cells are spindled with open chromatin and small nucleoli and are separated by variable amounts of collagen. Older lesions are often less cellular and more collagenous.

The association of soft tissue tumors, usually Gardner-type fibroma and desmoid-type fibromatosis, with colonic polyposis

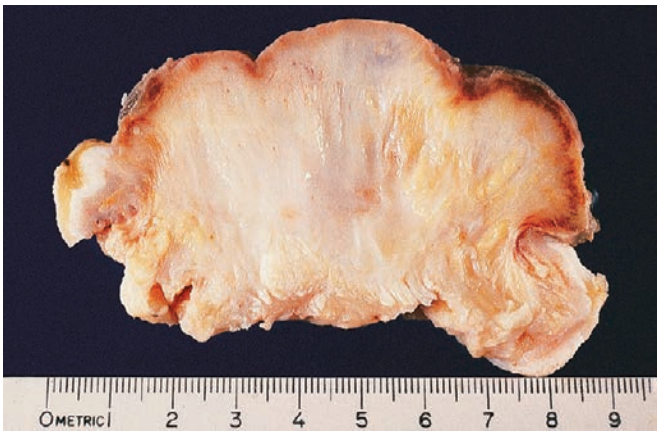

Figure 41.30 Plantar Fibromatosis. The tissue is whitish and unencapsulated with an elastic consistency.

and occasionally multiple osteomas is known as **Gardner syndrome**.[199] In this condition, the fibromatosis has a particular tendency to involve intra-abdominal structures, especially the mesentery, and to manifest itself following a surgical procedure in the area.[200,201] It is important not to misdiagnose intra-abdominal fibromatosis involving the intestinal wall (a not uncommon occurrence) as a gastrointestinal stromal tumor (GIST).[202] Along these lines, it should be mentioned that—despite early statements to the contrary—fibromatosis is a CD117-negative tumor, as opposed to the vast majority of GISTs.[203] As previously discussed, patients with Gardner syndrome can also develop *Gardner-associated fibroma*, a soft tissue tumor most often located in the back or paraspinal region and characterized microscopically by a bland hypocellular proliferation of spindle cells embedded in a background of haphazardly oriented coarse collagen fibers, similar to nuchal-type fibroma.[72]

Fibrosarcoma and Variants

Adult-type fibrosarcoma can arise from superficial and deep connective tissues such as fascia, tendon, and periosteum; they often grow slowly and appear well circumscribed.[204] They usually are soft and may contain area of necrosis and hemorrhage (Fig. 41.31).

Microscopically, the well-differentiated tumors (low grade) are easily recognized as fibroblastic; the cells are arranged in long fascicles that intersect at acute angles, resulting in a "herringbone" appearance (Fig. 41.32). Mitotic activity varies. High-grade tumors have closely packed, less well-oriented, smaller, rounder tumor cells with a less distinct fascicular arrangement, greater mitotic activity, and often extensive necrosis. It should be remembered that many other soft tissue tumors, particularly synovial sarcoma, MPNST, and UPS may harbor areas closely resembling fibrosarcoma. Careful examination of different blocks of the tumor coupled with select adjunctive studies will provide the correct diagnosis in almost all instances. Although a pleomorphic type of fibrosarcoma probably exists, one should question the diagnosis of fibrosarcoma in the presence of a soft tissue sarcoma with numerous tumor giant cells. As a matter of fact, the diagnosis of fibrosarcoma (especially the low-grade type) should be viewed as a diagnosis of exclusion.[205,206] Both immunohistochemical and ultrastructural studies have shown most of the cells show fibroblastic features, although it is common to also find cells with myofibroblastic differentiation, including the expression of SMA.[205] The distinction of fibrosarcoma from fibromatosis is critical, given that the former has a significant risk of metastasis and the latter only has a risk of local recurrence.

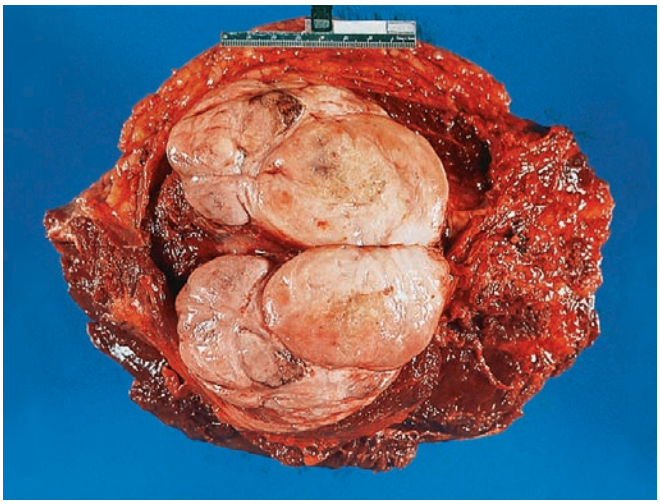

Figure 41.31 Well-circumscribed fibrosarcoma growing within skeletal muscle.

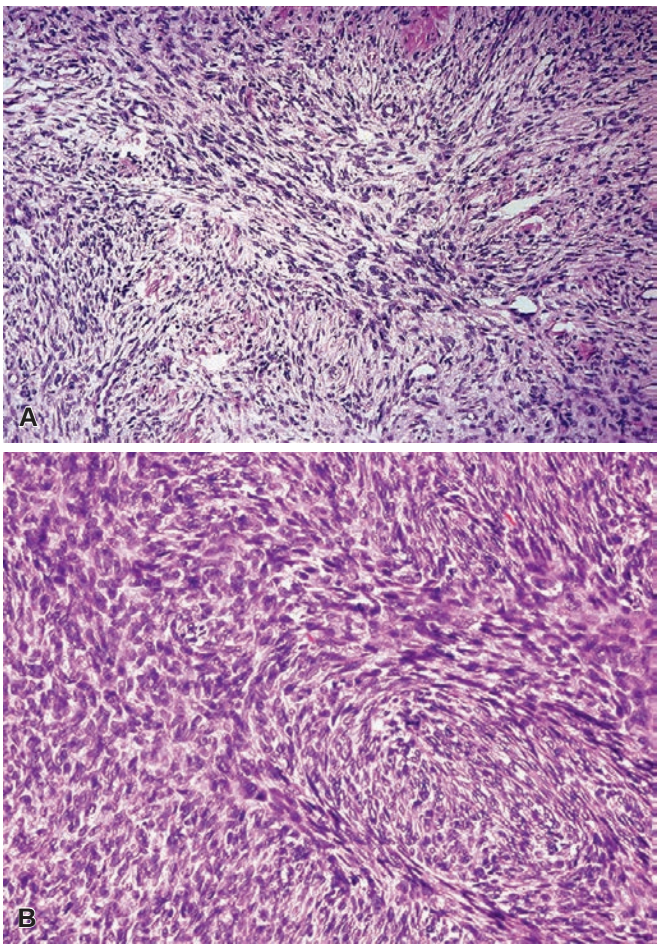

Figure 41.32 **Adult-Type Fibrosarcoma. A,** Low-power view. **B,** High-power view.

Generally, the more superficial and lower grade the tumor, the better the prognosis. In the study by Scott et al., the overall rate of recurrence was 42% at 5 years.[204] The status of the surgical margins was strongly predictive of local recurrence, but neither tumor grade nor stage were predictive factors. The treatment of choice is radical excision, and postoperative radiation therapy should be considered if microscopic residual or positive margins are encountered. Since subclinical microscopic metastases are presumed to exist in many patients at the time of surgery, adjuvant chemotherapy has been recommended following surgical excision of high-grade tumors.

Congenital fibrosarcoma (infantile fibrosarcoma) is an extremely cellular tumor characterized by very rapid growth and the capability for extensive local invasion, but its metastatic rate is negligible.[207] Microscopically, this tumor is composed of a cellular proliferation of spindle cells that are fairly uniform and arranged in fascicles or bundles, often admixed with lymphocytes and a hemangiopericytoma-like vascular pattern. At the molecular level, it is characterized by the *ETV6–NTRK3* gene fusion, which results from the chromosomal translocation t(12;15)(p13;q25).[208,209] This gene fusion is not present in adult-type fibrosarcoma or other pediatric fibroblastic tumors in the differential diagnosis. In addition, trisomies of chromosomes 8, 11, 17, and 20 are common.[210] Of interest, cellular congenital mesoblastic nephroma of the kidney shows identical genetic alterations, suggesting that these two entities are closely related.[211]

Low-grade fibromyxoid sarcoma (LGFMS), also known as Evans tumor, is a low-grade sarcoma with deceptively bland histologic features. Most patients are young to middle-aged adults and present with a slowly enlarging mass in the deep soft tissue of the extremities, although this tumor has been reported in virtually every anatomic site.[212–215] The tumor is of low to moderate cellularity with bland spindle-shaped cells deposited in a variably myxoid and collagenous matrix. There is often an elaborate network of capillaries in the myxoid zones, which are usually longer and less organized in comparison to the delicate vasculature of myxoid liposarcoma (Figs. 41.33 to 41.35). Some tumors show collagen rosettes (formerly known as hyalinizing spindle cell tumor with giant rosettes) (Fig. 41.36),[216] and others show cords of epithelioid cells with features overlapping that seen in sclerosing epithelioid fibrosarcoma (see later).[217,218] Rare cases show higher-grade areas with increased cellularity, mitotic activity, and nuclear pleomorphism. By immunohistochemistry, many express EMA and virtually all show strong staining for MUC4.[219,220] The vast majority harbor translocations involving either *CREB3L2* or *CREB3L1* with the *FUS* gene, resulting from either a t(7;16) or t(11;16), respectively.[221–223] Rare cases show involvement of *EWSR1* rather than *FUS*.[224,225]

Despite its bland histologic appearance, LGFMS can locally recur and metastasize. In the study by Folpe et al. in 2000, of 54 patients with follow-up, only 5 (9%) developed local recurrence, and 3 (6%) had metastatic disease; only 1 patient died of their tumor.[215] In a more recent study by Evans in 2011 with long-term follow-up, the rates of local recurrence, metastasis, and death were 64%, 45%, and 42%, respectively.[212,213]

Sclerosing epithelioid fibrosarcoma is a variant of fibrosarcoma that simulates the appearance of infiltrating carcinoma.[226,227] It is composed of small, round to ovoid tumor cells embedded in a dense hyalinized stroma. The scanty cytoplasm often has a clear appearance, and there may be a single file pattern of growth (Fig. 41.37). Necrosis and bone invasion may be found.[228] Up to 50% express EMA, and, like LGFMS, most express MUC4, particularly those with FUS translocations.[229] Some cases exhibit the same distinctive chromosomal translocation [t(7;16)] of LGFMS, suggesting a close relationship between these two tumor types.[220,225] Other examples of sclerosing epithelioid fibrosarcoma (like LGFMS) show involvement of *EWSR1* rather than *FUS*.[225,230] The tumor is associated with a high incidence of local recurrence and distant metastasis.

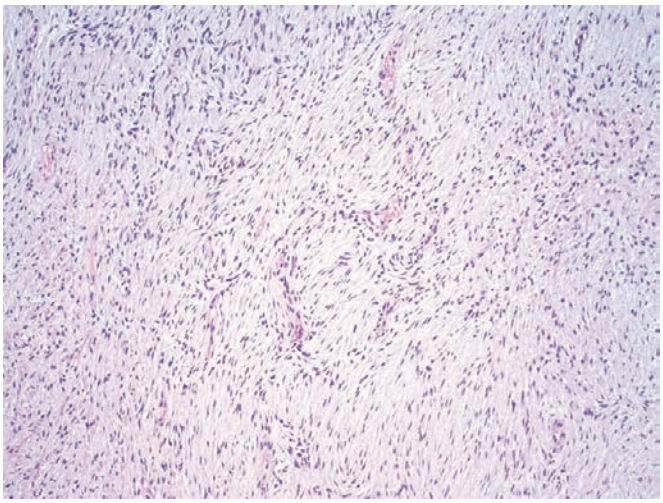

Figure 41.35 Bland spindle cells within myxoid stroma in low-grade fibromyxoid sarcoma.

Myxoinflammatory fibroblastic sarcoma (MIFS), also known as inflammatory myxohyaline tumor, is a low-grade sarcoma most commonly found in the distal extremities of adults.[231–233] This lesion can simulate an inflammatory condition, Hodgkin lymphoma, and various other types of soft tissue sarcomas, including myxofibrosarcoma. Microscopically, it has an infiltrative multinodular quality and a polymorphic cellular composition in a hyaline or myxoid background (Fig. 41.38). There is a dense mononuclear inflammatory infiltrate containing scattered stromal cells of either epithelioid or spindle shape, including some with large bizarre nuclei and prominent nucleoli resulting in a resemblance to Reed–Sternberg cells or virus-infected cells.[233] The immunohistochemical profile is nonspecific, but at least a subset of tumors have a recurrent t(1;10)(p22;q24) involving *TGFBR3* on chromosome 1 and *MGEA5* on chromosome 10.[234,235] Interestingly, this alteration has been identified in hemosiderotic fibrolipomatous tumor (also known as hemosiderotic fibrohistiocytic lipomatous tumor), and some cases of pleomorphic hyalinizing angiectatic tumor (PHAT) suggesting a relationship among these tumors.[234,236] Local recurrence is common, but distant metastases are exceptionally uncommon.[232,237]

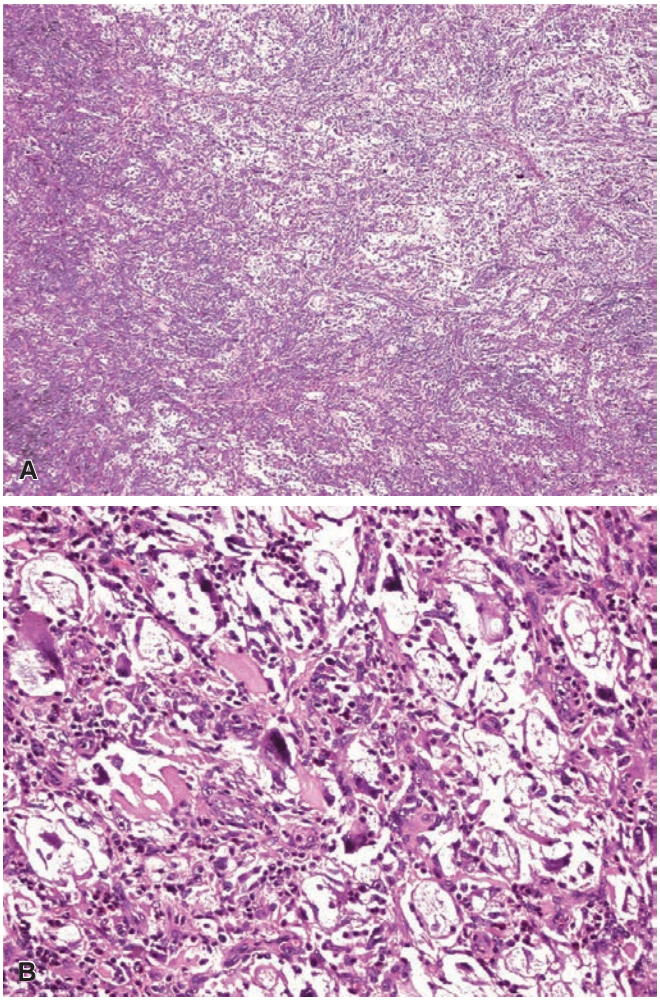

Figure 41.38 **Myxoinflammatory Fibroblastic Sarcoma. A,** Low-power view showing a heterogeneous appearance with alternating cellular and myxoid zones. **B,** Pseudolipoblasts and enlarged atypical smudgy cells can be seen.

Myofibroblastic Tumors

A particularly difficult issue in the classification of soft tissue tumors is the role played by myofibroblasts. Some authors have taken a very restrictive view of the definition of a myofibroblast (including the requirement of ultrastructural confirmation), whereas others do not believe ultrastructural confirmation should be required. Part of the problem is that there are no specific immunohistochemical markers for myofibroblasts, although the most common immunophenotype is strong staining for SMA with an absence of staining for desmin and h-caldesmon.[238]

The other problem concerns the fact that cells with myofibroblastic features can be found in a large number of benign and malignant soft tissue lesions, including lesions in which they constitute only a small percentage of the neoplastic cells. Therefore, if there is to be a category of myofibroblastic tumors, it would be wise to reserve it for lesions that are composed almost entirely of cells having myofibroblastic features.

Inflammatory myofibroblastic tumor is a distinctive entity that has gone by a number of different names, including inflammatory pseudotumor and inflammatory fibrosarcoma, among many others. Although they have been described in virtually every anatomic site, many of the cases arise in the mesentery or retroperitoneum of children or adults, often accompanied by anemia and fever.[239,240]

Histologically, a variety of patterns may be seen including a fasciitis-like pattern, cellular spindle cell areas, and hypocellular hyalinized zones. Lymphocytes and plasma cells are often intermixed within any of these patterns (Fig. 41.39). The constituent cells show the immunohistochemical features of myofibroblasts, as previously discussed, and up to 50% also stain for ALK.[240–243] There is imperfect correlation between ALK staining and *ALK* rearrangements approximately 50% of these tumors harbor clonal rearrangements of the *ALK* gene at 2p23.[244] Recently, gene fusions involving other kinases have been identified, including *ROS1* and *PDGFRB*.[244a] A number of other fusion partners have been identified including *TPM3*, *TPM4*, *CARS*, *ATIC*, *SEC31L1*, *RANBP2*, and *CLTC*.[245–249] Tumors in the abdomen and retroperitoneum have a higher propensity for aggressive clinical behavior than those arising elsewhere, including frequent local recurrences and definite risk of metastasis.[240,250] Although surgery is the mainstay of therapy, *ALK* inhibitors such as crizotinib have been found to be efficacious in treating aggressive lesions.[251,252]

Myofibrosarcoma

Sarcomas composed predominantly or exclusively of myofibroblasts do exist but are uncommon and are referred to as myofibrosarcoma or myofibroblastic sarcoma. At the high-grade end of the spectrum, such lesions often are grouped as UPS. Low-grade lesions have a peak incidence in the fourth decade of life[238,253] and most commonly arise in the head and neck region.[254] The tumor is composed of spindled- to stellate-shaped cells arranged into sheets, whorls, or intersecting fascicles with variable amounts of myxoid and collagenous stroma (Fig. 41.40). At least focal nuclear hyperchromasia is seen, a key feature in distinguishing this low-grade sarcoma from a reactive/benign process. There is often infiltration into the surrounding soft tissues, although mitotic activity is low and necrosis is absent. The cells show the characteristic immunophenotypic features of myofibroblasts. Most show indolent behavior, but some recur and still others progress to a higher-grade sarcoma and can metastasize.[238]

Fibrohistiocytic Tumors

This large, complex, and controversial family of tumors was originally defined by the presence of a dual cellular composition: cells with a fibroblastic appearance intimately mixed with others having some of the morphologic and functional attributes of histiocytes.[255] Stout and his colleagues at Columbia Presbyterian Hospital in New York City first proposed that these tumors originate from tissue histiocytes, some of which were said to acquire fibroblastic features.[256] Another proposed interpretation of these lesions is that they arise from primitive mesenchymal cells with the capacity for dual differentiation into histiocytes and fibroblasts.[257,258] Both theories assume the existence in these lesions of a true neoplastic histiocytic component. To be sure, some of the cells in these tumors do show phagocytic properties, accumulate fat and hemosiderin, exhibit lysosomes ultrastructurally, and manifest immunohistochemical reactivity for hydrolytic enzymes[259,260]; however, the specific cell markers of "true histiocytes" derived from bone marrow have been found to be absent in the tumor cells and present only in the osteoclast-like giant cells occasionally seen in these lesions.[261–263] In most studies, the majority of tumor cells have a phenotypic appearance resembling that of fibroblasts or myofibroblasts.[264] It seems increasingly evident that the tumors in the fibrohistiocytic group are pathogenetically diverse but share common morphologic features.

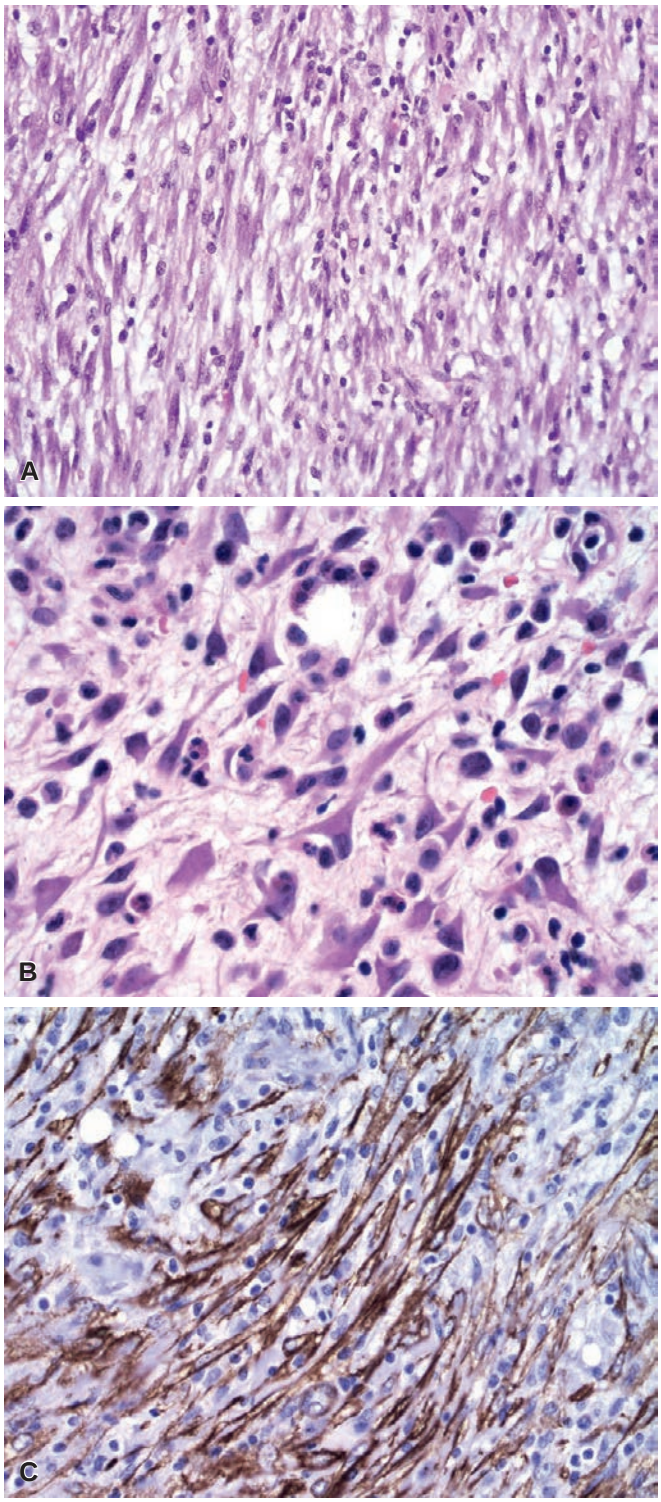

Figure 41.39 Inflammatory Myofibroblastic Tumor. A, Cellular zone with spindle cells and scattered inflammatory cells. **B,** High-power view of myofibroblasts. **C,** "Tram track" pattern of smooth muscle actin staining of myofibroblasts.

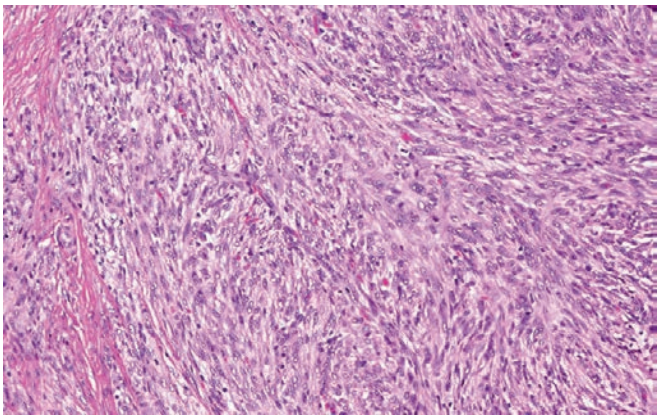

Figure 41.40 Cellular zone of a myofibrosarcoma with plump spindle cells arranged in fascicles.

Benign fibrous histiocytoma. Benign fibrous histiocytoma of skin (also known as dermatofibroma) and soft tissue typically arises in the extremities of young to middle-aged adults.[265] Microscopically, the usual case is composed of closely packed polygonal cells with little or no intervening stroma. The cytoplasm is eosinophilic and may contain lipid droplets. Inflammatory cells are frequently present, as are multinucleated cells (Figs. 41.41 to 41.43). Collagen trapping at the periphery of the lesion is a characteristic feature. Some lesions can be extremely cellular (**cellular fibrous histiocytoma**) (Fig. 41.44),[266,267] and some may have large atypical nuclei (**atypical fibrous histiocytoma**) (Fig. 41.45).[268,269] Still others are composed predominantly of cells with an epithelioid morphology (**epithelioid fibrous histiocytoma**). This variant has recently been associated with rearrangements of the *ALK* gene, with immunohistochemical staining in almost 90% of cases.[270] Some examples also show blood-filled tumor-lined spaces associated with extensive hemosiderin deposition (**aneurysmal fibrous histiocytoma**) (Fig. 41.46).[271]

The classic benign fibrous histiocytoma is superficially located in the skin, but deeply seated examples occur.[272] These have a better-developed storiform pattern, are more circumscribed, and may exhibit prominent hemangiopericytoma-like vessels. They have a 20% incidence of local recurrence. In extremely rare cases, these lesions can metastasize to distant sites.[273,274]

Other benign fibrohistiocytic lesions include xanthoma, solitary (juvenile) xanthogranuloma, and solitary/multicentric reticulohistiocytoma, all of which are described in further detail in Chapter 3.

Hemosiderotic fibrohistiocytic tumor (also known as *hemosiderotic fibrolipomatous lipomatous tumor*, or HFLT) characteristically occurs almost exclusively in the ankle region of elderly patients (usually females).[275] While some have referred to these lesions as "early PHAT" given that some cases of pleomorphic hyalinizing angiectatic tumor (PHAT) are surrounded by areas resembling this lesion,[276] others have found cytogenetic aberrations identical to those found in MIFS—namely a t(1;10) involving *TGFBR3* and *MGEA5*.[235,277] Histologically, it is composed of a poorly circumscribed proliferation of bland spindle cells admixed with fat and hemosiderin.

Cellular neurothekeoma is a tumor that some believe to be histogenetically related to benign fibrous histiocytoma, but this relationship remains unclear. It is clear, however, that this lesion is quite distinct from the lesion which used to be known as classical myxoid neurothekeoma, now better referred to as dermal nerve sheath myxoma. The latter entity is a benign schwannian neoplasm and is discussed later in this chapter.

Cellular neurothekeoma usually occurs in young patients, with a peak incidence in the second decade of life.[278,279] They occur more commonly in women and usually involve the head and neck region, shoulder, or upper extremities. Most are centered in the dermis, but they may extend to involve the underlying subcutaneous tissue in almost half of the cases.

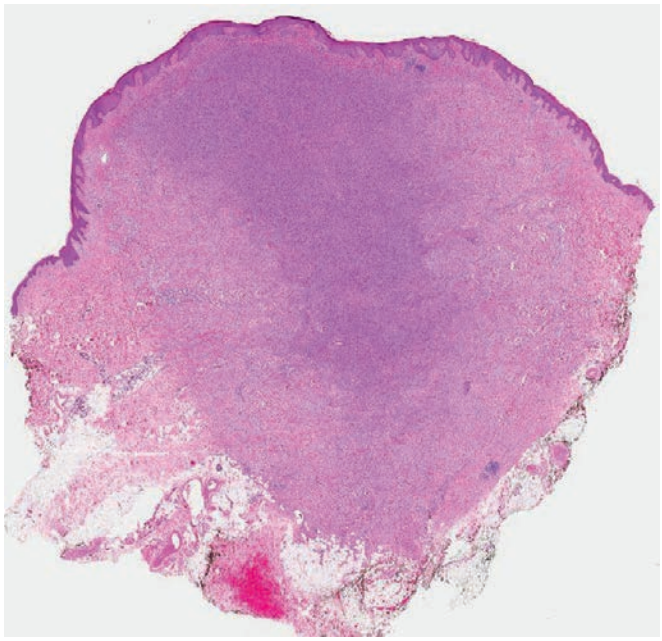

Figure 41.41 Low-power view of classical benign fibrous histiocytoma. The lesion is well circumscribed at its base, and epidermal hyperplasia is apparent.

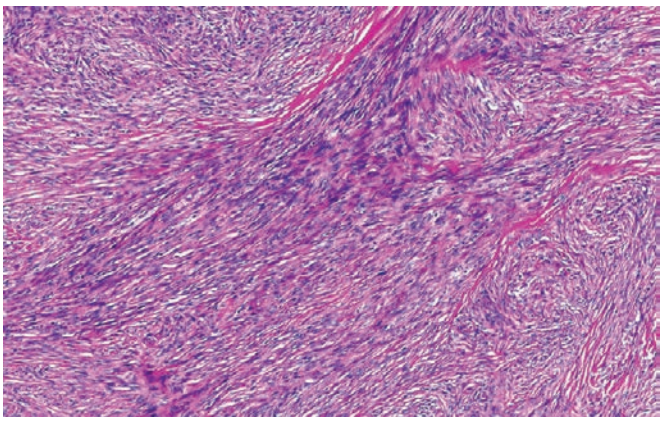

Figure 41.44 Cellular benign fibrous histiocytoma composed of a highly cellular proliferation arranged into fascicles. This is easily mistaken for a sarcoma.

Microscopically, a multinodular, lobular, or plexiform growth pattern is often apparent at low magnification. The tumor cells are typically arranged into nests of varying sizes and are often separated by bands of dense collagen (Fig. 41.47). A whorling growth pattern is frequently prominent, but some cases grow in solid sheets, and still others show prominent myxoid change, thereby making the diagnosis even more difficult. The tumor cells are epithelioid to spindle-shaped, with lightly eosinophilic cytoplasm and bland nuclei. Rare cases display moderate to marked nuclear atypia, which can raise its own challenges for this diagnosis.[279] Mitotic activity can be conspicuous, and rare cases can even show atypical mitotic figures.[278,279] By immunohistochemistry, the tumor cells coexpress CD10 and NKI/C3, but they are negative for S-100 protein.[280] Other frequently positive markers include smooth muscle actin and MiTF.[281]

Cellular neurothekeoma is a benign tumor that can locally recur, particularly for those tumors that arise on the face and those that are incompletely excised.[279] Interestingly, worrisome histologic features, including marked cytologic atypia, prominent mitotic activity, and atypical mitotic figures, have not been associated with a more aggressive clinical course.[279] Recent data (gene expression profiling data) suggest this tumor likely falls within the spectrum of fibrohistiocytic tumors.[282]

Fibrohistiocytic tumors of intermediate (borderline) malignancy. This group of tumors is characterized by local aggressiveness (manifested by a high tendency for local recurrence) but an extremely low rate of distant metastases. This category includes DFSP and its pigmented (Bednar tumor) and "juvenile" variants (giant cell

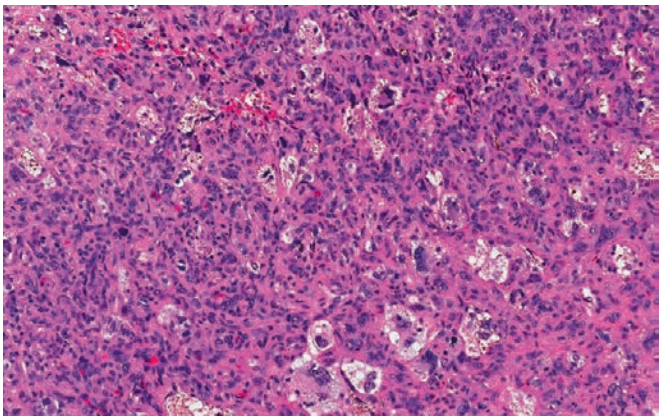

Figure 41.45 Scattered bizarre cells in atypical benign fibrous histiocytoma.

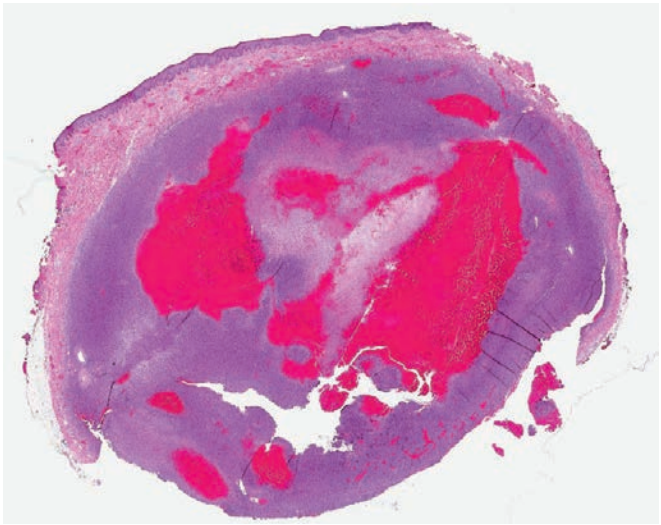

Figure 41.46 Low-power view of aneurysmal benign fibrous histiocytoma with tumor-lined blood-filled lakes.

fibroblastoma [GCF]), angiomatoid fibrous histiocytoma, plexiform fibrohistiocytic tumor, and soft tissue giant cell tumor of low malignant potential.

DFSP is typically centered in the dermis, but it can occur in deeper soft tissues.[283] This lesion is characterized microscopically by a lack of circumscription and a proliferation of uniform bland spindle cells arranged in a monotonous storiform pattern (Fig. 41.48). This storiform pattern can also be seen in benign fibrous histiocytomas, as well as in tumors of totally unrelated types (e.g., thymoma), and as such is not specific for DFSP. The collagen appears as nonpolarizable thin strands, in contrast to that present in most benign fibrous histiocytomas, which show prominent thickened entrapped collagen at the periphery.[284,285] Sometimes the tumor has prominent myxoid features.[286,287] The neoplastic cells infiltrate around adnexal structures and into the underlying subcutis in a "lace-like" pattern, thus making it difficult to surgically excise, accounting for the high rate of local recurrence. Virtually all examples stain strongly for CD34, but this marker lacks specificity. Given that at least focal CD34 positivity can be seen in many cutaneous mesenchymal neoplasms, there tends to be overinterpretation of this stain, resulting in a misdiagnosis of DFSP.

Virtually all cases of DFSP have a translocation that involves chromosomes 17 and 22, resulting in fusion of the collagen type I α I *(COL1A1)* and platelet-derived growth factor β *(PDGFβ)* genes, which can be detected by RT-PCR or FISH.[288] This can be used as an adjunctive test in difficult cases, given the specificity of this translocation. A recent study by Karanian et al. found FISH analysis to be helpful in 25% of cases and necessary in 5% of cases.[289]

As previously noted, a close link exists between DFSP and GCF, which shares the same translocation.[290] Indeed, the latter is often regarded as the "juvenile" variant of DFSP.[291–293] It should be noted, however, that classic forms of DFSP can also be seen in the pediatric age group.[294] GCF is characterized by a proliferation of spindle- to stellate-shaped cells deposited in a fibromyxoid stroma with tumor-lined cleft-like spaces with characteristic floret-like giant cells (Fig. 41.49). Like DFSP, this tumor stains strongly for CD34 and has a similar propensity for local recurrence.

Pigmented DFSP (Bednar tumor) looks like the usual DFSP except for the presence of a population of dendritic cells heavily loaded with melanin (Fig. 41.50); the occurrence of this variant is of interest because it raises the possibility of a peripheral nerve sheath origin.[295,296] An alternative possibility, that is, that the melanin-containing dendritic cells are not neoplastic but rather represent secondary melanocyte colonization, has been suggested.[297,298] This pigmented pattern has also been described in cases of GCF, reaffirming the close relationship among these entities.[299]

Some cases of DFSP (as well as GCF and Bednar tumor) progress to a higher-grade sarcoma, most commonly resembling a deep soft tissue fibrosarcoma (**fibrosarcomatous DFSP**). Rarely, the tumor can progress to a UPS ("MFH-like"). In the typical case, there is an abrupt transition from a less-cellular, bland, mitotically inactive spindle cell proliferation arranged in a storiform pattern to a far

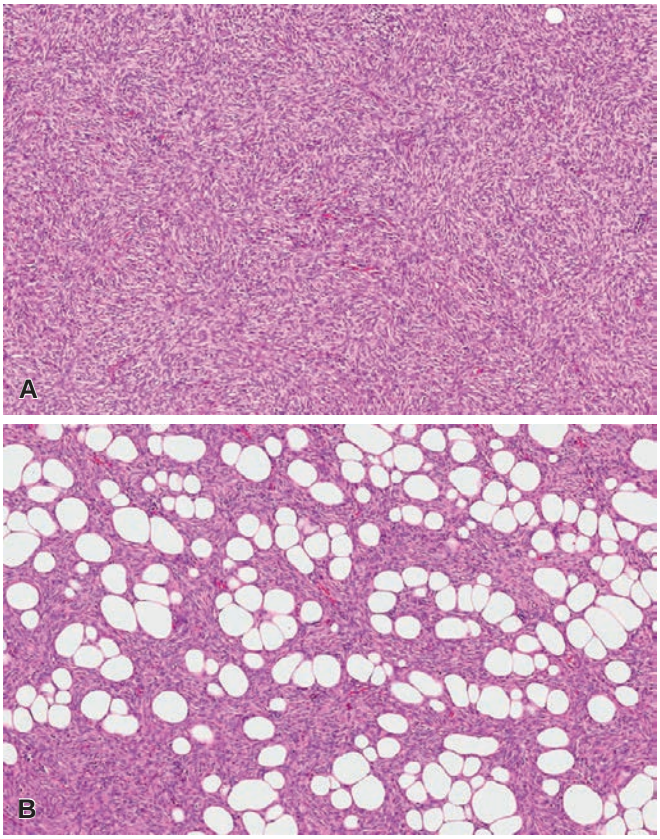

Figure 41.48 Dermatofibrosarcoma Protuberans. A, Characteristic storiform pattern. **B,** Lace-like infiltration into fat at the base of a dermatofibrosarcoma protuberans.

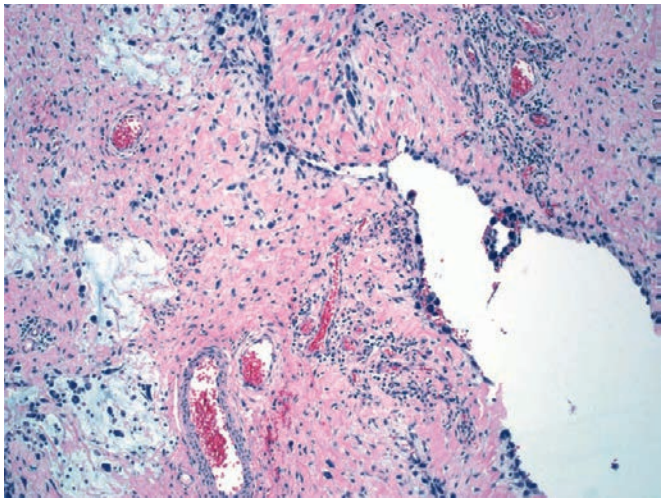

Figure 41.49 Giant cell fibroblastoma with myxoid and pseudovascular spaces lined by atypical giant cells.

more cellular proliferation of hyperchromatic, mitotically active spindle cells arranged in long fascicles (herringbone pattern) (Fig. 41.51). On occasion, this transition is more gradual, going from classical DFSP to a hypercellular DFSP to fibrosarcoma. Often but not always, there is decreased or absent CD34 staining in the fibrosarcomatous component. This transformation clearly increases the clinical aggressiveness of this tumor, with a higher rate of metastasis and occasionally even resulting in the death of the patient.[300] However, complete excision with tumor-free margins seems to improve the long-term outcome of these patients.[301]

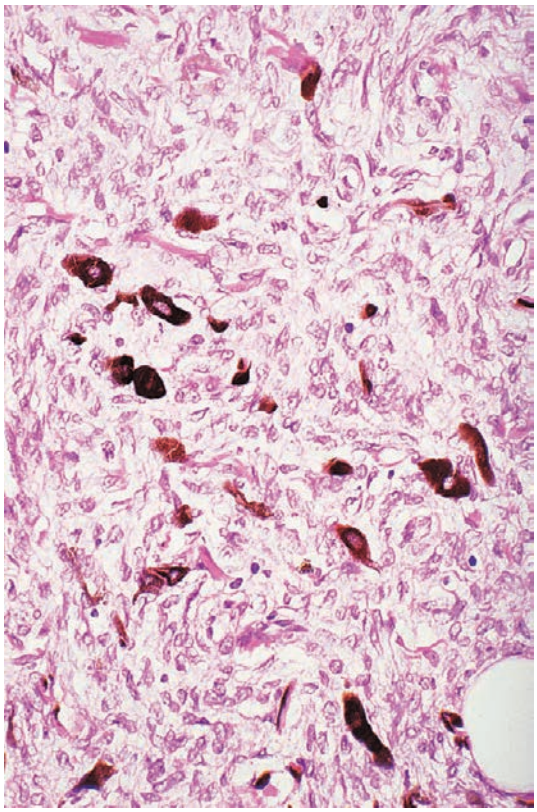

Figure 41.50 Pigmented dermatofibrosarcoma protuberans (Bednar tumor). Scattered pigmented cells are seen among the spindle cells.

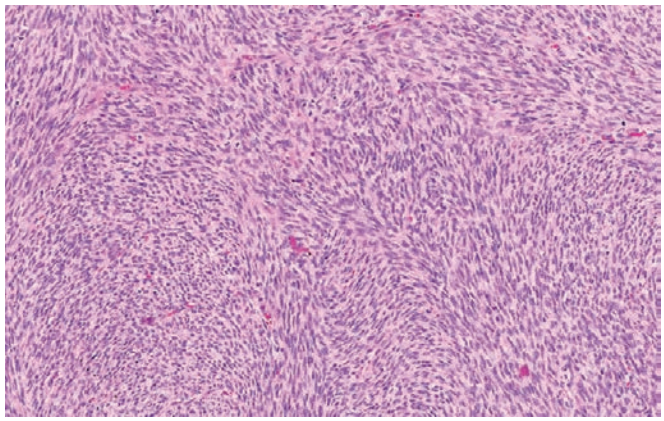

Figure 41.51 Fibrosarcomatous transformation of a dermatofibrosarcoma protuberans with a herringbone spindle cell pattern.

Angiomatoid fibrous histiocytoma was originally considered a variant of so-called malignant fibrous histiocytoma (MFH) but subsequently was found to be unrelated to that group of tumors. It usually arises in the extremities of children and young adults as a circumscribed, multinodular, or multicystic hemorrhagic tumor.[302–304] Microscopically, it is composed of epithelioid or sometimes spindle cells arranged in sheets and often punctuated by blood-filled tumor-lined spaces (Figs. 41.52 to 41.54). The cells have "histiocytoid" features and eosinophilic cytoplasm with mild nuclear pleomorphism, although occasionally marked nuclear pleomorphism can be seen.[305,306] Some cases lack the ectatic blood-filled spaces and are solidly cellular,

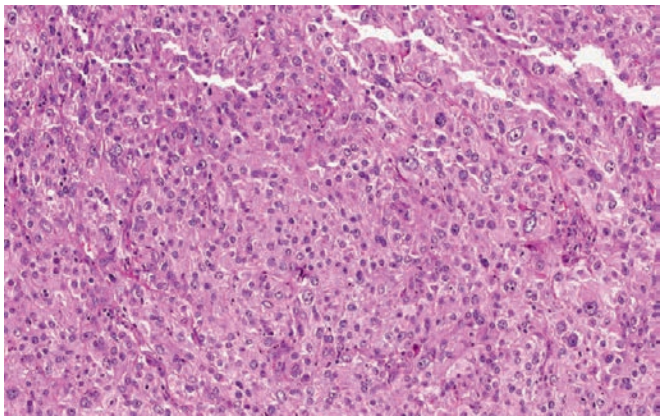

Figure 41.54 Eosinophilic histiocyte-like cells in a solid zone of angiomatoid fibrous histiocytoma.

and others show a prominent myxoid stroma.[307,308] The tumor is characteristically surrounded by nodular lymphoid aggregates, which may even simulate a lymph node, resulting in the mistaken impression of a tumor metastatic to a lymph node. By immunohistochemistry, the tumor stains for desmin in up to 50% of cases,[304] and staining for EMA and CD99 is also commonly seen. Recurrent chromosomal aberrations have been found, most commonly t(2;22)(q33;q12) with *EWSR1-CREB1* fusion, and less commonly t(12;16)(q13;p11) with *FUS-ATF1* fusion or t(12;22)(q13;q12) with *EWSR1-ATF1* fusion.[309–312] Angiomatoid fibrous histiocytoma is a low-grade tumor that has a tendency for local recurrence, but can also rarely metastasize to distant sites.[304]

Plexiform fibrohistiocytic tumor occurs almost exclusively in children or young adults.[313] It usually presents as a superficial, slowly growing lesion in the upper or lower extremities. Most are small ill-defined masses centered in the deep dermis or subcutis and are composed of an intimate admixture of spindled cells and nodules of round histiocyte-like cells with multinucleated osteoclast-like giant cells (Fig. 41.55). The spindle cells have fibroblastic features and are arranged in short fascicles and have bland nuclear features. The overall low-power appearance imparts a plexiform pattern of growth. The two areas vary in proportion from case to case. The histiocyte-like cells often stain for CD68, and the spindle cells express SMA (without desmin or h-caldesmon) consistent with myofibroblastic differentiation. The tumor recurs in up to 40% of cases and rarely metastasizes to lymph nodes or the lungs.[314–317]

Giant cell tumor of soft tissue (also known as soft tissue giant cell tumor of low malignant potential) is similar in many ways to giant cell tumor of bone.[318,319] It occurs in patients of all ages, most commonly in the superficial or deep soft tissues of the hand or arm. At low power, there are multiple tumor nodules that infiltrate the surrounding soft tissue. The predominant cell types are bland mononuclear cells, osteoclasts, and short spindle cells (Fig. 41.56). Although both mitotic activity and vascular invasion may be present, these lesions rarely recur or metastasize.[320–322] These lesions are histologically nearly identical to giant cell tumor of bone, but recent molecular studies suggest they are distinct entities.[322a]

Malignant Fibrohistiocytic Tumors

In prior editions of this textbook, MFH had a prominent place in this chapter. However, it has become apparent that this term encompasses a number of related and unrelated entities, and the term UPS has supplanted MFH as the preferred term for a high-grade pleomorphic sarcoma that usually arises in the deep soft tissue of elderly patients.[323] In Fletcher's classic paper re-reviewing cases previously classified as MFH, over 60% of cases were reclassified as some type of pleomorphic sarcoma showing a specific line of differentiation (e.g., pleomorphic liposarcoma, pleomorphic

leiomyosarcoma, pleomorphic rhabdomyosarcoma). About 12.5% of cases proved to be some other type of pleomorphic malignant neoplasm resembling a sarcoma, most commonly a sarcomatoid carcinoma. This still left about 25% of cases which were unclassifiable and by exclusion were felt to represent an UPS. This observation has been substantiated by others and hence the preference for the term UPS.[324,325]

As previously mentioned, most cases of UPS arise in the deep soft tissues of the extremities of middle-aged to elderly patients (Fig. 41.57), although they have been described in virtually every anatomic site. Of particular note are those cases arising in the retroperitoneum, as extensive sampling and molecular analysis for *MDM2* amplification usually reveal such lesions to represent the dedifferentiated component of a dedifferentiated liposarcoma.[326] The classic form of UPS shows both storiform and pleomorphic features, with plump spindle cells with marked cytologic atypia arranged in tight whorls (Fig. 41.58). Mitotic figures including atypical forms are typically seen, as are secondary elements including chronic inflammatory cells, xanthoma cells, multinucleated giant cells, and extensive areas of necrosis. Some examples have numerous giant cells, a lesion formerly referred to as *giant cell MFH* (Fig. 41.59).[318] Those with a prominent neutrophilic and xanthomatous infiltrate have also been referred to as *inflammatory MFH* (Fig. 41.60),[327] but inasmuch as most of these arise in the retroperitoneum, it is now believed that almost all tumors of this type also represent dedifferentiated liposarcomas.[328] Some examples show prominent myxoid change, with an elaborate curvilinear vascular pattern. In the past, *myxoid MFH* was used for such tumors that were greater than 50% myxoid. However, that term has

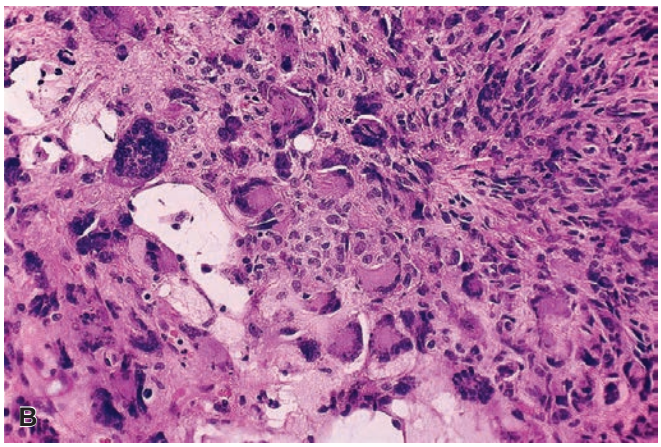

Figure 41.58 Undifferentiated Pleomorphic Sarcoma. A, Prominent storiform growth pattern. **B,** Marked nuclear pleomorphism and scattered giant cells are seen.

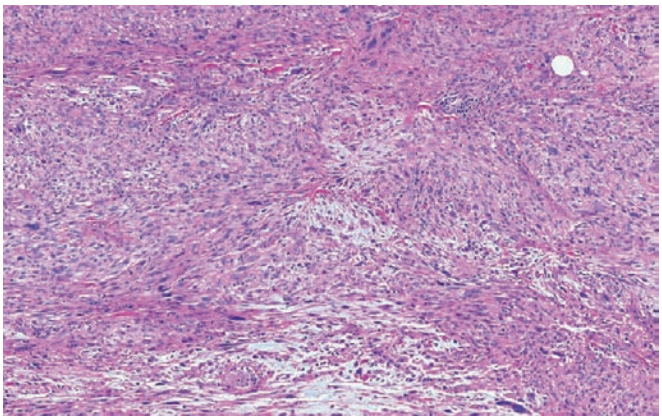

Figure 41.59 Undifferentiated pleomorphic sarcoma with very focal myxoid change comprising less than 5% of the tumor.

been replaced by *myxofibrosarcoma* (described in greater detail later in this chapter). Admittedly, an arbitrary distinction must sometimes be made between UPS with focal myxoid change and a high-grade myxofibrosarcoma.[327,329]

By immunohistochemistry, UPS has no distinctive staining pattern, although many show evidence of myofibroblastic differentiation with patchy staining for smooth muscle actin and the absence of staining for desmin or h-caldesmon.[330] "Aberrant" cytokeratin staining may occur focally and is not necessarily evidence of a sarcomatoid carcinoma.[331,332] By cytogenetics, UPS, like all types of

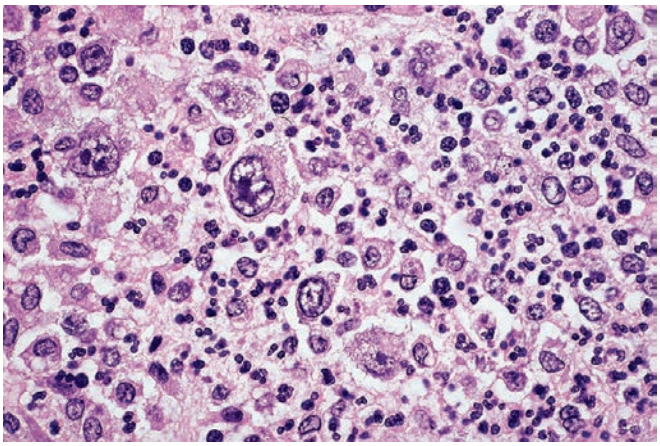

Figure 41.60 Undifferentiated pleomorphic sarcoma with prominent acute inflammation, a lesion formerly known as "inflammatory MFH."

pleomorphic sarcomas, has a complex but nonspecific karyotype, and, as such, this technique is not helpful in subtyping pleomorphic sarcomas.[333]

The tumor is prone to local recurrence and has the capacity to metastasize to distant sites, especially the lungs. Prognostic factors include tumor depth, tumor size, grade, extent of necrosis, and local recurrence.[334]

Myxofibrosarcoma is the term currently preferred for the tumor formerly known as myxoid MFH. Most of these tumors arise in the extremities of adults, often centered in the subcutis with attachments to the fascia.[314,329] Grossly, they often have a mucoid cut surface. Microscopically, the low-grade forms exhibit an abundant myxoid matrix, spindle cells with at least a minor degree of cytologic atypia, and an arborizing vascular pattern (Figs. 41.61 and 41.62).[335] At the higher end of the spectrum, tumors have greater cellularity, a greater degree of nuclear atypia, and an elaborate vascular pattern with interconnecting curvilinear vessels. These high-grade areas merge with foci resembling UPS. Lipoblast-like cells (pseudolipoblasts) may be identified, but these are not true lipoblasts but rather are cells that have imbibed the acid mucopolysaccharide-rich stroma resulting in cytoplasmic vacuoles. Rare cases show focal or even a predominant epithelioid morphology, making the diagnosis even more difficult.[336] There is a relationship between tumor grade (which can range from 1 to 3) and prognosis, but even low-grade tumors have the potential for local recurrence and tumor progression.[326,337–339]

Tumors of Synovial Tissues

Giant Cell Tumor of Tendon Sheath (Tenosynovial Giant Cell Tumor, Localized Type)

The localized form of **giant cell tumor of tendon sheath** is a common lesion seen on the distal extremities (hands more than toes) and is twice as common in women as men with a peak in the fourth through sixth decades of life.[340,341] The tumor grows slowly over time and presents as a discrete nodule, which is attached to deep structures. Erosion of adjacent cortical bone may occur, but true bony invasion is extremely rare.[342]

Microscopically, it is a well-circumscribed, lobulated mass partially invested by a dense collagenous capsule, although nodules may be seen outside of this capsule. There is a variable proportion of small and large mononuclear cells, multinucleated giant cells, xanthoma cells, inflammatory cells, and hemosiderin. Most tumors are

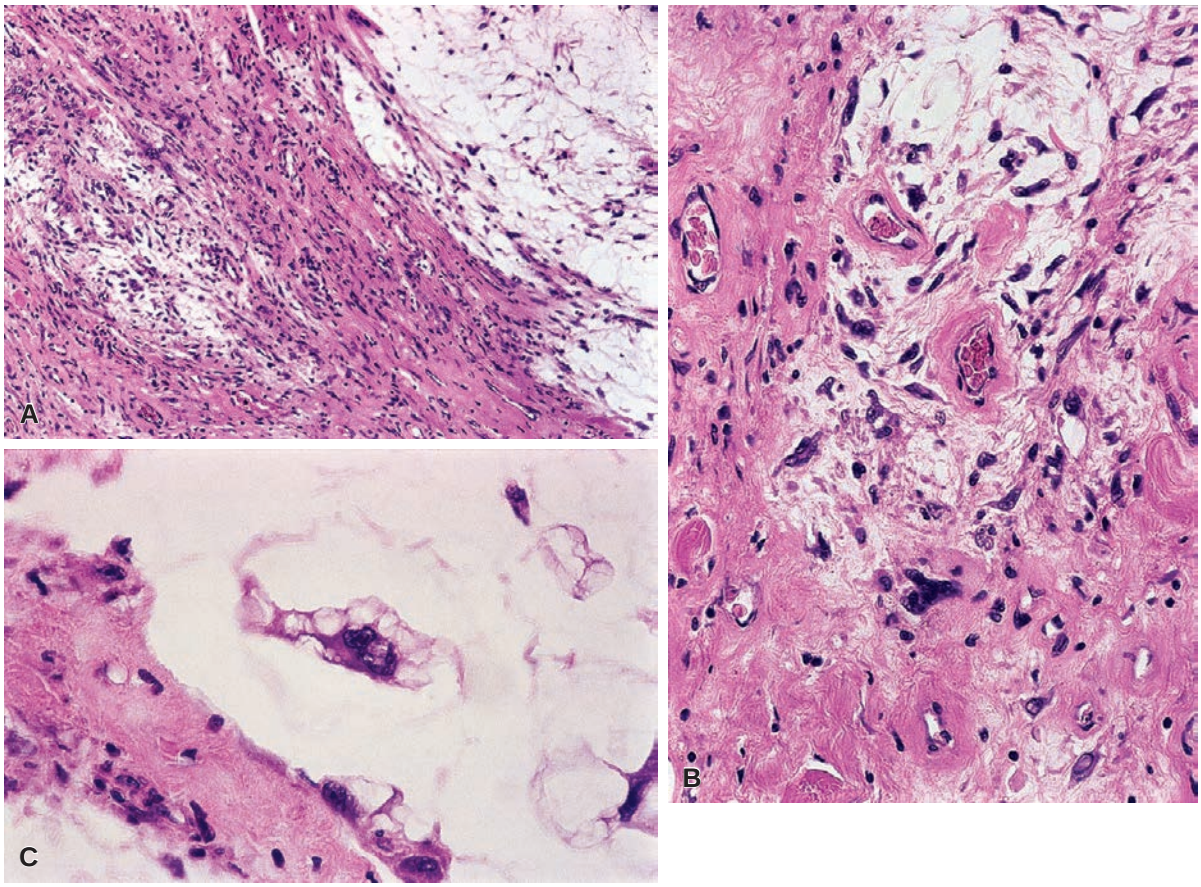

Figure 41.61 **Myxofibrosarcoma, Formerly Known as "Myxoid MFH." A,** Alternation of cellular and myxoid zones. **B,** There is moderate nuclear pleomorphism of the tumor cells. **C,** Rare lipoblast-like cells (pseudolipoblasts) are often seen.

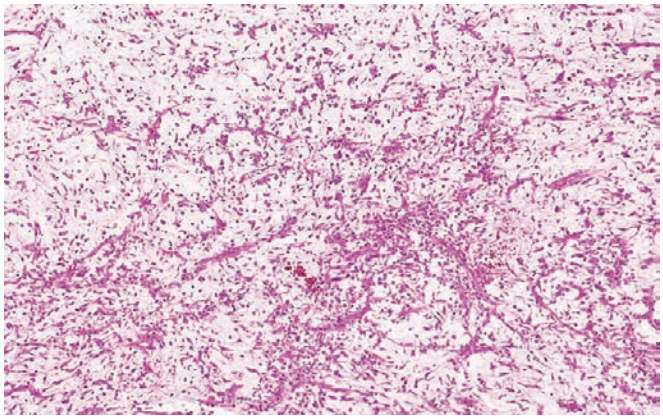

Figure 41.62 Myxofibrosarcoma with arborizing blood vessels and perivascular hypercellularity.

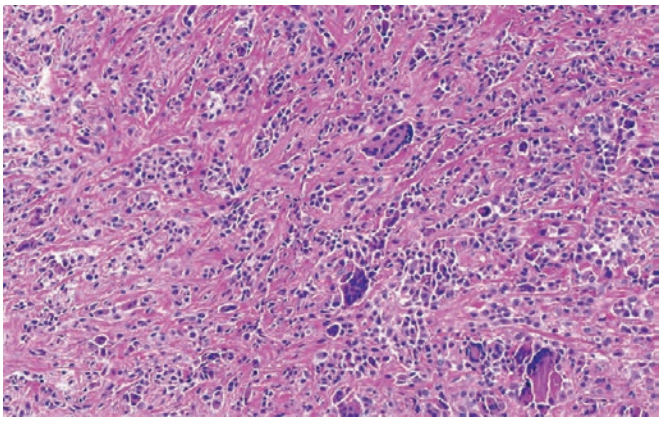

Figure 41.63 Giant cell tumor of tendon sheath with linear arrays of mononuclear cells deposited in a collagen background admixed with multinucleated giant cells.

moderately cellular, with cells blending with hyalinized collagen (Figs. 41.63 and 41.64). Others are less cellular and more extensively hyalinized. Multinucleated cells form by fusion of the smaller mononuclear cells, and in some cases, they are quite sparse, making recognition of this tumor more challenging. Cleft-like spaces are often a prominent feature at the tumor periphery. Some cases show high cellularity, vigorous mitotic activity and even involvement of vascular structures, but none of these features seems to portend a more aggressive clinical course.

By immunohistochemistry, the mononuclear cells stain for CD45, CD68, and CD163, consistent with histiocytic differentiation.[343–345] The larger mononuclear cells express clusterin, but the small mononuclear cells and multinucleated giant cells are negative for this antigen.[346] These same larger mononuclear cells also often express desmin,[346] an immunophenotype similar to normal synoviocytes. While some have argued for a non-neoplastic origin, the presence of clonal cytogenetic abnormalities[347] and, more specifically, rearrangements of the *CSF1* gene at 1p11-13[348,349] support a neoplastic origin.

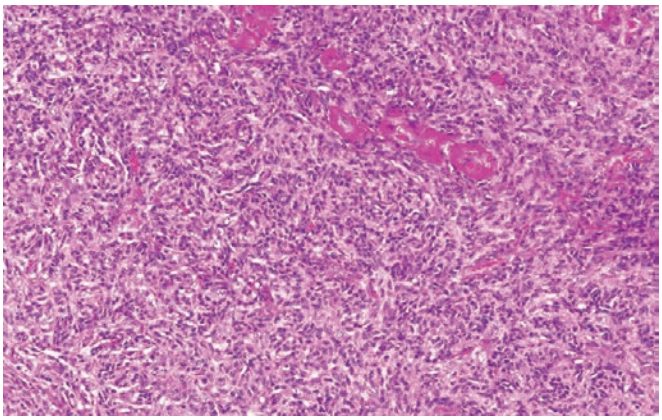

Figure 41.64 A monotonous population of mononuclear cells in a giant cell tumor of tendon sheath. No giant cells are seen in this case.

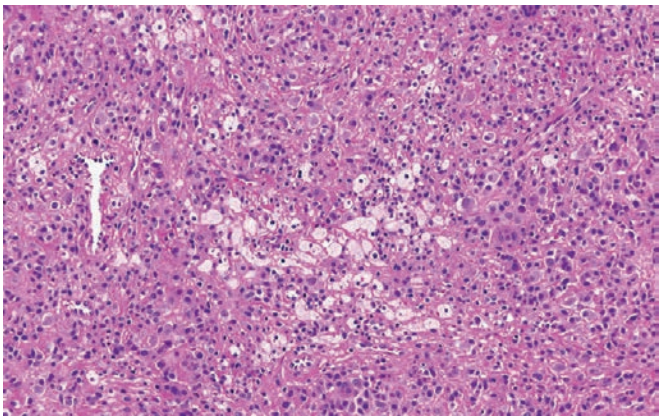

Figure 41.65 Sheets of mononuclear cells and xanthoma cells in a diffuse-type giant cell tumor.

The lesion is benign but locally recurs in 10%–20% of cases.[341,350,351] These recurrences are nondestructive and can be reexcised without much difficulty.

Very rarely, malignancy seems to arise in the setting of a giant cell tumor (**malignant giant cell tumor of tendon sheath**). This designation should be reserved for tumors with unequivocal malignant areas that arise either next to or subsequent to classical giant cell tumor.[352,353] The malignant areas are usually composed of sheets or discrete nodules of large ovoid cells with prominent nucleoli, although some resemble fibrosarcoma or UPS.[353] Up to 50% of these tumors metastasize, usually to regional lymph nodes. Wide local excision or even amputation is the recommended mode of therapy.

Giant Cell Tumor of Tendon Sheath, Diffuse-Type/ Pigmented Villonodular Synovitis

The **diffuse giant cell tumor of tendon sheath** can be regarded as the extra-articular counterpart of **pigmented villonodular synovitis**, which is an intra-articular process. In the majority of cases, soft tissue involvement is secondary to extensive growth from an intra-articular process, but some cases are exclusively in the soft tissues.[345,354,355] These lesions are far less common than the localized type, and they tend to occur in younger patients, with a peak incidence in the fifth decade of life.[345] They most commonly occur near the knee, followed by the ankle and foot. Unlike the localized form, they arise as a less circumscribed process with infiltration of surrounding tissues, accounting for the much higher rate of local recurrence. The cellular constituents and immunophenotype are identical to those seen in the localized form, although giant cells tend to be less conspicuous (Fig. 41.65). *CSF1* aberrations are also seen in these tumors, indicating a clear histogenetic connection to the localized form. Given the high rate of local recurrence, therapy should be directed at an attempt to remove the tumor as completely as possible while minimizing morbidity.

Tumors and Tumorlike Conditions of Peripheral Nerves

Proliferative lesions of peripheral nerves are divided into non-neoplastic (such as traumatic neuroma), benign tumors (such as schwannomas, neurofibromas, and perineuriomas), and malignant tumors, collectively designated as MPNSTs. Despite the fact that these lesions may overlap and coexist with each other, it is important to make a distinction among them in view of their markedly different natural history.

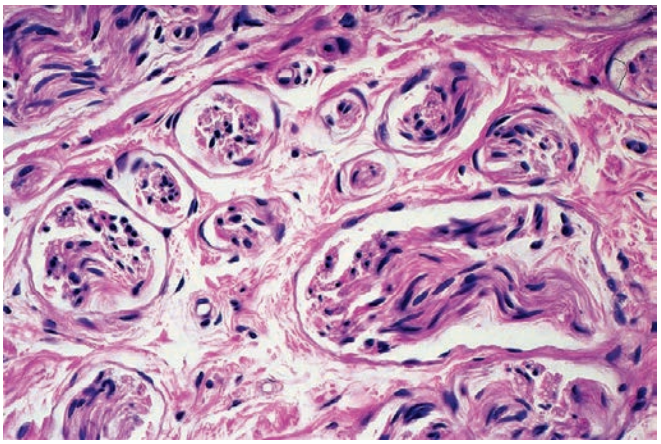

Figure 41.66 Traumatic neuroma with a haphazard distribution of nerve trunks surrounded by fibrous tissue.

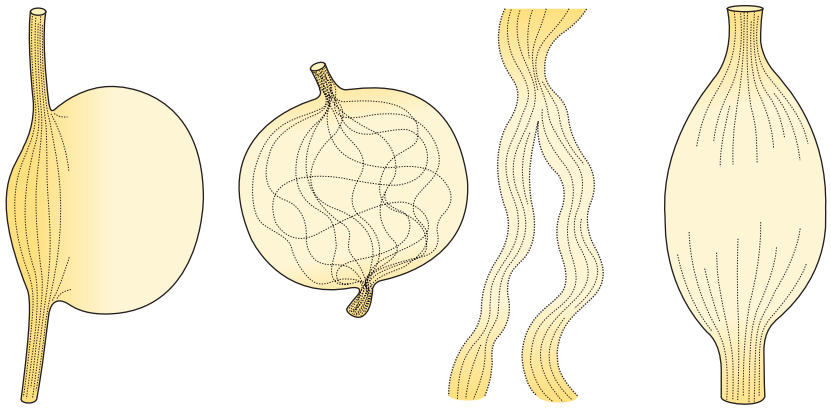
Neuroma

The large majority of neuromas follow trauma—hence their designation as **traumatic neuromas**. When a peripheral nerve is severed or crushed, the distal end undergoes wallerian degeneration, whereas the proximal end regenerates. If it fails to meet the distal end, a tangled mass of nerve fibers results. Microscopically, all the elements of a nerve can be recognized: axons, Schwann cells, perineurial cells, and fibroblasts (Fig. 41.66). In addition, scar tissue is often present. Not surprisingly, this lesion may be exquisitely painful. Immunohistochemically, the Schwann cells of traumatic neuroma show aberrant expression of the macrophage-associated antigens CD68 and Ki-M1P, in keeping with the macrophagic properties that they are known to acquire under these circumstances.[356] **Amputation neuroma**, a term made popular during the First World War, is a type of traumatic neuroma in which the original trauma involves the loss of part or all of an extremity.

Morton neuroma (Morton metatarsalgia) can be regarded as a subtype of traumatic neuroma caused by repeated mild trauma to the region.[357] Its typical location is the interdigital plantar nerve between the third and fourth toes. The lesion is more common in female adults. Microscopically, the affected nerve is markedly distorted with extensive perineurial fibrosis, often arranged in a concentric fashion.

Palisaded encapsulated neuroma (solitary circumscribed neuroma) presents as a small, solitary, asymptomatic papule in the



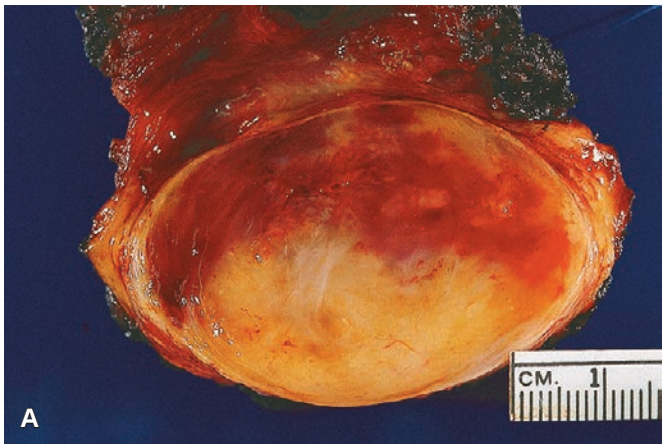


Figure 41.67 Schematic drawing emphasizing the main differences between the three major types of peripheral nerve tumors. Note diameter of nerve involved and behavior of neurites *(thin black lines)* in relation to the neoplasm. *MPNST*, malignant peripheral nerve sheath tumor.

skin,[358,359] usually arising on the face of middle-aged individuals. Microscopically, the lesion is centered in the dermis (in contrast to schwannoma, which is rarely seen in this location) and is characterized by a proliferation of Schwann cells and numerous axons located within a capsule derived from perineurium.[360] Immunohistochemically, the Schwann cells are reactive for S-100 protein, the axons for neurofilaments, and the capsule for EMA, the latter indicating the presence of perineurial cells.[360,361]

Schwannoma (Neurilemoma)

Schwannoma (neurilemoma) is one of the few truly encapsulated neoplasms. Its most common locations are the flexor surfaces of the extremities, neck, mediastinum, retroperitoneum, posterior spinal roots, and cerebellopontine angle. The nerve of origin often can be demonstrated in the periphery, flattened along the capsule but not penetrating the substance of the tumor (Fig. 41.67). Since this is a benign neoplasm that only rarely recurs locally, every attempt should be made to preserve the nerve, if this is of any clinical significance (e.g., facial nerve or vagus nerve). The great majority of cases occur sporadically, while a small percentage of cases are associated with type 2 neurofibromatosis (caused by a germline mutation in the *NF2* gene located on 22q12, which encodes merlin, also known as schwannomin).[362]

Grossly, the larger schwannomas often contain cystic areas (Fig. 41.68). The microscopic appearance is distinctive with Antoni A and B zones (Figs. 41.69 to 41.72). The Antoni A zones, which in small tumors comprise almost their entirety, are quite cellular, composed of spindle cells often arranged in a palisading fashion or in an organoid arrangement (Verocay bodies). In Antoni B zones, the tumor cells are separated by abundant edematous fluid that may form cystic spaces. Occasionally, isolated cells with bizarre hyperchromatic nuclei are observed (so-called ancient schwannoma) and are of no particular significance.[363] Mitoses are usually absent or rare. Thick-walled hyalinized blood vessels are a characteristic finding, sometimes with thrombosis. Some cases show prominent nuclear palisading, but this is not unique to schwannoma, as this feature may also be seen in smooth muscle tumors, among others. The traditional wisdom is that (in contrast to neurofibromas, see later) axons are not present in schwannoma, except in the portion of the

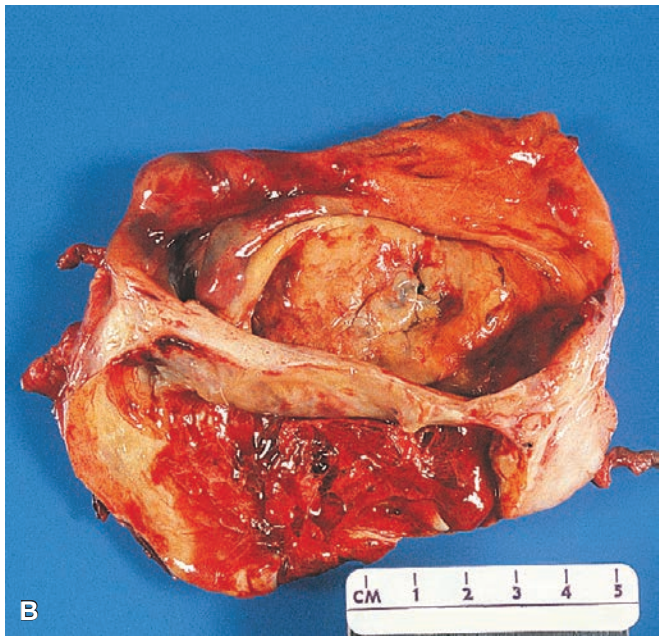

Figure 41.68 Gross Appearances of Schwannoma. The tumor shown in **B** has undergone marked secondary cystic changes.

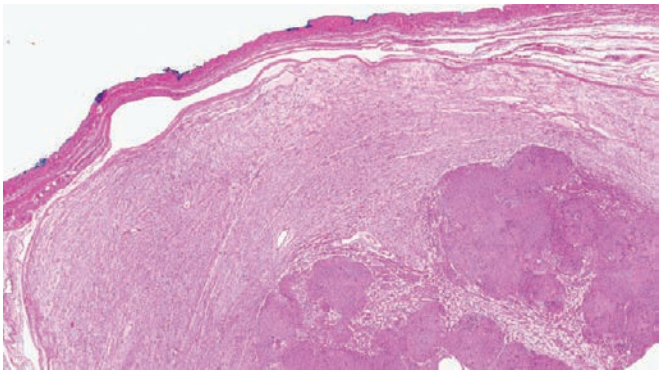

Figure 41.69 Low-power view of schwannoma with capsule and Antoni A and B areas.

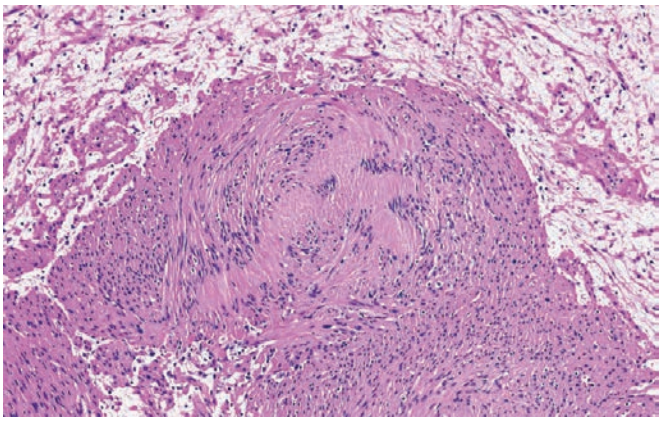

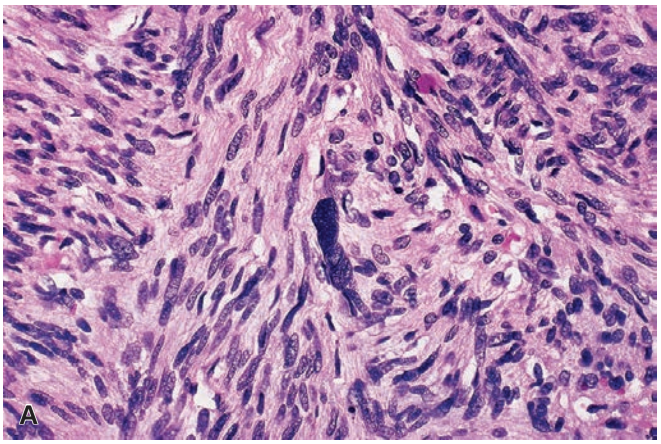

Figure 41.71 Verocay bodies in a schwannoma.

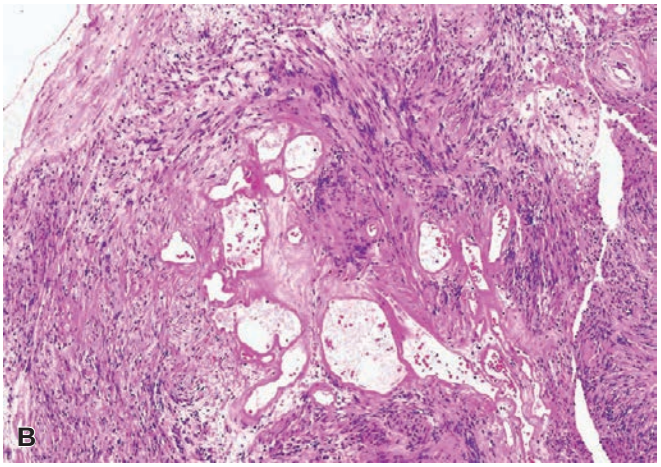

Figure 41.72 **Schwannoma. A,** Large hyperchromatic nuclei are seen. This does not necessarily indicate malignant change. **B,** Thick-walled hyalinized blood vessels are a prominent feature.

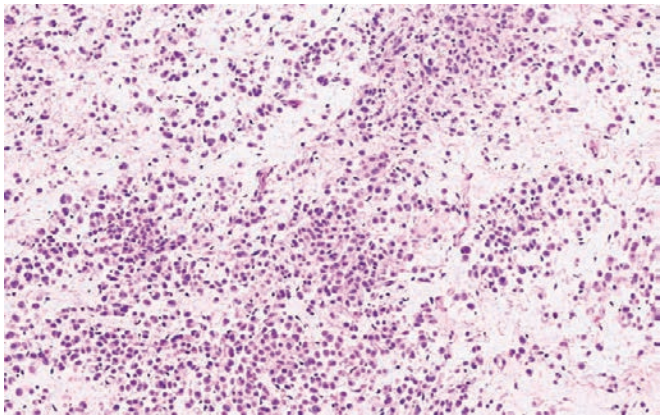

Figure 41.73 Epithelioid schwannoma with epithelioid Schwann cells deposited in a myxoid matrix.

capsule where the nerve is attached; however, recent studies employing an antibody against neurofilament have challenged that assumption.[336] Collections of foamy macrophages are sometimes seen, especially in larger neoplasms. More unusual is the presence of clusters of granular cells similar to those seen in granular cell tumors.[364] The rare occurrence of plexiform areas in schwannoma may cause them to be mistaken for neurofibroma. Most of these *plexiform schwannomas* are found superficially in the dermis or subcutaneous tissue, but they can also be deep-seated.[365,366]

Epithelioid areas can also be present, although much less commonly than in neurofibroma and MPNST.[367] When these areas predominate, the tumor has been referred to as *benign epithelioid schwannoma* (Fig. 41.73). Recently, it has been found that almost 50% of these lesions showed loss of INI1 expression.[367a] Some of these lesions can show striking cytologic atypia and in rare cases can transform into epithelioid MPNST. A few cases of schwannoma containing a glandular component have been described *(benign glandular schwannomas)*.[368,369] These should be distinguished from the pseudoglandular formations lined by low columnar or cuboidal

Schwann cells having an epithelial-like appearance,[370,371] as well as from entrapped sweat glands.

Rare schwannomas are found to contain melanin pigment. When this feature is prominent and accompanied by psammoma body formation, the possibility of the tumor representing a psammomatous melanotic schwannoma should be considered[372] (see subsequent sections). Rarely, schwannomas (and neurofibromas) can exhibit a lipoblastic component, accompanied by cells with signet ring–like features.[373] Other schwannomas have a predominant *microcystic/reticular* appearance; these manifest a predilection for visceral locations, particularly the gastrointestinal tract.[374]

Exceptionally, otherwise typical schwannomas or those with epithelioid features have been found to contain foci of small, round hyperchromatic Schwann cells with scanty cytoplasm, sometimes forming rosettes and simulating neuroblastoma.[375,376]

By electron microscopy, the tumor cells show features of schwannian differentiation with a continuous and often reduplicated basal lamina; numerous, extremely thin cytoplasmic processes; aggregates of intracytoplasmic microfibrils; peculiar intracytoplasmic lamellar bodies; and extracellular long-spacing collagen.[377] Immunohistochemically, the tumor cells show immunoreactivity for S-100 protein (Fig. 41.74), calretinin (in contrast to neurofibromas) and basal lamina components (such as laminin and type IV collagen).[335] Curiously, keratin is often expressed in retroperitoneal schwannomas but virtually never in peripheral schwannomas.[378] Genetically, schwannoma, whether sporadic or associated with type 2 neurofibromatosis, is characterized by somatic mutation (sporadic form) or germline mutation (type 2 neurofibromatosis) of the *NF2* gene in one allele, and loss of *NF2* in the remaining allele through deletion or monosomy 22.[379,380]

Malignant transformation of schwannoma is—in contrast to neurofibroma—an exceptionally rare event, but undoubtedly occurs.[381,382] Interestingly, in most of these cases the malignant component has exhibited an epithelioid morphology.[383]

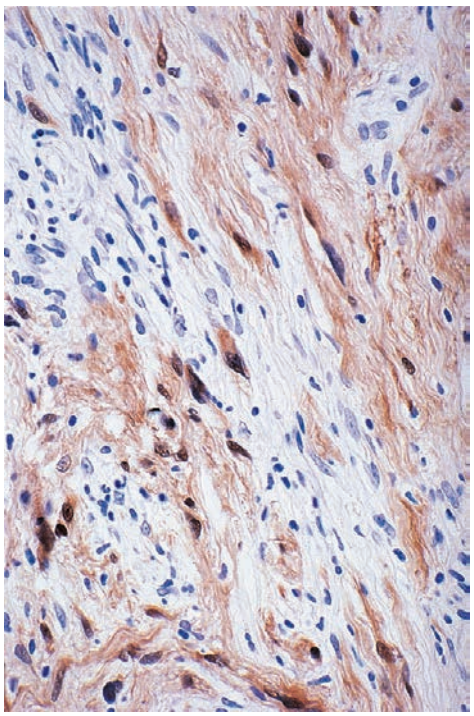

Figure 41.74 S-100 protein immunoreactivity in a schwannoma.

Cellular schwannoma is the term used for highly cellular schwannomas that are exclusively composed of Antoni A areas but lack Verocay bodies (Fig. 41.75).[384–386] These changes can be accompanied by nuclear atypia, mitotic activity, and focal necrosis. Most reported cases have been in the retroperitoneum, pelvis, and mediastinum. The differential diagnosis with a low-grade MPNST is a difficult distinction, but strong and diffuse S-100 protein staining is in keeping with a cellular schwannoma.

Psammomatous melanotic schwannoma is a distinctive type of peripheral nerve sheath tumor that occurs as a component of the Carney complex.[372] Most arise from the spinal nerve roots. As the name indicates, the tumor is characterized microscopically by the presence of melanin pigmentation and the deposition of psammoma bodies (Fig. 41.76). In contrast to all other types of schwannoma described in this section, the psammomatous melanotic variety is regarded as a low-grade malignancy because of its tendency for local recurrence and ability to metastasize. In fact, Torres-Mora et al. argue that the term "malignant melanotic schwannian tumor" is more appropriate given that 44% of patients in their series developed metastatic disease.[387]

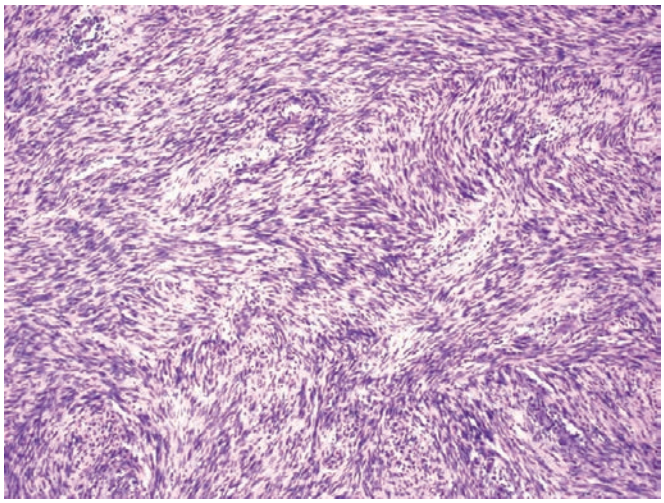

Figure 41.75 Cellular schwannoma with a compact proliferation of spindle cells arranged in short fascicles. Verocay bodies are not seen.

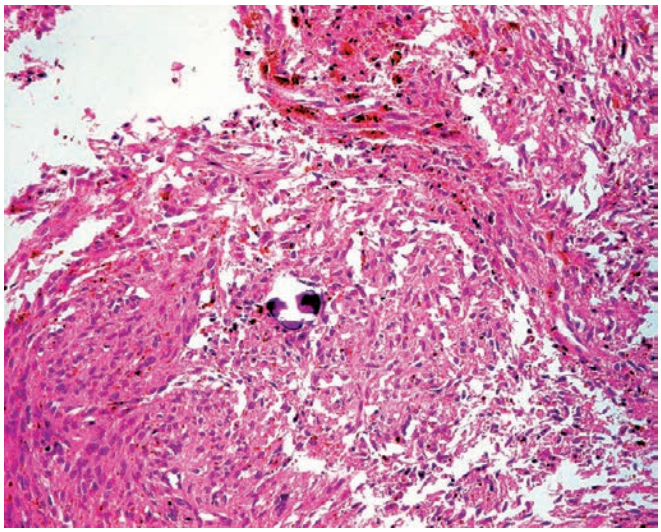

Figure 41.76 Psammomatous melanotic schwannoma in a patient with Carney syndrome.

Granular Cell Tumor

The classic location of granular cell tumor is the tongue, but it has been reported in innumerable other locations, such as skin, vulva, breast, larynx, bronchus, throughout the gastrointestinal tract, and soft tissue, among others.[388,389] Some patients have multiple lesions, particularly in the GI tract.[390] There are reports of congenital lesions, most of which arise in the gingiva, but such lesions are S-100-negative and probably represent a distinct entity (congenital epulis).[391,392]

These tumors are usually small, although we have seen cases measuring up to 5 cm in diameter. They have a hard consistency and ill-defined margins. This, together with the ulceration sometimes complicating the larger cutaneous tumors, explains why they are sometimes confused clinically and on gross inspection with a malignant neoplasm. The individual cells are large and their cytoplasm is filled with small, regular granules (Figs. 41.77 to 41.80). They alternate with larger round droplets having a homogeneous eosinophilic appearance and strong PAS positivity. The pattern of growth is ill-defined and pseudoinvasive; some can be found in the wall or lumen of blood vessels, not to be taken as a sign of malignancy.[393] If the tumor grows near an epithelial surface (e.g., skin, vulva, or larynx), pseudoepitheliomatous hyperplasia occurs that may be incorrectly diagnosed as squamous cell carcinoma.[394] Elastosis is often present in the stroma.[395]

Histochemically, the cytoplasmic granules contain large amounts of hydrolytic enzymes (such as acid phosphatase), and they are consistently positive for Luxol fast blue.[396] Ultrastructurally, they have the appearance of lysosomes. Other interesting electron microscopic findings are the presence of a second cell population with "angulated bodies" resulting in a Gaucher cell-like appearance[389,397] and of replicated basal lamina material around the granular cells, the latter suggesting repeated cycles of cellular injury and repair. Immunohistochemically, virtually all cases stain strongly for S-100 protein, as one would expect for a schwannian neoplasm; most also express Sox10.[398] Other stains often expressed include CD68, calretinin, and inhibin.[399,400]

The large majority of granular cell tumors pursue a benign clinical course. Most cases reported in the old literature as malignant granular cell myoblastomas are in reality examples of alveolar soft part sarcoma. However, there have been several well-documented cases of tumors with a light and electron microscopic appearance entirely consistent with that of granular cell tumor that have resulted in distant metastases.[401] Features favoring malignancy include necrosis, high mitotic activity, spindling of tumor cells, vesicular nuclei with large nucleoli, and high MIB-1 values.[401]

Although it is clear that most lesions diagnosed as true granular cell tumors show evidence of schwannian differentiation, a subset of tumors with granular cells likely are unrelated, particularly those

Figure 41.82 Typical gross appearance of a plexiform neurofibroma. This tumor is indicative of neurofibromatosis type 1.

that are S-100 protein negative[402–405]; many of these are cutaneous, polypoid lesions which stain for CD68 and NKI/C3.[403] The precise line of differentiation of these rare tumors remains obscure. Granular cell change may also be found in a number of other unrelated tumors including vascular and smooth muscle tumors.[406,407] We favor making the diagnosis of granular cell tumor only when the entire lesion is granular and S-100 protein positive and to designate the other cases according to their basic component, noting that focal granular changes are present.

Neurofibroma

The gross, microscopic, and ultrastructural features of neurofibroma, as well as its natural history, are distinct from those of schwannoma. The fact that in some instances the differential diagnosis may be difficult or that in isolated cases features of both lesions may coexist does not justify lumping them together.

The gross appearance of neurofibroma varies a great deal from lesion to lesion. As a rule, the tumors are not encapsulated and have a softer consistency than schwannoma (Fig. 41.81). The more superficial tumors appear as small, soft, pedunculated nodules protruding from the skin ("molluscum pendulum"). Deeper tumors grow larger. Tumors resulting in diffuse tortuous enlargement of peripheral nerves are designated as *plexiform neurofibromas* (Fig. 41.82) and are usually seen in the context of type 1 neurofibromatosis (von Recklinghausen disease, caused by a germline mutation in the *NF1* gene located on 17q11.2, which encodes neurofibromin).[408,409] The diffuse involvement of the nerves may make a complete resection impossible. This particular form of neurofibroma is more commonly seen in the orbit, neck, back, and inguinal region.

Microscopically, neurofibromas are formed by a combined proliferation of all the elements of a peripheral nerve: axons, Schwann cells, fibroblasts, and (in the plexiform type) perineurial cells. Schwann cells usually represent the predominant cellular element. Most have markedly elongated nuclei, with a wavy, serpentine configuration and pointed ends (Fig. 41.83). Ultrastructurally, they are seen to enclose axons in plasmalemmal invaginations (mesaxons).[410] They

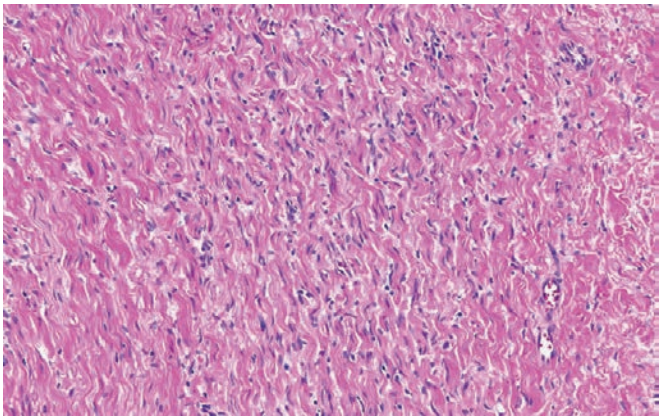

Figure 41.83 Neurofibroma with spindle cells deposited in a collagen matrix with a "shredded carrot" appearance.

are immunoreactive for S-100 protein and surrounded by basement membrane components.[411] A population of factor XIIIa-positive and CD34-positive cells is also present; the nature of these cells and their histogenetic relationship with normal nerve constituents is not clear.[412,413] EMA-positive perineurial cells are common in plexiform but not in ordinary neurofibromas.[414] The stroma contains a rich network of collagen fibers, among which almost all major types are represented (I, III, IV, V, and VI).[411] Mucinous changes in the stroma may be prominent and result in a mistaken diagnosis of myxoma or even myxoid liposarcoma.[415] As with schwannomas, neurofibromas may exhibit scattered large hyperchromatic nuclei; these *neurofibromas with atypia* may also have increased cellularity but mitotic activity is absent (Fig. 41.84).[416] The stroma of neurofibromas

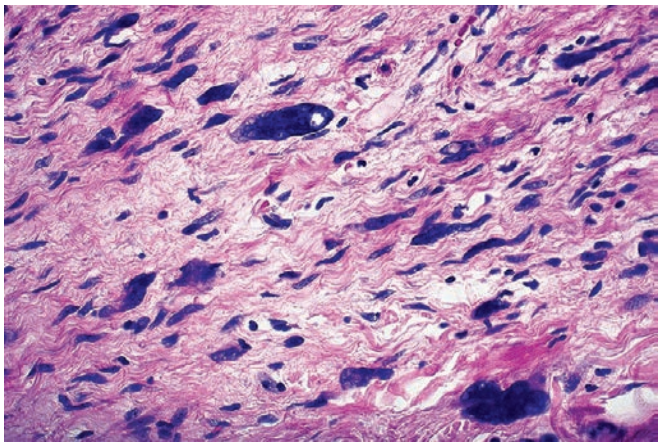

Figure 41.84 Neurofibroma with large bizarre hyperchromatic nuclei.

Figure 41.85 Marked deformation of distal upper extremity by diffuse neurofibromatosis. This patient developed a malignant peripheral nerve sheath tumor.

often contains numerous mast cells. Distorted organoid structures resembling Wagner–Meissner bodies or Pacinian corpuscles are sometimes seen.

In contrast to schwannomas, Verocay bodies, palisading of nuclei, and hyaline thickening of vessel walls are almost always absent in neurofibromas. Sometimes, otherwise typical neurofibromas contain melanin, a feature not unexpected in view of the embryologic relationship between Schwann cells and melanocytes.[415] These *pigmented neurofibromas* should be differentiated from blue nevi and malignant melanomas. Occasionally, an otherwise typical neurofibroma will show foci of skeletal muscle differentiation *(neuromuscular hamartoma; benign triton tumor)*.[417] Some neurofibromas (as well as other types of benign and malignant peripheral nerve tumors) may be partially composed of granular cells, similar in all respects to those of granular cell tumor.[418] Rare examples have prominent epithelioid features, similar to those seen in schwannoma and MPNST.[367]

Neurofibromas that occur in the setting of type 1 neurofibromatosis typically show a germline mutation of *NF1* in one allele and loss or mutation of *NF1* on the other allele, conforming to the "two-hit hypothesis" in tumorigenesis.[419] The genetic alterations are less clear in sporadic neurofibromas, but *NF1* alterations are present in at least some cases.[420]

Malignant transformation of neurofibroma should be suspected in the presence of mitotic activity in conjunction with increased cellularity, cytologic atypia, and the formation of fascicles.

Neurofibromatosis. Multiple neurofibromas represent the most important component of the genetically determined disorder known as type 1 neurofibromatosis or von Recklinghausen disease. This is one of the most common autosomal dominant diseases in humans, affecting one in about 3500 individuals.[421] The responsible gene *(NF1)* is located on chromosome 17q11.2 and encodes a ubiquitous protein known as neurofibromin, which is necessary for the correct negative regulation of RAS proteins.[422] In this setting, neurofibromas may occur in every conceivable site: axilla, thigh, buttock, deep soft tissue, orbit, mediastinum, retroperitoneum, tongue, gastrointestinal tract, and many others. Plexiform neurofibromas may result in massive enlargement of a limb or some other part of the body ("elephantiasis neuromatosa") (Fig. 41.85). In addition to neurofibromas, patients often have *café au lait spots*. This consists microscopically of an increase in the amount of melanin in the epidermal basal layer and is sometimes seen overlying a neurofibroma. It can be distinguished from the pigmented spots associated with McCune-Albright syndrome by virtue of its distribution and smooth, delicate margins.[423] Solitary café au lait spots are common in normal individuals, but when five or more are detected, type 1 neurofibromatosis should be suspected. Patients with this disease may also have GISTs, which are often present as multiple nodules in the small bowel,[424] and lack mutations in *KIT* and *PDGFRA*.[425,426]

Type 2 neurofibromatosis is genetically distinct from type 1, resulting from an alteration of the *NF2* gene located on chromosome 22q12 encoding merlin.[427] It is characterized by the presence of a variety of neoplasms in the CNS, the most distinctive of which are bilateral acoustic schwannomas. Meningiomas, astrocytomas, and tumors of other types also occur.[428]

A small proportion (between 5% and 20%) of patients with type 1 neurofibromatosis develop MPNST,[429] usually in large nerve trunks of the neck or extremities. For practical purposes, peripheral superficial neurofibromas never become malignant, and the only reasons for surgical removal are size and unsightliness.

Perineurioma

Benign tumors of the peripheral nerve composed predominantly or exclusively of perineurial cells are increasingly recognized. Microscopically, they are composed of extremely elongated cells arranged in parallel bundles, the appearance being not too dissimilar from that of neurofibroma or pacinian neurofibroma.[430] Some cases have a storiform pattern of growth and may correspond to the former *storiform perineurial fibromas*.[431] The diagnosis of perineurioma should be suspected in myxoid lesions of soft tissue in which a storiform or fascicular pattern of growth is evident (Fig. 41.86). There is an *intraneural* variant of perineurioma, associated with nonrandom chromosomal abnormalities and therefore presumably neoplastic.[432] It seems likely that at least some of the cases reported in the past as *localized hypertrophic neuropathy* belong in the same category.[433] Other recently recognized variants of this tumor include *sclerosing perineurioma*, which has a predilection for the fingers and palms of young adults[434]; *reticular (retiform) perineurioma*, with a predominant lace-like or reticular growth pattern composed of anastomosing cords of spindle cells; *plexiform perineurioma*; and the exceptionally rare *granular cell perineurioma*.[435] *Hybrid forms* of schwannoma and perineurioma have also been described,[436] as well as **malignant** forms of perineurioma, the latter representing a subtype of MPNST (see later).

Ultrastructurally, perineurioma is characterized by nonbranching, thin cytoplasmic processes coated by an external lamina and joined at their ends by a tight junction, few organelles, actin and vimentin filaments, and numerous pinocytotic vesicles (Fig. 41.87).[437]

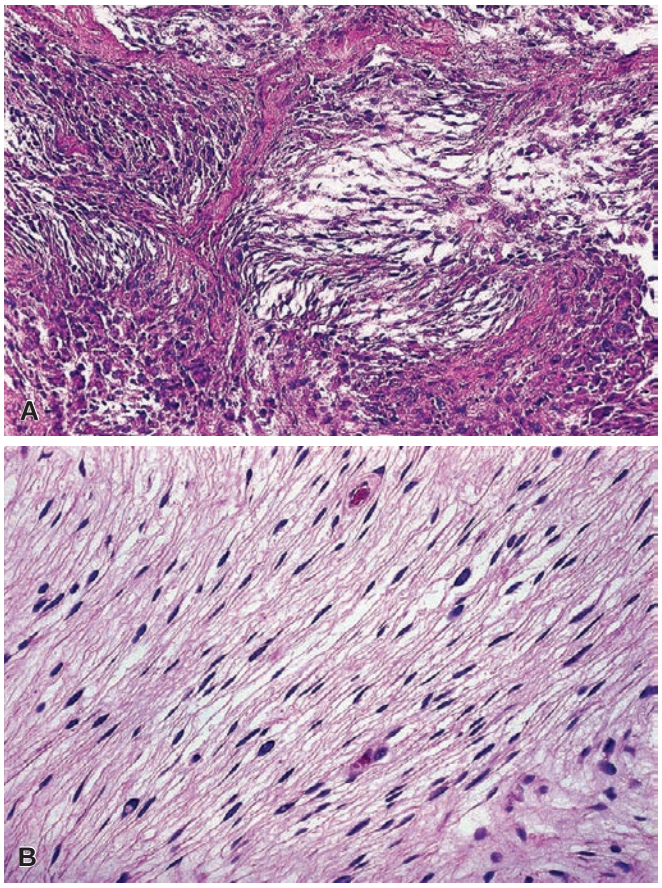

Figure 41.86 **A** and **B,** Two morphologic appearances of perineurioma. The tumor shown in **A** simulates a myxofibrosarcoma.

Immunohistochemically, the tumor cells are positive for EMA (Fig. 41.88), GLUT-1, CD34, and claudin-1, but they are negative for S-100 protein.[438] At the cytogenetic level, many cases show deletion of part or all of chromosome 22.[439] In addition, mutations of the *NF2* gene and loss of chromosome 13 have also been documented.[440]

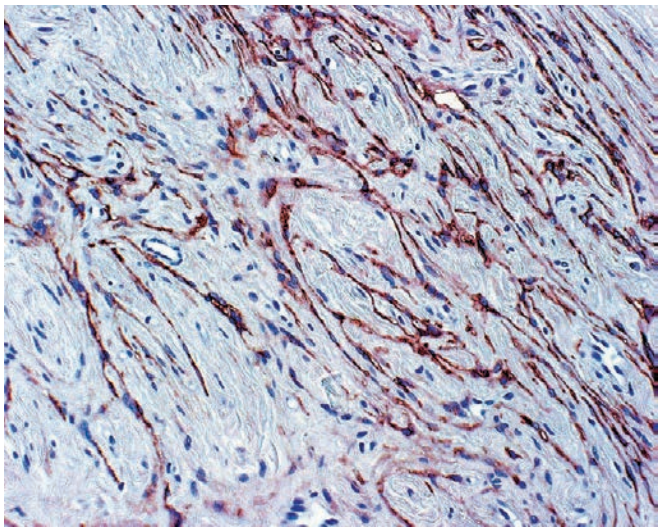

Figure 41.88 Epithelial membrane antigen immunoreactivity in perineurioma.

Dermal Nerve Sheath Myxoma

This is a benign, superficial myxoid neoplasm that most commonly arises on the distal extremities, particularly the fingers. Although originally categorized as a neurothekeoma, this lesion seems unrelated to cellular neurothekeoma, and there is compelling evidence to suggest true nerve sheath differentiation.[441,442] It has a gross and microscopic appearance reminiscent of myxoma, except for the prominent multinodularity with a fibrous border and the presence of plumper, epithelial-like cells and a distinct fascicular or plexiform arrangement (Fig. 41.89). Immunohistochemically, the cells stain for S-100 protein, unlike cellular neurothekeoma. Up to 50% locally recur.

Malignant Peripheral Nerve Sheath Tumor

MPNST is the currently preferred term for the neoplasm also known over the years as *malignant schwannoma*, *neurogenic sarcoma*, and *neurofibrosarcoma*. Approximately half of these tumors arise de novo, and the other half from neurofibromas as part of type 1 neurofibromatosis. Some arise in areas of previous irradiation typically after a latent period of at least 10 years,[443] and a few have originated from the Schwann cell-like (satellite cell) component of a ganglioneuroma.[444]

The large majority of MPNSTs arise in adults, but they have also been recorded in children.[445] The most common locations are the neck, forearm, lower leg, and buttock. They can also arise from cranial nerves or their branches. Grossly, the finding of a large mass producing fusiform enlargement of a major nerve, such as the sciatic nerve, is characteristic. Most MPNSTs are deep-seated, but they can occur in the subcutis or even in the skin.[446]

Because of its difficult microscopic recognition, errors are often made, more often than not by diagnosing MPNST as some other type of soft tissue sarcoma. There are two circumstances in which the diagnosis of MPNST should be the primary consideration in the presence of a malignant tumor of soft tissues composed of spindle cells: (1) when the tumor develops in a patient with type 1 neurofibromatosis; or (2) when the tumor is obviously arising within the anatomic compartment of a major nerve or in continuity with a neurofibroma. In the absence of these circumstances, the light microscopic diagnosis of MPNST is often only presumptive and dependent on a combination of features, none of which is

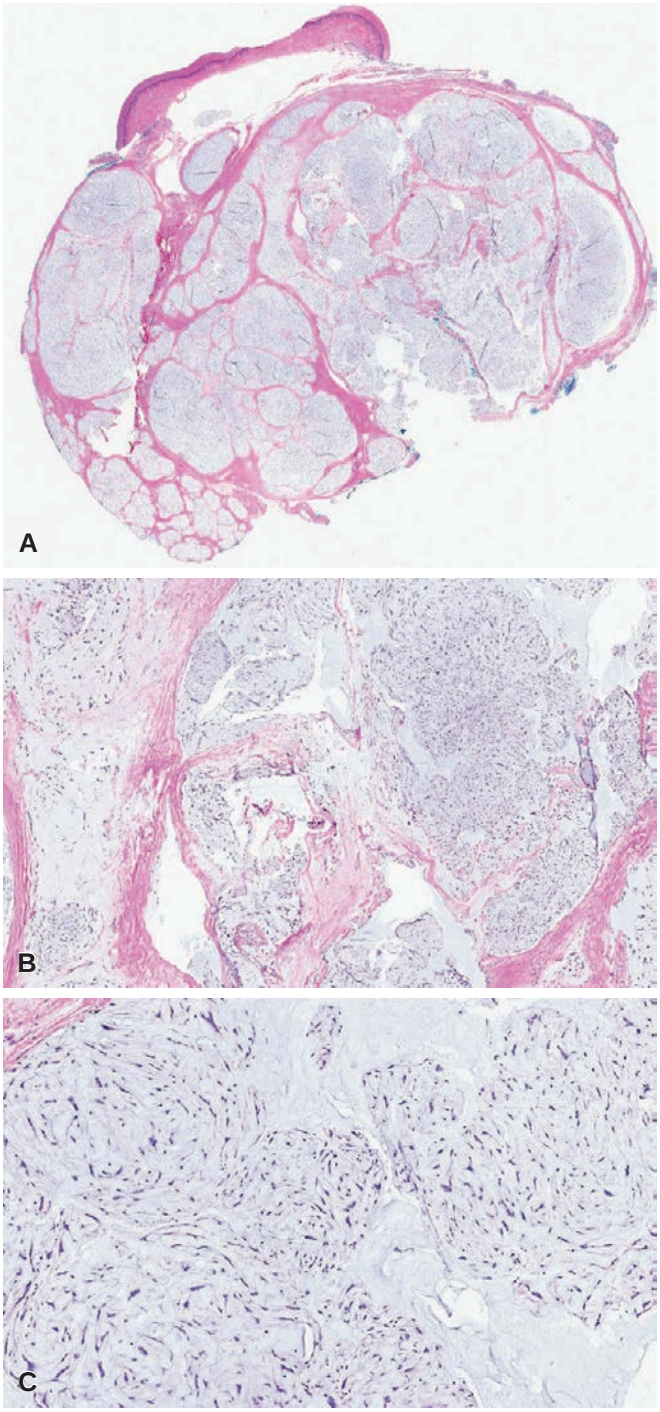

Figure 41.89 Dermal Nerve Sheath Myxoma. A, Low power. **B,** Medium power. **C,** High power. The lesion has a distinct lobulated appearance.

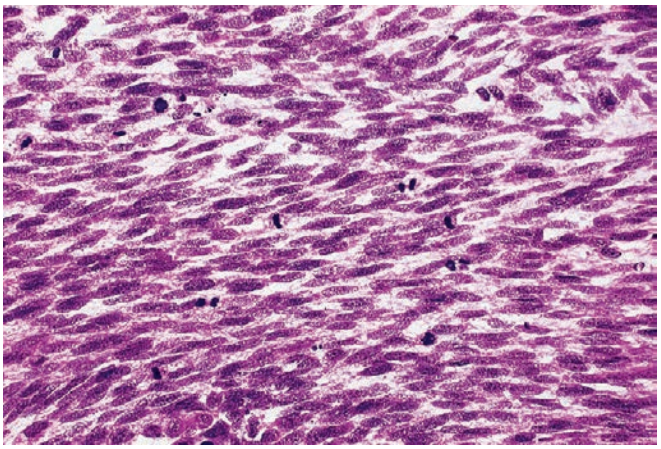

Figure 41.90 Malignant Peripheral Nerve Sheath Tumor. The marked hypercellularity and high mitotic activity in the absence of significant pleomorphism are commonly seen in this tumor type.

diagnostic by itself. They include: serpentine shape of the tumor cells; arrangement in palisades or whorls; marked contrast between the deeply hyperchromatic nuclei and the pale cytoplasm ("punched-out nuclei"); perivascular concentration of tumor cells, with a plumper shape; epithelioid appearance of the endothelial cells of these vessels; presence of large gaping vascular spaces resulting in a hemangiopericytoma-like appearance; and geographic areas of necrosis, with tumor palisading at the edges (Figs. 41.90 to 41.92). In most areas the appearance is that of an extremely cellular spindle cell neoplasm with easily identified mitotic figures. Although most tumors are quite monomorphic (a feature they share with monophasic synovial sarcoma), some can be extremely bizarre. At the light microscopic level, the latter can simulate the appearance of an UPS. Metaplastic tissues (heterologous elements) are present in approximately 15% of the cases, including chondrosarcomatous, osteosarcomatous, rhabdomyosarcomatous, or angiosarcomatous differentiation (Figs. 41.93 and 41.94).[447,448] The most well-known variant is characterized by the presence of rhabdomyosarcomatous

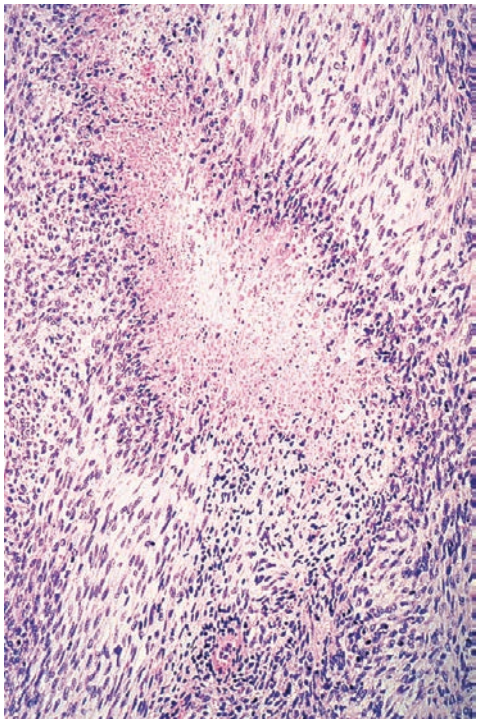

Figure 41.92 Malignant peripheral nerve sheath tumor with an area of necrosis.

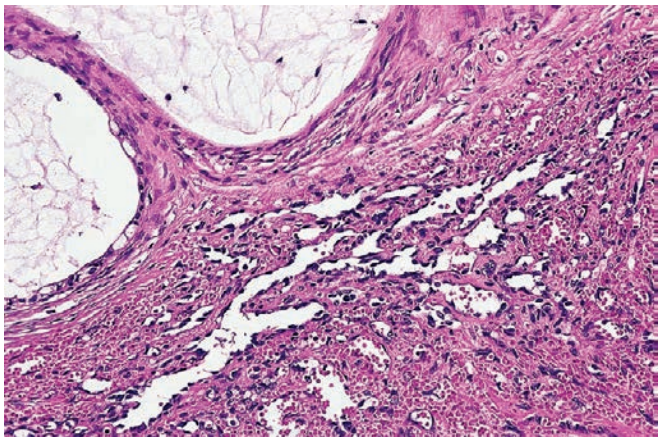

Figure 41.93 Malignant peripheral nerve sheath tumor with divergent angiosarcomatous differentiation as well as rare mucin-producing glands.

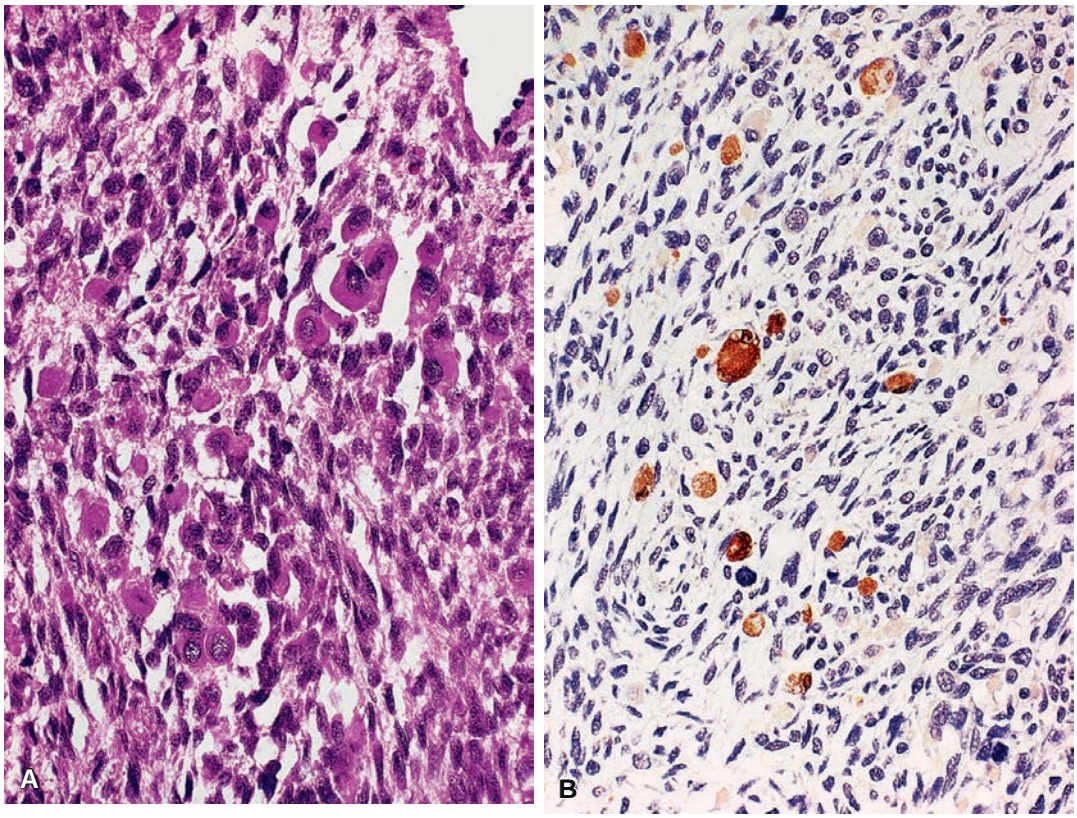

Figure 41.94 Malignant peripheral nerve sheath tumor with rhabdomyosarcomatous differentiation (so-called Triton tumor, **A**) with positive immunoreactivity for myoglobin **(B)**.

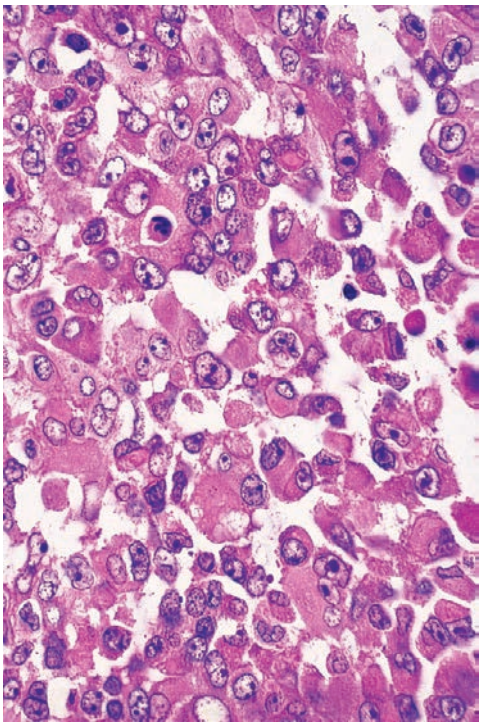

Figure 41.95 Epithelioid malignant peripheral nerve sheath tumor.

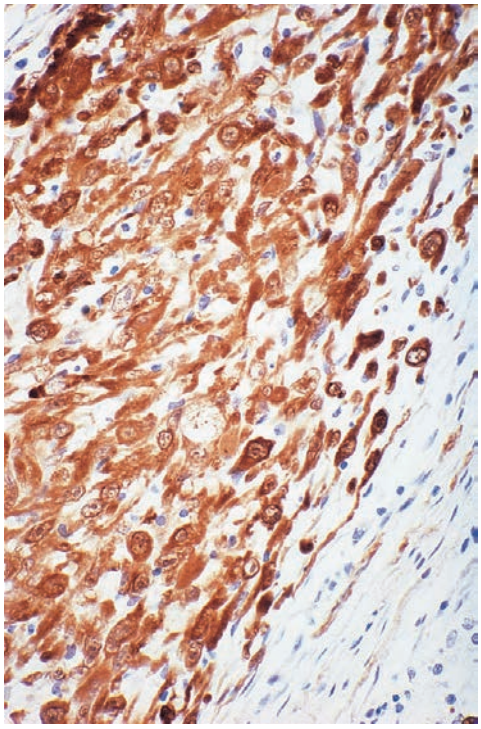

Figure 41.96 Strong S-100 protein immunoreactivity in epithelioid malignant peripheral nerve sheath tumor.

differentiation, often referred to as *malignant triton tumor*.[449] Areas of recognizable MPNST should be present to make such a diagnosis in these metaplastic tumors; otherwise a diagnosis corresponding to the morphologic appearance of the tumor is appropriate, even if the patient has type 1 neurofibromatosis. Although rare MPNSTs show foci of *glandular differentiation* (Fig. 41.93), this feature is found only in patients with type 1 neurofibromatosis.[450]

In some MPNSTs, part or most of the tumor is composed of plump cells with polygonal acidophilic cytoplasm and an epithelioid-like appearance; these are designated as *epithelioid MPNST* (Fig. 41.95).[451,452] These account for approximately 5% of all MPNSTs. Interestingly, most of the MPNSTs that have arisen from malignant transformation of benign schwannomas have been of the epithelioid type. Histologically, most cases show a vaguely nodular appearance with epithelioid cells arranged in sheets or cords. The cells have melanoma-like nuclei with prominent nucleoli. Some examples show rhabdoid morphology with paranuclear inclusions. Most stain strongly for S-100 protein, a pattern that contrasts with spindled MPNST (Figs. 41.96 and 41.97).[452] They lack melanoma-associated antigens (HMB-45 and Melan-A) and typically do not stain for cytokeratins. Almost 50% show loss of staining for SMARCB1 (also known as INI1) which is typically retained in melanoma.[453]

Conventional MPNST does not have a characteristic immunophenotype. Between 50% and 90% of these tumors stain for S-100 protein, typically in a patchy fashion.[454] Although often taken as evidence of nerve sheath differentiation, this marker lacks specificity given that other lesions in the differential diagnosis (e.g., synovial sarcoma) also stain for this antigen. More recently, Sox10, a neural crest transcription factor, has been found to be expressed in the majority of MPNSTs, including those which are S-100 protein negative.[398,455,456] CD34 and EMA may also be expressed in MPNSTs, likely reflecting focal perineurial differentiation. More recently, loss of histone H3K27 trimethylation by immunohistochemistry has been noted in approximately 50% of MPNSTs, with complete loss

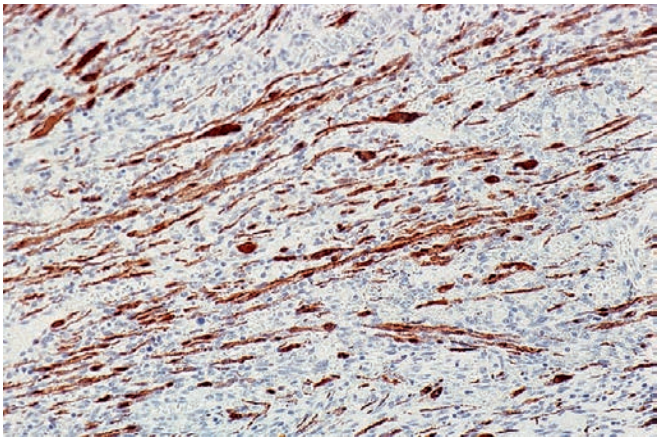

Figure 41.97 Patchy S-100 protein immunoreactivity in a spindle cell type of malignant peripheral nerve sheath tumor.

of staining in a higher percentage of cases as tumor grade increases.[456a] Although this marker is not particularly sensitive, it does seem to be highly specific for MPNST. Other markers reported in MPNST include nestin,[457] HMGA2,[458] and CD57.[459]

The clinical evolution is generally that of a highly malignant neoplasm, with frequent local recurrences and distant metastases.[460–462] Prognostic factors vary among studies; however, tumor size and metastatic disease at initial presentation are consistently identified as important variables. Most metastases occur in the lungs.

MPNSTs usually show a complex karyotype with numerical and structural abnormalities.[380,463] Whether occurring sporadically or in the setting of type 1 neurofibromatosis, both alleles of the *NF1* gene are often inactivated.[464] In addition, there are commonly mutations in the *TP53* gene, deletion of *CDKN2A* (9p21), and gain or amplification of 17q25, probably involving *BIRC5/SURVIVIN*.[465–468] More

Figure 41.98 Gross Appearance of Lipoma. Except for the circumscription, the appearance is indistinguishable from that of normal fat.

recently, loss of function mutations of the Polycomb repressive complex 2 (PRC2) components (*EED* or *SUZ12*) was identified in the vast majority of MPNSTs, including both NF1-associated and radiotherapy-associated MPNSTs.[468a]

Tumors of Adipose Tissue

Lipoma

Benign fatty tumors can arise in any location in which fat is normally present. The majority occur in the upper half of the body, particularly the trunk and neck, but they can develop in any other site, including hands and feet. Most lipomas are subcutaneous, an important point in the differential diagnosis with liposarcomas, which are almost always deep-seated. However, lipomas can also occur in the deep soft tissues; these are subclassified into *intramuscular* (most common in the trunk) and *intermuscular* (most common in the anterior abdominal wall).[469] Most patients are in the fifth or sixth decade of life. Only rarely are children affected. Lipomas may be single or multiple. Multiple lipomas are more common in women; many are seen in a familial setting, and some occur in patients with neurofibromatosis or multiple endocrine neoplasia. In **diffuse lipomatosis**, massive enlargement of a limb may be seen as a result of diffuse proliferation of mature adipose tissue. In the familial variant of this process, lipomatosis has a symmetric distribution.[470]

Lipomas can grow to a large size; they are usually encapsulated when located in the superficial soft tissues but tend to be poorly circumscribed when arising in deeper structures. Grossly, lipomas consist of bright yellow fat separated by fine fibrous trabeculae (Fig. 41.98). Microscopically, they are composed of mature adipose tissue with no cellular atypia. They are cytologically and immunohistochemically indistinguishable from normal fat, including positivity for S-100 protein and calretinin.[471]

Areas of fat necrosis, infarct, and calcification may be present. It is important not to confuse the histiocytes associated with fat necrosis with lipoblasts. The fact that they are often seen arranged in a circumferential fashion around a large lipid droplet (as is also the case in fat necrosis at other sites) is a helpful diagnostic sign. Rarely, lipomas harbor foci of mature metaplastic cartilage or bone.[472]

Ultrastructurally, only univacuolar mature adipocytes are present in typical lipomas.[473] Although the light microscopic and electron microscopic appearance of a lipoma does not differ significantly from that of normal adult fat, its lipid content as determined by biochemical extraction and the activity of lipoprotein lipase is different.[474]

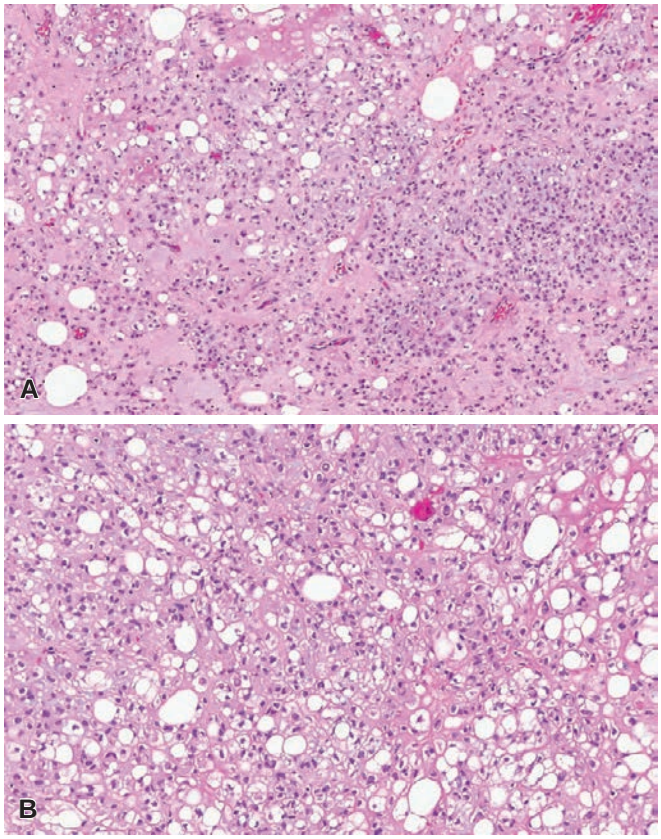

Figure 41.99 Chondroid Lipoma. A, Low-power and **B,** High-power views.

Morphologic variations that lipomas may exhibit include the following:

1. **Fibrolipoma**. This is characterized by the presence of prominent bundles of *mature* collagenous or myxocollagenous stroma intermixed with mature adipocytes, usually involving the distal extremities.[475,476]
2. **Myxolipoma.** This tumor shows extensive stromal myxoid change and should not be overdiagnosed as myxoid liposarcoma.[477]
3. **Chondroid lipoma.** This variant is usually deep-seated and is characterized by a component of eosinophilic and vacuolated cells containing glycogen and lipid that resembles brown fat cells, lipoblasts, and chondroblasts (Fig. 41.99).[478,479] This tumor can be mistaken for either chondrosarcoma or myxoid liposarcoma.
4. **Myolipoma.** This tumor is characterized by an admixture in variable proportions of mature adipose tissue and bundles of well-differentiated smooth muscle.[480]
5. **Spindle cell lipoma.** This is a benign fatty tumor characteristically located in the regions of the shoulder, upper back, and posterior neck of middle-aged adults but also found in many other locations, including the limbs, face, oral cavity, and trunk. It is composed of an admixture of mature lipocytes and uniform spindle cells set in a mucinous and fibrous background (Fig. 41.100).[481] Features that assist in distinguishing it from myxoid liposarcoma include the absence of lipoblasts and of a prominent plexiform vascular pattern, the presence of thick ("ropey") collagen bundles, and the great uniformity of the proliferating small spindle cells. In some instances the presence of irregular branching spaces with

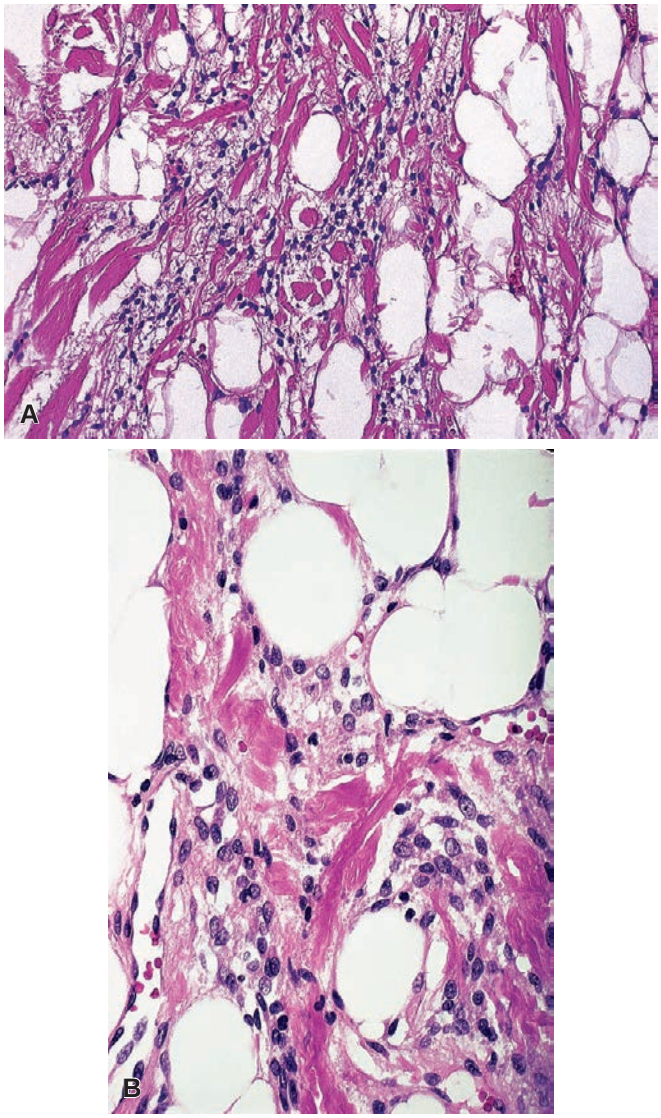

Figure 41.100 Spindle Cell Lipoma. Ropey collagen is a prominent feature.

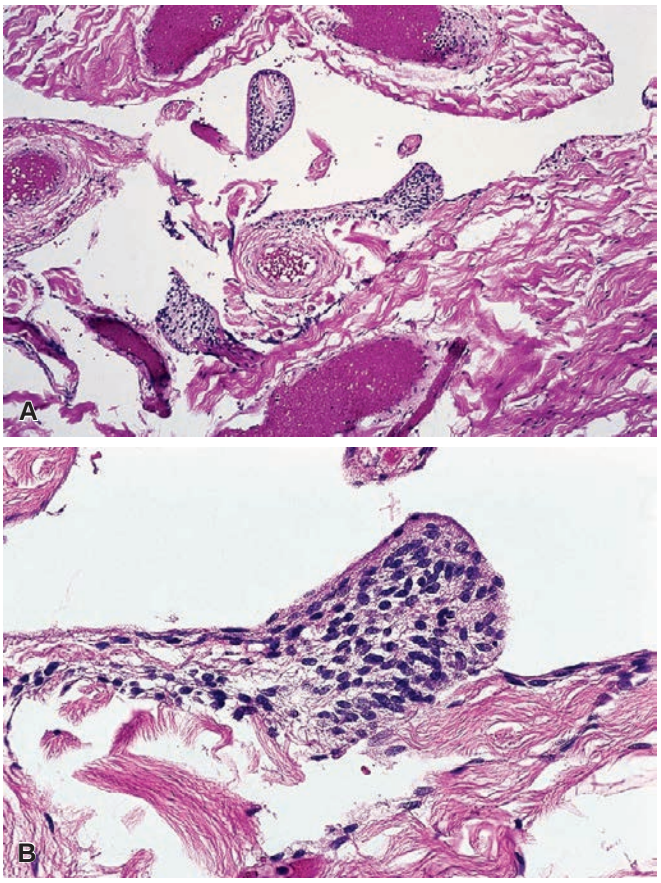

Figure 41.101 A and **B,** Spindle cell lipoma with a pseudoangiomatous appearance resulting from accumulation of tumor cells beneath artifactual tissue spaces.

villiform projections results in an angiomatoid appearance.[482] Although the spaces were originally thought to be nonvascular ("pseudoangiomatous"), they have been found to be lined by cells with the immunohistochemical features of endothelial cells (Fig. 41.101).[483] Cases of spindle cell lipoma in which mature fat is scanty or absent can be misdiagnosed as neurofibromas or even low-grade sarcomas (so-called fat-free spindle cell lipoma).[484] Immunohistochemically, these lesions uniformly express CD34, but this marker is commonly found in many other spindle lesions in the differential diagnosis.[485] This is also one of the lesions that typically shows loss of Rb-1 by immunohistochemistry given deletions in that tumor suppressor gene.[485a]

6. **Pleomorphic lipoma.** This is a lipoma containing hyperchromatic multinucleated ("floret-like") tumor cells. Given that this lesion is now felt to be histogenetically related to spindle cell lipoma, it is not surprising that it also most commonly is found in the posterior neck, upper back, and shoulder region of middle-aged men.[486] The tumor also has ropey collagen and prominent mast cells and often has areas identical to spindle cell lipoma (Fig. 41.102). It too stains strongly for CD34 (Fig. 41.103)[485] and similarly shows loss of Rb-1 staining.[485a] The most difficult differential diagnosis is with the sclerosing form of well-differentiated liposarcoma. The location of the lesion is an important clue, as is the presence of ropey collagen. Pleomorphic lipoma with little or no fat may be a diagnostic challenge.[487] Pleomorphic lipoma can be simulated microscopically by *subconjunctival herniated orbital fat*, a non-neoplastic process due to prolapse of the subconjunctival intraconal orbital fat.[488]
7. **Angiolipoma.** These well-circumscribed small tumors occur shortly after puberty. They are often painful and characteristically multiple. They are located in the subcutis, most commonly on the trunk or extremities. Vascularity often is limited to a band of tissue at the periphery of the neoplasm. Hyaline thrombi are common and constitute an important diagnostic sign (Fig. 41.104).[489] Angiolipomas in which the vascular component predominates *(cellular angiolipomas)* can be confused with Kaposi sarcoma or angiosarcoma.[490] The pain correlates well with the degree of vascularity.[491] The fact that angiolipomas lack chromosomal aberrations (like hemangiomas and unlike lipomas) suggests that they are hemangiomas with fat rather than true mixed tumors.[492] So-called *infiltrating angiolipomas* are unrelated to the lesion just described. They are probably not true mixed tumors but rather intramuscular large-vessel hemangiomas in which portions of the affected muscle tissue have been replaced by fat.[493]
8. **Myelolipoma.** This lesion combines mature adipose tissue and bone marrow elements and is most common in the adrenal gland,[494] although it also occurs in extra-adrenal sites (retroperitoneum, presacral region and mediastinum, among others).[495,496] Most occur

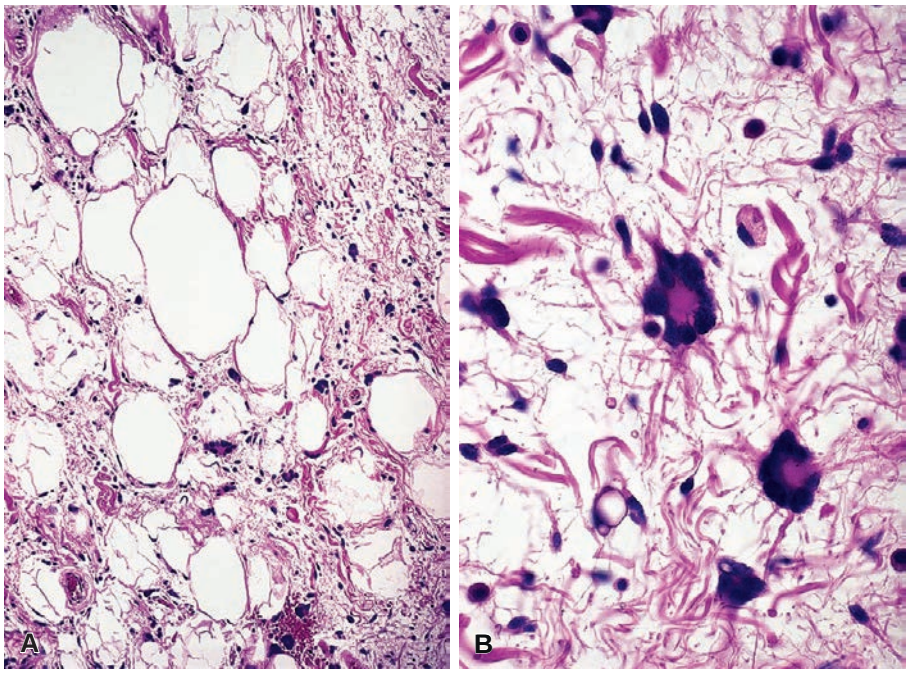

Figure 41.102 **A** and **B,** Pleomorphic lipoma with characteristic floret-type giant cells.

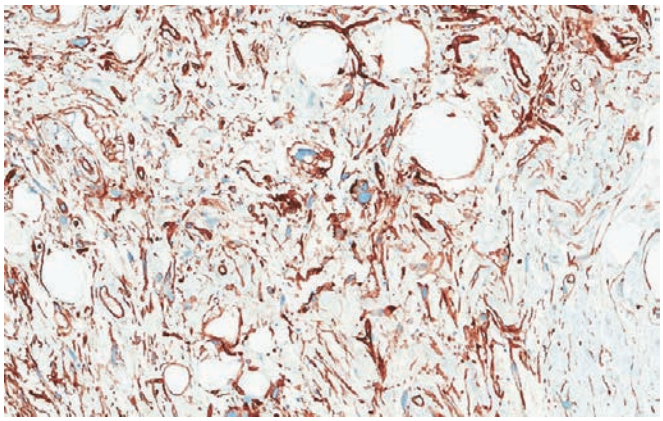

Figure 41.103 Strong CD34 staining in a pleomorphic lipoma.

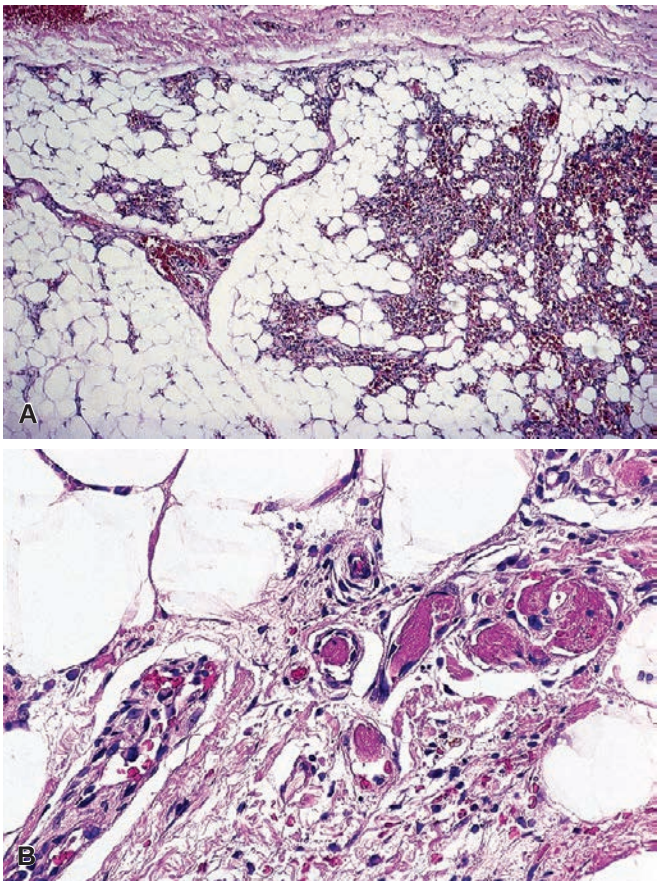

Figure 41.104 **Angiolipoma. A,** Intimate admixture of blood vessels and mature adipose tissue. **B,** Numerous fibrin thrombi can be seen.

in patients older than 40 years of age. Although many are small and found incidentally, others become enormous, and the latter cause symptoms that depend upon the site of origin.[497] Some are associated with hormonally active adrenal tumors, such as adrenal cortical adenomas,[498] adrenal cortical carcinomas,[499] and pheochromocytomas.[500] Given the identification of nonrandom, X-chromosome inactivation, a neoplastic origin has been proposed.[501]

9. **Intra/intermuscular lipoma.** These lesions are worrisome given their deep location, and they can grow to large sizes. Most arise in adults, more commonly in men, usually in the large muscles of the extremities, especially the thigh, upper arm, and shoulder.[502] Histologically, there is an intimate comingling of mature adipocytes and skeletal muscle fibers (Fig. 41.105). The latter may become atrophic and mimic the enlarged, hyperchromatic cells that are diagnostic of an ALT/well-differentiated liposarcoma. These lesions must be extensively sampled to exclude an ALT/well-differentiated liposarcoma. In addition, performing an analysis for *MDM2* amplification (preferably by FISH) can be exceedingly useful in excluding an ALT with the expectation that the

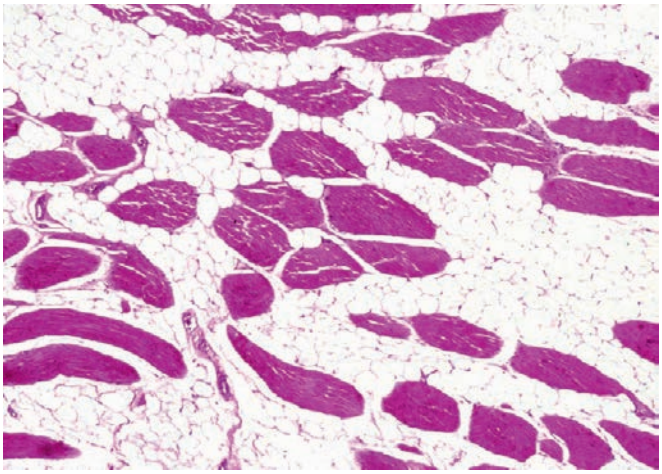

Figure 41.105 Intramuscular lipoma with interdigitation of mature adipose tissue and skeletal muscle.

intramuscular lipoma will be negative for *MDM2* amplification.[503] Due to the tumor depth, these lesions can be difficult to completely excise surgically, and, as such, they frequently recur,[502,504] but they have no capacity to undergo dedifferentiation or metastasis.

Cytogenetically, 80% of solitary lipomas exhibit chromosomal aberrations, such as rearrangements of 12q14–15, rearrangements of 6p21–22, or deletions of 13q12–14 and 13q22.[505–507] The gene involved in 12q14–15 is *HMGA2* (also known as *HMGIC*, which encodes a high mobility group protein), and the gene involved in 6p21–22 is *HMGA1*. In contrast with ALTs, marker ring or giant chromosomes are extremely rare.

Nearly all spindle cell and pleomorphic lipomas show deletions or unbalanced rearrangements of chromosome 13q and/or 16q, supporting the close link between these two tumor types and the fact that they are distinct from ALTs.[508–510]

Lipoblastoma/Lipoblastomatosis

Lipoblastoma/lipoblastomatosis affects almost exclusively infants and young children (below the age of 5 years),[511,512] but occasional cases in adolescents and young adults are on record.[513] It commonly involves the proximal portion of the lower and upper extremities. Grossly, the lesion is soft and lobulated. It is subdivided into lipoblastoma when well circumscribed and lipoblastomatosis when deep-seated and ill defined. Microscopically, it closely resembles fetal fat and may be confused with myxoid liposarcoma because of the presence of lipoblasts, a plexiform vascular pattern, and an abundant myxoid stroma (Fig. 41.106). It is distinguished from the latter by virtue of the young age of the patient, distinct lobulation, and absence of the characteristic translocation seen in myxoid liposarcoma involving the *DDIT3* gene. Cytogenetically, lipoblastoma/lipoblastomatosis is often associated with rearrangements of 8q11–13, with the implicated gene being *PLAG1* (pleomorphic adenoma gene).[514,515] A number of partner genes have been identified, such as *HAS2* on 8q24 and *COL1A2* on 7q22. Some cases show gain of chromosome 8, with or without simultaneous 8q11–13 rearrangement. The clinical course is benign, with a low risk of local recurrence. Lipoblastomas that are not removed in infancy mature into lipomas.

Hibernoma

Hibernoma is a rare benign neoplasm usually occurring in the interscapular region, axilla, and thigh, but it may arise in the mediastinum and retroperitoneum.[516] Its cut surface has a typical brown color, and its microscopic pattern is characteristic—an organoid arrangement of large cells with a centrally located nucleus and cytoplasm filled with many small vacuoles that stain for neutral fat (Fig. 41.107). Cytogenetically, it is often associated with rearrangements involving 11q13.[517,518]

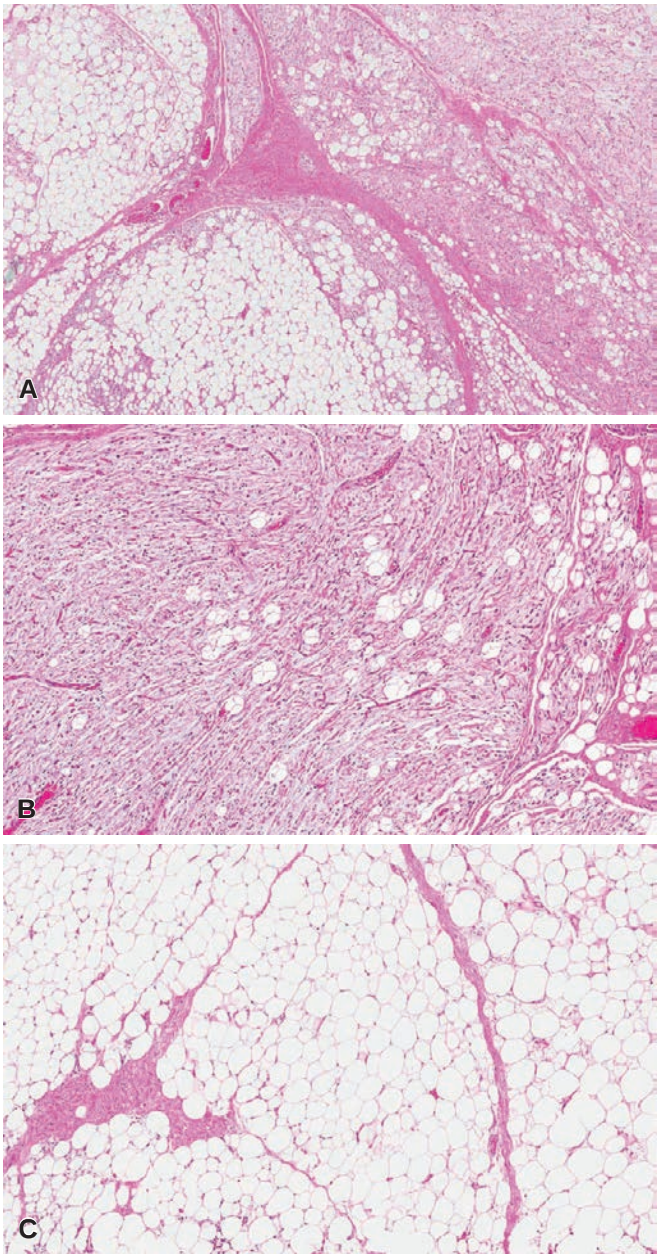

Figure 41.106 Lipoblastoma. A, Lobulated appearance and nodules of both mature adipose tissue and others with myxoid change. **B,** A myxoid nodule in a lipoblastoma showing some resemblance to myxoid liposarcoma. **C,** Area of mature adipose tissue in lipoblastoma.

This tumor has received its name because it resembles the brown fat of the hibernating glands of animals, a similarity that is maintained at the electron microscopic level.[519] Sometimes the features of hibernoma are seen mixed with those of ordinary lipoma or of spindle cell lipoma (hybrid tumors). Other hibernomas are accompanied by a myxoid matrix.[520] Malignant soft tissue tumors in which many of the tumor cells have features of brown fat occur and are regarded as a morphologic variant of liposarcoma.

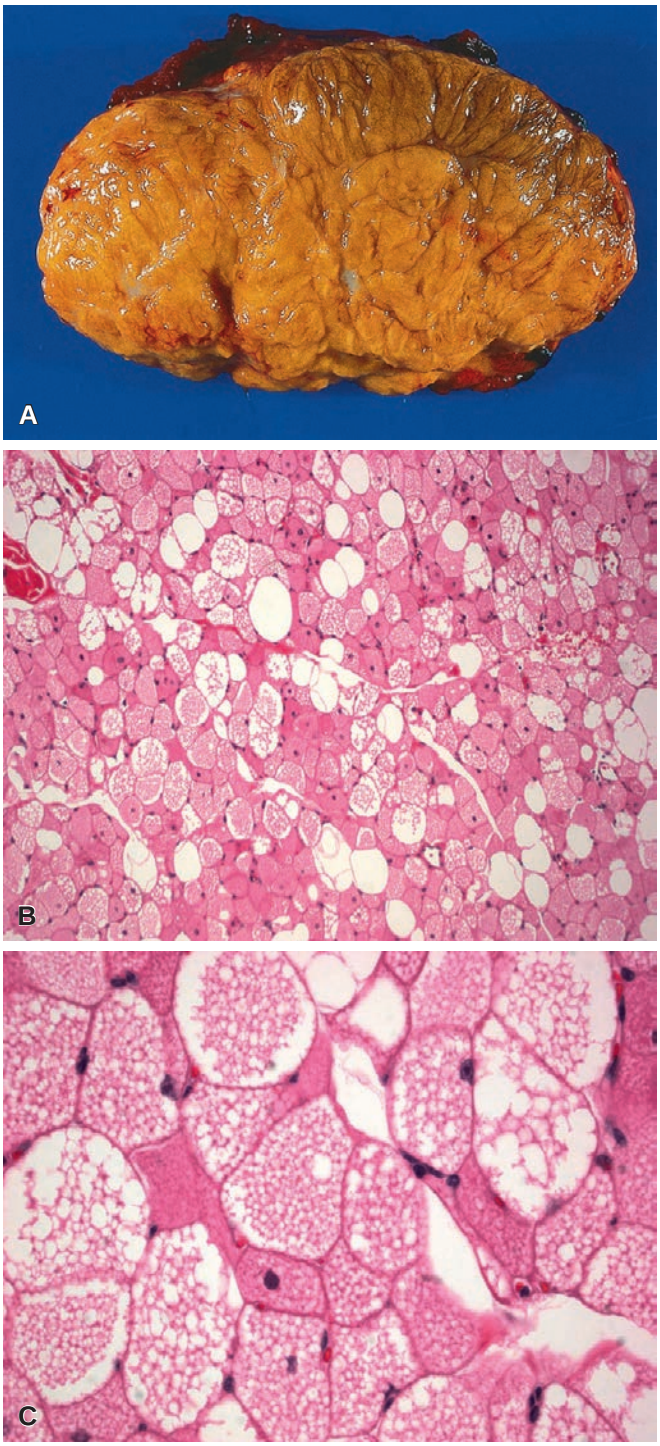

Figure 41.107 **A,** Gross appearance of benign adipose tissue that had features of both hibernoma and lipoma. Low-power **(B)** and high-power **(C)** views of a hibernoma.

Neural Fibrolipoma

Neural fibrolipoma (also sometimes referred to as *lipofibromatous hamartoma of nerves*) is a tumorlike lipomatous process that involves the volar aspect of the hands, wrists, and forearms of young persons.[521] Up to one-third are associated with macrodactyly.[521] Most are present at birth or within the first few years of life, and there is a female predominance when macrodactyly is present. Most commonly it affects the median nerve and its digital branches, but other nerves may be involved. Fibrofatty tissue is seen growing along the epineurium and perineurium and infiltrates the involved nerve, which itself is often atrophic (Fig. 41.108). Complete excision is not possible given the intimate involvement with the nerve.

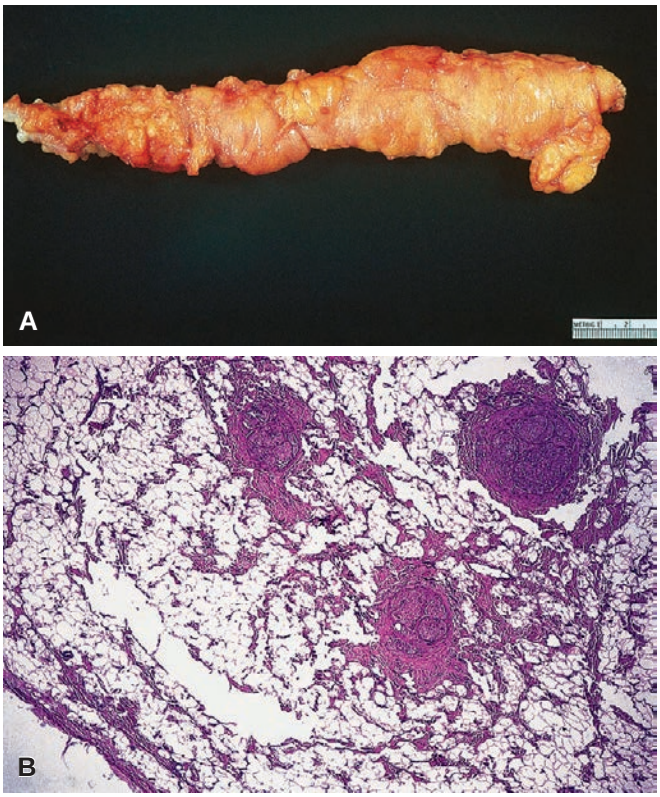

Figure 41.108 **A,** Gross and **B,** Microscopic appearance of fibrolipomatous hamartoma of nerve.

Liposarcoma

Liposarcoma is the most frequent soft tissue sarcoma in adults; this tumor is quite rare in adolescents and children, but unequivocal cases have been reported.[522,523] However, most cases so diagnosed in this age group (particularly in the past) were in reality examples of lipoblastomatosis or GCF.[524]

Liposarcomas are usually large and occur most frequently in the lower extremities (popliteal fossa and medial thigh), retroperitoneal, perirenal, mesenteric region, and shoulder area. Their relative frequency at these various sites is greatly dependent on the tumor subtype (see later). Although liposarcomas of the posterior neck, upper back, and shoulder certainly occur, it should be remembered that this is the classic site for benign adipose tissue tumors that can simulate liposarcoma, including spindle cell lipoma/pleomorphic lipoma, lipoblastoma/lipoblastomatosis, and hibernoma. Grossly, liposarcomas are well circumscribed but not encapsulated. Depending on the subtype, they may have a mucoid cut surface suggestive of myxoma, a bright yellow appearance mimicking lipoma, or a surface resembling cerebral convolutions.

Although not necessarily conspicuous or even required for the diagnosis of some subtypes (see later), the common morphologic denominator of liposarcoma is the *lipoblast*. This appears as a mononuclear or multinucleated cell with one or more cytoplasmic vacuoles that contain lipid. The nucleus is often pushed aside by a single large vacuole, resulting in a signet ring configuration, or it

Figure 41.109 Atypical Lipomatous Tumor. The neoplasm is well circumscribed and not much different from an ordinary lipoma.

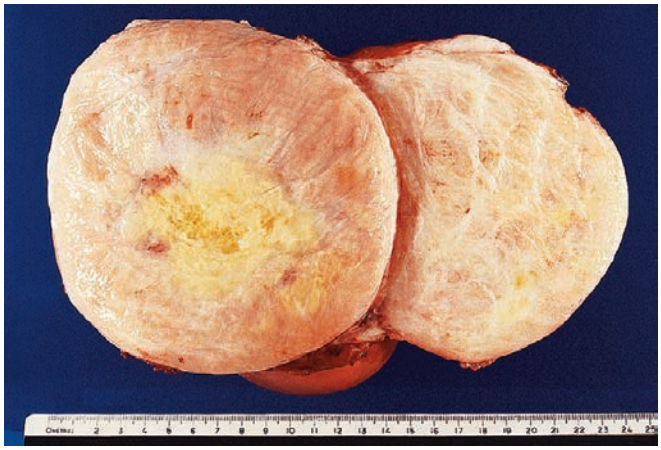

Figure 41.110 Gross appearance of a retroperitoneal atypical lipomatous tumor (well-differentiated liposarcoma) that microscopically combined features of the sclerosing and lipoma-like subtypes.

may remain centrally located but exhibit small sharp indentations by multiple small lipid vacuoles.

In their classic article on liposarcoma, Enzinger and Winslow divided liposarcomas into four types: myxoid, round cell, well differentiated, and pleomorphic, acknowledging the existence of mixed forms.[525] Several modifications have been incorporated into this classification in subsequent years, but the basic scheme remains essentially intact.

Atypical lipomatous tumor (ALT) is a synonym for **well-differentiated liposarcoma (WDL)** and is the most common subtype of liposarcoma. Grossly, it often resembles a usual lipoma (Figs. 41.109 and 41.110). Histologically, it also often resembles a lipoma on low-power examination, but closer inspection shows scattered tumor cells with large hyperchromatic nuclei. These atypical cells may be found preferentially in fibrous bands that traverse the adipose tissue lobules *(sclerosing subtype)* or be scattered among the mature adipocytes or within the walls of thick-walled blood vessels *(lipoma-like subtype)* (Figs. 41.111 to 41.114). Some of the atypical cells have features of lipoblasts by virtue of the cytoplasmic vacuoles producing nuclear indentations, but most do not. Some of the nuclei have sharply outlined vacuoles ("Lockhern"), which at the ultrastructural level are seen to correspond to invaginations of the nuclear membrane, that is, pseudoinclusions. It should be pointed out that occasional

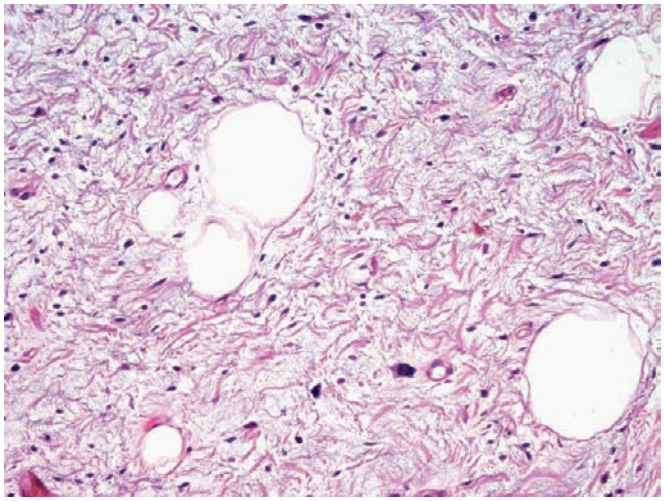

Figure 41.115 Myxoid area of atypical lipomatous tumor with rare atypical cells.

adipocytes with hyperchromatic and slightly enlarged nuclei containing pseudoinclusions can be seen in the non-neoplastic fat of somatic soft tissues and other sites, such as breast. True lipoblasts are often identified in ALT but are not required for the diagnosis.

It is not unusual for ALTs to exhibit secondary myxoid changes (Fig. 41.115); when prominent, these tumors may be confused with myxoid liposarcoma, a phenomenon which is most common in retroperitoneal tumors. However, these tumors have been shown to lack the characteristic cytogenetic aberration of myxoid liposarcoma (see later).[526] True mixed myxoid/well-differentiated liposarcomas, if they exist at all, are vanishingly rare.[527]

Occasionally, smooth muscle bundles are seen in these neoplasms, and these tumors have been referred to as *lipoleiomyosarcomas*, which should not be overinterpreted as dedifferentiated liposarcomas.[528] In other instances, a heavy inflammatory infiltrate of either neutrophilic or lymphoplasmacytic nature is present, with some of the inflammatory cells being located within the cytoplasm of the giant tumor cells. Tumors with this appearance have been called *inflammatory liposarcoma* and *lymphocyte-rich liposarcoma* (Fig. 41.116).[529,530] This inflammatory pattern can be seen in association with or independently from dedifferentiation.

The entity known as *spindle cell liposarcoma* is highly controversial. This lesion was originally described as a spindle cell variant of ALT, characterized by a population of relatively bland spindle cells arranged in fascicles and whorls and set in a variably myxoid stroma.[531] A reappraisal of cases initially diagnosed as spindle cell liposarcoma revealed some to be variants of ALT, others to be spindle cell lipomas, but most were found to cytogenetically distinct from either of these tumors.[532] In this study by Deyrup et al., patient age ranged from 15 to 82 years (mean, 50 years), and the tumors arose in the deep or superficial soft tissues of the groin, buttock, and thigh, among other sites. Clinical follow-up revealed no recurrences or metastases. The authors proposed the term "fibrosarcoma-like lipomatous neoplasm" to emphasize that it is a unique lipomatous tumor distinct from ALT, myxoid, and dedifferentiated liposarcoma.

More recently, Mariño-Enriquez et al. reported 232 cases of "atypical spindle cell lipomatous tumor."[532a] These lesions arose in patients ranging in age from 6 to 87 years (mean, 54 years) with a wide anatomic distribution including the limbs and limb girdles (63% of cases) and hands (17%) and feet (11%), with an equal distribution between subcutaneous and deeper locations. Histologically, the tumors were made up of mildly atypical spindle cells deposited in a variably myxoid or fibrous stroma with a prominent admixed lipomatous component with scattered atypical nuclei and univacuolated or multivacuolated lipoblasts. Immunohistochemically, the tumor cells stained for CD34 (64%), S-100 protein (40%), and desmin (23%). Interestingly, loss of Rb-1 expression was found in 57% of cases. Importantly, however, FISH for *MDM2* amplification was consistently negative, emphasizing the distinctness of this tumor from ALT/WDL. The vast majority of patients (87%) were alive with no evidence of recurrence or metastatic disease, but local recurrence was reported in 12% of patients; none of the patients developed metastasis or died of disease.

Cytogenetically, close to 80% of ALTs (including the dedifferentiated examples) show supernumerary ring or giant marker chromosomes, in stark contrast to lipomas of either ordinary or spindle/pleomorphic type.[506,533,534] At the molecular level, these chromosomal changes result in amplification of the 12q13–15 region, which includes *MDM2*, *SAS*, *HMGA2*, and *CDK4* genes. Demonstration of *MDM2* or *CDK4* amplification in tissue sections with the FISH technique is both highly sensitive and specific for distinguishing ALT from all variants of lipoma (Fig. 41.117).[535] Overexpression of these proteins by immunohistochemistry is also useful but is not as sensitive or specific as FISH.[536] Recently, it has been shown that

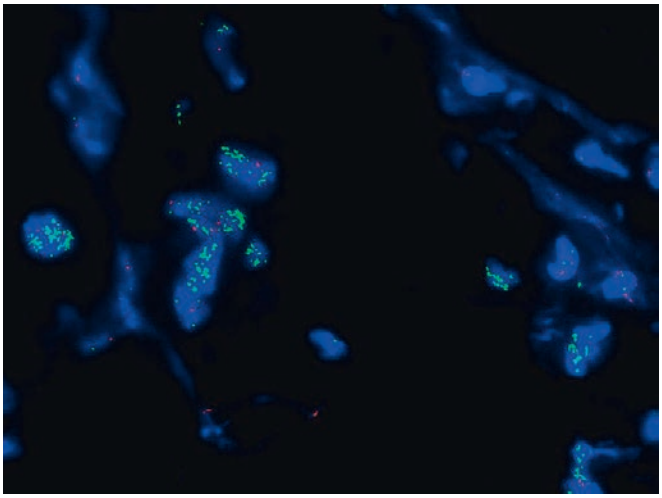

Figure 41.117 Fluorescence in situ hybridization showing amplification of *MDM2* (green signal) in atypical lipomatous tumor.

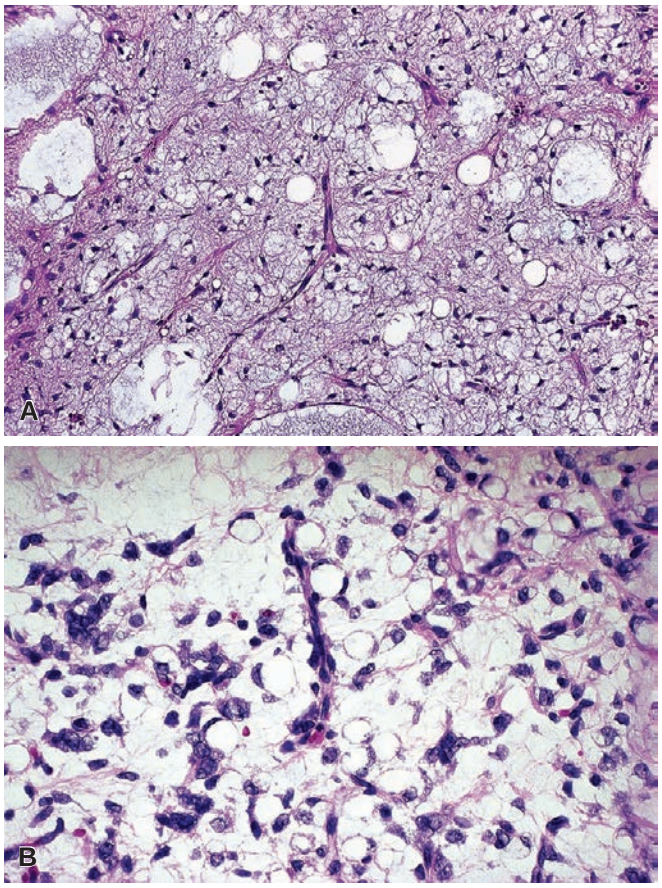

Figure 41.118 **A** and **B,** Myxoid liposarcoma.

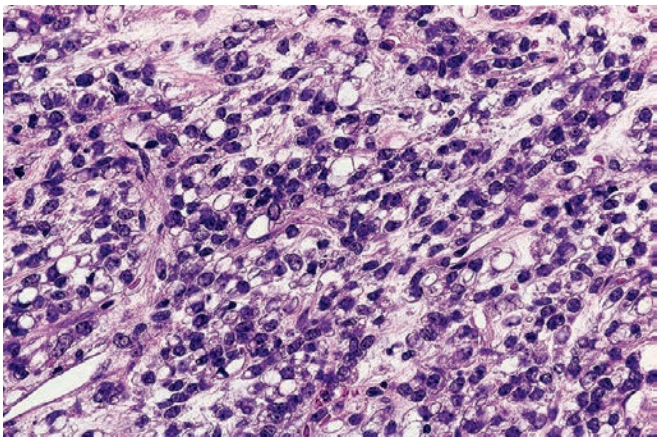

Figure 41.119 **Round Cell Liposarcoma.** This tumor is a poorly differentiated form of myxoid liposarcoma.

p16 (an important cell cycle regulator) is expressed in the majority of ALTs but apparently not in lipomas.[537,538]

Myxoid liposarcoma, which is the second most common type of liposarcoma, shows a marked predilection for the lower extremities, particularly the thigh and popliteal fossa. It practically never occurs in the retroperitoneum, and most cases so diagnosed are examples of ALT with prominent myxoid change.[539] Microscopically, myxoid liposarcoma has few or no mitotic figures and is characterized by proliferating lipoblasts in different stages of differentiation, a prominent anastomosing ("chicken wire") capillary network, and a mucoid matrix rich in hyaluronidase-sensitive acid mucopolysaccharides. The presence of a delicate network of thin-walled vessels is an important feature in the differential diagnosis with myxoma and other myxoid tumors (Fig. 41.118). The mucoid extracellular material may accumulate in large pools (so-called "pulmonary edema" pattern), thus simulating a tumor of lymph vessel origin. Metaplastic cartilage is found in rare instances.[540] The spindle cells show only mild atypia; a myxoid neoplasm with more striking atypia is likely a myxofibrosarcoma.

Cytogenetically, myxoid liposarcoma is characterized most commonly by the reciprocal translocation t(12;16)(q13;p11), which results in the *FUS-DDIT3* (formerly known as *TLS-CHOP*) fusion, and less commonly, t(12;22)(q13;q12) with *EWSR1-DDIT3* fusion.[526,541] *DDIT3* is a gene involved in adipocyte differentiation. The chimeric protein encoded by *FUS-DDIT3* can be detected immunohistochemically.[542]

Round cell liposarcoma is the high-grade variant of myxoid liposarcoma and is characterized by a cellular proliferation of round cells with high-grade nuclei (Fig. 41.119). The myxoid stroma and plexiform vasculature become inconspicuous. As little as 5% of the tumor being composed of such areas constitutes round cell liposarcoma and has a significant negative impact on prognosis.[543,544] As expected, this variant harbors the same translocations found in myxoid liposarcoma and on occasion, especially in cases in which lipoblasts are inconspicuous or the myxoid areas are not found, molecular analysis can be diagnostically helpful.[545]

Pleomorphic liposarcoma is a highly cellular, poorly differentiated neoplasm containing numerous tumor giant cells, some of them having the features of pleomorphic lipoblasts.[546–548] Mitoses and foci of necrosis are frequent. An *epithelioid variant* of pleomorphic liposarcoma has been described that simulates adrenal, hepatic, or renal cell carcinoma at the morphologic level (Fig. 41.120), including focal immunoreactivity for cytokeratins.[549,550] The differential diagnosis includes UPS and pleomorphic rhabdomyosarcoma; the recognition of pleomorphic lipoblasts is the only diagnostic criterion.

Dedifferentiated liposarcoma is the term used for the emergence of a generally nonlipogenic component within an ALT. The dedifferentiated component may already be present at the time of the original excision, but it may also emerge in recurrent or metastatic foci. It is much more common in retroperitoneal neoplasms, but it has also been documented in tumors of the extremities (Fig. 41.121).[551,552] Microscopically, the dedifferentiated component is

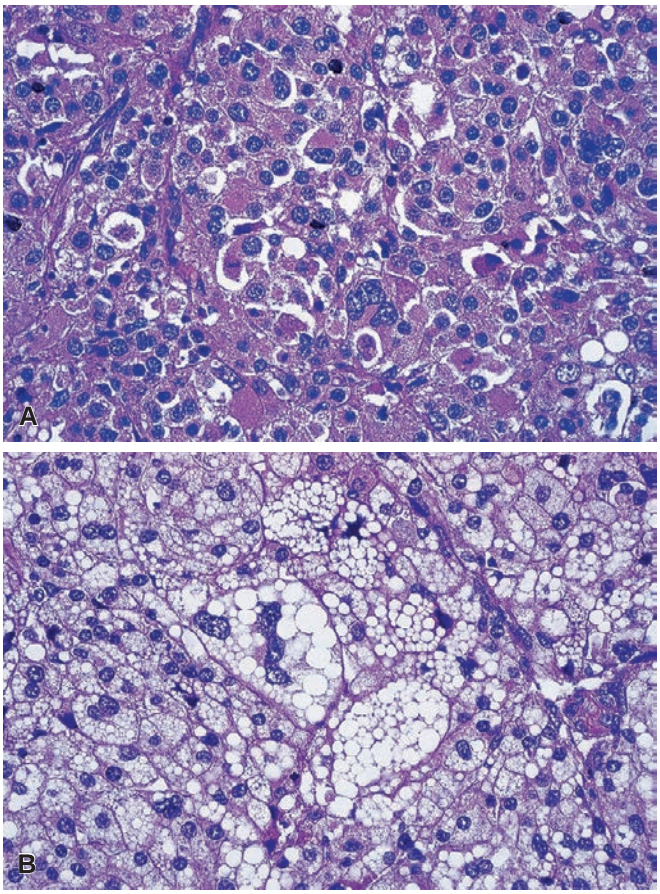

Figure 41.120 Epithelioid variant of pleomorphic liposarcoma **(A)**. The liposarcomatous nature of the tumor is better shown in **B**.

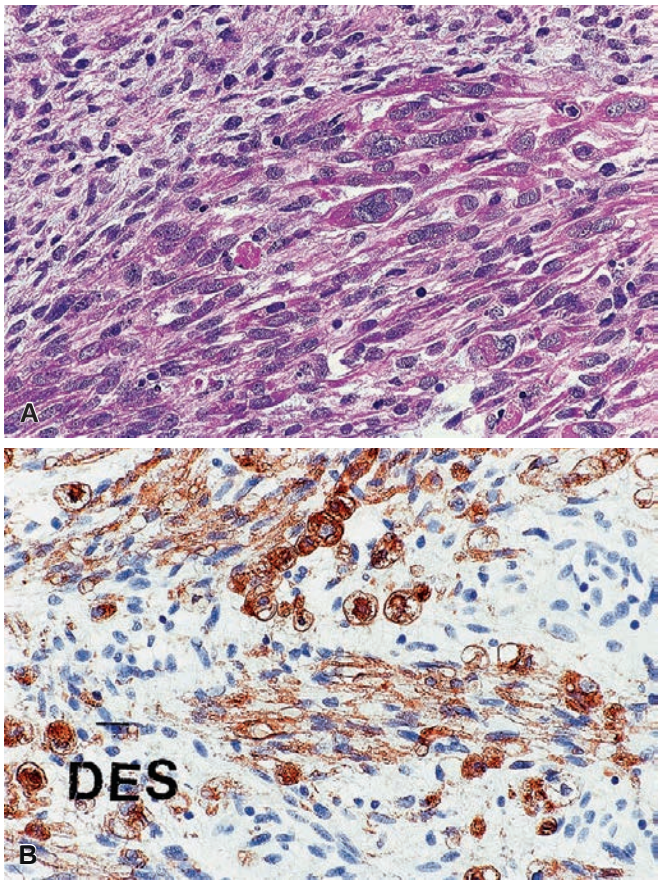

Figure 41.122 Dedifferentiated retroperitoneal liposarcoma. **A,** Divergent rhabdomyosarcomatous differentiation with **(B)** desmin immunoreactivity.

Figure 41.121 Dedifferentiated liposarcoma of retroperitoneum abutting the kidney, a common occurrence.

usually (but not always) high grade, with an appearance reminiscent of fibrosarcoma or UPS, with or without myxoid features.[553–555] Heterologous elements showing rhabdomyosarcomatous (Fig. 41.122), chondrosarcomatous, or angiosarcomatous differentiation may be present[556–558]; these foci, which are viewed as evidence of divergent differentiation, are accompanied by their respective immunohistochemical markers. Recently, the existence of a "homologous" form of dedifferentiation (with the appearance of a pleomorphic liposarcoma) has been proposed.[559,560] Occasionally, the dedifferentiated component appears in the form of a discontinuous micronodular pattern throughout the tumor.[552] In other cases, it exhibits a whorling pattern with a neural-like or meningothelial-like appearance associated with metaplastic bone formation.[561,562] A high percentage of dedifferentiated liposarcomas stain for PPAR-gamma, whereas this is true for only one-fourth of other sarcoma types.[563] Dedifferentiated liposarcoma shows the same genetic changes as the preexisting ALT but often shows additional genetic changes, such as amplifications (e.g., gain of 1q21–24, 6q22–24, 20q13, or 12q24), deletions (e.g., loss of 13q14–21 or 11q22–23), and *TP53* mutation.[564,565]

It should be noted that the dedifferentiated component does not have to be high grade, as some show resemblance to fibromatosis (Fig. 41.123), well-differentiated fibrosarcoma,[551] or osteosarcoma (so-called low-grade dedifferentiation).[566] Along these lines, Evans has proposed the existence of a *cellular atypical lipomatous tumor*, defined as an ALT with increased cellularity but fewer than five mitoses per 10 high-power fields in the nonlipogenic component.[553] Regardless of terminology, these cellular tumors are not to be equated with conventional high-grade dedifferentiated tumors in view of their significantly different behavior.[553]

Differential diagnosis. The benign lesions most commonly confused with ALT are lipoblastoma/lipoblastomatosis, spindle cell/pleomorphic lipoma, myxoid, inflamed or necrotic lipoma, lipogranuloma (such as that resulting from injection of liquid silicone), *localized lipoatrophy* (such as that seen at sites of insulin or steroid injections), *subconjunctival herniated orbital fat* (prolapse of subconjunctival intraconal orbital fat), and *massive localized lymphedema* (a

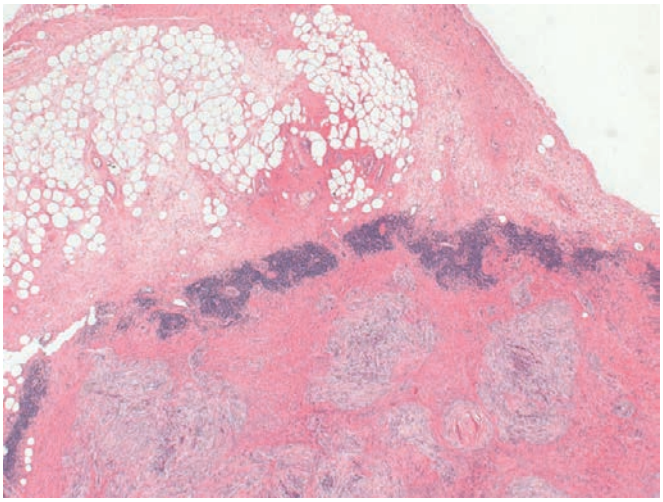

Figure 41.123 Area of so-called low-grade dedifferentiation which is devoid of adipocytic differentiation. This area shows extensive myxoid change and is more cellular than the usual atypical lipomatous tumor.

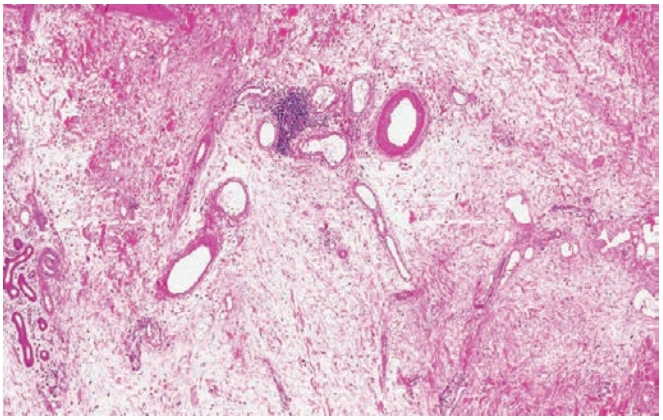

Figure 41.124 Massive lymphedema in a morbidly obese patient resembling an atypical lipomatous tumor.

non-neoplastic disease most often occurring in the lower extremities of morbidly obese patients) (Fig. 41.124).[567] We have also been impressed by the similarity to myxoid liposarcoma that lipomas present in individuals who have subjected themselves to a drastic diet program can have. As a general rule, the diagnosis of liposarcoma should be questioned for any tumor seen in the pediatric age group or any tumor that is small, superficial, embedded within a major muscle, or located in the neck region. Although bona fide liposarcomas have been documented in all of these situations, the features of malignancy need to be assessed in a particularly critical fashion because of the high frequency with which benign lesions simulate liposarcoma in these settings.

Treatment and prognosis. The primary treatment of all types of liposarcoma is surgical, inasmuch as radiation therapy and chemotherapy are generally of only dubious value.

Tumor location, size, and histologic subtype are the most important prognostic indicators. Both the pure myxoid liposarcomas and the ALT (particularly the latter) tend to recur locally. Although pure myxoid liposarcoma can metastasize, ALT does not unless it undergoes dedifferentiation. By contrast, round cell and pleomorphic liposarcoma often give rise to metastases, most often to the lungs.

Tumors and Tumorlike Conditions of Blood and Lymph Vessels

Hemangioma

Hemangiomas are frequently designated and regarded as tumors because of their usually localized nature and mass effect. However, the fact that they consistently lack chromosomal alterations speaks against a true neoplastic process. The presence or absence of nerve bundles intimately admixed with the vascular proliferation has been used to place them into a malformative or a neoplastic category, respectively.[568,569] Although clearly benign, they can become very large and unsightly and can even be fatal if they affect vital structures. They almost never become malignant, although a few well-documented examples of this complication are on record. Many arise in children, and a significant number are present at birth.[570] Over half arise in the head and neck area, but they can also occur in the trunk or extremities. Most hemangiomas are solitary; when multiple (with or without associated lesions in internal organs) or affecting a large segment of the body, the condition is known as *angiomatosis*.[571]

Hemangiomas have been classified according to their clinical appearance and the caliber of vessel involved. A close correlation exists between these two parameters.

Capillary hemangiomas are made up of small vessels of capillary caliber and can occur in any organ but is most common in the skin, where it appears as an elevated nodule with an intense crimson color. Such a hemangioma is traditionally known to dermatologists as a *strawberry hemangioma* because of its clinical appearance. It is usually present at birth or appears during the first month of life and enlarges rapidly during the first few months, only to stop growing when the child is approximately 6 months old. Subsequently, it becomes flaccid, pale blue, and covered with tiny wrinkles, and it eventually disappears completely.[572]

Microscopically, the lesion exhibits a lobular configuration on low-power examination (Fig. 41.125). Masses of closely packed spindle cells are seen with neoformed spaces that contain little blood. Mitotic figures are usually present and can be numerous. At the periphery, the tumor may be seen to invade subcutaneous tissue or skeletal muscle. Perineurial involvement has also been observed.[573]

By immunohistochemistry, most of the cells have the features of endothelial cells, including positivity for FVIII-RA, CD31, CD34, ERG, FLI-1, estrogen receptor-beta, annexin II (ANX2, a cell surface receptor for angiostatin), and LMO2 (a transcription factor involved in vascular and hematopoietic development).[166,574,575] The issue as to whether they also express lymph vessel–type markers, such as LYVE-1, remains controversial.[576,577] Hemangiomas also have a component of pericytes/smooth muscle cells and fibroblasts.[578]

Infantile hemangioma (also known as *cellular hemangioma of infancy*) is a form of capillary hemangioma.[579] Most cases are sporadic, but some appear to be familial and have been linked to mutations at 5q31-33.[580] Rare cases are associated with a number of other abnormalities, including *p*osterior fossa brain malformations, *h*emangiomas, *a*rterial cerebrovascular abnormalities, *c*ardiovascular abnormalities, and *e*ye anomalies (also known as PHACE syndrome).[581]

Most lesions appear shortly after birth and rapidly enlarge over several months, typically reaching their maximum size between the ages of 6 and 12 months. Many regress over the ensuing years, often resulting in a small pigmented scar.

Microscopically, these lesions have a multinodular pattern fed by a single arteriole.[582] The nodules are composed of plump endothelial cells and pericytes. The cellularity may be so striking such

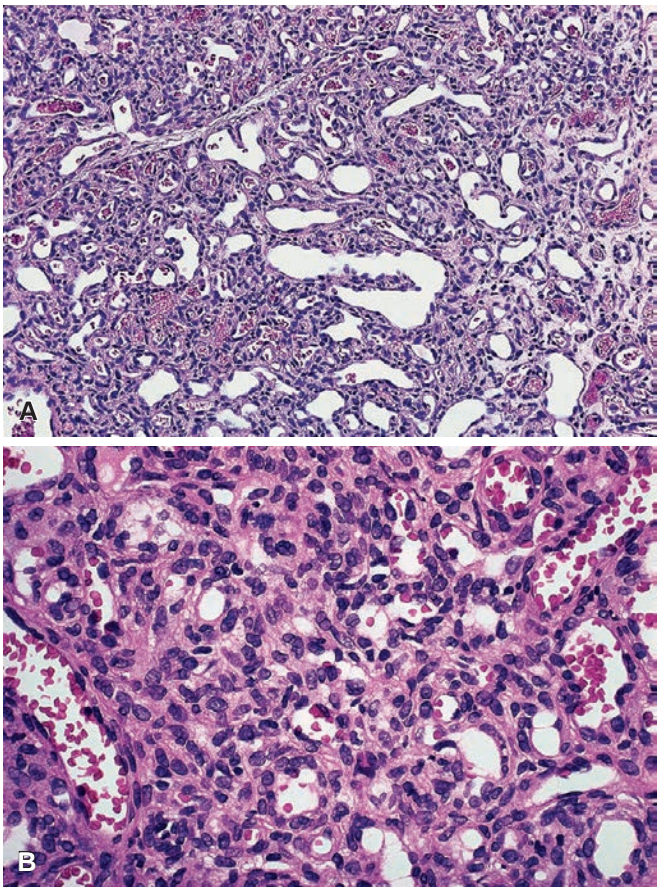

Figure 41.125 Infantile hemangioma. **A,** Vaguely lobulated architecture. **B,** The high cellularity and mitotic activity should not lead to an overdiagnosis of malignancy.

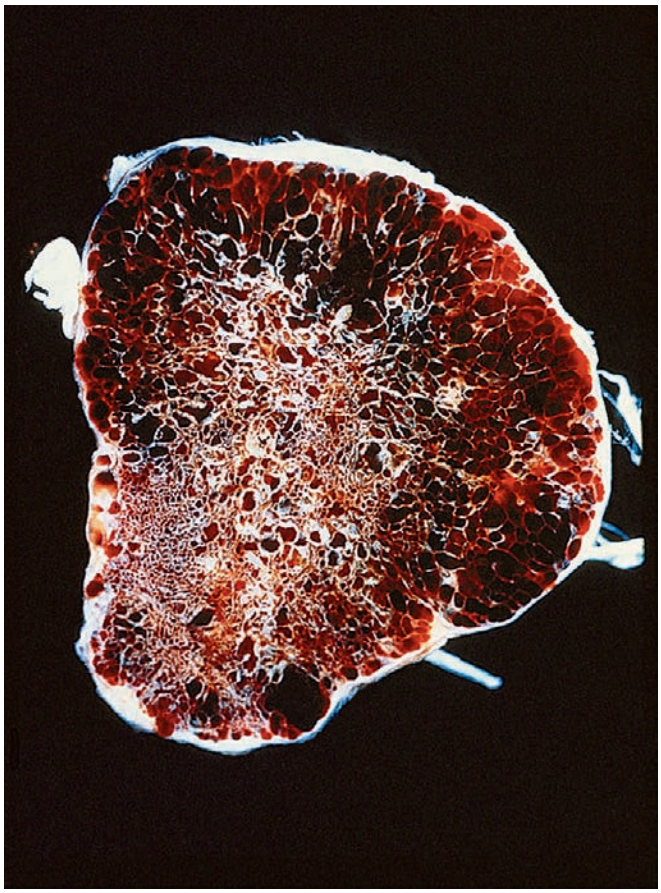

Figure 41.126 Cavernous hemangioma of soft tissues of the orbit.

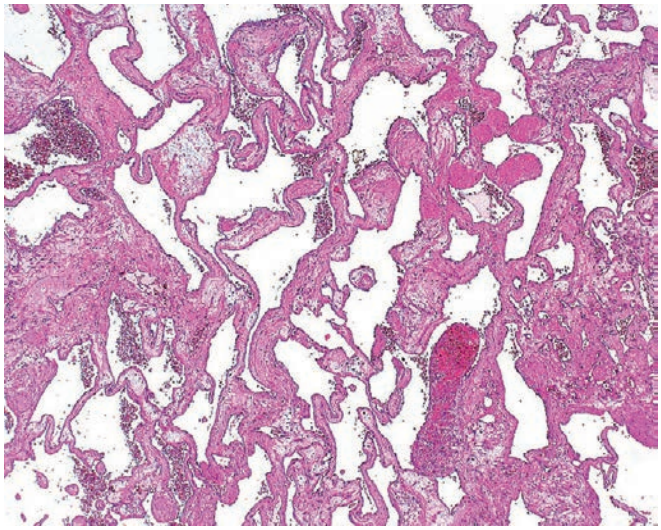

Figure 41.127 Cavernous hemangioma with widely dilated vascular spaces.

that the underlying vascular nature of the lesion may not be obvious. Mitotic figures are prominent, but the lobular growth pattern is consistent with a benign lesion. Immunohistochemically, these lesions characteristically express GLUT-1, a glucose transport receptor and a marker which is not found in other types of hemangioma.[583]

As previously mentioned, most of these tumors regress spontaneously, but some require surgery, corticosteroids, or laser therapy.[583]

Cavernous hemangiomas are composed of larger vessels with cystically dilated lumina and thin walls (Figs. 41.126 and 41.127). Those occurring in the skin are traditionally known as *port-wine nevus* or *nevus flammeus*. This lesion, which is present at birth, grows very slowly and in proportion to the growth of the patient; in time, it becomes nodular and soft. In contrast to the strawberry nevus, it does not regress spontaneously.[572] Large, deep cavernous hemangiomas may undergo thrombosis, ulceration, and infection. The thrombi may be seen in various stages of organization and recanalization, the latter including papillary endothelial hyperplasia (Masson lesion). They can also be associated with thrombocytopenia and with intravascular coagulation, which are corrected by removal of the tumor.[584] Cavernous hemangiomas containing dilated, interconnecting thin-walled channels with occasional pseudopapillary projections have been designated as *sinusoidal hemangiomas*.[585]

Large-vessel hemangiomas may be composed of vessels with the structure of veins *(venous hemangiomas)* or a combination of veins and arteries (*racemose*, *cirsoid*, or *arteriovenous hemangiomas*).[586] The structure of the vessel wall is often abnormal and not easily identifiable as arterial or venous. They occur in the back, gluteal region, thigh, and other sites; sometimes an entire extremity is involved. The association of varicose veins, cutaneous hemangiomas, and soft tissue and bone hypertrophy is known as *Klippel–Trénaunay syndrome*.[587] Thrombosis and calcification are common in large-vessel hemangiomas; the latter can be large enough to be detectable radiographically.

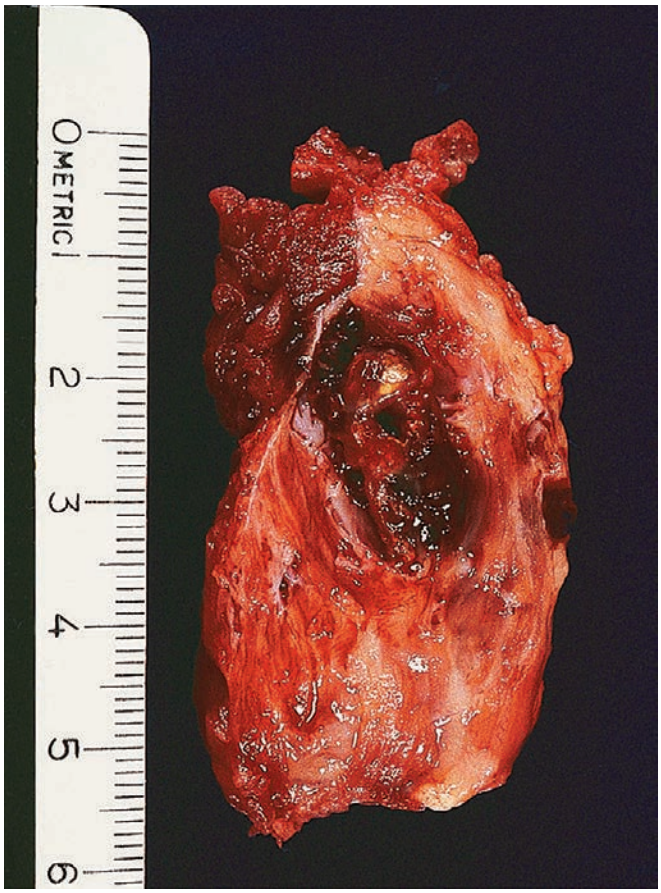

Figure 41.128 Gross appearance of an intramuscular hemangioma.

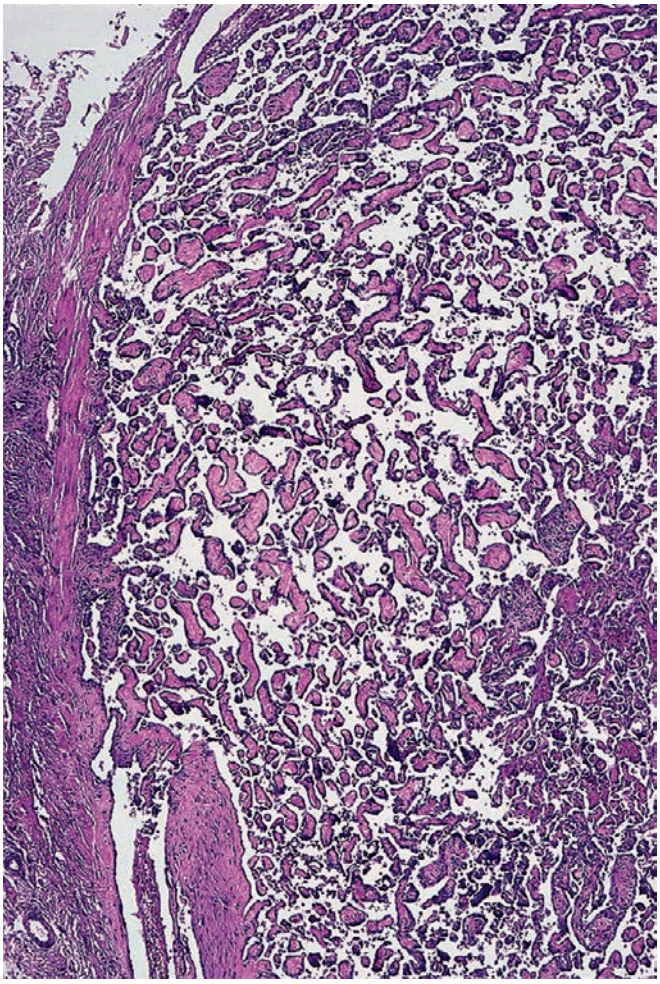

Figure 41.129 Intravascular Papillary Endothelial Hyperplasia. The confinement of the lesion to the vascular lumen with hyaline cores within the papillae is a characteristic feature.

Intramuscular hemangiomas usually have a venous or cavernous microscopic appearance (Fig. 41.128).[588] In other cases, they are very cellular, with plump nuclei, mitotic figures, intraluminal papillary projections, and even infiltration of perineurial spaces. It should be remembered that bona fide angiosarcomas of skeletal muscle are quite uncommon.

Intravascular papillary endothelial hyperplasia (Masson hemangioma or Masson lesion) is probably not a true neoplasm but is discussed here because of its capacity to simulate microscopically benign and malignant vascular tumors.[589] First described by Masson in hemorrhoidal vessels as "vegetant intravascular hemangioendothelioma," it is currently thought to represent an exuberant organization and recanalization of a thrombus, an interpretation supported by immunohistochemical studies.[590] It can occur in previously normal vessels or in varices, hemorrhoids, hematomas, hemangiomas, and angiosarcomas.[591] The de novo ("pure") form is usually found in the extremities (particularly the fingers) and the head and neck region. It simulates angiosarcoma because of the presence of papillary formations, anastomosing vascular channels, and plump endothelial cells (Fig. 41.129). It is identified because of the exclusively intravascular nature of the process; the lack of necrosis, bizarre cells, and atypical mitoses; the characteristically fibrinous and/or hyaline (deeply eosinophilic) appearance of the papillary stalks; and the frequent finding of residual organizing thrombi.

Spindle cell hemangioma, a vascular tumor originally described as spindle cell hemangioendothelioma,[592] may present at any age, has a male predominance, occurs preferentially in the dermis and subcutaneous tissue of the distal extremities, and combines histologically the features of cavernous hemangioma and Kaposi sarcoma.[593] The latter areas often have a component of epithelioid endothelial cells (Figs. 41.130 and 41.131). The immunohistochemical features are those of endothelial cells.[593] Development of recurrences or new lesions is common, but metastases have been documented in only one case following repeated recurrences and radiation therapy.[592] Some cases have occurred in patients with Maffucci or Klippel–Trénaunay syndrome.[594]

Epithelioid hemangioma (also known as *angiolymphoid hyperplasia with eosinophilia*) is an epithelioid vascular tumor which appears to be distinct from Kimura disease, although these two lesions have been frequently linked in the literature.[595,596] It typically occurs in young adults, more often in women, and is most often found in the head and neck region, particularly around the ear. Almost 50% of patients develop multiple lesions, usually in the same anatomic area. Some patients have associated lymphadenopathy and peripheral blood eosinophilia.

The lesion is typically circumscribed and centered either in the dermis or subcutaneous tissue, but rare examples involve the deep soft tissue or even parenchymal organs.[597] A lobular configuration is apparent at low magnification, often with a centrally located larger blood vessel. The characteristic cell is the epithelioid endothelial cell which lines the apparent vascular structures, often with abundant eosinophilic cytoplasm. Some show intracytoplasmic vacuoles indicative of vascular lumen formation. There is often a prominent

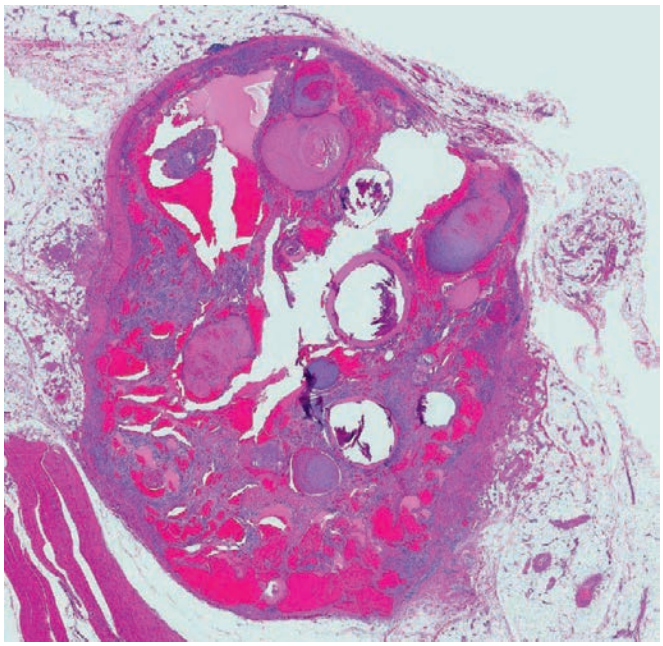

Figure 41.130 Low-power view of spindle cell hemangioma with rare phleboliths.

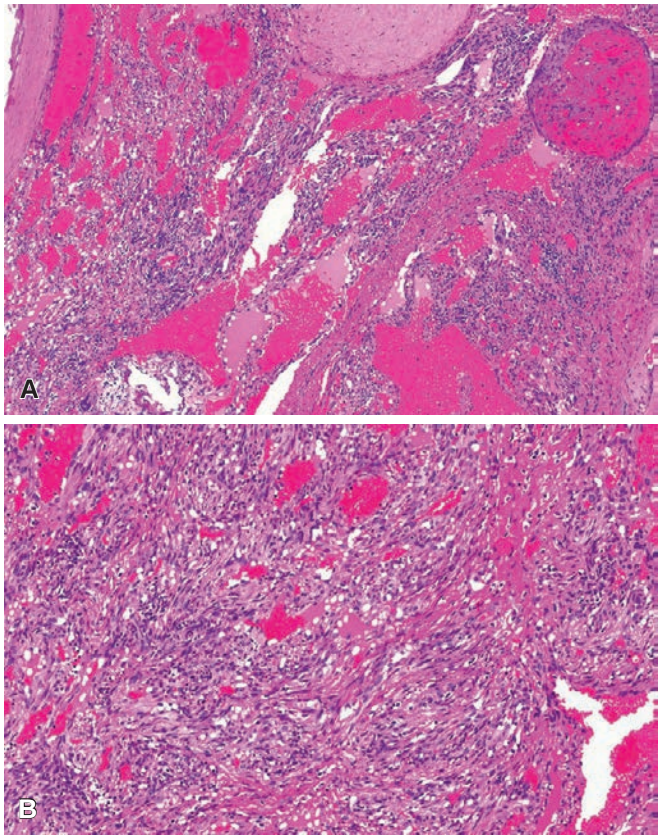

Figure 41.131 **Spindle Cell Hemangioma. A,** Cavernous spaces admixed with Kaposi-like spindle cells. **B,** Kaposi-like areas are prominent in this case.

inflammatory component, particularly eosinophils, but plasma cells, lymphocytes, and mast cells may also be present. Those tumors that show a more solid pattern of growth can be easily confused with a more ominous epithelioid neoplasm, such as epithelioid angiosarcoma or even epithelioid sarcoma.

Recently, a recurrent translocation involving the *FOS* gene has been identified in a significant proportion of epithelioid hemangiomas.[597a] Antonescu et al. described a subset of epithelioid hemangiomas with atypical features (solid growth, increased cellularity, mild to moderate nuclear pleomorphism, or necrosis) with a distinct *ZFP36-FOSB* fusion.[597b]

Although these lesions are clearly benign, up to one-third locally recur.[597] Some appear to be associated with antecedent trauma.[598]

Hobnail hemangioma (also known as targetoid hemosiderotic hemangioma) typically develops on the skin of the extremities of young adults and presents as a pigmented elevated lesion.[599] Histologically, the superficial aspect of the tumor consists of dilated vascular channels lined by hobnail endothelial cells, some of which have intraluminal papillary tufts. The deeper portion consists of slit-like capillaries which infiltrate the dermis but lack cytologic atypia (unlike angiosarcoma). The cells stain for CD31 and D2-40 but not CD34, suggesting true lymphatic differentiation.[599]

Anastomosing hemangioma is a recently described variant that most commonly arises in the genitourinary tract (especially the kidney), although it has also been reported in the paraspinal region and retroperitoneum.[600–602] Histologically, it is composed of tightly packed capillaries arranged in an anastomosing pattern resembling splenic red pulp. Hyaline globules may be seen, as well as extramedullary hematopoiesis.

Acquired tufted angioma (also known as angioblastoma of Nakagawa) seems to be identical to kaposiform hemangioendothelioma (described later in this chapter), and both arise in children and are associated with Kasabach–Merritt phenomenon (KMP).[603,604] However, it seems as if those lesions arising in adults unassociated with KMP have been labeled as acquired tufted angioma. In addition, the latter has been associated with a familial predisposition, suggesting an autosomal dominant pattern of inheritance.[604]

Angiomatosis is defined as extensive involvement of one tissue plane or across tissue planes by a vascular proliferation.[571,605] Most patients are less than 20 years of age and present with diffuse swelling, which may be associated with discoloration of the overlying skin. These lesions are composed of a variety of vessel types, including capillary-sized vessels admixed with large venous and cavernous vessels, often associated with abundant fat. In fact, it is easy to confuse this lesion with a lipomatous tumor rather than recognizing it as a primary vascular proliferation (hence the older term infiltrating angiolipoma). Almost all patients develop recurrences, which is probably related to incomplete excision due to the ill-circumscribed nature of this lesion.[571] These lesions do not appear to progress to angiosarcoma, and thus conservative excision is probably the best course of action in order to minimize morbidity.

Hemangioendothelioma

The term *hemangioendothelioma* has been used over the years for both benign and malignant vascular tumors composed of endothelial cells and therefore lacks specificity. Currently, its preferred use is for vascular tumors of an endothelial nature that occupy an *intermediate* (borderline malignancy) position between the benign hemangioma and the full-blown angiosarcoma.

Epithelioid hemangioendothelioma is composed of epithelioid endothelial cells with abundant and eosinophilic, often vacuolated cytoplasm. The nucleus is round, vesicular, and occasionally indented.[606] Vascular lumina are present, most of them small; some are located intracellularly and are responsible for the cytoplasmic vacuolation (Fig. 41.132). Mitoses, pleomorphism, and necrosis are

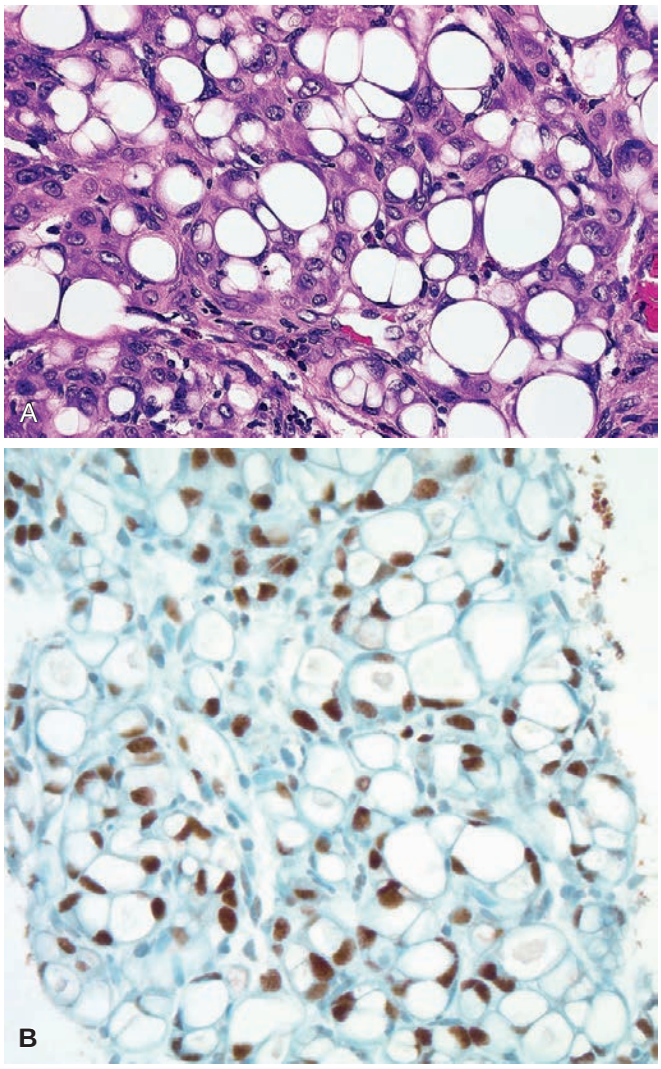

Figure 41.132 Epithelioid Hemangioendothelioma. A, Prominent cytoplasmic vacuolization resembling lipoblasts. **B,** Strong nuclear immunoreactivity for ERG is seen.

variable but area typically scanty or absent. An inflammatory infiltrate is often present at the periphery; this may contain well-formed germinal centers and/or a large number of eosinophils. The stroma may be scanty or have a prominent myxoid appearance. Osteoclast-like multinucleated giant cells may be present.[607] The endothelial nature of the tumor cells has been confirmed ultrastructurally and immunohistochemically (see later).

Tumors with this set of morphologic features have been described in a large number of sites, including skin, bone, lung, pleura, liver, peritoneum, and lymph nodes.[608] Those located in the soft tissue are seen in adults and often arise from the wall of a vein in an extremity.[606] They also occur in the head and neck area.[609] Local recurrences and distant metastases can develop, but the prognosis remains better than for angiosarcoma of either the conventional or epithelioid type (see later).[610] Mitotic activity and tumor size are associated with increased clinical aggressiveness.[611] A recurrent chromosomal aberration t(1;3)(p36.3;q25) has been reported in epithelioid hemangioendothelioma and involves *WWTR1* on chromosome 3 and *CAMTA1* on chromosome 1.[612,613] Doyle et al. found consistent nuclear expression of CAMTA1 in epithelioid hemangioendothelioma (86% of cases), indicating this marker might be extremely useful in recognizing difficult to diagnose examples of this tumor.[614]

A morphologically distinct subtype of epithelioid hemangioendothelioma is characterized by a marked histologic resemblance to epithelioid sarcoma, to the point of having been named *epithelioid sarcoma–like hemangioendothelioma*.[615] Despite some controversy, the preferred name is **pseudomyogenic hemangioendothelioma**.[616] One of the clues to the diagnosis is the presence of cytoplasmic vacuoles consistent with intracytoplasmic vascular lumen formation. Immunohistochemically, the tumor cells are immunoreactive for cytokeratins, CD31, and FLI-1 but not CD34.[615] Recently, a *SERPINE1-FOSB* fusion has been identified as a consistent genetic alteration in pseudomyogenic hemangioendothelioma and diffuse nuclear immunoreactivity for FOSB can be found in virtually all examples of this tumor.[616a]

Kaposiform hemangioendothelioma is a rare vascular tumor that arises most commonly in the retroperitoneum or deep soft tissue of the extremities in children, with almost 50% arising during the first year of life.[617,618] It shares features with capillary hemangioma and Kaposi sarcoma. An interesting phenomenon seen in patients with this tumor is a consumption coagulopathy and thrombocytopenia, known as KMP. Some cases are associated with lymphangiomatosis,[617] and one case has been described to arise in the setting of chronic lymphedema.[619]

Microscopically, there is a striking low-magnification appearance with tumor nodules surrounded by a desmoplastic stroma. The nodules show areas that resemble capillary hemangioma, whereas other areas resemble Kaposi sarcoma. Glomeruloid structures are a characteristic and striking feature. Thin-walled lymphatic vessels are often seen (albeit subtly) at the periphery of the tumor nodules. Markers indicating lymph vessel differentiation are often found, including PROX1, LYVE1, and D2-40, especially in the Kaposi-like areas, whereas the glomeruloid areas do not mark with these antigens, but rather stain for CD31 and CD34.[620] In contrast to infantile hemangioma, this tumor is negative for GLUT-1. The tumor is also negative for HHV8, which allows easy distinction from Kaposi sarcoma.

Clinical behavior depends upon the site, tumor extent, and presence or absence of KMP. Most patients are cured by complete surgical excision, but those with KMP may require cytotoxic agents and/or corticosteroids, as well as other drugs.[621–623] Up to 10% of patients die from KMP or the local effects of the tumor. Rare cases metastasize to regional lymph nodes, but distant metastases have not been reported.

Hobnail (Dabska-retiform) hemangioendothelioma is the preferred name that links the Dabska-type hemangioendothelioma and retiform hemangioendothelioma, given their many overlapping features, particularly the hobnail-shaped endothelial cell. The Dabska-type hemangioendothelioma was first described in 1969[624] as a tumor arising in the skin or subcutis of infants and young children. This seems to be the same tumor described under the terms *endovascular papillary angioendothelioma* and *papillary endolymphatic angioendothelioma*.[625–627] The retiform hemangioendothelioma has similar features but arises in adults and is characterized by long "retiform" vessels lined by hobnail endothelial cells.[628]

Hobnail hemangioendotheliomas are seen in both children and adults, with tumors showing the classic features of Dabska-type lesions arising in children and those with a retiform appearance arising in adults. Both appear as ill-defined, plaque-like lesions in the skin and subcutaneous tissue, most commonly in the distal extremities. Dabska-type lesions have well-formed vessels lined by hobnail endothelial cells with characteristic intraluminal papillations with fibrous cores lined by hobnail cells (Fig. 41.133). These vessels are surrounded by a dense fibrous stroma with prominent lymphocytes.[629]

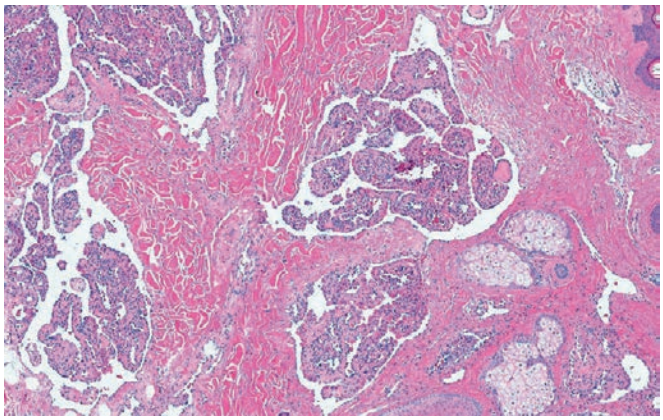

Figure 41.133 Intraluminal papillations with fibrous cores lined by hobnail endothelial cells in hobnail hemangioendothelioma, Dabska-type.

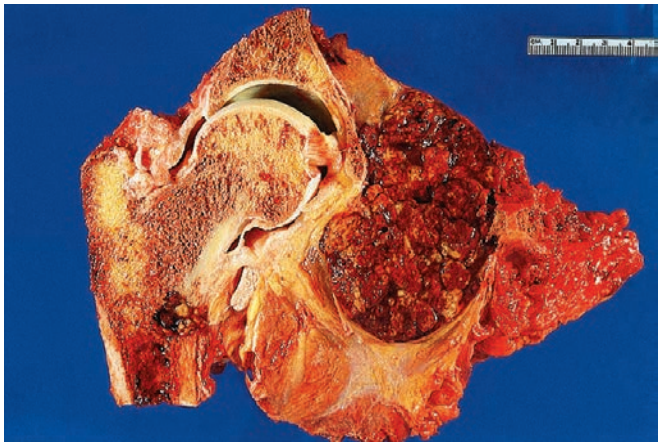

Figure 41.134 Gross hemorrhagic appearance of angiosarcoma in the region of the hip.

On the other end of the histologic spectrum, retiform-type lesions are characterized by elongated vessels which have been descriptively compared to the rete testis filling the dermis and extending into the subcutis lined by hobnail cells with a "matchstick" appearance.[630] Similar to Dabska-type lesions, the vessels are surrounded by hyaline stroma with prominent lymphocytes. Rarely one encounters Dabska-type intraluminal papillations. On occasion, tumors share features overlapping these two ends of the spectrum, lending further support to their grouping as hobnail hemangioendothelioma as a unifying concept. By immunohistochemistry, the cells express CD31 and CD34, as well as lymphatic markers including VEGFR-3.[626,631,632] These lesions have a propensity to recur locally and some metastasize to regional lymph nodes, but distant metastases do not seem to occur.

Composite hemangioendothelioma is the name that has been proposed for a vascular neoplasm showing various combinations of benign, low-grade malignant, and malignant components.[633,634] The two most common patterns are those of epithelioid and retiform hemangioendothelioma. This probably does not represent a specific entity but rather the manifestation of the fact that there is a great deal of overlap between the seemingly endless number of types and subtypes of vascular tumors that have been described.

Angiosarcoma

Angiosarcoma usually is seen in adults and the elderly, but it can also rarely occur in children.[635,636] The most common locations are the skin, soft tissue, breast, bone, liver, and spleen. Some soft tissue angiosarcomas arise from major vessels, such as the inferior vena cava, pulmonary artery, or aorta.[637,638] These tend to have a very undifferentiated appearance and a solid pattern of growth, to such an extent that they may not be identifiable as being of endothelial nature.[637] Accordingly, topographic terms such as intimal sarcoma, luminal sarcoma, and arterial/venous trunk sarcoma have been used for them.[639]

Angiosarcomas have been reported in previously irradiated fields,[640] around long-standing foreign bodies,[641] in arteriovenous fistulas[642] (including surgically constructed ones),[643] as a secondary somatic-type which develops in mediastinal or retroperitoneal germ cell tumors,[644] or arising within preexisting benign tumors (e.g., schwannoma, neurofibroma).[645]

Grossly, angiosarcomas tend to be highly hemorrhagic and deeply invasive (Fig. 41.134). Their microscopic appearance ranges from a pattern that is so well differentiated as to simulate a benign hemangioma to one so undifferentiated and solid as to simulate carcinoma, malignant melanoma, or other types of sarcoma.[646] The diagnostic areas of angiosarcoma are represented by the freely anastomosing vascular channels lined by atypical endothelial cells (Fig. 41.135). Clusters of reactive lymphocytes and clumps of hemosiderin are common.

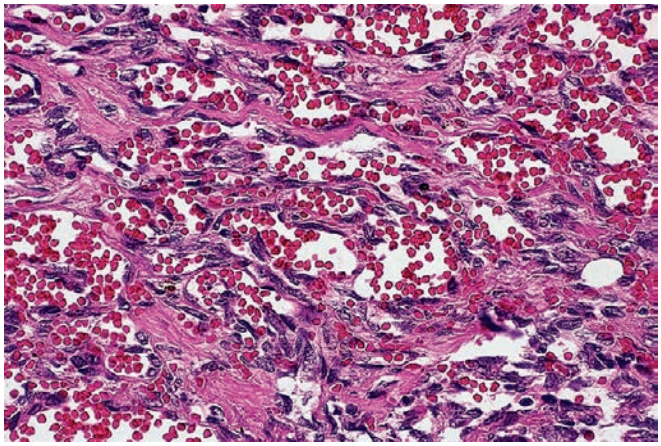

Figure 41.135 Angiosarcoma of the mediastinum showing anastomosing vascular channels.

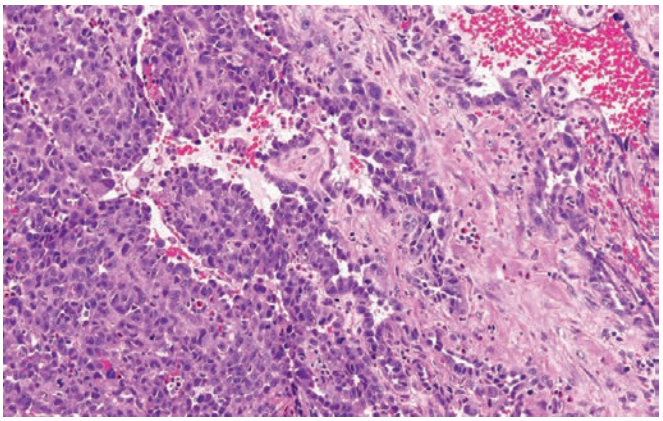

Figure 41.136 Epithelioid angiosarcoma with large epithelioid cells arranged in sheets and vasoformative spaces.

Variations in the appearance of the neoplastic endothelial cells are great. Their shape ranges from very elongated to plump and epithelioid (Fig. 41.136), and their size from small to giant, with occasional development of multinucleated forms.[647]

The differential diagnosis of angiosarcoma includes hemangioma for the better differentiated lesions, Kaposi sarcoma for those with a predominantly spindle component, and carcinoma or amelanotic melanoma for the poorly differentiated types. Metastatic renal cell carcinoma, because of its high degree of vascularity, is particularly notorious for its ability to simulate angiosarcoma; in this regard, it should be kept in mind that clear tumor cells are not a feature of angiosarcoma.

Immunohistochemically, various endothelial markers can be demonstrated depending on the degree of differentiation. Of these, CD31 and ERG are the most reliable.[6,648] In some cases (particularly the epithelioid variant) there is coexpression of cytokeratin, which can even be strong and diffuse.[649] In other cases there is expression of D2-40, suggesting differentiation toward lymph vessel endothelial cells.[650]

A well-defined clinicopathologic form of angiosarcoma involves the head and neck region (particularly the scalp) of elderly individuals. It begins in the skin but often extends into the subcutis. The clinical course includes repeated local occurrences over a long period of time, followed in some cases by lymph node and pulmonary metastases.[651,652]

Lymphangioma and Lymphangiomyoma

Most **lymphangiomas** represent malformations rather than true neoplasms and are thought to result from failure of the lymphatic system to communicate with the venous system.[653] Three forms exist: *capillary*, *cavernous*, and *cystic* (Fig. 41.137). The capillary form occurs in the skin, whereas the cavernous variety prefers deep soft tissues. Cystic lymphangioma has been traditionally known as *hygroma*. Its most common presentation is in the form of a poorly defined soft tissue mass in the neck of children, usually situated posterior to the sternocleidomastoid muscle and sometimes extending into the mediastinum. Those developing in utero often progress to hydrops and cause fetal death. Many of the fetuses have karyotypes consistent with Turner syndrome or other chromosomal abnormalities.[654,655] Some lymphangiomas are diffuse and/or multicentric, the condition being designated as *lymphangiomatosis*. These cases may be limited to the soft tissues or be accompanied by osseous and/or visceral manifestations.[656] A preferred location is the thoracic cavity, with resulting chylous pleural effusion and/or chylopericardium.[657,658] Other cases diffusely affect the extremities.[659]

Microscopically, lymphangioma consists of large lymphatic channels growing in loose connective tissue (Fig. 41.138). A few disorganized bundles of smooth muscle can be present in the wall of the larger channels. Focal areas of papillary endothelial proliferation similar to those described by Masson in blood vessels are sometimes found. Large collections of lymphocytes may be present in the stroma and cause mistakes in interpretation. Lymphangioma practically never becomes malignant and is curable by excision, although it can locally recur.

Lymphangiomyoma is the preferred term for a benign neoplasm seen exclusively in females and originally described as lymphangiopericytoma.[660,661] The localized form is restricted to the mediastinum and retroperitoneum, often seen in close association with the thoracic duct and its tributaries, and often results in chylothorax. Chylous ascites and chyluria (secondary to ureteral wall involvement) may also be present. The diffuse form of the disease, known as *lymphangio(leio)myomatosis*, typically involves the lung.[662]

Microscopically, there is a proliferation of intimately mingled lymph vessels and smooth muscle elements. Immunohistochemically, the lining cells show lymph vessel markers such as D2-40,[663] whereas the tumor cells (which are plumper and paler than those of ordinary leiomyomas) are reactive for actin, desmin, HMB-45, and other melanocytic markers, such as MiTF, tyrosinase, and melan-A.[664] This profile (particularly the HMB-45 immunoreactivity), plus their occurrence in patients with the tuberous sclerosis complex,[665] links these tumors with renal and extrarenal angiomyolipomas (including their epithelioid and monotypic variants), pulmonary clear cell ("sugar") tumor, clear cell myomelanocytic tumor, and other neoplasms into the continuously enlarging **PEComa** family.[666] Indeed,

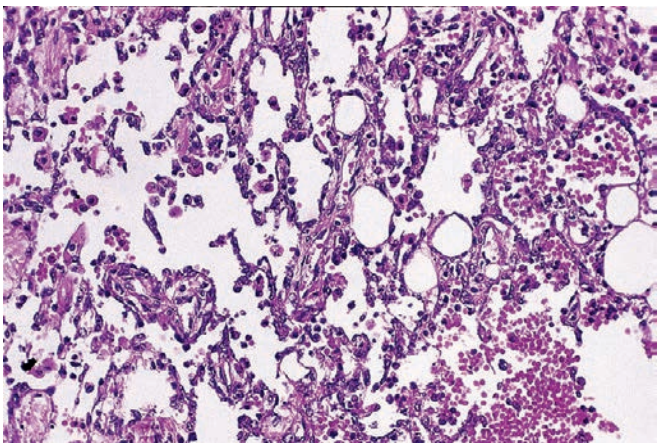

Figure 41.140 Post-mastectomy angiosarcoma showing an intricate network of neoplastic vessels.

cases are increasingly being reported of **PEComas** of soft tissue of both benign and malignant nature.[667–669] A subset of PEComas of soft tissue shows expression of TFE3 (a DNA-binding factor closely linked to MiTF) particularly those with a nested or alveolar soft part sarcoma-like growth pattern, and a perplexing link has been postulated between a subset of PEComas with melanotic Xp11 translocation renal cancers and melanotic Xp11 neoplasms.[670–672b]

Although immunohistochemical evaluation of hormone receptors in lymphangiomyoma/lymphangiomyomatosis has resulted in conflicting findings, good therapeutic results have been reported with progesterone therapy or oophorectomy.[673,674] More recently, mTOR inhibitors (sirolimus and everolimus) have shown promising results.[675]

Angiosarcoma associated with lymphedema (so-called **lymphangiosarcoma**) was first described by Stewart and Treves in 1949 in six patients who developed vascular sarcomas following radical mastectomy and axillary node dissection for breast cancer.[676] Chronic lymphedema was felt to be the predisposing factor in these patients, and subsequently, many cases of lymphedema-associated angiosarcoma have been described (Fig. 41.139). Histologically, there is a wide variation of patterns, ranging from solid undifferentiated areas to well-differentiated, capillary sized vessels with minimal cytologic atypia (Fig. 41.140). These are typically clinically aggressive lesions.[677,678]

With the decrease in the number of radical mastectomies performed during the past few decades, and the corresponding increase in the number of conservative breast operations followed by radiation, the pattern of breast carcinoma–associated vascular proliferative processes has changed. The malignant tumors developing under these circumstances have similar morphologic features, but the interval from the time of therapy is generally shorter, the tumor is in the skin overlying the breast rather than in the arm, and there is no accompanying lymphedema.[679] The matter is complicated by the fact that radiation therapy may also induce lymph vessel proliferations with the appearance of lymphangioma circumscriptum[680] or progressive acquired lymphangioma.[681] Furthermore, an increasingly large number of cases of *atypical vascular lesions* (AVLs) in the skin of radiated breast have been reported.[682] These lesions are characterized by dermal vascular proliferation and associated inflammation but not enough architectural or cytologic atypia to justify a diagnosis of malignancy.

Clinically, these lesions are small papules, often multifocal, that develop within 3 years of radiation. Most consist of ectatic vessels confined to the superficial dermis lined by flattened or hobnail cells that stain for CD31 and D2-40. Rare cases show infiltration and interconnecting vessels. It has recently been shown that postradiation angiosarcomas show amplification of *MYC*, whereas AVLs do not.[683,684] This can also be demonstrated using MYC antibodies.[685] The vast majority of patients with AVLs pursue a favorable clinical course[686,687]; however, rare cases seem to progress to angiosarcoma, particularly those deemed "vascular type" AVLs.[687]

Hemangioblastoma

So-called hemangioblastoma, a tumor characteristically located in the CNS and linked with the von Hippel–Lindau syndrome, can occasionally involve other sites, including soft tissues.[688–690] Some of the reported cases have been anatomically associated with a peripheral nerve.[691] As in the case for its more common CNS counterpart, the nature of the "stromal cells" located in between the numerous vessels remains controversial. The tumor cells express inhibin in almost all cases, but some stain for S-100 protein, GLUT1, SMA, and EMA.[688] This tumor seems to act in a clinically benign fashion. Some of these patients have von Hippel–Lindau syndrome.

Tumors of Smooth Muscle and Modified Smooth Muscles

Leiomyoma

Several types of leiomyoma exist. **Cutaneous leiomyomas** located in the dermis arise from arrectores pilorum muscles; they are characteristically superficial, small, multiple, and grouped.

Genital leiomyomas are solitary tumors that arise from smooth muscle bundles located in the superficial subcutaneous tissue of genital areas and structures that are topographically and functionally related to them, such as the nipple, areola, axilla, scrotum, penis, vulvar labia, and anal skin.

Vascular leiomyomas (angioleiomyomas) arise from the smooth muscle of blood vessels (Fig. 41.141). They occur more frequently in females and are usually located in the soft tissues of the lower limbs.[692,693] They constitute, together with traumatic neuroma, glomus tumor, eccrine spiradenoma, and angiolipoma, the classic five spontaneously painful nodules of skin and soft tissues.

Grossly, vascular leiomyomas are yellow or yellowish pink, sharply circumscribed, and fairly firm. Microscopically, they are made up of intersecting fascicles of smooth muscle cells encircling vascular lumina lined by normal endothelial cells. The vascular organoid appearance resulting from this feature is marked, but the vascular elastic lamina is absent. Mitotic activity is absent, and there is no

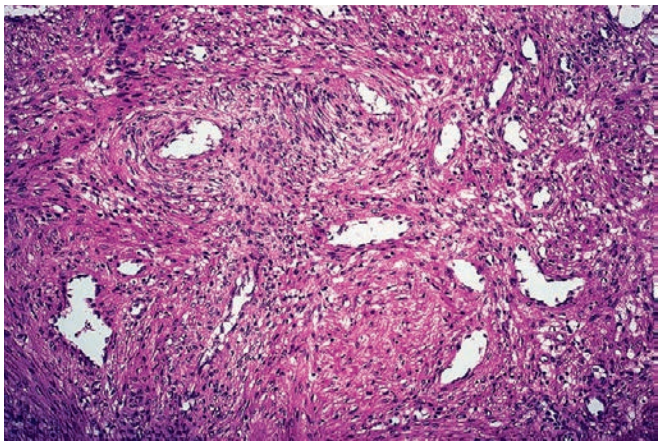

Figure 41.141 Vascular leiomyoma (angioleiomyoma) with neoplastic smooth muscle cells closely related to blood vessels.

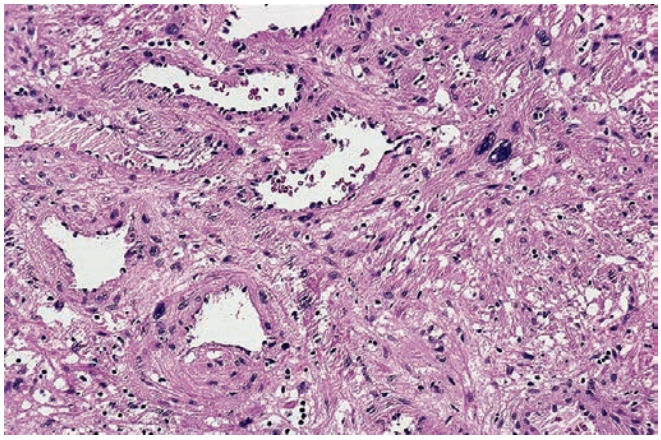

Figure 41.142 Vascular leiomyoma (angioleiomyoma) with scattered bizarre tumor cells, a feature of no prognostic significance.

necrosis or hemorrhage. Islands of mature fat or cartilage may be present in between the smooth muscle fibers. Occasionally, bizarre nuclear forms similar to those seen in uterine symplastic leiomyoma are encountered (Fig. 41.142).[694] Transitional forms with glomus tumor and myopericytoma are occasionally seen.[695]

The pain often associated with vascular leiomyomas is thought to be mediated by the nerves present within the tumor and in the capsule, whether by mechanical stretching or through mast cell mediation.[696,697] The behavior of these tumors is completely benign.

Deep-seated leiomyomas of nonvascular type occur most commonly in the extremities[698]; they can also be seen in the pelvic region of females where they stain for hormone receptors similar to uterine leiomyomas.[699]

Leiomyosarcoma

Leiomyosarcoma of soft tissue is typically a tumor of adults and the elderly, although cases in children are on record.[140,700–702] Smooth muscle tumors have also been seen with increasing frequency in immunosuppressed patients (HIV-infected individuals and organ transplant recipients), and such cases have been closely associated with Epstein-Barr virus infection (EBV-associated smooth muscle tumors).[50,703,704]

Most soft tissue leiomyosarcomas are located in the extremities, but they can occur anywhere, including the head and neck region.[705]

Figure 41.143 Leiomyosarcoma of Soft Tissues of the Arm. The fusiform shape of the tumor is due to the tumor following the course of the large blood vessels from which it arose.

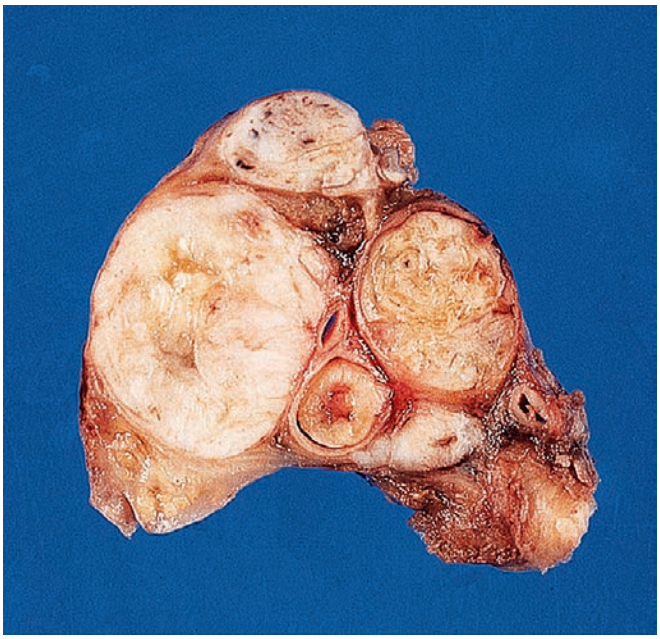

Figure 41.144 Leiomyosarcoma filling the lumen of the popliteal vein and its branches, as seen on cross section. The popliteal artery is uninvolved.

Many arise from the walls of arteries and veins of widely differing caliber, ranging from large ones (inferior vena cava, saphenous vein, femoral vein, pulmonary artery, femoral artery, and aorta, in that order of frequency) to venules and arterioles.[701,706] Those located in the inferior vena cava can result in Budd–Chiari syndrome.[707]

Grossly, leiomyosarcomas can be as well circumscribed as leiomyomas but are larger and softer and have a tendency to show tumor necrosis, hemorrhage, and cystic degeneration (Fig. 41.143). Those arising from major vessels can protrude in a polypoid fashion within the lumen or be predominantly intramural (Fig. 41.144).

Microscopically, the pattern of growth is predominantly fascicular, with the tumor bundles intersecting each other at wide angles (Fig. 41.145). Merging of tumor cells with blood vessel walls is an important diagnostic clue. In some cases the vascular pattern is particularly prominent, resulting in a hemangiopericytoma-like appearance. The individual cells have elongated, blunt-ended nuclei

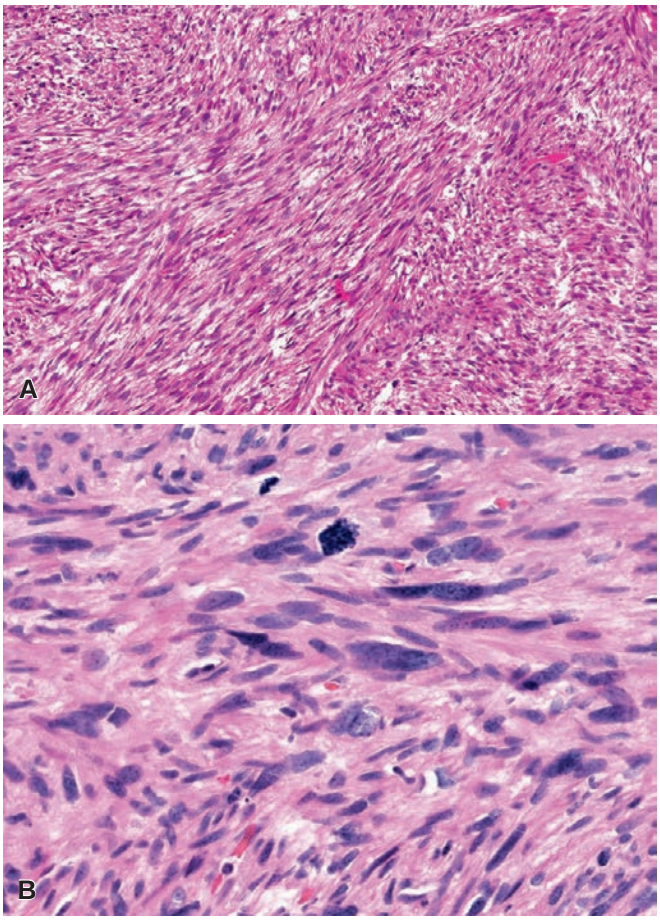

Figure 41.145 **A,** Low-power and **B,** High-power views of a leiomyosarcoma with arrangement into fascicles.

and acidophilic fibrillary cytoplasm, features that are also apparent in cytologic preparations. Palisading of nuclei may occur, a feature that may cause confusion with peripheral nerve sheath tumors. The degree of nuclear atypia is highly variable; in extreme cases, it may result in an "MFH-like" picture.[708] In fact, the most common line of differentiation seen in tumors formerly diagnosed as MFH is smooth muscle differentiation.[323] Cytoplasmic vacuoles are often located at one nuclear pole, sometimes indenting the nucleus, representing another diagnostic clue. Other features occasionally seen include granular cell change,[407] myxoid stroma,[709] inflammatory changes,[710] and osteoclast-like multinucleated giant cells.[711] Rhabdoid features can be present; as for other tumor types, this feature is an indicator of aggressive behavior.[712] The EBV-related tumors lack significant pleomorphism and often have a component of primitive round cells and numerous intratumoral T cells.[50]

Immunohistochemically, both leiomyomas and well-differentiated leiomyosarcomas show reactivity for SMA, smooth muscle myosin, desmin, h-caldesmon, and basal lamina components, including laminin and type IV collagen.[713,714] Surprisingly, normal and neoplastic smooth muscle cells may also stain for cytokeratins (Fig. 41.146) and EMA; this feature seems to be particularly prominent in tumors of the female genital tract and large vessels.[715,716] Estrogen receptor protein has also been detected in some of these tumors, raising the possibility of hormonal responsiveness.[717]

Cytogenetic analysis has shown a variety of chromosomal aberrations but no specific karyotype. Curiously, a relatively high number of these tumors show no detectable karyotypic abnormalities.[718–720]

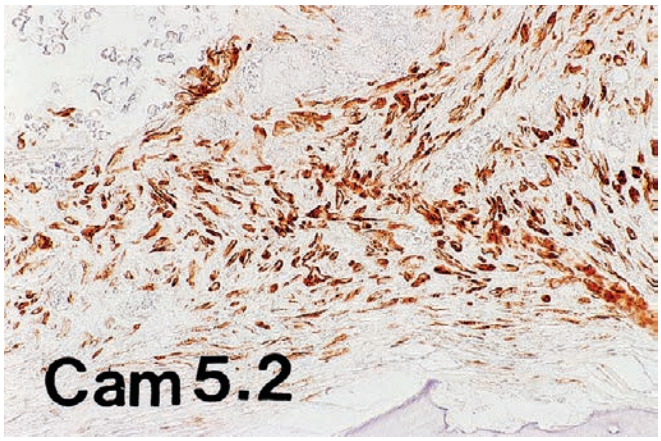

Figure 41.146 Immunoreactivity for low-molecular-weight cytokeratin *(CAM5.2)* in leiomyosarcoma.

Common genetic alterations include *RB1*, *CDKN2A*, *CCND1*, and *CCND3*.[140] The gene expression profiles of leiomyosarcomas greatly overlap with those of UPSs.[721,722]

The differential diagnosis between leiomyoma and leiomyosarcoma of the soft tissues depends on a combination of features. Nuclear atypia, even if focal, should prompt an evaluation of mitotic activity. Any degree of mitotic activity in conjunction with cytologic atypia should lead to strong consideration of a diagnosis of leiomyosarcoma. Prognosis in leiomyosarcoma correlates primarily with tumor size and depth, two parameters that are closely related. In one large series, 40% of cutaneous leiomyosarcomas recurred, but none metastasized; among the subcutaneous tumors, one-half recurred, and one-third resulted in metastases or tumor-related deaths.[723] Gustafson et al. found vascular invasion and age over 60 years to be independent risk factors for tumor-related death,[724] whereas Farshid et al. found tumor grade and surgical tumor disruption to be independent predictors of metastasis.[701] Simple enucleation of the tumor virtually guarantees local recurrence. The majority of these tumors eventually give rise to distant metastases, sometimes 15 years or more after the original excision.

It should be noted that all those previous comments are intended for the smooth muscle tumors located in soft tissues and do not necessarily apply to those in the uterus or gastrointestinal tract.

Epithelioid Smooth Muscle Tumors

Smooth muscle tumors of soft tissues may have an epithelioid configuration, in whole or in part, similar to that seen more often in mesenchymal tumors of the stomach and other intra-abdominal sites (Fig. 41.147).[725] We classify them as benign or malignant by using similar criteria to those applied for smooth muscle tumors in general. Immunohistochemical markers of smooth muscle differentiation tend to be expressed only focally and imperfectly in these tumors.[725]

Glomus Tumor

Glomus tumor originates in the neuromyoarterial glomus, a normal arteriovenous shunt abundantly supplied with nerve fibers and fulfilling a temperature-regulating function.[726] The classic location of the glomus tumor is the subungual region, but it can occur elsewhere in the skin, soft tissues (particularly in the flexor surface of the arms and about the knee), nerves, stomach, nasal cavity, and trachea.[727–729] It has also been reported in the sacrococcygeal region, arising from the coccygeal body (glomus coccygeum) and

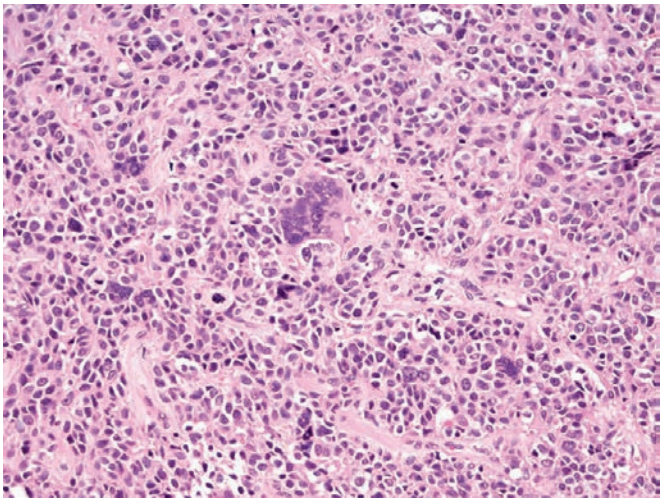

Figure 41.147 Epithelioid leiomyosarcoma composed of malignant epithelioid cells and rare giant cells.

associated with coccydynia,[730] but there is some question as to whether this is a true neoplasm or simply a normal structure of this region.[731]

Subungual lesions are always supplied by numerous nerve fibers and are exquisitely painful, two features often absent in glomus tumors arising elsewhere. The tumor may erode the terminal phalanx or even present as an intraosseous lesion in this location. Superficial lesions are well circumscribed. Glomus tumors in children tend to be multiple and of an infiltrative nature.[732] They may present clinically as varicosities of the lower extremities.

Microscopically, glomus tumors consist of blood vessels lined by normal endothelial cells and surrounded by a solid proliferation of round or cuboidal cells with perfectly round nuclei and acidophilic cytoplasm (Fig. 41.148). As seen under an electron microscope, the tumor cells have features of smooth muscle rather than of pericytes.[733] Immunohistochemically, they manifest reactivity for actin and basal lamina components but usually not for desmin.[734]

Three microscopic types of glomus tumor have been recognized: *solid*, *angiomatous (glomangioma)*, and *myxoid* (Fig. 41.149). The solid type can be confused with sweat gland tumor, melanocytic nevus, or metastatic carcinoma.[735] This is particularly the case when the tumor cells are very epithelioid and/or grow in a single file fashion.[736] The angiomatous type can have a diffuse quality, in the sense of looking like an angiomatosis with an increased number of glomus cells in the vessel wall.[737] An *oncocytic variant* of glomus tumor, in which the cytoplasm of the glomus cells is packed with mitochondria, has also been described.[738] Often the telltale relationship between tumor cells and blood vessels can be clearly seen only at the very periphery of the neoplasm. There also is a spectrum that overlaps with lesions including glomangiomyoma, glomangiopericytoma, and myopericytoma, all of which show evidence of perivascular myoid differentiation (Fig. 41.150).[189]

On rare occasions, glomus tumors behave in an aggressive fashion, with local recurrences, invasion of adjacent structures, and exceptionally even distant metastases.[737,739] In other instances, lesions with the typical cytoarchitectural features of glomus tumor merge with a cytologically malignant tumor; these have been designated *glomangiosarcomas*.[740]

There are also examples of cytologically atypical glomus tumors. A proposal has been made to subclassify these as symplastic, of uncertain malignant potential, and malignant.[737] Those called malignant (the only ones to metastasize) were defined as glomus tumors with a deep location and a size of more than 2 cm, or atypical mitotic figures, or moderate to high nuclear grade and five or more mitoses per 50 high-power fields.

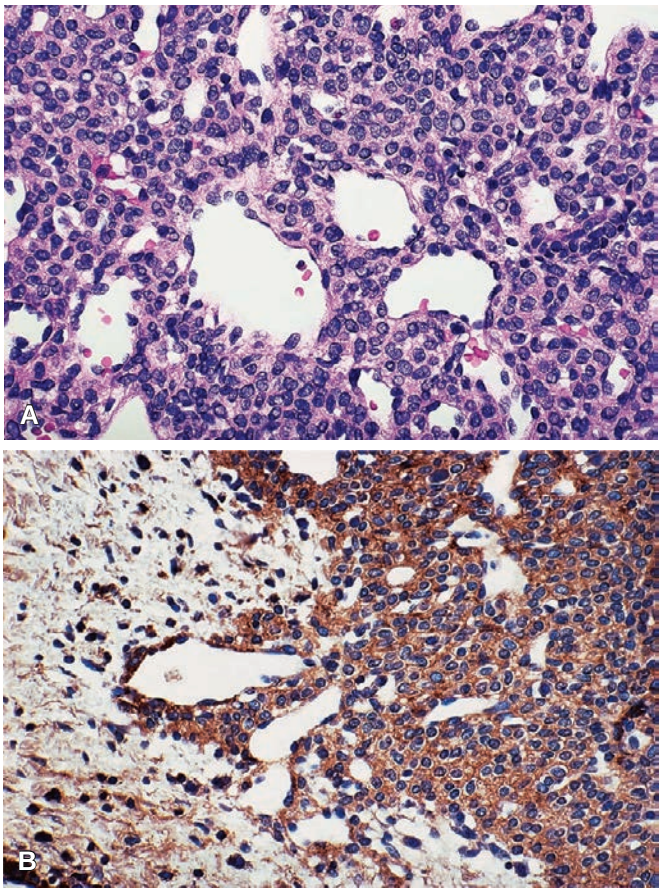

Figure 41.148 **A,** Glomus tumor with round glomus cells surrounding open vascular spaces. **B,** Strong SMA immunoreactivity is characteristic.

Tumors of Striated Muscle

Rhabdomyoma

Rhabdomyomas can be divided into distinct subtypes, although some overlap exists. Those known as the *adult* type are found almost exclusively in the oral cavity and its vicinity in adult patients.[741,742] Up to 20% may be multifocal.[743] Microscopically, the cells are well differentiated, large, rounded or polygonal, with abundant acidophilic cytoplasm containing variable amounts of lipid and glycogen. Some cells have features of "spider cells." Cross striations and intracytoplasmic rod-like ("jack straw") inclusions are frequent, and intranuclear inclusions may be seen. There is no mitotic activity or nuclear atypia. The differential diagnosis includes granular cell tumor, hibernoma, and the peculiar condition known as crystal-storing histiocytosis.[744]

The *fetal* form of rhabdomyoma is seen almost exclusively in two locations: the head and neck area (particularly the retroauricular area) in children under 3 years of age and the vulvovaginal region of middle-aged women.[745–747] The latter, also referred to as *genital rhabdomyoma*, is separated by some authors from the other fetal types. Microscopically, both forms are quite cellular, formed by immature skeletal muscle fibers (some containing cross striations)

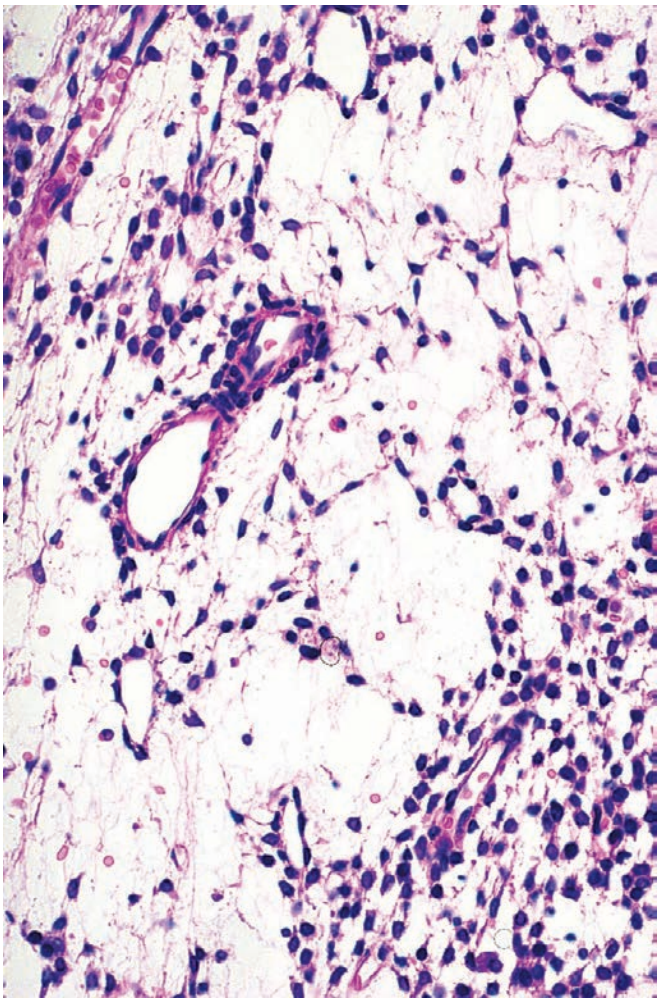

Figure 41.149 Myxoid zone in a glomus tumor.

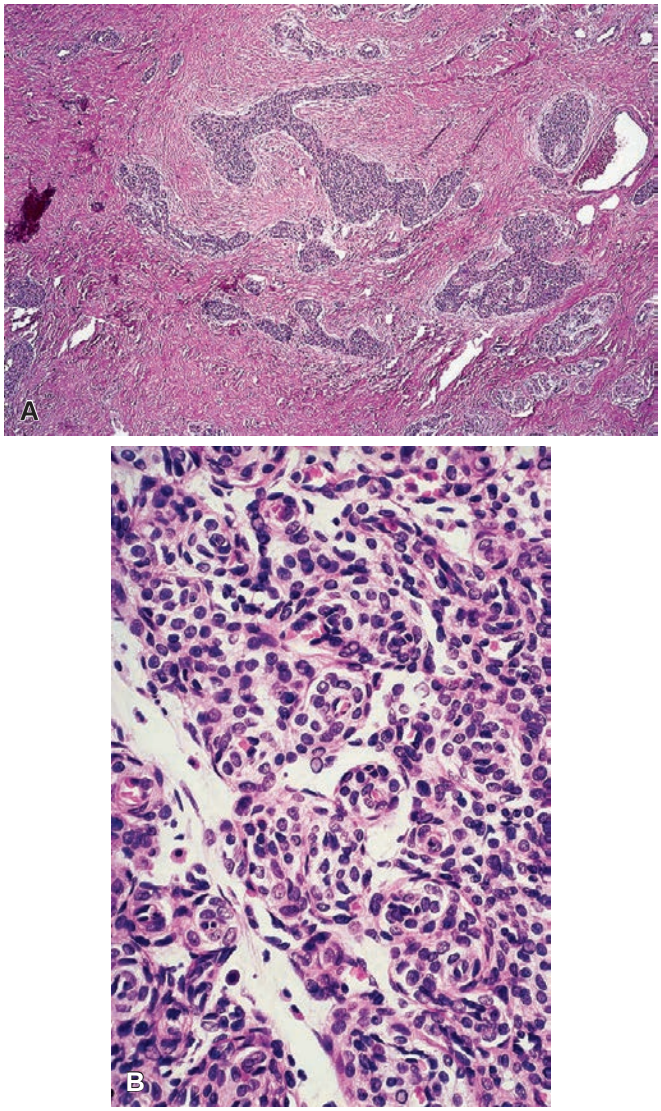

Figure 41.150 **Glomangiopericytoma. A,** Low-power and **B,** High-power views.

and primitive mesenchymal cells (Fig. 41.151). Their development is equivalent to that of fetal skeletal muscle of 7–12 weeks gestation. Nuclear atypia is absent, and mitoses are generally rare. The vulvovaginal cases tend to have a myxoid quality. Kapadia et al. have divided their cases of fetal rhabdomyoma into "classic" (having the previously described features) and "intermediate" types; the latter were characterized by the presence of large, ganglion cell-like rhabdomyoblasts with vesicular nuclei and prominent nucleoli, interlacing ribbon- or strap-like rhabdomyoblasts with deeply acidophilic cytoplasm, fascicles simulating smooth muscle, plexiform patterns with infiltration of fat, and intimate relationship with peripheral nerves.[747]

The main differential diagnosis of fetal rhabdomyoma is with embryonal or spindle cell rhabdomyosarcoma. The distinction can be extremely difficult because of the overlap of many histologic features. However, fetal rhabdomyomas tend to be well circumscribed and superficial and lack significant cytologic atypia, mitotic activity, and necrosis.

The immunohistochemical features of rhabdomyoma (especially the adult type) recapitulate those of normal skeletal muscle cells (desmin, muscle-specific actin). Ultrastructurally, hypertrophied Z band material, thick and thin filaments, numerous mitochondria (some with abnormal configuration or with inclusions), intranuclear bodies, and cytoplasmic bodies have been observed. Cardiac rhabdomyoma is distinct from the aforementioned lesions.

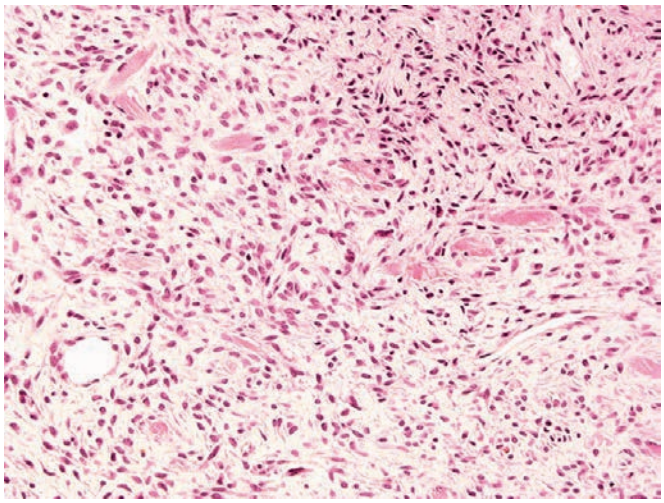

Figure 41.151 Fetal rhabdomyoma with eosinophilic spindle cells and rare cells with obvious cross striations.

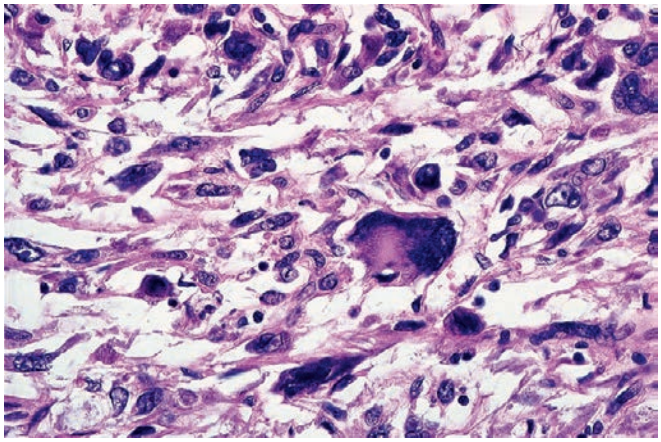

Figure 41.152 Pleomorphic rhabdomyosarcoma showing some resemblance to an undifferentiated pleomorphic sarcoma but with rare eosinophilic giant cells. This tumor stained for both desmin and myogenin.

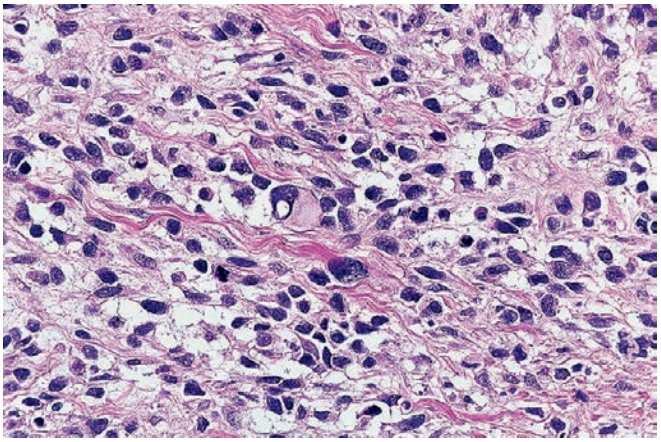

Figure 41.153 Embryonal Rhabdomyosarcoma. Most of the nuclei are oval; the cytoplasm is scanty and acidophilic.

Rhabdomyosarcoma

There are three major categories of rhabdomyosarcoma: pleomorphic, embryonal, and alveolar, as well as several less common subtypes.[748]

Pleomorphic rhabdomyosarcoma. This tumor, which constituted practically all the cases of rhabdomyosarcoma in the older literature, is actually the least common of the three major categories. It most often arises in the deep soft tissues of the extremities of adult patients,[749–752] although rare cases do arise in children.[749] It typically resembles an UPS except for the presence of scattered pleomorphic rhabdomyoblasts with cross striations (Fig. 41.152) and myogenin immunoreactivity.[753] One should be very careful to avoid the following pitfalls: (1) entrapped non-neoplastic skeletal muscle fibers; (2) release of myoglobin from necrotic muscle with subsequent nonspecific absorption by tumor cells, which thus become immunoreactive; and (3) presence of skeletal muscle differentiation in other malignant tumors. In regard to the latter event, it is somewhat ironic that the best evidence of skeletal muscle differentiation in malignant tumors is often found not in rhabdomyosarcoma per se but rather in tumors such as MPNST, malignant thymoma, mixed müllerian tumor of the female genital tract, malignant germ cell tumors (particularly extragonadal ones), medulloblastoma, and Wilms tumor. When defined by the restrictive criteria listed previously, pleomorphic rhabdomyosarcoma actually is a very rare neoplasm. The behavior of pleomorphic rhabdomyosarcoma seems not to be substantially different from that of other pleomorphic sarcomas of soft tissue.

The other two major types of rhabdomyosarcomas occur primarily in children and adolescents and constitute the most common form of soft tissue sarcoma in this age group.

Embryonal rhabdomyosarcoma. This tumor type most commonly arises in the head and neck region (particularly the orbit, nasopharynx, middle ear, and oral cavity), retroperitoneum, bile ducts, and genitourinary tract.[754] The large majority occur in children between the ages of 3 and 12 years, but they can also be seen in younger patients and adults.[755]

Microscopically, the tumor cells are small and spindle shaped (Fig. 41.153). Some have a deeply acidophilic cytoplasm. A feature of diagnostic value is the presence of highly cellular areas usually surrounding blood vessels, alternating with paucicellular regions that have abundant myxoid intercellular material. Cross striations may or may not be present; in contrast to pleomorphic rhabdomyosarcoma in adults, their presence is not indispensable for the light microscopic diagnosis, as long as all the other features are present.

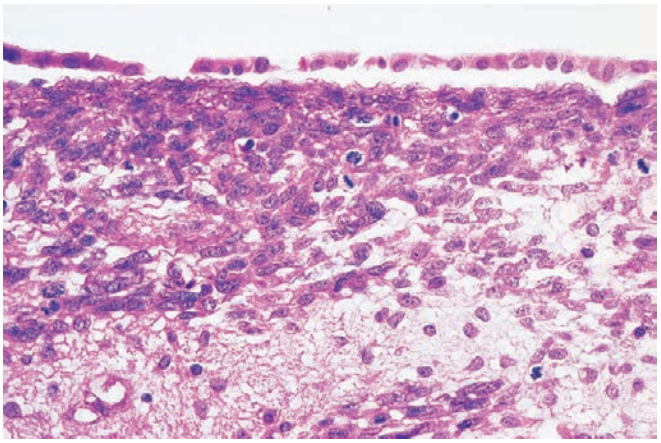

Figure 41.154 Botryoid rhabdomyosarcoma of common bile duct showing a concentration of tumor cells immediately beneath the epithelium ("cambium layer").

Confirmation of the diagnosis by select immunohistochemical markers is necessary.

The most common sites of metastatic involvement are the soft tissues, serosal surfaces, lung, bone marrow, and lymph nodes.[756] Cases associated with diffuse bone marrow involvement may simulate acute leukemia.[757] Rhabdomyosarcomas arising from genitourinary sites or extremities are particularly prone to metastasize to lymph nodes,[758] whereas tumors originating in head and neck structures adjacent to meningeal surfaces have a high incidence of direct meningeal extension.

The prognosis of embryonal rhabdomyosarcoma has markedly improved following multimodality treatment with excision, radiation therapy, and multidrug chemotherapy.[759] Over 80% of children now survive when the disease is localized to the region of origin.[760]

Embryonal rhabdomyosarcoma: variants and related tumors. When growing beneath a mucosal membrane, such as the vagina, urinary bladder, or nasal cavity, the tumor frequently forms large polypoid masses resembling a bunch of grapes—hence the name *sarcoma botryoides* (Fig. 41.154). This is regarded as a variation in the pattern of growth of embryonal rhabdomyosarcoma and is referred to as the *botryoid subtype*. A highly characteristic feature of these polypoid ("botryoid") tumors is the presence of a dense zone of undifferentiated tumor cells immediately beneath the epithelium known as a *cambium layer*.

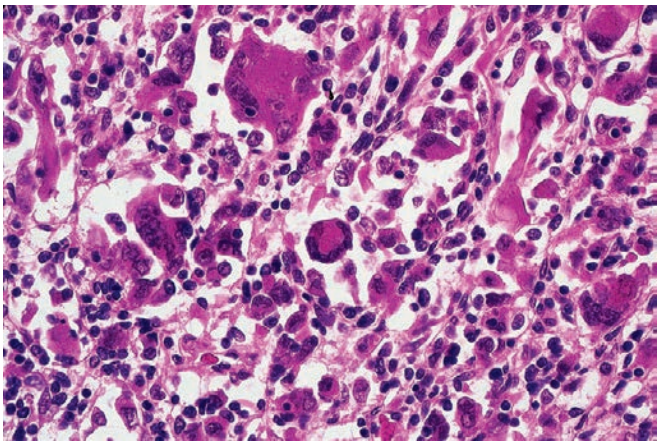

Figure 41.155 Embryonal rhabdomyosarcoma with anaplastic features in a child.

Occasional tumors within the embryonal category have focally anaplastic features, with bizarre nuclear forms; these should not be classified as pleomorphic rhabdomyosarcomas but rather as *embryonal rhabdomyosarcoma with anaplastic features* (Fig. 41.155). It has been suggested that they are associated with a more aggressive clinical course, especially when the anaplastic features are extensive[761]; conversely, well-differentiated tumors (with over 50% rhabdomyoblasts) are associated with an excellent response to chemotherapy.[762]

Tumors examined following multidrug chemotherapy tend to show a greater degree of differentiation than the pretherapy specimen, suggesting that the drugs have either induced maturation or resulted in a selection of the better differentiated components.[763,764]

Very rarely, accumulation of cytoplasmic glycogen or lipids in embryonal rhabdomyosarcoma results in a *clear cell appearance* that can simulate clear cell carcinoma.[765] Another morphologic variation is represented by tumor cells containing cytoplasmic globular inclusions composed of intermediate filaments and resulting in a *rhabdoid appearance*.[766]

Occasionally, in infants and children, tumors with a location and appearance otherwise characteristic of embryonal rhabdomyosarcoma are seen to contain collections of cells exhibiting neuronal, melanocytic, and/or schwannian differentiation; these have been interpreted by some as originating from the migratory neural crest (ectomesenchyme) and designated as *ectomesenchymomas*.[767,768] Most of these tumors have been located in the head and neck region.

Although originally described as variants of embryonal rhabdomyosarcoma, **spindle cell/sclerosing rhabdomyosarcoma** seems to represent related tumors that are distinct from classic embryonal rhabdomyosarcoma.[769] Most of the initially published cases of spindle cell rhabdomyosarcoma occurred in male children. The most common locations were the paratesticular area and the head and neck region, and their prognosis was reported to be favorable.[770] Subsequently, spindle cell rhabdomyosarcomas were reported in adults with preferential location in the head and neck region and a more aggressive clinical course than their pediatric counterparts.[771,772] Spindle cell rhabdomyosarcoma bears some resemblance to the tumors described by Lundgren et al. as *infantile rhabdomyosarcomas*, but it is not clear whether the two are identical.[773] The latter tumors microscopically simulated fibrosarcoma and were characterized by an aggressive clinical course.

Subsequently, the entity of *sclerosing rhabdomyosarcoma* was described and characterized by a prominent deposition of matrix material that simulated the appearance of an osteosarcoma or chondrosarcoma.[774,775] The initial reported cases arose in adults, but some have also been identified in children.[776,777] More recently, *MyoD1* mutations have been found in both spindle cell and sclerosing rhabdomyosarcomas, suggesting a strong relationship between these two entities.[778,778a] In fact, some data suggest that tumors with *MyoD1* mutations pursue a relatively aggressive clinical course.[778a] A subset of congenital cases of spindle cell/sclerosing rhabdomyosarcoma display *NCOA2* gene rearrangements, whereas tumors occurring in older children or adults tend to harbor *MyoD1* gene mutations, with or without mutations in *PIK3CA*.[778b] Immunohistochemically, spindle cell/sclerosing rhabdomyosarcomas tend to show even more nuclear immunoreactivity for *MyoD1* than for myogenin.[778]

Epithelioid rhabdomyosarcoma is a recently described variant that mostly arises in middle-aged to elderly patients, especially males, usually in the extremities, head and neck, or trunk.[779] It is composed of sheets of large epithelioid cells with abundant eosinophilic cytoplasm, vesicular nuclei, and prominent nucleoli reminiscent of melanoma or carcinoma.[780] It is highly aggressive, as one would expect based upon the high-grade histologic features.

Alveolar rhabdomyosarcoma predominates in an older age group (10–25 years) when compared to embryonal rhabdomyosarcoma and occurs more frequently in the extremities, the most common locations being forearms, arms, and perirectal and perineal regions. It also occurs in the head and neck, including the parameningeal region.[781,782]

Microscopically, small, round, or oval tumor cells are seen separated into nests by connective tissue septa (Figs. 41.156 to 41.158). The tumor cells in contact with these fibrous strands remain firmly attached to them, but the others tend to detach because of a lack of cohesiveness, which results in a typical alveolar or pseudoglandular appearance. The deep acidophilia of the cytoplasm and the presence of occasional multinucleated giant cells are important diagnostic features.[783] Cases in which the alveolar pattern is poorly developed are referred to as the "solid" variant of alveolar rhabdomyosarcoma and are particularly difficult to diagnose.[784]

The poor prognosis of alveolar rhabdomyosarcoma is distinctly worse than for the embryonal variety, even with the current multimodality therapies.[759] The lung and regional lymph nodes are the most common metastatic sites. Peripheral lymph node involvement may be the first manifestation of the disease. A common site for occult primary alveolar rhabdomyosarcoma is the perirectal-perineal region. As described in the following section, alveolar rhabdomyosarcoma is characterized by *PAX-FOXO1A* fusion; although this fusion is more common in patients who pursue an aggressive clinical course, this has not been found to be an independent marker of prognosis.[784a,784b]

Special Techniques in Rhabdomyosarcoma

Electron microscopic features. Ultrastructural examination may confirm a diagnosis of rhabdomyosarcoma through the identification of sarcomere-related structures, such as Z bands, thick and thin filaments in a hexagonal array, an A band containing thick filaments, and H and M bands, or leptomeric structures.[785] Drawbacks of this technique are those related to sampling and the absence of these features in the poorly differentiated cells. These facts, plus the availability of a large panel of relatively specific immunohistochemical (and, in the case of alveolar rhabdomyosarcoma, molecular) markers, has greatly diminished the diagnostic utility of electron microscopy in this field.

Histochemical and immunohistochemical features. Hardly any other tumor type has been described for which the array of markers is as varied as for rhabdomyosarcoma, and the list continues to grow.[786] There is a range of specificity and sensitivity among these markers, and this translates into their relative practical utility.

Myogenin is clearly the most sensitive and specific marker of rhabdomyosarcoma (Fig. 41.159). The myogenin gene codes for a phosphoprotein that induces skeletal muscle differentiation in

Figure 41.156 Gross Appearance of Alveolar Rhabdomyosarcoma. The tumor is embedded within skeletal muscle.

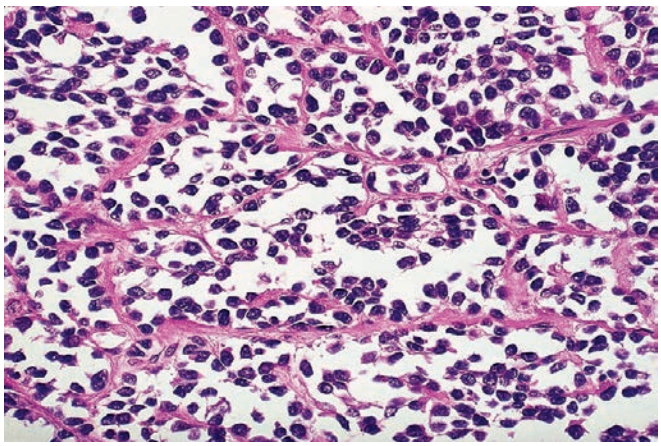

Figure 41.157 Typical low-power appearance of alveolar rhabdomyosarcoma with alignment of tumor cells along fibrovascular septa.

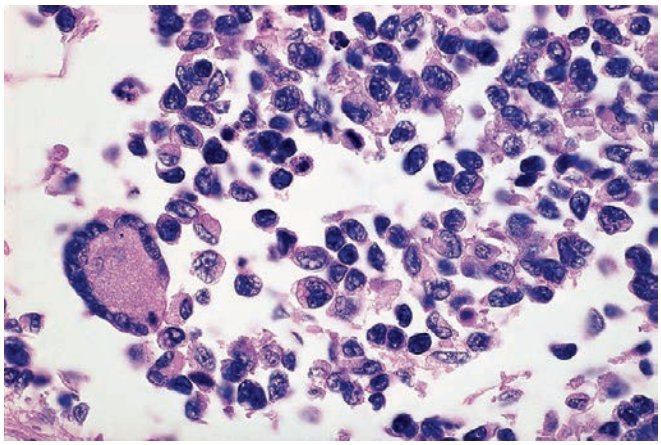

Figure 41.158 Alveolar rhabdomyosarcoma showing a multinucleated tumor giant cell among the smaller mononuclear cells, an important diagnostic clue.

mesenchymal cells. The protein can be demonstrated in the nuclei of the tumor cells in all types and virtually all cases of rhabdomyosarcoma, but it is expressed in a particularly strong and diffuse fashion in the alveolar type.[787–789] Diffuse expression of this marker has been found to be an independent marker of poor survival in pediatric rhabdomyosarcoma.[790] MyoD1 is a related nuclear protein with a similar degree of specificity, but—in contrast to myogenin—not well demonstrated in formalin-fixed, paraffin-embedded material, and therefore of lesser diagnostic utility.[789,791] Desmin is an intermediate filament that is a specific indicator for muscle differentiation, but it is present in both smooth and striated muscle. In general, only tumors with round rhabdomyoblasts or strap cells show positivity for this marker.[792] Rhabdomyosarcomas consistently express sarcomeric actin, which represents one of the best markers for this tumor.[793] Rhabdomyosarcoma cells also express muscle-specific actin, but little or no SMA. Other markers including myosin, myoglobin, titin, and Z-protein have also been reported but are less useful and less frequently used in clinical practice.

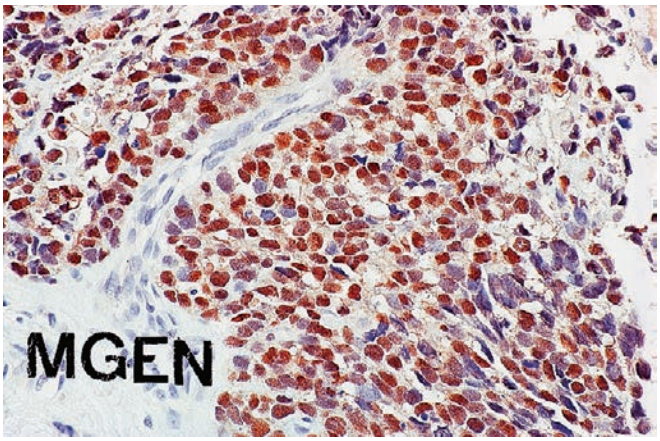

Figure 41.159 Strong nuclear immunoreactivity for myogenin (MGEN) in alveolar rhabdomyosarcoma.

This is a wide and somewhat confusing choice of options. In our institution, we most often utilize myogenin and desmin for the routine investigation of these neoplasms. It also should be mentioned that some cases, particularly the alveolar subtype, express cytokeratins and neuroendocrine markers.[794] As previously mentioned, the spindle cell/sclerosing rhabdomyosarcoma family tends to stain more intensely for MyoD1.

Molecular genetic features. Approximately 75%–80% of alveolar rhabdomyosarcomas are associated with the translocation t(2;13) or t(1;13), which results in the gene fusions *PAX3-FOXO1A* and *PAX7-FOXO1A*, respectively (*FOXO1A* being previously known as *FKHR*).[795–797] The translocations can be detected in paraffin-embedded tissue with the FISH technique.[798] There is limited correlation between the morphologic appearance and the presence or absence of *PAX/FOXO1A* fusion or type of fusion.[799] In a study by Sorensen et al., alveolar rhabdomyosarcomas with *PAX3-FOXO1A* were associated with a more aggressive clinical course than those having *PAX7-FOXO1A*.[797] Up to 20% of cases diagnosed morphologically as alveolar rhabdomyosarcoma are fusion *(FOXO1A)* negative. Interestingly, array analysis of such tumors has shown significant overlap with embryonal rhabdomyosarcoma, raising consideration that these tumors are in fact poorly differentiated embryonal rhabdomyosarcomas with morphologic features suggestive of the alveolar subtype.[800] *MYCN* amplification has been detected in close to half of alveolar rhabdomyosarcomas but not in the embryonal types.[801]

Embryonal rhabdomyosarcomas do not exhibit the distinctive genetic alterations of alveolar rhabdomyosarcomas. They often show complex karyotypes, commonly with gains of chromosomes 2, 8, and 13.[802] Most cases show allelic loss of 11p15, the same genetic region altered in Beckwith–Wiedemann syndrome (an imprinting disorder resulting from mutations or epigenetic events affecting imprinted genes at 11p15.5).[803]

Osseous or Cartilaginous Tumors

Soft tissue (extraskeletal) chondromas are seen most frequently in the soft tissues of the hands and feet of adults.[804,805] Grossly, they are lobulated, have a typical hyaline appearance, and are often calcified (Fig. 41.160). Some show features reminiscent of chondroblastoma with hypercellularity, numerous multinucleated giant cells, and delicate calcification (Fig. 41.161).[806] Chondrosarcomas of the hands and feet exist, but they are exceptionally rare.[807] The occasional presence of a cellular fibroblastic growth around the lobules may prompt confusion with calcifying aponeurotic fibroma. Also confusing is the fact that sometimes the cartilaginous cells have an acidophilic cytoplasm simulating that of a histiocyte and sometimes a vacuolated appearance reminiscent of a lipoblast. Local recurrence is not infrequent.

Soft tissue (extraskeletal) chondrosarcoma, when used without a qualifier, refers to a soft tissue neoplasm composed of lobules of well-differentiated cartilage. In general, these tumors exhibit a less aggressive behavior than their skeletal counterparts.[808]

Extraskeletal myxoid chondrosarcoma is a specific type of soft tissue tumor, which may have been incorrectly named, given that there is accumulating evidence to the effect that it is unrelated to cartilage (Fig. 41.162).[809,810] This tumor type rarely if ever occurs within bone.[811] Most of the cases arise in the extremities of adult patients,[812–814] but they have also been reported in the trunk and/or in children.[815] Microscopically, the tumor is characterized by a multinodular growth pattern, often associated with prominent hemorrhage and hemosiderin deposition. There are strands and cords of relatively small cells with acidophilic cytoplasm that are occasionally vacuolated, embedded in an abundant myxoid matrix. Well-differentiated chondrocytes are absent (Fig. 41.163). Glycogen is present in many of the tumor cells and acid mucopolysaccharides are abundant in the myxoid stroma, which are resistant to hyaluronidase treatment because they are largely composed of chondroitin-4-sulfate, chondroitin-6-sulfate, and keratan sulfate. Rhabdoid features may be present; as usual, they portend an aggressive behavior.[816] A high-grade form of myxoid chondrosarcoma has been described, characterized by the presence of numerous large epithelioid cells and a very aggressive behavior.[817]

Ultrastructurally, the most conspicuous features of the cells of myxoid chondrosarcoma are a well-developed granular endoplasmic reticulum (sometimes containing peculiar parallel microtubules, a very distinctive feature of this entity), abundant cytoplasmic filaments, and cytoplasmic glycogen.[818,819] In addition, some tumor cells have been shown to contain microtubules and neuroendocrine-type granules.[820] Immunohistochemically, myxoid chondrosarcomas are only focally positive for S-100 protein, much less so than one would expect in a true cartilaginous neoplasm. We and others have found that a high proportion of the cases show focal immunoreactivity for neural/neuroendocrine markers, such as NSE, CD56, synaptophysin, and Tau proteins (microtubule-associated proteins required for

polymerization of tubulin) but not for keratin.[821–823] These findings, which are supported by microarray analyses,[824] suggest that this peculiar lesion may represent a primary myxoid neuroendocrine tumor of soft tissue.

Cytogenetically, myxoid chondrosarcoma is characterized most commonly by a specific chromosomal translocation t(9;22)(q22-31;q11-12),[825] or t(9;17)(q22;q11) that results in the gene fusions *EWSR1-NR4A3* (formerly *EWS-CHN*) or *RBP56-NR4A3* (formerly *RBP56-CHN*), respectively.[826] These alterations are detectable in paraffin-embedded material with the FISH technique.[827]

Extraskeletal myxoid chondrosarcoma is an aggressive neoplasm that recurs locally and metastasizes distantly, particularly to the lungs[813,828,829]; in some instances, the lung metastasis is the first manifestation of the tumor.[830]

It seems likely that cases reported as *chordoid sarcoma* or *chordoid tumor*[831,832] belong to the same category as extraskeletal myxoid chondrosarcoma, whereas the cases published as *parachordomas*[833] are clearly related to myoepitheliomas of soft tissue.

Mesenchymal chondrosarcoma has been described in the orbit, dura, trunk, retroperitoneum, extremities, and kidney, among other locations.[834–836] Like its counterpart in bone, it is characterized microscopically by an alternating pattern of highly cellular undifferentiated small cells (often growing in a hemangiopericytoma-like fashion) and islands of well-differentiated cartilage (Fig. 41.164). Immunohistochemically, it may show a polyphenotypic profile, including expression of CD99 (in the small cell component), S-100 protein (in the cartilaginous component), and focal positivity for actin, desmin, myogenin, and NSE.[837] Despite the morphologic resemblance of the small cell component of mesenchymal chondrosarcoma to Ewing sarcoma/PNET, the chromosomal translocation associated with the latter is uniformly absent. Recently, these tumors have been found to harbor a *HEY1-NCOA2* gene fusion and more rarely a *IRF2BP2-CDX1* fusion.[838] The prognosis is poor.[836]

Soft tissue (extraskeletal) osteosarcoma is distinguished from chondrosarcoma by applying the same criteria used for skeletal tumors (i.e., the occurrence of osteoid and bone formation directly produced by the tumor cells, without interposition of cartilage).[839] It usually occurs in the extremities of adults.[840] A small proportion of these tumors arise following exposure to x-rays.[841] As for their counterpart in the skeletal system, the predominant histologic pattern may be osteoblastic, chondroblastic, fibroblastic, MFH-like, telangiectatic, or well differentiated (the latter being analogous to parosteal osteosarcoma) (Fig. 41.165).[842,843] The immunohistochemical profile is also analogous to that of skeletal osteosarcoma, including expression of osteocalcin, osteonectin, and SATB2.[844,844a] In general, the prognosis is much worse than for chondrosarcoma, the overall mortality rate being over 60%.[845] However, well-differentiated variants associated with an indolent clinical course do occur.[846] The most important differential diagnosis of extraskeletal osteosarcoma is with myositis ossificans. The presence of marked nuclear atypia and lack of differentiation ("zone phenomenon") are the critical distinguishing features. It should also be distinguished from other soft tissue tumors in which metaplastic bone is formed (e.g., synovial sarcoma, UPS).

Tumors of Extragonadal Germ Cells

Soft tissue teratomas are more frequent in females and present either at birth or in early childhood.[847,848] In some cases, there is an association with twinning or malformations. The most common locations, in descending order of frequency, are the sacrococcygeal area, head and neck, retroperitoneum, mediastinum, and CNS.[849,850] Taken as a whole, approximately three-fourths are benign. However, there are important variations in the incidence of malignancy according to location, completeness of resection, age, and sex.[848] Nearly all teratomas presenting in the neck during infancy are benign, usually asymmetric, and massive; the rare teratomas of the neck presenting in adults have a high incidence of malignancy.[851]

The terminology and diagnostic criteria used in the evaluation of these lesions are the same as for those of gonadal origin. The

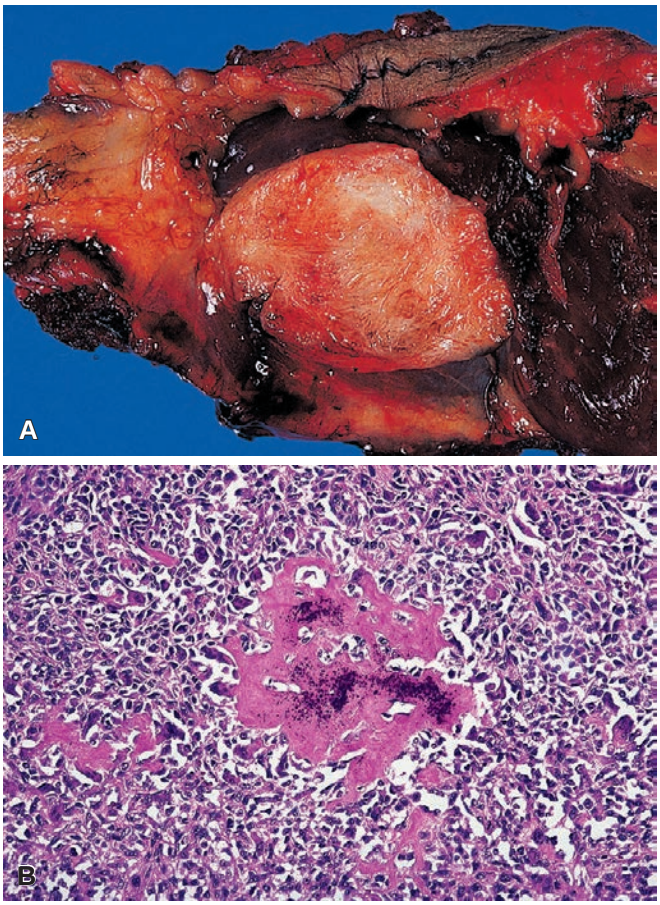

Figure 41.165 Extraskeletal Osteosarcoma. A, The neoplasm is embedded within skeletal muscle and is relatively well circumscribed. **B,** Extraskeletal osteosarcoma with a central nidus of neoplastic bone.

benign form is often multicystic and contains a variety of well-differentiated tissues. The malignant types may have the appearance of teratocarcinoma, embryonal carcinoma, or yolk sac tumor. Immature neuroectodermal components are common in otherwise mature teratomas; although they occasionally exhibit metastasizing capacity, their natural tendency is toward spontaneous maturation.[852]

Tumors of Neural Tissue (Other Than Peripheral Nerves)

Melanotic neuroectodermal tumor of infancy has been referred to by a variety of names including pigmented neuroectodermal tumor of infancy, melanotic progonoma, and retinal anlage tumor. It is a neurally derived neoplasm and is generally located at the root of the nose in infants (also referred to a nasal glial heterotopia), but it can occur in other sites.[853] The classic location is the maxilla, but it also has been reported in a number of other sites including the mandible, skull, and other bones, mediastinum, soft tissues (thigh, forearm, cheek), and epididymis.[854] Microscopically, most tumor cells are small and round, with the appearance of neuroblasts (Fig. 41.166). As a result, this tumor may be misdiagnosed as neuroblastoma. The diagnostic feature is the presence of pseudoglandular or alveolar formations lined by a wall of larger cells containing abundant CNS-type (spiculated) melanin in their cytoplasm. Rarely, a skeletal muscle component is present.[855] Immunohistochemically, the large cells are strongly reactive for cytokeratin and HMB-45 and less so for NSE, whereas the small cells show only positivity for NSE. Both cell components are negative for S-100 protein.[856,857] Ultrastructurally, there are melanosomes at various stages of maturation in the large cells and neurosecretory granules and cytoplasmic processes in the small cells.[855]

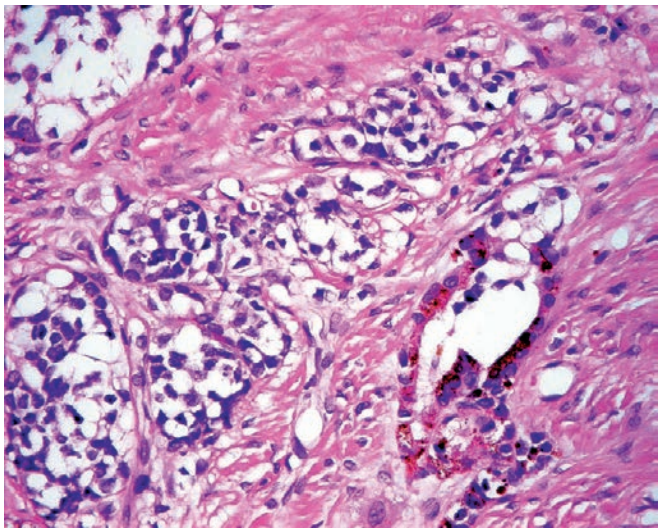

Figure 41.166 Melanotic Neuroectodermal Tumor of Infancy. Nests of neuroblast-like cells are adjacent to gland-like spaces lined by larger cells containing neural-type melanin.

Figure 41.167 Myxopapillary ependymoma of the sacrococcygeal region resulting in a huge protruding mass that is focally ulcerated. (Courtesy of Dr. Juan Jose Segura, San Jose, Costa Rica.)

The clinical course is usually benign. Most supposedly malignant varieties probably represent malignant teratomas with a pigmented neuroectodermal component. However, unquestionable recurrent and metastatic cases of pigmented neuroectodermal tumor of infancy have been reported.[855,858]

Meningiomas can present as a soft tissue mass at the base of the nose or scalp.[859,860]

Myxopapillary ependymomas can appear as soft tissue masses over the sacrococcygeal area, unconnected with the spine or spinal cord structures.[861] The clinical diagnosis is usually that of pilonidal cyst. Grossly, they are well circumscribed and can be shelled out easily (Fig. 41.167). Their microscopic appearance is homologous to that of their more common counterpart in the filum terminale and cauda equina (Fig. 41.168). Metastases arise in approximately one-fifth of cases.[862]

Myxopapillary ependymomas should be distinguished from sacrococcygeal ependymal rests, which probably represent their

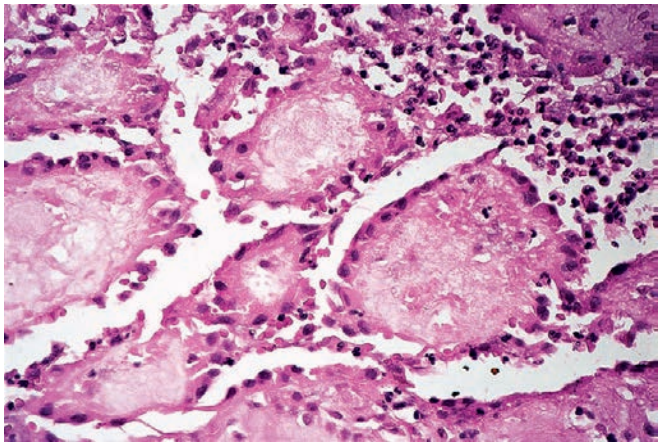

Figure 41.168 Myxopapillary ependymoma involving soft tissues of buttock. The tumor papillae have an abundant hyalinized core.

precursors. These are small (less than 0.5 cm) nodules that are usually found incidentally in tissue from pilonidal sinuses and consist of clusters of ependymal cells near the junction of the dermis and subcutis.[863,864]

Gliomas of soft tissue are generally located at the root of the nose in infants, but they can occur in other sites such as orbit, scalp, chest wall, and gluteal region[865]; they are probably not neoplasms but examples of heterotopic glial tissue (Fig. 41.169).[866]

Tumors of Hematopoietic Tissue

Malignant lymphomas may exceptionally manifest themselves initially as soft tissue masses, usually located in an extremity.[867] This occurrence is more common with non-Hodgkin lymphomas than with Hodgkin lymphoma, but both of these major types occur. Most cases are of B-cell derivation, but examples of peripheral T-cell lymphoma (including NK and NK-like T-cell lymphomas) with primary involvement of soft tissues are on record.[868,869] Exceptionally, these lymphomas develop in areas of post-mastectomy lymphedema and are confused clinically with angiosarcoma.[870]

True **histiocytic sarcomas** have been described in soft tissues.[871] Microscopically, they are composed of sheets of large epithelioid cells with abundant eosinophilic cytoplasm, round to oval (sometimes indented) nuclei, and large nucleoli. Some of the tumor cells are bi- or multinucleated. Immunohistochemically, they are reactive to CD45, CD45RO, CD68, and CD163. They also often express CD4, lysozyme, and CD31.[871]

Plasmacytomas of soft tissue represent, for the most part, direct extension from underlying osseous foci.[872] However, isolated soft tissue plasmacytomas can rarely occur in the absence of bone involvement; they have a tendency to become disseminated.

Extramedullary hematopoiesis may present in the form of nodules in the mediastinum, retroperitoneum, or other soft tissue areas; they have been described in agnogenic myeloid metaplasia and congenital spherocytosis and in other types of anemia,[873,874] and should be distinguished from myelolipoma.

Miscellaneous Tumors and Tumors of Uncertain Cell Type

Synovial Sarcoma

Synovial sarcoma typically arises near the knee and ankle joints of children and young adults,[875] but it can also occur in older patients.[876]

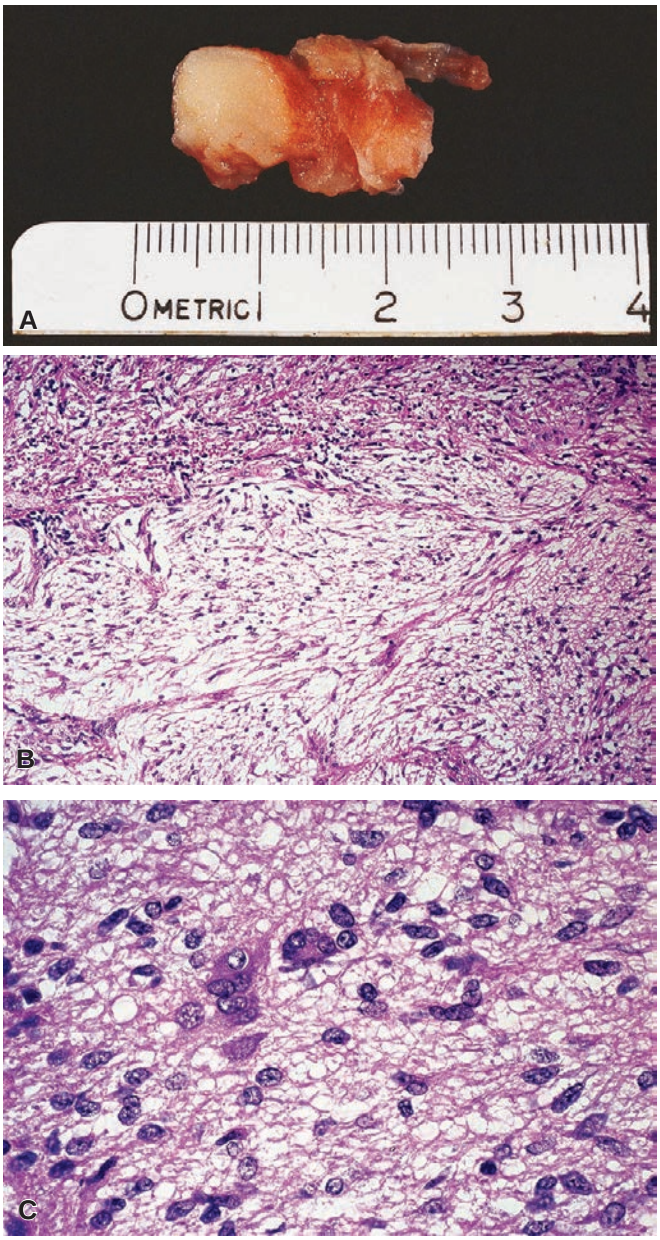

Figure 41.169 Soft Tissue Glioma Involving the Orbit. A, Gross appearance; **B,** Low-power view; **C,** High-power view showing the glial fibrillary background and scattered multinucleated cells. This lesion is probably a malformation rather than a true neoplasm.

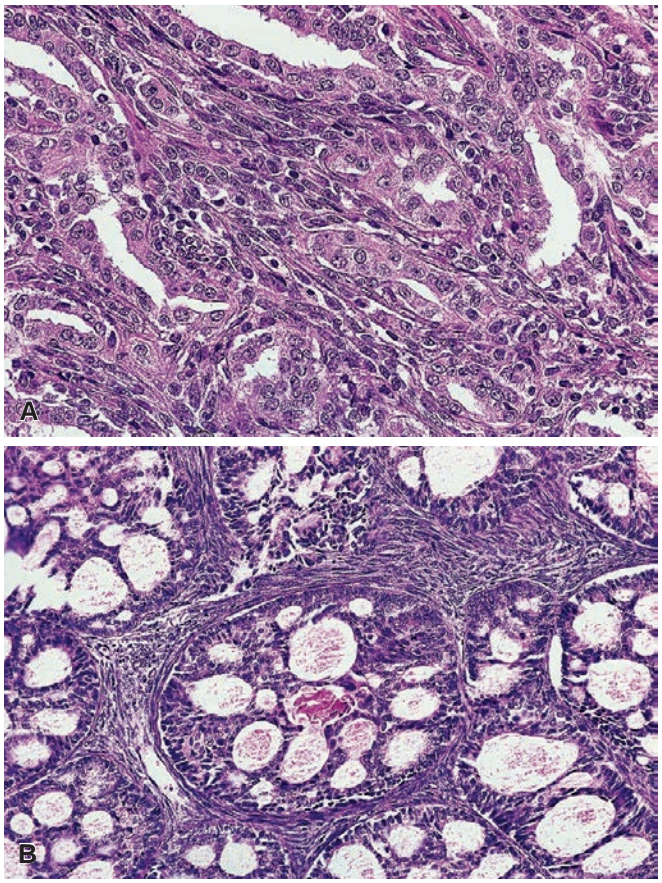
It also occurs around other joints, such as the shoulder and hip. It often grows close to the joints, tendon sheaths, and bursae, but it is extremely rare for it to actually invade the joint space and synovial membrane, with which it is probably unrelated. This tumor has been described in virtually every anatomic site so it should always be considered in the differential diagnosis of any cellular spindle cell tumor.

Grossly, it tends to be well circumscribed, firm, and grayish pink (Fig. 41.170). Focal calcification is frequent and may be detected radiographically.[877] When located in the hands or feet, it may be extremely small.[878]

Microscopically, one form of synovial sarcoma is that of a *biphasic* tumor composed of sharply segregated epithelial and sarcomatous components (the terms being used descriptively and not

Figure 41.170 Gross appearance of deep-seated synovial sarcoma involving periosteum of the femur in an adolescent boy.



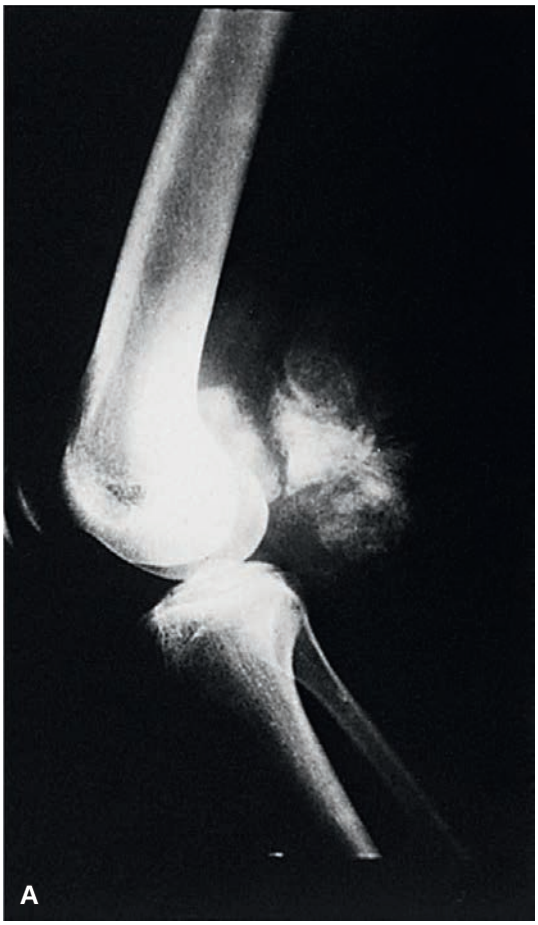


Figure 41.171 **A,** Typical biphasic appearance of synovial sarcoma. **B,** Synovial sarcoma with an adenocarcinoma-like appearance of the epithelial component.

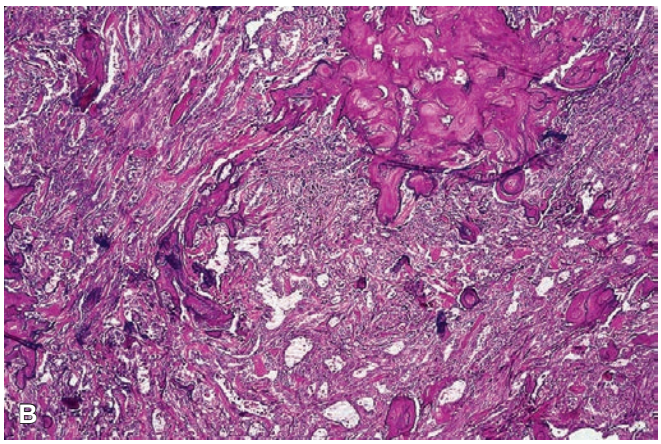

Figure 41.172 **A,** Radiographic appearance of a calcifying synovial sarcoma located in the popliteal space. **B,** Microscopic appearance. (**A,** from Varela-Duran J, Enzinger FM. Calcifying synovial sarcoma. A clinicopathologic study of 32 cases. *Cancer*. 1982;50:345–352.)

histogenetically) (Fig. 41.171). The epithelial areas usually appear in the form of gland-like spaces lined by cuboidal or columnar cells but can also present as solid nests of large pale cells.

The sarcomatous component is composed of spindle cells with a fibroblast-like appearance. It tends to be hypercellular but with a relatively monotonous appearance, plump nuclei, a focally whorled pattern, distinct lobulation or fasciculation, a focal hemangiopericytoma-like vascular pattern and a prominent number of mast cells. Hyalinization, calcification, and osseous metaplasia can be present. When the calcification is particularly heavy, the term *calcifying synovial sarcoma* has been used,[879] which rarely can be extensive enough to obscure the true nature of the tumor (Fig. 41.172).[880] In other instances, the stroma may have a prominent myxoid quality.[881]

Monophasic synovial sarcoma is composed of only one of the two components. In the large majority of cases, this applies to the spindle

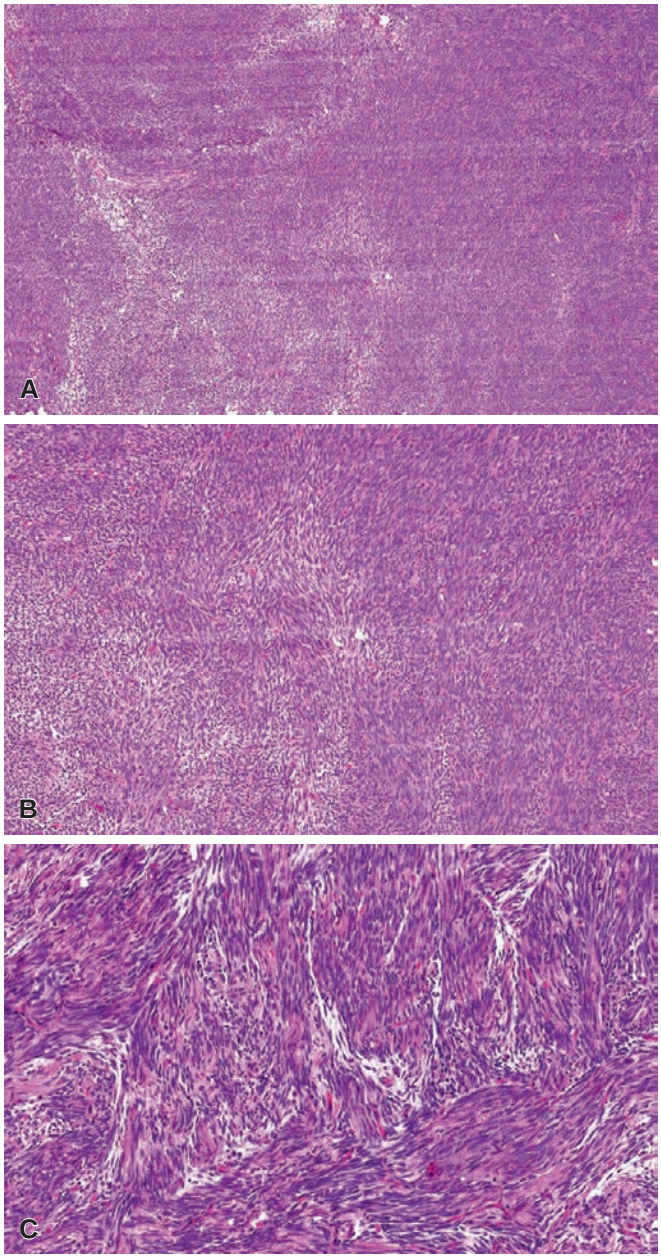

Figure 41.173 **A,** Low-power view of monophasic synovial sarcoma with spindle cells arranged in fascicles imparting a "marbled" appearance. **B,** Fascicles of spindle cells in monophasic synovial sarcoma. **C,** High-power view of uniform, slightly plump spindle cells in monophasic synovial sarcoma.

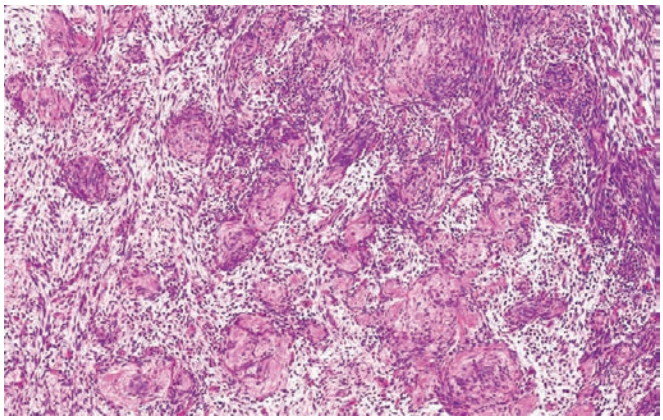

Figure 41.174 Myxoid areas with prominent collagen deposition in monophasic synovial sarcoma.

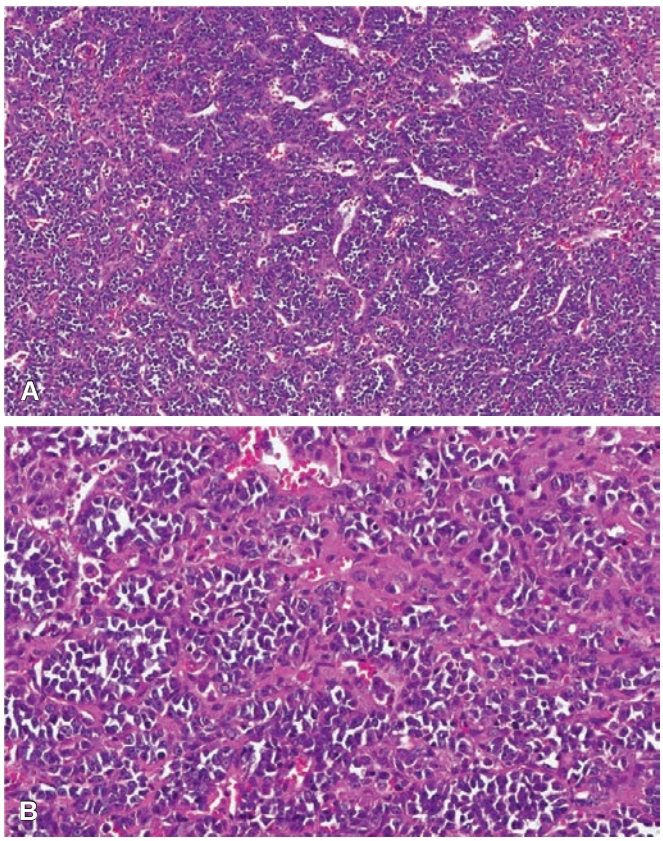

Figure 41.175 Low-power **(A)** and high-power **(B)** views of a poorly differentiated synovial sarcoma composed of high-grade round cells surrounding a hemangiopericytoma-like vascular pattern.

cell sarcomatous component, which is easily misdiagnosed as fibrosarcoma, MPNST, or some other spindle cell neoplasm (Figs. 41.173 and 41.174). A search for epithelial-looking foci should be carried out in these situations, as well as a thorough immunohistochemical (and possibly molecular) evaluation (see later).

Theoretically, a monophasic form of synovial sarcoma composed only of the epithelial elements of the tumor should also exist. The fact that in some neoplasms the glandular elements are so prominent as to simulate a metastatic adenocarcinoma cannot be denied.[882] However, the existence of a pure form of monophasic epithelial synovial sarcoma has yet to be convincingly demonstrated at the cytogenetic/molecular level.

A *poorly differentiated* form of synovial sarcoma also exists and is characterized by a greater degree of cellularity, atypia, and mitotic activity.[883–885] The tumor cells may be round, spindled, or large and clear (Fig. 41.175).[886]

Ultrastructurally, the epithelial areas have features of true glandular epithelium; subtle features of epithelial differentiation are sometimes also found in the spindle cell component, such as intercellular spaces within processes and specialized cell junctions.[887]

Immunohistochemically, there is strong reactivity for cytokeratin in the epithelial areas and often in the spindle cells as well, although

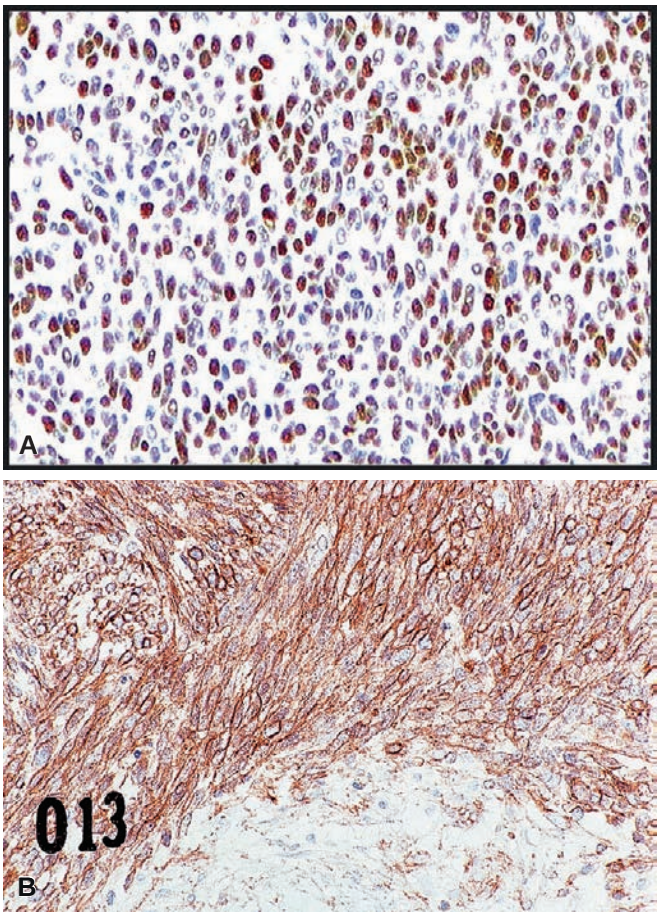

Figure 41.176 **A,** Strong nuclear TLE3 immunoreactivity in monophasic synovial sarcoma. **B,** Strong CD99 immunoreactivity in monophasic synovial sarcoma.

the latter areas usually stain in a patchy manner.[888] Synovial sarcoma shows positivity for cytokeratins 7, 14, and 19, as well as for the specialized cell junction-associated protein desmoplakin ZO-1, claudin-1, and occludin.[889–891] Some cases of monophasic synovial sarcoma stain for EMA and may not express cytokeratin. Patchy staining for S-100 protein is seen in up to 30% of cases and may cause confusion with MPNST,[892] although the former very rarely stain for SOX10, in contrast to the latter.[398] It has also been found that a significant number of cases of synovial sarcoma are immunoreactive for CD99, the marker characteristically associated with Ewing sarcoma.[893] Other frequently positive markers include BCL2,[894] calponin,[895] calretinin (which may cause confusion with mesothelioma),[896] and TLE1 (a transcriptional corepressor that inhibits Wnt signaling) (Fig. 41.176).[897] The latter marker typically shows strong and diffuse nuclear staining and, at least in our hands, rarely stains MPNST (usually in a small percentage of cells).

Synovial sarcoma exhibits in over 90% of the cases the chromosomal translocation t(X;18)(p11.2;q11.2), which results in the fusion of the *SS18* (formerly known as *SYT*) gene on chromosome 18 with either *SSX1* (in two-thirds of the cases) or *SSX2* (the other third) on chromosome X.[898] This highly specific genetic alteration can be detected with RT-PCR in fresh or paraffin-embedded material,[899] conventional cytogenetics or FISH,[900,901] and the hybrid protein SS18/SSX can be visualized immunohistochemically.[902] Notably, a high degree of correlation exists between the type of gene fusion and the tumor subtype, in that nearly all biphasic tumors carry the *SS18–SSX1* fusion, whereas most of those with *SS18–SSX2* are monophasic.[903]

Synovial sarcoma can recur locally and metastasize distantly, particularly to the lung and lymph nodes. The incidence of nodal metastases is in the range of 10%–15% (i.e., much higher than that of most soft tissue sarcomas of adults). Synovial sarcoma has been traditionally regarded as a tumor of ominous prognosis; in several series, however, the 5-year survival rate has approached 50%. The prognosis is even better for synovial sarcomas associated with heavy calcification (calcifying synovial sarcoma), where the survival rate reaches the figure of 80%.[879] The prognosis is also related to age (better in young patients),[904] site (better for distal lesions),[905] tumor size (better for tumors less than 5 cm in diameter),[906] status of the surgical margins,[907] mitotic activity (better for tumors having fewer than 15 mitoses per 10 high-power fields),[908] necrosis (worse for tumors having tumor necrosis of more than 50%),[909] rhabdoid cells (worse when present),[910] microscopic grade (which takes into account some of the parameters just listed),[911] dysadherin expression (worse when present, indicating E-cadherin dysfunction),[912] and DNA ploidy pattern (worse for aneuploid tumors).[913] Early reports that the type of gene fusion showed a significant association with prognosis[914] have not been confirmed in other series.[901,915,916]

Myxoma and Related Tumors

Myxomas almost always occur in adults and are more common in females (Fig. 41.177).[917] The diagnosis of myxoma in a child should be seriously questioned. A high proportion of myxomas arise within skeletal muscle (intramuscular myxoma), especially in the thigh region. The prognosis is excellent. In most of the reported series, there was not a single case of local recurrence.[917,918] Multiple intramuscular myxomas are nearly always seen in association with fibrous dysplasia of the bones of the same extremity.[919,920] The presence of multiple myxomas in the skin, breast, or other locations should raise the possibility of Carney complex, which also includes spotty cutaneous pigmentation, nodular pigmented adrenal disease, and other endocrine abnormalities.[921] Another important location of myxoma is the juxta-articular region *(juxta-articular myxoma)*, particularly near the knee.[922]

Microscopically, a typical myxoma has a bland and hypocellular appearance throughout, mitotic activity is practically absent, and blood vessels are extremely scanty (Fig. 41.178). Focal aggregates of foamy histiocytes may be present; these contain neutral fat with the oil red O stain and should not be confused with the lipoblasts of myxoid liposarcoma.[918]

Ultrastructurally, the principal cell of intramuscular myxoma resembles a fibroblast, with prominent granular endoplasmic reticulum, well-developed Golgi apparatus, and cytoplasmic filaments.[923] Immunohistochemically, the cells may stain for smooth muscle actin suggesting focal myofibroblastic differentiation, but the cells are negative for S-100 protein.

Genetically, intramuscular myxoma commonly exhibits activating mutations in the *GNAS1* gene, the same gene involved in the genesis of fibrous dysplasia of bone,[924] resulting in the downstream activation of the cellular oncogene protein c-Fos.[925] Mutations of *GNAS1*, on the other hand, are not seen in juxta-articular myxomas.[926]

The differential diagnosis of myxoma comprises two types of disease. The first is a group of neoplasms in which myxoid change can be a prominent secondary feature, such as liposarcoma, myxofibrosarcoma, chondrosarcoma, leiomyosarcoma, embryonal rhabdomyosarcoma, neurofibroma, nerve sheath myxoma, and aggressive angiomyxoma. If a myxoid tumor is hypercellular and hypervascular, the alternative possibility of low-grade myxofibrosarcoma should be considered. However, a *cellular variant* of myxoma has been described which is more cellular and more vascular than the ordinary type[927,928]; this tumor lacks the pleomorphism, nuclear atypia, and curvilinear vascular pattern of low-grade myxofibrosarcoma.

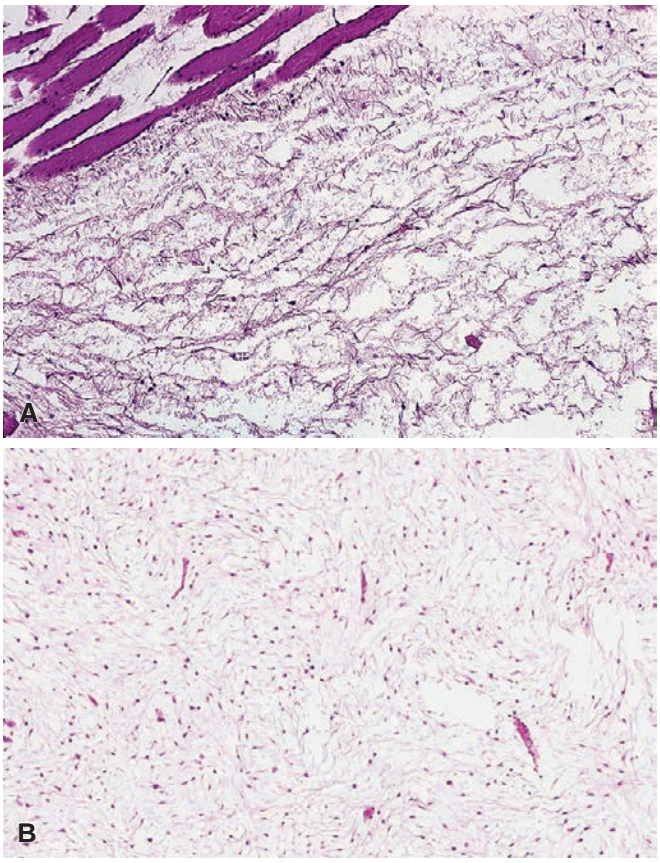

Figure 41.178 Low-power **(A)** and high-power **(B)** views of intramuscular myxoma with a paucity of blood vessels.

The second group of diseases from which myxoma should be distinguished is a variety of non-neoplastic disorders resulting in focal mucinous degeneration of the skin or soft tissues, such as nodular fasciitis, localized myxedema, mucous (myxoid) cyst, ganglion, follicular mucinosis (alopecia mucinosa), papular mucinosis, and cutaneous focal mucinosis.

Alveolar Soft Part Sarcoma

Alveolar soft part sarcoma most often arises in the deep soft tissues of the thigh and leg,[929] but it is not uncommon in the oral cavity and pharynx (including tongue).[930] Other sites of involvement include the mediastinum (sometimes arising from the pulmonary vein), stomach, retroperitoneum, orbit, bladder, uterus, and vagina.[931] Grossly, the tumors are well circumscribed, usually large, moderately firm, and gray or yellowish (Fig. 41.179). Areas of necrosis or hemorrhage are common in the larger neoplasms.[932]

Microscopically, the tumor cells are separated by fibrous septa into well-defined nests. Detachment of the central cells results in the typical alveolar pattern. The individual cells are large and have vesicular nuclei, prominent nucleoli, and a granular cytoplasm (Fig. 41.180). Mitoses are exceptional. PAS stain sometimes demonstrates the presence of diastase-resistant intracytoplasmic needle-like structures (Fig. 41.181A). These are seen by electron microscopy as membrane-bound crystals with a periodicity of 58–100 nm, sometimes arranged in a cross-grid pattern (see Fig. 41.181B).[933] Other ultrastructural features include numerous vesicles with an electron-dense content in the Golgi region (possibly representing the precursors of the crystals) and smooth tubular aggregates associated with plasmalemmal invaginations.[934]

Figure 41.179 Alveolar Soft Part Sarcoma. The tumor is multinodular, relatively well circumscribed, and embedded within skeletal muscle.

Alveolar soft part sarcomas occurring in children are often associated with a more solid pattern of growth and therefore tend to be misdiagnosed. Conversely, the alveolar appearance of this entity can be closely simulated by other malignant neoplasms, notably malignant melanoma (Fig. 41.182), PEComa, and renal cell carcinoma.

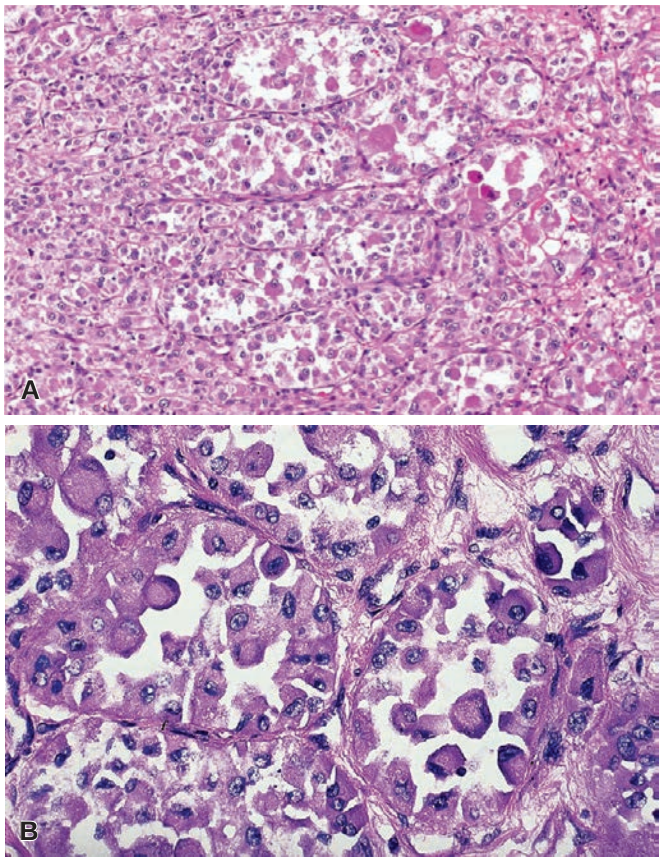

Figure 41.180 Low-power **(A)** and high-power **(B)** views of alveolar soft part sarcoma with a prominent nested growth pattern.

Sciubba, New Hyde Park, New York.)

Alveolar soft part sarcoma is highly malignant, despite its deceptively slow and indolent clinical course. Vein invasion is common. Blood-borne metastases appear in the lungs and other organs as long as 30 years or more following excision of the primary tumor.[929,935] Not infrequently, a metastasis in the lung or another organ is the first manifestation of the disease. There is a good correlation between tumor size and survival.[936]

The histogenesis of this unusual neoplasm has not yet been definitely established. We believe there is no convincing evidence to support the theory that this tumor represents a malignant counterpart of granular cell tumor, that it arises from nonchromaffin paraganglia, or that it is related to renin-producing cells of blood vessel walls. There are some data in recent years supporting the interpretation that alveolar soft part sarcoma is of myogenous derivation including the (admittedly inconsistent) immunohistochemical demonstration of smooth muscle and sarcomeric actin, desmin, Z-protein, fast myosin, β-enolase, and the MM isozyme of creatine kinase.[937–939] Some have demonstrated MyoD1 protein, a nuclear phosphoprotein that is the product of a regulatory gene that controls the commitment of a cell to a myogenic lineage, in the cells of this tumor.[940] In the end, this remains a tumor of uncertain histogenesis.

At the cytogenetic level, alveolar soft part sarcoma has been found to be associated with the chromosomal unbalanced translocation der(17)t(X;17)(p11.2;q25), which results in the fusion of the *TFE3* transcription factor gene to the *ASPSCR1* (formerly known as *ASPL*) gene.[941] Interestingly, a similar but balanced translocation has been detected in a type of renal neoplasm that is probably epithelial but which bears some morphologic resemblance to alveolar soft part sarcoma (see also Chapter 24). The presence of aberrant nuclear

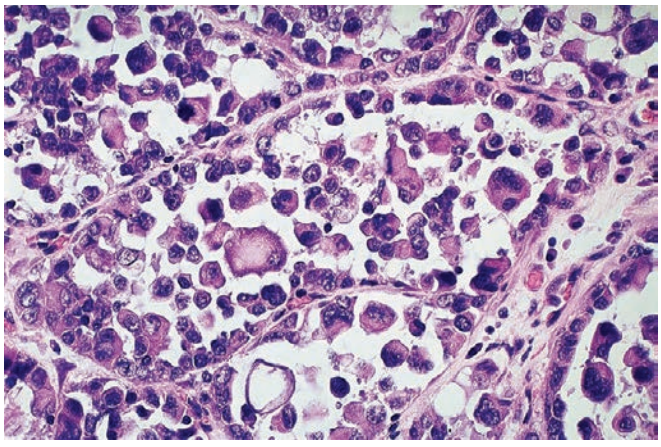

Figure 41.182 Metastatic malignant melanoma closely simulating the appearance of alveolar soft part sarcoma.

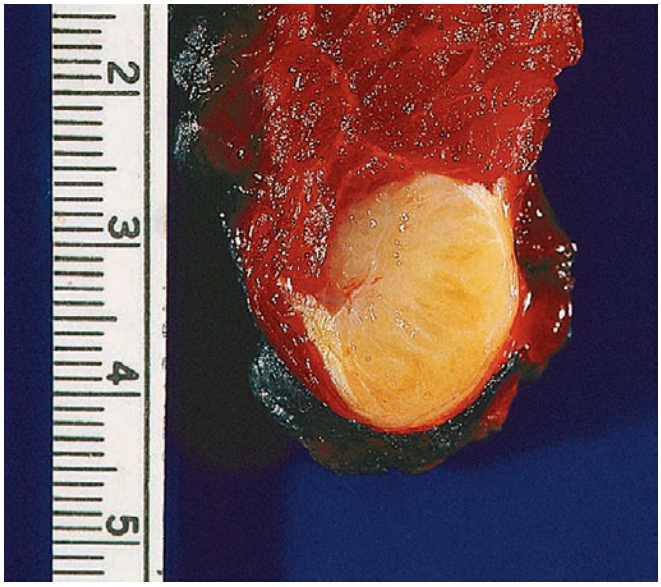

Figure 41.183 Gross appearance of clear cell sarcoma located in the posterior thigh.

expression of TFE3 can be demonstrated in these tumors by immunohistochemistry.[942]

Clear Cell Sarcoma

This malignant tumor arises chiefly in association with large tendons and aponeuroses of the extremities.[943,944] The feet are the most common site, but it has been described in many other sites. Most of the patients are young adults, and there is a male predominance.[945]

Grossly, the tumors are firm, well circumscribed, and gray or white, and cut with a gritty sensation (Fig. 41.183). Microscopically, solid nests and fascicles of pale fusiform or cuboidal cells are present. The nucleoli are large and deeply basophilic (Fig. 41.184). Multinucleated giant cells are often seen. Abundant extracellular and intracellular iron is present. In many of the cases the tumor cells also contain cytoplasmic melanin.[946] In keeping with this observation is the consistent immunoreactivity for S-100 protein, HMB-45, and melan-A,[947,948] as well as the ultrastructural observation of melanosomes.[949] Like conventional melanoma, clear cell sarcoma may rarely exhibit immunoreactivity for cytokeratin.[950]

Clear cell sarcoma is associated with the chromosomal translocation t(12;22)(q13;q12),[951,952] which results in the *EWSR1-ATF1* gene fusion and the expression of the melanocyte-specific splice form of the MiTF transcript.[953] Some cases have a t(2;22) resulting in the *EWSR1-CREB1* fusion, especially those arising in the GI tract.[954–956] However, at least some of the cases arising in the GI tract show no evidence of melanocytic differentiation and are more likely examples of **gastrointestinal neuroectodermal tumor** (GNET, also known as clear cell–like tumor of the GI tract).[957] The latter tumor is composed of nests or sheets of uniform epithelioid or oval to spindled cells with small nucleoli, rare mitoses, and scattered osteoclast-type multinucleated giant cells. Like true clear cell sarcoma, GNET stains strongly for S-100 protein, but there is no immunohistochemical or ultrastructural evidence of melanocytic differentiation.[958]

The clinical course of clear cell sarcoma is characterized by slow but relentless progression with frequent local recurrences and eventual nodal and distant metastases.[959,960] Large tumor size and necrosis are significant predictors of poor prognosis.[960,961]

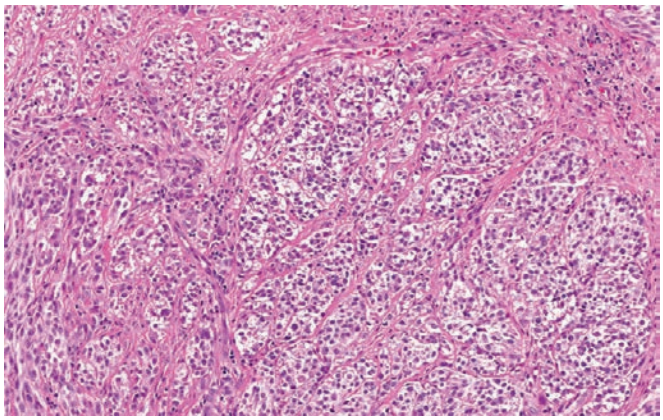

Figure 41.184 Clear cell sarcoma with nests of cells with clear cytoplasm.

Epithelioid Sarcoma

Epithelioid sarcoma usually affects adolescents and young adults.[962,963] The extremities are the most common location, particularly the hands and fingers. The tumors tend to be superficially located and are sometimes centered in the reticular dermis. Others are found in the subcutis or deeper soft tissues, particularly fascial planes, aponeuroses, and tendon sheaths. The necrosis often seen in the center of the nodules and the epithelioid appearance of the tumor cells may result in a mistaken diagnosis of infectious granuloma or, more frequently, necrobiotic granulomatous inflammation (Fig. 41.185).

One of the most characteristic features of this lesion is the striking acidophilia of the tumor, which is due to the combined effect of the staining characteristics of the cytoplasm and the extensive desmoplasia (Fig. 41.186). Metaplastic elements such as bone and cartilage are rarely present.[964] Sometimes, most of the tumor cells have a spindle shape and simulate other spindle cell neoplasms.[965] Some epithelioid sarcomas exhibit rhabdoid features; this is particularly common in the so-called proximal type (see later).[966,967]

Ultrastructurally, the tumor cells exhibit abundant intermediate filaments, desmosome-like cell junctions, and small intercellular spaces surrounded by filopodia or microvilli.[968] Immunohistochemically, the cells stain strongly for cytokeratins (Fig. 41.187), EMA, and often CD34.[969–972] Similar to malignant rhabdoid tumor, SMARCB1/INI1 expression is commonly lost in the neoplastic cells[973,974] and are a manifestation of deletions of the *INI1* gene on chromosome 22q11.2 (Fig. 41.188).[974] Regarding cytokeratin subtypes, Miettinen et al. found positivity for CK8 in 94% of the cases, CK19 in 72%, 34βEH12 in 48%, and CK7 in 22%.[968] CK5/6 is usually negative or expressed only focally, in contrast to squamous cell carcinoma.[975] Some tumors also express ERG, which can be a pitfall with epithelioid angiosarcoma.[976]

The histogenesis of this tumor remains obscure. It clearly exhibits features of epithelial differentiation, but whether the epithelial features present in these tumors derive from metaplasia of mesenchymal elements remains to be determined.

The tumor spreads to noncontiguous areas of skin, soft tissue, fascia, and bone, as well as by direct extension along fascial planes. Local recurrence is the rule, although it may take years for this to develop. Lymph node metastases are relatively common and constitute an ominous prognostic sign.[977] Sometimes lymph node metastasis is the first clinical manifestation of the disease. Metastases also occur in the lungs, other organs, and skin; for some peculiar reason, the scalp is a preferred site.[978] A more aggressive clinical course is associated

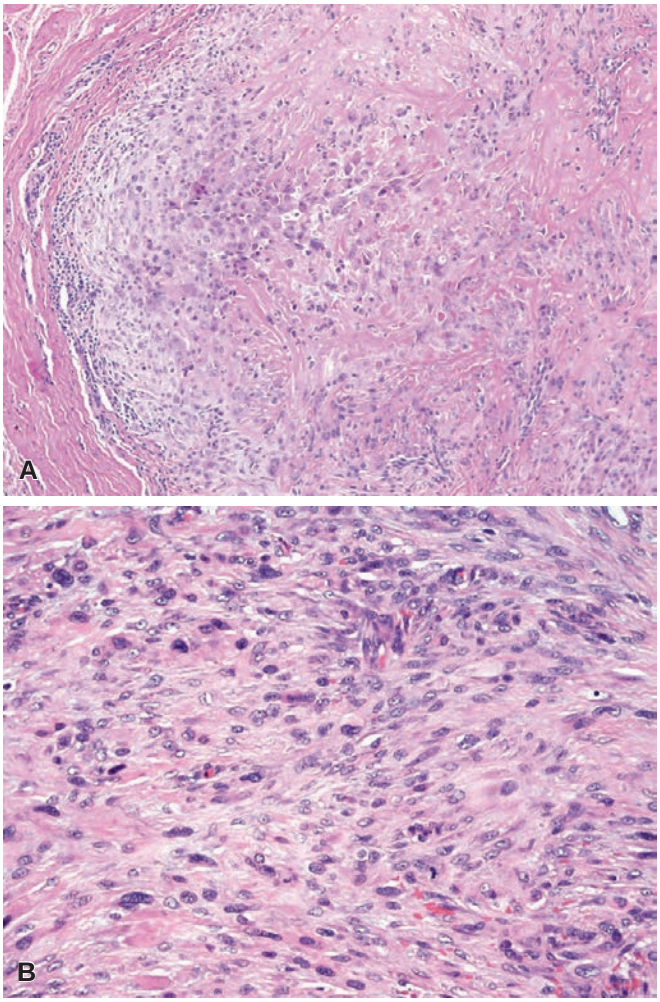

Figure 41.185 Low-power **(A)** and high-power **(B)** views of epithelioid sarcoma. Central necrobiotic areas simulate granuloma annulare or rheumatoid nodule.

with a proximal or axial tumor location, increased size and depth, hemorrhage, mitotic figures, necrosis, rhabdoid features, and vascular invasion.[979,980] Special mention should be made of the *proximal type* of epithelioid sarcoma, characterized by a proximal location (pelvis, perineal and pubic region, vulva, buttock), deep invasion, necrosis, and sometimes prominent rhabdoid features (Fig. 41.189).[981–983] Dysadherin (a cell membrane glycoprotein which downregulates E-cadherin) is expressed more commonly in proximal-type epithelioid sarcoma than in the conventional distal type.[984] Loss of SMARCB1/INI1 is found in almost all cases.[973,985]

Ossifying Fibromyxoid Tumor

Ossifying fibromyxoid tumor is a soft tissue neoplasm that usually presents in adult patients as a small, painless, well-circumscribed mass in the subcutaneous tissue or muscle of the extremities.[986,987] Microscopically, the tumor cells are typically arranged in a cord- or nest-like pattern within a myxoid matrix that blends with foci of fibrosis and osteoid formation. The low-power appearance is distinctive by virtue of lobulation and (in the majority of cases) an incomplete shell of mature bone in the region corresponding to the tumor capsule.[986] The tumor cells are small and round, with minimal atypia and few mitoses (Fig. 41.190).

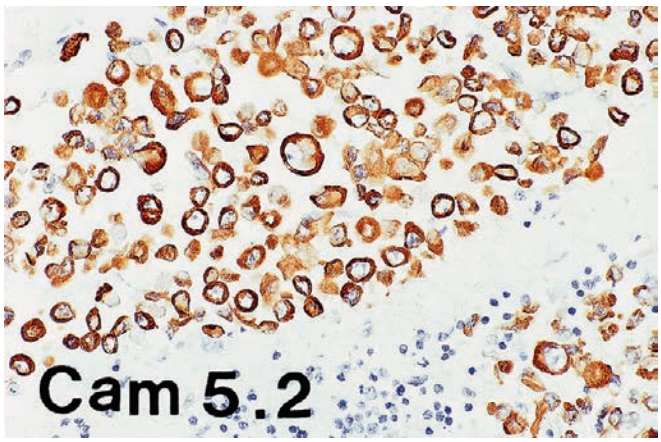

Figure 41.187 Strong cytokeratin immunoreactivity *(CAM5.2)* in epithelioid sarcoma.

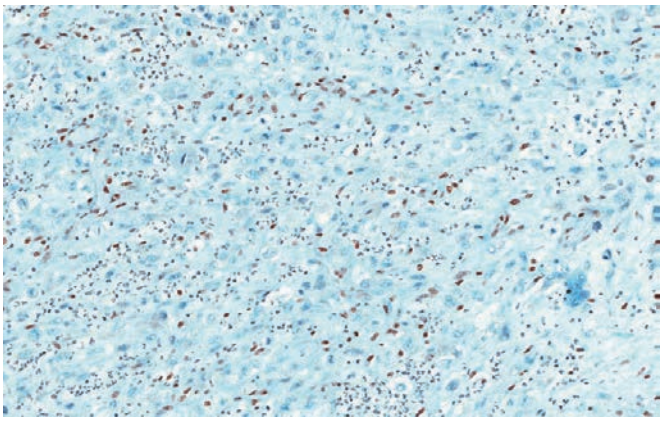

Figure 41.188 Loss of INI1 staining in epithelioid sarcoma. Internal control staining is present in endothelial cells and inflammatory cells.

Immunohistochemically, there is immunoreactivity for S-100 protein (which may be diffuse or patchy), associated with focal reactivity for Leu7 and glial fibrillary acidic protein and negativity for type II collagen.[987] Ultrastructurally, there are complex cell processes and basement membrane deposition suggesting schwannian differentiation.[988] However, the detection of desmin, SMA, and

cytokeratin, plus some ultrastructural features, raise consideration of partial smooth muscle or myoepithelial differentiation.[989,990] Recently, recurrent rearrangement of the *PHF1* gene has been reported in ossifying fibromyxoid tumor (found in almost 50% of the cases, including typical, atypical, and malignant cases).[990a] Rare examples of ossifying fibromyxoid tumor have also been reported with *CREBBT-BCORL1* and *KDM2A-WWTR1* fusions.[990b]

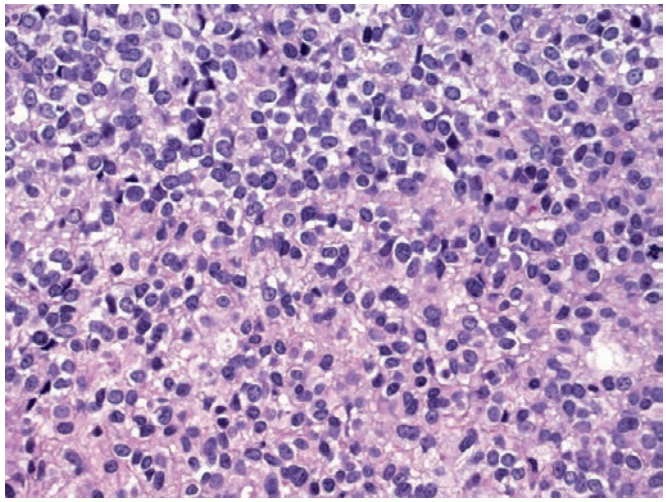

Figure 41.191 Uniform appearance of round cells in classical Ewing sarcoma.

The behavior of this tumor is indolent, but local recurrences develop in up to 25% of patients.[986,987] However, distant metastases are quite rare. Folpe and Weiss found that tumors with high nuclear grade or high cellularity with mitotic activity ≥2 mitotic figures/50 HPF should be considered sarcomas with potential for metastasis.[991]

Extraskeletal Ewing Sarcoma/Primitive Neuroectodermal Tumor (Ewing Family of Tumors)

Tumors morphologically indistinguishable from **Ewing sarcoma** of the skeletal system can present as soft tissue masses. In some cases, they simply represent soft tissue extensions of tumor originating in the underlying bone. In others, bone involvement is absent, and these are regarded as primary extraskeletal Ewing sarcomas.[992] Most of the patients are adolescents or young adults, and the usual sites of involvement are the deep soft tissues of the lower extremity and paravertebral region,[993] but they have been described in virtually every anatomic site. Occasionally, the tumors are superficial, with primary involvement of subcutis or skin.[994] Microscopically, like their skeletal counterpart, they are composed of uniform small, round, or oval cells containing cytoplasmic glycogen (Fig. 41.191). Ultrastructurally, the cells are rather primitive, with abundant cytoplasmic glycogen, poorly developed cell junctions and no overt evidence of neural differentiation.[995] The course is aggressive and distant metastases are common, particularly to lung and skeleton.

On a histologic spectrum with Ewing sarcoma is **peripheral PNET**,[996] which subsumes the clinicopathologic entity originally described as malignant small cell tumor of the thoracopulmonary region (Fig. 41.192).[997] Taken together, this group of neoplasms is often referred to as the Ewing family of tumors (EFT). The nosologic unity of Ewing sarcoma/PNET is strongly supported by the existence of numerous intermediate forms,[992] the strong immunoreactivity for CD99,[998] and—most important—the presence of a consistent chromosomal translocation, most commonly t(11;22)(q24;q12),[999] which leads to the fusion of the Ewing sarcoma gene *(EWSR1)* on chromosome 22 to the *FLI-1* gene (or other partners) on chromosome 11.[1000] This genetic alteration can be detected with RT-PCR or FISH in fresh or paraffin-embedded material.[1001,1002]

CD99 recognizes a cell membrane protein of yet unknown function, which is the product of *MIC2*, a pseudoautosomal gene located

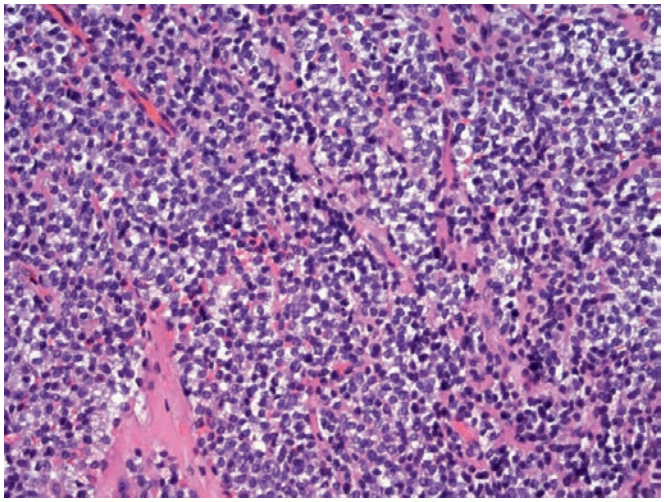

Figure 41.192 Low-power appearance of nests of cells in a peripheral primitive neuroectodermal tumor.

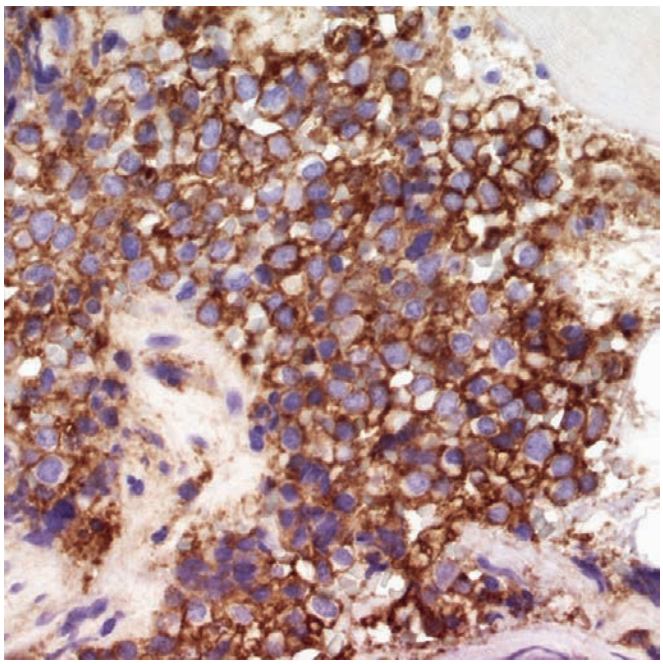

Figure 41.193 Strong CD99 membranous immunoreactivity in a classical Ewing sarcoma.

on the short arm of the X and Y chromosomes (Fig. 41.193).[1003] Although it is a highly sensitive marker of the EFT being found in approximately 95% of cases, it lacks specificity, since it can be detected (albeit with lower frequency) in many other round cell tumors. Importantly, cytokeratin reactivity has been detected in up to 20% of cases, and it may be quite extensive.[1004] Cell junction–related proteins, such as claudin-1 and occludin, are also sometimes expressed.[1005,1006] Many cases also stain with an antibody to FLI-1.[1007] More recently, NKX2-2 has been found to be a highly sensitive but not completely specific marker of this family of tumors, but might be a useful additional marker in the workup of round cell tumors.[1007a]

The claim that tumors having easily detectable neuroectodermal markers run a more aggressive clinical course than those without these markers[996] has not been substantiated.[998] Furthermore, most attempts to subdivide them on phenotypic grounds have been unsuccessful.[1008] When treated in a similar manner, degree of neuroectodermal differentiation has not been found to significantly impact prognosis, and hence the reason to be a "lumper" (EFT), as opposed to a "splitter."

The differential diagnosis of EFT of soft tissues includes alveolar rhabdomyosarcoma (especially the solid variant), malignant lymphoma, desmoplastic small cell tumor, and many other tumors with round cell morphology. A combined morphologic, immunohistochemical, and molecular approach will place most tumors into one or another of these categories.

Also recognized is a group of round cell neoplasms with Ewing-like features but lacking molecular evidence supporting their inclusion in the EFT. Such tumors have been referred to as "*Ewing-like*," but recent molecular discoveries have started to emerge amongst this group of neoplasms. By far, the largest group of Ewing-like round cell sarcomas is comprised of those with *CIC* rearrangements involving the *CIC* and *DUX4* genes located on chromosomes 4 and 19, respectively.[1009–1011] Rare examples show a *CIC-FOXO4* fusion.[1012] These tumors tend to be lobulated with high-grade round cells with focal cytoplasmic clearing and extensive areas of necrosis, often with myxoid change.[1009] A recent large study of 115 cases of *CIC*-rearranged sarcomas had a mean age of 32 years with a slight male predominance, with the vast majority of tumors (86%) arising in the deep soft tissues predominantly of the trunk and extremities.[1012a] Although most cases do show CD99 immunoreactivity (84%), the pattern is more often patchy when compared to the EFT. Most show nuclear WT1 immunoreactivity. In this study, the 5-year survival was only 43%, which was found to be significantly lower than the 77% 5-year survival in the control group of Ewing sarcoma patients.[1012a] Less commonly, a group of Ewing-like round cell sarcomas show evidence of a *BCOR-CCNB3* fusion, although there are less common partners for the *BCOR* gene.[1013–1015a]

Desmoplastic Small Cell Tumor

Desmoplastic small cell tumor is typically located within the abdominal cavity of young patients, especially males, but has also been seen in the pleural cavity, CNS, orbit, and other soft tissue sites.[1016,1017] It is characterized by nests and sheets of small round cells typically surrounded by desmoplastic stroma (Fig. 41.194). Foci of cells with rhabdoid morphology are often seen.[1018] Features which can also be seen include papillary architecture, Homer Wright–like rosettes and spindled zones. Immunohistochemically, this polyphenotypic tumor coexpresses vimentin, cytokeratin, and desmin, the latter typically in a distinct perinuclear globular pattern (Fig. 41.195).[1018] The vast majority also show nuclear positivity for the Wilms tumor gene product (WT1) using antibodies to the carboxy terminus.[1019] Up to 20% stain for CD99, a potential pitfall resulting in a misdiagnosis of EFT. Neural markers including NSE and CD57 are often expressed, but markers including S-100 protein and myogenin are negative.

The tumor is characterized by a unique t(11;22)(p13;q12) involving the *WT1* gene on 11p13 and *EWSR1* gene on 22q12.[1020,1021] This fusion can be detected by FISH or RT-PCR using fresh or paraffin-embedded tissue.[1022,1023] The tumor is highly aggressive, resulting in widespread metastases and often death within 5 years.[1017,1024]

Malignant Extrarenal Rhabdoid Tumor

Tumors with histologic features very similar to rhabdoid tumor of the kidney have been described in virtually every extrarenal site, particularly the soft tissues.[1025,1026] Most patients are infants or children, but it can also occur in adults. Microscopically, solid sheets of cells are present with deeply and homogeneously acidophilic cytoplasm (the

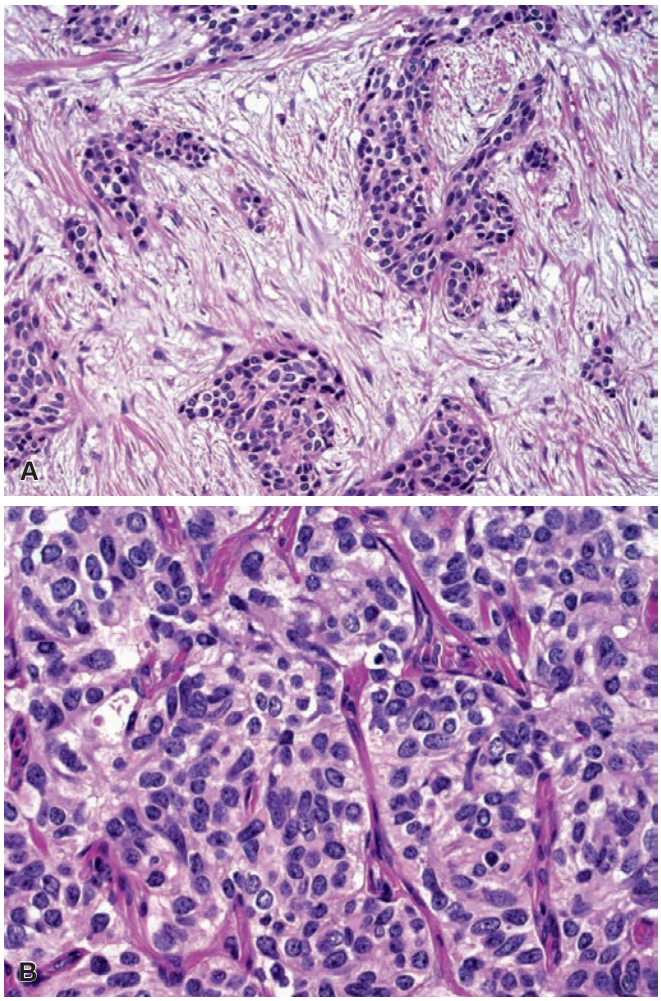

Figure 41.194 **A,** Nests of cells deposited on a desmoplastic stroma in desmoplastic small cell tumor. **B,** High-power view of round cells arranged in nests in desmoplastic small cell tumor.

result of packing by intermediate filaments), with lateral displacement of the nucleus (Fig. 41.196). Myxoid, pseudoalveolar, and hyalinized areas may be present.[1027] Immunohistochemically, there is positivity for vimentin and often for cytokeratin and EMA but generally not for skeletal muscle markers or S-100 protein (Figs. 41.197 and 41.198).[1025,1028] However, a great deal of phenotypic diversity has been recorded in these lesions, including the common expression of neural/neuroendocrine markers.[1025,1029,1030] "De novo" rhabdoid tumors (those that do not represent other specific tumor types showing rhabdoid morphology), like their renal and CNS counterparts, show alterations of chromosome 22, in the form of deletions or translocations involving 22q11.2 (harboring the *hSNF5/INI1/SMARCB1* gene), which can be demonstrated by FISH or loss of heterozygosity studies.[1031,1032] As such, loss of expression of SMARCB1 (INI1) can be revealed by immunohistochemistry in almost all tumors.[1033,1034]

Metastases occur early (to the lungs, liver, and lymph nodes), response to therapy is poor, and the clinical course is extremely aggressive.[1035] Evidence suggests that many rhabdoid tumors of soft tissues are actually an expression of a particular phenotype that can develop in a wide variety of tumor types, including epithelioid sarcoma, synovial sarcoma, desmoplastic small cell tumor, rhabdomyosarcoma, malignant melanoma, and various types of carcinoma.[1027,1029,1036] Of practical importance is the fact that the emergence of the rhabdoid phenotype is invariably associated with an aggressive and often lethal clinical course, regardless of the phenotype of the "parent" tumor.[1025,1037]

Phosphaturic Mesenchymal Tumor

An interesting association has been reported between some tumors of soft tissue or bone and osteomalacia or rickets.[1038,1039] The syndrome results from tumor production of a renal phosphaturic substance that depletes total body phosphates by inhibiting tubular reabsorption of phosphate.[1040] It is characterized biochemically by hypophosphatemia, renal phosphate wasting, and decreased serum 1,25-dihydroxyvitamin D3 levels.[1038] The soft tissue tumors associated with this complication have shown an array of microscopic features.[1041] In our experience, the most characteristic feature has been the association of hemangiopericytoma-like areas and osteoclast-like giant cells, with or without foci of osseous and cartilaginous metaplasia. A "grungy" or flocculent calcified matrix is particularly distinctive (Fig. 41.199). Recently, a unique *FN1-FGFR1* fusion has been detected in this tumor.[1042] Presumably as a result of this fusion, the tumor secretes high levels of fibroblastic growth factor-23 (FGF23) which can be detected by chromogenic in situ hybridization,[277] as commercially available antibodies to FGF23 have dubious specificity.[1041] The behavior is generally benign,[1039] but malignant examples are on record.[1041]

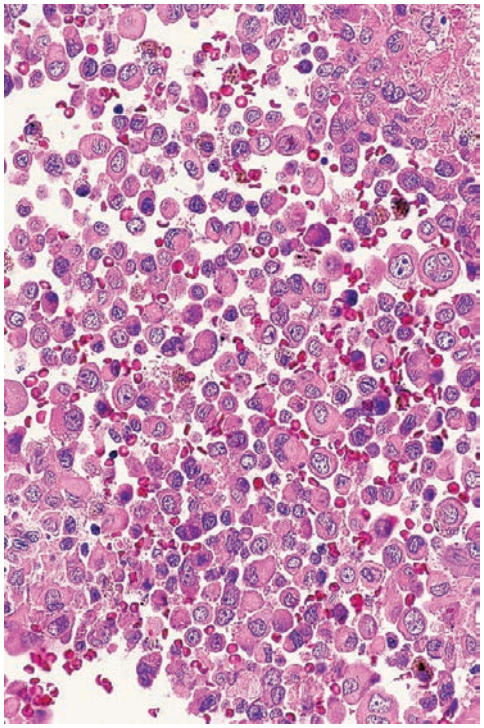

Figure 41.196 Soft tissue tumor of the vulvar region with rhabdoid features.

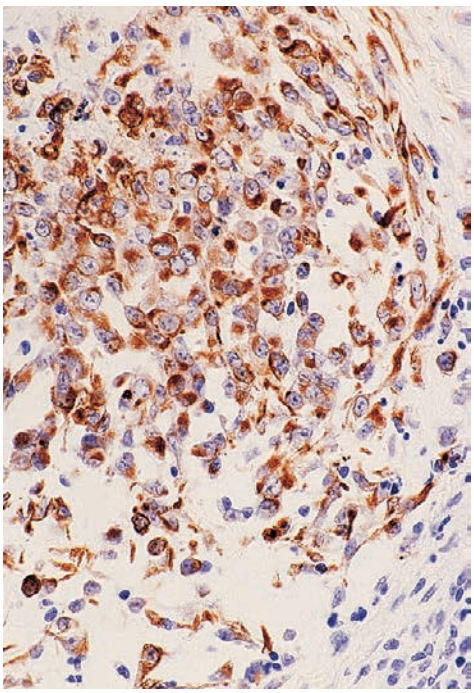

Figure 41.197 Rhabdoid tumor stained for cytokeratin. Perinuclear globular immunoreactivity can be seen in some of the cells.

Pleomorphic Hyalinizing Angiectatic Tumor

Most examples of pleomorphic hyalinizing angiectatic tumor (PHAT) arise in the soft tissues of adults, most commonly in the subcutaneous tissue of the lower extremities.[276,1043] PHAT can simulate schwannoma by virtue of the angiectatic vasculature, the presence of hemosiderin-laden macrophages, and the occurrence of a spindle cell component with scattered bizarre nuclear forms but little mitotic activity.[276,1043] Two diagnostic clues are represented by the nuclear pseudoinclusions and the fact that many of the bizarre cells are embedded within a fibrinous material surrounding the angiectatic vessels (Fig. 41.200). CD34 is focally positive and S-100 protein is negative, thereby excluding schwannoma. In some cases, a monomorphic, partially myxoid spindle cell component resembling HFLT may be identified at the periphery, possibly representing an early stage or precursor lesion (early PHAT).[276]

At the cytogenetic level, some cases of PHAT have been reported to harbor t(1;10) involving a *TGFBR3-MGEA5* fusion[236] similar to what has been described in HFLT and MIFS. This observation raises consideration that these three entities are histogenetically related along a histologic spectrum, but the relationship among these tumors remains a bit unclear.

Local recurrences have been described but not distant metastases.[1043] Some of the recurrences exhibit a sarcomatous appearance, such as high-grade myxofibrosarcoma.[1044]

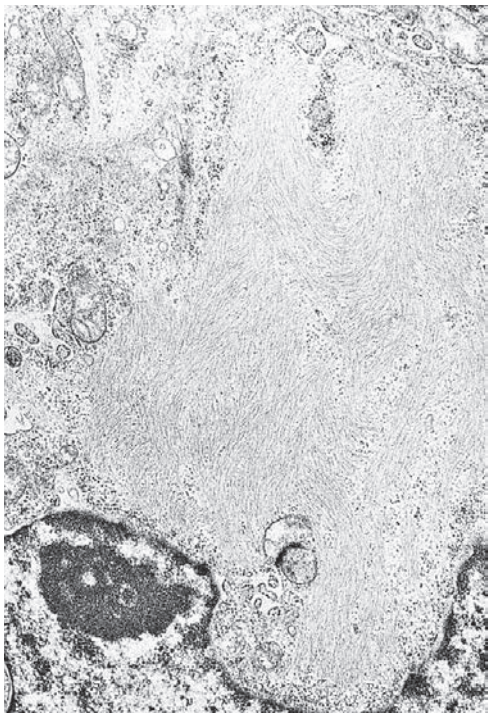

Figure 41.198 Electron microscopic appearance of rhabdoid tumor of soft tissue. The cytoplasmic organelles are displaced by a large aggregate of intermediate filaments. (×15,000; Courtesy of Dr. Robert A. Erlandson, Memorial Sloan-Kettering Cancer Center.)

Myoepithelioma of Soft Tissue

The proposal has been made that there exists in the soft tissue a group of tumors showing differentiation toward myoepithelial cells which can occur either in a pure form (myoepitheliomas) or in association with glandular structures (mixed tumors).[1045,1046] Microscopically, the myoepithelial component is present in the form of nests, cords and ductules of epithelioid cells, and/or nests of spindle cells within a hyalinized or chondromyxoid stroma (Fig. 41.201). Osteoid production and chondroid differentiation may be present. Immunohistochemically, there is often coexpression of cytokeratins and/or EMA, and S-100 protein (Fig. 41.202). Other myoepithelial markers may also be expressed including Sox10, SMA, calponin, GFAP, and p63.[1047]

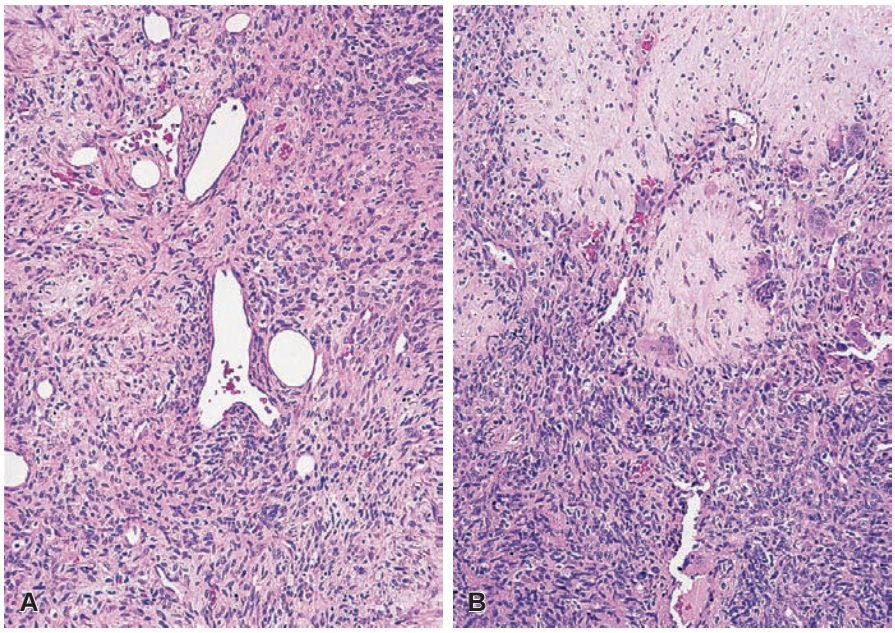

Figure 41.199 Phosphaturic Mesenchymal Tumor. A, This area has a prominent hemangiopericytoma-like quality. **B,** This area from the same tumor shows chondroid differentiation and scattered osteoclast-like giant cells.

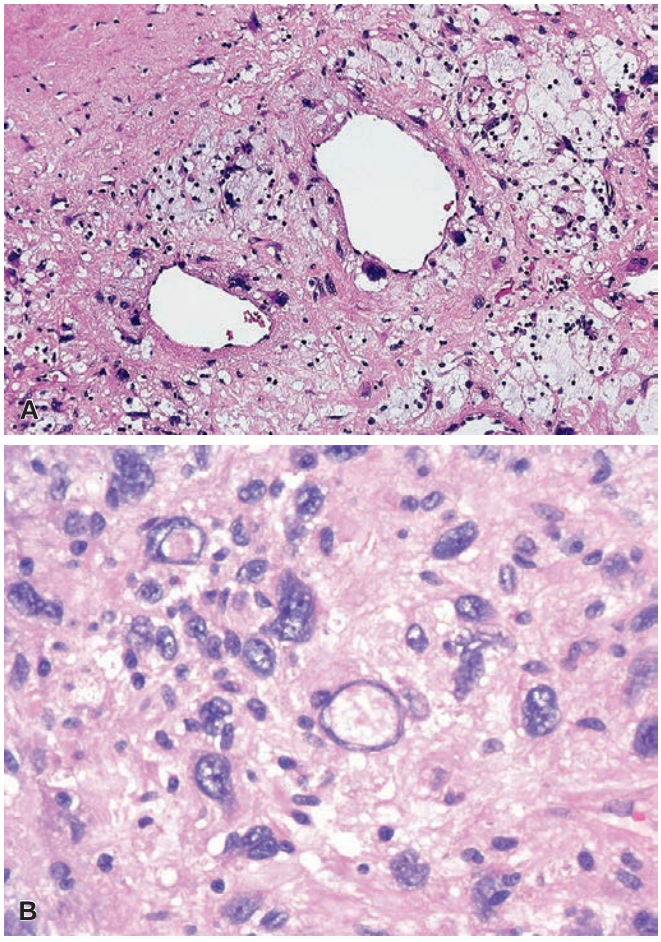

Figure 41.200 A, Pleomorphic hyalinizing angiectatic tumor with pleomorphic tumor cells surrounding dilated blood vessels. **B,** Intranuclear inclusions are identified in some of the neoplastic cells.

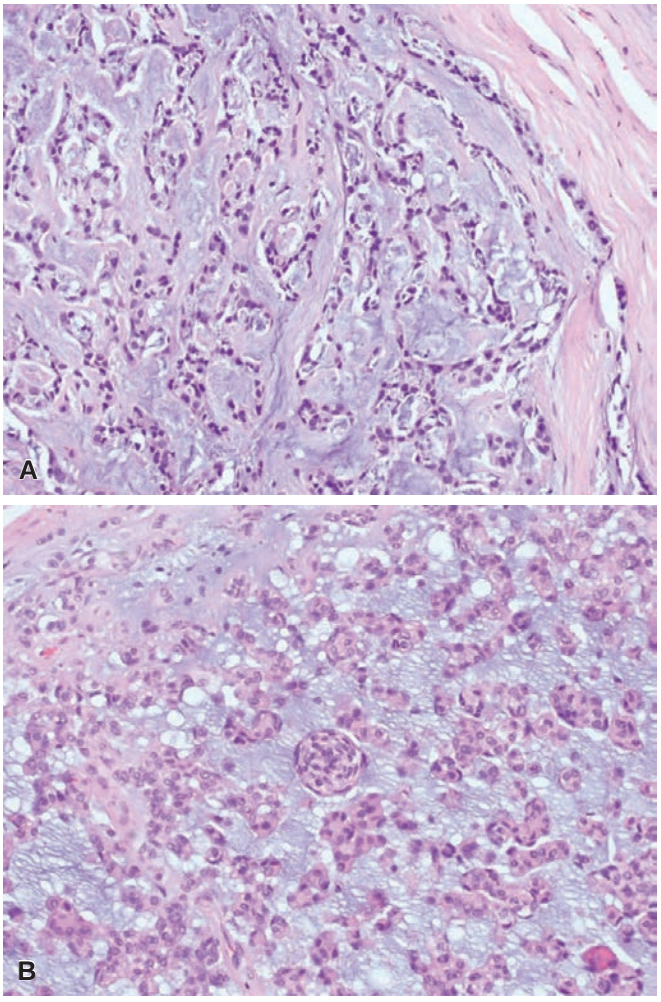

Figure 41.201 A, Myoepithelioma of soft tissue closely resembling extraskeletal myxoid chondrosarcoma with cords of cells deposited in a myxoid stroma. **B,** Parachordoma-like myoepithelioma of soft tissue.

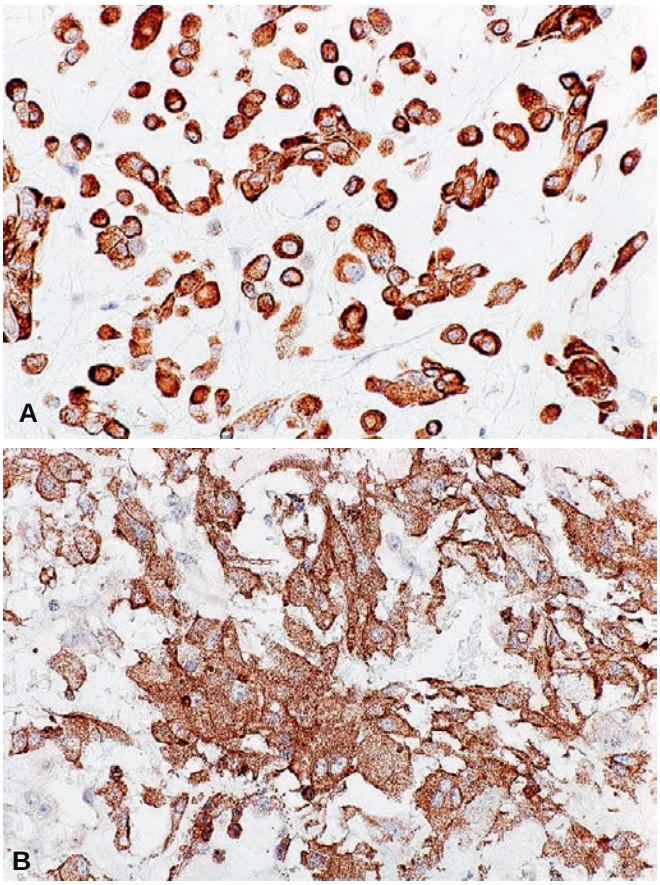

Figure 41.202 **A,** Strong cytokeratin immunoreactivity (CAM5.2) and **(B)** strong smooth muscle actin staining in myoepithelioma of soft tissue.

Recently, it has become clear that soft tissue myoepitheliomas are associated with aberrations of the *EWSR1* gene in up to 50% of cases.[1048] Although a variety of fusion partners have been found, the most frequent appears to be *POU5F1*, but others include *PBX3*, *ZNF444*, *FUS*, and *KLF17*.[1048–1050] Interestingly, some have also been found to harbor deletions of *SMARCB1*, resulting in loss of IN11 protein expression.[1051]

Clinically, these tumors have the capability for local recurrence and distant metastases. The malignant form of this tumor has been referred to as *myoepithelial carcinoma*, a relatively high percentage of them occurring in children.[1052] It has further been suggested that the mysterious neoplasm originally reported by Dabska as *parachordoma*[833] is almost certainly a myoepithelial neoplasm.[1047] Recently, a series of myoepithelioma-like *SMARCB1*-deficient tumors has been described in the vulvar region, which share many but not all features with classic myoepitheliomas.[1052a]

Other Tumors

Oncocytoma has been reported as a primary tumor of soft tissues, and we have seen a similar example.[1053,1054] The appearance does not differ from that of oncocytomas at other sites. It seems likely that this is also related to soft tissue myoepithelioma.

Metastatic Tumors

Skeletal muscle or other deep soft tissue metastases of carcinoma or melanoma occur, but only rarely do they represent the first clinical manifestation of the disease. Reported cases include metastases from carcinoma of the kidney, lung, breast, stomach, and large bowel (Fig. 41.203).[1055]

Figure 41.203 Carcinoma of the large bowel metastatic to soft tissues and skin.

Other Tumorlike Conditions

Bronchogenic cysts of skin and soft tissue are usually discovered at or seen after birth in male infants. The most common location is the suprasternal notch and manubrium sterni[1056]; despite their name, they are probably of branchial arch derivation (i.e., *branchiogenic*).

Tumoral calcinosis is characterized by the formation of large, painless, calcified masses in the periarticular soft tissues, especially along extensor surfaces.[1057] The elbows and hips are the most common sites (Fig. 41.204). Curiously, the knee is always spared. Acral lesions are similar histologically but are smaller and may be the first manifestation of scleroderma in patients who are normophosphatemic (Fig. 41.205).[1057]

The disease can be inherited as an autosomal dominant trait with variable clinical expressivity. Germline mutations in the *FGF23* (encoding a potent phosphaturic protein), *GALNT3* (encoding a glycosyltransferase for initiating O-glycosylation), or *SAMD9* (encoding tumor necrosis factor-α responsive protein) gene have been described.[1058–1060] The largest series have been reported from African countries. The serum calcium is usually normal, but there is hyperphosphatemia and elevated serum dihydroxyvitamin D levels.[1061] The disease may recur after excision.[1062]

Calcifying fibrous pseudotumor is a benign and probably nonneoplastic fibrous lesion characterized by the presence of abundant hyalinized collagen with psammomatous or dystrophic calcifications and a lymphoplasmacytic infiltrate (Fig. 41.206). Most patients are adolescents and young adults, and the behavior is benign.[1063] There is immunoreactivity for CD34 in most cases but not for ALK-1. The latter finding does not lend support to the suggestion that calcifying fibrous pseudotumor represents a late stage of inflammatory myofibroblastic tumor.[1064]

Amyloid tumor (amyloidoma) can present as a localized mass in the soft tissue, most commonly in the mediastinum and retroperitoneum.[1065] The amyloid may be of AL (more frequently) or AA type.[1066]

Aneurysmal (bone) cyst morphologically similar to that more commonly seen in the skeletal system can develop in the soft tissues.[1067,1068] Like nodular fasciitis, these lesions have been associated with *USP6* rearrangements.[1068]

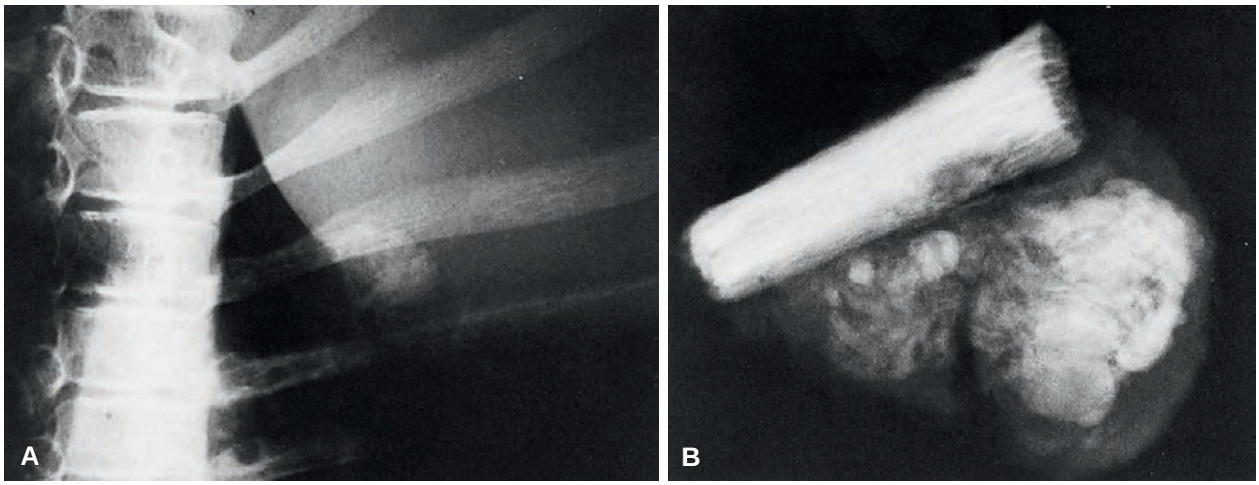

Figure 41.204 **A,** Radiograph showing an area of tumoral calcinosis adjacent to a posterior rib in a 9-year-old child. **B,** Radiograph of the excised specimen. Calcification is lobulated, splotchy, and independent of the eighth rib.

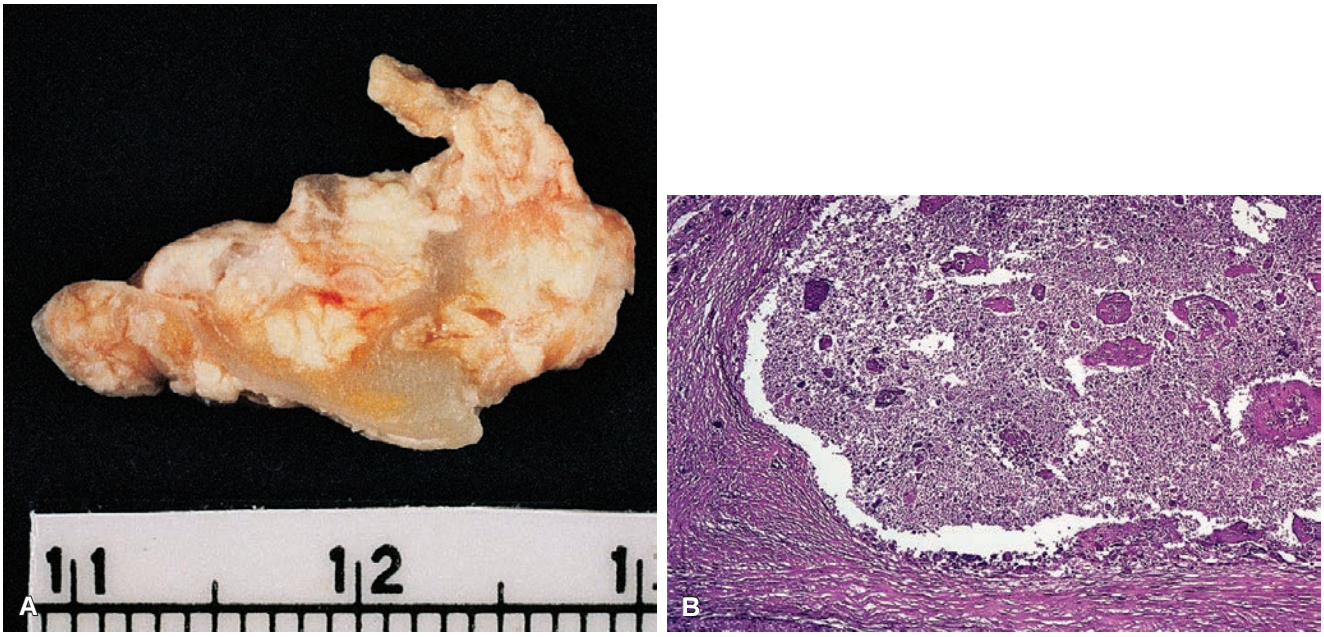

Figure 41.205 **Tumoral Calcinosis. A,** Gross appearance. The lesion is characteristically multinodular, and the material has a chalky quality. **B,** Microscopic appearance. Note the absence of cartilaginous features.

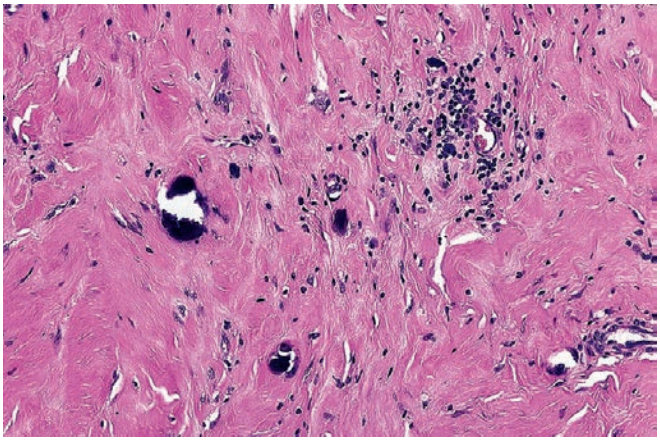

Figure 41.206 Calcifying fibrous pseudotumor with round calcific concretions seen against a fibrohyaline background containing scattered lymphocytes.

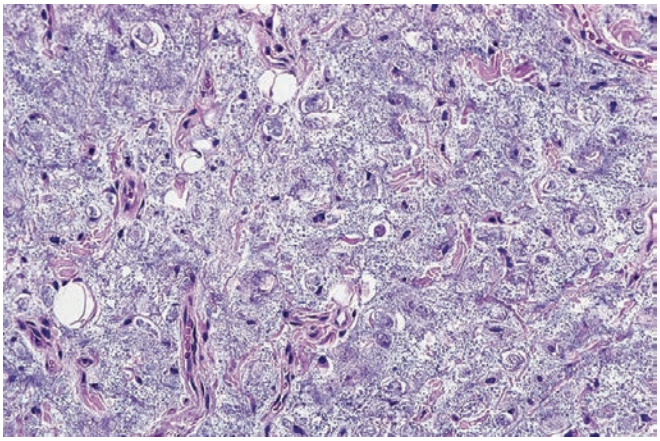

Figure 41.207 So-called mucicarminophilic histiocytosis. The highly myxoid quality of this lesion may induce confusion with a myxoid neoplasm.

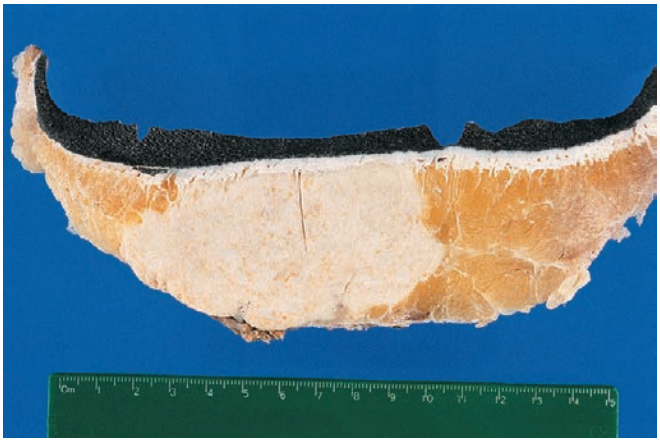

Figure 41.208 Gross appearance of Rosai–Dorfman disease (sinus histiocytosis with massive lymphadenopathy) involving skin and soft tissue in the buttock region.

Polyvinylpyrrolidone (PVP) granuloma is a tumorlike condition of skin or soft tissue that follows systemic injections of drugs containing PVP.[1069,1070] The prominent myxoid features and focal cellularity may simulate a neoplastic process, particularly myxoid liposarcoma and signet ring carcinoma (Fig. 41.207). PVP is localized in the cytoplasm of foamy histiocytes and multinucleated giant cells, many of which appear vacuolated. These cells are positive for mucicarmine, colloidal iron, Grocott methenamine silver, Congo red, Sudan black B, and argentaffin stains, and the PVP can be detected by infrared spectrophotometry.[1071] **Aluminum granuloma** is another iatrogenic process that occurs at sites of injection done for the purposes of vaccination or allergen desensitization.[1072,1073] The microscopic appearance is variable, the clue to the diagnosis being the presence of histiocytes with abundant violaceous granular cytoplasm.[1073]

Rosai–Dorfman disease (sinus histiocytosis with massive lymphadenopathy) may present as a mass in the soft tissue (Fig. 41.208), with or without associated lymph node involvement.[1074] It is most commonly located in the extremities, but it can also occur in the trunk and head and neck region. As is also the case in other extranodal sites, emperipolesis is usually conspicuous, and secondary collagen deposition is prominent.[1075] The cells stain strongly for S-100 protein but are negative for CD1a (Fig. 41.209).

Castleman disease of the hyaline-vascular type can rarely present as a subcutaneous or intramuscular mass.[1076,1077]

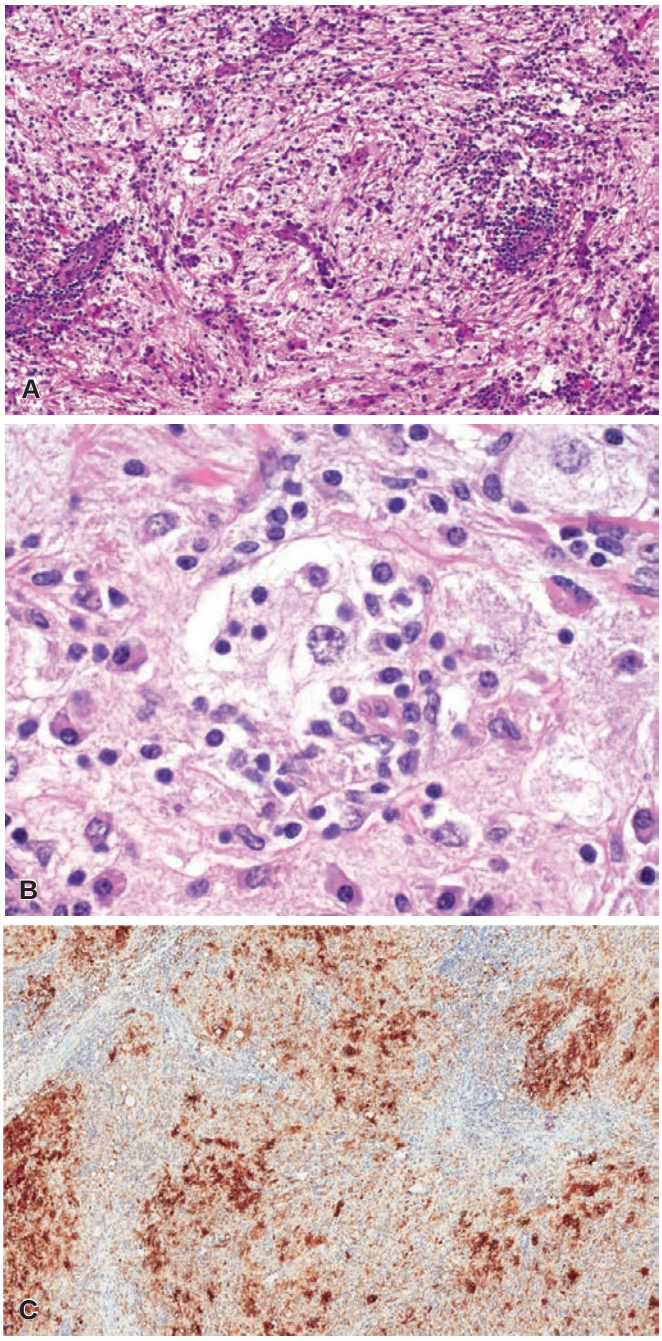

Figure 41.209 **A,** Characteristic heterogeneous low-power view of Rosai–Dorfman disease of soft tissue. **B,** Emperipolesis is present in this case. **C,** Strong S-100 protein immunoreactivity is characteristic.

Heart

Surgical pathology specimens received from cardiovascular procedures have evolved in parallel to advances and general trends in cardiovascular surgery over recent decades. Methods have been devised to relieve aortic, mitral, and pulmonary valvular stenosis (often by replacement with a prosthesis) and restore competency to regurgitant mitral, aortic, and tricuspid valves. Coronary artery bypass graft surgery has largely given way to less invasive endovascular coronary artery interventions for the symptomatic treatment of ischemic heart disease. Cardiac transplantation remains a mainstay of treating end-stage heart failure, and the pathologist plays a very important role in rejection monitoring. Increasingly though, mechanical circulatory support by various implanted ventricular assist device pumps is becoming a viable alternative when transplantation is not possible. Most operations for congenital cardiovascular malformations are directed toward increasing or redirecting the flow of blood by such procedures as ligating a patent ductus, closing atrial, ventricular (and atrioventricular) septal defects, creating new pulmonary flow conduits, or reconstructing stenotic arteries and valves orifices. The reader is referred to specialized texts dealing with these various abnormalities and their methods of treatment.[1–4]

Normal Anatomy

The major histologic components of the heart are pericardium, myocardium, endocardium, and the valves.[5] The *pericardium* is divided into fibrous (parietal) and serous (visceral, also known as epicardium) portions. It is lined by a single layer of mesothelial cells resting on a basement membrane and forms a cavity or potential space filled with a small amount (~60 cc) of fluid. The *myocardium* consists of bundles of cardiac muscle fibers (myocytes) separated by fibrous bands. The muscle fibers form a syncytium with end-to-end junctions, called intercalated discs, and sometimes side-to-side junctions. The nuclei of myocytes are centrally located, in contrast to those of skeletal muscle fibers (whose nuclei are peripheral). The *endocardium* consists of a single layer of endothelial cells that are continuous with those of the major blood vessels as well as a basement membrane and delicate supporting connective tissue. The *semilunar (pulmonary and aortic) valves* are composed of three layers: fibrosa (made of dense collagen), spongiosa (containing large amounts of

Abstract

Surgical pathology specimens from cardiovascular procedures are not the most frequently received in most laboratories, but they represent an important opportunity to guide clinical and surgical management of patients with cardiovascular disease. This chapter briefly reviews the normal features of cardiac tissues, arteries, veins, and lymphatics and discusses relevant aspects of pathologic conditions encountered in biopsy, resection, and explantation specimens.

Keywords

Endomyocardial biopsy,

Vasculitis pathology

proteoglycans, loosely arranged collagen fibers, and scattered fibroblasts), and ventricularis (identified by its profusion of elastic fibers). The *atrioventricular (mitral and tricuspid) valves* are composed of the annulus (a ring of circumferentially oriented collagen and elastic fibers), leaflets, chordae tendineae, and papillary muscles. The leaflets, like those of the semilunar valves, are composed of three layers: the spongiosa (on the atrial side, rich in proteoglycans), the central fibrosa, and the ventricularis (on the ventricular side, rich in elastic fibers).

Myocardial Biopsy

The procurement of myocardial or endomyocardial biopsies during cardiac catheterization has become a common procedure. These biopsies are obtained endovascularly through a catheter inserted in a systemic vein and directed to the right ventricle, or through a transthoracic route at the time of surgery for congenital or acquired heart disease. Examination of multiple levels increases the sensitivity of the procedure, particularly in cases of myocarditis.[6] Ultrastructural examination can be of importance, especially for the evaluation of drug toxicity.[7] In the particular case of Adriamycin chemotherapy toxicity, all biopsy pieces should be submitted for plastic resin embedding and "thick" toluidine blue-stained sections since this is the method upon which grading is based (Fig. 42.1).[8] Routine paraffin histologic sections are not as informative in this condition.

For inflammatory processes and other diseases with "patchy involvement" of the myocardium, the possibility of false-negative endomyocardial biopsy results should always be kept in mind because of the high likelihood of sampling error with small biopsy fragments (i.e. positive biopsies are informative, negative biopsies do not necessarily exclude the disease in question).

The current complication rate with the intravascular procedure at specialized centers is less than 1%. The most common complication is hemopericardium (which rarely requires pericardiocentesis or thoracotomy). Indications for myocardial biopsy include evaluation of myocarditis and sarcoidosis, detection and subtyping of amyloidosis, confirming storage disease and other infiltrative processes, monitoring of heart transplant rejection, and grading of Adriamycin toxicity.[9,10] They may also be performed to diagnose primary and metastatic tumors.

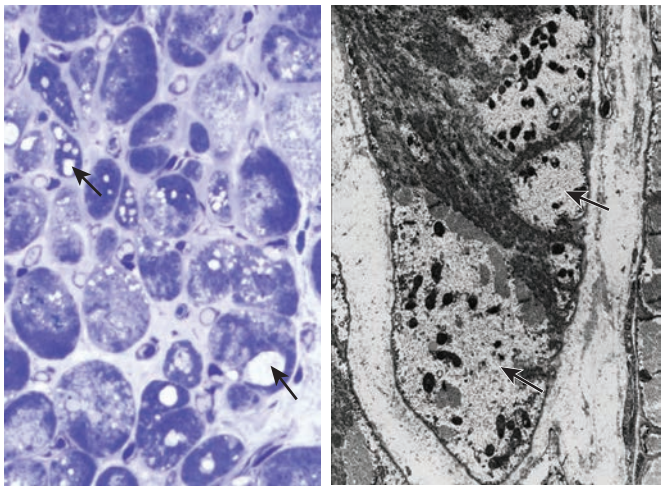

Figure 42.1 Adriamycin cardiotoxicity, manifesting as vacuolar areas of sarcoplasmic myofiber loss *(arrows)*. This change is apparent in both plastic embedded thick sections stained with toluidine blue O *(left)* and by transmission electron microscopy *(right)*.

Cardiomyopathy and Myocarditis

Hypertrophic Cardiomyopathy

This is an inherited disease of the myocardium characterized by left ventricular hypertrophy, usually in an asymmetric fashion, in the absence of a systemic or secondary cardiac cause for hypertrophy (such as hypertension or aortic stenosis) and with normal or reduced chamber size but preserved or hyperdynamic ejection fraction. It is genetically heterogeneous, with most cases caused by germline mutation in a sarcomeric protein gene (most commonly MYH7 and MYBPC3).[11] The main microscopic features of this condition (best seen in whole hearts, septal myomectomy specimens, or generous biopsies obtained via thoracotomy) are hypertrophy and interstitial fibrosis with myofiber "disarray." A nonspecific change that is commonly found in idiopathic hypertrophic myocardiopathy is *basophilic degeneration* of myocardium. This appears as pale blue (on H&E), finely granular material in the cytoplasm of isolated myocardial fibers and consists of polyglucosan deposits.

Idiopathic Dilated Cardiomyopathy

This common, but poorly understood myocardial disease has both genetic and acquired components. It is characterized by marked left ventricular chamber dilation with reduced ejection fraction. Abnormalities in the myocardial biopsy are consistently present but are nonspecific. They consist mainly of hypertrophy, fibrosis, and degenerative changes of myocardial fibers (including lipofuscin accumulation, basophilic change, and vacuolation due to myofiber loss).

Reasonable correlation has been found between the severity of the condition clinically and the extent and degree of microscopic abnormalities, although sometimes the focal nature of these changes and sampling error introduced by biopsy techniques may combine to give a misleading interpretation. Leukocytic infiltrates may be present in biopsies in this condition, an observation linking myocarditis with idiopathic dilated cardiomyopathy. About 30% of cases have an inherited basis, usually autosomal dominant, due to germline mutation in a gene encoding sarcomeric and other cardiomyocyte proteins.[12]

Restrictive (Restrictive/Obliterative) Cardiomyopathy

In the eosinophilic form of this disease in its active stage, a myocarditis with a heavy component of eosinophils is present (Fig. 42.2), along with eosinophil-rich mural thrombus at least in the active stage. In the non-eosinophilic form, or idiopathic restrictive cardiomyopathy, the left ventricle is normal size but the left atrium is markedly enlarged, reflecting physiologic ventricular stiffening and increased filling pressures during diastole. As with hypertrophic and idiopathic cardiomyopathies, the biopsy findings in this form are nonspecific.

Infiltrative Cardiomyopathies

This is the group of cardiac diseases in which endomyocardial biopsy can be particularly rewarding. However, the diagnosis of many of these conditions may be obtained more readily by biopsy of another, more easily accessible organ. These conditions include amyloidosis, hemochromatosis, and storage diseases.[13] As the name implies, these conditions results from insidious deposition of exogenous injurious material(s) in the interstitium, cardiomyocytes, or resident histiocytes in the heart. The presence of these deposits interferes with cardiac contractility and function, leading to a cardiomyopathy phenotype.

Other Cardiomyopathies

Ischemic cardiomyopathy is not a primary myocardial disease but a result of coronary artery occlusion with myocardial infarction and

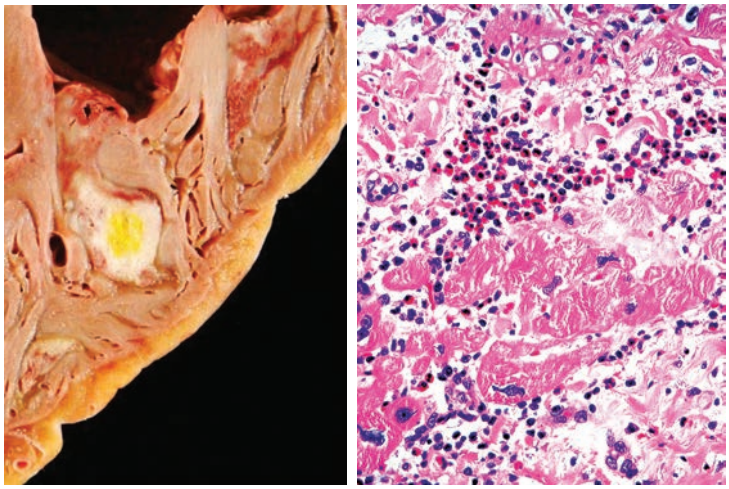

Figure 42.2 Restrictive eosinophilic endomyocardial disease, with organizing mural thrombus in the right ventricle apex *(left)*. The thrombus is eosinophil-rich and there is an associated eosinophilic myocardial infiltrate *(right)*.

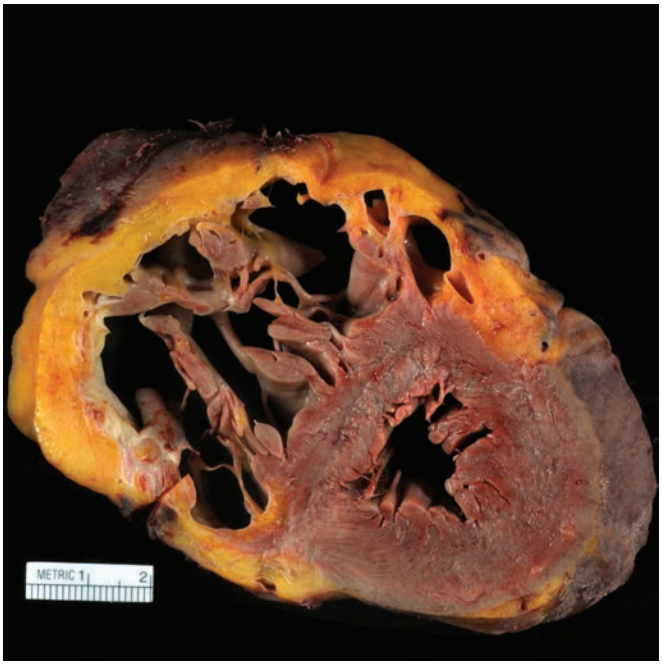

Figure 42.3 Arrhythmogenic cardiomyopathy, with primarily right ventricular involvement (by fibrofatty replacement of ventricular myocardium).

associated ventricular "remodeling" changes. This is characterized by congestive heart failure, ventricular arrhythmias, and left ventricular dilation and can be distinguished from idiopathic dilated cardiomyopathy by the presence of significant coronary artery disease and infarcts in the accompanying myocardial territories. **Arrhythmogenic cardiomyopathy (formerly "right ventricular dysplasia")** is another inherited cardiomyopathy associated with mutations in desmoglein, desmoplakin, plakoglobin, plakophilin-2, and related cell junction proteins. Its manifestations mainly affect the right ventricle.[14] The anatomic substrate is variable infiltration/replacement of the right ventricular myocardium by adipose and fibrous tissue (Fig. 42.3).

Left ventricular noncompaction (hypertrabeculation) cardiomyopathy is another unusual form of myocardial disease resulting from an embryonic failure of ventricular muscle bands to condense and coalesce during development, resulting in abnormal trabeculations in the left ventricle (comprising more than half of the ventricular wall thickness) and functionally impaired ejection fraction (Fig. 42.4). This heritable disorder has been associated with sarcomere and other sarcoplasmic proteins.[12]

Myocarditis

It is agreed that the diagnosis of myocarditis requires the presence of an inflammatory infiltrate *and* myocyte necrosis or degeneration (the two components of the so-called Dallas criteria).[15] The infiltrate is usually lymphocytic in nature, easily identifiable, and often admixed with histiocytes and occasional granulocytes (neutrophils and eosinophils) in routine sections. The H&E sections may be supplemented with CD3, CD4, CD20, CD45, and/or CD68 immunostains to increase sensitivity or clarify the nature of any ambiguous mononuclear cell,[16] but this is not necessary. In *hypersensitivity myocarditis*, the infiltrate is rich in eosinophils, is predominantly perivascular, and is accompanied by a lesser degree of myocyte injury. The myocyte alterations in myocarditis of any etiology can take the form of frank necrosis, vacuolization, or disruption and are better appreciated in longitudinally oriented cells. The presence of edema alone should not be used as a criterion for myocarditis. Fibrosis, if present, should be quantified (mild, moderate, or severe) and qualified (interstitial, endocardial, or replacement type), since this represents a more chronic change not likely to respond to acute immunosuppressive therapy.

Diagnostic terms to be used in subsequent biopsies (if obtained), using the first specimen as a reference point, are *ongoing* or *persistent* myocarditis when both the myocyte damage and the inflammation persist, *resolving* or *healing* myocarditis when these changes are substantially reduced, and *resolved* or *healed* myocarditis when these changes are no longer present (bearing in mind the high likelihood of sampling error and possible false-negative results).

The etiology of myocarditis can be viral, bacterial (including Whipple disease, *Coxiella*, and *Bartonella*), mycobacterial, fungal, or parasitic (particularly Chagas disease and toxoplasmosis, the latter often seen in AIDS patients). Myocarditis may also be caused by autoimmune disease (especially rheumatic fever "pancarditis"), drug-induced reaction, radiation, or as an expression of transplant rejection. In many cases of myocarditis, the condition remains idiopathic, although the recently introduced molecular diagnostic

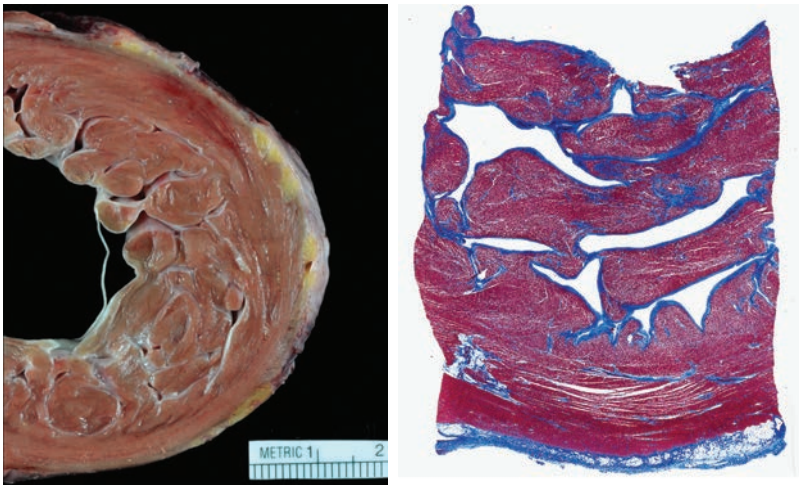

Figure 42.4 Left ventricular noncompaction cardiomyopathy with left ventricular hypertrabeculation comprising more than half of the ventricular thickness (highlighted by trichrome staining).

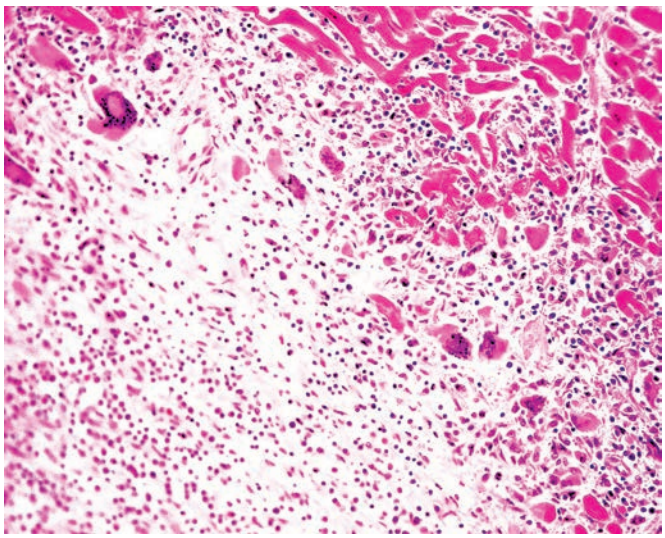

Figure 42.5 Giant Cell Myocarditis. Scattered multinucleated giant cells accompanied by lymphocytes are seen in association with loss of myocardial fibers. There are no granulomas and myocyte damage is widespread, and eosinophils are present in the background.

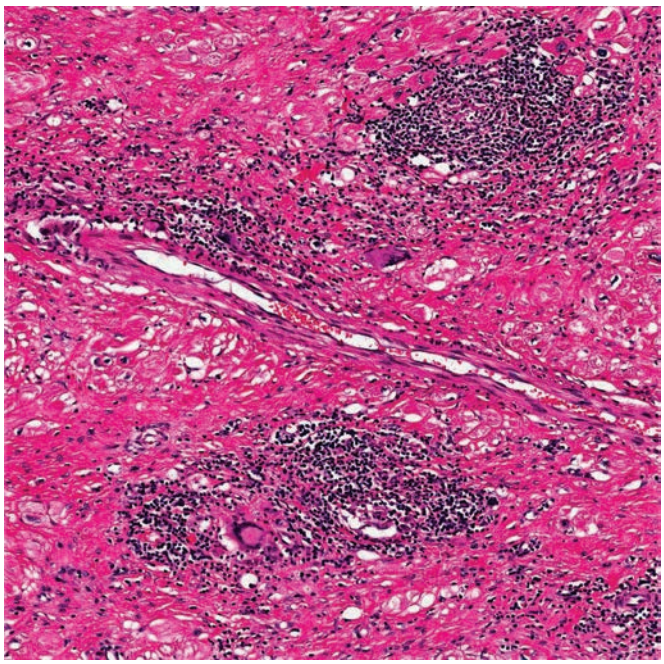

Figure 42.6 Cardiac sarcoidosis with multinucleated giant cells within well-formed granulomas. The surrounding myocytes are relatively intact.

approach may allow for the identification of viruses suspected of inciting the process (enteroviruses and adenoviruses).[16] *Giant cell myocarditis*, a particularly aggressive form, is characterized by more widespread multicentric destruction of the cardiac myocytes. The inflammatory infiltrate includes cytotoxic T cells, eosinophils, and the multinucleated cells that define the entity (Fig. 42.5). Well-formed granulomas are not seen in giant cell myocarditis.

Cardiac Sarcoidosis. The findings of typical sarcoid granulomas (as seen in lung or mediastinal lymph node biopsies) may be found in the heart as manifestation of cardiac involvement by systemically sarcoidosis, but cases in which the heart is the only involved organ have also been described.[17] Like other organs, the distribution of sarcoid granulomas tends for follow lymphatics, which are especially abundant around the cardiac conduction system tracts. Conduction block and cardiac arrhythmia are frequent signs of cardiac sarcoidosis clinically. Sarcoid appears as well-circumscribed, scar-like lesions distributed in patches throughout the full thickness of the myocardium. They appear fairly well demarcated histologically and without significant associated myocyte necrosis in the surrounding myocardium (Fig. 42.6).

Heart Transplant

Myocardial biopsy is the most sensitive and specific indicator of rejection. While historically a number of reporting approaches and grading schemes have been used to describe rejection findings,[18] an international "working formulation" was developed by the International Society for Heart and Lung Transplantation.[19,20] The approach outlined in this scheme includes assessment of both cell-mediated and antibody-mediated attacks on the graft. The main microscopic sign of cellular rejection is a perivascular and interstitial inflammatory infiltrate, predominantly lymphocytic, accompanied by focal necrosis of myocytes (similar to myocarditis) and edema (Fig. 42.7A and B).

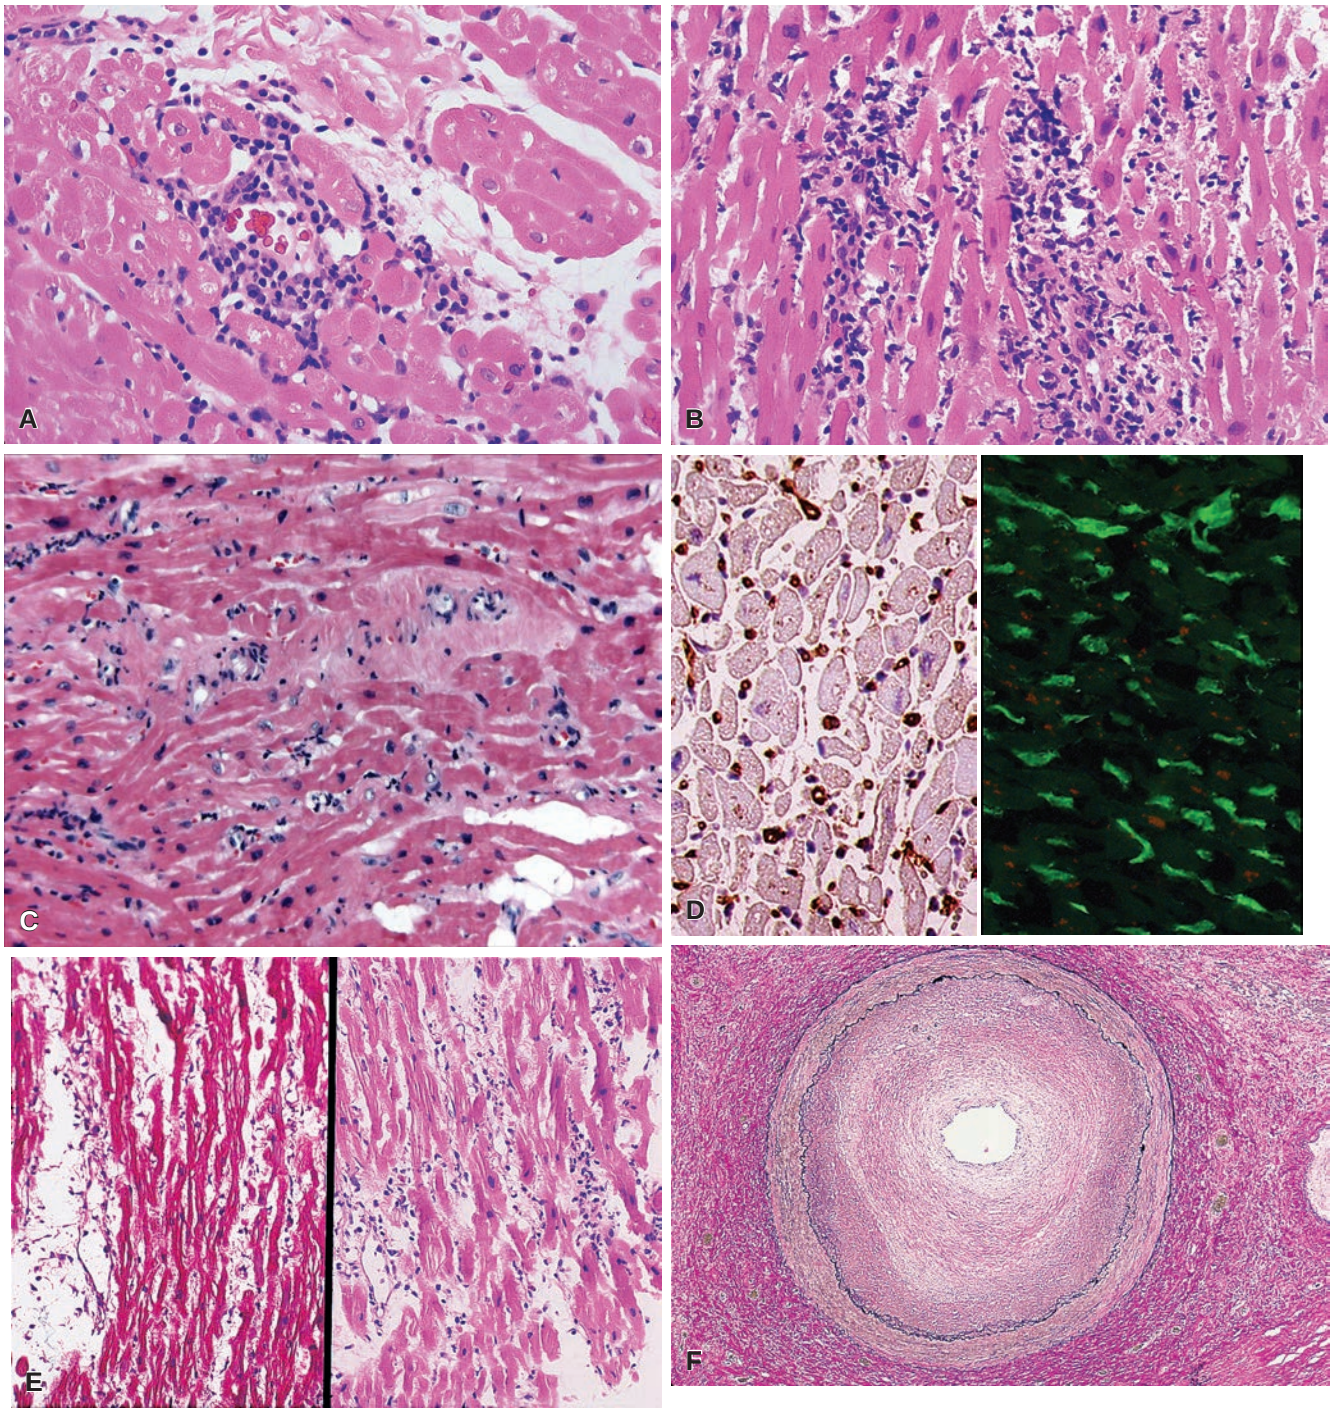

Figure 42.7 Pertinent Pathologic Changes in Cardiac Allografts. A, Endomyocardial biopsy with mild acute cellular rejection. There is patchy perivascular lymphocytic infiltrate with no myocyte injury. **B,** Moderate acute rejection showing inflammation and myocyte damage. **C,** Antibody-mediated rejection features including "activated intravascular mononuclear cells." **D,** Positive staining for complement component C4d by immunohistochemistry and immunofluorescence methods in antibody-mediated rejection. **E,** Acute/subacute ischemic changes including edema, inflammation and "wavy" myocytes showing focal contraction bands. **F,** Cardiac allograft vasculopathy with concentric narrowing of epicardial coronary artery by fibromuscular intimal proliferation. Note the preservation of internal elastic lamina (Elastic-van Gieson stain).

Table 42.1 ISHLT working formulation for cardiac transplant rejection

CELLULAR REJECTION		ANTIBODY-MEDIATED REJECTION	
0	Normal histologically	pAMR0	Normal histologically and negative immunopathology studies
1R	Interstitial or perivascular infiltrate with up to 1 focus of myocyte damage	pAMR1(H+)	Histologic features of AMR, but normal immunopathology studies

Data from Stewart S, Winters GL, Fishbein MC, et al. Revision of the 1990 working formulation for the standardization of nomenclature in the diagnosis of heart rejection. *J Heart Lung Transplant*. 2005;24(11):1710–1720; Berry GJ, Burke MM, Andersen C, et al. The 2013 International Society for Heart and Lung Transplantation Working Formulation for the standardization of nomenclature in the pathologic diagnosis of antibody-mediated rejection in heart transplantation. *J Heart Lung Transplant*. 2013;32(12):1147–1162.

Antibody-mediated rejection is assessed by evaluating the myocardial interstitial capillaries for "swollen"-appearing endothelial cells and accumulation of intravascular macrophages (collectively referred to as "intravascular activated mononuclear cells" in the working formulation). In addition, immunopathology methods are needed (frozen section immunofluorescence or paraffin immunohistochemistry) to test for deposition of complement split products and other potential indicators of antibody mediated immune mechanisms (Table 42.1) (see Fig. 42.7C and D).

Care should be taken to not misinterpret a previous biopsy site as indicative of rejection. Recent biopsy sites appear as a sharply outlined area of necrotic myocytes, sometimes associated with a thrombus and granulation tissue. Older biopsy sites show replacement fibrosis-type scarring, often with associated mononuclear inflammation. Rejection should also be distinguished from ischemic changes (see Fig. 42.7E), especially in the days and weeks following the transplant operation and in the setting of severe cardiac allograft vasculopathy. Another potential mimic of rejection is the so-called Quilty or nodular endocardial inflammatory lesion. These can be distinguished from cellular rejection on the basis of their rounded (rather than infiltrative) contours and subendocardial location.

A form of accelerated "arteriosclerosis" referred to as cardiac allograft vasculopathy (see Fig. 42.7F) is the major long-term complication of heart transplantation, occurring in the majority of grafts 10 years after transplant. Factors recognized to contribute to this disease include previous rejection episodes (especially antibody mediated rejection), circulating anti-donor antibodies detected by flow cytometry methods, and infections (especially with *Cytomegalovirus*).[21]

Other clinically impactful findings may be seen on transplant biopsies, such as EBV-associated post-transplant lymphoproliferative disorder and opportunistic infections such as *Toxoplasma* and *Cytomegalovirus*.[22] Immunohistochemical or in situ hybridization techniques may be helpful in confirming the presence of these.

Cardiac Valves

Surgeries to correct major valve defects (congenital and acquired) by resection and prosthetic replacement are the most frequently performed cardiac surgical procedures. It should be emphasized that often the most precise diagnosis will be made from the gross appearance of the valve and that usually the microscopic examination is of little value.[23] Photographic and radiographic examination of the specimen may also be helpful. The cause of valvular disease can nearly always be ascertained through careful examination of the gross specimen and knowledge of the clinical history. Microscopically, with the exception of rheumatic and myxomatous mitral valve disease, the features are fairly nonspecific, regardless of etiology, and include fibrosis, calcification, and occasional inflammatory cells. A hallmark of rheumatic valve disease is the presence of arterioles and other well-developed vessels within the valve tissue layers (which are avascular in normal and degenerative conditions). The major etiologies of valvular disease (excluding the pulmonary valve since it is rarely intervened upon) and their characteristic gross, microscopic, and clinical features are shown in Tables 42.2–42.4.

Mitral Valve

Nearly all cases of mitral valve stenosis (with or without mitral insufficiency) are acquired and postinflammatory (rheumatic) in nature. Among cases of mitral insufficiency, common causes include myxomatous (floppy) mitral valve disease (mitral valve prolapse), postinflammatory, and ischemic complication.[24] Grossly, rheumatic valves show a characteristic appearance that has been compared to repeated dipping in candle wax. The commissures are partially fused (from the annulus inward), giving a resemblance to a "fish mouth." The cords are also thickened and fused, appearing similar to the whiskers/tendrils of a catfish. As previously mentioned, the presence of vessels with the valve layers is a finding specific to rheumatic valve disease (Fig. 42.8).

Myxomatous valves shows leaflet thickening and redundancy, leading to the formation of dome-like deformities reaching above the level of the annulus. The annulus itself is also dilated. The chordae are often thin and attenuated, though with fibrosis (see Fig. 42.8). Chordal rupture is seen in over one-half of the cases, though the clinical intraoperative impression is often the only way of knowing this.

Microscopically, stromal accumulation of glycosaminoglycans is the distinguishing feature of myxomatous disease, leading to the appearance of "myxoid or myxomatous degeneration." There is no association with cardiac myxoma. Whether this alteration is the result of a genetically determined disease or a degenerative process of nonspecific nature remains controversial.[25,26]

Table 42.2 Features of mitral valve disease

	STENOSIS	REGURGITATION		
	RHEUMATIC[a]	MYXOMATOUS	POSTINFLAMMATORY	ISCHEMIC
Gross:	• Leaflet thickening (± calcification) • Commissural fusion • Cord thickening and fusion	• Leaflet thickening (gelatinous cut surface) • Mildly thickened cords without fusion	• Leaflet thickening (± calcification) • Cord thickening and fusion	• Normal leaflets • Scarred and retracted papillary muscles
Microscopic:	• Fibrosis, variable inflammation, vessels within valve layers	• Loose myxoid expansion of the spongiosa layer	• Fibrosis, variable inflammation, vessels within valve layers	• Normal leaflets • Ischemic (chronic) papillary muscle
Clinical:	Remote history of rheumatic fever	• Mitral valve prolapse • Often repaired rather than replaced	• Remote rheumatic fever • Irradiation • Healed endocarditis	History of left ventricle infarction (lateral and/or inferior)

[a]Often mixed stenosis and regurgitation

Table 42.3 Features of aortic valve disease

	STENOSIS			REGURGITATION	
	DEGENERATIVE	BICUSPID	POST-INFLAMMATORY	ANNULAR DILATATION	BICUSPID
Gross:	• Nodular calcific deposits ± ulceration • Calcification in sinus "pockets"	• Two cusps, usually different size, one with a "raphe" • Calcification around raphe and closing edge of leaflets	• Thickened, calcified leaflets • Commissural fusion	• Leaflets thin, soft, pliable • Leaflet enlargement, stretching • Leaflets ± rolling/ retraction	• Two cusps, usually different size, one with a "raphe" • Leaflet enlargement, stretching
Microscopic:	• Fibrosis, calcification, variable inflammation, ± ulceration	• Fibrosis, calcification, variable inflammation, ± ulceration	• Fibrosis, calcification, inflammation, vessels within valve layers	Normal leaflets	Normal leaflets
Clinical:	• Elderly, atherosclerosis risk factors	• Congenital, 1% of population • Replacement ~10 years sooner than degenerative	• Remote rheumatic fever • Irradiation • Healed endocarditis	• Aortic root dilatation • Ascending aortic aneurysm	• "Aortopathy" • Aortic root and ascending aortic dilatation

Ischemic mitral insufficiency is actually a papillary muscle abnormality, with the leaflets generally preserved. Scarring of the infarcted papillary muscle(s) leads to retraction and foreshortening of the tendinous cords, impairing coaptation during systole.

Aortic Valve

Aortic valve specimens that are removed because of stenosis may show degenerative calcification of congenitally bicuspid valves, calcification of a normally three-leaflet valve without commissural fusion (so-called senile type degeneration), rheumatic changes similar to those described for mitral leaflets, or calcification of congenitally unicommissural valves (Fig. 42.9). It should be mentioned that in some cases, it can be difficult to differentiate congenital bicuspid aortic from a three-leaflet valve that has calcified in a manner such that two of the leaflets fuse together. In these cases, the leaflet sizes can be a helpful clue (the nonconjoined cusp in bicuspid valves is often disproportionately large). The presence of a, usually midline, raphe on the conjoined cusp can also help with this. Pure aortic insufficiency is not related to calcification but to causes such as aortic root dilation, bicuspid valve, and others.

Pulmonary Valve

Specimens of pulmonary valve may be received in the surgical pathology laboratory because of congenital pulmonary stenosis (the majority as a component of tetralogy of Fallot). Bicuspid pulmonary valve is the most common structural anomaly. Pulmonary valve

Table 42.4 Features of tricuspid valve disease

	REGURGITATION			
	POSTINFLAMMATORY	**EBSTEIN ANOMALY**	**ENDOCARDITIS**	**CARCINOID VALVE DISEASE**
Gross:	• Thickened, calcified leaflets • Commissural fusion	• Abnormal, redundant leaflet tissue • Fenestrations • Muscular attachments	• Perforations • Cusp aneurysms • Vegetations	• Thickening • "Pasted-on" fibrous plaques
Microscopic:	• Fibrosis, inflammation, vessels within valve layers	• Disorganized leaflet layers	• Purulent inflammation • Fibrin • Microorganisms • Postinflammatory changes (chronic)	• Normal valve architecture • Layered fibrosis enrobing the valve
Clinical:	• Remote rheumatic fever • Irradiation • Healed endocarditis	• Rare congenital defect • Leaflet stuck to ventricle walls	• IV drug use • Septic pulmonary emboli	• History of metastatic carcinoid with high liver tumor burden • History of gonadal carcinoid

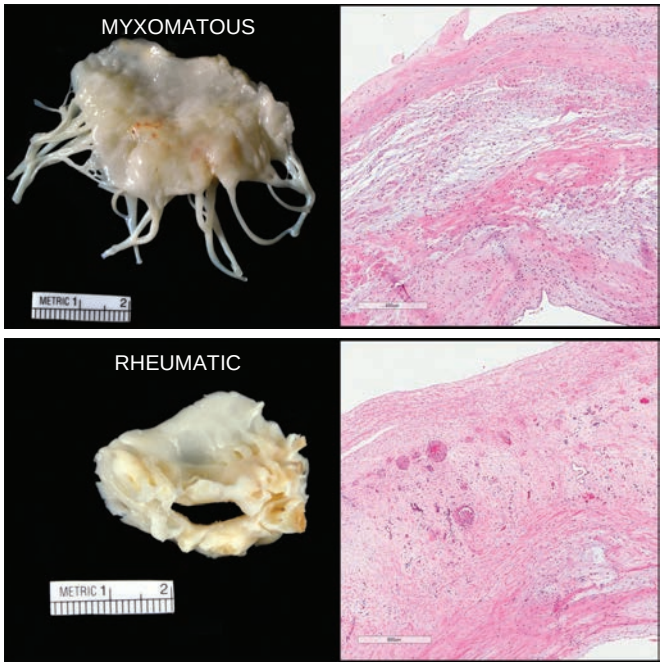

Figure 42.8 Gross and microscopic features of common mitral valve diseases (note the myxoid expansion of myxomatous disease and well-formed vessels in the valve layers in rheumatic disease).

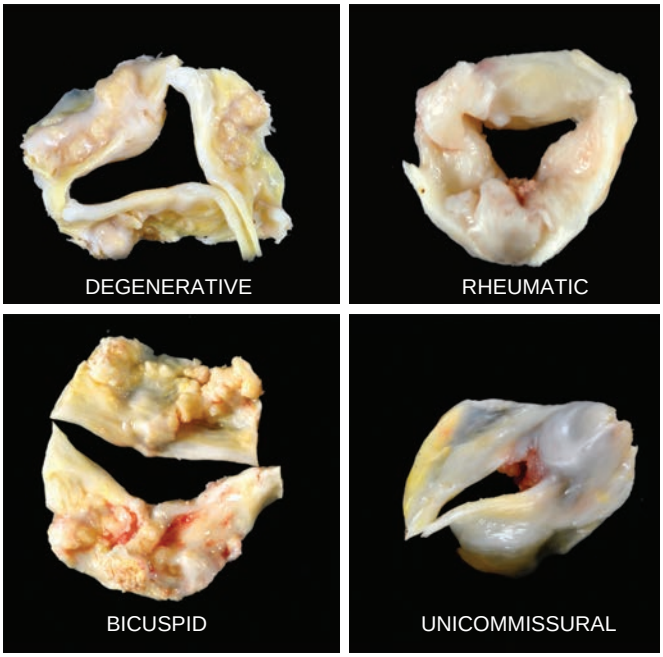

Figure 42.9 Gross features of aortic stenosis (note the number and proportionality of cusps and presence of commissural fusion help distinguish various disease processes).

endocarditis is another uncommon cause of surgery at this location.

Tricuspid Valve

Specimens of tricuspid valve can be the result of operations for pure insufficiency (by far the most common), combined stenosis and insufficiency, and pure stenosis (very rare). The most common causes of insufficiency are postinflammatory diseases, congenital disorders (such as Ebstein anomaly), pulmonary venous hypertension, and infective endocarditis.

Endocarditis

Complications of endocarditis include stenosis due to obstruction by bulky vegetations (often with associated embolic phenomena), and regurgitation due to leaflet destruction in the form of tears, perforations, and aneurysms. Preexisting valve abnormalities seem to predispose to endocarditis, such as bicuspid aortic valve and rheumatic disease. Vegetations are the hallmark of active and subacute endocarditis and grossly appear as fleshy, friable growths arising from the leaflet surfaces (Fig. 42.10). Histologically they are composed of fibrin clot that is rich in neutrophils. Bacterial colonies or other

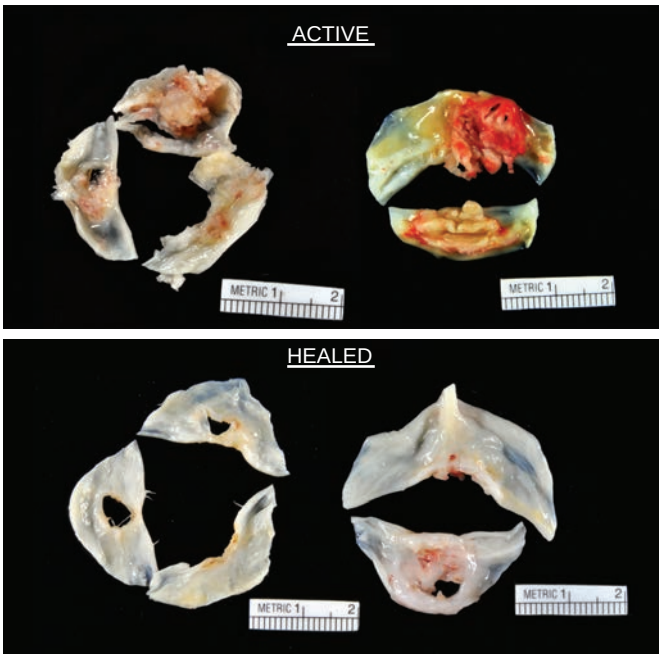

Figure 42.10 Gross features of aortic valve endocarditis (active and healed) involving three-leaflet and bicuspid valves.

microbes may be seen, especially with the help of special stains. Since surgery is often deferred as long as possible to allow for microbial killing by antibiotics (especially before implanting a foreign prosthesis in the infected bed), viable microorganisms may no longer be present. Healed endocarditis will no longer show vegetations grossly or histologically but instead may have perforations and/or leaflet aneurysms. Microscopically, healed endocarditis resembles rheumatic valve disease and may show disruption of the valve layer architecture and replacement fibrosis.

Prosthetic Valves

Given how common valve replacements have become and the finite lifespan of the prosthesis implanted, prosthetic valves are increasingly seen as surgical pathology specimens. The examination of mechanical and bioprosthetic valve prostheses is fairly straightforward and includes evaluating for the presence of thrombus, vegetation, calcification, and degenerative changes (such as leaflet tears for bioprosthetic valves). Microscopic study of these prosthetic valves has shown that, following insertion, a neo-endocardium develops at the junction with the heart wall, and from there it grows centripetally over the sewing cloth toward the valve lumen.[27] This fibrous ingrowth is referred to as "pannus," and can reach the point of causing flow obstruction.

Bioprosthetic valves may be constructed from porcine valve tissue, bovine pericardium, or preserved cadaveric homograft tissue. The pathologic changes that may be found in removed bioprosthetic heart valves include thrombosis, infection, cusp tears and perforations, fibrous sheathing, calcification, and several others. Mechanical valves may show thrombosis, infection, and various alterations associated with the valve design and the composition of the various elements. Regurgitation may be due to leaflet abnormalities or partial dehiscence of the sewing ring with a paravalvular leak.

Left Atrial Appendage

At the time of the correction of a mitral stenosis or other cardiac disease, the surgeon may "amputate" the left (and right) atrial appendage to either remove or prevent later mural thrombus formation and embolization. This is frequently accompanied by atrial ablation to disrupt atrial fibrillation pathways (the "maze" procedure). These appendages are usually abnormal, showing hypertrophy of the muscle and various other alterations. Incidental findings such as Aschoff nodules and amyloid deposits may be seen and often do not correlate with rheumatic disease or cardiac amyloid in the ventricles or systemically.[28,29]

Coronary Artery Bypass

Coronary artery bypass operations are a common treatment of coronary artery atherosclerosis, although the frequency has fallen with the wide availability and success of percutaneous intervention and stenting. Bypass grafting is still the preferred procedure for some coronary lesions and often accompanies open heart surgery when done for other reasons (e.g. aortic stenosis and coronary atherosclerosis). Conduits used to construct bypass grafts include veins (usually saphenous) and the internal mammary arteries (given their proximity to the heart). The 10-year patency rate of vein grafts is 50%–60% as compared to 80%–90% for internal mammary grafts.[30] Coronary bypass grafts on cardiac explant specimens should be evaluated by sampling: (1) the graft body at the point of greatest narrowing, (2) the anastomotic site, and (3) the native artery proximal and distal to the anastomotic site.

Coronary Artery Stents

Percutaneous endovascular approaches to treating coronary atherosclerosis have become the mainstay for this common disease in developed countries. After performing coronary angiography, it is possible to insert and expand a balloon in narrowed areas and leave a metallic stent in place to maintain an adequate luminal diameter. Endovascular extraction techniques can also be used to remove thrombus, and other obstructive material and intravascular ultrasound, optical coherence tomography, and other imaging modalities can be employed to characterize plaque morphology and composition. Stents placed may be "bare" metal alloy or may be coated with anti-inflammatory drug-eluting polymers to calm the foreign body reaction and prevent early stent thrombosis. Placement of these metallic stents renders routine histology methods completely useless in the evaluation of tissue specimens containing them. Special techniques have been devised to remove the metallic stent struts, and these are discussed in greater detail later (Arteries—Stents and Bypass Grafts).

Cardiac Tumors

Myxoma

Myxomas, together with papillary fibroelastomas, are the most common primary tumors of the heart.[31,32] Myxomas occur in two settings: sporadic and familial. Sporadic tumors occur more often in women and most often in middle adulthood. They arise most often in the left atrium and attach to the atrial septum. Familial myxomas tend to manifest at a younger age and are slightly more common in men. Sites outside the left atrium are also more common with familial tumors, as are multicentric tumors.[33] Besides cardiac myxomas, patients with the heritable Carney complex also may have cutaneous and labial lentiginosis, eyelid and cutaneous myxomas, myxoid mammary fibroadenomas (often multiple and bilateral), adrenocortical nodular dysplasia associated with Cushing syndrome, and large cell calcifying Sertoli cell tumor of the testis.[33] Carney complex patients harbor inactivating mutation of the protein

kinase A regulatory subunit gene *PRKAR1A*, which encodes a protein that plays an important role in cardiac development and myxomagenesis.[34]

Whether familial or sporadic, left-sided cardiac myxomas typically present with signs of mitral stenosis or insufficiency, and right-sided tumors with dyspnea, syncope, distension of neck veins, and other symptoms.[32] They may also lead to multiple emboli in the systemic or pulmonary circulation, depending on their location, but this is fundamentally different than metastasis. Myocardial, pulmonary, or cerebral infarcts may thus supervene. The production of emboli has been attributed to the overexpression of matrix metalloproteinases by the tumor,[35] but having a more frond-like than globose architecture may also predispose to embolization. Two-dimensional echocardiography, CT, MRI, gated radionuclide blood-pool scan, or cardiac catheterization can all visualize myxomas, but cannot differentiate between other pedunculated tumors or thrombi. Occasionally, the diagnosis is made only after histologic examination of an embolus removed from a distant site.

Grossly, myxomas are soft, polypoid, pale, lobulated masses, often attached by a stalk to the septum near the foramen ovale. Areas of hemorrhage may be present (Fig. 42.11). Calcification may occur, and this seems to be more common in those located in the right atrium. Extremely calcified myxomas have been referred to "petrified" myxoma.

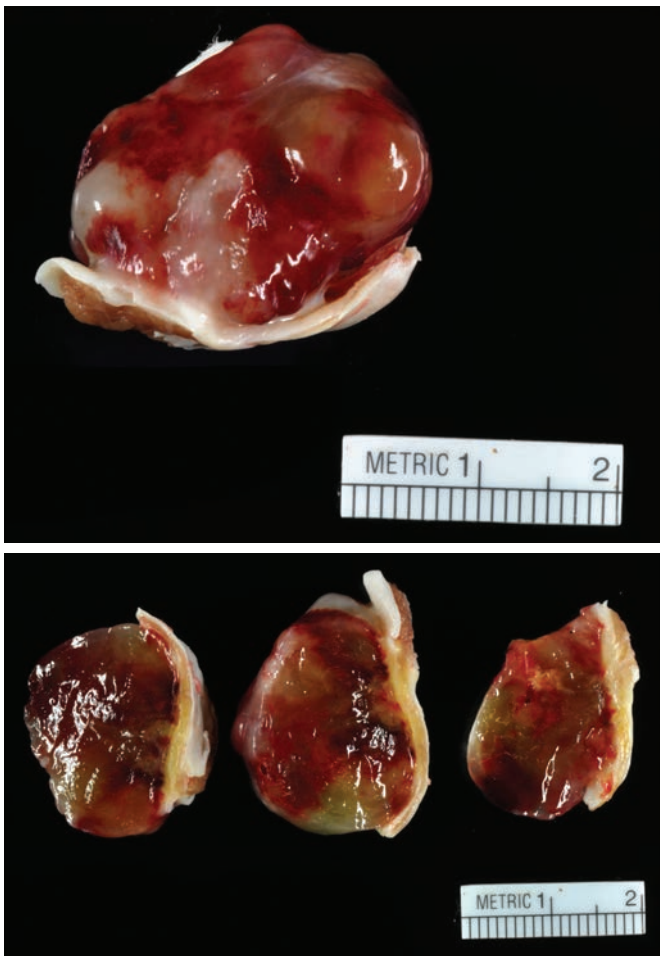

Figure 42.11 Gross Appearance of Cardiac Myxoma. The lesion has a polypoid shape and a hemorrhagic appearance. A portion of atrial septal wall is attached at the "stalk" base.

Microscopically, round, polygonal, or stellate cells are seen surrounded by abundant loose stroma rich in acid mucopolysaccharides. Some of these cells form solid syncytial cords, but the hallmark finding is the presence of myxoma cells in a ring that encircles small- and medium-size tumor vessels (Fig. 42.12). Mitoses, pleomorphism, and necrosis are absent or minimal. Other microscopic variations include surface thrombosis, Gamna–Gandy bodies, ossification ("petrified" myxoma), chondroid tissue, extramedullary hematopoiesis, and presence of thymic and foregut remnants. The latter may be somehow related to the most peculiar change that cardiac myxoma can exhibit, namely the presence of well-developed mucin-producing glands that may even be apparent grossly (Fig. 42.13A and B). This phenomenon, which has been referred to as *glandular myxoma*, can be confused with metastatic adenocarcinoma, particularly when showing atypical cytoarchitectural features. Another exceptional occurrence in cardiac myxoma is the development of a thymoma, presumably arising from the previously mentioned thymic remnants.[36] Neuroendocrine components have also been observed.

This diversity of tissue types arising within myxoma lends some credence to the theory that the line of origin for myxomas may be

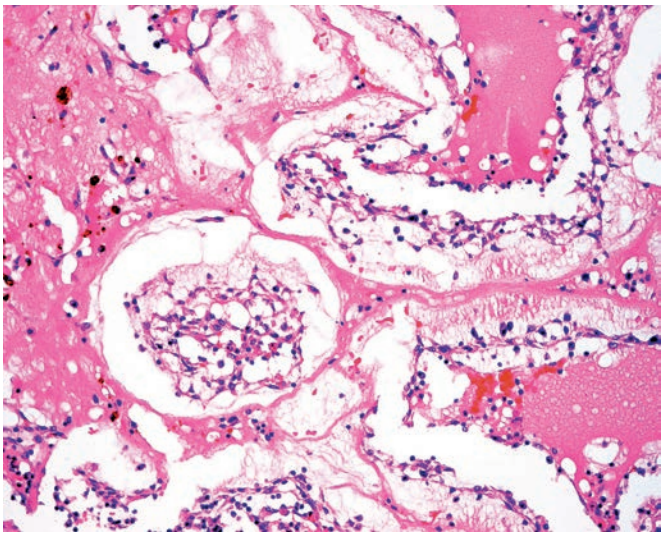

Figure 42.12 Cardiac myxoma showing a concentric arrangement of tumor cells around vascular spaces; highly characteristic of myxoma.

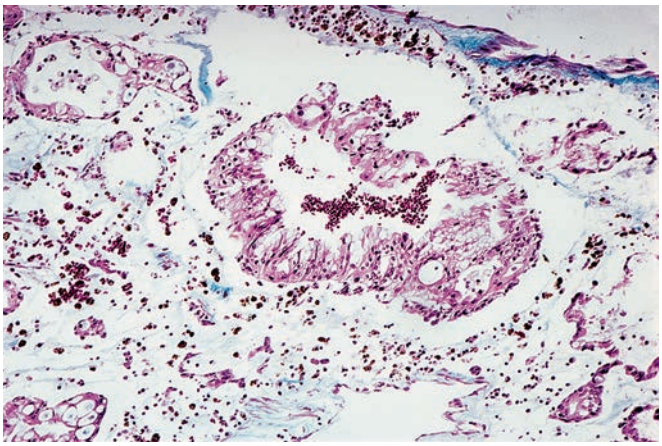

Figure 42.13 "Glandular" Myxoma. The glandular epithelium is tall columnar and contains intracytoplasmic mucin. This rare type of myxoma should not be confused with metastatic adenocarcinoma.

resident pluripotent cells. Ultrastructural studies have also suggested that myxomas arise from multipotential mesenchymal cells.[37] By immunohistochemistry, myxoma cells express endothelial markers (CD31, CD34, factor VIII), as well as calretinin, vimentin, actin, desmin, and smooth muscle myosin.[31,32] Cardiac myxoma expresses several cardiomyocyte-specific transcription factors, suggesting at least primitive cardiomyogenic differentiation as well.[38] The mucinous extracellular material stains for membrane-associated MUC1 and less so for secreted mucins MUC2 and MUC5AC. Areas of glandular differentiation may be positive for carcinoembryonic antigen (CEA), epithelial membrane antigen (EMA), and keratins.

Surgical excision of the ordinary myxoma is often curative. Several instances of local recurrence have been reported in the past; with the routine performance of partial atrial septectomy, together with the excision of the tumor, they have become very rare. Malignant transformation of myxoma is a controversial topic, and, in this author's opinion, convincing cases have not been concretely demonstrated.

Papillary fibroelastoma (fibroelastic hamartoma, fibroma, papilloma, papillary fibroblastoma) is nearly as common as myxoma, and they appear as small papillary ("sea anemone–like") growths that usually occur on the surface of the valves but may also be seen in other endocardial locations (Fig. 42.14).[31,32] It is often an incidental finding at surgery or autopsy but with the increasing resolution of cardial imaging modalities may also be found using these techniques. The myriad fronds of this tumor may be difficult to appreciate when the tumor is dry (and may actually resemble myxoma), but they readily become apparent when suspended in clear liquid (saline or formalin). Microscopically, the papillary architecture is obvious, with individual fronds consisting of a core of hyalinized hypocellular stroma that is rich in elastic fibers and a lining of hyperplastic endocardial cells (Fig. 42.15). Whether they represent a true neoplasm versus an exuberant reactive growth (organized mural thrombus, for example) remains unclear. A form of "secondary" papillary fibroelastoma is recognized in association with rheumatic valve disease, surgical scars inside the heart, and other sites of remote injury.[39]

Other Benign Tumors and Tumorlike Conditions

Rhabdomyoma and rhabdomyomatosis are mostly seen during the first decade of life, and clinically documented examples of tumor regression by adolescence have been reported. However, they can also present in adult patients. Most of the patients have tuberous sclerosis.[31,32] Grossly, rhabdomyomas present as one or more firm, white-yellow, well-circumscribed nodules. Microscopically, the most distinctive feature is the presence of "spider cells," so named because of their radial sarcoplasmic extensions. Immunohistochemically, they show reactivity for myoglobin, actin, desmin, vimentin, and sometimes HMB-45.[31] The latter is of interest because of the link of rhabdomyoma with tuberous sclerosis and the morphologic similarities with angiomyolipoma, another HMB-45-positive lesion.

Fibroma is seen mostly in the pediatric population. Although some are not detected until adulthood, it is believed fibromas are present from birth. Unlike rhabdomyoma, they are rarely multiple and rarely associated with a syndrome (namely basal cell nevus [or Gorlin], Beckwith–Wiedemann, or Sotos syndromes). They are most common in the left ventricle and ventricular septum and are usually large and intramural. Despite gross circumscription, the tumor borders are microscopically infiltrative, similar to what is seen in fibromatosis lesions. The ratio of hyalinized collagen to fibroma cells has been reported to increase with increasing patient age.[31,32]

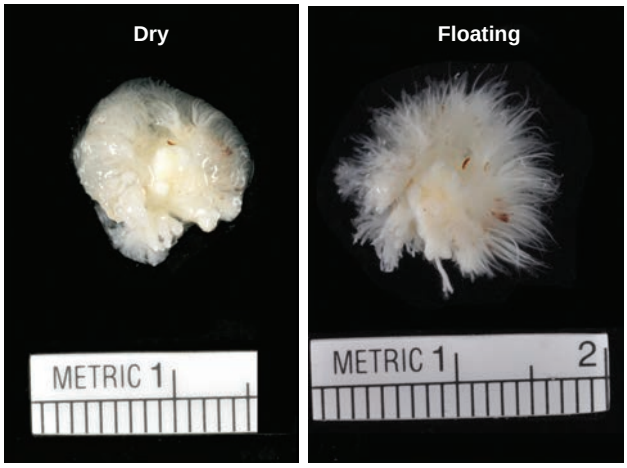

Figure 42.14 Gross features of papillary fibroelastoma (note how the delicate fronds become apparent when floating in clear liquid).

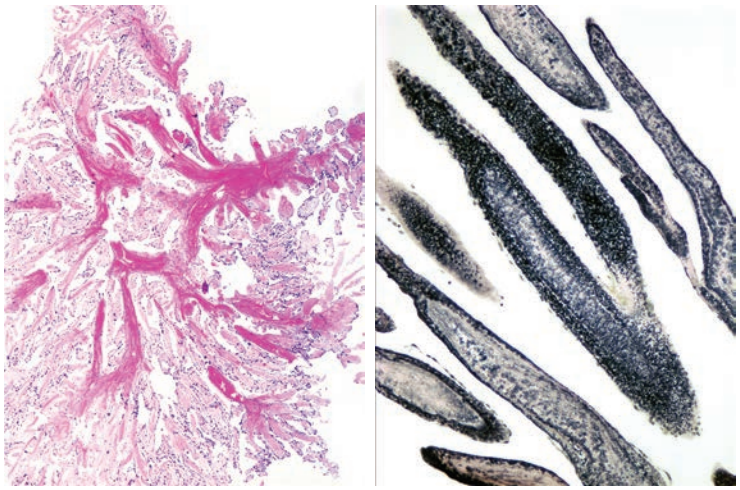

Figure 42.15 Microscopic features of papillary fibroelastoma with highly branched papillary architecture and dense elastin rich cores lined by flattened endothelium.

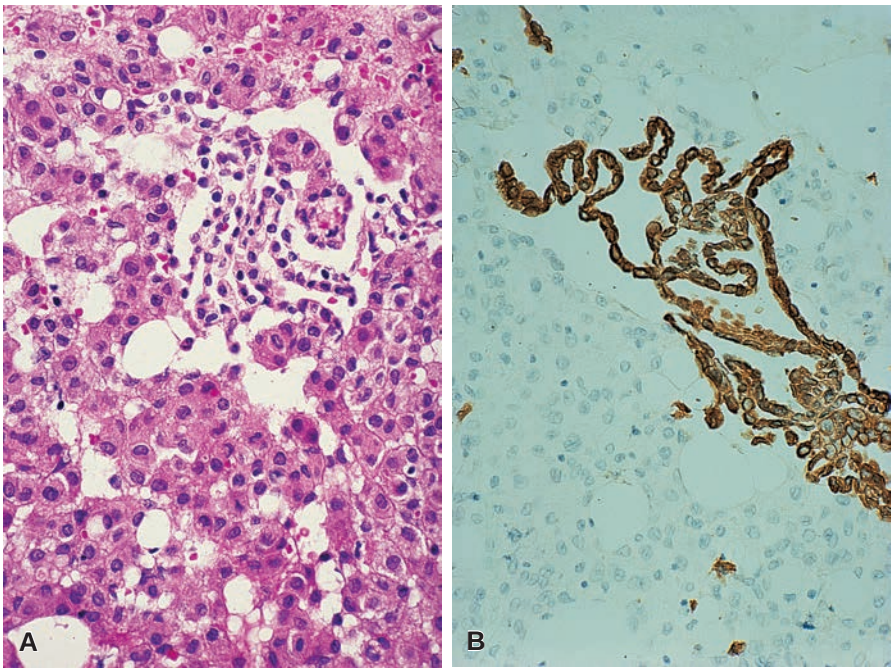

Figure 42.16 So-Called Cardiac MICE. A, This process is composed of an admixture of plump histiocytes and ribbons of small cuboidal mesothelial cells. **B,** The immunostain for keratin highlights the mesothelial cell component, which is surrounded by the negative histiocytes and other mononuclear cells.

Hamartoma of mature cardiac myocytes resembles hypertrophic cardiomyopathy microscopically but is confined as a localized process affecting only a discrete area of myocardium (often in a mass-like fashion). It is characterized by myofiber disarray, focal scarring, and arterial thickening but no inflammation or calcification. The usual but not exclusive location of this lesion is the left ventricle. Clinical correlation is important in this diagnosis, since histologically it is difficult to appreciate a distinct mass or even a border separating it from normal myocardium.[40]

Calcified amorphous tumor of the heart (cardiac CAT) is the name proposed for an endocardially based intracavitary cardiac mass characterized microscopically by nodular deposition of calcium in a background of degenerating blood cell elements and chronic inflammation. The clinical course is benign. The pathogenesis is obscure, but an origin from mural thrombi has been suggested.[41]

Mesothelial/monocytic incidental cardiac excrescences ("cardiac MICE") are incidental microscopic findings at the time of cardiac surgery (usually for valvular disease) or in an endomyocardial biopsy. They may be found attached to the endocardium, free-floating in the pericardial cavity, or even inside an aortic dissecting aneurysm. Ultrastructural and immunohistochemical studies have shown that the lesion is composed of an admixture of keratin-positive mesothelial cells and CD68-positive histiocytes (Fig. 42.16). Microscopically, the mesothelial cells form strips, tubules, and micropapillary formations surrounded by the smaller histiocytes. Huge round vacuoles are often present. Except for the latter, the appearance is very similar to that of nodular mesothelial hyperplasia seen in some hernia sacs.

MICE are thought to be an artifact produced by traumatic or iatrogenic violation of the pericardial cavity with resultant agglutination of mesothelial cells and the other constituents in a fashion similar to the "cell block" techniques used in cytopathology. Their main practical importance resides in the fact that a pathologist unaware of their existence may mistake them for a metastatic carcinoma or some other neoplasm.[42]

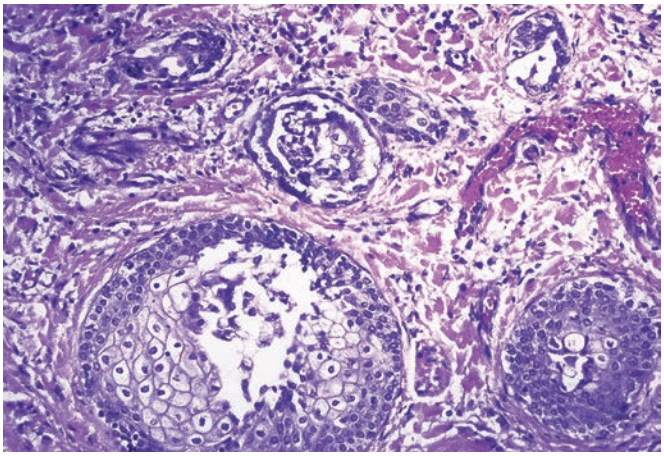

Figure 42.17 So-called cystic tumor of the atrioventricular nodal region. In this case the lining of the cysts had a definite squamoid quality.

Cystic tumor of the atrioventricular nodal region was regarded as a mesothelioma for many years, but there is now conclusive evidence that it represents a developmental abnormality of epithelial nature and endodermal origin. Specifically, it has been postulated that this condition represents a heterotopia of the ultimobranchial body analogous to solid cell rests of the thyroid gland. Because of its crucial location, it may result in complete heart block or be found at autopsy in cases of sudden death. Microscopically, the lesion consists of ductular structures, cysts, and solid nests of epithelial-like cells (Fig. 42.17). Electron microscopy studies have shown desmosomes and microvilli in the epithelial cells. Immunohistochemically, the cells are reactive for keratin, CEA, and B72.3 but not for factor VIII, calretinin, WT1, or thrombomodulin.[32] Hemangiomas and neural tumors may also occur in this location.

Adenomatoid tumor analogous to its more common counterpart in the male and female genital system has been reported in the heart. Here too the lesion is of mesothelial nature (as opposed to the tumor described in the preceding paragraph).[32]

Inflammatory myofibroblastic tumor has been reported in the heart, usually as an endocardial-based process. Its microscopic appearance is the same as that shown by this process in other locations. Positive staining for ALK and ALK gene rearrangements are a fairly constant finding. No metastases have been reported, but the lesion can result in myocardial infarct, syncope, and sudden death.[43]

Paraganglioma can present as a primary intracardiac neoplasm. The left atrium is the most common location; hypertension and elevated urine catecholamine levels are often present, in which case the term extra-adrenal pheochromocytoma has been used.[31] The microscopic, ultrastructural, and immunohistochemical features are similar to those of paraganglioma elsewhere, including an occasional pigmented example (see Chapter).

Other primary tumors of the heart include granular cell tumor (not to be mistaken for rhabdomyoma or histiocytoid cardiomyopathy), hemangioma (including the epithelioid and histiocytoid varieties), lymphangioma, lipoma (to be distinguished from lipomatous hypertrophy of the atrial septum), angiolipoma, schwannoma, ganglioneuroma, and benign teratoma.

Other non-neoplastic conditions reported in the heart are ectopic thyroid, extramedullary hematopoiesis, and Rosai–Dorfman disease.[32]

Primary Malignant Tumors

Sarcomas of the heart are exceptionally rare but are the most frequent type of primary cardiac malignancy. Despite significant advances in molecular sarcoma classification over the past decade, some highly pleomorphic cardiac tumors defy classification (i.e. pleomorphic undifferentiated sarcoma). Of those that can be placed into a lineage-specific category, angiosarcoma is the most common. They are typically located in the right atrium, where they present as a large mass (Fig. 42.18). Its microscopic appearance may be similar to that of angiosarcoma elsewhere (see Chapter), but others are more poorly differentiated. Ultrastructural and immunohistochemical features of endothelial differentiation can be demonstrated in some of the cases. It should be noted that the term "intimal sarcoma" has been applied to malignant tumors expressing an endothelial phenotype that arise in great vessels (particularly the pulmonary artery but also the aorta and its branches). The malignant cells in these tumor often grow along the surface of mural fibrin thrombus rather than invading through the vessel wall (hence the designation as "intimal"). More recently, the term has also been misapplied to any cardiac sarcoma showing molecular evidence of endothelial differentiation.[44,45] In terms of anatomic distribution and histomorphology, intimal sarcomas do appear to be distinct from other angiosarcomas. Kaposi sarcoma in its systemic form is another vascular malignancy that can involve the heart in immunocompromised (especially AIDS) patients.[46]

The second most common category of sarcoma is that of *myosarcoma*, either *leiomyosarcoma* or *rhabdomyosarcoma*. Leiomyosarcomas can have spindle cell, epithelioid, or myxoid features. Some of them contain scattered osteoclast-like multinucleated giant cells, like those more commonly seen in leiomyosarcomas of the uterine corpus. Other types described include *myxofibrosarcoma*, *pleomorphic undifferentiated sarcomas*, *osteosarcoma*, *fibrosarcoma*, *liposarcoma*, *synovial sarcoma* (Fig. 42.19), *Ewing sarcoma/primitive neuroectodermal tumor (PNET)*, and *malignant peripheral nerve sheath tumor*. All of these tumor types are more common in adults than children, and the prognosis is uniformly dismal.

Most patients with primary heart sarcomas present with intractable congestive heart failure, arrhythmias, or signs of superior vena cava obstruction.[32] The initial diagnosis is usually made incidentally while undergoing imaging studies, especially echocardiography. Attempts at tissue characterization by MRI may be made, along with assessing contrast enhancement. Metastatic lesions, especially in the lungs, may be the first manifestation of cardiac sarcomas. Though there are many exceptions, it is generally true that malignant tumors (especially angiosarcoma) are more frequently found in the right side of the heart and that benign neoplasms are more common on the left side.

Lymphoma presenting as a primary heart tumor is very rare.[47] Most of the reported cases have been of diffuse large B-cell type, some of which are EBV positive. Cases have been reported in

Figure 42.18 Gross appearance of a large angiosarcoma of the heart (right atrium).

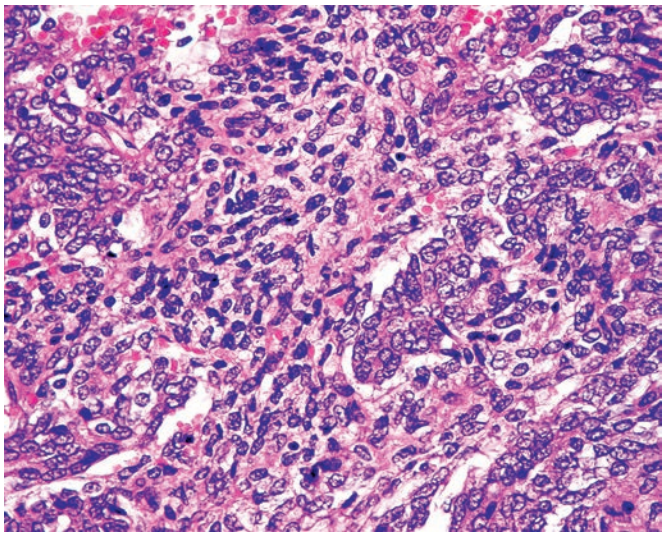

Figure 42.19 Primary synovial sarcoma of heart showing typical biphasic appearance.

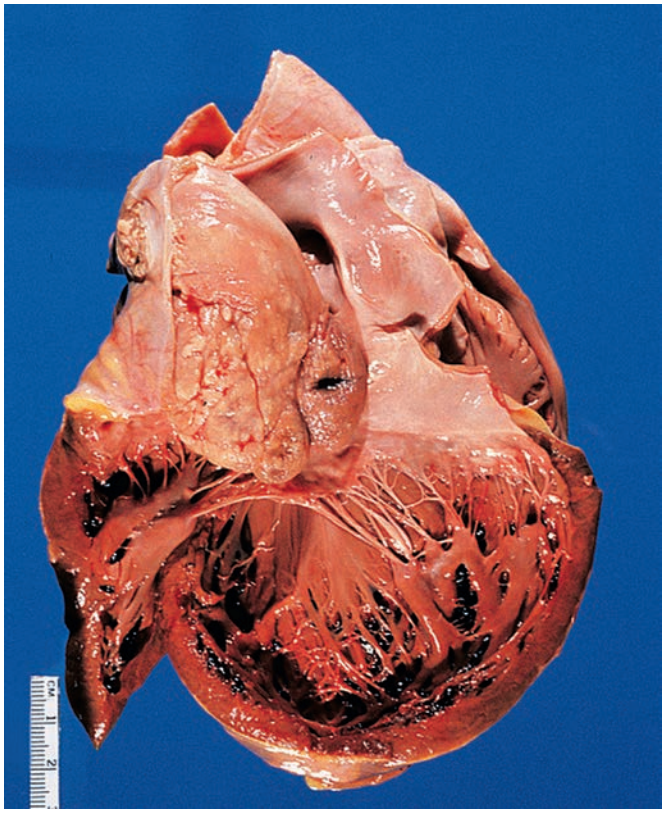

Figure 42.20 Large metastatic carcinoma in left atrium that was continuous with tumor in left pulmonary vein. This mass simulated an atrial myxoma by echocardiography. The primary tumor was a mucoepidermoid carcinoma of left submaxillary gland.

association with cardiac prostheses and mural fibrin thrombus.[48,49] Secondary cardiac involvement by advanced malignant lymphoma or leukemia is a relatively common event, although it is more often found at autopsy than clinically.

Metastatic Tumors

Involvement of the heart by metastatic carcinoma or by generalized malignant lymphoma is a more common event than primary malignancy of this organ, by a factor of 30 to 1. There metastases are rarely sampled by biopsy or surgical means unless the disease affects nonvital and accessible sites such as pericardium. Any portion of the heart can be involved by metastatic disease, including the conducting system, the latter resulting in heart block.[50]

In the majority of carcinomas metastatic to the heart, the primary tumor is in the thoracic cavity or contiguous areas, and the tumor reaches the heart by metastasizing to the mediastinal lymph nodes and from there extending in a retrograde fashion to the cardiac lymph vessels. Malignant tumors with a propensity for hematogenous spread to the heart are malignant melanoma, renal cell carcinoma, choriocarcinomas, and rhabdomyosarcoma. Rarely, the metastatic heart lesion presents as an isolated nodule (Fig. 42.20).

Pericardium

Pericardial cysts are discussed together with all other mediastinal cysts in Chapter 12. Other congenital abnormalities are extremely rare; they include the presence of ectopic tissue such as thyroid and liver.[51]

Pericarditis is of importance to the surgical pathologist for several reasons. A diagnosis of tuberculous pericarditis or sarcoidosis can be made from open pericardial biopsy (or "window" procedure) significantly impacting clinical treatment and prognosis. Acute nonspecific fibrinous, hemorrhagic, or purulent pericarditis is rarely biopsied but may be troublesome because of the reactive mesothelial hyperplasia and atypia that may mimic mesothelioma or other malignancy.

Chronic pericarditis is often accompanied by fibrosis and calcification and may lead to physiologic constriction (so-called constrictive pericarditis). This may result from tuberculosis and other infections, collagen–vascular diseases, malignant tumors, trauma, surgery, radiation therapy, or chemotherapy. Pathologic examination usually shows only dense fibrosis and a scanty inflammatory infiltrate, regardless of etiology. Residual granulomas may be found in the cases of tuberculous etiology, and bizarre atypical fibroblasts may be seen in the postirradiation setting. Calcification, either in a delicate "egg shell"–like fashion or as hard plate-like deposits, may also occur.[52] Importantly, some patients with bona fide constrictive pericarditis (confirmed intraoperatively) may not have pericardial thickening, and histologically the pericardium may appear entirely normal.[53]

Multilocular mesothelial inclusion cyst of the pericardium is morphologically and probably pathogenetically equivalent to the condition that bears the same name in the peritoneal cavity. Although originally designated as benign multicystic mesothelioma, it probably represents a reactive change secondary to chronic irritation.[54]

Mesotheliomas of the pericardium occur, but their frequency is much less than that for similar tumors in the pleura or peritoneum. They have been reported in the setting of tuberous sclerosis and may present as a single well-circumscribed mass, as multiple tumors, or as a diffuse growth encasing the heart. They are essentially identical to mesothelioma of the pleura (discussed in Chapter 11) and are staged accordingly.

Other primary tumors of the pericardium are exceptionally rare. One such group is represented by germ cell tumors: both mature teratoma and yolk sac tumor have been reported in this location. Angiosarcoma of pericardium may coat the pericardium in a diffuse fashion, thus simulating the pattern of growth of mesothelioma; some of these have been radiation induced. There have been isolated case reports of pericardial myolipoma, ectopic thymoma (associated with myasthenia gravis), and fibroma.

Metastatic carcinoma to the pericardium usually originates in the lung in the form of direct extension or lymphatic permeation. It may result in constrictive "pericarditis" as a result of the associated intense desmoplastic reaction or be associated with recurrent pleural effusion. Other tumors that commonly give rise to pericardial metastases are breast carcinoma, malignant melanoma, and malignant lymphoma (including HHV8-positive primary effusion lymphoma).[55] Cytology is the most important technique for the evaluation of malignant pericardial effusions. Pericardial biopsy may be necessary in some cases to confirm the diagnosis.

Arteries

Normal Anatomy

The reader is referred to standard textbooks and chapters on arteries, veins, capillaries, and lymph vessels for a description of the normal anatomy of these structures.[5,56] For the purposes of general surgical pathology, it will suffice to say arteries may be divided into three types: (1) elastic arteries (characterized by stacked layers of elastic tissue throughout the media layer), (2) muscular arteries (defined by the presence of two distinct elastic layers, an internal layer

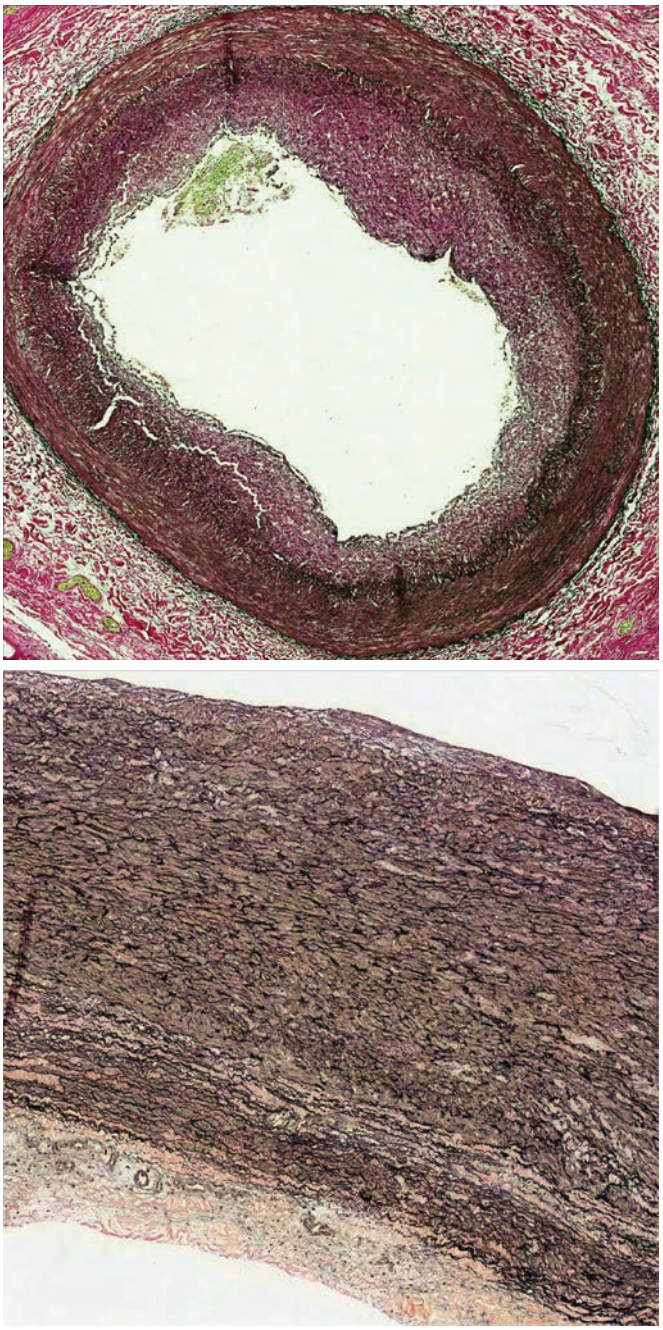

Figure 42.21 Comparative histology of muscular *(top)* and elastic *(bottom)* arteries.

separating intima from media, and an external separating media from adventitia) (Fig. 42.21), and arterioles (composed of only smooth muscle with no discernible elastic layer).

Arteriosclerosis and Atherosclerosis

Arteriosclerosis is a generalized progressive arterial disease associated with wall stiffening, localized luminal narrowing (of muscular arteries), and aneurysms. **Atherosclerosis** refers to a form of arteriosclerosis characterized by lipid-rich "atheroma" in the arterial wall. As the principal cause of heart attack and stroke, atherosclerosis remains the leading cause of death in developed countries.[57] Atherosclerosis is an intimal inflammatory process mediated by activated

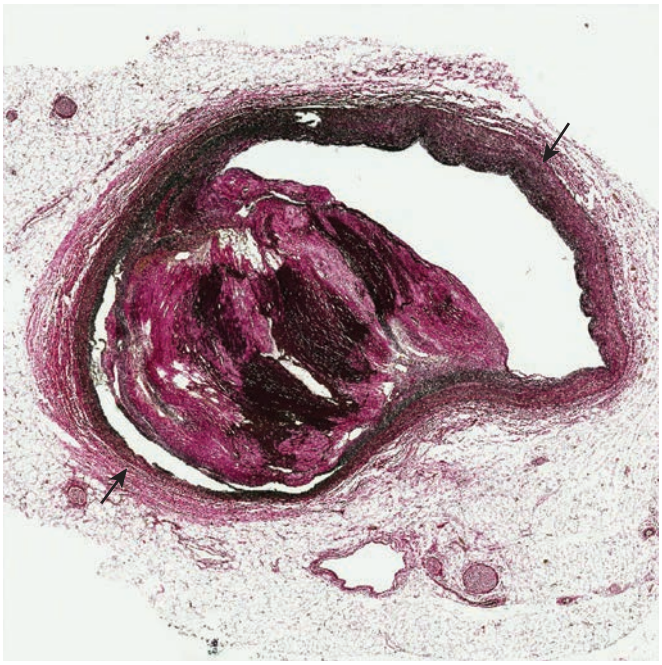

Figure 42.22 Arterial Wall Remodeling in Atherosclerosis. The wall segment underlying the atherosclerotic plaque shows marked thinning *(bottom arrow)* compared to the normal wall segment opposite the plaque *(top arrow)*.

endothelium and smooth muscle cells of the arterial wall.[58] Macrophages are also key participants, elaborating growth factor and cytokines that affect cell signaling pathways and lipid processing.[59,60] Other factors shown to be important in its pathogenesis include changes in lipid metabolism (especially oxidation of lipoproteins), increased endothelial permeability to serum lipoprotein complexes, endothelial activation/injury due to flow turbulence at major bifurcations, and activation of the clotting cascade resulting in thrombosis.

An important feature of atherosclerosis in particular is outward arterial "remodeling," ostensibly in order to maintain lumen diameter in the face of encroaching intimal atheromatous plaque.[61] In the extreme, this may lead to formation of a true atherosclerotic aneurysm. Histologic evidence of this outward remodeling manifests as thinning (atrophy) of the media underlying the plaque in comparison to the relatively thicker (hypertrophied) spared wall opposite a plaque (Fig. 42.22).

Plaque composition and morphology has gained considerable attention in recent years, as most lethal and morbid events relating to atherosclerosis are felt to be due to abrupt thrombosis rather than progressive luminal occlusion by plaque. This thrombosis results from exposing pro-thrombogenic plaque material to luminal blood through disruptions in the intima overlying the plaque. Plaques showing this type of atherothrombosis are said to be "ruptured" or "complicated" plaques, and plaques showing conditions optimal for this type of event, but without actual disruption as-of-yet, are referred to as "unstable" or "vulnerable" (Fig. 42.23).[62,63] Description of these features in surgical pathology reports are meaningful to and appreciated by clinical colleagues. Such descriptions should include the relative composition of the plaque: lipid rich ("soft"), fibrotic ("hard"), calcified, hemorrhagic, etc. The nature of the intima overlying the plaque (the "fibrous cap") in terms of its overall thickness and the presence of inflammation or erosion/ulceration should also be mentioned. Plaque instability is defined as abundant lipid-rich atheromatous material, hemorrhage, and a thin, inflamed

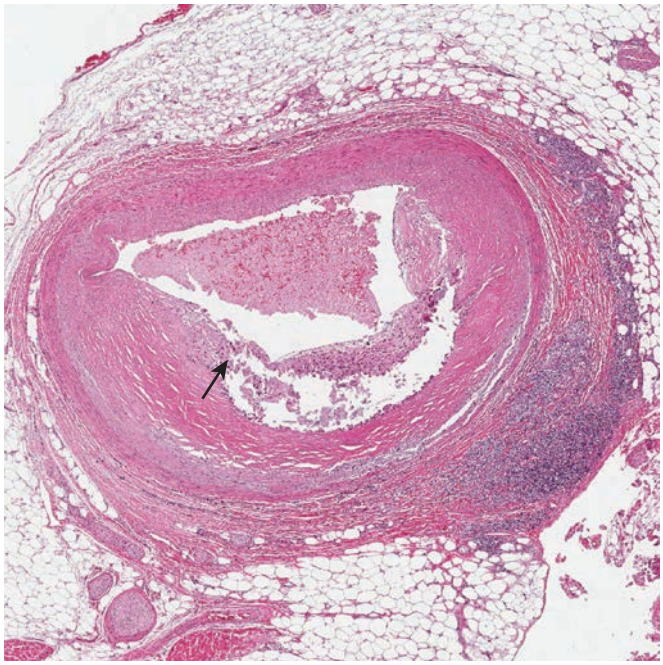

Figure 42.23 Ruptured Atherosclerotic Plaque and Luminal Thrombosis (Atherothrombosis). An arrow points to the site of probably plaque rupture (note the inflammatory infiltrate in the plaque and adventitia).

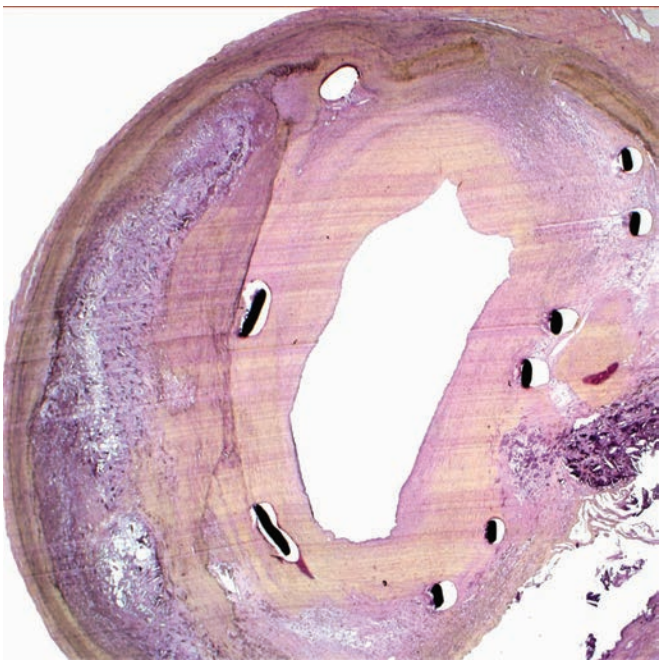

Figure 42.24 Cross section of stented artery, using plastic resin embedding techniques, metallic stent sections appear opaque *(black)*. The native plaque as well as neo-intimal plaque formation are apparent.

overlying fibrous cap. Obviously the presence of thrombus, recent or otherwise, also pertains. A numeric grading system (I–VI) for describing plaques has been developed but is largely restricted to research purposes.[64,65]

Arteriosclerosis and atherosclerosis are encountered in surgical pathology as part of the evaluation of specimens obtained from endarterectomy (carotid or coronary), heart transplantation, and amputation of ischemic limbs. They may also be encountered incidentally in a variety of other specimens. It should be noted that ascending aortic aneurysms, though common surgical specimens, rarely show atherosclerosis. During the placement of synthetic tube grafts (whether during an open vascular procedure or endovascular stenting) in the descending thoracic or abdominal aorta, it is common for the diseased arterial tissue to be left *in situ* rather than removed for examination.

With careful handling (both on the part of surgeons and pathology labs) it is possible to preserve cross sections through endarterectomy plaques in a manner that makes plaque composition and the degree of narrowing evident, even though only the intima is present. In some patients, thrombus may be aspirated endovascularly during percutaneous intervention. Histologic characterization of these clots (recent, degenerating, organized, etc.) is also clinically relevant, although precise dating based on these features is not currently feasible.[66,67]

Stents and Bypass Grafts

Arterial Stents

As mentioned earlier, angioplasty with stenting has become a mainstay and first line option for treating coronary artery disease and its complications. The role of open heart surgery for coronary bypass grafting has largely been relegated to use in patients with coronary disease who are already undergoing thoracotomy for another reason (such as valve replacement). However, these same techniques may be applied to other arteries as well. This discussion will include coronary stents but also applies to those placed in the carotid, renal, and other peripheral arteries, as well as the aorta.

Stents engineering developments have been considerable but are mostly beyond the scope of this textbook. Various metal alloys (e.g. cobalt chromium, nickel titanium, stainless steel) are used in their construction. The metallic frame may remain as "bare metal" or be coated with drug-eluting polymers to deliver anti-proliferative agents (e.g. everolimus, paclitaxel) over a sustained duration in an attempt to retard in-stent smooth muscle and fibroblast proliferation.[68,69]

The major complication following stent placement is the formation of thrombus within and/or adjacent to the stent. Patients receive aggressive anti-platelet and anticoagulation therapy for months after stent placement to prevent this. When stented specimens are removed and submitted for surgical pathology examination (whether as part of explanted hearts and other organs during transplant surgery or as arterial specimens), the primary clinical question to be addressed is stent thrombosis and neointimal narrowing.[70] Unfortunately, the metallic stent struts become embedded and incorporated into the vessel wall tissue, posing a major challenge for tissue processing and microtomy in the histology laboratory.

Several techniques exist for processing stented arterial specimens, but all involve extra effort, time, and expense so have not seen wide adoption in most labs. Still, the information gained from histology in these stented specimen certainly warrants consideration and attempts by these processing methods. Identifying the location of the stent, especially months or years after placement, may be a challenge and specimen radiography is invaluable in this endeavor. Methods for obtaining cross sections through the stented portion include resin embedding followed by sectioning using tungsten carbide blade microtomy or sanding/grinding to a specified thickness (~40 µm) before routine staining.[71] Using these methods the stent struts remain in the specimen and appear as black geometric profiles embedded in the tissue (Fig. 42.24). More recently, methods using strong acids[72] or reverse electroplating[73] to dissolve the metallic stent

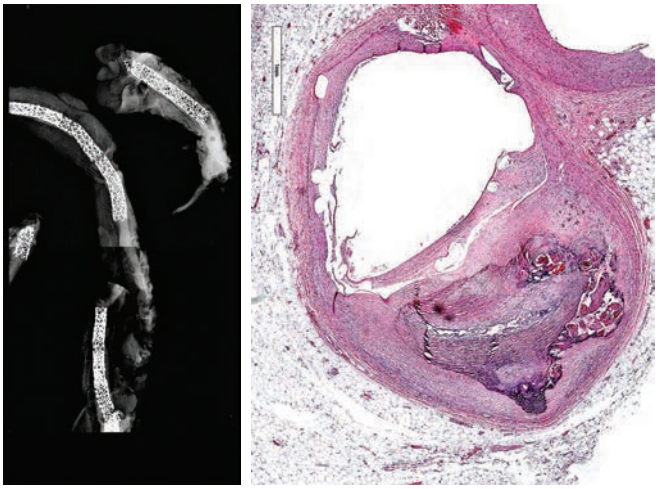

Figure 42.25 Cross Section of Stented Artery, Using Stent Dissolution Techniques. Holes can be seen where the stent struts were situated prior to dissolving *(right)*. Specimen radiography can be helpful in identifying the location of stents, prior to dissolving *(left)*.

struts have been described. After these methods are applied, the metal-free tissue can be sectioned and submitted for paraffin embedding like any other specimen. Histologic sections in such cases show the outline of tissue-strut interface, but the opaque metallic strut profiles are absent (Fig. 42.25). Practical experience with this method suggests not all stents are amendable to dissolution using this technique and strut fractures leave portions undissolved, making this a tedious and iterative endeavor. Stented specimens will be submitted for surgical pathology examination for the foreseeable future, and while better, more practical means of histologic examination are needed, laboratories should seek access to special techniques for processing at least a subset of these.

Arterial Bypass Grafts

Though coronary bypass grafts are by far the most common type to be encountered in surgical pathology, bypass graft conduits from other anatomic sites may be received as well. Where possible, cross sections from the anastomotic site, graft body, and distal vessel should be reviewed (Fig. 42.26). Since the graft conduits experience flow at arterial pressures, atherosclerosis may develop in the graft body, even in grafts of venous origin. Pseudoaneurysm formation at the anastomotic site is a frequent complication.

Aneurysms

Arterial aneurysms develop as a dynamic consequence of arterial wall weakening in the face of intraluminal arterial pressure. The wall changes leading to aneurysms may be atherosclerotic (as with abdominal aortic aneurysm), developmental (cerebral Berry aneurysm), degenerative (ascending aortic aneurysm), traumatic/vasculitic (pseudoaneurysms), or infectious (mycotic aneurysm) in nature.[74] Degenerative aneurysms tend to be "fusiform" with gradual, symmetric tapering contours, whereas nearly all other aneurysm types are asymmetric, abrupt, and "saccular." True aneurysms contain all three arterial layers (intima, media, and adventitia), although the usual dual elastic layers may not be distinguishable due to wall remodeling changes. False or "pseudo" aneurysms are merely contained ruptures resulting from some kind of penetrating wall injury and tend to occur at sites of traumatic injury, vasculitis, or prior surgical vascular anastomoses (Fig. 42.27).

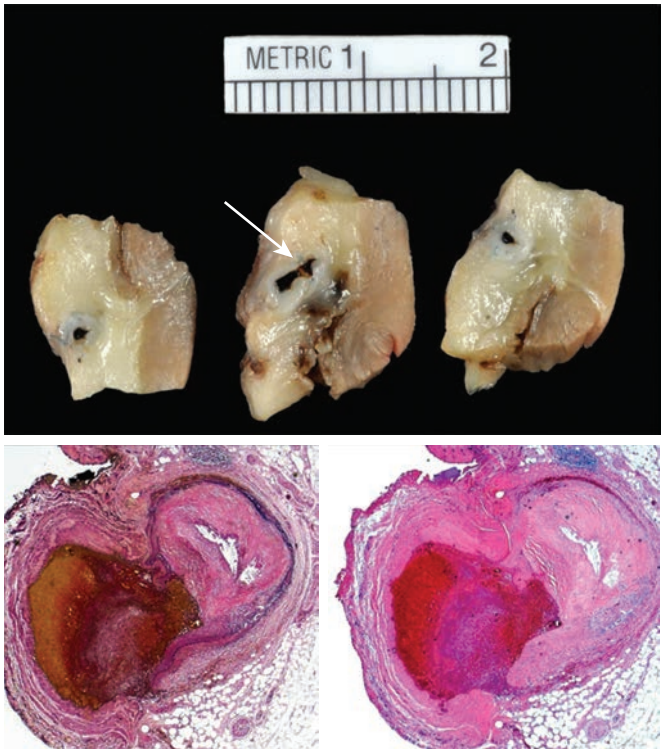

Figure 42.26 Routine Histologic Sampling of Bypass Grafts. The anastomotic site should be serially sectioned to locate the joining point of native vessel and graft *(arrow)*. Step sections through the block may be helpful in visualizing this histologically.

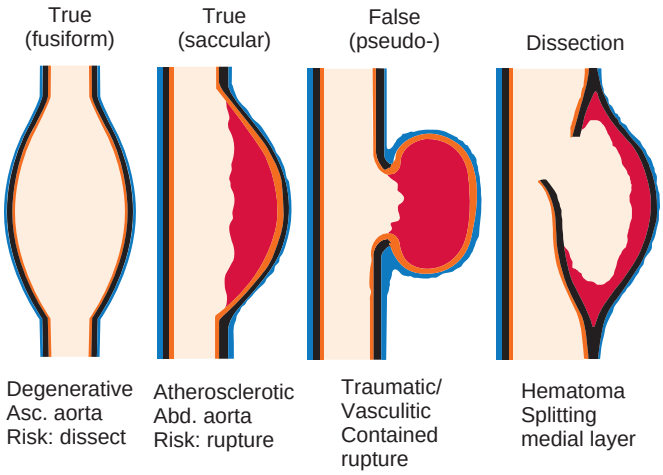

Figure 42.27 Arterial aneurysm types and their morphologic and clinical associations.

Aortic Aneurysms

As the largest artery, the aorta is the most common site of arterial aneurysm. There are important differences between aneurysms in the ascending versus descending thoracic and abdominal aorta. Size (diameter) and rate of change in size are reliable predictors of aortic aneurysm rupture risk, and site-specific guidelines exist for different anatomic locations.[75,76] Arterial dissection (discussed in more detail later) may give the same aneurysmal appearance externally but is fundamentally different. Like aneurysmal dilatation, dissection may also lead to vessel rupture. It should be made clear, however, that

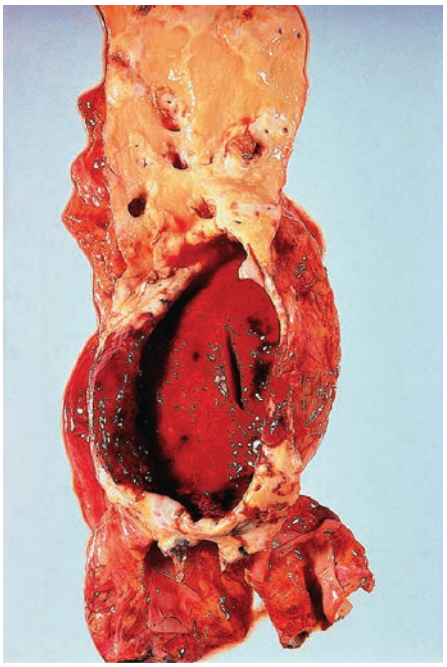

Figure 42.28 Abdominal aortic aneurysm with mural thrombus (note the presence of atherosclerotic changes and the asymmetric (saccular) configuration of the aneurysm.

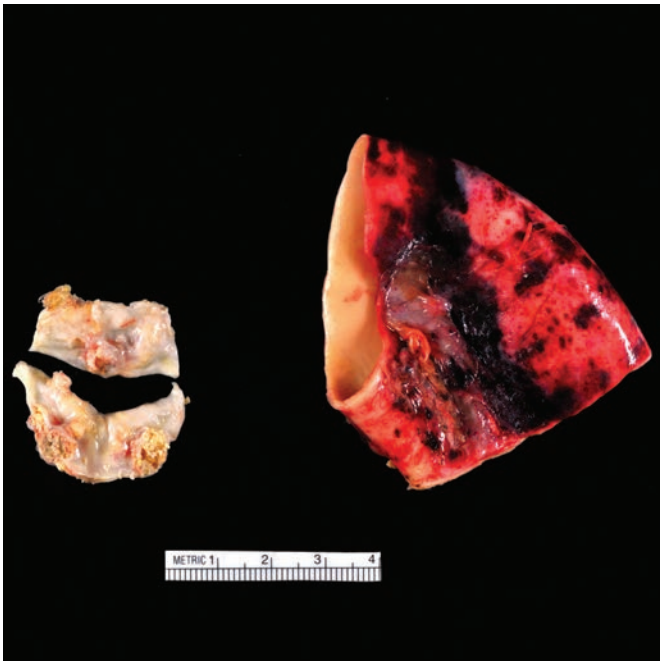

Figure 42.29 Ascending aortic aneurysm and bicuspid aortic valve. Note the uniform symmetric (fusiform) dilatation of the aneurysm.

dissection of the aorta is for all intents and purposes limited to the thoracic aorta and distinctly uncommon in atherosclerotic abdominal aneurysms.

Laminated mural thrombus is frequently present in saccular abdominal aneurysms and presents a potential source of emboli downstream (Fig. 42.28). Endovascular stent placement has largely replaced open surgical procedures for abdominal aortic aneurysms in most centers, so surgical specimens from the abdominal aorta have become scarce.[77]

The histologic features of atherosclerosis are described in detail previously. While luminal stenosis and occlusive atherothrombosis are rare in the aorta, the histology of the atheromatous plaques is similar for atherosclerotic aneurysms in comparison to those of smaller muscular arteries (with the addition of ulceration, inflammation, and laminated thrombus). Degenerative aneurysms located in the ascending aorta (Fig. 42.29) often show disruptions of the normal elastic laminar architecture (Fig. 42.30). Historic terminology for these has been imprecise and potentially misleading, including terms such as "necrosis" (which is seldom seen) and "cystic" (even though epithelial-lined structures are absent). An updated nomenclature scheme has been proposed, including the terms "mucoid extracellular matrix accumulation," "loss of smooth muscle nuclei," and "elastic fiber fragmentation," to more accurately characterize these changes.[78] This scheme is largely intended for use in comparative research studies. For the purpose of routine surgical pathology reporting, it is probably sufficient to state when degenerative changes are present in the media, realizing that correlation between histology and aneurysm etiology or size is poor (e.g. grossly impressive aneurysms may show normal media histologically).[79] Because of this, thorough sampling is encouraged (at least six pieces submitted). Histology is also not highly specific as to genetic etiology (Marfan, Loeys–Dietz syndrome, etc.), many of which are diagnosed based on clinical and genetic criteria.[80] Immunostaining for various proteins in the TGF-β signaling pathway, implicated in these diseases, may be useful in routine diagnosis but awaits further development.

Vasculitis in general is addressed in more detail later, but aortitis will be briefly addressed in this section since its primary manifestation is aortic aneurysm.[81] Giant cell and lymphoplasmacytic aortitis share overlapping features, with the obvious distinguishing feature being the presence of giant cells in the former, typically arrayed in collars and cuffs surrounding islands of collapsed elastic laminae devoid of smooth muscle nuclei (Fig. 42.31).[82] The presence of penetrating vasa vasorum in the mid to inner portion of the elastic media and increased medial collagen are also seen in these forms of aortitis. Clinically, giant cell and lymphoplasmacytic aortitis may be a large vessel manifestation of systemic vasculitis (namely giant cell or temporal arteritis, especially in the elderly) but organ-limited or isolated forms of aortitis are also recognized for which surgical resection may be curative.[83] Thorough rheumatologic assessment of the patient and possibly wider vascular imaging studies are often needed to guide management in these cases.

Aortitis of the abdominal aorta is distinctly different and represents either infection (often by *Salmonella* and other enteric organisms)[84] or so-called inflammatory abdominal aortic aneurysms. Infections may be primary in nature or secondary to seeding of thrombus within an existing atherosclerotic aneurysm. Inflammatory aneurysms are recognized as part of the continuum with IgG4-related disease and sclerosing mesenteritis. Such cases show mixed inflammatory infiltrate containing eosinophils, lymph follicles, storiform fibrosis, perineurial inflammation, obliterative phlebitis, and numerous IgG4-positive plasma cells.[85] Fistulas may develop as a complication of abdominal aortic aneurysms in particular, usually with catastrophic results.

Arterial Dissection

Dissection refers to a splitting apart of medial smooth muscle caused by an infiltration of luminal blood under arterial pressure. This often results in narrowing or occlusion of the "true" lumen and blockages in small arterial branches arising from the dissected artery.

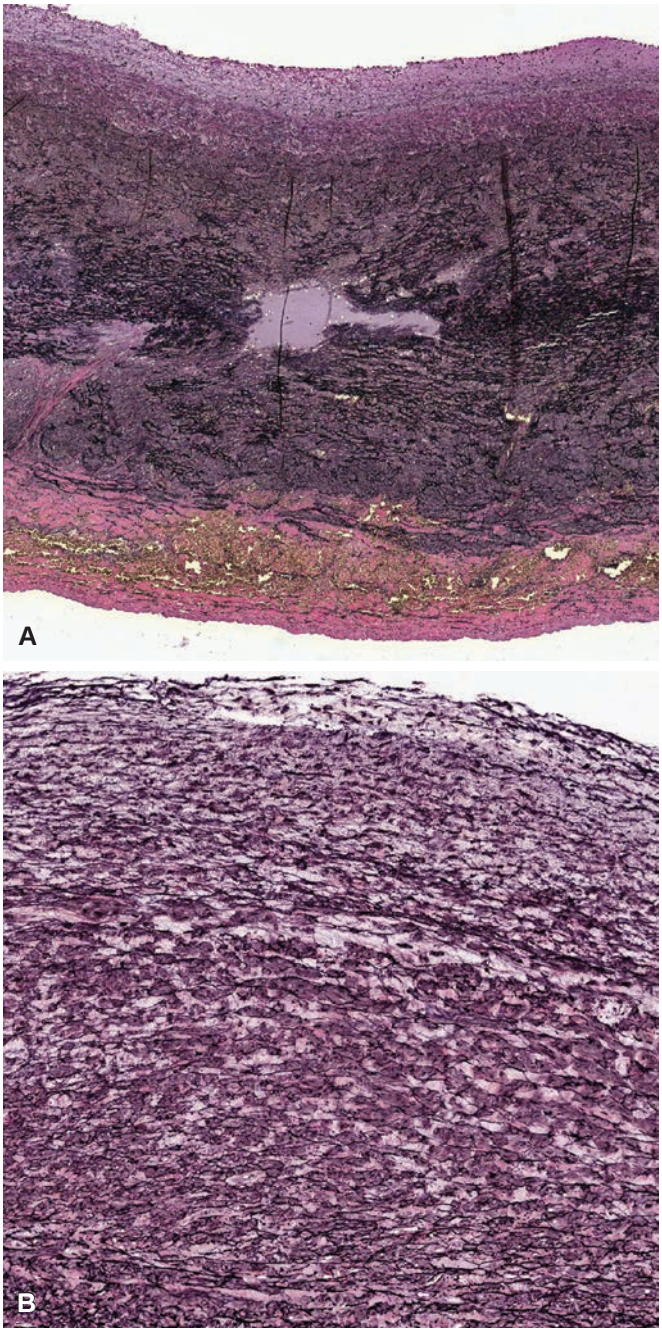

Figure 42.30 Medial Degenerative Changes in Ascending Aortic Aneurysm. A, "Cystic" change (translamellar mucoid extracellular matrix accumulation). **B,** More subtle elastic fiber fragmentation and intralamellar mucoid extracellular matrix accumulation.

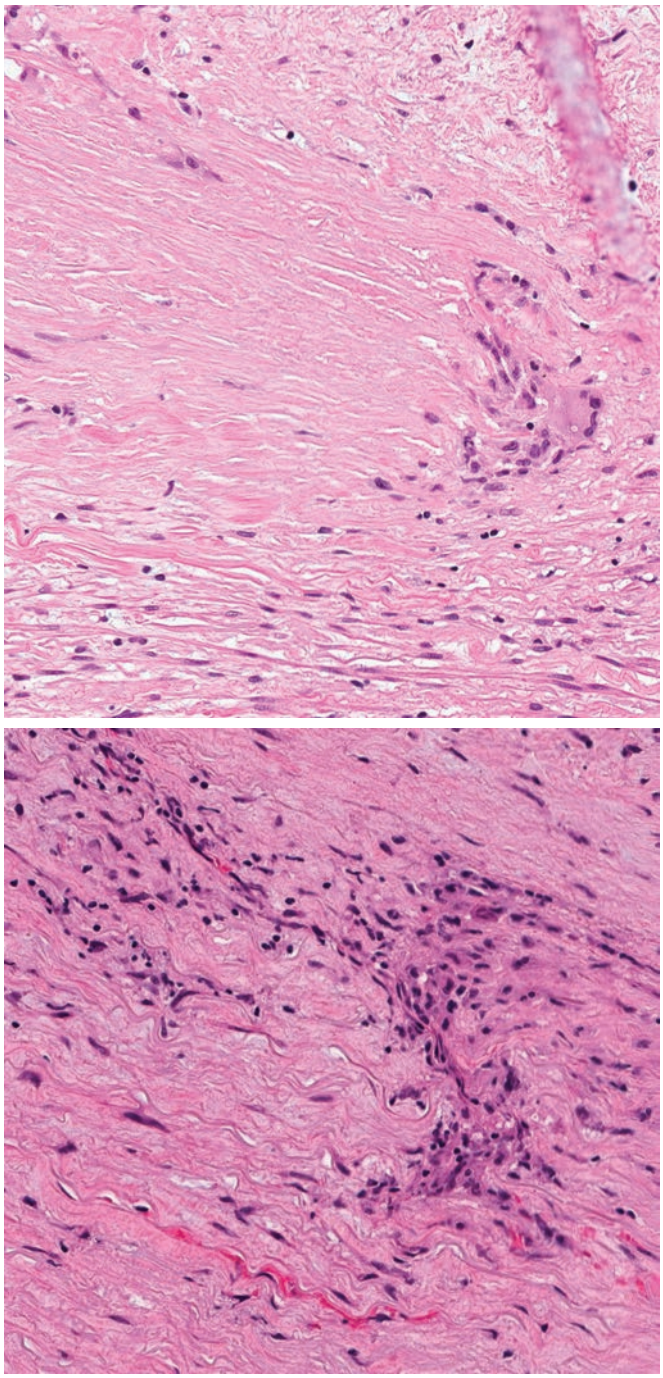

Figure 42.31 Aortitis with *(top)* and without giant cells *(bottom)*. The inflammatory component is intimately associated with areas of smooth muscle cell nuclear loss and elastic laminal collapse.

Underlying degeneration of medial elements is suspected as a precursor to dissection mechanistically but is not always convincingly demonstrated histologically. The dissection plane may extend to (and through) the adventitial connective tissue, resulting in vascular rupture and arterial hemorrhage.

Clinical factors associated with dissection include hypertension, Marfan syndrome and other related genetic disorders caused by TGF-β pathway mutations (the "TGF-β-opathies"), as well as pregnancy, bicuspid aortic valve, and traumatic (iatrogenic), atherosclerotic, or inflammatory injuries of the aortic media.[86,87]

The process of dissection is thought to begin as a transverse intimal tear that may be associated with intimal plaque located either in the ascending aorta or in the upper descending thoracic aorta near the origin of the left subclavian artery (Fig. 42.32).[88] Once this tear develops, the intramural layers of the aorta are rapidly separated by the force of the blood entering the wall (Fig. 42.33). The dissection usually involves the entire circumference of the aorta as it progresses distally. Lower extremity symptoms and signs of acute occlusion of the abdominal aorta may be prominent clinically because of distal aortic or iliac luminal occlusion by the leading

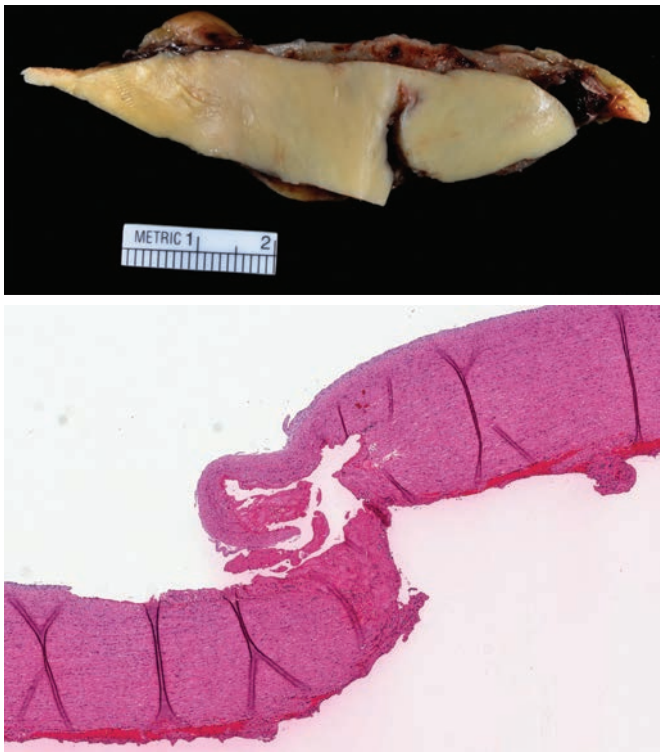

Figure 42.32 Intimal tear in the descending thoracic aorta with acute dissection. Histologically, the tear is associated with fibrin coating of the rupture tract.

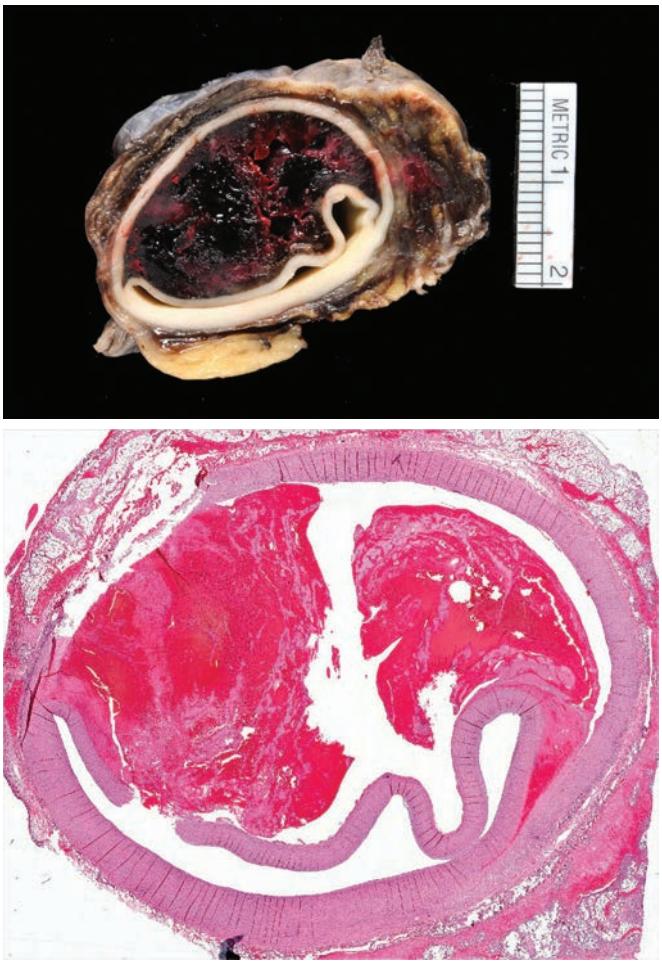

Figure 42.33 Aortic Dissection, Cross Section. Thrombus fills the intra-medial "false" lumen, compressing the true lumen beneath.

point of the dissection. Diagnostic imaging is essential in the evaluation of suspected aortic dissection.

Aortic dissections have been classified by two different systems. The most widely used (Stanford) system focuses on involvement of the ascending aorta (type A), regardless of what other segments may be involved, since these require urgent surgical intervention. Those not involving the ascending portion (type B) are often managed medically and more expectantly. In the other (DeBakey) system, type I dissection begins in the ascending aorta and extends beyond; type II is confined to the ascending aorta; type IIIA begins in the descending aorta and stops above the diaphragm; and type IIIB also begins in the descending aorta but extends below the diaphragm. Arterial dissection can also occur in muscular and elastic arteries other than the aorta, such as the renal, coronary, pulmonary, vertebral, and carotid vessels.

Acute dissection can be recognized grossly and histologically by the presence of blood and fresh fibrin within the dissection cavity, directly adjacent to exposed medial smooth muscle. Over time, the dissection cavity becomes reendothelialized. Chronic dissections are characterized by a fibrotic neo-intimal lining coating the dissection "false" lumen.

Coarctation of Aorta

Coarctation of aorta refers to discrete segmental congenital narrowing of the proximal aorta. It is classified according to its relation to the ductus arteriosus. Pre-ductal coarctation (proximal to the ductus arteriosus) is usually found early in life and creates systemic dependence on pulmonary artery flow (via the ductus—duct dependent). Post-ductal coarctation (by far the most common), manifests as a short, narrowed segment beginning just distal to the insertion of the ductus. As such, flow is only potentially restricted in the abdomen and lower extremities. Repair of coarctation is performed to restore flow but also prevent complications such as aortic rupture, endocarditis, hypertension, or congestive failure.[89]

Grossly, resected coarctation segments should be oriented to the point of insertion of the ductus/ligamentum and opened in a fashion that transects this longitudinally. Sections should be embedded so that the insertion point will be apparent histologically. Localized subintimal thickening is usually seen opposite this insertion point, beneath which the media lamina are distorted and thickened (Fig. 42.34).

Synthetic Arterial Substitution

GoreTex and Dacron synthetic tube grafts, as well as synthetic fabric lined stents, are often used in vascular surgery and occasionally require revision and replacement, resulting in surgical pathology specimens. Over time these grafts reendothelialize and develop a neo-intimal coating. Pathologic examination of these specimens should include evaluation of calcification, inflammation, thrombus, and the presence of anastomotic pseudoaneurysms.

Arterial Occlusive Disease

Thrombotic occlusions of the major arteries are often associated with arteriosclerotic changes described previously. The occlusive process is often clinically insidious, although final thrombotic

Figure 42.34 Aortic Coarctation. A discrete segment of marked narrowing in the pediatric aorta excised during coarctation repair *(top)*. Sections should be oriented in longitudinal section to the ductus arteriosus *(black arrow)*. Focal intimal thickening can often be seen opposite this *(white arrow)*.

obliteration of the lumen is occasionally quite rapid and may be clinically indistinguishable from embolization. In the distal aorta, thrombotic occlusion probably begins in the iliac arteries near the aortic bifurcation and propagates cephalad, occasionally to the level of the renal arteries. Thrombi and emboli can become secondarily infected by fungi, particularly *Aspergillus* and *Mucor*.

The syndrome of distal aortic occlusive thrombosis (Leriche syndrome) manifests with gradual progression of symptoms of pain and easy fatigability in the legs, hips, and back; intermittent claudication; and sexual impotence.[90] In this condition, arterial insufficiency in the lower extremities usually is manifested clinically by the absence of pulses below the umbilicus. If the process is partial, weak pulsations may be felt or a characteristic systolic murmur heard over the abdominal aorta and the femoral arteries.

Therapeutic approaches to occlusive arterial disease include surgical bypass using synthetic conduit, open thromboembolectomy with or without endarterectomy, and endovascular interventional thrombolysis. Microscopically, specimens from thromboendarterectomy may be fibrinous, organized, or some combination of the two, depending on the stage of the process and relative success of intrinsic thrombolytic activity.

Cystic Adventitial Disease

Cystic adventitial disease, a rare condition almost always affecting the popliteal artery, may cause luminal obstruction.[91] A collection

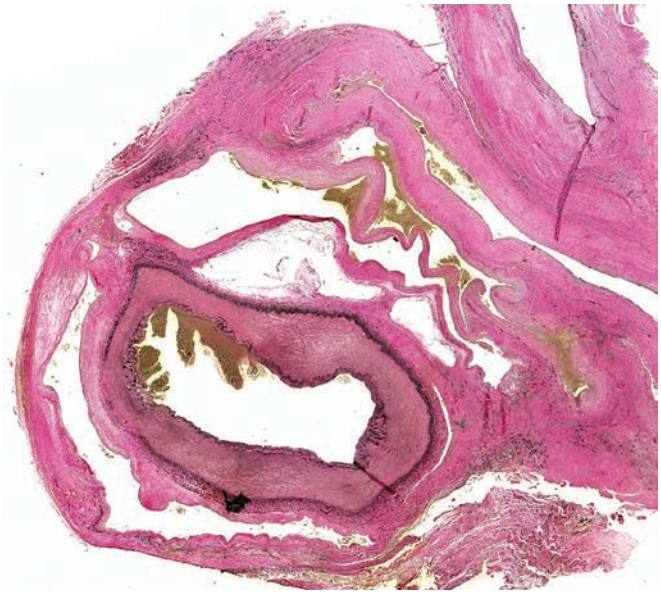

Figure 42.35 Cystic Adventitial Disease. Multiple irregular cystic spaces are seen surrounding the adventitia of this popliteal artery. Some appear to contain mucoid material.

of jelly-like material distends the wall (from the outside) and bulges into the lumen. Most cases occur in young men without a history of trauma and without general arterial change. The microscopic appearance of the involved arterial segments is that of mucin accumulation is dilated cystic spaces (Fig. 42.35). The etiology of this condition is not understood.

Fibromuscular Dysplasia

Fibromuscular dysplasia is a nonarteriosclerotic, noninflammatory vascular disease of unknown pathogenesis. Developmental, mechanical, and genetic factors may play a role. It usually becomes manifest during the third or fourth decades of life, although it also can be seen in children. It involves large- and medium-sized muscular arteries, such as the renal, carotid, axillary, and mesenteric arteries, sometimes in a multicentric fashion. Imaging techniques useful for the evaluation of this disease include CT scans, MRI, and angiography.[92]

Morphologically, it is characterized by a disorderly arrangement and proliferation of the cellular and extracellular elements of the wall, particularly the media although intimal (and ostensibly adventitial) forms have also been described, with the resulting distortion of the vessel lumen (Fig. 42.36). The absence of necrosis, calcification, inflammation, and fibrinoid necrosis are important negative diagnostic features. Morphologic varieties with predominant intimal or adventitial involvement have been described.[93] Treatment for this condition may include balloon dilation with stenting or resection and replacement with conduit such as saphenous vein or synthetic tube graft.

Mesenteric Vascular Occlusion

Mesenteric vascular occlusion (enterocolic lymphocytic phlebitis) may originate in veins or arteries. Rarely, occlusion of both occurs simultaneously. After the initiation of arterial or venous thrombosis, hemorrhagic infarction of the intestine and its mesentery develops if the process is rapid in onset and extensive. Arterial occlusions are

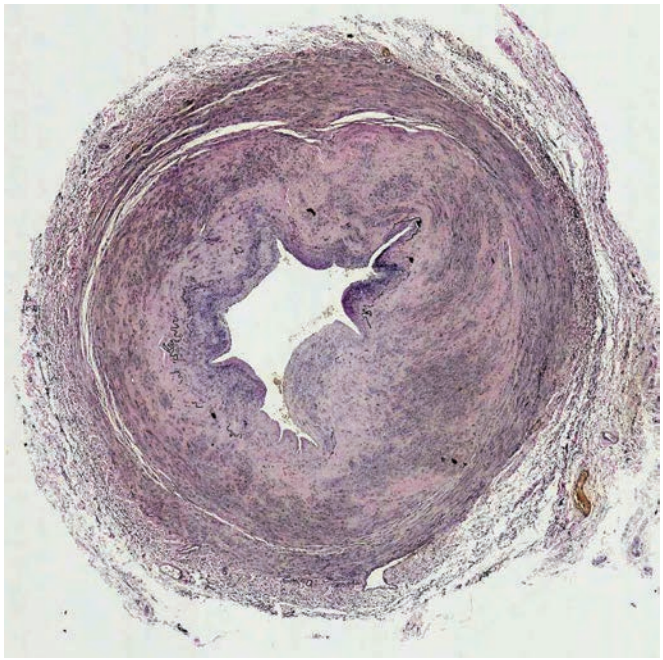

Figure 42.36 Fibromuscular Dysplasia (Medial Type). Irregular (festooned) luminal contours are created by disorganized medial smooth muscle arrangements.

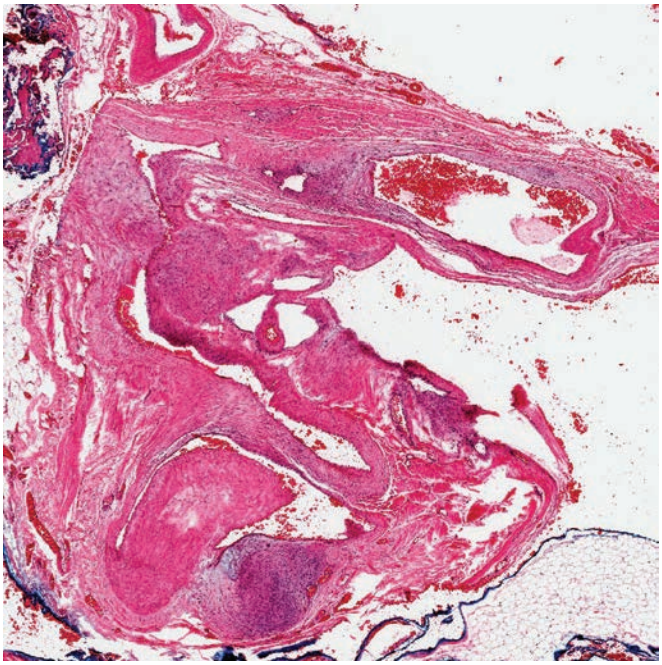

Figure 42.37 Arteriovenous Malformation. Irregular vascular spaces with varying wall thicknesses are seen in this soft tissue arteriovenous malformation.

often embolic in origin, whereas mesenteric venous thrombosis usually occurs in the setting of infection and cancer.[94]

Infarction of the bowel depends on the location, extent of occlusion, rapidity of its onset, and state of the collateral circulation, as well as the general physical condition of the patient. Acute occlusion of mesenteric arteries may produce bowel necrosis without the septic presentation seen in most cases of extensive venous thrombosis. Bloody diarrhea is less common and abdominal pain more common in arterial than in venous occlusions.[95]

Acquired Arteriovenous Fistula

Following trauma, especially involving perforating injury to both an artery and adjacent vein, a fistulous communication may form (either immediately or during the organization phase of healing). Thrombus frequently complicates these fistulas. Most patients present with a continuous pulsating (bruit) mass in the region of injury. There is usually venous dilation peripheral to the fistula. The dilation of the major artery entering an arteriovenous fistula may be marked, and the degenerative arterial wall changes may be extensive, although actual flow to downstream beds is compromised. Arteriovenous fistulas are associated with increase in cardiac output, pulse rate, and blood volume, which may lead to congestive heart failure (Fig. 42.37).

Arteriovenous Malformation (Congenital)

These lesions, occurring in soft tissue, lung, gastrointestinal organs, kidney, and the central nervous system are discussed in their organ-specific contexts in other chapters of this edition (see Chapters).

Thromboangiitis Obliterans

Thromboangiitis obliterans (Buerger disease) is a rare thrombotic and inflammatory disease of the arteries and veins of unknown etiology that occurs in young adults and is highly associated with tobacco use. Involvement of both medium-sized arteries and veins (and occasionally adjacent nerves as well), sets it apart from other forms of vasculitis. It is more common in men, with an age range between 20 and 35 years.[96] Microscopic examination of early arterial lesions shows panarteritis, often associated with thrombosis. The inflammatory process involves the entire thickness of the vessel wall and perivascular tissues, although the internal elastic lamina is usually preserved. Recanalization of thrombi may be seen but is often incomplete with numerous small vascular channels passing through the remaining fibrous tissue (Fig. 42.38). Treatment is largely symptomatic and includes the control of pain and the avoidance of tobacco. Late in the course, amputations may be necessary.

Arteritis

Inflammatory diseases of the arteries have been classified on the basis of the etiologic agent involved, the caliber and location of the vessel affected, and the type of microscopic change observed.[97,98] Imperfect as it is, a division based on the vessel caliber is quite useful. Within each group, the arteritides can be further subdivided into more or less specific types on the basis of associated features and/or pathologic appearance.

Large Vessel Arteritis

A group of related nonsyphilitic diseases primarily affect the aorta and its main branches and are characterized by chronic inflammation and patchy destruction of the elements of the media. They preferentially involve the ascending aorta and may result in aneurysm formation, as well as aortic root dilatation and valvular insufficiency, aortic arch syndrome, and aortic dissection.

Takayasu arteritis is characterized by chronic inflammation and fibrosis of the arterial wall, showing a predilection for the ascending aorta and primary aortic branches (arch vessels and renal arteries

in particular). Involvement of these branches accounts for the absence of pulses in the upper extremities that is often seen in these patients. Most patients with Takayasu disease are young, Asian, and female. The pattern of involvement includes granulomas and multinucleated giant cells, but there may be areas of more active inflammation including basophilic "dirty necrosis" as well (Fig. 42.39).[83] The coronary arteries may also be involved, particularly near the coronary ostia (Fig. 42.40).

Giant cell (or temporal) arteritis was originally thought to be a disease of temporal, cerebral, and retinal arteries. However, aortic and large arterial involvement was recognized in these patients, indicating that it is a systemic disease and best classified as a large vessel vasculitis syndrome. This condition, which is most common after age 70 is classically characterized by pain in the distribution of the temporal artery and localized tenderness. Other extracranial carotid artery branches may be affected as well, leading to jaw claudication, facial pain, and blindness (the most feared complication). The syndrome of *polymyalgia rheumatica*, characterized by muscle pain and tenderness involving mainly the muscles of the neck, shoulder, and pelvic girdle, and accompanied by an elevated erythrocyte sedimentation rate, occurs in at least half of these patients. Fortunately, this disease is almost universally responsive to corticosteroid therapy. Complications related to ascending aortic aneurysm are also a major concern.[81]

Microscopically, partial destruction of the wall by a lymphohistiocytic inflammatory infiltrate, often (but not always) containing

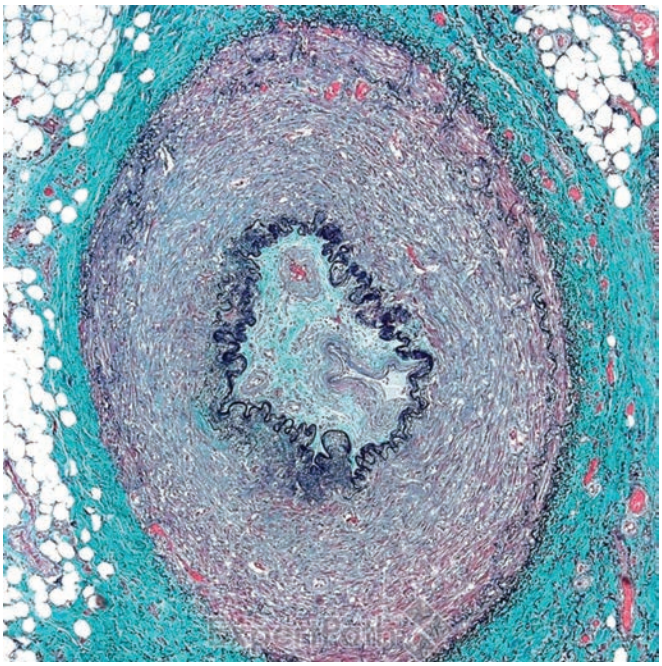

Figure 42.38 Thromboangiitis Obliterans (Buerger Disease). Hallmark features include transmural inflammation (of veins and arteries), recanalized luminal thrombus, and preservation of the internal elastic lamina.

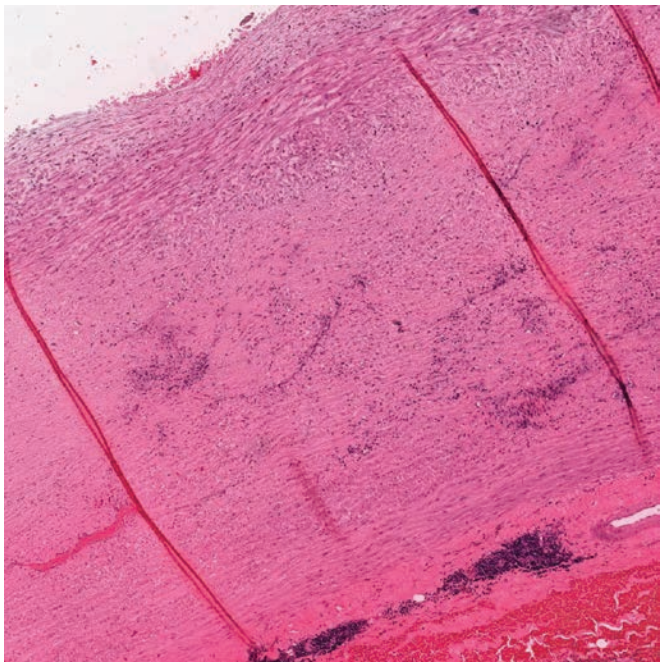

Figure 42.39 Takayasu Aortitis. Marked adventitial fibrosis and patchy lymphoplasmacytic inflammation, characteristic (although not entirely specific for) Takayasu disease.

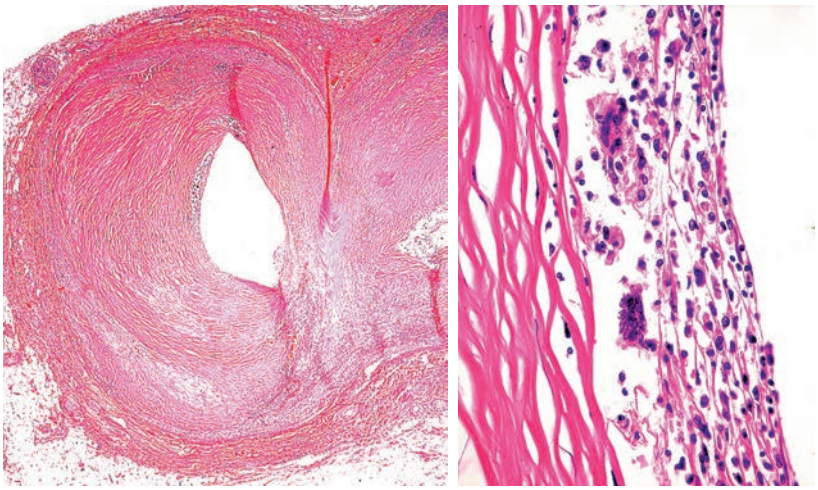

Figure 42.40 Coronary artery involvement by Takayasu arteritis, manifesting as fibrotic wall thickening with lymphoplasmacytic inflammation and intimal multinucleated giant cells (again the clinical context of aortitis with primary branch involvement in a young woman is needed to confirm Takayasu disease).

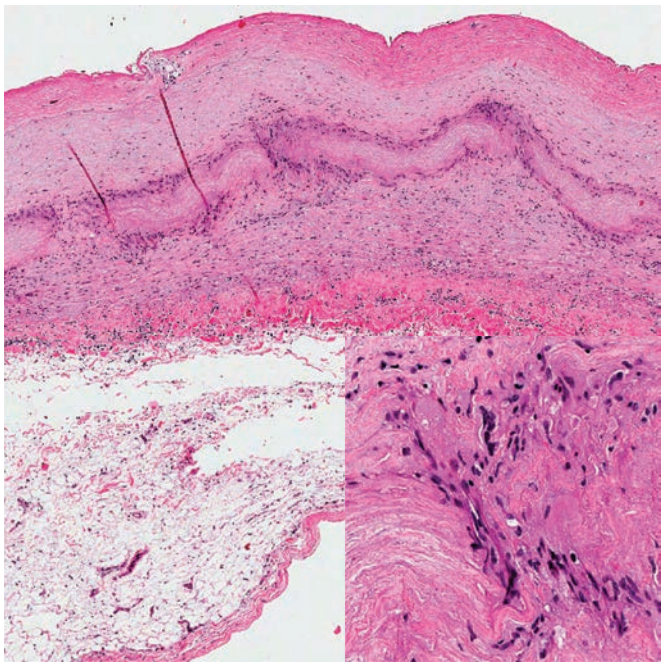

Figure 42.41 Giant cell aortitis with ribbon-like areas of elastic laminar collapse, cuffed by lymphohistiocytic inflammation including multinucleated giant cells *(inset).*

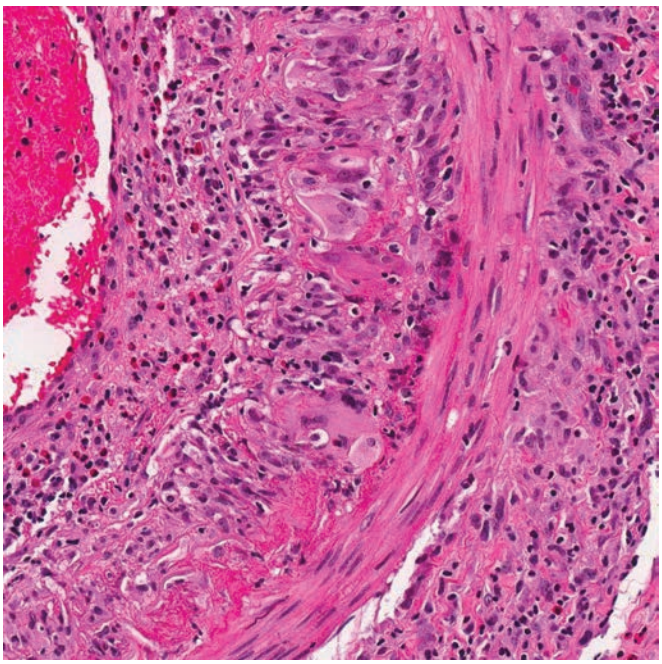

Figure 42.42 Giant cell—temporal arteritis showing transmural lymphohistiocytic inflammation with multinucleated giant cells near the internal elastic lamina.

multinucleated giant cells. In elastic arteries (especially the ascending aorta), this inflammation is found surrounding "islands" of acellular collapsed elastic lamellae (Fig. 42.41). In small muscular arteries, the giant cells are usually intimately associated with the internal elastic lamina, and some may even contain fragments of phagocytosed elastica in their cytoplasm. Transmural inflammation is the diagnostic hallmark of vasculitis in temporal artery biopsies (Fig. 42.42). The presence of perivascular inflammation in the absence of inflammatory changes in the vessel wall is not diagnostic of vasculitis. It is important to emphasize that the changes are often segmental and that a negative biopsy does not rule out the diagnosis. In one key series, only 60% of patients with clinical evidence of temporal arteritis had positive biopsies but the other 40% (showing arteriosclerosis or atherosclerosis) also responded to steroid therapy.[99] For this reason, exhaustive serial sections should be performed routinely on these specimens. The pathogenesis of this disease remains unknown, but autoimmune factors are thought to play an important role.

Aortitis can be seen associated with a host of other conditions, including rheumatoid arthritis, ankylosing spondylitis, scleroderma, granulomatosis with polyangiitis, Cogan syndrome, Behçet disease, and many others.[100]

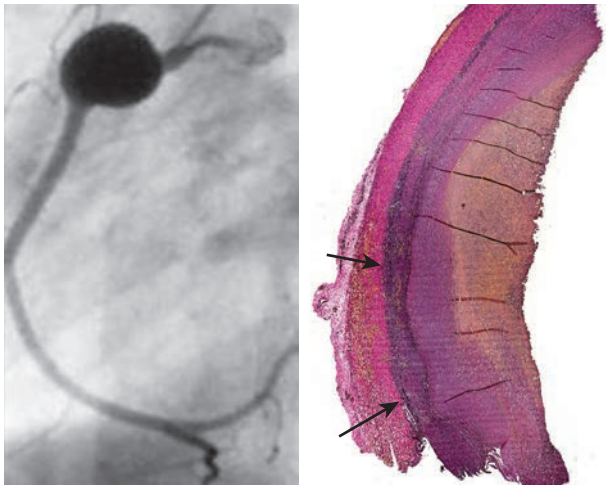

Figure 42.43 Coronary (Pseudo)aneurysm in Kawasaki Disease. Coronary angiogram showing a proximal (pseudo)aneurysm *(left)*. The aneurysm wall shows wisps of internal elastic lamina at one edge (confirming contained rupture—pseudoaneurysm).

Medium-Sized Vessel Arteritis

This group of diseases primarily affect muscular arteries, and all are characterized by active necrotizing inflammation leading to (often segmental) fibrinoid necrosis of the arterial wall. As this process resolves and evolves, pseudoaneurysms develop. Necrotizing arteritis and pseudoaneurysm formation are the hallmarks of the medium vessel vasculitis syndromes. **Kawasaki disease** is a pediatric condition that first presents as a mucocutaneous syndrome with lymphadenopathy in infants and children and later manifests as medium vessel arteritis with a particular predilection for the coronary arteries.[101] Recognition of the acute phase of this illness and treatment with aspirin and intravenous immunoglobulin are critical in preventing and forestalling the coronary artery complications. The disease may go unrecognized in childhood and only manifest later in adulthood as acute coronary syndrome due to complications of coronary pseudoaneurysm (Fig. 42.43).

Microscopically, the coronary and other affected arteries show transmural involvement of at least a segment of artery viewed in cross section. The inflammation is rich in neutrophils, and fibrin is abundant in the active phase. Healed lesions will show disruption of the internal and/or external elastic lamina(e) with replacement-type fibrosis. Confirmation of pseudoaneurysm also relies on demonstrating complete disruption of the elastic media and near-rupture

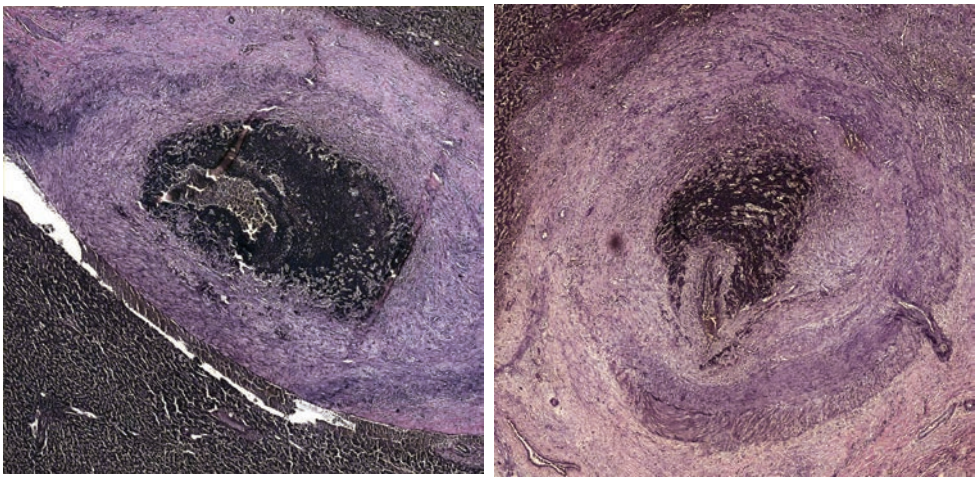

Figure 42.44 Polyarteritis Nodosa. Vascular lesions in the liver (elastic stains) showing features of active/subacute fibrinoid necrotizing arteritis *(left)* and segmental wall destruction with contained rupture (pseudoaneurysm) *(right)*. Temporal variability (active and healed lesions in the same organ) is a hallmark feature of polyarteritis nodosa.

contained only by adventitial connective tissue. Elastic staining is helpful in delineating this.

Polyarteritis nodosa, classically described at autopsy as visible nodular lesions at the points of arterial branchings, especially within the liver, spleen, and kidneys. This condition is recognized to have a strong association with chronic hepatitis B infection.[102] The skin and peripheral nerves may also be involved.[103,104]

Microscopically, the namesake nodular lesions are confirmed to be pseudoaneurysms or contained hemorrhages and the vessel walls involved by vasculitis with an active (fibrinoid) necrotizing arteritis process (Fig. 42.44). Another histologic hallmark of this disease is vascular lesions of varying ages or "temporal heterogeneity" with active and healed lesions seen in the same biopsy or surgical specimen.

Small Vessel Vasculitis

According to the revised Chapel Hill classification scheme, the small vessel vasculitis syndromes encompass those entities that preferentially affect arterioles, capillaries, and the venous side of circulation.[105] They may be broadly classified into three groups: (1) ANCA-mediated vasculitis, (2) immune complex–mediated vasculitis, and (3) vasculitis caused by direct antibody-mediated injury. The ANCA-mediated diseases include, primarily, microscopic polyangiitis, polyangiitis with granulomatosis, and eosinophilic granulomatosis with polyangiitis. Immune complex vasculitides include systemic lupus erythematosus, Henoch–Schönlein purpura, and other related disorders. Goodpasture syndrome is the prototypic vasculitis syndrome associated with direct antibody-induced injury. The pattern of inflammation in this group of diseases also tends to be acute and necrotizing, similar to the medium vessel vasculitis syndromes. Most of these conditions are discussed elsewhere in this text (particularly the pulmonary and renal chapters).

Single Organ Vasculitis

In recent years, several forms of vasculitis have been described that appear to be confined to a particular organ (and apparently cured by removal, where possible). These may involve the arterial or venous vessels in the particular organ. Examples include testicular vasculitis, uterine vasculitis, cutaneous vasculitis, gallbladder vasculitis, CNS vasculitis, and isolated aortitis.[105] Obviously a thorough and systemic rheumatologic evaluation is necessary to confirm the isolated nature of disease in these patients.

Tumors

The general subject of vascular tumors is dealt with in Chapter 41. Only those neoplasms involving major vessels are discussed here.

Great Vessels

Primary tumors of the "great vessels" (aorta or pulmonary artery) are almost invariably malignant and represent various types of sarcoma (fibrosarcoma, leiomyosarcoma, rhabdomyosarcoma, fibromyxosarcoma, and pleomorphic high-grade sarcoma). These intravascular tumors almost invariably lead to embolic metastases, and the overall prognosis is dismal.[32]

It is important to distinguish "intimal sarcoma" from other vascular sarcomas in these vessels. As mentioned previously, these tumors have a growth pattern that consists of highly pleomorphic cells with either epithelioid or spindled morphology spreading in a plaquelike fashion along the surface of acellular fibrin necrotic/thrombotic material lining the involved vessel (Fig. 42.45). There may not be any involvement of the underlying vessel wall.

Lymphomas and high-grade sarcomas have also occurred at the site of synthetic vascular prostheses and stents, as well as at the site of a surgically constructed arteriovenous fistula. Chronic immune stimulation by the foreign material at these sites is felt to play a key role in their pathogenesis.

Additional primary tumors and tumorlike conditions that may exhibit a predominant or exclusive intravascular location are epithelioid hemangioendothelioma, pyogenic granuloma, intravascular papillary endothelial hyperplasia, intravascular nodular fasciitis, synovial sarcoma, and intravascular leiomyomatosis. These entities are discussed elsewhere in this textbook.

Metastatic Tumors

These can lodge in large vessels and produce occlusion. Cases of major arterial occlusion from carcinoma of lung and other sites have been well documented.

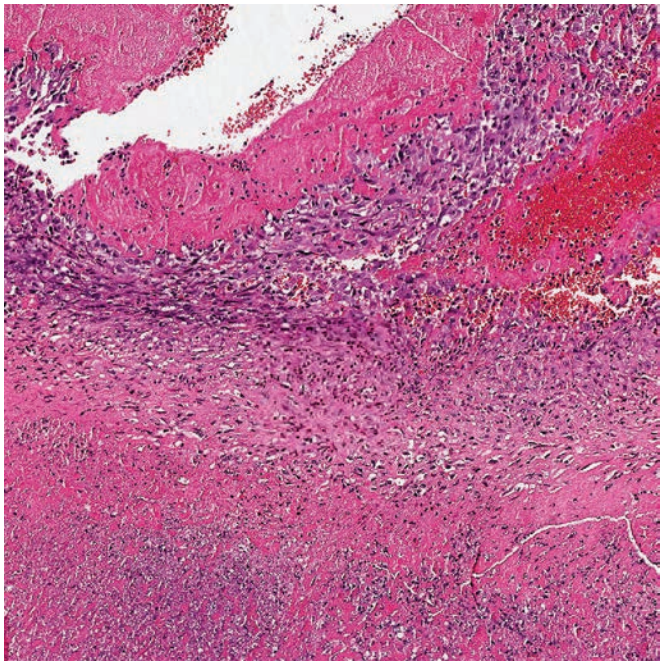

Figure 42.45 Intimal Sarcoma of the Descending Thoracic Aorta. Pleomorphic and spindled sarcoma cells are seen associated with fibrin thrombus overlying a bed of necrotic organizing fibrin debris.

Veins

Normal Anatomy

Veins have a three-layer histoarchitecture similar to arteries, but they lack an internal elastic layer separating the intima and media. The medial thickness is much thinner compared to arteries as well; in fact the adventitial layer is typically the thickest and most prominent layer in most veins. The adventitial smooth muscle is also arranged in bundles oriented in varying directions around the vessel circumference. The outer elastic layer is also less distinct than in arteries and may show fragmentation and splitting. Another important feature distinguishing veins from arteries is the presence of fibrous intimal valves in larger veins.

Thrombophlebitis and Thromboembolism

Thrombophlebitis is a thrombotic disease of veins accompanied by varying degrees of inflammation. Microscopically, the venous wall is edematous and the intimal endothelium focally eroded with resultant thrombus formation. This may be accompanied by transmural infiltration with chronic inflammatory cells. During the acute phase, attachment of the thrombus to the intima may be tenuous. As the acute inflammatory phase of the disease subsides, fibrosis develops, especially in the adventitia and media. The thrombus in this later phase may show organization or degenerative changes and becomes more fixed to the wall (or even incorporated into the fibrotic process).

The process of thrombophlebitis is associated with edema of the extremity, which may be marked. Paradoxically, the absence (or minor degree) or edema is probably more frequently associated with pulmonary emboli than is thrombophlebitis with marked edema. The degree of edema typically correlates directly with the degree of microscopic inflammation.[106] However, there are certainly exceptions to this general rule.

Thrombophlebitis may involve superficial veins, deep veins, or both. Clinical examination is notoriously inaccurate in the diagnosis of deep vein thrombosis, but when signs are present, the vein may be acutely inflamed and tender, and with superficial veins the overlying skin is red. When the thrombosis is limited to the superficial veins, there is usually little edema. However, thrombophlebitic edema may develop with marked rapidity and may be of great volume if the process extends into the deep venous system. In the most severe instances, "third spacing" of extracellular fluid in the leg may be sufficiently massive to cause shock and be accompanied by cutaneous blebs and necrosis *(phlegmasia cerulea dolens)*.

There is a statistically significant association between deep vein thrombosis and the presence of cancer in an internal organ, known as the *Trousseau syndrome.* Many of the tumors associated with this paraneoplastic complication are mucin-producing adenocarcinomas, often of the pancreas.

Pulmonary embolism is often thought to be primarily a complication of some surgical procedure or trauma such as fracture, particularly of the lower extremity, but the incidence of this complication is as high on medical as on surgical services. Some of the factors thought to favor intravenous thrombosis and subsequent pulmonary embolism are neoplasms, cardiac disease, venous stasis from any cause, infection in the immediate area of veins, trauma, spasm of vessels, intimal injury, increased coagulability, and immobilization of the limbs.

Pulmonary embolism may occur in all forms of thrombophlebitis, but it should be noted that sudden massive pulmonary emboli frequently occur in patients without antecedent symptoms or signs of peripheral thrombophlebitis.

In a classic autopsy-based study, McLachlin and Paterson reported several important observations.[106] They found that 75% of the venous thrombi arose in the veins of the thigh and pelvis and 25% in the smaller veins of the calf and feet, with 92% arising in the lower extremities. In over one-half of these there were pulmonary emboli. In their observations, they also stressed the finding of intravascular thromboses arising in relationship to the valve pockets.

For many decades, the development of deep venous thrombus and thrombophlebitis was attributed to the "Virchow's triad" hypothesis and the interaction of (1) hypercoagulability, (2) stasis, and (3) intimal injury. Blood pooling in the venous valve pockets was felt to serve as the nidus for thrombus formation in this scenario. However, in many patients thrombotic events occurred in the clear absence of one or more of these factors. More recently, a newer hypothesis has begun to supplant (or at least challenge) this paradigm. In this new model, localized (microenvironment) hypoxia develops in the venous valve pockets, as oxygen is consumed by the endothelium and venous wall, exhausting the local pool of static venous blood. This results in local hypoxia with injury to leukocytes and endothelial cells with possible platelet activation. When new blood enters this environment (through leg muscle contraction or postural change), the "fresh" intact leukocytes and platelets participate in the formation and propagation of a thrombus.[107]

The treatment of acute thrombophlebitis attempts to limit the extension of the process and to prevent pulmonary embolization through the use of heparin (convention and low-molecular-weight agents), warfarin, and newer anticoagulants. Elevation, rest with the maintenance of good hydration, elastic support, and anticoagulant therapy are also initial measures. Placement of upstream intravenous filters in the inferior vena cava has become an effective means of preventing pulmonary embolization but carries a risk of strut fracture, dislodging and migration, and other complications. Because of

long-term complications, placement of these devices is often temporary (several months) and current devices are designed to be retrievable endovascularly.[108]

Stasis Ulcers

"Downstream" complications of thrombophlebitis (i.e. pulmonary embolism) receive the primary focus for clinical significance, but there are also important "upstream" consequences occurring long term, such as venous stasis ulceration of the skin.

After managing embolization risk in patients with thrombophlebitis, measures should also be taken to avoid later stasis disease in the lower extremity. The use of elastic supports to help control any dependent edema in the extremity is generally effective and may be required for many months or years. With the passage of time, collateral venous channels may develop and communicate with the superficial venous systems, resulting in secondary superficial varicosities. Recanalization of the major deep veins is usually associated with this process. Significant varicosities in the postphlebitic extremity may be removed surgically.

Chronic venous insufficiency leads to manifestations of cutaneous pigmentation, brawny edema, dermal and subcutaneous fibrosis, extensive secondary varicosities, and ulceration of the skin develop in the lower extremity. The diagnosis of stasis disease is not usually difficult. Other rare causes of ulceration such as specific infections and neoplasms can be excluded by biopsy and culture.

Histologic features of venous stasis ulcers are not necessarily distinct from ulcers due to arterial insufficiency, but in one large series certain features were seen more often in the setting of venous stasis. These included diffuse edema, granulation tissue, hemosiderophages, and collagen-bundle degeneration, with fibrosis.[109]

Varicose Veins

Varicose veins occur more frequently in women than in men. They often develop in the second and third decades of life and may be present for many years without causing symptoms or complications. Their incidence is much higher in obese women, particularly those who have had several pregnancies (presumably through prolonged compression of pelvic veins by the gravid uterus). Varicosities may also be secondary to deep venous thrombosis.

Grossly, superficial veins of the leg become dilated and tortuous and lose valvular function. Microscopically, there is fibrosis beneath the endothelium and in the wall, with secondary elastosis and loss of muscle. Calcification may occur. Recent studies have demonstrated abnormalities in matrix metalloproteins that may explain the extracellular matrix (collagen) changes in varicose veins.[110] These may also help explain a hereditary or intrinsic susceptibility to varicose vein formation that has long been observed.

When severely symptomatic, or to prevent propagation to deeper veins and possibly increase thrombotic risk, surgical removal of varicosities may be performed. This is often done by minimally invasive endoscopic techniques. Surgical specimens received will show the changes described previously.

Tumors

Inferior Vena Cava

Most tumors arising in the inferior vena cava and other large veins are malignant and are largely represented by *leiomyosarcoma* (Fig. 42.46).

Tumors of smaller vessels are discussed in Chapter 41.

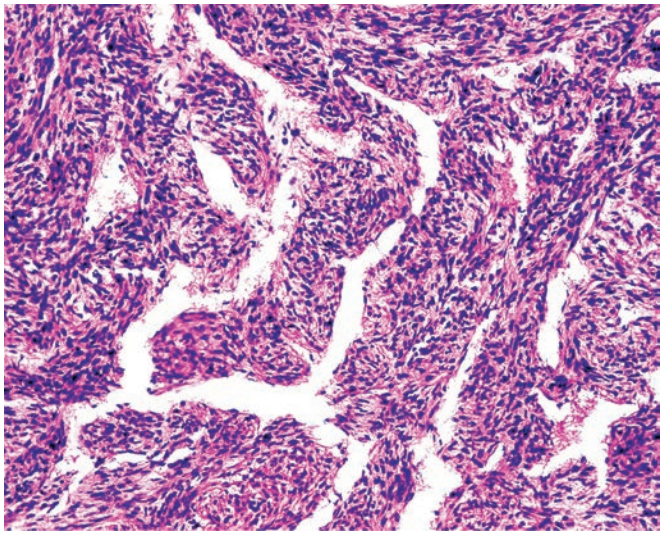

Figure 42.46 Leiomyosarcoma of inferior vena cava characterized by randomly oriented fascicles of malignant smooth muscle cells with a "staghorn" vascular pattern.

Lymph Vessels

Normal Anatomy

The smallest lymphatics resemble capillaries but often with a "gaping" lumen and elongated or irregular contours. The walls of large caliber lymphatic vessels also resemble capillaries, lacking elastic tissue and with only thin wisps of muscular media. Intimal valves may be seen in larger caliber lymphatics (similar to veins). Podoplanin (recognized by antibody clone D2-40) and LYVE-1 are antigens expressed specifically in lymphatic (but not venous or arterial) endothelium.

Lymphedema

With the exception of tumors of lymph vessels, such as lymphangioma and lymphangiosarcoma (see Chapter 41), the only primary lymphatic disease encountered clinically with some frequency is lymphedema. Chylothorax and chylous ascites also occur, but in nearly all instances these processes are secondary to trauma, neoplastic disease, or some infectious process.

Lymphedema stems from inadequate lymphatic drainage. It may be classified into postinfectious, post-traumatic, obstructive, and idiopathic etiologies. In some parts of the world, lymphedema resulting from *Schistosoma (Filaria)* is very common.[111] In the developed world, obstructive lymphedema is most often seen following obstruction of regional lymph nodes by malignant tumor or following node removal. The development of lymphedema of the arm after axillary node dissection is most common when postoperative infection complicates the surgical wound healing process or there is persistent cancer in the axilla. The advent of sentinel node sampling has significantly reduced the frequency of lymphedema.[112,113]

Lymphedema can also be seen in patients who give a history of as little trauma as a severely sprained ankle or following such infections as a furuncle. Many patients give no history of trauma or infection associated with the onset of their lymphedema. In such instances, the lymphedema is usually termed idiopathic. Congenital idiopathic lymphedema, also known as *Milroy disease*, is inherited in an autosomal dominant fashion.

Postmastectomy lymphedema and, to a lesser degree, Milroy disease can be complicated by the development of lymphangiosarcoma (see Chapter 41). Curiously, this complication is extremely rare in the cases of lymphedema resulting from schistosomiasis, although it may occur.

The swelling of lymphedema is usually slowly progressive. There is dilation of the dermal lymphatics, as well as the deeper fascial lymphatics. When the degree of swelling is advanced, there is a depression of hair follicles and gross dermal edema. In such cases, the cutaneous lymphatics may be sufficiently dilated to be associated with lymphorrhea following minor cutaneous abrasions or needle punctures. Tissue sections of such skin usually show markedly dilated dermal lymph vessels.

Whatever the mechanism, the slowly progressive nature of lymphedema in many patients is associated with dermal thickening and collagenous deposition in the subcutaneous tissues and fascia. Bouts of superficial cellulitis and lymphangitis often become superimposed on the lymphedema in an extremity. The presence of recurrent infection in such an extremity appears to hasten the deposition of collagen and may result in such a large amount of fibrotic replacement of subcutaneous fat and normal dermal structures as to make demonstration of dermal lymphatics impossible.

In a few patients with idiopathic lymphedema having no clinical evidence or history of lymphangitis or cellulitis in the extremity, enlarged regional lymph nodes have been removed. Microscopically, these nodes exhibit a mild chronic inflammatory infiltrate, sinusoidal fibrosis, and markedly dilated lymphatic channels.

Dermal and subcutaneous fibrosis similar to that seen in advanced forms of lymphedema also occurs about longstanding chronic stasis ulcers. Morbidly obese patients can develop *massive localized lymphedema* in the upper or lower limbs that can simulate histologically an atypical lipomatous tumor (well-differentiated liposarcoma) (see Chapter 41).

Expression of podoplanin (as detected by immunohistochemical methods using the D2-40 reagent clone) in lymphatic endothelium can be used to differentiate lymphatics from veins, venules, and other small caliber dilated vascular structures.[114] This staining technique has also been used to highlight lymphatic invasion in the vicinity of malignant tumors (Fig. 42.47). While arterial and venous endothelium lacks expression of podoplanin, it is present in other cell types, such as mesothelium, and may be expressed in several epithelial and vascular malignancies as well.

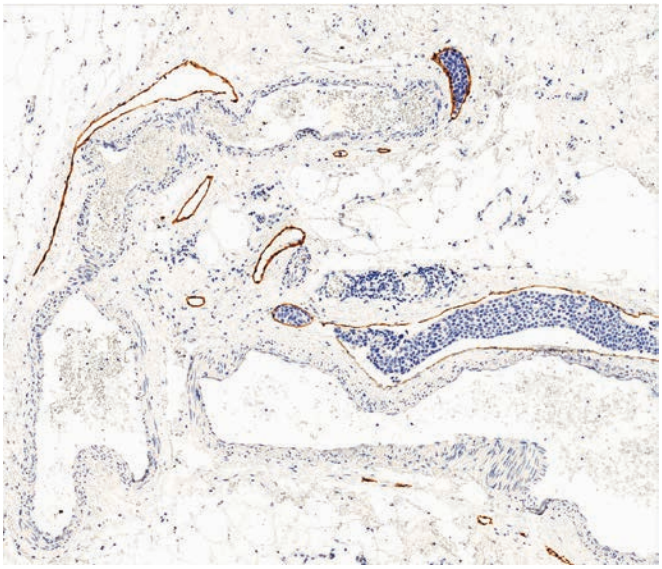

Figure 42.47 Podoplanin (D2-40) staining of breast tissue to evaluate for lymphatic invasion of an adjacent tumor. The lymphatic channel endothelium stains intensely for D2-40, whereas the arterial and venous endothelium does not.

Treatment of lymphedema consists primarily of elevation of the extremity, compression, and massage, which often must be continued (indefinitely) for many years. Secondary infections are treated with antibiotics. Conservative measures control lymphedema in most patients sufficiently to avoid operation.

Operative therapy is indicated only in a small minority of cases. Surgical approaches include excision of the thickened fibrotic skin, edematous subcutaneous tissue, and fascia overlying the muscles, followed by the split-thickness skin grafting. More recently, microsurgical techniques using fluorescence lymphography to guide creation of lymphaticovenous anastomoses have been developed as well.[115]

Tumors

Benign and malignant tumors of lymph vessels are discussed in Chapter 41 (Soft Tissues).

Normal Anatomy

Dauntingly complex and characterized by extraordinary variation in regional architecture, the gross and microscopic anatomy of the human central nervous system (CNS) cannot be surveyed here in detail. Instead, a brief review of anatomic landmarks and topographic relationships that bear particularly on issues of differential diagnosis is provided.

Confined within the cranium and vertebral canal, the CNS is ensheathed by connective tissue membranes that include a densely collagenous outer covering termed the *pachymeninx* or, more familiarly, *dura mater*, and delicate inner investments known as the *leptomeninges* or *pia-arachnoid*. Under normal circumstances, these are closely apposed and loosely joined by a layer of dural border cells that are easily disrupted (artifactually or by expanding lesions such as hematomas) to yield a "subdural space" that is, in fact, only a potential compartment. A sagittal dural fold referred to as the *falx cerebri* lies between the cerebral hemispheres, and a second such fold—the *tentorium cerebelli*—separates the superior cerebellar surfaces from the overlying temporal lobes of the cerebrum. Enclosed within the cranial dura, in addition to meningeal artery branches, are venous sinuses that serve both to drain the cerebral veins and to carry away cerebrospinal fluid (CSF) transported from the subarachnoid space by arachnoid villi that project into these conduits. Termed *pacchionian granulations,* as they achieve grossly visible proportions with normal aging, these villi are draped by specialized arachnoidal cells of interest to surgical pathologists as the likely progenitors of meningioma. Whereas the dura adheres tightly to the endosteal

Abstract

The complexity of the central nervous system (CNS) is daunting, particularly to those encountering relatively few CNS biopsies on a weekly basis. Nevertheless, the same basic rules of pathology utilized below the neck apply to diseases of the brain as well. This chapter provides a practical approach to the field of surgical neuropathology, with an emphasis on the common "bread and butter" differential diagnoses. Still, the authors have strived to create a sufficiently comprehensive resource in which rarer disorders encountered by the general pathologist or even the seasoned neuropathologist are also covered. More recently, this subspecialty has seen a dramatic impact on daily practice by molecular diagnostics, as reflected by the extensive changes in the WHO 2016 classification scheme of brain tumors, particularly in reference to gliomas and embryonal neoplasms. As such, there is now a much heavier focus on the use of biomarkers and surrogate immunostains to reach the most accurate "integrated diagnosis" possible. With this in mind, the text and images have been extensively updated for those topics where the greatest advances have been made since the last edition.

surfaces of the skull, at spinal levels it is attached only anteriorly to the vertebral bodies and is surrounded on its lateral and posterior aspects by a true compartment—the epidural space—which contains segments of the spinal nerve roots, blood vessels, and adipose tissue.

There are several localizing terms used in both clinical and radiographic parlance that may be of potential utility to the pathologist, as they may be encountered in neuroimaging reports and on specimen requisitions. Because the substance of the brain and spinal cord constitutes the central "neuraxis," lesions localized to the neuroparenchyma proper are often described as *intra-axial*, whereas those that simply abut the CNS from a meningeal or juxtameningeal site are said to be *extra-axial*. These qualifiers may be similarly invoked for spinal masses. The brain itself may be broadly but usefully parceled into *supratentorial* and *infratentorial* components, the former situated above and the latter below the tentorium cerebelli. The cerebellum and most of the brainstem, including the pons and medulla in their entirety, are infratentorial structures that may be collectively designated the posterior fossa contents. The supratentorial CNS consists of the cerebrum (subdivided into frontal, parietal, temporal, and occipital lobes) and deep nuclei of the basal ganglia, thalamus, and hypothalamus.

Within the CNS, connective tissue is scant and essentially restricted to the adventitia of blood vessels. There are no resident lymphoid elements. The parenchyma of the brain and spinal cord is composed principally of the bodies and cytoplasmic processes of neuroepithelial cell types, including neurons and various classes of glia. Subsumed under the latter designation are astrocytes, myelinating oligodendrocytes, and ependymal cells that line ventricular surfaces. These all have their neoplastic counterparts, classified generically as gliomas and subclassified as astrocytomas, oligodendrogliomas, and ependymomas, respectively. Close kin of the ependyma are the specialized epithelial elements of the choroid plexus, responsible for CSF production, and represented among brain tumors by papillomas and carcinomas. The neurosecretory parenchymal cells of the pineal gland, situated posterior to the roof (or "tectum") of the midbrain, may also be the targets of transformative events—thus the pineal parenchymal tumors.

On a practical note, there is paramount importance to the location of lesions in the CNS when one is formulating differential clinical and histologic diagnoses, particularly when considering neoplasms. Meningioma, for example, should be a remote consideration when confronted by an intra-axial mass but should loom large if a lesion is dura-based or fills the cerebellopontine angle (where schwannoma might also be reasonably suspected). By contrast, diffuse gliomas and metastatic carcinomas account for most cerebral hemispheric tumors (particularly in adulthood). Pilocytic astrocytomas, which mainly affect the young, exhibit a decided predilection for the cerebellum and third ventricular/hypothalamic region, whereas ependymomas frequent the fourth ventricles of children and the spinal cords of adults (where they constitute the most common intramedullary tumors). Primary CNS lymphomas are most often deep, periventricular white matter or basal ganglia masses, whereas germ cell tumors only exceptionally arise outside of a midline, pineal or suprasellar axis, and central neurocytomas are confined within the lateral ventricles. Similarly, the tapering conus medullaris and filum terminale of the distal spinal cord are the nearly exclusive hosts of myxopapillary ependymomas and CNS paragangliomas. Other neoplasms defined in part by localization include medulloblastoma (posterior fossa), papillary tumor of the pineal region, and chordoid glioma of the third ventricle. Many other such associations are to be found in this chapter. The foregoing should serve to underscore the potential benefits of a dialogue among pathologists, neuroradiologists, and neurosurgeons.

Developmental Abnormalities

Craniospinal Dysraphism

Defective midline closure of the embryonic neural tube or its mesodermally derived coverings accounts for the varied malformations collectively referred to as **dysraphic states**. Expressions of craniospinal dysraphism range from trivial skeletal abnormalities that pass undetected through life to lethal anomalies of the nervous system proper that result in intrauterine fetal demise. Considered here are those representatives of this complex group most likely to be approached by the neurosurgeon.

The large majority of dysraphic malformations occur along the spinal axis, where they are chiefly localized, although by no means restricted, to the lumbosacral region.[1,2] The minimal lesion—simple agenesis of the posterior vertebral arches—ranks among the most prevalent of congenital anomalies and is termed **spina bifida occulta**. Its presence may be suggested in otherwise asymptomatic cases by the finding of an overlying skin dimple or sinus tract, hyperpigmented patch, hairy tuft, angioma, or lipoma. **Spina bifida cystica** or **aperta** refers to the less common situation in which meningeal or neural tissues protrude through an osseous defect. The resulting lesion, generically designated a "**cystocele**," typically bulges from the posterior midline in saccular fashion and is subclassified according to the nature of its herniated elements, the major variants being **meningocele** and **myelomeningocele**. The latter, by definition, contains elements derived from the spinal cord, as well as its ensheathing meninges, and accounts for 80%–90% of cases. Cystoceles may also present as ventrally positioned, pelvic, or laterally situated paravertebral masses. The former are associated with sacral defects, the latter with hemivertebrae. It should be noted, however, that most "lateral meningoceles" are not true dysraphic lesions; instead, they represent arachnoidal diverticula that exit the spinal canal via widened neural foramina. These are most common at thoracic levels and are often encountered in the setting of type 1 neurofibromatosis (NF1). Rarely, meningomyeloceles present as finger- or tail-like appendages in the lumbosacral region.[3,4]

The resected **meningocele** is a discoid mass covered on its external aspect by skin that may be attenuated but that is not usually ulcerated or otherwise disrupted. A narrow pedicle representing the cystocele's attachment to the spinal canal may hang from its smooth, membranous inner surface. The sac proper is composed of collagenous tissue containing meningothelial cells disposed along irregular clefts, around alveolar spaces, in nests and long cords. Distinct dural and arachnoid membranes are not formed. Some examples are associated with tumorous accumulations of mature adipose tissue ("**lipomeningocele**"), and the sac wall may also exhibit a disorganized proliferation of nerve twigs, smooth muscle bundles, and blood vessels. Displaced but otherwise normal spinal nerve roots may lie within the meningocele cavity but can often be successfully repositioned and thus do not usually appear in surgical specimens. The finding of neuroglial tissue in any form converts the diagnosis to **myelomeningocele**. This ranges from microscopic nests of glia embedded in the cystocele wall to recognizable, albeit deformed, spinal cord. Variants include the **lipomeningomyelocele** (which may contain, in addition to mature adipose tissue, skeletal muscle and nephrogenic tissue rests[5]) and the **syringomyelocele** (or **myelocystocele**), the latter characterized by gross distension of its included spinal cord's central canal. Rarely, meningomyeloceles are encountered together with intraspinal cysts lined by enteric epithelium—the so-called **split notochord syndrome**[6]—or complex teratomatous masses regarded by some as bona fide germinal neoplasms and by others as dysembryogenic growths.[7] In any of these guises, the myelomeningocele is often covered by little more than a translucent

membrane that represents atretic skin and may include plaques of ependymoglial tissue. This is prone to ulceration, and predisposes to bacterial CSF invasion with ascending meningoventricular infection.

The outcome for infants afflicted by spina bifida cystica depends on the size and complexity of the malformation, particularly on the extent to which spinal cord elements participate in its genesis, and is frequently influenced by the presence of associated anomalies involving the spinal cord rostral to the cystocele, the cranium, and brain. Simple meningoceles are often associated with no neurologic impairment or only mild paraparesis; they are generally closed without incident and only exceptionally prove fatal. Unfortunately, the far more common meningomyelocele is usually complicated by significant and irreversible loss of lower extremity and bladder function. Furthermore, nearly all affected children also suffer an associated Arnold–Chiari malformation with hydrocephalus, the main structural features of this second anomaly being caudal displacement of the medulla and cerebellar vermis, kinking of the cervicomedullary junction, widening and shallowing of the posterior fossa, and, in many instances, deformation of the midbrain with aqueductal stenosis. Untreated, few survive childhood and even with aggressive surgical intervention the risk of death is considerable. The leading immediate causes of mortality are meningitis, pyelonephritis, pneumonia, and progressive hydrocephalus. Rarely, squamous carcinomas arise from the chronically irritated epidermis overlying unattended cystoceles.[8]

To the externally evident malformations just described should be added various intraspinal and juxtaspinal anomalies, often referred to as occult or "closed" dysraphisms, which are often imperceptible on physical examination because of their deep location. These, too, exhibit a predilection for the lumbosacral region, where they are typically discovered on neuroradiological evaluation for myelopathy. It is fixation of the filum terminale or spinal roots to these abnormal structures, with resulting traction on the cord (as evidenced by displacement of the conus medullaris below the level of the L2 vertebral body), that is often responsible for their principal neurologic manifestations—disturbed gait, bladder spasticity or hypotonia, and anococcygeal and perineal pain. Maldevelopmental lesions that may present as this "**tethered cord**" **syndrome** include intraspinal **lipomas**; **dermoid**, **epidermoid**, or **hindgut cysts**; **intrasacral meningeal diverticula** ("**occult meningoceles**"); and cystic intradural masses composed of neuroglial tissue ("**occult myelomeningoceles**"). The dividing collagenous or chondro-osseous septum characteristically present in cases of congenitally split spinal cord (**diastematomyelia**) is yet another potentially tethering anomaly, whereas the offending lesion in some instances is simply a short filum (typically thickened owing to fatty infiltration) or a fibrous band extending into the exposed spinal canal from the sacral subcutis. The latter is often associated with a telltale skin dimple or dermal sinus, can contain ciliated glandular elements as well as components of dermoid or epidermoid cyst, may include CNS tissue, peripheral nerve, ganglion cells, fat and muscle, and rarely exhibits a hamartomatous proliferation of included pacinian corpuscles.[2,9] Sizable **thoracolumbar hamartomas** that may contain nerves, adipose tissue, muscle, cartilage, bone, glandular structures, and primitive urinary tract-type tissues have also been described involving the spinal canal and exerting traction on the spinal cord,[10] as have developmental lesions of müllerian derivation. Fortunately, many of these associated malformations are amenable to surgical correction, and division of the immobilized filum frequently results in substantial neurologic improvement and relief of pain.

A distant second in incidence to the dysraphic cystoceles of the lumbosacral region are those involving the cranium.[1] These, too, hug the midline and, like their spinal counterparts, may contain meningeal derivatives alone or associated neural tissues. The latter, termed **encephaloceles**, vastly predominate. Approximately 80% of encephaloceles exit the cranial cavity in the region of the occiput via defects in the posterior wall of the foramen magnum or occipital bone. These are generally covered by intact scalp, subjacent to which are recognizable dural and leptomeningeal membranes, and may contain choroid plexus, cerebellar, and brainstem elements, in addition to substantial volumes of cerebral hemispheric tissue (Fig. 43.1). The extruded brain, which encloses a central CSF-filled chamber that may communicate freely with the ventricular system, can appear remarkably well formed but commonly exhibits microscopic abnormalities of cortical architecture, if not grossly anomalous gyration, and its covering leptomeninges frequently contain islands of heterotopic neuroglial tissue. Vascular compression at the level of the encephalocele's narrow intraosseous neck may result in secondary alterations such as hemorrhage and infarction. Excision and closure can often be performed without complication, but a regrettably large percentage of occipital encephaloceles are attended by malformations of the intracranial contents, microcephaly, and mental retardation.

Extraoccipital encephaloceles may protrude through defects in other portions of the cranial vault or bulge into the anterior or posterior fontanels but are more commonly of the sincipital or basilar types. Sincipital encephaloceles present as visible facial

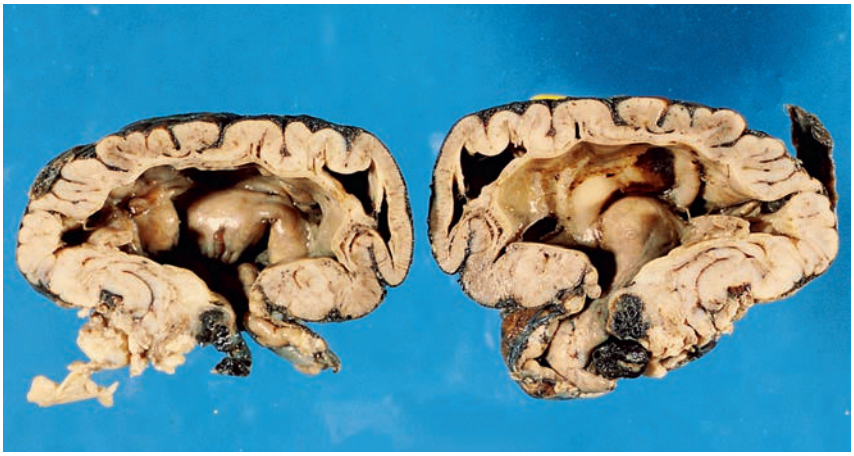

Figure 43.1 Encephalocele. A well-developed, gyriform cortical mantle characterizes this neurosurgical specimen from the occipital region of a newborn. (Courtesy of Dr. Humberto Cravioto, New York.)

swellings in the region of the forehead, nasal bridge, or orbit, whereas basal variants are situated in the nasal cavity, sphenoid sinus, nasopharynx, or pterygopalatine fossa and therefore are not externally evident. The latter includes transethmoidal encephaloceles that herniate through defects in the cribriform plate and constitute the most common polypoid intranasal masses encountered in the newborn. Prior to biopsy or resection, a congenital subcutaneous or submucosal mass in any of these locations must be carefully evaluated for an intracranial connection. Inasmuch as the encephalocele communicates with the subarachnoid space via its associated osseous defect, intracranial repair with dural closure is required if CSF leakage and meningitis are to be avoided. By contrast, simple neuroglial heterotopias occurring in these same regions (see later) have no intracranial connection and thus may be safely excised transnasally or transorally, depending on their precise situation. Both the heterotopia and true encephalocele often consist solely of aggregated astroglia embedded in fibrous tissue, though either may contain admixed neurons. Heterotopias of the nasal region rarely if ever harbor ependymal elements, a feature of some encephaloceles, but these may be encountered in examples situated in other sincipital or basilar locations. Included meninges are an inconstant feature of specimens derived from extraoccipital encephaloceles but, when identified, exclude heterotopia from further consideration.

Lastly, it should be noted that meningoceles and encephaloceles may also be acquired secondary to trauma or preceding neurosurgical procedures. "Endaural" examples may complicate chronic otitis media or mastoiditis and have been described as a late effect of cranial irradiation in childhood.[11]

Neuroglial and Meningeal Heterotopias

The **neuroglial heterotopia**, introduced in the preceding discussion of cranial dysraphism, is a surgically curable displaced mass of mature central neuroepithelial tissue unconnected to the brain proper. Paracerebral masses of this type only rarely achieve symptomatic size.[12] More common are small leptomeningeal examples that constitute occasional incidental findings on post mortem examination and that are frequently noted in association with major structural anomalies of the underlying nervous system (e.g. craniospinal cystoceles).[1,13] Usually, these are of little clinical import save for their rare roles in epilepsy and as potential progenitors of primary leptomeningeal glial or glioneuronal neoplasms. The heterotopias most likely to engage the surgical pathologist frequent the same locations favored by sincipital and basal encephaloceles—the bridge of the nose and nasal cavity, paranasal sinuses, palatal region, and nasopharynx—and are best regarded as "sequestered" variants of their dysraphic counterparts.[14,15] By far the most common of these maldevelopmental lesions, which have also been termed **glial choristomas**, is the so-called **nasal glioma**, an unfortunately confusing misnomer (Fig. 43.2). Neuroglial heterotopias may also present in the cranial bones, scalp, orbit, and submandibular region. Their structure varies, but most consist solely of solid glial nests embedded in fibrous tissue, and only about 10% contain neurons. Astrocytes usually predominate and are often the only neuroepithelial element present in nasal examples. Pharyngeal lesions are typically more complex, often containing ependyma-lined clefts and choroid plexus–like formations. Pigmented neuroepithelial structures suggesting retinal differentiation may also be rarely encountered. Heterotopias composed of cerebellar tissue have been reported in the anterior cranial fossa and orbit, among other unusual sites.[16]

The neuroglial nature of the lesions under discussion is usually obvious in routinely prepared histologic sections but may be confirmed in questionable cases by glial fibrillary acidic protein (GFAP) immunohistochemistry. The distinction of these rests from

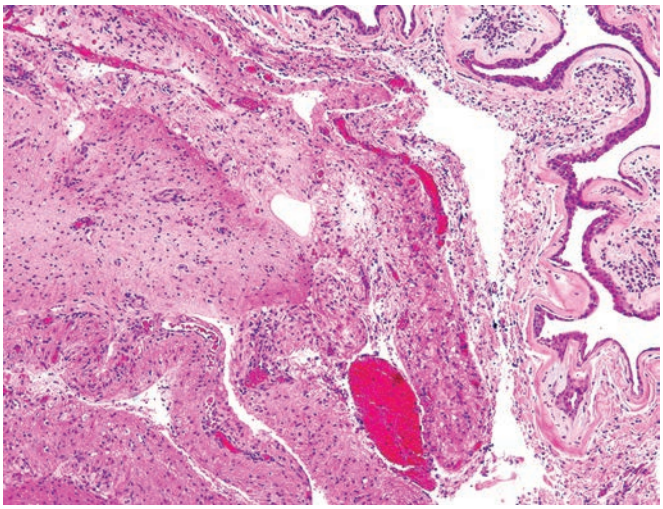

Figure 43.2 Nasal neuroglial heterotopia with fibrillar glial nests *(left)* underlying sinonasal mucosa *(right)*.

encephaloceles, a matter of considerable clinical significance, is addressed earlier. It should be noted that neuroglial heterotopias occasionally exhibit worrisome cytologic abnormalities and troubling hypercellularity, but this is without clinical significance. Rare heterotopias interpreted as having undergone focal neoplastic transformation have been reported, including an oligodendroglioma,[17] an oligoastrocytoma,[18] and a melanotic neuroectodermal tumor of infancy.[19] A probable instance of frontal lobe astrocytoma penetrating the cribriform plate to masquerade as a nasal glial heterotopia has also been described.[20]

In contrast to some sincipital and basal encephaloceles, neuroglial heterotopias do not contain meningeal elements. Displaced meningothelium, however, may be encountered in curious lesions of the scalp variously interpreted as hamartomas or as meningeal dysraphias that have lost their connection to the intracranial compartment in the course of development ("**sequestered meningoceles**").[21] These extracranial meningeal heterotopias are often noted at birth but may not come to surgical attention until adulthood. They are situated most often in the dermis or subcutis of the midline occipital region, at the vertex, in the posterior fontanel, or overlying the lambdoid suture. Regional alopecia is a common associated finding. The lesion consists of collagenous tissue containing irregular slit-like spaces lined by flattened meningothelial cells. These may also form solid cords or, rarely, small nests. Extracranial meningeal heterotopias may be misconstrued as melanocytic lesions, lymphangiomas, or even angiosarcomas[22] but can be distinguished in problematic cases by their immunoreactivity to epithelial membrane antigen (EMA). These maldevelopmental lesions could theoretically serve as precursors to the rare bona fide meningiomas arising in the scalp. Sacrococcygeal myxopapillary ependymal rests and their possible relationship to extramedullary ependymomas are discussed later in the section on ependymal neoplasms.

Choristomas and Hamartomas

Maldevelopmental rests composed of tissues foreign to the nervous system—"choristomas"—are only rarely encountered within the confines of the dura mater (and hardly ever involve the brain proper). An exception to this is the unusual lesion described as **complex choristoma of the gyrus rectus**.[23] Embedded in a gliotic matrix and containing, in addition to mature adipose tissue, benign adenosquamous epithelial components supported by myoepithelium and

arranged in nests, cords, or tubuloductal structures, this has been likened to the solid cell nests of the thyroid gland and cystic tumor of the atrioventricular node as sharing morphologic features and a potential derivation from neural crest progenitors. We have previously mentioned thoracolumbar hamartomas composed of various mesenchymal and epithelial components in the setting of spinal dysraphism, and note that comparable lesions have rarely been identified as intramedullary growths unaccompanied by dysraphic abnormalities.[24] **Ecchordosis physaliphora** is the term used to describe an intracranial or spinal intradural heterotopia exhibiting the histologic and ultrastructural features characteristic of notochord and its neoplastic counterpart, the chordoma.[25] Ecchordoses are most commonly situated just ventral to the pons, are frequently connected to notochordal remnants in the adjacent clivus via attenuated transdural stalks, and usually take the form of bosselated, gelatinous nodules loosely adherent to the basilar artery. They generally measure no more than 1–2 cm in greatest dimension and, for the most part, are autopsy curiosities. Whether larger, symptomatic examples are best regarded as "giant" ecchordoses or as bona fide intradural chordomas is questionable (see subsequent section on chordoma). Neuroradiologically detected ecchordoses have been described as generally T2 hyperintense and nonenhancing on magnetic resonance imaging (MRI), while chordomas usually exhibit contrast enhancement.[26] **Leptomeningeal rhabdomyomatosis** refers to microscopic aggregates of mature striated myofibers characteristically located in the prepontine region or cerebellopontine angles.[27] These may, in addition, harbor well-differentiated adipocytes, displaced neuroglial tissue, and aberrant peripheral nerve fibers, usually detected in complex with major developmental anomalies of the CNS. Rarely, nodules composed of striated or smooth muscle are encountered in cranial nerve divisions.[28,29] These may contain admixed neuromatous elements and adipose tissue and can achieve considerable size; they have been variously reported as **choristomas**, **neuromuscular** or **ectomesenchymal hamartomas**, **benign triton tumors**, and **rhabdomyomas** (Fig. 43.3), often manifesting with a refractory postoperative fibromatosis and therefore warranting limited surgery when suspected clinically or intraoperatively.[29] Also on record are several **müllerian choristomas of the lumbosacral region** associated with spinal dysraphism, potentially containing endometrium, endocervical glands, and smooth muscle bundles organized in uterus-like fashion.[30] There are also isolated reports of **intracerebral**[31] and **intraspinal**[32] **endometriosis**, although these are properly regarded as acquired, rather than developmental, lesions. Finally, there are the bizarre accounts of a minute adenoid cystic carcinoma arising in a cerebellopontine angle mass otherwise composed of mature salivary gland tissue,[33] and a second salivary heterotopia, also in the cerebellopontine angle, associated with a solitary fibrous tumor (SFT).[34]

Meningioangiomatosis is the designation traditionally applied to what has long been regarded as a hamartomatous or malformative process that usually occurs in sporadic fashion but may be associated with type 2 neurofibromatosis (NF2) as well.[35,36] Sporadic cases are nearly always solitary and present with seizures, whereas NF2-related examples are not infrequently multifocal and typically asymptomatic. The basic lesion (Fig. 43.4) is an en plaque proliferation of small blood vessels that dissects the cerebral cortex, halts abruptly at the gray–white junction, and is often accompanied by a spindle cell proliferation that may be tightly vasocentric or, in exuberantly cellular variants, arrayed in fascicular or storiform patterns. Loose whorling and schwannoma-like nuclear palisading may also be encountered. Extensive psammomatous calcification is common, as is vascular hyalinization and regions of fibrous tissue overgrowth. A curious feature of the lesion is the tendency of entrapped neurons to develop neurodegenerative neurofibrillary tangles.[35] Subcortical presentations are rare. The term meningioangiomatosis notwithstanding, participating spindle cell populations have exhibited a meningothelial immunophenotype (specifically, labeling for EMA) or ultrastructure (e.g. interdigitating cell processes with attaching desmosomes) in only a small minority of cases; they are consistently reactive for vimentin alone, being interpreted as predominantly fibroblastic by some observers.[37]

Meningiomas have been described as occasionally taking root within foci of meningioangiomatosis, but the interpretation of such accounts has been called into question. An analysis of candidate cases for genetic abnormalities commonly associated with meningothelial tumorigenesis found that regions of apparent "meningioangiomatosis" almost invariably shared with their neighboring meningiomas identical patterns of *NF2* and *DAL1* gene deletions,[35] but such deletions (one reported example excepted[38]) are not found in uncomplicated meningioangiomatosis. This would suggest that certain meningiomas spread along the cortical microvasculature in a meningioangiomatosis-like fashion. We have encountered rare

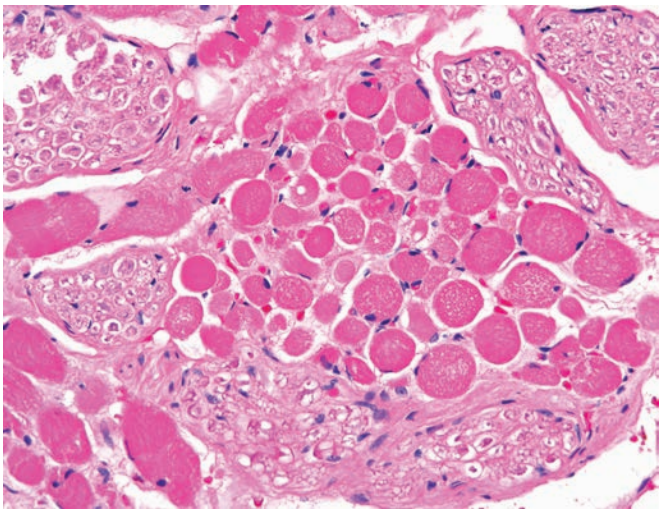

Figure 43.3 Neuromuscular choristoma composed of mixed fascicles containing peripheral nerve and skeletal muscle.

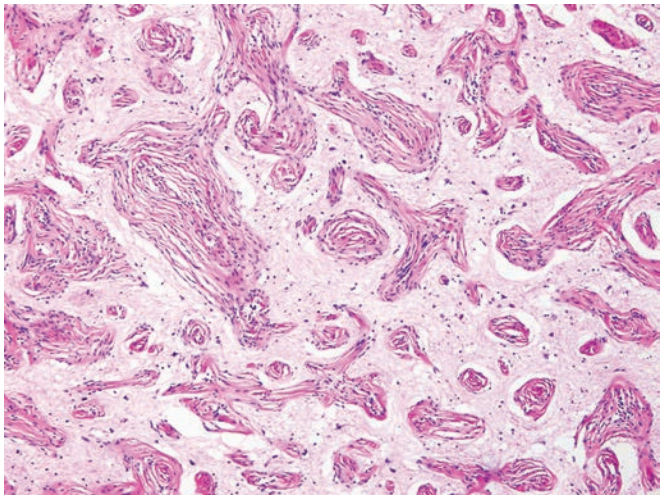

Figure 43.4 Meningioangiomatosis. This typical example exhibits dissection of the cerebral cortex by small blood vessels with accompanying perivascular spindle cells and occasional whorls.

examples of meningeal SFT/hemangiopericytoma (HPC), other meningeal sarcomas, and other primary and secondary meningeal neoplasms in association with a meningioangiomatosis-like pattern of spread as well.[39] We have also seen vascular lesions indistinguishable from meningioangiomatosis develop within irradiated cerebral cortex. Unusually cellular meningioangiomatoses may also be mistaken for bona fide neoplasms. Simple excision is the treatment of choice, but does not guarantee seizure control since patients with meningioangiomatosis may have complex electroencephalographic abnormalities indicative of multifocal, extralesional epileptogenic pathology.[37]

Cysts of the Central Neuraxis

Considered in this section are various non-neoplastic, developmental, or secondarily acquired lesions, only some of which qualify as "true" (i.e. epithelium-lined) cysts. Chief among the latter are the **colloid cysts of the anterosuperior third ventricle**.[40] These generally present in the third through fifth decades of life with manifestations of ventricular outflow obstruction, a consequence of their intimate relation to the foramen of Monro (Fig. 43.5). Thin-walled and often draped by adherent choroid plexus, colloid cysts are filled with a viscous, mucoid material that rapidly congeals on fixation. Their lining epithelium is prone to a low cuboidal attenuation resulting from pressure exerted by the cyst contents, but when well preserved is found to be of columnar respiratory type and is frequently populated by ciliated and goblet cell elements (Fig. 43.6). Only a basement membrane, inapparent at the light microscopic level, separates these from a delicate, fibrous capsule. The dense proteinaceous cyst contents, which often resemble the colloid of the thyroid, are periodic acid–Schiff (PAS) positive and may include hyphae-like aggregates of degenerate nucleoproteins. An inflammatory reaction to the contents of ruptured colloid cysts is responsible for most, if not all, cases of so-called xanthogranuloma situated in the third ventricle.[41]

Ultrastructural[42] and immunocytochemical[43] investigations of the colloid cyst (as well as Rathke cleft and neuroenteric cysts) support an origin from misplaced endodermal tissues. Its constituent epithelial cell types correspond closely to those typical of respiratory mucosae, sporting an apical glycocalyx coating, and express cytokeratins, EMA, and carcinoembryonic antigen (CEA) but not GFAP or the choroid plexus-associated transthyretin (prealbumin). Their occasional designation as "neuroepithelial" notwithstanding, similar histogenetic considerations apply to rare **endodermal-type cysts** of comparable structure situated within the posterior fossa, supratentorial compartment, optic nerve, and, as discussed later, the spinal canal.[44-48] Adenocarcinomatous transformation of such cysts has rarely been recorded in some of these, as has widespread craniospinal dissemination of histologically benign appearing endodermal-type cysts via the CSF.[46,49] Although also discussed in the context of pituitary disorders (see Chapter 44), the **Rathke cleft cyst**, a lesion having its origin in remnants of the stomodeum, is briefly noted here for the striking resemblance of its lining epithelium to that of the colloid cyst. Curiously, however, the latter rarely contains the metaplastic squamous elements common to Rathke cleft cysts and other cystic intracranial lesions putatively of endodermal lineage.

Intraspinal cysts resulting, in all likelihood, from the incomplete separation of developing endodermal and notochordal tissues in early embryonic life, have been variously designated as "**neurenteric**," "**foregut**," "**enterogenous**," and "**teratomatous**."[46] These intradural endodermal-type cysts are typically situated anterior to the spinal cord, are often associated with local vertebral abnormalities, and may be encountered with other developmental anomalies such as intestinal malformations and dermal sinuses. An intramedullary presentation is well recognized but far less frequently encountered.[50] Most examples exhibit a simple mural structure and columnar epithelial lining similar to that of the colloid cyst, but occasional variants contain specialized respiratory or gastroenteric-type "mucosa"

Figure 43.5 Colloid Cyst. The obstructive ventricular dilation (hydrocephalus) associated with this large example is characteristic of these lesions. Note the well-delineated cyst wall, which is bright in this contrast-enhanced magnetic resonance image.

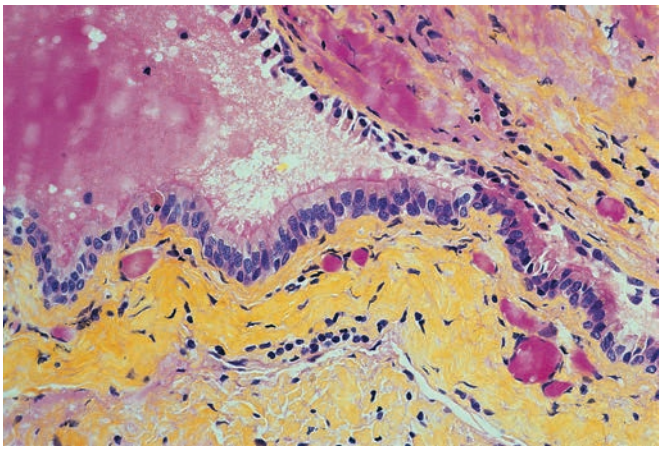

Figure 43.6 Colloid Cyst. A pseudostratified and ciliated columnar epithelium lines well-preserved colloid cysts. Note the supporting collagenous tissue of the cyst wall, *yellow* in this hematoxylin–phloxine–safranin preparation.

and the organized supporting elements (e.g. seromucinous glands, muscularis, cartilaginous rings, ganglion cells) of the developed alimentary tract or tracheobronchial tree.[51]

Two major variants of ectodermally derived neuraxis cyst are recognized, both lined by keratinizing squamous epithelium.[52] The **epidermoid cyst**, by definition, is devoid of cutaneous-type adnexal structures and filled by friable, often lamellated keratinous debris that radiates a pearly sheen as viewed through the thin, fibrous lesional capsule. **Dermoid cysts**, by contrast, include skin appendages, such as pilosebaceous units, eccrine and, occasionally, apocrine glands, as well as mural adipose tissue foreign to the epidermoid type. They may contain a greasy, yellowish-gray material admixed with hairs or just friable, keratin-rich debris similar to that of their epidermoid counterparts. Cysts of both types are, for the most part, developmental, presumably arising from surface ectodermal elements trapped in association with the developing CNS on closure of the neural groove or formation of the secondary cerebral vesicles. The occurrence of some examples, particularly dermoids, in complex with craniovertebral anomalies (e.g. spina bifida), malformations of the spinal cord, and dermal sinuses attests to their malformative nature. Acquired variants are well recognized; however, most of them are epidermoid and resulting from the traumatic[53] or iatrogenic[54] implantation of cutaneous tissues in the cranial or spinal subdural space.

Epidermoid and dermoid cysts are characterized by distinctive clinical as well as histologic features.[52] The former affect subjects of all ages, most coming to attention in young adulthood or middle age, whereas the latter usually present in childhood or adolescence. Epidermoid cysts are widely distributed, but the great majority are positioned intracranially, most commonly at the cerebellopontine angle. Rarely, posterior fossa examples conspicuously erode into, or lie embedded within, the cerebellum or brainstem. Supratentorial representatives exhibit a predilection for the parasellar region but may also be situated within the ventricular system, in the cerebral hemispheres, and in the suprasellar or pineal regions. Intraspinal epidermoid cysts are typically intradural and extramedullary but may on rare occasion lie entirely within the spinal cord.

Compared with its epidermoid counterpart, the dermoid cyst clings tightly to the midline. It, too, favors the posterior fossa but in this location characteristically occupies the cerebellar vermis or fourth ventricle. When situated above the tentorium, the dermoid cyst tends to a frontal, paramedian position on the skull base. An infantile, subgaleal variant typically resides in the anterior fontanel. Although generally outnumbered by epidermoid cysts, dermoids actually predominate at spinal levels. These exhibit a decided predilection for the lumbosacral region, where they constitute a manifestation of spinal dysraphism.

Although the clinical manifestations of dermoid and epidermoid cysts are principally referable to their local mass effects, either may present with signs and symptoms of "chemical" or infectious meningitis. The former results from cyst rupture and the spillage of irritating keratinous and lipid-rich debris into the ventricular system and subarachnoid space.[55] Repeated episodes of bacterial meningitis are a recognized complication of cysts associated with dermal sinuses offering access to the nervous system. Patients harboring posterior fossa dermoids and occipital sinuses may also suffer cerebellar abscesses. Neoplastic transformation is a well-documented but fortunately rare occurrence. In most cases, the underlying lesion is a cyst of epidermoid type and the secondary cancer a squamous carcinoma.[56] The bizarre phenomenon of an osteogenic sarcoma arising in association with a cerebellar epidermoid cyst has been recorded.[57] A temporal lobe example containing islands of keratinized, anucleate-appearing ("shadow") cells similar to those seen in pilomatricomas has been described.[58] Even histologically conventional cysts can recur following incomplete resection of their walls. Spontaneous seeding of the CSF by apparently benign epidermoid cysts with development of intraventricular or subarachnoid "daughter" lesions is a recorded curiosity.[59]

Inasmuch as epidermoid cysts may arise, albeit rarely, in the suprasellar region, their differential diagnosis includes Rathke cleft cysts with extensive squamous metaplasia and craniopharyngiomas. The former will usually harbor scattered mucicarminophilic goblet cells atop their squamous elements and do not feature the advanced keratinization typical of the epidermoid cyst. The formation of cytoplasmic keratohyaline granules, typical of the epidermoid cyst's maturing squames, is generally foreign to craniopharyngiomas. Furthermore, epidermoid and Rathke cleft cysts lack the latter's islands of "ghost cell" keratinocytes and its "machinery oil"-like contents and do not exhibit the basaloid elements and stellate reticulum of the adamantinomatous craniopharyngioma or the filiform architecture of its papillary variant. As regards further distinction of Rathke cleft cysts from craniopharyngiomas, one study of a limited number of cases found immunolabeling for BRAF V600E mutant protein in papillary craniopharyngioma, but not in Rathke cleft cyst with squamous metaplasia.[60] Cystic craniopharyngiomas of adamantinomatous type, in addition, often manifest foci of aberrant nuclear β-catenin immunoexpression that are not encountered in metaplastic Rathke cleft cysts.[61] The exceptional dermoid cyst presenting in the pineal or suprasellar region should be distinguishable from the mature cystic teratoma by its lack of glandular components (indicative of endodermal differentiation), muscle, or cartilage.

Glioependymal cysts are most commonly situated in the paraventricular white matter of the frontal and parietal lobes but may also lie within the cerebellum, brainstem, or spinal cord.[62-64] A derivation from developmentally displaced ventricular lining seems to explain the majority, while rare cerebellopontine angle and other extra-axial examples conceivably originate from subarachnoid neuroglial heterotopias.[65] Intramedullary glioependymal cysts often involve the conus medullaris, where they may actually represent cystic dilations of the ependyma-lined ventriculus terminalis.[66] As their name implies, they are lined by cells resembling mature ependyma. Like the cells of the more common endodermal type cysts, these may be ciliated but differ in that they do not exhibit goblet cell differentiation, are not coated by an apical glycocalyx, and do not rest on a basal lamina, being directly apposed to fibrillary neuroglial tissue. Representatives presenting in the subarachnoid space may, however, contain "supporting" astrocytic elements that fashion a continuous basement membrane separating them from a delicate fibrous capsule, reminiscent of the normal glia limitans.

The limited immunocytochemical studies reported to date suggest that the lining cells can express GFAP, S-100 protein, and rarely cytokeratin.[67,68] Failure to elaborate CEA or transthyretin (prealbumin) may serve to distinguish these lesions from endodermal or choroid plexus cysts, respectively. By definition, **choroid plexus cysts** are lined by cells with all the microscopic attributes of choroid plexus epithelium.[69]

Rarely, intraparenchymal brain cysts exhibit no specialized lining elements and are not associated with historical or tissue evidence of underlying trauma, hemorrhage, infarction, neoplasia, demyelinating disease, or infection that might account for their genesis. Most numerous are examples termed "**simple**" or "**gliotic**" **cysts**, presenting in the cerebellar hemispheric white matter of middle-aged or elderly adults.[70] That at least some of these clinically benign lesions are not congenital anomalies but represent instead "burnt-out" pilocytic astrocytomas has been suggested in view of the latter tumor's tendency to macrocystic alterations and the presence of a dense mesh of glial processes rich in Rosenthal fibers and scattered atypical astrocytes around many simple cerebellar cysts. Inasmuch as the neoplastic

components of cerebellar cysts associated with pilocytic astrocytomas and hemangioblastomas may be confined to diminutive mural nodules, careful inspection of cystic lesions in this location is mandatory and biopsy of various portions of their linings is prudent. Exceptional cysts arising outside the cerebellum are lined only by normal or mildly reactive neuroglial tissue, are juxtaventricular in location, and contain a fluid similar in its composition to CSF.[71] These likely derive from ventricular diverticula or represent collections of CSF that have dissected into the neuropil via congenital or acquired breaches in the ependyma. Lesions of macrocystic neuroradiological profile that similarly lack specialized lining elements have been reported to result from marked dilation of perivascular spaces, particularly in the cerebral hemispheric white matter.[72] It is the demonstration of traversing blood vessels that has been taken for evidence of the continuity of these pseudocysts, which are otherwise bordered by rarefied and gliotic neuroparenchyma, with the perivascular compartment.

Particularly prone to cystic change is the normal human pineal gland, but only rarely does this alteration result in a lesion of symptomatic proportions.[73] **Pineal cysts** that come to neurosurgical attention generally do so in the third through fifth decades of life, their presenting manifestations being indistinguishable from those of pineal neoplasms, including obstructive hydrocephalus and disturbances of ocular motility. Like the cerebellar lesions previously described, these are lined by a dense zone of piloid gliosis, rich in Rosenthal fibers and granular bodies but not exhibiting the loose microcystic component or degree of cellularity more typical of pilocytic astrocytomas. A second differential diagnostic consideration is the pineocytoma, as the cysts under discussion regularly contain elements of residual pineal parenchyma within their walls. These usually retain the organoid appearances typical of the normal gland, but in some cases their uniform, telltale lobularity is obscured as a result of longstanding compression. Appreciation of a given lesion's neuroradiological features and appearance at surgery is quite helpful in this regard, as pineocytomas are nearly always solid rather than cystic. Simple excision is curative.

Loculated accumulations of CSF enclosed by fibroconnective tissues derived from the leptomeninges are referred to as **arachnoid cysts**.[74] Etiologically diverse, some arachnoid cysts develop as sequelae of meningitis or trauma and are circumscribed by adhesions traversing the subarachnoid space. Most, however, are considered to begin as maldevelopmental clefts in the arachnoid membrane that subsequently undergo cystic dilation. Lesions of this type are lined by an attenuated meningothelium resting on a layer of supporting fibrous tissue that is macroscopically so thin as to be transparent. These most commonly occupy the Sylvian fissures, followed by the cisterna magna and cerebellopontine angles, but may occur in the suprasellar region and along the spinal neuraxis.[75] Intradiploic[76] and intramedullary[75] presentations have also been recorded. By virtue of their very gradual inflation, such lesions may produce striking deformities in neighboring neural tissues that are often unaccompanied by mass effects such as midline shifts or cerebral herniations. **Dural cysts** (cystically dilated intradural clefts) are rare and described mainly as intraspinal causes of myelopathy.[77] Comparable intracranial lesions have been reported to produce sagittal sinus occlusions.[78]

Most arachnoid "cysts" presenting at spinal levels are actually meningeal diverticula that can be shown to communicate with the subarachnoid space.[79] These may lie within or outside the dural sleeve, are potentially multifocal, and can be lined by meningothelial cells or composed solely of membranous fibrous tissue. Only a minority achieve symptomatic proportions, producing myelopathy or radicular syndromes, at times associated with erosion of adjacent vertebral bodies or the sacrum. Extradural variants arising in association with the posterior spinal roots, typically at lumbosacral levels, are often eponymously designated as **Tarlov perineurial cysts**.[80] Only exceptionally do these prompt neurosurgical intervention by causing perineal pain, sciatica, or bladder or bowel dysfunction. Rarely, cystically dilated or otherwise enlarged arachnoid granulations masquerade as dermoid (or other true) cysts or produce sizable lytic skull defects that arouse suspicion of neoplastic disease.[81]

Yet another cystic lesion that may impinge on the spinal neuraxis is the **juxtafacet** or "**ganglion**" **cyst**, a collection of acellular and often myxoid material bound within a fibrous capsule devoid of specialized lining elements.[82] The term **synovial cyst** has been employed for similar lesions interpreted as containing inflamed synovium.[83] Some examples contain metaplastic chondroid elements and foci of calcification. Cysts of comparable structure may rarely arise within the ligamentum flavum.[84] A degenerative abnormality, the juxtafacet cyst typically presents at lumbar levels in association with osteoarthritic changes of the vertebral column but may rarely occur in the cervical region. Myeloradiculopathy and bony erosion are its principal complications.

Cerebrovascular Disorders

Cerebral Infarction

Characterized by an abrupt loss of neurologic function ("stroke") referable to a circumscribed arterial territory within the affected brain, the common variety of **cerebral infarct**[1] is an ischemic lesion of later adult life confidently diagnosed at the bedside. Occasional examples, however, are silent at onset, evolve in subacute fashion as expansile intracranial "tumors" on conventional neuroradiological assessment, and are consequently sampled by the neurosurgeon. The histology of a given infarct will depend on the stage of development.[85,86] Biopsied tissues generally exhibit a spongy rarefaction reflecting the edema that is largely to blame for these lesions' associated mass effects, commonly evidence of intense vascular congestion, and may also be frankly hemorrhagic. Neurons, if recognizable, persist only in faded "ghost"-like profile or appear shrunken, angulated, and abnormally eosinophilic with a loss of intranuclear detail. Neutrophilic exudates may be apparent early on, but most lesions approached surgically have evolved to the point where mononuclear phagocytes, including lipid-laden foam cells, constitute their principal reactive elements. Organizing infarcts may feature a potentially alarming hypercellularity that is all the more misleading when accompanied, as is often the case, by capillary proliferation and endothelial hypertrophy resembling glioma-associated microvascular hyperplasia. Inasmuch as the cytologic features by which macrophages are recognized tend to be obscured in frozen sections but are immediately apparent in squash and smear preparations, routine use of the latter is recommended for intraoperative consultation. Once a lesion has been identified as being rich in phagocytes, the major differential consideration is demyelinating disease (see later). Nevertheless, demyelinating pseudotumors only exceptionally progress to tissue necrosis, are usually characterized by perivascular lymphoid cuffing and a relative preservation of axons foreign to brain infarcts, and generally afflict patients younger than those at risk for ischemic cerebral events.

Intracranial Aneurysms

The **saccular** or "**berry**" **aneurysm** ranks chief among surgically correctable cerebrovascular abnormalities and is unrivaled as a cause of massive subarachnoid hemorrhage in adults. These common lesions (prevalence of roughly 2%–6%) are somewhat more frequent in women and are encountered at all ages beyond puberty, although symptomatic examples cluster in the fifth through seventh decades

of life.[87,88] Risk factors include smoking, hypertension, increasing age, and positive family history, with mortality being as high as 50% after rupture. Some 10%–15% of cases have been estimated to occur on a familial basis. The factors critical in initiating the formation of saccular intracranial aneurysms remain undefined, and the majority are unassociated with local or systemic conditions known to promote vascular injury, but hemodynamic stress probably plays the major role in their development. On balance, the weight of evidence supports the hypothesis that these are primarily acquired, degenerative lesions rather than developmental anomalies. Arterial hypertension is widely regarded as playing an aggravating role in their evolution and may underlie an association with the adult form of aortic coarctation, type III polycystic kidney disease, and pheochromocytoma.[89,90] Connective tissue disorders that result in increased vascular fragility have mainly been associated with aneurysms of fusiform type but may also predispose to the development of saccular aneurysms, these having been described in the settings of type III collagen deficiency (Ehlers–Danlos syndrome type IV), pseudoxanthoma elasticum, and Marfan syndrome.[1,89] Aneurysms of the saccular variety occasionally occur together with fibromuscular dysplasia of the renal arteries, intracranial arteriovenous malformations (AVMs) or fistulas, and persistent primitive carotid–basilar anastomoses or other anomalies of the circle of Willis. The latter observations notwithstanding, the localization of most saccular aneurysms (discussed later) is at odds with the theory that they commonly originate in vestigial remnants of the embryonic cerebral vasculature.

Multifocal, saccular intracranial aneurysms usually lie within 3 cm of the internal carotid artery termini at the circle of Willis, and 80% involve divisions of the cerebral vasculature ventral to the posterior communicating arteries.[1] It is clear from autopsy studies that the middle cerebral arteries are most commonly affected, but most clinical series are dominated by anterior communicating and internal carotid artery examples because these are more prone to rupture.[87,91,92] That saccular aneurysms almost invariably bulge from points of acute angle vascular bifurcation has been interpreted by some observers as the natural consequence of increased hemodynamic impact or turbulence at these points and by others as reflecting an inherent vascular weakness secondary to focal gaps in the arterial media known to occur near circulatory forks.[91] Although such "defects" could theoretically influence the localization of some lesions, there actually appears to be little topographic concordance between their major distribution in the human cerebrovascular tree and that of saccular aneurysms.

On histologic examination, the walls of saccular intracranial aneurysms are composed principally of fibrous tissue, the muscular coats, and elastic laminae of parent vessels typically terminating abruptly at the points of aneurysmal outpouching. Atheromatous changes are common and may be florid but are characteristically confined to the aneurysmal sac and thus probably represent superimposed alterations of little direct etiologic significance. Much the same can be said of chronic inflammatory mural infiltration. Other secondary phenomena include partial or, in select instances, complete thrombotic occlusion, the latter presumably accounting for the occasional "disappearance" of untreated aneurysms assessed by periodic angiographic study.

Most saccular aneurysms remain asymptomatic, and even frank rupture may be followed by spontaneous thrombotic closure of the aneurysmal sac and clinical resolution, but should not trivialize the associated risk of catastrophic intracranial hemorrhage. Long-term follow-up studies of patients with angiographically proven saccular aneurysms suggest a 1%–2% annual incidence of rupture; approximately half of these bleeding episodes prove fatal.[87,88] Although subarachnoid hemorrhage alone may be lethal, dissection of blood into the brain proper or ventricular system is more often the cause of death. Massive intraparenchymal hematomas are most often a consequence of middle cerebral artery aneurysms, whereas anterior communicating examples are generally responsible for most episodes of fatal intraventricular hemorrhage (blood usually entering the anterior horn of the lateral ventricle after dissecting through the inferomedial frontal lobe). Another grave complication is cerebral infarction related to postrupture vasospasm, again encountered most commonly in aneurysms of the anterior communicating arteries.

Although most observers have concluded that considerable risk of rupture is attached to saccular aneurysms exceeding 1 cm in diameter and relatively little to examples measuring 5 mm or less,[89] none of these lesions can be regarded as entirely innocent. In fact, nearly 70% of saccular aneurysms that ruptured in the course of one long-term follow-up study measured 6 mm or less in diameter on angiographic assessment.[93] Aneurysms that achieve "giant" proportions (usually defined as having diameters of at least 3 cm) typically present with cranial neuropathies, evidence of ventricular outflow obstruction, or other mass effects, rather than hemorrhage. Rarely, the surgical management of saccular aneurysms is complicated by a local granulomatous response to cotton materials employed as reinforcement following aneurysmal clipping.[94] These "**textilomas**," "**muslinomas**," or "**gauzomas**" can achieve considerable size, presenting as contrast-enhancing masses with significant accompanying edema, and may produce headache, fever, obstructive hydrocephalus, cranial nerve palsies, and endocrinopathy. In some cases a nontumorous optochiasmatic arachnoiditis provoked by these materials causes visual loss.

Although the designation of **mycotic aneurysm** would seem to imply a fungal process, this term has been applied in practice to focal infectious arteritides of diverse cause that have in common only an element of vascular dilation. Most mycotic intracranial aneurysms are, in fact, bacterial in nature and evolve as complications of endocarditis or, less frequently, suppurative pulmonary infection.[1,95] Streptococcal and staphylococcal species are the usual offenders. The resulting lesions, often multifocal, tend to be situated on distal branches of the cerebral vasculature, are more often fusiform or irregular than berry-like in configuration, and are frequently of diminutive proportions. Fungal aneurysms are specifically addressed in the discussion of CNS mycoses. In brief, these are most often caused by *Aspergillus* and *Candida* species, generally involve the large cerebral arteries at the base of the brain, and tend to be larger at presentation than their bacterial counterparts.

Atherosclerotic intracranial aneurysms generally afflict older adults, usually arise in the setting of advanced and generalized cerebrovascular atheromatosis, typically involve supraclinoid portions of the internal carotid arteries or the basilar artery, and may assume saccular, fusiform, cylindrical, or conical configurations.[1] Fusiform lesions of the vertebrobasilar trunk are the single most common variant.[96] Atherosclerotic aneurysms are generally large, and frequently achieve giant proportions. Their presenting manifestations are more often related to compression of neighboring CNS structures or ischemic complications of progressive thrombosis than to hemorrhage, although some observers assert that the associated risk of rupture is underestimated. Far more common than discrete aneurysm formation is atherosclerotic "**dolichoectasia**"—diffuse dilation and tortuous elongation of the basilar or internal carotid arteries—and the two processes may coexist.

Dissecting aneurysms of the intracranial vasculature are rarities.[1] Most documented cases lack an etiologic explanation, although some have been attributed to trauma, syphilis, cystic medionecrosis, arteriosclerosis, fibromuscular dysplasia, or other local abnormalities of vascular structure. α1-Antitrypsin deficiency has also been linked to intracranial arteriopathy potentially complicated by dissection

or aneurysm formation.[97] Luminal stenosis secondary to the intramural accumulation of blood may result in bulbar or cerebral infarction; rupture typically produces catastrophic subarachnoid hemorrhage. Symptoms referable to mass effect constitute the least frequent manifestation of intracranial arterial dissection.

Exceptionally, tumors metastatic to the CNS present as "spontaneous" intracerebral or subarachnoid hemorrhages that ultimately prove secondary to **neoplastic aneurysm** formation. Most neoplastic intracranial aneurysms result from the embolization of cardiac myxomas to the cerebral vasculature,[98] but examples caused by choriocarcinomas and carcinomas of the lung are also on record.[99,100] The appearance of intracranial aneurysms years following therapeutic irradiation of the brain has also been documented.[101]

Considerable controversy surrounds the incidence of so-called **Charcot–Bouchard** (or "**miliary**") **microaneurysms** and their clinical significance.[1,102] The latter are described as 25–250 μ saccular or fusiform lesions most commonly involving lenticulostriate, perforating pontine, and corticomedullary junction arteries. Said to be particularly prevalent in hypertensive subjects, their rupture is regarded by some as a major cause of basal ganglionic, bulbar, and cerebellar hemorrhages. That aneurysms of Charcot–Bouchard type have received little attention in the surgical pathology literature could reflect the specialized tissue handling requisite to their identification. Studies from Japan, in which surgically evacuated hematomas were subjected to meticulous examination under the dissecting microscope (and serial thin sectioning of suspect lesions), suggest that microaneurysms are underappreciated as a factor predisposing to atraumatic lobar cerebral hemorrhage in both hypertensive and normotensive individuals.[103] Painstaking analysis in white individuals, on the other hand, has demonstrated that most "microaneurysms" actually represent complex vascular tortuosities and failed to establish a link between truly aneurysmal lesions and intracerebral hemorrhage.[104] Whether these discrepancies are simply methodologic or have their basis in genetic or environmental factors is unclear. In practice, it is virtually impossible to conclusively identify microaneurysms in routinely processed paraffin sections.

Vascular Malformations

A variety of non-neoplastic lesions resulting from focal anomalies in the development of the cerebrospinal circulation have been generically designated as vascular malformations. For practical purposes, these are divided into four relatively discrete morphologic categories, namely, capillary telangiectases, angiomas of venous or cavernous type, and AVMs.[1] Transitional or hybrid types, however, may be encountered. Also considered in this section are arteriovenous fistulas, since these are, strictly speaking, malformations, although they are generally regarded as acquired rather than developmental abnormalities.

Capillary telangiectases exhibit a curious predilection for the basis pontis (particularly the region of the median raphe) but are occasionally found to involve the cerebral hemispheres and spinal cord.[1] They usually constitute incidental findings on neuroimaging or autopsy and are only rarely complicated by symptomatic hemorrhage. On record is a massive pontomedullary case associated with a protracted history of bulbar dysfunction.[105] The lesion consists of loosely aggregated and variably ectatic capillary-type vessels (i.e. devoid of elastic or muscular mural elements) separated by normal or only mildly gliotic neuropil. A densely mineralized variant—the "**calcified telangiectatic hamartoma**" or "**hemangioma calcificans**"—is a recognized, albeit rare, cause of epilepsy, particularly of temporal lobe type.[106] Capillary telangiectases of the CNS complicate some examples of hereditary hemorrhagic telangiectasia, also known as Osler–Weber–Rendu disease.[1,107]

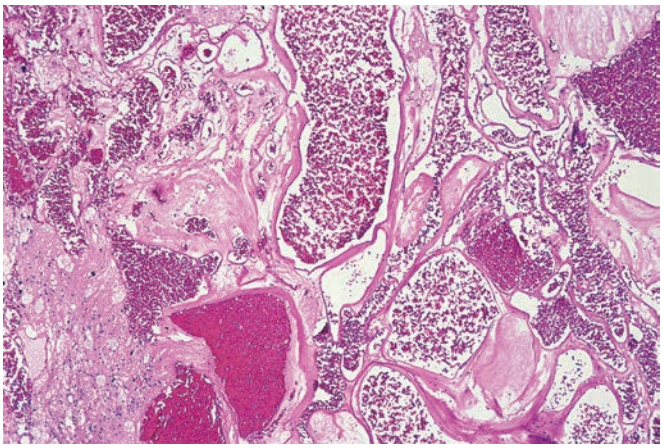

Figure 43.7 Cavernous Angioma. This cavernous angioma consists of ectatic and fibrous-walled vascular channels devoid of intervening neuroglial tissue. Neighboring brain parenchyma is present at the lower left.

The **venous angioma** is a loose collection of dilated veins typically found in the digitate or deep white matter of the cerebral or cerebellar hemispheres.[1] The radial convergence of their ectatic vessels on a central draining varix lends many of these lesions a diagnostic "caput medusae"-like profile on angiography. Although venous angiomas are the most common vascular malformations of the human CNS, it is the exceptional example that is responsible for intracranial hemorrhage or is otherwise symptomatic.[108]

The **cavernous angioma** or "**cavernoma**" differs from all other vascular malformations in that its constituent vessels are fashioned into a compact, globose mass, which is usually devoid of intervening CNS elements.[1] On gross inspection, a spongy core of blood-filled channels is encircled by a thin rind of indurated (gliotic) and rust-colored, hemosiderin-laden parenchyma. Histologic study reveals closely apposed, engorged vessels composed solely of fibrous walls (Fig. 43.7). Secondary alterations such as thrombosis and dystrophic calcification are common, with some lesions undergoing extensive metaplastic ossification as well. The existence of hybrid variants exhibiting in part the structure of capillary telangiectases has fueled speculation that cavernous angiomas may evolve from malformations of the former type,[109] but "mixed" or hybrid lesions remain exceptional. Cavernous angiomas may be situated anywhere along the neuraxis. Most examples lie above the tentorium, often in cerebral white matter subjacent to the motor strip, but the posterior fossa contents and spinal cord are not immune and even the cauda equina, cranial nerves, and epidural compartment may be involved. Multifocal cases are by no means rare. The designation of cavernous angioma has also been extended to certain extra-axial vascular malformations affecting dural venous sinuses, but these depart structurally from their counterparts positioned in the CNS proper in that they contain, in addition to compact cavernous elements, capillaries and muscular vessels of both arterial and venous type.[110] These distinctive lesions usually present as a consequence of cranial nerve compression and are generally mistaken for meningiomas on preoperative neuroimaging.

Cavernous angiomas may become manifest in childhood, but most symptomatic lesions are encountered in the third and fourth decades of life.[111] Familial cases transmitted in autosomal dominant fashion and linked to mutations of the "cerebral cavernous malformation" genes *CCM1*, *CCM2*, and *CCM3* (which are involved in integrin-mediated angiogenesis and programmed cell death) have been reported[1,112,113]; *KRIT1* abnormalities are also responsible for

an excess of cavernous angiomas among Hispanic–American kindreds of Mexican descent. Such variants may occur together with cavernous angiomas of the retina, hyperkeratotic venous malformations of the skin, vertebral hemangiomas, and café au lait spots.[114-116] The proximity of most cavernous angiomas to epileptogenic cerebrocortical tissues reflects the fact that seizures are their dominant clinical manifestation; less frequent complaints include focal neurologic deficits and headache. Although catastrophic hemorrhage is decidedly rare, cavernous angiomas are a recognized cause of intracranial hematomas, including both acutely symptomatic[117] and "encapsulated" lobar types[118]; the latter result in all likelihood from repeated subclinical episodes of bleeding and subsequent organization. A confident preoperative diagnosis of cavernous angioma may be established by neuroradiological means. The typical lesion, although "angiographically occult" (i.e. not apparent on arteriographic study), appears in T2-weighted magnetic resonance images as an irregularly hyperdense nodule unassociated with significant edema or mass effect but surrounded by a hypodense penumbra resulting from the accumulation of hemosiderin in adjoining neural tissues. Focal vascular lesions having a cavernous angioma-like neuroradiological profile may develop in the brain or spinal cord as a consequence of therapeutic CNS irradiation.[119] These seem slightly more prone to hemorrhage, develop most commonly in pediatric patients (especially when radiation is combined with methotrexate chemotherapy), and may exhibit transitional histologic features with regions of capillary and venous telangiectasis. Of note, both cavernous angiomas and AVMs (discussed later) in the CNS are likely to harbor GLUT1 immunoreactive endothelial cells; therefore, in contrast to cutaneous and soft tissue counterparts, this marker is not useful in their distinction from infantile hemangiomas.[120]

The most threatening of the congenital cerebrovascular anomalies is the **AVM**, a tangle of deformed arterial afferents and draining veins devoid of an interposed capillary bed.[1,121] AVMs may be situated in any region of the brain or spinal cord and can be restricted to the dura or choroid plexus, but most lie within the distribution of the middle cerebral arteries and involve the hemispheric convexities in contiguity with their covering leptomeninges. A majority present in early and mid-adulthood as a consequence of intracranial hemorrhage; other common manifestations include seizures, focal sensorimotor deficits, and headaches that are not clearly referable to episodes of bleeding.[122] Familial cases have been described,[123] and AVMs of the central neuraxis may be encountered in the context of Osler–Weber–Rendu disease (hereditary hemorrhagic telangiectasia).[107] The turbulent shunting of blood through AVMs of the brain is sometimes audible as a cranial or orbital bruit, can often be demonstrated on angiographic study, and may precipitate high output cardiac failure in afflicted infants and children, particularly those harboring extensive lesions drained by aneurysmally dilated galenic veins. Unfortunately, AVMs are complicated by fatal rupture with distressing frequency. Long-term observations suggest that symptomatic examples carry a 2%–4% risk of clinically significant hemorrhage per year and, if left untreated, will result in the deaths of at least one-fourth of affected patients as a direct result of rupture. The greatest risk of bleeding is associated with large size and concurrent saccular aneurysms, the latter of which may also rupture.[122]

AVMs vary in size from cryptic lesions not demonstrable by angiographic means and discovered only on sampling of surgically evacuated hematomas,[124] to enormous lobar examples that may focally span the full thickness of a cerebral hemisphere. Nevertheless, most are readily and accurately diagnosed preoperatively using modern imaging techniques.[125] Because their tortuous, cirsoid vascular components form a complex network of blood-filled channels, the nature of these lesions is often apparent on casual gross inspection. Intervening neural tissues are typically atrophic and gliotic, with evidence of rust-brown discoloration attesting to prior hemorrhage. Involved leptomeninges are thickened, opacified, and frequently siderotic as well. On histologic study (Fig. 43.8), the lesion is composed of variably ectatic and hyalinized veins, abnormally muscularized arteries, and structurally ambiguous vessels formed solely of fibrous tissue or displaying both arterial and venous characteristics.[1,121] Critical to the distinction of the true AVM from normal leptomeningeal vessels that may assume a malformative appearance in neurosurgical material as a result of artefactual compaction are the former's conspicuous mural anomalies, including striking fluctuations in medial thickness, architectural disarray or focal disappearance of the media altogether, or separation of the media into inner and outer coats by a seemingly aberrant elastic lamina. Cushions of fibromuscular tissue may also appear to project in polypoid fashion into the lumens of these abnormal vessels, and focal duplications and disruptions of the internal elastic lamina are common. Superimposed alterations include mural fibroplasia and atheromatosis, aneurysmal dilation, calcification, and thrombosis. Lesions subjected to preoperative embolization in an attempt to minimize blood loss during resection frequently exhibit an intraluminal foreign body response to the occluding material and may undergo focal necrosis,[126] whereas radiosurgical treatment causes fibrointimal hyperplasia with progressive vaso-occlusion.[127] Entrapped neuropil usually shows dense astrogliosis, neuronal depopulation, and ferruginous encrustation of included neuroglial elements. The interstices of select AVMs contain oligodendroglioma-like regions that may be intrinsic to the underlying maldevelopmental process, or the result of abnormal oligodendroglial aggregation caused by the ischemic contraction of entrapped white matter.[128] As noted previously, although systemic AVMs are often GLUT1 immunonegative—a helpful feature in the differential diagnosis with infantile hemangiomas—this marker is often positive in CNS examples.[120] The association of AVMs and bona fide gliomas is discussed under the heading of "Gliosarcoma and other gliomesenchymal tumors," as are malformation-like alterations occurring in the vascular stroma of neuroepithelial tumors.

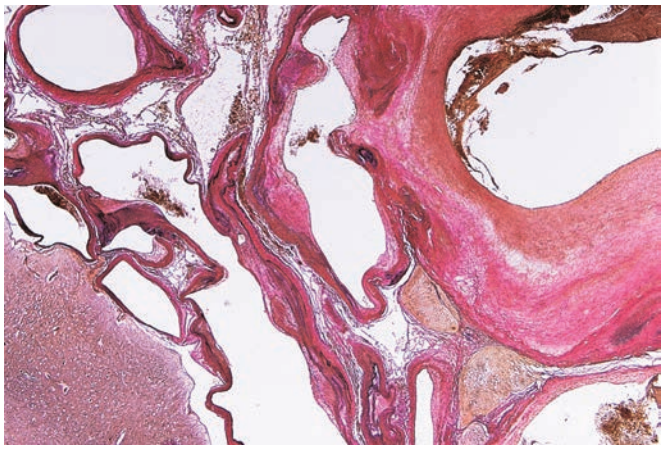

Figure 43.8 Arteriovenous Malformation. Ectatic, variably muscularized blood vessels with interrupted elastic lamina and fibrotic intimal thickening comprise this malformative lesion (van Gieson stain).

To the sporadic and familial malformations mentioned in preceding paragraphs can be added a host of vascular anomalies constituting manifestations of so-called **neurocutaneous syndromes** ("**phakomatoses**"), some clearly inherited while others are the apparent result of spontaneous mutation. The most widely recognized of these disorders is **encephalo-trigeminal angiomatosis**, known by the eponym of **Sturge–Weber syndrome**, defined as a florid

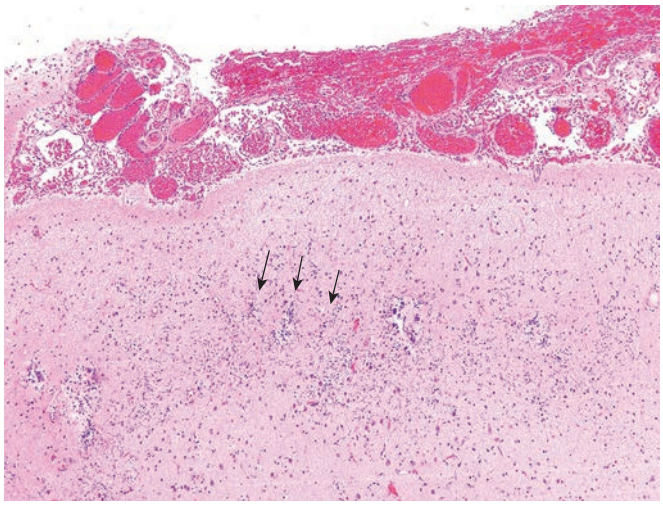

Figure 43.9 Sturge–Weber Syndrome. The cerebral resection specimen shows hemangioma-like venocapillary proliferation involving the leptomeninges, along with "tram-track" like cortical calcifications *(arrows)*.

venocapillary proliferation involving the leptomeninges and cortical mantle of one cerebral hemisphere (Fig. 43.9), in complex with a cutaneous hemangioma ("port-wine stain") lying at least in part in the ophthalmic distribution of the ipsilateral trigeminal nerve. Recent evidence also highlights the frequent association between Sturge–Weber syndrome and somatic *GNAQ* gene mutations.[129] Progressive mineralization of the involved cortex, centered initially on its abnormal perforating vessels, results in a gyriform, "tram-track" profile of radiologically demonstrable intracranial calcifications characteristic of the disease. Atrophy of the affected cerebral hemisphere is the rule, and patients typically suffer contralateral hemiparesis, often attended by motor seizures and mental retardation. The association of unilateral retinal angiomatosis and a cutaneous hemangioma in an ipsilateral trigeminal distribution with an AVM of the midbrain is referred to as **mesencephalo-oculo-facial angiomatosis** (also termed **neuroretinal angiomatosis**, **Bonnet–Dechaume–Blanc syndrome**, or **Wyburn–Mason syndrome**).[1] The generic designation of **cerebrofacial arteriovenous metameric syndrome** has been adopted by some observers to encompass this and other malformative vascular disorders involving the CNS, cutis, and subcutaneous tissues of the face, including rare variants affecting the pons and cerebellum in concert with the skin of the mandibular region and upper neck.[130] Capillary telangiectases and AVMs are also recognized, albeit rare, CNS manifestations of **hereditary hemorrhagic telangiectasia** (**Osler–Weber–Rendu** disease).[107] **Cobb syndrome** or **cutaneomeningospinal angiomatosis** is defined by the association of a dermal angioma (often of port-wine stain type) with an intraspinal hemangioma or AVM at corresponding dermatomal levels.[131]

Arteriovenous fistulas of the craniospinal vasculature are accorded only passing consideration here because their current management—surgical clipping or selective embolic occlusion of the offending communication—does not usually yield specimens for anatomic study, with the rare exception of associated venous aneurysms.[132] It is the absence of a plexiform, angiomatous nidus interposed between its feeding arteries and venous efferents that serves to distinguish the simple fistula from the AVM on angiographic and morphologic evaluation, although the latter's participating vessels may develop fistulous connections. Trauma clearly figures in the genesis of many examples (particularly carotid-cavernous sinus and vertebrovertebral types), as does neurosurgical injury and some associated systemic disorders such as fibromuscular dysplasia, type IV Ehlers–Danlos syndrome, and Osler–Weber–Rendu disease.[1] Many arteriovenous fistulas, however, present in spontaneous fashion. Those involving the cerebral arteries proper typically come to attention in childhood or early adult life, their clinical manifestations including headache, seizures, focal sensorimotor deficits, cardiac decompensation, and intracranial hemorrhage. Catastrophic rupture, however, appears to be exceptional. Fistulas developing below the tentorium are often localized to the dural sheaths of spinal nerve roots in the low thoracic region.[133] Lesions of this sort afflict men far more commonly than women, usually become symptomatic in or beyond middle age, and result in progressive paraparesis, paresthesias of the lower extremities, and sphincter disturbances. Known eponymously as **Foix–Alajouanine syndrome** or as **angiodysgenetic myelomalacia** or **venous congestive myelopathy**, this disorder is typified by serpentine elongation and distension of veins coursing over the dorsal surface of the thoracic spinal cord and is likely the result of protracted local venous hypertension caused by an overlap in the vascular drainage of the adjacent dural fistula and the cord itself. Fistulas involving the perimedullary vascular plexus[134] or distantly situated in the cranial or sacral dura[135] may cause a similar picture. The longstanding hemodynamic alterations in such cases can produce regional expansions of the spinal cord that mimic infiltrative neoplasms and prompt biopsy.[136] Characteristic histopathologic alterations include architectural distortion of the neuroparenchyma with gliosis, thickening and hyalinization of vascular walls, hemosiderin deposition, and varying degrees of myelin loss. Mild glial atypia, sometimes accompanied by Rosenthal fibers (piloid gliosis) may be encountered, and some of these lesions manifest vascular thrombosis and necrosis. Dural arteriovenous fistulas drained by ectatic or aneurysmally dilated cortical veins are particularly prone to hemorrhage.[132] Dural-based arteriovenous fistulas have also been implicated in the pathogenesis of vascular malformations occupying the sigmoid and transverse sinuses.[137]

Primary Angiitis

Among the less common forms of cerebrovascular disease is the idiopathic disorder variously described as "**isolated**," "**granulomatous**," or "**primary**" **angiitis of the CNS (also known as primary CNS vasculitis)**.[138] Inasmuch as many histopathologically confirmed cases do not have overtly granulomatous features, and as autopsy studies have found exceptional instances of extraneural vascular involvement, the last of these designations would seem the most accurate and is adopted here.

Primary angiitis of the CNS can occur at any age but usually afflicts young or middle-aged adults. Its principal clinical manifestations include headache, mental status changes, and focal neurologic deficits (particularly hemiparesis) that may evolve in progressive fashion or present abruptly as "stroke." Signs and symptoms of myelopathy occasionally dominate the clinical picture, but only rarely is there morphologic evidence of vascular injury that is accentuated at, or confined to, spinal levels.[139,140] If not promptly diagnosed and managed, the disorder generally proves progressive and fatal.

Short of biopsy for tissue confirmation, angiography is the most useful investigative procedure, and findings typical of vasculitis—particularly multifocal, segmental stenosis, dilation, or "beading" of small- to medium-caliber leptomeningeal arteries—are considered by some to constitute sufficient grounds for the institution of corticosteroid or cytotoxic therapy in the appropriate setting (i.e. when underlying infection and other systemic processes associated with secondary CNS angiitis have been excluded). However, arteriograms may be negative even in the face of florid vascular disease.[138] Less commonly encountered neuroradiological abnormalities include aneurysm formation and focal "mass" lesions secondary to infarction, which is often hemorrhagic.

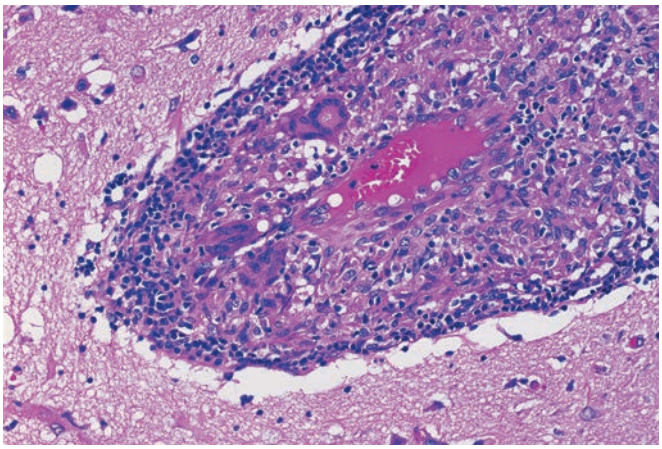

Figure 43.10 Primary Angiitis of the Central Nervous System. A frankly granulomatous inflammatory infiltrate replete with multinucleated giant cells expands the wall of this penetrating cerebrocortical blood vessel, found in biopsy material from a 34-year-old man with progressive encephalopathy.

Most observers regard biopsy as the sole means of confirming a presumptive clinical diagnosis of primary CNS angiitis, although false-negative samplings are a common consequence of the disorder's segmental distribution. Of note, however, biopsies are diagnostic in roughly 65% of cases when a radiographically detectable lesion is targeted, leptomeninges are included, and frozen section confirmation is utilized; in contrast, the majority of "blind biopsies" are nondiagnostic.[138] Small and midsized leptomeningeal and intracortical arteries usually bear the brunt of the injury, but neighboring veins are often involved, and the process may affect the large vessels at the base of the brain as well. Rarely, however, are inflammatory alterations confined to the latter. It should be emphasized that the histologic presentation of primary CNS angiitis is subject to considerable variation. Necrotizing polyarteritis-like or non-necrotizing lymphoplasmacytic variants are frequently encountered. Mural inflammation and vascular damage are definitional of CNS angiitis. Multinucleated giant cells of foreign body and Langhans type characterize the granulomatous examples, which is the most common pattern (Fig. 43.10), followed by lymphocytic forms, with necrotizing vasculitides (transmural fibrinoid necrosis) being the rarest form encountered.[138] When present, giant cells are not strictly associated with the elastic lamina and may lie in any part of the vessel wall. Secondary changes include thrombosis and, in longstanding cases, mural scarring and exuberant fibrointimal hyperplasia. The phenomenon of **"mixed" granulomatous vasculitis and amyloid deposition** is discussed in the "Cerebral Amyloid Angiopathy" section later. Nevertheless, trichrome or pentachrome, elastic, and amyloid stains are amongst the most useful ancillary approaches overall, with beta amyloid immunohistochemistry being more sensitive than a Congo red for amyloid angiopathy.[138]

Notwithstanding the fact that its histologic features are shared by cerebral vasculitides complicating a variety of systemic disorders,[138,141] primary angiitis of the CNS merits distinct nosologic status on clinical grounds. This is not to deny the possibility that this curious process might be triggered by diverse offenses to the cerebrospinal circulation. Although long suspected, an infectious etiology remains unproved. Noteworthy in this regard, however, is the epidemiologic association of primary CNS angiitis with cutaneous varicella-zoster infection and with underlying conditions, chiefly Hodgkin disease and other forms of hematolymphoid neoplasia, that predispose to this and other viral opportunists.[138,142] These observations are especially intriguing in view of the undisputed role of this virus as a cause of large vessel cerebral arteritis that is potentially indistinguishable from primary CNS angiitis.

Cerebral Amyloid Angiopathy

The deposition of amyloid in the walls of cerebral blood vessels is associated with aging and a variety of neurologic disorders, including Alzheimer disease, Down syndrome, dementia pugilistica, and certain types of spongiform encephalopathy. It is the association of this process—**cerebral amyloid angiopathy**—with intracranial hemorrhage that compels the attention of the neurosurgeon and surgical pathologist. Cerebral amyloid angiopathy is the most common nontraumatic cause of lobar cerebral hematoma in elderly subjects (the cohort at greatest risk) and has been estimated to account for some 5%–10% of all primary atraumatic brain hemorrhages, which are also commonly associated with superficial siderosis, microinfarcts, and subcortical small white matter damage, particularly in patients with the *ApoE4* genotype.[1,143] The disorder is not a manifestation of systemic amyloidosis and typically presents in sporadic fashion, although kindreds afflicted by heritable (autosomal dominant) syndromes of florid cerebrovascular amyloidosis and early death due to recurrent intracerebral hemorrhage have been described.[144] Beta amyloid peptide (Aβ), found also in cortical CNS vessels and neuritic plaques of asymptomatic senescence and Alzheimer disease, constitutes the principal amyloid deposited in sporadic cases.[144] Aberrant forms of Aβ, cystatin C, transthyretin, gelsolin, and other proteins resulting from point mutations in their encoding genes are the offending amyloidogenic agents in various heredofamilial types of CNS amyloidosis with vascular involvement. While a substantial proportion of sporadically affected patients have dementia, cerebral amyloid angiopathy, even when severe, is not necessarily associated with cognitive impairment or with Alzheimer disease.

The peripheral, lobar location of amyloid-associated cerebral hematomas contrasts sharply with the basal ganglionic or bulbar situation typical of hypertensive hemorrhages and reflects the particular susceptibility of superficial cortical and leptomeningeal vessels to amyloid-related damage. Chiefly affected are small-caliber arteries and arterioles, but veins may be involved as well. These exhibit mural expansion and, in advanced cases, effacement by acellular, eosinophilic material deposited in the adventitia and media (Fig. 43.11A). By definition, this possesses the histochemical properties and ultrastructural attributes common to all amyloids. This is therefore demonstrable as a dichroic, bluish-green birefringence in Congo red–stained sections viewed under polarized light, although Aβ-amyloid immunoreactivity is considerably more sensitive (see Fig. 43.11B). Amyloid-laden cerebral vessels generally maintain their patency but are subject to a variety of "vasculopathic" alterations. These include "double-barreling" (a targetoid, vessel-within-vessel configuration produced by what would appear to be a circumferential cleft in the media), glomeruloid arteriolar changes, obliterative fibrointimal proliferation, perivascular or intramural lymphocytic infiltration, microaneurysms, and, finally, fibrinoid necrosis. This last abnormality is restricted to vessels bearing a heavy amyloid burden and appears to play a particularly significant role in the pathogenesis of vascular rupture.[145]

As is often the case in extracranial locations, amyloid deposited in the cerebral vasculature occasionally elicits a foreign body–type response replete with multinucleated giant cells that attempt to phagocytize the offending material. Much rarer are examples of cerebral amyloid angiopathy associated with a true vasculitis of necrotizing and/or granulomatous type.[146,147] Such cases have been interpreted to represent, for the most part, idiosyncratic host reactions to the deposited protein (**"Aβ-related angiitis"** or **ABRA**), but it is

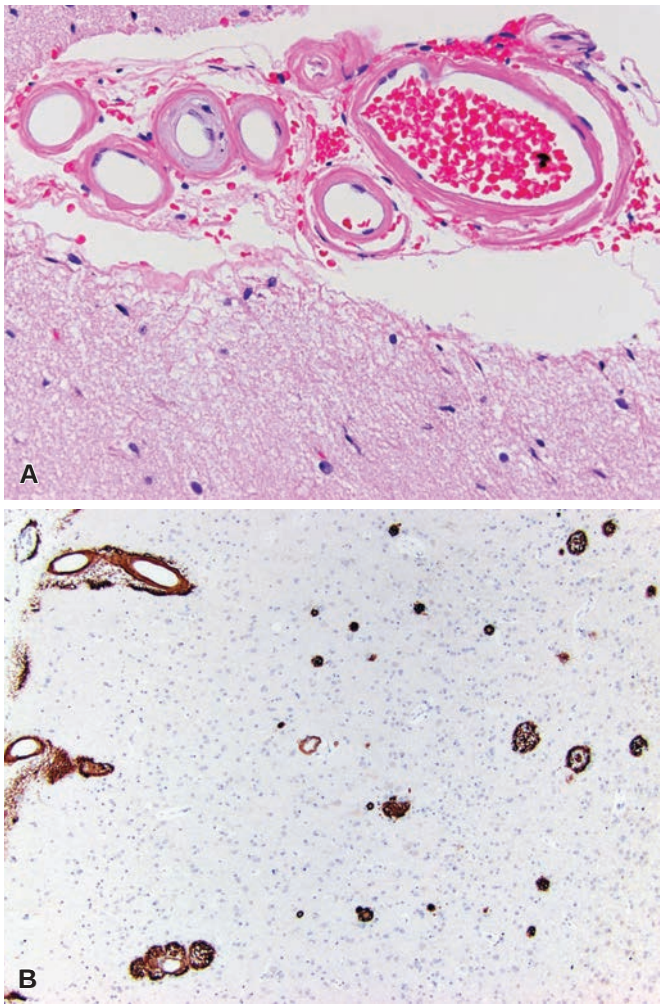

Figure 43.11 Cerebral Amyloid ("Congophilic") Angiopathy. As in extraneural locations, amyloid in the walls of cerebral vessels appears eosinophilic and amorphous **(A)** being further highlighted on immunostains for beta amyloid (often also showing diffuse or neuritic plaques in the cortex) **(B)**.

conceivable that primary cerebral vasculitides might aggravate, if not trigger, local amyloidogenic processes. Interestingly, most examples of angiitic cerebrovascular amyloidosis (including those reported under the rubric of combined granulomatous angiitis and cerebral amyloid angiopathy) do not present with intracerebral bleeding but rather as nonhemorrhagic lesions, some of which are mass forming and radiologically taken for neoplasia. Patients may also present with alterations of mental status, headache, seizures, or focal neurologic deficits of subacutely progressive nature. Sufferers are typically younger than patients with noninflammatory amyloid angiopathy but older than those with primary CNS vasculitis.[147]

Cerebral Autosomal Dominant Arteriopathy With Subcortical Infarcts and Leukoencephalopathy and the Autosomal Recessive Variant

Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) and a much rarer autosomal recessive form (CARASIL), as their names imply, are heritable conditions.[1,148] Hundreds of affected CADASIL kindreds have been identified worldwide, whereas only around 50 cases of CARASIL have been reported. CADASIL has been linked to missense mutations or, rarely, small deletions involving the *NOTCH3* gene at chromosome 19p13, the product of which is a transmembrane receptor protein and transcriptional regulator selectively expressed in vascular smooth muscle cells. Isolated nonfamilial cases seemingly due to de novo *NOTCH3* mutations have been described as well. In contrast, CARASIL, like other autosomal recessive disorders, requires biallelic inactivation, in this case of the high-temperature requirement A serine peptidase 1 *(HTRA1)* gene on chromosome 10q, known to be involved in musculoskeletal development.[148] Clinical manifestations of CADASIL include migraine with aura (often the earliest neurologic complaint), subcortical ischemic strokes, psychiatric symptoms, and cognitive deterioration eventuating in dementia. Most patients die within 15–25 years of their initial episodes of stroke. CARASIL follows a similar course but usually starts at an earlier age, with greater severity; it is also associated with low back pain due to disk herniation and spondylosis deformans (reflecting the more generalized connective tissue disorder), as well as premature diffuse baldness in men.[148] Imaging findings are similar in both disorders, though more diffuse in CARASIL. Nodular foci of periventricular T2 hyperintensity are characteristic and early changes seen in MR images are often apparent in presymptomatic individuals. With disease progression, lacunar white matter infarcts develop and confluent zones of increased T2-weighted MRI signal reflect a diffuse leukoencephalopathy, typically with sparing of U-fibers.

CADASIL is a nonarteriosclerotic and nonamyloidotic vasculopathy that principally involves small- and medium-sized arteries in the cerebral hemispheric white matter, but leptomeningeal and even systemic vessels are potentially affected by this generalized disorder.[1,148] Most recorded cases have been identified by brain biopsy, but sampling of skin, skeletal muscle, and peripheral nerve may be informative as well. The hallmark of CADASIL is accumulation of a granular, basophilic, and PAS-positive material in the tunica media of affected vessels with associated loss of medial smooth muscle cells, concentric mural sclerosis, and luminal narrowing. At the ultrastructural level, this distinctive material consists of osmiophilic, electron-dense granules 10–15 mm in size that lie free between degenerating myocytes or cluster within pericellular indentations. These deposits may be labeled by monoclonal antibodies to the NOTCH3 protein extracellular domain, which are specific for CADASIL, and may be identified in the presymptomatic phase of the disease. Accordingly, ultrastructural or immunohistochemical studies of small dermal or subcutaneous arteries in skin biopsy specimens have been advocated as screening procedures for family members at risk as well as in suspect cases. The pathology of CARASIL similarly shows marked arteriolosclerosis but without the characteristic vascular deposits or systemic involvement of CADASIL; in this respect, it overlaps with Binswanger's disease, but patients lack hypertension.[148] Confirmatory genetic assessment (e.g. single-strand conformational polymorphism analysis) is sometimes required for the diagnosis of either disorder.

Epidural Hematoma

The great majority of **epidural hematomas** follow cranial trauma complicated by temporal bone fracture and result from laceration of middle meningeal artery branches that penetrate the skull in the region of the pterion.[1] The accumulation of blood between the calvarium and endosteal surface of the dura mater is typically rapid, associated with acute deterioration of consciousness, and soon eventuates in death as a result of cerebral herniations if not promptly evacuated. Uncommon variants become symptomatic only long after

their initiating injuries. Delimited by encapsulating neomembranes formed of vascularized fibrous tissue, chronic epidural hematomas of this sort are usually of venous origin.

Subdural Hematoma

Subdural hematomas result from the dissection of blood into the potential space separating the normally apposed arachnoid and dura mater. Most overlie the cerebral convexities in the frontoparietal region and are thought to follow rupture of delicate bridging veins that traverse the arachnoid–dura interface en route to the superior sagittal sinus. These vessels are particularly susceptible to shearing forces generated by sudden angular acceleration of the head, as commonly occurs in the setting of trauma, and many subdural hematomas are clearly associated with cranial injury. Most "spontaneous" examples occur in the elderly, possibly because cerebral atrophy and resultant traction on these bridging vessels reduce their capacity to withstand otherwise trivial stresses. A similar phenomenon may promote the development of subdural hematomas following ventricular decompression for hydrocephalus. Patients who have received anticoagulants, are thrombocytopenic, are alcoholics, or have been treated with long-term hemodialysis are also at increased risk[149] of subdural hemorrhage. A small subset of subdural hematomas result from arterial injury. These are usually associated with major craniocerebral trauma.

The pathology of the subdural hematoma is a function of its age. If evacuated within days of onset, it consists simply of clotted blood. Often, however, the original bleeding episode passes unnoticed, and the hematoma becomes symptomatic only after it has elicited an organizational response resulting in its enclosure within a discoid sac fashioned of grayish-brown, collagenous neomembranes that adhere to the dura but develop no attachments to the underlying arachnoid. The latter feature reflects the fact that the mesenchymal elements responsible for encapsulation of the hematoma derive entirely from the dura, with the leptomeninges remaining curiously unmoved by the presence of blood in the subdural space and playing no part in its organization. Inasmuch as the histologic maturation of these limiting membranes proceeds in temporally predictable fashion, the chronicity of a given lesion may be estimated by thorough assessment of the membranes. Suffice it to say that the outer (juxtadural) membrane, which may attain a thickness of several millimeters, consists in the early stages of proliferating spindle cells and budding capillaries that penetrate the superficial aspect of the hematoma and come to lie in a loose connective tissue matrix containing admixed siderophages, scattered lymphocytes, and, in some cases, extramedullary hematopoietic elements (normoblasts). Infiltration by eosinophils may be striking. The inner membrane, by contrast, has a simpler thinner structure and is relatively avascular. Both membranes undergo progressive hyalinization and, with complete resorption of the hematoma, fuse to form a thin fibrous rind closely resembling the adjacent dura mater on microscopic study. In exceptional instances, the hematoma sac is transformed into a calcific, even ossified, shell.

The capacity of the chronic subdural hematoma to present in clinically delayed fashion as an expanding intracranial mass would seem a paradox. Once completed, the enclosing hematoma sac could conceivably function as a semipermeable membrane and permit the ingress of fluid drawn by osmotic forces from the CSF compartment or the capillary network in its outer lamina. A prosaic (but, perhaps, more likely) explanation would incriminate these delicate newly formed capillaries in episodes of rebleeding. Not infrequently, subdural hematomas that first come to attention in their chronic, encapsulated phases disclose evidence of recent, superimposed hemorrhage.

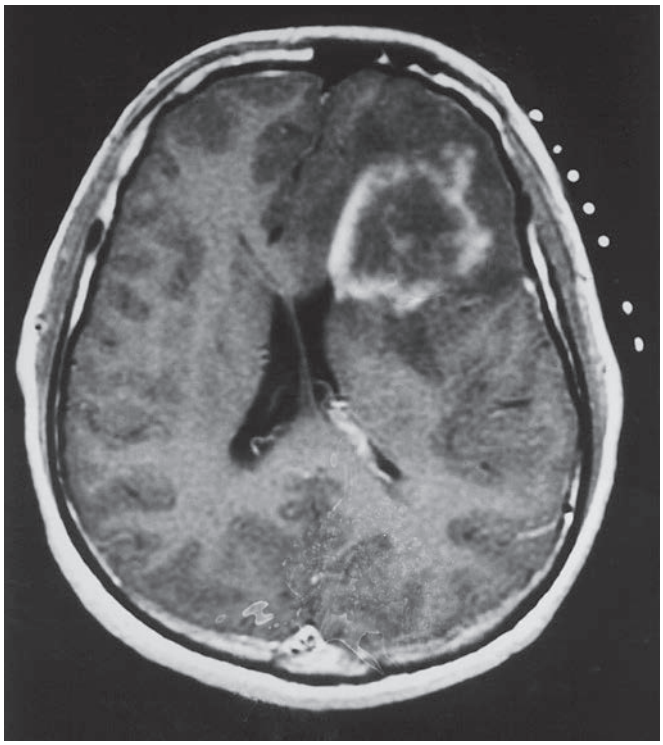

Figure 43.12 Demyelinating Pseudotumor. Taken following administration of a contrast agent that serves to delineate foci of blood–brain barrier breakdown as regions of bright signal, this magnetic resonance image demonstrates a lesion characterized by "ring" enhancement, conspicuous hypodensity of the surrounding white matter (indicative of edema), and mass effect evidenced by obliteration of the ipsilateral ventricular angle and shift of the neighboring cingulate gyrus across the midline. The neuroradiological diagnosis was "probably glioblastoma, abscess also a possibility." The patient, a 32-year-old man with subacutely progressive hemiparesis and somnolence, recovered completely following limited biopsy and a short course of corticosteroids. He remains asymptomatic 15 years after diagnosis.

Inflammatory Diseases

Demyelinating Diseases

The idiopathic demyelinating diseases of the CNS, of which multiple sclerosis is by far the most common, are usually regarded as "medical" disorders diagnosed on clinical grounds or at autopsy. In fact, demyelinating lesions of the cerebral hemispheric white matter and spinal cord may present as space-occupying "tumors" associated with considerable mass effect, edema, and disruption of the blood–brain barrier evidenced, on computed tomography (CT) or MR study, by diffuse or ring-like enhancement following administration of contrast media (Fig. 43.12).[150,151] Especially suspect on neuroradiological grounds is the lesion that exhibits an "open" or "broken ring" profile characterized by the abrupt cessation of rimming contrast enhancement where it abuts a ventricular surface or overlying cortex.[152] Patients may present with symptoms and signs referable to an expanding intracranial mass prior to receiving a diagnosis of a demyelinating disorder. Solitary examples, not surprisingly, prompt consideration of aggressive glial neoplasia or abscess formation, whereas multifocal variants suggest metastatic disease or even cerebral parasitosis when lesions exhibit cystic characteristics on scan. Such **demyelinating "pseudotumors"** understandably occasion neurosurgical intervention for purposes

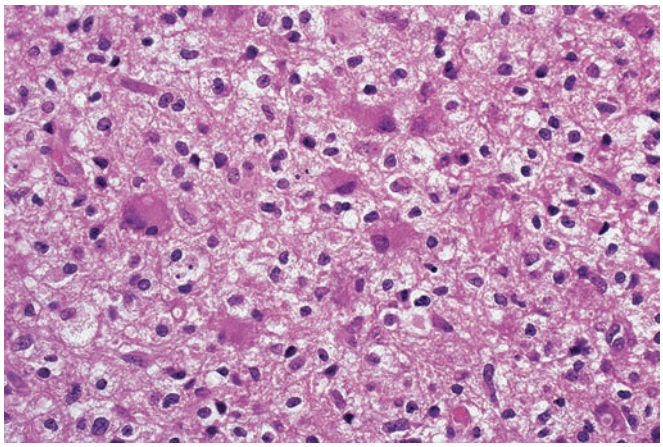

Figure 43.13 Demyelinating Pseudotumor. The hypercellularity of this lesion reflects infiltration by large numbers of macrophages, recognizable on careful study by their granular or foamy cytoplasm. Also apparent are several hyperplastic astrocytes.

of definitive diagnosis and thus enter the domain of the surgical pathologist.

The tumefactive demyelinating lesion shares with the active "plaque" typical of subacute multiple sclerosis a sharp delineation from adjacent, uninvolved white matter evident in biopsy samples that include its perimeter. Affected tissues exhibit diffuse infiltration by foamy, lipid-laden macrophages, reactive astrocytosis of variable intensity, and perivascular aggregates of small B and T lymphocytes (the latter also infiltrating the parenchyma), as well as occasional plasma cells (Fig. 43.13). The definitive characterization of the process as a demyelinating one ultimately requires the demonstration of relative axonal preservation in foci devoid of stainable myelin. This is readily accomplished by comparing serial sections assessed for myelin by a Luxol fast blue (LFB) stain (Fig. 43.14) and axon density using a neurofilament immunostain. In typical cases, large numbers of axons will course uninterrupted through regions in which myelin, if at all demonstrable, persists only as phagocytized debris in the cytoplasm of macrophages. It should be pointed out, however, that a variable element of axonal depopulation is the rule, with some particularly destructive examples causing cavitation.

In our experience, demyelinating pseudotumors are the non-neoplastic lesions most often misinterpreted on biopsy as gliomas, specifically as diffuse fibrillary astrocytomas or as oligodendrogliomas. Unfortunately, the consequences to patients subjected to cerebral irradiation may be devastating[153] and the potential causes for error numerous. A diagnosis of glioma may be prompted by cytologically atypical astrogliosis that characterizes some examples—an impression likely to be reinforced by the finding of scattered mitotic figures, as well as astrocytes that appear to be in atypical mitosis by virtue of a peculiar parcellation of their nuclear material ("granular mitoses") and Creutzfeldt cells forming fragmented micronuclei. Perivascular lymphoid infiltrates are an inconstant feature and, even when conspicuous, do not exclude a glioma. Even in their absence, however, the orderly spacing of gemistocytic astrocytes typical of hyperplastic states should suggest a reactive process.

Especially confounding is failure to distinguish the sheets of macrophages from glioma since their cell borders tend to blend into the fibrillary background, particularly in frozen sections. Therefore, the use of cytologic preparations is strongly advocated for purposes of intraoperative consultation, since the vacuoles and lack of processes are much easier to appreciate on a smear (Fig. 43.15). Immunocytochemical assay for monocyte/macrophage

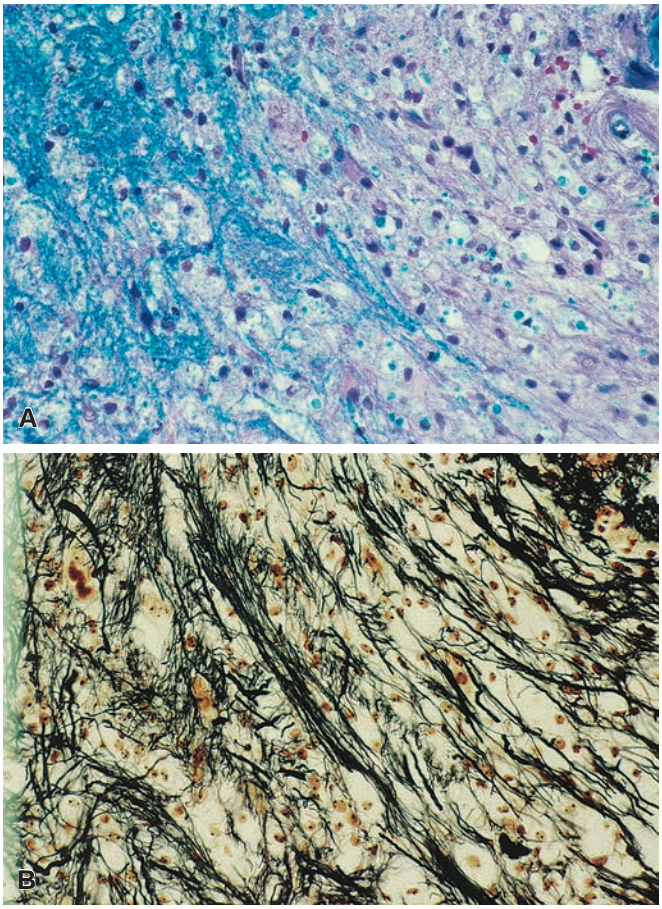

Figure 43.14 Demyelinating Pseudotumor. The interface of a demyelinated plaque *(right)* and normal white matter *(left)* is shown here in serial sections stained for myelin **(A)** and axons **(B)** by the Luxol fast blue and Bielschowsky methods, respectively. Myelin, *blue* in **A**, persists in the plaque only as globules present in the cytoplasm of macrophages. Axons, *stained black* in **B**, course uninterrupted into the region of demyelination.

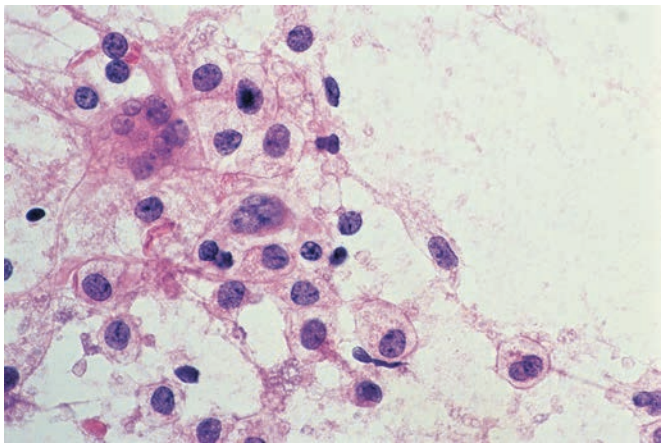

Figure 43.15 Demyelinating Pseudotumor. The presence of foamy macrophages in cytologic preparations argues strongly against a diagnosis of glioma at the time of intraoperative consultation. As shown here, somewhat atypical-appearing, multinucleate astrocytes are not uncommonly encountered in such specimens.

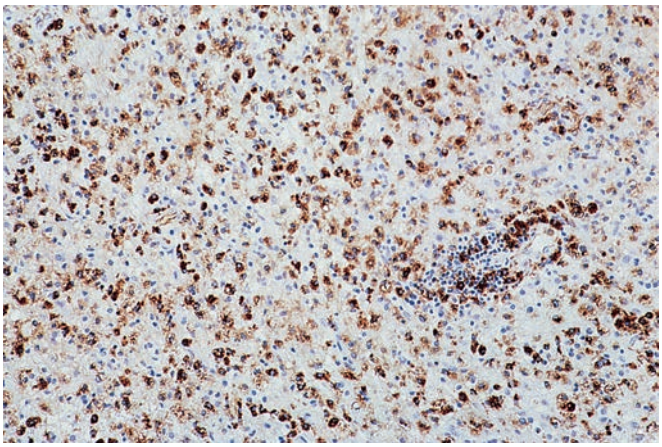

Figure 43.16 Demyelinating Pseudotumor. The density of infiltrating macrophages characteristic of demyelinating lesions is demonstrated in this immunoperoxidase assay for HAM-56.

markers such as HAM-56 (Fig. 43.16) and CD68 may also aid in circumventing problems of cell identification, particularly as applied to neurosurgical specimens exhibiting artefactual distortions. Diffuse infiltration by macrophages in large number is so rarely a feature of the untreated glioma as to virtually exclude this diagnosis. The ready identification of such cells in smears, crush preparations, or tissue sections should instead suggest a non-neoplastic, necrotizing process (such as organizing infarction) or a selectively demyelinating disorder. Primary CNS lymphomas inadvertently treated by the preoperative administration of corticosteroids may vanish on neuroradiological scan and can further simulate demyelinating disease by leaving behind only reactive lymphohistiocytic infiltrates; there should not be truly selective, regionally circumscribed myelin loss in this circumstance (see later discussions). Patients suffering from multiple sclerosis on occasion do develop glial neoplasms,[154] but there is no definite evidence that the incidence of the latter is increased in this population.

Although historically it was thought that tumefactive demyelinating lesions only rarely complicated the course of established multiple sclerosis,[150] more recent data suggest that the majority of patients with tumefactive lesions develop classic features with sufficient follow-up.[151] Lastly, mention is made of a **multifocal inflammatory leukoencephalopathy** described as complicating the chemotherapy of colorectal adenocarcinoma with 5-fluorouracil and levamisole.[155] The lesions in question were demyelinative and morphologically indistinguishable from active multiple sclerosis plaques. Whether one or both of these agents was directly responsible for this condition or somehow precipitated attacks of multiple sclerosis in patients predisposed to the disorder is unclear.

Noninfectious Inflammatory and Reactive Disorders, Xanthomatous Lesions, and "Histiocytoses"

The various oddities collected in this section have little in common beyond their etiologic obscurity and inflammatory or otherwise "reactive" histologic appearances. Many are better known as systemic disorders and are given detailed consideration elsewhere in these volumes. Specific description is here accorded to only those entities unique to the nervous system.

Idiopathic hypertrophic pachymeningitis (IHP) of cranial subtype is, as its name implies, an inflammatory and fibrosing disorder of unknown cause that affects the dura mater. This diagnosis is rendered less and less frequently as other etiologies are increasingly implicated, including intracranial hypotensive, infectious, neoplastic, and autoimmune etiologies, the latter most recently including IgG4 disease (see later).[156,157] Clinical manifestations include headache, progressive cranial neuropathies, and cerebellar ataxia of adult onset occurring in association with radiographically demonstrable thickening and abnormal contrast enhancement of the peribulbar meninges, tentorium, and falx. The process can involve the dura over the cerebral convexities or extend into the cavernous sinus and orbit, causing painful ophthalmoplegia. **Idiopathic hypertrophic spinal pachymeningitis**, a disease of the cervicothoracic region typified by compressive myelopathy, may represent a variant of the same basic disorder.[158] A subset of afflicted patients have extradural abnormalities collected under the rubric of "**multifocal fibrosclerosis**," including inflammatory orbital pseudotumor, idiopathic mediastinal and retroperitoneal fibrosis, sclerosing cholangitis, Riedel stroma, Peyronie disease, Dupuytren contracture, fibrosing orchitis, systemic vasculitis, and fibroinflammatory lesions of the subcutaneous tissues and lungs.

What may represent localized pseudotumoral variants have also been recorded,[159] although it is also important to recognize that IHP is a diagnosis of exclusion, with a subset recently reclassified as pachymeningitis complicating **IgG4-related disease** (Fig. 43.17), a sclerosing autoimmune disorder first described in the pancreas but now recognized almost everywhere in the body, including the pachymeninges and pituitary gland.[157,160,161] Although this diagnosis is made based on increased numbers of IgG4-positive plasma cells and an increased ratio of IgG4- to IgG-positive cells (e.g. >40%), too few cases have been published to establish definitive criteria for these sites.[162] Some also disclose dispersed lymphoplasmacytic infiltrates, exuberant fibroplasia, and, in some instances, necrosis and granuloma formation. Exclusion of tuberculosis, syphilis, mycotic infections, sarcoidosis, Wegener granulomatosis, rheumatoid disease, and other causes of chronic fibrosing meningitis is required. Secondary intracranial extension of inflammatory orbital pseudotumor or IgG4 disease may also produce a similar meningeal picture.[163,164] The clinical course of IHP is variable but often inexorably progressive. Corticosteroid administration and resection of compressing fibroinflammatory meningeal masses are of benefit to some patients. The reader should note that patients undergoing craniotomy, ventricular shunting, or even lumbar puncture alone may occasionally develop neuroradiological evidence of diffuse meningeal thickening and enhancement that is typically asymptomatic and without clinical significance. This is thought to represent a response to intracranial hypotension and may rarely occur spontaneously. Biopsy material in such cases may exhibit subdural fibroplasia, neovascularization, hemosiderin deposition, and meningothelial hyperplasia.[165,166]

Turning from the meninges to the brain proper, we briefly mention a form of chronic encephalitis, known eponymously as **Rasmussen syndrome**, that is characterized by intractable unilateral focal seizures or epilepsia partialis continua of childhood onset, progressive cerebral hemiatrophy with hemiparesis, and cognitive decline.[167] Long suspected (but never convincingly shown) to represent a persistent viral infection, the disorder may have an autoimmune component, as some afflicted patients harbor antibodies to native CNS antigens, including the glutamate GluR3 receptor. The neuropathology is nonspecific, consisting of perivascular and interstitial lymphoid infiltrates involving the cerebral cortex with microglial nodule formation, astrogliosis, and variable neuronal loss.[168] High-dose corticosteroids, intravenous gamma globulins, plasmapheresis, and surgery (including functional or actual hemispherectomy) have all been investigated in the treatment of Rasmussen syndrome and have proven beneficial to some patients. The last of these options is

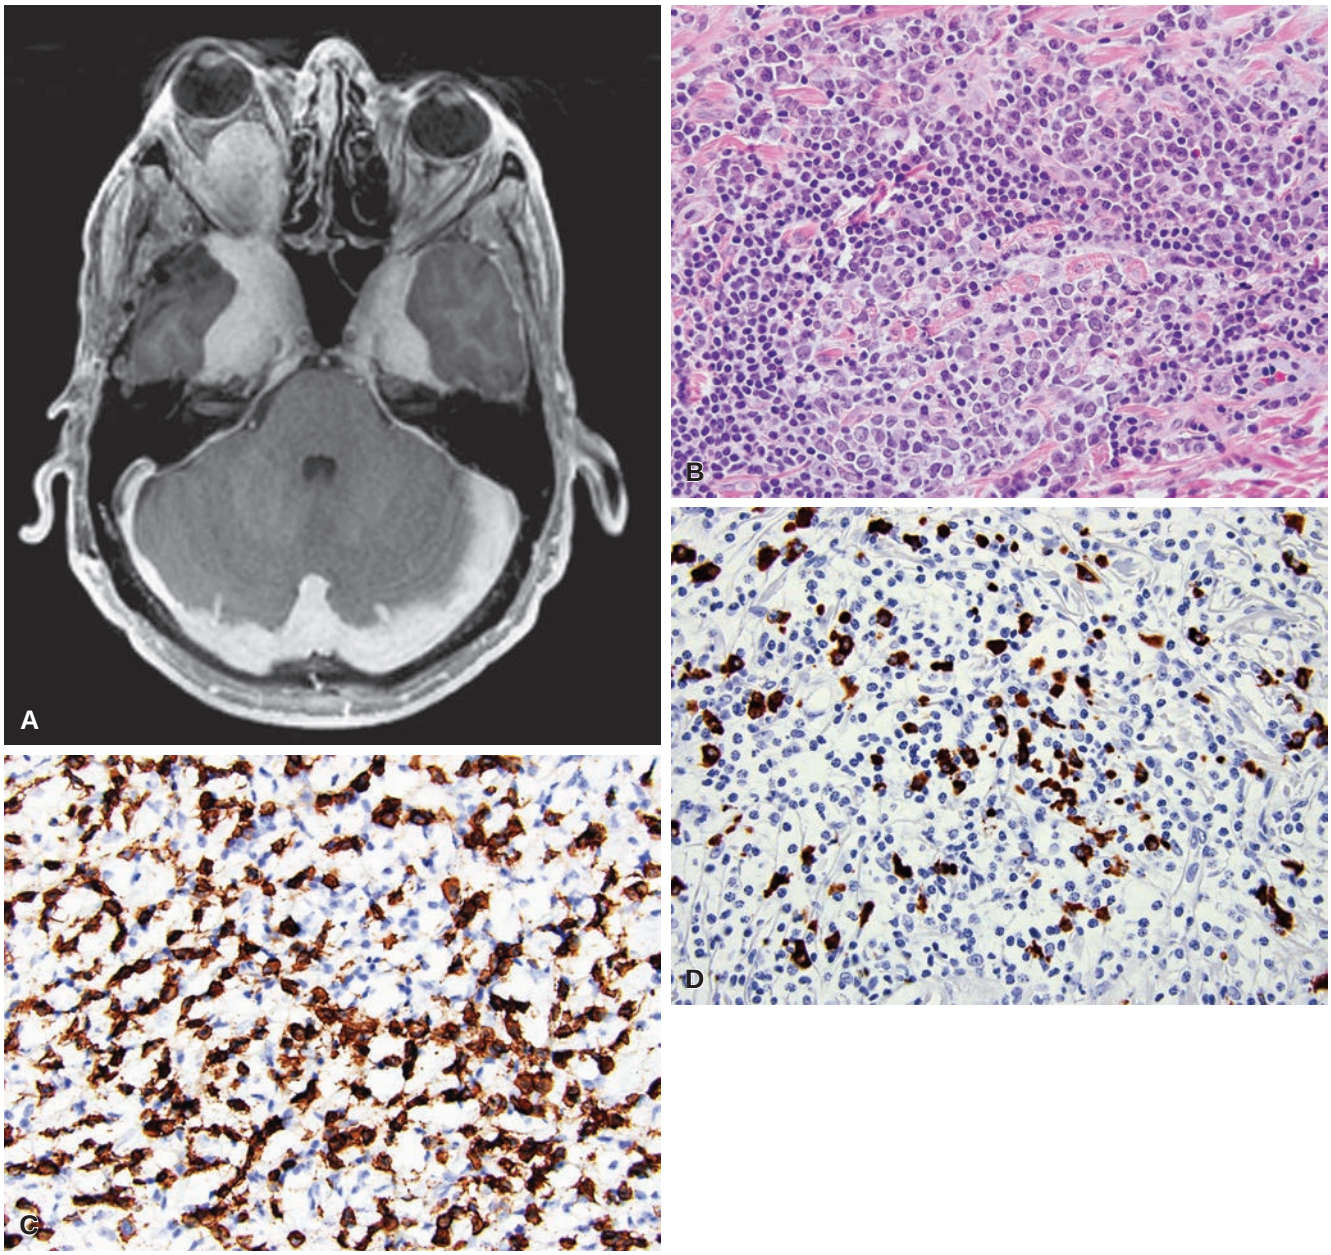

Figure 43.17 IgG4-Associated Pachymeningitis. Note the marked bilateral dural thickening on postcontrast magnetic resonance imaging **(A)**, the lymphoplasmacyte-rich infiltrate and occasional germinal centers on biopsy **(B)**, and the prominence of numerous CD138- **(C)** and IgG4- **(D)** immunoreactive plasma cells.

currently regarded as the approach of choice in typical childhood cases. More localized and clinically benign forms of idiopathic chronic encephalitis have been described, particularly in adolescents and young adults, that may mimic cerebral neoplasms.[169] Whether these represent Rasmussen variants is unclear.

Limbic encephalitis is an amnestic syndrome of adulthood typically encountered as a paraneoplastic phenomenon[170] complicating small cell carcinoma of the lung, but the disorder has also been reported in association with other tumor types (e.g. non-small cell lung cancers, Hodgkin disease, mammary adenocarcinomas, and testicular germ cell tumors) and, rarely, in the absence of demonstrable neoplasia.[171] Due to the latter and the fact that it is not always limited to a limbic distribution, others have advocated the broader term of **autoimmune-mediated encephalitis**.[172] Clinical manifestations progress in subacute fashion and consist principally of short-term memory loss, complex partial or generalized seizures, confusion, and disordered affect. Many examples evolve as one facet of a complex paraneoplastic disease that potentially involves the dorsal root ganglia, brainstem, cerebellum, spinal cord, autonomic ganglia, and myenteric plexi.[173] MRI studies often disclose abnormal T2 hyperintensity of the medial temporal regions (with contrast enhancement in some cases) and may prompt consideration of herpes simplex encephalitis (HSE) or a neoplasm. The brunt of the injury falls on the amygdaloid nuclei, hippocampi, and entorhinal cortices, biopsy material disclosing florid gliosis, perivascular lymphoid cuffing, microglial or "neuronophagia," and, in some cases, conspicuous neuronal depopulation. In contrast to HSE, the process is never overtly necrotizing, hemorrhagic, or attended by viral inclusions.

Useful in the evaluation of limbic encephalitis (the clinical manifestations of which often herald discovery of otherwise silent, low-stage tumors) are serum and CSF autoantibody studies, including anti-Hu, which is directed against neuronal nucleoproteins in the size range of 35–40 kDa and strongly correlated with the presence of underlying small cell lung cancer.[170,173] Demonstration of this autoantibody constitutes compelling evidence of a paraneoplastic etiology and mandates a search for occult neoplastic disease, especially within the chest cavity. Anti-Hu IgG appears to be elaborated in response to aberrant tumoral expression of this neuron-associated protein, prompting the hypothesis that an immunologic response directed against a triggering neoplasm cross-reacts with the nervous system with devastating neurologic consequences. Another neuronal autoantibody known as anti-Ta or anti-Ma2 is a powerful marker of paraneoplastic limbic encephalitis in the setting of testicular germ cell neoplasia.[170] Tumor localization and treatment may lead to neurologic improvement in patients with limbic encephalitis and is more effective than immune modulation in this regard. Occasional examples remit spontaneously.

The histologically distinctive masses reported as "**fibro-osseous lesions**" or "**calcifying pseudoneoplasms**" **of the neural axis** (Fig. 43.18) are composed principally of nonbirefringent, basophilic materials that may appear amorphous, somewhat chondromyxoid or coarsely fibrillar, ropey, or plate-like.[174,175] Rimming mononuclear and foreign body–type giant cells lend a granulomatous appearance to some examples. Mineralization is at least focally apparent in most cases and many exhibit mature lamellar bone formation as well. Meningioangiomatosis has been found adjacent to rare intracranial examples. These peculiar lesions are usually extra-axial and favor the spinal epidural compartment but may arise from the cranial floor or within the leptomeninges or even the brain. Although non-neoplastic, they may be complicated by considerable neurologic morbidity resulting from spinal cord compression or skull base destruction with cranial nerve and cerebrovascular compromise. Ossified intracranial nodules lacking the defining matrix described above may be formed in nonspecific response to trauma, infection, or hemorrhage and have been termed cerebral calculi or "brain stones." Rarely, symptomatic juxtaneural masses prove to be tophaceous lesions resulting from the crystalline deposition of sodium urate (**gout**), calcium pyrophosphate dihydrate (**pseudogout**), or calcium hydroxyapatite (**tumoral calcinosis**[176]). **Metaplastic hyalinization and ossification** of the leptomeninges is a common asymptomatic finding but may rarely cause progressive myelopathy associated, in some cases, with cavitation of the spinal cord.[177] While the term "**arachnoiditis ossificans**" has been used in such cases and many are clearly the sequelae of mechanical or microbial insults, inflammatory elements are generally lacking and there may be no history of a precipitating condition. Spinal cord injury can similarly be produced by ossification of the ligamentum flavum.[178]

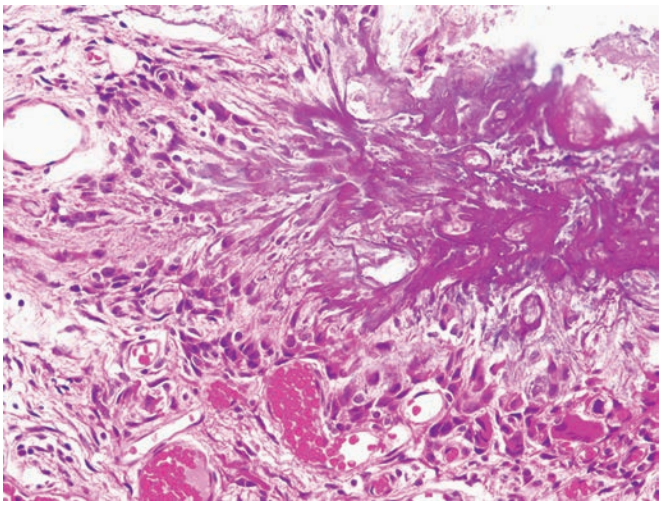

Figure 43.18 Fibro-Osseous Lesion/Calcifying Pseudoneoplasm of the Neuraxis. Fibroplasia and the deposition of a highly characteristic basophilic matrix material in plate-like or ropey masses define this unusual process.

Of those principally extraneural disorders that occasionally undergo surgery, most deserving of mention are Langerhans cell histiocytosis ("eosinophilic granuloma"), sarcoidosis, and sinus histiocytosis with massive lymphadenopathy (SHML) (Rosai–Dorfman disease). CNS involvement in **Langerhans cell histiocytosis** typically follows infiltration of the calvarial floor and exhibits a striking tropism for the region of the hypothalamus and infundibulum, the eponym **Hand–Schüller–Christian disease** being applied to the classic clinical triad of diabetes insipidus, proptosis, and skull base defects on roentgenographic study. While a similar topography is characteristic of those exceptional examples restricted (on presentation, at least) to the nervous system,[179] lesions situated within the meninges, choroid plexus, and brain are on record,[180] as are instances of cerebral invasion from contiguous primary foci in the cranial vault.[181] CD1a and/or langerin immunoreactive Langerhans cells may be only sparsely represented in biopsy material. Of note, both Langerhans cell histiocytosis and another histiocytic disorder that rarely involves the CNS, Erdheim–Chester disease (see later discussion), frequently harbor *BRAF* V600E mutations, which can be targeted therapeutically.[182,183] Xanthomatous masses consisting only of foamy macrophages can also be encountered, possibly representing "burnt-out" lesions, and a nonspecific chronic inflammatory picture with variable loss of myelin and axons may be seen (particularly in the cerebellum and brainstem).

Neurosarcoidosis most commonly assumes the form of a granulomatous basilar meningitis complicated by cranial neuropathies or, with extension of the process to the hypothalamic region, diabetes insipidus and other diencephalic syndromes. An accompanying granulomatous vasculitis may be apparent. While the overwhelming majority of patients have established systemic disease, primary CNS presentations have been described and can include pseudotumoral involvement of the leptomeninges,[184] dura,[185] cranial nerve,[186] and neuroparenchyma proper.[187] An example of necrotizing sarcoid granulomatosis presenting as a mass involving the temporal lobe and cavernous sinus has been depicted.[188] In fact, only a subset of patients evaluated for granulomatous disease of the CNS that is not demonstrably infectious will prove to have clinical manifestations (e.g. interstitial lung involvement, mediastinal lymphadenopathy) or laboratory evidence (elevated serum/CSF angiotensin converting enzyme levels) supporting a diagnosis of sarcoidosis. Unclassifiable, "pathogen-free" granulomatous disorders were found in one study to share a tendency to diffuse neuraxial involvement, combined leptomeningeal and neuroparenchymal (particularly spinal cord) infiltration, attendant angiitis, and a poor prognosis.[189]

Dura-based masses clinically indistinguishable from meningiomas constitute the usual pattern of CNS disease in cases of **Rosai–Dorfman disease** or **extranodal SHML**, though lesions involving the neuroparenchyma have been communicated.[190,191] These can represent the sole manifestations of the disorder and may be multifocal.

A similar predilection for the dura characterizes central neuraxial lesions that have been dubbed **inflammatory pseudotumors** or **plasma cell granulomas**,[192,193] though cerebral and choroid plexus examples have been encountered. There can be little doubt that these designations have been extended through the years to reactive lesions of disparate cause, to cases of extranodal SHML,

lymphoplasmacyte-rich meningiomas, and low-grade lymphomas of mucosa-associated lymphoid tissue (MALT) type. These terms, furthermore, have been applied indiscriminately to proliferations that should be segregated as **inflammatory myofibroblastic tumors** of the nervous system.[193] The latter are given further consideration in the subsequent discussion of nonmeningothelial mesenchymal tumors. Suffice it to say that diagnoses such as inflammatory pseudotumor and plasma cell granuloma must be rendered with full acknowledgment that they do not carry specific etiologic implications and judiciously reserved for masses harboring polyclonal lymphoplasmacellular populations unaccompanied by the conspicuous spindle cell components, anaplastic lymphoma kinase (ALK) expression, or *ALK* gene (2p23) rearrangements evidenced by tumors of the inflammatory myofibroblastic group. Potentially multifocal, plasma cell granulomas/inflammatory pseudotumors of the nervous system have been described in patients with systemic infections and immunologic disorders such as lupus and relapsing polychondritis.[193,194] IgG4-positive plasma cells may be encountered in the lesions of this group, but a link to IgG4-associated systemic autoimmune disease has not been clearly established.[192] A unique falcine mass possibly analogous to the **hyalinizing plasmacytic granuloma** of pulmonary origin contained "raft-like" islands of acellular, hyaline connective tissue associated with a foreign body-type giant cell response.[195]

Collectively designated as "xanthomatous" are diverse lesions sharing only a conspicuous component of foamy, lipid-laden macrophages. Mention has already been made of **xanthogranulomas** forming in relation to colloid cysts of the third ventricle. Lesions similarly composed of foamy macrophages, foreign body–type giant cells, cholesterol clefts, and reactive lymphoid infiltrates commonly occur in the glomus of the choroid plexus but only rarely attain symptomatic proportions.[196] **Cholesterol granulomas of the petrous apex** that are believed to result from chronically impaired aeration of the petrous air cells may produce headache and palsies of cranial nerves V–VIII, prompting neurosurgical intervention.[197] Dura-based masses described as **xanthomas** or **xanthogranulomas**, some of immense proportions, have been encountered in otherwise healthy subjects,[198] in association with abnormalities of lipid metabolism such as familial hypercholesterolemia,[199] and in the setting of systemic Weber–Christian disease (relapsing nodular nonsuppurative panniculitis[200]). Nevertheless, as already discussed, it remains important to rule out histiocytic disorders, such as Langerhans cell histiocytosis and juvenile xanthogranulomatois.[201] Xanthomatous CNS infiltrates may also complicate **Erdheim–Chester disease**, an enigmatic histiocytosis, the hallmark of which is symmetric and bilateral sclerosis of the long tubular bones with colonization of the marrow spaces by lipid-laden macrophages; *BRAF V600E* and *MAP2K1* mutations are common in this disease.[202,203] On record, in addition, are xanthomas of probable traumatic etiology,[204] arguably neoplastic "**fibroxanthomas**"[205] and **juvenile xanthogranulomas**.[201] CNS infiltration is a recognized complication of "**xanthoma disseminatum**,"[206] a systemic syndrome characterized by the widespread eruption of juvenile xanthogranuloma-like lesions in normolipemic subjects. The development of dura-based masses has also been described in the setting of **necrobiotic xanthogranuloma**,[207] a similarly generalized disorder often associated with plasma cell neoplasia and other lymphoproliferative diseases. Symptomatic leptomeningeal and neuroparenchymal infiltration by foamy macrophages containing intracytoplasmic erythrocytes and lymphocytes frequently complicates the course of **hemophagocytic lymphohistiocytosis**[208] in both its primary (autosomal recessive and infantile-onset) as well as secondary (infection-triggered or paraneoplastic, particularly lymphoma-associated) forms. A possible example restricted to the CNS has been reported.[209]

Reference has been made previously to mass-forming foreign body reactions complicating the surgical management of intracranial aneurysms. Various hemostatic substances placed within neurosurgical beds during resection of neoplasms (and other procedures) may similarly provoke a florid and potentially granulomatous inflammatory response that can mimic tumor recurrence.[210] The cited literature can be consulted for microscopic characteristics of the responsible agents, the reactive masses in such cases being referred to as "**gauzomas**," "**muslinomas**," "**textilomas**," or "**gossypibomas**" (from the Latin *Gossypium*, the genus of cotton plants, and the Kiswahili *boma*, meaning place of concealment).

Other odd neuropathologic processes that have been documented include **cerebral malakoplakia**[211] and the pseudoparasitic red blood cell alteration known as **myospherulosis**.[212] Lastly, we mention several described complications of systemic autoimmune (collagen vascular) disorders, including **rheumatoid meningeal nodules**,[213] **Wegener granulomatosis** extending to the intracranial dura from the sinonasal compartment[214] or presenting as meninges-restricted disease,[215] and a corticosteroid-responsive meningoencephalitis associated with cognitive impairment in the setting of **Sjögren syndrome**.[216,217] The term **nonvasculitic autoimmune inflammatory meningoencephalitis** has been applied to this non-necrotizing process, which is characterized by perivascular lymphoid cuffing with loose aggregates of microglia in the affected cerebral cortex. This picture, also associated with corticosteroid-reversible encephalopathy, may be encountered in patients without systemic complaints, some of whom have proven to harbor circulating antibodies to Sjögren syndrome antigens, elevated rheumatoid factor, or perinuclear antineutrophil cytoplasmic antibody.[217]

Infectious Diseases

Bacterial Infections

Bacteria are responsible for the overwhelming majority of suppurative infections involving the CNS and its coverings. Of particular concern to surgical pathologists are the common forms of brain and spinal epidural abscesses.

Approximately 20% of **brain abscesses** have no predisposing condition. The remainder arise in patients with established extraneural pyogenic infections, facilitating anatomic anomalies, or prior penetrating cranial trauma or neurosurgery.[218] The demographic features, localization, number, and microbiologic characteristics vary with the risk factors operative in individual cases.

The extraneural bacterial infections predisposing to brain abscess are usefully divided into those involving contiguous meningeal or parameningeal sites versus systemic sources. The fact that cerebral abscesses rarely complicate bacterial meningitis is curious, a notable exception being their significant association with neonatal cases caused by *Proteus mirabilis* and *Citrobacter diversus*.[218,219] More frequently implicated local sources of bacillary invasion are the paranasal sinuses, middle ear cavities, and mastoids.[218] Although the pathogenesis remains imprecisely defined, abscesses associated with these infections are commonly believed to result from the retrograde thrombophlebitic carriage of organisms into the cranial cavity via emissary veins. Typically solitary, these lesions tend to have characteristic topographic presentations. For example, cerebral abscesses related to frontoethmoid sinusitis characteristically settle in the anterobasal frontal lobes, whereas "otitic" examples including chronic mastoiditis are usually encountered in the temporal lobes or cerebellar hemispheres. Lesions complicating sphenoid sinusitis frequent the frontotemporal regions. The organisms most often isolated from brain abscesses in these clinical circumstances include aerobic or microaerophilic streptococci (especially members of the *Streptococcus intermedius "milleri"* group),

aerobic gram-negative bacilli (*Proteus*, *Escherichia coli*, *Klebsiella–Enterobacter*, and *Haemophilus* species), and *Bacteroides* species. Mixed infections are common. Other local suppurative processes associated with the subsequent development of brain abscess include dental sepsis and pyogenic infections of the face and scalp. Usually frontal in location, "odontogenic" abscesses typically follow tooth extraction or other dental manipulation and harbor mixed aerobic and anaerobic populations dominated by *Fusobacterium*, *Bacteroides*, and *Streptococcus* species. *Staphylococcus aureus* is the main offender with spread of facial or scalp infections; cerebral abscesses in this setting usually occur in cases complicated by cavernous sinus thrombosis. Mandibulofacial **actinomycosis** may also cause a brain abscess.[220] Spinal anomalies predispose to intramedullary abscesses, as do tumors of the spinal neuraxis, but such infections are decidedly rare.[221]

Hematogenous sources of infection usually result in multiple abscesses that commonly lie within the middle cerebral artery territories. Most start at the junction of the cortical mantle and underlying white matter since this is a common site of vascular branching with a filter-like effect, but the cerebellum, basal ganglia, thalami, and brainstem may also be involved. "Metastatic" lesions of this sort most often originate in the thorax, with chronic suppurating pulmonary disorders such as lung abscess and bronchiectasis leading the list of predisposing conditions.[218] Much less common among underlying sources of infection are bacterial endocarditis (characteristically acute), empyema, osteomyelitis, and infections of deep pelvic organs or abdominal viscera. Additional risk factors include various conditions in which the filtering function of the lung's capillary bed is abrogated (e.g. pulmonary arteriovenous fistulas) and cyanotic congenital heart diseases complicated by right-to-left shunts (e.g. tetralogy of Fallot, patent foramen ovale, ventricular septal defect, and transposition of the great vessels). The secondary polycythemia that regularly attends these anomalies may further promote the genesis of abscesses from infective emboli by causing microcirculatory sludging and regional brain hypoxia. Similar mechanisms may account for the significant risk of cerebral abscess in hereditary hemorrhagic telangiectasia (Osler–Weber–Rendu disease); most patients with this complication harbor pulmonary AVMs and exhibit hypoxemia with resultant cyanosis, clubbing, and polycythemia.[222] Iatrogenic causes of metastatic brain abscess include esophageal instrumentation for treatment of caustic strictures, or endoscopic injection of sclerosing agents for treatment of esophageal varices.[223]

The microbiology of the foregoing lesions is complex, but a few generalizations are possible. *Fusobacterium*, *Bacteroides*, and streptococci are most commonly cultured from brain abscesses associated with pulmonary sepsis, while actinomycotic[220] and nocardial[224] lesions (the latter often encountered in debilitated and immunosuppressed subjects) are also common secondary deposits from foci of established lung infection. Streptococci and *Haemophilus* species are the typical offenders in cases related to congenital heart disease, whereas *S. aureus* dominates isolates from examples complicating acute bacterial endocarditis.

Direct bacterial inoculation is probably the least frequent cause of abscess formation from either penetrating cranial trauma or neurosurgery.[218] *S. aureus* is the organism most often recovered from lesions arising in these circumstances, followed by *Streptococcus*, *Enterobacter*, and *Clostridium* species. *Propionibacterium acnes*, a gram-positive, anaerobic rod that causes a syndrome of shunt malfunction and immune-complex nephritis in patients with intraventricular catheters, has also emerged as an agent of traumatically and surgically acquired brain abscesses and epidural infection.[225,226] Trauma and intracranial hematoma accumulation, in addition, predispose to cerebral *Salmonella* abscess.[218] Brain abscesses remain diagnostically challenging from a clinical standpoint because their presenting manifestations and neuroradiological appearances are so nonspecific.

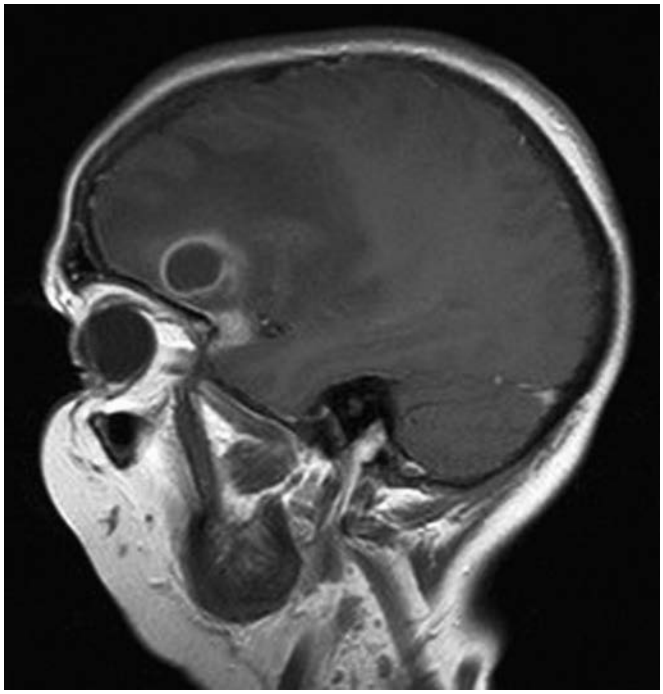

Figure 43.19 Cerebral Abscess. Ring enhancement of their developing pseudocapsules, budding of "daughter" lesions, and marked hypodensity of adjacent white matter reflecting severe edema are all characteristic of cerebral abscesses on postcontrast magnetic resonance imaging. In contrast to most glioblastomas (often a differential consideration), note the relatively thin and uniform rim of enhancement in this example.

It is noteworthy that only 40%–50% of affected patients are febrile. The more common signs and symptoms are those of any expanding intracranial mass: headache, altered mental status, focal sensorimotor deficits, seizure, nausea, and vomiting.[218] Although central hypodensity, rim enhancement, and surrounding edema are characteristic on CT or MRI studies (Fig. 43.19), these appearances may be shared by malignant neoplasms (particularly glioblastomas) and, on occasion, demyelinating disease. The enhancing pseudocapsules of abscesses tend to be thinner and of more uniform profile than in glioblastomas, typically acquire a dark signal on T2-weighted MRI (as they collagenize) that is foreign in neoplasia, and surround contents that are bright on diffusion-weighted imaging in contrast to the centrally necrotic and dark interior of glioblastoma. The apparent budding of smaller, "daughter" lesions from the main mass also suggests abscess.

Experimental, clinical, and histopathologic observations suggest that cerebral abscesses begin as ill-defined zones of bacterial multiplication and polymorphonuclear leukocytic infiltration (cerebritis) most commonly situated in white matter immediately subjacent to the cortical ribbon or at the gray–white junction.[218] With time, proliferating fibroblasts surround a central mass of fibrinopurulent debris and fashion a collagenous capsule resembling the pyogenic membranes formed in suppurative infections outside the nervous system (Fig. 43.20). This, in turn, is bordered by edematous, chronically inflamed, and gliotic brain tissue that may show evidence of acute cerebritis reflecting the host's failure to entirely wall off the primary locus of infection.

The rate and completeness of encapsulation varies considerably. *Nocardia* is especially notorious for poor encapsulation. Capsular organization is typically most advanced along the superficial, juxtacortical perimeter, with "daughter" lesions typically budding from

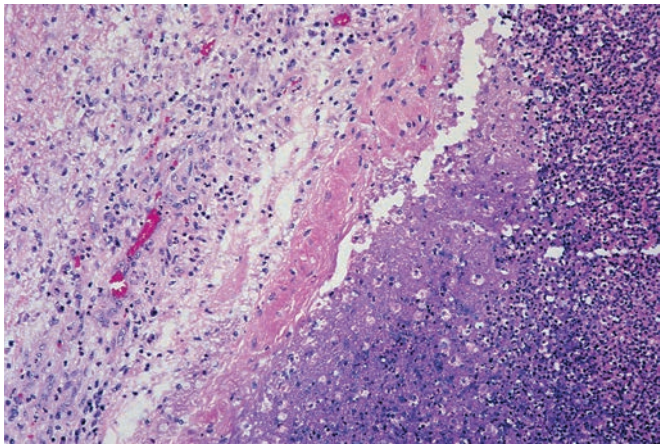

Figure 43.20 Cerebral Abscess. The lesion's purulent contents are separated from neighboring white matter by a granulation tissue–like zone of angioblastic and fibroblastic activity.

the deep aspects with subsequent rupture into the ventricular system rather than subarachnoid space. Because the mesenchymal elements responsible for capsule formation presumably derive from the adventitia of regional blood vessels and require oxygen for collagen fibrillogenesis, the relatively retarded organizational responses of paraventricular, as compared with cortical and paracortical, tissues may be a consequence of their less extensive vasculature. The intraventricular discharge of purulent material is among the most serious complications, often proving fatal.

In contrast to the largely intracranial localization of bacterial abscesses involving the CNS proper, 90% of epidural examples are spinal.[227] This "true" (as opposed to potential) space, containing adipose tissue, nutrient arteries, and an elaborate venous plexus, expands posterior and lateral to the dura mater, whereas above the foramen magnum this fibrous sheath adheres tightly to the inner aspect of the skull. Anterior tethering of the dura to adjacent vertebral bodies presumably accounts for the fact that most **epidural abscesses** of the spinal cord are posteriorly or posterolaterally positioned. Approximately half of these settle in the thoracic, and one-third in the lumbar region. Less accommodating is the epidural space at cervical levels, where the spinal canal is nearly filled by the cord itself, with sacral lesions also being rare.

Roughly 30%–40% of spinal epidural abscesses arise "spontaneously," with the remainder secondarily complicating infections at contiguous or distant sites, trauma, intravenous drug abuse, spinal surgery or other invasive procedures, including epidural catheterization and lumbar puncture. Of particular importance among predisposing infections are contiguous foci of vertebral osteomyelitis, psoas and perinephric abscesses, decubitus ulcers, and other cutaneous and soft tissue suppurations. Diabetes mellitus, alcoholism, and renal failure are also significant risk factors. Presenting clinical manifestations typically include fever, malaise, and backache. If antimicrobial therapy and neurosurgical decompression are delayed, infection may progress in stepwise fashion to radiculopathy, sensorimotor, and sphincter disturbances indicative of spinal cord dysfunction, and, finally, paralysis. *S. aureus* remains the most common culprit, distantly trailed by gram-negative aerobes such as *E. coli* and *Pseudomonas aeruginosa*, streptococci, and various anaerobes.

Although *Mycobacterium tuberculosis* is among the more common agents of spinal epidural abscess,[227,228] especially among intravenous drug abusers, the lesions it produces are typically granulomatous and caseating rather than suppurative. These usually arise in the low thoracic or lumbar region by extension from contiguous foci of tuberculous vertebral osteomyelitis or disk infection, but "primary" examples not associated with osseous, pulmonary, or other extraskeletal disease may be encountered. Diagnosis is complicated by the fact that patients often present with back pain of insidious onset and chronic evolution unattended by fever, leukocytosis, or evidence of tuberculosis on chest film. As with nontuberculous epidural abscesses, the consequence of delayed intervention is progressive neurologic dysfunction culminating in myelopathy or "Pott paraplegia." Other localized forms of mycobacterial CNS infection include **tuberculoma**,[228] **focal tuberculous meningoencephalitis**,[229] and the rare **tuberculous abscess**.[230] **Subdural tuberculous empyema** has also been described.[231] Tuberculoma, defined as an encapsulated, granulomatous, and centrally caseating inflammatory mass, is by far the most common variant of neuroparenchymal tuberculosis. It is usually unaccompanied by evidence of coextant meningeal infection and may settle anywhere along the neuraxis but favors the intracranial contents. An excess of pediatric examples present in the cerebellum, constituting the posterior fossa "tumors" encountered most frequently in some countries (e.g. India) where tuberculosis is rampant. Exceptionally, tuberculomas are dura based,[232] rather than intra-axial, or confined to the spinal cord.[233] Human immunodeficiency virus type 1 (HIV-1)-seropositive subjects[228] are at substantially increased risk of developing both tuberculous meningitis and neuroparenchymal tuberculomas, and instances of CNS infection by nontuberculous mycobacteria have also been documented in this setting.[234] *Mycobacterium avium-intracellulare* complex characteristically evoke a nongranulomatous response that may include conspicuous spindling of infected histiocytic elements—a phenomenon that can be confused with a mesenchymal or meningothelial neoplasm.[235]

Other distinctive bacterial infections of the nervous system proper include a bulbar encephalitis ("rhombencephalitis") caused by *Listeria monocytogenes*,[236] and cerebral Whipple disease, resulting from invasion of the neuropil by *Tropheryma whipplei*.[237] The latter process (which may rarely be confined to the CNS) is characterized in the brain, as elsewhere, by infiltrates of foamy macrophages exhibiting an intense, granular PAS positivity of their cytoplasm (which has a peculiar blue–gray tint in hematoxylin–eosin sections) and containing numerous rod-shaped bacillary forms on ultrastructural study. A florid reactive astrogliosis is the rule. *Bartonella henselae* (agent of cat-scratch disease and bacillary angiomatosis) has been described as causing space-occupying, inflammatory CNS lesions often in association with underlying immunodeficiency.[238]

Mycoses

CNS mycosis is particularly common in immunocompromised patients. Nevertheless, neuroinvasive fungal infection is only exceptionally seen by the surgical pathologist. Most space-occupying intracranial and intraspinal lesions of mycotic etiology develop in association with diffuse meningeal or disseminated systemic infection and, consequently, are diagnosed by study of the CSF or, in the latter scenario, are treated empirically. Many are discovered only at autopsy. *Cryptococcus neoformans*, pathogenic molds, *Candida* species, and the dimorphic and dematiaceous fungi collectively account for the vast majority of lesions encountered in neurosurgical practice.[239]

C. neoformans, the agent of a diffuse leptomeningitis that is the single most common CNS mycosis, occasionally proliferates in localized neuroparenchymal or choroid plexus-based, intraventricular masses known as cryptococcomas.[239] It is noteworthy that fewer than 5% of cryptococcomas arise in the setting of opportunistic infection. Cryptococcal meningitis, by contrast, often afflicts immunosuppressed patients (e.g. HIV, diabetes, organ transplant recipients,

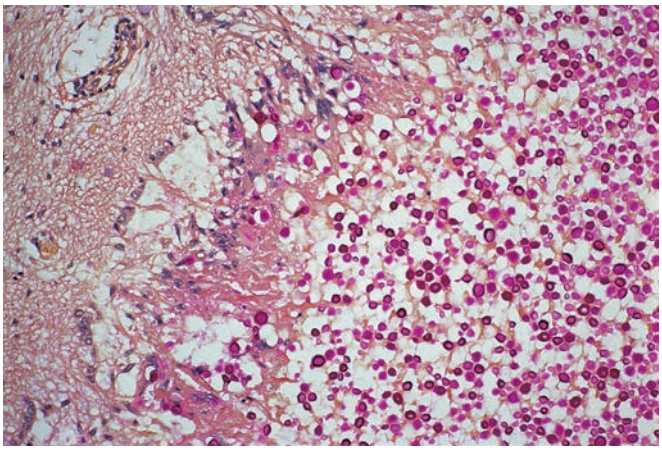

Figure 43.21 Cryptococcoma. This neurosurgical specimen, from a previously healthy 54-year-old man with a "tumor" primarily involving the choroid plexus and wall of the right lateral ventricle, demonstrates numerous yeast forms identifiable as *Cryptococcus neoformans* by their mucicarmine-stained capsules.

and patients being treated for hematologic or lymphoid neoplasia). The appearance of the cryptococcoma varies with the host's reaction and may range from no associated inflammation to necrotizing granulomas and pronounced desmoplasia. When cryptococci hold the advantage, the lesion consists mainly of mucoid or gelatinous material that reflects the conspicuous elaboration of capsular mucopolysaccharides characteristic of these organisms. This is often traversed in honeycomb-like fashion by fibrous connective tissue septa. At the other extreme are sclerotic, granulomatous masses containing only rare yeast forms. Exceptional examples mimic bacterial abscesses, containing purulent debris bound by a well-developed pyogenic membrane. *Cryptococcus* is typically ovoid or spheric in profile, measures 2–15 µm in diameter, replicates by budding from a narrow base, and is reliably distinguished from other yeast by demonstration of its mucicarminophilic capsule (Fig. 43.21) or by the Fontana–Masson stain in the increasingly frequently encountered capsule-deficient variants.

Fungi existing in pure hyphal form at both room temperature and 37°C are termed molds. The major CNS pathogens in this group include *Aspergillus* species, *Mucor* and related species, and *Pseudallescheria boydii* (also referred to as *Scedosporium apiospermum*). *Fusarium*, *Paecilomyces*, and *Penicillium* species, *Streptomyces griseus*, and *Acremonium alabamensis* are also occasionally neuroinvasive.[239] Opportunists all, these ubiquitous organisms only rarely attack otherwise healthy individuals and share a particular predilection for patients receiving maintenance doses of broad-spectrum antibiotics through protracted periods of neutropenia, as commonly occurs in the management of leukemias and lymphomas. CNS infections that occur in such settings result from systemic fungemia, are primarily intraparenchymal and usually multifocal, and are typically accompanied by evidence of systemic mycosis. The development of cerebral aspergillosis in patients treated for hematologic neoplasms, for example, is almost invariably preceded by symptomatic fungal infection of the lungs. Also at risk of blood-borne CNS seeding by pathogenic molds are patients taking corticosteroids, intravenous drug abusers, and, in the case of *P. boydii*,[240] victims of near drowning. Prior to the widespread use of immunosuppressive chemotherapeutic regimens for the treatment of cancer, *Aspergillus* generally invaded the CNS from primary foci of ocular, sinonasal, or middle ear infection. Alcoholic liver disease and Cushing syndrome have also been associated with CNS aspergillosis.[239] A second important form of meningeal and neuroparenchymal mycosis caused by these agents follows their direct intracranial spread from foci of orbital or paranasal sinus infection. This pattern of disease is typified by rhinocerebral mucormycosis, a disorder classically associated with diabetic ketoacidosis but also complicating other acidemic states (e.g. sepsis, profound dehydration, uremia), renal transplantation, and deferoxamine therapy.[239] In addition, skull fracture, penetrating trauma, and craniotomy may set the stage for CNS mycoses.

The neurologic manifestations, distribution, and morphology of CNS lesions caused by these agents vary with the clinical circumstances surrounding infection and the immune status of the host. A syndrome of multifocal stroke that reflects the shared tendency of pathogenic molds to occlude, invade, and trigger thrombosis of the leptomeningeal and perforating cerebral vasculature is particularly characteristic of cerebral disease evolving in the setting of disseminated systemic mycosis. The resulting lesions are basically infarcts, often hemorrhagic, that are secondarily colonized by fungi migrating through damaged blood vessel walls and that frequently exhibit little inflammatory reaction or limited suppuration. These are typically scattered in both cerebral hemispheres and often involve the deep nuclei, cerebellum, and brainstem. Contiguous fungal infiltration of the leptomeninges is common, but infection limited to these tissues is rare. Solitary lesions are exceptional, but examples produced by *Aspergillus* species,[241] *P. boydii*,[240] and other molds[239] are on record. These present with symptoms referable to an expanding intracranial mass, tend to occur in patients whose immune reflexes are relatively preserved, and may assume an abscess-like or even granulomatous character. Of particular note is a distinctive form of localized CNS mucormycosis characterized by a remarkably stereotypic predilection for the basal ganglia of intravenous drug abusers.[242] The more common rhinocerebral infections caused by advancing Mucorales are manifest as poorly delimited, necrotizing lesions again exhibiting the ischemic and hemorrhagic qualities typical of these angioinvasive organisms. True mycotic aneurysm has also been described as a consequence of cerebral aspergillosis.[243]

The definitive taxonomic classification of molds requires their isolation in culture or identification using molecular assays and cannot be accomplished on tissue morphology alone. Of the major CNS pathogens, both *Aspergillus* species and *P. boydii* appear in biopsy material as septate hyphae. *Aspergillus* species are usually somewhat stouter and more frequently branch at acute angles, but these are not reliably distinguishing features. By contrast, *Mucor* is a broad, ribbon-like hyphal organism that is pauciseptate and branches randomly.

Blastomyces dermatitidis, *Histoplasma capsulatum*, *Coccidioides immitis*, and *Paracoccidioides brasiliensis* are traditionally grouped as "dimorphic" fungi because of their growth as filamentous mycelia at room temperature and yeast at 37°C. All are capable of infecting the CNS, usually in the form of a chronic granulomatous meningitis in patients with coextant, active systemic mycoses. Limited extension to the cerebral cortex from contiguous foci of leptomeningeal infection is common but typically of no clinical consequence. Only rarely do neuroparenchymal lesions attain symptomatic proportions.[239] Again, these unusual fungal masses are generally, although not invariably, associated with clinically evident infection of extraneural tissues. Examples have been described both in the obviously immunodeficient and in patients with no clear risk factors for opportunistic disease. It is worth noting that roughly half of the intracranial blastomycomas and a majority of the histoplasmomas reported to date presented as solitary lesions. Brain invasion by *C. immitis* and *P. brasiliensis* is, by contrast, infrequently unifocal. In general, these organisms evoke a necrotizing, granulomatous tissue response replete with multinucleated giant cells and, in cases of blastomycoma and histoplasmoma,

foci of caseation that may prompt considerations of tuberculous infection. A suppurative/neutrophilic infiltrate is also commonly observed in otherwise granulomatous fungal masses. Cerebral endarteritis and mycotic intracranial aneurysm caused by *C. immitis* infection have been described,[244] as has massive dural and cerebral venous thrombosis associated with coccidioidal meningitis in an AIDS patient.[245]

The dematiaceous (from the genus *Dematium*) fungi are a group of pigmented hyphal yeasts best known as the agents of chronic skin and subcutaneous infections, such as Madura foot and tinea capitis. Extracutaneous disease is exceptional, but the brain is a common target in disseminated mycoses caused by these organisms. One member of the group, *Xylohypha bantiana (Cladosporium trichoides)*, appears to be specifically neurotropic and is responsible for most CNS infections,[246] which are often grouped with other deep mycoses caused by pigmented fungi under the rubric of phaeohyphomycosis. This organism is fully capable of invading the nervous systems of apparently immunocompetent hosts and, in many cases, does so in the absence of demonstrable foci of extraneural infection. Isolated patients have suffered immunosuppressive underlying conditions; have exhibited preexistent phaeohyphomycotic infections of the paranasal sinuses, ear, or lungs; or have apparently acquired the infection through traumatic intracerebral implantation or intravenous drug abuse.[247] Neuroparenchymal lesions consist of necrotizing granulomas, which are multifocal in about 50% of cases. A similar fraction is attended by fungal meningitis. In tissue sections, the agent appears as branching, septate hyphal, and yeast-like structures with a brown or olive-green hue. Culture or PCR testing is required for definite classification. Other pigmented fungi that have also been reported rarely[239] include *Drechslera–Bipolaris–Exserohilum* and *Curvularia* species, *Fonsecaea pedrosoi*, *Wangiella dermatitidis*, *Dactylaria constricta*, *Ramichloridium obovoideum*, and *Scopulariopsis brumptii*.

Cerebral candidiasis has emerged in recent years as one of the most common CNS mycoses encountered in immunosuppressed patients.[239] However, the great majority of cerebral *Candida* infections are discovered only at autopsy, resulting from fungemia in debilitated, moribund patients. The typical lesions are diminutive foci of suppuration scattered widely in the neuropil and associated in some cases with fungal meningitis. The formation of granulomas or macroabscesses, disease limited to the meninges, and vasculitis, with resultant infarction or the development of mycotic aneurysms,[239,243] have also been described, as has the extraordinary presentation of CNS candidiasis as a localized fungal mass.[248]

Parasitoses

The CNS parasitoses include a great variety of protozoal and helminthic infections. This discussion is limited to two representatives of particular importance to the surgical pathologist—neurocysticercosis and toxoplasmosis.

Neurocysticercosis, caused by larvae of the pork tapeworm, *Taenia solium*, is the most common parasitic cerebral infection encountered in worldwide neurosurgical practice.[249] Endemic to nearly all continents, the disease is particularly prevalent in Mexico (where it is the leading cause of space-occupying intracranial lesions), Central and South America, India, Africa, and China. An increasing incidence in the United States is largely attributable to cases occurring in immigrants from these regions. Infection is acquired by ingestion of food or water contaminated by feces containing the cestode's ova. These are partially digested in the host's stomach, evolving to oncospheres and subsequently penetrating the small intestinal mucosa to disseminate throughout the body, preferentially encysting in ocular tissues, striated muscle, and brain. The ensuing clinical disorder is named for the designation given the organism at this larval stage, *Cysticercus cellulosae*.

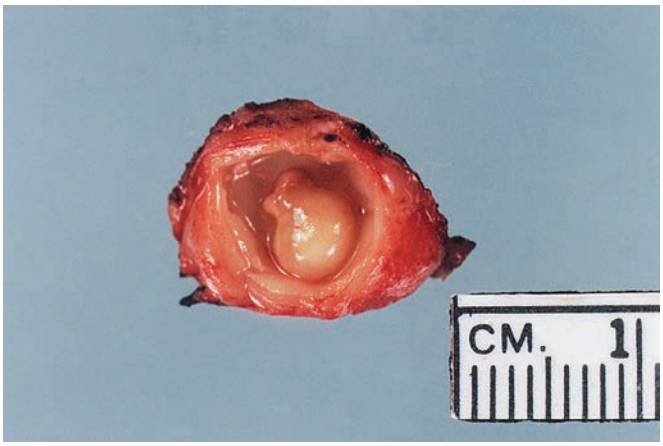

Figure 43.22 Neurocysticercosis. Typical of cerebral *Taenia solium* infestation is the solitary, encysted scolex demonstrated in this neurosurgical specimen from the left frontal cortex of a 32-year-old Haitian man with a history of seizures.

Cysticerci actually persist in parasitized tissues for long periods in asymptomatic form. The active clinical phase is triggered by the host's inflammatory response to the larva's death (~18 months following primary infection). The high incidence of focal or generalized seizures associated with the disorder reflects the fact that oncospheres reaching the CNS settle mainly in the epileptogenic cerebral cortex, but they may also colonize the ventricular system and basal cisterns in a distinctive pattern of infestation ("racemose" cysticercosis) resulting in obstructive hydrocephalus and consequent manifestations of elevated intracranial pressure. The presence of multifocal, rim-enhancing cerebral cysts on neuroimaging study suffices in many cases to prompt a diagnostic as well as therapeutic course of anthelmintic chemotherapy, but a substantial proportion of patients present with solitary lesions, and the host's reaction to the decaying parasite may convert the cyst to a deceptively solid inflammatory pseudotumor. Neurosurgical intervention may be obviated by CSF or serologic assay for specific anticysticercal antibodies or antigens, but false-negative results may be encountered, especially in subjects with unifocal disease.[249]

When not completely obscured by secondary inflammatory changes, the gross appearance of cysticerci excised in toto is virtually pathognomonic (Fig. 43.22). Individual cysts are of small diameter, are circumscribed by a rubbery fibrous pseudocapsule, and contain a single larval scolex represented by a spheric or ovoid grayish-white nodule measuring no more than 3–4 mm in greatest dimension. By contrast, cestode larval cysts produced by the morphologically similar *Multiceps multiceps* contain numerous scolices, and those caused by *Echinococcus granulosus* are considerably larger and endowed with a characteristically laminated wall. On histologic examination, the fibrous pseudocapsule is typically infiltrated by numerous lymphocytes and plasma cells, may contain eosinophils in abundance, and in some cases is the site of an active granulomatous reaction. The mummified remains of the degenerate scolex are covered by a wavy, somewhat refractile cuticle and consist largely of loose, reticular tissue containing numerous calcospherites. Relatively intact scolices possess a discernible subcuticular "pseudoepithelial" layer, small myofiber bundles, and four suckers armed with birefringent hooklets (Fig. 43.23). Racemose cysticerci evacuated from the ventricles or subarachnoid space present as grape-like clusters of interconnected larval "bladders" lacking organized scolices.

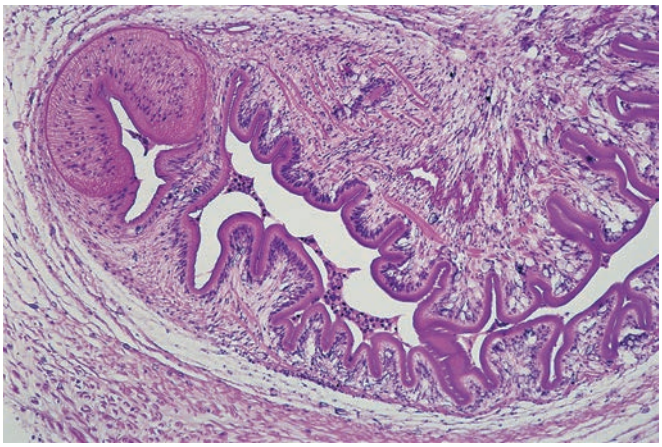

Figure 43.23 Neurocysticercosis. The parasite's main structural features include a prominent investing tegument or "cuticle," aggregated subcuticular cells, smooth muscle fibers, and four suckers, one of which is depicted at upper left.

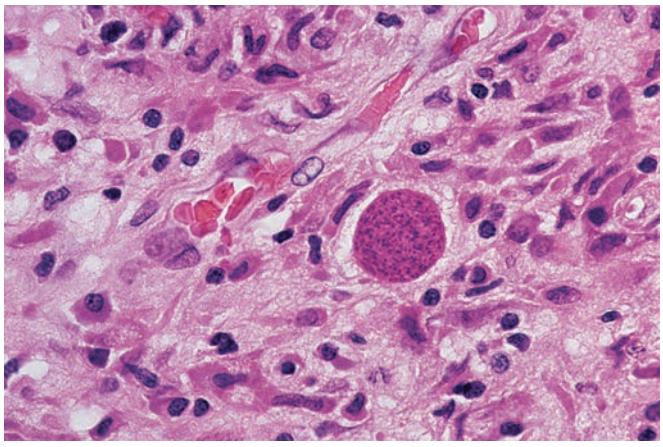

Figure 43.24 Toxoplasmosis. Minute, basophilic structures representing bradyzoites fill a protozoal pseudocyst with associated infiltrating lymphocytes, plasma cells, and macrophages.

Toxoplasmosis is the generic designation applied to localized or systemic infections caused by the obligate intracellular protozoan *Toxoplasma gondii*. CNS involvement may assume a number of distinctive clinicomorphologic guises,[250] but this discussion will focus on a "tumefactive" variant largely confined to immunocompromised hosts that is typically unassociated with clinical manifestations of extraneural parasitosis. Once regarded as rare and encountered principally among patients treated for hematolymphoid neoplasms (Hodgkin disease, particularly), this form of toxoplasmosis is now known to physicians the world over as a common AIDS-defining disorder and is in fact the leading cause of space-occupying intracranial lesions in the HIV-positive patients.[250] Bone marrow transplant recipients have also emerged in recent years as a population prone to CNS infections of this type. Mechanistically, there is a breakdown of cell-mediated immune surveillance, which is thought in most cases to permit reactivation of dormantly parasitized neural tissues. *T. gondii* is noted for its silent persistence in the brain following primary infection, which is usually asymptomatic and acquired by the consumption of inadequately cooked red meats containing encysted organisms, or by the inadvertent ingestion of foodstuffs, soil, or other materials contaminated by protozoal oocytes shed in the feces of domestic cats.

The clinical and neuroradiological features of CNS toxoplasmosis are variable and too nonspecific for definite diagnosis. Because *Toxoplasma* "abscesses" favor neuron-rich gray matter structures such as the cerebral cortex, basal ganglia, and brainstem, it should come as no surprise that seizures, progressive hemipareses, and cranial nerve deficits figure prominently among the initial manifestations. Many patients, however, present without localizing complaints, but rather with fever, headache, lethargy, and a subacute diffuse encephalopathy. Cranial MRI typically discloses multifocal, rim-enhancing nodular lesions with surrounding edema and mass effect, but exceptional examples are nonenhancing, and solitary abscesses are not rare. Isolated involvement of the spinal cord has been described.[251] A negative serum anti-toxoplasma IgG titer is evidence against, but does not entirely exclude, the diagnosis, particularly in severely immunocompromised patients. In the setting of HIV, it has become common practice to institute antimicrobial therapy on empiric grounds in suspect cases and to reserve neurosurgical intervention for patients who do not respond adequately. Most of the latter patients prove to harbor primary CNS lymphomas rather than toxoplasmosis.

The *Toxoplasma* "abscess," as it is commonly called, consists of a central mass of necrotic cellular debris surrounded by edematous and inflamed brain tissue that typically exhibits conspicuous vascular abnormalities. The latter include perivascular and intramural lymphoid infiltration, endothelial swelling, thrombosis, fibrinoid necrosis, and, in longstanding lesions, fibrous obliteration. It is within this perimeter zone that *Toxoplasma* are most numerous, but the necrotic core often lacks identifiable organisms. Two protozoal forms are evident in active lesions. The rapidly proliferating tachyzoite is responsible for tissue injury. These are faintly basophilic, measure approximately 4–8 μm in greatest dimension, and typically have a slightly crescentic or lunate profile (the Greek *toxon* means bow or arc). Because it is often difficult to visualize tachyzoites in routine histologic preparations and to confidently distinguish them from nuclear debris, the screening of suspect biopsy material with *Toxoplasma*-specific antibodies is strongly advised. More readily apparent, although present in less numbers, are intracellular pseudocysts and "true" (i.e. membrane-delimited) cysts that may attain diameters of up to 200 μm (Fig. 43.24). These are filled with minute, PAS-positive bradyzoites (named for their slow replicative cycles), are immunologically inert (i.e. unassociated with an inflammatory response), and represent the form in which *Toxoplasma* chronically persist in brain and other tissues. Within the CNS, bradyzoites appear to collect preferentially within neurons and perivascular macrophages. Again, it is immunodeficiency that somehow triggers their metamorphosis to tachyzoites and subsequent destructive invasion of neural tissues. Careful inspection of active lesions often reveals ruptured cysts as well. Like tachyzoites, bradyzoites are labeled by commercially available *Toxoplasma*-specific antibodies.

Spirochetal Infections

The two major CNS spirochetoses are neurosyphilis,[252] caused by *Treponema pallidum*, and neuroborreliosis, which is caused by the agent of Lyme disease, *Borrelia burgdorferi*.[253] The pathogenesis and varied clinical expressions of these complex syndromes are beyond the scope of this chapter; suffice it to say that intracerebral inflammatory pseudotumors (known as "gummas" in the case of treponemal disease and accompanied by necrosis and fibroplasia) are restricted to the late stages of systemic infection, constitute an uncommon manifestation, and are usually approached surgically only when the diagnosis is not suspected clinically.

Viral Infections

Herpes Simplex Encephalitis

Herpes viruses are responsible for a wide variety of neurologic infections. Our concern here is with a distinctive form of focal, necrotizing, and hemorrhagic encephalitis caused principally by herpes simplex virus type 1 (HSV1). **HSE** afflicts only 2–4 persons per one million persons a year but leads the list of potentially fatal nonepidemic viral cerebral infections.[254] Individuals of any age may be affected. The disease is often fulminant in its evolution and is characterized by fever, disordered affect, dysphasia, seizure activity, and deterioration of consciousness. CSF pleocytosis is the rule and may be accompanied by xanthochromia. Abnormalities are usually localized to one or both frontotemporal regions on neuroimaging. Brain biopsy has been generally replaced in the appropriate clinical circumstances by the availability of polymerase chain reaction (PCR)-based assays for HSV DNA in the CSF, a diagnostic method with high sensitivity and specificity.[254]

A remarkably stereotypic predilection for the anteromedial temporal lobes, orbitofrontal cortex, insulae, and cingulate gyri typifies HSE.[255,256] Experimental observations support the hypothesis that this "limbic" distribution reflects transolfactory spread of the agent to the CNS and suggest that at least some cases follow activation of virus residing latently in cerebral tissues. The histologic appearance of the disorder varies considerably with the duration of the clinical illness. The earliest appreciable changes, evident prior to the arrival of inflammatory infiltrates, include neuronal shrinkage and eosinophilia accompanied by vascular congestion, spongy cortical rarefaction, and pallor. This picture may closely mimic hypoxic–ischemic brain injury, leading to misdiagnosis as acute cerebral infarction, although close scrutiny of degenerating neurons often reveals a ground-glass viral cytopathic effect. It is during this early phase that careful search for the eosinophilic intranuclear viral inclusions is most likely to be successful (Fig. 43.25). These may be identified in cortical astrocytes and satellite oligodendroglia, as well as neurons, but are an inconstant feature.

The pronounced inflammatory reaction characteristic of fully developed HSE is usually apparent by the second week of clinical disease. Lymphocytes and plasma cells colonize the meninges, cuff penetrating blood vessels, and migrate into damaged cortex. Mononuclear cells may converge on infected neurons to form neuronophagic or so-called microglial nodules. These changes are often accompanied by hemorrhage and, in some cases, thrombosis and even fibrinoid vascular necrosis. Foamy macrophages eventually dominate the cellular infiltrate, ultimately clearing the necrotic debris, leaving only cavitated and gliotic remnants at sites of prior infection.

Immunocytochemistry and molecular genetic techniques may aid in the diagnosis of HSE in select biopsies exhibiting little alteration at the light microscopic level. Commercially available antibodies to HSV are widely available, and immunohistochemical assessment is strongly recommended in all cases of clinically suspected HSE, regardless of whether inspection of biopsy material reveals an inflammatory process (Fig. 43.26). In fact, Esiri's elegant correlative studies indicate that attempts at HSV antigen detection are most likely to succeed during the first week of encephalitic symptoms.[256] Coincident with a mounting inflammatory reaction, antigen expression declines steadily through the second and third weeks of the clinical illness and is not usually demonstrable thereafter. We have noted, however, the unusual persistence of viral antigens beyond this period in cases of HSE involving immunocompromised hosts, including cancer patients and individuals with underlying infection by HIV-1.[257,258] These appeared to be arrested at the noninflammatory, pseudoischemic phase characteristic of early HSE in otherwise normal individuals. HSE has also been documented in patients with primary brain tumors, raising the question of whether a neoplasm, and/or its surgical or adjuvant management, might trigger activation of latent HSV infection.

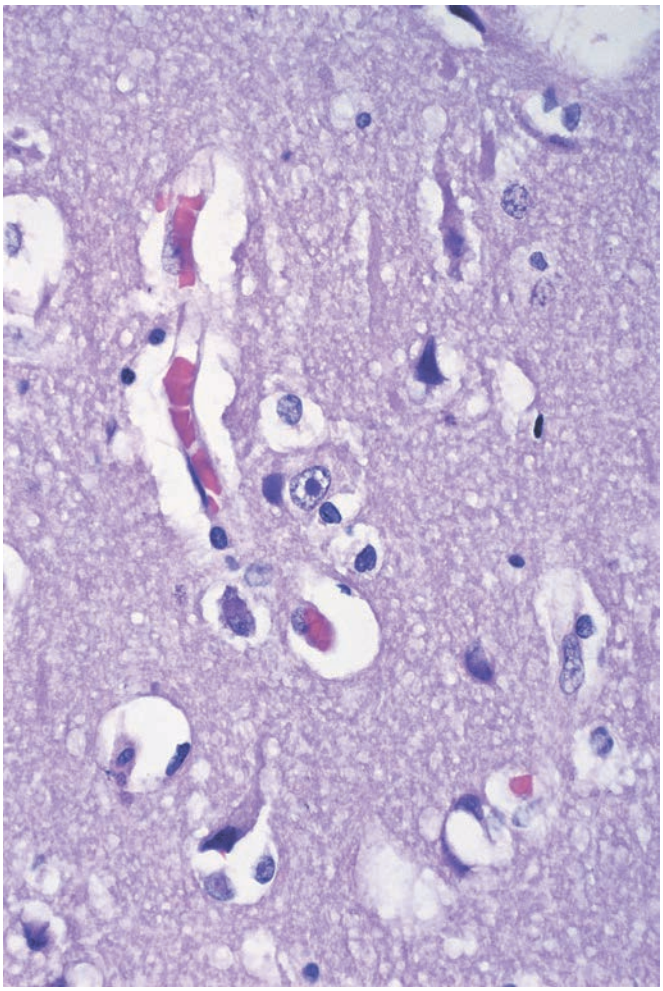

Figure 43.25 Herpes Simplex Encephalitis (HSE). As shown here, HSE may masquerade as a noninfectious, ischemic process (particularly if biopsied early in its clinical evolution). Note the noninflammatory appearance, neuronal shrinkage, pyknosis, and dissolution. The nucleus of a cell in the center of this field contains a well-defined Cowdry A inclusion body.

The reader is referred elsewhere for discussion of relapsing and chronic (including granulomatous) encephalitides that have been attributed to HSV infection.[259]

Progressive Multifocal Leukoencephalopathy

Progressive multifocal leukoencephalopathy (PML) is an opportunistic demyelinating disease caused by DNA viruses of the polyoma group. Nearly all clinical isolates responsible for the disorder have been strains of the ubiquitous **JC virus** (so designated for the initials of the first afflicted patient from whom the agent was recovered), with only exceptional cases linked to the related SV-40. PML is almost always associated with defective cell-mediated immunity and is currently encountered most frequently in the setting of AIDS, where it may be the presenting feature. The disease is characterized by subacutely evolving multifocal neurologic symptoms, chiefly

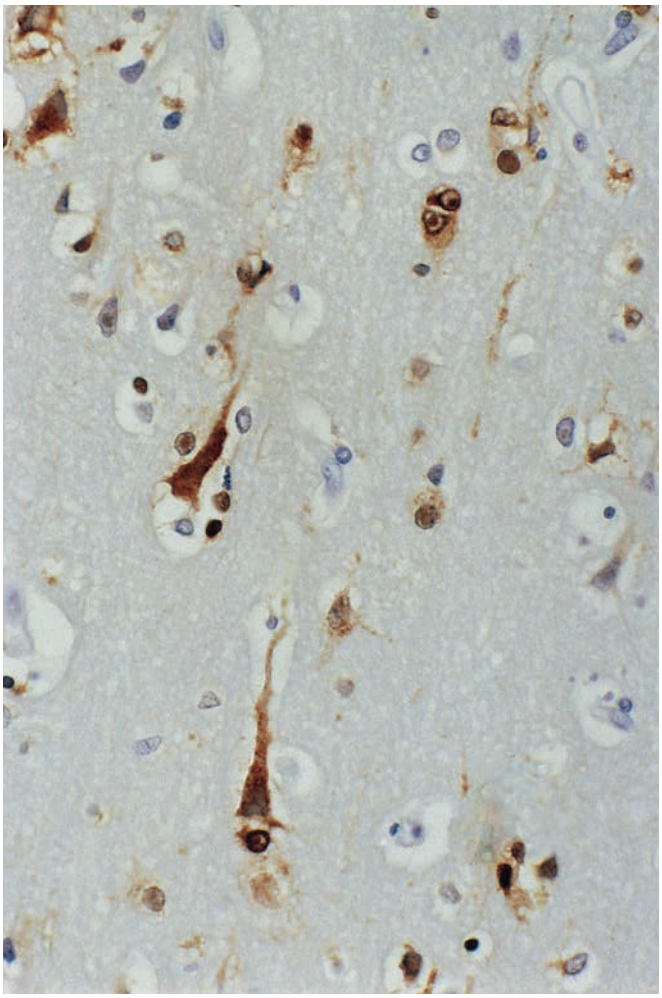

Figure 43.26 Herpes Simplex Encephalitis. In this immunoperoxidase preparation, the cytoplasm of neurons and inclusion bodies within the nuclei of satellite glia are labeled by antibodies to herpes simplex type 1.

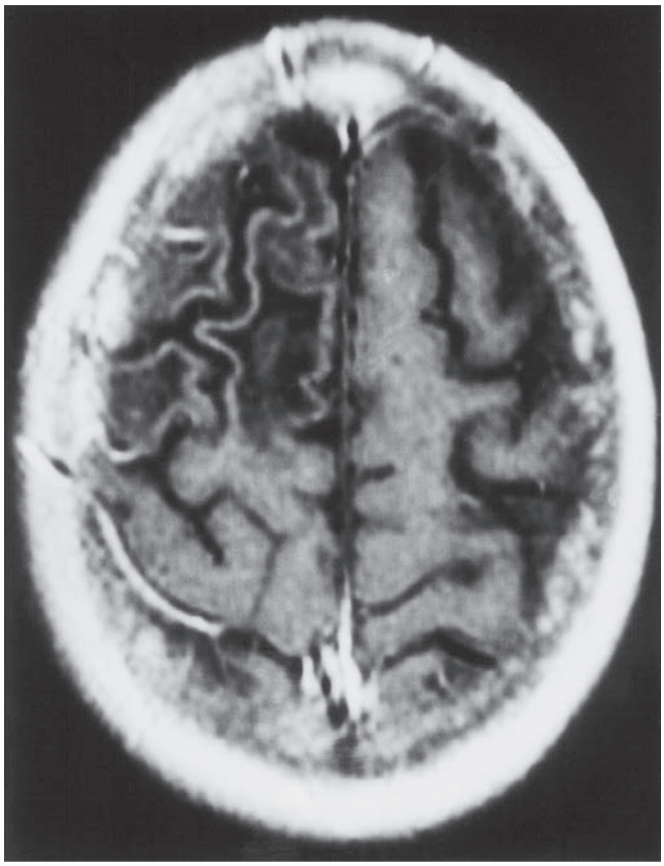

Figure 43.27 Progressive Multifocal Leukoencephalopathy. A postcontrast injection magnetic resonance imaging demonstrates the regional white matter hypodensity, absence of mass effect or abnormal enhancement, and cortical preservation that typify this demyelinating infection.

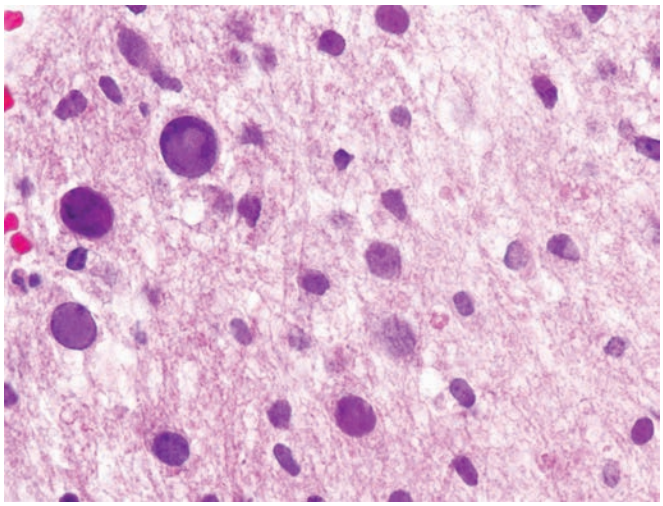

Figure 43.28 Progressive Multifocal Leukoencephalopathy. JC virus–infected oligodendrocytes in the left of this field exhibit the nuclear swelling, chromatin dissolution, and replacement by amphophilic, "ground-glass" inclusion material that is peculiar to this disorder.

motor deficits, cognitive decline, and visual loss. Although tumefactive variants have been described,[260] neuroimaging studies usually provide a clue to the nature of the process by demonstrating scattered white matter hypodensities not associated with mass effect or contrast enhancement (Fig. 43.27). PCR demonstration of JC virus–specific DNA from the CSF has emerged as a useful diagnostic procedure, reducing the need for brain biopsy.

Any level of the central neuraxis may be affected, but the cerebral hemispheric white matter generally bears the brunt of the injury. Cerebellar and bulbar localizations are less common, and the spinal cord is usually spared. It is the remarkable tropism of the JC virus for, and its replication within, oligodendroglia that is responsible for the alterations pathognomonic of PML. Infection of these cells results in progressive nuclear enlargement with plum-colored viral inclusions (Fig. 43.28). Considerably less common are demarcated eosinophilic inclusions of the sort that typify herpes virus infections. At the ultrastructural level, oligodendrocyte nuclei are distended by nonenveloped, spheric, or icosahedral particles measuring 33–45 nm in diameter. These are frequently aggregated in paracrystalline arrays and may be admixed with filamentous viral strands lending an appearance of "spaghetti and meatballs." Although immunocytochemical assays, in situ hybridization, and gene amplification

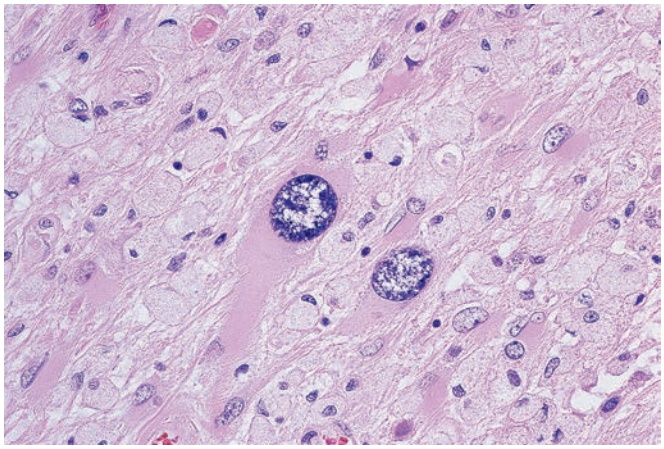

Figure 43.29 Progressive Multifocal Leukoencephalopathy. Grotesque cytologic alterations may result from infection of astrocytes by the JC virus. An accompanying infiltrate of foamy macrophages should militate strongly against the diagnosis of neoplasia, despite the worrisome appearances of these bizarre cells.

techniques may be used to confirm JC virus infection, the highly characteristic histology of PML cannot be overemphasized.[261]

With the ongoing infection and lysis of target cells, PML evolves as centrifugally expanding zones of oligodendroglial depletion and subsequent infiltration by foamy macrophages engaged in the scavenging and digestion of degenerating myelin sheaths. Early on, small plaques tend to cluster at the corticomedullary junction, probably reflecting hematogenous seeding of the CNS following reactivation of the agent in sites of systemic latency. Geographic zones of demyelination, resulting from the coalescence of these small lesions, become grossly evident as regions of white matter retraction, granularity, and yellowish-gray discoloration. In most cases, a relatively undisturbed cortical ribbon will span these devastated areas, although gray matter contributions have been recently emphasized.[261] This, and the characteristic persistence of axons in the face of total demyelination, reflects the resistance of neurons (cerebellar granule cells excepted) to JC virus infection. Some axonal loss, however, is the rule, and PML can progress to extensive white matter cavitation. Particularly widespread and destructive examples have been described in the setting of brain coinfection by HIV-1.[262]

A histologic feature of PML meriting further comment is atypical astrocytic hyperplasia (Fig. 43.29). In addition to florid astrogliosis, greatly enlarged bizarre, astrocytoma-like astrocytes are often found. These cytologic changes (often accompanied by morphologically atypical mitotic activity, Ki-67 expression,[263] and abnormal nuclear immunoreactivity for p53[264]) are believed to reflect a form of infection in which the agent's genome is spliced into that of the host cell.

PML is usually characterized by minimal inflammatory response to the agent; however, some variants exhibit intense perivascular and interstitial lymphoid infiltration. The latter often contain very few oligodendrocytes manifesting the nuclear cytopathic effects typical of JC virus infection and may prompt consideration of primary cerebral lymphoma, another recognized complication in immunosuppressed patients. It is this unusual form of PML that is most likely to present as a space-occupying, contrast-enhancing mass on CT or MRI study, further complicating the clinical delineation of these entities. A conspicuous inflammatory response and accompanying contrast enhancement on neuroradiological study characterize some examples affecting HIV-1–positive patients under highly active antiretroviral therapy (HAART) and typify biopsy material from a subset of AIDS patients surviving for considerably longer than the typical 3- to 6-month interval in which most PML patients progress to death.[265] The rare examples of spontaneously remitting PML have been of this unusually inflammatory type and presumably reflect elimination or immunologic containment of the JC virus following a transitory abrogation of its dormancy. Ironically, HAART-associated restoration of immune function may precipitate exaggerated inflammatory reactions to JC virus (as well as other pathogens, including mycobacteria, cryptococci, cytomegalovirus, and HIV-1) that result in paradoxic clinical deterioration.[266] This sometimes fatal "**immune reconstitution inflammatory syndrome (IRIS)**" is characterized by leptomeningeal and neuroparenchymal lymphoid infiltrates dominated by CD8+ T cells.[267,268]

Varicella-Zoster Virus Encephalitis and Cerebral Vasculitis

Varicella-zoster virus (VZV), the agent of chickenpox and shingles, causes a rare form of encephalitis sharing certain clinical and histologic features with PML.[269,270] The condition has to date been described exclusively in immunocompromised hosts (including patients treated for Hodgkin disease, other cancers, and AIDS) and may present months following resolution of cutaneous zoster or in the absence of a preceding exanthem. Described by some authors as a "leukoencephalitis," this chronic infection can settle anywhere along the central neuraxis but exhibits a striking predilection for the cerebral hemispheric white matter. It is characterized by multifocal, centrifugally expanding, and coalescent foci of demyelination and variable axonal loss with little inflammatory reaction. Many cases also feature small infarcts resulting from VZV-mediated vascular injury as further discussed later. The nuclei of oligodendrocytes situated on the periphery of demyelinating lesions exhibit a ground-glass or basophilic inclusion superficially similar to that of JC virus but without associated nuclear enlargement. Furthermore, neighboring astrocytes (and, in some cases, neurons and ependymal cells) infected by VZV contain well-demarcated Cowdry A-type intranuclear inclusions of the sort that typify herpes virus replication but lacking the atypical hyperplasia of PML. Ultrastructural study will disclose herpes-type nucleocapsids averaging approximately 100 nm in diameter within the nuclei of infected cells. These differ slightly from herpes simplex–type virions in that their core densities tend to be eccentrically positioned, but definite identification of VZV requires immunocytochemical assay, molecular hybridization studies, or culture.

In addition to encephalitis, VZV is recognized as a rare cause of cerebral vasculitis. This may involve large arteries at the base of the brain as well as smaller branches. Like the VZV-associated encephalitis, vasculitic complications typically follow resolution of the cutaneous exanthem. Two major variants have been described. One, a noninflammatory "angiopathy" afflicting immunocompromised hosts and associated in some cases with VZV encephalitis, is characterized by striking fibrointimal proliferation, thrombosis, and, in some cases, disruption of the elastica and thinning of the media without evident necrosis of mural elements.[271] The other is an overtly inflammatory and necrotizing angiitis designated by some observers as "granulomatous" because of the presence of multinucleated histiocytes within damaged vessel walls.[272,273] This often presents as hemiplegic stroke weeks after an episode of contralateral zoster ophthalmicus in a patient with no major evidence of defective immunity.[272] Several cases in HIV patients have shown both angiopathic and angiitic features, depending on the portion of vessel sampled, and there is suspicion that the former simply represents the chronic sequelae of an inflammatory process. In addition to thrombosis with consequent cerebral infarction, VZV angiitis may result in fusiform aneurysmal dilation, mural rupture, and subarachnoid hemorrhage.[273] Diagnosis requires localization of the virus (usually by immunocytochemical

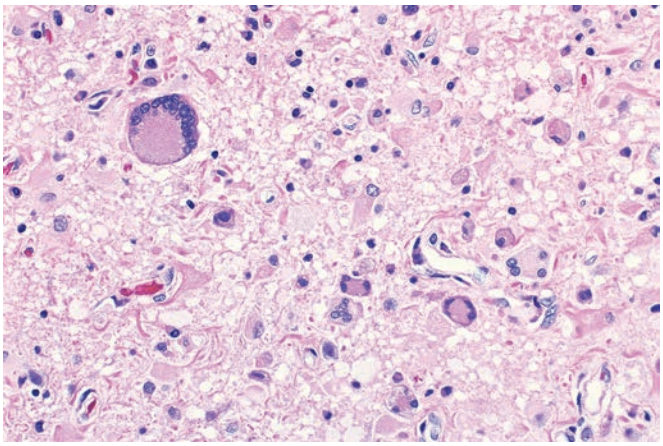

Figure 43.30 Human Immunodeficiency Virus Encephalitis. Nongranulomatous infiltrates centered loosely about blood vessels in the cerebral white matter (shown here) or basal ganglia and dominated by macrophages, including multinucleated forms resulting from retrovirally mediated cell fusion, characterize infection of the central nervous system by this agent. The associated astrogliosis and spongy rarefaction are common accompanying features.

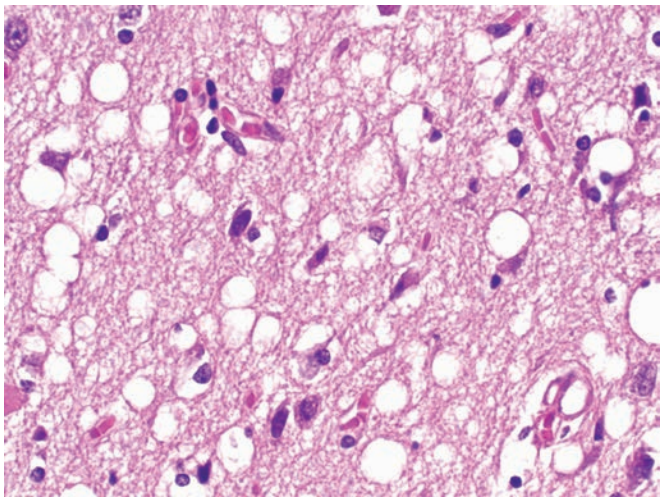

Figure 43.31 Creutzfeldt–Jakob Disease. Noninflammatory vacuolization of the cerebral cortex is the dominant alteration evident in this biopsy specimen from an elderly man with progressive dementia and myoclonus. This change typically precedes conspicuous neuronal dropout and astrogliosis, the other dominant findings in this prion-related disorder.

study) to elements of the vessel wall, typically smooth muscle cells in the media or intimal (myo)fibroblasts. Further consideration of VZV as a cerebrovascular pathogen is discussed earlier in the section on primary angiitis of the nervous system.

Human Immunodeficiency Virus Type 1 Encephalomyelitis

HIV-1 encephalomyelitis is not a disorder likely to engage the surgical pathologist but demands, nevertheless, some consideration in view of the unique nature of the neuropathologic alterations.[274] HIV-1 is alone among viral encephalitis agents in exhibiting no particular tropism for neuroectodermal cell types, as its replication in the nervous system occurs largely within marrow-derived macrophages and microglia. CNS infection is characterized by loosely arrayed, vasocentric, or paravascular inflammatory infiltrates concentrated in the cerebral hemispheric white matter, basal ganglia, and rostral brainstem (Fig. 43.30). These are dominated by mononuclear and multinucleated macrophages, the latter reflecting a process of virally mediated cell fusion that is the characteristic cytopathic effect of this and other members of the lentivirus subfamily of retroviruses. These cells, and their mononuclear precursors, harbor and release fully formed virions, which may be found budding from their plasmalemma, aggregated in membrane-delimited intracytoplasmic vacuoles, or lying free in the cytoplasm. The mature particle is spherical, averages 100–120 nm in diameter, and possesses a cylindrical or bar-shaped nucleoid usually positioned eccentrically and enclosed by a limiting membrane. Attendant changes include diffuse astrogliosis and microglial activation, generalized pallor of the cerebral white matter, and brain atrophy. The precise relationship of local HIV-1 replication to mechanisms of CNS injury remains a subject of active investigation.[274]

Prion-Associated Diseases

Though long ago grouped with the viral disorders, the unusual diseases collectively known as **transmissible spongiform encephalopathies** have resisted classification as conventional contagions and, in fact, occur in heritable and sporadic, as well as clearly infectious (mostly iatrogenically transmitted) forms. The pathogenesis of these rare entities remains a subject of controversy and ongoing investigation, but they clearly share anomalies of a native cell membrane constituent—the prion protein (PrP)—expressed at particularly high levels by central neurons. Conformationally altered, abnormally protease-resistant and amyloidogenic PrP isoforms ("prions") characteristically accumulate in affected tissues, with subsequent propagation sufficing for disease transmission in the absence of associated nucleic acids (i.e. not requiring the usual mechanisms of DNA or RNA replication).[1] Prion-associated illnesses include **kuru** (linked to the practice of ritual cannibalism among the Fore tribespeople of Papua, New Guinea), **Creutzfeldt–Jakob disease (CJD)**, "**variant**" **CJD** (linked to bovine spongiform encephalopathy, or "mad cow" disease), **Gerstmann–Straussler–Scheinker disease**, and **fatal familial insomnia**.[1] The following discussion is essentially limited to practical considerations in the diagnosis of CJD, the variant most commonly encountered in clinical practice.

The iatrogenic transmission of CJD via contaminated neurosurgical instruments, human growth hormone supplements, and a variety of allografts is well documented, but the large majority are sporadic and involve middle-aged or older adults having no evident exposure to contaminated materials or other individuals suffering the disorder. A familial variant associated with *PrP* gene mutations accounts for 10%–15% of cases.[1] The course of most patients is dominated by cognitive decline that progresses relentlessly in subacute fashion to profound dementia. Particularly characteristic accompanying features are generalized myoclonus, an electroencephalographic "burst suppression" pattern of periodic spike and wave complexes, and abnormally increased signal intensity in the basal ganglia and thalami on T2- and diffusion-weighted MRI sequences. The diagnosis is further suggested by appearance of a protein antigen (labeled 14-3-3) on CSF immunoassay. The afflicted are typically left vegetative within 6–8 months of symptom onset and rarely survive longer than a year after diagnosis.

The appearance of brain biopsy material, usually obtained from the nondominant frontal lobe, depends on disease duration and is particularly important for ruling out other disorders, especially the treatable ones.[1,275] The earliest change consists of spongy vacuolization of the cortex most pronounced in deeper laminae (Fig. 43.31). Rare

vacuoles may be localizable to neuronal perikarya, but most appear randomly scattered in the neuropil. The latter are situated principally within neuronal processes on electron microscopy, are often traversed by membrane-derived septa, and may contain granular or curled membranous profiles. With disease progression, spongiform change becomes increasingly florid and is attended by conspicuous astrogliosis, neuronal shrinkage, and depopulation. The end-stage cortex is left virtually devoid of recognizable neurons and largely replaced by the tangled processes of hyperplastic astrocytes. At no stage of the disorder is there evidence of an inflammatory response, and white matter abnormalities are limited to secondary axonal loss save for rare variants exhibiting spongy leukoencephalopathy.[276] A striking and diagnostic feature of prion-associated diseases, but one evident in only 5% of CJD cases, is the deposition of amyloid in "spiked ball" plaques that display radiate, spicular contours and are strongly PAS positive. Often referred to as "kuru" plaques, these are most often found in the cerebellar cortex (but may also be detected in cerebral gray matter) and are specifically recognized by antibodies to PrP.[1] Cerebrocortical examples may be numerous in familial CJD and are particularly conspicuous in "variant" CJD. Large, clustered deposits of PrP-immunoreactive amyloid in the cerebral and cerebellar cortices typify the dominantly inheritable Gerstmann–Straussler–Scheinker syndrome, also associated with PrP-encoding gene mutations and characterized clinically by a prominent component of progressive cerebellar ataxia.[1]

In the appropriate clinical setting, the presence of spongiform change alone suffices for a diagnosis of "probable" CJD. Definite diagnosis requires satisfaction of any one of the following criteria: (1) finding of spiked ball–type PrP amyloid plaques; (2) demonstration of protease-resistant PrP in biopsy material by specific immunohistochemical or immunoblot methods; (3) detection of a *PrP* gene mutation that is recognized as pathogenic; and (4) transmission of spongiform encephalopathy to an animal host. Readers are referred elsewhere for a fully annotated discussion of these specialized techniques.[1] A diagnosis of "probable" CJD should not be rendered on minimal histologic criteria inasmuch as scattered intracortical vacuoles and neuronal shrinkage are common artifacts of surgical manipulation. Vacuolization that is principally pericellular may also be caused by edema, hypoxia, autolysis, poor fixation, or processing, as well as toxic and metabolic encephalopathies. Furthermore, spongy changes that may mimic CJD (but that are often restricted to the superficial frontotemporal cortex, insula, or amygdala, and unattended by protease-resistant PrP deposition) can be encountered in otherwise typical examples of Alzheimer disease, cerebrocortical Lewy body disease, Pick disease, corticobasal degeneration, aphasic presenile dementia with lower motor neuron disease, and other dementing disorders. Conversely, an ostensibly negative biopsy should not reassure hospital staff handling tissues and fluids from suspect patients. The histopathologic alterations typical of CJD are not uniformly distributed in the involved brain, and methods such as immunohistochemical assessment and Western blot analysis may reveal protease-resistant PrP in neurosurgical specimens with little or no spongiform change.

Biopsy material from patients suspected of having CJD requires cautious handling, as even formalin-fixed and paraffin-embedded archival specimens retain transmissibility. Fixation protocols have been developed that virtually eliminate infectivity while yielding histologic sections of excellent appearance and antigenic integrity (these employ formic acid immersion following initial formalin fixation),[277] but the processing of suspect biopsy material in general surgical pathology laboratories is not recommended. Rather, these should be forwarded in formalin to specialized facilities such as The National Prion Disease Pathology Surveillance Center of the United States (cjdsurv@po.cwru.edu) that can assess specimens for *PrP* gene mutations as well as PrP deposition.

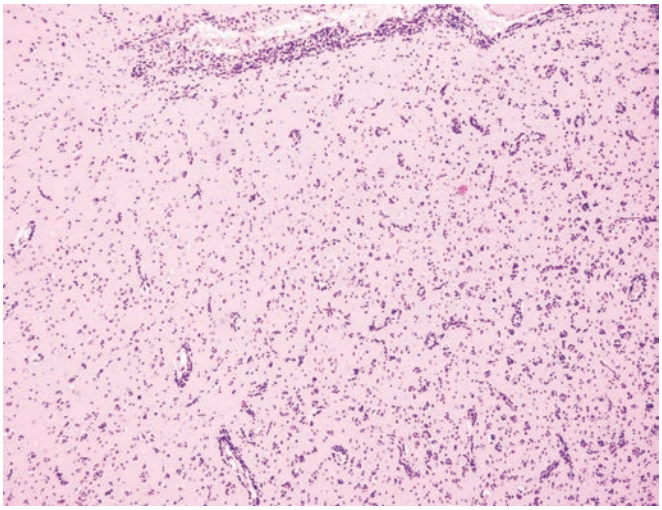

Figure 43.32 Diffuse astrocytoma forming secondary structures of Scherer, including subpial accumulation, perivascular aggregates, and perineuronal satellitosis.

Primary Tumors

Glial Tumors

Diffuse (Astrocytic and Oligodendroglial) Gliomas

The large group of clinically, pathologically, and genetically diverse glial neoplasms designated as diffuse gliomas encompasses those that tend to primarily grow in an infiltrative manner, with individual tumor cells spreading mostly along white matter tracts, perivascular spaces, subpial regions, and surrounding neurons (perineuronal satellitosis), the last three of which are referred to as "secondary structures of Scherer" (Fig. 43.32). Considerable advances have led to a revised World Health Organization (WHO) 2016 classification scheme, with newly incorporated "integrated diagnoses" that combine key morphologic and genetic features in order to establish diagnostic categories that are as biologically uniform as possible (Table 43.1). As a fundamental conceptual shift, for instance, it is now recognized that IDH-mutant diffuse astrocytomas and oligodendrogliomas have considerably more in common with one another than the more disparate entities that were previously lumped together based solely on lineage assumptions, such as diffuse and pilocytic astrocytomas. Although it was initially surprising to find mutations of this Krebs cycle–related gene in 10% of glioblastoma patients (nearly exclusively in the secondary form), this alteration was subsequently demonstrated in roughly 80% of all lower-grade (WHO grade II-III) gliomas, regardless of astrocytic or oligodendroglial lineage. Additional data suggest that further alterations such as *ATRX* and *TP53* mutations drive the precursor cell towards the astrocytoma morphology, whereas 1p19q codeletion with mutations of *TERT*, *CIC*, and *FUBP1* provoke the oligodendroglioma phenotype (Fig. 43.33). In contrast, the most common subtype of primary (de novo) glioblastoma in older adults is IDH-wildtype by definition, typically with associated *TERT* mutations, cytogenetic alterations such as trisomy 7 and monosomy 10, and epidermal growth factor receptor *(EGFR)* gene amplifications in roughly a third of cases. However, even within the overarching category of diffuse gliomas, neoplasms vary considerably in their epidemiologic features, morphologic attributes, growth patterns,

Table 43.1 Clinicopathologic and molecular features of integrated WHO 2016 glioma diagnoses

WHO 2016 DIAGNOSIS	CLINICAL CORRELATES	HISTOLOGIC CORRELATES	COMMON IHC AND MOLECULAR FEATURES
Diffuse astrocytoma, IDH-mutant, WHO grade II	Mostly young adults with cerebral, nonenhancing T2/FLAIR bright masses	Irregular, hyperchromatic nuclei	IDH1-R132H+ by IHC or *IDH1/2-mutant* by sequencing, p53+, ATRX–*
Gemistocytic variant	Same as above	At least 20% gemistocytes	Same as above
Diffuse astrocytoma, IDH-wildtype, WHO grade II	Same as IDH-mutant counterpart	Must exclude other entities, e.g., undersampled GBM, ganglioglioma, PXA, etc.	IDH-wildtype by IHC and sequencing
Diffuse astrocytoma, NOS, WHO grade II	Same as IDH-mutant counterpart	Same as IDH-mutant counterpart	Diagnosis based on histology alone
Anaplastic astrocytoma (AA), IDH-mutant, WHO grade III	Mostly nonenhancing or focally enhancing cerebral masses	Same as grade II astrocytomas but with mitotic activity	IDH1-R132H+ by IHC or *IDH1/2*-mutant by sequencing, p53+, ATRX–*
Anaplastic astrocytoma, IDH-wildtype, WHO grade III	Same as IDH-mutant counterpart	Must exclude other entities, especially undersampled or early GBM	IDH-wildtype by IHC and sequencing
Anaplastic astrocytoma, NOS, WHO grade III	Same as IDH-mutant counterpart	Same as IDH-mutant counterpart	Diagnosis based on histology alone
Glioblastoma (GBM), IDH-wildtype, WHO grade IV	Mostly older adults with rim-enhancing cerebral masses	Same as AA but with microvascular proliferation and/or necrosis	IDH-wildtype by IHC and sequencing in young patients or by IHC alone in older patients; TERT mutations, *EGFR* amplification/rearrangement, and 10q LOH common
Giant cell GBM variant	Greater tendency to superficial location and sharp demarcation	Predominance of large, bizarre multinucleated cells	Most are p53+ with *TP53* mutations; *EGFR* amplification rare
Gliosarcoma variant	Greater tendency to superficial location and sharp demarcation	Mesenchymal (sarcoma) metaplasia seen either de novo or at recurrence	Reticulin-rich, GFAP-sarcomatous elements; *EGFR* alterations rarer
Epithelioid GBM variant	Mostly children and young adults; greater tendency to superficial location, sharp demarcation, and CSF dissemination	Large melanoma-like cells and relatively sharp interface with brain; may have low-grade precursor, such as PXA	S100+, limited GFAP+ cells, but negative melanoma markers; *BRAF* V600E mutation in ~50%
Small cell GBM pattern	Mostly older adults with rim-enhancing cerebral masses, although roughly one third are nonenhancing initially (early stage)	Monomorphous small rounded to oval nuclei with delicate chromatin and occasional clear haloes, but high mitotic index	IDH-wildtype (100%), monosomy 10 (~95%), *EGFR* amplification (~70%)
GBM with primitive neuronal component pattern	Mostly adults with rim-enhancing masses and foci of markedly restricted diffusion on MRI	Diffuse glioma showing sharply demarcated hypercellular nodules with primitive neuronal features ("small blue cells," mitoses, molding, apoptotic cells, Homer Wright rosettes)	Gain of neuronal (e.g., SYN, NFP, Neu-N) and relative loss of glial (e.g., GFAP, OLIG2) phenotype in primitive foci; IDH-mutant or wildtype, monosomy 10, *MYC* or *MYCN* amplification
Glioblastoma, IDH-mutant, WHO grade IV	Mostly corresponds to "secondary GBM" with history of prior lower-grade astrocytoma; may also appear de novo	Classic GBM histology, including MVP and/or necrosis, often with microcystic foci as well	IDH1-R132H+ by IHC or *IDH1/2*-mutant by sequencing, p53+, ATRX–*, 10q LOH common, but *EGFR* alterations rare

Table 43.1 Clinicopathologic and molecular features of integrated WHO 2016 glioma diagnoses—cont'd

WHO 2016 DIAGNOSIS	CLINICAL CORRELATES	HISTOLOGIC CORRELATES	COMMON IHC AND MOLECULAR FEATURES
Glioblastoma, NOS, WHO grade IV	Same as IDH-wildtype counterpart	Same as IDH-wildtype counterpart	Diagnosis based on histology alone
Diffuse midline glioma, H3-K27M-mutant, WHO grade IV	Mostly children and young adults with midline (e.g., thalamus, brainstem, spine) gliomas	Wide histologic spectrum and may even appear low-grade; multinucleated cells more common	Mutant H3 K27M+ tumor cells by IHC or mutations of the *H3F3A* or *HIST1H3B/C* genes by sequencing
Oligodendroglioma, IDH-mutant, and 1p/19q-codeleted, WHO grade II	Mostly young to middle-age adults with cerebral nonenhancing masses	Rounded nuclei, delicate chromatin, crisp nuclear membranes, clear haloes, rich chicken-wire capillary network	IDH1-R132H+ by IHC or *IDH1/2*-mutant by sequencing, 1p/19q codeletion by FISH, LOH, or genomic techniques; ATRX-ret, p53 LI <10%‡
Oligodendroglioma, NOS, WHO grade II	Same as IDH-mutant counterpart	Same as IDH-mutant counterpart	Diagnosis based on histology alone
Anaplastic oligodendroglioma, IDH-mutant and 1p/19q-codeleted, WHO grade III	Same as grade II counterpart	Same as grade II cases but often with large epithelioid cells, macronucleoli; high mitotic index, MVP, and/or necrosis	IDH1-R132H+ by IHC or *IDH1/2*-mutant by sequencing, 1p/19q codeletion by FISH, LOH, or genomic techniques
Anaplastic oligodendroglioma, NOS, WHO grade III	Same as IDH-mutant counterpart	Same as IDH-mutant counterpart	Diagnosis based on histology alone
Oligoastrocytoma, NOS, WHO grade II†	Mostly young adults with cerebral, nonenhancing T2/FLAIR bright masses	Diffuse glioma with either mixed or equivocal morphologic features	Diagnosis based on histology alone
Anaplastic oligoastrocytoma, NOS, WHO grade III†	Mostly nonenhancing or focally enhancing cerebral masses	Same as above but with high-grade features	Diagnosis based on histology alone

Italicized entities and variants are currently considered provisional, pending additional scientific validation.
+, positive by IHC; –, negative by IHC. (Diffuse midline gliomas have yet to be assigned a WHO grade but have typically been highly aggressive [GBM-like] in the literature.) GFAP, glial fibrillary acidic protein; MVP, microvascular proliferation; NFP, neurofilament protein; SYN, synaptophysin.
*Tumoral loss of protein expression with retained expression in non-neoplastic cells providing a positive internal control. ATRX-ret, retained expression in tumor cells.
†When ancillary testing is applied, nearly all diffuse gliomas show molecular features of one of the more specific astrocytoma or oligodendroglioma diagnoses listed above; as such, the diagnosis of mixed gliomas (oligoastrocytomas) is limited to cases for which molecular testing is either unavailable or yields nondiagnostic findings. Nevertheless, it should be noted that extremely rare examples have been reported of oligoastrocytomas with discrete areas showing astrocytoma-like integrated morphology/molecular features and other areas showing oligodendroglioma-like integrated features. Similarly, cases that were previously diagnosed as "glioblastoma with an oligodendroglial component" (i.e., grade IV oligoastrocytoma) in the WHO 2007 scheme are now typically reclassified in the WHO 2016 scheme using molecular techniques as: (1) GBM, IDH-wildtype, (2) GBM, IDH-mutant, or (3) anaplastic oligodendroglioma, IDH-mutant, 1p/19q-codeleted.
‡Only rare oligodendrogliomas show strong p53 immunostaining in >10% of tumor cells, but such cases also demonstrate the diagnostic combination of IDH mutation and 1p/19q codeletion.

genetic profiles, and clinical behavior. For example, in addition to the major stratification of IDH-mutant versus IDH-wildtype tumors, there are major genetic and biologic differences in some of the pediatric/young adult counterparts and within different anatomic locations (e.g. pediatric low-grade gliomas with *FGFR1* or *MYB* alterations, H3 K27M-mutant diffuse midline gliomas, *BRAF* V600-mutant epithelioid glioblastomas, and H3 G34R/V-mutant high-grade hemispheric gliomas).

Diffusely Infiltrating Astrocytomas of Either IDH–Mutant Type or IDH–Wildtype

Diffusely infiltrating astrocytomas constitute the largest group, featuring an inherent tendency to biologic progression that reflects a stepwise accumulation of defined genetic abnormalities.[278] The tumor initiating events in the common sporadic forms have yet to be completely elucidated, although spontaneous mutations of the isocitrate dehydrogenase *(IDH)* gene complex, particularly *IDH1*, represent the earliest (possibly initiating) and most common genetic alterations in WHO grade II–III diffuse astrocytomas, secondary glioblastomas arising from these lower-grade precursors, and WHO grade II-III oligodendrogliomas.[279-281] Although traditionally divided on cytologic grounds into **fibrillary**, **gemistocytic**, and **protoplasmic** cell types, only gemistocytic is considered a sufficiently unique variant for inclusion in the 2016 WHO scheme. The fibrillary type, named for the filamentous cytoplasmic processes that lend to their constituent cells a resemblance to non-neoplastic "fibrous" astrocytes, is by far the most frequently encountered; as such, it is considered the de facto subtype when discussing diffuse astrocytomas in general. Nevertheless, the fibrillary processes often blend imperceptibly with background neuropil, such that most display an appearance of "naked nuclei" (Fig. 43.34). The protoplasmic type has never been objectively defined (i.e. the typical "cobweb-like" pattern is also encountered in some oligodendrogliomas and pilocytic astrocytomas), is poorly reproducible among pathologists, and is not known to be associated

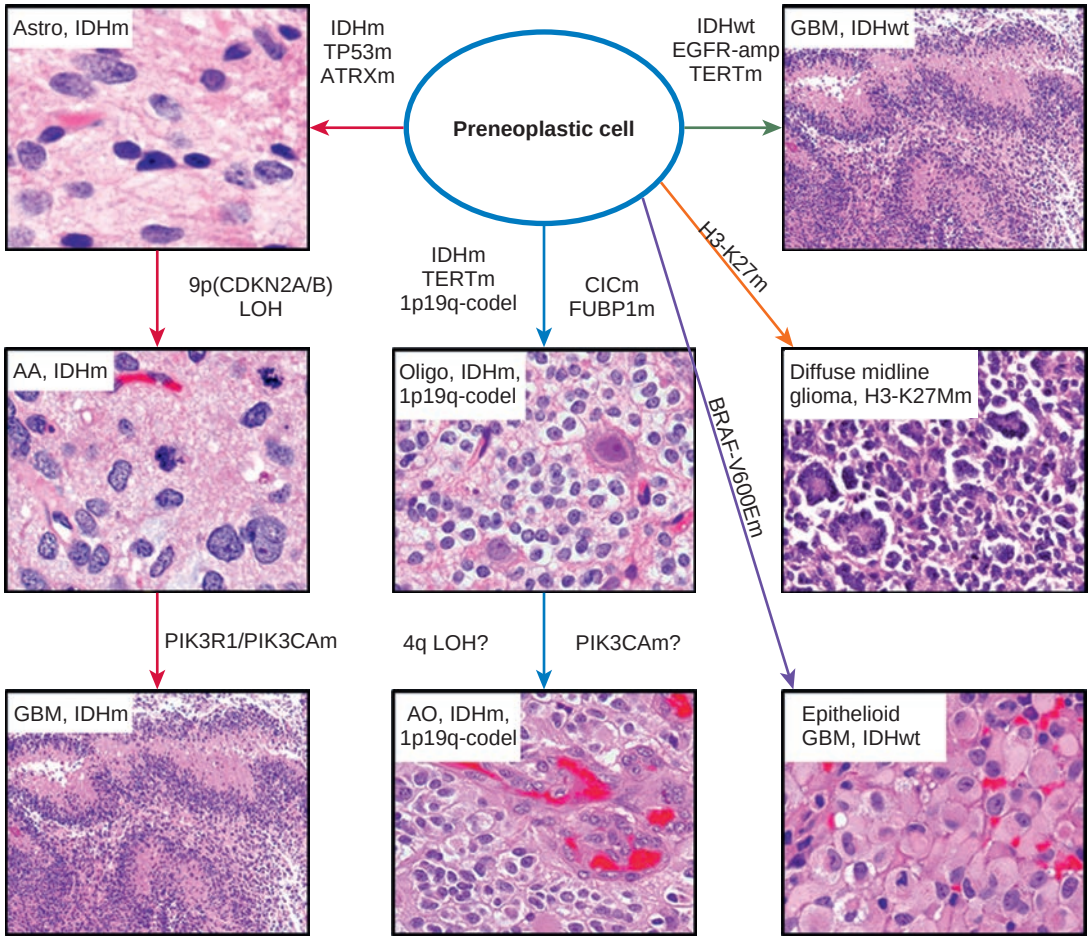

Figure 43.33 Genetic Model of Diffuse Gliomas. The left and middle columns represent the IDH-mutant subtypes, while the right column represents the most common IDH-wildtype categories. m, mutant; wt, wildtype; 1p19q-codel, 1p/19q codeletion

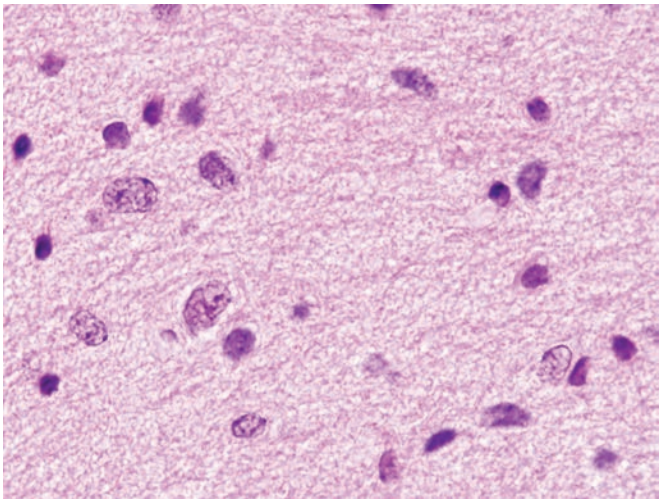

Figure 43.34 Diffuse Astrocytoma With Fibrillary Cytology. Note the appearance of "naked nuclei" with tumor cells seemingly embedded in a fibrillar background but containing irregular hyperchromatic nuclei with no discernable cytoplasm.

with a specific molecular phenotype, and thus it has been discarded from the latest WHO classification.

Diffuse astrocytic neoplasms often contain a minor complement of large tumor cells characterized by eccentric globose "bellies" of glassy eosinophilic cytoplasm and peripherally displaced nuclei that seem on the verge of extrusion from their parent cell bodies (Fig. 43.35). Termed gemistocytes (from the Greek *gemistos* for laden or full), these reflect an accumulation of glial-type intermediate filaments (GFAPs) that form compacted paranuclear whorls and extend into stout cytoplasmic processes. The designation of **gemistocytic astrocytoma** has been subjectively applied to tumors harboring these elements in varying density, but current WHO guidelines endorse the suggestion that gemistocytes constitute at least 20% of the neoplastic population by definition.[278] Gemistocytic astrocytomas are virtually restricted to the cerebral hemispheres of adults. They often exhibit conspicuous perivascular infiltration by lymphocytes and typically contain small, poorly differentiated neoplastic cells that appear more actively proliferative than their large-bodied companions in MIB-1 (Ki-67) immunolabeling studies.[282] Aberrant nuclear immunolabeling for p53 is commonly seen, a phenomenon that reflects the prevalence of *TP53* gene mutations in this variant. Recent studies suggest that they harbor *IDH* mutations slightly less often than fibrillary types (74% vs. 92%) and inactivate the *RRAS* and *ERCC1* genes in subsets of tumors but otherwise show similar genetic patterns to those of lower-grade IDH-mutant astrocytomas.[283]

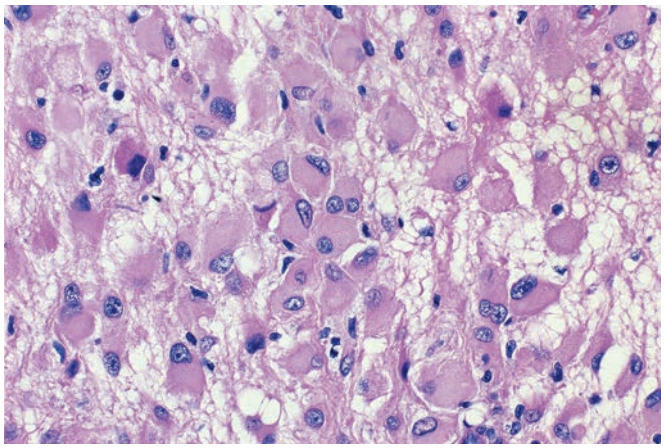

Figure 43.35 Gemistocytic Astrocytoma. Heavily dominated on initial resection by the large gemistocytes shown here, this example recurred 11 months after radiotherapy and chemotherapy. Re-resection demonstrated progression to glioblastoma. Note that these cells retain the oval and somewhat vesicular nuclei of astrocytes. For a comparison with the "minigemistocytic" variant of oligodendroglioma, see Fig. 43.61B.

Gliovascular structuring may be apparent, defined as radially arranged gemistocytes projecting short cytoplasmic processes towards centering blood vessels to form pseudorosettes that may bring ependymoma or astroblastoma to mind. However, the latter tumor types do not permeate neuroparenchyma in the diffuse fashion of gemistocytic astrocytoma. Care must also be taken lest the designation of gemistocytic astrocytoma be applied to oligodendroglial tumors composed of diminutive "mini"-gemistocytes, or to the exceptional oligodendroglioma undergoing macrogemistocytic change with tumor progression. These usually do not manifest perivascular lymphocytic cuffing, may exhibit a distinctively lobular or pavement-like architecture, and almost invariably harbor more classic clear cell features elsewhere. Furthermore, oligodendrogliomas usually display little or no nuclear p53 immunoreactivity (*TP53* mutations being uncommon) and, instead, feature combined chromosomal 1p and 19q deletions.

Gemistocyte-rich astrocytomas are currently graded in the same fashion as conventional astrocytomas. However, while acknowledging that the WHO grade II tumors do not automatically behave aggressively, our experience conforms to that of others who have found that gemistocytic astrocytomas tend to progress more rapidly.[282,284] It is for these reasons that the WHO classifies these as a distinct variant. Nevertheless, the majority of such studies preceded the molecular era, and it is possible that the *IDH* mutation status supersedes the negative prognostic implication when considering the morphology in isolation.

Diffuse (fibrillary) astrocytomas afflict subjects of all ages and may arise at any level of the central neuraxis, but cerebral hemispheric examples in adults are by far the most common. Here, they are characteristically centered in white matter, with a smaller subset of biologically distinct tumors originating in midline structures, such as the basal ganglia, thalami, brainstem, and spinal cord (discussed later under diffuse midline glioma, H3 K27-mutant). Headaches, seizures, focal sensorimotor deficits, and alterations of affect are the principal clinical manifestations of supratentorial lesions. Exceptional variants are situated entirely within the leptomeninges and subarachnoid space, where they may derive from heterotopic neuroglial rests.[285,286]

Neuro-oncologic practice now demands that the diffuse fibrillary astrocytomas be subclassified according to their molecular features and histologic grade. We endorse the three-tiered WHO system, stratifying tumors into **diffuse astrocytoma (WHO grade II)**, **anaplastic astrocytoma (WHO grade III)**, or **glioblastoma (WHO grade IV)**, according to histologic features along with the molecular substratifier of IDH-mutant or IDH-wildtype. Given that the majority of the WHO grade II–III examples are IDH-mutant, one must always consider other diagnostic possibilities for the infrequent IDH-wildtype examples, including early or undersampled glioblastomas, rarer "pediatric" molecular subtypes of diffuse glioma, and more favorable entities, such as pilocytic astrocytoma, pleomorphic xanthoastrocytoma, ganglioglioma, and others. The diagnosis of glioblastoma is generally reserved for astrocytic tumors of the highest grade and not applied to poorly differentiated gliomas of oligodendroglial or ependymal lineage. We would again emphasize the disheartening tendency of the diffuse astrocytoma, however differentiated and indolent at inception, to grow increasingly histopathologically alarming and clinically aggressive with the passage of time. A consequence of this inherent instability that affects diagnosis and management is the resulting regional heterogeneity for which this neoplasm is notorious, and in which zonal variations in histologic appearance and proliferative activity potentially confound the interpretation of limited tissue samples.

Well-differentiated diffuse astrocytomas (WHO grade II) typically present in the third or fourth decade of life and are less common after age 50 (beyond which higher grade forms predominate). A protracted preoperative course characterized by intermittent seizures or headache unassociated with focal neurologic deficits is particularly suggestive of a slowly evolving supratentorial astrocytoma (or other low-grade neoplasm). Complaints referable to such lesions may be present for years prior to their discovery, although the advent of sophisticated neuroradiological techniques has considerably shortened the average predetection interval. As low-grade astrocytomas do not usually provoke significant neovascularization of the infiltrated neural parenchyma, they appear in CT scans and T1-weighted MR images as nonenhancing low-density regions, given that contrast enhancement typically reflects blood–brain barrier disruption (Fig. 43.36). The presence of such enhancement suggests that a lesion shown by biopsy to be an astrocytoma has undergone focal anaplastic progression and should prompt careful review of postoperative neuroradiological studies to ascertain the adequacy of the biopsy (or lack thereof). In other non-enhancing examples, the lesion may best be appreciated on fluid-attenuated inversion recovery (FLAIR) or T2-weighted MR images (Fig. 43.37).

Grossly, WHO grade II astrocytomas are spatially indistinct, producing a diffuse expansion and induration of permeated CNS structures along with a highly characteristic blurring or effacement of gray–white landmarks (Fig. 43.38). They may acquire a somewhat mucoid consistency as a result of myxoid change but are not prone to spontaneous hemorrhage or necrosis. Histologic study typically discloses a cellular infiltrate percolating through recognizable neuropil in a patternless array, or with secondary structure formation (subpial aggregation, perivascular condensation, and/or perineuronal satellitosis) that stands in sharp contrast to the even distribution of hyperplastic astrocytes in reactive glial proliferations (Fig. 43.39). A common architectural feature of immeasurable utility in establishing the neoplastic nature of the process in question is microcystic change (Fig. 43.40), an alteration to which a variety of glial neoplasms (generally low grade) are prone but rarely, if ever, encountered in a reactive setting. A similar, though less specific, significance is attached to the finding of scattered calcospherites. A conspicuous admixture of foamy macrophages, on the other hand, militates strongly against the diagnosis of astrocytoma in the absence of prior therapy, and should instead prompt considerations of demyelinating disease and infarction. Conspicuous lymphocytic cuffing of regional blood vessels,

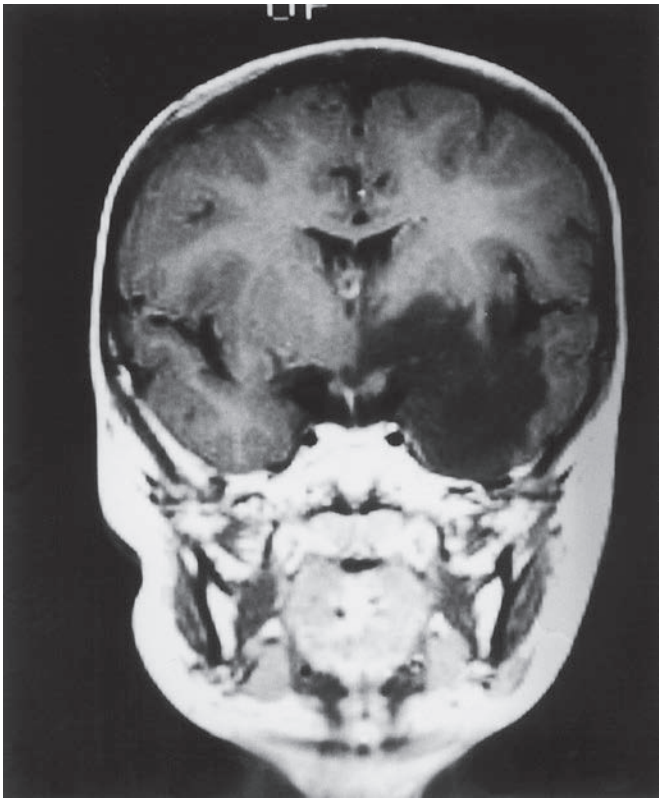

Figure 43.36 Diffuse Astrocytoma. Neuroradiological features common to the low-grade fibrillary astrocytoma in postcontrast magnetic resonance imagings, such as this temporal example, include generalized expansion and hypodensity of infiltrated regions with only modest mass effect, and no foci of bright signal enhancement that would indicate blood–brain barrier disruption.

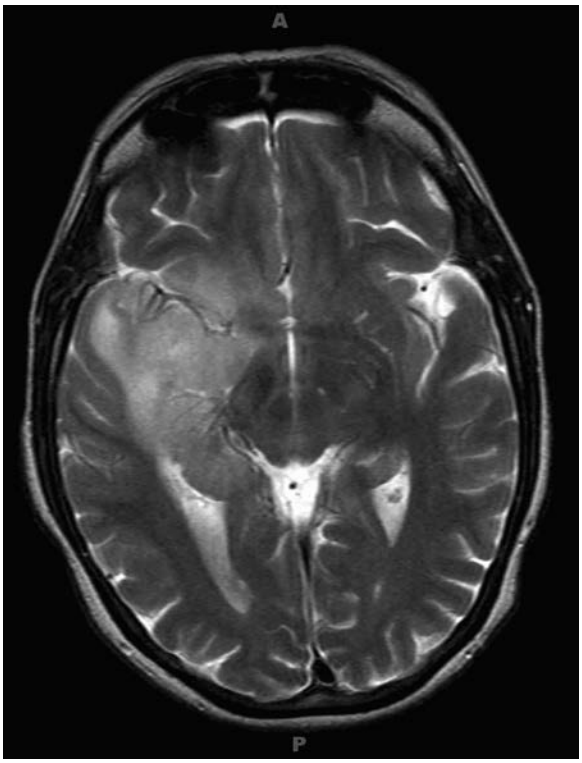

Figure 43.37 Diffuse Astrocytoma. T2-weighted magnetic resonance imaging showing an ill-defined fronto-temporal mass with increased signal intensity.

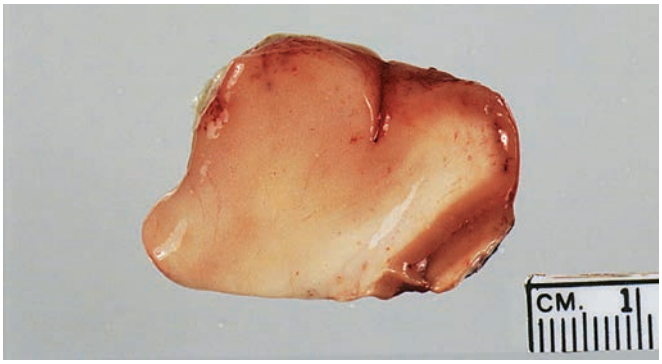

Figure 43.38 Diffuse Astrocytoma. The insidious permeation typical of the fibrillary astrocytoma is illustrated in this anterior temporal lobectomy specimen. The gyrus at right maintains a clearly demarcated cortical ribbon over its digitate white matter. Moving to the left, there is diffuse gyral expansion and effacement of these landmarks, reflecting tumoral infiltration. No discrete mass is formed, and, as is characteristic of low-grade examples, there is no evident hemorrhage or necrosis (see Fig. 43.48 for comparison).

the hallmark of inflammatory CNS disorders, occasionally attends conventional astrocytic neoplasms but among neuroepithelial tumors is most common in gemistocytic astrocytoma, pleomorphic xantho-astrocytoma, and ganglioglioma. Finally, by definition, WHO grade II astrocytoma should not reveal foci of microvascular proliferation (MVP), increased mitotic activity, or zones of necrosis.

At the cytologic level, astrocytomas of fibrillary type are composed, at least in part, of cells invested with delicate processes that taper from a modest perinuclear expanse of eosinophilic cytoplasm or are represented only as a background meshwork in which "naked" nuclei appear to lie embedded (see Figs. 43.34 and 43.39). These may be unipolar or multipolar but, in contrast to the cytoplasmic extensions characteristic of hyperplastic astroglia, do not usually sprout from the cell body in the radial, stellate array for which the astrocyte is named. They are particularly arresting in smear or crush preparations (Fig. 43.41), which are indispensable adjuncts (and expedient alternatives) to frozen section for purposes of intraoperative consultation. On ultrastructural study,[287] these processes contain bundles of 7–11 nm ("intermediate") filaments composed of GFAP, the principal cytoskeletal constituent elaborated by human astrocytes, and vimentin. Nuclei are typically oval in configuration with smooth contours, do not contain conspicuous nucleoli, often have a vesicular quality, but may be somewhat hyperchromatic.

Predisposing Factors. While most diffuse astrocytomas are unassociated with clearly predisposing factors, radiation-related cases are clearly recognized and occasional high-grade examples complicate NF1, the Li–Fraumeni (germline *TP53* gene mutation) syndrome, Turcot (brain tumor-polyposis) syndrome 1 (germline mutations in DNA mismatch repair enzymes), and rarer or less well-characterized familial disorders, including the multiple enchondromatosis syndromes known as Ollier or Maffucci disease.[288]

As mentioned previously, the most common and earliest known genetic alteration in the adult form is a gene mutation of *IDH1* or its homolog, *IDH2*. A single point mutation in codon 132 converting

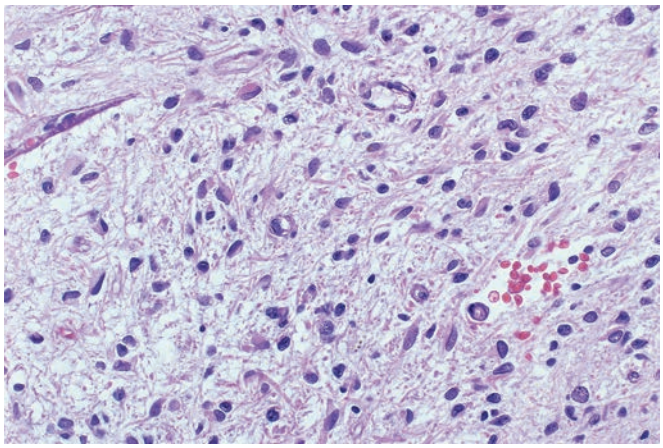

Figure 43.39 Diffuse Astrocytoma. Conspicuous cytoplasmic processes, mild nuclear pleomorphism, and only modest hyperchromasia are evidenced by the cells of this well-differentiated astrocytoma. The absence of mitotic activity supports its classification as a low-grade lesion. Note the dyscohesive growth pattern.

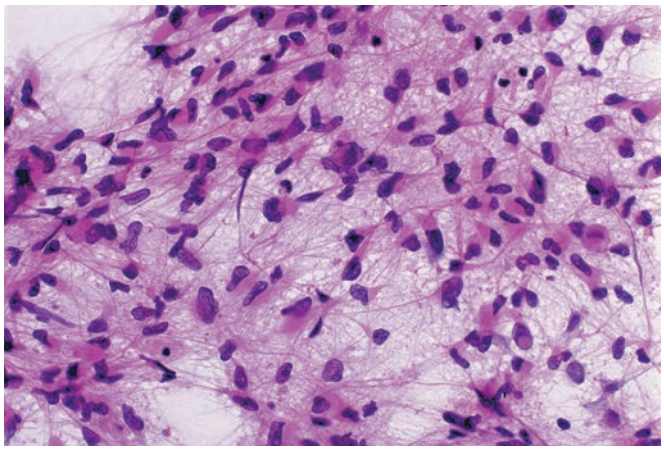

Figure 43.41 Diffuse Astrocytoma. A lack of cellular cohesion and conspicuous cytoplasmic processes—features that serve to distinguish astrocytomas from metastatic carcinomas, lymphomas, and other neoplasms—are apparent in this intraoperative crush preparation.

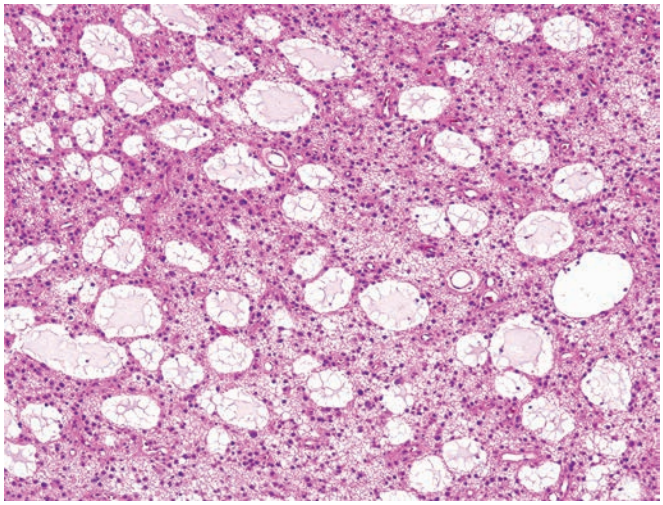

Figure 43.40 Diffuse Astrocytoma. Foreign to reactive astroglial proliferations, microcystic change is a particularly conspicuous feature of some low-grade astrocytomas.

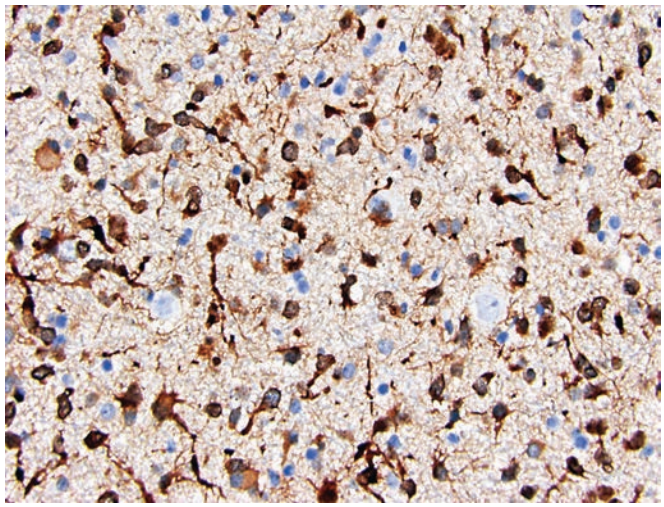

Figure 43.42 Diffuse Astrocytoma, IDH-mutant showing immunoreactivity for the IDH1 R132H mutant protein. Note the immunonegative cortical neurons in the background.

arginine to histidine accounts for up to 90% of all mutations. As such, the R132H mutant–specific immunostain is often used as the initial screening tool to detect this subtype (Fig. 43.42), followed by sequencing of *IDH1* codon 132 and *IDH2* codon 172 (homologous region) to look for rarer mutations in immunonegative examples of appropriately aged patients (most common in older children and adults under 55 years of age). Studies have shown that in most cases of anaplastic astrocytoma, IDH-wildtype tumors behave like primary glioblastoma, suggesting that the majority are either early forms of the latter or simply undersampled. In the case of WHO grade II astrocytomas that are IDH-wildtype, additional differential diagnostic considerations include the pediatric counterpart (more often showing *FGFR1* or *MYB* alterations) and long-term epilepsy-associated tumors (LEATs), such as ganglioglioma, pleomorphic xanthoastrocytoma, and dysembryoplastic neuroepithelial tumor (DNT) (often CD34 and/or BRAF V600E immunoreactive). The great majority of IDH-mutant astrocytomas also harbor mutations of the *ATRX* and *TP53* genes, both of which may be detected, in most cases, using immunohistochemical surrogates. Given its role in chromatin maintenance/remodeling, the alpha-thalassemia mental retardation X-linked (ATRX) protein is ubiquitously expressed in all non-neoplastic nuclei; in contrast, expression is usually lost in astrocytoma cells harboring somatic mutations (Fig. 43.43). In the case of the p53 protein, the half-life is normally so short that *TP53*–wildtype nuclei appear negative, whereas the most common mutations lead to protein stabilization and an "overexpression" pattern (Fig. 43.44). Interpretive care is warranted, however, as there are other scenarios leading to both false-positive and false-negative results by immunohistochemistry alone. One series of 157 diffuse gliomas reported an excellent correlation with *TP53* mutation when there was greater than 10% strong nuclear staining.[289] In terms of a notable example of false positives, JC virus–infected oligodendroglia and astrocytes in PML commonly exhibit strong nuclear p53 expression (as well as MIB-1 reactivity).

The **anaplastic astrocytoma, IDH-mutant (WHO grade III)** often evolves from a well-differentiated precursor lesion of the type just described, a sequence in which deletions of the *CDKN2A/B* genes

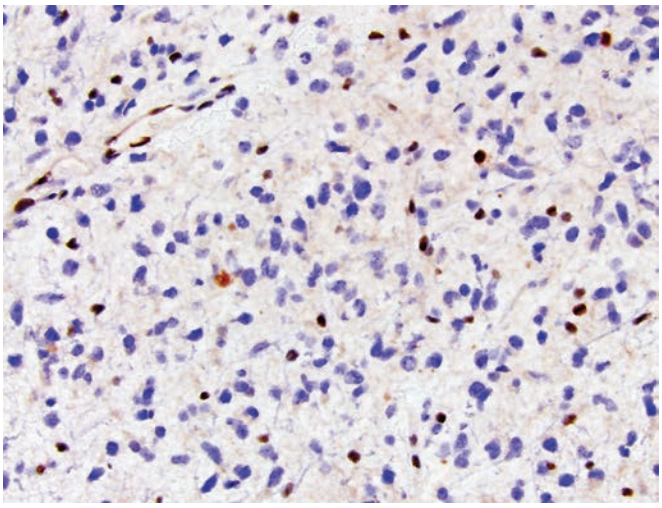

Figure 43.43 Diffuse Astrocytoma, IDH-Mutant. As in this example, most IDH-mutant astrocytomas additionally demonstrate loss of alpha-thalassemia mental retardation X-linked immunoreactivity in tumor nuclei. Note that non-neoplastic cells (endothelial, glial, inflammatory) retain expression serving as an internal positive control.

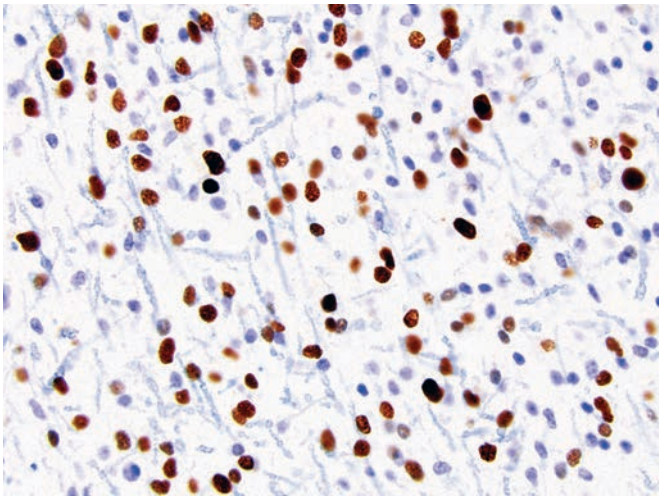

Figure 43.44 Diffuse Astrocytoma, IDH-Mutant. As in this example, most IDH-mutant astrocytomas also show p53 overexpression by immunohistochemistry.

that encode p16, p15, and $p14^{ARF}$, and others are implicated.[278] In contrast, the IDH-wildtype counterpart most often presents de novo and behaves like a primary glioblastoma in addition to showing the associated genetic alterations of the latter, including *TERT* mutations, monosomy 10/*PTEN* deletions, and *EGFR* amplification, among others. Morphologic evidence of tumor progression from a WHO grade II precursor may constitute a focal finding in what would otherwise qualify as a histologically favorable lesion. Microscopic examination of the prototypical case reveals an infiltrate that is at first glance more alarmingly cellular and cytologically atypical than that of the low-grade astrocytoma (Fig. 43.45), although biopsies derived from the tumor–CNS interface may contain only scattered neoplastic elements. Nuclear alterations commonly include angulation, dense hyperchromasia, and considerable variation in contour and dimension. Mitotic figures can be demonstrated and establish the diagnosis, although the precise cutoff required remains uncertain.

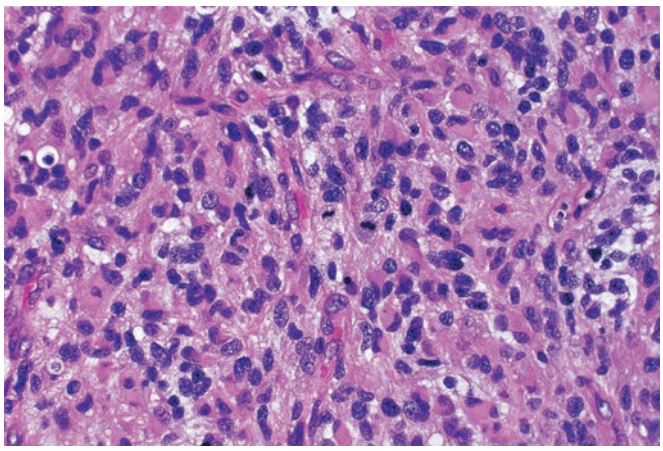

Figure 43.45 Anaplastic Astrocytoma. Compared with its low-grade counterpart (see Fig. 43.39), this lesion exhibits increased cellularity, the cytologic features of a fully malignant neoplasm, and, at center, mitotic figures.

In this regard, we would stress that the solitary mitotic figure found on close scrutiny of a generous biopsy or resection specimen does not an anaplastic astrocytoma make.[290] We will render this diagnosis, however, when confronted by any mitoses in a limited (e.g. stereotactic) neurosurgical sample. Even more importantly, IDH-mutant WHO grade II and III astrocytomas are not always associated with patient survival differences, when applying classically defined grading criteria.[291] As such, it is likely that the mitotic cutoff may ultimately need to be increased in order to avoid overgrading these molecularly defined astrocytomas.

An increase in regional blood vessels is permissible, as is hypertrophy of their lining endothelium, but complex and disorderly proliferation of vasoformative elements or zones of coagulative tumor necrosis in the setting of a diffuse astrocytoma mandate a glioblastoma diagnosis. Glioblastoma-like behavior also characterizes astrocytomas manifesting neither complex MVP nor necrosis, but that are composed predominantly of poorly differentiated and mitotically hyperactive small cell elements.[292] These small cell astrocytomas (covered further later in glioblastoma variants section) are uniformly IDH-wildtype, harbor *EGFR* gene amplification in roughly 70% of cases, and express the glioblastoma-associated mutant *EGFR-vIII* form in about 50%. We report such lesions as "high-grade astrocytomas of small cell type" and, while acknowledging that these fail to satisfy strict histologic criteria for the diagnosis of glioblastoma, comment on their grade IV biologic potential.

Although its unfortunate title would imply a neoplasm of embryonal character, the **glioblastoma (WHO grade IV)** simply represents the most aggressive of the infiltrating astrocytic tumors. "Primary" (mostly IDH-wildtype) and "secondary" (mostly IDH-mutant) variants are recognized, the former occurring de novo (i.e. unassociated with demonstrable precursor lesions), the latter resulting from the expansion of aggressive clones generated within pre-existent WHO grade II or III astrocytomas.[278] Not surprisingly, secondary glioblastomas share the high incidence of *IDH1*, *TP53*, and *ATRX* mutations of their lower-grade precursors.[293] With the exception of *TP53* mutations in roughly a fourth of cases, such abnormalities are rare among primary glioblastomas, these sharing instead a high incidence of *TERT* mutations, allelic losses of chromosome 10/10q, amplification and mutations of the *EGFR* gene on chromosome 7, mutations/deletions of the tumor suppressor *PTEN* gene on chromosome 10q23.3, and *CDKN2A/B* deletions on 9p21.3. *EGFR-vIII*, the major mutant form encountered in glioblastomas, seems highly

associated with such tumors.[278] Whether predictable differences in prognosis attach to these divergent oncogenetic pathways independent of patient age at diagnosis has been controversial. Secondary glioblastomas tend to affect a significantly younger cohort than primary variants (mean ages at presentation being ~40 vs. 55 years, respectively), and by all accounts advancing age per se is inversely correlated with survival in the setting of diffuse astrocytomas. The presence of *IDH* mutation is a highly favorable prognostic indicator per se in this regard, with studies suggesting that IDH-mutant glioblastoma patients have significantly longer survival times than IDH-wildtype anaplastic astrocytomas.[294]

The comprehensive genomic studies of The Cancer Genome Atlas Network and others have shown that glioblastomas are biologically far more complex than their division into the foregoing types and that there are perhaps at least six molecular subtypes, each with distinct demographic, anatomic, and clinical features.[295] In addition to the IDH-mutant group already discussed, there are two groups with mutations of the histone H3 subsets (*H3F3A* gene encoding H3.3 and less commonly, the *HIST1H3B* encoding H3.1; see Table 43.1 and Fig. 43.32). Whereas K27M mutations of either gene are associated with a highly aggressive new WHO entity, known as "diffuse midline glioma, H3 K27M mutant" (mostly thalamus, brainstem/pontine, and spinal gliomas), G34R/V mutations of the *H3F3A* gene are associated with more laterally localized hemispheric glioblastomas with a somewhat better, intermediate level prognosis.[295-298] Both affect predominantly children and young adults and are associated with relatively wide morphologic spectrums, including overrepresentation of giant cells in the K27M variant and a primitive-appearing subtype mimicking an embryonal neoplasm in the G34R/V subtype.[297,298] Of note, the H3 K27M variant is immunohistochemically detectable using mutant-specific antibodies (Fig. 43.46). Other genomically defined IDH-wildtype molecular subtypes include receptor tyrosine kinase types I (mostly *PDGFRA* amplification/overexpression) and II (mostly *EGFR* amplification/overexpression), as well as a mesenchymal subtype with relatively few copy number alterations.[295] An even rarer form is the epithelioid glioblastoma, which is also associated with younger age, an occasional precursor lesion of pleomorphic xanthoastrocytoma, and an association with *BRAF* V600E mutation (discussed later in greater detail).

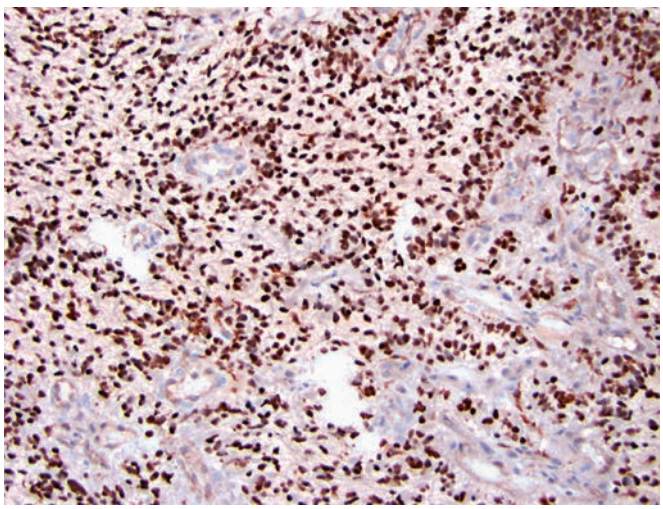

Figure 43.46 Diffuse Midline Glioma (Glioblastoma), H3 K27M-Mutant. This thalamic glioblastoma was characterized as the new WHO entity of "diffuse midline glioma, H3 K27M-mutant" based on immunohistochemical detection of the mutant protein in tumor nuclei.

Like astrocytomas of lower grade, glioblastomas may be discovered on evaluation for seizures or headache but are often attended by subacutely evolving neurologic deficits indicative of their more rapid growth and destructive invasion. A subset present in sudden, stroke-like fashion as a consequence of intratumoral hemorrhage, and occasional examples mimic metastatic disease by virtue of their multifocality.[299] Especially characteristic on CT or MR evaluation is a pattern of ring-like contrast enhancement that reflects their abnormal vascularization and tendency to spontaneous central necrosis (Fig. 43.47). On gross inspection, glioblastomas may seem relatively circumscribed and often appear to be more clearly demarcated from neighboring tissues than their better-differentiated counterparts—deceptively so, inasmuch as neoplastic cells regularly invade neuropil well beyond the apparent tumor perimeter. Hemorrhagic discoloration and foci of yellow softening indicative of coagulative necrosis impart a variegated appearance to most examples that should immediately suggest their virulent nature (Fig. 43.48). Histologically, glioblastoma is a highly cellular and mitotically active neoplasm. Its cytologic makeup is subject to extreme variation (thus the traditional designation of this lesion as glioblastoma "multiforme").

An arresting phenomenon common to many glioblastomas is a complex form of MVP, driven in paracrine fashion by tumor-derived mitogens such as vascular endothelial growth factor (VEGF), in which proliferating blood vessels are lined by hyperplastic (i.e. multilayered) and hypertrophic (i.e. enlarged) cells heaped up in disorderly fashion and sometimes transformed into glomeruloid or solid tufts

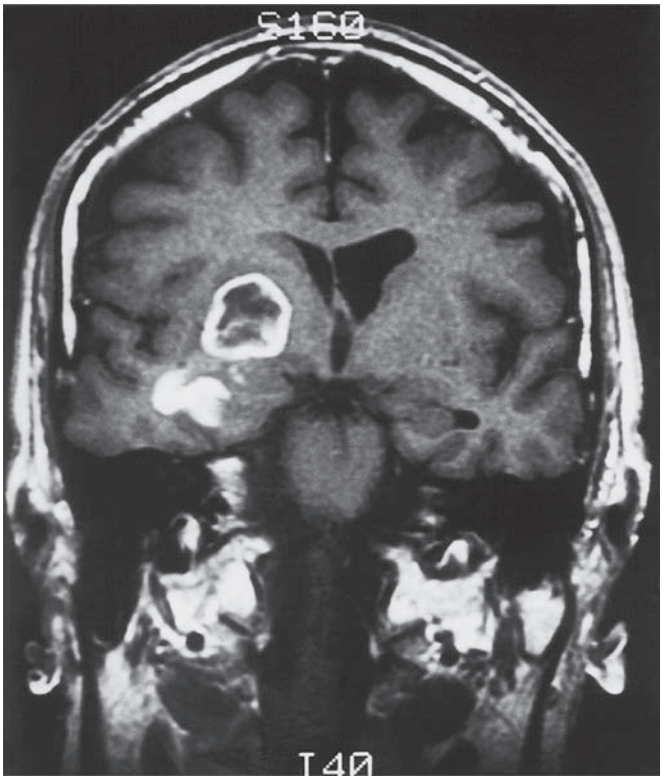

Figure 43.47 Glioblastoma. In postcontrast injection computed tomography or (shown here) magnetic resonance studies, many glioblastomas are characterized by a bright ("enhancing") ring (representing intact, abnormally vascularized tumor tissue in which the blood–brain barrier is disrupted) that surrounds a region of hypodensity (central necrosis). The gyriform temporal lobe enhancement below this basal ganglionic example attests to neoplastic infiltration beyond the deceptively well-delimited ring margin.

Figure 43.48 Glioblastoma. Foci of hemorrhage and geographic yellow discoloration indicative of necrosis impart a variegated appearance to this example.

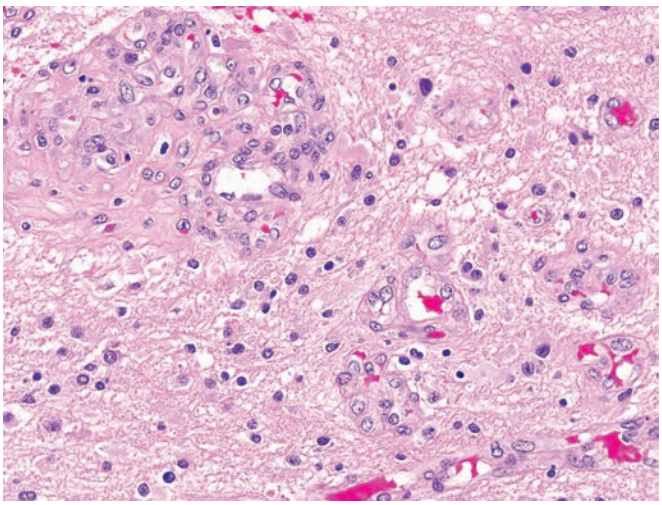

Figure 43.49 Glioblastoma. Note the complex, "glomeruloid" quality of the microvascular proliferation at right. Astrocytic elements are seen at left.

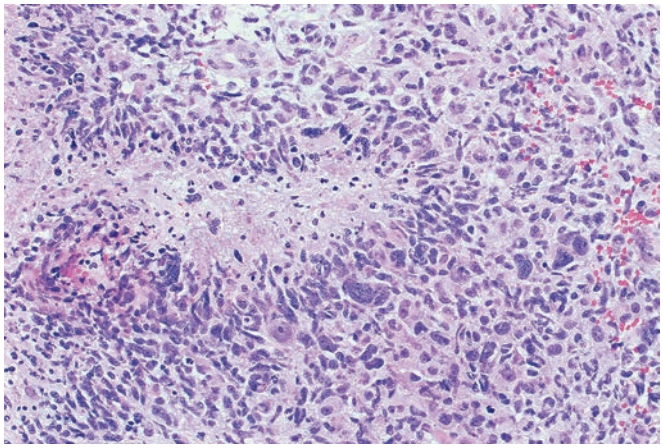

Figure 43.50 Glioblastoma. Dense cellularity, striking pleomorphism, and zones of coagulative necrosis lined by "palisading" tumor cells characterize the prototypical glioblastoma.

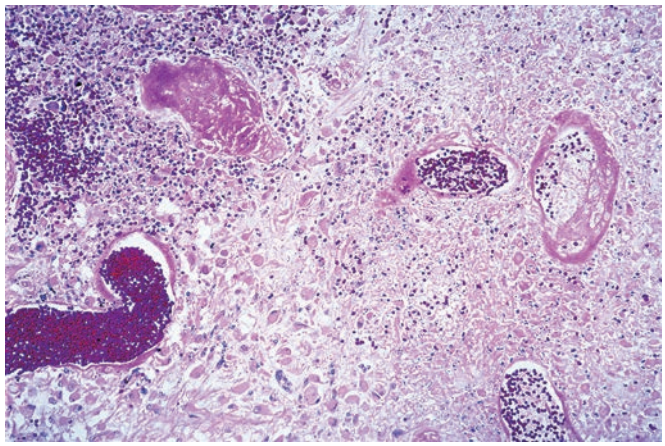

Figure 43.51 Radiation Effects. A marked reduction in cellularity, extensive necrosis, and necrotizing fibrinoid vasculopathy with vascular thrombosis and ectasia typify astrocytic neoplasms injured by irradiation.

(Fig. 43.49). Although often referred to simply as "endothelial" hyperplasia, this process involves a number of vessel-associated cell types, prominent among which are pericytic/myoid elements expressing smooth muscle–related antigens.[300,301] Its identification in neurosurgical material from patients not previously subjected to radiation therapy suffices for a diagnosis of glioblastoma by WHO criteria, as does the finding of focal coagulative tumor necrosis regardless of whether neoplastic cells align themselves about such zones in the prototypical palisades that are a "textbook" feature (Fig. 43.50).

Irradiation induces a variety of morphologic alterations in glioblastomas, the most predictable being widespread necrosis without surrounding increased tumor cell density (usually much reduced) and vasculopathic changes that include ectasia, fibrinoid necrosis, hyalinization, and obliterative mural fibroplasia (Fig. 43.51). Florid astrogliosis and infiltration by macrophages, the latter identifiable by their immunoreactivity for HAM-56, CD68, and other histiocytic markers, may complicate the recognition of neoplastic elements. Some re-resection specimens, in fact, consist solely of necrotic debris or contain only scattered atypical cells, including treatment-related, grotesque cells with karyomegaly, dense hyperchromasia, chromatin smudging and nuclear vacuolization. Although these cells are often neoplastic, albeit damaged, it may be difficult to distinguish them from hyperplastic non-neoplastic astrocytes displaying radiation atypia. From the opposite perspective, residual IDH-mutant astrocytoma cells may appear remarkably similar to reactive astrocytes cytologically (Fig. 43.52). Nevertheless, these elements do not imply disease progression and a need to shift therapy, and we report such specimens as exhibiting treatment effect with only minimal evidence of persistent (albeit "injured") tumor. The diagnosis of progression/recurrence rests on firmest grounds when aggregates of cytologically unaltered and mitotically active tumor cells can be demonstrated, and cellular palisading around foci of necrosis also constitutes unimpeachable testimony to treatment failure. In some instances, the necrotizing and vasculopathic changes described here will be found to involve brain tissue (typically white matter, which is

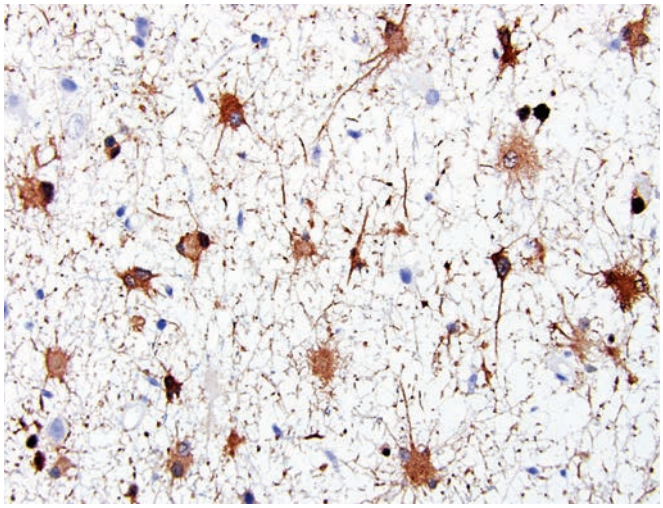

Figure 43.52 Radiation Effects. IDH1 R132H immunohistochemistry highlights residual postradiation astrocytoma cells with radiating processes, resembling reactive astrocytes.

particularly susceptible to ionizing irradiation) manifesting no tumoral infiltration. This toxic process (cerebral radionecrosis) characteristically interrupts a period of apparent remission and neurologic recovery measured in months (or, in some cases, years) and may mimic post-therapy relapse to clinical and neuroradiological perfection.

Gliosarcoma (the GBM Variant) and Other "Gliomesenchymal" Tumors

CNS tumors characterized by mixed neuroepithelial and mesenchymal features are a heterogeneous lot. We have previously alluded to the emergence of sarcomatous elements from neoplasms of the astrocytic, oligodendroglial, and ependymal series. The overwhelming majority of glial tumors manifesting this phenomenon are glioblastomas, and the designation of **gliosarcoma**, employed without qualification, is generally taken to connote a glioblastoma variant[302] (as opposed to "oligosarcoma"[303,304] or "ependymosarcoma"[305]). It has been suggested that approximately 2% of otherwise conventional glioblastomas generate malignant components of mesenchymal type,[278] and only gliosarcomatous neoplasms of this, the most common, type are accorded more extended treatment here. Clinically, some are divided into "primary" or "secondary" forms, based on whether or not they presented as gliosarcoma de novo or the sarcomatous component only arose after recurrence of a classic glioblastoma.[302,306,307] However, this should not be confused with the more common use of the terms primary and secondary in glioblastoma to refer to mostly IDH-wildtype versus IDH-mutant glioblastomas, respectively, the latter of which mostly arise from lower-grade astrocytoma precursors.

The great majority of gliosarcomas correspond clinically and molecularly to the primary or IDH-wildtype glioblastoma variant, with the exception that *EGFR* amplification is rare.[278] Nevertheless, occasional examples arise secondarily from lower-grade IDH-mutant diffuse gliomas.[302,308] Most arise in the absence of recognized predisposing factors, but gliosarcomas have also been associated with prior irradiation, including the intracranial instillation of Thorotrast.[309] At operation, many are initially mistaken for cerebral metastases or (when attached to the dura) meningiomas, errors resulting from their characteristic circumscription and firm textures. These attributes in turn reflect the high content of connective tissue fibers typical of the gliosarcoma but foreign to most other neuroepithelial neoplasms. A marmoreal admixture of gliomatous and sarcomatous tissues lends

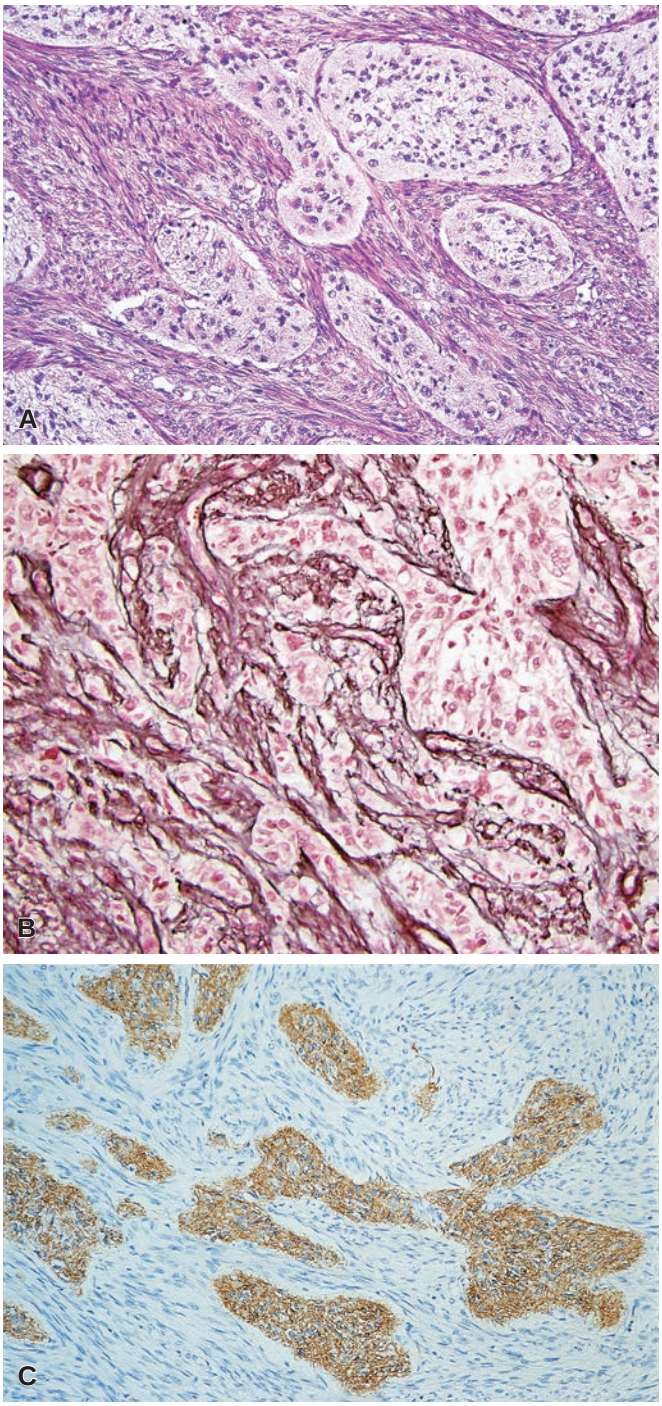

Figure 43.53 Gliosarcoma. A, Islands of astrocytic tumor tissue lie embedded in what otherwise appears to be a spindle cell sarcoma. **B,** Only the sarcomatous regions show dense intercellular reticulin deposition. In contrast, on immunoperoxidase assay **(C)**, only astrocytic elements mark with glial fibrillary acidic protein.

to these tumors a strikingly biphasic architecture on histologic study (Fig. 43.53A). The mesenchymal components would prompt the diagnosis of fibrosarcoma or undifferentiated pleomorphic sarcoma in a soft tissue setting, but chondro-osteogenic and myogenic differentiation may be encountered in this setting, and variants harboring angiosarcomatous, liposarcomatous, and mixed mesodermal-type elements have also been reported.[278,310-313] Squamous differentiation,

"adenoid" formations, and glandular structures may also be displayed within the glial regions of select cases.[314]

Distinction of the gliosarcoma's dimorphic constituents can be further accomplished using a combination of traditional histochemical and immunocytochemical techniques. Sarcomatous components are richly invested with connective tissue fibers demonstrable by reticulin impregnation methods (see Fig. 43.53B) and preparations for collagen, such as the Mallory trichrome stain, but do not express GFAP, the reverse being true of the glial population (see Fig. 43.53C). The identification of an architecturally and cytologically distinct, GFAP-negative component is requisite to the segregation of the true gliosarcoma from collagenized, spindle cell ("desmoplastic") glioblastomas and gliomas associated with a florid fibroblastic reaction by virtue of meningeal invasion. Similarly distanced from neoplasms of gliosarcomatous character are variants of astrocytoma and ependymoma that give rise to well-differentiated, GFAP-immunoreactive cartilaginous elements,[311] as well as "liposarcomatous,"[315] adipocyte-like constituents that retain GFAP expression.

The "malignant degeneration" of blood vessel–associated stromal elements was first held to account for the genesis of sarcomatous populations within glioblastomas.[316] The latter, as previously discussed, often manifest a florid and complex MVP driven by the tumoral elaboration of mitogens that act on endothelium, pericytes, smooth muscle cells, and fibroblasts. Each of these cell types came to be championed as a target of transformation within evolving gliosarcomas, as did histiocytes, myofibroblasts, and uncommitted adventitial elements. That this autocrine phenomenon could eventuate in sarcomatous outgrowth—a notion originally based on perceived histologic transitions from the hyperplastic to unarguably neoplastic—received only qualified support, however, from immunohistochemical and electron microscopic observations.

A rival histogenetic view of "metaplasia" favored neoplastic glial cells simply undergoing phenotypic shift with tumor progression, losing GFAP expression and assuming mesenchymal attributes.[317] Powerful backing for this scenario derives from molecular genetic studies demonstrating that gliomatous and sarcomatous components may harbor identical *TP53* and *PTEN* mutations, p16 (*CDKN2A*) deletions, and coamplifications of *CDK4* and *MDM2*. Whether a subset of tumors accorded this designation might still represent true composites, as opposed to neometaplastic lesions of clonal character, is arguable. The clonal nature of oligosarcomas and ependymosarcomas is similarly supported by shared patterns of chromosome 1p/19q codeletion[303,304] and of NF2/protein 4.1 gene family alterations,[305] respectively.

The designation "**gliofibroma**" has been extended to a heterogeneous group of neoplasms encountered for the most part in childhood, and having in common a population of astrocytes that may be invested by basal lamina material and that are embedded in a variably collagenized matrix.[318,319] Some appear to represent desmoplastic astrocytomas in which neoplastic glia, unaided by mesenchymal derivatives, are directly responsible for the elaboration of connective tissues, whereas other examples contain a second cellular population interpreted as fibroblastic or, in one study, schwannian.[320] The rarity and disparate morphologic features of the tumors reported under this rubric preclude useful generalizations regarding their histogenesis and clinical biology. A number of recorded cases have evidenced conspicuous cytologic atypia and mitotic activity, pursuing an aggressive course (with CSF-borne metastasis) and ending fatally, the benign connotations of the term "gliofibroma" notwithstanding.[318] A more favorable outcome seems to be attached to those lacking features of histologic anaplasia.

This discussion of gliomesenchymal tumors is concluded with passing reference to the various uses of the term "**angioglioma**." Originally applied to what would now be classified as the cellular variant of cerebellar hemangioblastoma, this designation has been most frequently invoked in reference to gliomas exhibiting degenerative vascular alterations resembling AVMs or cavernous angiomas.[321-323] Slow-growing lesions such as pilocytic astrocytomas, oligodendrogliomas, and gangliogliomas seem especially prone to such changes. These may appear hypervascular on angiographic study, exhibiting a tumoral "blush," but as a rule do not evidence the shunting characteristic of true AVMs. Only exceptionally are the latter found in contiguity with glial neoplasms. Most such lesions are regarded as "collision" tumors in which gliomatous and malformative tissues are fortuitously associated, but isolated reports of glial neoplasms secondarily arising at the sites of pre-existent AVMs and angiomas suggest that the gliotic reaction typical of tissues surrounding such longstanding vascular anomalies may rarely progress to neoplasia. A strikingly increased concentration of oligodendrocytes in and around some AVMs appears to result from "collapse" of chronically edematous and ischemic white matter or to represent part of the malformation process and should not necessarily prompt a diagnosis of oligodendroglioma.[128] Finally, we call attention to a group of exceedingly uncommon tumors interpreted as containing both gliomatous and hemangioblastomatous elements.[323] These, too, have been described as a form of "angioglioma," a nonspecific and potentially misleading term that is best abandoned.

Other Glioblastoma Variants and Patterns

Differentiated elements may be intermingled with bizarre multinucleated tumor giant cells, spindled, epithelioid (including rhabdoid) cells,[324,325] signet ring cells,[326] or small anaplastic forms, altogether devoid of identifying astrocytic features. The last often come to dominate the histologic picture at recurrence, selectively repopulating tumors subjected to therapy, but may also constitute the nearly exclusive elements of select **small cell glioblastomas** at presentation (Fig. 43.54). Given the monomorphism of this subtype and variable presence of arborizing capillaries, microcalcifications, and clear perinuclear haloes, the latter is often mistaken for anaplastic oligodendroglioma but differs from the latter in its lack of IDH1 R132H mutant protein expression and *1p19q* codeletions, as well as frequent chromosome 10 losses and *EGFR* amplification.[292,308]

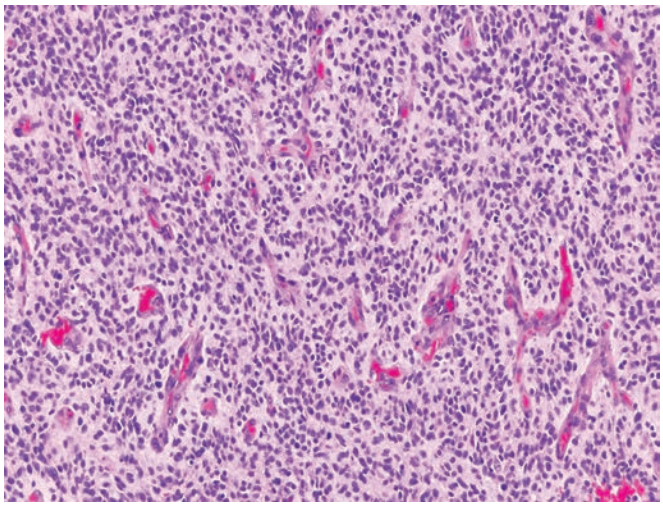

Figure 43.54 Glioblastoma, Small Cell Variant. In contrast to most glioblastomas, the small cell variant is relatively monomorphic with small, round to oval nuclei and minimal discernable cytoplasm. The presence of branching capillaries and clear haloes (not shown here) often invokes a differential diagnosis with anaplastic oligodendroglioma.

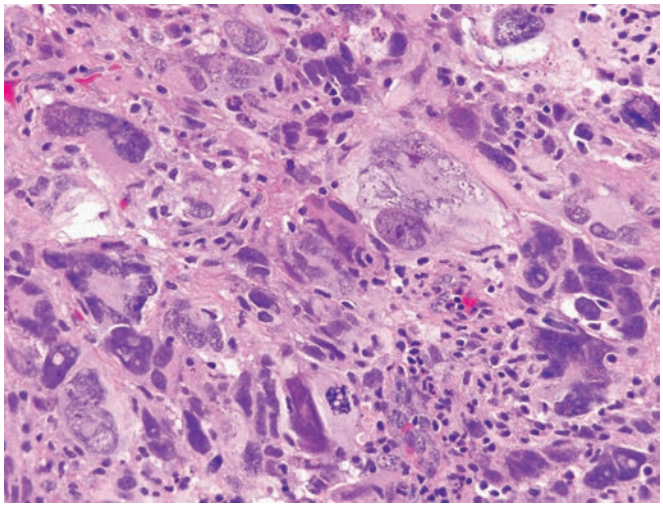

Figure 43.55 Glioblastoma, Giant Cell Variant. This subtype is characterized by numerous bizarre mononucleated and multinucleated giant cells, imparting a marked degree of pleomorphism that often raises a differential with pleomorphic xanthoastrocytoma.

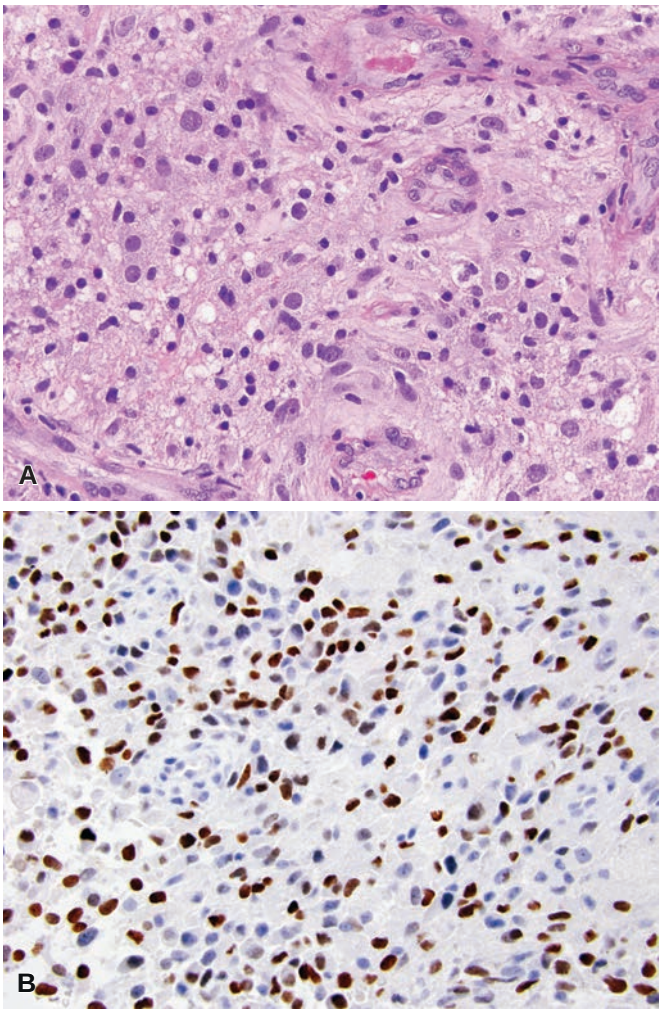

Figure 43.56 Glioblastoma, Granular Cell Variant. Although the granular to vacuolated cytoplasm of tumor cells is reminiscent of macrophages (thus raising a differential diagnosis with demyelinating disease), the larger cell size and presence of microvascular proliferation are clues to its malignant nature **(A)**. Further confirmation of the tumor's glial nature may be established with glial fibrillary acidic protein (not shown) and/or OLIG2 **(B)** immunostains.

Yet another variant, the **giant cell glioblastoma** (Fig. 43.55), shares with the secondary glioblastoma a younger patient age at onset, frequent *TP53* mutation, and lack of *EGFR* amplification and $p16^{INK4a}$ deletion. However, like the primary variant, it arises in the absence of a differentiated precursor lesion, is usually IDH-wildtype, is associated with a brief predetection clinical interval, and often manifests *PTEN/MMAC1* gene mutation.[327] Although most astrocytic neoplasms under discussion are confidently distinguished from primary cerebral sarcomas and tumors metastatic to the CNS by virtue of their characteristic cytologic features and patterns of infiltration, this one is known for its unusual circumscription, sarcomatoid cytologic features, and reticulin-rich matrix. Once regarded as a "monstrocellular" sarcoma, the glial nature is demonstrated by immunolabeling for GFAP and/or OLIG2. The same can be said for spindled and lipid-rich variants of glioblastoma.[328] Some high-grade astrocytic neoplasms have been misclassified as fibrosarcomas or pleomorphic sarcoma when immunohistochemical studies demonstrated cytoplasmic labeling for such nonspecific antigens as vimentin, α1-antitrypsin, or α1-antichymotrypsin but were not examined specifically for glial markers. The emergence of GFAP-negative sarcomatous components within astrocytic and other glial tumors ("gliosarcoma") was discussed previously (see Gliomesenchymal tumors). Still other aggressive and poorly differentiated astrocytic tumors contain glandular or gland-like ("adenoid") formations,[314] undergo squamous metaplasia, or assume clear cell cytologic features (owing to cytoplasmic lipidization) and a cohesive disposition in nests and sheets that bring "balloon cell" melanoma and carcinomas of renal or adrenocortical origin to mind.[329] Immunolabeling for cytokeratin and EMA may further conspire to obscure the glial lineage of these metaplastic elements in other astrocytic neoplasms. We emphasize in this regard the regular labeling of reactive and neoplastic astrocytes with the AE1/3 cytokeratin "cocktail" (thought to represent cross reactivity with GFAP) and the fact that they are usually nonreactive with CAM 5.2, CK7, CK20, and the noncytokeratin epithelial marker Ber-EP4.[330]

We further call the reader's attention to the existence of astrocytic tumors that undergo a striking granular cell metamorphosis resulting from the intracytoplasmic accumulation of engorged secondary lysosomes.[331] While these peculiar neoplasms may exhibit remarkably benign cytologic features (Fig. 43.56A), **granular cell astrocytomas** of this type are characterized as a group by a highly aggressive glioblastoma-like clinical course, even when lacking high-grade features such as high mitotic index, MVP, or necrosis. Immunolabeling of their cytoplasm for CD68 can result in the misidentification of such tumors as reactive histiocytic infiltrates, though the invariably intermixed true macrophages are typically much smaller and more intensely immunoreactive. In contrast, the tumor cells are often positive for glial markers, such as GFAP and OLIG2 (see Fig. 43.56B) but negative for histiocyte lineage-specific markers such as CD163.

Astrocytic neoplasms can contain ganglion cell–like forms or poorly differentiated/primitive elements that raise the question of neuronal or neuroblastic differentiation. While potentially exhibiting immunoreactivity for class III β-tubulin,[332] these constituents (and their patently astroglial neighbors) generally retain at least focal GFAP expression and usually fail to label for more neuron-restricted antigens such as synaptophysin (SYN) and the NeuN[333] and Hu[334] nucleoproteins. This is not to say, however, that the infiltrating astrocytomas are limited in their differentiating potential. Differentiation along neuronal lines, in fact, is now recognized as an occasional

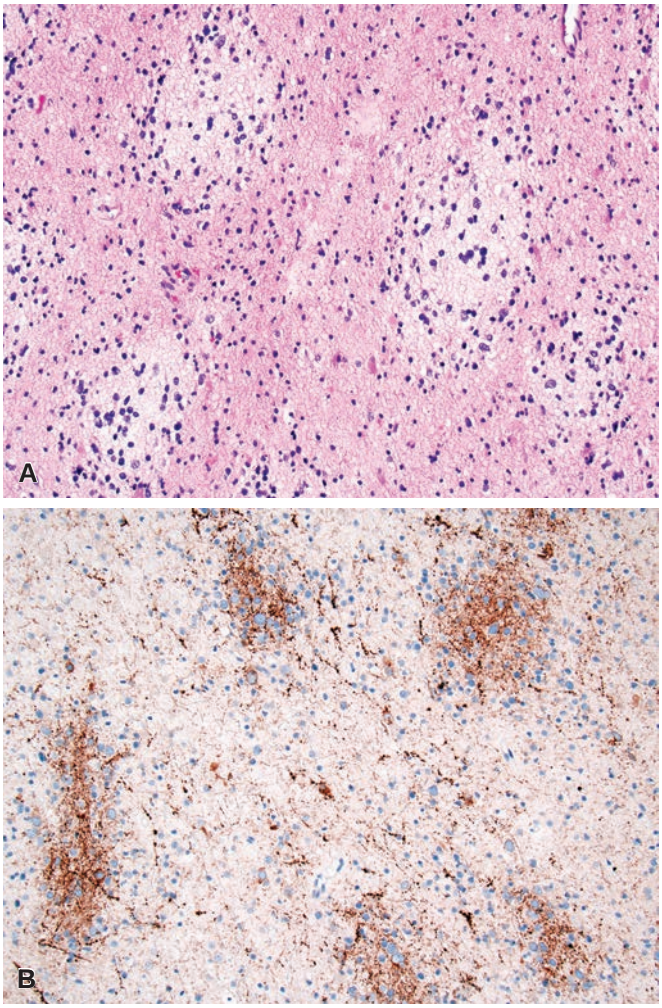

Figure 43.57 "Glioneuronal Tumor With Neuropil Islands." This entity represents a variant of diffuse astrocytoma of any grade with superimposed neuronal/neurocytic differentiation manifesting in pale neuropil-rich islands **(A)** that are synaptophysin immunoreactive **(B)**.

attribute of neoplasms otherwise qualifying as members of the astrocytic, oligodendroglial, and ependymal series. The entity dubbed "**glioneuronal tumor with neuropil-like islands**"[335] can, with much justification, be viewed as a peculiar variant of infiltrating astrocytoma with neuronal/neurocytic differentiation (Fig. 43.57). Typically dominated by fibrillary and gemistocytic astroglial components, at the WHO grade II or III level, this lesion is distinguished by its content of sharply delimited micronodular collections of a delicate meshwork exhibiting intense granular immunolabeling for SYN. These are rimmed in rosetted fashion or internally populated by neurocytic (oligodendrocyte-like) clear cells that often express NeuN and Hu. The diffuse growth pattern of this tumor, its predilection for the cerebral hemispheres of adults, the frequency with which it demonstrates IDH-mutant protein and aberrant p53 expression, and the clinical course (comparable to that of grade-matched infiltrating astrocytomas) are all consonant with the view that the glioneuronal tumor with neuropil-like islands is fundamentally of the conventional astrocytic group.[336]

Similar considerations apply to "**glioblastomas with primitive neuronal (or primitive neuroectodermal tumor [PNET]-like) components.**"[337] These harbor relatively well-demarcated nodules of high density, with cellular elements indistinguishable from those characterizing medulloblastomas and other embryonal neoplasms by virtue of their diminutive sizes, undifferentiated cytologic profiles, variable presence of Homer Wright rosettes, loss of GFAP and OLIG2 expression, immunolabeling for SYN (and other neuronal markers), and alarming proliferative activity (Fig. 43.58). Such components may emerge only in recurrent neurosurgical material and usually make their appearance in astrocytic tumors exhibiting the histology and genetic alterations typical of secondary glioblastomas. That this is an unusual form of biologic progression complicating glioblastomas is further suggested by the observation that widespread p53 reactivity and *PTEN* abnormalities (foreign to the great majority of embryonal CNS tumors) are commonly evidenced by both astroglial and primitive-looking populations, whereas the latter may selectively manifest *MYC* or *MYCN* amplifications (a phenomenon rare in astrocytomas, but not uncommon in neuroblastic tumors). A small subset also express mutant IDH1 protein and loss of ATRX expression.[308] The experience communicated to date indicates that a substantially increased risk of CSF dissemination attaches to glioblastomas of this kind, and optimal therapeutic approaches in such patients remain unclear.

Another rare variant is the **epithelioid glioblastoma**, often characterized by a younger age of onset (including pediatric), superficial localization, a surprisingly demarcated interface with adjacent brain, large epithelioid cells with abundant eosinophilic cytoplasm, large macronucleoli, and variable rhabdoid cytology, commonly imparting an initial impression of metastatic melanoma (Fig. 43.59).[324] In common with melanoma and virtually all gliomas, S-100 protein is strongly expressed, SOX10 may be positive, but other, more specific melanocytic markers, such as HMB-45, Melan-A, and MITF are negative. Complicating the differential even further is the fact that most cases show only limited staining for GFAP and OLIG2, while roughly half of cases express the BRAF V600E mutant protein. Of interest, a subset of such tumors arises secondarily from lower-grade precursors, the most common being PXA, another tumor type with frequent *BRAF* V600E mutation. As such, it is not entirely clear whether such examples are best considered a variant of anaplastic PXA (WHO grade III) or an epithelioid glioblastoma (WHO grade IV). In both the de novo and this "secondary" form, the clinical behavior is often highly aggressive, although a subset of long-term survivors have also been encountered. Additionally, dramatic response to BRAF inhibitors has been reported anecdotally in *BRAF* mutant examples.[325] Lastly, *ODZ3* tumor suppressor gene deletion on 4q34.3–q35.1 has been found to be another common alteration.[324]

Prognostic/Predictive Variables. The prognosis of a given fibrillary astrocytic neoplasm is a complex function of clinical, morphologic, and genetic variables, with the IDH status likely representing the most powerful stratifier, as discussed previously. In fact, this one feature often outweighs tumor grading, such that IDH-mutant glioblastoma patients often survive considerably longer than IDH-mutant anaplastic astrocytoma patients.[294] Patient age, functional status on presentation, tumor location, and histology all affect the outcome of supratentorial examples.[278] Faring best are young subjects harboring low-grade, IDH-mutant lesions that are unassociated with focal neurologic deficits and that are situated in the cerebral hemispheres. Follow-up studies of patients identified and managed since the advent of CT and MRI (i.e. in the era of "early" detection) suggest median survivals of up to 10 years under such relatively favorable circumstances, with death typically following tumor progression to glioblastoma.[278] Whether attempted gross total resection, chemotherapy, or radiotherapy prolongs the lives of patients with low-grade cerebral hemispheric astrocytomas is a contentious matter. Many neuro-oncologists elect to simply

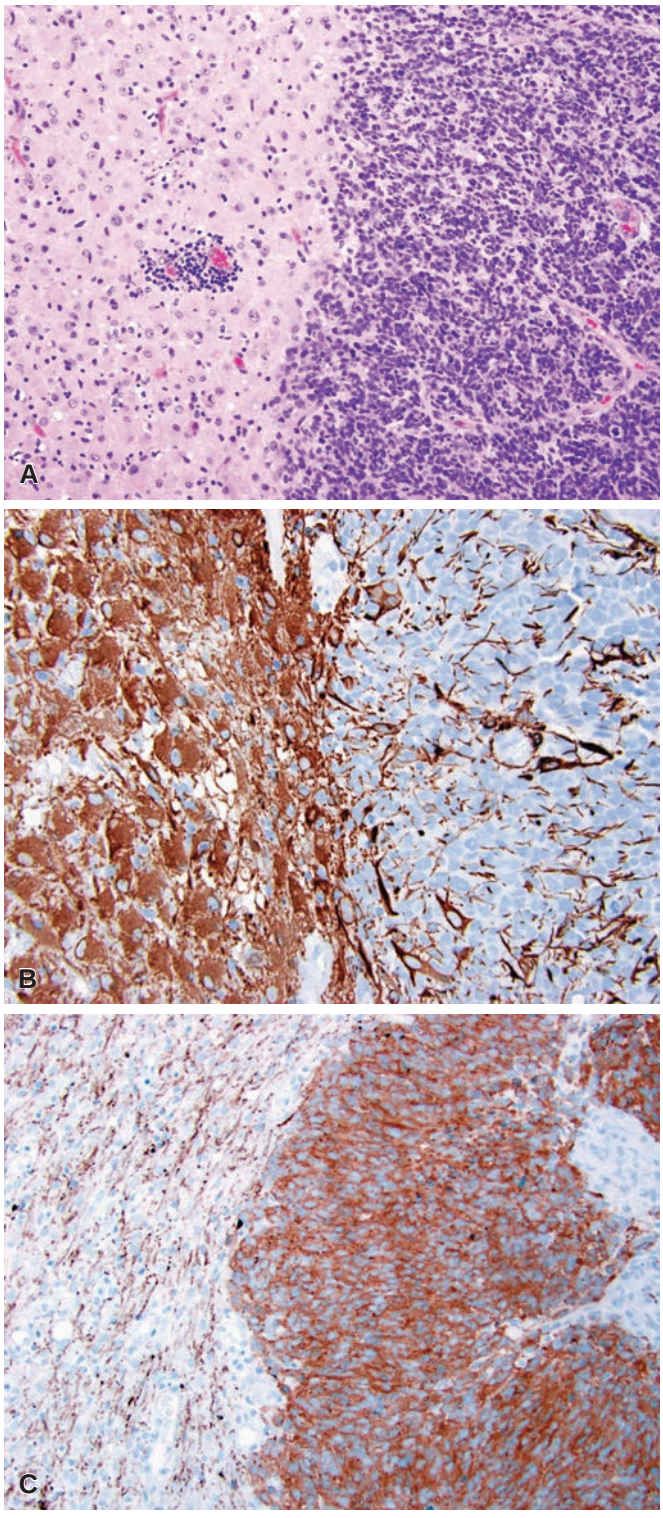

Figure 43.58 Glioblastoma With Primitive Neuronal Component (A, H&E; B, GFAP; C, Synaptophysin). This variant may arise from any diffuse glioma subtype, but astrocytomas are most common. They are characterized by sharp demarcation of a primitive-appearing component with diminished evidence of glial differentiation and increased evidence of neuronal differentiation. In this example, there is a gemistocytic astrocytoma component on the left giving rise to a primitive component on the right.

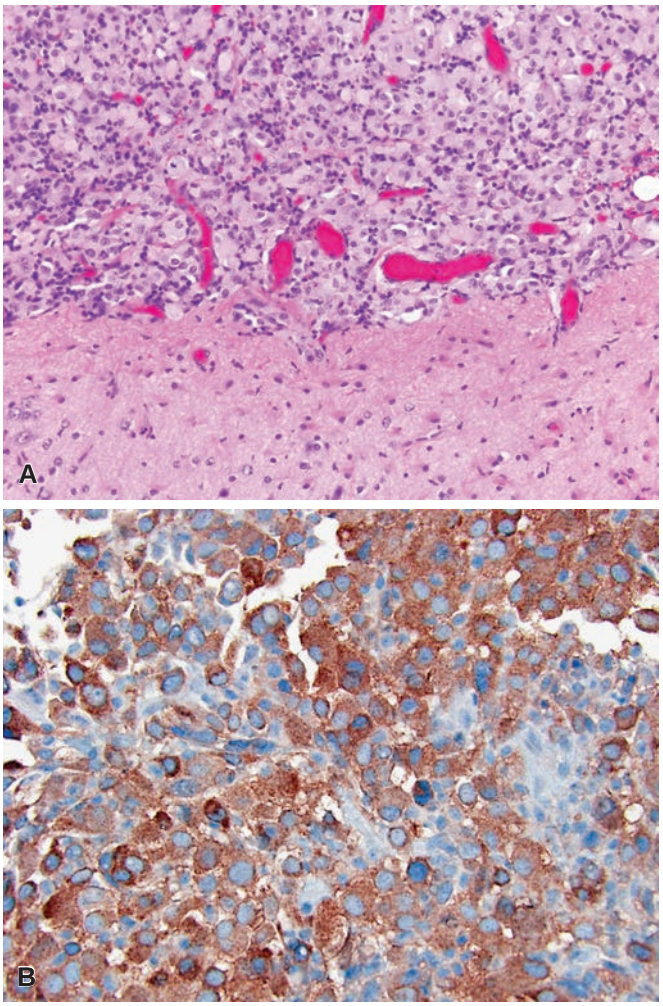

Figure 43.59 Glioblastoma, Epithelioid Variant. A, This variant is often surprisingly demarcated in growth pattern and harbors large epithelioid to rhabdoid glioma cells reminiscent of malignant melanoma. **B,** Roughly half of cases express the BRAF V600E mutant protein by immunohistochemistry.

follow affected individuals until there is compelling clinical or neuroradiological evidence of tumor growth. Comparably situated anaplastic astrocytomas and glioblastomas, by contrast, are unarguably aggressive neoplasms associated with median postoperative survival periods of 24–48 and 12 months, respectively, despite irradiation and adjuvant chemotherapy. Hemispheric H3 G34R/V-mutant examples, occurring primarily in children and young adults, carry an intermediate prognosis,[297,298] while the midline H3 K27M-mutant tumors are amongst the most aggressive (see later). Inactivation of the DNA repair enzyme O^6-methylguanine-DNA methyltransferase (MGMT), usually through promoter hypermethylation of its encoding gene, is emerging both as a predictor of enhanced tumor responsiveness to alkylating agent chemotherapy and generally favorable prognostic marker.[338] Under active investigation in the treatment of glioblastomas are agents against EGFR, its major mutant form *EGFR-vIII*, and downstream targets of these and other kinases. Ultimately, however, the insidious manner in which these lesions permeate brain tissues beyond their neuroradiologically defined and grossly apparent borders, along with their marked genetic heterogeneity, frustrates attempts at local disease control and sets the stage for progressive infiltration of neighboring cerebral parenchyma by

chemoresistant and, potentially, targeted therapy-resistant clones. This, the primary pattern of treatment failure, is occasionally complicated by the development of CSF-borne neuraxial metastases and, rarely, by spread to somatic sites, such as bone, lung, liver, or lymph node.[339] Most unusual, but well documented, are cases in which systemic metastases have been apparent on initial patient presentation,[339] and the bizarre phenomenon of inadvertent tumor transplantation via solid organ allografts has also been the subject of isolated reports.[340]

Similarly dismal is the prognosis attached to diffusely invasive midline astrocytomas, most of which involve the brainstem, thalamus, or spinal cord and are high grade at diagnosis. Given the predominant mutations in the histone H3 genes, *H3F3A* and *HIST1H3B*, the WHO 2016 scheme has referred to these neoplasms collectively as "**diffuse midline glioma, H3 K27M-mutant**" (see Fig. 43.46). Such tumors predominantly affect children (especially brainstem), although thalamic and spinal tumors are not uncommonly encountered in young adults; they tend to behave aggressively (survival beyond 2 years is rare), even when otherwise appearing lower grade by histology alone.[295-298] These lesions may even mimic pilocytic astrocytomas, gangliogliomas, or ependymomas in limited biopsies, so the index of suspicion should be high and the K27M mutant immunostain applied frequently for such midline gliomas.

Quantifiable methods for the determination of proliferative potential are now in wide use as adjuncts to the conventional morphologic assessment of astrocytic and other primary CNS neoplasms. Immunohistochemical assay for the Ki-67 antigen, a nonhistone nucleoprotein selectively expressed by actively cycling cells and demonstrable in paraffin-embedded material using the MIB-1 monoclonal antibody, has proven especially useful to surgical neuropathologists in this regard. Nevertheless, the performance of this reagent is subject to all the technical vagaries that attend immunohistochemical methods, such that it is often difficult to extrapolate results from one lab to another. General survey discloses a broad correlation of histologic grade and labeling index, but unfortunately reveals overlapping index ranges for low-grade astrocytomas (mostly <5%), anaplastic astrocytomas (mostly 5%–10%), and glioblastomas (mostly >10%). In practice, we employ MIB-1 only in the evaluation of histologically low-grade or "borderline" fibrillary astrocytomas and simply append in our reporting of values above 5% a comment to the effect that such levels suggest a heightened proliferative potential.

Oligodendrogliomas, IDH-Mutant and 1p/19q-Codeleted (and Its Rare Pediatric Counterpart)

Oligodendrogliomas are named for the resemblance of their constituent cells to native oligodendrocytes, although the notion that these neoplasms derive from the latter is unlikely; most recent data favors an origin from oligodendrocyte precursor cells instead of neural stem cells.[341,342] Characteristic clinical features include a predilection for young and middle-aged adults, a cerebral hemispheric localization (the frontal and temporal lobes being principally affected), an often protracted preoperative history of intermittent seizures or headache, and partial calcification on neuroradiological study (Fig. 43.60). Only exceptionally do oligodendroglial neoplasms arise below the tentorium, but no part of the CNS is immune. The literature includes accounts of tumors interpreted as oligodendrogliomas of brainstem, cerebellar, and spinal plus/minus leptomeningeal origin,[343-345] although the latter must be distinguished from a distinctive pediatric neoplasm now known as "diffuse leptomeningeal glioneuronal tumor" (described in greater detail later).[346] In the 2016 WHO scheme,[278] both IDH mutations and chromosome 1p/19q codeletions are required for the diagnosis of the more common adult form of oligodendroglioma.

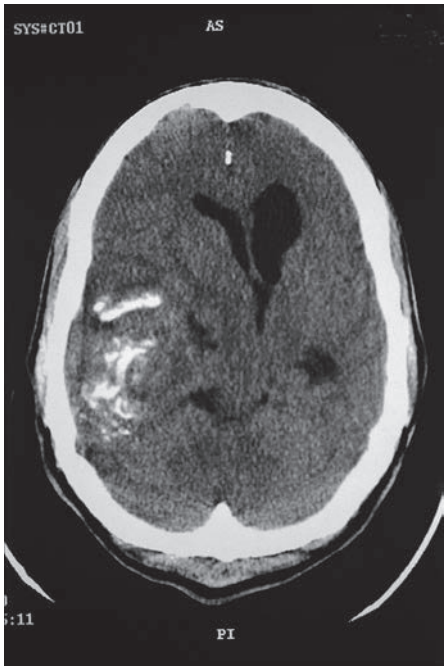

Figure 43.60 Oligodendroglioma. The bright signal abnormalities seen in this nonenhanced computed tomography study of a large right cerebral oligodendroglioma represent foci of intratumoral calcification. While evidenced by only a minority of oligodendroglial neoplasms, linear or plate-like calcifications of this sort are most suggestive of the diagnosis.

Oligodendrogliomas are usually found within white matter at operation, but extension into overlying cortex is the rule. Composed of soft, gray–pink tissue that often acquires a gelatinous consistency due to the accumulation of myxoid matrix materials, these tumors may feature cystic change and can contain foci of dense calcium deposition that are palpably gritty or even rock-hard. A vulnerability to artifactual cytoplasmic dissolution accounts for the classic histologic presentation of oligodendrogliomas as permeative or, in some cases, sheet-like proliferations of uniform rounded nuclei surrounded by optically clear halos (Fig. 43.61A). When well preserved, the nuclei show delicate neuroendocrine-like "salt and pepper" chromatin, small nucleoli, and distinct nuclear membranes. A fusiform spindling of tumor cells is occasionally apparent and some high-grade, "polymorphous" variants harbor markedly pleomorphic, giant cell subpopulations.[347] Oligodendrogliomas often contain scattered calcospherites, which may be clustered in laminar fashion within cerebral cortex along the advancing tumoral perimeter, and many are subtended by a plexiform ("chicken wire") network of thin-walled blood vessels. Of additional diagnostic utility is a tendency to perineuronal tumor cell aggregation ("satellitosis"). Perivascular and subpial growth are also commonly encountered, as are myxoid changes, microcyst formation, and nodular foci of increased cell density. In exceptional instances, tumor cells are segregated into prominent lobules by fibrovascular stromal elements, or stagger across the microscopic field in rhythmic palisades ("spongioblastic" pattern).

It should be emphasized that the "fried egg" cellular profil e of the prototypical oligodendroglioma is an artifact, and thus not seen in conventional frozen sections, intraoperative smears, or crush preparations. The first of these techniques almost invariably produces misleading nuclear angulations, whereas the latter preserve the rounded profiles of tumor cell nuclei which appear either naked or

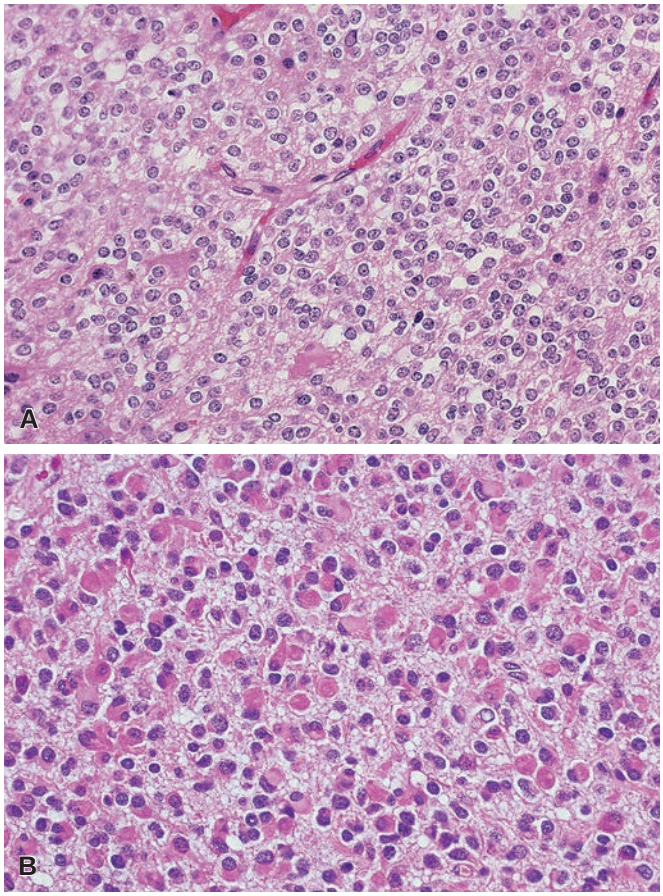

Figure 43.61 Oligodendroglioma. A, Uniform, round nuclei and clear perinuclear halos (artifacts of delayed fixation) typify well-differentiated oligodendrogliomas. "Minigemistocytic" variants **(B)** maintain oligodendroglial nuclear features while amassing globose paranuclear expanses of eosinophilic, hyaline or whorling fibrillar cytoplasm. Compare the size of these cells and their cytologic features with those of the gemistocytic astrocytoma depicted at identical magnification in Fig. 43.35.

irregularly encircled by pale eosinophilic cytoplasm in modest quantity. Distinct cytoplasmic expanses and cell membranes are also less appreciable in paraffin sections prepared from very promptly fixed surgical material. Perinuclear halos, on the other hand, constitute (along with nuclear shrinkage and oligodendrocyte-like rounding) deceptive artifacts potentially imposed on astrocytomas and other nonoligodendroglial neoplasms by the common practice of ultrasonic tumor aspiration.

Oligodendrogliomas often contain intensely GFAP-positive "minigemistocytes"[348,349] that may harbor inclusion-like, whorled intracytoplasmic bodies of filamentous substructure (see Fig. 43.61B). These are of no proven prognostic significance per se but tend to be particularly numerous in high-grade oligodendroglial tumors and may evidence transition to large and pleomorphic gemistocytes of astroglial type. So-called gliofibrillary oligodendrocytes, elements of conventional clear cell type characterized by perinuclear rims of GFAP-immunoreactive cytoplasm that may taper into short, unipolar cell processes, may also be apparent.[349] Other cytologic alterations that may be encountered in oligodendroglial neoplasms include cytoplasmic distension by a PAS-positive mucosubstance, the formation of eosinophilic granular cells stuffed with autophagic vacuoles,[350] and "signet ring" change resulting from the intracytoplasmic accumulation of degenerating mitochondria or from dilated profiles of rough endoplasmic reticulum.[351,352]

Unfortunately, there does not exist at present an immunocytochemical reagent that consistently and specifically identifies neoplastic cells as oligodendroglial. Immunolabeling for S-100 protein, membranous Leu7 (CD57), carbonic anhydrase C, and microtubule-associated protein type 2 (MAP-2) are characteristic but also shared by other glioma types. Cytoplasmic labeling for galactocerebroside and other oligodendrocyte-associated galactolipids is inconstant, and only exceptionally are tumor cells positive for myelin-associated glycoprotein, proteolipid protein, or other differentiation antigens that mark mature oligodendroglia. While oligodendrogliomas commonly display nuclear immunoexpression of the lineage-restricted OLIG1, OLIG2, and SOX10 transcription factors,[353,354] these markers are often positive in other neuroepithelial neoplasms as well, including astrocytomas and, in the case of OLIG2, a subset of neurocytic and embryonal tumors.[355] Of potentially more value may be diffuse cytoplasmic labeling for Nogo-A, a member of the reticulon family, but this antibody also lacks sufficient sensitivity and specificity for clinical utility.[356] In a similar vein, ultrastructural indices of oligodendroglial maturation are lacking in most cases.[357] Microtubules, free ribosomes, and mitochondria constitute the usual cytoplasmic contents and are unaccompanied by any unique organellar structures.

It is, in fact, what the oligodendroglioma fails to accomplish at the ultrastructural level or by way of antigen expression that often proves most useful in its distinction from certain mimickers that may assume astonishingly similar histologic guises. Specifically, it does not fashion the elaborate zonulae adherentes–type intercellular junctions, microlumens, microvillous or ciliary arrays of the clear cell ependymoma, or the clear synaptic or dense-core vesicles that betray the neuronal nature of central and extraventricular neurocytomas. The dot- and ring-like immunolabeling for EMA that corresponds to ependymal microlumen formation is not displayed by oligodendroglial tumors. Neurocytic neoplasms are further (and most efficiently) distinguished by a neuronal immunophenotype that includes diffuse matrix labeling for SYN and, in many instances, widespread immunoreactivity for the neuronal nuclear antigens Hu[334] and NeuN.[358] This is not to dismiss evidence that oligodendrogliomas occasionally exercise a potential for neuronal differentiation. In fact, labeling for a variety of neuron-associated antigens is common,[359] particularly SYN, and there have been notable examples of oligodendrogliomas harboring unarguably neurocytic elements in rosetted array[360] as well as ganglion cell components.[361] We would nevertheless emphasize that close scrutiny is required lest neoplastic infiltration of SYN-rich cortex (a frequent event) be seized upon as evidence of tumoral differentiation along neuronal lines. Again, NeuN assessment is useful in this regard, as immunoreactivity for this protein is foreign to the great majority of oligodendrogliomas,[358] and serves to highlight remaining native neurons in colonized gray matter. The decidedly oligodendroglioma-like dysembryoplastic neuroepithelial tumor departs from the neoplasms under discussion in its predilection for patients younger than 20 years of age, largely cortical topography, content of intracortical nodules with a "patterned" alveolar architecture, lack of *IDH* mutations, and intact chromosome 1p/19q status.

Unlike clear cell meningiomas (usually extra-axial and dura based), oligodendrogliomas are typically EMA negative, are not heavily glycogenated, and lack well-developed intercellular junctions at the electron microscopic level. Similar considerations apply to the identification of clear cell carcinomas, which may also exhibit cytokeratin reactivity.

As with the astrocytomas, by far the most reliable diagnostic aids in the diagnosis of the adult-type oligodendroglioma are molecular markers, including those with immunohistochemical surrogates. By definition, these tumors are IDH-mutant and show chromosome 1p/19q codeletion, the latter typically resulting from a non-balanced

t(1;19)(q10;p10) translocation[362,363] and associated in smaller subsets with mutations of *CIC* and *FUBP1*.[364,365] In contrast to their astrocytoma counterparts, which promote alternative lengthening of telomeres by *ATRX* mutations, senescence is avoided based on telomerase overexpression resulting from mutations of the *TERT* promoter region; as such, ATRX immunostaining shows retained nuclear expression in all cases.[366-368] Furthermore, oligodendrogliomas may contain minor populations that exhibit nuclear immunoreactivity for p53, but when there is widespread immunoreactivity or strong expression in greater than 10% of tumor nuclei, this phenomenon is far more characteristic of the astrocytoma group, in which it correlates relatively well with the presence of *TP53* mutations and tends to have an inverse correlation to the 1p/19q abnormalities previously mentioned.[289]

A variety of grading strategies have emerged from correlative studies of oligodendroglioma histology and outcome.[369] A two-tiered segregation into low- versus high-grade variants forms the basis of the WHO classification and has found wide application among neuropathologists.[278] Well-differentiated tumors that exhibit little in the way of mitotic activity and are devoid of proliferative microvascular alterations or necrosis are reported as "**oligodendroglioma, IDH-mutant and 1p/19q-codeleted, WHO grade II**." Nodular foci of increased cellularity alone are still compatible with this diagnosis. MVP and conspicuous mitotic activity—joined, in some cases, by necrosis and often accompanied by dense cellularity, enlarged epithelioid cells, and obvious nuclear atypia—are features of the "**anaplastic oligodendroglioma, IDH-mutant and 1p/19q-codeleted, WHO grade III**" (Fig. 43.62). The latter may evolve within an underlying oligodendroglial neoplasm of low-grade character. Other variables associated with an unfavorable clinical course include advancing patient age, contrast enhancement on neuroradiological assessment (a ring-enhancing profile seems especially ominous), and, in some studies, MIB-1 labeling indices in excess of 5%.[370,371]

Median survivals reaching up to nearly 15 years have been reported for 1p/19q-codeleted anaplastic examples in patients treated with adjuvant chemoradiation in clinical trials,[372,373] and survival may be even longer in the low-grade (WHO grade II) cohorts.[374] The *IDH* gene mutations previously mentioned in the discussion of diffuse astrocytic tumors occur at comparably high frequency in both low-grade and anaplastic oligodendrogliomas. In comparison to their adult counterparts however, few pediatric examples harbor IDH mutations and 1p/19q deletions (positive examples seen mostly in adolescent patients), with low-grade examples progressing to anaplastic oligodendrogliomas less often.[365,375,376]

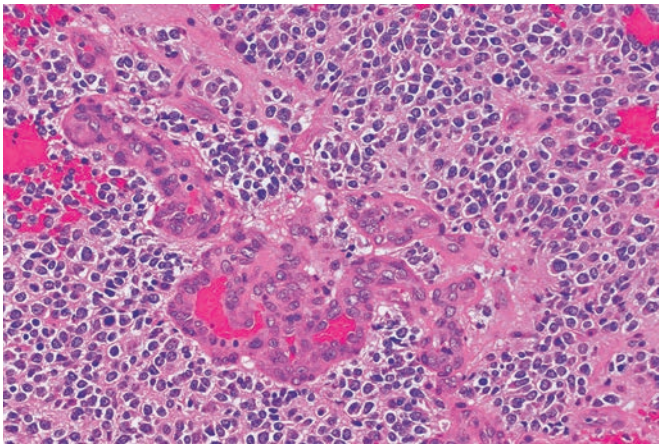

Figure 43.62 Anaplastic Oligodendroglioma. Microvascular proliferation, readily apparent mitotic activity, and cytologic atypism are features of this example.

Oligodendrogliomas usually kill by virtue of progressive neuroparenchymal infiltration following local recurrence. Leptomeningeal dissemination via the CSF is exceptional and distant metastasis rare.[377] Gliosarcomatous transformation has been recorded[303,304] but is exceptional in contrast to their astrocytic counterparts.

Mixed Gliomas

The only "mixed" gliomas broadly recognized by both neuropathologists and the WHO are those manifesting both astrocytic and oligodendroglial features, defined as neoplasms in which elements perceived as astrocytic or oligodendroglial in phenotype are closely and randomly intermingled or in which these components are spatially distinct. These infiltrative lesions most often arise in the cerebral hemispheres of adults (the frontal and temporal lobes are favored) and are termed **oligoastrocytomas** (WHO grade II) or **anaplastic oligoastrocytomas** (WHO grade III). The latter display high cellularity, conspicuous nuclear atypism, readily apparent mitotic activity, and, in some cases, complex microvascular hyperplasia. As noted previously, however, the vast majority of such cases can now be molecularly classified as either astrocytoma or oligodendroglioma, given that no unique oligoastrocytoma-associated molecular signature has been identified. As such, this diagnosis is discouraged in the 2016 WHO scheme, with the rare exceptions being diagnoses made in resource-poor practices on morphology alone (to which a designation of "NOS" for not otherwise specified is appended to the diagnosis), cases where molecular analysis does not clarify the lineage (e.g. rare pediatric counterparts), or exceptional examples wherein the molecular features of astrocytoma are found in one region of the tumor and the genetic signature of oligodendroglioma is encountered in other parts.[378,379] As such, it is expected that the diagnosis of oligoastrocytoma will become vanishingly rare in the near future and, in a similar fashion, the WHO grade IV counterpart of "glioblastoma with oligodendroglioma component" virtually always gets reclassified using molecular studies into one of three integrated diagnoses: (1) glioblastoma, IDH-wildtype with its standard poor prognosis, (2) glioblastoma, IDH-mutant with an intermediate prognosis, and (3) anaplastic oligodendroglioma, IDH-mutant, 1p/19q-codeleted with the most favorable prognosis.[365,380]

As another rare consideration, clear cell components histologically similar to oligodendroglioma may be found within otherwise conventional ependymomas, particularly supratentorial examples. The fact that these elements retain ependymal features at the ultrastructural level, and that some otherwise classic glioblastomas show perivascular pseudorosettes without discernable evidence of ependymal differentiation, calls into question descriptions of either mixed oligodendroglial or astrocytic and ependymal tumors. The diagnosis of "ependymoastrocytoma" should also not be invoked for the common fourth ventricular ependymoma harboring minor components of astrocytic appearance, or the occasional ependymoma that exhibits astrocytoma-like neuroparenchymal permeation along its perimeter.

Gliomatosis Cerebri

Gliomatosis cerebri, as traditionally and stringently defined, is a rare condition in which at least three cerebral lobes are permeated by neoplastic cells without focal mass formation, although genetic studies now suggest that this is simply an exaggeration of the normal diffusely infiltrative growth pattern of astrocytic and oligodendroglial neoplasms, given that all the common molecular subtypes may be represented.[381] As such, this is now considered a radiographically (or autopsy) defined growth pattern rather than a specific clinicopathologic entity in the 2016 WHO scheme.[278] Affected regions

are typically expanded in nondestructive ("pseudohypertrophic") fashion without formation of appreciable tumor nodules. The process may be remarkably diffuse, often extending from the cerebrum into deep gray matter, as well as brainstem, and potentially involving the entire central neuraxis. Confluent multilobar and bihemispheric zones of signal hyperintensity in T2-weighted and FLAIR studies are characteristic on MRI.[382] A large majority of gliomatoses qualify as WHO grade II or III lesions on histologic grounds, with a small minority presenting with grade IV features such as MVP and necrosis.

Non-Diffuse Astrocytoma Variants

Pilocytic Astrocytomas

Pilocytic astrocytomas typically present in childhood, adolescence, or early adult life—hence their prior designation by the prefacing "juvenile"—and exhibit a decided predilection for the cerebellum, third ventricular/hypothalamic region, and anterior optic pathway.[278] They constitute the great majority of tumors collected under the traditional appellations of "cerebellar astrocytoma" and "optic nerve glioma," including those examples of the latter, often bilateral, complicating NF1. NF1 patients are also at risk of developing cerebellar, and other extraoptic, astrocytomas of pilocytic type. Pilocytic astrocytomas may arise within the cerebral hemispheres, basal ganglia/thalami, or spinal cord and are over-represented within a clinically distinctive subset of bulbar tumors that deviate from the diffuse, fibrillary astrocytic neoplasms typical of the brainstem by virtue of their circumscription, their tendency to bulge into the fourth ventricle in "dorsally exophytic" fashion, and their far more favorable prognosis.[383]

Save for those tumors positioned in the anterior visual pathway, which produce a fusiform, "pseudohypertrophic" expansion of the optic nerve, and a subset of cerebellar examples having diffusely invasive components,[384] pilocytic astrocytomas tend to be relatively demarcated, nodular in contour, and frequently project into sizable cysts that may account for most of their mass effect and associated neurologic symptoms. Homogeneous contrast enhancement typifies the solid elements of the pilocytic astrocytoma, a feature serving, along with the tendency to macrocystic change and the high signal intensity often displayed on both T1- and T2-weighted MRI study, to distinguish this lesion from the diffuse astrocytoma on neuroradiological examination (Fig. 43.63).

The prototypical pilocytic astrocytoma is an architecturally and cytologically biphasic neoplasm arranged in alternating compact fascicular and loose, microcystic patterns (Fig. 43.64). The former component is fashioned of cells bearing the delicate, bipolar cytoplasmic processes for which the tumor is named (pilo—derives from the Greek root for hair). These are typically woven in a dense fibrillar matrix in which oval or spindly tumor cell nuclei appear to be embedded. The tumor cells' slender and remarkably elongated processes are optimally visualized in intraoperative cytologic preparations. In microcystic regions, neoplastic cells are arranged around, or float suspended in, pools of basophilic, myxoid material. It should be noted that the relative admixture of compact piloid and microcystic elements varies greatly from case to case. The latter are particularly likely to dominate cerebellar examples in children. Other common histologic features include oligodendroglioma-like clear cell foci and an angiomatoid vasculature characterized by complex arborization, hyaline mural fibroplasia, and ectasia. Microcalcifications may be encountered at the histologic level, though neuroradiologically evident tumoral calcification is rare. Mitotic activity is generally low, and MIB-1 labeling indices usually do not exceed 1%–3%, although the significance of focally increased proliferative activity—some of which may reflect inflammatory cells—is often limited in the absence of additional, more overtly malignant features (see later discussion of anaplasia).

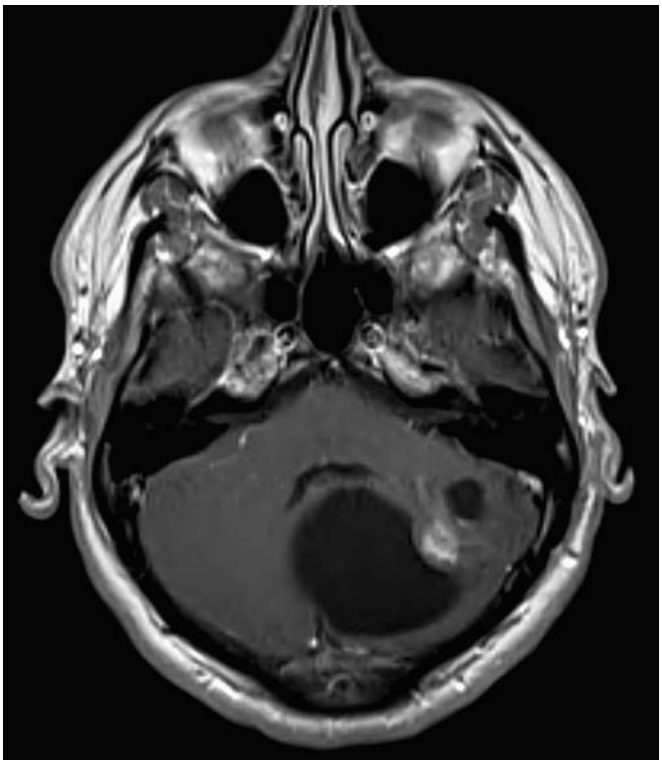

Figure 43.63 Pilocytic Astrocytoma. This typical cerebellar example is characterized by a solid, brightly contrast-enhancing mural component and associated cyst on T1-weighted postcontrast magnetic resonance imaging.

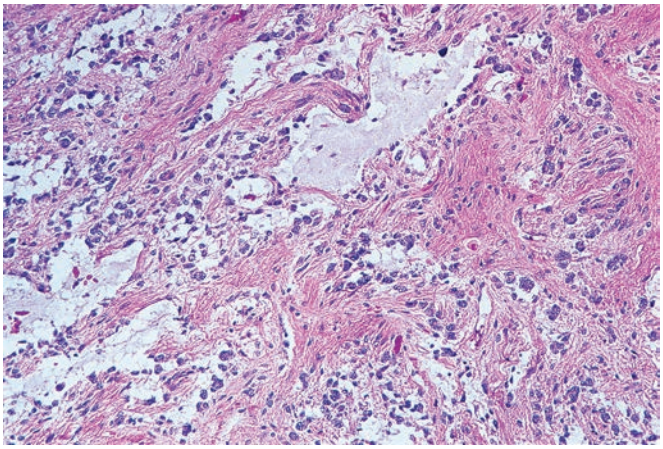

Figure 43.64 Pilocytic Astrocytoma. The biphasic cellular populations and architecture of the classic pilocytic astrocytoma are in evidence. The lesion's process-bearing spindle cell ("piloid") constituents fashion a densely fibrillar matrix, whereas its process-poor elements aggregate in regions of myxoid change that often progress to microcyst formation.

The cytoplasmic structures known as Rosenthal fibers and eosinophilic granular bodies are classically associated with pilocytic astrocytoma. Rosenthal fibers, which are vermiform acidophilic densities typically restricted to the tumor's richly fibrillated regions (Fig. 43.65), represent masses of granular, electron-dense material

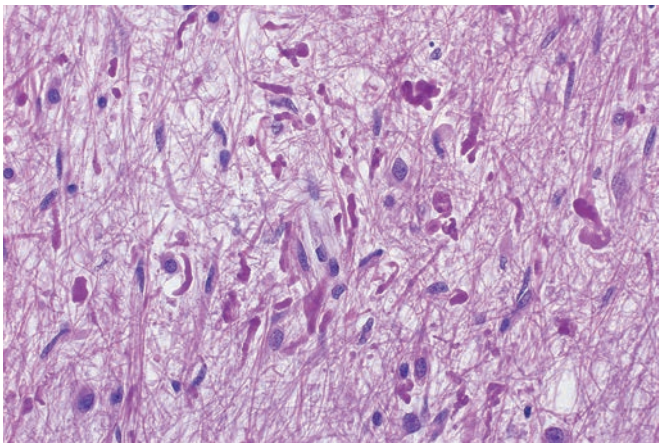

Figure 43.65 Pilocytic Astrocytoma. Varicose Rosenthal fibers lie among the otherwise delicate and hair-like cytoplasmic processes for which the pilocytic astrocytoma is named.

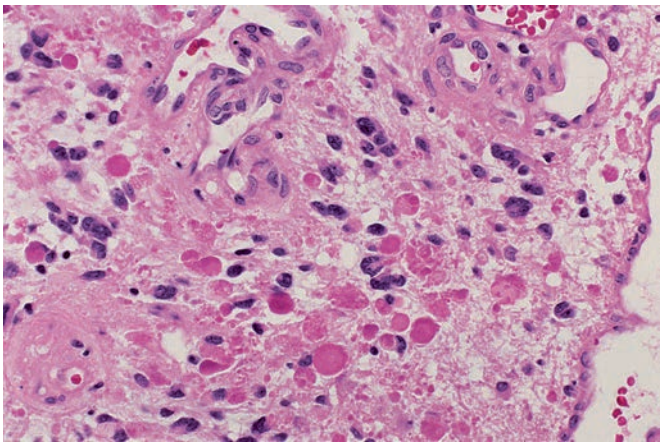

Figure 43.66 Pilocytic Astrocytoma. Eosinophilic granular bodies are typically associated with, although not restricted to, three indolent neuroepithelial tumors: the pilocytic astrocytoma, pleomorphic xanthoastrocytoma, and ganglioglioma.

surrounded by glial filaments. They may be labeled by antisera to alpha B-crystallin and a related 27-kDa heat shock protein, and GFAP positivity is typically restricted to the peripheral rim of Rosenthal fibers.[385] Eosinophilic granular bodies are clustered acidophilic globules (Fig. 43.66) that probably derive from lysosomes and are immunoreactive for α1-antitrypsin, α1-antichymotrypsin, ubiquitin, and alpha B-crystallin.[386] At the ultrastructural level, eosinophilic granular bodies represent membrane-bound collections of amorphous osmiophilic material and myelin-like figures lying within the cytoplasm of tumor cells.[386] It is important to note that neither of these cytoplasmic alterations is invariably present in, or pathognomic of, the pilocytic astrocytoma. Rosenthal fibers, for example, typically abound in the gliotic tissues adjacent to hemangioblastomas and craniopharyngiomas, whereas eosinophilic granular bodies are a conspicuous feature of many gangliogliomas and pleomorphic xanthoastrocytomas.

The exacting histologic indices by which the biologic potential of the diffuse fibrillary astrocytoma is gauged simply cannot be applied to the pilocytic variant, a WHO grade I neoplasm that is among the most indolent of all central neuroepithelial tumors. Isolated mitotic figures, glomeruloid vascular proliferation, multinucleated giant cell formation, and nuclear atypism (at times alarming, particularly in microcystic regions) are divorced, in this setting, from sinister prognostic import, as is the rather common finding of extension into the subarachnoid space. The vast majority of pilocytic astrocytomas are histologically and clinically benign. Rare examples undergo malignant transformation (including some following radiation therapy years before), typically associated with a distinct change in morphology, including focally increased cellularity, nuclear hyperchromasia/atypia, mitotic activity, and infiltrative growth resembling the high-grade diffuse astrocytomas. Nevertheless, it remains difficult to predict clinical behavior in such cases. In one series of 34 "anaplastic pilocytic astrocytomas," the most reliable grading feature was the presence of at least 4 mitoses/10 high-power fields in addition to hypercellularity and moderate-to-severe cytologic atypia; those lacking necrosis had clinical courses similar to WHO grade II astrocytomas, while those with superimposed necrosis were more comparable to WHO grade III counterparts.[387] High Ki-67 labeling index, increased p53 positivity, and loss of p16 expression are more common in such foci of anaplastic transformation.[387,388]

Pilocytic astrocytomas confined to the optic nerve and cerebellum lend themselves to curative neurosurgical resection, as do those arising in accessible cerebral hemispheric sites, though instances of recurrence (even decades) after radical removal are on record.[389] A less favorable prognosis attaches, understandably, to lesions involving the optic chiasm, hypothalamus, and other regions that preclude complete resection, but even in these loci the clinical evolution of subtotally resected pilocytic astrocytomas is typically protracted and may extend over a decade or more. Evidence from bromodeoxyuridine studies suggests that the proliferative activity of pilocytic astrocytomas may actually diminish over time,[390] and rare instances of spontaneous regression are on record.[391] Dissemination via the CSF, principally complicating opticohypothalamic lesions, is exceptional, despite the fact that pilocytic astrocytomas frequently infiltrate the adjacent subarachnoid space and leptomeninges extensively.[392] Metastatic deposits may remain remarkably stable and are not necessarily associated with early death. Radiation therapy may play a role in the development of the latter, as many tumors evidencing such biologic progression were subjected to this treatment years prior to recurring in anaplastic and aggressive form. In fact, some may represent independent, radiation-induced glioblastomas. Extracranial spread of opticohypothalamic pilocytic astrocytoma to the abdominal cavity via a ventriculoperitoneal shunt has been described[393] but is a curiosity. We refer the reader to our discussion of pilomyxoid astrocytomas (see later) for further comments on a potentially aggressive glioma of childhood that has been distinguished from pilocytic astrocytomas of conventional type.

We close this discussion of the clinical biology of pilocytic astrocytomas by emphasizing the importance of segregating these surgically curable neoplasms from diffuse fibrillary astrocytomas, which may arise in the cerebellum. The latter are typically resistant to all forms of therapy and, with rare exception, ultimately prove fatal. Pilocytic astrocytomas of the cerebellum occasionally consist in part of diffusely permeative elements that are indistinguishable from neoplastic cells of fibrillary astrocytic type, but these are noteworthy for their cytologic uniformity, mitotic inactivity, and lack of atypism, often accompanied by a more discrete appearance on neuroimaging despite an invasive growth pattern histologically.[384] The finding of such components, particularly in a pediatric case, should prompt a careful search for piloid or microcystic foci, but even in the absence of such tell-tale pilocytic features, the prognosis of ostensibly infiltrating astrocytomas of this kind in childhood is quite favorable.

Recent investigations of the pilocytic astrocytoma at the molecular genetic level have identified common and in some cases, nearly

pathognomonic alterations. Upregulation of the mitogen-activated protein kinase (MAPK) pathway, which bears on cell proliferation, differentiation, and apoptosis,[394] is apparently central to the pathogenesis of pilocytic astrocytomas. Whereas this pathway is affected in the setting of NF1 by functional loss of neurofibromin (product of the *NF1* gene and a negative regulator of MAPK pathway signaling through its inhibitory influence on Ras), it is a MAPK activator, *BRAF*, that has been implicated in the causation of most sporadically occurring astrocytomas of pilocytic type. The latter share, as their most common genetic abnormality, tandem duplications at chromosome 7q34 that result in the formation of an oncogenic *KIAA1549-BRAF* fusion gene lacking the autoinhibitory domain of wild-type *BRAF* and producing constitutive MAPK activation.[394,395] These events occur in pilocytic astrocytomas arising in varied CNS sites but seem especially characteristic of cerebellar examples. The observation that *KIAA1549-BRAF* fusions are generally foreign to diffuse astrocytomas, coupled with the immunity of pilocytic lesions to the *IDH1* gene mutations common to the former, allows for a strategy of molecular diagnostic segregation in problematic cases.[396] Other MAPK-activating events that have been detected in pilocytic astrocytomas include *FGFR1*, *BRAF V600E*, and *KRAS* mutations.[394,395]

Pilomyxoid Astrocytoma

Certain tumors historically included in the pilocytic astrocytoma group have garnered attention as a biologically distinct variant or, less likely, a separate entity. **Pilomyxoid astrocytoma** is a morphologically overlapping neoplasm[397,398] that usually arises in the hypothalamus or optic chiasm of an infant or young child but can be encountered in other locations (including the cerebellum). Similar to the classic pilocytic astrocytoma, these tumors contain a population of spindled (though less elongated), bipolar glial cells, but, in contrast, they lack a biphasic solid and microcystic growth pattern, instead exhibiting diffuse and prominent myxomatous change. Pilomyxoid astrocytomas also do not contain Rosenthal fibers and usually lack eosinophilic granular bodies. Many such tumors deviate further from conventional pilocytic histology in containing pseudorosette-like formations of neoplastic cells that appear to radiate from stromal blood vessels (Fig. 43.67). Mitoses are often present, though not numerous, and necrosis (without palisading) may be encountered. Diffuse GFAP and strong OLIG2 expression is the rule, and some examples also stain with SYN. MIB-1 labeling indices are highly variable, but often exceed the 1%–3% levels encountered in pilocytic lesions of the usual type.

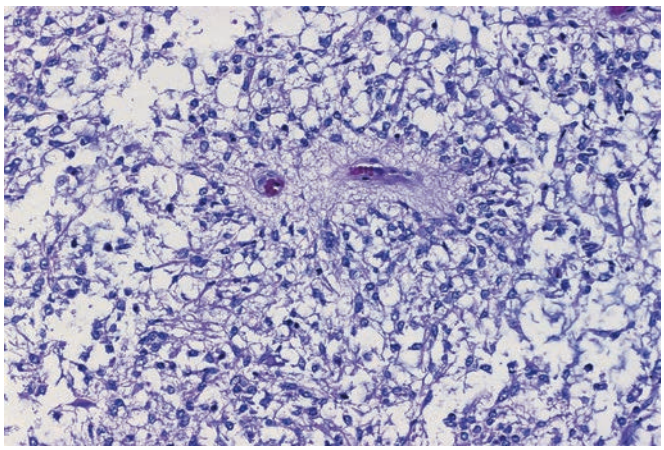

Figure 43.67 Pilomyxoid Astrocytoma. Spindled cytologic features, diffuse myxoid change, and focal perivascular pseudorosetting *(center top)* characterize this variant.

Clarification of whether pilomyxoid astrocytoma is a unique entity or a variant of pilocytic astrocytoma awaits additional study, although the former is currently favored and reflects its current standing in the WHO classification scheme.[278] We and others have encountered tumors manifesting hybrid pilomyxoid/pilocytic features, as well as neoplasms conforming in all respects to the pilomyxoid astrocytoma that have more conventional pilocytic histology upon recurrence.[399] In further attestation to a kinship, a subset of pilomyxoid astrocytomas have evidenced the same type of *BRAF* fusions encountered commonly in classic pilocytic astrocytomas.[400-402] Admittedly, a subset of pilomyxoid suprasellar neoplasms were shown in one study to possess certain fine structural attributes suggesting ependymal differentiation and raising the question of their origin from specialized paraventricular cells known as tanycytes.[403] These features included lengthy, bipolar cytoplasmic extensions with surface microvilli; rare cilia, blebs, coated vesicles and pits; "synaptoid" complexes; intercellular junctions; and foot processes terminating on delimiting, perivascular basement membranes. An origin from radial glia associated with the optic tract has also been proposed.[404] It must be conceded, however, that the diagnosis of pilomyxoid astrocytoma may have been extended to tumors of nonuniform cytogenesis combined with spindle cell morphology and a propensity to myxoid change. Whatever their origins, pediatric neoplasms demonstrating pure pilomyxoid astrocytoma histology carry a higher risk of local progression, symptomatic CSF seeding, and tumor-related death than pilocytic astrocytomas of the usual variety.[397,398] Nevertheless, an official WHO grade has not been assigned in the latest scheme, given the still limited and sometimes inconsistent clinical experiences.[278]

Pleomorphic Xanthoastrocytoma

The **pleomorphic xanthoastrocytoma (WHO grade II)** is a histologically alarming, yet biologically favorable neoplasm that typically presents in later childhood or early adult life and exhibits a predilection for the cerebral hemispheres, particularly the temporal lobes.[405,406] Cerebellar,[407] intramedullary,[408] intrasellar,[409] and retinal[410] examples have been described, as have morphologically similar tumors of the pineal region reported under the rubric of "pleomorphic granular cell astrocytoma."[411] Neuroradiological demonstration of a well-demarcated and partially cystic lesion containing superficially positioned, contrast-enhancing mural components of nodular or plaque-like contour is especially suggestive (Fig. 43.68). Usually unaccompanied by significant mass effect or edema, the latter may adhere to dura and can appear at operation to be predominantly extra-axial.

Evaluation of surgical specimens often shows much of the pleomorphic xanthoastrocytoma to occupy the leptomeninges and subarachnoid space but invariably discloses foci of brain parenchymal invasion in which neoplastic cells permeate Virchow–Robin spaces and the neuropil proper. The tumor is named for its potentially bizarre cytologic characteristics and the tendency of its constituent cells to intracytoplasmic lipid accumulation, although the latter is not a uniformly conspicuous feature. Most examples are composed of spindle-shaped elements in fascicular array admixed with tumor giant cells displaying worrisome, even grotesque, nuclear abnormalities (Fig. 43.69). The abundant cytoplasm of these cells may appear foamy or coarsely vacuolated—attesting to advanced lipidization—but more commonly assumes a ground-glass, finely granular or hyalin quality. Reactive lymphoid infiltrates (at times extensive) and aggregated eosinophilic granular bodies round out the histologic picture. The latter, an important clue to the diagnosis, are shared by certain other slowly growing neuroepithelial neoplasms, notably the pilocytic astrocytoma and ganglioglioma, and so likely reflect a process of cellular senescence. In fact, "composite" tumors harboring

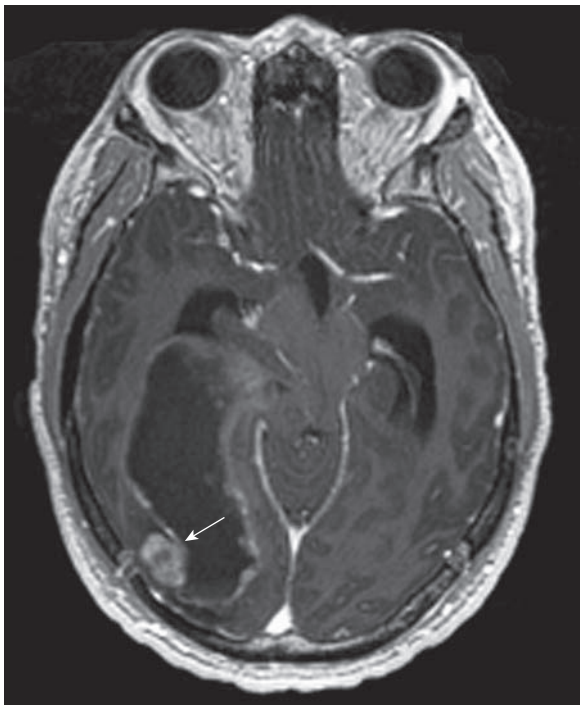

Figure 43.68 Pleomorphic Xanthoastrocytoma. This temporo-occipital example is represented by a sharply delimited, intensely and homogenously contrast-enhancing nodule *(arrow)* that projects into a large cyst on postcontrast magnetic resonance imaging. Pilocytic astrocytomas and gangliogliomas may exhibit identical neuroradiological profiles and are the major differential diagnostic considerations in this setting.

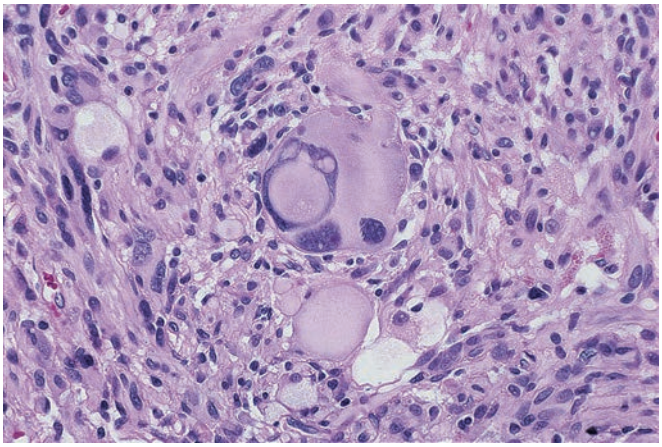

Figure 43.69 Pleomorphic Xanthoastrocytoma. Spindle and giant cells, including bizarre multinucleated forms, combine to give this relatively indolent neoplasm a most disturbing appearance. Note hyaline, granular, and vacuolar cytoplasmic alterations, the last attesting to lipid accumulation.

gangliogliomatous and xanthoastrocytomatous components are on record,[412] and we have rarely encountered cerebral hemispheric astrocytomas of pilocytic type with foci of leptomeningeal spread conforming to the histology of the pleomorphic xanthoastrocytoma in unalloyed form. Additional features described in select cases include a cohesive, nesting or alveolar growth pattern,[413] a hyalinizing, angiomatoid stromal vascular response,[414] and melanotic pigmentation.[415]

The sarcomatoid histologic presentation of the pleomorphic xanthoastrocytoma may be rendered all the more misleading by an intricate pericellular pattern of reticulin deposition, which is in flagrant violation of the neurohistochemical principle that such staining in glial, as opposed to mesodermally derived, neoplasms typically remains confined to supporting vasculature. This feature actually reflects the elaboration of encircling basal lamina material by tumor cells, demonstrable at the ultrastructural level or by collagen type IV or laminin immunostains.[413] This feature has been considered, along with the characteristically superficial location, as evidence of its derivation from a specialized class of subpial astrocytes having radially oriented cytoplasmic processes that are normally invested by basement membranes.[405] GFAP and/or OLIG2 expression, mandatory for definite diagnosis, effectively segregates this tumor from mesenchymal neoplasms,[405,416] though occasionally, typical examples may contain relatively few immunolabeled cells. Diffuse cytoplasmic immunoreactivity for S-100 protein is the rule, and tumor cells may be immunolabeled with α1-antitrypsin, α1-antichymotrypsin, and other "histiocytic markers."[417] The latter reagents stain a variety of neoplastic (including glial) cell types and are of notoriously little discriminatory value when applied to neurosurgical material. It is noteworthy that the tumors under discussion often harbor tumor cells that do not resemble ganglion cells, yet bind antibodies to SYN (among other neuronal antigens) and can exhibit ultrastructural features of neuronal differentiation (including clear [synaptic-type] and dense core vesicles).[418] This would suggest that pleomorphic xanthoastrocytomas are capable of divergent glioneuronal differentiation and would serve, along with shared clinicobiologic features, to further ally these curious neoplasms with gangliogliomas. Noteworthy in this connection (and useful for purposes of diagnosis) is the observation that many pleomorphic xanthoastrocytomas exhibit membranous immunolabeling of tumor cells for CD34, as well as immunoreactive non-neoplastic cells of highly ramified appearance in adjacent cortex (Fig. 43.70).[419] Furthermore, up to two-thirds of cases express the mutant BRAF V600E protein, a feature also seen in related neoplasms such as ganglioglioma and DNT.[420,421] Though not entirely specific, this genetic alteration represents both a diagnostically and potentially therapeutically useful biomarker, which seems to be retained in rare examples that undergo a peculiar form of anaplastic transformation to epithelioid glioblastoma (see glioblastoma variants and patterns).[324] These immunohistochemical features may aid in the distinction of pleomorphic xanthoastrocytomas from giant cell glioblastomas,[422] although care must be exercised since the labeling of giant cell (and other) glioblastomas for neuronal markers, CD34, and/or BRAF V600E have also been occasionally reported.[423]

Despite their disturbing morphology, pleomorphic xanthoastrocytomas tend to behave in relatively benign clinical fashion, and gross total resection usually suffices to achieve long-term tumor control. A closely characterized series of 74 cases with median follow-up of 7.6 years revealed 5-year recurrence-free and overall survivals of 71% and 90% for standard (WHO grade II) tumors versus 49% and 57%, respectively, for the anaplastic (WHO grade III) counterparts, the anaplastic designation defined primarily by the presence of at least 5 mitoses per 10 high-power fields[406]; this criterion has now been similarly adopted by the WHO. Higher-grade examples may assume a number of cytologic patterns (including epithelioid). Ironically, anaplastic foci are often less pleomorphic, yet more cellular and infiltrative, often resembling diffuse astrocytomas (including glioblastoma when accompanied by palisading necrosis). In addition to tumor grade, extent of tumor removal bears critically on both the risk of recurrence and death from disease, while patients with BRAF mutant tumors seemingly enjoy longer survivals than those with wildtype neoplasms.[406] This difference may become even

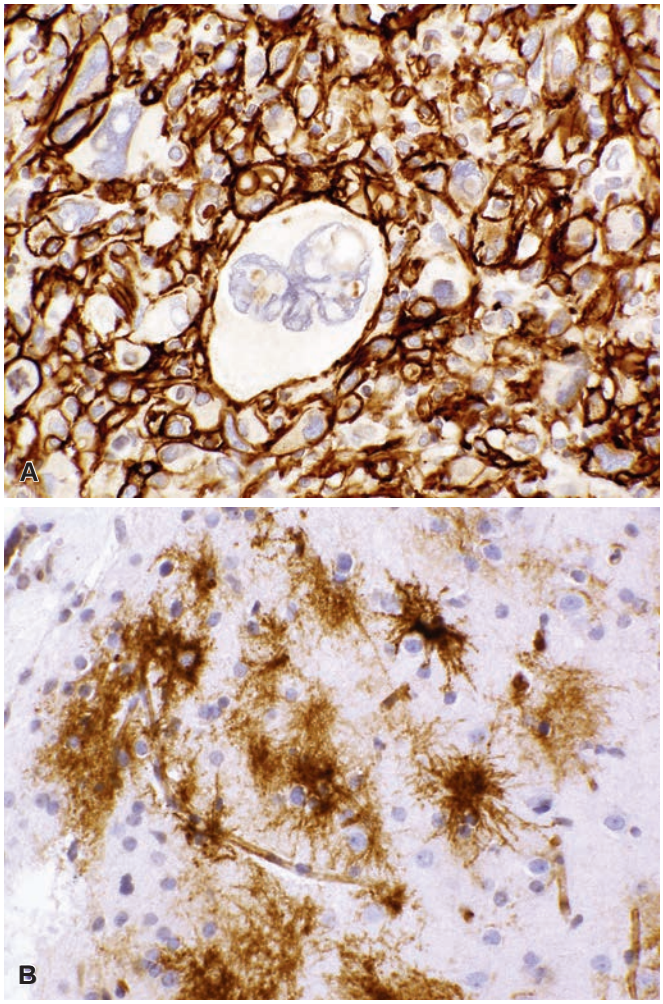

Figure 43.70 Pleomorphic Xanthoastrocytoma. The immunoexpression of CD34 by tumor cells **(A)** and by process-bearing neural cells in adjoining, uninvolved cerebral cortex **(B)** is characteristic. Note the membranous quality of the immunoreactivity.

more exaggerated in the future with increased use of BRAF inhibitors for clinically aggressive BRAF mutant pleomorphic xanthoastrocytomas. A recurring example with histologic evidence of anaplasia and an extensive clear cell component, as well as focally papillary growth, has been recorded.[424] We have encountered an example that developed sarcomatous components (pleomorphic "xanthoastrosarcoma")[419] as well as cases harboring elements morphologically and genetically resembling atypical teratoid/rhabdoid tumor (AT/RT) (including loss of INI1 expression),[425,426] the latter also arising from rare examples of ganglioglioma.[427] Local recurrence is the most common clinical pattern, although CSF-borne spread may also be encountered.[428,429]

Subependymal Giant Cell Astrocytoma (Tuberous Sclerosis)

The **subependymal giant cell astrocytoma** typically presents in the first or second decade of life as an intraventricular mass associated with obstructive hydrocephalus, a consequence of its practically unvarying location near the foramen of Monro (Fig. 43.71).[278,430] Only isolated reports describe extraventricular variants.[431,432] The lesion is virtually restricted to the setting of **tuberous sclerosis**, a disorder transmissible in autosomal dominant fashion via loci on chromosomes 9q34

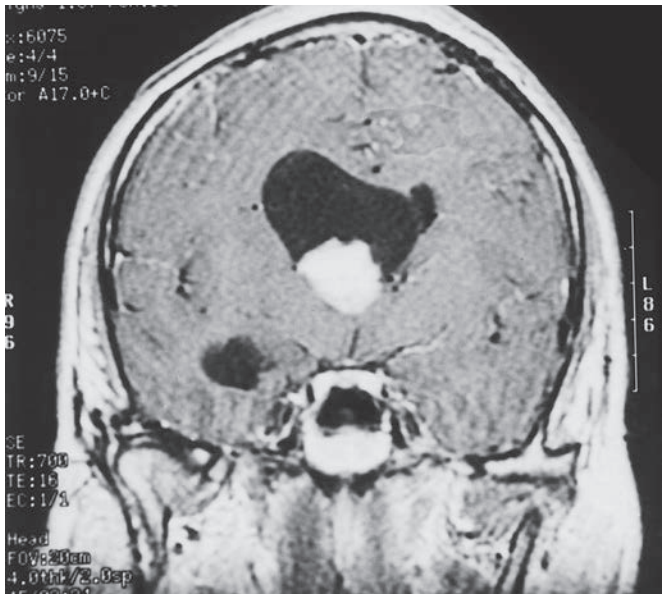

Figure 43.71 Subependymal Giant Cell Astrocytoma. This postcontrast injection magnetic resonance imaging demonstrates the subependymal giant cell astrocytoma's typically intraventricular location near the foramen of Monro (with resulting obstructive hydrocephalus), as well as its characteristic circumscription. This example was not associated with other features of tuberous sclerosis.

(TSC1) and 16p13.3 *(TSC2)* but often encountered in a nonfamilial form resulting from spontaneous mutation.[278] Traditionally defined by the triad of mental retardation, epilepsy, and midfacial angiofibromatosis ("adenoma sebaceum"), this phakomatosis is named for distinctive foci of gyral expansion ("tubers") that are populated by dysmorphic neurons and giant astrocytes in architectural disarray, and feature an abnormal firmness ("sclerosis") resulting from glial overgrowth. Periventricular "candle gutterings," essentially miniature versions of the tumors under discussion, are also characteristic. Dominant extracranial manifestations of the tuberous sclerosis complex include renal angiomyolipomas, cardiac rhabdomyomas, pulmonary lymphangioleiomyomatosis, fibrous dysplasia of bone, microhamartomatous rectal polyps, and various cutaneous lesions (hypopigmented macules, shagreen patches, subungual fibromas, and, as mentioned, facial angiofibromas). Some afflicted patients also harbor retinal hamartomas similar to the subependymal nodules just described, or larger masses that would qualify as retinal giant cell astrocytomas. A pineal region tumor of this type in a child with tuberous sclerosis has been documented.[432]

The subependymal giant cell astrocytoma is a sharply delineated, spherical or multinodular mass of fleshy, gray–pink tissue that is anchored to the ventricular wall over a broad front. Calcifications are common, and some examples exhibit foci of cystic change. Constituent cells are large, closely apposed, and characterized by polygonal (ganglion cell–like), rounded (gemistocyte-like), or spindled profiles (Fig. 43.72). Their eosinophilic cytoplasm often has a glassy or hyaline appearance, and their eccentrically positioned, vesicular nuclei, and prominent nucleoli distinctly resemble those of large neurons or ganglion cells. An intersecting fibrovascular stroma lends a lobular architecture to many examples, and tumor cell processes often condense about blood vessels in ependymoma-like fashion. A curious feature of many cases is infiltration by mast cells. Immunohistochemical assessment may reveal only few GFAP-positive elements and—designation of this neoplasm as an astrocytoma notwithstanding—may show some tumor cells to colabel for (or

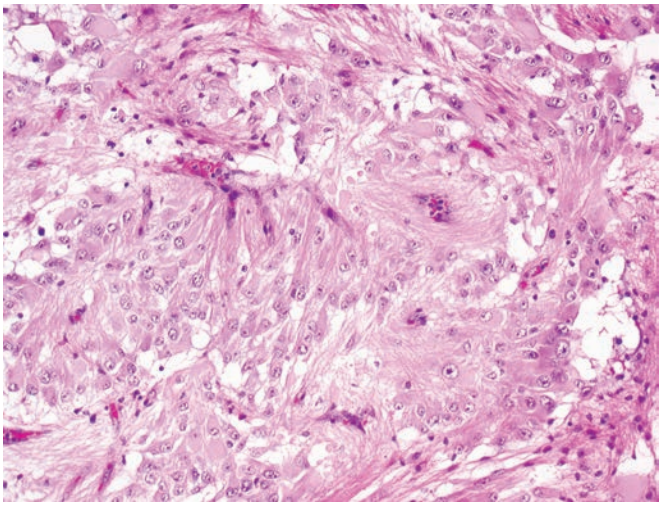

Figure 43.72 Subependymal Giant Cell Astrocytoma. Tumor cells that achieve truly giant proportions, often polygonal in contour and closely apposed in lobular array, are responsible for this neoplasm's name (but not evident in all cases). Note also the spindled elements and perivascular nuclear-free zones resembling the perivascular pseudorosettes of ependymomas.

exclusively express) neuronal antigens, such as class III β-tubulin, neurofilament proteins (NFPs), and, rarely, SYN.[433,434] Ultrastructural studies have demonstrated the presence of dense-core granules and synaptic formations in select cases, confirming the ability of subependymal giant cell astrocytomas to differentiate along neuronal, as well as glial, lines.[433] Accordingly, some neuropathologists prefer to designate these neoplasms simply as subependymal giant cell tumors. Ambiguous glioneuronal features also characterize the morphologically similar "balloon cells" seen in cortical tubers and focal cortical dysplasia type IIb, suggesting a disturbance of normal lineage commitment.[433] Subependymal giant cell astrocytomas do not exhibit immunolabeling for HMB-45, and typically have low MIB-1 indices.[435]

Subependymal giant cell astrocytomas enlarge slowly, rarely invade adjacent cerebral structures, and, isolated examples excepted,[436] have not been reported to exploit the CSF as a means of dissemination. Recurrence following gross total resection is rare, and these indolent neoplasms are not prone to malignant transformation. Although reported examples are few, cases with mitotic activity and foci of necrosis do not appear to behave in a particularly sinister fashion, although highly exceptional examples may manifest frankly anaplastic features with more aggressive clinical behavior.[437]

Desmoplastic Infantile Astrocytoma

The desmoplastic cerebral astrocytoma of infancy or desmoplastic infantile astrocytoma is a rare lesion now recognized as belonging to a tumor family capable of divergent and advanced glioneuronal differentiation. Accordingly, we address this entity along with its variant—the desmoplastic infantile ganglioglioma—in our discussion of neuronal and glioneuronal tumors.

Ependymal Tumors

This section includes those neoplasms that have traditionally been classified as ependymal tumors. Although astroblastoma, chordoid glioma of the third ventricle, angiocentric glioma, and papillary tumor of the pineal region all manifest at least some fine structural and immunohistochemical evidence of ependymal differentiation, they are discussed under separate headings that follow, consistent with the WHO format that segregates these distinctive lesions from the conventional ependymoma group.

Ependymomas constitute no more than 5%–9% of primary CNS neoplasms, their prevalence relative to other tumor types varying considerably with patient age and presenting location.[278] A majority of intracranial examples arise in childhood, whereas intramedullary variants more commonly afflict adults. The incidence of the former peaks in the first decade of life, ependymomas comprising approximately 10% of intracranial neoplasms in the pediatric population and up to 30% of those encountered in children under 3 years of age. At least two-thirds of these childhood tumors are situated within the fourth ventricle and consequently present with evidence of increased intracranial pressure secondary to obstructive hydrocephalus. Supratentorial lesions are more evenly distributed among children and adults and are more likely to be associated with seizures and focal motor deficits.

Ependymomas of the spinal cord (other than those of myxopapillary type) usually arise within cervicothoracic segments and exhibit a predilection for the fourth and fifth decades of life, constituting the most common intramedullary neoplasms of adulthood.[438] Principal clinical manifestations include pain localized to the neck or back, numbness and paresthesias of the distal extremities, atrophy of hand musculature, and gait disturbances. An intramedullary location and multifocality characterize ependymomas complicating NF2, a subset of sporadic spinal cord examples sharing with these predetermined variants alterations of the *NF2* tumor suppressor gene on chromosome 22q12.[278,439] Ependymomas may rarely arise within cranial nerves,[440] the sella turcica,[441,442] and retina[443] and have been reported to originate in the ovary and periadnexal pelvic tissues,[444] abdominal cavity,[445] liver,[446] mediastinum,[447] and lung,[448] though female genital tract and mediastinal cases may well represent "lopsided" (i.e. monodermal) teratomas.

Wherever situated, ependymomas tend to be well circumscribed and contrast enhancing on neuroradiological study. Supratentorial examples are often, but not invariably, found to communicate with or abut the ventricular system, lobar types frequently exhibiting cystic change and focal calcification. The latter is also a relatively common feature of posterior fossa lesions, which tend to be anchored to the floor of the fourth ventricle. Medulloblastomas, by contrast, only exceptionally undergo any appreciable mineralization and usually hang from the fourth ventricular roof when localized to the midline. Ependymomas may exploit CSF exit foramina to escape the restrictive confines of the fourth ventricle and, in so doing, can encircle the medulla and cervical spinal cord. Intramedullary variants produce a fusiform widening of involved segments and commonly precipitate syrinx formation, cystic dissection of the spinal cord usually progressing rostrally. MRI demonstration of a T2-hypointense "hemosiderin cap" atop the rostral pole of a well-delimited and enhancing intramedullary mass is particularly suggestive.

The conventional **ependymoma (WHO grade II)** is typified by a dense meshwork of fibrillary cytoplasmic processes that condense, collar-like, about stromal blood vessels in formations known as perivascular pseudorosettes (Fig. 43.73). These are accompanied in a minority of cases by canals, tubules, or true rosettes lined by epithelioid cells surrounding a rounded gland-like lumen (Fig. 43.74). The term "**cellular ependymoma**" may be used for densely populated examples with relatively narrow pseudorosettes but little mitotic activity, though this conveys no clinically useful information and is no longer considered a WHO sanctioned variant. Tumor cell nuclei are rounded or spindled, characteristically exhibit an evenly granular chromatin distribution, generally lack nucleoli, and may contain invaginated cytoplasmic pseudoinclusions or exhibit longitudinal nuclear grooving.[449] Optimally visualized in cytologic preparations, the last feature—along with the tendency of neoplastic ependymal

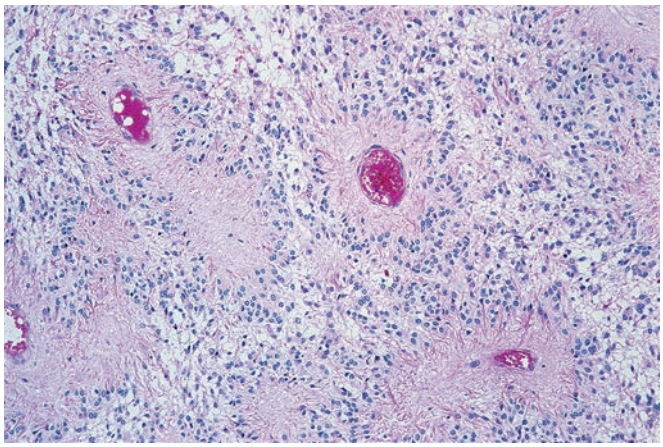

Figure 43.73 Ependymoma. The cytoplasmic processes of ependymal tumor cells condense about blood vessels to form pseudorosettes.

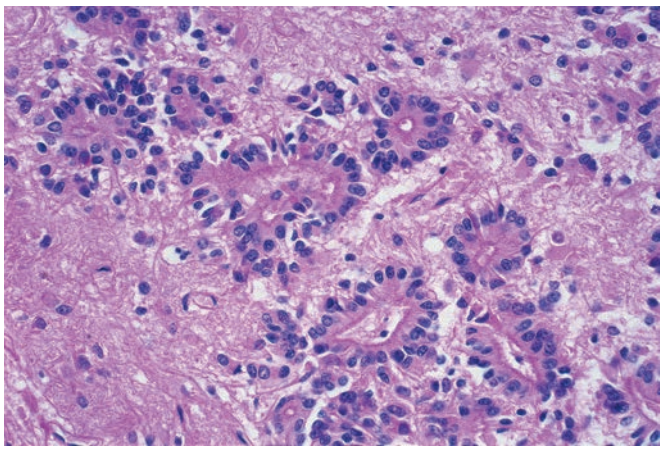

Figure 43.74 Ependymoma. The true ependymal rosette contains a well-defined central lumen. Clustered ciliary basal bodies ("blepharoplasts") are responsible for the enhanced, granular staining of tumor cell apices.

cells to remain attached to delicate blood vessels in papillary fashion when subjected to smearing or crushing—facilitates intraoperative diagnosis. While nuclear uniformity is the rule, pleomorphic elements may be admixed and "**giant cell**" **ependymomas** have been described within the cranial compartment, spinal cord, and filar region (see discussion of myxopapillary ependymoma later).[450] In the first of these locations, such cytologic changes are often accompanied by elevated mitotic activity and other features indicative of an aggressive biologic potential. Dystrophic calcification is a common finding in ependymomas, and some examples undergo osseous or chondroid metaplasia.[451] Melanotic ependymomas have been depicted,[452-454] as have "xanthomatous" variants containing intracytoplasmic lipid droplets,[455] examples harboring adipocyte-like ("lipomatous") elements,[456] and "epithelioid" subtypes characterized by the tight clustering of tumor cells in a conspicuously myxoid matrix.[457] Gemistocytic change may also be encountered in ependymomas, one report describing a case exhibiting globular, inclusion-like cytoplasmic bodies immunoreactive for GFAP.[457] Sarcomatous transformation ("ependymosarcoma") is exceptional but well documented.[458]

At the ultrastructural level, ependymomas exhibit a number of specialized cytoplasmic features characteristic of non-neoplastic ependyma.[459] Elaborate, zipper-like junctional complexes (zonulae

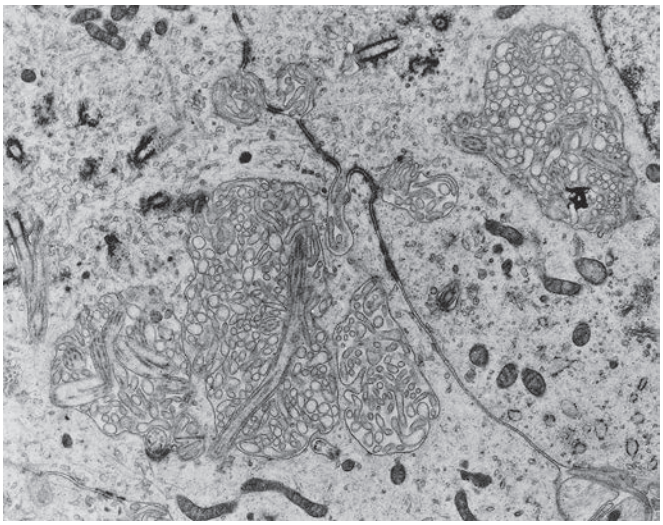

Figure 43.75 Ependymoma. Features indicative of ependymal differentiation at the ultrastructural level include the joining of tumor cells by elongated junctional complexes and the formation of lumens filled with microvilli and, in less number, cilia (×8800).

adherentes) bind their constituent cells and are likely responsible in some measure for the cohesive growth pattern and "pushing" margins typical of such tumors. Slender microvilli and (in smaller numbers) cilia sprout into the lumina of rosettes or intercellular clefts, again framed by membrane junctions of zonula adherens type (Fig. 43.75). Intracytoplasmic granules ("blepharoplasts") that are often apprehended by light microscopy along the apices of rosette-forming tumor cells in fact represent anchoring ciliary basal bodies. Also commonly observed on fine structural study is intracytoplasmic lumen formation, a phenomenon responsible in particularly pronounced cases for signet ring cell variants of ependymoma.[460] The phenomenon of microlumen formation by ependymal neoplasms has as its immunohistochemical correlate of dot- and ring-type patterns of cytoplasmic EMA labeling that are of considerable diagnostic value,[461] though not always apparent or entirely specific if displayed by only rare tumor cells (Fig. 43.76). Additional dot-like patterns may be seen with CD99 and/or D2-40 immunostains, which are similarly useful but not entirely specific; nonetheless, these patterns combined with only limited OLIG2 and SOX10 expression nevertheless aid in distinguishing ependymomas from astrocytic and oligodendroglial neoplasms.[462-466] Intermediate filaments composed principally of (and immunoreactive for) vimentin and GFAP are conspicuous in the cell processes (especially those involved in perivascular pseudorosettes), which, in select cases, may be coated by basal lamina material where they abut blood vessel walls.[467]

While maintaining a diagnostic ultrastructural and immunophenotypic fidelity to the ependymal line, a subset of ependymomas exhibit distinctly confounding histologic features. **Tanycytic ependymomas** (from the Greek *tanyos*—to stretch) may be confused with schwannomas, meningiomas, and fibrillary or pilocytic astrocytomas by virtue of their spindled cytology, fascicular growth patterns, and poorly developed, inconspicuous pseudorosettes (Fig. 43.77). Such tumors are typically encountered at spinal levels.[468] Ependymomas commonly contain, in addition to admixed elements of astrocytic appearance, cells characterized by rounded nuclear profiles and perinuclear cytoplasmic clearing. Variants dominated by the latter, **clear cell ependymomas**,[469,470] are practically restricted to the supratentorial compartment and often construed as oligodendroglial,

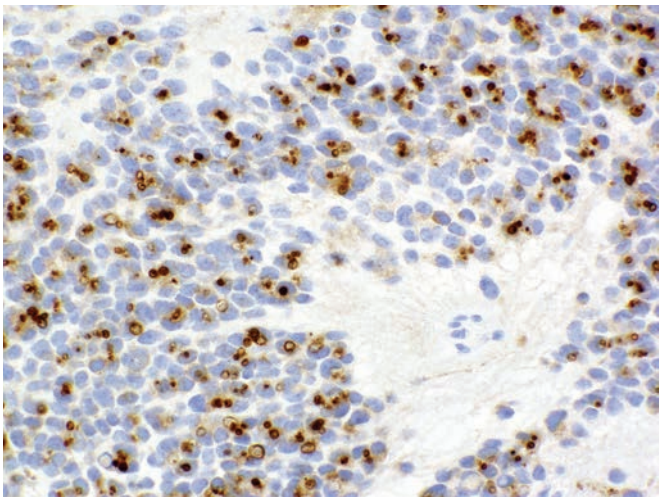

Figure 43.76 Ependymoma. Dot- and ring-type patterns of cytoplasmic immunolabeling for epithelial membrane antigen are diagnostically useful, though inconstant, features of this tumor group.

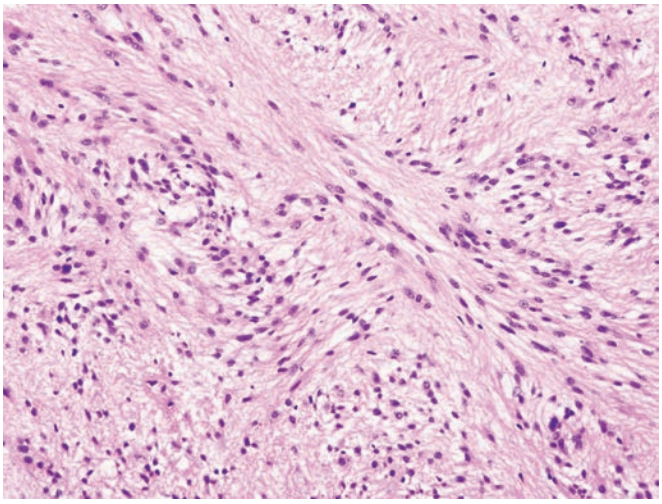

Figure 43.77 Tanycytic Ependymoma. The fascicular pattern and long slender processes of the tanycytic ependymoma often invokes a differential diagnosis with pilocytic astrocytoma and schwannoma. Useful clues in this case included intraparenchymal location, sharp demarcation, vague pseudorosettes, strong glial fibrillary acidic protein expression, and dot-like epithelial membrane antigen positivity (not shown).

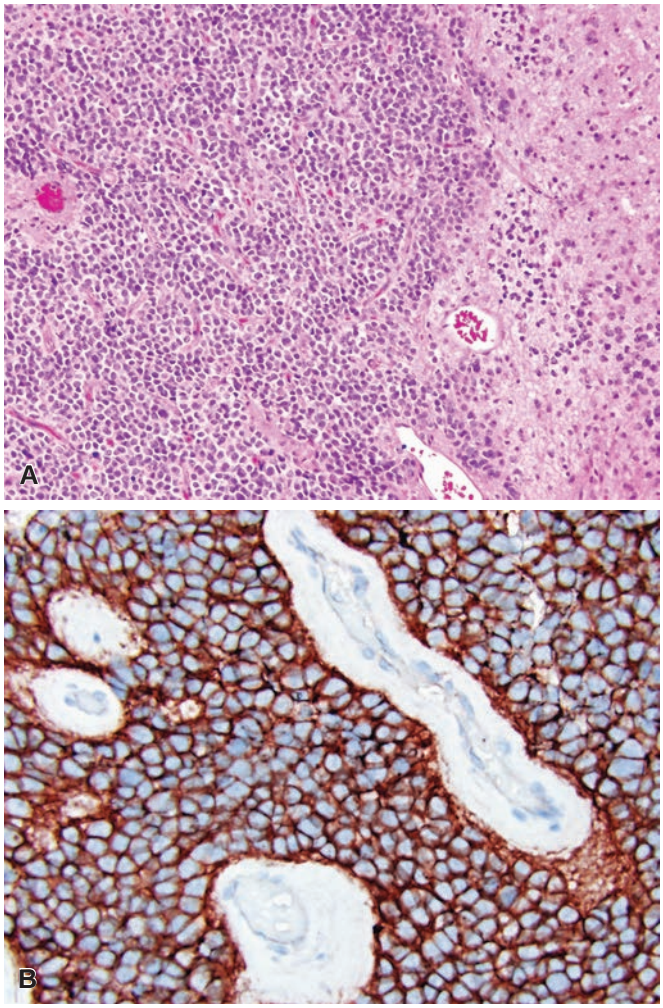

Figure 43.78 Clear Cell (RELA Fusion Positive) Ependymoma. A, The clear cell cytology and branching capillary network often suggests an oligodendroglioma, but note the sharp demarcation from adjacent brain on the right. **B,** Many such cases present as supratentorial masses and show RELA fusion by molecular analysis and L1CAM immunoreactivity.

a mischance made all the more inviting by the frequent presence of intratumoral calcospherules and a plexiform vascular network (Fig. 43.78A). Tumors of this kind often exhibit high-grade histologic features (e.g. high mitotic activity and MVP) and are prone to recur, often after relatively brief postoperative intervals. Again, these retain identifying ependymal attributes at the electron microscopic and immunohistochemical level, typically manifesting at least focal immunoreactivity of truncated perivascular cell processes for GFAP. On careful search they may be found to display dot-type EMA, CD99, and D2-40 expression, combined with no more than sparse OLIG2 expression and a solid rather than infiltrative growth pattern, as evidenced by lack of entrapped neurofilament-positive axons. These attributes permit their segregation from oligodendrogliomas and other potentially clear cell neoplasms, including extraventricular neurocytomas. The odd ependymoma, however, may harbor foci of neuronal differentiation.[471,472] In the latter regard, immunohistochemical labeling of some ependymomas, including clear cell forms, for SYN and the NeuN neuronal nuclear protein should be noted. Exceptional cases even exhibit overt neurocytic differentiation that can be appreciated on light microscopic assessment ("ependymoma with neuropil-like islands"),[472] but this rare phenomenon, like simple labeling for neuron-associated antigens, is typically restricted to minor components and contrasts with the widespread matrix expression of SYN and nuclear NeuN reactivity that characterizes many neurocytomas. Additionally, clear cell ependymomas may have prognostically unfavorable *RELA* gene fusions and L1CAM immunoreactivity (see Fig. 43.78B), characterizing a subset of supratentorial ependymomas (see later molecular features discussion).[473]

True **papillary ependymomas**—that is, tumors in which neoplastic ependymal cells assume a columnar configuration and are supported by fibrovascular cores rather than a fibrillary glial "stroma"—are very rare and need to be distinguished from metastatic papillary carcinomas, choroid plexus papillomas, and papillary meningiomas. Like other ependymomas, however, papillary variants label for S-100 protein, vimentin, EMA, CD99, D2-40, and GFAP. Apical EMA

reactivity (a feature potentially shared by ependymal rosettes) may be apparent, as may cytoplasmic decoration with the AE1/3 antikeratin "cocktail," but ependymomas usually do not immunolabel for CAM 5.2, CK7, CK20, or CK903.[467] If present at all, cytokeratin-positive tumor cells are typically few. One screening study[474] found 2 of 27 ependymomas to manifest nuclear immunoexpression of thyroid transcription factor (TTF)-1, though neither of these tumors (both localized to the third ventricle) was described as papillary. Epithelial neoplasms of the choroid plexus may show limited GFAP immunoreactive ependymal differentiation, but this phenomenon (which underscores a shared neurocytogenesis), when it occurs, is characteristically focal. Choroid plexus papillomas, furthermore, are generally distinct from intracranial ependymomas in their reactivity for E-cadherin but not neural cell adhesion molecule (NCAM),[475] more diffuse labeling for CAM 5.2 and CK7, expression of transthyretin, Kir 7.1, and stanniocalcin-1, and elaboration of continuous basement membranes demonstrable by immunohistochemical assessment for collagen IV or laminin.[476] Select papillary meningiomas have been described as GFAP immunoreactive (see "Meningothelial Tumors"), but these are extra-axial, dural-based neoplasms that coexpress somatostatin receptor 2a (SSTR2a)[477] and do not show ependymal characteristics by electron microscopy.

Location and extent of resection, along with the molecular phenotype (discussed later), have a significant effect on the prognosis of ependymomas. The intramedullary examples usually encountered in adults often prove amenable to control by surgical means alone in experienced hands.[438] The same cannot be said of tumors located within the cranial compartment. As posterior fossa ependymomas regularly colonize critical bulbar tissues along the floor of the fourth ventricle, few lend themselves to truly complete removal. The large majority recur despite adjuvant treatment, and approximately half kill afflicted children within 5 years of presentation (mortality rates being highest for those below 3 years of age).[278] Supratentorial lesions are also prone to regrowth, though resectable tumors may remain in remission for years after operation. The importance of histology as an independent predictor of prognosis remains controversial.[478] Unfortunately, analysis of this contradictory literature is complicated by the frequent application of nonuniform, highly subjective and consequently irreproducible grading parameters. Poorly differentiated tumors exhibiting dense cellularity and conspicuous mitotic activity (which may be accompanied by complex MVP and necrosis with palisading) merit the designation of **anaplastic ependymoma (WHO grade III)** on morphologic grounds (Fig. 43.79) and have proven more aggressive than their low-grade counterparts in some but not all studies. However, these histologic findings are not consistently predictive of an accelerated course or decreased survival times. The prognostic implications of only regional anaplasia in the form of nodular microscopic foci of increased cellularity and mitotic activity also needs clarifying, though it is likely that future molecular classification will more accurately reflect prognosis and guide patient management.[479] Interestingly, features of anaplasia are especially common in the intracranial ependymomas of young children, and only rarely encountered in adult-onset ependymomas of the spinal cord. Regional necrosis without palisades is a common finding in posterior fossa ependymomas and alone does not brand a lesion as anaplastic. As regards other morphologic features of possible biologic significance, microinvasion of bordering neuroparenchyma by dyscohesive tumor cells presaged recurrence in one study of pediatric ependymomas.[480] Elevated MIB-1 labeling indices have been correlated with aggressive histology and poor outcome, but widely varying "cutoff" values, ranging from 5% to 20% or higher,[481,482] have been reported as significant. Molecular genetic alterations, such as chromosome 1q gains, have been identified in subsets of anaplastic ependymoma but are not currently tested for in routine practice.[278]

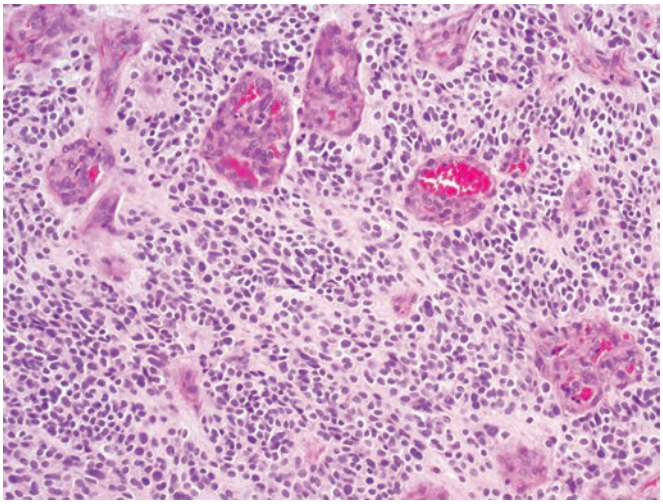

Figure 43.79 Anaplastic ependymoma, associated with hypercellularity, increased mitotic activity, and microvascular proliferation.

Despite their preferential distribution in and around the ventricular system, intracranial ependymomas only occasionally give rise to symptomatic CSF-borne metastasis; the utility of histologic assessment in predicting this complication is, again, open to question. Distant extraneural metastasis is rare, and fatal ependymomas usually kill by uncontrollable progression at the primary site.

The **myxopapillary ependymoma (WHO grade I)** is a morphologically distinctive variant virtually restricted to[483] the region of the conus medullaris and filum terminale. An origin in cervicothoracic segments of the spinal cord is exceptional, and intracranial presentation exceedingly rare.[484,485] Extradural ependymomas that arise in the subcutaneous tissues overlying the sacrococcyx[486,487] or, less often, in the sacrum proper are typically of myxopapillary type.[488] These curious lesions probably originate from ependymal rests representing remnants of the extradural filum terminale or coccygeal medullary vestige, a derivative of the caudal neural tube persisting beneath the skin of the postanal pit as an ependyma-lined cleft. Such rests can exhibit myxopapillary features and should not be construed as neoplastic by sole virtue of this growth pattern.[489] An ependymoma of the broad ligament having myxopapillary components has been recorded,[490] as has a retinal glioma with myxopapillary ependymal features,[491] and a cortical ependymoma with foci resembling angiocentric glioma.[492]

Myxopapillary ependymomas share, along with other intramedullary tumors of the ependymal series, a predilection for adults in the third to fifth decades of life, though nearly one-fifth of those in a large Mayo Clinic series[483] involved patients younger than 20 years of age. Nearly all produce low back pain. Other manifestations include sciatica, sensorimotor deficits, impotence, and urinary and fecal incontinence. Neuroimaging studies usually demonstrate a sharply delimited, contrast-enhancing mass. Surgical exploration typically discloses a highly vascularized, ovoid, or sausage-shaped mass that may be invested by a fibrous pseudocapsule derived from the stroma of the filum. Advanced examples can envelop the cauda equina, erode into neighboring bony structures, and infiltrate paraspinal soft tissues. A gelatinous appearance is characteristic on sectioning, and many examples are hemorrhagic.

The myxopapillary ependymoma is named for the manner in which cuboidal tumor cells drape themselves about a basophilic, mucinous material, which in turn collars stromal blood vessels and collects in microcystic spaces (Fig. 43.80). Many examples contain, in addition, spindled elements that may engage in the formation

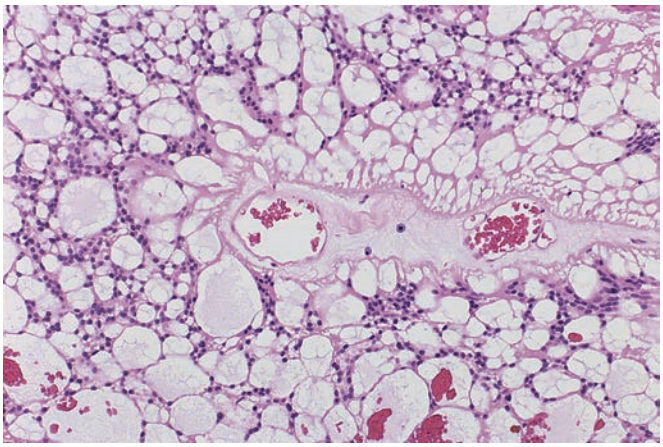

Figure 43.80 Myxopapillary Ependymoma. Note the manner in which mucinous material separates draping tumor cells from a hyalinized vascular core and accumulates in rounded microcysts.

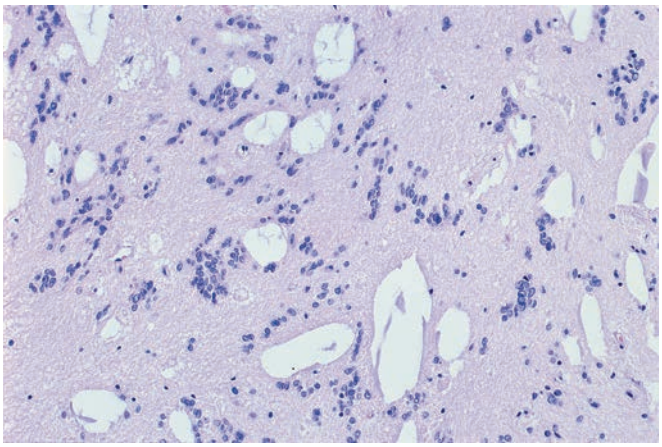

Figure 43.81 Subependymoma. The huddling of small tumor cells in an expansive fibrillar meshwork is characteristic of this entity. Microcystic changes commonly round out the histologic picture.

of gliovascular pseudorosettes. Variants displaying a conspicuous complement of pleomorphic tumor giant cells may be encountered.[493] Select cases feature eosinophilic spherules ("balloons"), possibly representing amalgamated collagen fibrils, as well as myxoid matrix components and basal lamina materials.[483] Common degenerative alterations include vascular sclerosis, hemorrhage, and hemosiderin deposition. Longstanding cases are at times characterized by extensive fibrous tissue overgrowth and virtual obliteration of their neoplastic cellular elements.

The histologic presentation of the myxopapillary ependymoma is in most cases sufficiently distinctive as to render it instantly recognizable to the pathologist familiar with this entity. Particularly myxomatous variants may assume a chordoma-like appearance, whereas examples dominated by spindle cell elements may be mistaken for schwannomas of spinal nerve root origin. A characteristic immunophenotype, as well as a patently ependymal fine structure, distinguishes myxopapillary ependymomas from these neoplasms, from mucinous carcinomas, myxochondroid meningiomas, and paragangliomas of the cauda equina region. The former share the coexpression of vimentin, S-100 protein, and GFAP with other ependymomas, but they do not elaborate chromogranin or CEA, and exhibit little (if any) labeling for CAM 5.2, CK7, or CK20. Tumor labeling by the AE1/3 cytokeratin "cocktail" may be encountered, although the dot and ring patterns of cytoplasmic EMA expression common to conventional ependymomas are usually not manifested by myxopapillary variants. The ultrastructural specializations previously detailed in reference to other ependymomas are faithfully evidenced by the myxopapillary type, though the latter may have less conspicuous cilia and microvilli, consistently elaborates basal lamina material that may invest cells as a continuous basement membrane and may contain a unique and specific ultrastructural marker consisting of microtubules aggregated within cisternae of rough endoplasmic reticulum.[494]

Myxopapillary ependymomas are usually indolent and amenable to surgical cure, but may recur even after ostensibly complete removal, and in some series have even been more aggressive than their WHO grade II ependymoma counterparts.[438] Of 77 patients in a Mayo Clinic series,[483] five (6.5%) died of their disease but did so following repeated local recurrences over periods ranging from 12 to 15 years. The presence of cytologic atypism and modest mitotic activity did not alter the prognosis in this study, whereas lesions amenable only to subtotal resection recurred and progressed more frequently than tumors lending themselves to complete removal. Adjuvant irradiation seems to improve outcome.[495] Frankly anaplastic histology is practically never encountered and is of uncertain significance in the face of gross total excision.[496] Myxopapillary ependymomas can spread via the CSF and rarely metastasize to the lungs, liver, lymph nodes, or bone.[495,497,498] Children seem to be at particular risk for CSF-borne dissemination, which may yet be kept under control for years by surgery and irradiation. Extraneural metastasis typically complicates stubbornly recurring tumors that have gained access to extravertebral soft tissues and is encountered at substantially increased frequency in patients with extradural variants arising in the sacrococcygeal region.[486,488] Neuroradiological survey of the spinal axis is mandatory before a diagnosis of primary intracranial myxopapillary ependymoma can be accepted. We have seen neurosurgical intervention prompted by complaints referable to expanding cerebellopontine angle or suprasellar myxopapillary ependymomas that proved to represent secondary deposits from filar region primaries. As was the case in one reported example,[499] the patients in question only later admitted to years of lower back pain.

We conclude this section with a brief account of the **subependymoma (WHO grade I)**, a lesion named for the resemblance of its constituent cells to, and proposed origin from, subependymal neuroglia distributed along the ventricular system. Most such tumors affect adults, are confined to the fourth ventricle, and are diminutive lesions that may be discovered incidentally; however, they can attain obstructing proportions.[500] Subependymomas situated in the lateral ventricles (particularly tumors originating about the foramen of Monro or from the septum pellucidum), third ventricle, cerebral aqueduct, or spinal cord are more likely to achieve symptomatic size.

Subependymomas are usually well delimited and lobulated. Small examples are typically solid and composed of rubbery or tough white tissue, whereas larger lesions often exhibit cystic change and foci of hemorrhagic discoloration. Calcification is common and may be extensive. Histologic examination discloses a multinodular growth pattern with small aggregates of tumor cells haphazardly disposed in a voluminous, hypovascular fibrillary meshwork that may be densely compacted or show spongy, microcystic rarefaction (Fig. 43.81). Tumor cell nuclei are generally uniform, having delicate oval contours and a punctate chromatin distribution. The occasional formation of ependymal rosettes, the occurrence of transitional or hybrid tumors containing elements of conventional ependymoma, and demonstrable ultrastructural ependymocytic specializations (e.g. zonulae adherentes, ciliary and microvillus arrays) all serve to ally

these neoplasms with the ependymoma family. These features notwithstanding, many subependymomas contain "astrocytoma-like" elements with fibrillary or gemistocytic profiles, which are devoid of prognostic import. We emphasize that subependymomas may contain a subset of cells with conspicuously enlarged and atypical nuclei, manifest modest mitotic activity, and exhibit foci of coagulative necrosis without palisading, but these findings are not predictive of an aggressive course. A melanotic example has been described,[453] as have cases containing sarcomatous elements.[305,501,502] Immunohistochemistry is rarely necessary, although occasional examples may be difficult to distinguish from pilocytic astrocytoma, especially on small biopsies. The immunoprofile is similar to that of ependymomas in general, including dot-like EMA positivity (though often in fewer cells than ependymoma) and a lack of the more widespread OLIG2- and SOX10-positive nuclei characterizing pilocytic astrocytomas.[465,466]

Excision is the treatment of choice for subependymomas, usually sufficing for control.[500]

Tumors of mixed subependymoma/ependymoma morphology are well recognized. In some studies these carry a higher risk of recurrence and are traditionally graded according to the histology of their conventionally ependymomatous components.[278]

Other Gliomas

Astroblastoma

The **astroblastoma** is a rare glial neoplasm that usually presents as a well-demarcated, contrast-enhancing mass in the cerebral hemisphere of a child, adolescent, or young adult.[503-505] The lesion is characterized by an often papillary or pseudorosetted architecture, with radially arranged cellular elements directing stout unipolar cytoplasmic processes toward centrally placed stromal blood vessels (Fig. 43.82). The latter are prone to progressive collagenous thickening and hyalinization, a striking feature of most cases that may advance to partial fibrous obliteration of the neoplastic tissue. Astroblastomatous cell processes are shorter, stouter, and less tapering than those forming ependymal-type pseudorosettes, differing further in their termination on target vessels as expanded footplates. Whereas ependymal pseudorosettes are generally embedded in a dense fibrillar matrix, the gliovascular structures of the astroblastoma are only tenuously supported by an intervening population of astrocyte-like tumor cells, or appear to float unanchored in tissue sections. Cytoplasmic immunolabeling for vimentin, S-100 protein, and GFAP are the rule, though the latter may be only focally demonstrable, and often highlights epithelioid cells rather than the fibrillar processes of astrocytomas and ependymomas.[503,505] Reactivity for low-molecular-weight cytokeratins and EMA has also been described,[506] but expression of SYN has not been demonstrated. In our experience (similar to ependymomas but unlike diffuse gliomas), neurofilament often highlights a predominantly solid growth pattern with few entrapped axons, while OLIG2 expression is often limited; as expected, IDH mutations are also lacking, though few cases have been studied to date.[507]

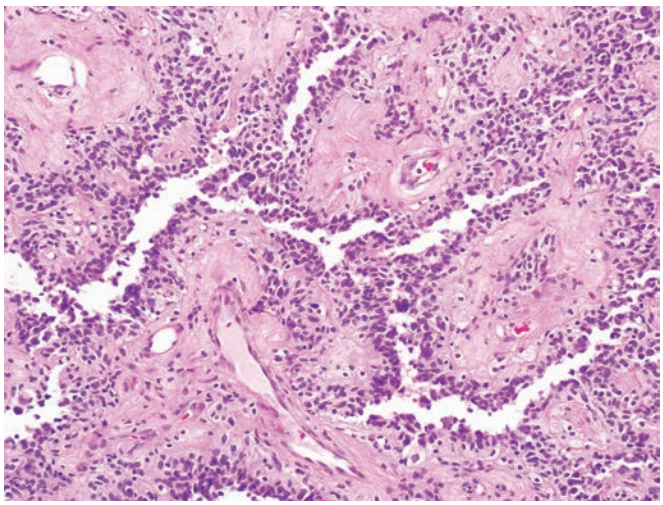

Figure 43.82 Astroblastoma. The stout and non-fibrillar cytoplasmic processes of this papillary neoplasm's constituent cells taper toward markedly hyalinized vascular cores.

Described ultrastructural attributes of the astroblastoma include a rich cytoplasmic complement of intermediate filaments, intercellular junctional complexes that may be well developed but that usually fall short of the elaborate zonulae adherentes characterizing ependymomas, and an investing basal lamina separating polar cell processes from adjoining stromal vessels.[505,508] In select cases, constituent cells have been found to display certain ultrastructural features characteristic of "tanycytes," which are ventricular lining elements that normally extend basal cytoplasmic processes towards regional capillaries. These include "purse string"-like constrictions of cell apices and crowning microvilli, as well as lamellar cytoplasmic interdigitations ("pleats") along lateral cell borders. Evidence of neuronal differentiation has not been detected.

Inasmuch as conventional astrocytomas of diffuse type (particularly gemistocytic variants) may occasionally harbor gliovascular formations comparable to those of the astroblastoma, the latter designation is best reserved for tumors with a pure, or at least dominant, architecture of the type just described, and a circumscribed, compact growth pattern. These may be divided into prognostically favorable and unfavorable types, although the correlation of histology and outcome is, admittedly, imperfect.[503-505] Tumors of orderly histologic aspect throughout and inconspicuous mitotic activity appear to be amenable to long-term control by surgical resection, the role of adjuvant therapy being unclear. Examples featuring regions of solid growth, conspicuous mitotic activity, and cellular atypia (accompanied, in some cases, by MVP and large zones of coagulative necrosis) are over-represented among recurring and fatal cases. These "anaplastic astroblastomas" may develop diffusely infiltrating components, some seeding the CSF. Rare examples may also overlap with other relatively demarcated gliomas such as anaplastic pleomorphic xanthoastrocytoma and epithelioid glioblastoma. That aggressive-looking variants may yet retain the circumscription typical of well-differentiated astroblastomas, rendering operative extirpation feasible, probably accounts for observations of unexpectedly long disease-free survival and cure in this setting, though most recorded cases have also been subjected to irradiation.

Whether astroblastomas constitute an entity sui generis is controversial, and some neuropathologists view these simply as variants of astrocytoma or ependymoma. One study suggests that combined gains of chromosomes 19 and 20q, generally foreign to conventional astrocytic and ependymal neoplasms, are particularly frequent in this rare tumor group.[503] Though this does not speak to the cytogenesis of astroblastomas, it does argue for their being accorded distinct nosologic status. Additionally, a recent genomics study suggests that a subset of these tumors is characterized by gene fusions involving the *MN1* gene on chromosome 22q12.3.[807]

Chordoid Glioma of the Third Ventricle

The rare neoplasms reported as **chordoid gliomas of the third ventricle** have occurred almost exclusively in adults, with a roughly 2:1 female to male ratio.[278,509,510] While tumors of comparable morphology and

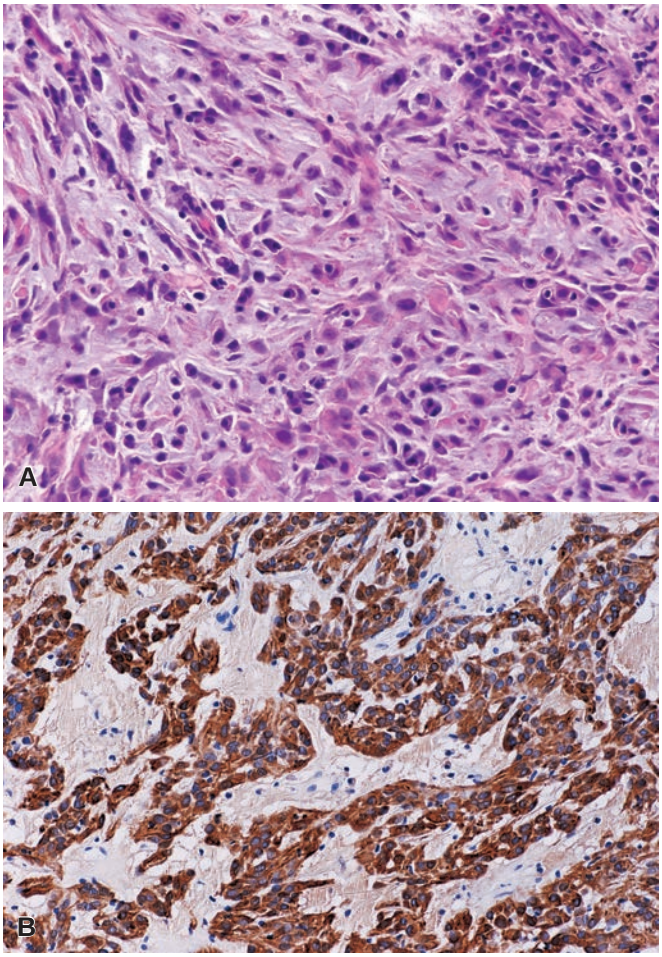

Figure 43.83 Chordoid Glioma of the Third Ventricle. Nests and anastomosing cords of epithelioid tumor cells arrayed against a variably myxoid stromal background typify this lesion **(A)**, which is distinguished from other chordoid neoplasms by its diffuse cytoplasmic immunolabeling for glial fibrillary acidic protein **(B)**. Note also in **A** the presence of plasma cells at upper right. These are often present in conspicuous numbers.

immunophenotype have been encountered in other locations,[511] these peculiar growths (as their name recognizes) have been nearly limited to the third ventricular/suprasellar compartment. MRI typically reveals a large, solid, sharply circumscribed and homogeneously contrast-enhancing mass producing obstructive hydrocephalus, associated with an array of clinical manifestations that potentially include headache, ataxia, visual and endocrine disturbances, marked fluctuations of weight, and psychotic/organic brain syndromes.

The chordoid glioma is noninfiltrative in its growth pattern and composed of epithelioid, oval to polygonal cells disposed as irregular cords or nests within a basophilic, myxoid matrix prone to coarse vacuolation (Fig. 43.83A). The latter may be PAS/PASD positive and faintly mucicarminophilic. Tumor cells possess eosinophilic cytoplasm and round or oval nuclei with finely granular or clumped chromatin and small nucleoli. Cell cords and nests may be outlined by reticulin fibers. A near constant feature of this peculiar neoplasm is interstitial and perivascular infiltration by lymphocytes and Russell body–bearing plasma cells. A unique pediatric example manifesting chondroid metaplasia has been recorded.[512] Pertinent to the differential diagnosis (which includes metastatic carcinoma, intradural chordoma, and chordoid meningioma) is the absence of true gland formation, physaliphorous cells, cellular whorls, intranuclear pseudoinclusions, and psammoma bodies. Mitoses are not found or are rare (MIB-1 labeling indices generally fall in the 0%–1.5% range), and conspicuous pleomorphism, MVP, and necrosis are also foreign to these lesions. Adjacent brain tissue typically manifests reactive gliosis with Rosenthal fiber formation.

A characteristic immunoprofile segregates chordoid gliomas from potential mimickers.[510,513] The former consistently show diffuse cytoplasmic labeling for GFAP (see Fig. 43.83B) as well as vimentin, express CD34 (with cell membrane accentuation), and may be focally S-100 protein positive but are EMA negative or only focally EMA immunoreactive. Limited labeling for a variety of cytokeratins has been reported, though the AE1/3 "cocktail" may yield a pattern overlapping with that of GFAP preparations due to cross reactivity. Along with a few other midline tumors near this region, nuclear TTF-1 expression is frequent, potentially suggesting an origin from the organum vasculosum of the lamina terminalis (see discussion later),[514] although similar expression in unrelated tumors such as pineocytomas and subependymal giant cell astrocytomas suggest that this may be a common feature of periventricular precursor cells in general.[515] Focal SYN expression was reported in select cases,[516] but examples assessed to date have not evidenced reactivity for NFPs, estrogen or progesterone receptors, desmin, chromogranin, or p53.[513] The limited ultrastructural experience communicated thus far suggests that chordoid gliomas differentiate along ependymal lines. While such pathognomonic ependymal specializations as microlumens delimited by intercellular junctional complexes of zonula adherens type have not been depicted, the formation of desmosome-like cytoplasmic attachments, microvilli, partially investing basal lamina, and, in one case,[517] aberrant juxtanuclear cilia would seem to ally these unusual tumors with ependymal neoplasms and to distance them from the astrocytic and oligodendroglial families, the latter further supported by a lack of IDH mutations.[514] In this connection, we would mention personal experience with an example containing papillary perivascular pseudorosettes and alveolus-like structures.[518] Chordoid gliomas have been described in one report[519] as sharing certain ultrastructural properties with specially modified ependymal cells that constitute the subcommissural organ—an ostensibly secretory body, situated in the dorsocaudal aspect of the third ventricle, that develops fully during human embryonic life and undergoes postnatal involution. Common features included zonation of cell bodies into a perinuclear region containing prominent profiles of rough endoplasmic reticulum and Golgi apparatus; an intermediate region occupied principally by mitochondria, smooth endoplasmic reticulum, and secretory-type granules; and an apical zone displaying a rich complement of intermediate filaments and crowning microvilli. An alternative origin from specialized ependyma lining the more rostrally situated lamina terminalis has been proposed,[514] which would account for the localization of relatively small tumors of this type (i.e. those not filling the entire third ventricle) to the latter region. Some workers[516] have found chordoid gliomas to consistently exhibit losses at chromosomes 9q21 and 11q13, the former alterations overlapping with those seen in select supratentorial ependymomas.

Chordoid gliomas of the third ventricle grow slowly, do not invade surrounding tissues, and have not been reported to metastasize via the CSF, but their attachment to hypothalamic/suprasellar structures complicates removal. Curiously, pulmonary thromboembolism has accounted for a disproportionate share of deaths occurring in the immediate postoperative period, a complication which is surprisingly common.[510,513,520] Incompletely resected examples may remain relatively stable but often regrow and can eventually prove fatal. The role of adjuvant therapy is undefined, although some suggest that postoperative radiosurgery is an effective approach when a complete resection cannot be safely achieved.[509]

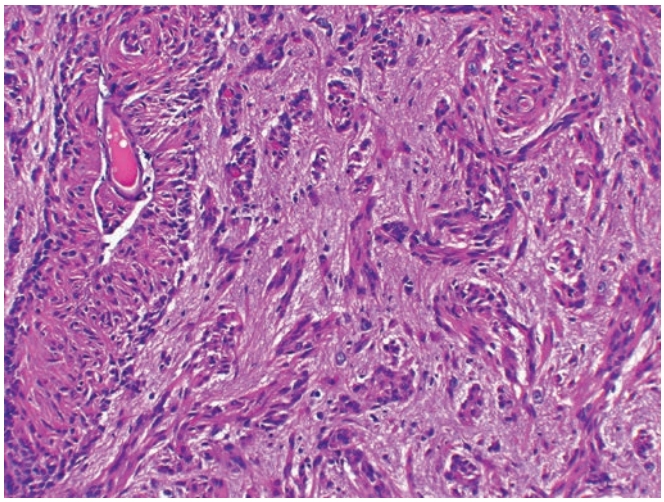

Figure 43.84 Angiocentric Glioma. Tumor cells of monomorphous, spindled profile sheath and collar cerebrocortical blood vessels in this typical example.

Angiocentric Glioma

Angiocentric glioma is a distinctive entity reported as "monomorphous angiocentric glioma" and "angiocentric neuroepithelial tumor" in two defining series.[521,522] Strongly associated with chronic, pharmacoresistant epilepsy having its onset in childhood or adolescence, this rare neoplasm is most often situated in the frontoparietal or temporal lobes, superficially positioned and largely cortical in topography. We have seen a possible example that arose from the tectum of the midbrain.[523] Relative circumscription, hyperintensity on T2-weighted and FLAIR sequences, and lack of contrast enhancement are regular MRI features, some examples manifesting stalk-like extensions of T2/FLAIR-hyperintense signal abnormality towards the underlying ventricular wall and rimming cortical T1 hyperintensity that may suggest the diagnosis.[521,524]

The hallmark of the angiocentric glioma is the manner in which native cerebrocortical blood vessels of all calibers are converted into a scaffolding, along which bipolar spindle cells of uniform cytologic profile are disposed in multilayered sleeves, and about which these neoplastic elements may also be radially arranged in ependymoma-like perivascular pseudorosettes (Fig. 43.84). A granular, stippled chromatin distribution within slender tumor cell nuclei further suggests an ependymocytic character. Spindled cells frequently align in perpendicular palisades beneath the pia and swirl in tight ("schwannoid") micronodules, may freely diffuse into the neuroparenchyma, and can form dense and intersecting fascicles that entirely replace the affected cortex. In some cases, tumor cells of rounded and epithelioid appearance also surround vessels and lie in sheets interrupted by irregular clefts and cavities. Additionally, rare examples include more solid foci with features of typical cortical ependymoma and may even show myxopapillary features.[492,525]

Immunohistochemical and ultrastructural assessments of the angiocentric glioma clearly indicate ependymal differentiation.[521,522,524] Tumor cells exhibit GFAP reactivity (a finding that removes meningioangiomatosis from further diagnostic consideration) and (in contrast to the spindled, bipolar constituents of the pilocytic and diffuse astrocytomas) frequently display dot-like cytoplasmic EMA labeling of the sort correlated with microlumen formation by ependymal neoplasms. EMA expression along cell surfaces may also be evident. The formation of microlumens delimited by zipper-like intercellular junctions has been confirmed at the ultrastructural level, with microvilli and cilia projecting into these structures. In explanation of a consistently extraventricular and cortex-based tumor manifesting these features, it has been proposed[521] that the angiocentric glioma derives from primitive neuroepithelial cells—the radial glia—that span the embryonic neuroepithelium and that may generate ependymocytes.

Angiocentric gliomas are mitotically inactive or display, at most, only rare mitoses. MIB-1 labeling indices are typically low, not exceeding 5% and usually falling below 2%. Clinical indolence is the rule, and these lesions may remain radiologically stable over protracted surveillance intervals, with simple excision generally effecting cure.[278] Malignant progression has been described[522] but is exceptional. Very few angiocentric gliomas have been genetically analyzed, although *MYB* gene alterations (mostly *MYB-QKI* fusion) have been reported, in common with several other low-grade pediatric gliomas.[526]

Choroid Plexus Tumors

The choroid plexus, a secretory organ responsible for the production of CSF, consists of a richly vascularized fibrous stroma draped by an epithelium that derives from neuroectodermal cells abutting the embryonic ventricular system. Only rarely do its specialized epithelial elements give rise to neoplasms, which generally affect children and present in sporadic fashion. Carcinomas (and, rarely, papillomas) of plexus origin, however, may be encountered in the familial Li–Fraumeni (germline *TP53* mutation) syndrome, while papillomas often complicate a complex of infantile flexor spasms, agenesis of the corpus callosum, and chorioretinal anomalies known as Aicardi syndrome, and have been recorded in cases of hypomelanosis of Ito with associated X;17(q12;p13) translocation.[278] As discussed further later, reports linking choroid plexus carcinomas to specific abnormalities of the AT/RT-associated *INI1* gene have been called into serious question.[527]

Tumors derived from the epithelium of the choroid plexus exhibit considerable morphologic and biologic diversity. The great majority, however, are benign neoplasms that replicate the villous architecture of the parent organ and are consequently termed **choroid plexus papillomas (WHO grade I)**.[278] Most of the latter come to attention during early childhood, displaying a predilection for the lateral ventricles. Adult cases, by contrast, are situated more often in the fourth ventricle or its lateral recesses, some presenting as tumors of the cerebellopontine angle. Multifocal presentations are on record,[528] as are ectopic neuroparenchymal,[529] suprasellar,[530] sacral nerve root-associated,[531] and sacral extradural[532] examples. Associated clinical manifestations are largely those of hydrocephalus resulting from ventricular outflow obstruction or the excessive production of CSF by these highly differentiated neoplasms. Rarely, plexus-related hydrocephalus in infancy is caused by villous hyperplasia of this organ.[533] Whether some diffuse lesions of this sort actually represent neoplasms (i.e. bilateral papillomas or papillomatosis) that can be identified by their proliferative activity as assessed in MIB-1 preparations is questionable.[534]

On gross inspection, the choroid plexus papilloma is a friable mass having a villiform or bosselated surface often likened to that of a cauliflower (Fig. 43.85). Lesions described as cystic forms of choroid plexus papilloma are exceptional.[535] Calcification, common to these tumors, imparts to some a gritty consistency or, when extensive, stony hardness that may hinder sectioning in the absence of decalcification. Histologic examination typically discloses a complex array of branching fibrovascular fronds covered by a monolayer of uniform cuboidal or columnar epithelial cells exhibiting minimal nuclear atypism and little, if any, mitotic activity (Fig. 43.86). In contrast to the "cobblestone" pattern of normal choroid plexus, papillomas typically display taller epithelial cells which lack the apical intercellular

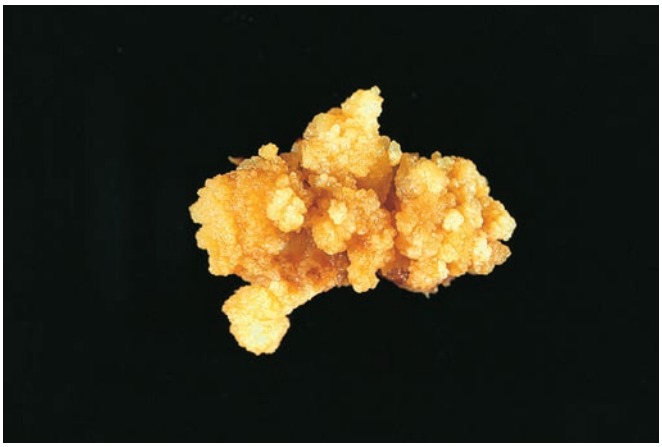

Figure 43.85 Choroid Plexus Papilloma. Note the characteristically bosselated surface of this surgically resected example. Deprived of its blood supply, the tumor tissue loses its normally hyperemic appearance and may assume a tan or golden hue.

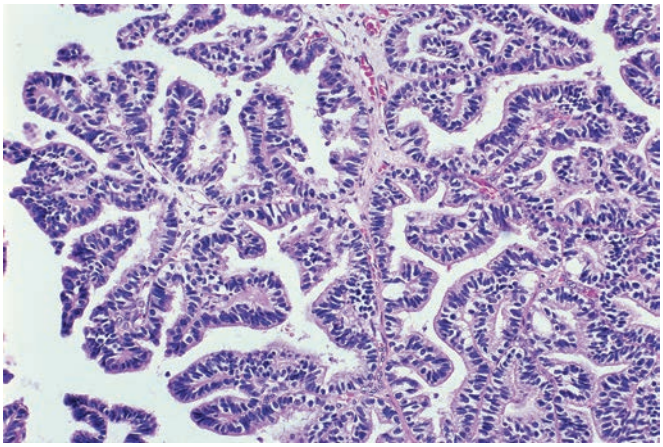

Figure 43.86 Choroid Plexus Papilloma. This example's delicate fibrovascular fronds are covered by an orderly, low columnar epithelium.

separations of their non-neoplastic counterparts. On ultrastructural study these cells rest on an uninterrupted basement membrane, are joined at their apices by elaborate junctional complexes, are crowned by microvilli, and may be ciliated.[536] The tumoral stroma, like that of the normal choroid plexus, may be conspicuously infiltrated by foamy macrophages and is, in select cases, the site of metaplastic bone or cartilage formation. The epithelial elements of some tumors undergo oncocytic change[537] (one reported example progressing to malignant "oncocytoma"[538]), and a rare melanotic variant of the choroid plexus papilloma has also been described.[539] These neoplasms may, in addition, show limited ependymal differentiation, signaled by foci in which tumor cells extend tapering, GFAP-immunoreactive cytoplasmic processes toward their fibrovascular cores. This finding presumably reflects the ontogeny of the plexus epithelium as a form of specialized ependyma, but choroid plexus papillomas do not elaborate the fibrillary glial "stroma" characteristic of ependymomas—an important differential diagnostic feature. Exceptional cases exhibit a gland-like, rather than papillary, growth pattern—an arrangement for which the designations of acinar or tubular choroid plexus adenoma have been invoked.[540] Some of these curious variants have been mucin producing.[541] Most peculiar, but convincingly documented, is the

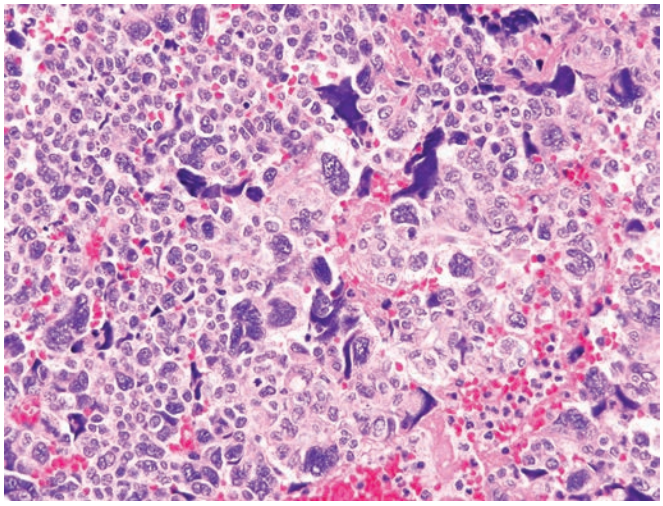

Figure 43.87 Choroid Plexus Carcinoma. In contrast to the choroid plexus papilloma, this tumor shows anaplastic cytology and a more solid growth pattern.

papilloma exhibiting overt neuronal differentiation signaled by micronodular collections of SYN-rich matrix ("choroid plexus papilloma with neuropil-like islands").[542]

The well-differentiated choroid plexus papilloma is usually amenable to curative resection. Regrowth at the primary site may be encountered, particularly after subtotal removal, but progression to carcinoma is rare[543] and focally recurrent lesions often remain surgically controllable. The capacity of otherwise conventional examples to seed the CSF and metastasize along the central neuraxis is a recognized but, fortunately, uncommon phenomenon.[544] More problematic is a subset of tumors, often dubbed **atypical choroid plexus papillomas**, that fall short of overt histologic malignancy but have unexpectedly complex architecture, cytologic atypia, modestly increased mitotic activity, focal necrosis, or penetration of juxtatumoral brain tissue. Some have noted an increased likelihood of recurrence and progression to histologic anaplasia on the part of tumors exhibiting worrisome morphologic traits of this sort, but this remains somewhat controversial.[545] It has been our experience, in fact, that "invasive" tumoral deposits are not infrequently identifiable along the perimeter of perfectly benign-appearing papillomas, where they are typically associated with a Rosenthal fiber–rich pilocytic astrogliosis attesting to a chronic and indolent process. No significance is attached to this finding.[278] The WHO recognizes atypical choroid plexus papillomas as grade II lesions, defining these as exhibiting, at a minimum, increased mitotic activity of two or more mitoses per 10 high-power microscopic fields. However, at least one study suggested that this finding is relevant only in older children.[546] Of note, while some genetic studies support a three-tiered prognostic scale for choroid plexus tumors, correlated in part with patient age, others lump the atypical papillomas squarely along with their WHO grade I counterparts.[547,548]

Choroid plexus carcinoma (WHO grade III) is the appropriate designation for frankly malignant epithelial neoplasms of plexus origin. The overwhelming majority of these rare tumors present in infancy or childhood and are situated in a lateral ventricle.[278] In contrast to their benign counterparts, choroid plexus carcinomas are often overtly anaplastic, highly proliferative, invasive, destructive, and typified by geographic foci of necrosis and hemorrhage (Fig. 43.87). Many, while maintaining a regional fidelity to the villiform architecture of the native plexus, contain foci in which their papillary structure breaks down and is replaced by nests and patternless sheets

of anaplastic cells exhibiting alarming pleomorphism and mitotic activity. Eosinophilic, PAS-positive and diastase-resistant globules are prominently displayed by some examples, and isolated cases have been described as containing melanotic cytoplasmic pigments.[549] These aggressive neoplasms often prove fatal, some escaping the confines of the ventricular system, seeding the subarachnoid space, and even metastasizing to extraneural sites, but cure of localized examples may be effected by gross total removal and adjuvant treatment.[550]

Application of an appropriate antibody panel can be recommended for purposes of distinguishing choroid plexus tumors from potential mimickers. Choroid plexus tumors often show cytoplasmic colabeling for vimentin, cytokeratins (CAM 5.2 and AE1/3 reactivity are the rule, though CK20 is highly variable in extent, one study[551] describing a CK7+/CK20– or CK7+/CK20+ immunophenotype in most plexus tumors), and S-100 protein (potentially expressed in nuclei as well). Neoplasms of the choroid plexus may, in addition, evidence their neuroepithelial lineage by expressing GFAP (usually in focal fashion), and the labeling of these tumors for SYN has also been described.[552] As previously discussed, intracranial ependymomas (including papillary variants) often exhibit widespread GFAP reactivity, contain few, if any, CAM 5.2– or CK7-positive elements, and are usually SYN negative. As compared to primary choroid plexus tumors, metastatic carcinomas are far more likely to exhibit immunoreactivity for EMA and the surface epithelial antigens identified by monoclonal antibodies HEA125 and Ber-EP4,[553] are less often S-100 protein positive, and (with rare exception) are GFAP negative. Cytoplasmic labeling for transthyretin, a 55-kDa protein involved in thyroxine and retinol transport, is a frequent feature of choroid plexus tumor immunophenotype but is inconstant (~70% of cases prove reactive) and shared by a subset of ependymomas, glioblastomas, and epithelial tumors metastatic to brain.[554]

Additional markers potentially useful in the identification of choroid plexus tumors, but not in general employed by neuropathologists, include antibodies to the excitatory amino acid transporter-1 (EAAT-1),[555] to Kir 7.1 (an inwardly rectifying potassium channel protein), and to stanniocalcin-1 (involved, among other functions, in calcium homeostasis).[554] Membranous EAAT-1 expression characterized 66% (23/35) of choroid plexus tumors but none of 77 metastatic carcinomas (including 64 papillary adenocarcinomas of varied origin) in one study.[555] Nearly 75% (17/23) of choroid plexus neoplasms (including all 5 carcinomas) tested in a second analysis manifested membranous cytoplasmic labeling for Kir 7.1, while 100 other primary and secondary brain tumors (including 19 ependymomas, 44 metastatic carcinomas, 11 glioblastomas, and 6 AT/RTs) proved nonreactive.[554] In the same study, cytoplasmic stanniocalcin-1 expression characterized 83% of choroid plexus tumors (including 3 of 5 malignant lesions) and single examples of DNT (neuronal labeling) and metastatic carcinoma of thyroid origin. Kir 7.1 and stanniocalcin-1 labeling may also distinguish plexus neoplasms from papillary tumors of the pineal region, discussed later in this chapter. EAAT-1 expression has been touted as a feature useful in distinguishing choroid plexus tumors from native choroid plexus,[556] though as stated earlier, this can usually be done morphologically, since choroid plexus tumors lack the normal "cobblestone" appearance of its non-neoplastic counterpart.

The INI1 (BAF47) immunostain is recommended for the purpose of distinguishing anaplastic choroid plexus carcinomas from AT/RTs, which share a predilection for infants and can regionally exhibit somewhat papillary or tubuloglandular growth patterns. This antibody recognizes the product of *SMARCB1*, a gene situated at chromosome band 22q11.2, that encodes a ubiquitously expressed protein active in chromatin remodeling. Whereas AT/RTs are left unlabeled by INI1 in consequence of their consistent association with biallelic gene inactivation, choroid plexus carcinomas regularly retained the expected nuclear reactivity with this reagent in a study of 20 cases classified as such by a group of experienced surgical neuropathologists.[527] Six additional neoplasms carrying referral diagnoses of choroid plexus carcinoma, but reclassified as AT/RTs, proved INI1 negative. While two (of four) plexus carcinomas analyzed exhibited monosomy 22, an abnormality that AT/RTs have in common with varied tumor types (e.g. meningiomas), none of seven assessed manifested mutations specifically involving *INI1*. Thus, the considerable morphologic and immunophenotypic overlap between choroid plexus carcinomas and AT/RTs likely accounted for prior misconception that *INI1* is involved in the carcinogenesis of both tumor types.

We stress that the diagnosis of choroid plexus carcinoma in an adult must be regarded with considerable skepticism (regardless of tumor location, morphology, or immunohistochemical characteristics), as this entity is vanishingly rare beyond childhood, and older patients presenting with intracranial carcinomas, including well-differentiated lesions of papillary configuration, almost invariably prove to have metastases from lung or other systemic primaries. With regard to the prognostic implications of immunophenotype in the setting of choroid plexus neoplasia, we would emphasize that the benign and malignant cannot be reliably distinguished on the basis of antigenic profile, though dampened expression of transthyretin and S-100 protein seems to be more characteristic of choroid plexus carcinomas and of papillomas that recur following resection.[554] Carcinomas may also be somewhat more prone to express CEA, though this is generally foreign to tumors of the choroid plexus family, and are more likely to exhibit widespread nuclear p53 labeling as well as MIB-1 (Ki-67) indices in excess of 5%–10%.[557] In one recent analysis, carcinomas lacking p53 immunoexpression and *TP53* mutations were associated with far more favorable courses than their p53-labeling and *TP53*-mutant counterparts, the latter often suggesting the possibility of Li–Fraumeni syndrome, a hereditary association which should therefore be raised in carcinomas with strong p53 expression.[558]

The reader's attention is called to a report describing as "**pigmented papillary epithelial neoplasm of the pituitary fossa**" a melanotic sellar tumor that underwent anaplastic spindle cell transformation following repeated resections and radiotherapy.[559] As suggested by the authors, this curiosity may represent an ectopic form of choroid plexus neoplasm.

Neuronal and Glioneuronal Tumors

Gangliocytoma and Ganglioglioma

A biologically heterogeneous assortment of CNS tumors, including gliomas and primitive neuroepithelial neoplasms of potentially aggressive character, are capable of neuronal differentiation and may spawn ganglion cell–like forms. The uncommon entities known as **gangliocytoma** and **ganglioglioma** (collectively termed "ganglion cell tumors") share a complement of large and essentially mature neurons unassociated, by definition, with recognizably embryonal elements. Much the more prevalent species, the ganglioglioma harbors an admixed glial population of neoplastic appearance that distinguishes this lesion from the pure gangliocytoma.[560] Ganglion cell tumors usually come to neurosurgical intervention within the first three decades of life[278,561] but may be encountered in older adults. By most accounts, they favor the supratentorial compartment, but examples have been described at all levels of the central neuraxis, and we concur with the observation that gangliogliomas constitute a significant percentage of pediatric tumors presenting in the brainstem and spinal cord.[562-564] Even cranial nerve cases have been depicted,[565,566] and an ectopic intraorbital presentation is also on record.[567] A

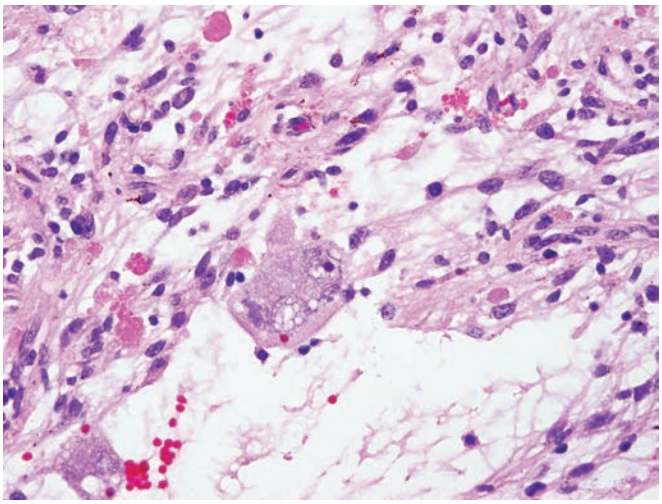

Figure 43.88 Ganglioglioma. The neoplastic nature of the ganglion cell tumor's large neurons is readily apparent from their cytologic abnormalities and multinucleation. Note admixed piloid astrocytic elements, microcystic architecture, and scattered eosinophilic granular bodies.

predilection for the temporal lobes accounts for the discovery of many ganglion cell tumors in the course of evaluation for partial complex epilepsy, often of protracted duration. Albeit nonspecific, neuroradiological presentation as a well-demarcated, partially cystic mass showing contrast enhancement of its solid components and foci of calcification is especially suggestive. The cerebral hemispheric lesion presenting as a discrete mural nodule within a cyst usually proves to be a ganglion cell tumor, pilocytic astrocytoma, or pleomorphic xanthoastrocytoma.

Common to the gangliocytoma and ganglioglioma is the irregular distribution of variably sized neurons, some of ganglion cell–like profile, in a delicate fibrillar matrix that is prone to spongy rarefaction and that often contains scattered calcospherules (Fig. 43.88). Microcystic changes are common in regions of predominantly glial composition. Whereas native neurons trapped in an advancing glial neoplasm generally manifest little cytologic alteration and tend to an even distribution and orderly polarity, the neuronal populace of the ganglion cell tumor often displays, in addition to obvious architectural disarray and anomalous clustering, conspicuous morphologic abnormalities that can include striking pleomorphism, multinucleation, cytoplasmic vacuolization, and gigantism. Some contain Alzheimer disease–type neurofibrillary tangles and other cytoplasmic inclusions seen in neurodegenerative and neuronal storage disorders.[568] Melanotic variants have been described,[569] as have ganglion cell tumors associated with (possibly progenitory) glioneuronal hamartomas,[570] with other maldevelopmental cerebrocortical anomalies,[571] and with the curious lesions known as DNTs (see later discussion).

The glial component of the ganglioglioma is typically astrocytic, GFAP positive, and well differentiated, usually assuming pilocytic or fibrillary guises.[572,573] Gemistocytic elements may be encountered but, if prominent, call the diagnosis into question. Gangliogliomas may contain pleomorphic xanthoastrocytomatous components, reference having previously been made in our discussion of the latter tumor type to "composite" lesions. While gangliogliomas may harbor constituents indistinguishable from conventional oligodendroglioma, the oligodendrocyte-like clear cells present in select ganglion cell tumors usually represent "neurocytes," that is, diminutive neurons.[574] A remarkable example of tanycytic ependymal differentiation on the part of a ganglioglioma is also on record.[575] Only exceptionally do gangliogliomas exhibit high-grade histologic features. This "malignant degeneration" typically involves their astroglial components and potentially results in a glioblastoma-like picture.[576]

Anaplastic ganglioglioma is the designation appropriate to the tumor densely populated by mitotically active glial cells, and MVP and necrosis may also be encountered; cytologic atypism alone, even if pronounced, does not constitute grounds for this diagnosis. Elements of anaplastic oligodendrogliomatous appearance have exceptionally been observed in malignant ganglioglial tumors.[577] Some cases of this sort, however, may actually represent oligodendrogliomas with ganglion cell components.[361] The recurrence of a ganglioglioma (3 years after subtotal resection and irradiation) as a high-grade neoplasm composed of cells exhibiting a hybrid neuronal/astrocytic phenotype on immunocytochemical and ultrastructural study has also been documented,[578] as have a neuroblastoma-like picture at relapse,[579] the emergence of sarcomatous components,[580] and bizarre examples of AT/RT evolving within gangliogliomas.[427]

Certain recurring histologic features merit emphasis as clues to ganglion cell tumor diagnosis. Eosinophilic granular bodies of lysosomal derivation that appear to aggregate in the matrices of many such tumors are noteworthy in this regard, as only the pilocytic astrocytoma and pleomorphic xanthoastrocytoma exhibit this presumably degenerative alteration with comparable frequency. Lymphoid infiltration can also be of some diagnostic utility to the pathologist not distracted by this common, "pseudoencephalitic" phenomenon. In fact, a florid inflammatory reaction extending into the substance of the lesion (i.e. not simply confined to the perivascular compartment) is only characteristic of gangliogliomas and the pleomorphic xanthoastrocytoma, the more so if plasma cells are found to participate. Desmoplasia, uncommonly associated with neoplasms of neuroepithelial lineage, needs be mentioned as imposing a disfiguring and deceptive spindling and fascicular or vaguely storiform architecture on the constituent cellular elements of some ganglion cell tumors. Stromal blood vessels, often prominent, frequently undergo sclerosis—ganglion cell tumors potentially masquerading as vascular malformations on angiographic and gross neurosurgical assessment.

Given their differentiated appearances, it should come as no surprise that ultrastructural studies have shown the tumoral neurons under discussion to elaborate cytoplasmic processes containing parallel microtubular arrays and clear, synaptic-type vesicles. These neurite-like extensions can terminate in well-developed synaptic complexes.[572] Neoplastic neuronal elements often harbor dense-core neurosecretory granules as well,[572] a feature generally foreign to native cortical neurons, and further depart from the latter in potentially containing spherical protein bodies characteristic of catecholaminergic neuronal populations.[581] While tumors of astrocytic lineage may assume ganglion cell–like cytologic profiles, they manifest none of these specialized neuronal features and in most instances are readily unmasked by their expression of GFAP.

The formation of aberrant axosomatic synapses is apparently responsible for the presence, in many ganglion cell tumors, of large neurons displaying a coarsely granular or linear deposition of reaction product about their perikarya on immunocytochemical assay for SYN (Fig. 43.89), a glycoprotein component of the presynaptic vesicle membrane.[572,574] This phenomenon bears significantly on the problem of distinguishing tumoral and native neurons—a comparable reaction pattern is not observed on immunoassessment of normal cerebral cortex—but must be cautiously interpreted. Circumperikaryal SYN labeling is a recognized attribute of some striatal, cerebellar, bulbar, and intramedullary neurons[582,583]; furthermore, cerebrocortical neurons entrapped within AVMs can evidence this immunoprofile.[582] An identical labeling pattern has been depicted in a lesion of the cerebral cortex reported as postradiation neuronal gigantism,[584] suggesting

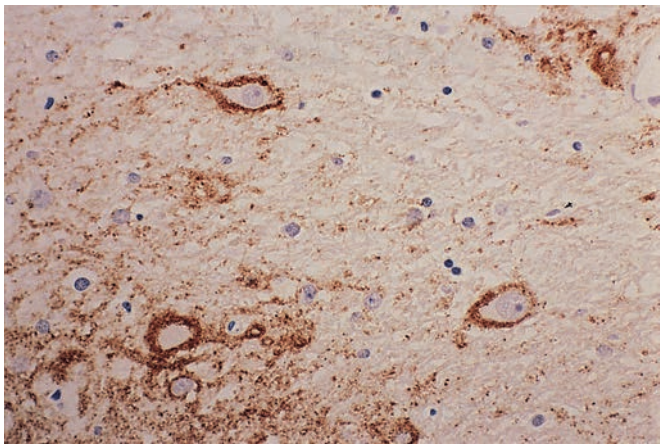

Figure 43.89 Ganglioglioma. Surface perikaryal labeling for synaptophysin characterizes the neuronal elements of some ganglion cell tumors on immunohistochemistry.

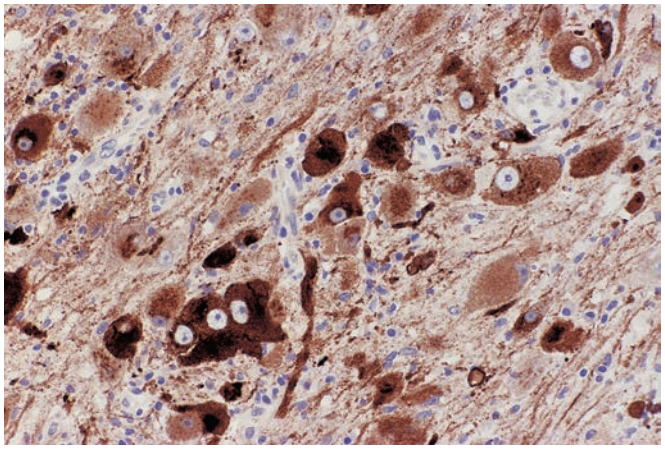

Figure 43.90 Ganglioglioma. Diffuse and strong cytoplasmic immunoreactivity for chromogranin A, a feature foreign to native cerebrocortical neurons, characterizes the neoplastic neuronal perikarya of some ganglion cell tumors.

that chronic, nonspecific neuronal injury may rarely provoke anomalous synaptic remodeling. Additional, and somewhat more specific (albeit inconstant), immunohistochemical evidence for the tumoral nature of a suspect neuronal population is intense and diffuse perikaryal labeling for chromogranin A (Fig. 43.90)—a reflection of the dense core granule formation noted previously.[572] Native CNS neurons outside the brainstem and cerebellum, by contrast, either fail to react (as do glia) or display only punctate and partial labeling of their perikarya for this antigen. Other aberrant immunophenotypic characteristics that can be displayed by the neurons populating ganglion cell tumors include failure to label for NeuN,[358] a nucleoprotein expressed (certain specialized neuronal subclasses, e.g. Purkinje cells, excepted) by their native counterparts throughout the CNS, and reactivity for nestin,[585] a cytoskeletal intermediate filament protein transiently elaborated by multipotent neuroepithelial stem cells but downregulated in differentiated neurons and glia. Nestin labeling may also be observed in astrocytic constituents within these tumors.[585] We do not use nestin immunostaining in clinical practice but can attest to the paradoxically but diagnostically useful (in distinguishing entrapped cortical neurons) NeuN-negative immunoprofile of many gangliogliomas, even when their neuronal components manifest thoroughly mature cytologic features. Some examples, however, retain entirely normal patterns of nuclear (and, at lower intensity, cytoplasmic) NeuN expression.[333] The neuronal constituents of ganglion cell tumors may also exhibit immunoreactivity for NFPs, MAP-2, class III β-tubulin, the neuronal nuclear protein designated as Hu,[334] α-synuclein, various neuropeptides, enzymes integral to catecholamine metabolism, and other neuron-associated antigens.[572,573] Restraint is advised in the interpretation of neuronal "marker" expression limited to minor cell subsets, a phenomenon that can be encountered in otherwise astrocytic, oligodendroglial, and ependymal tumors. In these circumstances, we revert to first principles and render the diagnosis most in accord with the clinical, radiological, and histologic features.

Yet another immunohistochemical feature having some utility in the identification of gangliogliomas is the fact that many exhibit regions of diffuse and intense CD34 reactivity that may include the surface labeling of neuronal perikarya as well as dense decoration of the tumoral matrix.[570,586,587] As mentioned in connection with the frequently CD34-positive pleomorphic xanthoastrocytoma, an entity exhibiting much overlap with gangliogliomas in its clinicobiologic and morphologic profiles, the expression of this antigen has been described as an attribute of neuroepithelial progenitor cells in some mammals (and is, of course, a constant property of endothelium in the CNS as elsewhere) but seems uniformly alien to differentiated neurons and glia in the human neuraxis. Gangliogliomas may further share with pleomorphic xanthoastrocytomas (and with some forms of focal cortical dysplasia) CD34-positive cells of ramified, dendritic appearance that are only apparent in immunohistochemical preparations, and which may be found to populate adjoining, ostensibly uninvolved cerebral cortex in surprising numbers (see Fig. 43.70B).[570,586,587] These distinctive elements are taken by some as evidence that gangliogliomas arise from developmentally dysregulated neural stem cells.[570,586] The reader who consults the references provided on this score will find rather contradictory statements regarding CD34 expression by conventional glial neoplasms, but the demonstration of "dysplastic" neural cells of this type in complex with intratumoral CD34 expression certainly argues against the diagnosis of an infiltrating glioma with entrapped neurons.

A final immunohistochemical characteristic of gangliogliomas that may aid in their identification (and in defining a target of adjuvant therapy for cases that prove refractory to conventional management) is the potential labeling of their neuronal and glial elements for BRAF V600E-mutant protein.[421,588] The most common genetic alteration identified in gangliogliomas to date, *BRAF* V600E mutation has been detected in 11%–60% of cases assessed in various series.[420,421,563,588] This wide variation in reported frequency may reflect diagnostic criteria for case inclusion, as well as the sensitivities of the differing assays employed for detection. Gangliogliomas arising at different levels of the neuraxis may also vary in this regard; for example, the 11% mutation rate quoted above comes from a series of intramedullary tumors,[563] and is well below the rates generally reported in the supratentorial series cited previously. Ganglion cell components may manifest accentuated BRAF V600E reactivity compared to glial populations.[588] A candidate for the diagnosis of ganglioglioma should not have *IDH1* or *IDH2* mutations or immunoreactivity for IDH1 R132H mutant protein, features strongly associated with infiltrating astrocytomas and oligodendrogliomas.[589]

The WHO classifies gangliocytomas and gangliogliomas as grade I lesions and assigns anaplastic gangliogliomas a grade III status in what amounts to a binary formulation.[278] Whether or not there is biologic relevance to the designation of a grade II or "atypical" ganglioglioma (i.e. one falling short of the overtly anaplastic, yet showing increased proliferative activity in complex with conspicuous

microvascular hyperplasia, unexpectedly high cellularity, or nuclear pleomorphism) is an assertion that awaits validation.[576,590] In practice, few gangliogliomas manifest atypical characteristics of the latter sort (let alone anaplasia). The large majority are characterized by remarkable clinical indolence, and malignant transformation is a decidedly uncommon phenomenon. Supratentorial examples of the usual low-grade type, if accessible, are generally cured by resection alone.[278,590] Bulbar and intramedullary variants are more prone to symptomatic regrowth following operation, possibly owing to surgical limitations imposed by the physical circumstances, but run a protracted clinical course as well.[562-564] Gangliogliomas harboring atypical or patently malignant glial elements have been over-represented among recurrent and fatal cases in some series,[576,590] but repeated observations that even frank anaplasia does not necessarily augur poorly in this setting are noteworthy.[591,592] This happy discrepancy likely reflects the tendency of gangliogliomas to expand in a compact, relatively noninvasive fashion that lends itself to successful neurosurgery. Some observers have suggested that close neuroradiological surveillance alone is reasonable following gross total excision of such tumors, but the optimal management of high-grade gangliogliomas remains in doubt, owing to their rarity. Subtotally resected examples certainly carry a significant risk of fatal progression due to locally aggressive growth and, in some cases, leptomeningeal seeding.[593] One remarkable example of diffuse leptomeningeal ganglioglomatosis may actually have represented advanced glioneuronal maturation of a metastasizing cerebellar medulloblastoma, as noted by the authors.[594] Whether immunohistochemical assessments of proliferative activity or p53 expression independently affect outcome following gross surgical extirpation of gangliogliomas is far from clear.[571,572,595] As a rule, gangliogliomas manifest low MIB-1 labeling indices, reported mean values falling in the 1%–3% range. Histologically anaplastic variants and recurrent lesions have been noted by some observers to evidence higher proliferation indices,[572] but, again, the independent predictive power of proliferation assays is not settled. MIB-1 reactivity is typically restricted to cells of glial appearance though, as previously mentioned, malignant elements of neuronal immunophenotype have been reported to emerge from gangliogliomas.[578,579] One study found *BRAF* V600E-mutant gangliogliomas to have significantly shorter recurrence-free intervals than non-mutant examples.[596]

We briefly call the reader's attention to the occurrence of "intrasellar gangliocytomas"—a heterogeneous collection of benign lesions, most of which arise via neuronal transdifferentiation within growth hormone-producing (or, less commonly, other pituitary) adenomas.[597] A small minority of these curious masses may represent ganglion cell tumors ab initio, or ectopic, hypothalamic-type neuronal hamartomas. Given separate consideration later are the distinctive entities known as desmoplastic infantile ganglioglioma and dysplastic gangliocytoma of the cerebellum (Lhermitte–Duclos disease).

Desmoplastic Infantile Ganglioglioma/Desmoplastic Infantile Astrocytoma

Originally characterized as distinct entities,[598,599] the **desmoplastic infantile astrocytoma** and **desmoplastic infantile ganglioglioma** are allied by common (and stereotypic) clinical, neuroradiological, morphologic, and biologic features.[278] Accordingly, they are given joint treatment in this section. Presentation in the first two years of life is characteristic (mean patient age at tumor discovery being 6 months, though examples in older children and teenagers have been reported), as is supratentorial localization (usually frontoparietal), and associated manifestations of increased intracranial pressure that include irritability, vomiting, macrocephaly, bulging fontanels, and forced downwards deviation of the eyes (the "sunset" sign). CT or MR demonstration of a superficially positioned, nodular or plaque-like mass that broadly adheres to the dura, exhibits homogeneous contrast enhancement, and is associated with a prominent subjacent cystic component of unilocular or multilocular aspect (Fig. 43.91) is virtually pathognomonic of this tumor family in the clinical setting just described. Most examples are quite large at operation (often measuring 10 cm or more in greatest span), are composed of tan–white tissue that is rubbery or firm to palpation owing to associated fibroplasia, and appear to lie largely outside the cerebrum proper.

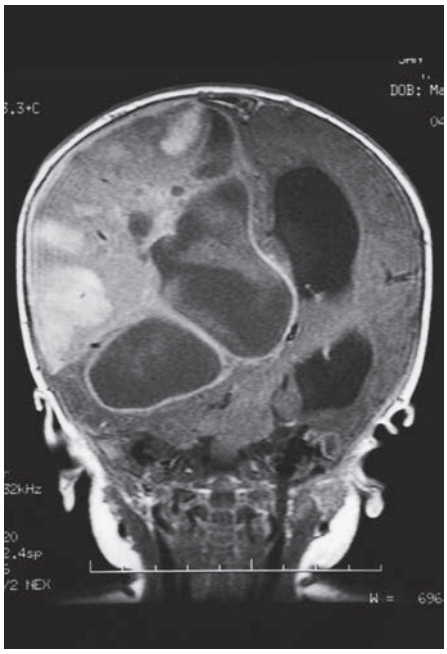

Figure 43.91 Desmoplastic Infantile Ganglioglioma/Astrocytoma. As demonstrated by this example in an 8-week-old boy, tumors of the desmoplastic infantile ganglioglioma/astrocytoma group are typically large cerebral growths exhibiting dural attachment of their superficially located and contrast-enhancing solid components with the formation of prominent underlying cysts.

Histologic study of desmoplastic infantile astrocytomas and gangliogliomas generally confirms their dural attachment and predilection for supracerebral growth, while invariably revealing tumor colonization of the adjoining cortex and frequently demonstrating spread along Virchow–Robin spaces. Common to these tumors are collagenized components of pseudomesenchymal appearance, as well as recognizably neuroepithelial elements (Fig. 43.92). The former, usually predominant, are populated by variably pleomorphic spindle cells in loose fascicular or storiform array, these patterns inviting confusion with bona fide fibrohistiocytic neoplasms, intracranial fibromatosis, or fibroblastic meningioma. Immunohistochemical assessment typically discloses a large complement of GFAP-positive astroglial forms within these desmoplastic regions, where they are admixed with nonlabeling elements that have proven on electron microscopic study to include fibroblasts.[598-601] Ultrastructural analyses have further shown that these neoplastic astrocytes are invested by basal lamina material, which accounts for a pericellular, reticulin-impregnable network immunoreactive for basement membrane–associated antigens such as type IV collagen.[600,601] As discussed in connection with the pleomorphic xanthoastrocytoma, this finding may signal differentiation along specialized subpial astrocytic lines.

In addition to sharing collagen-rich zones evidencing astrocytic outgrowth, the desmoplastic infantile astrocytoma and ganglioglioma are also characterized by the regular presence of seemingly

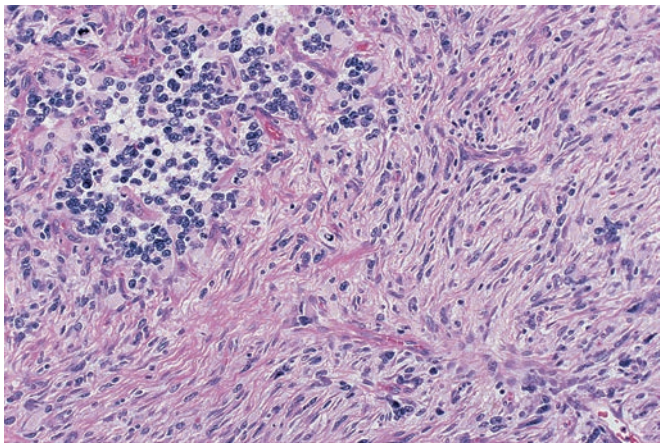

Figure 43.92 Desmoplastic Infantile Ganglioglioma/Astrocytoma. Distinctive features include collagenized regions dominated by spindled astrocytes in fascicular or storiform array and admixed small cells of primitive appearance in nodular aggregates.

undifferentiated small cell populations that inhabit reticulin-free islands or broader tissue expanses (see Fig. 43.92). These may achieve considerable density and can exhibit mitotic activity (usually at low level); however, even in areas dominated by such cells, MIB-1/Ki-67 labeling indices generally remain modest. In fact, most of the tumors under discussion exhibit MIB-1 indices below 5%, and many fall below the 2% level. High mitotic rates, MVP, and necrosis are clearly exceptional but occasionally encountered.[602,603] Small cell components, which appear to be primitive neuroepithelial constituents capable of divergent differentiation, can exhibit cytologic transition to fibrillary astroglial, gemistocytic, or neuronal morphology and may label for GFAP, various neuron-associated antigens (e.g. SYN, class III β-tubulin, NFPs, MAP-2, Hu), and desmin.[598,599] The specific diagnosis of desmoplastic infantile ganglioglioma is reserved for tumors containing recognizable neurons, but the expression of neuron-restricted epitopes by the ostensibly uncommitted small cells populating cases devoid of patently differentiated neuronal elements exposes the artifice in so subclassifying these unusual neoplasms of early life. When present, neuronal forms include mature, atypical, and ganglion cell–sized variants. While most prevalent in noncollagenized regions, these can be detected in desmoplastic areas as well (particularly with the aid of immunoscreening for SYN and neurofilament epitopes). A deep-seated example containing components of conventional ganglioglioma, gangliocytomatous foci, pilocytic astrocytoma-like regions, and elements suggesting Schwann cell differentiation has been recorded.[604] It would appear that only a small minority of these infantile neoplasms harbor the *BRAF* V600E mutations that are more prevalent among gangliogliomas of conventional type.[605]

Desmoplastic infantile gangliogliomas and astrocytomas may represent neoplasms of essentially embryonal character programmed to advanced maturation along glioneuronal lines. Their small cell components notwithstanding, a most favorable prognosis attaches to cases amenable to gross total resection, and thus these peculiar tumors are accorded WHO grade I status. Remarkable instances of their "spontaneous" regression following less than complete excision have been communicated.[606] Even frankly malignant histologic features (e.g. conspicuous mitotic activity and necrosis with palisading) do not necessarily augur an ominous prognosis if surgical removal can be effected,[600,603] but we would caution that very few "anaplastic" cases have been recorded to date. Recurrence following complete excision is exceptional, though subtotally removed examples may occasionally regrow over relatively brief intervals[607] and can prove fatal.[604] CSF-borne metastasis at presentation has been described in an account detailing the virulent behavior of a case that was atypical by virtue of its subcortical, partly intraventricular localization; unusually florid proliferative activity (including a MIB-1/Ki-67 labeling index of 45%); and anaplastic small cell elements that constituted one-third of the tumor bulk.[608] Tumor recurrence and biologic progression in the face of gross total resection, with the emergence of hyperproliferative small cell components and seeding of the ventricular cavities, have also been described,[609] as has transformation to glioblastoma-like histology on relapse.[610,611] It would appear, however, that adjuvant therapy can be reserved for refractory lesions that cannot be extirpated by surgical means alone.[602,603,612] It has been suggested that basal lamina formation by astrocytic elements may exert a restraining influence on the proliferation of these neoplasms, as basement membrane–associated proteins apparently promote cell differentiation and growth arrest when applied to human glioma lines.[601]

Central Neurocytoma and Extraventricular Neurocytic Neoplasms

The **central neurocytoma** is a neoplasm composed of highly differentiated, albeit diminutive, neuronal elements,[278,613] which is characterized by intraventricular location, attendant manifestations of obstructive hydrocephalus, a peak incidence in adults aged 20–40 years, and deceptively oligodendroglioma-like histology. It may be situated anywhere within the ventricular confines, possibly deriving from remnants of the subependymal matrix that retain postnatal proliferative capacity, but most often inhabits anterior portions of the lateral ventricles in the foramen of Monro region. It also frequently involves the septum pellucidum. Common neuroradiological features include cystic change, contrast enhancement of solid components, and conspicuous calcification (Fig. 43.93).

The central neurocytoma is remarkable for the cytologic conformity of its constituent cells (Fig. 43.94), which possess monomorphic nuclei of small diameter, rounded contour, and evenly granular chromatin content. Perinuclear clearing, a plexiform capillary microvasculature, and admixed calcospherules often conspire to render this lesion indistinguishable from the oligodendroglioma, though the central neurocytoma usually differs in its elaboration of a fine, neuropil-like fibrillar matrix that may separate streaming tumor cells, punctuate foci of sheet-like growth as anuclear islands, collar stromal blood vessels in pseudoependymomatous fashion, or constitute the cores of Homer Wright–like rosettes, referred to as "neurocytic rosettes" (although generally a bit larger and more irregular than Homer Wright rosettes, and without the associated primitive appearing nuclei of the latter). This unusual neoplasm can attain dense cellularity, but the typical example is virtually devoid of mitotic activity and does not exhibit MVP or necrosis. Admixed ganglion cell,[614] adipocyte-like,[615,616] and melanotic[617] components have been recorded, as have a case manifesting ependymal (as well as lipomatous) differentiation,[618] an example associated with a fourth ventricular tumor of medulloblastomatous appearance[616] and one interpreted as evidencing ganglioglomatous differentiation on recurrence.[619]

Cytoplasmic processes replete with parallel microtubular arrays, clear vesicles, and membrane-bound neurosecretory granules (the last typically in small number) attest to the neuronal nature of the central neurocytoma on electron microscopy, synapse formation signaling the particularly advanced maturation of some representatives.[613,614] Such findings effectively distinguish this entity from the oligodendroglioma and clear cell ependymoma, though we note one ultrastructural study depicting an unusual variant with oligodendrocyte-like lamellar cytoplasmic structuring,[620] and a second documenting

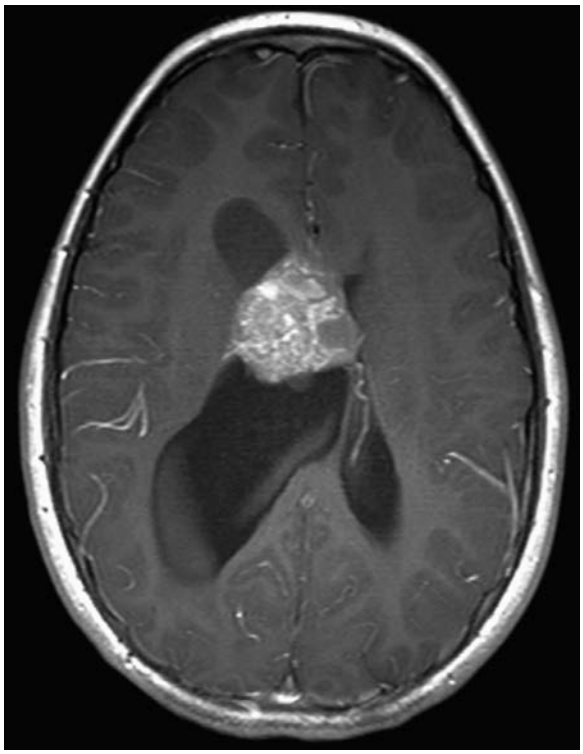

Figure 43.93 Central Neurocytoma. This postcontrast magnetic resonance imaging shows the neurocytoma's predilection for the lateral ventricles, its tendency to be centered about the septum pellucidum, regions of bright enhancement, and associated ventriculomegaly indicative of obstructive hydrocephalus.

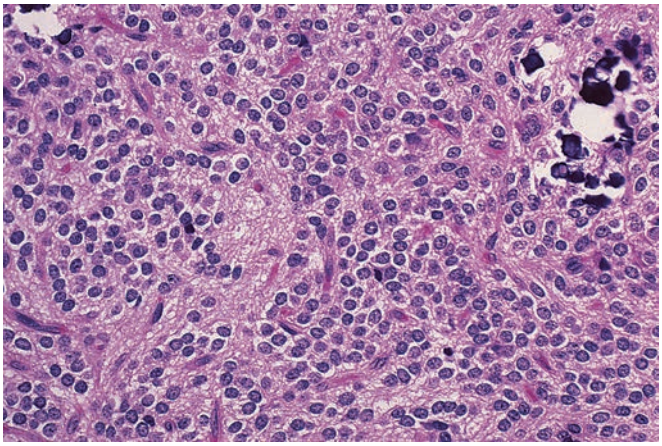

Figure 43.94 Central Neurocytoma. The typical neurocytoma is rather densely populated by small, monomorphous cells embedded in a variably abundant, delicate fibrillar matrix. Rounded nuclear contours, perinuclear clearing, a plexiform capillary arcade, and associated microcalcifications (the basophilic structures present at upper right) impart an oligodendroglioma-like appearance to this small cell neuronal neoplasm.

an intraventricular neoplasm with both neuronal and ependymal specializations.[621] We have also previously alluded to neurocytomatous components within otherwise conventional oligodendrogliomas[360] and to neuronal differentiation within ependymal neoplasms,[471] but these are exceptional (and usually focal) phenomena. The central neurocytoma, unless subjected to prolonged formalin fixation, almost invariably manifests widespread immunolabeling of its fibrillary

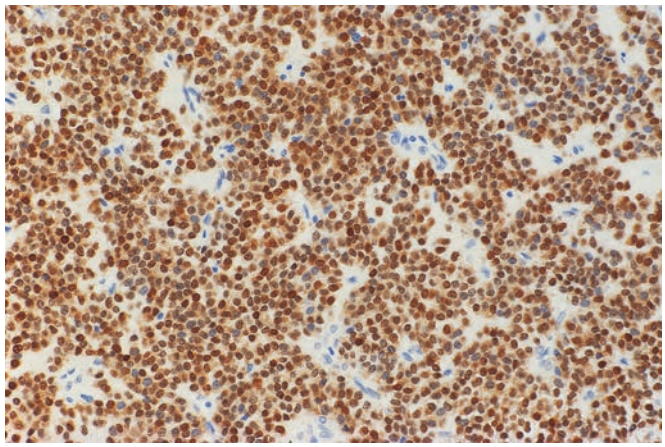

Figure 43.95 Central Neurocytoma. A phenomenon restricted in the normal central nervous system to advanced stages of neuronal maturation, immunolabeling for the NeuN nuclear antigen is shared by many central neurocytomas and attests to their well-differentiated nature.

matrix for SYN, which confirms the diagnosis in the appropriate setting and obviates more costly and time-consuming ultrastructural assessment.[613,614] It is also noteworthy that the chromosome 1p/19q co-deletions and *IDH1* or *IDH2* mutations displayed by canonical oligodendrogliomas are alien to central neurocytic neoplasms.[278,622] Central neurocytomas often exhibit labeling for the Hu[334] and NeuN[333] neuronal nuclear proteins (Fig. 43.95), further evidence of their neuronal character, though chromogranin A and NFP expression seem restricted to the rare variant exhibiting transition to ganglion cell–like morphology.[613,614] Chromogranin A immunoreactivity, by contrast, is a frequent attribute of pineocytomas and of pineal parenchymal tumors of intermediate differentiation that may be difficult to distinguish from central neurocytomas on histologic grounds alone and which share SYN positivity. The reader is referred to the discussion of pineal parenchymal neoplasms for reference to specific ultrastructural features that further segregate such tumors from neoplasms of conventional neuronal type. Central neurocytomas seem capable of glial differentiation,[623-625] but cytoplasmic GFAP immunolabeling is foreign to most and, if present, limited to tumor cells in relatively small number.

Central neurocytomas are classed as grade II lesions in the WHO formulation.[278] The prognosis for patients with resectable tumors is generally favorable, with complete excision alone effecting long-term tumor control in most cases. Tumors that cannot be surgically extirpated generally enlarge slowly and remain confined to the ventricular cavity, but incomplete resection was found to portend a poor outcome in one multicenter analysis.[626] Gross invasion of periventricular structures, dissemination via the CSF, and fatal progression are exceptional[614,627,628] and not necessarily predicted by lesion histology,[626] though "**atypical central neurocytomas**," characterized by features including readily apparent mitotic activity, macronucleoli, MVP, necrosis, and/or elevated MIB-1/Ki-67 labeling indices, have been over-represented among clinically aggressive lesions.[624,629,630] The finding of 3 or more mitoses per 10 high-power microscopic fields has emerged from some studies as indicative of an increased risk of postsurgical recurrence.[626,631] MIB-1/Ki-67 labeling "cutoff" values of 2%[624,629] or 3%[630] have been forwarded as indices of abbreviated recurrence–free survival as well, though these observations have not been borne out in some series.[626] Adjuvant therapy, particularly irradiation, may prove beneficial to some patients with disease refractory to surgical management.[632]

While the specific diagnosis of central neurocytoma should be reserved for the intraventricular neoplasm described above, tumors of comparable morphology and immunophenotype may arise within the substance of the brain[633,634] or spinal cord.[635] These can harbor admixed ganglion cell and astroglial elements,[633,634] a remarkable cerebellar example exhibiting rhabdomyomatous differentiation.[636] The literature further contains accounts of neurocytomatous tumors arising in a mature cystic teratoma of the ovary[637] and in the pelvis of a young adult male.[638] The clinical biology of these **extraventricular neurocytomas** and "**ganglio/glioneurocytomas**" remains to be fully characterized, but most reported to date have exhibited limited proliferative activity and have behaved in the fashion of benign or low-grade growths.[633,639,640] Gross total resection of these generally demarcated tumors is the treatment of choice. Atypical features (including mitotic activity in excess of 2 mitoses per 10 high-power microscopic fields, geographic necrosis, or MVP) have been correlated with an older age at diagnosis, MIB-1 labeling indices above 5%, tumor unresectability, and an increased risk of recurrence.[633,639,640] The nosology of aggressive, small cell glioblastoma–like neoplasms reported as malignant neurocytic tumors[641] is unclear. Potentially aggressive tumors reported as extraventricular neurocytomas manifesting chromosome 1p/19q co-deletion and t(1;19)(q10;p10) unbalanced translocations[642] are appropriately regarded as oligodendrogliomas evidencing neuronal differentiation. In this vein, we would also stress that *IDH1* and *IDH2* mutations have proven foreign to extraventricular neurocytic neoplasms thus far, as has immunohistochemical expression of the IDH 1 R132H mutant protein.[643,644]

Cerebellar liponeurocytoma is the current and WHO-recognized designation for an unusual lesion previously regarded as embryonal in nature by some observers, and variously termed a "lipomatous" or "lipidized" medulloblastoma, medullocytoma, neurolipocytoma, or lipomatous glioneurocytoma.[278,645-647] To date, it has been encountered only in adults (with a mean age at diagnosis of ~50 years). CT/MRI study typically discloses a relatively well-demarcated, contrast-enhancing cerebellar mass (vermian or hemispheric) with foci of bright signal on precontrast T1-weighted images reflecting the fatty component. The latter, variably represented, consists of lipid-laden neuroepithelial cells that resemble mature or multivacuolated adipocytes grouped within a tumor otherwise of central neurocytoma-like histology, immunophenotype, and fine structure. In fact, cerebellar liponeurocytomas have been found to overexpress, compared to normal adult cerebellum, an adipocyte-associated fatty acid-binding protein[648] and often lose their SYN positivity in comparison to more conventional appearing neurocytic cells (Fig. 43.96A). GFAP-immunoreactive glial elements are often present and concentrated in "lipomatous" regions (see Fig. 43.96B). An example with myoid differentiation is also on record.[649] Mitotic figures are scarce and MIB-1 labeling indices usually fall in the 1%–3% range, though isolated cases that would seem to qualify for the diagnosis have been reported to exhibit more conspicuous proliferative activity as well as MVP and focal necrosis.[650,651] Genetic analyses have not yet shown cerebellar liponeurocytomas to manifest diagnostic abnormalities, but have revealed expression profiles similar to those of the central neurocytoma and have disclosed features distancing these tumors from medulloblastomas.[652] Cerebellar liponeurocytomas have a higher incidence of *TP53* mutation and consistent absence of medulloblastoma-associated alterations such as isochromosome 17q formation or mutations involving Patched *(PTCH)*, adenomatous polyposis coli *(APC)*, or β-catenin *(CTNNB1)*.

An assessment of the literature regarding the prognosis of cerebellar liponeurocytomas is complicated by the inclusion in some reports and reviews, including a retrospective analysis[653] cited by the WHO, of cases that clearly represent medulloblastomas exhibiting tumor cell lipidization[654] or regional infiltration by foamy, CD68-labeling macrophages.[655] These generally have the same predilection for children, primitive appearance, and high (>20%) MIB-1 labeling indices that characterize conventional medulloblastomas as a group, and are predictably aggressive lesions. While conceding the existence of rare tumors that display overlapping histologic features and levels of proliferative activity, it can be said of typical cerebellar liponeurocytomas that most affected patients followed for 5 years or more have remained alive following resection (irrespective of adjuvant radiotherapy) and that seeding of the CSF has not been described. It would appear, however, that the risk of local (particularly late) regrowth following excision was much underestimated in early series (nearly half of reported cases are now known to have recurred), and it has become apparent that even perfectly innocent-looking and hypoproliferative examples can occasionally regrow with unexpected rapidity and prove uncontrollable.[656] Accordingly, the cerebellar liponeurocytoma is designated a grade II lesion in the current WHO classification.[278] Refractory behavior has also been documented on the part of some histologically atypical cases[650] (though these are too few to permit any firm conclusion regarding the impact of increased mitotic activity, elevated MIB-1/Ki-67 labeling or other aberrant features on outcome), as has the emergence of anaplastic

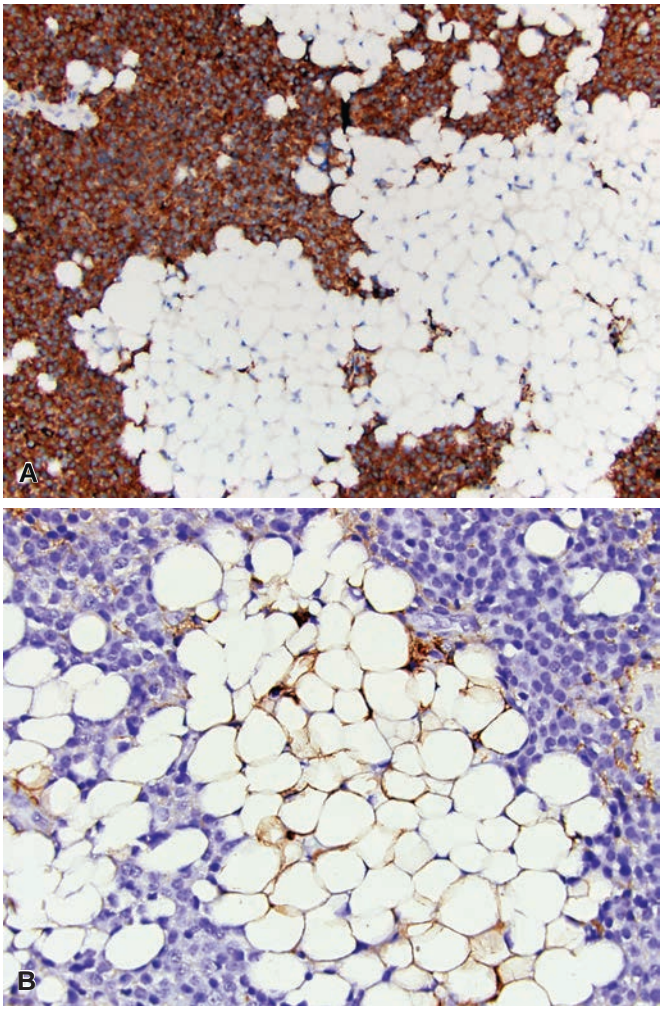

Figure 43.96 Cerebellar Liponeurocytoma. A, As in central neurocytoma, tumor cells are diffusely synaptophysin immunoreactive with the exception of most lipoma-like cells. **B,** In contrast, the latter often express glial fibrillary acidic protein.

histology and conspicuously increased MIB-1/Ki-67 labeling fractions on recurrence.[657]

Dysembryoplastic Neuroepithelial Tumor

DNTs are strongly associated with pharmacoresistant partial seizures in young subjects and only exceptionally come to attention in patients older than 20 years of age.[278,658-660] While the great majority are supratentorial and cerebral in position, the temporal lobes being particularly prone, lesions of strikingly similar morphology involving the septum pellucidum,[661,662] caudate nucleus,[663] brainstem,[664] and cerebellum[665] have been recorded, although the latter often overlap with rosette-forming glioneuronal tumor (see later discussion). Multifocal presentations have also been described.[666] Neuroradiological features of great utility in suggesting the diagnosis, and in distinguishing DNTs from conventional glial neoplasms (particularly oligodendrogliomas) with which they may be confused histologically, are their tendency to lie largely, if not entirely, within an expanded cortical ribbon (Fig. 43.97) and their multinodular bright signal qualities in T2-weighted MRIs. Examples extending into white matter often taper from a broad cortical base and assume triangular configurations, some seeming to point towards the subjacent ventricle.[667] Remodeling of the adjacent calvarium often attests to the indolent expansion of these unusual lesions, which are typically T1 hypointense (often with isointense rims or septations demarcating multiple hypointense tumor nodules in a bubbly pattern) and devoid of mass effect or associated edema.[667] A minority exhibit discrete foci of nodular or ring enhancement.

"Simple" and "complex" histologic variants of DNT are recognized.[658-660] Common to both and required for morphologic diagnosis is the presence of what has been termed the "specific glioneuronal element"—a proliferation of oligodendrocyte-like cells (OLCs) that appear to be arranged along bundled axons and ramifying capillaries (often coursing perpendicular to the cortical surface) and that are separated by a myxoid matrix in which well-differentiated neurons seem to float (Fig. 43.98). Mitoses are absent or exceedingly rare, and MIB-1 labeling indices do not usually exceed 1%–2%. The specific glioneuronal element colonizes a cortex that may exhibit background architectural disorganization (dysplasia), which is readily appreciated on low-power examination. OLCs can also be arranged around myxoid microcysts in alveolar fashion or about a fine fibrillar meshwork in cribriform, rosetted array. Stellate, GFAP-immunoreactive astrocytes may be found within the specific glioneuronal element of simple DNTs, and complex variants may harbor, in micronodular or more diffuse arrangement, additional glial components that may be indistinguishable from conventional oligodendroglioma, pilocytic, or fibrillary astrocytoma. These can colonize the leptomeninges/subarachnoid space, may exhibit considerable cytologic atypia, and have been described in some cases as manifesting low-level mitotic activity, MVP, and, rarely, necrosis.[659] An anomalous vasculature of hamartomatous aspect may be encountered. Curiosities include examples of DNT admixed with ganglioglioma[668] and a lesion interpreted as a melanotic DNT variant.[669]

The potential association with cortical dysplasia and characteristically young patient age at presentation have been taken as evidence that DNTs are potentially maldevelopmental in origin.[659] Aberrant CD34 expression, a phenomenon (previously discussed in connection with the pleomorphic xanthoastrocytoma and ganglioglioma) that may reflect local developmental dysregulation, may be associated with DNTs as well.[421,586,670] Approximately 30% of DNTs assessed to date, however, have exhibited *BRAF* V600E mutations,[421,671] and the recurrent behavior of some examples further suggests that these are neoplastic in nature (see later). Whether the OLCs that dominate their specific glioneuronal elements actually represent oligodendroglia is unclear. Some observers have found these cells, which are usually S-100 protein and OLIG2 positive but GFAP negative, to be immunoreactive for myelin oligodendrocyte glycoprotein.[672,673] Others have noted minor subsets labeling with such neuron-associated antigens as NeuN and the *N*-methyl-D-aspartate receptor subunit NR1[674] or showing dense core granule and axosomatic synapse formation at the ultrastructural level.[675] These may, then, be capable of divergent differentiation. As previously mentioned, NeuN labeling is typically foreign to oligodendrogliomas (save for rare variants exhibiting neurocytic differentiation).[674] Oligodendroglial tumors, however, may contain trapped, NeuN-positive neurons of small size that complicate segregation of these entities by immunohistochemical

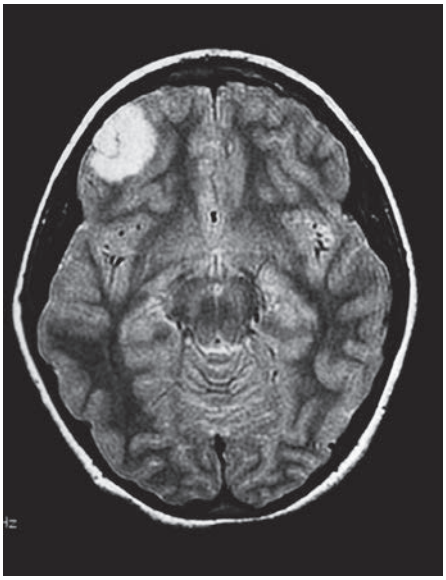

Figure 43.97 Dysembryoplastic Neuroepithelial Tumor. A gyriform focus of increased signal attests to the largely cortical localization of this superficial lesion, seen in a FLAIR MR sequence. Also characteristic is the absence of mass effect or white matter changes indicative of edema.

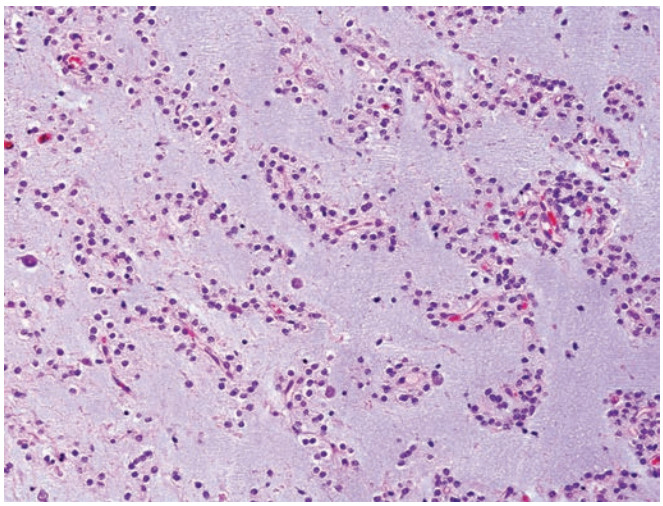

Figure 43.98 Dysembryoplastic Neuroepithelial Tumor. Extensive myxoid change and the disposition of small, oligodendrocyte-like cells along axonal fiber bundles and capillaries lend an alveolar or "patterned" appearance to the specific glioneuronal element of this distinctive lesion. Also present are mature neurons appearing to float in the mucoid matrix.

means alone. The *IDH1* and *IDH2* mutations,[280] frequent immunoreactivity for IDH1 (R132H) mutant protein,[676] and whole-arm chromosome 1p/19q co-deletions[677] that characterize canonical oligodendrogliomas are foreign to DNTs, but these alterations are rarely encountered in pediatric tumors that would otherwise seem to qualify as oligodendroglial neoplasms.[375] We think that the diagnosis of oligodendroglioma must be approached with considerable skepticism in childhood, particularly when a candidate lesion displays the cortical topography of the DNT. The reader is referred to the section on oligodendrogliomas for further discussion of this differential.

Patients with DNTs of both simple and complex type are usually cured by simple excision alone, and subtotally resected examples generally remain stable on neuroradiological surveillance.[658-660] Local recurrence of histologically typical DNTs following resection does happen but is clearly exceptional.[678,679] While a comparably favorable outcome has been recorded following complete surgical extirpation of complex variants exhibiting mitotic activity, MVP, or necrosis,[659] few such cases have been communicated, and judgment regarding their biologic potential must be reserved. Examples of malignant transformation after excision only[679,680] or following irradiation and chemotherapy[678,681] are extremely rare.

It has been proposed that certain DNT variants show neither a specific glioneuronal element nor a multinodular growth pattern, assuming, instead, the guises of oligodendroglioma, oligoastrocytoma, pilocytic or fibrillary (including high-grade) astrocytoma in unalloyed form.[682] The criteria posited for the identification of such "nonspecific" DNTs, which are said to be clinically benign and nonrecurring after simple removal irrespective of their histologic attributes, are: (1) association with partial seizures (with or without secondary generalization) beginning prior to 20 years of age; (2) absence of associated neurologic deficits or presence of a nonprogressive congenital deficit only; (3) supratentorial localization and cortical topography on CT/MRI; and (4) absence of associated edema or mass effect other than that related to cystic components. This is, understandably, controversial.

Papillary Glioneuronal Tumor

The **papillary glioneuronal tumor** seems to have a predilection for adolescents and young adults and tendency to a subcortical (often paraventricular) cerebral hemispheric localization.[278,683,684] Neuroradiological features include circumscription, contrast-enhancing solid components with associated cysts, and little in the way of accompanying mass effect or edema. A biphasic morphology is characteristic (Fig. 43.99). The glial element, which has papillary architecture, is represented by GFAP-immunolabeling cells of flattened to low cuboidal profile draped in monolayered or pseudostratified fashion over branching, hyalinized vascular cores. SYN-rich, nonpapillary neuronal populations that include neurocytes, large neurons of mature appearance, and intermediate forms are admixed or regionally segregated. These may exhibit nuclear NeuN expression.[685] Solid, nonpapillary regions may also harbor GFAP/NeuN-negative clear cell elements that label for OLIG2 and that may represent oligodendrocytic components[685]; some cases contain, in addition, minigemistocytes and conspicuously granulated cells of the sort found in oligodendrogliomas.[685,686] Myxoid change is common. Mitoses are generally absent or rare, there is typically no MVP or necrosis, and MIB-1/Ki-67 labeling indices usually do not exceed 1%–2%. A novel *SLC44A1-PRKCA* gene fusion seems characteristic of this entity.[687,688] Papillary glioneuronal tumors usually behave in WHO grade I fashion, and simple excision suffices to control most recorded cases.[689] Recurrent examples have exhibited mitotic activity (accompanied, in some cases, by MVP or necrosis) and/or elevated MIB-1 labeling fractions.[683,690,691] The extraneural dissemination of a recurrent, frankly anaplastic example has been communicated.[692] One review found no instances of postoperative tumor regrowth among cases having MIB-1/Ki-67 labeling indices below 5%, whereas one half of lesions with higher labeling fractions eventually recurred or progressed.[691]

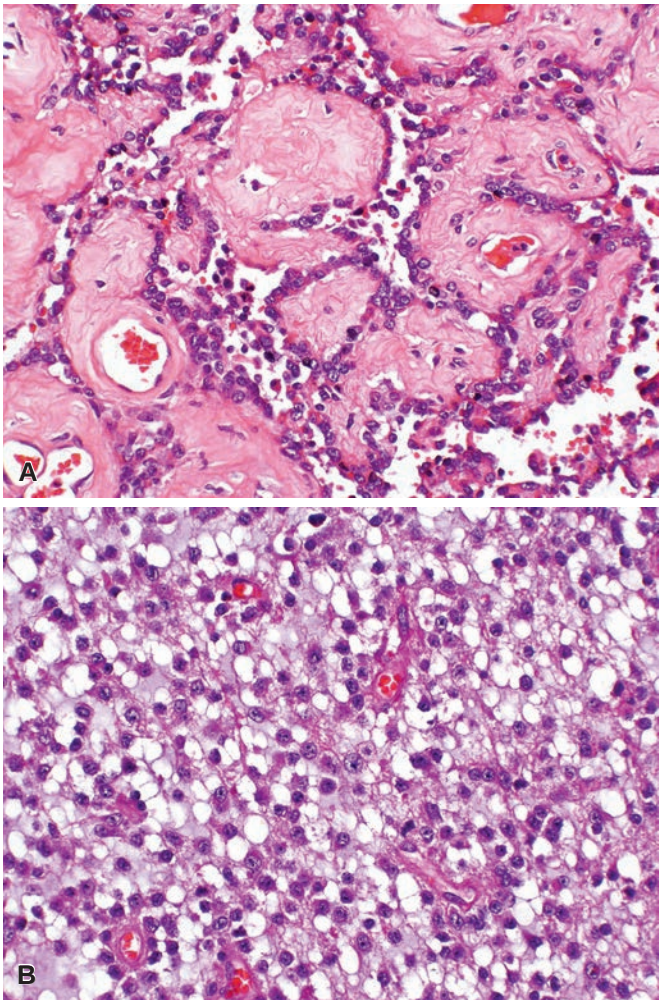

Figure 43.99 Papillary Glioneuronal Tumor. These fields from a single tumor demonstrate papillary **(A)** and nonpapillary **(B)** components. Glial fibrillary acidic protein expression confirmed the glial nature of the former, while the latter (represented in this case by neuronal elements of "intermediate" type) selectively labeled for synaptophysin. The vascular hyalinization in papillary regions **(A)** and bubbly, myxoid alterations in non-papillary foci **(B)** are common accompanying features.

Rosette-Forming Glioneuronal Tumor

Rosette-forming glioneuronal tumors exhibit a decided predilection for the fourth ventricular compartment but commonly involve the adjoining cerebellum, can extend into (or principally occupy) the cerebral aqueduct, and occasionally present as multinodular growths having bulbar components.[278,693,694] Most come to attention in adulthood, causing headache and nausea referable to obstructive hydrocephalus or cerebellar ataxia. Tumors of identical histology have been encountered in the pineal gland and third ventricle,[695] spinal cord,[696] and optic nerve/chiasm,[697] the latter case involving a patient with NF1. Relatively demarcated on MRI evaluation but

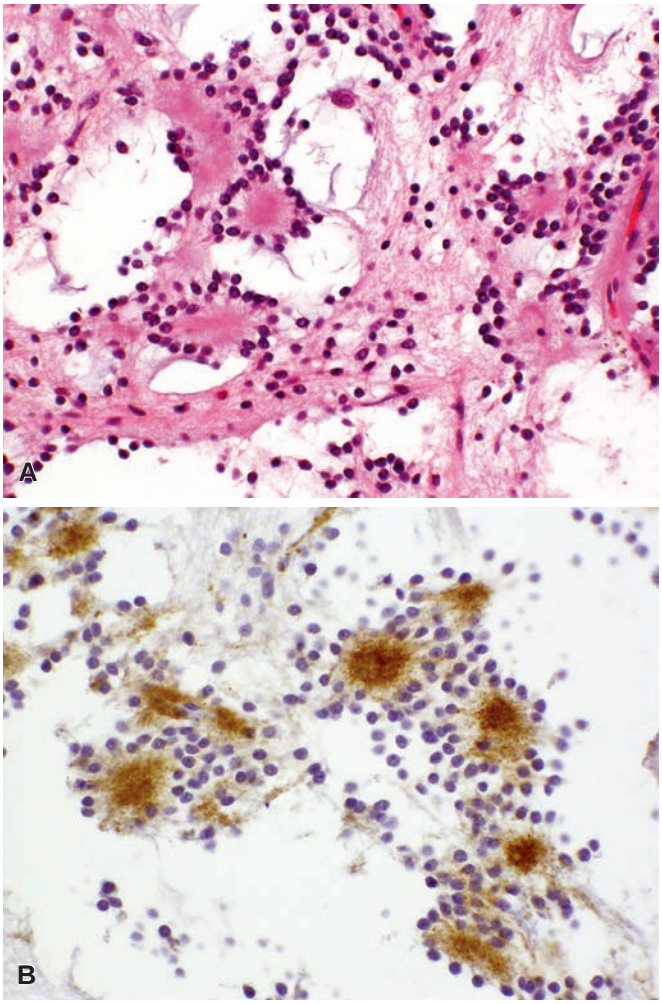

Figure 43.100 Rosette-Forming Glioneuronal Tumor of the Fourth Ventricle. Neurocytic rosettes of small diameter that often appear free floating **(A)** and that exhibit central immunolabeling for synaptophysin **(B)** are defining components of this entity.

accompanied in some cases by discrete "satellite" lesions separate from the main mass, these neoplasms are typically T2 bright/T1 hypointense and may exhibit nodular, ring-like or linear patterns of contrast enhancement.[693,694] They are composed in biphasic fashion of glial elements resembling pilocytic astrocytoma (these often hypocellular and associated with vascular hyalinization), and neurocytic populations that engage in the formation of diminutive, SYN-immunoreactive rosettes and narrow perivascular pseudorosettes that may be attended by myxoid alterations and that often seem to float within microcavities (Fig. 43.100). Components indistinguishable from conventional oligodendroglioma and labeling for neither GFAP nor SYN may be encountered. Some cases exhibit complex MVP, but mitotic activity is inapparent, necrosis is not observed, and MIB-1 labeling indices are quite modest (not exceeding 2%–3% and often no higher than 1%). *PIK3CA*[698] and *FGFR1*[699] mutations have been reported. Glioneuronal tumors of the fourth ventricle are indolent, WHO grade I lesions that may remain stable over lengthy periods of neuroradiological surveillance and that can be controlled by surgical means. Aggressive attempts to fully extirpate these neoplasms, however, have been complicated in a substantial number of reported cases by significant neurologic deficits. Late local recurrence following resection has been documented, as have examples evidencing

Figure 43.101 Diffuse Leptomeningeal Glioneuronal Tumor. This T2-weighted magnetic resonance imaging shows marked expansion of the intracranial and intraspinal subarachnoid spaces, including the basal cisterns.

intraventricular dissemination at diagnosis[700] or eventual CSF-borne spread.[689]

Diffuse Leptomeningeal Glioneuronal Tumor

The rare oligodendroglioma-like neoplasms that are now recognized as a distinct entity under the designation of diffuse leptomeningeal glioneuronal tumor typically present in childhood with manifestations of increased intracranial pressure (reflecting obstructive hydrocephalus), cranial neuropathy, or myelopathy.[346,701,702] Only exceptionally are adults affected. Widespread contrast-enhancement and thickening of the leptomeninges on MRI attests to the disseminated nature of this disease at diagnosis. Whereas tumor deposits along the spinal neuraxis commonly assume linear or plaque-like profiles on neuroradiological study, intracranial involvement often presents as a myriad of T2-hyperintense nodules preferentially clustered about the brainstem, in the basilar cisterns, over the cerebellar folia, and in the sylvian fissures (Fig. 43.101).[346] In T1-weighted sequences these hypointense nodules have empty, cyst-like appearances. Imaging studies demonstrate focal intra-axial involvement in 75%–80% of cases, typically quite limited in extent and most often localized within the spinal cord. Examination of the CSF demonstrates increased protein levels and, in some cases, reactive lymphocytosis, but is typically negative for tumor cells.

Diffuse leptomeningeal glioneuronal tumors are typically monomorphous and composed of oligodendrocyte-like clear cells with round nuclei, inconspicuous nucleoli, and perinuclear haloes (Fig. 43.102A). These may be disposed in sheets, irregular nests, or linear files within a collagenous matrix. We would emphasize that obscuring fibroplasia and crush artifact may confound biopsy interpretation, prompting (along with the presence in some cases of reactive lymphohistiocytic infiltrates) primary consideration of chronic arachnoiditis. Myxoid change is common as well and may be especially conspicuous in intracranial samples. Foci in which neoplastic neuronal elements of intermediate to large size lie in a neuropil-like matrix

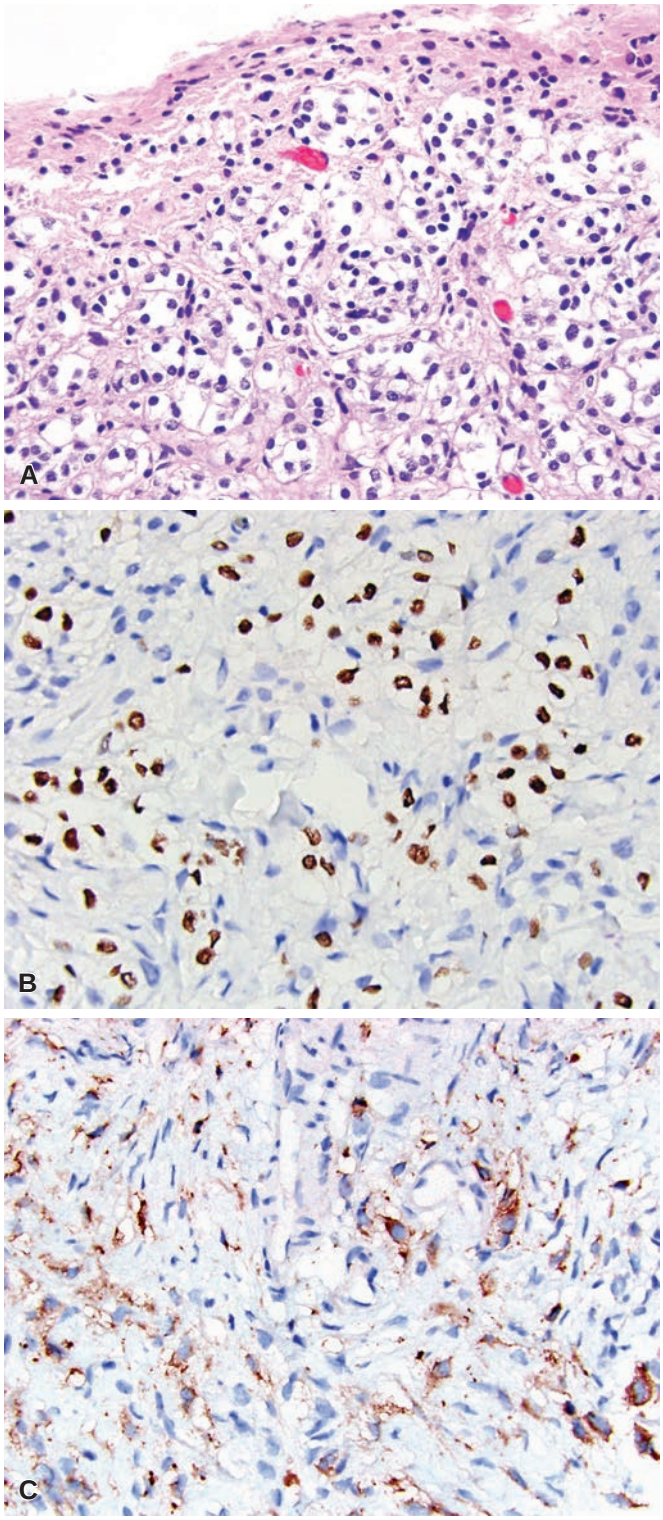

Figure 43.102 Diffuse Leptomeningeal Glioneuronal Tumor. A, Biopsy typically reveals a markedly expanded leptomeningeal layer with tumor cells resembling oligodendroglioma. Immunohistochemistry often reveals strong OLIG2 **(B)** and patchy synaptophysin **(C)** expression.

are occasionally encountered. Neuroparenchymal components often closely resemble infiltrating oligodendrogliomas but may harbor, or even be dominated by, tumor cells of astrocytic appearance. Histologic evidence of anaplasia that includes readily apparent mitotic activity and glomeruloid MVP characterizes a minority of examples at presentation or upon clinical progression,[346,703] necrosis being exceptional and usually encountered only in recurrent biopsy or autopsy material.

Immunohistochemical assessment reveals the neural nature of the leptomeningeal infiltrate. Tumor cells label for S-100 protein, OLIG2 (see Fig. 43.102B), and SYN (see Fig. 43.102C) in upwards of 70% of cases.[346,701,702] GFAP expression characterizes less than 50% of these lesions and is often focal, limited NeuN and NFP labeling have only occasionally been reported,[702] and reactivity for EMA or IDH1 R132H mutant protein is not seen. MIB-1/Ki-67 labeling indices vary greatly, ranging from <1% to 30%, with a median of 1.5% in the largest series on record.[346] Genetic studies have demonstrated BRAF-KIAA1549 fusion[703] and chromosome 1p deletion,[346,701,704] to be common and frequently concurrent events in this setting, occurring in 75% and 59% of cases, respectively, in a recent study.[704] Chromosome 1p/19q co-deletion is far less prevalent, one co-deleted example reportedly demonstrating the oligodendroglioma-associated t(1p; 19q) (q10; p10) translocation on fluorescence in situ hybridization (FISH) study.[705] *BRAF* V600E mutations have not been detected to date.[704]

Diffuse leptomeningeal glioneuronal tumors are often protracted in their clinical evolution and may exhibit stabilization of disease or only slow progression over many years but are associated with significant morbidity and mortality. In the largest reported series,[346] nearly 40% of patients succumbed to disease 3 months to 21 (median = 3) years from diagnosis. Eight of 24 patients with follow-up data lived longer than 10 years with disease. Decreased overall survival in this series was associated with initial biopsies manifesting any mitotic activity, glomeruloid MVP, or MIB-1/Ki-67 labeling indices of 4% or higher. Anaplastic progression with radiological evidence of peritoneal metastases that may have complicated ventriculoperitoneal shunting has been described.[703]

Multinodular and Vacuolating Neuronal Tumor

Whether the recently delineated multinodular and vacuolating neuronal tumor (MVNT), a rare entity, represents an indolent neoplasm, hamartoma, or focal expression of developmentally dysregulated neuronal migration and maturation is unclear. Most recorded cases have affected young to middle-aged adults and have been associated with seizures or seizure equivalents.[706-709] All were cerebral hemispheric and relatively superficial in location, an excess involving the temporal lobes. Particularly suggestive on MRI is the demonstration of small T2- and FLAIR-hyperintense nodules clustered in the digitate white matter and deep cortex. These may coalesce to form lesions several centimeters in size, but there is usually no evidence of associated contrast enhancement, edema, or mass effect. On histologic inspection, the tumor nodules have a variably spongy appearance reflecting vacuolar changes in their neuropil-like matrix and in the bodies of their constituent cells (Fig. 43.103). The latter vary considerably in their dimensions, potentially approaching ganglion cell–like proportions, but most often resemble mid-sized neurons with amphophilic cytoplasm, vesicular nuclei, and distinct nucleoli. Cytologic monomorphism is the rule. Mitotic activity is not seen. An associated astrogliosis is common and apparent disorganization ("dysplasia/microdysgenesis") of the native cortical architecture may be encountered.

MVNTs are characterized by an immature neuronal immunophenotype.[706-709] While GFAP-negative and invariably expressing HuC/HuD and OLIG2, antigens associated with early neuronal lineage

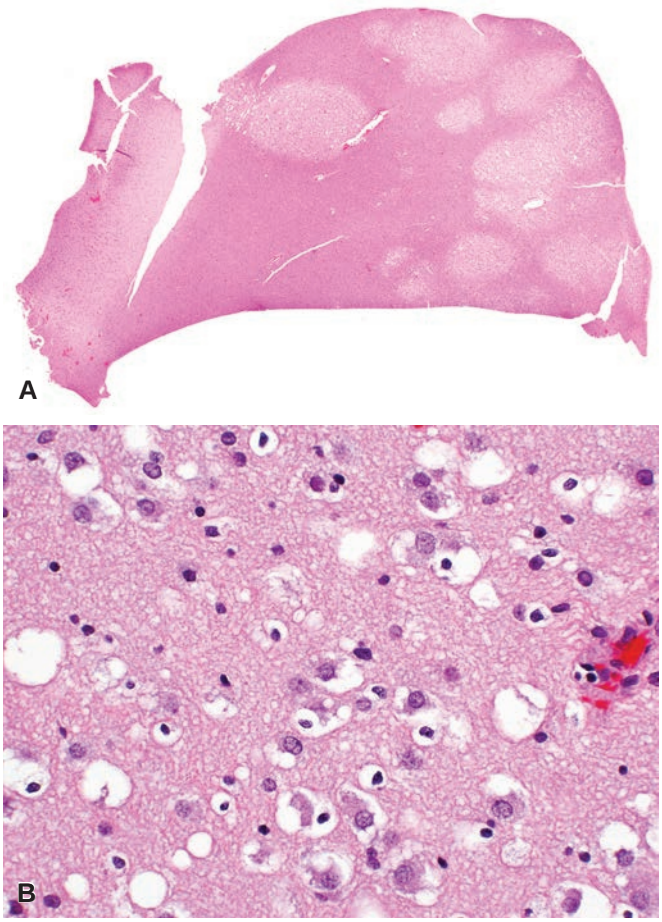

Figure 43.103 Multinodular and vacuolating neuronal tumor with pale nodules **(A)** composed of variably vacuolated neuronal cells **(B)**.

commitment and differentiation, tumor cells generally fail to label for markers of more advanced neuronal maturation such as NFPs and NeuN. They are chromogranin negative as well. Cytoplasmic SYN labeling is commonly seen but may be faint or undetectable, and the neuropil-like matrix usually manifests a granular reactivity that is much weaker than that of normal cortex. MIB-1/Ki-67 labeling activity is negligible. It is curious that, given their tendency to present in adult life, many MVNTs are associated with ramified, CD34-expressing neural elements in adjoining cortical tissues, which we have previously mentioned in connection with pleomorphic xanthoastrocytoma and ganglioglioma (both more prevalent in the pediatric cohort); this feature has been taken as indicative of local dysontogenesis. In contrast to these entities and to various other glioneuronal neoplasms associated with epilepsy in the young, however, the MVNTs studied to date have not shown evidence of *BRAF* V600E mutation on immunohistochemical[708] or formal molecular profiling,[706,707,709] nor have isolated assessments for BRAF-KIAA1599 or SLC44A1-PRKCA fusions been revealing.[709] In a similar vein, IDH mutations do not play a role in their pathogenesis.[706-709] Whatever the exact nature of the MVNT, it is benign. Simple excision would appear to suffice for control.

Hypothalamic Neuronal Hamartoma

Hypothalamic neuronal hamartomas are usefully subdivided into two basic clinicoanatomic groups.[710] "Parahypothalamic" variants—pedunculated lesions that bulge into the suprasellar cistern from attachments to the tuber cinereum or mammillary bodies—are principally associated with precocious puberty in boys. This may reflect the ectopic secretion of gonadotropic releasing factors by neurons populating hamartomas of this class.[711,712] "Intrahypothalamic" subtypes—sessile growths broadly anchored to the tissues lining the third ventricle—characteristically produce fits of pathologic laughter (known as gelastic seizures) that begin in infancy (Fig. 43.104). The development of more generalized, refractory epileptic syndromes, progressive cognitive impairment, and psychiatric disturbances often complicate lesions of the latter type as well.

Most hypothalamic neuronal hamartomas measure no more than 1–2 cm in maximum dimension, though giant examples may be encountered. Variably sized neurons are the dominant cell population, and these are embedded in a uniformly SYN-positive matrix that is generally indistinguishable from native neuropil and traversed in some cases by bundled axons of myelinated or nonmyelinated type. While large ganglion cell–like elements may be present, small- to mid-sized neuronal forms dominate most lesions (Fig. 43.105).[713] These are given to anomalous nodular clustering. Some cases manifest a gliotic appearance, but astrocytes and oligodendroglia are only minor cellular constituents.

Although most hypothalamic hamartomas present in isolated and sporadic fashion, the association of such lesions with a variety of malformative syndromes has been documented. Chief among the latter is the Pallister–Hall syndrome, linked in its autosomal dominant form to germline *GLI3* gene mutations and characterized by a complex of anomalies that includes imperforate anus, cryptorchidism, polydactyly, pituitary aplasia, hypoplasia of the adrenal and thyroid glands, and various cardiac and renal anomalies.[714,715] In affected infants, the hypothalamic lesion may contain small, immature-appearing neuroepithelial elements and has consequentially been termed a "**hypothalamic hamartoblastoma**,"[714] but the incompletely differentiated profiles of these cells (which may also populate nonsyndromic hamartomas) probably just reflect the very young age of the patients from whom they derive. Resection specimens

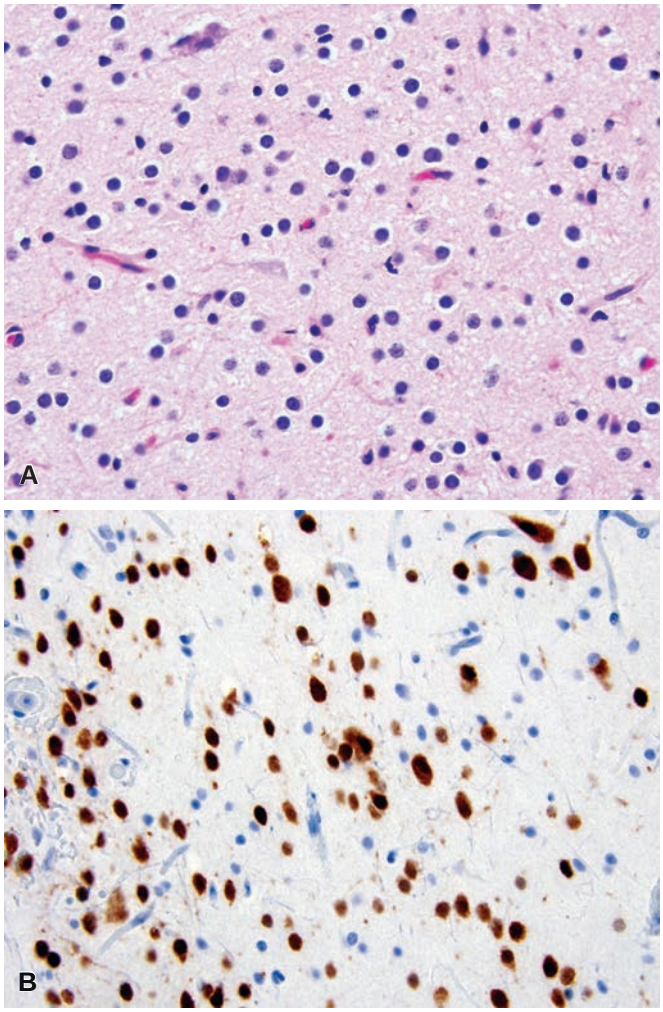

Figure 43.105 Hypothalamic Hamartoma. A, This example was composed of mildly disorganized gray matter composed predominantly of small neurocytic or oligodendrocyte-like neurons. **B,** Their neuronal lineage was confirmed on a Neu-N immunostain.

from affected individuals surviving infancy exhibit more mature neuronal features.[716]

Glioneuronal Hamartomas, Cortical Dysplasias, and Other Epileptogenic Lesions

A number of published series and reviews are recommended to readers interested in the various non-neoplastic lesions associated with refractory seizure disorders that compel neurosurgical intervention.[717-720] Inasmuch as operative approaches to this problem are practiced mainly in specialized referral centers and rarely engage the general surgical pathologist, we specifically consider here only one "tumoral" cause of pharmacoresistant epilepsy not addressed elsewhere in this text, the glioneuronal hamartoma.

Glioneuronal hamartomas figure with special prominence in surgical series addressing chronic temporal lobe epilepsy[717,718] but occur throughout the cerebral hemispheres[719] and may present as intraventricular growths.[721,722] Ranging from microscopic lesions to expansile gray nodules that may be grossly evident on evaluation of lobectomy specimens and visualized by neuroradiographic means, these are sometimes multifocal, are often associated with other features of faulty development (such as patchy cortical dysgenesis and neuronal ectopias in the temporal white matter), and may occur in complex with low-grade neuroepithelial neoplasms of varied type. Whether they serve as the progenitors of select gliomas, gangliogliomas, or DNTs (the more commonly associated lesions) is open to question. As noted previously, gangliogliomas do often share with these dysgenetic lesions expression of CD34, restricted in the developed human CNS to endothelial cells, but displayed by neural progenitors in some species.[723] Populated, in most cases rather sparsely, by neurons of medium to large size and admixed astrocytes that may exhibit hyperplastic features, glioneuronal hamartomas do not evidence the cellularity, pleomorphism, or conspicuous inflammatory infiltration of the bona fide ganglioglioma, nor do they manifest alveolar patterning or the myxoid alterations characteristic of the DNT. Similar to the latter, some glioneuronal hamartomas harbor oligodendrocyte-like clear cell elements (nodular aggregates that constitute microscopic hamartomas or "hamartias" commonly encountered in temporal lobectomies performed for epilepsy control),[717,718] but these are a minor component and further deviate from DNT in evidencing no special relationship to regional axons or the stromal vasculature. Hamartomas composed predominantly or exclusively of astrocytic forms can also be seen.[724] Spongiform change may be apparent within the lesion and can involve associated cortex in patchy fashion, this possibly representing a seizure-induced tissue disturbance. Finally, select variants contain dysmorphic cells of neuronal, astrocytic, or indeterminate lineage resembling those of the cortical tuber (the tuberous sclerosis complex is discussed in relation to subependymal giant cell astrocytomas). These include cells exhibiting a characteristically "ballooned" appearance of their glassy, eosinophilic cell bodies. Such cells are also the hallmark of a form of **focal cortical dysplasia (focal cortical dysplasia, type IIb** in the classification of the International League Against Epilepsy[719]) that is strongly associated with refractory seizures in childhood and that appears to represent a disorder of neuronal migration and differentiation.

Dysplastic Gangliocytoma of the Cerebellum (Lhermitte–Duclos Disease)

The **dysplastic gangliocytoma of the cerebellum**, also known by the eponymous **Lhermitte–Duclos disease**, principally affects adults in the third through fifth decades of life and usually comes to attention on evaluation for signs of cerebellar dysfunction, such as progressive ataxia and dysmetria or symptoms of intracranial hypertension reflecting mass effect on the fourth ventricle.[278] A "tiger-striped" alteration of the cerebellar cortex, produced by regionally thickened and abnormally T2-bright cerebellar folia without associated contrast enhancement, is virtually diagnostic on MRI assessment (Fig. 43.106). The histologic substrate of this curious disorder is variable replacement of the internal granule cell layer by an array of large neurons with attendant expansion and aberrant myelination of the overlying molecular layer (Fig. 43.107). The latter is prone to coarse spongy change and dystrophic microcalcification, often blood vessel–associated, while the subjacent folial white matter is thinned, if not cavitated. Neuronal elements are generally well differentiated in appearance, though some cases exhibit nuclear dysmorphism and hyperchromasia in scattered cellular elements.[725] Axons emanating from ganglionic constituents are oriented (relative to the pial surface) in parallel stacks within the deep molecular zone, and in perpendicular array more superficially. The orientation of these axons, their appearances in Golgi preparations,[726] and observed patterns of NFP expression on immunoassay[727] indicate that the abnormal neurons in this disorder are mainly outsized caricatures of the granule cells that they would seem to replace. Immunolabeling for the NeuN neuronal nuclear protein, foreign to Purkinje cells but a consistent

Figure 43.106 Dysplastic Gangliocytoma (Lhermitte–Duclos Disease). T2-weighted magnetic resonance imaging reveals the typical "tiger-stripe" pattern in the right cerebellar cortex.

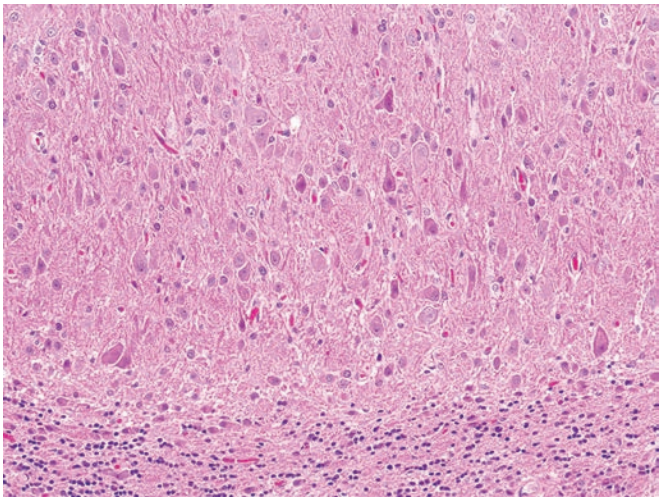

Figure 43.107 Dysplastic Gangliocytoma (Lhermitte–Duclos Disease). This resection specimen reveals replacement of the internal granular layer by large dysmorphic ganglion cells. Note scattered retained internal granular cell neurocytes in lower portion of figure.

feature of granule cell elements, further identifies these large neurons with the latter population.[333] Only minor subsets have been described as manifesting Purkinje cell–like attributes, including immunoexpression of Leu4, PEP-19, L7, and calbindin, as well as surface perikaryal labeling for such synaptic vesicle-associated antigens as SV2 and SYN.[728]

In adult-onset form, the dysplastic gangliocytoma of the cerebellum is now recognized as a lesion virtually pathognomonic of Cowden syndrome, occurring in nearly one-third of affected patients in one series.[729] An autosomal dominant phakomatosis linked to germline mutations of the *PTEN* gene on chromosome 10q23, this disease complex is chiefly characterized by multiple cutaneous tricholemmomas, oral papillomatosis, acral keratoses, macrocephaly/megalencephaly, gastrointestinal polyps of various types, thyroid abnormalities (principally goiter, but including follicular neoplasms), and a substantially increased risk of mammary adenocarcinoma (as well as benign fibroepithelial and papillomatous proliferations of the female breast). Germline mutations and variants of the succinate dehydrogenase B and D genes have been implicated in a similar, if not identical, syndrome.[730] Dysplastic cerebellar gangliocytomas presenting in the adult years regularly display inactivating *PTEN* mutations, irrespective of their association with other manifestations of Cowden syndrome, and underlying germline *PTEN* mutation has been consistently demonstrated in those affected patients studied to date.[731] Pediatric cases, by contrast, seem divorced from these associations.[731]

The linking of dysplastic cerebellar gangliocytomas in adulthood to *PTEN* mutation has done much to clarify the pathogenesis of this entity, which has been historically interpreted as a compensatory hypertrophy of internal granule cells in response to faulty development of the fetal external granular layer from which they derive, as a hamartomatous growth, or as a remarkably orchestrated neoplasm. *PTEN* acts as a regulator of cell size, survival, proliferation, and migration through its inhibitory influence on the phosphatidylinositol 3-kinase (PI3K)/AKT signaling cascade. Studies of both the human disease and murine "knockout" models[732] faithful to the former suggest that abrogated PTEN expression, with resulting activation of AKT and its downstream targets, suffices to produce the alterations characteristic of dysplastic cerebellar gangliocytomas in the absence of transforming events or cellular proliferation.[725,731] In fact, the enlarged internal granule cells persisting in these lesions represent in number a much reduced fraction of the normal populace, are amitotic, and are left unlabeled in MIB-1/Ki-67 preparations (though perivascular elements reasonably interpreted as reactive forms may exhibit immunopositivity).[725] The finding in some cases of what would appear to be granule cells aberrantly situated in the molecular layer attests to impaired migration, as well as compromised survival and dysregulated cell growth, in the evolution of this curious disorder.

Dysplastic gangliocytomas of the cerebellum behave in the manner of WHO grade I tumors, and gross total excision proves curative in most instances. Late local regrowth, however, complicates the course of some patients (particularly after macroscopically incomplete resection) and has been construed as evidence for the neoplastic nature of these lesions. Such "recurrences" may simply reflect the fact that internal granule cells in grossly normal folia remain at risk for gangliocytomatous change due to their *PTEN* mutant status. It is noteworthy that fully developed lesions are often bordered by cerebellar cortex exhibiting subtle enlargement of neurons in the superficial aspect of the internal granule cell layer,[725] a precursor abnormality not appreciable at operation. Given the germline nature of the genetic defect predisposing to dysplastic gangliocytomas, it should not be surprising that patients may develop (and can present with) multifocal cerebellar involvement.

Other Glioneuronal Neoplasms

As we have tried to make plain in the sections devoted to these entities, the neoplasms traditionally placed in the various glioma series can exhibit neuronal "marker" expression on immunohistochemical assessment and may on rare occasion show overt neuronal/neurocytic differentiation. The latter of these unanticipated phenomena merits acknowledging in surgical pathology reports but does not alter the basic classification of such tumors as astrocytic, oligodendroglial, or ependymal. In this connection, we refer readers

to our discussion of the infiltrating astrocytomas for consideration of the "glioneuronal tumor with neuropil-like islands" (essentially a diffuse, WHO grade II or III astrocytoma harboring micronodular loci of neurocytic differentiation) and "glioblastomas with primitive neuronal components." Oligodendrogliomas, ependymomas, and the odd choroid plexus papilloma containing neuronal populations in SYN-rich, neuropil-like matrices are all cited in our foregoing treatment of these tumor groups. The nosologic status of a recently reported, *BRAF* V600E-mutant neoplasm characterized by an admixture of pleomorphic xanthoastrocytoma-type elements and SYN-labeling cells of epithelioid appearance is unclear.[733]

Embryonal Tumors

Collectively described as "embryonal" are neoplasms sharing, in addition to a postulated derivation from primitive neuroepithelial precursors, a peak incidence in the early years of life and an aggressive clinical biology. Most such tumors are dominated by small, anaplastic cells apparently uncommitted to any particular cytogenetic pathway on conventional histologic assessment, but the capacity of these lesions to differentiate along neuronal, glial, and, on occasion, mesenchymal lines has long been recognized and is manifest in their considerable morphologic and immunophenotypic heterogeneity.

Controversy has long surrounded the nomenclature of these complex neoplasms. Their original designations were predicated on the notion that the histologic appearances of CNS tumors reflect the neoplastic transformation of specific cell types at recognizable stages of neuroembryogenesis.[734] Thus, medulloepithelioma was the name given to a tumor harboring structures resembling, and so presumed to originate from, the primitive medullary epithelium of the neural tube, whereas ependymoblastoma was used for an embryonal neoplasm seemingly committed to differentiation along ependymal lines alone, and so forth. However, the theoretical underpinnings of this scheme have been justly questioned, and an alternative, at least partially molecular-based approach has been adopted by the 2016 WHO scheme. In an attempt to be as precise as possible, the generic "PNET" designation has now been abandoned, although the new term of "embryonal neoplasm, NOS" remains an imprecise compromise for primitive neoplasms that are either not evaluated beyond basic histopathology or defy a more specific designation, even after genetic studies.[735] The remaining categories of medulloblastoma and its variants, atypical teratoid rhabdoid tumor, embryonal tumor with multilayered rosettes (C19MC altered), and CNS neuroblastoma/ganglioneuroblastoma are discussed here, whereas pineoblastoma is covered separately under pineal parenchymal neoplasms.

Medulloblastoma and Its Variants

The anatomic site defining cerebellar and dorsal brainstem tumors termed **medulloblastomas** are the most common of primitive neuroepithelial neoplasms arising in the CNS. They occur throughout life but are characterized by a peak incidence in children between 5 and 10 years of age.[278] Approximately 15%–25% of afflicted patients are beyond their teenage years[278,736,737]; adult-onset cases cluster in the third and fourth decades, and 65% are male. There are four major clinicopathologic and molecular subtypes (discussed later) that vary considerably, based in part on the three major age categories of infancy, childhood, and adolescence/adulthood (Table 43.2). At least 75% of childhood and nearly all infantile medulloblastomas arise in the cerebellar vermis, often expanding to fill the fourth ventricle and thus producing manifestations of obstructive hydrocephalus (lethargy, headache, and morning emesis) in addition to truncal ataxia and disturbed gait. The relative proportion of laterally positioned, hemispheric examples increases with age, with most examples seen in adolescent and young adult patients. In contrast, childhood medulloblastomas localized to the cerebellar peduncle, cerebellopontine angle, or dorsal brainstem are relatively tightly linked with the more favorable WNT subtype,[738-740] covered in greater detail later. Rare medulloblastomas interpreted as primary leptomeningeal growths have also been communicated.[741]

As visualized in CT and MR images, medulloblastomas are usually solid and contrast enhancing. Unlike ependymomas, which are the main differential diagnostic consideration in the fourth ventricular region, they are not prone to calcification and midline examples often appear to hang from the roof of this chamber rather than bulging upwards from its floor. Rare infantile examples corresponding to the extensively nodular variant adopt a grape-like or gyriform configuration based in the vermis or fourth ventricle.[742,743]

While usually sporadic, medulloblastomas are known to complicate certain heritable disorders (see Table 43.2).[278] **Type 2 Turcot syndrome**, an autosomal dominant condition, is defined by the occurrence of medulloblastoma in association with adenomatous polyposis of the colon and germline mutations of the *APC* gene (a negative regulator of the Wnt signaling pathway) on chromosome 5q21. A significantly increased risk of medulloblastoma also characterizes the **nevoid basal cell carcinoma**—or "**Gorlin**"—**syndrome**, an autosomal dominant complex caused by germline mutations of the *PTCH1* gene (chromosome 9q22.3) or less commonly, the *PTCH2* (1p34.1) or *SUFU* (10q24.32) genes, the latter of which is associated with roughly 20-fold increased risk of medulloblastoma over the roughly 2% incidence encountered with germline *PTCH1* mutations.[744] Among its many other manifestations are odontogenic keratocysts, dyskeratotic pitting of the palms and soles, craniomegaly and other skeletal anomalies, lamellar calcium deposition in the falx cerebri and diaphragma sellae, calcifying ovarian fibromas and multifocal basal cell carcinomas notable for their early age at onset, involvement of both sun-exposed and hidden skin, melanotic pigmentation, associated calcifications, and clinical indolence. As these genes are all involved in the Sonic Hedgehog (SHH) signaling pathway, it is not surprising that the majority of tumors are desmoplastic/nodular or extensively nodular SHH-activated medulloblastomas, primarily presenting during infancy. SHH-activated, *TP53*-mutant medulloblastomas arising in the setting of **germline *TP53* gene mutation** (including **Li–Fraumeni syndrome**), previously mentioned as predisposing to astrocytic neoplasms and other tumor types, are also known to complicate subtype D1 **Fanconi anemia**, caused by *BRCA2* (13q12.3) gene mutations (these also put patients at risk for the development of mammary carcinomas, Wilms tumors, and hematologic neoplasms), and may occur at increased frequency (along with oligodendrogliomas and meningiomas) in **Rubinstein–Taybi syndrome**. The latter, due to mutations in the *CREB*-binding protein gene on chromosome 16p13.3, is typified by congenital cognitive impairment, growth retardation, and microcephaly with abnormal facies and broad thumbs and toes. Also on record is the association of medulloblastoma with **Coffin–Siris syndrome** (the complex of mental retardation, postnatal growth impairment, joint laxity, and brachydactyly of the fifth digit with absence of the nailbed) and with germline mutations of a DNA repair protein–encoding gene, designated as *NBN* or *NBS1*, that has been implicated in the cancer predisposition **Nijmegen breakage syndrome**.[745]

Integrated/Molecular Medulloblastoma Diagnoses (Variants)

Suffice it to say for purposes of the present discussion that two main histologic variants are recognized, these being the "classic"

Table 43.2 Integrated medulloblastoma diagnoses in the 2016 WHO scheme

VARIANT/ SUBVARIANT	PEAK AGE	USUAL LOCALIZATION	HISTOLOGY	USUAL IMMUNOPROFILE	MOLECULAR FEATURES	PROGNOSIS
WNT-activated	Child to young adult	Dorsal BS, CPA, CBL peduncle	Classic	Nuclear β-catenin*	Monosomy 6, *CTNNB1* mutation	Good
SHH-activated and *TP53*-wildtype (infant)	Infant	Vermis	D/N or EN	GAB1+, YAP1+, limited p53	Germline or somatic *PTCH1* or *SUFU* mutations, LOH of 9q, 10q, and 14q	Good to average
SHH-activated and *TP53*-wildtype (adult)	Teen to young adult	Lateral CBL hemisphere	D/N, rare classic	GAB1+, YAP1+, limited p53	Somatic *PTCH1* or *SMO* mutations, LOH of 9q, 10q, and 14q	Average
SHH-activated and *TP53*-mutant	Child	Lateral CBL hemisphere or vermis	D/N, LC/A, rare classic	GAB1+, YAP1+, strong p53+	*PTCH1* or *SUFU* plus *TP53* (+/– germline) and *TERT* mutations, chromothripsis, gene amplifications	Poor
Non-WNT/ non-SHH (group 3)	Child	Vermis	Classic, LC/A	GAB1-, YAP1-	*MYC*-AMP, c-myc overexpression, i17q	Poor
Non-WNT/ non-SHH (group 4)	Child	Vermis	Classic, LC/A	GAB1-, YAP1-	i17q	Average

AMP, gene amplification; BS, brainstem; CBL, cerebellar; CPA, cerebellopontine angle; D/N, desmoplastic/nodular; EN, extensively nodular; LC/A, large cell/anaplastic.
*β-catenin is normally expressed in the cytoplasm of medulloblastomas, but nuclear translocation is relatively specific for WNT activation. Nevertheless, nuclear positivity may be very focal in some examples.

(Fig. 43.108A) and "desmoplastic/nodular" (Fig. 43.109A) subtypes as defined further later. Nevertheless, the WHO now recognizes clinicopathologically relevant molecular subtypes that, together with histology, form integrated diagnostic categories (similar to the approach for diffuse gliomas presented earlier). These are summarized in Table 43.2 and stem from transcriptome, methylome, and microRNA profiling studies showing that there are four major molecular categories (WNT, SHH, group 3, and group 4), with additional clinicopathologically relevant subdivisions within the SHH-activated medulloblastomas.[746-748] Recognizing that there remains great genetic overlap between groups 3 and 4, which also lack easily reproducible immunohistochemical surrogates for their detection, the WHO has also adopted the previously suggested terminology of non-WNT/non-SHH for these 2 subtypes combined.[749] With a diagnostic panel of 3 immunostains, one can now stratify these variants into **WNT-activated** (nuclear β-catenin and YAP1 positive; ~10%; see Fig. 43.108B), **SHH-activated** (cytoplasmic β-catenin, GAB1, and YAP1 positive; ~30%; see Fig. 43.109B), and **non-WNT/non-SHH** (cytoplasmic β-catenin, GAB1, and YAP1 negative; ~60%, with 20% group 3 and 40% group 4) medulloblastomas. By adding p53 as the fourth marker (see Fig. 43.109C), one can also detect the majority of the **SHH-activated and *TP53*-mutant** medulloblastomas with highly aggressive clinical behavior and an association with germline mutations in a subset (Li-Fraumeni syndrome); such cases typically display strong and widespread nuclear p53 positivity in addition to the GAB1 and YAP1 expression.[750-752] Additionally, there are mutational differences within the SHH group, associated with therapeutic implications, such that tumors with a *PTCH1* mutation are most likely to be responsive to Smoothened (SMO) inhibition, whereas tumors harboring a *SUFU* mutation or *MYCN* amplification are likely to be resistant.[753] Lastly, there are major prognostic differences, with the WNT-activated tumors being by far the most favorable (potentially curable with less aggressive/neurotoxic therapies), while the SHH-activated, *TP53*-mutant and the group 3 variants are the most lethal, potentially requiring more aggressive therapeutic strategies. Other unfavorable prognostic variables include individual genetic alterations (e.g. *MYC* amplification) and large cell/anaplastic variant histology, regardless of the underlying molecular subtype. Given that both histopathology (described in greater detail later) and molecular subtype provide independent prognostic information, the 2016 WHO recommendation is to include both within the integrated diagnosis line (e.g. medulloblastoma, *SHH*-activated and *TP53*–wildtype molecular variant, desmoplastic/nodular histology variant). As with the gliomas however, it is recognized that not everyone can provide a molecular characterization, and therefore there remains a fully sanctioned "medulloblastoma, NOS" diagnosis. As regards histogenesis, shared patterns of gene and antigen expression have been forwarded as evidence that the SHH-activated (mostly desmoplastic/nodular histology) medulloblastomas derive from elements of the fetal external granular layer (these migrate to the surface of the embryonic cerebellar cortex from the roof of the fourth ventricle and are the eventual source of internal granular neurons), while the WNT-activated medulloblastomas are thought to arise from precursor cells in the dorsal brainstem arising from the rhombic lip.[738]

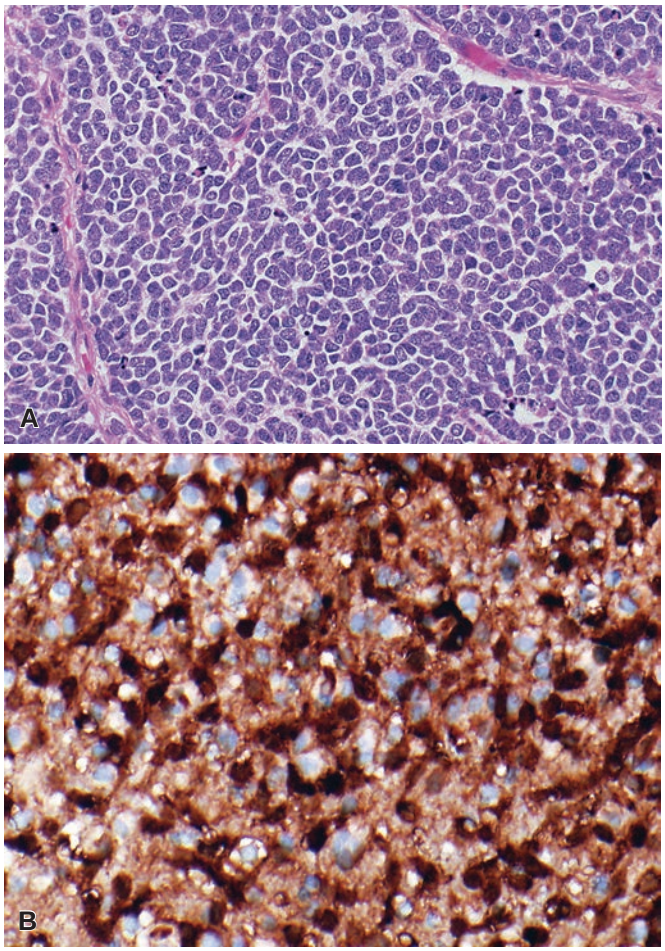

Figure 43.108 Medulloblastoma (Classic and WNT-Activated Subtypes). A, The classic medulloblastoma is a highly cellular neoplasm composed of diminutive, undifferentiated-looking elements possessed of little definable cytoplasm and prone to nuclear molding. **B,** A subset of classic medulloblastomas show evidence of WNT pathway activation, most often detected by the presence of nuclear β-catenin immunoreactivity.

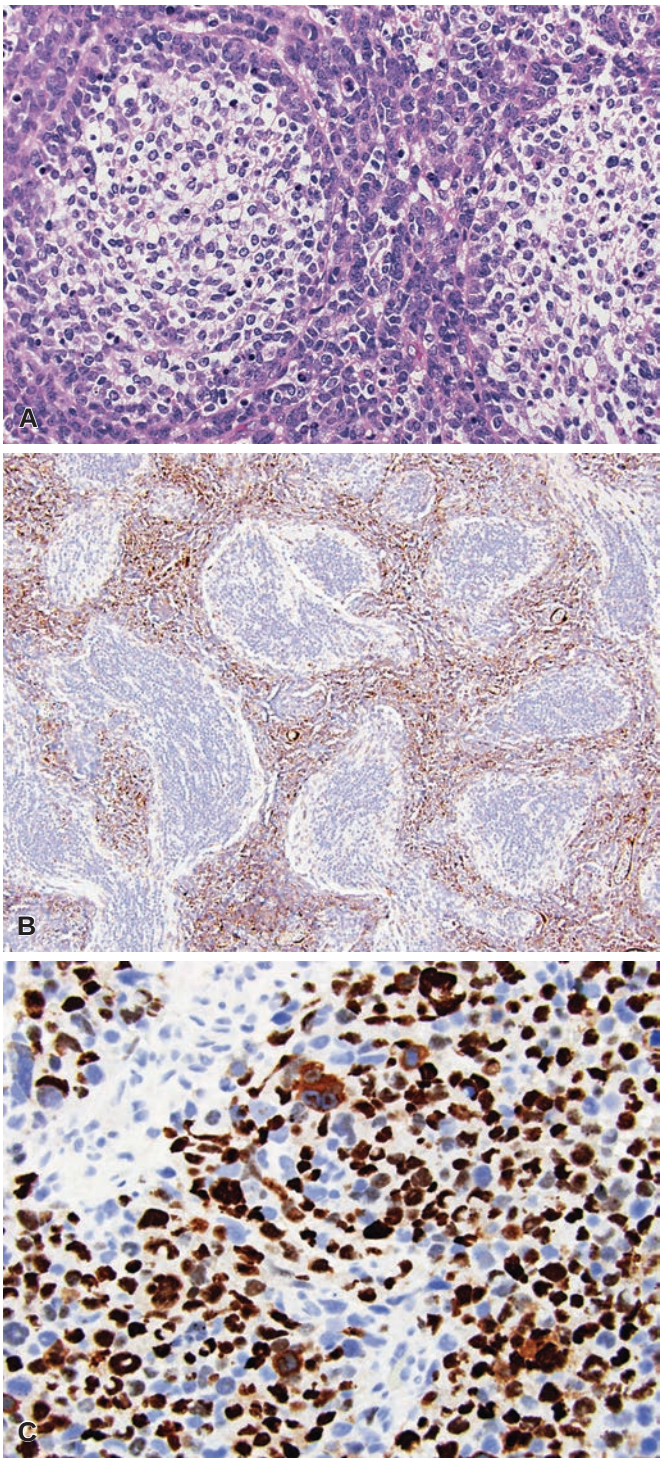

Figure 43.109 Medulloblastoma (Desmoplastic/Nodular and SHH-Activated Subtypes). A, Micronodular zones of reduced cellularity ("pale islands") are a striking feature of this medulloblastoma variant. **B,** Virtually all desmoplastic/nodular (and a smaller subset of classic) medulloblastomas show evidence of SHH pathway activation, including immunoreactivity to GAB1, often with strongest expression in the internodular regions. **C,** A poor prognosis subtype of SHH-activated medulloblastoma features p53 overexpression, often with superimposed anaplastic cytology.

Medulloblastoma Histopathology and Recognized Variants

Medulloblastomas are all classed as WHO grade IV neoplasms and are regarded collectively as potentially aggressive tumors requiring adjuvant treatment as well as surgical attack to prevent local recurrence and metastasis (particularly along CSF pathways). Although both classic and desmoplastic/nodular forms are unarguably capable of differentiating along glial, as well as neuronal, lines, it is the latter option that is far more frequently exercised. While overt ganglion cell maturation is exceptional, the overwhelming majority of medulloblastomas (including those of thoroughly undifferentiated histologic aspect) exhibit at least focal immunolabeling for SYN. Reliable indices of neuronal differentiation that can be appreciated at the light microscopic level include, in addition to the pale islands just described, Homer Wright rosettes, which are radial arrangements of tumor cell nuclei about small tangles of fibrillar material devoid of a centering lumen (Fig. 43.110). Ultrastructural studies have confirmed that the cores of such structures and the neuropil-like matrix of the pale island consist of neuritic cytoplasmic processes laden with microtubules in parallel array and joined by specialized

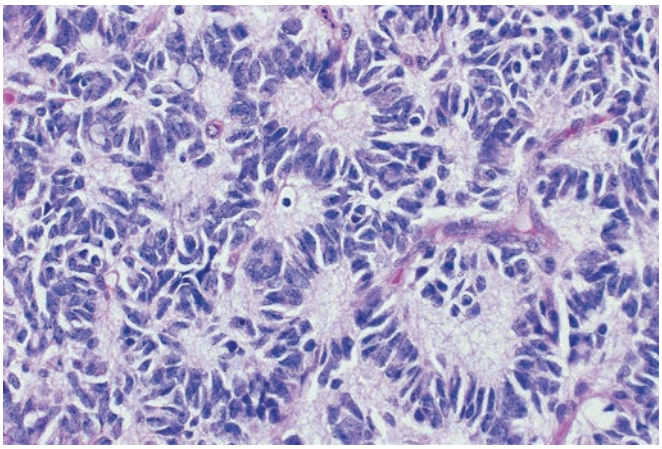

Figure 43.110 Medulloblastoma. Homer Wright rosettes consist of tumor cell nuclei disposed in circular fashion about tangled cytoplasmic processes. These structures are indicative of differentiation along neuronal lines.

adhesion plaques, features restricted in combination to embryonal neurons.[754] Furthermore, both the Homer Wright rosette and pale island constitute loci of concentrated immunoreactivity for SYN and other neuron-associated cytoplasmic antigens, including class III β-tubulin and microtubule-associated protein 2.[755] Pale islands also show upregulated immunoexpression of the TrkA and TrkC neurotrophin receptors.[756] Medulloblastomas may also contain populations immunoreactive for NFPs, as well as the Hu[334] and NeuN[358,756] neuronal nuclear antigens. Labeling for the latter reveals the oligodendrocyte-like elements of the pale island to be diminutive neuronal or "neurocytic" forms.

Classic medulloblastomas are often found on immunohistochemical assessment to be colonized by GFAP-positive elements lying near stromal blood vessels and displaying the stellate cytoplasmic configurations typical of reactive astroglia. These are generally taken to be entrapped, though the identification of similar cells in metastatic deposits raises the possibility that at least some represent neoplastic astrocytes of terminally differentiated nature.[278] GFAP-positive cells of indisputably neoplastic morphology are much less frequently encountered,[757] and glial differentiation sufficiently advanced as to be obvious on routine microscopic inspection is most exceptional. A conspicuous network of tumor cells having GFAP-reactive cytoplasmic rims and processes is often localized about the pale islands of desmoplastic/nodular medulloblastomas, suggesting that these micronodules are organized centers of divergent astroglial, as well as neuronal, outgrowth.[755] We mention in passing the immunolabeling of some medulloblastomas for photoreceptor-associated proteins, including rhodopsin and retinal S-antigen,[758] as well as curious variants containing neurosensory rosettes of Flexner–Wintersteiner type.[759] Shared by retinoblastomas and pineoblastomas, such evidence of photosensory differentiation has been taken to support the unified cytogenesis of these embryonal neoplasms, but this is an embattled hypothesis. The immunophenotypic potential of the medulloblastoma further includes reactivity for vimentin, desmin (typically limited to minor tumor cell subsets), nestin (a class VI intermediate filament protein expressed by many embryonic cell types, including neuroepithelial progenitors in the developing CNS), NCAMs, and nerve growth factors and their receptors.[278] Even cytoplasmic actin labeling has been described,[760] and exceptional cases may show cytokeratin (AE1/3) reactivity. The latter, when present, is usually a focal finding.

Regarding immunophenotype and its bearing on differential diagnosis, as previously emphasized, nearly all medulloblastomas (including those of thoroughly undifferentiated histologic aspect) label for SYN, a property that may be exploited to help exclude such potentially confounding lesions as the poorly differentiated fourth ventricular ependymoma, other anaplastic gliomas, and primary cerebellar lymphoma (typified by a B-cell profile). A pertinent "negative" is the general failure of medulloblastomas to express TTF-1,[474] as SYN-positive metastatic pulmonary small cell carcinoma potentially complicates the diagnostic picture when one is dealing with adult neurosurgical material. We have not encountered a solitary cerebellar metastasis as the presenting manifestation of an otherwise occult small cell carcinoma. The reader should consult the section dealing with AT/RTs for the differential diagnostic discussion of an embryonal neoplasm that often arises in the cerebellum and frequently harbors small cell components that may mimic the medulloblastoma to histologic perfection. Bona fide medulloblastomas do not exhibit anomalies of the rhabdoid tumor-associated *SMARCB1* gene or loss of its protein product on immunoexpression study with the INI1 antibody.[278]

We have elected to cite here only a small sample of the many studies detailing the immunohistochemical profile of medulloblastomas and make no attempt to dissect the conflicting (and, at present, clinically immaterial) data that have emerged from efforts to correlate the expression of neuronal, glial, and photosensory antigens with tumor behavior.[757,761,762] As highlighted previously, the integrated molecular diagnoses have essentially replaced these considerations, and provide a much more reliable scheme for clinical stratification.

Classic medulloblastomas are solid masses of friable, gray–white tissue composed, at their most primitive, of small, ostensibly undifferentiated cells closely arrayed in packed sheets (see Fig. 43.108). Nuclei are often densely hyperchromatic, round or angulated, invested with little or no definable cytoplasm (high nuclear to cytoplasmic [N/C] ratio), and prone to deformation ("molding") by their neighbors. A swirling or fascicular architecture may be encountered, as may nuclei disposed in tight perivascular pseudorosettes or regimented in compact, rhythmic palisades. Stromal elements are typically scant, consisting of small blood vessels that only exceptionally exhibit proliferative changes (only rarely comparable to the glomeruloid alterations characteristic of high-grade gliomas). Mitotic figures may abound, MIB-1 (Ki-67) labeling indices often exceeding 50%, but most medulloblastomas exhibit surprisingly little in the way of geographic necrosis. When present, however, necrotic zones may rarely be rimmed by palisading tumor cells in glioblastoma-like fashion. Patterns of local spread commonly evident in neurosurgical material include diffuse permeation of adjoining neuroparenchyma, arresting subpial accumulations of neoplastic cells that invite comparison to a persistent fetal external granular layer and extension into the subarachnoid compartment, with reinvasion of the underlying cerebellar cortex along a broad front or via penetrating perivascular Virchow–Robin spaces. Contact with the pia-arachnoid may incite considerable fibroplasia, in florid cases forcing tumor cells into single file, trabecular or even storiform arrays. Homer Wright (also known as neuroblastic) rosettes are a common, though not invariable feature of classic medulloblastomas. Rare examples feature pale nodules with neurocytic differentiation, but otherwise lack the reticulin-rich intercellular regions of desmoplastic/nodular medulloblastomas (see later); some have referred to such cases as being "biphasic,"[763] and they typically correspond to non-WNT/non-SHH (group 3 or 4) medulloblastomas molecularly. At the opposite end but similarly a diagnostic pitfall, some classic medulloblastomas show increased intercellular reticulin deposition within foci of leptomeningeal invasion, but otherwise lack the nodularity of desmoplastic/nodular medulloblastomas. It is of note that all WNT-activated medulloblastomas are the classic variant histologically, but classic

medulloblastomas are also encountered in all of the other molecular variants, such that further testing is needed before an integrated diagnosis is rendered. That said, a childhood onset medulloblastoma involving the dorsal brainstem, cerebellopontine angle, and/or cerebellar peduncle has a high likelihood of being the WNT-activated subtype.

Desmoplastic/nodular medulloblastomas commonly occupy the vermis in infantile examples but are otherwise over-represented among laterally situated, cerebellar hemispheric tumors occurring particularly among older children and adults. At operation, these neoplasms may seem meningeal based and are often lobulated, sharply demarcated, and firm, owing to the associated deposition of reticulin and collagen for which they are named. Desmoplastic/nodular medulloblastomas, however, feature characteristic "pale islands" with micronodular, reticulin-free zones that lend to many a low magnification appearance likened to follicular lymphoid hyperplasia, surrounded by reticulin-rich intercellular regions composed of more primitive appearing cells (see Fig. 43.109). Characterized by reduced cellularity, a rarefied fibrillar matrix, the emergence of an oligodendrocyte-like (but, in fact, neurocytic) populace, and downregulated BCL2 expression with increased apoptosis and a sharp decline in mitotic activity and MIB-1 (Ki-67) immunolabeling, the pale island is not merely free of connective tissues but represents a locus of progressive neuronal maturation and potential glial differentiation (as further addressed later). In recognition of this defining phenomenon (and to avoid confusion with collagenized medulloblastomas of otherwise classic appearance), the WHO specifically endorses the designation of these tumors as "desmoplastic/nodular." The lack of Homer Wright rosettes in most cases also helps distinguish this from the classic subtype. Using the strict diagnostic criteria outlined previously, all desmoplastic/nodular medulloblastomas fall into the SHH-activated molecular group.

Advanced neurocytic maturation also characterizes the rare tumors previously referred to as "**cerebellar neuroblastomas**" or "**neuroblastic medulloblastomas**," but now termed "**medulloblastomas with extensive nodularity**."[278,742] In essence, these are exaggerated forms of the desmoplastic/nodular medulloblastoma, exhibiting an even more strikingly lobular microarchitecture, with outsized reticulin-free zones having unusually elongated profiles, being particularly rich in SYN-immunoreactive fibrillary matrix material and boasting a population of small, amitotic, and uniformly rounded neurocytic cells arrayed in linear streams (Fig. 43.111). In contrast, the reticulin-rich intercellular zones with primitive cells are markedly reduced in comparison to conventional desmoplastic/nodular medulloblastomas. The differentiated neuronal nature of this population is apparent in that such cells elaborate cytoplasmic processes replete with clear and dense-cored secretory vesicles that may terminate in synaptic contacts. Some examples contain recognizable neurons of intermediate to large size, and this embryonal neoplasm may rarely undergo sequential maturation to ganglioneurocytic or gangliogliomatous histology,[764,765] a phenomenon (possibly treatment driven) recorded in isolated cases of conventional medulloblastoma as well.[766] Medulloblastomas of this sort seem to have a predilection for children younger than 3 years of age and to carry a more favorable prognosis than other subtypes (particularly in this age group).[742,767] Though not all such tumors comply, neuroradiological presentation as a cerebellar mass composed of contrast-enhancing nodules clustered in grape-like fashion is virtually diagnostic.[768] In common with their related desmoplastic/nodular medulloblastomas of infancy, this subtype is uniformly SHH activated.

Particularly aggressive behavior and treatment resistance characterize "**large cell**" and "**anaplastic**" **medulloblastomas** (Fig. 43.112).[769-771] The former descriptor has been applied to neoplasms conspicuously or wholly populated by monomorphic cells with large, rounded and vesicular nuclei, prominent nucleoli, and variably abundant eosinophilic cytoplasm. "Anaplastic" tumors exhibit marked variation in nuclear size and contour, multinucleated and bizarre giant cells inhabiting some examples. The cannibalistic wrapping of tumor cells about one another is a striking feature of many cases. In fact, the considerable cytologic overlap evidenced by neoplasms manifesting these alterations has prompted their consideration as a combined category of **large cell/anaplastic medulloblastoma** in the 2016 WHO. High mitotic rates are the rule and apoptotic cellular remains, typically abundant, may form confluent lakes and serpiginous seams. Cytoplasmic immunolabeling for SYN is generally retained (often in dot-like paranuclear form), and reactivity for NFPs and chromogranin may also be demonstrable. Focal GFAP expression has been documented but is uncommon. Of differential diagnostic utility are the observations that large cell/anaplastic medulloblastomas do not manifest the fibrillar to globose eosinophilic paranuclear inclusions, EMA immunoreactivity, chromosome 22 abnormalities, or loss of INI1 protein expression characteristic of the AT/RT.[278] Large cell/anaplastic features may be apparent at presentation or appear only at relapse, are often encountered in medulloblastomas that retain classic or desmoplastic/nodular components, and can emerge within

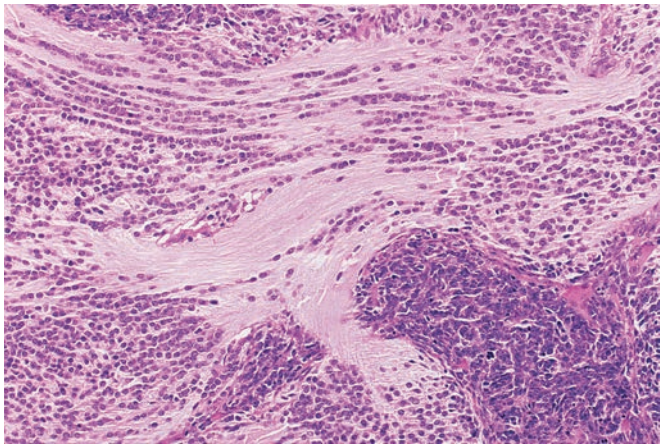

Figure 43.111 Medulloblastoma With Extensive Nodularity. This variant of medulloblastoma is typified by the linear streaming of rounded, "neurocytic" tumor cell nuclei within amassed cytoplasmic processes.

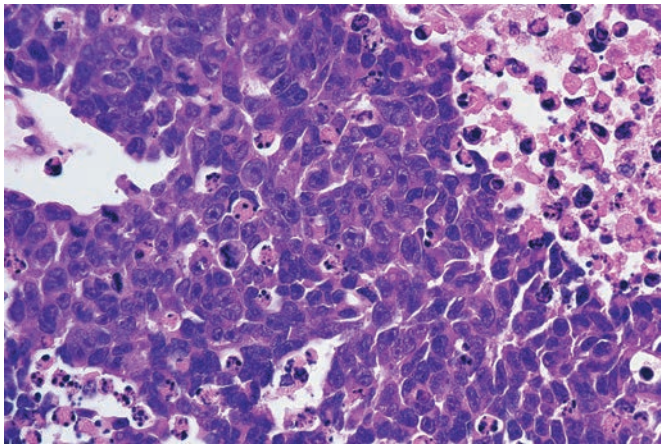

Figure 43.112 Large Cell/Anaplastic Medulloblastoma. Cellular enlargement, often prominent nucleoli, and pronounced mitotic and apoptotic activity are features of this virulent medulloblastoma subtype.

medulloblastomas with myogenic and/or melanotic differentiation (discussed later).[772,773] These observations, coupled with the demonstration that tumors characterized by large cell or anaplastic morphology may share "background" genetic profiles (e.g. isochromosome 17q formation) with conventional medulloblastomas while harboring many additional genomic aberrations,[746,774] indicate that the representatives of this group can be regarded not as fundamentally distinct medulloblastoma subtypes but as variants exhibiting progression-associated phenomena. Of further support for this notion, large cell/anaplastic medulloblastomas are encountered within all of the molecular classes, albeit with some over-representation in the unfavorable group 3 (non-WNT/non-SHH) subtype. *MYC* oncogene amplifications, previously mentioned as an adverse prognostic indicator, are also especially prevalent in this setting.[775,776]

The virulent clinical biology of large cell/anaplastic medulloblastomas has been acknowledged by some cooperative clinical trial groups in their categorizing of affected patients as "high risk" irrespective of age at presentation, extent of disease, and completeness of resection. In this vein, we mention that the formal grading of medulloblastomas according to the extent and severity of anaplastic alterations has proven clinically relevant and is becoming standard practice.[771] Given that cell size, pleomorphism, mitotic and apoptotic activity constitute continuous variables when medulloblastomas are considered as a class and that reproducible morphologic criteria for identifying such tumors are difficult to define, the WHO nonetheless stresses in their definition that the anaplasia or large cell phenotypes should be "severe" and represented across the majority of the tumor.

Certain rare medulloblastoma patterns merit additional comment. The **melanotic medulloblastoma** or **medulloblastoma with melanotic differentiation** (in suggested WHO parlance[278]) is defined by its content of pigmented cells disposed in tubules, papillae, or nests.[773,777,778] These are stained by conventional histochemical methods for the demonstration of melanin, can be shown to contain melanosomes in varying stages of maturation, label for HMB-45 as well as cytokeratins (AE1/3), and may reflect differentiation along the lines of the retinal pigmented epithelium. Although this lesion bears some histologic resemblance to the indolent melanotic neuroectodermal tumors of infancy that arise in the maxillary and epididymal regions, it is a highly malignant neoplasm prone to early and widespread neuraxis dissemination along CSF pathways. The **medullomyoblastoma** or **medulloblastoma with myogenic differentiation** (the latter being the sanctioned WHO term) is named for its heterologous rhabdomyoblastic elements.[772,779] Medulloblastomas of classic, desmoplastic/nodular, and large cell/anaplastic types may all spawn such components.[772] This curious entity has been variously interpreted as a medulloblastoma evidencing the extreme plasticity of its multipotent neuroepithelial precursors, as a tumor derived from neural crest (ectomesenchymal) progenitors recognized for their ability to differentiate along striated muscle lines, as a composite neoplasm populated by myoblastic constituents that arise via the secondary neoplastic induction of leptomeningeal or stromal elements, and, finally, as a lopsided, bidermal teratoma. Several examples reported under this designation have harbored cystic components with the appearance of mature, tridermal teratoma.[779] Some medullomyoblastomas have been found to harbor an isochromosome 17q, indicating a kinship with the conventional medulloblastoma group.[772] Variants containing both muscular and melanotic elements have also been described,[773] as has **medulloblastoma with chondroid differentiation**,[780] and a cerebellar tumor exhibiting evidence of isochromosome 17q formation and having medulloblastoma-type, ganglion cell, astrocytic, ependymal, cartilaginous, muscular, and glandular components.[781] A group of adult-onset tumors originally characterized as "**lipomatous medulloblastomas**" is now recognized to be more closely allied with neoplasms of neurocytic type. These are termed **cerebellar liponeurocytomas** (see Fig. 43.96) in current WHO nomenclature and are discussed elsewhere under that designation (see "Central neurocytoma and extraventricular neurocytic neoplasms"). Conventional medulloblastomas may rarely contain lipid-laden cells in conspicuous numbers, these usually proving to be foamy macrophages[649] but potentially representing lipidized tumor cells with adipocyte-like or lipoblastic profiles.[654]

Clinical Variables

At present, the therapeutic approach to medulloblastomas is predicated on clinical variables in addition to the integrated histologic and molecular diagnostic category.[278] The "standard risk" patient is generally defined as a subject 3 years of age or older who has undergone complete (or near-total) resection of a tumor confined to the posterior fossa. Protocols combining chemotherapy and whole neuraxis irradiation have achieved 5-year survivals exceeding 80% in this relatively favorable clinical setting, and very few such patients experiencing late relapse. Children below the age of 3 years at diagnosis and individuals of any age with evident CSF dissemination (found in ~30% of cases on initial evaluation), extraneural metastases or bulky (>1.5 cm^2) residual disease after surgery—"high-risk" patients—do not fare as well. Whether the excess mortality noted in the very young reflects intrinsic tumor biology or the reluctance of neuro-oncologists to expose the immature nervous system to the predictably toxic doses of radiation that have been considered requisite to achieving disease control is unclear. Certainly, the price exacted of childhood medulloblastoma survivors by conventional radiotherapy—growth failure, endocrinopathy, significant intellectual impairment, behavioral disturbances, and the induction of secondary neoplasms that include meningiomas, sarcomas, and glioblastomas—has been disheartening and continues to drive investigations aimed at reducing CNS radiation exposure in the pediatric cohort. In this connection, there is evidence to suggest that infants and young children with medulloblastomas of desmoplastic/nodular and extensively nodular type may be spared irradiation and managed with chemotherapy alone following tumor resection.[278] Whereas treatment failure in the posterior fossa or along the craniospinal axis is the rule, medulloblastomas do occasionally travel to more distant sites.[782] Skeletal deposits, often widespread, account for over 90% of systemic metastases, but the liver, lymph nodes, and lungs may be involved, as may the abdominal cavity (via ventriculoperitoneal shunts placed to relieve obstructive hydrocephalus). While medulloblastomas usually conform to the principle (Collins' law) that defines the period of risk for recurrence of embryonal childhood neoplasms as equal to the patient's age at diagnosis plus 9 months, late relapse (including extraneural dissemination) may also be encountered.

Embryonal Tumor With Multilayered Rosettes

This newly sanctioned WHO entity of **embryonal tumor with multilayered rosettes, C19MC-altered** includes most of the cases previously designated as either **embryonal tumor with abundant neuropil and true rosettes** (Fig. 43.113A) or **ependymoblastoma**, as well as subsets of tumors previously classified as either **medulloepithelioma** or "primitive neuroectodermal tumor" with atypical features or divergent differentiation.[278,783,784] Defined by the presence of an amplicon containing a microRNA cluster on chromosome 19, typically in association with LIN28 immunoreactivity (see Fig. 43.113B), cases with classic histology but not undergoing molecular analysis may be designated as **embryonal tumor with multilayered rosettes, NOS.** This highly aggressive lesion of infancy and early childhood has proven more prevalent than previously suspected, accounting for up

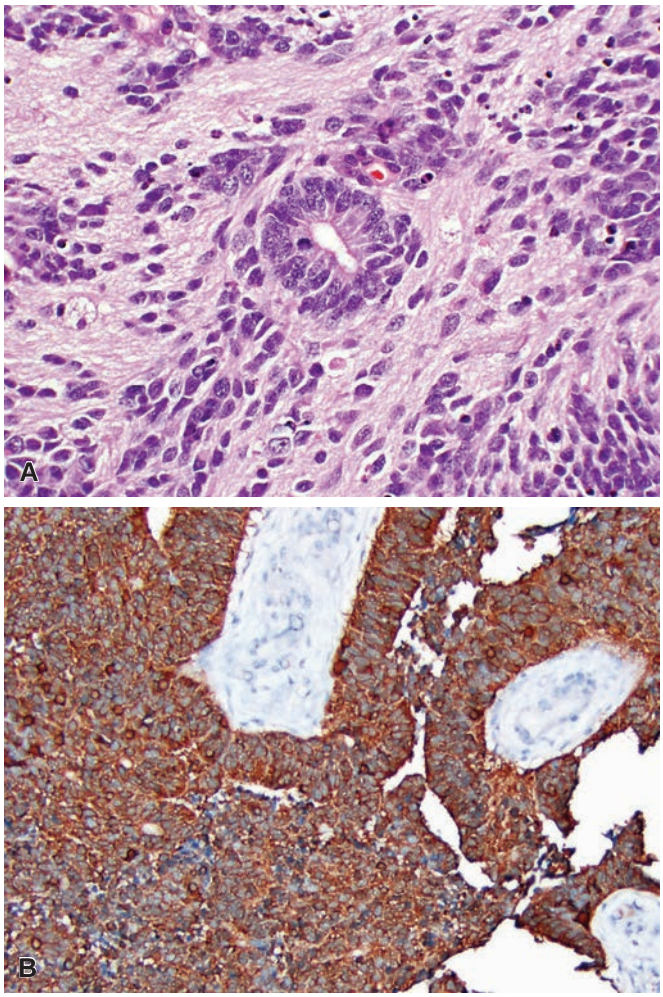

Figure 43.113 Embryonal Tumor With Multilayered Rosettes. **A,** Typical of the subtype with abundant neuropil and true rosettes is a delicate fibrillar matrix in which primitive neuroepithelial elements and ependymoblastic rosettes *(center)* are arrayed, the latter having well-defined (though often minute) lumens and being composed of mitotically active tumor cells with granular apical stippling. **B,** Immunoreactivity for LIN28 is diagnostically useful, regardless of whether the tumor resembles embryonal tumor with abundant neuropil and true rosettes, ependymoblastoma, or medulloepithelioma.

to a third of all supratentorial primitive neuroectodermal tumors in some series[355] and an even greater fraction of those arising in infants under 4 years of age (the median age in one large series being 29 months[784]). There is a strong predilection for the cerebral hemispheres, although roughly a fourth occur in extra-cerebral sites. In contrast to other CNS neoplasms of embryonal type, this embryonal tumor often displays little to no contrast enhancement on neuroradiological study. The entity often combines features of "ependymoblastoma" and "neuroblastoma" with the embedding of ependymoblastic rosettes in an expansive matrix that is rich in SYN and NFP on immunohistochemical assessment and that commonly exhibits broad zones of strikingly hypocellular neuronal tissue (see Fig. 43.113A). Also populating tumors of this group are undifferentiated and neuroblastic elements, which may form Homer Wright rosettes, and some examples containing ganglion cell components or manifest loci of neurocytic maturation in which tumor cells align in linear streams or aggregate in formations resembling the "pale islands" of the desmoplastic/nodular medulloblastoma. Regions exhibiting large cell/anaplastic medulloblastoma-like histology may be encountered as well. Ependymoblastic rosettes are represented by mitotically active elements in radial, pseudostratified array about central lumens of rounded profile and often diminutive diameter. The juxtaluminal apices of participating cells typically manifest a granular stippling and are joined, at the ultrastructural level, by zonula adherens–type intercellular junctions. MIB-1 labeling activity is high in these formations and in poorly differentiated, nonrosetted components. It should be noted, however, that this feature alone is not specific for this diagnostic entity and is occasionally encountered in other embryonal neoplasms such as AT/RT.[785] High-level genomic amplification at chromosome 19q13.42 (with upregulation of a microRNA cluster including oncomirs miRNA-372 and miRNA-373) is a defining molecular feature, although strong, (albeit often patchy) immunoreactivity for LIN28 serves as a useful and highly sensitive, but not specific, surrogate immunohistochemical marker, although subsets of medulloblastomas, AT/RTs, and high-grade astrocytic or ependymal gliomas can also express this marker.[783,784,786]

The embryonal tumor with multilayered rosettes is a virulent neoplasm that often proves resistant to surgical and adjuvant therapy. In the largest series yet published, 36 of 54 evaluable patients died of progressive disease, with median survival times from diagnosis a mere 13 months with therapy and less than 1 month without therapy.[784] Local failure is the rule, and leptomeningeal dissemination further complicates some cases.

Medulloepithelioma

The **medulloepithelioma**, when not accompanied by C19MC amplification and LIN28 positivity (see previous discussion), is a rare but highly aggressive neoplasm that typically arises in the cerebrum of an infant or child younger than 5 years of age.[787] Particularly characteristic is a deep, paraventricular localization—a topography adduced in support of a postulated origin from the lining germinal matrix of the developing forebrain—but medulloepitheliomas may also originate in the third ventricular/thalamostriate regions, cerebellum, brainstem, cauda equina, optic nerves,[788] and sellar/suprasellar compartments.[789] Ocular neoplasms of comparable morphology are well recognized and rare examples presenting as sciatic nerve[790] or pelvic[791] growths are on record. These extraneural variants are not further considered here.

Often attaining massive proportions, medulloepitheliomas are usually well circumscribed and composed of friable, gray–pink tissue evidencing hemorrhage, necrosis, and, in some cases, cystic change. Their defining feature is the formation of tubules, ribbons, or, less frequently, papillae resembling, and believed to represent a recapitulation of, the medullary epithelial structuring of the primitive neural tube (Fig. 43.114). These are fashioned of pseudostratified columnar cells that rest on a continuous, PAS-positive basement membrane and are sometimes capped by apical cytoplasmic blebs. PAS-positive material may also coat luminal surfaces as an ill-defined, granular pseudomembrane. Mitotic figures are readily identifiable and generally abluminal in location, a pattern reminiscent of the juxtaventricular proliferative activity characterizing early neurocytogenesis. Selective labeling of these inner, mitotically active elements for nestin, and full-thickness immunoreactivity of this neoplastic neuroepithelium for vimentin and microtubule-associated protein type 5 (MAP-5) are additional antigenic features shared with the embryonic neural tube.[792] Some observers have found focal labeling for GFAP, class III β-tubulin, and NFP epitopes within these arrays, but this is exceptional.[793] Also described are instances of apical immunoreactivity for EMA and focal cytoplasmic labeling for NSE and cytokeratins.[792,793] It should be noted that medulloepithelial structures vary greatly in extent from case to case and may constitute only a regionally limited

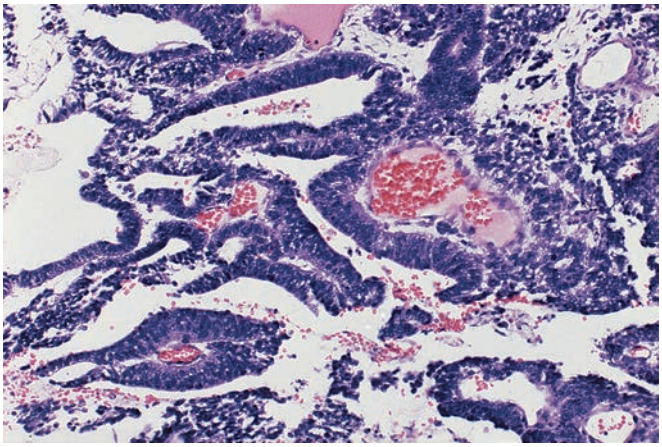

Figure 43.114 Medulloepithelioma. A tubulopapillary disposition of its columnar elements characterizes this primitive neuroepithelial neoplasm.

finding in an otherwise patternless, small cell neoplasm of thoroughly undifferentiated aspect.

In keeping with their proposed stem cell derivation, medulloepitheliomas often manifest divergent differentiation and maturation, at times advanced, along astrocytic, ependymal, neuronal, and, rarely, oligodendroglial lines.[787,793-795] A tubulopapillary, melanotic fourth ventricular neoplasm interpreted as a pigmented medulloepithelioma is on record,[796] as is an example containing chondroid, osseous, and skeletal muscle elements.[797] The exact nosologic position of the latter in relation to the immature teratoma, which may harbor medullary-type neuroepithelial formations, is problematic. Obviously, the presence of admixed nonteratomatous germ cell components and evidence of endodermal or somatic ectodermal differentiation should be sought and excluded before a diagnosis of medulloepithelioma is rendered, particularly if neoplastic mesenchymal tissues are identified.

The differential diagnosis of the medulloepithelioma must also include the embryonal tumor with multilayered rosettes and choroid plexus carcinoma. Medulloepitheliomas may contain ependymoblastic rosettes, but differ in that their neuromedullary components rest on basement membranes and do not fashion at the ultrastructural level such ependymal specializations as crowning cilia, microvilli, or complex intercellular junctions of zonula adherens type.[798] Choroid plexus carcinomas do not manifest divergent differentiation along astrocytic or neuronal lines and tend to a more obviously villiform architecture than is displayed by most medulloepitheliomas; also unlike the latter, they may display widespread immunoreactivity for S-100 protein and cytokeratins.

The medulloepithelioma is highly malignant and typically kills within 1–2 years of diagnosis, though aggressive surgical and adjuvant therapy may save some afflicted children, with age and extent of resection considered the most important prognosticators.[799] Uncontrollable growth at the primary site is the usual cause of death, but widespread leptomeningeal metastasis is frequent as well and may occur early in the disease course.

Central Nervous System Neuroblastic Tumors

The diagnosis of **CNS neuroblastoma** should be reserved for extracerebellar neoplasms of embryonal appearance that can be shown to differentiate solely along neuronal lines. Neuroblastomas of the central neuraxis are typified by a presentation in the first decade of life (usually prior to age 5 years) and localization to the cerebral hemispheres,[800,801] though they may arise within the ventricular system and intraspinal compartment.[802,803]

Consisting of friable gray tissue prone to necrosis, hemorrhage, and cystic change, neuroblastomas often achieve enormous proportions by the time they are discovered but tend to appear relatively circumscribed. Induction of a collagenous stroma lends a firm consistency and unusually lobulated contours to some examples. Although there is no biologic import to this division, several histologic variants are recognized. The "**classic**" **neuroblastoma** is composed of small, mitotically active cells containing densely hyperchromatic nuclei and disposed in highly populous sheets. A delicate fibrillary matrix consisting of tangled cytoplasmic processes is variably present. It is this subtype that is most likely to contain Homer Wright rosettes and large neurons of ganglion cell type. Occasional examples manifest a compact palisading of tumor cell nuclei within their neuropil-like matrices. Tumor cells may also palisade about foci of necrosis, although glioblastoma should always be excluded first when this pattern is encountered. The "**desmoplastic**" **neuroblastoma** is defined by fibrous stroma, most developed where tumor contacts the leptomeninges, that imposes lobular, trabecular, or single-file arrangements on its constituent cells. Larger than classic neuroblasts, the latter are characterized by vesicular nuclei, distinct nucleoli, and, in some cases, a modest paranuclear expanse of basophilic or amphophilic cytoplasm. The "**transitional**" **neuroblastoma** combines features of both the classic and desmoplastic variants. Only exceptionally do central neuroblastic tumors evidence the graded maturational alterations so often displayed by their retroperitoneal and posterior mediastinal counterparts, meriting designation as ganglioneuroblastomas.[804,805]

In the absence of Homer Wright rosettes or an unarguably neoplastic (as opposed to entrapped) neuronal population, the diagnosis of neuroblastoma needs ultrastructural or immunocytochemical support. Neurite-like cytoplasmic processes containing microtubules in parallel array, dense-core, and clear, synaptic-type vesicles signal neuronal differentiation. Attempts at synapse formation, usually abortive, are apparent in only a small minority of cases. Immunohistochemical assessment obviates the need for electron microscopic study if cytoplasmic SYN or NFP labeling can be demonstrated, and nuclear NeuN expression also attests to differentiation along neuronal lines. SYN reactivity is by far the most sensitive, albeit less specific marker, and is typically concentrated in the fibrillar matrix. GFAP expression should primarily be limited to cells reasonably interpreted as reactive astrocytes. These possess stellate cytoplasmic processes, are most numerous at the tumor–brain interface and, when present deeper within a lesion, usually lie near penetrating blood vessels. Some observers have credited central neuroblastic tumors with the capacity to generate GFAP-immunoreactive schwannian elements,[804] but the exact nature of the cells in question is far from clear.[806] Recent genetic studies also suggest rare subtypes, such as CNS neuroblastomas with FOXR2 activation, a Ewing sarcoma family tumor with CIC alterations, those with MN1 alterations, and examples with BCOR alterations.[807] It is therefore likely that this previously vaguely defined category will undergo considerable revisions in future classification schemes.

The interpretation of survival data reported for patients with cerebral neuroblastomas is complicated by the inclusion of cases in some series that would currently be regarded as examples of central neurocytoma or desmoplastic infantile ganglioglioma, both associated with a favorable prognosis, as well as primitive appearing astrocytic and ependymal neoplasms. Still, neuroblastomas seem more amenable to surgical and radiotherapeutic management than other primitive extracerebellar neoplasms.[800] The risks of local regrowth and CSF-borne metastasis, however, are high, and spread to extraneural sites is occasionally seen. Isolated instances of late local recurrence

in which reoperation has demonstrated maturation of central neuroblastomas to differentiated ganglion cell tumors[808] are noteworthy.

"Polar Spongioblastoma"

It is in deference to a traditional view[809] that the so-called **polar spongioblastoma** represents a primitive neuroepithelial neoplasm of distinctive character that we briefly address it here, but there has been considerable controversy as to whether the peculiar tumors awarded this designation constitute a unified entity,[810] and this diagnosis is no longer recognized in the WHO nosology. A tendency to arise in the walls of the third and fourth ventricles in childhood has been asserted, but no generalizations regarding clinical course emerge from the literature. The tumor is composed of spindled cells with fusiform nuclei that appear suspended in compact palisades between delicate unipolar or bipolar cytoplasmic processes in close parallel array. This arresting disposition has been likened to the radial arrangement of migrating glia ("spongioblasts") that characterizes the 16- to 18-week stage of human neuroembryogenesis.[809] Skeptics point to the fact that a comparably rhythmic architecture may be encountered in neoplasms that otherwise qualify as classic oligodendrogliomas, pilocytic astrocytomas, glioblastomas, ependymomas, neuroblastomas, and medulloblastomas.[810] To believers, however, a frequent admixture of conventional oligodendroglial and astrocytic elements has simply constituted evidence that the polar spongioblastoma derives from embryonic forbears committed to differentiate along glial lines. Uncritical acceptance of this entity is further complicated by its lack of defining immunohistochemical, ultrastructural, or molecular features. It is our view that the diagnosis of polar spongioblastoma, if resorted to at all, should be reserved for neoplasms that exhibit a compact, palisaded growth pattern throughout, and that lack the immunohistochemical or genetic features of better defined diagnostic entities.

Atypical Teratoid/Rhabdoid Tumor

The **AT/RT** is a highly aggressive neoplasm encountered principally in infancy and early childhood.[278,811,812] Adult-onset examples are distinct rareties.[813,814] Over 90% of afflicted patients reported to date have been less than 5 years of age at diagnosis (mean = 20 months), and nearly 50% have harbored tumors of the cerebellum or cerebellopontine angle, often with contiguous brainstem involvement. Supratentorial (cerebral or suprasellar) examples account for at least 40% of recorded cases, trailed distantly by pineal region and intraspinal variants. AT/RTs arising within cranial nerves have been depicted,[815] as have instances in which neoplasms resembling AT/RT have emerged from low-grade neuroepithelial neoplasms (pleomorphic xanthoastrocytoma, ganglioglioma, ependymoma, or DNT) in what apparently represents a bizarre form of tumor progression associated with loss of INI1 expression.[200,426,427,816] MRI typically discloses a bulky and contrast-enhancing mass, cystic and hemorrhagic alterations being common to this entity and its neuroradiological profile indistinguishable from that of medulloblastomas and other CNS embryonal neoplasms. Approximately 20%–25% of patients have evidence of CSF dissemination at diagnosis; many succumb to disease within months of diagnosis, and survival beyond 2 years has been the exception, although intensive adjuvant therapy protocols have been improving this bleak picture more recently.[817]

AT/RTs share with rhabdoid tumors of the infantile kidney and soft tissues a linkage to biallelic inactivation of *SMARCB1/hSNF5/INI1*, a gene mapping to chromosome 22q11.2 and encoding a ubiquitously expressed member of the SWI/SNF chromatin-remodeling complex.[818] Proteins of this family effect conformational alterations in the nucleosome that facilitate or restrict transcription factor access. Most AT/RTs demonstrate a pattern of *SMARCB1* inactivation conforming to the "two-hit" mechanism operative in classic tumor suppressor genes, loss of one copy resulting from partial deletion or monosomy 22 and the second suffering a nonsense or frameshift mutation (often in hotspot exons 5 and 9) that produces a novel stop codon. Also encountered are deletions or mutations involving both gene copies. While the majority of AT/RTs arise in sporadic fashion, germline mutations of *SMARCB1* underlie a familial rhabdoid tumor predisposition syndrome characterized by potentially multifocal, CNS, renal, and other extraneural primaries, mostly presenting in the first year of life.[819] As presently discussed, the loss of INI1 protein product expression that is a consistent feature of AT/RTs can be exploited to facilitate the identification of these neoplasms by immunohistochemical means.

AT/RTs are so designated in acknowledgment of their potentially complex histology. In fact, only a minority consist solely of rhabdoid cells and the latter (characterized in classic form by distinct cell borders, large and vesicular nuclei, macronucleoli, and globose, paranuclear cytoplasmic inclusions of hyalin appearance) may be only sparsely represented (or lacking entirely) among tumor cells with uniformly dense and eosinophilic, finely granular, vacuolated, wispy, or water-clear cytoplasm (Fig. 43.115A). These nonrhabdoid, large cell, mostly epithelioid elements can variably include spindled, polygonal, and bizarre, multinucleated cells disposed in nests or sheets. Bands of hyalinized collagen traverse some examples. Others

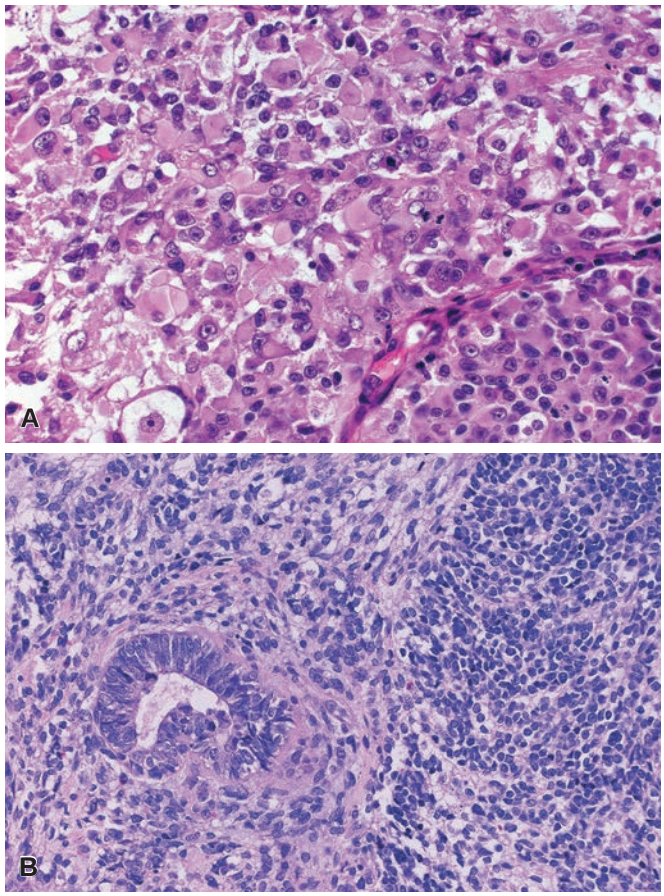

Figure 43.115 Atypical Teratoid/Rhabdoid Tumor. A, Neoplasms of this family typically contain at least some cells of large, rhabdoid phenotype. A second example **(B)** harbors, at right, small cell elements of primitive neuroepithelial appearance and a differentiated glandular structure, at left, embedded in a neoplastic component of mesenchymal appearance.

exhibit pseudopapillary formations or myxoid change and a chordoid growth pattern. The descriptor "teratoid" reflects the presence, in many tumors of this group, of varied neoplastic tissue components (see Fig. 43.115B). Most prominently represented are small cell elements of embryonal appearance indistinguishable from those that typify the medulloblastomas and other CNS embryonal tumors. The latter, encountered in 60%–70% of cases—and the vastly dominant component in some examples—usually assume an undifferentiated histologic profile but may fashion rosettes of Homer Wright, Flexner–Wintersteiner, or ependymoblastic type, some AT/RTs containing ependymal canal– or neural tube–like structures within their primitive neuroepithelial compartment. Spindle cell mesenchymal components may be present (these often having a fetal mesenchyme-like appearance) and some examples contain epithelial elements that may be represented by cohesive cell nests, adenoid and tubuloglandular structures or keratinizing squamous islands. Differentiation along striated muscle lines has not been reported.

Immunohistochemical assessment is critical to the distinction of AT/RTs from a variety of neoplasms that may assume rhabdoid cytologic features. A complex immunophenotype is the rule.[811,812] Rhabdoid and nonrhabdoid large cell elements invariably display labeling for vimentin (with intense staining of cytoplasmic inclusions, when present), are nearly always immunoreactive for EMA, and commonly label for GFAP and smooth muscle actin (SMA) as well. The percentage of cells reactive for each antigen is highly variable. EMA labeling may be diffuse or confined to cytoplasmic membranes, antibodies to SMA occasionally decorating a peripheral cytoplasmic ring with particular intensity (a pattern encountered in some smooth muscle tumors). In this connection, we would cite gene expression studies confirming the activation of a myogenic differentiation program in AT/RTs.[820] Immunoreactivity of the large cell components for cytokeratins (AE1/3, CAM 5.2) is also common, and some may be decorated by antibodies to NFP and SYN. Desmin reactivity, present in only a minority of cases, is usually restricted to mesenchymal or primitive regions (which may also label for NFP, SYN, and GFAP). Epithelial elements, not surprisingly, label for cytokeratins and, less commonly, EMA.

However, the most significant breakthrough in the immunohistochemical identification of AT/RTs has come with the development and marketing of the monoclonal antibody BAF47 or INI1 that recognizes the protein product of *SMARCB1*. The loss of gene expression at the protein level that regularly results from the *SMARCB1*-inactivating deletions and mutations characteristic of AT/RTs is reflected in a consistent failure of tumor cells to exhibit INI1 reactivity (Fig. 43.116).[821] It is a complete absence of nuclear labeling that must be demonstrated for confirmation of diagnosis (an irrelevant cytoplasmic blush may be observed), as regional loss of INI1 immunoreactivity (e.g. familial schwannomas) or diminished expression (e.g. synovial sarcoma) can be displayed by other tumor types. Results must be considered noninformative if endothelial cells, infiltrating mononuclear elements, and native CNS constituents fail to show the nuclear reactivity expected of these positive internal control populations. An attribute of most neoplasms that can assume strikingly rhabdoid guises, such as meningiomas, glioblastomas, choroid plexus carcinomas, germ cell tumors, large cell/anaplastic medulloblastomas, malignant lymphomas, and other potential mimickers, retained INI1 reactivity nearly excludes AT/RT from further diagnostic consideration in problematic cases. Molecular genetic analysis of *INI1* status may be required in the event of technical failure or equivocal labeling. It should also be noted that rare, mostly infantile examples of AT/RT are caused by inactivating mutations of other SWI/SNF chromatin remodeling complex components, such as the *SMARCA4* gene, encoding the BRG1 protein. Analogous to the more common form, complete loss of BRG1 expression can be detected immunohistochemically and familial examples are also documented.[822] Extremely rare cases showing all the typical clinicopathologic features of AT/RT but lacking demonstrable losses of INI1 or BRG1 may also be seen, though it is unclear whether this is part of the same spectrum or another entity. The WHO now recommends the term "**CNS embryonal tumor with rhabdoid cells**" for such cases and for those where neither immunohistochemical nor other molecular studies were performed.[278]

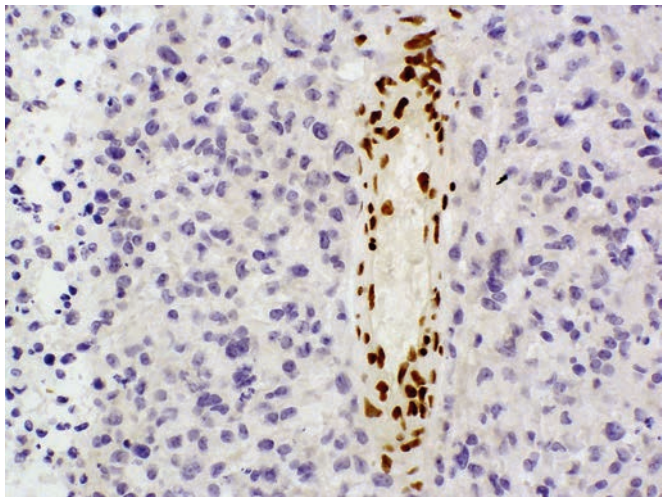

Figure 43.116 Atypical Teratoid/Rhabdoid Tumor. Loss of nuclear INI1 protein expression on immunohistochemical study characterizes this entity. Note retained expression by endothelial cells and perivascular mononuclear cell infiltrate.

Given that AT/RTs frequently harbor small cell components of primitive neuroepithelial appearance and that rare examples lack rhabdoid cells altogether, we also recommend that CNS embryonal tumors (particularly in infancy) be routinely screened for INI1 loss before diagnoses such as medulloblastoma, pineoblastoma, anaplastic choroid plexus carcinoma, or CNS embryonal tumor, NOS are rendered. As previously discussed in our treatment of choroid plexus tumors, suggestions that these are associated with AT/RT-type *SMARCB1* mutations and germline abnormalities of this gene may well reflect histologic misclassification of the tumors in question. We agree that INI1 assessment may be waived in the special circumstance of posterior fossa neoplasms exhibiting desmoplastic/nodular medulloblastoma histology, that is, displaying the "pale islands" that define the latter entity. This distinctive morphologic feature has been consistently correlated with retained INI1 labeling and evidence of SHH activation (see medulloblastoma section); it has never been shown, in our experience or to our knowledge, by a bona fide AT/RT. Readers should note that complete loss of INI1 expression has also been observed in epithelioid sarcomas, medullary carcinomas of the kidney, a novel form of undifferentiated soft tissue sarcoma affecting children, and in isolated examples of rhabdoid leiomyosarcoma.[821] Recently described intraventricular "**cribriform neuroepithelial tumors**" (CRINETs) of the infant CNS have reportedly demonstrated both INI1 silencing and *SMARCB1* abnormalities.[823] Lastly, recent genomic studies suggest that there are at least three molecularly distinct subtypes of AT/RT.[824]

Assorted Primitive Neuronal Tumors

It should be noted that although a peripheral counterpart akin to Ewing sarcoma still exists, the term "**PNET**" has been expunged from

the WHO 2016 lexicon for CNS tumors, due to the majority of such cases now qualifying for more distinct diagnostic entities. It was originally coined not as a generic appellation for embryonal neoplasms of every stripe, which it was to become, but to designate a cerebral tumor of infancy and childhood characterized by medulloblastoma-like histology and a propensity to disseminate along CSF pathways.

The problems inherent in defining a neoplasm largely on the basis of its undifferentiated appearances should be obvious. The diagnosis of a nonspecific form of "CNS PNET," now replaced by the term **CNS embryonal tumor, NOS** rests on firmest ground when applied to extracerebellar tumors of embryonal aspect, mostly occurring in childhood, exhibiting divergent neuronoglial differentiation and lacking the distinctive molecular features of entities such as the histone H3-associated midline or cerebral glioblastomas, anaplastic ependymoma, AT/RT, and embryonal tumor with multilayered rosettes (see appropriate sections). The demonstration of a polymorphous immunophenotype is useful in this regard, as some CNS embryonal tumors clearly coexpress SYN and multiple intermediate filament proteins (most often the complex of vimentin–GFAP–NFP but, occasionally, cytokeratins and desmin as well). The distinction of putative CNS embryonal tumors evidencing GFAP immunolabeling alone from highly anaplastic gliomas is murky. In practice, we find ourselves applying the former label to largely monomorphic, small cell neoplasms of childhood containing GFAP-positive elements, but manifesting neither the complex MVP nor the perinecrotic cellular palisading that typifies high-grade glial neoplasms (particularly astrocytomas) of conventional type. Immunoreactive cells often huddle in small clusters or aggregate about stromal blood vessels, are poorly fibrillated, and may assume a microgemistocytic appearance. We caution the reader against the low-percentage diagnosis of CNS embryonal tumors in adults, the majority of which end up showing molecular features of a high-grade glioma instead, especially the glioblastoma with primitive neuronal features (see earlier discussion).

CNS embryonal tumors may exhibit large cell/anaplastic features (with particularly unfavorable prognostic implications) of the kind characterizing some medulloblastomas.[825] Tumors of this kind (and their conventional small cell counterparts) must be shown to retain INI1 protein expression in order to exclude AT/RT as an alternative diagnostic possibility.

We have encountered cerebral neoplasms similar to a unique cerebellar lesion descriptively designated as a "**desmoplastic primitive neuroectodermal tumor with divergent differentiation**."[826] The recorded case was characterized by nests and cords of small neuroepithelial cells (some labeling for SYN, NFP epitopes, GFAP, and cytokeratins) embedded in a cellular "stroma" populated by desmin-immunoreactive elements. At recurrence, this exhibited strikingly epithelioid features and overt neuronal (ganglion cell) differentiation. Curiosities that potentially complicate the differential diagnosis of central embryonal neoplasms include intracranial examples of the **melanotic neuroectodermal tumor of infancy**,[827] the **desmoplastic small round-cell tumor** of Gerald and Rosai,[828] and the **Ewing sarcoma/peripheral PNET**.[829] The last two of these entities are characterized by specific t(11;22) chromosomal translocations foreign to embryonal tumors of central neuroepithelial type and critical to definitive tumor classification. Complete membranous immunolabeling for the *MIC2* gene product CD99, a characteristic feature of the Ewing sarcoma/peripheral PNET family, is only exceptionally (and focally) shared by CNS embryonal tumors, though a significant subset of these may exhibit a paranuclear dot-like pattern of reactivity.[825] Genetically confirmed intracranial examples of Ewing sarcoma/peripheral PNET have been described mainly as dura-based lesions. An intramedullary case is also on record.[830]

Pineal Parenchymal Tumors

The pineal gland is populated in the main by specially modified neuronal elements, known as pineal parenchymal cells or "pineocytes," that include among their functions the secretion of melatonin—a potent regulator of gonadotrophic and other endocrine hormonal activity. Tumors of pineal parenchymal lineage include the embryonal pineoblastoma, the mature pineocytoma, and lesions exhibiting mixed histology or intermediate degrees of differentiation.[278,831] As a rule, such neoplasms present as solid, contrast-enhancing masses associated with manifestations of obstructive hydrocephalus owing to aqueductal compression or disturbances of ocular motility (classically including the upwards gaze paresis termed Parinaud syndrome) resulting from pressure on the mesencephalic tectum. While pineal parenchymal tumors usually arise in sporadic fashion, germline mutations of the *RB1* and the *DICER1* genes predispose to pineoblastomas (as further discussed later), which have also been reported in rare association with familial adenomatous colonic polyposis as a possible variant of type 2 Turcot syndrome.[832-834]

The **pineoblastoma** is a WHO grade IV neoplasm characterized by a predilection for children and adolescents, aggressive local growth, and a proclivity for dissemination via the CSF. Primitive in appearance, it is densely populated by diminutive cells with hyperchromatic, round, or variably angulated and molded nuclei. These may exhibit brisk mitotic activity and are disposed in patternless sheets or lobules that are often punctuated by zones of coagulative necrosis and dystrophic calcification. The monotony may be relieved by the formation of Homer Wright rosettes, identical to those of the neuroblastoma and medulloblastoma, that attest (along with frequent tumoral SYN immunoreactivity) to a shared capacity for neuronal differentiation. Rare variants have been described as containing mature ganglion cell and glial elements,[835] and occasional examples evince an atavistic potential for photosensory differentiation that recapitulates the phylogenesis of the pineal gland as the primary photoreceptor of low vertebrates and "third eye" of some mammalian species. The pineoblastoma may thus fashion Flexner–Wintersteiner rosettes and fleurettes a la the retinoblastoma, can elaborate club-shaped cilia with the 9+0 axonemal array characteristic of photosensory cells,[836] and is capable of expressing various genes involved in visual signal transduction.[837] At the immunohistochemical level, they can express retinal phototransduction-associated proteins including the rhodopsin-binding S-antigen or "arrestin."[838]

The vestigial photosensory attributes of the human pineal gland are also obliquely evidenced by the occurrence of particularly aggressive and treatment-resistant pineoblastomas in complex with retinoblastomas. Afflicted patients carry germline mutations of the retinoblastoma *(RB1)* tumor-suppressor gene, and their ocular neoplasms are typically bilateral—hence, designation of this curious phenomenon as the "**trilateral retinoblastoma**" syndrome.[839,840] Rare pineoblastomas actually harbor melanotic elements in tubular array that have been likened to pigmented ciliary or retinal-type epithelium, similar cellular components transiently populating the developing pineal gland in humans.[841-844] That the latter is also home to an enigmatic population of myoid, striated muscle-type cells is noteworthy given the presence of rhabdomyoblastic differentiation in the "**pineal anlage tumor**"—a complex, pineoblastomatous neoplasm that may also contain melanotic and even chondroblastic elements. The similarity of such tumors to neoplasms derived from the primitive medullary epithelium of the optic vesicle (teratoid ocular medulloepitheliomas or "diktyomas") has been noted. An example composed of mature neurons, striated muscle cells, and melanotic components in the absence of primitive neuroepithelial elements is on record.[845] More recently, a subset of pineoblastomas have been noted with

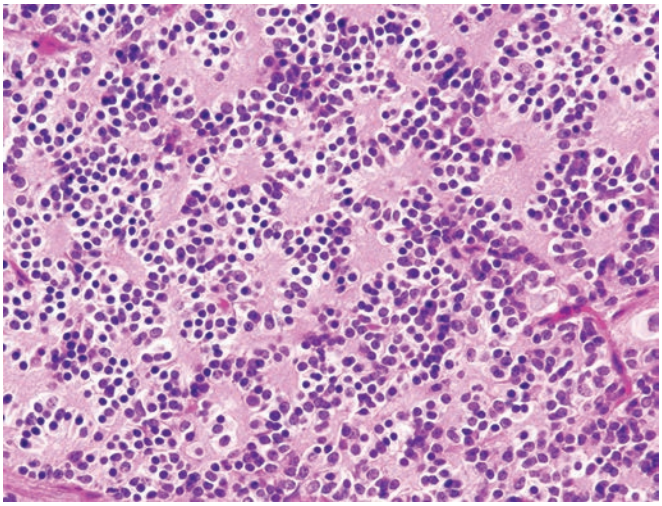

Figure 43.117 Pineocytoma. Shown here are the conspicuous rosettes that constitute a defining feature of this neoplasm. Note the benign oligodendroglioma-like/neurocytoma-like nuclear features, monomorphism, and absence of mitotic activity.

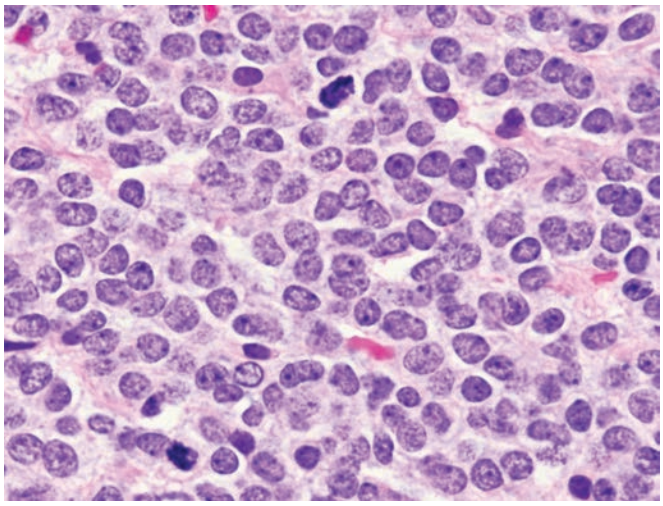

Figure 43.118 Pineal Parenchymal Tumor of Intermediate Differentiation. Note the sheet-like architecture, hypercellularity, lack of pineocytic rosettes, and increased mitotic activity, but the features fall short of the primitive "small blue cell" cytology seen in pineoblastoma.

mutations of the *DICER1* gene, including germline examples,[832] thus expanding the list of DICER1 syndromic manifestations, including pleuropulmonary blastoma, cystic nephroma, ovarian Sertoli–Leydig-type tumors, and many others.

The appellation of **pineocytoma** has been extended over the years to neoplasms of varying histology and disparate biologic potential. We concur in the view that this diagnosis is best reserved for the tumor in which neoplastic cells are arrayed about a conspicuous, anuclear meshwork of delicate, SYN-immunoreactive cytoplasmic processes in formations dubbed "pineocytic" or "pineocytomatous" rosettes.[831,846] Looking virtually identical to "neurocytic rosettes," they resemble outsized versions of the Homer Wright rosette but often have less regular contours (Fig. 43.117) and are frequently found in confluent arrangements alongside regions of uninterrupted, sheet-like or lobular tumor growth. Such lesions are largely devoid of mitotic activity, do not exhibit necrosis, and are typically dominated by monomorphous, cytologically benign-appearing elements with rounded nuclear profiles. They can, however, harbor admixed tumor giant cells with marked degenerative atypia (including hyperchromatic and multinucleated forms) to which no prognostic import attaches.[847] Ganglion cells may be identified within "**pleomorphic pineocytomas**" of the latter type.[848]

The cytoplasmic processes elaborated by pineocytoma cells distinctly resemble those of native pineocytes in the tendency of microtubule-laden, neurite-like cellular extensions to end as bulbous neurofilament immunoreactive expansions, containing clear vesicles of synaptic type, dense core ("neurosecretory") vesicles and vesicle-crowned rodlets ultrastructurally.[836,849] The last, also known as synaptic ribbons and recognized as a distinctive feature of mammalian pineocytes, consist of closely apposed, bar-like osmiophilic densities measuring approximately 700 nm in length by 50 nm in width that are surrounded by clear vesicles 60 nm in diameter. A further specialization shared with pineal parenchymal cells are paired cytoplasmic filaments, 8 nm in diameter, arrayed in helices of 26–30 nm periodicity. Synaptic junctions and such photosensory attributes as annulate lamellae and cilia of 9+0 configuration may also be apparent.

Given the fine structural profile just delineated, it should come as no surprise that the fibrillar matrix of the pineocytoma is GFAP negative but often immunolabels for NFP epitopes, class III β-tubulin, PGP 9.5, chromogranin A, and SYN.[838,846] Rhodopsin and retinal S-antigen immunoreactivity have also been documented[838,846] and further attest (as does expression of several phototransduction-associated genes at the RNA level[837]) to the photosensory differentiating potential of pineal parenchymal tumors. Intriguing in this connection is report of a pineocytoma associated with uveoretinitis.[850] Lastly, the differentiated nature of the pineocytoma is reflected in the observation that its constituent cells may evidence immunoreactivity for, or express messenger RNA encoding, enzymes involved in melatonin synthesis (including tryptophan hydroxylase, serotonin *N*-acetyltransferase, and hydroxyindole-*O*-methyltransferase).[837] While shared by pineoblastomas, the expression of genes encoding these enzymes appears to be comparatively upregulated in tumors of pineocytomatous aspect.

Restriction of the term pineocytoma to the distinctively rosetted neoplasm described above identifies a surgically curable, WHO grade I tumor that typically presents in young or middle-aged adults and that remains confined to the pineal region, expanding slowly and in noninvasive fashion.[278] The same cannot be said for exceedingly rare tumors described as harboring "mixed" pineocytomatous and pineoblastomatous elements,[846,851] these having the potential for aggressive behavior with CSF dissemination.[851] Lesions previously reported as papillary variants of pineocytoma would seem, in fact, to represent examples of the unusual entity discussed under "Papillary Tumor of the Pineal Region."

Falling within an incompletely characterized group now designated as **pineal parenchymal tumors of intermediate differentiation** are certain neoplasms that occupy a rather broad middle ground between the mature and embryonal extremes.[831,846] One variant is characterized by a neuroendocrine histologic profile in which small tumor cells are segregated into lobules subtended by a delicate vasculature, a second by a more sheet-like proliferation of neoplastic elements in a scant fibrillary matrix (Fig. 43.118). Cytoplasmic clearing lends an oligodendroglioma-like aspect to some examples, the differential including third ventricular neurocytoma. A neuronal/neuroendocrine immunoprofile similar to that of the pineocytoma puts the former issue to rest,[846] as neurocytic neoplasms share SYN expression but are usually chromogranin negative (save for examples with ganglion cell components). Some neuropathologists[846] include in this family "transitional" cases in which focal pineocytomatous rosette formation is apparent against a background of solid, lobular, or diffuse

growth. As a group, these pineocytic neoplasms can achieve relatively dense cellularity, occasionally evidence necrosis, and may exhibit mitotic activity, but fall short of the frank anaplasia and conspicuous proliferative activity that typify pineoblastomas. Many behave in relatively low-grade fashion,[846,851] but some frustrate all attempts at local control, and CSF-borne metastasis has been documented as an exceptional occurrence.[851] The WHO ascribes grade II–III biologic potential to intermediately differentiated pineal parenchymal tumors as a group without providing or endorsing particular criteria for their prognostic subdivision.[278] A four-tiered system has been proposed[846] in which grades 1 and 4 are reserved for the classically rosetted pineocytoma and pineoblastoma, respectively, while neoplasms of the intermediate group are accorded grade 2 status if they exhibit fewer than six mitoses per 10 high-power microscopic fields and retain immunoreactivity for 70- and 200-kDa NFPs, or designated as grade 3 should they fail to label for the latter or manifest higher mitotic indices. Transitional (i.e. focally rosetted) tumors are placed in the grade 2 category, the mixed pineocytoma–pineoblastoma qualifying as grade 3 in this schema. Select studies have demonstrated the ability of this method to stratify affected patients in a hierarchy of increasing risk for recurrence and tumor-related death,[846] but it has not yet found wide application among neuropathologists. As appears to be the case for otherwise conventional pineocytomas, the presence of pleomorphic tumor giant cells does not seem to be of any prognostic import when encountered in lesions of intermediate differentiation.[847]

Papillary Tumor of the Pineal Region

Presenting, on neuroradiological assessment, as a circumscribed and contrast-enhancing mass producing obstructive hydrocephalus (with the expected clinical manifestations), the **papillary tumor of the pineal region** is most often encountered in young or middle-aged adults but can afflict children and adolescents.[852-855] The entity is designated for the radial arrangement of constituent cells about supporting fibrovascular cores (Fig. 43.119A), the latter commonly exhibiting collagenous hyalinization, though regions of solid growth are frequently apparent and may vastly dominate the histologic picture. Papillary formations are composed of epithelial-looking elements, often pseudostratified, with columnar profiles, relatively well-defined cell borders, pale to slightly granular eosinophilic cytoplasm in vasocentric orientation, and peripherally displaced, rounded or oval nuclei manifesting a stippled chromatin distribution. Striking nuclear enlargement and pleomorphism may be displayed by tumor cells in areas of nested and sheet-like architecture, these solid components being punctuated in some cases by perivascular pseudorosettes, as well as true rosettes and tubules, of ependymal type. Mitotic figures are often apparent, though not in large numbers (no more than 10 per 10 high-power fields is the rule), and necrosis is commonly found but unattended by MVP. Neurosurgical specimens that contain adjoining pineal parenchyma or other native tissues typically demonstrate a well-demarcated, "pushing" tumor perimeter. Nevertheless, some show anaplastic features with both grades II and III being possibilities in the most recent WHO scheme.[278] A rare example showing a primitive small round cell component has also been reported, which may overlap with pineoblastoma and other embryonal neoplasms.[856]

Ultrastructural studies have shown the papillary tumor of the pineal region to have ependymocytic characteristics.[852] The latter include the forming of tight junctions and zonulae adherentes that bind cell apices, these crowned by microvilli and punctured by rare cilia. The presence of dense-core cytoplasmic vesicles and parallel paranuclear arrays of rough endoplasmic reticulum with cisternal dilation by granular material attest, however, to neuroendocrine and

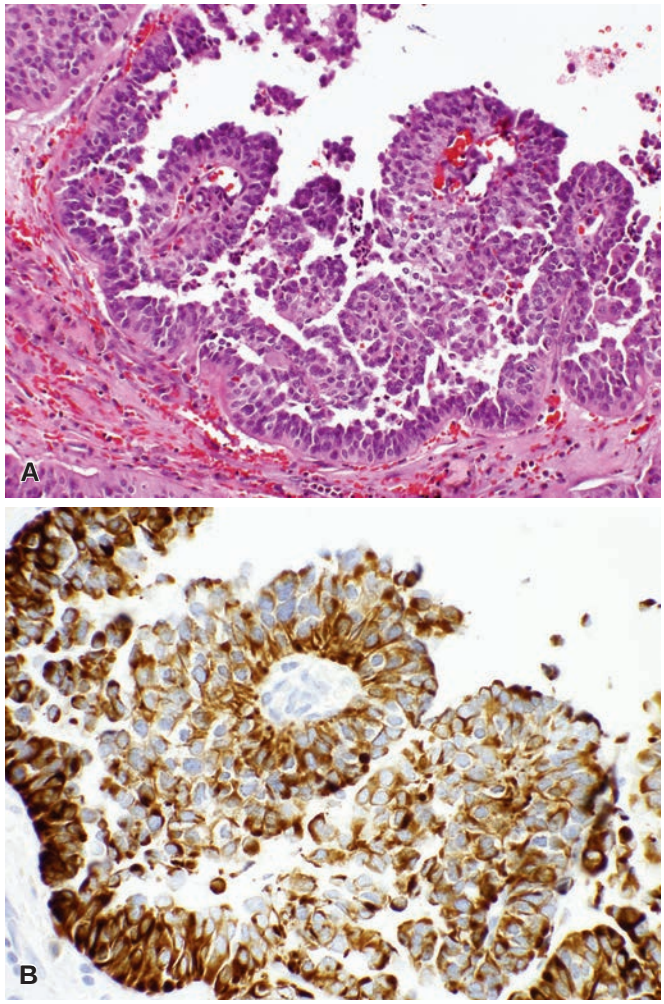

Figure 43.119 Papillary Tumor of the Pineal Region. Perivascular structuring **(A)** and strong immunoexpression of CK18 **(B)** typify the cellular elements of this lesion.

secretory functions foreign to conventional ependymal cells. These hybrid features, coupled with shared antigenic and gene expression signatures, have been taken as evidence of a tumoral origin from specially modified ependymocytes that are known to colonize the developing pineal parenchyma from the neighboring subcommissural organ.[837,852,853]

Morphologic evidence of ependymal differentiation notwithstanding, the neoplasms under discussion depart from ependymomas in their general failure to express GFAP (limited immunoreactivity of perivascular cell bodies has been observed in fewer than 10% of recorded cases), by the finding in only exceptional examples of dot- or ring-type EMA labeling (though diffuse and focally membranous cytoplasmic expression can be seen), and in the observation that papillary tumors of the pineal region regularly manifest reactivity for cytokeratins, claudin subtypes, E-cadherin, and NCAM.[852,857] Cytokeratin expression may take the form of generalized cytoplasmic immunopositivity or dot-like intracytoplasmic immunopositivity. Most constant and often diffuse in distribution are CK18 expression (see Fig. 43.119B) and labeling with the KL1 antibody (recognizing acidic and basic keratin proteins 40–68 kDa in size), many examples exhibiting at least regional immunoreactivity with the AE1/3 and CAM 5.2 "cocktails" as well. It is the papillary component that is most likely to prove cytokeratin positive. Only a minority of

communicated cases have shown focal CK5/6 or CK7 expression and CK20 negativity seems the rule. These curious neoplasms share with choroid plexus papillomas and carcinomas cytoplasmic immunolabeling, frequently widespread, for vimentin and S-100 protein (with regular nuclear expression of the latter antigen) as well as the potential to express transthyretin, but seem far more likely to exhibit MAP-2 reactivity and far less likely to manifest Kir 7.1 or stanniocalcin-1 positivity.[852,854,855] A subset of recorded examples have evidenced SYN and chromogranin A reactivity (usually focal and of weak intensity), a small number of cases demonstrating nestin expression.[854,855,858] Immunolabeling for NSE is constant but of no discriminatory value, while all cases assessed to date have been NFP negative.

Papillary tumors of the pineal region are prone to recurrence and can be fatal. A multicenter, retrospective analysis of 31 affected patients demonstrated 5-year overall and progression-free survival rates of 73% and 27%, respectively.[854] Twenty of 21 recurring tumors did so locally, one also seeding the spinal leptomeninges and a second producing such "drop" metastases in the absence of regrowth at the primary site. Incomplete resection appears to carry a heightened risk of symptomatic relapse. The role of adjuvant therapies in the management of these lesions remains to be defined, as does a prognostically meaningful system of pathologic grading. Molecular studies reveal nearly ubiquitous chromosome 10 deletion, losses of 3 and 22q in subsets, gains of chromosomes 8p and 12, as well as overexpression of SPDEF, the latter of which is in common with the subcommissural organ, a potential site of origin.[853]

We mention a report of **papillary tumors of the spinal cord** that share many histologic, immunophenotypic, and ultrastructural features with the pineal region growths discussed in this section.[857] These, too, demonstrate differentiation along ependymal lines.

Meningiomas

The designation of meningioma has been extended through the years to diverse neoplasms sharing only a tendency to arise within the histogenetically complex tissues of the leptomeninges or dura mater. Thus, such dissimilar entities as the meningeal solitary fibrous tumor/hemangiopericytoma (SFT/HPC) and hemangioblastoma—currently accorded separate nosologic status among tumors of the CNS and its coverings—were once yoked under the regrettable rubric of "angioblastic" meningioma and widely assumed to derive from a common progenitor. In a similar vein, it is recognized that most, if not all, tumors reported as melanotic or pigmented meningiomas actually represent meningeal melanocytomas. Neuropathologists now label as meningiomas only those neoplasms exhibiting morphologic or immunophenotypic evidence of an origin from meningothelial cells, specialized elements that populate the arachnoid membranes and cap the arachnoidal villi associated with intradural venous sinuses and their tributaries.

Meningiomas may make their appearance in childhood or adolescence, but most are encountered in middle or later adult life.[278,859-862] Females are afflicted more commonly than males (especially at spinal levels), and some studies suggest an increased prevalence in women with mammary carcinomas. Rare meningiomas have actually harbored metastatic deposits derived from breast primaries.[863] Coupled with their frequent expression of progesterone (and, less commonly, estrogen as well as androgen) receptors[278] and the rapid enlargement of some examples during pregnancy or the luteal phase of the menstrual cycle, these observations indicate that the growth of meningiomas is subject to hormonal influence. The association of multifocal meningiomas with NF2 is noteworthy, the genetic locus for which resides on chromosome 22q12. Allelic loss involving this band is a frequent feature of meningiomas, including sporadic variants, as are *NF2* gene mutations (particularly common in fibroblastic and transitional variants). The presentation of a meningioma in childhood or adolescence should trigger investigation for underlying NF2.[862] Familial examples occurring outside the setting of classic NF2 have also been described, including rare examples of schwannomatosis with germline *SMARCB1* mutations,[864] although the genetic underpinnings for most remain unclear.[865] Ionizing cranial irradiation, including the low doses previously given for treating tinea capitis or obtaining full mouth dental X-ray series, emerges from a number of epidemiologic studies as conferring significant risk for subsequent meningioma development, radiation-related lesions being more often multiple, histologically atypical, and clinically aggressive than those arising in sporadic fashion.[866-870] Less clear is the etiologic role of craniocerebral trauma,[871] but the presentation of select meningiomas in the immediate vicinity of a prior skull fracture or in close physical association with traumatically implanted foreign bodies has been convincingly documented.[872,873] Also on record are meningiomas found to lie just over glioblastomas or other gliomas.[874] Most "collision" tumors of this sort are undoubtedly fortuitous lesions, but it is conceivable that the occasional meningioma evokes a hyperplastic glial reaction that subsequently progresses to neoplasia. As mentioned in our prior discussion of hamartomatous lesions, tumors interpreted as meningothelial neoplasms originating in foci of meningioangiomatosis have been described but most likely represent meningiomas with unusual patterns of perivascular growth.[35]

Most meningiomas arise within the cranial cavity, are dura based and found in the vicinity of the superior sagittal sinus, over the cerebral convexities, or in contact with the falx cerebri. Basally positioned examples favor the sphenoid ridge, olfactory grooves, tuberculum sellae, and parasellar region. Still others are anchored to the petrous ridge, presenting as cerebellopontine angle tumors when posteriorly situated. Intracranial meningiomas may also originate within the tela choroidea or stroma of the choroid plexus and rest entirely within the ventricular system. At spinal levels, meningiomas clearly favor the thoracic region, cervical examples being uncommon and lumbar lesions rare. Also recognized are epidural and intra-osseous meningiomas as well as variants located entirely outside the craniospinal confines. The latter are usually encountered in the head and neck region and include orbital (i.e. optic sheath), glabellar, sinonasal, oropharyngeal, subgaleal, juxtaparotid, and cutaneous examples.[875-877] Rarely, ectopic meningiomas are situated at even greater removes from the central neuraxis (e.g. in the mediastinum,[878] lung,[879,880] or brachial plexus[881]). As discussed elsewhere in these volumes, the cellular aggregates originally regarded as minute pulmonary "chemodectomas" or meningothelial-like nodules are actually composed of elements having the ultrastructure and immunophenotype of meningothelium.[880,882] Whether these serve as the substrate from which pulmonary meningiomas develop is unknown.

On neuroradiological (Fig. 43.120) and gross assessment (Fig. 43.121), the typical meningioma is a solid, lobulated, or globose mass that is broadly anchored to the dura mater. Cystic variants, although uncommon, are well recognized, and the term meningioma en plaque may be invoked for the occasional lesion that presents (usually over the sphenoid ridge) as a poorly delimited, carpet-like growth. Adjoining neural tissues are generally deflected at the "pushing" perimeters of these tumors, but grossly evident dural infiltration or invasion of nearby venous sinuses is not uncommon. Some examples insidiously permeate the neighboring skull, provoking a highly characteristic form of osteoplastic expansion and bony remodeling known as hyperostosis or, if chronically neglected, come to attention as visible masses in the scalp. None of these findings brand a meningioma as atypical or anaplastic, although involvement of the cranial floor greatly prejudices matters against the neurosurgeon and so predisposes to tumor recurrence and progression following

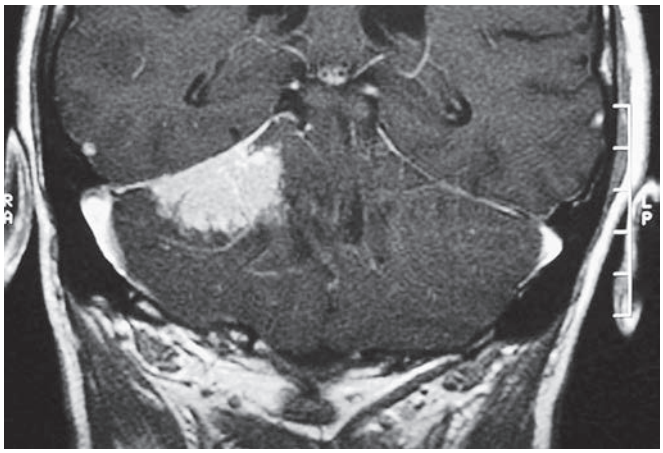

Figure 43.120 Meningioma. Circumscription, homogeneous contrast enhancement and anchorage to the dura (in this case, the tentorium) typify the meningioma. This magnetic resonance imaging also demonstrates thickened and abnormally enhancing dural "tails" extending from the lesional borders—a finding suggestive, though not diagnostic, of this tumor entity.

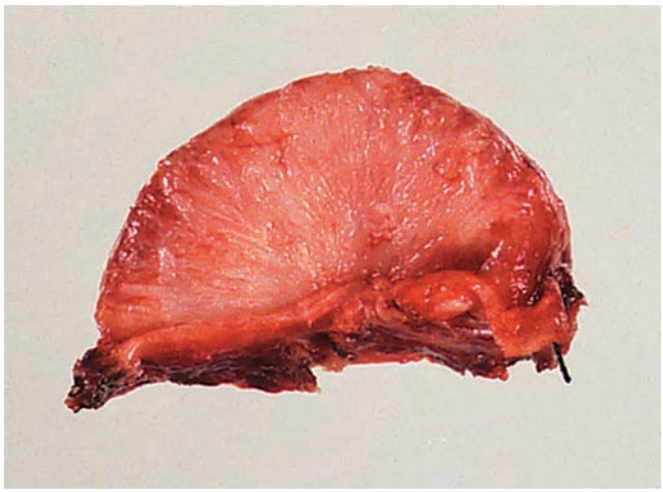

Figure 43.121 Meningioma. The broad dural base depicted here is characteristic.

attempted resection. Highly suspect, however, is the lesion that cannot be easily separated from the adjacent brain or spinal cord, as this may imply transgression of the pia-arachnoid and invasion of the neuroparenchyma proper—nevertheless, the surgeon's gross impression of brain invasion does not correlate well with microscopic confirmation, likely due to some cases adhering to pia rather than truly invading parenchyma.[883] Neuroradiological features that should prompt concern include indistinct tumoral margins, a "mushrooming" growth pattern characterized by multinodular projections from the main mass, foci that fail to enhance on contrast administration (these often representing regions of necrosis), and edema of the neighboring brain on CT or MR study.[884,885] However, some benign meningioma subtypes (e.g. angiomatous, microcystic, secretory, and lymphoplasmacyte-rich variants) are recognized for their regular association with peritumoral cerebral edema. Restricted diffusion on MRI, a finding often associated with increased cellularity, has also been associated with higher-grade histology.[886,887]

On sectioning, most meningiomas are gray-tan and soft, but collagenized examples have a rubbery texture and a whorled or

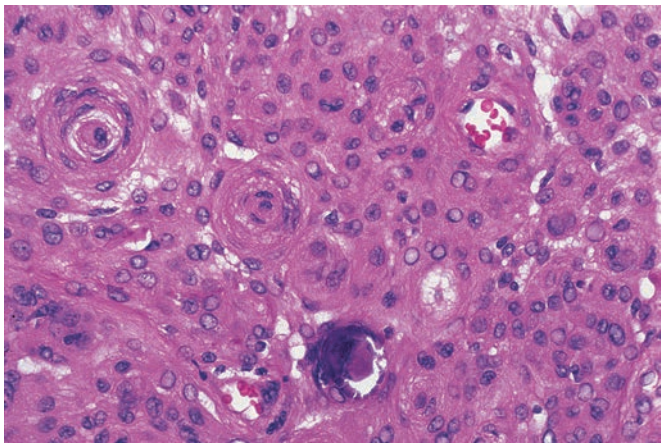

Figure 43.122 Meningioma. Indistinct cytoplasmic boundaries, nuclear clearing ("pseudoinclusions"), cellular whorls, and a psammoma body are all apparent in this view of a meningotheliomatous (syncytial) meningioma.

trabeculated cut surface (resembling that of the leiomyoma), whereas variants rich in stromal mucopolysaccharides acquire a somewhat gelatinous consistency. Calcification is often readily apparent and infiltration by foamy macrophages at times results in foci of yellow discoloration, a phenomenon that may also reflect the accumulation of lipids within tumor cells. Grossly apparent regions of gray–black pigmentation characterized a unique example of meningioma colonized by hyperplastic leptomeningeal melanocytes.[888]

Meningiomas are notorious for the variety of their cytologic and histologic presentations, but most assume one of several prototypical guises. **Meningotheliomatous** variants are characterized by a lobular microarchitecture and are populated by cells having delicate round or oval nuclei, inconspicuous nucleoli, lightly eosinophilic cytoplasm, and indistinct cytoplasmic borders (thus their outdated alternate designation of "syncytial" meningiomas). Common to these (and other subtypes) are tumor cells concentrically wrapped in tight whorls, nuclear clearing ("holes") and pale nuclear "pseudoinclusions" consisting of invaginated cytoplasm, and the lamellated calcospherules known as psammoma bodies (Fig. 43.122). While none of these features is pathognomonic of meningioma, their demonstration in the setting of an extra-axial, dura-based mass carries considerable diagnostic weight. In contrast to the epithelioid appearances of meningotheliomatous variants, **fibrous** (or **fibroblastic**) **meningiomas** adopt a mesenchymal profile, being variably collagenized and consisting of spindled tumor cells in fascicular or storiform array (Fig. 43.123). An example containing crystalline structures rich in tyrosine has been described.[889] **Transitional meningiomas**, as their name implies, are hybrids, maintaining a lobular arrangement but having a tendency to cellular elongation and streaming. These are often particularly rich in compact cellular whorls and endowed with psammoma bodies in conspicuous numbers. When the latter are present in profusion, the term **psammomatous meningioma** may be applied. Tumors of this type characteristically occur in middle-aged to elderly women and exhibit a particular predilection for the intraspinal compartment. It should be noted that none of the foregoing growth patterns is of any special biologic significance, and most neuropathologists dispense with these qualifying adjectives in their reports.

To these classic subtypes of meningioma can be added histologic variants too numerous to be accorded detailed discussion or depiction here. Only the more distinctive are acknowledged. Unless otherwise stated, these depart in no way from the benign course pursued by meningiomas of more conventional appearance.

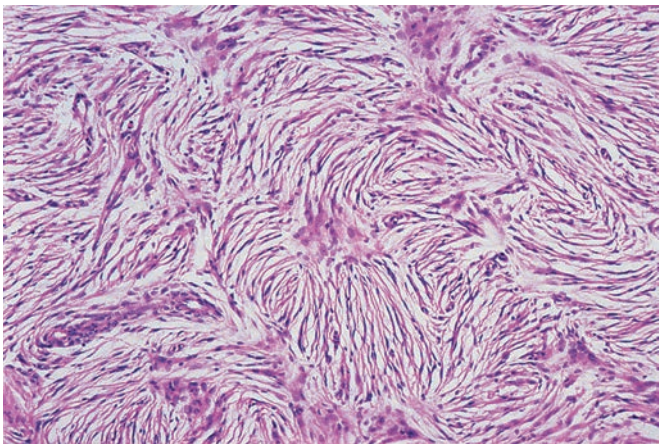

Figure 43.123 Meningioma. Cellular spindling and a fascicular or storiform architecture are evidenced by meningiomas of "fibroblastic" type.

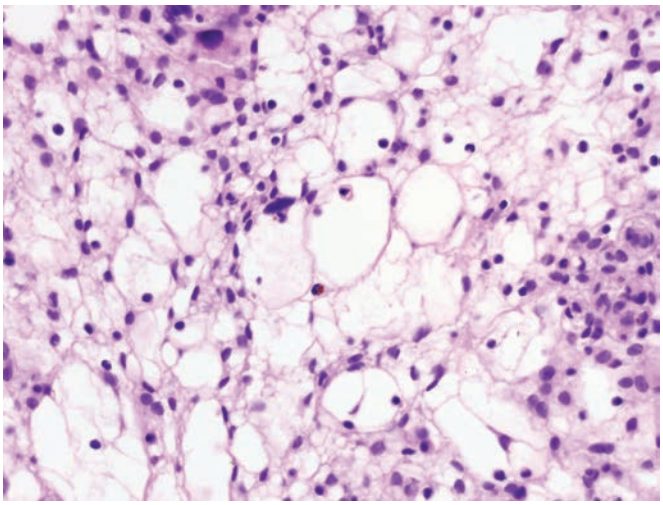

Figure 43.124 Microcystic Meningioma. The wispy "cobweb-like" pattern results from extracellular fluid accumulation and characterizes this variant.

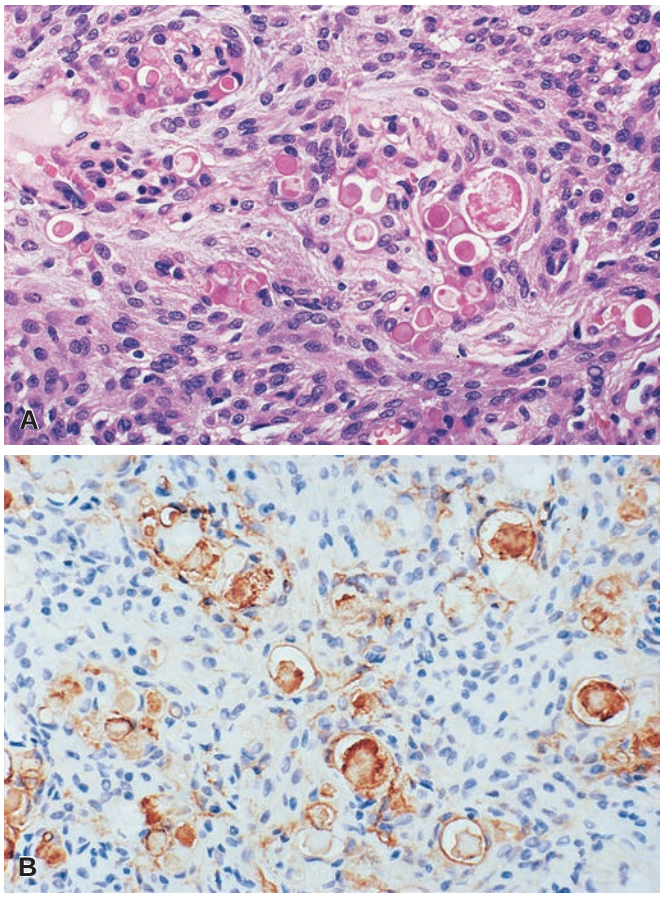

Figure 43.125 Secretory Meningioma. This variant of meningothelio-matous meningioma harbors eosinophilic globules **(A)** that label with antibodies to carcinoembryonic antigen **(B)**.

The **microcystic meningioma**[890,891] is named for its content of variably sized intercellular vacuoles, these often appearing empty but in some instances containing a lightly PAS-positive fluid derived in all likelihood via the transudation of plasma across a characteristically rich, and frequently hyalinized, stromal vasculature. Some examples actually progress to the formation of macrocysts and harbor only minor solid components. Constituent cells may exhibit cytoplasmic clearing due to glycogen (not to be confused with the more diffuse accumulation in the clear cell variant) or lipid accumulation and often assume spindled or stellate profiles that, along with their tendency to disaggregation, can prompt consideration of a low-grade, microcystic astrocytoma in the differential diagnosis (Fig. 43.124). Nuclear pleomorphism, karyomegaly, and a smudgy hyperchromasia are common but are unattended by mitotic activity and are divorced from any sinister prognostic import, as is the common finding of severe peritumoral cerebral edema on preoperative neuroradiological study.

The **secretory meningioma**,[892] a variant of the meningothelio-matous subtype, is distinguished by its content of "pseudopsammoma bodies"—globular hyaline inclusions that are eosinophilic, intensely PAS positive, and diastase resistant (Fig. 43.125A). On ultrastructural study, these can be shown to lie within microvillus-lined intracellular lumina and may be immunolabeled for human secretory component, IgM, IgA, and CEA (see Fig. 43.125B). Nearly always benign, the secretory meningioma may yet masquerade as a malignant neoplasm by virtue of its occasional association with elevated serum CEA levels,[893] an especially confounding phenomenon in the patient with a prior history of systemic cancer, and with subacutely progressive neurologic deficits referable to severe edema of juxtatumoral cerebral tissues.[891] Recent evidence suggests that the majority of secretory meningiomas harbor mutations in the *TRAF7* and *KLF4* genes.[894]

The **lymphoplasmacyte-rich meningioma** is a tumor infiltrated by chronic inflammatory elements, at times so heavily that its meningothelial (and neoplastic) nature is obscured (Fig. 43.126).[895,896] There can be no doubt that at least some reported cases would be better classified as dura-based examples of inflammatory disorders, inflammatory myofibroblastic tumor, or SHML (Rosai–Dorfman disease). An association with hypergammaglobulinemia and/or anemia has been occasionally noted.[896] Peritumoral lymphoplasmacytic infiltrates with germinal center formation are also conspicuous features of a peculiar meningeal tumor noteworthy for its **chordoid histology** and presentation in childhood or adolescence with manifestations of the **Castleman syndrome**—polyclonal dysgammaglobulinemia, iron-refractory anemia, hepatosplenomegaly, and retarded growth and sexual maturation.[897,898] Resection typically effects a remission of the systemic disorder, but this obscure neoplasm may recur and behave in locally aggressive fashion. The relationship

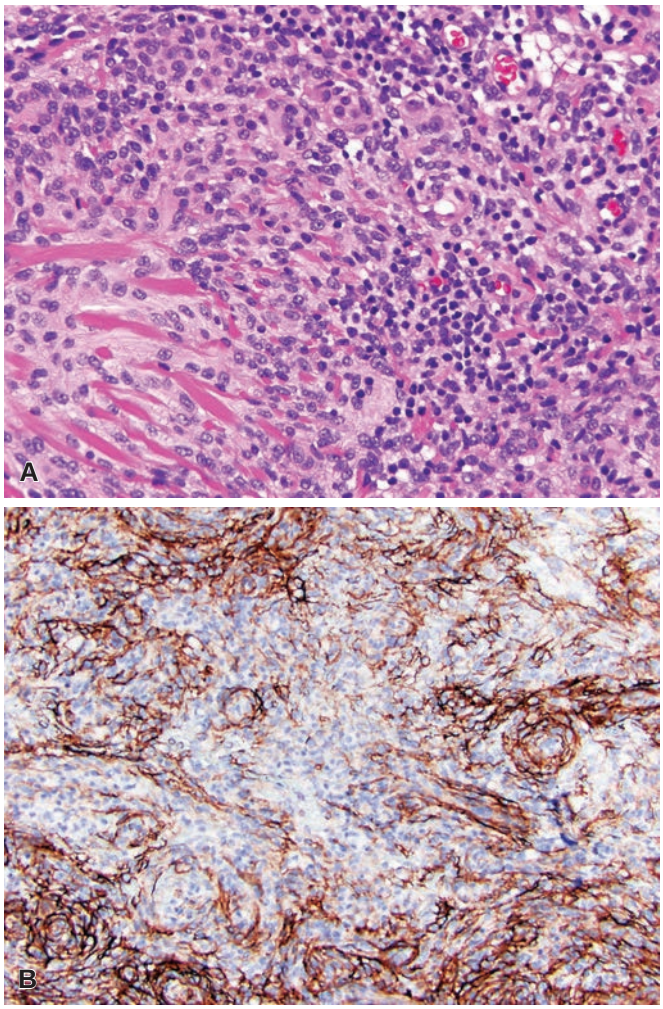

Figure 43.126 Lymphoplasmacyte-Rich Meningioma. The brisk inflammatory infiltrate in this case partially obscures the underlying meningioma **(A)**, the latter of which is highlighted by an immunostain for somatostatin receptor 2a **(B)**.

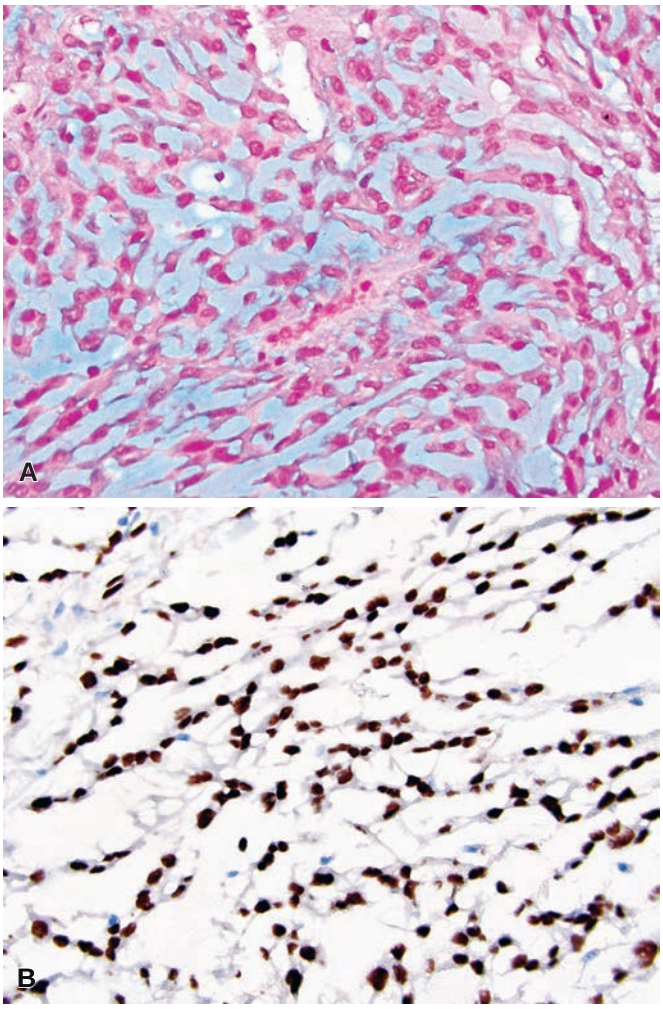

Figure 43.127 Chordoid Meningioma. A, The ribbon-like architecture, vacuolated cytoplasm, and alcian blue–positive mucinous stroma provides a remarkable resemblance to chordoma of the bone. **B,** However, these tumors express the same immunomarkers as conventional meningiomas, often including progesterone receptor.

of this lesion to adult-onset **chordoid meningiomas** (WHO grade II),[899] which are only exceptionally accompanied by conspicuous inflammatory components or indications of Castleman syndrome, and potentially masquerade as chordomas or metastatic mucinous carcinomas, is unclear (Fig. 43.127). The latter, also reported as "myxoid" or "mucinous" meningiomas when otherwise lacking epithelioid cytology, proved in one analysis to be far more prone to local regrowth following subtotal resection than meningothelial tumors of conventional type.[899] We have encountered what appeared to be a primary pulmonary example.[900]

Metaplastic meningiomas can contain bone, cartilage, or adipocytic elements. Progressive xanthomatous change, that is, nonspecific cytoplasmic lipidization, rather than true metaplasia seems to account for so-called **lipomatous meningiomas**.[901] We would call particular attention to rare variants that may be misconstrued as sarcoma owing to potentially lipoblastic cytologic features, and the occurrence in some examples of troubling nuclear abnormalities that are almost certainly degenerative in nature.[902,903] Neoplasms exhibiting meningothelial and rhabdomyosarcomatous[904] or leiomyosarcomatous[905] differentiation are also on record. Still other meningiomas evidence foci of schwannoma-like nuclear palisading; pseudoglandular and rosette-like structures[906]; a nesting arrangement reminiscent of paraganglioma[907]; granular cytoplasmic inclusions[908]; or a hyalinized stromal vasculature so exuberant and domineering as to suggest a malformative process or hemangioblastoma (**angiomatous meningioma**), the latter recently associated with characteristic chromosomal gains (Fig. 43.128).[909,910] The last of these variants shares with microcystic and secretory meningiomas a generally benign clinical profile, despite a tendency to cause conspicuous edema of the adjoining cerebrum and sometimes marked degenerative nuclear atypia. Sclerosing meningiomas that appear to undergo progressive fibrous obliteration are noteworthy for their frequent presentation in the pediatric group and favorable outcome, despite a tendency to foci of disturbing hypercellularity, pleomorphism, and cerebrocortical infiltration.[911-913] Some observers have suggested that at least a subset of sclerosing childhood meningiomas are pseudoinvasive lesions arising within cortical foci of meningioangiomatosis,[914] but whether the latter entity serves as a substrate for the development of meningothelial neoplasms has been called into question.[35]

A subset of meningothelial neoplasms evidence clear cell, oncocytic, or rhabdoid features. The significance of such alterations when partially developed or encountered only focally is unsettled

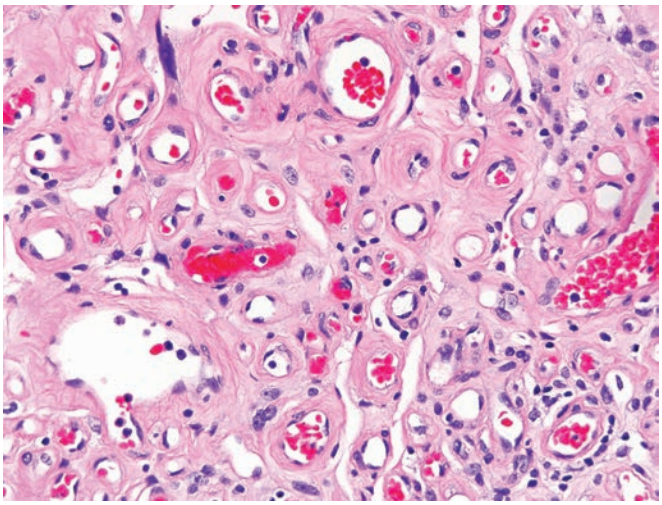

Figure 43.128 Angiomatous (Vascular) Meningioma. The marked hypervascularity (often with hyalinization) and degenerative nuclear atypia may obscure the meningothelial nature of this variant.

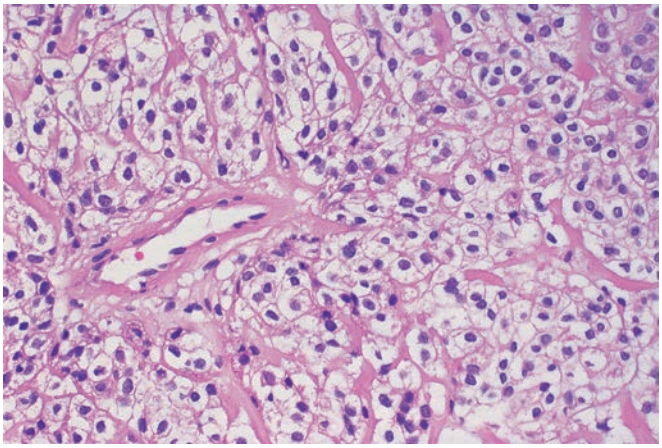

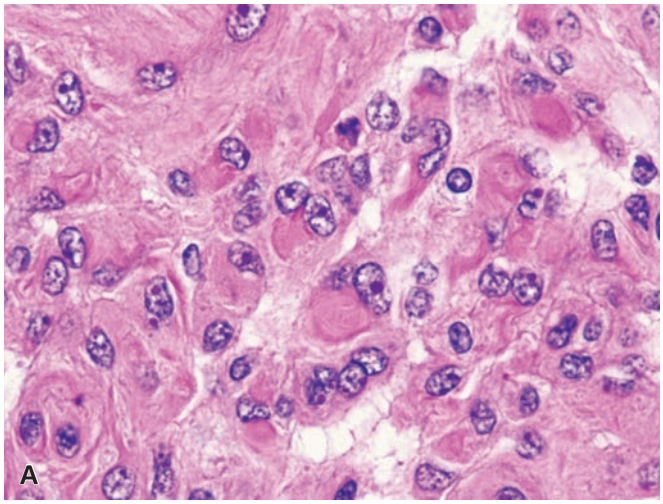

Figure 43.129 Clear Cell Meningioma. The example shown here arose from the filum terminale of a 9-year-old girl. Note cytoplasmic clearing, traversing collagenous bands, and absence of meningothelial-type whorls.

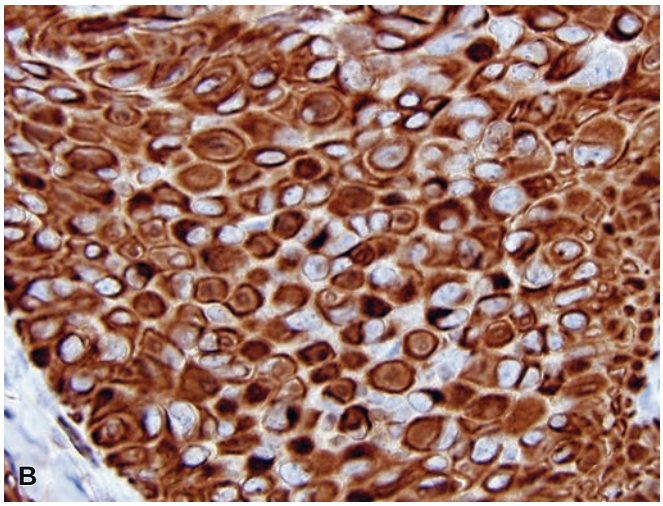

Figure 43.130 Rhabdoid Meningioma. Rhabdoid features include loss of cohesion, large eccentrically placed vesicular nuclei, macronucleoli, and a paranuclear fibrillar to globular eosinophilic inclusion **(A)**, which is often further highlighted on vimentin immunohistochemistry **(B)**.

but probably of lesser significance.[915] In contrast, tumors exhibiting prominent changes of this sort merit distinct designation owing to their potential for a more aggressive biology. **Clear cell meningiomas** (WHO grade II) are the most deceptive of the lot.[916,917] These are characterized by a predilection for young subjects (including children), and are most often found in the spinal canal, cerebellopontine angle, or foramen magnum region. They are usually extra-axial and dura based but may be associated with cranial nerves, spinal roots, or the cauda equina. A fourth ventricular presentation has been described,[918] as has familial occurrence, the latter recently associated with germline *SMARCE1* mutations.[919,920] We have encountered a bulbar example in a 2-year-old child.[921] Composed of glycogen-rich, water-clear cells that are often disposed in patternless sheets traversed by bands of homogeneous to amianthoid-like interstitial and perivascular collagen (Fig. 43.129), these unusual tumors typically manifest little or nothing in the way of classic meningothelial attributes (e.g. whorls or nuclear pseudoinclusions) and may be only focally and faintly immunoreactive for EMA, a marker of specialized arachnoidal cells expressed by most meningiomas in diffuse fashion. High recurrence rates, a potential for CSF-borne spread, and increased mortality characterize this intrinsically aggressive meningioma variant, despite the fact that most examples do not evidence conspicuously increased mitotic activity, necrosis, or other histologic features that would arouse suspicion.

That rhabdoid cytology is, in general, a marker of increased biologic potential is borne out by the discouraging behavior of most meningiomas displaying this profile, which may be evident on initial presentation or appear only in recurrent material.[922] **Rhabdoid meningiomas** (WHO grade III) in fully developed form usually retain meningotheliomatous regions but boast a prominent population of cells with vesicular nuclei, prominent nucleoli, and globose, paranuclear inclusion-like bodies representing compacted cytoplasmic vimentin filaments or rarely other intermediate filaments, such as GFAP (Fig. 43.130). Cells are usually arranged in lobules or sheets, but a papillary growth pattern may also be encountered.[923] Conspicuously increased mitotic activity is the rule, and brain invasion is common; most such tumors qualify as atypical or frankly anaplastic by the WHO/Mayo Clinic criteria presently discussed. In one reported series, 87% of afflicted patients experienced at least one recurrence, and 53% died of tumor progression.[922] The prognosis for cases showing rhabdoid change in the absence of elevated proliferative activity or other malignant indicators does not appear to be nearly

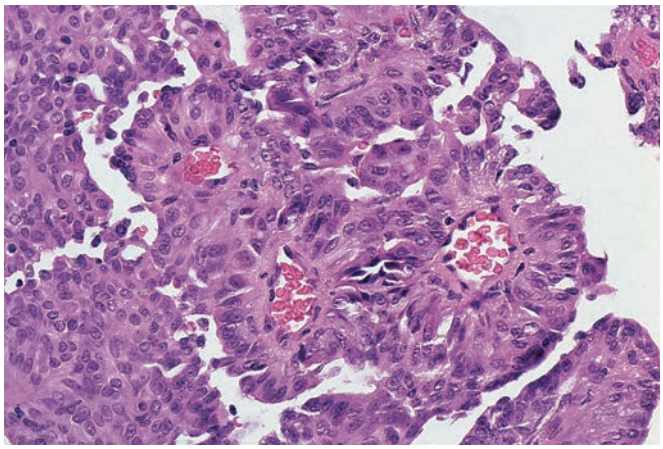

Figure 43.131 Papillary Meningioma. This intraspinal example, which also exhibited features of an atypical meningotheliomatous meningioma with increased mitotic activity and foci of necrosis (not shown here), metastasized to lung, lymph node, and bone.

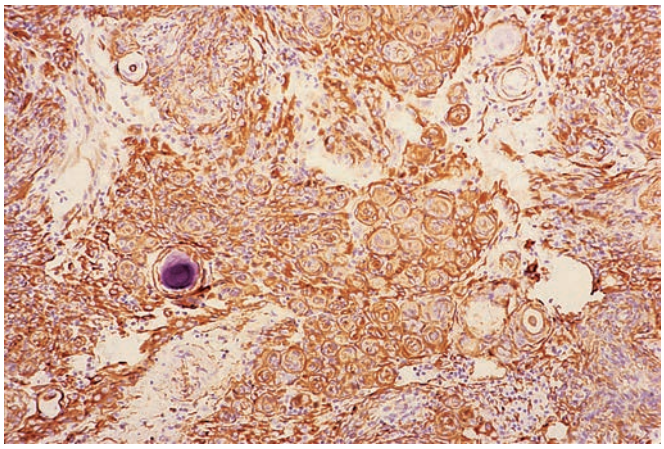

Figure 43.132 Meningioma. Cytoplasmic labeling for epithelial membrane antigen on immunoperoxidase assay, depicted here, characterizes the overwhelming majority of meningiomas, regardless of their histologic subtype.

as poor, but these need close observation nonetheless.[915] Similar considerations seem to apply to oncocytic meningiomas, that is, meningothelial neoplasms demonstrating fine cytoplasmic granularity due to an accumulation of mitochondria.[924] High mitotic rates, necrosis, brain invasion, and recurrence have been over-represented in the few cases recorded to date and in examples that we have encountered in consultation. A series of clinically innocent cases lacking these ominous histologic features has been communicated,[925] though the illustrated example raises questions regarding the criteria for case inclusion in the cited study.

A final variant meriting specific comment in view of its distinctive histology and clinical biology is the **papillary meningioma** (WHO grade III), a tumor characterized by the ependymoma-like perivascular pseudorosetted structuring of its constituent cells.[926,927] The latter can be seen to extend variably elongated cytoplasmic processes toward vessel walls, fashioning structures that disaggregate and come to float unanchored in tissue sections (Fig. 43.131). Regions exhibiting a more conventional meningothelial appearance are nearly always identifiable but usually depart from the typical in evidencing worrisome hypercellularity, mitotic activity, and, in some cases, foci of coagulative necrosis. Stubborn local recurrence, a capacity for extraneural metastasis, and often fatal outcome characterize papillary meningiomas. An excess of reported cases has presented in childhood or adolescence as compared to conventional types of meningioma.

Distinction of the meningioma from potential counterfeits occasionally requires the use of electron microscopy, immunohistochemistry, or genetic analysis. The most constant and distinctive ultrastructural feature of meningothelial neoplasms is the complex interdigitation of tumor cell processes without intervening basal lamina material (elaborated frequently by the meningeal HPC and uniformly by the schwannoma), although fibroblastic variants tend to a more parallel alignment. Intercellular junctional complexes are frequent and include well-developed desmosomes, a conspicuous cytoplasmic complement of intermediate filaments rounding out the ultrastructural picture. The latter consist of vimentin, regularly demonstrable by immunohistochemical methods regardless of tumor subtype. Of particular diagnostic utility is the observation that a large majority of meningiomas exhibit (at least focally) membranous, as well as diffuse, cytoplasmic immunolabeling for EMA (Fig. 43.132),[278] a feature foreign to nerve sheath tumors other than the rare perineurioma and to most HPCs, SFTs, and other fibroblastic neoplasms.[928,929] Expression of claudin-1, though not observed as regularly as labeling for EMA, may also be of discriminatory value in distinguishing meningothelial tumors from these potential mimickers, although claudin-1 positivity is frequently encountered in perineuriomas as well.[930,931] However, an even more sensitive recently identified marker is SSTR2a, which is strongly and diffusely positive in nearly all meningiomas regardless of grade (see Fig. 43.126B).[477] It is not entirely specific and is commonly expressed in a wide variety of neuroendocrine neoplasms, though fortunately, those are not often in the differential diagnosis. Unlike meningeal SFT/HPCs, meningiomas exhibit only weak or focal labeling for CD99 and BCL2.[928] Nuclear immunoreactivity for progesterone receptors is common but inversely associated with grade.[932] Reactivity for S-100 protein, if present, is usually limited to the cytoplasm of a subset of neoplastic cells but may occasionally be encountered in diffuse form (particularly in fibrous/fibroblastic meningiomas). As regards cytokeratin expression, meningiomas often share with native arachnoidal lining cells (and with epithelial cancers) immunolabeling for CK18 but are typically CK20 negative regardless of histologic pattern.[933] Focal reactivity for CK7, CK8 (CAM 5.2), CK19, and AE1/3 may be encountered (and is a consistent feature of the inclusion-bearing elements that define meningiomas of secretory type), but widespread labeling for these antigens suggests that a dura-based mass represents metastatic carcinoma. One study found diffuse AE1/3 and CAM 5.2 expression by 4 of 12 high-grade/anaplastic meningiomas but no labeling of either malignant or benign (n = 20) examples for CEA, Ber-EP4, B72.3, or CD-15 (all commonly expressed by carcinomas).[934] Expression of p63 is also seen in a subset of meningiomas, including higher-grade examples, and this should therefore not be taken as evidence of squamous cell carcinoma.[875,935] GFAP-labeling of papillary,[936] rhabdoid,[922,937] and "whorling–sclerosing"[938] meningiomas have been depicted but are curiosities. Whether this phenomenon always reflects true GFAP expression is open to question. As previously noted, meningiomas rarely exercise an ability to differentiate along myogenic lines, and some otherwise conventional examples focally label for muscle-associated actins.[939] Unlike chordomas, chordoid meningiomas do not exhibit nuclear reactivity for brachyury.[940] Rhabdoid meningioma variants do not manifest the loss of nuclear INI1 protein expression (BAF47 antibody) that is a consistent feature of AT/RTs.[941]

Genetically, biallelic inactivation of the *NF2* gene on chromosome 22 leads to loss of merlin (also known as schwannomin) expression and is the most common alteration in meningiomas, accounting as the

initial driver mutation in essentially all NF2-associated and up to 60% of sporadic examples.[942,943] The majority of such tumors are convexity or parasagittal transitional and fibrous meningiomas, also representing the subtypes that most frequently undergo progression to atypical or anaplastic meningioma. In contrast, skull base meningiomas are mostly non-NF2 driven, WHO grade I meningothelial variants, with recent studies[944-946] implicating driver mutations of (1) the *TRAF7* gene (mutated in 8%–24% of all cases), almost always in combination with *KLF4* mutations (which are also implicated in 93%–100% of secretory meningiomas[894]); (2) the *AKT1* (*AKT1* E17K) gene in about 13% of cases; and (3) the *SMO* gene in roughly 5% of cases. Rare driver mutations involve the SWI/SNF family members, *SMARCB1* (mostly in schwannomatosis patients), and *SMARCE1* (mostly in familial and sporadic cases of clear cell meningioma).[864] Progression to higher-grade meningiomas is mostly associated with chromosomal losses cytogenetically, though the most strongly implicated candidate tumor suppressor and oncogenes include *CDKN2A/B, hTERT, NDRG2, MEG3, RPS6KB1, TIMP3,* and *TSLC1*.[947,948]

Meningiomas of conventional histologic type grow slowly and are amenable to surgical cure when complete excision can be effected, as is usually the case for examples arising over the cerebral convexities or along the spinal axis. Even tumors so favorably situated, however, may recur following gross total resection, the magnitude of this risk emerging only on long-term observation. In one study, for example, respective 5-, 15-, and 25-year relapse rates for histologically benign and completely excised intracranial meningiomas were 3%, 15%, and 21%, respectively.[885] By all accounts, the likelihood of regrowth is considerably higher for the less accessible olfactory groove and sphenoid wing meningiomas, with en plaque examples and lesions invasive of the cranial floor proving particularly troublesome.[949] But while there can be no gainsaying the influence of tumor location on outcome in this setting, it is clear that certain morphologic features serve to independently define a subset of high-risk meningiomas to which a substantially increased likelihood of postoperative recurrence attaches. Recognizing that a number of grading strategies have proven useful in the identification of potentially aggressive meningothelial neoplasms, we can endorse with minor reservations a Mayo Clinic proposal,[883,950] adopted with only slight modifications in the last three WHO formulations.[278]

Application of the WHO/Mayo Clinic criteria outlined here broadly stratifies meningothelial tumors into three tiers of increasing biologic potential—**meningioma (WHO grade I)**, **atypical meningioma (WHO grade II)** (Figs. 43.133 and 43.134), and **anaplastic meningioma (WHO grade III)** (Fig. 43.135). The stated criteria are applied whether present as focal findings (often the case) or in more diffuse form. In this scheme, atypical meningiomas are defined as:

1. containing four or more mitotic figures per 10 high-power microscopic fields (0.16 mm^2)
   or
2. brain invasion, with tumor breaching beyond the pia
   or
3. exhibiting at least three of the following features:
   a. hypercellularity
   b. patternless, sheet-like growth
   c. macronucleoli
   d. small cell components with high nuclear:cytoplasmic ratio
   e. zones of spontaneous (i.e. noniatrogenic as seen after embolization) necrosis.

Anaplastic meningiomas are defined as:

1. containing 20 or more mitoses per 10 high-power microscopic fields (0.16 mm^2)
   or
2. exhibiting a loss of differentiated features resulting in carcinoma-, melanoma-, or sarcoma-like appearances.

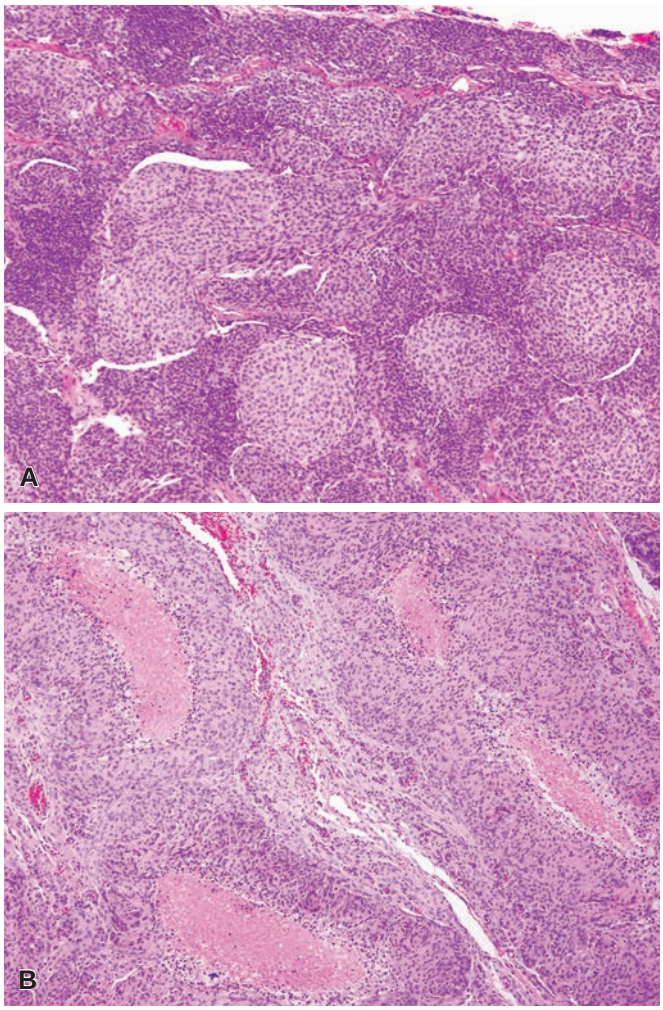

Figure 43.133 Atypical Meningioma. Low-magnification clues include two-dimensional sheeting architecture (loss of whorling and fascicles) and small cell formation (clusters of tumor cells with high N/C ratio) **(A)**, as well as spontaneous (e.g. not embolization-induced) necrosis **(B)**.

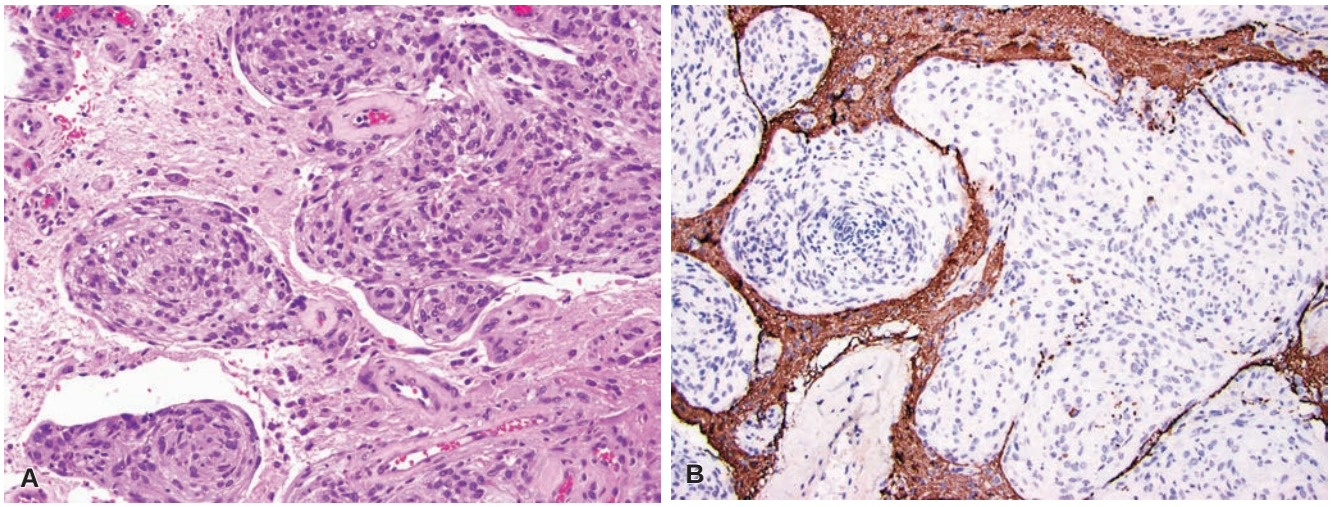
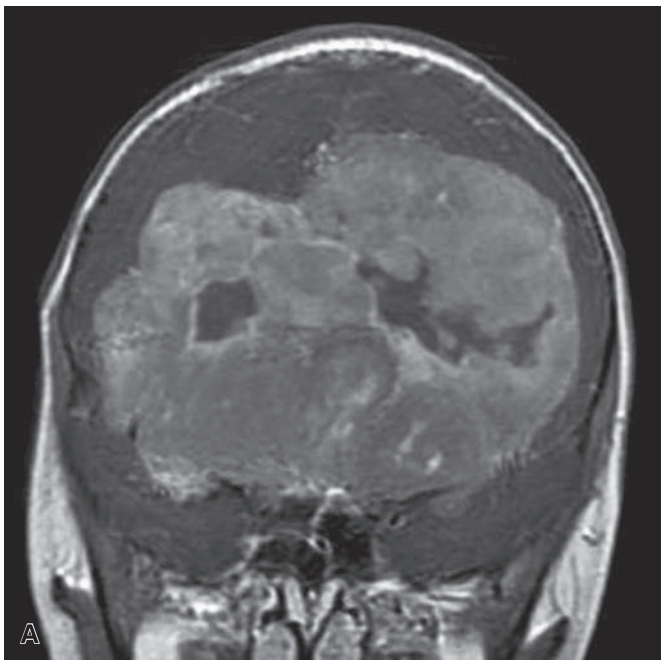
Readers should note that WHO grade II status is also accorded to fully developed clear cell and chordoid meningiomas, while papillary and rhabdoid variants are designated as WHO grade III tumors.

We would emphasize that preoperative embolization of meningiomas, undertaken to reduce their blood supplies and facilitate removal, often results in regions of necrosis with evident mitotic activity (and increased MIB-1 reactivity) in adjoining tumor tissue,[951] potentially rendering problematic application of the foregoing criteria. This phenomenon is often, though not invariably, signaled by the presence of clearly foreign material within the tumoral vasculature. The finding of multiple zones of necrosis that appear to be at the same acute stage of development suggests such intervention, but, in any case, pathologists should consult their clinical colleagues on this issue prior to releasing reports. The study cited earlier suggests that WHO/Mayo Clinic mitotic criteria remain valid in these circumstances, but confirmation in additional large series would be reassuring.

Brain invasion is defined as tongue-like extensions of tumor beyond the pial barrier (see Fig. 43.134A), which can often be confirmed with a GFAP stain (see Fig. 43.134B) in equivocal cases,





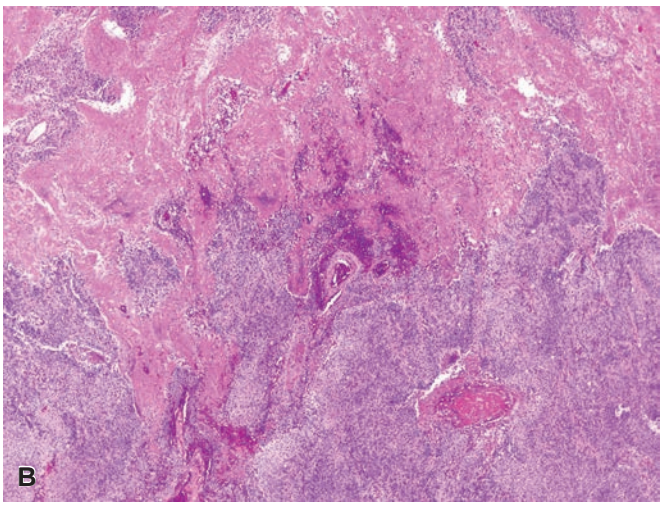


Figure 43.134 Atypical Meningioma. Another criterion for atypical meningioma in the WHO 2016 scheme is brain invasion, characterized by tongue-like protrusions into adjacent gliotic brain **(A)**, which can be further verified using glial fibrillary acidic protein immunohistochemistry **(B)**.

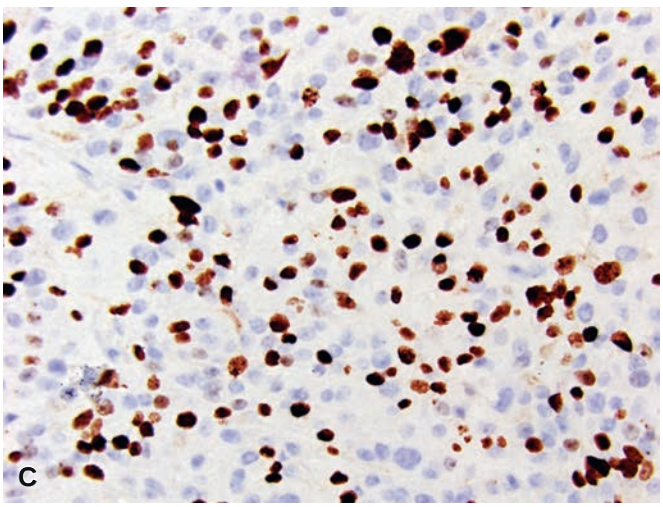

Figure 43.135 Anaplastic Meningioma. A, On postcontrast magnetic resonance imaging, this tumor was large, had irregular borders with adjacent brain, and displayed central areas of low signal intensity corresponding to foci of necrosis. Histologically, there was extensive geographic necrosis **(B)**, a mitotic index over 20 per 10 high-power fields (not shown), and a Ki-67 labeling index greater than 20% **(C)**.

the latter highlighting entrapped glial nests within the main tumor mass. Such meningiomas, in fact, span the histologic spectrum, some being of otherwise benign appearance, such cases typically showing recurrence-free and overall survival times similar to atypical meningiomas diagnosed by other criteria.[883] For this reason, the 2016 WHO now considers brain invasion as another criterion for atypical meningioma.[278] In contrast, the demonstration of brain invasion per se adds relatively little to the predictive power of the WHO/Mayo Clinic scheme as a prognostic model once a given tumor has satisfied the listed criteria for designation as atypical or anaplastic. As stated earlier, rare meningiomas—especially pediatric examples—may demonstrate extensive perivascular invasion along Virchow–Robin spaces, potentially mimicking meningioangiomatosis and/or brain invasion.[35,914] However, the pia is not actually breached in this scenario and therefore, this pattern alone is insufficient for a WHO grade II designation.

In the experience that served as the basis for these recommendations, respective 5-year recurrence rates for conventional versus atypical meningiomas were 12% and 41% following gross total resection.[883,950] Atypical tumors carried a 5-year mortality rate of approximately 20%. Anaplastic meningiomas, by contrast, recurred in the large majority of cases and were associated with a 68% 5-year mortality rate and a median survival of only 18 months. Nevertheless, patients undergoing complete excision, postoperative radiation therapy, and/or whose tumors lacked *CDKN2A*/p16 losses have considerably better survival times, the first two of these also significantly impacting survival in the atypical meningiomas.[952-955] Other findings that have been correlated with worrisome histology and increased biologic potential in the setting of meningothelial neoplasia include elevated MIB-1 labeling indices and, in some studies, failure to express progesterone receptors.[278] Regarding the former, meningiomas of conventional type and indolent behavior usually have MIB-1 labeling indices below 4%–5%, but there is considerable overlap in the values recorded for benign, atypical, and anaplastic lesions, as well as for recurring versus nonrecurring tumors.[956-958] Consequently, the predictive power of this assessment in the individual case is somewhat compromised. Others have successfully utilized the mitotic index marker pHH3 in a similar fashion.[959] It is noteworthy that disturbing histologic features, including elevated mitotic MIB-1 indices and brain invasion, seem to be over-represented among meningiomas occurring in the pediatric group.[862] As reviewed in the reference just cited, most studies have found these morphologic attributes to correlate with an increased risk of recurrence and fatal outcome in this patient cohort, but, overall, grading is much less predictive in children. Progression-associated genetic markers, such as chromosome 1p and 14q deletions, may also be more prevalent in meningiomas of childhood and adolescence compared to adult-onset examples.

While application of the WHO/Mayo Clinic guidelines discussed previously can be recommended as a means of stratifying affected patients into groups at increasing risk of recurrence and meningioma-related death, pathologists and attending clinicians must realize that prognostic certainty is not to be found in the proposed criteria—particularly in the mitotic thresholds that separate the typical, atypical, and anaplastic. It has long been our practice to specifically comment when confronted by any meningioma containing more than the very occasional mitosis found on careful scrutiny, as close neuroradiological surveillance is prudent in this circumstance even if a gross total excision has been effected. Further supporting this notion, recent studies have shown that meningiomas with one or more atypical features insufficient for a WHO grade II designation, nevertheless have higher recurrence rates than those with none.[956] It also bears emphasizing that within the broad spectrum of meningiomas that qualify as merely "atypical" by WHO/Mayo Clinic criteria are to be found examples (e.g. the tumor exhibiting 14 mitoses per 10 high-power microscopic fields, necrosis, and cerebrocortical invasion) that may not be as predictably virulent as anaplastic variants but that are capable of frankly malignant clinical behavior.

Although local regrowth is the major pattern of treatment failure, aggressive meningioma variants can spread via the CSF and, on occasion, travel to extraneural sites such as the lung, liver, bone, and lymph node.[960] We would point out, however, that an excess of distant metastases recorded in the literature have derived from "angioblastic" variants that would now be classified as meningeal SFT/HPCs. Examples of "**benign metastasizing meningioma**" have been well documented but remain curiosities.[961,962] As noted, venous sinus invasion is a feature of many meningiomas and is not predictive of hematogenous dissemination or germane to the designation of a given lesion as atypical or anaplastic. In a similar vein, little significance attaches to foci of pronounced nuclear pleomorphism associated with "degenerative atypia," provided that nucleolar enlargement, mitotic activity, or other atypical features are not in evidence. X-chromosome inactivation studies and *NF2* gene mutation analyses suggest that the majority of "multifocal" meningioma (particularly those characterized by the presence of three or more spatially distinct tumors) actually represent clonal proliferations with dural spread.[278,963]

Nonmeningothelial Mesenchymal Tumors

Excepting the obscure process known as primary meningeal sarcomatosis and the congenital lipomatous tumors of the lumbosacral spinal canal and cranial cavity, the varied lesions surveyed in this section represent the homologues of neoplasms encountered far more frequently in the somatic soft tissues and bones than along the central neuraxis.[278,964-966] Accordingly, little attempt is made to describe or depict their histopathologic, ultrastructural, and immunophenotypic profiles, all of which are given detailed attention elsewhere in these volumes. However, we would emphasize the hazards in diagnosis occasioned by the existence of both neuroepithelial and meningothelial tumors that mimic the tumors under discussion in this section. Whereas CNS neoplasms exhibiting spindled or bizarre, "monstrocellular" cytologic features were once presumed to be mesodermal in derivation if they could be shown to elaborate an intercellular reticulin network, it is now clear that candidates with this feature must be subjected to immunohistochemistry for evidence of cytoplasmic GFAP expression if entities such as the sarcomatoid or "giant cell" glioblastoma, desmoplastic cerebral astrocytoma/ganglioglioma, and pleomorphic xanthoastrocytoma are to be excluded. In addition, the possibility must always be borne in mind, particularly in adult cases, that the biopsy ostensibly demonstrating a malignant mesenchymal tumor derives, in fact, from a gliosarcoma. Especially suspect in this regard are limited specimens with features of fibrosarcoma or pleomorphic sarcoma, but the gliosarcoma, as already indicated, may also contain angiosarcomatous, osteosarcomatous, chondrosarcomatous, liposarcomatous, and myosarcomatous components. Inasmuch as primitive neuroepithelial neoplasms such as the medulloblastoma with myogenic differentiation and certain variants of pineoblastoma contain striated muscle elements, putative embryonal rhabdomyosarcomas of the CNS must be screened for telltale evidence of neuronal and/or glial differentiation at the ultrastructural or immunohistochemical levels. Finally, electron microscopic study and immunocytochemical assessment for STAT6, SSTR2a, EMA, and CD34 labeling may serve to distinguish the fibrosarcoma-, SFT-, or HPC-like meningioma from the genuine soft tissue neoplasm. These guidelines are offered, of course, with the full realization that poorly differentiated neoplasms may lose expression of key marker antigens or express aberrant antigens.

Meningeal Solitary Fibrous Tumor/ Hemangiopericytoma

Though long described as separate entities, it is now clear that the **SFT**, WHO grade I, **HPC**, WHO grade II, and **anaplastic HPC**, WHO grade III represent a wide spectrum of histologic appearances within a single biologic entity, which is defined by the same genomic inversion at the 12q13 locus found in the soft tissue SFT counterparts; this alteration fuses the *NAB2* and *STAT6* genes, resulting in nuclear translocation of the STAT6 protein that can be readily identified by immunohistochemistry, thus providing a highly sensitive and specific surrogate biomarker for routine diagnostic practice.[967-969] By far, these are the most common mesenchymal nonmeningothelial neoplasms and virtually always present as dural-based masses mimicking meningioma. Whereas the soft tissue approach has now progressed to a two-tiered scheme of SFT and malignant SFT, the traditional CNS approach has been three-tiered and for now, the WHO 2016 scheme has opted to maintain diagnoses of SFT/HPC of grades I, II, or III based on histologic pattern and mitotic index.[278]

The classic **SFT** diagnosis (now **SFT/HPC, WHO grade I**) is in all respects identical to those originating in the pleura and extrapleural somatic tissues, featuring a haphazard architecture with thick lace-like bands of hyalinized to amianthoid-like collagen and thin-walled branching (staghorn) vessels (Fig. 43.136).[970-972] Usually dura-based (and so taken for meningiomas on preoperative assessment), these may also arise within the lateral ventricles, sellar region, the substance of the spinal cord, or spinal nerve roots.[972] Most such tumors are benign in appearance and clinical behavior, with gross total resection usually proving curative; only exceptional cases showing aggressive morphologic features (e.g. conspicuous mitotic activity) or behavior (local invasion of brain or distant metastasis following repeated local recurrence) are on record.[972] In addition to nuclear STAT6 positivity, neuraxial SFTs share with their systemic counterparts a characteristic immunophenotype, including strong and diffuse cytoplasmic labeling for CD34, frequently intense BCL2 reactivity, and failure to express S-100 protein or EMA, that facilitates their distinction from schwannomas (S-100–protein positive) and fibrous meningiomas (usually both S-100 protein and EMA reactive, while STAT6 is negative or limited to cytoplasmic positivity).

Although their cytogenesis remains a contentious issue, select dura-based tumors once regarded as "angioblastic" variants of meningioma are in fact, distinct entities within the SFT/HPC spectrum. **Meningeal HPC** (now **SFT/HPC, WHO grade II**) are largely tumors of adulthood that do not exhibit the distinct predilection for women characteristic of meningiomas, and that strongly favor the intracranial compartment. Although sharing features of the classic SFT, they tend towards greater cellularity, higher nuclear to cytoplasmic ratio, lesser degree of collagenization, and more prominent staghorn vasculature. Mitotic figures are often found, but maximal indices should not exceed 5 mitoses/10 high-power fields (see anaplastic section later). Their distinction from meningiomas with potentially misleading pericytomatous growth patterns is usually straightforward, as these tumors often contain psammomatous calcospherites and tumor cells concentrically arrayed in tight whorl formations—both foreign to the HPC, as are the intranuclear pseudoinclusions typical of meningothelial elements and their neoplastic derivatives. Also alien to the meningioma, but a feature of many HPCs, is a network of "reticulin" investing individual tumor cells. This appears to represent basal lamina material at the ultrastructural level.[973] The HPC further departs from the meningioma on electron microscopic study in that, although joined by rudimentary junctions, cytoplasmic processes are neither bound by well-developed desmosomes nor intertwined in complex fashion. Serving also to segregate these lesions from neoplasms of meningothelial lineage is an immunophenotype that often includes

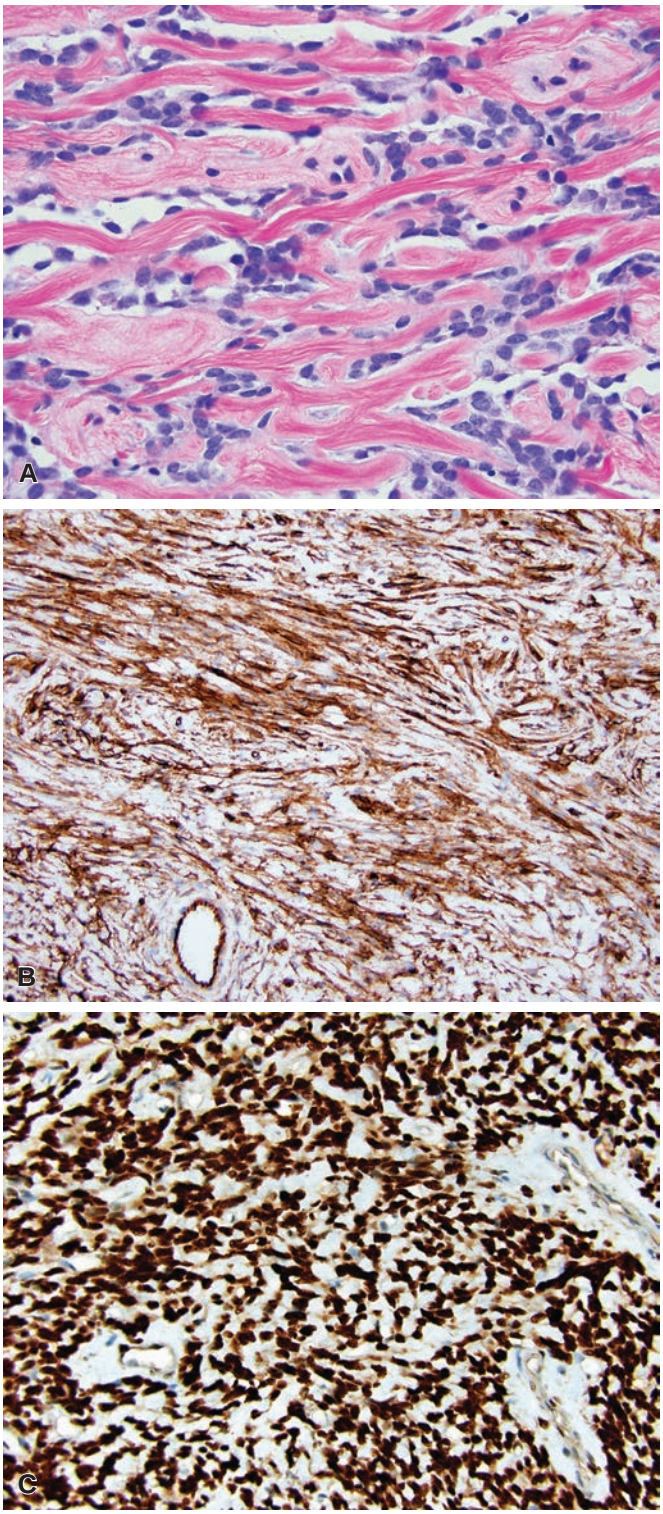

Figure 43.136 Solitary Fibrous Tumor/Hemangiopericytoma, WHO Grade I. A, Demonstrating the classic solitary fibrous tumor histology, this tumor is predominantly spindled and shows lace-like brightly eosinophilic intercellular collagen. Immunohistochemistry reveals diffuse CD34 **(B)** and nuclear STAT6 **(C)** positivity.

the already mentioned nuclear STAT6 positivity, along with widespread and strong labeling for CD99 and BCL2 but only focal, if any, EMA or claudin-1 expression.[928,931] Mesenchymal chondrosarcomas of dural origin routinely harbor anaplastic small cell elements in pericytomatous architectural array and thus enter the differential diagnosis, but the meningeal HPC lacks chondroid components. As mentioned previously, meningeal HPCs may evidence labeling for CD34, but this is usually weak and patchy as opposed to the diffuse and strong cytoplasmic reactivity typical of SFTs.[278,972] Regrowth at the primary site despite seemingly complete initial resection is commonly seen in the setting of meningeal HPC, although this may take years to become clinically apparent. Even with the addition of postoperative radiotherapy, many afflicted patients die as a direct result of intracranial tumor progression (often after a protracted course characterized by repeated local recurrence) or extracranial metastasis (typically a late complication that develops in at least 20%–25% of cases).[974-976] Most often seeded are the lungs, bones, and liver, but retroperitoneal organs, such as kidney and pancreas, may also be involved.

While all HPCs must be regarded as having the potential to recur locally and disseminate, histologic features may be of some efficacy in identifying the most predictably aggressive variants. Recommendations emerging from a large Armed Forces Institute of Pathology (AFIP) study[975] and adapted in slightly modified format by the WHO are that "**anaplastic HPCs**" (now **SFT/HPC, WHO grade III**) are distinguished from their grade II counterparts by the presence of 5 or more mitoses per 10 high-power fields (Fig. 43.137); necrosis is also commonly found but is not necessary for the diagnosis.[278] In the AFIP series, median overall survival was significantly shorter for patients with anaplastic tumors (62 months) compared to those with lower-grade lesions (144 months).[975] A more recent study of SFTs and HPCs from Marseille, France used similar criteria and suggested two subtypes within the grade II category, though this remains to be validated; it is nevertheless of interest that only the mitotic index was of statistical significance in predicting survival on multivariate analysis.[971] Similar to meningiomas, studies suggest that both complete resection and radiotherapy in the WHO grade II and III categories improve recurrence-free and overall patient survival times.[976-978] Additional experience will be needed to determine whether the current three-tiered approach is best suited for future meningeal SFT/HPC classification and grading or whether the simplified two-tiered approach of SFT versus malignant SFT utilized by soft tissue pathologists is preferable in the CNS as well.

Fibroblastic, Myofibroblastic, and "Fibrohistiocytic" Tumors

Benign neuraxial neoplasms of fibroblastic or myofibroblastic type reported under designations other than SFT/HPC are exceedingly rare; whether at least some such cases represent examples of the latter is arguable. The literature thus contains accounts of CNS "**fibroma**"[979] (sometimes referred to as fibromyxoma owing to mucoid stromal alterations) and "**sclerosing fibrous tumor**"[980] as well as **angiofibroma**[981] and **myofibroblastoma**.[982] **Dural fibromatosis (desmoid)**[983] has also been described, in some cases as a complication of neurosurgery, as has the intracranial presentation of **childhood cranial fasciitis**.[984] Fibroblasts additionally participate in the formation of so-called intracranial "**fibroxanthomas**," but these, often dominated by foam cells, may be reactive in nature and are considered under the rubric of xanthomatous lesions.

Fibrosarcomas of the CNS are commonly attached to the dura or leptomeninges, but some examples are situated entirely within the substance of the cerebrum or cerebellum.[965] Radiation is clearly recognized as predisposing,[985,986] especially to sellar fibrosarcoma

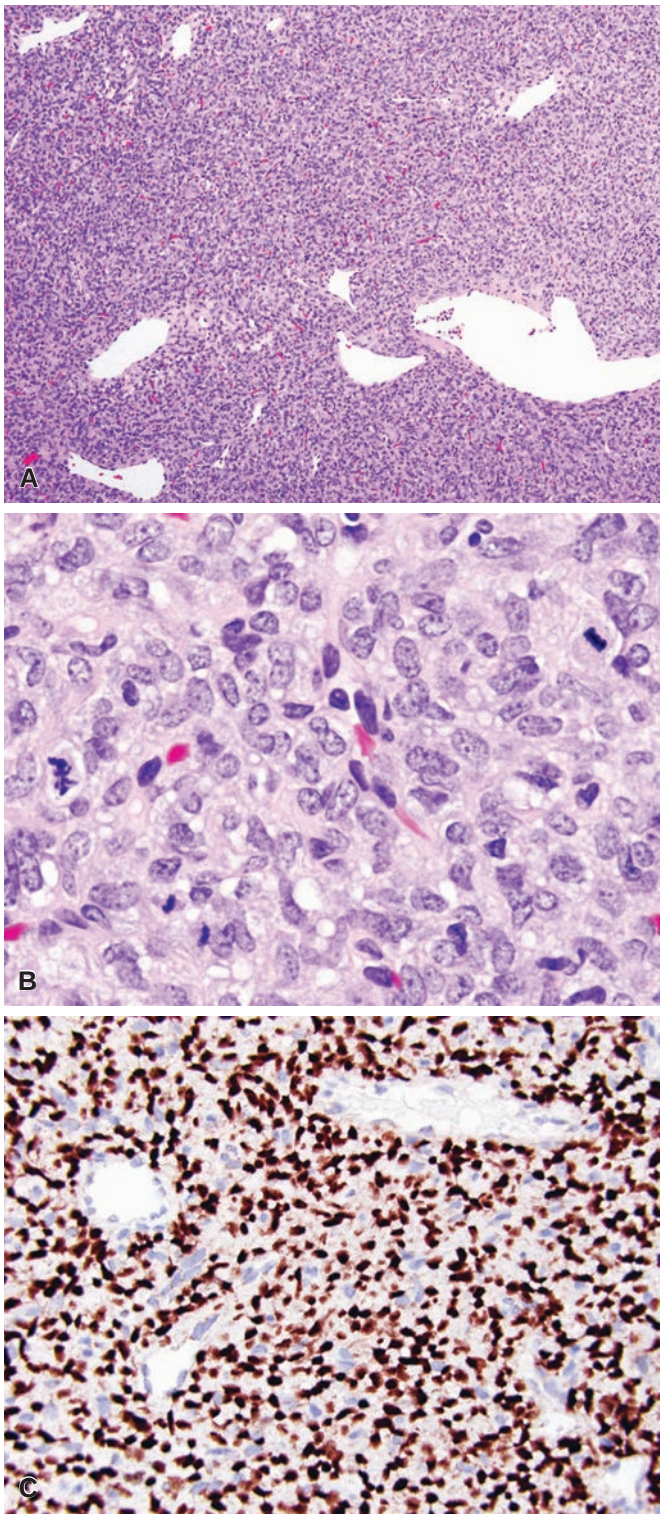

Figure 43.137 Solitary Fibrous Tumor/Hemangiopericytoma, WHO Grade III. In comparison to the case in Fig. 43.136, this one is more cellular, less collagenized, and includes greater than 5 mitoses/10 hpf (**A** and **B**). Note also the typical hypervascularity, including gaping thin walled blood vessels **(A)**. Immunohistochemically, CD34 highlighted the rich vascularity but was negative in tumor cells (not shown), while STAT6 was diffusely expressed in tumor nuclei **(C)**.

in patients so treated for pituitary adenomas, but a spontaneous counterpart within the sella turcica has also been described.[987] Symptomatic local recurrence is the rule even after gross total resection of circumscribed, superficially positioned lesions, and patients with high-grade lesions usually succumb to their disease within several years of diagnosis, some developing leptomeningeal and distant, extracranial metastases. Low-grade variants seem more amenable to surgical control. Similar considerations apply to the pleomorphic sarcomas previously reported under the rubric of intracranial "**malignant fibrous histiocytoma**" (a nonspecific diagnosis no longer utilized).[965,988] Rare intracerebral **angiomatoid fibrous histiocytomas**, including one with a t(12;22)(q13;q12) translocation resulting in a clear cell sarcoma-like type 1 *EWS/ATF-1* gene fusion, have been documented.[989,990] The spectrum of malignant fibroblastic tumors encountered along the neuraxis includes MUC4 immunoreactive[991] **low-grade fibromyxoid sarcomas** histologically similar to its soft tissue counterpart[992] and **sclerosing epithelioid fibrosarcomas**.[993] The latter may assume a deceptively benign, hypocellular, and amitotic appearance but seems prone to local recurrence and distant metastasis.

Also, the non-neoplastic lesions that can justifiably be regarded as "inflammatory pseudotumors" or "plasma cell granulomas" must be distinguished from bona fide examples of **inflammatory myofibroblastic tumor** involving the CNS.[193] The last of these is a neoplasm, often meningioma-like on neuroradiological study, that departs from the inflammatory pseudotumor group by virtue of its lack of association with underlying systemic infection or immunologic dysfunction, conspicuous content of spindle cells with cytologic atypism, frequent immunoexpression of ALK, and *ALK* gene (2p23) or *ROS1* (6q22.1) rearrangements.[994,995] Gross total resection has been associated with a favorable course in most CNS cases communicated to date.[193]

Lipoma and Liposarcoma

Intradural tumors composed of mature adipose tissue may be encountered anywhere along the neuraxis but are most common at spinal levels, where they can be divided into a congenital, maldevelopmental group situated principally in the lumbosacral region and a smaller, arguably neoplastic subset tending to a thoracic location. The former have already been discussed as manifestations of spinal dysraphism. Commonly occurring in complex with spina bifida and its cutaneous stigmata, "**lipomas**" of this type figure prominently among intraspinal anomalies complicated by fixation of the filum terminale, caudal displacement of the conus medullaris, and the traction-induced myelopathy known as the "tethered cord" syndrome. These malformative lesions not infrequently contain heterotopic components such as smooth and striated muscle ("**myolipoma**"),[996] aberrant peripheral nerve fibers, meningothelial derivatives ("**occult" lipomeningocele**), ependyma, and other neuroglial elements ("**occult" lipomeningomyelocele**).[997] We have encountered an example that harbored mesonephroid tubules and glomeruloid structures lined by an orderly cuboidal epithelium, reference having been made to such "nephrogenic rests" in the discussion of lipomeningomyeloceles complicating spinal dysraphism. Although entrapment of the cauda equina and permeation of the conus usually preclude thorough resection of these intraspinal masses, dramatic neurologic improvement can often be effected by debulking, division of the tethered filum, and dural reconstruction.

In contrast to the congenital lipomatous tumors of the lumbosacral canal, lipomas occurring at higher levels of the spinal axis are typically not associated with regional anomalies of the vertebrae or intraspinal contents and usually consist of mature fat alone. Only rarely are these entirely intramedullary,[998] one report describing a thoracic example with admixed smooth muscle (**leiomyolipoma**).[999] Much more common are **leptomyelolipomas**,[1000] which present as subpial masses plastered over a highly variable length of the spinal cord, incorporating nerve roots and blending into the neuroparenchyma proper. These features frustrate attempts at complete excision, but, again, long-term symptomatic relief is often achieved by simple debulking. Uncommon examples contain conspicuous vascular elements and are dubbed **angiolipomas** or **angiomyolipomas**, but such lesions are more often epidural in location.[1001] An extradural location also characterized an intraspinal example of **osteolipoma** arising in the cervical region.[1002] Symptomatic accumulation of adipose tissue in this compartment is also a recognized, albeit rare, complication of natural obesity and of corticosteroid administration. Known as **spinal epidural lipomatosis**,[1003] this may consist of brown fat ("**hibernoma**").[1004] **Intradural hibernoma** has also been described.[1005]

Intracranial lipomas are usefully segregated into a midline group and laterally situated variants, most of which involve the eighth cranial nerve. The former exhibit a decided predilection for the region of the corpus callosum but may also settle along the tuber cinereum, above the quadrigeminal plate, in the ambient cisterns, and in the third ventricle.[1006] Most are incidentally discovered at autopsy, but epileptogenic callosal examples are well recognized, tuberal variants may eventuate in hypothalamic dysfunction, and lesions impinging on the third ventricle or aqueduct of Sylvius may be complicated by progressive hydrocephalus. Sleep apnea has exceptionally been recorded in association with lipomas involving the mesencephalic tectum and rostral pons.[1007] In any of these locations, the midline lipoma is clearly maldevelopmental, being frequently associated with structural anomalies of neighboring neural tissues (e.g. agenesis of the corpus callosum) and occasionally occurring in complex with cranial defects or congenital intracranial cysts of colloid or epidermoid type. The added presence, in some instances, of cartilage, bone, smooth or striated muscle, heterotopic peripheral nerves, ganglion cells, neuroglia, and choroid plexus further attests to their malformative basis, although some observers have speculated that these more complex lesions may represent teratomas or teratoid neoplasms.[1008] As in the spinal compartment, exceptional variants merit designation as **angiolipomas**[1009] or **osteolipomas**.[1010] The latter preferentially involve the suprasellar/interpeduncular regions and tuber cinereum. A peculiar tentorial tumor having chondromatous, osseous, and lipomatous components ("**osteochondrolipoma**") has been reported.[1011]

Intracranial lipomas situated off the midline tend to present in the cerebellopontine angle or internal auditory canal and are usually mistaken for acoustic schwannomas on clinical evaluation.[1012,1013] The eighth cranial nerve is typically permeated in diffuse fashion, its fibers divided into small fascicles embedded in mature adipose tissue, and other cranial nerves may be engulfed in like manner by large lesions lying adjacent to the brainstem. These may contain dysmorphic vascular elements as well as smooth muscle bundles and striated muscle fibers, suggesting a maldevelopmental etiology ("**lipochoristoma**"). On rare occasions, intracranial lipomas settle in the region of the sylvian fissure, encasing middle cerebral artery branches and infiltrating temporal cortex.[1014] As attempts at en bloc resection may result in severe neurologic injury, it has been suggested that these and cerebellopontine angle examples be subjected to the minimum debulking required to relieve local mass effects. The intrinsically high signal characteristic of fat on T1-weighted MR study may facilitate the accurate preoperative identification of neuraxial masses as lipomas.

Liposarcomas are among the least common of all malignant mesenchymal tumors reported to involve the CNS or its coverings. Only isolated meningeal examples are on record.[965] The reader is reminded that cells resembling lipoblasts or adipocytes may be

encountered in hemangioblastomas as well as "lipidized" neoplasms of meningothelial and neuroepithelial lineage.

Osseous and Cartilaginous Tumors

Osseous plaques adherent to the falx cerebri and undersurface of the dura in the region of the superior sagittal sinus are common incidental findings at autopsy and are generally asymptomatic. Although termed **osteomas**, these almost certainly represent reactive, metaplastic lesions and may occur with increased frequency in the setting of chronic renal failure.[1015] In a similar vein, the spinal arachnoid frequently undergoes patchy ossification, but only rarely is this process so extensive as to produce myelopathy.[1016] Examples of bona fide **osteogenic sarcoma** arising from the meninges or brain have been depicted but are exceptional.[1017] We have previously mentioned a case of cerebellar osteogenic sarcoma arising in association with an epidermoid cyst.

Bosselated masses of mature hyaline cartilage known as **chondromas** (or **osteochondromas** when they contain bony elements) may bulge into the cranial cavity from its floor or, much less commonly, may arise from the dura.[1018,1019] Examples complicating the generalized skeletal chondromatoses designated as **Maffucci syndrome** and **Ollier disease** have also been depicted.[1020,1021] **Intracranial chondrosarcomas** of conventional type usually originate in the skull base, but meningeal and neuroparenchymal primaries are recognized,[1022] reports including isolated cases following cranial irradiation and evolving from chondromas.[1023,1024] Lack of brachyury positivity distinguishes chondrosarcoma from chondroid chordomas, which are often in the differential.[1025] Curiously, the **mesenchymal chondrosarcoma** seems to have a special predilection for the dura among extraosseous sites.[1026] Examples arising in the leptomeninges and brain[1027] are also on record. Rarest of all cartilaginous intracranial neoplasms is the **extraskeletal myxoid chondrosarcoma**.[1028]

Endothelial Tumors

The overwhelming majority of vasoformative tumors involving the CNS are maldevelopmental anomalies (previously considered in the discussion of vascular malformations). Endothelial neoplasms of the neuraxis[278] include **hemangiomas** (potentially multifocal and typically of capillary type with lobular growth features),[1029-1031] **hemangioendotheliomas** of spindled, epithelioid (recently associated with *WWTR1-CAMTA1* or *YAP1-TFE3* fusions[1032]), and polymorphous types (the first arguably benign and the latter two best regarded as low to intermediate malignant potential lesions),[1033] and aggressive **angiosarcomas** of conventional type.[1034] Also on record is a unique cerebral neoplasm exhibiting hybrid components of "angiogenic" leiomyosarcoma and epithelioid angiosarcoma,[1035] and CNS involvement by AIDS-associated **Kaposi sarcoma** has been documented.[1036] We have not encountered an example of cutaneous or visceral angiosarcoma presenting as a neuraxial mass, but metastatic atrial myxoma may masquerade as intracranial epithelioid hemangioendothelioma.[1037]

The designation of hemangioendothelioma has been extended to certain benign vasogenic meningocerebral lesions that structurally resemble the cellular ("juvenile") capillary hemangiomas encountered as cutaneous "nevi" in infancy.[1031] We have also had the opportunity to study an epileptogenic frontal lobe mass, associated with a history of antecedent cranial trauma, which exhibited the features of lobular capillary hemangioma (or so-called pyogenic granuloma) and are familiar with a case in which morphologically similar, but multifocal cerebral hemispheric lesions regressed after corticosteroid administration.[1038] Multifocal involvement of the spinal cord and cauda equina by lesions having capillary hemangiomatous features has also been described.[1039] Finally, the spectrum of primary endothelial proliferations potentially involving the nervous system includes the process known as **intravascular papillary endothelial hyperplasia** or **Masson vegetant intravascular hemangioendothelioma**.[1040] Intracranial variants, which may evolve from preexisting vascular malformations or develop within dural venous sinuses, can achieve enormous proportions, may regrow if subtotally excised, and have occasionally proved fatal as a result of associated mass effects.

Myogenous Tumors

Embryonal rhabdomyosarcomas account for most primary myogenous neoplasms of the CNS reported to date.[1041-1043] These tend to segregate into a posterior fossa subset, characterized by a presentation in childhood and a predilection for the cerebellum, and a supratentorial group of adult onset typified by a cerebral hemispheric localization. Rare cases of **pleomorphic** and **alveolar rhabdomyosarcoma** have been documented to arise in the cerebrum as well.[1044] The midline, vermal position of many intracranial rhabdomyosarcomas arising in the pediatric population and the recognized capacity of the cerebellar medulloblastoma to differentiate along skeletal muscle lines ("medullomyoblastoma") have prompted speculation that both tumor types might originate from a common, primordial progenitor in the rhombic roof. Whatever their histogenesis, primary rhabdomyosarcomas of the CNS are high-grade neoplasms; few patients remain alive 2 years after diagnosis despite aggressive irradiation and chemotherapy. Neuraxis dissemination and extracranial metastasis may complicate local tumor progression. Mention should be made of a diffuse leptomeningeal variant unassociated with a demonstrable neuroparenchymal component,[1045] but this diagnosis requires rigorous exclusion of an occult primary focus in the orbit, paranasal sinuses, nasopharynx, or middle ear since rhabdomyosarcomas originating in these parameningeal regions frequently seed the subarachnoid space. Non-neoplastic, cranial nerve–associated proliferations of skeletal, and, in some instances, smooth muscle have been variously designated as **rhabdomyomas**, **neuromuscular hamartomas/choristomas**, and **benign ectomesenchymomas/Triton tumors**. These have been previously treated in our discussion of hamartomas and choristomas. **Malignant ectomesenchymoma**, a neoplasm having rhabdomyosarcomatous elements with admixed ganglion cell components, has also been described as originating in the CNS, with a rare example showing transcriptome similarities to malignant peripheral nerve sheath tumor[1046]; however, a more recent study has shown frequent *HRAS* mutations, a feature suggesting a closer genetic link with embryonal rhabdomyosarcomas.[1047]

Sporadic instances of **leiomyoma**[1048] or **leiomyosarcoma**[1049] originating from the meninges or within the neuroparenchyma have been described, these exceedingly rare neoplasms including such oddities as **diffuse leptomeningeal leiomyomatosis**,[1050] **angioleiomyoma**,[1051] **pleomorphic angioleiomyoma**,[1052] and the **composite leiomyosarcoma–epithelioid angiosarcoma**[1035] to which we have previously referred. Intracranial neoplasms interpreted as **myopericytomas** have also been reported and may be associated with *NTRK1* gene fusions.[1053] At special risk of developing neuraxial (as well as systemically situated) smooth muscle tumors are the immunocompromised, particularly patients with AIDS.[1054,1055] Such tumors are usually associated with the dura or situated in juxtaneuraxial sites such as the parasellar region or cavernous sinus but may involve the brain.[1056] They range in appearance from highly differentiated leiomyomas to frank leiomyosarcomas and, in our experience, include epithelioid variants of small, clear cell cytologic type that may be difficult to recognize as being of smooth muscle character. As is the case for their systemic counterparts arising in a background of immunosuppression, neuraxial variants consistently harbor Epstein–Barr virus (EBV) as evidenced by nuclear labeling for EBV-associated

nuclear antigen 2 (EBNA-2) and EBV-encoded RNA-1 (EBER-1) on immunohistochemical and in situ hybridization assessment, respectively. EBV-associated myopericytomas have rarely been reported to complicate AIDS.[1057]

Other Mesenchymal Tumors

In addition to the various mesenchymal neoplasms of the CNS exhibiting specific diagnostic features, there is a disparate collection of anaplastic tumors to which only descriptive appellations such as high-grade "spindle cell," "pleomorphic," or "undifferentiated" sarcoma can be given.[278] Reported under the rubric of **primary leptomeningeal sarcomatosis** are poorly characterized variants typified by diffuse tumoral proliferation restricted to the subarachnoid space and unaccompanied by dominant foci of bulky disease.[1058] These may present with signs and symptoms of polyradiculopathy, spinal cord compression, or intracranial mass effect and are often misdiagnosed initially as chronic meningitides of infectious etiology or as manifestations of neurosarcoidosis or other inflammatory disorders. The differential diagnosis includes leptomeningeal carcinomatosis, gliomatosis, lymphomatosis, melanomatosis, and medulloblastomatosis. Neoplasms that seem to represent the intracranial equivalents of soft tissue and skeletal **myxomas** have been described,[1059] but myxoid meningioma and metastatic atrial myxoma must be excluded before this diagnosis can be accepted. Also to be found are reports of a dural **epithelioid sarcoma**,[1060] **synovial sarcomas** originating in the dura, spinal nerve roots or nerve plexi,[1061-1063] a peculiar **angiomyxofibromatous tumor** of the falx,[1064] and the bizarre phenomenon of **phosphaturic mesenchymal tumor** (a lesion recognized for its association with paraneoplastic osteomalacia secondary to tumor-induced renal phosphate wasting) masquerading as meningioma[1065] or spinal nerve sheath tumor.[1066] Last, we mention a primary intracranial example of **aneurysmal bone cyst** (with confirmatory 17p13 rearrangement involving the ubiquitin-specific protease 6 [USP6] locus) that presented as a cerebellopontine angle growth.[1067] The **Ewing sarcoma/peripheral primitive neuroectodermal tumor** group has been previously addressed in our discussion of embryonal neoplasms.

Nerve Sheath Tumors of the Craniospinal Axis

Inasmuch as nerve sheath tumors arising within the cranial cavity and spinal canal are the morphologic and biologic homologues of their more common, peripherally situated counterparts, the reader is referred to Chapter 41 of this text for a detailed treatment of their diagnostic, structural, and immunophenotypic features.

Schwannomas are the most frequent variant to abut the central neuraxis, usually presenting in adulthood as tumors of the cerebellopontine angle or lumbosacral spinal extramedullary space.[278] Nearly all cerebellopontine angle tumors originate in the vestibular branch of cranial nerve VIII ("acoustic neuroma" therefore being a misnomer) and produce hearing loss. Schwannomas arising at spinal levels exhibit a similar predilection for sensory divisions of the neuraxis, typically involving the posterior roots. These often assume a "dumbbell" configuration as they squeeze through adjacent intervertebral foramina and expand into the paravertebral soft tissues. Schwannomas may involve cranial nerves other than the eighth nerve and lie within the central neuroparenchyma proper.[1068,1069] Intraventricular[1070] and dura-based[1071] cases have been depicted as well. Bilateral eighth nerve examples are a defining feature of **NF2**, an autosomal dominant disorder linked to inherited or newly acquired mutations involving a gene localized to chromosome 22q12.[278] Affected kindreds are prone to an assortment of neoplasms, all typified in this setting by multifocality, that includes craniospinal schwannomas, meningiomas, and intramedullary ependymomas. Inactivating mutations of the *NF2* gene on chromosome 22 also characterize most acoustic schwannomas occurring in sporadic fashion. Multifocal, nonvestibular schwannomas divorced from other manifestations of NF2 constitute a syndrome known as **schwannomatosis**, although rare familial examples are now known to also include vestibular schwannomas or meningiomas.[1072,1073]

The schwannoma's characteristic Antoni A and B structure, nuclear palisading (Verocay bodies), infiltration by foamy macrophages, and vascular hyalinization usually suffice for its recognition, NF2-associated variants often evidencing a multilobulated growth pattern on gross and microscopic assessment, with recent evidence suggesting that this pattern results from fusion of multiple clonally distinct schwannomas.[1074] Rosenthal fibers and eosinophilic granular bodies may rarely be encountered in vestibular examples,[1075] possibly reflecting chronic stimulation of astrocytes native to the central portion of cranial nerve VIII.[1076] On occasion, meningiomas exhibit schwannoma-like features such as nuclear palisading and are the most frequent mimic. These two tumor types may also collide in patients with NF2, but "composite" lesions of this kind only rarely occur outside this clinical setting.[1077] Immunocytochemical techniques and electron microscopic study may both be usefully applied to distinguishing schwannian from meningothelial neoplasms and to the elimination of SFT/HPC from the differential. Schwannomas are characterized by diffuse cytoplasmic S-100 protein expression and pericellular immunolabeling for laminin and type IV collagen, the latter (and a corresponding reticulin network) reflecting investment of their elongated cellular processes by a continuous basal lamina foreign to the typical meningioma. Most examples also express widespread nuclear SOX10 expression, a useful and more specific marker of either schwannian or melanocytic lineages.[1078-1080] They may also show focal GFAP expression.[1081] Cytoplasmic expression of EMA—a regular feature of meningothelial tumors—is usually absent from the schwannoma or restricted to normal perineurial cells incorporated into the latter's capsule and thus limited to its periphery. Admittedly, however, some observers have described EMA-reactive neoplastic elements in the substance of hybrid nerve sheath tumors with mixed features of schwannoma and perineurioma.[1068] It is worth remembering that meningiomas only rarely present in the lumbosacral regions favored by schwannomas of the spinal roots. SFT/HPCs are typically negative for S-100 protein, instead labeling for nuclear STAT6.[969] Nuclear and cytoplasmic expression of calretinin has been described as a trait segregating schwannomas from neurofibromas, although S-100 and SOX10 is also less widespread in neurofibromas due to the presence of nonschwannian components.[1082]

A small minority of intracranial and intraspinal schwannomas are of the "cellular" type.[1083-1085] In contrast to its histologically conventional counterpart, the **cellular schwannoma** is a densely populated spindle cell tumor, typically devoid of Antoni B areas and Verocay bodies, that may contain foci of mitotic activity and is often misconstrued as a malignant peripheral nerve sheath tumor.[1079] The lesion shares with the classic schwannoma foci of vascular hyalinization, infiltration by lymphocytes and foamy macrophages, widespread S-100, SOX10, and collagen IV immunoreactivity, lack of EGFR expression, and highly differentiated Schwann cell features at the ultrastructural level. Such tumors may be more prone than conventional variants to recur locally following excision, but a metastasizing example has never been described. Finally, **granular cell tumors of schwannian lineage** have been noted to involve cranial and spinal nerves or nerve roots.[1086-1088]

Melanotic schwannoma (malignant melanotic schwannian tumor) is a unique nerve sheath tumor displaying mixed schwannian and melanocytic features, with melanosomal melanin production

and a decided predilection for the spinal nerve roots.[1089,1090] Rare intramedullary examples have also been recorded.[1091] Given their shared expression of melanocytic markers, such as HMB-45, Melan-A, and SOX10, some of these tumors are extremely difficult to distinguish from meningeal melanocytoma or melanoma, although the latter are characterized by unique *GNAQ* and *GNA11* mutations not encountered in melanotic schwannomas.[1092] A clear neural origin and more nested collagen IV/reticulin-rich patterns are also useful in this distinction, albeit not universal. Most melanotic schwannomas reported to date were stated to evolve in benign fashion, though recorded follow-up intervals for many of these cases were limited. However, the risk of local recurrence is seen in 25%–35%,[1090,1093] and metastases are also common, particularly for spinal examples.[1090,1094] A subset of melanotic schwannomas containing psammomatous concretions and/or lipoma-like fat accumulation constitutes part of the heritable **Carney complex**,[1095,1096] which includes cardiac, cutaneous, and mammary myxomas; spotty pigmentation; large cell calcifying Sertoli cell tumors of the testis; and evidence of endocrine hyperfunction (principally Cushing syndrome and acromegaly, the former associated with primary pigmented nodular adrenocortical disease); however, such **psammomatous melanotic schwannomas** may also be encountered sporadically. Given these unique clinicopathologic associations and frequent loss of PRKAR1A expression (rather than involvement of the *NF2* gene, which is more typical of conventional schwannomas), the alternate term of **malignant melanotic schwannian tumor** has recently been advocated.[1090]

Most craniospinal **neurofibromas** represent manifestations of NF1 ("peripheral" or classic Recklinghausen disease), transmitted in autosomal dominant fashion by a locus on chromosome 17q11.2.[1097] This complex disorder includes, in addition to multifocal cutaneous and more deeply situated plexiform neurofibromas, dermatologic abnormalities (café au lait spots and axillary freckling), pigmented hamartomas of the iris (Lisch nodules), various skeletal defects, and glial neoplasms, chief among which are pilocytic astrocytomas of the anterior optic pathways. Spinal localized intraneural neurofibromas arising in this setting typically do so at multiple levels. Only rarely are cranial nerves involved. Curious lesions interpreted as plexiform neurofibromas of the cauda equina have also been reported in patients without evidence of NF1.[1098]

Well documented, but uncommon, are **malignant nerve sheath tumors** (MPNSTs) originating in cranial or spinal nerve roots.[1099,1100] These may develop de novo or from underlying schwannomas or neurofibromas, can arise spontaneously or complicate NF (particularly NF1), and in roughly 10% of cases, follow local irradiation (including radiosurgery).[1101-1103] Intracerebral[1099,1100] and intraventricular[1104] presentations have been described. Recorded examples include malignant **Triton tumors** (i.e. variants exhibiting rhabdomyoblastic differentiation), which seem to have a somewhat worse prognosis regardless of NF1 status.[1105] A most remarkable instance of intraspinal schwannoma spawning rhabdomyosarcomatous, primitive neuroectodermal, and epithelial elements has also been reported.[1106] Malignant paraspinal nerve sheath tumors that may invade the canal and threaten the spinal cord often originate in neurofibromas, particularly those of plexiform or localized intraneural types, and so are strongly associated with NF1.[1107] Of note, a couple of more diagnostically specific immunohistochemical markers have recently been reported in association with sporadic, NF1 associated, and radiation induced MPNSTs, with supportive findings including the losses of neurofibromin and/or H3K27me3 expression.[1079,1101,1108-1110]

Oddities that round out this brief survey include **neurothekeomas** of the craniospinal neuraxis,[1111,1112] **soft tissue–type perineuriomas** presenting as intraventricular growths,[1113] **intraneural perineuriomas** originating in cranial nerve divisions,[1114] and craniospinal examples of **localized hypertrophic neuropathy**.[1115] Whereas the last of these entities probably represents a reactive hyperplasia characterized by the concentric wrapping of S-100 protein-expressing, EMA-negative Schwann cells about individual axons in formations known as "onion bulbs," the intraneural perineurioma is a bona fide neoplasm in which morphologically similar structures ("pseudo-onion bulbs") reflect concentric periaxonal proliferation by EMAlabeling, S-100 nonreactive elements of perineurial cell type. **Hybrid nerve sheath tumors** combining schwannoma, neurofibroma, and/or perineurioma are also on record, being somewhat over-represented in familial disorders, such as NF1, NF2, and schwannomatosis.[1068] Nevertheless, caution should be exercised to avoid over-interpretation of neurofibroma-like Antoni B areas within a schwannoma as evidence of a hybrid nerve sheath tumor. Last, we mention the occurrence of **traumatic neuromas** in the CNS, most involving the spinal cord and some developing in association with tumors such as intramedullary ependymomas.[1116,1117]

Lymphoproliferative, Histiocytic, and Myeloproliferative Disorders

As secondary spread of systemic lymphoproliferative and myeloproliferative disorders to the CNS does not often occasion neurosurgical intervention for diagnostic purposes, only a few general observations on this problem are offered. At greatest risk of such dissemination are patients suffering from acute leukemias,[1118] particularly of lymphoblastic type; diffuse leptomeningeal infiltration is the dominant pattern of CNS involvement encountered in this setting. In some cases, extensive permeation of cranial and spinal nerve roots accompanies the unrestrained proliferation of leukemic cells in the subarachnoid compartment. Circumscribed, dura-based, or (rarely) intracerebral masses composed of leukemic cells principally complicate the acute myelogenous leukemias but have virtually disappeared from clinical practice since the advent of modern cytoreductive therapy. Variously designated as **chloromas**, **granulocytic sarcomas**, **myeloid sarcomas**, or **myeloblastomas**, these tumors usually develop in subjects who are demonstrably leukemic, but exceptionally constitute the initial manifestation of relapse following apparently successful treatment or arise in otherwise normal individuals as harbingers of subsequent bone marrow and peripheral blood involvement.[1119,1120] Parameningeal masses of **extramedullary hematopoietic** tissue have been reported to produce neurologic dysfunction, mainly as a result of spinal cord compression, in patients with thalassemia or myelofibrosis.[1121,1122]

Involvement of the CNS in the course of node-based non-Hodgkin lymphoma is uncommon and usually limited to permeation of the leptomeninges ("meningeal lymphomatosis") or, less often, infiltration of the spinal epidural space.[1123] Cerebral infiltrates are decidedly unusual in this setting and typically complicate advanced (stage IV) disease, an excess of cases occurring in patients with diffuse large cell or lymphoblastic subtypes and involvement of other extranodal sites. By contrast, patients presenting with non-Hodgkin lymphoma of the eye—an extension of the CNS—frequently develop lymphomatous lesions of the brain proper.[1124] A subset of malignant lymphomas, principally non-Hodgkin variants, are confined at diagnosis to the epidural compartment and paraspinal tissues, usually arising in the midthoracic region and prompting evaluation for compressive myelopathy.[1125] Only exceptionally are the meninges colonized or the neural parenchyma penetrated in the course of systemic **Hodgkin disease**,[1126] **plasma cell myeloma**,[1127] **Waldenström macroglobulinemia**,[1128] or **mycosis fungoides**.[1129]

The designation of **primary central nervous system lymphoma (PCNSL)** is reserved for malignant lymphoid neoplasms restricted at presentation to the brain, spinal cord, or meninges.[1130] Although

the association of PCNSL with states of diminished immune responsiveness has long been appreciated, and its particular predilection for victims of AIDS firmly established, the majority of afflicted patients suffer no predisposing illness. Sporadic cases most often present in the sixth or seventh decades of life and manifest a 1.5 to 2:1 male/female ratio, whereas immunodeficiency-related examples reflect the demographics of HIV-1 infection, inherited immunologic disorders, diseases prompting organ transplantation, and other conditions necessitating iatrogenic immunosuppression. Most patients suffer the usual symptoms of an expanding intracranial mass, although PCNSLs tend to arise in the deep cerebral hemispheric white matter, corpus callosum, and basal ganglia and thus are not as prone to produce seizures as gliomas or metastatic deposits that involve epileptogenic cortical tissues. Frontocallosal and periventricular examples may prompt evaluation for personality change, depression, progressive psychomotor retardation, or frank psychosis. Rapidly progressing dementia has been associated with a distinctive subset of PCNSLs that diffusely permeate the brain rather than forming bulky masses ("**lymphomatosis cerebri**").[1131] Some tumors are discovered in the course of work-up for persistent uveocyclitides unresponsive to conventional ophthalmologic treatment, a manifestation of ocular involvement that often occurs in complex with cerebral infiltration.[1124]

Suggestive of PCNSL on CT or MR study (Fig. 43.138) are solid, nodular masses displaying hyperdensity in precontrast images, diffuse (as opposed to rim) enhancement on administration of contrast media, evidence of widespread subependymal infiltration, and multifocality. The last is apparent in some 25%–40% of sporadic examples and the majority of HIV-1–associated and post-transplant cases.[1132] Especially suspect in older adults are lesions that regress substantially with corticosteroid administration alone prior to biopsy, as occasional lymphomas disappear (transiently) with such treatment and masquerade as multiple sclerosis. Cases of lymphomatosis cerebri depart from the typical on MR assessment in their failure to form localized masses or enhance, characteristically demonstrating only diffuse, nonspecific white matter hyperintensity on T2-weighted and FLAIR sequences.[1131] Extensive central necrosis, a feature foreign to sporadic examples, lends to many HIV-1–associated or other immunodeficiency-associated PCNSLs a "ring"-enhancing radiological appearance that may be indistinguishable from *Toxoplasma* abscesses. A definite diagnosis of PCNSL usually requires biopsy but may be accomplished by demonstration of malignant lymphoid cells in CSF. Immunocytochemistry (for B-cell "markers"), flow cytometry, and PCR-based molecular assessment (for immunoglobulin heavy chain [IGH] gene rearrangements) have been applied to CSF specimens as methods of facilitating nonsurgical diagnosis.[1133]

PCNSLs may arise anywhere along the neuraxis. Approximately 75% are situated in the supratentorial compartment, these favoring the deep structures enumerated above. Most of the remainder involve the cerebellum or brainstem, with only rare examples isolated to the spinal cord, cauda equina or craniospinal nerve roots.[1134,1135] The designation of "**neurolymphomatosis**" has been applied to cases of the last two types and to lymphomas of nerve that are more peripherally localized.[1134] A small fraction of PCNSLs present as diffuse leptomeningeal infiltrates in the absence of demonstrable intraparenchymal disease,[1136] such as the **human herpesvirus 8–associated "primary effusion lymphoma"** of the subarachnoid space as a complication of AIDS.[1137] Dura-based lymphomas are given separate consideration later in this discussion (see later). Grossly, hematolymphoid lesions of the CNS proper are poorly defined in most instances and composed of dry, granular, tan–white, or grayish-pink tissue that may evidence small foci of necrotic softening or hemorrhagic discoloration. Extensive necrosis and conspicuous hemorrhage are most commonly encountered in AIDS-related and other cases associated with immunocompromise, which may closely mimic *Toxoplasma* abscesses on gross examination (particularly after adjuvant treatment), and in lesions complicating transplantation. A striking histologic feature of many PCNSLs is the tendency for tumor cells to aggregate in Virchow–Robin spaces and to infiltrate the walls of cerebral vessels (Fig. 43.139). This is commonly associated

Figure 43.138 Primary Central Nervous System Lymphoma. As demonstrated in this postcontrast injection magnetic resonance imaging, primary cerebral lymphomas exhibit a predilection for the deep, paraventricular white matter and tend to striking and fairly homogeneous enhancement in "sporadic" (as opposed to AIDS-related) cases.

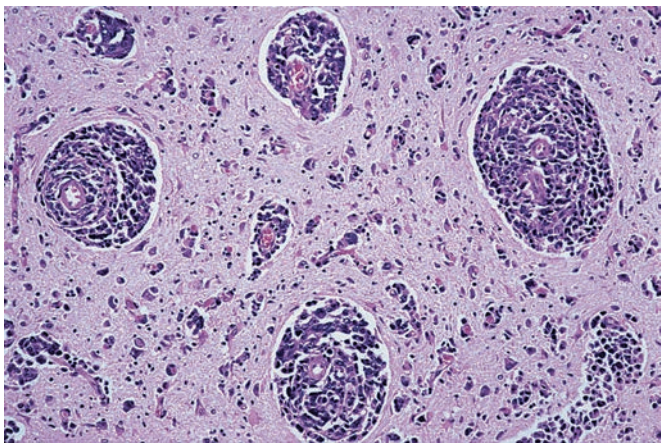

Figure 43.139 Primary Central Nervous System (CNS) Lymphoma. Although not apparent in all cases, a vasocentric growth pattern with tumoral infiltration of blood vessel walls and Virchow–Robin spaces is common to primary CNS lymphomas. Systemic lymphomas secondarily involving the neuroparenchyma may also preferentially grow in this fashion.

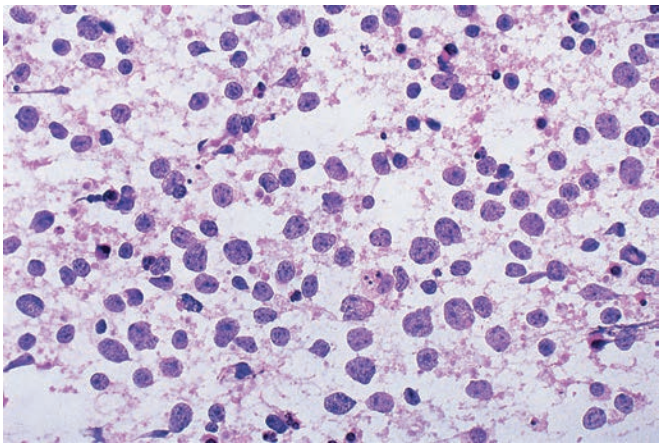

Figure 43.140 Primary Central Nervous System (CNS) Lymphoma. An intraoperative smear preparation demonstrates the large cell cytology and nuclear features characteristic of CNS lymphoma. The lack of cellular cohesion or cytoplasmic processes, respectively, are useful in discriminating this tumor from metastatic carcinoma and glioblastoma multiforme, two neoplasms that commonly enter the clinical differential diagnosis.

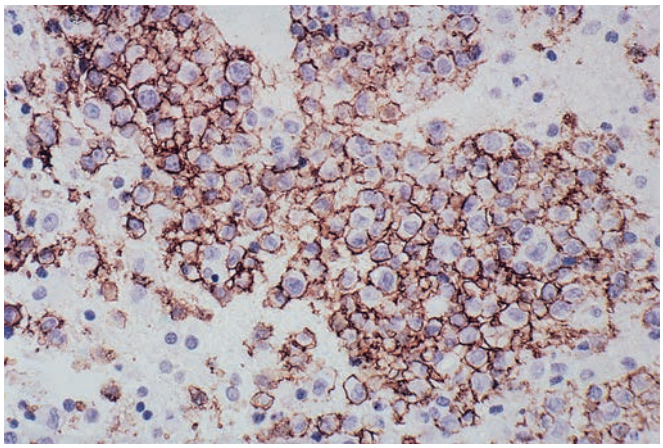

Figure 43.141 Primary Central Nervous System (CNS) Lymphoma. The great majority of lymphomas arising in the CNS are of B-cell type and, as shown here, label for CD20 on immunoperoxidase (L-26) assay.

with reticulin deposition in concentric, ring-like patterns. Most neuroparenchymal PCNSLs are high-grade non-Hodgkin lesions of diffuse large cell type,[1124,1130] but all major cytologic variants have been reported in this location, including low-grade lymphomas of small lymphocytic or lymphoplasmacytic type (sometimes in association with immunoglobulin deposition and/or crystal storing histiocytes),[1138] anaplastic large cell lymphomas,[1139] and such oddities as signet ring cell[1140] and extranodal, choroid plexus-based marginal zone lymphoma.[1141] Follicular (nodular) lymphoid neoplasms, however, are practically never encountered in this setting.[1142] Some observers have noted an over-representation of immunoblastic and small noncleaved Burkitt-like cell types among PCNSLs, particularly those involving AIDS patients and other immunosuppressed hosts, compared with node-based or other extranodal primary tumors.[1143] Regardless of the cytologic variety, touch preparations are useful in establishing the lymphoid nature of a given tumor at the time of intraoperative consultation (Fig. 43.140).

The overwhelming majority of PCNSLs exhibit a B-cell immunophenotype,[278] including labeling for CD20, CD19, PAX5, and CD79a in the absence of CD3 or CD45RO expression (Fig. 43.141). Other evidence of their B-lymphocytic lineage include clonal *IGH* gene rearrangements and certain characteristics shared with germinal center B cells, including recurrent translocations of the *BCL6* gene and BCL6 protein expression in 60%–80% of cases. PCNSLs, however, commonly have "activated" (nongerminal center) B-cell features as well.[1144,1145] Thus, one sizable analysis found an activated B-cell immunophenotype in over 90% of studied examples, these labeling for CD10, BCL6, and MUM1, respectively, in 2.4%, 55.5%, and 92.6% of cases.[1146] There is also evidence of somatic hypermutation, with activating mutations most commonly involving the *IG*, *BCL6*, *BCL2*, *MYC*, *PIM1*, *PAX5*, *RHOH*, *KLHL14*, *OSBPL10*, and *SUSD2* genes.[278,1147] Losses involving chromosome 6p21.32 occur in about 73% of cases, often preventing the expression of HLA class I and II gene products.[278] Epigenetic mechanisms are also important, with hypermethylation leading to inactivation of the *DAPK1* (in 84% of cases), *CDKN2A* (75%), *MGMT* (52%), and *RFC* (30%) genes. Other characteristics shared by PCNSLs and diffuse large cell lymphomas of activated B-cell type arising outside the neuraxis include an IgM phenotype without evidence for immunoglobulin class switch, high-level expression of BCL2 mRNA and protein in the absence of t(14;18)(q32;q21)/*IGH–BCL2* fusion, and frequent gains of chromosome 18q21 that include the *BCL2* and *MALT1* oncogenes.[278] The last of these phenomena constitutes the most common genetic abnormality displayed by PCNSLs and affects (with upregulated expression of other family members, upstream modulators and targets) activation of the nuclear factor kappa B (NFκB) signaling cascade.[1148] Increased NFκB signaling could explain, at least in part, the observations that PCNSLs are highly proliferative (MIB-1/Ki-67 indices regularly exceeding 50%–70% and potentially rising above 90%) while exhibiting relatively low-level apoptotic activity.

It is to be emphasized that PCNSLs often harbor a conspicuous complement of admixed T cells that can confound interpretation of the histologic and immunohistochemical picture, but these reactive elements usually appear as small, well-differentiated lymphocytes that are readily distinguished from the large, atypical B cells on which the diagnosis rests. Particularly deceptive are biopsies derived from the perimeter of PCNSLs, where reactive T lymphocytes often constitute a dominant and obscuring population, or from masses showing regression following preoperative corticosteroid administration. These "sentinel lesions" may be selectively relieved of their neoplastic B-cell components, heavily infiltrated by foamy macrophages, and partially demyelinated, a phenomenon that may prompt, along with their radiological and clinical resolution, misdiagnosis of multiple sclerosis or demyelinating pseudotumor as the primary disease process.[1149] It is worth remembering that multiple sclerosis is, for the most part, a disorder of the young. Furthermore, it has been our experience that inadvertently "treated" lymphomas do not leave behind the sharply demarcated zones of selective and total myelin loss with axonal preservation typical of multiple sclerosis or demyelinating pseudotumors. Clonal B-cell populations have rarely been described as participants in multiple sclerosis,[1150] but atypical B lymphocytes should not be seen in this disorder. **Primary natural killer (NK)/T-cell lymphomas of the CNS** constitute no more than 2%–4% of PCNSLs in series from the West but account for a significantly higher proportion of cases afflicting Japanese and Koreans.[1151,1152] These may be over-represented among leptomeningeal and infratentorial primaries. The spectrum of variants reported to present as CNS primaries includes anaplastic large cell lymphomas.[1136,1153]

Neuroparenchymal PCNSLs of the usual (i.e. diffuse large B-cell) type can be driven into remission by adjuvant means but usually recur (often at CNS sites remote from the initial focus of disease) and prove fatal. High-dose, methotrexate-based chemotherapeutic

regimens have achieved median survival intervals of 32–60 months.[1130] Although extent of resection has traditionally been considered irrelevant, with aggressive surgeries generally avoided, this concept has recently been challenged.[1154] As toxic leukoencephalopathy has emerged as a frequent complication of combined radiochemotherapeutic approaches, current management strategies and ongoing clinical trials are focused on frontline chemotherapy alone (including potentially promising protocols involving autologous stem cell transplantation), potentially augmented by targeted or immunomodulatory therapies, such as rituximab.[1155] The outlook for patients with intra-axial T-cell PCNSLs is similar or perhaps slightly better at present.[278,1156] Those exceptional examples of low-grade, small lymphocytic or lymphoplasmacytic B-cell lymphoma arising in the central neuraxis seem to be less aggressive and amenable to longer-term control.[1157] A grim prognosis attaches to AIDS-associated PCNSLs, though improvement in survival has been effected since the advent of HAART.[1156] The usual pattern of treatment failure in the setting of PCNSL is progressive, frequently multifocal infiltration of the CNS proper, attended, in some cases, by leptomeningeal dissemination. Ocular involvement is experienced by many patients as the disease evolves, but systemic lymphomatous infiltrates develop in no more than 10% of cases.[1124]

As the central neuraxis normally lacks a resident lymphoid population, the histogenesis of PCNSLs is obscure. Specifically, whether primary neuroparenchymal and leptomeningeal lymphomas actually arise in these locales or are peripherally generated and selectively home to (or opportunistically colonize and, shielded from immune surveillance, persist within) the CNS is unclear. Infections or other inflammatory processes could summon lymphocytes to the CNS and thus set the stage for their subsequent neoplastic transformation (a particularly plausible scenario in the immunodeficient), but only exceptionally has PCNSL been described in patients with proven neurologic infections or other unarguably reactive processes characterized by lymphoid infiltration.[1158] Given the recognized ability of the EBV to immortalize B cells in vitro and to drive a polyclonal, systemic lymphoproliferation that may evolve to frank lymphoma in immunocompromised hosts, it is noteworthy that immunodeficiency-associated PCNSLs, such as AIDS-related examples and post-transplant lymphoproliferative disease involving the CNS regularly harbor this agent, whereas sporadic PCNSLs rarely do, with the exception of **EBV-positive diffuse large B-cell lymphoma of the elderly**, the latter thought to represent an increasing state of systemic "immunosenescence" in patients above the age of 50.[1159-1161] EBV has also been incriminated in a low-grade lymphoproliferative disorder resembling polymorphic B-cell hyperplasia in an HIV-1–infected child[1162] and in a polyclonal cerebellar lymphoproliferation that progressed to lymphoma in an apparently immunocompetent adult.[1163]

Primary lymphoproliferative disorders of the CNS other than non-Hodgkin lymphoma of the neuroparenchyma and leptomeninges merit brief discussion. **Primary dural lymphomas** are uncommon lesions that typically mimic meningiomas and that are usually B-cell tumors of **low-grade, marginal zone (MALT) type**.[1164] These may show intratumoral amyloid deposition, and a subset may be associated with numerous IgG4-positive plasma cells, although systemic evidence of IgG4 disease is typically absent.[1165] Other dural-based variants have been described,[1166] including **T cell–rich B-cell lymphoma**,[1167] small lymphocytic lymphoma, diffuse large B-cell lymphoma, anaplastic large T-cell lymphoma, and low-grade follicular lymphoma of small cleaved type.[1166,1168] Only rarely is **Hodgkin disease** confined, on presentation, to the CNS.[1126,1169,1170] PCNSLs derived from immunodeficient hosts, however, not infrequently harbor pleomorphic cellular elements that may be misconstrued as Reed–Sternberg cells. The peculiar disorder historically described as "neoplastic angioendotheliomatosis," formerly regarded as an intravascular variant of angiosarcoma, is now known to be an unusual form of malignant lymphoma, typically of large B-cell type (though T-cell variants are recognized[1171]), exhibiting a remarkable tropism for blood vessels in the skin, adrenal glands, and CNS, the latter occurring in over 75%–85% of cases; the lack of CD29 and ICAM1(CD54) adhesion molecule expression is thought to preclude transvascular migration in these systemically derived tumor cells.[278,1172] Accordingly, the disorder is now termed **intravascular large B-cell lymphoma**. Patients often present with neurologic dysfunction—progressive encephalopathy, dementia, or stroke—that reflects multifocal cerebral infarction resulting from occlusion of vascular lumina by malignant lymphoid cells (Fig. 43.142). Cerebrovascular aneurysm formation with rupture and intracranial hemorrhage has also been reported to complicate intravascular lymphoma,[1173] as has the development of extravascular lymphomatous masses in the CNS and a rare association with autoimmune hemolytic anemia.[1174,1175] Rare cases have been described as limited to the brain or spinal cord,[1176] one of which occurred in a child with AIDS.[1177]

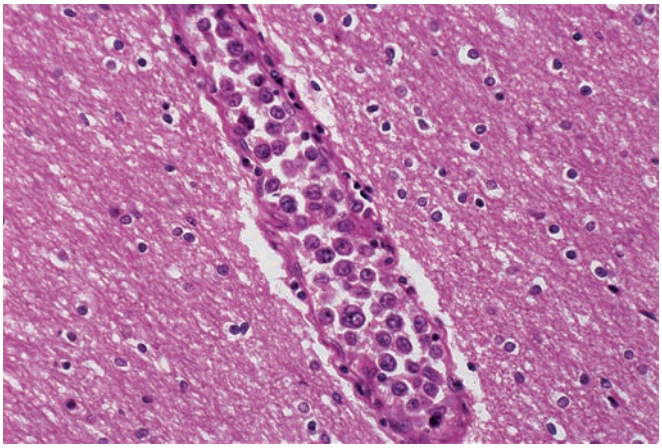

Figure 43.142 Intravascular Large B-Cell Lymphoma. Large, highly atypical cells fill a small blood vessel in the white matter of a 63-year-old woman subjected to brain biopsy for progressive cognitive impairment. Positive immunoassays for leukocyte common antigen and CD20 confirmed their lymphoid nature and B-cell phenotype, respectively.

Other oddities include **Castleman disease** confined to the meninges[1178] or involving spinal nerve roots,[1179] primary **plasmacytoma** of the dura,[1180] brain[1181] or spinal cord[1182] (including cases described as developing against a background of **atypical plasma cell hyperplasia**[1183]), and CNS **amyloidomas**; only rare examples of the latter have been associated with an underlying hematopoietic malignancy, such as low-grade lymphoma.[1138] Amyloidomas of the gasserian ganglion are further recognized as an unusual cause of trigeminal neuropathy, these also representing localized lesions and not complicating or presaging generalized plasma cell dyscrasia.[1184] The vasocentric deposition in brain of type-restricted immunoglobulin light chains (amyloid forming in some cases and accompanied by modest infiltrates of small lymphocytes and mature, but monoclonal, plasma cells) has also been reported under the rubric of **CNS light chain deposition disease**[1138,1185] or as a form of **cerebral amyloid angiopathy**.[1186] The deposits in question have been almost exclusively of lambda light chain type, cerebral and gasserian amyloidomas also being composed of lambda light chain material and harboring clonal lambda-expressing plasma cells,[1138] but an example exhibiting kappa restriction has been communicated.[1187] Tumors interpreted as true **histiocytic sarcoma**,[278] **follicular dendritic cell sarcoma**,[1188] or

"**microglioma**"[1189] of the brain have been described. The histiocytic sarcomas are rare and highly aggressive but similar to the histiocytic disorders Langerhans cell histiocytosis and Erdheim–Chester disease, they may express BRAF V600E mutation and respond to inhibitors.[1190] Finally, there is so-called **lymphomatoid granulomatosis**, an angiocentric and necrotizing lymphoproliferative disorder historically described as a prelymphomatous condition involving the CNS in association with pulmonary disease but occasionally reported to localize in the brain alone.[1191] Several of these isolated cerebral variants involved patients with AIDS[1192] and a number eventuated in recognizable lymphoma. Arguably, at least some of these cases represented angiocentric forms of malignant lymphoma ab initio. The participation of EBV in this process has been documented.[1191]

Germ Cell Tumors

Whether **germ cell tumors** of the CNS derive, as long presumed, from primordial germ cells that aberrantly migrate to the developing central neuraxis or, as more recently proposed, from native stem cell elements remains a speculative matter, but the fact remains that these uncommon neoplasms are morphologically and immunophenotypically indistinguishable from germinal tumors arising in the gonads (as well as other extragonadal sites), and a subset manifests genetic abnormalities, such as X chromosome gains, increased chromosome 12p copy number, and isochromosome 12p formation, characteristic of testicular (and other extracranial) primaries.[1193] The last genetic lesion, a marker alteration in the setting of testicular germ cell tumorigenesis, does not appear, however, to be as prevalent among intracranial examples. Approximately 90% of CNS germ cell tumors are discovered in the first two decades of life, case rates peaking in 10- to 12-year-olds. In Western series, these account for no more than 0.5% of all primary intracranial neoplasms and 3% of those encountered in children, but their incidence is increased two-fold or more in Japan, Taiwan, and Korea.[1193] Sharing with other extragonadal germ cell tumors a predilection for the midline, at least 80% of CNS examples arise along an axis extending from the suprasellar cistern and infundibulum to the pineal gland (these constituting the most common neoplasms encountered in the latter location). A synchronous suprasellar and pineal region presentation is well recognized, though exceptional, as are cases confined to the cerebral hemispheres, basal ganglia or thalami (these may be bilateral), ventricles, spinal cord, and sella turcica. Metachronous intracranial primaries are on record, but rare.[1194] Males are afflicted more than twice as frequently as females when all sites are considered, but gender distribution varies with tumor localization: the large majority of pineal examples affect boys, but suprasellar lesions occur more often in girls.

CNS germ cell tumors generally arise in sporadic fashion but are recognized to complicate Klinefelter syndrome,[1195] and their incidence may be increased in the setting of Down syndrome as well.[1196] Suprasellar examples produce visual field defects, diabetes insipidus, and hypothalamopituitary failure, whereas pineal region tumors compress the tectal plate and aqueduct, presenting with symptoms and signs of obstructive hydrocephalus that are often accompanied by a vertical gaze paresis, known eponymously as Parinaud syndrome. The secretion of beta human chorionic gonadotropin (β-hCG) by neoplastic syncytiotrophoblast may stimulate testosterone production in boys and result in "precocious puberty" (isosexual pseudoprecocity), as this may release the immature testes from tonic inhibitory controls secondary to pineal and hypothalamic injury. The proposed follicle stimulating hormone–like activity of hCG[1197] or additional elaboration of cytochrome p450 aromatase,[1198] which catalyzes estrogen formation from C19 steroids, could explain the exceptional occurrence of precocious puberty in girls with hCG-producing intracranial germ cell tumors.

The macroscopic features, histologic, and immunohistochemical criteria governing the identification and subclassification of CNS germ cell tumors differ in no way from those previously articulated in discussion of their more common gonadal counterparts and are not reprised here.[1193,1196,1199] **Germinoma** has by far the highest incidence among tumors of this group. This neoplasm is essentially identical to the seminoma in histologic appearance and antigenic profile. While the microscopic diagnosis is usually straightforward, the germinoma that has elicited a florid lymphoplasmacytic and granulomatous reaction may masquerade as tuberculosis, sarcoidosis, or other inflammatory process.[1200] Immunohistochemical screening facilitates the visualization of tumor cells obscured by such an infiltrate and is mandatory when dealing with inflamed biopsy material deriving from the suprasellar–pineal axis (a unique report of apparently **idiopathic** "**pinealitis**" notwithstanding[1201]). D2-40, CD117 (c-kit), and OCT4 antibodies outperform reagents against placental alkaline phosphatase (PLAP) in this regard,[1202] membranous reactivity for the first two being more germinoma-specific than nuclear OCT4 expression (which is shared by embryonal carcinomas). In connection with the CD117/c-kit expression characteristic of germinomas, it is noteworthy that these lesions, in contrast to other intracranial germ cell tumor types, often harbor activating *KIT* gene mutations.[1203,1204] Nuclear immunolabeling for NANOG, a homeodomain transcription factor, is a further feature of germinomas useful in their identification.[1205] These tumors may also express (as can other germ cell neoplasms in varying fashion) the RNA-binding LIN28 protein[1206] and the POU5F1,[1202] HESRG,[1207] UTF1,[1208] and SALL4[1209] transcription factors. We would call the reader's attention to unusual forms of "diffuse" CNS germinoma that permeate the neuroparenchyma in glioma-like fashion rather than forming discrete tumor masses.[1210] A minority of otherwise pure germinomas harbor syncytiotrophoblastic giant cell elements that are β-hCG-immunoreactive and associated with elevated levels of this oncoprotein in serum and CSF. Whether this phenomenon is associated with an increased recurrence risk has been a matter of controversy,[1211] but such tumors clearly do not behave in the highly aggressive fashion of choriocarcinomas.

Apart from germinoma, only CNS germ cell tumors of the teratoma family are likely to be encountered in pure form.[1212] **Teratomas** constitute the majority of congenital CNS germ cell tumors, one account describing the remarkable discovery of a primary intracranial example in the fetus of a woman with an independent ovarian teratoma.[1213] This tumor group includes the **mature teratoma** (composed entirely of adult-type tissues), the **immature teratoma** (defined by a content of incompletely differentiated components exhibiting fetal appearances), and the **teratoma with malignant transformation** (i.e. one spawning a secondary cancer of conventional somatic type). As regards the last entity, sarcomas of undifferentiated or rhabdomyosarcomatous aspect,[1212,1214,1215] leiomyosarcoma,[1216] adenocarcinomas of enteric type,[1217,1218] squamous carcinoma,[1212] and erythroleukemia[1219] have all been reported to arise from intracranial, teratoma-containing germ cell tumors, and we have seen in consultation a mature pineal teratoma partially overgrown by malignant hemangioendothelioma. Whether the account of an intrasellar tumor having components of germinoma and Burkitt-like B-cell lymphoma reflects such somatic malignant change or a collision of unrelated entities is unclear.[1220] A carcinoid has been encountered within a teratomatous tumor of the spinal axis,[1221] though some argue that intraspinal "teratomas" are complex malformations[7] rather than true germinal neoplasms.[1222] Rarely, intracranial teratomas achieve extraordinary degrees of organization and contain fetus-like bodies.[1223] The designation of **intracranial fetus-in-fetu** has been applied to

these curiosities but is more exactingly restricted by some observers to cases of apparently abortive twinning in which one developing fetus is incorporated into the cranium of the other.[1224] While the spontaneous maturation of teratomas has been recorded,[1225] re-resection specimens composed entirely of fully differentiated somatic tissue elements usually derive from initially immature teratomatous neoplasms or mixed germ cell tumors subjected to adjuvant therapy. The apparent maturation in such circumstances may simply reflect the selective ablation of incompletely differentiated cellular components. The progressive, seemingly paradoxical enlargement of these ostensibly mature neoplasms has been referred to as the "growing teratoma syndrome." The formation and expansion of tumoral cysts may well contribute to this phenomenon, but Ki-67/MIB-1 assessment can demonstrate surprising levels of proliferative activity within the fully differentiated tissues of such recurrent lesions.[1226]

Embryonal carcinoma, **yolk sac tumor**, and **choriocarcinoma** may all arise within the CNS, but only rarely are these encountered in unalloyed form. Far more frequent is their presence within mixed germ cell tumors, which often contain elements of germinoma and teratoma as well. We again emphasize the importance of immunohistochemical assessment in the evaluation of such lesions. Specifically, screening for alpha-fetoprotein is critical if minor components of yolk sac tumor are not to be overlooked (bearing in mind, however, that teratomatous glands of enteric type may also label for this antigen) and assessment for CD30 expression is of great value in distinguishing embryonal carcinomas from other germ cell tumor types. SALL4 expression is also helpful in the identification of yolk sac tumors (as is glypican-3), which is a more sensitive marker than alpha-fetoprotein, but lacks comparable specificity as other germ cell tumors, including germinomas and embryonal carcinomas, also label for this stem cell transcription factor.[1209] The pathologist reporting a mixed germ cell neoplasm should specify the participating tumor types and their relative representation.

Histologic subclassification emerges from a number of multivariate analyses as bearing most heavily on CNS germ cell tumor prognosis.[1212,1227,1228] The best outcomes attach to pure germinomas in localized form (which are radiocurable in over 90% of cases, as well as chemosensitive) and to mature teratomas that can be completely resected. The spontaneous regression of germinoma has been recorded,[1229] a phenomenon that may well be mediated by the tumor-infiltrating lymphocytes characteristic of this neoplasm. Yolk sac tumors, embryonal carcinomas, choriocarcinomas, and mixtures thereof frequently resist both surgery and adjuvant treatment, carrying a high mortality, though aggressive regimens that include vigorous chemotherapy as well as irradiation have achieved survival rates of 60%–70% in this setting.[1211] These virulent lesions destructively infiltrate local structures and may disseminate via the CSF, as can the germinoma. Extraneural spread is a rare complication that includes spontaneous systemic metastasis (mainly to lung and bone) as well as seeding of the peritoneal cavity via ventriculoperitoneal shunts placed for relief of obstructive hydrocephalus. Some observers have found immature teratomas and mixed tumors composed mainly of germinoma and teratomatous elements to be associated with an "intermediate" risk of recurrence and progression.[1212] One analysis could not attach any prognostic significance to chromosome 12p status (either isochromosome formation or polysomy) in the setting of intracranial germ cell neoplasia.[1230]

Melanocytic Tumors

We have previously mentioned melanogenesis as a function occasionally exercised by nerve sheath tumors as well as central neuroepithelial neoplasms of varying types. The CNS and its coverings also host tumors posited to derive from dendritic melanocytes of neural crest origin that normally populate the pia-arachnoid. The latter are especially numerous over the ventral medulla and high cervical spinal cord, regions that often evidence a peppery discoloration on gross inspection, but the growths for which they are held accountable are by no means restricted to these areas and, while largely leptomeninges based, may be anchored to the dura mater or situated in the substance of the brain, spinal cord, or pineal gland. Most such lesions fall into one of several fairly homogeneous diagnostic categories. As described later, these include well-differentiated and relatively indolent tumors that are termed melanocytomas, as well as frankly malignant melanomas, either form occurring in localized mass-like or diffuse leptomeningeal form.[278] They may also constitute manifestations of a generalized neurocristopathy. The syndrome of **neurocutaneous melanosis** (known also as **Touraine syndrome** in its heritable, autosomal dominant form) is defined by the association of giant or multifocal nevi of congenital type with discrete meningeal melanomas or, more commonly, an unrestrained (and ultimately fatal) proliferation of melanocytic elements, often deceptively benign in appearance, throughout the subarachnoid compartment and within Virchow–Robin spaces.[1231,1232] The spread of this process to the abdomen via ventriculoperitoneal shunts placed to relieve obstructive hydrocephalus has been described.[1233] In addition, meningeal melanocytomas and melanomas (including cases with BRAF V600E mutation) have been reported in complex with nevus of Ota, characterized by congenital cutaneous, ocular, and retrobulbar soft tissue hyperpigmentation in a maxillo-ophthalmic trigeminal nerve distribution.[1234-1237] Intracranial melanoma has also been described in the setting of NF1.[1237]

Melanocytomas usually present in middle age or later adult life as circumscribed, extra-axial masses attached to the leptomeninges. Most arise along the spinal neuraxis (some in association with nerve roots), intracranial examples exhibiting a decided predilection for the posterior fossa and Meckel's cave.[278] Only exceptionally do such tumors involve higher levels of the intracranial compartment,[1238] a remarkable case confined to the lateral ventricular system having been described.[1239] Characteristic MRI findings include iso/hyperintensity on T1-weighted images, a hypointense (dark) profile on T2-weighted study—these features reflecting the paramagnetic properties of melanin—and homogeneous contrast enhancement.

Consisting grossly of tan–brown to coal-black tissue, melanocytomas are frequently composed of uniform spindle cells arrayed in fascicles and compact whorled nests (the latter accounting for the once prevalent perception of these tumors as pigmented meningiomas) (Fig. 43.143). Whorling may be centered on delicate stromal blood vessels, and cellular dehiscence often produces a pseudopapillary appearance at low magnification. Epithelioid forms may be admixed, but rarely do these dominate the histologic picture.[1238] Tumor cell nuclei may exhibit longitudinal grooving when spindled and typically contain centrally positioned eosinophilic nucleoli that are easily seen, but of relatively small diameter. Candidates for the diagnosis of melanocytoma should not harbor macronucleoli, evidence conspicuous nuclear atypia or pleomorphism, contain more than the (very) occasional mitotic figure, or exhibit necrosis.[1238] Cytoplasmic melanization is usually advanced, particularly at the periphery of whorled nests (which are often bordered by clustered melanophages), and can obscure all cytologic detail. Virtually amelanotic examples may be encountered but are exceptional. Ultrastructural studies will confirm the presence of mature melanosomes and may show basement membrane material (also demonstrable in type IV collagen immunopreparations) to incompletely invest some cellular processes or to surround groups of neoplastic melanocytes,[1240] though the extensive basal lamina formation about individual cells and complex cytoplasmic interdigitation characteristic of most melanotic schwannomas are foreign to the melanocytoma.

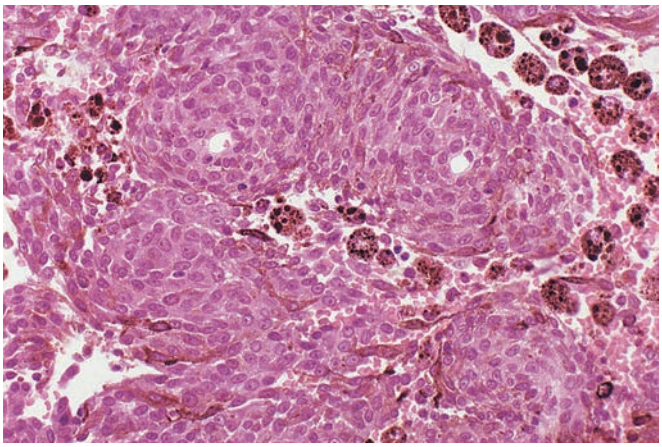

Figure 43.143 Meningeal Melanocytoma. The tendency to cellular whorling manifested by this example, resected from the cervical region of a 34-year-old man with a protracted history of neck pain and gait disturbance, accounts for the potential misclassification of melanocytomas as melanotic meningiomas. Note finely divided brown pigment in the cytoplasm of some tumor cells (as opposed to coarse pigment granules in melanophages), delicate and monomorphous nuclear features, lack of mitotic activity, and absence of necrosis.

Immunoreactivity for vimentin, S-100 protein, SOX10 (personal experience), and HMB-45 is regularly present in melanocytomas—in contradistinction to meningiomas—with melanocytomas also being EMA negative.[1238] Tumor cells may also label for MART-1 (Melan-A/A103), tyrosinase, and microphthalmia transcription factor.[1239,1241] A curious oncocytic (i.e. mitochondrion-rich) neoplasm of apparently melanocytomatous nature has been reported.[1242]

Melanocytomas are slowly expanding and generally amenable to surgical control if gross total removal can be accomplished. They have been reported to recur following resection and to invade adjoining neuroparenchyma, but the literature on this score is difficult to interpret, owing to their rarity and the application of nonuniform diagnostic criteria to these unusual lesions.[1238] The largest and most closely analyzed series to date included, under the rubric of melanocytoma, only well-differentiated leptomeningeal neoplasms with minimal cytologic atypism, small nucleoli, low mitotic counts (maximally one per 10 high-power fields and below this level in most cases), MIB-1 labeling indices not exceeding 2%, and no necrosis or involvement of CNS proper.[1238] None recurred following gross total excision or subtotal resection, irrespective of adjuvant radiotherapy (median follow-up period of 36 months). We have encountered, however, a fatal tumor meeting all of the foregoing criteria that widely seeded the CSF. One report further describes late local recurrence and hepatic metastasis complicating the course of a foramen magnum region melanocytoma.[1243] Neoplasms otherwise acceptable as melanocytomas can partially colonize the spinal cord (extending along perivascular spaces in association with florid Rosenthal fiber formation attesting to their chronicity) or may prove, in the main, to be intramedullary at operation.[1244] The latter, termed "**intermediate grade melanocytic neoplasm**" by some,[1238] may cause debilitating myelopathy and is far more likely than its wholly leptomeningeal counterparts to recur after resection but nonetheless pursue a protracted course. Given the morphologic attributes and relatively favorable clinical biology of most melanocytomas, it should come as no surprise that these have been likened to ocular melanomas of spindle A and B types, as well as to cellular blue nevi.

Malignant melanomas of the CNS may present as diffuse leptomeningeal growths ("**melanomatosis**") or discrete masses.[278] Proliferations of the former sort are particularly characteristic of childhood examples occurring as part of the **neurocutaneous melanosis** complex[1232] but may be encountered at any age and in the absence of unusual dermal nevi. Clinical manifestations of intracranial hypertension, cranial nerve deficits, a meningitic or subarachnoid hemorrhage-like picture, and diffuse leptomeningeal enhancement on CT or MRI are typical of **primary leptomeningeal melanomatosis**, which can be diagnosed by demonstration in CSF samples of tumor cells that are melanin laden or immunoreactive for S-100 protein and HMB-45.[1245] Death within months of diagnosis is the rule. Solitary variants of CNS melanoma (other than those complicating neurocutaneous melanosis) mainly afflict adults and become symptomatic by virtue of their compression or invasion of neural structures. These generally share with melanocytomas an origin in the pia-arachnoid and a predilection for the posterior fossa and intraspinal compartment that stands in contrast to the intracerebral distribution characteristic of melanomas metastatic to the central neuraxis. Still, meticulous search for a cutaneous, mucosal, or ocular primary must prove unrevealing before a malignant melanoma can be accepted as indigenous to the CNS. Spindle cell, epithelioid, and mixed cytologic features may be encountered, with evidence of malignancy including nuclear and nucleolar enlargement, coarse hyperchromatism, readily apparent mitotic activity, necrosis, and neuroparenchymal invasion.

High rates of regional recurrence, a potential for subarachnoid dissemination, and substantial mortality attach to localized CNS melanomas that cannot be surgically extirpated (unfortunately, this comprises a majority of cases). Some observers, however, have found a low incidence of CSF-borne metastasis as well as unexpectedly favorable outcomes following gross total resection in this setting, drawing parallels to the histology and behavior of spindle B, epithelioid, and mixed ocular melanomas.[1238]

It is noteworthy that melanocytic tumors of the central neuraxis occasionally defy ready placement in either the melanocytoma or melanoma camp, maintaining relatively reassuring cytologic profiles while exhibiting modest mitotic activity or invasive growth. These "**atypical**," "**borderline,**" or "**intermediate grade**" **melanocytic neoplasms** are capable of recurrence, but the magnitude of this risk is unclear.[1238] In addition, cases of frankly malignant melanoma apparently evolving from melanocytomas have been communicated.[1246] On record is an intracerebral **balloon cell melanoma** that may have arisen from a meningocortical melanocytic "nevus."[1247]

In terms of genetic work-up, primary melanocytic neoplasms of the CNS, particularly those of the melanocytoma group, may harbor activating somatic mutations of the G alpha q *(GNAQ)* and guanine nucleotide–binding protein, alpha-11 *(GNA11)* genes identical to those that have been identified in uveal melanomas (as well as cellular blue nevi and nevi of Ota[1092,1232,1248]). In further analogy to uveal counterparts, other common alterations include losses of chromosome 3 and 6q, potentially in association with inactivation of *BAP1* (though not yet encountered) or mutations of *SF3B1* or *EIF1AX* genes in those undergoing malignant transformation to melanoma.[1249] Mutations of the *TERT* promoter, *NRAS*, *BRAF*, and *KIT* genes are uncommon in primary CNS melanoma, in contrast to cutaneous and acral counterparts; as such, the finding of such mutations may be useful in suggesting a metastatic deposit, rather than primary disease. Nonetheless, most pediatric CNS melanomas, especially those associated with neurocutaneous melanosis are driven by *NRAS* mutations, with codon 61 as the site of most common involvement.[1250]

Paraganglioma

Primary **paragangliomas** of the craniospinal axis typically arise in either the jugulotympanic area or the region of the cauda equina,

presenting as delicately encapsulated intradural masses attached to the filum terminale or, less commonly, spinal roots.[278,1251,1252] Afflicted patients are usually in their fifth or sixth decades and commonly complain of either pulsatile tinnitus and/or lower cranial neuropathies for the former location or chronic low back pain that may be accompanied by sciatica, sensorimotor deficits, and sphincter disturbances in the latter. Functional silence is the rule, manifestations referable to the release of biogenic amines being most exceptional. Paragangliomas have also been reported to originate at cervicothoracic levels,[1253] in the pineal region,[1254] cerebellopontine angle,[1255] cerebellum,[1256] cerebrum,[1254] and sellar/suprasellar compartments.[1257] An intrasellar presentation in the setting of von Hippel–Lindau (VHL) disease is on record.[1258] Simple resection usually suffices to cure these uncommon neoplasms, which are generally indolent and noninvasive, but exceptional instances of recurrence in the face of ostensibly complete removal, erosion into neighboring bone, CSF-borne spread, osseous metastasis, and tumor-related death following inadequate excision are well documented.[1253,1259] One paraganglioma of the cauda equina reported for its unusual local regrowth and metastasis to cerebellum 22 years after gross total resection was subsequently found to have occurred in a patient with germline mutation of the succinate dehydrogenase gene-subunit D *(SDHD)*,[1260] an anomaly associated with hereditary paragangliomas of the head and neck. This example of late "recurrence" may have represented the syndromic development of multifocal primaries. Nevertheless, the jugulotympanic and cauda equina paragangliomas are far less likely to be familial than their systemic counterparts.

Apart from a more frequently realized potential to express cytokeratins and to transdifferentiate along ganglion cell and, rarely, schwannian cell lines (phenomena of no clinical import but recognized in the designation of some examples as "gangliocytic" or "ganglioneuromatous," respectively),[1261,1262] paragangliomas of the CNS are histologically, ultrastructurally, and immunophenotypically comparable to their systemic counterparts.[278] Accordingly, we do not describe these neoplasms here other than to emphasize that some depart from the classic arrangement of epithelioid tumor cells in cohesive nests ("Zellballen") and display, instead, spindled cytology and vaguely storiform growth or a vasocentric, pseudopapillary architecture superficially similar to that of the myxopapillary ependymoma but unaccompanied by mucoid change. Paragangliomas are readily distinguished from the latter (and from other tumors that may share a similar intraspinal topography, such as schwannomas and meningiomas) by virtue of their argyrophilia, content of dense-core granules on ultrastructural study, and immunolabeling of chief cells for SYN and chromogranin, while scattered sustentacular cells stain more intensely with S-100 protein than adjacent chief cells. A neoplasm of the cauda equina showing both ependymal and paraganglionic differentiation has been described[1263] but is a curiosity. Paragangliomas have also been reported to variably express NFPs, GFAP, serotonin, somatostatin, and other neuropeptides.[1253] Melanotic and oncocytic examples are on record,[1253,1264] one of the latter exhibiting locally aggressive growth.

Chordoma

Chordomas are familiar to all pathologists (and are given full description and differential diagnostic treatment elsewhere in these volumes) as destructive tumors of the clivus and sacrococcygeum that presumably originate from remnants of the primitive notochord persisting at these sites. Attention is called to entirely extraosseous, intradural variants that typically lie ventral to the brainstem and that present in adulthood by reason of progressive hydrocephalus, bulbar dysfunction, or intratumoral hemorrhage.[25] Chordomas have also been described as originating in the intraspinal compartment (including a remarkable example associated with the filum terminale[1265]), as arising from the tentorium,[1266] and as occupying the anterior third ventricle[1267] (though the actual identity of the last of these reported curiosities in relation to the chordoid glioma of the third ventricle is problematic, to say the least). The relationship of the intradural chordoma to the ecchordosis physaliphora,[1268] a notochordal heterotopia of comparable morphology that also favors the prepontine regions, remains a subject of debate.[1269] Although some lesions designated as intradural chordomas are clearly neoplasms and are likely derived from displaced notochordal remnants, others may simply represent outsized, symptomatic ecchordoses. Ecchordoses have been described as failing to exhibit the contrast enhancement typical of chordomas on neuroradiological assessment,[26] but the number of studied examples has been quite limited. Gross total excision of these circumscribed masses holds the promise of cure, whatever the terminology employed in their designation. Nuclear immunolabeling for brachyury readily distinguishes chordomas from chordoid meningiomas and chordoid gliomas, as well as mucinous adenocarcinomas and chondrosarcomas (including extraskeletal myxoid types).[940] The sections dealing with these entities may be consulted for other patterns of antigen expression useful in this regard, although note is also made of rare pediatric examples featuring anaplastic or poorly differentiated cytology.[1270] Such cases may be more aggressive, including extraneural metastasis. In common with AT/RTs, the *SMARCB1* gene is often inactivated in such cases, leading to loss of INI1 expression, although retained expression of brachyury aids in the diagnostic distinction.[1271,1272]

Hemangioblastoma (von Hippel–Lindau Disease)

Hemangioblastomas are familiar to most physicians as the hallmark of **VHL disease**, variants associated with this heritable condition constituting some 20%–25% of examples encountered in clinical practice.[278,1273] An autosomal dominant disorder caused by germline mutations of a tumor suppressor gene localized to chromosome 3p25–26, the VHL complex classically includes, in addition to hemangioblastomas of the CNS and retina, visceral cysts (particularly of the kidney, liver, and pancreas), renocortical carcinomas of conventional clear cell type, adrenal pheochromocytomas, and papillary cystadenomas of the epididymis. Affected individuals may also develop endolymphatic sac tumors of the inner ear; hepatocellular adenomas and carcinomas; paragangliomas; endocrine tumors of the pancreas, thyroid gland, and gastrointestinal tract; central neuroepithelial neoplasms; visceral angiomas; and papillary cystadenomas of probable mesonephric origin involving the female genital adnexae. Sporadic hemangioblastomas may also exhibit (though less constantly than VHL-associated cases) mutations or other inactivating abnormalities of the *VHL* gene, which appears to be normally involved in aspects of angiogenesis and cell cycle regulation, and share with syndromic examples frequent losses of chromosome 6q.[1274]

The large majority of hemangioblastomas arise within the cerebellum and produce the neurologic manifestations expected of an expanding posterior fossa mass, extracerebellar examples favoring the medulla and spinal cord (including its covering leptomeninges, nerve roots, and cauda equina).[278] No division of the central neuraxis is entirely immune (especially in the setting of VHL), and these curious neoplasms have rarely been documented to originate in the optic nerve, cerebrum, ventricular system, sella turcica, spinal extradural compartment, or at sites considerably further removed from the CNS (e.g. in association with the radial and paraspinal nerves, within the pancreas, kidney, adrenal gland, bladder, retroperitoneum, intestines, soft tissues, orbit, nasal skin, presacral region,

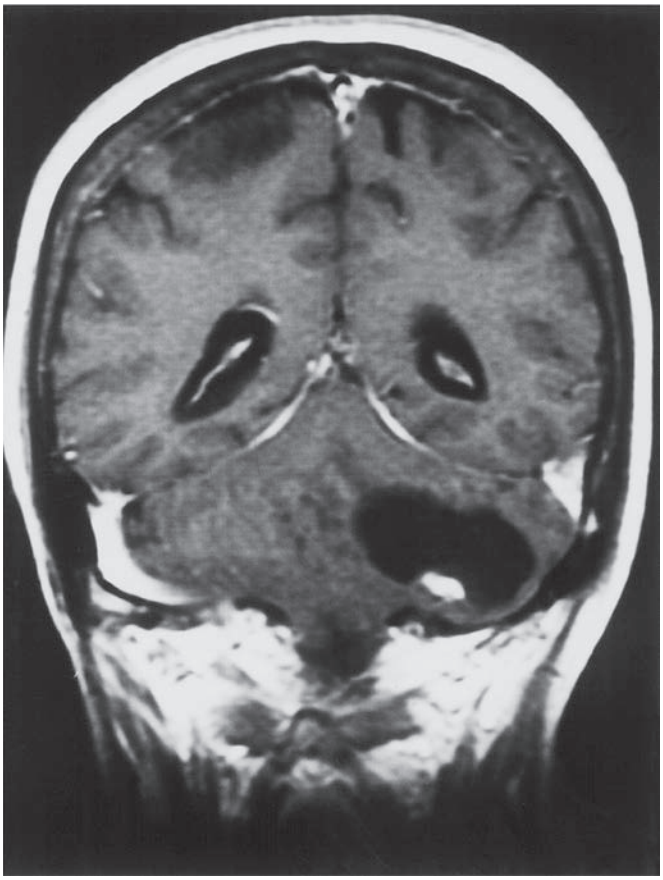

Figure 43.144 Hemangioblastoma. Most hemangioblastomas arise in the cerebellar hemispheres, where, as emphasized in this postcontrast injection magnetic resonance imaging, they present as diminutive, brightly enhancing, and sharply delimited mural nodules projecting into sizable cysts.

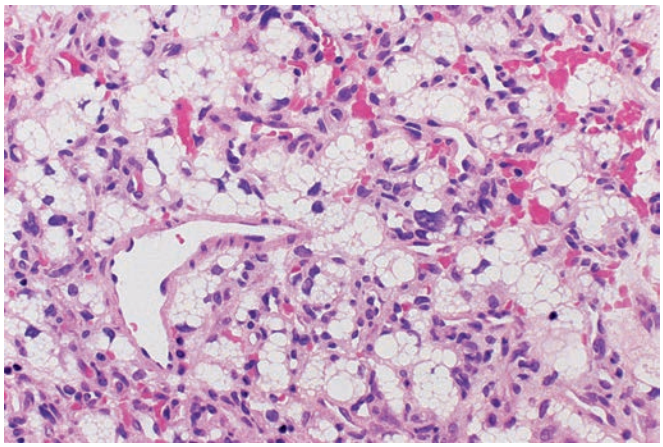

Figure 43.145 Hemangioblastoma. The neoplasm's defining "stromal" cells are most readily visualized when lipid accumulation imparts a foamy or vacuolated quality to their pale cytoplasm.

and maxilla).[1275-1278] Underlying VHL disease carries a special risk of multifocal (including retinal) hemangioblastomas and an increased incidence of extracerebellar primaries. The mean age at diagnosis of VHL disease–associated hemangioblastomas is approximately 30 years, sporadic examples peaking in incidence about a decade later.[278]

The hemangioblastoma often constitutes a sharply circumscribed mural nodule, at times diminutive, in what is otherwise a smooth-walled cyst or, at spinal levels, syrinx (Fig. 43.144). A clear demarcation from adjacent native tissues is typical of the hemangioblastoma, its characteristic reddish-brown and yellow coloration reflecting, respectively, a rich vasculature, and high lipid content. The former component, an anastomosing network of delicate, capillary-like channels supplied by feeding vessels of larger caliber, is responsible for the naming of this entity and its traditional classification as a primary vascular neoplasm. In fact, the sole neoplastic element of the hemangioblastoma—known as the "stromal cell"—inhabits the interstices between ramifying vascular arcades and is recognized by a pale cytoplasm often rich in neutral fats and, as a consequence, vacuolated or foamy in appearance (Fig. 43.145). Aggregation of stromal cells in cohesive nests and lobules lends to "cellular" hemangioblastomas,[1279] an epithelioid histologic presentation that invites confusion with metastatic renocortical carcinoma of clear cell type (these tumors, parenthetically, may collide in the setting of VHL disease[1280]), whereas their paucity in "reticular" variants results in a picture that may be misconstrued as simply angiomatous.

Potentially misleading as well is the tendency of stromal cells to exhibit conspicuous nuclear abnormalities, presumably degenerative, reminiscent of those encountered in neoplasms of neuroendocrine type. These changes, which may include unsettling karyomegaly, pleomorphism, and chromatin smudging, are typically unaccompanied by much, if anything, in the way of mitotic activity and are of no prognostic import. The odd hemangioblastoma will manifest mitoses in more worrisome number, but, again, this finding is not predictive of a malignant course. Regular features of additional note include infiltration by mast cells and, at the tumor–brain interface, a florid piloid astrogliosis replete with Rosenthal fibers but lacking the microcystic elements typical of the juvenile pilocytic astrocytoma. Foci of extramedullary hematopoiesis may be found in hemangioblastomas, some 10% of which present with polycythemia in consequence of erythropoietin production by stromal cells.[1281] Examples of hemangioblastoma arising in association with AVM have been reported[1282] and, as mentioned in our discussion of gliomesenchymal neoplasms, the designation "angioglioma" has been extended to rare tumors interpreted as containing a mixture of hemangioblastomatous and neoplastic glial tissues.

Investigations of stromal cell ultrastructure and immunophenotype have been the basis for widely divergent proposals regarding the cytogenesis of hemangioblastomas. The most recent data suggest a derivation from developmentally arrested cells that normally generate, in embryonic life, the blood islands recognized as loci of early hematopoietic activity (i.e. an origin from true "hemangioblasts"), to some extent vindicating the original name given to this tumor long before the biology was elucidated.[1283,1284] Under appropriate microenvironmental conditions, the cultured stromal cell similarly resembles the multipotent hemangioblast in its reported capacity to spawn erythrocytic, granulocytic, and endothelial elements. In this regard, it is of interest to note the frequent endothelial and sometimes, stromal cell GLUT1 immunoreactivity in hemangioblastomas.[1278,1285] Nonetheless, stromal cells do not label for such endothelial "markers" as CD31 and CD34 and only exceptionally have been described as expressing (and then in small numbers) Factor VIII–related antigen, other endothelium-associated proteins, or lectins.[278]

Additional aspects of hemangioblastoma immunophenotype are of practical significance. GFAP reactivity (a small subset of cellular variants excepted[1279]) is typically restricted to entrapped astrocytes or to stromal cells preferentially distributed along the tumor–neuroparenchymal border, a phenomenon that could well

reflect nonspecific adsorption or phagocytosis of antigen produced in adjoining gliotic tissues (the occurrence of hemangioblastomas outside the CNS [all GFAP negative] certainly militates against a glial histogenesis[1278]). That stromal cells often label for S-100 protein, NSE, and CD56/NCAM facilitates the distinction of hemangioblastomas from SFTs/HPCs and hemangiomas[1278,1286] (this staining pattern, along with reported immunoreactivity for a variety of neuropeptides[1287] and sightings of dense-core intracytoplasmic granules on ultrastructural study,[1288] have been previously taken as evidence that stromal cells may differentiate along neuroendocrine lines). Particularly important is the observation that stromal cells can exhibit immunolabeling with some anticytokeratins, but most fail to express EMA, the latter further distinguishing the hemangioblastoma from metastatic renocortical carcinoma and lipidized, angiomatous meningiomas. The latter further depart from clear cell carcinomas of renocortical origin in proving CD10 negative, in generally remaining unlabeled by the AE1/3 anticytokeratin "cocktail" and in being far more likely to exhibit widespread immunoexpression of inhibin-alpha, brachyury, and aquaporin 1 (a water channel protein).[1289-1291] While some have found the D2-40 antibody (raised against the M2A fetal gonadal antigen) to label many hemangioblastomas but not metastatic clear cell renal carcinomas,[1292] others have found this reagent lacking in both sensitivity and specificity for purposes of this distinction.[1291]

Hemangioblastomas typically manifest only modest MIB-1/Ki-67 labeling activity, median indices in one large study being less than 1% (range <1%–2%) for reticular and 4% (range <1%–8%) for cellular subtypes.[1279] These differences achieved statistical significance, but proliferative activity as assessed by this immunohistochemical method has not been shown to bear independently on outcome.

Hemangioblastomas are benign (WHO grade I) neoplasms that usually lend themselves to curative resection. Excised tumors may exceptionally recur, however, and patients afflicted with VHL disease are prone to develop additional primaries.[1273] Studies suggesting that cellular variants of hemangioblastoma may be somewhat more prone to recurrence than reticular forms require confirmation.[1279] CSF dissemination by histologically conventional hemangioblastomas ("hemangioblastomatosis") is a rare complication, often occurring years after ostensibly successful resection of cerebellar examples.[1293,1294]

Other Primary Tumors

A unique, **tuberous sclerosis–associated papillary tumor of the hypothalamus** has been reported.[1295] This low-grade lesion expressed cytokeratins 8/18 but not GFAP, SYN, NFPs, NeuN, adenohypophyseal hormones, or choroid plexus–associated antigens such as transthyretin, stanniocalcin-1 or Kir 7.1. The **CRINETS**[823] are intraventricular neoplasms of infancy and early childhood that have ribboned, trabecular, rosetted, and variably dilated tubuloglandular formations composed of poorly differentiated cells with low columnar profiles. Apical EMA labeling as well as immunoreactivity for vimentin, MAP-2C, SYN, and cytokeratins (focal) have been described, but cells do not express GFAP or Kir 7.1. While rhabdoid components have not been identified within these curious lesions, they fail to label for INI1 protein and can exhibit *SMARCB1* gene mutations, but otherwise have relatively stable genomes.[1296] The latter (and conspicuous proliferative activity) notwithstanding, CRINETs seem far more amenable to control by combined surgical and adjuvant means than neoplasms of the AT/RT group. The list of neoplastic oddities that have been encountered along the central neuraxis further includes a **malignant myoepithelioma** of the cranial dura,[1297] a spinal nerve root "**oncocytoma**" of indeterminate lineage,[1298] lumbar intradural masses representing misplaced **adrenocortical neoplasms**,[1299] and a number of **ectopic**, **suprasellar pituitary adenomas** situated in the third ventricle/hypothalamic region.[1300,1301] A survey of intracranial sarcomas previously cited in the discussion of nonmeningothelial, mesenchymal neoplasms includes an example of cerebral **ectomesenchymoma**—a tumor composed of ganglion cell and rhabdomyosarcomatous elements.[966]

Secondary/Metastatic Tumors

Secondary involvement of the CNS by direct extension or hematogenous metastasis is a common complication of systemic cancer and a phenomenon that frequently prompts diagnostic, as well as palliative, neurosurgical intervention. Because we have already touched on this subject in reference to lymphoproliferative and myeloproliferative disorders, this discussion is concerned only with invasion of the central neuraxis by solid tumors.

That neoplasms arising in and around the skeletal confines of the brain and spinal cord often come to impinge on these structures should come as no surprise. Examples include the pituitary adenoma with suprasellar or retrosellar expansion, the jugulotympanic paragangliomas that exploit neighboring foramina of the calvarial floor to present as a mass in the cerebellopontine angle, and sacrococcygeal chordomas that engulf the roots of the cauda equina. Ceruminous gland carcinomas and other neoplasms arising in the ear may occasionally billow into the middle cranial fossa to present as intracranial masses.[1302,1303] A substantial risk of local skull base destruction and invasion of contiguous meninges, potentially complicated by dissemination in the subarachnoid space, is seen in embryonal rhabdomyosarcomas originating in head and neck sites, particularly the nasopharynx, paranasal sinuses, and middle ear.[1041] Similarly situated carcinomas of mucosal or minor salivary gland derivation may behave in like fashion, but some of the latter instead track insidiously along regional nerve fiber bundles to achieve radiologically detectable proportions only within the cranial compartment.[1304,1305] Neglected, basal cell or squamous carcinomas of the face and scalp may also reach the CNS by permeating the calvarium or by propagation within perineurial spaces.[1306] The neurotropic spread of a malignant mesothelioma to the spinal cord via the brachial plexus is also on record.[1307] Cancers arising in more distant sites may secondarily infiltrate the nervous system after first metastasizing to juxtaneural structures, the vertebral column apparently serving as an especially important way station in this regard. Epidural spinal cord compression by malignant tumors, for example, is most frequently caused by carcinomas of pulmonary, prostatic, or mammary origin that have spread to the vertebrae, neoplastic cells commonly entering the spinal canal via the bony foramina traversed by vertebral veins.[1308] A similar sequence of events is postulated to account for the high incidence of vertebral and paravertebral metastases in cancer patients developing diffuse leptomeningeal carcinomatosis, principally a complication of adenocarcinomas derived from the lung and breast.[1309] This diagnosis is usually established by the demonstration of malignant cells on cytologic inspection of the CSF.

More common than instances of secondary CNS infiltration by contiguous malignant tumors are blood-borne neuraxial metastases.[1310] The principal offenders in this regard are carcinomas of the lung and breast, followed by malignant melanomas, renocortical carcinomas, and adenocarcinomas of colorectal origin.[278] Carcinomas of the lung are the systemic cancers most likely to present initially as intracerebral tumors, accounting for roughly half of all such cases and up to 85% of lesions exhibiting adenocarcinomatous histology. Increasingly effective management of systemic disease may account for perceived rises in the incidence of intracranial deposits from ovarian carcinomas[1311] and osseous or soft tissue sarcomas,[1312] but

the latter remain most uncommon as neurosurgical specimens. Sarcomas typically spread to the lungs en route to the brain but may give rise to isolated cerebral or dura-based metastases that, in exceptional instances, herald discovery of the primary tumor.[1313] The prominence in some series of alveolar soft part sarcoma giving rise to intracranial metastases[1314] is noteworthy, as it is one of the rarest tumor types among mesenchymal neoplasms. Mention should also be made of HIV-1–associated Kaposi sarcoma traveling to the cranial compartment,[1315] but this remains a curiosity even in the presence of widespread cutaneous and visceral involvement. Unusual, but well documented, is the transmission of maternal cancer (particularly melanoma) to the developing fetus via the placenta.[1316]

Although blood-borne tumor emboli may lodge at any level of the central neuraxis, a few useful generalizations can be made regarding the topography of metastatic lesions. Intramedullary metastases (i.e. those involving the spinal cord parenchyma) are rare,[1317] the great majority of metastatic deposits coming to lie in the supratentorial or infratentorial compartments. In general, the distribution of metastases within the latter conforms to their relative volumes and blood supply.[1318,1319] Thus, most lesions settle within frontoparietal cerebral tissues subtended by the middle cerebral artery (the dominant tributary of the circle of Willis); tumor emboli often lodge within the "watershed" zone representing the terminus of this vascular territory. For reasons that are not clear, colorectal, uterine, and renocortical carcinomas are over-represented among cancers seeding the cerebellum.[1319] Prostatic adenocarcinomas also exhibit a curious predilection for this structure when they metastasize to the brain, but their deposits are more typically skull and/or dura-based and only exceptionally involve the neural parenchyma proper.[1320] Dural metastases in women most often derive from mammary carcinomas.[1318,1320] As a rule, those tumors that frequently travel to the CNS (e.g. malignant melanoma and carcinomas of the lung) tend to produce multiple metastases, whereas cancers that only occasionally involve the brain (e.g. gastrointestinal adenocarcinomas) are often represented by solitary deposits. A clinical study in which nearly one-half of cancer patients with brain metastases were found to have unifocal lesions on neuroradiological assessment[1319] is noteworthy. A particularly compelling case for neurosurgical intervention can be made in this setting because metastatic lesions are usually compact in their growth patterns and thus lend themselves to excision. Patients who undergo surgical extirpation of single metastases (usually followed by radiotherapy) may be restored to many months (or even years) of useful function, live longer, and enjoy a better quality of life than those whose tumors are simply irradiated using conventional external beam techniques.[1318] Refined stereotactic and radiosurgical techniques are increasingly employed to address metastases and may improve the outlook for patients with deep-seated or multifocal lesions.

In contrast to the common glial neoplasms of adulthood, metastatic nodules tend to be sharply circumscribed and possessed of "pushing" margins (Fig. 43.146). Much of their mass effect may be derived from edematous expansion of neighboring white matter, often disproportionate to the small size of the offending deposits and usually more pronounced than the edema accompanying primary brain tumors. Most metastases are relatively superficial in location, straddling the gray–white junction to involve both cerebral cortex (thus the high incidence of associated seizures) and digitate white matter. Intralesional hemorrhage occasionally brings brain metastases to light, an especially common phenomenon in the settings of germ cell neoplasia, renocortical carcinomas, and melanomas, although given their higher frequencies overall, lung carcinomas remain in this differential of hemorrhagic metastases.

On histologic examination, most secondary cancers conform to the histology of their donor tumors and are readily distinguished from primary neoplasms of the brain or meninges on casual inspection. Features that aid in the segregation of poorly differentiated carcinomas from anaplastic gliomas include a cohesive architecture, abrupt interface with adjacent neural tissue, "peritheliomatous" pattern of tumor cell preservation about stromal blood vessels in cases evidencing coagulative necrosis, and absence of complex microvascular hyperplasia. The last, however, is an arresting feature of some metastatic small cell carcinomas derived from the lung. A confident diagnosis of metastatic carcinoma can often be made at the time of surgery by examination of smear or crush preparations in which the cellular cohesion of most epithelial neoplasms is preserved (Fig. 43.147). The reader is reminded that glial neoplasms of varied type, including fibrillary astrocytomas, may be labeled by antibodies to cytokeratins (particularly the AE1/3 "cocktail") and, on occasion, EMA.[330,1310,1321] It would appear that CAM 5.2, CK7,

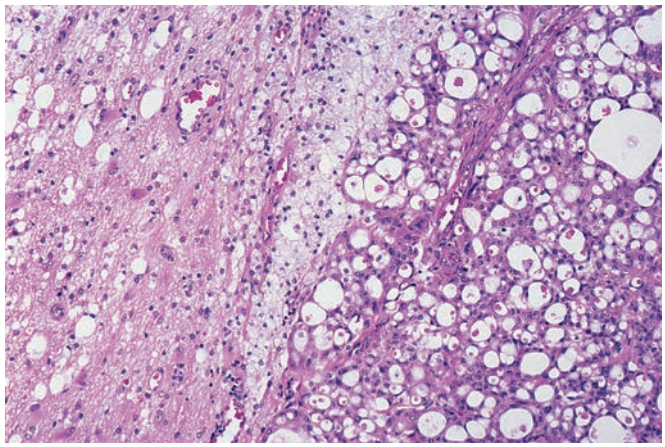

Figure 43.146 Metastatic Carcinoma. A cohesive growth pattern and clearly delimited tumor–central nervous system interface are hallmarks of neoplasms metastatic to the brain. The adenocarcinoma *(right)*, derived from a primary in the left lung, "pushes" against adjacent cerebral white matter.

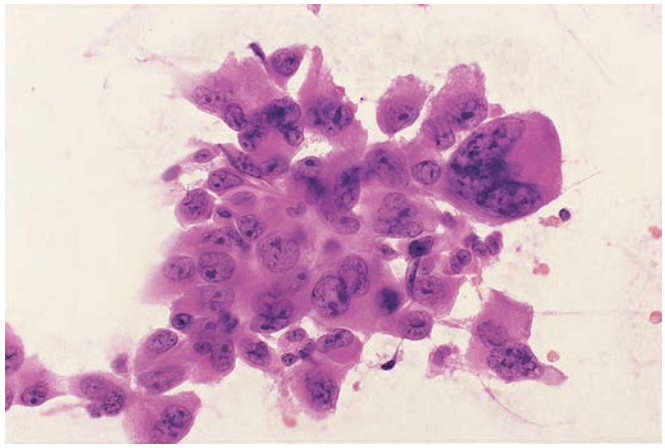

Figure 43.147 Metastatic Carcinoma. The cellular cohesion characteristic of most epithelial neoplasms and foreign to gliomas and lymphomas is generally maintained in cytology preparations, facilitating rapid intraoperative diagnosis. Note also the absence of cytoplasmic processes and presence of conspicuous nucleoli, the latter also alien to most neuroepithelial tumors, in this smear preparation of a poorly differentiated pulmonary adenocarcinoma that presented as a solitary, right frontal lobe brain mass.

CK20, and Ber-EP4 perform in more discriminating fashion as epithelial markers in this regard. GFAP labeling of metastatic carcinomas, while documented, is an exceptional event.[936,1322] As metastases usually remain faithful to the donor immunophenotype, immunohistochemical algorithms may focus the search for a systemic primary in the patient who does not have a history of cancer.[1310] Nuclear labeling for TTF-1, for example, should raise strong question of a metastatic deposit deriving from a differentiated carcinoma of the thyroid gland or nonsquamous carcinoma of the lung,[1323] although care must be taken regarding which clone is used, since a less specific version may also stain glioblastomas.[1324] Depending on the histologic findings in a given case, the differential diagnosis of a suspected metastasis may include, in addition to an epithelioid or sarcomatoid glioblastoma, the capillary hemangioblastoma, papillary ependymoma, choroid plexus tumor, and meningioma. Each of these is considered separately elsewhere in this chapter.

In closing, mention is made of certain unusual forms or presentations of secondary CNS involvement by malignant neoplasms. These include diffuse seeding of the periventricular tissues by metastatic small cell carcinomas of the lung[1325] (a pattern of spread mimicking the topography of some primary CNS lymphomas), miliary or "encephalitic" cerebral carcinomatosis or melanomatosis with widespread vascular cuffing by tumor cells on microscopic study but no conspicuous mass lesions,[1326] and occlusion of major cerebral vessels by neoplastic emboli resulting in ischemic stroke.[1327] Intracardiac tumors such as myxomas are the lesions most often implicated in cerebral infarcts secondary to neoplastic embolization, but this phenomenon has also been recorded in association with carcinomas arising in the head and neck, lungs, colon, and other visceral sites. As mentioned in the discussion of primary mesenchymal tumors of the CNS, deposits derived from occult atrial myxomas may be misconstrued as cerebral epithelioid hemangioendotheliomas.[1037] Atrial myxomas are also responsible for most neoplastic cerebrovascular aneurysms,[98] a metastatic complication of cancer noted in our prior treatment of vascular disorders. Yet another vascular complication of intracranial metastasis is subdural hemorrhage secondary to dura-based lesions.[1320]

Acknowledgments

Dr. Rosenblum: Dr. Rosemary Purrazzella, my wife, was patience itself and will hopefully find this useful in her own practice of surgical pathology (small reward).

Dr. Perry: Firstly, I am extremely grateful to my coauthor, Marc Rosenblum, for graciously allowing me to update his "baby" from the 9th edition of this text, which was already so beautifully written and illustrated that it made my role remarkably simple and pleasurable. I am also eternally thankful to my wife, Andrea, for her extraordinary patience and support during the many long hours I spent on this and similar projects.

44 Pituitary Gland

B.K. Kleinschmidt-DeMasters and Arie Perry

CHAPTER CONTENTS

Overview of sellar region masses, *2086*
- Embryologic origins of anterior and posterior pituitary gland, *2086*
- Anterior pituitary hormones and transcription factors, *2087*
- Normal pituitary cell types, *2089*

Pituitary adenomas, *2090*
- General features, *2090*
- Grading, Size, Invasiveness, and MIB-1 Labeling Rate (Designation of "Atypical" No Longer Utilized), *2094*
- Intraoperative evaluation, immunohistochemistry, and electron microscopy, *2096*
- Histologic features of adenoma subtypes, *2098*
- Ectopic pituitary adenoma, *2106*
- Pituitary apoplexy, *2106*

Mixed pituitary adenoma–gangliocytoma, *2106*
Pituitary carcinoma, *2106*
Rathke cleft cyst, *2106*
Hypophysitis, *2107*
Craniopharyngioma, *2107*
Pituicytoma, spindle cell oncocytoma, and granular cell tumor of neurohypophysis, *2108*
Metastatic tumors, *2110*

Overview of Sellar Region Masses

The overwhelming majority of sellar region masses are pituitary adenomas (85%), followed by craniopharyngioma (3%), Rathke cleft cyst (2%), meningioma (1%), and metastases (0.5%); other lesions such as hypophysitis, pituicytoma, spindle cell oncocytoma, and granular cell tumor of neurohypophysis are rare.[1] However, when these other sellar masses do occur, most so closely mimic pituitary adenoma on neuroimaging studies that the clinical/neuroimaging diagnosis is incorrect and thus, diagnosis falls to the surgical pathologist, necessitating discussion of their histologic features.

Today, immunohistochemistry (IHC) has largely supplanted electron microscopy (EM) for much of general surgical pathology, and while there is still a possible role for the latter in diagnosing very rare subtypes of pituitary adenomas, the chapter will be directed towards practicing surgical pathologists who generally do not have ready access to EM. Previous editions of this book,[2] as well as the World Health Organization (WHO) fascicle,[3] can be consulted for gross and EM images. Antibodies specific for anterior pituitary hormone immunohistochemical antibodies, as well as for those directed against transcription factors (pituitary transcription factor-1 [PIT1] for prolactin [PRL]-, growth hormone [GH]-, and/or thyroid-stimulating hormone [TSH]-immunoreactive tumors, steroidogenic factor-1 [SF1] for gonadotroph adenomas, TPIT for corticotroph adenomas), are becoming more widely utilized. However, not all are readily available, and several recently proposed alternate ways to use these antibodies in smaller panels for pituitary adenoma classification will be discussed.

Embryologic Origins of Anterior and Posterior Pituitary Gland

The anterior lobe (pars distalis) is derived from Rathke pouch, a tube of tissue which invaginates from the fetal oral (stomodeal) ectoderm anterior to the roof of the primitive mouth, forms by the fourth to fifth week of human gestation,[4,5] migrates dorsally towards the base of the brain, and comes in contact with the diencephalon. At the sixth fetal week, a down-pouching of the floor of the third ventricle and diencephalon forms and Rathke pouch detaches from the oral epithelium and becomes a separate structure. Cellular proliferation begins, with the ventral part of Rathke pouch giving rise to the pars distalis and the dorsal part to the pars intermedia.[5] The diencephalic diverticulum thereafter narrows and is obliterated.

The infundibular stalk and posterior gland arise from the infundibular anlage in the floor of the third ventricle.[6] Early in gestation, cells in the infundibular anlage and ependymal and subependymal cells of the fetal third ventricle manifest nuclear immunostaining for TTF1.[6] As early as 12 weeks' gestation, the posterior gland (neurohypophysis) shows nuclear TTF1 immunoreactive pituicytes (Fig. 44.1), and this is retained in adults (Fig. 44.2).[7] In contrast, the immature cerebral cortex and lateral ventricles show no TTF1 immunoreactivity; anterior pituitary (adenohypophysis) cells are

Abstract

The overwhelming majority of sellar region masses are pituitary adenomas (85%), followed by craniopharyngioma (3%), Rathke cleft cyst (2%), meningioma (1%), and metastases (0.5%); other lesions such as hypophysitis, pituicytoma, spindle cell oncocytoma, and granular cell tumor of neurohypophysis are rare. However, when these other sellar masses do occur, most so closely mimic pituitary adenoma on neuroimaging studies that the clinical/neuroimaging diagnosis is incorrect, and thus diagnosis falls to the surgical pathologist, necessitating discussion of their histologic features. Today, immunohistochemistry (IHC) has largely supplanted electron microscopy (EM) for much of general surgical pathology, and while there is still a possible role for the latter in diagnosing very rare subtypes of pituitary adenomas, the chapter is directed toward practicing surgical pathologists who generally do not have ready access to EM. Antibodies specific for anterior pituitary hormone immunohistochemical antibodies usually allow ready subclassification of pituitary adenomas, but subtyping is significantly augmented by the use of IHCs directed against transcription factors (PIT1 [pituitary transcription factor-1] for prolactin, growth hormone, and/or thyroid-stimulating hormone [TSH] immunoreactive tumors, SF1 [steroidogenic factor-1] for gonadotroph adenomas, TPIT for corticotroph adenomas). The terminology of "null cell" adenoma today is restricted to uncommon hormone-negative/transcription-factor negative adenomas. Thyroid transcription factor 1 (TTF1) shows nuclear immunoreactivity in the vast majority of pituicytomas, spindle cell oncocytomas, and granular cell tumors of neurohypophysis and further aids in diagnosis.

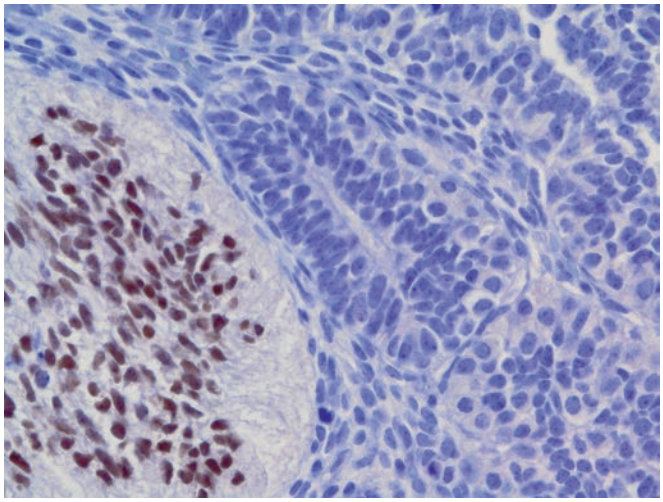

Figure 44.1 Fetal pituitary gland at 12 weeks' intrauterine gestational age shows TTF1 immunoreactive nuclei already identifiable in the posterior gland *(at left)* but not in the anterior gland *(at right)*.

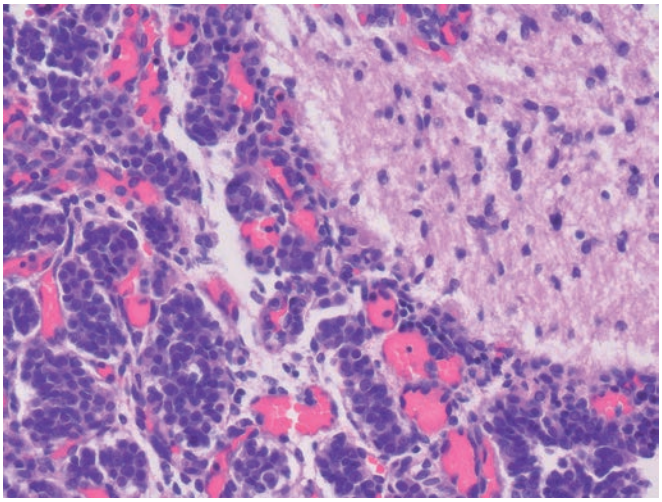

Figure 44.3 Fetal pituitary gland at 22 weeks' intrauterine gestation shows clear distinction between fibrillary posterior *(upper right)* and highly vascular epithelial anterior *(lower left)* portions of the gland.

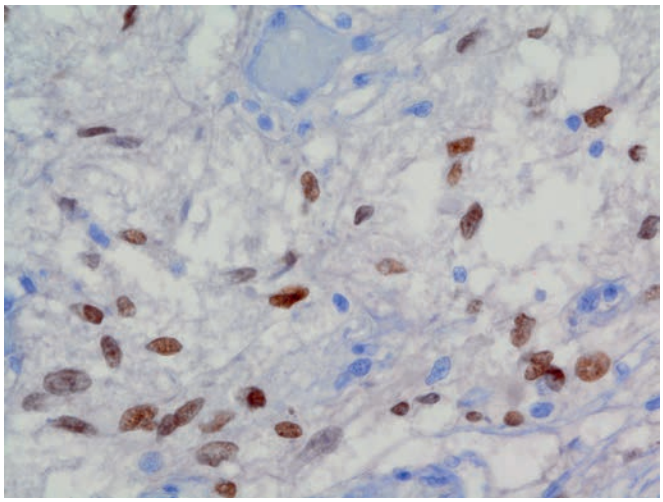

Figure 44.2 Adult posterior pituitary gland with nuclear TTF1 immunoreactivity; TTF1 IHC does not distinguish between normal posterior gland and TTF1 IHC(+) sellar region tumors, such as pituicytoma, spindle cell oncocytoma, and granular cell tumor of the neurohypophysis.

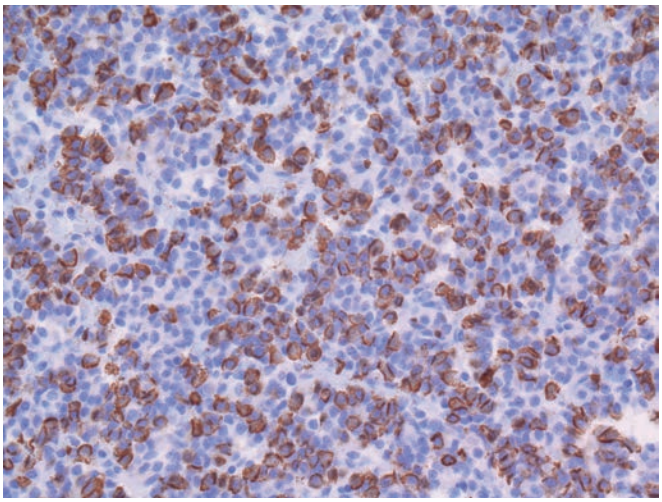

Figure 44.4 Fetal pituitary gland at 22 weeks' intrauterine gestation already shows immunoreactivity for anterior pituitary hormones, with growth hormone from the lateral wings illustrated here.

entirely negative, both embryologically and in adulthood.[6] Today it is recognized that 3 rare neurohypophyseal neoplasms, i.e., pituicytoma, spindle cell oncocytoma, and granular cell tumor, are derived from pituicytes and share this TTF1–positive lineage.[6–8] TTF1 IHC thus serves as an excellent diagnostic tool in differentiating these 3 tumors from TTF1 immunonegative pituitary adenomas, meningiomas, schwannomas, and other spindle cells masses.[9]

By the 14th week of human gestation, pituitary development is essentially complete.[5] The two parts of the pituitary gland are easily distinguished during fetal development (Fig. 44.3) and the anterior gland shows immunoreactivity for specific anterior pituitary hormones (Fig. 44.4). After birth, the gland grows rapidly, reaching a plateau at about 3 years of age; rapid growth again occurs between ages 10 and 13 years.[10] Modern neuroimaging allows distinction between adult anterior (adenohypophysis) and posterior (neurohypophysis) lobes (Fig. 44.5).

Anterior Pituitary Hormones and Transcription Factors

Six distinct hormone-secreting cell types appear during anterior pituitary gland development: the corticotroph (adrenocorticotropic hormone–secreting, ACTH), somatotroph (GH-secreting), lactotroph (PRL-secreting), mammosomatotroph parent cell for GH and PRL, gonadotroph (follicle-stimulating hormone- and luteinizing hormone-secreting, FSH and LH, in a single cell), and thyrotroph (TSH).[11] A number of different pituitary-specific transcription factors also play a role in the determination of pituitary cell lineages.[11,12] Of these, however, only PIT1 (associated with PRL-immunoreactive, GH-immunoreactive, and TSH-immunoreactive adenoma subtypes, Fig. 44.6) and SF1 (associated with gonadotroph lineage tumors, Fig. 44.7) are typically widely available for diagnostic use. Other hormones and transcription factors, such as TPIT, ER, and GATA2,

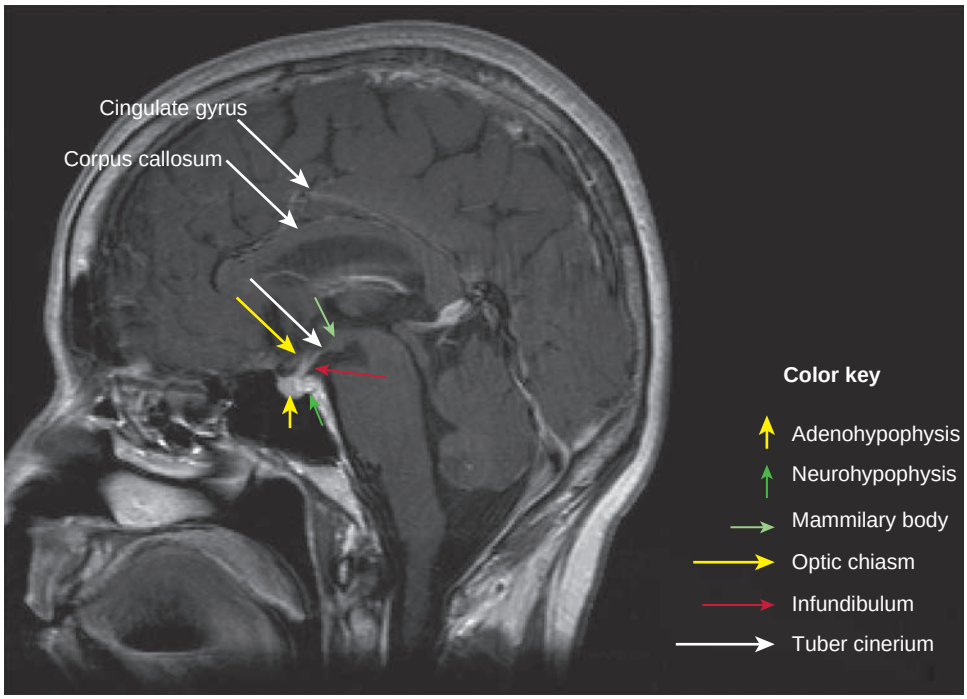

Figure 44.5 Sagittal magnetic resonance imaging (MRI) scan shows normal adult anterior and posterior pituitary and sellar region anatomy. The posterior pituitary "bright spot" is a normal MRI finding, referring to the intrinsically high T1 signal in the posterior pituitary attributed to the storage of vasopressin.

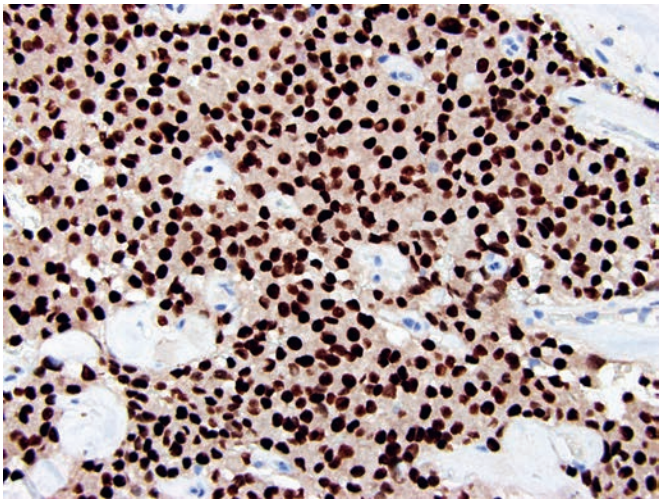

Figure 44.6 Diffuse immunoreactivity with PIT1 transcription factor identifies shared lineage in a large family of adenoma types: sparsely granulated prolactinomas, densely granulated prolactinomas, acidophil stem cell adenomas, densely granulated growth hormone adenomas, sparsely granulated growth hormone adenomas, mixed GH-PRL adenomas, thyrotroph adenomas, and plurihormonal PIT1-positive adenomas, formerly known as "silent type 3 adenomas."

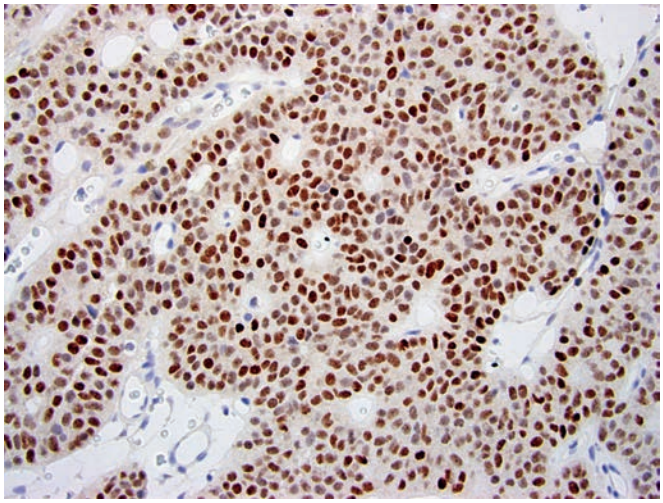

Figure 44.7 Steroidogenic factor-1 (SF1) is the transcription factor associated with gonadotroph adenomas, and the presence of nuclear IHC is the defining feature of this adenoma type, even if follicle-stimulating hormone (FSH) and/or luteinizing hormone (LH) IHC are not present. Null cell adenomas, in contrast, are SF1 negative, as well as negative for PIT1 and adrenocorticotropic hormone (ACTH).

are often only available at laboratories specializing in pituitary adenomas.[13]

Most pituitary adenomas show hormone expression profiles that recapitulate these expected developmental lineage pathways. Corticotrophs and gonadotrophs usually show only lineage-specific, relatively restricted hormonal expression driven by TPIT and SF1, respectively. For example, corticotroph cell adenomas usually show immunoreactivity for ACTH but none of the other hormone types. Thus, given the general unavailability of TPIT IHC in general practice, this family lineage is usually identified by ACTH immunoreactivity. However, a recent study showed that a minority (32/119) of hormone-negative adenomas with only a few (<1%) entrapped ACTH-positive cells were found to be Tpit immunoreactive, identifying them as clinically silent corticotroph adenomas.[14] Clinically, patients with these tumors had demographic and neuroimaging features similar to clinically silent corticotroph adenomas that have larger numbers

of ACTH-positive cells.[14] Thus, future categorization of corticotroph adenomas may require the use of more specific transcription factor immunostaining.

Gonadotroph adenomas manifest immunoreactivity only for FSH-β and/or LH-β, with or without alpha subunit (αSU) (all secreted by the same cell in the normal anterior pituitary gland), but not other hormone types. Estrogen receptor (ER) is also positive in gonadotrophs, but this antibody cannot substitute for FSH and LH in classifying gonadotroph adenomas, due to limited utility because of tissue fixation issues, as well as the fact that PRL-producing adenomas are also ER positive.[13] Currently, by definition, a gonadotroph adenoma must express FSH-β and/or LH-β, or, in the absence of availability of these antibodies, nuclear SF1, in order to distinguish it from other types of hormone-negative adenomas, although the majority of hormone-negative adenomas (i.e., negative for GH, PRL, ACTH, FSH, LH, TSH) are also, in fact, SF1-driven gonadotroph adenomas.[14]

In contrast, GH, PRL, and sometimes αSU and TSH are often coexpressed in PIT1-lineage tumors, due to their common transcription factor and precursor during fetal development—the "parent" mammosomatotroph cell. There is fluidity between four of the cell types (GH, PRL, mammosomatotroph, and TSH cells), which are able to reversibly transdifferentiate under physiologic or disease conditions[11]; this perhaps further explains the wide variation in expression of these hormone types in PIT1-driven adenomas. Table 44.1[13] and WHO 2017 Classification lists the lineages of pituitary adenomas, as driven by PIT1, SF1, and Tpit.

Table 44.1 Pituitary adenoma type by transcription factor family

Pituitary transcription factor (PIT1)	Densely granulated somatotroph (growth hormone) adenoma Sparsely granulated growth hormone adenoma Mixed growth hormone–prolactinoma Mammosomatotroph adenoma Sparsely granulated prolactin secreting (lactotroph) adenoma Densely granulated prolactin secreting (lactotroph) adenoma Acidophil stem cell adenoma Thyrotroph (TSH) adenoma Plurihormonal PIT1-positive adenomas (formerly silent subtype 3 adenoma) Clinically functioning GH/PRL/TSH plurihormonal adenomas with acromegaly and thyroid dysfunction
Steroidogenic factor (SF1)	Gonadotroph adenoma, with or without IHC(+) for FSH, LH*
TPIT	Densely granulated ACTH (corticotroph) adenoma Sparsely granulated ACTH (corticotroph) adenoma Crooke cell adenoma Clinically silent ACTH adenoma (either densely granulated, i.e., subtype I, or sparsely granulated, i.e., subtype II)
Transcription factor negative/unknown	Null cell adenoma†
Unusual plurihormonal types with hormonal combinations not readily explained by cytodifferentiation	Uncertain lineage

*Presence of SF1 defines gonadotroph adenoma even if hormone negative)
†Should be defined as SF1, PIT1, ACTH/TPIT IHC negative (TPIT IHC not as widely available); category severely reduced by use of transcription factor IHCs.

Normal Pituitary Cell Types

The normal anterior gland is arranged in relatively evenly sized clusters of cells, known as acini, which contain an assortment of cell types (Fig. 44.8) and are outlined by reticulin fibers (Fig. 44.9). Hormone cell types in the anterior gland are not equally distributed, with larger numbers of PRL- and GH-positive cells in the lateral portions (lateral wings) and larger numbers of ACTH-positive cells, and to a lesser extent TSH-positive cells, in the median mucoid wedge. IHC (+) cells are more diffusely distributed.

Anterior pituitary cells are immunoreactive for synaptophysin, and variably with chromogranin A and CAM5.2. Virtually all pituitary adenomas are diffusely synaptophysin positive (Fig. 44.10) but show variable immunoreactivity with the other two antibodies. Box 44.1[15–19] lists the histochemical and IHC profiles of anterior and posterior pituitary gland cells as well as for adenomas in general.

In contrast to the complex anterior pituitary gland, the posterior lobe is more histologically monotonous and composed of unmyelinated axons and specialized glia. The gland has a glial, fibrillary appearance with prominent delicate blood vessels. Small fragments of normal posterior gland are often found in surgical resection specimens of Rathke cleft cysts and occasionally in resection specimens for pituitary adenomas. Swellings of axons that store oxytocin or vasopressin can occasionally be discerned on H&E (Herring bodies) and are normal findings. Anti-neurofilament is the single best stain for confirming the identity of the axon-rich posterior gland (Fig. 44.11) and distinguishes it from other lesions (such as pituicytoma, pilocytic astrocytoma, and meningioma) that might mimic normal posterior gland. Although it may be alarming to the surgical pathologist when these fragments of posterior gland are found within a surgical specimen, it is important to remember that the posterior gland is a storage site, not a synthesis site, for these hormones. Preoperative presentation of pituitary adenomas with diabetes insipidus is distinctly uncommon, and postoperative posterior pituitary gland dysfunction after modern trans-sphenoidal resection is usually limited to transient diabetes insipidus that resolves after several days. Removal of these small fragments of posterior gland appears to have no long-lasting deleterious clinical effects in most patients.

The infundibular stalk is part of the posterior lobe and contains closely juxtaposed, thin-walled blood vessels that transport hypothalamic release and release-inhibiting factors to the anterior gland. When the infundibular stalk is compressed by a mass lesion, or undergoes any traumatic or circulatory disruption, the delicate, thin-walled vessels of the hypothalamic–hypophyseal portal system are pinched off and hypothalamic release and release-inhibiting factors do not reach the pituitary gland. Under normal physiologic conditions, the one anterior pituitary hormone that is more tonically inhibited than stimulated is PRL; the hypothalamic inhibiting factor is dopamine. Interruption of the infundibular stalk by any mass

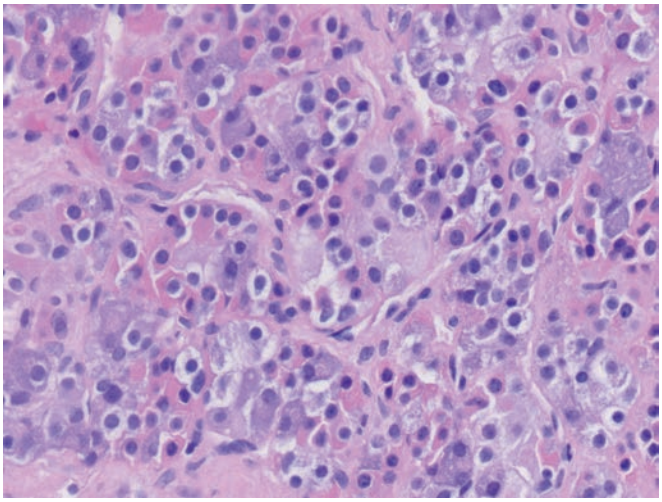

Figure 44.8 Normal anterior pituitary gland shows an assortment of cell types on H&E arranged in clusters known as acini; the different cell types vary in numbers between the lateral wings, where more GH and PRL cells are located, versus the median wedge where more ACTH cells are found.

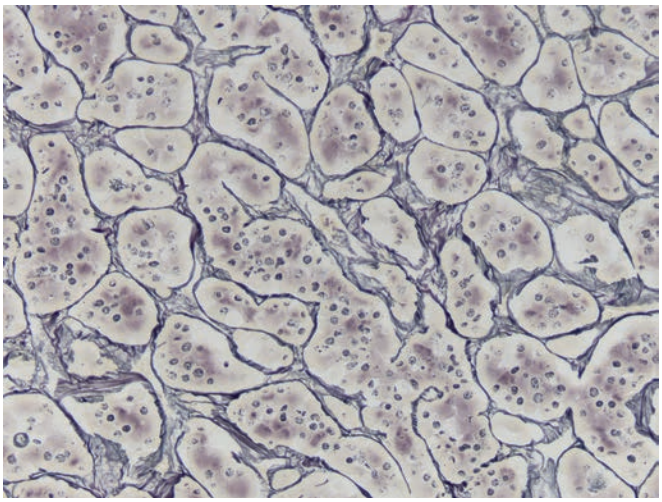

Figure 44.9 Reticulin stain better allows for appreciation of the normal acinar pattern of the anterior pituitary gland than does H&E staining.

lesion will abrogate passage of inhibitory dopamine to the anterior gland and result in hyperprolactinemia of a modest degree (30–200 ng/dL [or 250 ng/dL]).[20]

Pituitary Adenomas

General Features

Adenomas constitute 10%–15% of all intracranial neoplasms in most neurosurgery practices. The vast majority of adenomas are sporadic, and mutations in known oncogenes have little role in the pathogenesis of most sporadic pituitary adenomas.[21] The only somatic mutation that has been identified in a significant proportion of sporadic pituitary tumors is the *GSP* mutation, which causes constitutive activation of the cAMP pathway.[21] This mutation occurs in approximately 30%–40% of sporadic GH-secreting pituitary adenomas but not other adenoma types. Abnormalities in signaling and feedback pathways have been demonstrated in pituitary tumors, but they are unlikely to be the primary events responsible for sporadic tumors.[21] Pituitary adenomas are clonal, but no specific chromosomal alterations are characteristic. Increasing chromosomal imbalances have, however, been demonstrated in recurrent tumors.[22]

Familial adenomas account for 5% or less of all adenomas,[23–25] with germline mutations in the *MEN1* gene associated with multiple

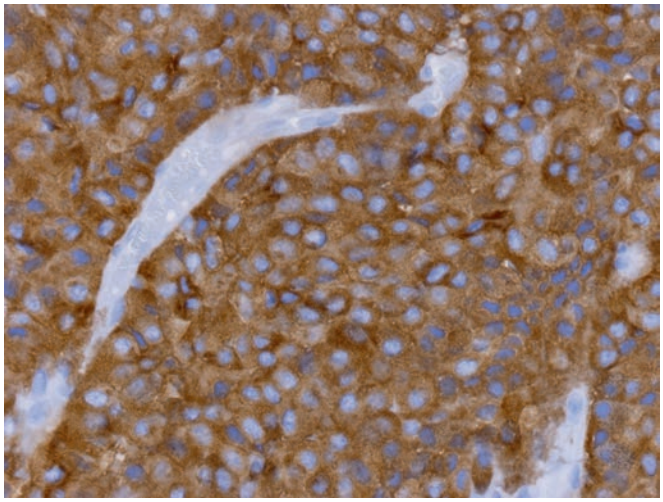

Figure 44.10 All pituitary adenomas, regardless of cell type, are diffusely immunoreactive for synaptophysin; blood vessels show lack of immunostaining in this image.

Box 44.1 Histochemical and general immunohistochemical profile for pituitary adenomas and normal gland

Reticulin: disruption of acinar pattern in all adenomas, expansion in rare hyperplasia

Periodic acid–Schiff (PAS): strongly positive in densely granulated ACTH adenomas

Cytokeratin 7: negative or only rare positive cells in almost all adenomas

Cytokeratin 20: positive in most densely granulated ACTH adenomas, negative in sparsely granulated GH adenomas; positive in all sparsely granulated but not in any densely granulated GH adenomas; positive in nontumorous Crooke cells in patients with hypercortisolism of any etiology

CAM5.2 (keratin 8/18): extensive and diffuse in all densely granulated ACTH adenomas, most densely granulated GH adenomas in perinuclear pattern, all sparsely granulated GH adenomas in a fibrous body pattern, most mixed GH-PRL adenomas, half of all prolactinomas, gonadotroph adenomas, and null cell adenomas

Synaptophysin: positive in normal anterior and posterior gland and all adenomas

Neurofilament: positive in axons in normal posterior pituitary gland

Glial fibrillary acidic protein, S-100: focally present in posterior gland; identifies nonhormone–containing folliculostellate cells in anterior pituitary gland

Chromogranin A: characteristic of gonadotroph adenomas; lacking in both PRL and ACTH functioning adenomas; poorly expressed in GH and GH-PRL functioning adenomas

Estrogen receptor: all prolactin IHC+ adenomas (sparsely, densely granulated lactotroph adenomas, acidophil stem cell, mixed GH-PRL, mammosomatotroph adenomas); gonadotroph adenomas (due to fixation issues can be focal and weakly positive)

Data from references[14–18].

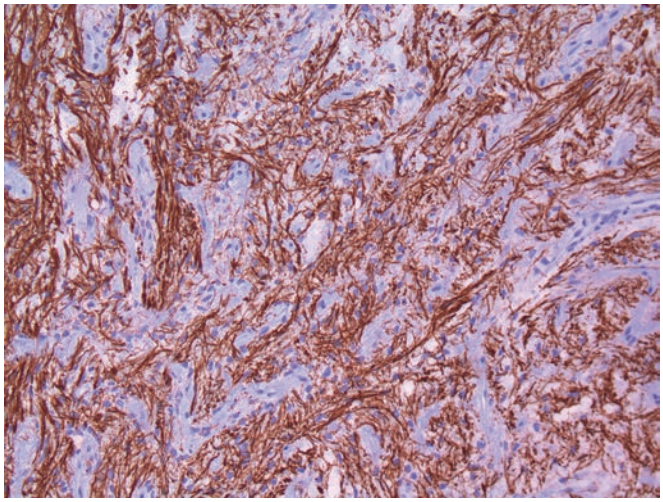

Figure 44.11 Normal posterior gland contains abundant axons, highlighted here by neurofilament immunohistochemistry; this can occasionally be very helpful in distinguishing normal posterior gland from spindle cell tumors such as schwannoma or meningioma that occasionally frequent the sellar region.

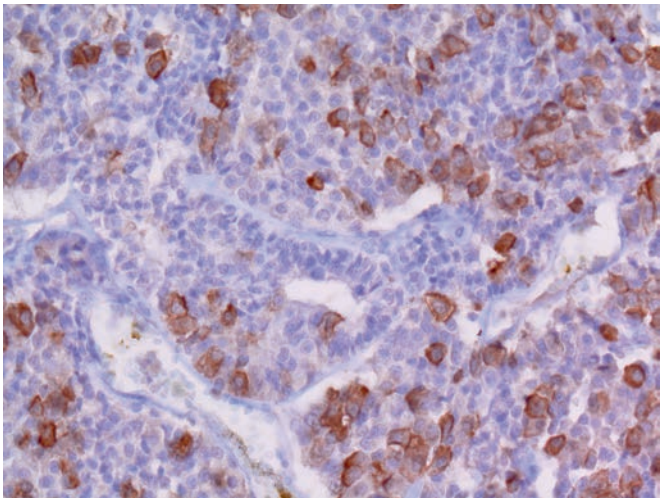

Figure 44.12 Pituitary blastoma is a very rare infantile pituitary tumor that is associated with *DICER1* mutation and is almost inevitably IHC(+) for ACTH, as in this example.

endocrine neoplasia (MEN) type 1 identified in 2.7% of individuals with apparently sporadic pituitary adenomas.[26] Pituitary adenoma predisposition syndromes include MEN 1 (gene *MEN1*, chromosome 11q13, results in all pituitary tumor types),[27] Carney complex (gene *PPKR1A*, chromosome 17q22–24, associated with GH- or PRL-secreting adenomas),[28] MEN 4 (gene *CDKN1B*, chromosome 12p13), and familial isolated pituitary adenomas (FIPA, gene *AIP*, chromosome 11q13.32).[23–25,29]

The practical issue for both pathologist and clinician is when to suspect/advise work-up for genetic mutations in a patient with a pituitary adenoma. While those with known multiple endocrine tumors and/or family history are obvious, it is becoming apparent that young patients with seemingly sporadic pituitary macroadenomas may be candidates for assessment. In one study of 174 macroadenoma patients of at least age 30 years, and without hypercalcemia or MEN 1-associated lesions, 12% had mutations of *AIP* or *MEN1* (8.6% and 3.4%, respectively). However, when pediatric patients (≤18 years old) were assessed, 22% (10/46 patients) had such mutations.[30]

No strong relationship to birth control pill use has been established. Endocrine end-organ failure is not related to pituitary adenoma development either, except in the rare instance of TSH hyperplasia in patients with longstanding hypothyroidism evolving into adenoma. Antecedent or concomitant hyperplasia with adenoma is exceedingly rare. Although hormone receptor mutations in pituitary cells is an attractive hypothesis for adenoma causation, at least in gonadotroph adenomas no activating mutations in the gonadotropin-releasing hormone *(GNRH)* receptor gene have been identified.[31]

Pituitary adenomas usually develop in the third to sixth decades, but pediatric examples certainly occur.[32] Infantile pituitary blastomas, which are rare lesions associated with *DICER1* mutations, are hormonally active and at least focally immunoreactive for ACTH (Fig. 44.12); however, these represent an entity distinct from pediatric pituitary adenomas.[33] Pituitary adenomas are not related to *DICER1* mutations.

Conversely, pituitary adenomas coming to neurosurgical resection at the other extreme of the age spectrum are not rare. In a retrospective study from 1992 to 2002, detailing patients aged 75 years or older who had symptomatic lesions requiring neurosurgical intervention, pituitary adenomas were the third most frequent tumor type.[34]

The relative frequency of the various pituitary adenoma types differs, depending on whether one is looking at autopsy or surgical material (Table 44.2). Ezzat et al. found that 22.5% of persons harbor pituitary lesions on neuroimaging studies, and 14.5% of autopsy pituitary glands contain microadenomas.[35] The most frequently occurring adenoma found as an incidental finding at autopsy is the PRL-secreting adenoma (Fig. 44.13).[36]

As PRL-secreting adenomas are now routinely treated chemically with dopamine agonists such as bromocriptine, Parlodel, or cabergoline, patients no longer come to surgery unless they are drug intolerant or have other mitigating circumstances. In one of the largest series of 3489 pituitary tumors from nine centers in Germany,[1] FSH/LH cell adenomas predominated in surgical material (see Table 44.2); this study, as in most, however, antedates use of SF1 IHC and numbers may actually be even larger. ACTH-producing adenomas were fourth in incidence, and TSH-secreting tumors were very rare. Many clinically nonfunctional/clinically silent adenomas classified in the past as "null cell" are now recognized, with improved IHC, to either show focal individual cells that are immunoreactive for gonadotrophic (FSH, LH) hormones[3] and/or express SF1 (see Fig. 44.7) and thus occur within the same biologic spectrum and lineage pathway as gonadotroph adenomas. Indeed, the majority of both clinically silent/nonfunctioning and hormone-negative adenomas express SF1.[14] As noted above, the use of SF1 IHC divides gonadotroph adenomas from other types of hormone-negative adenomas, and the use of TPIT IHC may further reduce numbers of true null cell adenomas, although reliable commercially available antibodies have been lacking to date.[14] Two or more adenomas arising within the anterior pituitary gland of a single patient have also been reported, but these multiple lesions within the same gland of a patient are more commonly recognized at the time of autopsy when the entire pituitary gland is available for histologic review.[1] Double adenomas within a single patient's pituitary gland are less commonly recognized in surgically resected material.

Particularly complex are those clinically functioning adenomas that result in acromegaly and hyperprolactinemia, as detailed in Table 44.3.[13] Except for dual GH and PRL elevations, generally, only one, or rarely two, hormones are produced in sufficient quantities to result in elevated serum levels and produce clinically discernible endocrinopathies. If the tumor is inefficient at producing hormones,

Table 44.2 Comparison of pituitary adenoma types at surgery and postmortem exam

ADENOMA TYPE	ADENOMAS COMING TO SURGERY (%) (*n* = 3403)[a]	SUBCLINICAL ADENOMAS POSTMORTEM (%) (*n* = 334)[b]
Densely granulated GH cell adenoma	9.2	0.90
Sparsely granulated GH cell adenoma	6.3	1.20
Sparsely granulated prolactin cell adenoma	8.9	39.5
Densely granulated prolactin cell adenoma	0.3	—
Mixed bicellular GH/prolactin cell adenoma	5.2	0.30
Mammosomatotroph adenoma	1.1	—
Acidophil stem cell adenoma	0.2	—
Densely granulated ACTH cell adenoma	7.2	8.08
Sparsely granulated ACTH cell adenoma	7.9	5.69
Crooke cell adenoma	0.03	0.30
TSH cell adenoma	1.5	0.60
FSH/LH (gonadotroph) cell adenoma	25.2	6.6
Null cell adenoma	19.8	23.1
Null cell adenoma, oncocytic variant	5.8	9.3
Plurihormonal adenoma, including plurihormonal PIT1-positive adenoma	1.3	2.7
Unclassified	2.1	1.8

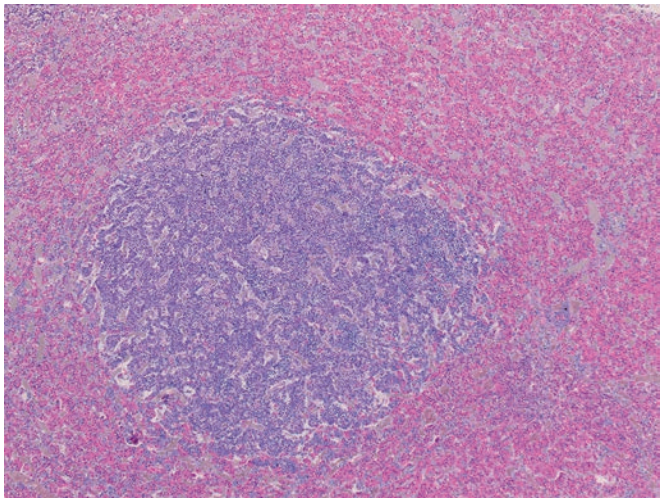

Figure 44.13 Incidental pituitary adenomas are a frequent finding not only on premortem neuroimaging studies but at the time of autopsy; this one was a prolactinoma.

the mass effects and hypopituitarism predominate because of compression of the optic chiasm and normal gland.

Necessity of Subtyping of Pituitary Adenomas

Subtyping of pituitary adenomas by hormonal type and subtype is still necessary, as pituitary adenomas are not a homogeneous entity and each subtype has its own clinical presentation, tendency for invasiveness, hormonal secretion pattern, histopathologic features, appropriate treatment, and varying response to medical therapies. Some adenomas are well-differentiated tumors that closely mimic their non-neoplastic anterior pituitary counterparts, such as densely granulated GH adenomas or the common sparsely granulated PRL adenomas (which resemble stimulated nontumorous lactotrophs by EM),[37] while others (such as sparsely granulated GH adenomas, acidophil stem cell adenomas, and the rare silent subtype 3, which is still impossible to diagnose confidently without EM) are less differentiated.

Not surprisingly, those adenomas showing advanced differentiation by EM more closely mimicking that of normal nontumorous anterior pituitary cells show greater response to medical therapies (i.e., prolactinomas with dopamine agonists, or densely granulated GH adenomas with somatostatin analogues) than do poorly differentiated tumors (rare densely granulated lactotroph adenomas, acidophil stem cell adenoma, or sparsely granulated GH adenomas).[13] Thus, subtyping predicts which adenomas are likely to be clinically responsive to medical therapy and may direct the use of alternate therapies, based on subtype. An example of the latter is that sparsely granulated GH adenomas that are not controlled with somatostatin analogs consistently respond to the alternate use of, or addition of, a GH receptor antagonist.[38] Subtyping does not usually dictate the use of adjuvant radiation therapy. Instead, recurrent, invasive aggressive adenomas that cannot be completely surgically resected may be candidates for radiation therapy or radiosurgery.[13,39] However, adjuvant radiation is generally not administered after the first resection, or simply because of subtotal resection. For instance, incompletely resected indolent adenomas, such as gonadotroph adenomas, can usually be managed conservatively without adjuvant radiation.[40]

Correlation of Immunohistochemistry With Clinical Features and Serum Hormone Levels

Some adenomas are strongly secretory and produce the hypersecretory syndromes of hyperprolactinemia, acromegaly/gigantism, or Cushing disease (lactotroph, somatotroph, and corticotroph adenomas, respectively [see Table 44.3]), while others are mostly clinically silent/nonfunctional, such as gonadotroph adenomas and null cell adenomas. Other rare types of silent adenomas (silent corticotroph, somatotroph, lactotroph, and thyrotroph adenomas) and variably

Table 44.3 Pituitary adenomas causing acromegaly or hyperprolactinemia

Pituitary Adenomas Causing Acromegaly/Gigantism, With GH, CAM5.2 Pattern IHC Pattern	
Densely granulated somatotroph (growth hormone) adenoma—**diffuse, strong GH IHC(+)**	**CAM5.2 perinuclear**
Intermediate/mixed/transitional growth hormone adenoma (behaves like densely granulated growth hormone adenoma—**diffuse, strong GH IHC(+)**	**CAM5.2 mostly perinuclear, fibrous bodies less than 70%**
Sparsely granulated growth hormone adenoma—**weak, focal GH IHC(+)**	**CAM5.2 fibrous bodies greater than 70%**
Mixed growth hormone-prolactinoma—**GH IHC(+) in varying degrees and distribution (small groups to scattered admixed cells); Prolactin IHC(+) stronger than in densely or sparsely granulated GH adenoma**	**CAM5.2 pattern depends on whether GH component densely or sparsely granulated. that is, subset of cells perinuclear versus dot-like fibrous body**
Mammosomatotroph adenoma—**diffuse, strong GH IHC(+), often with alpha subunit, PRL, sometimes FSH, LH**	**CAM5.2 mostly perinuclear, fibrous bodies rare if present at all**
Plurihormonal PIT1 positive adenoma**—rare aggressive subtype composed of monomorphic cells diagnosable by electron microscopy only; some being recognized as producing mild acromegaly, less commonly hyperthyroidism or mild hyperprolactinemia**	**CAM5.2 perinuclear in most, occasional fibrous bodies or negative CAM5.2**
Pituitary Adenomas Causing Hyperprolactinemia, With PRL, CAM5.2 Pattern IHC Pattern	
Sparsely granulated prolactin secreting (lactotroph) adenoma—**diffuse strong PRL, Golgi pattern**	**CAM5.2 often moderate, no fibrous bodies**
Densely granulated prolactin secreting (lactotroph) adenoma—**diffuse, strong PRL, may be perinuclear rather than Golgi**	**CAM5.2 no fibrous bodies**
Acidophil stem cell adenoma—**diffuse cytoplasmic PRL IHC(+) except in rare instances where Golgi pattern present; focal GH in approximately ½ of cases**	**CAM5.2 approximately 2/3 with fibrous bodies, usually scattered rather than prominent; sometimes CAM5.2 IHC negative or perinuclear pattern**

Adapted from Gomez-Hernandez K, Ezzat S, Asa SL, Mete Ö. Clinical implications of accurate subtyping of pituitary adenomas: perspectives from the treating physician. *Turk Patoloji Derg.* 2015;(31 suppl 1):4–17.

clinically functional adenomas (acidophil stem cell and plurihormonal adenomas made up of multiple cell types) also exist.[13,41] In some endocrinologically functional adenomas, serum level of hormone strongly parallels the size of the adenoma, as in sparsely granulated PRL adenomas (typical prolactinoma). In others, such as corticotroph adenomas associated with Cushing disease, tumor size does not correlate with severity of clinical features or serum hormone levels.[42] Indeed, florid Cushing disease can be produced by ACTH-secreting adenomas that are only millimeters in size. As is always the case, IHC is a test that is "static" in time, that is, it measures content within the cytoplasm at a singular time point but does not provide information regarding secretory rates of a hormone product, if any. Gonadotroph adenomas, for example, usually show immunoreactivity for FSH and/or LH but almost never produce a clinical hypersecretory condition; these tumors are in fact the most common subtype of clinically nonfunctioning/silent adenomas even if immunoreactive for FSH and/or LH[41] Hormone-negative pituitary adenomas, defined as negative for specific anterior pituitary hormones by IHC, are today recognized to be most commonly of gonadotroph lineage as well, as identified by positive immunostaining for the transcription factor SF1.[14]

At times, discordance between immunoreactivity and clinical features is actually helpful in subtyping. An example of the latter is acidophil stem cell adenomas, which show variable immunopositivity for prolactin and variable elevation in serum levels of prolactin, and almost always show a discordance between tumor size (often large) and serum prolactin levels (typically only modestly elevated) when compared to similarly sized sparsely granulated PRL adenomas (i.e., typical prolactinomas).[13] Correlations between subtypes of adenomas and neuroimaging features also exist.[43]

Clinically Nonfunctional/Clinically Silent Adenoma Versus Hormone-Negative Adenoma

While all hormone-negative adenomas (i.e., negative for the standard anterior pituitary hormones GH, PRL, ACTH, FSH, TSH, +/− LH) are clinically silent/clinically nonfunctional, the reverse is not true. Namely, adenomas may secrete such small amounts of hormone, as in gonadotroph adenomas with focal immunoreactivity for FSH and/or LH, that they are clinically silent. Alternatively, in some instances such as clinically silent ACTH adenomas, the adenoma may show immunoreactivity for ACTH, but the hormone product may be biologically nonfunctional. The most common type of clinically silent adenoma is the gonadotroph adenoma, followed by clinically silent ACTH adenomas. Clinically silent GH, PRL, and TSH adenomas are rare. Hormone-negative adenomas can be further subclassified as to lineage origin by IHC for transcription factors SF1, PTI1, and TPIT. Most hormone-negative adenomas are SF1 driven and are thus classified as gonadotroph adenomas. The second most frequent hormone-negative adenoma type is TPIT driven and

thus they are classified as corticotroph adenomas[14]; PIT1-driven hormone-negative adenomas are very rare.

Grading, Size, Invasiveness, and MIB-1 Labeling Rate (Designation of "Atypical" No Longer Utilized)

World Health Organization grade is not assigned to pituitary adenomas, since numerical grades have historically been utilized by neuroimaging colleagues for assessing CT and resonance MRI extent of disease.

The Hardy system from 1973, utilizing grade as assessed from CT and MRI studies, is as follows:

Grade I: Microadenomas, defined as intrapituitary lesions measuring less than 1 cm in diameter
Grade II: Macroadenomas, defined as at least 1 cm in diameter
Grade III: Locally invasive tumors (small or large) that cause bony erosion of sella turcica
Grade IV: Macroadenomas with invasion of extrasellar structures such as bone, hypothalamus, cavernous sinus.[44]

The Protocol for Primary Pituitary Tumors[44] does not require listing of the specific Hardy system grade but does include in the checklist the "Tumor Size (from imaging)" as microadenoma (<1 cm) or macroadenoma (≥1 cm).

Microadenomas remain confined to the sellar region[2] and may cause some degree of hypofunction of the normal anterior pituitary gland due to compression but seldom result in compromise of posterior pituitary gland function. Indeed, diabetes insipidus is quite uncommon with pituitary adenomas of any size.

Macroadenomas more severely distort adjacent tissues, with traction on the dura of the sellar floor or the dura overlying the sella (the diaphragma sella), causing headaches. Macroadenomas often grow directly upwards (Fig. 44.14), compressing the nearby optic chiasm in its midportion, an area containing crossing axons emanating from retinal cells within the medial retinal fields. Since these medial retinal fields are responsible for lateral visual fields, the classic symptom of optic chiasm midline compression in a pituitary adenoma is bitemporal hemianopsia. Macroadenomas may also extend into the sphenoid sinus and mimic primary nasopharyngeal neoplasms clinically and by neuroimaging features (Fig. 44.15).

As noted by Saeger et al. "hormonally active adenomas are usually diagnosed at an earlier stage than hormonally inactive tumors, the latter being diagnosed mostly due to the effect of local pressure exerted by the already existing large tumor." In the large German registry, 95%–100% of hormonally inactive tumors were macroadenomas.[1] Nearly 100% of gonadotroph, null cell, sparsely granulated GH adenomas, clinically silent ACTH adenomas, TSH adenomas, acidophil stem cell adenomas, and plurihormonal PIT1-positive adenoma are macroadenomas. These are all relatively clinically nonfunctioning (gonadotroph) or aggressive (sparsely granulated GH adenoma, silent ACTH adenoma, acidophil stem cell adenoma, and plurihormonal PIT1-positive adenoma). However, more indolent functioning tumors, such as densely granulated GH adenomas, also present as macroadenomas in more than half of instances, as do prolactinomas in males. Table 44.4 lists which tumor subtypes are usually microadenomas versus macroadenomas.

As previously described, some specific subtypes are more likely to present as microadenomas. Corticotroph adenomas producing Cushing syndrome present as microadenomas in 80% of cases.[1] Also usually presenting as microadenomas are prolactinomas in premenopausal females. As noted by Saeger et al. microprolactinomas, even in patients who refuse therapy, have a low tendency to develop into macroadenomas and therefore may represent a distinct subset of prolactinomas.[1]

Although the protocol for reporting primary pituitary tumors[44] does not require a special designation of giant adenoma, this term has been utilized for adenomas with a maximum size of greater than 4 cm (see Fig. 44.15). Macroadenomas, and especially giant adenomas, often show cysts and hemosiderin pigment either by neuroimaging or in the tumor specimen. Many giant adenomas

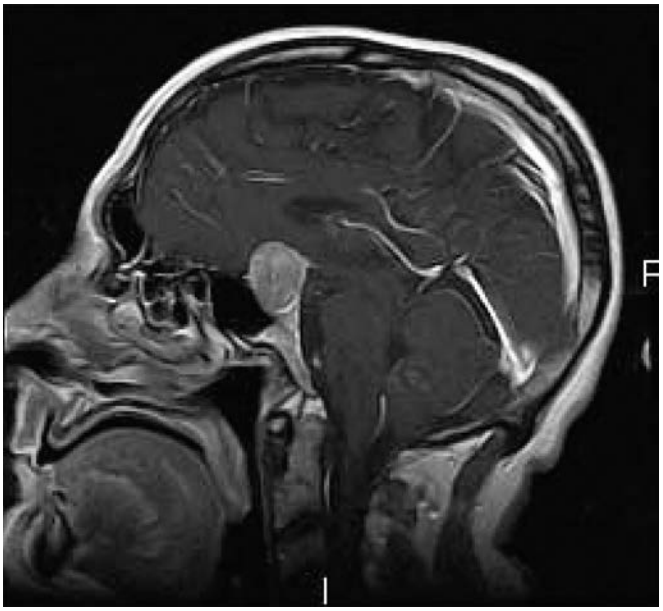

Figure 44.14 Pituitary adenomas more than 1 cm in greatest dimension are termed macroadenomas; compare with the sagittal MRI shown of normal gland in Fig. 44.5.

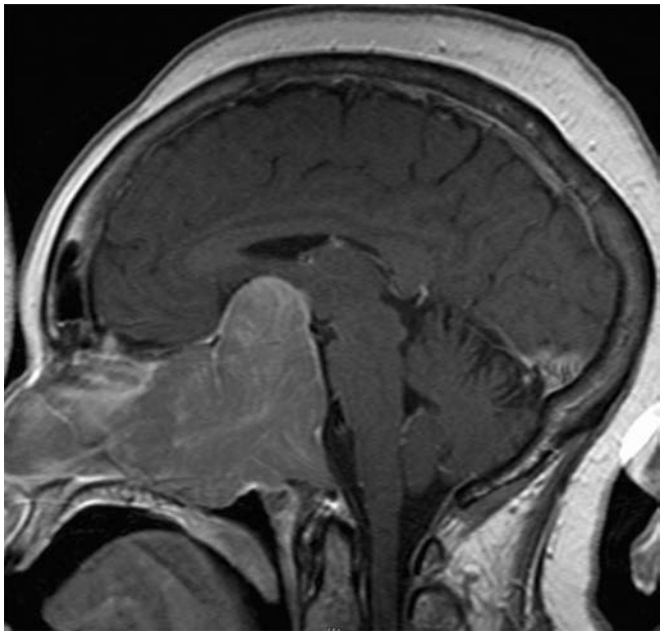

Figure 44.15 Giant pituitary adenomas, defined as greater than 4 cm, sometimes extend into the nasopharyngeal space, mimicking a nasopharyngeal carcinoma.

Table 44.4 Microadenomas versus macroadenomas by subtype

MICROADENOMAS	85% PRESENT AS MACROADENOMAS	NEARLY 100% PRESENT AS MACROADENOMAS
Prolactinomas in females	Densely granulated GH cell adenomas	FSH/LH adenomas
ACTH-secreting adenomas (80% microadenoma)	Sparsely granulated GH cell adenomas Plurihormonal adenomas Mixed GH/PRL tumors Prolactinomas in males	TSH adenomas Acidophil stem cell adenomas Null cell adenomas Silent type 3 adenomas*

*Currently referred to as "plurihormonal PIT1-positive adenoma."
Adapted from Saeger W, Ludecke DK, Buchfelder M, et al. Pathohistological classification of pituitary tumors: 10 years of experience with the German Pituitary Tumor Registry. *Eur J Endocr.* 2007;156(2):203–216.

are gonadotroph adenomas or prolactinomas in males.[45] Clinically silent corticotroph adenomas may also grow to this large size, as well as rarer clinically silent GH, TSH, and PRL+ adenomas.[43] Despite giant size, clinically silent corticotroph adenomas usually manifest a low MIB-1 index, whereas other subtypes producing giant adenomas may show elevated MIB-1 rates.[43] Thus, MIB-1 rates can be different in different subtypes of equal size, and proliferation rate does not parallel adenoma size in either macroadenoma or giant adenoma.

Invasiveness

Local invasion of extrasellar structures does not constitute malignancy in pituitary adenomas; only metastasis is sufficient behavior to connote pituitary carcinoma. Pituitary carcinoma is an exceedingly rare disorder, constituting only 0.12% of all pituitary region masses in the German series.[1]

Nevertheless, invasiveness does preclude gross total resection and therefore affects recurrence. Invasiveness is defined as extension into sellar floor bone, the cavernous sinus, and/or the diaphragma sella,[1] usually as assessed on preoperative neuroimaging studies. However, it differs among studies as to whether "invasion" is judged to be present based on preoperative MRI, intraoperative impression, or histologic features. Macroadenomas are more likely to be invasive than microadenomas.

Studies have verified that invasion is more likely to be identified microscopically by the pathologist than by imaging or by the surgeon intraoperatively.[46,47] Fragments of bone, evidenced as attenuated bone spicules (Fig. 44.16), can be recognized as entrapped within an invasive macroadenoma by the pathologist, and according to the new Protocol for Primary Pituitary Tumors,[44] should be reported. The presence of respiratory epithelium juxtaposed to adenoma tissue is a sign of invasion of the sphenoid sinus (Fig. 44.17). Dural invasion is best assessed by the pathologist when a designated dural sample has been submitted by the surgeon (Fig. 44.18). Invasion of the cavernous sinuses can only be accurately assessed by neuroimaging, since the surgeon avoids entering the cavernous sinuses at the time of surgery and histologic specimens from this area do not come to the pathologist.

The MIB-1 (i.e., Ki-67) labeling index (LI) in noninvasive tumors is typically less than 3%. The LI is generally higher in invasive adenomas but does not correlate perfectly. Invasiveness further correlates with histologic subtype in the sense that it parallels microadenoma versus macroadenoma status.[1] As an example of this correlation between adenoma size and invasive tendencies, ACTH adenomas, which are microadenomas in 80% of cases, are by far the least likely to show invasiveness.[1] Conversely, the majority of macroadenomas are invasive.

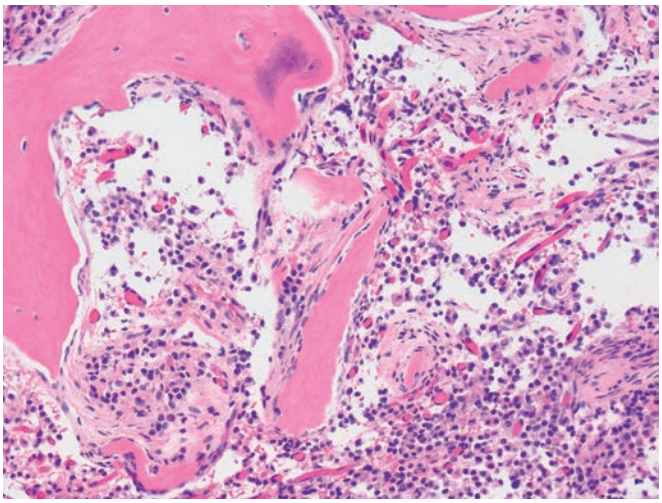

Figure 44.16 The protocol for examination of pituitary tumor specimens suggests that bony invasion seen microscopically should be "included in the protocol when known." This sparsely granulated growth hormone adenoma, a subtype known to be aggressive, encompasses bone spicules from the invaded sellar floor. However, even "benign," less aggressive subtypes may invade the sella.

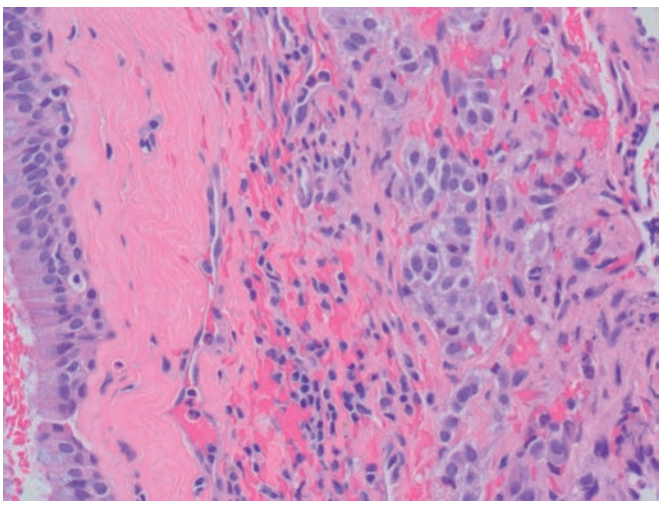

Figure 44.17 The protocol for examination of pituitary tumor specimens suggests that nasal sinus invasion seen microscopically should be "included in the protocol when known." Note the adenoma (at right) immediately adjacent to respiratory mucosa of the sinus *(at extreme left).*

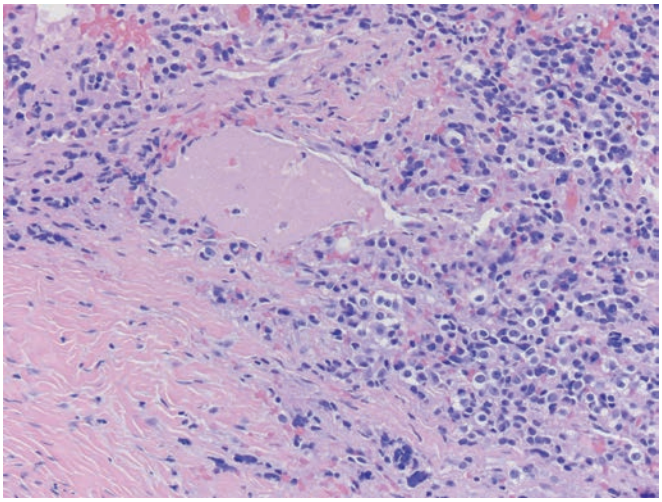

Figure 44.18 Dural invasion is far more commonly identified microscopically when the surgeon specifically submits a specimen of dura for examination; note the hypercellular adenoma *(upper right)* in contrast to the hypocellular dura *(lower left)*.

Designation of Atypical Adenomas No Longer Utilized in WHO 2017

The 2004 WHO Classification of Tumors: Tumors of Endocrine Organs suggested that "atypical adenomas" be defined as "excessive" p53 immunoreactivity, MIB-1 proliferative index greater than 3%, and increased mitotic activity.[3] Since that time, several studies in the past had tried to re-address histologic criteria that correlate with "atypical adenomas."[48–51]

Trouillas proposed a clinicopathologic classification system that combined proliferation rate (defined by 2 of the following 3 features: mitoses >2/10 HPFs; Ki-67 ≥ 3%; or nuclear p53 staining in >10 strongly positive nuclei/10 HPFs) and invasion as assessed by either histologic and/or MRI evidence of cavernous or sphenoid sinus invasion.[16] Of importance, "atypical" histologic features did not correlate tightly with subtype of adenoma, and furthermore, most of these studies looking at "atypical" features lack follow-up for recurrence rates in typical versus atypical adenomas (Table 44.5).

Several workers prior to the WHO 2017 publication called attention to the problems with the use of "atypical adenoma" for pituitary adenomas and suggested, instead, that "pituitary adenoma with elevated MIB-1 index, see comment," could be utilized as the diagnosis. They noted that such a comment should prompt closer clinical follow-up,[9] in order to avoid the automatic administration of radiation therapy after the initial resection. Radiation therapy is a consideration for tumors that recur in a relatively short interval after initial resection ("declare themselves" biologically) and cannot be cured surgically. Adjuvant radiation is especially considered in patients with hypersecretory subtypes where the endocrinologic dysfunction cannot be controlled medically, but that is a clinical decision and should not be based on histology alone.

The new 2017 WHO Classification system acknowledges that parameters in addition to labeling indices may be of prognostic significance in pituitary adenomas, including tumor size, clinical presentation, invasiveness, metastasis, or spinal spread (carcinoma), as well as IHC. The term "atypical" is no longer utilized. They note that Ki-67 labeling still has value and while Ki-67 is usually elevated throughout an adenoma, when focal areas show elevated labeling, those areas should be used for counts.

The use of p53 IHC in pituitary adenomas has been even more controversial than the use of MIB-1, and less standardized (see Table 44.5); some groups do not advocate using p53 IHC at all.[9]

Intraoperative Evaluation, Immunohistochemistry, and Electron Microscopy

If an intraoperative frozen section consultation is requested, work-up starts with choosing the technique that best allows for optimal preservation of material for permanent sections and IHC; freezing of tissue may abrogate some IHC results. Intraoperative touch preparations can be used in most cases instead of actual frozen sections, and demonstrate abundant exfoliation of a monotonous population of cells (Fig. 44.19). Generally, the number of cells shed onto the glass slide roughly parallels the size of the tissue fragment used for the touch imprint. Specifically, if very small amounts of tissue are available for touch preparation, the numbers of cells that will be found on the touch preparation by the pathologist performing the intraoperative consultation will be small, even though the touch preparation has been made from a true adenoma. Cytologic monotony of adenoma cells seen on the touch preparation versus cytologic heterogeneity of cells contrasts presence of adenoma versus nonadenomatous anterior pituitary gland for the pathologist. Diagnosis of pituitary adenoma at the time of touch preparation does not require the presence of mitotic figures, since only occasionally can they be identified (see Fig. 44.19), but accurate subtyping is not possible on touch imprints and awaits permanent sections and IHC. A caveat in using touch imprints is that a large number of cells can be shed onto the slide in instances where the surgeon has been extensively "slicing and dicing" the gland in an attempt to identify the adenoma; in such instances the reticulin investiture that surrounds acini is severely disrupted and a larger number of cells shed onto the slide than would ordinarily be seen with a nontumorous anterior gland. However, the shed population is a heterogeneous, mixed cell population of anterior pituitary gland cells, as noted previously.

If attempting to distinguish a pituitary adenoma from other sellar region masses, including metastases, it is important to remember that all adenomas show diffuse immunopositivity for synaptophysin (see Fig. 44.10). If the issue is normal anterior gland versus adenoma, then the single most informative test is a reticulin stain, since all adenomas show disruption of the normal acinar pattern; however, there can be some variation in the abnormal pattern of reticulin fibers that results (Figs. 44.20–44.22).

Immunohistochemical panels for subtyping adenomas are often utilized on a routine basis once the diagnosis of an adenoma is established. One proposed panel includes synaptophysin and CAM5.2 (for assessment of fibrous bodies, replacing the need for EM identification of fibrous bodies), plus the common specific pituitary antibodies (PRL, GH, FSH, TSH, ACTH). LH and αSU are less critical to assess, since FSH is almost always expressed to a greater degree than LH in gonadotroph adenomas.[9] Even if subtyping beyond this level is desired, EM is only infrequently necessary for classification. Indeed, in the German registry experience, EM had to be utilized in only 22 problem cases out of the total 3489 adenomas.[1] One possible practice is to set aside a small piece of tissue in glutaraldehyde that can be used in the unlikely event that EM becomes necessary.

An alternate, and perhaps more reasonable, panel has been proposed by McDonald et al. using PIT1, SF1, and ACTH IHC as an initial screen for pituitary adenomas.[52] Once the diagnosis of adenoma is established, those adenomas that are SF1 positive would be defined as gonadotroph, and no further testing would be necessary,

Table 44.5 Criteria for atypical adenoma in recent large series

AUTHOR	NUMBER OF ADENOMAS	NUMBER OF ATYPICAL ADENOMAS	SUBTYPES OF ADENOMAS	HISTOLOGIC CRITERIA FOR ATYPICAL DESIGNATION
Miermeister et al.[48]	4232	121 (2.9%)	Prolactin cell adenomas: 32 cases (32.7%) ACTH cell adenomas: 28 cases (28.6%) GH cell adenomas: 14 cases (14.3%) Null cell adenomas: 11 cases (11.2%) Mixed GH/PRL adenomas: 6 cases (6.1%) FSH/LH adenomas: 5 cases (5.1%) TSH adenomas: 2 cases (2.0%)	Minimum of 3 of 4 parameters had to be present: increased p53 IHC, MIB-1 index, mitotic activity, 10 representative high-power fields assessed; invasiveness assessed by combination of preoperative MRI, surgical reports, or confirmed by "clear" histology
Summary: Histologic criteria found to be most information for designation of atypical adenoma of cells (sensitivity for atypical pituitary adenoma 85%, specificity 93%); invasiveness (sensitivity 88%, specificity 53%) [invasiveness not limited to atypical pituitary adenoma and invasive status had lowest specificity for differentiating pituitary adenoma from atypical pituitary adenoma] No clinical follow-up to compare recurrence rates of atypical versus typical adenomas				
Yildirim et al.[49]	133	13 (8.9%)	Nonsecretory adenomas: 9 cases (69.3%) (not further specified as to subtype) Prolactinomas: 3 cases (23.1%) Somatotroph: 1 case (7.6%)	Patients had to have Ki-67 indices above 3% and "increased mitotic activity" to be called atypical pituitary adenoma (those with only elevated Ki-67 indices not called atypical), invasiveness assessed on neuroimaging
Summary: Of adenoma patients with recurrence, 11 were typical adenomas (11/133, 8.2%), 5 were atypical adenomas (5/13, 38.4%)				
Zada et al.[50]	121	18 (15%)	ACTH adenoma: 2 cases (11%) Gonadotroph adenoma: 1 case (6%)	p53 IHC not specified, MIB-1>3%, invasiveness judged by MRI
Summary: No clinical follow-up to compare recurrence rates of atypical versus typical adenomas				
Scheithauer et al.[51]	78 with follow-up	6 (14.7%)	Prolactinomas: 2 cases TSH adenomas: 2 cases GH adenoma: 1 case Silent subtype 3*: 1 case No clinically functional or silent ACTH adenomas or gonadotroph adenomas	
Summary: "MIB-1 and P53 LIs, those parameters related to tumor recurrences in the 2004 who classification of endocrine tumors, were not statistically significant in identifying atypical adenomas, i.e., tumors prone to recur."				

*Currently referred to as "plurihormonal PIT1-positive adenoma."

Data from Miermeister CP, Petersenn S, Buchfelder M, et al. since the percentage of FSH versus LH positive cells is not clinically relevant. Those with PIT1 immunoreactivity would then be explored further with IHC for GH, PRL, TSH, and CAM5.2. If TPIT becomes more widely available, this would also optimize initial immunohistochemical screening using transcription factors. A third system that blends the two previously discussed panels utilizes a panel containing GH, PRL, CAM5.2, TSH, ACTH, and SF1, avoiding FSH, LH, and αSU. A limitation of classification using any of these systems is the fact that TPIT antibodies are not widely available. Hence, without access to this antibody, a percentage of hormone-negative adenomas that would otherwise be recognized as being TPIT driven—despite having few or no ACTH positive cells—will be missed.[14]

Finally, in more sophisticated laboratories specializing in pituitary adenomas, ER-α and GATA2 can be utilized to further aid subtyping.[19] And while PIT1 lineage tumors may produce GH, PRL, and/or TSH, ER-α coexpression is further characteristic of the subset of PIT1 adenomas with PRL-production, whereas GATA2 coexpression is a feature of the subset of PIT1 adenomas that are thyrotrophs.[19] ER-α expression is also seen in gonadotroph adenomas that are PIT1 negative and SF1 positive. ER-α expression may be affected by tissue

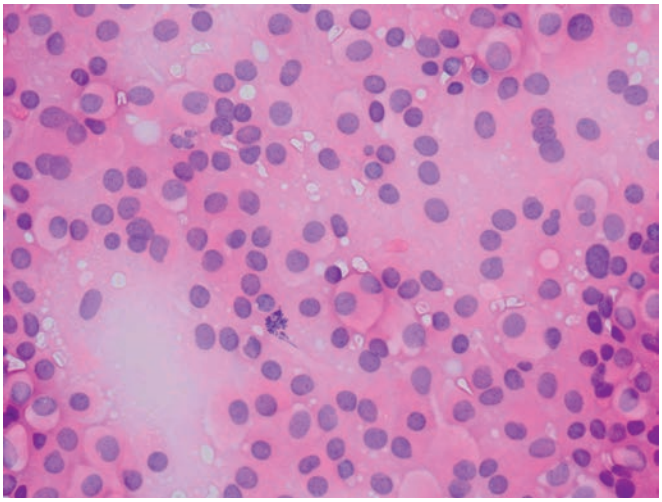

Figure 44.19 Touch preparations at the time of intraoperative consultation show abundant exfoliation of relatively monomorphic adenoma cells onto the slide, with the volume of cells shed roughly proportional to the size of the adenoma tissue fragment. Note the mitotic figure *(central)* in this example, although mitoses are not often identified. Indeed, if several mitoses are found on touch imprint, suspicion for an elevated MIB-1 proliferation index in the adenoma should be raised.

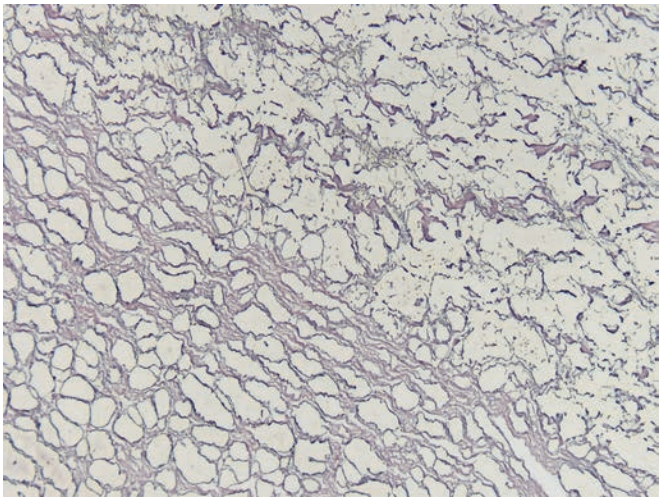

Figure 44.20 Reticulin stain is the single best histochemical stain for confidently identifying adenoma, although there may be some variation in the degree of acinar disruption/dissolution. In this microadenoma, note the disruption of the reticulin pattern *(upper right)* as compared to the sharp demarcation from intact anterior gland *(lower left)*.

fixation and thus cannot be substituted for PRL or SF1/FSH/LH IHC in identifying prolactinomas and gonadotroph adenomas, respectively.[18]

Other transcription factors present at even earlier embryologic time periods (Prop-1, Pitx2, and Hesx1) or later stages paralleling that of SF1 (DAX-1) and TPIT (NeuroD1)[40] are used only for research purposes currently. Prop-1 in particular is a transcription factor expressed immediately antecedent to PIT1 and GATA2 expression developmentally and therefore is a common precursor to both GH/PRL/TSH lineage and FSH/LH lineage pituitary cells. This common ancestor to both PIT1 and SF1 lineages may explain why αSU, FSH, and/or LH IHC expression can sometimes be detected in adenomas, such as densely granulated GH adenomas.

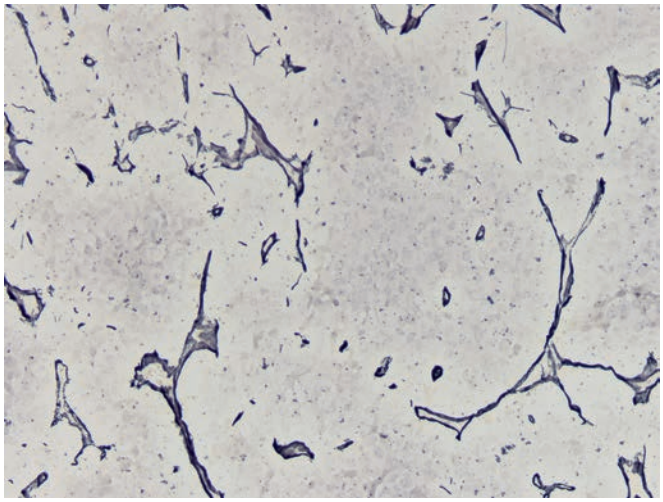

Figure 44.21 Reticulin stain in a macroadenoma usually shows preservation of reticulin fibers only around vascular structures.

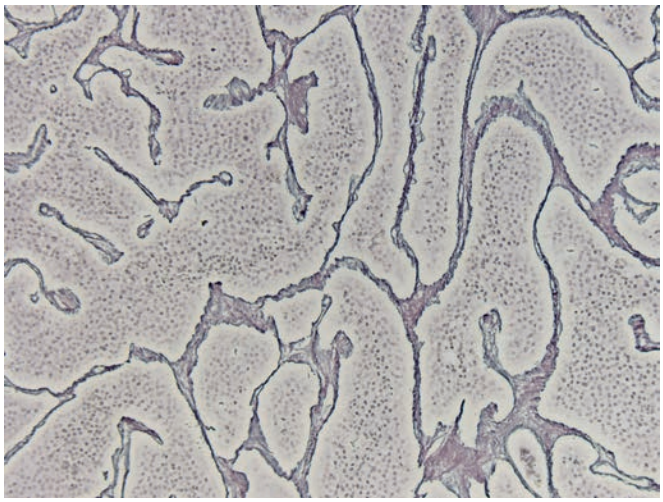

Figure 44.22 A variation of acinar disruption causing a macronodular pattern can be seen in some macroadenomas, especially gonadotroph adenomas; this is still an abnormal pattern (compare with Fig. 44.9).

Histologic Features of Adenoma Subtypes

Older classification systems that specify what percentages of pituitary adenomas are prolactinomas, GH adenomas, etc. are today outmoded since the published percentages antedate the development of IHCs for transcription factors. Specifically, the advent of SF1, PIT1, and, in some laboratories, TPIT, has allowed better lineage classification. For example, today it is recognized that the majority of hormone-negative pituitary adenomas, defined as immunonegative for antibodies directed against specific anterior pituitary hormones, and formerly called "null cell adenomas," are in fact immunoreactive for SF1 (the transcription factor that indicates gonadotroph lineage) while a few are immunoreactive for TPIT (the transcription factor that indicates corticotroph lineage). It is also relevant that the most common pituitary adenoma subtype seen at autopsy is prolactinoma, although with advent of medical therapies which obviate need for surgical intervention and resection of prolactinomas, these are not the most common adenoma type to come to surgery and hence the surgical pathologist. Thus, in surgical practice the most common subtype of adenoma encountered is gonadotroph adenoma–lineage tumors.

This is due to the fact that gonadotroph adenomas (with FSH and/or LH IHC) plus the formerly designated "null cell"/hormone-negative adenomas, and most of the tumors formerly called "oncocytoma," collectively constitute 30%–35%, followed by either prolactinomas or GH adenomas, depending on the surgical practice. Densely and sparsely granulated GH subtypes show near equal numbers. Corticotroph adenomas are fourth in frequency. Importantly, almost all other subtypes are less than 2% each of the total.

Gonadotroph Adenoma

Gonadotroph adenomas are usually clinically silent, indolent tumors found in older adults and are the most likely to come to surgical excision. Histologically, gonadotroph adenomas have a range of cytoarchitectural features, ranging from sheet-like, solid architecture (Fig. 44.23) to a macronodular pattern (Fig. 44.24). There is often focal hemosiderin deposition and cytoplasmic clearing (Fig. 44.25). More abundant eosinophilic cytoplasm or oncocytic change is sometimes seen in a subpopulation of adenoma cells (Fig. 44.26), but this should not be misinterpreted as a separate, so-called double adenoma. A nearly pathognomonic appearance is that of elongated cells surrounding blood vessels in a pseudorosette-like pattern that resembles ependymoma (Fig. 44.27); there may even be discohesion between the cells with preservation around the vessels yielding a pseudopapillary architecture (Fig. 44.28).

Positive immunostaining for nuclear transcription factor SF1 is sufficient to diagnose gonadotroph adenoma (see Fig. 44.7). If additional immunostaining is performed for FSH (Fig. 44.29), LH (Fig. 44.30), and αSU, the positive staining is characteristically quite patchy and focal. FSH IHC is much more likely to be expressed in isolation than LH. This regional diversity for hormone expression in only a subpopulation of cells contrasts with the diffuse immunoreactivity

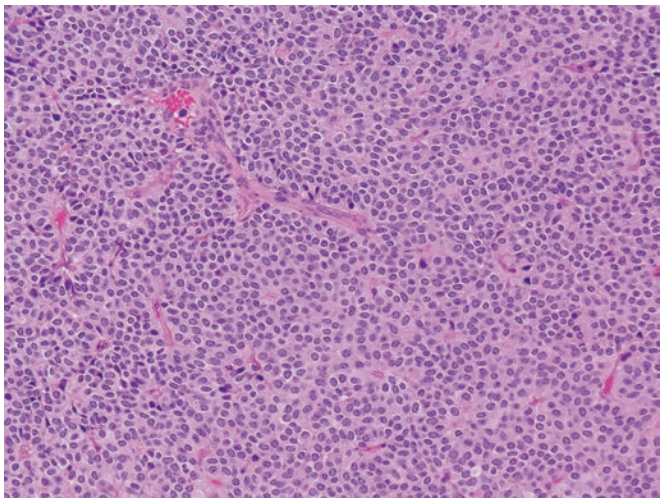

Figure 44.23 Gonadotroph adenomas manifest several different architectural patterns, including the sheet-like arrangement of cells shown here.

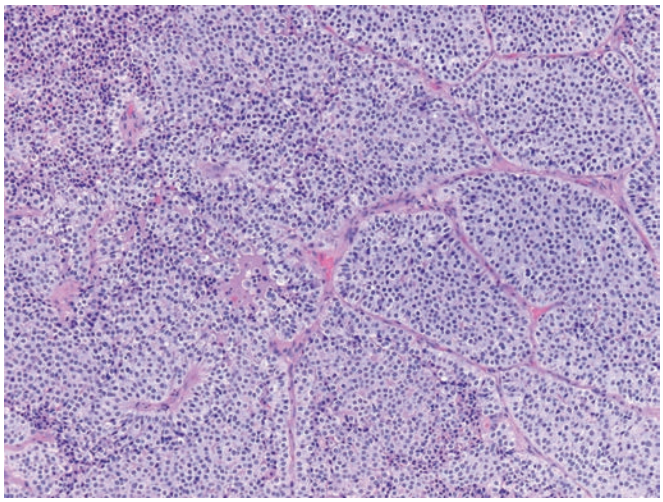

Figure 44.24 Gonadotroph adenomas may show a macronodular pattern; compare this image with the reticulin stain illustrating this pattern in Fig. 44.22.

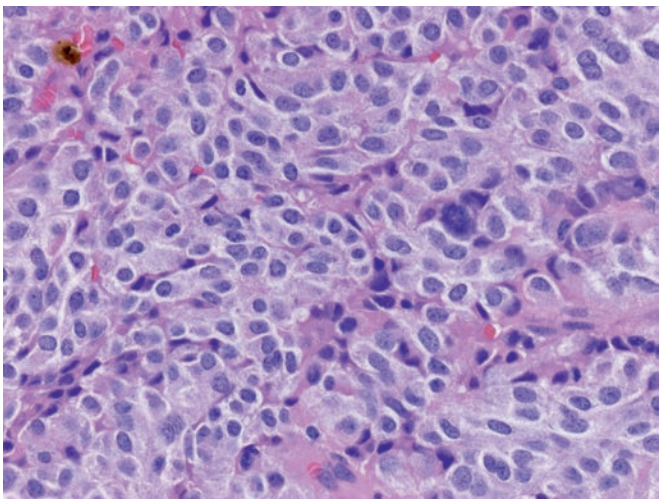

Figure 44.25 Gonadotroph adenomas occasionally have clear cytoplasm. This example has some degree of nuclear pleomorphism; all adenomas can contain occasional cells with nuclear enlargement and hyperchromatism, and this is of no prognostic importance.

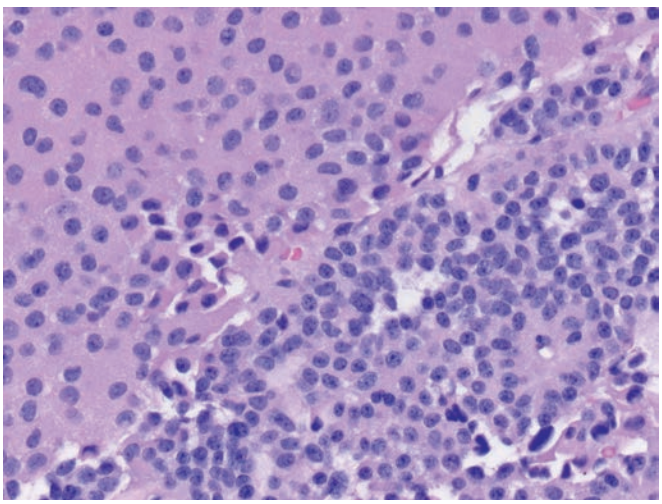

Figure 44.26 Gonadotroph adenomas frequently contain subpopulations of cells with abundant oncocytic cytoplasm *(upper left)* and cells with scant chromophobic cytoplasm *(lower right)*. This dichotomous population should not be misinterpreted as a "double" or "dual" adenoma since the same transcription factor (SF1) and/or FSH/LH immunostaining is seen in both components.

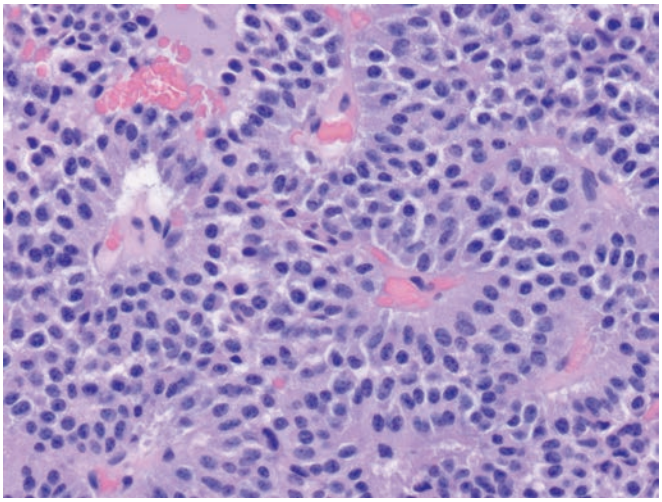

Figure 44.27 Gonadotroph adenoma may mimic ependymoma with perivascular structuring of adenoma cells around blood vessels.

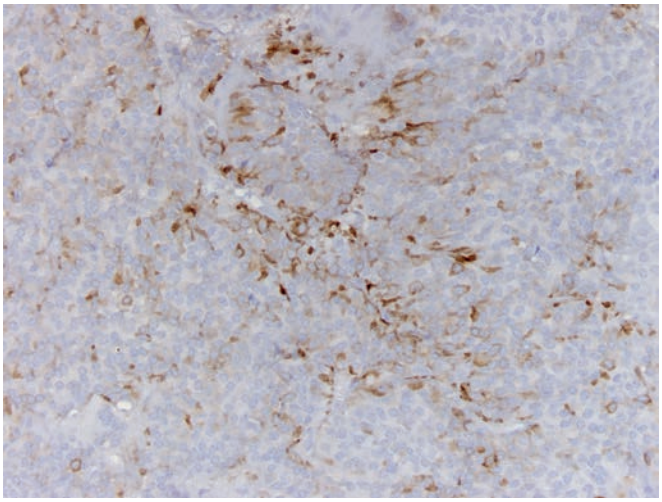

Figure 44.29 Gonadotroph adenomas may show patchy FSH positivity but never diffuse staining as in prolactinomas or densely granulated GH or ACTH adenomas.

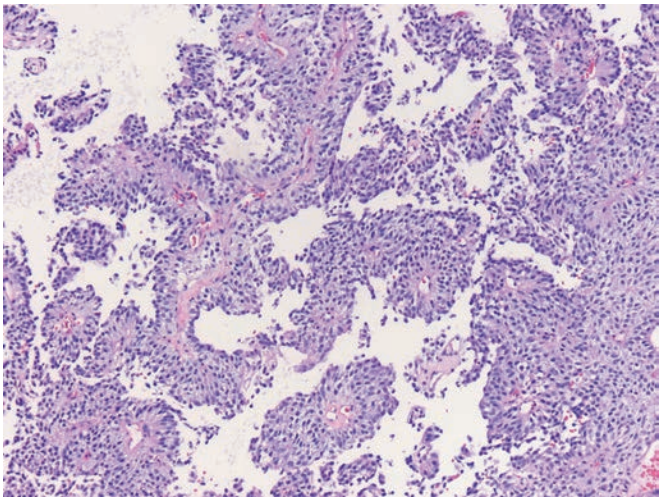

Figure 44.28 Gonadotroph adenoma often shows discohesion of cells, leaving the preserved cells clustered around blood vessels and forming pseudopapillary patterns.

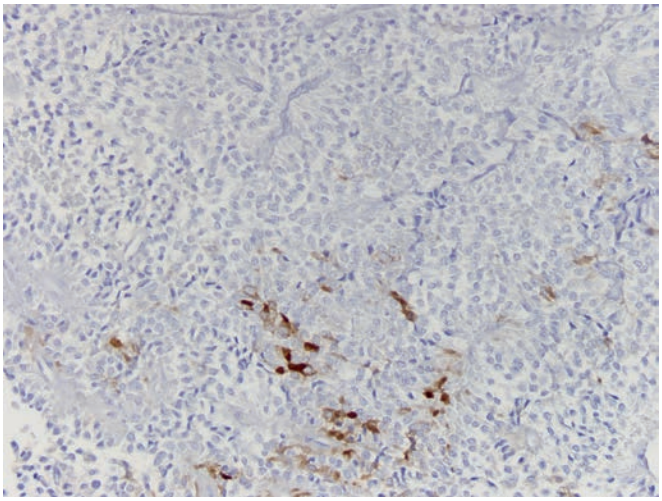

Figure 44.30 Gonadotroph adenoma shows patchy LH IHC(+), but this is usually in a smaller subpopulation of the adenoma cells than is FSH IHC(+), or may not be present at all.

pattern seen in most prolactinomas, densely granulated GH adenomas, and densely granulated ACTH adenomas.

Hormone-Negative Adenoma

Hormone-negative adenomas (i.e., negative for PRL, GH, ACTH, FSH, LH, TSH) are not equivalent to nonfunctioning adenomas, because hormones can be expressed by IHC in several adenoma types, yet the tumors are clinically silent (no hormonal syndrome recognized and/or no elevation of hormone serum levels). The majority of hormone-negative adenomas today have been found to be gonadotroph adenomas, with the advent of SF1 and higher fidelity FSH and LH antibodies. A significant subset of hormone-negative adenomas have been shown to be of TPIT origin (i.e., corticotroph lineage), but few hormone-negative adenomas are PIT1 driven.[14]

Not surprisingly, then, most hormone-negative adenomas show histologic features that are nearly identical to gonadotroph adenomas (Fig. 44.31). Cysts (Fig. 44.32) and hemosiderin pigment deposits are often found in large tumors of both types. Some studies suggest that "null cell adenomas" may have differing biologic behavior than gonadotroph adenomas,[53] but more work needs to be done. Today, "null cell adenoma" is used only for adenomas with no markers for either specific hormones or transcription factors.

Somatotroph Adenoma

GH-producing adenomas are almost always clinically active and, in pure form, exist in two subtypes, densely granulated and sparsely granulated.

Histologically, the densely granulated variant features diffuse growth of a monotonous population of slightly pleomorphic, medium-sized cells, often with an angular profile. There is diffuse, moderate to strong immunostaining for GH, and CAM5.2 shows reactivity throughout the cytoplasm in a perinuclear pattern (Fig. 44.33). Densely granulated GH adenomas may also contain a small percentage of cells that are immunoreactive for αSA or PRL (usually less than 5%).[54]

Sparsely granulated GH tumors also have a diffuse growth pattern, but the cells lack the acidophilia on H&E that is seen in densely

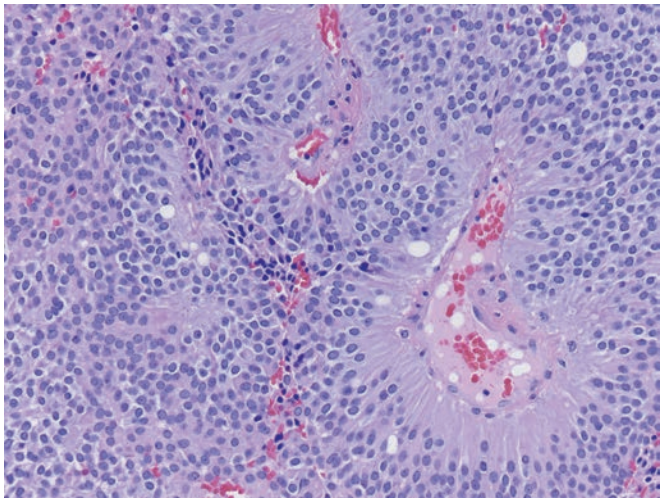

Figure 44.31 Hormone-negative adenomas often show a perivascular "pseudorosette" like pattern identical to that seen in gonadotroph adenomas.

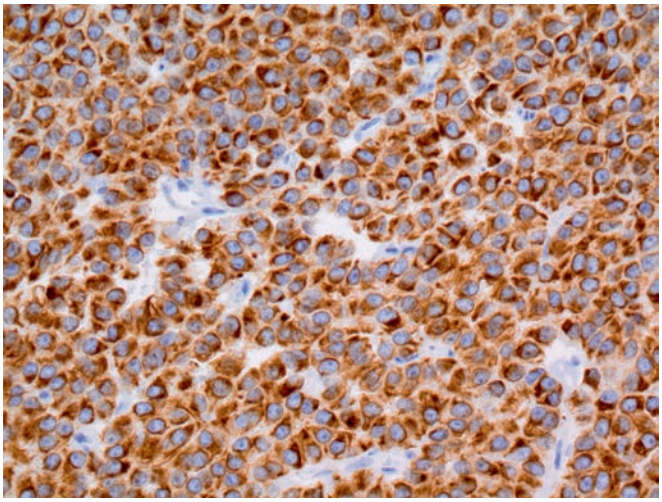

Figure 44.33 Densely granulated growth hormone adenomas show perinuclear keratin that is present throughout the cytoplasm with CAM5.2 immunostaining.

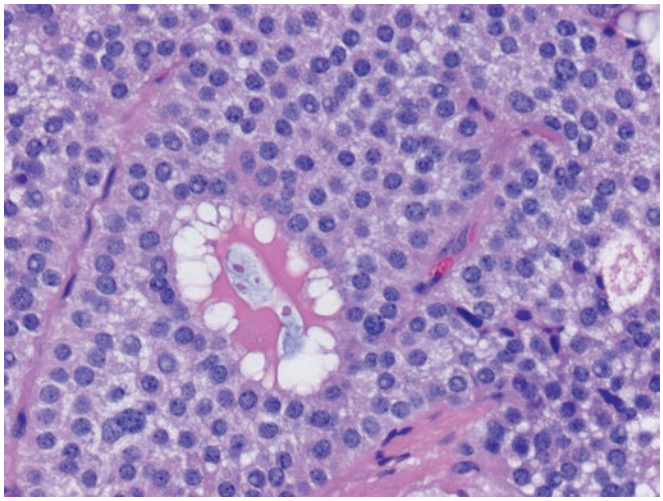

Figure 44.32 Hormone-negative adenomas may be composed of a very monomorphic population of cells, punctuated only by a few mucin-filled microcysts.

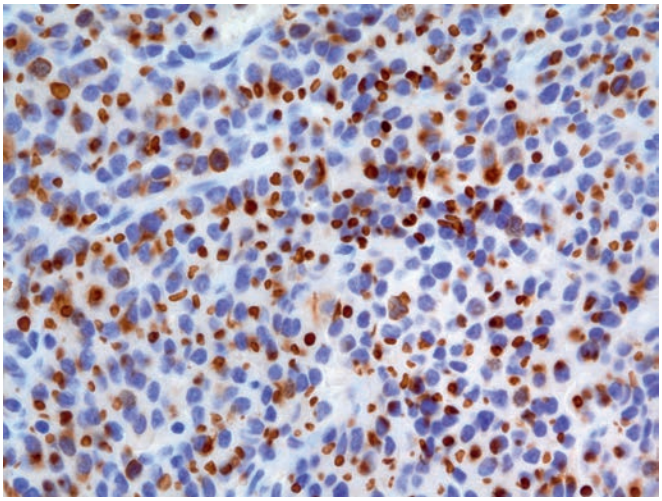

Figure 44.34 Sparsely granulated GH adenomas, by definition, have dot-like cytoplasmic round fibrous bodies in greater than 70% of adenoma cells with CAM5.2 immunostaining.

granulated tumors. Cells of sparsely granulated GH may also have more eccentrically placed nuclei and paranuclear clearing and occasionally may show cellular pleomorphism. These tumors show weaker, patchier GH immunoreactivity, and are usually αSA and PRL negative. The signature feature of sparsely granulated GH adenomas is the finding of widespread, ball-like, cytoplasmic "fibrous bodies" with CAM5.2 immunostaining in greater than 70% of cells (Fig. 44.34).[38,54] CAM5.2 IHC has replaced the need for EM to find fibrous bodies. Sparsely granulated GH adenomas also show down-regulation of E-cadherin, further contrasting them with densely granulated and intermediate/mixed/transitional GH adenomas (see later), which show varying degrees of retained expression.[55]

An intermediate/mixed/transitional form of GH adenomas that produces acromegaly has been increasingly recognized. In these tumors, CAM5.2 IHC shows predominantly perinuclear CAM5.2 cytoplasmic staining but also highlights admixed cells with fibrous bodies or intermediate forms of keratin accumulation; some resemble smaller sized fibrous bodies (Fig. 44.35).[54] The numbers of fibrous bodies seen in sparsely granulated GH adenomas far exceeds that seen in these intermediate/mixed/transitional adenomas. Intermediate/mixed/transitional adenomas behave as densely granulated GH adenomas in terms of good response to somatostatin analogues.[38,55]

Mixed Growth Hormone and Prolactin Adenoma, Mammosomatotroph Cell Adenoma

This group of mixed GH-PRL adenomas totals 6.5% of all adenomas in the German registry.[1] Mixed GH-PRL adenomas are bicellular–bihormonal adenomas that are more frequent (5.2%) than monocellular mammosomatotroph cell adenomas (1.1%), which contain tumor cells that coexpress GH and PRL.[1] Bicellular adenomas contain a combination of sparsely granulated PRL-secreting cells with either densely or sparsely granulated GH-secreting tumor cells.[56] These tumors produce acromegaly, and by IHC most show more GH than PRL expression; clinically, both GH and PRL excess can occur. The

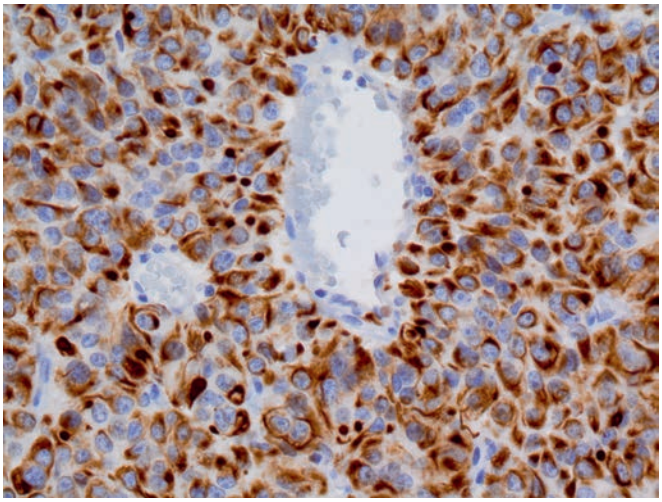

Figure 44.35 Intermediate/mixed/transitional growth hormone adenomas show a predominance of perinuclear CAM5.2 staining but have occasional admixed fibrous bodies or keratin accumulations that are not easily categorized as either perinuclear or fibrous bodies. These adenomas behave like densely granulated growth hormone adenomas, especially in terms of response to somatostatin analogues, and should not be misconstrued as sparsely granulated GH adenomas.

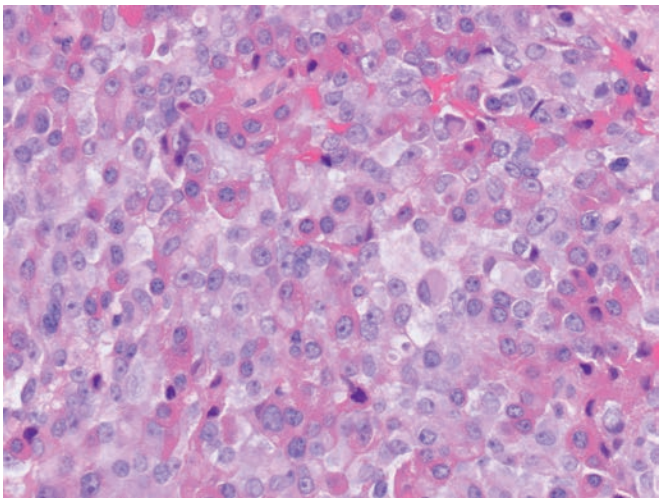

Figure 44.36 This mixed GH-PRL adenoma clearly shows two admixed populations of chromophobic and eosinophilic cells on H&E.

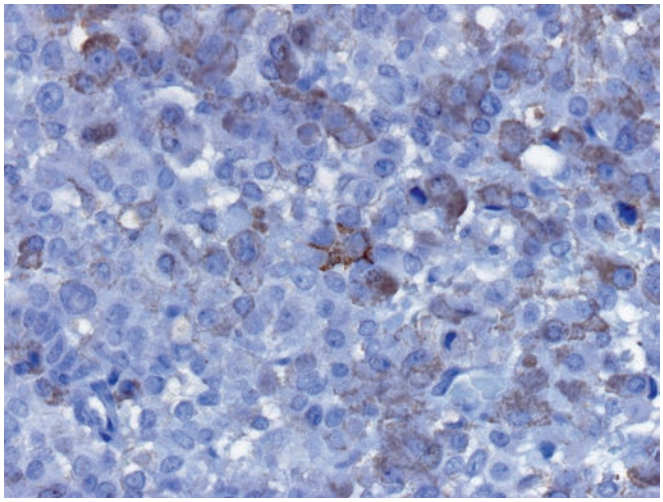

Figure 44.37 Mixed GH-PRL adenomas present with acromegaly, and a significant percentage of the adenoma cells stain with GH.

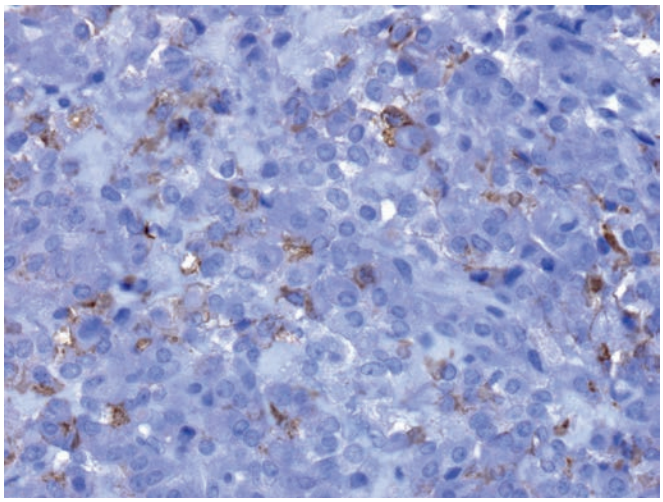

Figure 44.38 Although mixed GH-PRL adenomas present with acromegaly, they are often associated with hyperprolactinemia as well and as shown here contain a higher percentage of PRL+ cells than densely granulated GH adenomas, which should only contain occasional cells that are immunoreactive for PRL.

two cell types can often be identified on H&E (Fig. 44.36), and are paralleled by strong GH (Fig. 44.37) and PRL (Fig. 44.38) expression in tumor subsets. PRL expression is present in a higher percentage of cells than in pure densely granulated GH adenomas (defined by some as less than 5% of cells).[54] Some might prefer to use the term mixed GH-PRL for those adenoma patients with clinical acromegaly but also serum hyperprolactinemia.[56]

Mammosomatotroph adenomas appear identical to densely granulated GH adenomas on light microscopy. They also present with acromegaly and are immunoreactive for GH. They variably express αSU and PRL, and by EM show a single cell type with combined GH and PRL hormone secretion. While confident discrimination between true bicellular mixed GH-PRL adenomas and monocellular mammosomatotroph cell adenomas requires EM, the distinction is considered clinically unimportant by most, but not all workers.[56]

Lactotroph Adenoma

Table 44.3 summarizes the types of tumors that produce prolactin excess, resulting in varying degrees of hyperprolactinemia. Almost all PRL-secreting adenomas are sparsely granulated. Histologically, sparsely granulated PRL-secreting adenomas show diffuse or trabecular growth patterns and demonstrate increased nuclear chromatin content (Fig. 44.39). Diffuse strong immunostaining for PRL is demonstrable in a paranuclear Golgi region pattern (Fig. 44.40). Additional features may include psammomatous calcifications (which are virtually confined to PRL-secreting adenomas), stromal hyalinization (Fig. 44.41) or amyloid derived from PRL. Prolactin secreting adenomas are one of the more common adenoma subtypes in some studies[48] that show increased mitotic rate and MIB-1 indices (Fig. 44.42).

Should patients come to surgical resection after long-term dopamine agonist therapy, specimens will often demonstrate severe cytoplasmic shrinkage with near-naked nuclei and decreased PRL immunoreactivity; this appearance should not be mistaken for

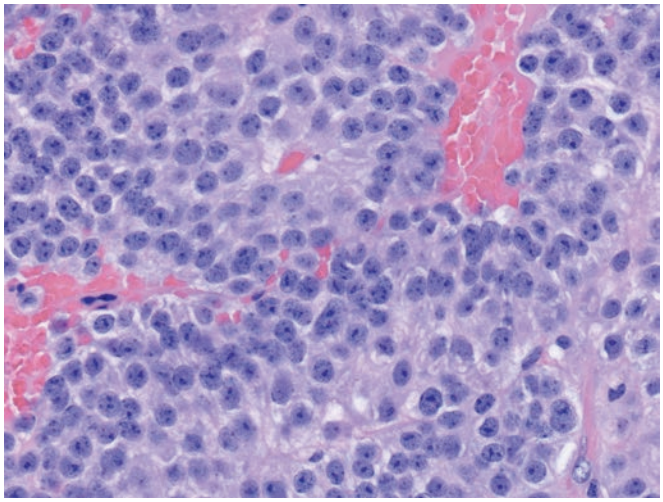

Figure 44.39 Sparsely granulated prolactinomas constitute the overwhelming majority of prolactinomas, and usually feature a sheet-like growth pattern; note the relative prominence of nucleoli (compare with Fig. 44.32).

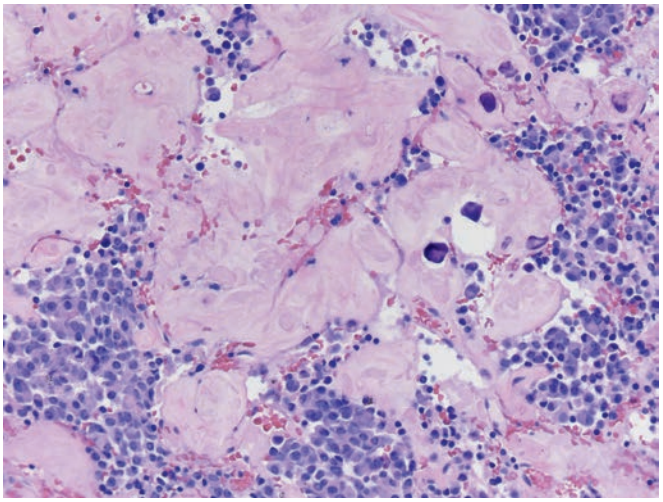

Figure 44.41 Sparsely granulated prolactinomas occasionally show stromal hyalinization and microcalcifications, both of which are pictured here.

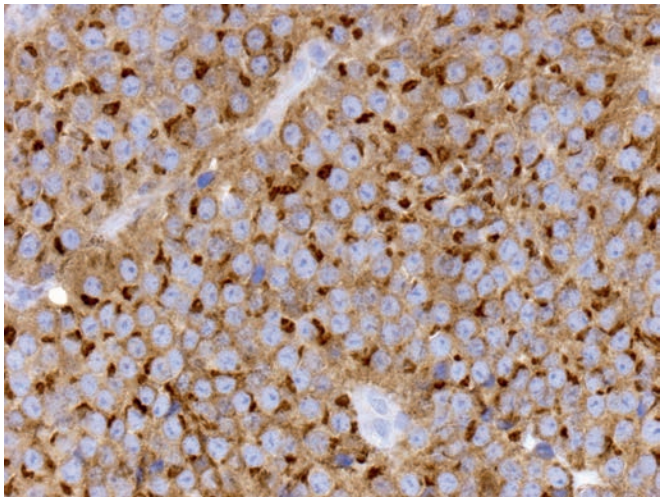

Figure 44.40 Sparsely granulated prolactinomas show PRL positivity in an arc-like cytoplasmic pattern, the so-called Golgi pattern. In contrast, the very rare densely granulated PRL positive adenomas show PRL immunoreactivity throughout the cytoplasm.

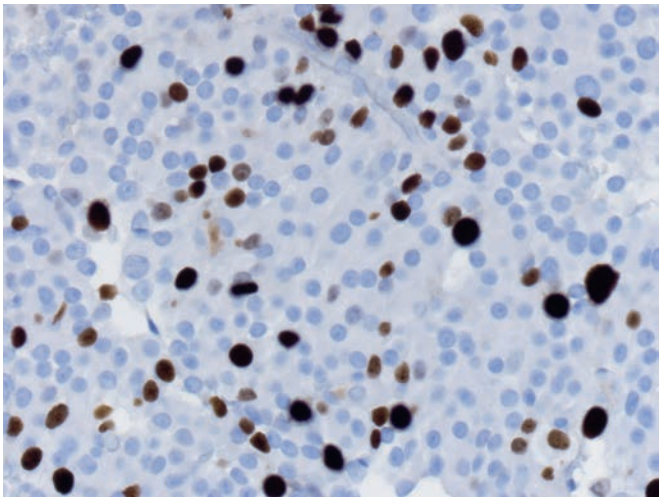

Figure 44.42 Atypical adenomas are defined by an elevated MIB-1 labeling index, although this does not correlate perfectly with adenoma subtype. Indeed, even the well-accepted "aggressive" adenoma subtypes, such as sparsely granulated GH, acidophil stem cell, and silent ACTH adenoma, do not invariably show elevated indices. In some studies, the most common subtype to show elevated MIB-1 is sparsely granulated prolactinoma, as illustrated here. Acidophil stem cell adenoma was excluded in this case by clinical and EM features.

lymphocytes or a small cell neoplasm, such as lymphoma or a metastatic small cell carcinoma. Fibrosis will also be evident in such cases. These changes may not be evident following short-term treatment.

Densely granulated PRL adenomas are exceedingly rare, are PIT1 driven, and show PRL immunoreactivity that fills the cytoplasm of the cell in a diffuse rather than in a Golgi pattern of staining.[13,19] These tumors may behave more aggressively.

Acidophil stem cell adenomas are also rare tumors. They are typically locally invasive macroadenomas that manifest with a relatively short clinical history. The tumor is monomorphous, is chromophobic to slightly acidophilic, contains fibrous bodies by CAM5.2 IHC, and may show large cytoplasmic vacuoles (Fig. 44.43). Mitochondrial accumulation with giant mitochondria is the pathognomonic feature, which imparts an oncocytic change on H&E; identification of this feature has required EM in the past.[57] Whether IHC for mitochondrial antibodies can assist in diagnosis is an unsettled question (Fig. 44.44). Immunostaining shows some reactivity for PRL, with focal GH-positive cells or no GH immunoreactivity at all. This correlates well with clinical features in that this adenoma is usually associated with hyperprolactinemia, but the blood PRL levels are disproportionally low for the size of the lesion, and clinical response to dopamine agonists may be suboptimal. Acromegaly is infrequent and usually mild, if present at all.[58] Finally, a poorly differentiated adenoma, the so-called clinically silent subtype 3 adenoma (currently, "plurihormonal PIT1-positive adenoma"), has recently been recognized to be monomorphous and also of PIT1 lineage.[59]

Corticotroph Adenoma

Corticotroph adenomas are by far the most clinically challenging adenoma type. Because the overwhelming majority of corticotroph

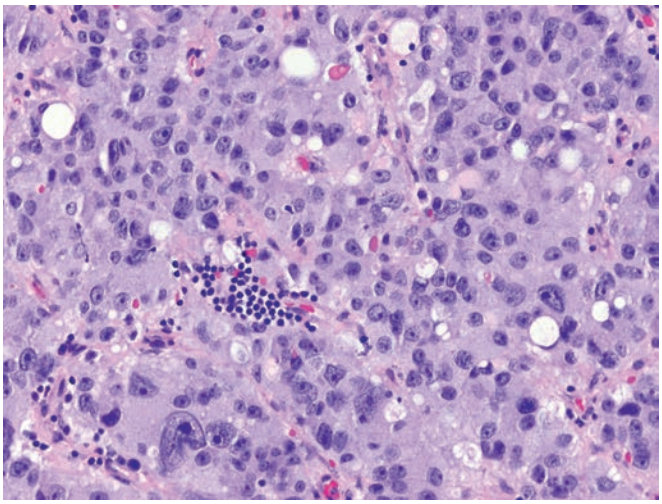

Figure 44.43 Acidophil stem cell adenoma usually presents as a large tumor, with relatively mild hyperprolactinemia for tumor size in comparison to sparsely granulated prolactinomas. Acidophil stem cell adenomas cannot be confidently diagnosed without electron microscopic examination, however. One clue in some cases is the presence of large clear vacuoles corresponding to the giant mitochondria seen on EM.

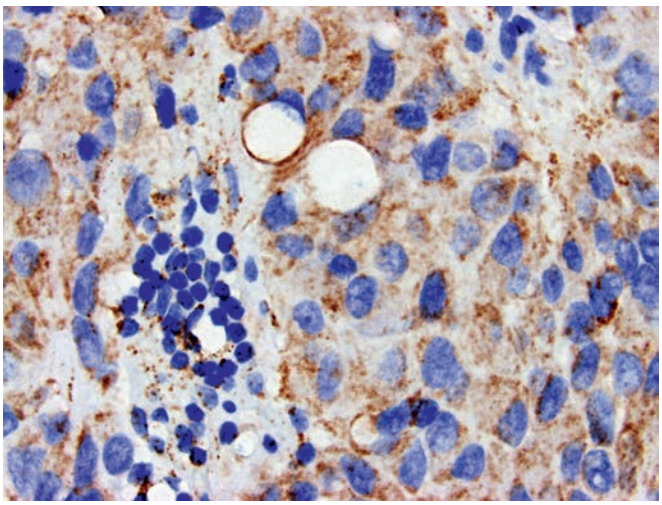

Figure 44.44 Acidophil stem cell adenomas usually require EM for confident diagnosis, but antimitochondrial antibodies are being investigated as possible surrogate IHC markers; note how the immunoreactivity rims the vacuole, indicating that the vacuole is indeed a mitochondrion.

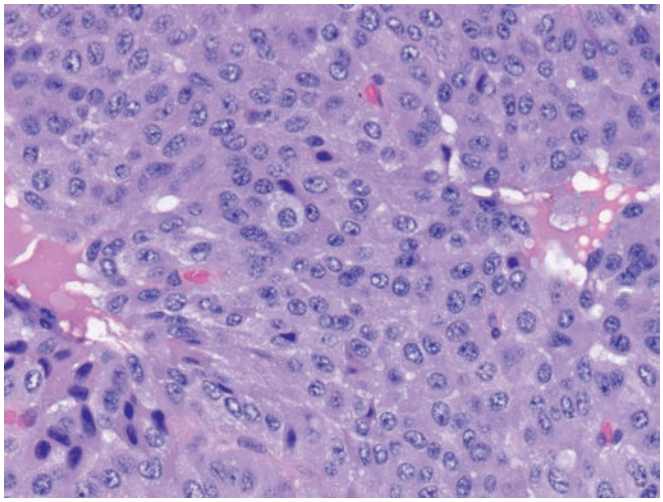

Figure 44.45 This densely granulated corticotroph adenoma is composed of sheets of large cells with basophilic cytoplasm.

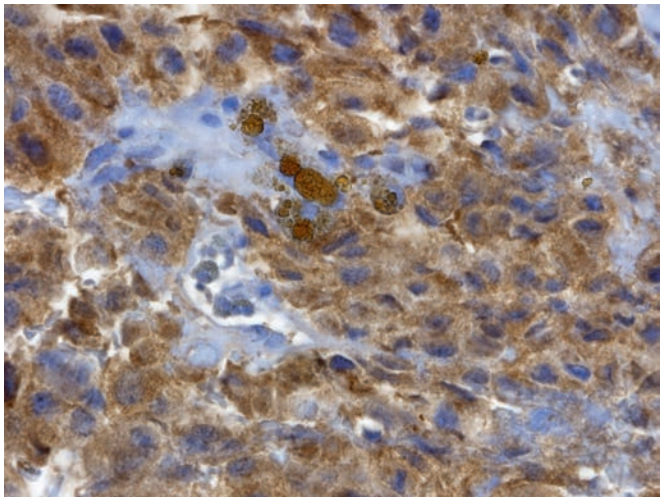

Figure 44.46 Densely granulated corticotroph adenomas show diffuse ACTH immunoreactivity throughout the tumor. Unlike sparsely granulated prolactinomas where adenoma size parallels the serum level of prolactin, minute ACTH adenomas, even millimeters in size, may cause Cushing disease and significantly elevated serum levels.

adenomas (80%) are microadenomas—and 10%–20% are so small that they fall below the resolution level even of modern neuroimaging—petrosal sinus sampling is often necessary to document pituitary gland origin for ACTH excess.

Most ACTH-secreting adenomas occur in women. Clinical features of Cushing disease (i.e., Cushing syndrome caused by a corticotroph pituitary adenoma) may be dramatic, with acquisition of fat in multiple body sites resulting in truncal obesity with thin extremities, and atrophy of the skin with plethora, easy bruisability, and violaceous striae on the abdomen and chest. Additional symptoms include osteoporosis, increased risk of infections, and neuropsychiatric changes.

ACTH-secreting adenomas are equally divided into densely and sparsely granulated types. Densely granulated ACTH adenomas grow as sheets of monotonous round cells, often arranged around blood vessels (Fig. 44.45). Cells show abundant, PAS-positive cytoplasm and strong diffuse immunoreactivity for ACTH only (Fig. 44.46). Sparsely granulated ACTH adenomas show less cytoplasmic volume (Fig. 44.47), are chromophobic to weakly PAS positive, and demonstrate weaker, more focal ACTH positivity (Fig. 44.48).

An interesting aspect to ACTH-secreting adenomas is that, unlike the previously mentioned adenoma subtypes, clinically silent ACTH adenomas are not uncommon, in contrast to the rarity of silent GH- or PRL-positive adenomas. Clinically silent ACTH-secreting adenomas show a range of ACTH immunoreactivity, are histologically identical to their clinically active counterparts, and may include basophilic densely granulated (silent type 1) and chromophobic sparsely granulated (silent type 2) variants. Thus, pathologists cannot distinguish a clinically dramatic tumor from a truly clinically silent ACTH+ adenoma without clinical correlation. Clinically silent ACTH adenomas are generally considered to be one of the aggressive

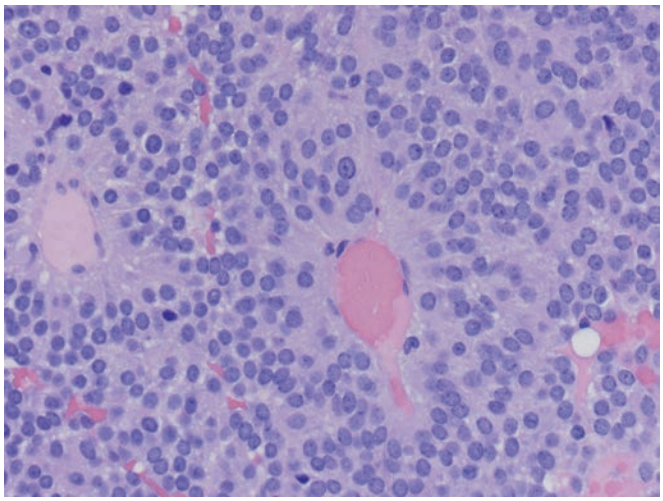

Figure 44.47 Sparsely granulated corticotroph adenomas are usually chromophobic.

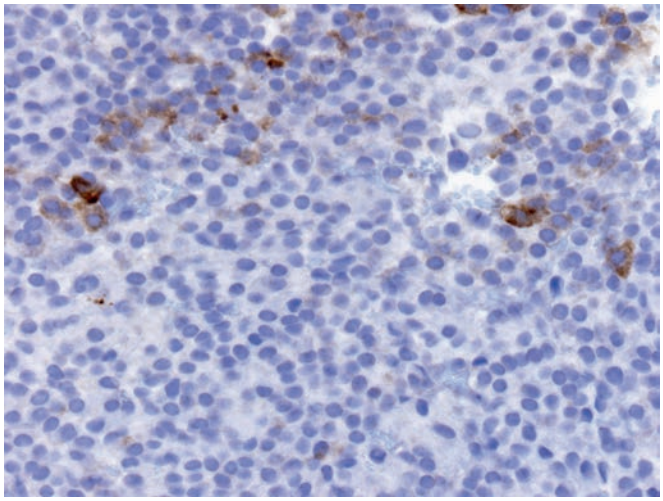

Figure 44.48 Sparsely granulated corticotroph adenomas show focal or patchy ACTH positivity.

adenoma variants,[41] as they have been shown to have an increased frequency of cavernous sinus invasion and progression/recurrence compared to other clinically silent adenomas such as gonadotroph adenomas.[60]

The emergence of clinical symptoms referable to a corticotroph adenoma enlarging after adrenalectomy is known as Nelson's syndrome. Nelson's syndrome occurs when an ACTH adenoma was present but was either so small as to be missed intraoperatively or the patient could not undergo surgical excision for medical reasons in the first place; in either case, the result is the adenoma not being surgically excised. Second line therapy may include a second attempt at surgical removal, medical management, or radiation therapy, but if all that fails, the negative effects of unremitting hypercortisolism may lead to a third line of therapy, bilateral adrenalectomy. Following removal of both adrenals, the corticotroph pituitary adenoma may then eventually enlarge, possibly due to the removal of the negative feedback of cortisol that had been previously produced by the adrenals. The adenoma shows histologic features similar to other ACTH adenomas and variable mitotic activity.

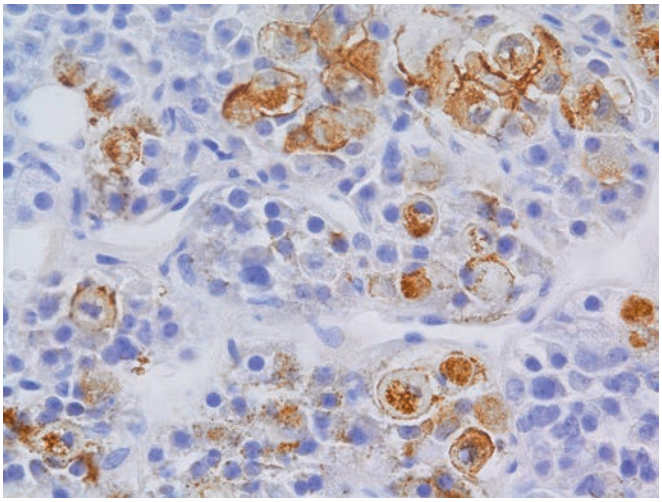

Figure 44.49 Crooke cells in adjacent nontumorous anterior pituitary gland testify to the presence of hypercortisolism, and this change should be sought in any included anterior gland from a corticotroph adenoma resection specimen. Rings of keratin push the ACTH-positive granules close to the nucleus, as well as to submembrane sites.

A specific, albeit uncommon, variant of ACTH-immunoreactive adenoma is the Crooke cell adenoma. In this variant, the cells recapitulate intermediate filament-rich Crooke cells. The ring-like cytoplasmic filament accumulation causes dispersal of secretory granules (and hence the ACTH immunostaining) to the peripheral submembrane region or displaces them internally next to the nucleus. In the largest study to date of 36 cases,[60] only 65% of patients with Crooke cell adenomas manifested Cushing disease (the remainder being silent variants); 81% were macroadenomas and 72% were invasive. All were surgically treated but 60% of patients experienced recurrences, 24% had multiple recurrences, and 12% died; two examples evolved to pituitary carcinoma.[61] Far more frequent than Crooke cell adenoma is the presence of non-neoplastic Crooke cells in the adjacent nontumorous pituitary gland (Fig. 44.49); their presence ensures that functional hypercortisolemia was present, either from an ACTH clinically active adenoma or from iatrogenic steroid administration.

ACTH hyperplasia is an uncommon cause of Cushing syndrome. Diagnosis is predicated on recognizing expansion, rather than destruction, of acini that contain relatively homogeneous populations of ACTH-immunoreactive cells. Given the normal irregular distribution of cell types in the anterior pituitary gland and the normal "basophil" invasion into the posterior pituitary with aging, this diagnosis is often challenging.

Thyroid Stimulating Hormone–Producing Adenoma

Constituting less than 1% of all adenomas, these tumors are macroadenomas and invasive. Hyperthyroidism is usually due to thyroid causes, and a pituitary adenoma is a much rarer explanation. Histologically, these tumors grow in a diffuse pattern and often show a perivascular pseudorosette-like arrangement. Nuclear pleomorphism and spindled morphology is more common in this subtype, and perivascular stromal fibrosis can be encountered. The adenoma cells are chromophobic, may show focal subplasmalemmal dot-like positivity with PAS due to lysosomal accumulation, and are variably immunoreactive for αSU and TSH. Occasional cases develop after longstanding hypothyroidism, but most present without predisposing causes.

Plurihormonal PIT1-Positive Adenoma (Formerly Silent Subtype 3 Adenoma) and Other Unusual Plurihormonal Adenoma Types

The term "plurihormonal" should not be used for adenomas showing combinations of GH/PRL/TSH or GH + FSH/LH/αSU. The new 2017 WHO Classification recognizes plurihormonal PIT1-positive adenomas, clinically functioning adenomas such as GH/prolactin/TSH-producing adenomas when acromegaly and thyroid dysfunction are present, and rare adenoma types with unusual IHC combinations not readily explained by cytodifferentiation/transcription factor histogenesis.

Double or even triple adenomas within a single gland are uncommon but a well-recognized occurrence. The general surgical pathologist should note that if consideration of "plurihormonal adenoma" is raised by IHC, it is far more likely that the rare "aberrant" hormone staining is due to a few entrapped nontumorous anterior pituitary cells encompassed within an adenoma, albeit usually at the edges of tissue fragments.

Ectopic Pituitary Adenoma

The sphenoid sinus and the suprasellar region are the predominant sites for ectopic adenomas;[62,63] less common locations include clivus nasal cavity, cavernous sinus, parasellar region, and sphenoid wing. Rare cases of ectopic adenomas occur in petrous temporal bone, superior orbital fissure, third ventricle,[64] and temporal lobe. Many ectopic adenomas are immunoreactive for ACTH or PRL.[62,63] Ectopic adenomas may cause apoplexy (see later).[65]

Pituitary Apoplexy

Pituitary apoplexy is the sudden onset of clinical symptoms, usually headache, cranial nerve palsy, or visual disturbances, due to a pituitary mass. Pituitary apoplexy usually is due to changes in a pituitary adenoma, not normal gland or other sellar region masses, and corresponds histologically to bland infarction (Fig. 44.50), hemorrhagic infarction, or acute hemorrhage.[66] Pituitary adenomas presenting with clinically evident apoplexy come to surgery because of the need for surgical decompression of the optic chiasm or cavernous sinus. If due to hemorrhage alone, most of the clot may be lost to intraoperative aspiration, and the surgical pathologist would need to correlate the material they receive with preoperative neuroimaging findings and intraoperative impressions. Cases with the greatest interval between symptom onset and surgery show peripheral rim enhancement by preoperative MRI, which can be mistaken for other processes such as pituitary abscess.

Pathologically, this rim enhancement corresponds to granulation tissue, T-cell lymphocytic infiltration, and possible fibrosis at the edge of the infarction or hemorrhage. Occasionally this reaction overshadows the necrotic adenoma and contributes to diagnostic confusion for the pathologist as well. Despite extensive tumor necrosis, reticulin staining usually still allows confident identification of the resected material as an adenoma with a disrupted acinar pattern. Immunohistochemical staining is most informative in cases with necrosis more proximate to the time of surgical intervention. Most apoplexy occurs in macroadenomas such as gonadotroph adenomas, prolactinomas in males, and hormone-negative/null cell macroadenomas.[66]

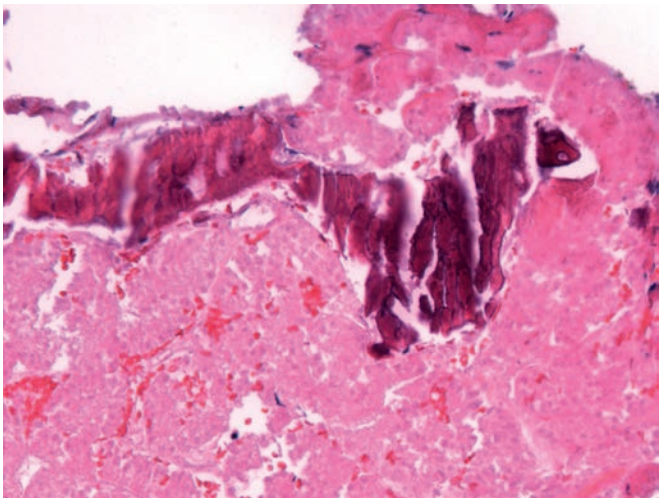

Figure 44.50 Pituitary apoplexy can be seen in several types of adenomas, usually macroadenomas, and may either manifest as bland necrosis, as illustrated here in an adenoma that was present within clival bone, or as acute/subacute hemorrhage.

Mixed Pituitary Adenoma–Gangliocytoma

The entity has appeared in the literature under several names,[67] including pituitary adenoma with neuronal choristoma (PANCH).[68] Several hypotheses have been offered for these lesions, but differentiation of adenoma cells into ganglion cells is favored.

These tumors usually present identically to pituitary adenomas by clinical, neuroimaging, and intraoperative criteria, with the neuronal metaplastic element often representing a surprise of no clinical importance. The pituitary adenoma often predominates, and the two components may be either sharply demarcated from one another or intimately admixed. Most often the adenoma is a GH-secreting type, especially the sparsely granulated subtype. The gangliocytoma portion consists of a neuropil-like, finely fibrillar matrix in which are embedded large, uninucleate or binucleate neurons with normal or even bizarre appearance. The eosinophilic neuropil is hypocellular and composed of ganglion cell processes with the expected reaction for axons with synaptophysin and anti-neurofilament; however, it is usually devoid of a significant glial element and thus is negative for glial fibrillary acidic protein.

Pituitary Carcinoma

Pituitary carcinoma is defined by the presence of cerebrospinal and/or systemic metastases. Vanishingly rare at less than 0.5% of all pituitary region masses,[1] the most important feature to recognize is that these usually evolve from invasive aggressive adenomas over several years, rather than presenting *de novo* as previously undiagnosed metastasizing tumors.[69] Most are invasive macroadenomas at the time of diagnosis and are hormonally active with Cushing syndrome or hyperprolactinemia.

Rathke Cleft Cyst

Symptomatic cysts account for approximately 6%–10% of patients who present in neurosurgical series with sellar and suprasellar lesions. Indications for surgical drainage include headaches, visual disturbances, and/or pituitary hormonal deficiencies. The cyst contains dense eosinophilic amorphous mucin with small strips of simple cuboidal or pseudostratified columnar, ciliated epithelial cyst wall

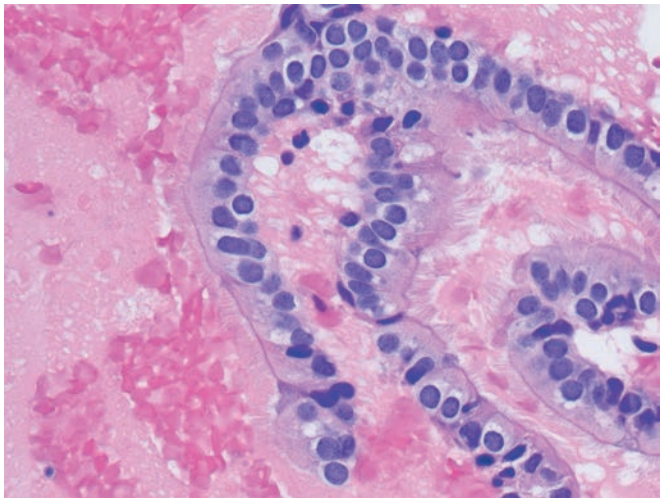

Figure 44.51 Rathke cleft cyst contains variably dense colloid-like proteinaceous contents, usually visible as amorphous eosinophilic material *(left)*. The lining epithelium is often not sent to the pathologist, but, when received, may be columnar ciliated epithelium (as seen here), low cuboidal, or even show squamous metaplasia.

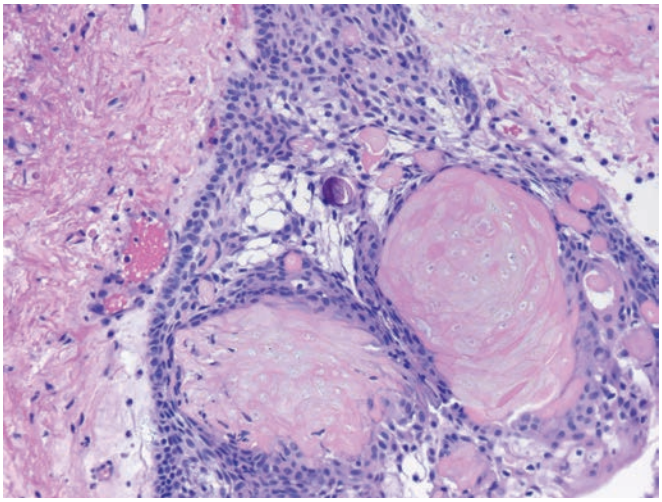

Figure 44.52 Adamantinomatous craniopharyngioma is characterized by peripherally palisaded nuclei, clusters of eosinophilic cells devoid of nuclear staining, so-called ghost cells (also known as wet keratin), focal calcification, and often, surrounding piloid gliosis with Rosenthal fiber formation *(upper right and at left)*.

lining (Fig. 44.51). Squamous metaplasia may correlate with increased incidence of recurrence.

Hypophysitis

Hypophysitis is an inflammatory infiltrate of the pituitary gland but is not a single disorder.[70–76] Secondary hypophysitis is diagnosed when an infectious agent or systemic disease can be identified as affecting the sellar region, such as sarcoidosis, Wegener granulomatosis, Sjögren syndrome, Langerhans cell histiocytosis, and Erdheim–Chester disease. A number of secondary cases currently have been linked with ipilimumab therapy.[74] Germ cell tumors of the central nervous system often involve suprasellar sites and may be accompanied by a profuse lymphocytic or granulomatous reaction that overshadows the neoplastic cells. Lymphoma uncommonly presents as pituitary disease but should be excluded in these cases. Cases in which there is a coexistent pituitary adenoma, craniopharyngioma, or Rathke cleft cyst[73,75] associated with the inflammation can also cause secondary hypophysitis, and these dual pathologies need to be excluded.

Primary hypophysitis was originally thought to occur almost exclusively in young women during late pregnancy or in the early postpartum period, especially the third trimester. More recent series show less association with pregnancy and indicate that males and females are nearly equally affected.[73] Concomitant autoimmune disorders, especially Hashimoto's thyroiditis and Graves' disease,[74] are seen in a significant percentage of cases.[73]

Primary hypophysitis is most commonly divided into lymphocytic, granulomatous, and xanthomatous types, with some workers additionally recognizing mixed xanthogranulomatous and necrotizing forms.[76] Lymphocytic hypophysitis is the most frequent subtype of primary hypophysitis currently encountered by pathologists, followed by granulomatous.[73]

Craniopharyngioma

These tumors have two peaks of occurrence, one in the first to second decade and the second in the fifth decade. The childhood tumors are more often calcified and are almost exclusively of the adamantinomatous type with peripherally palisaded nuclei, stellate reticulum, ghost cells, focal calcification, and often surrounding piloid gliosis with Rosenthal fiber formation (Fig. 44.52). This type is now known to be associated with beta catenin mutation and WNT pathway activation, with nuclear beta catenin immunoreactivity, although an important point is that positivity is generally confined to cells within squamous morules, sometimes surrounding clumps of wet keratin ("ghost cells") (Fig. 44.53).[77]

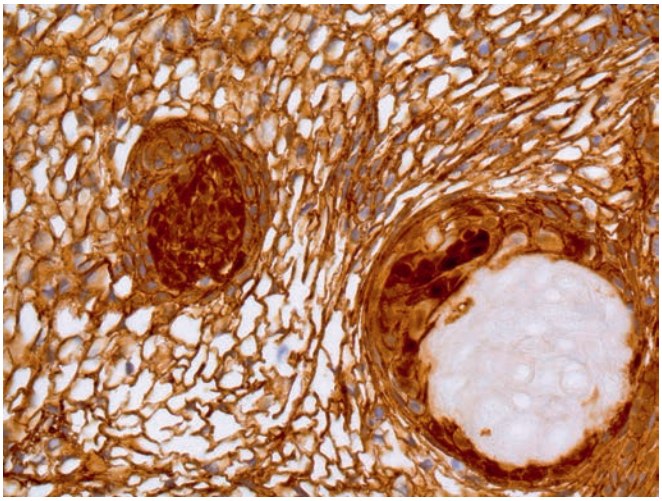

Figure 44.53 Adamantinomatous craniopharyngioma has an underlying mutation in β-catenin and translocation of the protein to the nucleus, which can thus be documented by immunohistochemistry. It should be noted that nuclear β-catenin staining is never seen in all tumor cells, but instead concentrates in cells immediately adjacent to wet keratin or within whorled squamous nests (seen in the plane of section at *lower right*).

Papillary craniopharyngioma is composed of nonkeratinizing stratified squamous epithelium that is devoid of a keratohyalin layer (unlike epidermoid cyst) or wet keratin, ghost cells, or calcification (unlike adamantinomatous craniopharyngioma) (Fig. 44.54). It is

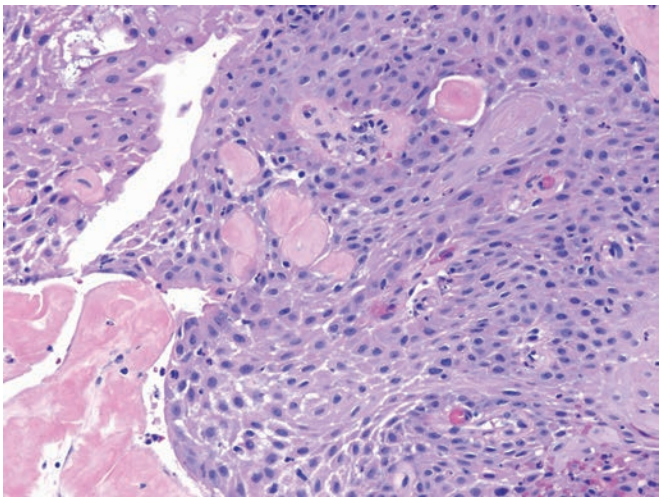

Figure 44.54 Papillary craniopharyngioma lacks the prominent peripheral palisaded nuclei, wet keratin, and calcification of the adamantinomatous variety; note the hyalinized, collagenous whorl-like structures that should not be mistaken for wet keratin.

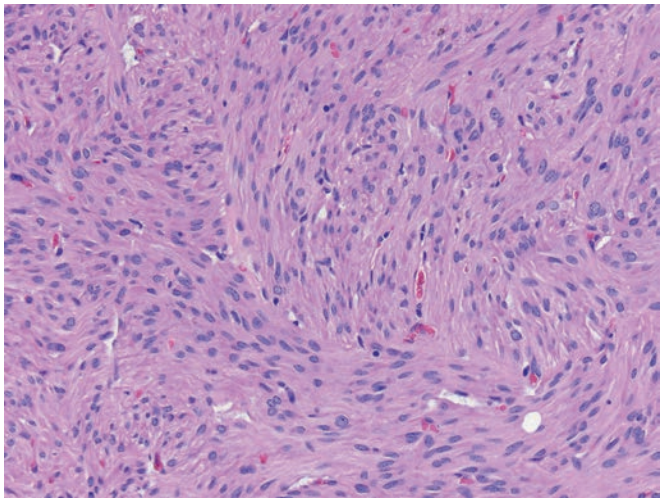

Figure 44.56 Pituicytoma is a spindle cell sellar region mass easily mistaken on light microscopy for meningioma, schwannoma, or even normal posterior pituitary gland.

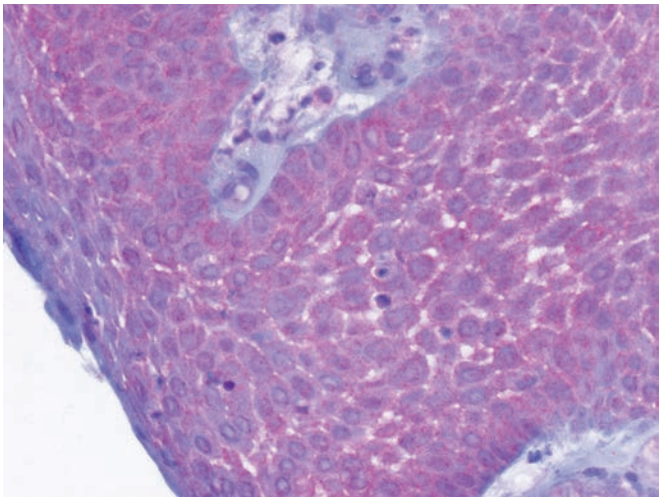

Figure 44.55 Papillary, squamous craniopharyngiomas are composed of benign nonkeratinizing epithelium devoid of a keratohyaline layer, unlike epidermoid cysts. Unlike adamantinomatous craniopharyngioma, papillary craniopharyngioma manifests mutation in *BRAF* V600E, which is paralleled by BRAF VE1 immunoreactivity, as shown here with a red chromogen.

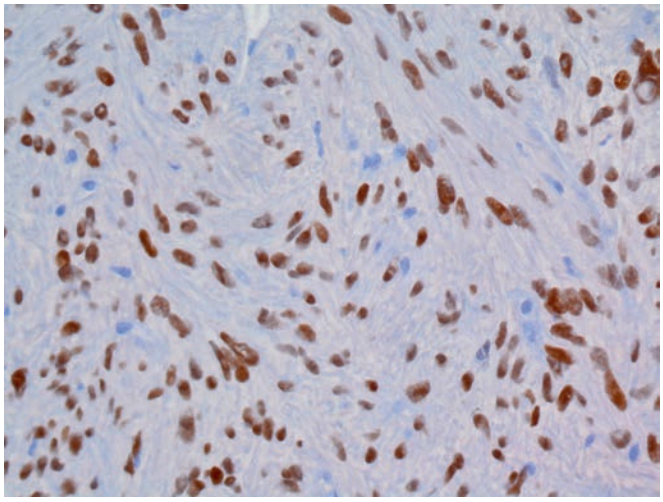

Figure 44.57 Pituicytoma, like the related spindle cell oncocytoma and granular cell tumor of infundibulum, shows nuclear reactivity for TTF1, negating consideration of meningioma, schwannoma, or even pituitary adenoma. The cell density and architectural pattern distinguishes it from TTF1+ normal posterior gland.

almost exclusively seen in adults and is related to mutations in *BRAF* V600E,[78] which is paralleled by BRAF VE1 immunoreactivity (Fig. 44.55). Malignant degeneration is rare in craniopharyngiomas.[79]

Pituicytoma, Spindle Cell Oncocytoma, and Granular Cell Tumor of Neurohypophysis

These three rare entities are WHO grade I sellar masses that clinically and radiographically mimic nonfunctional pituitary adenomas. All three are recognized today to be derivatives of normal posterior gland pituicytes, and share nuclear TTF1 immunoreactivity with the normal posterior gland.[6–8] Pituicytoma is a monomorphic spindle cell tumor composed of plump cells arranged in fascicles (Fig. 44.56), typically with only rare mitoses. Unlike meningioma, the tumor lacks calcification or whorls. Pituicytoma shows strong immunoreactivity for S-100 protein, variable immunoreactivity for glial fibrillary acidic protein, and nuclear TTF1 positivity (Fig. 44.57).[80] Cases have been reported as incidental findings at autopsy, in association with other endocrine neoplasms or presenting with hemorrhage.[7]

Spindle cell oncocytoma is similar, but with epithelioid cells, mild to moderate nuclear atypia (Fig. 44.58), and sometimes a minor lymphocytic infiltrate.[81] EM or mitochondrial IHC (Fig. 44.59) shows numerous mitochondria, which is the feature that distinguishes these lesions from pituicytoma. Recurrence, sometimes after long time periods, has been reported.[7] Granular cell tumor of the neurohypophysis, characterized by lysosomal-rich cytoplasm, is the least

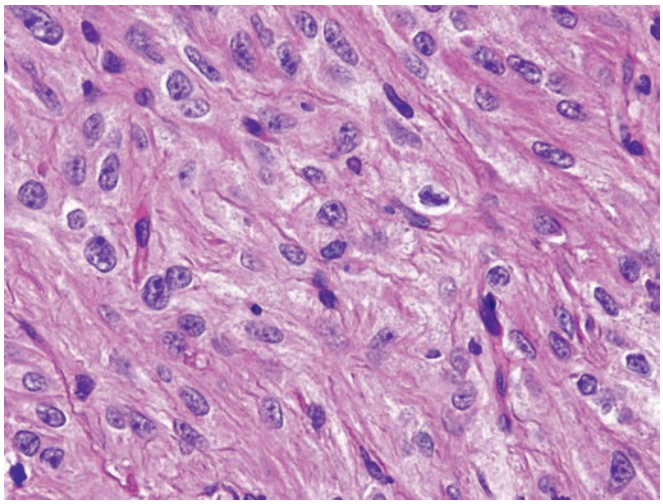

Figure 44.58 Spindle cell oncocytoma is composed of cells with plumper, more epithelioid-appearing eosinophilic cytoplasm but does have overlapping features with pituicytoma, most notably the shared TTF1 immunoreactivity.

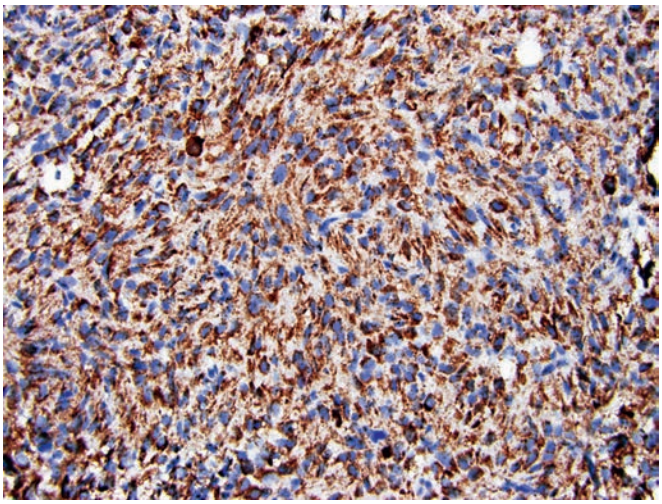

Figure 44.59 Spindle cell oncocytoma is characterized by more abundant cytoplasmic mitochondria than are present in pituicytoma, as seen here on anti-mitochondrial immunohistochemistry.

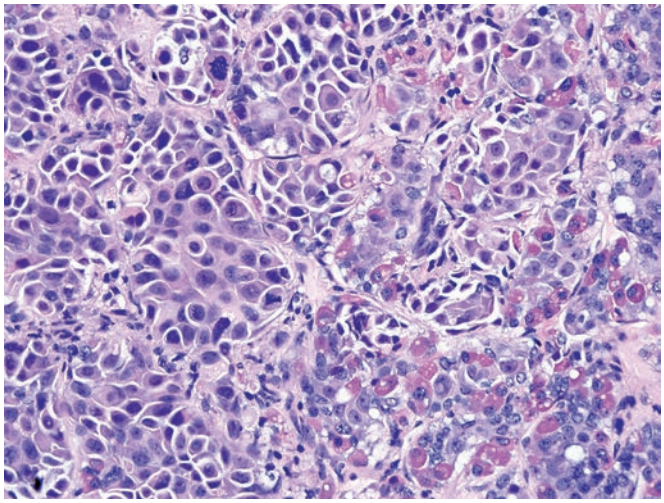

Figure 44.60 Metastases to the pituitary gland usually obliterate or compress the gland, but occasionally the tumor and residual anterior pituitary cells are intimately admixed; compare the metastatic breast carcinoma at left with the normal anterior pituitary gland showing all three cell types (chromophobes, basophils, eosinophils) at right.

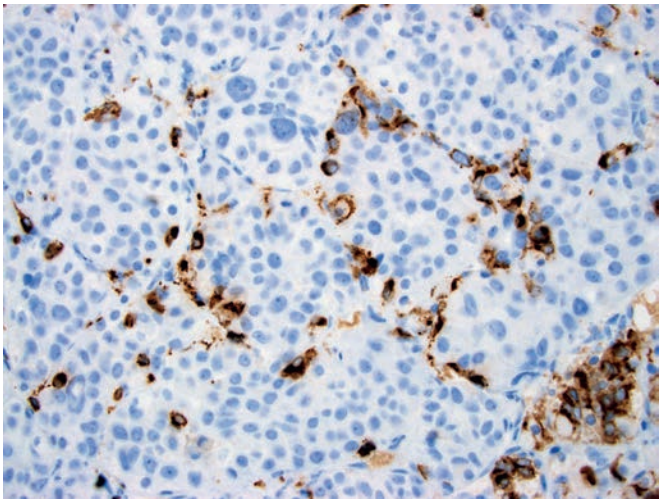

Figure 44.61 Metastatic breast carcinoma to the pituitary gland has so intimately infiltrated the anterior pituitary that acini are not totally destroyed; prolactin-immunoreactive residual normal anterior pituitary cells envelop nests of the metastatic tumor.

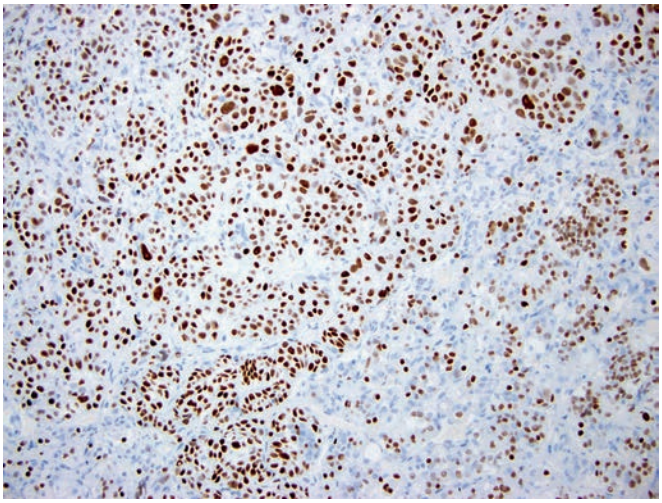

Figure 44.62 In this case the metastatic breast carcinoma shows strong diffuse nuclear immunoreactivity for estrogen receptor. Note, however, that the residual normal anterior pituitary gland, at lower right, also contains a few scattered, smaller-sized nuclei that are also ER positive. These are either gonadotrophs or lactotrophs.

frequent of the three entities, with small incidental tumors predominating over clinically evident examples.

Metastatic Tumors

Pituitary metastases constitute less than 1% of all intracranial metastases premortem, but up to 2% of postmortem cases show pituitary gland involvement.[82] The autopsy incidence is particularly high in patients with breast carcinoma.[82] In clinically evident cases, metastases from breast and lung are the most frequent, followed distantly by prostate and renal cell carcinomas. Metastases to the pituitary gland usually obliterate or compress the gland and therefore usually do not cause significant diagnostic confusion. Occasionally, however, the metastatic tumor is intimately associated with recognizable residual anterior gland (Fig. 44.60). In these instances, pituitary acini may not be totally destroyed and residual normal anterior pituitary cells may envelop nests of the metastatic tumor (Fig. 44.61). IHC may be required to distinguish metastatic cells from residual pituitary cells (Fig. 44.62).

Involvement of the neurohypophysis, extrasellar bone, and dura causes most pituitary metastases to clinically present as diabetes insipidus, in contrast to pituitary adenomas.[82] Meningiomas, and rarely chordomas or other bony neoplasms of the sella, can mimic adenomas by neuroimaging.

Introduction

This chapter will cover primarily those entities that come to the attention of the surgical pathologist; therefore most non-neoplastic entities of the intraocular tissues will be excluded. Dystrophies and degenerative conditions of the cornea also represent a complex subject which will not be covered here. For a more detailed description of these and other diseases, the reader is referred to one of the many specialized textbooks available.[1–7] As with all surgical specimens, a complete description of the lesion and a meaningful clinical history are invaluable. Clinical photographs are especially helpful in ophthalmic pathology.

Normal Anatomy

The *eyelids* are divided into a cutaneous and a conjunctival portion. The former is composed of stratified squamous epithelium and the latter of a much thinner conjunctival epithelium. In addition to standard pilosebaceous units, skin appendages of eyelids include sebaceous glands of Zeis, apocrine glands of Moll, and eccrine sweat glands, as well as the large sebaceous meibomian glands embedded in the thick fibrocellular tarsal plate.

The *lacrimal gland* is largely of serous type, with a minor mucinous component in the ductal portion and a layer of myoepithelial cells in the larger peripheral ducts. In addition to the main lacrimal gland in the orbit, accessary lacrimal glands of Wolfring and Krause are present at the base of the tarsal plate and conjunctival fornix, respectively. The *lacrimal passages* allow tears produced by the lacrimal gland to be transported from the eye into the *nasal cavity*. Tears enter from the ocular surface into upper or lower *punctum* and drain through the *canaliculus* into the *lacrimal sac* and then the *nasolacrimal duct*, which opens in the nasal cavity. The canaliculus is lined by stratified, nonkeratinized epithelium, while both the lacrimal sac and the nasolacrimal duct are lined by *stratified columnar epithelium* containing mucus-secreting goblet cells.

The *orbit* contains, in addition to the ocular globe and the lacrimal gland, the following structures: the optic nerve and its meningeal covering, Tenon's capsule, the extraocular muscles, blood vessels, and a delicate framework of fibroadipose connective tissue.

The *conjunctiva* is a thin mucous membrane that lines the inner surface of the eyelids and most of the anterior surface of the ocular globe. The conjunctival epithelium is composed of two to five layers of columnar cells that rest on a continuous basal lamina. This epithelium contains mucin-secreting goblet cells and melanocytes.

Abstract

The eye and ocular adnexa contain a number of specialized structures, as well as tissues similar to those found at other body sites. Pathology in this region therefore represents a mixture of unique and common entities. This chapter reviews the normal anatomy and histology of the eye, eyelid and orbit, as well as neoplastic and non-neoplastic ophthalmic diseases encountered by surgical pathologists. Some specialized aspects of non-neoplastic ocular pathology, including corneal dystrophies, are not covered.

Keywords

eye
orbit
eyelid

The *caruncle* is a small, fleshy protuberance that fills the triangular space between the medial margins of the upper and lower eyelids. It is covered by epithelium similar to conjunctiva, but contains pilosebaceous units and sweat glands.

The *cornea* consists of six distinct layers: epithelium, epithelial basal lamina, Bowman layer (an acellular structure made up of collagen fibers, which cannot regenerate), stroma, Descemet membrane (a basal lamina produced by the underlying corneal endothelial cells), and a single layer of very flat cells known as "endothelium," but not related to vascular endothelium. A region of epithelial progenitors known as the *limbus* surrounds the cornea.

The thick *sclera* encloses the globe and is mainly composed of a dense collagenous stroma admixed with occasional elastic fibers and scattered fibroblasts.

The *intraocular tissues* comprise the uveal tract (iris, ciliary body, and choroid), the retinal pigment epithelium, the retina, the crystalline lens, and the various intraocular compartments. A detailed description of these structures and how they age is beyond the scope of this book but has recently been reviewed.[8]

Eyelids

Most of the pathologic processes that involve the eyelids are those that affect the skin in general and are considered in detail in Chapters 2 and 3. Some consideration, however, is given in this chapter to those lesions that are either peculiar to the lids or present particular problems in this location.

Developmental Anomalies

Dermoid cysts typically involve the upper eyelid along the lateral brow margin, where ectoderm becomes entrapped during embryologic bony fusion, and often represent forward extension of a mass that is primarily intraorbital (Fig. 45.1). Microscopically, the cysts are lined by well-differentiated epidermal and dermal tissues containing all of the usual skin appendages. The lumen is filled with keratinous debris, sebum, and hairs. In places where these contents have been extruded into the surrounding tissues, a severe foreign body inflammatory reaction may be observed (Fig. 45.2).

Inflammation

Inflammation of the eyelids *(blepharitis)* may be the result of viral, bacterial, rickettsial, mycotic, or parasitic infections; chemical or physical irritants; hypersensitivity states; or systemic dermatologic disorders. These inflammatory processes are rarely biopsied. Eversion or sagging of the eyelid, known as *ectropion*, is often corrected surgically and results in specimens showing conjunctival goblet cell loss and squamous metaplasia (Fig. 45.3).

Granuloma annulare *(Pseudorheumatoid nodule)* can occasionally involve the eyelid and eyebrow and rarely the episcleral and orbital tissues; it generally presents in children and young adults.[9]

Necrobiotic xanthogranuloma with paraproteinemia is characterized by multiple nodules or plaques that involve the periorbital areas (including eyelids) along with other parts of the body. A dysproteinemia is frequently present, and the lesions can also be associated with multiple myeloma. Microscopically, the granulomas are characterized by collagen "necrobiosis" together with foamy macrophages and Touton giant cells.[10]

Chalazion

Chalazion is an extremely common lesion. It represents a lipogranuloma that develops in and about a meibomian gland as a consequence of the effects of obstruction. The sebaceous material discharged into the tarsus provokes an intense granulomatous inflammatory reaction (Fig. 45.4).

Although chalazion begins as a deep-seated process, not infrequently it erupts through the conjunctival surface of the eyelid and

Figure 45.1 Dermoid cyst of right upper eyelid.

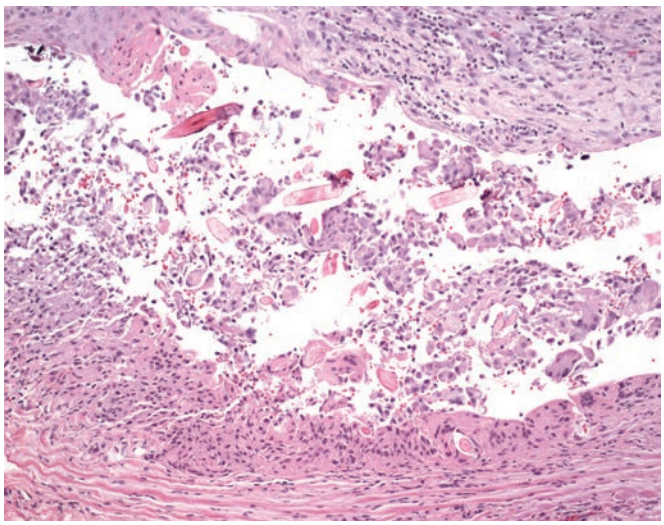

Figure 45.2 Ruptured orbital dermoid cyst containing hair with foreign body reaction.

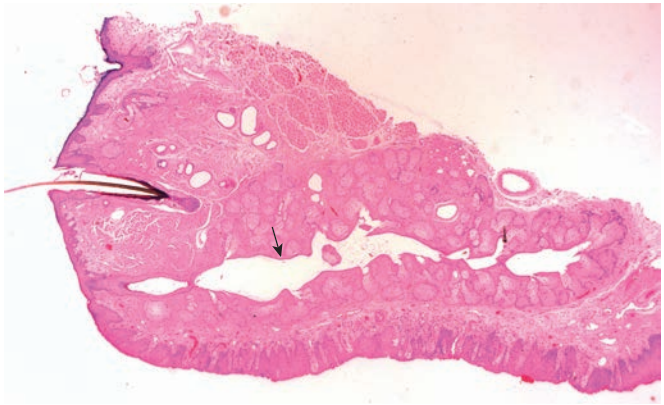

Figure 45.3 Eyelid Ectropion. The meibomian gland duct is also dilated *(arrow)*.

can be associated with an overlying pyogenic granuloma. Ordinarily, this lesion is readily recognized and treated; however, if one or more recurrences develop after curettage, sebaceous carcinoma arising from the meibomian gland or other neoplasm must be ruled out.

Microscopically, the typical chalazion reveals multiple foci of granulomatous inflammation (Fig. 45.5). In the center of many of the granulomas there are small globules of fat, which in paraffin sections present as empty, round to ovoid spaces.

Cysts

Benign cysts of the skin of the eyelids and along the lid margins are relatively common, comprising approximately one-third of lesions removed from the lids. The most common of these are the *keratinous cysts* discussed in Chapter 3. Keratinizing intratarsal *Meibomian gland cysts* have recently been described, which arise from ductal epithelium and, in contrast to cutaneous keratinous cysts, are positive for keratin 17 and carcinoembryonic antigen (CEA).[11]

Cysts arising from blocked sweat glands are common in the periocular region and are known as sudoriferous cysts or hidrocystoma. They are filled with a watery fluid and can be multilocular (Fig. 45.6). *Apocrine* and *eccrine hidrocystoma* are differentiated by the tall apical epithelial snouts and "decapitation" secretion in the former, and flatter epithelial profiles in the latter. In one institutional series of 5504 eyelid cases, hidrocystomas represented 8% of all benign lesions.[12]

Tumors and Tumorlike Lesions

Tumors and Tumorlike Lesions of Surface Epithelium

Basal cell carcinoma is by far the most frequent neoplasm arising in any of the palpebral tissues.[13] The overwhelming majority are easily excised without sequelae. On rare occasions, if left untreated for long periods, they may invade the orbit, nose, or both, and exenteration of the orbit may become necessary. Microscopic examination of the margins by frozen section at the time of surgery is a useful technique for ensuring that total removal of the tumor has been achieved.

Basal cell carcinomas arise from the cutaneous surface of the eyelids and rarely, if ever, from the conjunctiva. This point is of some diagnostic significance, for a *papilloma* of the palpebral conjunctiva, or more ominously a *sebaceous carcinoma* involving the conjunctiva and lid margin, may resemble basal cell carcinoma.

Squamous cell carcinoma is responsible for 4%–12% of all malignant epithelial tumors of the eyelid.[14] Most cases are located in the lower lid.[14] A small percentage of these tumors are of the adenoid (pseudoglandular or acantholytic) type.[15] Clear cell or vesicular change can also be seen in squamous carcinoma and can mimic sebaceous carcinoma. Vacuolar adipophilin expression is useful in distinguishing sebaceous carcinoma from basal or squamous cell carcinoma.[16,17]

Figure 45.4 Chalazion of right upper eyelid.

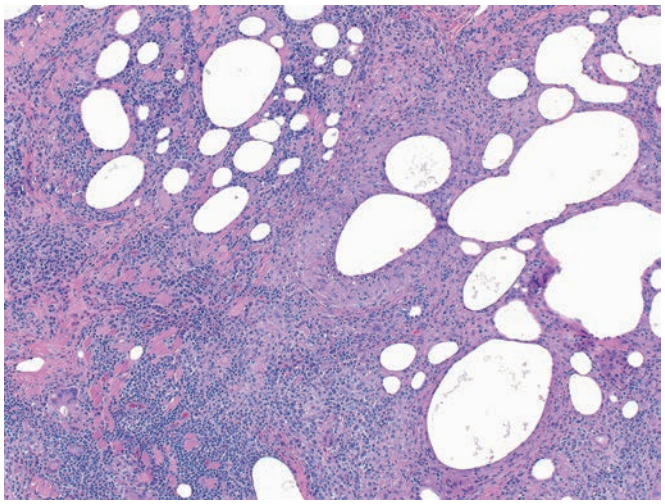

Figure 45.5 Multiple foci of granulomatous inflammation with lipid drop-out spaces in chalazion.

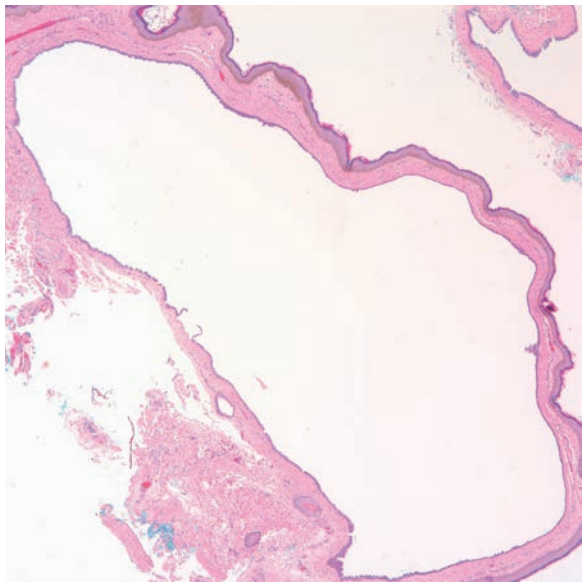

Figure 45.6 Obstruction of outflow from the gland of Moll can lead to apocrine hidrocystoma.

Merkel cell carcinoma can occur in the eyelid, its morphologic appearance being the same as elsewhere in the skin. Most reported cases have been located in the upper eyelid, where they have presented as a large, nontender, red, or violaceous mass.[18]

Non-neoplastic keratotic lesions may closely resemble squamous cell carcinomas. They include such entities as papilloma, pseudoepitheliomatous hyperplasia, keratoacanthoma, inverted follicular keratosis, irritated seborrheic keratosis, actinic keratosis, and cutaneous horns. The histopathologic features of these lesions are described in Chapter 3.

Adnexal Tumors

Sebaceous adenomas and carcinomas may arise from the cutaneous sebaceous glands, the glands of Zeis, or the meibomian glands (Fig. 45.7).[19] They seem to be more common in Asian countries.[20] Muir–Torre syndrome should be considered when sebaceous adenomas or carcinomas are diagnosed around the eye, but the association at this site is not as strong as elsewhere on the skin.[21,22] Some of these carcinomas have been seen as a second malignancy following radiation therapy for retinoblastoma (RB).[23] Periocular sebaceous carcinomas can clinically mimic a range of conditions and are not infrequently misdiagnosed as squamous cell or basal cell carcinomas.[24]

Solitary adenomas of the meibomian and Zeis glands are rarely seen. Indeed, while sebaceous carcinomas can show considerable histologic variation, in the eyelid they tend to be more poorly differentiated that at other cutaneous sites (Fig. 45.8). DNA mismatch repair defects are less common in sebaceous neoplasms arising in the eyelid than elsewhere on the skin.[22]

The most common presentation of sebaceous carcinoma in the eyelid is as round highly cellular nests of poorly differentiated tumor cells in the dermis, sometimes with central necrosis in a comedocarcinoma pattern (see Fig. 45.8). While better-differentiated cells with vacuolated cytoplasm can sometimes be identified, they are generally rare and sometimes completely absent. In such situations immunostains for adipophilin have been used to document sebaceous differentiation.[17] EMA immunostains are generally less useful, as they only highlight well-differentiated sebaceous cells. Oil red O stains for fat can also be helpful but are limited to frozen sections.

Additional valuable clues to the diagnosis can be found in the pattern of tumor dissemination, as intraepithelial spread through the conjunctiva is quite common, and is not seen in basal cell carcinoma (Fig. 45.9). Indeed, sometimes intraepithelial sebaceous carcinoma is encountered in the conjunctiva in the absence of a clear subepithelial tumor mass. This is sometimes referred to as "*in situ*" sebaceous carcinoma, although it is not clear if this represents a true primary conjunctival lesion or spread from an occult site. Pagetoid involvement of the overlying skin can also occur, resulting in a clinical picture of chronic blepharoconjunctivitis, sometimes with no clear mass lesion present.

In the series of sebaceous carcinoma by Rao et al.,[25] 23 out of 104 patients died from metastatic disease, confirming the fact that sebaceous carcinoma is a more aggressive neoplasm when located in the ocular adnexa. Features indicative of a poor prognosis were orbital or vascular invasion, involvement of both eyelids, poor

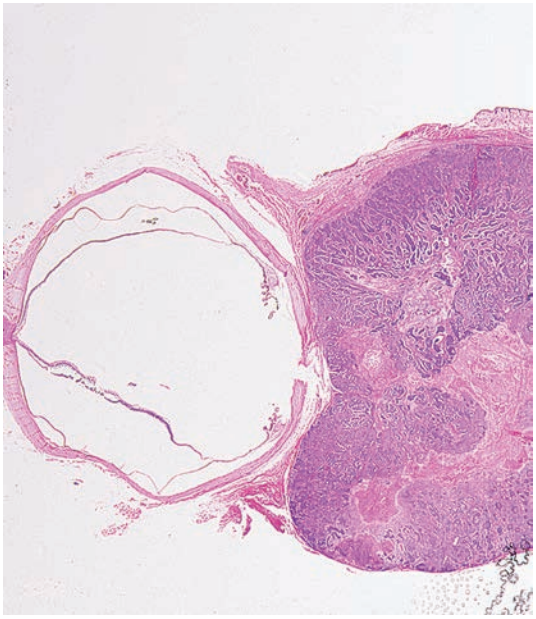

Figure 45.7 Whole mount of sebaceous gland carcinoma compressing but not infiltrating the ocular globe. The tumor is sharply circumscribed and very cellular and has areas of necrosis.

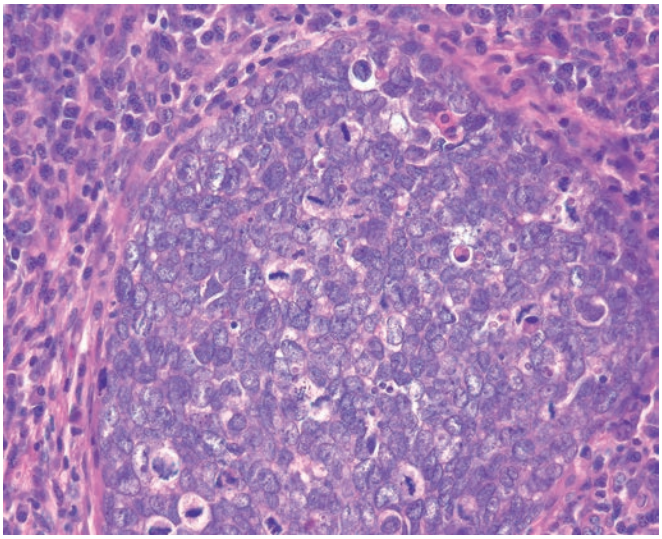

Figure 45.8 Poorly differentiated sebaceous carcinoma.

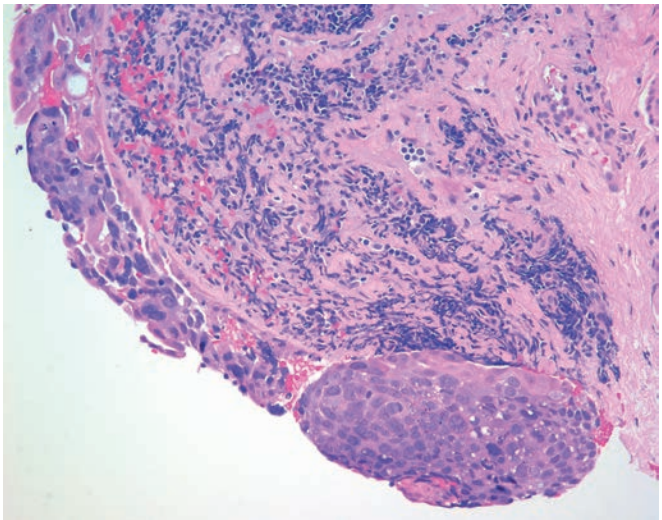

Figure 45.9 Sebaceous carcinoma replacing the majority of the conjunctival epithelium.

differentiation, multicentric origin, large size, a highly infiltrative pattern, and pagetoid spread.[23] Mapping biopsies from multiple sites on the eyelid and ocular surface are sometime taken prior to definitive excision of a sebaceous carcinoma; p16 and p53 immunostains can be useful in highlighting intraepithelial tumor cells in these situations.[24]

Endocrine mucin-producing sweat gland carcinoma (EMPSGC) of the eyelid is composed of bland, round to oval cells with variably solid, cystic, and papillary growth patterns (Fig. 45.10). These lesions are distinctive due to their focal expression of EMA and neuroendocrine markers such as synaptophysin and chromogranin, in conjunction with mucin production (Fig. 45.11). They appear to represent a precursor of invasive mucinous carcinoma of skin, which can also present around the eye.[26,27] Diffuse expression of cytokeratin 7, CEA, estrogen receptor proteins, and other apocrine markers is common and can be useful in distinguishing EMPSGC from other sweat gland tumors.[28] While local recurrence is not uncommon, this group of tumors rarely metastasize or prove fatal, and expression of neuroendocrine markers does not appear to be of prognostic significance.[27]

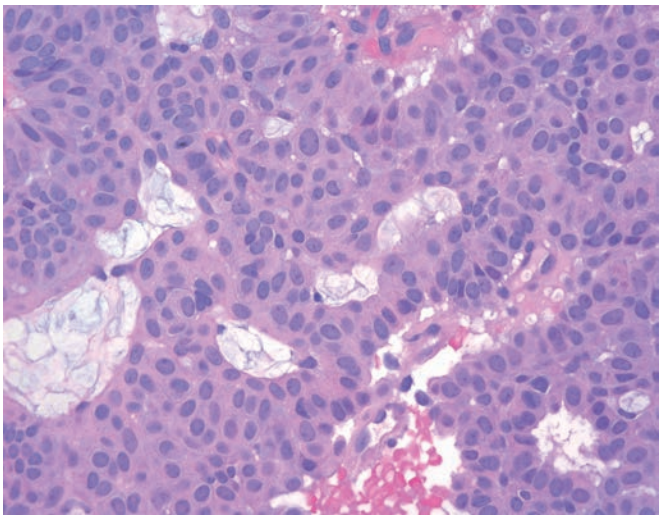

Figure 45.10 Endocrine mucin-producing sweat gland carcinoma showing predominantly solid growth with small mucin-filled cystic spaces.

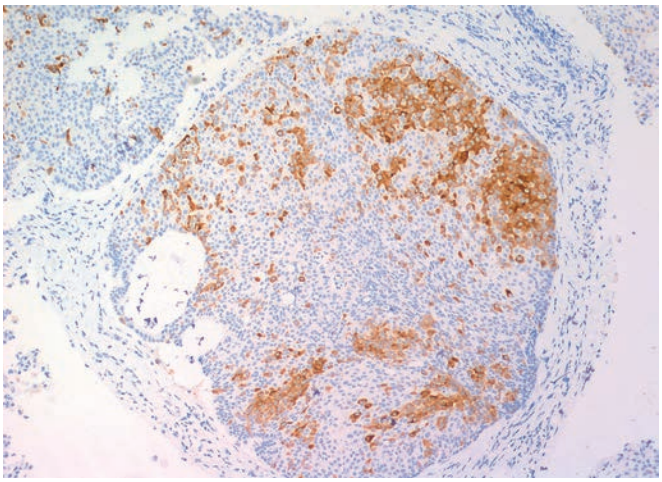

Figure 45.11 Expression of synaptophysin and other neuroendocrine markers is generally focal in endocrine mucin-producing sweat gland carcinoma.

Signet ring/histiocytoid carcinomas morphologically similar to those seen at other sites can arise in the eyelid.[29] Before making the diagnosis of a primary tumor, the possibility of a metastasis from the breast or other organs needs to be ruled out.

Melanocytic Tumors

Melanocytic nevi may be observed in either the cutaneous or the conjunctival surface of the eyelids. The lid margin is a particularly common site, and the divided or "kissing" nevus is a rare but developmentally interesting variant.[30] Most nevi are of the junctional or compound type, but all variants can be encountered at this site, including nevi associated with the Meibomian gland (Fig. 45.12). A more diffuse and deeply situated melanotic lesion of the lids thought to be related to incomplete melanocyte precursor migration is the *nevus of Ota* (congenital oculodermal melanosis). This is a form of extrasacral mongolian spot involving the face in areas supplied by the first and second branches of the trigeminal nerve. This type of nevus occurs more frequently in Asians and blacks than in whites. It is associated with an increased incidence of melanoma and melanocytoma of the eyes, orbit and meninges, with *GNAQ* mutations identified in malignant lesions.[31] *Melanosis oculi* is a related congenital anomaly characterized by variable hyperpigmentation of the conjunctiva, episclera, sclera, uveal tract, and, occasionally, the optic nerve. Patients with this disorder have an increased incidence of ocular malignant melanoma.[32] So-called **acquired melanosis** is a disorder that may involve either surface or both surfaces of the eyelid in association with the conjunctiva and is described in the section on the conjunctiva.

Melanoma of the eyelid is rare.[33] It may originate from a nevus that has been present for many years, from an acquired melanosis of variable duration, or de novo. Nodal metastasis at presentation has been significantly correlated with American Joint Committee on Cancer T category and time to local recurrence or metastasis.[34]

Lymphoid Tumors and Tumorlike Conditions

The morphologic appearances and diagnostic problems presented by these lesions when located in the eyelid are largely similar to those of analogous lesions of the skin, conjunctiva, and orbit; the latter are fully discussed later in this chapter. The only differences of note are that the percentage of malignant tumors seems to be

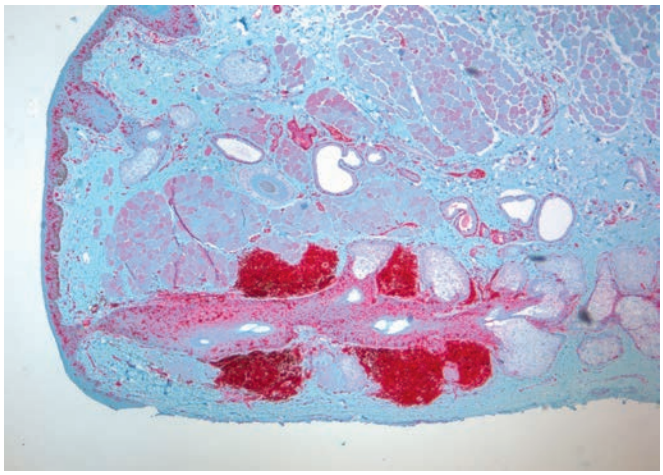

Figure 45.12 MART1 immunohistochemistry highlights a melanocytic nevus associated with the meibomian gland.

higher for lymphoid masses in the eyelid than for those in the other sites, and that the eyelids seem to be the preferential site of involvement for the rare anaplastic large cell lymphoma of the ocular region.[35]

Mesenchymal Tumors and Tumorlike Conditions

Angiomas may present as small lesions confined to the eyelid or extend deep into the orbit.[19] Hemangiomas are more common than lymphangiomas. Their histopathologic characteristics are described in Chapter 3.

The so-called *port-wine stain* (nevus flammeus) is of special interest not only because of its significant cosmetic effect, but also because it may be associated with malformations in other tissues. In the *Sturge–Weber syndrome*, the facial hemangioma may be associated with choroidal hemangioma, glaucoma, and meningeal hemangioma, all on the ipsilateral side (Fig. 45.13).

Masson hemangioma (intravascular papillary endothelial hyperplasia) can develop in the eyelid, either de novo or engrafted on a preexisting vascular lesion. *Hemangiopericytoma* also occurs in the eyelid and orbit, the current interpretation being that it represents a *solitary fibrous tumor* with a hemangiopericytoma-like pattern of growth.[36] Cases have also been reported of *epithelioid hemangioendothelioma*.[37] and *myoepithelioma*.[38]

Neurofibromas can present as isolated lesions or as a component of von Recklinghausen disease. Although believed to be present from birth, these tumors frequently show accelerated growth during childhood or later. **PEComas** (perivascular epithelioid cell tumors) can exceptionally involve the eyelid.[39]

Xanthelasmas are slightly elevated yellow plaques located on the medial aspect of the upper and lower eyelids (Fig. 45.14). They are rarely indicative of any serious systemic disturbance and are usually removed for cosmetic reasons. Most of the patients are in the fifth or sixth decade of life. Patients with familial hypercholesterolemia may develop these lesions at a younger age. Microscopically, these lesions show large, pale-staining, fat-laden histiocytes throughout the subepithelial tissues (Fig. 45.15). If atypia is present, the possibility of primary or metastatic histiocytoid carcinoma should be considered.

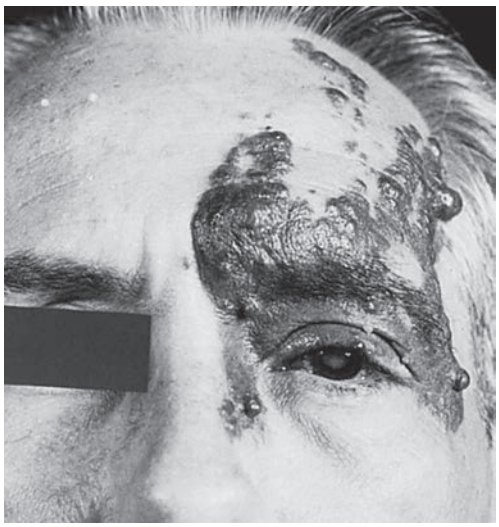

Figure 45.13 Sturge–Weber Syndrome. The patient, a 42-year-old man, had had facial hemangioma all his life and was blind in the ipsilateral eye because of retinal degeneration, glaucoma, and cataract. Choroidal hemangioma was found in the enucleated eye, but clinical study failed to disclose evidence of an intracranial lesion. (Courtesy of the Veterans Administration Hospital, Hines, IL.)

Amyloidosis can occur in the eyelid and conjunctiva as a localized mass. It presents as a chronic painless mass, usually not associated with any systemic disease, although myeloma and related conditions can be present.[40]

Metastatic Tumors

Carcinomas from various sites can metastasize to one or both eyelids, sometimes as the first manifestation of the disease. A notorious diagnostic trap in this area is the mammary lobular carcinoma having striking histiocytoid features and simulating an inflammatory process (Fig. 45.16).[41]

Lacrimal Gland

While most lacrimal gland lesions are orbital, they can extend into the eyelid or arise from accessory lacrimal glands in the eyelid base. Lacrimal gland lesions are divided into nonepithelial and epithelial groups. Among the epithelial tumors, benign mixed cell tumor (pleomorphic adenoma) is the most common. The nonepithelial

lesions, which make up over half of the cases, include inflammatory pseudotumor, lymphoid hyperplasia, nonspecific dacryoadenitis, sarcoidosis, Mikulicz disease, Sjögren syndrome, and lymphoma. Nonspecific chronic dacryoadenitis, comprised of patchy or diffuse lymphoplasmacytic infiltrates, is the type the pathologist sees most frequently. However, some specific systemic conditions should be considered.

Mikulicz Disease (IgG4-Related Disease)

When chronic dacryoadenitis is associated with enlargement of the parotid or other salivary glands, it has been referred to as *Mikulicz syndrome*. This may be the result of a variety of specific diseases, including sarcoidosis, tuberculosis, syphilis, mumps, Graves disease, malignant lymphoma, and leukemia, or associated with lymphocytic infiltration and formation of lymphoepithelial lesions historically known as Mikulicz disease. Increased numbers of IgG4-expressing plasma cells are generally found in Mikulicz disease, and it is now thought to represent part of the IgG4-related disease spectrum.[42–44]

Sjögren Syndrome

This chronic autoimmune syndrome occurs most frequently in middle-aged women. Mononuclear cell aggregates are found around the ducts and acini of salivary, lacrimal, and labial glands and result in oral and ocular dryness. However, specific inflammatory cell thresholds of the type used in labial salivary gland biopsy do not exist for lacrimal glands, making it difficult to establish a firm diagnosis based on periocular biopsies.

Tumors and Tumorlike Conditions

Most neoplasms of the lacrimal gland arise in the orbital lobe, where the gland is firmly attached to the orbital rim about the lacrimal fossa. The bone tends to restrict growth in its direction; hence, the enlarging tumor characteristically displaces the eye downward and nasally. A recent study of 702 malignant tumors of the lacrimal gland in the Surveillance, Epidemiology, and End Results (SEER) database identified lymphoma (58%), adenoid cystic carcinoma (13%), adenocarcinoma (4%), and mucoepidermoid carcinoma (4%) as the most common entities.[45]

Epithelial tumors have, on the whole, histopathologic, ultrastructural, and immunohistochemical features very similar to those of the salivary glands (see Chapter 6).[46–49] *Benign mixed tumors* (pleomorphic adenomas) account for approximately 50%–60%, *malignant mixed tumors* (carcinomas ex-pleomorphic adenomas) for 5%–10%, *adenoid cystic carcinomas* for 20%–30%, and other carcinomas for 5%–10%. Many of the mixed tumors have a predominant component of hyaline cells of presumed myoepithelial nature (Fig. 45.17). *Oncocytomas*, *epithelial–myoepithelial carcinomas*, and *myoepithelial carcinomas* have also been reported.[50–53] The carcinomas have a poor prognosis overall, although earlier detection and complete excision has resulted in some long-term survivors.[49]

The appearance of an invasive squamous cell carcinoma of the lacrimal gland can be simulated by *necrotizing sialometaplasia*, in a manner akin to that seen with greater frequency in minor (and sometimes major) salivary glands.[54]

Lymphoid tumors and tumorlike conditions (malignant lymphomas, lymphoid hyperplasias, and chronic inflammatory processes) are important causes of enlargement of the gland. In one orbital series including 114 lacrimal gland lesions, 55% were nonepithelial, with nonspecific chronic dacryoadenitis being most common, followed by malignant lymphoma and reactive lymphoid hyperplasia.[55] Chronic dacryoadenitis, particularly when it is associated with sclerosis, may be part of the spectrum of IgG4-related diseases.[56,57] However, most cases of mild dacryoadenitis lack increased numbers of IgG4-positive cells.[58] Lymphomas of the lacrimal gland are most often MALT or other low-grade B-cell neoplasms; however, more aggressive forms such as mantle cell lymphoma and diffuse large B-cell lymphoma can present at this site as well (Fig. 45.18).

Mesenchymal tumors of the lacrimal gland are exceptional. They comprise a few case reports of solitary fibrous tumor,[59] giant cell angiofibroma (a morphologic variant of solitary fibrous tumor),[60] collagenous fibroma (desmoplastic fibroblastoma),[61] and granular cell tumor.[62,63]

Lacrimal Passages

Diseases of the lacrimal passages that are of importance to the surgical pathologist are characterized by epiphora (the imperfect drainage of tears so that they flow over the lid margin onto the cheek) and by varying degrees of swelling, induration, and inflammation of the lower eyelid at its nasal end. Although inflammatory obstructions of these passages are common, neoplastic lesions are relatively rare.

Canaliculitis and Dacryocystitis

Canaliculitis and *dacryocystitis* may be the result of direct spread of inflammatory processes in neighboring structures such as the conjunctiva or nasal cavity, but more often their pathogenesis is obscure. Acute and chronic types are recognized, and the inflammatory reaction may be suppurative, granulomatous, or necrotizing, with the formation of fistulous tracts to the skin surface below the eyelid near the base of the nose.

The lacrimal passages become filled with purulent exudate in the acute suppurative types, whereas in the chronic forms the passages are narrowed by inflammatory thickening of the walls of the lacrimal canal or sac. Occasionally, there is hyperplasia of the lining epithelium and hypersecretion of mucus. At times, reactive hyperplasia of the sac may be difficult to distinguish squamous or transitional neoplasms.

Sarcoidosis may involve the lacrimal sac as an extension of upper respiratory tract disease.[64]

Mucocele

Lacrimal mucocele is another complication of chronic inflammation of the lacrimal sac. A low-grade obstructive lesion with a relatively

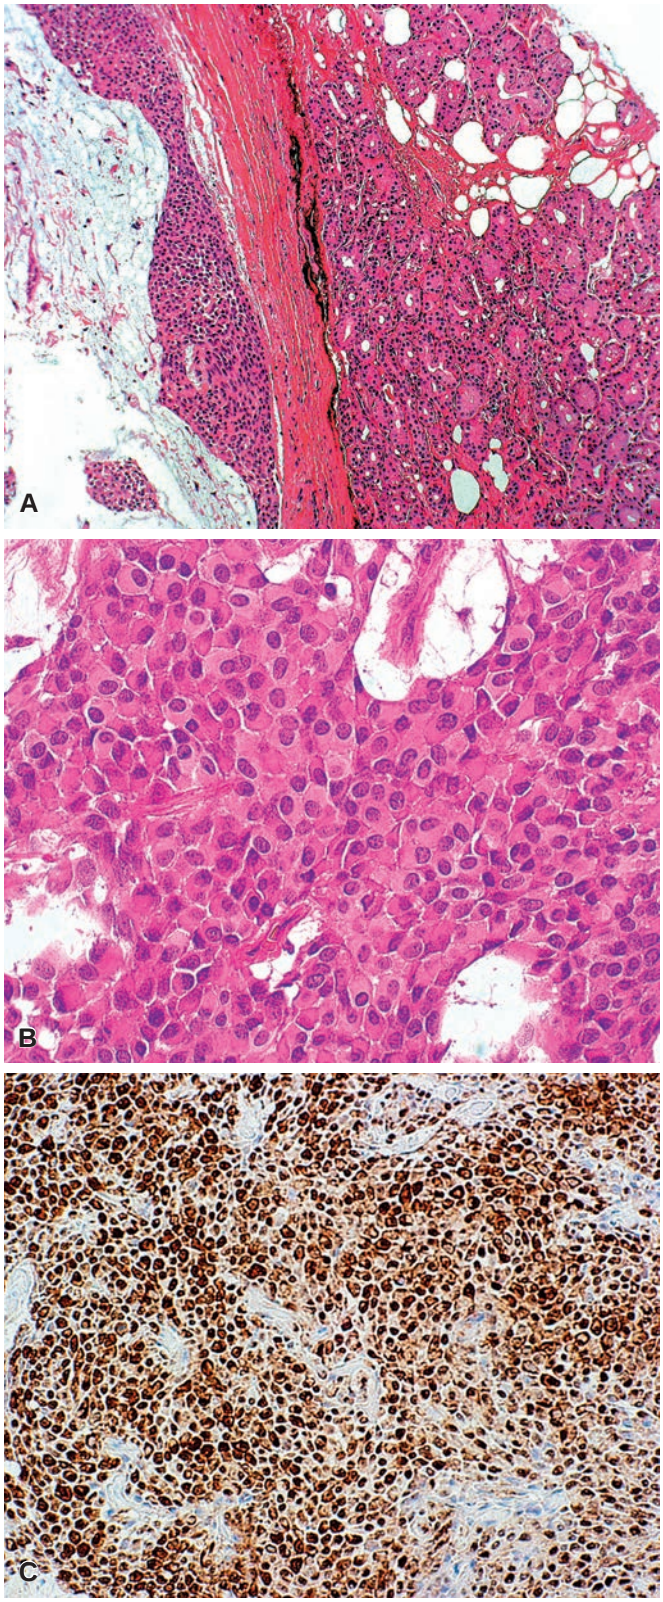

Figure 45.17 Benign mixed tumor of lacrimal gland largely composed of so-called hyaline cells: **A**, low-power view showing encapsulated quality; **B**, high-power view showing a diffuse eosinophilic appearance of the cytoplasm; **C**, strong immunoreactivity for S-100 protein.

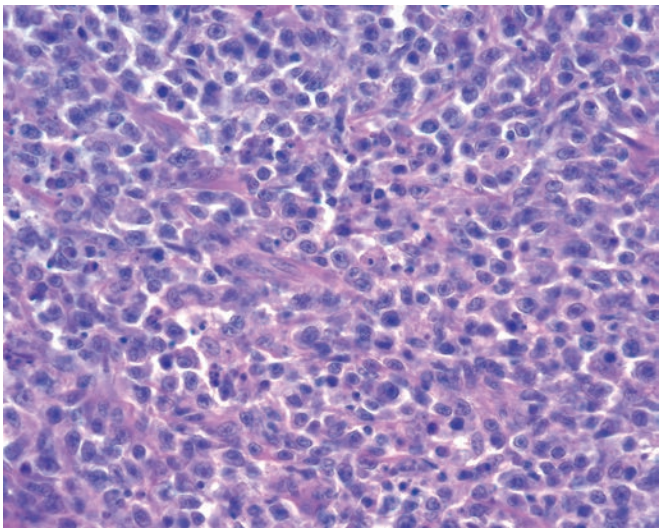

Figure 45.18 Diffuse large B cell lymphoma involving lacrimal gland and orbit.

intact and possibly hypersecreting mucosa may lead to great distention of the sac by accumulated secretions.

The contents of the cyst may be clear or milky, fluid or gelatinous, fibrinous or flocculent, sterile or infected. Microscopically, the cyst wall reveals varying degrees of atrophy, degeneration, hyperplasia, hypersecretion of the mucosa, and chronic inflammation of the subepithelial tissues.

Dacryolithiasis

Dacryolithiasis and concretions in the nasolacrimal duct ("tear stones") are of uncertain pathogenesis, but they are generally believed to be the result of low-grade inflammatory processes, including mycoses. If such concretions are crushed and examined microscopically, they will be seen to contain myriads of mycelial elements embedded in a relatively acellular matrix. Others are laminated, mineralized stones with recognizable fungal or bacterial forms.

Tumors

Neoplasms of the lacrimal passages are relatively rare but must be excluded when any space occupying or obstructive process is encountered. Primary epithelial tumors account for approximately 75% of these, with mesenchymal tumors, lymphoma, melanoma, and other rare lesions comprising the rest.[4] On clinical grounds, it is usually not possible to distinguish malignant tumors of the lacrimal passages from benign neoplasms and pseudotumors of this structure.

Papillomas may form in the punctum, within the nasolacrimal duct, or in the lacrimal sac. Squamous, transitional or mixed histologic features are recognized, and they can grow in an exophytic or inverted pattern.[4,65] Lesions showing inverted growth are more often associated with recurrence and malignant transformation. The microscopic features of *squamous papillomas* are similar to those at other sites, with stratified squamous epithelium and focal dyskeratosis. *Transitional cell papillomas* are composed of cells with features intermediate between columnar and squamous epithelium, including stratified elements and goblet cells or mucin but in general no surface keratin or prominent intercellular bridges (Fig. 45.19).[66] HPV has been identified in both papillomas and carcinomas of the lacrimal sac but not by all investigators.[67]

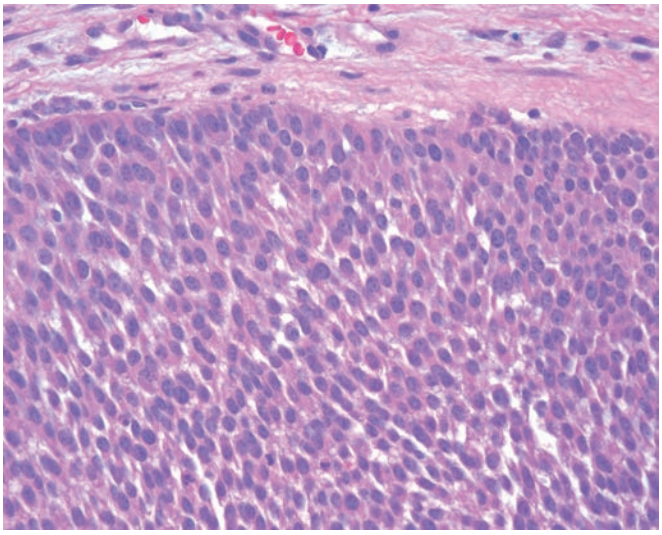

Figure 45.19 Transitional cell papilloma of lacrimal sac with inverted growth pattern. This lesion later recurred as an invasive carcinoma.

Figure 45.20 **A**, Exophthalmos of approximately 10 months' duration in a 65-year-old woman who finally died of congestive heart failure. **B,** At autopsy, extraocular muscles were found to be massively thickened.

Oncocytic tumors may develop in the lacrimal sac but are less common than in the caruncle.[68] Most of the cases are benign oncocytomas, but oncocytic carcinomas have also been reported.[4]

Any malignant tumor of the lacrimal passages except carcinoma is exceedingly rare, and even carcinoma is distinctly uncommon. When they occur, these tumors are usually moderately differentiated **squamous cell carcinomas**, similar in appearance to those arising from the mucosa of the nasal cavity or in the conjunctiva. Transitional cell carcinomas have also been reported and tend to have favorable outcomes.[4,69] Both can form papillary projections into the lumen and spread along natural surfaces, but, as noted previously, often infiltrate directly into adjacent tissues. Foci of carcinoma with increased mitotic rate and cytologic atypia can be found to arise within better-differentiated papillomas, or the entire papillary lesion may be malignant.

Other reported malignant tumors of the lacrimal sac include **mucoepidermoid carcinoma**,[70] **lymphoepithelioma-like carcinoma**,[71] **rhabdomyosarcoma**,[72] **malignant melanoma**,[73] and **malignant lymphoma**.[74] Interestingly, and in contrast to most other periocular sites, the rare lymphomas of the lacrimal sac tend to be of the diffuse large B-cell type.[75]

Orbit

The clinical hallmark of orbital disease is *exophthalmos*. This may not necessarily be caused by a true neoplasm, and therefore the surgical pathologist may never encounter any specimen from the many patients who present with this finding. Indeed, the most common cause of exophthalmos is *thyroid ophthalmopathy*, which is rarely biopsied.

As for the relative frequency of lesions that cause exophthalmos, many of the statistics that have been reported merely reflect the bias of the specialist involved. To the radiologist, for example, one of the most common orbital lesions producing displacement of the eye is a mucocele arising from a paranasal sinus. The ophthalmologist, however, would place mucocele far below such entities as thyroid ophthalmopathy, hemangioma, and inflammatory pseudotumor.[76] Procedures useful for the diagnostic evaluation of orbital masses include computed tomography (CT) scan, magnetic resonance imaging (MRI), and fine-needle aspiration.

Thyroid Ophthalmopathy

A common cause of orbital disease and of exophthalmos is thyroid ophthalmopathy (dysthyroid ophthalmopathy, thyroid eye disease, Graves orbitopathy), in which there is a dysfunction of the pituitary–thyroid axis. Patients with this condition may be hyperthyroid, hypothyroid, or euthyroid. There is often a history of hyperthyroidism or some form of treatment.

Unilateral orbital involvement occurs with sufficient frequency in both forms of dysthyroid ophthalmopathy to warrant this condition always being considered in the differential diagnosis of orbital tumors (Fig. 45.20).

Histopathologic changes observed in severe cases, which are most likely to come to the attention of the surgical pathologist, include widespread edema and chronic inflammation of the orbital tissues. The most striking gross alterations are observed in the extraocular muscles, which may be massively enlarged. Relative sparing of the tendons and orbital fat can help to differentiate thyroid orbitopathy from idiopathic orbital inflammation.[6] Muscle fibers degenerate and become hyalinized. A great increase in the interstitial connective tissue, including both cellular elements and ground substance/glycosaminoglycans, is observed particularly in the muscles.

Inflammatory Processes

Secondary inflammation of the orbit can occur from lesions arising in the face, eyes, nose, sinuses, orbital bones, blood vessels, brain, and meninges. Generally, it is only when such inflammations simulate neoplasms that orbital exploration is undertaken and tissue is obtained for histopathologic diagnosis, although biopsies to diagnose infection are also performed. Both bacterial and fungal orbital disease should be considered when inflamed or necrotic specimens are received. In addition, fungal infection can sometimes result in a fibrosing response, with infectious organisms present in only a small fraction of the tissue.

Granulomatous diseases, including those due to tuberculosis, mycosis, sarcoidosis, and polyangiitis with granulomatosis (Wegener's) are rare (Fig. 45.21). Orbital cholesterol granulomas or cholesteatomas generally involve the superior orbit and frontal bone.[77] It has been suggested that the term cholesteatoma be reserved for cases in which an epithelial lining is identified.[78]

Mucocele is the result of chronic inflammatory disease of the frontal and/or ethmoid sinuses. The lesion erodes through the wall of the sinus to produce an inferolateral displacement of the globe. The onset is usually insidious, and the enlargement is symptomless and slow.

Histopathologically, this cystic mass is lined by mucus-secreting sinus mucosa with variable degrees of inflammation and scarring. Sheets of mucin-containing macrophages can sometimes be found around these lesions.

Rosai–Dorfman disease (sinus histiocytosis with massive lymphadenopathy) can present in the orbit (Fig. 45.22).[79] Children are often affected, and the lacrimal gland can also be involved.[80] The infiltrate is composed of large histiocytes (some exhibiting lymphocytophagocytosis/emperipolesis), lymphocytes, and plasma cells; fibrosis can be very prominent.

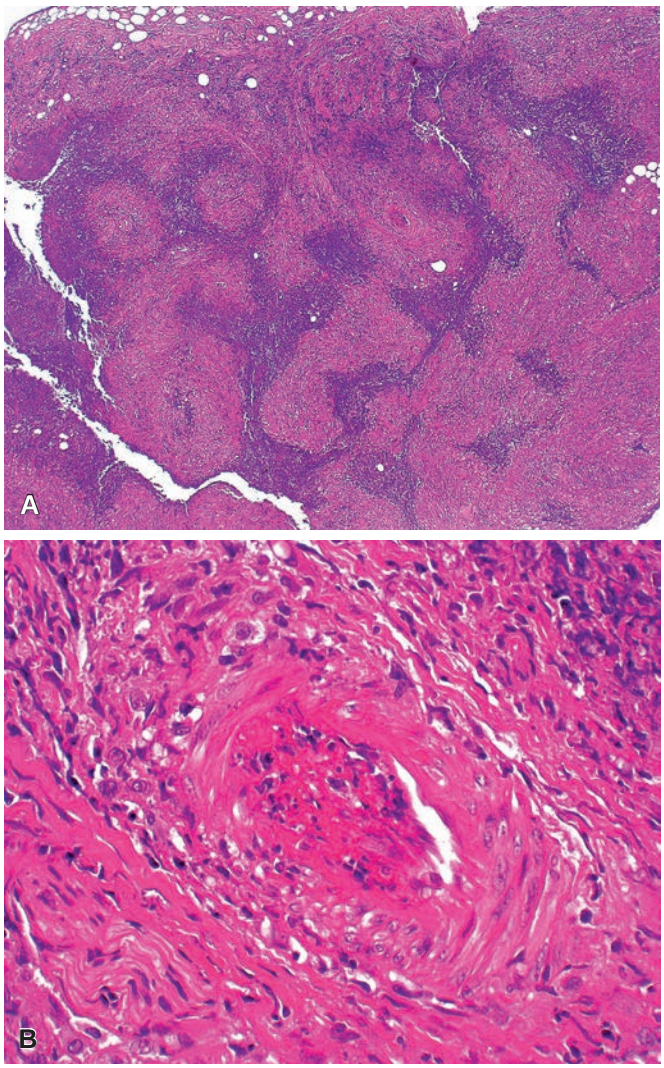

Figure 45.21 Polyangiitis with granulomatosis involving orbit: **A**, multiple confluent granulomas; **B**, vasculitis with thrombosis.

IgG4-related disease can involve all orbital structures, including lacrimal gland, extraocular muscle, and soft tissue (Fig. 45.23).[57] Somewhat increased numbers of IgG4-positive plasma cells can be identified in a range of conditions, including thyroid orbitopathy and granulomatosis with polyangiitis, and diagnostic standards in the orbit are still evolving.[81,82] A consensus group in Japan has proposed criteria, which are somewhat different from those at sites away from the eye, for ophthalmic IgG4-related disease.[44] Fibrosis and phlebitis can be absent in the periocular tissues, and lymphoid follicles with germinal centers are more frequently observed. A ratio of IgG4+ cells to IgG+ cells of 40% or above or more than 50 IgG4+

Figure 45.22 Large intraorbital mass in a case of Rosai–Dorfman disease.

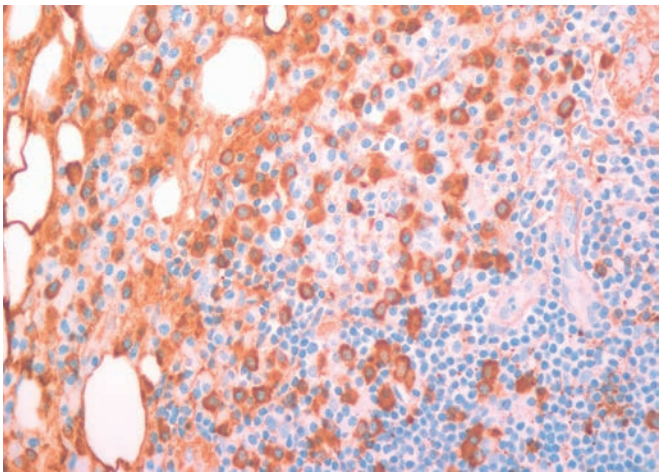

Figure 45.23 Increased numbers of IgG4-positive cells in an inflammatory process involving the lacrimal gland and orbit. The ratio of IgG4/IgG-positive cells was over 60% in this case, and serum IgG4 levels were also greatly elevated.

cells per high-power field was suggested. Xanthogranulomatous inflammation can also be associated with IgG4-related orbital disease.[58]

Inflammatory pseudotumors of the orbit (idiopathic orbital inflammation) are much more frequent than specific infections. These pseudotumors represent an etiologically and pathogenetically heterogeneous group.[6,83,84] In some instances, they have been found associated with involvement of paranasal sinuses.

The pathologic features they share include the following:

1. The formation of an indurated orbital mass often surrounding the optic nerve and incorporating one or more of the extraocular muscles.
2. A tissue reaction that includes exudation of fluid, excessive production of ground substance, mobilization of chronic inflammatory cells, vascular proliferation, and hyperplasia of connective tissue.
3. The absence of demonstrable etiologic agents or of otherwise diagnostic histopathologic alterations indicative of specific disease entities such as lymphoma, vasculitis, infection, or lupus erythematosus. A subset of lesions previously diagnosed as idiopathic orbital inflammation are now thought to represent IgG4-related disease.[82]

This is not to say, however, that the microscopic features are uniform from case to case (Fig. 45.24). In some instances the proliferation of blood vessels and ground substance resembles that of exuberant granulation tissue. At times, there is lymphoid hyperplasia with follicle formation. Other cases with prominent involvement of extraocular muscles suggest the possibility of dysthyroid ophthalmopathy.

A well-developed granulomatous reaction around small pools of fat is observed in certain cases. Such lesions may suggest traumatic fat necrosis. Others containing large numbers of cholesterol clefts and many foamy macrophages and giant cells suggest an area of old suppuration or hemorrhage. Periphlebitis is prominent in certain cases, and some of these may present a significant tissue eosinophilia, suggesting the possibility of a hypersensitivity angiitis, a parasitic infection, or Kimura disease.

Patients with orbital pseudotumors are usually in the third to fifth decade and in good health. The exophthalmos is of relatively sudden onset and in at least one half of the patients is associated with moderate to severe orbital pain and with lid and conjunctival edema. The pain is generally responsive to steroid therapy, although this is less often the case in lesions with prominent sclerosis. Diplopia is often present secondary to limitation of ocular motility in one or more fields of gaze, but visual acuity is usually unimpaired. Intracranial extension can occur.[85]

The lesion often can be palpated through the eyelids; if so, the surgeon may be able to reach it easily for a biopsy. Deeper lesions are not so readily accessible for biopsy, and if the clinical signs and symptoms are characteristic of inflammatory pseudotumor, steroids are often given without a biopsy, especially since systemic steroids often produce dramatic alleviation of signs and symptoms. The CT scan can be helpful in localizing the lesion.

Primary Tumors

Mesenchymal Tumors and Tumorlike Conditions

Rhabdomyosarcoma is the most common soft tissue sarcoma of the orbit in childhood.[55] The types seen in this age group are embryonal and alveolar, the latter being associated with a more aggressive clinical course. Some cases have occurred as a second primary tumor following irradiation for bilateral RB.[86]

Hemangiopericytoma and **solitary fibrous tumor** are closely related and part of a morphologic continuum.[87,88] The former term has been used when the tumor is diffusely hypercellular and vascularity is prominent, while the latter has been generally employed when it contains keloid-like collagen and an alternation of hypercellular and hypocellular areas (Fig. 45.25).[89] Strong immunoreactivity for CD34 and BCL2 is present, particularly in the cases with a solitary fibrous tumor pattern.[90,91] As at other sites, nuclear STAT6 immunostaining is also diagnostically helpful.[92] Rare cases behave in a malignant fashion, particularly when features of hemangiopericytoma are present.

Giant cell angiofibroma is characterized by a richly vascularized proliferation of spindle cells containing pseudovascular spaces and multinucleated giant cells, often of the so-called floret type.[93] CD34 is positive. This lesion, which is not limited to the orbit, is now thought to represent a variant of solitary fibrous tumor rich in giant cells.[88,92,93]

Alveolar soft-part sarcoma can present as a primary orbital tumor.[94] The age of occurrence, microscopic appearance, and evolution are similar to those seen in the other location of this tumor (see

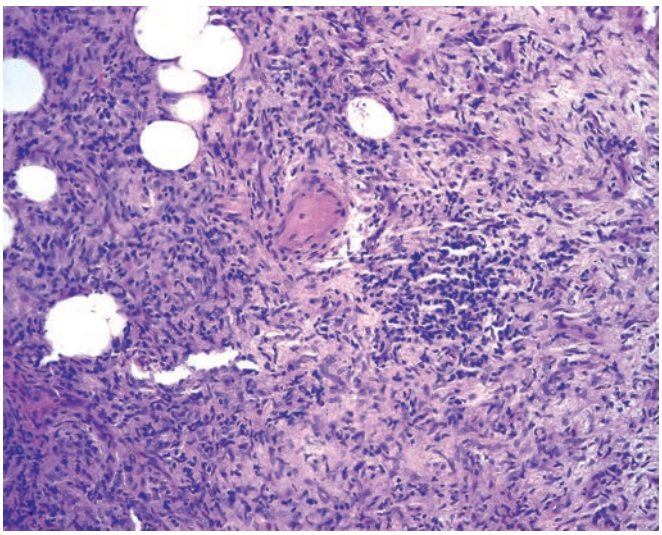

Figure 45.24 Inflammatory Pseudotumor of Orbit. Lymphocytes, plasma cells and spindle cells of fibroblastic/myofibroblastic appearance permeate the adipose tissue of the orbit.

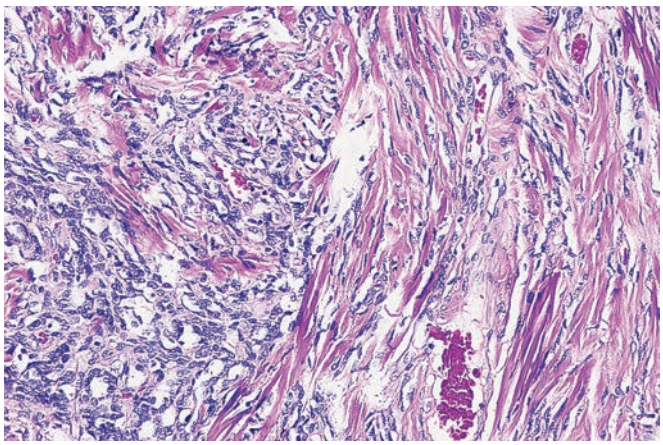

Figure 45.25 Solitary Fibrous Tumor of Orbit. The alternation of hypercellular and hypocellular areas is characteristic. The collagen has a keloid-type quality. This tumor was strongly immunoreactive for CD34.

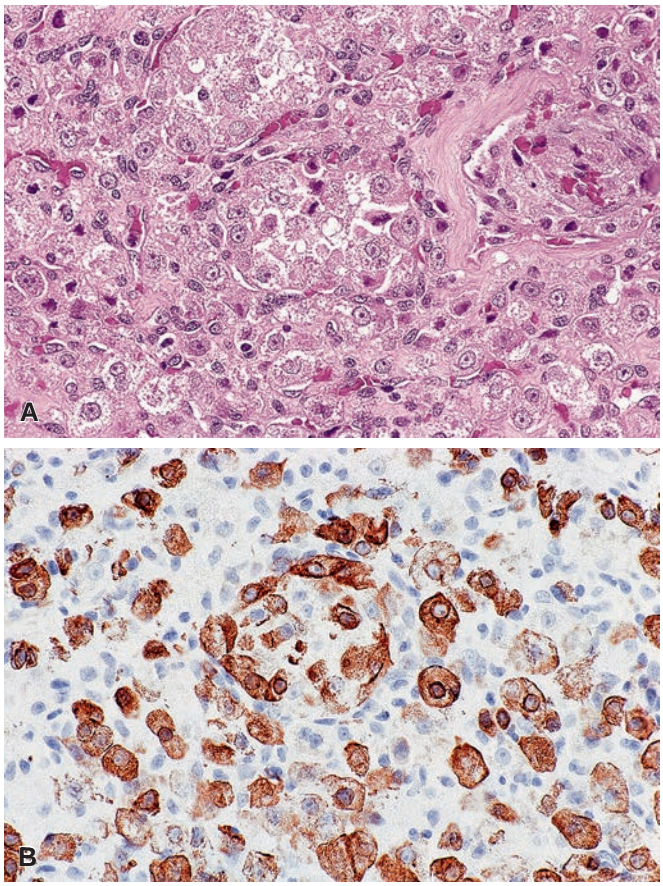

Figure 45.26 **A,** Alveolar soft part sarcoma of orbit. **B,** This degree of desmin immunoreactivity is unusual, but it constitutes strong evidence for muscle differentiation.

Chapter 25; Fig. 45.26). The clinical course is indolent, distant metastases sometimes occurring 10 years or more after initial therapy.[95]

Osteosarcoma has been reported, sometimes as a late complication of radiation therapy to the area.[96] Other malignant mesenchymal tumors, all extremely rare, include **leiomyosarcoma**,[97] **liposarcoma**,[98] **fibrosarcoma**,[99] **mesenchymal chondrosarcoma**,[100] **angiosarcoma**,[101] and **Ewing sarcoma/PNET**.[102]

Angiomas are relatively common orbital tumors, with hemangiomas occurring much more commonly than lymphangiomas.[103,104] In the infant, these soft, blue, compressible tumors are diffuse throughout the orbit and often extend forward into the eyelids. Surgical removal is difficult; fortunately, however, most hemangiomas spontaneously regress by 4 years of age. If the tumor is so large that the visual axis is covered and the eye is at risk for the development of deprivation amblyopia, such lesions can often be reduced in size using systemic steroids or oral propranolol. In the adult, these tumors are usually encapsulated cavernous hemangiomas situated close to the back of the eye and can be surgically "shelled" out. These tumors rarely present difficulties in histopathologic diagnosis, for they are not significantly dissimilar from angiomas elsewhere. In the infant, the lesion is usually of capillary type (the majority expressing GLUT-1, in contrast to vascular malformation) and in the adult of cavernous type (Fig. 45.27).[105,106]

Schwannoma and **neurofibroma** represent a small percentage of orbital tumors. Almost all orbital schwannomas are well-encapsulated tumors that can be completely removed surgically by

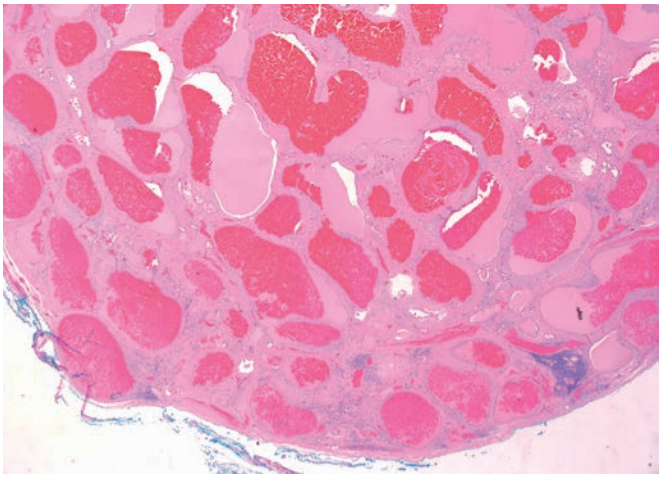

Figure 45.27 A well-circumscribed cavernous hemangioma of the orbit in an adult.

orbitotomy; some are cystic.[107] Orbital neurofibromas are usually but not always an expression of von Recklinghausen disease.[108] There may be a gross deformity of the orbit and eyelid and, on palpation, the lid has been referred to as "a bag of worms."

Other benign mesenchymal tumors that have been observed at this site are **lipoma, chondroma**, **orbital infantile myofibroma**,[109] and **osteoma**.

Tumorlike proliferations also occur within the orbit, including **nodular fasciitis**[110] and **intravascular papillary endothelial hyperplasia** (Masson hemangioma).[111] A particularly interesting type of pseudomalignant lesion is seen as a result of prolapse of intraconal orbital fat below the conjunctiva, which can simulate an atypical lipomatous tumor microscopically.[112] This non-neoplastic lesion, known as **subconjunctival herniated orbital fat or "prolapsed orbital fat,"** shows adipocytes with intranuclear vacuoles ("Lochkern"), abundant so-called floret cells (similar to those seen in pleomorphic lipoma), and inflammatory cells, but not cells with large hyperchromatic nuclei within fibrous septa, as regularly seen in true atypical lipomatous tumors.

Langerhans cell histiocytosis can involve the orbit and result in prominent exophthalmos. S-100 and CD1a immunoreactivity is useful in distinguishing these cases from Erdheim–Chester and Rosai–Dorfman disease, which can also occur at this site. As in the CNS, localized disease is generally associated with a good prognosis.[113]

Erdheim–Chester disease of the orbit is generally easily recognized due to presence of systemic disease involving long bones but occasionally has a predominantly periocular presentation.[114] It is characterized microscopically by diffuse xanthogranulomatous inflammation, and S-100 and CD1a are generally not detected. However, as in Langerhans cell histiocytosis, BRAF V600E mutations are commonly identified.[115]

Glioma of Optic Nerve

Gliomas of the optic nerve proper are relatively rare, slow-growing tumors that can arise within the intracranial or orbital segments of the nerve. Because of their indolent behavior and typical radiological appearance, they are biopsied less frequently than in the past.[116] Indeed, tumors limited to the optic nerve sometimes stop growing spontaneously and can require little or no therapy. As these gliomas increase in size, they tend to form a bulbous enlargement of the

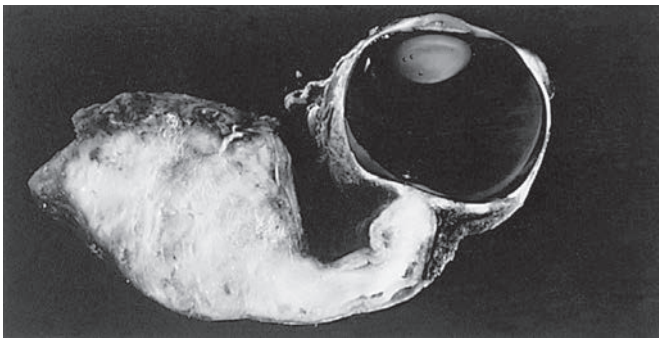

Figure 45.28 Glioma that has produced massive enlargement of the orbital segment of the optic nerve. The tumor has completely effaced characteristic architectural features of the nerve and its meninges.

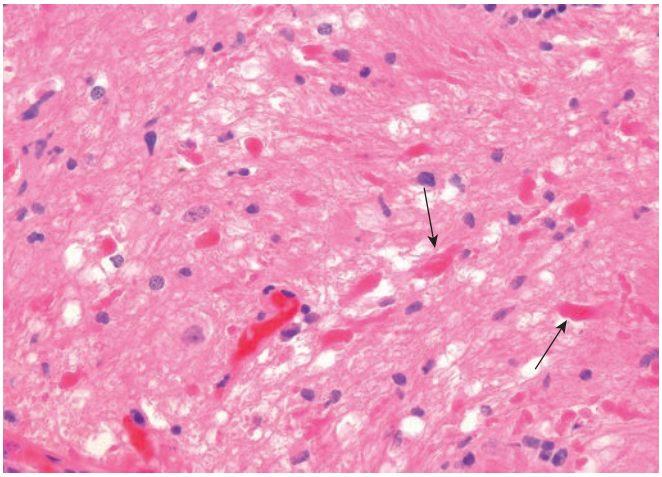

Figure 45.29 Pilocytic astrocytoma with prominent Rosenthal fibers *(arrows)*.

nerve (Fig. 45.28). They also extend along the nerve peripherally toward the eye and centrally toward the brain. Another growth pattern exhibited by a majority of optic nerve gliomas is infiltration through the pia and arachnoid. This leads to significant thickening of the leptomeninges and can include both neoplastic glia and reactive meningothelial cells, although the former generally predominate.

Microscopically, almost all optic gliomas are *pilocytic astrocytomas*, similar to those occurring in the cerebellum and elsewhere in the CNS. Rosenthal fibers and eosinophilic granular bodies are generally present, and florid vascular proliferation is sometimes noted (Fig. 45.29). Microcystic change is also often encountered. Considerable cytologic variation exists, not only from case to case but also in different portions of a given tumor. Varying degrees of cellularity are observed, but generally these neoplasms are characterized by a low degree of anaplasia with bland, round to oval cells showing bipolar hair-like processes. There are sometime areas of myxoid degeneration within the tumor. However, lesions which are monomorphous with a perivascular orientation of bland cells, prominent myxoid changes, and a lack of Rosenthal fibers may represent the somewhat more aggressive *pilomyxoid astrocytoma*. This variant is particularly common in the hypothalamic region but is still thought to form part of the pilocytic astrocytoma spectrum due to its capacity to mature into a classic pilocytic histology.[117]

Gangliogliomas are sometimes encountered in the optic nerve and are also low grade. Malignant astrocytomas, characterized by dense cellularity, high mitotic index, marked pleomorphism, necrosis, and vascular proliferation, are extremely rare in the optic nerve proper.

Figure 45.30 Meningioma of Optic Nerve. The meninges are greatly thickened, and the optic nerve reveals severe compression and atrophy *(arrows)*.

One should be consider the possibility of a cellular pilocytic astrocytoma with degenerative or reactive changes before diagnosing a high-grade astrocytoma at this site.

Gliomas of the optic nerve typically make their presence known during the first decade of life, with minimal exophthalmos, optic nerve atrophy, or papilledema and with a characteristic thickening of the nerve on CT or MRI scan. There is a distinct association of these tumors and von Recklinghausen disease, and the presence of bilateral optic nerve astrocytomas is essentially pathognomonic for neurofibromatosis type 1 (NF1). Duplications resulting in *BRAF* gene fusions are identified most optic pathway gliomas not associated with NF1, and identification of this molecular change can be useful in distinguishing these tumors from reactive piloid gliosis or other neoplasms.[116]

Meningioma

Meningiomas of the orbit can be primary (i.e., arising from the meninges of the optic nerve) or secondary lesions that invade into the orbit from the sphenoidal ridge (Fig. 45.30).[118] Occasionally, orbital meningiomas without clear links to either the coverings of the optic nerve or brain are identified. Orbital meningiomas generally produce visual loss, optic atrophy, and sometimes exophthalmos. Those arising from the inner portion of the sphenoidal ridge can cause severe compression of the optic nerve within the optic canal, resulting in papilledema or optic atrophy. CT and MRI scans have facilitated the diagnosis and localization of these tumors, with primary meningioma often showing a "tram-track" extension along the nerve (Fig. 45.31). Microscopically, most orbital meningiomas are of the meningothelial type, although many subtypes are encountered (Fig. 45.32).[118] The differential diagnosis includes exuberant arachnoidal/meningothelial hyperplasia, hemangiopericytoma/solitary fibrous tumor, Rosai–Dorfman disease, and lesions such as metastatic carcinoma with prominent associated desmoplasia.

Lymphoid Tumors and Tumorlike Conditions

Some periocular lymphoid neoplasms develop in the course of a previously recognized malignant lymphoma or leukemia. Others present initially around the eye, and while systemic involvement is eventually documented in a subset of patients, in many disease remains localized to the orbit, conjunctiva, or eyelid.[119]

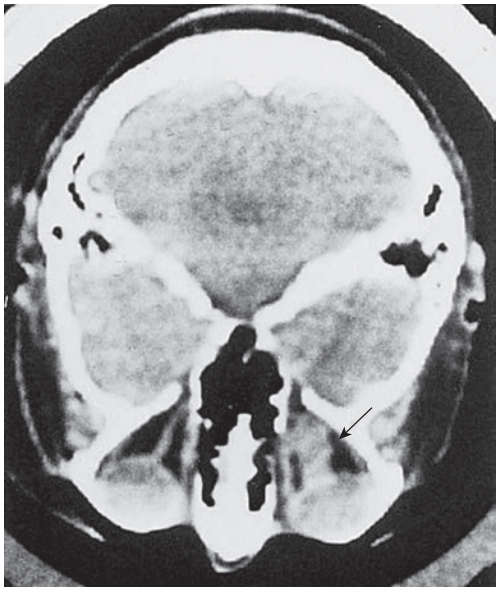

Figure 45.31 CT scan showing perioptic meningioma of left orbit *(arrow)*.

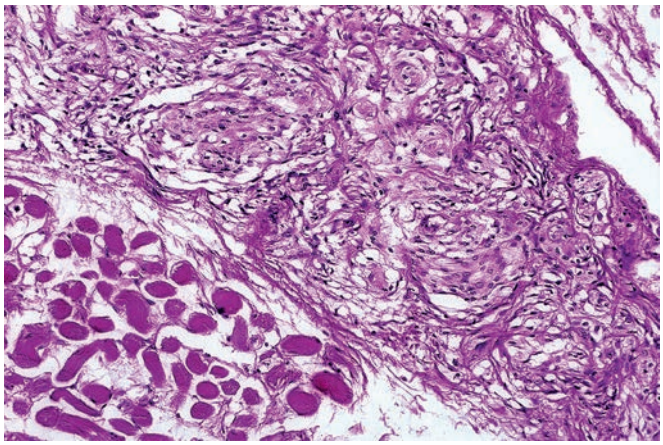

Figure 45.32 Meningioma of Orbit. The tumor has a typical meningothelial appearance.

Microscopically, the latter lesions fall into three groups:

1. Lesions that are obviously malignant, usually non-Hodgkin lymphomas. These are quite rare and include diffuse large B-cell lymphomas, including an Epstein–Barr virus–positive subset seen in the elderly[120] and anaplastic large cell lymphoma, which is often located in the eyelid.[35] An international cooperative study including 106 diffuse large B-cell lymphoma patients with disease in the ocular adnexa found that systemic tumor was present in only 43% of cases.[121]
2. Lesions that are fairly obvious examples of reactive hyperplasia with considerable polymorphism, a variety of cell types, vascular proliferation, and prominent follicles with germinal centers. IgG4-related sclerosing disease is one possible cause for the formation of such lesions.[42] As discussed earlier in this section, idiopathic orbital inflammation (orbital pseudotumor) can also present in this fashion, although follicles with germinal centers are generally less common.
3. Lesions that are characterized by a rather uniform and monotonous but widespread proliferation of small lymphocytes, frequently associated with involvement of orbital fat, blood vessels, and nerves (Figs. 45.33 and 45.34). It is this group that presents the most difficult problems in differential diagnosis[122] When neoplastic, most of these lesions belong to the category of extranodal marginal zone lymphoma (MALT lymphoma), however follicular lymphoma, mantle cell lymphoma, and small lymphocytic lymphoma can also be encountered.[122–124] In contrast, diffuse large B cell lymphomas predominate in the lacrimal sac.[75] The microscopic appearance of orbital MALT-type lymphomas is similar to that at other sites, including the inconsistent presence of plasmacytoid cells and the exceptional secondary change known as crystal-storing histiocytosis (although lymphoepithelial lesions are relatively uncommon).[125]

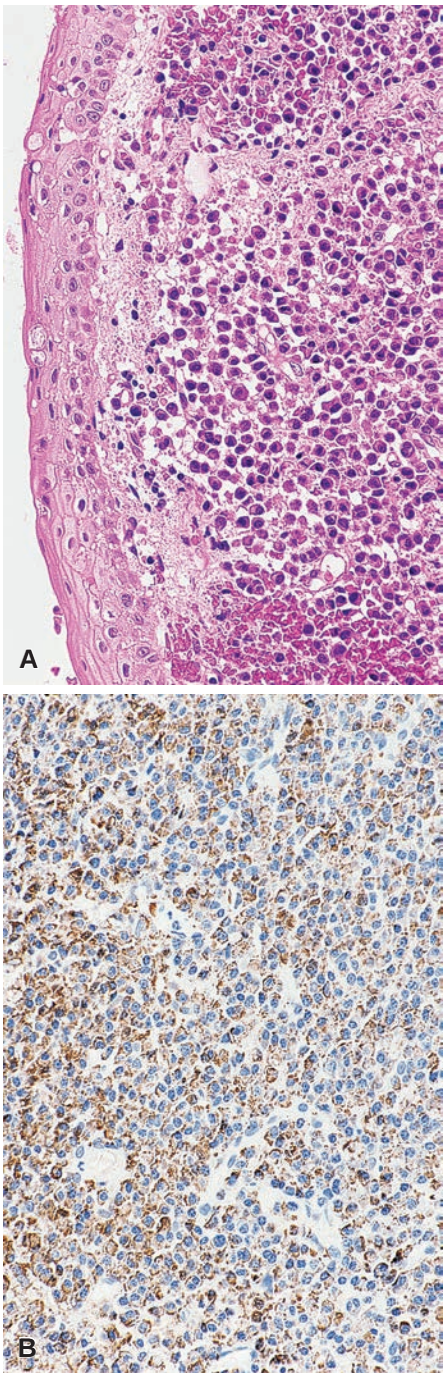

Figure 45.33 A, Malignant lymphoid proliferation of conjunctiva composed of small tumor cells with prominent plasmacytoid features. **B,** There is strong immunoreactivity for kappa light chain.

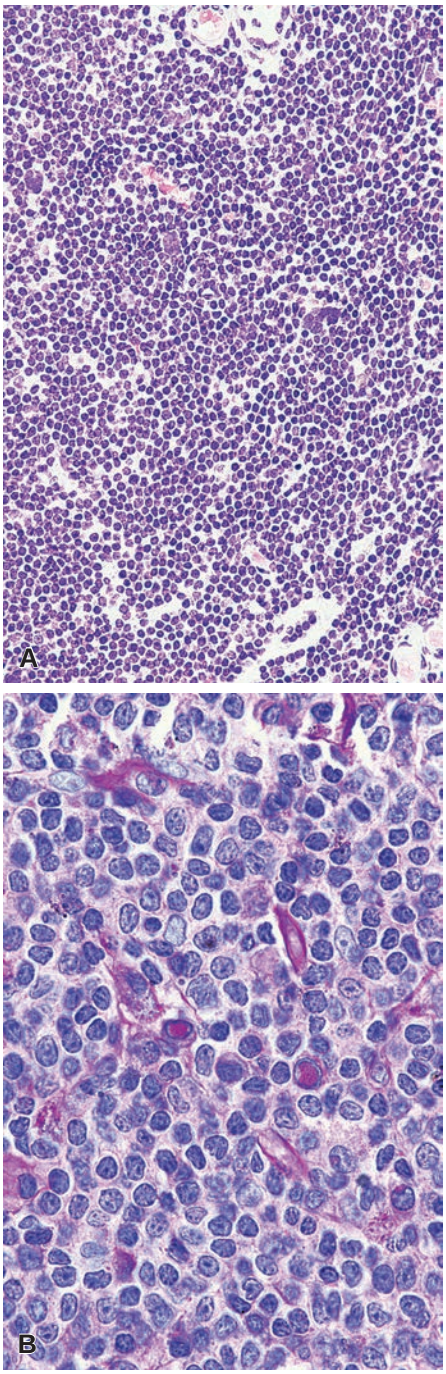

Figure 45.34 Small Lymphocytic Proliferation of Orbit. A, Low-power appearance showing a monotonous infiltrate of small lymphoid cells. **B,** PAS stain in another case, showing PAS-positive intranuclear inclusions composed of inspissated immunoglobulin (Dutcher bodies). The occurrence of these formations favors a neoplastic nature for the proliferation.

Most studies focusing on this third group of lesions have shown that it is very difficult to predict which of them will develop into systemic lymphomas, whether one evaluates them by standard morphologic criteria, by cell marker analysis, or by gene rearrangement techniques.[126,127] Many patients with small lymphocytic proliferations localized to the ocular tissues enjoy a relatively indolent clinical course.[128,129] Lymphoid infiltrates of the conjunctiva are associated with a lower incidence of extraocular lymphoma (20%) than those of the orbit (35%) or eyelid (67%).[130] Overall 5-year survival rates for ocular adnexal lymphoma were 86% in one series, and increased stage may be associated with shorter disease-free survival.[131]

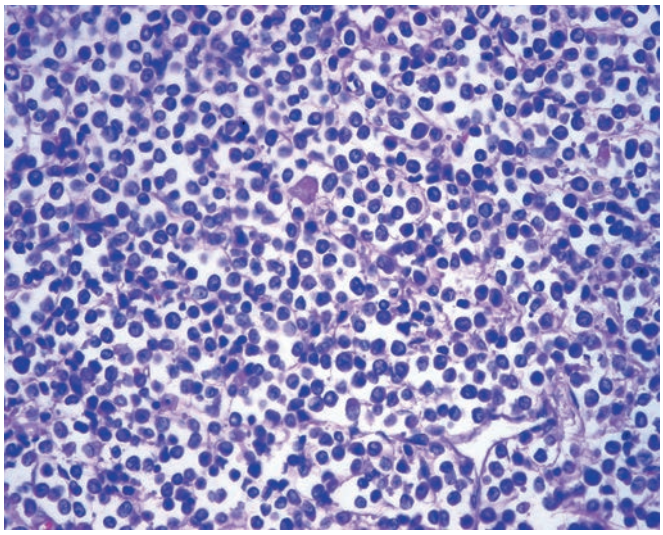

Figure 45.35 So-Called Granulocytic Sarcoma of Orbit. This represents a localized focus of acute myelocytic leukemia.

An Italian group[132] has made a provocative claim that patients with ocular adnexal lymphoma have a high prevalence of *Chlamydia psittaci* (the etiologic agent of psittacosis) infection in both tumor tissue and peripheral blood mononuclear cells, suggesting that this organism may contribute to development of the lymphomas. However, other series from other parts of the world have given very different results.[124] Some cases of ocular lymphoma have been reported as arising against the background of IgG4-related sclerosing disease.[42,133]

Acute myeloid leukemia can involve the orbit as an initially localized lesion (granulocytic sarcoma; Fig. 45.35).

Metastatic Tumors

Direct spread to the orbit from adjacent structures can occur with primary intraocular tumors such as RB or uveal malignant melanomas. Carcinomas of the paranasal sinuses may fail to produce diagnostic symptoms until orbital extension has occurred.

Hematogenous metastases to the orbit may be seen with many different tumors, but only rarely are these the initial manifestations of a carcinoma. Breast cancer represents the commonest distant metastasis in adults, with renal carcinoma representing the second most frequent type in one study.[134] Lobular breast carcinoma often infiltrates through the orbital soft tissue as single cells or in short lines and can be difficult to identify in desmoplastic or inflamed specimens.

In children, neuroblastoma has a notorious reputation for metastasizing to the orbit but rarely does so before other diagnostic signs appear. Primary embryonal rhabdomyosarcoma should not be misinterpreted as a metastatic tumor.

Carcinoid tumors of the lung or small bowel can also metastasize to the orbit or ocular globe[135]; occasionally an orbital carcinoid tumor is found in the absence of any other disease, suggesting the possibility that it may be primary at this site.[136]

Conjunctiva

Specimens from the conjunctiva are thin and tend to fold into distorted patterns when placed into fixative. To prepare the tissue so that it can be oriented properly, the surgeon should spread the

lesion onto a small piece of filter paper and allow it to dry for a few seconds before gently placing the filter paper with the adherent specimen into the jar with the fixative. Specimens should never be put onto sponges because these will expand when placed into the fixative, thus distorting the specimen.

Developmental Anomalies

Dermoid "tumors" of the bulbar conjunctiva are firm, localized, elevated opaque masses that typically occur at the limbus, often encroaching on the cornea (Fig. 45.36). These are solid choristomatous masses, not to be confused with dermoid cysts of the orbit. Over the lesion, the surface epithelium and the subepithelial connective tissue present the histologic features characteristic of epidermis and dermis, respectively. A few hairs typically project from the tumor. The bulk of the mass is composed of thick bundles of collagen. In some lesions, skin appendages are few, and adipose tissue is present; these are known as *dermolipomas* (Fig. 45.37). Additional choristomatous elements including glandular tissue can also sometimes be present. Ocular dermoids may be part of *Goldenhar syndrome*, in which there are frequently bilateral limbal lesions as well as extra-auricular appendages and vertebral abnormalities.

Cysts

Benign epithelium-lined inclusion cysts of the conjunctiva can arise after accidental or surgical trauma or, rarely, de novo. Microscopic identification of goblet cells in the lining and periodic acid–Schiff (PAS)-positive secretions in the lumen are the diagnostic keys, although focal squamous metaplasia in the cyst wall can sometimes obscure the nature of the lesion.

Degeneration

Pinguecula is a common degenerative process affecting primarily the subepithelial connective tissues of the bulbar conjunctiva in the interpalpebral region. This gives rise to an elevated yellowish lesion over which the epithelium may become atrophic or thickened. Since these lesions are not progressive, they are seldom excised. Histologically, the most characteristic feature is actinic elastosis affecting a band-like zone beneath the epithelium, which is highlighted by Verhoeff–van Gieson stains. Secondary hyalinization and calcareous degeneration also may be observed. The epithelium over pingueculae typically becomes atrophic, but at times it becomes acanthotic and dyskeratotic. Intraepithelial dysplasia must be ruled out in pinguecula, as well as in the other lesions discussed later.

Pterygium extend over the cornea and are therefore a clinically more significant lesion than the pinguecula (Fig. 45.38). Microscopically, they represent conjunctival epithelium with variable goblet cell loss and a variably fibrotic underlying stroma (Fig. 45.39). There is usually some stromal actinic elastosis but also a variable amount of acute and chronic inflammation. Reactive atypia is common in the epithelium and should be distinguished from ocular surface squamous dysplasia, which generally features sharper lateral borders.

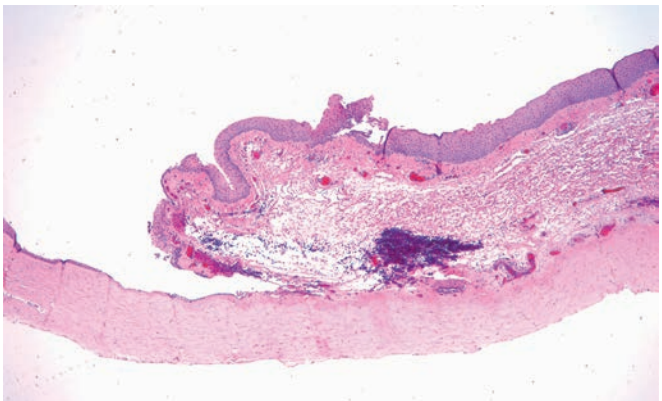

Figure 45.39 Pterygium tissue extends over a cornea.

Graft-Versus-Host Disease

The major histopathologic changes seen in the eyes of patients undergoing bone marrow transplantation involve the conjunctiva, cornea, choroid, and lacrimal gland. The major change in the ocular surface is keratoconjunctivitis.[137]

Inflammation

Scattered lymphocytes and plasma cells are normal components of the conjunctival substantia propria, but prominent inflammatory lesions of the conjunctiva are sometimes biopsied. In many cases only a nonspecific increase in chronic inflammation is present, but some specific non-neoplastic disease patterns can be detected microscopically. Low-grade B-cell lymphomas, generally extranodal marginal zone lymphoma (MALT lymphoma), should also be considered.

Follicular conjunctivitis is characterized clinically by gray-white elevations with avascular centers, representing subepithelial lymphoid follicles, many with well-formed germinal centers.[6] This lymphoid proliferation is often a reaction to viral or bacterial infection. *Chlamydial conjunctivitis*, also known as *trachoma*, is seen in adults as an acute or chronic bilateral keratoconjunctivitis. It can show a microscopic appearance of follicular conjunctivitis indistinguishable from viral infection, and in later stages inflammatory pannus is prominent. The diagnosis is based on the finding of so-called Halberstaedter–Prowazek inclusions in epithelial cells on conjunctival scrapings, or more specific immunoassays.[6,138]

Papillary conjunctivitis (also known as vernal conjunctivitis) is typically seen in the eyelid and is associated with allergic reaction. The raised inflammatory foci have fibrovascular cores and contain lymphocytes and plasma cells with scattered eosinophils. Giant papillary conjunctivitis can also be caused by hypersensitivity reactions to long-term contact lens use.[6]

Sarcoidosis can result in conjunctival noncaseating granulomatous inflammation; these granulomas are generally quite discrete and localized in the substantia propria.

Ligneous conjunctivitis is a peculiar form of chronic pseudomembranous conjunctivitis that presents as a woody induration of the eyelids, together with the formation of a pseudomembrane on the tarsal conjunctiva. The cardinal feature histologically is the presence of large hyaline masses that may simulate amyloid.[139] The disease is thought to be due to plasminogen deficiency.[140]

Actinic granuloma can develop in the bulbar conjunctiva; its microscopic appearance is equivalent to that of its more common cutaneous counterpart, with granulomatous inflammation surrounding a region of elastotic degeneration.[141]

Sjögren syndrome manifests itself in the conjunctiva by a polymorphic inflammatory infiltrate in the stroma, accompanied by metaplasia of the epithelium and a decreased number of goblet cells.[142]

Ocular cicatricial pemphigoid is the name given to mucous membrane pemphigoid involving the ocular surface. Bullae are rare, and diagnosis is based on direct immunofluorescence tests, although these are often negative in patients thought clinically to suffer from the disease.[143]

Tumors and Tumorlike Conditions

Epithelial Tumors

The large majority of epithelial tumors of the conjunctiva arise from the surface epithelium, but a few originate from an accessory lacrimal gland located within the conjunctiva.[144] *Oncocytoma* and other neoplasms can also arise from adnexal structures in the caruncle.[68]

Papillomas are relatively common lesions of the conjunctiva with a tendency for recurrence after apparent complete excision. In children the papillomas are often multiple. The lesions have a typical papillomatous or "mulberry" surface appearance with small vessels coming up to the surface.

Microscopically, the typical papilloma reveals pronounced acanthosis and varying degrees of keratinization, koilocytosis, and nonspecific inflammation. Goblet cells are generally retained at least focally (Fig. 45.40) and can be highlighted using PAS stains. Human papillomavirus (HPV) type 6/11 has been found in these lesions by in situ hybridization or PCR in many cases.[145] Conjunctival papillomas occasionally contain dysplastic foci, although when inflammation is prominent the possibility of reactive atypia should be considered. Papillary carcinomas can arise on the conjunctiva and in many cases represent secondary papillomatous change in a lesion that was originally flat.

Conjunctival intraepithelial neoplasia (CIN) almost always arises on the ocular surface rather than the eyelid and varies considerably in its clinical appearance. They may present clinically as an area of leukoplakia, as a papillomatous growth, or as a complication of pterygium or pinguecula (Fig. 45.41). The incidence of CIN is significantly increased in immunosuppressed patients. The histopathologic characteristics of ocular surface CIN are somewhat similar to those observed elsewhere on mucous membranes, although the degree of dysplasia is often not as pronounced. This is particularly true of lesions which appear papillary clinically, in which microscopic examination can reveal thickening of the epithelium with loss of goblet cells, suprabasal mitoses, disordered growth, and lack of appropriate superficial maturation but only modest cellular enlargement and nuclear atypia. In such cases, the identification of sharp borders at the edges of the lesion can be critical in differentiating it from non-neoplastic reactive changes in the epithelium. Clinically leukoplakic lesions generally show more squamous differentiation and superficial parakeratosis but also have well-defined edges (Fig. 45.42). Koilocytic change is often lacking, and more recent studies suggest that high-risk HPV is generally not present in CIN or conjunctival carcinoma.[146] Some have suggested that cutaneous HPV subtypes may play a role in the development of ocular surface squamous neoplasia, particularly when patients are immunosuppressed due to infection with HIV.[147]

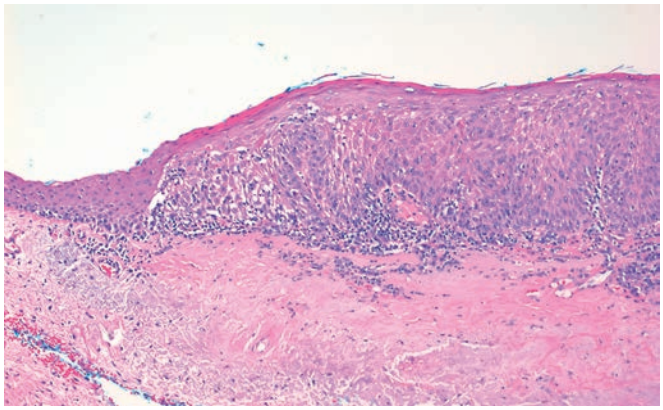

Figure 45.42 Conjunctival intraepithelial neoplasia typically shows sharp peripheral borders with nondysplastic epithelium.

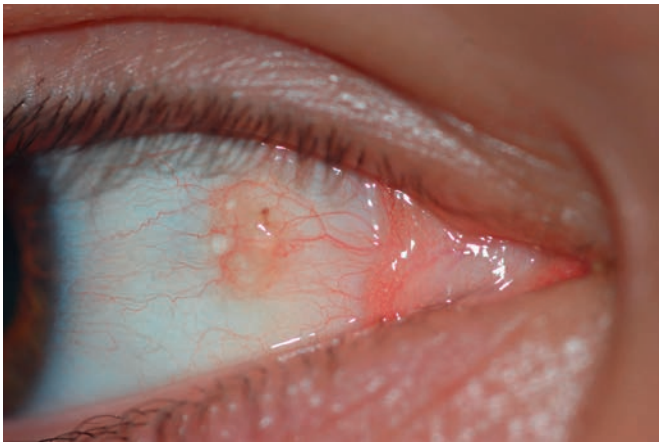

Figure 45.44 Lightly pigmented conjunctival lesion that proved to be a benign nevus.

Dysplasia in CIN is generally classified as mild, moderate, or severe based on the thickness of epithelial involvement.[4] Cases in which essentially the entire epithelium is abnormal, with no normal superficial maturation, are classified as carcinoma in situ (CIS). CIN and conjunctival CIS can both progress in invasive squamous carcinoma.

Hereditary benign intraepithelial dyskeratosis is an autosomal dominant disease characterized by thick leukoplakic lesions that affect the bulbar conjunctiva bilaterally. The acanthosis, dyskeratosis, and parakeratosis can mimic carcinoma, but the condition is benign. It is most frequently encountered in descendants of Native American tribes from North Carolina but can occur in other populations as well.[148]

Invasive squamous cell carcinoma of the conjunctiva generally arises from intraepithelial dysplasia and is relatively rare in regions where early "precancerous" or "in situ cancerous" lesions are efficiently excised. Metastatic spread is uncommon, and even aggressive local disease can often be treated with surgery (Fig. 45.43).[149,150] As for other types of ocular surface squamous neoplasia, sun exposure and immunosuppression due to HIV infection represent major risk factors. Invasive conjunctival carcinomas with *adenosquamous* ("mucoepidermoid") features often behave in a more aggressive fashion.[151] *Spindle cell carcinoma* of conjunctiva is another variant, which can invades more often into the globe and orbit.[152]

Melanocytic Tumors and Tumorlike Conditions

Nevi of the bulbar conjunctiva, like those of the skin, may be observed from birth or first become noticeable at any time during childhood, adolescence, or later. At times a nevus known to have been present since infancy appears to become much larger and more pigmented at puberty. Characteristically, conjunctival nevi are discrete, flat, or slightly elevated lesions located on the globe in the interpalpebral zone, but they vary greatly in size, shape, and position. They also exhibit much variation in degree of pigmentation, with a significant number being essentially amelanotic (Fig. 45.44).

Microscopically, conjunctival nevi are generally of the junctional, compound, or subepithelial varieties, with the latter corresponding to the intradermal nevus of skin. A few are of the Spitz or blue nevus type.[153] Frequently, there are numerous solid and cystic inclusions of conjunctival epithelium intimately incorporated into the subepithelial component of these nevi (Fig. 45.45). At times, the epithelial inclusions may so dominate the clinical and histopathologic picture that the nevoid nature of the lesion is overlooked, and MITF, MART1, or other markers can be useful in highlighting the melanocytic component. The presence of the epithelial inclusions is supportive evidence for benignity, since they are rare in melanomas. Dilatation or proliferation of these cystic epithelial components may also account for clinical growth in lesions that appear nonproliferative microscopically.

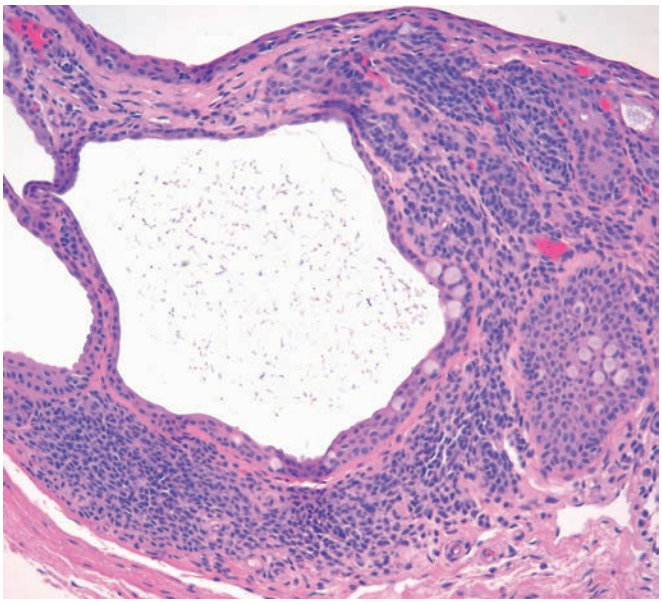

Figure 45.45 Conjunctival nevus with many associated cystic epithelial inclusions. Small round cells about large cysts are not inflammatory cells but nevus cells.

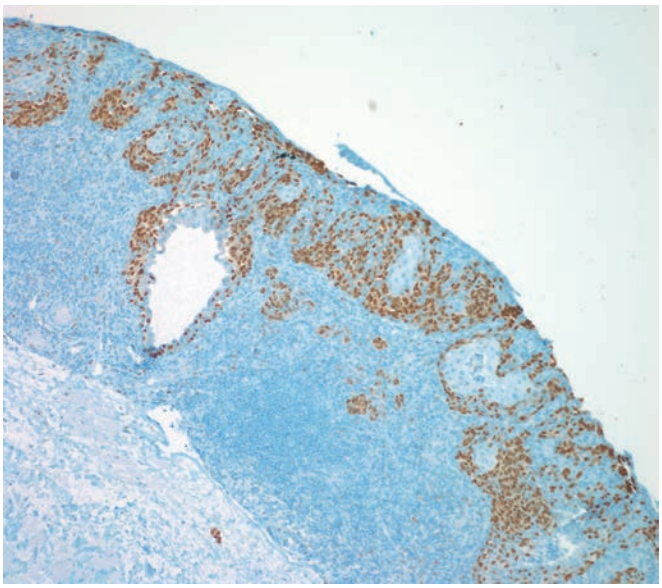

Figure 45.46 An inflamed "juvenile" conjunctival compound nevus in a 10-year-old boy. MITF immunostains highlight melanocytic cells in the conjunctival base and surrounding invaginating epithelial cysts and nests, while deeper region show dense chronic inflammation.

Conjunctival nevi in children, which are usually of junctional or compound types, tend to show a confluent pattern of lentiginous growth and a lack of maturation that may lead to overdiagnosis of melanoma.[154] They can also grow rapidly and show increased cytologic atypia when inflamed, and many regard the *inflamed juvenile conjunctival nevus* as a distinct entity (Fig. 45.46).[155]

Conjunctival melanosis is a confusing term commonly used among ophthalmologists and ophthalmic pathologists to describe a range of entities. Many are benign, such as congenital complexion associated pigmentation, also known as "racial" conjunctival melanosis, which is usually bilateral and does not grow.[156] Primary acquired melanosis (PAM) is the most frequently encountered lesion of clinical

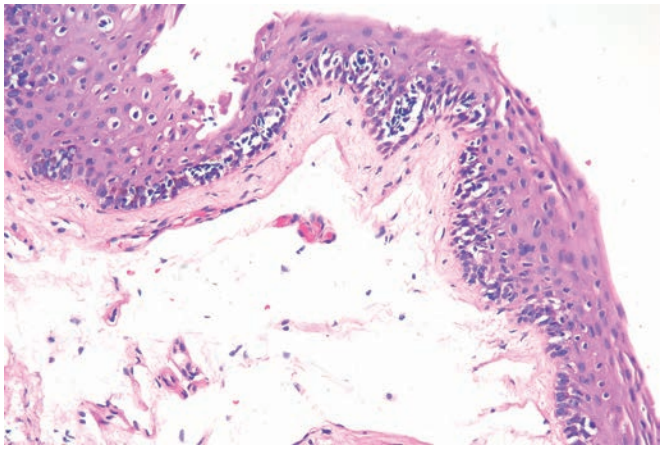

Figure 45.47 Primary acquired melanosis (PAM) with moderate atypia showing lentiginous proliferation of atypical melanocytes in the conjunctival base and some pagetoid spread.

concern, and it has been estimated that approximately 75% of conjunctival melanomas arise from PAM.[157] However, as discussed later, only PAM with severe atypia is thought to commonly give rise to melanomas. PAM has also been referred to as precancerous melanosis, atypical melanocytic hyperplasia, conjunctival melanocytic intraepithelial neoplasia (C-MIN), and malignant melanoma in situ.[158–161] Most cases are seen in the fifth decade of life or later, and the typical presentation is that of a diffuse nonelevated granular pigmentation of the conjunctiva. The most common site is the bulbar conjunctiva, but it can also involve the cornea, caruncle, or palpebral conjunctiva. The extent of the lesion and the degree of pigmentation may fluctuate during the course of the years. PAM is generally divided into lesions without atypia and those with mild, moderate, or severe atypia, although several variations on this general scheme are used.[4,157,162,163] Many now consider lesions in which atypical melanocytes involve more than 75% of the epithelial thickness or slough from the surface to represent melanoma in situ.

Microscopically, PAM without atypia consists of increased conjunctival epithelial pigmentation with little or no increase in melanocytes and an absence of cytologic melanocytic atypia.[157,164] In PAM with atypia, an increase in the number of melanocytes is seen along the basal layer, individually or in clusters, associated with various degrees of atypicality and sometimes pagetoid spread (Fig. 45.47).[160,163,164]

The nature and significance of this lesion have been controversial. It has been postulated that all cases of acquired melanosis exhibiting atypia are malignant melanomas in situ.[158] Most researchers have found that only a subset of lesions with more severe atypia give rise to invasive melanoma, however. In the series of Folberg et al.,[164] none of the lesions without atypia progressed to invasive melanoma, whereas 40% of those with atypia did. Sugiura et al.[165] divided their 29 cases into a *low-risk* and a *high-risk* group based on largely on nuclear morphology and epithelioid features, with the *high-risk group* showing a high association with malignant melanoma. Shields et al. reported on 311 eyes with PAM divided into groups with no atypia, mild atypia, and severe atypia.[157] Progression to melanoma never occurred in cases with no or mild atypia and in only 13% of patients with PAM with severe atypia. Thus it appears that only PAM lesions with prominent melanocytic proliferation and cytologic atypia are likely to progress to invasive melanoma.

Some of the confusion surrounding PAM is due to use of the term "melanosis" to describe both hypersecretion of melanin and melanocytic proliferation. It has therefore been suggested that the

terms *conjunctival hypermelanosis* and C-MIN be used instead of PAM to describe lesions without or with melanocytic proliferation.[160] This system proposed by Damato and Coupland also includes a more standardized system for grading atypia based on radial and vertical melanocyte spread as well as cytologic features.

Malignant melanoma of the conjunctiva, a rare lesion, may arise without an apparent precursor lesion, or it may be the sequela of a nevus or PAM (Figs. 45.48 and 45.49).[157,160] The microscopic appearance is similar to that of its cutaneous counterpart. The prognosis is related to the subsite and size of the primary tumor, which are central to the current American Joint Committee on Cancer staging criteria. The presence of epithelioid cells is also associated with worse clinical outcomes. In the series of 382 cases reported by Shields et al., the 10-year mortality was 9% for tumors arising from PAM or nevus and 35% for those arising de novo.[166] Factors predictive of death on multivariate analysis were de novo origin, fornix location, and nodularity. The treatment varies from local excision to exenteration of the eye, depending on the extent of the disease.

Lymphoid Tumors and Tumorlike Conditions

The morphologic appearances and diagnostic problems posed by lymphoma when they present in the conjunctiva are similar to those of analogous lesions of the eyelid and orbit as discussed previously. The clinical appearance of the conjunctival lymphoma is that of salmon-colored, smooth masses. Most are extranodal marginal zone lymphoma (81%) or follicular lymphoma (8%).[167] **Rosai–Dorfman** disease can also present as fleshy or papillomatous lesions on the conjunctiva, limbus, and cornea.[168]

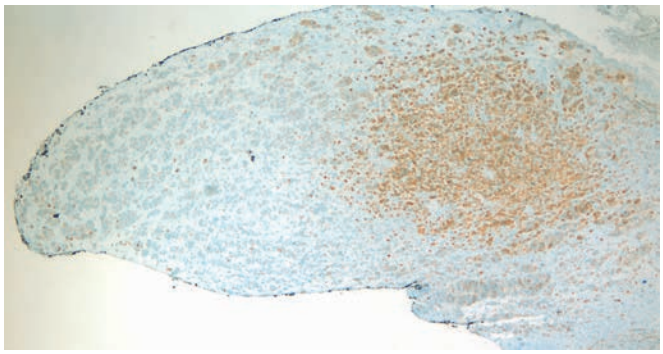

Figure 45.48 Malignant melanoma arising in a conjunctival nevus, with HMB45 negative nevoid nests in the left of the specimen, and more diffuse HMB45-positive cells on the right.

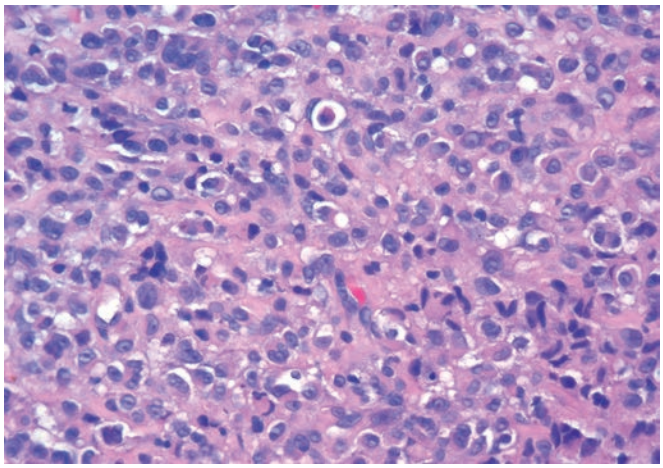

Figure 45.49 Conjunctival melanoma cells corresponding to the HMB45-positive region in Fig. 45.48.

Other Tumors

Myxoma has been reported as a primary tumor in the conjunctiva, cornea, eyelid, and orbit. Grossly, the conjunctival lesions have a smooth, fleshy, gelatinous appearance. Local excision is curative.[169] **Vascular tumors** involving the conjunctiva include hemangioma and Kaposi sarcoma.[170] **Merkel cell carcinoma** has been seen as an apparently primary conjunctival tumor.[171]

Intraocular Tissues

As stated in the Introduction of this chapter, only tumors and tumorlike conditions of these structures will be discussed.

Malignant Melanoma

General and Clinical Features

Melanomas arising from the pigmented or potentially pigment-producing cells of the uvea are the most frequent primary intraocular neoplasms in adults. Rarely, they occur in adolescents and children.[172] Many are thought to arise from preexisting benign nevi, although only a small fraction of uveal nevi progress to melanoma.[2,173] Risk factors for uveal melanoma, in addition to nevi, include a fair complexion, light irides, oculodermal and ocular melanocytosis, and von Recklinghausen disease.[2,174]

Malignant melanoma may be located at any point in the uveal tract, but most arise in the choroid, with less than a quarter found in ciliary body or iris.[2] Melanoma of the iris typically presents as an elevated mass with varying degrees of pigmentation but can also consist of multiple small nodules (tapioca iris melanoma) or generate a broad carpet of growth on the surface (Fig. 45.50). Choroidal melanoma also may vary in pigmentation but characteristically is an irregular, slate-gray, solid, subretinal tumor producing an overlying retinal detachment and decreased vision (Fig. 45.51). They generally appear as a discoid, globular, or mushroom-shaped mass but can

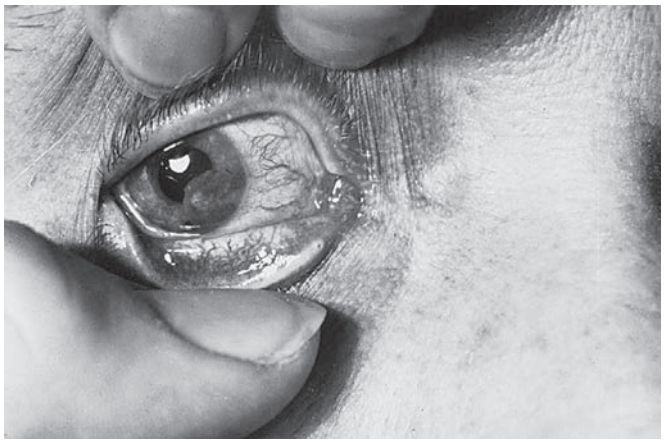

Figure 45.50 Melanoma of iris that had been observed over a period of 10 years, during which time it became progressively larger and encroached on the pupil. Iridectomy revealed it to be of spindle A cell type. The tumor recurred and necessitated enucleation for secondary glaucoma 15 years after iridectomy. (Courtesy of Dr ME Nugent, Bismarck, ND.)

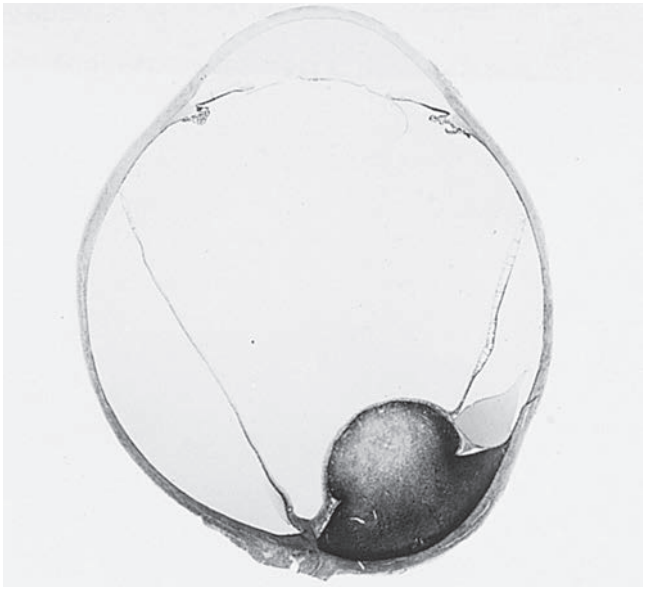

Figure 45.51 Malignant melanoma of choroid that, by erupting through Bruch's membrane, has formed a mushroom-shaped subretinal mass.

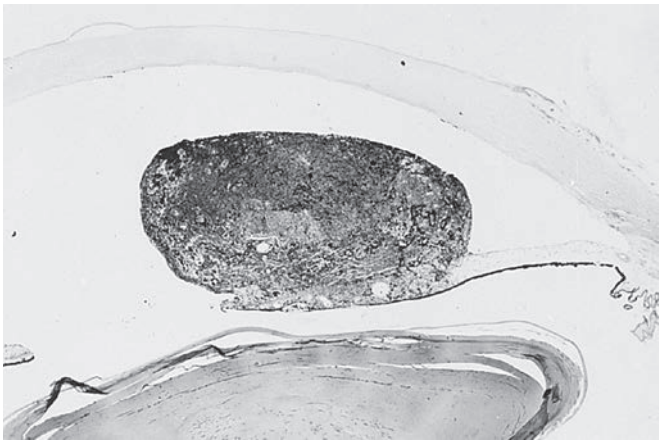

Figure 45.52 Melanomas of iris are frequently visible through the cornea. Hence, their duration and rate of growth are often known by the patient or family long before other subjective or objective manifestations appear.

sometimes spread diffusely or extend out along scleral canals into the orbit. Visual disturbance caused by retinal detachment is one presenting complaint. At times, malignant melanomas of the posterior uvea are not discovered until the enucleated eye is examined in the laboratory.

Diagnosis and staging can be problematic in cases with clinically unsuspected tumors when fragmented specimens are removed by evisceration.[175] Iris tumors are more often recognized early, for they can be seen by the patient and family long before symptoms appear (Fig. 45.52).

Clinically, there are many lesions that simulate uveal malignant melanoma.[176,177] The most important are metastatic carcinoma, localized hemorrhage beneath the retina or between the pigment epithelium and choroid, focal areas of proliferation of the retinal pigment epithelium, posterior scleritis, and benign tumors such as nevi and hemangiomas. Other melanocytic lesions of the choroid which must be distinguished from melanoma include *melanocytoma* and *bilateral diffuse uveal melanocytic proliferation* (BDUMP).

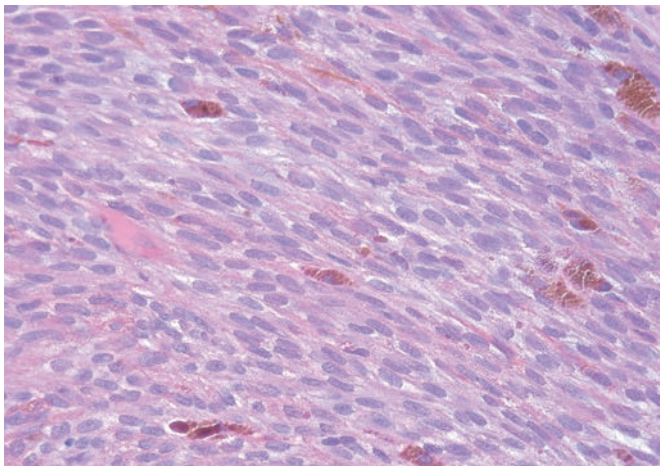

Figure 45.53 A choroidal melanoma comprised predominantly of spindle A cells.

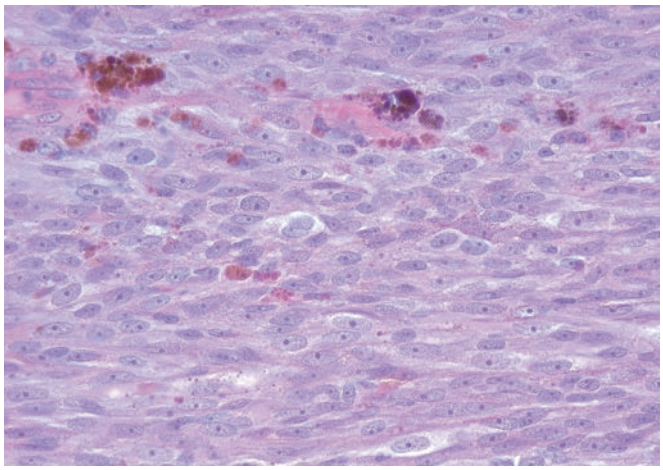

Figure 45.54 A choroidal melanoma comprised predominantly of spindle B cells.

Microscopic Features

Microscopically, uveal melanomas have been traditionally divided into three types: spindle A, spindle B, and epithelioid, which may occur singly or in combination.[2,178] Spindle A cells are slender, benign-appearing cells that have relatively small fusiform nuclei and no nucleoli (Fig. 45.53). Spindle B cells are larger and more pleomorphic, merging on the one hand with spindle A cells and on the other with epithelioid cells. They typically possess large ovoid nuclei containing prominent nucleoli (Fig. 45.54). Both spindle A and spindle B tumors tend to be quite cohesive. Some of these tumors have a distinctly fascicular pattern of growth. Epithelioid cells are still larger and more irregular (Fig. 45.55). They have an abundance of cytoplasm and may be truly gigantic. The nuclei are large, and their nucleoli are often strikingly prominent. Multinucleated forms or balloon cells can be seen. Epithelioid cells are characteristically less cohesive than the spindle cells. It is rather unusual for these tumors to be composed of a single cell type. Mixtures of spindle A and B cells or mixtures of spindle and epithelioid cells are common.

The microscopic differential diagnosis of primary uveal melanoma includes benign pigmented nevi, and it can be difficult to distinguish a small spindled melanoma from a nevus. Iris lesions are particularly problematic, as they are often small and cytologically bland. The

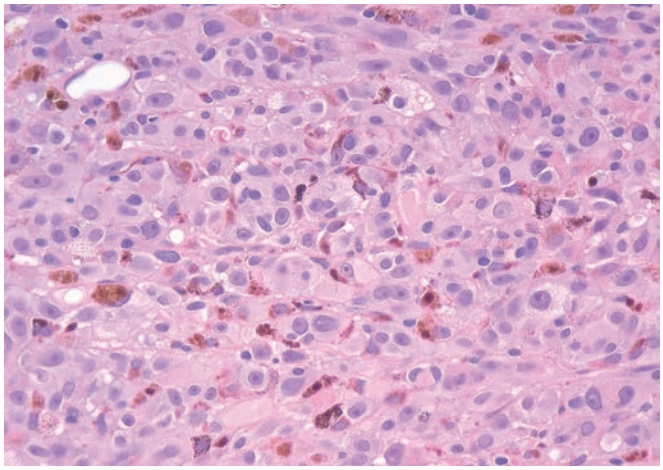

Figure 45.55 A choroidal melanoma comprised predominantly of epithelioid cells.

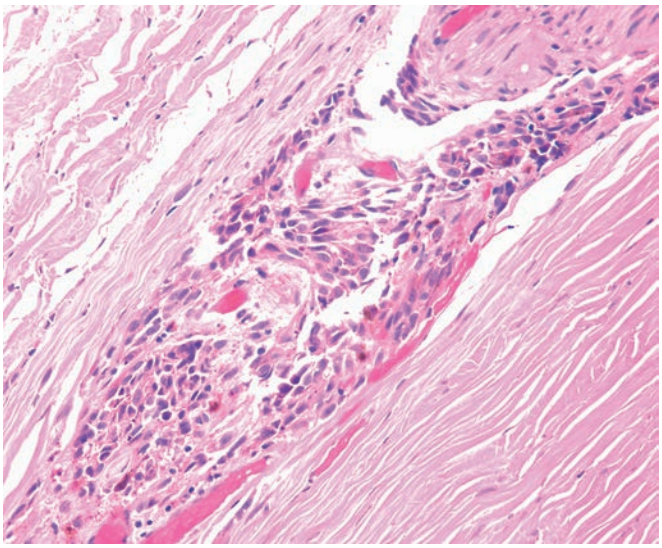

Figure 45.56 Uveal melanoma cells extending through a scleral canal.

presence of nucleoli and signs of proliferation, as well as invasion into adjacent structures, are all helpful in establishing a diagnosis of melanoma. Primary uveal melanomas should also be distinguished from intraocular metastases of cutaneous malignant melanoma. In addition, amelanotic melanomas raise the differential diagnosis with metastatic carcinoma, and spindle cell melanomas with a fascicular pattern of growth may resemble neurofibromas, schwannomas, or leiomyomas. The latter consideration applies particularly to tumors of the ciliary body.

Immunohistochemical and Molecular Genetic Features

Immunohistochemically, malignant melanomas are reactive for S-100 protein, HMB-45, MITF, and Mart-1 (Melan-A).

Cytogenetically, common alterations of clinical significance include chromosome 3 loss, chromosome 6p gain, and chromosome 8q gain.[179,180] Mutations in the *GNAQ* or *GNA11* genes are found in most cases, representing the most common known oncogenic mutation in this cancer, and probably an early event in oncogenesis.[173,181] Mutations in *BAP1* are thought to occur later in tumor progression and are common in lesions which metastasize.[182,183] Immunohistochemical evaluation of BAP1 loss may also have diagnostic utility.[184]

Spread and Metastases

Lymphatic channels are not present in the eye, thus uveal melanoma spread hematogenously, primarily to the liver, lung, and skin.[185] Extraocular extension through scleral canals is rare (Fig. 45.56), but extensive extrascleral growth generally prompts orbital exenteration.[173] Invasion of uveal melanoma along the optic nerve is very rare. Both loss of chromosome 3 (monosomy 3) and specific gene expression profiles have been used to predict metastatic spread and patient survival.[183] Increasingly, FNA is performed to obtain tissue for molecular analysis.[180,183]

Treatment

Uveal melanoma treatment depends on tumor location and multiple clinical factors. Small melanomas of the iris can be treated by iridectomy or iridocyclectomy, while larger or disseminated tumors arising at this site may require radiotherapy or enucleation.[173] Small to moderately sized melanomas of the choroid and ciliary body are general treated by radiotherapy (plaque or proton beam) or less frequently transpupillary thermotherapy. Enucleation of the eye results in better outcomes with larger tumors.[173,176,177] Treatments for metastatic disease are unfortunately of only limited utility.

Prognosis

The overall mortality from metastasis of melanoma of the uveal tract 15 years after enucleation is close to 50%, with only very limited success in treating metastatic disease.[173,176] The prognosis of this tumor depends on multiple clinical, pathologic, and molecular factors, which are summarized here:

1. *Tumor size and proliferation*. Larger tumors have a worse prognosis than smaller ones.[173,179] For choroidal and ciliary body tumors, both the largest basal diameter in contact with the sclera and the thickness should be measured and play a key role in current pathologic staging protocols.[186] Mitotic index should also be reported.
2. *Location*. Tumors located in the iris generally have a better prognosis. In contrast, melanoma involving the ciliary body are associate with shorter survival.[179,186]
3. *Extrascleral extension and growth*. Extrascleral extension only occurs in a minority of patients with uveal melanoma but is associated with worse outcomes, particularly when the tumor forms a large mass outside the confines of the globe.[179]
4. *Cell type*. Spindle A tumors are associated with the best outcomes and epithelioid tumors the worst. Many cases show a mixture of spindled and epithelioid cells.
5. *Lymphocytic infiltration*. The presence of a large number of lymphocytes in the tumor stroma has been found to be significantly associated with decreased survival.[187]
6. *Vascularization*. Specific patterns of "vascular mimicry" by neoplastic cells have been associated with outcome. Melanomas with "closed vascular loops" highlighted on PAS stains behave more aggressively than others.
7. *Chromosome 3 loss*. Loss of chromosome 3 (monosomy 3) is a well-established molecular change strongly associated with metastatic tumor spread.[188]

8. *Gene expression profile.* Gene expression profiling studies have shown that uveal melanomas cluster into two molecular groups—tumors with the class 1 signature rarely metastasize, whereas those with the class 2 signature have a very high rate of metastasis.[189] Low expression of genes on 3p is also associated with a poor prognosis.[190]
9. *BAP1 gene mutation.* Mutations in the *BAP1* gene are also frequent in metastasizing uveal melanoma.[182] Immunohistochemical loss of BAP1 protein detected using immunohistochemistry is also associated with tumor spread and poor outcomes.[184,191]

Melanocytomas are densely pigmented benign tumors that generally arise near the optic nerve head but occasionally develop more anteriorly.[192] On bleach preparations, the cells are epithelioid but have bland nuclei. Because they are benign and very rarely progress, making the distinction between uveal melanocytoma and melanoma is clinically important.

Retinoblastoma and Related Lesions

General Features

RB is the most common intraocular neoplasm of children. It has long been thought to arise from retinal stem or progenitor cells, and recent studies suggest both early progenitors and cone precursors as cells of origin for distinct molecular groups of tumors.[193–195] RBs can present at birth but are usually diagnosed between 1 and 2 years of age, with heritable cases arising in younger infants. Approximately 60% of the cases are unilateral, and the other 40% are bilateral (Fig. 45.57), with all bilateral cases and 15% of unilateral cases representing a heritable form of the disease.[196]

The responsible gene is located at chromosome 13q14 and designated *RB*.[197] Patients with hereditary RB have a germ cell mutation in one allele and develop the RB as a result of a somatic mutation in the second allele, whereas in patients with sporadic RB both mutations are somatic.[198] This model, known as Knudson's "two-hit hypothesis," has become a paradigm of tumorigenesis.[199] The yearly incidence of inherited RB mutations is 1 in 15,000 to 20,000 live births.[196]

Clinical and Gross Features

RBs characteristically present as a leukocoria (white pupillary reflex; Fig. 45.58) or less often as a strabismus. Rarely, extraocular extension with the formation of an orbital mass is the presenting manifestation.

RBs may be flat and diffuse or elevated and may show multicentric foci of origin, especially in the hereditary type. They may protrude into the vitreous (endophytic type; Fig. 45.59), often with vitreous seeding, or they may grow between the retina and the pigment epithelium (exophytic type).[195] Since the tumors tend to outgrow their blood supply, necrosis is often extensive and many minute foci of calcification are often present in these areas of necrosis (Fig. 45.60). In fact, these areas of calcification may be appreciated by x-ray examination prior to enucleation.

Some patients have presented with bilateral RB and a morphologically similar intracranial neoplasm, generally localized in the region

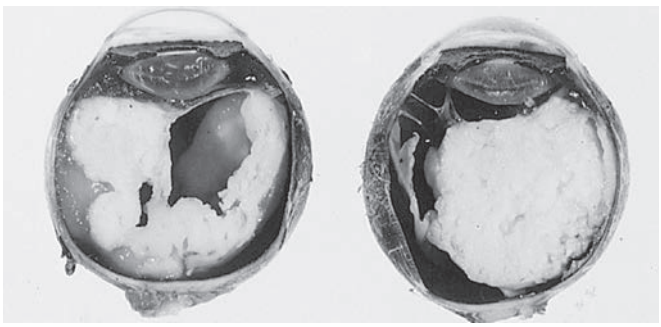

Figure 45.57 Bilateral retinoblastoma showing a white mass consisting of detached retina and neoplastic tissue immediately behind the lens in each eye.

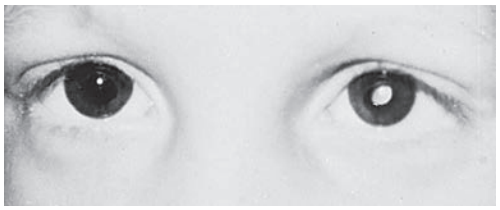

Figure 45.58 Prominent white reflex attributed to retinoblastoma present in the dilated pupil of the left eye.

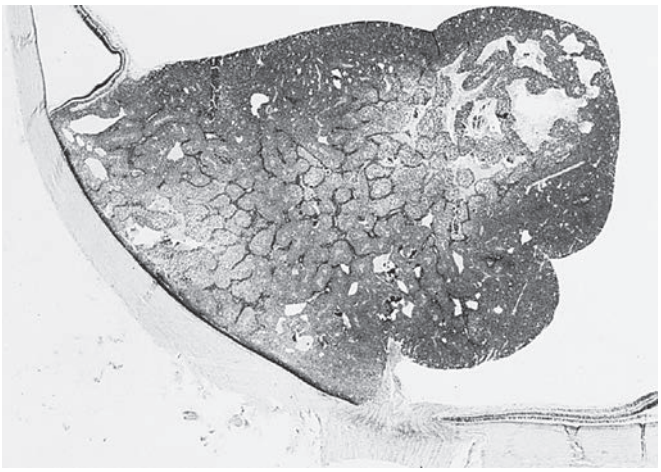

Figure 45.59 Retinoblastoma presenting as a highly cellular neoplasm with scant stroma. The tumor tends to outgrow its blood supply, and irregular areas of necrosis are commonly observed.

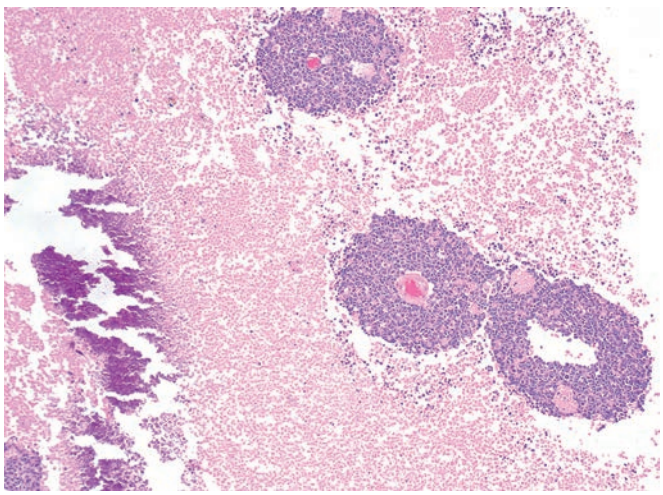

Figure 45.60 Retinoblastoma with a collar of viable cells about nutrient vessels with necrotic cells further away. Calcification is seen on the left.

of the pineal gland, in keeping with the "third eye" nature of the latter structure.[200] These are referred as *trilateral RBs* and are found in 3%–5% of hereditary cases.[201]

The clinical differential diagnosis of RB includes any disease process that leads to retinal detachment or a retrolental mass in a child under 6 years of age.[195] Lesions in this category include traumatic or idiopathic retinal detachments, familial exudative vitreoretinopathy, persistent hyperplastic primary vitreous (persistent fetal vasculature), massive retinal gliosis, coloboma, Coats disease, toxocariasis, astrocytic hamartoma of tuberous sclerosis, and medulloepitheliomas. Some of these disorders are discussed elsewhere in this chapter.

Microscopic Features

Microscopically, RBs are composed of dense masses of small round cells with hyperchromatic nuclei and scanty cytoplasm.[202] Dystrophic calcification and hematoxyphilic DNA deposits in and around blood vessel walls are often seen in necrotic areas. Both neuroblastic Homer Wright rosettes containing a central tangle of processes and Flexner–Wintersteiner rosettes with true lumens can be found, with the latter most common in younger patients (Fig. 45.61). In well-differentiated tumors, "fleurettes" in which cytologically bland cells produce a bouquet of eosinophil processes recapitulating photoreceptor inner segments are seen. Tumors showing an extreme degree of differentiation are designated as *retinocytomas* and regarded as benign (Fig. 45.62).[195,203] These lesions carry the same initiating genetic changes as conventional RBs; they present as small placoid, noninvasive lesions composed entirely of benign-appearing cells with numerous fleurettes, lacking necrosis or mitotic activity.[203] It has also recently been recognized that anaplastic changes similar to those in other embryonal tumors of the brain can be encountered in RB and are associated with worse clinical outcomes (Fig. 45.63).[204]

Electron Microscopic, Immunohistochemical, and Molecular Genetic Features

Ultrastructural evidence of photodifferentiation has been found in the tumor cells of RB (Fig. 45.64).[205,206] Immunohistochemically, there is reactivity for general neuronal proteins such as synaptophysin, as well as markers of retinal differentiation such as retinal-binding protein, retinal S-antigen, interphotoreceptor retinal-binding protein, cone opsin, and rod opsin.[207–209] Interestingly, retinal S-antigen has also been detected in tumors of the pineal gland and in cerebellar medulloblastomas.[209,210] The MIB-1 labeling index is extremely high. Limited p53 immunostaining is present in over half of the cases. In contrast to Ewing sarcoma/PNET, most neuroblastomas are negative for CD99.[211]

Besides loss-of-function mutations in the *RB* gene, other common genetic alterations in RB include gain of 1q, 2p, 6p, and 13q and loss of 16q.[212–215] Some cases also show amplifications of the *NMYC*, *MDMX*, or *MDM2* gene[216] In rare cases, NMYC amplification can substitute for *RB* gene loss as an initiating genetic event, and these tumors tend to be more anaplastic in their microscopic appearance.[217]

Spread and Metastases

RB has a tendency to invade the optic nerve, from which it can extend to the brain or be carried there by the cerebrospinal fluid (Fig. 45.65).[217] Large exophytic tumors with secondary glaucoma

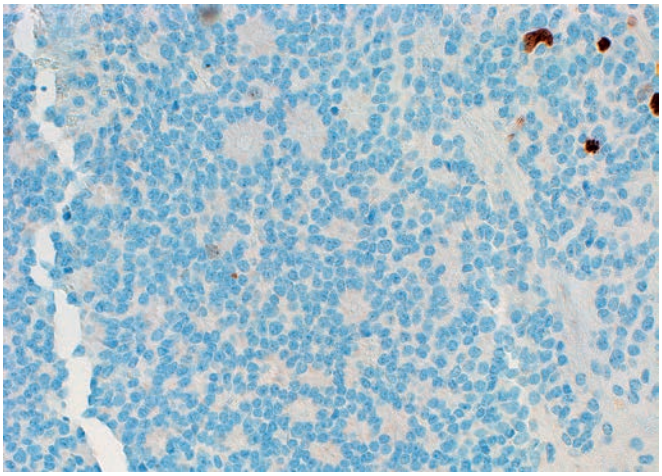

Figure 45.62 Retinocytoma with small bland cells, fleurettes, and a very low Ki67 proliferation index.

(Courtesy of Dr Robert A Erlandson, Memorial Sloan Kettering Cancer Center.)

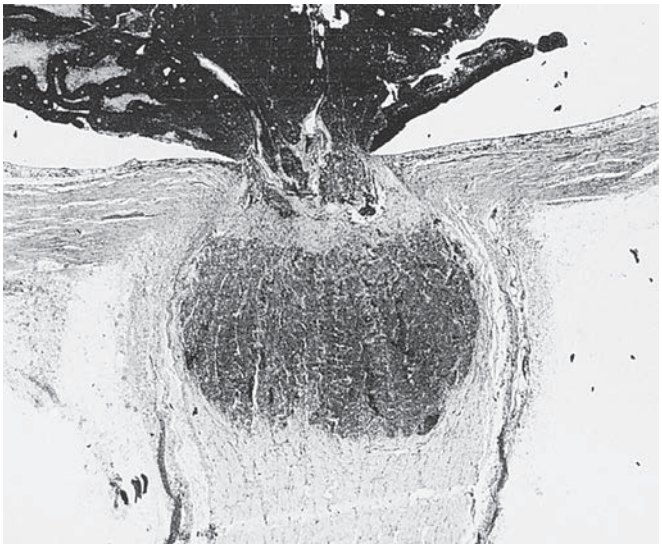

Figure 45.65 Retinoblastomas exhibit a tendency to spread out of the globe by way of the optic nerve *(arrows)*. It is therefore of utmost importance for the surgical pathologist to determine whether such optic nerve extension has occurred and, if it has, to what extent.

are at highest risk for optic nerve invasion. RB can also invade the uveal tract, and "massive" choroidal invasion of over 3 mm is associated with hematogenous metastasis (Fig. 45.66). Vitreous seeding is also associated with chemoresistance and poor outcomes (Fig. 45.67). Distant metastases can be limited to the cranial vault or involve distant sites, particularly the skeletal system.[218]

Treatment

The treatment of RB depends on the extent of the disease, including the presence of bilateral lesions, but has changed significantly over the last decade. Historically, early cases were managed with unilateral radiation, cryopexy, or xenon arc photocoagulation, while larger

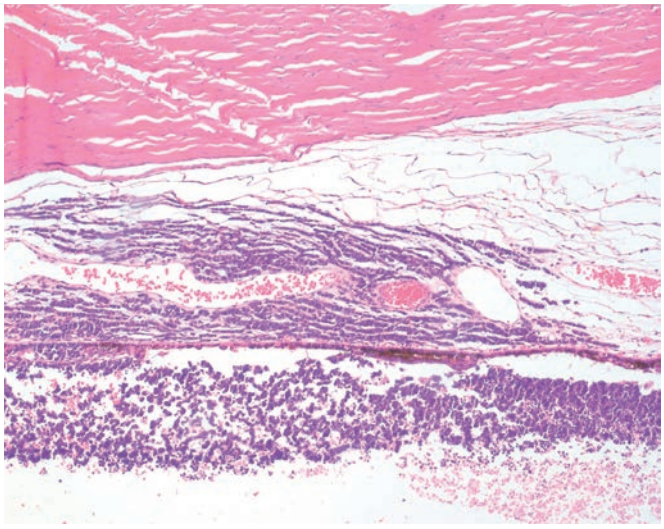

Figure 45.66 Retinoblastoma invades from the subretinal space at the bottom of the image into the overlying choroid *(arrows)*.

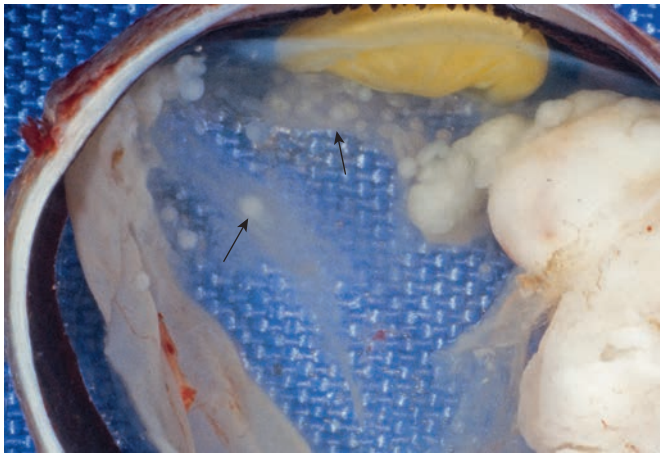

Figure 45.67 Endophytic retinoblastoma on the right with scattered white vitreous seeds *(arrows)* behind the lens, which appears yellow.

lesions were removed by enucleation.[219,220] More recently, increased emphasis has been placed on chemotherapy. Systemic chemoreduction therapy followed by consolidation including cryotherapy for small anterior tumors, thermotherapy/laser photocoagulation for posterior tumors, and plaque radiation/brachytherapy for larger tumors yields very good results.[195] Some centers now use local intraarterial delivery to ameliorate systemic complications.[221] For very large or recurrent lesions, enucleation is still sometimes required. The use of more aggressive treatments can be contingent on pathologic staging.

Prognosis

In developed countries, nearly all children with RB are long-term survivors. Microscopic features that correlate with prognosis and the need for more aggressive treatment in RB, and which therefore need to be carefully analyzed by the pathologist,[195,222] are as follows:

1. *Invasion of optic nerve*. In an operation for suspected neuroblastoma, the surgeon will attempt to obtain a long segment of optic nerve attached to the globe. Transverse sections of this nerve should be examined microscopically at the prelaminar and retrolaminar levels, including the surgical margin.[222] The levels of invasion of the optic nerve by RB have been divided into prelaminar, laminar,

and retrolaminar, the latter further subdivided into lesions with or without resection line involvement.[222] The prognosis decreases with each of these levels.[118,223,224]

2. *Invasion of the choroid*. Massive invasion of the choroid by RB cells, defined as 3 mm or greater in extent, is an unfavorable prognostic sign.[223] Tumor cells must extend through Bruch's membrane and into the choroid, and sub-retinal pigment epithelium spread does not qualify (Fig. 45.68). Scattered clumps of tumor cells carried over the choroid during specimen processing should also not be diagnosed as true tumor invasion.

Long-term survivors have a greater incidence of development of malignant tumors. The incidence has ranged from 6% to 20% after 10 years and in one series has reached 90% at 30 years. The most common types have been osteosarcoma and rhabdomyosarcoma, but several other types have been encountered, including rhabdoid tumors.[225,226] This predisposition for a second malignancy, which should be distinguished from a recurrence of the RB,[227] is seen almost exclusively with the hereditary form of the disease.[228]

Lymphoid Tumors and Tumorlike Conditions

Patients with leukemia can have neoplastic infiltrates in the choroid, retina, vitreous, and anterior chamber, particularly at autopsy, but these are rarely encountered in surgical specimens.

Intraocular **malignant lymphoma** is a relatively rare disease. In contrast to other portions of the ocular apparatus, in which MALT-type lymphomas predominate, most intraocular lymphomas are aggressive diffuse large B-cell lymphomas.[229] In over 90% of the cases the eye lesion heralds the presence or development of extraocular lymphoma in the central nervous system. As in the brain, tumor cells are large with prominent nucleoli and are often surrounded by extensive apoptotic debris, which can obscure the diagnostic component.

Other Primary Tumors

Fuchs adenoma (benign ciliary epithelioma, Fuchs epithelioma) is a benign tumor of the ciliary body usually found incidentally in a surgically enucleated eye or on post mortem examination. Microscopically, it is formed by interlacing trabeculae of uniform, nonpigmented ciliary epithelial cells surrounded by an amorphous, hyaline, PAS-positive material (Fig. 45.69).[230]

Medulloepithelioma, also known as *diktyoma*, is a rare tumor that histologically resembles the embryonal retina or medullary epithelium of the brain. Most cases arise from the ciliary epithelium in children, but a few have been found in the optic nerve or retina. They are composed of tubules and bands of poorly differentiated neuroectodermal cells lining a PAS-positive basement membrane (Fig. 45.70). Teratoid and nonteratoid groups are recognized, with the former containing a variety of heteroplastic elements such as cartilage or muscle. Recent genetic studies indicate that they are distinct from medulloepithelioma of the central nervous system.[231]

Leiomyomas can develop in the ciliary body or the iris. Some of these tumors are regarded as of possible neural crest origin and designated as *mesectodermal leiomyomas.*[232] Epstein–Barr virus–-associated smooth muscle tumors have been reported in immunosuppressed patients.[233]

Hemangioblastomas (generally as a component of von Hippel–Lindau disease) are sometimes found in the retina. The tumors are sometimes called "retinal angiomas" by clinicians but feature the same neoplastic stroma seen in the same entity in the brain (Fig. 45.71). A case of PEComa has been described in the ciliary body.[39]

Astrocytic hamartomas of retina occur in patients with tuberous sclerosis and are similar in appearance to subependymal giant cell astrocytomas in the brain. They are generally benign but occasionally grow in a more aggressive fashion.[234]

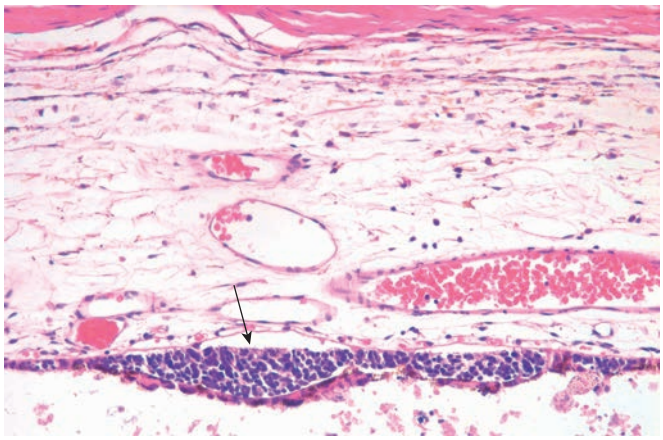

Figure 45.68 Retinoblastoma cells extend under the retinal pigment epithelium but do not invade through Bruch's membrane into the overlying choroid *(arrow)*.

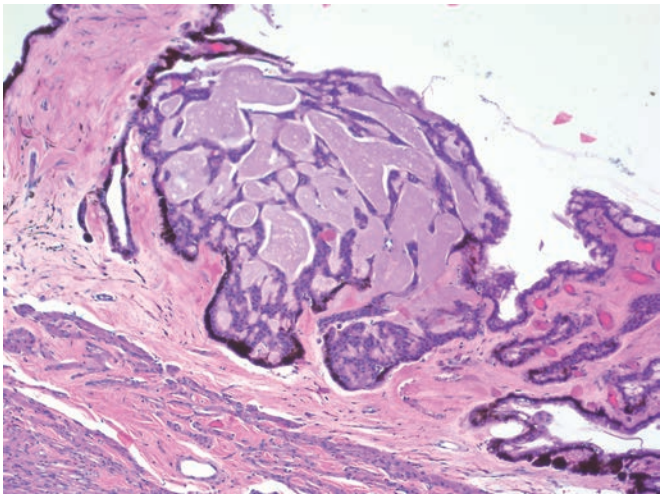

Figure 45.69 Fuchs adenoma are benign, generally incidental lesions comprised of nonpigmented ciliary epithelial cells and amorphous, hyaline material.

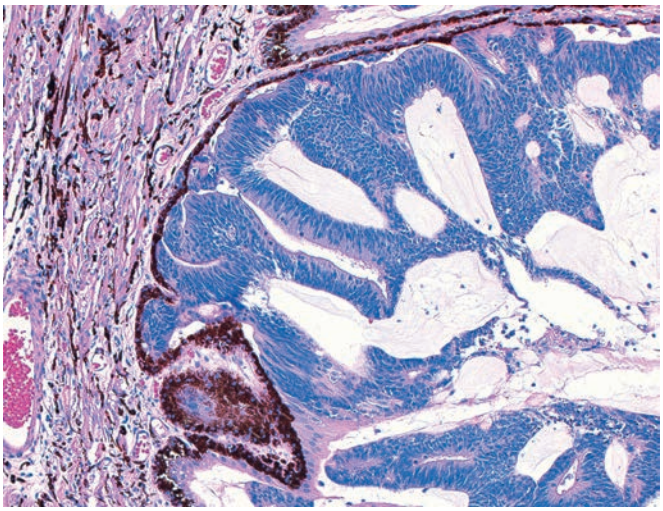

Figure 45.70 Ciliary body medulloepithelioma (non-teratoid) with primitive neuroectodermal cells lining well-defined surfaces.

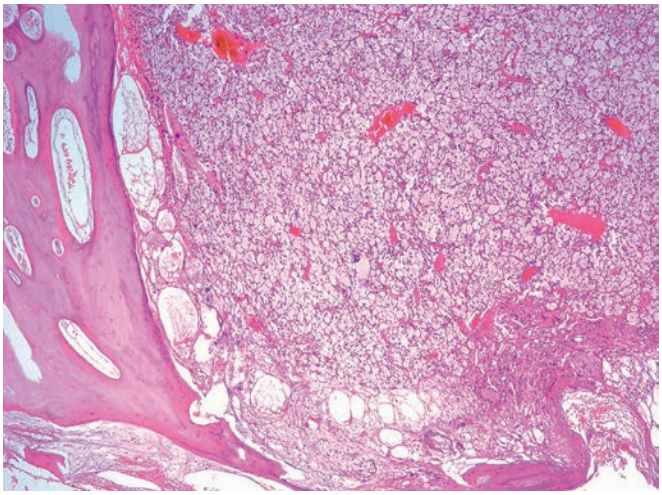

Figure 45.71 This very large hemangioblastoma grew within the eye over several decades. The pale, vacuolated neoplastic cells are interspersed with proliferating vessels. Secondary bone formation is present in the left side of the image.

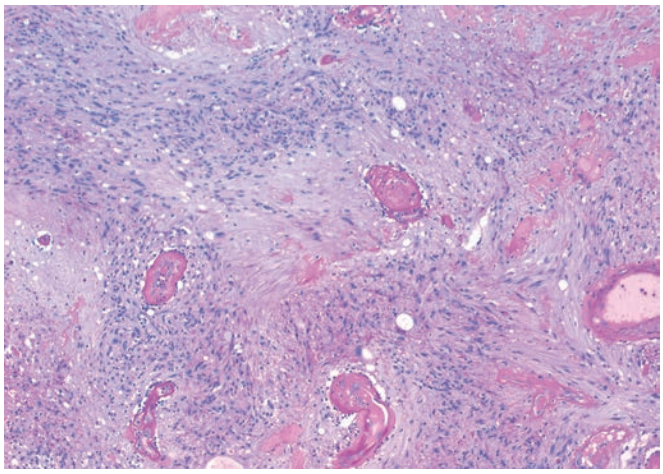

Figure 45.72 A "reactive" retinal astrocytic tumor which grew as a relatively discrete lesion over approximately 1 year. PAS stains highlight the prominent vessels between solid proliferations of spindled glia.

"Reactive" retinal astrocytic tumors can occur following trauma or as an apparently spontaneous finding. They are also sometimes designated *vasoproliferative tumors of retina* when the vascular component is prominent or *massive retinal gliosis* when growth is particularly diffuse. The primary cells within the lesion are spindled GFAP-positive glia (Fig. 45.72). It is unclear if these are clonal neoplasms or purely reactive, but thus far no signature genetic changes have been identified.[235]

Juvenile xanthogranuloma can occur in the iris and result in spontaneous hyphema and/or secondary glaucoma. It occurs almost exclusively in young children and is associated with skin lesions of similar microscopic appearance.[236]

Metastatic Tumors

The intraocular tissues can be involved by metastatic carcinoma and, less commonly, by metastatic cutaneous melanoma and metastatic sarcoma. In fact, if one were to do serial sections routinely on all autopsy eyes, cases of metastatic carcinoma would outnumber the primary tumors. The difference, of course, is that most of the patients were asymptomatic for ocular symptoms while alive. The most common primary lesions involved are in the breast in the female and in the lung in the male, with the gastrointestinal tract next in frequency.[237] The ocular metastasis occasionally may be the initial manifestation of the disease, and the primary lesion is discovered only after the eye has been enucleated. The posterior choroid is the most common site for these metastases.[238] Anterior uveal involvement is much less common, and retinal metastases are rare. Diffuse thickening of the choroid along both sides of the optic nerve is the most common presentation, but bulky tumor masses resembling malignant melanomas also may be observed.

Cytology

In certain cases the pathologist may be called on to examine material that has been aspirated from either the aqueous or the vitreous fluid and processed as cytospins or passed through a Millipore filter. The main differential diagnosis in the vitreous is infection, uveitis, trauma or reactive/degenerative conditions, and diffuse large B cell lymphoma.
