Normal Anatomy

The bladder is a hollow viscus with the shape of a four-sided inverted pyramid when empty and of a rounded structure when distended. It is divided into the following portions: *superior surface* (also known as *dome*, and covered by the pelvic parietal peritoneum), *posterior surface* (also known as *base*), and the two *inferolateral surfaces*.[1] The *trigone* is located at the base of the bladder and is continuous with the *bladder neck*, in which the posterior and inferolateral walls converge to open into the urethra. The lymphatic drainage of the bladder is primarily through the external and internal iliac nodes; portions of the bladder neck region may drain to the sacral or common iliac nodes.

The layers of the bladder are the mucosa, muscularis propria (MP), and adventitia. The latter is covered by serosa at the dome. The mucosa is formed by the epithelium and lamina propria, which often contains (rarely) a continuous or discontinuous muscularis mucosae (MM). The epithelium of the bladder has been traditionally referred to as *transitional*, but the preferred term *urothelium* is more informative and accurate. It is generally six to seven cells thick in the contracted bladder, but only two or three cells thick in the distended bladder. It has three layers: superficial, intermediate, and basal. The superficial layer is made up of a single row of large cells having abundant eosinophilic cytoplasm and referred to as umbrella cells. The umbrella cells may also have large multilobated nuclei and prominent cytoplasmic vacuolization. The intermediate cells have a cuboidal to low columnar shape, oval nuclei with fine chromatin and frequent nuclear grooves, moderately abundant cytoplasm, and well-defined margins. The basal layer is made up of a row of cuboidal cells that lie on a thin continuous basal lamina.

The lamina propria is composed of loose connective tissue containing a rich vascular network, lymph vessels, and a few elastic fibers. A rather prominent collection of arteries and veins is present in the midportion of the lamina propria and divides this layer into an inner and an outer zone. Smooth muscle cells are also present in the lamina propria, usually as isolated bundles, sometimes as a discontinuous thin layer, and rarely as a continuous layer.[2] This layer of smooth muscle is designated as MM. These can be confused with the muscle bundles of the MP when evaluating the depth of invasion of a bladder neoplasm (particularly in a biopsy specimen), a serious problem since tumor staging and treatment are largely based on the presence or absence of MP invasion. Isolated bundles of muscle immediately adjacent to urothelium, with loose haphazard fiber orientation and irregular outlines, favor MM. Topographic and morphologic variations exist that complicate this evaluation: (1) the more superficial location of the MP and the inconspicuousness of the MM in the trigone; (2) the occurrence of *hyperplastic MM*,

Abstract

This chapter reviews the spectrum of diseases that occur in the urinary bladder, ranging from congenital malformations to inflammatory conditions to neoplasms. Congenital lesions include exstrophy and urachal remnants. The spectrum of cystitis includes infectious (e.g. emphysematous and granulomatous), malakoplakia, eosinophilic, and interstitial cystitis. Urothelial carcinoma is covered in detail to include variant forms, grading, and staging. Finally, rare mesenchymal lesions (e.g. myofibroblastic proliferations, sarcomas, and various benign lesions) are discussed.

defined as MM composed of more than three layers of muscle fibers appearing as fascicles parallel to the surface epithelium or as rounded bundles, this being particularly prominent in the dome[2,3]; (3) the presence of superficially located MM at the insertion of the ureter into the bladder; and (4) an indistinct border between the MP and the lamina propria.[3,4] In general, if individual muscle bundles, either as individual small fascicles or separate distinct rounded bundles, are separated by intervening stroma, then MM should be carefully considered. Immunostaining for smoothelin (a novel smooth muscle-specific marker expressed only in fully differentiated smooth muscle cells) has been touted as having utility in this distinction, in the sense that a strong and diffuse reaction is characteristic of MP, in contrast with MM, in which the staining is absent or weak and focal.[5–8] Not surprisingly, some degree of overlap exists in the degree of reactivity for smoothelin (not to mention significant variability between titers), which calls for extreme caution in its interpretation.[9] Because of these issues, we do not use smoothelin for staging.

The MP is vaguely divided into inner, central circular, and outer longitudinal layers; these are best individualized in the bladder neck region.

Islands of mature adipose tissue are commonly present throughout the wall of the urinary bladder, particularly in the deep portion of the lamina propria; therefore, the presence of carcinoma in adipose tissue is not sufficient for designation as extravesical invasion.[10]

Small paraganglia may be found in the adjacent connective tissue, usually in association with neural structures.[11]

Congenital Abnormalities

Urachal Lesions

The urachus is a 5–6-cm vestigial structure located between the dome of the bladder and the umbilicus that results from the involution of the allantoic duct and the cloaca.[12] During development, it connects the bladder with the allantois. At birth the urachus retracts from the bladder, and when regressed into a fibrous cord, it is called the median umbilical ligament. Its lumen may persist within the bladder wall and be continuous with the bladder cavity. The lining may be of transitional or columnar type. Schubert et al.[13] found tubular urachal remnants in 32% of 122 bladders studied at autopsy.

Anomalies related to urachal remnants most often occur in children, but they can also first present in adults.[14] They include the following: *patent urachus* through which urine may pass, *blind sinuses* in the anterior abdominal wall, *abscesses*, *granulomatous omphalitis*, and intravesical polypoid multicystic masses (*"hamartomas"*).[15–19]

Tumors may also develop from this structure, of which *adenocarcinoma* is the most common; the majority of these cases are well-differentiated, mucin-producing tumors, but enteric type and signet ring carcinomas also occur (Fig. 25.1).[20–23] Other tumor types include *villous adenoma*, *transitional cell (urothelial) carcinoma*, *small cell carcinoma*, and *squamous cell carcinoma*.[21,24–26] Most of these tumors arise from the intramural portion of the urachus and grow into the wall of the bladder, sometimes in the absence of mucosal involvement. Others occur beneath the peritoneum of the anterior abdominal wall between the umbilicus and the bladder dome. The overall prognosis is poor, the main reason being that the location of the tumor does not result in early symptoms and precludes a timely diagnosis. Depending on the extent of the disease, the treatment can be either umbilectomy with partial cystectomy or en bloc radical cystoprostatectomy/umbilectomy.[27,28] Because of the unique anatomic considerations, a specific urachal staging system is often utilized.[29]

Figure 25.1 Gross Appearance of Adenocarcinoma Arising From Urachal Remnants. A, The tumor protrudes as a polypoid ulcerated mass from the dome of the bladder. **B**, The cut surface shows a large intramural mass of mucinous appearance.

Exstrophy

Bladder (cloacal) exstrophy is a congenital abnormality characterized by absence of the anterior vesicle and lower abdominal wall, with eversion of the posterior bladder wall.[30] These changes may be partial or complete and are often associated with other anomalies of the urogenital tract. Malignant change was found in 3 (7.5%) of 42 patients with exstrophic bladder reported by Engel and Wilkinson.[31] It has been calculated that the risk of neoplasia in adults born with exstrophy is 17.5% and that the highest risk (38%) is for those patients who have been exposed to mixing of urine and feces in a colorectal reservoir.[32] The tumor type in most series has usually been adenocarcinoma, occasionally admixed with squamous elements.[31,33] In addition, the occurrence of a unique benign "bladder exstrophy polyp" has been proposed.[34]

The treatment of bladder exstrophy depends on the specific features of the malformation and may consist of reapproximating or closing

the defect, in addition to repairing the other abnormalities that often accompany this condition.[35,36]

Diverticulosis

Most diverticula of the bladder are acquired and develop because of partial urinary obstruction in the urethra or bladder neck, usually as a result of prostatic nodular hyperplasia.[37,38] The longstanding increased muscular contractions required to empty the bladder cause thickening of the wall and mucosal herniation in areas of weakness. Other diverticula are thought to be congenital.[39]

Bladder diverticula are most commonly located in the posterior wall above the trigone, in the region of the ureteral orifices, or in the dome at the site of an obliterated urachus. The communication into the bladder is usually large but may be pinpoint in size. The wall of the diverticulum usually consists of fibrous tissue with little or no muscle. Squamous metaplasia of the lining epithelium often occurs if there is associated inflammation, and associated nephrogenic adenomas are not uncommon.

Complications of bladder diverticula include lithiasis, free perforation into the peritoneal cavity, and tumor development.[40] The tumors are usually urothelial carcinomas,[41,42] but there seems to be a higher incidence of other tumor types.[43–45] They may grow to a large size before detection because of their hidden location. The development of neoplasia may be related to the obstruction, chronic inflammation, epithelial hyperplasia, and squamous metaplasia to which these diverticula are prone. Staging is difficult with invasive carcinomas in diverticula because of the absence of MP, but most large tumors are regarded as pT3.

Lithiasis

Bladder calculi occur much more often in male than in female individuals. Most of the patients are elderly, but children are at high risk in endemic areas, such as Turkey and the Far East.[46] They represent a frequent complication in paraplegics and quadriplegics. The majority of these stones are solitary and composed of phosphate salts; others are made up of urate and oxalate salts.[47] The most common associated abnormality is nodular hyperplasia of the prostate gland, likely secondary to urinary stasis.

Treatment modalities include removal by cystostomy, mechanical (endoscopic) cystolithotripsy, and extracorporeal shock wave therapy. The latter has been found to be a simple, effective, and safe modality for the treatment of most cases and is becoming the therapy of choice, particularly in adult patients.[48–50] Recurrence develops in about 10% of the patients.

Endometriosis and Related Müllerian-Type Changes

Endometriosis may involve the bladder as an isolated focus or in association with similar lesions in other sites (Fig. 25.2).[51] In most instances, there is a history of a previous operation in the area or of symptoms related to the female genital tract.[52] The disease is also rarely reported in men following estrogen therapy for prostatic carcinoma. In the most florid cases, a mass can be palpated at the base of the bladder. Serosal foci are the most common and are usually asymptomatic. Foci occurring in the bladder wall, beneath an intact mucosa, result in a bluish cast on cystoscopic examination and may be accompanied by marked hyperplasia of the vesical muscle in a fashion analogous to that seen in uterine adenomyosis[53]; these can present with persistent hematuria during menstruation. Radiographically, the lesion may be indistinguishable from an intravesical neoplasm.[54]

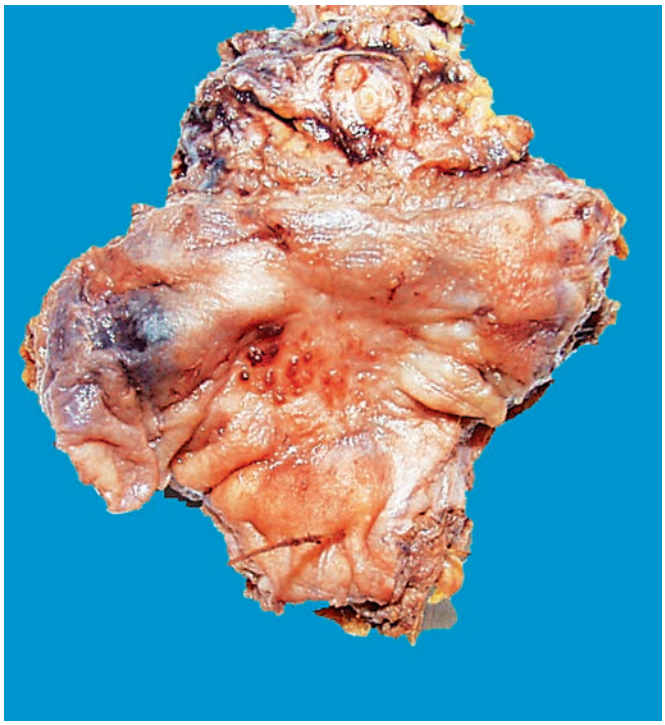

Figure 25.2 Gross Appearance of Endometriosis of Bladder. Multiple small red nodules protrude from the bladder surface.

In addition to classic endometriosis composed of endometrial glands and stroma, one can encounter tubal-type epithelium (including ciliated cells, peg cells, and intercalated cells) and endocervical-type epithelium (columnar mucinous cells). The former change is referred to as *endosalpingiosis* and the latter as *endocervicosis*. When they occur in combination, the picturesque term *müllerianosis* is sometimes used.[55,56] Florid cases of endocervicosis may simulate adenocarcinoma.[57–59] True malignant tumors can develop in this setting, including endometrioid adenocarcinoma,[60] clear cell carcinoma,[61] endometrioid adenosarcoma,[62] and endometrial stromal sarcoma.

The treatment of endometriosis of the bladder includes hormonal manipulation and resection; depending on the location, the latter may be carried out laparoscopically.[63–65]

Amyloidosis

Amyloidosis of the bladder may be the expression of a generalized process or (more commonly) present as a nodular localized mass ("amyloid tumor").[66] The latter are often misinterpreted as neoplasms, both clinically and cystoscopically.[67,68] The histologic appearance is diagnostic. The amyloid material is made up in most instances of AL protein (immunoglobulin [Ig] light chain), but some cases have been found to be transthyretin related.[69–71] Most reported patients with adequate follow-up have remained free of disease following local excision of the mass; therefore, the presence of an amyloid tumor should not be necessarily regarded as a manifestation of myeloma or plasmacytoma.[71–73]

Cystitis

Interstitial Cystitis (Painful Bladder Syndrome)

The classic clinical description of interstitial (Hunner) cystitis (or painful bladder syndrome) is that of an adult or elderly female with ulceration and marked submucosal edema of the bladder resulting in prominent

lower abdominal, suprapubic, or perineal pain and urinary frequency, unresponsive to medical therapy.[74] Because of the consistent presence of ulceration, the disease is also known as *Hunner ulcer*.

The lesion can be located anywhere in the bladder. Microscopically, there is mucosal ulceration covered by fibrin and necrotic material. The underlying lamina propria and muscularis show edema, hemorrhage, granulation tissue, and a mononuclear inflammatory infiltrate that sometimes exhibits a predominantly perineural location.[75,76] Mast cells are usually present and sometimes numerous; they are found beneath the ulcer, within the detrusor muscle bundles, and between the epithelial cells in the adjacent mucosa, but CD117 immunostains have not proven helpful in establishing a more definitive diagnosis.[77,78] None of these microscopic features is pathognomonic.[79] Cases lacking ulceration are considered by some authors to represent a different condition affecting a younger patient population.[80]

The etiology of this disorder remains obscure.[81] The search for infectious organisms has been unrewarding.[82] Hyperexpression of human leukocyte antigen (HLA) class I molecules,[83,84] strong urothelial staining for IgA,[85] and increased sympathetic outflow into the bladder[86,87] suggest the participation of autoimmune mechanisms, whereas the finding of a reduction in the expression of heat shock protein 60 suggests a defect in the proliferative response of the urothelium.[88] The treatment is usually medical, but surgical intervention (including supratrigonal or total cystectomy) may be necessary in severe cases.[89–92]

Eosinophilic Cystitis

Eosinophilic cystitis is a descriptive term that is used in distinct clinical settings. The first is seen in women and children and is often associated with allergic disorders and eosinophilia.[92,93] The second presents in older men and is usually an incidental finding associated with bladder injury related to other disorders of the bladder and prostate.[94,95] Exceptionally, the disease is due to parasitic infestation.[96]

Clinically, the allergic associated form of eosinophilic cystitis presents with dramatic and recurrent episodes of dysuria and hematuria.[97] Rarely, it may result in ureteral obstruction.[98] The cystoscopic appearance is that of a diffusely edematous and erythematous mucosa, with broad-based polypoid growths that may simulate a neoplastic process.[99] Microscopically, a dense inflammatory infiltrate rich in eosinophils, often accompanied by fibrosis and muscle necrosis and sometimes by giant cells, is present.[100,101] This condition is not related to Langerhans cell histiocytosis. The treatment of choice is transurethral resection (TUR) of the bladder lesions and a combination of steroids and antihistamines.[102,103]

Emphysematous Cystitis

Emphysematous cystitis (cystitis emphysematosa) is an inflammatory condition caused by gas-forming bacteria (such as *Clostridium perfringens*) and characterized by the presence of gas-filled vesicles in the bladder wall.[104] Patients with diabetes, neurogenic bladder, chronic urinary infection, and malignant hematologic conditions are predisposed to the disease.[105–108] In some series, as many as half of the patients with emphysematous cystitis suffered from diabetes. Microscopically, multinucleated giant cells are seen partially lining the cysts.[108] The treatment consists of antibiotic therapy and relief of bladder outlet obstruction.[106]

Tuberculosis and Bacillus Calmette–Guérin-Induced Granulomas

Tuberculosis remains the most frequent cause of granulomatous inflammation of the bladder in many parts of the world. It invariably develops from secondary foci, most often located in the kidney, as demonstrated in the classic study by Auerbach in 1940.[109] About 10% of the patients have a history of pulmonary tuberculosis.[110] Most bladder lesions are found in the region of the trigone, especially around the ureteral orifices. Early lesions are superficial and small, with a floor of soft caseous material and a peripheral hyperemic zone. As the disease progresses, multiple ulcers coalesce to form larger ones that illicit fibrosis and involve the underlying musculature. In males, there may be secondary involvement of the prostate, whereas in females the disease may be complicated by vesico-vaginal fistula.[111]

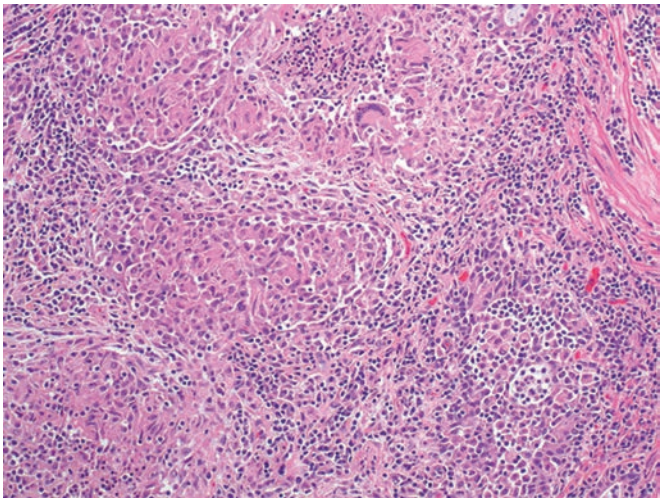

Figure 25.3 Granulomas induced by BCG therapy for urothelial carcinoma.

Intravesical administration of bacillus Calmette–Guérin (BCG), as used for the treatment of superficial carcinoma of the bladder, can result in granulomatous inflammation of this organ, which may be detected microscopically or on cytologic examination of bladder wash specimens (Fig. 25.3).[112,113] The changes can extend to the prostate[114] and sometimes may even lead to systemic clinical disease, including lung involvement.[115,116]

Malakoplakia and Related Conditions

Malakoplakia of the bladder is characterized by the appearance of multiple nodular thickenings of the mucosa and underlying stroma, usually in the region of the trigone, which may be mistaken for carcinoma.[117,118] It has been associated with immune deficiency states and has been reported on several occasions in renal transplant recipients.[119,120]

Microscopically, collections of histiocytes with granular eosinophilic cytoplasm accumulate beneath the surface epithelium. In some of these cells, rounded, concentrically layered intracytoplasmic inclusions known as Michaelis–Gutmann bodies (or calcospherites) are seen (Fig. 25.4); these are basophilic and periodic acid–Schiff (PAS) positive and stain for iron and calcium. Ultrastructurally and immunohistochemically, intracellular bacteria can be identified.[121–123] The presence of transitional forms between these bacteria, lipid inclusions, and Michaelis–Gutmann bodies suggests that the latter represent the result of bacterial degradation.[124] Accordingly, malakoplakia is presently regarded as a defect in the host macrophage (phagolysosomal) response to a bacterial infection, usually from gram-negative coliform bacilli.[124–126] **Xanthogranulomatous cystitis** is morphologically and probably pathogenetically similar to malakoplakia, but it lacks Michaelis–Gutmann bodies.[127] Some of the reported cases have been associated with malignant tumors.[128]

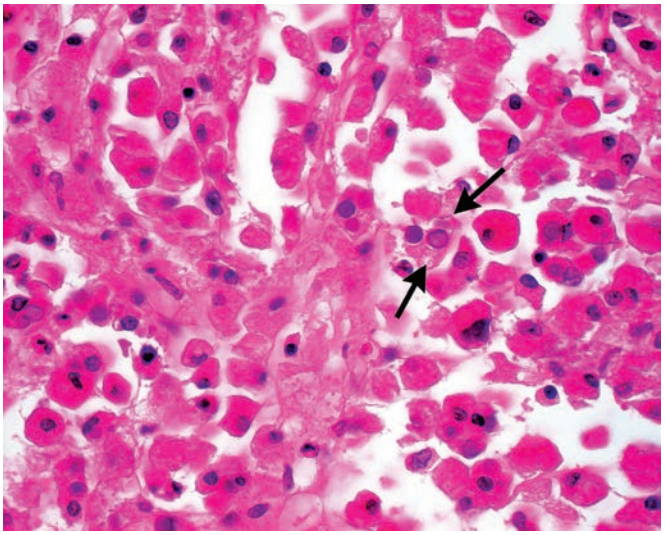

Figure 25.4 High-power view of malakoplakia of bladder, showing numerous histiocytes with Michaelis–Gutmann bodies *(arrows)*.

Malakoplakia may also involve the renal pelvis and parenchyma, ureter, prostate gland, testis, epididymis, broad ligament, endometrium, retroperitoneal structures, colon, stomach, appendix, lymph nodes, brain, lungs, bones, skin, and several other sites.[129–132]

It is important to keep in mind that, on rare occasion, malakoplakia of the bladder coexists with other lesions, such as tuberculosis and carcinoma.[133]

Other Forms of Cystitis

Other reasonably distinct types of cystitis that have been described are *hemorrhagic cystitis*, *giant cell cystitis*, *follicular cystitis*, *radiation cystitis*, *gangrenous cystitis*,[134] *myxoid cystitis* (which may contain lymphocytes with a chordoid appearance),[135] and *encrusted cystitis*.[136]

Hemorrhagic cystitis is a well-recognized complication of cyclophosphamide therapy for bone marrow transplantation and systemic vasculitis,[137–139] but it has also been seen in the absence of medication.[140] Some cases of hemorrhagic cystitis have been found to result from herpes simplex virus or cytomegalovirus.[141,142] Severe cases of hemorrhagic cystitis may necessitate the performance of a total cystectomy.[143]

HIV-infected and other immunosuppressed patients may develop cystitis of various types, including malakoplakia (see previous section) and *Toxoplasma* cystitis.[144]

Cystitis secondary to *ketamine administration* (an anesthetic agent also used in the management of pain) or ketamine abuse can be accompanied by prominent reactive urothelial changes that can mimic carcinoma.[145]

Metaplastic and Tumorlike Conditions

The bladder epithelium is prone to a remarkably wide range of metaplastic changes, most of them induced by chronic inflammation. Although clearly related to each other and often coexisting, they have traditionally been regarded as distinct entities of either inflammatory or neoplastic nature.

Intestinal metaplasia and **cystitis glandularis** result from chronic inflammation or other causes of mucosal irritation and are seen commonly with ureteral reimplantation, neurogenic bladder, or bladder exstrophy.[146,147] They may regress completely if the underlying pathogenetic factor is removed. Grossly, they usually present as irregular lesions that may be confused cystoscopically with carcinoma. The trigone is the area most commonly affected, but rare instances of involvement of the entire bladder mucosa have been reported.[148] Similar lesions may be present in the ureter and renal pelvis.

Microscopically, the initial change is focal proliferation of the basal layer of the urothelium, which produces buds that later become solid nodules (*von Brunn nests* or *islands*) located within the lamina propria. Some of these nodules develop a central cystic area. When the cells lining the cyst maintain an urothelial appearance, the condition is called *cystitis cystica*; when the luminal cells acquire luminal oriented cytoplasm imparting a glandular appearance, it is referred to as *cystitis glandularis* (Fig. 25.5). When morphologic features analogous to those of colonic epithelium are present, the process is designated as *intestinal (glandular, colonic) metaplasia* (see Fig. 25.5).[149–151] As would be expected, intestinal metaplasia is characterized by reactivity for CDX2 and CK20, whereas cystitis glandularis shows positivity for CK7.[152] We have anecdotally seen very rare examples with gastric type metaplasia. The common occurrence of transitional forms suggests that these represent various stages or manifestations of the same basic process.

When very florid, these metaplastic changes can mimic urothelial carcinoma, particularly the nested variant.[153] Rare cases may also be associated with extensive mucin extravasation, but reported follow-up data have confirmed a benign outcome (Fig. 25.6).[154]

Although intestinal metaplasia, especially when extensive, has been suggested as a risk factor for the development of adenocarcinoma,[153] most studies have not shown increased risk.[155] Certainly, the rare cases with associated glandular dysplasia may progress.[156]

Nephrogenic adenoma (nephrogenic metaplasia) has been regarded in the past as a benign neoplasm and designated as nephrogenic adenoma, but most authors currently favor the interpretation that it represents a localized or diffuse metaplastic change of the urothelium in response to chronic infection, calculi, or prolonged catheterization.[157] However, the startling claim has been made, backed by very convincing cytogenetic data, that at least some of these lesions—as seen in renal transplant recipients—represent implants into eroded bladder mucosa of tubular cells from the kidney.[158] Regardless of histogenesis, these are benign lesions.

Most cases are seen in adults, but children can also be affected.[159] Grossly, these lesions can be papillary, polypoid, or sessile; approximately 20% are multiple.[160] Their microscopic appearance is quite heterogeneous with numerous architectural patterns that are often admixed including small tubular, papillary, sheet-like with clear cytoplasm (diffuse), fibromyxoid, and flat (Fig. 25.7).[161–163] The lesional cells are low cuboidal and may have a hobnail arrangement in tubules or on papillae; thick basement membrane material often surrounds the tubules. Small tubules often have an intraluminal blue myxoid material that may simulate a signet ring cell. Immunohistochemically, they are positive for keratin 7 and PAX-8. Expression of racemase, GATA-3 (often patchy), and rarely focal high molecular weight cytokeratin or p63 may cause confusion with prostatic or urothelial carcinoma, but NKX3.1 is negative in nephrogenic adenoma.[164,165,165a,165b] Rare cases are associated with some degree of nuclear enlargement, hyperchromasia, and pleomorphism; there is no evidence that these cases, referred to as *atypical*, have a precancerous potential.[166] The main differential diagnosis is with clear adenocarcinoma and signet ring adenocarcinoma. In the rare cases in which the pattern of growth is papillary, the lesion may simulate a papilloma or papillary carcinoma of urothelial type, but the single cuboidal lining of nephrogenic adenoma is distinct.

Polypoid cystitis is a benign process of a reactive nature which may simulate a neoplasm grossly.[167] The typical site of involvement is the posterior wall above the trigone, but on occasion the entire

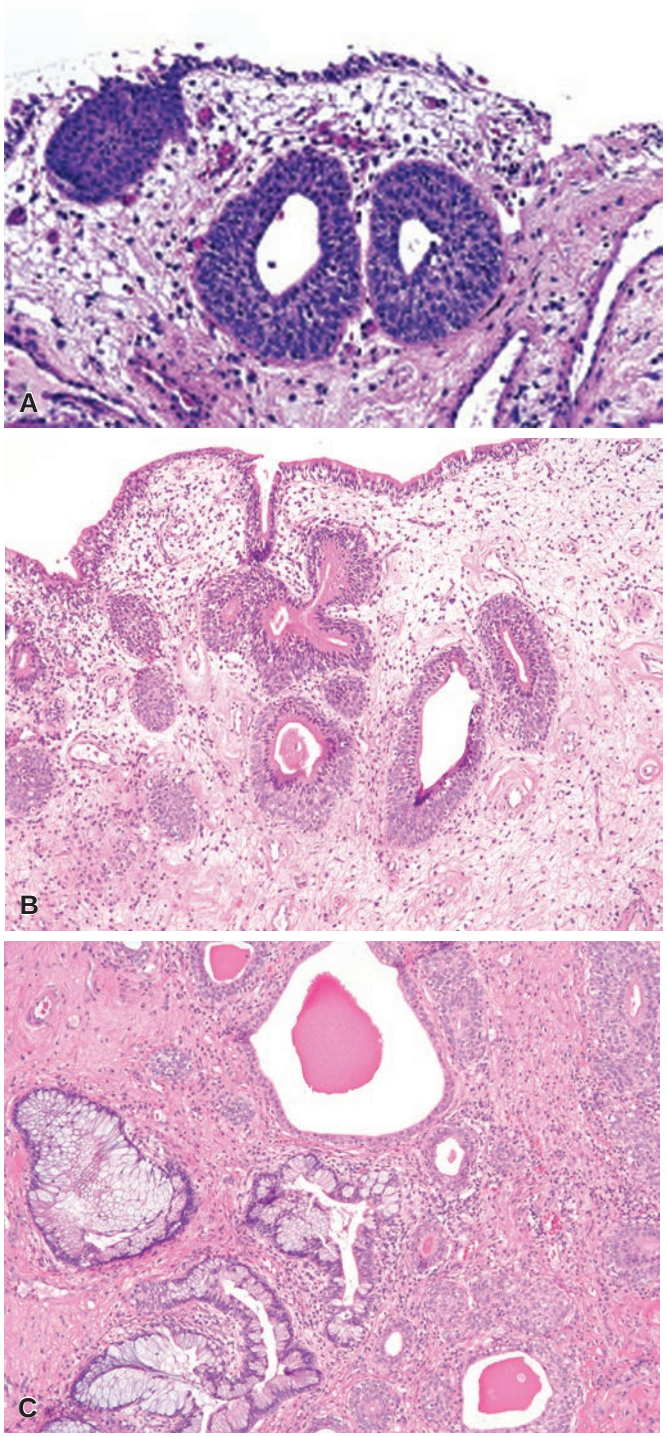

Figure 25.5 **A,** Cystitis cystica has invaginated urothelial nests with a central lumen lined by urothelial cells, while **(B)** cystitis glandularis is characterized by luminally oriented eosinophilic cytoplasm. **C,** Some cases of cystitis glandularis have intracytoplasmic mucin (intestinal metaplasia) that is often admixed with otherwise typical von Brunn nests and cystitis cystica.

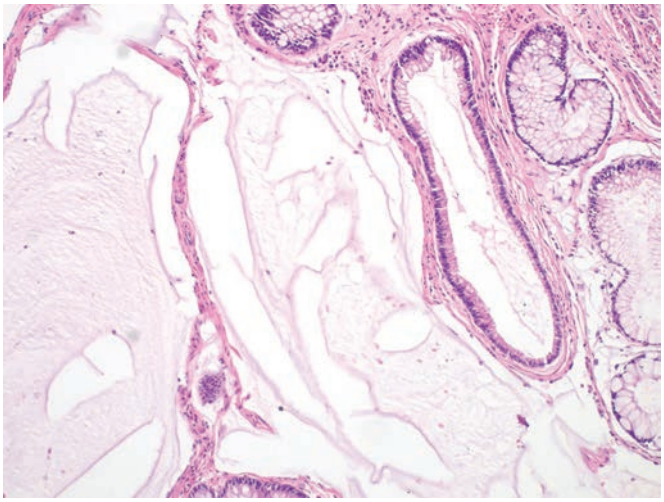

Figure 25.6 Rare cases of cystitis glandularis with intestinal metaplasia have abundant extravasated mucin that may cause a large mass lesion simulating malignancy.

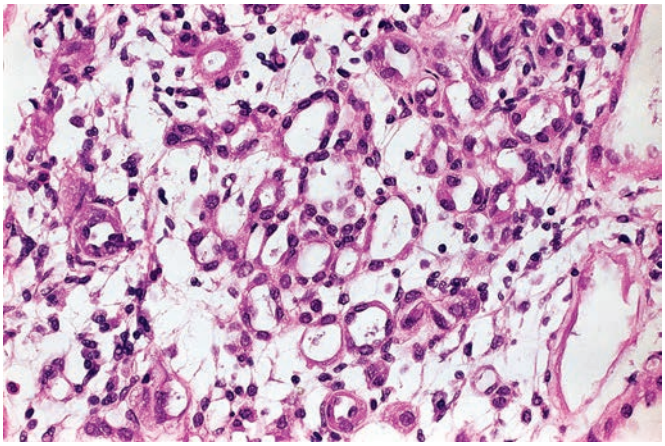

Figure 25.7 **Nephrogenic Adenoma.** A complex clustering of gland-like formations lined by cuboidal to flattened cells is seen surrounded by an edematous stroma.

bladder is affected. Gross variants of this condition include *bullous cystitis*, in which the elevations are broad and rounded, and *papillary cystitis*, in which they are thin and filiform.[167] The latter, which is thought to represent a late stage of the disease, is often overdiagnosed as a low-grade papillary urothelial neoplasm by the pathologist (but less so by the urologist). The diagnosis is best made at low power by virtue of the edematous or fibrous nature of the inflamed stroma, the broad-based, simple, nonbranching appearance of the fronds, and the normal or reactive appearance of their lining epithelium in terms of thickness and cytology (Fig. 25.8).[168] Inflammation is scanty, and significant epithelial atypia is absent; however, reactive urothelial atypia may be prominent.[169] Stellate mononuclear or multinucleated fibroblasts may be present; these are similar to those seen in analogous reactive conditions beneath other epithelium-covered surfaces, such as the nasal cavity, oral cavity, and vagina.

The better known cause of polypoid cystitis is catheterization of the bladder; the more frequent the procedure, the greater the frequency and severity of the condition, which reaches its peak at 3 months.[169] However, in only a minority of reported cases of polypoid cystitis is there a history of recent catheterization.[167] It has also been seen in association with radiation therapy and malignant tumors.

Postoperative granulomas can develop following catheterization and diathermy. The microscopic appearance may be that of a foreign-body granuloma or resemble a rheumatoid nodule by virtue of central necrosis surrounded by a palisading of histiocytes and scattered

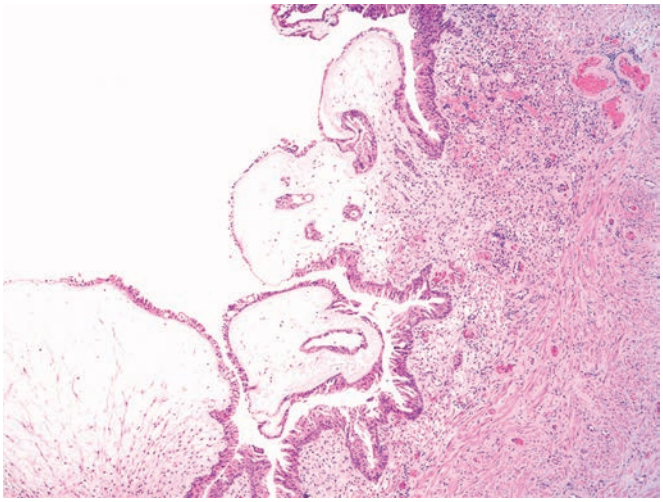

Figure 25.8 Papillary/polypoid cystitis is characterized by either broad bulbous projections or relatively broad-based simple excrescences, often with marked lamina propria edema.

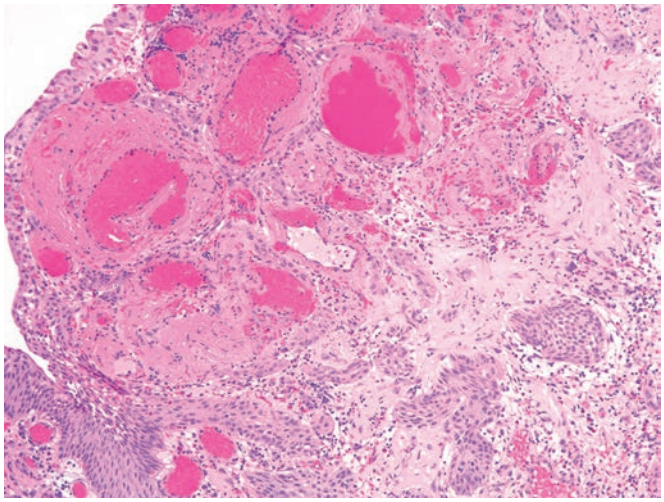

Figure 25.9 Postradiation architectural and cytologic atypia of bladder epithelium. These changes are sometimes overinterpreted as carcinoma, but the admixture of epithelium and fibrin, and the associated vascular ectasia and congestion are characteristic of this benign process.

giant cells.[170,171] There is often an associated granular eosinophilic material.[171a] These lesions heal by fibrous scarring.

Prostatic-type polyps similar to those more commonly occurring in the prostatic urethra have been seen in the bladder neck, around the ureteral orifices, and at the dome.[172]

Fibroepithelial polyps are most commonly seen in children. Most are located near the verumontanum or bladder neck. Microscopically, they are lined by normal-appearing urothelium. The stroma is fibrous, without the prominent edema and inflammation seen in polypoid cystitis.[173] The pattern of growth is polypoid, with or without papillary projections. The most important differential diagnosis is with the botryoid variant of embryonal rhabdomyosarcoma.[174]

Pseudocarcinomatous proliferation can occur as a result of radiation therapy, with or without associated ulceration.[175] Very rarely, morphologically similar changes have been reported unassociated with irradiation or chemotherapy in patients with systemic diseases of one type or another.[176] The atypical epithelium is urothelial, but a "squamoid" appearance is common, and it may extend to the subepithelial tissues (Fig. 25.9).[177] The presence of vascular ectasia and atypical fibroblasts in the stroma represent important diagnostic clues.[178,179] Another important key to the diagnosis is the presence of pseudoinvasive urothelial nests wrapping around blood vessels associated with fibrin deposition.[179]

"Collagen polyps" result from the injection of collagen into the bladder or urethral wall as treatment of urinary stress incontinence. Microscopically, the polyps show a submucosal accumulation of degraded collagen surrounded by a modest inflammatory reaction.[180]

Other reported types of tumorlike conditions of the bladder include **xanthoma**,[181] **extramedullary hematopoiesis**,[182] and **hamartoma** (occurring in association with the Beckwith–Wiedemann syndrome).[183]

Urothelial Carcinoma

General and Clinical Features

Urothelial carcinoma (historically known as transitional cell carcinoma or "TCC") comprises approximately 90% of all primary tumors of the bladder (Fig. 25.10). As with most other carcinomas, its development seems to depend on a combination of genetic and

Figure 25.10 Exophytic and papillary pattern of growth of a urothelial carcinoma arising in a bladder with hypertrophy of the wall due to prostatic nodular hyperplasia. The tumor, which was located in the left lateral wall, was treated by total cystoprostatectomy. The prostate shows an incidental infarct.

environmental factors.[184–186] Among the latter, chemical factors are thought to be of great importance.[186] Bladder tumors are more common in industrial areas (especially in those associated with petrochemicals), and their incidence is increased with exposure to cigarette smoke and arylamines.[187–190]

Other environmental factors include aniline dyes (particularly benzidine and β-naphthylamine),[191,192] auramines, phenacetin, and cyclophosphamide.[193–195] *Schistosoma haematobium* is pathogenetically related to both urothelial and squamous cell carcinoma of the bladder.[196,197] The role of HPV has been controversial, but most of the available evidence suggests that it does not play a significant role in the genesis of this tumor.[197–199] It is believed that there is a slight increased risk for the development of bladder carcinomas in patients who had been treated with radiation therapy for prostatic carcinoma.[200]

Most cases of urothelial carcinoma of the bladder present in patients over the age of 50 years, but they can also rarely occur in

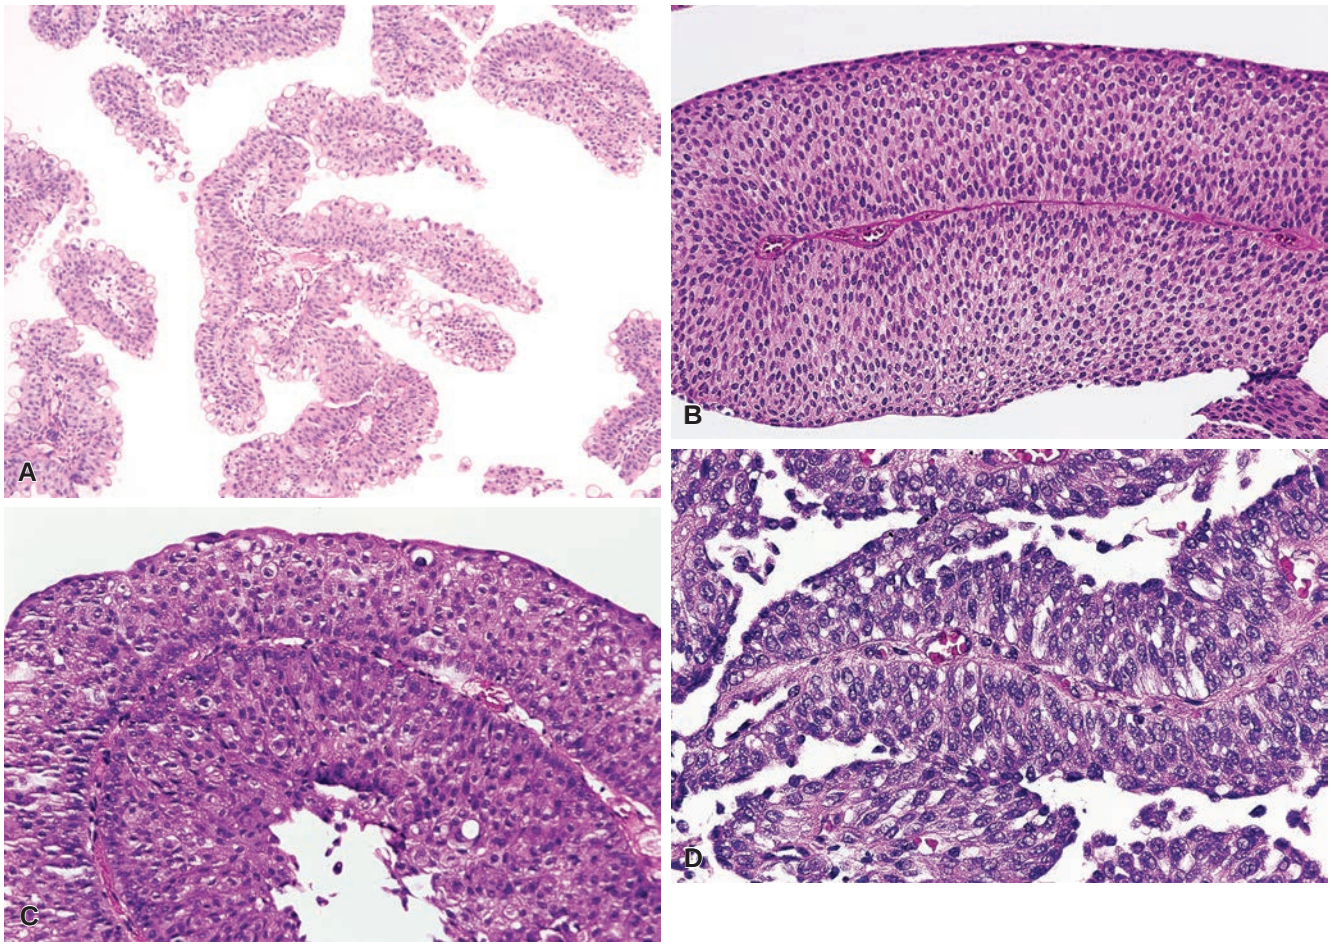

Figure 25.11 Various Types of Noninvasive Papillary Urothelial Neoplasms of the Bladder. A, Papilloma. **B,** Papillary urothelial neoplasm of low malignant potential (PUNLMP). **C,** Low-grade papillary urothelial carcinoma. **D,** High-grade papillary urothelial carcinoma.

younger adults and children.[201–204] The latter tend to be low-grade, indolent neoplasms, but occasional highly aggressive examples are reported in young adults.[205]

Men are affected more often than women, and white individuals more often than patients of African descent. Gross or microscopic hematuria is the most common form of presentation, followed by symptoms related to secondary urinary tract infection. Dysuria is more often seen with high-grade tumors, perhaps because of involvement of the bladder wall.

Urothelial tumors can arise anywhere in the bladder. In a series of approximately 1000 cases, the location was listed as follows: lateral walls, 37%; posterior wall, 18%; trigone, 12%; neck, 11%; ureteric orifices, 10%; dome, 8%; and anterior wall, 4%.[206] They have also been reported within bladder diverticula. When located around the ureteral orifices, they may produce partial or complete blockage of one or both ureters, with resulting hydronephrosis and pyelonephritis. Synchronous or metachronous multicentricity is common.

Noninvasive Papillary Urothelial Neoplasia

Several classification systems for urothelial carcinoma have been proposed over the years. These represent attempts at grading the increasing degrees of architectural disarray and particularly *cytologic* atypia of a single tumor type. The main such systems were those of Ash in 1940,[207] Mostofi in 1960,[208] Bergkvist et al. in 1965,[209] Malmstrom et al. in 1987, and World Health Organization (WHO) in 1973.[210] These have been superseded by the classification jointly proposed in 1998 by the WHO and the International Society of Urological Pathology (ISUP) and recommended by the current 2016 WHO classification.[211–216] Its main features are the division of the neoplastic lesions into flat and papillary, and the separate evaluation of the papillary neoplasms for grade (based on architecture and cytology) and invasiveness (divided into lamina propria and MP levels). The types of papillary neoplasms recognized in this classification are the following: *urothelial papilloma*; *papillary urothelial neoplasm of low malignant potential (PUNLMP)*; *low-grade papillary urothelial carcinoma*; and *high-grade papillary urothelial carcinoma* (Fig. 25.11). The criteria used to place the tumors into these categories are listed in Table 25.1. The major changes from the traditional 1973 WHO grading system were to label the lowest risk tumors as "papilloma" and "low malignant potential" (avoiding the term carcinoma for the latter group that was formerly called grade 1 carcinomas) and to lower the diagnostic threshold for a high-grade diagnosis, which was a consensus decision based on clinical follow-up data showing higher progression rates for the more atypical subset of WHO 1973 "grade 2" carcinomas.[210]

The grading of urothelial tumors of the bladder is of great prognostic significance. Thus, the tumors at the lower end of the spectrum (called papillomas in the WHO/ISUP scheme) have a low

Table 25.1 Histologic features used to classify urothelial papillary lesions according to the scheme proposed by the World Health Organization/International Society of Urological Pathology

	PAPILLOMA	PAPILLARY NEOPLASM OF LOW MALIGNANT POTENTIAL	LOW-GRADE PAPILLARY CARCINOMA	HIGH-GRADE PAPILLARY CARCINOMA
Architecture				
Papillae	Delicate	Delicate; occasionally fused	Fused, branching, and delicate	Fused, branching, and delicate
Organization of cells	Identical to normal	Polarity identical to normal; any thickness; cohesive	Predominantly ordered, yet minimal crowding and minimal loss of polarity; any thickness; cohesive	Predominantly disordered with frequent loss of polarity; any thickness; often discohesive
Cytology				
Nuclear size	Identical to normal	May be uniformly enlarged	Enlarged with variation in size	Enlarged with variation in size
Nuclear shape	Identical to normal	Elongated, round–oval, uniform	Round–oval; slight variation in shape and contour	Moderate–marked pleomorphism
Nuclear chromatin	Fine	Fine	Mild variation within and between cells	Moderate–marked variation both within and between cells with hyperchromasia
Nucleoli	Absent	Absent to inconspicuous	Usually inconspicuous[a]	Multiple prominent nucleoli may be present
Mitoses	Absent	Rare, basal	Occasional, at any level	Usually frequent, at any level
Umbrella cells	Uniformly present	Present	Usually present	May be absent

[a]If present, small and regular and not accompanied by other features of high-grade carcinoma.

The World Health Organization/International Society of Urological Pathology consensus classification of urothelial (transitional cell) neoplasms of the urinary bladder. *Am J Surg Pathol*. 1998;22:1435–1448.

incidence of recurrence and a negligible incidence of concurrent in situ or invasive carcinoma, while higher grade tumors have more propensity for recurrence and progression.[217,218]

It should be kept in mind that the differentiation of these neoplasms may vary from area to area[219]; therefore, a biopsy or TUR may show a different grade from the one that will be found in the surgical specimen.[220–222] It is also good to remember that this grading system has been devised for its application to noninvasive urothelial neoplasms and that it does not have much discriminatory power when applied to the invasive component.[223]

Urothelial papilloma of exophytic type is characterized by a relatively simple branching papillary architecture, typically without epithelial confluence between papillary excrescences.[217,218,224,225] The lining urothelium appears histologically normal with orientation of the neoplastic cells streaming upward (perpendicular to the basement membrane), often with very prominent umbrella cells. Not uncommonly, the papillary cores contain dilated lymphatics or a distinct gland-in-gland pattern. *PUNLMP* is similar, but the lining appears thickened (hyperplastic) on low-power examination compared with normal urothelium.[212,226] In contrast, *noninvasive low-grade papillary urothelial carcinoma* has a more disorganized urothelium that loses polarity with mild cytologic atypia. The papillae may be more complex and confluent compared with papilloma and PUNLMP. *Noninvasive high-grade papillary urothelial carcinoma* are not all markedly pleomorphic, but at a minimum show cellular disorder with a combination of nucleomegaly, some variation in nuclear size and shape, and irregular nuclear chromatin (i.e., hyperchromasia). At the extreme end of the high-grade spectrum, there may be solid confluent epithelial growth between papillae and marked anaplasia.

While "papillary urothelial hyperplasia" with or without atypia was recently proposed as a urinary bladder lesion consisting of undulating folds of urothelium without the cytologic atypia and the well-developed branching fibrovascular cases of papillary neoplasms,[227–229] the WHO classification has recommended classifying true papillary lesions as neoplasms using the previously described categories. In cases with very early epithelial tufting in which the diagnosis as a papillary neoplasm is uncertain, the descriptive diagnostic term "urothelial proliferation of uncertain malignant potential" has been suggested.[216]

Endophytic/Inverted Urothelial Neoplasia

Inverted urothelial papilloma is thought to represent a benign epithelial tumor that may be distinct from exophytic urothelial papilloma. It is more commonly seen in adult and elderly males and is almost always located in the trigone, bladder neck, or prostatic urethra.[230,231] It is usually solitary and presents with hematuria and/or obstruction.

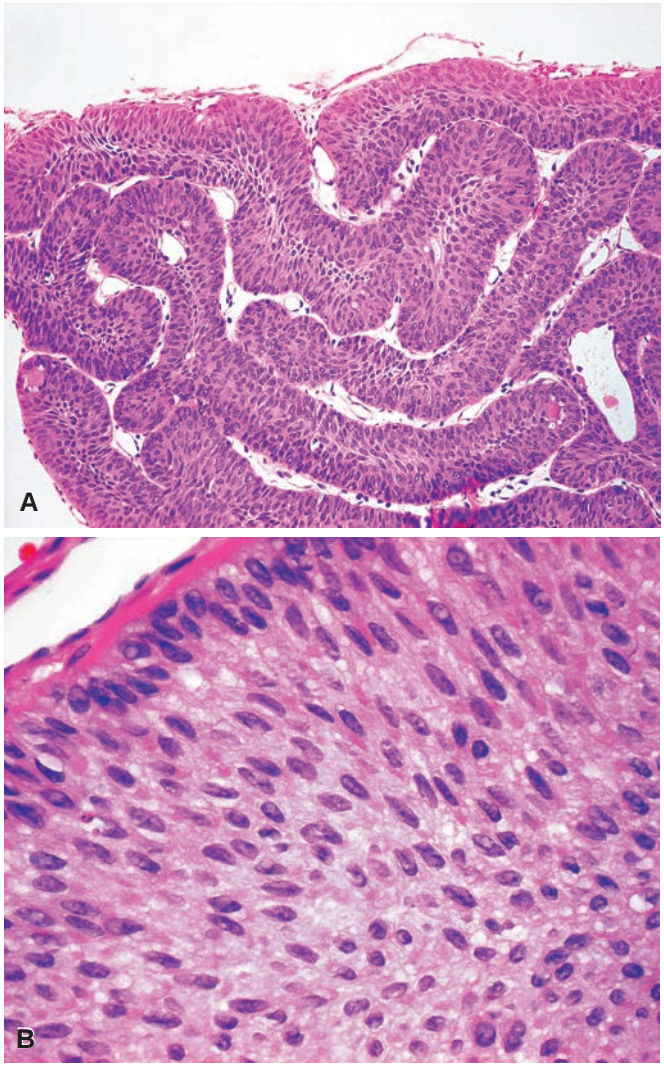

Figure 25.12 Inverted Papilloma of Bladder. A, The proliferation has a festoon-like quality and is located below a flat epithelium. **B,** High-power view showing the oval to spindle shape of the cells and their lack of atypia.

Cystoscopy reveals a polypoid and usually pedunculated lesion of smooth contours (Fig. 25.12). Microscopically, the most characteristic feature is the invagination of the epithelium, which usually shows no atypical features (see Fig. 25.12). Occasionally, this epithelium may show a foamy or vacuolated cytoplasm.[232] Papillae are absent or present only very focally, and connective tissue is very scanty.[233] In some lesions, there is a distinct trabecular arrangement, with peripheral palisading of the tumor cells and central cellular spindling; in others, there are islands of urothelial cells accompanied by gland-like and mucin-secreting structures.[234] The latter type may actually represent an unduly proliferative form of cystitis glandularis or cystica.[234,235] Exceptionally, a neuroendocrine component made up of granular eosinophilic cells is present.[236] There is no evidence that inverted papilloma (even if accompanied by some degree of supposedly "degenerative" type epithelial atypia)[237] predisposes to the development of carcinoma, but there is occasional coexistence of the two lesions.[238,239]

The entire spectrum of urothelial neoplasia seen in papillary lesions may have a similar noninvasive inverted growth with anastomosing cords and endophytic nests of urothelium.[240] *Inverted PUNLMP* has not been extensively studied, but rare urothelial neoplasms with an inverted pattern have some features of papilloma but have other areas with mild expansion of the nests or cords.[226] These areas maintain a relatively ordered arrangement of the bland urothelial cells. *Noninvasive low-grade papillary urothelial carcinoma, inverted type* has similarly expanded cords and nests but has a degree of architectural disorder and mild atypia similar to its exophytic counterpart. *Noninvasive high-grade papillary urothelial carcinoma, inverted type* has a similar low-power expanded cord-like architectural growth with rounded contours; however, the cytological features are sufficient for designation as high grade.

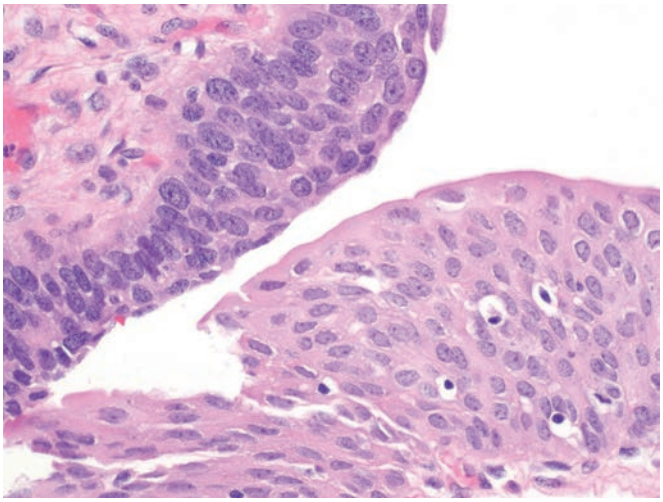

Figure 25.13 Urothelial Carcinoma in situ of Bladder. Note the nucleomegaly and irregular, clumpy chromatin *(upper left)* as compared to adjacent normal urothelium *(lower right)*.

Flat Urothelial Lesions With Atypia

Historically, flat urothelial lesions with atypia were classified at different centers using variable terminology, but the WHO/ISUP 2016 classification (based on modifications from WHO/ISUP 1998)[212] is now more uniformly utilized throughout the world. The diagnostic categories include **reactive urothelial atypia**, **urothelial atypia of unknown significance**, **urothelial dysplasia**, and **urothelial carcinoma in situ (CIS)**. The most important diagnostic thresholds are those for definitive reactive changes and definitive CIS.

Reactive urothelial atypia is frequently associated with acute and chronic inflammation from a variety of causes (e.g., infection, indwelling catheter, calculi).[241] The inflammatory cell infiltrate may involve the lamina propria, but intraurothelial inflammation is most common. Urothelium with reactive atypia often has a basophilic appearance; their nuclei are enlarged and may be somewhat rounded, but they are typically monomorphic without significant variation in size and shape. In general, the nuclei are no larger than the size of approximately three lymphocytes. Importantly, the nuclear chromatin remains fine, but prominent nucleoli (sometimes multiple) are not infrequent. Mitoses may be frequent and can involve the upper levels of the urothelium, especially in patients with recent indwelling catheters.

Urothelial CIS is histologically heterogeneous, but there are general over-reaching features (Fig. 25.13).[242] Compared with normal urothelium, nuclei are often more rounded and enlarged, often greater than 4–5 times the size of a lymphocyte.[243] The urothelial cells, in contrast to reactive atypia, become disorganized, losing their orientation perpendicular to the basement membrane. The

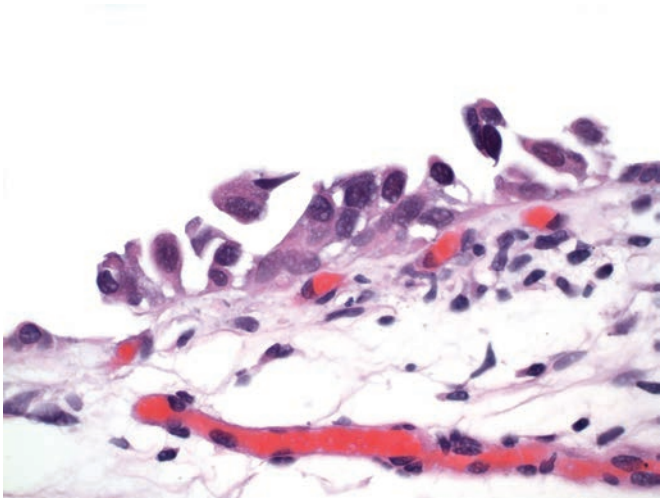

Figure 25.14 Urothelial Carcinoma in situ of Bladder. The tumor has detached from the underlying stroma, only a few residual malignant cells remaining, resulting in the picture known as clinging or denuding carcinoma in situ.

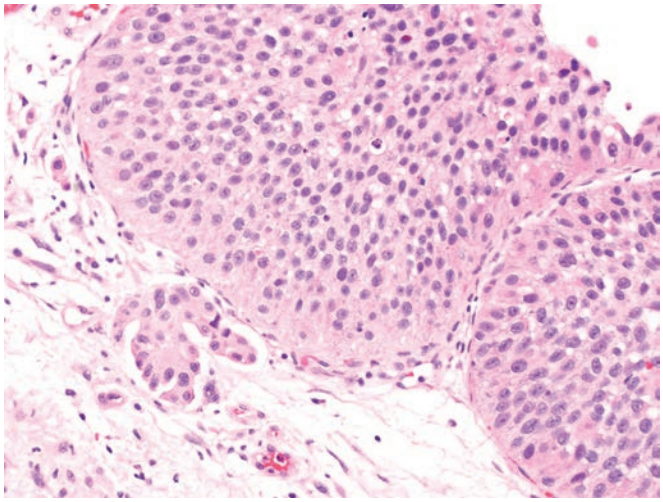

Figure 25.15 Focal superficial lamina propria invasion by urothelial carcinoma of bladder, which is characterized by detached clusters of urothelium with cytoplasmic eosinophilia, irregular contours, and surrounding stromal retraction.

nuclear chromatin becomes coarse, nuclear membranes are often irregular, and nucleoli may be present or absent. Mitotic figures are often easily seen and may be atypical. Unlike many other anatomic sites, the nuclear-to-cytoplasmic ratio of the neoplastic cells may not be increased as abundant cytoplasm is often preserved. Diverse patterns of CIS may be seen and include undermining growth, pagetoid spread, and denuding/clinging CIS (Fig. 25.14). Rare cases may show glandular differentiation.[244] It is important for the term CIS not to be equated with "*superficial carcinoma*"; the latter is used by urologists for tumors that have not invaded into the MP regardless of their type and grade, and therefore it does not represent a pathologic entity.[211] Similarly, one should realize that while papillary urothelial carcinomas that do not invade the stroma could be conceptually considered "carcinomas in situ" (pTa), they are not designated as such to avoid lumping together two conditions with markedly different morphologic features, natural history, and probably molecular pathways.[245,246]

Classification of flat urothelial atypias that fall short of the threshold for CIS, yet have cytologic features beyond definitive reactive atypia are more problematic. Urothelial dysplasia suffers from poor interobserver reproducibility, and large studies that link dysplasia (excluding cases that would be regarded as CIS by current definitions) to the risk of developing CIS are, in our opinion, lacking. Lesions classified as dysplasia typically have some degree of cellular disorganization but only mild nuclear enlargement and only mild atypia. Subtle cellular crowding or overlap may be seen in normal urothelium and should not be interpreted as "atypical." Because of these problems, some experts prefer to combine the categories of "atypia of unknown significance" and "urothelial dysplasia" into a single category for daily practice, such as "flat urothelial atypia, cannot exclude early flat neoplasia (dysplasia)." In general, both diagnostic categories would simply be followed clinically to exclude development of a more definitive, higher-grade lesion, so the distinction is not critical to clinical management. Adjunctive testing by immunohistochemistry (e.g., CK20, CD44, p53, Ki-67, CK5/6) has been evaluated in this setting,[247–249] but studies have not documented independent predictive value for disease progression in these borderline cases; therefore, it is our opinion that true clinical utility is questionable. The critical morphologic task is the distinction of atypia/dysplasia from CIS as the later diagnosis prompts therapy. The presence of marked nuclear enlargement (≥5–6 times the size of a lymphocyte), significant nuclear chromatin hyperchromasia, and brisk mitotic activity generally strongly suggest CIS.

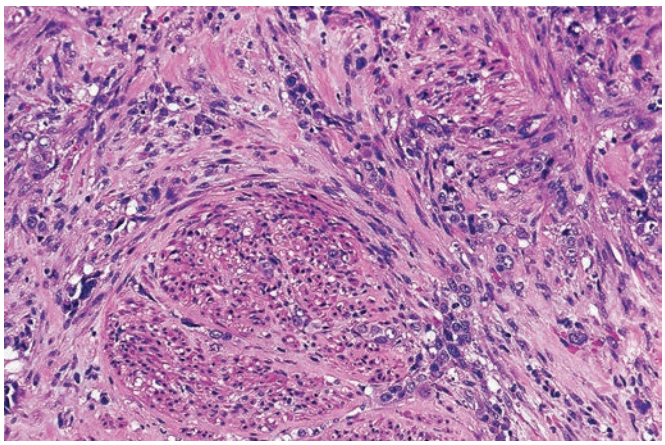

Figure 25.16 Muscularis propria invasion by urothelial carcinoma of bladder.

Invasive Urothelial Carcinoma

Invasive urothelial carcinoma has a heterogeneous morphology, including numerous described variant forms. Typical invasive urothelial carcinoma shows irregularly distributed nests of urothelial cells, either with rounded or jagged contours. Stromal response to invasive urothelial carcinoma varies widely but includes fibrosis, inflammatory reaction, desmoplasia, myxoid change, stromal retraction clefts, or no response. Early invasion into the lamina propria may consist of small solid nests and/or clusters of urothelial cells with cytoplasmic eosinophilia (so-called paradoxical maturation), often with surrounding retraction (Fig. 25.15).[250] Irregular infiltration to level of the MP is diagnostic of malignancy and represents a critical treatment threshold (Fig. 25.16).

Invasive urothelial carcinomas with divergent differentiation are not uncommon, and most are characterized by squamous or less commonly glandular differentiation (Fig. 25.17). The presence of

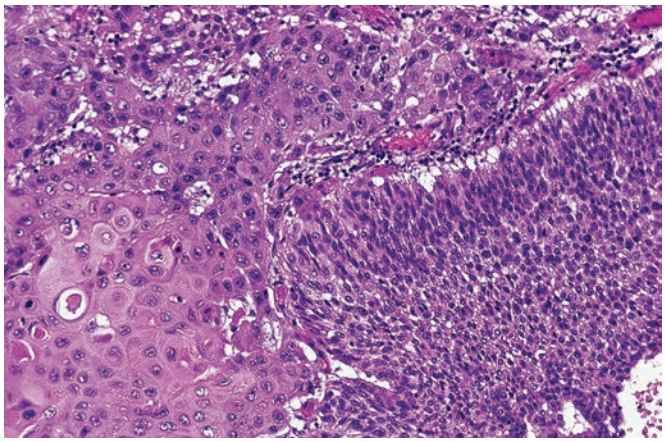

Figure 25.17 Urothelial carcinoma with squamous differentiation.

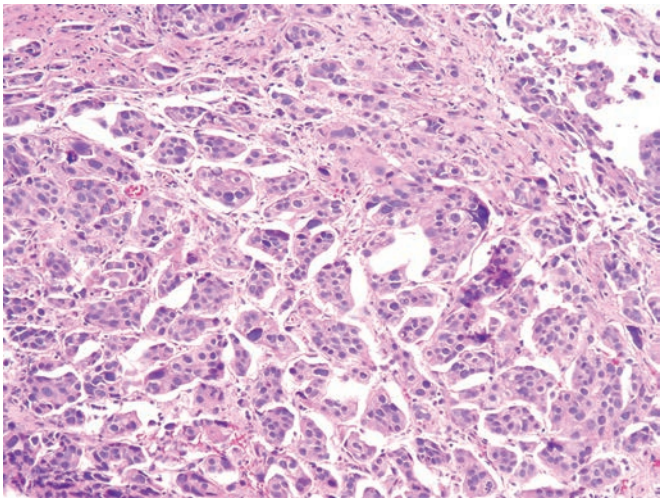

Figure 25.18 Invasive micropapillary carcinoma of the bladder.

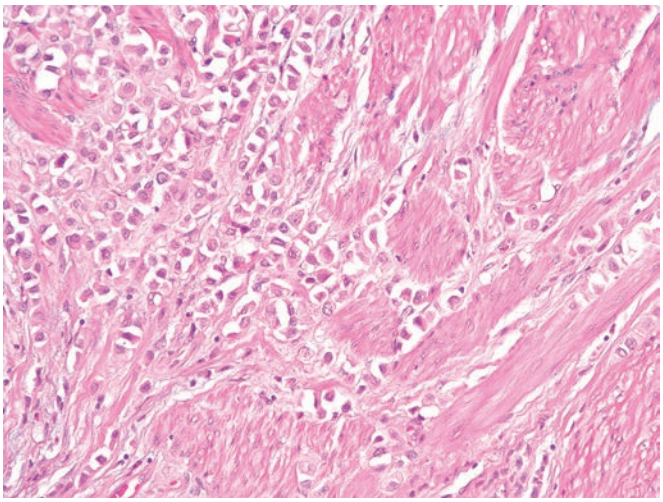

Figure 25.19 Plasmacytoid carcinoma of the bladder.

a typical urothelial carcinoma component (either invasive, papillary, or in situ) is usually sufficient for classification as urothelial, as opposed to primary squamous cell carcinoma or adenocarcinoma (discussed later). Urothelial carcinomas may have areas with morphologic and immunohistochemical features indicative of trophoblastic differentiation (often admixed syncytiotrophoblasts) and are sometimes accompanied by serum elevations of hCG.[251,252] Occasionally the entire lesion has the appearance of a *choriocarcinoma*, in which case it needs to be distinguished from a metastatic tumor.[253,254] Some urothelial carcinomas are associated with immunohistochemical reactivity for hCG and other placental glycoproteins, even if they lack identifiable foci of choriocarcinoma.[255] This feature is particularly common in the high-grade tumors but is not usually pursued diagnostically because of questionable independent clinical significance.[256]

Many variant forms of urothelial carcinoma are described, but not all have independent prognostic significance. A few variant forms may have important clinical significance, particularly micropapillary, plasmacytoid, and small cell carcinoma (the later discussed in the neuroendocrine section). In addition, some variants of urothelial carcinoma are histologically subtle, and awareness is important to avoid underdiagnosis. A discussion of some specific variant patterns follows:

Micropapillary carcinoma of the bladder was described in 1994 as a variant that histologically mimics ovarian serous carcinoma.[257] It is typically characterized by rather confluent "back-to-back" retraction spaces and multiple epithelial aggregates/nests in a single retraction space (Fig. 25.18).[258] Most are invasive into the MP at diagnosis, and lymph node metastases are common.[259–261] While controversial, some have advocated for immediate cystectomy for micropapillary carcinoma, regardless of stage; for that reason, it is important to not overdiagnosis micropapillary based on stromal retraction alone.[262] Also, noninvasive carcinomas with micropapillary excrescences should not be designated as "micropapillary" because they do not seem to have the same clinical implications as invasive disease.[263] Recent data suggest that prominent stromal retraction clefts may be an independent prognostic factor, independent of classic micropapillary morphology.[264]

Plasmacytoid carcinoma is morphologically similar to lobular breast cancer and diffuse-type gastric cancer.[265–268] The monomorphic round neoplastic cells are discohesive and grow singly or in clusters (Fig. 25.19). They often have homogeneous eosinophilic cytoplasm and an eccentrically placed nucleus, but intracytoplasmic vacuoles are also common in scattered cells. Because of this latter feature, distinction from signet ring cell type adenocarcinoma is based on the presence of associated extracellular mucin.[216] Immunophenotypically, plasmacytoid carcinoma typically expresses cytokeratins, CD138, CK20, and GATA3, but p63 is less sensitive in this variant.[269] ER expression is typically absent, a helpful feature in the distinction from metastatic lobular breast cancer (which also expresses GATA3). Intraoperative evaluation of the ureters at the time of cystectomy must carefully focus on the periureteral tissues, as plasmacytoid carcinoma not uncommonly extends along the adipose tissue.[270] Plasmacytoid carcinoma has a pattern of spread that is distinct from typical urothelial carcinoma, with involvement of serosal surfaces, parenchymal organs (e.g., ovary), and recurrence as malignant effusions.[271] A recent study has shown frequent somatic *CDH-1* loss-of-function mutations in plasmacytoid variant.[272]

Nested urothelial carcinoma (along with the similar carcinomas large nested, tubular, and microcystic) were originally described as "deceptively bland," an apt name.[273] Because nested carcinoma is characterized by rounded aggregates of cytologically bland urothelium, the irregular distribution of these aggregates in the suburothelial tissues is diagnostically important in the distinction from benign von Brunn nests (Fig. 25.20).[274–276] Some cases have central cystic change (i.e., microcystic variant) mimicking cystitis cystica or glandularis,

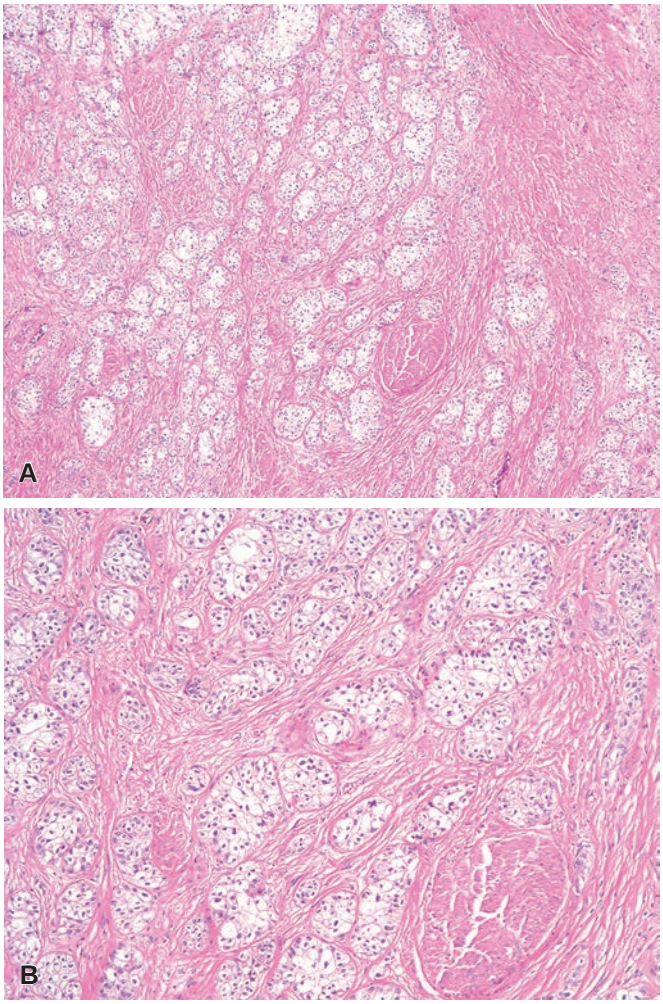

Figure 25.20 Nested Urothelial Carcinoma. A, Low-power magnification shows the irregular deep infiltration by the urothelial nests despite bland cytologic features **(B)**.

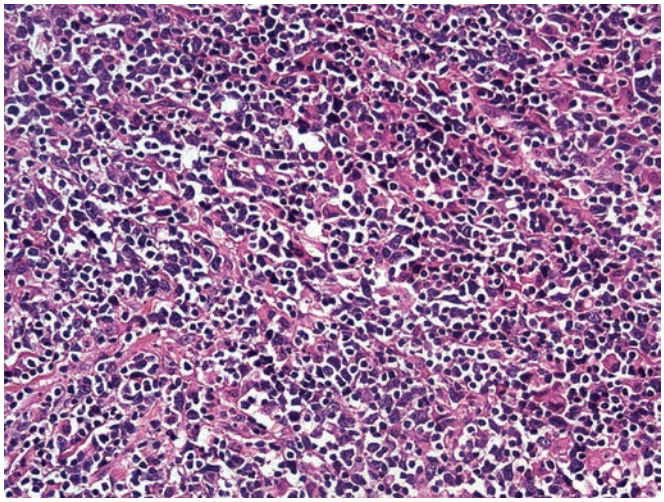

Figure 25.21 Lymphoepithelial-like carcinoma of the bladder.

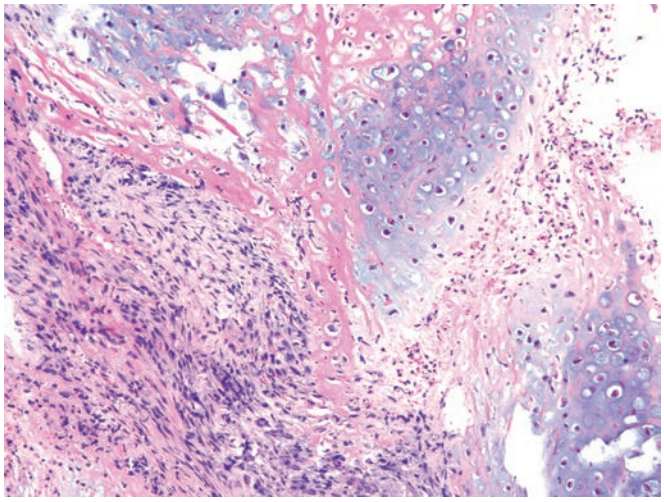

Figure 25.22 Sarcomatoid carcinoma of bladder with heterologous differentiation.

but they too have an irregular distribution that often extends deeply into the underlying tissues.[273] A recent study has suggested that *TERT* promoter mutation is common in nested urothelial carcinoma and may have diagnostic utility in difficult cases.[277]

Lymphoepithelioma-like carcinoma has only recently been described at this site; its appearance is that of a nonkeratinizing carcinoma associated with a heavy inflammatory infiltrate.[278–280] Some cases are pure, in which the carcinoma may be masked by the inflammatory cells (Fig. 25.21), but most represent a focal or extensive change in a tumor having otherwise the appearance of a urothelial carcinoma.[281–283] None of the cases so far studied has shown evidence of Epstein–Barr virus (EBV) infection by in situ hybridization.[283]

Sarcomatoid (spindle cell, metaplastic) carcinoma is a high-grade neoplasm of the bladder in which a malignant epithelial component, clearly identifiable as such (of urothelial, glandular, squamous, or undifferentiated type), coexists with areas having a spindled "sarcoma-like" appearance (Fig. 25.22).[284–289] The latter may have a nonspecific spindle cell or pleomorphic morphology (sometimes admixed with osteoclast-like giant cells),[290–296] or may exhibit specific features of mesenchymal differentiation, such as rhabdomyosarcoma, chondrosarcoma, osteosarcoma, liposarcoma, or pleomorphic undifferentiated sarcoma.[297,298] When such specific features are present, the tumor may be designated as *carcinosarcoma*,[294,299] but we view this as a variation of the same basic process. Whether areas of specific mesenchymal differentiation occur or not, transitions may be seen between the two major components, suggesting that the sarcoma-like areas are also of epithelial nature.[300] Further evidence of the epithelial nature of these proliferations is provided by the immunoreactivity for keratin often detected in the sarcoma-like component.[301–303] Exceptionally, the epithelial component is made up of small cells with neuroendocrine features.[304] On other occasions, the tumor has prominent myxoid or sclerosing features.[305]

Grossly, these tumors are often large and polypoid. They are equivalent in most respects to their more common counterparts located in the upper aerodigestive tract[300]; as in those, the obvious epithelial component is sometimes present only in the form of CIS on the surface and at the periphery of the invasive sarcoma-like tumor.[306] The differential diagnosis includes true sarcomas, inflammatory myofibroblastic tumor, and urothelial carcinomas with reactive stroma.[307]

Most patients with sarcomatoid carcinoma are elderly males, and the death rate is about 50%.[298] Sequential involvement of ureter and renal pelvis may occur.[308] Metastases develop in regional lymph nodes and distantly; they may consist of only the epithelial

or the sarcoma-like component.[309] The treatment of this tumor should be the same as for high-grade urothelial carcinoma of equivalent stage.[285]

Immunohistochemical Features

The immunophenotype of urothelial carcinoma is heterogeneous, particularly across variant forms. The neoplastic cells typically express CK7, CK20, p63, and high-molecular-weight cytokeratin.[310] GATA3 commonly shows nuclear staining in urothelial carcinoma, but the specificity is poor for a work-up of "carcinoma of unknown primary," and is less commonly expressed in variant types.[311,312] Different uroplakin antibodies have also been reported to show immunoreactivity in urothelial carcinoma, but there is less experience with their use and their sensitivity and specificity in invasive carcinomas has been questioned; however, uroplakin II may have more utility as collective experience increases.[313–316]

Molecular Genetic Features

The underlying genetic profile of urothelial carcinoma is complex and has not yet been incorporated into standard pathologic evaluation. There are two independent pathways of urothelial carcinoma development, although occasional overlaps between the two can occur.[317–321] One pathway is represented by low-grade papillary urothelial neoplasm (including PUNLMP and low-grade papillary urothelial carcinoma), which is characterized by frequent local recurrence but not metastasis, and which only uncommonly progresses to high-grade papillary urothelial carcinoma or muscle-invasive urothelial carcinoma. Low-grade papillary urothelial neoplasms show activation of the RAS-MAPK pathway, which results from activating mutation of the fibroblast growth factor receptor gene *FGFR3* (60%–80%) or *HRAS* gene (15%–30%). Interestingly, mutations of these two genes are mutually exclusive. Chromosome 9q deletion is common, with several candidate genes having been implicated, including *TSC1* (tuberous sclerosis complex 1), *PTCH* (patched homolog) and *DBC1* (deleted in bladder cancer 1). *PI3KCA* gene mutation is present in 10%–27% of cases.

The second pathway, which is less common, is represented by CIS and ≥pT2 urothelial carcinoma; there is a tendency for the former to progress into the latter (60%–80% in 5 years), which then acquires metastatic potential. Urothelial CIS commonly shows mutations or deletions in the tumor suppressor genes *TP53* (70%), *RB* (37%), and *PTEN* (35%), frequently accompanied by deletion of chromosome 9. Similar changes are seen in muscle-invasive urothelial carcinomas (pT2–pT4), but there are often additional genetic alterations, such as 3pDel, 5qDel, 6qDel, 10qDel, 11pDel, and 18qDel.

It is unclear whether there is a third molecular pathway, involving high-grade papillary urothelial carcinoma and pT1 carcinoma, which may evolve from flat dysplasia or high-grade transformation of low-grade papillary neoplasm. In such tumors, there is a high frequency of 9pDel, with homozygous deletion of the *CDKN2A (INK4A)* gene, which encodes P16. *FGFR3* and *TP53* mutations may also be present. Recent studies have suggested molecular subtypes that are similar to those described in breast adenocarcinoma (i.e., luminal, basal, etc.), but this has not been implemented into standard practice.[322] Other commonly reported genetic abnormalities involve *TERT* and *Notch*.[323,324]

Reporting in Transurethral Resection and Cystectomy Specimens

Bladder tumors should be sampled or removed with a "cold" biopsy instrument. Ideally, the biopsy should include a portion of the underlying muscle. The urologist should not fulgurate a papillary tumor without biopsy simply because it appears benign. It is recommended that, in addition to the main tumor, biopsies be taken from apparently normal adjacent mucosa and from three other sites (one lateral to each ureteral orifice and one from the upper posterior wall).[325] These biopsies should be submitted separately and sectioned at various levels. The pathology report of a bladder biopsy that contains a tumor should clearly include: invasive or noninvasive, grade (ISUP 1998/WHO 2016), depth of invasion, presence of muscle, lymphovascular invasion, and concomitant lesions (e.g., CIS). A synoptic checklist, such as provided by the College of American Pathologists, for examination and reporting of bladder specimens is commonly utilized.[326] Two important points: (1) the term "muscle invasion" is imprecise, and depending on the depth of invasion we recommend using the terms either invasive into "lamina propria" or "MP (detrusor muscle)," as appropriate; (2) retraction artifact is common and the diagnosis of definitive lymphovascular invasion should be rendered only when unequivocal blood vessel wall is seen. We do not generally use immunohistochemistry for endothelial markers in routine practice.

Detection of residual tumor cells in biopsy specimens from patients having had a prior biopsy or TUR can be very challenging. Immunostains for keratin should be used only with great care since reactive myofibroblasts are commonly positive as well.[327]

Treatment

The therapy of bladder carcinoma needs to be individualized, taking into account the age of the patient and the surgical risk; the extent, stage, and microscopic grade of the tumor; and the presence of CIS elsewhere in the bladder.[328–333]

The recommended treatment for extensive CIS is total cystectomy. For small and apparently localized lesions, intravesical chemotherapy may induce temporary and sometimes complete remission[334–336]; however, in 40%–70% of the cases, new tumors will develop, usually within a 6–12-month period.[337] An initially controversial but now widely accepted therapy for "superficial" bladder carcinomas (either pTa or pT1 papillary and/or CIS) is intravesical immunotherapy with the BCG, which in some series has shown remarkable reduction of the tumor recurrence rate[338–341]; microscopically, this therapy results in superficial mucosal erosion, submucosal granulomatous inflammation, and reactive epithelial atypia.[342]

Urothelial carcinomas without MP invasion are usually treated initially with TUR, and in high-grade or invasive pT1 tumors this is often supplemented with intravesical chemotherapy, especially in cases of multiple or recurrent tumors.[343–346] Carcinomas with MP invasion irrespective of grade, and tumors resistant to conservative therapy are generally best treated by radical cystectomy, with or without preoperative chemotherapy.[336,347–350] In some centers, they have also been treated by radiation alone.[351–353]

Radical cystectomy in the male includes the bladder, prostate, seminal vesicles, and adjacent perivesical tissues; in the female, it may include the bladder, uterus, tubes, ovaries, anterior vagina, and urethra. Argument persists as to whether a total urethrectomy should be part of the procedure in males.[354] In some centers, the radical cystectomy is combined with en bloc pelvic lymph node dissection.[355,356] At present, operative mortality for radical cystectomy is low, and pyelonephritis is no longer a frequent complication.

The addition of neoadjuvant chemotherapy to the cystectomy has improved the survival of patients with advanced bladder carcinoma,[357] and emerging immune-modulators show some initial promise (e.g., anti-PD-L1).[358] Segmental (partial) cystectomy has fallen into disfavor because of the high rate of recurrence in the residual bladder.

Other Primary Carcinomas

Primary Glandular Lesions of the Bladder (Adenocarcinoma and Related Tumors)

Villous adenoma is microscopically similar to its colorectal counterpart.[359] As in the latter location, it can be pure or associated with a tubular component (tubulovillous adenoma).[360] It is often associated with cystitis glandularis or cystica,[361] and it should be distinguished from bladder extension of well-differentiated colorectal carcinoma or appendiceal low-grade mucinous epithelial neoplasia (the latter pitfall having been learned the hard way).[362] As is also the case in other locations, villous adenoma of the bladder has a tendency to undergo malignant transformation in the form of invasive adenocarcinoma, so complete sampling of the lesion for histologic examination is important.[363,364]

In situ adenocarcinoma is an extremely rare form of intraepithelial bladder malignancy, which is associated with an elevated risk of development of high-grade urothelial carcinoma, including small cell carcinoma and micropapillary carcinoma.[365] This is particularly the case if the in situ adenocarcinoma is present in a pure form.[366]

Bladder adenocarcinomas constitute approximately 2% of the malignant tumors of this organ.[367] These likely develop from sequential changes in the surface urothelium initiated by chronic inflammation—from cystitis glandularis with intestinal metaplasia to dysplasia and finally to adenocarcinoma. It is important to reiterate that this is a rare event, and cystitis glandularis should not be regarded (or treated) as a precursor lesion in the absence of dysplasia.[368] The tumors arising on this basis are usually located in the trigone area.[369] Other adenocarcinomas arise in bladders with exstrophy,[31] in diverticula,[43] or at the dome of the bladder from urachal remnants (Fig. 25.23).[21,369,370]

Grossly, advanced cases appear as fungating masses that ulcerate the mucosa and invade the bladder wall. The surface of the mucin-producing tumors is covered with thick, slimy, gelatinous material.[371] Microscopically, there is a wide range of glandular differentiation, the better differentiated examples eliciting the differential diagnosis with intestinal metaplasia (Fig. 25.24).[372,373] Deep invasion of the muscle is the rule, but very superficial examples of this tumor have been observed.[366] The mucin histochemical profile is similar but not identical to that of colorectal adenocarcinoma.[374–378] Some tumors have been found to contain both Paneth cells and endocrine cells.[379,380]

Immunohistochemically, primary bladder adenocarcinoma differs from colorectal adenocarcinoma by the fact that the pattern of staining for β-catenin, if present, is primarily membranous (and to a lesser degree cytoplasmic) rather than nuclear.[381] It is also more commonly positive for keratin 7 (6.5% vs. 0%) and less commonly for keratin 20 (53% vs. 94%).[382,383] GATA3 nuclear reactivity is relatively rare in bladder adenocarcinomas.[384] Additionally, a recent study documented SATB2 nuclear expression in approximately 50% of primary bladder adenocarcinomas, precluding its use in the distinction from colorectal primary adenocarcinoma.[384a] Because of the degree of morphologic and immunophenotypic overlap, in our opinion the possibility of a colorectal adenocarcinoma should almost always be excluded by radiographic and optimally endoscopic evaluation.

The overall prognosis of primary adenocarcinoma is poor: in one series of 64 cases, the 5-year survival was only 18%.[372] As in the case of urothelial carcinoma, stage is the most important prognostic factor. The pattern and frequency of metastases are also similar to those of high-grade, conventional urothelial carcinoma.

A distinct variant of bladder adenocarcinoma is the **clear cell type**,[383,385] which is morphologically identical to its counterpart in the gynecologic tract, can also occur in the urethra (Fig. 25.25). It is usually papillary and is characterized microscopically by a mixture of tubular glands, papillae, cysts, and areas of solid growth. Two of its most distinctive features are the presence of hobnail cells and abundant cytoplasmic glycogen.[385,386] This lesion is distinguished

from the more common nephrogenic adenoma on the basis of clinical, gross, and microscopic features; sheets of clear cells, marked pleomorphism, mitotic activity, and necrosis favor a diagnosis of malignancy.[160,385] Some cases are more monomorphic and more closely mimic nephrogenic adenoma; in such cases areas with more pronounced atypia or invasive patterns of growth are typically found.[387] On occasion, clear cell carcinoma is seen admixed with urothelial carcinoma.[388] Nearly all of these tumors are thought to arise from the urothelial epithelium of the bladder by a process of metaplasia, as also suggested by their similar immunohistochemical profile.[61,389] However, some are probably of müllerian origin and related to endometriosis/müllerianosis, as suggested by the great female preponderance and the presence in some of these tumors of benign müllerian components.[61,390] The immunoreactivity for PAX8 that they share with nephrogenic adenoma adds another layer of complexity to their histogenesis.[391] Metastases can develop in regional lymph nodes and distally (Fig. 25.26).

Another distinct type of adenocarcinoma is **signet ring carcinoma**. Microscopically, the tumor cells are usually small and uniform with an eccentric nucleus caused by an intracytoplasmic mucin vacuole. Because of significant overlap with plasmacytoid urothelial carcinoma, the 2016 WHO classification has defined signet ring cell adenocarcinoma as those cases in which the cells are associated with pools of extravasated mucin.[392] The clinical course of the disease has been rapidly progressive and fatal in nearly all the reported cases with follow-up information, but these previous reports likely include cases that would now be regarded as plasmacytoid.[393]

Yet another variant of bladder adenocarcinoma is **hepatoid adenocarcinoma**, thus adding the bladder to the increasingly long list of organs in which this tumor type—which mimics the morphologic and immunohistochemical features of hepatocellular carcinoma—can occur.[394–396]

Neuroendocrine Neoplasms

Paraganglioma (extra-adrenal pheochromocytoma) can present as a primary bladder neoplasm localized within the wall (Fig. 25.27).[397] Most patients are young adult women.[398] The histologic appearance and immunohistochemical profile are the same as for paragangliomas in other sites (Fig. 25.28).[399] The tumor can be misdiagnosed as urothelial carcinoma, especially in TUR specimens, and especially those tumors with sclerotic stroma.[400] The expression of GATA3 is typical in paraganglioma, another feature that may cause diagnostic confusion. Morphologic variants include *oncocytic paraganglioma*[401] and *composite paraganglioma–ganglioneuroma*.[402] Some patients have symptoms produced by the excessive secretion of catecholamines, sometimes associated with voiding.[403] Multicentricity is rare. Local recurrence and metastases may occur, an indication that these tumors

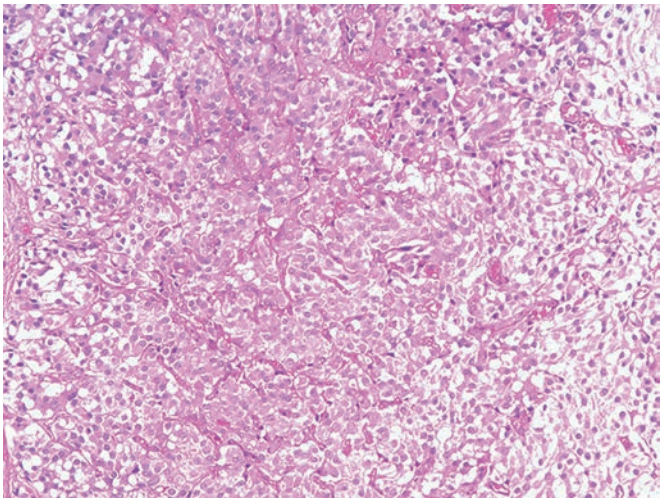

Figure 25.28 Microscopically, paragangliomas often show this subtle nested pattern, but sheet-like growth and stromal hyalinization may also occur.

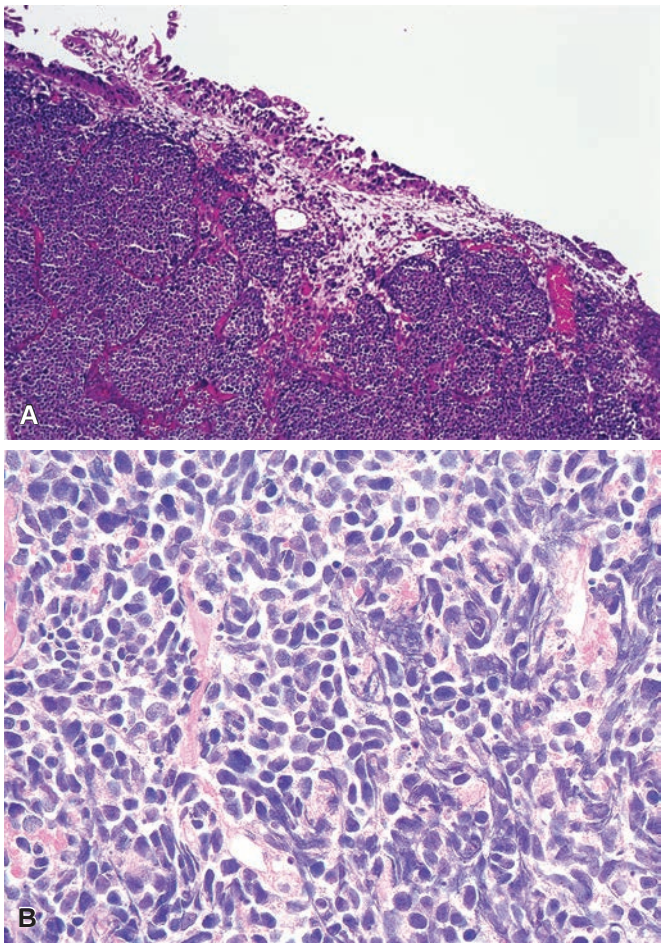

Figure 25.29 Small Cell Neuroendocrine Carcinoma of Bladder. **A,** Low-power view showing a solid mass of small cell carcinoma covered by mucosa with carcinoma in situ. **B,** High-power view of the invasive small cell component.

should not be necessarily regarded as benign. As usual, clinical stage is the most useful prognostic indicator.[398] Recently, it has been noted that paraganglioma of the urinary bladder may be more frequently associated with a genetic predisposition syndrome (germline *SDH* mutation) and immunohistochemical screening with the SDHB antibody might be warranted.[404,405] Recent series reported that 27% and 17% of bladder paragangliomas had loss of SDHB and verified mutations; additionally, they were more commonly clinically malignant.[404,406] Finally, some cases may also be associated with von Hippel–Lindau disease.[407]

Like most other epithelium-lined organs, the urinary bladder can be the site of tumors exhibiting various degrees of endocrine differentiation. One manifestation of this phenomenon is the presence of scattered endocrine cells in otherwise typical adenocarcinomas; these tumors behave like adenocarcinomas lacking these elements and should be labeled as such. Another is the exceptionally rare **carcinoid tumor** of the bladder, which exhibits typical architectural features at the light microscopic level and numerous dense-core granules on ultrastructural examination.[408–410] More common is the highly malignant bladder tumor known as **small cell carcinoma**, which is morphologically similar to its homonyms in the lung and other organs (Fig. 25.29).[411–416] This may be seen in a pure form or combined with in situ or invasive urothelial carcinoma, adenocarcinoma, squamous cell carcinoma, or sarcomatoid carcinoma.[414,416,417] Age, sex, and symptoms at presentation are comparable to those of urothelial carcinoma.[418] Most cases are already advanced when first diagnosed.[419] Microscopically, small cells with very hyperchromatic nuclei and extremely scanty cytoplasm are seen growing in a predominantly solid fashion. Immunohistochemically, there is often reactivity for chromogranin and/or synaptophysin, but by WHO criteria the morphologic features are sufficient for diagnosis in classic cases. The staining pattern for low-molecular-weight keratin (CAM 5.2) has a dot-like perinuclear pattern, and CD44 v6 is usually absent (in contrast to urothelial carcinoma).[420] Close to half of the cases stain for TTF-1, sometimes leading to a mistaken diagnosis of metastatic pulmonary small cell carcinoma.[421] The typical profile of small cell carcinoma of the bladder (as opposed to high-grade urothelial carcinoma) is p16+, p63–, and CK20–.[422]

Some small cell carcinomas of the bladder have been associated with hypercalcemia[423] or ectopic ACTH production.[424] The diagnosis can be suspected on cytologic preparations,[425] and the behavior is extremely aggressive.[417,418] Metastatic spread occurs quickly, the most frequent sites of involvement being regional lymph nodes, liver, bones, and peritoneal cavity.[418]

Large cell neuroendocrine carcinoma is defined in the bladder, as in other sites, as a high-grade neoplasm exhibiting neuroendocrine features at the H&E level, high mitotic activity, and evidence of neuroendocrine differentiation at the immunohistochemical level.[426–428]

Squamous Cell Carcinoma and Related Tumors

Condyloma acuminatum can involve the bladder, often in conjunction with similar lesions in the external genitalia and adjacent areas.[429] Koilocytosis may be seen microscopically, and HPV may be detected by surrogate techniques (e.g., CISH or PCR).

Squamous papilloma is architecturally similar to condyloma acuminatum, but it lacks cytopathic (HPV-type) epithelial changes and is negative for HPV DNA, suggesting a lack of relation among the two lesions. Most occur in elderly women and follow a benign clinical course, with occasional local recurrences.[430]

Squamous metaplasia refers to the replacement of urothelium by stratified squamous epithelium. This has been subdivided into

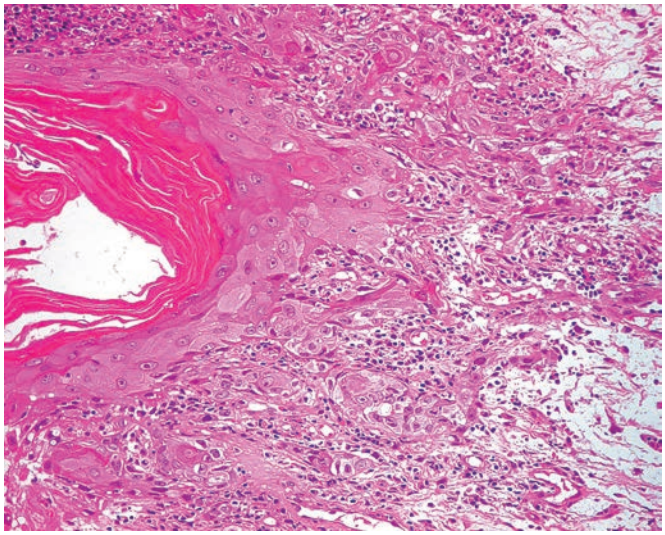

Figure 25.30 Pure Squamous Cell Carcinoma of Bladder. The tumor is heavily keratinized.

a *nonkeratinizing* and a *keratinizing* type.[151,431] The former, seen only in females, is so common in the trigone as to be regarded as normal. The keratinizing type is more common in males and is usually associated with chronic irritation.[432,433]

Squamous cell carcinoma comprises approximately 5% of all malignant bladder tumors.[434] Some of these neoplasms arise on a background of chronic cystitis with marked squamous metaplasia and/or dysplasia.[433,435,436] Cases have also been reported in association with exstrophy, defunctionalized bladder, chronic infection, lithiasis, chronic indwelling catheters, and prolonged medication with cyclophosphamide.[437] Another well-known association, reported from Egypt, Sudan, and other countries, is with schistosomiasis.[438–440] Some neoplasms classified as pure squamous cell carcinomas of the bladder probably represent metaplastic changes in tumors that were originally of urothelial type.[441]

Since focal squamous cell changes are common in high-grade urothelial tumors, the term *squamous cell carcinoma* should be reserved for those tumors that are purely squamous throughout, typically with associated background keratinizing squamous metaplasia (Fig. 25.30).

Grossly, these tumors are usually large, ulcerated, and necrotic. Microscopically, most are poorly differentiated and have nearly always invaded the muscularis mucosa at the time of diagnosis.[442] Immunohistochemically, they show reactivity for high-molecular-weight keratin and p63; therefore, these markers cannot be used in the differential diagnosis with squamous cell carcinoma of the uterine cervix.[443] The prognosis is very poor regardless of the degree of differentiation.[444] Death within the first year occurred in 59% of the patients reviewed by Newman et al.[445] In another series, the 5-year survival rate was 37% for patients with submucosal or muscular invasion and 13% for those with perivesical invasion.[446]

A high frequency of chromosome 9p allelic loss and *CDKN2* tumor-suppressor gene alterations have been found in squamous cell carcinoma of the bladder, in contrast with urothelial carcinomas.[447]

Basaloid squamous cell carcinoma morphologically similar to its counterpart in the upper aerodigestive tract occurs exceptionally in the bladder.[448]

Verrucous carcinoma of the bladder has also been described in the urinary bladder and is identical to that seen in the head and neck region.[449]

Warty carcinoma arising from condyloma, morphologically similar to the homonymous penile tumor, has been described in the bladder.[450]

Squamous cell CIS, without associated invasive carcinoma, is exceptionally rare in the bladder. It should be distinguished from keratinizing squamous metaplasia, verrucous squamous metaplasia, squamous papilloma, and condyloma acuminatum.[451]

Myofibroblastic Proliferations of the Urinary Bladder

All myofibroblastic proliferations of the urinary bladder have fairly similar morphology and immunophenotype, regardless of etiology. Many classification schemes, such as the WHO 2016, term most of these proliferations as "inflammatory myofibroblastic tumor"; however, numerous diagnostic terms have been use in the literature, creating significant confusion for urologists, oncologists, and pathologists alike. We discuss three separate scenarios, procedure related (postoperative spindle cell nodule), carcinoma related (pseudosarcomatous stromal proliferation adjacent to carcinoma), and those unrelated to a known local insult (inflammatory myofibroblastic tumor). Most importantly, these lesions should be distinguished from malignant spindle cell lesions based largely on recognition of the cytologic features of myofibroblasts.[452] Compared to myofibroblasts in other sites, bladder lesions more commonly show a strong and diffuse reactivity for low-molecular-weight keratin (Fig. 25.31A)[303]; they also stain for actin and variably desmin, but are negative for EMA and high-molecular-weight cytokeratin (see Fig. 25.31B).[303]

Postoperative spindle cell nodule is a lesion that may follow surgical interventions in the area, particularly TUR.[453,454] Microscopically, it may simulate the appearance of a sarcoma (particularly leiomyosarcoma) because of its marked cellularity and high mitotic activity (Fig. 25.32).[453,455] It appears a few weeks following a TUR procedure and is characteristically located in the operative area. Cystoscopically, it typically presents as a small sessile friable nodule that bleeds easily. The fascicular pattern of growth, ulcerated surface, red blood cell extravasation, and lack of significant nuclear hyperchromasia, together with the history of a recent surgical procedure, are distinctive.

Inflammatory myofibroblastic tumor is the term currently favored by the WHO for the entity originally described as *inflammatory pseudotumor.*[456] It is a polypoid bladder growth, characterized by the proliferation of generally spindle cells in a myxoid and inflammatory background (Fig. 25.33).[457,458] While it is often described as most commonly seen in children, we anecdotally see more cases in adults, possibly due to our specific consult bias. The main differences with postoperative spindle cell nodule (which we regard as a similar condition) are a tendency to reach a larger size, greater prominence of the myxoid stroma, lesser degree of cellularity, greater variability in nuclear size, and more prominent nucleoli.[457–459] Fibrosclerotic areas may be present.[416,460] The differential diagnosis includes embryonal/botryoid rhabdomyosarcoma in children and leiomyosarcoma and sarcomatoid carcinoma in adults. Close evaluation of cytologic features is usually sufficient for classification as myofibroblastic, particularly in adults, but immunohistochemical evaluation can be of help in selected cases. Since myogenin is expressed only by rhabdomyosarcoma, it is a very useful exclusionary test in children. High-molecular-weight cytokeratin and p63 are markers of sarcomatoid carcinoma, while h-caldesmon is more strongly and diffusely expressed by smooth muscle tumors.[461]

Inflammatory myofibroblastic tumor was previously regarded as a reactive condition, as implied by its original name.[454,462] Its distinction from ordinary sarcomas and carcinomas is certainly of importance because of its generally indolent nature.[463] However, several pieces

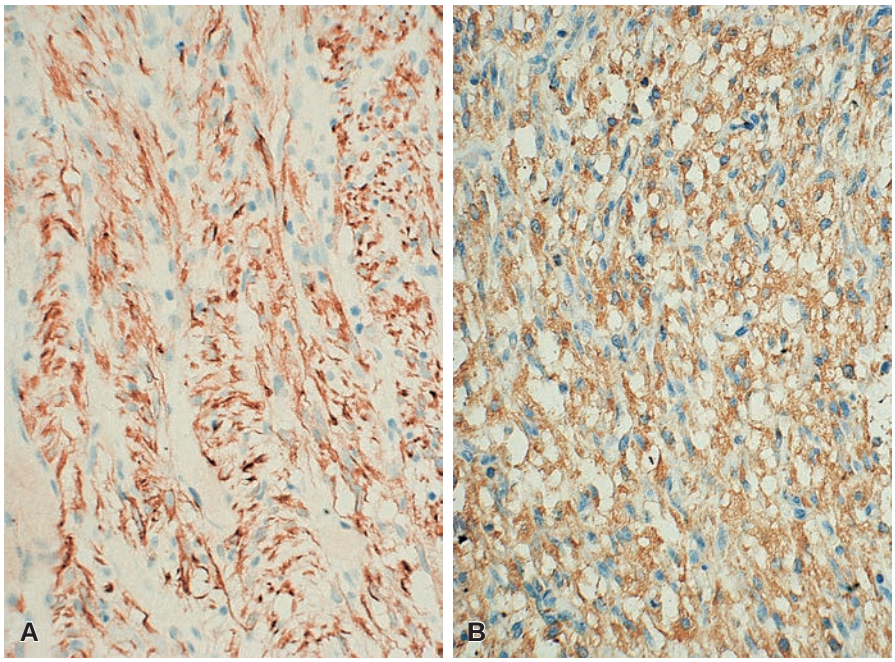

Figure 25.31 Immunophenotype of myofibroblastic proliferations of the urinary bladder. Strong immunoreactivity for keratin **(A)** and actin **(B)**.

of evidence have accumulated in recent years which suggest that this entity is a neoplastic process, albeit of a low-grade nature. This includes the occurrence of cases with deep infiltration of the wall and extension into the perivesical soft tissue,[457] the occurrence of cases with focally obvious sarcomatous features,[464] and the demonstration of a nonrandom chromosomal translocation involving 2p23 that results in the expression of anaplastic lymphoma kinase (ALK).[465–467] Accordingly, this entity has been renamed *inflammatory myofibroblastic tumor.*[468] Of diagnostic importance is the fact that ALK immunoreactivity or rearrangement is not reported in conventional sarcomas or in sarcomatoid carcinomas of the bladder.[469]

Pseudosarcomatous stromal reactions have been described adjacent to urothelial carcinomas, the reactive tissue having a nodular fasciitis-like appearance.[470,471] The distinction from sarcomatoid (spindle) urothelial carcinoma may be difficult. Like inflammatory myofibroblastic tumor, these pseudosarcomatous lesions may show

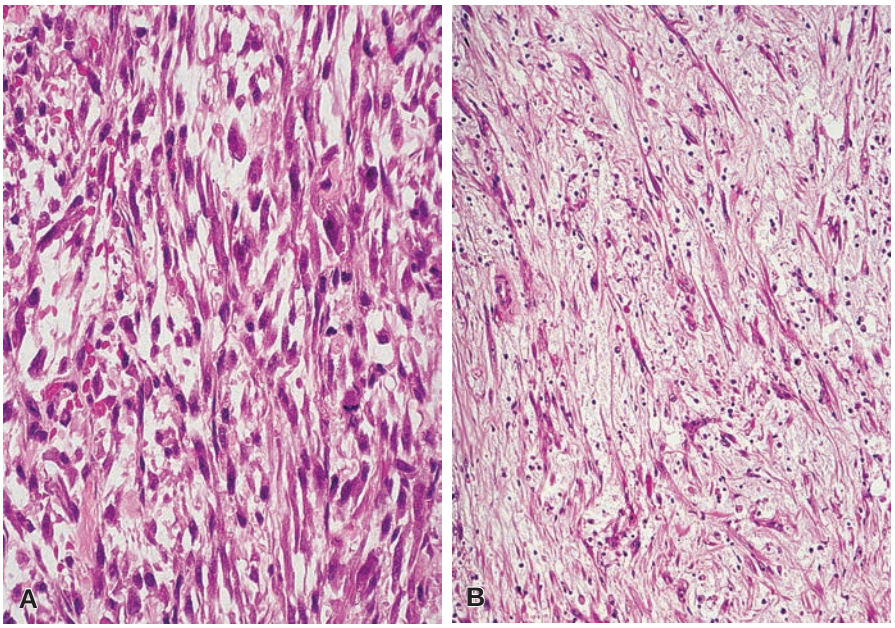

Figure 25.33 **A** and **B**, Inflammatory myofibroblastic tumor. Highly cellular spindle cell proliferation showing a moderate degree of atypia and somewhat edematous stroma. There is an associated inflammatory mononuclear component.

immunoreactivity for ALK, but differ from them in the sense of not showing consistent ALK rearrangement at the molecular genetic level.[466] These associated myofibroblastic proliferations are not infrequently misinterpreted as muscularis propria, which would impact staging.

Leiomyosarcoma is most commonly seen in adults. Approximately half of the cases are located in the bladder dome.[472,473] They infiltrate the bladder muscle, an important feature in the differential diagnosis with leiomyoma.[474] Microscopic grading of the tumor based on nuclear atypia, mitotic activity, and tumor necrosis correlates closely with outcome.[475] Some of these tumors are partially or extensively myxoid, resembling inflammatory myofibroblastic tumor (inflammatory pseudotumor) to such a degree that the distinction may become impossible.[472,476,477] Immunohistochemically, they are reactive for actin and typically desmin.[472]

Embryonal rhabdomyosarcoma (particularly the botryoid subtype) is the most common malignant tumor of the bladder in children. Sporadic cases have been seen in association with Wilms tumor; one such case was reported in a child with Dandy–Walker syndrome.[478] The trigone is the most common location. Grossly, the tumor has a myxoid appearance and polypoid shape (Fig. 25.34). It infiltrates surrounding tissues, but distant metastases are rare. Microscopically, it shows myxoid tissue in which small malignant cells are seen (Fig. 25.35A). These are characteristically grouped beneath the epithelium ("cambium layer") (see Fig. 25.35B). Cross striations may or may not be present. Desmin and (first and foremost) myogenin are the immunostains to be employed for confirmation of the diagnosis. In the past, the prognosis for this tumor was poor, with isolated cures being achieved with radical cystectomy or radiation therapy. The addition of multidrug chemotherapy to these modalities has notably increased the survival rates, even when the surgical resection was incomplete.[479] The prognosis is better for tumors exhibiting the classic polypoid pattern of growth than for those with diffuse intramural spread. Specimens from recurrences often show a marked maturation of the rhabdomyosarcomatous elements, presumably induced by chemotherapy.[480]

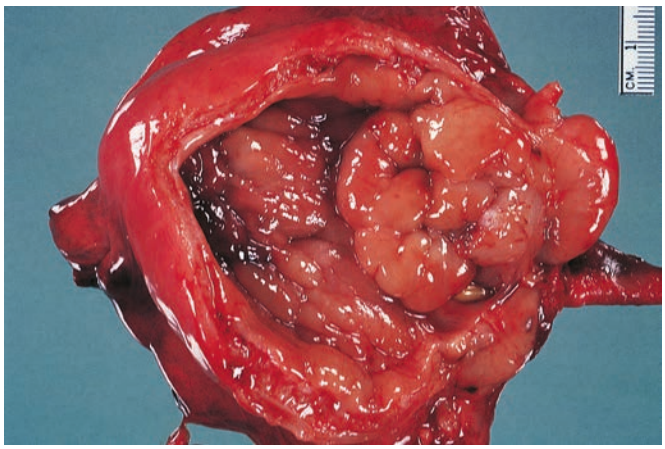

Figure 25.34 Gross appearance of botryoid rhabdomyosarcoma of bladder. A huge tumor mass is seen filling the bladder lumen.

Solitary fibrous tumor can present as a mass in the bladder wall with histologic features identical that seen in other sites. The availability of a dependable STAT6 antibody as a sensitive and specific surrogate for the *NAB2-STAT6* fusion makes diagnosis straightforward in most cases. Most reported cases have behaved in a benign fashion, but general prognostic rules may be applied regardless of anatomic site.[481,482]

Other rare **benign tumors** of the bladder include *mucin-secreting "cystadenoma" of possible müllerian origin*,[483,484] *leiomyoma*,[485] *hemangioma*,[486–488] *intravascular papillary endothelial hyperplasia* (Masson lesion),[489] *arteriovenous malformation*,[490] *lymphangioma*,[491] *chondroma*,[492] *granular cell tumor*,[493] *schwannoma*,[494,495] *neurofibroma(tosis)*,[496–499] *diffuse ganglioneuromatosis*,[498] and various morphologic types of *PEComa*[500] (*angiomyolipoma*[501] and *clear cell myomelanocytic tumor*[502]). The hemangiomas are usually seen in children; they are usually located in the lateral or posterior walls, are sessile, are sometimes associated

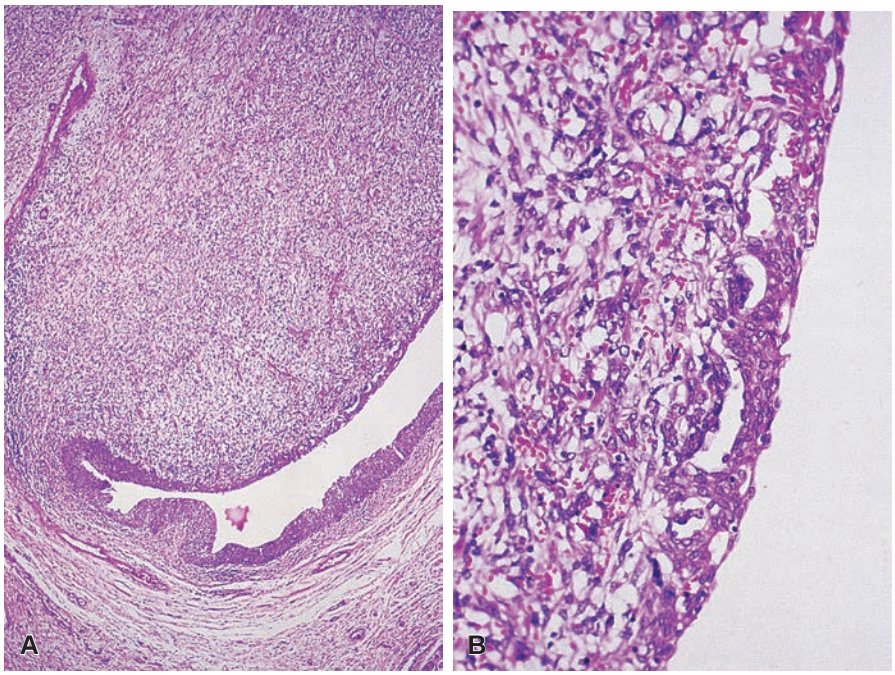

Figure 25.35 Microscopic Appearance of Botryoid Rhabdomyosarcoma. A, Low-power view showing polypoid mass protruding beneath a flattened epithelium. **B,** High-power view showing "cambium layer." Clusters of tumor cells present immediately beneath the epithelium result in a nevoid appearance.

with cutaneous hemangiomas, and may be the cause of gross painless hematuria.[488] The diagnosis of leiomyoma should be reserved for those smooth muscle tumors that are noninfiltrative and lack mitotic activity, cytologic atypia, and necrosis.[475]

Other sarcomas of the adult bladder include (nonbotryoid) *rhabdomyosarcoma*[503] (often with an alveolar morphology and morphologically similar to small cell carcinoma[504,505]), *rhabdoid tumor*,[506–508] *angiosarcoma* (including the epithelioid variety),[509,510] *alveolar soft part sarcoma*,[511] *malignant peripheral nerve sheath tumor*,[512] so-called *malignant fibrous histiocytoma*[513,514] (including its inflammatory[515] and myxoid[516] variants), *osteosarcoma*,[298,517] *soft tissue–type clear cell sarcoma*,[518] *malignant PEComa*,[519] *GIST-type tumor*,[520] and *malignant mesenchymoma*.[521] Care should be exercised to rule out by appropriate sampling and immunohistochemical testing the alternative possibility of a sarcomatoid carcinoma (carcinosarcoma)(see previous section).[522]

Ewing sarcoma has been described presenting as a bladder mass. It is immunoreactive for CD99, is associated with a fusion of *EWSR1* with one of several members of the ETS family of transcription factors, and should not be confused with small cell neuroendocrine carcinoma.[523,524]

Other Tumors

Primary **malignant melanoma** can occur in the bladder,[525–527] although not as commonly as in the urethra or as metastases in the bladder from a melanoma arisen elsewhere.[528] Variants have been described having clear cell features,[529] or associated with melanosis (i.e., pigmentation of the basal layer of the non-neoplastic transitional epithelium).[527]

Malignant lymphoma can involve the bladder as a primary site. Grossly, it may appear as a solitary mass, as multiple masses, or as a diffuse lesion with mass formation. Often the lesions are covered by normal mucosa. Microscopically, they are nearly always of non-Hodgkin type, and most are low-grade small cell lymphomas of the so-called *MALT type*.[530–532] Accordingly, they tend to remain localized for a long period of time. The bladder also can be involved by *leukemia*, *plasmacytoma*,[533,534] *multiple myeloma*,[535] *peripheral T-cell lymphoma*,[536] *Hodgkin lymphoma*,[537] and *anaplastic large cell lymphoma* (including its sarcomatoid variant).[538,539]

Most cases of **metastatic tumor** in the bladder are from breast carcinoma[540–542] and malignant melanoma,[528] but they have also been reported from several other sites, including lung, kidney, stomach, pancreas, and ovary.[543–545] The latter may closely mimic a primary bladder neoplasm.[546] The large majority of these metastatic deposits are solitary.[543] Direct extension into the bladder can occur with carcinomas of large bowel, prostate, and cervix.[543,547,548] In difficult cases, immunohistochemistry is very useful in the distinction of urothelial from poorly differentiated prostatic adenocarcinoma. Urothelial carcinomas generally express p63 and GATA3, while prostatic carcinomas express PSA and NKX3.1.[549,550]

Prostate

Normal Anatomy

The prostate is a pear-shaped glandular organ that weighs up to 20 g in the normal adult male and that depends for its differentiation and subsequent growth on androgenic hormones synthesized in the testis, acting through a poorly understood mesenchymal–epithelial interaction.[1] It is most commonly divided into the anterior fibromuscular stroma and three distinct glandular zones as described by McNeal: peripheral zone, transition zone, central zone.[2-5] The transition zone envelops the urethra in the mid portion of the prostate and is the anatomic region enlarged by benign prostatic hyperplasia. The central zone (which together with the seminal vesicles is thought to be derived from the wolffian duct) is shaped like an inverted pyramid at the base of the prostate and contains the ejaculatory ducts as they course to the prostatic urethra at the verumontanum, a posterior prominence in the prostatic urethra. The prostatic glands of the central zone may have a unique morphology with more deeply eosinophilic cytoplasm and/or more complex intraluminal architecture consisting of papillary infolding or epithelial bridges (Fig. 26.1). The peripheral zone envelops the transition zone and extends caudally to comprise most of the apex. Finally, the anterior tissues consist of smooth muscle (extending from the base), skeletal muscle from the anterior fibromuscular sling (extending from the apex), and adipose tissue in the extraprostatic compartment. The prostate is enveloped by a fibromuscular layer usually referred to as a "capsule," but it has been pointed out that this is most definitely not a well-defined anatomic structure with constant features.[6]

The glandular component of the organ is traditionally divided into acini and ducts, the latter subdivided into large (primary, major, excretory) and peripheral (secondary, minor); however, unlike other organs, there is little morphologic difference between the two. Both acini and ducts contain luminal secretory cells, a surrounding outer layer of basal cells, and scattered neuroendocrine cells (which are often unrecognizable). The secretory cells, which are located in the luminal side of the gland, contribute a wide variety of products to the seminal fluid. Histologically, these cells form an undulating luminal surface and are characterized by relatively pale cytoplasm that contains minute closely packed vacuoles that may be difficult to appreciate. They produce prostate-specific acid phosphatase (PSAP) and prostate-specific antigen (PSA), both of which can be readily identified immunohistochemically and have been proved of great diagnostic utility because of their organ-related specificity. Secretory cells coexpress various keratins,[7,8] but they do not include high-molecular-weight types such as 34βE12, a fact of diagnostic significance. More recently, immunoreactivity for NKX3.1 (nuclear) and prostate-specific membrane antigen (PSMA; cytoplasmic) has been demonstrated in prostatic secretory cells, which may very useful diagnostically.[9-11] The normal prostatic secretion is a neutral mucosubstance. On occasion, one encounters scattered individual columnar mucin-secreting cells in non-neoplastic prostatic epithelium, particularly in areas of atrophy.[7,12,13]

The basal cells form a thin layer that separates the luminal secretory cells from the basement membrane. Morphologically, basal cells often appear as small inconspicuous, almost pyknotic nuclei at the base of the secretory cells. When prominent (such as in hyperplasia), they are more basophilic than secretory cells and commonly have large nuclei with open chromatin and small pin-point nucleoli. They characteristically express high-molecular-weight cytokeratin (e.g. 34βE12 and CK5/6) and p63, a fact that has been exploited in the differential diagnosis between well-differentiated carcinomas (in which basal cells are absent) and benign conditions that simulate it (in which they are generally present, although sometimes in a patchy discontinuous fashion).[14] Under

Abstract

This chapter covers the full spectrum of prostatic diseases that may be seen by the pathologist in the daily evaluation of biopsy and resection material. Normal histology, normal anatomy, and benign lesions are compared to inflammatory and neoplastic conditions. Prostatic adenocarcinoma is covered in detail to include clinical diagnosis, histology, variants, staging, grading, and molecular findings. Finally, rare lesions of the seminal vesicles and Cowper's glands are addressed.

normal conditions these basal cells do not have the phenotype of myoepithelial cells, in the sense that they lack immunoreactivity for S-100 protein or smooth muscle actin.[15,16] However, they can be viewed as being equivalent to the myoepithelial cells of the breast and other glandular organs. Support for this interpretation derives from the fact that they can undergo clear-cut myoepithelial metaplasia in conditions such as sclerosing adenosis.[17] They do not express PSA or PSAP, but they have been shown to exhibit strong immunoreactivity for androgen receptors focally.[18,19] They are thought to represent a multipotential population that gives rise to all epithelial lineages present in the normal, hyperplastic, and neoplastic prostate.[20]

The neuroendocrine cells express chromogranin A and B, secretogranin II, and various peptide hormones such as somatostatin, calcitonin, and bombesin[21,22]; they coexpress PSA, suggesting a common origin with the secretory cells.[23] However, they are negative for androgen receptors.[24] While often inconspicuous, occasional cells with red neuroendocrine granules may be seen (Fig. 26.2).

Near the urethra, the large prostatic ducts may be lined by urothelium that is continuous and indistinguishable from that lining the prostatic urethra. In contrast to bladder epithelium, its surface does not display umbrella cells, but rather a single layer of columnar cells that are immunoreactive for PSA and PSAP. On occasion, this epithelium undergoes squamous metaplastic changes; these were very common at the time estrogen therapy was widely employed for prostatic carcinoma.[25]

The prostatic stroma is notable because of its large content of smooth muscle fibers. It has been pointed out that the presence of this muscular stroma duplicates the function of myoepithelial cells in other organs, such as breast, and makes the presence of myoepithelial cells in the prostate superfluous. Prostatic stromal cells have been found to contain androgen receptors.

Peripheral nerves are evenly distributed in the apex, mid gland, and base[26]; they are of importance to pathologists because of the high frequency with which the loose connective space that surrounds them is involved by adenocarcinomas of this organ.

The prostatic lymph vessels drain into the pelvic lymph nodes and from there into the retroperitoneal chain.

Ectopia

Ectopia of prostatic tissue is a very rare event, save for the benign prostatic-type polyps discussed in Chapter 25 (Bladder). It has been described in the bladder (especially in the trigone and in association with urachal remnants),[27] root of the penis, epididymis,[28] testis, seminal vesicle,[29] retrovesical space, submucosa of the anal canal,[30] pericolic fat/pararectal space, uterine cervix and vagina,[31] and spleen.[32,33]

Nodular Hyperplasia

Benign prostatic hypertrophy is the usual name applied to a common benign disorder of the prostate that, when extensive, results in varying degrees of urinary obstruction, sometimes requiring surgical intervention. The term *nodular hyperplasia*, as proposed by Moore[34] in his classic study, is a more exact designation. The disease represents a nodular enlargement of the gland caused by hyperplasia of both glandular and stromal components. This results in an increase in the weight of the organ well beyond the 20 g regarded as normal for adult individuals. The clinical incidence of this disease is only 8% during the fourth decade, but it reaches 50% in the fifth decade and 75% in the eighth decade.

No predisposing or protecting factors (other than castration) have been identified. It has been established that prostatic nodular hyperplasia occurs only in individuals with intact testes and that it is an androgen-dependent disorder.[35,36] Specifically, it has been suggested that nodular hyperplasia may result from an initial activation of mesenchymal clones with embryonal functions that stimulate development of the glandular component.[37] In turn, this may result from dihydrotestosterone accumulation within the gland, resulting from decreased catabolism of the molecule and enhanced intracellular binding.[38] A peculiar immunohistochemical finding that may throw some light on this issue is the demonstration that p27 protein (a negative regulator of the cell cycle) is prominently expressed in the epithelial and stromal cells of the normal prostate, but is essentially negative in nodular hyperplasia.[39]

At autopsy the average weight of a prostate gland affected by nodular hyperplasia is 33 g ± 16 g. Specimens obtained surgically weigh 100 g on average, but on rare occasions weights of over 800 g have been recorded. Grossly, variously sized nodules with a gray to yellow color and a granular appearance are seen projecting above the cut surface (Fig. 26.3).

A cross section of an entire gland with early involvement clearly shows that nodular hyperplasia begins in the transition zone. This

Figure 26.3 Gross appearance of nodular hyperplasia in material obtained from suprapubic prostatectomy. Note the multinodular appearance and the admixture of solid and microcystic areas.

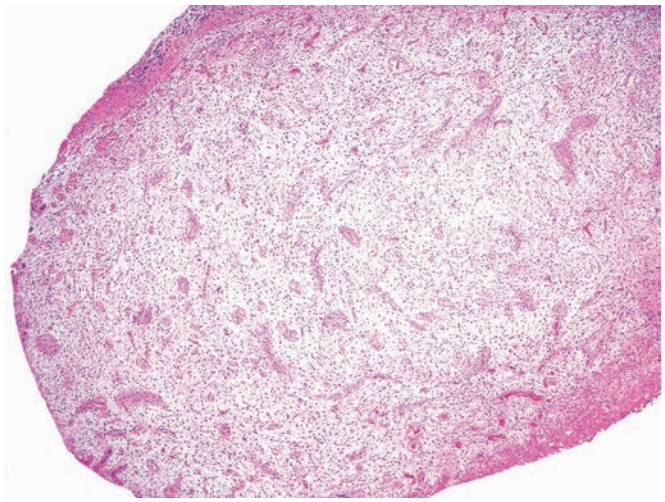

Figure 26.4 Stromal Nodule in Benign Prostatic Hyperplasia. The characteristic prominent blood vessels may be seen even at low power.

fact supports the interpretation that this zone of the gland reacts differently to hormonal stimuli than the outer zones. In most instances the nodules congregate on both sides of the urethra, causing compression and urinary obstruction. In others, the disease may result in a *midline dorsal nodule* at the bladder neck protruding into the bladder lumen, so-called "median-lobe hypertrophy." With increased growth, the peripheral zone of the organ is pushed aside and compressed; in florid examples, the transition zone may extend into and comprise much of the apex.

Microscopically, the earliest change is a stromal proliferation about small sinusoidal spaces in the periurethral regions and, to less degree, in the periductal and intralobular areas (Fig. 26.4). This stromal proliferation (which in the periductal areas may have a concentric or an eccentric quality) contains more smooth muscle

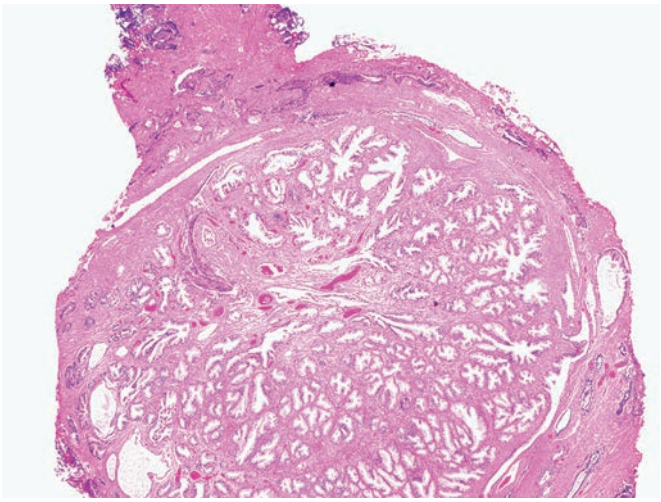

Figure 26.5 Nodular hyperplasia of prostate on TUR with detached well-circumscribed nodules of glands. *TUR*, Transurethral resection.

and less elastic tissue than the normal stroma. This is followed by hyperplasia of the glandular component, so that in the well-developed disease the nodules are composed of varying proportions of both elements.[40] These proportions are somewhat different in patients with symptomatic and those with asymptomatic nodular hyperplasia.[41] The glands are dilated or even cystic and often contain an inspissated secretion of glycoprotein nature (corpora amylacea), which is sometimes calcified.[42] The epithelium ranges from flat to columnar, sometimes facing each other in the same gland ("functional polarization"); the cytoplasm is pale, and the nuclei are regular and centrally located (Fig. 26.5). The nucleoli are inconspicuous. Papillary infoldings are common. A basal cell layer is seen immediately above a well-developed basement membrane.

Small clusters of lymphocytes are common in the interstitium and around the ducts. They are probably the result rather than the cause of the hyperplasia[43]; a diagnosis of chronic prostatitis is not warranted because of their mere presence.

Many morphologic variations of this basic theme exist, some of them resulting from the overgrowth of one component over the other and others form the emergence of distinctive patterns. It should be pointed out that there is little relation between a diagnosis of nodular hyperplasia made on a biopsy specimen and either the weight of the gland or the score system used to measure urinary obstructive symptoms.[44]

The treatment for nodular hyperplasia includes medical or surgical management.[45] Medical alternatives to surgery include various medications aimed at blocking the actions of androgens by preventing their secretion or their conversion to their tissue active form or at relaxing the stromal muscle cells.[46-51] Among these, the drug most widely used is finasteride, which works by inhibiting 5-α reductase, the enzyme that converts testosterone to the potent androgen dihydrotestosterone.[52] The morphologic changes induced by this compound in the prostate are thought to be relatively minor and nonspecific. The involved area may be excised by various techniques, such as transurethral resection (TUR), suprapubic prostatectomy, and laser enucleation.[53-55] It should be realized that these procedures remove *only the newly formed nodules.* The compressed peripheral portions of the gland remain; these expand by stromal growth to surround the prostatic urethra and may be the source of recurrent hyperplasia.[34] Not surprisingly, the chance of a patient undergoing a second operation for this disorder is substantially higher after a TUR than an open prostatectomy.[56]

Infarct

Infarct of the prostate occurs predominantly in large prostates affected by nodular hyperplasia.[55] Its reported incidence is probably related to the thoroughness of the microscopic examination. In the glands carefully studied by Moore,[34] it was found to be present in 18%–25% of cases. It has been traditionally reported in TUR specimens, but it can also be recognized in prostatic needle biopsies.[57] The size and number of the infarcts are directly related to the degree of prostatic hyperplasia. True infarcts occurring on a vascular basis should be distinguished from necrotic changes involving a gland or group of glands but sparing the stroma, a change sometimes seen in nodular hyperplasia.

The mechanism of infarct is unknown but may be related to the presence of prostatic infection or trauma resulting from an indwelling catheter, cystitis, or prostatitis, all of which may result in thrombosis of the intraprostatic portion of the urethral arteries.

Grossly, prostatic infarcts vary in size from a few millimeters up to 5 cm. They are speckled, gray-yellow, and often contain streaks of blood. The peripheral margins are usually sharp and hemorrhagic and may impinge on the urethra (Fig. 26.6). Microscopically, the infarcts are of ischemic type, with sharply outlined areas of coagulative necrosis involving glands *and stroma*. Prominent squamous metaplasia may develop in the ducts at the periphery of the infarct, a change that should not be confused with squamous cell carcinoma (Fig. 26.7). This metaplastic change is confined to the expanded ducts, keratinizes only rarely, and does not extend to the surrounding prostatic tissue.[58] It should be remembered that true squamous cell carcinomas of the prostate are exceptionally rare and are most often seen after radiation therapy.

Most prostatic infarcts are clinically silent. Occasionally, they cause acute urinary retention because of the accompanying edema.[59] Since they are often adjacent to the urethra, gross hematuria can also occur. Diffuse oozing of blood from the overlying mucosa may be seen cystoscopically. They may cause serum elevation of PSAP and PSA.[60] Removal of the infarcted area promptly returns these levels to normal; if it does not, further work-up is indicated.

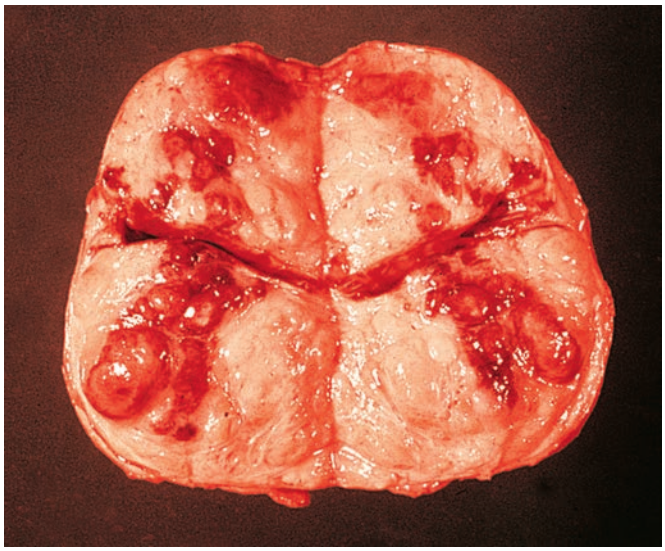

Figure 25.6 Gross Appearance of Infarct of Prostate. The lesion has a bright red color and bulges on the cut surface. Nodular hyperplasia is also present.

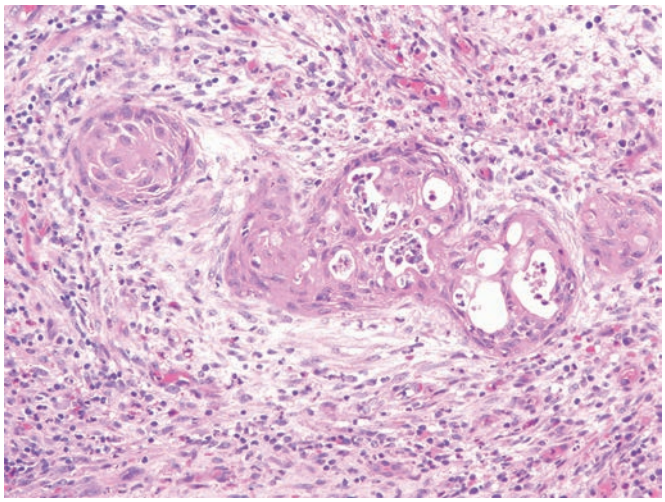

Figure 26.7 Prominent squamous metaplastic changes at the edge of a prostatic infarct. These are sometimes overdiagnosed as carcinoma.

Prostatitis

Acute prostatitis is rarely seen in surgical specimens. In general, prostatitis is a clinical, not a pathologic diagnosis. So-called *chronic prostatitis* is more common, but it is important to distinguish the true infectious processes of this organ from the inconsequential mononuclear infiltrates often seen in biopsies or accompanying nodular hyperplasia. While the latter phenomenon has been dignified by terms such as "chronic nonbacterial prostatitis" or "lymphocytic prostatitis," it is generally best to reserve the term "prostatitis" for clinical infections.[61,62] Therefore, we do not report the presence of chronic inflammation on biopsy unless it is quite marked and only with the descriptive term "marked chronic inflammation." In bacterial prostatitis, the route of infection remains uncertain in most cases. Some cases follow gonococcal or nongonococcal urethritis, and others result from periurethral infection associated with indwelling urethral catheterization. Gram-positive bacteria are the most common pathogens found in cultures from prostatic fluid.[63,64] *Adenovirus prostatitis*, as seen in immunosuppressed patients, can exhibit prominent necrotizing features.[65] While biopsy would be unusual for a clinically apparent infection, microscopically it usually appears as a *localized* process involving a small number of ducts or acini. The lumina are distended and filled with secretion mixed with inflammatory cells, among which neutrophils predominate. The stromal component, on the other hand, is mainly mononuclear and is composed of a mixture of lymphocytes, plasma cells, and histiocytes. In the presence of a monotonous infiltration of mature lymphocytes throughout the organ, the alternative diagnosis of involvement by chronic lymphocytic leukemia should be considered. We have seen rare prostate biopsies with CMV inclusions within epithelial and endothelial cells.

Prostatitis is often accompanied by elevation of serum PSA, particularly following a digital rectal examination, which should return quickly to normal following successful antibiotic treatment.[66,67]

Autoimmune prostatitis (IgG4-related sclerosing disease) has recently been proposed as a disease entity, characterized by elevated serum IgG4 levels and sometimes associated with systemic or multifocal lesions involving other organs.[68,69] In the histologically typical case, a mixed inflammatory infiltrate rich in plasma cells is seen, accompanied by fibrosis and obliterative phlebitis.[70]

Abscess

In the past, the majority of prostatic abscesses resulted from gonorrhea. At present, most have an obstructive etiology and are the

manifestation of secondary infection of the prostate from an infected pool of residual urine.[71] *Escherichia coli* is the organism usually responsible. In one series,[72] 36% presented with acute urinary retention and 31% with perineal or suprapubic pain. Prostatic fluctuation on digital rectal examination is the most characteristic sign, transrectal ultrasound is the most reliable diagnostic method, and transurethral drainage under antibiotic coverage is the treatment of choice.[73,74]

A relatively common form of prostatic abscess in east Asia and northern Australia is *melioidosis*, an infectious disease produced by the gram-negative bacterium *Burkholderia pseudomallei*.[75,76]

Tuberculosis and Bacillus Calmette–Guérin-Induced Granulomas

The prostate, epididymis, and testis are the organs most commonly involved in tuberculosis of the male genital system.[77] Of 105 autopsy cases included in the classic study by Auerbach,[78] the prostate was involved in 100, and in 35 it was the sole site in the system. In most cases, the infection is the result of hematogenous spread from the lungs (or, less often, from the skeletal system), but it may also result from direct invasion from the urethra.[79]

Early tuberculous lesions in the prostate are seldom detected on palpation. It is only when the disease is advanced that enlargement occurs and fluctuant, tender zones may be felt. Grossly, the lesions are usually bilateral. Confluent caseous zones occur with liquefaction and cavitation, until finally the prostate becomes an enlarged mass with multiple cavities. It may perforate into the urethra and extend into the urinary bladder. With still further spread, sinus tracts may form into the rectum, perineum, and peritoneal cavity. Healing with calcification may supervene, a change detectable by radiographic examination. In the late stages, the prostate becomes shrunken, fibrotic, and hard, to the point that it may simulate carcinoma on palpation.

Microscopically, the initial lesion is in the stroma but quickly spreads to the acini. Well-developed lesions show confluent foci of caseation with incomplete fibrous encapsulation. There is little tendency for the formation of typical tubercles.

Patients treated with intravesical bacillus Calmette–Guérin (BCG) for bladder carcinoma may develop granulomas in the prostate similar to those seen more often in the bladder itself (see Chapter 25).[80] These granulomas may be of noncaseating or caseating type.[81] They may be located along the periurethral or transitional zone or involve the gland diffusely. Stains for acid-fast organisms are usually negative, although occasionally a few organisms are visualized.

Other Specific Infections

The prostate can be involved by *blastomycosis*,[82] *coccidioidomycosis*,[83,84] *actinomycosis*,[85] *cryptococcosis*,[86-89] *histoplasmosis*,[90] *aspergillosis*,[91] *Cytomegalovirus* (CMV),[92] and *candidiasis*.[93,94] Many of these infections occur in the setting of immunosuppression resulting from AIDS or other disorders.[86,88,90]

Chlamydia trachomatis[62] and *Trichomonas vaginalis*[95] have been identified in the prostate gland, but their possible role as etiologic agents of prostatitis remains to be determined. The *Chlamydia* organism can be detected in tissue by immunohistochemical and in situ hybridization techniques.[96,97]

Granulomatous Prostatitis

Nonspecific granulomatous prostatitis, sometimes described as *"idiopathic,"* is applied to a rare prostatic disorder thought to represent an initially immune-mediated process accompanied by a reaction to the prostatic secretions released from obstructed ducts.[98-100] Most cases occur in glands affected by nodular hyperplasia in patients over 50 years of age. The clinical triad of high fever, symptoms of prostatitis, and a hard prostate on palpation is present in one-fifth of cases and may suggest the diagnosis.[101] A preoperative diagnosis of carcinoma is suspected in about 30% of cases because of the firmness of the lesion, caused by the dense fibrosis.

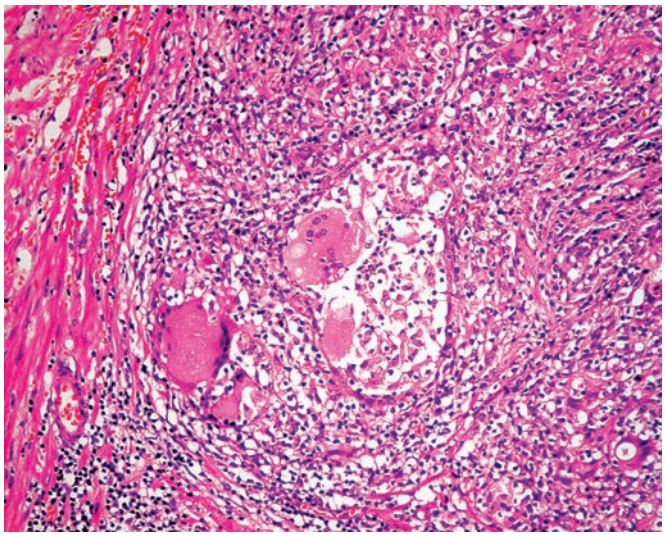

Figure 26.8 Nonspecific Granulomatous Prostatitis. The inflammatory infiltrate, which contains scattered multinucleated cells, is characteristically centered on a prostatic acinus.

Grossly, the gland is firm to stony hard. The cut surface shows obliteration of the architecture, with formation of yellow granular nodules. Microscopically, large nodular aggregates of histiocytes, epithelioid cells, lymphocytes, and plasma cells are seen. Characteristically, these granuloma-like formations are centered in the lobules (Fig. 26.8). A tubercle-like reaction with multinucleated giant cells, as well as collections of neutrophils, eosinophils, and detritus within the ducts, also may be seen. Microorganisms and caseation necrosis are absent. The microscopic changes can simulate carcinoma in needle biopsy specimens.[102] Immunohistochemical studies have shown a concentration of T cells in and around damaged ducts and glands.[103]

Prostatitis With Eosinophils

Most cases of prostatitis associated with a predominant eosinophilic infiltrate, sometimes intense, belong to one of the following categories[104,105]:

1. **Eosinophilic prostatitis** (allergic prostatitis, allergic granuloma of prostate), characterized by small stellate necrobiotic nodules surrounded by palisading epithelioid histiocytes and eosinophils, resembling rheumatoid nodules.[106,107] Vasculitis may be found. Patients often have a history of allergy and asthma and usually exhibit peripheral eosinophilia; in some cases, systemic vasculitis is present. Some of these cases have been thought to be a component of the Churg–Strauss syndrome.[108] Elevation of serum PSA levels may occur in this disorder.[109]
2. **Iatrogenic inflammation**, a morphologically similar condition in patients lacking these systemic symptoms that develops after a surgical procedure to the area, usually occurs in a TUR but sometimes a prostatic needle biopsy.[104,110-112] The interval between the surgical procedure and the appearance of the prostatitis ranges from less than 1 month to several years; eosinophils are more numerous when this interval is shorter. An associated

granulomatous response may represent a reaction to collagen altered as a result of the surgery or to metal deposition from the instruments themselves.[113] Some of these granulomas are elongated and tortuous, whereas others are wedge shaped, with their base facing the cauterized tissue.[104,114]

3. **Parasitic infestation** resulting from metazoa are rarely reported and, as in other sites, may be associated with an intense eosinophilic infiltrate.[115]

Other Inflammations

Malakoplakia can involve the prostate, usually in association with bladder disease (see Chapter 25).[116,117] As in the latter site, it should be viewed as a peculiar form of tissue reaction to bacterial infection. The infiltrate is usually located around prostatic ducts and has a mixed composition. The diagnosis is possible on needle biopsy specimens.[118] A similar condition but lacking Michaelis–Gutmann bodies has been described as **nodular histiocytic prostatitis**.[119] Reactive histiocytic infiltrates may closely mimic the morphologic appearance of prostatic adenocarcinoma after hormonal ablation. Malakoplakia may sonographically simulate prostatic carcinoma.[120] It can also be seen in prostates having carcinoma in other portions of the gland.[121]

Vasculitis of either necrotizing, fibrinoid, or granulomatous type can involve the prostate as an isolated event.[122,123]

Hair granuloma, described exceptionally in TUR specimens, is thought to result from hair from the perineal area being introduced into the prostate by an earlier perineal prostatic needle biopsy.[124]

Calculi

Prostatic calculi are seen in about 7% of prostates with nodular hyperplasia.[125] They should be distinguished from those found in the prostatic urethra, which may have their origin in the bladder, ureter, or renal pelvis.

The corpora amylacea seen in glands with nodular hyperplasia may act as the nucleus for stone formation as a result of improper drainage, infection of the acini, and calcium deposition. Blood clots, epithelial detritus, and bacteria are also present in the stone nucleus. The main inorganic elements are phosphated salts (calcium, magnesium, aminomagnesium, potassium), calcium carbonate, and calcium oxalate.

Because of their extreme hardness, large prostatic calculi may be erroneously diagnosed as carcinoma on palpation. They are radiopaque and easily detectable in plain-film x-rays. They are not associated with an increased risk for the development of prostatic carcinoma.[126] If they are extremely large and numerous, a prostatectomy may be required.

Tumorlike Conditions

The microscopic appearance of prostatic malignancy in general and of prostatic adenocarcinoma in particular can be simulated by a bewildering number of processes, all of benign nature, most of them not even neoplastic, and some simply representing examples of normal structures in an unexpected place.[127-130]

Normal tissue from ***seminal vesicle***, ***ejaculatory duct***, ***Cowper's glands***, and ***paraganglia*** can be found incidentally in prostatic resection specimens or biopsies and lead to diagnostic errors.[131-135] This is particularly true for the seminal vesicle because of its complex papillary arrangement and sometimes striking nuclear aberrations. A clue to the nature of this epithelium is the presence of abundant lipofuscin granules in the cytoplasm and/or the presence of scattered, large atypical epithelial cells (Fig. 26.9).[136] It should be noted, however, that a similar pigment can be occasionally found in benign and malignant prostatic epithelium[137] and that the distal seminal vesicle epithelium may show some immunoreactivity for PSA. Another clue is provided by the immunoreactivity of the seminal vesicle–ejaculatory duct epithelium for PAX-8, PAX-2, and GATA3.[138-140] **Rectal tissue** can be introduced in the prostate in the course of a needle biopsy[141]; when these glands are distorted, they can mimic prostatic cancer.[142] Finally, it should be kept in mind that normal and hyperplastic prostatic glands may be seen in a **perineurial location** and simulate perineurial invasion by carcinoma.[143-145]

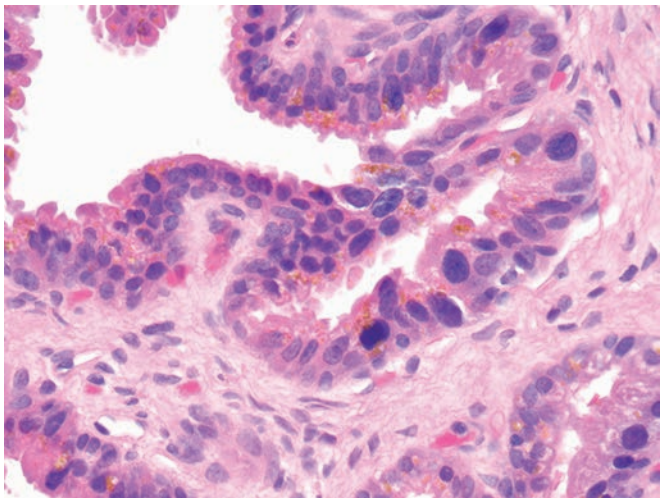

Figure 26.9 Benign Seminal Vesicle Epithelium Present in a Prostatic Needle Biopsy. The marked nuclear pleomorphism, which is characteristic, may prompt an overdiagnosis of carcinoma. Note the abundant intracytoplasmic pigment.

Microscopic Mimics of Prostatic Neoplasia

Florid hyperplasia of mesonephric remnants is extraordinarily rare but can involve the prostate and periprostatic tissues and mimic prostatic carcinoma.[146-149] They are most common in the anterior fibromuscular stroma and adjacent anterolateral periprostatic tissue or toward the base posteriorly and posterolaterally, either within or exterior to the prostate and around the seminal vesicle. As in other sites, these remnants are most commonly characterized by crowded small glands with a somewhat lobular arrangement, often with intraluminal eosinophilic secretions (Fig. 26.10). Rare cases may have ill-formed glands with infiltrative-like growth or some intraluminal papillary infoldings.

Foamy macrophages can appear in clusters ("xanthomas") and mimic high-grade prostatic carcinoma.[150,151]

Signet ring–like changes can develop in stromal cells and lymphocytes as a result of the effects of diathermy or other injuries and simulate signet ring adenocarcinoma. It is seen most often in TUR specimens, but it has also been described in prostatectomy specimens.[152]

Extramedullary hematopoiesis rarely involves the prostate in patients with myelofibrosis; the atypical megakaryocytes present in it should not be confused with malignant cells.[153]

Benign prostatic atrophy is an age-related phenomenon that occurs exclusively in the peripheral zone of the prostate.[154] A Working Group has proposed that prostatic atrophic lesions to be divided into the following subtypes: (1) *simple atrophy*; (2) *simple atrophy with cyst formation*; (3) *postatrophic hyperplasia*; and (4) *partial atrophy*.[155] Postatrophic hyperplasia may simulate carcinoma because of its complex arborization and surrounding fibrosis; however, the cytoplasm is scanty, and the lobular architecture is retained

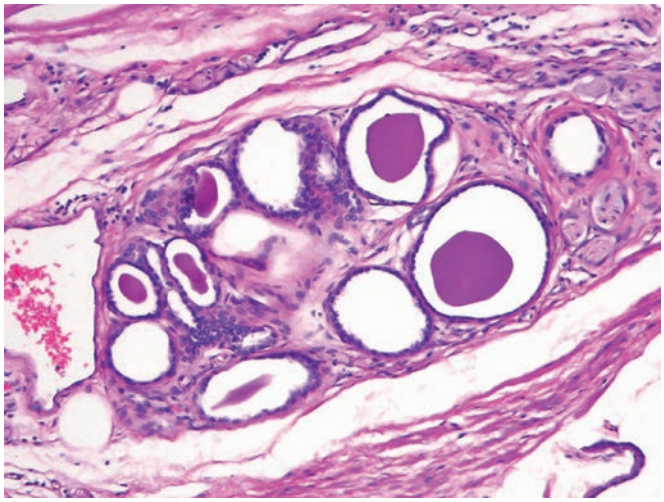

Figure 26.10 Mesonephric remnants within periprostatic stroma. (Courtesy of Dr. Samson Fine, Memorial Sloan Kettering Cancer Center, New York, NY.)

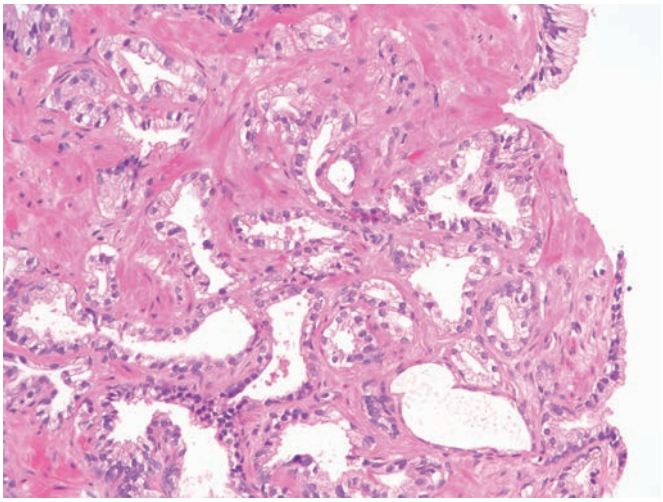

Figure 26.12 Partial atrophy, the most common mimic of prostatic carcinoma in routine practice, may be pseudoinfiltrative; however, the angulated/tapered shape of the glands and the loss of luminal cytoplasm are characteristic.

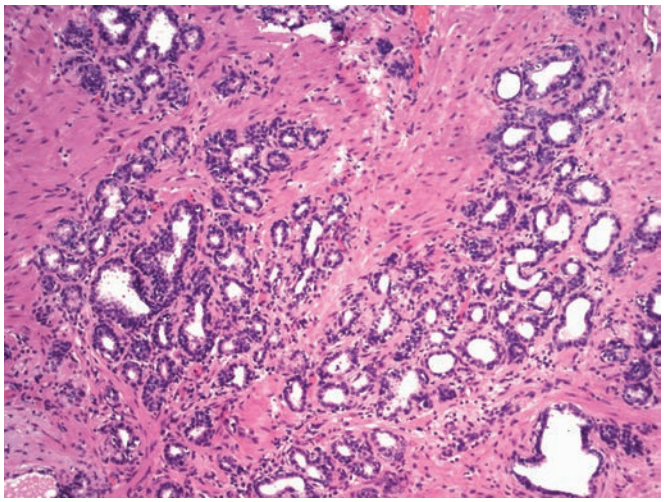

Figure 26.11 Postatrophic hyperplasia of the prostate retains its lobular architecture.

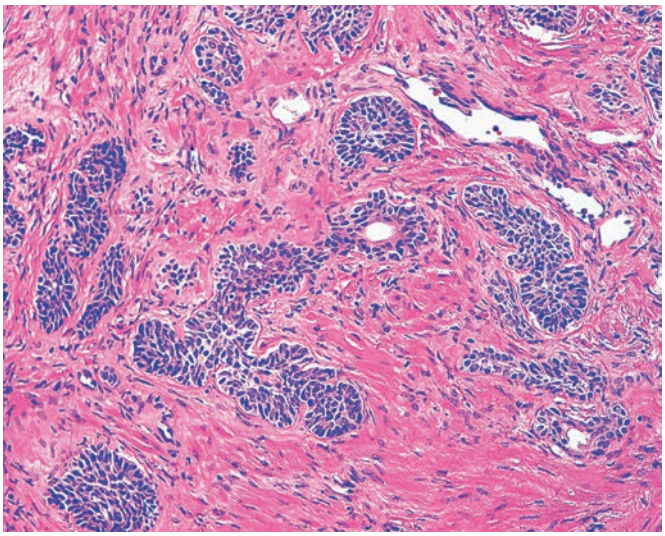

Figure 26.13 Basal cell hyperplasia often grows as solid nests or circumferential nodules of dark cells around residual prostatic secretory cells.

(Fig. 26.11).[156-159] Gland size and shape are typically variable, including round, oval, elongated, slit-like, and stellate forms. The individual cells have a very basophilic appearance because of the scant cytoplasm. The nuclei are regular and devoid of hyperchromasia,[160] but the nucleoli may be prominent.[161] The stroma may show elastosis in addition to fibrosis.[162] By immunohistochemistry, postatrophic hyperplasia glands are strongly immunoreactive for basal cell markers, making this a useful adjunct in difficult cases.

Partial atrophy is by far the most common benign mimicker of prostatic carcinoma on needle biopsy.[163] It is composed of crowded pseudoinfiltrative glands with reduced luminal cytoplasm. The glands are often angulated and preserved lateral cytoplasm is characteristic (Fig. 26.12). Nucleoli may be enlarged and some cases have visible nucleoli.[163] An association with fully developed atrophic changes of the simple or postatrophic hyperplasia type is a useful diagnostic feature.[164,165] Unfortunately, immunophenotypic analysis with basal cell markers and AMACR is problematic, as basal cells may be patchy or absent and luminal AMACR reactivity is common (reported in 30%–70% of cases).[163,166]

Squamous metaplasia can be seen at the periphery of infarcts, after TUR, as a result of hormonal manipulation, or sometimes with no obvious predisposing cause.

Basal cell hyperplasia is usually seen in the transition zone, but it may also occur in the peripheral portion of the gland.[167] It appears as small, generally solid nests of benign-appearing epithelial cells with minimal cytoplasm (Fig. 26.13). There is always an accompanying nodular hyperplasia of the usual type, with frequent merging of the two processes.[145] In *florid* basal cell hyperplasia, the proliferation is unduly complex.[168] Nuclear enlargement, hyperchromasia, and nucleolar prominence are seen in some cases and have been described as *atypical basal cell hyperplasia;* however, this seems to be of no clinical significance.[169] Other morphologic variations include the presence of intracytoplasmic globules (an allegedly diagnostic feature), psammomatous calcification, squamous changes, and a cribriform pattern of growth.[170,171] Basal cell hyperplasia may be the progenitor of the so-called adenoid basal cell tumor, which some

authors consider to be the extreme end of hyperplasia.[170] The proliferating basal cells are immunoreactive for high-molecular-weight keratin (34βE12) and p63 but not for actin.[172] The lesions are consistently negative for racemase.[173]

Urothelial "metaplasia" is characterized by the presence of a stratified epithelium composed of oval to spindled cells perpendicularly oriented to the lumina and having scanty pale eosinophilic to clear cytoplasm. The nuclei are elongated, vesicular, often with longitudinal grooves and inconspicuous nucleoli.[174] This is common in glands and ducts near the prostatic urethra and should be regarded as a normal finding.

Clear cell cribriform hyperplasia is an uncommon and controversial form of hyperplasia. The cytoplasm of the hyperplastic glandular cells often has a clear appearance, hence the original designation as *clear cell* cribriform hyperplasia (Fig. 26.14).[175] An important clue in the differential diagnosis with invasive carcinoma is the presence of a prominent row of basal cells at the periphery of the lesion, which are highlighted by the 34βE12 keratin stain.[176] In contrast to intraductal carcinoma (its closest mimic), nuclei are small, nucleoli are inconspicuous, and mitotic figures are absent.

Sclerosing adenosis has an appearance similar to the homonymous lesion in the breast. It appears as a well-circumscribed nodule composed of variably sized and shaped (often compressed) glands and small clusters of epithelial cells embedded in a cellular, often myxoid stroma (Fig. 26.15). The clusters contain both a continuous basement membrane and a layer of basal cells. The latter are immunoreactive for keratin, S-100 protein, and smooth muscle actin, suggesting myoepithelial differentiation.[17,177,178] In some cases, there can be more pronounced cytologic atypia *(atypical sclerosing adenosis)* mimicking carcinoma.[179]

Adenosis (also known as *atypical adenomatous hyperplasia*) has a low-power appearance similar to that of well-differentiated adenocarcinoma in the sense of featuring a complex and disorderly cluster of crowed glands with an expansile margin but lacking prominent nucleoli or other nuclear abnormalities (Fig. 26.16).[176,180] It is usually an incidental microscopic finding in the transition zone, but it may rarely present as a mass lesion.[181,182] Acidic mucin is often present in the lumen of the glands.[183,184] While the relationship of adenosis to carcinoma has been debated, there are no strong data to support its role as a precursor; therefore, it is now simply considered a benign mimic.[185-188]

Lotan et al.[189] have described a variant of adenosis affecting younger patients, involving the peripheral zone of the prostate in a diffuse fashion (rather than localized to the transition zone), and possibly representing a risk factor for prostatic carcinoma; however, no subsequent validation studies have followed.

Radiation changes are characterized by cytologic atypia associated with retention of the lobular architecture, squamous metaplasia, stromal fibrosis, atypical fibroblasts, and vascular alterations. These changes can be very long lasting (up to 72 months in one series).[190] Radiated prostate glands often appear more angulated with small slit-like lumina, and they often have marked cytologic atypia (Fig. 26.17). After radiation, these cells typically have a basal immunophenotype, so basal cell markers are very useful in difficult cases. It should be noted that these radiated prostatic cells also commonly express GATA3 (a known basal cell marker), which could potentially lead to confusion with urothelial carcinoma.[191,192]

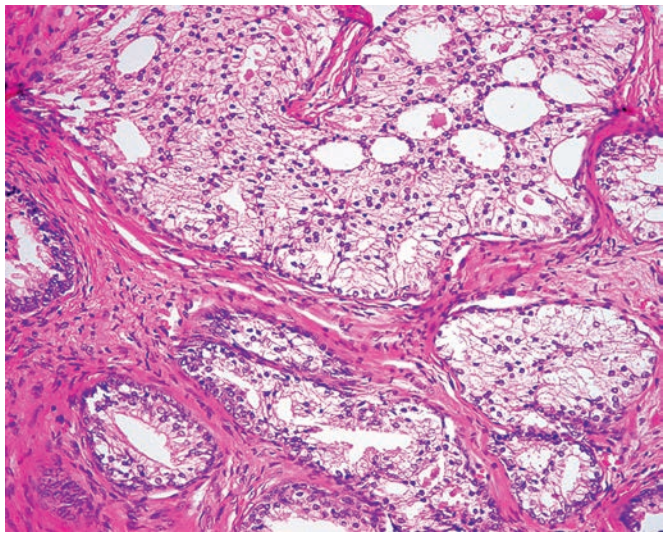

Figure 26.14 Clear cell hyperplasia of prostatic transition zone with a focally cribriform pattern of growth.

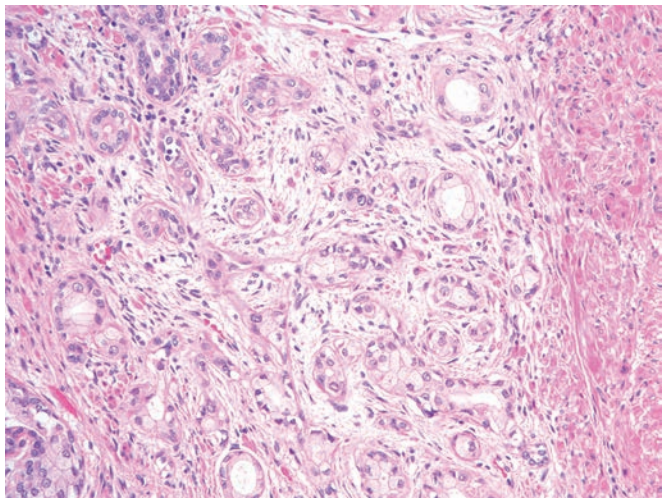

Figure 26.15 Sclerosing Adenosis of Prostate. The features are similar to those of its better-known mammary counterpart.

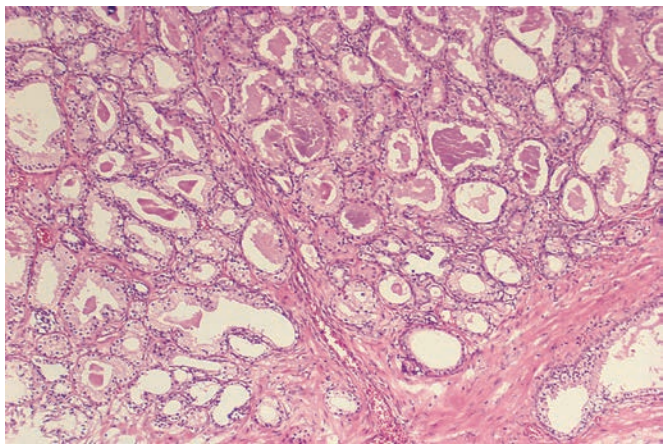

Figure 26.16 Adenosis of the prostate is characterized by crowded benign glands mimicking a well-differentiated adenocarcinoma.

Carcinoma

General Features

Carcinoma of the prostate is the most common internal malignancy among men in the United States and is responsible for 10% of

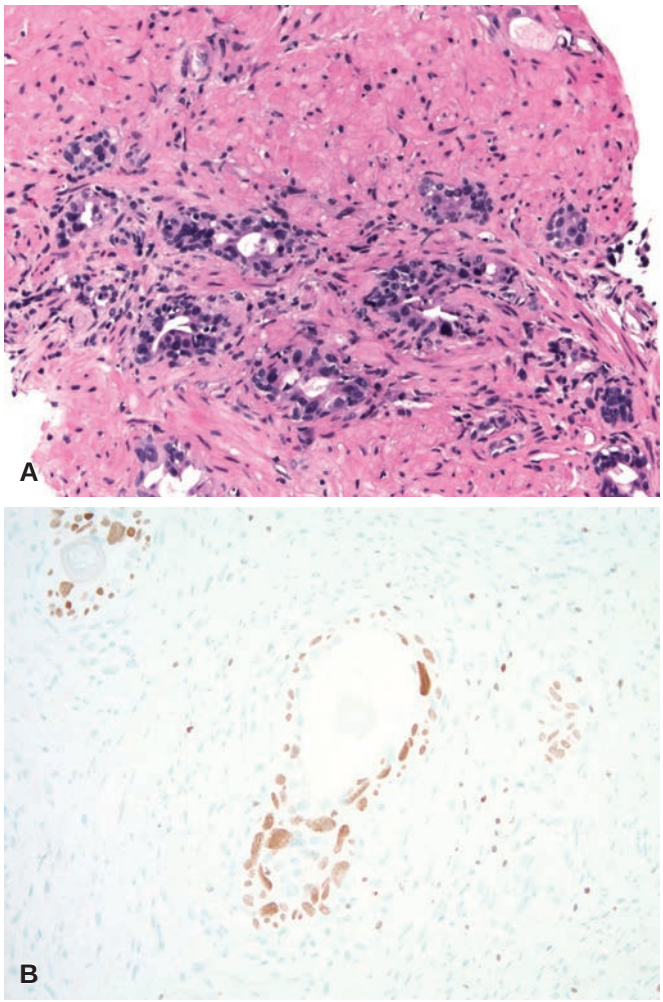

Figure 26.17 **A,** Radiation changes in prostate: the acini show marked nuclear pleomorphism. On low power, the lobular architecture was retained. **B,** Immunostain for GATA3 shows nuclear reactivity in the atypical cells, which may cause confusion with urothelial carcinoma.

cancer deaths in this population.[193] In the United States, an estimated 180,890 new cases of prostate cancer were diagnosed in 2016.[194] Rates among black males are one and a half those of white males.[195] The age-adjusted incidence is on the increase in most countries. Hormonal factors play a role in the development of prostatic carcinoma, a fact that has been dramatically highlighted with the statement that "essentially all men with circulating androgens will develop microscopic prostate cancer if they live long enough."[196] The disease does not occur in males castrated before puberty, and its incidence is low in patients with hyperestrogenism resulting from liver cirrhosis. It has been estimated that 5%–10% of prostatic carcinomas have a genetic link.

Almost 75% of the men diagnosed with prostatic cancer are age 65 or older, but the tumors can be seen in younger patients.[197] Their frequency increases with age, a fact well substantiated by careful observations at autopsy. The frequency with which incidental carcinoma is found at post mortem examination varies between 15% and 70%[198] and is directly related to the age of the patient and the thoroughness of the sampling. Similar figures have been obtained from the examination of cystoprostatectomy specimens performed for bladder carcinoma: in one such series, incidental prostatic adenocarcinoma was found in 42% of the specimens.[199]

Clinical Features

In general, most prostatic adenocarcinomas are now detected by serum PSA screening. Despite the recent controversy regarding PSA screening and the U.S. Preventive Services Task Force, the problem of overtreatment is evolving such that many men are now offered the option of active surveillance or watchful waiting.[200,201] PSA is secreted by all but the most undifferentiated prostatic tumors.[202] Gram for gram, the average prostatic carcinoma produces 10 times or more the amount of PSA produced by normal tissue, and this is reflected in the circulatory levels of this marker. The test, when performed over time, has a relatively high sensitivity and specificity, is rapid and inexpensive, and is minimally invasive.[203-205] Mild serum elevations of PSA can be seen with nodular hyperplasia, but levels above certain thresholds (such as 4 mg/mL) call for serial determination, with the performance of a biopsy if they continue to rise. Almost half of patients with prostatic carcinomas have levels over 10 mg/mL. Elevations of serum PSA also occur in prostatitis, prostatic infarct, and major trauma to the prostate, such as needle biopsy or TUR, but these elevations should be transitory and resolve with proper treatment.

Pathologic Features

Prostatic carcinomas can be divided into two major histologic categories: acinar and ductal. This morphologic distinction was initially based on the belief of a different site of origin for the two tumors; however, this histogenetic approach has been challenged by the observations that the two patterns are sometimes seen together in the same tumor and that the two types may coexist in the same prostate as anatomically separate lesions.[206,207] Therefore, the alternative proposal has been advanced that it is the *site* of the growth rather than the *origin* that governs the tumor architecture.[207] Even more problematic is the fact that histologic criteria for ductal subtype vary and interobserver reproducibility for the diagnosis is not high.[208] The large majority of the tumors are acinar, and most studies dealing with grading, staging, prognosis, and therapy of prostatic carcinoma refer exclusively to them.

Adenocarcinoma of Acinar Type

Most prostatic adenocarcinomas arise in the peripheral zone, which extends into the anterior regions of the prostate. However, a small percentage of tumors do actually arise in the prostatic transition zone or rarely central zone.[209]

Grossly, the tumor may be difficult to see but usually can be identified as a gray or yellowish, poorly delineated, firm area (Fig. 26.18). Early detection efforts are resulting in the identification of increasingly smaller tumors. As a matter of fact, residual carcinoma may be unidentifiable grossly or even microscopically in a radical prostatectomy specimen performed because of a positive biopsy (so-called vanishing cancer phenomenon or minimal residual cancer).[210] In such cases, a thorough reexamination to the point of compulsiveness (referred to as "methodically limited targeted approach") will unearth the carcinoma in about 75% of the cases.[211] The frequency of the "vanishing cancer phenomenon" is decreasing rapidly due to the increased use of active surveillance and the more frequent use of radical prostatectomy for larger, higher grade carcinomas. In our experience over the past few years, the only prostatectomies with no identifiable cancer were performed for Gleason score 3 + 3 = 6 carcinoma comprising 1 mm or less of a single biopsy.

Microscopically, prostatic adenocarcinomas exhibit a wide spectrum of appearances, ranging from highly differentiated neoplasms (Fig. 26.19) that are distinguished from the non-neoplastic

Figure 26.18 Gross Appearance of Prostatic Adenocarcinoma. The tumor appears as an irregularly shaped, yellow mass with punctate foci of necrosis in a gland that is also involved by nodular hyperplasia.

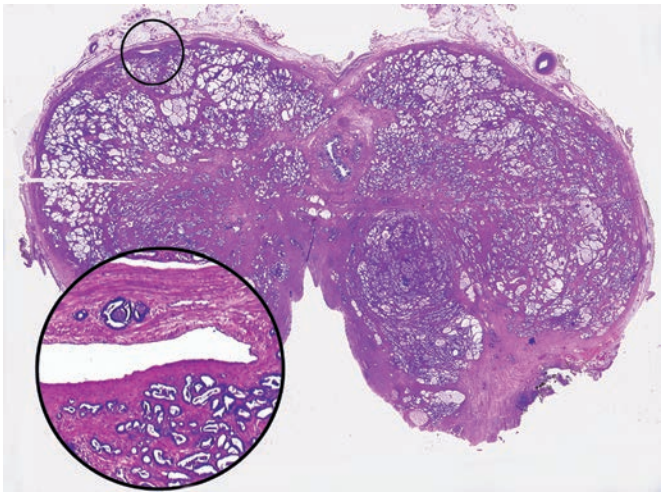

Figure 26.19 Whole mount of radical prostatectomy specimen showing involvement by an extremely small prostatic carcinoma located at the periphery of the organ and accompanied by perineurial invasion, the latter better seen in the inset.

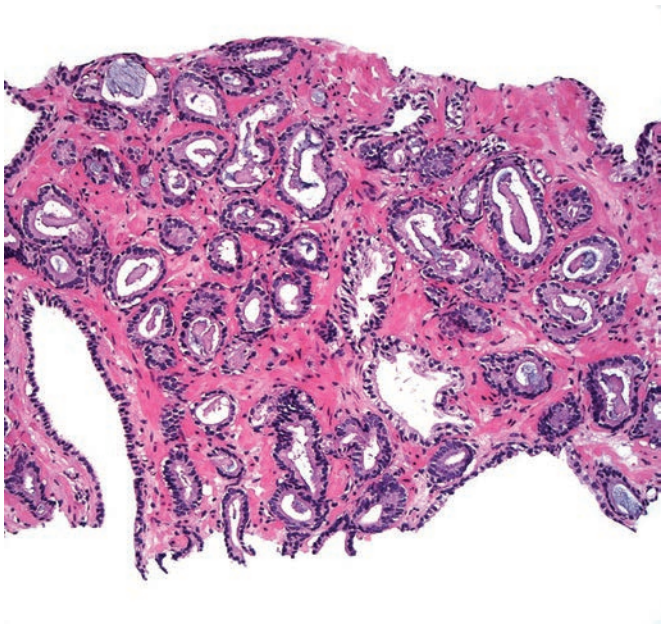

Figure 26.20 Microscopic Appearance of Prostatic Carcinoma. Well-differentiated Gleason score 3 + 3 = 6 adenocarcinoma composed of medium-sized glands. Note the irregular shape of the glands and presence of intraluminal basophilic secretion. The contrast with the non-neoplastic glands present in the field is obvious.

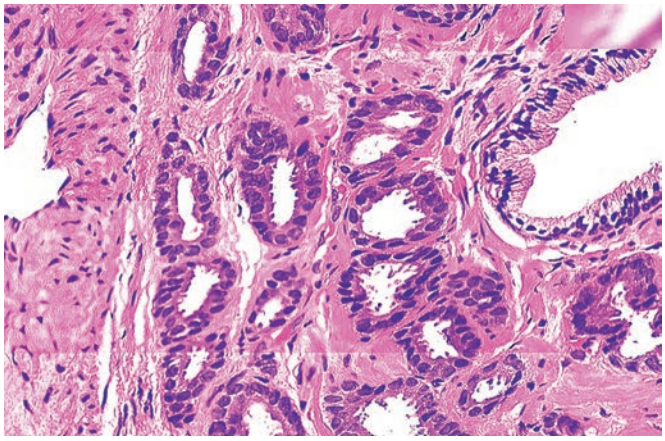

Figure 26.21 Gleason score 3 + 3 = 6 prostatic adenocarcinoma composed of small crowded glands.

gland only with great difficulty to rare anaplastic tumors.[212,213] The architectural patterns of prostate cancer can be quite varied, but the four major cytoarchitectural patterns described by Totten et al., and coauthored by Arthur Purdy Stout, still represent a useful framework for discussion.[159] These patterns are: medium-sized glands, small glands, diffuse individual cell infiltration, and cribriform. We would also add the pattern of small tumor nests (so-called poorly formed glands). Carcinomas composed of *medium-sized glands* are detected on low-power examination by virtue of the closely spaced arrangement of those glands, the prominent luminal cytoplasm with orientation of nuclei against the basement membrane, the smooth inner luminal surface, and the scanty intervening stroma (Fig. 26.20). Tumors made up of *small glands* appear as expansive nodules on low power or as an infiltrative population of individual glands that percolate between benign glands (Fig. 26.21). The individual glands have a regular round configuration and small size. Both of these architectural patterns (but particularly the latter) are accompanied by cytologic abnormalities in the form of nuclear enlargement, nuclear hyperchromasia, and prominent nucleoli ("macronucleoli," defined as measuring >1 μ in diameter).[214,215] Mitoses are also of significance, but they are rarely found in well-differentiated tumors composed of either medium-sized or small glands. The pattern of *diffuse cell infiltration* resembles somewhat that of invasive lobular carcinoma of the breast (Fig. 26.22), but this pattern is relatively rare. The *cribriform* pattern varies in the dimension of the epithelial aggregates, ranging from large expanses of anastomosing epithelium to small- or medium-caliber glands with complex intraluminal proliferations (Fig. 26.23). The gland-forming types of prostatic adenocarcinoma are usually lined by a single cell layer, but occasionally they exhibit a stratified epithelium that may simulate PIN.[216] An additional pattern of growth that has recently been described is that referred to as *glomeruloid*. It is characterized by the presence of intraluminal ball-like clusters of

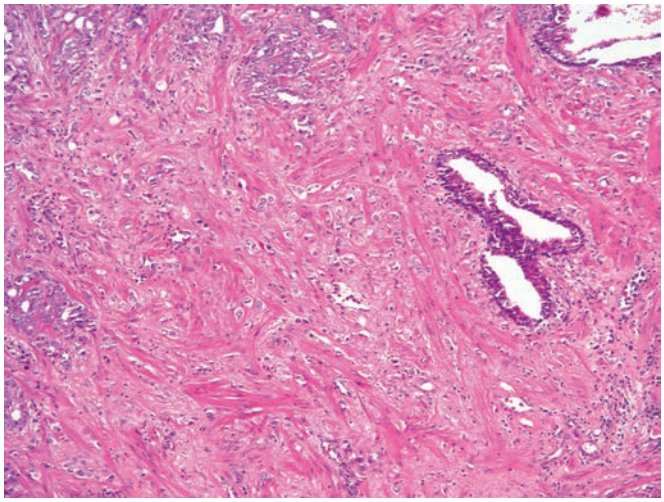

Figure 26.22 Poorly differentiated Gleason score 5 + 5 = 10 prostatic adenocarcinoma growing in a diffuse fashion. The appearance is reminiscent of that of invasive lobular carcinoma of breast.

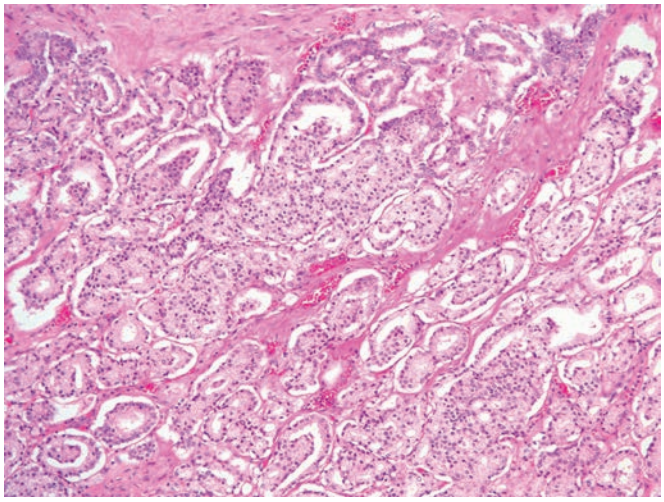

Figure 26.23 Prostatic adenocarcinoma with cribriform histology.

tumor cells[217] and is regarded by many as a pathognomonic sign of malignancy (Fig. 26.24).[218]

The claim has been made that the rare prostatic adenocarcinomas arising in the transition zone have a distinct morphology, characterized by glands of variable size with tall columnar cells displaying basally located nuclei and clear to pale pink cytoplasm, but these features are neither specific nor consistent.[209]

Squamous metaplasia is an uncommon but well-documented finding in prostatic carcinoma (especially of the high-grade type). It is often, but not always, seen in the setting of prior hormonal or radiation therapy and is associated with a poor prognosis.[219]

The patterns just mentioned are often seen in combination, either synchronously or metachronously. For instance, a pattern of diffuse cell infiltration can be seen after the partial removal of a better differentiated neoplasm.[220] It should be mentioned here that it is on these patterns and their admixture, as seen on low-power examination, that the Gleason grading scheme (to be described later) is primarily based.

The presence of prostatic glands within perineurial spaces is common in these tumors.[221] This finding is a strong indicator of malignancy but is pathognomonic only when circumferential.[144]

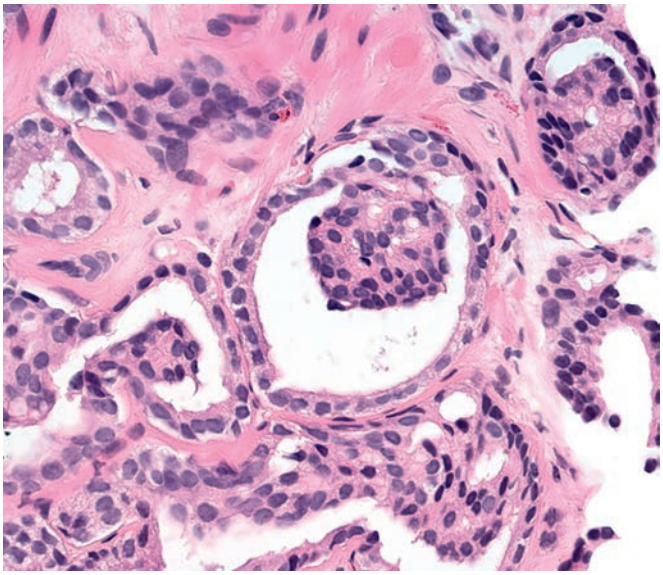

Figure 26.24 Prostatic adenocarcinoma with glomerulations is regarded as Gleason pattern 4.

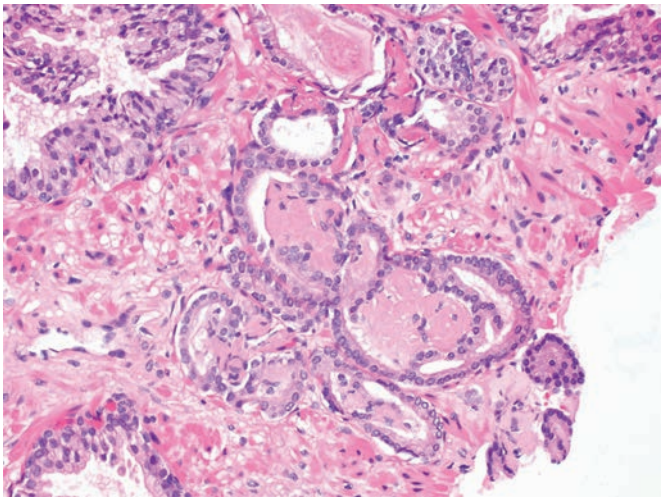

Figure 26.25 Prostatic adenocarcinoma with mucinous fibroplasia/collagenous micronodules.

The stroma surrounding the neoplastic glands may show a combination of hypercellularity and deposition of a basophilic ground substance (*"mucinous fibroplasia"* or *"collagenous micronodules"*), which has also been suggested as a pathognomonic feature of cancer (Fig. 26.25).[222,223]

Deeply eosinophilic protein crystalloid structures are seen in the glandular lumina of 10%–23% of prostatic carcinomas and are particularly common in tumors composed of medium-sized glands (Fig. 26.26).[224,225] Their presence usually indicates malignancy, but their occasional occurrence in benign glands has been documented.[226] When the latter is the case, their presence should not be viewed as indicating a significant risk factor for the subsequent development of cancer.[227,228] The intraluminal secretion of malignant glands often has a bluish hue ("wispy blue mucin"), indicative of a mucinous composition. The presence of corpora amylacea in the glandular lumen is not necessarily a sign of benignancy, as formerly believed; these formations can also be exceptionally found in association with malignant glands.[229,230]

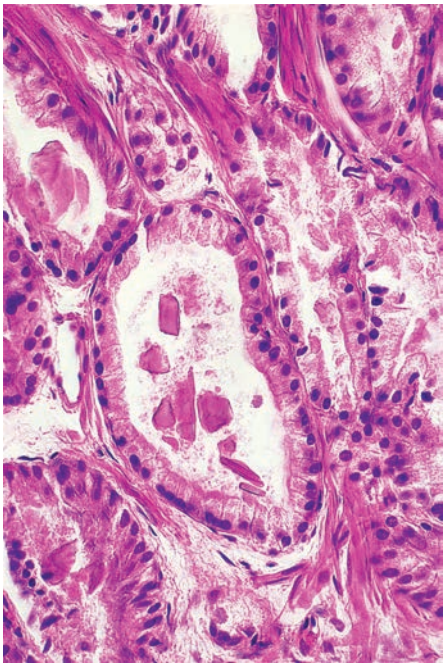

Figure 26.26 Well-differentiated prostatic adenocarcinoma showing intraluminal crystalloids.

Many variations of this already complex "basic" pattern have been described. Some are distinctive enough to be regarded as separate microscopic types, and are described later, in a section of their own. Others are variations of less degree, although still important because of the diagnostic errors they may engender. These treacherous variations of prostatic adenocarcinoma include:

1. *Foamy gland carcinoma*. The cytoplasm of the carcinoma cells usually has a nondescript, finely granular appearance, but on occasion it is clear or foamy ("xanthomatous") because of the massive accumulation of lipids (Fig. 26.27).[231] When this feature is prominent, the tumor is known as *foamy gland carcinoma*.[231] Its microscopic recognition can be difficult, particularly at metastatic sites.[232] The voluminous tumor cells are cuboidal to columnar, and the nuclei are small and often pyknotic. Nucleoli are not particularly conspicuous.[233] Most foamy gland carcinomas are assigned a low Gleason score (3 + 3 = 6), but a high-grade form of this variant exists.[234]
2. *Prostatic adenocarcinoma with atrophic features*. This variant, which mimics a benign hyperplastic change, is composed of tumor cells with an attenuated cytoplasm, such that the nuclei occupy almost the entire cell height (Fig. 26.28). These cells are identifiable as malignant because of their infiltrative pattern of growth, nuclear enlargement, macronucleoli, and most often the presence of adjacent carcinoma of the ordinary type.[235-237]
3. *Pseudohyperplastic prostatic adenocarcinoma*. As indicated by its name, this variant resembles many of the features of hyperplastic glands at the architectural level, including papillary infoldings and gland branching. On low power, the tumor has a deceptively bland microcystic appearance, a feature that it shares with the atrophic type.[238] Clues that identify the lesion as malignant are nuclear enlargement, orientation of nuclei at the basement membrane, macronucleoli, mitoses, and intraluminal crystalloids.[239,240]
4. *PIN-like adenocarcinoma*. Rare invasive prostatic adenocarcinomas may have medium- to large-caliber glands and a stratified epithelial lining, simulating high-grade prostatic intraepithelial neoplasia (PIN).[216,241] Unlike PIN, these carcinomas have a crowded arrangement beyond the normal anatomic distribution of normal glands (Fig. 26.29). In some cases, the neoplastic cells may appear pseudostratified columnar.[214] While the term "PIN-like ductal adenocarcinoma" has been applied to these later cases, we recommend avoiding use of the term "ductal" since these carcinomas behave similar to low grade acinar adenocarcinomas.
5. *Aberrant p63 expressing carcinoma*. A rare subset of prostatic adenocarcinomas express nuclear p63 in the neoplastic secretory cell population.[242,243] They lack a basal cell population, both by p63 and other high-molecular-weight keratins. These carcinomas often have a somewhat atrophic appearance with scant cytoplasm, slit-like luminal spaces, and occasional intraluminal eosinophilic secretions (Fig. 26.30A and B). This rare subset of carcinomas is also thought to be molecularly distinct.[244]

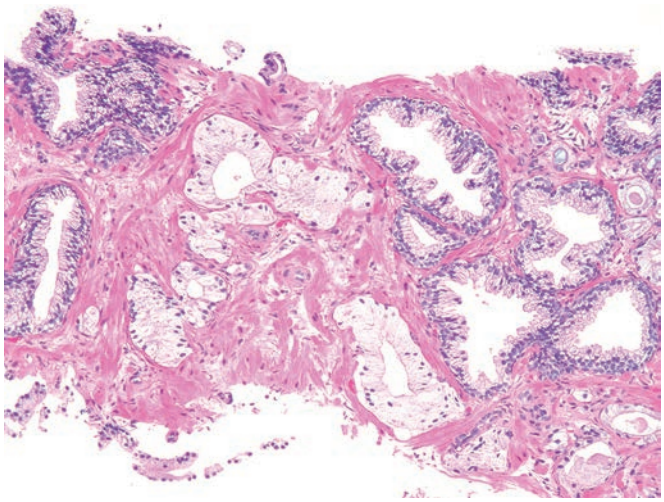

Figure 26.27 Prostatic adenocarcinoma with foamy gland features. The nuclei are often small and condensed in this specific variant.

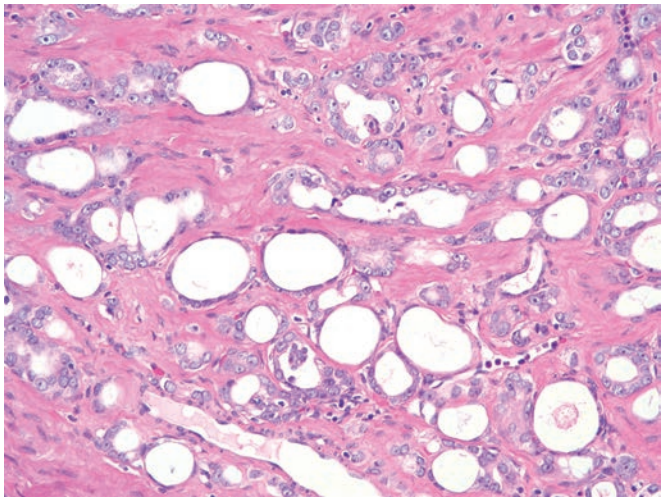

Figure 26.28 Prostatic adenocarcinoma with atrophic features. Despite the lack of cytoplasm, the glands were infiltrative and the nuclei maintained cytologic features of carcinoma.

"Minimal Adenocarcinoma" and Atypical Small Acinar Proliferation

A particularly vexing and increasingly frequent problem in the handling of prostatic needle biopsies is represented by the foci of small atypical glands that are suspicious but not diagnostic

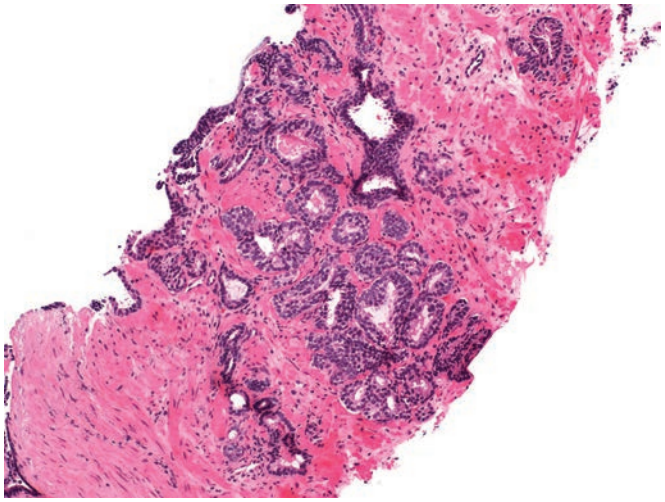

Figure 26.29 Prostatic adenocarcinoma with PIN-like features.

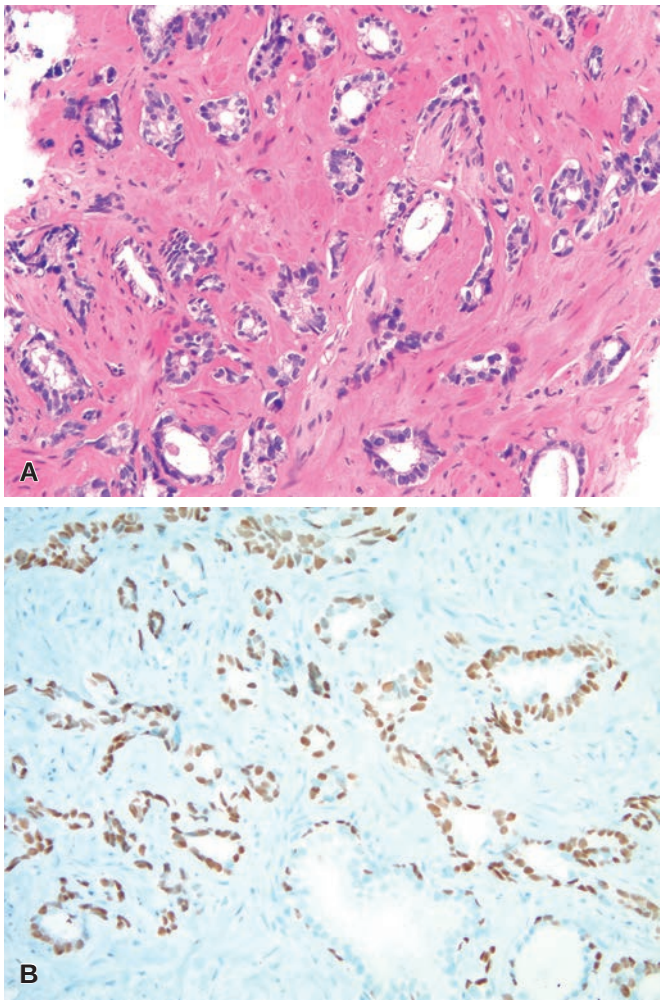

Figure 26.30 **A,** H&E section of an aberrant p63 expressing carcinoma showing somewhat atrophic features with paired p63 immunostaining **(B)**. Importantly, the nuclear staining is in a secretory cell pattern, not a basal cell pattern.

of carcinoma. Minimal criteria for the unequivocal diagnosis of malignancy have been presented.[245-247] These criteria have been particularly well spelled out and illustrated by Grignon.[248] For the cases in which the recommended threshold is not reached, terms such as "atypical glands suspicious of malignancy" and *"atypical small acinar proliferation (ASAP) suspicious of malignancy"* have been proposed.[249-252] However, no matter which criteria are employed, there is inevitable variability in the diagnosis as focal carcinoma versus "atypical suspicious."[253] Approximately 4%–6% of prostatic biopsies cannot be confidently placed into a benign or malignant category, either with morphology alone or after immunostaining with 34βE12 keratin and/or racemase.[254-256] It therefore seems to us wholly appropriate to express this uncertainty in the pathology report, whether using the ASAP acronym or with a descriptive "canned" text, as frustrating as this may be for the urologist and the patient.[257] One thing is certain: a patient with such a diagnosis warrants a second biopsy.[251,258]

Ductal Adenocarcinoma

The other major (but numerically less significant) type of prostatic carcinoma is the ductal subtype, which may be more commonly seen in a periurethral location (Fig. 26.31).[259-262] Cystoscopic examination may show a polypoid villous or an infiltrative urethral component. Microscopically, ductal carcinoma is characterized by papillary and cribriform architecture lined by columnar pseudostratified malignant epithelium (Fig. 26.32).[263] Many prostatic carcinomas presenting as macrocystic tumors (i.e. cystadenocarcinomas) have ductal features.[264] Rarely, the tumor is accompanied by pagetoid spread in the prostatic urethra.[265] Because ductal adenocarcinomas may show intraductal spread, intact basal cells may be identified by immunostains and should not alter a malignant diagnosis.[266] The tumors tend to have a more advanced stage at presentation and a higher short-term survival rate than typical acinar carcinomas, but not when controlled for grade, tumor volume, and stage.[267]

An important point for pathologists is that some prostatic ductal carcinomas may present as small prostatic urethral polyps identified by a transurethral evaluation. The morphologic findings may suggest a villous adenoma of the urothelial tract or a benign prostatic urethral polyp[268]; however, the presence of cribriform growth and/or lining by columnar cells should prompt careful consideration of prostatic adenocarcinoma (Fig. 26.33). Immunoreactivity with PSA and/or NKX3.1 can help with confirmation of prostatic epithelial

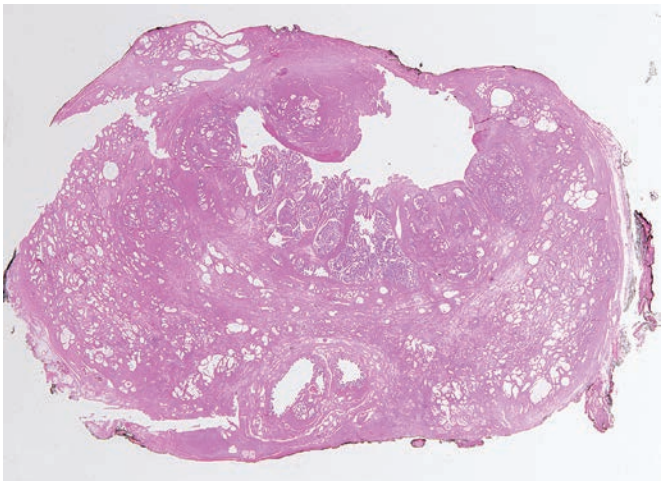

Figure 26.31 **Whole Mount of Ductal Adenocarcinoma.** The tumor is centrally located and has a distinctly papillary configuration.

origin. As in more typical forms of ductal adenocarcinoma, basal cell markers may show a patchy layer of preserved cells. Despite the morphologically subtle features, most of these tumors are high grade and high stage at radical prostatectomy. In approximately 10% of ductal carcinomas diagnosed on transurethral biopsy, no residual tumor is found at radical prostatectomy; therefore, some authors recommend transrectal prostate biopsies to assess extent of disease prior to definitive surgery.[269]

Immunohistochemical Features

Two immunohistochemical markers for prostatic epithelium demonstrable in routinely processed material with polyclonal or monoclonal antibody are PSAP and PSA.[270-273] They do not distinguish between benign and malignant processes in the prostate, but are of great use in identifying the prostatic origin of metastatic tumors, since they are positive in all but the most undifferentiated cases[274-276] and in occasional advanced cases following hormonal therapy.[277] NKX3.1 is a more recently described nuclear marker that has improved sensitivity and specificity over PSA and PSAP and is rapidly becoming the prostatic epithelial marker of choice in many departments.[9,11,278] A combination of these markers is useful in the differential diagnosis between poorly differentiated prostatic and urothelial tumors, especially if used as part of a panel together with high-molecular-weight cytokeratin, p63, and/or GATA3.[279,280]

Another prostate-related marker is so-called "PSMA."[281] This is a membrane-bound glycoprotein that is expressed in all types of prostatic adenocarcinoma. Curiously, this expression *increases* from benign epithelium to high-grade PIN to adenocarcinoma.[282]

The most promising marker to have appeared in recent times and claimed to be highly sensitive for prostatic carcinoma is P504S, a cytoplasmic protein that has been isolated through microarray screening.[283-285] It is an α-methylacyl-CoA racemase (referred to herein as *racemase*) that plays a role in the beta-oxidation of branched-chain fatty acid and fatty acid derivatives.[283] It is related to tumor differentiation,[286] it is not always present in carcinoma,[287] it can be expressed in a very heterogeneous fashion in the same case,[266] and can also be detected in atypical adenomatous hyperplasia, partial atrophy, some benign glands, and PIN.[288,289] The most specific pattern of immunoreactivity is strong circumferential luminal staining. While it can be useful for the detection of small foci of carcinoma in needle biopsies,[290,291] and for the confirmation of a diagnosis of malignancy in particularly difficult types of prostatic carcinoma (such as foamy gland and pseudohyperplastic), it must be used very cautiously with careful morphologic correlation.[292]

Prostatic carcinoma cells are often immunoreactive for androgen and progesterone receptors, but much less so for estrogen receptors.[293-296] The latter is related to the Gleason grade and score.[297] HER2/NEU protein is overexpressed in androgen-independent prostatic cancer, a situation somewhat analogous to that operating in breast carcinoma.[298] Exceptionally they show nuclear staining for CDX2, a potentially dangerous trap in the differential diagnosis with intestinal adenocarcinoma.[299]

Prostatic carcinoma cells are reactive for low-molecular-weight keratins.[300] In contrast to urothelial carcinoma, they stain only rarely for CK7 and CK20.[279,301] However, studies have shown the CK7/CK20 phenotype of prostatic adenocarcinoma is very heterogeneous in high-grade carcinomas, limiting its diagnostic utility.[302] Given the sensitivity and specificity of the NKX3.1 and GATA3 panel for the distinction of poorly differentiated prostatic versus urothelial origin, we would argue that CK7/CK20 profiling is no longer appropriate.

Antibody 34βE12 identifies the high-molecular-weight keratin present in the basal cells in the prostatic glands and is therefore of considerable diagnostic use, it is usually present (although sometimes discontinuously) in benign glands and absent in ordinary adenocarcinoma (of peripheral ducts and acini) regardless of grade.[303-305] Three caveats, however, are in order: (1) this marker is often present, either as a continuous or discontinuous layer, in ductal carcinoma[306]; (2) it may also be expressed, albeit exceptionally, in the carcinoma cells themselves (depending on the antibody clone utilized),[307] a point to remember in the differential diagnosis with urothelial carcinoma[243,308,309]; and (3) most importantly, it may be lacking in small foci of atypical glands, and therefore its absence is not necessarily diagnostic of carcinoma.[310,311] Useful measures proposed to optimize the detection of this important marker include the use of antigen retrieval[312] the systematic preparation of "intervening" unstained slides, in view of the fact that the lesion being evaluated may otherwise be no longer present in the residual block[313]; and the restaining of destained hematoxylin–eosin sections if the above procedure had not been carried out.[314] Other markers that are being used for the same purpose are keratin 5/6 and p63[315-317] or combinations thereof.[289]

A particularly powerful technique for the evaluation of small acinar proliferations is the use of an immunohistochemical multiplex

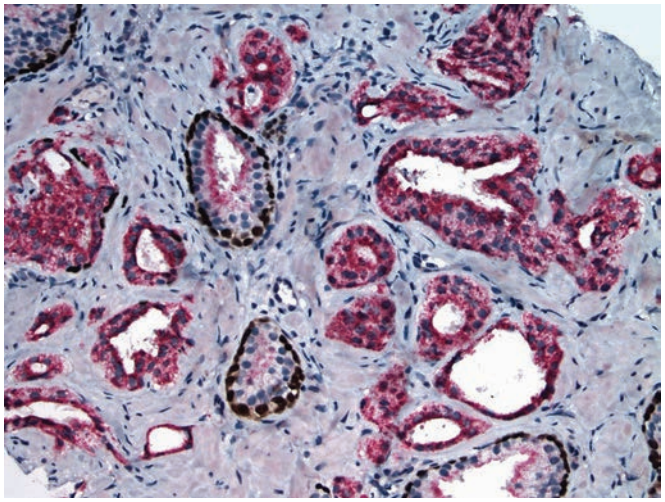

Figure 26.34 Immunohistochemical multiplex stain with HMWCK, p63, and P504S. The carcinoma cells show strong circumferential luminal staining for P504S with an absence of basal cells.

composed of racemase, 34βE12, and p63, or simply racemase and 34βE12.[318-321] Variations in the theme include cocktails made up of 34βE12 and p63,[322] and/or PSA, 34βE12 and/or p63.[323] In an ideal world, a malignant gland should show luminal reactivity for P504S in the luminal cells and absence of staining for the two basal cell markers, whereas the opposite should be true for benign glands (Fig. 26.34).[319] Most of the time it works this way, but the reader will not be surprised when told that exceptions occur with all three of the stains and, therefore, with the resulting pattern.[324,325] These stains should only be used in evaluating a focus suspicious for carcinoma by initial morphologic review and never in blind screening fashion.

Molecular Profile and Genetic Susceptibility

Many cytogenetic and molecular alterations have been described in prostatic adenocarcinoma.[326-329] Allelic loss has been found in about half of the cases,[330-332] and the suggestion has been made that chromosomes 8p, 10q, 13q, 16q, and 17p may be the sites of tumor suppressor genes.[330,333,334]

One of the most common genetic alterations in prostatic adenocarcinoma, found in approximately half of all cases, is fusion of the androgen-responsive serine protease gene *TMPRSS2* (21q22.2) with one of the *ETS* transcription factor gene family members.[334] The latter include *ERG* (21q22.2), *ETV1* (7p21.2), *ETV4* (17q21), and *ETV5* (3q27), with *ERG* accounting for >90% of cases. *TMPRSS2–ERG* fusion usually results from an interstitial deletion at 21q22.2–22.3, which causes juxtaposition of the two genes normally located 3 Mb apart. This molecular alteration appears to be an early event in the development of prostate adenocarcinoma. Interestingly, expression of the fusion transcript is bypassed and downregulated as tumor progresses to become androgen resistant.[335] There have been reports on the association of presence of *TMPRSS2–ERG*, certain gene fusion variants, or increased *ERG* copy number to be correlated with higher clinical stage and more aggressive disease,[334] but most reports have not found any correlation.[336]

Point mutations in *SPOP* are identified in approximately 10% of prostate cancers and are commonly associated with deletions of *CHD1*.[337,338] This *SPOP*/*CHD1*association and their mutual exclusivity with ETS rearrangement suggest a distinct molecular subtype.

Loss of the *PTEN* tumor suppressor gene is a common somatic event in prostate cancer, ranging from 10% to 70% in reported series, and correlates with high-grade and high-stage disease at radical prostatectomy.[339,340] Initial work studied deletions in the *PTEN* locus at 10q23 by FISH, showing that heterozygous *PTEN* deletion is more common than homozygous deletion.[341] Recent studies have shown that immunohistochemical evaluation for PTEN protein loss may serve as a sensitive surrogate for gene deletions.[342,343]

Mutations of *TP53* have been found in a subset of prostatic carcinomas characterized by a highly proliferative pattern and an aggressive behavior.[344] Conversely, alterations of *TP53* and *MDM2* genes are infrequent in clinically localized ordinary adenocarcinomas.[345,346] They are also seen more commonly in samples from metastatic sites than in those from primary tumors.[347] Alterations of the *RB* tumor suppressor gene occur in a significant fraction of prostatic adenocarcinomas.[348] *HER2* gene amplification is seen in about one-third of prostatic adenocarcinoma cases; it correlates with tumor grade, stage, and nondiploid DNA content.[349] It also seems to correlate with androgen independence of the tumor.

Prostatic carcinomas treated with androgen ablation therapy often eventually become androgen resistant. The latter phenomenon usually results from aberrant activation of the androgen receptor by gene amplification, mutation, phosphorylation, activation of coregulators, or androgen-independent activation.[334,350]

Positive family history of prostate cancer in a first-degree relative is an established risk factor for the disease (two- to three-fold risk).[351] While it is estimated that inherited factors account for 40%–50% of cases, it has been difficult to delineate specific genes. This is likely due to the high incidence of prostate cancer in in the general population and the fact that high- to moderate-penetrant gene variants tend to be rare, while more common genetic variants tend to have low penetrance.[352] *BRCA2* mutations have been associated with increased prostate cancer risk (and more aggressive prostate cancer), in addition to their more common breast and ovarian cancer risk.[353-355] *HOXB13* mutation also predisposes to prostate cancer, and a histologic and molecular correlation study demonstrated frequent "pseudohyperplastic morphology" as well as low prevalence of ERG fusion in this group.[356,357] Patients with mutations in mismatch repair gene (Lynch syndrome) also have an increased risk for prostate cancer.[358]

Other Microscopic Types

Several distinct morphologic types of prostatic carcinoma exist, most of them probably representing variants of acinar adenocarcinoma.[359,360] These include the following:

1. **Prostate adenocarcinoma with neuroendocrine differentiation.**

   This is a very difficult area in prostate pathology because of lack of consensus and poor reproducibility. One group of authors has proposed a morphologic classification that includes: usual prostate adenocarcinoma with neuroendocrine differentiation, adenocarcinoma with Paneth cell neuroendocrine differentiation, well-differentiated neuroendocrine tumor (carcinoid tumor), small cell carcinoma, large cell neuroendocrine carcinoma, and mixed neuroendocrine carcinoma-acinar adenocarcinoma.[361] This classification scheme has been recently adopted by 2016 WHO committee. A major problem is that many otherwise typical high-grade prostatic adenocarcinomas express neuroendocrine markers by immunohistochemistry (ranging from 10% to 100% in various series), but this finding has no proven clinical significance.[362] Therefore, immunohistochemistry for neuroendocrine markers is not recommended for cases of morphologically typical high-grade acinar adenocarcinoma.

   A rare subtype of **prostatic adenocarcinoma has Paneth cell–like neuroendocrine differentiation**, characterized by patchy or diffuse presence of cells with eosinophilic cytoplasmic granules. These carcinomas may grow in nests, cords, and single cells, but studies suggest they are clinically indolent and should not be

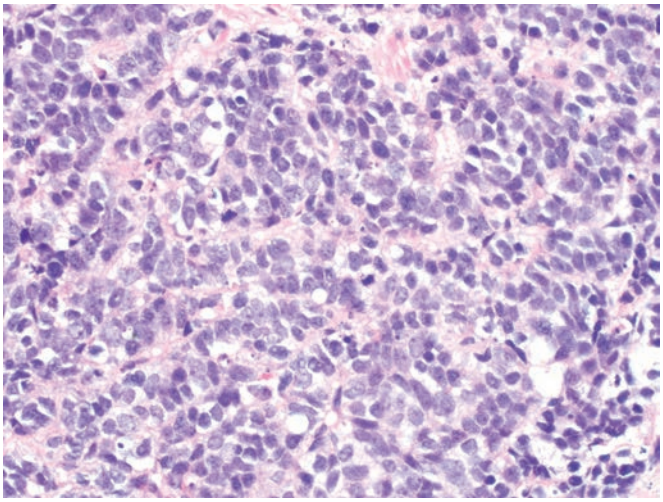

Figure 26.35 Small cell carcinoma of the prostate, morphologically identical to its lung counterpart.

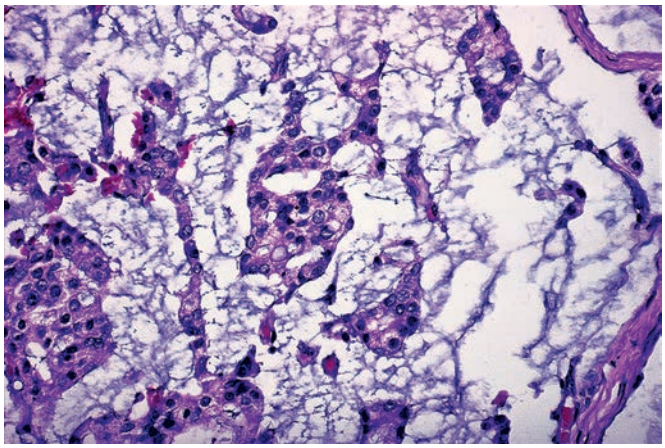

Figure 26.36 Mucinous Adenocarcinoma of Prostate. Most of the mucin is located extracellularly.

graded.[363,364] Primary **well-differentiated neuroendocrine tumor** ("carcinoid tumor") of the prostate gland is exceedingly rare and is morphologically identical to those occurring in other anatomic locations.[365] These may be more common in multiple neuroendocrine neoplasia syndromes.[366] As in other sites, well-differentiated neuroendocrine tumors often have a favorable prognosis.

Small cell carcinoma is morphologically similar to the homonymous lung tumor (Fig. 26.35).[367-369] This can present in a pure form or be associated with ordinary adenocarcinoma, either synchronously or metachronously.[368,370,371] Some of these tumors have resulted in Cushing syndrome[372] or inappropriate antidiuretic hormone secretion.[373] Features of endocrine differentiation are demonstrable immunohistochemically in some but not all of these cases.[374,375] In one large series, 88% of the tumors were positive for at least one neuroendocrine marker. PSA is positive in less than 20% of the cases, TTF-1 in about one-half, and CD44 reportedly in 100%.[368,376] These tumors feature a large number of apoptotic cells,[377] and their behavior is very aggressive.[367] On occasion, morphologically different forms of neuroendocrine differentiation (Paneth cell–like and small cell) are seen in the same neoplasm.[378] The main differential diagnosis is with high-grade (Gleason 5) prostatic adenocarcinoma.[379] In pure form, it may be difficult to determine if a small carcinoma is of prostatic or urothelial origin; however, that distinction has little relevance to treatment.

The last member of the neuroendocrine family to have been described in the prostate is **large cell neuroendocrine carcinoma**. Some of the reported cases have arisen after long-term hormonal therapy for prostatic adenocarcinoma.[380] This category is most problematic with regard to diagnostic criteria and reproducibility because of overlap with otherwise typical high-grade acinar adenocarcinomas.

2. **Mucinous (mucin-secreting) adenocarcinoma.** This tumor is accompanied by the formation of large amounts of intracellular and extracellular mucin, comprising 25% or more of the tumor (Fig. 26.36).[381,382] Its microscopic appearance is reminiscent of mucinous carcinoma of the breast. Microglandular, cribriform, "comedo," solid, and hypernephroid patterns may be present.[383] PSAP and PSA stains are usually positive. This tumor is said to differ from the ordinary prostatic adenocarcinoma by the rarity of bone metastases, the lack of hormone dependency, and less degree of response to radiation therapy. As a group, they do not seem to be more aggressive than garden-variety prostatic adenocarcinomas.[384] The differential diagnosis includes extension of mucinous carcinoma from the large bowel and Cowper's gland carcinoma.[385,386] Rare mucinous adenocarcinomas of urothelial origin are also described in the prostatic urethra and should be distinguished from those of prostatic origin.[387] Occasional mucin-secreting adenocarcinomas contain a population of neuroendocrine (including Paneth-like) cells.[388]
3. **Signet ring carcinoma.** This highly malignant neoplasm grows in a solid, acinar, or single file fashion and is composed primarily or exclusively of tumor cells with a signet ring configuration resulting from the intracellular accumulation of mucin.[389-392] Ultrastructurally, the cells have intracytoplasmic lumina lined by microvilli.[393] A treacherous artifact closely mimicking signet ring cells may be seen in the stromal cells and lymphocytes present in the stroma of TUR specimens.[394] The differential diagnosis includes involvement by either signet ring cell adenocarcinoma or plasmacytoid urothelial carcinoma of the urinary bladder or prostatic urethra.
4. **Adenosquamous carcinoma.** Some of these cases have been seen de novo, whereas others have occurred after radiation or hormonal therapy of ordinary adenocarcinomas (Fig. 26.37).[219,395-398]
5. **Squamous cell carcinoma.** Pure squamous cell carcinoma of the prostate is an extremely rare neoplasm. It can occur de novo or after hormonal therapy.[219,399-401] It has also been seen presenting as a well-circumscribed nodule in the prostatic transition zone.[402] It is closely related to adenosquamous carcinoma and in most cases probably represents the extreme manifestation of a similar metaplastic squamous change.
6. **Adenoid basal cell tumor.**[403,404] This process resembles adenoid cystic or basal cell carcinoma of the salivary gland. Some authors have regarded it as analogous to these carcinomas, while others classify it within the spectrum of basal cell hyperplasia.[170,263,405] The natural history of this tumor is much more indolent than that of the bona fide adenoid cystic carcinoma.[403,406] The key microscopic features are expansile pattern of growth, multinodularity, a cribriform architecture with luminal-basal lamina–like material, a surrounding fibromyxoid stroma (resembling stromal hyperplasia), common occurrence of squamous differentiation, and merging with foci of basal cell hyperplasia (Fig. 26.38). PSAP and PSA staining is negative or focally positive. The differential diagnosis includes acinar adenocarcinoma with cribriform pattern of growth, basaloid carcinoma (see immediately next), and true adenoid cystic carcinoma. As for the alternative term basal cell

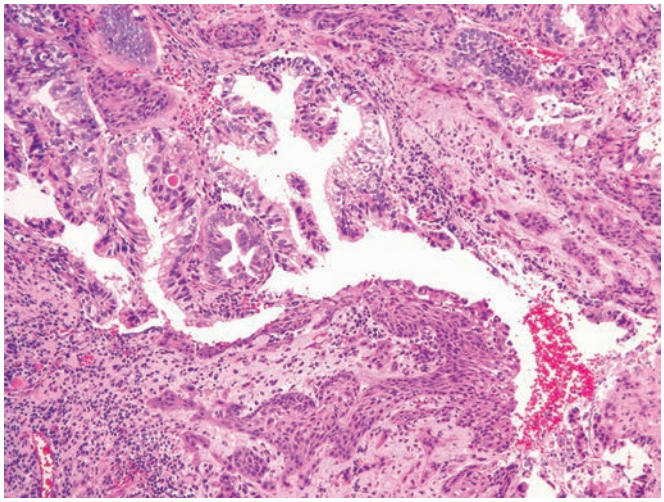

Figure 26.37 Adenosquamous carcinoma of the prostate gland, occurring after radiation therapy.

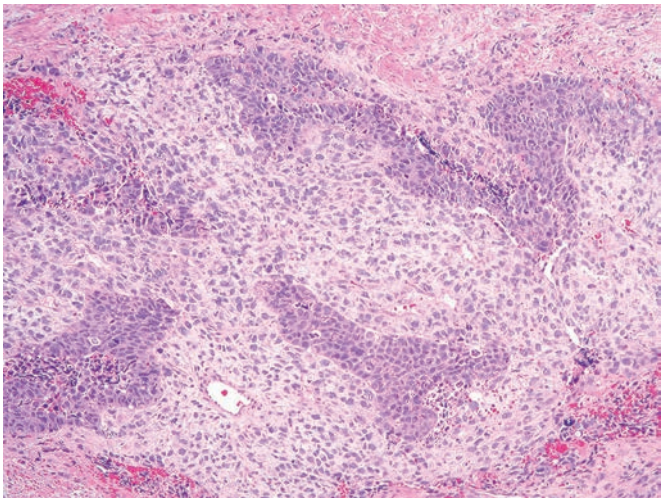

Figure 26.39 Sarcomatoid carcinoma of the prostate gland.

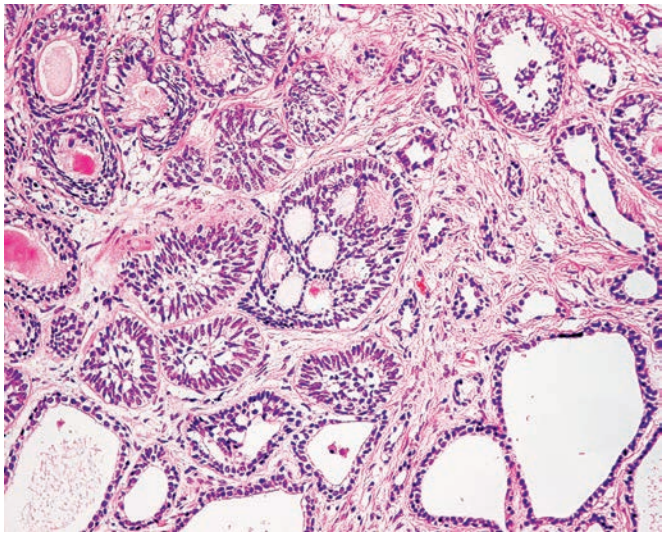

Figure 26.38 So-called adenoid basal cell tumor of prostate. The central tumor nest shows an appearance reminiscent of that seen in adenoid cystic carcinoma of salivary glands.

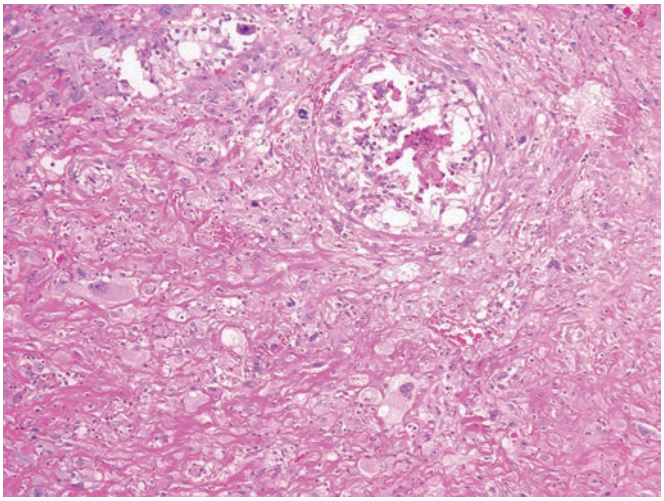

Figure 26.40 Pleomorphic giant cell carcinoma of the prostate gland.

carcinoma, in our opinion it should be avoided on morphologic and behavioral grounds.

7. **Basal cell carcinoma and adenoid cystic carcinoma.** While extremely rare, basal cell carcinoma is highly aggressive and has morphologic features comparable to those of basaloid (cloacogenic) carcinoma of the anal canal and basaloid squamous cell carcinoma of the upper aerodigestive tract[403,407] and should be clearly separated from adenoid basal cell tumor. Unfortunately, this is not always done and confusion ensues. Adenoid cystic carcinoma of the prostate is often reported under the term "basal cell carcinoma," but it has distinct morphology identical to its salivary gland counterpart.[170,408] Additionally, an identical *MYB* rearrangement is found in some cases, strongly supporting a unique neoplasm distinct from basal cell carcinoma.[408]
8. **Lymphoepithelioma-like carcinoma.** The appearance of this tumor is analogous to that of nasopharyngeal lymphoepithelioma.[409]
9. **Sarcomatoid carcinoma.** This tumor combines features of recognizable carcinoma with sarcomatoid elements, the latter having either nonspecific spindle cell or giant cell features, or showing divergent differentiation toward cartilage, bone, and/or skeletal muscle (Fig. 26.39).[410-413] The recently described *pleomorphic giant cell adenocarcinoma* can be regarded as a subtype of sarcomatoid carcinoma (Fig. 26.40).[414,415] The epithelial component is usually of adenocarcinoma type, but it may also have squamous features.[416] As in other sites, the distinction between carcinosarcoma and sarcomatoid carcinoma is arbitrary and probably unwarranted; most of the available evidence suggests that, whether a specific mesenchymal component is present or not, the tumor is in all likelihood of epithelial derivation.[410,417-419]

Intraepithelial Proliferative Lesions

PIN is the currently preferred term for a process involving prostatic ducts and acini, which has also been described as ductal–acinar dysplasia.[420,421] It is often multicentric and may be seen in all anatomic regions of the prostate gland. While originally divided into different "grades," only high-grade PIN is diagnosed and reported in modern practice. The reproducibility and clinical significance of lower-grade lesions is questionable at best. On scanning magnification, the glands of high-grade PIN appear more basophilic than surrounding glands due to the high nuclear to cytoplasmic ratio, nuclear crowding, and

more amphophilic cytoplasm. The presence of large nuclei with prominent nucleoli is the defining feature (Fig. 26.41). Importantly, to avoid overdiagnosis one should not need high-power magnification to see the nucleoli of high-grade PIN. The secretory cell nuclei near the basement membrane typically have the most pronounced cytologic atypia. Morphologic variations of PIN include *tufting*, *micropapillary*, *cribriform*, and *flat/atrophic* patterns at the architectural level, and *inverted (hobnail)* and *foamy* types at the cytologic level.[422-425] Of these, the cribriform pattern is the most difficult to distinguish from invasive tumors or intraductal carcinoma, particularly in biopsy specimens.[426] The presence of more than very focal cribriform architecture within a medium caliber gland should prompt consideration of intraductal carcinoma (see later).

Several studies have shown a statistical association between high-grade PIN and prostatic carcinoma, in the sense that PIN has been found in 59%–100% of step-sectioned radical prostatectomy specimens. It has also been shown that in prostates containing both PIN and adenocarcinoma, there is a good degree of concordance in the DNA ploidy pattern of both lesions.[427-429] These findings have led to the suggestion that PIN may have a high predictive value as a marker for carcinoma and to the recommendation to follow closely patients in whom PIN is identified in a prostatic biopsy.[430,431] It has also been shown that low-grade PIN is a relatively common finding in young male patients.[432]

In a study by Kronz et al.[433] repeat prostatic biopsy in patients with previous biopsy of high-grade PIN revealed invasive carcinoma in 32.2% of the cases. The incidence was 30.2% if only 1 or 2 cores had showed PIN, 40% with 3 cores, and 75% with >3 cores. If invasive cancer was not diagnosed on the first two follow-up biopsies, it was unlikely to develop later. If PIN was accompanied by the presence of adjacent small atypical glands, the risk of cancer on repeat biopsy was 46%.[434] Several more recent series have shown a much lesser degree of risk, to the point of raising questions at the predictive value of high-grade PIN.[435] However, Netto et al.[436] reestablished the prognostic significance of PIN by showing a 39% risk of finding prostatic carcinoma on repeat biopsies if the original biopsy had shown widespread (present in 4 or more biopsy cores) high-grade PIN. It would seem then as if the risk of cancer were directly related to the number of cores involved by PIN and not so much to the morphologic subtype.[437] Argument still persists as to the need for re-biopsy in men with only high-grade PIN on biopsy, regardless of extent. Particularly in the era of active surveillance, a few foci of high grade PIN often do not alter clinical follow-up strategies.

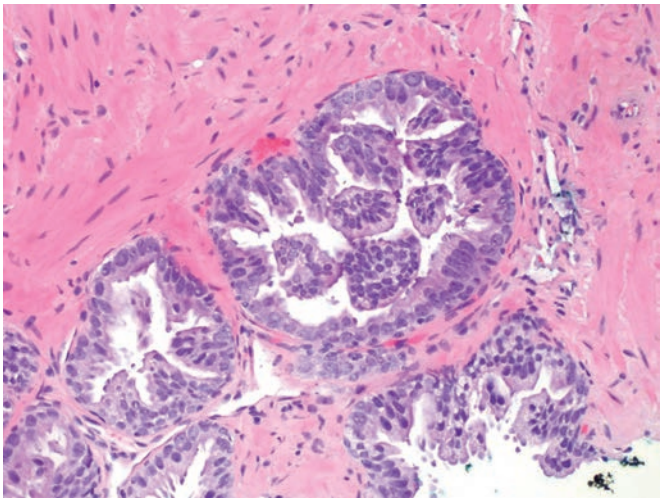

Figure 26.41 High-grade prostatic intraepithelial neoplasia.

Intraductal Carcinoma

While originally described in 1973,[438] intraductal carcinoma has become better recognized over the past decade and is now a distinct entity in the WHO Classification.[439] Numerous studies show the presence of intraductal carcinoma on biopsy is commonly associated with high-grade, high-stage disease at radical prostatectomy,[440-442] and predicts poor disease-specific survival.[443] Intraductal carcinoma is generally regarded as a late phase of intraductal spread by an aggressive carcinoma, but rare cases show only intraductal carcinoma, even at radical prostatectomy.[441]

Because intraductal carcinoma must be distinguished from PIN, precise histologic criteria are critical. Guo and Epstein defined intraductal carcinoma as malignant epithelial (i.e. prostatic secretory) cells filling large prostatic acini or ducts, with at least partial preservation of basal cells, forming either: (1) solid or dense cribriform patterns or (2) loose cribriform patterns or micropapillary patterns with either marked nuclear atypia (nuclear size 6× normal or larger) or nonfocal comedonecrosis. These malignant cells often involve and expand branching ducts and extend into adjacent acini (Fig. 26.42 A and B). Intraductal carcinoma is not factored into the Gleason grade but should be reported separately. Providing a comment discussing the prognostic significance with supporting references is often

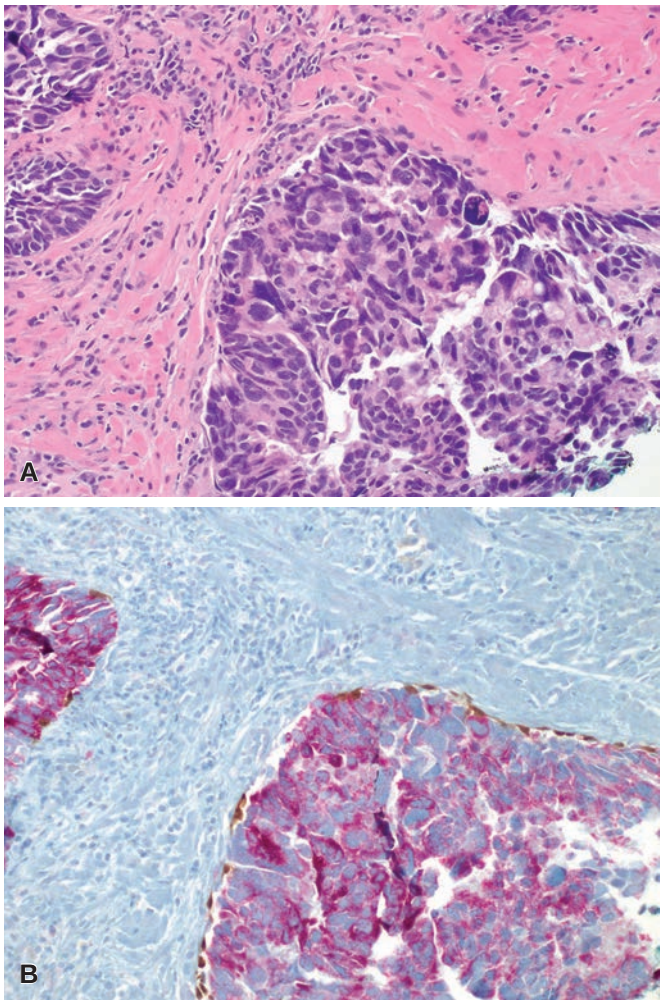

Figure 26.42 **A,** Intraductal carcinoma is characterized by a dense population of malignant cells filling the lumen. **B,** By definition, there is an intact basal cell layer (high molecular weight keratin, p63, and racemase stain).

helpful as varying levels of familiarity with this lesion are encountered.

Intraductal carcinoma may have histologic overlap with ductal adenocarcinoma, invasive acinar adenocarcinoma with cribriform architecture, and prostatic colonization by urothelial carcinoma. Ductal adenocarcinoma of the prostate often spreads within ducts (with retained basal cells), so the distinction from intraductal carcinoma may be difficult. Ductal carcinoma often has a true papillary architecture and neoplastic cells with a pseudostratified columnar morphology, compared to the typical cuboidal cells with relatively round nuclei in intraductal carcinoma. Invasive acinar adenocarcinoma with cribriform architecture typically has a more irregular distribution, other patterns of invasion, more variation in size and shape of the cribriform structures, and an absence of basal cells by immunohistochemistry. Urothelial carcinoma colonizing prostate glands may be distinguished by an absence of prostatic marker expression and reactivity for high-molecular-weight keratin, p63, and/or GATA3.

The distinction of high-grade PIN from intraductal carcinoma is critical for clinical management. Complex cribriform or solid architecture bridging the entire luminal space and extending into adjacent glands/ducts strongly argues for intraductal carcinoma. If the proliferation is not dense and/or does not bridge the entire space, then one must adhere to the nuclear pleomorphism criterion (i.e. 6× normal). Some cases are difficult to definitively classify, but given the implication of an intraductal carcinoma diagnosis, strict criteria must be followed. In borderline cases, a descriptive diagnosis such as "atypical intraductal proliferation" with an appropriate comment is justified to ensure re-biopsy. PTEN protein loss by immunohistochemistry has been suggested as surrogate marker to aid in the diagnosis of intraductal carcinoma, but its use is not widespread.[444,445]

Tissue Examination

Routine histologic evaluation of prostate tissue is generally based on initial transrectal biopsy or TUR specimens, and definitive radical prostatectomies. There is general agreement that adequate sampling of the core biopsy material entails cutting and staining three levels per core (step sections), with additional section(s) to be taken if atypical features are found.[446-449] Saving in-between unstained levels for possible immunohistochemistry is utilized at many centers and helps avoid loss of small atypical foci in deeper level sections. Specific recommendations on the amount of information to be included in the pathology reports of adenocarcinomas in core needle biopsy specimens are also available.[450,451]

The presence of tumor in a TUR specimen may signify extensive spread by conventional carcinoma from the peripheral portion of the gland or may be a manifestation of the rare type of carcinoma from the transition zone. The probability of detecting a carcinoma in a TUR specimen is directly related to the amount of sampling.[452] It has been estimated that if five blocks or 12 g of randomly selected chips are submitted, approximately 90% of the carcinomas will be detected.[453,454] With examination of eight blocks, the probability of detection rises to 98%.[455,456] The need for submission of remaining tissue in the cases in which incidental carcinoma is found depends on whether the lesion is a T1a (recommended) or T1b (not needed).[457]

Radical prostatectomy specimens can be examined by performing whole-mount sections or by accurately mapping the organ with standard-size sections.[458-461] The former produces material that is easier to evaluate and esthetically more pleasing but at a considerable investment of time and money. The mapping with standard-size sections, if properly done, provides roughly the same amount of information. For small, nonpalpable tumors, it has been recommended to sample the entire posterior region of the organ and to take an additional sections from the mid-anterior region of each lobe; if the latter is found to be positive, the entire ipsilateral region should be sampled.[461] The International Society of Urological Pathology (ISUP) has provided detailed recommendations for the evaluation and submission of radical prostatectomy specimens.[462]

Metastases

The most common sites of metastatic spread of prostatic carcinoma are the skeletal system and lymph nodes. Bone metastases are usually multiple but can be solitary.[463,464] They are characteristically osteoblastic and can radiographically simulate Paget disease or even osteosarcoma,[465] but they can also be mixed or entirely osteolytic. Sometimes, the appearance of a bone metastasis precedes by several years the urologic manifestations. Lumbar spine, sacrum, and pelvis are the most common locations, supposedly as a result of tumor spread via Batson's vertebral venous system.[466] However, any other bone can be involved through the systemic circulation.[467] Microscopically, clusters of malignant glands are seen surrounded by exuberant new bone formation. When the bone metastases are extensive, they can be accompanied by hypocalcemia, hypophosphatemia, and increased serum alkaline phosphatase levels.[468] Immunohistochemical reactions for PSAP, PSA, and NKX3.1 are usually positive, even after decalcification.

The most common pathway of nodal involvement is to the pelvic chains, from which the tumor spreads to the retroperitoneal nodes. However, in some instances, retroperitoneal node metastases may occur in the absence of pelvic node metastases; these patients are less likely to have metastases to bladder and rectum but more likely to have them in lungs and liver.[469] Rarely, metastases are also found in periprostatic/periseminal vesicle lymph nodes or in the perirectal lymph node basin.[470,471] The performance of surgical staging (including bilateral pelvic lymphadenectomy) has provided important information on the frequency of regional lymph node involvement and the pattern of spread of prostatic carcinoma.[472-475] Stage T1c tumors (nonpalpable, asymptomatic tumors) found because of serum PSA elevation have a very low incidence (<5%) of positive nodes. Latent prostatic carcinomas detected at autopsy are almost never accompanied by nodal metastases.[476]

Metastases can also occur in supradiaphragmatic lymph node groups.[477] Sometimes, involvement of a left supraclavicular[478,479] or a mediastinal node[480] is the first manifestation of the disease. Most of these tumors are poorly differentiated and not particularly suggestive of a prostatic origin on microscopic examination[481]; immunohistochemical staining is extremely valuable in establishing the prostatic origin of a metastatic adenocarcinoma.[482,483] In an older man, this possibility should always be considered when facing a poorly differentiated carcinoma of unknown primary site with relatively monomorphic round nuclei.

Lung metastases are not as rare as formerly believed; most of them exhibit a lymphangitic pattern of spread. Massive pleural effusion may be the initial symptom. On occasion, the process simulates primary lung carcinoma.[484] The pattern of growth may be microacinar, tubulopapillary, or carcinoid-like. Metastatic ductal adenocarcinoma may simulate metastatic colonic adenocarcinoma.[485]

Rarely, metastatic prostatic carcinoma is found unexpectedly in orchiectomy specimens.[486] Prostatic carcinoma also may metastasize to the breast, sometimes bilaterally, particularly in patients taking estrogens. This phenomenon is often confused clinically with gynecomastia and microscopically with primary breast carcinoma. In this regard, it is pertinent to note that several cases of primary breast carcinoma have been reported in patients treated with estrogen for prostatic carcinoma.

Other metastatic sites include liver, adrenal gland, central nervous system (including dura), eye, skin, and unusual locations such as

umbilicus ("Sister Mary Joseph nodule"), penis, and salivary gland.[486-498] In general, the degree of microscopic differentiation of the metastases and of PSA expression follows quite closely that of the primary tumor.[499,500] However, in almost half of the cases the Gleason score appears higher than in the primary tumor.[501]

Staging and Grading

Prostatic carcinoma spreads initially within the various compartments of the prostate itself, including ducts and acini, fibromuscular stroma, perineurial spaces, and blood vessels.[502,503] Extraprostatic invasion is common. Advanced tumor may extend into the seminal vesicles,[504,505] apex (distal aspect) of the gland, prostatic urethra (very rarely), and urinary bladder.[506]

The staging of prostatic adenocarcinoma in a radical prostatectomy specimen depends on histologic evaluation for extraprostatic extension. This may occur as infiltration of the carcinoma beyond the soft tissue plane at the prostatic interface with adipose tissue (Fig. 26.43), or less commonly beyond the contour of the prostate gland. Microscopic invasion of the smooth muscle taken at the bladder neck is also defined as extraprostatic extension (pT3a); however, this should be distinguished from direct invasion of the urinary bladder (pT4 disease), which generally requires macroscopic tumor involving the bladder with histologic confirmation, often by separate biopsy. In the interpretation of needle biopsies or radical prostatectomies, it should be remembered that there are normally bundles of striated muscle within the prostate gland, especially in the apex and anterior aspects; therefore the presence of prostatic glands adjacent to a skeletal muscle fiber is not necessarily evidence of carcinoma, nor is the presence of skeletal muscle adjacent to a carcinoma evidence that the tumor has extended outside the gland. Tumors should be listed as exhibiting seminal vesicle invasion (pT3b disease) only if the muscular wall of this organ is infiltrated by tumor.[507]

Rectal invasion is much less common, supposedly because of the resistance offered by the tough fibromuscular structure covering the posterior aspect of the prostate known as Denonvilliers fascia.[508] This invasion can manifest in the form of an anterior rectal mass (with an intact or ulcerated mucosa), an annular rectal stricture resulting from circumferential infiltration, or subserosal implants.[509] The diagnosis can be made from a colorectal biopsy, but only if the pathologist thinks of the possibility (a good example of Dr. Ackerman's "The man from Istanbul syndrome"!).[510,511]

The microscopic grading system developed by Gleason in conjunction with the Veterans' Administration Cooperative Urological Research Group[512,513] is currently preferred (with the modifications discussed later) to the other grading systems that have been proposed over the years.[514-518] It is based on the degree of glandular architectural differentiation and the growth pattern of the tumor in relation to the stroma as evaluated on low-power examination (Figs. 26.44–26.47; Table 26.1). The predominant tumor pattern (referred to as "primary") is graded from 1 to 5, and the "secondary" pattern (if present) is graded similarly, with the two numbers being added to obtain the Gleason *score* or *sum*. If the tumor has the same pattern throughout (i.e. it has only a "primary" pattern), the number is multiplied by 2 in order to obtain the final score.[519] Some tumors have a tertiary (or minor) pattern, which is reported only if it is of a higher grade.[520,521] In biopsies, the minor high-grade pattern is incorporated into the Gleason score. Gleason patterns 1 to 2 are not clinically meaningful in modern practice, so the grading system effectively begins at Gleason score 3 + 3 = 6.[451]

Criteria for Gleason pattern assignment have evolved over the past 50 years. Under the 2014 criteria, Gleason pattern 3 is comprised only of well-formed glands with central lumina.[451] Importantly, cribriform glands are no longer allowed in the pattern 3 category.

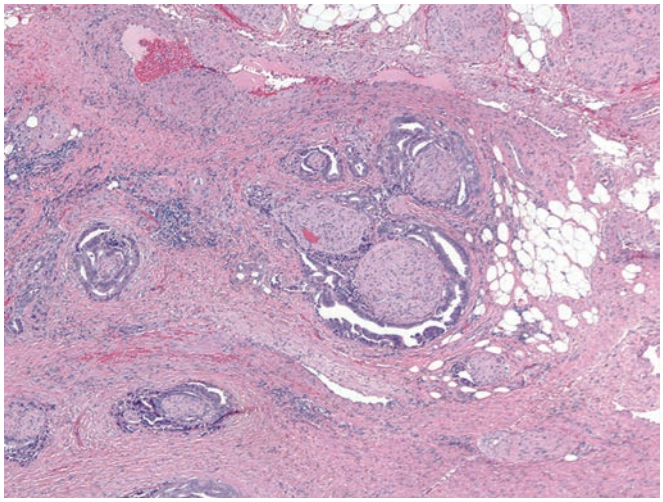

Figure 26.43 Extraprostatic extension as evidenced by prostatic adenocarcinoma extending into adipose tissue.

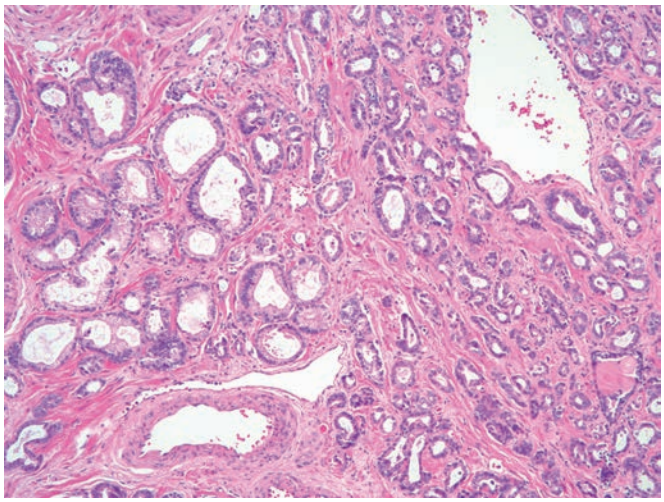

Figure 26.44 Prostatic adenocarcinoma, Gleason score 3 + 3 = 6/10 (Grade Group 1) characterized by distinct well-formed glands.

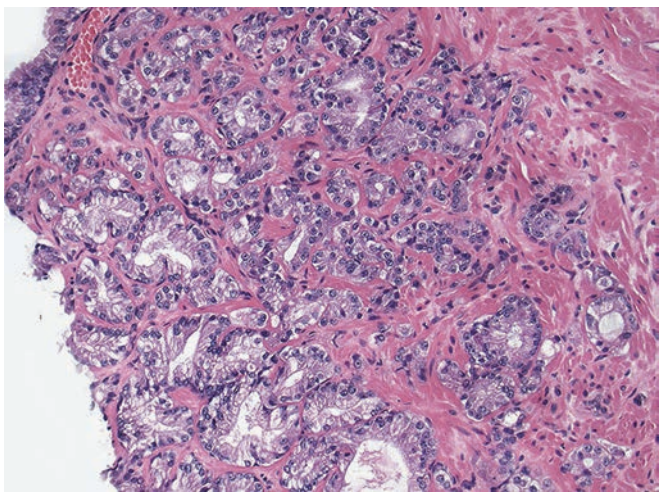

Figure 26.45 Prostatic adenocarcinoma, Gleason 3 + 4 = 7/10 (Grade Group 2). Pattern 4 is composed of "poorly formed glands."

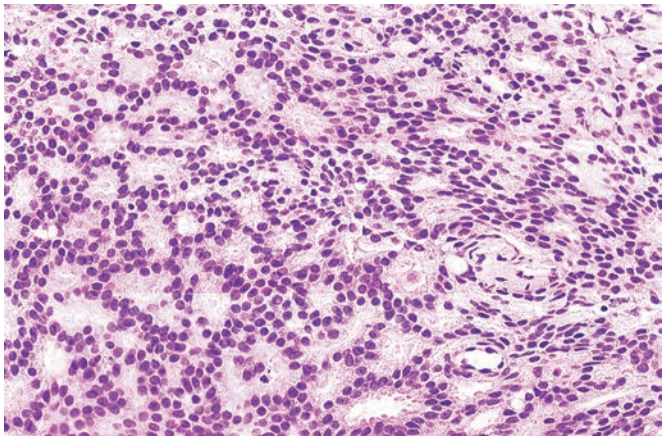

Figure 26.46 Gleason pattern 4 carcinoma characterized by cribriform glands.

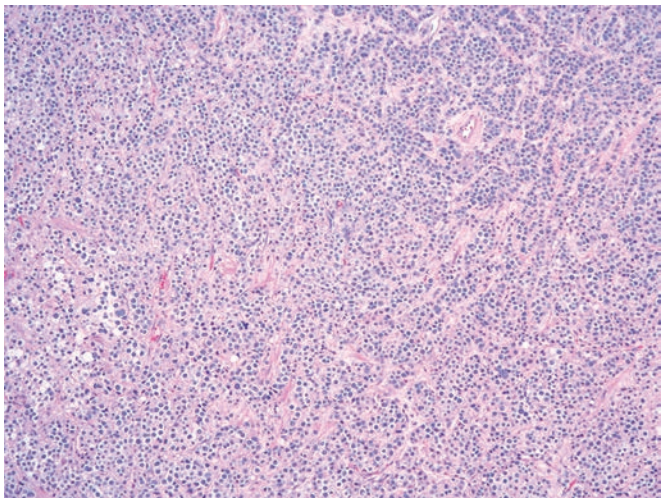

Figure 26.47 Gleason pattern 5 characterized by solid sheet-like growth.

Gleason pattern 4 is heterogeneous and includes cribriform glands, glomerulations, "fused glands," and poorly formed glands. Pattern 5 carcinomas lack gland formation and are comprised by sheets, cribriform glands with central comedonecrosis, and single infiltrating cells mimicking lobular breast cancer. Subtle variants, such as pseudohyperplastic, atrophic, or "PIN-like" carcinoma, are graded by the same criteria but are typically Gleason score 3 + 3 = 6. Grading in the setting of mucinous fibroplasia is problematic, but the ISUP recommends to "subtract away" the mucinous fibroplasia and to grade based on underlying gland architecture.

As active surveillance has become more accepted, the threshold for distinguishing Gleason score 3 + 3 = 6 from 3 + 4 = 7 carcinomas has become more important. Historically, this has been the threshold for identifying aggressive cancer, an idea that is now being questioned as more men with 3 + 4 = 7 carcinomas are offered surveillance at some centers. The threshold for determining the presence of focal "poorly formed glands" varies and reproducibility for this decision is low[522]; therefore, the ISUP has suggested a conservative grading approach, such that difficult borderline cases are graded "down" to avoid potential for overtreatment.[451]

More recently, the Grade Group system has become adopted as a way to better report the Gleason score categories (see Table 26.1).[451,523-525] The Grade Group categories range from 1 to 5, such that low-risk tumors (Gleason score 3 + 3 = 6) are more appropriately designated as Grade Group 1. Additionally, it prevents collapsing of Gleason score categories, such as 3 + 4 = 7 and 4 + 3 = 7, which are more clearly separated as Grade Groups 2 and 3, respectively. This system also offers a framework for potential modifications, such as incorporating the presence of cribriform morphology.[526]

Table 26.1 2014 modified Gleason grading and Grade Group comparison

GRADE GROUP	GLEASON SCORE	HISTOLOGIC FEATURES
1	≤3 + 3 = 6	Only individual discrete well-formed glands
2	3 + 4 = 7	Predominantly well-formed glands with lesser component of poorly formed glands, fused glands, glomerations, or cribriform glands
3	4 + 3 = 7	Predominantly poorly formed glands, fused glands, glomerations, or cribriform glands with lesser component of well-formed glands (if >5%)[a]
4	4 + 4 = 8 3 + 5 = 8 5 + 3 = 8	Only poorly formed glands, fused glands, glomerations, or cribriform glands[a] Predominantly well-formed glands with lesser component of sheets, cribriform glands with comedonecrosis, or single cells Predominantly sheets, cribriform glands with comedonecrosis, or single cells with lesser component of well-formed glands (if >5%)[a]
5	≥4 + 5 = 9	Only sheets, cribriform glands with comedonecrosis, or single cells[a]

[a]A lower-grade component, when less than 5% of the carcinoma, is not incorporated into the grade.

Microscopic grading of prostatic adenocarcinoma has been found to correlate well with PSAP and PSA levels,[527,528] clinical and pathologic staging,[529-531] incidence of lymph node and bone metastases,[532,533] survival rate, and response to therapy.[534-536]

Treatment

The management choices for localized prostatic carcinoma are radical prostatectomy, external radiation therapy, brachytherapy, evolving focal therapies (e.g. cryotherapy or high-intensity focused ultrasound [HIFU]), and active surveillance (or watchful waiting).[537]

Hormonal manipulation in the form of estrogens, luteinizing hormone–releasing hormone (LH-RH) analogues, and antiandrogens has mostly replaced orchiectomy as a palliative measure in locally advanced and metastatic tumor, particularly to relieve the severe pain sometimes associated with skeletal disease.[538-541] Marked tumor regression can occur as the result of apoptosis, manifested microscopically by vacuolization of the cytoplasm, rupture of cell membranes, pyknosis, naked nuclei, and decreased expression of racemase.[542-544] Combined endocrine therapy (LH-RH agonist and flutamide) results in a striking vacuolization of the tumor cells, which may appear as isolated elements with a hemangiopericytoma-like appearance.[545-551] Another alteration that has been described following neoadjuvant

androgen ablation therapy is a peculiar pseudomyxoma-like change in the prostatic stroma resulting from mucin extravasation.[552] These alterations may result in considerable difficulties in recognizing the tumor cells. In such instances, immunohistochemistry (particularly for PSMA) can be of diagnostic assistance.[553]

Systemic chemotherapy historically has had minimal benefit in hormone-refractory metastatic prostatic carcinoma; however, newer options are now available including chemotherapeutic agents (e.g. docetaxel and cabazitaxel) and next-generation hormonal therapies (e.g. abiraterone and enzalutamide).[554-557]

Prognosis

Many parameters have been evaluated for their ability to predict outcome in patients with prostatic carcinoma, and they are listed next. Because of the usually long natural history of the disease, the PSA-free survival and PSA recurrence have been used in some of the studies as surrogates for actual survival and recurrence, respectively.

1. *Clinical stage*. This is a very important prognostic determinant, and it has become even more so with the incorporation of newer technology.
2. *Pathologic stage*. This represents the ultimate indicator of tumor extent and, as such, the most accurate predictor of prognosis currently available.[558,559] Naturally, there is also a relationship between prognosis and the status of the individual factors that determine the stage, such as the prostatic capsule, the seminal vesicles, and the lymph nodes.[560] Thus, there is a strong association between the level of tumor invasion into or through the prostatic capsule and the grade, volume, and rate of recurrence of the tumor.[561] There is also an association between the radial distance of extraprostatic extension (as measured by an ocular micrometer) and PSA recurrence.[562] In cases with nodal metastases, the prognosis is worse when they are multiple rather than solitary, when they are detectable grossly rather than only microscopically, when their overall volume is large, and when they are accompanied by extracapsular extension.[563-566]
3. *Microscopic grading*. A direct correlation exists between clinical or pathologic staging and microscopic grading regardless of the grading system used.[567] In addition, there is convincing evidence that microscopic grading using the Gleason score system (or related Grade Group system) is superior to the others as an independent prognostic variable.[516,451,523-525] In a particularly impressive multivariate analysis of 185 cases of prostatic carcinoma treated by radical prostatectomy, Gleason score was by far the best predictor of progression. In another study involving 1143 consecutive patients who had radical prostatectomy for localized prostatic carcinoma, Gleason grade was found to be the only significant predictor of disease outcome.[568] There is some suggestion that the predictive power of the Gleason scheme could be increased even further by taking into account the tertiary pattern whenever present.[569]
4. *Surgical margins*. In a multivariate analysis of over 500 retropubic prostatectomy specimens, positive margins strongly correlated with progression.[570] Several other studies have confirmed the value of margin status as an indicator of an increased risk of tumor progression.[571-573] Positive margins indicative of extraprostatic extension should be distinguished from those resulting from *capsular incision*, in which the surgeon transects either benign or malignant prostatic tissue and leaves the edge of the prostate within the patient, a not particularly easy determination.[574]
5. *Tumor volume*. It has been shown that tumor volume, as measured in whole sections of prostatectomy specimens with morphometric techniques, correlates with Gleason score, capsular penetration, capsular margins of resection, seminal vesicle invasion, and lymph node metastases.[575] However, there is some question whether measurement of tumor volume provides additional prognostic information beyond that given by the parameters already listed (particularly the Gleason score), and it is therefore difficult to justify in routine practice the use of a technique that involves the performance of step sections of the whole specimen and the measurement of the tumor at 3-mm intervals with computer-assisted image analysis.[576] Some reasonable compromises have been proposed to make the determination more acceptable to the overwhelmed general surgical pathologist.[576-579] Common methods include visual estimate of percent gland involvement and/or providing the greatest (or two greatest) linear dimensions of tumor. While on the subject of tumor volume or surface, it could be mentioned that even the roughest estimations of tumor amount in core needle biopsy material—such as percentage of cancer or number of positive cores—bear a prognostic significance.[580] Therefore, it becomes important for the pathologist to provide a quantitative estimate of tumor amount in prostate needle biopsy specimens.[581,582] Providing the length of cancer in millimeters per biopsy core is favored at many centers.
6. *Race*. Men of African descent have a mortality from prostatic carcinoma that is almost twice that of white males. This is due, at least in part, to the fact that they are more likely to have a more advanced stage at presentation. When the disease is stratified for grade and stage, survival is similar in the two races.[583]
7. *PSA serum levels*. The serum level of PSA is related to prognosis in prostatic carcinoma, as an indirect indicator of tumor volume, tumor extension, and response to therapy.[584]
8. *Lymphovascular invasion*. Permeation of vascular channels as detected in whole-mount specimens of radical prostatectomy has been found to correlate with Gleason score, extraprostatic extension, seminal vesicle involvement, and likelihood of tumor progression.[585] Furthermore, peritumoral lymph vessel invasion is associated with an increased likelihood of regional lymph node metastases.[586]
9. *Neuroendocrine features*. Neuroendocrine features correlate with poor differentiation and poor prognosis in all types of prostatic carcinoma.[587,588] Furthermore, a relationship has been claimed to exist between the degree of neuroendocrine differentiation and tumor progression.[589] As discussed previously, criteria for designation as "neuroendocrine" are not precise.
10. *Prominent reactive stroma.* Tumors with abundant (grade 3) reactive stroma ("stromogenic") are more likely to recur, regardless of whether this feature is evaluated in radical prostatectomy specimens or in needle biopsies.[590,591]
11. *Androgen-receptor status*. High levels of androgen receptor as measured immunohistochemically are associated with aggressive clinicopathologic features and decreased PSA-free survival.[592] Mutations of the androgen-receptor gene have been detected in metastatic prostatic carcinoma and postulated to be the reason for the androgen independence of such tumors.[593]
12. *DNA ploidy*. Tumor aneuploidy, as determined by image or flow cytometry, correlates both with a higher Gleason score and with local and distant spread.[594-598] It also predicts an increased probability of grade shifting from the biopsy to the prostatectomy specimen.[599] However, there is still no agreement as to whether this technique provides independent prognostic information.[600-603] The Karolinska Institutet authors, who have obtained the most impressive results with this technique,[604] believe that the controversies related to its use are largely related to methodologic inadequacies.[605]
13. *Proliferation index*. The Ki-67 labeling index of prostatic carcinoma has been said to predict tumor-specific mortality both in cases

of limited disease and in cases associated with lymph node metastases.[606,607] The combined determination of Gleason score and proliferation index constitutes a particularly powerful prognostic tool but is not utilized in routine practice.[608]

14. *Chromosomal abnormalities*. Patients with clonal karyotypic abnormalities are said to have shorter survival rates than those with normal karyotypes.[609]
15. *P53 expression*. The *TP53* tumor suppressor gene has been found to be mutated in a subset of advanced-stage prostatic carcinomas.[610-613] It remains to be seen whether this finding is of value independent of stage and grade.
16. *PTEN* loss. *PTEN* inactivation is more common in advanced stage disease and has been suggested a marker of aggressive prostate cancer.[339,340,342,343]

The problem with these multitudinous markers, as in other areas of tumor pathology, is that most of them are indeed predictive of prognosis in an univariate analysis, but their power diminishes considerably or disappears altogether when corrected for other factors (particularly stage and grade), that is, when they are subjected to multivariate analysis.[614-617] Several attempts have been made to combine some of these factors to produce multiple and hopefully more powerful prognostic indices.[580] The most clinically relevant factors useful in clinical management remain: preoperative serum PSA level, TNM stage grouping, histologic grade as Gleason score (or Grade Group), and surgical margin status.[618]

Other Tumors (in Infants and Children)

Embryonal rhabdomyosarcoma is by far the most common malignant prostatic tumor in infancy and childhood (Fig. 26.48). It produces a firm, smooth enlargement of the prostate. Extraprostatic extension is the rule; nodal metastases are less common than in rhabdomyosarcoma of head and neck.[619] Microscopically, these tumors are very cellular, especially around blood vessels. These hypercellular foci alternate with areas of myxoid or edematous change and with foci of necrosis. Most of the tumor cells are small, varying in shape from round to oval to spindle. Occasional bizarre forms with a more abundant, brightly acidophilic cytoplasm are also found. The microscopic appearance is distinctive, even in the absence of cross striations, but supportive evidence should be sought through immunocytochemical markers (see Chapter 41). In a child or young adult, the diagnosis of rhabdomyosarcoma must be considered when faced with a spindle cell proliferation. The current therapy for this tumor, which consists of multidrug chemotherapy combined with limited surgery and radiation, has proved highly effective; pelvic exenteration is reserved for the few unresponsive cases.[620,621]

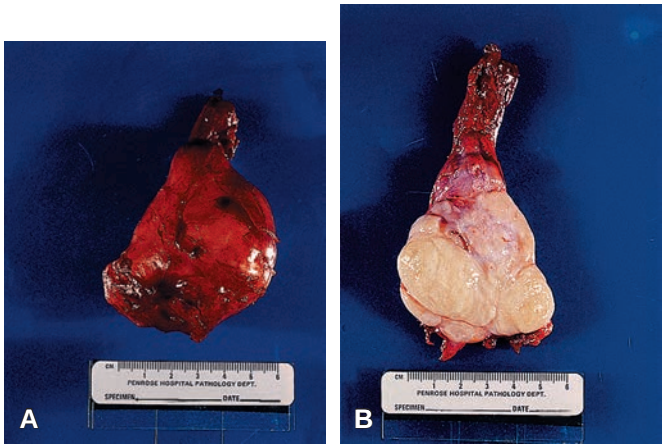

Figure 26.48 **A,** Outer aspect and **B,** cut surface of embryonal rhabdomyosarcoma of prostate in a child.

Other Tumors (in Adults)

Benign neoplasms of the adult prostate are exceptionally rare.

Melanosis of the prostate refers to the presence of melanin-containing elongated cells in the prostatic stroma. The microscopic appearance is analogous to that of *blue nevus*.[622,623] The pigmented spindle cells are immunoreactive for S-100 protein,[624] and melanosomes can be demonstrated ultrastructurally.[625] This condition should be distinguished from lipofuscin pigmentation of the prostatic epithelium, which is equivalent to that more often seen in the seminal vesicle.[626,627]

Cystadenoma of the prostate presents as a large, multilocular mass composed of glands and cysts lined by prostatic-type epithelium lying in a hypocellular fibrous stroma.[628,629] It may extend into the retroperitoneum and be attached to the prostate by a small pedicle.[630]

Leiomyoma has been described, sometimes featuring atypical bizarre giant cells.[631] However, it should be remembered that most cases so diagnosed are in reality foci of purely stromal overgrowth in nodular hyperplasia[632] or lesions belonging to the group listed immediately next.

Postoperative spindle cell nodules resembling sarcomas can develop as a result of an exuberant stromal reaction after a TUR procedure, the interval ranging from a few weeks to several months.[633,634] They present as friable reddish nodules in the prostatic bed and may be the source of postoperative bleeding. The superficial portion looks like granulation tissue, but the deep areas simulate sarcoma (particularly leiomyosarcoma) because of their extreme cellularity and high mitotic activity. Intersecting fascicles of spindle cells with extravasated red blood cells between are seen, but the nuclear chromatin remains fine. The proliferating cells, which in all likelihood are myofibroblastic, show immunohistochemically a strong and unexpected reactivity for keratin. They also express actin inconstantly and are EMA negative. The temporal relationship of these changes with a surgical procedure and their so far invariably benign evolution support a reactive pathogenesis.[634]

Inflammatory myofibroblastic tumor, similar in all regards to the more common homonymous lesion of the bladder (see Chapter 25), is sometimes seen in the prostate. Microscopically there is a proliferation of spindle cells of myoid (myofibroblastic) appearance in a well-vascularized and myxoid background.[625] As in the bladder and in other sites where it occurs, there are serious questions as to whether it really is a reactive pseudoneoplastic condition (as its original name *inflammatory pseudotumor* implies) or whether it should be regarded as a low-grade mesenchymal neoplasm, as most authors currently believe. If the latter, it would not belong to the category of "tumorlike lesions," but it was chosen to discuss it here because of the similarities and possible histogenetic commonality with postoperative spindle cell nodule.

Proliferative lesions of the specialized prostatic stroma comprise a number of entities with a wide range of morphologic appearances and clinical behavior.[635] They are grouped into two major categories: *prostatic stromal tumor of uncertain malignant potential (STUMP)* and *stromal sarcoma* (Figs. 26.49 and 26.50).[636,637] Four histologic patterns are identified in the STUMP category, ranging from scattered atypical stromal cells to lesions having a pattern of growth closely resembling ***phyllodes tumor*** of breast.[638,639] Prostatic stromal sarcoma shows greater cellularity, mitoses, necrosis, and stromal overgrowth. Immunohistochemically, these lesions are positive for CD34 and actin (the latter in less than half of the cases), and progesterone receptors (but only rarely estrogen receptors). STUMP lesions have a tendency to local recurrence, whereas stromal sarcomas have also

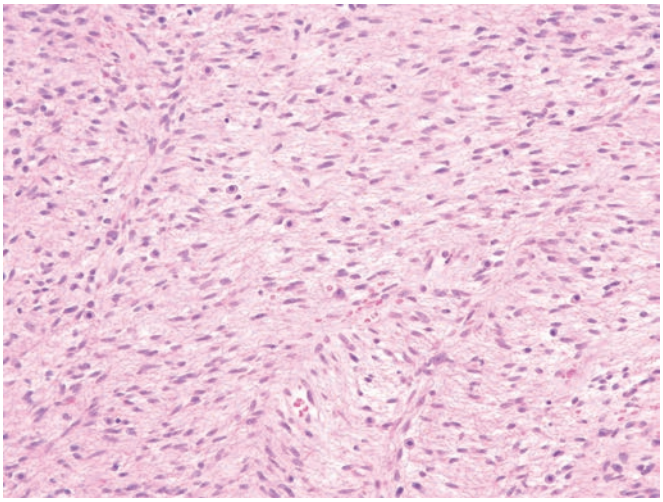

Figure 26.49 Prostatic stromal neoplasm of uncertain malignant potential with bland cytology.

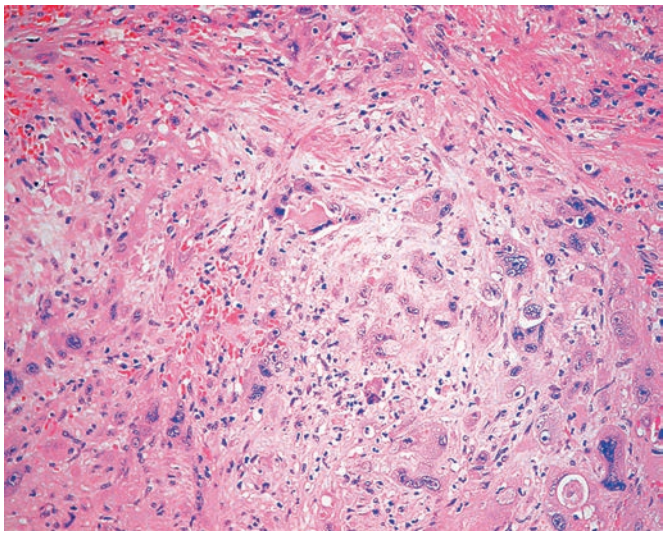

Figure 26.51 Angiosarcoma with epithelioid features involving the prostate. Note the cytoplasmic vacuolization. The diagnosis was confirmed immunohistochemically.

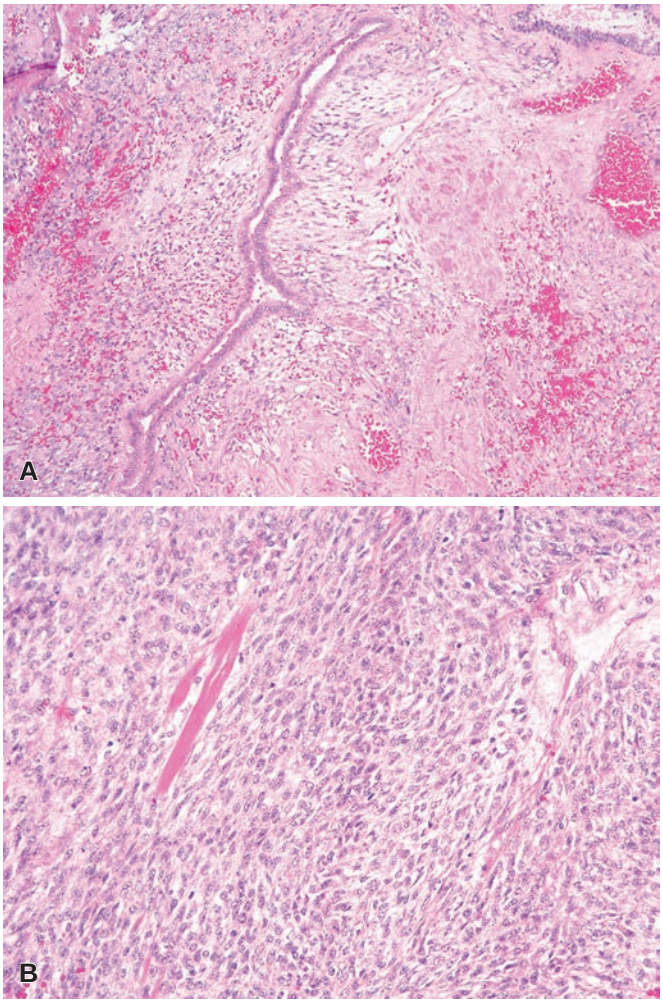

Figure 26.50 Prostatic stromal sarcoma with phyllodes-like pattern **(A)** showing marked cytologic atypia **(B)**.

the potential for distant metastases.[636] At resection, progression of STUMP to prostatic stromal sarcoma has been reported. STUMPs do not typically have the prominent blood vessels, some with surrounding hyalinization, seen in benign stromal hyperplasia.

Solitary fibrous tumor of the prostate, of which benign and malignant forms exist, shares many features with the previously described lesions (down to the positivity for progesterone but not for estrogen receptors), to the point of raising the question as to whether a separation among the two is warranted. However, the identification of the NAB2-STAT6 fusion in solitary fibrous tumor has made this distinction possible.[640] A novel STAT6 antibody provides a surrogate for the fusion and is very useful to confirming the diagnosis of solitary fibrous tumor.[641,642]

Other sarcomas of the adult prostate include **leiomyosarcoma** (to be distinguished primarily from postoperative spindle cell nodule, an exercise of crucial importance); **synovial sarcoma** (the existence of which in an intraprostatic location has been corroborated cytogenetically and molecularly[643-645]); **pleomorphic rhabdomyosarcoma; angiosarcoma** (Fig. 26.51); **"fibrosarcoma"**; and undifferentiated pleomorphic sarcoma.[646-649] The last two entities always remain diagnoses of exclusion in view of the lack of specific morphologic or other markers. Just as importantly, it is well to remember that—as in many other organs—one should consider the alternative and more likely possibility of sarcomatoid carcinoma/carcinosarcoma before making a diagnosis of primary sarcoma of one of those types. After radiation therapy, the possibility of a radiation induced sarcoma should also be considered.

Gastrointestinal stromal tumors (GISTs) can rarely involve the periprostatic region and be present in a prostatic needle biopsy. Most arise in the rectum and involve the prostate by direct extension.[650]

Malignant mixed tumor of salivary gland type, Wilms tumor, and **yolk sac tumor (endodermal sinus tumor)**, morphologically analogous to those seen in the salivary glands, kidney, and gonads, respectively, have been reported.[651-653]

Malignant lymphoma can involve the prostate. Most patients have previous or concurrent evidence of extraprostatic disease, but others are incidental findings.[654,655] The majority of the cases are small lymphocytic lymphomas, but other types can occur, including large B-cell lymphoma,[656] Hodgkin lymphoma,[657] and angiotropic

lymphoma.[658,659] Involvement of the prostate is seen in about 8% of the cases of leukemia.[660] This includes granulocytic sarcoma and chronic lymphocytic leukemia, the incidence in the latter reaching 20%.[73] Prostatic involvement by leukemia or lymphoma may result in acute urinary obstruction.

Secondary neoplastic involvement of the prostate occurs through direct extension by carcinoma of the bladder and urethra,[661] colorectum and anus,[662] and soft tissue tumors.[663,664] For bladder cancer treated with radical cystoprostatectomy, the incidence is as high as 32%–38%, this feature carrying a negative prognostic connotation.[665,666] Distant metastases have been seen from lung carcinomas, melanomas, renal cell carcinomas, and other tumor types.[663,667,668]

Prostatic Urethra

Because of its strategic location in relation to the prostate and bladder, the prostatic urethra is often involved secondarily in diseases of these two organs. Thus, direct extension of urothelial carcinoma of bladder and of carcinoma of prostate (particularly ductal) occurs with high frequency. In addition, there are some conditions that can affect primarily the urethra itself. They include the following:

1. **Postoperative spindle cell nodule** (see Chapter 25).
2. **Nephrogenic adenoma** similar to its more common bladder counterpart can occur in the prostatic urethra and can be mistaken for prostatic adenocarcinoma.[669,670] This lesion probably represents either a benign metaplastic response of the urothelium to injury or the result of mechanical implantation of renal tubules into the urethral mucosa (see Chapter 25). In keeping with the latter theory, nephrogenic adenoma has been found to be consistently positive for S-100A1, a calcium-binding protein normally expressed in renal tubular cells, as well as PAX2 and PAX8, both being renal transcription factors.[671-673] A potential pitfall is represented by the fact that the cells of nephrogenic adenomas often express racemase and may lack expression of basal cell markers.[674,675]
3. **Prostatic urethral polyps** composed of secretory cells of prostatic origin may be a source of hematuria in young adults.[676] They may have a villous configuration and tend to be found in the verumontanum but also along most of the posterior and lateral surfaces of the prostatic urethra.[677,678] They have traditionally been thought to arise from ectopic prostatic tissue located in the prostatic urethra but are more likely of hyperplastic–metaplastic nature.[679] They stain intensely for both PSAP, PSA, and also NKX3.1 in our experience.[680] These must be distinguished from subtle patterns of prostatic ductal carcinoma presenting as urethral polyps (see earlier). Most are cured by transurethral fulguration, but instances of local recurrence have been described.
4. **Inverted urothelial papilloma.** Their morphology and clinical significance are similar to those of their more common homonym in the bladder.[681]
5. **Urothelial carcinoma.** Very rarely, carcinoma of urothelial type is seen in the prostatic urethra in the absence of bladder or prostatic disease.

Seminal Vesicles and Cowper's Glands

The seminal vesicles have a thick muscular wall and highly complex mucosal folds. The epithelium is composed of columnar and basal cells. The cytoplasm of the former characteristically contains large amounts of lipofuscin pigment.

"Monstrous" cells are a common feature of the epithelium of this organ, particularly in older individuals. They are thought to represent an involutionary phenomenon and should not be confused with a malignant process.[136] The presence of lipofuscin pigment in the cytoplasm is the most important clue to their nature, even if it lacks specificity, in the sense that it can also be rarely seen in the prostate.

Hyaline globules are often found in the muscular wall of the organ; they are thought to be of degenerative nature and have no clinical significance.

Amyloidosis is detected in the form of subepithelial deposits in about 5%–10% of seminal vesicles.[682,683] The involvement is bilateral, subepithelial, of a nodular quality, and usually accompanied by involvement of the vasa deferentia and ejaculatory ducts.[684] It has been suggested that this abnormality may be more common in patients with hormonally treated prostatic adenocarcinoma.[685] This finding has no clinical significance and does not warrant a work-up for systemic amyloidosis.

Tuberculosis of the seminal vesicle is usually secondary to infection in the prostate; therefore the greatest amount of involvement is in the portion of the glands immediately adjacent to this organ.[78]

Cysts arising from the ducts of the seminal vesicle present as a soft cystic mass between the rectum and the base of the bladder. Congenital examples may be bilateral, associated with ipsilateral renal agenesis, ureteral anomalies, and oligospermia.[686,687] Acquired cysts result from obstruction secondary to chronic prostatitis.[688] Benign lesions of the seminal vesicles with a multilocular appearance and more cellular stroma have sometimes been designated as *cystadenomas*[689] or as *cystic epithelial–stromal tumors* (Fig. 26.52), but malignant examples also exist.[690,691]

Primary carcinomas of the seminal vesicle are pathologic curiosities.[692] Many of the reported cases probably represent secondary invasion from carcinoma originating in other sites, particularly the prostate. To make a diagnosis of primary carcinoma of the seminal vesicle, there must be no involvement of the prostate, and stains for PSA must be negative. They are instead immunoreactive for CA 125 and cytokeratin 7 (although not for cytokeratin 20).[693] Most cases have a prominent papillary configuration.[694]

Other reported types of primary malignant tumors of the seminal vesicles are **leiomyosarcoma**,[695] malignant mixed epithelial-stromal tumors (also reported as adenosarcoma and malignant phyllodes tumor),[691,696] **choriocarcinoma**,[697] **male adnexal tumor of probable wolffian origin**,[698] and **angiosarcoma**. In our experience, some of the latter have been of the epithelioid type.

Secondary involvement of seminal vesicles is common in prostatic carcinoma,[504] and it also occurs in in situ and invasive urothelial carcinoma of the bladder.[699]

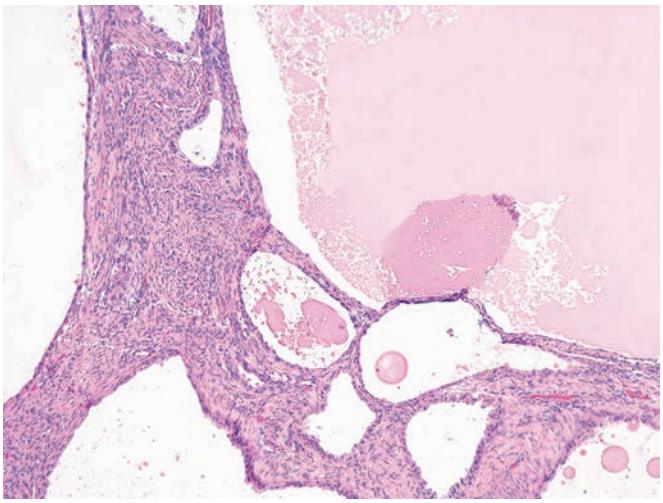

Figure 26.52 Mixed epithelial-stromal tumor of seminal vesicle.

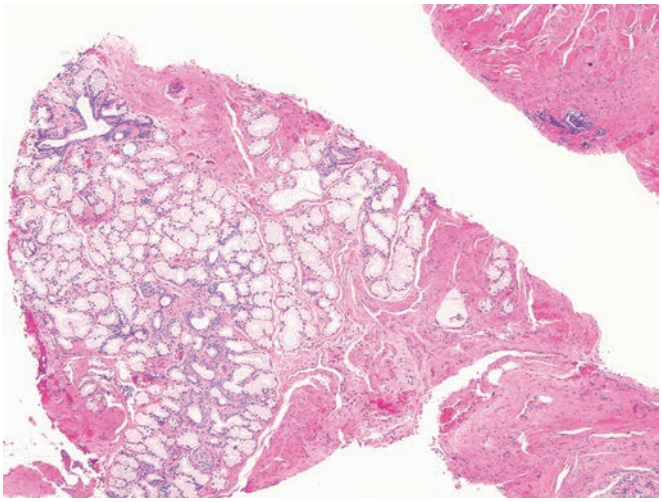

Figure 26.53 Normal benign Cowper's gland on needle core biopsy has features similar to minor salivary gland tissue.

Normal Cowper's glands are sometimes seen in specimens from prostatic resections or needle biopsies.[131] They form well-demarcated lobules composed of small, compact glands radiating from a central excretory duct lined by pseudostratified epithelium (Fig. 26.53). The best way to identify these glands is to remember that they have the appearance of mucinous minor salivary glands embedded within skeletal muscle.[131]

Adenocarcinomas of Cowper's gland are even less common than carcinomas of seminal vesicles, and the same care should be exercised in ruling out the alternative possibility of a prostatic origin.[700] They are mucin producing and may ulcerate through the skin of the scrotum. Rarely, carcinomas with salivary gland-like morphology may also occur at this site.[701]

Testis

Normal Embryology and Anatomy

The growth and development of the human testis can be divided into three major phases: (1) static, from birth to age 4 years; (2) growth, from age 4 to 10 years; and (3) developmental (maturation), from age 10 years to puberty.[1,2] At birth, the seminiferous tubules are compactly filled with small undifferentiated cuboidal cells. Leydig cells are seen in the newborn because of the influence of maternal hormones, but then disappear to reappear only later. Increases in tubule and cell size are slow and gradual, with barely perceptible growth from age 4 to 10 years, increasing tortuosity, and lumen formation. At age 10 years, a definite spurt is noted, coinciding with the appearance of gonadotropins and 17-ketosteroids in urine. Mitotic figures appear in the tubular cells, and Leydig cells again become recognizable in the interstitium. At age 11 years, mitotic activity is pronounced, and primary and secondary spermatocytes appear. At age 12 years, spermatids are numerous. Finally, spermatozoa appear. The number of maturing tubules with active spermatogenesis increases gradually until the adult stage is reached. Because of the great variation in the age at which puberty normally occurs, the age of the individual cannot be determined by histologic study of the testis after the 12th year.[1]

The normal adult testis is a paired organ that lies within the scrotum suspended by the spermatic cord. The average weight of each testis is 15–19 g, the right usually being 10% heavier than the left.[3] The organ is covered by a capsule composed of three layers: the outer serosa or *tunica vaginalis* (covered by a flattened layer of mesothelial cells), the *tunica albuginea*, and the inner *tunica vasculosa*. The posterior portion of the capsule, called the mediastinum, contains blood and lymph vessels, nerves, and the mediastinal portion of the rete testis. The parenchyma is divided into approximately 250 lobules, each lobule containing up to four seminiferous tubules. The usual testicular biopsy is composed of three to five lobules together with portions of the septa (which should not be misinterpreted as areas of fibrosis). The seminiferous tubules are bound by a limiting membrane made up of basal lamina and alternating layers of myoid cells and collagen fibers. These tubules contain germ cells in various stages of development and Sertoli cells.[4]

The maturation of germ cells in man covers a period of about 70 days and follows these steps: spermatogonium (of which two types have been described, known respectively as A and B), primary spermatocyte (further subdivided depending on the stage of meiosis into preleptotene, leptotene, zygotene, pachytene, and diplotene), secondary spermatocyte, spermatid, and (mature) spermatozoon (Fig. 27.1).[4,5] Until spermatozoa are formed, all progeny of a spermatogonium are held together by a narrow cytoplasmic bridge. This maturation proceeds in an orderly overlapping helical pattern along the length of the tubule[6]; as a consequence, not all stages of differentiation of germ cells are seen in any one cross-sectional view of a seminiferous tubule. *This normal pattern should not be confused with a maturation arrest.*

Sertoli cells have a columnar shape, lie on the basement membrane of the tubule, and send cytoplasmic prolongations around the germ cell elements.[7] Their nuclei are irregularly shaped, are highly folded, and have a prominent nucleolus. The cytoplasm may contain Charcot–Bottcher crystalloids, which represent bundles of filaments. Immunohistochemically, the intermediate filament of Sertoli cells is vimentin, but coexpression of keratin and desmin is present in the fetal testis and can reappear in pathologic conditions.[8]

The interstitium contains stromal elements (including the already mentioned myoid cells) and Leydig cells. The latter occur either singly or in clusters and are often associated with nerve fibers.[9] Their cytoplasm contains lipid droplets, lipochrome pigment, and sometimes Reinke crystalloids, which appear ultrastructurally as hexagonal

Abstract

This chapter covers the spectrum of diseases that involve the testis and testicular adnexa. Inflammatory conditions, including common infectious etiologies, are addressed. Germ cell tumors are discussed in detail and are organized as suggested by the latest WHO 2016 classification, according to their association with germ cell neoplasia or not. The full spectrum of sex-cord stromal tumors is also addressed to include new molecular data and variants. Finally, rare diseases of the rete testis, epididymis, and spermatic cord are reviewed.

Keywords

prisms.[4] Immunohistochemically, there is reactivity for inhibin and Melan-A (Mart-1). Leydig cells gradually decrease in number with aging.

Cryptorchidism

In 1 out of every 10 males, the testis has not descended into the scrotum at the time of birth, but has remained in the inguinal region or abdomen, the former situation being about four times as common as the latter.[10,11] Most of these "retained" or "retractile" testes descend into the scrotum during the first year of life. In only 1 in 100 individuals will a permanent retention of the testis outside the scrotum occur, a condition known as cryptorchidism. The exact pathogenesis is unknown, but most evidence favors a role for testosterone under the influence of the hypothalamic–pituitary axis.[12] If by the age of 2 or 3 years the testis has not spontaneously descended into the scrotum (or sooner, if the abnormality is bilateral), an open or laparoscopic orchiopexy should be carried out; otherwise permanent anatomic alterations will occur.[11,13,14]

Cryptorchidism is unilateral in 80% of the cases. Of patients with bilateral cryptorchid testes in whom repair is performed before the age of 5 years, 50% are fertile and 31% are normospermic.[15] The microscopic appearance of the prepubertal testicle as seen in a small biopsy at the time of orchiopexy is a good predictor of the degree of post-pubertal spermatogenesis and, therefore, of fertility.[16]

Grossly, cryptorchid testes in adults are small and brown. The testicular tubules are atrophic, and their basement membrane is greatly thickened. The Leydig cells are prominent; some of them may be present inside the tubules.[17] Not infrequently, foci of hyperplastic Sertoli cells occur. They are usually multiple and may appear grossly as minute white nodules. In some instances, atypical germ cells are seen at the base of the tubules; these are indicative of germ cell neoplasia in situ (GCNIS, intratubular germ cell neoplasia [IGCN]) and are the forerunner of malignancy. Traditionally, the atrophy and infertility associated with cryptorchidism have been attributed to the higher intrascrotal temperature. However, the facts that boys with cryptorchidism have histologically abnormal seminiferous tubules also in the contralateral descended testis[18] and that men who had unilateral cryptorchidism corrected in childhood have lower sperm counts and higher serum concentrations of follicle-stimulating hormone as adults than do normal men[19] suggest that even unilateral cryptorchidism is associated with a bilateral testicular abnormality.

A cryptorchid testis is more likely to develop a germ cell tumor than is a normally placed organ. Of 7000 cases of testicular germ cell tumors reviewed in a classic study by Gilbert and Hamilton,[20] 10.9% occurred in cryptorchid organs. The incidence of malignancy is greater in the abdominal than in the inguinal testis. Seminoma is the most common type, but other germ cell tumors also occur.[21,22] The contralateral testis in patients with unilateral cryptorchidism also has an increased incidence of malignancy.[23,24] If a cryptorchid testis is surgically placed in the scrotum, it may still develop a germ cell neoplasm, especially if the operation has been done at a late age.[25] Dow and Mostofi[26] reported 14 cases of such tumors occurring in patients who had had orchiopexy between the ages of 11 and 36 years. In a large Swedish study, the relative risk of testicular cancer among cryptorchidic patients who underwent orchiopexy before reaching 13 years of age was 2.23 as compared to the Swedish general population, whereas for those treated at 13 years of age or older, the relative risk was 5.40.[27] Because of these findings, it has been recommended that high-positioned testes that have not been surgically placed into the scrotum before mid-adolescence be removed.[28]

Atrophy and Infertility

Atrophy of the testis may result from a large variety of causes: the already mentioned cryptorchidism; the orchitis of mumps, especially when the infection occurs at or after puberty[29]; liver cirrhosis, as a result of increased circulating endogenous estrogens not metabolized by the diseased liver[30]; administration of estrogens or gonadotropin-releasing hormone analogue in the treatment of prostatic carcinoma[31]; radiation exposure; chemotherapy, particularly cyclophosphamide[32,33];

and exposure to an environmental toxin, the nematocide dibromochloropropane.

In advanced testicular atrophy of any of these etiologies, the tubules are small, with thick basement membranes and few or no germ cells. The interstitial tissue shows varying degrees of fibrosis, and there may be an increased number of Leydig cells.

An extreme degree of testicular atrophy occurs in the testicular regression ("vanishing testis") syndrome, a condition characterized by a rudimentary epididymis and spermatic cord with no identifiable testicular tissue.[34] There is instead in this location a dense fibrovascular tissue ("nubbin") with foci of calcification and hemosiderin deposition.[35] The suggestion has been made that this condition results from testicular infarct, presumably caused by torsion occurring in utero.[36] It affects approximately 5% of patients with cryptorchidism.[34]

Various degrees of testicular atrophy occur frequently in AIDS-affected patients, the precise pathogenesis being unclear.[37,38]

The effect of vasectomy on testicular morphology is minimal but detectable; there is thickening of the tubular wall, reduction in the number of spermatids and Sertoli cells, and sometimes foci of interstitial fibrosis.[39]

The male factor is the primary or contributing cause of infertility in 40%–60% of the cases.[40] The causes of male infertility fall into one of three categories: pretesticular, testicular, and post-testicular.[41–43] The pretesticular causes are extragonadal endocrine disorders, usually originating in the pituitary or adrenal gland. The testicular causes are primary diseases of the testes, and little treatment is available at the present time. The post-testicular causes consist mainly of obstructions of the ducts leading away from the testes. These obstructions may be congenital, postinflammatory, or postsurgical and include Young syndrome, in which the obstructive azoospermia is combined with chronic sinopulmonary infections.[44] These obstructions have generally little or no adverse effect on spermatogenesis. Treatment consists of epididymovasostomy or vasovasostomy to bypass the obstruction. Impaired sperm mobility, presumably because of faulty maturation or storage of spermatozoa in the epididymis, and immunologic factors are included among the post-testicular causes of infertility.[45]

The evaluation of the infertile male includes a thorough clinical history and examination, semen analysis, quantitation of leukocytes in semen, and search for antisperm antibodies. Tests of sperm function include evaluation of cervical mucus interaction, ova penetration, and the hemizona assay. Additional tests, performed in selected cases, are transrectal ultrasonography, venography, and testicular biopsy.[46,47] The latter is particularly useful in the individual with azoospermia and normal endocrine findings.[48–51] Punch biopsy is not nearly as satisfactory as an open surgical biopsy. The material should be handled with extreme care.[52] Zenker and Bouin fixatives preserve cytologic features better than formalin; however, some hospitals no longer allow their use. Fine-needle aspiration cytology has been proposed as an alternative to testicular biopsy,[51] some studies showing a high correlation between the two methods.[53]

Biopsy specimens from infertile men with total lack of spermatozoa (azoospermia) usually show one of the following conditions[54]:

1. Germ cell aplasia (Sertoli cell-only syndrome) (29%), in which the tubules are populated by only Sertoli cells (Fig. 27.2), measure 100–150 µm in diameter, and may show some thickening of the tubular basement membrane; germ cells are completely absent.[55] Leydig cells are usually normal but on occasion are found to be reduced in size and number.
2. Spermatocytic arrest (26%), characterized by a halt of the maturation sequence (Fig. 27.3), usually at the stage of the primary spermatocyte (presumably at the end of the meiotic prophase at late pachytene)[56]; no spermatids or spermatozoa are present despite the presence of abundant cells in division; Leydig cells are normal.
3. Generalized fibrosis (18%).
4. Normal spermatogenesis (27%).

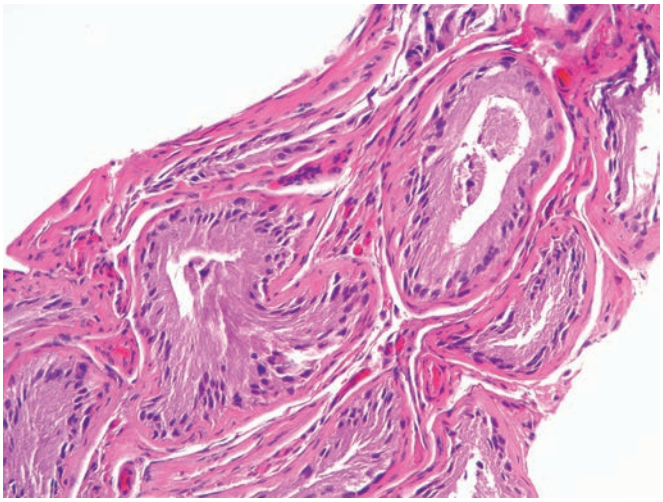

Figure 27.2 Testis biopsy showing Sertoli cell only syndrome.

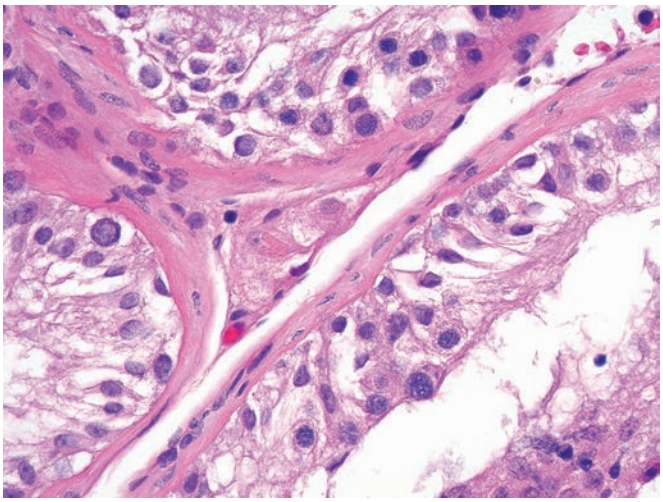

Figure 27.3 Testis biopsy showing maturation arrest at the spermatocyte phase.

The last finding suggests the diagnosis of obstructive azoospermia and implies the bilateral obstruction or absence of some part of the duct system.[57] In the series of Nistal et al., of patients with obstructive azoospermia of known etiology, over half had a normal testicular biopsy, whereas most of the others exhibited subtle alterations of the adluminal compartment of the seminiferous tubules (early or late sloughing of primary spermatocytes), possibly induced by the increase in hydrostatic pressure.[58]

In patients with a reduction in the number of spermatozoa (oligospermia), the following microscopic patterns are recognizable, often combined: (1) incomplete spermatocytic arrest, characterized by arrest of spermatogenesis in some of the tubules; (2) regional or incomplete fibrosis; (3) spermatogenic hypoplasia (hypospermatogenesis), characterized by tubules with a reduced population of germ cells and a poor order of spermatogenesis; (4) tubular hyalinization, a probably heterogeneous group that includes Klinefelter syndrome, in which the tubules have a small diameter and a markedly thickened basement membrane, and Leydig cells are often increased

in number; (5) mixed atrophy, that is, the synchronous occurrence of seminiferous tubules containing germ cells and tubules with Sertoli cells only; and (6) normal or essentially normal spermatogenesis, usually implying a partial occlusion of some part of the duct system.[59–61] Another pattern sometimes described is that of sloughing and disorganization, in which spermatogenesis has a disorderly appearance and the tubular lumina are filled with desquamated immature cells. We have found that this pattern is rather nonspecific, since it can be seen in spermatogenic hypoplasia as well as with testicular blockage; it also can be closely simulated by artifactual detachment of germ cells resulting from rough handling of the biopsy. The degree of spermatogenic hypoplasia, a very subjective evaluation, can be estimated with quantitative techniques.[7,62]

Multinucleated giant stromal cells of reactive nature have been observed in cases of testicular atrophy after estrogen therapy.[63]

In the series of over 800 cases of azoospermia studied via testicular biopsy by Girgis et al.,[64] the etiology was obstructive in about 55%. In more than half of these, epididymovasostomy proved beneficial. Patients with varicocele are often oligospermic and infertile. The most common patterns at biopsy are those of spermatogenic hypoplasia plus sloughing and disorganization.[65] The azoospermia commonly seen in patients with cystic fibrosis is obstructive, secondary to structural abnormalities of the epididymis and vas deferens.[66]

Biopsies are rarely done in patients with testicular failure involving primarily the endocrine function, since the diagnosis is usually established by hormonal determinations. Failure of pubertal maturation is the cardinal symptom if the disease is congenital or begins in childhood.[44] Three different patterns can be seen in testicular biopsies: (1) hypogonadotrophic eunuchoidism (60%), accompanied by low gonadotropin levels and characterized by small, infantile tubules with scattered spermatogonia and Sertoli cells but few or no Leydig cells; (2) Klinefelter syndrome (30%), with fibrosis of tubules, prominent thickening of the basement membrane, and Leydig cell hyperplasia[67]; and (3) testicular aplasia (10%), characterized by the absence of testicular tissue and elevation of urinary gonadotropin levels. Patients with Klinefelter syndrome have an increased incidence of breast carcinoma[68]; cases of Leydig cell tumor and testicular and extragonadal (mainly mediastinal) germ cell tumors also have been reported in this population.[69–71]

Figure 27.4 Gross Appearance of Granulomatous Orchitis. The testis has firmer consistency, and is enlarged and vaguely nodular.

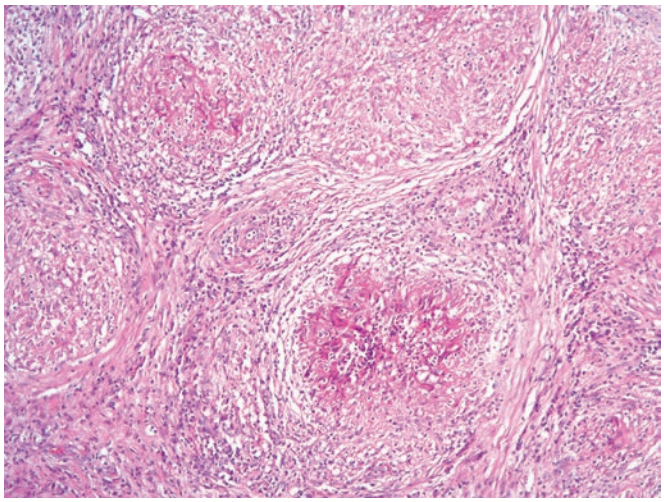

Figure 27.5 Microscopic appearance of granulomatous orchitis associated with tuberculosis.

Other Non-Neoplastic Lesions

Infarct of the testis is usually the result of torsion of the spermatic cord, but it may also be due to venous thrombosis secondary to pyogenic epididymo-orchitis (see later), a sequela of inguinal hernia repair,[72] or, rarely, vasculitis of various causes, such as that accompanying Crohn disease.[73] Intermittent torsion may cause histologic changes that mimic other etiologies.[74]

Viral-type orchitis can simulate testicular neoplasia at the microscopic level. The architecture is preserved, but there is hemorrhage, edema, and a patchy lymphohistiocytic infiltrate within and between the seminiferous tubules.[75]

Granulomatous orchitis is characterized grossly by a solid nodular enlargement of the testis (Fig. 27.4) and microscopically by granulomatous lesions centered in the seminiferous tubules, as described in the classic paper by Spjut and Thorpe.[76] Epithelioid cells, multinucleated giant cells, lymphocytes, and plasma cells are present. The granulomatous response is at least in part secondary to the products of disintegrated sperm. A history of trauma to the region is often obtained.[77] The clinical evolution is benign, but this should obviously be distinguished from infectious etiologies.[78,79]

Malakoplakia can affect the testis, either alone or accompanied by epididymal involvement.[80] It is associated with abscess formation, atrophy of tubules, and the characteristic Michaelis–Gutmann bodies. Thrombosed blood vessels are often found.[81] Bacteria (mainly coliform organisms) may be found on culture. Three other proliferative histiocytic disorders that occasionally involve the testis are juvenile xanthogranuloma,[82] Rosai–Dorfman disease (sinus histiocytosis with massive lymphadenopathy),[83] and xanthogranulomatous orchitis.[84,85]

Pyogenic epididymo-orchitis may be complicated by venous thrombosis and septic infarct of the testis.[86] *Escherichia coli* is the organism usually recovered. Microscopically, many similarities exist between this condition and granulomatous orchitis, suggesting a common ischemic background.

Tuberculosis, atypical mycobacteriosis,[87] leprosy, sarcoidosis,[88] syphilis, and Crohn disease can involve the testis (Fig. 27.5).[73,89] Clinically, a syphilitic gumma can resemble a neoplasm.

Other infectious agents responsible for orchitis are *Toxoplasma* (in immunosuppressed patients), fungi, parasites, and *Brucella*. These are rarely seen as surgical specimens.[90]

Multinucleated stromal giant cells are a relatively common and clinically insignificant finding in the testis. They seem to be age related and are said to be particularly common in cases of testicular atrophy due to estrogen therapy.[91]

Necrotizing vasculitis can involve the testis, either as a manifestation of polyarteritis nodosa or other systemic disease or as an isolated finding.[92,93]

Ectopic spleen in the scrotum (splenogonadal fusion syndrome) results from a congenital malformation occurring at a stage when the splenic and gonadal anlages are topographically close.[94] In the continuous variant, there is a fibrous or splenic tissue-containing cord that connects the spleen and the scrotal ectopic splenic tissue. In the discontinuous variant, the connection is lost, and the ectopic splenic tissue appears as a scrotal accessory spleen, which may clinically simulate a tumor. All of the reported cases have been on the left side.[95]

Cystic dysplasia of the testis is a rare congenital defect that results in the formation of numerous irregularly shaped cystic spaces within the mediastinum testis.[96] The cysts are lined by flattened cuboidal epithelium that morphologically and immunohistochemically resembles the epithelium of rete testis.[97] Thus this condition merges with those described in the section on rete testis.

Cysts located within the testicular parenchyma away from the rete testis are lined by a similar flattened cuboidal (non-ciliated) epithelium and may have a similar pathogenesis.[77]

Testicular implants (silicone gel-filled) can elicit a tissue reaction similar to that seen in breast implants. Microscopically, it is characterized by a fibrous capsule infiltrated by lymphocytes and foamy macrophages, and occasionally featuring a synovial-like cleft at the interphase.[98]

Tumors

Testicular tumors can be divided into five general categories: germ cell tumors (90%) arising from the germinal epithelium of the seminiferous tubules; sex cord–stromal tumors; mixed germ cell–sex cord–stromal tumors; primary tumors not specific to the testis; and metastatic tumors.

Germ Cell Tumors

Classification

This current classification of testicular neoplasia is based on the recent restructuring of terminology recommended by the WHO 2016 classification. In this system, germ cell tumors are divided into categories based on their relationship with germ cell neoplasia in situ (GCNIS), previously termed intratubular germ cell neoplasia, unclassified (ITGCN).[99] In addition, minor changes to the nomenclature of sex cord–stromal tumors are based on more recent molecular genetic data.

Germ Cell Tumors Associated With Germ Cell Neoplasia In Situ

Clinical Nomenclature. Although somewhat confusing when approached from a histologic perspective, urologists and oncologists divide testicular germ cell tumors into two categories: "seminoma" (pure classic seminoma) and "non-seminoma" (any other pure or mixed subtype, including those with an admixed seminoma component). The latter is often described as "non-seminomatous germ cell tumor" (NSGCT).

Incidence. Testicular germ cell tumors make up only a small percentage of all malignant neoplasms in men (approximately 1%), but are the most common malignant tumors in young men between 25 and 29 years of age. The worldwide incidence is 1.5 cases per 100,000, with rates highest in Norway and Switzerland. Their incidence seems to be increasing, at least for seminomas.[100]

Predisposing and Accompanying Factors. The main factors thought to predispose to testicular germ cell tumors are cryptorchidism, disorders of sex development, family history, testicular microliths in subfertility, and prior germ cell tumor. Hereditary forms are described, but almost all are related to low penetrance autosomal recessive susceptibility genes.[101–106] Specifically, the AZFc region (gr/gr microdeletion) of chromosome Y, 12q22 (KITLG), and 5q31 (RAS-ERK-MAPK pathway) are proposed as susceptibility loci, in some cases possibly due to interactions with c-KIT.[107–109] It is also suggested that PTEN hamartoma tumor syndrome, Li–Fraumeni syndrome, and neurofibromatosis type 1 may rarely be associated with germ cell tumors.

Age. There is a good correlation between age and the incidence of the different types of testicular tumor.[99] The median age at presentation is 35 years for seminoma, 25 years for non-seminoma, and 30 years from non-seminomas that include a seminomatous component. In individuals over 60 years of age, germ cell tumors are rare. Seminomas (and spermatocytic tumor described below with germ cell tumors unrelated to GCNIS) are the most common germ cell tumors in this age group, outnumbered only by malignant lymphomas.[110,111]

Presentation. Most testicular germ cell tumors present with progressive, painless enlargement of the testis. A small tumor may be found in a testis by palpation or ultrasonography. They may grow slowly or with appalling speed. Sometimes, the initial presentation is in the form of a metastatic deposit in the retroperitoneum, lung, or mediastinum. Presentation with significant clinical symptomatology is uncommon in seminoma, but relatively common for choriocarcinoma, in which the patient may have gynecomastia; large mediastinal, pulmonary, liver and/or brain metastases; and markedly increased levels of serum human chorionic gonadotropin (hCG).[112,113]

Bilaterality. Bilateral testicular involvement by germ cell tumors is seen in 1.0%–2.7% of the cases according to different series.[114–117] The risk of bilaterality rises to 15% if both testes are undescended. It can be seen as a synchronous or, more commonly, as a metachronous event. The tumors may have a different histology.[118] In the presence of bilateral testicular tumors in an elderly patient, the most likely diagnosis is malignant lymphoma.

Molecular Genetic Features. Germ cell tumors of adults and adolescents (almost always of the post-pubertal GCNIS-associated type) show one or more copies of an isochromosome of chromosome 12p (i(12p)) or other forms of 12p amplification. Since this genetic aberration is absent in isolated GCNIS, the gain of genes on 12p appears to be crucial for the development of invasive germ cell tumor.[119–121] 12p harbors multiple genes that promote cell growth.[122–125] Other common non-random genetic changes include loss of chromosome 1p, 11, 13, 18, or Y and gain of chromosome 21, 7, 8, or X.[126–132] *KIT* mutation and/or amplification (most commonly in seminoma) and *KRAS* mutation are also described in a small subset of cases.[133,134] In cases of NSGCT with an admixed seminoma component, in which the two components were evaluated separately from a genetic standpoint, some showed similar clonal abnormalities (suggesting an origin from the same stem cell), whereas others did not.[130,135,136]

Spermatocytic tumor shows completely different genetic features (with an absence of 12p abnormality), and are discussed separately.[121]

Spread and Metastases. It has been generally assumed that the first manifestation of local spread of testicular germ cell tumors is in the tunica albuginea, but invasion of the testicular hilum is actually a much more common event.[137] Since this may be grossly inapparent, microscopic sampling of this region is mandatory, as discussed in staging.[138,139]

In terms of lymph-borne metastases, testicular tumors spread first to periaortic and iliac lymph nodes and later to mediastinal and left supraclavicular nodes. Retroperitoneal lymph node metastases are on the side of the tumor in about 80%–86% of cases and bilateral in about 13%–20%. The presence of contralateral metastases in the absence of ipsilateral metastases is rare.[140,141] Characteristically, the first retroperitoneal metastases are highly placed, immediately below the renal vessels. In general, involvement of inguinal lymph nodes does not occur unless there is invasion of the skin of the scrotum, tumor recurrence in a cutaneous scar, or a history of previous operation in the area (such as correction of cryptorchidism, herniorrhaphy, or scrotal orchiectomy).[142] Blood-borne metastases occur most frequently in lungs, liver, brain, and bone.[143] There is a high incidence of brain metastases in choriocarcinoma and of bone metastases in seminoma.[144] Embryonal carcinoma frequently metastasizes early, and choriocarcinoma almost always has widespread metastases by the time the tumor is diagnosed. Teratoma occurring in the postpubertal testis can be accompanied by metastases no matter how well-differentiated the primary tumor appears, which is why the mature/immature designation is no longer recommended.[99]

The microscopic appearance of the metastases may differ from that of the primary tumor. In general, classic seminoma metastasizes as classic seminoma, but it may also spread as other types.[144] In combined mixed germ cell tumors with admixed seminoma, the non-seminomatous component is the one most likely to metastasize. Late metastases of testicular germ cell tumors often have a teratomatous appearance.[145] Mixed germ cell tumors with focal choriocarcinoma tend to metastasize as pure choriocarcinomas. Surgical removal of the postchemotherapy residual tumors is recommended.[146–148] In some instances, total spontaneous regression of the primary tumor or of the metastatic foci has been observed.[149–151] Sometimes, tumor foci with a somatic-type malignancy (rather than germ cell) appearance develop in these metastases.

The microscopic appearance of the lung metastases after chemotherapy correlates well with prognosis. The presence of total necrosis or fully mature elements is indicative of a good prognosis[146,152,153]; viable non-teratomatous components are associated with a decreased survival, and the presence of sarcomatous elements is a particularly ominous sign.[154,155]

Treatment. The initial treatment for all testicular germ cell tumors is inguinal orchiectomy with high ligation of the spermatic cord ("radical orchiectomy").[156] The subsequent treatment of confirmed low-stage testicular germ cell tumors is evolving. Depending on the institution, orchiectomy may be followed by retroperitoneal lymphadenectomy, chemotherapy, or surveillance.[157–159] Radiation therapy is used less commonly. Many groups have recommended treating stage I seminoma or even NSGCT with orchiectomy alone, with further therapy for only those cases that show relapse on close monitoring.[160–164] Along similar lines, it has been suggested that stage II NSGCT could be treated with orchiectomy and retroperitoneal lymphadenectomy, with chemotherapy reserved for those patients who develop relapse.[165,166] The "surveillance only" approach is more controversial in patients with a predominance of the embryonal carcinoma or in tumors exhibiting blood vessel invasion because of the high probability of distant metastases under these circumstances; however, high-risk pathology is not an absolute contraindication in certain settings, given that therapies still have high cure rates for relapses.

Controversy exists as to whether patients undergoing orchiectomy for germ cell tumors should also have a biopsy of the contralateral testis searching for IGCN.[167] Most authors do not favor this approach, but the practice varies significantly by country.[168] We never receive such biopsies.

Prognosis. With current treatment protocols, testicular germ cell tumors represent the most curable solid cancer in men, even when metastatic spread is present. For stage I tumors, whether seminoma or non-seminoma, cure rates are close to 100%. With metastatic spread, cure rates remain high, but vary with prognostic groups as defined by the International Germ Cell Cancer Collaborative Group classification.[169] Even in this metastatic group, overall cure rates are over 80%, and salvage therapy may cure over half of the patients with initial treatment failures. Later relapses (defined as >2 years after initial treatment with complete remission) are less common, but may occur and portend an adverse prognosis, particularly when associated with secondary somatic malignancy.

Noninvasive Germ Cell Neoplasia

Germ Cell Neoplasia In Situ (Intratubular Germ Cell Neoplasia, Unclassified). The in situ stage of germ cell neoplasia has been variably designated as IGCN, in situ carcinoma, or testicular intraepithelial neoplasia.[170–172] The WHO 2016 classification (based on the consensus of an international panel) now promotes the diagnostic term *germ cell neoplasia in situ* (*GCNIS*).[99] It is most often seen in the residual testis in organs harboring an invasive germ cell malignancy, the frequency being higher than 80% in some series.[173,174] It is also seen in the contralateral testicle in approximately 5% of patients with testicular tumors.[175,176] Interestingly, the appearance of GCNIS is usually the same regardless of the nature of the invasive germ cell component. All types of post-pubertal germ cell tumor have been found to be associated with GCNIS.

Although usually restricted to the seminiferous tubules, GCNIS sometimes colonizes the rete testis, where it results in a pagetoid appearance that can be very confusing to the unwary (Fig. 27.6).[177]

Sometimes, GCNIS is found incidentally in the absence of an obvious tumor, occasionally in children or adolescents with various disorders of sex development,[178] but most often in the study of post-pubertal testicular biopsies performed for the study of infertility or in cases of current or corrected cryptorchidism.[179,180] It is important to recognize GCNIS in these settings because it is regarded as an almost obligate precursor to invasive disease; 50% progress within 5 years and longer progression intervals of up to 15–20 years are reported.

Histologically, GCNIS is characterized by atypical germ cells at the base of the seminiferous tubules (Fig. 27.7A). Spermatogenesis is typically absent or greatly reduced within involved tubules, but

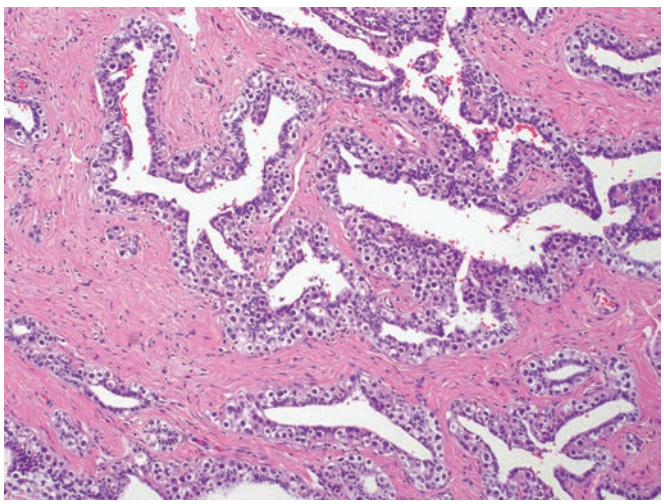

Figure 27.6 Pagetoid Extension of Seminoma Into Rete Testis. This should not be misinterpreted as a nonseminomatous component.

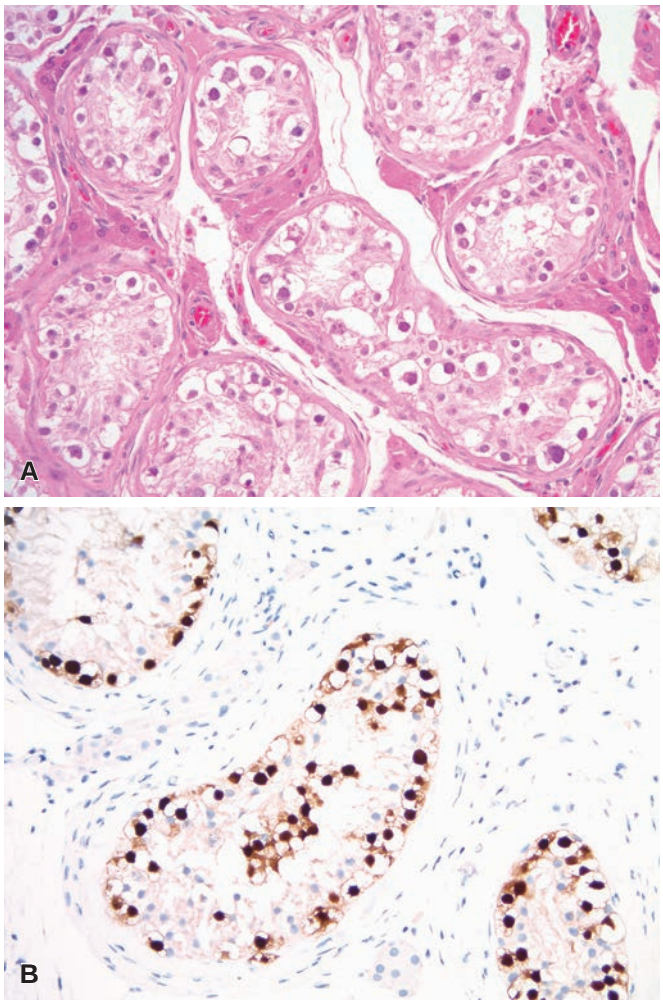

Figure 27.7 **A**, Microscopic appearance of germ cell neoplasia in situ (GCNIS) in routinely stained section. A row of atypical germ cells with clear cytoplasm is seen against a thickened basement membrane. No spermatogenesis is occurring in these tubules. **B**, Nuclear OCT3/4 expression in GCNIS.

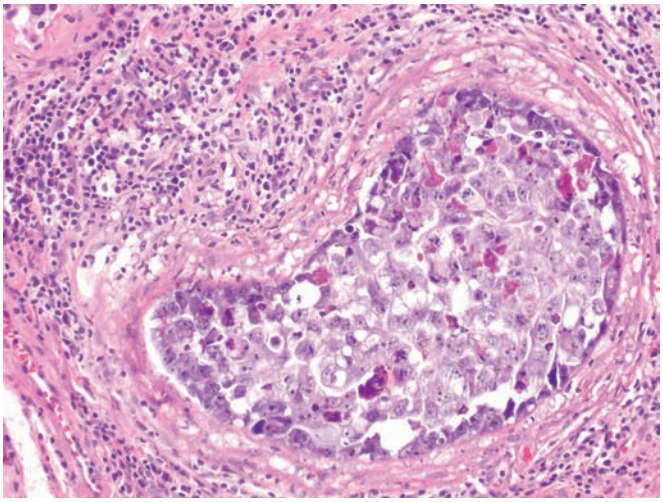

Figure 27.8 Intratubular Embryonal Carcinoma.

pagetoid spread to adjacent tubules creates a pattern with interspersed spermatogonia. Concomitant with the proliferation of atypical germ cells, the lamina propria of the tubule often becomes thickened and hyalinized. The atypical cells have a clear cytoplasm rich in glycogen and closely resemble classic seminoma. In some cases, intraluminal microliths or associated trophoblastic giant cells are seen.[181] Immunohistochemically, the neoplastic cells express markers of embryonic germ cells and seminoma, but placental alkaline phosphatase (PLAP), CD117 (c-KIT), OCT3/4, and podoplanin (D2-40) are most clinically useful because they are not expressed in normal spermatogonia (see Fig. 27.7B). GCNIS has a heterogeneous distribution from case to case, ranging from nearly 100% of seminiferous tubules to only focal[182–184]; it is least prominent in the region close to the epididymis. The differential diagnosis includes vacuolization of seminiferous tubule cells (a probable degenerative change), as well as maturation delayed gonocytes and maturation arrest at the stage of spermatogonia.[185] Exceptionally rare cases of metastatic carcinoma, melanoma, or even lymphoma may colonize seminiferous tubules.[186] Immunohistochemistry with OCT3/4 or other specific markers can resolve most difficult cases, so considering these other diagnostic possibilities is important. It is also important to screen for a subtle component of invasive seminoma (intertubular pattern), particularly when extensive GCNIS is identified in the absence of an obvious invasive component.[187]

Specific Forms of Intratubular Germ Cell Neoplasia. GCNIS is the most common histologic type of noninvasive germ cell neoplasia, but other types are rarely seen. When other types are present, associated GCNIS and invasive components are almost always present. In intratubular seminoma, atypical germ cells indistinguishable from those of seminoma are seen packing the tubules and totally replacing the normal Sertoli and germ cells.[188] An admixed intratubular syncytiotrophoblastic component may be present, but is nearly always accompanied by syncytiotrophoblasts within the invasive component of the tumor, whenever present.[181] In contrast to GCNIS, the invasive component of intratubular seminoma, if present, is nearly always a pure seminoma or a mixed germ cell tumor with a seminomatous component.

With intratubular embryonal carcinoma, the tubules contain highly malignant cells, identical to those seen in embryonal carcinoma (Fig. 27.8).[189] Foci of central necrosis and calcification are common in this lesion.[190,191] This finding is more common in smaller tumors, and, if needed, the diagnosis may be confirmed by documenting immunoreactivity for CD30.[189]

The possibility of other forms of germ cell neoplasia (i.e., yolk sac tumor, teratoma, or choriocarcinoma) being identified in an intratubular pattern exists, but the finding is extraordinarily rare.[192] On some occasions, all one sees is a collection of tubules with necrotic cells, often heavily calcified.[193]

Invasive Germ Cell Neoplasia

Seminoma. Seminomas make up 30%–40% of all testicular tumors (Fig. 27.9). While seminoma was historically divided into two types (classic and spermatocytic), the stark differences between these two tumors warrant their separation and use of the new terminology "spermatocytic tumor" for the latter; therefore, seminoma now refers only to the classic type.[99]

Seminoma has a characteristic gross appearance. It is usually solid, homogeneous, and light yellow to tan, and may contain sharply circumscribed zones of necrosis (Fig. 27.10). This macroscopic appearance may be similar to lymphoma or mesenchymal neoplasms. Areas of cystic change or hemorrhage are usually not seen, so their presence should raise the strong possibility of a nonseminomatous component and warrants thorough sampling of these foci.

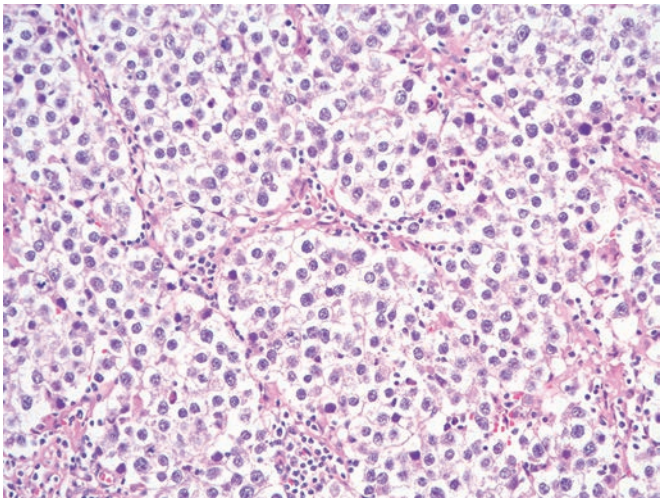

Figure 27.9 Classic Seminoma of Testis. Compact nests of large tumor cells are separated by fibrous septa heavily infiltrated by lymphocytes.

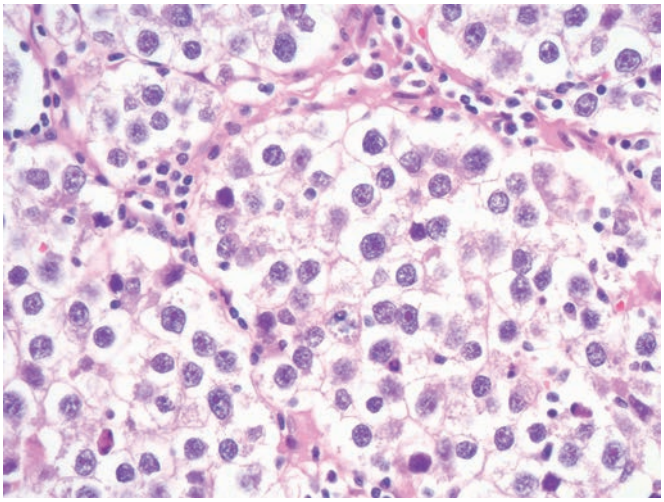

Figure 27.11 Seminoma, characterized by uniform cells with clear cytoplasm, sharp cell membranes, and centrally located nuclei, some with flattened edges.

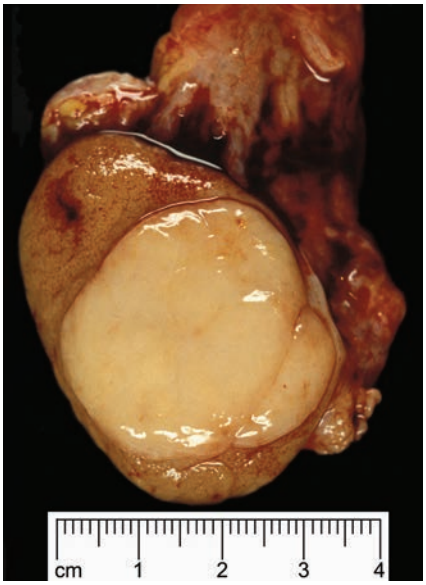

Figure 27.10 Typical tan, bulging homogeneous appearance of seminoma.

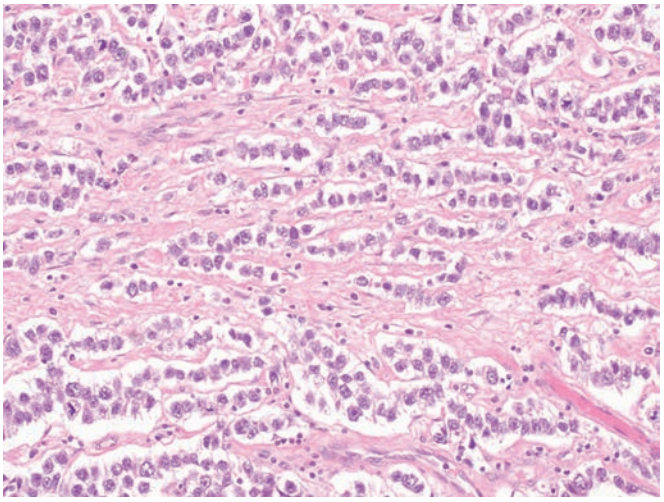

Figure 27.12 Seminoma With Cord-Like (Single File) Growth Pattern.

Microscopically, the individual tumor cells are uniform and relatively evenly spaced with abundant clear cytoplasm, sharply outlined cell membranes, and large centrally located nuclei with finely granular chromatin and flattened edges (Fig. 27.11). Central nucleoli are often prominent and may be multiple. The number of mitoses is highly variable. In some cases, the cells appear more crowded with denser cytoplasm that may impart a plasmacytoid appearance, more closely mimicking lymphoma. The tumor cells are typically arranged in nests outlined by fibrous bands; in 80% of the cases, these bands are infiltrated by lymphocytes (the large majority of T-cell type), plasma cells, and histiocytes.[194,195] Other morphologic patterns that are seen and may cause diagnostic difficulty include: cord-like (single file), tubular, trabecular, microcystic, intertubular, and signet ring–like vacuoles (Figs. 27.12 and 27.13).[187,196–200] A granulomatous reaction is not uncommon and ranges from focal collections of epithelioid histiocytes to well-formed granulomas obscuring much of the tumor (Fig. 27.14). Occasional Langhans-type multinucleated giant cells may also be present.

Seminoma cells contain variable, but usually abundant amounts of cytoplasmic glycogen, imparting the clear cytoplasmic appearance. Immunohistochemically, they exhibit reactivity for PLAP, CD117 (c-KIT), OCT 3/4, SALL4, SOX17, D2-40 (podoplanin), and NANOG, but are generally negative for high-molecular-weight keratin, epithelial membrane antigen (EMA), CD30, glypican-3, p63, and SOX2, features of importance in the differential diagnosis with embryonal carcinoma.[201–221] Some positivity for low-molecular-weight and wide-spectrum keratin is seen frequently, and may show a subtle dot-like pattern.[205,222] Rare cases with focal positivity for CD30 and EMA are reported in the litertaure,[223] but one must carefully consider the possibility of focal embryonal carcinoma in such cases.[209,224] Significantly, some of these immunomarkers are retained despite extensive tumor necrosis.[225,226] Despite the extensive literature on immunohistochemistry in germ cell tumors, it should be emphasized

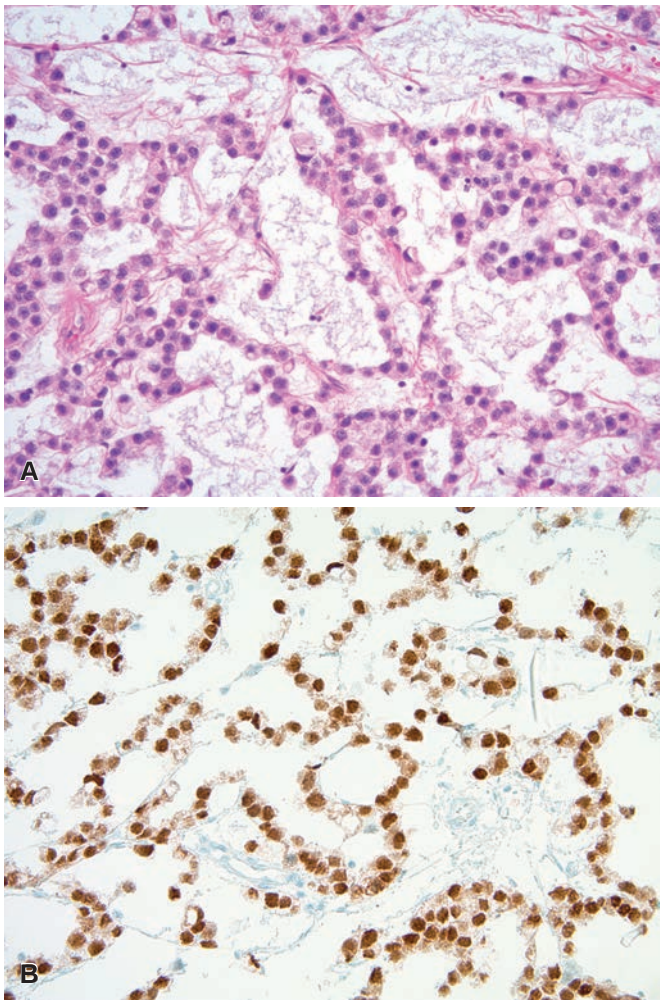

Figure 27.13 Seminoma With Microcystic Growth Pattern. **A,** Hematoxylin and eosin; **B,** OCT3/4 immunostain.

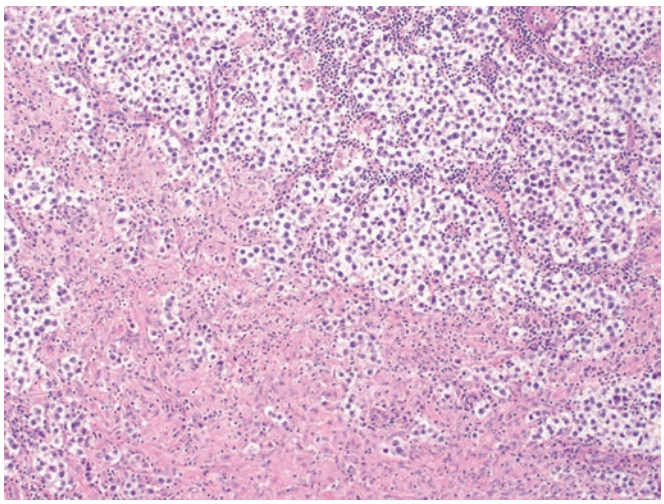

Figure 27.14 Seminoma Associated With Marked Granulomatous Reaction.

that morphology is sufficient for diagnosis in the vast majority of cases.

The concept of anaplastic seminoma was originally defined by Mostofi as a seminoma with features of the classic type having three or more mitoses per high-power field and characterized by a more aggressive clinical course.[192,227] In the era of modern chemotherapy, this distinction is not clinically relevant; therefore, use of that diagnostic category is no longer recommended.[99]

Seminoma with syncytiotrophoblastic giant cells constitutes 10%–20% of all seminomas. These multinucleated giant cells are either isolated, intimately admixed with the seminoma cells, or in the form of syncytial masses that are often associated with foci of hemorrhage (Fig. 27.15A). As in other sites, these cells express cytokeratin and hCG (see Fig. 27.15B); this latter finding explains why some seminoma patients have serum elevations of this hormone.[228] These clusters of syncytiotrophoblasts may be cytologically atypical and, when associated with hemorrhage, are often mistaken for choriocarcinoma. The diagnosis of testicular choriocarcinoma requires a distinct dimorphic population of associated cytotrophoblasts and syncytiotrophoblasts. The presence of intratumoral syncytiotrophoblasts should not alter the diagnosis as seminoma or the expected prognosis.

Embryonal Carcinoma. Embryonal carcinoma has a grossly more variegated appearance than seminoma (Fig. 27.16). It is mainly solid and gray or white, with foci of hemorrhage and necrosis. The latter may be so extensive as to render the diagnosis difficult. Microscopically, architectural patterns are heterogeneous but include solid sheets, papillary, glandular, and nested formations (Fig. 27.17).[191,229,230]

In the differential diagnosis with seminoma, the cells of embryonal carcinoma are more anaplastic, with numerous mitoses (often atypical) and apoptotic bodies, and exhibit prominent variation in size and shape. Multiple large nucleoli are present and overlapping of nuclei is typical.[230] Not uncommonly, a layer of ischemic or apoptotic cells with more eosinophilic cytoplasm may be present at the edges of the tumor imparting a biphasic appearance; this "appliqué" pattern should not be mistaken for choriocarcinoma (Fig. 27.18).[191,231] Immunohistochemically, embryonal carcinoma cells are reactive for keratin (including keratin 19 and high-molecular-weight forms), CD30, OCT 3/4, SALL4, NANOG, and SOX2 but not for CD117, glypican-3, or SOX17.[204,209,215,216,218,219,221,222,232–235] D2-40 staining is reported as more variable.[216] In general, CD30 is most useful for diagnostically challenging cases; however, the reactivity for CD30 may disappear following chemotherapy.[236] Reactivity for OCT3/4 tends to persist both in the primary tumor and in the metastases.[234]

Post-Pubertal Teratoma. Under the current WHO criteria, testicular teratomas should be divided into prepubertal and post-pubertal subtypes, which generally correspond to the patient's age in relation to puberty (but not always).[99] The terms "mature" and "immature" (which are applied in the ovary) or "malignant teratoma" no longer apply to testicular tumors because the terms have been used variably and serve only to confuse oncologists and urologists with regard to the well-recognized malignant potential of all post-pubertal type teratomas regardless of morphology.[147]

Pure post-pubertal teratomas represent approximately 5% of all germ cell tumors, but mixed germ cell tumors contain a component in approximately half of cases. Grossly, it is predominantly cystic and multiloculated (Fig. 27.19). Foci of cartilage are usually evident, whereas the presence of bone is infrequent.

All types of tissue can be seen microscopically in testicular post-pubertal teratoma, the most common being neural tissue, cartilage, and various types of epithelium (Fig. 27.20). The epithelial component can differentiate in the direction of gastrointestinal, respiratory,

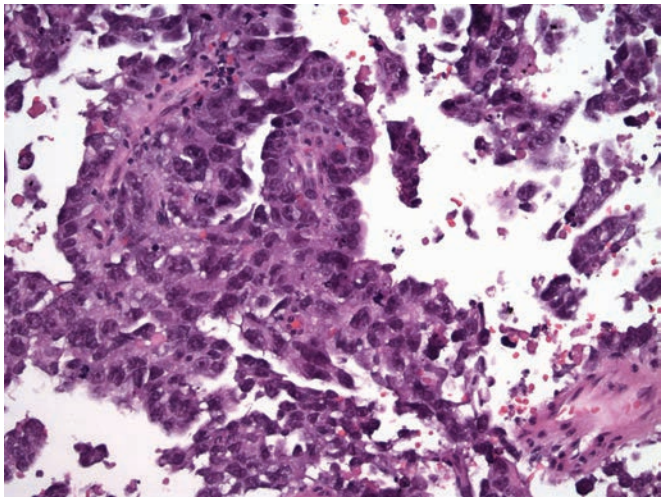

Figure 27.17 Embryonal Carcinoma With Papillary Growth Pattern.

cutaneous, or virtually any other tissue type. All of the cells normally present in the corresponding somatic structures may be identified, including neuroendocrine cells in the case of gastrointestinal epithelium, and meningothelial cells (to the point of forming meningioma-like structures) in the case of neural tissue.[237,238] Sometimes one of the components of the teratoma (such as cartilage) predominates to the near exclusion of the others.[239] Areas of cellular monomorphic spindle cells often show circumferential swirling growth around glands, another characteristic feature of post-pubertal teratoma.

A high proportion of post-pubertal teratomas exhibit some areas of tissue that in the past might be regarded as histologically "immature," a designation of poor reproducibility. The presence of these tissues, which may consist of stroma, epithelium, or neural components, does not change the overall prognosis or expected response to therapy; therefore, diagnosis as a post-pubertal type teratoma is sufficient.

Some post-pubertal teratomas have components of primitive neuroepithelial tissue with the appearance of neuroblastoma or peripheral neuroectodermal tumor (PNET).[240,241] In these cases, the criteria for somatic type malignancy must be applied in order to determine the minimal threshold required for classification as secondary somatic PNET (as discussed later). The distinction from dermoid cyst, epidermoid cyst, and related lesions are discussed under prepubertal-type teratoma.

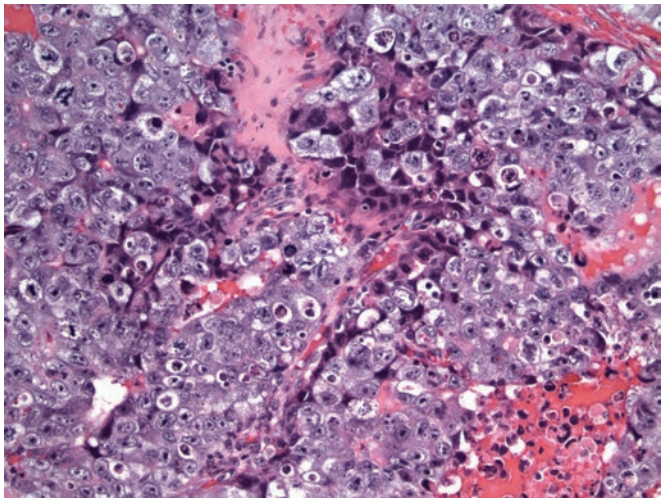

Figure 27.18 Embryonal Carcinoma With Overlapping Nuclei and Marked Pleomorphism. Mitotic activity and apoptotic cells are often abundant. Degenerative cells with eosinophilic cytoplasm create an "appliqué" pattern.

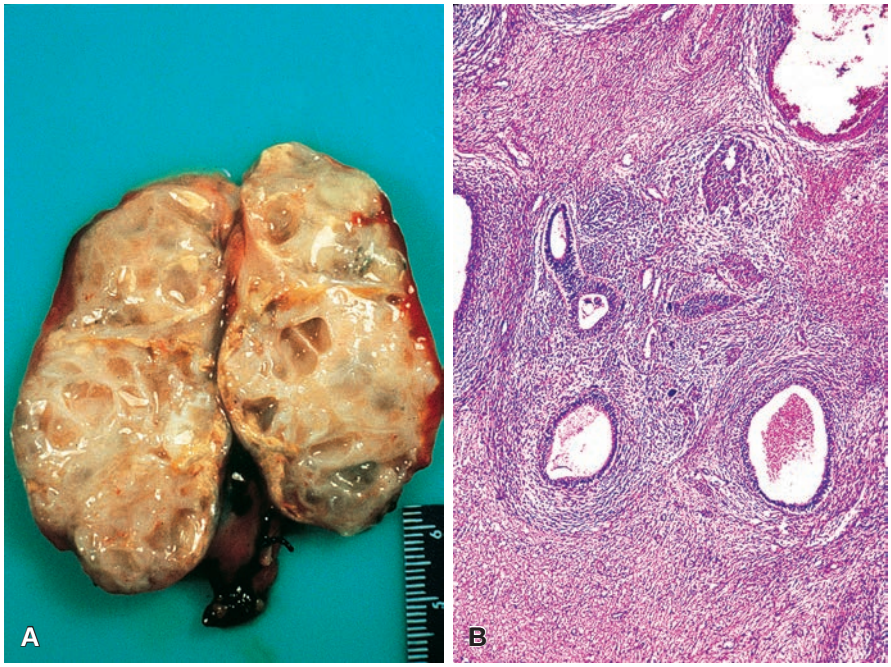

Figure 27.19 Post-Pubertal Teratoma. A, Gross appearance. **B,** Microscopic appearance. Hypercellular stroma is seen growing in a concentric fashion around glandular formations.

Yolk Sac Tumor. Although numerous names have been applied over the years, yolk sac tumor is the preferred term for this pattern of germ cell tumor that may recapitulate the yolk sac, allantoid, and extraembryonic mesenchyme.[242–250] In the post-pubertal setting, it is typically a component of a mixed germ cell tumor. Increased awareness of the different morphologic patterns that yolk sac differentiation may exhibit (as a result of correlative studies with immunocytochemical techniques) has led to an ever-increasing percentage of yolk sac elements being described in association with other germ cell components, particularly embryonal carcinoma.

Yolk sac elements in germ cell tumors of adults are difficult to discern on gross inspection. Microscopically, diagnosis depends on recognition of the full diversity of the histologic spectrum.[251] The microcystic reticular pattern is common and is characterized by collections of cells with intracytoplasmic vacuoles of varying size that create a sieve-like meshwork (Fig. 27.21). Associated areas with larger macrocysts may also be seen. Myxomatous patterns are underrecognized and often misinterpreted as stromal components, either reactive or teratomatous (Fig. 27.22). They consist of myxoid stroma with an admixed hypocellular population of bipolar to stellate spindle and/or epithelioid cells. Solid yolk sac tumor may closely mimic seminoma and recognition requires appreciation of the more varied cytology with scattered polygonal tumor cells and larger more pleomorphic cells (Fig. 27.23).[252] In contrast to seminoma, fibrous septa and lymphocytes are typically absent. Occasional examples of solid yolk sac tumor have less clear cytoplasm imparting a

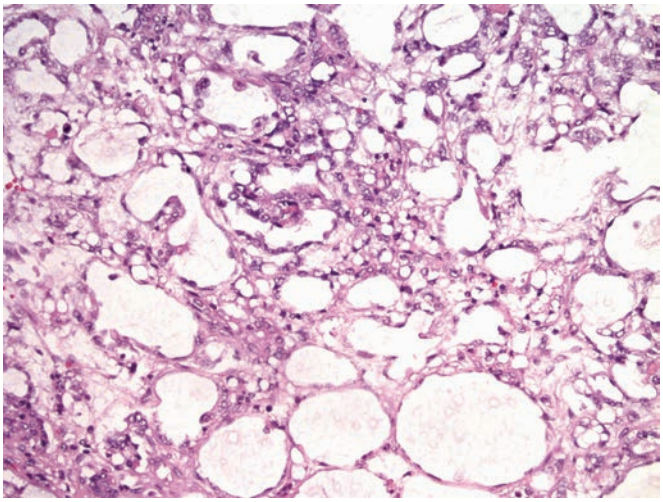

Figure 27.21 Yolk Sac Tumor With Reticular Pattern.

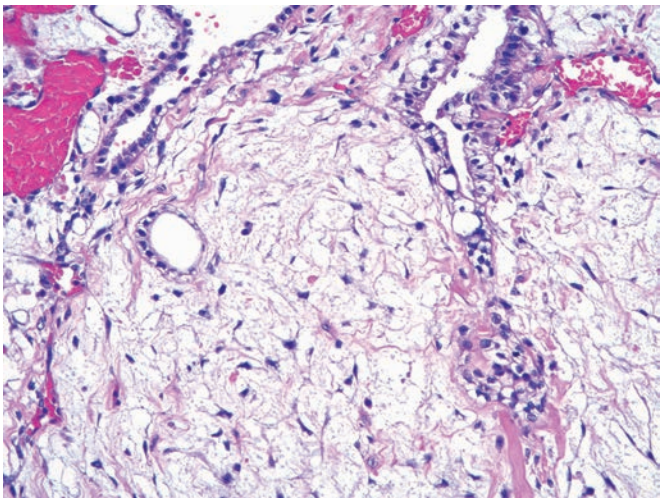

Figure 27.22 Yolk Sac Tumor With Myxoid Spindle Cell and Focal Glandular Patterns.

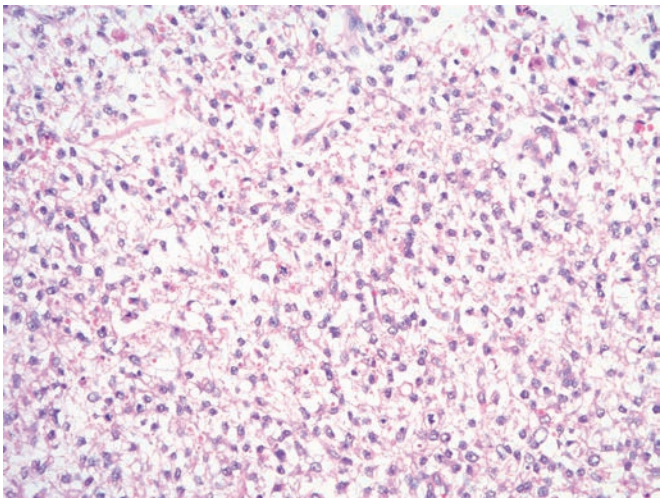

Figure 27.23 Solid yolk sac tumor may mimic seminoma, but cells are more variable in appearance.

"blastemal-like" appearance. Glandular patterns of yolk sac tumor may have enteric type features or subnuclear vacuoles reminiscent of secretory endometrium. The distinction from teratoma glands may be difficult, but yolk sac glands lack a smooth muscle layer or the cellular "encircling" stroma of teratoma; instead, they are typically intimately admixed with other yolk sac patterns. In this respect, the distinction of individual foci as either glandular yolk sac tumor or glandular teratoma may be somewhat subjective and is often based on "the company they keep." Some examples of yolk sac tumor create a pattern of interconnecting glands with a more alveolar pattern. Endodermal/perivascular patterns are characterized by a central blood vessel with supporting connective tissue and a surrounding layer of cuboidal tumor cells. Perivascular Schiller–Duval bodies are the one of the classical features of yolk sac tumor, but they are over-emphasized in education and not required for diagnosis. Hepatoid patterns consist of round epithelioid cells with eosinophilic cytoplasm growing in sheets or trabeculae, similar to normal hepatocytes with or without intracytoplasmic lipid. A spectrum of papillary patterns may be seen, with lining cells showing characteristic cytologic features of yolk sac tumor. Sarcomatoid/spindle cell patterns have close histologic overlap with secondary somatic sarcoma, but they are often seen in direct continuity to other patterns of yolk sac tumor, often with gradual transition to the myxomatous pattern. The parietal pattern is easy to overlook and is characterized by densely eosinophilic basement membrane like material surrounding a subtle, hypocellular population of tumor cells. The polyvesicular vitelline pattern is less common, but is composed of dilated gland-like spaces (with or without constrictions creating a "bead-like" pattern) lined by a flattened, atrophic epithelium.[253] These "vesicles" are often surrounded by a loose stroma.

Variants of yolk sac tumor that tend to be misinterpreted are those exhibiting a hepatoid pattern (featuring fetal-type liver cell cords), a solid pattern, or a well-differentiated glandular pattern (resembling fetal lung or intestine, the latter also referred to as primitive intestinal or enteric pattern).[252,254,255] Hyaline intracytoplasmic and extracytoplasmic round inclusions are commonly seen in yolk sac tumors.

The cells of yolk sac tumor are also consistently positive immunohistochemically for keratin.[256] A SALL4+, OCT3/4– immunophenotype is highly characteristic of yolk sac tumor,[204] and glypican-3 and CDX2 expression is also typical.[221,257–259] In our experience, AFP stains have high background and are difficult to interpret compared to some of the newer markers; therefore, as a matter of preference we rarely employ its use. It should also be emphasized that solid yolk sac tumor loses AFP reactivity in up to 38% of cases.[252]

Choriocarcinoma. Choriocarcinomas account for about 5% of testicular tumors. They are usually hemorrhagic and partially necrotic. Rarely the primary tumor may completely regress, leaving only a scar containing hemosiderin pigment. Microscopically, these tumors show giant syncytiotrophoblastic cells with large, atypical nuclei intermingled with cytotrophoblasts (Fig. 27.24).[112] The syncytiotrophoblastic cells are consistently immunoreactive for hCG and keratin.[260,261] It has been noted that keratin 7 stains trophoblastic cells (whether in a choriocarcinoma or in other germ cell tumors), but not any of the other tumor components in germ cell tumors.[262] As already mentioned, cells with the morphologic appearance of syncytiotrophoblasts can be seen in several other types of testicular germ cell tumor; however, their presence as isolated elements or even as syncytial clusters (with or without accompanying hemorrhage) in a testicular germ cell tumor is not sufficient for a diagnosis of choriocarcinoma (Fig. 27.25). It is only when these cells are intimately mixed with cytotrophoblastic elements in a biphasic pattern that the diagnosis of choriocarcinoma is justified.[263] Something similar can be said concerning serum levels of chorionic gonadotropins. Although classically elevated in choriocarcinomas, they also may

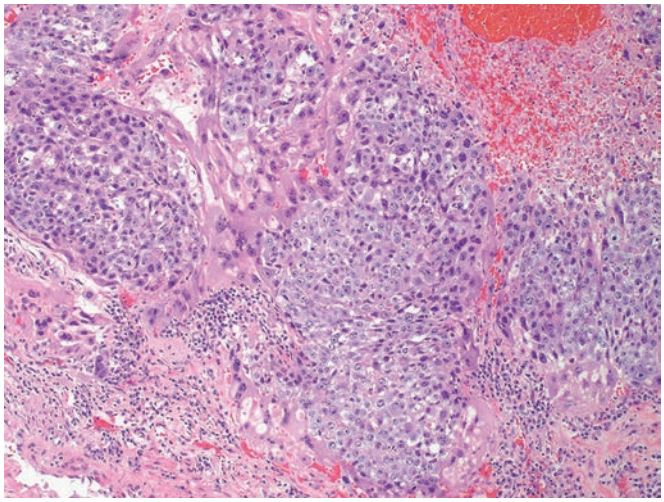

Figure 27.24 Microscopic Appearance of Testicular Choriocarcinoma. There is close intermingling of cytotrophoblast and syncytiotrophoblast, which recapitulates that seen in normal chorionic villi.

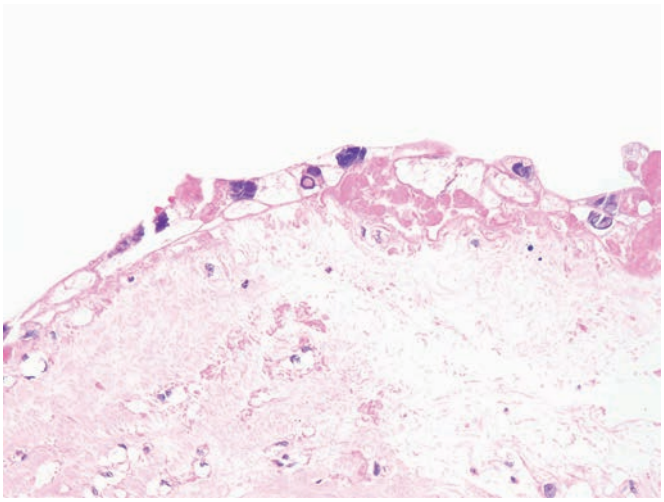

Figure 27.26 Cystic Trophoblastic Tumor.

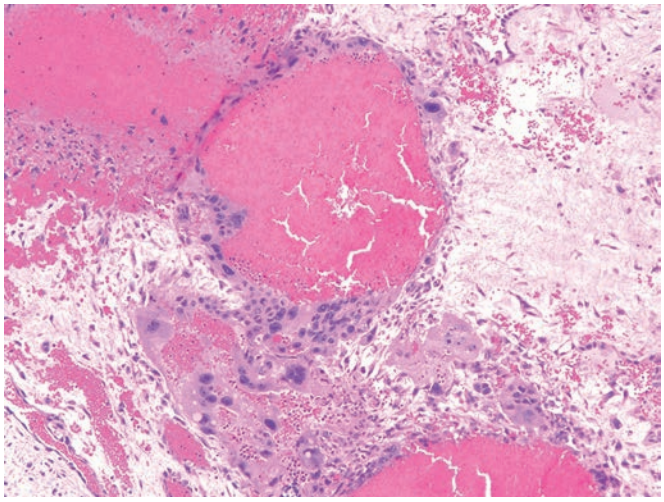

Figure 27.25 Clusters of atypical syncytiotrophoblasts with hemorrhage are NOT diagnostic of choriocarcinoma. The dimorphic relationship to cytotrophoblasts is needed. The background in this case is yolk sac tumor.

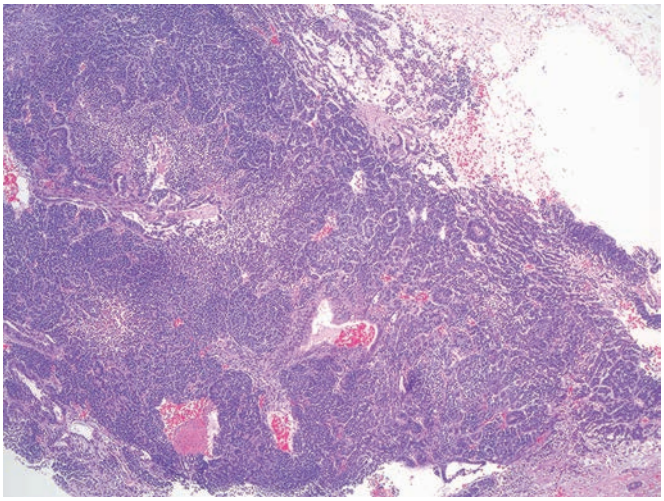

Figure 27.27 Somatic Type Malignancy in Teratoma. A low-power field is composed of primitive neuroectodermal tumor (resembling its central nervous system counterpart).

be increased in any other type of testicular germinal tumor, so the diagnosis of choriocarcinoma should be made on the basis of the microscopic pattern rather than on the basis of the hormone being produced. It should also be mentioned that in exceptional circumstances one can find a trophoblastic testicular tumor formed almost exclusively of cytotrophoblasts (so-called monophasic choriocarcinoma), but this is more common in the post-treatment setting.[264] A monophasic syncytiotrophoblastic form is not recognized.

Non-Choriocarcinomatous Trophoblastic Tumors. Other rare types of trophoblastic neoplasia are described in the testis, including *placental site trophoblastic tumor* and *epithelioid trophoblastic tumor*.[264] The morphology is identical to their gestational counterparts (fully described in Chapter 33). These rare tumors may also occur in recurrences.[265]

The *cystic trophoblastic tumor*, which may occur in the testis, is more commonly seen in the post-therapy setting within retroperitoneal lymph node dissection specimens.[266,267] They consist of multiple cysts lined by a variable layer of mononuclear trophoblastic cells characterized by eosinophilic cytoplasm, large nuclei with dark smudgy chromatin, only rare mitoses, and frequent intracytoplasmic lacunae (Fig. 27.26).[266,267] These may be associated with minor elevations in serum human chorion gonadotropin and evidence suggests that they represent "matured" forms of choriocarcinoma. Most importantly, for clinical management the cystic trophoblastic tumor should be regarded similarly to teratoma as it has no increased risk for disease progression and warrants no additional therapy.

Somatic-Type Malignancies in Germ Cell Tumors. Occasionally, testicular germ cell tumors develop malignancies—referred to as somatic type—having appearances analogous to those of conventional tumors of nongerm-cell nature. The malignant component is often in the form of sarcoma (such as rhabdomyosarcoma) or neuroepithelial type neoplasms similar to those in the central nervous system (primitive neuroectodermal tumor) (Fig. 27.27),[268,269] but it may also present in the form of epithelial malignancy (such as adenocarcinoma). This phenomenon is designated as somatic type malignancy; older terms such as "teratoma with malignant transformation" are not recommended.

By definition, the somatic-type malignancy should consist of a pure population of the atypical cells showing an expansile or infiltrative growth that occupies at least one low-power field (×4

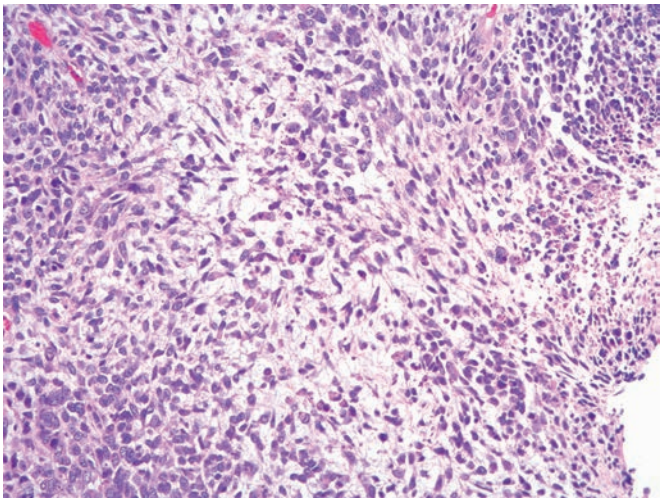

Figure 27.28 Sarcomatoid yolk sac tumor (expressed SALL4 and glypican-3) behaves similarly to somatic type sarcoma.

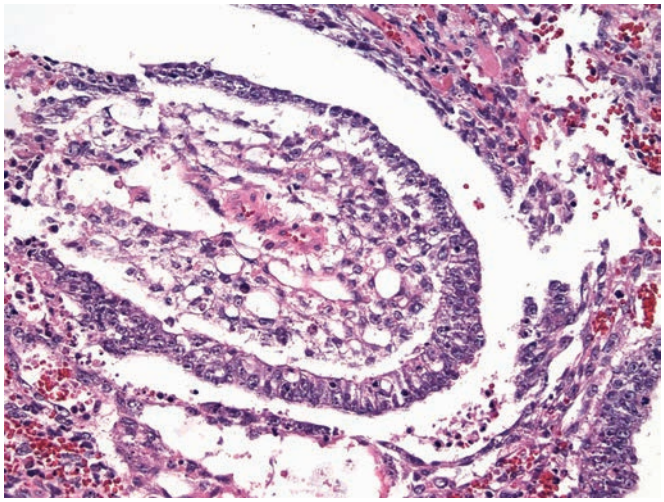

Figure 27.29 Embryoid body pattern of mixed yolk sac tumor and embryonal carcinoma.

objective, 5 mm in diameter). Similar cell populations admixed within the otherwise typical varied components of a post-pubertal teratoma do not have prognostic significance and, therefore, should not change the overall classification. Studies of clonality and 12p status have shown that in most cases the somatic-type neoplasms arise from the preexisting germ cell tumors[270,271]; as such, primitive neuroectodermal tumors do not have the EWSR1 rearrangement typical of Ewing sarcoma.[272] In general terms, the emergence of somatic malignancy in a testicular germ cell tumor represents a poor prognostic sign, at least when invading outside of the testis or when presenting at a metastatic site.[268,269] It has been shown that tumors with more mature skeletal muscle differentiation developing in the retroperitoneum after chemotherapy for metastatic germ cell tumor exhibit a clinical behavior more in keeping with a teratoma than with an adult-type rhabdomyosarcoma and should therefore be separated under the diagnostic term "differentiated rhabdomyomatous tumor."[273] While a subset of post-chemotherapy malignant spindle cell tumors may represent a sarcomatoid form of yolk sac tumor, they behave similar to other secondary somatic sarcomas; therefore, distinction may not be critical for clinical management (Fig. 27.28).[274,275]

Carcinomatous forms of somatic malignancy are most commonly enteric or mucinous type adenocarcinomas.[271,276–278] These carcinomas often lose markers of germ cell origin, but may retain SALL4 expression.[276] Glandular patterns of yolk sac tumor should be considered before a somatic carcinoma is diagnosed.[276]

Unlike mediastinal germ cell tumors, secondary somatic hematopoietic neoplasms would be extraordinarily uncommon in the testis.

Somatic type malignancies do not show the excellent response to cisplatin-based chemotherapies seen with germ cell tumors; therefore, treatment should be tailored to the specific histologic type of malignancy present.[271]

Specific Histologic Patterns of Mixed Germ Cell Tumor. Some germ cell tumors have a distinctive appearance resulting from their unique architectural admixture of yolk sac tumor and embryonal carcinoma and have been given descriptive names. Polyembryomas are characterized by the presence of multiple embryoid bodies throughout the neoplasm.[279] Histologically, they are characterized by a linear core of embryonal carcinoma directly adjacent to an "amniotic-like" space with an underlying yolk sac tumor competent with reticular or microcytic features (Fig. 27.29). Diffuse embryoma

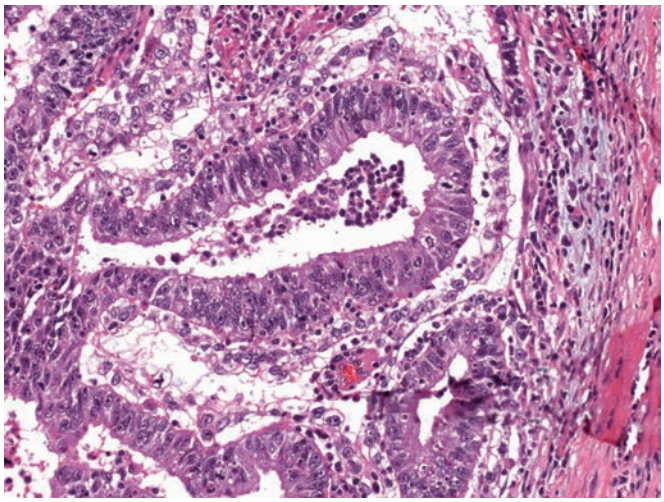

Figure 27.30 Diffuse embryoma pattern of mixed yolk sac tumor and embryonal carcinoma.

features an equal admixture of yolk sac tumor and embryonal carcinoma that are arranged in "stacked" linear arrays (Fig. 27.30).[280,281] The two components have a subtle but distinct cytologic difference with the yolk sac component having smaller nuclei. These almost never occur in a pure form, but rather as a component of a variety of mixed germ cell tumors.[282]

Regressed Germ Cell Tumors. It is well recognized that a small subset of testicular germ cell tumors undergoes partial or complete regression (<5%). These patients may present with retroperitoneal metastases, but only nonspecific findings on testicular ultrasound. Histologically, regression is characterized by a well-demarcated fibrotic scar with variable lymphoplasmacytic inflammation, ischemic "ghosts" of hyalinized tubules, increased numbers of small blood vessels, hemosiderin-laden macrophages, and coarse intratubular calcifications.[151] The identification of GCNIS in the adjacent testicular parenchyma is a strong corroborating finding.

Diagnosing Metastatic Germ Cell Neoplasia. It is not uncommon to receive biopsies of nodal or parenchymal-based lesions where the differential diagnosis of a germ cell tumor might be considered. Improved immunohistochemical germ cell markers are helpful

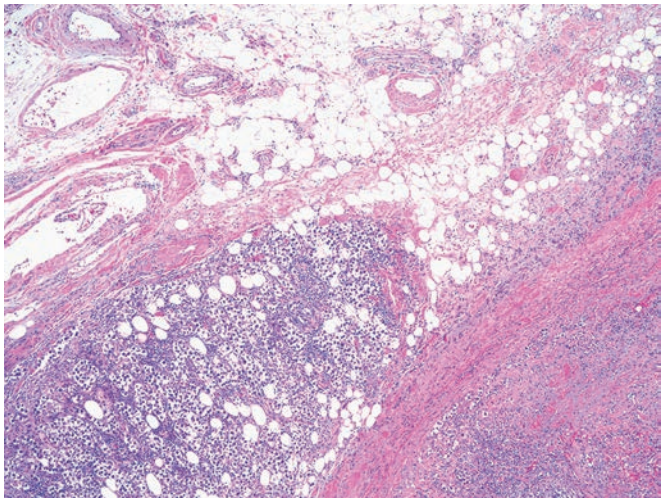

Figure 27.31 Seminoma infiltrating into the renal hilar tissue, indicating pT2 disease.

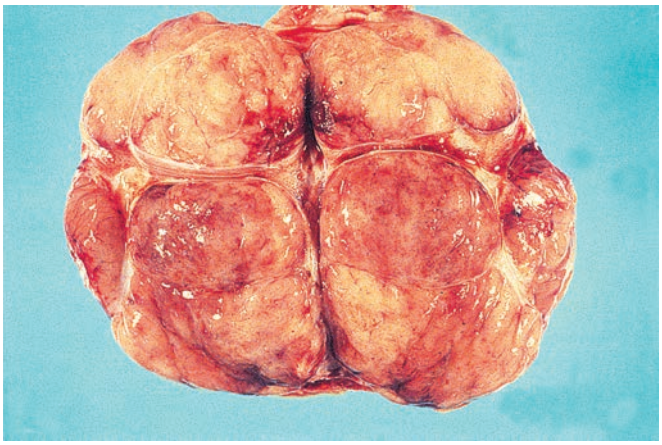

Figure 27.32 Gross Appearance of Spermatocytic Tumor. A large tumor of myxoid appearance bulges on the cut surface.

(particularly SALL4 and OCT3/4), but close clinical and histologic correlation is essential as these markers are not entirely specific.[283,284] SALL4 is expressed in some high-grade serous carcinomas of the gynecologic tract, a subset of adenocarcinomas of the upper gastrointestinal tract that may have unusual "immature" or "fetal" features (particularly the esophagus and GE junction), urothelial carcinoma, rhabdoid tumors (kidney and extrarenal), blastemal tumors of children (e.g., Wilms tumor and hepatoblastoma), as well as rarely in other carcinomas from various sites.[285–287] OCT3/4 stains a subset of large cell lymphomas, is commonly expressed in medullary carcinoma of the kidney, and may rarely stain poorly differentiated carcinomas from various sites.[288,289] It should also be remembered that yolk sac tumor may express PAX-8. As mentioned previously, CD30 reactivity may be lost in metastatic embryonal carcinoma.[236] There is much less published experience with other novel markers of germ cell origin such as SOX17, NANOG, and MAGEA4, particularly with regard to expression in other carcinoma types.

Staging on Orchiectomy Specimens. The major keys to staging in the testis are identifying the extent of invasion beyond the testis and the presence of lymphovascular invasion. In latest version of the AJCC staging manual, invasion of testicular hilar soft tissue (Fig. 27.31) and tumor size are now emphasized. For pure seminoma limited to the testis, 3 cm is an important cutoff.[139]

Germ Cell Tumors Unrelated to Germ Cell Neoplasia In Situ

Overview. With the exception of spermatocytic tumor, this group of germ cell tumors typically occurs in the pediatric or prepubertal setting. In children, seminomas and embryonal carcinomas are practically nonexistent. Only yolk sac tumor and teratoma occur with any frequency, and they may be admixed.[290] The majority of pure yolk sac tumors occur in infants under 2 years of age.[249] Prepubertal type teratoma may occur only very rarely in post-pubertal patients.[291] Tumors developing in prepubertal gonads tend to be diploid and are not associated with i(12p) or with GCNIS.[121] Prepubertal type teratoma is the only testicular germ cell tumor lacking gross chromosomal aberrations.[292] Yolk sac tumor in infants and children commonly shows loss of 1p and 6q and gain of 1q, 20p, and 22. Teratoma of the prepubertal testis has never been shown to metastasize. Pure yolk sac tumors occurring in infants or children metastasize to periaortic or other lymph node groups only rarely.[249] The incidence of retroperitoneal spread in pure yolk sac tumors of infants is too low to justify a lymphadenectomy.[293] Similarly, teratomas occurring in infants or children should be treated by orchiectomy alone.

Spermatocytic tumor shows completely different genetic features from classic seminoma. Isochromosome 12p is not found. Numerical chromosomal aberrations are common and gain of chromosome 9 is characteristic; recent studies have identified that this corresponds to additional copies of the *DMRT1* gene.[294] Activating mutations in the *FGFR3* and *HRAS* genes are also reported in a smaller subset of spermatocytic tumors, typically in older patients.[295]

Spermatocytic Tumor. These rare tumors (previously called spermatocytic seminoma) should be clearly separated from classic seminoma and its variants. It comprises approximately 1% of testicular germ cell tumors and typically occurs in an older age group (mean, 52–59 years) compared to seminoma.[99,296] Grossly, it has a soft, gelatinous appearance (Fig. 27.32). Microscopically, it is composed of cells with round nuclei growing in sheets with or without a nodular pattern separated by scant fibrous stroma. Edema is frequent and may create a cystic appearance. The overall tinctorial quality is more amphophilic than classic seminoma because the cytoplasm is denser and lacks glycogen,[297] a useful clue to considering the possibility of spermatocytic tumor. Although variable, the prototypical morphology is a polymorphous population of three cell types: small round cells (lymphocyte-like), intermediate cells similar in size to classic seminoma, and giant cells that may be multinucleate (Fig. 27.33). Some

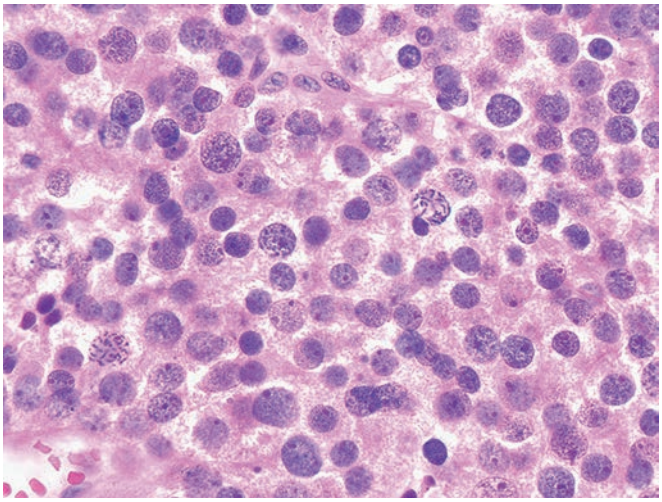

Figure 27.34 Typical chromatin pattern of spermatocytic tumor.

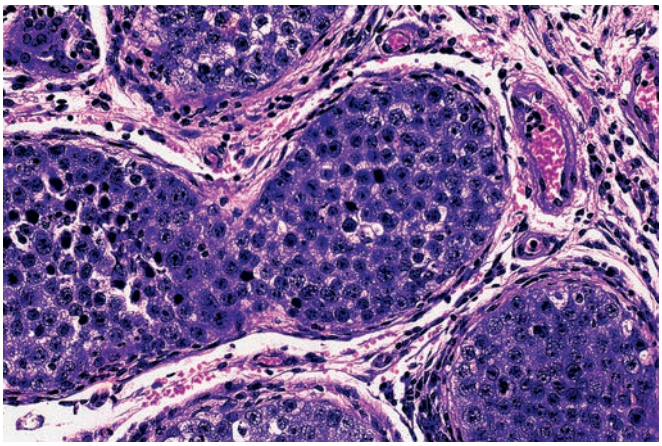

Figure 27.35 Extensive intratubular growth of spermatocytic tumor.

of the nuclei have a filamentous appearance (spireme-like chromatin) suggestive of an early stage of meiotic division (Fig. 27.34). Mitoses and apoptotic bodies may be numerous. Intratubular edema may also be present, inducing a "pseudoglandular" pattern. Prominent intratubular growth is often seen at the periphery (Fig. 27.35), but this should not be equated with GCNIS, which is not seen. Areas of lymphocytic infiltration and granuloma formation are typically absent.[298]

Rare cases of spermatocytic tumor have a more monomorphic population of intermediate size cells, often with prominent nucleoli. In the past, the term "anaplastic spermatocytic seminoma" has been used for this pattern. The few reported cases have so far behaved no differently than spermatocytic tumor without this feature; therefore, the term is not recommended.

In contrast to classic seminoma, immunoreactivity for PLAP and OCT3/4 is absent, which is very helpful in diagnosis.[299] Focal and inconstant positivity for keratin may be observed, as in classic seminoma.[299] SALL4, CD117, and DMRT1, as well as SAGE1, SSX, and OCT2 (germ cell tumor markers that are expressed in spermatogonia), are positive in spermatocytic tumor.[204,294,300,301]

In contrast to classic seminoma, spermatocytic tumor occurs only in the testicle and is never seen in combination with other admixed germ cell components. It is more commonly bilateral, and the prognosis is excellent. Metastases are extraordinarily rare, and therefore simple orchiectomy is considered sufficient therapy.[297,302] It is worth restating that, although spermatocytic tumor occurs moist commonly in men over age 50 years, the GCNIS-related classic seminoma is actually more common.

Spermatocytic tumor may be complicated by a secondary sarcoma, most commonly rhabdomyosarcoma or undifferentiated sarcoma (Fig. 27.36). This development is accompanied by frequent metastases and high mortality rate.[303–305]

Prepubertal Teratoma. Prepubertal type teratomas, which are clinically benign, by definition have no association with GCNIS, dysgenetic gonadal changes, 12p abnormalities, or adjacent regressed components. They have some major histologic differences when compared to their post-pubertal counterparts, including more organoid arrangement of the distinct elements into structures resembling normal tissue. For example, epithelial lined tubular structures are often surrounding by a muscular layer and secondary structures are often present, such as cutaneous adnexa in skin or minor mucinous glands in bronchial-like tissue. Significant cytologic atypia is usually absent. Special types include dermoid cyst and epidermoid cyst (Fig. 27.37).[99,306] In difficult cases, molecular studies evaluating for chromosome 12p abnormalities may be of great aid; moreover, one might consider this test required if the diagnosis is considered in a patient that is post-pubertal (or over 12 years of age).

The current WHO classification considers well-differentiated neuroendocrine tumors ("carcinoid tumors") (Fig. 27.38), which are extremely rare in the testis, as monodermal teratomas within the spectrum of prepubertal-type teratomas given that: (1) most lack associated GCNIS, (2) some are associated with other forms of prepubertal-type teratoma, and (3) absence of 12p abnormalities in most cases.[99] These tumors may be pure, associated with teratoma showing prepubertal features, or associated with either a dermoid or epidermoid cyst.[307–310] Importantly, the possibility of a metastasis from an extragonadal primary site (such as the gastrointestinal tract) must be excluded clinically before the diagnosis of a primary pure neuroendocrine neoplasm of the testis is accepted. While most of these tumors are benign regardless of their association with a teratomatous component or not, metastases are reported; however, metastases are more commonly seen in cases with more aggressive features (e.g., increased mitotic activity or necrosis).

Two seemingly contradictory points for pure primary testicular neuroendocrine neoplasms are that 12p abnormalities have been reported in at least some cases and that most cases occur in a much

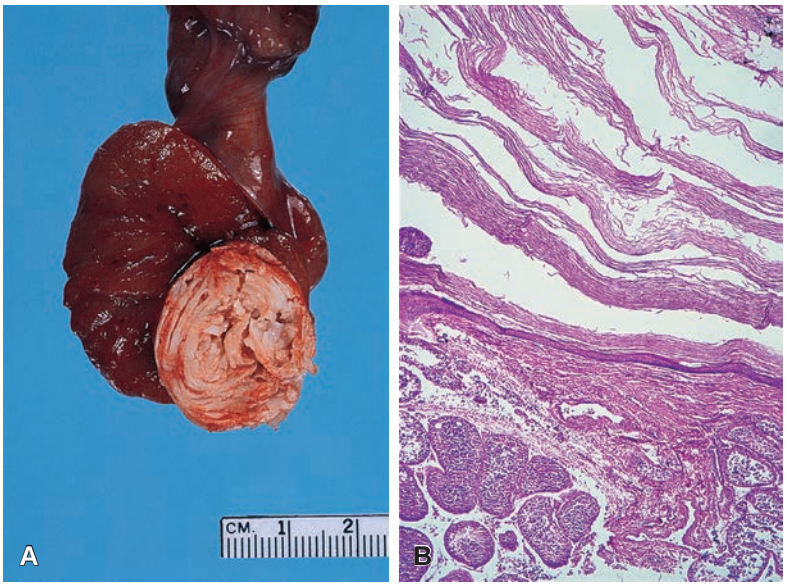

Figure 27.37 Epidermoid Cyst of Testis. A, The lesion is sharply outlined and contains laminated layers of keratin. **B**, Microscopic appearance of epidermoid cyst of testis. Keratin squames are laid down by well-differentiated squamous epithelium. There are no skin adnexal structures.

Figure 27.39 Gross Appearance of Pure Yolk Sac Tumor in an Infant.

older age group than typical for prepubertal type germ cell tumors, suggesting biologic heterogeneity and the possibility that classification could evolve with more study.[311,312]

Mixed Teratoma and Yolk Sac Tumor, Prepubertal. Mixed tumors of the testis in the prepubertal setting are rare, but consist of admixed prepubertal-type teratoma and yolk sac tumor.[313] The yolk sac component may be focal. Although other types of germ cell tumor are not seen, exceptional cases may progress to primitive neuroectodermal tumor or other secondary somatic type malignancy.

Yolk Sac Tumor, Prepubertal. Prepubertal yolk sac tumors typically occur in young children (median age of 16–20 months).[314] These tumors have a similar spectrum of morphologic features and immunophenotype to their post-pubertal counterpart, but lack the isochromosome 12p. Grossly, the pure yolk sac tumor of infancy has a soft consistency and a microcystic appearance on cross section (Fig. 27.39). For pathologists used to classifying germ cell tumors in adults, the degree of cytologic atypia may suggest the possibility of an embryonal component, but that combination is essentially not seen in the pediatric age group. Juvenile granulosa cell tumor (described later) may be a close histologic mimic.

Sex Cord–Stromal Tumors

Leydig Cell Tumor and Related Lesions

Leydig cell tumors comprise between 1% and 3% of all testicular tumors. About 3% are bilateral, either synchronously or metachronously.[315] A few have been described in cryptorchid testes and others in patients with Klinefelter syndrome (where they may simply represent florid hyperplasia). There is also an uncommon association with hereditary leiomyomatosis and renal cell carcinoma syndrome

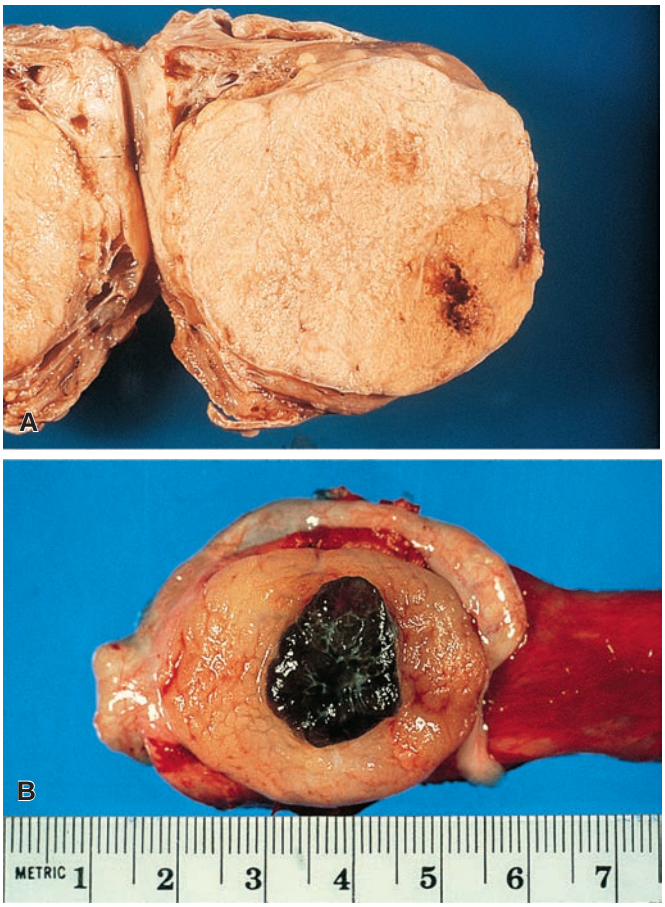

Figure 27.40 Gross Appearance of Leydig Cell Tumor. A, The tumor, which has replaced most of the testis, has a granular yellow appearance. **B,** This tumor, occurring in a child, is solid, well circumscribed, and dark brown.

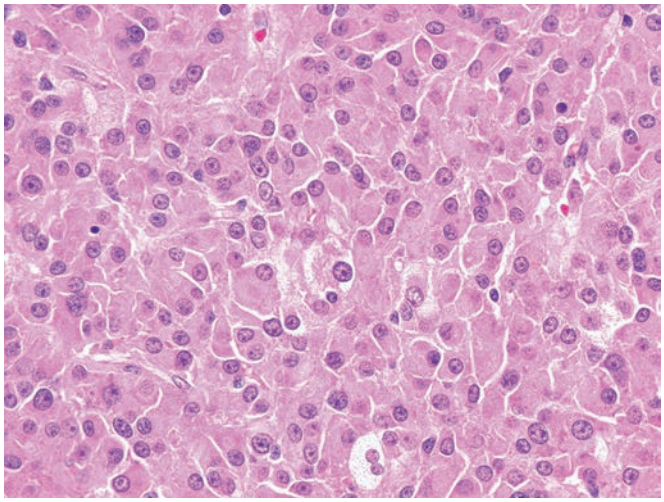

Figure 27.41 Leydig Cell Tumor of Testis. The neoplasm is characterized by solid growth of polygonal cells with abundant granular acidophilic cytoplasm.

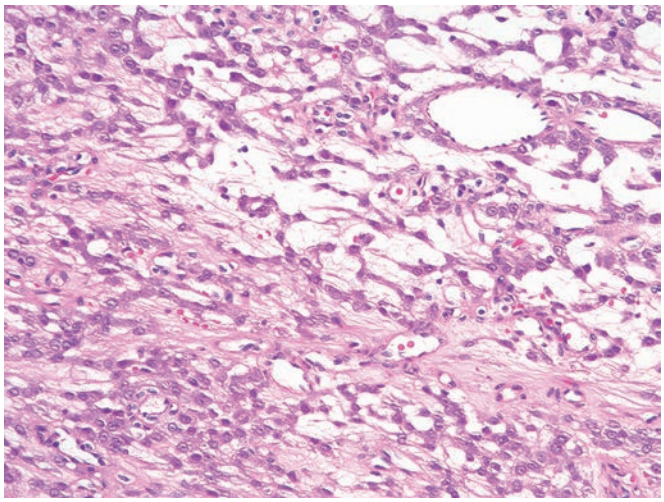

Figure 27.42 Leydig cell tumor with microcystic pattern, which may closely mimic yolk sac tumor.

(i.e., germline *FH* mutation).[316] In rare cases, they occur in patients with a germ cell tumor in the contralateral testis, either synchronously or metachronously.[317] They may produce endocrine changes because of increased production of androgens and/or estrogens.[318,319] Most occur in adults, with a palpable testicular mass and gynecomastia being the most common symptoms. The few that occur in childhood cause precocious pseudopuberty with growth of pubic hair and penis, but without spermatocytic maturation in the non-neoplastic testis (hence the prefix pseudo); these symptoms usually regress after removal of the tumor.[320]

Grossly, Leydig cell tumor presents as a generally small (average size, 3 cm), sharply delimited solid nodule embedded within the testicle (Fig. 27.40). The brown color it usually exhibits is one of its most distinguishing gross features. In rare cases, Leydig cell tumor or other gonadal stromal tumors are found outside the testis proper.[321]

Microscopically, the tumor cells have well-defined outlines, deeply acidophilic but occasionally clear cytoplasm, and a round or oval (occasionally grooved) nucleus (Fig. 27.41). Some of the cells have a plasmacytoid appearance. Lipochrome pigment and Reinke crystalloids are sometimes present, the latter well demonstrated with Masson trichrome stain. As with most other endocrine tumors, marked variation in the size and shape of the tumor cells may occur, with the presence of bizarre forms with giant nuclei. The pattern of growth is generally solid, but trabecular, myxoid, pseudofollicular, and microcystic formations can be present (Fig. 27.42).[322,323] Occasionally, there is prominent spindling of tumor cells, metaplastic ossification or adipose metaplasia.[324–327] On occasion, the ultrastructural appearance is reminiscent of fetal-type Leydig cells.[328]

The markers that have proved to be of the greatest utility for the evaluation of these tumors are inhibin, calretinin, SF-1, CD99, and Mart-1 (also known as Melan-A and detected with the antibody A103).[329–334] Expression of S-100 protein, synaptophysin, and cytokeratin is variable.[335–337] Nuclear β-catenin is absent.[337]

An activating mutation of the gene encoding the luteinizing hormone receptor has been detected in some cases of pediatric Leydig cell tumor.[338]

Most Leydig cell tumors behave in a benign fashion, but about 5% show evidence of malignant behavior in the form of metastatic disease, particularly to lymph nodes, lung, and liver.[339,340] Malignant Leydig cell tumors occur exclusively in adults, are usually unaccompanied by endocrine changes, are larger than the benign variety (average size, 7.5 cm), are more commonly infiltrative, and tend to exhibit necrosis, blood vessel invasion, nuclear atypia, numerous mitoses (>3 mitoses per 10 high-power fields), and lack of lipochrome pigment.[341] Sarcomatoid (spindle cell) changes can be present in

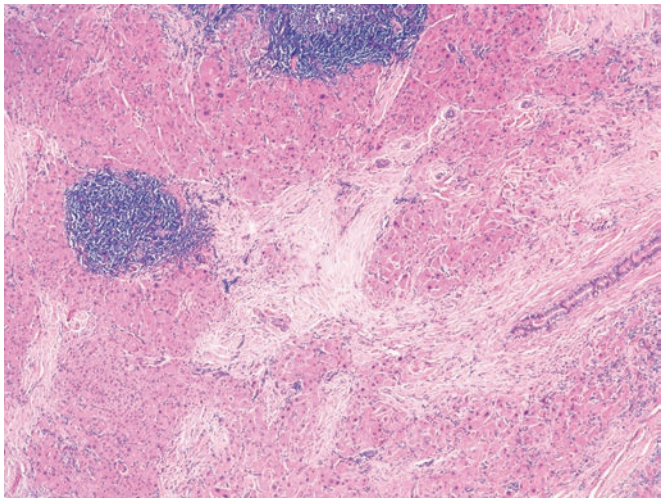

Figure 27.43 "Testicular Tumor" of the Adrenogenital Syndrome. Multiple nodules are present, divided by fibrous septa.

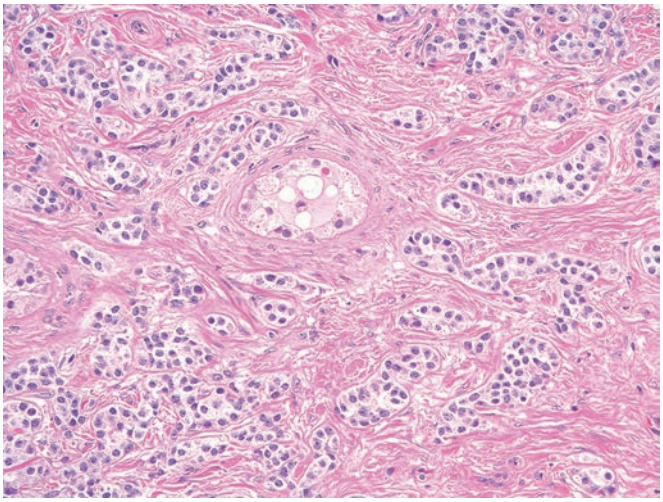

Figure 27.44 Microscopic appearance of Sertoli cell tumor, not otherwise specified.

the metastatic foci.[342] Metastasizing Leydig cell tumors have a higher MIB-1 index and a much higher incidence of aneuploidy than their nonmetastasizing counterparts.[343,344]

Leydig cell tumors are usually treated with simple orchiectomy. Malignant tumors may need retroperitoneal node dissection.

The differential diagnosis of Leydig cell tumor includes the following conditions:

1. Nodular Leydig cell hyperplasia, as seen in cryptorchid testes and other conditions. These lesions are typically smaller, often in a background of increased interstitial Leydig cells. Macroscopic Sertoli nodules are described, but are distinguished by their associated basement membrane material and tubules with fetal-type Sertoli cells and spermatogonia.[345a]
2. Large cell calcifying Sertoli cell tumor, which may have a component with a Leydig cell–like appearance (described later).
3. Testicular "tumor" of the adrenogenital syndrome. This perhaps constitutes the most important and difficult differential diagnosis. This lesion is usually discovered during early adult life as a palpable mass; examples in children tend to be smaller and found incidentally. The adrenogenital syndrome is of the "salt-forming type" in two-thirds of cases. The testicular masses are usually bilateral and located at the hilum. Grossly, they are well-circumscribed, brown–green masses that are separated into lobules by prominent fibrous bands.[345] Microscopically, there are sheets, nests, and cords of cells with abundant eosinophilic cytoplasm broken up by bands of fibrosis (Fig. 27.43); these cells often contain more prominent lipochrome pigment, and Reinke crystalloids are absent. Bilaterality of the lesions, associated clinical and laboratory features, and therapeutic response (decrease in size after corticosteroid therapy) are the most important features distinguishing these lesions—which may represent nodular hyperplasias of ectopic adrenal cortical cells rather than true neoplasms—from Leydig cell tumors.[345,346] Immunophenotypic studies suggest that expression of synaptophysin and lack of nuclear androgen receptor staining favor a tumor of adrenogenital syndrome, but novel markers such as DLK1 (FA1) may be more specific.[347–350]
4. Yolk sac tumor. This is true for the cases of Leydig cell tumors exhibiting a prominent microcystic pattern of growth.[322]

Tumors and Tumorlike Conditions of Sertoli Cells

Sertoli cell tumors and tumorlike conditions form a complex and poorly understood group of proliferative disorders composed of cells with morphologic features of Sertoli cells or related specialized gonadal stromal cells.[351]

Areas of Sertoli cell hyperplasia (also known as hypoplastic tubules, dysgenetic zones, tubular adenomas, and Sertoli cell nodules) are seen in half of patients with cryptorchid testes. However, they have also been found in 20% of non-neoplastic testes in patients with testicular tumors[352] and in about the same proportion in an autopsy study of scrotal, otherwise normal testes; the frequency of these foci decreases with age.[353] Exceptionally, these nodules have been reported within the epididymis rather than in the testis.[354]

Sertoli cell adenomas are not uncommon in patients with the testicular feminization (androgen insensitivity) syndrome.[355–357] Microscopically, they are composed of elongated tubules lined by Sertoli-like cells.

Sertoli cell tumors (not otherwise specified [NOS]) arise in the descended testis of normal individuals and are sometimes associated with gynecomastia.[358–360] Grossly, the tumors are well circumscribed, white or yellow, and firm, with focal cystic areas. Microscopically, the diagnostic feature is the presence of cord-like or tubular formations lined by elongated cells having the appearance of Sertoli cells (Fig. 27.44). In other areas, the tumor is solid and can be confused with seminoma (Fig. 27.45). The cytoplasm is moderate to abundant, with a pale to intense eosinophilic quality. Lipid vacuoles are present in some cases.[360] Exceptionally, Sertoli cell tumors are accompanied by a heterologous sarcomatous component.[361] Immunohistochemically, Sertoli cell tumors typically show reactivity for keratin, SF-1, CD99, calretinin, melan A, and WT1 but are negative for PLAP and CD117 (c-KIT).[331–334,362,363] Inhibin is positive in only 50% of tumors, while nuclear β-catenin is expressed in 60%–70%.[337,364]

About one-tenth of Sertoli cell tumors behave in a malignant fashion, the most common site of metastatic involvement being the iliac and para-aortic lymph nodes.[365] Features that should raise the suspicion of malignancy in Sertoli cell tumors include mitotic figures, pleomorphism, large tumor size, and necrosis, particularly when occurring together.[360] Parenthetically, misinterpretation of a Sertoli cell tumor as seminoma is more likely to occur in these malignant forms.[366] The treatment of Sertoli cell tumor is orchiectomy. Surgical excision of metastatic lesions—when present—is recommended, inasmuch as radiation therapy and chemotherapy have not proved particularly effective.[367]

Sclerosing Sertoli cell tumor represents a morphologic pattern within the spectrum of Sertoli cell tumor, NOS.[368] Grossly, they tend to be

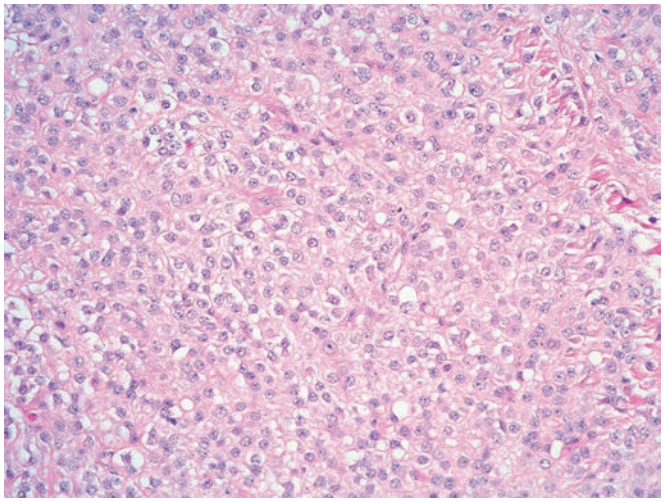

Figure 27.45 Sertoli cell tumor, NOS with solid growth, which may mimic seminoma.

Figure 27.47 Gross Appearance of Large Cell Calcifying Sertoli Cell Tumor of Testis. The tumor is distinctly multinodular. The dark nodules had a prominent component of Leydig cells.

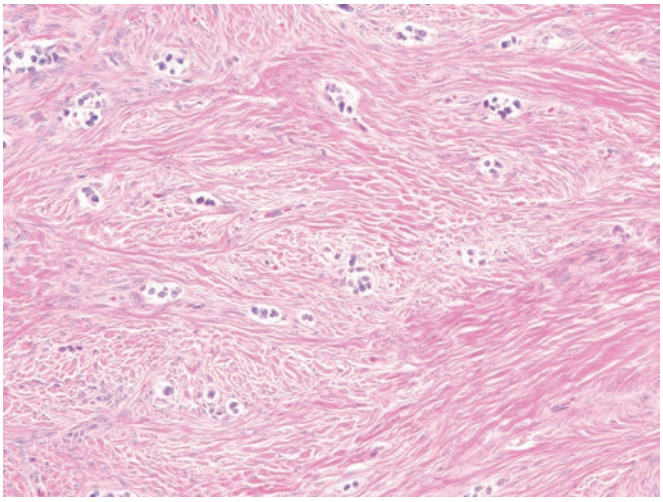

Figure 27.46 Sclerosing Sertoli Cell Tumor.

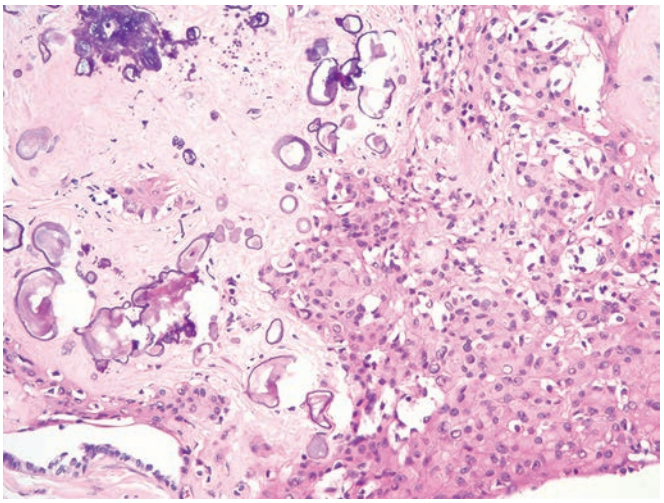

Figure 27.48 Large Cell Calcifying Sertoli Cell Tumor.

small, well demarcated, hard, and yellow–white to tan. Microscopically, they are formed of simple and anastomosing cords and rare tubules within a prominent densely sclerotic acellular stroma that, by definition, comprises greater than 50% of the tumor (Fig. 27.46).[368] Sclerosing Sertoli cell tumor was previously separated as distinct variant, but the shared *CTNNB1* mutation with non-sclerotic forms support a single subtype of diverse morphology; however, documentation of this pattern is recommend because it seems to have a lower metastatic rate when strictly defined.[369]

Large cell calcifying Sertoli cell tumor is usually seen in patients under 20 years of age and is often part of the Carney complex, which may also include testicular Leydig cell tumors, pituitary tumors, pigmented nodular hyperplasia of the adrenal cortex, cardiac myxomas, spotty pigmentation of skin, and other abnormalities; however, 60% are sporadic.[370,371] Both syndromic and non-syndromic forms may have a *PRKAR1A* mutation.[372] Bilaterality and multifocality are very common in syndromic forms, but sporadic tumors are commonly unilateral and unifocal (Fig. 27.47). Microscopically, this lesion is characterized by sheets, cords, and solid tubules of cells with abundant acidophilic cytoplasm, separated by abundant fibrous tissue that contains large areas of calcification (Fig. 27.48).[373] An intratubular component is commonly seen. Ultrastructurally, the features are those of Sertoli cells, including the presence of Charcot–Bottcher crystalloids.[374–376] Immunoreactivity for inhibin, S-100 protein, and SF-1 is common, while β-catenin expression is absent.[334,336,337,377] While most are benign, metastases do rarely occur and are often associated with large size, increased mitotic rate, extratesticular spread, necrosis, lymphovascular invasion, and more pronounced cytologic atypia.[378]

Another subtype, *intratubular large cell hyalinizing Sertoli cell neoplasia*, is seen in patients with the Peutz–Jeghers syndrome,[379–381] and are associated with germline *STK11* mutations.[382] These Sertoli cell proliferations typically present in prepubertal males with gynecomastia and they are often multicentric and bilateral. Histologically, randomly distributed seminiferous tubules are expanded by large Sertoli cells with bland cytologic features and pale eosinophilic cytoplasm, as well as associated globular deposits of eosinophilic basement membrane material (Fig. 27.49). In rare cases, an invasive component is present that has morphologic features resembling those of the Peutz–Jeghers syndrome associated ovarian tumor known as "sex-cord tumor with annular tubules." These tumors behave in a clinically benign fashion.

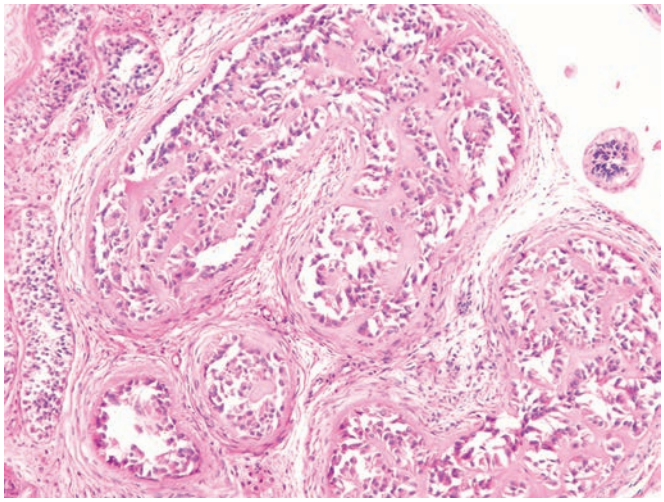

Figure 27.49 Intratubular hyalinizing Sertoli cell neoplasia may be seen in Peutz-Jeghers syndrome.

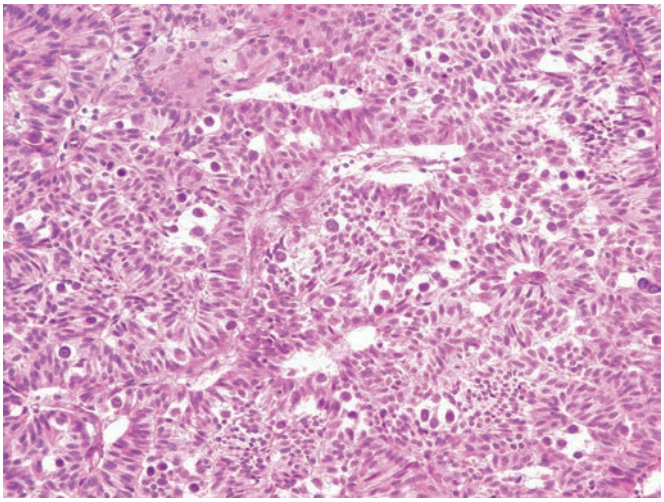

Figure 27.51 Rare mixed germ cell-sex cord-stromal tumor with Sertoli-like and spermatocytic tumorlike components. (Case courtesy of Dr. Michal Michal, Czech Republic.)

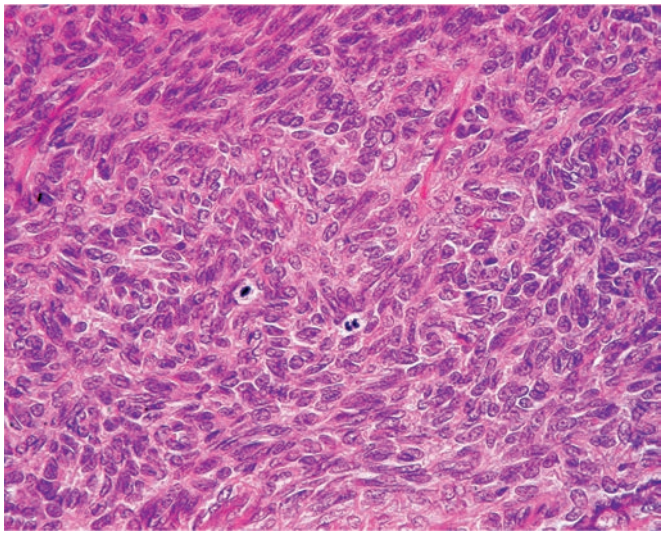

Figure 27.50 Adult form of granulosa cell tumor involving testis. Note the occasional longitudinal grooves, the oval to spindle shape of the tumor cells, and the high mitotic activity.

Other Sex Cord–Stromal Tumors

Some neoplasms belonging to this category have an appearance analogous to that of the adult or the juvenile forms of ovarian granulosa cell tumor.[383–386] The adult form, which is the more common, presents as a testicular mass without evidence of endocrine function, although isolated examples of gynecomastia are on record.[387] The pattern of growth may be admixtures of diffuse (most common), insular, spindled, trabecular, corded, "watered-silk," palisading, or pseudopapillary, as in the ovarian counterpart (Fig. 27.50).[386,388] Similarly, Call–Exner bodies may be present. Immunohistochemically, they are somewhat heterogeneous, but reactivity for inhibin, calretinin, Mart-1 (Melan-A), SF-1, S-100 protein, smooth muscle actin, CD99, FOXL2, and low-molecular-weight keratin (focal) is common, but not for EMA or nuclear β-catenin.[389] Metastases have occurred in about 10% of the reported cases and are more common in association with size greater than 4 cm, lymphovascular invasion, and infiltrative growth.[386,388]

The juvenile form is the most common testicular tumor in infants younger than 6 months of age and may even be congenital.[383,384,390–393] The morphology is identical to its ovarian counterpart and may closely mimic yolk sac tumor. SALL4 and glypican-3 are consistently negative, aiding in this distinction. The immunophenotype is similar to adult-type granulosa cell tumor. It is sometimes associated with cytogenetic abnormalities affecting the Y chromosome and with ambiguous genitalia.[394,395] Some of the tumors have developed in undescended testes.

Fibroma-thecoma of gonadal stromal origin with an appearance similar to that of its vastly more common ovarian counterpart can also occur in the testis.[396,397] Some of these tumors are grossly yellow–white, that is, akin to ovarian fibrothecomas. Still others are analogous to ovarian fibroma with minor sex-cord elements.[398] These tumors are clinically benign, even when increased mitotic activity is present.

Signet ring stromal tumor, an entity well known in the ovary, has now been also described in the testis.[399,400] A recent series of 13 cases suggests a close relationship to pancreatic solid pseudopapillary neoplasm, including *CTNNB1* mutations.[401] A novel tumor called myoid gonadal stromal tumor was also recently described.[402] Finally, mixed or unclassified forms of testicular sex cord–stromal neoplasia may also rarely occur.

Mixed Germ Cell–Sex Cord–Stromal Tumors

The better-known member of this group is gonadoblastoma, a tumor that arises nearly always in individuals with an underlying gonadal disorder, either pure or mixed gonadal dysgenesis, or male pseudohermaphroditism,[403] and which is fully discussed in Chapter 35. Only extraordinarily rare cases have developed in the testis of phenotypically and karyotypically normal males.[404]

One should be careful not to misinterpret sex cord–stromal tumors of the testis with entrapped germ cells as evidence of a mixed germ cell–sex cord–stromal tumor.[405] However, rare mixed germ cell–sex cord–stromal tumors with a morphology different from gonadoblastoma, as described by Talerman, also exist.[406,407] These consist of a sex cord–stromal component with either a granulosa cell tumor or Sertoli cell tumor appearance, intimately admixed with scattered cells showing histologic and immunophenotypic features of spermatocytic tumor (Fig. 27.51). After personally reviewing the cases published by Michal and colleagues, we agree that the distribution of the germ cells and their invasion into hilar tissues argue for the

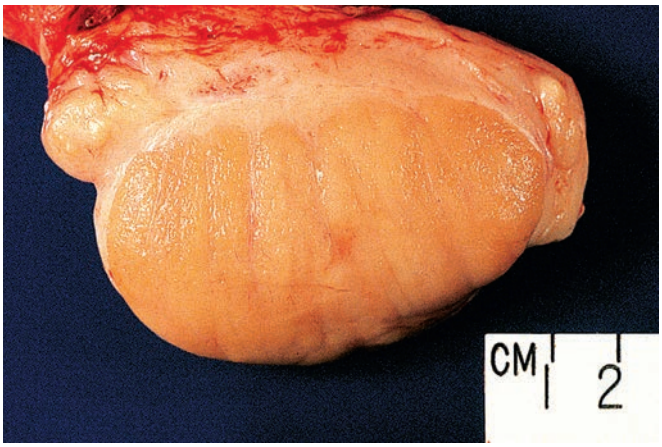

Figure 27.52 Gross appearance of malignant lymphoma of large cell type, which completely replaces the testis.

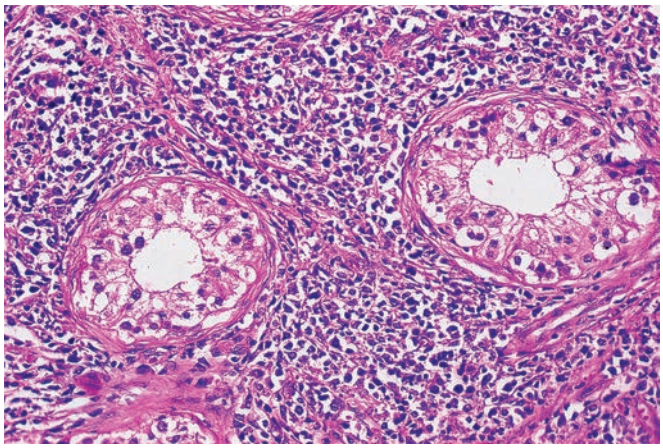

Figure 27.53 Malignant Lymphoma of Testis. There is diffuse infiltration of the interstitium by neoplastic lymphocytes, which surround and separate atrophic tubules.

existence of a distinct mixed lineage neoplasm.[407] To date, this rare tumor has followed a benign clinical course.

Malignant Lymphoma and Related Tumors

Malignant lymphoma comprises 5% of all testicular malignancies. It is the most common testicular tumor in elderly persons, but it can occur in any age group, including children.[408] It has a much greater tendency for bilaterality than germ cell tumors; as a matter of fact, about 50% of cases of bilateral testicular tumors are malignant lymphomas.[409]

Nearly all cases are of non-Hodgkin type. By far the most common variety is diffuse large B-cell lymphoma, but small lymphocytic lymphoma, follicular lymphoma (see later), anaplastic large cell lymphoma (including the neutrophil-rich variety of the latter), NK/T-cell lymphoma, and intravascular (angiotropic) lymphoma also occur.[410–416]

Grossly, large cell lymphoma results in a solid homogeneous replacement of the testicular parenchyma not too dissimilar from that of seminoma (Fig. 27.52). Microscopically, there is a predominantly interstitial proliferation of large tumor cells that surrounds and infiltrates the seminiferous tubules (Fig. 27.53).[417] The presence of scattered malignant cells within the tubular epithelium should not be confused with intratubular germ cell neoplasia. There is a high incidence of vascular invasion.[418] Testicular lymphomas are sometimes misdiagnosed as spermatocytic tumor or "anaplastic" seminoma, and anaplastic large cell lymphomas may be misinterpreted as embryonal carcinoma (Fig. 27.54).[414] Immunohistochemical (and, if needed, molecular) evaluation should establish the correct diagnosis without much difficulty.[419] Phenotypically, most testicular large B-cell lymphomas belong to the nongerminal center B-cell–like subgroup.[420] Immunophenotypically, one must be aware of OCT3/4 and SALL4 expression in a subset of diffuse large B cell lymphomas.[289] CD30 and EMA expression in anaplastic large cell lymphoma, which may overlap with embryonal carcinoma, is more commonly recognized.

Diffuse large cell lymphoma of the testis is treated with orchiectomy and chemotherapy, sometimes combined with radiation therapy.[421] Nearly half of the patients are found to have systemic disease at the time of diagnosis and their prognosis is poor.[422,423] A high proportion of relapses occur in the CNS or contralateral testis.[421,423,424]

Follicular lymphoma has been rarely described in the testis and epididymis both in adults and children. In contrast to conventional follicular lymphomas, the tumor is often localized and *BCL2* gene rearrangement is lacking. It typically runs a clinically indolent course.[425]

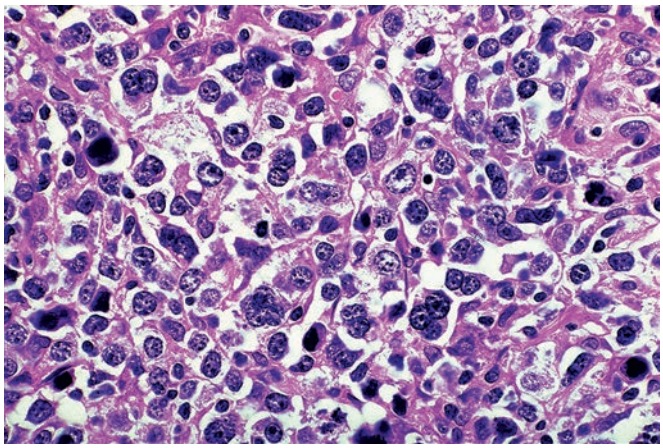

Figure 27.54 Cases of large B-cell lymphoma with pleomorphic features such as that depicted in this photograph can be misdiagnosed as seminoma, spermatocytic tumor, or embryonal carcinoma.

Plasmacytoma of testis may be seen as a manifestation of multiple myeloma or as an isolated lesion.[426] The latter is by far the most common situation, even if the testicular involvement may be the first clinical manifestation of the disease.[427,428]

Leukemic involvement of the testis is more commonly seen with lymphocytic leukemia, but it also may occur in the myeloid types.[429] It is not uncommon for the latter ("myeloid sarcoma") to be initially misdiagnosed as large cell lymphoma.[430,431] Children with acute lymphocytic leukemia develop clinical evidence of testicular involvement in about 8% of cases,[432] but the microscopic rate of involvement is over 20%.[433] Often the testis represents the first sign of relapse after bone marrow remission.[434] Assistance for the identification of residual disease can be obtained by the use of specific immunohistochemical markers.[435]

Other Primary Tumors

A spectrum of vascular malformations and neoplasms may involve the testis and paratestis,[436,437] and these should be distinguished from adenomatoid tumor.[438,439] A unique vascular lesion with predilection

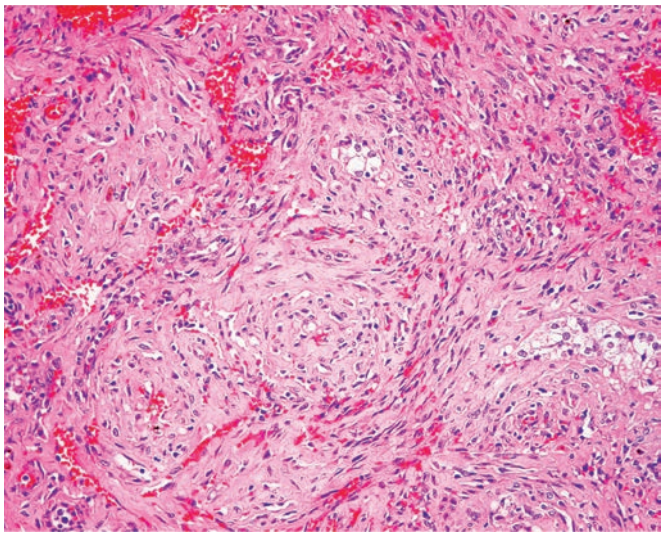

Figure 27.55 Kaposi sarcoma of the testis in an HIV-infected individual.

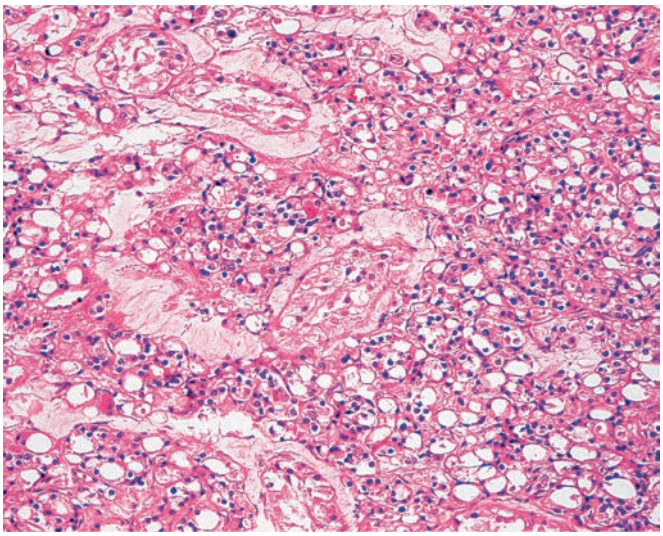

Figure 27.57 Prostatic Adenocarcinoma Metastatic to Testis. This not too rare occurrence is sometimes misdiagnosed as sex cord–stromal tumor.

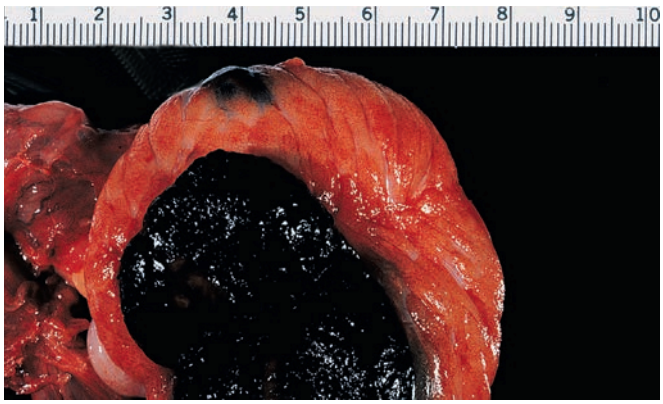

Figure 27.56 Malignant Melanoma Metastatic to Testis. The black color of the tumor is due to massive melanin deposition.

for the testis (and kidney) has been described as "anastomosing hemangioma."[437,440] These tumors have a lobular architecture and consist of anastomosing sinusoidal capillary–sized vessels with a lining endothelial layer showing scattered hobnail arrangement.

Juvenile xanthogranuloma and myofibroma can present as intratesticular masses in children.[441–443]

Lipomatosis of the testicle has been documented by ultrasound and biopsy in individuals affected by Cowden syndrome.[444]

Primary sarcoma of the testis is rare, both in children and in adults. Cases of fibrosarcoma, leiomyosarcoma, Kaposi sarcoma, angiosarcoma, adenosarcoma, and Ewing sarcoma have been reported (Fig. 27.55).[445–449] In the presence of a tumor of sarcomatous appearance involving the testis, the possibility of a somatic-type malignancy in a germ cell tumor, a sarcomatous transformation of a spermatocytic seminoma, or a Sertoli cell tumor should be entertained (see corresponding sections).

Metastatic Tumors

Metastatic tumors in the testicle are most commonly from the lung, prostate, kidney, stomach, or skin (melanoma) (Fig. 27.56).[450–455] It is very rare for them to be the first clinical sign of disease.[452,456] When this is the case, the tumors tend to be unilateral and solitary, thus mimicking the presentation of a primary tumor.[186] Historically, the testicular metastases originating in the prostate have usually been incidental findings in orchiectomy specimens performed for hormonal ablation (Fig. 27.57).[457]

The microscopic diagnosis is usually easy, but sometimes the tumor simulates the appearance of a primary sex cord–stromal tumor, particularly Leydig cell tumor. The presence of conspicuous intrarete or intratubular growth can also be confusing.[186] Secondary prostatic carcinoma in the testis appears to be associated with a better prognosis than secondary prostatic carcinoma in the penis.[458] Metastatic Merkel cell tumors to the testis can be confused with malignant lymphoma.[459] Metastatic signet ring carcinoma from the gastrointestinal tract may acquire features analogous to those of ovarian Krukenberg tumor.[460]

In children, the testis can be involved by metastatic neuroblastoma from the adrenal or other sites.[461,462]

Testicular Adnexa

Normal Anatomy

The rete testis, located at the hilum of the testis, has a complex tubular architecture (particularly when undergoing reactive hyperplastic changes).[4,463] It receives the luminal contents of the seminiferous tubules and is divided into three components: septal, mediastinal or tunical, and extratesticular (bullae retis).[4] The rete testis empties into the ductuli efferentes, which consist of 12–15 tubules aggregated in the region of the head of the epididymis; they are lined by pseudostratified ciliated and nonciliated epithelium.[4,464,465]

The epididymis is a tubular structure connecting the ductuli efferentes to the vas deferens and is composed anatomically of three portions: head (caput), body (corpus), and tail (cauda).[4] The epididymal epithelium is composed of tall columnar (principal) cells; narrow, darker-staining columnar cells; basal cells; and clear cells. "Monstrous" pleomorphic epithelial cells similar to those commonly found in the seminal vesicles can be seen in the epididymis and should not be confused with a malignant process.[466,467] Prominent cilia are present in the tall columnar cells.[468] These cells may feature variously sized intranuclear eosinophilic periodic acid–Schiff (PAS)-positive inclusions, similar to those also found in the vas deferens

and seminal vesicles. They may also exhibit bright eosinophilic intracytoplasmic granules and globules, resulting in a Paneth cell–like appearance, which may also be seen in the ductuli efferentes.[464,469]

The vas deferens is a 30–40 cm tubular structure arising from the caudal portion of the epididymis. The distal portion joins the excretory duct of the seminal vesicle to form the ejaculatory duct, emptying into the prostatic urethra at the level of the verumontanum. The vas is lined by pseudostratified epithelium composed of ciliated columnar and basal cells.[4,470] Prominent intranuclear inclusions may be seen.[471] The muscle coat, which is extremely thick, is composed of inner and outer longitudinal coats and a middle oblique or circular zone.

Four small testicular appendages of vestigial nature exist.[4] Of these the most constant is the appendix testis or hydatid of Morgagni, which represents a remnant of the cranial portion of the müllerian duct. It is a round or oval, sessile or pedunculated, 1- to 10-mm structure attached to the tunica albuginea at the upper pole of the testis. The other appendages are the appendix epididymis (a remnant of the cranial portion of the mesonephric duct), the vas aberrans or organ of Haller (a remnant of mesonephric tubules), and the paradidymis or organ of Giraldes (also a remnant of mesonephric tubules).

Immunophenotypically, the adult excretory system has similar findings throughout its course.[472] The epithelium of the rete testis, ductus efferentes, epididymis, and vas deferens all typically express PAX-8, PAX-2, AR, and CK7.[472,473] The adult rete testis is unique in its reactivity for WT1 and calretinin. Immunoreactivity for CD10 in the epithelium of both the vas deferens and testicular/epididymal appendages has been used to support a wolffian (mesonephric) derivation.[474,475]

Rete Testis

Non-Neoplastic Lesions

Rete testis dysgenesis is a constant accompanying feature of cryptorchid testicles. Morphologically, it is characterized by underdevelopment of the rete, which is lined by columnar or large cuboidal cells.[476]

Calcifying nodules can be seen protruding into the rete testis channels; these probably represent dystrophic changes and are of no clinical significance.[477] They are different from the microlithiasis that can be seen in the rete testis, epididymis, and efferent ducts in an intraluminal, subepithelial (most frequent), or interstitial location.[478]

Cystic dilation (transformation) of the rete testis can occur as a result of obstruction of the epididymis or of the intratesticular excretory ducts secondary to varicocele.[479,480] Other cases have been seen in the absence of obstruction in patients with renal failure treated with hemodialysis,[481] sometimes associated with deposits of calcium oxalate crystals.[482] There may be an accompanying smooth muscle hyperplasia.[483]

Rete testis–associated steroid cell nests are described as nodules of eosinophilic cells growing in cords within or adjacent to the rete testis that are distinct from adnexal Leydig cells.[484]

Hyperplasia of rete testis (or adenomatous hyperplasia) may be confused with a malignant neoplasm. It may present in adult patients with a grossly evident solid or cystic mass in the testicular hilum. More commonly, the lesion is very small and detected as an incidental microscopic finding. Microscopically, there is a tubulopapillary and occasionally cribriform proliferation of rete testis epithelium with bland cytologic features.[485] Some cases of rete testis hyperplasia are accompanied by the deposition of hyaline globules, simulating the appearance of yolk sac tumor.[486] Immunohistochemically, there is reactivity for keratin and EMA, while actin, desmin, and S-100 protein are negative.[487] The behavior has been benign in all reported cases. The pathogenesis is unknown; in cases associated with germ cell tumor of the testis, it may represent a reaction to the invasion by the latter.[486]

Neoplasms

Very rare benign tumors of the rete testis now described under the term "adenoma" are likely all related and have been described as cystadenoma, benign papillary tumor, and adenofibroma of the rete testis. A unique subset sometimes exhibits sertoliform features and expresses inhibin, the "sertoliform cystadenoma."[479,488]

Adenocarcinoma of the rete testis is a very rare neoplasm, which may be difficult to distinguish from malignant mesothelioma of the tunica vaginalis.[489,490] Some of these tumors have a distinctly papillary appearance, while others are more tubuloglandular or consist of irregular anastomosing "retiform" glandular patterns.[491] Intratubular invasion of the testis may occur.[492] Cases have been described with a spindle cell (metaplastic) component,[493] and others having focal sertoliform differentiation similar to that seen in rete cystadenoma.[494] Diagnostic criteria include: (1) involvement centered in the hilum of the testis, (2) no features of another specific testicular/paratesticular tumor subtype, (3) lack of any other primary tumor (i.e., exclusion of metastasis), and (4) immunohistochemical exclusion of mesothelioma and ovarian type carcinoma.[489,495] Transitions from carcinoma to benign rete epithelium have been suggested as a corroborating feature of a primary rete adenocarcinoma, but this pattern may be closely mimicked by metastatic carcinomas. Because of their extreme rarity, rete primary carcinomas seem to have a nonspecific immunophenotype based on the findings in very few cases. Mesothelioma commonly expresses WT1, CK5/6, and calretinin (while negative for B72.3 and BerEP4), while high-grade serous type carcinomas are also often WT1 positive and have abnormal p53 staining patterns. Rete testis carcinomas may express PAX-8 (overlapping with gynecologic type carcinomas),[473] and their reactivity patterns with mesothelial markers are not fully evaluated. As noted, benign rete epithelium often expresses both WT1 and calretinin.

Secondary involvement of the rete testis by testicular germ cell tumors may occur in the form of pagetoid spread.[496] This relatively common event (particularly with seminoma) should not be confused with a primary tumor of the rete tetsis.[497]

Epididymis

Non-Neoplastic Lesions

Nonspecific epididymitis may be caused by *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, *E. coli*, or other organisms (Fig. 27.58). It may lead to testicular necrosis secondary to hypoperfusion caused by ischemia.[498] Chlamydial epididymitis is mainly proliferative, whereas bacterial epididymitis tends to be destructive and abscess forming.[499]

Tuberculosis of the epididymis may result in confluent caseation of this organ, as described by Auerbach in his classic work on urogenital tuberculosis.[500] When extensive, the infection can spread into the testis and clinically simulate a malignant tumor.[501] The source of infection may be hematogenous or through the prostate, the former being the more common. When the infection is hematogenous, the process begins in the epididymal interstitial tissue and preferentially involves the head, often with sparing of the vas deferens. When it originates in the prostate, there is involvement of the tail of the epididymis and the vas.

Fungal infections that can involve the epididymis include coccidioidomycosis[502] and histoplasmosis.[503]

Figure 27.58 Acute and Chronic Epididymitis. The inflammation has not spread to the testicle.

Figure 27.59 Granulomatous Epididymitis With Focal Extension Into the Testis. Some of the granulomas have a necrotic center. No microorganisms were identified on special stains.

Granulomatous ischemic lesion is the term proposed by Nistal et al.[504] for a granulomatous process involving the head of the epididymis accompanied by partial necrosis of the ductal wall, which they interpreted as having a probable ischemic pathogenesis.[504]

Spermatic granuloma of the epididymis (epididymitis nodosa) presents grossly as a nodule measuring up to 3 cm in diameter, most often located in the head. Microscopically, a granulomatous reaction is seen around collections of spermatozoa. This lesion is thought to result from damage to the epithelium and basement membrane of epididymal ducts by inflammation or trauma,[505] with the subsequent spillage of sperm into the interstitium that elicits a granulomatous response.

Idiopathic granulomatous epididymitis is a diagnosis of exclusion, which is justified for cases of granulomatous inflammation lacking features that would place it in any of the specific categories mentioned in this section (Fig. 27.59).[506] Obviously, infection, germ cell tumor

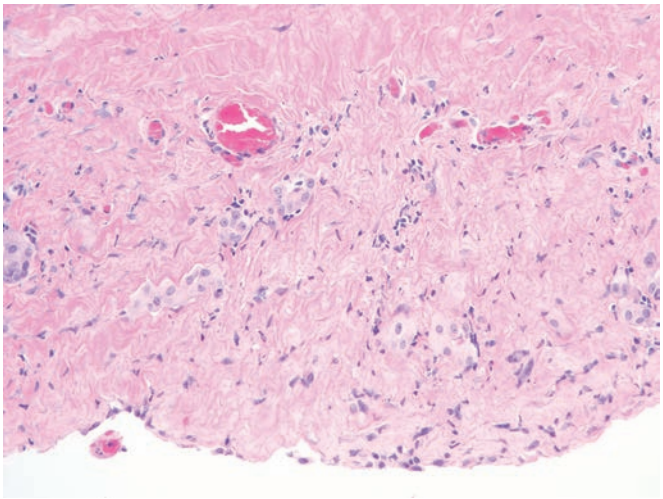

Figure 27.60 Reactive mesothelial cells in the fibrous wall of a hydrocele, mimicking a neoplasm.

with granulomatous response, and vasculitis must be excluded. Necrotizing vasculitis can occur in the epididymis as an isolated finding or as a manifestation of a systemic disease; since there are no apparent morphologic differences between the two forms, clinical evaluation and follow-up of these patients are indicated.[507–509] The most common forms of systemic vasculitis are polyarteritis nodosum and "granulomatosis with polyangiitis (Wegener's)."[509]

Spermatocele represents a cystic dilation of efferent ducts, with their lumina filled with masses of sperm. The cysts are lined by ciliated tall columnar cells, and the wall is made up of loose connective tissue rather than smooth muscle. Secondary changes, such as cholesterol clefts and foreign body giant cell reaction, are common.

Cribriform hyperplasia of the epididymis has a pattern reminiscent of cribriform atypical ductal hyperplasia of the breast. Lack of mitotic activity or well-established marked cytologic atypia argues against carcinoma. Some degree of cytologic atypia, often with large pleomorphic, multinucleated cells, is common and should not be interpreted as malignancy. It is apparently not associated with adenomatous hyperplasia of the rete testis.[467,510]

A variety of nonspecific, non-neoplastic tumoral reactions, likely unrelated to inflammatory myofibroblastic tumor, have been described in the paratestis under various names including inflammatory pseudotumor, pseudosarcomatous myofibroblastic proliferation, fibrous pseudotumor, fibromatous periorchitis, and nodular periorchitis.[511] These have varied cellularity depending on the ratio of myofibroblasts to dense collagen; calcifications may be present. It is important to carefully exclude de-differentiated liposarcoma before diagnosing a non-neoplastic process in the paratestis, as some examples may have myofibroblastic features.[512]

Finally, hydrocele repair specimens are fairly common. While they typically consist of fibrous tissue with nonspecific chronic inflammation, occasional cases contain histologic features that may simulate a neoplastic process, including hyperplastic mesothelial cells (Fig. 27.60), florid nodular collections of histiocytes, and peculiar aggregates of incidental benign small blue cells of proposed sloughed rete epithelial origin (Fig. 27.61).[513–515]

Tumors

Adenomatoid Tumor and Mesothelioma

Adenomatoid tumor, a benign mesothelial tumor, is the most common neoplasm of the epididymis, typically occurring in patients

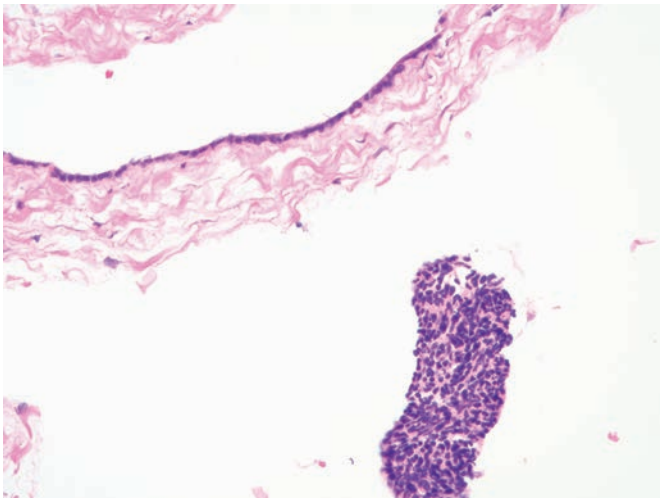

Figure 27.61 Spermatoceles or hydroceles rarely contain aggregates of small blue cells, likely of rete testis origin. They are of no clinical importance.

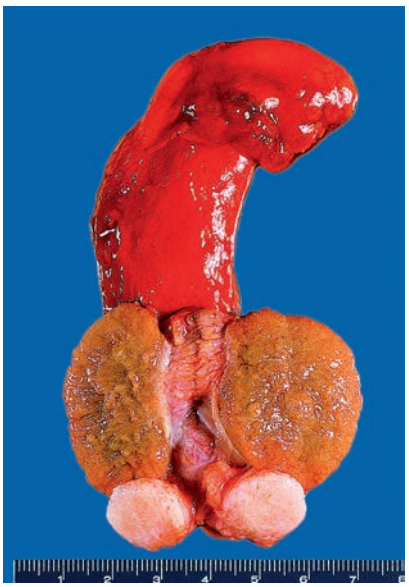

Figure 27.62 Typical gross appearance of adenomatoid tumor of epididymis.

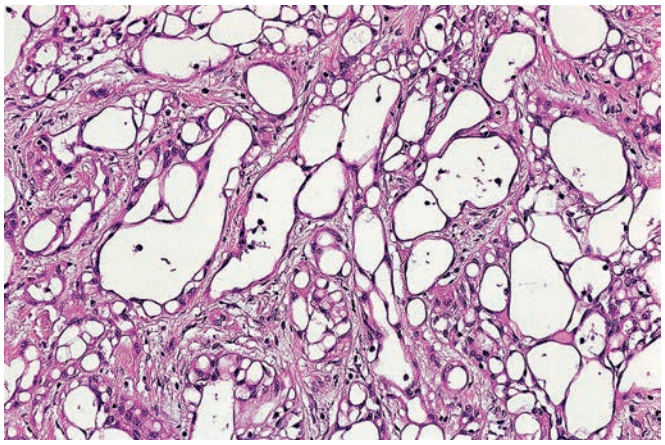

Figure 27.63 Adenomatoid tumor, showing typical conglomerate of cystically dilated spaces lined by cuboidal cells, whereas others are lined by flattened cells with the appearance of endothelial cells.

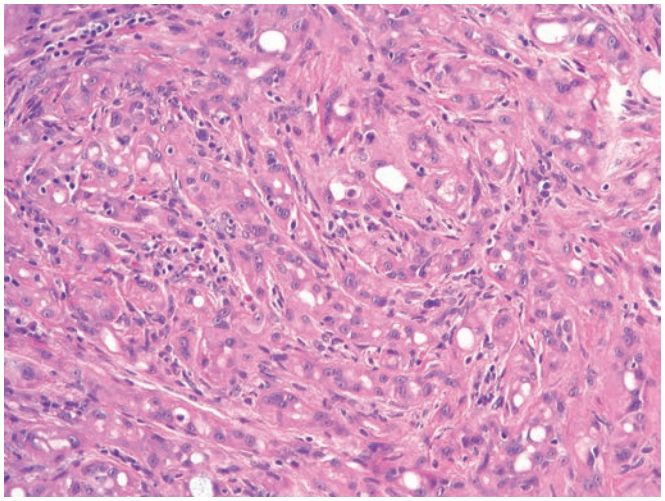

Figure 27.64 Adenomatoid Tumor With Epithelioid Features.

in the third or fourth decade of life.[516] This tumor also occurs in the testicular spermatic cord and ejaculatory duct in males and in the fallopian tube and uterus in females.[517–519] It presents clinically as a mass, sometimes associated with pain. Grossly, it appears as a small (average size, 2 cm), solid, firm, gray-white nodule and occasionally containing small cysts (Fig. 27.62). Microscopically, the lesion is unencapsulated and poorly circumscribed (in contrast with its female counterpart), and on rare occasions it may extend to the adjacent testis. There is a proliferation of cells ranging from cuboidal to flattened, which form solid cords with an epithelial appearance alternating with channels having dilated lumina simulating vascular structures (Fig. 27.63). The tumor cells may exhibit prominent cytoplasmic vacuolization. Tubular areas often have an atrophic lining and distinctive thread-like strands crossing the luminal space are common.[518] Examples with an oncocytic and epithelioid appearance may mimic carcinoma, mesothelioma, a vascular neoplasm, or a sex cord–stromal tumor (Fig. 27.64). The prominent intervening stroma may contain abundant smooth muscle and elastic fibers[520]; it may also have a reactive desmoplastic quality and be infiltrated by inflammatory cells. Rare cases may have extensive infarct-type necrosis with associated reactive atypia.[521] The behavior of adenomatoid tumor is invariably benign, even when extending into the testis.

Immunocytochemically, there is strong reactivity for pankeratin, calretinin, D2-40, and WT1, while negative for CEA (Fig. 27.65).[517–519]

Adenomatoid tumor should be distinguished from true vascular tumors, which can also occur in this area. As expected, endothelial tumors are typically immunoreactive for ERG, CD34, and CD31; however, they may also coexpress keratin.

Mesothelioma of the usual type has also been described in this region, arising from the tunica vaginalis testis (Fig. 27.66).[522–525] Most cases are malignant, similar to those seen in the peritoneal cavity and—like them—occasionally associated with asbestos exposure.[526–528] They exhibit a wide age range of occurrence (with occasional examples in children), a wide differentiation spectrum, and a generally aggressive behavior (with potential for late recurrence or metastasis).[522,529,530] Like their more common counterparts in the

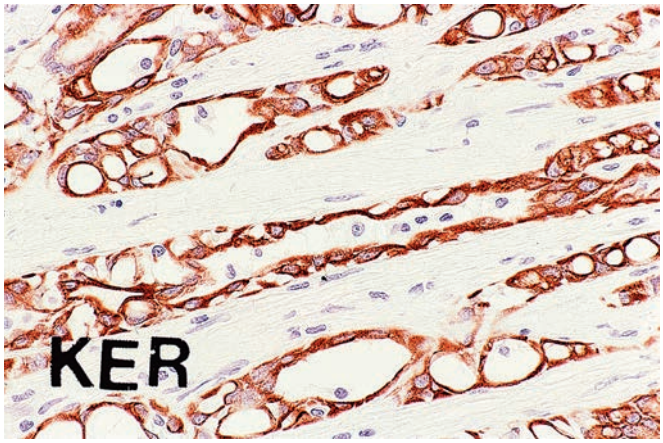

Figure 27.65 Adenomatoid Tumor With Typical Keratin Reactivity.

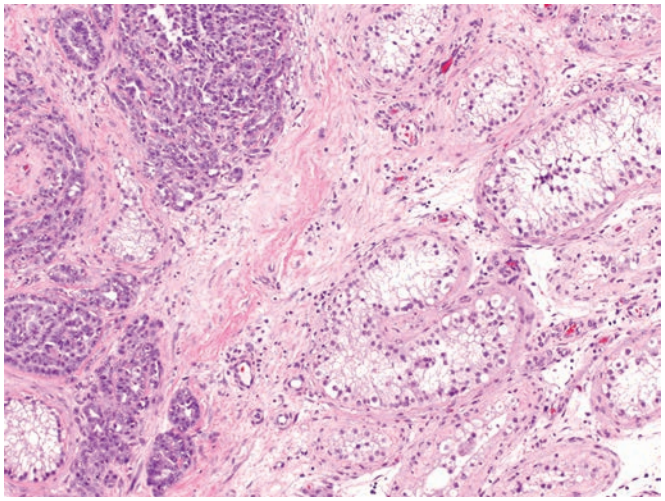

Figure 27.66 Mesothelioma infiltrating the testis with a tubular architecture.

Figure 27.68 Bilateral Clear Cell Papillary Cystadenoma.

main abdominal cavity and in the pleura, they are immunoreactive for pan-keratin, calretinin, D2-40, and CK7 and negative for CK20 and CEA.[525] Sarcomatoid mesotheliomas, which mimic a variety of spindle cell lesions, may also occur.

The classification of small localized low-grade papillary mesothelial lesions is problematic. Well-differentiated papillary mesotheliomas are similar to those described in the peritoneum of women.[531] In men, they are often found unexpectedly in a "hydrocele sac."[532,533] The diagnosis should be restricted to cases with papillae and tubules lined by a single layer of cytologically bland cuboidal to flattened mesothelial cells (Fig. 27.67). They often have little mitotic activity, and no invasion should be present. While long-term follow-up for such cases is limited, they seem to follow a much less aggressive course than typical mesothelioma (when diagnosed under these strict criteria).

Other Tumors and Tumorlike Conditions

(Clear cell) papillary cystadenoma of the epididymis may be unilateral or bilateral and exhibits a familial incidence.[534] It is regarded as the epididymal component of von Hippel–Lindau (VHL) disease and is often seen with other manifestations of the disease, especially when bilateral. Grossly, it measures 1–5 cm and is well circumscribed, either cystic or solid (Fig. 27.68). Microscopically, papillary infoldings lined by columnar cells with abundant clear cytoplasm are the distinctive feature (Fig. 27.69).[535] Immunohistochemically, they are reactive for pankeratin, keratin 7, and PAX-8.[536] It has been noted that the histology and immunophenotype of papillary cystadenoma of the epididymis, including the cup-like pattern of CA9 expression, are identical to the clear-cell papillary subtype of renal cell carcinoma.[537] Because patients with VHL disease may present with concomitant clear cell papillary cystadenoma of the epididymis and clear cell renal cell carcinoma of the kidney, distinction from metastasis is important; strong and diffuse CK7 expression would support clear cell papillary cystadenoma.[538] Allelic deletion of the VHL gene has been detected in these tumors,[539] as well as expression of vascular endothelial growth factor.[540]

Carcinoma of the epididymis is an extremely rare lesion; it has the microscopic appearance of either adenocarcinoma (more commonly) or undifferentiated carcinoma and is associated with a poor prognosis.[541] The pattern of growth of the adenocarcinoma can be

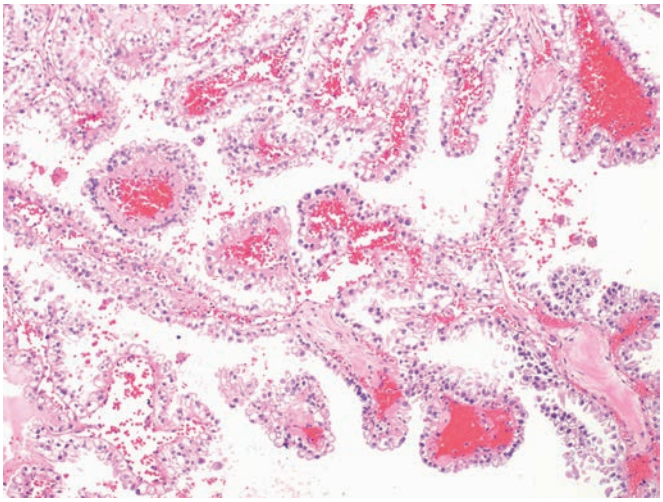

Figure 27.69 Clear cell papillary cystadenoma has a mixed papillary and tubular architecture with a lining of bland clear cells.

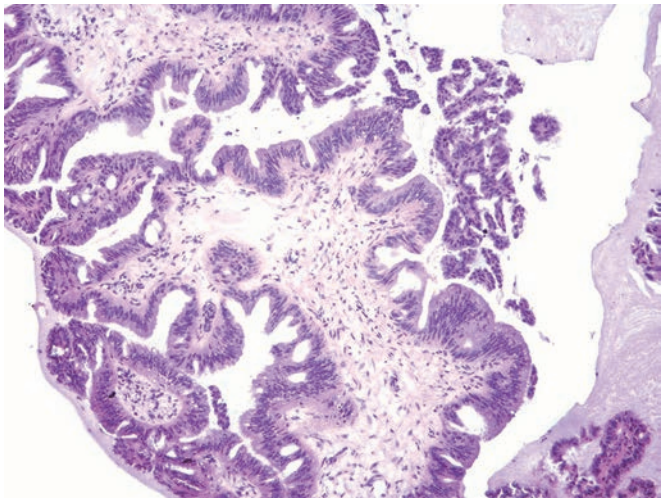

Figure 27.71 Müllerian type borderline tumor of the paratestis.

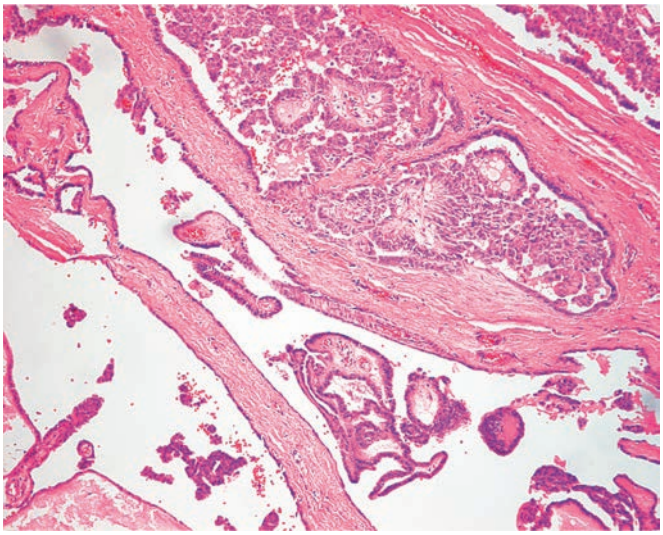

Figure 27.70 A rare adenocarcinoma of the epididymis.

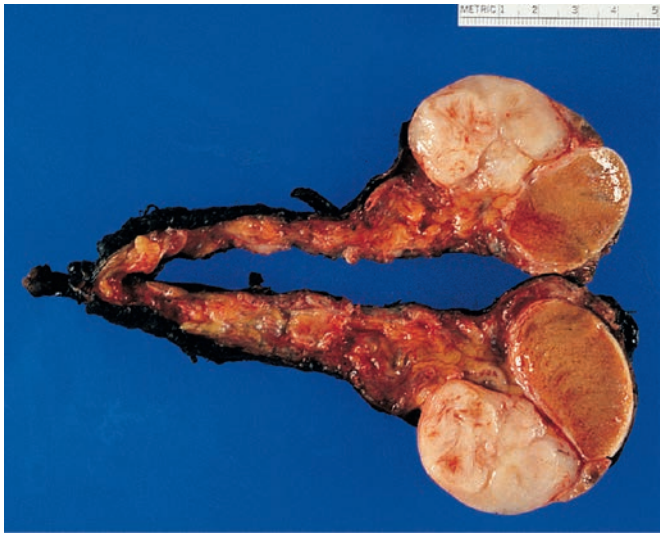

Figure 27.72 Leiomyosarcoma of the paratestis.

tubular, tubulocystic, or tubulopapillary, and there is often a conspicuous component of clear cells (Fig. 27.70).[542] Rare tumors combine epididymal-like cells and mucin-producing cells.[543]

Ovarian tumors of surface epithelial type, including serous, mucinous, endometrioid, clear cell, and Brenner varieties, may occur in the paratesticular region but are extremely rare.[544–547] They may be unilateral or bilateral.[548] Most have benign or borderline features (Fig. 27.71), but some have the appearance of serous carcinoma and can result in nodal and distant metastases.[549,550] The similarities with surface epithelial tumors of the female genital tract includes the expression of estrogen and progesterone receptors.[551] Another example of the analogy between the male and female genital tracts is provided by the isolated examples of endometriosis-like lesions in the paratesticular region of males treated with estrogens.[547]

Other tumors of this region include leiomyoma and leiomyosarcoma (Fig. 27.72),[552,553] hemangioma,[554] lymphangioma,[555] rhabdomyoma,[556] pigmented neuroectodermal tumor of infancy,[557] malignant lymphoma,[558,559] and plasmacytoma.[427] In some cases of the latter, the epididymal involvement represents the first clinical manifestation of the disease.[427]

Secondary tumors, in the majority of instances, represent a direct extension from testicular lesions. Prostate, lung, and kidney account for most of the others.[560]

Pseudotumors centered in the epididymis and composed of reactive myofibroblasts may be encountered in children after testicular torsion.[561] In children, an additional benign paratesticular lesion includes meconium periorchitis, which is related to in uteri bowel perforation, and may mimic a myxoid neoplasm (Fig. 27.73). It consists of mucin, heterotopic calcification, and fibrosis, and fetal squamous cells may also be present.[562]

Spermatic Cord

Torsion of the spermatic cord, if not treated promptly, may result in testicular infarct. Most cases occur in the first year of life, with a second peak toward puberty.[563] In 64% of the cases, the torsion is located in the intravaginal portion of the cord.[564] The adipose tissue around the cord may undergo fat necrosis, sometimes of the so-called lipomembranous type.[565] The treatment varies from untwisting of the torsion and fixation of the testis to orchiectomy, depending on

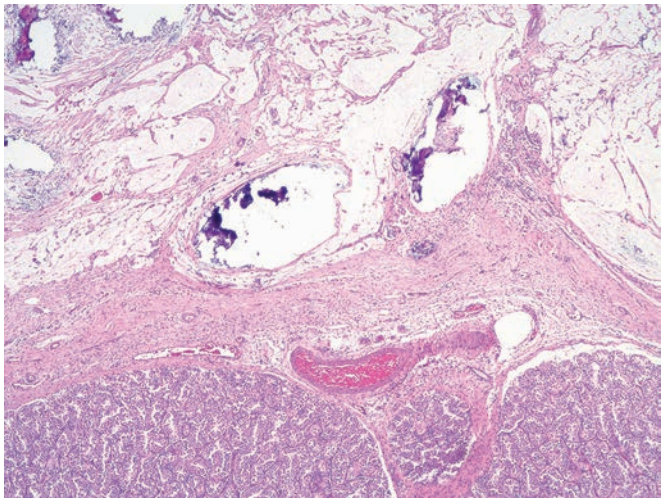

Figure 27.73 Meconium periorchitis in a child with cystic fibrosis.

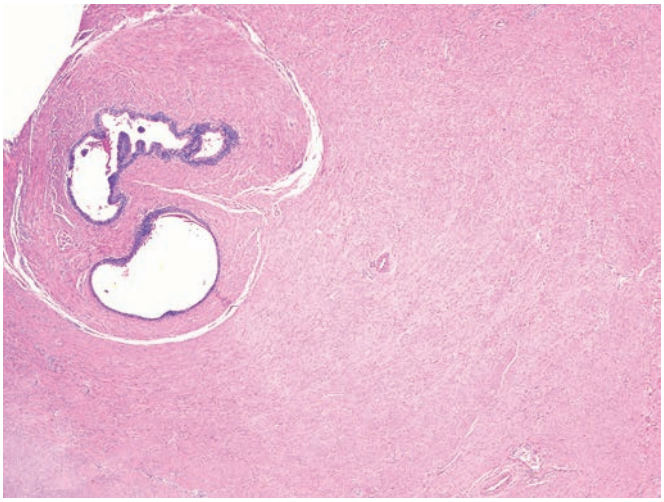

Figure 27.75 Smooth muscle hyperplasia of the testicular adnexa with dense sheets of benign smooth muscle cells encasing normal structures.

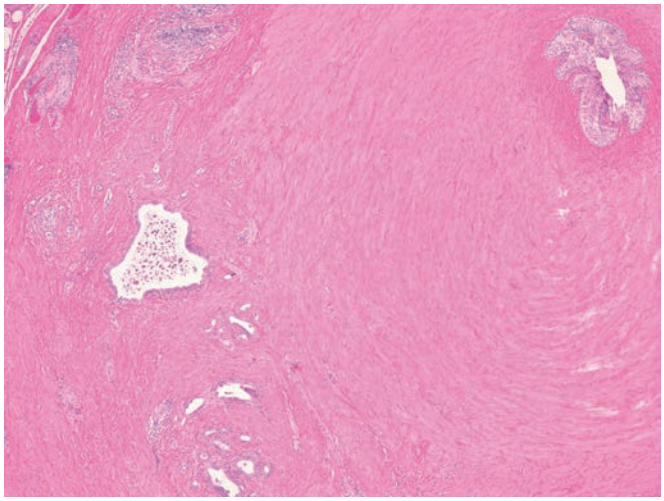

Figure 27.74 Vasitis nodosa with benign proliferating ductules deep in the wall of the vas deferens.

the viability of the testis as determined at surgery. Whatever procedure is carried out, the opposite testis should be fixed to the dartos musculature as a preventive measure.

The differential diagnosis of torsion of the spermatic cord includes torsion of a testicular appendage, a condition that results in a dramatic clinical picture out of proportion with the minute size and significance of this structure.[566,567] The appendix testis, a vestigial structure of müllerian derivation, is the one most often involved (92%). Parenthetically, tumors arising from this structure have been described.[568]

Giant cell vasculitis has been reported as an isolated event in the spermatic cord and presenting as a mass lesion.[569]

Vasitis nodosa is a granulomatous condition of the vas that resembles spermatic granuloma of the epididymis.[570] Most of the reported cases have appeared after vasectomy or herniorrhaphy.[571] The presence of proliferating ductules with a disorganized intramural location and perineural invasion may be found and should not be interpreted as a sign of malignancy (Fig. 27.74).[572]

Proliferative funiculitis is the name given to a pseudosarcomatous myofibroblastic proliferation of the spermatic cord.[573] Most of the reported cases have been incidental findings at inguinal herniorrhaphy. The microscopic appearance is similar to that of nodular fasciitis as seen in soft tissue. The pathogenesis is probably ischemic, sometimes resulting from torsion. These lesions are in all likelihood analogous to those sometimes seen under similar circumstances within the substance of the epididymis (see previous section).

Smooth muscle hyperplasia of testicular adnexa presents as a localized increase in mature smooth muscle of the spermatic cord or paratestis growing between or around vessels or efferent ducts (Fig. 27.75).[574] It can reach a diameter of 7 cm and may have an obstructive etiology.

Primary tumors of the spermatic cord can be of many types. Because of the intimate anatomic connection of the spermatic cord with the scrotum and the tunica vaginalis testis, it is often impossible to decide from which of these anatomic compartments these tumors have arisen. This is particularly true when the tumors in question are large, as is often the case. Indeed, one gets the impression that tumors are assigned into spermatic cord, tunica vaginalis, scrotal, epididymal, and paratesticular categories on a very arbitrary basis.[575,576] From a topographic and surgical standpoint, it would perhaps be more appropriate to simply divide them into those of the scrotum and those of the inguinal canal, without attributing them to a particular anatomic structure unless the gross and microscopic features of the case allow this to be done. In any event, the most common tumor of this region is the lipoma.[577] It is surrounded by tunica vaginalis and derives its blood supply from the vessels of the cord. The nodular collections of mature fatty tissue often seen in front of a hernia sac are not true lipomas.

The family of genital stromal tumors, identical to those in the vulvovaginal region, may also be seen in the paratestis, including cellular angiofibroma, aggressive angiomyxoma, and mammary-type myofibroblastoma. Nomenclature for these tumors has evolved over time, creating some confusion, but most neoplasms reported as "angiomyofibroblastoma-like tumor of the male genital tract" would now be classified as cellular angiofibroma.[578,579] These tumors are typically well circumscribed and consist of short, cytologically bland spindle cells set within a collagenous stroma and associated with variable thick-walled hyalinized blood vessels (Fig. 27.76). The cells show variable immunoreactivity for CD34 and smooth muscle actin, with less frequent staining for desmin; in addition, they harbor 13q rearrangements with *RB1* deletion/loss.[580] Aggressive angiomyxoma (deep angiomyxoma) may rarely occur in the spermatic cord or scrotum.[581] Compared to cellular angiofibroma, these lesions are

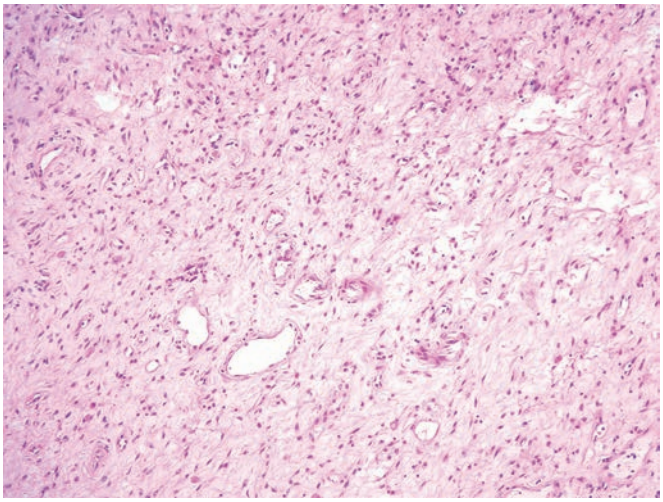

Figure 27.76 Cellular angiofibroma of the inguinal canal.

less cellular and have a more myxoid background, but associated blood vessels are variable. Additionally, aggressive angiomyxoma is often more infiltrative. Immunophenotypically there is varying expression of actin, CD34, and desmin. These lesions, which may recur locally, are characterized by *HMGA2* gene rearrangement on 12q14.3.[582] Protein expression of HMAG2 by immunohistochemistry is a sensitive marker of aggressive angiomyxoma, but is not specific as it is also expressed in smooth muscle tumors, adipocytic tumors, nodular fasciitis, and benign fibrous histiocytoma.[583,584] Mammary-type myofibroblastoma may also occur in the inguinal/spermatic cord or paratesticular region. Like their breast counterpart, these may have morphologic features very similar to a cellular spindle cell lipoma; however, they typically have rather diffuse expression of desmin. Similar to cellular angiofibroma, they have *RB1* deletion/loss.[585] Local recurrence is rare for both cellular angiofibroma and mammary-type myofibroblastoma. Rare cases of cellular angiofibroma show cytologic atypia or sarcomatous transformation, but these changes have not been associated with an aggressive course.[586] Neoplasms fitting the current strict definition of angiomyofibroblastoma are not well-documented at this site.

Papillary cystadenoma of the spermatic cord may present as an inguinal mass.[587] The morphologic resemblance it bears with borderline ovarian serous tumors suggests a müllerian derivation.[588]

Other reported primary tumors of this region include hemangioma, lymphangioma, leiomyoma, rhabdomyoma, solitary fibrous tumor, desmoid fibromatosis, fibrous hamartoma of infancy, and paraganglioma.[581,589–594]

The most common malignant tumor of this region in children is embryonal rhabdomyosarcoma, but the rare spindle cell/sclerosing variant may also occur.[553,595] In children and young adults, desmoplastic small round cell tumor should always be considered before a diagnosis of carcinoma is rendered.[596]

In adults, well-differentiated liposarcoma (atypical lipomatous tumor) or de-differentiated liposarcoma predominate, but cases of leiomyosarcoma, fibrosarcoma, epithelioid hemangioendothelioma, and undifferentiated pleomorphic sarcoma also occur.[597–602]

The standard treatment for the sarcomas occurring in adults consists of orchiectomy with high ligation of the cord.[603] Since local recurrence is very common after this procedure, the administration of postoperative radiation therapy has been advocated.[604,605]

Secondary involvement of the spermatic cord by testicular germ cell tumors may occur as a result of direct extension or vascular invasion. It is important to distinguish this prognostically significant finding from contamination induced at the time of the gross dissection, which is common. The latter occurrence, which is particularly common with seminoma (probably because of its very friable nature), can be minimized with meticulous handling and processing, specifically by taking spermatic cord sections prior to dissection of the main testis mass.[606]

Penis

Normal Anatomy

The main anatomic components of the penis are the *corpus* (shaft), *glans*, and *prepuce* (foreskin). The corpus is composed of the *corpora cavernosa* (made up of a net of vascular spaces surrounded by the tunica albuginea) and the inferiorly located *corpus spongiosus*, in the center of which runs the penile urethra. All of these structures are covered by skin, a smooth discontinuous muscle layer known as *dartos*, and an elastic sheath designated as *Buck fascia*. The latter separates the penis into dorsal (corpora cavernosa) and ventral (corpus spongiosum) portions, a distinction highlighted by computed tomography (CT) and magnetic resonance imaging (MRI) techniques.[1]

The skin of the glans is made up of nonkeratinized stratified squamous epithelium, five to six cell layers thick; this becomes keratinized after circumcision.[2] The glans is separated from the shaft by the *balanopreputial sulcus* in the dorsal and lateral aspects and by the *frenulum* in the ventral region.

The male urethra is divided into three portions: *prostatic* (the short proximal segment surrounded by the prostate), *membranous* or *bulbomembranous* (extending from the lower pole of the prostate to the bulb of the corpus spongiosum), and *penile* (which passes longitudinally through the corpus spongiosum). The terminal enlarged portion of the penile urethra is known as the *fossa navicularis*.

Microscopically, the lining of the urethra is of urothelial type in the proximal (prostatic) portion, of stratified squamous type in the distal portion corresponding to the fossa navicularis, and of stratified or pseudostratified columnar ciliated epithelium in the rest of the canal.[1] Glandular structures associated with the urethra are the *intraepithelial glands* or Morgagni lacunae (one-layer cylindrical intraepithelial glands), *Littré glands* (tubuloacinar mucinous glands present along the full length of the corpus spongiosum), and the bulbourethral or *Cowper glands* (mucous acinar structures located deeply at the level of the membranous urethra).[1]

The lymphatic drainage of the penis is to the superficial and deep inguinal nodes. There are centrally located anastomoses between lymph vessels that result in bilateral drainage.

Non-Neoplastic Lesions

Small accessory urethral canals or periurethral ducts may open in or about the fossa navicularis and produce symptoms because of secondary inflammation.[3] The *median raphe cyst* that has been described in the central aspect of the glans in young men probably represents a cystic dilation of these structures (Fig. 28.1).[4]

Mucoid cyst can be found on the prepuce or glans penis. It has a lining of stratified columnar epithelium, often associated with intraepithelial mucous glands (Fig. 28.2).[5,6]

Mucinous metaplasia refers to the presence of mucin-producing cells in the surface epithelium in the prepuce or glans penis. It is seen in the elderly and appears to be a metaplastic change associated with severe chronic inflammation, particularly Zoon balanitis (see later).[7,8]

Inflammation of Littré glands can clinically simulate a penile tumor.[9]

Dermatoses of various types can involve the skin of the penis. These include eczematous dermatitis, seborrheic dermatitis, fixed drug eruption, psoriasis, lichen planus, lichen nitidus, and lichen sclerosus et atrophicus.

Lichen sclerosus has traditionally been known in this location as *balanitis xerotica obliterans*.[10] Evidence suggests that lichen sclerosus plays a role in the development of non-human papilloma virus (HPV)-related squamous cell carcinoma (Fig. 28.3A and B).[11]

An inflammatory condition clinically resembling Bowen disease is *balanitis circumscripta* (Zoon balanitis), characterized microscopically by epidermal atrophy and a dense inflammatory infiltrate rich in plasma cells.[12,13]

Abstract

This chapter covers the spectrum of diseases that involve the penis and scrotum. Inflammatory lesions, including those of infectious etiology, are reviewed in detail. The discussion of squamous cell carcinoma follows the latest WHO 2016 classification; therefore, both non-invasive (i.e. penile intraepithelial neoplasia) and invasive variants are divided into HPV and non-HPV types. Other rare mesenchymal tumors are also addressed, as are tumors that frequently involve the male urethra and scrotum.

Keywords

penis
scrotum
male urethra
squamous cell carcinoma
verrucous carcinoma
penile intraepithelial neoplasia
human papilloma virus

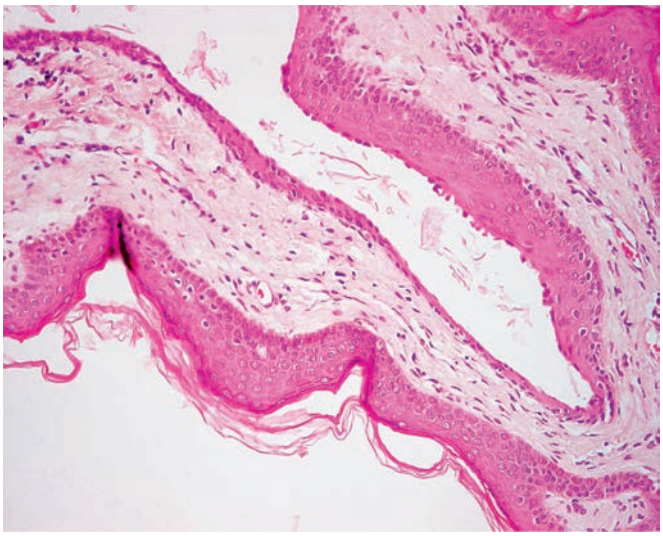

Figure 28.1 Median Raphe Cyst. This probably results from cystic dilation of accessory urethral canals or periurethral ducts.

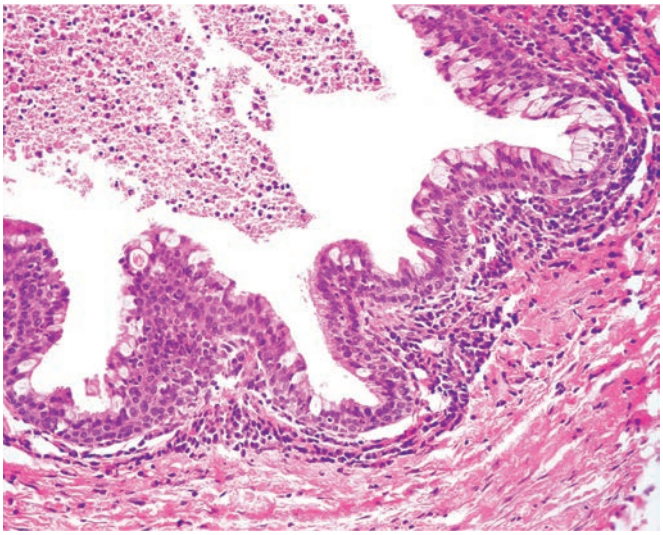

Figure 28.2 Mucoid Cyst of Penis. The lesion is lined by stratified columnar epithelium containing mucin-secreting cells.

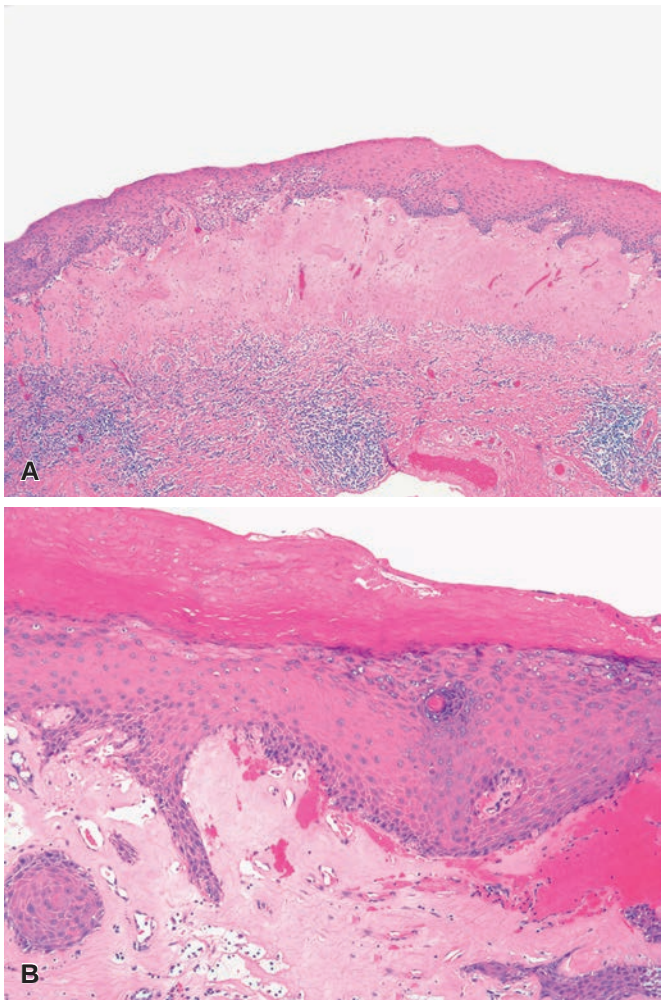

Figure 28.3 Lichen Sclerosus. A, The dense hyalinized band of dermal collagen, chronic lymphocytic inflammation, and loss of rete ridges is characteristic. **B,** Acanthosis and hyperkeratosis defines squamous hyperplasia, in this case associated with lichen sclerosus.

Deep *granuloma annulare* can be localized to the penis.[14]

Amyloidosis presenting as a localized mass in the shaft of the penis has been reported.[14]

Primary syphilis (chancre) consists microscopically of a thin and sometimes ulcerated epidermis accompanied by a dense dermal inflammatory infiltrate rich in plasma cells and lymphocytes (Fig. 28.4A). The blood vessels show marked endothelial cell swelling and proliferation, as well as infiltration of the wall by inflammatory cells ("endarteritis obliterans"). Spirochetes can be demonstrated with the Warthin–Starry silver stain or immunohistochemically, both in the epidermis and in the dermis (particularly in and around the proliferating vessels) (see Fig. 28.4B).

Chancroid, the most common cause of genital ulceration in Africa, is characterized microscopically by vasculitis in the deep dermis, manifested by perivascular and intramural lymphocytic and histiocytic infiltrates associated with swelling of endothelial cells, sometimes admixed with neutrophils and/or multinucleated giant cells.[15] The overlying epidermis shows psoriasiform hyperplasia and spongiosis, sometimes accompanied by neutrophils in the malpighian and horny parakeratotic layers.

Genital **herpes** is caused by the herpes simplex virus (HSV), most commonly HSV2. It presents as small skin vesicles that rupture to form small painful ulcers. Histologically, the edges of the ulcer show multinucleated keratinocytes with ground-glass nuclear inclusions and molding (Fig. 28.5). The diagnosis may be made by Tzanck preparations.

Tuberculosis and other granulomatous inflammations can on rare occasions present as penile nodules.[16]

Abscess and **gangrene** of the penis are described.[17]

Granulomatosis with polyangitis (Wegener's granulomatosis) can be localized to the penis and clinically simulate a carcinoma.[18]

Behçet disease is a symptom complex of oral and genital ulcers and iritis.[19,20] Microscopically, various types of vasculitis may be encountered.

Peyronie disease (plastic induration of the penis) is a progressive fibrous thickening arising in the connective tissue layer between the corpora cavernosa and the tunica albuginea. It causes pain and penile curvature toward the side of the lesion on penile erection.[21–23] Microscopically, the lesion is composed of hyalinized fibrous tissue, at times containing cartilage and bone (Fig. 28.6).[24] It may be

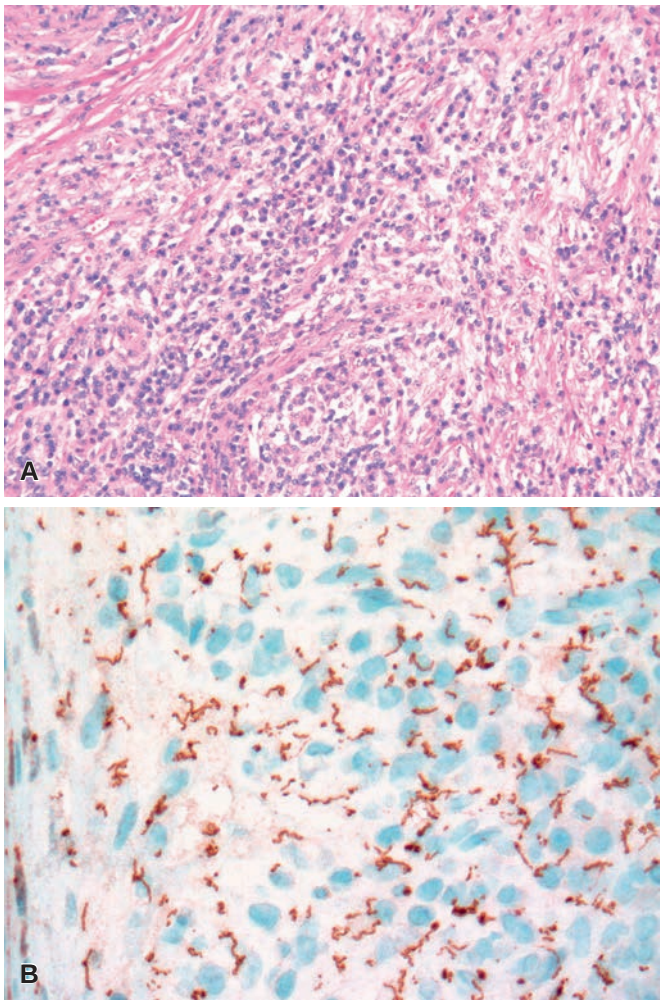

Figure 28.4 Syphilis. A, The dense plasma cell–rich inflammatory infiltrate, often around blood vessels, is characteristic. **B,** Immunostain for *Treponema pallidum*.

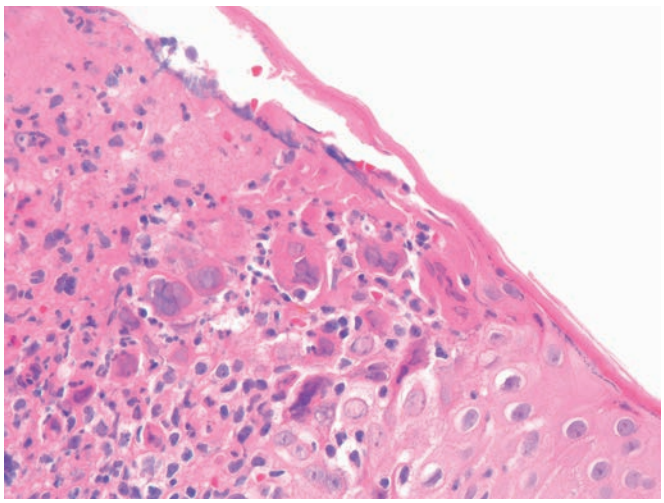

Figure 28.5 Herpes with prototypical viral cytopathic effect at the edge of the ulcer.

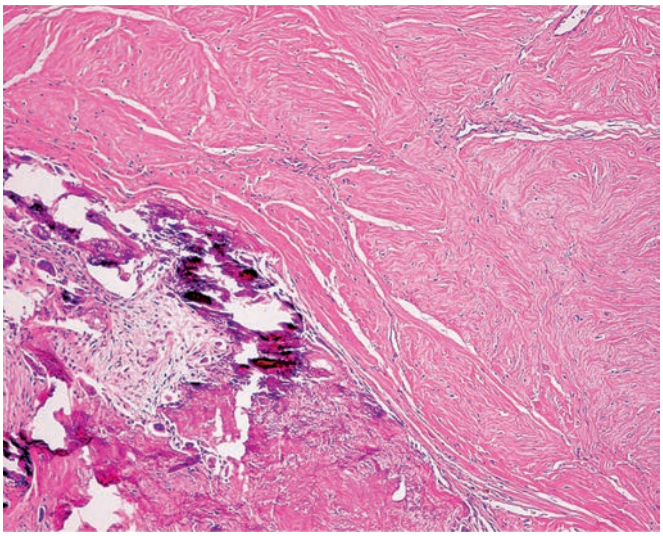

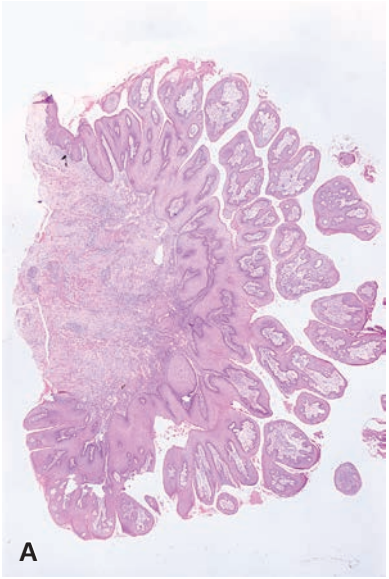

Figure 28.6 Peyronie Disease. The lesion is composed of densely hyalinized tissue that has undergone focal dystrophic calcification.

Figure 28.7 Large Lesions of Condyloma Acuminatum in an HIV-Infected Patient. The glans penis also shows herpesvirus infection.

associated with Dupuytren contracture[25] and may be treated by surgical techniques, topical therapy (including low intensity shock wave therapy), and intralesional injections of various agents.[26,27] Although older literature often regarded Peyronie disease as a form of "fibromatosis," current data argue strongly against any relationship to true desmoid tumor. It is most likely a sclerosing inflammatory process with an initial acute inflammatory response to microvascular trauma and a subsequent chronic fibrosing phase. TGF-β1 likely serves as a pro-fibrotic factor in the development of this condition.[28,29]

Condyloma acuminatum of the penis is a venereal disease caused by HPV and is most commonly seen between the ages of 20 and 40 years. It presents as a papillary growth at the penile meatus or fossa navicularis or in other regions of the glans (Fig. 28.7). Almost

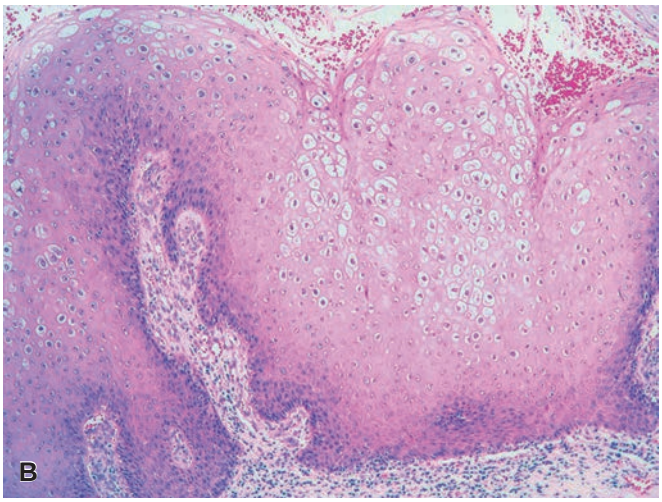

Figure 28.8 Condyloma Acuminatum. A, Complex papillary pattern composed of well-differentiated squamous epithelium is seen. **B,** Virus-induced cytopathic changes are present.

30% of the polypoid lesions of the male urethra are examples of this entity. Microscopically, there are complex papillary infoldings of squamous epithelium accompanied by vacuolization of keratinocytes and nuclear abnormalities ("koilocytosis") (Fig. 28.8A and B). The virus can be demonstrated by immunocytochemical and in situ hybridization techniques, but this is typically not necessary.[30,31] A subset of condylomas have a histologic appearance similar to seborrheic keratosis, and the distinction may be difficult without HPV evaluation (Fig. 28.9).

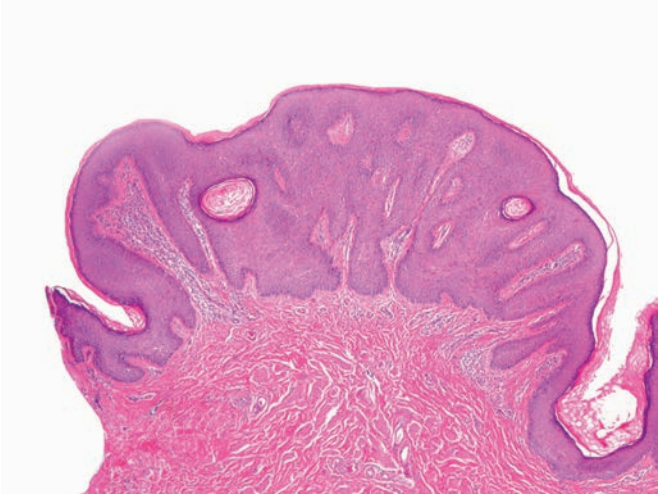

Figure 28.9 Some condylomas have a low-power appearance simulating seborrheic keratosis.

Tumors

Squamous Cell Carcinoma

The vast majority of malignant tumors arising in the penis are squamous cell carcinomas. They are relatively infrequent in the United States, accounting for fewer than 1% of all malignancies in males.[32] However, it is very common in some Asian, African, and Latin American countries, where it may constitute over 10% of all carcinomas.[33,34] It most commonly affects patients in their fourth to fifth decade.

If circumcision is done shortly after birth, carcinoma of the penis develops very rarely. If the operation is delayed until the age of 10 years, carcinoma is more likely to develop.[35] It is possible that carcinoma is related to personal hygiene and the carcinogenic effect of smegma, factors that might be enhanced by failure to circumcise.[36] In keeping with this assumption, an association has been found between penile cancer and long phimotic foreskins.[36,37]

Cases have also been reported in association with lichen sclerosus et atrophicus (balanitis xerotica obliterans)[38] and lichen planus.[39] In resection specimens for the well-differentiated spectrum of squamous cell carcinoma, lichen sclerosus is often seen together with squamous hyperplasia and the differentiated form of penile intraepithelial neoplasia (PeIN), suggesting a precancerous role for that condition.[40]

The association of penile carcinoma with HPV is well documented.[41,42] McCance et al.[43] found HPV-16 DNA sequences in 49% and HPV-18 DNA in 9% of 53 cases from Brazil. Recent data suggest that HPV-related carcinomas are decreasing in some countries, but are on the rise in the United States.[44] The association of HPV with various microscopic subtypes is also well established.[45–49] Based on these findings, the classification of penile squamous cell carcinoma has evolved to an HPV-based nomenclature as presented later.

Morphologic Features and Tumor Types

Most squamous cell carcinomas of the penis arise in the glans, prepuce, and coronal sulcus, in this order of frequency (Figs. 28.10 and 28.11). Their pattern of growth may be superficially spreading, predominantly exophytic (fungating, verruciform) or predominantly endophytic (infiltrative, ulcerating, vertical). Mixtures of these patterns occur, and there may be multicentricity.[50] In general, the exophytic tumors are better differentiated than their endophytic counterparts. At the microscopic level, penile squamous cell carcinomas are now broadly divided into HPV and non-HPV associated. The relative proportion of each group varies by geographic region, probably based largely on levels and types of HPV infection.

Precursor Lesions

Penile Intraepithelial Neoplasia

PeIN is an early neoplastic lesion of the squamous epithelium of the penis that retains an intact basement membrane (i.e., noninvasive

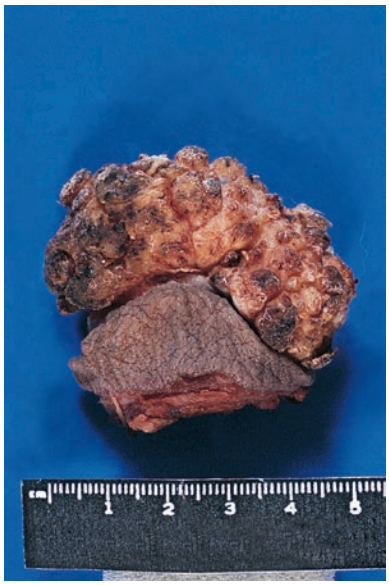

Figure 28.10 Outer aspect of squamous cell carcinoma of the glans penis showing a papillomatous pattern of growth.

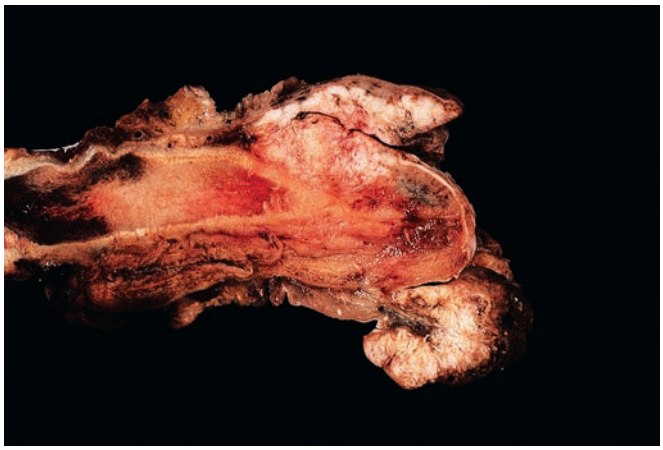

Figure 28.11 Penile squamous cell carcinoma with extensive involvement of the prepuce (foreskin).

lesion) and is the precursor to invasive squamous cell carcinoma. A variety of diagnostic names have been used in the past (such as Bowen disease, erythroplasia of Queyrat, dysplasia, and carcinoma in situ), but these have been replaced by the current PeIN terminology.[51,52] These lesions, like their invasive counterparts, can also be subdivided into HPV and non-HPV associated types.[48] Non-HPV–associated types generally occur in an older age group, compared to those associated with HPV.

Human Papilloma Virus Related (PeIN)

Basaloid (undifferentiated) PeIN typically involves the glans penis in young men. The morphologic features are similar to high-grade squamous intraepithelial lesions of the cervix with full-thickness involvement by small monotonous immature cells with high nuclear-to-cytoplasmic ratio (Fig. 28.12).[48] Mitotic activity and apoptotic bodies may be frequent, but squamous maturation is not characteristic. These lesions show diffuse staining for p16. Studies have shown a common association with HPV type 16.

Warty (Bowenoid) PeIN has more complex architecture than basaloid PeIN, with a papillomatous surface and more abundant

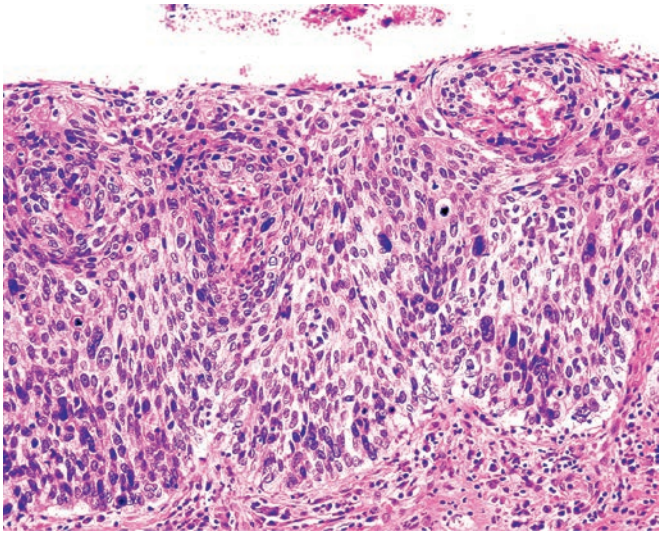

Figure 28.12 Basaloid penile intraepithelial neoplasia (PeIN).

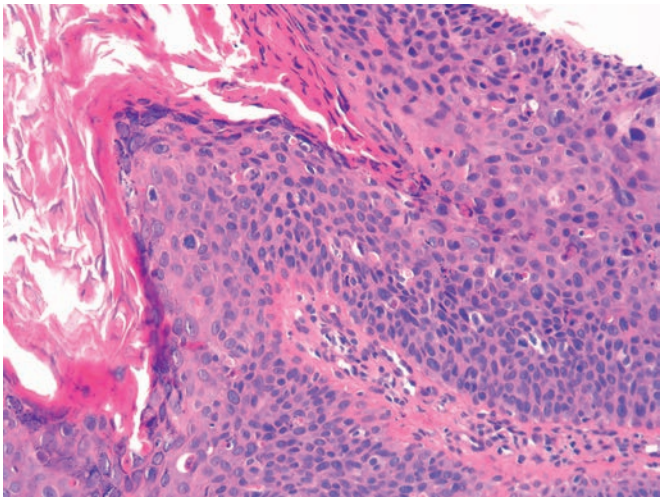

Figure 28.13 Warty-basaloid penile intraepithelial neoplasia (PeIN).

surface keratin. There is also more nuclear pleomorphism, and well-developed koilocytotic atypia is characteristic.[48] Another contrasting point with basaloid PeIN is frequent squamous maturation in the warty variant. This lesion also expresses strong p16, but the associated HPV type is more variable.

Warty-basaloid PeIN, as the name implies, shows an admixture of basaloid and warty features.[48,53] The surface may show papillations with koilocytotic atypia, while the basal half has a more uniform basaloid population of cells (Fig. 28.13). These lesions seem to have more overlap with basaloid PeIN, having a strong association with HPV-16.[46]

Human Papilloma Virus Unrelated (PeIN)

Differentiated PeIN has been associated with lichen sclerosus or other chronic inflammatory conditions.[11] In contrast to HPV-associated PeIN (such as basaloid PeIN that affects the glans penis), differentiated PeIN generally involves the foreskin. Clinically, these often have a plaque-like or raised macular growth. Microscopically, they are similar to their vulvar counterparts with thickened squamous epithelium and elongated rete ridges, which may show bridging. The degree of cytologic atypia varies, but the most subtle cases show only basal atypia, often with abnormal maturation/keratinization near the base

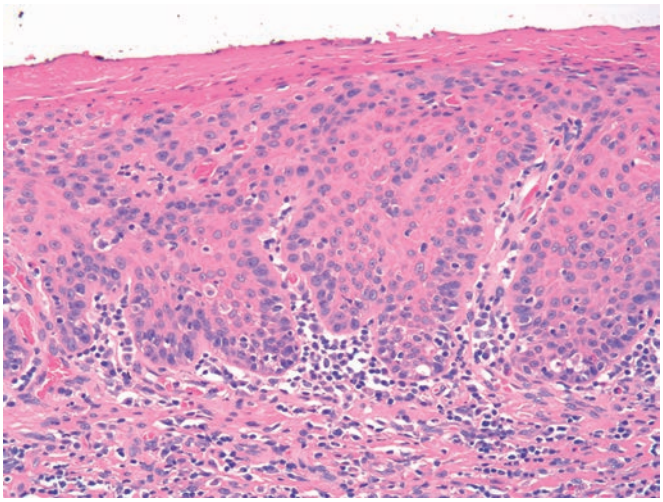

Figure 28.14 Differentiated penile intraepithelial neoplasia (PeIN).

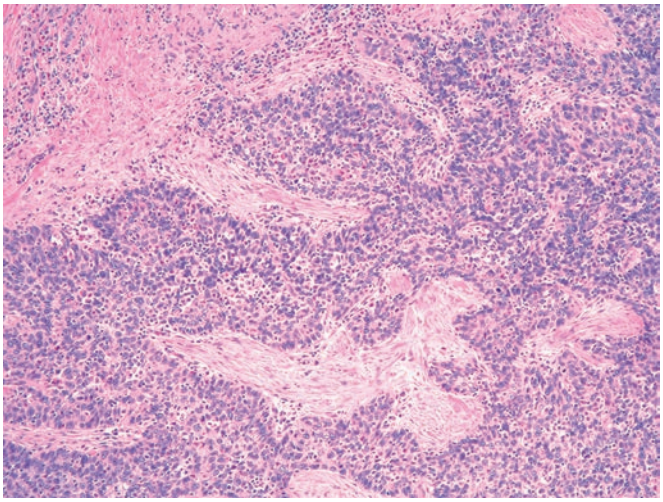

Figure 28.15 Invasive basaloid carcinoma of penis, an HPV-related variant of squamous cell carcinoma.

or in the rete ridges (Fig. 28.14). Because of the subtle histologic features, distinction from reactive epithelial changes may be difficult in some cases. Immunophenotypically, differentiated PeIN is typically p16 negative, but shows some increase in Ki-67 proliferation rate. p53 nuclear staining may be strong and diffuse, but is variable.[54] p16 immunostains have a high sensitivity and specificity for discriminating differentiated PeIN from basaloid, warty, and warty-basaloid PeIN.[55] When differentiated PeIN is associated with an invasive component, it is typically a keratinizing or well-differentiated variant.

Invasive Carcinoma

Human Papilloma Virus Related. Basaloid squamous carcinoma is a biologically aggressive form of penile carcinoma related to HPV-16 in most cases and typically arising on the glans. It is characterized by broad anastomosing sheets of basaloid cells with little cytoplasm that irregularly infiltrate the underlying stroma, sometimes with associated central necrosis (Fig. 28.15). Typically, numerous mitotic figures and apoptotic bodies are easily identified in a single high-power field. As expected, these tumors show strong and diffuse reactivity for p16. Occasional cases have an exophytic papillary component resembling the architecture of a urothelial neoplasm, which is described as "**papillary basaloid carcinoma.**"[56]

Warty carcinoma is a large slow-growing tumor with exophytic and papillomatous architecture, mimicking condyloma or verrucous carcinoma; however, its cytologic features are distinct. In contrast to other subtypes, warty carcinoma exhibit nuclear pleomorphism with perinuclear clearing and koilocytotic atypia (Fig. 28.16).[57] The invasive front has a burrowing pattern with irregular, jagged downgrowth. Some cases have mixed features of warty and basaloid carcinoma.[47] As with the precursor warty PeIN, the associated HPV type is variable.

Other rarer subtypes of HPV-related squamous cell carcinoma include lymphoepithelial-like, medullary, and clear cell carcinoma.[58–61] Some cases may also show neuroendocrine differentiation.

Non-Human Papilloma Virus Related. Squamous cell carcinoma of the "usual type" is the prototypical invasive carcinoma, similar to keratinizing carcinomas of the head and neck (Fig. 28.17A and B). It might be thought of as a "diagnosis of exclusion" after other subtypes are ruled out. It is graded similar to other sites, ranging from well to poorly differentiated based on nuclear pleomorphism and keratinization. Grade is typically based on the highest-grade component present, regardless of extent.

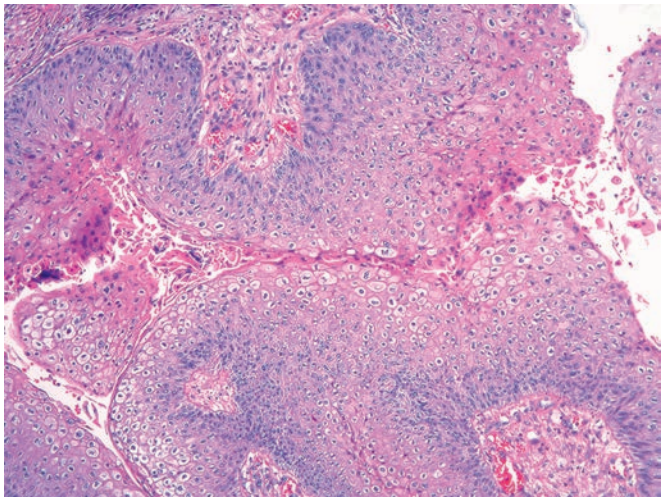

Figure 28.16 Invasive warty carcinoma is characterized by well-developed koilocytotic atypia.

Verrucous carcinoma, which constitutes 2% to 3% of all penile cancers, generally affects older men in their sixth to seventh decade. Microscopically, it is characterized by papillomatosis with hyperkeratosis and acanthosis. It has a more regular architecture than warty carcinoma, particularly at its base, where it features broad-based bulbous expansions of squamous epithelium lacking irregular stromal penetration (Fig. 28.18).[57,62,63] By definition, verrucous carcinoma is composed of cytologically bland cells with very little atypia, except for a subtle degree of nuclear enlargement near the base. It lacks koilocytotic atypia. Tumors combining features of squamous cell carcinoma of the usual and verrucous types are referred to as *hybrid tumors* and generally have an outcome based on the non-verrucous component.[62,64]

Other described subtypes of non-HPV–related squamous cell carcinoma include carcinoma cuniculatum (Fig. 28.19),[42] pseudohyperplastic (Fig. 28.20A and B),[65] pseudoglandular,[66] papillary,[67] adenosquamous,[68] sarcomatoid (Fig. 28.21),[69,70] and mixed types.

Molecular Genetic Features

The molecular pathogenesis of penile cancer is not as well developed as for many other carcinoma types. As suggested by the histologic

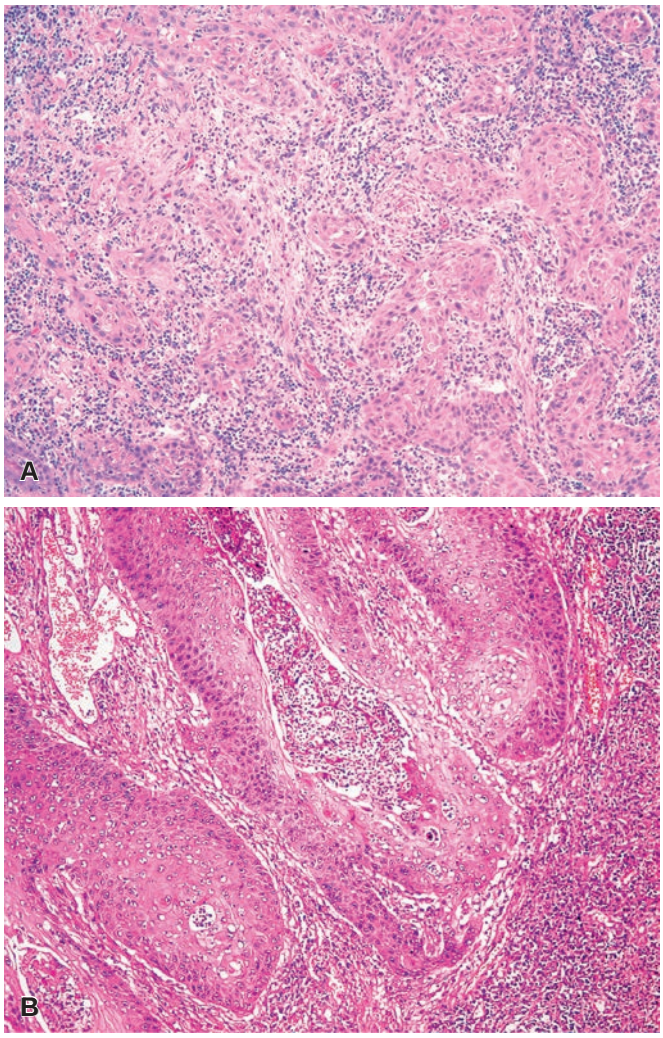

Figure 28.17 **A,** Invasive squamous cell carcinoma, usual type, shows irregular invasion of underlying stroma without features of other subtypes. **B**, Moderately differentiated invasive squamous cell carcinoma, usual type.

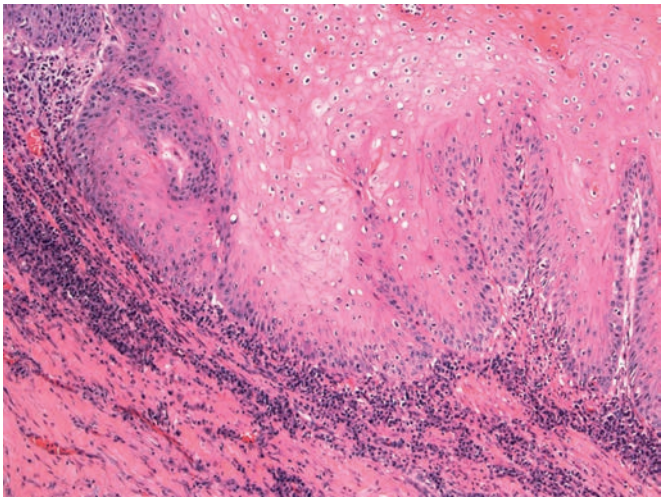

Figure 28.18 Verrucous carcinoma is characterized by a broad-based "pushing" interface with underlying stroma.

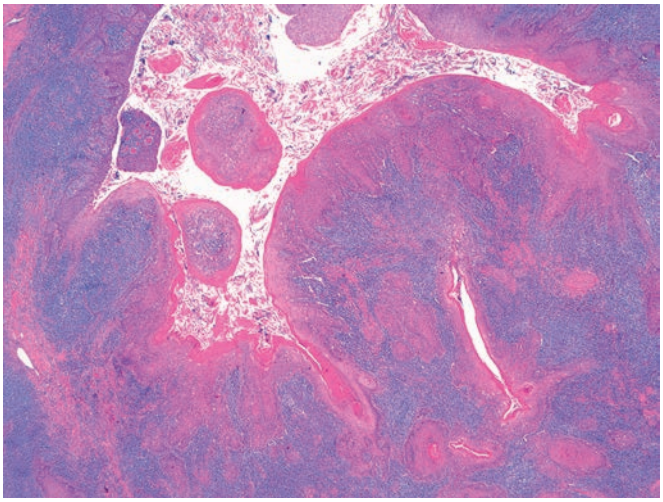

Figure 28.19 Carcinoma cuniculatum often has a central opening simulating a cyst.

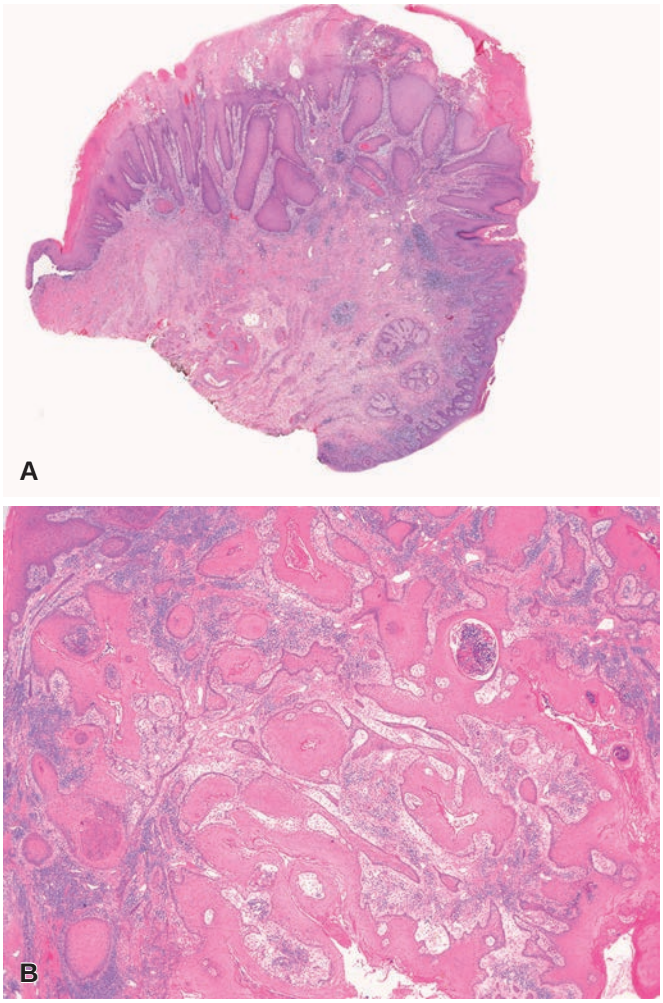

Figure 28.20 **Pseudohyperplastic Squamous Cell Carcinoma. A,** On low power, there are markedly irregular invaginations of squamous epithelium. **B,** The histologic features are extremely well differentiated.

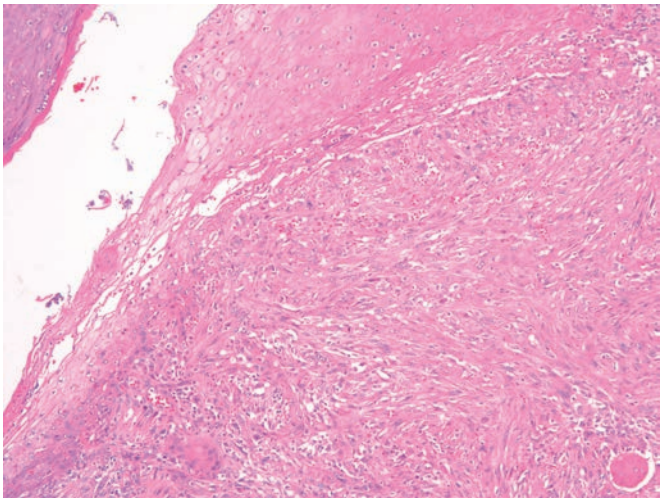

Figure 28.21 Squamous Cell Carcinoma of Penis With Spindle Cell (Sarcomatoid) Features. There is a blending of the carcinoma islands with the sarcoma-like component.

classification, studies support two main genetic pathways: high-risk HPV pathogenesis and non-HPV pathogenesis.[71] Abnormalities in the *Rb*/p16/p21 pathway are common in the HPV tumors, similar to those of the uterine cervix and head and neck region.[72] *TP53* mutations are not typical in the HPV-associated subset. For non-HPV–related squamous cell carcinoma of the penis, there seem to be two pathways: high chromosomal instability and *TP53* mutation.[73,74]

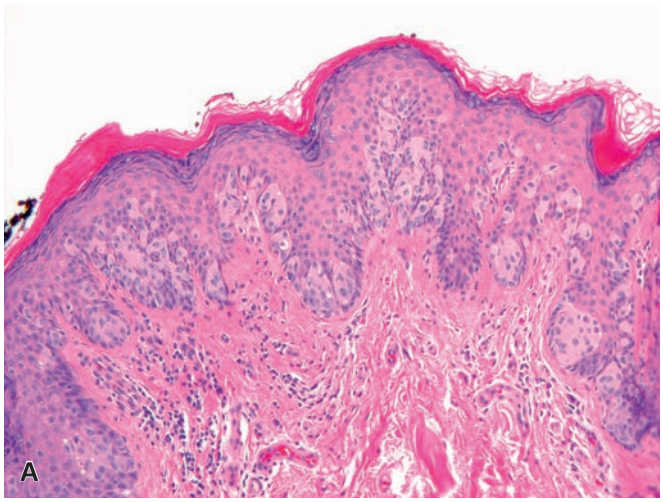
Spread and Metastases

Squamous cell carcinoma arising within a penile compartment (glans, prepuce, or coronal sulcus) often spreads to involve others. Early invasion of the Buck fascia is common in carcinomas of the coronal sulcus. Local spread into the urethra is also a common finding, especially among the deeply invasive tumors. Velazquez et al.[75] have listed the following five major routes of local spread of penile cancer: (1) horizontal superficial spread from one compartment to another; (2) following the penile fascia; (3) through spaces created by feeding vessels in the tunica albuginea; (4) vertical spread involving step-by-step different compartments; and (5) along the urethral epithelium.

The overall incidence of inguinal lymph node metastases is 15%. The first node usually involved ("sentinel node") belongs to the superficial epigastric group and is located medial to and above the epigastric–saphenous junction.[76] Because carcinomas are often associated with secondary infection, enlargement of inguinal nodes is very common and clinical appraisal is extremely inaccurate.[77] Lymph node metastases are uncommon in exophytic tumors; when present, they usually appear late in the evolution of the disease. Conversely, they are common in deeply invasive tumors, sometimes accompanied by spread to other lymph node groups. Metastases do not occur in verrucous carcinomas,[62] but may be present in hybrid carcinomas.[78] They are particularly common in basaloid and spindle cell carcinomas.[63] In the series of Cubilla et al.,[50] inguinal lymph node metastases were present in 82% of deeply invasive tumors with minimal or no in situ component, 42% of "superficially invasive" tumors, and 33% of multicentric tumors. Nodal metastases were very rare in tumors that invaded only the lamina propria, and relatively common in tumors that had invaded the urethra.

Treatment and Prognosis

Carcinoma of the penis can be treated by local resection or by partial or total penectomy, according to the size and location of the lesion and its microscopic type.[79–82] Local recurrence occurs in about one-third of the cases, usually due to insufficient surgery or positive margins.[83] It is extremely rare if all the surgical margins are negative, even if narrow (≤10 mm).[84] Controversy still exists as to the role of elective inguinal lymphadenectomy. Most authors advocate it except for very small and early lesions,[79,85,86] but others have questioned the need for this procedure, which is associated with significant morbidity.[87,88] Since lymph node metastases do not occur in verrucous carcinoma, this tumor is therefore treated with resection of the primary lesion only.[62] As in other sites, radiation therapy has been described in association with anaplastic transformation.[89]



The overall 5- and 10-year survival rates for squamous cell carcinoma of the penis are 77% and 71%, respectively.[90] The prognosis is related to the following factors:

1. *Stage*. As usual, this is the most important parameter.[91] However, it should be noted that there is a considerable difference between clinical and pathologic stage, which is attributable to the difficulty of assessing clinically corpora cavernosa invasion and inguinal lymph node metastases[92,93] and the fact that a biopsy alone is insufficient to stage this tumor accurately.[83] The close relationship that exists between the depth of invasion of the penile anatomic landmarks and prognosis renders essential an accurate anatomic dissection and sampling of the penectomy specimen.[94] If metastases are present in two or more nodes, the chances of cure are very small.[95]
2. *Local invasion*. Invasion of the corpora cavernosa or preputial skin is a significantly adverse prognostic factor.[96]
3. *Microscopic type*. Verrucous carcinoma is associated with a much better prognosis. Basaloid and sarcomatoid carcinomas are associated with high rate of nodal metastases and poor survival.[63,96]
4. *Microscopic grade*. The grade of the tumor shows a very good correlation with prognosis. Presence of a grade 3 component, regardless of its amount, is a sign of poor prognosis.[85,97–99]
5. *Vascular invasion*. This is an indicator of poor prognosis, which seems to retain its value independently of staging and microscopic grading.[85,98,100]
6. Perineurial invasion.[101]

Other Carcinoma Types

Primary **extramammary Paget disease** is less common in the penis than in the scrotum or perineum; it may be purely intraepidermal or associated with invasion of the dermis.[102,103] Rare cases are associated with an underlying sweat gland carcinoma. As in other sites, Paget disease may present clinically as a pink to red plaque, but early lesions may mimic benign inflammatory conditions. Histologically, there is a population of large atypical cells with abundant pale cytoplasm that are present within the epidermis, either singly or in clusters (Fig. 28.22A). Small gland-like lumina may be present, and the cells may colonize underlying adnexal structures.

The differential diagnosis includes mainly PeIN ("squamous cell carcinoma in situ") with a pagetoid growth, melanoma, and secondary involvement from an anatomically adjacent adenocarcinoma. Primary Paget disease must be carefully distinguished from secondary involvement by occult carcinomas from regional anatomic sites, most commonly urethra and bladder (but very rarely prostatic). When extending to involve perineal and perianal regions, rectal adenocarcinomas should be considered. While immunophenotypes may vary considerably, primary Paget disease often has a CK7+/CK20–, Her2+, BerEP4+, GCDFP15+, CEA+ phenotype (see Fig. 28.22B).[104,105] CDX2 and p63 are typically negative in primary Paget disease. It should be noted that Paget disease is positive for GATA-3, limiting its utility

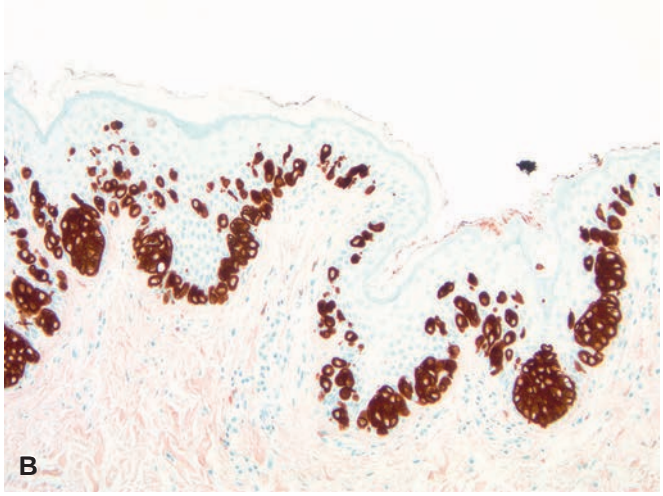


Figure 28.22 **Extramammary Paget Disease. A,** A population of atypical cells with clear cytoplasm, either as singe cells or clusters, involves the epidermis. **B,** Cytokeratin 7 shows strong cytoplasmic reactivity.

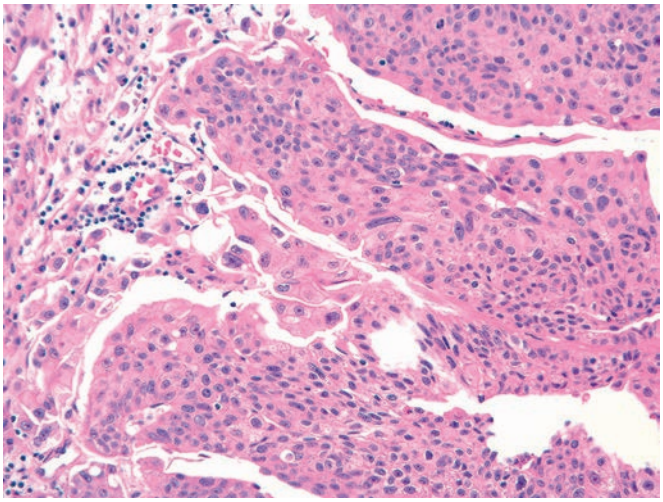

Figure 28.23 Urothelial carcinoma of penile urethra.

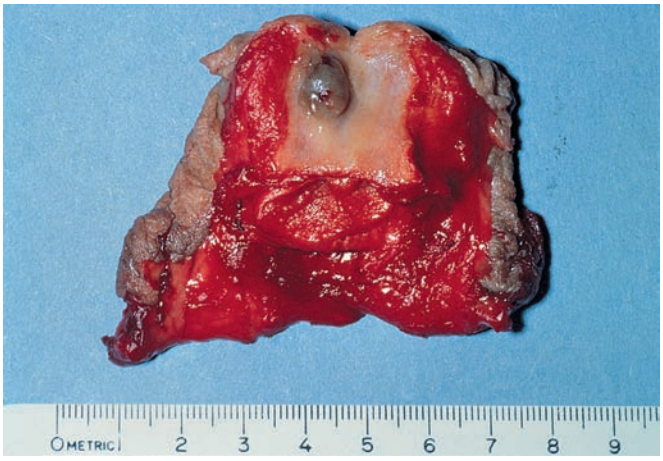

Figure 28.24 Malignant melanoma presenting as a polypoid blue-colored mass protruding from the urethra.

in distinction from urothelial origin[106,107]; however, expression of CK20 and uroplakin III (with absence of CEA) would support urothelial carcinoma.[108] Expression of CK5/6, other high-molecular-weight cytokeratins, and/or p63, and absence of GCDFP15 and CEA staining would support squamous lineage.[109] S-100, SOX-10, or HMB-45 reactivity, and absence of keratins, would support melanocytic origin.[110,111] Rectal adenocarcinomas often express CK20, CEA, and CDX2, but CK7 reactivity is more variable.[112,113]

Basal cell carcinoma of the penis is microscopically similar to its counterpart elsewhere in the skin; to the best of our knowledge, no instances of metastatic behavior have been reported.[114] Obviously, a sharp distinction should be made between this tumor and basaloid squamous cell carcinoma.

Tumors of Penile Urethra

Benign tumors of the penile urethra are extremely rare. Isolated cases of **inverted urothelial papilloma** similar to their bladder counterparts have been reported.[115] **Condyloma acuminatum** can extend into the distal portion of the urethra. **Leiomyoma** of the male urethra is much less common than in the female urethra, but its existence has been documented.[116]

Carcinoma of the male urethra is a rare disease. In some cases, it follows stricture produced by trauma or gonorrhea. In some series as many as 44% of the patients had a history of venereal disease.[117] The most common location of the tumor is the bulbomembranous portion, followed by the penile portion.[118] Microscopically, 75% of the tumors are *squamous cell carcinomas*; most of the others (usually located in the prostatic portion) are *urothelial carcinomas* (Fig. 28.23). A few cases of *adenocarcinoma* have also been reported[119]; possible sources for them are metaplastic urethral mucosa, bulbourethral (Cowper) glands, and periurethral (Littré) glands.[120] Some of these adenocarcinomas have been of mucinous (colloid) type.[121]

The prognosis and treatment of urethral carcinoma depend more on location and stage than on microscopic type or grade.[122] Anterior or distal lesions have a much better prognosis than posterior or proximal lesions. In general, the anterior lesions drain to inguinal nodes, whereas posterior lesions drain into pelvic nodes.[117] The treatment is primarily surgical.

Primary **malignant melanoma** of the urethra also occurs; the shape of these tumors is typically polypoid and their prognosis is exceedingly poor (Fig. 28.24).[123,124]

Malignant lymphoma presenting in the urethra is rare.[125]

Other Penile Tumors and Tumorlike Conditions

Hirsutoid papillomas (also known as papillomatosis corona penis or glans) appear as small, polypoid, 1–2 mm lesions in the corona of the glans, usually on its dorsal aspect. They can be solitary or multiple and have the microscopic appearance of fibroepithelial polyps.[126,127]

Lymphedematous fibroepithelial polyp of the glans and prepuce is a non-neoplastic lesion with a polypoid or cauliflower-like gross appearance that is usually secondary to chronic condom catheter use and which can reach a size of 7.5 cm (!).[128]

Adnexal tumors of sweat gland (such as *eruptive syringoma*), sebaceous, or hair follicle type rarely occur in the penile skin.[129–131]

Melanocytic lesions of the penis can be of benign or malignant nature. **Lentigo** of the common variety occurs most commonly in the glans as a relatively large (up to 2 cm), multifocal, irregularly shaped lesion of variegated pigmentation. It is also known as (atypical) melanotic macule and is characterized microscopically by basal cell hyperpigmentation, epithelial hyperplasia, and lack of melanocytic atypia.[132,133] **Nevi** of various types also occur, including *blue nevus*.[134] **Malignant melanoma** may arise in the glans or prepuce; metastases to lymph nodes are common.[135,136]

Soft tissue tumors of the penis are located for the most part in the shaft. Among the benign tumors, those of vascular, neural, and smooth muscle derivation are the most common.[137,138] These include, among others, hemangioma (including the epithelioid variety).[169,140] Fordyce angiokeratoma, lymphangioma,[90] schwannoma,[141] neurofibroma,[142,143] traumatic neuroma (secondary to trauma or circumcision[144]), granular cell tumor,[145–147] leiomyoma,[148] myofibroma,[149] and verruciform xanthoma.[150] The list of malignant soft tissue tumors includes angiosarcoma,[151,152] Kaposi sarcoma (some occurring in the setting of AIDS),[153–155] fibrosarcoma, malignant peripheral nerve sheath tumor, epithelioid sarcoma,[137,156] pleomorphic undifferentiated sarcoma,[157–159] clear cell sarcoma,[160] leiomyosarcoma,[139,161] and osteosarcoma.[162,163] *Myointimoma* is the term proposed by Fetsch et al.[164] for a peculiar vascular myointimal proliferation composed of cells with myoid features involving the corpus spongiosum of young men (Fig. 28.25), including adolescents and children.[165] The etiology is unknown and the evolution is benign; however, some have suggested that it represents intravascular fasciitis of the corpus spongiosum.

Malignant lymphoma of the penis usually represents secondary involvement by nodal lymphoma.[166,167] *Langerhans cell histiocytosis* can present in the male genitalia and lead to confusion microscopically with Paget disease.[168]

Metastatic carcinoma to the penis is rare.[169–171] Priapism is one of the forms of presentation.[172] The most common sources are prostate, bladder, rectum, kidney, testis, and lung, in that order of frequency.[173–175] Sometimes the tumor in the penile skin is epidermotropic and exhibits the features of extramammary Paget disease, whether arising from an underlying sweat gland carcinoma[176] or a distant site, such as the bladder.[177]

Scrotum

Normal Anatomy

The scrotal sac is a seven-layer structure that invests the testes, adnexa, and distal spermatic cord. The seven layers are the epidermis, dermis, tunica dartos (composed of smooth muscle bundles), the three layers of Colles fascia (intercrural, cremasteric, and infundibuliform), and the parietal layer of the tunica vaginalis. The latter consists of a flattened layer of mesothelial cells resting on a well-developed basement membrane.[178]

The scrotal lymphatics drain into the ipsilateral superficial inguinal lymph nodes. Anastomotic connections to the lymphatics of the contralateral network across the raphe occur.

Non-Neoplastic Lesions

Many paratesticular lesions are described in the chapter on paratestis and spermatic cord. We cover only lesions involving the epidermis and superficial tissue of the scrotum in this section.

Ectopic testicular parenchyma can be found within the tunica albuginea. Theoretically, it could be the source of extratesticular germ cell, Leydig cell, and Sertoli cell tumors.[179]

Idiopathic calcinosis of the scrotum is characterized by multiple asymptomatic nodules in the scrotal skin that begin in childhood or adolescence and tend to increase in size and number (Fig. 28.26). Occasionally, they break down through the skin and discharge a chalky content. Microscopically, amorphous basophilic masses are seen in the corium, often associated with a prominent foreign body reaction (Fig. 28.27).[180]

The pathogenesis is obscure, but the presence in some cases of a layer of squamous epithelium surrounding the calcium deposits suggests that this lesion may be the result of massive calcification of keratinous cysts derived from hair follicles.[181,182]

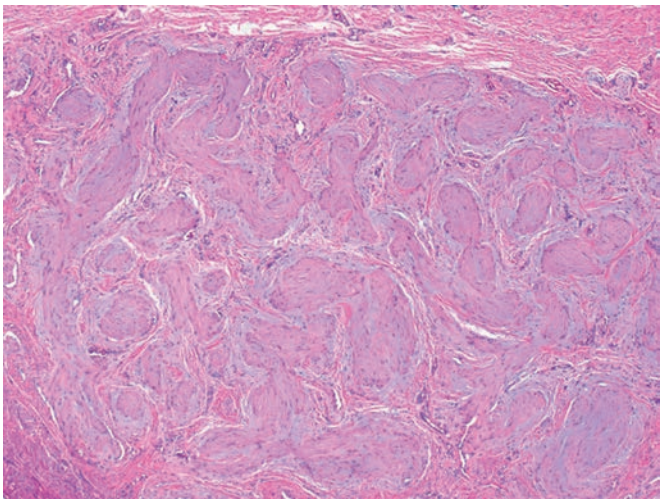

Figure 28.25 Myointimoma of the corpus spongiosum.

Figure 28.26 Idiopathic Calcinosis of Scrotum. (Courtesy of Dr. Juan J Segura, San José, Costa Rica.)

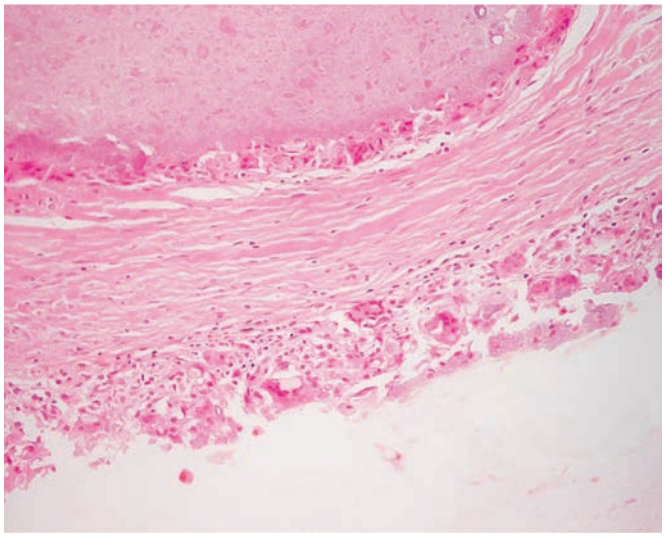

Figure 28.27 Idiopathic calcinosis of scrotum, with accompanying foreign body–type giant cell reaction.

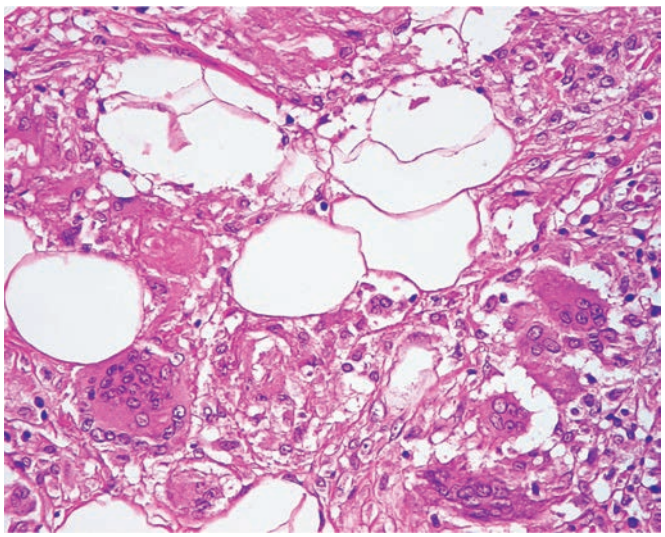

Figure 28.28 Sclerosing Lipogranuloma of Scrotum. Prominent histiocytic and multinucleated giant cell reaction around empty spaces, which presumably contained lipid material.

Sclerosing lipogranuloma is a rare condition of the penis and scrotum that affects adults and is usually painless. Microscopically, foci of fat necrosis are intermingled with collections of histiocytes, foamy macrophages, and multinucleated giant cells, accompanied by extensive areas of fibrosis and hyalinization (Fig. 28.28).[183] A history of trauma is present in a minority of the cases. Oertel and Johnson[184] made the startling suggestion that the lesion is usually a sequel to injections of exogenous material ("paraffinoma"), after their demonstration of paraffin hydrocarbons by infrared spectrophotometry in nearly all of their cases. The microscopic differential diagnosis includes adenomatoid tumor, lymphangioma, and atypical lipomatous tumor (sclerosing well-differentiated liposarcoma).

Scrotal fat necrosis can result from exposure to cold; it usually presents as bilateral masses below the testis, in the lower portion of the scrotum.[185]

Cysts of the tunica albuginea are lined by a single row of low cuboidal to columnar cells, which may be ciliated. The cavity contains clear fluid. The pathogenesis is unknown.[186,187]

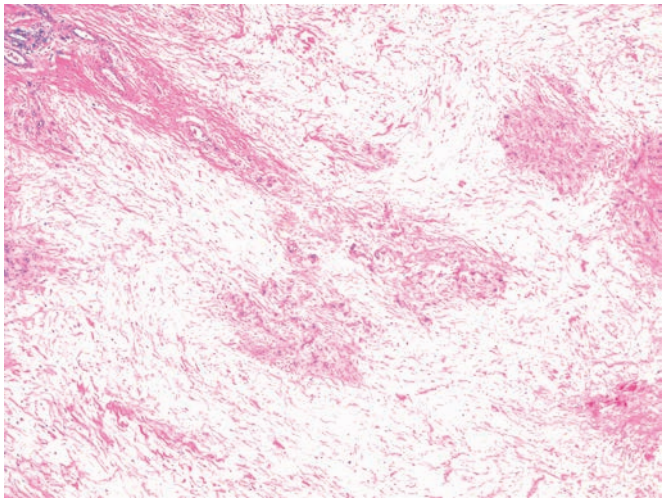

Figure 28.29 Massive Localized Lymphedema of the Scrotum. The lobular collections of capillary sized blood vessels are typical.

Accessory scrotum is the term generally used for the presence of a congenital perineal nodule adjacent to the scrotum composed of fat and smooth muscle. The condition is regarded by some authors as a hamartoma.[188]

Crohn disease can involve the scrotum in the form of an erythematous, nontender swelling.[189]

Fournier gangrene is a necrotizing subcutaneous (fascial) infection of the perineum and external genitalia.[190] It is usually characterized by an abrupt onset in previously healthy young males, but it can have an indolent onset and presents over a broad age range.[191,192] Some cases are idiopathic, others are secondary to urethral strictures with extravasation, and still others are seen as a complication of chemotherapy in patients with hematologic malignancies.[193]

Massive localized lymphedema, while more commonly described in the thigh, also occurs in the scrotum. This is a localized tumor-like collection of edema fluid due to lymphatic obstruction, most commonly associated with morbid obesity[194]; however, the etiology in younger patients is not well understood.[195] Histologically, the edema fluid is associated with loose connective tissue and intermixed lobular collections of small capillary-sized blood vessels (Fig. 28.29). Hyperplastic bundles of dartos muscle are also described.

Tumors

Both benign and malignant tumors of the scrotum are rare. Most of the benign tumors arise in the skin from cutaneous adnexa and have a morphologic appearance analogous to that of other cutaneous sites.

Leiomyoma is the most common benign mesenchymal tumor of this region (Figs. 28.30 and 28.31)[196]; some of them have bizarre (symplasmic) nuclear features.[197,198]

Squamous cell carcinoma is extremely rare in the general population, but is notorious in the oncology literature for being the first malignancy linked to occupational exposure (found in chimney sweeps, paraffin workers, tar workers, and cotton mill workers).[199] Wide local excision with bilateral ilioinguinal lymphadenectomy is the treatment of choice, with more limited surgery advocated in early cases.[200]

Other reported malignant tumors of the scrotal skin are **basal cell carcinoma**[201] and **Paget disease**.[202]

Sarcomas involving the scrotal wall are rare; most of the reported cases have been of smooth muscle derivation, that is, *leiomyosarcomas*.[196,203]

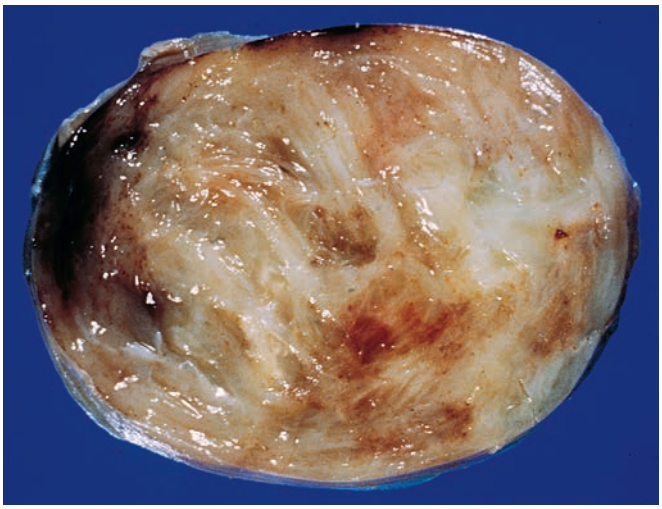

Figure 28.30 Gross appearance of vascular leiomyoma of scrotum.

Normal Anatomy

Adrenal Gland

The adrenal gland is a composite of two endocrine organs, one mesodermally derived (cortex) and the other neuroectodermally derived (medulla).[1-3] The function of the adrenal cortex is to secrete several steroid hormones known as corticosteroids, all of which are produced by a series of complicated enzymatic steps from cholesterol (Fig. 29.1). They are classified into three groups—mineralocorticoids, glucocorticoids, and sex hormones (adrenal androgens)—depending on their biologic action. The enzymes responsible for their production can be assayed biochemically and detected immunohistochemically.[4]

The adrenal glands are located in the retroperitoneum, superomedial to the kidneys. The combined adrenal weight in normal adult individuals should not exceed 6 g; there are no apparent sex differences.

The adrenal cortex is divided into three zones, all of which are under the influence of adrenocorticotropic hormone (ACTH): glomerulosa, fasciculata, and reticularis (Fig. 29.2). The zona glomerulosa, which lies immediately beneath the capsule and is the site of mineralocorticoid (aldosterone) production, is composed of well-outlined cells aggregated into small clusters and short trabeculae. The zona fasciculata, which is the site of glucocorticoid and sex hormone production, forms a broad band made up of large cells with distinct membranes arranged in two cell-wide cords. The cytoplasm is characterized by the presence of innumerable small lipid-containing vacuoles, some of which indent the centrally located nucleus in a fashion similar to that seen in sebaceous cells and lipoblasts; these cells are sometimes referred to as spongiocytes or clear cells. The zona reticularis is also involved in the secretion of glucocorticoids and sex hormones (particularly the latter). Its cells, which are arranged in a haphazard fashion, are smaller than those in the zona fasciculata and have a cytoplasm that is granular and acidophilic, with little or no lipid (so-called compact cells). Some of these cells contain lipofuscin in their cytoplasm.[1]

The predominant cell type in the medulla is the pheochromocyte (medullary cell or chromaffin cell), which is admixed with scattered cortical cells and ganglion cells. The pheochromocyte is a rather large cell of polygonal shape and poorly outlined borders. Its abundant cytoplasm is distinctly granular and usually basophilic, although it may be amphophilic or even eosinophilic. Occasional cells feature cytoplasmic hyaline ("colloid") droplets, which are strongly positive with periodic acid–Schiff (PAS) stain.[1] A second cell population of the medullary region is represented by the sustentacular cells, which are located at the periphery of the nests and trabeculae; they are difficult to identify in routinely stained preparations but are readily demonstrated by immunostaining for S-100 protein.[1]

Ultrastructurally, the cells of the adrenal cortex share two important features that are common to all steroid-producing cells: abundant smooth endoplasmic reticulum and numerous mitochondria. The mitochondria have lamellar cristae in the zona glomerulosa and

Abstract

This chapter covers the features of normal adrenal gland and the full spectrum of benign and malignant alterations that may be encountered in routine practice. Adrenal cortical hyperplasia types, emphasizing newer molecular correlates, are detailed. The spectrum of adrenal cortical neoplasia (including adenoma, carcinoma, and borderline lesions) is addressed, and the adjunctive techniques useful in difficult cases are reviewed. Adrenal medullary lesions, pheochromocytoma, and medullary hyperplasia, are also discussed. Finally, the spectrum of rare intra-adrenal tumors and extra-adrenal paragangliomas are covered.

tubulovesicular cristae in the zona fasciculata and reticularis.[5] The medullary cells can be divided into two types on the basis of the size of the cytoplasmic dense-core neurosecretory granules they contain: norepinephrine containing (electron opaque, often eccentrically located within a dilated sac, about 250 nm in diameter) and epinephrine containing (finely granular, filling the enclosing membrane, about 190 nm in diameter).

The immunohistochemical features of the cells are discussed in connection with the respective neoplasms.

Paraganglion System

The paraganglion system is formed by numerous collections of neuroepithelial cells ("chief cells") scattered throughout the body,[6] their common morphologic denominator being the presence of numerous cytoplasmic neurosecretory granules containing catecholamines.[7,8] Microscopically, all paraganglia have a similar morphologic appearance characterized by chief cells arranged in well-defined nests ("Zellballen") encircled by a thin layer of S-100 protein–positive sustentacular cells. The most conspicuous member of the paraganglion system is the already described adrenal medulla, a neuroeffector system connected with the orthosympathetic system. Extra-adrenal paraganglia can be divided into two broad categories: those related to the parasympathetic system (ninth, tenth, and possibly third and fifth nerves) and those connected with the orthosympathetic system. The former are usually nonchromaffin, are concentrated in the head, neck, and mediastinum, and are thought to have a chemoreceptor function. The latter are chromaffin, predominate in the retroperitoneum along the thoracolumbar para-aortic region, and probably represent lesser homologues of the adrenal medulla. Sometimes small paraganglia are found incidentally in sites such as the bladder, prostate, gallbladder, splenic capsule, and mesosigmoid[9]; special care should be exercised not to confuse them with foci of metastatic carcinoma (Fig. 29.3).[9,10]

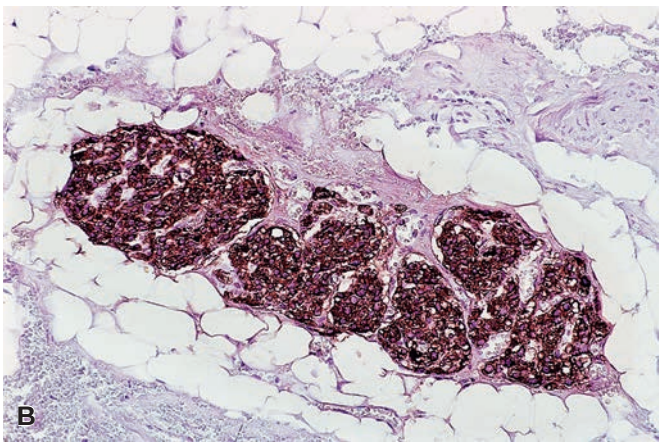

Figure 29.3 Normal paraganglion found incidentally in the retroperitoneal region. **A,** Hematoxylin–eosin; **B,** chromogranin.

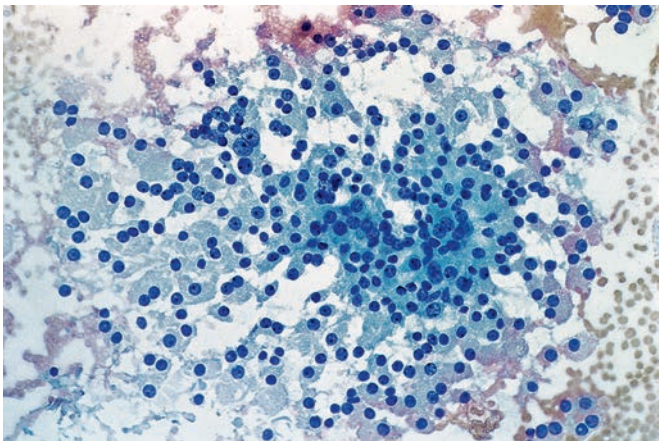

Figure 29.4 Fine-needle aspiration specimen from an adrenal cortical adenoma.

Biopsy and Cytology

The specimens from adrenal gland received in the laboratory usually consist of the entire organ, but in selected cases the diagnosis can be achieved through the performance of an ultrasonically or computed tomography (CT)-guided biopsy[11,12] or fine-needle aspiration cytology (Fig. 29.4).[13-15] The latter procedure is particularly useful for the diagnosis of metastatic tumors to this organ. In the series of Suen and Chan,[16] a success rate of 86% was achieved in obtaining cellular material for diagnosis. A high rate of diagnostic accuracy for adrenal core biopsy (an overall sensitivity for malignancy of 94.6% and a specificity of 95.3%) was reported in a recently concluded multi-institutional trial of 220 consecutive patients.[17]

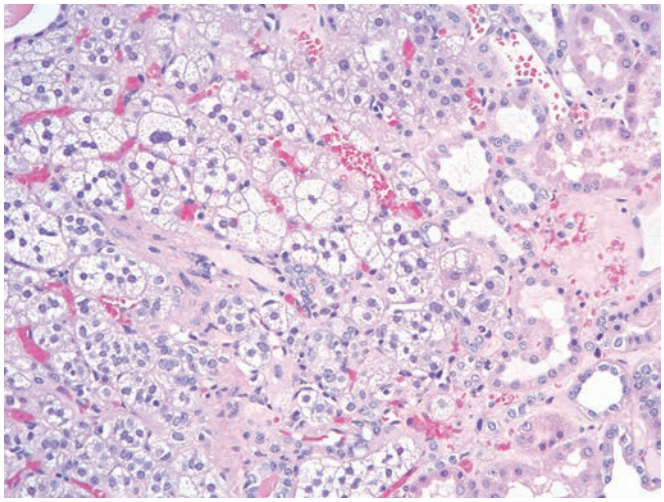

Figure 29.5 Adrenal renal fusion showing adrenal cortical tissue admixed with renal tubules *(on right)*.

Lesions of Adrenal Cortex

A variety of pathologic processes may arise from adrenal cortical tissue. These include malformations, heterotopias, hyperplasias, and neoplasms. Hyperplasias have been divided into clinical groups as diffuse, micronodular, and macronodular types, while neoplasms are classified as adenoma or carcinoma. Even more than in other organs, these diagnostic categories are not as discrete as might be assumed and classification based purely on histology may be impossible in a given case. The integration of the histologic and macroscopic features with endocrine findings, clinical history, and evolving molecular genetic "signatures" are likely to produce the most accurate diagnoses.

Adrenal Adhesion and Union

The adrenal gland may rarely have an abnormal connection to the liver or kidney.[18,19] When an intervening capsule is present (without intervening fat), this is referred to as *adhesion*. The term *union* (or fusion) is used when the two tissue types are intermingled (Fig. 29.5). Occasional biopsies of such lesions may be easily confused with renal cell carcinoma.

Adrenal Heterotopia

Heterotopic (accessory) adrenal cortical tissue has been reported in numerous locations, many of them resulting from some cells of the adrenocortical primordium becoming associated with and migrating alongside the gonads. The most common site is the retroperitoneal fat close to the adrenal gland. Other described sites include the region of the celiac plexus, the kidney (in an intrarenal location, to be distinguished from renal–adrenal fusion[18]), along the course of the spermatic and ovarian veins, the testis, adjacent to the tail of the epididymis, the broad ligament near the ovary, the ovary itself (but only exceptionally), the canal of Nuck, hernial and hydrocele

sacs, the mesoappendix, and the liver. It has also been rarely reported in distant sites such as lung, intradural space, and brain.[20-23] The epididymis associated with the ectopic adrenal tissue may show various types of malformation.[24] The ectopic cortical tissue is almost never accompanied by a medullary component.

These ectopic nests may undergo marked hyperplasia in patients with Nelson syndrome or other conditions associated with increased ACTH production,[25] and they occasionally give rise to ectopic adrenal cortical adenomas and carcinomas.[22,26-28]

Adrenal Hyperplasia

Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia, an inborn error of metabolism, is a family of autosomal recessive disorders that produce defects in adrenal steroid production.[29,30] It is responsible for the large majority of cases of adrenogenital syndrome developing within the first year of life, but it can also first present clinically during adulthood.[31] Specific symptoms and their severity are variable, depending on the specific mutation, the residual enzyme activity, and the sex of the patient.

In approximately 95% of the cases, the defect is an absence of the enzyme 21-hydroxylase, which results in the accumulation of 17OH-progesterone and its catabolite pregnanetriol and in a deficiency of cortisol.[32] The clinical picture may include pure virilizing syndrome, electrolyte disturbances (e.g. "salt losing" forms), or more mild symptoms.[33] The second most frequent form is due to a deficiency of 11β-hydroxylase and is characterized by virilization and hypertension. Several other variants, all exceptionally rare, have been described, including 17OH deficiency, 3 βHSD2 deficiency, P540 oxidoreductase deficiency, lipoid congenital adrenal hyperplasia (*STAR* mutation), and P540 cholesterol side chain cleavage enzyme deficiency.[30,34-36] The specific genes encoding each of the steroid biosynthetic enzymes have been cloned, and the common mutations (and their variants) in these genes are being determined.[37,38] The most important of these is the *CYP21A2* gene on chromosome 6p21.3, but over 100 separate mutations are reported even in this most common form.[39-41] The pathologic change is the same in all types and is characterized by diffuse cortical hyperplasia, especially of the zona reticularis. The treatment consists predominantly of hormone replacement, but a balance of measures to address normal development and later psychosocial, sexual, and fertility issues may be challenging.[36] The testicular "tumors" occurring in patients with adrenal cortical hyperplasia are discussed in Chapter 27.

Primary Pigmented Nodular Adrenal Cortical Hyperplasia

This morphologically distinct form of adrenal hyperplasia (sometimes referred to as "micronodular adrenal disease") may be isolated or a component of Carney complex[42] and is characterized by ACTH-independent Cushing syndrome typically in younger age groups. The adrenal glands, which may be small, normal sized, or slightly enlarged, show multiple pigmented cortical nodules with atrophy of the intervening cortex.[43,44] These nodules are primarily composed of eosinophilic, lipid-poor cells similar to those of the normal zona reticularis, and many cells contain lipofuscin/neuromelanin pigment (Fig. 29.6). The cells show intense immunoreactivity for all the steroidogenic enzymes.[45] Occasional additional features include microscopic foci of necrosis, mitoses, and a trabecular pattern of growth.[46] Some patients have germline mutations in *PRKAR1A*. Although rare, this etiology should be carefully considered in children who present with Cushing disease.[47] Other similar hyperplasias are rarely seen in patients with *PDE11A* or *PDE8B* mutations.[48,49]

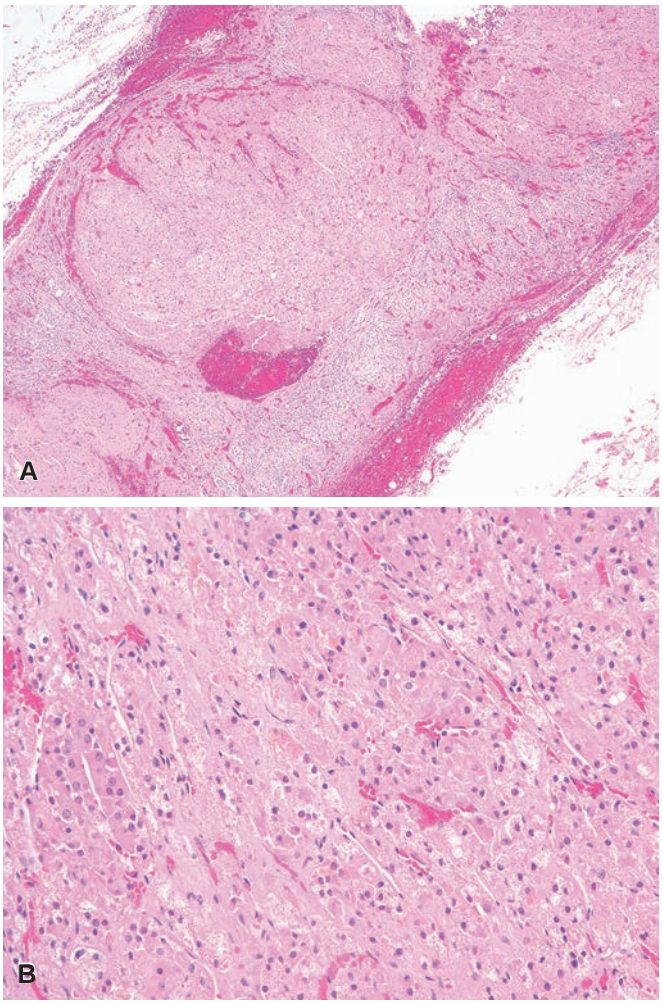

Figure 29.6 Primary pigmented nodular adrenal cortical hyperplasia. **A,** A micronodular pattern of growth is characteristic. **B,** Nodules are comprised of eosinophilic cells containing brown pigment.

Other Adrenocortical Hyperplasia

Acquired hyperplasia, which is always bilateral, may result in a diffuse or a nodular ("adenomatous" or "adenomatoid") enlargement of the adrenal gland (Fig. 29.7). An adrenal gland in an adult can be regarded as hyperplastic if it weighs over 6 g, provided that a careful dissection of the fat has been carried out. Most cases of *diffuse* cortical hyperplasia are due to ACTH hyperproduction by either the pituitary gland or an ACTH-producing neoplasm in the lung or some other organ. Thus they are referred to as ACTH dependent or—in the former instance—pituitary dependent. In some cases, however, the pathogenesis remains obscure.

Grossly, the cortical zone of the adrenal appears thickened. Microscopically, an increased thickness of the zona reticularis and fasciculata is observed, the relative proportions varying from case to case.[50] Occasionally, cells with large hyperchromatic nuclei are seen in some of the nodules. Many of the cells in the fasciculata layer appear compact and lipid depleted. Ultrastructurally, these cells have abundant smooth endoplasmic reticulum and long

Figure 29.7 Adrenal cortical hyperplasia showing multinodular pattern of growth.

microvilli that interdigitate with the microvilli of adjacent cells.[50] Flow cytometric and image analysis studies have shown the presence of aneuploid and polyploid cell populations.[50]

Most cases of ***macronodular cortical hyperplasia***, which are unrelated to ACTH production and are therefore referred to as ACTH independent or adrenal dependent, present with Cushing syndorme.[51] In some instances, they may represent a later stage of diffuse hyperplasia, in which the lesion has undergone a transition from pituitary dependent to adrenal dependent.[52,53] The bilateral adrenal glands can become massively enlarged, mimicking a neoplasm, and the cortex between cortical nodules is commonly atrophic. A rare subset of cases presents in children and may be associated with McCune–Albright syndrome (*GNAS* mutation).[54] Recent studies suggest the presence of germline or somatic mutations in *ARMC5*, particularly in cortisol secreting forms of the disease.[55,56]

Adrenocortical Neoplasms

Traditionally, adrenocortical neoplasms have been divided into adenomas and carcinomas. Many tumors can be easily placed into one category or another, but there is an intermediate ("borderline") group for which the distinction is difficult and to some extent arbitrary (further discussed in the differential diagnosis section).

Adrenocortical Adenoma

Clinical Features

Adrenal cortical adenomas represent the most common primary adrenal lesion seen in routine diagnostic practice. They may be functioning (producing aldosterone, cortisol, or sex hormones) or nonfunctioning. These are either detected by symptoms of a hormonal secretory product with subsequent identification on CT scan or incidentally at the time of imaging for other reasons.

Morphologic Features

Grossly, adenomas are usually solitary. Adenomas are characteristically small, rarely exceeding 5 cm in greatest diameter or 50 g in weight.[57] Adenomas are well circumscribed and typically encapsulated. The cut surface of an adenoma usually has a solid homogeneous yellow to tan appearance (Fig. 29.8). Larger tumors may have areas of central hemorrhage.

Microscopically, the adenomas may recapitulate the appearance of the zona fasciculata, the zona glomerulosa, or, more commonly,

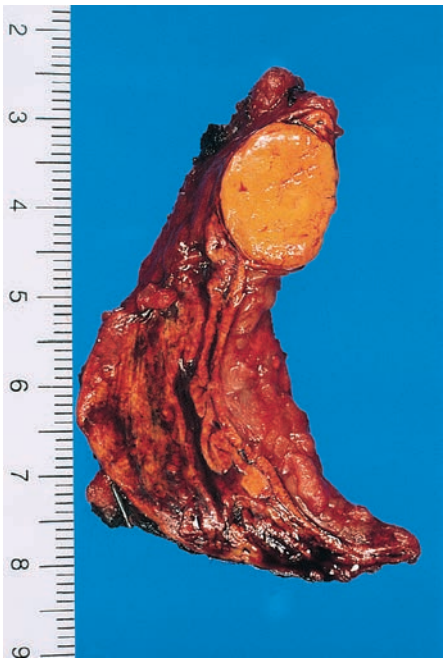

Figure 29.8 Gross appearance of adrenal cortical adenoma with single nodule, well-circumscribed growth, and typical golden yellow color.

a combination of both (Fig. 29.9). Prototypically, the cells are clear to lightly eosinophilic and are filled with small lipid vacuoles. The cells are often organized in nests or cords that are associated with a rich capillary vasculature or sinusoidal network. Occasional bizarre nuclear forms can be seen, as in most other endocrine neoplasms. However, *mitoses are exceptionally rare or absent*.[58] Morphologic variants of adrenocortical adenomas include:

1. Adrenocortical adenoma containing foci of *myelolipoma* are reported but are of no clinical consequence.[59,60]
2. *Black adenoma*.[61] Occasionally, adenomas (as well as hyperplastic nodules) have a dark brown to black color because of the presence of pigment, representing either lipofuscin[62] or rarely neuromelanin.[63] Most of these "black adenomas" or "black nodules" are nonfunctioning and found incidentally at autopsy, but on occasion they have been associated with primary aldosteronism[64] or Cushing syndrome.[65] These nodules have a higher radiologic density than the ordinary yellow cortical tumors.[65]
3. *Adrenocortical oncocytic adenoma (oncocytoma)*. This is a neoplasm in which the tumor cells are packed with mitochondria (Fig. 29.10). Both benign (i.e. oncocytoma) and malignant forms exist, the former predominating.[66-70] Most are nonfunctioning.[71,72] Interestingly, at the ultrastructural level the mitochondria retain the tubulovesicular cristae that are typical of steroid-producing cells, and they may also contain peculiar cytoplasmic crystalline inclusions.[73,74] The typical prognostic features used to distinguish adenoma from carcinoma are not optimized for oncocytic tumors, so modified classifications have been adopted (see differential diagnosis later and Box 29.1).[68]
4. *Myxoid adrenocortical neoplasms.* Adrenocortical adenomas can rarely have prominent myxoid stroma. Myxoid tumors seem to behave more aggressively than would be predicted by the Weiss criteria; therefore, the diagnosis of myxoid adrenocortical adenoma should be made with extreme caution.[75-78]
5. *Lipoadenoma.* Cases have been reported of adrenocortical adenomas (as well as nodular cortical hyperplasias) containing abundant mature adipose tissue.[79-81]

Box 29.1 Weiss criteria for the classification of adrenal cortical neoplasms[a]

Tumor necrosis
Mitotic rate >5 mitoses per 50 high-power fields
Atypical mitoses
High nuclear grade (Fuhrman criteria for grade III or IV)
Diffuse architecture
<25% clear cells
Invasion of venous structures
Invasion of sinusoidal structures
Invasion through the capsule

[a]The presence of ≥3 of these criteria correlates with malignant potential.

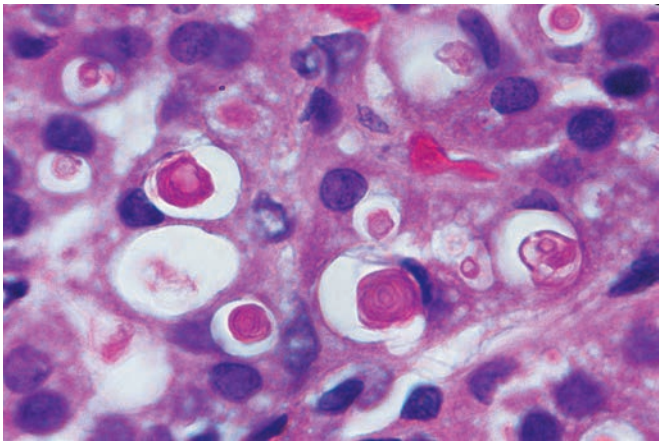

Figure 29.11 So-called spironolactone bodies. They appear as concentric laminated eosinophilic structures.

Hormone Production in Adenomas

Nonfunctioning Lesions. Whereas instances of cortical hyperplasia and adenomas are found commonly at post mortem examination of asymptomatic individuals,[82] most of the nonfunctioning adrenal cortical lesions seen in the past as surgical specimens were carcinomas.[83] This has changed markedly since the advent of ultrasonography, CT, and magnetic resonance imaging, which have allowed the detection of a large number of benign asymptomatic adrenocortical adenomas.[84-86]

Aldosterone-Producing Adenoma. In primary aldosteronism (Conn syndrome), the excessive amount of secreted aldosterone results in urinary loss of potassium, retention of sodium, suppressed renin levels, hypertension, and muscle weakness.[87-89]

Microscopically, one would expect these adenomas to have an appearance similar to that of the zona glomerulosa, since this is the area in which aldosterone is produced in the normal adrenal gland. Although this is sometimes the case, most of the tumor cells resemble those of the zona fasciculata or have characteristics intermediate between zona glomerulosa and zona fasciculata cells (so-called hybrid cells). The zona glomerulosa of the nontumoral gland is normal, hyperplastic, or atrophic.[90] In patients who have been treated with spironolactone, a characteristic cytoplasmic structure may appear in the tumor cells, as well as in the cells of the adjacent zona glomerulosa. It is a whorled, multilaminar collection of membranes, as large as 20 µm in diameter, and is thought to derive from the smooth endoplasmic reticulum (Fig. 29.11).[91,92] Typical evaluation of a patient suspected of having primary aldosteronism includes pharmacologic exploration of the renin–angiotensin–aldosterone system[87] and radiographic examination of the adrenal glands to distinguish primary aldosteronism from cases of renovascular and essential hypertension.

Cortisol-Producing Adenoma. Cushing syndrome is the result of hyperproduction of cortisol, often leading to characteristic external features (weight gain with central obesity, round face, skin striae, hirsutism), hypertension, hyperglycemia, poor wound healing, proximal muscle weakness, and increased risk for opportunistic infection.[93] It has a primary adrenal cause (i.e. ACTH independent) in only 20% of cases.[94-97] In rare cases the adrenal neoplasm associated with Cushing syndrome is not of cortical origin but rather a pheochromocytoma.[98] In cases of Cushing syndrome–associated adrenal cortical tumor, the remaining adrenal cortex often shows signs of atrophy. Diagnosis can be aided by various types of cortisol testing, including the dexamethasone suppression.

The presence of a large adrenal mass in a patient with Cushing syndrome is typically indicative of carcinoma. Similarly, cases of Cushing syndrome associated with obvious changes of virilization ("mixed" type) and markedly increased excretion of 17-ketosteroids are almost always the result of cortical carcinoma.[57,99]

Sex Hormone–Producing Adenoma. The most common cause of virilization in childhood is congenital adrenal hyperplasia; however, if an adrenal neoplasm is present, carcinomas are more common than adenomas.[100,101] The probability that an adrenal cortical tumor is of a malignant nature is about 70% if it results in virilization in an adult woman and even higher if the virilization is accompanied by Cushing syndrome.[102-104] In adult male patients with feminization, the incidence of malignancy approaches 100%.[105] In patients with adenomas, symptoms depend on the hormone secreted. Estrogen excess in men may produce gynecomastia or sexual dysfunction, while androgen excess in women causes variable hirsutism, virilization, and amenorrhea.

Other Functional Manifestations. Less common manifestations of adrenal cortical lesions (particularly carcinomas) include hypoglycemia,[106] polycythemia,[107] and inappropriate secretion of antidiuretic hormone.[108]

Electron Microscopic, Histochemical, Immunohistochemical, and Molecular Genetic Features

While most adrenocortical adenomas are recognizable by morphology alone, select cases may require immunophenotypic analysis. Immunohistochemically, the cells of adrenocortical neoplasms are immunoreactive for synaptophysin (but generally not chromogranin!), inhibin, Melan-A (Mart-1; A103), and SF-1 (Fig. 29.12).[109-115] They also stain for calretinin (usually in a focal fashion)[116] and keratin (about half of adenomas, but focally and erratically).[117]

The molecular mechanisms of adrenocortical adenomas continue to be elucidated. Many driver mutations are closely associated with specific hormone production and other clinicopathologic features.

Approximately 40% of sporadic aldosterone-secreting adenomas are associated with somatic mutations in *KCNJ5* and are more frequently seen in young women with more severe hyperaldosteronism. Other mutations in *ATP1A1*, *ATP2B3*, *CTNNB1*, and *CACNA1D* are also reported, but tumors with *KCNJ5* mutations tend to be larger.[118-121] In cortisol-producing adenomas, somatic mutations in *PRKACA* are common and are identified in approximately 35%–65% of cases with Cushing syndrome.[122,123] Nonfunctioning adenomas most commonly have mutations in *CTNNB1*, which encodes the β-catenin protein.[124] Adrenal cortical adenomas are also associated with some

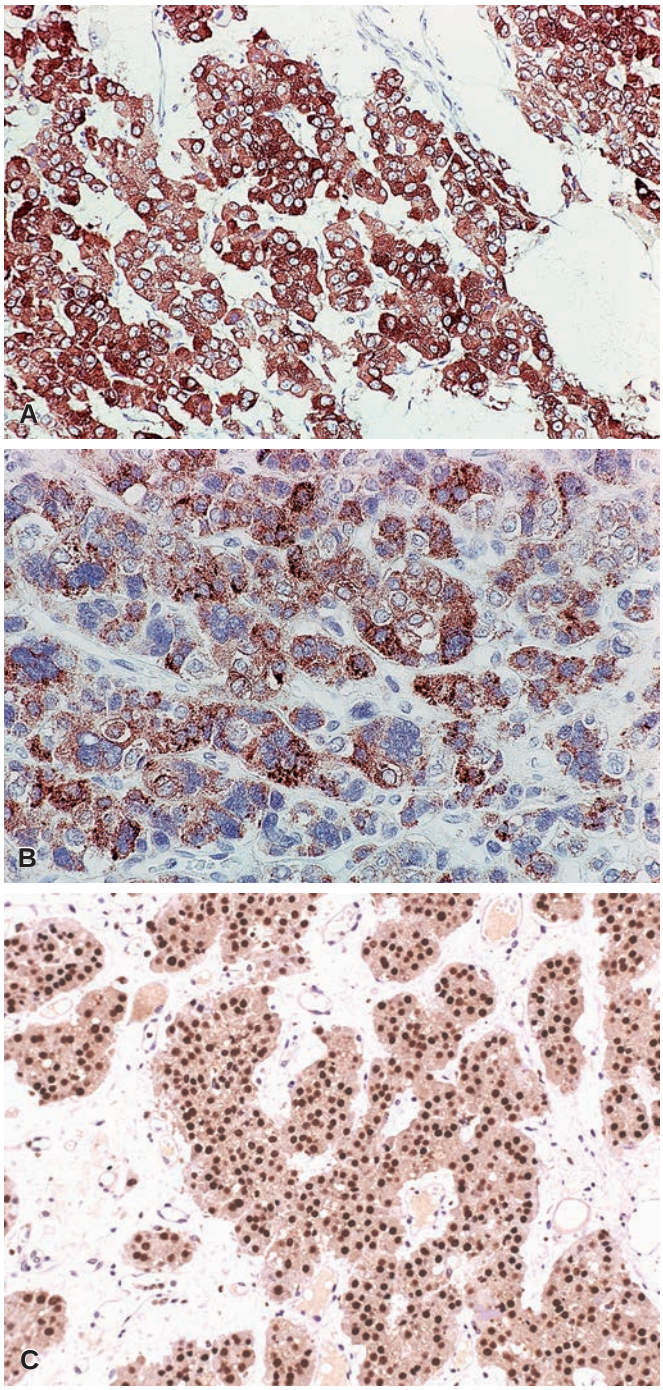

Figure 29.12 Immunohistochemical reactivity of adrenal cortical neoplasm. **A,** Inhibin; **B,** Melan A; and **C,** SF-1.

hereditary syndromes, including Carney complex, Li–Fraumeni, MEN type 1, Beckwith–Wiedemann, familial adenomatous polyposis, and McCune–Alright.[125]

Adrenocortical Carcinoma

Clinical Features

Cortical carcinomas are relatively uncommon. They have a bimodal age distribution, with peaks in the first and fifth decades of life.[126-133] Patients may present asymptomatically (incidental lesion detected at imaging), with symptoms related to local mass effect, with symptoms of metastatic disease, or with symptoms of excess steroid production. Highly necrotic carcinomas may result in fever and thus simulate an infectious disease clinically. Palpable adrenocortical neoplasms are malignant in practically every instance. CT scan is the most useful technique for the detection, pretreatment staging, and determination of resectability of these tumors.[134]

A diagnosis of adrenocortical carcinoma in children and young adults should prompt exclusion of Li–Fraumeni syndrome by molecular analysis for germline mutation in the *TP53* gene, since this association is found in more than half of the cases, regardless of family history.[135-137] Adrenocortical carcinomas also occur with increased frequency in patients with Beckwith–Wiedemann syndrome.[138]

Morphologic Features

Grossly, carcinomas are usually solitary. Most carcinomas weigh more than 10 g, and some may reach 1000 g or more before being discovered.[57] A capsule may be present around carcinomas, but this is often infiltrated by tumor. The cut surface of a carcinoma shows a variegated pattern, with soft and friable intratumoral nodules (Fig. 29.13). Areas of necrosis and hemorrhage are frequent in carcinomas. Invasion of major veins is a frequent finding in carcinoma and often leads to total occlusion, thrombosis, and embolism.

Microscopically, carcinomas exhibit a wide range of differentiation, from tumors that are so well differentiated as to be almost impossible to distinguish from adenoma to totally undifferentiated neoplasms composed of giant cells with abundant acidophilic cytoplasm and bizarre hyperchromatic nuclei, sometimes multiple (Figs. 29.14 and 29.15). Occasionally, the tumor is heavily infiltrated by neutrophils, with some of the latter located within the cytoplasm of the tumor cells.

The key distinguishing histologic features between adenoma and carcinoma are discussed in a later section. Morphologic variants of adrenocortical carcinoma include:

1. *Adrenocortical oncocytic carcinoma*. The typical prognostic features used to distinguish adenoma from carcinoma are not optimized for oncocytic tumors, so modified classifications have been proposed (see differential diagnosis later and Box 29.2).[68]
2. *Myxoid adrenocortical neoplasms* (Fig. 29.16). Optimized criteria remain to be determined for this rare group of tumors, but studies suggest more aggressive behavior than would be predicted by standard prognostic parameters (see differential diagnosis later).[75-78]
3. *Sarcomatoid carcinoma*, a self-explanatory designation. As in other sites, when the carcinomatous and the sarcoma-like elements are sharply segregated, the alternative term *carcinosarcoma* has been used.[104,139,140]

Electron Microscopic, Histochemical, Immunohistochemical, and Molecular Genetic Features

Immunohistochemically, carcinomas express the same cortical lineage markers as adenomas (i.e. inhibin, Melan-A, and SF-1) but with lower sensitivity.[109-115,141]

Knowledge of the molecular mechanisms of adrenocortical carcinomas in both children and adults, and their differences from adenomas, is expanding rapidly.[141-145] The most recent data show that adrenal cortical carcinomas have a number of different driver mutations (including *p53*, *ZNFR3*, *CTNNB1*, *PRKAR1A*, *CCNE1*, and *TERF2*), frequent IGF2 overexpression, and whole genome doubling as a mechanism of disease progression.[142] The Cancer Genome Atlas (TCGA) study also proposed a prognostic molecular subtype model based on DNA methylation signature.[142] These

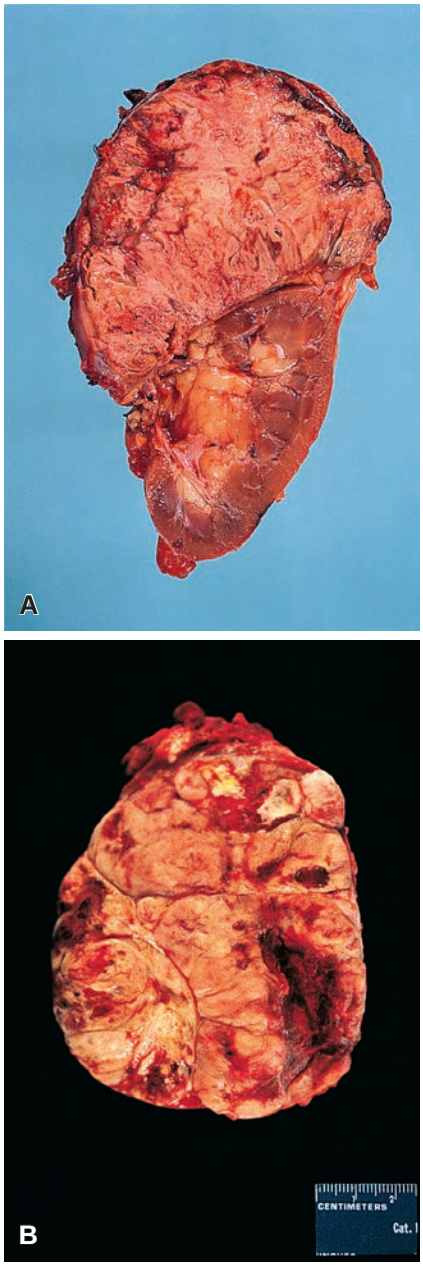

Figure 29.13 **A** and **B,** Gross appearance of adrenal cortical carcinoma. Both tumors are large and exhibit areas of hemorrhage and necrosis. The tumor shown in **A** has destroyed the upper pole of the kidney.

discoveries could lead to more integrated histologic/molecular classification in the near future.

Finally, as with adenomas, carcinomas may be associated with hereditary neoplasia syndromes, including Li–Fraumeni, Lynch (hereditary nonpolyposis colorectal cancer), MEN type 1, NF1, Beckwith–Wiedemann, familial adenomatous polyposis, and Carney complex.[125]

Differential Diagnosis

The principal differential diagnostic problems in this area are distinguishing: (1) between adrenocortical adenoma and carcinoma; (2) between adrenocortical carcinoma and renal cell carcinoma; and (3) between adrenocortical and adrenomedullary tumors.

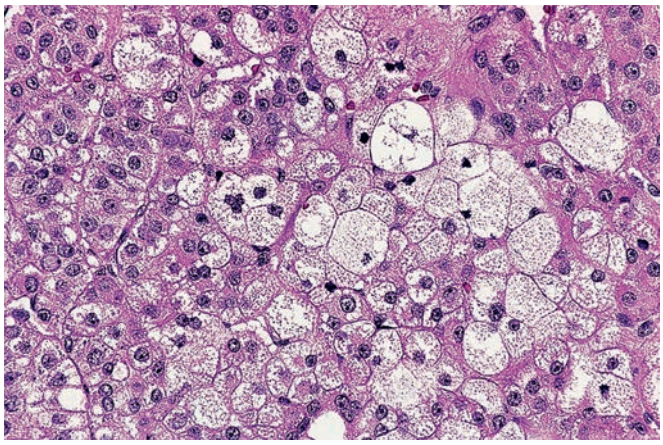

Figure 29.14 Adrenal cortical carcinoma with more intratumoral heterogeneity.

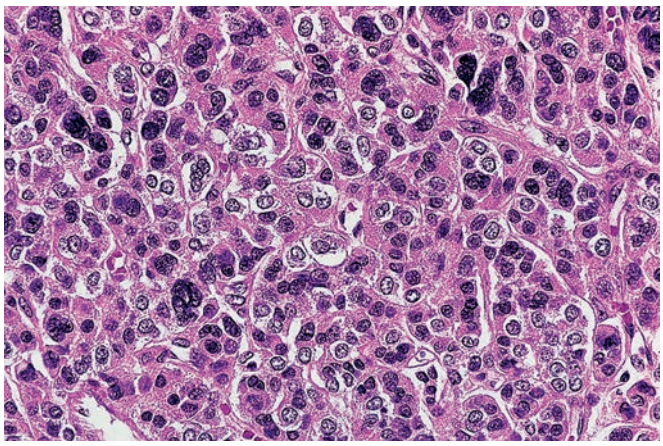

Figure 29.15 Adrenal cortical carcinoma. There is nuclear hyperchromasia, diffuse pattern of growth, and mitotic activity.

Box 29.2 Lin-Weiss-Bisceglia criteria for the classification of adrenal cortical neoplasms[a]

Major criteria

Invasion of venous structures
Mitotic rate >5 mitoses per 50 high-power fields
Atypical mitoses

Minor criteria

Size >10 cm and/or weight >200 g
Tumor necrosis
Invasion of sinusoidal structures
Invasion through the capsule

[a]The presence of one major criterion correlates with malignant potential (i.e. adrenal cortical carcinoma). The presence of 1–4 minor criteria has a weaker correlation, and the term "adrenal cortical neoplasm of uncertain malignant potential" has been suggested.

The majority of adrenocortical adenomas and carcinomas are fairly easy to diagnose; however, a subset of cases may present a true diagnostic challenge. Adenomas tend to be smaller, more homogeneous, and lacking hemorrhage and necrosis.[146,147] Specifically, lesions under 50 g are generally cured by excision, even if exceptions occur.[148] Microscopically, mitotic activity (especially if accompanied

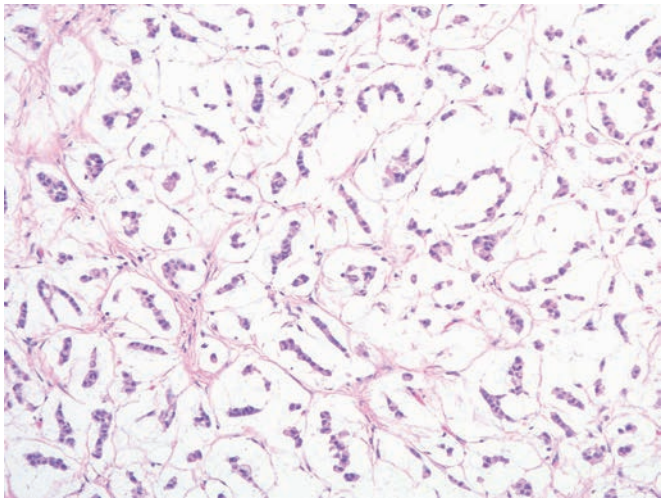

Figure 29.16 Myxoid adrenal cortical neoplasm with cord-like pattern of growth.

by atypical forms) and venous invasion correlate best with recurrence or metastasis.[58,147,149-151]

Weiss[150] proposed a prognostic model, which is the most widely utilized today, based on analysis of the following nine microscopic findings: nuclear grade III or IV, mitotic rate greater than 5 per 50 high-power fields (HPFs), atypical mitoses, less than 25% clear cells, diffuse architecture, necrosis, capsular invasion, venous invasion, and sinusoidal invasion (see Box 29.1). In general, tumors with 3 or more features are regarded as having malignant potential. The value of this approach has been proven by independent observers, both in adults[152,153] and in children.[154] This is also true for the slightly revised version proposed by Weiss.[155]

It must be emphasized, however, that these schemes may not be entirely applicable to adrenocortical tumors occurring in childhood, those of oncocytic type, and those with myxoid features. For oncocytic tumors, the WHO recommends the Lin-Weiss-Bisceglia criteria (see Box 29.2), which weights features into major (>5 mitoses per 50 HPFs, atypical mitotic figures, venous invasion) and minor (necrosis, sinusoidal invasion, capsular invasion, size >10 cm and/or weight >200 g) criteria.[68] In this system, the presence of any single major criterion within the tumor is sufficient for designation as malignant, while tumors with 1–4 of the minor criteria are designated as "uncertain malignant potential." Myxoid tumors are rare and the largest series to date is only 14 cases; therefore, optimal criteria for classification have not been developed.[75-78] In our experience and in several reported cases, very bland myxoid adrenocortical tumors may behave in a surprisingly malignant fashion.

It has been highlighted by Dehner that the Weiss criteria seem less predictive of aggressive behavior in the pediatric population (i.e. many tumors classified as "carcinoma" seem to be clinically indolent).[156] Several groups have proposed criteria for risk stratification specific to pediatric patients, often placing increased emphasis on tumor weight.[157-159]

Numerous special techniques have also been tested as possible ancillary aids to this differential diagnosis. At present, Ki-67 immunohistochemistry and reticulin stains are sometimes used in difficult cases. Ki-67 proliferation rates of adenomas are typically less than 5%.[160-163] In normal adrenal cortex and adenomas, reticulin stains highlight a network of reticulin fibers that encircle small nests of cells. In carcinomas, abnormal reticulin patterns are more commonly seen, characterized by larger confluent sheets of neoplastic cells with a patchy distribution of fragmented or thickened reticulin fibers.[164-166] Recently, two additional immunohistochemical markers have been described that reportedly stain most carcinomas, but very few adenomas: matrix metalloproteinase type 2[167] and insulin-like growth factor (IGF2); however, these have not been fully implemented into standard practice.[168,169] Incorporating some of the more robust adjunctive tests into histologic prognostic algorithms holds promise.[164,170]

The fact that so many parameters have been evaluated for this purpose provides indirect evidence that none—short of detection of metastases—discriminates in an absolute fashion between adenomas and carcinomas, particularly in pediatric cases.[128,158,171,172] A combined evaluation of clinical features, size or weight, microscopic appearance, and immunohistochemical/molecular genetic data is necessary.[147,150,173,174] Even so, the pathologist and the clinician should accept the fact that a sharp distinction between adenomas and carcinomas may be impossible at the practical level and unsound at the conceptual level. Except for the cases situated at the two extremes, it may be more honest and accurate to designate the tumors as *adrenocortical neoplasms*, followed by an estimate of the risk of the tumor recurring or metastasizing on the basis of all the evaluable parameters, a list which is rapidly expanding.[175] The alternative is to have an intermediate category designated as *borderline* or of *uncertain malignant potential*, as it is being increasingly done in other tumor types in spite of the initial disapproval and irritation of some.

The second important differential diagnosis is between adrenocortical neoplasia and renal cell carcinoma, which can invade the adrenal gland directly or metastasize to it, either ipsilaterally or contralaterally.[176] Microscopically, these two tumors resemble each other a great deal. In fact, Grawitz originally regarded clear cell renal cell carcinoma to be of adrenocortical origin![177] Two features favoring the diagnosis of renal cell carcinoma are the presence of glands (particularly if they contain numerous red blood cells) and abundant cytoplasmic glycogen, but neither is pathognomonic. Immunohistochemically, much is written with regard to immunoreactivity for cytokeratin, EMA, renal cell carcinoma marker, and CD10 as markers of renal cell carcinoma,[114,178] but for routine practice it is our experience that PAX-8 offers the highest level of sensitivity and specificity as a renal epithelial marker.[114,179] Positivity for SF-1, inhibin, Melan-A (Mart-1, A103), and synaptophysin favors adrenocortical lineage.[114] The nuclear reactivity pattern of SF-1 makes it easier to interpret and an ideal pair with PAX-8 in this differential diagnostic distinction. This also applies to fine-needle aspiration specimens.[180,181]

Regarding the differential diagnosis between adrenocortical and adrenomedullary tumors (which can be very difficult but for some reason is rarely mentioned), the former should be favored in the presence of inhibin, Melan-A, SF-1, and calretinin positivity, whereas the latter is more likely if chromogranin reactivity is present.[115,182] Synaptophysin is of no help since it stains both tumor types.[115,182] GATA3 shows nuclear expression in approximately 70% of pheochromocytomas, while only rarely positive in adrenal cortical carcinoma; however, it should be remembered that GATA3 reactivity is seen in many metastatic carcinomas.[183,184]

Spread and Metastases

Whereas adrenocortical adenoma is encapsulated, adrenocortical carcinoma often spreads to the retroperitoneum and infiltrates the kidney. Blood-borne metastases are frequent and are already present at the time of the diagnosis in half of the cases.[185] The most common sites of metastatic involvement are liver (60%), regional lymph nodes (40%), lungs (40%), peritoneal and pleural surfaces, and bone.[127,186] Poorly differentiated ("anaplastic") tumors may be more likely to metastasize to skin.[187] Some of these may masquerade as primary tumors in these metastatic sites.[188-190]

Treatment and Prognosis

The primary treatment of adrenocortical neoplasms is surgical excision.[191] Unfortunately, the carcinoma often recurs, and its radiosensitivity is usually poor.[192,193] Chemotherapy and/or mitotane therapy may be utilized with advanced disease.[190,194-197] Mitotane has very significant side effects; therefore, markers predictive of treatment response are being investigated.[198,199] In most series, half of the patients are dead within 2 years of the onset of the symptoms, and the 5-year survival rate is between 20% and 35%.[194]

Some correlation exists between microscopic degree of differentiation in adrenal cortical carcinoma and survival.[200] Proliferative activity—whether measured by counting mitoses or through other means—seems to be the pathologic feature of greatest prognostic significance and is utilized for grading in many centers.[155,160,201-203] In the two grade system, low-grade carcinomas have less than 20 mitotic figures per 50 HPFs, while high-grade carcinomas ≥20.[203] Proliferation rate as determined by Ki-67 and/or the combination of morphology (necrosis and mitotic count >5 per 50 HPFs) and Ki-67 have been validated as highly predictive of outcome in carcinomas.[170,204] However, improved Ki-67 scoring reproducibility is needed.[205]

Staging

Two major systems are utilized for the staging of adrenal cortical carcinoma: the AJCC/TNM and the European Network for the Study of Adrenal Tumours (ENSAT) staging systems[206]; however, the current WHO classification recommends the ENSAT system.[125] Both are based on conventional TNM categories that depend on tumor size (greater or less than 5 cm), infiltration outside of the adrenal gland (into fat or adjacent organs), any lymph node involvement, and distant metastasis. The ENSAT utilizes different TNM stage groupings for stage III and stage IV disease.[207,208] A modified European Network for the Study of Adrenal Tumours (mENSAT) staging system has been proposed that further incorporates tumor grade.[202]

Lesions of Adrenal Medulla

Tumors and tumorlike conditions of the adrenal medulla segregate into two distinct categories, acknowledging the existence of hybrid and transitional forms:

1. **Neuroblastic tumors**, which are characteristically seen in infants and children but can also present in adults (particularly ganglioneuroma).
2. **Adult neuroendocrine tumors and tumorlike conditions**, represented by pheochromocytoma and adrenal medullary hyperplasia. These are characteristically seen in adults, although they can also appear in children (particularly if part of a genetically determined syndrome).

Neuroblastoma

General and Clinical Features

The term neuroblastoma encompasses a spectrum of tumors showing variable degrees of differentiation, including neuroblastoma, ganglioneuroblastoma, and ganglioneuroma. Neuroblastomas are usually seen in young children; over 80% are detected in those under the age of 4 years, and the median age at diagnosis is 21 months. Typical examples in adults occur but are exceptional.[209,210] There is no sex predilection. Neuroblastomas can exhibit familial incidence (approximately 1% of cases)[211] and may be associated with the Beckwith–Wiedemann syndrome,[212] Hirschsprung disease,[213] and Turner syndrome (especially if the neuroblastoma itself is congenital).[214,215] Neuroblastoma can also occur in patients with neurofibromatosis type 1[216] or congenital central hypoventilation syndrome.[217,218] The usual presentation of neuroblastoma is in the form of an abdominal mass first noted by the parents. Rare cases have been reported associated with watery diarrhea (although not nearly as commonly as with ganglioneuroma), Cushing syndrome, heterochromia iridis and Horner syndrome (in cervical or mediastinal tumors), opsoclonus/myoclonus (a paraneoplastic autoimmune process), and several other manifestations.[219] About 70% of the neuroblastomas occur in the retroperitoneum, and the majority of these involve the adrenal gland; however, they can be found anywhere along the sympathetic chain, including the neck and mediastinum.

Synchronous or metachronous bilaterality is extremely unusual.[220] Many cases are diagnosed before biopsy, as neuroblastoma retains the ability to metabolize catecholamines, and often secretes homovanillic acid (HMA) and vanillylmandelic acid (VMA), both of which may be detected in the urine.[123] I-metaiodobenzyl guanidine (MIBG) scintigraphy commonly highlights the primary tumor and foci of metastases.

Morphologic Features

Grossly, neuroblastomas are usually large, soft, gray, and relatively well circumscribed; areas of hemorrhage, necrosis, and calcification are often present (Fig. 29.17). Sometimes the hemorrhage is so extensive as to mimic a hematoma. Cystic degeneration can also occur, to the point of simulating the appearance of an adrenal cyst. Multifocality is present in less than 10% of the cases.[221]

Microscopically, the pattern of growth is vaguely nodular or nested as a result of the presence of delicate, incomplete fibrovascular septa. Hemorrhage, which is common, occasionally leads to the formation of pseudovascular or alveolar structures. Calcification may be a prominent feature; it may appear as a dustlike basophilic stippling, as closely aggregated round concretions, or surrounding individual tumor cells in a "chicken-wire" fashion. Necrosis is also a rather constant feature, sometimes leaving viable tumor cells grouped around blood vessels. Typical neuroblasts are small and regular, with round, deeply staining nuclei slightly larger than lymphocytes. A small amount of pink cytoplasm is present, continuous with the intermixed neuropil. Neuropil appears as a lightly eosinophilic fibrillary material; it is composed of a tangled mass of neurites as revealed by silver stains, immunohistochemistry, or electron microscopy. Homer Wright rosettes are present in about a fourth to a third of the cases; they are characterized by collections of tumor cells not related to blood vessels, arranged around a central area filled with neuropil (Fig. 29.18).[222] In contrast to the structures formed by retinoblastomas, ependymomas, and carcinoid tumors, the rosettes of neuroblastomas *do not* have a central lumen. On occasion, the lobular pattern just described becomes prominent, the tumor nests being surrounded by elongated S-100 protein–positive cells in a "Zellballen" configuration reminiscent of that seen in paraganglia and paragangliomas.[223]

Based on the International Neuroblastoma Pathology Classification (INPC), the tumor cells show a spectrum of differentiation from primitive neuroblasts to ganglion cells and their classification depends on the relative amounts of these components (Table 29.1). This classification applies to untreated neuroblastomas; chemotherapy often induces maturation and/or nuclear anaplasia; therefore, post-chemotherapy neuroblastoma should be diagnosed only as "neuroblastoma with chemotherapy effect."

The most primitive neuroblast lacks discernable cytoplasm. Tumors comprised entirely of these primitive cells without any associated neuropil, termed "**undifferentiated neuroblastoma**," have significant morphologic overlap with lymphoma or other small round blue cell tumors (Fig. 29.19A). Neuroblast differentiation and Schwannian stroma development go hand in hand. When less than 5% of

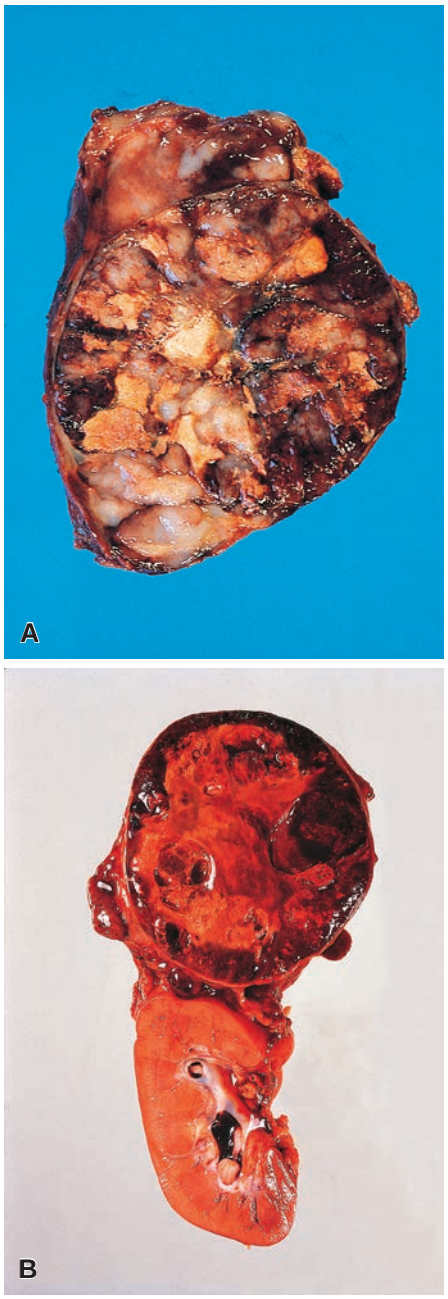

Figure 29.17 Gross appearance of adrenal neuroblastoma. **A,** The tumor exhibits a variegated appearance resulting from hemorrhage and necrosis. **B,** Suprarenal location strongly suggests the diagnosis of neuroblastoma in a child.

neuroblasts show ganglion cell differentiation (equal volumes of nucleus and cytoplasm, see Fig. 29.19B) the tumor is classified as "**poorly differentiated neuroblastoma**." Poorly differentiated neuroblastomas have a definite component of neuropil, which makes the diagnosis more straightforward than the undifferentiated form. When a tumor has greater than 5% ganglion cell differentiation, but is composed of less than 50% Schwannian stroma, the diagnosis is "**differentiating neuroblastoma**" (Fig. 29.20). When the Schwannian stroma represents greater than 50% of the tumor (which is always accompanied by greater than 5% ganglion cell differentiation), the term "**ganglioneuroblastoma, intermixed**" is applied. Finally, "**ganglioneuroma**" is diagnosed when the tumor is composed

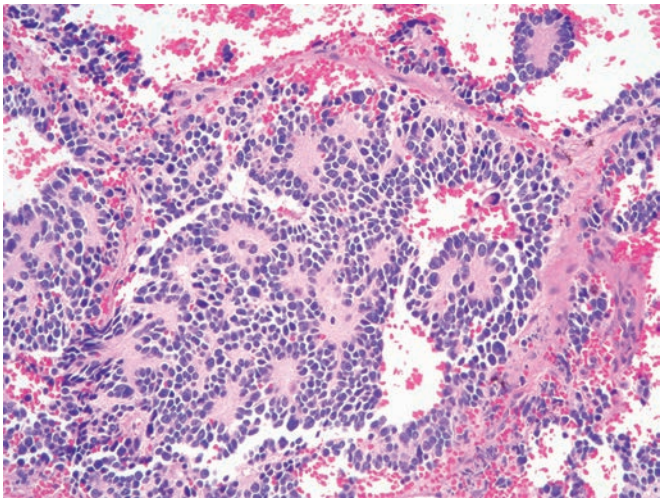

Figure 29.18 Homer Wright rosettes in neuroblastoma. Note the absence of a central lumen.

completely of Schwannian stroma and ganglion cells. In children, ganglioneuromas should be diagnosed with caution; they should be thoroughly sampled and should not show any persistent nests of neuroblastic cells and no recognizable neuropil.[224] Ganglioneuroma is further stratified in children. When clusters of maturing ganglion cells are present (without associated neuropil), the term "ganglioneuroma, maturing" is used. When ganglion cells are scattered throughout the Schwannian stroma individually (in association with surrounding sustentacular cells), the tumor is classified as "ganglioneuroblastoma, mature" (Fig. 29.21). In adults, ganglioneuromas are almost always mature.

A subset of neuroblastic tumors shows any type of Schwannian "stromal-rich" neuroblastic tumor (otherwise typical ganglioneuroma or ganglioneuroblastoma, intermixed) with a distinct grossly identifiable nodule composed of a more primitive "stromal-poor" histology (Fig. 29.22), which is most commonly poorly differentiated neuroblastoma or differentiating neuroblastoma. Such tumors are classified as "**ganglioneuroblastoma, nodular type**" and should include a separate classification for the nodular component, which drives the prognosis. It is critically important to carefully evaluate all gross specimens with thin sectioning to assess for such macroscopic nodules.

Finally, a rare pleomorphic (anaplastic) form of neuroblastoma characterized by the presence of bizarre giant tumor cells has been described; however, this diagnostic term should not be used in post-therapy specimens where chemotherapy induced atypia is not uncommon.[225,226]

Electron Microscopic, Histochemical, Immunohistochemical, and Molecular Genetic Features

Ultrastructurally, neuroblastoma cells are characterized by the presence of neurites, neurosecretory granules, and synaptic endings.[151,227] The neurites form a complex interdigitating meshwork in the center of the Homer Wright rosettes.

Immunohistochemically, neuroblastoma cells express NSE, chromogranin, synaptophysin, microtubule-associated proteins, and NB-84.[228-241] Recent studies strongly suggest that immunohistochemistry for PHOXB2 represents the most sensitive and specific marker for neuroblastoma.[242-244] These, together with molecular techniques, are of great use in the differential diagnosis between undifferentiated

Table 29.1 The International Neuroblastoma Pathology Classification

STROMA	HISTOLOGIC FEATURES	DIAGNOSIS
Schwannian stroma poor	• No Schwannian stroma/no neuropil • Requires adjunctive diagnostic tests	Neuroblastoma, Undifferentiated
	• Presence of neuropil allows for H&E diagnosis • Less than 5% differentiating neuroblasts	Neuroblastoma, Poorly Differentiated
	• More abundant neuropil • >5% differentiating neuroblasts	Neuroblastoma, Differentiating
Schwannian stroma rich (>50%)	• Schwannian stroma comprises >50% of the tumor • Microscopic foci of neuropil contain neuroblastic cells at varying stages of maturation • By definition, no macroscopic nodules present	Ganglioneuroblastoma, Intermixed
Schwannian stroma dominant	• Schwannian stroma is the predominant element of the tumor • Scattered ganglion cells are mature or maturing • No neuropil is present	Ganglioneuroma, Maturing
	• Schwannian stroma is the predominant element of the tumor • Scattered ganglion cells are mature with surrounding satellite cells • No neuropil is present	Ganglioneuroma, Mature
Composite stroma rich/dominant and stroma poor	• Grossly visible nodule consists of any type of stroma poor neuroblastoma • Background of ganglioneuroblastoma or ganglioneuroma • Nodular component should also be classified	Ganglioneuroblastoma, Nodular

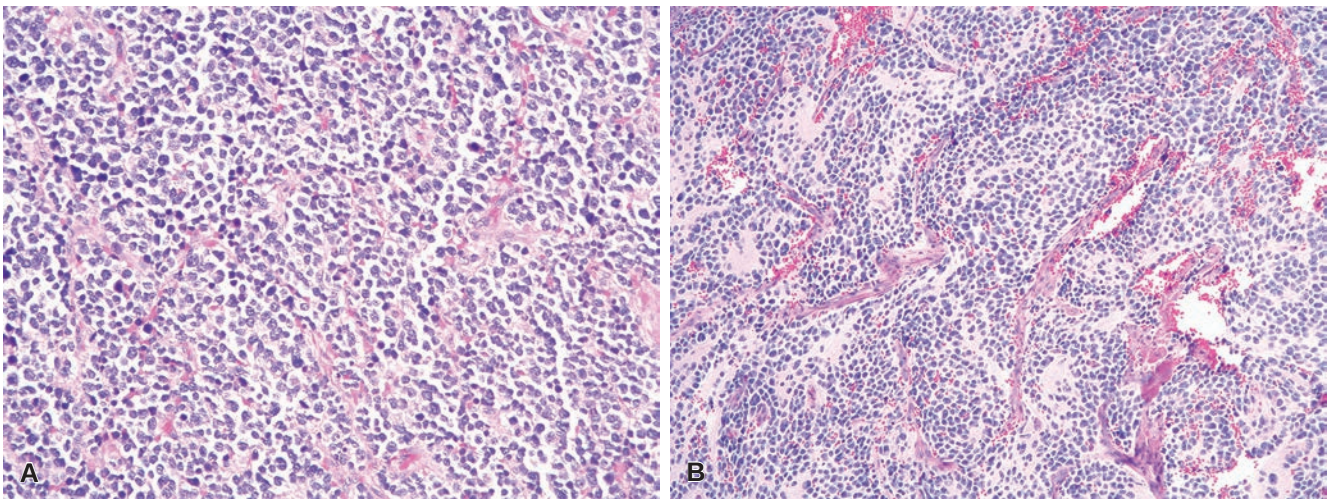

Figure 29.19 **A,** Undifferentiated neuroblastoma. There is no neuropil or cellular differentiation. Adjunctive diagnostic studies and clinical context are important in such cases. **B,** Poorly differentiated neuroblastoma is more lobular and associated with neuropil, the latter making diagnosis more straightforward.

neuroblastoma and other small round blue cell tumors of infancy, such as rhabdomyosarcoma, Ewing sarcoma, and malignant lymphoma.[236] When associated neuropil is present (as in poorly differentiated neuroblastoma), adjunctive studies are rarely needed for diagnosis. While sensitive, the antineuroblastoma antibody NB-84 has proved less than specific, in that it also stains several other types of small round blue cell tumors.[245,246] It should be emphasized that exclusion of other diagnostic possibilities and correlation with clinical setting and laboratory findings (e.g. child with intra-abdominal mass and elevated urine catecholamine metabolites) represent the optimal approach for diagnosing undifferentiated neuroblastoma.

Several genes involved in neural crest development also serve as oncogenes in neuroblastoma, including *MYCN*, *ALK*, and paired-like homeobox 2B *(PHBX2B)* genes. Neuroblastoma typically shows a complex karyotype, and the chromosomal translocation t(11;22) characteristic of Ewing sarcoma is not found.[247] The most common genetic alteration is gain of 17q (up to 80% of cases), either in the form of an unbalanced translocation or as whole chromosome gain; this feature is associated with an unfavorable outcome.[248] The well-known amplification of the *MYCN* oncogene, which is most commonly assessed by the fluorescence in situ hybridization (FISH) technique and defined as greater than 10 copies per diploid genome, occurs in approximately 25% of cases.[249-251] While this feature is an adverse prognostic factor, it is not specific to neuroblastoma. Low-risk neuroblastomas are often hyperploid. High-risk tumors more often have segmental chromosomal abnormalities, commonly in 1p, 1q, 3p, 11q, 14q, and 17p (including *MYCN* amplification). Germline mutations in *ALK* are a major cause of familial neuroblastoma.

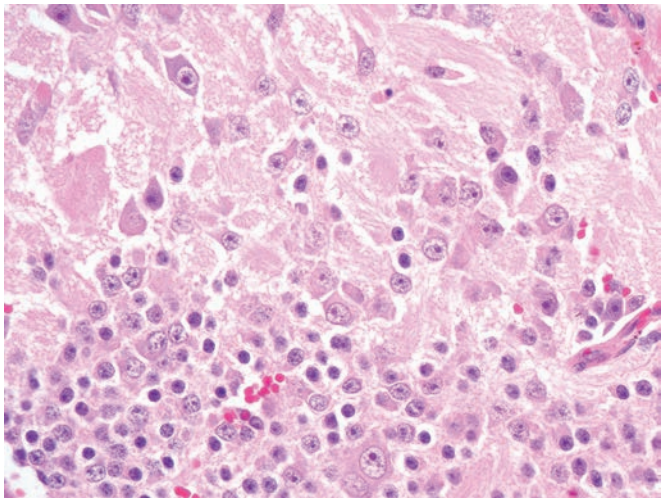

Figure 29.20 Differentiating neuroblastoma contains greater than 5% of cells with varying levels of maturation, typically acquiring a more ganglion-like appearance.

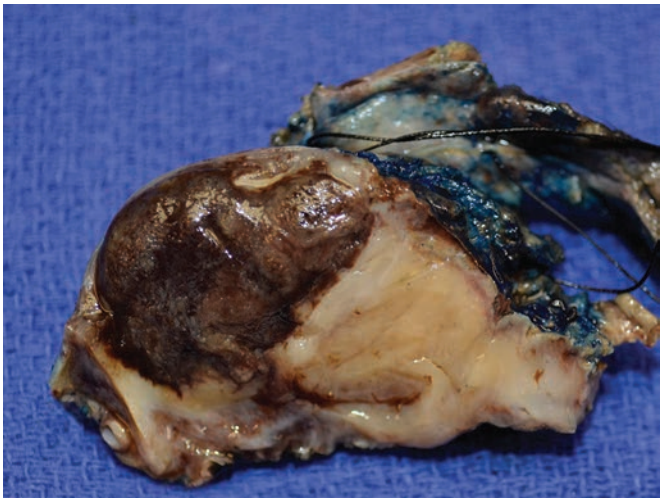

Figure 29.22 Ganglioneuroblastoma, nodular type, is characterized macroscopically by the tan ganglioneuromatous component that contains a dark nodule with stroma-poor neuroblastoma morphology. (Courtesy of Dr. Jason Jarzembowski, Medical College of Wisconsin.)

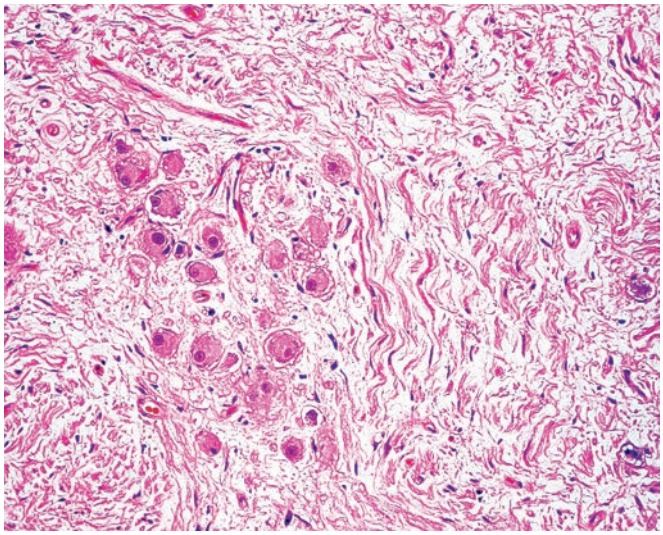

Figure 29.21 Ganglioneuroma of adrenal gland showing clusters of mature ganglion cells surrounded by fascicles of Schwann-like cells (i.e. Schwannian stroma). This diagnosis requires the absence of both neuropil and any nests of neuroblastic cells, which would warrant classification as ganglioneuroblastoma, intermixed.

An International Committee has recently published an authoritative report on the guidelines for the molecular diagnosis of neuroblastoma.[252]

The rare cases of familial neuroblastoma (1%–2%), which typically present at younger age and may have multifocal disease, are reported to have mutations in *ALK* (most common) and *PHOX2B*.[253] Familial neuroblastoma has also been linked to susceptibility alleles, including 16p12-13.

Spread and Metastases

Adrenal neuroblastomas locally invade the surrounding tissues. They may show intraspinal (dumbbell) extension[254] or spread into the kidney. The most common sites of distant metastases are lymph nodes, bone marrow, bone, liver, orbit, and dura.[255-257] Bone metastases are usually multiple and sometimes symmetrical, a point to remember in the differential diagnosis with Ewing sarcoma. Intracranial and pulmonary metastases are rare. Most recurrences and metastases develop within 2 years after excision of the primary tumor, but occasional instances of very late recurrences are on record.[258] The pattern of tumor metastasis is altered by therapy.[259]

Morphologic evaluation of bone marrow for neuroblastoma cells is a routine component of clinical staging and has been standardized for use in definitive diagnosis and risk stratification. The use of immunostains and PCR to increase the yield of detection has been advocated, particularly using the emerging marker PHOX2B.[260]

Therapy and Prognosis

The treatment of neuroblastoma depends on the risk of relapse. Low-risk patients may be observed only, while high-risk patients require multimodal therapy including varying combinations of surgery, chemotherapy, radiation, autologous bone marrow transplant, immunotherapy, and (more recently) targeted therapy.[261-264] Patient age, stage, histologic grading (including specific neuroblastoma diagnosis and mitosis–karyorrhexis index [MKI]), and MYCN amplification status are the backbone of risk stratification.

1. *International Neuroblastoma Pathology Classification (INPC)*.[265-269] The INPC histologic system is applicable to pretreatment specimens only (see Table 29.1). It provides further classification as "favorable" or "unfavorable" histology when combined with patient age and MKI (Table 29.2).[268,270,271] Combinations of patient age, tumor stage, MKI, and MYCN status determine the Children's Oncology Group (COG) neuroblastoma risk group system: low, intermediate, and high risk of disease recurrence.[271,272]
2. *Mitosis-karyorrhexis index (MKI)*.[269] The MKI is a count of all mitotic and karyorrhectic figures present per 5000 neuroblasts. The number of mitotic and karyorrhectic figures can vary across fields in a large pretreatment resection, but the reported MKI should be representative of all tumor represented on the slides (see MKI averaging method later). Once at least 5000 neuroblasts are exceeded in the denominator, one calculates the percentage for the MKI (mitotic + karyorrhectic figures / neuroblasts). This index is categorized as low (<100/5000; 2%), intermediate (100–200/5000; 2%–4%), or high (>200/5000; >4%). The following guidelines and tips may aid in appropriate MKI determination:

Table 29.2 International Neuroblastoma Pathology Classification: favorable and unfavorable histology groups[a]

AGE AT DIAGNOSIS	FAVORABLE HISTOLOGY	UNFAVORABLE HISTOLOGY
Any age	• Ganglioneuroblastoma, intermixed • Ganglioneuroma, mature or maturing	• Neuroblastoma, undifferentiated • Neuroblastoma of any subtype, with high MKI
<18 months	• Neuroblastoma, poorly differentiated, with low or intermediate MKI • Neuroblastoma, differentiating, with low or intermediate MKI	
18–60 months	• Neuroblastoma, differentiating, with low MKI	• Neuroblastoma, poorly differentiated • Neuroblastoma, differentiating, with intermediate MKI
>60 months	• None	• Neuroblastoma of any subtype

[a]For **Ganglioneuroblastoma, nodular subtype**, favorable versus unfavorable designation is based on the subtype of the Schwannian stroma poor neuroblastoma component using the same age and MKI-based criteria.
MKI, Mitosis–karyorrhexis index.

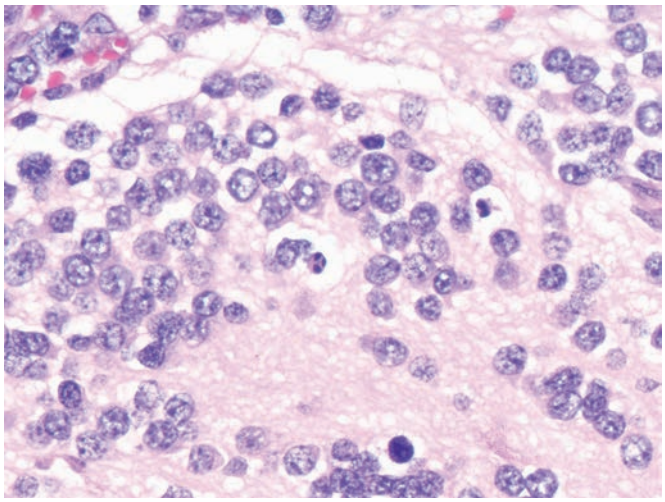

Figure 29.23 Karyorrhectic bodies have eosinophilic cytoplasm and condensed, fragmented nuclear chromatin.

a. *Karyorrhectic figures*. These are recognized by small pyknotic nuclei, which may appear crescentic, angulated, or round, and should have recognizable eosinophilic cytoplasm (Fig. 29.23). Caution should be exercised to avoid counting lymphocytes.
b. *MKI averaging method*. Unlike many mitotic count systems, MKI should be weighted and not determined by areas of highest count. Determine if the tumor is homogeneous or heterogeneous with respect to mitotic-karyorrhectic figures. If heterogeneous, determine regions that may be high, intermediate, or low. Count fields in those regions proportionally to their composition of the overall tumor.
c. *Counting and magnification*. The MKI should never be visually estimated! Ideally using a manual differential counter, count 40× fields to record the number of mitotic-karyorrhectic figures over the denominator of neuroblasts present. Most poorly differentiated neuroblastomas average 600-800 neuroblasts per 40× field, but differentiating neuroblastoma may be as low as 100–200. For the average poorly differentiated neuroblastoma, a count of ten 40× fields will yield greater than 5000 neuroblasts.
d. *Necrosis*. When counting MKI, areas of necrosis should be avoided.
3. *MYCN amplification*. Amplification of the *MYCN* oncogene, which occurs in approximately 25% of the cases, is associated with rapid clinical progression.[273-276] This also applies to stage IV cases[277] but not to stage IVS patients.[278] This amplification can be detected by FISH or PCR techniques.[279,280] Rare cases with genotype-phenotype discordance are reported (i.e. MYCN amplification with favorable histology). Two prognostic subgroups are identified in these discordant neuroblastomas with the poor prognostic group characterized by prominent nucleoli (i.e. "bull's eye" tumor).[281]
4. *Chromosomal abnormalities*. In patients without MYCN amplification, 11q deletion and 17q gain predict a worse prognosis. In the International Neuroblastoma Risk Group system, an unbalanced 11q aberration would place a child in the intermediate risk group when other factors are favorable.
5. *Flow cytometric DNA pattern*. A favorable clinical outcome has been found in association with an aneuploid stem line and a low percentage of tumor cells in the S, G_2, and M phases of the cell cycle.[282,283] The non-aneuploid tumors secrete higher levels of DOPA, dopamine, and HVA and are more likely to present in higher clinical stages.[284] Diploid tumors tend to exhibit an unfavorable histology and high proliferative activity.[285] While the proven clinical utility could be debated, it is our experience that flow cytometric testing may rarely be requested by pediatric oncologists when the constellation of findings closely straddles the border of two risk groups with possible therapeutic implications; however, fresh tissue is required. This is most useful in children less than 2 years of age.

Staging

There are two widely recognized staging systems for neuroblastoma, the International Neuroblastoma Staging System (INSS) and the International Risk Group Staging System (INRGSS).[286-288] The INSS is a surgical staging system, while the INRG is influenced by preoperative imaging. The INSS staging is described in Table 29.3 as it directly relates to surgical pathology. At the time of gross evaluation and sectioning, correct staging requires that lymph nodes attached to and removed with the primary tumor be evaluated separately from other submitted lymph nodes.

Adrenal Medullary Hyperplasia

Hyperplasia of the adrenal medulla may result in symptoms similar to those of pheochromocytoma, and its distinction form the latter

Table 29.3 International Neuroblastoma Staging System

STAGE	DEFINITION
Stage I	• Localized tumor with complete gross excision • Ipsilateral "non-adherent" lymph node negative microscopically • May include positive margins (microscopic residual disease) • May include positive lymph node if adherent to resected tumor
Stage IIA	• Localized tumor with incomplete gross excision • Ipsilateral "non-adherent" lymph node negative microscopically
Stage IIB	• Localized tumor with incomplete gross excision • Ipsilateral "non-adherent" lymph node positive microscopically • Any enlarged contralateral lymph node confirmed microscopically negative
Stage III	• Unresectable unilateral tumor crossing vertebral column with or without regional lymph node involvement • Localized unilateral tumor with contralateral lymph node involvement • Unresectable midline tumor with bilateral tumor infiltration or lymph node involvement
Stage IV	• Any primary tumor with distant metastasis to lymph node, bone, bone marrow, liver, skin or other organs not defined as stage IVS
Stage IVS	• Infant younger than 12 months • Localized primary tumor (stage I, IIA, or IIB) with dissemination limited to skin, liver, and/or bone marrow • Bone marrow involvement must have <10% cellularity • Bone marrow must be metaiodobenzyl guanidine scan negative

may be problematic.[289] It may be nodular or diffuse and is always bilateral. Diffuse hyperplasia may be characterized by extension of the medullary cells into the alae and tail. Ultrastructurally and immunohistochemically, the features are similar to those of normal medullary cells: chromogranin and synaptophysin reactivity can be consistently demonstrated.[290]

Advanced cases of medullary hyperplasia are easy to recognize, but earlier phases may need morphometric studies to detect minor increases in medullary volume and weight, inasmuch as random sectioning techniques are grossly inadequate for this purpose.[291,292] In most cases, the medullary hyperplasia is a component of multiple endocrine neoplasia (MEN 2A and 2B) and is the background against which pheochromocytomas (sometimes multiple and bilateral) develop in these patients.[293,294] It has also been reported in association with neurofibromatosis, cystic fibrosis, germline *SDHB* mutation, *MAX* mutation, and Beckwith–Wiedemann syndrome.[295-298]

Pheochromocytoma

General and Clinical Features

Pheochromocytomas are primary neoplasms of the adrenal chromaffin cells and are essentially sympathetic paragangliomas of the adrenal medulla. While the term *"extra-adrenal pheochromocytoma"* has been historically used for extra-adrenal paragangliomas that are either functioning and/or connected with the orthosympathetic system (such as those arising in the bladder or in the Zuckerkandl body), it is probably best to avoid that diagnostic term altogether. Both pheochromocytomas and paragangliomas secrete norepinephrine, but only the former have the capacity to also secrete epinephrine, since the adrenal cortex is necessary for the needed methylation step. Indeed, the pure norepinephrine-producing adrenal pheochromocytomas have been found to have a deficiency of phenylethanolamine *N*-methyltransferase.[299]

The clinical signs and symptoms of hormonally active pheochromocytomas derive from the catecholamines they secrete. Hypertensive episodes are usually intermittent, but at times may be sustained. They may be precipitated by drugs, anesthetic agents, parturition, surgery for an unrelated condition, or massaging of the tumor.[300] The complete symptomatic triad of sweating attacks, tachycardia, and headaches clinically suggests the presence of a pheochromocytoma, but is seen in less than one-fourth of patients. Rarely, pheochromocytoma and paraganglioma may be associated with a paraneoplastic syndrome secondary to other ectopic secretory products: Cushing syndrome (most common), diarrhea/hypokalemia/achlorhydria (typically in composite tumors with a component of ganglioneuroma or ganglioneuroblastoma), or polycythemia (with *EPAS1* or *EGLN1/2* mutations).[301-305]

Confirmation of the diagnosis is usually obtained by testing for evidence of catecholamine production, typically by plasma free metanephrines or urinary fractionated metanephrines.[306,307] Provocative pharmacologic tests are used only when the biochemical results are equivocal.[300] CT imaging for the preoperative detection is often reserved for patients with corroborative biochemical evidence of pheochromocytoma.

Morphologic Features

The weight of pheochromocytomas ranges from a few grams to over 2000 g, and they are typically 3–5 cm. They are often circumscribed, usually soft, and, on section, yellowish white to reddish brown (Fig. 29.24). The larger tumors often have areas of necrosis, hemorrhage, and cyst formation. The adrenal gland usually is compressed or incorporated within the tumor.[308]

Microscopically, the tumor cells are characteristically arranged in well-defined nests ("Zellballen") bound by a delicate fibrovascular stroma. Other patterns include more diffuse growth, trabecular arrangement, or prominent sclerosis.[308] The cells vary considerably in size and shape and have a finely granular basophilic or amphophilic cytoplasm (Fig. 29.25). The nuclei are usually round or oval with prominent nucleoli and may contain inclusion-like structures resulting from deep cytoplasmic invaginations.[309] Intracytoplasmic hyaline globules are common.[310] Lipid accumulation may develop in the cytoplasm and lead to confusion with adrenal cortical tumors on both gross and light microscopic examination.[311-313] Melanin pigment is occasionally present.[314,315] Nuclear gigantism and hyperchromasia are common and *are not* an expression of malignancy.

Exceptionally, the cells of pheochromocytomas are found to contain a large number of mitochondria (in addition to the neurosecretory granules) and thus acquire an oncocytic appearance.[316,317]

Isolated ganglion cells are sometimes found in pheochromocytoma. More rarely, a true composite tumor will be found to be composed of a mixture of pheochromocytoma and ganglioneuroma, ganglioneuroblastoma, or neuroblastoma, a finding not surprising in view of the close histogenetic relationship of the cell types.[318-321] Some of these combined tumors have occurred in the setting of MEN 2a.[322] Other combinations that have been described are

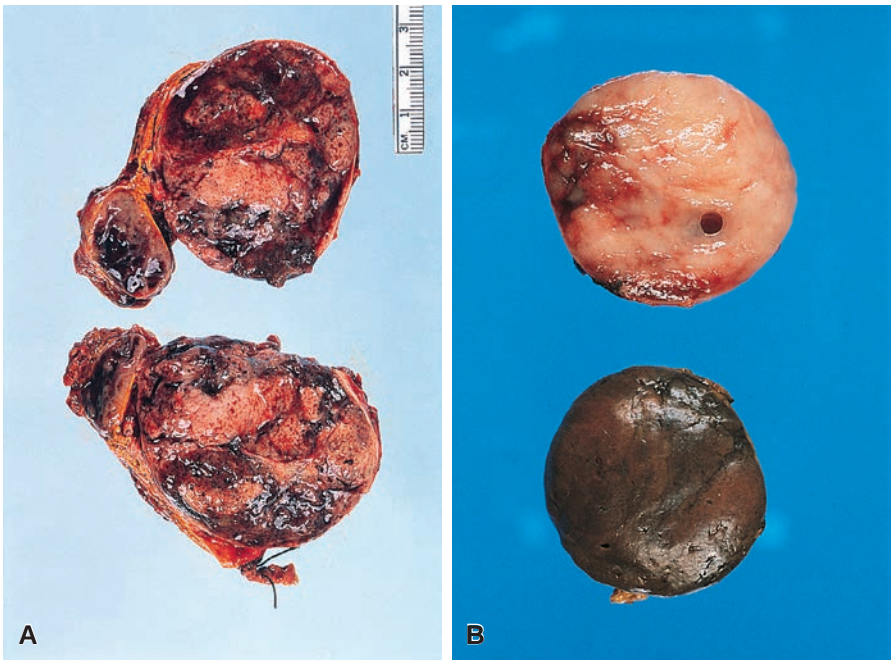

Figure 29.24 Gross appearance of adrenal pheochromocytoma. The tumor shown in **A** has a markedly variegated appearance. The lower half of the specimen shown in **B** was fixed in Zenker fluid and has acquired the typical dark brown color indicative of a positive chromaffin reaction.

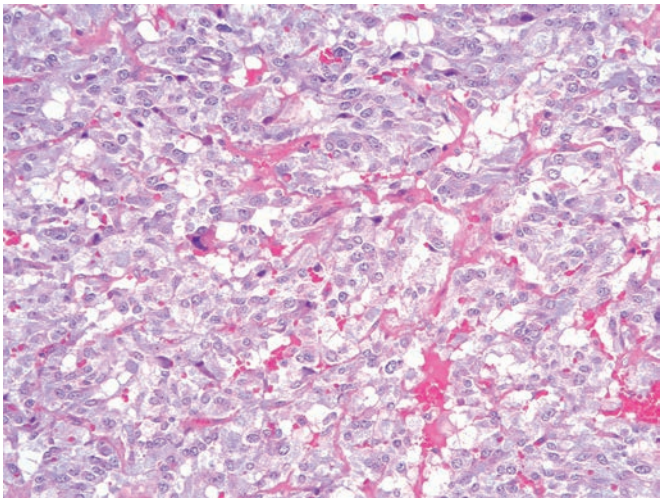

Figure 29.25 Adrenal pheochromocytoma shows the typical "Zellballen" configuration and abundant granular amphophilic cytoplasm of the tumor cells.

pheochromocytoma with spindle cell sarcoma,[323,324] some of possibly malignant peripheral nerve sheath nature,[325] pheochromocytoma with cortical adenoma, and pheochromocytoma with neuroendocrine carcinoma.[326]

Electron Microscopic, Histochemical, Immunohistochemical, and Molecular Genetic Features

Ultrastructurally, the cells of pheochromocytoma contain numerous dense-core granules of neurosecretory type; in the typical case they segregate into two size categories, corresponding to their respective content of norepinephrine and epinephrine.[7,327,328]

Immunohistochemically, pheochromocytoma cells are typically immunoreactive for chromogranin (strong and diffuse) and GATA-3 (nuclear).[115,182-184] PHOX2B expression by immunohistochemistry is recently reported in pheochromocytomas, but not as commonly in well-differentiated neuroendocrine neoplasms.[329] Cytokeratin expression is variably reported, but is typically negative; keratin staining is known to be most common in paragangliomas of the cauda equina.[330,331] Surrounding sustentacular cells, which form a peripheral coat around the "Zellballen," are strongly reactive for S-100 protein; however, they are present in variable numbers.[332-335] S-100 protein may also show weak cytoplasmic staining of the chromaffin cells. Immunostains for SDHB are being increasingly utilized as initial screening for SDH family mutations because other SDH mutations also result in loss of the SDHB protein due to a shared epitope.[336-339]

With recent progress in the molecular biology of adrenal pheochromocytoma, it is now apparent that at least 30% may be hereditary and germline mutations in well over 15 different known hereditary susceptibility genes are now described, including *SDH* family (most common), *NF1*, *VHL*, *RET*, *MAX*, *EPAS1*, and *FH*. Many patients present with a solitary tumor suggesting sporadic disease; however, between 8% and 24% of patients with apparently sporadic pheochromocytoma and no family history are carriers of germline mutations in one of these genes.[340-343] When compared with the sporadic examples, syndromic pheochromocytomas tend to occur in a younger age group, are more commonly bilateral, and are more frequently associated with other primary neoplasms.[344] Pheochromocytomas in children are less likely to be malignant, but more likely to be bilateral, or associated with MEN.[345,346]

Other common genetic changes, including allelic losses at 1p, 3q, 11q, 17p, and 22q, are frequent.[347-352] Alterations in chromosome 11 and losses at 6q and 17p are found more commonly in tumors with malignant behavior.[347,348]

Interestingly, somatic mutations in some of these same hereditary susceptibility genes are identified in sporadic tumors, with *NF1* being

most common.[353-363] Sporadic tumors may also harbor *HRAS* or *BRAF* mutations (~9% of cases), and *TP53* in 2%–3%.[364]

Spread, Metastases, Treatment, and Prognosis

We know of no reliable morphologic markers of malignancy for this tumor other than the presence of metastases. In fact, the current WHO classification no longer includes a "malignant pheochromocytoma" category.[365] As a group, however, pheochromocytomas associated with metastases are usually larger, have more necrosis, and are composed of smaller cells than their benign counterparts.[308] Although the statement is often made that only 10% of pheochromocytomas are malignant, several series in adults with long-term follow-up suggest that the real incidence is much higher since metastases may arise many years after initial diagnosis.[366,367]

Morphologic parameters such as proliferative activity, cytologic abnormalities (extreme pleomorphism, spindling, cellular monotony), diffuse architectural growth, necrosis, and invasion (vascular or capsular) have proven to be poor prognostic determinants in this tumor, at least when evaluated independently. While no prognostic system is uniformly adopted, combining histologic features into a scoring system in a way similar to the one that has been successfully employed for adrenocortical tumors has been proposed, including the Pheochromocytoma of the Adrenal Gland Scaled Score (PASS) and the Grading System for Adrenal Pheochromocytoma and Paraganglioma (GAPP).[368,369] The GAPP employs six criteria (histologic pattern, cellularity, coagulation necrosis, vascular/capsular invasion, MIB-1 immunoreactivity, and types of catecholamine produced) and divides the tumors accordingly into well, moderately, and poorly differentiated (with 10-year survival rates of 83%, 38%, and 0%, respectively).[369,370] More recently, SDHB protein loss by immunohistochemistry was shown to add additional prognostic information by predicting for higher risk of metastatic disease.[370-372]

Other reportedly unfavorable prognostic factors are high proliferative index (as measured with MIB-1 or topoisomerase alpha II staining)[373-377]; absence of S-100 protein–positive sustentacular cells[334]; increased expression of tenascin; and expression of the gene for human telomerase reverse transcriptase (*hTERT*).[378,379]

Metastatic pheochromocytomas most commonly involve local lymph nodes, bone, liver, and lung. Metastases should only be diagnosed at sites where normal chromaffin cells are absent to avoid misclassification of multifocal primaries (which are not uncommon in familial cases). The primary treatment of pheochromocytoma is surgical excision. Most patients with metastatic tumor die within 1 year of diagnosis, but long-term relapse-free survival is possible for locally invasive neoplasms.[334,366]

Staging

The 8th edition of the AJCC staging manual now includes pheochromocytoma.[364,380]

Other Adrenal Lesions

Adrenal hemorrhage of massive proportions can occur in infants within the first few days after delivery; it may present as an abdominal or retroperitoneal mass, septicemia, or adrenal insufficiency.[381] In the first instance, surgery is indicated to rule out the possibility of neuroblastoma.[382] This differential diagnosis also applies to the surgical and pathologic findings, since neuroblastoma can undergo marked hemorrhagic necrosis. Massive adrenal hemorrhage must also be distinguished from renal vein thrombosis. This hemorrhage can be unilateral (more commonly on the right side) or affect both glands; if the patient survives, calcification rapidly develops around its periphery (Fig. 29.26).[383] The postulated causes include fetal hypoxia, septicemia, thrombocytopenia, coagulopathies, and disseminated thromboembolic disease.

Figure 29.26 Adrenal gland massively replaced by hemorrhage. There was no evidence of a tumor in any of the many sections taken.

Adrenal cysts can be clinically confused with retroperitoneal neoplasms because of their occasionally large size of up to 30 cm in diameter (Fig. 29.27).[384] They are sometimes bilateral. Microscopically, the wall is composed of partially calcified fibrous tissue without an epithelial lining.[385] In some instances, intracystic mature adipose tissue or myelolipomatous metaplasia is encountered.[386] The content may be serous or blood-colored fluid. The mechanism of formation remains controversial. It would seem that two main variants exist.[387-389] The first, known as *endothelial (vascular) cyst*, contains serous fluid, is multiloculated, has an endothelial lining, and often contains adrenal cortex in the wall. The second, known as *hemorrhagic cyst* or *pseudocyst*, contains clotted blood and hyalinized thrombus with attenuated adrenal cortex in the outer fibrous wall.[390] It has been suggested that both cyst types arise on the basis of a vascular anomaly,[391] perhaps of lymphatic nature in the first instance and of blood vessel type in the second.[387] Hemorrhagic cysts can occur as a component of Beckwith–Wiedemann syndrome.[392,393] In rare cases, *epithelial-lined ("true") adrenal cysts* are seen; their histogenesis is probably similar to that of epithelial-lined cysts of the spleen and possibly derived from mesothelial structures.[394] These should be distinguished from *bronchogenic cysts*, which sometimes present as adrenal masses,[395,396] and with adrenal cortical and medullary neoplasms with marked secondary cystic changes.[397] It follows that thorough sampling of the specimen is crucial in making this distinction.

Adrenal cytomegaly refers to the presence in the adrenal cortex of foci of bizarre polyhedral cells with eosinophilic granular cytoplasm and large hyperchromatic nuclei with pseudoinclusions. This condition is usually detected in infancy, often as a component of Beckwith syndrome; it is not likely to be seen as a surgical specimen.[398]

Heterotopic tissue in the adrenal gland is highly unusual. This includes *liver tissue* (usually resulting from adrenohepatic fusion, but sometimes occurring as a separate nodule),[399] and *thyroid tissue*.[400]

Tuberculosis of the adrenal glands is one of the classic causes of Addison disease[401]; the glands are enlarged, calcified, and massively replaced by granulomatous inflammation.[402]

Malakoplakia involving the adrenal gland has been reported in infants[403] and adults.[404]

Myelolipoma is a lesion characterized by the presence within the adrenal gland of adult fat containing active bone marrow elements

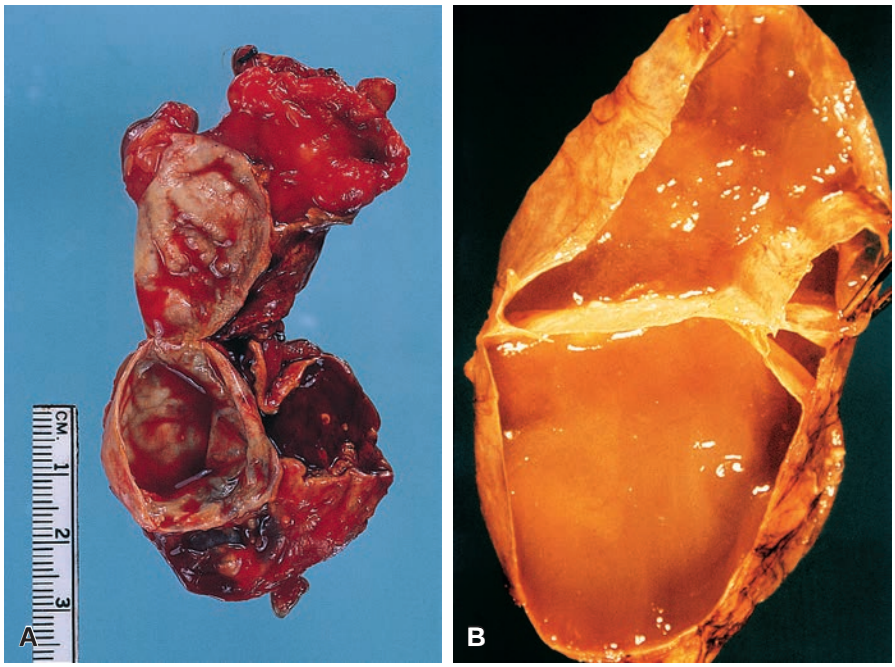

Figure 29.27 Gross appearance of adrenal cyst. The cyst shown in **A** has a unilocular appearance, whereas that shown in **B** is divided into two portions by a prominent septum.

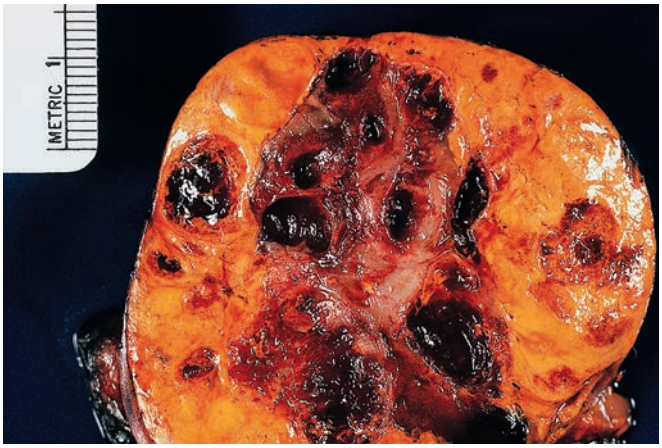

Figure 29.28 Gross appearance of adrenal myelolipoma. *Yellow* areas with the appearance of adipose tissue alternate with hemorrhagic foci composed of bone marrow tissue.

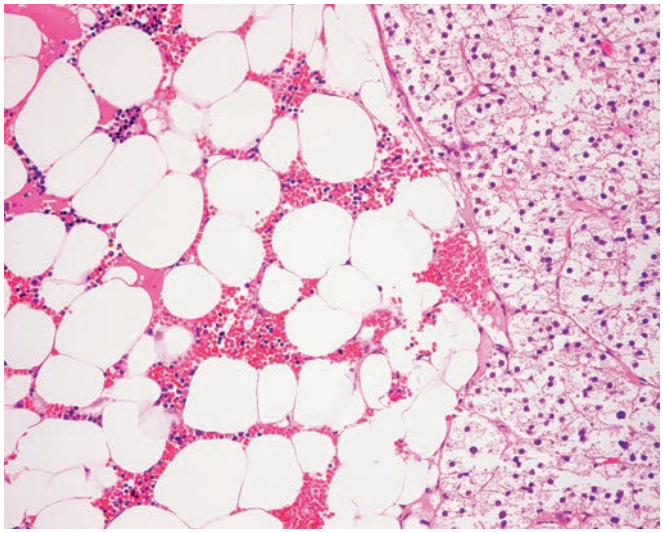

Figure 29.29 Adrenal myelolipoma composed of bone marrow elements and mature fat.

(Figs. 29.28 and 29.29).[405-407] There is a wide variation in cellularity. The bone marrow component shows normal trilineage hematopoiesis, but with a markedly increased number of megakaryocytes.[408] Most cases are found incidentally, either at autopsy or through CT scanning done for other reasons. Only occasionally will the lesion attain a size large enough to become clinically apparent.[409,410] Bilaterality is rare.[411] The tumors are hormonally inactive, most of the patients being obese adults. Traumatic rupture leading to hemoperitoneum may supervene.[412] Myelolipoma has been seen in association with adrenal cortical tumors accompanied by Cushing syndrome,[413] with congenital adrenal hyperplasia,[414] and with adrenal ganglioneuroma.[415] Cases of pure adrenal myelolipoma associated with Cushing disease have also been reported.[413,416] In contrast to other extramedullary foci of hematopoiesis in adults (which are usually the expression of a hematologic disease), adrenal myelolipoma is practically always accompanied by a normal bone marrow.[417] Recent cytogenetic studies have shown that adrenal myelolipoma is a clonal lesion.[408]

Benign mesenchymal tumors of the adrenal gland, all exceptionally rare, include lipoma, hemangioma, lymphangioma, leiomyoma, solitary fibrous tumor, calcifying fibrous tumor, and schwannoma.[418-425]

Adenomatoid tumor has been reported in a primary adrenal location (Fig. 29.30); as in other sites, its nature is in all likelihood mesothelial. The behavior is benign.[426-431]

Sex cord stromal tumors are rarely reported in the adrenal gland, including granulosa and Leydig cell tumors.[432-435] These have occurred in postmenopausal women, and the pathologic features are identical to those encountered in the gonads. Patients have often presented with symptoms of hormonal production.

Sarcomas primary in the adrenal gland are exceptionally rare. They include *leiomyosarcoma*[436] (some in association with HIV infection[437]), *malignant peripheral nerve sheath tumor*,[438,439] *synovial saarcoma*,[440] and *angiosarcoma* (often epithelioid).[441,442] There have also been isolated reports of *Ewing sarcoma* arising in the adrenal gland, to be distinguished from the considerably more common neuroblastomas,[443] and a case of an intra-adrenal neoplasm indistinguishable from renal *Wilms tumor*.[444]

Malignant lymphoma involving the adrenal gland is usually a manifestation of widespread disease. Only a few cases have been reported as having an apparently primary adrenal location.[445,446] Most of the cases have been of B-cell type,[447] and several of these were Epstein–Barr virus (EBV) associated.[448] Fibrin-associated EBV-positive large B-cell lymphoma is a subtle, yet distinct form of lymphoma with an indolent clinical behavior that has been described in adrenal cysts and may be cured by surgical excision.[449] There have also been cases of T-cell lymphoma,[448] anaplastic large cell lymphoma,[450] and intravascular lymphoma.[451] If the adrenal replacement is extensive bilaterally, adrenal insufficiency may result.[452,453]

Malignant melanoma as a primary adrenal tumor is reported; however, the differential diagnosis includes melanotic pheochromocytoma and metastatic melanoma, both of which are considerably more common.[454]

Metastatic tumors to the adrenal glands are very common at autopsy but sometimes also present as surgical specimens simulating a primary adrenal neoplasm (Fig. 29.31). Bilaterality is the rule. CT scanning is the method of choice for their detection. If extensive enough, they may lead to Addison disease.[455,456] The most common sites of the primary tumor are lung, breast, gastric, skin (melanoma), pancreas, hepatobiliary, and kidney. Renal metastases can be contralateral and may grossly and microscopically simulate the appearance of adrenocortical carcinoma or adenoma (Fig. 29.32).[457]

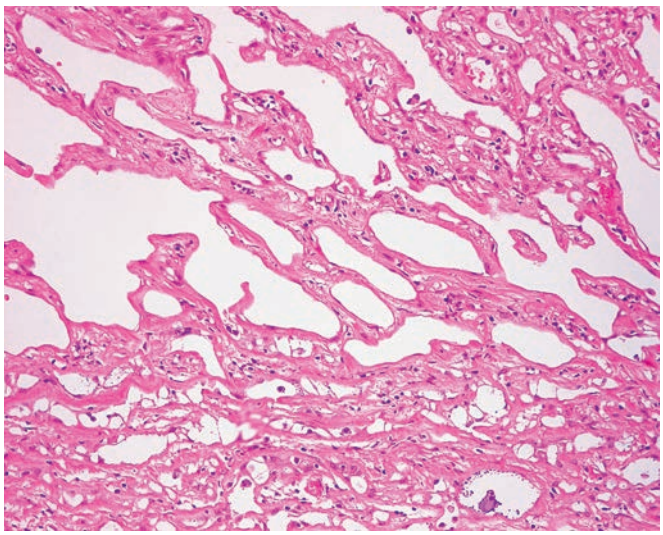

Figure 29.30 Adenomatoid tumor of adrenal gland. The appearance closely simulates that of a vascular tumor.

Tumors and Tumorlike Lesions of Other Paraganglia

Generalities

Paraganglioma is the generic term applied to nonepithelial tumors of paraganglion cells regardless of location.[458,459] The only exception, largely on the basis of tradition, is the already discussed paraganglioma of the adrenal medulla, which is universally known as *pheochromocytoma*. Extra-adrenal paragangliomas may arise in the parasympathetic paraganglia (mostly of the head and neck) or the sympathetic paraganglia (found along the sympathetic nerve chain adjacent to the vertebral bodies in the abdomen, pelvis, and thorax and along sympathetic nerve fibers). Paragangliomas have been found in practically every site in which normal paraganglia are known to

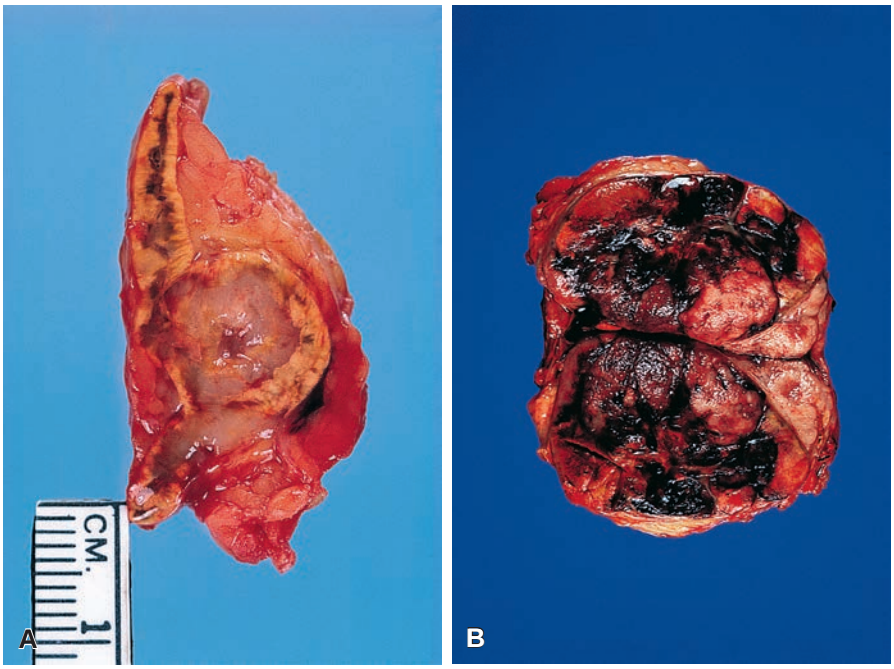

Figure 29.31 Metastatic carcinoma to adrenal gland. **A,** The whitish, ill-defined mass present in the center of the gland represents metastatic squamous cell carcinoma from the esophagus. **B,** Enlargement of the gland by a markedly hemorrhagic tumor representing metastatic breast carcinoma.

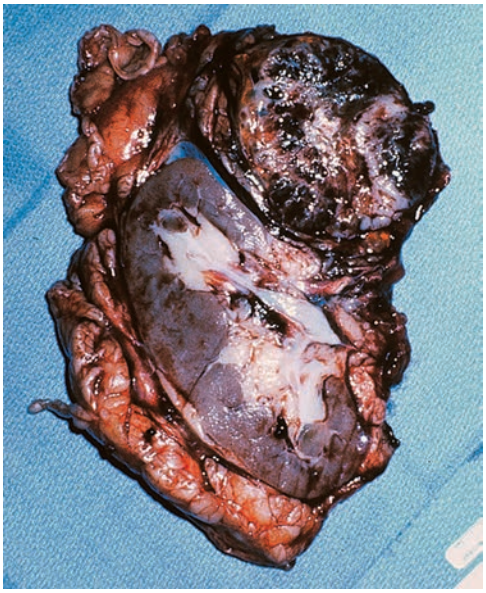

Figure 29.32 Renal cell carcinoma metastatic to contralateral adrenal gland and simulating a primary adrenal cortical tumor at the gross and microscopic level.

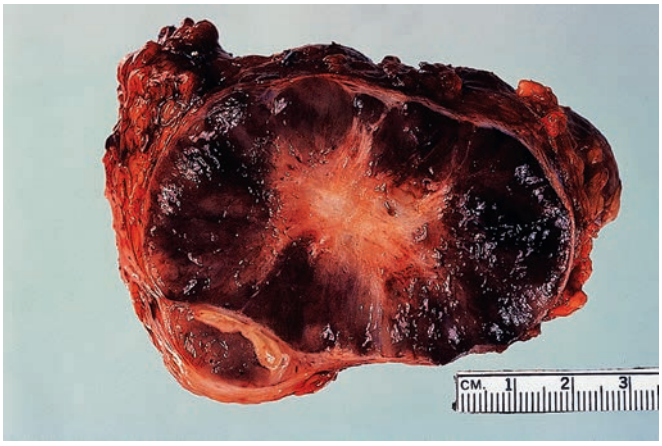

Figure 29.33 Gross appearance of paraganglioma. The brown appearance of the cut surface is characteristic. A large central scar is present.

occur, their description sometimes preceding that of the corresponding normal structure.

Morphologic Features

The gross and microscopic appearance of paragangliomas is practically the same regardless of location and indistinguishable from that of adrenal pheochromocytoma (Fig. 29.33); however, head and neck paragangliomas have been described as more cellular. Well-defined nests of cuboidal cells ("Zellballen") are separated by highly vascularized fibrous septa (Fig. 29.34). The individual cells have a moderately abundant granular basophilic cytoplasm. On occasion, a brown melanin-like pigment is present (*pigmented* or *black* paraganglioma).[460,461] As with many other endocrine tumors, bizarre nuclei and vascular invasion are sometimes found, neither of which should be taken as evidence of malignancy. Mitoses are exceptional, except in poorly differentiated tumors. The stroma can be very abundant; it often has a hyalinized quality and may undergo osseous metaplasia.[462] The sclerosing variant can be easily overdiagnosed as a malignant tumor because of the pseudoinvasive appearance of the tumor nests.[463]

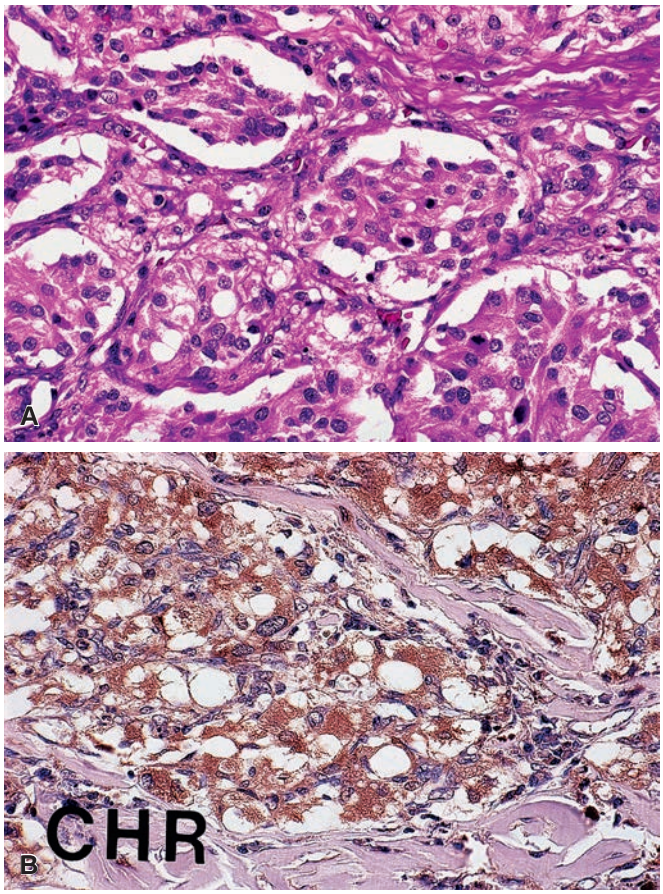

Figure 29.34 Paraganglioma. **A,** "Zellballen" formation in paraganglioma and **B** expression of chromogranin.

Electron Microscopic and Immunohistochemical Features

Ultrastructurally, the tumor ("chief") cells contain large numbers of cytoplasmic neurosecretory granules whose appearance is similar to those seen in normal paraganglia.[464,465] Giant mitochondria with paracrystalline inclusions may also be present.[466] The second cell type present in these tumors is the sustentacular cell, which wraps around the chief cells and lacks dense-core granules. Biochemical assays of the tumor have confirmed the presence of norepinephrine and sometimes also of epinephrine and dopamine.[467,468] Immunohistochemically, positivity has been found for NSE, chromogranin, synaptophysin, neurofilaments, opioid peptides, serotonin, somatostatin, and various other peptide hormones.[465,469-473] Interestingly, compared to other sites, head and neck paragangliomas are more frequently chromogranin negative.[474] Similar to pheochromocytoma, GATA3 and PHOX2B also show frequent immunoreactivity in extra-adrenal paragangliomas.[184,329,475] Keratin is almost always negative, but rare cases have focal staining (a fact of importance in the differential diagnosis with neuroendocrine carcinomas),[476] the curious exception being paraganglioma of the filum terminale in which stronger keratin reactivity is more common.[477] The sustentacular cells can be demonstrated with S-100 protein, another feature of importance in the differential diagnosis from other endocrine neoplasms (Fig. 29.35).[335,478]

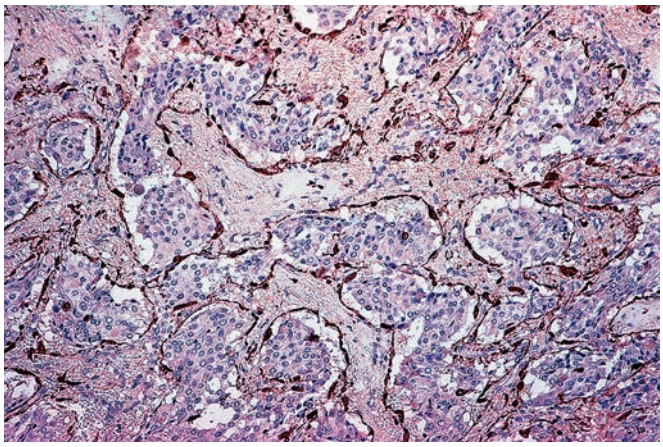

Figure 29.35 Sustentacular cells immunostained for S-100 protein at the periphery of the tumor nests of paraganglioma.

Treatment and Prognosis

Surgical excision is the standard treatment for paraganglioma. There are no reliable morphologic criteria by which to separate the benign from the malignant forms; therefore, risk assessment models (similar to gastrointestinal stromal tumors) have been proposed. Like pheochromocytoma, the GAPP may be applied to extra-adrenal paragangliomas for risk stratification.[368,369] Increasing tumor size (>5 cm), *SDHB* mutations, *MAX* mutations, and increasing Ki-67 proliferation rate are also risk factors for metastatic behavior.[370-372] Common sites of metastasis include bone, lymph nodes, lung, and liver.[479]

Paraganglioma Subtypes

Parasympathetic (Head and Neck) Paragangliomas

Most paragangliomas of the head and neck are nonfunctioning with only very rare cases secreting catecholamines. Paragangliomas of the head and neck (particularly carotid body tumors, Fig. 29.36) are about 10 times more frequent in persons living at high altitudes than in those at sea level[480,481]; these have been invariably benign.[482,483] While carotid body is most common,[484-487] other frequent sites of origin include middle ear, vagus nerve, and larynx.[488-496] Head and neck paragangliomas are commonly benign, but approximately 5% follow a malignant course. Metastatic paragangliomas of the head and neck are more commonly functioning, present at younger age, and have multifocal disease.[479]

The rate of germline mutations specifically in head and neck paragangliomas approaches at least 20%.[497] The most common mutations involve genes encoding the subunits of succinate dehydrogenase (i.e. hereditary paraganglioma syndrome), including *SDHD*, *SDHB*, *SDHA*, and *SDHC*.[498-500] Tumors with *SDHB* mutations have a high rate of developing metastasis (approximately 30%).[501] Other less common mutations described in the head and neck tumors include *VHL*, *TMEM127*, *RET*, and *NF1*.[502]

Sympathetic Paraganglioma

Sympathetic paragangliomas occur most commonly in the retroperitoneum, typically adjacent to the adrenal gland or kidney, but other sites include Zuckerkandl body,[503-505] heart,[506] gallbladder,[507] urinary bladder (one of the most frequent),[508] uterus,[509,510] and spinal cord (especially lumbar region and cauda equina) (Fig. 29.37).[511,512]

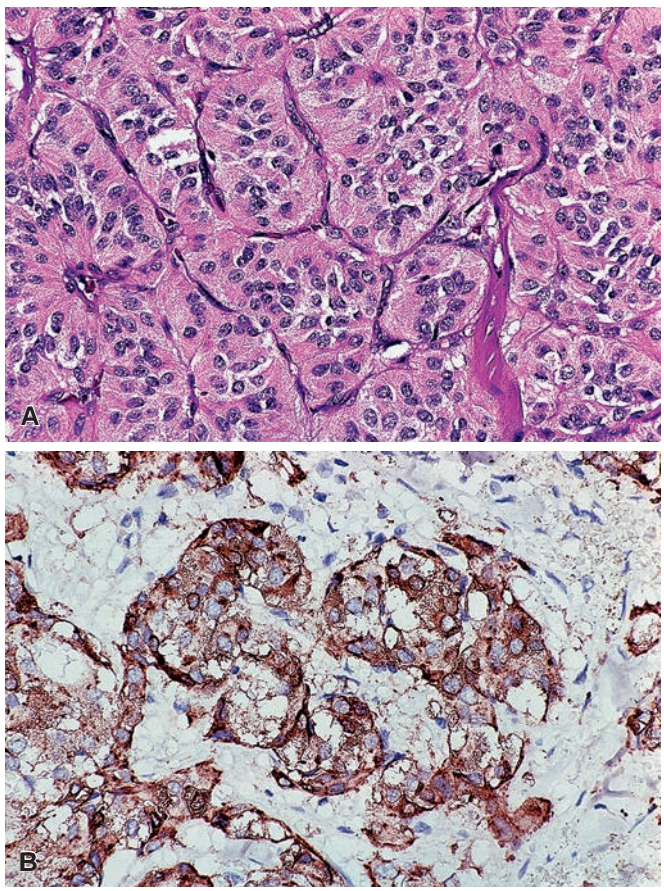

Figure 29.37 Paraganglioma of cauda equina. **A**, Hematoxylin–eosin; **B**, chromogranin.

As already mentioned, the latter are the only paragangliomas likely to show immunoreactivity for keratin. Some of these tumors are discussed with their respective organs. The sympathetic paraganglia are capable of catecholamine synthesis with production of norepinephrine alone or norepinephrine and dopamine.[513]

The molecular genetic profile of sympathetic paragangliomas is similar to that described for pheochromocytoma. Sympathetic paragangliomas are hereditary in up to 30% of cases, and should be strongly suspected in younger patients.[514]

Normal Anatomy

The vulva is composed of the following anatomic structures: mons pubis, clitoris, labia minora, labia majora, vulvar vestibule and vestibulovaginal bulbs, urethral meatus, hymen, Bartholin and Skene glands and ducts, and vaginal introitus.[1,2]

The *labia majora* are lined by keratinized skin containing all the cutaneous adnexa: hair follicles, sebaceous glands, apocrine glands, and sweat (eccrine) glands.[3] The *labia minora* are covered by nonkeratinized stratified squamous epithelium on their vestibular surfaces but have a thin keratinized layer on their lateral side. Skin adnexa are usually absent in them, but on occasion, one encounters both sweat and sebaceous glands.

The *Bartholin gland* is the major vestibular gland and has a tubuloalveolar structure. It is made up of acini composed of mucus-secreting columnar cells and a duct lined with transitional epithelium.[4] *Minor vestibular glands* are of simple tubular type and are lined with a mucus-secreting columnar epithelium that merges with the stratified squamous epithelium of the vestibule.

Skene or *periurethral glands* are analogous to the male prostate gland; they are lined by a pseudostratified mucus-secreting columnar epithelium that merges with the transitional-type epithelium of the ducts, which in turn joins with the stratified squamous epithelium of the vestibule.

The *hymen* is lined by nonkeratinized stratified squamous epithelium on both surfaces.

The *clitoris* contains erectile tissue similar to that present in the corpora cavernosa of the penis.

Most of the vulvar lymph vessels drain to the superficial inguinal nodes, but those in the clitoris empty directly into the deep chain.

Mammary-Like Glands of the Vulva and Related Lesions

Mammary-like glands of the vulva, formerly thought to be ectopic breast tissue related to the "milk line," are now recognized as a normal finding in the vulva,[5] and are found primarily in the sulcus between the labium minus and labium majus. These glands consist of ducts, variably with associated acini, lined by glandular epithelium identical to that of the breast. The ducts draining these glands empty through the skin. Clear cells (Toker cells) may be found singly or in clusters where these ducts traverse the epidermis. This tissue is subject to many of the physiologic and pathologic changes that occur in the normally situated breast and some that seem peculiar to this location. These include swelling and secretion of milk during pregnancy, cysts,[6] peculiar hyperplastic changes,[7] so-called pseudoangiomatous stromal hyperplasia (PASH; see Chapter 36),[8] fibroadenoma (including the juvenile type),[8–10] (Fig. 30.1) phyllodes tumor,[11,12] and carcinoma.[6,13–15] Most of the latter have been of ductal type, but any histotype/molecular subtype, i.e. luminal, basal-like, HER2, may be encountered.[16–18] In addition, it is likely that ectopic mammary tissue is the source of the common benign vulvar tumor known as papillary hidradenoma.

Abstract

Vulvar pathology encompasses a wide range of inflammatory and neoplastic conditions. Although generalized dermatopathies can involve the vulvar skin, we will focus on those specific conditions that involve the vulva preferentially or exclusively. Most neoplasms of the vulva arise from the squamous epithelium; unlike squamous cell neoplasia of sun-exposed skin, vulvar squamous cell carcinoma can metastasize and is associated with significant mortality. Vulvar squamous carcinoma can arise from human papilloma virus (HPV)–independent or HPV-associated pathways, and these differ with respect to age at onset, molecular events during pathogenesis, risk factors, precursor lesions, and prognosis. Neoplasms other than squamous cell carcinoma can arise from specialized epithelia (e.g., Bartholin gland or mammary-like glands of the vulva) or hormone receptor–expressing mesenchymal cells of the vulva.

Inflammatory Diseases

Syphilis in women often manifests itself initially in the vulvar region. The fully developed syphilitic chancre is composed microscopically of plasma cells, lymphocytes, and histiocytes, and is covered by a zone of ulceration infiltrated by neutrophils and necrotic debris. The microscopic appearance is not specific, but the combination of numerous plasma cells and endarteritis should alert to the diagnosis. Your diagnostic report can suggest the possibility of syphilis, based on the histopathologic findings, indicating to the clinician the need to exclude this possibility with appropriate serologic testing on the patient. Additionally, immunostains for *Treponema pallidum* are now available and allow for easy confirmation of the causative organisms.[19] Sometimes, the possibility of syphilis is first suggested on the basis of the microscopic examination of an enlarged inguinal lymph node if this node shows a combination of capsular and pericapsular fibrosis, follicular hyperplasia, plasma cell infiltration, and endarteritis. The latter feature, which represents the most useful clue to the diagnosis, is particularly well seen in or outside the nodal capsule (see Chapter 37).

Granuloma inguinale (donovanosis) is a chronic infection caused by *Klebsiella* (*Calymmatobacterium*) *granulomatis*, a gram-negative, nonmotile, encapsulated bacillus.[20–22] It begins as a soft elevated granulomatous area that enlarges very slowly by peripheral extension and ulcerates. Microscopically, there is a dense dermal inflammatory infiltrate composed of histiocytes and plasma cells, with a scattering of small abscesses.[23] The diagnosis rests on the demonstration of Donovan bodies, which appear as small round encapsulated bodies inside the cytoplasm of the histiocytes. They can be seen in hematoxylin-eosin (H&E) sections but are best demonstrated with Giemsa or Warthin-Starry stains. Pronounced pseudoepitheliomatous hyperplasia, which may accompany chronic lesions, should be distinguished from the very rare squamous cell carcinoma that may arise in such areas.[24] The infection can spread to the retroperitoneum and simulate a soft tissue neoplasm.[25]

Lymphogranuloma venereum (LGV) is a venereal disease produced by *Chlamydia trachomatis* organisms (specifically L-serovars).[26–28] It mainly affects lymph vessels and lymphoid tissue. The initial small ulcer at a site of venereal contact often goes unnoticed. The first clinical manifestation is swelling of inguinal lymph nodes caused by stellate abscesses surrounded by pale epithelioid cells.[29] There is extensive scarring as the disease progresses, often leading to fistulas and strictures of the urethra, vagina, and rectum. It is increasing in incidence, especially in homosexual men.[30] The diagnosis can be confirmed by submission of swabs for nucleic acid amplification, with LGV genotyping on samples positive for *Chlamydia*.[30] Rainey[31] reported 11 cases of squamous cell carcinoma or adenocarcinoma arising from lymphogranulomatous strictures. Most of the tumors were located in the anorectal area.

Crohn disease can involve the vulvar region.[32–35] In some cases, the vulvar lesions are associated with perineal disease and fistula formation, whereas in others they are separated from the anal lesions by normal tissue. Grossly, erythematous areas appear that later ulcerate. Microscopically, noncaseating granulomas may be found. The process reported as *vulvitis granulomatosa* is probably related to Crohn disease, in that some of the patients have subsequently developed either intestinal Crohn disease or cheilitis granulomatosa.[36]

Behçet disease can, rarely, involve the vulvar region, where it presents as a microscopically nonspecific ulceration.[37,38]

Necrotizing fasciitis of the vulva may be seen in diabetic women. It is associated with a high mortality rate; wide excision of the diseased tissue is the treatment of choice.[39]

Vulvar vestibulitis is a disorder characterized microscopically by a nonspecific chronic inflammatory infiltrate predominantly involving the mucosal lamina propria and the periglandular/periductal connective tissue of the vestibular region.[40] It is unrelated to human papilloma virus (HPV).[41]

Plasma cell vulvitis (of Zoon) is an uncommon condition of uncertain etiology. It typically presents as a solitary, asymptomatic, sharply defined red/brown patch. Microscopically, there is a dense band-like mononuclear inflammatory infiltrate in the superficial dermis, consisting predominantly (>50%) of plasma cells.[42] The differential diagnosis includes secondary syphilis and lichenoid drug reaction, but neither of these conditions present as a solitary lesion resembling those of plasma cell vulvitis.

Spongiotic and Lichenoid Reactions of the Vulvar Skin

There exists a group of vulvar diseases that are pathogenetically unrelated but that have several features in common at the clinical level. They typically present as a long-standing lesion consisting of irregular areas of thickened skin, often accompanied by severe pruritus. The color is usually white, in which case the clinically descriptive term *leukoplakia* has been used (note that this is not an acceptable histopathologic diagnosis!). In other instances, the lesions are red or a mixture of both colors. They are easily traumatized and excoriated. In some of these lesions the vulvar soft tissues are atrophied and shrunken, in which case the clinical term *kraurosis vulvae* has been employed.

In the presence of a lesion with some of these clinical features, it is essential to reach a specific diagnosis, and this often necessitates the performance of a biopsy.[43] Multiple biopsies may be necessary if the lesion is large or varies in appearance from place to place. Although a key function of the biopsy is to exclude neoplasia, it is important to reach a specific diagnosis as this will guide subsequent management, and the former practice of diagnosing benign "vulvar dystrophy" or "squamous hyperplasia" is not acceptable.[44,45] What follows is a list of the most commonly encountered inflammatory conditions of the vulva; this list is by no means exhaustive but will be sufficient to handle most vulvar biopsies taken for a non-neoplastic inflammatory process that will be encountered in general surgical pathology practice, focusing on those entities that chiefly involve the vulva. The vulvar skin can be secondarily involved in a wide range of inflammatory dermatopathies and the reader is referred to Chapter 2 for a full discussion of these conditions.

Spongiotic dermatitis (eczematous reaction) is a nonspecific pattern of cutaneous inflammation, familiar to those whose practice includes a significant dermatopathology component. It is characterized histologically by intercellular edema in the epidermis (spongiosis) with intraepithelial lymphocytes, and less commonly neutrophils and/or eosinophils. Pure acute spongiotic reactions are rarely encountered in vulvar biopsies, but spongiotic dermatitis is not uncommonly seen admixed with a chronic process, especially lichen simplex chronicus (discussed below), so awareness of the histopathologic features is important. Eczematous reactions confined to the vulva are most commonly attributable to allergic or irritant contact reactions, with drug reaction and atopic reaction less common. In patients with allergic contact reaction, the precipitant may be difficult to identify, clinically, as the reaction can persist for variable periods of time after removal of the irritant. Management consists of scrupulous avoidance of irritants/allergens.[46] When longstanding, there is progression to lichen simplex chronicus and it is our impression that many cases of lichen simplex chronicus start as an acute spongiotic dermatitis.

Lichen simplex chronicus is probably the most common diagnosis rendered on vulvar biopsies. It can affect nonvulvar sites or be limited to the vulva, where it manifests as pruritic scaly plaques.[46] The microscopic findings reflect chronic irritation, and the diagnosis of lichen simplex chronicus does not indicate a single disease entity but instead reflects chronic irritation of vulvar skin from any cause. On histopathologic examination there is hyperkeratosis (predominantly orthokeratosis, with parakeratosis focally present, for example, as sites of excoriation) with epidermal hyperplasia and a patchy, predominantly lymphocytic inflammatory infiltrate in the superficial dermis (Fig. 30.2). Because lichen simplex chronicus reflects trauma, and can appear secondary to many different primary dermatopathic conditions, it is important to search for an underlying disease process that has precipitated the lichen simplex chronicus. That being said, in most cases no underlying condition can be identified. Cutaneous fungal infections can result in changes of lichen simplex chronicus but can be ruled out with periodic acid–Schiff–diastase (PAS-D) stain. The differential diagnosis of lichen simplex chronicus, especially for the clinician, is vulvar intraepithelial neoplasia (VIN), but lichen simplex chronicus lacks the atypia of VIN (differential diagnosis discussed in more detail later, in the section on differentiated VIN [dVIN]).

Lichen planus is an idiopathic inflammatory dermatopathy characterized by pruritic red/purple papules.[46] While there is usually extragenital involvement, vulvar lesions may be the only finding at presentation. The lesions resolve after 12–18 months in most patients. The histopathologic findings are a band-like infiltrate in the superficial dermis, with damage to basal keratinocytes, resulting in apoptotic keratinocytes (Civatte bodies). The inflammatory infiltrate does not extend into the suprabasal keratinocytes. Hyperkeratosis with wedge-shaped hypergranulosis is a common finding. Lichen planus is considerably less common than lichen simplex chronicus or lichen sclerosus. The absence of basal keratinocyte degenerative changes aids in the distinction of lichen simplex chronicus from lichen planus. Lichen planus involves mucosal membranes and other extragenital sites, which is a clinical finding that can also serve to distinguish lichen planus from lichen sclerosus. The histopathologic features useful in differential diagnosis between lichen planus and lichen sclerosus are discussed in the following paragraphs.

Lichen sclerosus (also spelled sclerosis) of the vulva may occur in any age group, including children (Fig. 30.3).[47] In the latter group, the vulvar region represents the most common location, and there is a high incidence of spontaneous involution at the time of puberty.[48] The microscopic features are similar but not identical to those seen in this disorder when it occurs elsewhere in the skin (see Chapter 2) (Fig. 30.4). It has been stated that the minimal histologic criteria for the microscopic diagnosis of lichen sclerosus (LS) are the presence

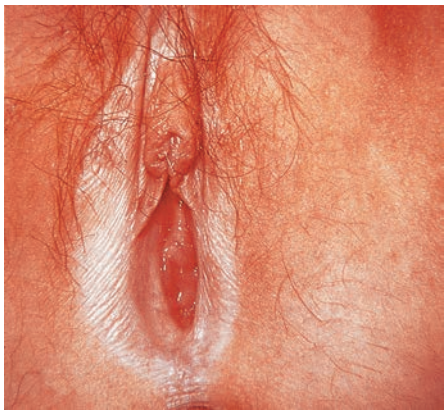

Figure 30.3 Clinical appearance of vulvar lichen sclerosus.

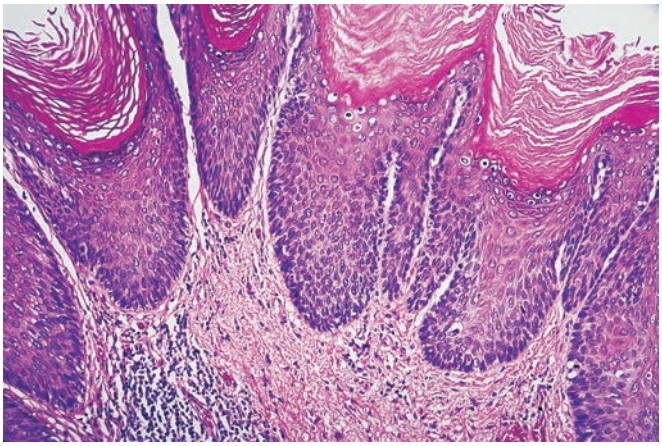

Figure 30.2 Lichen simplex chronicus, with hyperkeratosis, epidermal hyperplasia, and chronic inflammation of the underlying stroma. There is no significant atypia.

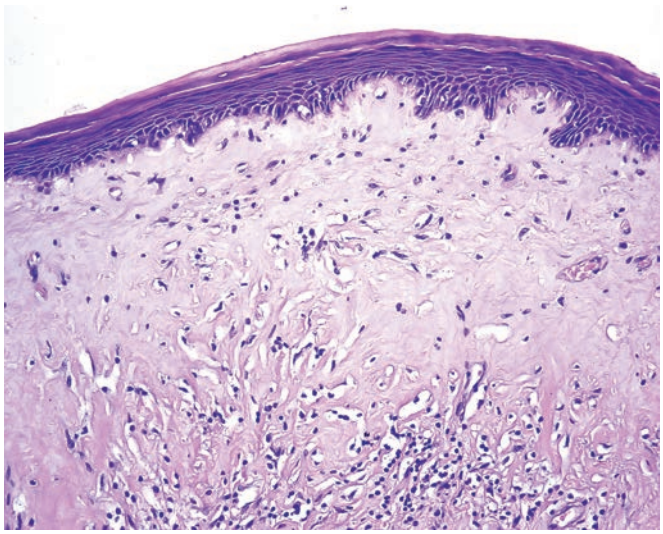

Figure 30.4 Lichen sclerosus of vulva. A thick hypocellular edematous layer is bounded by atrophic epidermis on one side and inflamed stroma on the other.

of a vacuolar interface reaction pattern in conjunction with dermal sclerosis (homogenized and hyalinized eosinophilic collagen bundles) of any thickness in between the inflammatory infiltrate and the epithelium and/or vessel walls.[49] In the early stages, LS may be difficult to diagnose as it may be indistinguishable from lichen planus.[50] In such cases, the differential diagnosis should be noted, and it can be indicated in the pathology report that with follow-up it will declare itself to be either lichen planus or LS, as in LS the pathognomonic superficial hyalinized collagen will appear. The diagnostic alterations of early LS may be very subtle and often are more prominent in adnexal structures than in the interfollicular skin.[51] The overlying epidermis is characteristically atrophic, but on occasion it may show foci of hyperplasia[52]; however, the presence of hyperplasia in LS, especially as a focal finding, forming a clinically recognizable discrete lesion with an abrupt change from the adjacent atrophic epithelium, should always raise the differential diagnosis of dVIN arising in LS. The presence of basal atypia and altered maturation (loss of the granular cell layer) in the hyperplastic focus is evidence supporting a diagnosis of dVIN.

It is now accepted that LS is a precancerous condition, associated with an increased risk of developing dVIN and HPV-independent squamous cell carcinoma. The risk, however, is relatively small. In one series, squamous cell carcinoma developed in only one of 92 patients,[53] and in another it was found in 12 (4%) of 290 patients followed for a mean period of 12.5 years.[54] In a large (n = 507) prospective study of patients with LS, 0 of 357 patients who were compliant with treatment recommendations developed invasive squamous cell carcinoma or VIN, compared to 7 of 150 patients who were not fully compliant.[55] While many invasive HPV-independent vulvar squamous cell carcinomas are seen in a background of LS at the time of diagnosis, newly diagnosed LS (in the absence of neoplasia) can be managed medically with a relatively low risk of progression. The designation "atypical LS" has been used for cases of LS where there is basal atypia of the atrophic epithelium, greater than would be expected in usual LS.[56] Atypical LS has been reported to show overexpression of p53,[56,57] and atypical LS may well be a step in the pathway towards development of dVIN, but we do not have the ability to render the diagnosis of atypical LS reproducibly, nor do we understand its clinical significance; therefore, it cannot be considered to be a robust clinically relevant diagnosis. In practice, the presence of basal atypia in LS should be documented in the Comment field of the surgical pathology diagnostic report, indicating that it may be associated with increased likelihood of malignant transformation, with recommendation for close follow-up.

Human Papilloma Virus and Vulvar Pathology

The role of HPV in vulvar pathology is analogous to the one it plays in the vagina and cervix, and is discussed in detail in connection with the latter (see Chapter 32). In the vulva, this includes condyloma (acuminatum and flat), as well as high-grade squamous intraepithelial lesion (HSIL) VIN2/3 and HPV-associated invasive squamous cell carcinoma. The vulva differs from the cervix in that there are a significant number of HPV-independent squamous cell carcinomas, unlike in cervix, where virtually all squamous cell carcinomas are HPV-associated. It is becoming apparent that the HPV-independent intraepithelial and invasive squamous cell neoplasms are more aggressive than their HPV-associated counterparts in the vulva.[58–60] Accordingly, attention will be paid to the differences (histopathologic and natural history) between these two subtypes of vulvar squamous neoplasia, which are summarized in Table 30.1. With respect to diagnosis, immunostaining for p16INK4a has emerged as a sensitive and specific surrogate for detection of HPV-associated versus HPV-independent vulvar squamous neoplasia, with sensitivity of 100% and specificity of 98%–99%.[61,62]

Table 30.1 Human Papilloma Virus-dependent and Human Papilloma Virus-independent Vulvar Intraepithelial Neoplasia and Vulvar Squamous Cell Carcinoma

	HPV-ASSOCIATED	HPV-INDEPENDENT
Prevalence in VIN without invasive carcinoma	87%	13%
Prevalence in invasive squamous cell carcinoma	29%	71%
Age (peak incidence)	Sixth decade	Eighth decade
Histologic features of precursor	HSIL (VIN2/3)	Differentiated VIN (dVIN)
Histologic type of invasive carcinoma	Warty/basaloid	Well-differentiated keratinizing
Lichen sclerosus	Generally absent	Often present
Nonsurgical treatment of VIN	Imiquimod and other antiviral/ immunomodulatory treatments effective	No role for antiviral treatment
Survival/prognosis	Less aggressive	Significantly higher recurrence rates and mortality

dVIN, Differentiated vulvar intraepithelial neoplasia; *HPV*, human papilloma virus; *HSIL*, high-grade squamous intraepithelial lesion; *VIN*, vulvar intraepithelial neoplasia.

Staining is most reliably performed on intraepithelial lesions or early invasive carcinomas, as p16 expression can be lost during tumor progression. Polymerase chain reaction (PCR) for HPV DNA allows for viral genotyping and is highly sensitive, but lacks specificity.[60] In situ hybridization for HPV is highly specific, but is more expensive than immunostaining and has a longer turnaround time; however, it can be valuable in establishing HPV status for those cases where the clinical, histomorphologic, and p16 immunostaining data are not concordant.[62] Detection of mRNA of HPV oncogene E6 can be used to establish an etiologic role for HPV by demonstrating that the virus genome is being transcribed. However, such testing is not widely available, and p16 immunostaining is currently the most important surrogate test of HPV status.

Condyloma and Seborrheic Keratosis

Vulvar **condyloma** is a venereal disease caused by HPV, usually type 6. Although according to the 2012 Lower Anogenital Squamous Terminology (LAST) recommendations, these lesions should be diagnosed as (VIN1) (low-grade squamous intraepithelial lesion [LSIL]),[63] the diagnosis of condyloma is well established, while a diagnosis of LSIL may lead to confusion. The diagnosis of VIN1 was not used for vulvar lesions for the 8 years prior to the LAST recommendations, as the 2004 International Society for the Study of Vulvar Diseases had dropped it from recommended terminology as it was generally accepted to not have a specific meaning. It was instead viewed as a collection of different conditions, including low-risk HPV infection.[64] While we are able to endorse LSIL (CIN1) for cervical

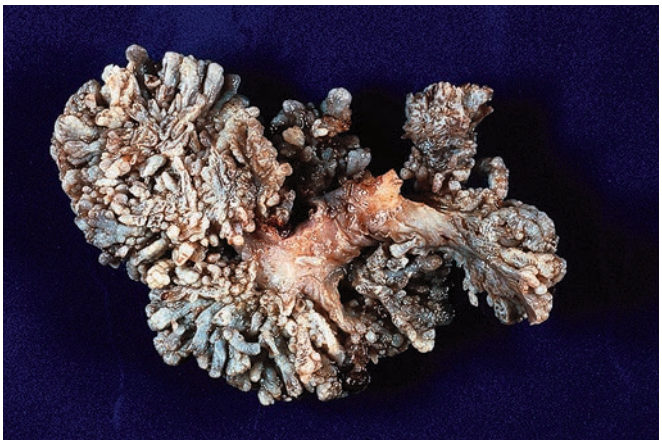

Figure 30.5 Large condyloma of vulva.

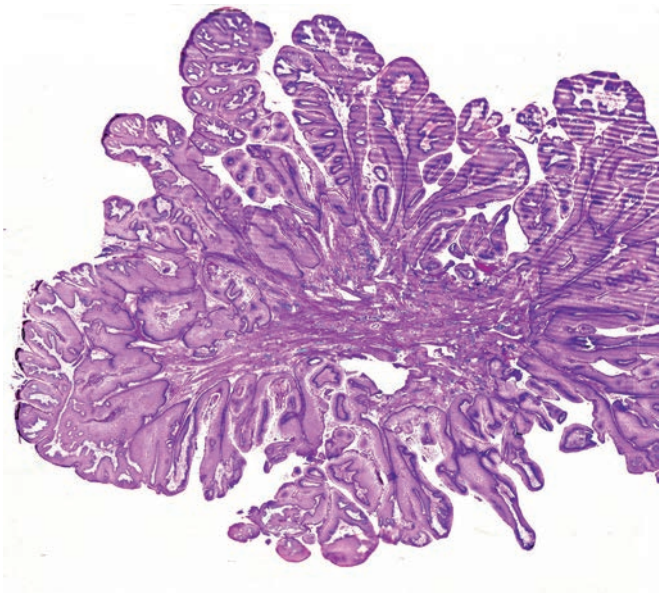

Figure 30.6 Whole mount of condyloma acuminatum of vulva.

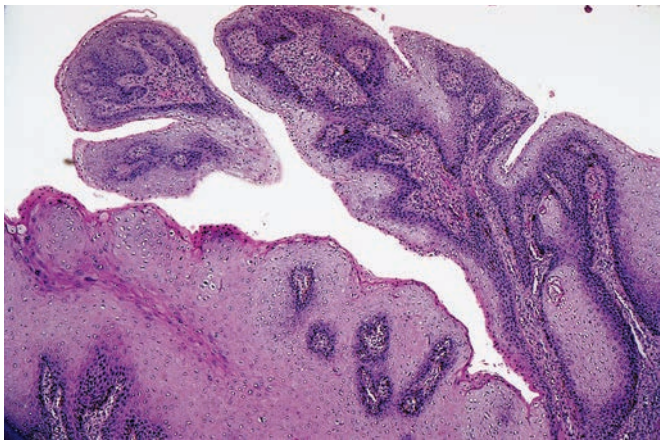

Figure 30.7 Papillomatous shape of vulvar condyloma.

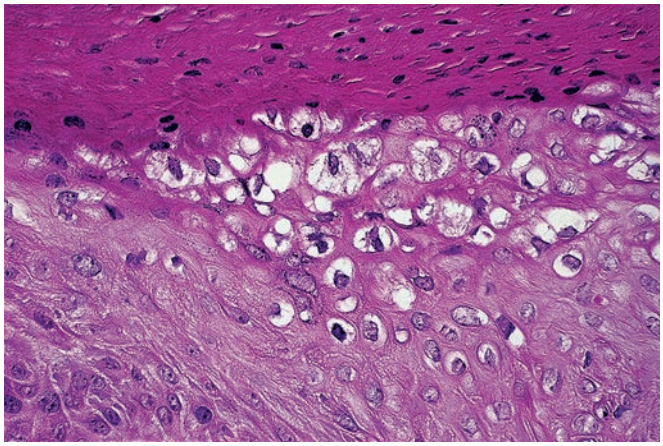

Figure 30.8 Prominent koilocytotic changes in vulvar epithelium.

lesions, we do not recommend adopting this terminology for condylomatous vulvar lesions, and recommend, instead, the diagnosis of "condyloma." The better-known form of condyloma is **condyloma acuminatum,** which is characterized grossly by one or several soft elevated masses of variable size (Fig. 30.5). Microscopically there is a complicated papillary arrangement of well-differentiated undulating squamous epithelium supported by delicate, well-vascularized connective tissue stalks containing mononuclear inflammatory cells (mainly CD4+ and CD8+ cells) (Figs. 30.6 and 30.7).[65] The other form of condyloma, which is actually much more common, is the **flat condyloma** (not to be confused with the *condyloma latum* of syphilis). The cytologic features are similar in both forms. Koilocytosis of the malpighian epithelium and lymphocytic infiltration of the stroma are regular features (Fig. 30.8). Koilocytosis refers to the combination of perinuclear cytoplasmic clearing and wrinkling of the nuclear membrane (nuclear "raisins"). As a rule, this change is not as florid in vulvar condylomas as it tends to be in condylomas of the cervix. A typical condyloma shows minimal basal or parabasal cell atypia, orderly maturation, and a smooth transition to koilocytotic intermediate and superficial cells; mitoses may be numerous but are all typical.[66,67] In contrast, the lesions of VIN2/3 exhibit abnormal mitoses and nuclear pleomorphism, enlargement, and hyperchromasia in the basal and parabasal cell layers, as well as "block positivity" on p16 immunostaining, with strong nuclear and cytoplasmic immunoreactivity in all cells of at least the basal third of the epithelium, but with positivity usually extending into the upper half (see later section). The increased proliferative activity of condyloma (in contrast to fibroepithelial polyp and squamous papilloma) can be easily appreciated with the Ki-67 stain.[68] The DNA content of condylomas is diploid and polyploid (including tetraploidy and octaploidy), in contrast to the aneuploid pattern seen in most cases of VIN2/3.[69]

Sometimes one sees verrucopapillary vulvar lesions that lack the viral cytopathic effects (koilocytic change) of condyloma; these are often referred to as *squamous papillomas* and usually contain genital HPV types by PCR.[70] Conversely, there may be multinucleated atypia of the epithelial squamous cells associated with reactive conditions in the absence of HPV infection.[71] A final consideration in the diagnosis of condyloma in children is that verruca vulgaris, due to HPV2, can occur on the vulva of children and be morphologically indistinguishable from condyloma.[72] It is therefore important to exercise caution in diagnosing condyloma in children (with the implication of a venereal infection/sexual abuse). We recommend that HPV testing to document genital-type HPV be required to support a diagnosis of condyloma in this setting. Another vulvar lesion which needs to be discussed here is the process morphologically indistinguishable from cutaneous seborrheic keratosis, which in this particular

location is usually associated with HPV infection.[73] The differential diagnosis of condyloma also includes a lesion characterized by *epidermolytic hyperkeratosis*, which could be related to Darier disease or represent a form of Hailey–Hailey disease.[74] The acantholysis is usually suprabasal, but we have also seen it at the level of the granular layer. A final important differential diagnosis is verrucous carcinoma. Despite the name, verrucous carcinoma is not associated with HPV and is part of the spectrum of non-HPV-associated vulvar squamous neoplasia; it is distinguished from condyloma by examination of the epidermal/dermal junction. Verrucous carcinoma is characterized by a distinctive pattern of bulbous downgrowths with pushing margins, and will be discussed in greater detail later in this chapter.

The traditional therapy for condyloma consisted of podophyllin application. Microscopically, this results in epidermal pallor, necrosis of keratinocytes, and marked increase in mitosis; these changes wane after 72 hours and are essentially gone in 1 week.[75] Occasionally, similar microscopic changes are seen in the absence of podophyllin therapy.[76] The treatment of choice for these lesions at present is carbon dioxide laser.[77]

Squamous Intraepithelial Lesions

It is now appreciated that squamous neoplasia of the vulva can be subclassified into HPV-associated and HPV-independent forms, which differ with respect to etiology, age at diagnosis, natural history, and morphology (i.e., they are different diseases). These differences are summarized in Table 30.1. In North America, most preinvasive lesions (VIN) are HPV-associated (HSIL) (VIN2/3) rather than dVIN, while most invasive squamous cell carcinomas are HPV-independent; this is thought to reflect the more rapid progression of dVIN to invasive carcinoma.[60] The presence of an admixture of HPV-associated and HPV-independent squamous neoplasia in the vulva is in contrast to the uterine cervix or vagina, where virtually all squamous neoplasia is HPV-associated. Because of the histopathologic differences between HPV-associated and HPV-independent squamous neoplasia (both intraepithelial and invasive), they will be considered separately in the following sections. It is important to acknowledge that clinical and morphologic features (based on examination of H&E stained slides) cannot distinguish between HPV-associated and HPV-independent squamous neoplasia in every case; however p16 immunostaining is a sensitive (100%) and specific (>98%) marker of HPV-associated squamous neoplasia in the vulva.[61,62] Interpretation of p16 immunostaining, as for cervical lesions, is based on the presence or absence of "block" positivity, defined as intense nuclear and cytoplasmic staining of *every* cell in the basal third of the epithelium (Fig. 30.9). p16 positivity, so defined, is evidence of HPV-associated VIN or invasive squamous cell carcinoma. Note that p16 staining intensity often decreases in the superficial layers of HSIL (VIN2/3), as the neoplastic squamous epithelium undergoes maturation.

Human Papilloma Virus-Associated Squamous Intraepithelial Neoplasia: High-Grade Squamous Intraepithelial Lesion (VIN2/3)

The in situ or pre-invasive lesion of HPV-associated vulvar squamous neoplasia is, as noted previously, referred to as HSIL or high-grade vulvar intraepithelial neoplasia (VIN2/3) and is entirely analogous to equivalent lesions in the vagina (VaIN2/3), cervix (CIN2/3), or anal mucosa (AIN2/3).[63] The recommended terminology for preinvasive lesions associated with oncogenic HPV (most commonly HPV16 or 18, but a number of other oncogenic HPV genotypes have also been reported), according to the LAST recommendations, is HSIL (VIN2 or VIN3).[63] In practice, it is not possible to reproducibly distinguish between VIN2 and VIN3, nor is the distinction clinically relevant. It has been proposed that VIN2 be used for cases where the "dysplasia" does not extend into the upper third of the squamous epithelium, while VIN3 be diagnosed in cases with full-thickness or near-full-thickness dysplasia; biologically this is a curious proposition, as all cells in VIN2/3 are neoplastic and transformed by oncogenic HPV (i.e., the full thickness of the epithelium is replaced by a clonal neoplastic proliferation, irrespective of whether there is some degree of flattening or maturation of the superficial cells). Any distinction between VIN2 and VIN3, accordingly, is arbitrary, and one may simply call all such cases VIN3 or VIN2/3, in practice. If this seems a touch iconoclastic, it is worth noting that according to the 2004 recommendations of the International Society for the Study of Vulvovaginal Disease, the diagnosis of "high-grade VIN" was used for all lesions that would be diagnosed as VIN2 or VIN3 according to the LAST criteria,[64] and many of us used this simplified system for almost a decade and found it entirely satisfactory.

HSIL (VIN2/3) usually presents as a slightly elevated, plaque-like lesion with a red velvety appearance.[78] It is typically centered in the labia majora, and it may extend to the perineum and anus. Microscopically, there is hyperkeratosis and parakeratosis, acanthosis, and a variable number of multinucleated dyskeratotic cells and abnormal mitoses involving the entire thickness of the epidermis (Fig. 30.10). The acrotrichium (intraepidermal portion of the hair follicle) is often involved, whereas the acrosyringium (intraepidermal portion of the sweat gland) is usually spared.[79,80] On occasion, the tumor cells are arranged in a nested pattern and/or have a clear cytoplasm, thus simulating Paget disease.[81,82] The lesions of HSIL (VIN2/3) may be uniformly composed of cells with high N:C ratio (basaloid pattern VIN2/3) or there may be maturation as the cells move toward the

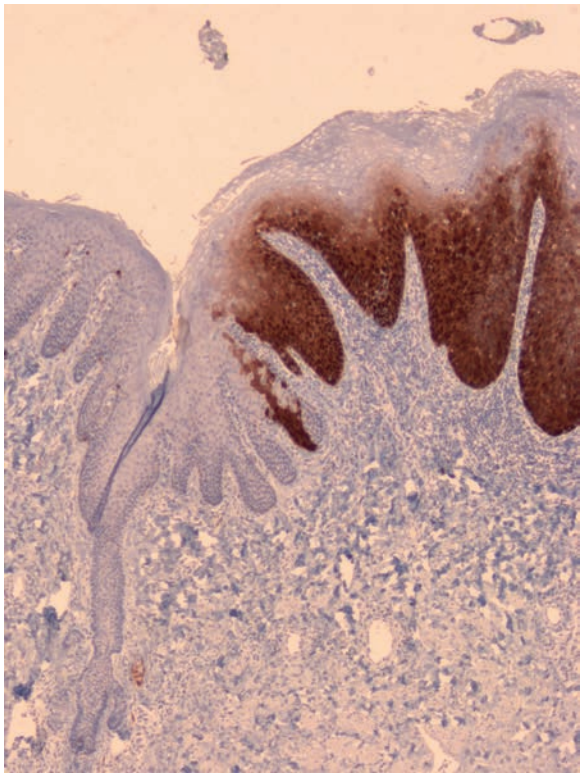

Figure 30.9 "Block" immunoreactivity for p16, with strong nuclear and cytoplasmic staining of all cells of at least the basal third of the epithelium, in HSIL (VIN2/3), as a surrogate test for the presence of oncogenic HPV.

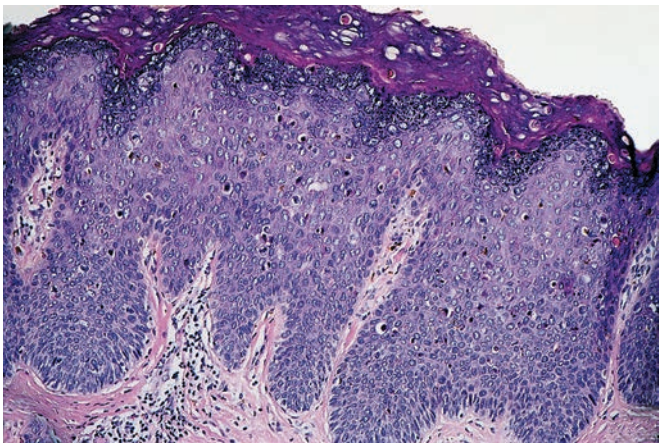

Figure 30.10 Typical microscopic appearance of HSIL (VIN2/3).

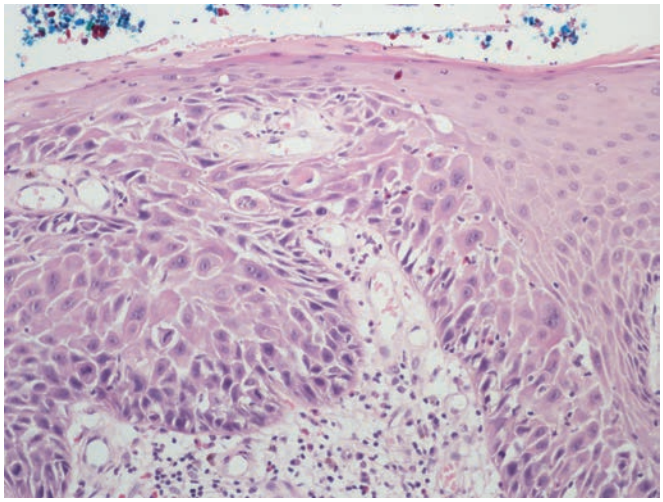

Figure 30.11 Differentiated VIN (dVIN), showing basal epithelial atypia.

surface, with epithelial hyperplasia and koilocytic change (warty pattern VIN2/3). This latter pattern can mimic condyloma but shows greater atypia, as well as block p16 positivity.

The type of HSIL (VIN2/3) that was, historically, designated as *bowenoid papulosis* presents as multiple, often pigmented, papules in or near the vulva of young patients. Clinically, they resemble verrucae, small condylomas, or nevi, but microscopically they show striking cytologic atypia, similar to that of Bowen disease/usual HSIL.[83] It is important to note that the terms Bowen disease and Bowenoid papulosis may be used clinically but the pathologic diagnosis is HSIL (VIN2/3) for both, as there are no histopathologic features for reliably distinguishing between them. The designations of "warty" or "basaloid" VIN similarly are not routinely used in practice, as they are not of clinical significance.

It has been stated that, if left untreated, HSIL (VIN2/3) will progress into invasive carcinoma in approximately 10% of cases, but the rate of transformation varies widely among the different series.[84] The therapy for HSIL (VIN2/3) depends on the age of the patient and the size, configuration, and distribution of the lesions.[84] Localized lesions can be treated by wide local excision, skinning vulvectomy, laser, or topical therapy.[85] Imiquimod, an immune-response modulator, can be used to treat HSIL (VIN2/3), with many lesions showing a response, sometimes a complete response.[86]

It is anticipated that with increasingly widespread use of vaccination against HPV, cases of HSIL (VIN2/3) will start to decrease in the coming years. It has been increasing, especially in younger women. The frequent history of an abnormal cervical smear is important, and all patients with a past history of HSIL or HPV-associated squamous cell carcinoma elsewhere in the lower anogenital tract are at increased risk for vulvar disease.

Human Papilloma Virus-Independent Squamous Intraepithelial Neoplasia: Differentiated Vulvar Intraepithelial Neoplasia

VIN of differentiated type (dVIN) is consistently negative for HPV, arises in elderly women, is frequently associated with squamous hyperplasia and LS, and is related to invasive squamous cell carcinoma of keratinizing type.[56,87–89] Microscopically, it is characterized by (1) epidermal hyperplasia with parakeratosis and elongated and anastomosing rete ridges, (2) significant basal cytologic atypia, and (3) cells with abundant eosinophilic cytoplasm (Fig. 30.11).[89] It is increasingly appreciated that dVIN is under-recognized in clinical practice, as the aforementioned changes may not all be present or may be subtle.[90,91] Immunostaining is of limited use as a diagnostic adjunct, as Ki-67 staining intensity overlaps with that of reactive conditions in the differential diagnosis, and there is a variable pattern of p53 expression; while some cases show complete loss or convincing overexpression of p53, consistent with underlying *TP53* mutations, this is not a consistent finding.[89,92–94] p16 immunostaining is consistently negative (i.e., lacking the block positivity associated with oncogenic HPV-associated VIN). It is important to note that HPV-independent VIN may be higher grade and may even mimic the basaloid pattern seen in HSIL (VIN2/3).[95] This variant of HPV-independent VIN can be distinguished from HPV-associated HSIL (VIN2/3) by p16 immunostaining; as well, it typically shows abnormal p53 immunoreactivity (complete absence or strong diffuse positivity), in our experience. What to call such a lesion is another matter, as it is not adequately addressed in current classification systems. Poorly differentiated dVIN presents itself as a potential designation (to join other oxymoronic diagnoses such as large cell variant of small cell carcinoma or oxyphilic variant of clear cell carcinoma), but it may be preferable to simply diagnose it as an HPV-independent high-grade squamous intraepithelial lesion and explain the unconventional terminology in the comment field of your report. dVIN is infrequently diagnosed in the absence of invasive squamous cell carcinoma, suggesting that it progresses rapidly to invasion. This view is supported by a small case series of dVIN without invasive carcinoma, where most patients developed invasive carcinoma, with a median interval between diagnosis of dVIN and invasive carcinoma of 1.9 years, a significantly worse outcome than for HSIL (VIN2/3).[60]

Vulvar acanthosis with altered differentiation (VAAD) is characterized by marked acanthosis, a variable verruciform architecture, loss of the granular layer, cytoplasmic pallor at the surface, and multilayered parakeratosis. It has been suggested that VAAD (which is consistently negative for HPV) may be a precursor or a risk factor for verrucous carcinoma.[96]

Invasive Squamous Cell Carcinoma

General Features

Squamous cell carcinoma accounts for approximately 95% of the malignant tumors of this organ.

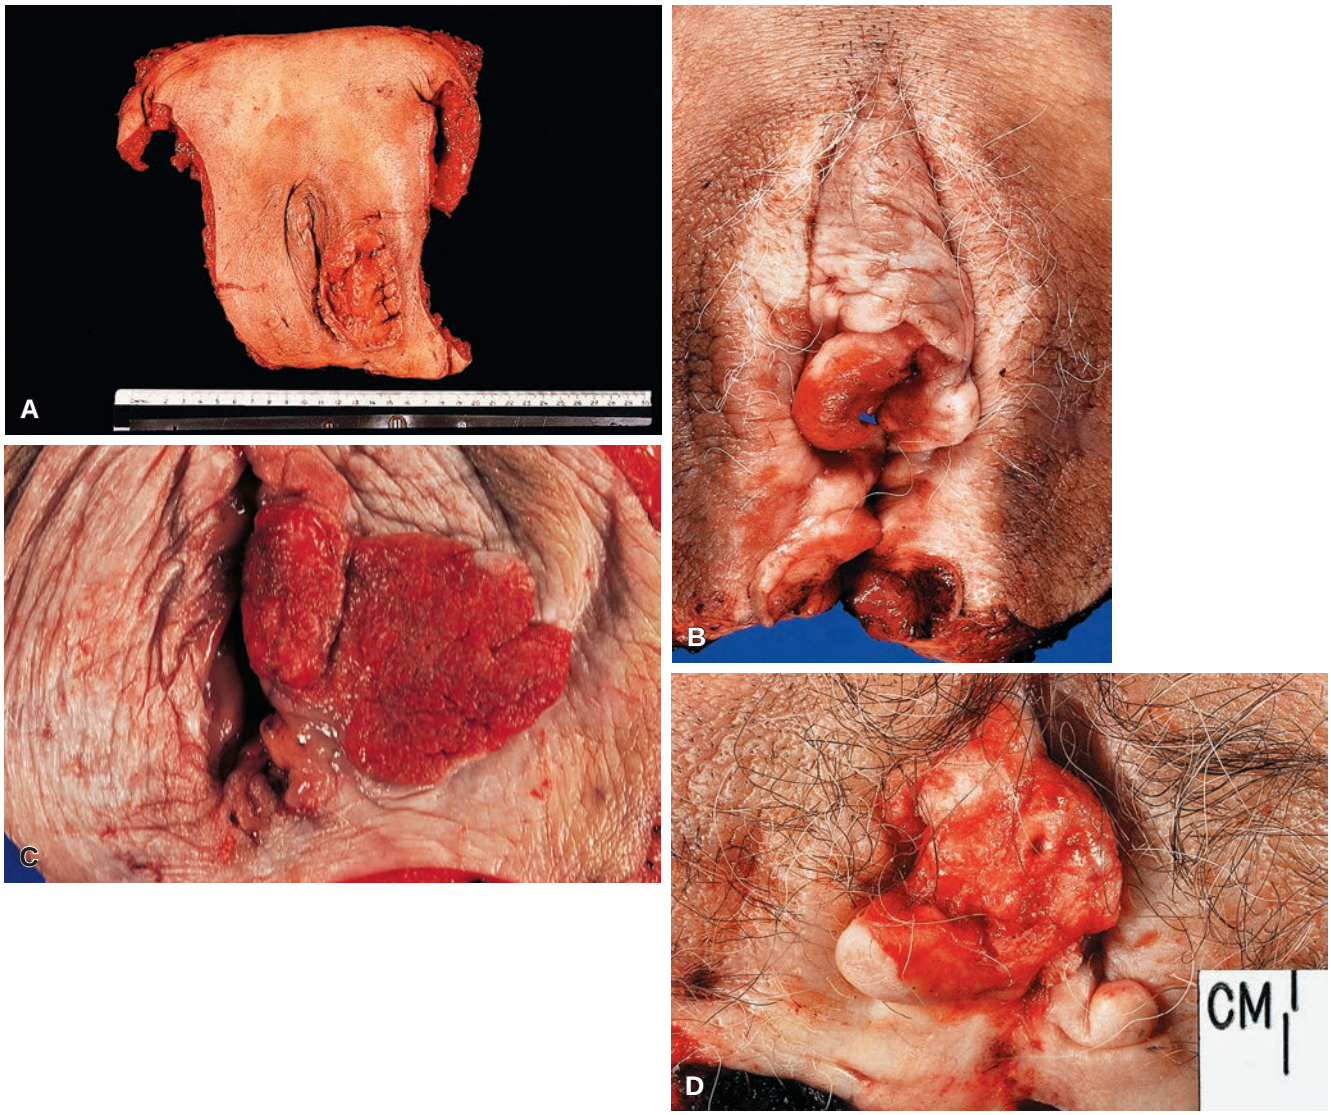

Figure 30.12 Gross Appearance of Invasive Squamous Cell Carcinoma of Vulva. A, Tumor of labium majus. **B**, Tumor of clitoris. **C**, Tumor involving both labia. **D**, Huge tumor mass involving all vulvar structures.

Invasive squamous cell carcinoma of the vulva arises most commonly on the labia majora but may be found on the labia minora or in the region of the clitoris (Fig. 30.12).[97] The immunohistochemical features of vulvar squamous cell carcinoma are not distinctive.

Human Papilloma Virus-Associated Invasive Squamous Cell Carcinoma

HPV-associated invasive squamous cell carcinomas are less common than HPV-independent carcinomas of the vulva.[98,99] Patients with HPV-associated disease are, on average, a decade or more younger than those with HPV-independent tumors, and they often have a history of prior cervical cytology abnormality, cervical intraepithelial neoplasia (CIN), or cervical carcinoma. It is curious that the vulvar squamous cell carcinomas that develop after a successfully treated cervical squamous cell carcinoma appear to be derived from the same malignant clone, but behave more like an independent primary vulvar carcinoma than a metastasis.[100] HPV-associated squamous cell carcinomas are more common in patients who are immunocompromised. Morphologically, most HPV-associated carcinomas are of basaloid or warty pattern (Fig. 30.13); however a significant minority are well or moderately differentiated keratinizing carcinomas,[62] and thus are morphologically indistinguishable from HPV-independent carcinomas. Warty-pattern carcinoma[101] should not be confused with verrucous carcinoma, despite the fact that the gross appearance of the latter has sometimes been described as "warty." The term "warty pattern carcinoma," if used at all, should be reserved for the squamous cell carcinomas in which the tumor cells display marked pleomorphism, enlargement, atypia, and multinucleation. These features are often associated with koilocytotic atypia in the adjacent epithelium. Basaloid-pattern carcinoma[101] has an appearance analogous to its counterpart in the upper aerodigestive tract and penis. Peripheral palisading is prominent (see Fig. 30.13). Typical HSIL (VIN2/3) may be found adjacent to the invasive carcinoma, and is strong evidence that the carcinoma is HPV-associated.

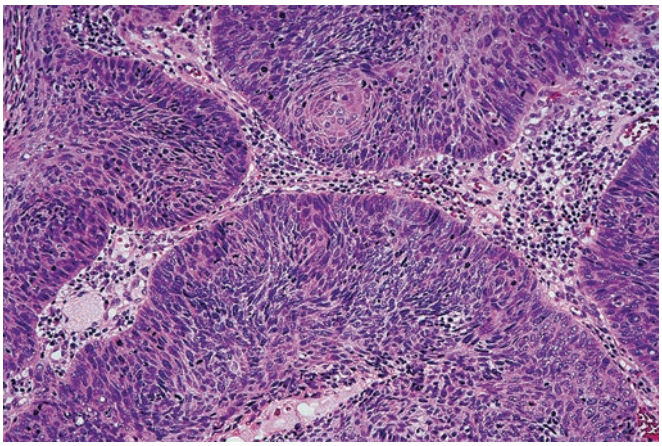

Figure 30.13 Basaloid-pattern invasive squamous cell carcinoma of vulva, a pattern typical of HPV-associated vulvar squamous cell carcinoma. Note the peripheral palisading and deep basophilic staining pattern.

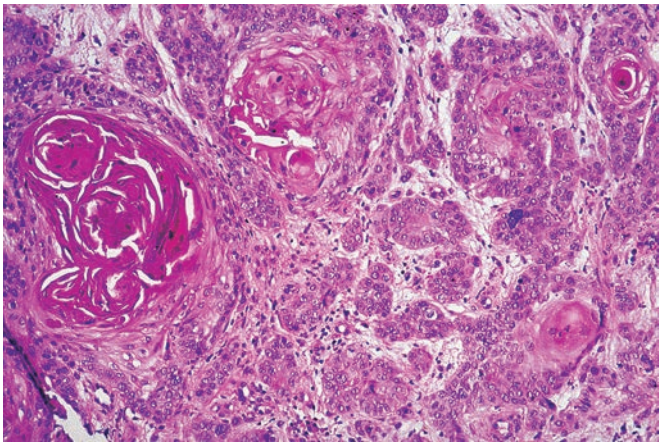

Figure 30.14 Microscopic appearance of invasive well-differentiated keratinizing squamous cell carcinoma of vulva. Such tumors are typically HPV-independent.

Human Papilloma Virus-Independent Invasive Squamous Cell Carcinoma

HPV-independent vulvar squamous cell carcinoma occurs in older women and often is in the setting of lichen sclerosus. Most HPV-independent squamous cell carcinomas are well or moderately differentiated keratinizing squamous cell carcinomas (Fig. 30.14). dVIN may be present at the edge of the lesion, a finding that supports the interpretation that you are dealing with an HPV-independent squamous cell carcinoma. HPV-independent squamous cell carcinoma may be high-grade and, rarely, sarcomatoid, either at presentation or with progression from a more differentiated carcinoma, in the course of recurrence(s). Verrucous carcinoma is a distinctive variant of HPV-independent carcinoma, and will be discussed in a later section.

Spread and Metastases

Regional lymph node metastases occur in approximately 20% of cases.[102] Tumors of the labia spread first to inguinal lymph nodes, whereas those located in the clitoris may metastasize directly into the deep nodes. It should be noted that ulceration and inflammation in vulvar carcinoma often lead to reactive enlargement of inguinal lymph nodes, which may be confused clinically with metastatic disease, so clinical assessment of nodal status is unreliable.

The technique of sentinel lymph node biopsy is used as a staging criterion and therapeutic guide for vulvar carcinoma,[103] and this procedure is highly accurate in predicting the inguinofemoral lymph node status of those patients.[104] The optimal protocol for handling sentinel nodes upon receipt in the laboratory, and the significance of micrometastases or isolated tumor cells, specifically with respect to sentinel nodes associated with vulvar squamous cell carcinoma, remain to be determined; however, the eighth edition of the American Joint Committee on Cancer's *AJCC Cancer Staging Manual* now includes a pN0(i+) category for isolated tumor cells (Table 30.2).[105]

Therapy

The usual treatment of invasive carcinoma is radical vulvectomy with bilateral radical inguinal lymph node dissection.[106] Iliac lymphadenectomy and pelvic exenteration are reserved for advanced cases.[107] Conversely, early cases can be treated with a more conservative approach in the form of wide local excision;[108] it has been shown that leaving a 1-cm tumor-free surgical margin results in a high rate of local control.[109] Alternative methods include radiation therapy (either alone or together with chemotherapy[110]) and the combination of wide local excision and radiation therapy.[111,112]

Prognosis

The overall 5-year survival rate in patients treated for vulvar squamous cell carcinoma has been in the 50%–75% range in most large series.[112–114]

1. *Stage*. The most important prognostic factors are included in the staging system and are represented by *tumor diameter*, *depth of invasion*, and *lymph node status*.[109,113,114,115–117] The latter is by far the most significant parameter.[118,119]
2. *Extracapsular nodal spread*. In cases with involved nodes, the presence of extracapsular spread and large size of the metastatic focus are poor prognostic indicators.[120,121]
3. *HPV status.* As noted previously, HPV-associated vulvar carcinomas are associated with a more favorable prognosis, as has also been seen for squamous cell carcinomas of the head and neck. Infiltrative margins,[122,123] fibromyxoid stromal response,[124] and abnormal p53 immunostaining[125,126] are all features that are reported to be prognostic indicators, but also are associated with HPV-independent carcinomas, so it is not clear whether their prognostic significance is independent of HPV status.

Superficially Invasive Squamous Cell Carcinoma

The term *superficially invasive squamous cell carcinoma* is a "Histologic Type" designation in the widely used 2016 update to the College of American Pathologists Protocol for Examination of Specimens from Patients with Carcinoma of the Vulva.[127] This refers to those carcinomas in which the depth of penetration is less than 1 mm (see Fig. 30.13). **Depth of invasion in vulvar carcinoma is the measurement in millimeters from the epithelial-stromal junction of the adjacent, most superficial dermal papilla to the deepest point of invasion.** It should be noted, with humility, that there is suboptimal reproducibility in pathologists' assessments of whether there is invasion, and in measuring the depth of invasion; when 11 pathologists reviewed 50 cases, the number considered to show invasive squamous cell carcinoma ranged from 21 to 44, depending

Table 30.2 Definitions of American Joint Committee on Cancer TNM: Vulva

DEFINITION OF PRIMARY TUMOR (T)		
T CATEGORY	**FIGO STAGE**	**T CRITERIA**
TX		Primary tumor cannot be assessed
T0		No evidence of primary tumor
T1	1	Tumor confined to the vulva and/or perineum Multifocal lesions should be designated as such. The largest lesion or the lesion with the greatest depth of invasion will be the target lesion identified to address the highest pT stage. Depth of invasion is defined as the measurement of the tumor from the epithelial-stromal junction of the adjacent most superficial dermal papilla to the deepest point of invasion.
T1a	IA	Lesions 2 cm or less, confined to the vulva and/or perineum, and with stromal invasion of 1.0 mm or less.
T1b	IB	Lesions >2 cm, or any size with stromal invasions of >1.0 mm, confined to the vulva and/or perineum
T2	II	Tumor of any size with extension to adjacent perineal structures (lower/distal third of the urethra, lower/distal third of the vagina, anal involvement)
T3	IVA	Tumor of any size with extension to any of the following—upper/proximal two-thirds of the urethra, upper/proximal two-thirds of the vagina, bladder mucosa, or rectal mucosa—or fixed to pelvic bone
DEFINITION OF REGIONAL LYMPH NODE (N)		
N CATEGORY	**FIGO STAGE**	**N CRITERIA**
NX		Regional lymph nodes cannot be assessed
N0		No regional lymph node metastasis
N0(i+)		Isolated tumor cells in regional lymph node(s) no >0.2 mm
N1	III	Regional lymph node metastasis with one or two lymph node metastases each <5 mm, or one lymph node metastasis ≥ 5 mm
N1a[a]	IIIA	One or two lymph node metastases, each <5 mm
N1b	IIIA	One lymph node metastasis = 5 mm
N2		Regional lymph node metastasis with three or more lymph node metastases, each <5 mm, or two or more lymph node metastases = 5 mm, or lymph node(s) with extranodal extension
N2a[a]	IIIB	Three or more lymph node metastases, each <5 mm
N2b	IIIB	Two or more lymph node metastases ≥ 5 mm
N2c	IIIC	Lymph node(s) with extranodal extension
N3	IVA	Fixed or ulcerated regional lymph node metastasis
DEFINITION OF DISTANT METASTASIS (M)		
M CATEGORY	**FIGO STAGE**	**M CRITERIA**
M0		No distant metastasis (no pathologic M0; use clinical M to complete stage group)
M1	IVB	Distant metastasis (including pelvic lymph node metastasis)

[a]Includes micrometastasis, N1mi and N2mi.
Note: The site, size, and laterality of lymph node metastases should be recorded.

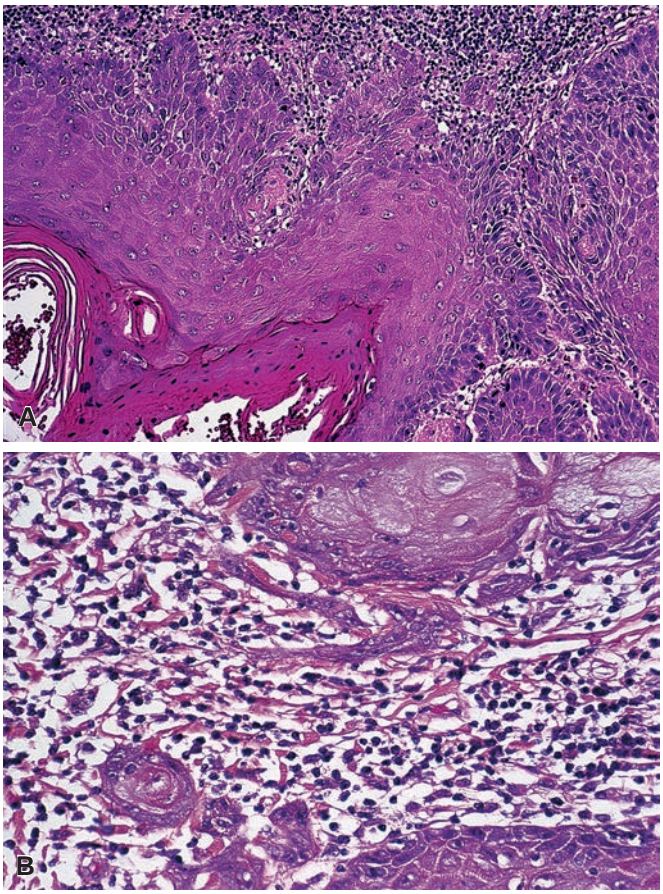

Figure 30.15 Superficial Invasive Squamous Cell Carcinoma. **A**, Low-power appearance. **B**, High-power view, showing small clusters of tumor cells detaching from the in situ component and invading a heavily inflamed stroma. All invasive cells are present within 1 mm of the overlying epidermal-dermal junction.

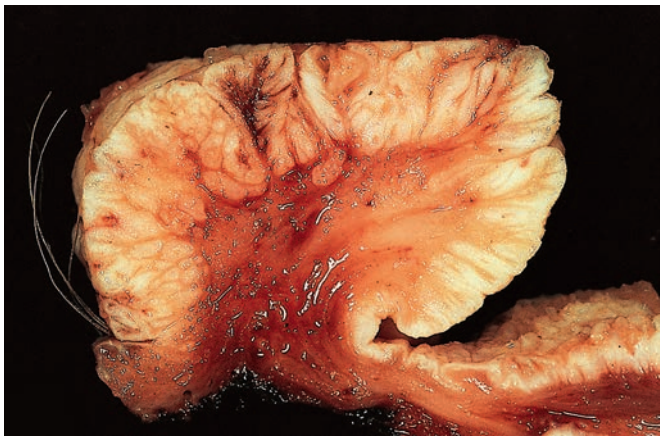

Figure 30.16 Cut surface of verrucous carcinoma of vulva. (Courtesy of Dr Pedro J Grases Galofré; from Grases Galofré PJ. Patología ginecológica. *Bases para el diagnóstico morfológico.* Barcelona: Masson; 2002)

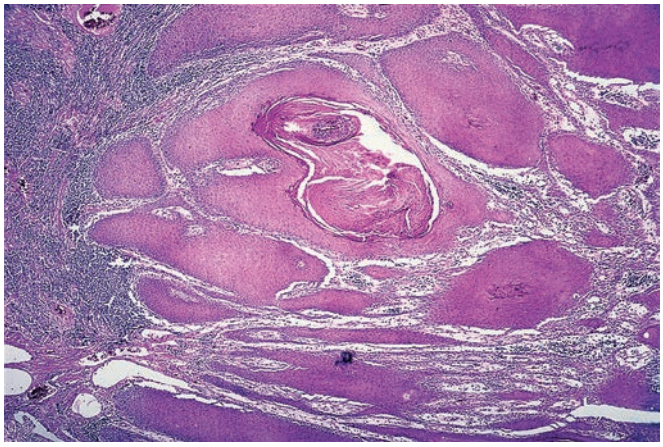

Figure 30.17 Bulbous pegs of well-differentiated squamous cells infiltrate the stroma in vulvar verrucous carcinoma.

on the reviewing pathologist.[128] This limitation notwithstanding, in those tumors where depth of invasion is considered to be less than 1 mm (Fig. 30.15), consideration can be given to forgoing lymph node sampling, although some oncologists would offer even these patients sentinel lymph node biopsy.

Verrucous carcinoma is a reasonably distinctive type of squamous cell carcinoma of the vulva, similar to its more common counterpart in the upper aerodigestive tract. It may grow to quite large dimensions, has a typical exophytic appearance, and infiltrates locally (Figs. 30.16 and 30.17). Metastases are practically nonexistent,[129,130] and therefore inguinal lymphadenectomy is not indicated.

The differential diagnosis of verrucous carcinoma includes condyloma acuminatum and conventional squamous cell carcinoma. It is distinguished from the former by its generally larger size and the presence of club-shaped fingers of epithelium invading the underlying stroma in a well-circumscribed ("pushing") fashion.[131] The distinction from squamous cell carcinoma rests entirely on two criteria, which often go together: the presence in the latter of cytologic atypia and/or a clearly infiltrative pattern of growth. The occurrence of either of these features removes the lesion from the verrucous carcinoma category and puts it into the squamous cell category. Immunohistochemically, staining for keratin is more uniform and homogeneous in verrucous carcinoma than in squamous cell carcinoma.[132]

Paget Disease

Paget disease is a malignant tumor of the vulva that can be subclassified as primary Paget disease, or secondary Paget disease when it represents spread from an underlying carcinoma of rectum, bladder, or endocervix. The former is far more common in practice, and will be the focus of the following discussion. Paget disease is a vulvar adenocarcinoma of uncertain histogenesis. It could be viewed as a sweat gland carcinoma arising primarily from the intraepidermal portion of the glands (acrosyringium),[133] as a carcinoma of multipotential (adnexal stem cells) residing in the infundibulo-sebaceous unit of the hair follicles and other adnexal structures that differentiate along glandular (sweat gland) lines,[134] or as being derived from a population of CK7-positive clear cells associated with the openings of the ducts of the mammary-like glands of the vulva, known as Toker cells.[135]

Clinically, Paget disease presents as a crusting, elevated scaling erythematous rash in the labia majora, labia minora, and/or perineal skin of adult and elderly patients (Fig. 30.18). Microscopically, the epidermis contains large pale tumor cells that form solid nests, glandular spaces, or a continuous layer along the epidermal basement membrane and also in pilosebaceous structures and sweat ducts

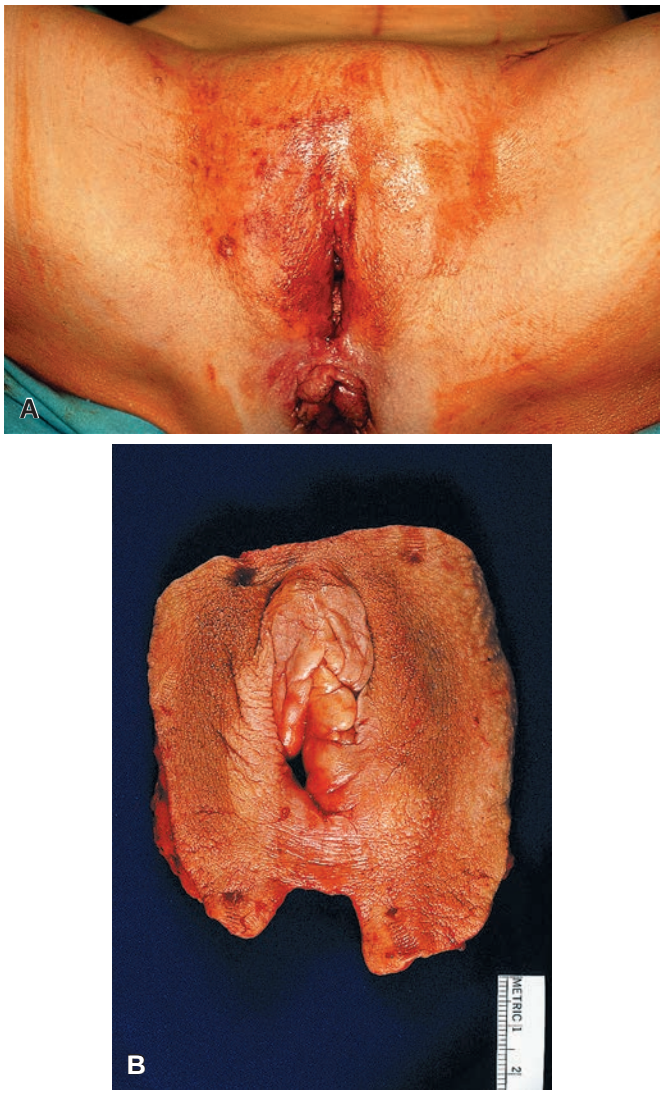

Figure 30.18 **A** and **B**, Clinical and gross appearance of vulvar Paget disease. In both cases the disease is very extensive.

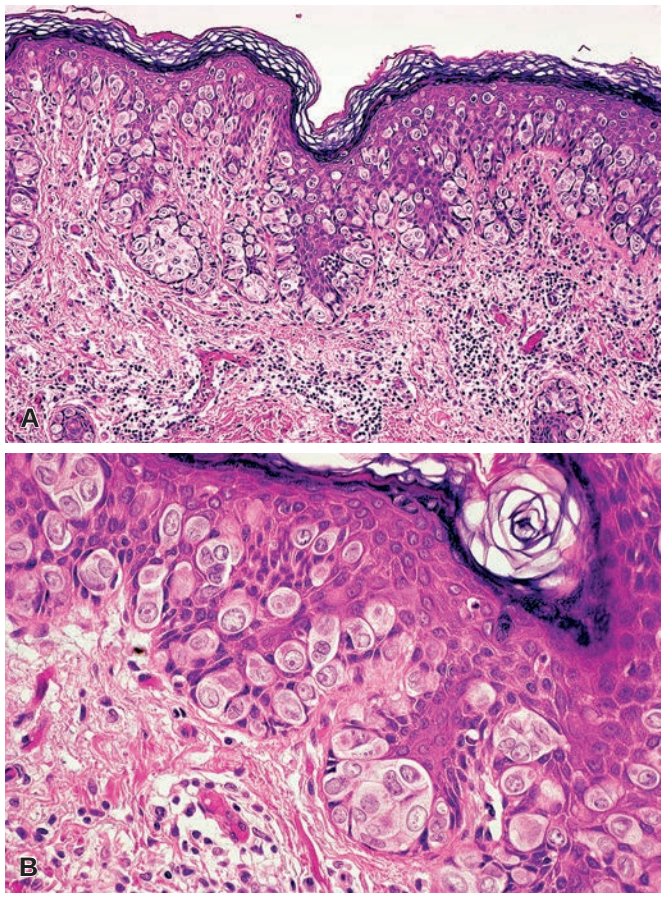

Figure 30.19 **A** and **B**, Low- and medium-power appearances of vulvar Paget disease. The large clear tumor cells are distinct from the malpighian layer.

(Fig. 30.19). A cleft often develops between the row of malignant cells and the overlying keratinocytes, resulting in a low-power appearance sometimes reminiscent of an acantholytic suprabasal bulla. Paget disease can also be misinterpreted as malignant melanoma. It should be noted that the presence of melanin granules in some tumor cells *does not* rule out the diagnosis of Paget disease. Histochemically, some or all of the tumor cells contain acidic mucin, as evidenced by their positivity for Mayer mucicarmine and aldehyde fuchsin stains.[136] Immunohistochemically, these mucins are positive for MUC1 and MUC5AC, the latter in striking contrast with Paget disease of the breast.[137,138] They are also reactive for HGM-45, a marker associated with gastric surface mucous cells.[139] Vulvar Paget disease also expresses pankeratin, cytokeratin 7 (CK7), epithelial membrane antigen (EMA), carcinoembryonic antigen (CEA), B72.3, and GCDFP-15 (a marker of apocrine differentiation) (Fig. 30.20).[140–144] S-100 protein is positive in up to one-third of the cases, depending on the immunostaining protocol used, and HMB-45 and Melan-A are negative.[145,146] There is also negativity for CDX-2, in contrast to a secondary Paget disease associated with rectal carcinoma.[147] Vulvar Paget disease variably expresses estrogen and progesterone receptors and frequently expresses androgen receptor.[148,149]

Regarding the keratins, the usual profile of primary vulvar Paget disease is CK7+/CK20–.[150,151] If it is instead CK20+ (and GCDFP-15 negative), the possibility of secondary Paget disease (especially of rectal or urothelial nature) should be suspected.[150,152] Confirmation of the latter can be obtained with uroplakin-III immunostains.[153] A recent study has reported that nuclear GATA3 expression is typical of primary vulvar Paget disease, a potential diagnostic pitfall when considering secondary urothelial carcinoma.[154] Overexpression and amplification of HER2 is found in a subset of cases.[155]

As already indicated, Paget disease of the vulva differs in several respects from Paget disease of the breast. The latter is nearly always associated with an underlying carcinoma, which may be intraductal or invasive, and the intraepidermal malignant cells are more often than not mucin-negative. In contrast, the majority of the cases (about 90%) of vulvar Paget disease are not associated with an invasive carcinoma[156] and are usually (although not always) positive for mucin stains, as previously noted.[157–159] The incidence of invasive carcinoma ("invasive Paget disease") in primary vulvar Paget disease ranges from 0%–30% depending on the series,[160–162] with some of the invasive cases being in the microinvasive or minimally invasive (>1 mm) category, a finding not associated with lymph node or distant metastases, based on a limited number of reported cases.[163]

If no invasive component is found in the resected specimen, the prognosis is good. Metastases do not occur under these circumstances, although local recurrence is common (about 30%), sometimes in the form of invasive carcinoma.[156,163,164] Therefore, excision should include a margin of normal skin and the underlying subcutaneous

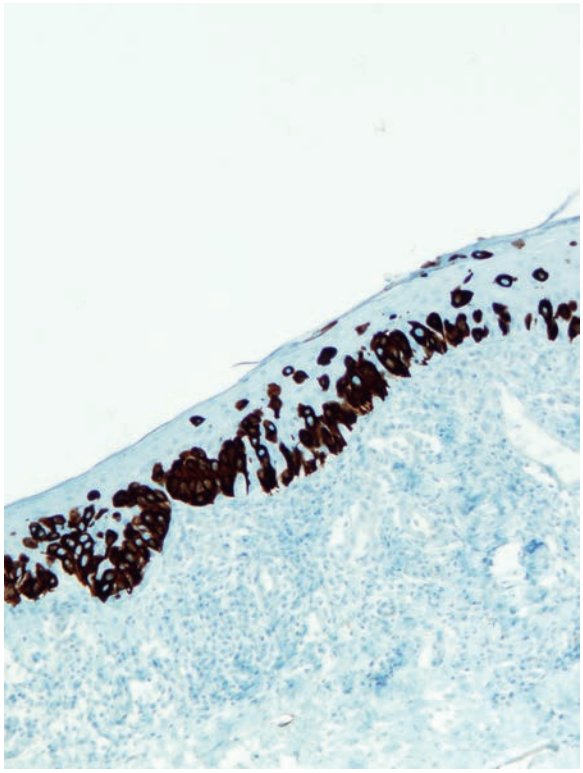

Figure 30.20 Cytokeratin 7 expression in vulvar Paget disease.

tissue. Unfortunately, the microscopic extent of the disease is often greater than that suspected from clinical examination, and this should be taken into account at the time of surgery.[165] The status of resection margins is only minimally related to the incidence of local recurrence.[163] In some instances local recurrence has been seen in the vulvar split-thickness skin graft.[166] Cases of Paget disease with an invasive component beyond the microinvasive stage have a high likelihood of nodal involvement.[163]

Other Epithelial Tumors

Hidradenoma papilliferum is a benign vulvar tumor that usually presents as a small, well-circumscribed nodule covered by normal skin. Occasionally, it ulcerates through the skin and clinically may simulate carcinoma. Microscopically, it has a complex papillary glandular pattern, with stratification and some degree of pleomorphism and mitotic activity, sometimes brisk.[167] A myoepithelial layer is always apparent (Fig. 30.21). Traditionally, this tumor has been regarded as being of sweat gland origin. However, its close morphologic and immunohistochemical similarity to intraductal papilloma of the breast and nipple adenoma suggests an origin from vulvar mammary-like tissue. All acceptable examples of this tumor have behaved in a benign fashion.[168,169] However, a case of intraductal carcinoma of mammary-type apocrine epithelium has been reported as arising from this tumor.[170]

Benign lesions of epidermal or skin adnexal type occur in the vulva. These include *verruca vulgaris*,[72] *syringoma*,[171] *chondroid syringoma* (benign mixed tumor),[172] *myoepithelioma*,[173] *pigmented apocrine hamartoma*,[174] *adenolipoma*,[175] *benign pilar tumor*,[176] *other trichogenic tumors*,[177] *warty dyskeratoma*,[178] and *inverted follicular keratosis*.[179] Although not necessarily a benign skin adnexal tumor, we thought of mentioning here also the occasional occurrence of vulvar *keratoacanthoma*.[180,181]

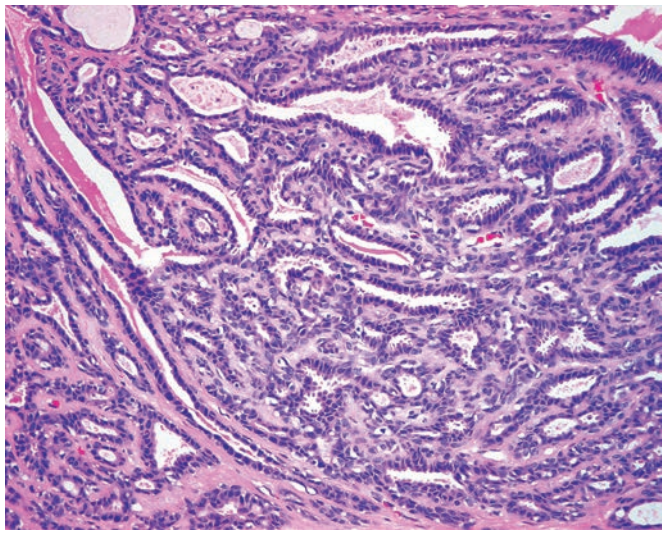

Figure 30.21 Hidradenoma papilliferum of vulva. This tumor probably arises from ectopic breast tissue.

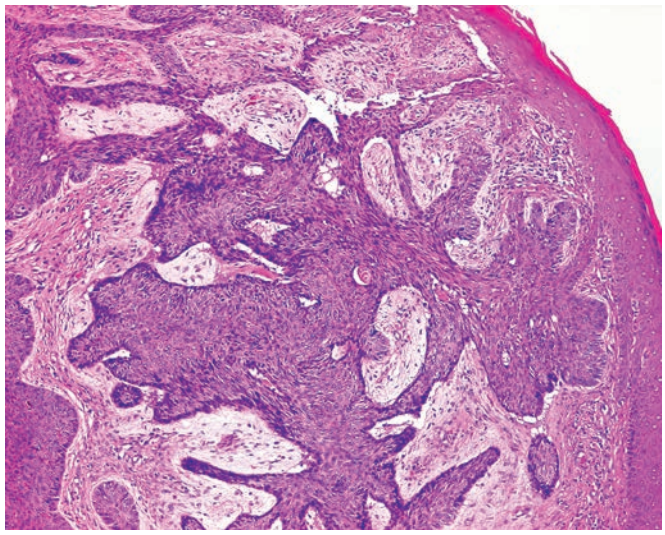

Figure 30.22 Basal cell carcinoma of vulva. It is important to distinguish this tumor from squamous cell carcinoma, especially the basaloid variant of the latter.

Basal cell carcinoma of the vulva usually presents as a nodular mass in the labia majora of elderly patients; it may grow very large and ulcerate.[182,183] Its microscopic appearance and behavior are the same as those of basal cell carcinomas elsewhere in the skin, and solid, keratotic, and adenoid types have been described (Fig. 30.22). The differential diagnosis includes HPV-associated squamous cell carcinoma with a basaloid pattern.[101] It should be remembered that, as elsewhere in the skin, basal cell carcinoma may exhibit abrupt squamous differentiation of possible follicular type, a change that does not affect the natural history of the lesion; such tumors should not be referred to as basosquamous carcinomas.

The incidence of nodal metastases in vulvar basal cell carcinoma is extremely low and is largely restricted to deeply invasive lesions.[183]

Merkel cell carcinoma has been reported in the vulva, sometimes in association with HPV-associated squamous neoplasia (invasive or intraepithelial).[184,185] Its behavior has been very aggressive.[186]

In a single case tested, there was no evidence of Merkel cell polyomavirus.[185]

Sweat gland carcinoma of the vulva is exceptional; it may present with a variety of morphologic patterns and should be distinguished from metastatic adenocarcinoma.[187] A case has been described showing *mucinous and neuroendocrine* features,[188] another with features of *malignant myoepithelioma*,[189] and another resembling *polymorphous low-grade adenocarcinoma* of the salivary glands[190] (see also under Bartholin gland).

Sebaceous carcinoma can occur in the vulva; its appearance is similar to that of its more common counterpart in the head and neck region.[191]

Melanocytic Tumors

Melanocytic nevi occur in the vulva, particularly in the labia majora. Those seen in adults are nearly always of intradermal or compound type. Sometimes, a prominent junctional component is seen in nevi of younger women, in which the enlarged junctional nests vary in size, shape, and position, and may lead to an overdiagnosis of malignant melanoma.[192,193] The term (*atypical*) *genital nevus* is sometimes employed for this microscopically troublesome lesion, which may exhibit a striking degree of cytologic and architectural atypia.[194,195] Benign lentigo (lentigo simplex) may also occur on the vulva. Genital melanotic macules are typically larger (up to 1.5 cm) than a lentigo; while they show similar basal hyperpigmentation to lentigo, there is typically less epidermal hyperplasia. There may be dermal melanophages present.

Melanoma is the second most common malignant tumor of the vulva, following squamous cell carcinoma and representing roughly 5% of all malignant tumors at this site.[196,197] The large majority of the patients are older than 50 years at the time of diagnosis, a fact of great importance in the differential diagnosis with genital nevus.[198,199] Most lesions are advanced (Clark level III or IV) at the time of diagnosis (Fig. 30.23).[200] The microscopic appearance is similar to that of cutaneous melanoma (see Chapter 3) (Fig. 30.24A).

Figure 30.23 Gross appearance of vulvar malignant melanoma. The tumor is large, polypoid, deeply pigmented, and ulcerated.

An important differential diagnosis is with Paget disease, a situation complicated by the fact that on occasion the two tumors coexist.[201] Sometimes the melanoma is formed of spindle cells growing in fascicles and simulating sarcoma (see Fig. 30.24B).

The usual treatment is radical vulvectomy with bilateral inguinal lymph node dissection, but small lesions with depths of ≤1.75 mm may be treated with wide local excision.[202–204] The overall 5-year survival rate is approximately 35%.[205,206] Lymph node status, level or thickness of the primary tumor, and ulceration are the most important prognostic parameters.[206–210] There is some suggestion that the DNA ploidy pattern may also provide prognostic information.[211] Vulvar melanomas may have c-KIT or NRAS mutations more frequently than melanomas arising at other anatomic sites, but BRAF mutations are rare.[212–214]

Malignant blue nevus of the vulva leading to ovarian metastases has been recorded.[215]

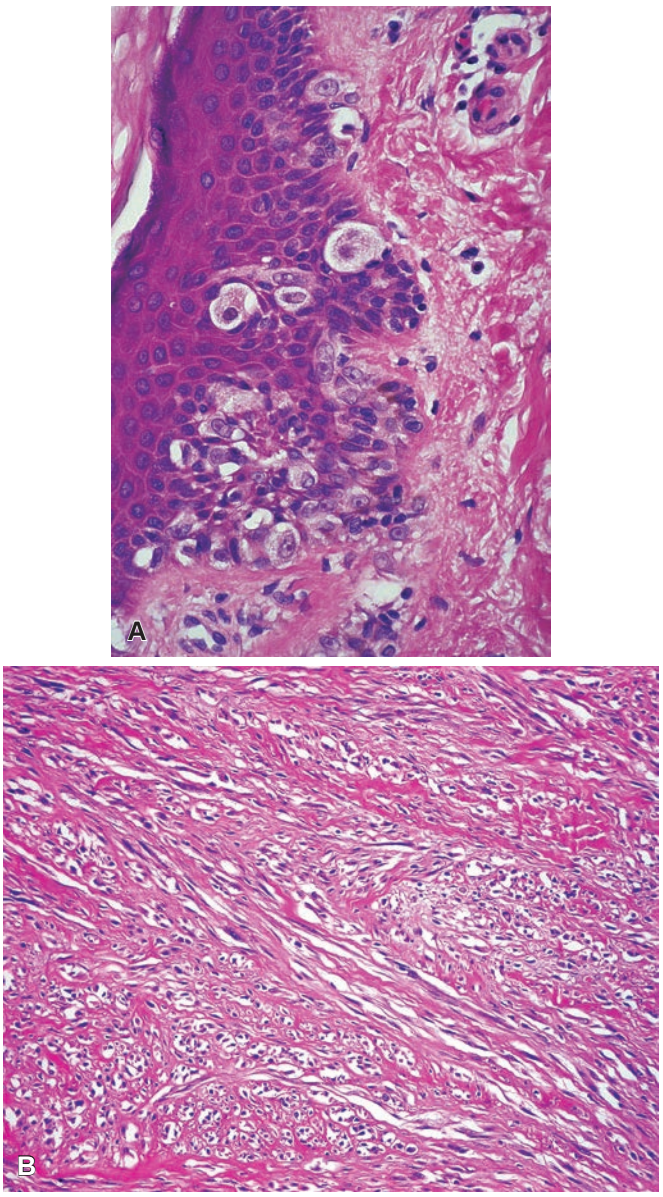

Figure 30.24 **Malignant Melanoma of Vulva. A**, Superficially spreading type, showing typical intraepidermal growth of pagetoid cells. **B**, Melanoma growing in the form of fascicles of spindle cells and simulating a mesenchymal neoplasm.

Figure 30.25 Aggressive angiomyxoma protruding in a polypoid fashion through one of the labia.

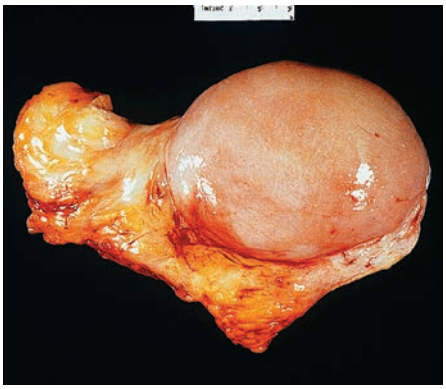

Figure 30.26 Cut surface of vulvar aggressive angiomyxoma. The tumor is soft, gelatinous, and appears encapsulated.

Aggressive Angiomyxoma and Related Lesions

Aggressive angiomyxoma is a soft tissue neoplasm that usually arises within the perineum. It often presents as a vulvar mass and clinically simulates a Bartholin gland cyst (Fig. 30.25).[216,217] Most patients are in the second or third decade of life, but cases have also been reported in children.[217,218] A similar tumor has been described in the scrotal region in males.[219]

Grossly, the appearance is edematous and ill-defined (Fig. 30.26). Microscopically, a hypocellular stroma devoid of atypicality or mitotic activity is seen intermingling with sizable vessels having dilated lumina and frequent hyaline thickening of the adventitia (Fig. 30.27). This tumor is distinguished from the more common and innocuous fibroepithelial polyp described below because of its larger size, deeper location, and lack of bizarre stromal cells. The differential diagnosis also includes angiomyofibroblastoma, cellular angiofibroma, and massive vulvar edema (see later). Superficial angiomyxoma is a closely related tumor that, as its name implies, has a more superficial location (frequently exophytic) and also differs from aggressive angiomyxoma in being well circumscribed.[220] The ultrastructural and immunohistochemical features of aggressive angiomyxoma are those of primitive

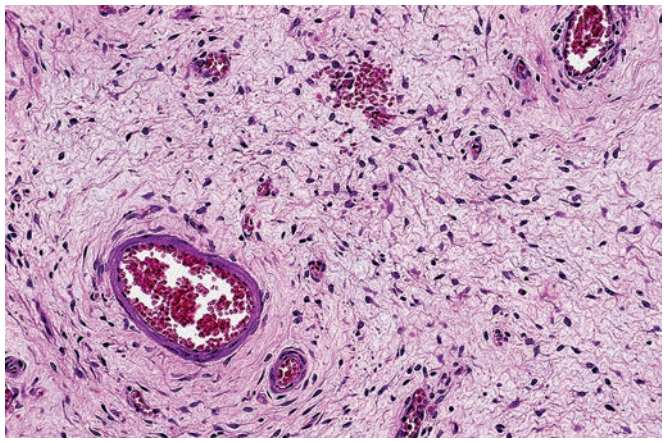

Figure 30.27 Microscopic appearance of aggressive angiomyxoma. The lesion is hypocellular and features large-sized vessels.

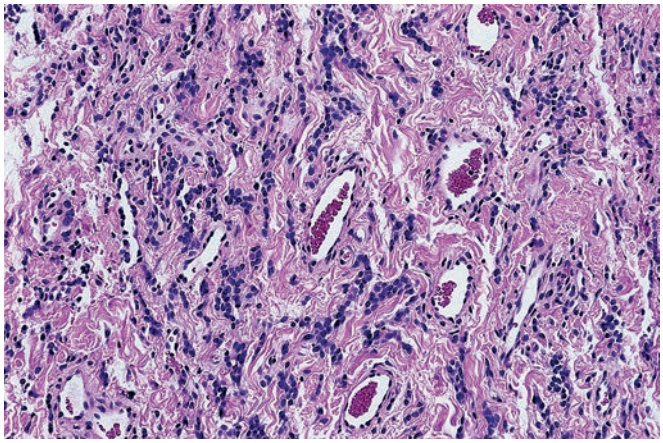

Figure 30.28 Vulvar angiomyofibroblastoma. Rows of small oval cells are separated by fibrous strands.

mesenchymal cells focally exhibiting myoid traits.[221,222] Stains for acidic mucins are only weakly positive, suggesting that the stroma is more edematous than myxoid. Immunohistochemically, there is positivity for desmin (less so in the male counterpart of this lesion), smooth muscle actin (about half of the cases), CD34 (about half), and estrogen and progesterone receptors (100%, irrespective of gender).[223,224] One-fourth of the cases also show keratin AE1/AE3 positivity.[225] Some cases analyzed cytogenetically have shown a chromosomal translocation involving the region 12q14–15,[226] where the high mobility group AT-hook 2 gene *HMGA2* is translocated, resulting in overexpression of this molecule.[227–229] It should be noted that HMGA2 overexpression is not specific for aggressive angiomyxoma and can be seen in other neoplasms, including leiomyoma.[229] One case of aggressive angiomyxoma was found to have a t(5;8)(p15;q22) translocation.[230]

Recurrence in the ischiorectal and retroperitoneal spaces is common, probably because of the difficulties encountered in achieving a complete surgical excision.[231] In addition, two typical cases have been reported in association with lung metastases.[232,233] Dramatic response to therapy targeting the hormone receptors on the tumor cells has been reported.[234]

Angiomyofibroblastoma is a benign vulvar tumor characterized by alternating hypercellular and hypocellular areas admixed with small blood vessels.[235–237] Spindle and plump stromal cells aggregate around the vessels (Fig. 30.28). These cells are immunoreactive for

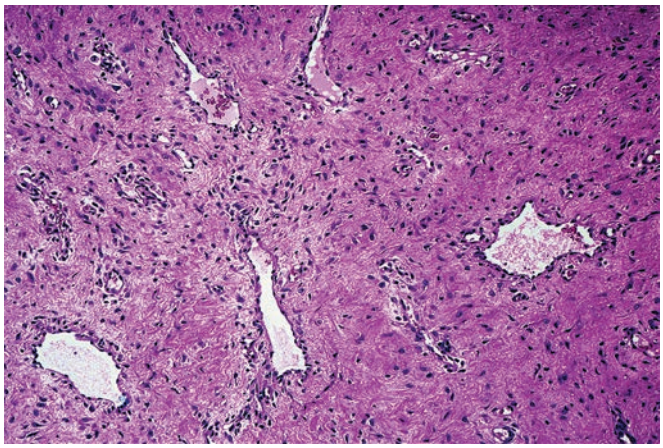

Figure 30.29 Angiofibroma of vulva. The microscopic appearance is reminiscent of nasopharyngeal angiofibroma. (Slide courtesy of Dr. Robert E Scully, Boston, MA)

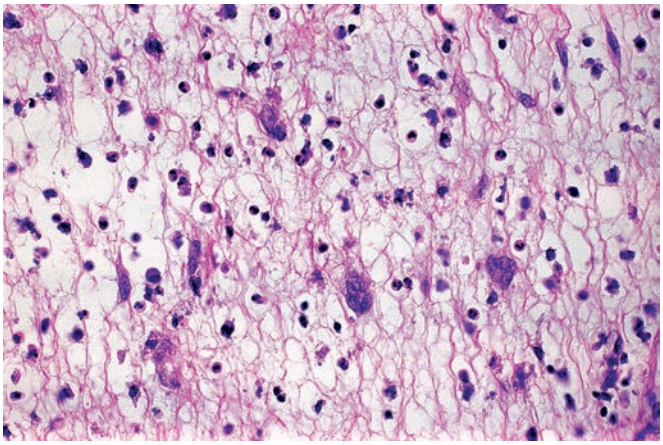

Figure 30.30 Vulvar polyp containing reactive stromal cells, some of which are multinucleated.

vimentin, desmin, and hormone receptors, but usually not for actin or keratin.[238,239] There may be a component of mature adipose tissue; when abundant, the tumor is referred to as the *lipomatous variant*.[240] The behavior is benign, with an extremely low rate of local recurrence, but a case with sarcomatous transformation ("angiomyofibrosarcoma") has been reported.[241] A relationship between angiomyofibroblastoma and tamoxifen therapy has been suggested.[242]

The typical example of angiomyofibroblastoma differs from aggressive angiomyxoma by virtue of its circumscribed borders, higher cellularity, abundance of blood vessels, plump stromal cells, minimal stromal mucin, and rarity of red blood cell extravasation.[235,243] However, enough common features and transitions occur between it and aggressive angiomyxoma to suggest that they are closely related entities.[222,244–246]

Cellular angiofibroma has well-circumscribed margins, like angiomyofibroblastoma. Microscopically, it is composed of uniform, bland, spindle-shaped mesenchymal cells accompanied by numerous thick-walled vessels and inconspicuous islands of mature fat (Fig. 30.29).[247] The tumor is cellular and can be mitotically active.[248] Once again, it is hard to escape the suspicion that this tumor is histogenetically related to the others described in this section, their common denominator being an origin from the specialized hormone receptor–positive mesenchymal tissue within the lower female genital tract.[99,223]

Other Tumors and Tumorlike Conditions

Asymmetric labium majus enlargement in the pre- and early pubertal age may clinically mimic a neoplasm.[249] It tends to regress spontaneously and probably represents an asymmetric physiologic enlargement in response to the normal hormonal surges in this age group.

Massive vulvar edema may be seen secondary to obesity and immobilization.[250] It is similar if not identical to the condition described as *vulvar hypertrophy with lymphedema (or massive localized lymphedema)*.[251] It can simulate aggressive angiomyxoma, but the clinical features should alert the gynecologist and the pathologist to the correct diagnosis.

Fibroepithelial polyp is a superficially located lesion composed of a loose myxoid stroma covered by normal squamous epithelium. Bizarre, stellate, frequently multinucleated cells may be present (Fig. 30.30).[252–254] Some lesions are moderately hypercellular. The combination of hypercellularity and bizarre tumor cells may result in overdiagnosis.[255] As in other sites where this lesion occurs, desmin immunoreactivity may be present.[256]

Prepubertal vulvar fibroma is a controversial entity and some authors regard it as a non-neoplastic hormonally driven lesion identical to **asymmetric labium majus enlargement**.[249,257] It presents at a median age of 8 years. It is grossly ill-defined and is microscopically composed of bland spindle-shaped cells in a variably collagenous to edematous or myxoid stroma lacking atypia and mitotic activity. It may recur locally after excision.[258]

Smooth muscle tumors of both benign and malignant types occur.[259] The leiomyomas include a myxoid variety that can simulate aggressive angiomyxoma,[260] and the leiomyosarcomas include epithelioid and myxoid variants.[261,262] Nielsen et al.[259] evaluated the tumors on the basis of size (≥5 cm), infiltrative margins, mitoses (≥5/10 HPF), and moderate to severe cytologic atypia. Tumors that had three or all four of these features were regarded as leiomyosarcomas, tumors that had none or one of the features were called leiomyomas, and tumors that had two features were designated atypical leiomyomas.

Nonepithelial tumors and tumorlike conditions of many other types have been described in the vulva and its surroundings, most of them of soft tissue type.[263,264] They include *endometriosis*, *varices*,[265] *hemangioma* and *hemangiomatosis* (sometimes as a component of Maffucci syndrome),[266] *lymphangioma* (which may clinically simulate warts),[267] *angiokeratoma*,[268] *epithelioid hemangioendothelioma*,[269] *glomus tumor*[270,271] and *glomangiomyoma*,[272] *angiosarcoma*[273] (including the *postradiation epithelioid type*),[274] *solitary fibrous tumor*[271] (Fig. 30.31), benign and malignant *granular cell tumors* (some with accompanying pseudoepitheliomatous hyperplasia)[275–277] (Fig. 30.32), *schwannoma*,[278] *neurofibroma*(*tosis*),[279,280] *malignant peripheral nerve sheath tumor*,[281,282] *sclerosing lipogranuloma*,[283] *yolk sac tumor*,[284] *rhabdomyosarcoma*[285,286] (usually occurring in children and belonging to the embryonal/botryoid variety), *benign lymphoid hyperplasia*,[287] *verruciform xanthoma*,[288] *Langerhans cell histiocytosis*,[289–291] *nodular fasciitis*,[292] *postoperative spindle cell nodule*,[293] undifferentiated pleomorphic sarcoma,[294] *dermatofibrosarcoma protuberans*[295–297] (including cases with fibrosarcomatous transformation[298]), *Ewing sarcoma/PNET*,[299] *synovial sarcoma*[300] (including the monophasic type[301]), *fibromatosis/desmoid tumor* (sometimes associated with pregnancy),[302,303] *atypical lipomatous tumor*,[304] a lesion resembling *lipoblastoma*,[305] *malignant lymphoma*,[306,307] *paraganglioma*,[308] *alveolar soft part sarcoma*,[309] and *epithelioid sarcoma*.[310]

Epithelioid sarcoma is of importance because of its relatively high frequency at this site and the fact that it tends to run a more

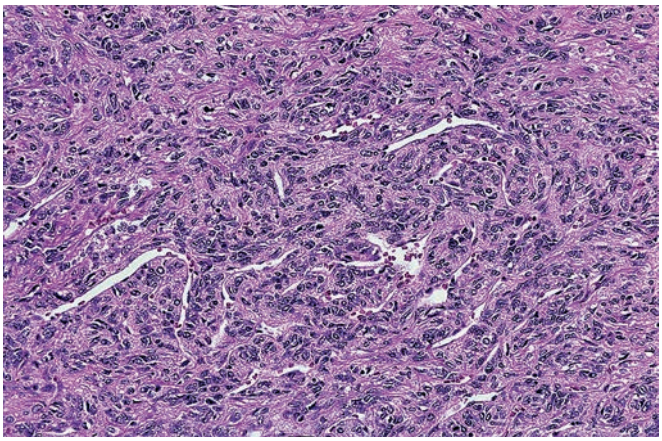

Figure 30.31 A rare example of solitary fibrous tumor involving soft tissues of vulva.

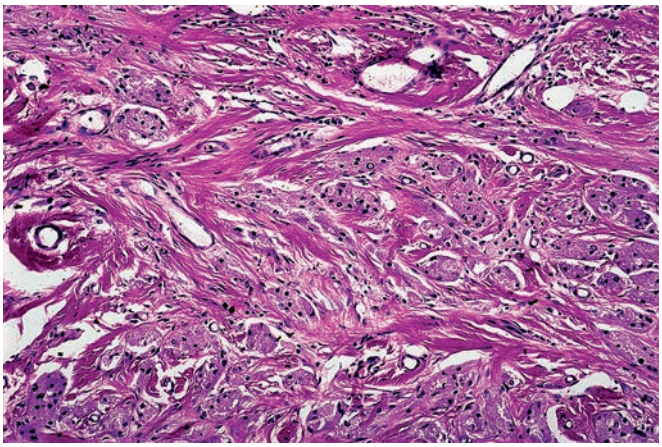

Figure 30.32 Granular cell tumor of vulva.

aggressive course here than in its usual location in the distal extremities. This may at least partially result from the fact that this tumor, when located in the vulva, often exhibits rhabdoid features, known to be associated with an aggressive course.[311] As a matter of fact, it may be difficult to decide whether to designate a vulvar tumor with these features as an epithelioid sarcoma or as a malignant rhabdoid tumor.[312,313] The overlap between these two entities extends to the molecular level as both may show loss of SMARCB1 (INI1) expression.[314] The term proximal-type epithelioid sarcoma has been employed for this particular situation, of which the vulva is a prime example (see Chapter 41).

Metastases to the vulva usually originate from the cervix (almost 50%), endometrium, kidney, or gastrointestinal tract.[315] Most are expressions of generalized disease.[316] The labium majus is the most common location.[317]

Lesions of Bartholin Glands and Related Structures

Cysts and abscesses of the Bartholin glands are the result of chronic bacterial inflammation. The lining of the cyst, which is usually of transitional or squamous type, can be destroyed partially or totally by the inflammatory infiltrate. The nature of the cyst can be established by the presence of residual mucinous glands in the fibrotic and inflamed connective tissue that forms the cyst wall. The secretion product is a nonsulfated sialomucin.[4] Sometimes, extravasation of this mucus into the stroma may induce changes similar to those seen in "mucocele" of the oral cavity.[318] The cyst may be treated by excision or marsupialization.[319] Exceptionally, the inflammatory infiltrate is found to have the features of *malakoplakia*.[320]

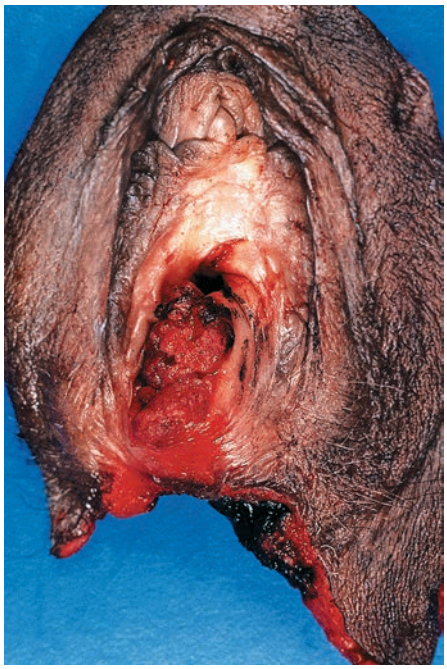

Figure 30.33 Large carcinoma arising from the Bartholin gland.

Mucous cysts of the *vulvar vestibule* are usually solitary and lined by mucin-producing columnar cells.[321]

Benign tumors and tumorlike conditions of this area include adenoma of minor vestibular glands[322] (which may well represent focal hyperplastic changes secondary to trauma and inflammation), nodular hyperplasia, adenomyoma,[323] mucinous cystadenoma,[324] and papilloma.[325]

Carcinomas of the Bartholin gland[326–329] may take the form of squamous cell carcinoma (the most common) (Fig. 30.33), adenocarcinoma,[330] urothelial (transitional cell) carcinoma, a variant of HPV-associated squamous cell carcinoma (Fig. 30.34), salivary gland–type basal cell and epithelial-myoepithelial adenocarcinoma,[331,332] small cell (neuroendocrine) carcinoma,[333] and adenoid cystic carcinoma (including the tubular variety) (Fig. 30.35).[334–336] Lymph node metastases are common. HPV is often found in the squamous cell carcinoma type,[337] as well as in the transitional cell carcinoma type.[338] The adenoid cystic carcinomas can have the NF1B gene rearrangements, similar to those commonly seen in salivary gland adenoid cystic carcinomas.[339] The overall survival rate is in the neighborhood of 60%.[324,340]

Lesions of the Female Urethra

Urethral caruncle has the appearance of a small raspberry protruding from the meatus; it bleeds easily and may become infected. It occurs only in the female urethra and is not a true neoplasm but rather a reactive polypoid lesion. Microscopically, chronic inflammatory cells, dilated vessels, and hyperplastic epithelium are seen in varying proportions. Mistaken diagnoses of malignancy can result from overinterpretation of islands of reactive epithelium or scattered bizarre stromal or lymphoid cells.[341] There is a tendency for these lesions to recur following excision, probably because of persistence of the original inciting factors.

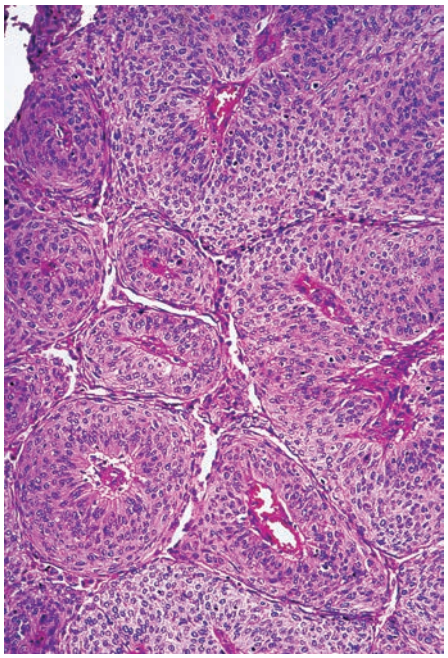

Figure 30.34 Bartholin gland carcinoma of transitional type, a variant of HPV-associated squamous cell carcinoma.

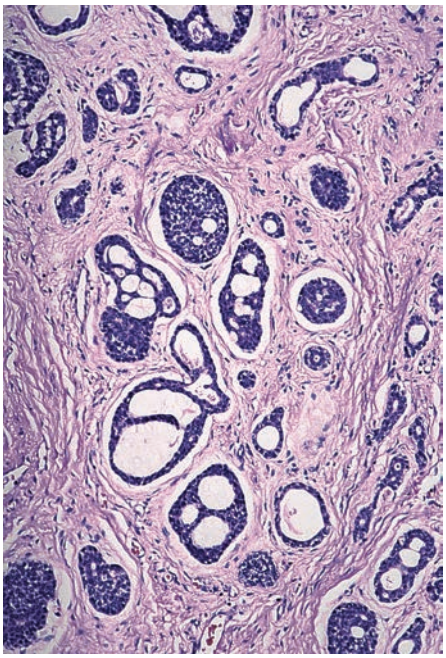

Figure 30.35 Bartholin gland carcinoma of adenoid cystic type.

Prolapse of the urethral mucosa can occur in childhood and clinically simulate a vulvovaginal neoplasm.[342]

So-called **nephrogenic (mesonephric) adenoma** has been traditionally regarded as a metaplastic change resulting from inflammation rather than a true neoplasm. It is microscopically similar to the more common lesions located in the bladder neck.[343,344] Similarly, an occurrence in the urethra of mucinous epithelium of *colonic* type can also be explained on a metaplastic basis, although a congenital origin is also possible.[345]

Villous adenoma has been reported in the urethra in association with tubulovillous adenoma and adenocarcinoma of the rectum.[346]

Urethral carcinoma occurs in elderly patients and presents with bleeding or dysuria.[347,348] The majority of the cases arise from the meatus, at the junction of the transitional and squamous epithelium. In a series of 35 cases, 19 were anterior (vulvourethral), 4 were posterior (vesicoureteral), and 12 involved the entire urethra.[349]

Microscopically, most urethral carcinomas are of squamous cell type.[350,351] Other types include urothelial (transitional cell) carcinoma, columnar/mucinous adenocarcinoma,[352] signet ring adenocarcinoma,[353] and clear cell adenocarcinoma.[354,355] Interestingly, nearly half of the carcinomas reported as arising in urethral diverticula have been adenocarcinomas of either conventional or clear cell type.[356,357] Some of the urethral adenocarcinomas have been associated with adenomatous hyperplasia of the periurethral glands.[358] HPV has been detected by PCR techniques in a high proportion of urethral carcinomas.[359]

The prognosis of urethral carcinoma is relatively poor, except when the disease is limited to the anterior portion of the urethra.[360] In one large series, the 5-, 10-, and 15-year actuarial survival rates were 41%, 31%, and 22%, respectively.[361] The usual treatment is radiation therapy,[361–363] but depending on their size and location, they can also be treated by surgery alone or surgery plus irradiation.[364,365]

Leiomyoma of the urethra, although extremely unusual, is the most common type of benign mesenchymal tumor at this site.[366]

Melanoma of the urethra is a highly aggressive neoplasm that is treated by total urethrectomy with bilateral inguinal lymph node dissection.[367–368]

Malignant lymphoma can exceptionally present as a urethral tumor.[369]

Metastatic tumors in the urethra usually originate in other portions of the female genital tract, particularly endometrium.[351]

Normal Anatomy

The vagina is a tubular structure derived from the paired müllerian ducts that extend from the vestibule of the vulva to the uterus.[1–6] It is composed of three main layers: mucosa, muscularis, and adventitia. The mucosa is composed of stratified squamous epithelium resting on loose connective tissue stroma. The squamous epithelium is responsive to steroid hormones, its appearance depending on the age of the individual and the time of the menstrual cycle.[5]

The subepithelial stroma or lamina propria contains elastic fibers and a rich venous and lymphatic network. Polygonal to stellate stromal cells—some multinucleated—may be present. These cells are immunoreactive for desmin and hormone receptors.

The wolffian (mesonephric) duct in the vagina is represented by *Gartner's duct*,[6] which runs deeply along the lateral vaginal walls. Microscopically, this usually appears in the form of a small single duct, sometimes surrounded by a cluster of small glands, all of them lined by a simple cuboidal epithelium. The presence of inspissated eosinophilic secretion in the lumen is a characteristic feature of these remnants. These cells are immunoreactive for GATA3 and CD10.[7]

Ectopic tissues exceptionally found in the vagina include *prostatic glands*[5] and *sebaceous glands*.[1]

The lymphatic drainage of the vagina is rather complex. The vessels in the upper anterior wall join those of the cervix and terminate in the medial chain of the external iliac nodes (interiliac nodes). Those in the posterior vagina drain into deep pelvic, rectal, and para-aortic nodes. Some of those of the lower vagina (including the hymenal portion) go to the interiliac nodes; others traverse the paravesical spaces and drain into the inferior gluteal nodes. Finally, the vessels that anastomose with those from the vulva drain to the femoral nodes.[2,3]

Adenosis and Related Lesions

Adenosis of the vagina was originally described as a partial or complete conversion of the vaginal mucosa from squamous to endocervical-type glandular epithelium (Fig. 31.1),[8] but the concept was later expanded to embrace the presence of any müllerian-type glandular epithelium in the vagina. Sandberg[9] found occult vaginal adenosis in 9 (41%) of 22 vaginas from postpubertal girls obtained at autopsy but in none of 13 prepubertal patients. Kurman and Scully[10] obtained similar results, suggesting that vaginal adenosis can arise on a congenital basis but that steroid hormones probably play a stimulatory role in their development. Excess mucous discharge is the most common complaint in symptomatic cases. Grossly, adenosis appears as red granular spots or patches that do not stain with Lugol solution. Microscopically, the glands may be mucin-secreting and similar to those of the endocervix (most commonly) or have a lining resembling tubal or endometrial mucosa (Fig. 31.2).[11] Depending on the predominant epithelial component, *mucinous (endocervical)* and *tuboendometrial* forms of vaginal adenosis have been described. The glandular-type epithelium of vaginal adenosis may be in the lamina propria or it may line the surface of the vagina. Chronic inflammation and squamous metaplasia (mature, immature, or atypical) are common accompanying features (Fig. 31.3). The latter, which is poor in cytoplasmic glycogen, can obliterate the glandular lumen and appear as a peg continuous with the surface, a feature that may be misinterpreted as high-grade squamous intraepithelial lesion (HSIL)/vaginal intraepithelial neoplasia 2/3 (VaIN2/3) or even as invasive squamous cell carcinoma.[12] One should be aware, however, that lesions with the features of HSIL (VaIN2/3) can superimpose themselves on foci of adenosis; the identifying features are the same as those described for similar lesions in the chapter on the uterine cervix.

Abstract

The vagina is the least likely part of the female reproductive tract to be sampled for diagnostic purposes, and most pathologic conditions involving the vagina are more commonly encountered in the vulva or cervix. There are exceptions, however, ranging from congenital abnormalities like transverse vaginal septum through to vaginal adenosis, mixed tumor of vagina, and prolapsed fallopian tube at the vaginal apex occurring after hysterectomy. Most neoplasms of the vagina are squamous intraepithelial neoplasia/invasive squamous cell carcinoma secondary to oncogenic HPV. The vagina can also be secondarily involved by tumors arising elsewhere in the reproductive tract, or from extragenital sites.

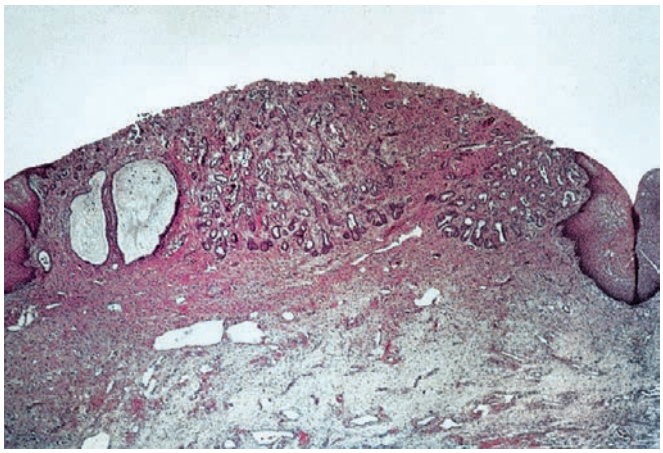

Figure 31.1 Vaginal adenosis with the surface squamous epithelium replaced by glandular epithelium and glands extending down into the superficial lamina propria.

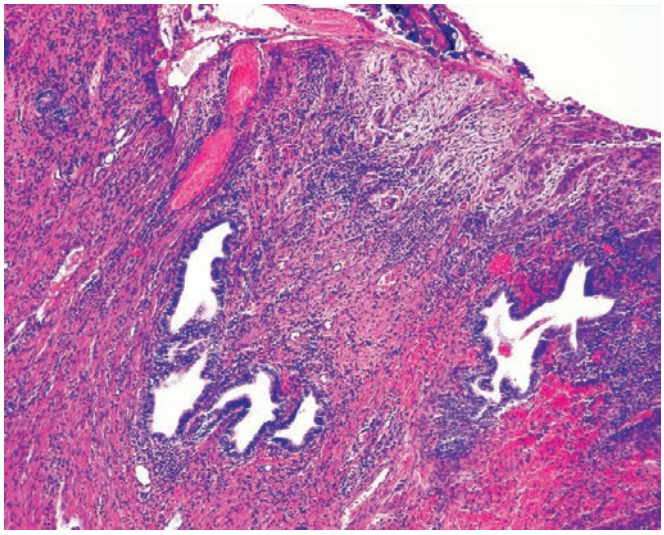

Figure 31.2 Vaginal adenosis of tuboendometrial type beneath an ulcerated surface. Other areas of this specimen showed adenocarcinoma arising from the adenosis.

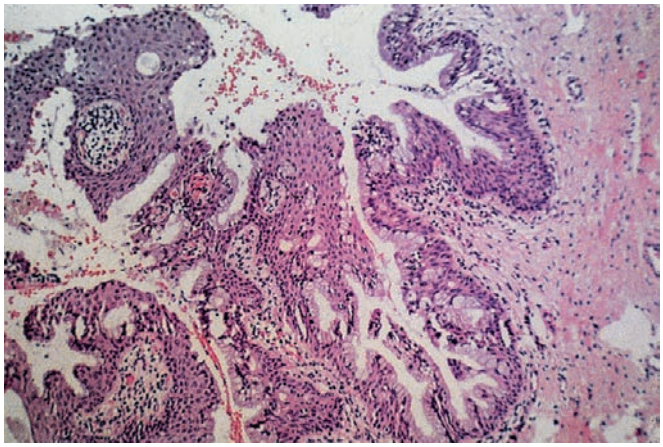

Figure 31.3 Extensive squamous metaplasia in vaginal adenosis.

Sometimes the squamous metaplasia is so extensive that the only evidence of a preexisting adenosis is found in the form of rare intercellular pools or intracellular droplets of mucin, as shown by mucicarmine or other mucin stains. It has been suggested that, as these women grow older, vaginal adenosis regresses by the process of squamous metaplasia.[13]

Microglandular hyperplasia can develop within lesions of vaginal adenosis. It is important not to confuse this benign lesion with adenocarcinoma.[14]

A footnote of historical interest relates to the causal relationship between vaginal adenosis and exposure in utero to diethylstilbestrol (DES). The reported incidence of adenosis in the exposed population has varied from 35% to more than 90% in the different series.[15] It has been shown that the incidence of vaginal adenosis and related colposcopic abnormalities is close to 100% if the drug was begun during or before the eighth week of pregnancy and only 6% if it was begun during the fifteenth week or later.[16] The microscopic features of adenosis in women exposed in utero to DES are identical to those seen in unexposed women.[17,18] **Transverse ridges** and other structural anomalies are also related to DES administration.[19,20] They are found in the upper vagina or cervix in about one-fourth of the exposed population, and microscopically the ridge is composed of a core of fibrous tissue lined by mucinous epithelium, metaplastic squamous epithelium, or, rarely, tubal or endometrial epithelium.

Other Non-Neoplastic Lesions

Transverse vaginal septum is a congenital malformation that occurs as a result of failure of fusion of the distal müllerian duct and the anogenital sinus. It can completely obstruct the vagina and present with primary amenorrhea. Histologically it is characterized by central smooth muscle (not seen in the hymen) and may show adenosis of the epithelium on the proximal side of the septum. It is distinct from the longitudinal vaginal septum associated with duplication (complete or partial) of the genital tract, and it may be associated with other anomalies.[21]

Condylomas can occur in the vagina and show similar papillomatous architecture and viral cytopathic effect (koilocytic change, with large nuclei showing irregular nuclear contours) as condyloma occurring at other body sites, for example, vulva or penis. Indolent infections caused by *Trichomonas vaginalis* and *Candida albicans* are relatively common, especially during pregnancy.[22] **Lymphogranuloma venereum** can involve the vagina during the late stage of the disease and result in stricture. **Xanthogranulomatous reactions**[23] and **malakoplakia**[24] may occur as a result of unusual bacterial infections and lead to pseudotumor formation or strictures (Fig. 31.4). The use of *tampons*, especially if left in place long term, can result in gross vaginal ulcers, as can pessaries.[25]

Occasionally, following vaginal hysterectomy, the **tubal fimbria** may become entrapped in the healing vaginal apex, a finding that must not be confused with a neoplastic process.[26] The clinical presentation is that of a mass grossly resembling "granulation tissue" at the vaginal apex, usually appearing within 6 months following a hysterectomy.[27] Occasionally, the tubal prolapse is associated with an exuberant stromal response with an angiomyofibroblastic appearance, a feature which adds to the diagnostic difficulty.[28]

Endometriosis and the related condition known as **endocervicosis** occur in the vagina, but less commonly than in other genital tract sites.[29] Most cases are seen in connection with episiotomy scars.

Cysts of the vagina can be of several different types.[30] The most common is the *epithelial inclusion cyst*, lined by squamous epithelium and sometimes resulting from surgery or trauma. Another common type is characterized by a simple lining of mucin-secreting, tall columnar, nonciliated epithelium of endocervical type, sometimes

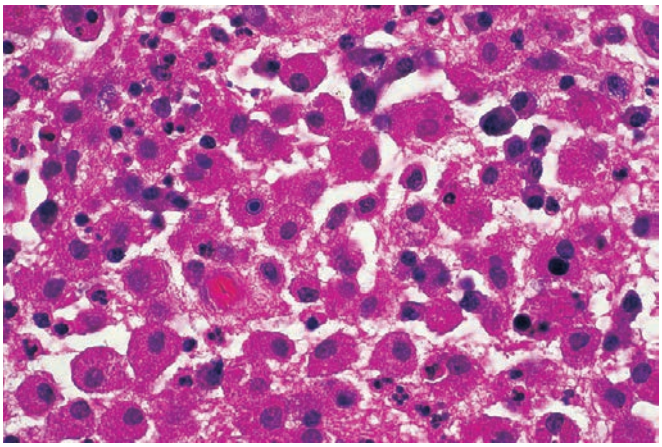

Figure 31.4 Malakoplakia of Vagina. This periodic acid–Schiff stain shows numerous histiocytes containing particulate material in their cytoplasm.

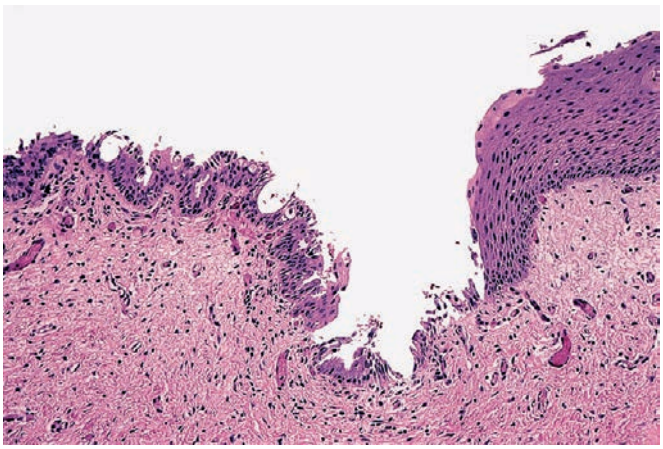

Figure 31.5 Vaginal cyst lined by müllerian epithelium connecting with surface squamous epithelium.

associated with focal squamous metaplasia; this has been designated *müllerian cyst* and can be found anywhere in the vagina (Fig. 31.5). *Mesonephric (Gartner duct) cyst* is rare; it is located in the anterolateral or lateral vaginal wall and is lined by low cuboidal epithelial cells, sometimes ciliated, that do not secrete mucin. Other rare cystic lesions of the vagina include *urothelial cysts* (located in the suburethral portion and probably arising from paraurethral glands and Skene ducts), *emphysematous vaginitis*,[30,31] and the already mentioned *endometriosis*.

Benign Epithelial Tumors

Müllerian papilloma, having a branching configuration and a lining of a single layer of cuboidal cells, has been rarely described in children. It may present on the mucosal surface as polyps or intramurally. *Papillary müllerian cystadenofibroma* of the vagina is probably a histogenetically closely related tumor.[32]

Squamous papilloma may be seen in the adult vagina as a solitary lesion or as multiple small projections (micropapillomatosis). Both variants are unrelated to HPV in most cases.

Tubulovillous adenoma and villous adenoma of the vagina, morphologically similar but immunohistochemically distinct (i.e., positive for ER and CK7 expression) to their colorectal counterparts, have been described.[33,34] They are unrelated to HPV, and their histogenesis is poorly understood at this time but may represent the vaginal counterpart to the HPV-independent adenocarcinoma in situ of the cervix, given that association with invasive adenocarcinoma has been described.

Mixed tumor (spindle cell epithelioma) is usually located in or near the hymenal ring. It is composed of small stromal-type spindle cells intermixed with mature squamous cells and glands lined by mucinous epithelium (Fig. 31.6).[32,35] Ultrastructural and immunohistochemical studies support an epithelial nature.[36] There may also be immunoreactivity for CD34, ER, PR, h-caldesmon, and CD10.[35,37] The lesion is benign, but it may recur locally if incompletely excised.[36,38]

Tubulosquamous polyp is a recently described distinctive vaginal lesion characterized microscopically by the presence of well-circumscribed expansile nests of epithelial cells embedded in a hypocellular fibrous stroma. The epithelial component is generally of both squamous and glandular type, the former predominating.[39] They may be solid/polypoid or cystic, with the former being more commonly located in the upper vagina and the latter in the lower third. Prostatic-type tissue can sometimes be found within this polyp, and the glandular tissue may stain positively for prostate-specific antigen (PSA).[40]

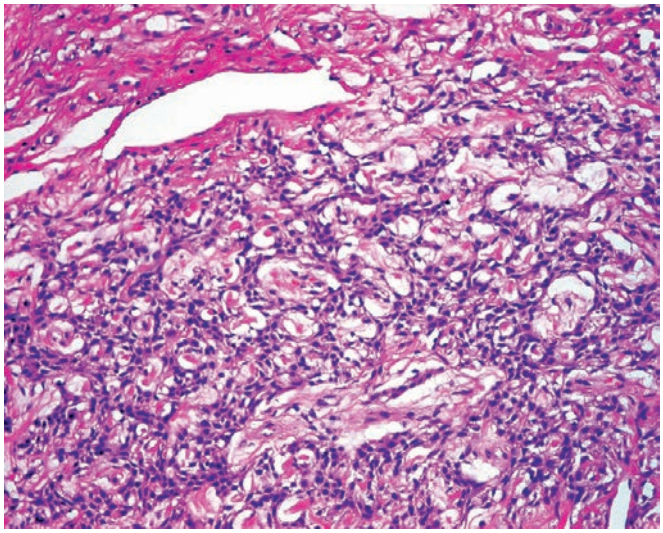

Figure 31.6 Mixed Tumor of Vagina. The plexiform pattern of growth seen in this field is characteristic of the entity.

Squamous Intraepithelial Lesions

Atypical premalignant squamous epithelial lesions of the vagina are designated **HSIL (VaIN2/3)**, using the terminology proposed by LAST (Lower Anogenital Squamous Terminology Standardization Project) for squamous intraepithelial neoplasia associated with anogenital HPV infection (Fig. 31.7).[41] It should be noted that the vaginal lesions usually arise from native squamous epithelium, in contrast to most cervical cases, which originate from *metaplastic* squamous epithelium. HSIL (VaIN2/3) is multifocal in about half of cases and very frequently associated with concomitant, subsequent, or prior (in situ or invasive) neoplasms elsewhere in the lower genital tract, especially the cervix.[42–44] The upper third of the vagina is the most common site, in which case the vaginal and cervical lesions may be confluent.[45] The HPV genotype distribution in HSIL (VaIN2/3) is similar to that of HSIL elsewhere in the genital tract.[46] The type of treatment depends largely on the extent of the disease and may

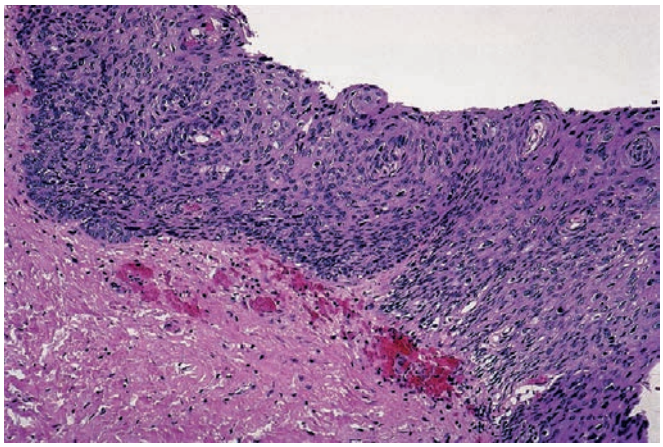

Figure 31.7 High-grade squamous intraepithelial lesions/vaginal intraepithelial neoplasia (HSIL/VaIN3).

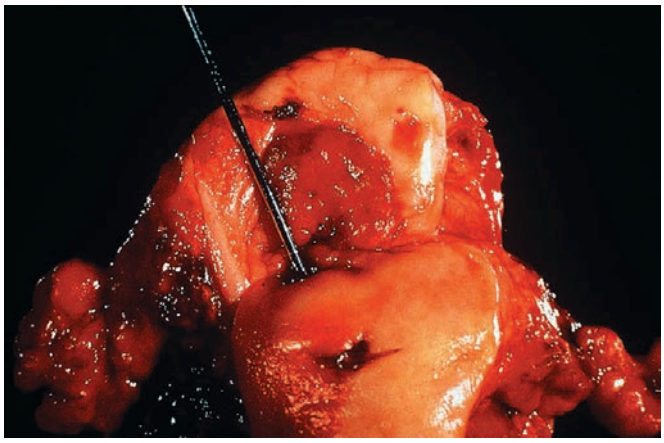

Figure 31.8 Invasive squamous cell carcinoma resulting in a large ulcerated mass.

consist of local excision, partial or total vaginectomy, CO_2 laser therapy, or administration of topical 5-fluorouracil.[42,43,47]

It is important not to overdiagnose transitional cell metaplasia as HSIL (VaIN2/3), the criteria for the differential diagnosis being the same as for the uterine cervix.[48] Additionally, vaginal atrophy may closely mimic squamous intraepithelial neoplasia because of the high nuclear-to-cytoplasmic ratio.

Invasive Squamous Cell Carcinoma

Primary carcinoma of the vagina is much less common than carcinoma of the vulva or cervix and often presents in patients with a prior diagnosis of HSIL or invasive carcinoma of cervix or vulva.[49–51] It is HPV-associated in a large majority of cases and is largely a disease of the elderly.[52,53] As with vulvar squamous cell carcinomas, the HPV-independent tumors are associated with a worse prognosis than the more common HPV-associated squamous cell carcinoma.[54] Since most carcinomas involving the upper vagina represent direct extension from cervical carcinomas, only vaginal tumors that spare the uterine cervix are regarded as primary. Those involving both areas are classified as cervical carcinomas with vaginal extension, regardless of the relative proportion of involvement. The same reasoning holds true for carcinomas involving vulva and distal vagina; these are considered to be vulvar carcinomas with vaginal extension, by convention.

Most primary vaginal carcinomas are grossly nodular or ulcerative (Fig. 31.8).[55] The upper third and the anterior or lateral walls are the most common sites of origin.[56] A few cases have arisen in surgically constructed neovaginas.[57,58]

Microscopically, the morphologic appearance of vaginal squamous cell carcinomas duplicates that of their vulvar counterparts and can be well-differentiated keratinizing type (Fig. 31.9) or can show basaloid or warty morphology (Fig. 31.10).

Vaginal carcinoma is usually treated by a combination of external and intracavitary radiation[59–61]; local excision can be employed for small tumors and radical surgery for selected cases located in the upper vaginal third or posterior wall.[62] The overall 5-year survival rate is between 40% and 50% but is significantly higher (~75%) for patients with stage I disease (Table 31.1).[63] The prognosis is similar whether the patient has a previously treated cervical carcinoma or not.[64] Most recurrences occur within 1 year of therapy and carry an ominous prognosis. Upper lesions tend to recur locally, whereas lower lesions are more commonly associated with pelvic sidewall and distal recurrence.[65]

Table 31.1 Definitions of AJCC TNM: vagina

DEFINITION OF PRIMARY TUMOR (T)		
T CATEGORY	**FIGO STAGE**	**T CRITERIA**
TX		Primary tumor cannot be assessed
T0		No evidence of primary tumor
T1	I	Tumor confined to the vagina
T1a	I	Tumor confined to the vagina, measuring ≤2.0 cm
T1b	I	Tumor confined to the vagina, measuring >2.0 cm
T2	II	Tumor invading paravaginal tissues but not to pelvic sidewall
T2a	II	Tumor invading paravaginal tissues but not to pelvic wall, measuring ≤2.0 cm
T2b	II	Tumor invading paravaginal tissues but not to pelvic wall, measuring >2.0 cm
T3	III	Tumor extending to the pelvic sidewall[a] and/or involving the lower third of the vagina and/or causing hydronephrosis or nonfunctioning kidney
T4	IVA	Tumor invading the mucosa of the bladder or rectum and/or extending beyond the true pelvis (bullous edema is not sufficient evidence to classify a tumor as T4)
DEFINITION OF REGIONAL LYMPH NODE (N)		
N CATEGORY	**FIGO STAGE**	**N CRITERIA**
NX		Regional lymph nodes cannot be assessed
N0		No regional lymph node metastasis
N0(i+)		Isolated tumor cells in regional lymph node(s) no greater than 0.2 mm
N1	III	Pelvic or inguinal lymph node metastasis
DEFINITION OF DISTANT METASTASIS (M)		
M CATEGORY	**FIGO STAGE**	**M CRITERIA**
M0		No distant metastasis
M1	IVB	Distant metastasis

[a]*Pelvic sidewall* is defined as the muscle, fascia, neurovascular structures, or skeletal portions of the bony pelvis. On rectal examination, there is no cancer-free space between the tumor and pelvic sidewall.
From Amin M, Edge S, Greene F, et al., eds. *AJCC Cancer Staging Manual*. Vol 8. New York, NY: Springer; 2017.

The existence of *microinvasive (superficially or minimally invasive) carcinoma* as a distinct clinical entity in the vagina has been proposed, but the concept faces the same theoretic and practical difficulties for a precise definition as in the vulva and cervix, a problem exacerbated by the rarity of vaginal carcinoma.[66] The College of American Pathologists checklist for vaginal tumors does include a category of superficial invasive squamous cell carcinoma, defined as 3 mm or less invasion with no lymphovascular invasion, which identifies a group of patients with reduced (but not negligible) chance of lymph node metastases.[66]

Clear Cell Carcinoma

Clear cell (adeno)carcinoma characteristically occurs in the anterior or lateral wall of the upper vagina or in the uterine cervix. Formerly it was most often encountered in children, adolescents, and young adults post in utero exposure to DES.[12,56] Since DES stopped being used during pregnancy, it has become a very rare form of vaginal carcinoma. Microscopically, there are tubules and cysts lined by clear cells alternating with more solid areas and papillary formations (Fig. 31.11).[67] Mitotic figures are variable but usually scanty. The tumor cells have abundant clear cytoplasm because of the presence of glycogen. Intracytoplasmic mucin is either absent or scanty. Hobnail-shaped cells are frequently seen protruding into the glandular lumen. The microscopic differential diagnosis needs to be made primarily with microglandular hyperplasia, which can occur in areas of vaginal adenosis, and the Arias-Stella reaction related to pregnancy or progestational agents. Yolk sac tumor is theoretically in the differential diagnosis but occurs almost exclusively in infancy and early childhood (<4 years old). The immunohistochemical profile of these tumors is not well characterized but appears to be similar to that of the more common clear cell carcinomas of endometrium and ovary.[68]

The prognosis is relatively favorable; small, asymptomatic tumors usually are cured by surgery. Tumors that are large, that are close to the resection margins, or that have penetrated more than 3 mm into the wall tend to recur locally.[69]

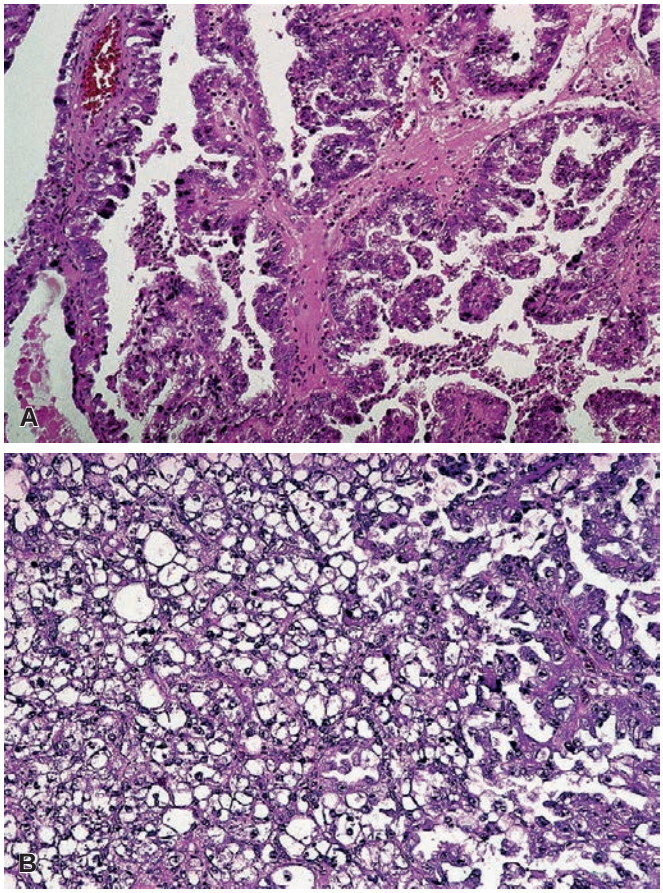

Figure 31.11 Clear Cell Carcinoma of Vagina. A, Papillary pattern; **B,** prominent clear cell features.

Other Carcinoma Types

Verrucous carcinoma is an extremely well-differentiated variant of squamous cell carcinoma. Like its vulvar and cervical counterparts, it invades locally but is practically never associated with lymph node metastases. The local spread can be quite extensive and reach the rectum and coccyx.[70] It should be distinguished from condyloma acuminatum, which may rarely involve the vagina; the criteria are the same as those described in the section on the vulva. Most verrucous carcinomas are unrelated to HPV.[71]

Endometrioid adenocarcinoma can occur in the vagina, and most cases are located at the vaginal apex.[72] It is thought to arise on the basis of vaginal endometriosis.[73] The presence of the latter is important in supporting a primary vaginal tumor as opposed to secondary spread from the endometrium. The combination of p16 and ER immunostaining, most commonly used to distinguish HPV-associated cervical adenocarcinoma (diffuse p16 reactivity, ER–) from endometrioid adenocarcinoma of the endometrium (patchy p16 reactivity, ER+) can shed light on the pathogenesis of an adenocarcinoma present in a vaginal biopsy, but cannot distinguish between a primary vaginal adenocarcinoma of endometrioid type arising from endometriosis versus secondary vaginal involvement from an endometrioid carcinoma of endometrium, or primary vaginal adenocarcinoma of HPV-associated type versus secondary involvement by an endocervical adenocarcinoma. Note that metastatic involvement of the vagina is more common than primary vaginal adenocarcinoma, and a primary endometrial or cervical adenocarcinoma must be excluded on clinical grounds as there are no primary site-specific immunomarkers. Endometriosis is also the presumed origin for most cases of adenocarcinoma located in the rectovaginal septum and having no mucosal involvement of either the vagina or rectum.[74,75]

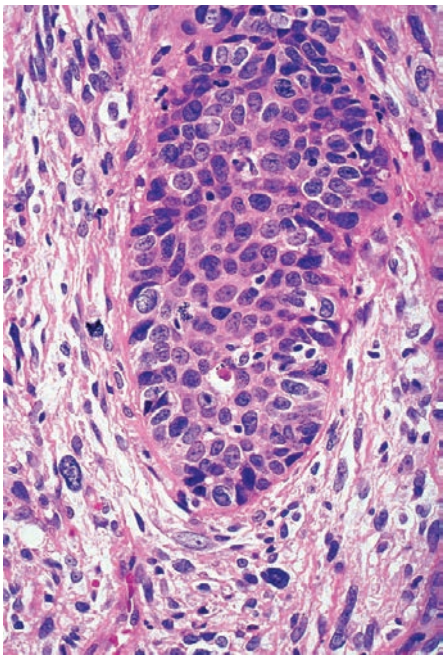

Figure 31.12 Spindle cell (sarcomatoid) carcinoma of vagina. Elongated cells with a mesenchymal-like appearance surround a well-defined nest having a clear-cut epithelial appearance.

Mesonephric (wolffian) adenocarcinoma is an exceptionally rare tumor located paravaginally, along the course of the wolffian-derived ducts of Gartner.[76,77] They morphologically and immunophenotypically resemble the more common mesonephric adenocarcinomas of the cervix and uterine corpus. They may be biphasic, with a spindle cell component.[76]

Sarcomatoid carcinoma (carcinosarcoma) of the vagina is equivalent to the more common sarcomatoid carcinomas of the upper aerodigestive tract (Fig. 31.12).[78,79]

Mucinous adenocarcinoma of vagina has been described in middle-aged and elderly patients, occasionally arising on the basis of endocervicosis.[80] Its microscopic features are indistinguishable from those of its more common endocervical counterpart.[81] In a few reported cases, the appearance has been reminiscent of enteric epithelium.[33,82] Its relationship with HPV is not known at this time.

High-grade (neuroendocrine) carcinoma can occur in the vagina, either in a pure form or associated with squamous or glandular elements.[80,83–85] They can be either small cell or large cell type. Most cases have been treated by a combination of radiation therapy and chemotherapy.[84] A case of neuroendocrine carcinoma of the vagina with a *Merkel cell* phenotype has also been reported.[86]

Other carcinoma types that have been described in the vagina are *urothelial (transitional cell) carcinoma*[87] (including a pagetoid form[88] and a variant described as *papillary squamotransitional*[89]), *lymphoepithelioma-like carcinoma*,[90,91] *basaloid carcinoma*,[92] adenoid basal carcinoma, and adenosquamous carcinoma.

Mesenchymal Tumors and Tumorlike Conditions

Fibroepithelial polyps may be seen in adult women (especially during pregnancy) or in neonates.[93,94] They are probably not true neoplasms but rather manifestations of hormone-induced localized hyperplasia of the loose subepithelial connective tissue zone[95]; others

Figure 31.13 Curious mushroom-like appearance of vaginal fibroepithelial polyp. (Courtesy of Dr. Pedro J. Grases Galofré; from Grases Galofré PJ. *Patología ginecológica. Bases para el diagnóstico morfológico*. Barcelona: Masson; 2002.)

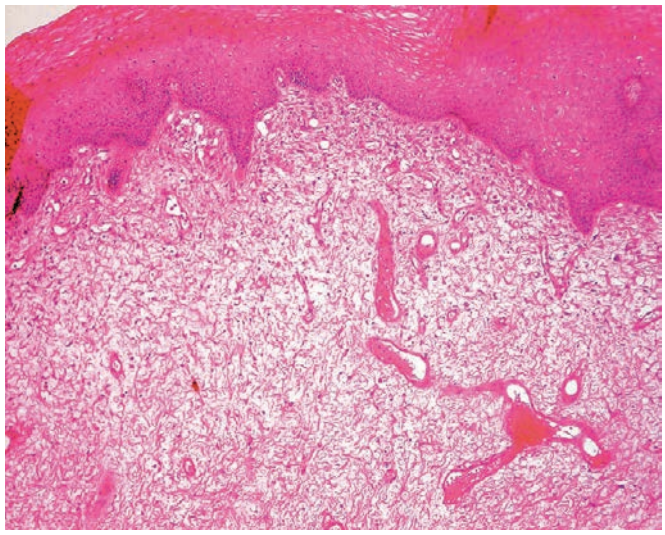

Figure 31.14 Fibroepithelial polyp of vagina showing loose fibrovascular stroma covered by slightly thickened but otherwise unremarkable squamous epithelium.

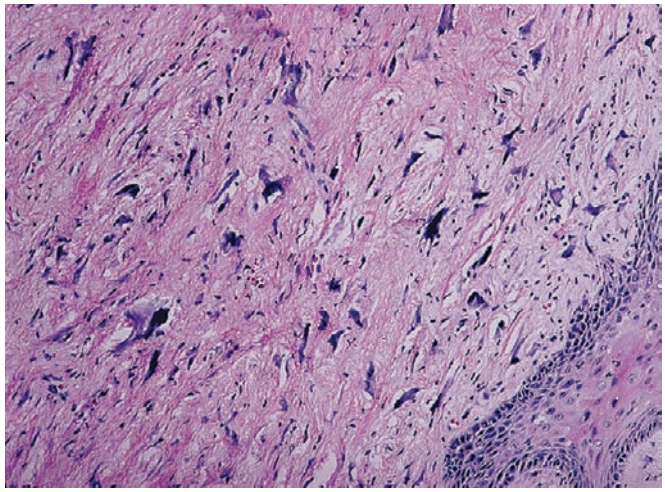

Figure 31.15 Atypical benign stromal cells in a vaginal polyp.

may represent the end stage of granulation tissue (Fig. 31.13).[96] Microscopically, they are formed of a central fibrovascular core and a covering of normal-appearing squamous epithelium (Fig. 31.14). Sometimes the stroma is markedly edematous[95]; in other instances it is hypercellular and/or contains scattered highly atypical stromal cells of stellate shape (Fig. 31.15).[97–100] These stromal cells are commonly immunoreactive for desmin and steroid receptors but usually not for actin.[101,102] The clinical appearance, nuclear atypia, and desmin immunoreactivity may lead to a mistaken diagnosis of embryonal rhabdomyosarcoma or other types of malignant tumor.[94,103] The slow pace of growth at the clinical level and the fact that a cambium layer, epithelial invasion, and cross striations are absent are among the distinguishing features; they also lack expression of the myoblastic markers myogenin and MyoD1 on immunostaining.

Aggressive angiomyxoma can present as a protruding intravaginal mass and extend through the paravaginal soft tissue.[104]

Angiomyofibroblastoma, superficial myofibroblastoma, and **solitary fibrous tumor** are other types of benign mesenchymal neoplasms of fibroblastic/myofibroblastic nature that have been reported in the vagina.[105–107] The angiomyofibroblastoma has an appearance identical to that of its vulvar counterpart, and the superficial myofibroblastoma represents a minor variation on the theme of benign polypoid tumors of the hormonally responsive mesenchymal cells of the region.[108] Solitary fibrous tumor, as in other sites, can be confirmed with *STAT6* nuclear expression by immunohistochemistry.

Postoperative spindle cell nodule is a pseudosarcomatous vaginal lesion that occurs a few weeks following hysterectomy or some other surgical procedure in the region and which presents as a small friable reddish mass in the vaginal vault.[109,110] Microscopically, it shows ulceration, granulation tissue, and a very hypercellular spindle cell proliferation characterized by a fascicular pattern of growth, many mitotic figures, and numerous extravasated red blood cells, resulting in a Kaposi sarcoma-like appearance (Fig. 31.16).[109] It can also be confused with sarcoma (particularly leiomyosarcoma) and sarcomatoid carcinoma. Immunohistochemically, there may be reactivity for low-molecular-weight keratin, which may contribute to the misinterpretation of the lesion. Clues to its recognition are the distinctly fascicular pattern, the Kaposi sarcoma-like areas, fine nuclear chromatin, the absence of pleomorphism, the fact that the mitoses—although abundant—are all typical, and, most important, the history of a recent operation in the area.

Leiomyoma is the most common benign mesenchymal tumor of the vagina.[108,111] The patients are adults, and any region of the vagina can be affected. A peculiar case has been seen containing paraganglioma-like tissue within.[112]

Leiomyosarcoma can attain a large size and ulcerate.[113] The majority of the cases manifest their malignancy only through local recurrence. The criteria of malignancy used by Tavassoli and Norris[111] were the presence of moderate to marked atypia and five or more mitotic figures per 10 high-power fields. Poorly differentiated tumors are associated with a high mortality rate.[114]

Rhabdomyoma presents as a polypoid mass.[115] All of the reported cases have occurred in adult patients, an important differential point with botryoid rhabdomyosarcoma, discussed later. Microscopically, the lesion consists of interweaving and haphazardly oriented

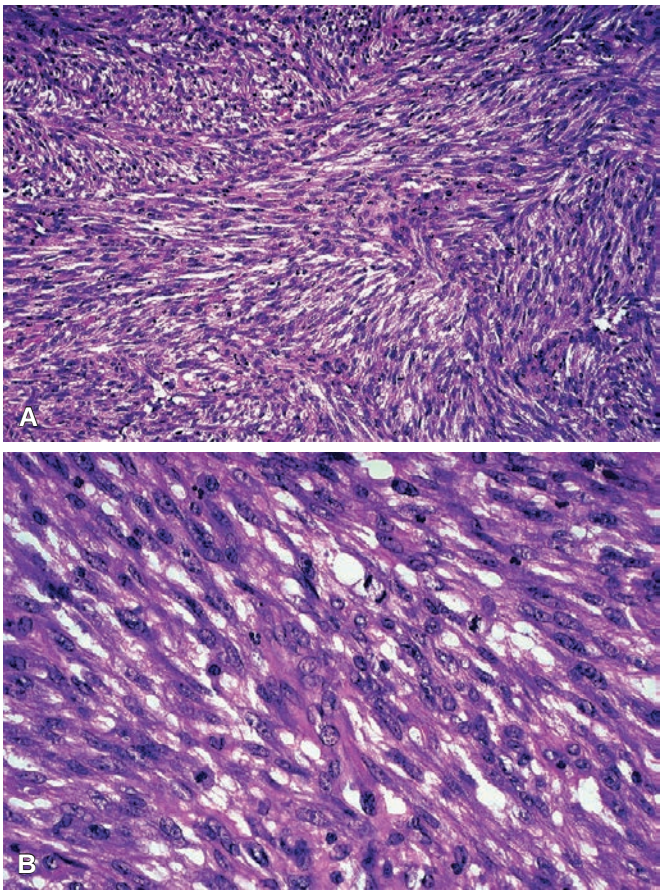

Figure 31.16 **A** and **B,** Medium- and high-power views of postoperative spindle cell nodule. The lesion is extremely cellular and mitotically active, but there is little pleomorphism.

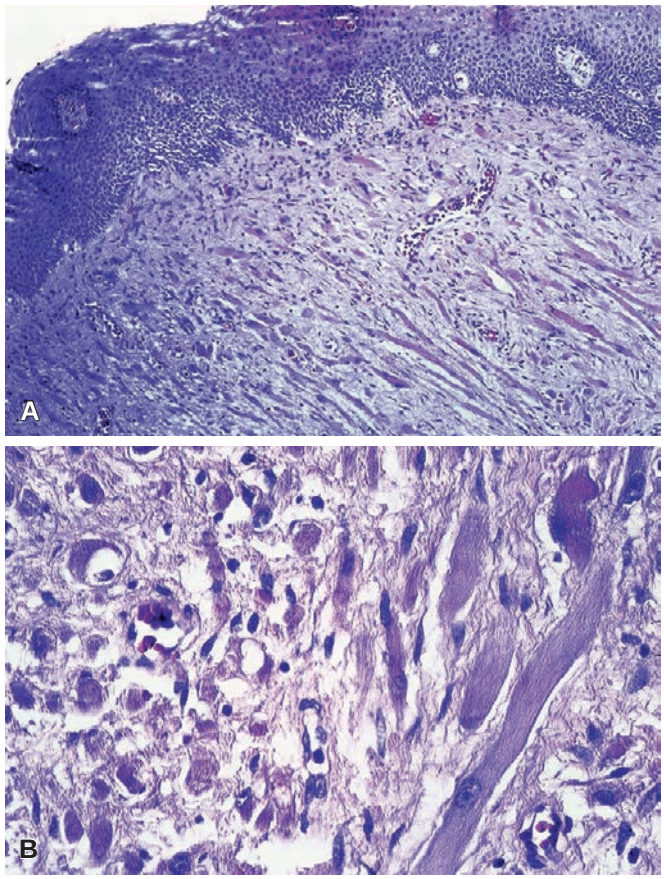

Figure 31.17 **A** and **B,** Vaginal rhabdomyoma composed of bundles of mature skeletal muscle cells scattered in the stroma beneath normal squamous epithelium.

bundles of spindle- to strap-shaped cells, some with cross striations (Fig. 31.17).[116] Mitoses are scanty or absent, and there is no concentration of neoplastic cells beneath the epithelium.

Other benign mesenchymal tumors that have been reported in the vagina are *hemangioma, hemangiopericytoma,*[117] *glomus tumor,*[118] *benign "triton" tumor,*[119] *angiomyolipoma,*[120] *(cellular) schwannoma,*[121] and *neurofibroma.*[122]

Embryonal rhabdomyosarcoma (sarcoma botryoides) is a rare polypoid invasive tumor that usually arises from the anterior vaginal wall (Fig. 31.18).[123] Approximately 90% of cases occur in girls under 5 years of age, with close to two-thirds appearing during the first 2 years. Grossly, it presents as a conglomerate of soft polypoid masses resembling a bunch of grapes—hence its designation as "botyroid."

Microscopically, a myxoid stroma is seen containing a mixture of fusiform, round, or spindle cells (Fig. 31.19). Some of these cells contain a bright eosinophilic granular cytoplasm suggestive of rhabdomyoblastic differentiation. Their racquet- or strap-shaped form mimics that of the cells seen during normal muscle embryogenesis. Cross striations may or may not be present. An important diagnostic feature is the crowding of the tumor cells around blood vessels and, most important, beneath the squamous epithelium. The latter results in a distinctive subepithelial dense zone (the "cambium layer" of Nicholson) (Fig. 31.20). Invasion of the overlying epithelium can be seen. Foci of neoplastic cartilage may be found; these tend to occur in older patients and/or in tumors located higher in the vagina or cervix, and they are said to be associated with a better prognosis. Botryoid tumors are currently regarded as a variation

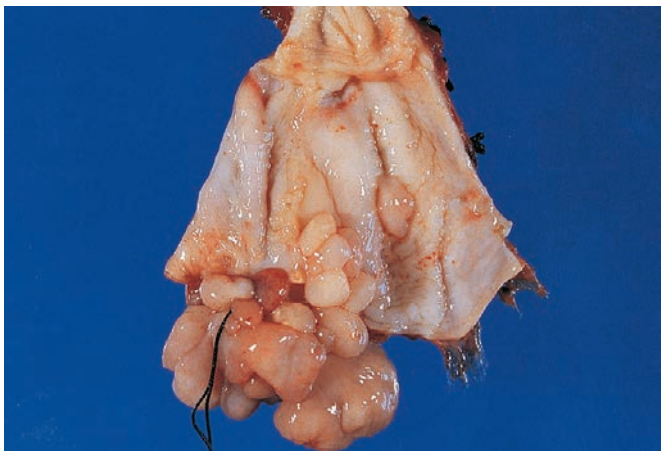

Figure 31.18 **Botryoid Embryonal Rhabdomyosarcoma of Vagina.** The grape-like configuration of this lesion is characteristic.

in the growth pattern of embryonal rhabdomyosarcoma, due to their location immediately beneath an expansile epithelial lining. They cause death more often by direct extension than by distant metastases.[124] Of the 15 autopsied cases reviewed by Hilgers et al.,[125] the tumor was confined to the pelvis in about half.

The treatment of this tumor, traditionally consisting of radical surgery,[126,127] is now primarily based on chemotherapy, which can

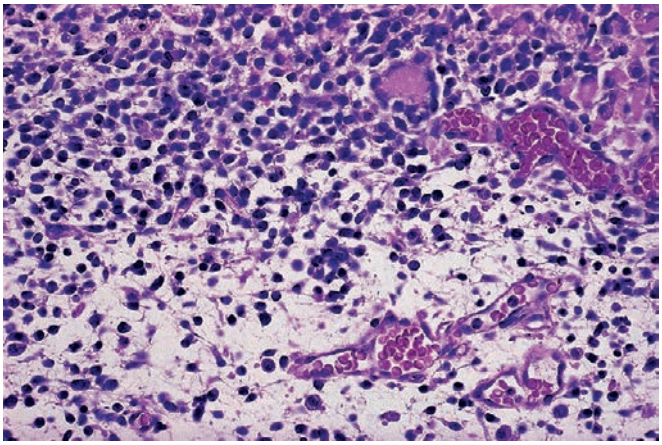

Figure 31.19 Microscopic Appearance of Embryonal Rhabdomyosarcoma. The differential diagnosis is that of small round cell tumors.

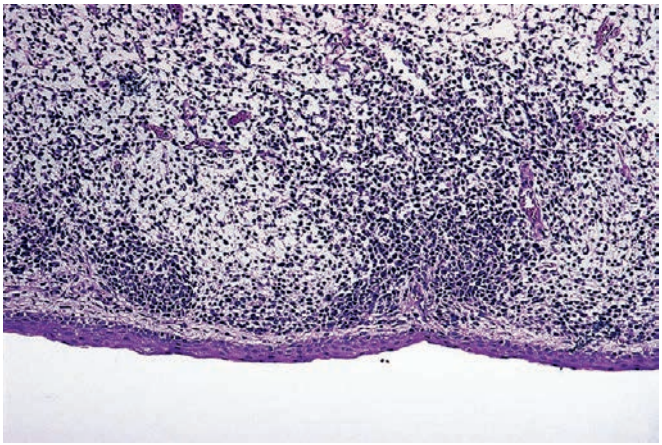

Figure 31.20 So-called cambium layer beneath non-neoplastic epithelium in embryonal rhabdomyosarcoma.

be combined with radiation therapy and/or surgery depending on the circumstances.[128]

Other primary sarcomas that have been reported in the vagina are *stromal sarcoma* of endometrial type,[129] *malignant peripheral nerve sheath tumor*,[129] *angiosarcoma*[130] (sometimes arising as a complication of radiation therapy[131]), *alveolar soft part sarcoma*,[132–134] synovial sarcoma,[135] and Ewing sarcoma/PNET.[136] Confirmation of the characteristic molecular abnormalities, where available (e.g., EWS translocation in Ewing sarcoma), is key to accurate diagnosis of these rare sarcomas.

Melanocytic Tumors

Melanoma can occur as a primary vaginal tumor in elderly patients.[137–140] It presents as a soft polypoid mass, blue or black, and frequently ulcerated (Fig. 31.21).[141] Most cases are located in the lower one-third and in the anterolateral aspect.[142] Microscopically, the appearance is similar to that of the cutaneous melanomas, although they tend to show greater anaplasia and pleomorphism (Fig. 31.22). An intraepithelial component of lentiginous appearance should be looked for to substantiate a local origin, although this feature can be destroyed by the tumor ulceration. The prognosis is extremely poor.[138,143,144] BRAF and KIT mutations were not identified in a series of primary vaginal melanomas, but 12% of cases had

Figure 31.21 Malignant Melanoma of Vagina. (From Norris HJ, Taylor HB. Melanomas of the vagina. *Am J Clin Pathol*. 1966;46:420–426.)

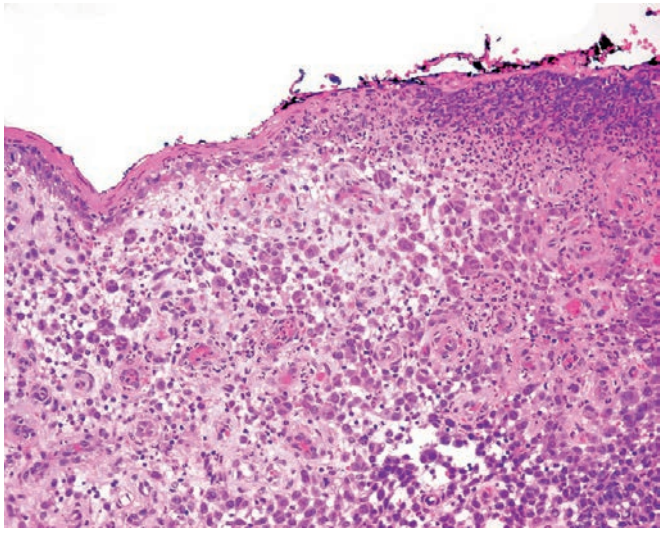

Figure 31.22 Malignant Melanoma of Vagina. The tumor has an undifferentiated appearance, is largely amelanotic, and has an ulcerated surface.

NRAS mutations and another 12% had KIT amplification.[145] The melanocytes that have been identified in 3% of normal vaginas[139] most likely represent the cell of origin of this neoplasm, sometimes through a preceding stage of melanosis or atypical melanocytic hyperplasia.[146,147]

Blue nevus of the ordinary type can present as a primary vaginal lesion.[141]

Other Primary Tumors

Yolk sac tumor (endodermal sinus tumor) typically affects infants under 2 years of age and is more commonly located in either the posterior wall or the fornices.[148,149] Clinically, it can simulate rhabdomyosarcoma.[150] Microscopically, the most important differential diagnosis is with clear cell (adeno)carcinoma, a tumor with which it has been confused in the past. Immunohistochemically, reactivity for SALL4 and alpha-fetoprotein favors yolk sac tumor, and reactivity

for Leu-M1 favors clear cell carcinoma.[151] In early series, most patients with vaginal yolk sac tumor died with generalized metastases,[152] but the combination of surgical excision and multidrug chemotherapy (sometimes with the addition of radiation therapy) has resulted in many long-term cures.[129,153]

Malignant lymphoma can affect the vagina secondarily or sometimes as the only site of involvement; nearly all cases are of non-Hodgkin type.[154–156] The largest group is represented by diffuse large B-cell lymphomas.[157] A case has been reported in association with malakoplakia.[158] Vaginal involvement can also occur in *acute myeloid leukemias* (granulocytic sarcoma).[159]

Other primary tumors of the vagina or paravaginal region, all exceptionally rare, are *Brenner tumor*,[160,161] *female adnexal tumor of probable wolffian origin*,[162] *PEComa*,[155] *myoepithelioma*,[163] and *gastrointestinal stromal tumor* (presenting in the vaginal wall or in the rectovaginal septum).[164,165]

Metastatic Tumors

Metastatic carcinoma to the vagina arises most commonly in the uterine cervix and endometrium, followed by the ovary, large bowel, and kidney.[166–168] Some cases represent direct extension, and others are distant metastases. The metastases from endometrial adenocarcinoma are often submucosal and located in the upper third of the organ.

Other tumors that can metastasize to vagina are melanoma[169] and malignant trophoblastic neoplasms, including epithelioid trophoblastic tumor.[170]

Normal Anatomy

The cervix is the lower portion of the uterus which connects this organ to the vagina through the endocervical canal. It is divided into a portion that protrudes into the vagina *(portio vaginalis)* and one that lies above the vaginal vault *(supravaginal portion)*. The outer surface of the portio vaginalis is known as the exocervix or ectocervix, and the portion related to the endocervical canal corresponds to the endocervix. The opening of the endocervical canal onto the exocervix is known as the *external os*, whereas the grossly indistinct upper limit of the endocervical canal is designated the *internal os*.[1]

Most of the exocervix is covered by nonkeratinizing squamous epithelium that in childbearing age is composed of three layers: basal cell, midzone (stratum spongiosum), and superficial. The portion of the midzone immediately above the basal layer is referred to as the *suprabasal layer*. The morphologic appearance of the various layers varies with age; in the postmenopausal period, the cells are atrophic and exhibit a high nuclear-to-cytoplasmic ratio. These changes should not be misinterpreted as evidence of squamous intraepithelial lesions (SILs)/cervical intraepithelial neoplasia (CIN).

Histochemically, the cells above the basal layer show variable amounts of glycogen, readily appreciated in sections with a periodic acid–Schiff (PAS) stain and clinically by the application of the iodine (Lugol or Schiller) test. Immunohistochemically, the cells of the basal layer are positive for low-molecular-weight keratin and tissue polypeptide antigen (TPA) but not for high-molecular-weight (epidermal type) keratin or for involucrin.[2–6] The latter two markers become positive in the cells above the basal layer. Basal cells are also immunoreactive for estrogen receptors.[7]

The glandular mucosa of the endocervix is formed by a layer of columnar mucus-secreting cells, the histochemical reactivity for the mucin depending on the time of the menstrual cycle.[8] These cells rest on a normally inconspicuous layer of subcolumnar "reserve" cells, which are also positive for TPA.[2] These "reserve" cells (in particular, those located at or near the squamocolumnar junction) are primarily involved in the processes of squamous metaplasia, high-grade squamous intraepithelial lesion (HSIL) (CIN2/3), and carcinoma. The glandular epithelium is immunoreactive for estrogen receptors.[7] In addition to lining the surface, it invaginates into the stroma to produce elongated clefts (usually <5 mm deep but sometimes as deep as 1 cm or more), forming the endocervical glands.

The area where the squamous and glandular epithelia meet is known as the *squamocolumnar junction* (Fig. 32.1). It should be noted that this junction is not located in the anatomic external os but rather in the adjacent exocervix, a fact that renders it easily accessible to the colposcope. The portion of endocervical mucosa covering the exocervix is sometimes referred to as *ectropion* and, inaccurately, as *erosion*. This is a very unstable region, in which replacement of one epithelium for another repeatedly occurs, a process that Robert Meyer allegorically referred to as "the fight of the epithelia." Today, this area is more prosaically known as the *transformation zone*.

Scattered endocrine cells are found in both the normal endocervix and exocervix,[9,10] and melanocytes are occasionally detected along the exocervical basal layer.[11]

The stroma of the cervix is mainly made up of fibrous tissue admixed with elastic fibers and scattered smooth muscle fibers. It has a dominant CD34 immunophenotype, whereas the endometrial stroma has a dominant CD10 phenotype.[12]

Remnants and Ectopias

Mesonephric rests are remnants of the wolffian ducts that are found surrounded by the endocervical stroma in about a third of women.

Abstract

Diseases of the uterine cervix account for a burden of human suffering and mortality that is disproportionate to its size, due to the susceptibility of the epithelium of the cervical transformation zone to infection by oncogenic human papilloma virus (HPV). Despite the introduction of cervical screening programs, cancer of the cervix remains one of the most common cancers. With the introduction of vaccination against HPV it can be anticipated that there will be a decrease in the number of surgical pathology specimens taken for evaluation of primary diseases of the cervix, but this is years off and in the near term, the pathology of the cervix will be important in any general surgical pathology practice.

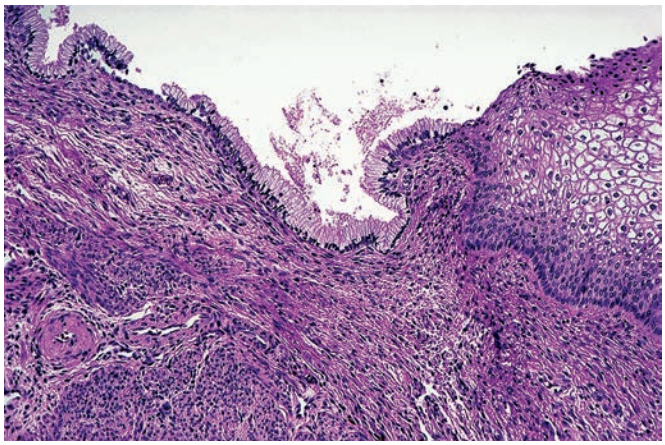

Figure 32.1 Transition zone of uterine cervix between exocervical squamous cells and endocervical mucin-producing glandular epithelium.

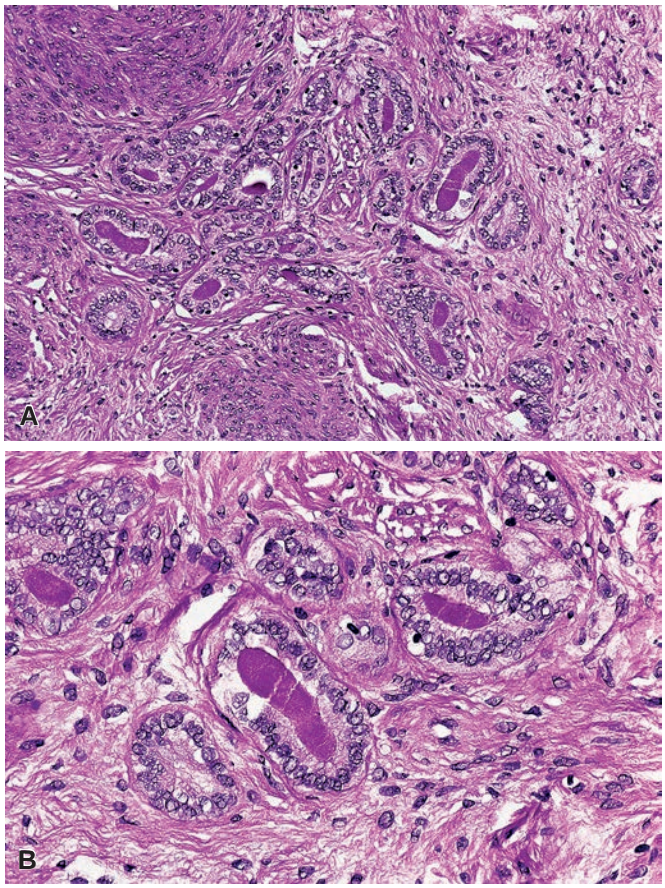

Figure 32.2 **A** and **B**, Florid mesonephric rests in endocervix. Note the eosinophilic inspissated secretion in the glandular lumen, an important diagnostic clue.

They are composed of tubules lined by a single row of cuboidal cells; they typically contain an inspissated deeply eosinophilic secretion in the lumen (Fig. 32.2). They are immunoreactive for PAX8, PAX2, and GATA3, a fact potentially useful for their distinction from endocervical adenocarcinoma and other glandular proliferations of the cervix.[13,14]

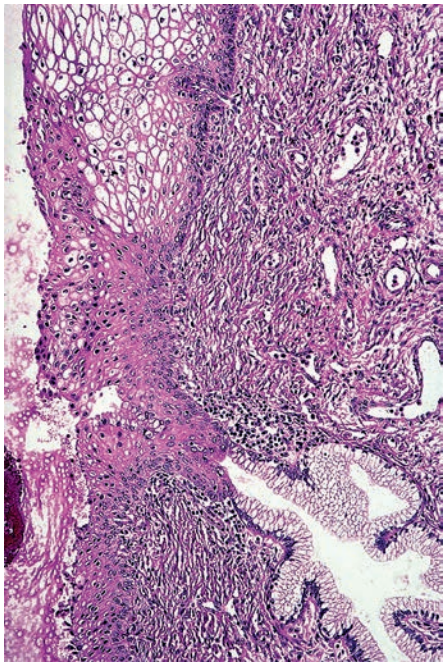

Figure 32.3 Squamous metaplasia of endocervix involving surface epithelium and glandular opening.

Ectopic tissues sometimes found in the cervix include *cutaneous adnexa* (sebaceous glands and hair follicles),[15] *prostatic tissue* (sometimes referred to as "female prostate"),[16–18] and *mature cartilage islands*.[19] The latter (which may be metaplastic rather than ectopic) should not be confused with the cartilaginous component of a carcinoma or a rhabdomyosarcoma.

Squamous and Other Metaplasias

Various types of metaplastic change of the cervical epithelium occur, their appearance being related to the type of mucosa affected. Squamous metaplasia, by far the most common (to the point that some regard it as a normal finding) is centered on the transformation zone; transitional metaplasia involves the exocervical squamous epithelium; and tubal, tuboendometrial, and intestinal metaplasia affect the glandular epithelium of the endocervix.

The term **squamous metaplasia** is used to designate the focal or extensive replacement of the mucus-secreting glandular epithelium by stratified squamous epithelium, which, in its late stage, is morphologically indistinguishable from the epithelium normally lining the exocervical portion (Fig. 32.3). The pathogenesis of this process, also known as *prosoplasia*, has been a subject of a heated controversy over the years. It is now generally agreed that it most commonly arises on the basis of proliferation and metaplasia of reserve cells. It is possible that in other instances it results from direct ingrowth of mature native squamous epithelium into the endocervical mucosa from the exocervix, possibly as a healing mechanism of a true cervical erosion.[20] Strictly speaking, the latter is not a metaplastic process but rather one of "squamous epithelialization." However, it is common usage to employ the term squamous metaplasia regardless of the presumed mechanism for the change.

Some degree of squamous metaplasia is present in almost every uterine cervix during the childbearing years. Most commonly, the process involves only the superficial epithelium and is recognized by the presence of squamous epithelium overlying endocervical glands. In other instances, it involves the glandular component as

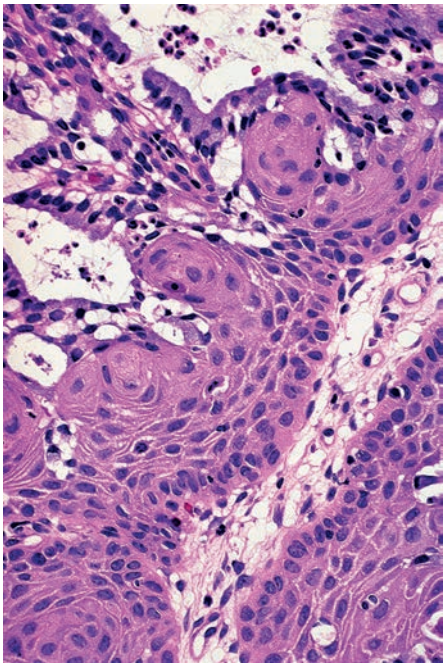

Figure 32.4 Complex pattern resulting from cervical squamous metaplasia. It may result in an overdiagnosis of squamous cell carcinoma.

well, resulting in a complex microscopic appearance that can be confused with invasive carcinoma by the inexperienced (Fig. 32.4).

Ultrastructural and immunohistochemical markers of squamous epithelium appear *pari passu* with the morphologic changes.[21,22] Variations on this theme, probably representing various stages within a continuum, have been described as *reserve cell hyperplasia* and as *immature, intermediate*, and *mature squamous metaplasia*.[23] The presence of cytologic atypia in immature squamous metaplasia raises the possibility of SIL/CIN; p16 immunostaining can be used to establish a diagnosis of HSIL (CIN2/3), but there remains significant overlap in the morphologic features between atypical immature metaplasia and low-grade squamous intraepithelial lesion (LSIL), with resulting interobserver variability in distinguishing between these two possibilities.[23–28] The diagnosis of SIL is discussed in more detail later in this chapter.

All of the above changes are characterized by a flat architecture and are, therefore, different from the condyloma and other papillary processes, including so-called papillary immature metaplasia (immature condyloma).

Although most cervical carcinomas arise in areas of the cervix that sometime in the past had been involved by squamous metaplasia, the latter process has no premalignant connotations per se. Actually, it is so common and insignificant that, unless quite extensive and/or involving the glandular component, we tend to ignore it altogether in our pathology reports.

A somewhat different appearance is seen often in the cervix of prolapsed uteri. The clinical appearance is usually referred to as "leukoplakic." Microscopically, the process involves mainly the exocervical portion and is characterized by the appearance of granular and horny layers in the epithelium. This process, which is also unrelated to carcinoma, is best designated as *keratosis*. Sometimes this epithelium contains scattered large pale cells, a change that has been dignified by the term *pagetoid dyskeratosis*.[29]

Transitional metaplasia is seen in the exocervix of older women, and it is often associated with atrophy. It morphologically resembles transitional (urothelial) epithelium, and it involves the entire thickness

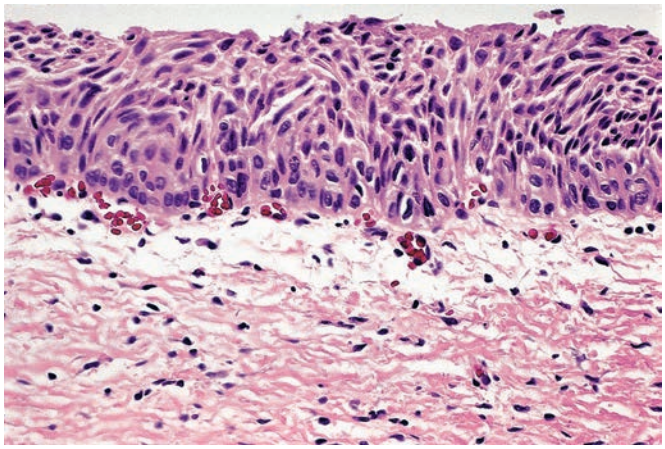

Figure 32.5 Typical appearance of transitional metaplasia, which lacks the nuclear atypia of HSIL (CIN2/3).

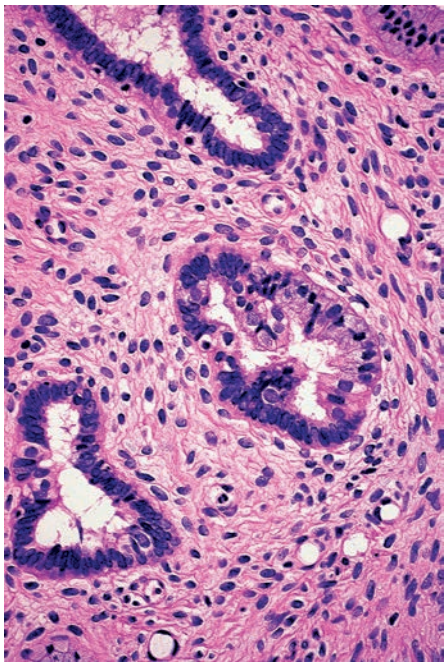

Figure 32.6 Tubal metaplasia of endocervix. Some of the lining cells are ciliated.

of the mucosa, without evidence of normal squamous maturation. The nuclei are oval and devoid of atypical features. Their long axes, which are arranged perpendicularly to the surface, often exhibit longitudinal grooves (Fig. 32.5).[30,31] Immunohistochemically, there is positivity for CK13, CK17, and CK18 but not for CK20.[32] Its phenotypic profile is very similar to that of senile atrophy.[33] Although this entity has engendered some controversy in the past, with respect to its relationship to SIL,[34] it is now regarded as an entirely benign metaplastic change that differs from atrophy only in consisting of a greater number of cellular layers.[35,36]

Tubal metaplasia is diagnosed when a specimen from the endocervix (usually from the upper portion) is found to contain all three cell types found in the normal fallopian tube (i.e., ciliated, secretory, and intercalated; Fig. 32.6).[37,38] In many instances, the appearance of the metaplastic epithelium combines features of tubal and endometrial mucosa, in which case the term *tuboendometrial*

(tuboendometrioid) metaplasia is employed.[39–41] Diagnostic difficulties may result from the fact that these glands may be deeply seated, irregularly shaped, cystically dilated, and/or accompanied by a hypercellular, edematous, or myxoid stroma.[42] The condition can be identified in cytologic preparations.[43]

Combined staining for Ki-67 and p16 is of help in the differential diagnosis from in situ and invasive endocervical adenocarcinoma, as tubal metaplasia shows a lower proliferative index and lacks the strong, diffuse, block positivity for p16 seen in human papilloma virus (HPV)-associated adenocarcinomas.[40,44] Tubal metaplasia is often found after conization, and it has therefore been suggested that it represents aberrant differentiation following injury.[45]

A *pseudoinvasive* form of the condition has been described in women with a history of in utero diethylstilbestrol (DES) exposure, suggesting that it may be a form of DES-related adenosis.[46]

Intestinal metaplasia is a vanishingly rare condition, which may be accompanied by extravasation of mucin into the stroma.[47] The presence of goblet cells in the endocervix should prompt a search for dysplastic change/adenocarcinoma in situ; this may be HPV associated or HPV independent.

Oxyphilic (eosinophilic) metaplasia is characterized by the presence of large cuboidal or polygonal epithelial cells with dense eosinophilic, focally vacuolated cytoplasm and variable nuclear atypia in the endocervical glands.[48,49] The differential diagnosis includes HSIL (CIN2/3) with eosinophilic cells, which can be recognized based on the presence of mitotic activity and p16 immunoreactivity.[49]

Inflammatory Lesions

Chronic cervicitis is an extremely common condition in adult females, at least at the microscopic level. It affects preferentially the squamocolumnar junction and endocervix, and it may be accompanied by hyperemia, edema, fibrosis, and metaplastic changes in the epithelium. The etiology is variable.[50] In most cases the disease is asymptomatic. Given that the presence of inflammatory cells at the squamocolumnar junction is normal (this being the junction between the sterile endometrial cavity/endocervix and the exocervix/vagina), it is a highly subjective distinction between "normal cervix" and a degree of inflammation that merits designation as "chronic cervicitis."

Herpes simplex infection of the cervix is now recognized as a relatively common occurrence. The microscopic appearance at the time of biopsy is usually that of an intense nonspecific inflammation with ulceration (Fig. 32.7A). Only rarely are diagnostic multinucleated squamous cells with intranuclear inclusions encountered (see Fig. 32.7B).[51] The diagnosis can be confirmed by immunocytochemical demonstration of the viral antigen.[52,53]

***Chlamydia trachomatis* infection** is now recognized as the most common venereal disease in the Western world. The microscopic appearance in the cervix is that of a chronic nonspecific inflammation, with reactive epithelial atypia and sometimes prominent formation of lymphoid follicles.[54,55] The organisms are not visible in routine histologic slides and only with difficulty in cytologic preparations, but they can be detected by immunocytochemical techniques.[55] Culture isolation is regarded as the standard for diagnosis of active infection. Chlamydial cervicitis can be associated with CIN, but there is no evidence of a causal relationship.[56]

Syphilis can affect the cervix, usually in the form of a primary chancre.[57]

Amebiasis may produce a polypoid and ulcerated mass in the cervix clinically simulating carcinoma, and it may also engraft itself upon a preexisting cervical carcinoma.[58,59]

Actinomycosis of the cervix occurs, but it needs to be distinguished from the more common pseudoactinomycotic radiate granules that may form around microorganisms or biologically inert substances.[60]

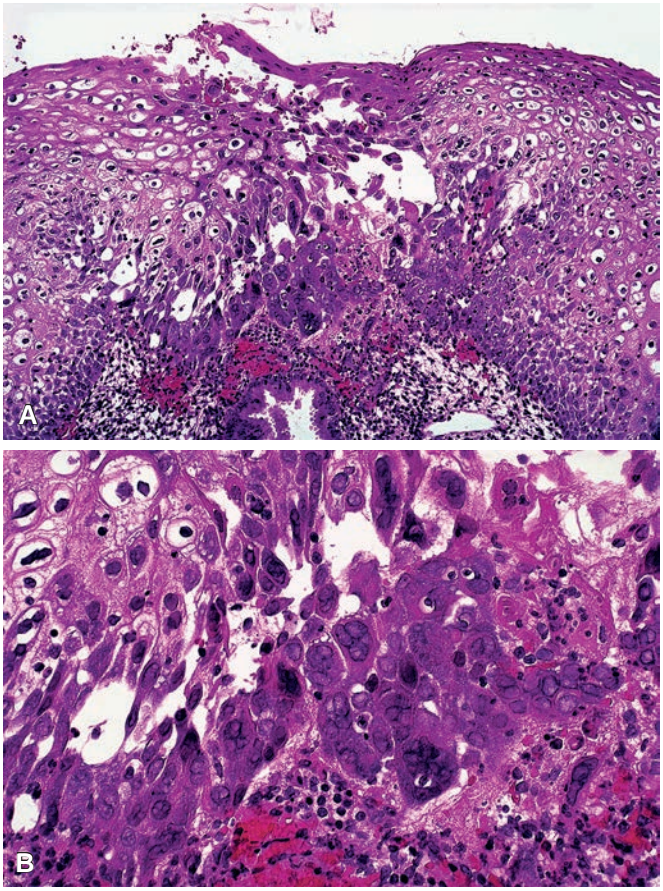

Figure 32.7 **A** and **B**, Low- and high-power appearance of herpes simplex infection of cervix. Multinucleated epithelial cells and intranuclear inclusions are evident in the high-power view.

Bilharziasis (schistosomiasis), common in Africa and Central America, can involve any portion of the female genital tract, including the cervix.[61]

Malakoplakia occurs rarely in the cervix, sometimes in association with disease in the uterine corpus, renal pelvis, or kidney.[62]

Ceroid granuloma of the type more commonly seen in the gallbladder has, exceptionally, been found to involve the cervix.[63,64]

Localized arteritis of the cervix has been described, accompanied by inflammation and ulceration, and apparently restricted to this anatomic site.[65,66] The cervix can also be involved in cases of granulomatosis with polyangiitis (formerly known as Wegener granulomatosis).[67]

Non-Neoplastic Glandular Lesions

Endocervical polyps are not true neoplasms but are probably the result of chronic inflammatory changes ("chronic polypoid cervicitis"). They are usually small but may reach several centimeters in diameter. Microscopically, dilated endocervical glands are seen in an edematous, inflamed, and fibrotic stroma. HSIL (CIN2/3) is an occasional incidental finding in a polyp. Occasionally, the configuration of these polyps is that of a branching papillary structure, in which case the term *papillary endocervicitis* is employed (Fig. 32.8).[47] This lesion is to be distinguished from so-called superficial cervicovaginal myofibroblastoma, which is equally benign and perhaps histogenetically related.[68] Exceptionally, cells with the morphology of signet

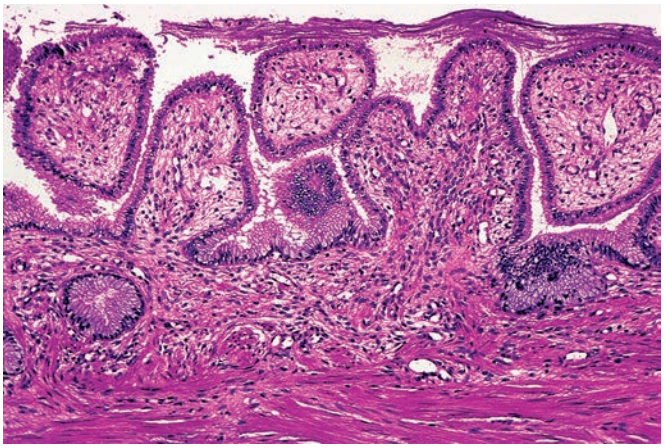

Figure 32.8 Chronic endocervicitis resulting in a papillary configuration at the surface. This pattern is sometimes referred to as papillary endocervicitis.

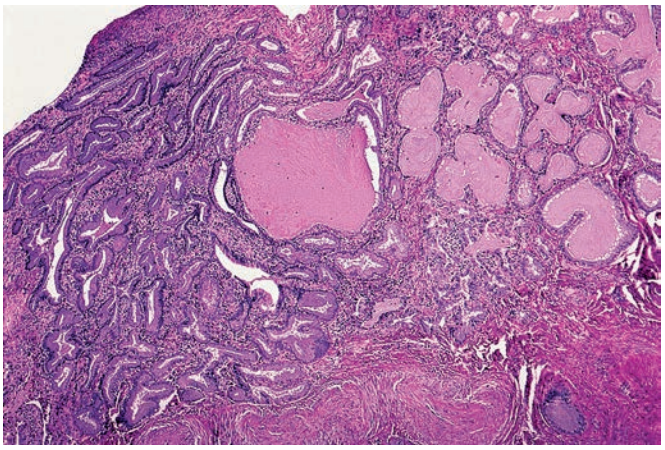

Figure 32.9 Cervical tunnel clusters of predominantly cystic type.

ring cells are seen within an ulcerated endocervical polyp; they are probably the result of ischemia and should not be overdiagnosed as signet ring cell carcinoma.[69]

Nabothian cysts are thought to develop from blockage of the endocervical glands secondarily to inflammation and associated changes; they appear grossly as cystic spaces filled with mucoid material and microscopically as cystically dilated glands lined by a flattened epithelium, sometimes focally absent. Occasionally they extend deeply into the cervical wall, a phenomenon that should not be mistaken for malignancy.[70]

Tunnel clusters, as originally described by Fluhmann, are the result of localized proliferation of endocervical glands (clefts), with side channels growing out from them. This may be accompanied by dilation resulting from the accumulation of inspissated, deeply eosinophilic secretion in the lumen (Fig. 32.9).[71]

Microglandular hyperplasia of the endocervical epithelium was originally described in women using oral contraceptive drugs and, less frequently, during pregnancy.[72,73] However, it can also be seen in the absence of these conditions and even in postmenopausal patients.[74] The relationship between microglandular hyperplasia and oral contraception or other hormonal perturbations has been questioned.[75] Microscopically, the typical case is characterized by a complex proliferation of small glands lined by flat epithelial cells with little or no atypia (Fig. 32.10). The condition usually evolves

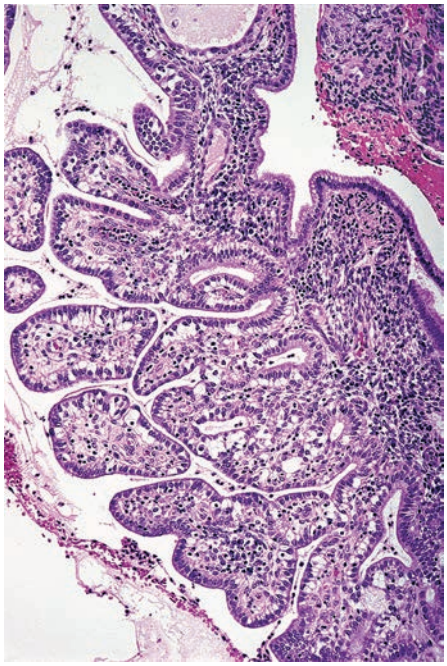

Figure 32.10 Microglandular Hyperplasia of Cervix. The papillary configuration seen here is common in this condition.

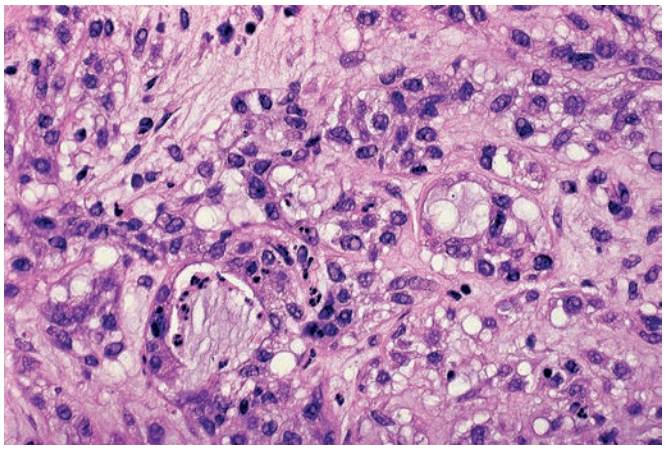

Figure 32.11 Predominantly Solid Form of Microglandular Hyperplasia. This variety is particularly likely to be overdiagnosed as a malignant process.

into squamous metaplasia, resulting in a complex microscopic picture that may be confused with carcinoma (Fig. 32.11). Additional features that may lead to overdiagnosis include areas of solid proliferation, pseudoinfiltrative pattern, signet ring cells, focal atypia, and occasional mitotic figures.[76] The intervening stroma invariably shows chronic inflammation. There is usually no immunocytochemical reactivity for carcinoembryonic antigen (CEA), a useful feature in the differential diagnosis with endocervical adenocarcinoma.[77] Microglandular hyperplasia must be distinguished from endometrial adenocarcinomas with microglandular hyperplasia-like features[78]; these carcinomas are seen in older patients, predominantly within the endometrial biopsy/curettings rather than the endocervical curettings, are often associated with atypical endometrial hyperplasia, and lack the p63 expressing reserve cells present in microglandular hyperplasia.

The **Arias–Stella reaction,** as seen during pregnancy, can involve the endocervical glands. The nuclear abnormalities are similar to

those seen more commonly in the endometrial mucosa and should not be confused with malignancy.[79–81] The microscopic appearance is quite variable and includes cells with vacuolated clear cytoplasm, intraglandular tufts, hobnail cells, oxyphilic cytoplasm, filiform papillae, nuclear pseudoinclusions, and cribriform intraglandular growth.[82] In contrast to clear cell carcinoma, the Arias–Stella reaction does not form a mass lesion, lacks a desmoplastic stromal response, and does not have an infiltrative pattern.[82]

Atypical reactive proliferation of the endocervical mucosal surface can be seen following endometrial sampling for endometrial carcinoma or other diseases. It shows nuclear stratification, short micropapillary processes, squamous metaplasia, hobnail cells, and mild cytologic atypia (i.e., many of the features that are associated with microglandular hyperplasia). It should not be interpreted as endocervical involvement by an endometrial carcinoma.[83]

Diffuse laminar endocervical glandular hyperplasia (DLEGH) is a non-neoplastic condition characterized by a proliferation of medium-sized, evenly spaced, well-differentiated glands within the inner third of the cervical wall, sharply separated from the underlying stroma, and often accompanied by chronic inflammation (Fig. 32.12)[84]; it should not be confused with adenoma malignum, from which it is distinguishable because of the fact that stromal infiltration, desmoplastic stromal response, and cytologic atypia are absent.[80]

Lobular endocervical glandular hyperplasia (LEGH) is characterized by a distinctly lobular proliferation of small- to medium-sized glands, often centered around a larger central gland.[85] The mucin secreted by some of these lesions is of gastric type.[86] In contrast to adenoma malignum, LEGH lacks irregular stromal infiltration, desmoplastic stromal response, and significant cytologic atypia. Interestingly, the phenotype of this process is similar to that of pyloric glands.[87] A possible pathogenetic relationship between the two conditions (and with HPV-independent mucinous adenocarcinomas of the cervix) has been suggested on the basis of some immunohistochemical and molecular genetic similarities,[87,88] as well as their occasional association.[86,89]

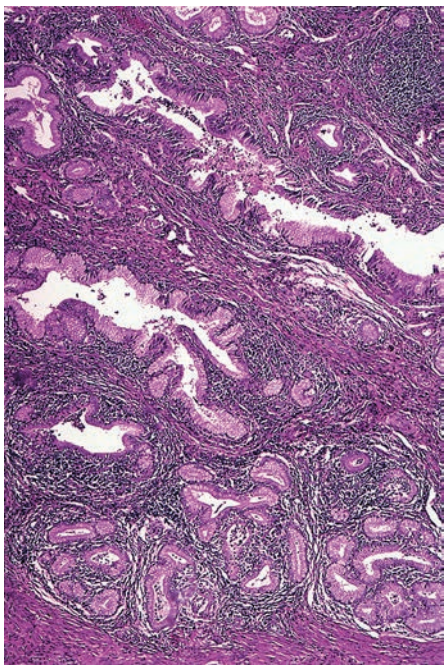

Figure 32.12 Diffuse Laminar Endocervical Hyperplasia. The glands are medium sized, evenly spaced, and well differentiated.

Mesonephric duct rests can undergo cystic dilation or be affected by florid and even atypical hyperplastic changes (Fig. 32.13).[90–92] This hyperplasia may have a lobular, diffuse, or ductal pattern (Fig. 32.14).[93] Rare malignant tumors arising from these structures also occur. Mesonephric remnants are also rarely involved by HSIL (CIN2/3).[94] It is doubtful whether the rare benign polypoid lesion found in the cervix and vagina of young children and described as *mesonephric papilloma* is related to these remnants.[95,96] Microscopically, it is a superficially located lesion composed of delicate connective tissue stalks covered by a layer of cuboidal cells and is probably of müllerian derivation.

Non-Neoplastic Stromal Lesions (Including Endometriosis and Related Processes)

Multinucleated stromal giant cells can be present beneath the cervical epithelium and be mistaken for a malignancy. They are often accompanied by edema and may result in a vaguely polypoid-appearing lesion.[97,98] These cells are of a reactive fibroblastic/myofibroblastic nature and analogous to those seen in other sites covered by mucosal membranes, such as vulva, vagina, anus, oral cavity, and nasal cavity.[99,100]

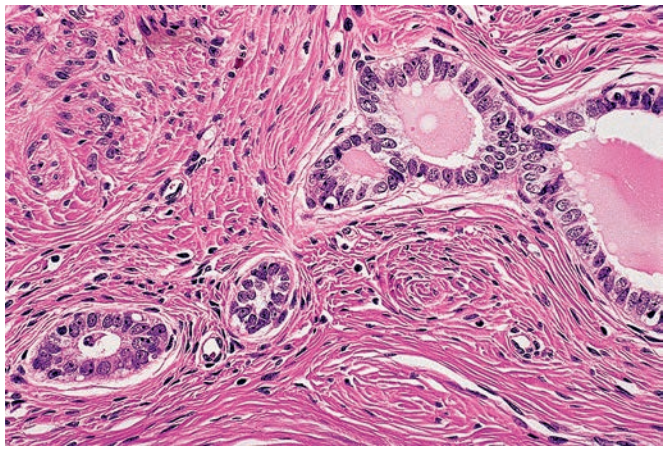

Figure 32.13 Hyperplastic mesonephric rests with mild atypia.

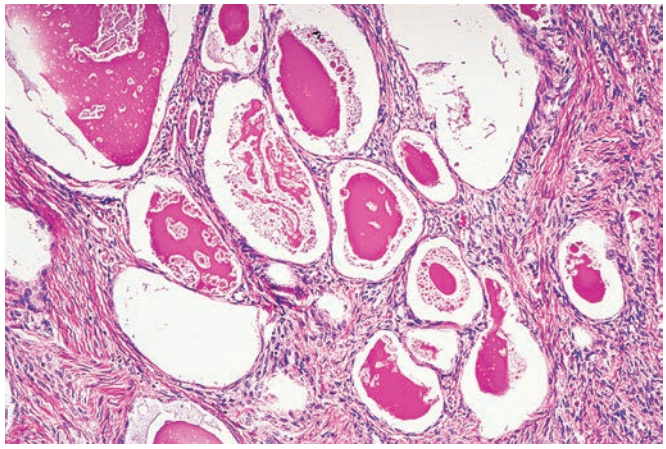

Figure 32.14 Mesonephric glands embedded within the stroma of the uterine cervix exhibiting cystic dilation. The presence of a dense eosinophilic secretion is characteristic.

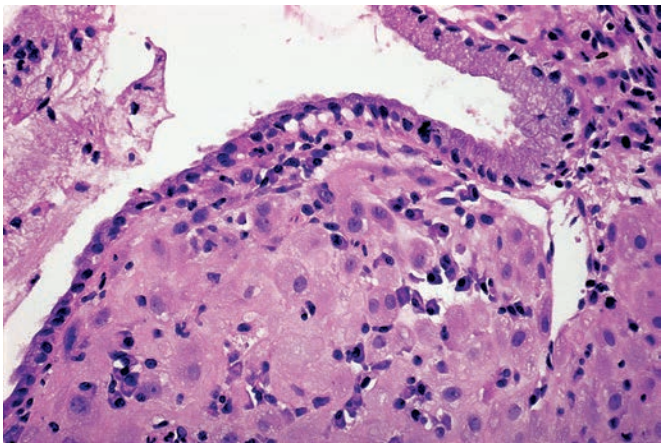

Figure 32.15 Focus of ectopic cervical decidual reaction.

Decidual reaction in the cervix during pregnancy usually presents as multiple, small, yellowish or red elevations of the cervical mucosa. They are soft and friable and bleed easily with trauma. Rarely, they develop into fungating masses difficult to distinguish grossly from carcinoma.[101] Microscopically, the decidual cells are characterized by abundant pale granular cytoplasm and bland nuclei (Fig. 32.15). Immunostains for keratin are negative.

Placental site nodule appears as a well-defined hyalinized lesion located immediately beneath the mucosa.[102] It is composed of intermediate trophoblasts exhibiting cytoplasmic vacuolization.[103,104] Some nuclear atypia may be present. This lesion can be confused with carcinoma and with neoplastic cartilage. Immunohistochemically, the trophoblastic cells are reactive for keratin (another factor that may lead to a mistaken diagnosis of malignancy) but also for human placental lactogen.

Endometriosis of the cervix presents as blue or reddish nodules and may result in abnormal uterine bleeding. Both endometrial glands and stroma are needed to establish the diagnosis. However, the proportion of the two components may vary greatly from case to case. On occasion, the process is composed exclusively of endometrial stroma ("stromal endometriosis") and may be confused with a neoplasm.[105] Another source of confusion arises when the endometriosis is superficial, in which case it may be overinterpreted as endocervical glandular dysplasia or adenocarcinoma in situ, one of the reasons being that it may be mitotically active.[106] It differs from tuboendometrial metaplasia of the endocervix because of the concomitant presence of endometrial-type stroma, however scarce. A lesion with an appearance resembling a miniature uterus in the cervix ("uterus-like mass") has been interpreted as a form of superficial endometriosis with florid smooth muscle metaplasia.[107] A bizarre variation on the theme is represented by **endocervicosis**, which can present as a deep-seated cervical mass simulating endocervical adenocarcinoma.[108]

Necrobiotic granulomas resembling tuberculosis or rheumatoid nodules have been seen following cervical surgery.[109] They are probably histologically and pathogenetically analogous to those described postoperatively in the prostate (see Chapter 26).

Florid mesenchymal reactions can develop from the cervical stroma as a result of various surgical interventions and lead to confusion with sarcoma.[110] Some of these have a nodular fasciitis-like appearance and may be looked upon as the genitourinary equivalent of this soft tissue lesion.

Myxoid changes of probable degenerative nature can sometimes be seen in the cervical stroma (and in the myometrium) in the absence of any other pathology.[111]

Human Papilloma Virus and the Lower Female Genital Tract

The role of HPV in the pathogenesis of both condyloma and carcinoma is so well established that it is easy to forget that relatively recently this relationship was completely unsuspected. It has now been demonstrated that greater than 99% of cervical carcinomas are associated with oncogenic HPV,[112] and the molecular mechanisms of virus-mediated oncogenesis are understood in considerable detail. zur Hausen deservedly won the Nobel prize in 2008 for his work establishing the link between HPV and cervical cancer, and we now see the circle closing, with both primary HPV screening to detect premalignant lesions, and HPV immunization to prevent such lesions increasingly being adopted. Against that background we should acknowledge that this is a rapidly advancing field, and what you read in this section will undoubtedly be out of date prior to the next edition of this text. It is possible to envision a world where the burden of disease due to HPV is dramatically reduced, but that is years away, and for the foreseeable future we will be contending with biopsies and resection specimens where the diagnostic issue is the presence or absence of HPV-associated premalignant changes or malignancy. In the following section we will focus on the biology of HPV, so that we can relate it to histopathologic changes described later.

HPV is a DNA virus and is classified based on the viral genome into different genotypes, each designated by a number (e.g., HPV-6).[113] HPV-2 is the most common cause of verruca vulgaris, but the focus of the following discussion are the genital HPV genotypes, transmitted by sexual contact and associated with either condyloma, in the case of the low-risk HPV genotypes such as 6 and 11, or cervical carcinoma, in the case of the high-risk genotypes (also referred to as oncogenic genotypes, later), of which HPV-16 and 18 are the most important. Other HPV genotypes considered to be oncogenic include 31, 33, 35, 39, 45, 51, 52, 56, 58, and 59.[114] Other genotypes are considered to be possibly oncogenic, of uncertain oncogenic potential (i.e., insufficient information to classify), or non-oncogenic; HPV-6 and 11 are in the latter group. Among the oncogenic HPV genotypes, the risk varies, with some being more likely to be associated with malignant transformation.

The genital HPVs are epitheliotropic and the high-risk HPV types, in particular, have a tropism for the metaplastic squamous cells at the squamocolumnar junction.[115,116] This has very important consequences for cytologic screening as most precursor lesions and carcinomas arise at this site, which is amenable to sampling with a brush or spatula. For example, if the lesions of HPV-associated neoplasia of the genital tract were randomly distributed within the squamous mucosa of the vagina and ectocervix, screening would have failed as it has in the oral cavity.

Potentially infectious virus particles must reach the proliferating basal cells for productive infection to take place, and it is thought that a micro-injury to the squamous epithelium is required for this to happen.[117] In the case of glandular epithelium, in which there is a single layer of cells, the proliferating stem cell compartment should, in theory, be more accessible; however, it remains that infection of squamous cells is more likely than the cervical glandular epithelial cells for reasons that are not well understood. Once the virus particles are taken up by the basal epithelial cells the infection may become silent (e.g., through methylation of the viral genome, so that episomic viral DNA remains in the cell but is not transcribed or translated), or productive infection may result. Such an infection may result in orderly expression of viral genes as the host squamous cells mature, with assembly and release of infectious virus particles at the epithelial surface. This is typically associated with koilocytic change, a viral cytopathic effect in which the E4 protein encoded by the viral genome

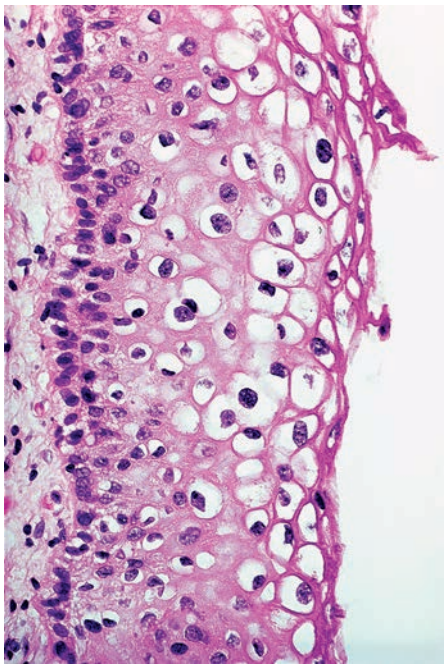

Figure 32.16 Koilocytotic changes in cervical squamous epithelium involved by LSIL (CIN1). These are diagnostic of HPV infection.

causes disruption in the cytoplasmic keratin matrix. The resulting koilocyte is a superficial or intermediate mature squamous cell characterized by a sharply outlined perinuclear vacuolation, dense- and irregular-staining peripheral cytoplasm, and an enlarged nucleus with an undulating (raisin- or prune-like) nuclear membrane and a rope-like chromatin pattern (Fig. 32.16).[118] Binucleation and multinucleation can occur.[119] It is important that these nuclear changes—which may be accompanied by either a diploid or polyploid nuclear DNA distribution[120]—be present somewhere in the lesion for the diagnosis of koilocytosis (and, by inference, HPV infection) to be made, or else other forms of cytoplasmic clearing (notably those related to glycogen accumulation) will be mistakenly included in this category.[121,122] This orderly expression of the viral genome as the squamous cells mature and move to the surface results in LSIL, discussed in more detail later. There may also be, in the case of high-risk/oncogenic HPV infection, deregulated expression of the viral genome. The E6 and E7 proteins encoded by the genomes of these HPV genotypes bind and inactivate the proteins encoded by the *TP53* and *RB* anti-oncogenes, resulting in unfettered proliferation of the host cell. This leads to decreased E4 expression and virion production, and decreased or absent koilocytic change, and increases the likelihood of integration of the viral genome into the host genome, acquisition of other genetic abnormalities in the host cell, and malignant transformation. Not all viral infections lead to transformation and most are cleared by the immune system of the host, through cell-mediated immunity.

HPV can be detected by electron microscopy (as intranuclear crystalline and occasionally filamentous inclusions), but its specific identification depends on nucleic acid hybridization, which can be done with or without amplification, from DNA or RNA, in either a liquid-based or *in situ* analysis.[123–127] Before talking about specific techniques for HPV detection, it is important to reiterate that the presence of HPV DNA may reflect (1) virus particles on the surface of the epithelium secondary to recent exposure, without infection, (2) productive infection that will be cleared completely by the host, (3) a latent infection, or (4) oncogenic HPV DNA that is integrated into the host genome. If the productive infection is by low-risk HPV (6 or 11), it leads to LSIL/condyloma, with viral cytopathic effects, while productive infection with high-risk HPV, most commonly 16 or 18, can lead to LSIL or can progress to HSIL or invasive squamous cell carcinoma. Thus identification of the specific genotype of HPV is of import, but even the identification of high-risk HPV does not mean that there is premalignant change or malignancy, and especially in the young, HPV may be cleared by the host. The Hybrid Capture HPV test, a signal-amplified hybridization microplate-based array designed to detect multiple HPV genotypes, is an example of a liquid based nucleic acid detection technique.[128] These assays are the most sensitive, providing more sensitivity than in situ hybridization techniques. However, they can be too sensitive and may detect virus that has not infected the host or is in the process of being cleared by normal immune mechanisms. Critically for surgical pathology practice, p16 immunohistochemistry has emerged as a highly sensitive and specific surrogate test for infection by high-risk HPV.[129,130] The p16 antioncogene is expressed at high levels in cells due to absence of the normal downregulation of p16 expression by phosphorylated RB protein; in cells infected by high-risk HPV this occurs through inactivation of the RB protein by the viral E7 protein. This results in high-level expression of p16, seen as strong nuclear and cytoplasmic immunoreactivity. There must be "block" positivity for p16 immunostaining to be indicative of high-risk HPV infection (i.e., strong nuclear and cytoplasmic staining of every cell in the basal third of the epithelium), with this staining typically extending into the middle and upper thirds. Correct interpretation of p16 immunostaining is only possible if the staining protocol has been properly validated, and appropriate controls run. There are a number of antibody clones specific for p16, and it is incumbent on each lab to optimize the staining for the clone they have chosen, a responsibility that is sometimes neglected. Immunoreactivity for p16 is not specific for HPV and other tumor types, unrelated to HPV, that have dysregulation of RB can show strong p16 staining (e.g., high-grade serous carcinoma of tubo-ovarian or endometrial origin). p16 expression can be lost through mutation, as cervical cancer progresses, but this appears to be rare in the in situ lesions of HSIL or in situ adenocarcinoma, so that p16 can serve as a very useful surrogate test for high-risk HPV in the cervix. The indications for use of p16 are covered in greater detail later in this chapter. Expression of the viral E5 oncoprotein mRNA is considered a better marker of HPV having a causative role in oncogenesis, in a given case (as HPV DNA may be present as a bystander if there is no transcription of the viral oncogenes), but such testing is currently not widely available in clinical laboratories.

Tumors

Squamous Cell Carcinoma and Its Precursors

Squamous Intraepithelial Lesions/Cervical Intraepithelial Neoplasia

We recommend use of the Bethesda terminology for cytology specimens[131–134] and the diagnostic terminology proposed by the LAST committee,[133] which is based on the Bethesda classification, for surgical pathology specimens. SIL terminology has gained wide acceptance, but there are still holdouts for the CIN terminology and we will adopt the practice, permitted under the LAST recommendations, of providing a two-part diagnosis, with SIL first and the equivalent CIN in parenthesis thereafter. LSIL will thus appear as "LSIL (CIN1)." CIN2 and CIN3 are both considered HSIL, and the distinction between CIN2 and CIN3 is arbitrary and not clinically relevant. Subtle differences in natural history have been reported

for CIN2 versus CIN3, but we would attribute these to inclusion in the former group of some cases better classified as CIN1, rather than being an indication that CIN2 and CIN3 are distinct diseases. Accordingly, we will not make an effort to distinguish between CIN2 and CIN3, instead using the terminology HSIL (CIN2/3) for all high-grade lesions.

Most SIL are initially detected cytologically, which leads to colposcopic biopsy. Occasionally SIL will be an incidental finding, sometimes appearing in endometrial biopsy specimens. It is anticipated that there will be a decline in SIL with widespread HPV vaccination, but this has not impacted on practice yet. With primary HPV testing rather than cytologic screening, as discussed in the Cytology section later in this chapter, there will be more patients referred for colposcopic examination, so familiarity with SIL and its mimics will be important for those practicing general surgical pathology for the foreseeable future.

LSIL (CIN1) is inclusive of condyloma in the LAST criteria.[133] The former practice of attempting to determine whether there is or is not dysplasia within condyloma (i.e., condyloma ± CIN1) has mercifully been brought to an end. Koilocytic viral cytopathic effect (see Fig. 32.16) is the pathognomonic feature of condyloma; it is doubtful whether LSIL (CIN1), as an indicator of HPV infection, can be reproducibly diagnosed in the absence of koilocytic change. Condyloma can be exophytic or flat. The former, **condyloma acuminatum**, are considerably less common than the latter and are visible grossly as a polypoid lesion characterized microscopically by papillomatosis, acanthosis, koilocytosis, and a variable degree of inflammatory infiltration of the stroma. An undulating appearance of the epithelium is a characteristic feature on low-power examination. A mild degree of atypia in the squamous component is common and need not be mentioned; if more severe, it should be evaluated and graded as for the flat SIL (i.e., is there HSIL [CIN2/3] present).

Condyloma acuminatum is associated with HPV-6 or HPV-11 in 70%–90% of the cases, but occasionally other types—such as HPV-16—are encountered. When the latter is the case, high-grade cytologic atypia may be found. The differential diagnosis of condyloma acuminatum includes verrucous carcinoma, discussed in more detail later. **Inverted transitional cell (urothelial) papilloma**, similar to its more common bladder counterpart, has been described in the cervix.[127,135] It is probably not related to HPV and is included here only because it enters into the differential diagnosis with the other polypoid benign lesions of this region. Papillary transitional lesions can mimic condyloma acuminatum at low power, but there is no koilocytic change and the cells have very uniform nuclear features, with even chromatin and nuclear grooves. Squamous papilloma is the diagnosis that has been suggested for lesions that architecturally resemble condyloma acuminatum, are composed of benign squamous cells, without dysplasia, but lack koilocytic change. These may be related to condyloma but have cleared the HPV infection, but this is speculative. They are not considered to have premalignant potential.

Flat condyloma, so-called, is more commonly encountered than condyloma acuminatum, and is the classic lesion of LSIL (CIN1). It is typically not recognizable grossly. Microscopically, there is a relatively normal basal cell layer, expanded or hyperplastic parabasal cell layer, orderly maturation, mitotic activity confined to the lower third of the epithelium (but few or no abnormal mitoses), and koilocytosis (Fig. 32.17). A degree of dysplasia of the lower third of the epithelium is acceptable within the spectrum of LSIL, although the distinction between "dysplasia" and reactive expansion of the parabasal layer due to increased proliferation is highly subjective. This lack of ability to distinguish between koilocytic change (HPV effect) with or without dysplasia contributed to them being combined as LSIL in the Bethesda classification. At this point we would most emphatically recommend that the old chestnut that mild, moderate,

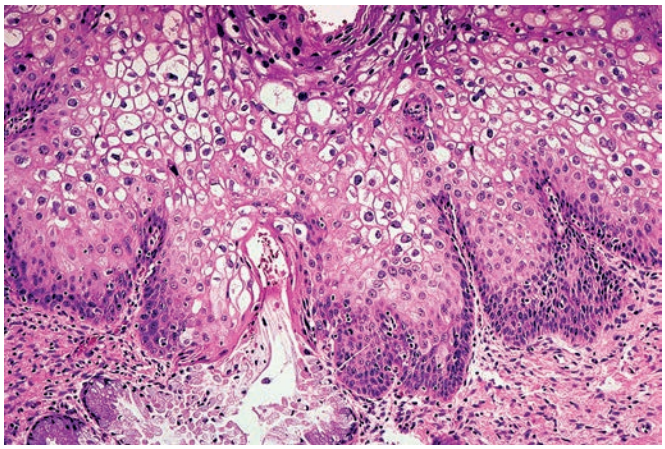

Figure 32.17 HPV-induced LSIL (CIN1) lesion characterized by acanthosis, papillomatosis, and koilocytotic changes.

and severe cervical dysplasia (CIN1-3), respectively, are distinguished by dysplasia in the lower third, lower two thirds, and full thickness of the squamous epithelium be relegated to the bin reserved for medical trivia of historical interest only. This observation is still repeated to trainees and has no underlying mechanistic basis. The Bethesda classification reflects the biology of in situ squamous neoplasia of the cervix, especially as it relates to HPV, with a bipartite LSIL/HSIL system.[134] The proliferation rate of LSIL (CIN1) is higher than that of inflamed or metaplastic cervical squamous epithelium. Most LSIL, apart from condyloma acuminatum, is associated with high-risk HPV types.

The natural history of LSIL is that most will clear spontaneously and relatively few will progress to HSIL (CIN2/3). Risk factors for progression include the presence of high-risk HPV, but, as noted previously, high-risk HPV are present in most LSIL. Cytokeratin 7, a marker of squamous cells of the transformation zone, has been proposed as a marker of LSIL that is more likely to progress.[115] This is based on the observation that LSIL/condyloma can arise on the ectocervix or elsewhere in the lower female genital tract and at these other sites there is little risk of progression to HSIL.[115,116] In contrast, the metaplastic squamous epithelium of the transformation zone is especially susceptible to progression when infected by high-risk HPV. CK7 is a marker of these metaplastic cells and, while it shows promise of being a marker of increased likelihood of progression from LSIL to HSIL, further validation is required before it enters routine practice.[136]

HSIL (CIN2/3) may be seen macroscopically, when extensive (Fig. 32.18), but is best appreciated colposcopically. On microscopic examination, it is characterized by a high N:C ratio in all layers of the epithelium, not just the basal and parabasal layers, but most importantly by striking nuclear atypia (Fig. 32.19). There is prominent mitotic activity, with atypical mitoses typically present, and mitotic figures are found in the upper layers of the epithelium. There are cases where the differential diagnosis rests between LSIL and HSIL and the recommendation is that in such lesions p16 immunostaining be used as an adjunct; if there is strong and diffuse block positivity, a diagnosis of HSIL (CIN2/3) can be rendered. It is important to note that diagnosis of LSIL or HSIL is made primarily based on H&E, with use of p16 immunostaining only in selected borderline cases.[129]

At a practical level, HSIL can be safely treated by conization, electrodiathermy, cryosurgery, laser, or loop electrosurgical excision, all of them done under colposcopic guidance.[137–141] In making the final decision regarding the timing and type of therapy for this group

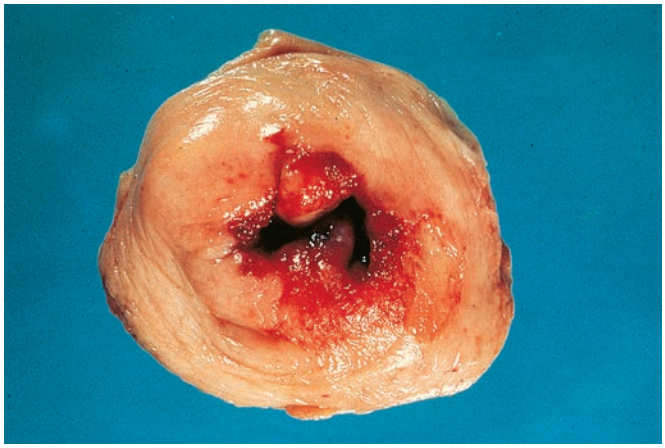

Figure 32.18 Gross appearance of HSIL (CIN2/3) extensively involving the uterine cervix. (Courtesy of Dr Hector Rodriguez-Martinez, Mexico City.)

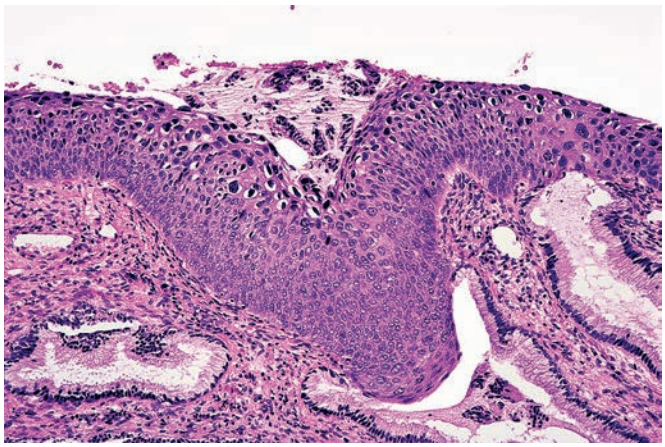

Figure 32.20 Extensive involvement by HSIL (CIN2/3) of surface epithelium and glands of endocervix.

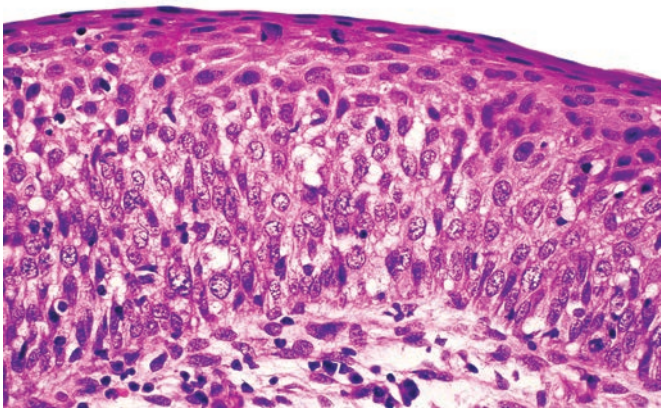

Figure 32.19 HSIL (CIN 2/3). There is proliferation and atypia, with increased N:C ratio and loss of normal maturation.

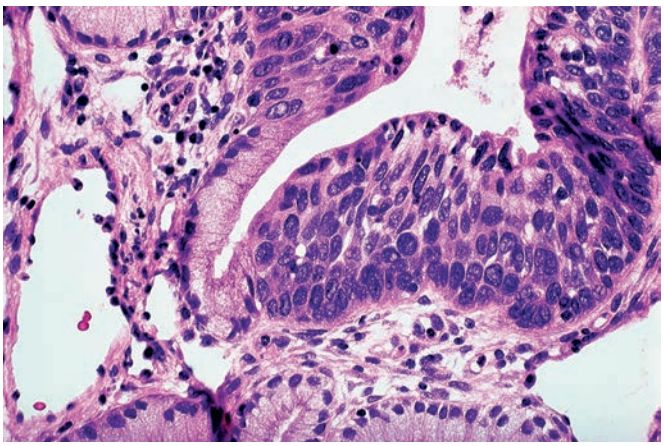

Figure 32.21 Partial replacement of endocervical glandular epithelium by HSIL (CIN2/3).

of lesions, the microscopic diagnosis is only one of the factors to be considered, albeit a very important one. The extension of the lesion, age of the patient, parity, and the desire to have more children all have to be considered. Both the surface and the possible depth of involvement also have to be taken into account, as extension of HSIL (CIN2/3) into endocervical glands is common. (Figs. 32.20 and 32.21) Anderson and Hartley[142] calculated that destruction of tissue to a depth of 2.92 mm would eradicate all involved glands in 95% of the patients, whereas destruction to a depth of 3.8 mm would eradicate 99.7%. Positive margins and glandular involvement by HSIL (CIN2/3) are independent predictors of residual or recurrent disease.[143–145]

Once the pathologist has made the diagnosis of HSIL (CIN2/3) in a cervical biopsy, it is the responsibility of the gynecologist to determine the presence or absence of invasive carcinoma. Thorough cervical sampling and the proper sectioning of tissue should establish whether or not invasive carcinoma exists. If the latter is found, conventional methods of therapy may be instituted. Whenever the therapy is conservative, long-term follow-up (longer than 5 years) is imperative. In one series, patients with continuing abnormal cytology after initial treatment of HSIL (CIN2/3) were found to be 25 times more likely to develop invasive carcinomas than women with normal follow-up cytology.[146]

The differential diagnosis of HSIL (CIN2/3) includes florid squamous metaplasia and transitional metaplasia. It should also be mentioned that the iodine test, used to delineate the extent of cervical disease prior to conization, can induce shrinkage, cytoplasmic eosinophilia and vacuolization, and pyknosis in the epithelial cells (particularly when they are abnormal to begin with).[147]

Superficial Invasive Squamous Cell Carcinoma

Invasive squamous cell carcinomas in which the depth of stromal invasion is minimal (3 mm or less, and <7 mm in breadth, Stage Ia1) have been segregated from the others and designated as "superficial invasive carcinoma" (Fig. 32.22 and Table 32.1).[148–151]

The justification for the recognition of this as a distinct entity is that the natural history of the lesion is quite different from that of ordinary invasive carcinoma and more akin to that of HSIL (CIN2/3).[151–153] Accordingly, the treatment can be generally conservative, although it needs to be individualized.[148,154,155] The common occurrence of pleomorphism, cellular differentiation, presence of conspicuous nucleoli, and individual cell keratinization in the areas of microinvasion has been emphasized (Fig. 32.23).[150] Since these features are rarely seen together in HSIL (CIN2/3), their presence in an apparently intraepidermal cervical lesion should stimulate the

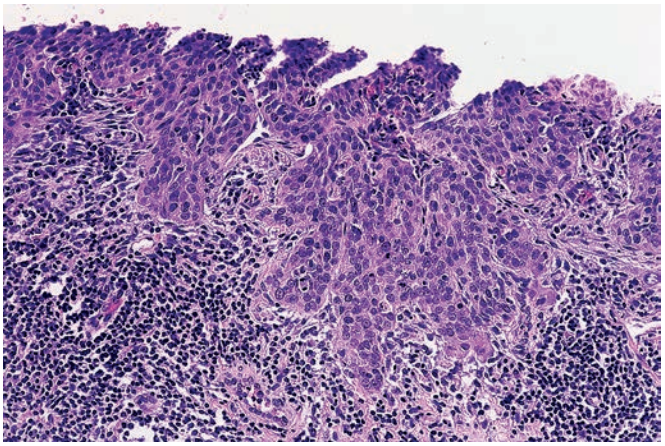

Figure 32.22 Low-power appearance of superficial invasive squamous cell carcinoma of cervix.

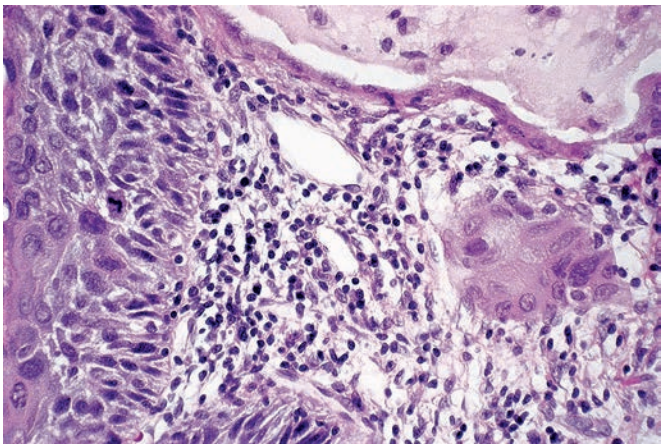

Figure 32.23 Small focus of invasion underlying HSIL (CIN2/3). Note the greater degree of squamous differentiation in the microinvasive component.

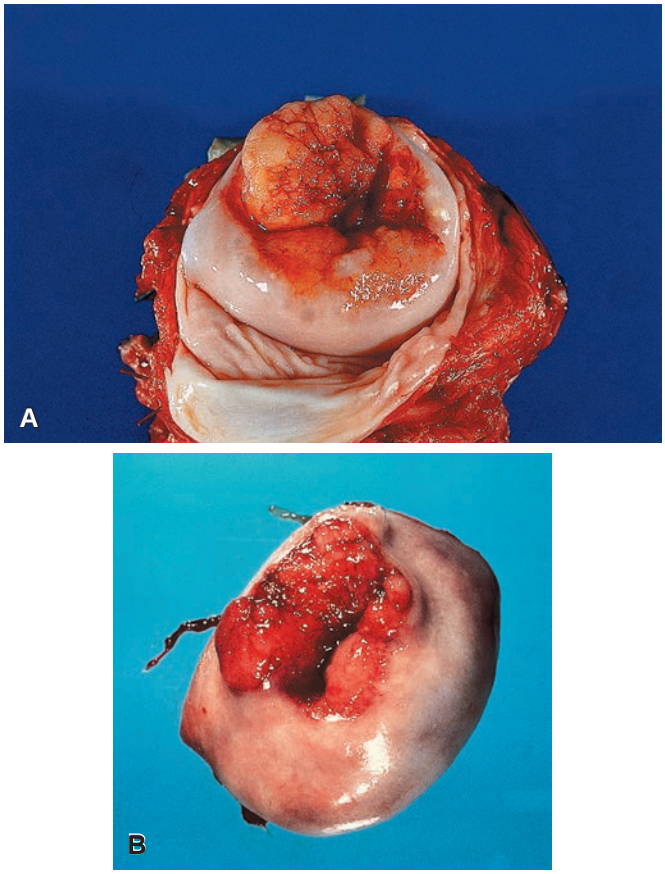

Figure 32.24 **A and B,** Gross appearance of invasive squamous cell carcinoma of cervix.

search for areas of invasion.[156] Another feature that should raise the suspicion of early stromal invasion is the presence of a desmoplastic stroma rich in acid mucosubstances and characterized by metachromatic staining properties.[157] In the area of invasion, there is a breach of the basement membrane. Hasumi et al.[158] found that one (0.9%) of 106 patients with invasion up to 3 mm had lymph node metastases, whereas four (13.19%) of 29 patients with invasion of 3.1–5 mm had nodal metastases. This study served as the original basis for the definition of superficial invasion as 3 mm or less depth of invasion, with conservative surgery (as for HSIL [CIN2/3]) as treatment of choice, in contrast to the radical surgery, with parametrial and lymph node resection, used for more deeply invasive carcinomas.

Invasive Squamous Cell Carcinoma

General Features

Invasive squamous cell carcinoma of the cervix is still the most common malignant tumor of the female genital tract in most countries and the most frequent neoplasm among women in many of them.[159,160] As noted previously, almost all are HPV associated, but rare HPV-independent squamous cell carcinomas do occur,[161] especially verrucous carcinoma. Accordingly, risk factors for the development of cervical squamous cell carcinoma reflect increased likelihood of HPV exposure, such as age at first intercourse, early marriage, multiparity, and low socioeconomic level,[162–164] as well as cigarette smoking.

Host immune response factors contribute to the persistence of HPV infection and progression to HSIL (CIN2/3). Genes in the human leukocyte antigen (HLA) region of chromosome 6 are associated with increased susceptibility to the transforming properties of high-risk HPV. Impaired immune function, such as immunosuppressant therapy in organ transplantation recipients and HIV infection, is associated with a 5- to 10-fold increased risk of cervical neoplasia.[165]

Squamous cell carcinoma can be associated with microscopically similar tumors in the lower and upper genital tracts. In some of these cases, the same clonal pattern has been demonstrated, consistent with a cervical origin of the tumor followed by migration to other areas.[166] Despite this molecular evidence of clonality and therefore metastatic behavior, these metachronous tumors (that usually involve first cervix, and later vulva) behave like independent primary tumors.

Morphologic Features

Grossly, cervical carcinoma may be polypoid or deeply infiltrative (Fig. 32.24). The bulky carcinomas that grow out of the cervix are less likely to invade surrounding structures than are the infiltrating ones. The general truism that exophytic tumors are less aggressive than endophytic tumors thus holds true for cervical squamous cell carcinoma.

Some tumors are either clinically inapparent or simply missed by the examiner and are first discovered on pathologic examination

Table 32.1 Definitions of AJCC TNM for cervical carcinoma

Primary Tumor (T)

T CATEGORY	FIGO STAGE	T CRITERIA
TX		Primary tumor cannot be assessed
T0		No evidence of primary tumor
T1	I	Cervical carcinoma confined to the uterus (extension to corpus should be disregarded)
T1a	IA	Invasive carcinoma diagnosed only by microscopy. Stromal invasion with a maximum depth of 5.0 mm measured from the base of the epithelium and a horizontal spread of 7.0 mm or less. Vascular space involvement, venous or lymphatic, does not affect classification
T1a1	IA1	Measured stromal invasion of 3.0 mm or less in depth and 7.0 mm or less in horizontal spread
T1a2	IA2	Measured stromal invasion of more than 3.0 mm and not more than 5.0 mm, with a horizontal spread of 7.0 mm or less
T1b	IB	Clinically visible lesion confined to the cervix or microscopic lesion greater than T1a/IA2. Includes all macroscopically visible lesions, even those with superficial invasion.
T1b1	IB1	Clinically visible lesion 4.0 cm or less in greatest dimension
T1b2	IB2	Clinically visible lesion more than 4.0 cm in greatest dimension
T2	II	Cervical carcinoma invading beyond the uterus but not to the pelvic wall or to lower third of the vagina
T2a	IIA	Tumor without parametrial invasion
T2a1	IIA1	Clinically visible lesion 4.0 cm or less in greatest dimension
T2a2	IIA2	Clinically visible lesion more than 4.0 cm in greatest dimension
T2b	IIB	Tumor with parametrial invasion
T3	III	Tumor extending to the pelvic sidewall* and/or involving the lower third of the vagina and/or causing hydronephrosis or nonfunctioning kidney
T3a	IIIA	Tumor involving the lower third of the vagina but not extending to the pelvic wall
T3b	IIIB	Tumor extending to the pelvic wall and/or causing hydronephrosis or nonfunctioning kidney
T4	IVA	Tumor invading the mucosa of the bladder or rectum and/or extending beyond the true pelvis (bullous edema is not sufficient to classify a tumor as T4)

Regional Lymph Node (N)

N CATEGORY	FIGO STAGE	N CRITERIA
NX		Regional lymph nodes cannot be assessed
N0		No regional lymph node metastasis
N0(i+)		Isolated tumor cells in regional lymph node(s) no greater than 0.2 mm
N1		Regional lymph node metastasis

Distant Metastasis (M)

M CATEGORY	FIGO STAGE	M CRITERIA
M0		No distant metastasis
M1	IVB	Distant metastasis (including peritoneal spread or involvement of the supraclavicular, mediastinal, or distant lymph nodes; lung; liver; or bone)

*The pelvic sidewall is defined as the muscle, fascia, neurovascular structures, and skeletal portions of the bony pelvis. On rectal examinations, there is no cancer-free space between the tumor and pelvic sidewall.

From Amin M, Edge S, Greene F, et al. (eds.). AJCC Cancer Staging Manual. 8th ed. New York: Springer; 2017.

of a uterus removed for a benign condition.[167] Still others develop in the cervical stump left from a supracervical hysterectomy.[168]

Microscopically, three cellular variants of cervical squamous cell carcinoma exist, although admixtures and intermediate forms abound: *large cell nonkeratinizing*, *keratinizing* (Fig. 32.25), and *small cell*.[169–171] The latter should be distinguished from small cell neuroendocrine carcinoma, a tumor morphologically similar to small cell carcinoma of the lung and exhibiting features of neuroendocrine differentiation; immunohistochemistry may be necessary for this purpose. Although these patterns can be morphologically distinctive, they are not clinically relevant, in terms of planning treatment or prognosis.[172,173]

Some cervical squamous cell carcinomas have a distinctly papillary pattern of growth; these need to be distinguished from verrucous carcinoma.[174]

Other squamous cell carcinomas are accompanied by acantholysis, which may result in a pseudoglandular pattern.[175] Amyloid deposition

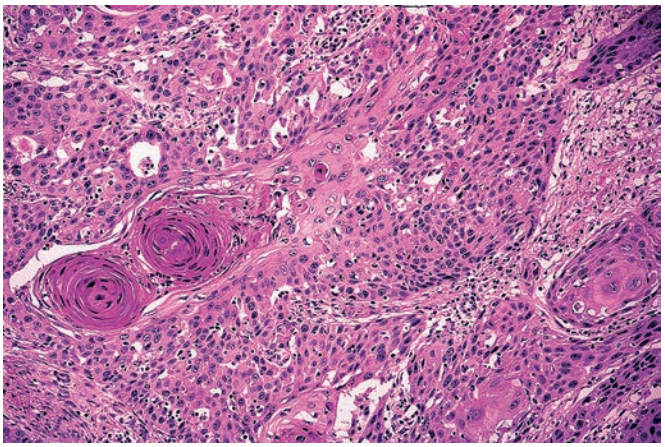

Figure 32.25 Microscopic appearance of invasive squamous cell carcinoma of cervix of large cell keratinizing type.

in the stroma has been documented in some other cases.[176,177] On occasion, cervical squamous cell carcinoma is found to be associated with intense infiltration by mature eosinophils, with or without accompanying peripheral blood eosinophilia; production of eosinotactic and eosinopoietic substances by the tumor cells has been suggested as the pathogenetic mechanism.[178,179]

Mucicarmine stains will demonstrate the presence of scattered droplets of cytoplasmic mucin in a minority of cases having the morphologic features of squamous cell carcinoma in routinely stained sections, a finding analogous to that sometimes encountered in carcinomas of the lung and other sites.[180] Their behavior seems to be the same as that of squamous cell carcinomas lacking mucin secretion.[180]

The exceptional occurrence of sebaceous differentiation in cervical carcinoma has also been documented.[181]

Immunohistochemical and Molecular Genetic Features

Immunohistochemically, squamous cell carcinomas of the cervix express keratins (nearly 100% of the cases), CEA (90%),[182] p63 (a homologue of p53 preferentially expressed in basal and immature cervical squamous epithelium),[183] and p40. The range of keratins found in the tumor varies somewhat depending on the subtype, but it is very wide.[184] There may also be reactivity for β-human chorionic gonadotrophin (β-hCG),[185] and for parathyroid hormone–related gene (although these tumors rarely give rise to hypercalcemia).[186]

In contrast to the situation in many other human malignancies, the *TP53* gene is rarely mutated in cervical squamous cell carcinoma; this is also true for the biologically related *MDM2* gene.[187] Despite the lack of mutation in *TP53*, the function of the gene is inactivated due to the effect of HPV-associated E6 protein, which binds to p53 protein, causing its rapid degradation.[165] The *RB* gene function is similarly inactivated due to binding of HPV-associated E7 protein with RB protein.[165]

Spread and Metastases

Cervical carcinoma spreads characteristically by direct extension to the vagina, corpus (endometrium and myometrial wall), parametrium, lower urinary tract, and uterosacral ligaments (Fig. 32.26).[188,189]

Lymph node metastases are also common. The pattern of involvement generally proceeds in a sequential fashion. The first station is represented by the paracervical, hypogastric, obturator, and external iliac groups and the second by the sacral, common iliac, aortic, and inguinal groups.[190] The incidence of nodal involvement is directly related to the stage of the disease. Hematogenous metastases were rare in older series, but with better control of the local lesion, they have increased in frequency.[189] Lung (9%) and bone (4%) are the most common sites.[191–193] Ovarian metastases are less common than with endometrial adenocarcinoma, but they do occur.[194]

The differential diagnosis between primary pulmonary squamous cell carcinoma and a pulmonary metastasis from a cervical carcinoma, which can be very difficult on morphologic grounds, is greatly aided by the detection of HPV in the latter by in situ hybridization, PCR, or immunostaining for p16.[195,196]

Treatment

Invasive carcinomas of the cervix that are more advanced than stage Ia1 can be treated with curative intent by surgery or irradiation with or without chemosensitization.[197–200] The choice depends on the extent of the tumor, the general condition of the patient, and the expertise available at the institution where the patient is treated. Early lesions can be treated just as effectively with hysterectomy or intracavitary radiation with platinum chemotherapy to radiosensitize the tumor cells[198,201,202]; for stage IIa lesions, irradiation alone and a combination of irradiation and surgery have yielded equivalent results in randomized studies.[203] As a rule, however, one is looking to use either surgery OR radiation therapy as the primary treatment modality, and not both, which results in the patient experiencing the morbidity and mortality of both procedures. Surgery is generally preferred for early carcinomas as the patients are typically young and surgery does not have the complication of late (>10 years) development of secondary malignancies in the radiated field. In some centers sentinel lymph node(s) are sent for frozen section at the start of the procedure, and if positive, radical hysterectomy is not performed since radiation therapy is indicated based on the positive node. If the sentinel node(s) frozen section is negative, surgery proceeds as planned, with the understanding that frozen section is not completely sensitive and that on permanent sections occasional micrometastases will be detected that were not present on frozen section examination.[204]

Early lesions can be treated conservatively with radical vaginal trachelectomy, a fertility-preserving procedure where the cervix is excised at the level of the upper endocervix or lower uterine segment along with a vaginal cuff and parametria, and pelvic lymph nodes.

In cases of central pelvic relapse of cervical carcinoma, pelvic exenteration should be seriously considered because a considerable number of the patients will have tumor confined to the pelvis.[205] This operation removes all pelvic viscera and lateral pelvic lymph node–bearing tissue. The bladder (anterior exenteration), rectum (posterior exenteration), or both may be removed, depending on the location of the tumor. At laparotomy, the surgeon should examine the upper abdomen carefully, particularly the periaortic area, for evidence of spread outside the pelvis. Any suspicious lymph nodes or liver nodules should be submitted to the pathologist for frozen section before the operative procedure is begun. Gross appraisal of enlarged extrapelvic nodes is unreliable, whereas frozen section examination is a highly accurate procedure.[206] The study of the surgical specimen should include a careful examination of the lymph nodes, the lateral edges of the resection, and the local extent of the tumor. Microscopically, the nodes, vessels, and adjacent organs should be examined for evidence of tumor. The finding of greatest prognostic relevance in the pathologic evaluation of pelvic exenteration specimens is the presence or absence of lymph node metastases.[207]

The microscopic examination of postradiochemotherapy specimens can be difficult due to the extent of regressive changes manifested in the tumor cells by cytoplasmic eosinophilia, vacuolization, and foamy degeneration. Prognostically, the most important feature to look for in these specimens is tumor embolism.[208]

Prognosis

The prognosis of cervical carcinoma is related to the following parameters:

1. *Clinical stage*. As for most other human malignancies, stage is the most important prognostic determinator.[209] It should be noted that clinical staging (FIGO) is used for cervical cancer, unlike for other organs. TNM staging is possible, but only for patients treated surgically; many patients are treated primarily by radiotherapy, and surgical pathology staging is not possible in these cases.
2. *Nodal status*. This is another crucial predictor, which is incorporated into the staging scheme.[210,211]
3. *Size* of the largest involved node[212] and *number* of positive nodes.[213]
4. *Size of the primary tumor*, as determined by measurement of the tumor's greatest diameter[214,215] or by volumetric techniques.[216]
5. *Depth of invasion*.[217–219]
6. *Endometrial extension*. The presence of this feature decreases the survival rate by 10%–20%.[220]
7. *Parametrial involvement*, as detected microscopically.[221]
8. *Blood vessel invasion*.[222–225]

Microscopic grade is not of prognostic significance, whether one uses the Reagan–Ng or the Broders method of grading.[225,226] This is in contrast to most other carcinomas. Our persistence in assigning a grade in pathology reports for cervical squamous cell carcinoma is a curiosity and will presumably stop in the near future, given that it is a useless practice. A similar comment applies to cell type (e.g., large cell nonkeratinizing) of squamous cell carcinoma; as noted previously, it is also not of prognostic significance.[172,173]

Other Microscopic Types

Verrucous carcinoma is a highly differentiated variant of squamous cell carcinoma with a polypoid pattern of growth, an extremely well-differentiated cytologic appearance, and a capacity for local invasion but not for metastatic spread. Some cases have been found to extend into the endometrial cavity.[227] Verrucous carcinoma should be distinguished both from condyloma acuminatum and from ordinary squamous cell carcinoma with a prominent papillary pattern of growth.[228,229] The general gross and microscopic features of this tumor are described in Chapter 30.

Spindle cell carcinoma (sarcomatoid carcinoma; squamous cell carcinoma with sarcoma-like stroma; carcinosarcoma) is morphologically analogous to the homonymous tumor in the upper aerodigestive tract.[230] It may contain osteoclast-like giant cells,[231] and there is often evidence of HPV infection.[232] The recognizable epithelial component of this tumor, when present, is of squamous type; this is in contrast with the malignant mixed müllerian tumor, in which that component is usually glandular. It is advisable to keep these tumors (both of which can occur in the cervix) in separate categories, although both of them probably represent carcinomas with a sarcoma-like component.

Basaloid (squamous cell) carcinoma is characterized by prominent peripheral palisading, an infiltrative growth pattern, and minimal stromal reaction (Fig. 32.27).[233] The behavior of this tumor is aggressive, as is also the case with the homonymous neoplasm in the upper aerodigestive tract. It is, therefore, very important to clearly separate this tumor from adenoid cystic carcinomas and adenoid basal carcinomas.[234]

Lymphoepithelioma-like carcinoma resembles its more common counterpart in the upper respiratory tract by virtue of the large size of the tumor cells, vesicular nuclei with prominent nucleoli, syncytial appearance, and heavy lymphocytic infiltration.[235–237] Some cases have been found to secrete β-hCG, as is also occasionally the case with conventional squamous cell carcinoma.[238] The possible association of this tumor with either EBV or HPV remains controversial.[239–241] This tumor type shows considerable overlap with the *circumscribed* type of cervical carcinoma that has been described.[242]

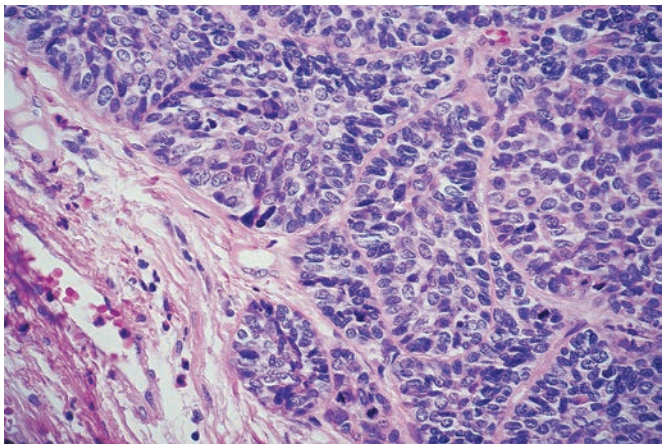

Figure 32.27 Basaloid Squamous Cell Carcinoma of Uterine Cervix. The tumor grows in the form of well-defined nests showing peripheral palisading.

Adenocarcinoma

Background

Adenocarcinomas account for approximately 20% of all cervical cancers.[243,244] They appear to be relatively more common in those areas where cervical screening programs have reduced the incidence of invasive squamous cell carcinoma, as cervical screening is relatively less successful in detecting precursor lesions of adenocarcinoma.[245] Cervical adenocarcinomas have traditionally been subclassified based on tumor cell type, but this is slowly giving way to a classification mirroring that of vulvar squamous cell carcinoma (i.e., HPV associated versus HPV independent. The basis for this shift is the recognition that the morphologic features and prognosis are significantly different for tumors in these two major categories.[246–259] This is a recent development, and there remains much to be learned about the HPV-independent cervical adenocarcinomas in particular, but in recognition of this emergent trend the HPV-dependent and HPV-independent variants will be considered separately, later. As for other lower genital tract carcinomas, p16 immunostaining can serve as a surrogate test for HPV status, with "block positivity" indicating an HPV-associated tumor.[250–252] p16 immunostaining is not perfect, as p16 expression can be seen in any tumor with loss of p53 function and dysregulation of RB signaling, and has been described as an uncommon finding in HPV-independent cervical adenocarcinoma.[253] Conversely, p16 expression can be lost through mutation during progression of an HPV-associated tumor; therefore, when staining a large carcinoma one should preferentially select a block with adenocarcinoma in situ, which is almost invariably positive for p16 in HPV-associated cervical adenocarcinoma. In practice, if the morphologic features and p16 staining result are concordant, a tumor can be confidently classified as HPV associated or HPV independent. If there are discordant features, molecular testing for HPV nucleic acid can be used to determine HPV status, just as in vulvar squamous cell carcinomas.[247]

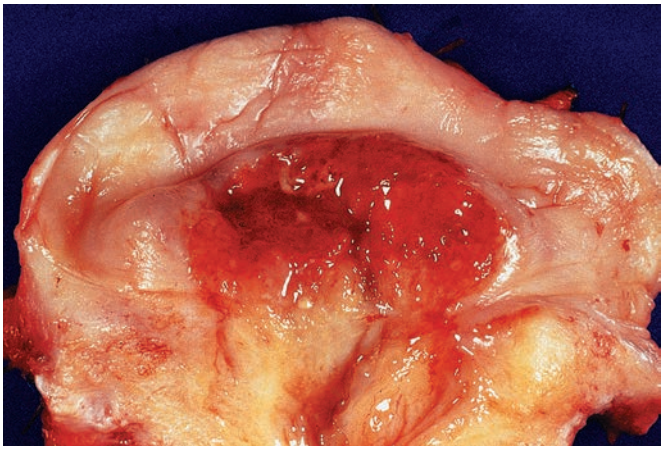

Figure 32.30 Gross appearance of endocervical adenocarcinoma.

In situ Adenocarcinoma

The documentation of the existence of an in situ stage of cervical adenocarcinoma lagged behind that of squamous cell carcinoma but is well established, at least for the HPV-associated cervical adenocarcinomas.[254,255] Cytologic atypia (manifested by nuclear hyperchromasia and pleomorphism) and increased mitotic figures are the two most important identifying features (Fig. 32.28). The presence of numerous apoptotic bodies is another diagnostic clue.[256] This combination of increased mitotic activity and numerous apoptotic bodies is characteristic of lesions induced by oncogenic HPV. The changes can be very subtle and limited to the endocervical surface.[257]

The mucins secreted by the in situ malignant glands may be similar to those of the normal endocervical mucosa or may resemble the pattern of intestinal goblet cells.[258] The latter, which is referred to as intestinal-type cervical adenocarcinoma in situ, shows consistent expression of CDX2.[259] Most in situ cervical adenocarcinomas are positive for CEA.[260] The cell proliferative index (as measured by Ki-67 immunostaining) is increased, there is an abnormal expression of cell cycle–related molecules, and the expression of hormone receptors is either decreased or absent.[261] Strong nuclear cytoplasmic positivity for p16, as a result of the association with HPV, is characteristic.[262] Glandular dysplasia short of that seen in carcinoma in situ has been described[263–268] but has not emerged as a well-defined diagnostic entity and is not a recommended category for routine diagnostic practice.

An important differential diagnosis of in situ cervical adenocarcinoma is with tubal or tubal–endometrial metaplasia.[269] The cells of tubal or tuboendometrial metaplasia can have increased N:C ratio but lack the stratification, nuclear atypia, numerous apoptotic bodies, or increased mitotic activity of adenocarcinoma in situ. Patchy p16 positivity may be seen in tubal or tuboendometrial metaplasia, but they lack the strong diffuse "block" positivity of adenocarcinoma in situ.

Almost half of the invasive HPV-associated cervical adenocarcinomas and approximately 75% of their in situ counterparts have an associated HSIL (CIN2/3) of the overlying epithelium.[270–272]

Stratified mucin-producing intraepithelial lesions (SMILEs) are uncommon intraepithelial lesions that may be seen in association with adenocarcinoma or adenosquamous carcinoma of the cervix.[273,274] More typical HSIL (CIN2/3) or adenocarcinoma in situ may also coexist. SMILE consists of stratified epithelial cells with nuclear atypia and a high proliferation index/strong diffuse p16 positivity that differs from HSIL in there being abundant intracellular mucin (Fig. 32.29). It is considered to be an uncommon variant of adenocarcinoma in situ or adenosquamous carcinoma in situ.[273]

Conization or LEEP is the treatment of choice for in situ adenocarcinoma of the cervix.[275] The circumferential extent of tumor is a marker of residual/recurrent disease, and it is therefore important to include this information in the pathology report.[276,277]

Human Papilloma Virus–Associated Cervical Adenocarcinoma

General Features

The HPV-associated tumors account for a large majority of cervical adenocarcinomas. These tumors present no distinguishing gross characteristics compared to their squamous cell counterparts (Fig. 32.30). Microscopically, the most common pattern is that of a well-differentiated glandular pattern with mucin secretion, some of which can leak into the stroma (Fig. 32.31).[278–282] However, the degree of differentiation varies, and poorly differentiated forms exist. Most HPV-associated cervical adenocarcinomas are of "usual type," as per the 2014 WHO classification of cervical adenocarcinomas, but other cell types can be seen and are described later. These morphologic variants may coexist in a given case, and there is considerable

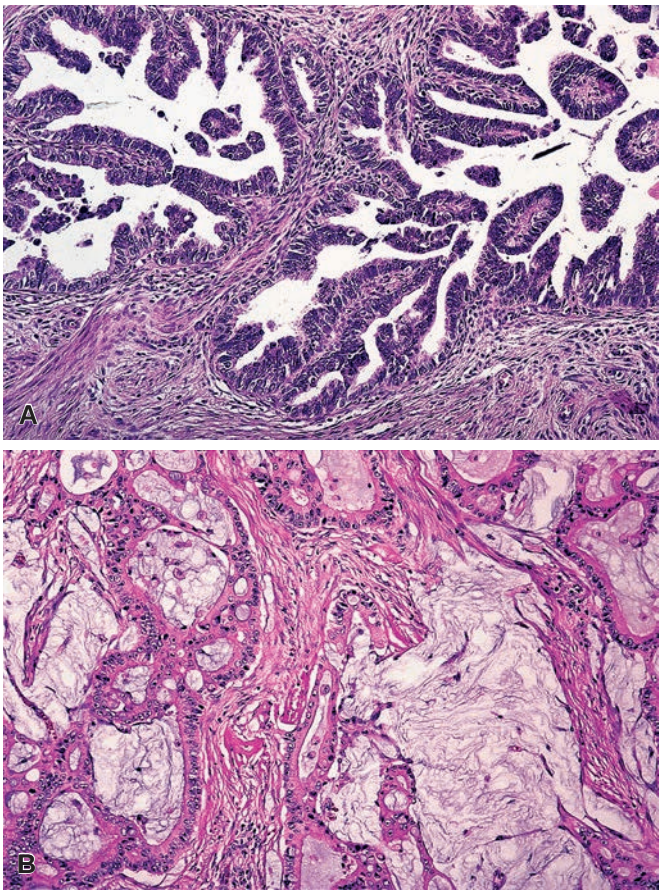

Figure 32.31 Microscopic appearance of HPV-associated adenocarcinoma of usual type. Note the variable amounts of mucin in **A** compared with **B**.

inter-observer variation in their application. Moreover, they are of doubtful significance as meaningful subcategories of HPV-associated cervical adenocarcinoma as they do not impact on patient management.

Histochemically, alcian blue– and mucicarmine-positive material is found intracellularly in nearly all cases of conventional cervical adenocarcinoma.[283] Among the mucins, there is positivity for MUC1 in nearly 100%, MUC2 in 40%, MUC4 in 75%, and MUC5AC "in most."[284] Keratins, EMA, and CEA are consistently expressed, whereas vimentin is not.[285–288] Estrogen and progesterone receptors are expressed in only one-fourth of the cases.[289] About one-fourth of endocervical adenocarcinomas are positive for CDX2, CK20, or both; this profile usually (but not always) correlates with intestinal differentiation.[290,291] It should be noted that intestinal differentiation, with goblet cells, can be encountered in HPV-associated tumors but is also commonly seen in HPV-independent tumors. Cervical adenocarcinomas have also been shown to contain argyrophilic (presumably neuroendocrine) cells,[292] a variety of peptide hormones,[293] and mammaglobin (although not as commonly as endometrial adenocarcinoma).[294]

A pattern-based classification of cervical adenocarcinoma that can be applied irrespective of histotype/HPV status has been proposed by Roma et al.[295] Invasive adenocarcinomas are subclassified as category A, B, or C. Category A is characterized by well-demarcated glands with rounded contours, with no destructive invasion (i.e., no single cell infiltration or lymphovascular invasion); this category includes tumors that would be considered to be entirely in situ by some observers. Category B shows limited destructive invasion, while category C shows diffuse destructive invasion. The most interesting finding is that none of the patients with A pattern invasion in their tumors had nodal metastasis.[295] In a follow-up study, it was demonstrated that the interobserver agreement in assignment of invasive category was superior to that of diagnosis of invasive versus noninvasive by typical criteria.[296] The main drawback to application of the classification is that, while the reproducibility is good ($\kappa = 0.65$), there are significant numbers of cases where pathologists cannot agree on the category,[296] making it difficult to make treatment decisions (i.e., whether to do radical surgery with lymph node dissection) based on this feature. An important practical point that has come out of this classification is confirmation that in those too frequent cases where the differential diagnosis rests between in situ adenocarcinoma and the subtle category A pattern of invasion, the distinction is not clinically important because both groups have an excellent prognosis with minimal chance of nodal metastasis. One final observation is that it in our experience category C pattern of invasion appears to be more commonly encountered in HPV-independent gastric-type adenocarcinomas; it will be interesting to see if this is a significant association and, if so, whether the pattern of invasion or HPV status is the more important prognostic indicator.

Cervical adenocarcinoma spreads directly to endometrium and vagina and metastasizes to the regional nodes, with a distribution pattern similar to that of cervical squamous cell carcinoma (see earlier). It can also metastasize to the ovaries, especially when extending to the lower uterine segment.[297,298] Those reported cases of combined endocervical adenocarcinoma and ovarian mucinous adenocarcinoma (and occasionally even tubal adenocarcinoma)[299,300] that were formerly considered to be independent primary tumors represent metastases of the cervical tumor to these organs.[297,298] p16 immunostaining or HPV testing of the ovarian tumor is useful in confirming the metastatic nature of these lesions.

The preferred therapies for cervical adenocarcinoma are surgery (especially for early lesions), chemo/radiation, or a combination of radiation and surgery.[301–303] The incidence of residual tumor in the hysterectomy specimens after intracavitary treatment is much higher than for squamous cell carcinoma.[304] The prognosis depends on the clinical stage, amount of tumor (as determined by tumor volume), microscopic grade, and nodal status.[305–310] In most series, the overall prognosis has been less favorable than for the squamous cell counterpart, but the more aggresive HPV-independent cervical adenocarcinomas have not been excluded from these analyses and it's possible that they acccount for the subtle differences seen between adenocarcinomas and squamous cell carcinomas.[307,311,312] There is not much difference among the various histologic subtypes of HPV-associated cervical adenocarcinoma.[313] The presence of nodal metastases is an ominous prognostic sign.[314]

Morphologic Variants of Human Papilloma Virus–Associated Cervical Adenocarcinoma

Most endocervical adenocarcinomas diagnosed as **endometrioid adenocarcinoma** of cervix in the past are better diagnosed as usual type (HPV-associated) adenocarcinoma as they show the high mitotic rate, numerous apoptotic bodies, and strong diffuse p16 positivity, as well as frequent admixture with more conventional appearing HPV-associated cervical adenocarcinoma. The differential diagnosis includes endometrioid adenocarcinoma of the endometrium, which can be accompanied by a very deceptive pattern of cervical spread,[315] which is discussed further later.

Serous (papillary) carcinoma is analogous in appearance to the homonymous uterine and ovarian neoplasm, including the common occurrence of psammoma bodies.[316,317] It may be seen in association with usual type endocervical adenocarcinoma.

Villoglandular (papillary) adenocarcinoma presents as an exophytic polypoid lesion with papillae lined by endocervical, endometrial, or intestinal-type epithelium showing only mild atypia (Fig. 32.31). The appearance of the superficial portion is similar to that of colorectal villous adenoma.[318] At the base they show Silva pattern A,[295] with smooth contoured glands, without infiltrative features, and these may be in situ lesions. Most cases are associated with adenocarcinoma in situ and/or HSIL (CIN2/3).[319,320] The prognosis is excellent[321] but only if strict architectural and cytologic criteria (exophytic growth, smooth border with underlying stroma, bland appearance of the nuclei) are applied.[322] This diagnosis should NOT be made based on a small biopsy as there may be conventional invasive cervical adenocarcinoma underlying and a diagnosis of "well-differentiated villoglandular adenocarcinoma" will suggest a very favorable prognosis that does not reflect the underlying infiltrative component.

Adenosquamous (mixed) carcinoma combines adenocarcinoma with a well-defined squamous component.[323] Adenosquamous carcinoma should be distinguished from squamous cell carcinoma without glandular formations but with histochemically demonstrable intracellular mucin.[324] When compared grade by grade and stage by stage with adenocarcinomas and squamous cell carcinomas, no prognostic differences are found.[325,326]

Glassy cell carcinoma has been described as a distinct type of poorly differentiated adenosquamous carcinoma.[327] It occurs in a younger age group (mean age, 41 years) than other cervical neoplasms and often has been associated with pregnancy. The tumor cells have a moderate amount of cytoplasm with a ground-glass or finely granular appearance, a prominent eosinophilic and PAS-positive cell membrane, and large nuclei with prominent nucleoli. Mitoses are numerous. A prominent inflammatory infiltrate, often rich in eosinophils, is regularly seen in the adjacent stroma, and this may be accompanied by peripheral blood eosinophilia.

In pure cases of glassy cell carcinoma, glandular or squamous differentiation is absent, although it can be consistently detected by ultrastructural examination.[328] Other cases show an admixture with mucin-producing adenocarcinoma and/or clear-cut squamous foci, raising the question whether it is justified to regard glassy cell carcinoma as a distinct entity.[329,330] It is likely that there is significant interobserver variation in use of this diagnosis. The prognosis is poor.[331,332]

Adenoid cystic carcinoma is a specific variant of cervical adenocarcinoma that tends to occur in elderly multigravid women of African descent[333] and is associated with a particularly poor prognosis.[334,335] The morphologic appearance is similar to that of the homonymous tumors of salivary glands. Like the former, it may be cribriform (the most common pattern) or grow in a predominantly solid fashion.[336] Adenoid cystic differentiation may be present admixed with other patterns of HPV-associated cervical adenocarcinoma.[337]

Adenoid basal carcinoma (tumor; epithelioma) should be distinguished both from adenoid cystic carcinoma and from basaloid (squamous cell) carcinoma. Although it shares many phenotypic features with adenoid cystic carcinoma,[338] it is a very low-grade lesion, in contrast with the two neoplasms with which it can be confused. It is usually discovered incidentally, it does not produce a mass lesion, and—when pure—it does not result in metastases.[339,340] The consistent presence of oncogenic HPV has been documented.[341] The lesion blends with the process that has been called *adenoid basal hyperplasia*. Brainard and Hart[339] have proposed grouping these two conditions under the term *adenoid basal epithelioma* to emphasize their indolent nature. Adenoid basal carcinoma can be associated with frankly invasive carcinoma, which can show a range of morphologic features (e.g., squamous cell, adenoid cystic, or small cell neuroendocrine carcinoma); the behavior in these cases reflects the aggressive component.[342]

Other variants of endocervical adenocarcinoma, all of them exceedingly rare, are a microcystic type,[343] a signet ring type,[344,345] a small intestinal (enteric) type,[346,347] and a type with choriocarcinomatous and hepatoid differentiation.[348] The HPV status of these rare cervical adenocarcinoma variants remains to be elucidated.

HPV-Independent Cervical Adenocarcinomas

General Features

Only approximately 10% of cervical adenocarcinomas (and thus 2% of cervical carcinomas overall) are HPV independent,[349,350] and this is not a homogeneous group of neoplasms, as noted in the discussion of the different variants below. What they do seem to have in common is that they are not as likely to be identified on cytology smears, are more likely to present at advanced stage, and are associated with a worse prognosis compared to HPV-associated carcinomas.[247–250,253] The difficulties in cytologic detection probably reflects both the bland cytologic features of many of these tumors, as well as their location being more often in the upper endocervical canal, while usual type HPV-associated adenocarcinomas are characteristically at the squamocolumnar junction (like their HPV-associated squamous counterparts). At this time our understanding of these rare tumors is incomplete, but with accurate histopathologic diagnosis we will rapidly learn more about them, and it can be hoped that this will lead to improved management/patient outcomes. Indeed, unless pathologists accurately recognize these tumors, there is unlikely to be progress as clinical research starts with diagnosis.

Morphologic Variants of Human Papilloma Virus–Independent Cervical Adenocarcinoma

Gastric-type adenocarcinoma is a subcategory under "Mucinous carcinoma" in the 2014 WHO classification, along with intestinal type and signet ring type. This is an unfortunate grouping, as it combines tumors of radically different pathogenesis (i.e., HPV-independent and HPV associated). Gastric-type adenocarcinoma of the endocervix remains an ill-defined concept, but it is starting to be more widely recognized and routinely diagnosed.[247–250,253] It is characterized by well-formed glands lined by cells with voluminous clear or eosinophilic cytoplasm and distinct cell borders (Fig. 32.32).[247,248] They lack the high mitotic rate and numerous

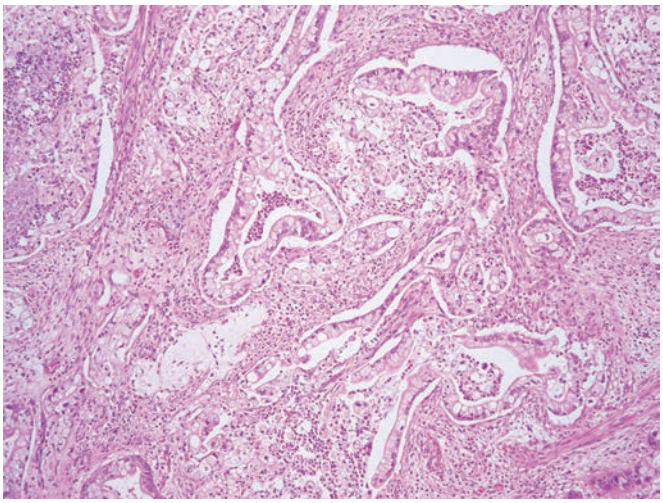

Figure 32.32 Gastric-type adenocarcinoma of cervix.

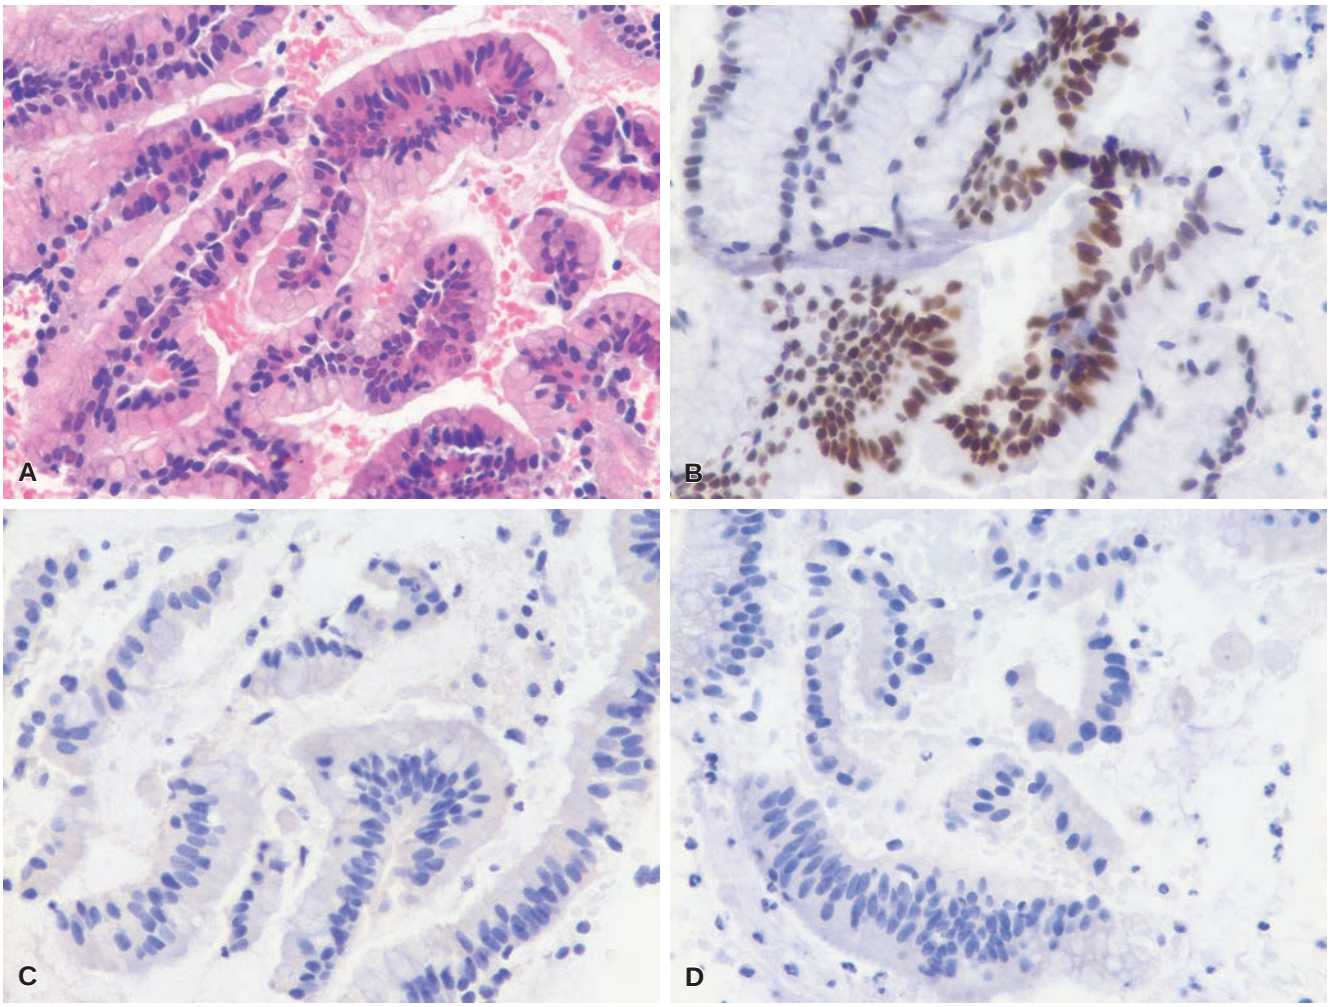

Figure 32.33 **A,** Endocervical curettings of a low-grade gastric-type adenocarcinoma of cervix. The cells show focal positivity for CDX2 **(B)** and are negative for ER **(C)** and p16 **(D)** expression.

apoptotic bodies of HPV-associated cervical adenocarcinoma. p16 immunostaining is helpful in distinguishing between gastric-type cervical adenocarcinoma and usual type HPV-associated adenocarcinoma, as the former typically shows no or only focal staining. There can be increased p16 immunostaining in a gastric-type adenocarcinoma that undergoes tumor progression to a higher-grade tumor (e.g., with *TP53* mutation), but this is uncommon.[253] CEA positivity can be used in the differential diagnosis with benign lesions such as microglandular hyperplasia that are CEA negative. The cells of gastric-type adenocarcinoma are usually completely negative for ER expression, an important consideration in distinguishing them from normal endocervical glandular epithelium or endometrioid carcinoma of endometrium; CDX2 expression is seen in approximately half of gastric-type adenocarcinomas (Fig. 32.33).[253] There can be considerable intratumoral variability in morphology, and although cells with abundant intracytoplasmic mucin are characteristic, there can be tumor progression and areas with less differentiated features and higher-grade nuclei. Goblet cells can be seen in approximately 25% of cases. At the advancing edge of the tumor, single cell invasion and/or signet ring cells may be identified. Most gastric-type adenocarcinomas are stage II–IV at presentation, in contrast to HPV-associated cervical adenocarcinoma where most are stage I.[249,254]

Adenoma malignum (minimal deviation adenocarcinoma) is a designation applied to particularly well-differentiated gastric-type cervical adenocarcinomas. It can be so well differentiated architecturally and cytologically that it can be diagnosed only as malignant because of the presence of distorted glands with irregular outlines deeply positioned in the cervix, and the fact that a portion of the infiltrating tumor is associated with a stromal response (Fig. 32.34).[351–354] Indeed, it is this very well-differentiated appearance that sets adenoma malignum apart from gastric-type adenocarcinoma, but it should be acknowledged that this distinction is artificial and adenoma malignum is best thought of as being within the category of gastric-type adenocarcinoma. It is not uncommon for a patient with adenoma malignum to have multiple superficial biopsies before a diagnosis of malignancy is made, because of the very bland cytologic features. About half of the cases have small foci with a less well-differentiated appearance; by definition this should comprise less than 10% of the tumor. Vascular and perineural invasion may be present. The fact that these tumors, like the more obvious adenocarcinomas, are CEA positive is of importance in the differential diagnosis with benign lesions such as microglandular hyperplasia.[355,356] HIK1083 has been introduced as a putative new marker for adenoma malignum, but this has not entered wide usage.[357] The differential diagnosis also includes endocervical-type *cervical adenomyoma*[358] and

the condition known as *florid deep glands*,[359] in which atypia, architectural disarray, and desmoplastic stromal reaction are lacking. Curiously, **LEGH** is seen in association with 20% of adenoma malignum but less than 5% of non-adenoma malignum gastric-type adenocarcinoma.[247] Even though well differentiated, adenoma malignum is associated with advanced stage at presentation and poor prognosis, similar to that of less differentiated gastric-type adenocarcinomas.[247] Approximately one-third of gastric-like adenocarcinomas may be designated as adenoma malignum.[247] Some cases are associated with Peutz–Jeghers syndrome,[351,360] and mutations of the *STK11* gene (a tumor suppressor gene responsible for this syndrome and located at 19p13.3) have been found in over half of the cases of adenoma malignum.[361]

Clear cell carcinoma (formerly called *mesonephric carcinoma*) of the cervix is of müllerian rather than of mesonephric origin.[362] Glands lined by large cells with abundant clear cytoplasm are characteristic (Fig. 32.35). "Hobnail" cells are common, as are intraglandular papillary projections. Grossly, the tumor is usually exophytic. This tumor type is rare now, but there was a cluster of cases in young women associated with DES exposure in utero. At this time, most cases are encountered in older women.[363]

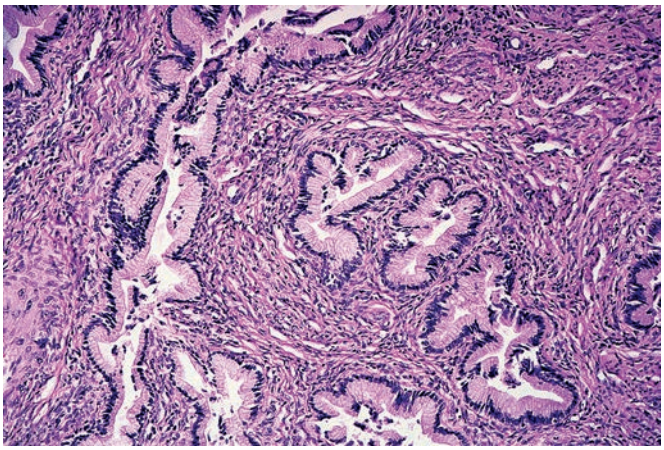

Figure 32.34 Adenoma malignum (minimal deviation adenocarcinoma), the very well-differentiated variant of gastric-type HPV-independent adenocarcinoma of cervix.

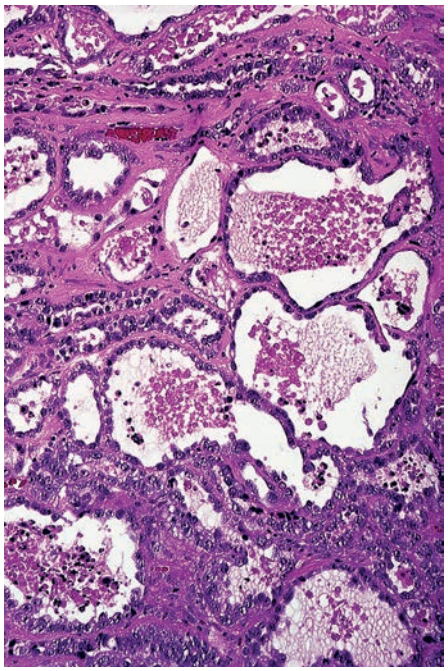

Figure 32.35 Clear cell adenocarcinoma of cervix showing tubular, microcystic, and tubulocystic features.

Mesonephric (adeno)carcinoma is a very rare tumor. Most of the cases that have been reported as such in the past probably represent müllerian-type adenocarcinomas or yolk sac tumors. True mesonephric carcinomas are often found adjacent to mesonephric hyperplasia (sometimes florid and atypical) and may exhibit a variety of patterns, such as ductal (resembling endometrioid adenocarcinoma), small tubular, retiform, solid, sex cord–like, and spindle (Fig. 32.36).[364–366] The immunohistochemical profile is similar to that of mesonephric rests and includes positivity for CD10, GATA3, and calretinin.[357] Tumors in which the epithelial component is admixed with either a homologous or a heterologous sarcoma-like component have been referred to as **malignant mixed mesonephric tumors**.[367]

Early Invasive Adenocarcinoma

Although early invasive adenocarcinoma is included in the College of American Pathologists checklist for reporting cervical adenocarcinoma, no definition is provided and it is preferable to simply measure depth of invasion and assign stage accordingly, exactly as described for squamous cell carcinoma of the cervix earlier in this chapter. That being said it must be acknowledged that it is considerably more difficult to both recognize and, when present, measure depth of invasive cervical adenocarcinoma.[296] Irregular nests of tumor cells and individual tumor cells are relatively uncommon, especially in HPV-associated cervical adenocarcinoma and adenoma malignum variant of HPV-independent adenocarcinoma. Invasion may only be recognized when glands with smooth contours are present in the outer half of the wall of the cervix (deeper than normal endocervical glands) or neoplastic glands are present in close proximity to thick-wall blood vessels (as defined by the distance from the closest gland to a thick-wall vessel being less or equal to the thickness of the vessel wall).[368] The prognosis for patients with equivocal or at most superficially invasive adenocarcinoma is favorable. For example, Ostor reported on 219 cases where there was invasion to a depth of 5 mm or less, and only 5 (2%) had nodal metastases.[369] Interestingly, 73 patients whose tumors showed Silva pattern A invasion (i.e., rounded glandular contour) were all alive and well on follow-up. These findings, from disparate studies, indicate that superficially

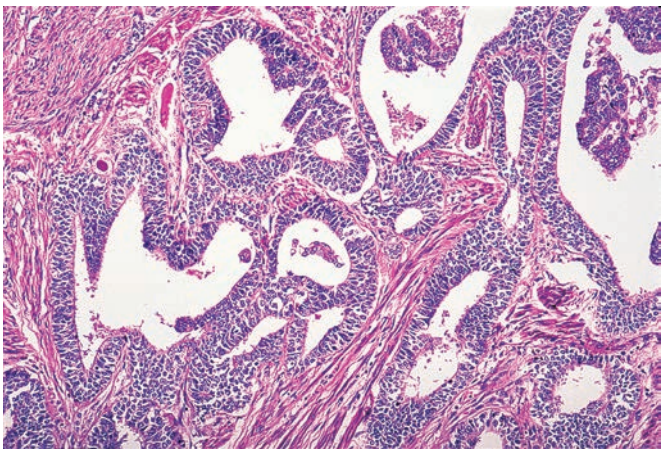

Figure 32.36 Mesonephric adenocarcinoma of cervix.

invasive cervical adenocarcinoma, especially if there is no destructive invasion, have a very favorable prognosis. In view of the generally indolent behavior of adenocarcinomas with equivocal or at most superficial invasion, a conservative type of surgery is advisable for most cases.[370]

Differential Diagnosis With Endometrial Adenocarcinoma

The differential diagnosis between endocervical and endometrial adenocarcinoma can be very difficult. The differential diagnosis is most commonly between usual type HPV-associated cervical adenocarcinoma and endometrial adenocarcinoma of endometrioid type, and it is this differential diagnosis that we will focus on. It should be noted that the guidelines do not apply if one is dealing with an HPV-independent cervical adenocarcinoma. We have encountered cases of gastric-type and mesonephric adenocarcinoma of the cervix where p16 negativity led to an erroneous diagnosis of endometrial carcinoma in a curetting specimen, so it is important to be mindful of the histologic features on H&E and not rush into immunostains.

Features that favor a primary endocervical origin are the following:

1. Presence of in situ adenocarcinoma in the cervical glands.
2. Negativity for vimentin.[371]
3. Negativity or only weak positivity for estrogen or progesterone receptor expression.[372,373]
4. Presence of HPV nucleic acid by in situ hybridization or PCR.[373]
5. Block positive immunoreactivity for p16.[374]

With regard to p16 immunostaining, it is important to note that up to 80% of the cells of some endometrioid carcinomas of endometrium can be p16 positive, but these tumors consistently lack the strong nuclear and cytoplasmic positivity characteristic of most HPV-associated endocervical adenocarcinomas of usual type. It is possible that a true endometrioid carcinoma could arise from cervical endometriosis; such a tumor would be HPV independent and immunophenotypically indistinguishable from endometrioid carcinoma arising in the uterine corpus or lower uterine segment; if these occur, they are rare. Tumors of the lower uterine segment are most commonly of endometrial-cell origin and indistinguishable from their counterparts arising in the uterine corpus rather than being related to endocervical adenocarcinomas.

Neuroendocrine Carcinoma

A small number of cervical carcinomas exhibit clear-cut evidence of neuroendocrine differentiation, as detected by ultrastructural, histochemical, and/or immunohistochemical criteria. These tumors have been variously called (atypical) carcinoid tumor, argyrophil cell carcinoma, (extrapulmonary) small cell carcinoma, (neuro) endocrine carcinoma, and carcinoma with (neuro)endocrine differentiation, the choice in terminology depending on the degree of differentiation of the tumor, the extent of endocrine features present, and the observer's bias.[375,376] It is preferable to use terms similar to those employed at other sites, as recommended in the 2014 WHO Classification, that is, low-grade neuroendocrine tumor (carcinoid or atypical carcinoid) or high-grade neuroendocrine carcinoma (small cell neuroendocrine carcinoma or large cell neuroendocrine carcinoma). It is important to remember that one can find neuroendocrine marker expression in cervical carcinomas of conventional type, a fact that should not result in a change of their designation; a diagnosis of neuroendocrine tumor can only be made in the presence of features of neuroendocrine differentiation recognizable on H&E.[377]

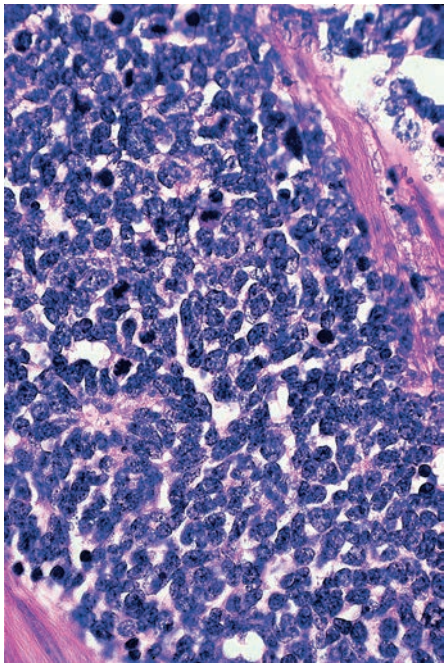

Figure 32.37 High-grade small cell neuroendocrine carcinoma of cervix.

Low-grade neuroendocrine tumors of the cervix are vanishingly rare, so we are left with small cell and large cell neuroendocrine carcinomas. The age distribution of patients with neuroendocrine carcinomas of the cervix is the same as for squamous cell carcinoma. They also show a similar association with HPV.[378–380] The carcinoid syndrome is invariably absent, but some cases have been seen in association with Cushing syndrome[381] and with inappropriate secretion of antidiuretic hormone (ADH).[382] In contrast to squamous cell carcinoma, HSIL (CIN2/3) changes in the adjacent epithelium are rare.[380,383] The histologic features of these tumors are identical to those of their more common counterparts occurring at other body sites. The large cell neuroendocrine carcinomas show variable organoid arrangement, with trabecular, insular, glandular, and spindle patterns of growth, while small cell neuroendocrine carcinomas are composed of monomorphic small cells with scant cytoplasm and hyperchromatic nuclei (Fig. 32.37). Most cases are pure, but others are combined with squamous cell carcinoma[384] or adenocarcinoma.[385–387] Immunohistochemically, positivity may be found for CD56,[388] chromogranin (but only in the better differentiated examples), and/or synaptophysin, but some tumors may be negative for all three markers. Generic neuroendocrine markers[389,390] and a variety of peptide hormones may be expressed (Fig. 32.38).[391] TTF-1 expression may be seen, so it does not aid in distinction from a lung primary.[392] p16 expression suggests HPV participation in the genesis of these tumors, which may be further confirmed at the molecular level.[393–396]

The large majority of these cervical neoplasms are histologically and clinically aggressive. The treatment, especially for high-grade lesions, usually consists of a combination of surgery, radiation therapy, and chemotherapy.[396] The prognosis is generally poor.[378,397–399] Naturally, there is also a close relationship between clinical stage and prognosis.[400] Both small cell and large cell neuroendocrine carcinomas with a polypoid shape or arising in polyps may be associated with a more favorable prognosis.[401]

Cytology

The broadest and most successful application of clinical cytology has been in the diagnosis of invasive carcinoma of the uterine cervix

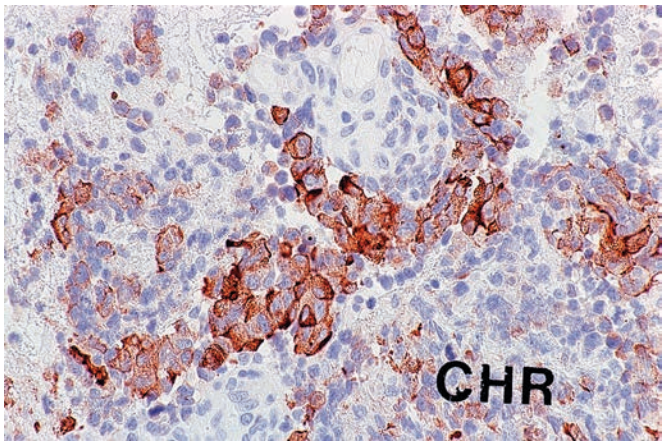

Figure 32.38 Strong focal immunoreactivity for chromogranin in neuroendocrine carcinoma of cervix.

and precursor lesions through the technique. Only a brief overview of cervical cytology can be provided in this chapter, and readers are referred to reference materials dedicated to cervical cytology, such as the excellent Bethesda 2014 website, for more detail on cytopathologic diagnosis of cervical smears.[402] There is a looming transition in which primary testing for HPV will have a place of more prominence, but there will also undoubtedly be large numbers of cervical cytology smears in need of skilled interpretation over the coming years, so that cervical cytology is undoubtedly going to be an important component of anatomic pathology practice. Cervical cytology was first described by Aureli Babès, a Romanian pathologist, further developed by George Papanicolaou at Cornell University, and is universally known as the Pap test[403,404] (Fig. 32.39). Today, it is widely used worldwide as a screening test in asymptomatic populations.[405,406]

Mass cytologic screening has shifted the presentation of cervical carcinoma from the clinical to the preclinical stage, saving many lives. In an often quoted article, Christopherson and Scott[407] reported a 70% decrease in mortality from carcinoma of the uterine cervix between 1970/1971 and 1955/1956 in women younger than 60 years of age. It should be emphasized that cervical cytology is a screening test, and the sensitivity is less than 100%. The success of cervical cancer screening programs in reducing mortality due to cervical cancer has led some to have unrealistic expectations for the performance of cervical smears in detection of premalignant and malignant lesions of the cervix.

Special techniques are applicable to cytology smears, including immunohistochemistry and in situ hybridization.[408] For instance, it has been shown that Ki-67 staining of cervical smears can improve the diagnostic accuracy of cervical LSIL,[409,410] while immunostaining for p16 is also of value in detection of HSIL.[411] The most important development, however, is development of sensitive automated HPV testing, with the previously described Hybrid Capture test being a leading example of the technology used. HPV testing was initially deployed as a triage test for patients with atypical cells that fell short of being diagnosable as SIL; results of HPV testing were used to guide referral for colposcopic examination in this setting. More recently there has been a move towards either co-testing (i.e., performing both conventional cervical smear cytologic examination and HPV testing) or primary HPV screening, where only HPV testing is performed as a screening test with no cervical smear cytology examination. The basis for the increasing use of HPV testing is that it is more sensitive than cervical cytology.[412–415] In the ATHENA study of more than 45,000 women, HPV testing had a sensitivity of 85%–90% in the four participating laboratories, while the sensitivity of cervical screening was both less, and showed more interlaboratory variation (42%–73%).[413–415] Given the added cost of co-testing, with little improvement in sensitivity, it is likely that there will be a move to primary HPV screening over the coming years. One such approach would stratify patients based on their HPV test results as follows: (1) women with negative tests will have no further testing done and return for HPV screening at regular intervals; (2) when testing is positive for HPV-16 or 18, there is reflex referral for colposcopic examination; and (3) with detection of other HPV genotypes, cervical cytology smears are prepared to guide referral to colposcopic examination (and if those smears are negative repeat testing is done in 12 months, which is at an accelerated interval). Primary HPV screening has already been instituted in some parts of the world (e.g., Mexico and Turkey).

The reader has undoubtedly noted that this is an area in transition. The uncertainty and change is also impacted by the emergence of patients at the age for initiation of screening (starting no earlier than at age 25) who were vaccinated against HPV as children or young adults. There are predictable effects of these highly effective vaccines on screening programs, in that there will be less HSIL in this population and this lower prevalence will lead to further decreases in both the sensitivity and specificity of cervical cytology screening, which is likely to disappear as a primary screening modality in immunized patients. HPV testing in this population will suffer from decreased specificity (although sensitivity should remain high) and more of the positive tests will be associated with transient infections that will be cleared by the immunized patients rather than progress to SIL. As well, there will be a higher proportion of non-HPV-16 and non-HPV-18 detected, and in these patients the risk of progression to HSIL is less.

The recommended terminology to be used in cervicovaginal cytology is that of the 2014 Bethesda classification.[428] There has been very significant evolution of diagnostic terminology within the memory of many senior practitioners, which we will briefly review. Papanicolaou's original system had five "classes" of increasing atypia. Although this nomenclature fulfilled a very important role in the establishment of the technique, it was eventually abandoned because of the vagueness of the information provided. A "class III" smear, for instance, could represent anything from a moderate dysplasia to an invasive carcinoma. Therefore, it was progressively replaced in the 1960s by the nomenclature then in vogue among histopathologists (i.e., negative, benign atypia, dysplasia [mild, moderate, or severe], carcinoma in situ, and invasive carcinoma).[416,417] During the 1970s, many institutions switched to the CIN system for both cytologic and histologic specimens. In 1988, at the initial Bethesda meeting, it was recommended to classify SIL in the following categories: (1) atypical squamous cells of undetermined significance (ASCUS); (2) low-grade SIL; (3) high-grade SIL; and (4) squamous cell carcinoma.[418–420] This classification was criticized on several grounds, one of them being the claim that it leads to overtreatment of many individuals whose smears are placed in the low-grade SIL category.[421,422] Partly as a response to these criticisms, the system was revised in 2001 in order to facilitate triage of women for more intensive screening only when a strong suspicion of a high-grade lesion is present.[423,424] The current classification (Bethesda 2014) includes the following categories for squamous cell abnormalities:

1. Atypical squamous cells:
   a. Of unknown significance (ASCUS)
   b. Cannot exclude high-grade squamous intraepithelial lesion (ASC-H)
2. Low-grade squamous intraepithelial lesion (LSIL)
3. High-grade squamous intraepithelial lesion (HSIL)
4. Squamous cell carcinoma

The recommendation is for women with ASCUS to be managed using a program of two repeat cytology tests, immediate colposcopy,

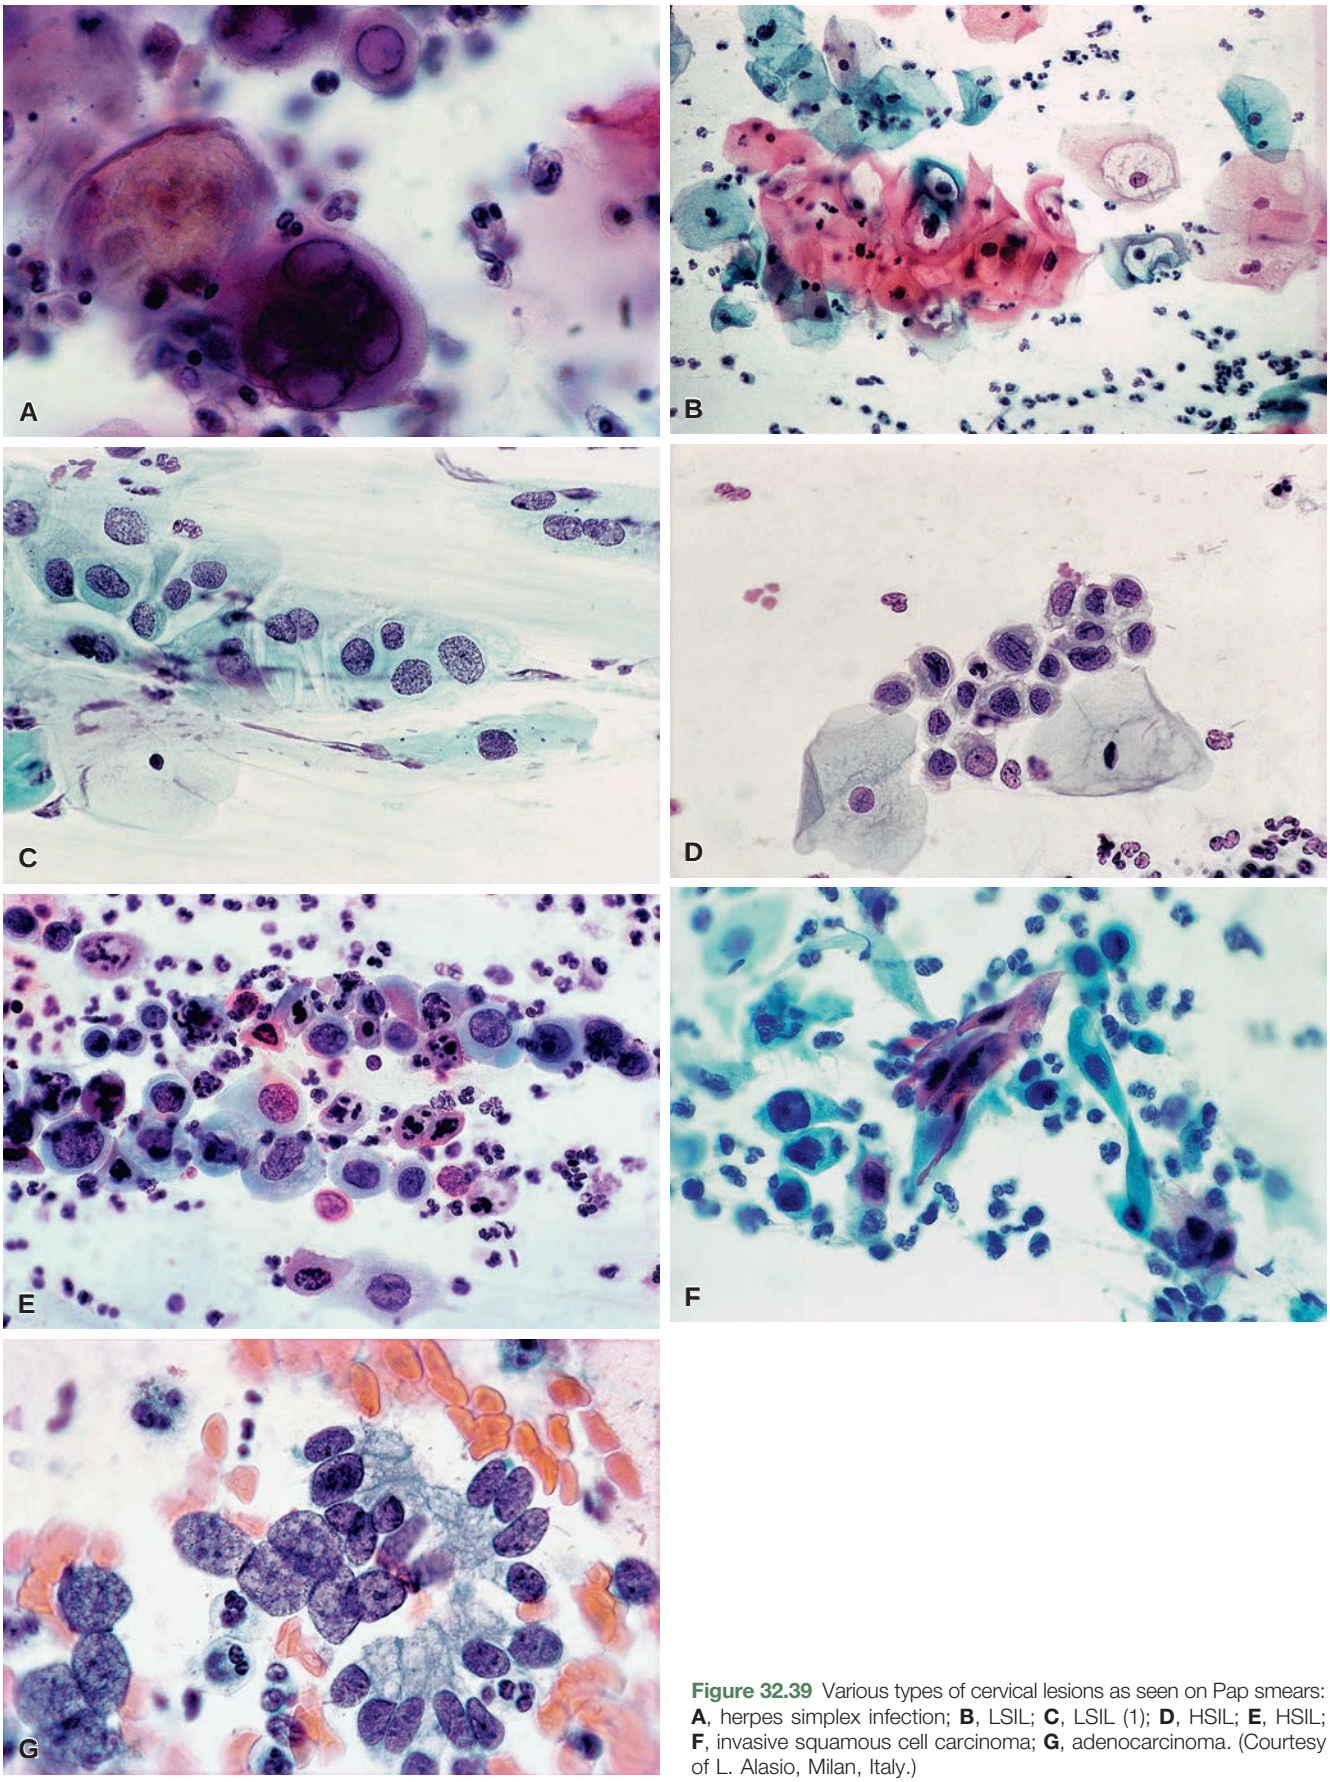

Figure 32.39 Various types of cervical lesions as seen on Pap smears: **A**, herpes simplex infection; **B**, LSIL; **C**, LSIL (1); **D**, HSIL; **E**, HSIL; **F**, invasive squamous cell carcinoma; **G**, adenocarcinoma. (Courtesy of L. Alasio, Milan, Italy.)

or DNA testing for high-risk types of HPV, while patients with LSIL or HSIL are reflexly referred for colposcopic examinaiton.[425]

Whether there is co-testing or primary HPV screening, and even if the uptake of the vaccine is 100%, there will still be cervical cancer and cervical cancer deaths. There remain pockets of patient resistance to vaccination, based on pseudoscience and despite demonstration that HPV is so ubiquitous that 80% of sexually active women will be exposed by age 50. Furthermore, not all cervical cancers are related to HPV; in the previous section we discussed the HPV-independent cervical adenocarcinomas (e.g., gastric type or clear cell carcinomas) and these will not be detected by HPV testing and are suboptimally detected by cervical screening.

Other Tumors and Tumorlike Conditions

Carcinomas of one type or another comprise approximately 99% of all primary cervical malignancies. The remaining 1% is made up of a large variety of neoplasms.

Embryonal (botryoid) rhabdomyosarcoma presents in children and adolescents as a myxoid polypoid mass covered by attenuated epithelium.[426–428] The appearance is generally similar to that of the homonymous vaginal tumor. However, some of the cervical cases occurring in older patients have been seen to contain cartilage and to be associated with a better prognosis, (Fig. 32.40).[429] **Alveolar rhabdomyosarcoma** has also been reported.[430]

Carcinosarcomas (malignant mixed müllerian tumors) also present as polypoid masses but generally occur in much older patients, the average age in one series being 65 years.[431] Some tumors look identical to their more common uterine counterparts, but in others the recognizable epithelial component has an adenoid basal or squamous appearance.[431,432] When the latter is the case, the appearance blends with that of spindle cell (sarcomatoid) carcinoma.

Müllerian adenosarcoma[433,434] and **stromal sarcoma** of endometrial type also occur in the cervix (Fig. 32.41), the former sometimes featuring foci of ovarian sex cord–like structures.[435] **Smooth muscle tumors**, both benign and malignant, also occur in the cervix (Fig. 32.42).[436] The diagnostic criteria are the same as for those in the uterine corpus, but the ratio may be slightly different (comparatively more leiomyosarcomas are found in the cervix). Some of the reported leiomyosarcomas have been of the myxoid variety,[437] and others have had a xanthomatous appearance.[438]

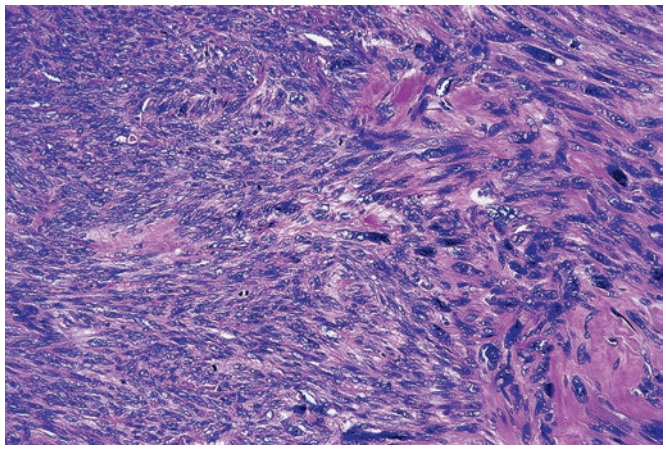

Figure 32.42 Poorly differentiated leiomyosarcoma of cervix.

Other primary cervical tumors and tumorlike conditions include *teratoma*,[439,440] *glial polyp (glial heterotopia, glioma)* of probable fetal origin,[441] and *ganglioneuroma*[442]; *yolk sac (endodermal sinus) tumor* (closely simulating the clinical appearance of embryonal rhabdomyosarcoma)[443]; *choriocarcinoma*[444]; *sebaceous carcinoma*[445]; *extrarenal Wilms tumor*[446]; *traumatic (amputation) neuroma*[447] (some occurring postpartum)[448]; *neurofibroma*[449]; *schwannoma*[450] (including the pigmented variety)[451]; *malignant peripheral nerve sheath tumor*[452,453]; *solitary*

fibrous tumor[454]; *pigmented neuroectodermal tumor of infancy*[455]; *melanosis* (sometimes developing after cryotherapy for SIL)[456–458]; *blue nevus*[459–461] (Fig. 32.43); *cellular blue nevus*; *malignant melanoma*[462,463] (including the desmoplastic variety[464] and a type simulating malignant peripheral nerve sheath tumor[465]); *benign mesenchymoma*[466]; *hemangioma*[467] (Fig. 32.44); *glomus tumor*[468]; *angiosarcoma*[469]; *osteosarcoma*[470]; *alveolar soft part sarcoma*[471–473]; and *Ewing sarcoma/PNET*[474–476]).

Malignant lymphomas of the cervix present with vaginal bleeding and a subepithelial mass without obvious ulceration.[477] Most are diffuse large B-cell lymphomas and many are accompanied by extensive fibrosis (Fig. 32.45).[475,478–481] An important differential diagnosis is with **lymphoma-like lesions** resulting from focally florid lymphoid proliferation associated with chronic cervicitis or as an expression of infectious mononucleosis[482,483]; these are identified by the polymorphic nature of the infiltrate (including mature plasma cells, small lymphocytes, and neutrophils), surface ulceration, and minimal or no sclerosis. Despite the occasional detection of clonality in some cases, the disease has so far followed a benign clinical course.[484] *Granulocytic sarcoma (chloroma)*,[485–487] *Hodgkin lymphoma*, *inflammatory pseudotumor*,[488] localized *amyloidosis*,[457] and *Rosai–Dorfman disease* (sinus histiocytosis with massive lymphadenopathy)[489] can also present initially as a cervical mass.

Metastatic carcinomas to the cervix (excluding direct invasion from endometrial carcinoma) can originate from genital or extragenital organs; the most common sites are the ovary, large bowel, stomach, breast, and kidney (Fig. 32.46).[490,491] Some of them clinically and pathologically simulate the appearance of primary cervical carcinoma, including invasive and in situ cervical adenocarcinoma.[492] Knowledge of the clinical findings may make this mistake avoidable.

An exceptional event is represented by replacement of the endocervical (and endometrial) mucosa by metastatic mucinous tumor of the appendix.[479]

Normal Anatomy

The adult nulliparous uterus is a hollow, pear-shaped organ that weighs 40–80 g and measures 7–8 cm along its longest axis. It is divided into the *cervix* (discussed in Chapter 32) and the *corpus*. The portion of the corpus cephalad to a line connecting the insertion of the fallopian tubes is the *fundus*. The two lateral regions of the fundus associated with the intramural portion of the fallopian tubes are referred to as the *cornua*. The portion of the corpus that connects with the cervix is called the *isthmus* or *lower uterine segment*.

The uterine cavity has a triangular shape and a length of approximately 6 cm. It is lined by the endometrial mucosa, which constitutes the inner layer (endometrium) of the organ. It is surrounded by a thick muscular layer (myometrium) and a serosal covering, the latter extending to the point of peritoneal reflection. Two useful clues to distinguish the anterior from the posterior side of a hysterectomy specimen at time of gross examination are: (1) the fact that the point of peritoneal reflection is *lower* on the posterior side; and (2) the fact that the uterine insertion of the fallopian tube is *posterior* to the insertion of the round ligament.[1]

The uterine lymph vessels drain to a rich network of lymph nodes, the main groups being parametrial and paracervical; internal (hypogastric), external, and common iliac; periaortic; and inguinal.

The endometrial mucosa is made up of glands and stroma. It is divided into a deeply seated *basal* layer and a superficial *functional* layer. The basal layer is the equivalent of the reserve cell layer of other epithelia and is responsible for the regeneration of the endometrium following menstruation. It is made up of weakly proliferative glands and spindled stroma. The functional layer is subdivided into two strata, the *compactum* (toward the surface) and the *spongiosum* (close to the basalis). The stroma is mainly composed of endometrial stromal cells (whose appearance changes considerably during the menstrual cycle, see later section) and vessels (of which the spiral arterioles are the most distinctive). Also present are stromal granulocytes. The immunohistochemical profile of endometrial stromal cells is "CD10 dominant" in relation to CD34, whereas the reverse is true for the endocervical stroma.[2] The phenotypic profile of the endometrial glands will be discussed in connection with the various pathologic conditions that affect that tissue[3,4]; suffice to warn the reader that two markers associated with breast and lung/thyroid—that is, mammaglobin and thyroid transcription factor-1 (TTF-1), respectively—can be expressed by endometrial cells.[5,6]

During childbearing age, the normal endometrium undergoes a series of sequential changes in the course of the ovulatory cycle that prepare it to receive the ovum (Fig. 33.1).[7] If the ovum is not fertilized, the proliferative endometrium is cast off by menstruation, and the cycle repeats itself. A normal endometrial cycle is associated with changes in both endometrial glands and stroma that allow the pathologist to diagnose microscopically the phase of the menstrual cycle.[8] In a series of classic articles, Noyes and colleagues.[9,10] set forth specific criteria by which a relatively accurate dating of the endometrium was made possible (Fig. 33.2). At one time it was common for pathologists to be asked to "date" endometrial biopsy specimens (i.e. assess the development of the endometrial glands and stroma, relative to the time of ovulation) that were taken for investigation of infertility, but such requests have dramatically decreased over the

Abstract

Endometrial biopsy and curetting specimens are among the most commonly encountered in general surgical pathology practice and can show a wide range of pathologic alterations. Many relate to perturbations in the normal hormonal environment, secondary exogenous hormones or shifts in endogenous hormone levels, for example, during the perimenopausal period. Endometrial carcinoma is the most common malignancy of the female reproductive organs and recent insights into the genomic subtypes of endometrial cancer have changed our understanding of the pathogenesis of endometrial carcinoma. As well as carcinomas, a range of sarcomas and biphasic tumors, such as adenosarcoma, also occur in the uterine corpus, and these are reviewed.

past decade; nevertheless all surgical pathologists should be familiar with the normal cyclical changes in the endometrium.

In general, the changes are quite uniform throughout the functional endometrium.[9] The surface epithelium is less responsive to the hormonal influences than the glandular epithelium. For subnuclear vacuolation to be regarded as evidence of ovulation, it should be present in at least 50% of the functional glands present in the section, as patchy development of subnuclear vacuoles is a common finding in endometrium subject to prolonged unopposed estrogenic stimulation (so-called disordered proliferative endometrium). Neutrophils, which are seen in large numbers in areas of tissue degradation (beginning on day 26) are very rare during the other days of the cycle; they should be distinguished from the already mentioned stromal granulocytes, which do not stain for chloroacetate esterase.[11]

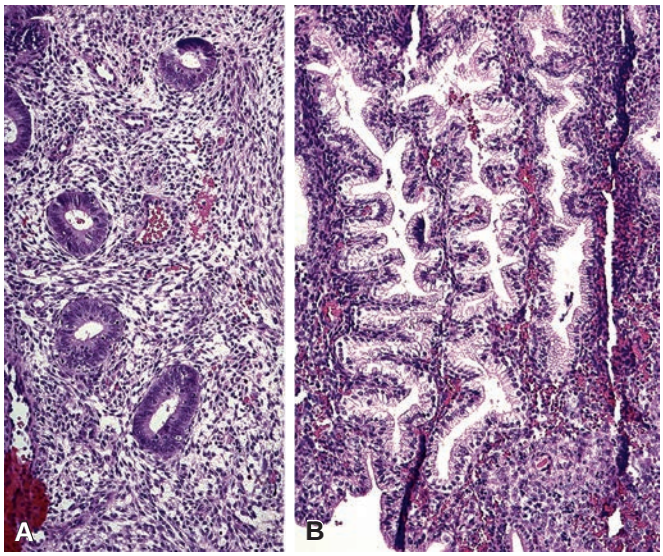

Figure 33.1 Normal Endometrium. A, Proliferative; **B,** secretory.

The cellular condensation with nuclear crowding, squamoid appearance, and focal cytoplasmic eosinophilia seen in menstrual specimens should not be confused with a malignant or other pathologic process. The possibility of overdiagnosis is even greater in the rare instances in which the menstrual endometrium is seen within the lumen of blood vessels.[12] It should be noted that endometrial tissue can also be found in myometrial vessels independently from menstruation.[13]

The basal layer of the endometrium is not subject to the influence of progesterone. Similarly, the mucosa of the lower uterine segment responds only sluggishly to the hormonal stimulation and can appear different from sampled functionalis.[14] This mucosa gradually merges with that of the endocervix; the hybrid endometrial–endocervical appearance of both glands and stroma allows its recognition in endometrial sampling (either biopsy or dilation and curettage [D&C] specimens).

The reappearance of glandular secretion and stromal edema once predecidual reaction is established—leading to the simultaneous presence of these three features in an endometrial specimen—is evidence that a fertilized ovum has implanted. An exaggerated expression of this pregnancy-related phenomenon is the ***Arias-Stella reaction***, as originally described by the Peruvian pathologist Javier Arias-Stella.[15] In this condition, secretory or proliferative changes in the endometrial glands are accompanied by prominent nuclear changes, manifested by hyperchromasia and marked enlargement (Fig. 33.3). Normal and abnormal mitoses may also be present.[16] These changes are almost always focal and may also occur in the cervix, endocervical polyps, adenomyosis, and endometriosis.[17] They are more often seen in postabortion curettings (present in 20%–70% of cases and persisting for weeks), but they are also seen in normal orthotopic or ectopic pregnancies, hydatidiform mole, choriocarcinoma, and (very rarely) following the administration of exogenous hormones.[18,20] In hydatidiform mole and choriocarcinoma, the nuclei of the endometrial cells may attain gigantic sizes. The most important

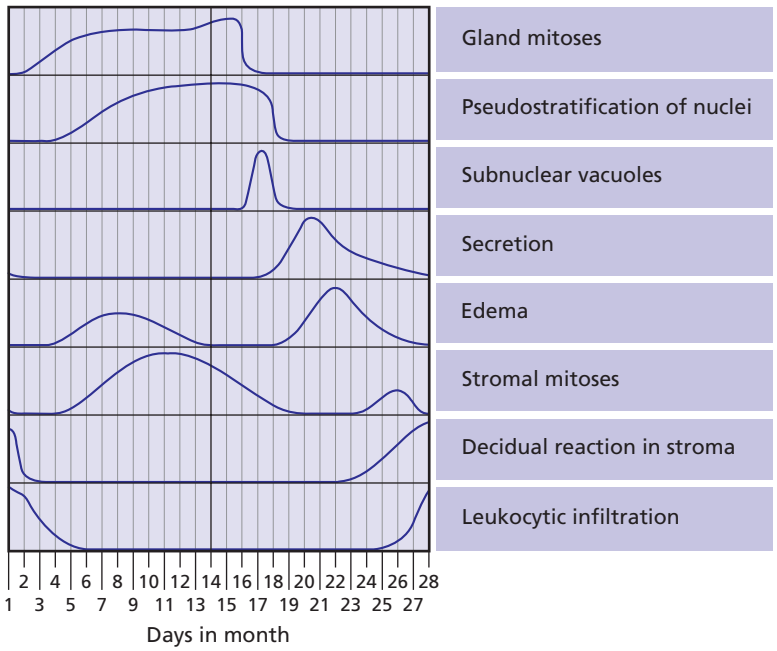

Figure 33.2 Cyclic Changes in Endometrium. Approximate relationship of microscopic changes. (From American Society for Reproductive Medicine. Noyes RW, Hertig AT, Rock J. Dating the endometrial biopsy. *Fertil Steril*. 1950;1:3–25).

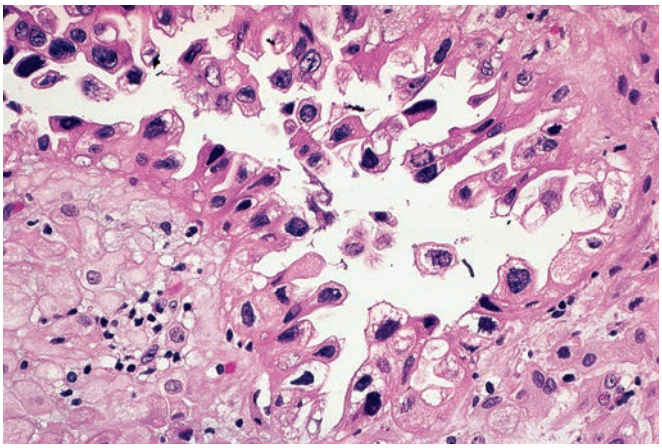

Figure 33.3 Arias-Stella Reaction in Endometrial Mucosa. This is not to be confused with a malignant condition.

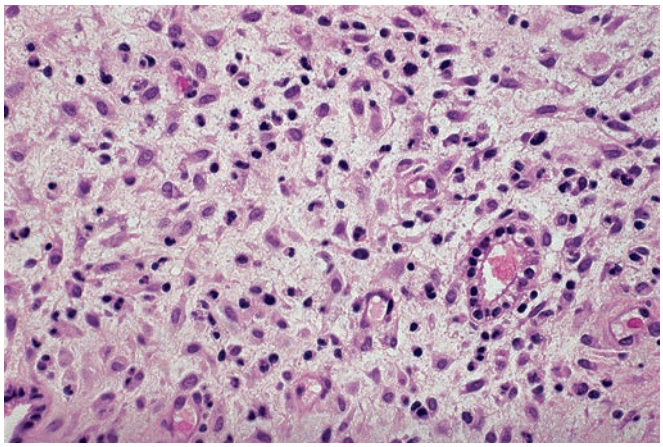

Figure 33.4 Typical appearance of endometrium after long-term administration of contraceptive pills. The glands are sparse and atrophic, whereas the stroma is prominent and has deciduoid features, reflecting the predominant progestin effect.

differential diagnosis is with serous and clear cell types of endometrial adenocarcinoma. Immunostains for Ki-67 and p53 are helpful in this regard, their being usually low and wild type–pattern, respectively, in the Arias-Stella reaction.[21]

Another interesting pregnancy-related endometrial alteration (often associated with the Arias-Stella reaction) is the focal appearance of optically clear nuclei in the glandular cells, simulating viral inclusions; these are due to the replacement of normal chromatin by a fine filamentous network that is immunoreactive for biotin.[22–24]

Exceptionally, an "idiopathic" decidual reaction is seen in the postmenopausal endometrium in the absence of an exogenous or endogenous source of progesterone excess.[25]

After the menopause the endometrium becomes inactive (simple glands lined by metabolically inactive, non-mitotic cuboidal epithelial cells and associated stroma) or atrophic (strips of inactive surface epithelial cells with no or minimal stroma). These glands may become cystically dilated (cystic atrophy), but the lining cells have an atrophic appearance, in contrast to the proliferative columnar cells lining cystic glands in endometrial hyperplasia without atypia. Although a distinction can be made between inactive and atrophic endometrium histologically, based on the presence or absence of endometrial stroma, it is not clinically relevant. Endometrial biopsy for postmenopausal bleeding is one of the most common specimens encountered in practice, with most such specimens showing the expected inactive/atrophic endometrium. In most series, approximately 5%–15% of the cases of postmenopausal bleeding are due to endometrial carcinoma and a similar proportion to endometrial polyps.[26,27] Degenerative and other changes in the endometrial blood vessels have been suggested as a possible etiology in the majority of cases where no significant pathology is identified (i.e. there is only the expected inactive/atrophic endometrium).[28,29]

The myometrium has a rich network of thick-walled vessels in its midportion, a landmark that can be recognized grossly. A peculiar vascular architecture sometimes encountered in the myometrium is that of arteries apparently free-floating within cleft-like spaces, which have been interpreted as venous channels.[30]

Effects of Hormone Administration

Estrogen Therapy

Exogenous administration of estrogen preparations exposes the cycling or postmenopausal endometrium to a potent stimulus.[31] Endometrial hyperplasia is a frequent development in women taking unopposed estrogen, and this can progress to atypical hyperplasia and adenocarcinoma.[32,33] The large majority of tumors arising secondary to unopposed estrogen are well differentiated and superficial and are associated with an excellent prognosis.[34]

Progestational Agents

Owing to the widespread use of progestational agents for therapeutic and contraceptive purposes, endometrial changes secondary to progestational effects are commonly encountered in practice.[35–37] The effects of exogenous progestins are seen primarily in the stroma, which predominates and shows striking pseudodecidual changes (Fig. 33.4).[38] In contrast to the prominent stromal development, the glands are small, widely separated by stroma, and atrophic appearing.

In endometrium from patients taking oral contraceptive pills, the effects in the endometrium reflect the progesterone predominance and variably show the features described previously, that is, stromal predominance, with pseudodecidual changes, and small atrophic glands.[39] On very rare occasions, focal glandular changes of the Arias-Stella type may appear in patients taking contraceptive pills. In most cases, discontinuation of the hormones results in a restoration of a normal endometrial pattern in a matter of weeks.

Patients receiving hormone replacement therapy for postmenopausal symptoms will typically be on low-dose combination (estrogen and progestin) therapy; the goal is to relieve symptoms but to not have stimulation of the endometrium. Thus, the endometrium should appear inactive or atrophic. If a patient on postmenopausal hormone replacement therapy presents with bleeding and the biopsy shows proliferative changes, this reflects excessive estrogenic stimulation of the endometrium; if the dosage is not altered, continued bleeding is likely.

Endometrial changes secondary to treatment of endometrial hyperplasia with high-dose progestin therapy will be covered later, in the section on endometrial hyperplasia.

The **Mirena coil (levonorgestrel)**, increasingly used for the treatment of menorrhagia/endometrial hyperplasia, can induce a large variety of alterations in the endometrial mucosa, including pseudodecidualization, mucinous changes, ulceration, inflammatory infiltrates, stromal hyaline nodules, superficial micropapillary changes, infarcted decidua, dystrophic calcification, and others.[40]

Progesterone receptor modulators used in the management of endometriosis and uterine leiomyomas most commonly cause only minimal and inconsistent changes in the endometrial mucosa but can cause cystic dilated glands that raise the differential diagnosis of endometrial hyperplasia.[41] These changes can be distinguished from hyperplasia by the appearance of the epithelial cells lining the cysts, which appear inactive and may contain abortive subnuclear vacuoles.[42] Abnormal stromal vessels are commonly seen.

Tamoxifen

Tamoxifen is a synthetic anti-estrogen used in the treatment and prophylaxis of breast carcinoma. Not only does it have an anti-estrogenic effect on the endometrium when competing with ovarian estrogen secretion, it also has a paradoxical estrogenic effect in the absence of ovarian estrogen secretion.[43–45] It is associated with an increased frequency of proliferative endometrial lesions, including hyperplasias, polyps, and malignant tumors,[46,47] but the latter are not seen often enough to justify routine endometrial biopsies in this population.[48] None of the changes associated with tamoxifen are pathognomonic[49] and, accordingly, biopsies taken from women receiving tamoxifen therapy are diagnosed using terminology and diagnostic criteria identical to those used for patients not on tamoxifen. With respect to endometrial carcinomas developing in patients on tamoxifen, in two reported series a significant number of the cases were high-grade tumors associated with a poor prognosis,[50–52] but in others there was a great predominance of low-grade endometrioid adenocarcinomas,[53] and the former studies may reflect some selection bias.

Endometritis

Acute endometritis is usually seen in association with abortion, the postpartum state, or instrumentation. Gonococcal endometritis is rarely seen by the pathologist because of its very transient nature. Before making a diagnosis of acute endometritis, the pathologist should remember that neutrophils are normally present in the endometrium on days 26, 27, and 28.[54]

Chronic endometritis, characterized by an infiltrate of lymphocytes and plasma cells (often with an additional minor component of eosinophils[55]), may follow pregnancy or abortion, be the result of an intrauterine device (IUD), be associated with a submucosal leiomyoma, or be accompanied by mucopurulent cervicitis and/or pelvic inflammatory disease (PID).[56,57] The presence of chronic endometritis is associated with infertility/recurrent implantation failure. There, is some evidence that antibiotic therapy in these patients can result in improved outcomes in subsequent in vitro fertilization cycles, thus it is an important and clinically actionable diagnosis.[58] The most common symptoms are vaginal bleeding and pelvic pain, but most patients are asymptomatic.[57] It should be emphasized that lymphoid follicles, with or without germinal centers, are a normal occurrence in the functional layers of the endometrial mucosa and, therefore, should not be considered as evidence of chronic endometritis.[59] Therefore, identification of plasma cells constitutes the most important criterion for the diagnosis of chronic endometritis, whether by conventional criteria or—as suggested by some—by immunostaining the sections for immunoglobulins,[60] CD38,[61] VS38,[61] or syndecan-1 (Fig. 33.5).[62] However, it should be kept in mind that scattered plasma cells can be found in the absence of endometritis[63] and the demonstration of rare plasma cells with immunostains should not lead to overdiagnosis of endometritis. Clearly there remains important work to be done in refining the diagnostic criteria for chronic endometritis. The possibility of inflammation should be suspected—and plasma cells searched for—whenever there is an abnormal cyclic pattern, a focal mononuclear infiltrate, inflammatory cells in the glandular lumina, dense stroma, a stellate stromal pattern of proliferation, or foci of necrosis or calcification (Fig. 33.6). Glandular alterations commonly accompany the inflammatory reaction. The presence of neutrophils in the endometrial surface is a good predictor of PID, especially if combined with plasma cells in the endometrial stroma.[64]

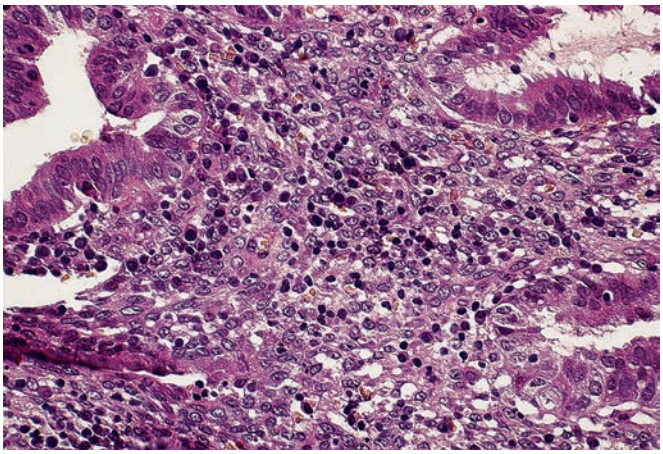

Figure 33.5 Chronic endometritis showing an inflammatory infiltrate rich in lymphocytes and plasma cells.

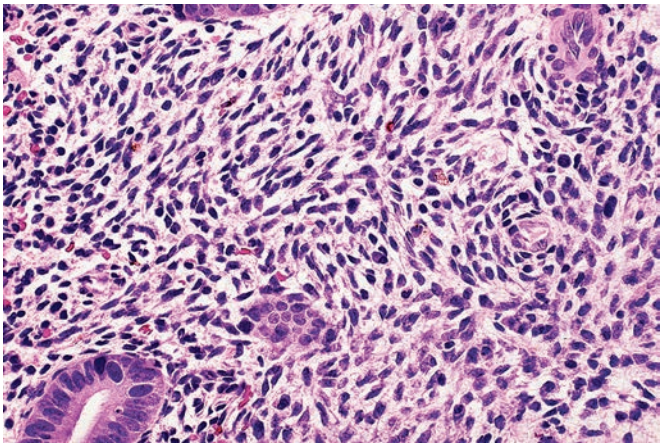

Figure 33.6 The oval to spindle and occasionally stellate shape of endometrial stromal cells is a clue to the diagnosis of chronic endometritis.

The myometrium is usually spared in most types of endometritis (sarcoidosis excluded, see later) unless the inflammation is very severe.

IUDs inserted for the purpose of contraception result in many biologic changes.[65,66] The most common change is focal or extensive chronic endometritis, which may be accompanied by necrosis and squamous metaplasia.[67,68] On occasion, the inflammation spreads through the fallopian tubes to produce PID and sometimes tubo-ovarian abscesses.[69,70] One of the agents involved in the inflammatory process is *Actinomyces* (Fig. 33.7).[71–73] The organisms can be detected in microscopic sections or in cytology preparations,[74] but care should be exercised in distinguishing them from pseudoactinomycotic radiate granules; the latter lack central branching filaments and diphtheroid forms.[75] The changes that can develop following the insertion of the Mirena coil were described in the previous section.

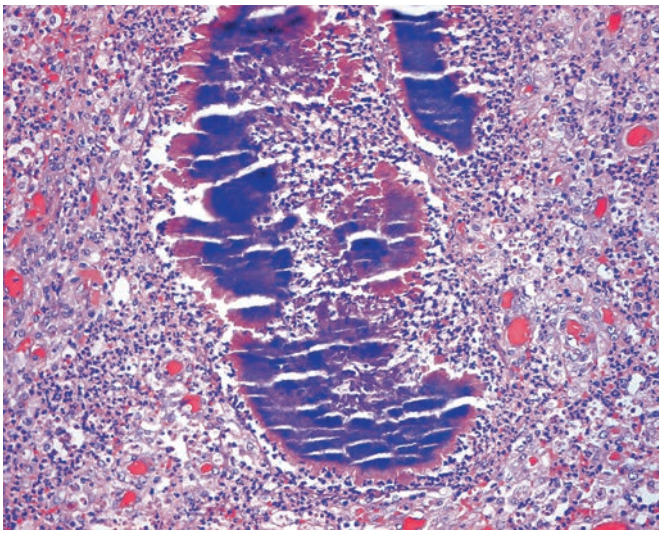

Figure 33.7 IUD-Related Uterine Actinomycosis. The disease had spread to the pelvic cavity.

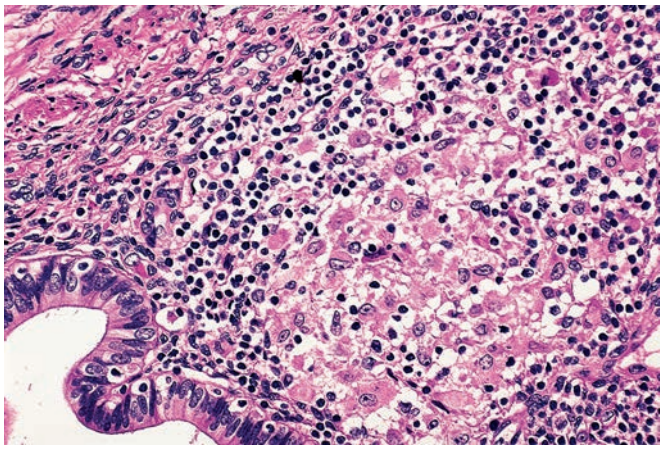

Figure 33.8 Noncaseating granuloma in endometrial mucosa consistent with sarcoidosis.

Pyometra refers to the accumulation of pus within the endometrial cavity. It is the consequence of the combined effect of obstruction and infection. Whiteley and Hamlett[76] reviewed 35 cases in postmenopausal patients. Only five were secondary to carcinoma; the remaining 30 were the result of benign cervical stricture originating from senile atresia, surgery, or cauterization.

Hematometra is the accumulation of blood within the endometrial cavity, usually as a result of cervical occlusion. This may lead to the disappearance of the endometrial mucosa and its replacement by sheets of lipid-containing histiocytic cells, a process known as *histiocytic* or *xanthogranulomatous endometritis* when diffuse and as *nodular histiocytic hyperplasia* when localized.[77,78] Sometimes the histiocytes are found to contain a yellowish-brown cytoplasmic pigment, in which case the term *ceroid-containing histiocytic granuloma* has been used.[79]

Endometrial tuberculosis is rare in the United States but still common in other parts of the world. Menstrual disturbances are common. The microscopic diagnosis is based on the demonstration of acid-fast bacilli in tubercles or culture. The presence of plasma cells and leukocytes probably results from secondary infection.[80] Tubercles may be missed unless multiple levels of curettings are examined. Since the granulomas tend to concentrate in the superficial functional layers of the endometrium, it is recommended that the biopsy be taken during the late secretory phase, and tissue should be submitted for culture as well as histopathologic examination.

Chlamydial infection has been identified through the immunohistochemical demonstration of chlamydial antigens in endometrial epithelial cells[81,82] or by polymerase chain reaction (PCR).[83] These cases are associated with severe acute and/or chronic inflammation. Plasma cells tend to be very numerous; as a matter of fact, it has been proposed that the presence of these cells is linked to *Chlamydia* infection.[84]

Viral infection of the endometrium is probably more common than generally suspected. Cytomegalovirus endometritis and diffuse papillomatosis (condyloma) have both been documented[85,86]; the former can have a granulomatous quality.[87]

Coccidioidomycosis of the uterus has been reported in the United States in a few cases as a localized infection; it probably results from a clinically inapparent and completely resolved primary lung infection.[88,89]

Postoperative granulomas of the endometrium have been described following endometrial ablation procedures; they may be thought of as the female counterpart of those seen in the prostate or bladder following transurethral resection (TUR).[90,91]

Malakoplakia of the endometrium has been reported, sometimes in a recurrent fashion and occasionally in association with endometrial adenocarcinoma.[92]

Sarcoidosis of the uterus occurs, but it remains a diagnosis of exclusion (Fig. 33.8).[93] In contrast to tuberculosis, the granulomatous reaction usually spreads to the myometrium.[94] Granulomatous endometritis can also follow hysteroscopic resection of the endometrium.[95]

Giant cell arteritis may involve the uterus and other genital organs of elderly women, either as an isolated finding (i.e. no systemic symptoms and normal acute phase reactants) or as part of a generalized process.[96–98] The former event is more frequent than the latter,[98] but sometimes female genital tract disease is the first manifestation of systemic periarteritis nodosa.[99] Over 90% of patients with isolated vasculitis of the myometrium have a nongranulomatous histology.[100]

Metaplasia

The endometrial glands and stroma are subject to a variety of metaplastic changes, many of them hormonally induced. They are often accompanied by hyperplastic changes in the endometrial glands but can occur independently from them and, therefore, need to be evaluated separately. They should not be regarded by themselves as evidence for the existence of a neoplastic process, but the presence of squamous metaplasia and mucinous metaplasia, in particular, should heighten awareness of the possibility of coexistent hyperplasia. Papillary syncytial and ciliated cell metaplasia are much less likely to be associated with hyperplasia. The endometrial metaplasias include:

1. **Squamous (morular) metaplasia**. This is most commonly encountered in hyperplastic endometrium but can be seen in association with leiomyoma or uterine polyps.[101] Frank keratinization is very rare *(ichthyosis uteri)*. A more common finding is the presence of nonkeratinizing squamoid cells occurring either diffusely (adenoacanthosis)[102] or in the form of berry-like aggregates (morules or morular metaplasia; Fig. 33.9).[103] Most are seen in premenopausal women, in those receiving exogenous hormones, or in association with polycystic ovary syndrome

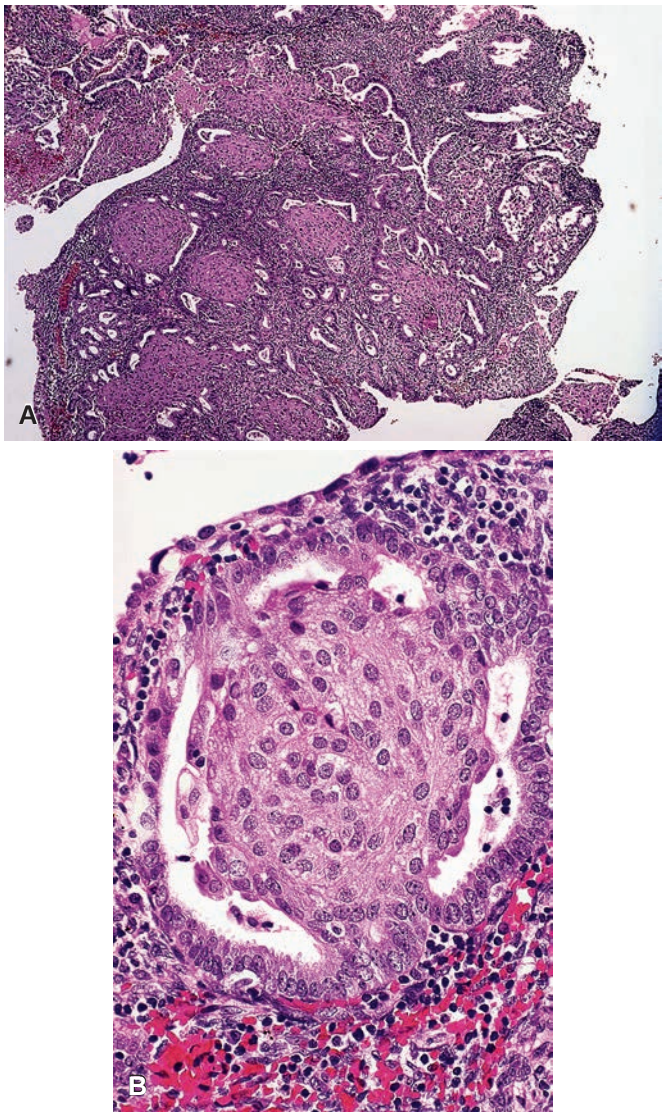

Figure 33.9 **A** and **B,** Squamous metaplasia of endometrium with morule formation.

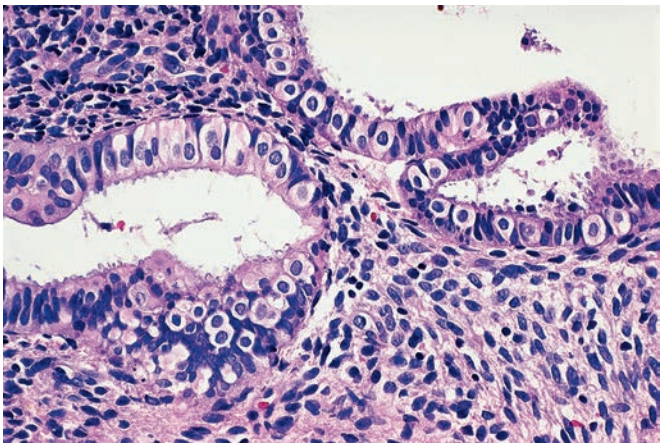

Figure 33.10 **Tubal Metaplasia of Endometrial Mucosa.** All three cell types that make up the normal mucosa of the fallopian tube can be recognized.

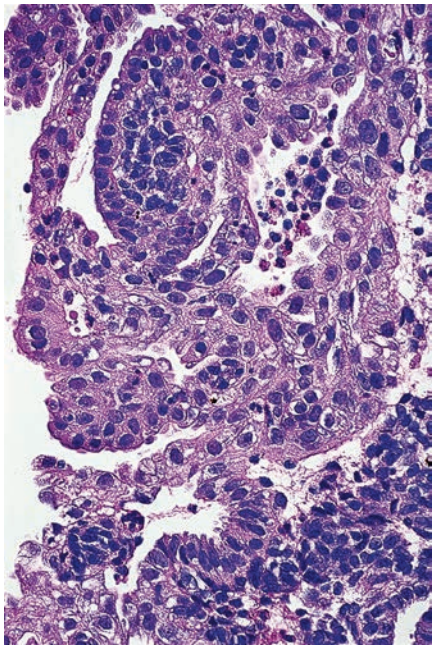

Figure 33.11 Papillary (syncytial) metaplasia of endometrium.

(PCOS).[104,105] This change is distinguished from well-differentiated endometrial adenocarcinoma with squamous metaplasia because of the benign appearance of the glandular elements, without glandular crowding or atypia. The morules represent a functionally inert tissue, in the sense of being devoid of sex hormone receptors and having an extremely low proliferation rate.[106] Surprisingly, they are immunoreactive for the intestinal transcription factor CDX2.[107]

2. **Ciliated cell (tubal) metaplasia**. Scattered ciliated cells are normally present in the endometrial mucosa; when markedly increased in number, the appearance resembles that of a fallopian tube, and the term listed earlier is used (Fig. 33.10).[108] Ciliated cell metaplasia is common in atrophic endometrium, to the point where it need not be commented on this setting. Occasionally the condition is associated with atypical nuclear features *("atypical tubal metaplasia")*, but even under these circumstances it does not seem to constitute a factor of significant risk for the development of endometrial adenocarcinoma.[109]
3. **Papillary syncytial metaplasia** (papillary syncytial change). This alteration is characterized by the presence of syncytial to papillary aggregates of eosinophilic cells along the surface epithelium (Fig. 33.11). It is often seen in association with endometrial breakdown.[110]
4. **Mucinous metaplasia**. In this condition, the endometrial mucosa reverts to a pattern morphologically, histochemically, and ultrastructurally similar to that of the endocervical mucosa (Fig. 33.12).[111,112] It is particularly common in endometrial polyps. The main differential diagnosis is with normal cervix or atypical mucinous proliferation of the endometrium/mucinous variant of endometrial adenocarcinoma.[113] With regards to the differential diagnosis with normal cervix, mucinous metaplasia can be recognized by its involvement of endometrial tissue (i.e. association with endometrial stromal cells and non-metaplastic endometrial glandular epithelium), and by the absence of reserve cells. Mucinous metaplasia should be focal, bland, and without glandular architectural features; in their presence a diagnosis of

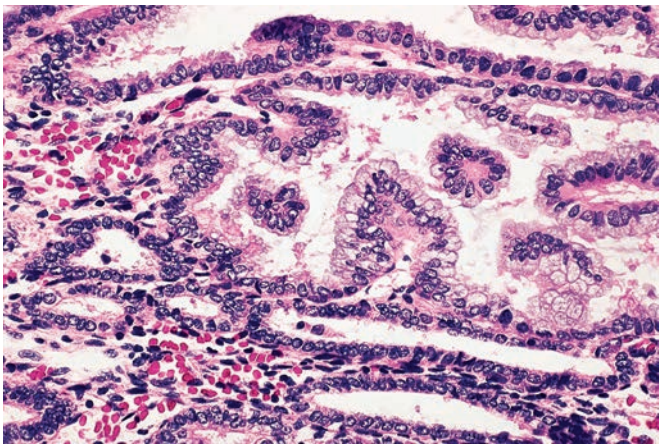

Figure 33.12 Mucinous Metaplasia of Endometrium. Note the basal location of the nuclei and the mucin-containing cytoplasm of the columnar cells.

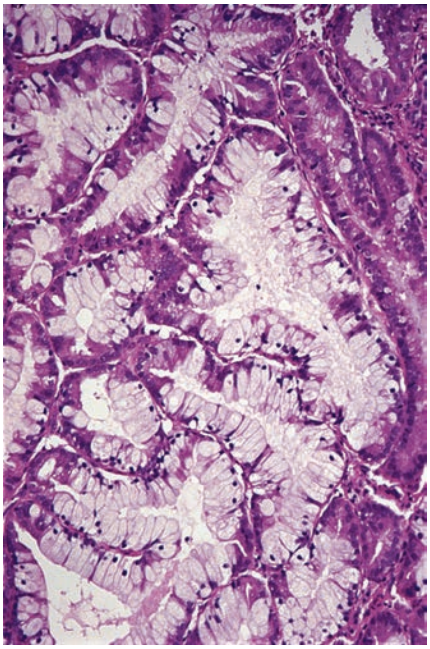

Figure 33.13 Clear Cell Metaplasia of Endometrium. The cytoplasm has a finely granular quality.

atypical mucinous glandular proliferation (discussed later) should be entertained.

5. **Eosinophilic (oxyphilic; oncocytic) metaplasia**. This is characterized by cells with abundant eosinophilic cytoplasm.[114] It is distinguished from atypical endometrial hyperplasia and the exceptionally rare oncocytic carcinoma by the absence of glandular crowding and atypical nuclear features.[115,116]
6. **Hobnail and clear cell metaplasia**. In these closely related metaplastic changes, the epithelium is clear, with tall cells having apically located nuclei (Fig. 33.13). The differential diagnosis is with clear cell (mesonephroid) adenocarcinoma.[115]
7. **Arias-Stella reaction.** See under Normal anatomy.
8. **Stromal metaplasia**. This includes the formation within the endometrial stroma of islands of smooth muscle,[117] cartilage,[118] and bone.[119] It should be noted that in most instances the presence of cartilage or bone is the result of retained fetal parts.[120]

Figure 33.14 Gross Appearance of Uterus Involved by Adenomyosis. The wall is irregularly thickened and contains small hemorrhagic foci.

Adenomyosis and Endometriosis

Adenomyosis refers to the presence of islands of endometrial glands and stroma deep within the myometrium, whereas *endometriosis* is the term employed for the occurrence of endometrial tissue outside the uterus.[121] These two disorders are usually regarded as closely related, but their microscopic appearance is somewhat different. In most cases, adenomyosis is made up of the nonfunctional (basal) layer of the endometrium and is frequently connected with the mucosa. Endometriosis, on the other hand, is composed of the functional layers of the endometrium. As such, it may go through proliferative, secretory, and menstrual stages similar to those of its orthotopic counterpart. However, studies using conventional morphologic techniques, immunohistochemistry, and cell proliferation markers have shown that the endometriotic lesions are consistently more proliferative than the normally located endometrium, both during childbearing years and in postmenopause.[122–124] Adenomyosis is rare in postmenopausal women, except for the tamoxifen-associated cases, which tend to show stromal fibrosis, glandular dilation, and various metaplastic changes.[125]

Many pathogenetic theories have been proposed over the years for endometriosis: origin from congenital müllerian or wolffian rests, implantation of endometrium, lymphatic or hematogenous spread, and serosal metaplasia.[126,127] The finding of clonality, both within and a single endometriotic focus,[121,128] and across multiple foci from the same patient,[129] as well as the demonstration of oncogenic mutations in the epithelium of endometriosis,[130] lend support to the implantation theory but it should be noted that more than one pathogenetic mechanism may be involved.

Both endometriosis and adenomyosis may result in pelvic pain, characteristically associated with the menstrual period. Between 30% and 40% of women with endometriosis are infertile, the exact mechanism being still obscure. Exceptionally, adenomyosis may lead to rupture at the time of pregnancy.

Adenomyosis results grossly in an enlarged and globular uterus because of the myometrial hypertrophy that regularly accompanies it.[131,132] This enlargement is often asymmetrical. The diagnosis may be suspected on cut section in the presence of depressed small cystic lesions in obvious but ill-defined bulging zones of muscle hypertrophy (Fig. 33.14). Adenomyosis may form nodules, grossly, in which case the designation adenomyoma or adenomyotic nodule can be used.[133] Leiomyomas in utero with adenomyosis may themselves be involved by the process; distinction between leiomyoma with adenomyosis and adenomyoma/adenomyotic nodule is subjective but is made

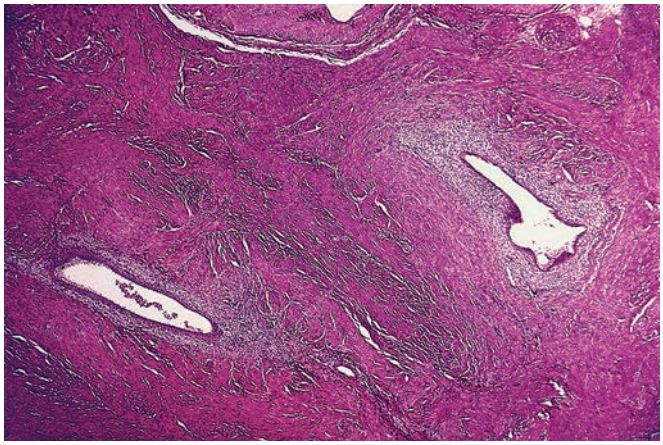

Figure 33.15 Intramyometrial foci of endometrial glands and stroma in adenomyosis.

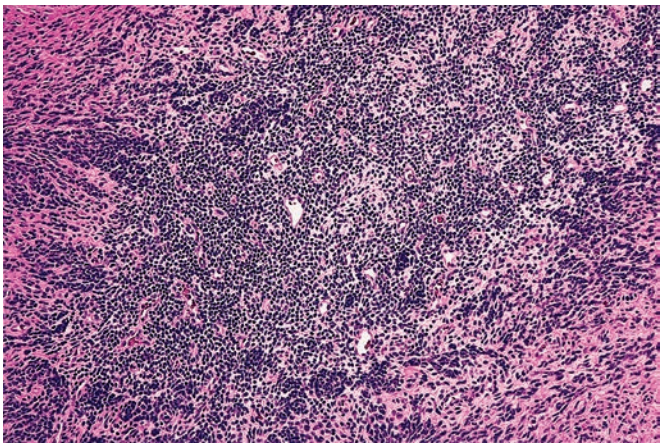

Figure 33.16 So-Called Stromal Adenomyosis. An ill-defined island of endometrial stroma is deeply embedded within the myometrium.

based on the endometrial glands and stromal being only at the periphery of the nodule in the former while they are present throughout the latter.

Microscopically, the diagnosis of adenomyosis depends on the thresholds used by the individual pathologist, some of which are very liberal indeed.[134] The interface between endometrium and myometrium is normally an irregular one, without interposition of a submucosal layer; invaginations of the endometrial basal layer into the superficial portions of the myometrium should be regarded as a normal finding. By convention, the diagnosis of adenomyosis should be reserved for those cases in which endometrial glands and stroma are seen in the myometrium at a distance of at least one low-power field from the endometrial–myometrial junction (Fig. 33.15).

Microscopically, the endometrium of adenomyosis usually has a proliferative appearance, consistent with its basal layer nature. When the normally located endometrium is in the secretory phase, this is also true for one-fourth of the foci of adenomyosis.[135] These foci can be involved by any of the diseases affecting the orthotopic endometrium, including hyperplasia and adenocarcinoma.[136] It is important to recognize this phenomenon, lest a case of in situ or superficial endometrial adenocarcinoma associated with similar changes in the foci of adenomyosis be misinterpreted as a deeply invasive malignancy.[137] Involvement of adenomyosis by endometrial adenocarcinoma does not seem to affect outcome.[138]

Vascular involvement may be present and should not be overinterpreted as a sign of malignancy.[139]

Some small islands of adenomyosis are made up predominantly of endometrial stroma (*stromal adenomyosis*, *incomplete adenomyosis* or *adenomyosis with sparse glands*; Fig. 33.16)[140]; however, any sizable intramyometrial focus composed entirely of endometrial stroma is likely to represent an endometrial stromal sarcoma.[141]

Endometriosis, which is thought to occur in 1%–7% of women in the United States,[142,143] is a major cause of pelvic pain and subfertility.[144] It can be located in the cervix, vagina, vulva, rectovaginal septum, ovary, fallopian tubes, uterine ligaments, appendix, small and large bowel, bladder and ureters, pelvic peritoneum, hernia sacs, lymph nodes, kidney, and skin, and even within skeletal muscles, peripheral nerves, pleura, lung, and nasal cavity (Figs. 33.17 and 33.18). The specific features as they pertain to the various sites are discussed in the respective chapters. Spontaneous cutaneous endometriosis is limited to the umbilicus and inguinal area.[145] In other locations, such as the lower abdominal wall, it practically always arises in surgical scars (particularly those from cesarean sections).

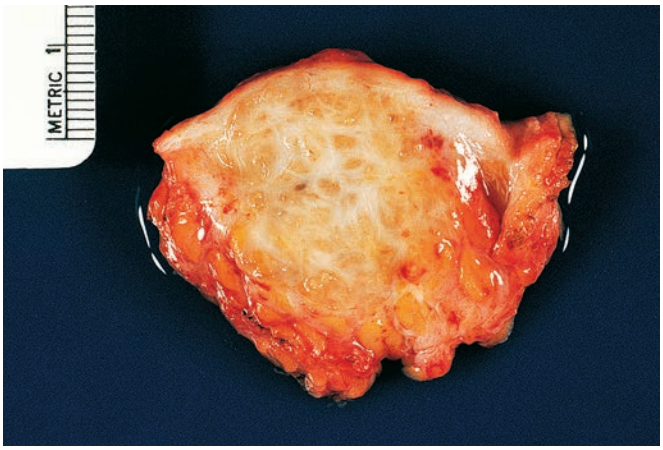

Figure 33.17 Gross appearance of endometriosis involving the anterior abdominal wall.

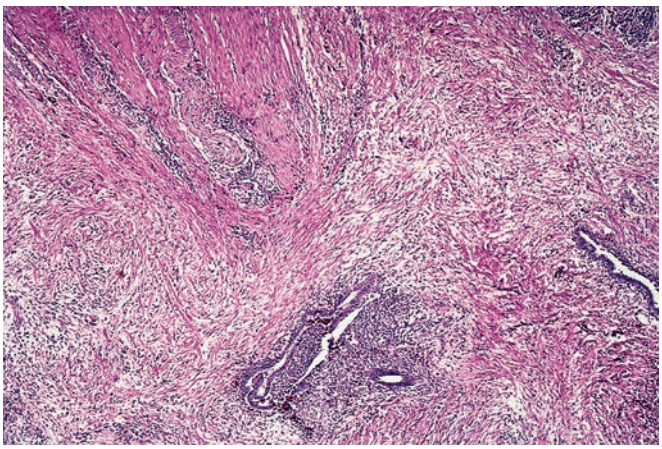

Figure 33.18 Endometriosis involving the umbilical region.

Grossly, endometriosis appears as bluish cystic nodules, often surrounded by fibrosis. Exceptionally, it may present as multiple polypoid masses grossly simulating a neoplastic process (*polypoid endometriosis* or *endometriotic polyposis*).[146,147] These masses can be located in the colon, ovary, uterine serosa, ureter, fallopian tubes, and several other sites.[147]

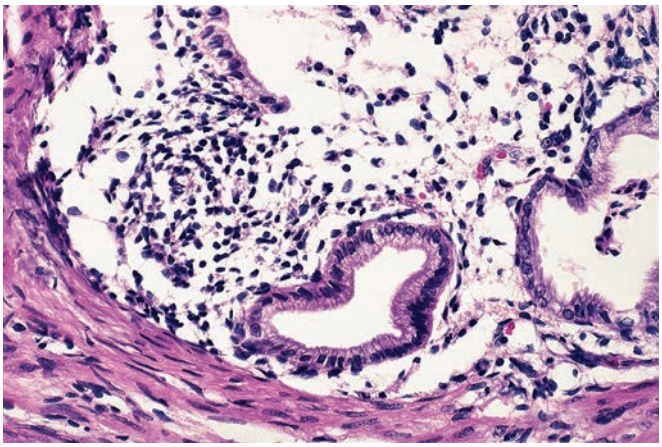

Figure 33.19 So-Called Endocervicosis. The stroma has an endometrium-like quality, but the glands are of endocervical type.

Microscopically, endometrial glands and stroma are seen, often embedded in a dense fibrous mass exhibiting signs of fresh and old hemorrhage.[148] The stromal component of endometriosis can undergo smooth muscle metaplasia.[149] Along those lines, it is still being argued whether the nodular lesion resembling a miniature uterus, which can be found in several places within the peritoneal cavity (ovary, small bowel, etc.), is a peculiar variant of endometriosis with smooth muscle metaplasia of the stroma or a malformation of the müllerian ducts.[131,150,151]

Other morphologic variations in the theme of endometriosis, some of which can be of confusing interpretation, include the presence of stromal micronodules, stromal elastosis, prominent myxoid changes, perineurial invasion, and regeneration of the surrounding skeletal muscle.[152–155] Endometriotic foci can undergo prominent mucinous metaplasia, a change that can result in a mistaken diagnosis of well-differentiated mucinous adenocarcinomas. Such change has been interpreted as a metaplasia toward endocervical-type epithelium and designated as *endocervicosis* (Fig. 33.19).[148]

Although well-documented cases of endometriosis of lymph nodes exist, most cases so designated are made up of glands lined by ciliated or nonciliated cuboidal epithelium unaccompanied by stroma, limited to the capsule or cortical area of the node[156]; as such, they are more reminiscent of fallopian tube than endometrial epithelium and are better designated as *endosalpingiosis*. They have been found in approximately 14% of nodes in females but practically never in males.[157]

Endosalpingiosis is particularly frequent in the pelvic peritoneum in connection with low-grade ovarian serous tumors. It can also present in the form of a florid cystic mass and involve the uterine wall in a transmural fashion.[158,159]

The combination of endometriosis with endocervicosis and/or endosalpingiosis is sometimes referred to as müllerianosis.[160]

Endometriosis, like adenomyosis, is subject to any of the metaplastic, hyperplastic, and atypical changes that may supervene in the orthotopic endometrium.[162] More importantly, it may undergo malignant transformation.[163,164] The most common forms are endometrioid and clear cell carcinoma,[146,165–167] but endometrial stromal sarcoma, carcinosarcoma, and adenosarcoma have also been reported.[168] Benign and borderline tumors of either serous or endometrioid nature can also develop, both from conventional endometriosis and from endosalpingiosis.[169–172] The most common site for endometriosis-related neoplasms is within endometriotic cysts of the ovary, with pelvic peritoneum, rectovaginal septum, intestinal wall, and other sites being much less common.[167,173]

The treatment of endometriosis may be hormonal or surgical depending on the circumstances.[174] It is believed that the laparoscopic ablation of minimal and mild endometriosis enhances fecundity in infertile women.[175]

Dysfunctional Uterine Bleeding

Bleeding not associated with an organic cause in women of childbearing age belongs to the large and somewhat nebulous category known as **dysfunctional uterine bleeding**. Examination of specimens obtained on D&C or endometrial biopsy from patients with dysfunctional uterine bleeding is done primarily to exclude neoplasia/preneoplastic changes, or other pathology that may be causing the abnormal bleeding, such as an endometrial polyp. A wide range of changes can be seen in the endometrium that differ from normal proliferative or secretory endometrium, but attempts by pathologists to classify these changes into categories that can guide treatment have been largely unsuccessful. On a personal note, it was a disheartening experience as a senior surgical pathologist to talk to a group of younger gynecologists and find out how little clinical value there was in my carefully crafted reports describing minor morphologic changes in the endometrium associated with dysfunctional uterine bleeding! What follows is a description of some of the histologic abnormalities that may be encountered in endometria sampled for dysfunctional uterine bleeding, but the suggested diagnostic terminology is provided in the upcoming section on "Curettage and biopsy."

The presence of fibrin clumps in the endometrial stroma (a finding not usually present in the normal menstrual endometrium),[123] the identification of fragmented pieces with dense stromal cellularity (a process known as *stromal crumbling*), and the presence of an increased number of apoptotic bodies at the base of the glands (so-called Benirschke granules)[176] may all be seen. Another type of defect seen in the ovulatory group of bleeders is known as *irregular shedding of the endometrium*. The term refers to a regularly recurring menorrhagia in which the bleeding phase of the cycle requires 7 days or more for completion, without subsequent prolongation of the cycle. This is due to a lag in the shedding of the secretory endometrium, which is normally completed by the fourth day of menstruation.[177] Tissue obtained five or more days after the onset of menstrual bleeding shows retained secretory endometrium in addition to fragmented menstrual and/or early proliferative endometrium.

The term *membranous dysmenorrhea* has been used for a rare condition characterized by the painful passage of an endometrial cast of the uterus during the first few days of menstruation. This cast has the microscopic appearance of decidua. The disease is thought to result from a hyperprogestational response and may be induced by the administration of high doses of progesterone.[177]

Anovulatory cycles result in exuberant *disordered proliferative endometrium*, recognized by irregularity of glandular outlines, with more complexity of gland profiles than is encountered in normal proliferative phase. There is not sufficient glandular crowding to warrant a diagnosis of endometrial hyperplasia. The glandular epithelial cells lack atypia and show nuclear features similar to those of normal proliferative glands. There may be abortive subnuclear vacuoles and apoptotic bodies within glands. Anovulatory cycles are common in PCOS but also very common at puberty and in the perimenopausal period. Distinction between disordered proliferative endometrium and normal proliferative endometrium, on one hand, and endometrial hyperplasia without atypia on the other, is subjective. The general rule of diagnosing an abnormal state only when changes are clear-cut can be applied in this situation; only diagnose disordered proliferative endometrium when the architecture of the glands is too abnormal to fit into the spectrum of

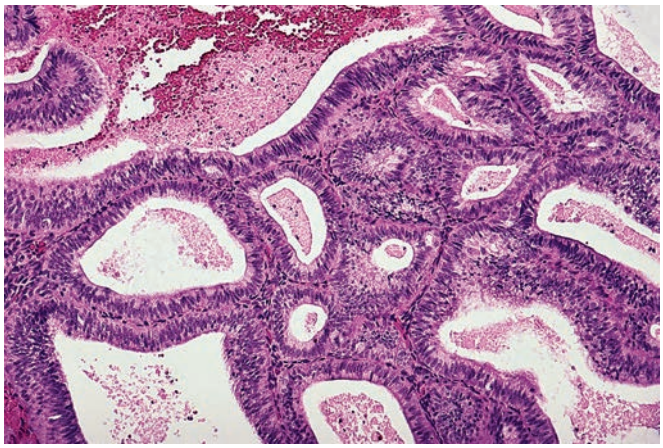

Figure 33.20 Endometrial Hyperplasia Without Atypia. There is mild irregularity of glandular architecture, and crowding.

normal proliferative endometrium. Distinction between disordered proliferative endometrium and hyperplasia without atypia will be discussed next.

Endometrial Hyperplasia Without Atypia, Atypical Hyperplasia, and Variants

Endometrial hyperplasia is recognized by increased gland-to-stroma ratio and glandular architectural irregularity and complexity. There have been many classifications of endometrial hyperplasia over the years, but the one in current use is the one put forward by the World Health Organization (WHO) in 2014.[124]

Endometrial hyperplasia without atypia occurs as a result of unopposed estrogenic stimulation of the endometrium and is on a continuum with disordered proliferative endometrium. There is glandular branching, irregularity, and crowding (Fig. 33.20). The diagnostic threshold for diagnosis of endometrial hyperplasia without atypia, rather than disordered proliferative endometrium, is highly subjective, but at the point where glands predominate over stroma, a diagnosis of endometrial hyperplasia without atypia is appropriate. In the past, endometrial hyperplasia was subdivided into simple and complex hyperplasia, based on the degree of glandular architectural complexity; this is no longer done as it is not a clinically relevant subclassification. The risk of progression to carcinoma with endometrial hyperplasia without atypia is low (1%–3%).[178] The chief differential diagnosis is with atypical hyperplasia, and this is based on the assessment of cytologic atypia; the criteria for recognition of atypia are presented in the next section.

Atypical hyperplasia is the precursor lesion of low-grade endometrioid adenocarcinoma. It shows glandular crowding and irregularity in addition to cytologic atypia. The nuclear atypia is characterized by enlargement, rounding, pleomorphism, and presence of nucleoli. Quite apart from these descriptive terms, the presence of cytologic atypia is most reliably recognized by comparison of the cytologic features in the hyperplastic focus to those of proliferative endometrial glandular epithelial cells outside the area of hyperplasia (Fig. 33.21).[124,179] This approach to diagnosis of cytologic atypia, proposed by Mutter and colleagues, has enhanced the reproducibility of the diagnosis of atypical hyperplasia.[126,180] It is exactly equivalent to the way we evaluate colonic biopsies for adenomatous change and, as is the case for colonic adenomas, the cytologic atypia within the atypical hyperplasia reflects a clonal proliferation of cells with some but not all the mutations necessary for transformation

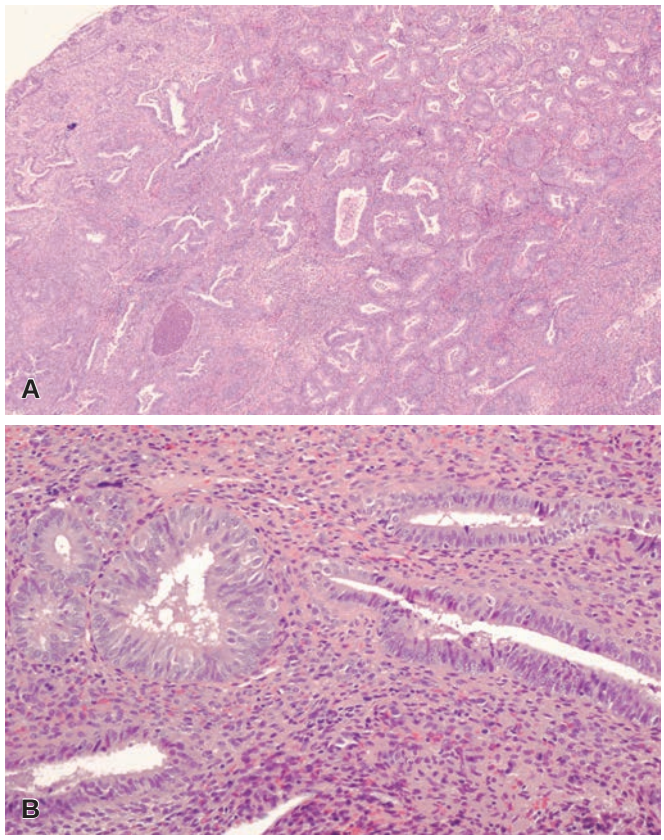

Figure 33.21 A, Endometrial hyperplasia with atypia, in a polyp; **B,** low-power, showing the glandular crowding, and **C,** high-power, from the edge of the hyperplastic focus, showing the cytologic difference between the atypical epithelium (on the left) and non-atypical epithelium.

to carcinoma. One cautionary note is warranted on using this approach to diagnose cytologic atypia; if there is coexistence of proliferative endometrium and inactive endometrium, there are going to be differences between the nuclei in the two areas, but this does not reflect premalignant change. The recognition of atypia is based on cytologic differences between the endometrium in the hyperplastic focus and proliferative endometrium in non-hyperplastic endometrium.

The presence of metaplastic changes complicates the interpretation of cytologic features, and we can offer no easy to solution to this vexing, recurrent problem: is this atypical hyperplasia or hyperplasia without atypia, but with metaplastic changes? This is further complicated by the frequent coexistence of metaplasia and atypical hyperplasia. As a practical guideline, the greater the degree of glandular crowding, the more likely it is that the cytologic changes are atypical.

Endometrioid intraepithelial neoplasia (EIN) is an alternative diagnostic term for atypical hyperplasia. The EIN terminology was proposed by Mutter, who developed the much improved diagnostic criteria for recognition of premalignant change in the endometrium.[134,179,181] What has happened is that there has been universal adoption of the new criteria for diagnosis of endometrial premalignancy, but less uniform adoption of EIN terminology. Thus, at this time, atypical hyperplasia and EIN are completely synonymous diagnostic terms, reflecting the same diagnostic criteria.

The incidence of carcinoma in women with atypical hyperplasia has been in the neighborhood of 15% and has reached 30% in

some series.[125,178,182,183] A significant minority of women who have a diagnosis of atypical hyperplasia made on biopsy or curettings will have adenocarcinoma (almost invariably low grade and minimally or non-myoinvasive) diagnosed on the subsequent hysterectomy specimen.[184]

The distinction between a case of atypical hyperplasia with severe architectural and cytologic atypia and a well-differentiated adenocarcinoma can be very difficult, largely because of the fact that endometrial hyperplasia and carcinoma represent different points in a disease continuum at the morphologic, ultrastructural, immunocytochemical, and molecular genetic levels.[139,185,186] A careful reading of the landmark study by Longacre and colleagues is recommended.[187] Although more than 20 years have passed since the publication of this paper, it remains a beautiful example of good study design, and the data produced continue to inform everyday practice. The presence of confluence of glands, such there are no longer small glands surrounded by stroma, or a papillary/villoglandular architecture are features supporting a diagnosis of well-differentiated adenocarcinoma. On biopsy or curettings it has been recommended that the diagnosis of "atypical hyperplasia, cannot exclude low-grade adenocarcinoma" be used for those cases where the features are intermediate between atypical hyperplasia and grade 1 endometrioid adenocarcinoma, and we endorse this view. We do not recommend the use of this terminology for hysterectomy specimens.

There is an increasing trend to treat atypical hyperplasia or even low-grade adenocarcinoma with high-dose progestin therapy,[188] so as to avoid hysterectomy and preserve fertility. The interpretation of findings in follow-up biopsies is complicated by prominent progestational effects, including squamous and mucinous metaplasia of the epithelium and stromal decidual reaction. In our experience, there are three possible diagnostic results for these follow-up specimens: either 1. There is no evidence of residual hyperplasia, 2. There is residual hyperplasia with treatment effects (metaplasia and decidual change), or 3. There is residual hyperplasia that shows no treatment effects, and may even show more severe atypia or progression to frank carcinoma, when compared to the pretreatment biopsy.

Atypical mucinous glandular proliferation of the endometrium is considered to be a precursor of mucinous carcinoma. It is recognized based on glandular crowding and complexity with prominent mucinous metaplasia of the glandular lining cells, but these cells can show minimal cytologic atypia.[124] We have previously acknowledged the difficulty in distinguishing between atypical hyperplasia and carcinoma, but it is even more difficult for mucinous proliferations. The likelihood of adenocarcinoma in the hysterectomy after a diagnosis of atypical mucinous glandular proliferation was 45% in a recent study.[189] Atypical mucinous glandular proliferation of the endometrium should therefore be considered to be a premalignant lesion with significant chance of progression or coexistent carcinoma, with hysterectomy being the preferred treatment. Awareness of atypical mucinous proliferation of the endometrium is important as we have seen this premalignant change misdiagnosed as normal endocervical tissue.

Papillary proliferation of the endometrium (PPE) was first described by Lehman and Hart[190] and is characterized by a prominent papillary architecture, with papillae covered by epithelial cells with minimal cytologic atypia (Fig. 33.22). There is a variation from small foci of simple papillae with short nonbranching stalks to extensive complex papillae with elongated stalks and branches. The absence of significant nuclear atypia separates this from carcinoma. The lining epithelium consists of a single layer cells with pale eosinophilic or mucinous cytoplasm, sometimes ciliated. Papillary proliferation frequently involves an endometrial polyp. PPE has

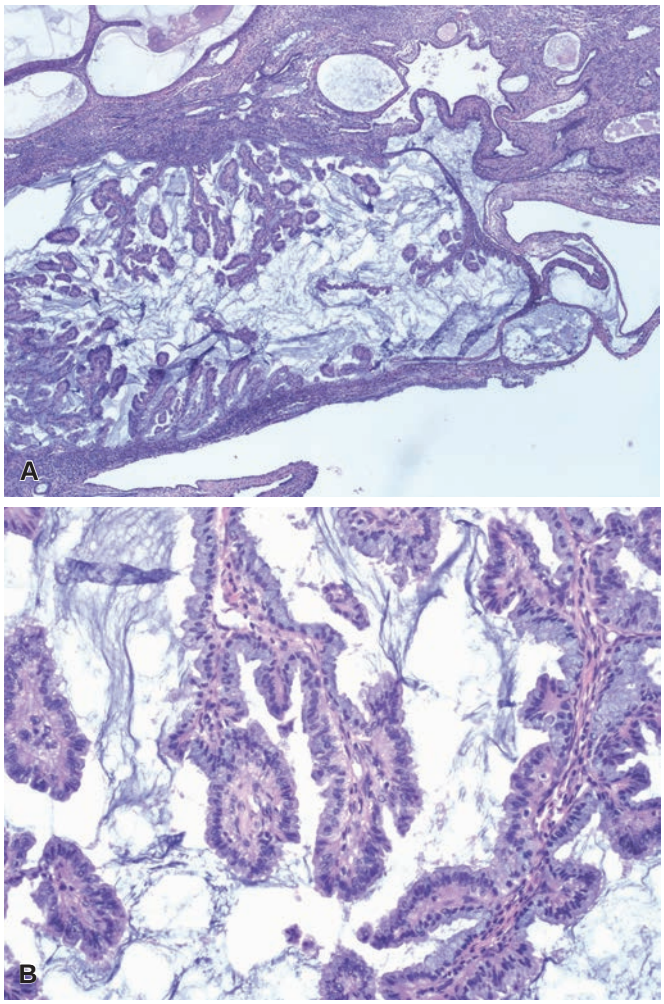

Figure 33.22 Papillary Proliferation of the Endometrium (PPE). A, PPE in an endometrial polyp; **B,** bland mucinous epithelial cells cover the papillae. This single focus, confined to a polyp, is simple PPE.

subsequently been subdivided into simple and complex forms, by Ip et al.[191] Simple PPE is characterized by short, predominantly nonbranching stalks (occasional secondary branches may be seen) localized to 1 or 2 foci involving the surface of polyps, non-polypoid endometrium, or within cystically dilated glands, or involvement of <50% of a polyp. Complex PPE consists of complex papillae (short or long stalks with frequent secondary and complex branching) and/or diffuse involvement (three or more foci within a specimen, or involvement of >50% of polyp). Complex PPE, in particular, often coexists with conventional atypical hyperplasia or even carcinoma. The clinical significance of simple PPE is considered equivalent to that of hyperplasia without atypia, while complex PPE is equivalent to atypical hyperplasia, based on a limited number of reported cases.[191]

The term **(atypical) secretory hyperplasia** has been applied to a pattern of architectural abnormalities and cellular atypia within a secretory endometrium, with the atypical glands resembling those seen in the sixteenth to the seventeenth day of the normal cycle.[128,132,192] This change should be distinguished from the Arias-Stella reaction and from hormonally treated conventional endometrial hyperplasia. The natural history of this condition is not well known, but involution appears to be relatively common when the background endometrium also shows secretory changes.[192] Normal secretory endometrium

appears relatively crowded, and it is best to be conservative in diagnosis of hyperplasia in the setting of secretory endometrium.

Curettage and Biopsy

Tissue from the endometrial cavity taken for diagnostic purposes was traditionally obtained by *dilation* of the cervical canal and *curettage* of the endometrial cavity (D&C). Information about endocervical extension of an endometrial neoplasm can be obtained by performing a *fractional curettage* (i.e. a separate sampling from the endometrial and endocervical cavities during the same procedure). The endocervical specimen should be obtained first so as to minimize contamination from the endometrium. However, even when this precaution is taken, small isolated tumor fragments may be found in endocervical curetting specimens in cases where there is no infiltration of the cervix by tumor. Therefore, the presence of endocervical extension of a tumor can only be diagnosed if cancer and normal endocervical glands are seen *in the same tissue fragment*. Otherwise, simply record the presence of carcinoma in the material submitted from the endocervix and let the clinician decide whether this is significant on the basis of the findings at the time of curettage.

Endometrial biopsy has emerged as an alternative to D&C for the evaluation of the endometrium.[127] It can be performed safely in the office (but causes significant discomfort and pathologists should not be cavalier in recommending resampling of the endometrium). Biopsy may also be carried out under hysteroscopic guidance.[121] A meta-analysis study with the use of the Pipelle showed a detection rate for endometrial adenocarcinoma of 99.6% in postmenopausal women and 91% in the premenopausal group.[136] Another issue is the accuracy of the grading of endometrial carcinoma done in a biopsy when compared with that seen in the hysterectomy specimen. In one study, the concordance was 45% for grade I, 63.3% for grade II, and 75.6% for grade III, the overall concordance being 64.5%.[193] Even comparing the diagnosis of low-grade (grade I or II) versus high-grade (grade 3) carcinoma in biopsy/curettings versus hysterectomy, there remains distressing variation, but with some improvement (kappa—0.7).[194] Histotype diagnosis (i.e. endometrioid, serous, clear cell, etc.) shows only moderate agreement between biopsy/curettings and hysterectomy (kappa—0.44).[194]

A curious artifact that can be seen in hysteroscopically assessed tissue is *pseudolipomatosis*, a condition analogous to its more common counterpart in the gastrointestinal tract. It results from air or gas entering into the endometrial mucosa and simulating fatty infiltration.[195]

An exceptionally rare occurrence is the failure to find tumor in a hysterectomy specimen following a diagnosis of adenocarcinoma in an endometrial biopsy. This distressing event, which has been referred to as *vanishing endometrial carcinoma* (in analogy to the same phenomenon as described in the prostate) is probably explained by the very minute size of the tumor, most or all of which has been removed by the biopsy procedure.[196]

The language used in reporting on endometrial biopsies where there are only benign findings is highly variable from pathologist to pathologist, in contrast to the standardized language and formatting we use for cancer specimens. There remain pathologists who believe that they are being called upon to determine whether ovulation has occurred, even though this has not been an expectation for more than a decade, while other pathologists report in great morphologic detail on biopsies taken for infertility when their clinical colleagues only want reassurance that there is no polyp, endometritis, or hyperplasia/carcinoma. Please do discuss with clinicians their needs, so that you can better serve your patients by providing clinically relevant information in your surgical pathology reports. We do believe, however, that more uniform reporting of benign endometrial biopsy specimens will enhance the value of our reports, improving their comprehensibility. A guideline for uniform diagnostic categories to use in reporting endometrial biopsies has been proposed by the Canadian Gynecological Pathology Special Interest Group (Box 33.1); when trialed in practice, more than 90% of cases could be reported using this template, in a range of practice scenarios.

Box 33.1 Suggested terminology for signing out benign endometrial biopsy or curetting specimens

Diagnosis (choose one or more)

- Non-diagnostic sample (no endometrial tissue present)
- Scant fragments of inactive endometrial surface epithelium and/or stroma; this is a suboptimal specimen for histopathological assessment and may not be representative*
- Inactive/atrophic endometrium
- Proliferative endometrium
  - Normal proliferative
  - Weakly proliferative
  - Disordered proliferative
- Secretory endometrium
  - Normal secretory
    - Date ___
    - Polypoid secretory endometrium
  - Irregular secretory
- Menstrual endometrium
- Endometrial polyp(s)
- Endometrial hyperplasia without atypia
- Chronic endometritis
- Changes consistent with exogenous hormonal therapy
  - Progestin
  - Progesterone receptor selective agonist
  - Oral contraceptive
- Products of conception
  - Chorionic villi
  - Chorionic plate
  - Chorionic membranes
  - Implantation site trophoblast
  - Exaggerated implantation site
  - Embryonic/fetal tissue
- Pregnancy-related endometrial changes
- Pregnancy-related endometrial changes only; no products of conception identified
- Placental site nodule/remote implantation site
- Adipose tissue, mesothelium—lined tissue or other extrauterine tissues present

*Fewer than 10 strips of epithelium in an endometrial biopsy or curettage specimen is suboptimal and is associated with decreased sensitivity and negative predictive value.[197]

A final comment is called for on the criteria for insufficiency in an endometrial biopsy or curetting. Remember that the expected finding in a postmenopausal woman is scant inactive or atrophic endometrium. The presence of strips of atrophic endometrium is normal in this clinical scenario and should not be considered insufficient for diagnosis, a diagnosis that should be reserved for instances where there is no endometrial tissue sampled. Sakhdari et al. have suggested that the presence of 10 or more endometrial strips constitutes an adequate sample, while fewer than 10 strips is suboptimal (negative predictive values in the group with an adequate sample was >99% versus approximately 80% in the group with a suboptimal sample).[197] This finding should be validated independently, but it appears that there are three categories of samples: adequate, benign but suboptimal because of their scanty nature (<10 strips of endometrial epithelium), and insufficient for diagnosis (no endometrial tissue sampled).

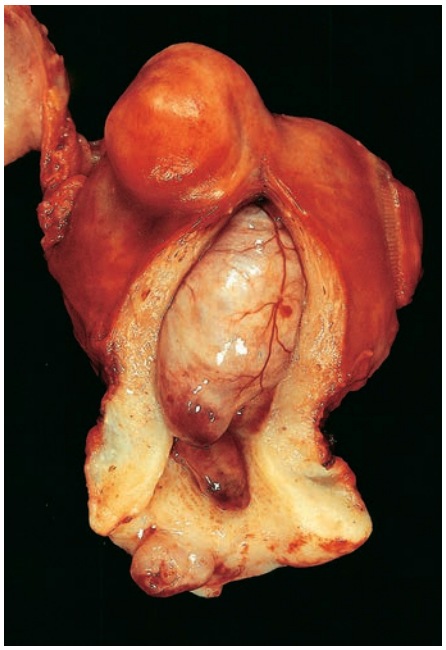

Figure 33.23 Huge Endometrial Polyp Filling the Endometrial Cavity. There is also a smaller endocervical polyp and a subserosal leiomyoma. (Courtesy Dr. Pedro J Grases Galofrè; from Grases Galofrè PJ. *Patologia ginecològica. Bases para el diagnòstico morfològico*. Barcelona: Masson; 2002.)

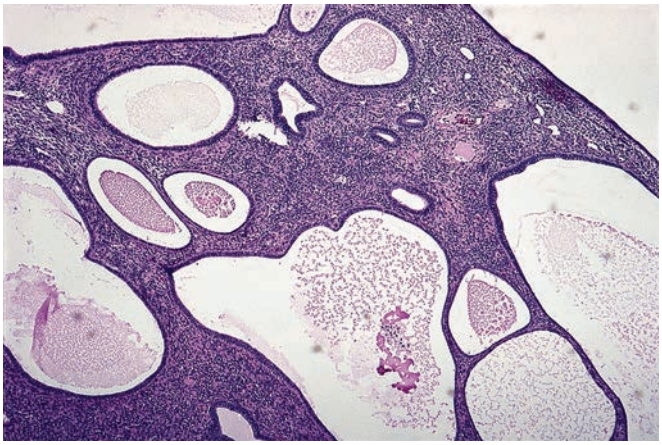

Figure 33.24 Low-power appearance of endometrial polyp showing cystically dilated glands and a fibrous stroma with thick-walled vessels.

Tumors

Endometrial Polyps

Endometrial polyps protrude into the endometrial cavity and often exhibit changes secondary to vascular insufficiency or prolapse (Fig. 33.23). They consist of epithelial and stromal components, and a key to recognition in fragmented specimens, e.g. endometrial curettings, is the altered cellularity of the stroma compared to normal endometrium, with the polyp stroma usually showing reduced cellularity with a more "fibrous" appearing and spindle cell stroma, compared to normal endometrial stroma. The glands usually show some degree of cystic change. They may be lined by an active pseudostratified epithelium containing mitotic figures or, in the postmenopausal patient, by a flat, inactive epithelium (Fig. 33.24). The abnormal glandular architecture may raise the possibility of endometrial hyperplasia, but the absence of glandular crowding excludes the diagnosis of hyperplasia. Note that hyperplasia (without atypia or atypical) or carcinoma may be present in an endometrial polyp and are diagnosed using the same criteria as are used in the absence of a polyp.

The glands and stroma of the polyp are unresponsive to progesterone stimulation and retain their integrity throughout the menstrual cycle. The frequent coexistence of endometrial polyps and endometrial hyperplasia points to a shared pathogenesis for these two lesions. The clinical significance and management of atypical hyperplasia are the same irrespective of whether it involves or is confined to an endometrial polyp.[198]

Exceptionally, the stroma of endometrial polyps contains scattered atypical (bizarre) cells.[199,200]

Endometrial polyps occur with increased frequency after tamoxifen exposure. These are characteristically multiple, large, and fibrotic and may exhibit stromal decidualization and mucinous metaplasia.[201–203]

With the increasing use of hysteroscopy, we frequently receive endometrial biopsies of polypoid endometrium that microscopically is seen to be normal secretory endometrium. Unfortunately there is no uniform diagnosis used for this relatively common scenario, and proposed diagnoses include "polypoid secretory endometrium" or "secretory pseudopolyp."

Endometrial polyps having smooth muscle fibers (not connected with blood vessel walls) in addition to the customary glands and stroma are designated as **adenomyomatous polyps** (polypoid adenomyomas) (Fig. 33.25).[204] In order to make this diagnosis, the smooth muscle should be integral to the polyp; benign endometrial polyps when they start to prolapse often draw smooth muscle into the polyp stalk, and this phenomenon does not warrant diagnosis as adenomyomatous polyp. They have a characteristic hard consistency and a grayish color.

An important variation on the theme is the **atypical polypoid adenomyoma**.[205–208] These tend to occur in premenopausal women (average age, 40 years) and present with abnormal uterine bleeding (Fig. 33.26). Some are associated with Turner syndrome.[209] Microscopically, they are identified by the fact that the glands occurring between the endometrial stroma and smooth muscle exhibit varying degrees of hyperplasia and atypia (often with squamous morular metaplasia), sometimes approaching the appearance of low-grade carcinoma (Fig. 33.27).[210] Recognition is important to avoid misdiagnosis as adenocarcinomas with myometrial invasion. The behavior reflects the degree of complexity and atypia of the epithelial component, which can range from atypia without hyperplasia, to atypical hyperplasia and, on occasion, frank carcinoma of low-grade endometrioid type.

At the molecular level, atypical polypoid adenomyomas share several alterations with hyperplasias.[211]

Endometrial Carcinoma

General and Clinical Features, Including Molecular Subtypes

Carcinoma of the endometrium is the most common gynecologic malignancy in developed countries.[212] The highest incidence rates are in the United States and Canada, but in recent years there has been a decline in incidence and mortality. It typically occurs in elderly individuals, 80% of the patients being postmenopausal at the time of diagnosis.[213] However, it can occur in any age group and has even been reported in association with intrauterine pregnancy.[214] Most endometrial adenocarcinomas occurring in women aged 40 years or younger are of endometrioid type, well to moderately differentiated, and early stage disease.[215] Conversely, tumors of elderly patients are more likely to be grade 2 or 3 and to have more advanced disease at the time of diagnosis.[216]

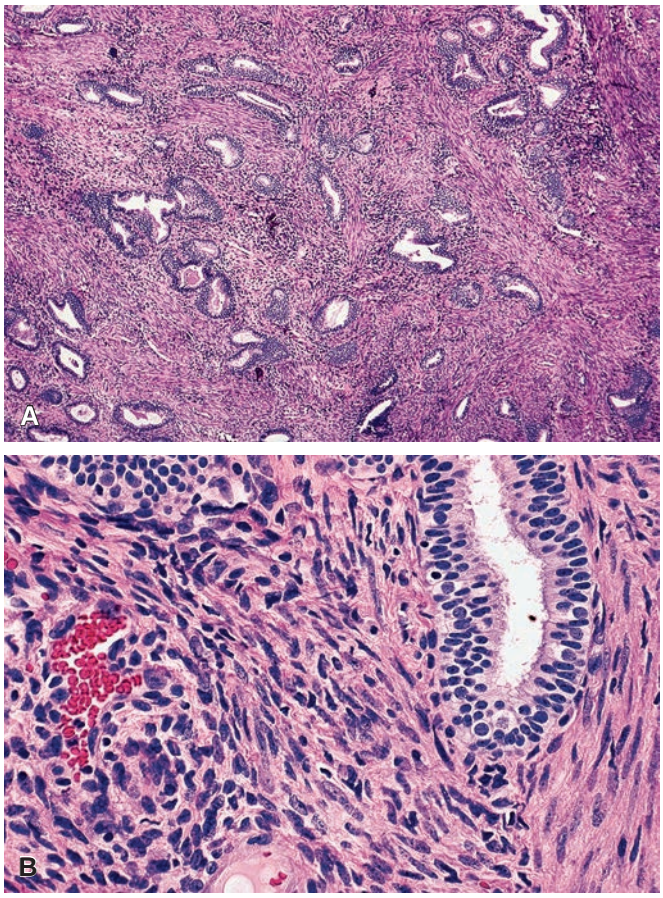

Figure 33.25 **A** and **B,** Low- and high-power appearance of adenomyomatous polyp.

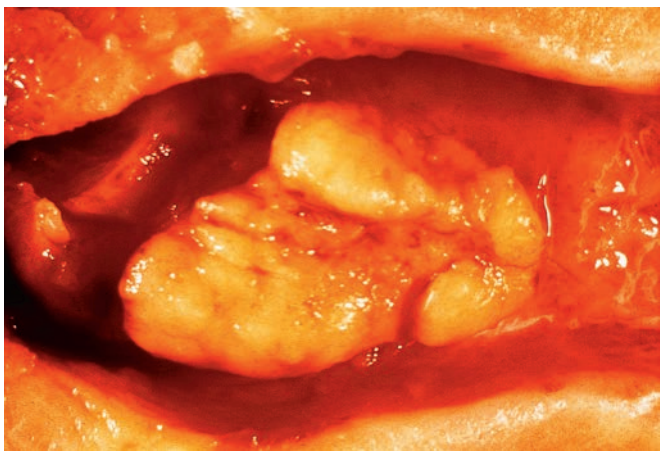

Figure 33.26 **Atypical Polypoid Adenomyoma.** The gross appearance is not substantially different from that of an ordinary polyp.

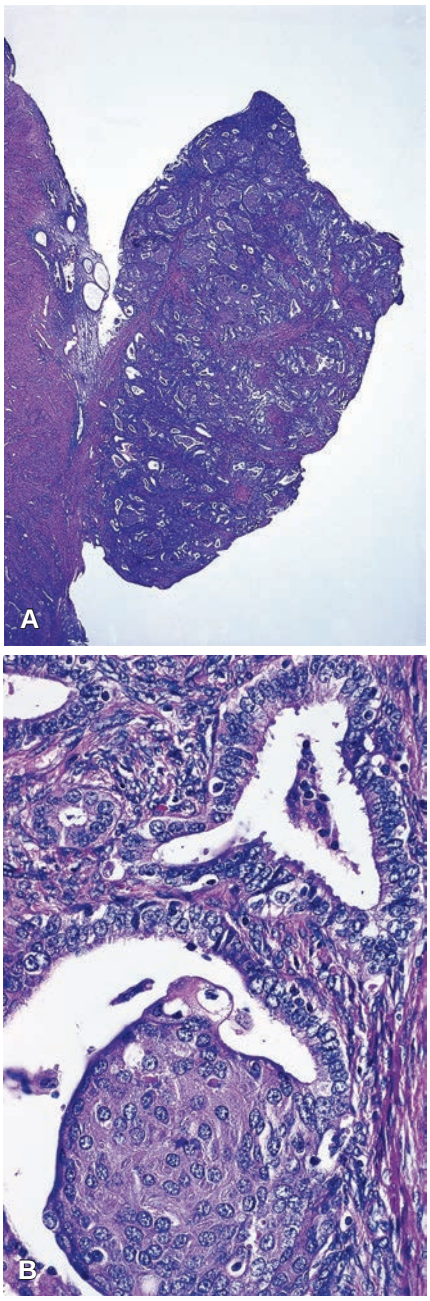

Figure 33.27 **A** and **B,** Whole-mount and high-power appearance of atypical polypoid adenomyoma. Note the glandular architectural complexity, metaplastic changes, and atypia.

Bokhman proposed that endometrial carcinoma be divided into two types, type I and type II, on the basis of their pathogenesis: one—by far the more common—occurring as a result of excess estrogenic stimulation and developing against a background of endometrial hyperplasia, and the other developing de novo, independent of estrogen stimulation, in older women.[217–219] The prototype for type I endometrial carcinoma is low-grade endometrioid carcinoma, while the prototype for type II endometrial carcinoma is serous carcinoma.

Patients at high risk for the first category include the obese, diabetic, hypertensive, and infertile; those with failure of ovulation (including PCOS) and dysfunctional bleeding; longstanding estrogen users; breast cancer patients treated with tamoxifen (see later); those with severe degrees of endometrial hyperplasia; and—to a much lesser degree—those with functioning granulosa cell tumors and thecomas.[220–222] Tumors in this category are typically low grade and the prognosis is favorable; treatment with progestins is an option, especially if preservation of fertility is desired.

There are no well-defined risk factors for patients with type II carcinomas. Occasional cases have been reported in patients with BRCA germline mutations,[215] but this is uncommon and certainly

much less frequently encountered than with high-grade serous carcinoma of tubo-ovarian origin.[223] The prognosis of patients with type II carcinomas is much worse than that of patients with type I carcinomas.

The Cancer Genome Atlas (TCGA) study of 373 endometrial carcinomas opened important new windows onto the molecular subclassification of endometrial carcinoma.[223] As well as confirming the presence of type I and type II subtypes, which are characterized by low numbers of somatic copy number alterations (CN low)/wild-type expression pattern of p53, and high numbers of somatic copy number alterations in the genome (CN high)/abnormal expression of p53, respectively, two additional endometrial carcinoma molecular subtypes were identified, based on their mutation profiles: hypermutated endometrial carcinomas and ultramutated endometrial carcinomas. Together these latter two subtypes account for approximately one-third of endometrial carcinomas. The clinical significance of identification of these subtypes is still being explored but could prove to be dramatic, impacting on surgical and adjuvant treatment decisions.[224-232]

Hypermutated endometrial carcinomas are characterized by microsatellite instability (MSI) secondary to dysfunction of one of the enzymes that repairs DNA sequence abnormalities by the post-replicative DNA mismatch repair pathway. A surrogate test for identification of tumors in this category is immunohistochemistry for mismatch repair enzymes (MLH1, PMS2, MSH2, MSH6), which is increasingly preferred to MSI testing (Fig. 33.28). Because of dimerization of MMR proteins, screening for MMR deficiency (MMR-D) can be done by immunostaining for just two of the proteins, MSH6 and PMS2; if both are expressed the tumor is MMR intact. 3%–4% of endometrial carcinomas arise in patients with Lynch syndrome, and these tumors are MMR-D. The endometrial carcinomas in Lynch syndrome patients often present at a young age.[233–235] MMR-D endometrial carcinomas tend to be higher grade and associated with peritumoral and intratumoral lymphocytic infiltrates.[233,234] Although most are endometrioid, they may be nonendometrioid histology.[233] Most MMR-D endometrial carcinomas are not associated with Lynch syndrome; the MMR-D phenotype in these cases is secondary to somatic events, most commonly promoter methylation of *MLH1*, with loss of protein expression. Compared to MMR-D endometrial carcinomas in patients with Lynch syndrome, those with somatic *MLH1* promoter methylation arise in older patients and are more likely to be endometrioid type, show mucinous differentiation, and have tumor infiltrating lymphocytes.[236]

Ultramutated endometrial carcinomas have 10-fold more mutations than the hypermutated tumors, and the molecular basis for this is mutations, almost invariably somatic, in the polymerase-epsilon (POLE) gene, resulting in loss of the exonuclease proofreading function and increased mutation rates. The tumors associated with POLE exonuclease domain mutations (POLE EDMs) are associated with a very favorable prognosis, even though they are often higher grade.[224–226,237] They are typically of endometrioid histotype and, like the MMR-D tumors, are commonly associated with prominent lymphoid infiltrates (Fig. 33.29).[227]

The clinical, molecular, and pathologic features associated with each of the major molecular subtypes of endometrial carcinoma (type I/CN low/p53 wildtype, type II/CN high/p53 abn, MMR-D, POLE EDM) are summarized in Table 33.1, and the differences in prognosis are shown in Figure 33.30. The conventional histopathologic features of endometrial carcinoma, such as grade and histotype, correlate imperfectly with the molecular subtypes, so for the foreseeable future we will include these findings in our pathology reports. Accordingly, the remainder of this section will focus on the histopathologic assessment of endometrial carcinoma.

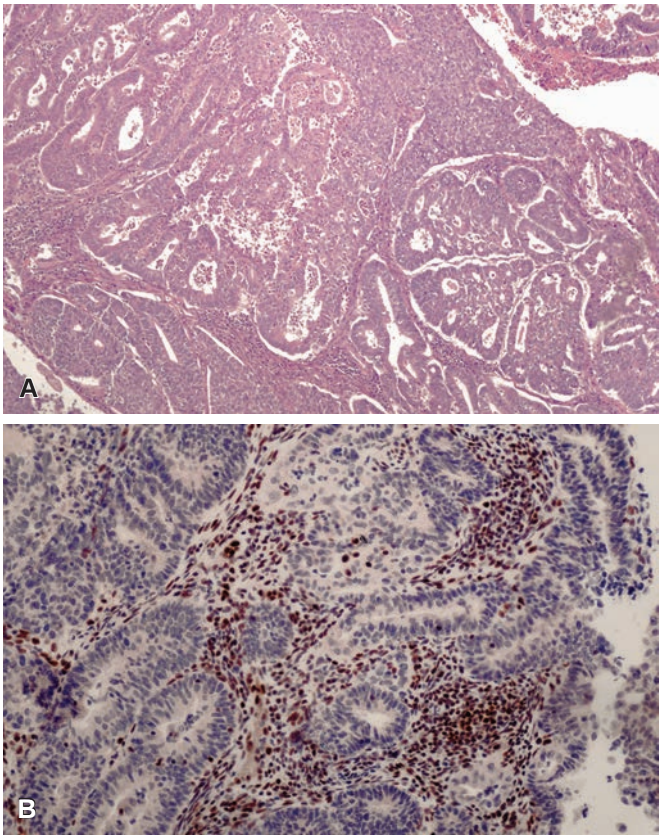

Figure 33.28 Hypermutated/Mismatch Repair Deficient Endometrial Carcinoma. There is heterogeneity in the appearance of the tumor, with more solid areas alternating with glandular areas (**A**) and a prominent lymphoid infiltrate. Immunostaining shows loss of expression of MLH1 in the tumor cells, with retained expression in lymphocytes and stromal cells (**B**).

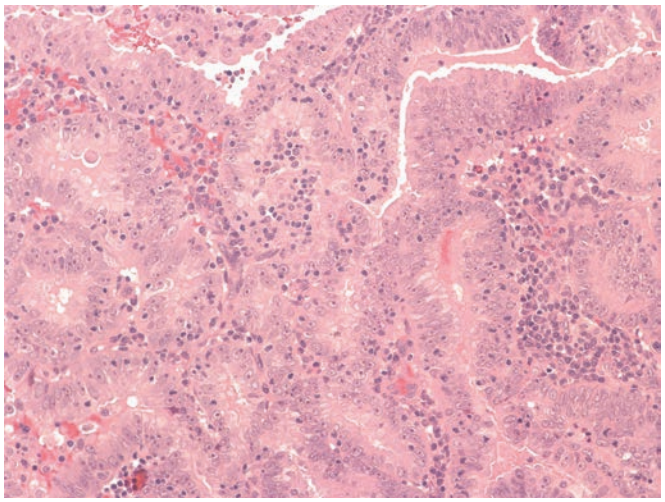

Figure 33.29 Ultramutated/Polymerase Epsilon Exonuclease Domain Mutated (POLE EDM) Endometrial Carcinoma. The cells of this endometrioid carcinoma show high-grade nuclear features, and there is a prominent lymphoid infiltrate, features associated with POLE EDM tumors.

Table 33.1 Genomic-based endometrial carcinoma subtypes

TCGA CATEGORY[223]	GENOMIC ALTERATION	SURROGATE MARKER	FORMER DESIGNATION[229]	AGE[217]	PROGNOSIS	HISTOTYPE
CN low	Few mutations, low # of somatic copy number alterations	Absence of POLE EDM, MMR-D and p53 abn	Type I	65 years	Intermediate	Endometrioid (usually grade 1 or 2)
CN high	Few mutations, low # of somatic copy number alterations	p53 abn	Type II	72 years	Poor	Serous and some grade 3 endometrioid
Hypermutated	Many mutations	MMR-D	NA	66 years	Intermediate	Mostly endometrioid, may be high grade
Ultramutated	Very many mutations	POLE EDM	NA	62 years	Favorable	Endometrioid, may be high grade

CN high, High numbers of somatic copy number abnormalities; *CN low*, low numbers of somatic copy number abnormalities; *MMR-D*, mismatch repair deficient; *NA*, not applicable; *p53 abn*, abnormal p53 expression by immunohistochemistry that is either complete absence of expression or strong diffuse overexpression; *POLE EDM*, mutations in the POLE exonuclease domain; *TCGA*, The Cancer Genome Atlas.

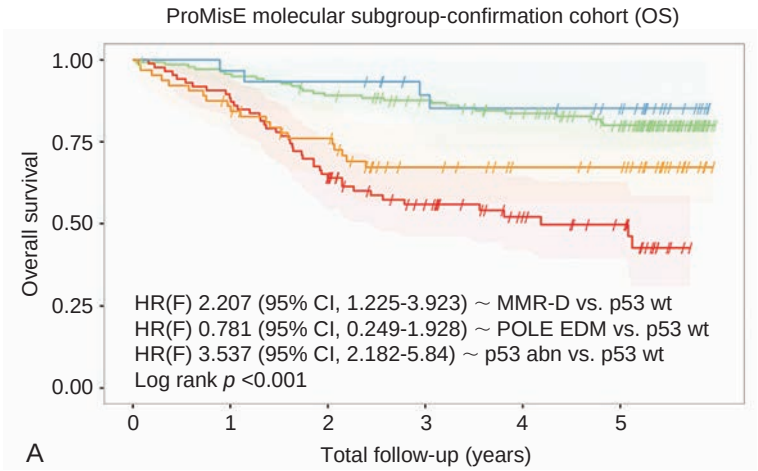
Pathologic Features

Grossly, carcinoma of the endometrium may form broad-based polypoid masses or infiltrate diffusely into the myometrium (Fig. 33.31). In general, extensive myometrial invasion is accompanied by clinically detectable uterine enlargement. However, notable exceptions occur; sometimes deep myometrial extension is accompanied by a normal-sized uterus, the pattern of growth resembling that of adenoma malignum of cervix.[223]

Endometrial carcinoma can develop in any anatomic region of the mucosa. Tumors developing in younger women have a greater tendency to involve the lower uterine segment (isthmus).[238] Most tumors thought to have arisen in the isthmus are best included among the endometrial rather than the cervical carcinomas, based on the clinical and biomarker expression profiles.[239] Small carcinomas restricted to a cornu can be missed by a biopsy or D&C.

Microscopically, approximately 80% of endometrial malignant epithelial tumors are conventional adenocarcinomas, which are usually divided into well (grade 1, 50%), moderately (grade 2, 35%), and poorly differentiated (grade 3, 15%) tumors (Fig. 33.32A–C). The FIGO three-grade system is primarily based on the growth pattern (relative proportion of glandular and solid areas), with grade 1 having 5% or less solid growth, grade 2 5%–50% solid growth, and grade 3 >50% solid growth, but it also makes provisions for nuclear atypia, with grade increased by one in the presence of notable nuclear atypia, defined as grade 3 nuclei in more than 50% of the tumor.[223,240] Because there are minimal prognostic differences between grade 1 and grade 2, and they are treated identically with respect to adjuvant chemotherapy and radiation therapy, it has also been proposed that grade 1 and 2 be combined as "low grade."

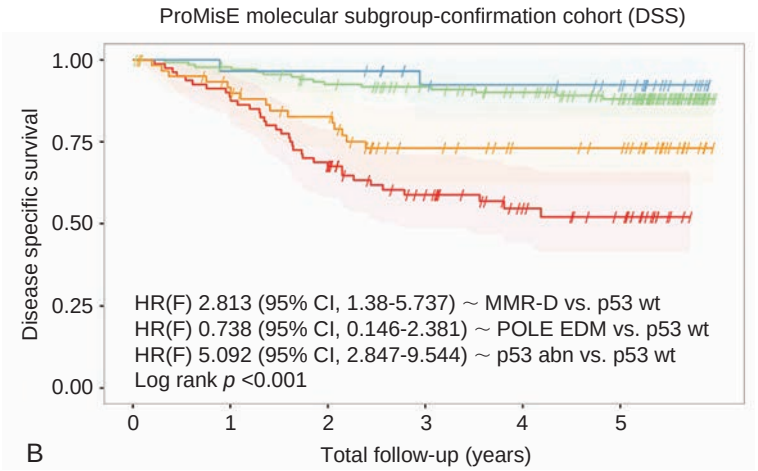
The better differentiated tumors closely recapitulate the light and electron microscopic features of the non-neoplastic endometrium,[241,242] hence the term "endometrioid" that is used for them. Over one-fourth of the endometrioid carcinomas have papillary (villoglandular) foci, either on the surface or in the invasive areas (see Fig. 33.32D).[243] These tumors should be sharply separated from the much more aggressive serous carcinomas.[244–246] A further variation on the theme is represented by endometrioid adenocarcinomas containing small nonvillous papillae. These papillae can arise either from an otherwise unremarkable endometrioid carcinoma or from the villous projections of the villoglandular variant of this tumor.[247] It should also be noted that the most superficial portions of endometrial adenocarcinomas can exhibit patterns closely simulating various hyperplastic and metaplastic conditions of the endometrial mucosa.[248]



The stroma of endometrial adenocarcinoma may contain collections of foamy cells, probably the result of tumor necrosis.[249] However, these cells can also be seen in hyperplasia and in the absence of proliferative epithelial changes. Their immunophenotype corresponds to that of histiocytes rather than endometrial stromal cells.[250]

The non-neoplastic endometrium of a uterus harboring an endometrioid adenocarcinoma is often hyperplastic and only exceptionally exhibits a normal secretory pattern.[251]

The frequency and extent of myometrial invasion by carcinoma correlate with the microscopic grade of the tumor.[187] High-grade tumors are significantly associated with cervical involvement and lymphovascular invasion.[253] Care should be exercised to distinguish true myometrial extension by carcinoma from expansion of the endometrial–myometrial junction and from atypical or malignant changes involving preexisting foci of adenomyosis[254]; the latter condition is recognized by the presence of endometrial stroma around the intramyometrial proliferating glandular foci.[255] It has been proposed that CD10 immunostaining can help in this distinction by highlighting the endometrial stroma associated with the adenomyosis when present.[256] However, a warning has been sounded to the effect that CD10 immunoreactivity can also be found around foci of invasive adenocarcinoma,[257] and we do not recommend immunostaining in the assessment of myometrial invasion. If there is doubt about the presence of myometrial invasion, it can be communicated in the surgical pathology report by indicating that "no definite myometrial invasion" is identified.



Extension of the endometrial carcinoma into the cervix occurs in over 10% of cases, usually by direct invasion,[258,259] but can also be discontinuous with the endometrial tumor (presumably by mucosal "drop" implantation or via lymphatic spread). This extension may be grossly evident or become apparent only on microscopic examination. It is important, for staging purposes, to distinguish between surface/mucosal involvement only, which does not impact on stage, and invasion of the cervical stroma, which does result in a tumor being stage II.[223,259] Assessment of cervical stromal invasion is challenging, and there is considerable interobserver variability in assessment of this important feature and, consequently, tumor stage.[260]

With respect to the molecular subtype of endometrioid carcinomas, the low-grade (grade 1 or grade 2) tumors consist of type I/CN low/p53 wild type, MMR-D and POLE mutant tumors, while high-grade

(grade 3) endometrioid carcinomas can be any of the four molecular subtypes.

The differential diagnosis between endometrial and endocervical carcinoma is discussed elsewhere.

Variants of Endometrioid Carcinoma and Other Endometrial Carcinoma Histotypes

Numerous morphologic forms of endometrial adenocarcinoma have been described. Some, such as adenocarcinoma with squamous differentiation, mucinous carcinoma, and secretory carcinoma, are thought to represent variants of ordinary ("endometrioid") adenocarcinoma. Others, notably serous carcinoma, carcinosarcoma, and clear cell carcinoma, are regarded as being of nonendometrioid type, although any of them can be seen coexisting with endometrioid adenocarcinoma.

Adenocarcinoma with squamous differentiation (formerly known as adenoacanthoma if low grade and adenosquamous carcinoma if high grade) refers to endometrioid adenocarcinoma containing squamous elements derived from metaplasia of the tumor glands (Figs. 33.33 and 33.34). Its natural history closely parallels that of the ordinary endometrioid adenocarcinoma of a similar degree of differentiation lacking squamous changes.[261] **Glassy cell carcinoma** is a variant of endometrioid carcinoma with squamous differentiation that has occasionally been reported in the endometrium; its appearance is similar to that of its more common cervical counterpart.[262,263]

Corded and hyalinized endometrioid carcinoma (CHEC) is characterized by epithelial cells in cords separated by hyalinized stroma. Spindled epithelial cells are also commonly encountered.[264] The nuclei are grade 1 or 2, which serves to separate these low-grade variants of endometrioid carcinoma with carcinosarcoma, with which they are often confused.

The **microcystic, elongated, and fragmented** (MELF) pattern of invasive endometrioid adenocarcinoma is recognized for its subtle histologic features that may be easily overlooked (particularly at the time of frozen section analysis for depth of myoinvasion) and its possible staging implications.[265] MELF is characterized by small pockets of a fibromyxoid stromal reaction that contain varying patterns of admixed eosinophilic carcinoma cells: small glands with attenuated epithelium (i.e. microcysts), elongated glands with a flattened lining mimicking endothelial cells, or clusters of detached cells or individual cells. Associated lymphocytes and neutrophils are common. Lymphovascular invasion in the myometrium and lymph node metastases are commonly identified, and often have a very subtle "histiocyte-like" appearance.[266–268] Data on the long-term clinical significance of this pattern of endometrial cancer are still emerging.

Secretory carcinoma is characterized by neoplastic glands having subnuclear vacuolization resembling that of a normal 17-day secretory

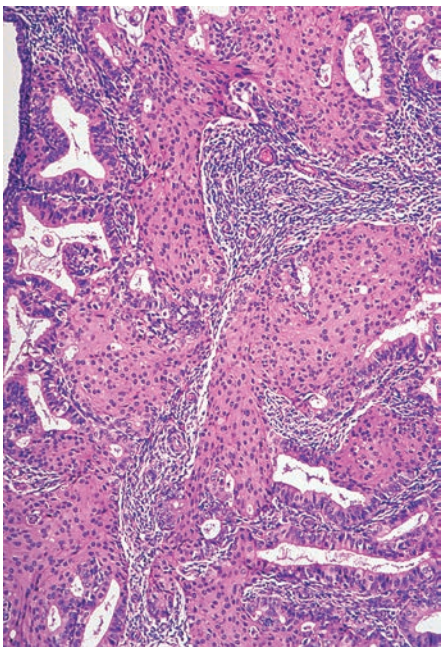

Figure 33.33 Well-differentiated endometrioid adenocarcinoma with squamous metaplasia.

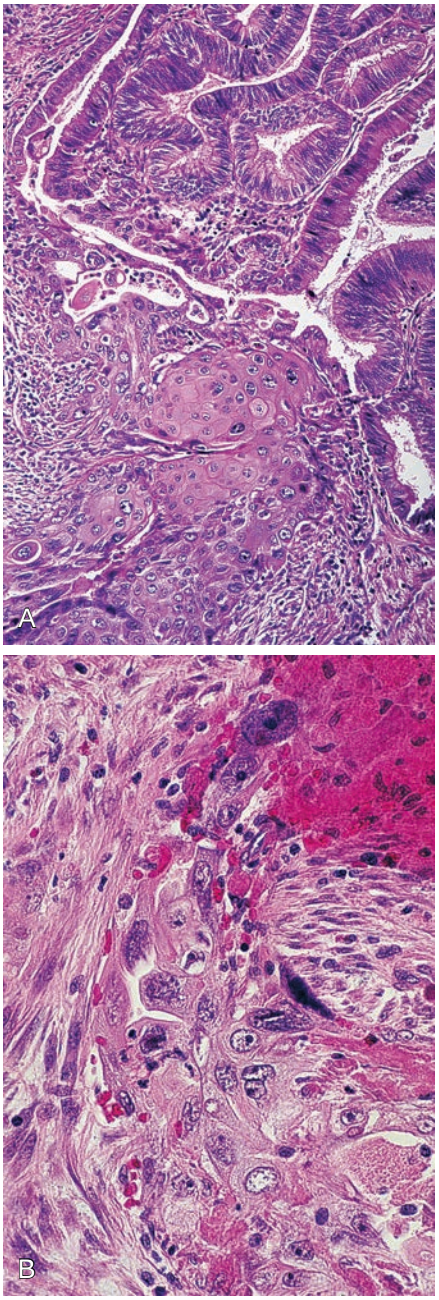

Figure 33.34 **A** and **B,** Endometrial adenocarcinoma of endometrioid type with squamous metaplasia. In contrast to the case shown in Fig. 33.36, the squamous component has markedly atypical cytologic features.

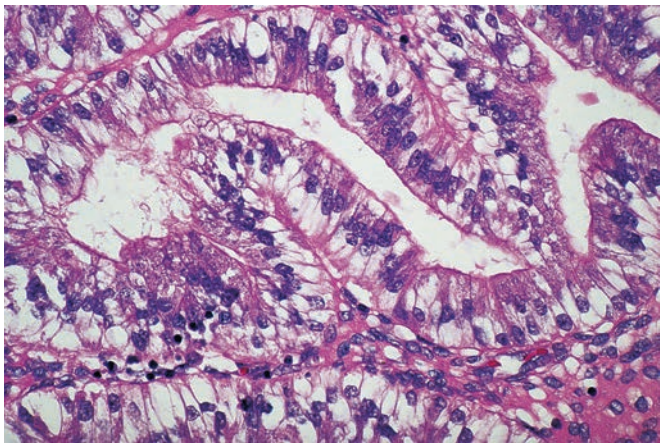

Figure 33.35 Secretory Carcinoma of Endometrium. This well-differentiated lesion is a variant of endometrioid adenocarcinoma and is composed of cells with abundant clear to finely granular cytoplasm. It should be distinguished from clear cell carcinoma.

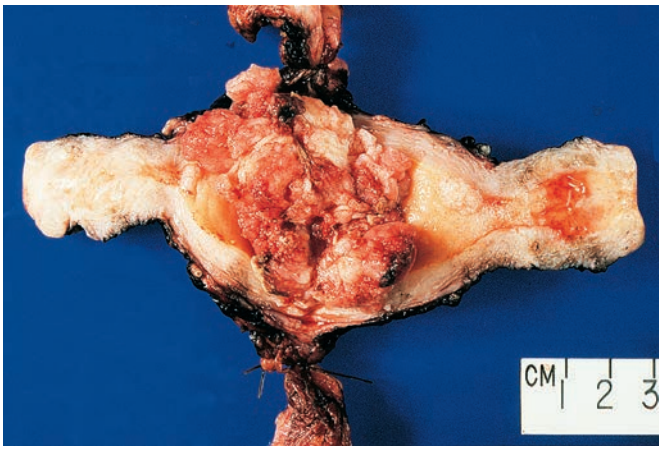

Figure 33.36 Gross appearance of serous carcinoma of endometrium. The neoplasm fills the endometrial cavity.

endometrium and accompanied by a late secretory pattern in the adjacent noninvolved endometrium (Fig. 33.35).[269] This tumor is believed to be the expression of a pattern that may be present diffusely or focally in a well-differentiated endometrioid carcinoma, usually as a result of progesterone stimulation. It should be distinguished from clear cell carcinoma, described later.[270–272]

Mucinous adenocarcinoma is a tumor subtype characterized by abundant intracellular mucin within the tumor cells.[273] Areas of mucinous differentiation are relatively common in usual endometrioid adenocarcinoma and is not of clinical significance. By definition, mucinous adenocarcinoma must consist predominantly (i.e. >50%) of tumor cells showing mucinous differentiation, and when so defined, this is a rare variant of endometrial adenocarcinoma. It is distinguished from atypical mucinous glandular proliferation of the endometrium (the mucinous equivalent of atypical hyperplasia) by increased glandular architectural complexity. Cytologic atypia is of limited help in this differential diagnosis as it is often minimal, even in mucinous carcinoma. There is often a prominent neutrophilic infiltrate in the epithelium of mucinous carcinoma of the endometrium. The distinction between endometrial mucinous adenocarcinoma and primary endocervical adenocarcinoma can be made based on immunostains, with the former showing strong diffuse ER and PR positivity, in most instances, and lacking block p16 positivity, while cervical mucinous carcinomas show block p16 positivity if HPV-associated, or are ER/PR negative if HPV-independent adenocarcinomas of gastric type.[274,275] On occasion, endometrial adenocarcinomas of mucinous or mixed mucinous–endometrioid type exhibit a conspicuous *microglandular* pattern associated with eosinophilic mucinous intraluminal secretion and prominent acute inflammation, the overall picture simulating the appearance of endocervical microglandular hyperplasia.[276,277]

Serous carcinoma is a highly aggressive form of endometrial adenocarcinoma closely resembling tubo-ovarian high-grade serous carcinoma (Fig. 33.36).[278-280] It is characterized by a complex papillary pattern of growth, a high degree of cytologic atypia (pleomorphism, hyperchromasia, giant nucleoli), numerous mitoses, extensive necrosis, psammoma bodies (30% of the cases), and prominent myometrial invasion (Fig. 33.37). It should be distinguished from the already mentioned (and much more common) endometrial adenocarcinoma with a villoglandular pattern of growth, with which it shares several architectural features.[281] A key aspect in this regard is the consistently high-grade nature of its cytologic features.[282] Conversely, papillae

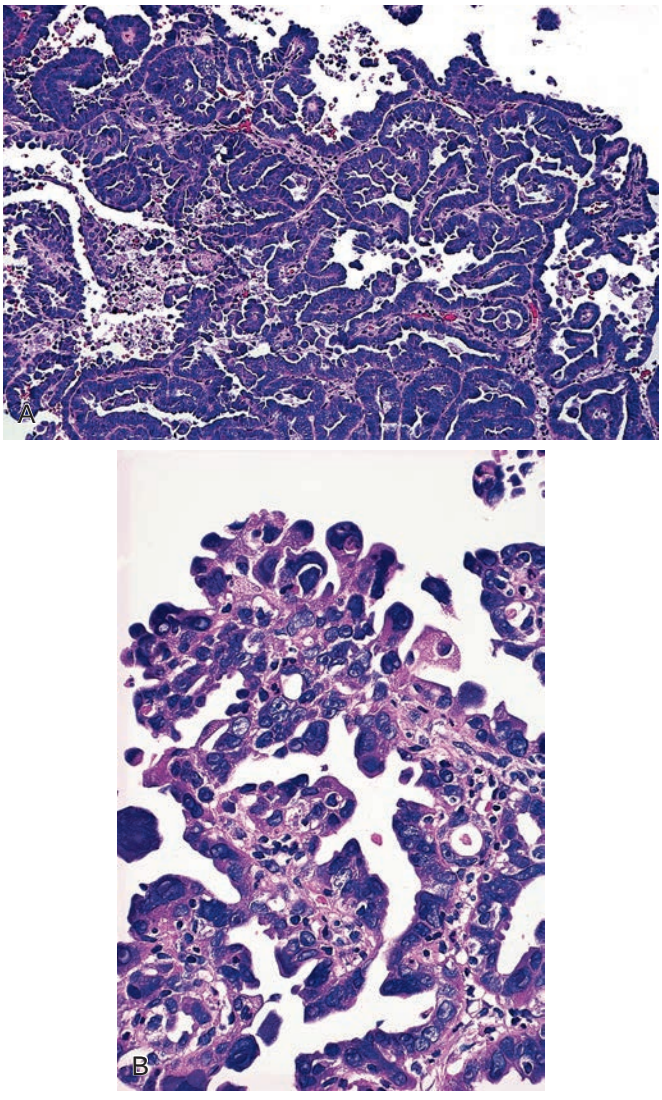

Figure 33.37 A and **B,** Low- and high-power appearance of serous carcinoma. Note the high nuclear grade.

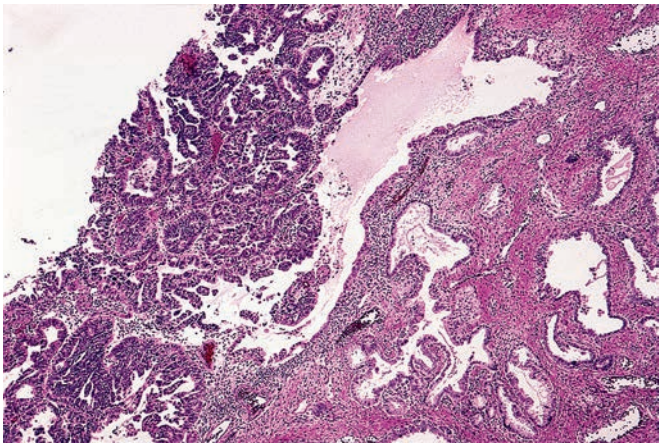

Figure 33.38 Serous carcinoma limited to the superficial portion of an endometrial polyp.

may be scanty, the tumor growing predominantly in the form of tubuloglandular structures with angulated outlines and compressed lumens, raising a differential diagnosis with endometrioid carcinoma.[283] The glandular luminal margin in serous carcinoma with glandular differentiation appears ragged, in contrast to the smooth margin typical of endometrioid adenocarcinoma. It should be mentioned here that psammoma bodies are not necessarily indicative of a serous-type tumor, since occasionally they are also seen in endometrioid carcinomas.[241]

Uterine serous carcinoma can coexist with endometrioid adenocarcinoma of the uterus,[284] be confined to an endometrial polyp, or be entirely intramucosal ("minimal serous carcinoma") (Fig. 33.38).[242,284–291] Even when confined to a polyp there can occasionally be extra-uterine spread, presumably by a transtubal route.[292,293] A putative precursor of serous carcinoma has been described under the term *endometrial glandular dysplasia*.[277,294,295] In patients with widespread involvement by high-grade serous carcinoma in which there is endometrial involvement, most such tumors are endometrial primary tumors.[292] WT1 is less commonly positive in endometrial serous carcinoma than in tubo-ovarian serous carcinoma, but it is not a reliable marker in an individual case. When there is extensive serous carcinoma with significant endometrial involvement, it is our practice to stage it as an endometrial primary tumor and not do immunostains.[293]

Immunohistochemically, abnormal immunostaining for p53 (either strong and diffuse staining or complete absence of staining) is characteristic of serous carcinoma, although not every serous carcinoma will show abnormal p53 staining, and approximately 30% of high-grade endometrioid carcinomas show abnormal p53 immunoreactivity. Thus staining for p53 does not help in distinguishing between serous carcinoma and high-grade endometrioid carcinoma, but it can be useful in cases of glandular tumors with greater atypia than is expected for a low-grade endometrioid carcinoma, but lacking unequivocal high-grade cytologic features of serous carcinoma. Abnormal p53 immunostaining in these so-called "ambiguous" cases supports a diagnosis of serous carcinoma.[296] By molecular classification, the serous carcinomas are almost all type II/CN high/p53 abn subtype.

Carcinosarcoma (formerly referred to as malignant mixed müllerian tumor) was for many years considered to be a variant of uterine sarcoma but is now, based on a number of lines of evidence, classified as an endometrial carcinoma with metaplastic sarcomatous differentiation. Carcinosarcomas are practically always seen in postmenopausal patients, although exceptions occur.[297] Grossly, they

Figure 33.39 Carcinosarcoma of uterus resulting in a huge polypoid mass.

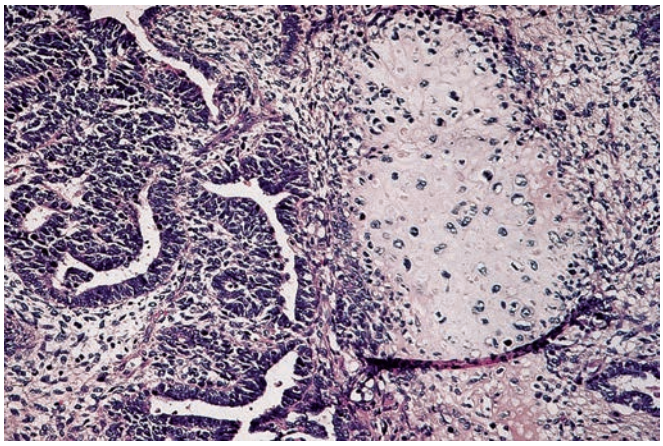

Figure 33.40 Glandular and mesenchymal components of carcinosarcoma. Heterologous elements in the form of cartilage are present.

present as large, soft, polypoid growths involving the endometrium and myometrium, sometimes protruding from the cervix (Fig. 33.39). Foci of necrosis and hemorrhage are common.

Microscopically, the distinctive feature of carcinosarcomas is the *admixture of carcinomatous and sarcoma-like elements*, resulting in a characteristic biphasic appearance (Fig. 33.40). The transition between carcinoma and sarcoma should be abrupt; if it is not, consider one of the mimics of carcinosarcoma, such as dedifferentiated carcinoma or endometrioid carcinoma with corded and hyalinized (CHEC) pattern. The carcinomatous component is usually of glandular type, whether endometrioid, clear cell, or papillary serous (particularly the latter).[298] As a rule, it has a poorly differentiated appearance and is of a high-grade nature; therefore, a careful search for sarcomatous elements should be carried out whenever such patterns are found in an endometrial biopsy, particularly if accompanied by extensive necrosis and hemorrhage. Squamous cell, undifferentiated, and

primitive neuroectodermal patterns may also be seen.[299,300] Cases have also been described with melanocytic[301] and yolk sac differentiation.[302]

The appearance of the sarcomatous component is the basis for the time-honored division of these neoplasms into a *homologous* and a *heterologous* variety. In the former, the malignant stroma is composed either of round cells resembling those of the endometrial stroma or of spindle cells resembling leiomyosarcoma or fibrosarcoma. In the latter, specific heterologous mesenchymal elements (such as skeletal muscle, cartilage, bone, or adipose tissue) are also present (see Fig. 33.40). Identification of cross striations, or of skeletal muscle markers by immunocytochemistry (e.g. myogenin), is required to document the presence of a rhabdomyosarcomatous component. In some cases this component is so prominent as to overgrow the epithelial elements and to mimic a pure rhabdomyosarcoma.[281] Conversely, the sarcoma-like component may be very inconspicuous. The metastases are most commonly purely epithelial but may be mixed or purely sarcomatous. Exceptionally, a rhabdoid component is present.[303]

Keratin expression is always detectable in the epithelial areas but is also present, albeit reduced, in the sarcomatous component in most cases.[304] Carcinosarcomas can show genetic changes of a type I endometrial carcinoma with progression (i.e. both *PTEN* and/or *ARID1A* mutations AND mutation in *TP53*), or those of a type II endometrial carcinoma (*TP53* mutations without *PTEN* or *ARID1A* mutations), and carcinosarcoma may be an end result of tumor progression in both pathways.[305] Carcinosarcomas are rare among the hypermutated/MMR-D or ultramutated/POLE mutant tumors but there is relatively little data available regarding this point at the time of writing.

Carcinosarcomas are easily distinguished from teratomas by their occurrence in an older age group and by the absence of skin appendages, glia, thyroid, and other tissues; however, as already noted, they may exceptionally contain neuroectodermal elements.[299] They should also be clearly separated from embryonal rhabdomyosarcoma (sarcoma botryoides). The latter term should be reserved for the tumor of childhood or adolescence arising from the cervix or vagina that exhibits skeletal muscle differentiation but lacks a carcinomatous component.

Carcinosarcomas are highly aggressive neoplasms, perhaps more so than even the higher grades and the more unfavorable histotypes of endometrial carcinoma.[306] Extension into the pelvis, lymphatic and vascular permeation, and distant lymph-borne and blood-borne metastases are all common. If the tumor has extended to the serosa of the uterus or beyond at the time of surgery, the prognosis is very poor. In several series, tumors having only homologous stromal elements have been found to have a better prognosis than those with heterologous elements.[307–310] It should be pointed out, however, that the difference between the two is generally small, in some series absent altogether, and far outweighed by the stage of the disease.[311–313]

Carcinosarcomas are the most common uterine tumors to arise in the uterus after irradiation, typically for cervical carcinoma; these postirradiation tumors start to appear 8–10 years after radiation therapy and are associated with a particularly poor prognosis.[314,315]

Clear cell carcinoma is composed of large clear cells with distinct cellular margins containing variable but usually large amounts of glycogen (Figs. 33.41 and 33.42).[271,316] The papillary formations and "hobnail" cells found in this variant of adenocarcinoma resemble those seen in the ovarian, cervical, and vaginal tumors that carry the same name. The ultrastructural and immunohistochemical features of this tumor support their being of müllerian origin, and not mesonephric as was originally believed.[317–320] Most patients are postmenopausal.

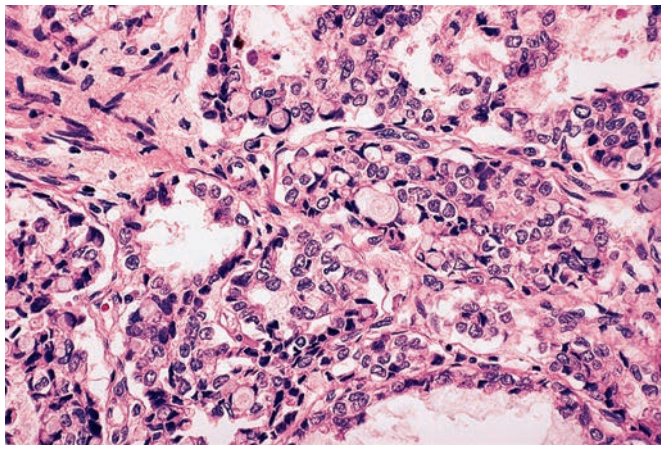

Figure 33.41 Clear cell carcinoma of endometrium.

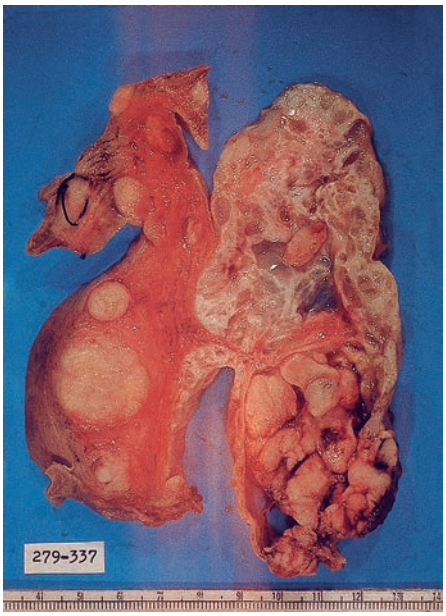

Figure 33.42 Gross appearance of a clear cell carcinoma involving a large endometrial polyp. (Courtesy Dr. Juan José Segura, San José, Costa Rica.)

A rare variant of clear cell carcinoma is characterized by a predominant or exclusive component of large eosinophilic (oxyphilic) cells.[321] Unlike serous carcinomas, most clear cell carcinomas express p53 in a wild type pattern. They are typically negative for ER and PR expression. A putative precursor lesion has been described, characterized by endometrial cells with clear and/or eosinophilic cytoplasm and varying degrees of nuclear atypia.[322]

Undifferentiated carcinoma and the closely related **dedifferentiated carcinoma**, where there is a component of low-grade endometrioid carcinoma present,[323] have emerged as a distinct entity. It grows in the form of solid sheets of cells without any signs of differentiation (Fig. 33.43).[323,324] Epithelial differentiation is inconspicuous and the differential diagnosis may include sarcoma or hematopoietic malignancy. It is important to distinguish it from a grade 3 endometrioid adenocarcinoma because of its worse prognosis.[325] Some of the reported cases of undifferentiated carcinoma have occurred in young women and have pursued a fulminant clinical course.[326] Undifferentiated and dedifferentiated carcinoma are characterized by mutations in genes in the SWI/SNF chromatin

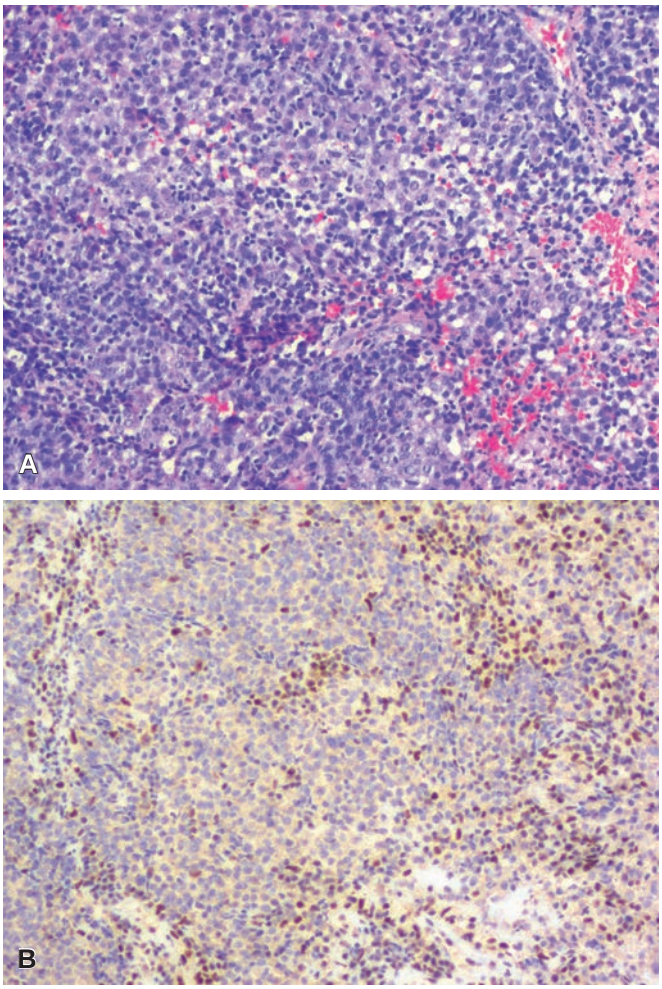

Figure 33.43 Undifferentiated carcinoma (**A**), with loss of MLH1 expression in the tumor cells (**B**).

remodeling complex (the same gene family mutated in ovarian small cell carcinoma of hypercalcemic type) and they typically show weak/focal expression of keratins, loss of PAX8 expression and wild type p53 expression, with frequent loss of expression of mismatch repair proteins (see Fig. 33.43B).[327–329]

Small cell (neuroendocrine) carcinoma usually presents grossly as bulky (sometimes polypoid), ill-defined, and invasive tumor. In rare instances it is seen confined to an endometrial polyp.[330] Microscopically, its appearance is similar to that of its more common cervical counterpart. It may be associated with areas of ordinary endometrioid or serous adenocarcinoma or be seen as a component of carcinosarcoma.[331–333] Immunohistochemically, there is usually reactivity for neuron-specific enolase (NSE) and low-molecular-weight keratin and sometimes also for chromogranin and synaptophysin. Dense-core secretory granules can be detected ultrastructurally. The behavior is very aggressive.[334] As in the lung, cervix, and other sites, tumors with similar high-grade neuroendocrine features but composed of cells of intermediate or large size exist, either pure or admixed with endometrioid adenocarcinoma.[324,335] In this context, it should be noted that a minor population of endocrine cells—as detected with argyrophilic stains—is present in 25%–50% of otherwise typical endometrial adenocarcinomas.[336,337] Some of these cells have been found to contain chromogranin, NSE, 5-hydroxytryptamine (5-HT; serotonin), somatostatin, adrenocorticotropic hormone (ACTH), and indolamines.[338,339]

Squamous cell carcinoma occurring in the endometrium in a pure form is extremely rare,[340,341] and it is, therefore, particularly important to rule out the alternative possibility of extension of a cervical carcinoma.[342] Some cases have developed in elderly patients with pyometra, presumably on the basis of a preexisting endometrial squamous metaplasia.[343] One reported case was associated with *spindle cell (sarcomatoid)* changes,[344] and another was of the *verrucous type*.[345]

Giant cell carcinoma is a rare pleomorphic form of high-grade endometrial adenocarcinoma featuring poorly cohesive sheets and nests of bizarre multinucleated giant cells.[346,347] It may be combined with better differentiated areas showing endometrioid or clear cell carcinoma features.[347]

Endometrial carcinoma with trophoblastic (choriocarcinomatous) or yolk sac differentiation should be distinguished from the giant cell carcinoma (just described), as well as malignant germ tumor, and gestational choriocarcinoma.[348] The multinucleated syncytiotrophoblast-like cells present in the choriocarcinomatous differentiation are strongly immunoreactive for human chorionic gonadotropin (hCG), while yolk sac differentiation is associated with expression of alpha-fetoprotein.[349–351] The conventional endometrial adenocarcinoma areas are more likely to have a serous than an endometrioid morphology.

Endometrioid carcinoma with sertoliform (sex cord–like) differentiation similar to that more commonly seen in ovarian endometrioid tumors has been reported.[352,353] This phenomenon is to be distinguished from the uterine tumors resembling ovarian sex-cord tumors (UTROSCTs). The term *corded and hyalinized endometrioid carcinoma* (so called CHEC pattern) is probably a variant of this sex cord–like differentiation, and it is important to distinguish it from carcinosarcoma, a more aggressive neoplasm.[264]

Hepatoid adenocarcinoma has been reported as arising from the endometrium, in association with alpha-fetoprotein production.[354]

Signet ring cell adenocarcinoma has been described as a primary uterine tumor.[355] Before making this diagnosis, all attempts should be made to rule out the alternative possibilities of metastasis (particularly from breast and stomach) and of vacuolated decidual cells and stromal histiocytes simulating signet ring cells.[356]

Lymphoepithelioma-like carcinoma looks like its homonym in other sites. The few reported cases have not shown evidence of Epstein–Barr virus infection.[357]

Rhabdoid tumor of the uterus represents, in at least some of the cases, a dedifferentiated form of endometrial adenocarcinoma, as is strongly suggested by its occasional coexistence with a conventional adenocarcinoma appearance.[358]

Mesonephric (adeno)carcinoma of the endometrium, that is, a tumor truly derived from wolffian remnants and, therefore, unrelated to the clear cell carcinoma described earlier (which in the past was inaccurately called mesonephric), has been described, presenting as a myometrial mass.[359–361] It may be more common than is generally appreciated, as it can resemble low-grade endometrioid carcinoma and many such tumors have undoubtedly been signed out as such in the past. The expression of TTF-1, CD10, and GATA3 and absence of ER and PR expression are helpful diagnostic features.

Histochemical and Immunohistochemical Features

Immunohistochemically, endometrial adenocarcinomas of the conventional (endometrioid) type are positive for keratin (especially keratins 7, 8, 18, and 19),[362,363] vimentin,[364,365] and PAX8.[366] Coexpression of keratin and vimentin is the norm.[367] Some tumor cells have also been found to contain glial fibrillary acidic protein.[363]

Estrogen and progesterone receptors are present in most cases of endometrial adenocarcinoma of endometrioid type, with

low-grade tumors being almost invariably positive.[368–370] Expression of ER and PR is variable in high-grade endometrioid and serous carcinomas and uncommon in clear cell carcinoma.[371] A finding of diagnostic significance is that WT1, which is nearly always positive in serous tumor of the tube and ovary and its metastases, is generally negative or only weakly expressed in serous carcinoma of the endometrium,[372–374] as well as in other types of primary endometrial carcinoma.[375] A potential pitfall is represented by TTF-1, a marker classically associated with lung and thyroid carcinoma but which can be also be expressed in endometrial (and endocervical) adenocarcinoma.[376,377]

Note that there are no immunomarkers that are completely sensitive or specific for histotype, and the diagnosis of endometrial carcinoma histotype should be based on evaluation of H&E-stained slides. As mentioned previously, in the specific instance of a glandular neoplasm with "ambiguous features" (i.e. nuclear atypia that exceeds what is usually seen in low-grade endometrioid carcinoma but is insufficient to confidently diagnose serous carcinoma), p53 immunostaining can be used to help in the differential diagnosis between low-grade endometrioid and serous, with wild type p53 expression supporting the former diagnosis.[296]

Molecular Genetic Features

Earlier in this section we described how TCGA identified four subtypes of endometrial carcinoma, based on genomic features: type I/low somatic copy number abnormalities/p53 wild type (endometrioid, typically low grade); type II/high somatic copy number abnormalities/p53 abnormal (mostly serous with a few high-grade endometrioid); hypermutated/MMR deficient (mostly endometrioid); ultramutated/POLE exonuclease domain mutated (endometrioid, often high grade).[228–230,232] Up until now we have attempted to understand the molecular genetic features of endometrial carcinoma in the context of histotype, but in the future all molecular studies should take into account the four genomic subtypes.

The major genetic abnormalities that have been detected in endometrioid adenocarcinomas are mutations in the *PTEN* gene (most cases) and frequent mutations in *PIK3CA*, *KRAS*, *ARID1A*, and *CTNNB1*, whereas serous carcinomas have *TP53* mutations (>90% of cases).[382–389] Mutations in *PPP2R1A* are a feature of endometrial serous carcinomas but not serous carcinomas of tube and ovary.[390]

DNA aneuploidy is present in approximately one-fourth of endometrial carcinomas; positive tumors tend to be of advanced surgical stage and higher microscopic grade, associated with deeper myometrial invasion, and accompanied by lymph node metastases. As expected, aneuploidy is the rule in serous carcinoma but can also be seen in a minority of endometrioid carcinomas.[391,392]

Spread and Metastases

The two obvious sites of direct spread of endometrial carcinoma are the myometrium and the cervix, both of these having important prognostic connotations.[393] For staging purposes, myometrial invasion is divided into two stages: up to 50% of the myometrial thickness or invasion to 50% or more of the myometrial thickness. This apparently straightforward determination is actually fraught with many potential inaccuracies.[394] The arcuate vascular plexus of the myometrium has been used as a guideline for this measurement, in the sense that carcinomatous infiltration into or through this plexus can be taken as surrogate evidence that the tumor has invaded over 50% of the myometrium.[393] This can be a useful approach when the uterine corpus is distorted by leiomyomas, for example, making measurement of depth of invasion difficult. A particularly difficult situation arises if there is coexistent adenomyosis. On the one hand, involvement of adenomyosis foci by carcinoma can be overinterpreted as deep myometrial invasion; on the other, it has been claimed that involvement of adenomyosis by carcinoma is an indicator of the likely presence of true myometrial invasion elsewhere in the myometrium.[395]

Invasion of the endocervix by endometrial carcinoma is relatively common, and the histologic features were discussed previously.

Lymphovascular invasion is the most important route of spread of endometrial cancer. It has recently been shown that "substantial" rather than minimal or focal lymphovascular invasion is of prognostic significance; the prognosis of patients with one or two lymphatic channels containing tumors is indistinguishable from that of patients without lymphovascular invasion.[396] A warning here is in order. We are referring to the artifact known as *vascular pseudoinvasion* sometimes seen in laparoscopic hysterectomy specimens and characterized by conspicuous tumor fragments in the lumen of thick-walled vessels in the outer myometrium or in ectatic vessels anywhere in the myometrium. These tumor fragments are detached from the vascular wall, lack an inflammatory perivascular infiltrate, and are accompanied by tumor fragments in myometrial clefts.

The most common sites of extrauterine spread in endometrial adenocarcinoma of the endometrioid type are the pelvic and paraaortic lymph nodes and the ovaries (see next section). Nodal metastases occur in approximately 5%–25% of clinically stage I tumors and are more likely to occur in invasive high-grade tumors (even if such tumors are superficial), in large sized and/or deeply invasive tumors regardless of grade, in tumors with cervical extension, and in tumors with vascular invasion.[397–399]

Serous carcinoma has a particular propensity for lymph vessel permeation. Involvement of peritoneal surfaces (particularly in the pelvis) occurs early in the disease and can be present even at the intraepithelial stage.[400] In these cases, molecular analysis has shown that the disease is clonal, indicating origin at a single site with secondary early spread.[393,399,401] An additional route of spread of endometrial carcinoma is transtubal,[293,403] but another warning is in order. On occasion, the keratin present in endometrial carcinoma with squamous metaplasia desquamates into the uterine cavity and from there travels via the fallopian tube to produce implants on the peritoneal surface, leading to the formation of foreign body granulomas.[404] This finding should not be regarded as evidence of metastatic disease *in the absence of viable neoplastic cells.* Follow-up data on these patients suggest that these keratin granulomas have no prognostic significance.[405]

The most common sites of recurrence of endometrial carcinoma are the vaginal vault and pelvis. Serous carcinoma characteristically spreads throughout the abdominal cavity in a fashion similar to that of tubo-ovarian serous carcinoma. Metastases of endometrial carcinoma in the bladder can simulate a primary neoplasm of this organ.[406]

Distant metastases of endometrial carcinoma are more common in the lung, liver, bone, central nervous system, and skin. The latter tend to occur in the head and neck region, particularly the scalp.

Coexistent Uterine and Other Genital Tract Carcinomas

Approximately 8% of endometrial carcinomas are accompanied by a simultaneous **ovarian carcinoma.** When they are of similar microscopic types—which is usually the case—it has been difficult to decide whether there are two independent tumors or whether one of the sites represents a metastasis.[407] Features in the endometrial tumor that are considered to favor an independent primary are stage Ia, grade 1 or 2, without lymphovascular invasion, while the ovarian tumor should similarly be organ confined and low grade.[408] There is ample evidence, based on large case series, that these tumors

behave as independent stage I primary tumors rather than as stage II ovarian carcinoma or stage III endometrial carcinoma.[407,409] High-grade tumors should be considered metastatic (almost always from endometrium to ovary, as discussed previously) until proven otherwise.[407] Other features considered to favor a metastatic nature for the synchronous ovarian tumor include the following: bilateral involvement, multinodular pattern of growth, presence of associated surface implants, and prominent lymphatic or vascular invasion within the ovarian stroma.[410] The clinical outcome data make interpretation of whole genome or whole exome sequencing data challenging, as these clearly indicate a clonal origin for synchronous ovarian and endometrial tumors in a large majority of cases.[411,412] The empirical evidence supports the practice of using the older clinicopathologic criteria in staging, as they result in the appropriately conservative treatment, and in this circumstance molecular testing results should not enter into the decision on whether to stage as independent primary tumors. Please note that in taking this pragmatic approach we are not suggesting that the synchronous tumors have risen independently; this would be akin to suggesting that, based on available evidence, the world is flat. We are simply advocating an approach to staging that is supported by clinical outcome data and will not lead to overtreatment of patients.

Endometrioid carcinomas have been described involving simultaneously the uterine corpus and the fallopian tube; in about half of them the fallopian tube tumors were located in the distal or fimbriated end, and some of the tumors were in situ.[413] Approximately 20% of serous carcinomas of endometrium are associated with metastatic tubal mucosal involvement.[293] We undoubtedly are seeing more cases of endometrial carcinoma with involvement of the fallopian tube mucosa since the introduction of more extensive sampling of tubal fimbria, but we do not yet know the clinical significance of this finding.

Treatment

The usual treatment of endometrial carcinoma is total abdominal hysterectomy with bilateral salpingo-oophorectomy. Whenever feasible, this should be supplemented by surgical staging (including biopsies of pelvic and para-aortic lymph nodes) if any of the following is present: greater than 50% myometrial invasion, grade III tumor, cervical involvement, extrauterine spread, unfavorable histologic component (serous, clear cell, or undifferentiated), or palpably enlarged nodes.[415] Radiation therapy, which was administered routinely in conjunction with surgery (either preoperatively or postoperatively), is no longer favored, except for patients with poor prognostic factors that put them at a high risk of recurrence.[416] This has largely been the result of randomized clinical trials showing that radiation therapy decreases local recurrences but does not influence disease specific or overall survival.[417]

Progestational agents can be curative for early stage, low-grade tumors, and in more advanced tumors, although usually not curative, occasionally induce striking temporary regressions in the primary tumor as well as in the metastases.[418,419] Well-differentiated carcinomas treated with progestins show a decreased gland-to-stroma ratio, decreased glandular cellularity, decreased or absent mitotic activity, loss of cytologic atypia, and a variety of cytoplasmic changes, including mucinous, secretory, squamous, and eosinophilic metaplasia.[420]

The treatment of serous carcinoma consists of hysterectomy with bilateral salpingo-oophorectomy, omentectomy, and surgical staging, the latter including peritoneal cytology and pelvic and para-aortic lymph node sampling. This is usually followed by adjuvant therapy, except for the minimally invasive tumors.[421–425]

Tumor relapse may appear in the form of local recrudescence (50%), distant metastases (28%), or both (21%); the median interval is between 1 and 2 years.[426] Local recurrences can be treated successfully with aggressive radiation therapy.[427]

Prognosis

Factors of prognostic importance in endometrial adenocarcinoma are the following:

1. *Tumor stage*, as defined by the FIGO system.[428] As for most of the common epithelial malignancies, stage is the strongest prognostic indicator and all biomarkers must be evaluated for significance independent of stage.
2. Level of *infiltration* of the myometrial wall, as incorporated into the FIGO staging system.[461] Tumors with invasion of over onehalf of the myometrium fare worse than those invading less than one-half.[429–432] Among the latter (stage Ia tumors), there is no significant difference between those that invade up to one-third and those that invade greater than one-third but less than one-half.[433]
3. *Microscopic grade* of differentiation, as defined by the FIGO system.[431,434,435] As already stated, originally this system was primarily based on architectural rather than nuclear features, except for the serous and clear cell types, which are by definition high-grade tumors.[436] The addition of a nuclear parameter to the FIGO system has improved its prognostic significance.[437] High-grade tumors have a worse prognosis regardless of their histologic subtype.[438]
4. *Age.* Patient age has consistently been an important prognostic factor, with advanced patient age associated with worse outcomes, but this has recently been questioned; Haley et al., in a large series, showed no significance for age as a prognostic factor in patients with early stage endometrial carcinoma, when carefully matched for tumor grade/histotype and other pathologic variables.[439] This illustrates the difficulty in assessing the relative strength of prognostic markers, when they co-vary, as age does with type II/serous/advanced stage.
5. *Histotype*. Among high-grade tumors (grade III endometrioid, serous, and clear cell) some studies show that histotype is of prognostic significance while other studies do not; the likely explanation is that the grade III endometrioid carcinomas are a heterogeneous group, and include all four molecular subgroups (i.e. copy number low, copy number high, ultramutated and hypermutated), and the subgroups of grade III endometrioid as defined based on the genomic abnormalities have very different prognoses.[440]
6. *Lymph vessel invasion*. Tumor permeation of lymph vessels is a poor prognostic sign,[441,442] particularly if extensive.[396,444]
7. *Molecular subtypes:* The four molecular subtypes of endometrial cancer, identified based on TCGA study, were discussed previously in this section and have emerged as important prognostic subgroups of endometrial carcinoma (see Table 33.1).
8. *Others*. Parameters said to be indicative of favorable outcome are absence of L1CAM expression,[229] absence of β-catenin mutation,[229,446] and diploid cellular DNA content.[392,448]

Endometrial Stromal Tumors

Tumors composed of endometrial stroma tend to occur in middle-aged women (average age, 45 years) and often present with vaginal bleeding.[449]

Microscopically, the low-grade endometrial stromal neoplasms are composed of uniform, predominantly oval, small cells, very closely resembling those of the endometrial stroma, individually enveloped by reticulin fibers, which characteristically encircle small vessels that resemble spiral arterioles (Fig. 33.44).

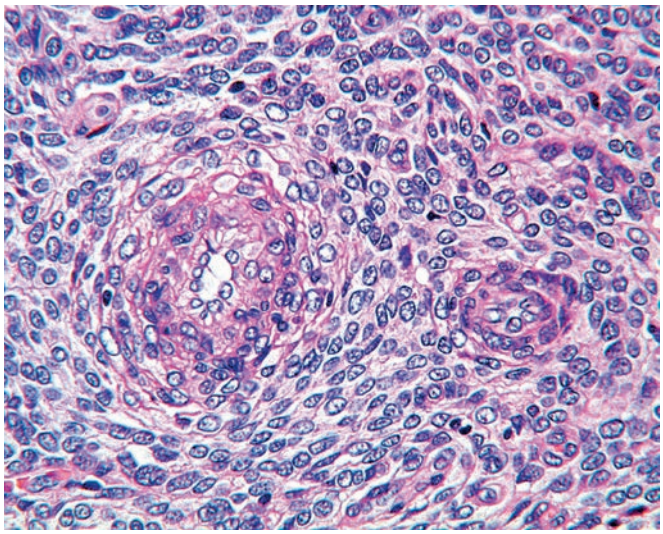

Figure 33.44 Typical microscopic appearance of low-grade endometrial stromal tumor, showing bland oval cells arranged concentrically around spiral arterioles.

Figure 33.45 Endometrial Stromal Nodule. The lesion is characteristically well circumscribed and has a yellow color.

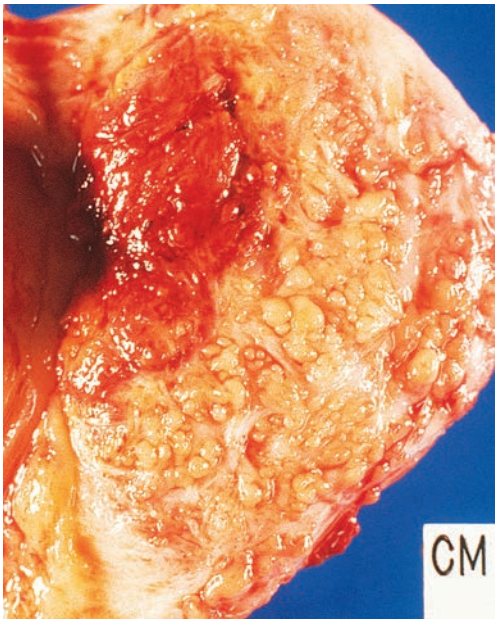

Figure 33.46 Low-grade endometrial stromal sarcoma showing diffuse permeation of the myometrium in the form of small nodules bulging on the cut surface.

Endometrial stromal tumors are divided into low-grade and high-grade stromal neoplasms; the former are further subdivided according to the type of margins into: (1) a benign category (endometrial stromal nodule) having pushing margins; and (2) a malignant category (low-grade endometrial stromal sarcoma) having infiltrating margins.[450–452] Distinction between endometrial stromal nodule and low-grade endometrial stromal sarcoma is made solely based on the margin between the tumor and myometrium, and it follows that this distinction is not possible based on endometrial biopsy/curettings. Endometrial stromal neoplasia is recognized in a biopsy/curetting by the presence of confluent areas of stroma measuring more than 5 mm, without glands; in such a case, one can only diagnose "low-grade stromal neoplasm" and defer definitive classification to the hysterectomy specimen.

Endometrial stromal nodules appear grossly as solitary sharply circumscribed masses of soft consistency and a characteristic yellow-to-orange color (Fig. 33.45). They do not invade veins, lymphatics, or the myometrium. The prognosis is excellent; recurrence did not occur in any of the 60 cases studied by Tavassoli and Norris,[430] even when some irregularities in the margin, high mitotic counts, or glandular foci were present. Cases in which the irregularities at the margins are pronounced but which lack the typical, usually extensive infiltration of the endometrial stromal sarcomas listed later have been referred to as *endometrial stromal tumors with limited infiltration*.[453] Their behavior seems to be as favorable as that of the conventional stromal nodules. Genetically, endometrial stromal nodule is characterized by t(7;17), which results in *JAZF1–JJAZ1* fusion.[454–456] The differential diagnosis is with cellular leiomyoma and markers of importance in this context are CD10 (consistently positive), h-caldesmon (consistently negative), and HDAC8 (consistently negative); note that desmin and smooth muscle actin may show weak immunoreactivity in low-grade endometrial stromal neoplasms.[457–461]

Low-grade endometrial stromal sarcomas infiltrate the myometrium and have a particular tendency to permeate lymph vessels (Figs. 33.46 and 33.47). The latter feature sometimes can be detected grossly by the presence of yellowish, ropy, or ball-like masses filling dilated channels. They may also present as polypoid masses (Fig. 33.48). The local invasion may extend into the broad ligament, tubes, and ovaries. Their low-power appearance is very distinctive, in the sense of showing extensive myometrial permeation by sharply defined tumor islands with pointed edges, somewhat reminiscent of those seen (in an altogether different context) in thymoma. Other commonly encountered features in low-grade endometrial stromal sarcomas include foci of hyalinization and scattered foamy cells.[462] Morphologic variations (other than those described in greater detail later) include the presence of a prominent fibrous or myxoid component,[463] adipose metaplasia,[464] a component of epithelioid cells with abundant eosinophilic cytoplasm,[465] scattered tumor cells

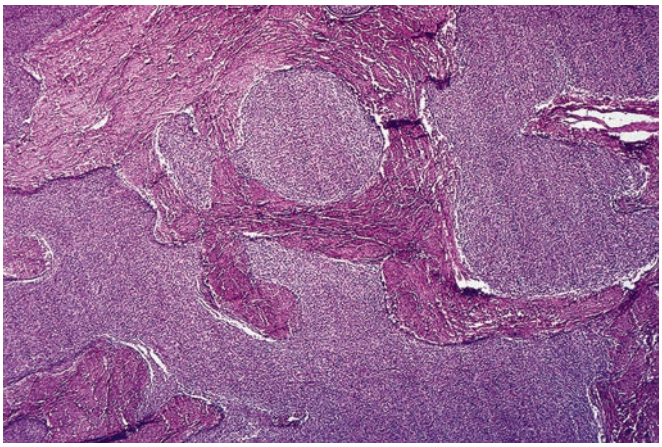

Figure 33.47 Typical low-power appearance of endometrial stromal sarcoma.

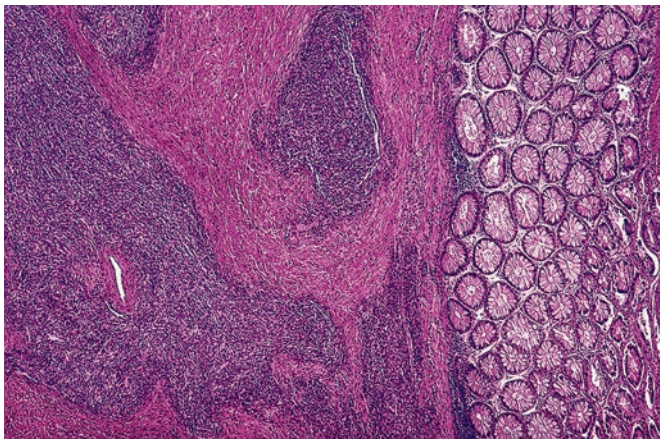

Figure 33.49 Low-grade endometrial stromal sarcoma metastatic to wall of large bowel.

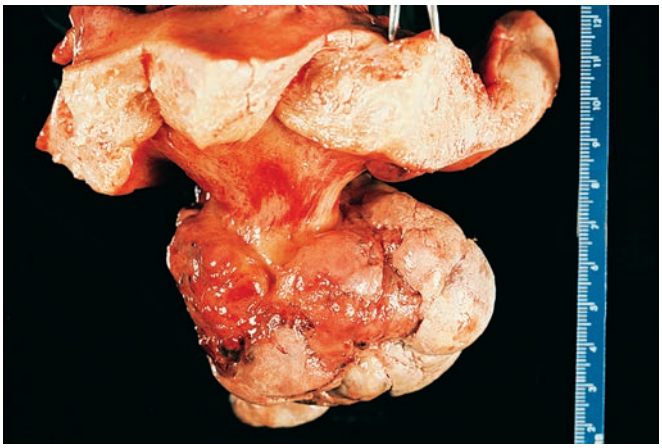

Figure 33.48 Low-grade endometrial stromal sarcoma presenting as a huge polypoid mass within the endometrial cavity. This pattern of growth is unusual in this tumor type.

with "symplastic" nuclei,[464,466] and papillary/pseudopapillary formations.[467]

The natural history of low-grade endometrial stromal sarcoma is characterized by slow clinical progression, repeated local recurrences (in the pelvis, ovary, intestinal wall, other intra-abdominal sites, and anterior abdominal wall), and occasional metastases (Figs. 33.49 and 33.50).[468]

Size of the tumor and extrauterine extension are important prognostic features. Low-grade stromal neoplasms less than 4 cm in diameter practically never recur, and tumors confined to the uterus at the time of the initial surgery infrequently do so.

The tumor cells contain estrogen and progesterone receptors, and the tumors respond to administration of progestins.[469,470] Genetically, about 50% of cases show t(7;17) with *JAZF1–SUZ12 (JJAZ1)* fusion (identical to that seen in endometrial stromal nodule, but differ in showing concurrent silencing of the unrearranged *SUZ12* allele). Other less common genetic abnormalities include t(6;7) with *JAZF1–PHF1* fusion, t(6:10) (*EPC1-PHF1*) and t(1:6) (*MEAF6-PHF1*).[454–456] These genetic findings may be utilized to aid in the diagnosis of endometrial stromal sarcoma by using fluorescence in situ hybridization (FISH) or reverse transcriptase-polymerase chain reaction (RT-PCR). It should be noted that as well as the translocations described previously, a significant minority of low-grade endometrial stromal sarcomas have rearrangement of JAZF1 or PHF1 by FISH, without identification of the fusion partner.[471]

The differential diagnosis between low-grade endometrial stromal neoplasm and a smooth muscle tumor was discussed previously, but a related issue is the phenomenon of tumors that show both endometrial stromal and smooth muscle differentiation, based on both light microscopic examination and immunostaining. If the smooth muscle differentiation is present in the form of an inconspicuous focus in the midst of an otherwise typical endometrial stromal tumor, it can be ignored for diagnostic purposes.[472] A distinct histologic pattern is the presence of relatively discrete nodules of small epithelioid tumor cells, which stain strongly with desmin, embedded in hyalinized collagen, the so-called "starburst" pattern.[473] If sizable (one-third or more of the tumor mass), the neoplasm is referred to as **combined smooth muscle–stromal tumor.**[474,473] These combined tumors often show the t(7;17) with *JAZF1–SUZ12* fusion characteristic of low-grade endometrial stromal neoplasms and behaviorally seem to be closer to endometrial stromal tumors than to smooth muscle tumors, and—on the whole—are very indolent; therefore, the diagnostic term *endometrial stromal sarcoma with smooth muscle differentiation* is commonly used.[474]

Epithelial-like formations may appear in endometrial stromal tumors in the form of solid masses, glandular structures, or anastomosing cords. Some of these formations have been likened to those of ovarian sex-cord neoplasms (particularly granulosa cell tumors) and the tumors containing them have been referred to as **uterine tumors resembling ovarian sex-cord tumors (UTROSCTs;** Fig. 33.51).[455,475] Some cases feature an epithelial retiform component resembling rete ovarii.[476] Their immunohistochemical and ultrastructural profile has varied considerably in the reported series, ranging from myogenous to epithelial.[477] However, at least some of the cases have shown a phenotype consistent indeed with a sex-cord line of differentiation, including reactivity for inhibin, CD99, and Melan-A.[478–481] Uterine tumors in which these structures predominate to almost the exclusion of others have generally behaved in a benign fashion,[475] but occasional metastasizing examples are on record.[482]

The uterine neoplasm known as **plexiform tumor** or **tumorlet** is an occasional incidental finding in a hysterectomy specimen. They are typically less than 1 cm and invariably benign. Their histogenesis is controversial, and they have been claimed to be of endometrial stromal,[483] myofibroblastic,[484] and smooth muscle derivation.[485,486]

A different type of epithelium-like formation that can be seen in endometrial stromal tumor is represented by **endometrioid**

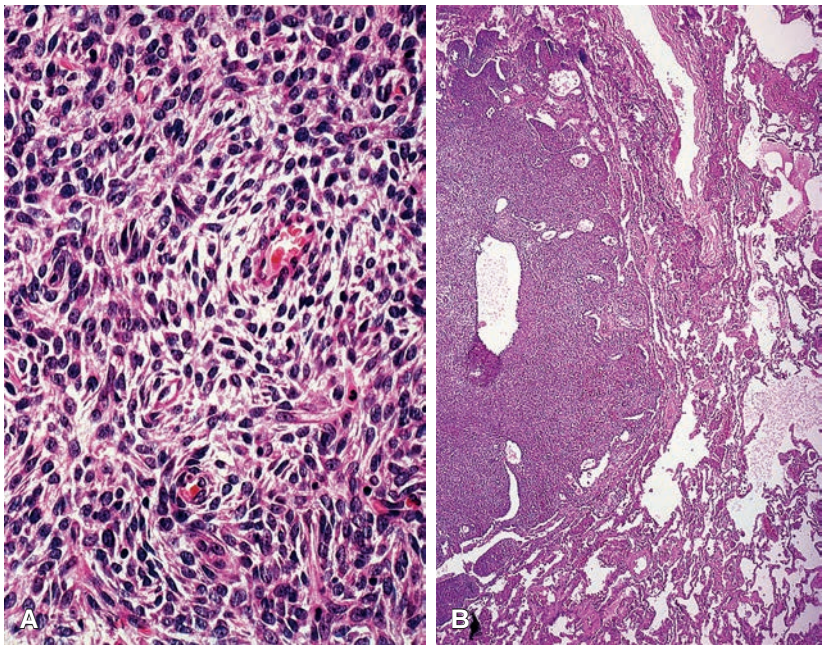

Figure 33.50 **A** and **B,** Low- and high-power appearance of low-grade endometrial stromal sarcoma metastatic to lung. This lesion may be misdiagnosed as spindle carcinoid tumor, hemangiopericytoma, or solitary fibrous tumor.

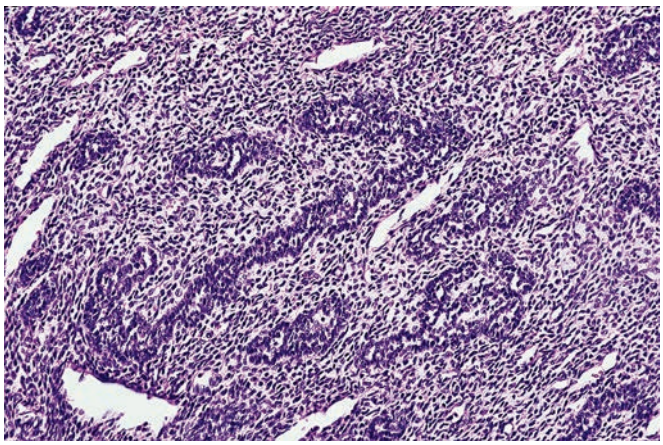

Figure 33.51 Low-grade endometrial stromal sarcoma with structures resembling ovarian sex cord tumors.

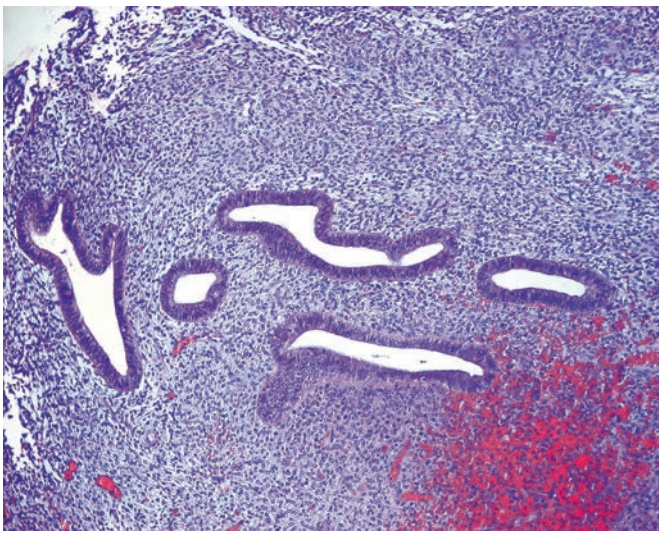

Figure 33.52 Peritoneal metastasis from endometrial stromal sarcoma accompanied by benign endometrioid glands.

glandular foci having a benign, atypical, or carcinomatous appearance (Fig. 33.52).[487,488]

Tumors with the appearance of low-grade endometrial stromal neoplasms may be found in the cervix,[489] ovary, pelvis, and retroperitoneum.[490] Some of these are seen in association with endometriosis, from which presumably they have arisen.[491] These extrauterine tumors may have any of the morphologic features and variations described in connection with the uterine neoplasms, including ovarian sex cord–like structures and endometrioid glandular proliferation.[492] A note of caution is in order. Before making a diagnosis of primary extrauterine low-grade endometrial stromal tumor, one should make an effort to rule out a metastasis from a uterine lesion, knowing that these metastases are often solitary and that they can occur years or decades after the excision of the original tumor, which (to complicate things further) might have been misdiagnosed as a peculiar-looking smooth muscle tumor.[493,494]

High-grade endometrial stromal sarcoma is a rare tumor; however, as it was only recently described, the true incidence is unknown. On low power it infiltrates the myometrium in a manner similar to that of low-grade endometrial stromal sarcoma.[495] The microscopic appearance is variable, ranging from low-grade spindle cell areas to a high-grade uniform small round cell component (Fig. 33.53).[496] It lacks conspicuous pleomorphism, which sets it apart from undifferentiated uterine sarcoma (see later). The mitotic activity is typically greater than 10 MF/10 HPF, in contrast to low-grade endometrial stromal sarcoma. The high-grade component of these tumors is negative for ER, PR, and CD10 but positive for expression of cyclin D1 (which unfortunately is not a specific marker of this tumor) and also express c-kit/CD117.[497] The low-grade

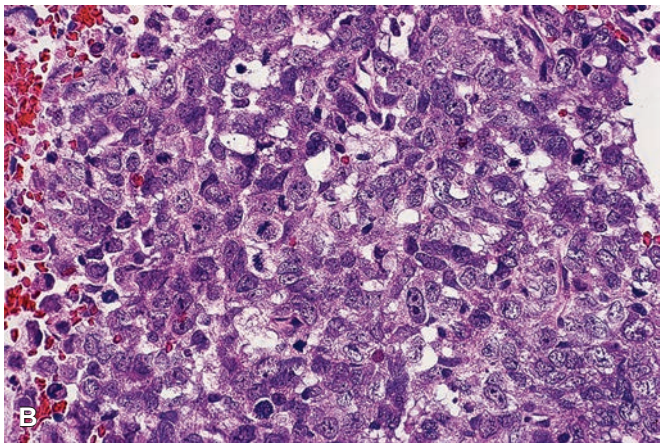

Figure 33.55 **A** and **B,** Gross and microscopic appearance of undifferentiated uterine sarcoma.

spindle cell component shows a more conventional endometrial stromal cell immunophenotype (ER, PR and CD10 positive). These tumors are characterized by t(10:17) with fusion of *YWHAE* and *NUTM2* (formerly known as *FAM22*). Genetic testing, for example, FISH, is an important diagnostic adjunct.[498] The prognosis of high-grade endometrial stromal sarcoma is intermediate between that of low-grade endometrial stromal sarcoma and undifferentiated uterine sarcoma. Responses to anthracycline chemotherapy have been reported and accurate diagnosis is important in guiding management.[499]

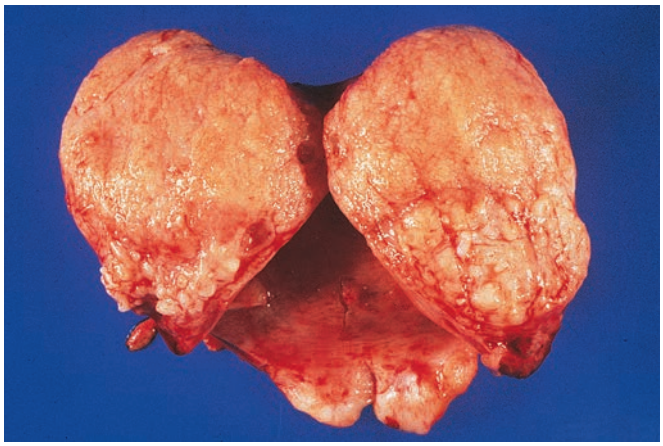
A second variant of high-grade endometrial stromal sarcoma has been described, characterized by spindled cells with abundant myxoid stroma and brisk mitotic activity, an appearance mimicking that of myxoid leiomyosarcoma (Fig. 33.54).[500] These tumors have *ZC3H7B-BCOR* gene fusion and follow an aggressive clinical course.

Recent studies suggest that BCOR immunohistochemical staining may serve as a sensitive and specific surrogate for identifying high-grade endometrial stromal sarcomas, regardless of the underlying genetic alteration (i.e. tumors with *BCOR* and *YWHAE* alterations are both immunoreactive).[501]

Undifferentiated uterine sarcoma shows a marked degree of nuclear pleomorphism and atypicality and lacks the vascular pattern and other distinctive features of endometrial stromal sarcoma (Fig. 33.55). It is an altogether different neoplasm from the lower grade, translocation-driven sarcomas described previously and behaves in a very aggressive manner. It is may prove to be a mixed group, histogenetically, with some being of endometrial stromal cell or smooth muscle cell origin, and others being monophasic carcinosarcoma, which it resembles morphologically.

Müllerian Adenosarcoma and Related Tumors

Müllerian adenosarcoma is a distinctive type of uterine tumor, consisting of sarcomatous stroma, typically low grade, and benign glandular elements.[502–504] It usually presents in elderly individuals as a bulky polypoid growth filling the endometrial cavity, less commonly as an intramural nodule (Fig. 33.56). Microscopically, it can bear a striking similarity to phyllodes tumor of the breast (Fig. 33.57). The stromal elements usually resemble endometrial stroma by light and electron microscopic examination but are more



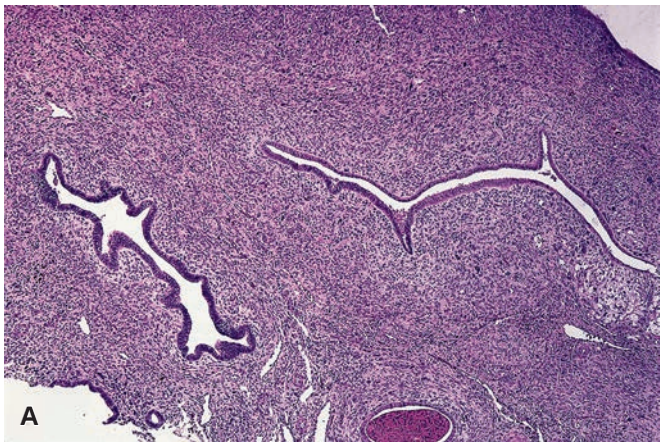


Figure 33.56 Müllerian Adenosarcoma. The tumor shows less degree of necrosis and hemorrhage than the usual malignant mixed müllerian tumor.

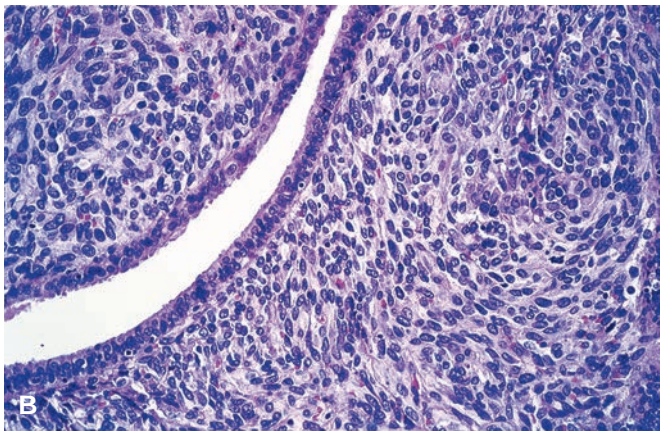

Figure 33.57 A and **B,** Low- and high-power view of müllerian adenosarcoma. The resemblance to phyllodes tumor of breast is obvious.

spindled.[505,506] As a rule, they do not appear as bizarre and undifferentiated as in the classic MMMT, although multinucleated giant cells and heterologous elements occur in approximately 20% of cases. The latter are usually of skeletal muscle type, but peculiar components such as angiosarcoma have also been observed.[507,508] Extensive areas of stromal fibrosis may result in a deceptively benign appearance.[503]

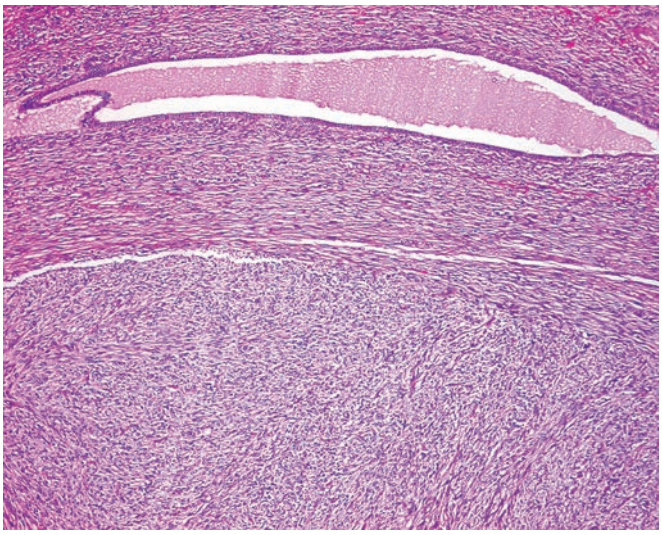

Figure 33.58 Müllerian adenosarcoma *(top)* with sarcomatous overgrowth *(bottom)*.

Like phyllodes tumor of the breast, müllerian adenosarcomas can show overgrowth by a pure sarcoma having a higher grade and exhibiting a greater mitotic rate than the sarcomatous component of the associated adenosarcoma (Fig. 33.58). These *müllerian adenosarcomas with sarcomatous overgrowth* behave in an aggressive fashion and are often associated with postoperative recurrence or metastases and a fatal outcome, in contrast to the usually indolent behavior of usual adenosarcoma.[504,509] The presence of high-grade cytologic features and sarcomatous overgrowth occur together and the prognostic significance of just high-grade cytologic features OR sarcomatous overgrowth in a low-grade tumor is not clear, as very few cases have been reported.

In the past, **uterine adenofibroma** was recognized as a benign counterpart of adenosarcoma.[510–513] The dividing line between the two groups was never sharp,[514] and it is clear that tumors with the characteristic features of uterine "adenofibroma" have occasionally been found to invade myometrium and pelvic veins, so it is now recommended that all such tumors be diagnosed as adenosarcoma.[515] Cases have been reported of adenosarcoma involved by adenocarcinoma.[516]

Leiomyoma

Leiomyomas of the uterus are extremely common neoplasms. The overall incidence is between 4% and 11%, but it rises to nearly 40% in women over the age of 50 years. Clinically apparent lesions are less common in parous than nulliparous women and premenopausal than postmenopausal women.[517] They are known to shrink after menopause; this is associated both with fibrosis and with a reduction in the size of the individual tumor cells.[518,519] The normal myometrium of leiomyoma-containing uteri expresses higher levels of estrogen receptors, a fact that may be related to their pathogenesis.[520] Leiomyomas are much more common in black women, in whom they have a tendency to be very numerous (Fig. 33.59).

Many of these tumors are small and go undetected; a systematic and meticulous study of 100 consecutive hysterectomy specimens revealed leiomyomas in 77 of them, 84% of the tumors being multicentric.[521]

These tumors occur subserosally, intramurally, or submucosally (Fig. 33.60) and produce symptoms referable to their size and location. The conventional teaching (which, like most conventional

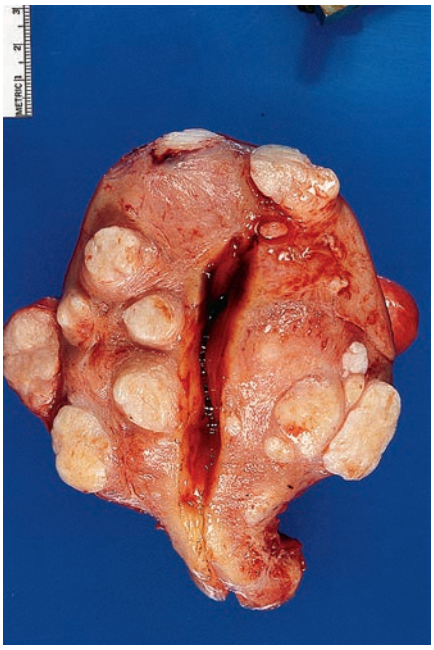

Figure 33.59 Multiple uterine leiomyomas.

Figure 33.60 Large uterine leiomyoma with intramural and subserous involvement.

teachings, is only partially true) is that the submucous tumors produce metrorrhagia, sometimes massive, (because of endometrial ulceration), the intramural ones result in menorrhagia (because they interfere with myometrial contraction), and the subserosal ones usually remain asymptomatic. They may become large enough to block the ureters, interfere with pregnancy, or cause inflammatory complications. In rare instances, uterine leiomyomas have been associated with polycythemia, which regressed after the tumor was excised ("myomatous erythrocytosis syndrome").[522] These tumors, which are usually very large, have been shown to be the source of erythropoietin.[523]

Submucosal tumors often result in secondary endometrial changes that range from gland distortion to atrophy and ulceration. They may fill the endometrial cavity and emerge from the cervical canal as polypoid growths ("myoma nascens"). Under these circumstances,

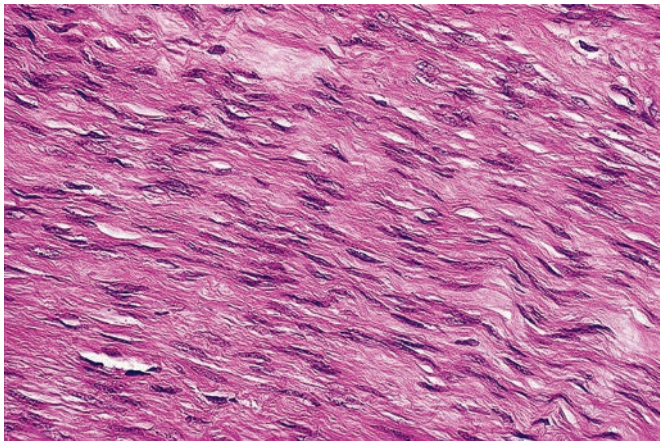

Figure 33.61 Elongated spindle cells with fibrillary acidophilic cytoplasm in the usual type of uterine leiomyoma.

their surface is usually ulcerated and infected, the gross appearance thus simulating that of a malignant neoplasm.

It may be difficult to make a diagnosis of leiomyoma when only a few small fragments of smooth muscle are present in a curettage specimen. Unless these fragments show an obvious increase in cellularity or decreased cellularity/hyaline changes, one is unable to decide whether they originated in a submucosal leiomyoma or whether they represent normal superficial myometrium.

Grossly, the cut surface of a typical leiomyoma has a white whorled appearance that has been likened to raw silk. Microscopically, the tumor is formed by interlacing bundles of smooth muscle cells separated by a greater or lesser amount of well-vascularized connective tissue (Fig. 33.61). Ultrastructurally, the features are those of smooth muscle cells with varying degrees of differentiation.[524] Exceptionally, the tumors may contain skeletal muscle–like cells (which, however, lack cross striations and are myogenin negative; see also under Leiomyoma variants) and rhabdoid cells.[525] The stroma may contain a scattering of lymphocytes. Mast cells are often conspicuous, in contrast with leiomyomas of other sites.[526,527] On average, they are more numerous in cellular leiomyomas and leiomyomas with bizarre nuclei than in either ordinary leiomyomas or leiomyosarcomas.[522]

Cytogenetic alterations are common in uterine leiomyomas. The most consistent are rearrangements of 6p (involving the *HMGA1* gene), del(7q), +12 (involving the *HMGA2* gene), and t(12;14) (involving the *HMGA2* gene).[528-532] These have led to the discovery that disruptions or dysregulations of the high-mobility group proteins HMGA1 and HMGA2 contribute to the development of these tumors.[410,533] Mutations in *MED12* are present in most conventional leiomyomas but are less common in some leiomyoma variants.[534,535]

The treatment of uterine leiomyomas (including that of most of the many variants listed later) varies depending on the size and number of lesions, the age of the patient, and her desire to have children. Most asymptomatic leiomyomas need not be excised. Symptomatic neoplasms can be treated by hysterectomy or, in the case of patients who desire to become pregnant, by myomectomy.[536] Medical therapy includes administration of gonadotropin-releasing hormone analogs, such as leuprolide acetate depot. This may result in a decrease in the size of the leiomyoma—probably as a result of ischemic injury and cellular atrophy—but it does not result in significant pleomorphism or increased mitotic activity.[537–541] The decrease in cell size and increase in collagenization have also been documented at the ultrastructural level.[542] Other authors have reported tumor infiltration by lymphocytes of predominantly T-cell type[543,544]

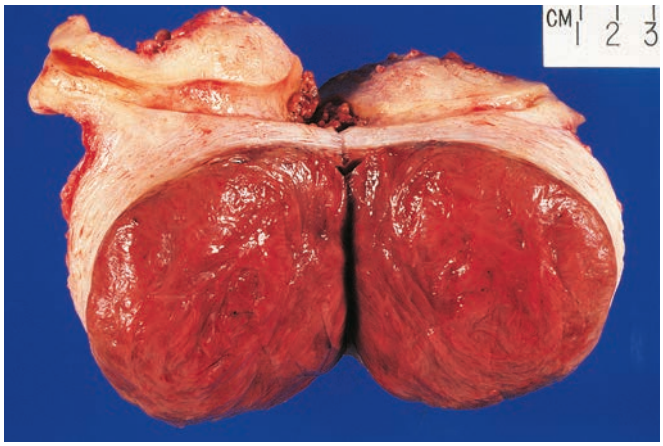

Figure 33.62 This uterine leiomyoma has undergone massive so-called red degeneration.

and vasculitis.[545] Immunohistochemically, leuprolide-treated leiomyomas show a decrease in cell proliferation indices and in hormone receptor expression.[546] Selective progesterone receptor modulators are increasingly used to treat symptomatic leiomyomas, as they have been shown to be effective for both a single course of therapy and repeated treatments.[547] Pathologists should be aware of the effects of these agents on the endometrium, described earlier in this section.

Another treatment modality for uterine leiomyoma is arterial embolization with tris-acryl gelatin microspheres.[548] This results in massive necrosis, sometimes accompanied by calcification, thrombosis, and a foreign body-type reaction to the injected material.[549,550] Infarct-type necrosis has also been observed in uterine leiomyomas of women treated with tranexamic acid, an antifibrinolytic agent.[551]

Leiomyoma Variants

Many variations on the basic theme previously described exist. Most of these are the result of secondary changes and are detectable in approximately 65% of cases. These include hyaline degeneration (63%), myxoid changes (19%), calcification (8%), cystic changes (4%), and fatty metamorphosis (3%). There is no relation between symptomatology and the presence of these changes.[552]

Red degeneration (present in 3% of cases) can result in abdominal pain, vomiting, and fever. This change is characterized grossly by a bulging surface and a homogeneous dark red appearance and microscopically by extensive coagulative necrosis. It may be associated with pregnancy or the use of contraceptive drugs (Fig. 33.62).

Apoplectic leiomyoma is pathogenetically related to red degeneration and is characterized by stellate zones of recent hemorrhage within nodules of hypercellular smooth muscle, with few or no mitotic figures.[553] Many variations on this basic theme exist, some of which can simulate malignancy.[554]

Hydropic degeneration is characterized by the accumulation of edema fluid, often associated with collagen deposition. It may have a diffuse, perinodular, or other patterns (Figs. 33.63 and 33.64).[555,556] The appearance may simulate intravenous leiomyomatosis or myxoid leiomyosarcoma.[555] Regarding the latter, leiomyomas with hydropic degeneration have a delicate filigree pattern rather than thick fascicles, and the extracellular material is edema fluid rather than mucopolysaccharides. Also, the presence of medium- to large-caliber blood vessels "floating" in the extracellular material is more characteristic of hydropic change.

Myxoid leiomyoma must be distinguished from both hydropic degeneration and myxoid leiomyosarcoma. The latter is recognized

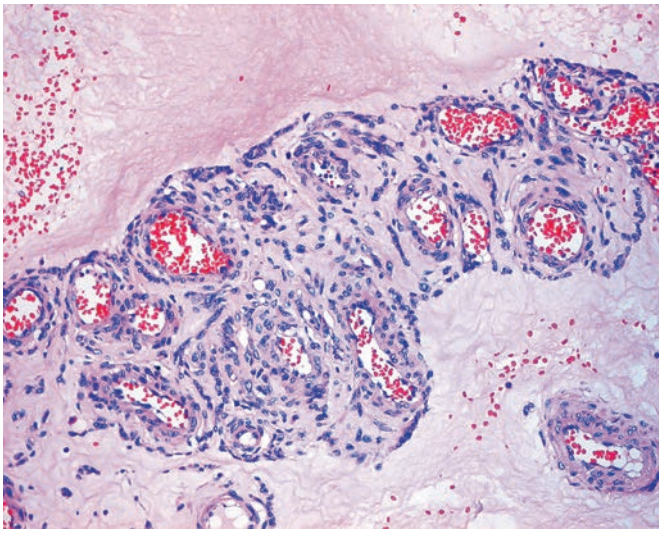

Figure 33.64 So-called perinodular hydropic degeneration in uterine leiomyoma.

because of the presence of destructive myometrial invasion and the conventional features of malignancy.[557]

Leiomyoma with lymphoid infiltration may simulate a malignant lymphoma because of the massiveness of the inflammatory component, which is made up of small lymphocytes, immunoblasts, and plasma cells.[558] Germinal centers may be present. The surrounding myometrium is relatively unaffected.[559,560] A variation on the theme is represented by the leiomyomas with a heavy infiltration by eosinophils.[561]

Cellular leiomyoma is a term reserved for those tumors having markedly increased cellularity but no coagulative necrosis, atypia, or an excessive number of mitotic figures (Fig. 33.65). It is a diagnosis that should be used sparingly; many leiomyomas can be more cellular than the surrounding myometrium, but the designation of cellular leiomyoma should be made only for tumors at the upper end of this spectrum of increased cellularity. Their natural history is the same as for the ordinary leiomyoma. The differential diagnosis includes leiomyosarcoma and endometrial stromal neoplasms.[562] At the cytogenetic level, cellular leiomyoma has been

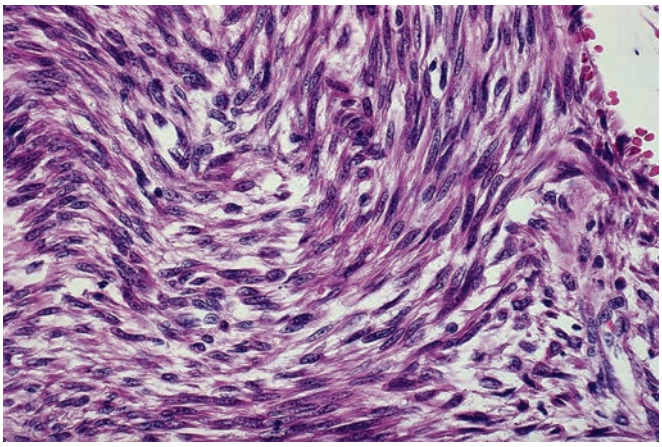

Figure 33.65 Cellular leiomyoma. There is no pleomorphism, undue mitotic activity, or necrosis.

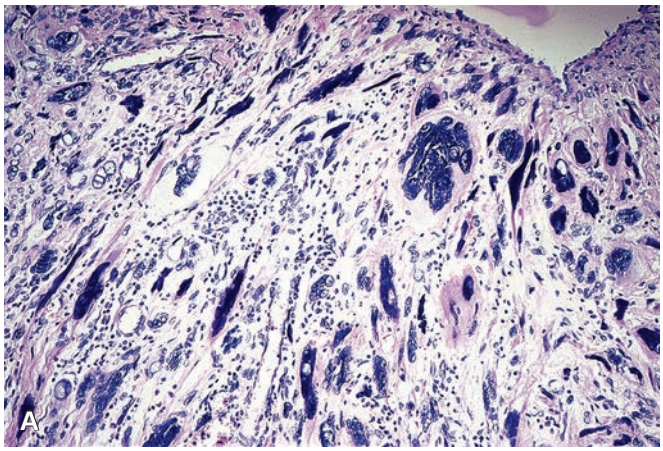
found to be accompanied by loss of almost the entire short arm of chromosome 1.[563]

Leiomyoma with bizarre nuclei (also referred to in the past as atypical, bizarre, symplastic, or pleomorphic leiomyoma**)** contains foci with bizarre tumor cells showing variation in size and shape, hyperchromatic nuclei, and multinucleated forms but no infiltration of myometrium, coagulative necrosis, or increased mitotic activity (Fig. 33.66).[564] Rarely, the entire tumor is composed of such cells. The usual assumption has been that the symplastic cells represent a degenerative phenomenon, but they have been shown to be actively proliferating.[565] There should be no more than an occasional mitotic figure or the designation of smooth muscle tumor of uncertain malignant potential (STUMP) should be used (see later).



Mitotically active leiomyoma refers to tumors having from 5 to 15 mitotic figures per 10 HPF but lacking coagulative necrosis or cytologic atypia (Fig. 33.67).[566,567]

Leiomyolipoma (lipoleiomyoma) contains an admixture of smooth muscle and mature adipose tissue (Fig. 33.68).[568-571] It is believed that some of these tumors and the even rarer **lipomas** result from adipose metaplasia in leiomyomas.[569,572] The differential diagnosis includes lipid-rich angiomyolipomas (PEComas), which are HMB-45 positive (see later).[573] **Palisaded leiomyoma** is characterized by a degree of nuclear palisading such as to simulate a schwannoma.[574]

Epithelioid leiomyoma is partially or totally composed of rounded or polygonal cells (Fig. 33.69). Mixtures of epithelioid, clear cell, and plexiform patterns occur frequently enough to suggest that they represent variants of a single entity.[575,576] A transition to typical smooth muscle is sometimes observed. Morphologically similar tumors occur in the round ligament.[577]

Cotyledonoid dissecting leiomyoma is so designated because its gross appearance resembles that of placental tissue. The tumor is exophytic, bulky, and extends from the uterine wall into the broad ligament and pelvic cavity.[578,579] Microscopically, the appearance is that of a leiomyoma with extensive degenerative changes (Fig. 33.70). Despite its dissecting pattern, it lacks vascular invasion and is benign. Variations exist of leiomyomas that are cotyledonoid but not dissecting,[580] and dissecting but not cotyledonoid.[581,582] Believe it or not, there is also a cotyledonoid hydropic intravenous leiomyomatosis.[583]

Parasitic leiomyoma is the term given to the uterine leiomyoma that has become separate from the uterus and has acquired vascular connections with the omentum, pelvic wall, or other intra-abdominal sites, such as the cecal wall. The low-lying retroperitoneal smooth

muscle tumors occurring in females and behaving in a benign fashion probably belong to this category, in the sense of being composed of myometrium-type smooth muscle, whether they actually arise from the myometrial wall or not.[584] Expression of estrogen receptor is a feature of smooth muscle tumors of the female reproductive tract; ER is rarely expressed in non-gynecologic smooth muscle tumors.[585]

Leiomyoma with skeletal muscle differentiation has been reported as an exceptional event.[586,587]

Angioleiomyoma (vascular leiomyoma) is a variant of uterine leiomyoma characterized by a swirling of the spindle cells around myometrial vessels, similar to that seen in the homonymous tumor of soft tissues. This tumor is thought to arise not from the parenchymal myometrial cells (as all other uterine leiomyomas are presumed to), but rather from the smooth muscle cells of the vessel walls.[588]

Diffuse leiomyomatosis is the term given to involvement of almost the entire myometrium by innumerable, ill-defined leiomyomas, many of microscopic size.[589,590] Clonality analysis done in a case of this condition supports the interpretation that these minute leiomyomas are independent tumors.[591] This extremely rare condition, which is probably analogous to so-called *seedling leiomyomas*,[592] should be distinguished from the nebulous *primary myometrial hypertrophy* or *myometrial hyperplasia*, defined as a uterus weighing over 120 g in the absence of any mass-like myometrial lesion.[593,594]

Hereditary leiomyomatosis and renal cancer syndrome is a rare autosomal dominant condition in which there is a germline mutation in the fumarate hydratase gene. Patients with this syndrome typically have multiple leiomyomas at an early age and the tumors are characterized by atypical nuclei with prominent nucleoli and occasional multinucleate forms.[595,596] While other histologic features have been described in the uterine tumors, such as perinucleolar halos (as also seen in the kidney tumors), hemangiopericytomatous vasculature, and brightly eosinophilic globules,[596,597] it is not possible to reliably recognize the syndromic leiomyomas based on H&E; immunostaining for overexpression of S-(2-succinyl) cysteine (2-SC) can serve to identify those tumors associated with the syndrome.[598]

Intravenous leiomyomatosis is an extremely rare condition characterized by the growth of mature smooth muscle inside the

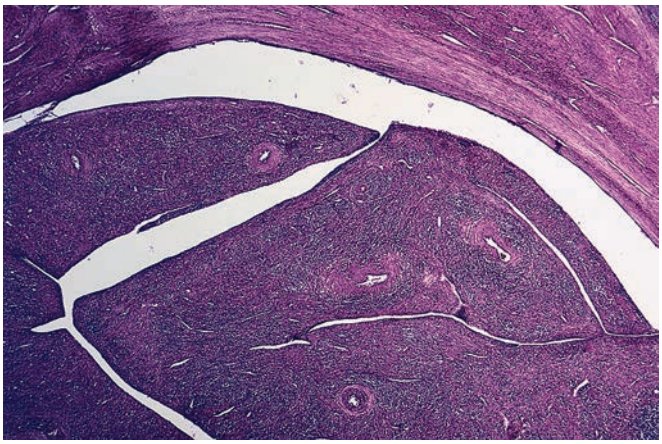

Figure 33.71 Large plugs of mature smooth muscle filling the vascular lumina in intravenous leiomyomatosis.

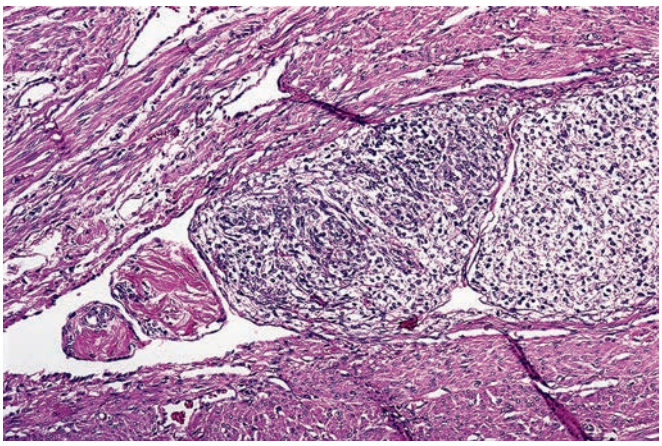

Figure 33.72 Intravenous leiomyomatosis composed of clear smooth muscle cells.

lumen of uterine and pelvic veins (Figs. 33.71 and 33.72).[599,600] It is often associated with typical uterine leiomyomas.[601] The clinical and gross features are similar to those of low-grade endometrial stromal sarcoma, but grossly apparent involvement of veins is more prominent. At the microscopic level, intravenous leiomyomatosis is composed of elongated smooth muscle cells, whereas endometrial stromal sarcoma is made up of round or oval endometrial stromal cells. Mitotic figures are rare or absent. The vessel permeation often extends to vessels in the broad ligament and in uterine and iliac veins; from there, it can proceed along the vena cava and even reach the right atrium.[602] However, distant metastases are exceptionally rare, and the long-term prognosis is excellent.[603] Cases have been described in which the microscopic appearance of the intravenous masses was that of lipoleiomyomas,[604] and others in which the intravenous leiomyomatosis was associated with a benign metastasizing leiomyoma in the lung.[605]

Benign metastasizing leiomyoma is the name given to the uterine tumor having the typical features of a leiomyoma (sometimes on the cellular side but invariably lacking coagulative necrosis, increased mitotic activity, and significant atypia) which is accompanied by nodules in the lung, regional lymph nodes, or other sites having a similar appearance and presumably representing metastases from it.[606] The extrauterine nodules may be just as bland-looking as the original uterine tumor or show features of leiomyosarcoma or STUMP.[607] The interval between hysterectomy and the appearance of the lung nodules is, on average, 15 years. The nodules tend to be multiple, and they have an average size of approximately 2 cm. The patients tend to be younger than those with conventional leiomyosarcoma, and the clinical course is much more indolent, with a median survival of 94 months after the excision of the metastases.[608] Some of these occurrences may be explained on the basis of inadequate sampling of the original tumor, but the fact that in many instances the extrauterine foci have a microscopic appearance that is just as bland suggests that this cannot be the explanation for the entire category. Parenthetically, the similarities with ordinary leiomyomas also apply to their hormone receptor profile (high) and proliferative activity (low).[608,609] They also can show deletion of the long arm of chromosomes 19 and 22.[610] Another possibility that has been advanced is that the extrauterine foci represent independent neoplasms.[611] However, the fact that they have been found to be clonally related speaks in favor of metastasis from a uterine neoplasm.[612,613]

Although this occurrence is unsettling, it is entirely credible. Other examples of tumors that generally behave in a benign fashion but once in a great while result in metastases having the same "benign" appearance certainly exist, benign mixed tumor of the salivary gland being a prime example. We simply have to accept the fact that tumors do not need to have the conventional morphologic attributes of malignancy to be able to metastasize. As to whether the particular neoplasm discussed in this section should be called a metastasizing leiomyoma or a low-grade leiomyosarcoma mimicking a leiomyoma depends on whether one wishes to designate tumors according to their morphology (in which case it would be a leiomyoma) or their behavior (in which case it would be a leiomyosarcoma). We favor the designation of low-grade leiomyosarcoma, once these bland tumors have been found to metastasize and thus declared their biological potential; in this regard, it may be opportune to quote here Julian Huxley—the famous biologist, zoologist, humanist, and popular writer—who, in his lecture on "Biological aspects of cancer," given at the Sloan Kettering Institute in 1955, stated when discussing the policy for designating lesions solely on the basis of their morphology: "This seems a regrettable example of specialist scholasticism. Cancer (malignancy) must be defined operatively in terms of what the tumor cells do, not what they look like; otherwise the term ceases to have biological meaning."[614]

Leiomyosarcoma

Clinical and Gross Features

Leiomyosarcomas occur in an older average age group than leiomyomas (median age, 54 years), although they can also occur in younger patients. Some of the epidemiologic findings in patients with leiomyosarcoma parallel those from studies in endometrial carcinoma and suggest a role for unopposed estrogen stimulation.[615] Some leiomyosarcomas are grossly similar to ordinary leiomyomas, but the majority are soft or fleshy, with necrotic or hemorrhagic areas and signs of invasiveness (Fig. 33.73).[616]

Microscopic Features

Microscopically, typical leiomyosarcomas are hypercellular, with nuclear atypia and pleomorphism, mitotically active (with some of the mitoses being atypical), and with areas of necrosis (Fig. 33.74).[617] Alas, not all leiomyosarcomas will exhibit simultaneously all of these features, whereas some leiomyomas can display one or several of them.[564] The relative importance of these criteria for the differential diagnosis between leiomyoma and leiomyosarcoma is the subject of a special section later.

Figure 33.73 Leiomyosarcoma resulting in a large intramural and submucous mass. There are foci of hemorrhage and necrosis.

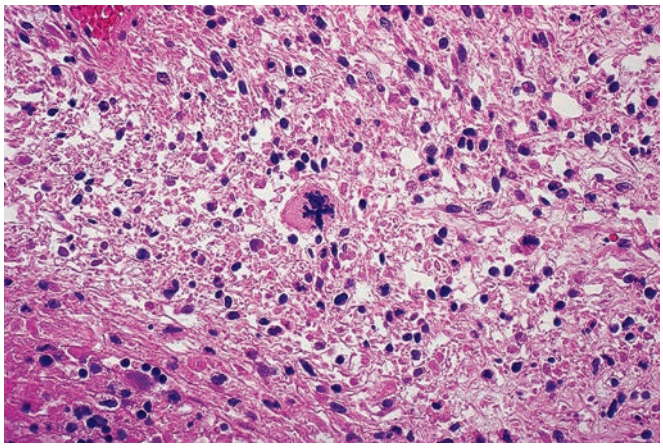

Figure 33.74 Leiomyosarcoma showing hypercellularity, pleomorphism, atypical mitoses, and necrosis.

Electron Microscopic, Immunohistochemical, and Molecular Genetic Features

Ultrastructurally and immunohistochemically, the features of leiomyosarcoma are those of smooth muscle cells.[619,620] There is consistent immunoreactivity for smooth and common muscle actin, desmin, calponin, h-caldesmon, and vimentin.[621] There is also common reactivity for low-molecular-weight keratin (as identified with CAM 5.2) and epithelial membrane antigen,[622] a feature that may lead to a mistaken interpretation, particularly if the tumor cells have an epithelioid appearance.[623] Estrogen and progesterone receptors are expressed, although with less degree of intensity than in leiomyomas.[624,625] The immunohistochemical profile of uterine leiomyosarcomas is somewhat different from that of leiomyosarcomas arising outside the female reproductive tract, probably due at least in part to the estrogen dependency of the former.[585,627]

At the molecular genetic level, there is no evidence of progression from leiomyoma to leiomyosarcoma.[456] Leiomyosarcomas are characterized by complex karyotypes comparable to their soft tissue counterparts. Breakpoint clusters have been mapped to 1q32 and 10q22.[456] In contrast to leiomyoma, there is commonly *TP53* mutation, which usually results in overexpression of p53.[625,629,630]

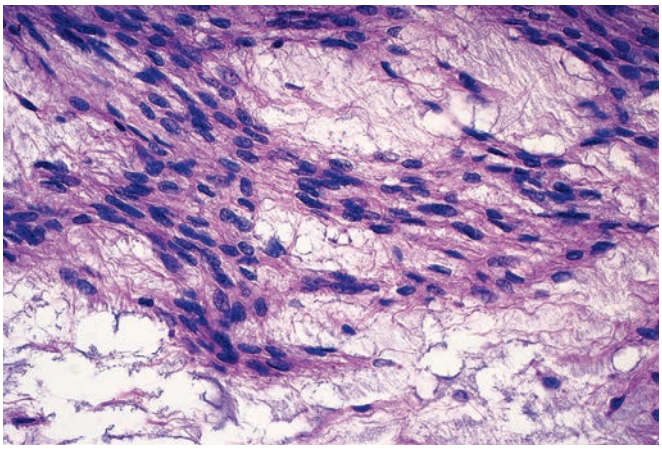

Figure 33.75 Uterine myxoid leiomyosarcoma. (Courtesy Dr. Robert E Scully, Boston.)

Leiomyosarcoma Variants

Epithelioid leiomyosarcoma are rare and must be distinguished from their benign counterpart (i.e. epithelioid leiomyoma).[631–633] General criteria apply (see earlier), such as marked atypia, larger size, infiltrating margins, mitotic activity, and presence of necrosis, and also absence of hyalinization.[631–633] Because of the rarity of epithelioid smooth muscle tumors, the criteria for distinction between benign and malignant are not as well developed as for the more common spindle cell smooth muscle tumors, and the designation of STUMP can be used for tumors with one or two concerning features, where an unequivocal diagnosis of leiomyosarcoma cannot be made. The differential diagnosis also includes endometrial stromal tumors, metastatic carcinoma,[634] and uterine gastrointestinal stromal tumor (GIST), which stain with GIST markers CD117 and DOG-1.[635]

Myxoid leiomyosarcoma can arise in the uterine wall, broad ligament, and other pelvic sites.[636] Grossly, it has a gelatinous appearance and deceptively well-circumscribed borders. Microscopically, however, it is invasive. The stroma is highly myxoid and the tumor cells are arranged as bundles of typical smooth muscle cells alternating with nondescript mesenchymal cells (Fig. 33.75). The main differential diagnosis (an important one) is with leiomyoma with hydropic degeneration. Regarding this differential, it is important to point out that the mitotic count criteria used for the usual leiomyosarcoma (see later) do not apply, in the sense that myxoid leiomyosarcomas tend to recur and metastasize whether mitoses are scanty (which is the usual situation) or numerous.[636,637]

Leiomyosarcoma with osteoclast-like giant cells occurs more frequently in the uterus than in any of the other places where malignant smooth muscle tumors can develop. The smooth muscle nature of the tumor cells—as confirmed immunohistochemically—distinguishes this entity from so-called "malignant giant cell tumor."[638]

Intravenous leiomyosarcomatosis, an exceptionally rare condition, can be viewed as the malignant counterpart of intravenous leiomyomatosis.[639]

Leiomyosarcoma with skeletal muscle differentiation is a vanishingly rare phenomenon similar to that sometimes seen in endometrial stromal sarcoma.[640]

Spread, Metastases, Treatment, and Prognosis

Uterine leiomyosarcoma usually spreads within the pelvis and in the form of distant metastases to the lung, bone, and other sites.[641] It is an aggressive neoplasm and most patients, even with Stage I tumors, die of disease; a curious phenomenon has occurred, attributable to more accurate diagnosis of benign leiomyoma variants that mimic leiomyosarcoma in current practice, that is, the outcomes of patients with stage I leiomyosarcoma in recent series appear worse than in the past.[642] Lymph node metastases are exceptional. The standard treatment is total abdominal hysterectomy with bilateral salpingo-oophorectomy. Prognostic factors include the following:

1. *Tumor stage.* Extension outside the confines of the uterus is a finding of ominous prognosis.[643] In one series of 20 patients in whom this occurred, there were no survivors beyond 29 months.[644]
2. *Tumor size.* This is a significant prognostic factor for tumors confined to the uterus.[645]
3. *Microscopic grade.* There is no accepted grading system for uterine leiomyosarcomas, and no consistent correlation has been found between survival and the histologic grade of the tumor. Specifically, the grading system used for sarcomas of the somatic soft tissue is not applicable.[646] Nonetheless, occasional leiomyosarcomas with more uniform nuclear features, lower mitotic rate, and apparently better outcomes do occur, [647] but we lack criteria to consistently recognize them in practice (except in retrospect).

Relationship Between Morphology and Behavior of Uterine Smooth Muscle Tumors

The majority of uterine smooth muscle tumors are readily classifiable into benign or malignant.[124,648] There are some lesions, however, for which that placement is very difficult, sometimes excruciatingly so.[650] The morphologic reasons for this, which at the same time represent the main criteria upon which to base a decision, are the following:

1. *Necrosis.* Two patterns of necrosis have been identified in smooth muscle tumors, respectively, named coagulative tumor cell necrosis and hyaline ischemic-type. In the former there is an abrupt transition between the necrotic and the viable cells. On low power, the typical appearance is that of a cuff of preserved tumor cells around large vessels surrounded by large expanses of necrotic tumor. On high power, two of the classic morphologic forms of nuclear necrosis (pyknosis and karyorrhexis) are evident. In hyaline/ischemic-type necrosis, there is a distinct zonal pattern reminiscent of an evolving infarct: a center of "bland" necrosis (i.e. one in which nuclear debris is difficult to see), a periphery of granulation tissue, and a layer of hyalinized collagen in between. Coagulative tumor cell necrosis, as defined previously, is currently regarded as the most important criterion of malignancy in these tumors. Unfortunately (but predictably) there is considerable interobserver variation in assessment of coagulative tumor cell necrosis.[651]
2. *Mitotic activity.* This remains another important criterion despite the admittedly imprecise fashion in which it is measured in terms of lack of standardization and poor reproducibility,[652–654] in the sense of being influenced by the thickness of the slide, microscope magnification factor, size of tumor cells, proportion of tumor cells to stroma, and observer criteria.[655] Regarding the latter, a common mistake among neophytes is to count the pyknotic nuclei often seen scattered around in smooth muscle tumors (whether from lymphocytes, mast cells, or smooth muscle cells) as mitotic figures. Another theoretical source of variation is the interval between excision and fixation, but this seems not to be important. Some practical measures can be taken to improve accuracy. One is to scan the sections for the *most active area*, do the mitotic count in 10 *consecutive fields* in that area, and repeat the procedure a minimum of *four times.* Another obvious measure is to sample the tumor adequately. Kempson[652] recommends a total of *at least 10 sections or one section for each centimeter of diameter, whichever is greater.* Note that this guideline applies to tumors with atypical gross or microscopic features, and not the majority of usual benign leiomyomas. HPF usually means the combination of a 10× eyepiece and a 40× objective. If the operator is using a 15× eyepiece and/or a 63× objective, adjustments should be made. The criteria for identifying mitotic figures should be strict. The members of the Multicenter Morphometric Mammary Carcinoma Project proposed the following:[656]
   1. The nuclear membrane must be absent, so cells must have passed the prophase.
   2. Clear, hairy extensions of nuclear material (condensed chromosomes) must be present, and clotted (beginning metaphase), in a plane (metaphase/anaphase), or in separate clots (telophase). Regular extensions with an empty central zone favor a nonmitosis.
   3. *Atypia.* This refers to the combination of pleomorphism (meaning marked differences in size and shape) and nuclear hyperchromasia, and should already be evident on low-power examination. It is classified as focal or extensive, and graded (acknowledging the subjectivity of the exercise) as mild, moderate, or severe.
   4. *Cellularity.* The term is self-explanatory and the determination just as subjective. This is one of the least important parameters in this exercise.
   5. *Tumor borders*, that is, the relationship of the tumor with the surrounding myometrium.

   The evaluation of these criteria, alone and in combination, allows a fairly accurate *but not infallible* prediction of tumor behavior. The points worth stressing are the following:
   1. The weight of the morphologic factors, in order of significance, is coagulative tumor cell necrosis, high mitotic activity, pleomorphism, and cellularity (remembering that most leiomyosarcomas are evidently malignant at presentation, based on macroscopic evidence of invasiveness and metastasis, so that very detailed histomorphologic assessment is not necessary).
   2. Tumors that are hypercellular but lack the other criteria are to be regarded as benign cellular leiomyomas.
   3. Noninfiltrative tumors with atypia (even if marked and diffuse) should not be regarded as malignant if they lack coagulative tumor cell necrosis and mitotic activity is less than 10/10 HPF. Rather, they belong to the category of *leiomyoma with bizarre nuclei* if mitoses are rare (<2/10 HPF) and to the category of STUMP if mitotic activity is 2–10/10 HPF.
   4. Tumors with increased mitotic activity (up to 15 mitoses per 10 HPF) but lacking coagulative tumor cell necrosis and atypia are to be regarded as *mitotically active leiomyomas*.
   5. Tumors with coagulative necrosis and diffuse atypia and/or increased mitotic activity (>10 per 10 HPF) should be regarded as leiomyosarcomas.
   6. Tumors with coagulative necrosis but neither atypia nor increased mitotic activity should be diagnosed as STUMP.
   7. Tumors with diffuse moderate-to-severe atypia *and* 10 or more mitoses per 10 HPF should be called leiomyosarcoma even if they lack coagulative tumor cell necrosis.

   These recommendations are primarily based on the careful and painstaking work done by Richard Kempson and colleagues over a 35-year period.[648,655,657–661] Some modifications are made, based on the 2014 WHO guidelines,[662] and this approach to diagnosis is illustrated in a simplified form for the benefit of the reader in Table 33.2. Although Kempson and colleagues did not propose a "STUMP"

Table 33.2 Criteria and diagnostic terms for uterine smooth muscle tumors

COAGULATIVE TUMOR CELL NECROSIS	MITOTIC COUNT PER 10 HPF	ATYPIA		DIAGNOSIS
Present	Greater than 10	Moderate to severe (focal or diffuse)		Leiomyosarcoma
		None to mild		Leiomyosarcoma
	Equal to or less than 10	Moderate to severe (focal or diffuse)		Leiomyosarcoma
		None to mild		STUMP
Absent	Greater than 10	Moderate to severe	Diffuse	Leiomyosarcoma
			Focal	STUMP
		None to mild		Mitotically active leiomyoma (up to 15 mitoses/10 HPF are allowed)
	1 to 10	Moderate to severe	Diffuse	STUMP
			Focal	STUMP
		None to mild		Mitotically Active Leiomyoma

Data from Kempson RL, Hendrickson MR. Smooth muscle, endometrial stromal, and mixed Mullerian tumors of the uterus. *Mod Pathol*. 2000;13:328–342.

category, it has been retained in this table, in keeping with the WHO classification.[662]

In our opinion, one would serve the patient and the clinician better (and would also be closer to expressing the truth) by doing away with the traditional binary classification of these tumors into benign and malignant (i.e. leiomyoma versus leiomyosarcoma), which is improved only slightly by the addition of a STUMP category, and by switching to a nomenclature that would simply identify these neoplasms as smooth muscle tumors, followed by an estimation (ideally expressed in percentages) of the probability of the tumor recurring or metastasizing, based on a careful evaluation of all the parameters discussed in this section and any others that may be found of help in this regard. Until and unless such a radical change in nosology takes place, and as long as we subject ourselves to the current Manicheist approach, the above recommendations will have to do.

Two additional comments are in order. These considerations have been devised for the conventional type of uterine smooth muscle tumor and cannot be applied unchanged to the variants. For instance, myxoid leiomyosarcoma is to be diagnosed as such even if in most cases it lacks coagulative necrosis, increased mitotic activity, and severe atypia.

The other comment applies to the hope that the abundant information that is being obtained regarding the genotypic features of these tumors will provide assistance to the pathologist in terms of an accurate prognostic assessment and a precise therapeutic recommendation. The most promising modality to date is comparative genomic hybridization with determination of a genomic index; this can separate leiomyomas, with minimal genomic perturbation, from leiomyosarcomas, and identifies STUMPs with high versus low risk of recurrence but is some ways off from being sufficiently validated for everyday use.[663] It is fair to say that the decision to place a uterine smooth muscle tumor into a given prognostic category remains for now largely dependent on the time-honored morphologic criteria.

PEComa

Perivascular epithelioid cell tumors (PEComas) are tumors showing both melanocytic and smooth muscle differentiation.[664] They occur at non-gynecologic sites, and their recognition in the uterus was delayed because of their rarity and the overwhelming number and variety of uterine smooth muscle tumors; undoubtedly in the past these were diagnosed as smooth muscle tumors, especially of the epithelioid variant. Some of these tumors are associated with pelvic lymphangiomyomatosis and/or have developed in patients with tuberous sclerosis.[665-668] They can be benign or malignant; because there are few reported cases, the criteria for diagnosis of malignancy are not well established.[664,669] The uterine corpus is the most common location of PEComas of the female reproductive organs; grossly they resemble smooth muscle tumors. Microscopically they consist of epithelioid cells or a mixture of epithelioid and spindle cells. Conspicuous sclerosis is present in some tumors. Necrosis is present in almost half, as is significant nuclear atypia. Mitotic activity is variable, from undetectable to brisk. The tumor cells consistently stain for HMB-45, with a minority of case showing immunoreactivity for Melan-A or MiTF.[664,670] Smooth muscle markers (smooth muscle actin, desmin, caldesmon) are expressed in approximately 2/3 of cases.[664] Features associated with malignancy include size greater than 5 cm, infiltrative margin, high nuclear grade, increased cellularity, mitotic rate >1/50 HPF, vascular invasion, and necrosis.[669] The absence of ALL these features is associated with benign behavior, while it has been suggested that the presence of one feature should lead to designation as "uncertain malignant potential," and two or more of these features is associated with malignant behavior in most cases.[664,669]

There are case reports of PEComatosis, with multiple PEComas variously involving the female reproductive organs, bowel wall, omentum, and lymph nodes.[671]

Both syndromic (tuberous sclerosis complex) and sporadic PEComas are associated with TSC1 or TSC2 inactivation.[672] TFE-3 translocations have been identified in a subset of PEComas.[560,673]

Inflammatory Myofibroblastic Tumor

Inflammatory myofibroblastic tumor is similar to PEComa in that it can occur at many sites in the body but when it was present in the uterus it has often been mistaken for a smooth muscle tumor. Inflammatory myofibroblastic tumors of the uterus can occur at any age, including in childhood.[675–677] They can appear ill-defined grossly but tend to resemble leiomyomas. The microscopic appearance is identical to inflammatory myofibroblastic tumors occurring elsewhere in the body; the plump spindle cells can be separated by edematous stroma, grown in fascicles, or there can be stromal hyalinization (Fig. 33.76).[677] The myxoid areas can raise the differential diagnosis of myxoid leiomyosarcoma or a myxoid pattern of endometrial stromal sarcoma, such as the subtype with *BCOR* alteration.[676] A

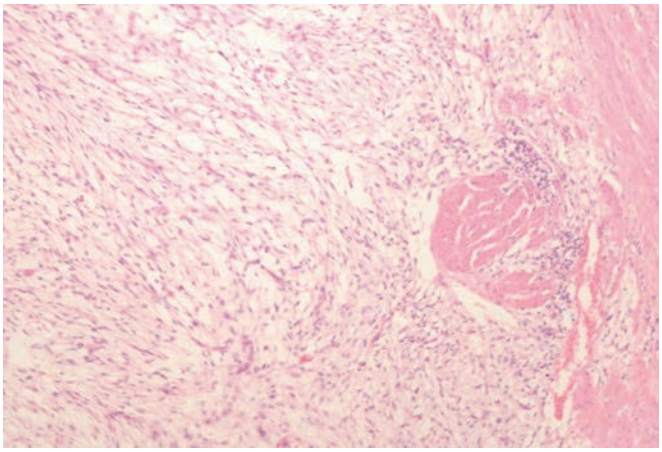

Figure 33.76 Inflammatory myofibroblastic tumor.

mononuclear inflammatory infiltrate rich in plasma cells is invariably present but may be sparse in areas. ALK immunoreactivity is an important diagnostic adjunct, distinguishing inflammatory myofibroblastic tumor from smooth muscle neoplasms.[677] Some have pursued an aggressive course.[676]

Gestational Trophoblastic Neoplasia

There is a group of diseases related to normal or abnormal gestation that have as a common denominator the proliferation of trophoblast and that are generically designated as *(gestational) trophoblastic neoplasia*. The individual disorders differ remarkably in appearance and clinical significance. The major ones are hydatidiform mole (complete, partial, or invasive), placental site trophoblastic tumor, and choriocarcinoma.[678] The pathogenesis of these remains poorly understood, but genomic imprinting is believed to play a key role in the formation of hydatidiform moles.[679-681]

Hydatidiform Mole

In hydatidiform moles, the trophoblastic proliferation is associated with swelling of the villi. They are subdivided into complete and partial types, and either type can be invasive.

Complete Mole

Complete hydatidiform mole is caused by abnormal gametogenesis and fertilization. The nuclei of the trophoblastic cells in this disease contain only paternal chromosomes and are, therefore, androgenetic in origin.[682,683] In most cases the chromosomal number is normal; 85% of cases are 46,XX and 15% are 46,XY. In a minority of cases, the DNA pattern is tetraploid, these generally occurring in an older age group.[656]

There is a striking geographic variation in the frequency of complete mole. In Southeast Asia, the reported incidence is at least 4 to 5 times greater than in the United States.[684,685] Yet higher incidences have been reported from Mexico (1:200), the Philippines (1:173), India (1:160), Taiwan (1:125), and Indonesia (1:82).[686] A history of previous term birth reduces the risk of molar pregnancy, whereas a history of a previous mole greatly increases the probability of developing another.[685,687,688] "Repetitive" moles are usually of complete type, but they can be of partial type, or a complete mole may be followed by a partial mole.[689]

Clinically, the uterus involved by a complete mole is disproportionately large for the stage of pregnancy.[690] Serum hCG levels continue to rise after the 14th week, as opposed to the drop typically seen in the course of normal gestation. Evidence of toxemia of pregnancy (hypertension, edema, albuminuria) is frequently found, and this typically occurs during the early stages of the pregnancy. Exceptionally, hyperthyroidism develops as a result of a thyroid stimulator secreted by the molar tissue, perhaps residing in the hCG molecule itself.[691–693] At the time of the medical consultation there may be vaginal bleeding, a sign that the mole has begun to abort spontaneously.

Grossly, the complete mole has been typically described as a "bunch of grapes," with all or nearly all the villi showing hydropic degeneration. The individual vesicles measure anywhere from 1 to 30 mm in diameter, and the total weight is usually over 200 g. In a hysterectomy specimen, these swollen villi are seen to fill and distend the uterus (Fig. 33.77). Characteristically, there are no identifiable embryo, cord, or amniotic membranes. The exceptional cases of bona fide complete mole in which an embryo is present almost invariably represent a twin gestation.[694,695]

Microscopically, the two constant features of a complete mole are *trophoblastic hyperplasia* and *vesicular swelling*, the latter probably representing a secondary phenomenon. The severity of the changes varies considerably from case to case and from villus to villus and may be difficult to appreciate in very early cases, as evidenced by the high degree of interobserver and intraobserver diagnostic variability.[696–698] Some of the villi are surrounded by an attenuated layer of degenerating trophoblast. In others, the trophoblast forms large hyperplastic sheets of cells (Fig. 33.78). The distended core of the villus is traversed by widely separated, broken strands of fibrillar material ("cistern" formation). Vessels seem absent or very scanty in hematoxylin–eosin-stained sections, even though they do not seem very diminished in number in CD34-stained preparations.[699] The stromal changes of molar villi, which include stromal mucin and stromal nuclear debris (apoptosis), appear very early and represent a diagnostic clue.[700–702] The trophoblastic hyperplasia characteristically has a circumferential but haphazard arrangement around the individual villi, as opposed to the polar proliferation seen in normal first-trimester villi. The plexiform pattern of intermixed syncytiotrophoblast and cytotrophoblast seen in choriocarcinoma does not occur. Trophoblastic hyperplasia with atypia also occurs at the implantation site, to a much greater degree than in hydropic villi of abortion or partial moles.[703]

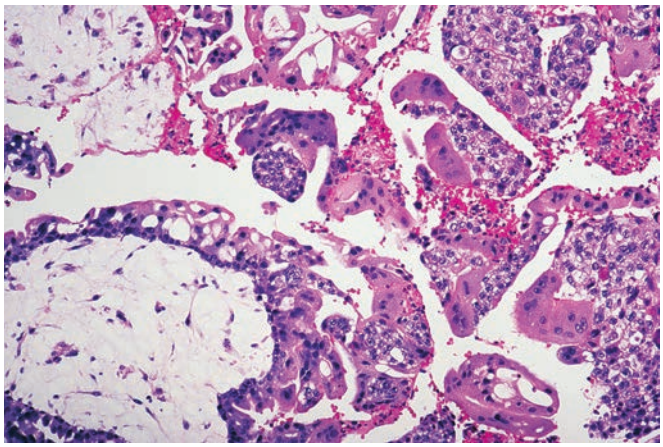

Figure 33.78 Complete mole showing large villi with stromal edema and marked trophoblastic proliferation.

Ultrastructurally, the molar trophoblast closely resembles that seen during the first trimester of a normal pregnancy.[704]

Immunohistochemically, hCG is widely distributed and PLAP is patchily distributed in the molar syncytiotrophoblast regardless of gestational age, whereas hPL tends to increase with increased gestational age.[705,706] Both the α- and β-subunits of inhibin are evident in the molar syncytiotrophoblast.[707,708] A very useful marker for the differential diagnosis of complete mole is $p57^{kip2}$ protein, a cell cycle inhibitor and tumor suppressor encoded by a strongly paternally imprinted gene. It is expressed in the cytotrophoblast and villous mesenchyme of normal pregnancy, spontaneous abortions, and partial moles but absent or very markedly decreased in complete moles because both copies of the *TP57* gene are of paternal origin.[709–712]

By flow cytometry, complete moles are most commonly diploid, with the non-diploid being tetraploid in a most instances.[713] Heterozygous (dispermic) moles, including dispermic heterozygous XY moles, are associated with a higher incidence of persistent trophoblastic disease than homozygous (monospermic) moles.[714]

The initial therapy of complete mole consists of evacuation of the uterus by curettage.[715] This is followed by sequential quantitative determination of the β-subunit of hCG.[716,717] The standard recommendation has been to measure the serum level of hCG at 10, 20, 30, 45, and 60 days after termination of the molar gestation. In approximately 80% of cases, normal levels will be reached by day 60. If there is rising titer between day 45 and day 60 or the level is still elevated by day 60, chemotherapy is administered; this is necessary in approximately 20% of cases.[718] With this approach, the cure rate is close to 100%.[719] Unfortunately, the use of etoposide has been found to be associated with an increased risk of development of second tumors.[720]

Other authors recommend the administration of chemotherapy to those patients who have a plateau of three high values of hCG over a 2-week period after evacuation of the mole (approximately 20%–30% of cases). Still others recommend waiting for 4 weeks or even 2 months before initiating chemotherapy, especially if the hCG levels are low.[721]

In a series of 738 patients with mole, spontaneous regression occurred in 81%. Of the remaining patients, 17% developed an invasive mole, and 2% developed choriocarcinoma.[722] The presence of villi or atypical trophoblast following the evacuation of a molar pregnancy indicates "persistent trophoblastic disease," but the decision of whether to give chemotherapy or not still largely depends on the hCG levels.

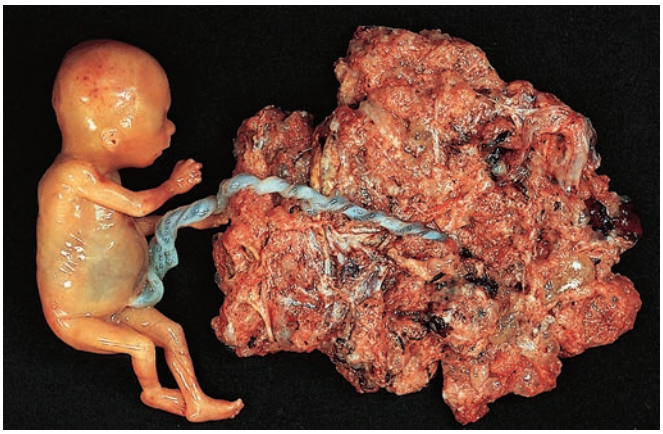

Figure 33.79 Partial Mole With Attached Fetus. The fetus showed no abnormality and was connected to the mole by a normal umbilical cord. (Courtesy Dr. Pedro J Grases Galofré; from Grases Galofré PJ. *Patología ginecológica. Bases para el diagnóstico morfológico*. Barcelona: Masson; 2002.)

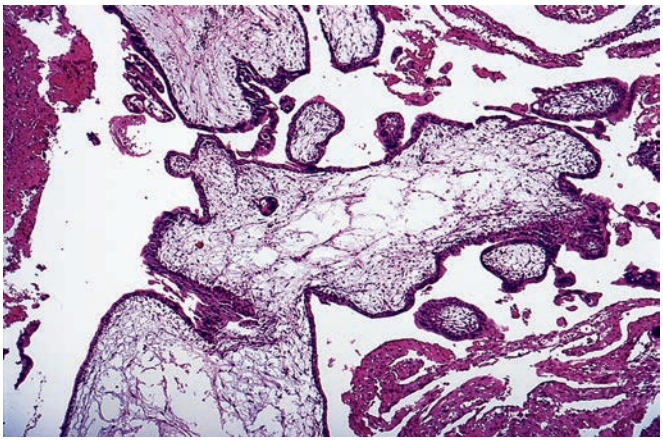

Figure 33.80 Partial mole showing scalloping of villi and isolated trophoblastic cells embedded in the stroma.

Partial Mole

Approximately 15%–35% of all moles are of the partial type. In contrast to complete mole, the condition is often associated with the presence of an embryo, although this is usually abnormal ("blighted ovum"). The volume of placental tissue is relatively normal, and the grossly vesicular villi are mixed with normal-appearing ones (Fig. 33.79). The former often show focal edema leading to central "cisternal" formation and stromal inclusions of trophoblast (Fig. 33.80). Many of the villi have an irregular, scalloped outline and contain vessels with fetal (nucleated) red blood cells. Fibrosis of the villous stroma is common. Trophoblastic proliferation is present, although generally to less degree than in complete mole; cytoplasmic vacuolization of the syncytiotrophoblast is prominent.[723]

Most partial moles are triploid (69,XXX or 69,XXY) and a few show trisomy 16.[724–726] The extra material is of paternal derivation (so-called "diandric triploidy").[727]

Because of the generally small size of the lesion, the uterine size is nearly always small or appropriate for the gestational age. Serum hCG levels—although elevated—tend to be relatively low, and the ovarian theca-lutein cysts that commonly accompany complete moles do not occur.[728] The risk for the development of choriocarcinoma

following a partial mole is very low, but a few well-documented cases are on record.[729,730] Furthermore, some series document a 5%–10% incidence of persistent disease (lower in those evacuated early),[731] indicating that follow-up of these patients is mandatory.[732–734] Some of the recurrences have been in the form of invasive mole[735–737] and some in the form of lung metastases.[738]

As already pointed out, not all placentas of triploid conceptuses show partial molar transformation; some (perhaps the majority) have a normal morphologic appearance.[739] The triploid fetuses in both groups tend to die at about 8 weeks menstrual age.[740]

Partial moles should be distinguished on one hand from complete moles and on the other from the hydropic villi seen in 15%–40% of spontaneous abortions and with rare conditions such as placental stem villous hydrops, mesenchymal dysplasia, and Beckwith–Wiedemann syndrome.[741] As noted previously, the pattern of p57 immunostaining, with expression in cytotrophoblast and villous mesenchyme, serves to distinguish between complete and partial mole but is not helpful in the distinction between partial mole and hydropic abortion. With regard to the differential diagnosis between partial mole and hydropic abortion, in the latter gross villous swelling and cistern formation are not present. As already stated, the villous trophoblast in spontaneous abortions either is attenuated or—if proliferating—has a polar distribution. Furthermore, trophoblastic atypia is absent or minimal. Flow cytometry studies are of great assistance in the evaluation of this problem, with triploidy favoring a diagnosis of partial mole, being mindful that triploid spontaneous abortions do occur, but lack histologic features of partial mole.[727,732,742] Flow cytometry for ploidy assessment is not widely available and FISH for HER2, which is, can serve as a surrogate test, as trisomy for chromosome 17, as determined with the HER2 and centromeric probes used for breast and gastric cancer HER2 FISH, is an indicator of triploidy.[743] The "gold standard," however, in the diagnosis of mole is genotypic analysis using the technology developed for DNA fingerprinting/forensic identification, as it allows determination of copy number and parent of origin of the DNA, improving diagnostic accuracy.[744] This approach is not widely available and is relatively expensive, so the diagnosis of molar pregnancy is still based largely on routine histology with liberal use of p57 immunostaining.

Invasive Mole

The term *invasive mole* refers to a hydatidiform mole (nearly always of the complete type but occasionally of the partial type) in which villi penetrate deeply the myometrium and/or its blood vessels (Figs. 33.81–33.83).[745,746] This phenomenon, which occurs in 16% of all complete moles, is an exaggerated expression of the capacity of normal trophoblast for invasion, a necessary property for implantation.

The myometrial permeation in invasive mole may be extensive and may lead to persistent hemorrhage, but the serosa is usually intact. However, uterine perforation may occur. The vascular invasion may result in trophoblastic nodules in sites outside the uterus, such as the vagina, lung, brain, and spinal cord.[747,748] The lung nodules have a characteristic radiographic appearance[749,750]; they continue to produce hCG and have a similar tendency for hemorrhagic complications. The clinical manifestations depend on the site involved: a sizable mass in the lung may regress spontaneously without ever causing symptoms, whereas a deposit in the brain may produce fatal hemorrhage.[751,752]

It should be mentioned that invasive mole is distinguished from the usual mole by its invasiveness and from choriocarcinoma by the presence of villi, which are also present in the "metastatic" foci. The degree of trophoblastic proliferation in invasive mole does not differ significantly from that of its ordinary counterpart. Patients

Figure 33.81 Gross Appearance of Invasive Mole. A hemorrhagic mass has permeated half of the thickness of the myometrial wall.

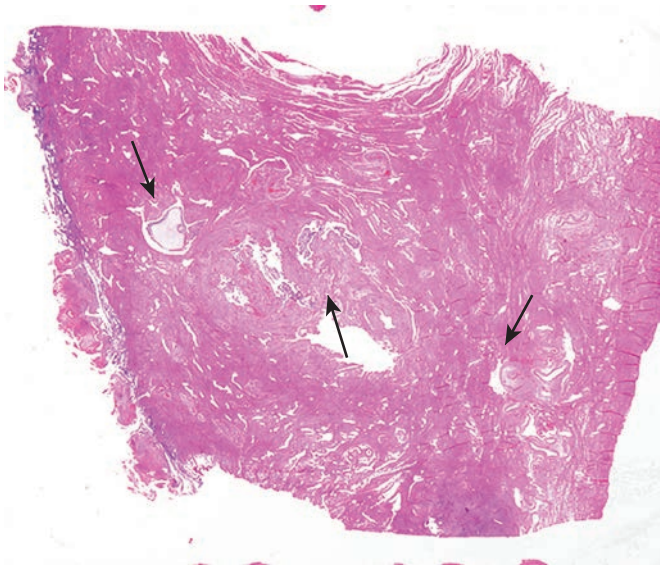

Figure 33.82 Whole-Mount View of Invasive Mole. Abnormal villi are seen permeating the thickened myometrium *(arrows)*.

with invasive mole are primarily treated with chemotherapy, but hysterectomy may be indicated in some circumstances.[746,753]

Choriocarcinoma

Choriocarcinoma, when untreated, is the most aggressive form of gestational trophoblastic neoplasia. Most cases occur following a complete hydatidiform mole; consequently, this malignant tumor is more common in areas of the world in which hydatidiform mole is prevalent. It has been estimated that 1%–2% of complete moles are followed by choriocarcinoma.[754]

Choriocarcinoma can also be preceded by a partial mole (a very unusual event), ectopic pregnancy, nonmolar intrauterine abortion, or term pregnancy.[755–757] In the latter instance, which is exceptionally rare, the tumor may appear as one or more masses in an otherwise normal placenta or develop following the delivery.[758–760] In addition, cases of "in-situ" choriocarcinoma arising from the trophoblast of stem villi in the first trimester of pregnancy have been described.[761]

In cases of choriocarcinoma following abortion—whether molar or not—the latent period is almost always less than 1 year, although it can be considerably longer ("latent choriocarcinoma").[762] At the time of the diagnosis of the malignancy, the average age of the patient is 29 years.

Grossly, choriocarcinoma characteristically forms soft, dark red, hemorrhagic, round nodular tumor masses (Fig. 33.84). Microscopically, the tumor is composed of clusters of cytotrophoblast separated by streaming masses of syncytiotrophoblast, resulting in a characteristic dimorphic plexiform pattern (Fig. 33.85).[763] Hemorrhage and necrosis are usually present but have no real diagnostic significance, since they are also commonly found in spontaneous abortions. Villi are characteristically absent; as a matter of fact, their presence is said to rule out the diagnosis of choriocarcinoma no matter how atypical the trophoblastic cells may be.[764]

Immunohistochemically, choriocarcinoma cells are positive for hCG and keratin. There may also be reactivity for hPL, SP1, and CEA.[765] There can be a minor component of intermediate trophoblastic cells immunoreactive for hPL, CD146 (Mel-CAM), HLA-G, and inhibin.

The natural history of untreated choriocarcinoma is characterized by the development of early hematogenous metastases, the most common sites being the lung, brain, liver, kidney, and bowel.[766–768] They can be clinically solitary, may occur in the most unusual places, and often present with massive hemorrhage.[769] Interestingly, the fetus is rarely involved, even in cases of widespread metastatic disease.[770] Residual tumor in the uterus of patients dying of disseminated choriocarcinoma may be inconspicuous or altogether absent.[771]

Many of the morphologic changes seen in other organs in patients with choriocarcinoma are the result of increased secretion of hCG and other hormones by the tumor cells. These include hyperplasia of endocervical glands, decidual reaction (both endometrial and ectopic), Arias-Stella phenomenon, bilateral enlargement of the ovaries by theca-lutein cysts ("hyperreactio luteinalis"), and hyperplasia of mammary lobules. The detection of ovarian theca-lutein cysts long after a case of choriocarcinoma has been treated is usually a sign of persistent disease.[772] In the endometrial decidual reaction of patients with choriocarcinoma, the spiral arterioles fail to develop as they do in the normal cycle, the appearance of the mucosa being similar to that seen after the administration of progestogens.[771]

The evolution of the treatment of choriocarcinoma (and of gestational trophoblastic neoplasia in general) is one of the greatest success stories in medical oncology.[773] When treated by surgery alone, the cure rate was only 40% for tumors apparently restricted to the uterus and less than 20% for those accompanied by metastases.[774] With the use of chemotherapy, the survival rate is close to 100% for cases restricted to the uterus and approximately 83% for patients with metastatic disease.[775,776] Low- and high-risk patient groups have

Table 33.3 FIGO/WHO Prognostic Index Score for gestational trophoblastic neoplasia

	SCORE[a]			
PROGNOSTIC FACTOR	**0**	**1**	**2**	**4**
Age (years)	≤39	>39	—	—
Antecedent pregnancy	Hydatidiform mole	Abortion	Term	—
Interval (months)[b]	4	4–6	7–12	>12
β-hCG (IU/L)	$<10^3$	10^3–10^4	10^4–10^5	$>10^5$
Largest tumor, including uterine tumor	<3 cm	3–5 cm	>5 cm	–
Site of metastases	Lung	Spleen, kidney	Gastrointestinal tract	Brain, liver
Number of metastases identified	—	1–4	5–8	>8
Prior chemotherapy	—	—	Single drug	Two or more drugs

[a]The total score for a patient is obtained by adding the individual scores for each prognostic factor: low risk, 0–6; high risk, ≥7.
[b]Interval is time between end of antecedent pregnancy and start of chemotherapy.
From Kurman RJ, Carcangiu ML, Herrington CS, Young RH, eds. *WHO Classification of Tumors of the Female Reproductive Organs*. Lyon: IARC; 2014.

been identified on the basis of location of metastases, hCG, and duration of the disease (Table 33.3).[777]

In most cases the uterus can be retained. Hysterectomy is performed in those patients in whom preservation of the reproductive function is not desired and/or who are unresponsive to chemotherapy alone. Surgery also remains useful in controlling life-threatening hemorrhage from metastatic lesions.[778,779]

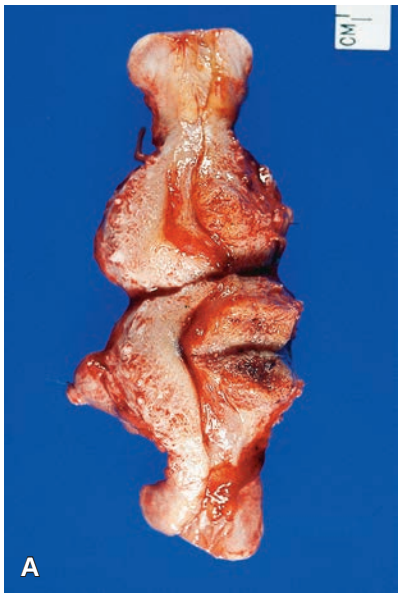
The importance of early diagnosis, prompt institution of therapy, and monitoring of the effects of treatment with sequential quantitative determination of hCG production cannot be overemphasized. In regard to the latter, it should be mentioned that hCG secretion is by no means restricted to gestational choriocarcinomas. It can also occur in nongestational choriocarcinoma; other ovarian and testicular germ cell tumors; melanoma; malignant lymphoma; and carcinomas of the esophagus, stomach, pancreas, kidney, liver, lung, urinary bladder, uterus, adrenal gland, breast, and other sites. A feature common to many of these tumors is the presence of tumor giant cells shown to contain hCG by immunocytochemical techniques.[780]

Genetic studies using the same technique used to aid in diagnosis of molar pregnancy, described previously, and distinguish gestational from nongestational choriocarcinoma by identification of paternal DNA.[744]

Placental Site Trophoblastic Tumor and Related Lesions of Intermediate Trophoblast

Placental site trophoblastic tumor is a rare form of trophoblastic disease.[782–784] About 75% of cases follow a normal pregnancy, with only 5% of the reported patients having had a preceding molar pregnancy.[785] A paternally derived X chromosome and the absence of a Y chromosome may be necessary for its formation, consistent with an origin from the trophectoderm of a female conceptum.[786,787] It presents grossly as a myometrial mass that can be well localized or ill defined (Fig. 33.86A). Hemorrhage is not as conspicuous as in invasive mole or choriocarcinoma. The uterine penetration may be deep, and perforation may result, either spontaneously or following curettage.

Microscopically, large trophoblastic cells with abundant eosinophilic cytoplasm and nuclear pleomorphism are seen invading the myometrium and vessel lumina (see Fig. 33.86B). The morphologic, ultrastructural, and immunohistochemical features of these cells correspond to those of intermediate trophoblast.[788–791] As such, the immunoreactivity for hPL is strong and widespread, whereas that for hCG tends to be focal.[792,793] There is also positivity for keratin, CD66a (CEACAM1), CD146 (Mel-CAM), pregnancy-associated major basic protein, HLA-G, and inhibin.[794–796] The DNA pattern, as determined by flow cytometry, is usually diploid,[797,798] and this seems to also be the case in the rare examples with malignant behavior.[799] The Ki-67 labeling index is higher than in exaggerated placental site reaction but lower than in choriocarcinoma.[800] There is no expression of p63, an useful feature in the differential diagnosis with epithelioid trophoblastic tumor (see later).[801]



Although this condition was initially considered to be an exuberant form of syncytial endometritis,[782] additional experience has shown that it is instead a neoplastic process with a 10%–20% mortality rate if not treated properly.[802] Some cases have resulted in widespread metastases;[797,803] these have generally shown a high mitotic count in the primary tumor, extensive necrosis, and/or a preponderance of cells with clear cytoplasm.[783]

Serum hCG levels in placental site trophoblastic tumor are usually not as high as in choriocarcinoma and may not accurately reflect the extent of the disease. Sometimes the tumor is totally resistant to chemotherapy.[804,805] A distinctive renal glomerular lesion accompanied by proteinuria and hematuria and characterized by occlusive eosinophilic deposits in the glomerular capillary lumina has been observed in connection with this neoplasm.[806]

The differential diagnosis of placental site trophoblastic tumor includes other gestational trophoblastic diseases, as well as nonneoplastic placental proliferations of intermediate trophoblast, especially placental site nodule. In contrast to placental site nodule, placental site trophoblastic tumor shows confluent growth of intermediate trophoblast and Ki-67 labeling index of greater than 10%. The distinction with choriocarcinoma is made because of a lack of a dimorphic population of cytotrophoblast and syncytiotrophoblast (although scattered multinucleated cells may be present), lack or paucity of hemorrhage, and the presence of an interdigitating pattern of muscle invasion.

Epithelioid Trophoblastic Tumor

Epithelioid trophoblastic tumor, the latest entry into the gestational trophoblastic disease family, was originally described as a peculiar

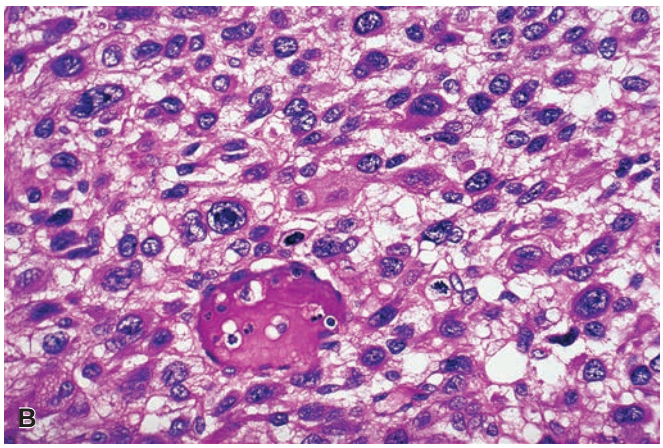


Figure 33.86 A and **B,** Placental site trophoblastic tumor. **A,** Gross appearance. A solid hemorrhagic nodule is seen distending the myometrium and protruding into the endometrial cavity. **B,** Microscopic appearance. Medium-sized cells of intermediate trophoblastic type are seen growing in a diffuse fashion into the myometrium. The biphasic pattern resulting from the admixture of cytotrophoblast and syncytiotrophoblast, which is typical of choriocarcinoma, is absent.

change in the metastatic foci of choriocarcinoma surgically excised following chemotherapy[807] but is now known to also occur de novo. Like the other members of the family, it usually occurs in the reproductive age group (although it can be seen after menopause),[808] and it presents with abnormal vaginal bleeding. The primary tumor most commonly occurs in the endomyometrium but can sometimes be centered in the uterine cervix,[809] develop outside the uterus in places such as the broad ligament,[810] or even present as a primary lung tumor, simulating microscopically squamous and pleomorphic carcinomas of this organ.[811] hCG levels are usually elevated. Grossly, it is solid and cystic, discrete, and hemorrhagic. Microscopically, it is composed of a relatively uniform population of intermediate trophoblastic cells forming nests and solid masses. Necrosis is extensive, and there is a hyaline matrix with a geographic configuration (Fig. 33.87). The appearance closely simulates that of a carcinoma. Immunohistochemically, there is diffuse reactivity for keratin, α-inhibin, EMA, p63, HLA-G, and E-cadherin but only focal reactivity

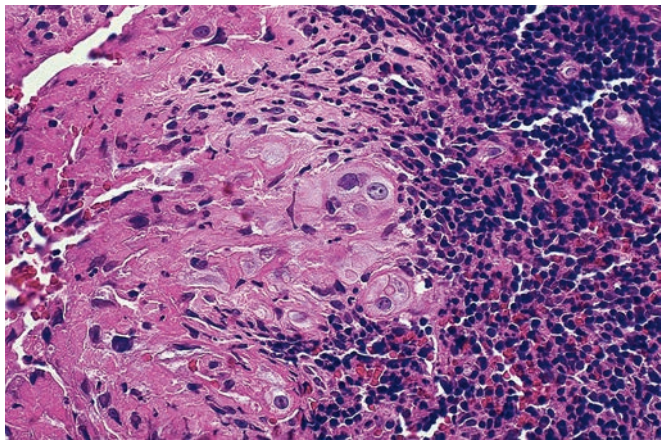

Figure 33.87 Epithelioid Trophoblastic Tumor. The microscopic appearance closely simulates carcinoma of either squamous or glassy cell type.

for hPL, hCG, PLAP, and CD116 (Mel-CAM).[812] Positivity for cyclin E helps in the differential diagnosis with placental site trophoblastic tumor, and lack of reactivity for p16 is useful in the differential diagnosis with cervical and other types of carcinoma.[813] Shih and Kurman[814] believe that the tumor is composed of chorion laeve-type intermediate trophoblast. Molecular genetic analysis has confirmed its trophoblastic origin by demonstrating a Y-chromosomal locus and/or new (paternal) alleles not present in the adjacent normal uterine tissue.[815] It behaves as a malignant tumor, with metastases to lung and other sites.[814]

Tumorlike Conditions of Intermediate Trophoblast. Nonneoplastic proliferations of intermediate trophoblast that can create serious problems in the differential diagnosis with malignant trophoblastic tumors are exaggerated placental site reaction, placental site nodule, and placental site plaque.[816]

Exaggerated placental site reaction was called syncytial endometritis in the past, but this was a double misnomer since the lesion is not primarily of inflammatory nature and is not composed of syncytiotrophoblast. As the currently preferred name indicates, it is believed to be the result of excessive but otherwise normal infiltration of the implantation site by intermediate trophoblast (Fig. 33.88). Its distinction from placental site trophoblastic tumor can be difficult because the cytologic and immunohistochemical features are very similar. Exaggerated placental site is to be favored when the lesion is microscopic in size, lacks mitotic activity, contains a hyaline material between the trophoblastic cells, and is admixed with decidua and villi.

Placental site nodules and plaques appear as single or multiple, mostly well-circumscribed, variably cellular round or flat lesions (nodules and plaques, respectively) that tend to be extensively hyalinized (Fig. 33.89).[817,818] Most cells have abundant amphophilic or acidophilic cytoplasm, irregularly shaped nuclei, and very scanty mitotic activity, but others have a glycogen-rich clear cytoplasm.[819] Mallory bodies (representing abnormal cytoplasmic aggregates of keratin filaments) may be present.[820] These nodules and plaques, which can also occur in the cervix, fallopian tube, and other sites,[821,822] are distinguished from placental site trophoblastic tumor because of their smaller size, better circumscription, extensive hyalinization, degenerative appearance, and paucity of mitotic activity.[823,824] It has been pointed out that placental site nodules and plaques closely resemble the intermediate trophoblast of the chorion laeve rather than that at the implantation site. As such, they are diffusely positive

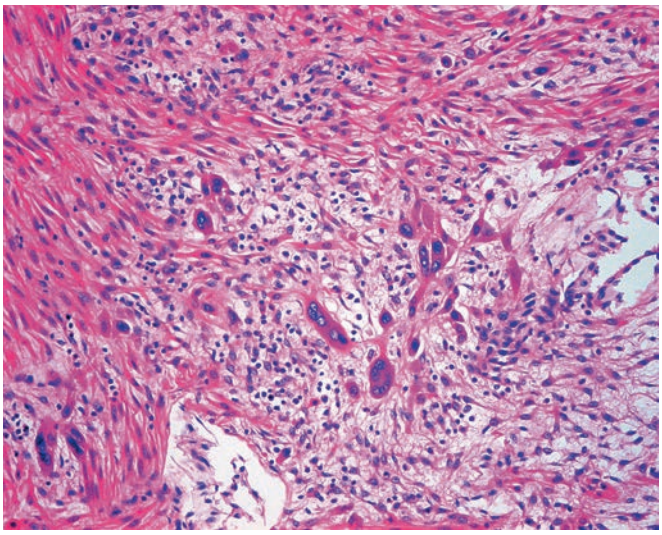

Figure 33.88 Trophoblastic cells infiltrating the myometrium in a tumorlike fashion in exaggerated placental site reaction.

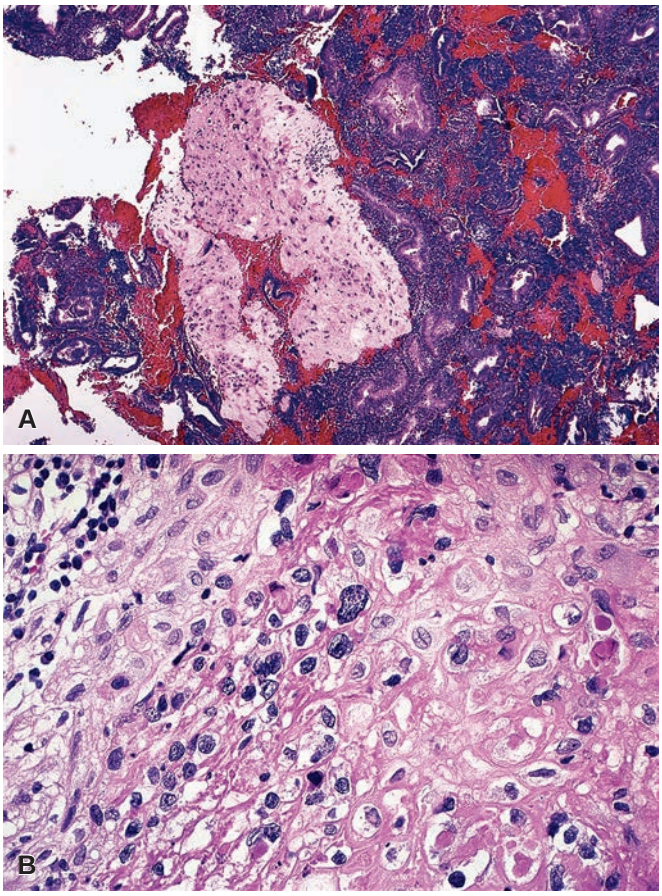

Figure 33.89 **A** and **B,** Low- and medium-power appearance of placental site nodule. The appearance is vaguely chondroid and can be easily misinterpreted.

for PLAP but only focally positive or negative for hPL and CD146 (Mel-CAM).[819]

The differential diagnosis between placental site trophoblastic tumor and the non-neoplastic proliferations previously mentioned may not be always possible in a curettage specimen. In such cases, subsequent curettings and monitoring of serum levels of hCG and hPL become imperative.

Other Tumors and Tumorlike Conditions

Postoperative spindle cell nodules similar to those occurring in the vagina have been observed in the endometrium.[825]

Idiopathic granulomas similar to those more commonly seen in the ovary (and known there as idiopathic ovarian cortical granulomas) have been occasionally seen in the uterus. Most of them were multiple and located in the myometrium.[826]

Extramedullary hematopoiesis can occur in the uterus in the absence of any hematologic disorder or systemic disease (but see Granulocytic [myeloid] sarcoma later).[827] Most of the reported cases have been located in endometrial polyps or leiomyomas and have been associated with chronic anemia.[828]

Myxoid changes can occur in the myometrium in the absence of any other pathology.[829]

Adenomatoid tumors identical to those more commonly seen in the fallopian tube are sometimes found in the uterine wall, usually beneath the serosa and close to the cornua.[830,831] Exceptionally, they will be apparent in a curetting specimen. These tumors are usually small (mean diameter, 2 cm) and macroscopically are usually mistaken for leiomyomas. They are characterized microscopically by adenoid, angiomatoid, solid, and cystic patterns occurring singly or in combination (Fig. 33.90).[832,833] The most cystic examples can simulate lymphangiomas. Their mesothelial nature has been established on the basis of ultrastructural and immunohistochemical findings (including reactivity for calretinin, WT1, and D2-40).[834–839]

Arteriovenous fistula in the wall of the uterus may produce large pulsating masses. The vascular connections are demonstrable by angiography.[840]

Benign mesenchymal tumors other than those already described are extremely rare. They include *hemangioma* of the endometrium,[841] *solitary fibrous tumor* (some associated with hypoglycemia),[842,843] and *lipoma.* The latter may result, at least in some instances, from adipose metaplasia of leiomyomas.[569,570]

Sarcomas of types other than those already described can arise in the uterus. They include *chondrosarcoma,*[846] *osteosarcoma,*[847] *rhabdomyosarcoma,*[848–851] *malignant peripheral nerve sheath tumor,*[852] *angiosarcoma,*[853–855] so-called *malignant fibrous histiocytoma,*[856] *malignant mesenchymoma* (one arising in a leiomyoma),[857] *alveolar soft part sarcoma,*[858] GIST,[859] so-called *rhabdoid sarcoma,*[860] *Ewing sarcoma/PNET,*[861–863] and *tumors with neuroectodermal differentiation* but lacking the *EWSR1* gene rearrangement (Fig. 33.91).[864,865] Some of these sarcomas have developed following radiation therapy for cervical carcinoma or other malignancies.[866] Some of the angiosarcomas have been of epithelioid type, immunoreactive for keratin, and apparently arising within leiomyomas.[867]

Before making a diagnosis of uterine sarcoma (particularly if the tumor is very pleomorphic and/or with heterologous elements), the more likely possibility of an MMMT with predominance of the sarcoma-like component should be ruled out with thorough sampling.[868]

Malignant lymphomas can present initially in the endometrium (including an endometrial polyp[869]), myometrium, or both.[870–873] The patients typically complain of bleeding and a mass. Most tumors are of diffuse large B-cell type.[874–876] Cases of low-grade B-cell lymphoma (including marginal zone B-cell lymphoma),[876,877] T-cell lymphoma,[878] Hodgkin lymphoma,[879] angiotropic lymphoma,[880] and intravascular large B-cell lymphoma[881] with primary uterine involvement have also been described. Malignant lymphomas should be distinguished from florid but reactive lymphoid proliferations involving the endometrium (lymphoma-like lesion),[882,883] and massive lymphoid infiltration of leiomyomas (see earlier). In these benign conditions,

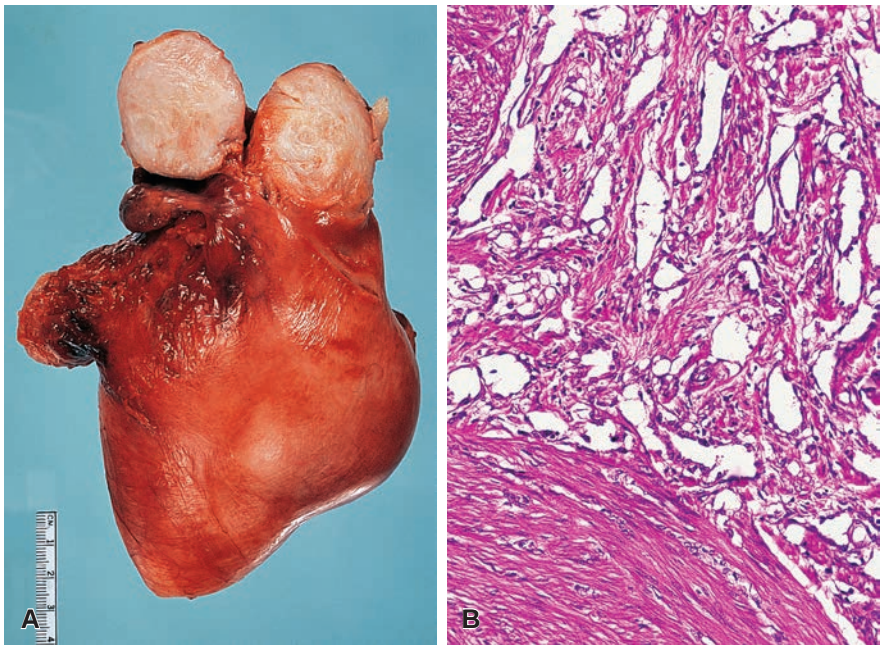

Figure 33.90 **A** and **B,** Adenomatoid tumor of uterus. **A,** Gross appearance. The location at one of the cornua is characteristic. **B,** Microscopic appearance showing tubular formations lined by flattened mesothelial cells.

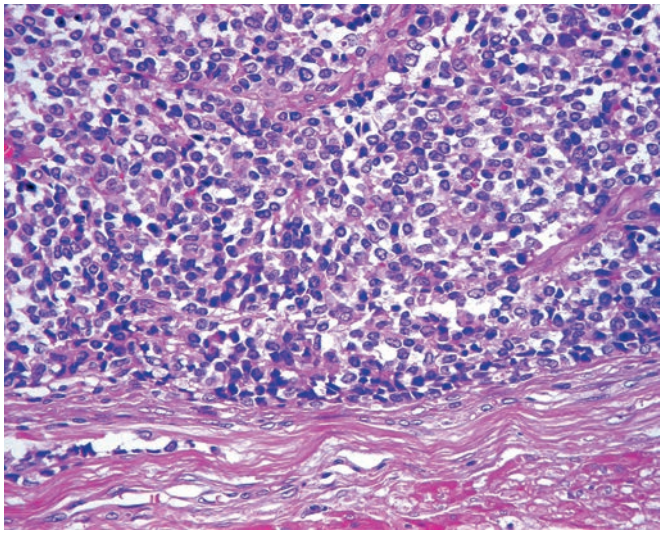

Figure 33.91 Ewing sarcoma/primitive neuroectodermal tumor presenting as a uterine mass, a most unusual occurrence.

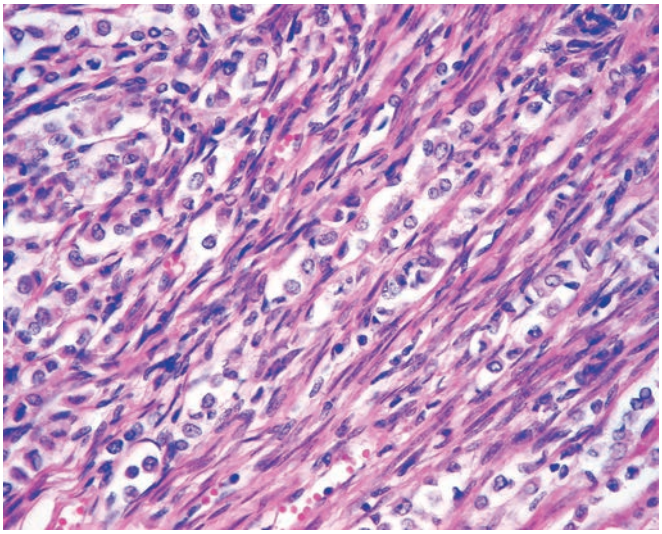

Figure 33.92 Lobular breast carcinoma metastatic to myometrium. Note the Indian file pattern of growth.

the large lymphoid cells are usually accompanied by plasma cells, small lymphocytes, and/or neutrophils.[884] **Granulocytic (myeloid) sarcoma** and **plasmacytoma/myeloma** can also involve the uterus, occasionally as the first manifestation of the disease.[871,885–887]

Other exceptionally rare primary uterine tumors include **Brenner tumor**[888] (microscopically identical to its ovarian counterpart and sometimes having a polypoid configuration),[889] **extrarenal Wilms tumor** (with or without teratoid features),[890,891] **desmoplastic small cell tumor**, **glioma**,[892] **carcinoid tumor**,[893] **paraganglioma**[894] (including a pigmented variant[895]), and **yolk sac (endodermal sinus) tumor**.[896]

Metastatic carcinoma from extrapelvic sites may metastasize to the uterus and cause uterine bleeding as the presenting symptom. The breast, gastrointestinal tract, kidney, and skin (melanoma) are the most frequent primary sites.[897–899] The myometrium is more often involved than the endometrium (Fig. 33.92) and sometimes the leiomyomas present contain metastatic tumor; however, it is not rare for the malignancy to be present in material from endometrial curettings, especially in cases of lobular carcinoma of the breast,[900] and also with neuroendocrine carcinomas and other neoplasms.[901] Exceptionally, a well-differentiated mucinous neoplasm of the appendix will coat the endometrial surface in a pseudomyxomatous fashion.[902] On occasion, a metastatic breast lobular carcinoma has been seen involving a tamoxifen-associated endometrial polyp,[903] and a melanoma has been seen to metastasize into a uterine adenomyoma.[904]

Normal Anatomy

The **fallopian tube** or salpinx is a tubular hollow structure measuring 11–12 cm in length that runs throughout the apex of the broad ligament and spans the distance between the uterine cornus and the ovary. It is divided into four segments: *intramural* (inside the uterine wall), *isthmus* (2–3 cm, thick-walled), *ampulla* (a thin-walled expanded area), and *infundibulum* (a trumpet-shaped ending that opens into the peritoneal cavity through the ostium and is fringed by the *fimbriae*). One of the latter structures, known as the *ovarian fimbria*, attaches the tube to the ovary.

The inner aspect of the tube is lined by mucosa arranged in the shape of longitudinal, branching folds (known as *plicae*), which merge with the fimbriae. There is good correlation between the microscopic features of this mucosa and its salpingoscopic appearance.[1] Microscopically, the epithelium is composed of three distinct cell types: *secretory*, *ciliated*, and *intercalated (peg)*.[2] Amylase is secreted by the epithelium, and its presence can be demonstrated immunohistochemically.[3] Endocrine cells have been found only exceptionally. A low degree of proliferative activity takes place normally in the tubal epithelium, more so during proliferative/follicular phase of the menstrual cycle, compared to the secretory/luteal phase.[4] At the time of menstruation, as well as a few days postpartum, the tubal mucosa may be normally infiltrated by neutrophils, probably as a reaction to blood and necrotic debris (*"physiologic salpingitis"*); it is accompanied by negative cultures and should not be confused with a bacterial or other infectious salpingitis.[5,6]

The muscular wall *(myosalpinx)* is composed of an inner circular layer and an outer longitudinal layer; the isthmus near the uterotubal junction also possesses an inner longitudinal layer.

The lymphatics of the fallopian tube leave the tubal wall within the mesosalpinx, where they join efferent lymphatics from the ovary and uterus and follow the ovarian vessels to terminate in the aortic lymph nodes. Other lymphatics course within the broad ligament and drain into the interiliac nodes; a separate lymphatic channel from the ampulla of the tube follows the broad ligament to terminate in the superior gluteal lymph nodes.

The **broad ligament** is the peritoneal fold that supports the uterus on either side, extending from this organ to the pelvic wall. It comprises the mesovarium, mesometrium, and mesosalpinx. The broad ligament and the adjacent areas contain a variety of tubular structures related to the müllerian and wolffian systems that may give rise to grossly evident cysts.[7] Most of these are lined by müllerian-type epithelium and have been variously referred to—depending on their specific location and presumed histogenesis—as *parovarian cyst*, *paratubal cyst (hydatid of Morgagni)*, *subserosal müllerian cyst*, *Kobelt cyst (appendix vesiculosa)*, *paroöphoron cyst*, *epoöphoron cyst*, and *rete ovarii cyst*.[8] *Walthard cell nests*, which can also be cystic, are of a different (probably mesothelial) nature.

The **round ligament** is a fibrous cord attached to the superior lateral border of the uterus that passes over the external iliac vessels and the inguinal ligament to leave the abdominal cavity through the deep inguinal ring. From there, it follows the inguinal canal to anchor itself in the labium majus. It serves to orient the uterus by the fact that its insertion is *anterior* to that of the fallopian tube.

Inflammation

Bacterial infection of the fallopian tube is a common disease, and its incidence keeps increasing. It may follow invasive procedures (such

Abstract

The fallopian tube has received increasing attention in this millennium, leading to the recognition that most extra-uterine high-grade serous carcinomas arise in the tube rather than the ovary. With more careful examination of the fallopian tube, increasing numbers of incidental findings are being identified by surgical pathologists; while most are not clinically significant, some do have implications for patient care, and accurate diagnosis is critically important. In addition to neoplastic changes, inflammatory/infectious processes involving the tube are relatively common; although they usually do not lead to surgery, they can do and it is important to for pathologists to be familiar with the spectrum of inflammatory changes in the tube.

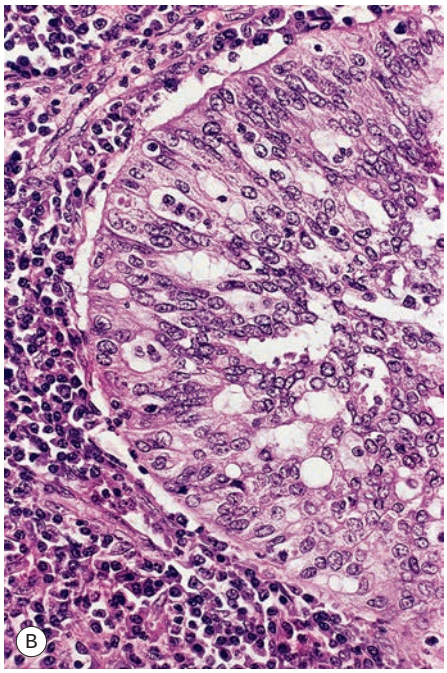

Figure 34.2 **Chronic Salpingitis. A**, Blunting of villi due to heavy inflammatory infiltrate. **B**, Marked secondary reactive hyperplasia of the mucosa, which may simulate a malignant process.

as curettage or the insertion of intrauterine devices[9]), and it may accompany endometriosis,[10] but in most cases it is due to an ascending infection, often sexually transmitted (Fig. 34.1).[11] The inflammation may result in fusion of tubal plicae and obliteration of the ostium (Fig. 34.2A). Obstruction of the fimbriated end and, less commonly, of the intramural or isthmic portion leads to tubal infertility.[12] Microscopically, the trapped epithelial spaces produce a complicated gland-like pattern that can simulate malignancy (see Fig. 34.2B).[13]

The lumen is often distended and filled with secretions or pus (**pyosalpinx**) (Fig. 34.3). Massive intraluminal hemorrhage may lead to the formation of **hematosalpinx**, a rare condition that needs to be distinguished from the much more common form secondary to ruptured tubal pregnancy. In chronic inflammatory cases, the tubal wall is markedly fibrotic, and serosal adhesions are prominent. The inflammatory exudate often spreads to the ovary, resulting in the formation of a **tubo-ovarian abscess** and obliteration of the pelvic anatomic relationships (Fig. 34.4). The rupture of such an abscess may lead to localized or generalized peritonitis,[14] and it is recommended that fluid collections of greater than 3 cm be drained laparascopically.[15] **Hydrosalpinx** is generally regarded as the end stage of a purulent salpingitis in which pus has been reabsorbed and replaced by a transudate of plasma.[16] The external gross appearance has been likened to that of a retort (Fig. 34.5). Exceptionally, the involvement is limited to the intramural portion of the tube. The wall is thin and fibrotic, with atrophy or even disappearance of the smooth muscle wall. The epithelium is flat and focally absent.

Pelvic inflammatory disease (PID) is the generic term used for inflammatory processes of this region in which the fallopian tube is the epicenter of the inflammation.[17–19] *Neisseria gonorrhoeae* and chlamydia account for most cases.[20–22] Polymicrobial tuboperitoneal infection (resulting from *Bacteroides fragilis*, peptostreptococci, peptococci, and other organisms) is responsible for most of the remaining cases. In established tubo-ovarian abscesses, the most common agents recovered are coliform organisms. *N. gonorrhoeae* was isolated only once in a series of 93 cases by Mickal et al.[14] This finding, however, does not rule out its role as a possible initiating factor before superinfection has occurred, in view of the fact that isolation of *N. gonorrhoeae* is inversely proportional to the number of episodes of salpingitis.[23]

Tuberculosis of the tube develops by the hematogenous route. Most patients are young, and infertility is common.[24,25] In advanced cases, both tubes are replaced by caseous tuberculous masses (Fig. 34.6). There is often extreme proliferation of the tubal mucosa in association with granulomatous inflammation, and this may lead to a mistaken diagnosis of carcinoma. The endometrium is concomitantly involved in approximately 80% of cases.[26]

Granulomatous inflammation of the tubes can also be produced by *Schistosoma*, *Oxyuris vermicularis*, *Actinomyces*, *Coccidioides immitis*, and other organisms.[27] *Sarcoidosis* and *Crohn disease* may be accompanied by tubal involvement.

Foreign bodies introduced for diagnostic or therapeutic measures can induce a bizarre granulomatous response (Fig. 34.7). Reaction to the *lipiodol* that used to be introduced in the Rubin test may be so proliferative as to resemble a neoplasm. The push of a uterine sound may drive lubricant into the tube, causing *lipoid granulomas*.[28]

Xanthogranulomatous (pseudoxanthomatous) salpingitis is characterized by an expansion of the tubal plicae by an infiltrate of foamy histiocytes (Fig. 34.8). The distinction some authors make between xanthogranulomatous and pseudoxanthomatous salpingitis is probably unwarranted.[29] Some cases may be due to endometriosis, and, therefore, the term "salpingitis" may be inaccurate.[30] Accordingly, some authors refer to it as *pseudoxanthomatous salpingiosis*.[31]

Giant cell arteritis is occasionally found in the tubes, ovaries, and uterus of postmenopausal patients, either as an isolated finding (most frequently) or as a manifestation of a generalized immune-mediated disease.[18,32,33]

Torsion

Torsion of the fallopian tube and ovary is usually secondary to inflammation or tumor, but occasionally it develops in a previously normal organ, the appearance at surgery being that of a hemorrhagic infarct. This phenomenon can occur in adults,[34] as well as in infants and children.[35,36] In children, torsion of the normal adnexa is about one-third as common as torsion of an ovarian cyst or tumor.[37] If the operation (which can be carried out laparoscopically) is done early enough, untwisting of the adnexa may lead to full recovery. Without surgical intervention, cases may resolve spontaneously or result in a necrotic and calcified mass, which may later detach from the uterus. It has been suggested that this complication, when occurring in previously normal adnexa, is due to the fact that the infundibulopelvic ligament extends along the edge of the ovarian ligament so that the tube and ovary hang on a very narrow stalk.

Tubal Pregnancy

The incidence of tubal pregnancy has increased in recent times.[38] It is often the consequence of chronic salpingitis, which leads to inflammatory destruction of the lining folds and retention of the ovum.[39,40] Congenital tubal abnormalities, functional tubal disturbances, and salpingitis isthmica nodosa are responsible for a minority of the cases.[39,41] A history of infertility is associated with an increased risk of tubal pregnancy.[42]

In tubal pregnancy the gestational sac is completely made up of tubal tissue, with no participation from the ovarian or intraligamentary tissues. Following implantation of the ovum in the tubal epithelium (usually in the ampullo-isthmic or midtubal portion), chorionic villi and extravillous (intermediate) trophoblasts can grow predominantly intraluminally[43] or penetrate into the wall, just as they do in the uterus,[39,44] except that the wall here is much thinner. Trophoblastic invasion of muscle and vessels is a common finding of no clinical significance. Hydropic changes and polar trophoblastic proliferation can occur; they should not be overdiagnosed as hydatidiform mole.[45] Changes resembling atherosclerosis may be seen in tubal arteries at the site of implantation, analogous to those occurring in the uterus in orthotopic pregnancy.[46] The fallopian tube epithelium may undergo clear cell hyperplasia.[47] Although a few tubal pregnancies have gone to term,[48] the usual outcome is abortion. The maternal vessels rupture into the gestational sac and cause hematosalpinx (Fig. 34.9). In the presence of a large hematosalpinx, it may be difficult to identify the products of gestation; numerous blocks *from the intratubal blood clot* should be taken for this purpose. Tubal rupture can occur (usually near the end of the second month) because of destruction of the tubal wall by the invading trophoblast, and this may result in severe intra-abdominal hemorrhage. This rupture may result in a brisk reactive proliferation of the mesothelium, with formation of papillae and psammoma bodies. These changes should be recognized as reactive and not misinterpreted as metastases or implants from an ovarian serous neoplasm. The necrotic trophoblastic tissue may be retained for a long time and appear as hyalinized ghost outlines of chorionic villi.[49] On occasion, the appearance of these retained tissues corresponds to that of so-called *placental site nodule*, as described in the uterine corpus.[50,51]

The usual treatment for tubal pregnancy is salpingectomy or laparoscopic salpingostomy (evacuation of the tubal implantation with preservation of the tube).[43,52,53] Conservative laparoscopic procedures for tubal ectopic pregnancy can result in extratubal trophoblastic implants accompanied by persistent beta human chorionic gonadotropin (β-hCG) postoperative serum titers.[54] Exceptionally, omental deposits of fetal parts are seen as a sequela of salpingectomy for ruptured ectopic pregnancy.[55]

Uterine curettings in the presence of a *viable* tubal pregnancy show gestational endometrium, sometimes associated with the Arias-Stella reaction. When trophoblastic elements are not obvious in routinely stained sections from the curettings, some authors have suggested the utility of immunohistochemical stains for hCG, human placental lactogen (hPL), and keratin in the confirmation of an intrauterine pregnancy; however, we have not found this useful in routine practice.[56,57] After death of the embryo or fetus there may be expulsion of the endometrial decidual cast, regeneration of the epithelium, and reestablishment of the cyclic pattern. Therefore, the presence of a proliferative, secretory, or menstrual endometrium in a patient with an adnexal mass does not rule out the possibility of an ectopic pregnancy.

Other Non-Neoplastic Processes

Walthard cell nests are small, glistening, round collections of flat to cuboidal cells with the appearance of urothelium located on the tubal serosa,[58] sometimes accompanied by cystic changes. They are probably of mesothelial rather than müllerian or wolffian nature.[58]

Figure 34.10 Ectopic decidual reaction in the fallopian tube. This is a very common finding during pregnancy.

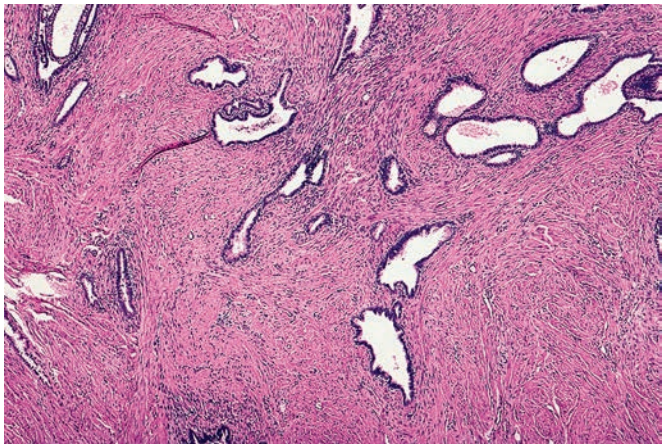

Figure 34.11 Low-power view of salpingitis isthmica nodosa.

They should not be mistaken for serosal implants in patients with ovarian neoplasms.

Paratubal cysts, traditionally known as *hydatids of Morgagni*, are commonly seen as small round cysts attached by a pedicle to the fimbriated end of the tube. Their wall is paper-thin and their content is clear. Occasionally, they attain a large size and may undergo torsion.[59] Most are lined by tubal columnar epithelium containing both ciliated and secretory cells, sometimes projecting in a papillary fashion into the lumen and covered by a thin layer of smooth muscle.[60] Their appearance is consistent with origin from müllerian-type structures. Other paratubal cysts, lined by flat cells and surrounded by a thin fibrous wall, are regarded as of mesothelial origin.[61]

Endometriosis frequently involves the tube in the form of nodules located in the wall or serosa.[62] In this context, it should be mentioned that the most common manifestation of ectopic endometrium in the tube is focal replacement of tubal epithelium by uterine mucosa[63]; however, it is doubtful whether this mucosal colonization of the isthmus by endometrial epithelium and stroma is related to conventional endometriosis; it may, however, be associated with infertility.

Cases have also been reported of the pathogenetically related *müllerianosis* (endometriosis plus endosalpingiosis plus endocervicosis) in the mesosalpinx.[64]

Endosalpingiosis is a term used for the presence of ectopic tubal epithelium beyond the anatomic confines of the tube.[65] It is usually located in the peritoneum but also lymph node and other sites in the pelvis and consists of small cystic structures lined by an epithelium of tubal type cells (secretory, intercalated, and ciliated cells). Since this disorder is often associated with ovarian low-grade serous tumors, it is discussed in more detail in the next chapter.

Decidual reaction of the tubal mucosa is a common finding in specimens of tubal ligation obtained at the time of cesarean section; it appears as small nodular collections of decidual cells covered by a flattened, sometimes inflamed epithelium (Fig. 34.10). Similar changes have been documented following hormonal therapy.[66]

Arias-Stella reaction can occur in the fallopian tube epithelium in association with either orthotopic or tubal pregnancy.[67]

Salpingitis isthmica nodosa is a usually bilateral lesion that presents grossly as a well-delimited nodular enlargement of the isthmic portion of the tube.[65] Microscopically, cystically dilated gland-like formations are seen surrounded by hypertrophic muscle (Fig. 34.11). Radiographic and tridimensional reconstructive studies have shown that the cystic formations are connected to the lumen of the tube. Although classically regarded as the result of inflammation (hence its name), convincing evidence has been presented that its pathogenesis is analogous to that of uterine adenomyosis.[68] It is accompanied by infertility in approximately half of patients, and it may also lead to ectopic pregnancy.[69]

Tubal sterilization procedures can lead to a sequence of morphologic alterations, which include proximal luminal dilation, plical attenuation, chronic inflammation with pseudopolyp formation, and plical thickening in the distal segment.[70] The appearance varies depending on the length of time that has elapsed from the sterilization procedure.[71]

Metaplastic changes of several types can develop in the fallopian tube mucosa. *Transitional cell (urothelial) metaplasia* is usually located in the fimbriae, where it may mimic serous tubal intraepithelial carcinoma (STIC). It is distinguished from it because of the uniformity in cell size and shape, low nucleocytoplasmic ratio, lack of nuclear atypia, presence of nuclear grooves, lack of mitoses, and absence of abnormal p53 expression or increased staining for Ki-67.[72,73] *Eosinophilic metaplasia* (sometimes accompanied by mucinous changes) presenting as a sharply outlined papillary lesion is occasionally encountered; the initial descriptions were in tubes removed in the immediate postpartum period (Fig. 34.12).[74,75] Their behavior is benign. This lesion, which has been called *metaplastic papillary tumor*, is morphologically similar to "papillary tubal hyperplasia," discussed in more detail later. It is an interesting lesion but is not of clinical significance, in that no further treatment is indicated. *Mucinous changes*, probably of metaplastic nature, have also been described in fallopian tubes.[76] When associated with appendiceal and ovarian mucinous tumors, however, we suspect that this is secondary spread to the fallopian tube mucosa, having encountered a case with HER2 amplification in both the primary tumor and fallopian tube mucinous epithelium. It has been described in a patient with Peutz-Jeghers syndrome who had both ovarian mucinous neoplasms and mucinous epithelium in tube and endometrium.[77]

Papillary endothelial hyperplasia can develop in tubal vessels and simulate an angiosarcoma; as in other sites, it is the expression of organization and recanalization of thrombi.[78]

Fallopian tube prolapse into the vaginal apex following vaginal hysterectomy can simulate the microscopic appearance of recurrent endometrial adenocarcinoma or, if the stroma predominates, an aggressive angiomyxoma.[79]

Proliferative Epithelial Lesions

Proliferative epithelial lesions may be found during the microscopic examination of a specimen from tubal ligation or salpingectomy.

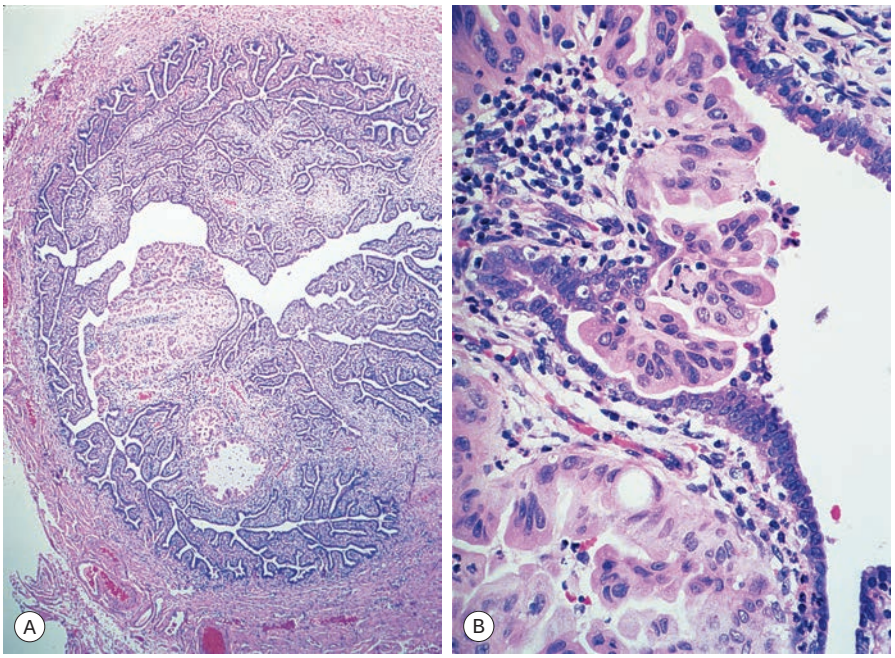

Figure 34.12 **A** and **B**, So-called metaplastic papillary tumor of fallopian tube. This lesion is characterized by a papillary proliferation of acidophilic epithelium. This process is probably the same as "papillary tubal hyperplasia."

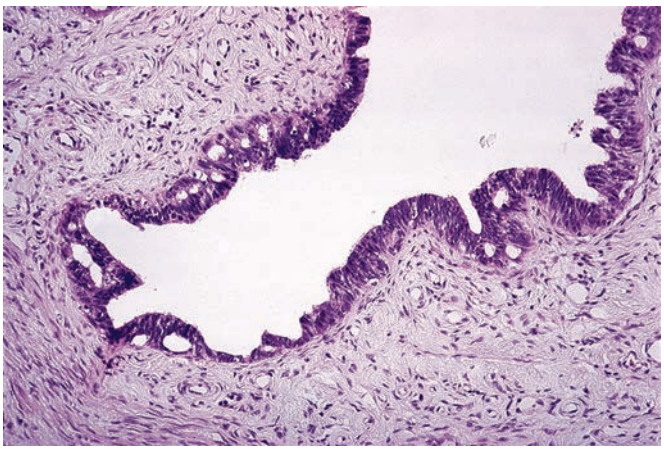

Figure 34.13 Hyperplasia of the tubal epithelium; this is a common incidental finding of no clinical significance and must be distinguished from STIC.

They may show one or more of the following features: nuclear crowding, stratification, loss of polarity, mild to at most moderate atypia, occasional mitoses, acidophilic metaplasia, and papillary formations (Fig. 34.13).[80] Mild degrees of this change are extremely common; in one study, they were found in 83% of all tubes examined and are benign.[81]

Some of the above changes have been found in association with other lesions or situations, such as salpingitis and exogenous or endogenous estrogen stimulation; such florid reactive proliferations have in the past been confused with STIC, but lack the high-grade nuclear atypia of STIC and are completely benign.[81–85]

The term **papillary tubal hyperplasia** has been proposed for a papillary lesion composed of rounded papillary clusters of bland tubal epithelial cells that project into the tubal lumen. They can be seen as an incidental finding in salpingectomy specimens from women with serous borderline tumors, or unassociated with any ovarian pathology, and Kurman et al. have suggested that they are precursors of serous borderline tumor and endosalpingiosis.[86] Such a relationship is highly speculative, as they are not seen in association with most serous borderline tumors. In one case *RAS* mutations were found in an ovarian serous borderline and in papillary tubal hyperplasia present in both fallopian tubes, suggesting a clonal relationship.[87] Morphologically, papillary tubal hyperplasia appears to be the same as the metaplastic papillary tumor, described originally by Scully and colleagues as a rare incidental and benign finding in the fallopian tube. It is likely that papillary tubal hyperplasia is more commonly encountered now that fallopian tubes are being more carefully examined, but they remain distinctly uncommon and their relationship, if any, low-grade serous neoplasia remains to be elucidated.

Carcinoma

Traditionally, primary carcinoma of the fallopian tube has been regarded as very rare, accounting for approximately 1% of primary genital tract malignancies.[88] This figure, however, was based on diagnostic criteria that reserved the diagnosis of primary fallopian tube carcinoma for cases where there was minimal ovarian involvement; the presence of ovarian mass(es) resulted in tumors being designated as primary ovarian carcinoma.[89] These criteria are based on the so-called dominant mass theory, which has been thoroughly discredited. For example, ovarian involvement associated with mucinous appendiceal neoplasms, gastric carcinoma, colorectal carcinoma, and cervical adenocarcinoma is frequently larger that the primary tumor, and while the associated ovarian tumors were mistakenly considered to be independent primary tumors in the past, they have been convincingly demonstrated to be metastasis. A superior approach to identification of primary site is to characterize the anatomic site of unifocal lesions of high-grade serous carcinoma (HGSC), before there is metastatic spread and involvement of multiple sites. In both sporadic and hereditary cases of HGSC the earliest,

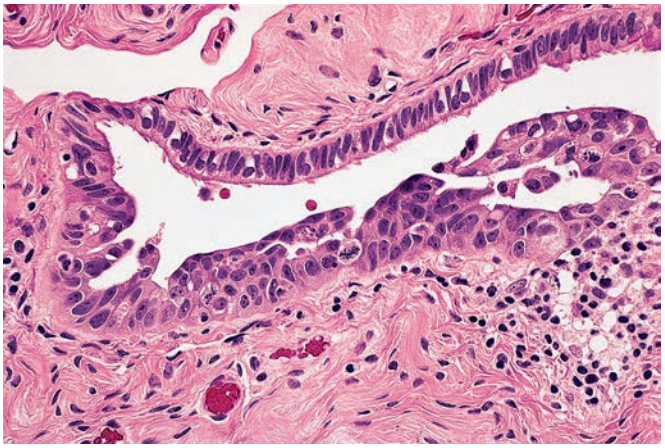

Figure 34.14 Serous Tubal Intraepithelial Carcinoma. Note the abrupt transition from benign tubal epithelium to cells with pleomorphic nuclei. Abnormal p53 immunostaining and a high (>10%) Ki-67 labeling index can help confirm the diagnosis.

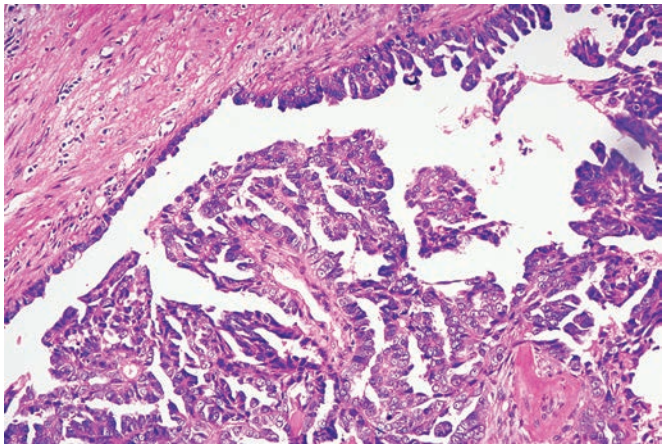

Figure 34.15 High-power view showing the complex papillary architecture that is characteristic of high-grade serous carcinoma.

Figure 34.16 Fallopian tube filled by high-grade serous carcinoma. This uncommon finding is seen in association with obstruction of the fimbrial end of the tube.

unifocal lesions are almost always in the fallopian tube.[89,90] There are certainly cases of HGSC where the fallopian tube is normal, even after careful examination, but these are a minority.[90]

Serous Tubal Intraepithelial Carcinoma

The earliest fully malignant lesion of HGSC is STIC. It most commonly, but not exclusively, involves the fimbriae and is characterized by increased nucleus to cytoplasm ratio with rounded nuclei, loss of cell polarity, coarsely clumped chromatin, prominent nucleoli, and the presence of mitotic activity involving non-ciliated (i.e., secretory) cells (Fig. 34.14). The cells are morphologically identical to those seen in HGSC, and the immunophenotype is also the same with WT1 expression, high (usually >50%) Ki-67 labeling index, and abnormal p53 staining. The diagnostic criteria for STIC have since evolved and guidelines for diagnosis have been published, which include the use of p53 and Ki-67 immunostaining[91–93]; high-grade nuclear atypia, together with abnormal p53 staining and a Ki-67 labeling index greater than 10% allow for a reproducible diagnosis of STIC.[93] Adherence to these criteria results in a high degree of interobserver diagnostic agreement. In practice, immunohistochemistry can be reserved for those cases where morphology alone is insufficient for unequivocal diagnosis; a diagnosis of STIC in a patient with advanced stage HGSC can usually be made without resorting to immunostains.

Fallopian tube epithelial lesions with atypia that do not meet all the criteria for STIC are variously referred to as tubal intraepithelial lesion in transition (TILT) or serous tubal intraepithelial lesion (STIL).[94–97] These lesions are of uncertain significance and, in our opinion, these diagnostic terms should not be used in routine practice; additional research is required to determine the clinical significance, if any, of such lesions. Similarly p53 signatures should not be reported. These take the form of small foci of intense p53 nuclear staining involving consecutive secretory cells, most commonly but not exclusively in the fimbriae, in the absence of cytologic atypia.[98] p53 signatures are common in normal fallopian tube and should not be commented on in a diagnostic surgical pathology report.

STIC, if unassociated with invasion or extratubal disease, will usually follow a benign course.[99,100] Exceptions have been reported. As is the case with serous carcinoma of endometrium confined to a polyp, the favorable prognosis of STIC is only true if there has been an adequate staging procedure, as apparently noninvasive STICs have been associated with trans-coelomic spread and stage III disease. Thus, only when there has been confirmation of no extratubal disease should observation be elected in patients with incidentally diagnosed STIC.

High-Grade Serous Carcinoma

The clinical and pathologic features of HGSC are the same, whether the tumor is considered to have arisen in fallopian tube, ovary, or peritoneum (Fig. 34.15). There has been a shift in our understanding of where most HGSC originate,[89] but it has not impacted significantly on management our outcomes. In keeping with tradition, we will leave a more comprehensive discussion of HGSC for the section on ovarian carcinoma, later in this chapter, even though there is evidence that most arise in the fallopian tube.[89,90] Although most patients with HGSC present with ascites and an adnexal mass, the nature of the adnexal involvement can vary. In patients with predominantly tubal involvement, a history and/or morphologic evidence of coexisting or preceding salpingitis is common, and reduced access by tumor cells to the peritoneal cavity may explain the unusual tumor distribution (Fig. 34.16). Staging of HGSC is the same, whether the tumor is considered to have arisen from fallopian tube and ovary.

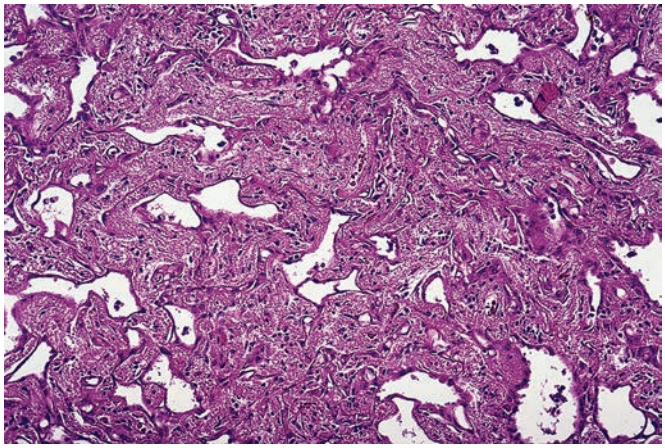

Figure 34.17 Adenomatoid tumor of fallopian tube accompanied by smooth muscle hyperplasia.

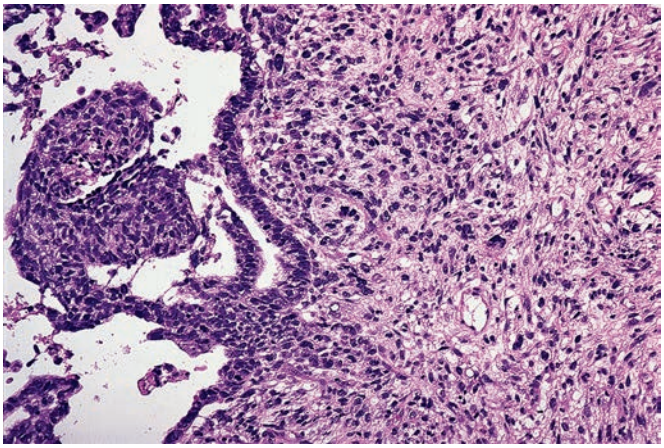

Figure 34.18 Carcinosarcoma (malignant mixed müllerian tumor) of fallopian tube, showing the typical biphasic pattern.

Other Carcinomas

Although HGSC is most common, all carcinomas reported in the ovary can occur in the fallopian tube, including endometrioid (the second most common type, including spindle cell, oxyphilic, adenoacanthomatous, adenosquamous, and squamous types), mucinous, seromucinous, clear cell, and hepatoid.[11,101–107] The endometrioid carcinomas typically present as intraluminal masses and may microscopically simulate a neoplasm of wolffian origin.[108]

A carcinoma extensively involving both endometrium and tube should be classified as a primary endometrial tumor; serous carcinoma of the endometrium involves the fallopian tube in 20% of cases when the fallopian tube is carefully examined.[109] Such tumors stain as would be expected of endometrial serous carcinoma, with weak or negative WT1 staining, in contrast to the strong WT1 positivity characteristic of tubo-ovarian HGSC.

Borderline epithelial neoplasms have also been described in the fallopian tube. As in the ovary, they can be of serous, endometrioid, or mucinous type.[110,111]

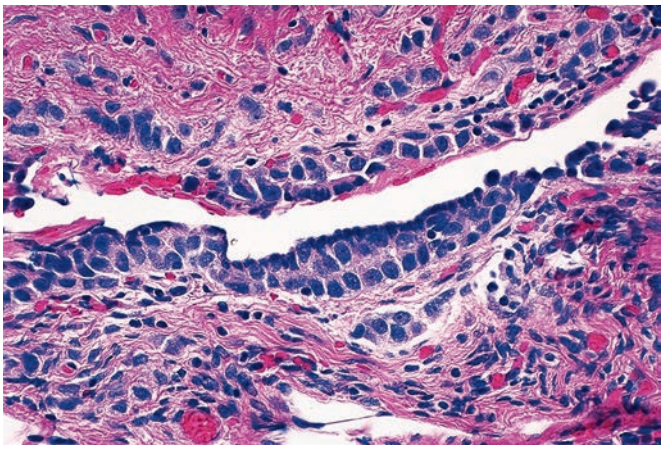

Figure 34.19 Metastatic lobular carcinoma of breast growing beneath tubal epithelium.

Other Tumors

Adenomatoid tumor is a benign, usually small lesion that may be found within the wall of the tube or beneath the uterine serosa near a cornu.[112] The gross and microscopic features are identical to those of its epididymal counterpart (see Chapter 27). The ill-defined, seemingly infiltrating margins may lead to a mistaken diagnosis of carcinoma.[113] A marked degree of smooth muscle hyperplasia may be present and obscure the true nature of the lesion (Fig. 34.17). There is now agreement on the basis of ultrastructural and immunohistochemical findings (the latter including positivity for calretinin, WT1, CK5/6, and D2-40[112,114]) that this entity is of mesothelial (rather than wolffian, müllerian, or endothelial) derivation and that it represents a unique variant of benign mesothelioma largely restricted to the genital region,[115,116] as originally postulated by Pierre Masson.

Papillary cystadenoma of the mesosalpinx has been seen in patients with von Hippel–Lindau disease.[88] Allelic deletions of the *VHL* gene have been detected in these cases.[117]

Mucinous lesions of the fallopian tubes comprise a wide variety of processes, which include mucinous metaplasia (see earlier), mucinous cystadenoma, "mucinous borderline tumor," and mucinous adenocarcinoma. Some of these lesions have occurred in patients with Peutz-Jeghers syndrome, others in association with in situ or invasive adenocarcinoma of other portions of the female genital tract (such as endocervix), and still others in conjunction with mucinous neoplasms of the appendix.[118,119] It is likely that the latter are tubal metastases or implants of appendiceal primaries.

Approximately 50 cases of tubal **teratomas** have been published, nearly all cystic and benign[120]; one of them contained a *carcinoid tumor* and another was entirely composed of mature thyroid tissue *(struma salpingis)*.[121] Other reported benign tubal tumors, all very rare, are **leiomyoma, hemangioma, adenofibroma,**[122–124] **sex-cord tumor with annular tubules** (associated with endometriosis),[125] and **papilloma**.[121] The latter should be distinguished from the more common papillary hyperplasia associated with inflammation and hyperestrinism.

Malignant tumors other than carcinoma include **carcinosarcoma (malignant mixed müllerian tumor)**[88,124,126–128] (some bilateral[129]) (Fig. 34.18), **leiomyosarcoma, gestational choriocarcinoma,**[130] and **synovial sarcoma**.[131] The first three tumor types resemble, grossly and microscopically, their more common uterine counterparts; tubal extension from the latter should always be considered in the differential diagnosis. Tubal involvement by **malignant lymphoma** is always the expression of systemic disease. Most **metastases** to the tube originate from other genital organs (Fig. 34.19).[111]

Tumors and Tumorlike Conditions of Broad and Round Ligaments

The **round and broad ligaments** are only rarely the site of primary disease.[107,132] **Striated muscle heteroplasia** is an inconsequential incidental finding, thought to represent aberrant persistence of gubernacular rhabdomyoblasts.[133]

Cystic formations derived from müllerian or mesonephric (wolffian) rests can be found in or around the broad ligament.

Wolffian tumor (female adnexal tumor of probable wolffian origin) is a distinctive lesion originally described in the broad ligament and subsequently also recognized in the ovary. In its most typical form, it is seen within the leaves of the broad ligament or hanging on a pedicle from it or the fallopian tube. Grossly, it is predominantly solid. Microscopically, it is composed of epithelial cells growing in diffuse, trabecular, and tubular patterns (Fig. 34.20). Mitotic activity and capsular invasion may be present, but the prognosis is generally good.[134,135] The differential diagnosis of wolffian tumor includes endometrioid carcinoma and sex cord–stromal tumor. The presence in the broad ligament is a finding in favor of wolffian tumor. Caution must be used in interpretation of immunostains as there is often expression of sex cord–stromal markers, and inconsistent expression of markers of mesonephric differentiation, such as GATA3.

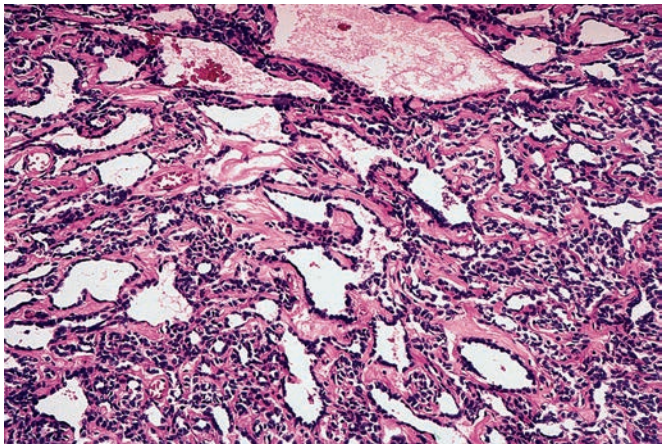

Figure 34.20 Wolffian tumor of the broad ligament. The sieve-like low-power appearance is characteristic.

Other tumors and tumorlike conditions that can be found in the broad ligament unassociated with either uterine or ovarian disease are *endometriosis* (including the possibly related condition known as uterus-like mass)[136]; *borderline serous tumors*[137]; *serous*, *endometrioid*, *clear cell*, and *mucinous carcinomas*[138,139]; *papillary cystadenomas* and other neoplasms associated with von Hippel–Lindau disease[140,141]; *ependymoma*[142]; *smooth muscle tumors*; and other types of *mesenchymal neoplasm*. Some of the carcinomas of this region are thought to arise from foci of endometriosis.[139]

Normal Anatomy

The ovaries are paired pelvic organs located on the sides of the uterus close to the lateral pelvic wall, behind the broad ligament and anterior to the rectum. They are connected to the broad ligament by the mesovarium (a double fold of peritoneum), to the uterine cornu by the ovarian (or utero-ovarian) ligament, and to the lateral pelvic wall by the infundibulopelvic (or suspensory) ligament. During the reproductive period, their average size is $4 \times 2 \times 1$ cm and their average weight is 5–8 g; after menopause, they shrink to one half or less of this size.

The ovarian lymph vessels drain to large trunks that form a plexus at the hilus, from which they travel through the mesovarium to drain into the para-aortic nodes; others drain into the internal iliac, external iliac, interaortic, common iliac, and inguinal nodes.

The ovary is covered by a single layer of modified mesothelium known as *ovarian surface epithelium* or OSE. This epithelium is immunoreactive for keratin, epithelial membrane antigen (EMA), Ber-EP4, CA 125, vimentin, estrogen and progesterone receptors (ER and PR), and follicle-stimulating hormone.[1,2] Epithelial inclusion glands/cysts are commonly found in the cortex. Interestingly, although the OSE is negative for PAX8, the lining cells of the epithelial inclusion cysts are typically PAX8 positive.[3]

The *ovarian stroma* is divided into a cortical and a medullary region, but the boundaries between them are indistinct. It is composed mainly of spindle-shaped stromal cells resembling fibroblasts, typically arranged in whorls or a storiform pattern. The cells may contain cytoplasmic lipid and are surrounded by a dense network of reticulin fibers. They are immunoreactive for FOXL2, ER, and PR.[1] Some of these cells have myoid ("myofibroblastic") features and exhibit immunoreactivity for smooth muscle actin and desmin.[4,5] Foci of smooth muscle hyperplasia may be found, most often in perimenopausal or postmenopausal women.[4] Metaplastic bone formation can also occur.[6] Other cells that may be found in the ovarian stroma are luteinized stromal cells (singly or in small nests, mainly in the medulla), decidual cells, nests of cells resembling endometrial stromal cells, mature fat cells, and neuroendocrine cells.[1,6,7]

The life cycle of the *ovarian follicle* includes primordial, maturing (primary, secondary, tertiary, and graafian), and atretic forms, together with corpora lutea and corpora albicantia for those that have reached full maturation. Primordial follicles contain germ cells that have originated from the yolk sac endoderm and migrated into the ovary, where they develop into oogonia and oocytes.[1] The maturing follicle is composed of the oocyte, the granulosa layer, and the two theca layers. *Granulosa cells* lack a reticulum around them and are immunoreactive for vimentin, FOXL2, and ER and show variable/weak immunoreactivity for keratin.[1] They feature small rosettelike formations known as Call–Exner bodies, which contain at their center a deeply eosinophilic filamentous material consisting of excess basal lamina. The stroma-derived *theca cells* form an internal layer (which is typically luteinized) and an external layer (which is very cellular and can simulate a neoplastic process

Abstract

A broad range of pathologic conditions are encountered in the ovary in routine surgical pathology practice. Indeed, there is no organ in the body that can lay claim to a greater variety of primary neoplasms. This reflects the complex function of the ovary in reproduction, as site of germ cells and their supporting sex cord–stromal cells; both cell types can give rise to benign or malignant tumors. The most common ovarian neoplasms, however, are epithelial. Although the histogenesis of epithelial ovarian tumors of different cell types (histotypes) remains controversial, recent years have seen significant advances and these have solidified the important concept that the different histotypes of epithelial ovarian cancer are distinct diseases. This, in turn, has led to an emphasis on accurate histotype diagnosis by surgical pathologists.

when cut tangentially). Internal theca cells are an important site of sex steroid production, as determined indirectly by the immunohistochemical detection of enzymes involved in steroid hormone biosynthesis.[8,9]

The mature *corpus luteum* is a 1.5–2.5-cm round yellow structure with lobulated outlines and a cystic center. Both the granulosa and the theca cells that form it show prominent luteinization. Morphologic criteria for the dating of the corpus luteum have been established.[10] The corpus luteum of pregnancy is characterized by its larger size, bright yellow color, prominent central cavity, and the presence of hyaline droplets and calcification.[1]

At the ovarian hilus, there are clusters of cells analogous to testicular Leydig cells known as *ovarian hilus cells*. They are closely associated with large hilar veins and lymph vessels and may form nodular protrusions within their lumina. They also exhibit an intimate relationship with the nerves of the region.[1,11] They may contain Reinke crystalloids, lipids, and lipochrome pigment. Hyperplasia of these cells is found following the administration of chorionic gonadotropin, in pregnancy, and in the presence of choriocarcinoma.[1]

The *rete ovarii*, present in the ovarian hilus, represents the ovarian counterpart of the rete testis. It consists of a network of clefts, tubules, cysts, and papillae lined by an epithelium of variable height and surrounded by a cuff of spindle cell stroma. This epithelium is immunoreactive for keratin and CA 125.[12]

Walthard cell nests may be cystic or solid. They are located in the mesovarium, in the adjacent mesosalpinx, or within the ovarian hilus and have a lining of transitional/urothelial appearance (sometimes mucin producing), which is probably of mesothelial nature.

The previous description mainly pertains to the fully developed ovary in women of childbearing age. The many modifications exhibited by the prepubertal and postmenopausal ovary are beyond the scope of this chapter. It should be mentioned, however, that prominent cystic follicles are normally seen during the first few months of life and at puberty and that the shrunken postmenopausal ovary ("ovarium gyratum") has thick-walled medullary and hilar vessels (which should not be mistaken for hemangiomas). These atrophic ovaries may also contain clinically inconsequential granulomas and hyaline scars.[1]

The immunohistochemical profiles of the various cell components of the ovary are discussed further in connection with the tumors of the respective structures.

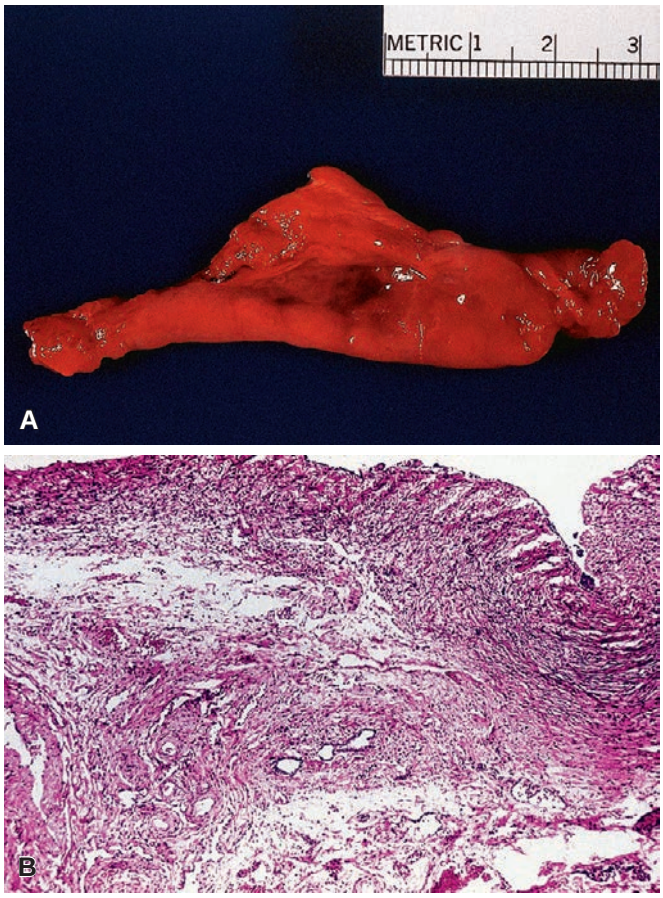

Figure 35.1 Streak Gonad in Turner Syndrome. A, Gross appearance; **B**, microscopic appearance.

Gonadal Dysgenesis

Patients with gonadal dysgenesis have abnormally developed gonads and infantile sexual development. The conditions mentioned here are mainly those associated with an abnormal sex chromosome constitution ("abnormalities in sex determination"), to be distinguished from those such as male and female pseudohermaphroditism, persistent müllerian duct syndrome (due to a defect in the müllerian inhibiting substance system), and end-organ defects[13] ("abnormalities in genital differentiation").[14,15]

Sometimes, gonadal tissue is biopsied or removed in the course of evaluation of these malformations.[16,17]

Klinefelter syndrome is usually characterized by the karyotype 47,XXY and is further discussed in Chapter 27.

In patients with **gonadal dysgenesis**, either "**pure**" (with a 46,XX or 46,XY karyotype) or associated with the somatic features of **Turner syndrome** (with a 45,XO karyotype), both gonads are represented by a streak of fibrous tissue that resembles ovarian stroma (Fig. 35.1).[18–20] These patients do not seem to have an increased incidence of gonadal tumors (in the absence of Y chromosome specific sequences),[21] but various types of nongonadal neoplasm (such as atypical polypoid adenomyoma of uterus, leukemia, and soft tissue tumors) have been reported in patients with the syndrome.[22,23] Also, several cases of Turner syndrome have been reported in association with endometrial adenocarcinoma; in some of these, prolonged estrogen therapy had been administered.[24]

In **mixed gonadal dysgenesis** (usually characterized by a 45,X/46,XY mosaicism or 46,XY phenotype), one gonad is represented by a streak gonad or streak testis and a contralateral testis (that is typically cryptorchid) or bilateral streak testis.[25] Individuals with this condition are particularly prone to the development of gonadoblastomas, a complication prevented by early removal of the gonads.[26] The tumors may totally obliterate the testicular elements and thus lead to an incorrect typing of the dysgenesis.

True hermaphrodites may have ovotestes containing both ova and immature seminiferous tubules or other combinations of ovary and testis (Fig. 35.2). [27–29] The most common karyotypes are 46,XX (60%), 46,XY (12%), and mosaic (28%). Multiple tumors can occur in these gonads.[30]

The familial syndrome of **testicular feminization** is the most common type of male pseudohermaphroditism. It occurs in individuals with a normal male chromosome constitution with an end-organ defect (androgen insensibility). It is characterized by the presence of several well-developed female secondary sex characteristics. These patients consult a gynecologist because of amenorrhea or sterility. They are found to have a vagina, no uterus, and bilateral cryptorchid testes. The latter often contain nodular masses of immature tubules that should not be confused with Sertoli–Leydig cell tumor (Fig. 35.3).[31,32] The syndrome is of further clinical importance because

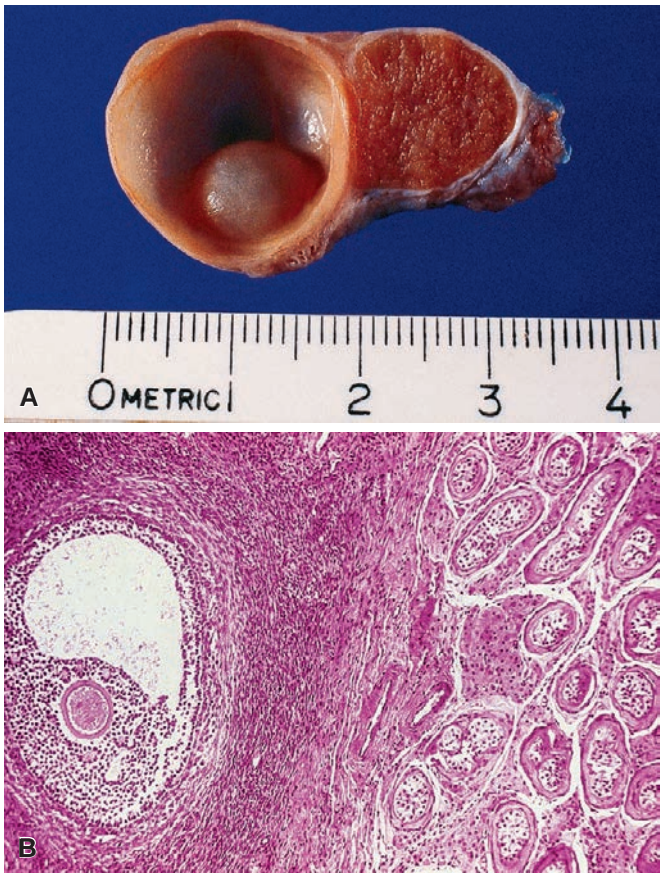

Figure 35.2 **Ovotestis in True Hermaphroditism. A**, Gross appearance. The testicular component is represented by the solid nodule, whereas the ovarian component has a largely cystic appearance. **B**, Microscopic appearance of the two components.

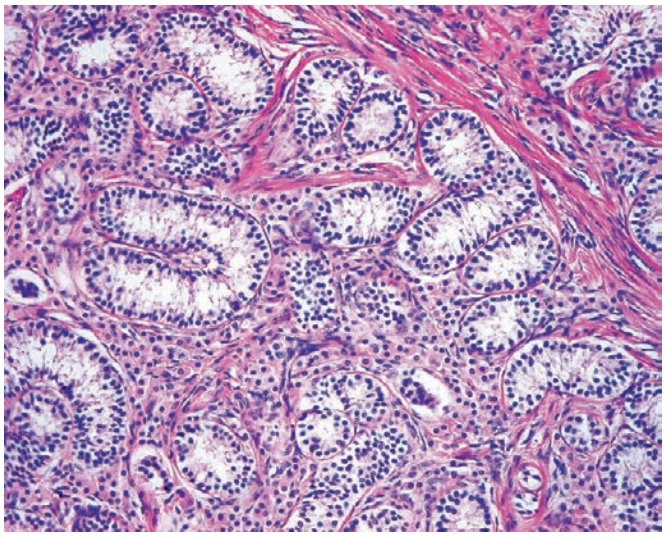

Figure 35.3 Immature testicular tubules in testicular feminization syndrome.

of the eventual occurrence of malignant tumors in the cryptorchid testes of approximately 9% of these patients. For this reason, the testes should be removed after puberty and supplemental estrogen therapy given. A classification of disorders of sexual development is presented in Table 35.1.

Cysts, Stromal Hyperplasia, and Other Non-Neoplastic Lesions

Ovarian diseases of surgical importance can be broadly divided into non-neoplastic cysts, inflammations, and neoplasms. Non-neoplastic cysts are sufficiently common as to be the norm during the reproductive years; cysts up to 6 cm, detected by ultrasound, can be followed and most will resolve spontaneously, reflecting their functional nature.

Inclusion cysts ("cortical inclusion cysts") are common in older women; they are generally small and multiple and have no clinical significance. Most of them probably arise from invaginations of the surface epithelium, with subsequent loss of the connection with the surface (Fig. 35.4A).[33] Microscopically, they are lined by a flattened, cuboidal, or columnar epithelium; tubal metaplasia is frequent (see Fig. 35.4B). Psammoma bodies may be seen in their lumen or in the adjacent stroma. By definition cortical inclusion cysts are less than 1 cm and if larger they are considered to be serous cystadenomas, if there is tubal epithelium, or benign simple cysts if lined by nondescript flattened or cuboidal epithelium. This rule need not be firmly adhered to; in general, if a cyst is clinically evident it can be designated a cystadenoma or benign simple cyst, while a small cyst that is an incidental finding can be designated an inclusion cyst. This practice reflects the arbitrary nature of the definitions, with a continuum existing between inclusion cyst and serous cystadenoma.

Follicular cysts form by distention of developing or atretic follicles and usually do not exceed 10 cm in diameter (Fig. 35.5). It has been proposed that cystic follicular structures be designated as (normal) *cystic follicles* when measuring less than 2.5 cm and as *follicular cysts* when exceeding this diameter. The latter may occur at any age from infancy to menopause and are asymptomatic in the majority of cases. Occasionally, twisting of the pedicle occurs, with resulting hemorrhagic infarction of the ovary. In children, the cysts may be seen in conjunction with precocious puberty.[34,35] During reproductive life, they may be associated with endometrial hyperplasia and metrorrhagia.[36] The cyst fluid may contain estrogens.

The cyst wall is lined by theca, with or without an inner granulosa layer (Fig. 35.6). The theca layer is frequently luteinized. The granulosa layer may be luteinized after puberty but not before. **Multiple luteinized follicular cysts** (theca–lutein cysts; hyperreactio luteinalis) are common in cases of hydatidiform mole and choriocarcinoma but also have been seen in twin pregnancies and, exceptionally, in uncomplicated single pregnancies (Fig. 35.7).[37] **Large solitary luteinized follicular cyst** is a rare lesion presenting during pregnancy and puerperium, unaccompanied by endocrine abnormalities. The median diameter of this type of cyst is 25 cm.[38] Marked focal atypia is often seen in the luteinized cells of this lesion.[39]

Polycystic (sclerocystic) ovaries are characterized by multiple follicular cysts or cystic follicles with varying degrees of luteinization of the theca interna, and dense fibrosis of the superficial cortex. Evidence of previous ovulation (i.e. corpora lutea or albicantia) is sparse or absent (Fig. 35.8).[40,41] Various clinical manifestations may develop in patients with polycystic ovaries, including amenorrhea and sterility, endometrial hyperplasia, and frank virilism; these fall under the collective designation of polycystic ovary syndrome (PCOS), formerly (and still occasionally) referred to as Stein–Leventhal syndrome. The pathogenesis of PCOS is poorly understood.[38,42–43] These patients have "masculinizing" pituitary and ovarian responses to stimulation by the specific gonadotropin-releasing hormone agonist nafarelin, suggesting that the regulation of the ovarian 17-hydroxylase and C-17,20-lyase activities is abnormal.[44] Dysregulation of 11β-hydroxysteroid dehydrogenase, causing increased oxidation of cortisol to cortisone, has also been documented.[45]

Table 35.1 Disorders of sexual development

SYNDROME	GONAD	DUCTS	EXTERNAL GENITALIA	PUBERTY	BARR	CHROMOSOMES	HORMONES FSH	HORMONES 17-KS	ESTROGEN	REMARKS
Klinefelter	Testis with hyalinized sclerotic tubules and clumped Leydig cells	Male	Male	Normal penis with small testes; partial androgen lack	"True" are chromatin positive, a few are 2+ or 3+	All chromatin positive have 2 Xs and a Y in at least some cells. Chromatin negative are 46,YY	↑↑	N or ↑	N	Affects 1:400 newborn males
Turner	Streak gonad with whorled stroma	Female	Female	No pubertal development; rare cases show mild virilization	50% chromatin negative	Second sex chromosome missing or abnormal in some or all of the cells	↑↑	↓	↓	1:7000 newborns, more common in abortuses; short stature
True hermaphrodite	Ovary and testis	All have uterus, most have tubes too, a few have vasa	Ambiguous but 80% favor the male	80% have gynecomastia, 50% menstruate	80% chromatin positive	60% are 46,XX in blood cells only; Y present in most of the others	N	N	N	—
Mixed gonadal dysgenesis	Streak plus testis or tumor	Female; vas found occasionally	Vary from female (often with clitoromegaly) to male with hypospadias to normal male	Virilization, sometimes complete; breast development only with tumors	Chromatin negative	Almost all are mosaics including XO stem; many have Y-bearing stem as well	↑	N	?	—
Dysgenetic male pseudohermaphroditism	Dysgenetic testis	Mixed male and/or female	Variable virilized	Rarely patients may be fertile	Chromatin negative	Some are XO/XY	↑	N	?	—
Familial male pseudohermaphroditism that ranges from testicular feminization to	Immature infertile testis	No uterus, ± rudimentary vas	Female with short, blind vagina	Breasts develop but sexual hair is missing	Chromatin negative	46,XY	↑ or N	↑ or N	N	Sex-linked recessive or sex-limited autosomal dominant
Reifenstein syndrome	Infertile testis	Male	Male with hypospadias ± cleft scrotum	Androgen lack is evident in incomplete virilization	Chromatin negative	46,XY	↑ or N	↑ or N	?	
Female Pseudohermaphroditism										
1. Congenital adrenal hyperplasia	Ovary	Female	Variably virilized	Amenorrhea with virilization	Chromatin positive	46,XX	N	↑↑	N	Autosomal recessive
2. Nonadrenal	Ovary	Female	Variably virilized	Normal	Chromatin positive	46,XX	N	N	N	Consider maternal exposure to progestins or androgens

↑, Increased; ↑↑, markedly increased; ↓, decreased; *N,* normal.

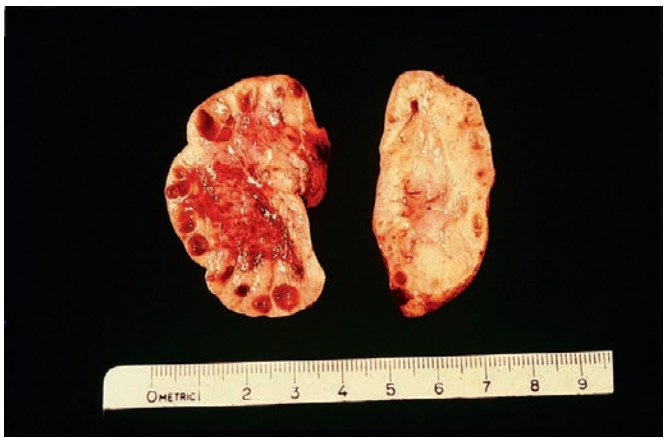

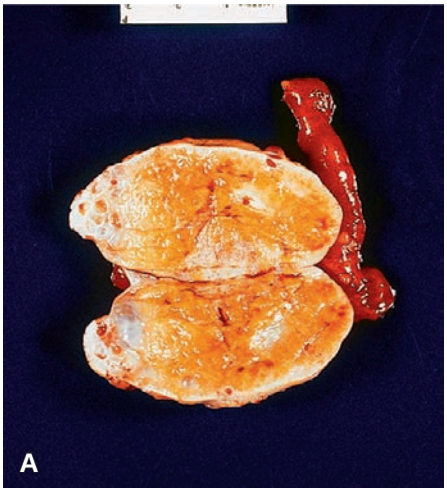

Figure 35.8 Outer aspect and cut surface of ovary in a patient with polycystic ovary syndrome. Note the numerous follicular cysts beneath the ovarian surface and the absence of corpus luteum.

In general, the ovaries of patients with PCOS have the macroscopic and microscopic features of polycystic ovaries just described. The histologic appearance does not correlate well with clinical manifestations in a given patient, and sclerocystic changes can be seen as an incidental finding in asymptomatic patients whose ovaries are removed for unrelated reasons. Polycystic ovaries have also been observed in association with primary hypothyroidism.[46]

Most patients with PCOS will respond favorably, with restoration of the menstrual cycle, to medical treatment, typically metformin (an oral hypoglycemic agent) and an aromatase inhibitor such as letrazole.[47,48] The endometrium of patients with PCOS may become hyperplastic, and endometrial carcinoma may develop against this

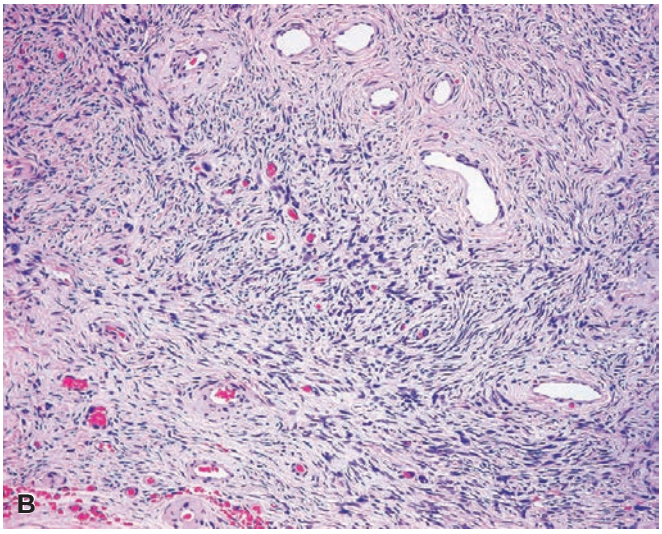

Figure 35.9 Ovarian Stromal Hyperplasia. A, Gross appearance. The cut surface is solid and has a yellowish hue. **B**, Microscopic appearance. The ovarian stroma is hypercellular.

Figure 35.11 Gross Appearance of Corpus Luteum Cyst. The luminal content is typically hemorrhagic.

background, the tumor typically being well differentiated and superficial.[49,50]

Stromal hyperplasia and hyperthecosis is characterized by a diffuse or nodular proliferation of plump ovarian cortical stromal cells encroaching on the medulla (Fig. 35.9).[7] Ovaries involved by stromal hyperplasia typically measure more than 5 cm in greatest dimension. Patchy luteinization of these cells may be present, a finding termed *stromal hyperthecosis*. Stromal hyperplasia and hyperthecosis may be associated with estrogenic or androgenic effects, obesity, hypertension, and an abnormal glucose tolerance test or even frank diabetes. The onset of symptoms may be abrupt, thus simulating a virilizing ovarian tumor. Immunohistochemical studies have shown androgen production by the luteinized stromal cells, suggesting that estrogenic effects in these cases are mediated through peripheral aromatization of these androgens.[51]

The boundaries between polycystic disease and stromal hyperplasia are ill-defined (Fig. 35.10)[41,52]; however, typical stromal hyperplasia lacks cysts and is usually more refractory to therapy.

Corpus luteum cysts are single and usually less than 6 cm in diameter. They may develop at the end of the menstrual cycle or may occur in pregnancy (Fig. 35.11). The cyst wall is composed of luteinized granulosa and theca cell layers. Hyaline bodies and foci of calcification may be found in the cysts associated with pregnancy. The fluid content is often bloody. If the cyst ruptures, hemorrhage into the peritoneal cavity occurs (sometimes over 500 mL), and an erroneous diagnosis of ruptured ectopic pregnancy may be made.[53] It should be remembered that the corpus luteum is normally a cystic structure. The arbitrary diameter of 2.5 cm has been proposed to distinguish the (normal) *cystic corpus luteum* from a *corpus luteum cyst*, in a manner analogous to that employed for follicle-related cystic formations. Distinction between a corpus luteum cyst and a luteinized follicular cyst can be arbitrary; the former diagnosis is favored when the degree of luteinization is similar to that of the cells in a normal corpus luteum.

Ectopic decidual reaction can occur in the ovary during pregnancy and occasionally even in the absence of current or recent pregnancy.

So-called **luteomas of pregnancy** are yellow or orange solid nodules that may reach sizable proportions (Fig. 35.12).[39] They have been typically encountered during cesarean section in multiparous women, sometimes accompanied by a mild degree of virilization.[54,55] If left undisturbed, they will regress after delivery.[56] Microscopically, the lesions are composed of masses of uniform theca–lutein cells (Fig. 35.13). Occasionally, there is an associated granulosa cell proliferation.[57] All of the reported lesions have been benign. It is reasonable to regard them as nodular hyperplasias of theca–lutein

Figure 35.12 Bilateral pregnancy luteomas in a 29-year-old woman that were discovered incidentally at the time of cesarean section performed for cord prolapse. The tumors bled excessively on manipulation by the surgeon and had to be removed.

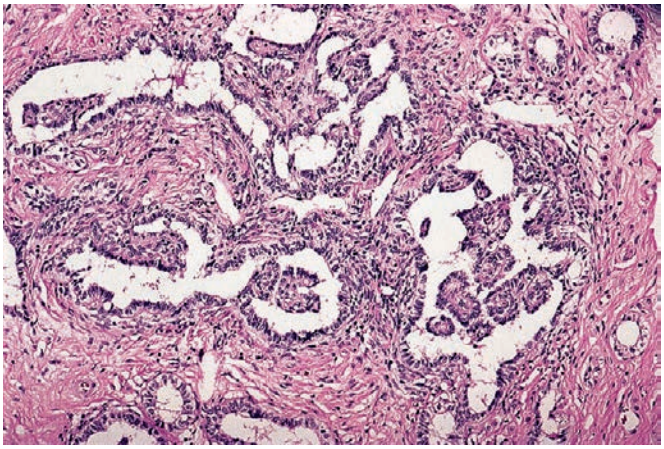

Figure 35.14 Benign hyperplastic changes in rete ovarii. This alteration is of no clinical significance.

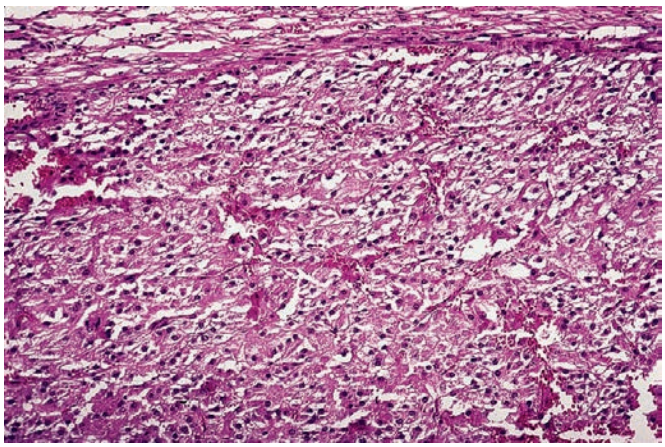

Figure 35.13 Solid growth pattern of pregnancy luteoma.

cells rather than true neoplasms.[55] If pregnancy luteoma is correctly identified by frozen section, no further surgery is necessary. A steroid cell tumor should not be diagnosed based on frozen section of an ovarian mass performed at the time of C-section as it is more likely to be a luteoma of pregnancy, and an incorrect diagnosis of steroid cell tumor may lead to an unnecessary oophorectomy. This scenario illustrates, as well as any example, the importance of having adequate clinical history at the time of intraoperative consultation/frozen section.

Developmental cysts derived from wolffian (mesonephric) and müllerian (paramesonephric) remnants are common in the region of the ovarian hilus. Suffice it to say here that, according to some authors, it is possible to distinguish these two types of tissue—and sometimes the cysts derived from them—on microscopic grounds.[58] Wolffian structures are lined by cuboidal, predominantly nonciliated epithelium resting on a well-developed basement membrane; müllerian formations are lined by generally taller, ciliated and nonciliated epithelium with larger nuclei and resting on an inconspicuous basement membrane. Such a distinction is not clinically important and may not be possible in some cases, and the designation of "Benign parovarian (or paratubal) cyst" may be used. Both may have a smooth muscle coat. According to these criteria and some ultrastructural differences,[59] **hydatids of Morgagni** (pedunculated cysts at the fimbriated end of the fallopian tube) are believed to be of müllerian origin, whereas most **parovarian** and **paratubal cysts** (in the tubo-ovarian ligament) and **Gartner duct cysts** (in the vaginal wall) are thought to arise from wolffian remnants.

Cysts of the rete ovarii are characterized by a hilar position, an epithelial lining of variable height that is usually nonciliated, crevices along the inner surfaces, and a fibromuscular wall that often contains hyperplastic hilus cells.[50] The rete ovarii may also be the site of benign proliferative lesions that have been variously reported as adenomatous hyperplasia[60] and adenoma (Fig. 35.14).[61]

Epidermoid cysts, lined by benign squamous epithelium without evidence of skin adnexal structures or other teratomatous elements, are exceptionally rare and are of uncertain histogenesis.[62–64]

Squamous metaplasia of the OSE accompanied by subjacent fibrosis has been described in patients on long-term peritoneal dialysis.[65]

Amyloidosis can exceptionally present in the form of bilateral ovarian masses.[66]

Supernumerary ovaries are extremely rare.[67] Most of the reported cases have measured less than 1 cm. They should be distinguished from **accessory ovaries**, which are small portions of ovarian tissue situated near—and sometimes connected to—the normally placed organ.[68]

Inflammation

Nonspecific inflammation of the ovary usually spreads from the endometrium and is practically always associated with tubal involvement. A large, loculated cystic mass filled with pus or secretion is often the result, the ovarian stroma forming part of the cystic wall (tubo-ovarian abscess or cyst). Exceptionally, a solid mass rich in foamy macrophages develops in long-standing cases *("xanthogranulomatous oophoritis")*.[69,70]

Granulomatous infections such as tuberculosis occur in the ovary. Invariably this is hematogenous in origin and often also involves the tube and endometrium. In time, the infection may subside and leave a large tubo-ovarian cystic mass. Other infectious agents responsible for granulomatous oophoritis are *Actinomyces* (particularly common after the introduction of intrauterine devices), *Schistosoma*, and *Enterobius vermicularis*. Rarely, *sarcoidosis* and *Crohn disease* involve the ovary, the latter as a result of direct extension from the bowel. *Foreign body granulomas* can occur in the ovarian surface secondarily to talc, cornstarch, carbon pigment (at the site of fulguration surgery),[71] other foreign materials,[72] and keratin; the latter may originate from a ruptured ovarian cystic teratoma or may have spilled through the fallopian tube from an endometrial

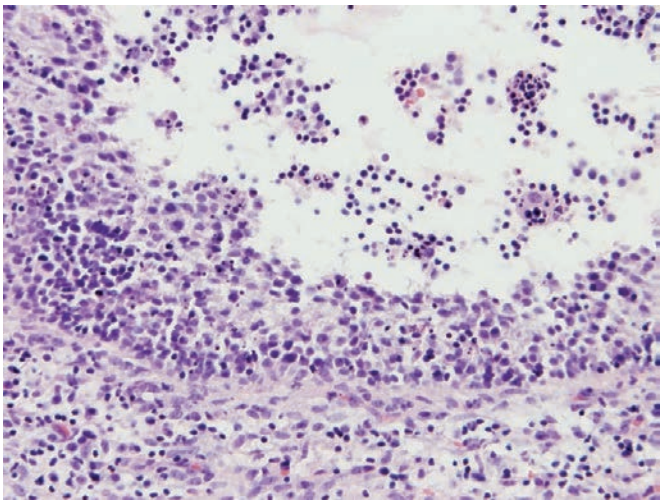

Figure 35.15 Lymphocytic and plasmacytic infiltrate of a developing follicle in autoimmune oophoritis.

Figure 35.16 Inner surface of cyst in a case of ovarian endometriosis. The color is typically brown.

adenocarcinoma of endometrioid type, with squamous differentiation.[73] *Palisading granulomas* of unknown etiology have also been reported, most of them in patients with a history of previous pelvic surgery.[74]

Autoimmune oophoritis is a poorly understood cause of premature ovarian failure characterized microscopically by lymphocytic and plasma cell infiltration in relation to developing follicles but not primordial follicles (Fig. 35.15).[71,75] It results in primary ovarian failure with either primary or secondary amenorrhea.[76,77] Many of the reported cases have been associated with adrenal failure (Addison disease), hypothyroidism, or both conditions.[76,78]

Eosinophilic perifolliculitis is characterized by a predominantly eosinophilic infiltrate around the follicles; it is not clear how this rare disorder relates to autoimmune oophoritis.[79]

Giant cell arteritis occasionally involves the ovary of elderly women; it may occur as an isolated finding (most frequently) or as a component of generalized giant cell arteritis.[80]

Endometriosis

The ovary is the most common site of endometriosis, as defined by the presence of endometrial glands *and* stroma outside the uterus.[81] The pathogenesis of endometriosis remains incompletely understood; suffice it to say that endometriosis shows evidence of clonality and in a minority of cases the epithelium has an activating KRAS mutation.[82,83] Ovarian endometriosis is usually associated with infertility, and it remains active during the childbearing years.[84,85] Pain associated with the menstrual cycle is the most common symptom; infrequently, the disease is complicated by massive ascites or perforation into the peritoneal cavity.[86] Grossly, it usually presents as small, slightly raised, blueberry-like spots on the ovarian surface, often accompanied by fibrous adhesions. In cases with extensive involvement, the entire ovary may be converted into a "chocolate cyst" as a result of repeated hemorrhages (Fig. 35.16). Microscopically, the typical lesions are composed of endometrial glands, endometrial stroma, and fresh and old (hemosiderin-containing) hemorrhagic foci (Fig. 35.17).[87] The endometrial stroma is responsible for the bleeding; it has cells with a "naked nucleus" surrounded by reticulin and typical spiral arterioles, in conjunction with old and recent hemorrhage. Unfortunately, this diagnostic combination of findings is not always present. The more advanced the endometriotic lesion, the more difficult the diagnosis and the greater the number of sections required to make it. Not infrequently, the repeated hemorrhages have totally destroyed the endometrial tissue, the cyst being lined by several layers of hemosiderin-laden macrophages with a thick fibrous wall. Under these circumstances, the most the pathologist can do is to report the case as a hemorrhagic cyst and comment that the changes are "consistent" with those of endometriosis. Sometimes, the lesion is entirely composed of *necrotic pseudoxanthomatous nodules*, to be distinguished from infectious granulomas and necrotic neoplasms (Fig. 35.18).[88] Other morphologic variations of endometriosis include the formation of Liesegang rings,[89] stromal elastosis,[90] and smooth muscle hyperplasia,[91] the latter sometimes resulting in the formation of uterus-like masses.[92]

The ectopic endometrial tissue of endometriosis is subject to most of the influences that affect the intrauterine endometrium. Ovarian endometriosis more often undergoes malignant transformation than endometriotic foci elsewhere in the pelvis. Somewhat confusingly, two different premalignant changes have been described within ovarian endometriosis, and both have been termed "atypical endometriosis." The first consists of cells that do not show significant stratification but which have prominent nuclear atypia (Fig. 35.19).[93–96] These cells are thought to be a precursor of clear cell carcinoma and can have ARID1A mutations and show an immunophenotype intermediate between endometriosis and clear cell carcinoma.[97] The other premalignant change seen in ovarian endometriosis is morphologically identical to atypical endometrial hyperplasia, with glandular crowding and atypia.[98] This is thought to be the precursor of endometrioid carcinoma. Although clear cell and endometrioid carcinomas account for most malignancies arising in endometriosis, a wide range of other malignancies may also be encountered in association with ovarian endometriosis (e.g. carcinosarcoma, adenosarcoma, endometrial stromal sarcoma, seromucinous borderline tumor, and, rarely, serous borderline tumor or low-grade serous carcinoma).

Tumors

Classification

The classification of ovarian tumors is primarily morphologic and based on the cytologic features of the tumor cells. This approach has served us well over the years, with recent molecular studies, for the most part, supporting this morphology-based classification system and demonstrating that it accurately reflects both histogenesis/cell of origin, and the underlying molecular abnormalities of the different

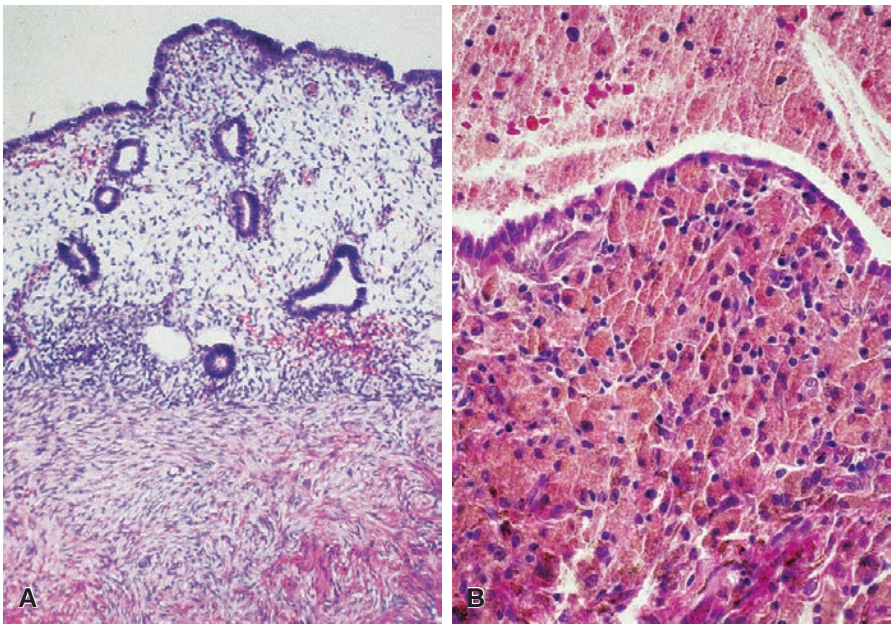

Figure 35.17 Ovarian Endometriosis. A, In this area endometrial tissue faithfully reproduces the appearance of normal endometrium, in terms of both glands and stroma. **B,** A more common appearance resulting from repeated hemorrhage and accumulation of hemosiderin-laden macrophages.

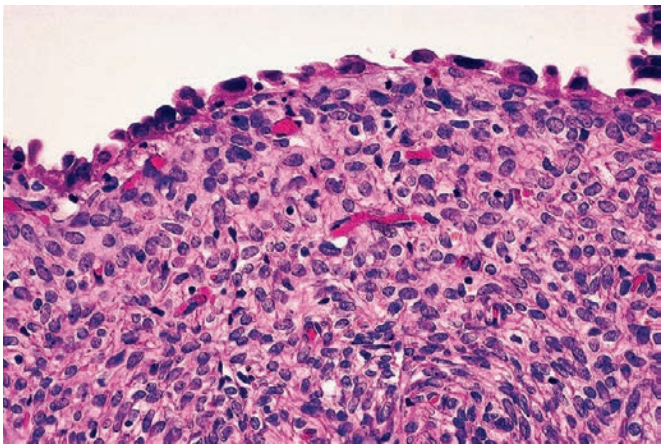

Figure 35.19 Atypia of the cells lining an ovarian endometriotic cyst, a change referred to as atypical endometriosis.

ovarian tumor subtypes.[99] While there have been some minor adjustments made, reflected in the 2014 WHO classification system,[100] the fundamental premise that the ovary contains four major types of tissue, all of which can give rise to a variety of neoplasms, has remained unchanged for decades. These four tissue types are:

1. Epithelium
2. Germ cells
3. Sex cords
4. Ovarian stroma, specialized and nonspecific.

Epithelial Tumors

Overview

Epithelial tumors, numerically the most important group of neoplasms, have traditionally been thought to derive from the OSE[101] and were thus referred to as "surface epithelial" tumors. It is now appreciated that the epithelial tumors of the ovary are of diverse origins, histogenetically, and the cell of origin of each histotype will be discussed in the section devoted to that specific histotype, later in this chapter.

Epithelial ovarian tumors are subclassified based on cell type as **serous, endometrioid, clear cell, mucinous, seromucinous,** or **transitional (Brenner)**.[100] It is now appreciated that the histotype reflects differences in cell of origin and molecular abnormalities, and subclassification based on cell type, or histotype, has taken on increased importance in recent years.[100]

Within each histotype, tumors are further subclassified as **benign, borderline,** or **malignant.** Benign tumors are characterized by epithelium with benign nuclear features and differentiated cytoplasm; for example, the benign serous tumors feature cells with cilia, morphologically identical to the normal ciliated cells of the fallopian tube. Benign epithelial tumors can be further subclassified based on whether they are predominantly cystic, cystic and solid, or

predominantly solid with fibromatous stroma, as cystadenoma, cystadenofibroma, and adenofibroma, respectively.[99] There is an arbitrary cutoff between cystadenoma and cystadenofibroma, with the latter having at least 25% solid component. This subclassification based on the gross appearance of the tumor is not clinically relevant, beyond allowing correlation with radiologic findings.

The borderline category is characterized by cytologic atypia, but without evidence of invasion, and its existence as a diagnostic entity has been controversial. Although it has been stated that this category is unique to ovarian tumors, other "borderline" tumors do exist, such as low-grade mucinous neoplasm of the vermiform appendix. Attempts have been made to eliminate the borderline category of ovarian epithelial tumors, so that tumors are classified as either benign or malignant[102,103]; however, the borderline category has survived these attempts. The key to the survival of "borderline" as a diagnostic entity can probably be found in its history as a subcategory of ovarian epithelial tumors[104]; it was recognized that there were advanced-stage tumors that did not behave like usual high-stage ovarian carcinoma, and in these patients adjuvant treatment did more harm than good. Creation of a borderline designation for these unusual tumors allowed for a more conservative management to emerge. This is true specifically for serous and seromucinous borderline tumors, where a significant minority of cases (15%–40%) are associated with extra-ovarian implants (i.e. stage II or III), and yet there is a favorable prognosis. Although the borderline category has been extended to the other ovarian histotypes (e.g. clear cell, endometrioid), such tumors are invariably stage I and can be expected to behave in a benign fashion when diagnosed using strict criteria.

The distinction between borderline and malignant is based on the presence of "invasion" in the latter; the criteria for invasion differ from histotype to histotype, and histotype-specific discussions are provided later in this chapter. The malignant epithelial tumors ("carcinomas") show other striking differences between histotypes, which are summarized in Table 35.2,[105] and described in more detail in the histotype-specific sections of this chapter, later. It is important to recognize that although histotype of ovarian carcinoma was considered to not be diagnostically reproducible or clinically relevant in the past, that has changed, and ovarian carcinoma histotype can be diagnosed with very high interobserver agreement[106–108] and increasing clinical significance. There remain 1%–2% of ovarian carcinomas that show unusual morphologic features and defy histotype assignment, but in most tumors the diagnosis of histotype is straightforward on routine H&E stains. The importance of histotype in ovarian carcinoma can be illustrated by consideration of two aspects of ovarian carcinoma: stage at presentation and association with hereditary cancer susceptibility syndromes.

The stage at presentation of ovarian carcinoma of different histotypes are shown in in Table 35.3.[109] For patients presenting with high-stage disease (i.e. stage III or IV), the large majority are high-grade serous, while patients presenting with tumors confined to the adnexa are more likely to have a tumor other than high-grade serous carcinoma (HGSC), which account for a minority of such cases. The histotype of organ confined ovarian carcinomas, e.g. presenting at the time of frozen section for an adnexal mass that was thought to be an endometriotic cyst preoperatively, are very different than those diagnosed in patients with ascites and omental involvement.

Familial Ovarian Cancer Syndromes

There are two common autosomal dominant hereditary cancer syndromes: hereditary breast and ovarian cancer syndrome (HBOCS) and Lynch syndrome, with the former first described by Henry Lynch and the latter named after him for his pioneering work in establishing

Table 35.2 Features of the five major histologic types of ovarian carcinoma.

	HGSC	CCC	EC	LGSC	MC
Mean age	63	55	58	53	45
5-Year survival (stage III only)	40	23	66	71	NA
Origin	Fallopian tube	Endometriosis	Endometriosis	Cystadenoma	Germ cell, transitional epithelium
Molecular abnormalities	Genomic instability; TP53 mutation; homologous recombination DNA damage repair defects; CCNE1, NOTCH3 activation; Rb, NF1 inactivation	Wnt-catenin activation; ARID1A-chromatin remodeling complex inactivation; PI3K activation; PTEN inactivation, MMR abnormalities		KRAS/BRAF/MEK pathway activation	ERBB2/KRAS/BRAF/MEK pathway activation
Inherited syndromes	HBOC	LS	LS	?LS	?LS
Sensitivity to platinum-based chemotherapy	Sensitive	Relatively resistant	Relatively resistant	Relatively resistant	Relatively resistant
Adjuvant/targeted therapies licensed or in trial	PARPi; immune checkpoint inhibitors	Radiotherapy; Sunitinib	mTOR inhibitors	Selumetinib (MEK1/2 inhibitors)	Trastuzumab

the importance of these hereditary cancer syndromes; both are associated with an increased risk of ovarian carcinoma, but the histotypes of the carcinomas encountered in these syndromes are completely different. Germline mutations in BRCA1 or BRCA2, which encode proteins involved in high-fidelity repair of double-strand (DS) DNA breaks, account for 95% of cases of HBOCS, and these patients have an estimated 45% lifetime risk of developing ovarian carcinoma, although the risk varies depending on the specific mutation, being higher in patients with BRCA1 mutations than those with BRCA2 mutations.[110,111] In HBOCS, patients are at increased risk of developing HGSC but not at significantly increased risk of developing other histotypes of ovarian carcinoma, borderline tumors, germ cell tumors or sex cord–stromal tumors.[112,113] Of patients newly diagnosed with HGSC, 15%–20% will have a germline BRCA1 or BRCA2 mutation; consideration should therefore be given to genetic counseling and testing for HBOC in all such patients.[114]

Lynch syndrome, secondary to mutations in genes involved in another DNA repair pathway that is, mismatch repair, is associated with an 8%–10% lifetime risk of developing ovarian carcinoma,[115,116] and the carcinomas that arise in patients with Lynch syndrome are of those histotypes associated with endometriosis (i.e. endometrioid and clear cell).[117,118] The likelihood of a clear cell or endometrioid carcinoma of the ovary being associated with Lynch syndrome appears to be the same as that of colorectal carcinoma or endometrial carcinoma (i.e. 3%–5%). Therefore, if screening for Lynch syndrome mutations through immunostaining for mismatch repair enzymes in newly diagnosed carcinomas is being done, it has been suggested that it should be inclusive of not just colorectal and endometrial carcinoma, but the 20% of ovarian carcinomas of endometrioid or clear cell type.[118]

Serous Tumors

Serous tumors make up about one-fourth of all ovarian tumors and most occur in adults. A critical advance in our understanding of ovarian neoplasia is the recent recognition that low-grade serous neoplasms are a different disease than HGSC.[119–124] In the past it was thought that HGSCs arose through progression of low-grade serous neoplasms, but it is now recognized that, despite the shared "serous" or fallopian tube cell type, the low-grade and high-grade serous tumors are not closely related. Differences include cell and site of origin, molecular events during pathogenesis and response

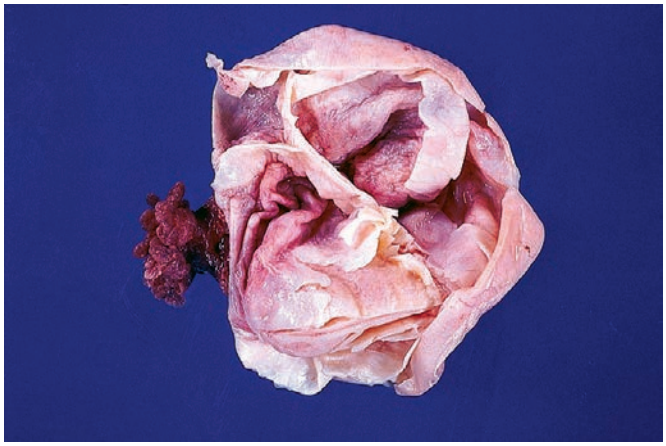

Figure 35.20 Smooth outer and inner surfaces of the cystic formations in a case of ovarian serous cystadenoma.

Figure 35.21 Inner aspect of serous cystadenoma showing papillary structures protruding within.

to chemotherapy, among others. Accordingly the low-grade and high-grade serous tumors will be discussed separately.

Low-Grade Serous Neoplasia

This category is inclusive of benign and borderline serous tumors and low-grade serous carcinoma. Grossly, these tumors typically consist of cystic masses, usually unilocular, containing a clear but sometimes viscous fluid (Fig. 35.20). Papillary formations are often present, most of them protruding into the cavity but some occasionally occur on the outer surface (Fig. 35.21). In serous borderline tumors the papillae lining cysts are more delicate than the predominantly stromal papillae of benign serous tumors (Fig. 35.22). The low-grade serous carcinomas tend to be solid but lack conspicuous areas of necrosis and hemorrhage.

Microscopically, cuboidal to columnar cells are seen lining the wall of the cysts and the papillae (Fig. 35.23). They are similar to normal tubal epithelium at both a light and electron microscopic level.[125] Hobnail cells can be present, not to be taken as evidence of the presence of a clear cell carcinoma component.[126] In borderline tumors and low-grade serous carcinomas, calcific concretions with concentric laminations (psammoma bodies) are often present.

A morphologic spectrum of proliferation exists in these tumors. At one end is the benign **serous cystadenoma**, in which the cysts

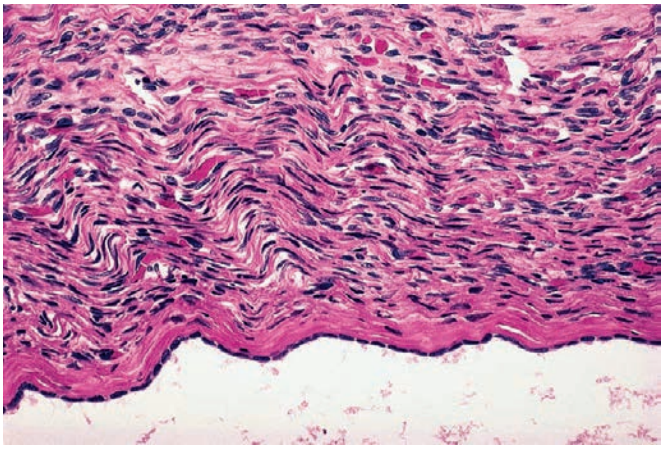

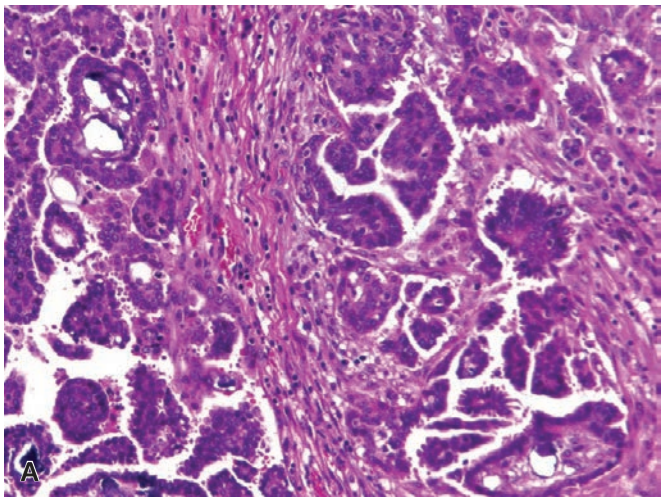

Figure 35.23 Single layer of bland-looking epithelial cells lining one of the cystic structures of a serous cystadenoma.

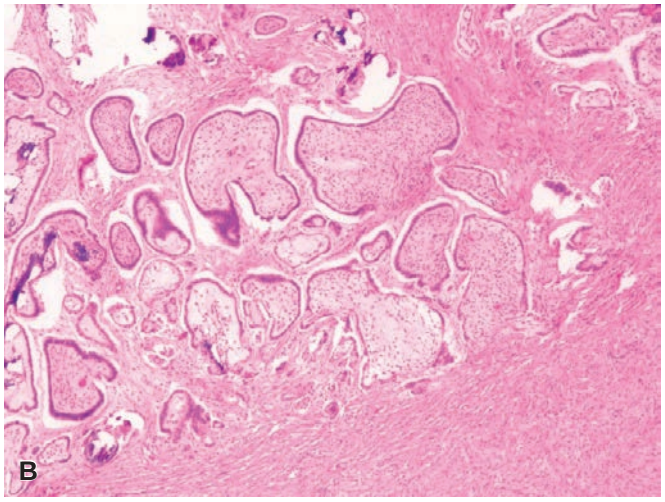

Figure 35.24 Low-Grade Serous Carcinoma. Invasion is evident as micropapillae and individual cells infiltrating the stroma **(A)** and as macropapillae, with broad central cores, also infiltrating the stroma **(B)**; note the clear space surrounding the invasive cell clusters.

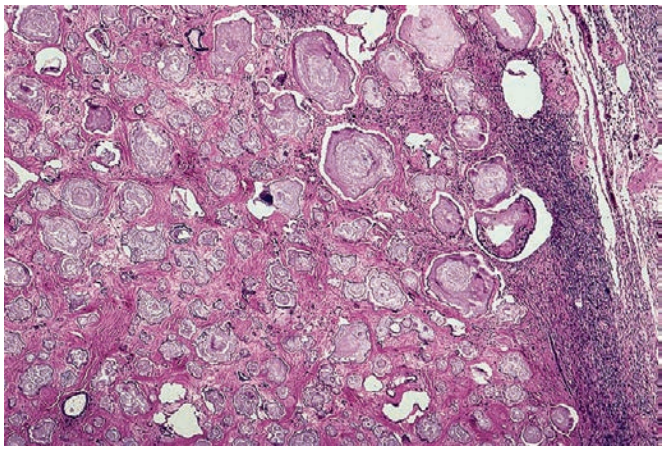

Figure 35.25 Low-grade serous carcinoma with innumerable psammoma bodies, so-called serous psammocarcinoma.

and the papillae (if present) are lined by a single layer of cells, without atypia, architectural complexity, or invasion (see Fig. 35.23). At the other end is low-grade serous carcinoma, characterized by low-grade nuclear atypia, mitotic activity, stratification, glandular complexity, branching papillary fronds, and *stromal invasion* (Fig. 35.24). Stromal invasion in low-grade serous carcinoma can show a number of patterns, which may be admixed in a single tumor,[127] and include: A. single cells and small, compact, irregular nests of cells, B. micropapillae and complex papillary forms (see Fig. 35.24A), C. inverted macropapillae, in which the neoplastic epithelium covers broad fibrovascular stromal stalks (this is the least common pattern; see Fig. 35.24B), D. cribriform, E, glandular or cystic, and F. solid sheets with slit-like spaces. In all of these patterns there is typically a clear space surrounding the neoplastic cells. **Serous psammocarcinoma**, so called, is a rare variant of low-grade serous carcinoma characterized by massive psammoma body formation (Fig. 35.25).[128] In between these two ends of the spectrum are serous borderline tumors, characterized by cellular stratification, detached cell clusters, atypia and occasional mitotic figures, but lacking stromal invasion (Fig. 35.26).[129,130] Borderline tumors account for approximately 15% of all serous tumors.[131–135] Ciliated cells are invariably present in benign serous tumors, less common in serous borderline tumors and uncommon in low-grade serous carcinoma.

In summary, benign serous tumors (serous cystadenoma, serous cystadenofibroma, or serous adenofibroma) are distinguished from

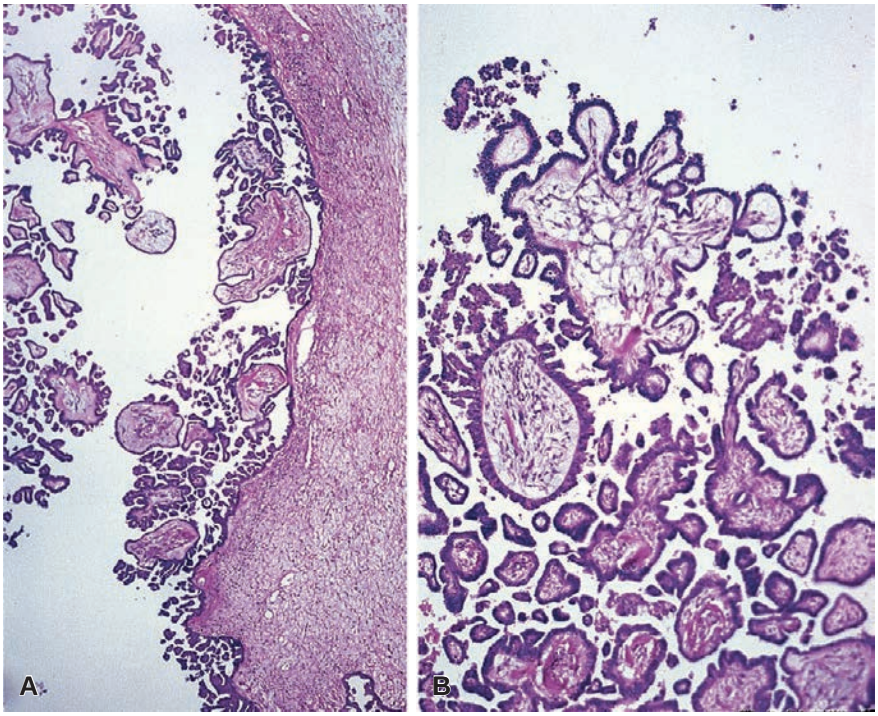

Figure 35.26 Low-power **(A)** and medium-power **(B)** appearance of ovarian borderline serous neoplasm. The growth is entirely exophytic.

serous borderline tumor by the absence of cellular stratification and atypia. The finding of detached clusters of epithelial cells is important evidence of cellular stratification; epithelial pseudostratification with apparent multilayered epithelium can be seen due to tangential sectioning, but this never leads to the presence of detached cell clusters. When the "borderline" features are present only focally (i.e. account for less than 10% of the cyst lining) in an otherwise benign tumor, the designation *"cystadenomas with focal proliferation or focal atypia"* can be used and these tumors also have a benign course.[131,136]

Borderline serous tumors are distinguished from low-grade serous carcinoma by the absence of stromal invasion. It should also be noted that microinvasion in serous borderline tumors, defined as one or more invasive foci measuring less than 5 mm in greatest dimension, is a relatively common finding in serous borderline tumor, seen in 10%–15% of cases, and is not of prognostic significance (Fig. 35.27).[100,137,138] The microinvasive foci typically appear as individual cells or clusters of cells with abundant eosinophilic cytoplasm ("eosinophilic metaplastic cells") that show a low Ki67 labeling index.[139,140] It should be noted that in 50% or more of low-grade serous carcinomas there is a coexisting borderline component, from which the low-grade serous carcinoma has presumably arisen. A special circumstance is when there is a serous borderline tumor of the ovary and invasive low-grade serous carcinoma in the extra-ovarian implants (a situation that in the past would have led to a diagnosis of "serous borderline tumor with invasive implants). Recognition of invasive carcinoma in extra-ovarian implants is based on the criteria proposed by Bell et al.[141]: the presence of a haphazard infiltrative growth pattern that destroys the architecture of the invaded tissues. Surface peritoneal involvement does NOT constitute evidence of invasion in extra-ovarian implants; there must be invasion into underlying tissue. The presence of invasion at extra-ovarian sites should lead to a diagnosis of low-grade serous carcinoma, even if the ovarian tumor is entirely borderline.[100,142]

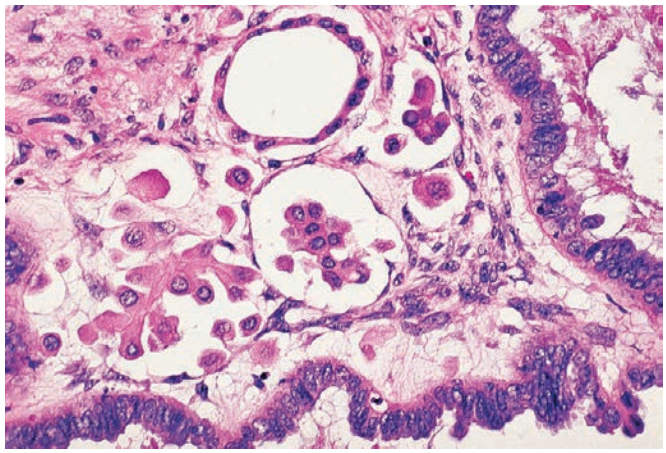

Figure 35.27 Serous borderline tumor with focal microinvasion represented by clusters of cells with abundant eosinophilic cytoplasm.

Low-grade serous carcinomas are distinguished from the much more common HGSCs by their frequent association with serous borderline tumor and a lesser degree of nuclear pleomorphism (less than threefold variation in nuclear size). In cases where there remains difficulty in deciding between these two possibilities, the low-grade serous carcinomas have a much lower mitotic rate than HGSCs (12 or fewer MF per 10 HPF),[119–121] and p53 immunostaining shows a normal pattern, compared to the abnormal staining (so-called all or nothing patterns) present in 95% of HGSCs.

Prognosis

The benign serous tumors are invariably benign, while the prognosis of serous borderline tumors is dependent primarily on stage. Stage Ia tumors, without surface involvement, positive washings or

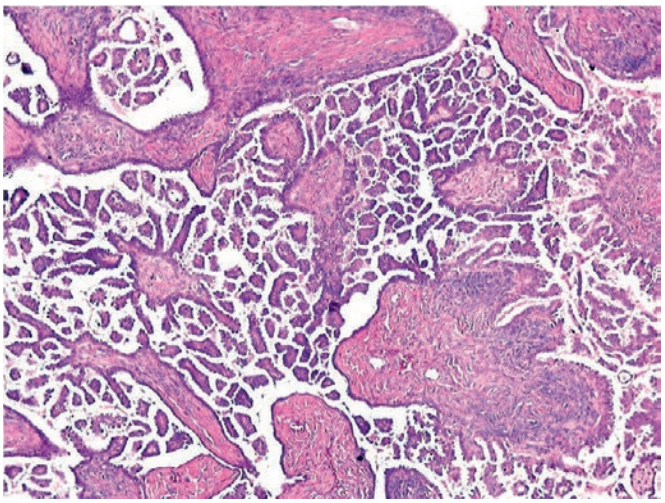

Figure 35.28 Ovarian serous borderline tumor with a micropapillary pattern of growth.

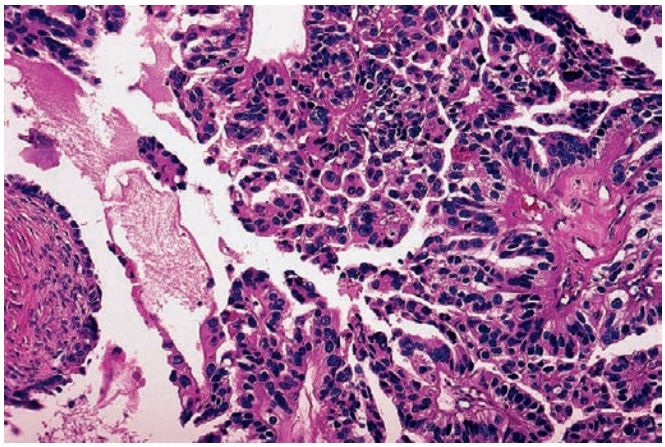

Figure 35.29 High-grade serous carcinoma with papillary architecture.

extra-ovarian implants, are associated with an excellent prognosis. Curiously the presence of nodal involvement is not associated with an adverse outcome in patients with serous borderline tumor. Micropapillary architecture is associated with a worse prognosis in patients with serous borderline tumor, but it is not established whether this is independent of the well-known association of micropapillarity with higher stage and a component of invasive low-grade serous carcinoma (either within the ovary or at extra-ovarian sites).[143–146] Micropapillary architecture is defined as nonhierarchical branching of elongate filiform papillae and/or a cribriform architecture, with the latter being considerably less common than the former. The papillae should be at least 5 times as long as wide (Fig. 35.28), and the micropapillary focus must be confluent for at least 5 mm. Kurman and colleagues have suggested that serous borderline tumor with micropapillary features should be diagnosed as noninvasive low-grade serous carcinoma; micropapillarity in a stage Ia tumor is not associated with a different prognosis than in a stage Ia conventional serous borderline tumor,[145] and it is therefore not justified, in our opinion, to introduce a new diagnostic term for these patients (i.e. noninvasive low-grade serous carcinoma), especially when the diagnostic criteria have not been shown to be highly reproducible. The borderline category was introduced in the 1950s to clearly indicate that there is a different natural history for patients with these tumors, compared to those with usual carcinoma, and this rationale is still applicable and constitutes an argument against use of the terminology of "noninvasive low-grade serous carcinoma." As noted previously, micropapillary architecture is more likely to be associated with either higher stage disease (ovarian surface involvement or extra-ovarian implants), or the presence of invasive low-grade serous carcinoma, and recurrence as carcinoma is also more common in these tumors, so when micropapillarity is present it should be documented in the pathology report and a careful search for evidence of higher stage or invasion is warranted, but that is the only action we would currently recommend based on the presence of micropapillary variant of serous borderline tumor.

The prognosis of low-grade serous carcinoma is highly dependent on stage. For stage Ia disease the prognosis is excellent, but in most reported cases there is extra-ovarian spread at the time of diagnosis and these patients have a poor prognosis, similar to that of patients with HGSC.[126,147] With recurrence and tumor progression, low-grade serous carcinomas can become higher grade, with increased mitotic activity. These tumors differ from usual HGSC in lacking *TP53* mutations[124] (i.e. they are not examples of "progression" from low-grade serous carcinoma to HGSC of the usual type).[148]

Immunohistochemistry and Molecular Pathology

Immunohistochemically, the typical keratin profile of low-grade serous tumors is CK7+/CK20–.[149] They also express CK8, 18, and 19, EMA, B72.3,[150–152] vimentin,[153] glial fibrillary acidic protein (GFAP) (occasionally),[152] the β-subunit of human chorionic gonadotropin (hCG) (in a minority of cases),[154] and receptors for estrogen and progesterone.[155,156] A small minority (around 10%) of serous tumors stain for calretinin and/or inhibin, a potentially confusing finding in the differential diagnosis with sex cord–stromal tumors.[157] WT1 and PAX8 stain most low-grade ovarian serous tumors.[158–160] Serous borderline tumors and low-grade serous carcinoma have relatively few mutations and are typically diploid. The most common mutations are in *KRAS* and *BRAF*.[100,123]

High-Grade Serous Carcinoma

Most HGSCs show bilateral ovarian involvement. Tubal fimbrial involvement is often noted on gross examination and is usually unilateral. On sectioning the ovarian masses are solid and cystic, with conspicuous hemorrhage and necrosis. Microscopically, HGSC is characterized by morphologic heterogeneity, and there is often an admixture of different architectural patterns including papillary, micropapillary, slit-like, glandular, microcystic/ microglandular, solid, and transitional-like patterns. While papillary elements and slit-like spaces are characteristic of HGSC (Figs. 35.29 and 35.30), well-formed rounded glands are also common, resulting in a pseudoendometrioid appearance (Fig. 35.31). The tumor cells usually have scant to moderate amounts of cytoplasm, but occasionally there is abundant eosinophilic or clear cytoplasm, or cells with vacuoles and intracytoplasmic mucin, resulting in a signet ring appearance. The neoplastic cells consistently show high-grade nuclear features, with significant pleomorphism and a high mitotic rate with frequent abnormal mitotic figures. As a rule, high-power microscopic fields with multiple mitoses are easily found, and individual bizarre tumor giant cells are also often present, features that are helpful in ruling out low-grade serous carcinoma. Areas of necrosis are common, but psammoma bodies are less frequently encountered than in low-grade serous carcinoma.

Prognosis

When there is a general discussion of "ovarian carcinoma" it is usually concerned with HGSC, as it accounts for 70% of all cases

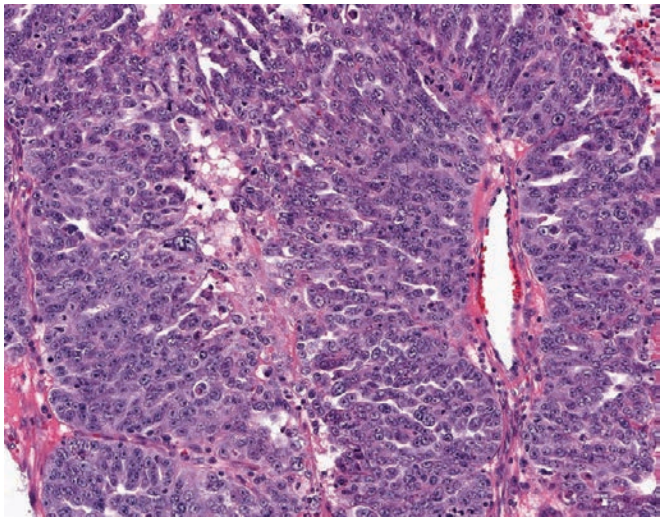

Figure 35.30 High-grade serous carcinoma with slit-like spaces.

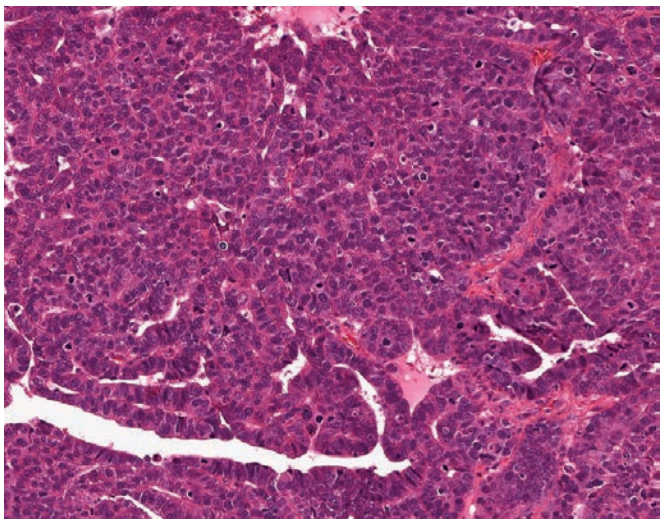

Figure 35.31 High-Grade Serous Carcinoma With Gland Formation. This is a common finding in high-grade serous carcinoma and is not evidence of a component of endometrioid carcinoma.

(see Table 35.2) and a disproportionate number of the deaths due to disease. The latter is attributable to these tumors being high-stage at diagnosis, which is itself attributable to most of them originating in the tubal fimbria (discussed later). There has unfortunately been little progress in treatment of HGSC. Although most patients experience a remission, recurrence and death due to progressive disease are usual. Treatments targeting the molecular abnormalities of HGSC, such as PARP inhibitors, show great promise,[161] but they have not yet entered practice as adjuvant treatment, where they would be given with curative intent. Nonetheless, the activity they show against recurrent HGSC is impressive and they will undoubtedly become more widely used over the coming years.

Site of Origin

There is now irrefutable evidence that most extrauterine HGSCs arise from the fallopian tube (most commonly the fimbrial end) from a precursor lesion referred to as serous tubal intraepithelial carcinoma (STIC).[162–167] It was first recognized that the fimbrial end of the fallopian tube is the site of origin of a large majority of HGSCs in patients with a germline BRCA1 or BRCA2 mutations, based on the fimbrial location of early carcinomas identified in risk-reducing salpingo-oophorectomy specimens.[166,168–170] This observation became possible only with more detailed and systematic examination of the fallopian tubes; introduction of the **S**ectioning and **E**xtensively **E**xamining the **FIM**bria (SEE-FIM) protocol[166] resulted in a dramatic increase in the number of STICs and small invasive HGSCs detected. It is now clear that STIC and small tubal mucosal HGSCs are found in sporadic "ovarian" HGSCs at comparable frequency to what is seen in high-risk patients with HBOCS. Adding to the cases with STIC those where the fimbrial end of the tube is overgrown and incorporated into an adnexal mass, one is left with fewer than 20% of HGSCs where there is not tubal involvement. It is also clear that the tubal lesions usually precede the disease in the ovaries and other extratubal sites.[170] Four recent studies have reported on HGSC diagnosed as an incidental finding at surgery carried out for unrelated reasons; these occurred in women who were not at high risk for ovarian cancer.[171–174] The tubal mucosa was involved in 100% (48 of 48) of cases and STIC, with or without an invasive mucosal carcinoma, was identified in 98% (47 of 48).

It should be remembered that fallopian tube mucosal involvement and ovarian involvement by uterine or nongynecological primary tumors can occur and can mimic STIC. Most cases with both endometrial serous carcinoma (either intraepithelial or invasive) and concomitant unilateral or bilateral HGSC in the ovary (and/or STIC or HGSC in the fallopian tube) represent adnexal metastases from an endometrial primary.[161] WT1 may be of value in these cases, as most tubal HGSCs exhibit diffuse nuclear positivity with WT1, while most uterine serous carcinomas are negative. Unfortunately, there is some overlap in that a proportion of uterine serous carcinomas are WT1 positive (the percentage has varied between studies, but may be up to 30%) and a small percentage of tubal HGSCs are WT1 negative.[175]

While the assignment of primary site in HGSC does not change management, it is often a requirement for tumor registries, and a uniform approach to site assignment is desirable. The following guidelines take into account recent advances in our understanding of the histogenesis of HGSC, described previously[176]: A. Primary site should be assigned as tubal in the presence of STIC or invasive mucosal HGSC in either fallopian tube, or when either tube is partly or fully incorporated into and inseparable from a tubo-ovarian mass. B. Primary site should be assigned as ovarian only when there is ovarian involvement and the fallopian tubes are clearly visible, have been dissected away from the surface of the ovaries, fully examined by a standardized SEE-FIM protocol and neither STIC nor invasive mucosal carcinoma is present in either tube. C. Primary site should be assigned as peritoneal only when both tubes and both ovaries are grossly and microscopically normal; primary peritoneal HGSC should only be diagnosed in a specimen from primary surgery (as neoadjuvant chemotherapy can impact on the ability to assign primary site by changing the disease distribution) and only after complete examination of both tubes and both ovaries using a standard protocol.

Differential Diagnosis

The differential diagnosis between HGSC and low-grade serous carcinoma was discussed in the preceding section. The differential diagnosis also includes endometrioid carcinoma, clear cell carcinoma, and undifferentiated carcinoma (Fig. 35.32). As endometrioid-like glandular formation, clear cell change or solid undifferentiated architecture are rarely present throughout a well-sampled tumor, the presence of typical HGSC will establish the diagnosis. In problematic cases (e.g. a small biopsy with limited tissue available to seek different architectural patterns), immunostaining may

help (Table 35.4). For a diagnosis of undifferentiated carcinoma, it should be undifferentiated throughout; by definition, even a minor component showing differentiation excludes a diagnosis of undifferentiated carcinoma. Similarly, one should resist the urge to diagnose mixed HGSC and endometrioid carcinoma, or HGSC and clear cell carcinoma. True admixtures of these components are rare, and most purported examples are, based on clinical and immunohistochemical features, HGSC with glandular architecture, or clear cells, respectively.[177,178]

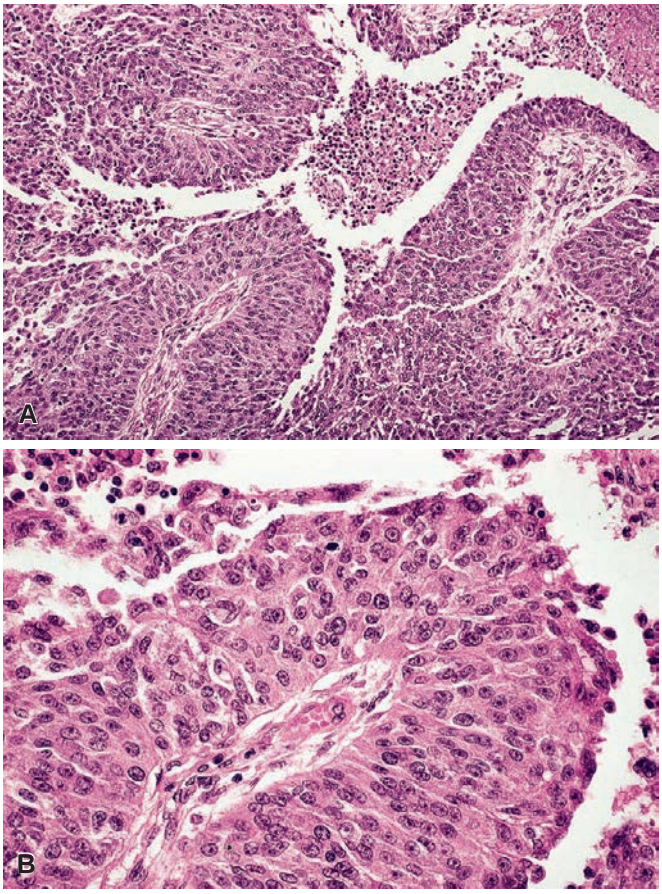

Figure 35.32 **A** and **B,** High-grade serous carcinoma with solid and transitional-like architecture.

Immunohistochemistry and Molecular Morphology

The immunoprofile of HGSC, compared to other ovarian carcinomas, is show in Table 35.4. With regard to the differential diagnosis with mesothelioma, MOC31, Ber-EP4, PAX8, and hormone receptors are more likely to be expressed by serous carcinoma, whereas calretinin, thrombomodulin, and CK5/6 are more likely to be seen in mesothelioma.[179–182] The Cancer Genome Atlas (TCGA) study, with sequencing of more than 300 tubo-ovarian HGSCs,[183] confirmed the ubiquity of *TP53* mutations and also highlighted the fact that apart from *TP53*, *BRCA1*, and *BRCA2*, there are few *recurrent* mutations in HGSC, in contrast to many other tumor types. It is, instead, characterized by aneuploidy and large numbers of somatic copy number alterations, rather than recurrent mutations. The mechanism accounting for this phenotype is the presence of defects in cellular mechanisms that allow for high-fidelity repair of DNA double strand breaks, which leads to mutation-prone repair mechanisms and resultant aneuploidy/copy number abnormalities. Genetic abnormalities accrue rapidly within the dividing tumor cells, leading to dramatic intratumoral heterogeneity at both the genetic and morphologic level. In a study of advanced-stage HGSC where tumor from multiple anatomic sites in the same patient was compared, fewer than 50% of mutations were present in all sampled specimens.[184] Thus, loss of the ability to repair DNA double strand breaks is as an early event in HGSC, followed by accrual of large numbers of copy number abnormalities that result in striking inter- and intra-tumoral heterogeneity. A minority of HGSCs have amplification of cyclin E1 (CCNE1), a molecular abnormality that is mutually exclusive of BRCA mutation and is associated with a worse prognosis/platinum resistance, compared to HGSCs without CCNE amplification.[185–187] CCNE amplification often coexists with AKT amplification, and treatment directed against cyclin-dependent kinase-2 (CDK2) and AKT, with small molecule kinase inhibitors, is a potential approach to targeted treatment of these platinum resistant HGSCs.[188]

Mucinous Tumors

Mucinous neoplasms are less common than serous neoplasms and are bilateral in less than 10% of cases.[189] As with their serous counterparts, ovarian mucinous tumors have been divided into *benign* **(mucinous cystadenoma)**, *borderline*, and *malignant* **(mucinous carcinoma);** most mucinous tumors are benign or borderline. Grossly, they tend to grow larger than the serous types and are partially or completely cystic, often multiloculated and have a smooth surface. A fluid to viscous material of mucoid nature is present in the lumen (Figs. 35.33–35.35).

Table 35.4 Markers of value in histotype diagnosis of ovarian carcinoma

	HGSC	LGSC	ENDOMETRIOID	CLEAR CELL	MUCINOUS
WT1	Diffuse positive	Diffuse positive	Negative	Negative	Negative
p53	Mutation type	Wild type	Wild type or mutation type	Wild type	Wild type or mutation type
p16	Diffuse positive	Focal positive	Focal positive	Variable	Variable
ER	Diffuse or focal positive or negative	Diffuse positive	Diffuse positive	Negative	Negative or focal positive
HNF-1β	Negative	Negative	Negative	Diffuse or focal positive	Variable
Napsin A	Negative	Negative	Negative	Diffuse or focal positive	Negative

Figure 35.35 Gross Appearance of Mucinous Cystadenocarcinoma. The neoplasm is predominantly solid, but some mucin-containing cystic spaces can still be appreciated.

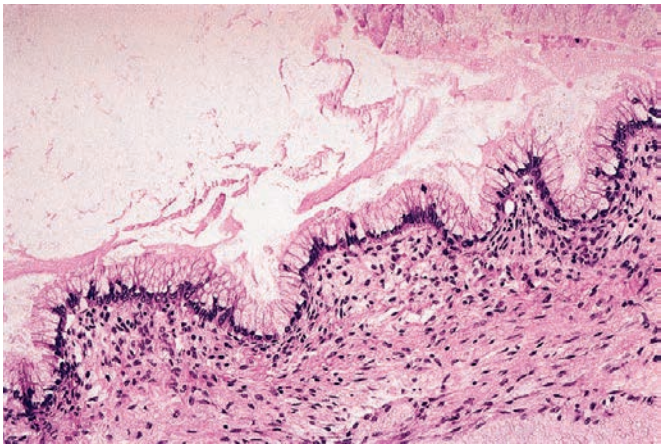

Figure 35.36 Lining of Mucinous Cystadenoma. Goblet cells are evident.

The epithelium is referred to as *intestinal* (in contrast to the endocervical-like epithelium of seromucinous tumors, described in the next section) and is characterized by an epithelial lining with a "picket fence" appearance, goblet cells, Paneth cells, endocrine cells, the secretion of gastrointestinal or pancreatobiliary type mucin,[190] and the production of intestinal enzymes such as lipase, trypsin, amylase, and sucrase (Fig. 35.36).[191] The endocrine cells, which are more common in the borderline category, are argyrophil and sometimes argentaffin.[192] 5-Hydroxytryptamine (serotonin, 5-HT), ACTH, gastrin, somatostatin, and other peptide hormones have been detected in this endocrine cell population by immunohistochemistry.[193–196] There is usually no clinical evidence of hormone excess, but cases associated with Zollinger–Ellison syndrome have been described.[197] Exceptionally, there is a focal component of signet ring cells, which may lead to a mistaken diagnosis of Krukenberg tumor,[198] but it should be noted that the presence of signet ring cells usually is an indication that you are dealing with a metastasis to the ovary.[199]

Occasionally, mucinous tumors of intestinal type are found in association with a teratoma or carcinoid tumor in the same ovary.[200] These uncommon mucinous neoplasms associated with teratomatous elements are of germ cell origin, based on the frequent finding of homozygosity, with genotypic concordance between the mucinous neoplasm and the teratoma.[201,202] Those mucinous tumors lacking a teratomatous component have a normal heterozygous genotype, indicating that they are most probably of somatic cell origin. The mucinous tumors of germ cell origin are more likely to be associated with mucin dissection through the ovarian stroma (pseudomyxoma ovarii). Importantly, the mucinous tumors of germ cell origin, which can be benign, borderline, or malignant, have a fully intestinal immunophenotype (i.e. CK20+, CK7–, unlike the mixed intestinal/müllerian immunophenotype typical of mucinous tumors without a teratomatous component [CK20 and CK7+]).

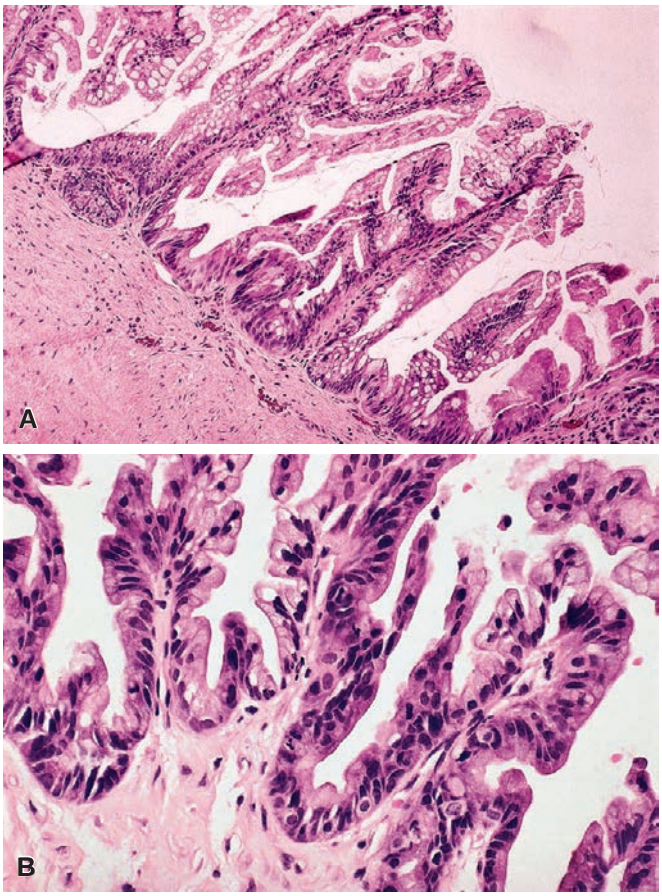

Figure 35.37 **A** and **B,** Mucinous borderline tumor of intestinal type, with focal intraepithelial carcinoma.

The distinction between benign and borderline mucinous tumor is based on the presence of cytologic atypia and stratification in the latter (Fig. 35.37), which is absent in the former. It is easy to understand how this distinction can be highly subjective. If borderline change is focal, occupying less than 10% of the cyst lining, which is otherwise benign, the designation of mucinous cystadenoma with focal atypia or focal proliferation has been suggested, and all such tumors have been benign on follow-up.[203] Almost all mucinous borderline tumors of intestinal type have been associated with a benign clinical course, but very rare exceptions have been reported.[204] The distinction between mucinous borderline tumor and carcinoma is based on the presence of invasion, and two patterns of invasion are recognized in mucinous tumors. The most common is expansile pattern, in which there is marked complexity of the glandular architecture. There is minimal or no intervening stroma between the glands, which show cribriform or labyrinthine patterns (Fig. 35.38). The contours of the gland margins are smooth, unlike what is seen with infiltrative or destructive pattern of invasion. The architecturally complex glands are invariably lined by atypical cells, showing increased layering and papillae (e.g. budding, bridging, and/or appearance of solid foci; see Fig. 35.38).[199,205] Infiltrative pattern of invasion (also referred to as "destructive invasion") is recognized by the presence of single cells or irregular cell clusters in stroma that may show desmoplasia. This pattern of invasion is less common and may be associated with a worse prognosis than purely expansile pattern of invasion; however, it should be noted that tumors with only expansile pattern of invasion are fully malignant and may metastatsize.[199,205]

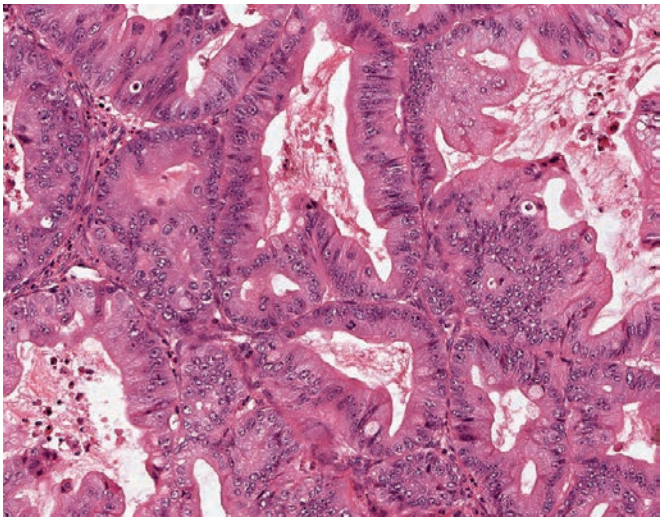

Figure 35.38 Mucinous carcinoma with expansile pattern of invasion; there is minimal stroma between the closely packed glands.

Within the borderline category we also recognize mucinous borderline tumor with focal intraepithelial carcinoma (see Fig. 35.37B).[199] The degree of cytologic atypia is greater than what is encountered in a usual mucinous borderline tumor; it is analogous to adenomatous polyps of the colon with high-grade dysplasia, featuring malignant-appearing epithelial cells showing increased stratification and sometimes cribriform architecture. Clinically, the outcome for patients with mucinous borderline tumor with intraepithelial carcinoma is usually favorable, but occasional patients have experienced a fatal recurrence.[199,206] Mucinous borderline tumors with microinvasion (<5 mm) should be distinguished from frankly invasive (≥5 mm) carcinoma; microinvasion is usually associated with an excellent prognosis.[199,207,208]

There is a subgroup of mucinous tumors in which the stromal component is particularly prominent. These have been designated *mucinous adenofibroma* or *cystadenofibroma* if benign and *mucinous adenocarcinofibroma* and *cystadenocarcinofibroma* if malignant. The benign ones are sometimes misinterpreted as malignant and even as metastatic because of the irregularly shaped glands in a "desmoplastic" stroma,[209] or as microinvasive because of the presence of micronests of cells.[210]

Exceptionally, ovarian mucinous tumors have been found to contain foci of: (1) *sarcoma-like nodules*, with a configuration and cytologic composition similar to those of giant cell tumor of soft parts,[211] characterized by a lack of reactivity for keratin[212]; (2) *sarcoma*, usually spindle shaped, sometimes with heterologous features,[213,214] and also unreactive for keratin; and (3) *anaplastic carcinoma*, with pleomorphic round to spindle cells that are immunoreactive for keratin.[215,216] The distinction between the latter two lesions is very tenuous, both on microscopic and histogenetic grounds (as it is in the pancreas or thyroid under similar circumstances), and both are associated with a poor prognosis unless they present as stage I lesions.[217] Actually, we favor the interpretation that the sarcoma-like nodules themselves are not a reactive phenomenon,[218] but rather are of neoplastic nature and related histogenetically to the other two processes, a possibility also expressed by others[219] and supported by the occasional overlap and coexistence of these various lesions.[217] However, it is important to consider the sarcoma-like nodules separately because of their better prognosis.[211,216,218,220] On occasion, the appearance of the mural nodule is that of a benign leiomyomatous growth.[221]

Immunohistochemically, the tumor cells of ovarian mucinous tumors express CEA (more so the intestinal types and/or malignant tumors),[222] keratin, EMA (particularly if malignant),[223] MUC5AC (a gastrin mucin gene), DPC4 (a nuclear transcription factor inactivated in about half of pancreatic adenocarcinomas),[224] hepatocyte nuclear factor 1,[225] and hepatocyte nuclear factor 4 alpha.[226] Importantly, the tumor cells express markers of gastrointestinal type differentiation such as CK20, SATB2 (very rarely), and CDX2,[224,227–230] as well as CK7, which is more strongly expressed than the intestinal markers in most cases.[230] As noted previously, mucinous tumors of germ cell origin have a more purely intestinal immunophenotype (strong diffuse CK20, SATB2 and CDX2, with negative CK7). In contrast to other types of ovarian epithelial tumor, PAX8 is often negative, as are WT1 and ER.[161]

Only rarely is a mucinous tumor arising from the ovary accompanied by extensive deposits of intra-abdominal mucin (pseudomyxoma peritonei); a large majority of these tumors are metastatic to the ovary and peritoneal cavity from an appendiceal origin, and are, therefore, discussed in Chapter 16.

The chief differential diagnosis is with metastatic carcinoma. A simple algorithmic approach has been advocated for the distinction between primary and metastatic mucinous tumors of the ovary, relying in size and laterality. Tumors that are unilateral, smooth surfaced and more than 13 cm, without mucinous ascites, are highly likely to be primary ovarian mucinous neoplasms.[231] The differential diagnosis also includes high-grade serous or endometrioid carcinoma, especially in those mucinous carcinomas where there is loss of intracellular mucin with increasing grade. The presence of a lower grade or borderline area can support the diagnosis of mucinous carcinoma, as can the absence of WT1 immunoreactivity and negative (or only focally positive) immunostaining for ER (see Table 35.4).

Seromucinous Tumors

Formerly considered a variant of mucinous tumor, the seromucinous neoplasms have been recognized as a distinct tumor type in the 2014 WHO classification. They differ from mucinous tumors of intestinal type morphologically and clinically, and such a distinction is therefore justified. They have also been referred to as *endocervical*, *endocervical-like*, or *müllerian*, and are characterized by a papillary architecture similar to that of serous tumor but with a lining of tall nonciliated cells with basally located nuclei and abundant intracellular mucin (Fig. 35.39). The stroma of the papillae is typically edematous and infiltrated by neutrophils. Seromucinous tumors express müllerian-type markers (such as hormone receptors, CA 125, and mesothelin) and resemble endocervical epithelium both at the light and electron microscopic level.[232] It has been pointed out that the seromucinous tumors share more morphologic and immunohistochemical features with the endometrioid or serous (or even clear cell) carcinomas than they do with mucinous tumors of intestinal type.[233–235] Seromucinous borderline tumors frequently have *ARID1A* mutation and show loss of ARID1A protein expression, at a frequency similar to that of endometrioid tumors.[236] In addition to the mucinous component, there are often admixed serous and, occasionally, squamous or clear cell components, leading to a proposal that a more apt designation for the seromucinous group of neoplasms would be "mixed müllerian" tumors. Having only just set these tumors apart as a separate entity in the 2014 WHO classification, it is difficult to muster enthusiasm for a name change so soon.

Most seromucinous tumors are benign or borderline, and only a handful of carcinomas have been reported. The borderline tumors are associated with a favorable prognosis, even when extra-ovarian implants are present.

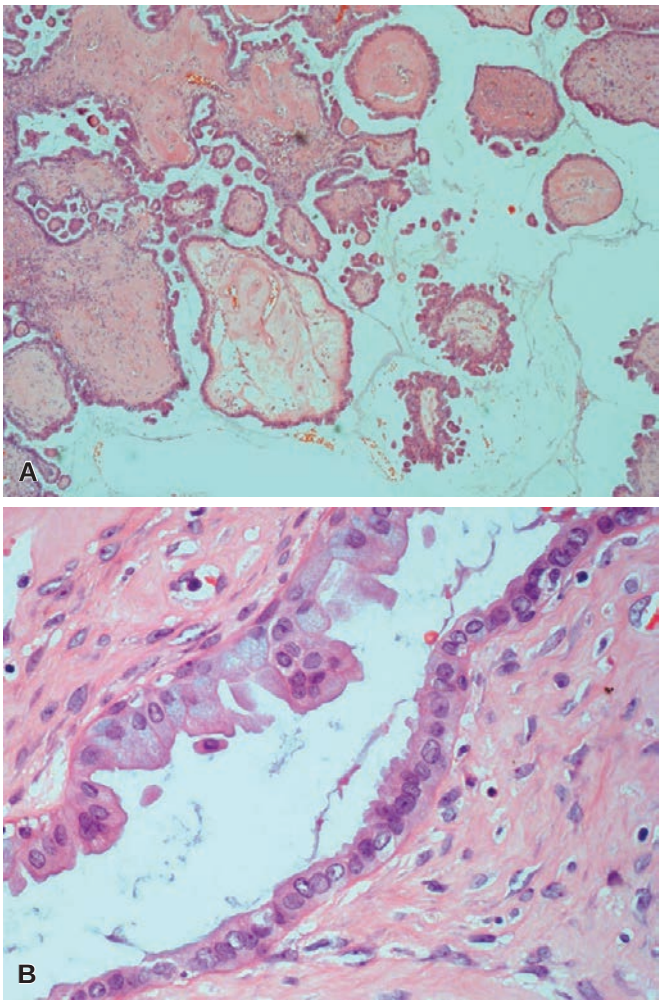

Figure 35.39 Seromucinous Borderline Tumor. At lower magnification **(A)** it resembles serous borderline tumor, but with prominent edema of the stroma in papillae. At higher magnification there is prominent intracellular mucin in some of the cells **(B)**.

The differential diagnosis for a benign seromucinous tumor includes a benign mucinous tumor of intestinal type. In practice, it is not clinically relevant to subtype a benign mucinous tumor, and a diagnosis of "mucinous cystadenoma" (or adenofibroma), without further qualification, can be made based on H&E as it would be an inappropriate use of resources to apply special stains in this setting. The seromucinous borderline tumors are sufficiently distinctive such that there is usually no doubt about the diagnosis on routine H&E stains alone. The presence of conspicuous intracellular mucin sets them apart from serous borderline tumor, the tumor they most resemble. Although seromucinous carcinoma has been reported, it is not entirely clear how they differ from the more commonly diagnosed endometrioid carcinoma with mucinous differentiation.

Endometrioid Tumors

Endometrioid carcinoma comprises 10% of all primary ovarian carcinomas (see Table 35.3). Coexistent endometriosis can often be demonstrated,[237] and some of the tumors can be seen arising from these endometriotic foci. However, the identification of endometriosis is not a prerequisite for the diagnosis of endometrioid carcinoma.

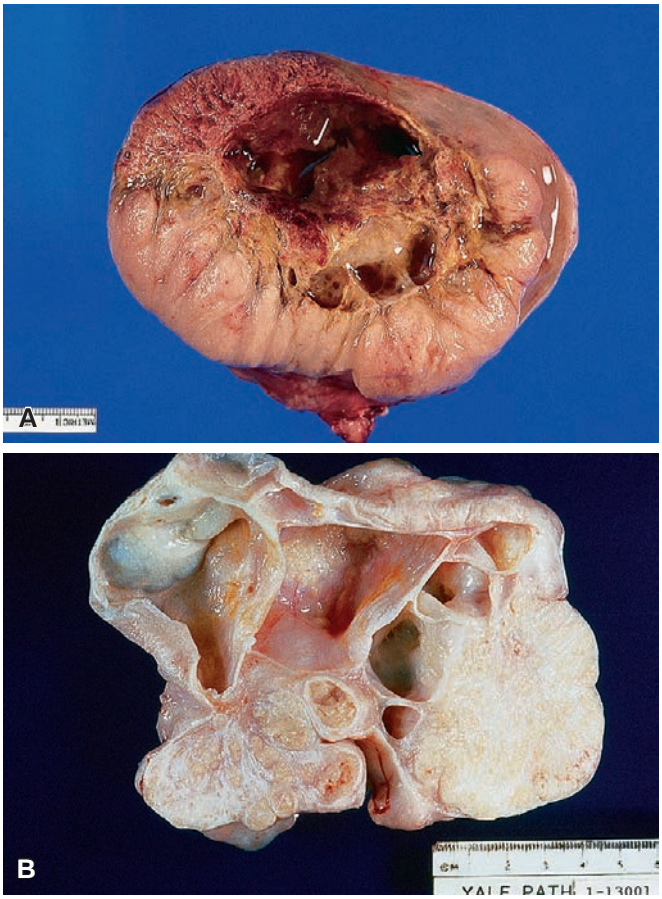

Figure 35.40 **A** and **B,** Gross appearances of ovarian endometrioid carcinoma. Both tumors show a combination of solid and cystic appearances.

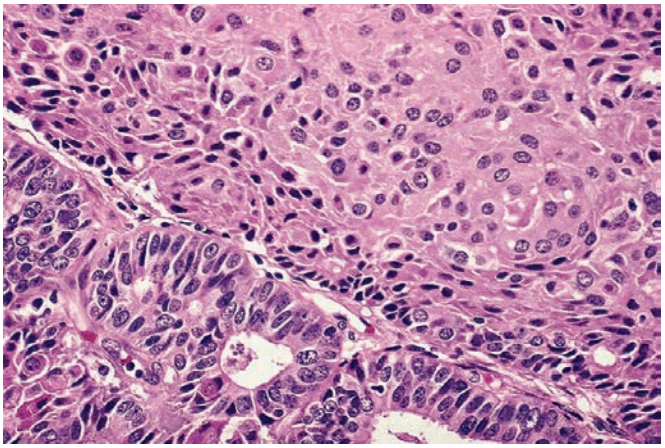

Figure 35.41 Well-differentiated endometrioid ovarian carcinoma with extensive squamous differentiation.

Grossly, endometrioid carcinoma may present as a cystic or solid mass (Fig. 35.40). The content tends to be hemorrhagic rather than serous or mucinous. Visible papillary formations are usually absent or inconspicuous. Microscopically, the tumors strongly resemble the appearance of the ordinary type of endometrial adenocarcinoma—hence their name (Fig. 35.41).[238,239] Most are well differentiated (grade 1 or 2, according to the FIGO grading system used for endometrial carcinomas of endometrioid type), with or without papillary formations. Half of the tumors have foci of squamous metaplasia (see Fig. 35.43).[240] Morules may express CDX2 and β-catenin (nuclear translocation).[241] In contrast to serous tumors, psammoma bodies are exceptional. Approximately 10% of endometrioid carcinomas have a component of non-neoplastic luteinized stromal cells.

The keratin produced by these ovarian neoplasms can result in the formation of peritoneal keratin granulomas.[74] It seems likely that at least some of the reported cases of primary **squamous cell carcinomas** of the ovary represent the extreme expression of this metaplastic tendency of endometrioid carcinoma.[242–245] Parenthetically, the other large category of ovarian squamous cell carcinoma is that associated with benign cystic teratomas (i.e. secondary somatic transformation).[246]

Histochemically, mucin may be found within the glandular lumina and in the apical border of the tumor cells. Some tumors show mucinous metaplasia, just as can be seen in endometrioid carcinomas of the endometrium; these tumors lack goblet cells and strongly express ER, which serves to distinguish them from mucinous tumors of intestinal type (see Table 35.4). Scattered argyrophil cells are seen in almost half of cases.[247]

Immunohistochemically, the tumor cells are positive for keratin, EMA, vimentin, and PAX8, whereas CEA is usually negative or weak.[248] There can also be positivity for CA 19-9 and hPL.[249,250]

Mutations leading to β-catenin deregulation are found in nearly half of ovarian endometrioid adenocarcinomas.[251] Many endometrioid and clear cell carcinomas (i.e. ovarian tumors related to endometriosis) have mutations of *ARID1A*, a tumor suppressor gene, in stark contrast with serous carcinomas, which do not have this mutation.[98]

In some endometrioid carcinomas, the neoplastic glands are small and tubular or solid and elongated, simulating the pattern of sex cord–stromal tumors, particularly of Sertoli–Leydig cell type.[252,253] These are referred to as endometrioid carcinoma resembling sex cord–stromal tumors.[254] Features that favor a diagnosis of endometrioid carcinoma in such cases are the older age of the patients, the usual absence of endocrine manifestations, and the occurrence elsewhere in the tumor of larger tubular glands, foci of squamous metaplasia, luminal mucin accumulation, adenofibromatous components, immunoreactivity for keratin (including CK7) and EMA, and negativity for inhibin.[255,256] Other endometrioid carcinomas simulate the appearance of granulosa cell tumors, from which they can be distinguished on immunohistochemical grounds.[257]

Other morphologic variations of endometrioid carcinoma include presence of yolk sac elements,[258,259] tumors composed of ciliated cells,[260] tumors composed of oxyphilic (oncocytic) epithelium,[261,262] and tumors containing foci of collagenous spherulosis that simulate squamous metaplasia.[263] Endometrioid carcinomas containing foci of hepatoid differentiation have also been described.[264] Just as for endometrial endometrioid tumors, there can be de-differentiation with emergence of undifferentiated carcinoma from a low-grade endometrioid tumor.[265] This is associated with loss of expression of one or more proteins of the SWI/SNF chromatin remodeling complex (BRG1, INI1, ARID1A, ARID1B) and mutation of the corresponding gene(s) in most cases.[266]

Benign and borderline types of endometrioid ovarian tumors exist, in addition to the malignant ones.[261,267–269] Most of the benign endometrioid tumors, which are rare, have a prominent stromal component and have been designated as adenofibromas or cystadenofibromas, depending on the degree of cystic change (Fig. 35.42). Sometimes, benign and malignant areas coexist in the same case.[270,271] In the borderline category, the epithelial changes are equivalent in all respects to those of atypical endometrial hyperplasia (Fig. 35.43). The distinction between borderline endometrioid tumor and low-grade endometrial carcinoma is made based on the same criteria
