CHAPTER 42

Ear

Tony J. C. Wang and K. S. Clifford Chao

ANATOMY

The external, middle, and inner components of the ear develop from the three embryonic layers: ectoderm, mesoderm, and endoderm.

The external ear consists of the auricle or pinna, the external auditory meatus (canal), and the tympanic membrane (Fig. 42.1). The auricle is composed of elastic cartilage covered with skin. The external auditory meatus connects the tympanic membrane to the exterior and is approximately 2.4 cm long. The outer third is cartilaginous, and the inner two-thirds is bony and slightly narrower. The external auditory canal is anterior to the mastoid process and posterior to the parotid gland at the temporomandibular joint (TMJ). The inferior border of the canal lies near the jugular bulb and the facial nerve as it descends through the stylomastoid foramen. The skin lining the auditory canal is continuous with that of the auricle, and in the outer one-third of the canal, it contains hair follicles and sebaceous and ceruminous glands. The tympanic membrane, which is made of multiple layers of squamous epithelium, separates the auditory canal from the middle ear.

The middle ear houses the auditory ossicles, the tympanic cavity, and opens into the eustachian tube to communicate with the pharynx. The middle ear cavity is lined with a mucoperiosteal membrane, and the eustachian tube is lined with stratified columnar epithelium and has numerous mucous glands in the two-thirds of the tube closer to the pharynx. The overall length of the eustachian tube is 3.5 cm.[1]

The inner or internal ear lies in the petrous portion of the temporal bone and consists of the bony labyrinth and the membranous labyrinth. The membranous labyrinth, which holds the organ of hearing, is housed within the bony labyrinth. The cochlea, which is responsible for hearing, and the vestibule, which is responsible for balance, are part of the inner ear.

Blood supply to the auricle and the external auditory canal comes from branches of the posterior auricular artery and the superficial temporal artery, which arise from the external carotid artery. Blood is supplied to the middle ear region from branches of ascending pharyngeal and middle meningeal arteries and from the artery of the pterygoid canal. The inner ear is supplied by the internal auditory artery, which is a branch of the basilar artery, and from the anterior inferior cerebellar artery.

The nerves innervating the ear include cranial nerves V, VIII, IX, and X. The eighth cranial nerve or vestibulocochlear nerve is responsible for auditory and vestibular function. It exits from the brainstem between the pons and the medulla and follows the internal acoustic meatus.

For the external ear, lymphatic vessels of the tragus and anterior external portion of the auricle drain into the superficial parotid lymph nodes. The posterior and superior aspects of the auricle drain into the retroauricular lymph nodes, and the lobule drains into the superficial cervical group of lymph nodes. Lymphatics from the middle ear and the mastoid antrum pass into the parotid nodes and into the upper deep cervical lymph nodes. The lymphatics in the middle ear and eustachian tube are rather sparse, and the inner ear has no lymphatics.

EPIDEMIOLOGY

Malignant disease of the auricle is common (accounts for 6% of all skin cancer), but cancers of the middle ear and external auditory canal are rare, with an incidence of approximately 1 per million people.[2–4] Tumors of the external ear are most often cutaneous malignancies and may be related to sun exposure.[5,6] Other predisposing factors described, although their significance is in question, are otorrhea, chronic eczema, chronic dermatologic conditions, and chronic ulcerations from trauma.[7]

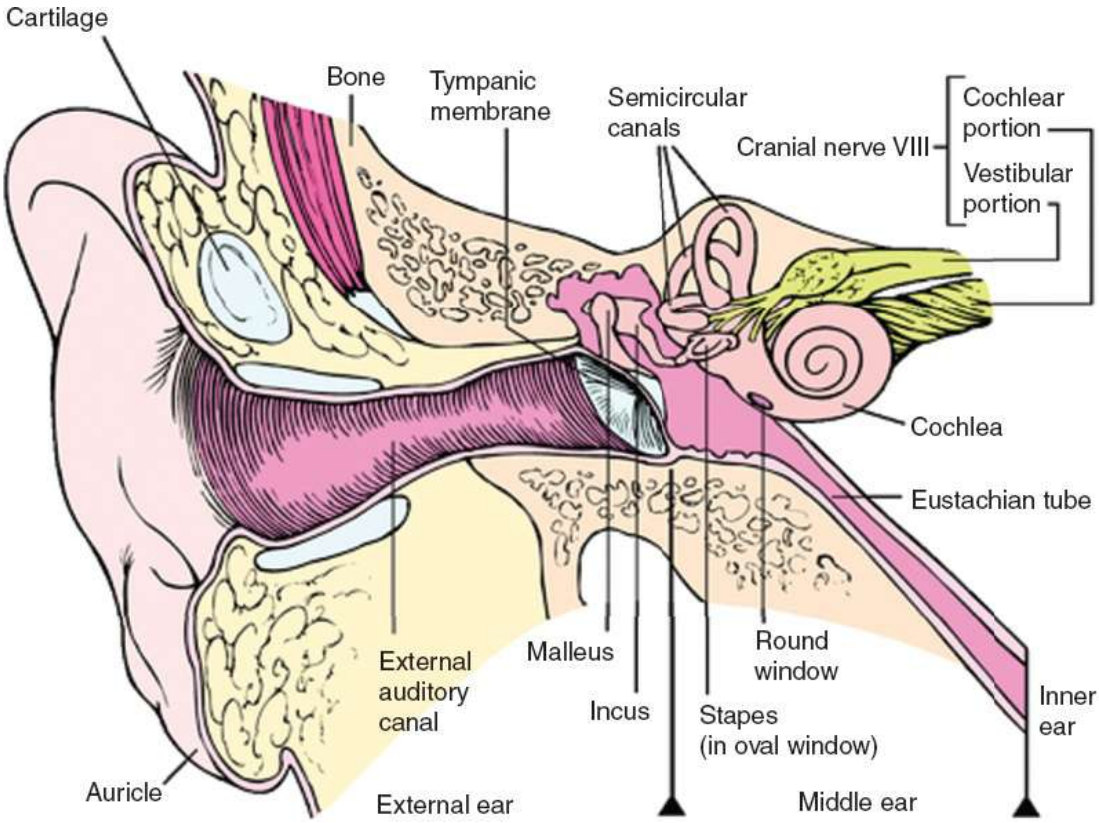

FIGURE 42.1. Ear anatomy.

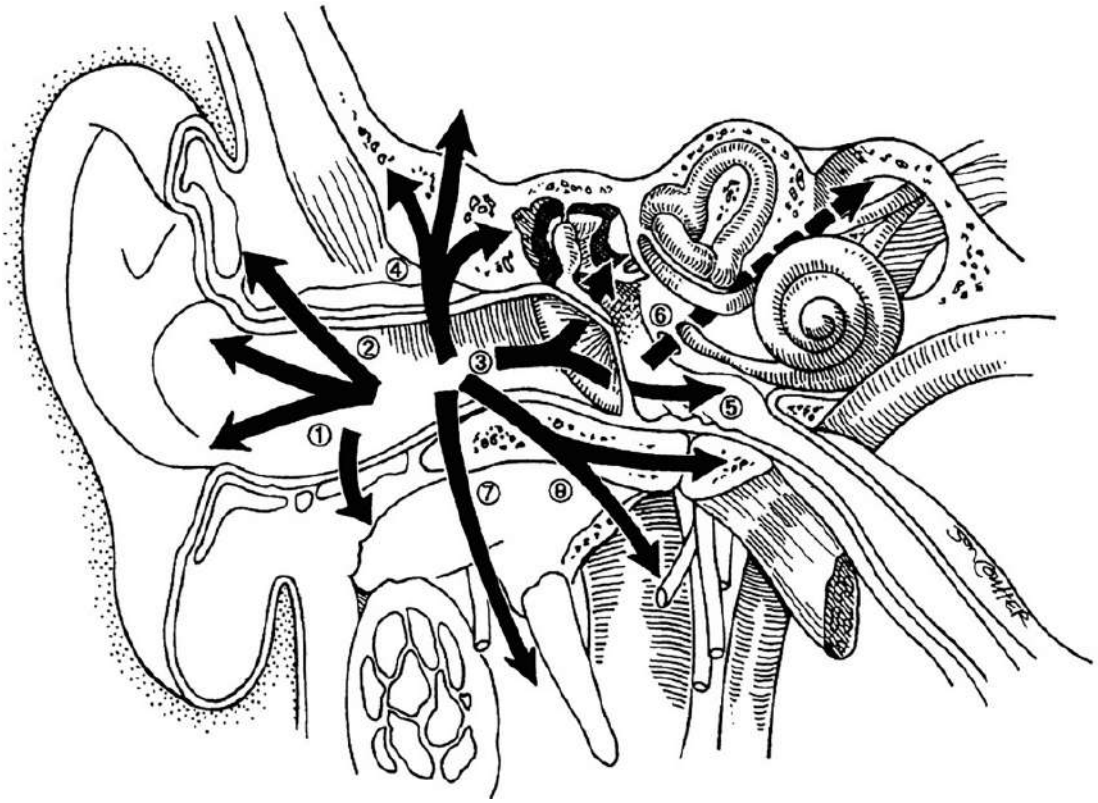

FIGURE 42.2. Coronal anatomy of pathways of spread of primary cancer of the external auditory canal. Cancer can spread (*1*) anteriorly through the cartilaginous canal into the parotid gland, (*2*) through the concha into the postauricular sulcus, (*3*) through the tympanic membrane into the middle ear, (*4*) posteriorly into the mastoid, (*5*) into the anterior mesotympanum to the carotid artery and eustachian tube, (*6*) into the inner ear through the round window or otic capsule, (*7*) along the extratemporal facial nerve into the infratemporal fossa, and (*8*) inferomedially into the jugular fossa, carotid artery, and lower cranial nerves. (Reprinted from Moody SA, Hirsch BE, Myers EN. Squamous cell carcinoma of the external auditory canal: an evaluation of a staging system. *Am J Otol* 2000;21[4]:582–588. With permission.)

Tumors of the external ear most commonly occur in patients 60 to 70 years of age; tumors of the middle ear and the mastoid are more common in patients 40 to 60 years of age.[8,9] More women than men have middle ear tumors, but more men have tumors of the external ear.[10,11]

CLINICAL PRESENTATION

External Ear

Basal cell carcinomas are more common than squamous cell carcinomas in the external ear, with a ratio of 1.3 to 1.[8] They present as small ulcerations, mostly on the helix.[12,13] For squamous cell carcinomas, lymph node metastases occur in approximately 10% to 15%.[14] The common sites of lymph node metastases in order of frequency are the parotid gland, the upper deep cervical chain, and the postauricular nodes.[9,14] The rate of regional metastasis is higher in advanced disease and may involve the level 5 cervical lymph node group.[15]

External Auditory Canal

Most patients present with symptomatic lesions of the external auditory canal. Pruritus and pain are common. Swelling behind the ear, decreased hearing, and facial paralysis are seen in advanced cases. Spread of the tumor into the lymphatic areas is more common than to other areas of the ear (around 20%).[16,17] Tumors arising in the cartilaginous portion of the canal invade the cartilaginous walls and spread into the bony canal areas. However, those arising in the bony canal have a more effective barrier (preventing spread) and therefore progress predominantly along the main axis of the canal, eventually invading the middle ear or the cartilaginous part of the canal. Local spreading route is depicted in Figure 42.2. Distant metastases are rare.

DIAGNOSTIC WORKUP

Table 42.1 summarizes workup and diagnostic procedures. A history and physical including otoscopy and careful lymph node exam should be performed. Neurologic exam finding of cranial nerve deficits may be an indication of advanced disease. A baseline audiology testing should be performed prior to any treatment.

TABLE 42.1 DIAGNOSTIC EVALUATION FOR CARCINOMA OF THE EAR

History
Physical examination
Otoscopy
Neurologic exam for cranial nerve function
Careful assessment of regional lymph nodes
Laboratory tests
Complete blood count
Blood chemistry
Radiographic studies
High-resolution computed tomography (standard)
Magnetic resonance imaging (selected patients)
Arteriography (optional)
Biopsy
Other studies
Audiology testing

Both multidetector computed tomography (CT) and magnetic resonance imaging (MRI) play an important role in visualizing tumors of the ear.[18] CT can show abnormal soft tissue, soft tissue enhancement, and distortion of the normal tissue planes. Most importantly, when evaluating EAC tumor, CT can provide accurate prediction of bone erosion, such as wall of the EAC, middle ear, TMJ, carotid artery canal, and jugular fossa and thus can help to determine the extension and the operability of tumors (Fig. 42.3).[19–21] Sometimes MRI can differentiate the tumor from mastoiditis and cholesteatomas and provide excellent delineation of soft tissue tumor margins, muscle infiltration, intracranial extension, dural or cerebral involvement, and vessel encasement.[21,22] Except in selected cases, angiography and jugular venography have also been abandoned in favor of CT.

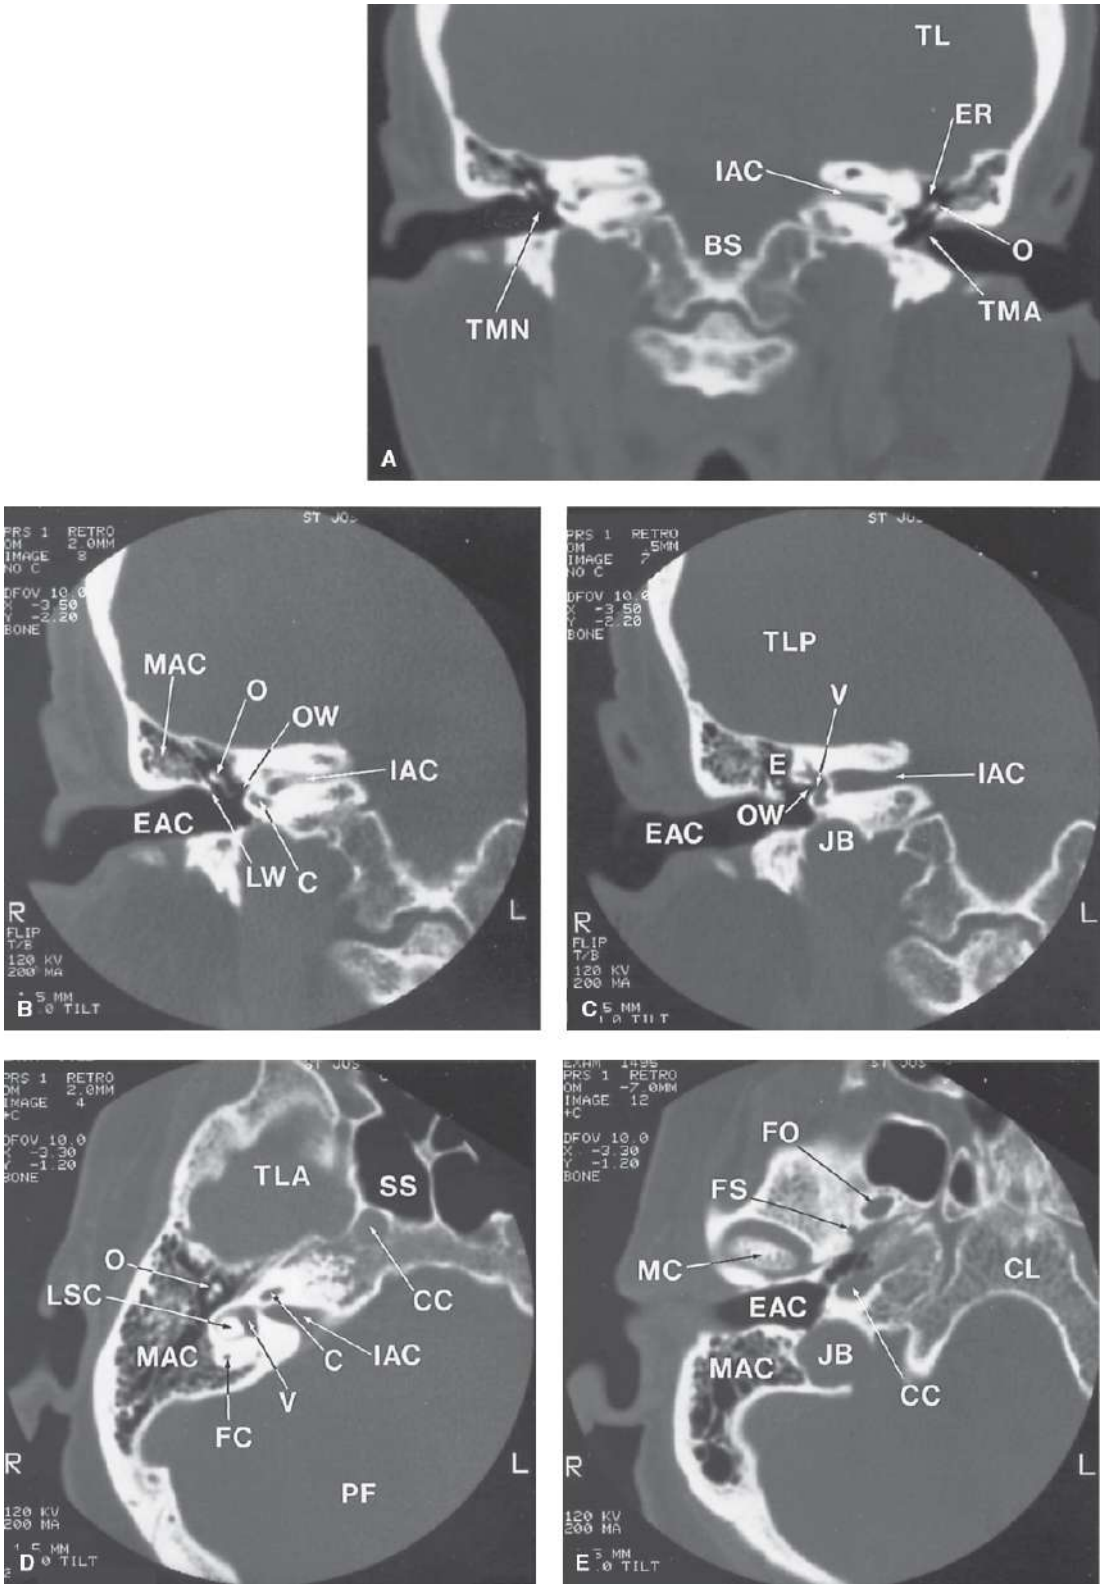

FIGURE 42.3. Normal anatomy of the ear. **A–C:** Coronal sections. **D** and **E:** Transverse sections. BS, brainstem; C, cochlea; CC, carotid canal; CL, clivus; E, epitympanum; EAC, external auditory canal; ER, epitympanic recess; FC, facial canal; FO, foramen ovale; FS, foramen spinosum; IAC, internal auditory canal; JB, jugular

bulb; LSC, lateral semicircular canal; LW, lateral wall, epitympanic recess (scutum); MAC, mastoid air cells; MC, mandibular condyle; OS, ossicles; OW, oval window; PF, posterior fossa; TLA, temporal lobe, anterior portion; TLP, temporal lobe, posterior portion; TMN, tympanic membrane, normal appearance; TMA, tympanic membrane, abnormally thickened; SS, sphenoid sinus; V, vestibule. (Courtesy of Robert Gresick, MD, DePaul Health Center, St. Louis, MO.)

Diagnosis is always established by biopsy and occasionally by aspiration of the exudative material or by surgical exploration. A bone scan may be done to determine the changes in the temporal bone around the tumor, but it provides very nonspecific information and is not a recommended method of evaluation.

PATHOLOGIC CLASSIFICATION

Approximately 85% of the tumors involving the auditory canal, middle ear, and mastoid area are squamous cell carcinomas. Infrequently, basal cell carcinomas, adenocarcinomas, adenoid cystic carcinomas, and melanomas are seen.[23] Even rarer are sarcomas, specifically embryonic rhabdomyosarcomas. Ceruminous gland tumors and papillomas rarely arise in the auditory canal.[7,23,24] Carcinoid tumor of the middle ear is rare, and only 50 cases have been reported in the literature.[25,26] Endolymphatic sac tumor or aggressive papillary middle ear tumors are distinct from middle ear adenomas and act aggressively. They are characterized by slow growth but extensive local invasion and bone destruction.[27,28]

PROGNOSTIC FACTORS

Lesions of the external ear are usually more easily controlled than are lesions of the middle ear or mastoid. External ear lesions are usually diagnosed earlier; they are mostly cutaneous, and adequate surgery or radiation therapy is usually effective.[3,9,29] Presence of large lesions involving the middle ear and those with extension into the temporal bone or soft tissue is a poor prognostic sign and more difficult to treat.[2,30,31] There does not appear to be a correlation between tumor differentiation, positive margins, or perineural disease and survival, although they may serve as a predictor for local control in tumors involving the temporal bone.[30,32,33] Seventh cranial nerve palsy associated with middle ear tumors indicates poor survival showed in pooled-data survival analysis, and have been adopted into staging system. Spread of tumors to the lymph nodes usually indicates a poor prognosis because this is often a late event in the natural history

of the disease.[17,32,34] Nomogram for predicting overall survival and cause-specific survival in middle ear cancer patients has been proposed using SEER database.[35]

STAGING

The seventh edition of the American Joint Committee on Cancer (AJCC) staging manual[36] includes the external ear in its staging system under *Cutaneous Squamous Cell Carcinoma and Other Cutaneous Carcinomas* (Table 42.2). A group from the University of Pittsburgh proposed a staging system for squamous cell carcinoma of the external auditory canal and temporal bone, which was updated in 2002.[17,37–39] The primary tumor stage is determined by the level of bony erosion, size, and involvement of the middle ear. Lymph node disease is considered advanced stage with poor prognosis. This staging system has often been cited in the literature (Table 42.3).[2,17,34,38,40–46]

TABLE 42.2 THE AMERICAN JOINT COMMITTEE ON CANCER AND INTERNATIONAL UNION AGAINST CANCER STAGING SYSTEM FOR EAR CANCER

Stage	Staging Criteria
T Category	
Tx	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma *in situ*
T1	Tumor 2 cm or less in greatest dimension with fewer than two high-risk features[a]
T2	Tumor >2 cm in greatest dimension or tumor any size with two or more high-risk features[a]
T3	Tumor with invasion of maxilla, mandible, orbit, or temporal bone
T4	Tumor with invasion of skeleton (axial or appendicular) or perineural invasion of skull base
N Category	
Nx	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastases
N1	Metastasis in a singly ipsilateral lymph node, 3 cm or less in greatest dimension
N2a	Metastasis in a single ipsilateral lymph node, >3 cm but not >6 cm in greatest dimension
N2b	Metastasis in multiple ipsilateral lymph nodes, none >6 cm in greatest dimension
N3c	Metastasis in bilateral or contralateral lymph nodes, none >6 cm in greatest dimension
N3	Metastasis in a lymph node, >6 cm in greatest dimension

M Category			
M0	No distant metastases		
M1	Distant metastases		
Stage Grouping			
0	Tis	N0	M0
I	T1	N0	M0
II	T2	N0	M0
III	T3	N0	M0
	T1	N1	M0
	T2	N1	M0
	T3	N1	M0
IV	T1	N2	M0
	T2	N2	M0
	T3	N2	M0
	T any	N3	M0
	T4	N any	M0
	T any	N any	M1

[a]High-risk features for the primary tumor (T) staging include depth of invasion >2-mm thickness, Clark level ≥ IV, and perineural invasion; anatomic location primary site on ear or hair-bearing lip; and cells that are poorly differentiated or undifferentiated.

TABLE 42.3 Pittsburgh Tumor Staging System (Modified)[40]

Stage	CT or Pathology Findings
T1	Tumor limited to the EAC without bony erosion or evidence of soft tissue involvement
T2	Tumor with limited EAC bone erosion (not full thickness) or limited (<0.5 cm) soft tissue involvement
T3	Tumor eroding the osseous EAC (full thickness) with limited (<0.5 cm) soft tissue involvement, or tumor involving the middle ear and/or mastoid
T4	Tumor eroding the cochlea, petrous apex, medial wall of the middle ear, carotid canal, jugular foramen, or dura, or with extensive soft tissue involvement (>0.5 cm), such as involvement of TMJ or styloid process, or evidence of facial paresis

GENERAL MANAGEMENT

External Ear

Tumors of the external ear are most often treated with limited surgery or external radiation therapy. Treatment in early stages with irradiation is usually in the form of megavoltage electron beam therapy or orthovoltage.[47,48] Most radiation techniques have been fairly successful in the treatment of lesions in this area, with local control rates of 80% to 97%.[3,49–51] Caccialanza et al.[3] reported a 5-year cure rate of 78% with a mean follow-up of 2.4 years for 115 carcinomas of the pinna treated with definitive kilovoltage radiation to a total dose of 45 to 70 Gy in 2.5- to 5-Gy fractions given two to three times per week. Surgery is beneficial if the lesion has invaded the cartilage of the ear or extends medially into the auditory canal. If squamous cell carcinoma of the external ear is treated with surgery alone, there is a recurrence rate of 14% to 19%.[9,52] Mohs surgery is another option, with reported local recurrence rates of 5% to 7%.[29,53] Advanced lesions involving a significant portion of the ear canal are managed with a combination of irradiation and surgery. Palmer and Snell[54] describe the use of radical soft tissue and subtotal temporal bone excision with deltopectoral flap coverage for extensive tumors of the auricular area.

Treatment of draining lymphatics is normally not required for early stages of external ear tumors.[13] Afzelius et al.[12] indicate that lesions >4 cm and those with cartilage invasion have an increased risk of nodal spread; they recommend prophylactic neck dissection.[55] Most investigators do not agree with this approach because the overall chance of lymph node involvement in tumors of the external ear is only 16%. Osborne et al.[56] reported that parotidectomy may be unnecessary in management of advanced auricular carcinoma without clinically positive parotid disease.

Interstitial irradiation using afterloading ^{192}Ir, particularly for tumors smaller than 4 cm, is also an effective method of treatment, affording excellent local control with good cosmesis[51] (Table 42.4).

External Ear Canal and Middle Ear

Radical surgery followed by postoperative radiation therapy is an acceptable method of treatment for more advanced lesions of the external auditory canal and lesions in the middle ear and mastoid.[31,44,58] Pfreundner et al.[31] recommended a postoperative radiotherapy dose of 54 to 60 Gy for patients with negative margins. Positive margins warrant higher doses of 66 Gy because of higher recurrence rates. Except in tumors that are detected early, neither modality alone is considered optimal, and a combination of the two produces the

best results.

Lesions of the outer part of the auditory canal require local excision with at least a 1-cm margin between the lesion and the tympanic membrane if there is no radiographic evidence of invasion of the mastoid. Surgery for tumors of the auditory canal is performed through a U-shaped incision with elevation of the flap from below. A split-thickness skin graft is usually required to cover the deficit along the auditory canal.

TABLE 42.4 TREATMENT OF CARCINOMA OF THE EXTERNAL EAR

	Modality	
Result	**Surgery**	**Irradiation**
Cure at 3 yr[57]	330/358 (92%)[a]	141/174 (81%)
Cure at 5 yr[3]		(78%)
Local control at 2 yr[29,50]	82/87 (94%)[b]	60/62 (97%)
Local control at 2 yr[48]		(86%)[c]
Local control at 4 yr[51]		60/61 (99%)
Local control at 5 yr[49]		128/138 (93%)
Local control at 5 yr[48]		(79%)[c]

[a]Results given as number of successful outcomes/patient population.
[b]Treatment by Mohs micrographic surgery.
[c]Included advanced primary tumors.

When the tumor involves the bony auditory canal and impinges on the tympanic membrane but does not involve the middle ear or the mastoid, a partial temporal bone resection may be necessary; in this procedure, the auditory canal, tympanic membrane, malleus, and incus are removed along with the TMJ, and the defect is grafted with a split-thickness skin graft. Postoperative radiation may be indicated, depending on margin status.

Middle Ear and Temporal Bone

In management of temporal bone tumors originating from the middle ear and mastoid area, surgical options include subtotal temporal bone resection, total temporal resection, lateral temporal resection, or mastoidectomy. Complete resection with clear margins may be difficult to achieve, given that important structures reside around the temporal bone.[40,55,59–61] Postoperative radiation therapy is recommended and increases local tumor control.[31,40,62] In studies that

suggest limited benefit of postoperative irradiation, the results may be related to the extent of the tumor.[63] Given that total and subtotal temporal bone resection can result in significant morbidity, some investigators favor limited surgery with postoperative or perioperative radiation, or even definitive radiotherapy in early or unresectable lesions.[62,64,65] Stereotactic ablative radiotherapy (SABR) may represent a new treatment option for organ preservation. A study used 37.5 Gy/3 fractions or 40 Gy/5 fractions radiotherapy as a first-line treatment, resulting in 3-year OS rates: 69% for T1/2, 79% for T3 (95% CI, 47–93), and 0% for T4 disease with limited toxicities.[66] Masashi et al. reported their experience on treating unresectable locally advanced SCC of the external auditory canal and middle ear with carbon ion therapy. The 3-year local control was 54%.[67] Chemotherapy has been used in tumors of the ear. The common regimen includes cisplatin, docetaxel, and mitomycin via intravenous or intra-arterial.[68,69] A meta-analysis suggested that preoperative CRT followed by surgery may improve the survival of patients with external auditory canal SCC and that definitive CRT may be equivalent to surgical resection.[70] However, additional trials are necessary to determine efficacy because there was no control trial in this meta-analysis.

RADIATION THERAPY TECHNIQUES

Tumors involving the pinna can be treated with megavoltage electrons or with superficial or orthovoltage irradiation. The fields can be round or polygonal, drawn around the tumor to spare surrounding normal tissues. For small, superficial tumors, margins of 1 cm are adequate. However, more extensive lesions require large portals, which may encompass the entire pinna or external canal and require 2- to 3-cm margins around the clinically apparent tumor (Fig. 42.4). Lesions involving the pinna must be treated with slow fractionation (1.8 to 2 Gy daily) to prevent cartilage necrosis. Doses of 66 Gy over a period of 6.5 weeks are required to achieve adequate tumor control.

Large lesions of the external auditory canal are treated with radiation or combined with surgery; the portals should encompass the entire ear and temporal bone with an adequate margin (3 cm). The volume treated should include the ipsilateral preauricular, postauricular, and subdigastric lymph nodes. Treating lymphatics beyond the jugulodigastric area is usually not necessary.

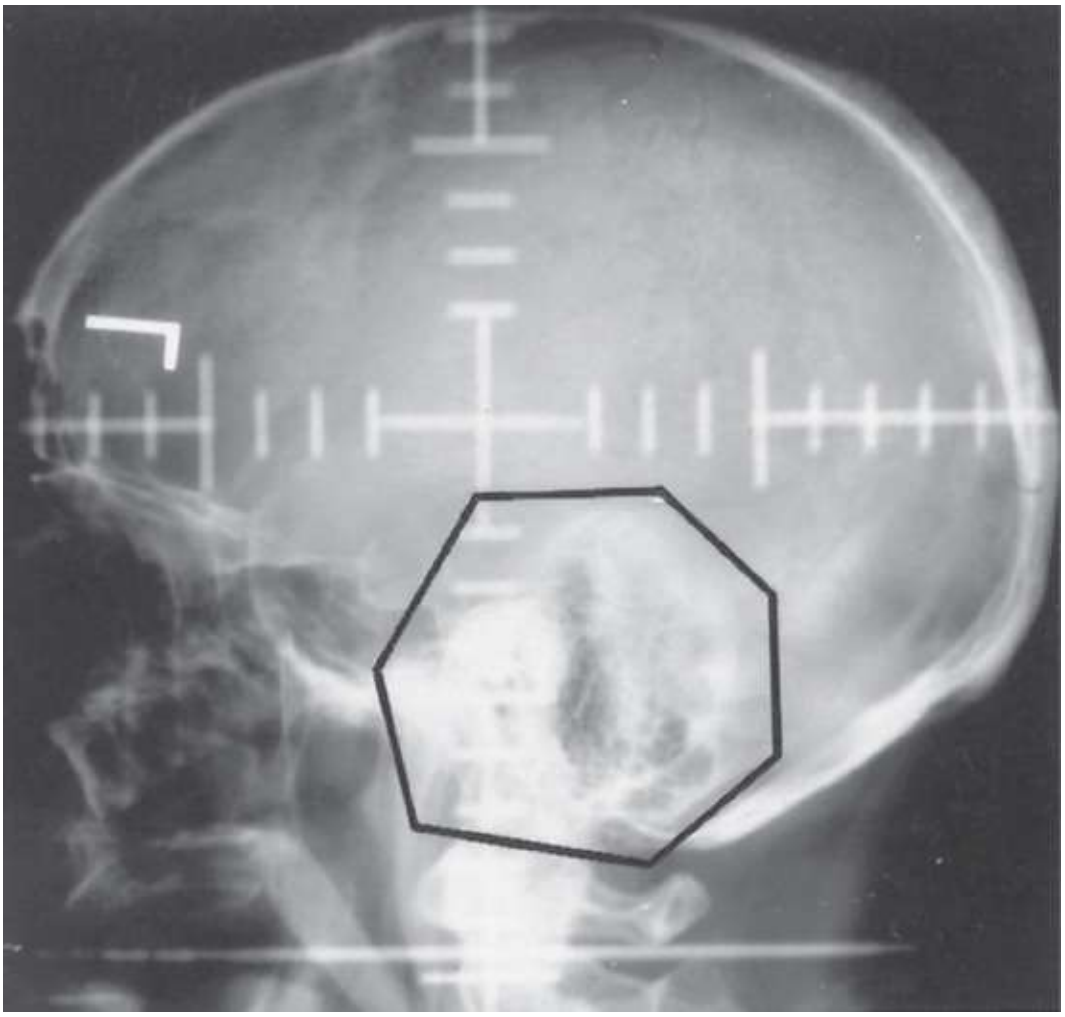

FIGURE 42.4. Example of treatment portal for tumor of the middle ear involving the petrous bone. The mastoid is included in irradiated volume.

The use of intensity-modulated radiotherapy (IMRT) can help improve target coverage and spare normal critical structures. Careful understanding of lymphatic drainage and tumor extension is crucial for target delineation and to avoid geographic miss. Pretreatment CT or MRI scans should be reviewed along with any operative or pathology reports.

In the definitive treatment of advanced external auditory canal or middle ear cancers, gross target volume (GTV) should include the clinical and radiographic gross disease (Fig. 42.5). Clinical target volume 1 (CTV1) should encompass the GTV with a 0.3- to 0.5-cm margin to a dose of 66 to 70 Gy at 2 Gy per fraction. CTV2 should include CTV1 with a 0.5- to 0.7-cm margin, as well as the preauricular nodes, postauricular nodes, ipsilateral upper cervical neck (level II), and parotid gland to a dose of 63 Gy at 1.8 Gy per fraction. A CTV3 can be considered for some patients with more advanced and aggressive tumors for

treatment of the ipsilateral middle and lower neck (level III and IV) and contralateral upper neck (level II) to a dose of 56 Gy at 1.6 Gy per fraction. Planning target volumes are created with a 3- to 5-mm margin around the CTVs.

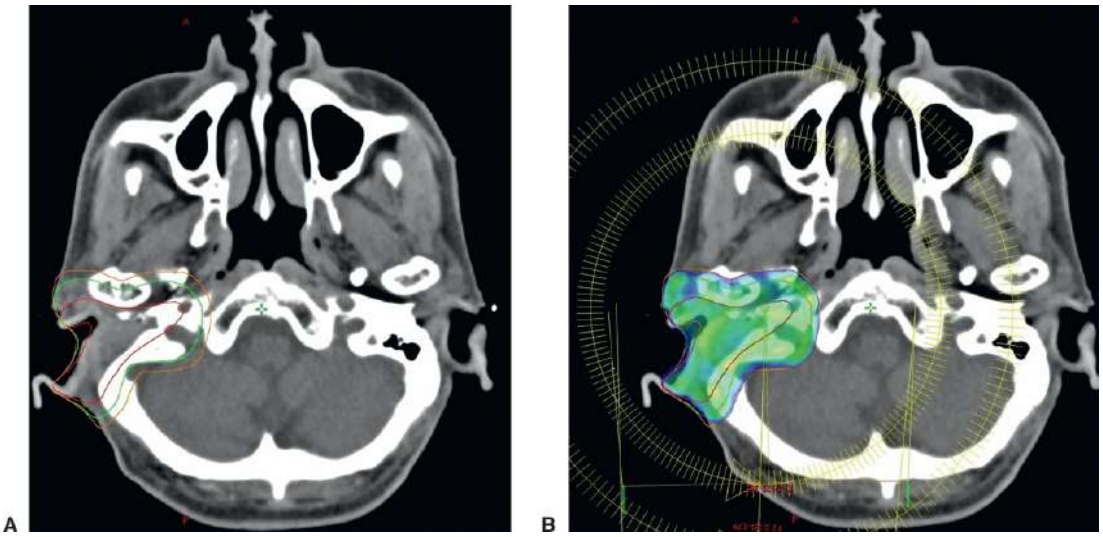

FIGURE 42.5. **A:** Treatment plan for external auditory canal squamous cell carcinoma: gross target volume (GTV) is in red, high-risk clinical target volume (CTV1) is in green, and planning target volume (PTV) is in orange. **B:** Dose color wash of 2 full-arc volumetric modulated arc therapy (VMAT) plan.

Chen et al.[62] described the target volumes for postoperative IMRT of the external auditory canal and middle ear. In the postoperative setting, CTV1 includes the original tumor region, surgical bed, soft tissue invasion, areas with positive residual disease, or positive margins to a dose of 60 to 66 Gy at 2 Gy per fraction. CTV2 includes CTV1 with a 0.5- to 0.7-cm margin, depending on the anatomy, and the ipsilateral upper neck (level II), including the parotid region, to a dose of 54 to 60 Gy at 1.8 Gy per fraction. In some patients, CTV3 is included to cover the ipsilateral middle to low neck (level III and IV) with or without the contralateral upper neck (level II) to a dose of 50 to 54 Gy at 1.6 Gy per fraction. Plans should be optimized to cover 95% of the planning target volume with 100% of the prescribed dose. In this case series, marginal failure occurred at the preauricular space and glenoid fossa of the TMJ. Caution should be taken to cover the area.

Extremely advanced tumors that are unresectable should be treated with high-energy ipsilateral electron beam therapy (16 to 20 MeV) alone or mixed with photons (4 to 6 MV), wedge pair (superior inferiorly angled beams) techniques using low-energy photons, or IMRT. IMRT is a reasonable option if nodal coverage is indicated. Doses of 60 to 70 Gy over 6 to 7 weeks are required.

Doses higher than this may produce osteoradionecrosis of the temporal bone. If various types of radiation therapy beams are available, individualized treatment plans should be devised (Fig. 42.6). Most patients receiving radiation therapy to the middle ear and temporal bone regions benefit from immobilization devices such as the Aquaplast system. When electron beam radiation therapy is used, use of water bolus in the external auditory canal and concha may reduce the auricular complications.

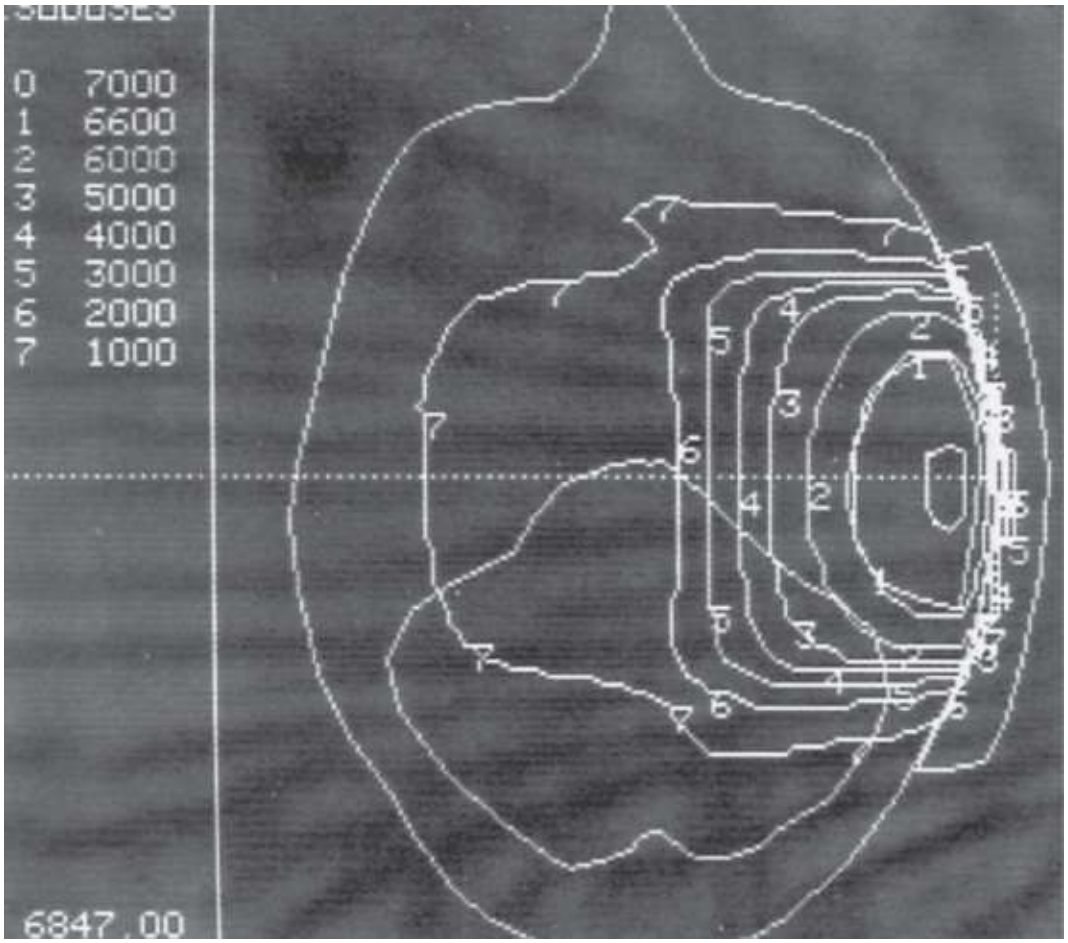

FIGURE 42.6. Computerized isodose distribution for treatment of a middle ear tumor using a combination of 4-MV photons (20%) and 16-MeV electrons (80%).

Palliative Radiation Therapy

Radiation therapy offers significant palliation in recurrent or advanced disease. Pain relief is reported in 61% of patients with tumors of the auditory canal and middle ear.[71] Recurrences developing after previous irradiation may be re-treated with low-dose radiation therapy and hope for control of tumor in approximately 20% of patients.[72] When a small-volume local recurrence occurs

after previous radiation therapy, fractionated high dose rate treatment may be considered.

RESULTS OF THERAPY

The series of patients reported from several institutions are small. Results of treatment with various modalities are shown in Table 42.4. In more extensive lesions, combinations of surgery and irradiation have yielded satisfactory results. Overall 5-year survival rates with combination therapy for tumors involving the middle ear and external auditory canal range from 40% to 60%, whereas patients with early-stage tumors achieve a 70% 5-year survival rate with no evidence of disease.

Data from a multi-institutional series (Fig. 42.7) indicate that there is a negative association between disease-free survival and extent of disease using the University of Pittsburgh staging system.[44] These data also provide evidence of the success of combined surgery and postoperative irradiation for malignancies of the temporal bone.[73,74]

NORMAL-TISSUE COMPLICATIONS

Organs at risk should include the brainstem, spinal cord, cochlea, eye, optic nerve, chiasm, lens, larynx, oral cavity, parotid glands, and temporal bone. Normal-tissue constraints are given in Table 42.5.

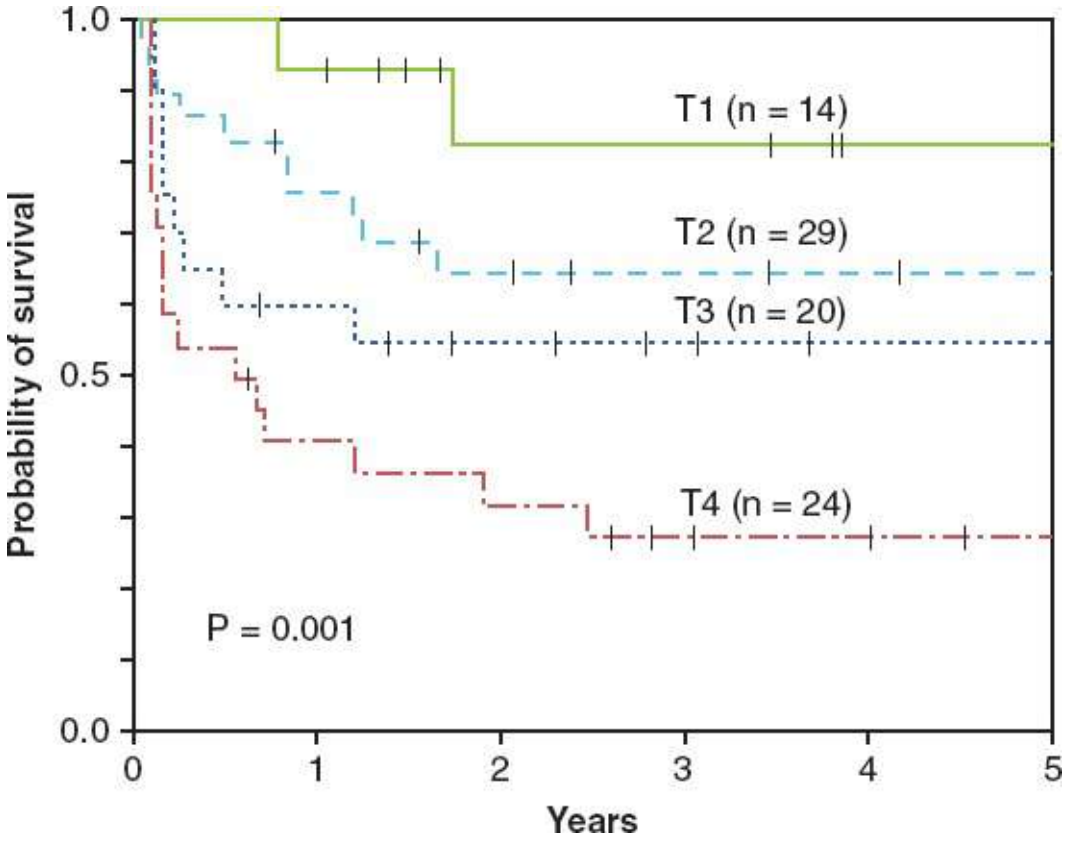

FIGURE 42.7. Data from patients with tumors of middle ear and external auditory canal from a multi-institutional series demonstrate the association between disease-free survival and extent of disease using the University of Pittsburgh staging system. (Reprinted from Ogawa K, Nakamura K, Hatano K, et al. Treatment and prognosis of squamous cell carcinoma of the external auditory canal and middle ear: a multi-institutional retrospective review of 87 patients. *Int J Radiat Oncol Biol Phys* 2007;68[5]:1326–1334. Copyright © 2007 Elsevier. With permission.)

For conventionally fractionated radiation therapy, the mean dose to the cochlea should be limited to less or equal to 45 Gy, or more conservatively 35 Gy, to reduce sensorineural hearing loss.[85] Modeling of some of the sensorineural hearing loss data from the *Quantitative Analysis of Normal Tissue Effects in the Clinic studies* are presented in (Fig. 42.8). The phenomenological binomial equation of Zaider and Amols was used.[86] Chen et al.[89] noted that hearing loss at a given radiation dose increased as frequency of the sound increased. The data are reasonably covered by theoretical curves having a characteristic dose (parameter α_2) of about 10 Gy (Table 42.6).

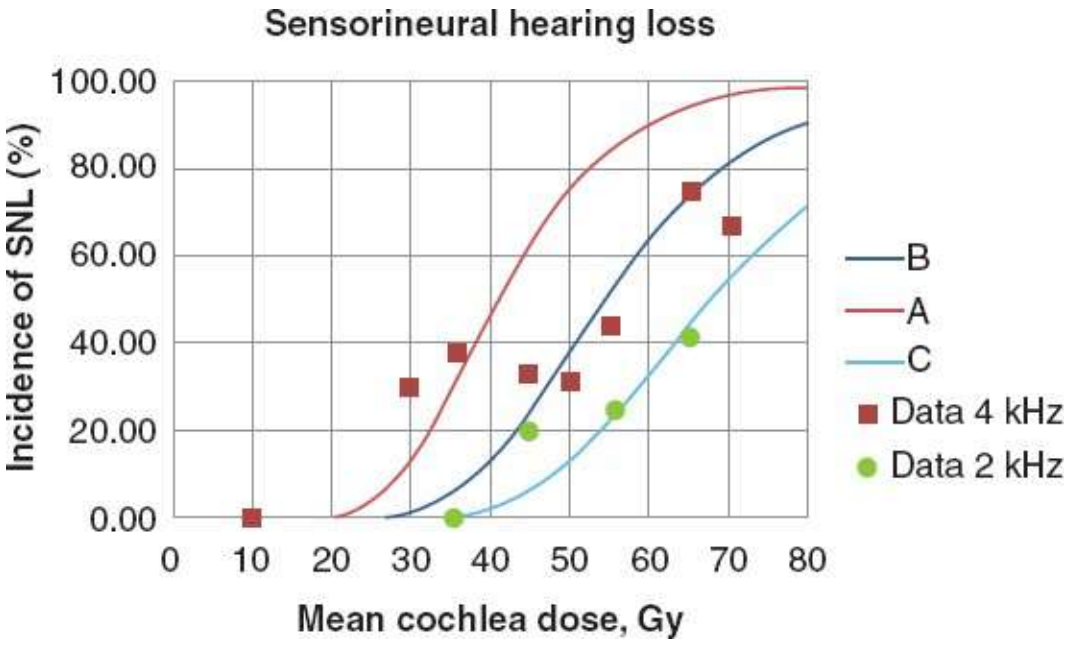

FIGURE 42.8. Modeling of quantitative analysis of normal tissue effects in the clinic sensorineural hearing loss data using the phenomenologic binomial equation of Zaider and Amols.[85–88] Data for 2 kHz are shown as circles and those for 4 kHz as squares. All points are taken from Figure 1a, b of Bhandare et al.[85,87] Theoretical curves use a simple two-parameter variant of the nested exponential equation (10) of Zaider and Amols[86,88]: $P(D) = 100 \exp[-\alpha_1 \exp(-\alpha_2 D)]$. The three curves are drawn with $\alpha_1 = 40$; the central curve has $1/\alpha_2 = 13.3$ Gy (*B*), and outer curves are for $1/\alpha_2$ = (*A*) *green*, 10 Gy and (*C*) *blue*, 16 Gy. SNL, sensorineural hearing loss.[88] (From Burri RJ. Ear. In: Chao C, Perez CA, Brady LW, eds. *Radiation oncology: management decisions*. Philadelphia, PA: Lippincott Williams & Wilkins, 2011:203–209. With permission.)

SEQUELAE OF TREATMENT

Possible sequelae with surgery are hemorrhage, infection, loss of facial nerve function, and, rarely, carotid artery thrombosis. Occasionally, vertigo is reported after temporal bone resection. Vertigo may last for 2 weeks, and a period of unsteadiness may last for a few months. Permanent deafness usually occurs on the operated side.

Radiation therapy sequelae include cartilage necrosis of the external auditory canal and osteoradionecrosis of temporal bone.[13,87] Very rarely, secondary infection and meningitis are reported.[11] Because of the proximity of the brainstem and medulla oblongata, it is extremely difficult to deliver a high dose of irradiation to the temporal bone without a significant risk of injury to these structures. An overall 10% incidence of bone necrosis can be expected after administration of 60 to 65 Gy. After external ear lesions are treated with

interstitial irradiation, there is a 4% incidence of late cutaneous and cartilage necrosis. Risk of necrosis increases for lesions >4 cm.[51] A majority of patients can experience acute grade 2 and 3 skin toxicities with postoperative IMRT.[62] Following definitive or postoperative radiation, there is a 30% incidence of xerostomia.[58]

TABLE 42.6 NORMAL TISSUE DOSE CONSTRAINTS

Structure	Constraints
Brainstem	Maximum <60 Gy
Spinal cord	Maximum <45 Gy
Cochlea	Mean dose <45 Gy
Optic nerve	Maximum <55 Gy
Optic chiasm	Maximum <55 Gy
Lens	Maximum <10 Gy
Larynx	Mean dose <44 Gy; maximum <66 Gy
Oral cavity	Mean dose <35 Gy
Parotid gland	Combined parotid glands mean dose <25 Gy or spare one parotid gland mean dose <20 Gy
Temporal bone	Limit to <70 Gy to reduce osteoradionecrosis chance

CHAPTER 43

Locally Advanced Squamous Carcinoma of the Head and Neck

David M. Brizel and Jessica L. Geiger

INTRODUCTION

Approximately 60,000 patients are diagnosed annually with squamous cell head and neck cancer (HNC) in the United States.[1] Worldwide, approximately 600,000 patients are afflicted. Nearly 60% of this population presents with locally advanced but nonmetastatic disease. Locoregional failure constitutes the predominant recurrence pattern, and most fatalities result from uncontrolled local and/or regional disease.

Historically, radiation therapy (RT) alone was the standard nonsurgical therapy for locally advanced disease. The state of the art regarding radiation dose fractionation has evolved from once-daily treatment to hyperfractionation and accelerated fractionation.[2–5] These newer strategies lead to a 7% to 10% improvement in locoregional control relative to once-daily treatment schemes. A meta-analysis of randomized trials testing modified fractionation schemes against conventional once-daily fractionation demonstrated that hyperfractionation was the most effective strategy, leading to an 8% absolute improvement in 5-year survival.[6] Nonetheless, even the most effective RT regimens result in local control rates of 50% to 70% and disease-free survivals (DFSs) of 30% to 40%.

This circumstance stimulated the investigation of treatments combining RT and chemotherapy. Review articles describe in detail the different chemotherapeutic agents and RT schemes of these treatment programs.[7,8] Randomized trials of induction cisplatin and 5-fluorouracil (5-FU) chemotherapy followed by standard fractionation versus laryngectomy and postoperative RT in advanced larynx and hypopharynx cancer performed by the Veterans Administration Cooperative Group[9] and the European Organization for the

Research and Treatment of Cancer (EORTC), respectively, initially showed that larynx preservation could be achieved without compromising overall survival.

Most randomized clinical trials show the superiority of combined RT and chemotherapy to RT alone for the treatment of locally advanced, nonmetastatic HNC. A meta-analysis of individual patient data from >17,346 participants in 93 trials conducted from 1965 to 2000 (Meta-Analysis of Chemotherapy in Head and Neck Cancer [MACH-NC]) demonstrated that the use of radiotherapy and concurrent chemotherapy resulted in a 19% reduction in the risk of death and an overall 6.5% improvement in 5-year survival compared to treatment with RT alone ($P < .0001$).[10] This benefit was predominantly attributable to a 13.5% improvement in locoregional control. The 2.9% reduction in the risk of distant metastases was not statistically significant (Fig. 43.1).

The MACH-NC also demonstrated a 2% improvement in 5-year survival from the use of induction chemotherapy followed by RT, which was not significant. A subset analysis of trials that used cisplatin and 5-FU as the induction regimen did show a 4% improvement in overall survival.[11] An update of the MACH-NC meta-analysis confirmed the superiority of concurrent chemoradiotherapy (CRT) compared with RT alone across all HNC primary sites.[12]

Randomized comparisons of concurrent chemoradiation versus induction chemotherapy followed by radiotherapy alone are few but confirm that the former strategy is superior.[13,14] The Radiation Therapy Oncology Group (RTOG) conducted a three-arm trial of radiation alone versus radiation and concurrent cisplatin versus induction cisplatin followed by irradiation in larynx carcinoma. Concurrent therapy constituted the most effective means of larynx preservation and provided the best disease control, albeit without a statistically significant survival benefit.[15]

RT and concurrent chemotherapy represents the most commonly used strategy and is a biologically attractive approach because some chemotherapeutic agents may both radiosensitize cells and provide additive cytotoxicity. The superiority of concurrent CRT relative to RT alone has been demonstrated in randomized trials in squamous cell carcinoma of other anatomic sites including the esophagus and uterine cervix.[16–18]

Certain issues must be considered when evaluating randomized trials of CRT for advanced HNC. The first consideration relates to the effectiveness of the RT-alone control arm. Specifically, does it represent optimal single-modality treatment? If the CRT regimen is more effective than RT alone but the radiation

is suboptimal, then it is difficult to accurately gauge whether or not the combined modality regimen represents a true improvement in therapy. The second consideration concerns the toxicity of CRT itself. Typically, both acute and late toxicities from CRT are greater than those from RT alone.[19–21]

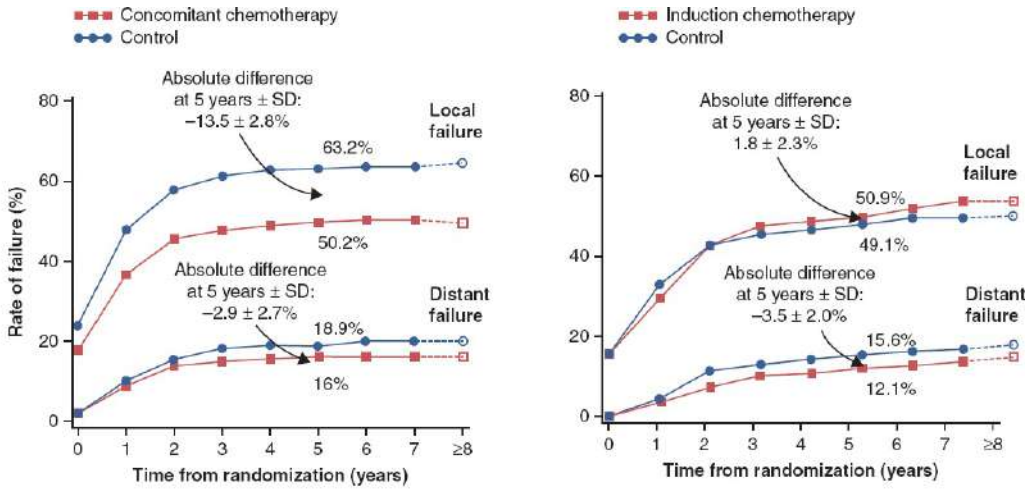
Acute mucositis constitutes the most significant impediment to the timely delivery of concurrent therapy. Because prolongation of total treatment time adversely affects the success of RT in HNC,[22–24] a major challenge has been the development of treatment schedules that integrate RT and chemotherapy and yet do not excessively increase total treatment time. A thorough understanding of toxicity is mandatory as avoidance of the functional morbidity associated with surgery in advanced HNC is one of the main reasons for the utilization of concurrent therapy in the first place.

HISTORICAL DEVELOPMENT OF RADIATION AND CONCURRENT CHEMOTHERAPY

CRT may be administered in synchronous or alternating schemes. Synchronous administration results in the delivery of RT and chemotherapy (CT) on the same days. Typically, chemotherapy will be given for 1 or more days at the initiation of RT and then repeated in the same fashion several weeks later. Alternating regimens usually sandwich RT and CT around one another. Radiation and drugs are therefore not necessarily given on the same days. In such a scheme, CT would be given during the first week of treatment with RT following in subsequent week(s) before CT is given again.

Synchronous Radiation and Single-Agent Chemotherapy

Synchronous treatment is completed more quickly than is alternating treatment. It is therefore preferable from a theoretical standpoint in terms of addressing the issue of accelerated repopulation, albeit at the expense of increased acute side effects. Early randomized trials of conventionally fractionated RT and CT used single-agent chemotherapy. These studies are summarized in Table 43.1. The experimental arms of RTOG 90-03,[2] EORTC 22791,[4] and DAHANCA 6-7[5] are included to provide a basis for comparison with optimal regimens of RT alone.



Local failure and distant failure/person-years by period

	Years 0–2	Years 3–5	Years ≥6	Years 0–2	Years 3–5	Years ≥6
Local failure						
Control	493/1,648	22/406	2/165	497/2,627	38/1,073	10/684
Chemotherapy	373/1,837	20/603	1/240	519/2,749	58/1,142	22/751
Distant failure						
Control	82/1,756	8/416	1/166	90/2,788	18/1,116	8/711
Chemotherapy	83/1,915	6/616	0/241	62/2,929	23/1,204	9/773

FIGURE 43.1. Data from the Meta-Analysis of Chemotherapy in Head and Neck Cancer (MACH-NC) illustrating that the major therapeutic benefit of platinum-based chemotherapy results from an improvement in locoregional disease control when the drugs are given concurrently with radiotherapy. No significant improvement occurs with induction chemotherapy followed by radiotherapy.

Both the Northern California Oncology Group (NCOG) and the EORTC tested radiation and synchronous bleomycin against RT alone.[25,26] Acute toxicity was worse in the combined-modality arm in both trials, but the outcomes were quite different with respect to efficacy. The EORTC trial showed no improvement in DFS or survival, and the RT/bleomycin combination in the NCOG program led to a statistically significant doubling of locoregional control and DFS, as well as a near-significant improvement in overall survival from 24% to 43%.

Differences in study design and execution may explain the discrepancy between outcomes in the EORTC and NCOG trials. Fractionation was similar in the two studies, but patients in the EORTC trial received 15 mg of bleomycin twice weekly during the first 5 weeks of RT for a total dose of 150 mg, whereas the NCOG patients received 5 mg twice weekly for a total dose of 70 mg. Acute mucosal and skin toxicity was worse in the RT/bleomycin arm in both trials. Toxicity significantly prolonged the RT delivery time in 30% of the combined-modality patients in the EORTC trial but not in any of the RT-alone patients. This prolongation of treatment time and associated tumor repopulation in such a

large proportion of patients may have negated any benefit accrued from the use of concurrent therapy. There were no differences in overall treatment time between the two treatment arms in the NCOG trial. An important lesson from these two studies is that the dose administration schedules of concurrent chemotherapy must be carefully designed so that toxicity does not adversely affect overall treatment compliance.

The Christie Hospital in Great Britain evaluated RT and 100 mg/m^2 of single-agent methotrexate (MTX) given at the commencement of and after 2 weeks of a 3-week course of treatment.[27] Most of the 313 patients in this protocol received 50 to 55 Gy in 15 or 16 fractions. Mucositis was significantly greater in the patients receiving MTX, but there was no difference in long-term toxicity. The addition of MTX increased local control from 50% to 70% (P = .02) and survival from 37% to 47% (P = .07). The greatest benefit was seen in patients with oropharyngeal primary tumors who constituted one-third of the study population. Local control with RT/MTX was 78% versus 38% with RT alone (P = .002) in this patient subset. Survival was 25% with RT alone and 50% with RT/MTX (P = .009). Unfortunately, the data from this trial are not generally applicable to current clinical practice because of the large radiation fraction sizes that were used.

5-FU has been used in conjunction with RT more frequently than any other chemotherapeutic agent. Lo et al.[28] reported the first study to show a significant improvement in local control and survival with the addition of bolus 5-FU to RT in squamous carcinoma of the oral cavity. Browman et al.[29] compared RT and continuous infusion 5-FU against RT alone in a placebo-controlled randomized trial sponsored by the National Cancer Institute of Canada. All 175 patients received 66 Gy in 2-Gy fractions. 5-FU was given at 1,200 mg/m^2/d for the first 3 days of the 1st and 3rd weeks of irradiation. Confluent mucositis was more frequent in the 5-FU arm than in the placebo arm (32% vs. 11%; P = .001), as was weight loss >15% from pretreatment baseline (41% vs. 11%; P < .0001). This increased acute toxicity did not prolong the delivery of RT in the RT/5-FU arm relative to the RT/placebo arm. Two-year DFS and survival were 30% and 50% for RT/placebo patients and 50% and 63% for RT/5-FU patients (P = .06 and .08), respectively.

TABLE 43.1 RANDOMIZED TRIALS OF ONCE-DAILY IRRADIATION AND CONCURRENT CHEMOTHERAPY IN ADVANCED HEAD AND NECK CANCER

Institution	N	Radiotherapy	Chemotherapy	Outcome RT vs. RT/CCT; *P* Value	Comments
RTOG 90-03 Accelerated fractionation	268	72 Gy/42 days	None	LC: 54% DFS: 39% S: 51%

5-FU, 5-fluorouracil; bid, twice daily; Bleo, bleomycin; CDDP, cisplatin; CI, continuous infusion; DFS, disease-free survival; EORTC, European Organization for the Research and Treatment of Cancer; LC, local control; MMC, mitomycin C; MTX, methotrexate; NCI, National Cancer Institute; NCOG, Northern California Oncology Group; NICR, National Institute for Cancer Research; NS, not significant; RT/CCT, radiotherapy and concurrent chemotherapy; RTOG, Radiation Therapy Oncology Group; S, survival.

The relative radioresistance of hypoxic cells *in vitro* is well understood.[28,30] Clinically, the existence of hypoxia in both head and neck primary tumors and metastatic lymph nodes has been described, and its adverse impact on the prognosis of patients treated with RT has been demonstrated.[31,32] Investigators from Yale University designed their treatment strategy around this principle. They treated 195 patients in two randomized trials with mitomycin C (MMC). This agent is predominantly metabolized in and preferentially cytotoxic to hypoxic cells. The Yale treatment program consisted of 68 Gy ± MMC on days 1 and 43 of RT. Local control was improved with the addition of MMC from 54% to 76% (P = .003). Survival improved from 42% to 48%, but this was not statistically significant. The majority of patients in these trials received adjuvant postoperative or preoperative irradiation, however. Only 74 (38%) received definitive, primary RT, and the benefit from the addition of MMC in this subset is unclear.[33]

Synchronous Radiation and Multiagent Chemotherapy

Cisplatin (CDDP) also has radiosensitizing properties.[34] The combination of CDDP and 5-FU is also one of the most active cytotoxic drug combinations against squamous cell HNC. Consequently, investigators have incorporated both of these drugs into a variety of concurrent treatment strategies. A randomized trial from the Cleveland Clinic assigned patients to receive 66 to 72 Gy ± two cycles of synchronous CDDP (20 mg/m^2/d × 4) and infusional 5-FU (1,000 mg/m^2/d × 4) during weeks 1 and 4 of RT.[35] The main objective of this study was primary site organ preservation. Surgical salvage was allowed for patients with persistent disease. Acute toxicity was significantly greater in the combined-modality treatment arm, especially with respect to weight loss. Mucosal recovery

usually required 8 to 12 weeks after completion of RT and chemotherapy. There were no differences in the total time required for RT delivery, however. Three-year DFS was significantly better for the patients receiving chemoradiotherapy (67% vs. 52%; $P = .03$). Three-year survival with primary site preservation was also higher in the combined-modality group (57% vs. 35%, $P = .02$), although there was no significant difference in overall survival.

MMC and 5-FU were used together in a trial of 209 patients conducted at the Princess Margaret Hospital.[36] Patients were treated with continuous-course RT alone at 2.5 Gy/day to 50 Gy in 28 days. Patients randomized to receive RT/chemotherapy received the same dose-fractionation scheme as did those receiving RT alone but over a total time of 56 days because of a planned 4-week treatment interruption after 25 Gy. Bolus MMC (10 mg/m^2) was given on days 1 and 43. Two cycles of continuous infusion 5-FU (1,000 mg/m^2/d) were given on days 1 to 4 and 43 to 46. The intent of the treatment break was to maintain comparable levels of acute toxicity in the two treatment arms. Acute toxicity was, in fact, equivalent in the two groups. Unfortunately, however, there was no difference in 4-year local control (~40%) or survival (~40%).

The Princess Margaret trial raises an important question: Can one quantify the contribution provided by concurrent chemotherapy in terms of the delivery of an equivalent dose of irradiation? Approximately 0.6 Gy/day is necessary to compensate for the tumor repopulation that transpires with each day of prolongation of standard course RT.[23] Thus, the total dose in the Princess Margaret Hospital RT/chemotherapy arm would have to have been about 67 Gy [(2.5 Gy × 20) + (0.6 Gy/day × 28 days)] in order to have been isoeffective with the 50-Gy regimen in the RT-alone arm. The equivalent efficacy of the two treatments in this trial therefore suggests that the chemotherapy compensated for the tumor repopulation that occurred during the treatment break. Thus, one could argue that the chemotherapy was equivalent to approximately 17 Gy of additional irradiation. There can be no doubt as to the inferiority of the split-course fractionation scheme in this trial had it been delivered without chemotherapy and compared head to head against the continuous-course RT regimen. Conversely, if the combined-modality treatment had been given with continuous-course RT, it would quite probably have been more efficacious than the RT-only regimen.

A Spanish three-arm randomized trial ($N = 859$) provides additional information that is pertinent to the estimation of the radiotherapeutic dose equivalent provided by the delivery of concurrent chemotherapy.[37] Patients were

assigned to receive one of the following regimens:

1. 2 Gy/day to 60 Gy/42 days
2. 1.1 Gy twice daily to 70.4 Gy/44 days
3. 2 Gy/day to 60 Gy/42 days with concurrent bolus 5-FU 250 mg/m^2 given every other day

Progression-free survival and overall survival were significantly worse in arm A as compared with arms B and C, as one would expect. Arms B and C were equally efficacious. Not accounting for the different fractionation in arms B and C and the unconventional administration of chemotherapy, it is still clear that the addition of 5-FU was comparable to dose escalation of approximately 10 Gy. A recent modeling analysis of phase III trials comparing CRT with RT only suggests that concurrent chemotherapy provides the equivalent of a 10- to 12-Gy dose escalation.[38]

Neither the Princess Margaret nor the Spanish trial delivered maximally intensive radiotherapy in their respective control arms. The rationale for treatment intensification with the addition of concurrent chemotherapy as opposed to simple RT dose escalation is weak in such a context. The situation may be dramatically different, however, when the RT-alone arm is maximally intensive such as in RTOG 90-03 or EORTC 22791. Dose escalations of 10 to 12 Gy are not possible with accelerated regimens that already deliver 72 Gy during 6 weeks or with hyperfractionated regimens delivering 79 Gy in 7 weeks (see Radiation Fractionation Scheme section). Concurrent chemotherapy, however, can be added to modified fractionation regimens ≥70 Gy.

Alternating Radiotherapy and Chemotherapy

Alternating therapy produces less acute mucosal toxicity than does synchronous therapy but may prolong the overall treatment time by several weeks. Although longer treatment times adversely affect efficacy in programs of standard RT alone because of tumor repopulation, the significance of overall treatment time (for RT) in a continuous course of alternating RT and chemotherapy is controversial. Some investigators have suggested that the usual time–dose relationships do not apply.[39]

The National Institute for Cancer Research in Italy conducted a phase III trial comparing RT with alternating RT and chemotherapy in 157 patients with unresectable HNC.[40,41] The RT arm was designed to give 70 Gy/7 weeks via standard fractionation. The combined-therapy arm scheduled chemotherapy on weeks 1, 4, 7, and 10 and radiation (60 Gy) on weeks 2 to 3, 5 to 6, and 8 to 9.

Each 2-week cycle of radiation consisted of 20 Gy/10 fractions. Each cycle of chemotherapy included 5 days of bolus CDDP (20 mg/m^2/d) and bolus 5-FU (200 mg/m^2/d). The incidence of grade 3/4 mucositis (18% to 19%) was the same in both treatment groups. However, RT treatment delays occurred more often in the RT-alone patients: 32% with a 1-week prolongation and 25% with a ≥2-week prolongation. Corresponding delays in the combined-modality-treatment group were 11% and 15%, respectively. The median dose of RT delivered in the combined-modality-treatment group matched the planned dose of 60 Gy, but it was only 62 Gy in the RT-alone group. Five-year actuarial survival was significantly better in the combined-modality-treatment patients (24% vs. 10%; P = .01), as were DFS (21% vs. 9%; P = .008) and local control (64% vs. 32%; P = .04).

Given the similar levels of acute toxicity, it is unclear why treatment times were prolonged and total doses reduced so extensively in the RT-only patients. Better protocol compliance in the control arm might well have changed the outcome of this trial. There are no other randomized trials of RT and alternating chemotherapy. Further randomized trials of alternating therapy will be necessary to determine its true value because the deficiencies of the National Institute for Cancer Research study prevent definitive conclusions.

Despite its drawbacks, the Italian study, like the Princess Margaret Hospital trial, strongly reinforces the idea that in some settings, chemotherapy counteracts tumor repopulation during treatment. The total RT treatment time was prolonged in the combined-modality arms in both studies. The fundamental difference between these two trials is that patients received no treatment during the RT break in the Princess Margaret Hospital trial and the patients in the Italian trial received chemotherapy during each interruption of RT.

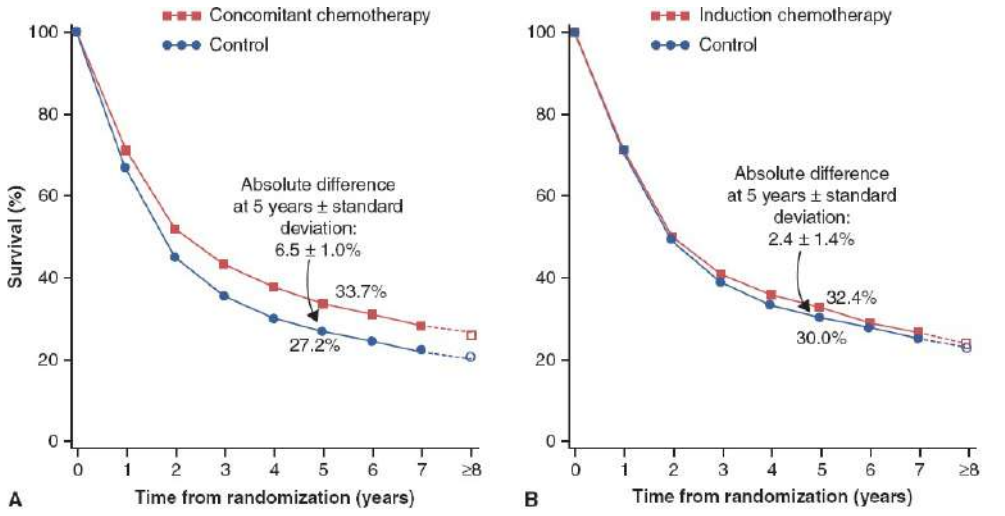
CONTEMPORARY RANDOMIZED TRIALS OF RADIOTHERAPY AND CONCURRENT CHEMOTHERAPY

Curative Intent Treatment

The French cooperative group trial, GORTEC 94-01, was performed in patients who had stage III/IV oropharyngeal carcinoma.[20,42] Radiotherapy consisted of conventional 2 Gy, once-daily fractionation to 70 Gy. Patients on the CRT arm also received three cycles of concurrent carboplatin (70 mg/m^2) and continuous infusion 5-FU (600 mg/m^2/d × 4 days). Two hundred twenty-six patients were enrolled in the trial. CRT resulted in significant improvement in 5-year

locoregional control (48% vs. 25%; *P* = .002), DFS (27% vs. 15%; *P* = .01), and survival (23% vs. 16%; *P* = .05). This improvement in efficacy was accompanied by a significant increase in acute mucositis (grade ≥ 2) from 39% to 71% (*P* = .005). Severe acute cutaneous and hematologic toxicity and worse nutritional status were also significantly more prevalent in the patients who received combined-modality therapy. Severe late toxicity, primarily cervical fibrosis, occurred in 27% of the combined-modality patients and in 12% of those treated with RT alone (*P* = .04). Severe dental complications were twice as frequent in the combined-modality patients (37% vs. 18%; *P* = .01).

Wendt et al.[43] conducted a multi-institutional trial of CRT versus RT for patients with unresectable stage III/IV HNC. CRT patients received three cycles of cisplatin, 5-FU, and leucovorin during a 7-week period. Cisplatin was given as a 60 mg/m^2 bolus. 5-FU was given as an initial 350 mg/m^2 bolus followed by a 4-day continuous infusion of 350 mg/m^2/d. Leucovorin was also given for 4 days at 100 mg/m^2/d. Radiotherapy was given as three cycles of 23.4 Gy at 1.8 Gy bid in both treatment arms. It coincided with the chemotherapy on the CRT arms. Planned treatment breaks were given between the cycles of treatment to ameliorate treatment-induced mucositis. The cumulative dose of RT in both treatment arms was 70.2 Gy in 7 weeks.



Death/person-years by period

	Years 0–2	Years 3–5	Years ≥6
Control	2,500/6,298	672/3,658	217/2,487
Chemotherapy	2,187/6,647	706/4,576	278/3,194

Death/person-years by period

	Years 0–2	Years 3–5	Years ≥6
Control	1,283/3,535	393/2,276	137/1,417
Chemotherapy	1,318/3,820	392/2,608	167/1,530

FIGURE 43.2. Data from the Meta-Analysis of Chemotherapy in Head and Neck Cancer (MACH-NC), which demonstrates that adding concurrent chemotherapy to radiotherapy provides a significant improvement in survival but that induction chemotherapy does not. **A:** Concomitant chemotherapy. **B:** Induction chemotherapy.

One-third of the 270 patients enrolled had oropharynx primary tumors. CRT doubled both 3-year local control (35% vs. 17%; $P < .004$) and survival (49% vs. 24%; $P < .003$) (Fig. 43.2). As in the GORTEC 94-01 oropharyngeal trial, confluent mucositis was significantly higher (38% vs. 16%; $P < .001$) with the use of CRT.

Treatment of advanced nasopharynx carcinoma (NPC) with radiation and concurrent chemotherapy was the subject of an intergroup study in which patients in both arms received conventionally fractionated RT (1.8 to 2.0 Gy/day) to a total dose of 70 Gy.[44] Those patients who were randomized to concurrent chemotherapy also received three cycles of cisplatin during RT at a dose of 100 mg/m^2. After the completion of RT, they received an additional three cycles of adjuvant cisplatin at 80 mg/m^2 and 4-day continuous infusions of 5-FU at 1,000 mg/m^2/d. All patients had stage III/IV, M0 disease. In spite of the initial plan of enrolling 270 patients, the trial was terminated early when an interim analysis demonstrated the superiority of the combined-modality regimen. One hundred ninety-three patients were enrolled, and the median follow-up was 2.7 years. Three-year progression-free survival favored the combined-modality patients (69% vs. 24%; $P < .001$). Similarly, 3-year survival was 78% versus 47% ($P = .005$) in favor of the patients who received concurrent chemotherapy (Fig. 43.3). Approximately, one-third of the patients in the combined modality arm did not receive some or all of their adjuvant chemotherapy.

The value of adjuvant chemotherapy in NPC has been controversial ever since the findings of this study were published. A multinational clinical trial is currently being conducted attempting to identify who might benefit from it (clinicaltrials.gov identifier NCT02135042). It is now understood that the majority of NPC is World Health Organization (WHO) grade 2 to 3 and that serum Epstein-Barr virus deoxyribonucleic acid (EBV DNA) titers are elevated in most of these patients. Furthermore, the titers become undetectable by the completion of local therapy in most of these patients, and they have an excellent prognosis, whereas the prognosis is poor for those whose titers remain detectable. On this trial, those patients whose titers become undetectable will be randomized (phase III) to adjuvant cisplatin/5-FU versus observation with a primary endpoint of overall survival. Those patients whose titers remain detectable will be randomized (phase II) to adjuvant cisplatin/5-FU versus paclitaxel/gemcitabine with a primary endpoint of progression-free survival.

Table 43.1 summarizes the data from the trials of conventionally fractionated irradiation and concurrent chemotherapy.

One must ask not only whether CRT is more effective than conventionally fractionated RT but also whether it is superior to hyperfractionated or accelerated fractionation irradiation as these strategies represent the most efficacious single-modality treatment strategies. A prospective randomized trial from Duke University was one of the first to provide insight into this issue.[45] Patients with locally advanced HNC were randomized to hyperfractionated irradiation alone versus split-course hyperfractionation with concurrent CDDP/5-FU chemotherapy. Patients in the RT-alone arm received 1.25 Gy bid continuous course to 75 Gy in 6 weeks, whereas those patients on the CRT arm received 1.25 Gy bid split course to 70 Gy in 7 weeks. Chemotherapy was given during weeks 1 and 6 of irradiation (CDDP 12 mg/m^2/d × 5 days; 5-FU continuous infusion was 600 mg/m^2/d × 5 days).

The time–dose aspects of the RT in the combined-modality arm are similar to those of the previously discussed trials. The time–dose characteristics of the RT in the control arm were similar to certain aspects of both the concurrent boost arm (decreased treatment time) and the hyperfractionation arm (increased total dose) of RTOG 90-03. Most importantly, these characteristics made the RT more intensive in the control arm than in the experimental CRT arm. This study design was intentional because a primary objective of the trial was to determine whether a lower dose of RT with concurrent chemotherapy would be superior to maximally intensive/effective RT alone.

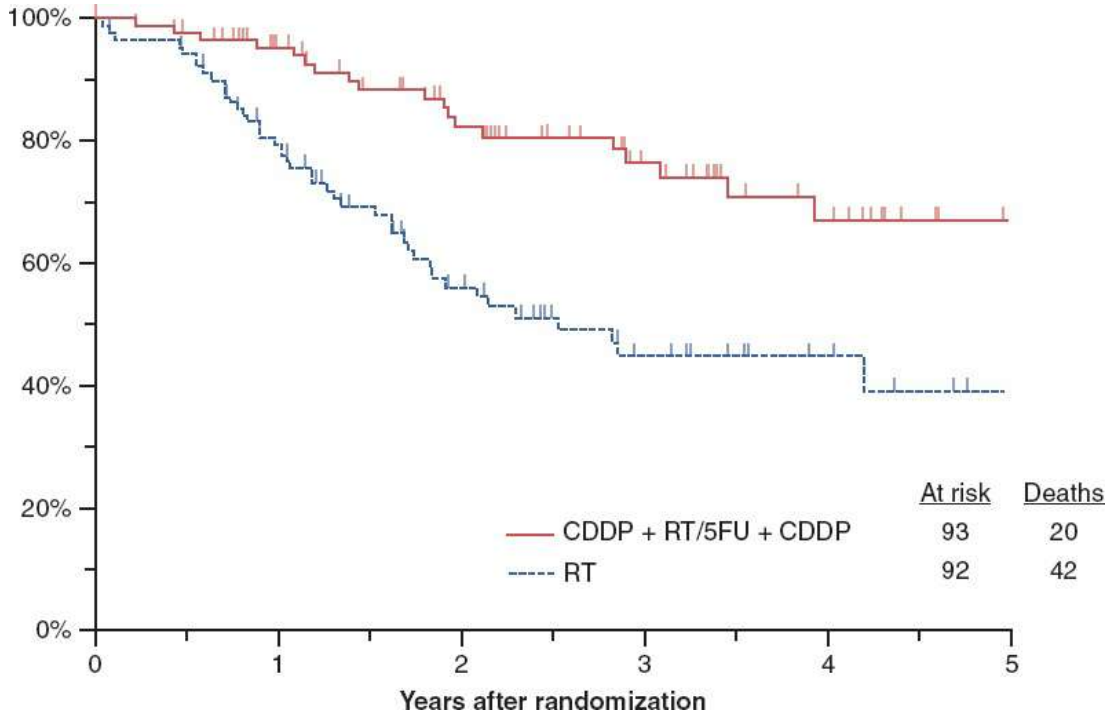


FIGURE 43.3. Three-year survival in the Intergroup Nasopharynx Carcinoma Trial was significantly better (*P* = .005) for those patients who received concurrent cisplatin and postirradiation adjuvant cisplatin/5-fluorouracil (78%) than for those who received radiotherapy alone (47%). These results led to early trial closure.

Fifty-four percent of the patients presented with unresectable disease, and approximately 40% of the primaries were located in the oropharynx. One hundred sixteen patients were enrolled, and the updated median follow-up now exceeds 5 years. Locoregional control was 70% versus 44% (*P* = .006), favoring the combined-modality patients. An unpublished update of the 5-year survival revealed superiority in the combined-modality patients (42% vs. 27%; *P* = .04) (Fig. 43.4). Confluent (grade 3) mucositis was seen in approximately 75% of the patients in both arms, the main difference being that the mean time to resolution of mucositis was 50% longer in the patients receiving radiation and concurrent chemotherapy (6 vs. 4 weeks).

Jeremic et al.[46] evaluated hyperfractionated irradiation (1.1 Gy bid to 77 Gy) with or without concurrent low-dose daily cisplatin (6 mg/m^2) in stage III/IV patients. One hundred thirty patients were enrolled; primary tumors originated in the oropharynx in approximately one-third of the population. Fifty-nine percent presented with T3 or T4 primaries, and 80% had nodal involvement. Five-year locoregional control (50% vs. 36%; *P* = .04), progression-free survival (46% vs. 25%; *P* = .007), and overall survival (46% vs. 25%; *P* = .007) (Fig. 43.5) were all significantly improved with the addition of concurrent chemotherapy. Of note, the distant metastasis-free survival was also improved in the concurrent therapy patients (86% vs. 57%; *P* = .01).

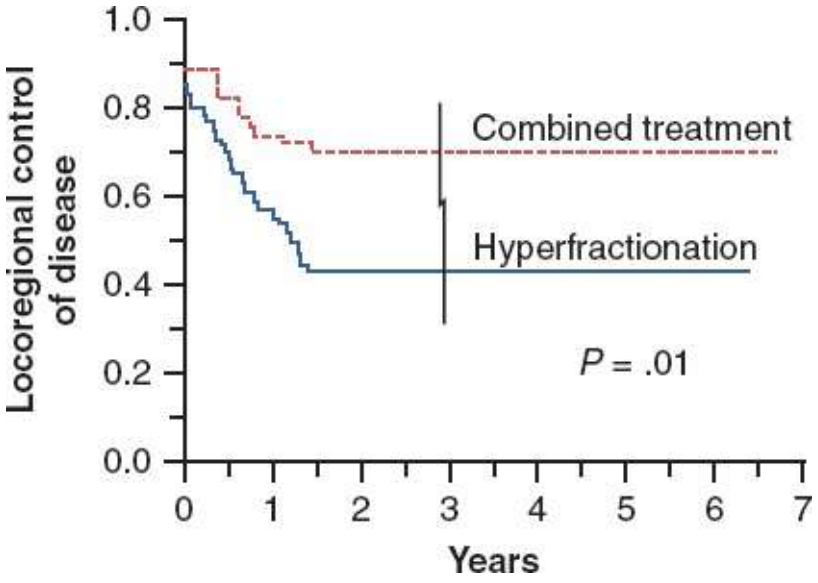

FIGURE 43.4. Five-year locoregional control in the Duke University randomized trial of continuous-course accelerated hyperfractionation (44%) versus split-course accelerated hyperfractionation and concurrent cisplatin/5-fluorouracil (*P* = .01). Extended follow-up has demonstrated that the survival benefit of combined modality treatment is also statistically significant.

A German multicenter trial also confirmed that CRT is superior to maximally intensive single-modality irradiation.[19] Three hundred eighty-four patients, 93% of whom had either stage III or IV oropharyngeal or hypopharyngeal primaries, were enrolled. As in the Duke trial, the total dose of RT delivered in the CRT arm was lower than that in the RT control arm. RT patients received 77.6 Gy in 6 weeks (14 Gy at 2 Gy once daily followed by 63.6 Gy at 1.4 Gy twice daily), and CRT patients received 70.6 Gy during 6 weeks (30 Gy at 2 Gy/day followed by 40.6 Gy at 1.4 Gy twice daily). Chemotherapy consisted of mitomycin C (10 mg/m^2) on days 5 and 35 and 5-FU given as a single bolus of 350 mg/m^2 and a 5-day continuous infusion of 600 mg/m^2/d. Two-year survival was significantly better in the combined-modality arm (54% vs. 45%; *P* = .05), as was locoregional control (61% vs. 45%; *P* = .001). Acute and chronic toxicities were equivalent in the two treatment populations.

A French cooperative group (FNCLCC-GORTEC) tested a related concept in 163 patients with technically unresectable carcinomas of the oropharynx and hypopharynx.[47] RT was administered at 1.2 Gy twice daily to a total dose of 80.4 Gy/46 days to oropharyngeal primary tumors and 75.6 Gy/44 days to hypopharyngeal primary tumors. The experimental arm received the same RT and concurrent CDDP (100 mg/m^2) on days 1, 22, and 43 of RT. Three 5-day cycles of continuous infusion 5-FU were also administered. The first cycle was 750 mg/m^2/d and the second and third cycles were 430 mg/m^2/d. Three-year DFS favored the concurrent chemoradiation arm (48% vs. 25%; *P* = .002), as did overall survival (38% vs. 20%; *P* = .04). Post hoc subset analyses demonstrated that the larger (and statistically significant) benefit was confined to the patients with oropharyngeal carcinomas. However, the trial was not designed to compare treatment efficacy in these two different primary sites of origin.

5-FU, 5-fluorouacil; bid, twice daily; CDDP, cisplatin; CF, conventional fractionation; CI, continuous infusion; DFS, disease-free survival; LC, local controls; MMC, mitomycin C; RT/CCT, radiotherapy and concurrent chemotherapy; RTOG, Radiation Therapy Oncology Group; S, survival; V-CHART, Vienna-Continuous Hyperfractionated Accelerated Radiation Therapy.

A three-armed randomized trial from the University of Vienna compared conventionally fractionated RT (2 Gy daily to 70 Gy) against continuous hyperfractionated accelerated RT with and without mitomycin C (V-CHART + MMC and V-CHART, respectively).[48] Radiation therapy was given as an initial 2.5-Gy fraction followed by 1.65 Gy twice daily to a total dose of 55.3 Gy in 17 days. MMC was given as a 20 mg/m^2 bolus on day 5 of RT. Of the 239 patients enrolled, 85% had T3/4 primary tumors, and 79% had nodal involvement.

Three-year actuarial locoregional control was 48% for V-CHART + MMC versus 32% for V-CHART and 31% for conventional fractionation (CF) (P = .05 and .03, respectively). Survival including death from all causes was also improved to 41% in the V-CHART + MMC arm as compared with 31% for V-CHART and 24% for CF (P = .03).

The incidence of confluent mucositis was 90% in both experimental arms as compared with 33% in the CF arm. The median time to complete resolution of mucositis was 6 to 7 weeks in all three arms. Grade 3/4 hematologic toxicity, primarily thrombocytopenia, developed in 18% of the V-CHART + MMC patients. Table 43.2 summarizes the data from the trials that used modified fractionation and concurrent chemotherapy and includes the RTOG 90-03 and EORTC 22791 data as a point of reference for optimally delivered RT alone.

Adjuvant Postoperative Irradiation

The role of chemotherapy for patients receiving primary resection and postoperative irradiation has been studied less extensively than in the definitive irradiation setting. The National Cancer Institute Head and Neck Contracts Program[49] conducted a three-arm trial that evaluated the addition of one cycle of preoperative cisplatin and bleomycin with or without six cycles of sequential cisplatin (80 mg/m^2) maintenance chemotherapy after surgery and postoperative irradiation. The control arm consisted of surgery and postoperative irradiation alone. This trial enrolled 443 patients and demonstrated no benefit with respect

to locoregional control or survival from the addition of chemotherapy. Nearly half of the patients who were randomized to receive maintenance chemotherapy never received it. Despite this flaw in study execution, the incidence of distant metastases as the site of first relapse was 9% in the patients assigned to maintenance chemotherapy as opposed to 19% in those who were not ($P = .02$).

Intergroup Study 0034 readdressed the issue of postoperative chemotherapy in a trial that randomized patients after surgery to three 21-day cycles of sequential cisplatin (100 mg/m^2) and infusion 5-FU (1,000 mg/m^2/d for 5 days) followed by 50 to 60 Gy versus 50 to 60 Gy alone with no chemotherapy.[50] Again, there was no significant improvement in locoregional control or overall survival associated with the use of chemotherapy, but the incidence of distant metastases was reduced from 30% to 20% ($P = .02$).

In contrast to the use of sequential postoperative RT and chemotherapy, the EORTC conducted a randomized trial in which patients were given either postoperative RT alone (2 Gy daily to 66 Gy) or the same RT with three cycles of cisplatin (100 mg/m^2) on days 1, 22, and 43 of irradiation.[51] Three hundred thirty-four patients were enrolled. Two-thirds of patients in the combined-modality arm received all three cycles of chemotherapy. The median follow-up is 5 years. Three-year DFS was increased from 41% to 59% ($P = .001$), and 3-year survival was increased from 49% to 65% ($P = .006$) in favor of the group of patients receiving concurrent therapy. Acute mucosal toxicity greater than grade 3 was significantly higher in the concurrent treatment arm (41% vs. 21%; $P = .001$).

The RTOG led an intergroup trial (9501) that randomized 459 high-risk postoperative patients to receive 60 to 66 Gy with or without concurrent CDDP in the same dose and schedule as in the EORTC study.[52] Sixty-one percent of patients in the concurrent therapy arm received all three cycles of CDDP. The median follow-up for this study is 4 years; 2-year actuarial locoregional control favored the combined-modality arm by 82% versus 72% (hazard ratio [HR], 0.61; $P = .61$), with only eight local or regional recurrences occurring beyond the 2-year point. DFS also favors concurrent therapy (HR, 0.78; $P = .04$). There was no statistically significant difference in survival (HR, 0.84; $P = .19$). Acute toxicity grade 3 or higher was higher in the concurrent therapy patients (77% vs. 34%; $P < .001$), but late toxicity was similar (21% vs. 17%).

A comparative analysis of the pooled data from these two studies revealed extracapsular extension (ECE) and/or microscopically involved surgical margins were the only risk factors for which the addition of chemotherapy to

postoperative radiation was significant.[53] Patients with two or more involved lymph nodes in the absence of ECE did not benefit from the addition of chemotherapy. A trend in benefit to the addition of chemotherapy was seen in patients with stage III to IV disease, perineural invasion, lymphovascular space invasion, and enlarged level IV to V lymph nodes secondary to oral cavity or oropharynx tumors. As such, concurrent chemoradiotherapy remains the standard of care for adjuvant therapy in patients with locally advanced squamous cell HNC and the presence of ECE and/or positive surgical margins. Long-term follow-up of RTOG 9501 found no significant outcome differences in analysis of all randomized patients; however, a subgroup analysis of patients with positive surgical margins and/or ECE demonstrated improved locoregional control and DFS with the addition of chemotherapy, further supporting these findings as poor risk factors in this disease.[54] Despite these recommendations, a retrospective analysis of the National Cancer Database identified a subset of patients with negative surgical margins and no ECE who still received adjuvant CRT.[55] Survival benefits of CRT versus RT alone increased in patients with multiple positive lymph nodes, despite the findings of the EORTC and RTOG studies, highlighting the need for ongoing evaluation into other poor risk factors for disease recurrence.

PRINCIPLES FOR THE CHOICE OF CONCURRENT TREATMENT REGIMENS

Three general statements can summarize the previously reviewed randomized trials:

RT with concurrent chemotherapy is more efficacious than conventionally fractionated RT alone in advanced HNC.

Concurrent therapy appears to be more effective than maximally intensive single-modality RT administered via a modified fractionation regimen.

Acute and late toxicities are increased with the use of concurrent chemotherapy.

No consensus exists, however, regarding either the optimal radiation dose-fractionation scheme or the optimal scheduling of chemotherapy in these concurrent regimens. These controversies pose a decision-making dilemma to the physician when it is time to devise a treatment plan. The application of certain principles may serve as a guide in this selection process, though. The radiochemotherapy regimen should be more effective than maximally effective

single-modality radiation.

Radiation Fractionation Scheme

One rational approach to the choice of radiation dose fractionation within the context of concurrent chemotherapy would start with the selection of an optimal single-modality therapy and a definition of both its clinical efficacy and toxicity. Different dose-fractionation schemes in concurrent treatment programs could then be normalized to one another using the biologically equivalent dose (BED) concept.[56] The BED = $nd[1 + d/(a/b)]$, where n = the number of fractions delivered, d = the dose per fraction, and a/b = 10 for tumors and acute-responding normal tissues and 2 for late-responding tissues. The intent of this normalization process is to allow a comparison of these different treatment programs in order to identify those having a favorable profile in terms of maximizing the probability of tumor control while minimizing the risk of late toxicity. Kasibhatla et al.[38] evaluated prospective trials of CRT in order to estimate the radiotherapeutic dose equivalence of the concurrent chemotherapy. They concluded that, with respect to the tumor, the administration of concurrent chemotherapy was equivalent to the delivery of an additional 10 to 12 Gy. Subsequently, Lee and Eisbruch[57] estimated that concurrent chemotherapy was equivalent to the delivery of an additional 8 Gy when the development of acute mucositis was used as the endpoint.

Whether modified fractionation irradiation and concurrent chemotherapy are superior to conventionally fractionated irradiation and concurrent chemotherapy was addressed in the RTOG 0129 clinical trial.[58] Both RT and chemotherapy constituted experimental variables in this trial. Patients (N = 743) were randomized to receive accelerated fractionation/concomitant boost to 72 Gy/6 weeks as per RTOG 90-03 and two cycles of concurrent bolus cisplatin (100 mg/m^2) or conventionally fractionated RT 70 Gy/7 weeks and three cycles of concurrent bolus cisplatin (100 mg/m^2). Eight-year survival was 48% in both arms, and there were no differences observed in progression-free survival, locoregional failure, or distant metastases. The findings show that one can compensate for the elimination of the third dose of cisplatin by the more intensive radiation schedule. It should also be pointed out that on the conventionally fractionated arm, only 69% of patients could tolerate all three doses of CDDP, a common occurrence with the use of high-dose CDDP regimens. Outcome was also the same in the conventionally fractionated arm patients who only received two cycles of CDDP versus all three cycles.

Chemotherapy Scheduling Considerations

Many investigators consider 100 mg/m^2 bolus dosing of CDDP on days 1, 22, and 43 of RT to be standard. This schedule was originally developed for use in clinical trials of induction chemotherapy and later incorporated into CRT regimens. This traditional cyclical approach to delivery of concurrent CDDP has not been compared directly with schedules that use smaller, more frequent doses. In fact, randomized clinical trials comparing so-called nonstandard schedules of platinum-based CRT against RT alone[43–45,59,60] have treated large numbers of patients with efficacy that compares favorably with bolus CDDP CRT regimens.[14,44,61] A retrospective single-institution review of 104 patients treated in the adjuvant setting with either bolus CDDP or weekly CDDP concurrently with RT revealed no significant difference in survival outcomes by chemotherapy dosing schedule.[62]

Schedules that deliver smaller and more frequent doses of chemotherapy are also quite effective in improving outcome.[63] Given the efficacy of these nonstandard platinum schedules, they may be preferable to cyclical bolus administration on two counts. More frequent administration could provide radiosensitizing chemotherapy during a larger proportion of the course of RT. Smaller individual doses of drug may lead to less chemotherapy-induced morbidity without compromise of efficacy.[64,65] Concurrent CRT using such schedules has proven very effective and become the standard of care in squamous carcinoma of the uterine cervix.[17,66–68]

Compliance is a significant problem with the standard three-cycle concurrent CDDP paradigm. Nearly one-third of patients do not receive all cycles, and subset analyses suggest that two cycles are as effective as three.[14,47,51,52] RTOG 0129 and other studies have suggested that there may be a minimum cumulative threshold dose of approximately 200 mg/m^2 of cisplatin that is required to achieve maximal benefit when used concomitantly with radiation.[69–71] Schedules that administer chemotherapy more frequently throughout the course of RT deliver approximately the same cumulative dose as would result from two cycles of bolus CDDP, with treatment-related morbidity being the outcome that is most affected by drug administration schedule and cumulative dose >200 mg/m^2.[71]

Weekly cisplatin regimens have been increasingly used, in large part because of their relative ease of administration and the clinical impression of reduced toxicity. It is important to stress the limitations of this experience. No direct prospective comparison has been made between the weekly and the every-3-

week regimens. The randomized data justifying weekly drug administration are equivocal. The North American Head and Neck Intergroup, in an older trial, compared radiation alone with radiation and weekly cisplatin (20 mg/m^2/wk) in patients with unresectable disease. No survival difference was observed between the two treatment arms, but it is very important to recognize that the total cisplatin dose was only 140 mg/m^2.[72]

In nasopharyngeal cancer, Chan et al.[73] reported a comparison of radiation with radiation and concurrent cisplatin (40 mg/m^2/wk). Progression-free survival was not different between the two treatment arms, and a marginal overall survival difference was only appreciated after adjustment for stage and age. This survival difference was restricted to those patients with T3 or T4 tumors, and no difference was observed in the likelihood of distant metastatic disease. Thus, despite the enthusiasm for weekly cisplatin dosing regimens, there is little objective evidence supporting their use, and the every-3-week regimen must still be considered standard.

Recently, a Chinese trial compared 70 Gy of conventionally fractionated irradiation against the same regimen given with weekly concurrent cisplatin (30 mg/m^2) in 230 patients with WHO stage II nasopharynx cancer.[74] No adjuvant chemotherapy was given. Five-year overall survival was significantly better in the combined-modality arm (95% vs. 86%; P = .007). The benefit was due to an improvement in distant metastases–free survival (95% vs. 84%; P = .007). Interestingly, concurrent chemotherapy did not improve locoregional control most likely because of the excellent results in the control arm (93% vs. 91%).

Phase III comparisons of platin- and non–platin-based concurrent treatment regimens are almost nonexistent, and the relative benefit of concurrent platin versus fluorouracil or taxane therapy is unknown. Meta-analysis data have suggested that fluorouracil or cisplatin regimens are more successful than carboplatin- or mitomycin-based treatments[75] and that concurrent platin monotherapy is better than non-platin monotherapy.[10] In a single small phase III trial, a weekly paclitaxel concurrent regimen appeared equivalent to a weekly cisplatin concurrent schedule.[76] Overall, however, the data must be considered limited and not definitive.

Most concurrent chemotherapy regimens use a single agent, an approach that, in general, suboptimally exploits the potential systemic adjuvant benefits of this modality. In most other diseases, multiagent chemotherapy has been considered a better approach in controlling distant disease. In HNC, multiagent induction chemotherapy regimens have clearly demonstrated an impact on distant

metastases, a benefit observed both from single trials and in a large meta-analysis.[10] This same meta-analysis demonstrated a significant but less pronounced impact on distant metastases from concurrent treatment schedules. No clear survival difference has been identified when comparing concurrent single-agent platin regimens and concurrent multiagent schedules.

Radiation has also been administered in conjunction with concurrent high-dose intra-arterial cisplatin. This approach has the hypothetical advantage of allowing selective delivery of chemotherapy to the tumor while sparing uninvolved organs and allowing for the administration of intravenous sodium thiosulfate, a systemic cisplatin neutralizing agent designed to protect the kidneys. Although the procedure proved technically challenging, a phase II multi-institutional trial proved feasible.[77] However, a phase III trial comparing concurrent radiation and intra-arterial versus intravenous cisplatin revealed no benefit,[78] and this mode of administration is not recommended.

The most frequently utilized regimen for concurrent chemoradiotherapy remains single-agent high-dose cisplatin given every 3 weeks, despite strong feelings and considerable rhetoric. Limited evidence suggests that cisplatin may be more effective than carboplatin.[79] Taxanes are also active agents against squamous HNC but have not been studied extensively as components of CRT regimens. The ongoing trial RTOG 1216 is a three-arm study comparing standard postoperative cisplatin–RT with single-agent docetaxel and RT as well as the combination of RT with docetaxel and cetuximab, a monoclonal antibody targeting the epidermal growth factor receptor (EGFR).

Radiotherapy and Molecularly Targeted Agents

Recent efforts to integrate radiation and systemic therapy have focused on molecularly targeted agents. The EGFR is the target most often addressed and best studied in HNC. The EGFR is up-regulated in approximately 90% of patients with squamous cell HNC and has been associated with a poor prognosis.[80–82] In patients with recurrent or metastatic disease, a modest response rate has been observed with the anti-EGFR monoclonal antibody cetuximab, both with and without cytotoxic chemotherapy, as well as with the oral tyrosine kinase inhibitors gefitinib and erlotinib.[83–87] Even more impressive is the disease stability that has been identified after treatment with these agents. This experience has prompted further exploration of these agents in definitive management.

Bonner et al. reported the results of the first phase III randomized trial

exploring the role anti-EGFR therapy in the definitive management of a solid tumor.[88] This trial compared the use of RT alone with radiation and concurrent cetuximab in the treatment of patients with stage III or IV nonmetastatic squamous cell carcinoma of the oropharynx, hypopharynx, or larynx. Cetuximab therapy consisted of a loading dose of 400 mg/m^2 followed by a weekly dose of 250 mg/m^2 for the duration of the RT. An updated analysis reported in 2010 confirmed the initial results.[89] The addition of cetuximab to RT improved the median overall survival from 29 to 49 months (P = .018) and the 5-year overall survival from 36% to 46%. The incidence of grade 3 or greater toxicity including mucositis did not differ between the two groups, except for a greater incidence of acneiform rash and infusion reactions in those patients treated with cetuximab. An interesting but unplanned subgroup analysis suggested that the benefit was greater in the cetuximab-treated patients with oropharynx cancers, smaller primary tumors, and more advanced nodal involvement. Males, patients with a better performance status, and patients who were younger also seemed to do better. This demographic distribution suggested the possibility that the drug was more effective in those patients with human papillomavirus (HPV)-associated disease, although HPV testing of the tumor specimens was not performed. It was also notable that survival was better in the cetuximab-treated patients who developed a cetuximab-induced rash.

It is important to recognize that the control arm of this trial, RT alone, is no longer considered a treatment standard for most patients with stage III and IV locoregionally advanced squamous cell HNC. Consequently, the relative benefit of cetuximab and radiation compared to a more standard radiation and concurrent chemotherapy combination is unknown. RTOG attempted to define this better in its 0522 trial comparing concurrent radiation, cetuximab, and cisplatin with radiation and cisplatin alone.[90] As expected, the skin reactions were worse in those patients given cetuximab, but late toxicities were not different. No differences were observed in any survival outcome including progression-free survival, overall survival, or patterns of disease failure. Given the results of this study, there is currently no justification for adding cetuximab to the standard radiation and cisplatin regimens used in definitive management outside of a clinical trial.

The findings in RTOG 0522 conflict with the observation made in the metastatic disease setting. There, a phase III randomized trial compared cisplatin and fluorouracil with cisplatin, fluorouracil, and cetuximab.[86] This study demonstrated an improvement in survival from the addition of cetuximab to

standard chemotherapy, and it remains unclear why the RTOG 0522 trial did not demonstrate a similar outcome improvement. RTOG 0920 is evaluating adjuvant RT plus cetuximab with adjuvant RT alone in an intermediate-risk defined patient population without positive surgical margins or ECE. This phase III study remains ongoing.

The question also remains unanswered as to whether concurrent radiation and cetuximab is equivalent or even superior to radiation and cisplatin. This issue is currently being addressed by the RTOG 1016 study, which compares these two regimens in a more selected patient population with HPV-positive oropharynx cancer. It is anticipated that the survival outcomes on the two treatment arms will be equivalent but that a difference may emerge in terms of late toxicity, function, or quality of life. It is of note that a retrospective study reported from Memorial Sloan Kettering Cancer Center suggested the possibility that locoregional control and survival were better in patients treated with radiation and cisplatin when compared to patients given radiation and cetuximab.[91] Although these results were upheld on multivariate analysis, prospective validation is required given the very significant differences in patients selected for these treatments. The randomized phase II TREMPLIN study prospectively compared the two regimens administered after three-drug induction chemotherapy. Given the nature and size of this trial, however, it is difficult to interpret any outcome comparisons.[92] In a phase III Canadian study, locally advanced HNSCC patients were randomized to standard fractionation RT plus high-dose cisplatin versus accelerated fractionation RT plus the anti-EGFR antibody panitumumab.[93] No survival differences between the two groups were demonstrated, though intrinsic study design was flawed, including no distinction of HPV-related oropharynx tumors and low event rate. Furthermore, unlike cetuximab, panitumumab added to cytotoxic chemotherapy in the metastatic setting did not show a survival benefit compared with chemotherapy alone.[94]

DEVELOPMENTAL ASPECTS OF COMBINED-MODALITY THERAPY

Induction Chemotherapy and Sequential Chemoradiation

The use of induction chemotherapy for locoregionally advanced squamous cell HNC continues to be an attractive treatment option. The dramatic tumor shrinkage seen in previously untreated patients after cisplatin-based chemotherapy regimens would intuitively suggest that an improvement in

locoregional control and even survival should also result. Multiple phase III clinical trials, however, have failed to demonstrate any reproducible impact from induction treatment schedules on overall outcome.[95,96] A marginal survival benefit was identified by the large Meta-Analysis of Chemotherapy in Head and Neck Cancer (MACH-NC) using fluorouracil and platin induction chemotherapy, but this survival improvement was dwarfed by that obtained with the use of concurrent treatment regimens (Fig. 43.2).[10]

A frequent observation from these induction trials, however, has been a reduction in distant metastases.[9,97,98] The fact that this did not impact on overall survival likely reflects the historically limited importance of distant metastases in the natural history of this disease. Recently, however, with the increasing locoregional control achieved by concurrent treatment regimens, distant metastases have emerged as a more frequent cause of treatment failure[99,100] This observation has led to the suggestion that there may be a role for the reintroduction of chemotherapy into current multimodality treatment schedules.[101]

Coincident with this resurgent interest in induction schedules has been the recognition that the widely used and very successful cisplatin and fluorouracil combination may not be the optimal induction regimen. Considerable phase III experience now exists demonstrating the superiority of three-drug–containing regimens (fluorouracil, cisplatin, and taxane) when compared to fluorouracil and cisplatin alone[102–105] (Table 43.3). In these studies, successful induction was followed by definitive RT with or without concurrent chemotherapy.

It is important to note that three of these studies demonstrated a survival benefit favoring the three-drug induction regimen. Long-term follow-up of TAX 324 confirmed this survival benefit of adding docetaxel to cisplatin and fluorouracil with no difference in late toxicities.[106] A meta-analysis of these studies also found the taxane-containing induction regimens to be superior to platinum-fluorouracil alone.[107] This should not be interpreted as evidence that three-drug induction chemotherapy is a new standard of care. Induction chemotherapy followed by definitive radiation or chemoradiation is not a generally established sequence of treatment modalities, and the superiority of one induction regimen over another does not define induction chemotherapy as a standard of care.

Nonetheless, there are several situations where induction chemotherapy may have a role. In the larynx preservation setting, induction fluorouracil and cisplatin followed by definitive radiation in responders has been compared

directly with concurrent chemoradiation with single-agent cisplatin and with RT alone.[15] Although the laryngeal preservation and locoregional control were superior in the concurrent chemoradiotherapy arm, laryngectomy-free survival and distant metastatic control were equivalent between the two chemotherapy regimens.[15] It is of note that overall survival was unchanged by the addition of chemotherapy. Thus, induction chemotherapy can be considered an acceptable larynx preservation strategy. The superiority of the three-drug docetaxel, cisplatin, and fluorouracil regimen when compared to fluorouracil and cisplatin in the larynx preservation setting has been established,[105] although the subsequent use of concurrent treatment regimens after three-drug induction has proven difficult.[92]

TABLE 43.3 TAXANE, CISPLATIN, AND FLUOROURACIL (TPF) VERSUS CISPLATIN AND FLUOROURACIL (PF) INDUCTION CHEMOTHERAPY: RANDOMIZED TRIALS

	Hitt 2005[94]	Vermorken 2007[95]	Posner 2007[96]	Pointreau 2009[97]
Taxane	Paclitaxel	Docetaxel	Docetaxel	Docetaxel
Definitive treatment	Variable	Radiation	Radiation/weekly carboplatin	Variable
Response rate				
PF	68%	54%	64%	59%
TPF	80%	68%	72%	80%
***P* Value**	<.001	.006	.07	.002
Survival	2 y	3 y	3 y	3 y
PF	54%	26%	48%	60%
TPF	67%	37%	62%	60%
***P* Value**	.06	.02	.002	.57

Of greater interest has been the use of induction chemotherapy in what has been termed *sequential treatment* regimens, that is, induction chemotherapy followed by concurrent chemoradiotherapy.[108] The rationale for this approach is that the addition of induction chemotherapy can, by improving the distant metastatic control, improve upon the overall survival achieved after concurrent chemoradiotherapy alone. These treatment schedules are intensive and require considerable commitment from both patient and physician. Toxicity, when compared to concurrent chemoradiotherapy alone, will be increased, and the administration of multiple doses of both induction and concurrent cisplatin is

challenging.[92]

A preliminary report by Hitt and Lopez-Pousa from their study of three-drug induction chemotherapy followed by chemoradiotherapy compared with chemoradiotherapy alone suggested a benefit for the induction arm, though the final analysis revealed no difference in survival between the treatment groups[107,109]. A successful phase II randomized experience has been reported by Paccagnella et al.[110] comparing induction docetaxel, cisplatin, and fluorouracil before chemoradiotherapy with chemoradiotherapy alone. Another phase II study of induction chemotherapy followed by concurrent chemoradiation incorporated cetuximab in both the induction regimen and concurrent therapy.[111] The induction chemotherapy in both arms consisted of cetuximab, paclitaxel, and carboplatin, and the concurrent chemotherapy was either cetuximab, fluorouracil, and hydroxyurea or cetuximab and cisplatin. Both arms were considered successful with 2-year PFS of both arms higher than historical controls.

Two phase III studies, DeCIDE[112] and PARADIGM,[113] which compared induction chemotherapy followed by concurrent chemoradiotherapy to concurrent CRT alone failed to show a survival advantage with the sequential treatment strategy. The DeCIDE trial had a 5% incidence of treatment-induced mortality in the sequential arm compared to 0% in the CRT arm. This difference may have offset any survival benefit attributable to the lower incidence of distant metastases in the sequential arm. A meta-analysis of induction chemotherapy followed by concurrent CRT with CRT alone revealed decreased distant metastasis rate with induction chemotherapy; however, no statistically significant differences in OS, PFS, overall response rate (ORR), or locoregional recurrence rate were demonstrated.[114]

A third rationale for induction chemotherapy has been explored by the University of Michigan investigators. Their premise is that induction chemotherapy can serve as a predictive tool and allow for the appropriate selection of the subsequent definitive HNC management strategy. Patients responding to induction chemotherapy can be approached nonoperatively, whereas those in whom induction is unsuccessful should proceed to surgical resection. This strategy is based on the long-standing recognition that patients responding to induction chemotherapy are also those who respond best to RT.[115]

This approach has been used successfully in patients with advanced larynx cancer.[116,117] The treatment schedule began with a single cycle of induction cisplatin and fluorouracil, followed by concurrent chemoradiotherapy with high-

dose single-agent cisplatin in responders. At least a partial response to single-cycle induction was achieved in 75% of patients, and larynx preservation ultimately proved possible in 70% of the entire patient cohort. It was of particular import that those patients requiring laryngectomy because of a failure to respond to induction chemotherapy achieved an overall survival equivalent to the chemotherapy responders.

This experience proved less successful in their patients with oropharynx and oral cavity cancer, however.[118] Furthermore, the relegation of induction chemotherapy to a purely predictive tool is disquieting to both medical and radiation oncologists. Induction adds significant cost and toxicity, and one would hope that it might provide an additional survival benefit or an improvement in distant metastatic disease control. Perhaps, other less toxic predictive "biomarkers" than responsiveness to induction chemotherapy might emerge in the future.

Thus, induction chemotherapy, particularly using the three-drug cisplatin, fluorouracil, and taxane combination, remains a very active but incompletely developed tool. Its ultimate impact on survival, distant metastases, and our treatment paradigms remains to be seen. Toxicity considerations will play an important role in the choice of therapeutic strategies. Overall, more treatment means more toxicity as treatment is escalated along the continuum from conventional once-daily RT only to the most intensive combined-modality regimens. The total toxicity burden imposed upon a patient may increase as much as fivefold.[119] These considerations are particularly relevant to sequential therapy programs. Compliance rates for an entire course of treatment with these regimens are only 65% to 70% in the most experienced hands.[102,120]

Other Targeted Agents

Other EGFR monoclonal antibodies are also being explored in the HNC patient population, both in the metastatic setting and in conjunction with radiation, including panitumumab and zalutumumab.[121,122] The oral tyrosine kinase inhibitors including gefitinib, erlotinib, and others have undergone limited phase II testing as part of definitive treatment schedules. Results from these studies have been mixed and enthusiasm is restrained.[123–126]

Treatments directed against other molecular targets, most notably the vascular endothelial growth factor receptor (VEGFR), are also now being integrated with definitive RT schedules.[127,128] Overexpression of VEGF in HNC is associated with a twofold increase in the risk of death from disease.[129] Yoo et al. performed

a pilot study in 29 patients that integrated dual targeting of EGFR with erlotinib and VEGFR with the antibody bevacizumab into a regimen of platinum-based chemoradiation for newly diagnosed, locally advanced, nonmetastatic disease.[130] Three-year progression-free survival was 82%. One of the most important facets of this trial was that it utilized functional metabolic imaging with the performance of serial dynamic contrast-enhanced magnetic resonance imaging (DCE-MRI) scans to assess response to treatment. DCE-MRI quantitatively measures tumor perfusion and vascular permeability, which is expressed by the parameter K^{trans}. Patients whose disease recurred after treatment had lower baseline pretreatment median K^{trans} values, which rose during the earliest phases of therapy. Patients who did not fail, however, had higher baseline median K^{trans} values that decreased during therapy. These data suggest that K^{trans} could potentially serve as an imaging biomarker to guide initial treatment selection based on pretreatment prognosis or to guide treatment modification based on a favorable or unfavorable response to the early phases of treatment.[131]

Hypoxia is one of the most important characteristics of the aggressive malignant phenotype.[132–135] Poorly oxygenated tumors are less likely to respond to surgery,[136] radiotherapy,[31,137,138] and chemotherapy. Hypoxic primary tumors are more likely to develop distant metastases after treatment.[139] A review of 397 HNC patients who underwent tumor oxygenation measurement demonstrated that hypoxia was strongly associated with treatment failure independently of stage and therapeutic modality.[32]

Tirapazamine, a bioreductively activated compound, is one to two orders of magnitude more cytotoxic to hypoxic cells than well-oxygenated cells and also potentiates the activity of cisplatin.[140,141] Phase I/II studies in advanced squamous HNC demonstrated efficacy with acceptable toxicity when this drug was incorporated into cisplatin-containing CRT regimens and suggested that the benefit of the drug was restricted to those patients who had hypoxic tumors as assessed by ^{18}F-misonidazole positron emission tomography (PET) scanning.[142,143]

Two phase III trials were conducted to determine whether targeting of hypoxic cells with tirapazamine/cisplatin CRT was superior to cisplatin CRT. The first trial (HeadSTART) enrolled 880 patients. No benefit was observed from the addition of tirapazamine.[144] A large number of patients had significant protocol deviations with respect to the delivery of radiotherapy, however. A subset analysis of patients who correctly received all of their treatment according to the protocol guidelines did demonstrate an advantage in patients who received

tirapazamine.[145] Another important consideration is that patients enrolled into this trial were not selected according to whether or not they had hypoxic tumors, which would have increased the power to detect a benefit from the drug if in fact one existed. A second trial with the same treatment schema was launched with a planned enrollment of 550 patients but was prematurely closed because of an unexplainable excess of deaths during treatment in the tirapazamine arm.

Immunotherapy

As HNC is seen as an immunosuppressive disease, immunotherapy represents an additional modality of treatment. The KEYNOTE and CHECKMATE trials were completed in patients with recurrent/metastatic disease not amenable to local therapies and refractory to platinum-based chemotherapy and studied the programmed cell death 1 (PD-1) inhibitors pembrolizumab and nivolumab, respectively. In a phase Ib expansion cohort study in patients with R/M HNSCC, half of patients demonstrated a decrease in tumor burden.[146] Nivolumab improved overall survival in a phase III randomized clinical trial enrolling patients with platinum-refractory R/M HNSCC.[147] Both therapies were granted FDA approval in 2016 for patients with R/M HNSCC with platinum-refractory disease.

There is current interest in utilizing immunotherapies in the locally advanced HNSCC setting in conjunction with radiotherapy. NRG HN003 is studying the addition of pembrolizumab to the backbone of postoperative cisplatin chemoradiotherapy in high-risk patients, in attempt to intensify therapy and improve outcomes. Using immunotherapy in place of cytotoxic chemotherapy is an attractive option for evaluation in deintensification studies for improved toxicity profiles while maintaining high cure rates in good prognosis, HPV-related oropharynx patients.

Summary

The use of modified daily fractionation as opposed to conventional once-daily fractionation improves the prognosis of patients who receive curative intent RT for advanced HNC. Radiation therapy and concurrent chemotherapy in turn are superior to both single-modality conventional and modified fractionation radiation therapies in the nonsurgical management of advanced HNC. Anti–EGFR-targeted therapy also enhances the effectiveness of RT. The role of EGFR inhibition in a chemoradiation setting is under investigation. Likewise, the benefit of adding induction chemotherapy to a platform of chemoradiation is

being tested. Hypoxia-targeted therapy remains investigational.

The increased acute and late toxicity that results from combining these multiple modalities poses immediate challenges. These include the need to develop criteria for a priori selection of those patients with advanced-stage disease who can still be adequately treated with radiotherapy alone and the need to create effective strategies for toxicity prophylaxis and management. These efforts will allow for the optimal integration of radiotherapy, chemotherapy, biologically targeted therapy, and immunotherapy for those patients requiring combined modality therapy.

CHAPTER 44

Nasopharynx

Benjamin H. Lok, Jonathan E. Leeman, and Nancy Y. Lee

ANATOMY

The nasopharynx is a cuboidal chamber, slightly broader in the transverse dimension than the anterior–posterior dimension (Fig. 44.1). Anteriorly, it is continuous with the nasal cavity via the posterior choanae, whereas inferiorly, it communicates with the oropharynx. The roof of the nasopharynx is formed by the basilar portion of the sphenoid and occipital bones and the floor by the superior surface of the soft palate and nasopharyngeal isthmus. The lateral walls of the nasopharynx contain the pharyngotympanic tube (*Eustachian tube*) openings, which are bounded by a prominence known as the *torus tubarius*. The *torus* is formed by the cartilage of the pharyngotympanic tube elevating the mucous membrane of the lateral nasopharynx. Posterior to the *torus* is the pharyngeal recess otherwise known as the *fossa of Rosenmüller*. The lateral walls, including the pharyngeal recess (*fossa of Rosenmüller*), are the most common origin of nasopharyngeal malignancies. The posterior wall of the nasopharynx contains the superior pharyngeal constrictor muscle, pharyngobasilar fascia, and buccopharyngeal fascia.

The superior pharyngeal constrictor only extends superiorly to the skull base in the midline, and laterally the pharyngobasilar fascia serves to attach the constrictor muscle to the base of the skull at the basiocciput and petrous portion of the temporal bone. This lateral area of muscular deficiency is otherwise known as the *sinus of Morgagni*, through which the pharyngotympanic tube and levator veli palatini pass. The pharyngobasilar fascia is continuous with the foramen lacerum and is in close proximity to the foramen ovale, foramen spinosum, jugular foramen, hypoglossal canal, and carotid space. The proximity of these foramina to the *sinus of Morgagni* assumes importance in the consideration of intracranial extension (Fig. 44.2). A summary of the various foramina located in the base of skull is presented in Table 44.1.

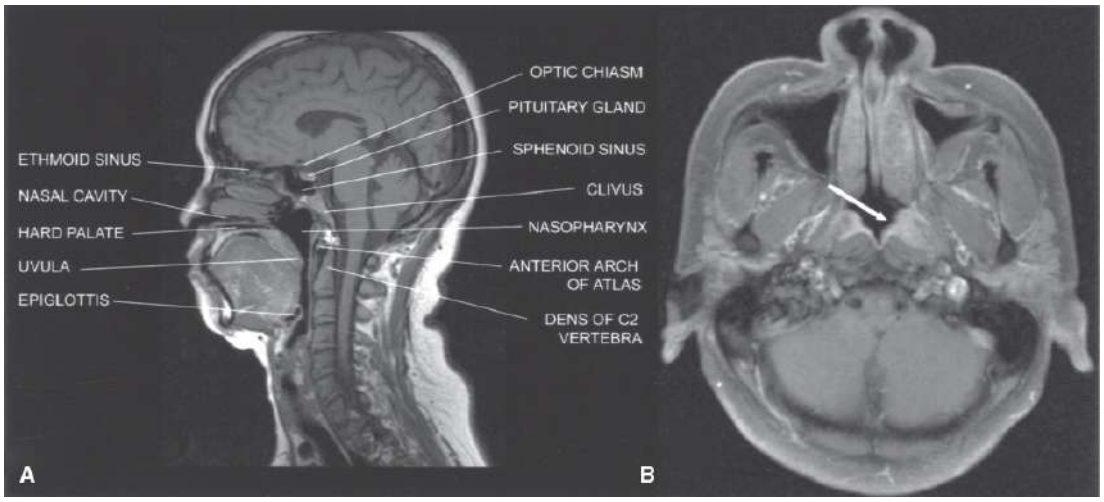

FIGURE 44.1. A: Midsagittal magnetic resonance image (MRI) of the head, showing the nasopharynx and related structures. **B:** Axial contrast-enhanced MRI showing a small tumor in the left fossa of Rosenmüller (*arrow*) and normal structures in the rest of the nasopharynx.

The afferent innervation of the nasopharynx anterior to the pharyngotympanic tube orifice is provided by the maxillary division of the trigeminal nerve (V_2) and, posterior to the tubal orifice, the glossopharyngeal nerve. Motor supply is via the pharyngeal branches of the glossopharyngeal nerve, vagus nerve, and sympathetic fibers from the superior cervical ganglion. The arterial supply of the nasopharynx is provided by the ascending pharyngeal artery, sphenopalatine artery, and the artery of the pterygoid canal. Venous drainage is provided by the pharyngeal plexus that drains into the internal jugular veins directly or via communication with the pterygoid plexus.

EPIDEMIOLOGY AND ETIOLOGY

Nasopharyngeal carcinoma is an uncommon cancer in most parts of the world. The age-adjusted incidence rate (per 100,000 people per year) among men ranges from 0.6 in the United States and Japan to 5.4 in Algeria; 5.8 in the Philippines; 11.0 in Singapore; 17.2 among Eskimos, Indians, and Aleuts in Alaska to 17.8 and 26.9 in Hong Kong and Guangdong province in Southern China, respectively.[1–3]

A bimodal age distribution is observed in low-risk populations. The first peak incidence arises between 15 and 25 years of age, with the second peak at 50 and 59 years of age.[4–6] In high-risk populations, the peak incidence occurs in the fourth and fifth decade of life.[4] Both genders have a similar age distribution;

however, the male to female incidence ratio is 2:1 to 3:1.[7]

This distinct racial and geographical distribution of nasopharyngeal carcinoma suggests a multifactorial cause. Current epidemiologic and experimental data identify at least three important etiologic factors: (1) genetic, (2) environmental, and (3) viral.

The high incidence of nasopharyngeal carcinoma among Southern Chinese and populations of Southern Chinese descent suggests a component of genetic susceptibility. A genome-wide association study of nasopharyngeal cancer found three susceptibility loci[8] and confirmed a linkage study that found a gene closely linked to the HLA locus conferred a greatly increased risk of this disease.[9] In addition, several HLA haplotypes, including A2, B46, and B17, are associated with an increased risk of developing nasopharyngeal carcinoma.[10,11]

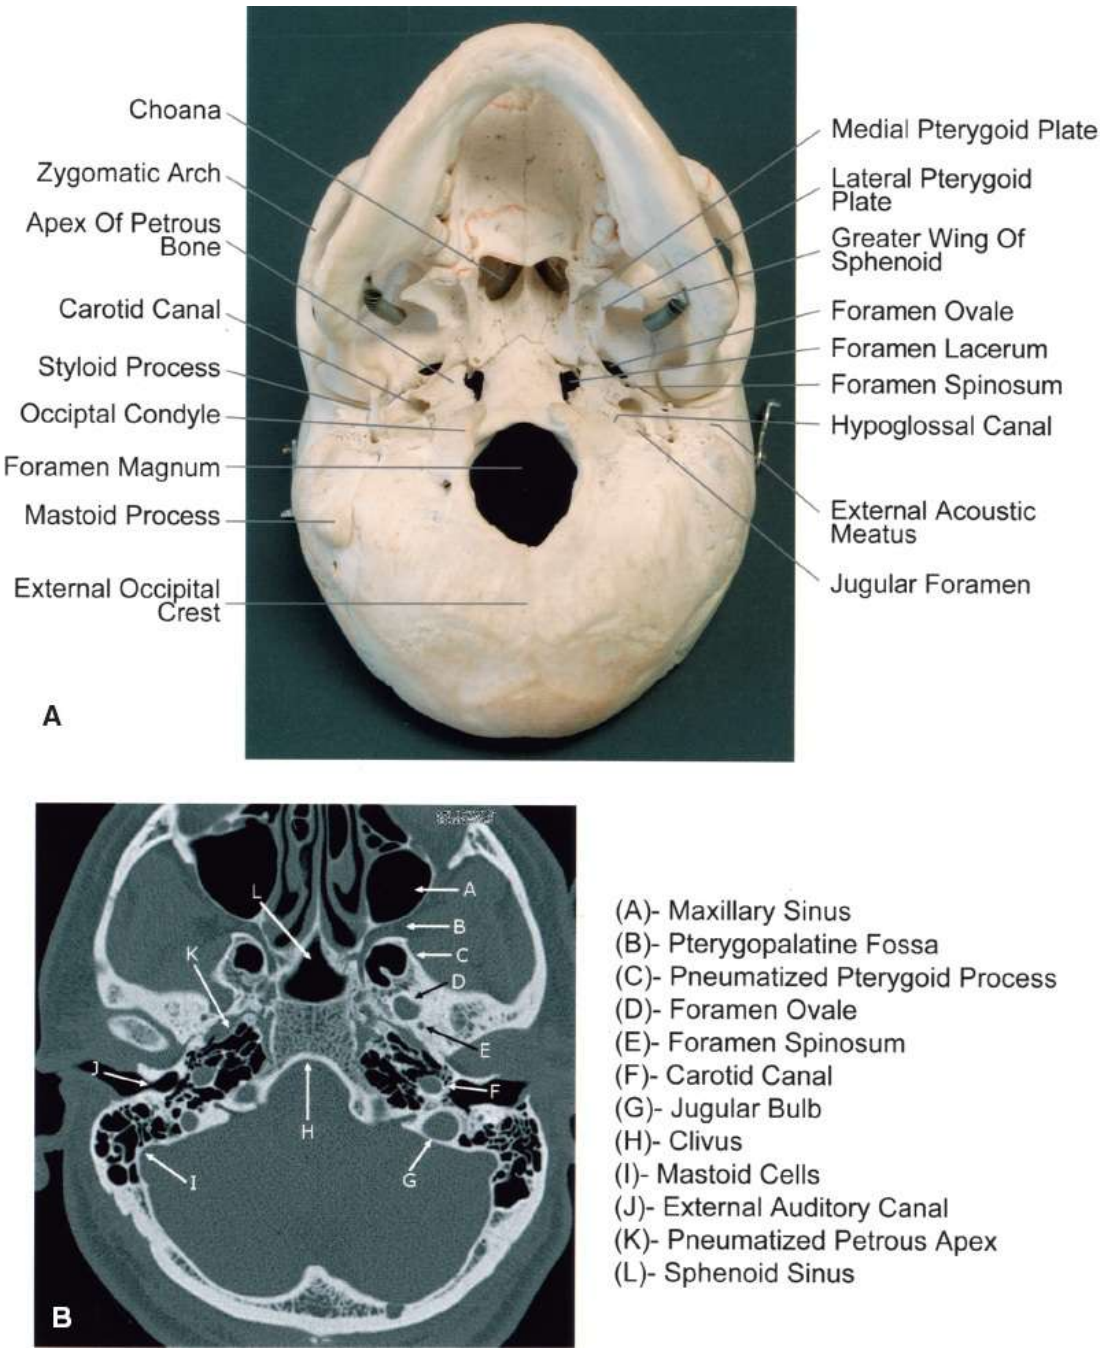

FIGURE 44.2. **A:** Basal view of skull illustrating the foramina of the base of the skull and the occupying structures. **B:** Axial computed tomography scan illustrating the bony anatomy.

TABLE 44.1 FORAMINA OF THE BASE OF THE SKULL AND ASSOCIATED ANATOMIC STRUCTURES

Foramen/Fissure	Cranial Nerve	Other Structures
Cribriform plate	Olfactory nerve (I)	Anterior ethmoidal nerve

Optic foramen	Optic nerve (II)	Ophthalmic artery
Superior orbital fissure	Oculomotor (III), trochlear (IV), ophthalmic division of trigeminal (V_1) nerve, abducent (VI) nerves	Ophthalmic vein, orbital branch of middle meningeal and recurrent branch of lacrimal arteries, sympathetic plexus, filaments from carotid plexus
Foramen rotundum	Maxillary division of trigeminal (V_2) nerve	
Foramen ovale	Mandibular division of trigeminal (V_3) nerve	Accessory meningeal artery, lesser superficial petrosal nerve
Foramen lacerum		Internal carotid, sympathetic carotid plexus, vidian nerve, meningeal branch of ascending pharyngeal artery, emissary vein
Foramen spinosum	Recurrent branch of V_3 nerve	Middle meningeal artery and vein
Stylomastoid foramen	Facial (VII) nerve	
Internal acoustic meatus	Auditory (VIII) nerve	Internal auditory artery
Jugular foramen	Glossopharyngeal (IX), vagus (X), spinal accessory (XI) nerves	Inferior petrosal sinus, transverse sinus, meningeal branches from occipital and ascending pharyngeal arteries
Hypoglossal canal	Hypoglossal (XII) nerve	Meningeal branch of ascending pharyngeal artery
Foramen magnum		Spinal cord, spinal accessory nerve, vertebral vessels, anterior and posterior spinal vessels

The high consumption of salted fish in Southern China has been implicated as an important environmental factor.[12–15] Dimethylnitrosamine, a carcinogen found in salted fish, has been shown to induce carcinoma in the upper respiratory tract in rats.[13] Other potential environmental etiologic factors that have been associated with nasopharyngeal carcinoma include alcohol consumption and exposure to dust, fumes, formaldehyde, and cigarette smoke,[16,17] although definitive conclusion has been elusive. Descendents from Chinese who have migrated from endemic areas to Western countries show progressively lower risk, but their incidence remains higher than the indigenous populations.[18–20] Buell[18] observed that American-born second-generation Chinese had a lower risk than the Asian-born first generation, whereas whites born in Southeast Asia had an increased risk compared to American-born whites. Dickson and Flores[20] reported that the incidence rate in Chinese who were natively born in China was 20.5, compared with 1.3 for Chinese and 0.2 for whites born in Canada. Taken together, environmental factors appear to play a role in the etiology of

nasopharyngeal cancer.

Epstein-Barr virus (EBV) has been associated with nasopharyngeal carcinoma, especially the nonkeratinizing type, irrespective of ethnic or geographic origin.[21] Premalignant lesions of nasopharyngeal epithelium show increased levels of EBV, suggesting that EBV infection may influence the early stages of tumorigenesis in NPC.[22] Detection of a single form of EBV DNA in tumors suggests that clonal expansion from an initial EBV-infected and, ultimately, EBV-transformed cell is likely. EBV's tumorigenic potential is due to a set of latent genes, latent membrane proteins (LMP1, LMP2A, and LMP2B) and EBV-determined nuclear antigens (EBNA1 and EBNA2), which are the proteins predominantly expressed in NPC.[23] LMP1 is the principal oncogene with evidence that the C-terminal activating regions of the protein activate a variety of signaling pathways including mitogen-activated protein (MAP) kinases, phosphoinositol-3-kinase (PI3K), nuclear factor κ-B (NF-κB), and epidermal growth factor receptor (EGFR).[24,25] LMP1 is also required for cell immortalization and is present in 80% to 90% of NPC tumors.[26] This mounting evidence highlights the likely etiologic role for EBV in NPC.

NATURAL HISTORY

Local Extension

A summary of structures locally infiltrated by nasopharyngeal carcinoma at diagnosis is provided in Table 44.2.

Anterior

Anteriorly, it is common for the extension and infiltration of tumor into the nasal fossa. Invasion of the lateral wall of the nasal fossa can lead to involvement and destruction of the pterygoid plates. Beyond these structures, though less common, is invasion of the posterior ethmoid and maxillary sinuses. In advanced disease, infiltration of the orbital apex (typically through the inferior orbital fissure) can occur.

Superior and Posterior

Superiorly, tumors can directly invade the base of skull, the sphenoid sinus, and the clivus. The foramen lacerum, positioned directly above the pharyngeal recess (*Rosenmv··ller fossa*), is a vulnerable spot through which the tumor may enter the cavernous sinus and the middle cranial fossa to invade cranial nerves II to VI

(Fig. 44.3). Figure 44.4 demonstrates involvement of the trigeminal cave (*Meckel cave*) and the maxillary branch of the trigeminal nerve (V_2). The foramen ovale also allows access for tumor to invade the middle cranial fossa, in addition to the petrous portion of the temporal bone, and the cavernous sinus. Posteriorly, invasion of the prevertebral (longus capitis) muscles is commonly seen.

TABLE 44.2 Structures Locally Infiltrated by Nasopharyngeal Carcinoma at Diagnosis[a]

Structures Involved	Frequency (%)
Adjacent soft tissue	
Nasal cavity	87
Parapharyngeal space, carotid space	68
Pterygoid muscle (medial, lateral)	48
Oropharyngeal wall, soft palate	21
Prevertebral muscle	19
Bony erosion/paranasal sinus	
Clivus	41
Sphenoid bone, foramina lacerum, ovale, rotundum	38
Pterygoid plate(s), pterygomaxillary fissure, pterygopalatine fossa	27
Petrous bone, petro-occipital fissure	19
Ethmoid sinus	6
Maxillary antrum	4
Jugular foramen, hypoglossal canal	4
Pituitary fossa/gland	3
Extensive/intracranial extension	
Cavernous sinus	16
Infratemporal fossa	9
Orbit, orbital fissure(s)	4
Cerebrum, meninges, cisterns	4
Hypopharynx	2

[a]Based on magnetic resonance imaging of 308 patients from Pamela Youde Nethersole Eastern Hospital, Hong Kong.

Inferior

Extension inferiorly to the oropharynx is not unlikely, with potential involvement of the tonsillar pillars, the tonsillar fossa, and the lateral and

posterior oropharyngeal walls. In advanced disease, invasion of the C1 vertebra posteriorly and inferiorly can occur. Direct invasion of the soft palate is uncommon.

Lateral

Lateral extension occurs early with involvement of the lateral parapharyngeal space along with invasion of the levator and tensor veli palatini muscles (Fig. 44.5). In advanced disease, invasion of the pterygoid muscles can occur. Direct extension of the tumor or lateral retropharyngeal lymph node metastasis in the parapharyngeal space may lead to invasion or compression of cranial nerves IX to XI as they transpire the jugular foramen, cranial nerve XII as it emerges from the hypoglossal canal, and the cervical sympathetic nerves. Direct invasion or compression of the internal carotid artery can occur in advanced disease (Fig. 44.6). Tumor can directly invade the middle ear through the pharyngotympanic tube (*Eustachian tube*).

Note the resultant serous otitis media (*right arrow*). **B:** Axial contrast-enhanced MRI showing enhanced tumor involving the parapharyngeal space and medial pterygoid muscles (*arrow*).

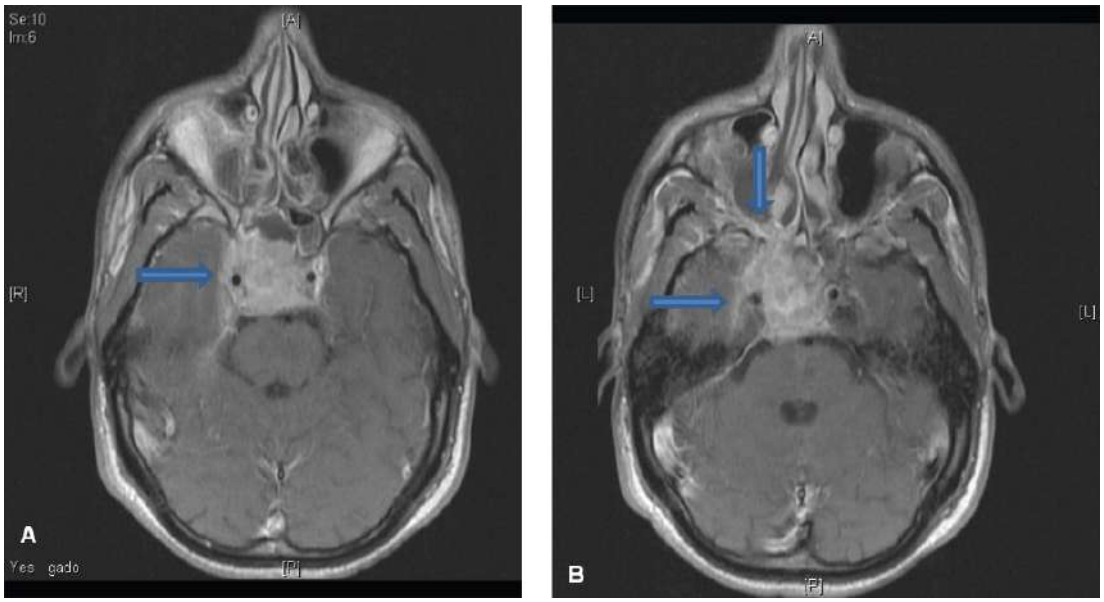

FIGURE 44.6. A: Axial contrast-enhanced magnetic resonance image (MRI) demonstrating involvement of the cavernous sinus by nasopharyngeal carcinoma. **B:** Axial contrast-enhanced MRI showing invasion of the pterygopalatine fossa (*vertical arrow*) with spread to cavernous sinus (*horizontal arrow*).

Lymphatic Spread

The nasopharynx is comprised of a vast of avalvular lymph capillary network that exists in the mucous membrane leading to frequent involvement of regional neck nodes (Fig. 44.7). Up to 85% to 90% of cases present with lymphatic

spread to the ipsilateral nodes.[27–29] Bilateral spread is present in approximately 50% of cases. The distribution of NPC-involved nodes at diagnosis is shown in Figure 44.8. An anatomic and radiographic study that directly examined lymphatic vasculature concluded that there are two major lymph collectors of the nasopharynx (Fig. 44.7B).[30] One lymph collector runs along the lateral side of the pharyngeal wall, whereas the second runs more posteriorly. The lateral lymph collector empties into multiple first tier nodes, which include the lateral pharyngeal node, the jugulodigastric/subdigastric node, and the third, fourth, and fifth nodes of the retropharyngeal group.[30] The posterior lymph collector empties into the first node (*node of Rouviere*) of the retropharyngeal group (Fig. 44.9). This direct study is corroborated clinically by frequent observation of lateral and retropharyngeal lymph node involvement by MRI of CT scans, even though they remain impalpable. Metastasis to the jugulodigastric and superior–posterior cervical nodes is also common. From these first tier nodes, further metastatic spread to the midjugular, lower jugular, and posterior cervical and supraclavicular nodes can develop. Seldom, submental and occipital nodes can be involved secondary to lymphatic obstruction caused by widespread cervical lymphadenopathy. Mediastinal lymph nodes and, occasionally, axillary nodes may be involved with the presence of supraclavicular lymphadenopathy.

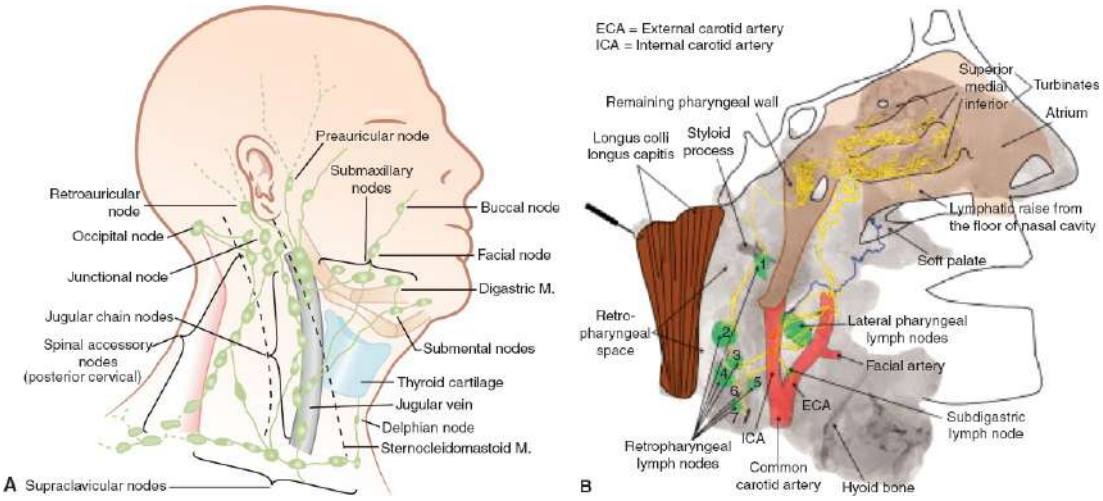

FIGURE 44.7. A: Pathways for lymphatic spread of nasopharyngeal carcinoma. (Redrawn from Rouviere H. *Anatomy of the human lymphatic system.* Ann Arbor, MI: Edward Brothers; 1938:27, with permission.) **B:** Two major lymph collectors of the nasopharynx, (i) lateral lymph collector and (ii) posterior lymph collector. *Yellow,* lymphatic vessels from the nasal cavity. *Blue*, lymphatic vessels from soft palate. *Green*, lymph nodes. Retropharyngeal nodes are numbered. *Red*, carotid artery. *Dark brown*, longus muscles. *Light brown*, remaining pharyngeal and nasal wall. (From Wei-Ren P, Suami H, Corlett RJ, et al. Lymphatic drainage of the nasal fossae and nasopharynx: Preliminary anatomical and radiological study with clinical implications.

Hematogenous Dissemination

Distant metastasis is present in 3% to 6% of the cases at presentation and may occur in 18% to 50% of cases during the disease course.[31–35] The rate of distant metastasis is highest in patients with advanced neck node metastasis,[27,36,37] especially with low-neck involvement.[38,39] The bone is the most common distant

metastatic site followed by the lungs and liver,[40] with lung metastasis being associated with better prognosis than other sites. Brain and skin metastases rarely occur.[41,42]

CLINICAL PRESENTATION

Nasopharyngeal carcinoma presents in patients with symptoms in one or more of the following three categories: (1) neck masses, usually appearing in the upper neck, (2) presence of tumor mass in the nasopharynx (epistaxis, nasal obstruction and discharge), (3) skull base erosion and palsy of cranial nerves V and VI because of tumor extension superiorly (headache, diplopia, facial pain, and numbness).

The frequency of various presenting symptoms and signs is summarized in Table 44.3. A neck mass is the most common presenting symptom, followed by nasal and aural symptoms. The physical signs commonly present at diagnosis are enlarged neck node(s) and, less often, cranial nerve palsy. The cranial nerves V and VI are frequently involved, whereas cranial nerves I, VII, and VIII are rarely involved (Table 44.4).[29,45]

Cervical lymphadenopathy is present in up to 87% of patients.[46] Typically, a mass is observable in the upper posterior neck and palpable beneath the superior portion of the sternocleidomastoid muscle close to the mastoid process. This is caused by metastasis to the parapharyngeal nodes or superior–posterior cervical nodes of the spinal accessory chain.

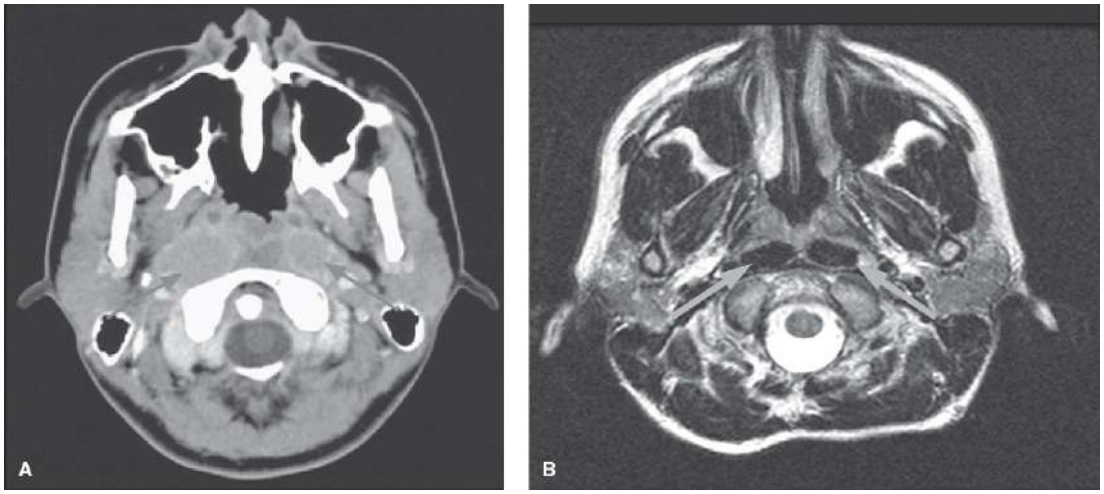

FIGURE 44.9. **A:** Axial contrast-enhanced computed tomography scan showing involvement of bilateral retropharyngeal lymph nodes (*arrows*) by nasopharyngeal carcinoma. **B:** Axial T2-weighted magnetic resonance image (MRI) showing involvement of bilateral retropharyngeal lymph nodes (*arrows*) by nasopharyngeal

carcinoma.

TABLE 44.3 SYMPTOMS AND PHYSICAL SIGNS OF NASOPHARYNGEAL CARCINOMA AT PRESENTATION

Symptom/Sign	Chao and Perez[43] (*n* = 164) (%)	Lee et al.[29] (*n* = 4,768) (%)
Neck mass	66	76
Enlarged neck node(s)		75
Nasal (discharge, bleeding, obstruction)	>37	73
Aural (tinnitus, hearing impairment)	41	62
Headache	40	35
Cranial nerve palsy	23	20
Neurologic symptoms		
Ophthalmic (diplopia, squint)		11
Facial numbness		8
Slurring of speech		2
Sore throat	16	
Weight loss		7
Trismus		3
Distant metastases		3
Dermatomyositis		1

DIAGNOSTIC AND STAGING WORKUP

Diagnosis of nasopharyngeal carcinoma is made by biopsy of the primary tumor. This can typically be performed with local anesthesia in an outpatient setting. Biopsy by direct visualization with general anesthesia may be necessary for diagnosis when the tumor is not visible or when the patient cannot cooperate. Not uncommonly, the tumor is submucosal and not visible. For suspicious cases of a nasopharyngeal primary tumor with lack of visible tumor, random biopsies of the most commonly involved sites are warranted: pharyngeal recess (*fossa of Rosenmüller*) on each of the lateral walls and superior–posterior wall of the nasopharynx. Fine needle aspiration of a suspicious neck mass may establish the presence of metastatic nasopharyngeal carcinoma in the regional lymphatics. This may be performed prior to the biopsy of the nasopharynx when the primary tumor is not clinically detectable.

Table 44.5 lists the pretreatment diagnostic evaluations and staging

evaluations that are generally recommended for NPC.

Complete physical examination should include thorough palpation of the neck, cranial nerve examination, percussion and auscultation of the chest, palpation of the abdomen for possible liver involvement, and percussion of the spine and bones for possible bone metastasis. CT and MRI of the head and neck are useful in the evaluation of tumor erosion into the bony structures of the base of skull along with retropharyngeal and cervical lymphadenopathy. However, MRI is the preferred imaging technique in the staging evaluation of nasopharyngeal carcinoma.[47–49] The current AJCC T classification requires a search for tumor invasion into the soft tissue (e.g., parapharyngeal space) and bony structures. MRI may be necessary for proper staging because CT has limitations in accurately defining tumor extension into these regions[50] and MRI was used[51] for the study that informed the updated 2017 AJCC system. MRI is superior to CT in delineating muscle and soft tissue involvement and examination of the skull base.[50,52,53] When utilizing MRI, thin slices (3 mm) should be used for accurate staging (Fig. 44.10). Thicker slices (e.g. ≥5 mm) risk misdiagnosis of what may be a higher T-stage disease.

TABLE 44.4 INCIDENCE OF CRANIAL NERVE INVOLVEMENT BY NASOPHARYNGEAL CARCINOMA AT DIAGNOSIS

Cranial Nerve	Chao and Perez[43] (*N* = 164) (%)	Chan et al.[44] (*N* = 722) (%)

TABLE 44.5 RECOMMENDED PRETREATMENT DIAGNOSTIC EVALUATIONS FOR NASOPHARYNGEAL CARCINOMA

General
Medical history
Physical examination:
Palpation of neck node (record size, laterality, and lowest extent of enlarged nodes)

- Testing of cranial nerve (including assessment of vision and hearing functions)
- Exclusion of gross signs of distant metastases

Fiber-optic endoscopy examination
- Nasopharyngoscopy and biopsies
- ± Panendoscopy

Otologic assessment
- Inspection of tympanic membranes (as clinically indicated)
- Baseline audiologic testing (preferable)

Laboratory studies
- Complete blood count
- Liver function tests (LFTs)
- Urinalysis
- EBV-specific serologic tests
  - Immunoglobulin A (IgA)
  - Antiviral capsule antigen (VCA) titers
  - Serum EBV DNA levels

Radiographic studies

Assessment of locoregional extent (imaging of the nasopharynx, paranasal sinuses, base of skull, nasal cavity, and neck)
- Magnetic resonance imaging (study of choice)
- Computed tomography (acceptable alternative)

Chest radiograph (posterior–anterior and lateral)

Additional metastatic workup if clinically indicated or N3 disease
- Positron-emission tomography (study of choice)
- Computed tomography of the chest and abdomen
  - In patients with abnormal LFTs or clinical suspicion of lung or liver metastasis
- Bone scan
  - In patients with advanced locoregional disease, symptoms suggestive of bone metastasis, or an elevated serum alkaline phosphatase

Ng et al.[54] compared MRI and CT in assessing the extent of disease. The study found a significantly higher sensitivity of MRI for skull base involvement (60% vs. 40%), intracranial involvement (57% vs. 36%), retropharyngeal node (58% vs. 21%), and tumor infiltration of prevertebral muscles (i.e., longus colli muscles) (51% vs. 22%) compared to CT. By MRI, T-staging was modified in 27% of patients, with 22% being upstaged and 4% being downstaged.

MRI and CT scans can detect lymph node metastasis that may not be clinically evident on physical examination.[55] According to a study by Van den Brekel et al.,[56] lymph node metastasis is commonly recommended to be radiologically defined by the presence of central necrosis, extracapsular spread, shortest axial diameter ≥10 mm (11 mm for the jugulodigastric node and 5 mm

for the retropharyngeal node), or a cluster of ≥3 lymph nodes that are borderline in size.

Detailed evaluation of nodal enlargement by palpation and imaging should consist of the size and location of the node, unilateral/bilateral involvement, and assessment of supraclavicular fossa involvement. Figure 44.8 defines the anatomical boundaries of the supraclavicular fossa, and Figure 44.11 demonstrates an example of bilateral cervical lymph node involvement seen by radiologic studies.

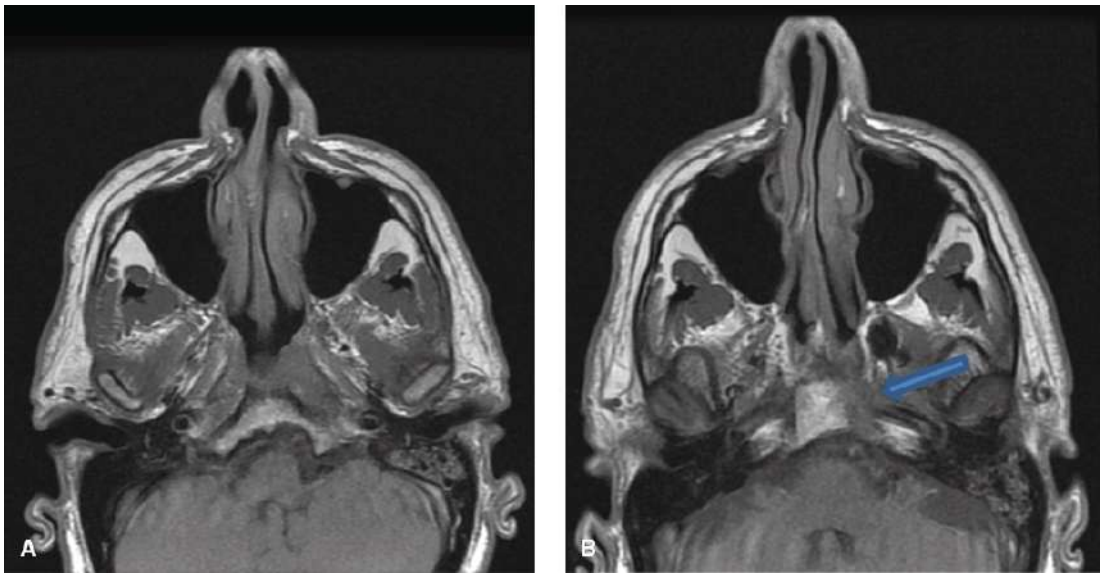

FIGURE 44.10. A: Axial T1-weighted magnetic resonance image (MRI) with 5-mm slices. **B:** Axial T1 MRI with 3-mm slices, skull base invasion (*arrow*) upstaged this tumor from T1 to T3.

A complete search for distant metastasis is recommended for patients with advanced locoregional disease (e.g., N3 disease) or patients with suspicious clinical or laboratory findings. PET-CT scanning (Fig. 44.12) is now commonly utilized in place of conventional staging by CT, bone scans and ultrasound, and appears to be at least as sensitive. Chang et al.[57] demonstrated that [18F]fluorodeoxyglucose (FDG)-PET was superior to conventional workup (i.e., chest x-ray, isotope bone scan, and abdominal ultrasound) in the detection of distant metastases, where 12% of patients were upstaged to stage IVC. PET, in the study, offered a sensitivity and specificity of 100% and 90.1%, respectively. However, large comparative studies of these various staging modalities have yet to be reported.[57–59]

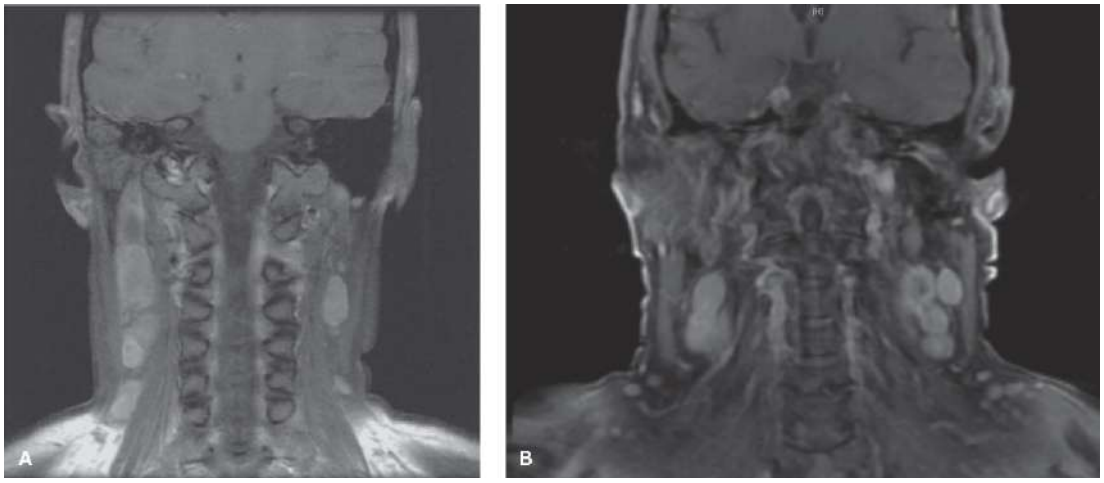

FIGURE 44.11. Two examples of coronal magnetic resonance images (MRI) showing bilateral cervical lymphadenopathy. There is orderly downward lymphatic spread toward the supraclavicular fossa.

The intimate association of EBV with nasopharyngeal carcinoma, independent of geographic and ethnic background, has provided clinicians with a tumor marker for disease diagnosis. Immunoglobulin (Ig) A (IgA) antiviral capsid antigen (VCA) and IgG anti–early antigen (EA) antibodies are both sensitive for diagnosing nasopharyngeal carcinoma; however, IgA anti-VCA has better specificity.[60] More than 90% of untreated nasopharyngeal carcinoma patients from California, East Africa, and Hong Kong have elevated IgA antibody titers.[61–63] Elevated IgA anti-VCA and IgG anti-EA antibody titers are typically associated with nonkeratinizing carcinoma (both the differentiated and undifferentiated histologic subtype). Neel et al.[64] reported 82% and 86% of patients with nonkeratinizing carcinoma had elevated IgA anti-VCA and IgG anti-EA antibody titers, respectively, in contrast with only 16% and 35%, respectively, in patients with the keratinizing histologic type. IgA anti-VCA antibodies may serve as a screening test in high-risk patients as it can be found elevated in patients months before the onset of symptoms.[65,66] A baseline test of plasma EBV DNA may be useful for prognosis, and levels over time can be utilized as surveillance in a posttreatment setting.[67,68]

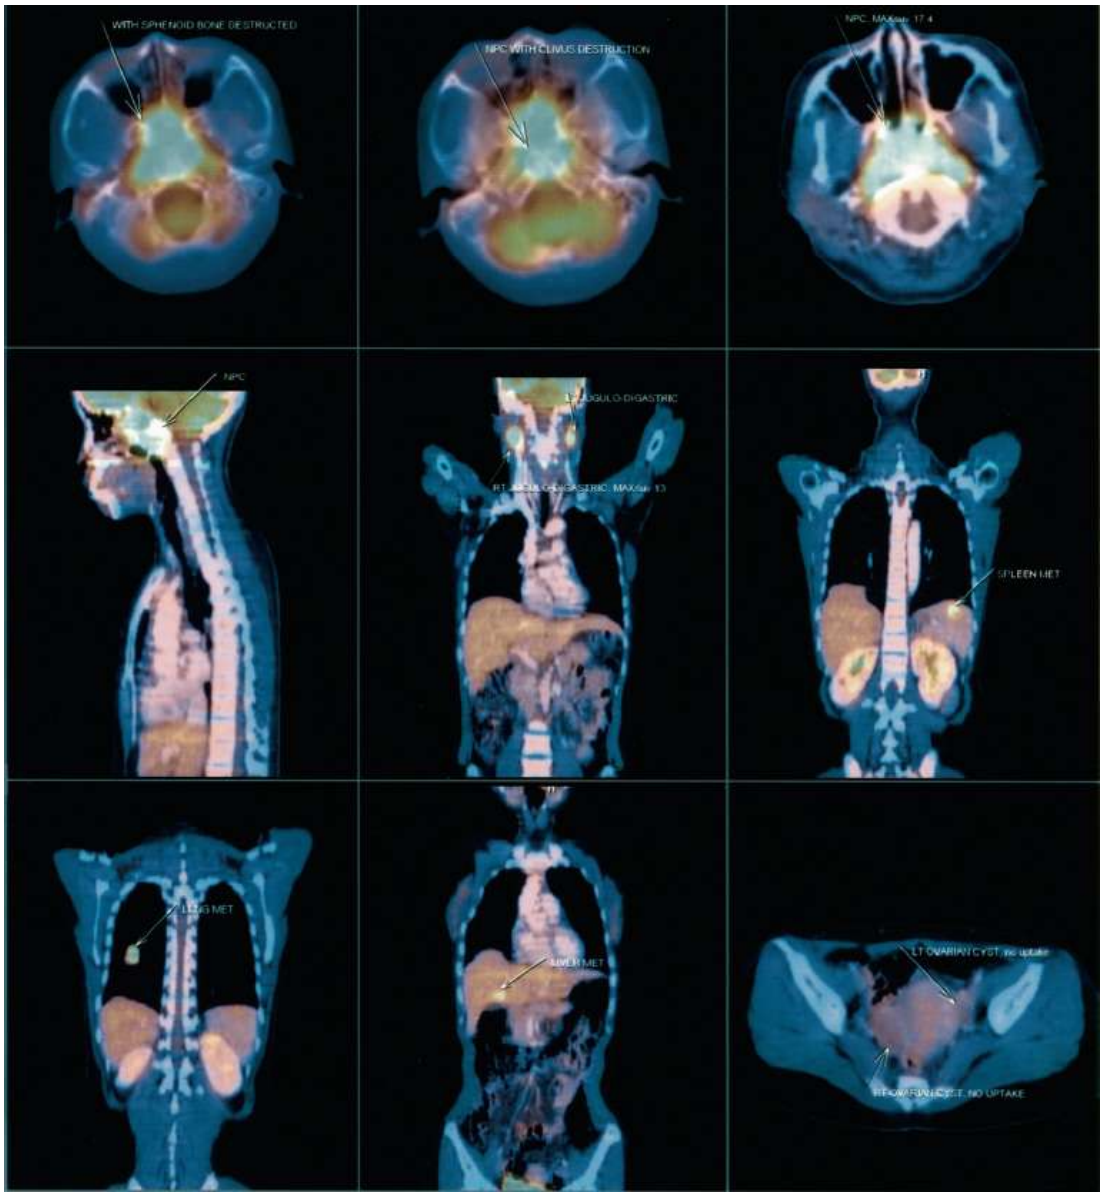

FIGURE 44.12. Positron emission tomography coupled with computed tomography (PET-CT) for a patient with nasopharyngeal carcinoma. Physical examination and biochemistry did not show any sign suggestive of distant metastases. X-ray of the chest was normal. PET-CT revealed multiple distant metastases in the lung, liver, and spleen, in addition to extensive local infiltration and bilateral cervical lymph nodes. (From Chan J, Bray F, McCarron P, et al. Nasopharyngeal carcinoma. In: Pathology and genetics of head and neck tumours. *World Health Organization Classification of Tumours*. Lyon, France: IARC Press, 2005. Copyright © Dr. A. W. M. Lee. STAGING SYSTEM

Various staging systems have been devised to predict prognosis and guide treatment strategy for patients with nasopharyngeal carcinoma.[69–72] The

American Joint Committee on Cancer (AJCC), Union for International Cancer Control (UICC), and Ho staging systems are the most commonly used systems in the English literature. The AJCC and UICC systems are virtually identical in their 2002 version, and this continues in the 2010 and 2017 updates. Each system has particular limitations; however, they continually evolve and build upon each other's experience. Table 44.6 displays the 2017 AJCC staging system currently in use.[73]

It is important to understand changes to the staging system over time for interpretation of older studies, which use prior classifications. The designation "T0" has been added for an EBV-positive unknown primary with cervical lymph node involvement. Tumors confined to the nasopharynx have similar outcomes to tumors that extend to the nasal cavity and oropharynx.[20,74] From the 2002 to the 2010 system (Table 44.7 and 44.8, respectively), T2a was therefore downstaged to T1, which is defined as tumor confined to the nasopharynx or tumor that extends to the nasal cavity and/or oropharynx. Tumors with parapharyngeal involvement were classified as T2 in the 2010 system and were no longer subdivided as T2b. Tumors with parapharyngeal space involvement are at higher risk for local and regional recurrence, as well as a high rate of distant metastasis.[76] Now, in the 2017 version, adjacent muscle involvement (including medial pterygoid, lateral pterygoid, and prevertebral muscle) is now designated as T2. Cranial nerve involvement has been shown to carry a worse prognosis than skull base involvement[27,38,77,78]; as such, T3 disease includes involvement of the bony structures of the skull base, whereas T4 includes involvement of the cranial nerves. The previous T4 criteria of extension to the "masticator space" or "infratemporal fossa" have been replaced in the 2017 by a specific description of soft tissue involvement "beyond the lateral surface of the lateral pterygoid muscle, parotid gland" to avoid ambiguity.

Nasopharyngeal carcinoma has a unique pattern of nodal spread as compared to other sites in the head and neck region, which is reflected in the nodal staging classification. Retropharyngeal nodes are the first echelon of nodal metastases,[79] and retropharyngeal lymph node involvement independent of laterality and without cervical lymph node involvement was defined as N1 beginning in the 2010 system. Spread to the low-neck correlates strongly with the development of distant metastasis.[38,39] The previous N3b criterion of supraclavicular fossa extension was changed to lower-neck involvement (as defined by nodal extension below the caudal border of the cricoid cartilage) in the 2017 update. Additionally, N3a and N3b have been merged into a single N3 category. Lastly,

the previous substages IVA (T4 N0-2 M0) and IVB (any T N3 M0) are now merged to form IVA, whereas the previous IVC (any T any N M1) is now staged as IVB.

TABLE 44.6 AJCC STAGING OF NASOPHARYNGEAL CANCER, 2017

Stage	Staging Criteria		
T category			
TX	Primary tumor cannot be assessed		
T0	No evidence of primary tumor		
T1	Tumor confined to the nasopharynx or extension to oropharynx and/or nasal cavity without parapharyngeal involvement		
T2	Tumor with extension to parapharyngeal space and/or adjacent soft tissue involvement (medial pterygoid, lateral pterygoid, prevertebral muscles)		
T3	Tumor with infiltration of bony structures at skull base, cervical vertebra, pterygoid structures, and/or paranasal sinuses		
T4	Tumor with intracranial extension; involvement of cranial nerves, hypopharynx, orbit, and parotid gland; and/or extensive soft tissue infiltration beyond the lateral surface of the lateral pterygoid muscle		
N category			
NX	Regional lymph nodes cannot be assessed		
N0	No regional lymph node metastasis		
N1	Unilateral metastasis in cervical lymph node(s) and/or unilateral or bilateral metastasis in retropharyngeal lymph node(s), 6 cm or smaller in greatest dimension, above the caudal border of cricoid cartilage		
N2	Bilateral metastasis in cervical lymph node(s), 6 cm or smaller in greatest dimension, above the caudal border of cricoid cartilage		
N3	Unilateral or bilateral metastasis in cervical lymph node(s), larger than 6 cm in greatest dimension, and/or extension below the caudal border of cricoid cartilage. Metastasis in lymph node(s) >6 cm

These modifications to the staging classifications will require continued examination to determine if they improve prognostic accuracy.

PATHOLOGIC CLASSIFICATION

The vast majority of malignant nasopharyngeal tumors are carcinoma (80% to 99%), with the remainder of these lesions (about 5%) being lymphomas.[80] Other rare malignant tumors of the nasopharynx include adenocarcinoma, plasmacytoma, melanoma, and sarcomas. Regarding nasopharyngeal carcinoma, the most current World Health Organization (WHO) pathologic classification, released in 2017,[81] includes three major types (Fig. 44.13). Keratinizing squamous cell carcinoma is distinguished by the presence of keratin pearls or intracellular keratin. Nonkeratinizing carcinoma is characterized by the complete absence of keratin formation and is further subdivided into differentiated and undifferentiated subtypes. The third type is known as basaloid squamous cell carcinoma[82] and is composed of closely packed small tumor cells that form a lobular and, at times, palisading pattern along with focal squamous carcinoma elements. Basaloid squamous cell carcinoma is quite rare with a frequency of less than 0.2%[44] (Fig. 44.13). The nonkeratinizing type has a strong association with EBV positivity.[83] The keratinizing type may have a correlation with human papilloma virus (HPV); however, the small sample size of these studies requires continued investigation.[84]

The histologic differences between these three types are by no means distinct. Lesions can share intermediate features, and some may be histologic hybrids. Lymphoepithelioma or lymphoepithelial carcinoma is considered a morphologic variant of undifferentiated carcinoma in which many lymphocytes are found among the tumor cells. Geography, race, and national origin affect the distribution of the WHO histologic types (Table 44.9). The frequency of nonkeratinizing carcinoma varies from 99% in Hong Kong to 75% in the United States.[44]

Of note, the former WHO classification remains quite commonly used and classifies the three histologic types as (I) squamous cell carcinoma, (II) nonkeratinizing carcinoma, and (III) undifferentiated carcinoma.[69] This leads to unnecessary confusion with the new WHO classification as the former classification has been used in the majority of, albeit older, studies.

PROGNOSTIC FACTORS

The extent of local invasion, regional lymphatic spread, and distant metastasis, as reflected by the TNM staging, is the most important prognostic factor. In general, advanced T category is associated with worse local control and overall survival; advanced N category predicts increased risk of distant metastasis and worse survival. The presence of distant metastasis (M1) upon presentation usually indicates poor prognosis, and treatment has conventionally been palliative in nature. A summary of the patterns of failure and survival rate for the different stages can be found in the *Results of Treatment* section.

The association of bone erosion, cranial nerve palsy, and lower nodal level with poorer survival is largely undisputed.[85–88] However, the prognostic significance of parapharyngeal extension has been a topic of controversy. In a study of 364 patients, Chua et al.[89] showed that greater tumor extension as defined by extension to the prestyloid space or extension to the anterior part of the masticator space was associated with a worse local failure-free rate (L-FFR of 72% vs. 86%) and lower distant failure-free survival rate (D-FFR of 68% vs. 87%) compared to tumors with no extension or extension only to the retrostyloid space. Other investigators have reported similar significant findings.[76,87,90–92] Cheng et al. found parapharyngeal space extension to be the key factor in distant metastasis, even in N1 and N2 NPC.[93]

However, Teo et al. did not find parapharyngeal space involvement to be an independent significant prognosticator in a study of 903 patients.[86] Au et al.,[94] using the AJCC/UICC definition of extension beyond the pharyngobasilar fascia in a study of 1,294 patients, also found that parapharyngeal extension was not a significant factor upon multivariate analysis.

These contradictory findings may be attributed to varying definitions of parapharyngeal space and incidence in the different series,[76,86,87,90] prompting some to advocate for consideration of the degree of parapharyngeal space extension in future staging systems.[92] In addition, suboptimal imaging by CT and conflation with retropharyngeal node enlargement likely contribute to the

debate.[95,96]

Nevertheless, the 2010 AJCC staging system (Table 44.8) downgraded involvement of the oropharynx and/or nasal cavity without parapharyngeal extension from T2a to T1 while designating the presence of parapharyngeal extension to be the sole determinant of T2 classification. This was in light of recent multiple large retrospective studies that found no significant difference in disease failure hazard ratios between former AJCC 2002 T2a and T1.[93,97–99]

In the current 2017 AJCC staging system,[73] further refinement to T2 stage has been defined. Soft tissue involvement of the medial and lateral pterygoid muscles was downstaged to T2 (from T4 in the 2010 AJCC system), based on a large analysis of 1,609 patients who all were staged by MRI and received IMRT.[51]

Another prognostic factor to consider is the gross volume of the primary tumor (GTV-P). Although it is highly correlated to T-stage, considerable variability in tumor volume exists within the same T-stage, and evidence increasingly suggests that tumor volume as an independent significant factor can better predict prognosis than T category as specified by both AJCC/UICC and Ho staging systems[100–104] (Fig. 44.14).

In a study of 308 patients staged with MRI, Sze et al.[102] showed that those with GTV-P <15 cm^3 had significantly higher L-FFR than those with ≥15 cm^3 (97% vs. 82% at 3 years; $P < .01$). Multivariate analysis confirmed GTV-P to be a strong significant factor independent of T category by 1997 AJCC/UICC fifth edition; the risk of local failure increased by 1% for every 1 cm^3 increase in volume. A similar observation between GTV and clinical outcomes has been observed in other head and neck tumors, including oropharyngeal cancers.[105] Further study is required to determine how tumor volume may be optimally incorporated into future staging systems.

Most series have found significantly better prognosis for females and younger patients.[85,94,106] In 759 patients, Sham and Choy[85] showed a higher 5-year survival rate in females compared with males (45% vs. 28%) and in patients younger than 40 years of age versus older than 40 (50% vs. 40%, $P = .002$). However, they did not find age to significantly affect the 10-year survival rate. Multivariate analysis of 1,294 patients by Au et al.[94] also showed worse cancer-specific death rates in males (HR = 1.28, $P = .02$) and patients older than 50 years (HR = 1.79, $P < .001$).

Although not all studies have found histology to be an independent prognostic factor,[27,107] many have found nonkeratinizing and undifferentiated carcinomas (formerly known as lymphoepitheliomas) to be more radiosensitive and offer better prognosis than keratinizing squamous cell carcinoma.[31,108,109] Of note, regarding ethnicity as a prognostic factor, a study by Corry et al.[110] showed no prognostic difference between ethnic Asian and non-Asian patients with nonkeratinizing carcinoma.

EBV, HPV, and Other Biomarkers

Because of the association of EBV with NPC, various anti-EBV antibodies have long been studied for their potential as biomarkers. Although some studies have shown that elevated level of serum anti-EBV antibodies could indicate the presence[63,111,112] of disease, others have shown anti-EBV antibody titers to have little value for posttreatment surveillance.[64,113,114] The prognostic value of such titers prior to treatment has also been controversial. Although Xu et al.[115] found that high EBV DNAase–specific neutralizing antibody at diagnosis predicted significantly worse event-free and overall survival, others found that a number of antibodies (VCA-IgG, VCA-IgA, EA-IgG, EA-IgA, EBNA-IgG, EBNA-IgA) could not predict prognosis.[112,116,117]

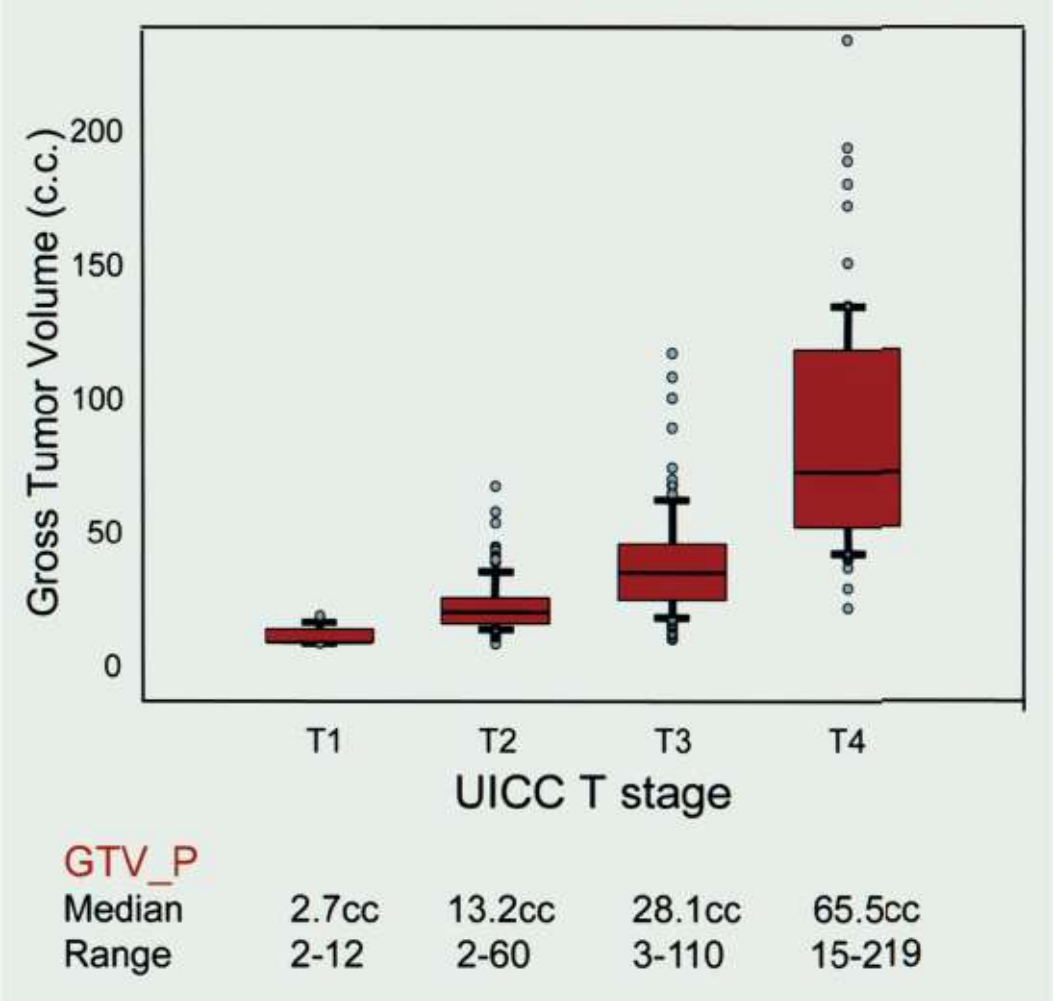

FIGURE 44.14. The correlation between T-category and gross volume of primary tumor (GTV-P). (UICC, International Union Against Cancer.) (Modified from Sze W, Lee A, Yau T, et al. Primary tumor volume of nasopharyngeal carcinoma: Prognostic significance for local control. *Int J Radiat Oncol Biol Phys* 2004;59:21–27.)

Circulating cell-free DNA of EBV in the plasma of NPC patients is a significant prognostic marker and has been found to be superior to serum anti-EBV antibodies.[117] Lo et al.[118] showed that plasma EBV DNA had high sensitivity (96%) and specificity (93%) for detecting NPC, whereas Ma et al.[119] showed that circulating EBV DNA levels correlated significantly with tumor burden. Studies by Lo et al.[120] and Lin et al.[67] found that high pretreatment levels were associated with advanced stages and poor prognosis. Meanwhile, Leung et al.[68] showed that pretreatment plasma EBV DNA load was an independent prognostic factor for OS in 376 patients and could be used to segregate early-stage patients into poor-risk and high-risk subgroups. Thus, pretreatment EBV DNA assays have the potential to complement TNM staging

in guiding treatment.

The ability of posttreatment EBV DNA to prognosticate outcomes has also been studied. Le et al.[121] found no correlation between pretreatment EBV DNA levels and survival; they did find posttreatment levels to be a strong significant predictor of outcome; patients with no detectable EBV DNA had a 2-year OS rate of 94% versus 55% for patients with detectable posttreatment levels ($P < .002$).

Other studies have also consistently reported that patients with elevated posttreatment EBV DNA load have had higher risk of tumor recurrence.[67,120,122–124] Using multivariate analysis to compare various prognostic factors for NPC, Lin et al.[125] found that the combined EBV DNA load (pretreatment and 1-week posttreatment) was the single most significant factor.

The ability of posttreatment EBV DNA to influence decisions regarding adjuvant therapy is currently being investigated in the NRG Oncology cooperative group HN001 trial (NCT02135042). This phase II randomized/phase III trial offers differing treatment regimens to patients with stage IIB to IVB NPC on the basis of post-CRT EBV DNA levels. The hypothesis is that posttreatment EBV DNA can be used to risk stratify patients following a course of definitive concurrent CRT. In this way, it could serve as a biomarker potentially identifying those at the highest risk for recurrence and most likely to benefit from adjuvant chemotherapy. Therefore, in the phase III cohort, patients with undetectable post-CRT EBV DNA will be randomized to observation alone versus standard adjuvant chemotherapy consisting of cisplatin and 5-FU. The primary endpoint for this portion of the trial is OS with the hypothesis that observation will be noninferior to adjuvant chemotherapy. Patients with detectable post-CRT EBV DNA are randomized in the phase II portion of the trial to standard adjuvant chemotherapy or a non–cross-resistant, experimental doublet consisting of paclitaxel and gemcitabine with the hypothesis that experimental chemotherapy will be associated with superior PFS. The outcomes of this trial may allow for the creation of individualized treatment recommendations using post-CRT EBV DNA as a guide.

Both Wang et al.[126] and An et al.[127] demonstrated that the clearance rate of plasma EBV DNA during the first month of salvage chemotherapy could predict tumor response and overall survival in patients with metastatic/recurrent NPC; undetectable levels after the first cycle indicated significantly better survival. These data suggest that early evaluation of plasma EBV DNA can offer

oncologists timely insight for potential alterations in the therapeutic regimen for patients with a slow clearance rate. In addition, Wang et al.[128] prospectively monitored the plasma EBV DNA of 245 NPC patients in clinical remission with assays every 3 to 6 months and found the plasma EBV DNA assay to have much greater sensitivity, specificity, and accuracy than FDG-PET in predicting relapse, suggesting its utility for posttreatment surveillance.

HPV-associated oropharyngeal carcinomas are now recognized as a separate subtype in the 2017 version of AJCC.[73,129] However, the implications of HPV to NPC with respect to etiology, prognosis, and treatment are unclear. Stenmark et al.[130] reported on a 61-patient cohort from the Midwestern United States where 30% of patients were HPV-positive/EBV-negative. The patient outcomes in OS, PFS, and LRC were worse in this HPV-positive/EBV-negative subgroup, when compared to EBV-positive tumors. Lin et al.[131] evaluated NPC cases from southern China (n = 86) and Stanford, California, USA (n = 108), where no HPV-positive cases were detected in the Chinese cohort, whereas 5 of 11 EBV-negative cases in the Stanford cohort harbored HPV as confirmed by PCR. Of note, these 11 EBV-negative patients had a trend toward worse survival. Dogan et al.[132] reported on a case series of 90 patients with NPC where 6 patients with confirmed nasopharyngeal origin were HPV-positive. These HPV-positive patients had a similar OS to EBV-positive NPC, whereas EBV/HPV-negative NPC had worse OS. Because of these conflicting studies and limited patient numbers, future work will be required to determine the prognostic significance of HPV positivity in NPC.

As with other head and neck squamous cell carcinomas, epidermal growth factor receptor (EGFR) is commonly expressed in patients with NPC. Chua et al.[133] found expression of EFGR in 89% of patients, in which overexpression was associated with significantly poorer disease-specific survival. Others have reported similar findings of prognostic significance.[24,134,135] Ma et al.[134] performed multivariate analysis on several biomarkers in 78 patients, including microvessel density, Ki67 antigen, p53 oncoprotein, HER2, and EGFR, and found EGFR to be the only independent prognostic factor.

The study by Hui et al.[136] showed that 58% of NPC patients had expression of hypoxia-inducible factor 1α (HIF-1-alpha), 57% had carbonic anhydrase IX (CA IX), and 60% had VEGF. Those with positive hypoxic profile (high expression of HIF-1-alpha and CA IX) had a worse progression-free survival (P = .04); those with both positive hypoxic and angiogenic profile (high VEGF) were strongly associated with worse progression-free survival (P = .0095).

Multiple other studies have also shown that overexpression of these markers, particularly VEGF, is associated with poorer survival.[137–139]

Other biologic factors that might have prognostic significance include E-cadherin and β-catenin,[140] c-erbB2,[141] p53,[142] NM23-HI,[143,144] and interleukin-10.[145] Further validation of these potential biomarkers is needed.

TREATMENT STRATEGY

Because of the anatomic location, proximity to critical structures, surgical exposure, and tumor resection with sufficient margins have been very challenging.[146] Primary surgical intervention was rare after the 1950s for these reasons, with surgical interventions employed mainly for biopsy to gain histologic confirmation and salvage therapy for persistent or recurrent cancer. Primary treatment since has typically employed radiation therapy (RT) alone and, more recently, in combination with chemotherapy.

Radiation Therapy

To achieve the best therapeutic ratio, every single step in the RT procedures (localization of gross tumor and target volumes, immobilization, optimization of dose fractionation, determination of treatment techniques, and precision in RT delivery) is important.

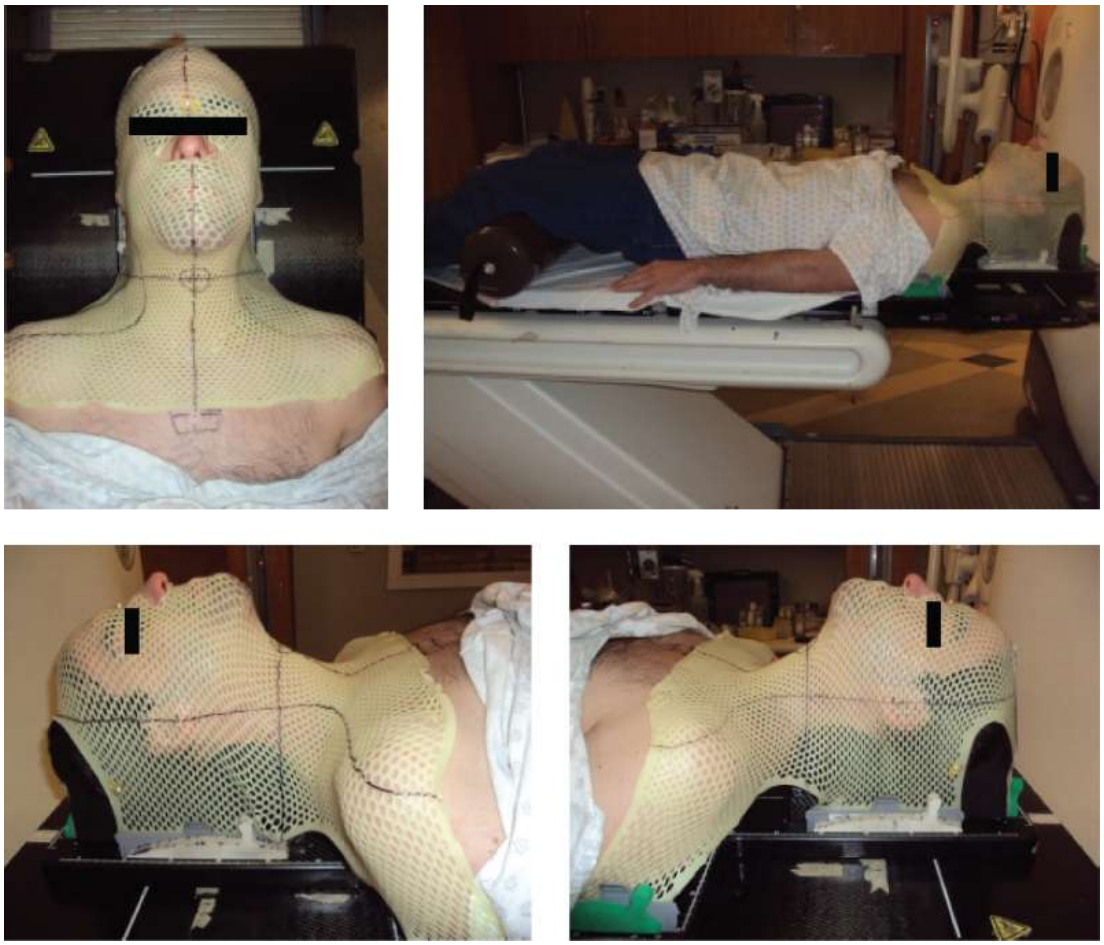

FIGURE 44.15. Immobilization of patient in a customized thermoplastic mask covering the whole head-to-shoulder region.

For planning, the patient should be set up in a supine position with head extended for adequate separation between the primary tumor/retropharyngeal nodes and the upper neck nodes. The tip of the uvula and the base of the occiput should be on a parallel plane to the beam axis. The patient is immobilized with a thermoplastic mask covering the head to shoulder region (Fig. 44.15). For patients to be treated by conventional two-dimensional (2-D) technique, a mouth bite is useful to minimize the dose to the oral cavity with enlarged neck nodes to be marked with wire before imaging.

Dose, Time, and Fractionation

A significant dose–response has been observed in the majority of retrospective studies, based on patients irradiated with 2-D techniques. Marks et al.[147] and Vikram et al.[148] showed that local control was significantly improved in patients who received >67 Gy to the tumor target. Perez et al.[27] observed that patients

with T1-2 tumors had a local tumor control rate of 100% for those given >70 Gy, compared with 80% for those treated with 66 to 70 Gy. However, local control for patients with T3-4 tumors remained below 55%, even with a total dose >70 Gy. Similar findings were reported by Mesic et al.,[149] where ≥70 Gy achieved better local control for T1-2 tumors compared with 60 Gy (94% vs. 76%), but higher doses or larger fields did not significantly improve outcomes in T3-4 tumors. These observations suggest that, besides consideration of the prescribed dose, the problem of sufficient coverage has to be overcome for advanced tumors.

Lee et al.[150] reported a study of 1,008 patients with T1 tumors irradiated by four different fractionation schedules and demonstrated that total dose was the most important radiation factor (P = .01). Dose fraction did not affect local control; however, it was a significant risk factor for temporal lobe necrosis.[151,152] Therefore, a fractional dose of >2 Gy should be avoided[153] (see section *Sequelae of Treatment*).

The impact of the time factor is more contentious. A randomized study by Marcial et al.,[154] where 62 patients were treated with split-course irradiation (30 Gy in 10 fractions over 2 weeks, then a 3-week rest period, and followed by an additional 30 Gy in 10 fractions) compared with 59 patients with 66 Gy in 33 fractions in 6.5 to 7 weeks, demonstrated no significant difference in 5-year local control (86% vs. 80%), nodal control (86% vs. 78%), or disease-free survival (40% vs. 30%).

However, Vikram et al.[148] observed that patients with interruption of RT for ≥21 days had significantly poorer local tumor control than patients without interruptions (34% vs. 67%). Similar findings have been subsequently reported,[155,156] with the general consensus that prolongation is likely to be detrimental, even for nonkeratinizing NPC.

In general, the prescription recommended for NPC is to a total dose of about 70 Gy over 7 weeks to the gross tumor along with 50 to 60 Gy for elective treatment of potential risk sites.

Tumor Target Volumes

The GTV should encompass the primary nasopharyngeal tumor, gross retropharyngeal lymphadenopathy, and gross nodal disease as determined by clinical, endoscopic, and radiologic examinations. Lymph nodes ≥1 cm or with evidence of central necrosis are considered gross nodal disease. For patients given induction chemotherapy, it is recommended that the targets be determined

by the prechemotherapy extent.

Prophylactic neck radiation is usually recommended in N0 patients because of the high incidence of occult neck node involvement. Lee et al.[35] found patients with a clinically negative neck who underwent elective neck irradiation had a significantly lower nodal recurrence rate than those untreated (11% vs. 40%). Additionally, even with successful salvage by subsequent treatment, patients with nodal recurrence had a significantly greater incidence of distant metastases than those without recurrence (21% vs. 6%).

The clinical target volume (CTV) includes the GTV, regions of microscopic disease, and potential infiltrative spread. Different centers may have different philosophies in defining the margins and dose level. For example, Table 44.10 shows the delineation criteria for the various CTVs currently employed at Memorial Sloan Kettering Cancer Center. A gross disease CTV (CTV_{70}) is defined as the GTV plus an additional margin of 5 mm to 1 cm surrounding all gross disease. The margin may be decreased to as small as 1 mm in critical regions near the brainstem or spinal cord. The high-risk subclinical CTV ($CTV_{59.4}$) encompasses the GTV including all potential areas of microscopic spread of disease. This volume should include at a minimum the entire nasopharynx, retropharyngeal lymph nodal regions, clivus, skull base, pterygoid fossae, parapharyngeal space, sphenoid sinus, posterior fourth to third of the nasal cavity, and posterior fourth to third of the maxillary sinuses. This $CTV_{59.4}$ should also include lymph nodal groups that are at risk of potential microscopic disease spread: bilateral upper deep jugular (junctional, parapharyngeal), submandibular, subdigastric (jugulodigastric), midjugular, posterior cervical, and retropharyngeal lymph nodes. In patients with clinically N0 neck, it is not necessary to include level I nodal regions.

TABLE 44.10 Example of Guideline on Anatomic Structures/Boundaries for Delineating Clinical Target Volumes (CTV) for Intensity-Modulated Radiation Therapy[a]

CTV	Delineation of CTV Structures	Anatomic Boundaries
CTV_{70}	GTV + ≥5 mm margin (can be reduced to as low as 1 mm for tumors in close proximity to critical structures/neurologic structures)[b]	
$CTV_{59.4}$	CTV_{70} + ≥5 mm margin (as low as 1 mm when close to critical structures)[b]	

Entire nasopharynx	5–10 mm from mucosal surface of nasopharynx Anterior: Junction with nasal choana Lateral: Medial border of parapharyngeal space Caudal: Caudal border of C1 vertebra
Base of skull	Posterior: Anterior 1/2 to 2/3 of clivus (entire clivus, if involved) Lateral: Lateral border of foramen ovale
Parapharyngeal spaces	Lateral: Lateral border of styloid processes
Inferior sphenoid sinus	Cranial: Lower half of sphenoid sinus (in T3-T4 disease, include entire sphenoid sinus)
Posterior nasal cavity	Anterior: Posterior fourth to third of nasal cavity
Posterior maxillary sinuses	Anterior: Posterior fourth to third of maxillary sinuses (to ensure pterygopalatine fossae coverage)
Cavernous sinus, include high-risk patients (T3, T4 bulky disease involving roof of nasopharynx)	
High-risk nodal levels (include all bilaterally)	(a) Upper deep jugular (junctional, parapharyngeal) (b) Submandibular [level I][c] (c) Subdigastric (jugulodigastric) [level II] (d) Midjugular [level III] (e) Low jugular and supraclavicular [level IV] (f) Posterior cervical [level V] (g) Retropharyngeal

[a]Based on guideline currently used at Memorial Sloan Kettering Cancer Center and detailed in RTOG 0615.
[b]CTV margins may also be limited to exclude the bone *not* at risk for subclinical disease or air.
[c]Bilateral IB lymph nodes can be spared if patient is node-negative. The treatment of level IB may result in the delivery of clinically significant radiation doses to normal structures such as the floor of the mouth, mandible, and upper pharyngeal mucosa above the hyoid. At the discretion of the treating radiation oncologist, level IB may also be spared or limited to the anterior border of the submandibular gland in low-risk node-positive patients. Patients presenting with isolated retropharyngeal nodes or isolated level IV nodes are considered low risk for level IB involvement. Treatment of level IB should be considered in node-negative patients with extensive involvement of the hard palate, nasal cavity, or maxillary antrum.
GTV, gross tumor volume: All gross primary tumor and involved lymph nodes.
PTV, planning target volume: CTV + 3- to 5-mm margin.
Total dose prescription at:

PTV_{70}: 70 Gy in 33 fractions (2.12 Gy per fraction). $PTV_{59.4}$: 59.4 Gy in 33 fractions (1.8 Gy per fraction).

The planning target volume (PTV) is defined as the CTV including a circumferential margin of typically 3 to 5 mm to all the CTVs to account for setup errors and potential patient motion. The PTV margin may be decreased to as small as 1 mm in regions near critical normal structures such as the brainstem or spinal cord.

Conventional 2-D Treatment Techniques

One of the most common RT approaches employed is comprised of two phases.[157] Phase I consists of large lateral opposing faciocervical fields that encompass the primary tumor and the upper neck nodes in one volume, with a matching lower anterior cervical field for the lower cervical lymphatics. Phase II is used after 40 Gy to limit the dose to the spinal cord. This three-field technique includes lateral opposing facial fields coupled with anterior facial field for the primary tumor. Typical treatment fields and radiologic landmarks are shown in Figure 44.16. Shrinking treatment fields by cone down after 50 to 60 Gy should be done, when possible, to increase protection of critical structures.

The three-field technique in phase II allows the dose to be minimized to the temporomandibular joints and the bilateral temporal lobes. However, coverage may not be sufficient for tumors with extensive posterior–lateral extension to the parapharyngeal spaces or caudal extension to the oropharynx. To remedy this deficit, an additional dose is delivered by a posterior–lateral field with avoidance of neurologic structures.[158]

Three-Dimensional (3-D) Conformal Treatment Techniques

Nasopharyngeal carcinoma presents most typically as a concave tumor allowing for computerized 3-D treatment plans to be an important technical advance for improved radiation delivery. Several investigators have designed multifield conformal plans, including the seven-field technique used at Memorial Sloan Kettering Cancer Center (MSKCC) (United States)[159] and the “boomerang” technique used at Peter MacCallum Cancer Center (Australia).[160] When compared to conventional 2-D plans, 3-D planning demonstrated better tumor dose coverage while decreasing normal tissue dose in several studies.[86,161,162]

Leibel et al.[163] from MSKCC demonstrated that the target volume underdosed at the 95% isodose level was lowered with 3-D plans when compared with 2-D plans (7% vs. 22%). On average, the mean tumor dose increased 13% leading to

an estimation that tumor control would increase by 15%. However, a subsequent study in which 68 patients received this technique for a boost of 19.8 to 25.2 Gy following phase I conventional 2-D treatment for 50.4 Gy to a total dose of 70.2 to 75.6 Gy did not show significant improvement; the 5-year L-FFR was 77% and late toxicity grade ≥3 was 25%.[159]

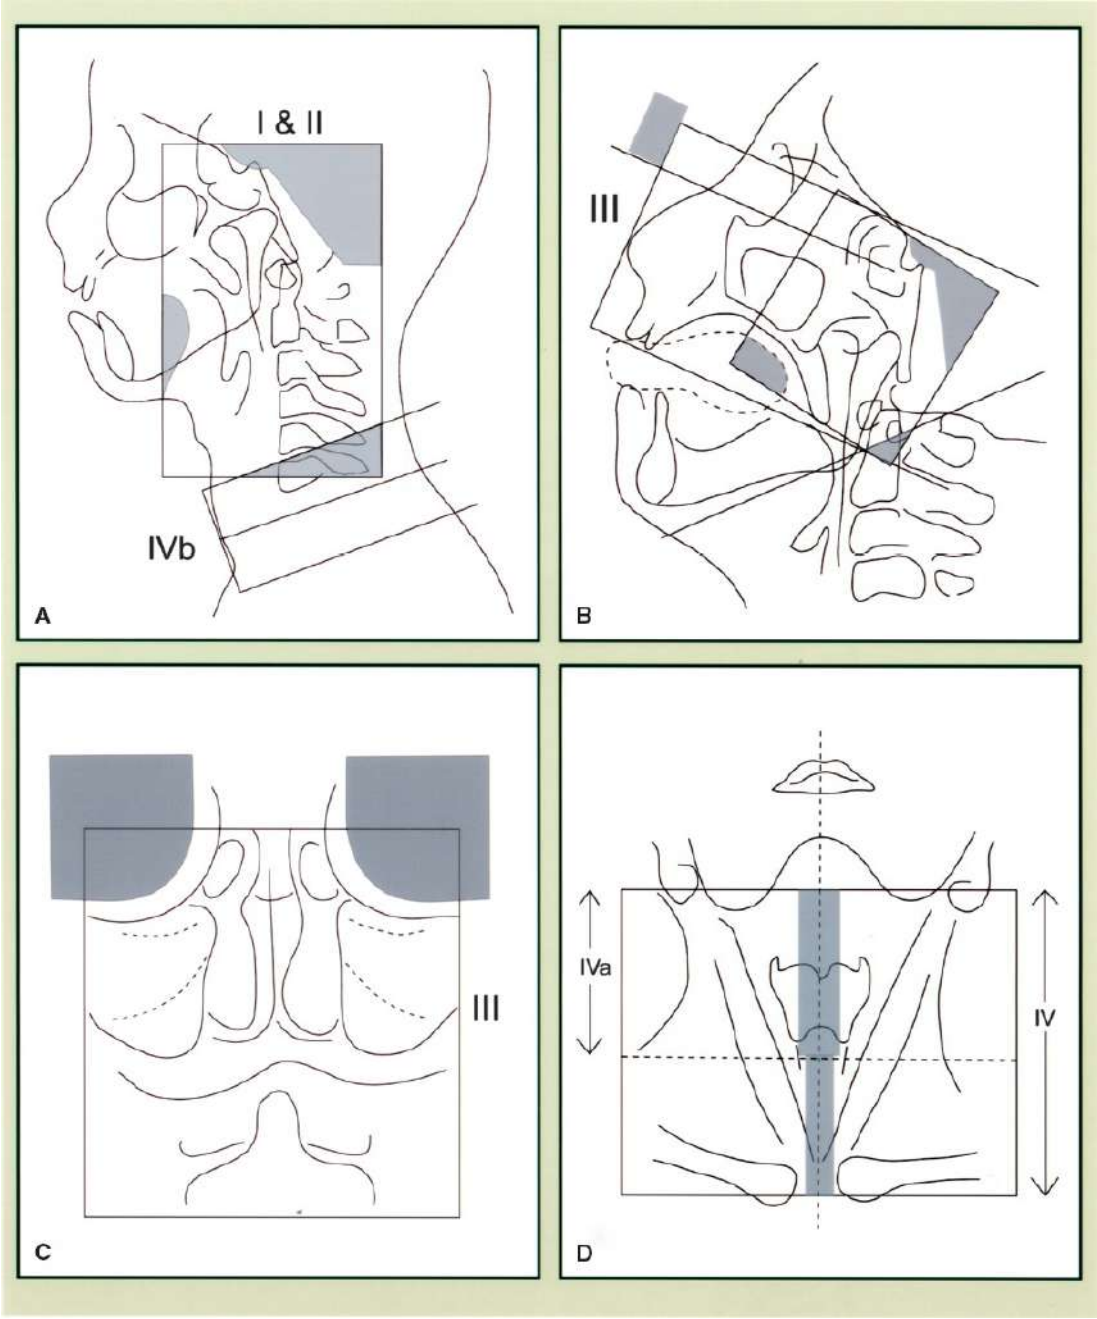

FIGURE 44.16. Conventional two-dimensional radiotherapy using Ho's technique. **A:** Phase I, lateral-opposed faciocervical fields (I–II) and lower anterior cervical field (IVb). **B:** Phase II, sagittal view showing lateral-opposed facial fields and noncoplanar

anterior facial field (III). **C:** Coronal view of anterior facial field (III). **D:** Anterior cervical field for whole neck (IV).

More encouraging results were obtained by Jen et al.,[164] who compared 72 patients treated with 3-D conformal technique with 108 patients treated with 2-D technique. A significant improvement in 3-year L-FFR for T4 (86% vs. 47%), and event-free survival for both stage III (80% vs. 56%) and stage IV (82% vs. 33%), was observed. Furthermore, the incidence of xerostomia at 3 years was significantly less with 3-D conformal treatment (69.2% vs. 98.0%), although for most other late toxicities, little difference was seen.

IMRT Techniques

IMRT has supplanted conventional radiotherapy in the treatment of NPC in an increasing number of institutions throughout the world. The intensity of the radiation beams can be modulated to deliver a high dose to the tumor with a superior target volume coverage while significantly limiting the dose to surrounding normal tissues.[165–170] Following the initial publication[171] and the subsequent update on IMRT for NPC from the University of California, San Francisco (UCSF),[169] several other institutions have utilized IMRT with similar excellent treatment outcomes.[172–178]

Another point of interest is the possibility of biologic enhancement by simultaneous modulated accelerated radiation therapy (SMART), also known as dose painting, as a new way of delivering an accelerated fractionation (AF) schedule, a concept that was first reported by Butler et al.[179] for the treatment of other head and neck cancers with IMRT.

These differing methods and dose fractionation regimens for IMRT are being investigated by different groups; Table 44.11 summarizes the key features along with reported results. The majority of the patients in these series received additional chemotherapy and/or enhanced RT with boosts or AF. All reported encouraging early results with local control in excess of 90% at 2 to 4 years.

At the University of California, San Francisco, patients were typically prescribed 70 Gy to the $PTV_{gross\ disease}$ and involved lymph nodes in 2.12 to 2.25 Gy fractions, whereas the $PTV_{high\text{-}risk\ subclinical}$ were prescribed 59.4 Gy in 1.8 fractions, and a clinical negative neck ($PTV_{low\text{-}risk\ subclinical}$) received 54 Gy at 1.64 Gy fractions all in conventional once-daily fractions.[169,180] Bucci et al.[180] reported the updated results of 118 patients, which confirmed excellent locoregional control of 96%. Yet, distant failure remained high (28%) despite

broad use of concurrent–adjuvant CRT. OS was 74% at 4 years.

At Memorial Sloan Kettering Cancer Center, Wolden et al.[172] reported their initial experience with 74 patients, where 59 were treated with AF using the concomitant boost method and 15 by the SMART method/dose painting. For the SMART cohort, a total dose of 70.2 Gy at 2.34 Gy/fraction was given to the gross disease, and the "microscopic" PTV received 54 Gy at 1.8 Gy/fraction. There was a trend, but no statistically significant improvement in 3-year L-FFR than for patients treated by 3-D conformal boost (91% vs. 79%, P = .11). Updated results by Setton et al.[186] on 177 patients confirmed excellent rates of disease control (92% 3-year and 83% 5-year local control) and survival (87% 3-year and 75% 5-year OS) with this technique. Additional dose escalation by SMART boost in 50 patients with T3 to T4 tumors was reported by Kwong et al.[182] from Queen Mary Hospital (Hong Kong). They sought to deliver a total dose of 76 Gy at 2.17 Gy/fraction to the gross tumor. The early result for locoregional control was excellent (96% at 2 years); however, serious late toxicities were observed, including 4% of patients having a life-threatening hemorrhage from carotid artery pseudoaneurysm and another 4% developing temporal lobe necrosis with a median follow-up of 2.1 years.

Two different IMRT approaches are currently being utilized by different centers: (1) an extended whole-field (EWF) IMRT technique, in which the total target volume is encompassed in the IMRT plan, or (2) a split-field (SF) IMRT technique, in which the target volumes superior to the vocal cords are treated with an IMRT plan and the lower neck nodes are treated with a conventional low anterior neck field.[187–189] Discussions among practitioners on which IMRT technique is best have been persistent. Concerns of potential failures at the SF matchline because of potential underdosing, or even complications resulting from overdosing, have caused many centers to implement EWF IMRT, even when no clinically involved neck nodes are evident in the matchline region. These concerns may be caused by the treatment delivery system that is used at centers where a perfect match between the IMRT fields and the low anterior neck field is not possible. However, with a EWF technique, an unnecessary dose of radiation is delivered to the normal glottic larynx.[190] Whereas with the SF IMRT technique, the dose to the vocal cords is minimal because of shielding by a midline Cerrobend block or the multileaf collimator (MLC). At the moment, no IMRT matchline failures or complications have been reported with the SF IMRT technique.[171]

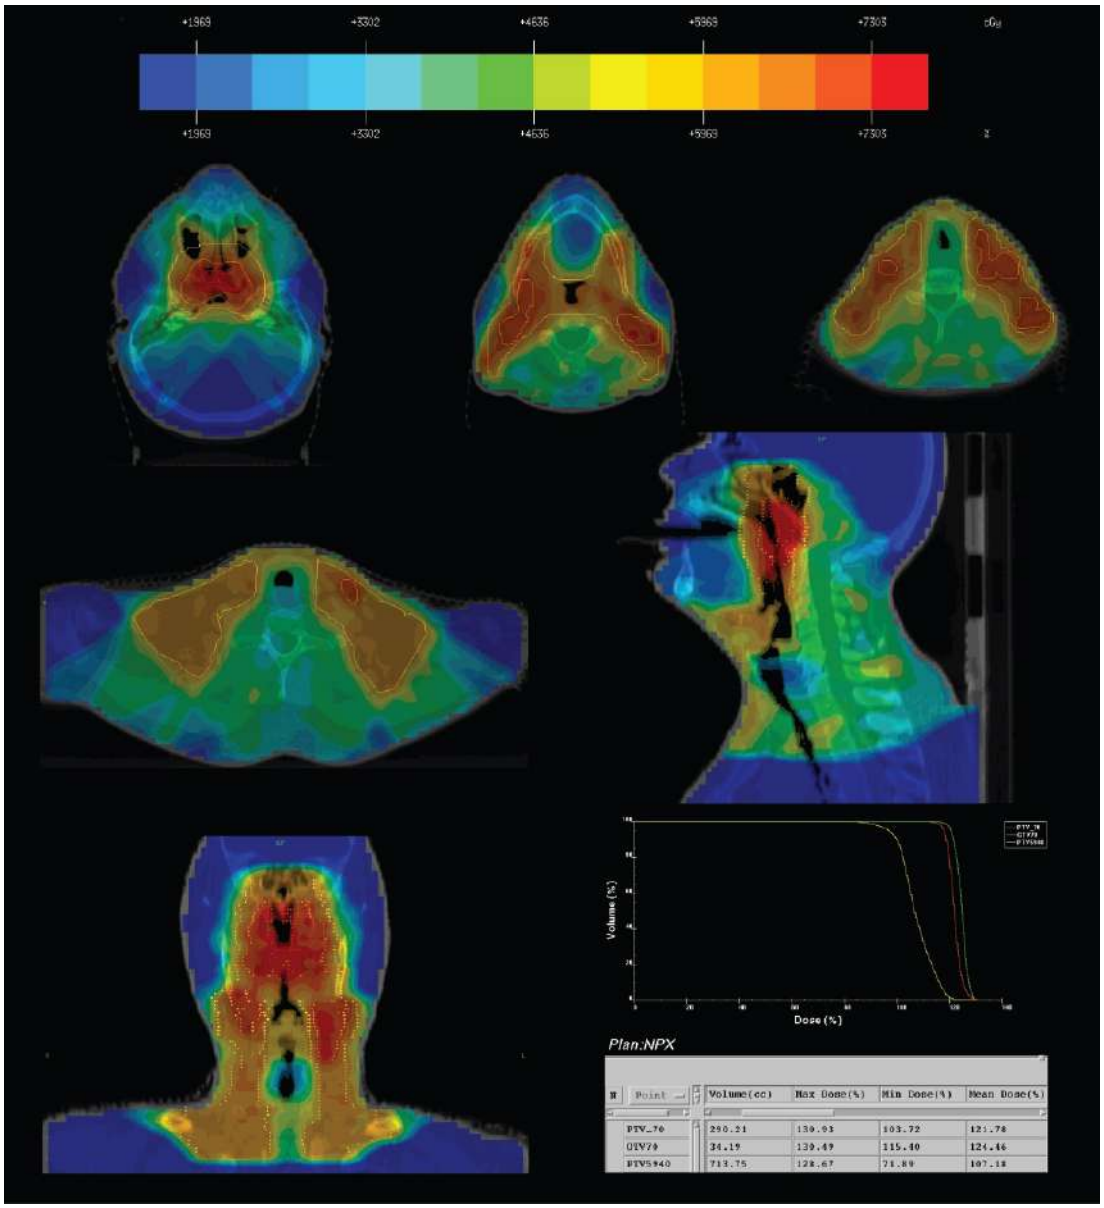

FIGURE 44.17. Intensity-modulated radiation therapy for a patient with T2N2M0 nasopharyngeal carcinoma treated at Memorial Sloan Kettering Cancer Center, showing delineation of gross tumor targets (GTV) and planning target volumes (PTV) for 70 Gy and 54 Gy, the dose distribution, and the dose volume histogram (DVH) for GTV, PTV_{70}, and $PTV_{59.4}$.

Figures 44.17 and 44.18 show examples of MSKCC IMRT plans delivered

with the dynamic multileaf collimator (MLC) system using a sliding window technique to patients with early and advanced disease, respectively. A total dose of 70 Gy at 2.12 Gy/fraction to the $PTV_{gross\ disease}$ and 59.4 Gy to the $PTV_{high\text{-}risk\ subclinical}$ is given over 33 once-daily fractions (Table 44.10). For the low-neck, if split-field IMRT is used, a dose of 50.4 Gy at 1.8 Gy/fraction/day is generally prescribed. However, if the low-neck is included in the IMRT fields and is considered at low risk for nodal involvement, the $PTV_{low\text{-}risk\ subclinical}$ typically receives 54 Gy at 1.64 Gy/fraction/day.

Inverse planning involves the appropriate specification of normal tissue dose constraints. It is important to note that overstrigent use of normal tissue constraints might result in inadequate cover of tumor targets; therefore, optimal balance is essential. Different dose-constraint guidelines have been suggested.[191,192] An example of dose-constraint guidelines is provided in Table 44.12, which displays the guidelines presently used at Memorial Sloan Kettering Cancer Center.

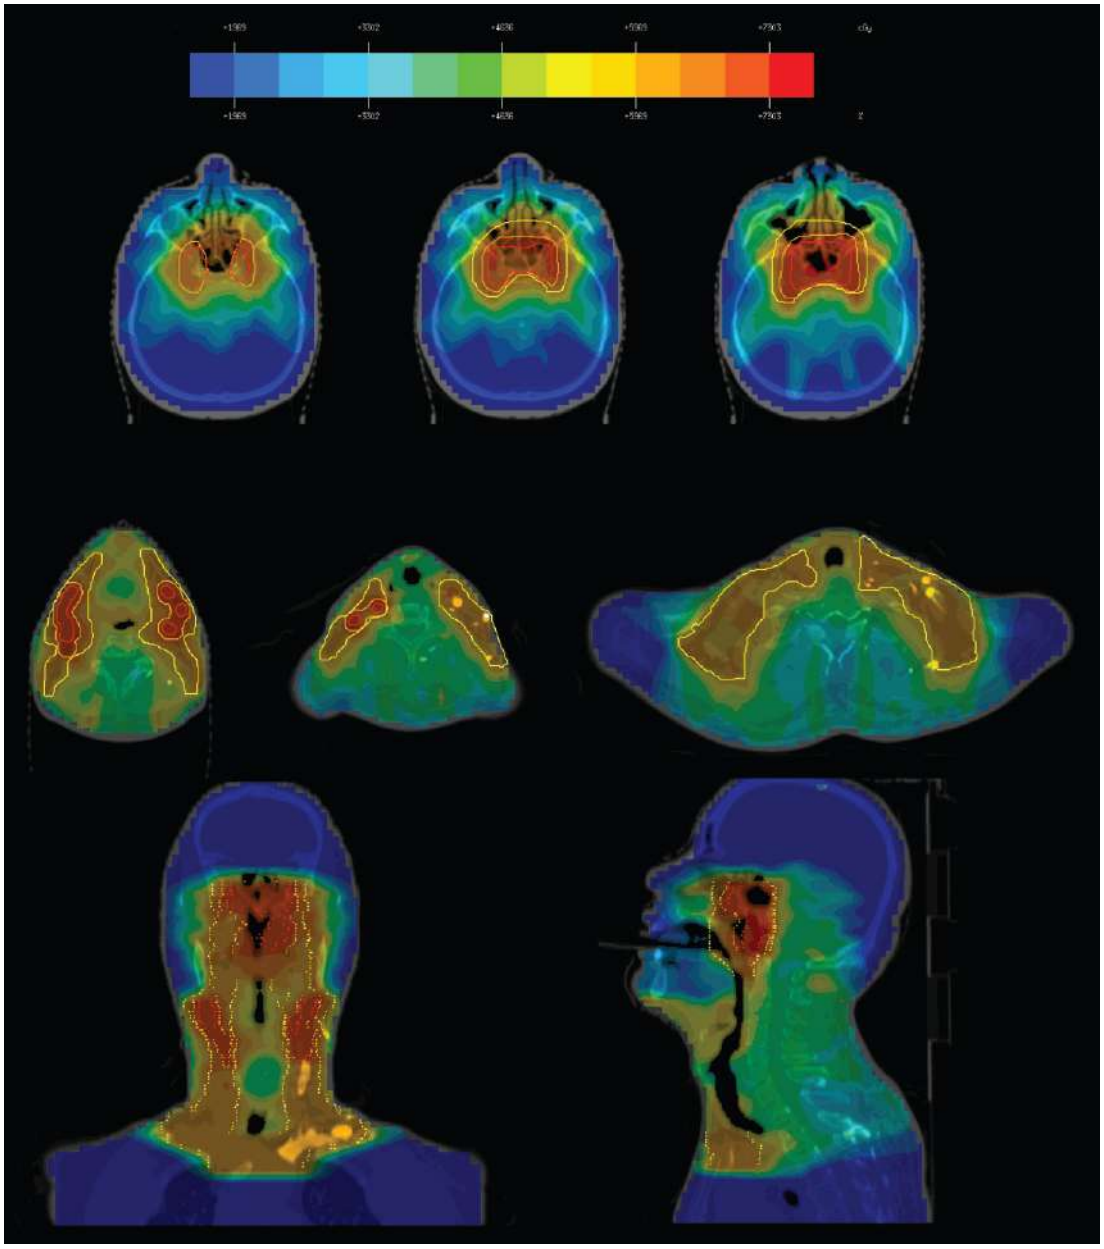

FIGURE 44.18. Intensity-modulated radiation therapy for a patient with T4N2M0 nasopharyngeal carcinoma treated at Memorial Sloan Kettering Cancer Center, showing delineation of gross tumor (GTV) and planning target volumes (PTV) for 70 Gy and 54 Gy, and the dose distribution.

Dose Escalation

Excellent local tumor control has been reported by delivering an additional boost to patients with early disease treated by conventional 2-D technique.

Brachytherapy

The most commonly used method is brachytherapy. Intracavitary

insertions[193–201] or interstitial implants[202–205] have been used in T1 to T3 nasopharyngeal carcinomas as a boost treatment following external beam radiation therapy (EBRT) or in the treatment of recurrent disease, either alone or in combination with EBRT. Brachytherapy is not suitable for treatment of tumors with intracranial extension because of the rapid reduction of dose as distance from the radioactive source increases. Since the advent of IMRT as primary radiotherapy for nasopharyngeal carcinoma and with its demonstration of excellent local control, the use of brachytherapy as a boost treatment following definitive IMRT has dramatically declined. Multiple applicators and techniques have been developed for the delivery of intracavitary brachytherapy.[195–197,199,201,206] In the past, intracavitary brachytherapy was delivered using low–dose rate (LDR) techniques. However, currently remote afterloading and fractionated high–dose rate (HDR) techniques are more commonly used (Fig. 44.19).[206]

TABLE 44.12 Intensity-Modulated Radiation Therapy for Nasopharyngeal Carcinoma: an Example of Normal Tissue Dose Constraints[a]

Structures	Constraints
Critical Structures	
Brainstem	Max < 5 Gy or 1% of PTV cannot exceed 60 Gy
Optic nerves	Max < 54 Gy or 1% of PTV cannot exceed 60 Gy
Optic chiasm	Max < 54 Gy or 1% of PTV cannot exceed 60 Gy
Spinal cord	Max < 45 Gy or 1 cc of the PTV cannot exceed 50 Gy
Mandible and temporomandibular joint	Max < 70 Gy or 1 cc of the PTV cannot exceed 75 Gy
Brachial plexus	Max < 66 Gy
Temporal lobes	Max < 60 Gy or 1% of PTV cannot exceed 65 Gy
Other Normal Structures	
Oral cavity	Mean < 40 Gy
Parotid gland	Mean ≤ 26 Gy (should be achieved in at least one gland) or at least 20 cc of the combined volume of both parotid glands will receive < 20 Gy or at least 50% of the gland will receive < 30 Gy (should be achieved in at least one gland)
Cochlea	V55 < 5%
Eyes	Mean < 35 Gy, max < 50 Gy
Lens	Max < 25 Gy

Glottic larynx	Mean < 45 Gy
Esophagus, postcricoid pharynx	Mean < 45 Gy

PTV, planning target volume.

Table 44.13 summarizes reports on the use of brachytherapy as a boost for dose escalation. Most studies demonstrated that local control up to 90% to 95% could be achieved for T1-2 tumors without excessive late damages. A retrospective comparison by Wang[196] from Massachusetts General Hospital (United States) reported that for T1 to T2 patients who received a 10- to 15 Gy, LDR brachytherapy boost after 60 to 64 Gy by EBRT had a 5-year L-FFR of 90% versus 54%, respectively, with $P = .001$ for patients receiving EBRT alone to 65 to 70 Gy. A similar study by Teo et al.[212] where delivery of 18 to 24 Gy in 3 fractions by HDR brachytherapy and showed a significant improvement of the 5-year L-FFR of 95% compared with a 90% 5-year L-FFR for EBRT only patients ($P = .016$).

However, a report by Ozyar et al.[210] of patients with T1 to T4 tumors treated with HDR brachytherapy boost of 12 Gy in 3 fractions did not show improvement over EBRT alone (3-year L-FFR: 86% vs. 94%; $P = .23$). More recently, a prospective trial by the International Atomic Energy Agency (IAEA) studied 275 patients with locoregionally advanced NPC disease (TNM stage III or M0 stage IV) who were all treated by induction chemotherapy followed by concurrent chemoradiotherapy to 70 Gy; then one randomized arm received a brachytherapy boost of 11 Gy LDR or 3 fractions of 3 Gy HDR. With a median follow-up of 29 months, the authors reported no additional benefit of brachytherapy boost compared with chemoradiotherapy alone toward 3-year OS (63.3% vs. 62.9%, $P = .742$, respectively), locoregional-FFR (54.4% vs. 60.5%, $P = .647$), or distant metastasis-free survival (52.6% vs. 59.8%, $P = .496$).[214]

One major limitation of brachytherapy is that the dose delivered is adequate only for superficial nonbulky tumors. Furthermore, optimal positioning of the applicators depends both on the individual clinician's skill and the patient's anatomic features.

Stereotactic Radiosurgery

Stereotactic radiosurgery or fractionated radiotherapy allows for precise delivery of highly conformal RT with a rapid dose falloff and provides an alternative for dose escalation. Hara et al.[215] reported a study of 82 patients with T1 to T4 tumors showing excellent 5-year L-FFR of 98% after receiving a median SRT boost of 12 Gy (range, 7 to 15 Gy) following EBRT to 66 Gy. However, despite the addition of concurrent chemotherapy in 76% of the patients, the distant failure rate was 32% and OS was 69%. With a median follow-up of 40.7 months for living patients, 12.1% of patients developed radiographic temporal lobe necrosis (only 2.4% were symptomatic with seizures) and 3.6% developed retinopathy. The risk was especially high in patients with T4 tumors.

Altered Fractionation

Over the past few decades, studies have been conducted to explore the role of altered fractionation regimens in head and neck cancers, along with nasopharyngeal cancers. Hyperfractionation, accelerated fractionation, and a combination of which were explored in conjunction with concurrent chemotherapy.

Sanchiz et al.[216] conducted a large randomized trial examining twice-daily (BID) versus once-daily (QD) irradiation for head and neck cancer including tumors of the nasopharynx. 859 patients with advanced head and neck cancers (T3-T4, N0-3, M0 by UICC staging), which included 92 patients with nasopharyngeal carcinoma, were randomly assigned to QD irradiation (Group A), BID irradiation (Group B), or QD irradiation with concurrent 5-FU chemotherapy (Group C). Groups B and C showed a significant improvement in median duration of response and OS when compared to Group A. No significant differences were seen between Groups B and C.

The first randomized trial on accelerated fractionation (AF) for NPC by Teo et al.[217] used an uncommon schedule of 2.5 Gy/fraction QD for 8 fractions before randomization to an experimental arm using 1.6 Gy BID for an additional 32 fractions versus a control arm treated with 2.5 Gy QD for another 16 fractions. The trial was terminated early because of excessive neurologic toxicities in the AF arm (49% vs. 23%). For this series of 159 patients (62% with

T1-2 tumors), the AF arm did not achieve a significant improvement in tumor control (5-year L-FFR, 89% vs. 85%). Jen et al.[218] reported on 222 patients where 76 patients received hyperfractionated RT at 1.2 Gy/fraction BID and 12 patients received accelerated–hyperfractionated RT at 1.6 Gy BID to a median dose of 80 Gy for these twice-daily RT groups. The remaining 134 patients are treated by conventional QD fractionation to a median dose of 70 Gy. The patients treated by BID fractionation did not demonstrate a statistically significant difference in 5-year L-FFR when compared to QD fractionation (T1-3, 93% vs. 86%; T4, 44% vs. 37%, respectively). The 1.2 Gy/fraction regimen did not cause excessive toxicity; however, patients treated with 1.6 Gy/fraction had a 27% incidence of temporal lobe necrosis.[219] See section *Sequelae of Treatment* for more details regarding the influence of dose fractionation on brain necrosis.

To minimize the risk of late damage, the more moderate AF schedule of the Danish Head and Neck Cancer Study Group 6 to 7 Trials using 2 Gy/fraction, 6 fractions per week[220] of 1,476 patients with head and neck cancer, of which 435 had pharyngeal tumors, including the nasopharynx, demonstrated accelerated fractionation resulted in significantly improved 5-year L-FFR (76% vs. 64% for 6 and 5 fractions, respectively, $P = .0001$) and disease-specific survival (73% vs. 66%, for 6 fractions and 5 fractions, respectively, $P = .01$) but not OS. This same fractionation schedule was tested retrospectively for NPC by Lee et al.[221] They reported for patients irradiated to a total dose of 66 Gy with 2-D technique when on an accelerated fractionation (AF) schedule had significantly higher L-FFR than those treated with conventional 5 fractions per week. The benefit was significant particularly for T3-4 tumors (87% vs. 62%; $P < .01$), and multivariate analyses confirmed that fractionation was an independent prognostic factor for overall progression (AF group, HR = 0.63, 95% CI, 0.41 to 0.98; $P = .04$). Additionally, no significant increase in late toxicity was observed at 3 years (20% vs. 15%).

This schedule was then used in the subsequent NPC-9902 trial initiated by the HKNPCSG,[222] which aimed to assess the therapeutic benefit of AF and/or concurrent–adjuvant chemoradiotherapy (CRT), that randomized 189 patients with locally advanced NPC (T3-T4, N0-1, M0) to four arms: (1) conventional fractionation (CF) alone, (2) AF (six fractions/week) alone, (3) CF with concurrent chemotherapy, and (4) AF with concurrent chemotherapy. Preliminary results with a median follow-up of 2.9 years showed that AF per se did not demonstrate a significant improvement in event-free survival (EFS)

when compared with CF (AF vs. CF: HR 0.68, 95% CI 0.37 to 1.25, *P* = .22). However, AF combined with CRT (arm 4) achieved a strongly significant improvement when compared with CF alone (EFS: 94% vs. 70%, *P* = .008) but without an improvement in OS. A significant increase in acute and late toxicity in the AF combined with CRT arm was also noted.

From these and other experiences with altered fractionation schedules in the treatment of nasopharyngeal carcinoma, in addition to other head and neck cancers, it has been concluded that both total dose and overall treatment time are important factors in determining outcomes.[223] With the increasing use of IMRT, dose escalation—to allow ample dose delivery to the gross and subclinical disease—has become achievable without associated changes in rates of toxicity, considerably improving the therapeutic ratio of concurrent chemoradiation and causing the above fractionation schemes to fall out of favor.

Chemotherapy

Nasopharyngeal carcinoma is generally regarded to be a highly chemosensitive disease. Although radiotherapy alone is the standard treatment for stage I NPC, concurrent chemoradiotherapy (CRT) with or without adjuvant chemotherapy is the current standard for locally advanced disease (stages III to VB) based on multiple randomized controlled trials and meta-analyses (Table 44.14). Although there is less evidence for CRT in intermediate-stage (2010 AJCC stage II) disease, it is currently recommended that such patients be treated with CRT in light of pooled data from two phase III trials[236,237] and a more recent phase III trial from Chen et al.[233] In more detail, Chen and colleagues[233] demonstrated that Chinese stage II (equiv. to AJCC II-III; only 13% of the study's patients were AJCC 2010 stage III) NPC patients that received concurrent chemoradiotherapy had a superior 5-year OS compared to those treated with radiation alone (94.5% vs. 85.8%, *P* = .007) with improved distant control (94.8% vs. 83.9%, *P* = .007). Multivariate analyses found that the number of chemotherapy cycles was the only independent factor associated with improved OS, progression-free survival, and distant control. With the addition of chemotherapy, an increase in acute side effects was observed, but no significant increase in late effects was reported.

Concurrent Chemoradiotherapy

The landmark Intergroup 0099 trial was the first to document a significant survival benefit for CRT versus RT alone.[224] This trial randomized 147 patients

with locally advanced NPC to either RT alone or CRT, at centers located in the United States. Chemotherapy consisted of concurrent cisplatin (CDDP; 100 mg/m^2 on days 1, 22, and 43), followed by three cycles of adjuvant CDDP (80 mg/m^2 on day 1) and 5-fluorouracil (5-FU; 1,000 mg/m^2/d on days 1 to 4) every 4 weeks. Radiotherapy was delivered in 1.8 to 2 Gy fractions to a total dose of 70 Gy. The trial was closed early because of a significant overall survival benefit in favor of CRT (78% vs. 47% at 3 years). A 5-year update confirmed progression-free survival (58% vs. 29%) and overall survival (67% vs. 37%) in favor of CRT. Reactions to these findings were initially tempered by several limitations of the trial. Results achieved in the RT arm were much poorer than those generally obtained at centers treating endemic NPC. Outcomes in the CRT arm were in fact more consistent with outcomes obtained in endemic areas using RT alone. Another concern was that 24% of the enrolled patients had disease of keratinizing histology, and it was unknown whether the same benefit would be seen in endemic areas with predominantly undifferentiated disease.

Subsequent trials confirmed the benefit of concurrent CDDP-based chemotherapy in endemic populations. Wee et al.[228] reported the results of 221 stage III to IVB patients from Singapore randomized to receive either RT alone or CRT. Chemotherapy consisted of a slightly modified version of the Intergroup regimen: CDDP (25 mg/m^2 on days 1 to 4) for 3 cycles every 3 weeks, followed by adjuvant CDDP (20 mg/m^2 on days 1 to 4) and 5-FU (1,000 mg/m^2/d on days 1 to 4) for 3 cycles. Radiotherapy was delivered to a dose of 70 Gy in 2-Gy fractions. Three-year overall survival for the CRT and RT arms was 85% and 65%, respectively (P = .006). CRT reduced the incidence of distant metastasis by 17% at 2 years (P = .003).

Langendijk et al.[238] performed a meta-analysis of 10 trials that randomized NPC patients to conventional RT or CRT. The 10 studies included 4 neoadjuvant trials,[239–242] 3 concurrent (+/- adjuvant) trials,[224,225,243] 2 adjuvant trials,[244,245] and 1 neoadjuvant + adjuvant trial.[246] The authors found a pooled hazard ratio for death of 0.82, with an absolute survival benefit of 4% at 5 years. Subgroup analysis revealed that the overall survival benefit was only significant for those patients receiving concurrent chemotherapy, with a hazard ratio for death of 0.48 and absolute survival benefit of 20% at 5 years. Analysis of the neoadjuvant chemotherapy trials found a significant reduction in locoregional recurrence and distant metastasis, but no overall survival benefit.

These results, in combination with results from a second meta-analysis[247] and the Singapore trial, reported by Wee et al.,[228] confirmed CRT as the standard approach in stage III, IVA, and IVB NPC. At many centers, the standard course of chemotherapy has been based on the US Intergroup regimen, which consisted of concurrent high-dose CDDP (100 mg/m^2 × 3 cycles) and adjuvant CDDP/5-FU for 3 cycles. This regimen is associated with significant acute and late toxicities, and patient compliance is frequently difficult to achieve. In the Intergroup 0099 trial, for example, only 63% completed all 3 cycles of concurrent chemotherapy, and only 55% were able to receive all 3 courses of adjuvant therapy.[224] As a result, weekly CDDP has been adopted by many

institutions, especially for patients with poor nutritional status.[248] In a phase III trial, comparing CRT versus RT alone in 350 patients with locally advanced disease, Chan et al.[227] demonstrated good efficacy and tolerability for a regimen consisting of weekly CDDP (40 mg/m^2). Seventy-eight percent of patients in the CRT arm received at least 4 cycles of CDDP, and CRT was associated with a statistically significant survival benefit after adjusting for age and disease stage. A more recent randomized study by Chen et al.[249] confirmed that OS and locoregional control of weekly CRT were superior to RT alone with weekly CDDP, though it did observe greater acute (63% vs. 32%) and late (33% vs. 26%) toxicity in the CRT arm. In addition, a retrospective comparative study by Jades et al.[250] found similar clinical outcomes and toxicity profiles between concurrent weekly CDDP and the every 3 weeks schedule. Ultimately, whether weekly CDDP is equivalent to the every 3 weeks Intergroup regimen remains to be directly evaluated in a randomized fashion.

Other Chemotherapy Agents

Weekly oxaliplatin (70 mg/m^2) has been demonstrated to have good tolerability and efficacy, albeit in the setting of a small phase III trial of 115 patients randomized to CRT or RT alone.[229] Carboplatin has also been employed as a substitute to high-dose CDDP, with comparable efficacy, in a noninferiority trial reported by Chitapanarux et al.[251] Two hundred and six patients were randomized to either concurrent high-dose CDDP and adjuvant CDDP/5-FU or concurrent weekly carboplatin and adjuvant carboplatin/5-FU. The trial had 80% power to detect a hazard ratio for death of 1.25 at 3 years. No significant difference in disease-free survival or overall survival was seen at a median follow-up of 26 months. Disease-free survival was 59.6% and 64.7% (P = .522) for the carboplatin and CDDP arms, respectively.

Cetuximab to target epidermal growth factor receptor (EGFR; EGFR overexpression is observed in >80% of NPC patients) has been examined in a phase II trial with optimistic findings.[252] The 2-year rates of OS, locoregional progression-free survival, distant metastasis-free survival, and progression-free survival were 89.9%, 93.0%, 82.8%, and 86.5%, respectively. Bevacizumab, to exploit the angiogenesis pathway (vascular endothelial growth factor; VEGF is overexpressed in about two-thirds of NPC patients), has been studied in a phase II trial where the agent was added to the standard chemoradiotherapy schedule and demonstrated promising results.[253] Lee et al. reported, with a median follow-up of 2.5 years, a 2-year OS, locoregional progression-free survival, distant

metastasis-free survival, and progression-free survival of 90.9%, 83.7%, 90.8%, and 74.7%, respectively.

Adjuvant Chemotherapy

Although good efficacy and tolerability have been shown for select alternative regimens, the greatest body of evidence for concurrent CRT has been with the CDDP-based US Intergroup regimen of concurrent plus adjuvant chemotherapy. Nevertheless, it is unknown whether the adjuvant chemotherapy component of the US Intergroup regimen contributed to its survival benefit.

Compliance with adjuvant chemotherapy can be especially difficult, as patients are recovering from the acute effects of CRT. Randomized trials comparing RT alone to RT plus adjuvant chemotherapy have all been negative to date.[245,246] Moreover, there are data to suggest a survival benefit for concurrent CRT without adjuvant chemotherapy.[225,227]

In 2011, Chen et al.[254] reported a randomized trial that compared concurrent CRT to concurrent CRT plus adjuvant chemotherapy (CDDP/5-FU) in 508 patients. With a median follow-up of 38 months, there were fewer failures at any site in the concurrent chemoradiotherapy plus adjuvant chemotherapy group versus the chemoradiotherapy group only (14% vs. 16%); however, this difference was not statistically significant (P = .13). It is important to note that this trial was not designed as a noninferiority trial against the standard. In addition, compliance was an issue in this study, where about 18% of patients randomized to the adjuvant arm did not receive adjuvant chemotherapy.[254] Until further data emerges, adjuvant chemotherapy is considered by many to be optional in the setting of concurrent CRT. In light of these conflicting data, a biomarker such as posttreatment EBV DNA to help stratify patients for treatment with adjuvant chemotherapy versus observation would be extremely valuable. As discussed above, this is currently being investigated in the NRG Oncology HN001 trial, which randomizes patients with undetectable post-CRT EBV DNA to observation versus standard adjuvant chemotherapy consisting of cisplatin and 5-FU.

Neoadjuvant Chemotherapy

The role of adding neoadjuvant chemotherapy prior to concurrent CRT remains undefined but is an area of great interest, given predominantly distant pattern of failure experienced among patients with locally advanced NPC. Figure 44.20 demonstrates the potential value of induction chemotherapy in tumor control.

Until recently, only phase II data existed regarding the use of induction chemotherapy in this setting. However, the results of three large phase III randomized trials were recently published. In a multicenter phase III study conducted by Sun Yat-sen University, 480 patients with stage III to IVB NPC were randomized to cisplatin chemoradiation with or without docetaxel, cisplatin, and fluorouracil induction therapy.[255] With median follow-up of 45 months, patients treated with induction chemotherapy had significantly improved 3-year failure-free survival (80% vs. 72%, $P = .034$), overall survival (92% vs. 86%, $P = .029$), and distant failure-free survival (90% vs. 83%, 0.031). Overall toxicity was higher in the induction arm, with 73% versus 54% of patients in the CRT alone arm experiencing a grade 3 or 4 adverse event ($P < .0001$). In another phase III multicenter trial reported by Cao et al.,[256] 476 patients were randomized to cisplatin chemoradiation with or without cisplatin and fluorouracil induction therapy. Patients treated with induction chemotherapy had significantly higher 3-year disease-free survival (82.0% vs. 74.1%, $P = .028$) with a strong trend for improved 3-year distant failure-free survival (86.0% vs. 82.0%, $P = .056$); however, there was no difference in overall survival, and toxicity was significantly increased during concurrent chemoradiation in patients who received induction.

The preliminary results of a phase III trial, organized by the Hong Kong Nasopharyngeal Cancer Study Group (NPC-0501), were recently reported. This study by Lee et al.[257] randomized 706 patients to one of three arms: (1) CDDP/5-FU induction chemotherapy plus concurrent CDDP-RT, (2) concurrent CDDP-RT plus adjuvant CDDP/5-FU, or (3) CDDP/capecitabine induction chemotherapy plus concurrent CDDP-RT. In addition, patients in each of these three arms were randomized to either conventional or accelerated RT. Because of the multiarmed design, patient numbers were limited in each of the six arms. Overall, the benefit of induction chemotherapy with respect to OS remains uncertain; however, the capecitabine induction arm demonstrated an improved toxicity profile that may inform future studies. Additional phase III trials are ongoing, and the OS results from the Sun Yat-sen trial must be confirmed in other studies before induction chemotherapy can be considered standard in the treatment of locally advanced NPC.

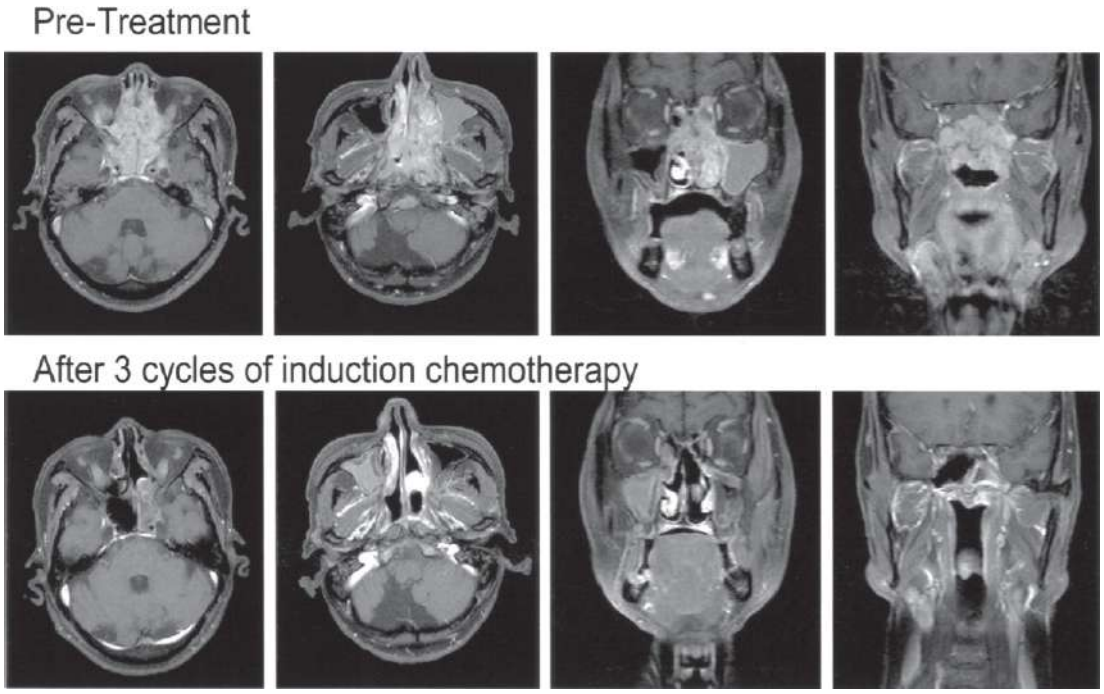

FIGURE 44.20. Magnetic resonance imaging showing shrinkage of primary tumor by induction chemotherapy using cisplatin and 5-fluorouracil before proceeding to concurrent cisplatin and radiotherapy. (Reprinted from Lee AW, Lau KY, Hung WM, et al. Potential improvement of tumor control probability by induction chemotherapy for advanced nasopharyngeal carcinoma. *Radiother Oncol* 2008;87[2]:204–210. Copyright © 2008 Elsevier Ireland Ltd. PERSISTENT/RECURRENT NPC

Because long-term survival can be achieved for a substantial proportion of patients with early locoregional recurrence and useful palliation for those with extensive disease, aggressive salvage treatment is usually advocated. Several approaches can be used successfully, including surgery, brachytherapy, and EBRT. Chemotherapy is generally used in conjunction with local treatment in patients with advanced disease.

Early Detection and Diagnosis

Although progress in surgical and reconstructive techniques and radiotherapy delivery methods has led to improvements in the control rate for primary treatment of NPC, local failure remains a problem for patients with advanced T category. Distinction should be made between persistent disease (tumors that do not completely regress following primary treatment) and recurrent disease (tumors that re-emerge after initial complete regression) because the prognoses and therapeutic considerations are different, with better survival and control rates

for persistent disease.[258]

As tumors regress at different rates following RT, one difficult decision is when to consider residual tumors as genuine persistence and proceed with salvage treatment. In one prospective study by Kwong et al.,[259] serial biopsies of the nasopharynx were performed on 803 patients after RT treatment to observe the time course of histologic remission for NPC and determine its prognostic significance. The 5-year L-FFR was 82% for patients who achieved early histologic remission (<5 weeks) and 77% for those with delayed remission (5 to <12 weeks), but only 40% for those with persistent disease at 12 weeks, despite subsequent salvage treatment.[259] Thus, although delayed histologic remission was not a poor prognostic factor, positive biopsies beyond 12 weeks did indicate poor prognosis. The optimal time for intervention remains uncertain, but because it is important to avoid both unnecessary overtreatment and excessive delay in treatment, the authors recommended an observation period of 10 weeks before additional treatment.[259]

Early detection of locoregional failure is crucial for a better chance of salvage, and regular follow-up after completion of primary treatment is recommended. Frequently used methods include manual palpation, rigid nasopharyngeal endoscopy and nasopharyngeal biopsies, imaging techniques (e.g., CT and MRI), and serologic tests (e.g., anti-EBV titers, plasma EBV DNA levels).

Nasopharyngoscopy is more sensitive than CT and MRI in detecting tumor persistence/recurrence and is the preferred method for initial screening.[260,261] If a patient presents with suspicious endoscopic findings or elevated anti-EBV titers, a nasopharyngeal biopsy is performed to confirm diagnosis. CT or MRI is performed upon a confirmed diagnosis to delineate the tumor extent.[262] Although MRI has limitations in separating tumor recurrence from radiation fibrosis,[263] it is superior to CT in demonstrating extent of soft tissue tumors, as well as identifying submucosal infiltration, marrow infiltration in the skull base, perineural invasion, and intracranial spread.[260,264,265]

Technetium-99m methoxyisobutylisonitrile (MIBI) single-photon emission computed tomography (SPECT) may be a useful tool for differentiating persistent or recurrent tumor from radiation fibrosis[266] and was shown by Kostakoglu et al.[267] to be superior to MRI performed at 3 to 6 months post-RT in diagnosing complete response. The advent of FDG-PET is another valuable development. FDG-PET and MRI were compared in 67 NPC patients 4 to 70 months after completion of RT and found FDG-PET superior to MRI in all

aspects in detection of local recurrence, with increased sensitivity (100% vs. 62%) and specificity (93% vs. 44%).[268] It may also contribute useful information to questionable findings on MRI.[269,270]

Paraneoplastic syndrome (PNS) can signal a silent neoplasm and may precede the clinical manifestation itself of persistent or recurrent NPC. PNS can follow the course of the tumor and can sometimes be used to diagnose recurrence and monitor its evolution with the most common dermatologic manifestation being dermatomyositis and the syndrome of inappropriate antidiuretic hormone secretion (SIADH) being a common endocrinologic presentation.[271]

Circulating cell-free DNA of EBV may be another useful tool for early detection of treatment failure. A longitudinal study by Lo et al.[120] showed that elevation of EBV DNA levels was noted in patients with relapse up to 6 months before detectable clinical disease. In addition, EBV DNA copy number has been shown to predict margin status postsalvage nasopharyngectomy. Wei et al.[272] reported that in early recurrent NPC patients with elevated EBV DNA copies, surgical resection reduced the copy number of EBV DNA postoperatively and that negative surgical margins are associated with zero EBV DNA copies postoperatively.

The incorporation of plasma EBV DNA measurements as screening prior to PET in detecting posttreatment failures of NPC has been investigated. In a prospective study by Wang et al.,[128] 245 NPC patients in remission were monitored prospectively via plasma EBV DNA assay every 3 to 6 months, where 36 patients with abnormal EBV DNA tests and 5 patients with clinical suggestion signs of recurrence, but undetectable EBV DNA levels, underwent FDG-PET scans. Elevated EBV DNA levels correctly predicted all 36 recurrences, whereas the 5 patients who presented with clinical signs suggestive of recurrent disease but with undetectable EBV DNA levels did not have recurrent disease. The authors concluded that plasma EBV DNA appears to be a useful biomarker for posttreatment surveillance in NPC.

Meanwhile, the clearance rate of plasma EBV DNA during the first month of chemotherapy has also been found to predict tumor response and patient survival in 30 patients with recurrent NPC and may have potential as an early prognostic marker to help guide salvage treatment.[126]

Additional Radiation for Persistent Disease

Excellent results have been reported when using brachytherapy for locally persistent disease after a full course of EBRT (Table 44.15, part A), with 5-year

L-FFR in the range of 87% to 95% for patients with initial T1 tumors (AJCC 2002 T1-2a).[212,258,273,274,276] Preliminary evidence suggests that patients with disease persisting from initial T2 tumors (AJCC 2002 T2b) could also be effectively treated by brachytherapy.[275]

[a]Median dose.
EBRT, external beam radiotherapy; HDR-ICB, high–dose-rate intracavitary brachytherapy.

Stereotactic RT is a valuable alternative for delivering additional EBRT. Yau et al.[278] studied 755 patients with T1-4 tumors and found that 7% had positive biopsies 8 weeks after completion of primary RT. Twenty-one patients were treated with fractionated stereotactic RT to a median dose of 15 Gy and achieved a 3-year L-FFR of 82%, which was similar to the corresponding L-FFR of 86% in the complete responders and was significantly better than the corresponding L-FFR of 71% in 24 patients treated with high–dose rate brachytherapy to a median dose of 20 Gy.

Reirradiation for Recurrent Disease

Various radiation therapy modalities are used to treat recurrent NPC, including intracavitary brachytherapy, external beam irradiation, interstitial implantation, particle beam radiotherapy, and stereotactic radiosurgery (Table 44.16).[195,200,201,203,204,291] IMRT has also been used with excellent preliminary results, with control rates of up to 100% for rT1-3.[287]

The most important prognostic factors are the TNM stage of the tumor at the time of recurrence and reirradiation dose. Thorough restaging, including metastatic workup, is necessary. A study of 891 patients with local recurrence from 1976 to 1985 by Lee et al.[292] showed that only 32% of reirradiated patients achieved local salvage, with 54% developing regional and/or distant failure. Most series using conventional 2-D technique showed that doses ≥60 Gy were associated with better outcome.[195,201,281,282] For IMRT, 60 to 70 Gy is recommended, taking into account factors such as previous radiation amount, overlap between previously treated area and target for reirradiation, interval between RT courses, tumor bulk, and whether concurrent chemotherapy will be given.[293]

Lee et al.[294] retrospectively compared the symptomatic late toxicity rate in 487 patients with two courses of EBRT versus 3,635 patients with one course and found that the major determinant of late complications was severity of damage during the initial course and that the sum of total biologic dose tolerated (BED-∑) was higher than expected with a single-course treatment (BED-1). This suggested partial recovery of normal tissue (especially in patients reirradiated after 2 or more years) and higher tolerance for reirradiation when primary treatment was given with better sparing of normal tissues. Assuming an α/β ratio of 3 Gy, the BED-∑ that incurred 20% toxicity at 5 years was 129% that of BED-1.

Brachytherapy has been widely used for treatment of recurrent NPC (Table 44.15, part B) and can be used effectively on its own for early-stage recurrent NPC.[258,273] Using interstitial implants with radioactive gold grains, Kwong et al.[258] reported a 5-year L-FFR of 63%; complications included headache (28%), palatal fistula (19%), and mucosal necrosis (16%). Law et al.[273] achieved excellent local salvage up to 89% using iridium mold, but the complication rate was 53%.

The combination of brachytherapy and EBRT is useful, particularly when conventional 2-D technique is used. Lee et al.[281] showed that patients reirradiated by combined modalities had an improved 5-year L-FFR of 45%

compared with 32% by EBRT alone and 29% by brachytherapy alone. The superiority of the combined method has been supported by other studies.[195,201,277,279] A study from Memorial Sloan Kettering Cancer Center (MSKCC) associated combined modality treatment (CMT), consisting of EBRT followed by brachytherapy, achieved similar L-FFR with previous historical series. CMT also demonstrated fewer late grade 3 or higher events compared with patients receiving EBRT alone (8% vs. 73%, respectively).[288]

2-D, conventional two-dimensional external radiotherapy and/or brachytherapy; 3-D, three-dimensional conformal radiotherapy; IMRT, intensity-modulated radiation therapy; SBRT, stereotactic body radiation therapy.

Stereotactic radiosurgery or fractionated stereotactic radiotherapy is another useful tool for retreatment of local recurrence, as it allows for rapid falloff of radiation dose outside tumor volume and near surrounding critical structures and can be used either alone for smaller lesions or in combination with EBRT for larger ones. Control rates ranging from 53% to 86% have been reported.[295–298] For advanced recurrence with extension beyond the nasopharynx, this method offers better dose coverage than brachytherapy. A higher salvage rate from adding stereotactic radiation as a boost after EBRT has been reported.[284,296,299] Although most series reported a low risk of complications, massive hemorrhage with potential fatal outcome has been described.[296] Radiosurgery should thus be avoided when there is direct tumor encasement of the carotid artery or when a high cumulative dose has already been delivered. Fractionated stereotactic radiotherapy has shown improved late toxicity profile compared to 3-D conformal RT[289] and single-dose radiosurgery[300] and may also give better local control rates compared with single-fraction radiosurgery.[301]

Advances in imaging technology and radiotherapy techniques have made it possible to reduce target volume without jeopardizing local control, reducing complication rates. Table 44.17 summarizes the treatment outcome and severe late complications by external beam reirradiation. Past series using 2-D technique achieved 5-year survival rates in the range of 16% to 63%, and the incidence of temporal lobe necrosis ranged from 2% to 27%. The use of 3-D conformal radiotherapy showed improving results. In one study by Chang et al.,[284] none of the patients reirradiated by 3-D technique developed temporal

lobe necrosis compared with 14% of those reirradiated by 2-D technique. Zheng et al.[285] reported a 5-year local salvage rate of 71% from 3-D technique, but the actuarial rate of late toxicities (grade 4) was still as high as 49%.

The use of IMRT for reirradiation has shown very encouraging short-term results. Using IMRT to deliver 68 to 70 Gy, Lu et al.[286] reported 100% salvage rate without any severe late complications in a series of 49 patients with a median follow-up of 9 months. Using IMRT to a median dose of 54 Gy in 31 patients (with or without induction chemotherapy and stereotactic boost), Chua et al.[287] reported a 1-year control rate of 100% for rT1-T3 and 35% for rT4, with late complications (> grade 3) of 25% (at 1 year). Using a median dose of 70 Gy in 70 patients, Qiu et al.[290] reported a locoregional salvage rate of 66% with similar toxicity rate at 2 years. Although rT staging did not predict control rate, original T classification remained a significant adverse prognostic factor and may serve as a strong marker for the underlying locally aggressive biology of the original disease. Longer follow-up is needed to better evaluate treatment results and sequelae resulting from IMRT.

As another alternative, proton-beam therapy (PBT) allows for delivery of radiation therapy dose distributions that are typically more conformal than can be achieved with IMRT. This is due to the physical properties of the proton beam that result in maximal dose delivery at a narrow specified depth in the tissue, a phenomenon known as the Bragg peak. Because of the increased precision, PBT is especially useful in the setting of reirradiation, where it is critically important to minimize overlap of radiation fields from multiple treatments, particularly for the dose to surrounding sensitive organs such as the cranial nerves and brain. An analysis of dose volume histograms from patients who underwent reirradiation with PBT for recurrent NPC found that patients with optimal dose coverage of target volumes experienced significantly improved outcomes (overall survival of 83% for optimal coverage, 17% for suboptimal coverage), highlighting the importance of high-quality radiotherapy for producing good outcomes in the recurrent setting.[304]

A multi-institutional study that included 92 patients who underwent reirradiation with PBT for multiple types of recurrent HNC found a favorable

toxicity profile compared to historical controls of patients retreated with photon techniques.[305] This included a low risk of grade 3+ dermatitis (8.7%) and dysphagia (7.1%). Furthermore, locoregional failure was found to be only 25% at 1 year. However, two deaths occurred as a result of bleeding events, reflecting the increased risk of serious vascular toxicity with a second course of radiotherapy. In all cases, the risks of toxicities associated with retreatment must be weighed against the risk of uncontrolled tumor progression that is usually associated with significant morbidity and impairment in quality of life.

Chemoradiotherapy may also improve treatment outcome for recurrent NPC in certain patients, and most recent salvage radiation series have included cisplatin-based chemotherapy for advanced-stage disease.[287,288,290,306] Using gemcitabine and cisplatin as induction chemotherapy followed by reirradiation with IMRT in 20 patients (95% rT3-4), Chua et al.[287] reported a 1-year local salvage rate of 75%. In a study of 35 patients (66% rT3-4), Poon et al.[306] reported a 1-year EFS of 42% by concurrent cisplatin followed by adjuvant chemotherapy with cisplatin and 5-fluorouracil. However, although concomitant chemoirradiation is increasingly used to treat primary NPC, it remains uncertain whether concomitant chemoirradiation is appropriate for retreatment of purely local recurrences (rT1-2), because of high rates of toxicity and potential complications.

Surgical Treatment

For patients with persistent nodal disease, radical neck dissection is the preferred treatment for persistent or recurrent lymph node involvement in the neck when there is no distant metastasis[307] and may achieve a 5-year nodal control rate of 66% and disease-free survival rate of 37%.[308] In cases with extension of disease beyond lymph nodes into nearby structures, additional afterloading brachytherapy to tumor bed may improve local control.[309]

Surgical management at the primary site is hampered by difficulties in obtaining adequate exposure and obtaining adequate surgical margins.[146,310–312] Various approaches have been employed, including an infratemporal approach from the lateral aspect[313]; transpalatal, transmaxillary, and transcervical approaches from the inferior aspect[312,314]; and an anterior–lateral approach.[315] More recently, minimally invasive techniques, such as a transnasal approach and an endoscopic approach, have also been employed successfully.[316] Although controversial, salvage surgery by nasopharyngectomy can be a viable option in certain patients in which the disease is localized in the nasopharynx, with

acceptable results reported for rT1-3 tumors.[266] Wei et al.[317] reported a 5-year control rate of 62% and 5-year disease-free survival rate of 49% in 60 patients who received curative resections. Typically, all patients with recurrence have undergone prior radical RT, thereby associated complications of trismus and palatal fistula being common; however, the mortalities associated with these surgical procedures are low.

Recurrent NPC is frequently located in the pharyngeal recess on the lateral wall. Access to this region is crucial for complete tumor extirpation. Wei and Sham[318] advocated the anterior–lateral approach or maxillary swing approach for localized recurrence in the nasopharynx. After facial incisions and the necessary osteotomies, the maxilla bone is swung laterally while remaining attached to the anterior cheek flap as one osteocutaneous entity (Figs. 44.21 and 44.22). The nasopharynx with the tumor and its surrounding area including the paranasopharyngeal region are then widely exposed for resection. Upon completion of nasopharyngectomy, the maxilla is replaced and attached to the remainder of the facial skeleton with miniplates.

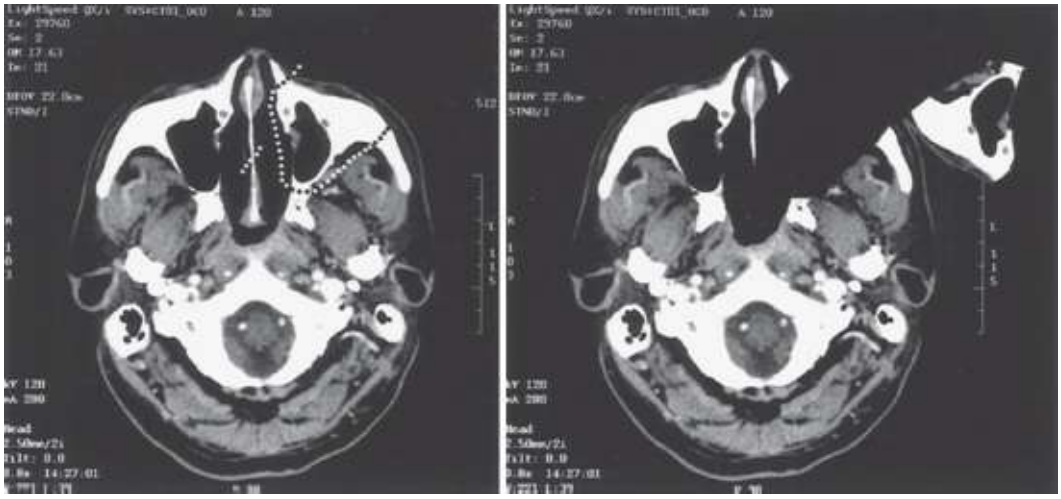

FIGURE 44.21. A: Computed tomography shows planned osteotomies of the maxilla and the posterior part of the nasal septum (*broken line*). **B:** The maxilla is swung laterally while still attached to the anterior cheek flap.

Wei et al.[315] reported 161 patients with salvage nasopharyngectomy employing this approach performed at Queen Mary Hospital (Hong Kong) for recurrent NPC following primary treatment by radical RT. Twelve patients had prior brachytherapy as a salvage procedure. All patients were recurrent stage T1 with 78% of these patients achieving negative tumor resection margins, confirmed by frozen section, with the remaining patients demonstrating

microscopic tumor at the internal carotid artery or the skull base during surgery, making further complete resection unattainable. All patients recovered from this anterior–lateral approach and were discharged. Regarding treatment-associated morbidities, trismus of varying grades was present in 60% and palatal fistula in 25% of patients. Recent modification of the palatal incision has eliminated the problem of palatal fistula.[319]

FIGURE 44.22. The left maxilla is swung laterally, exposing the nasopharynx (*arrow*).

Satisfactory long-term results can be achieved when persistent/recurrent tumor is completely resected. Several recent surgical series reported locoregional control and OS rates of 40% to 72% and 30% to 54%, respectively.[316,320–322] Postoperative reirradiation is recommended for patients with positive surgical margins and/or advanced disease[317,323,324] and may be beneficial even when surgical margins are negative.[266]

For recurrent tumors, margin status, adjuvant treatment type, and parapharyngeal space involvement were significant prognostic factors for local control, whereas dura or brain involvement, local recurrence, and adjuvant treatment type predicted survival.[316] Preoperative EBV DNA levels and PET-CT can assist in predicting the outcome of salvage nasopharyngectomy, and PET-CT may predict the presence of extracapsular spread of metastatic lymph nodes.[325]

RESULTS OF TREATMENT

Specific results of various treatments are mentioned in the previous respective sections. This section focuses on summarizing these results.

The local and regional control rates in select conventional radiotherapy series are listed in Tables 44.18 and 44.19. Control of the primary lesion using conventional radiotherapy varied with the T classification (Table 44.18), ranging

from 64% to 97% for T1 lesions, 54% to 94% for T2 lesions, 34% to 100% for T3 lesions, and 40% to 71% for T4 lesions.[27,31,32,148,149,326,327] Dose escalation with intracavitary brachytherapy if using non-IMRT treatment techniques[196] has been shown to improve local control. Stereotactic radiosurgery boost after external beam radiotherapy (both conventional and IMRT) has also shown improved local control.[328,329] Nonkeratinizing squamous cell carcinoma (both differentiated and undifferentiated subtypes) had improved local control rates when compared to keratinizing squamous cell carcinoma in T2 to T3 lesions but not in T1 or T4 lesions.[27,224,238]

[a]Estimated from survival curve.
OS, overall survival.

Excellent nodal control rates in the neck have been demonstrated by conventional radiotherapy even after involvement of extensive cervical lymph node metastasis (Table 44.19). The neck nodal control rates ranged from 82% to

100% for N0, 86% to 92% for N1, and 78% to 89% for N2 to N3 disease.[27,32,149] Five-year survival rates ranged from 36% to 58% (Table 44.20).[27,31,32,149,326,327,330]

The 5-year survival rate with conventional non-IMRT radiotherapy correlated with the T-stage, as well as with the N-stage (Table 44.21), being 60% to 76% for T1, 48% to 68% for T2, 27% to 55% for T3, and 0% to 29% for T4 lesions[32,326] and 42% to 78% for N0, 27% to 70% for N1, and 32% to 52% for N2 to N3 disease. When nodes in the lower neck and/or the supraclavicular fossa are involved, prognosis is poor.

Contemporary series with IMRT, demonstrated excellent local and regional control was achieved in 97% and 98% of the patients treated at UCSF, respectively.[169] An update of the UCSF experience continued to show excellent local control of approximately 96%.[180] Subsequently, several other institutions also recently published their results, which further demonstrate excellent local control rates ranging from 82% to 100% and regional control rates ranging from 91% to 98% (Table 44.22).[153,172–174,182,184–186,252,253,331,332,334–340]

The RTOG conducted a phase II trial using IMRT+/- chemotherapy in the treatment of nasopharyngeal carcinoma where patients with ≥T2 (i.e., ≥T2b by AJCC 2002) and/or node-positive disease also received concurrent CDDP followed by adjuvant CDDP and 5-FU chemotherapies. The results showed that a multi-institutional setting can reproduce the excellent results (local control rate of 92.3%) observed from single-institution studies.[331] This reproducibility of

excellent locoregional control rates in a multi-institutional trial, along with several single-institution studies, with IMRT is encouraging; however, distant metastases remain a therapeutic challenge despite extensive use of chemotherapy. The distant recurrence rate ranges from 10% to 15% at 2 years[185,331] and 4-year rates are as high as 34% (Table 44.22).[169] Novel systemic therapies or regimens are needed for improved distant control and overall survival of this disease.

SEQUELAE OF TREATMENT

Overall Incidence and Types

Because of the anatomic proximity of the nasopharynx to critical structures, and the need for high-radiation doses and adequate field coverage, the risks of radiation-induced toxicities are substantial. The overall complication rate from conventional treatment ranged from 31% to 66%, with severe sequelae including temporal lobe necrosis, hearing loss, xerostomia, neck fibrosis, cranial nerve dysfunction, endocrine dysfunction, soft tissue necrosis, osteonecrosis, and transverse radiation myelitis.[28,32,39] The diagnosis of irradiation injury can be difficult, as other possible causes (tumor recurrence in particular) must be excluded.

[d]Bone necrosis, fracture, or osteomyelitis.
[e]Cataract, retinitis, corneal ulcer.
NR, not reported.

The toxicity results of five major series using conventional irradiation for NPC are summarized in Table 44.23.

The series of 378 patients treated at MDACC during 1954 to 1992 showed an actuarial frequency rate in grade ≥4 toxicity of 16, 19, and 29% at 5, 10, and 20 years, respectively.[28] Despite the use of higher-radiation doses, Sanguineti et al. showed a reduction in the 10-year actuarial rate of severe toxicity from 14% in 1954 to 1971 to 5% in 1983 to 1992.[28] Other investigators have reported similar findings.

The decreased rates of complications over time were likely due to the use of newer oblique and opposed lateral field techniques instead of single central field, custom blocking, and image-guided (CT) treatment planning.[28]

Because of the extremely narrow therapeutic treatment margin of NPC, maximum conformity and precision in RT delivery are crucial for minimizing the risk of late damage. The emergence of IMRT is a major advance for improving physical dose distribution and has increased the potential for protecting normal tissues. Studies on patients treated with IMRT thus far have shown substantial sparing of salivary function,[169,173,174] whereas other benefits will require longer follow-up to confirm.

The improved conformity offered by IMRT has led to attempts at dose escalation in order to achieve better tumor coverage for patients with extensive locoregional infiltration. However, studies have shown that dose escalation together with concurrent chemotherapy may lead to severe toxicities.[182,341] Furthermore, extensive use of concurrent CRT independent from incorporation of dose escalation has been shown to significantly increase toxicities (grade ≥3) compared to RT alone.[222,224,228,230,231,342,343]

Temporal Lobe Necrosis

Temporal lobe necrosis (TLN) is perhaps the most troublesome complication. Studies on NPC patients treated with conventional 2D-RT found that TLN accounted for up to 65% of all irradiation-induced deaths; large fractions (>2 Gy) and overacceleration of treatment schedule greatly increased risk, with

incidence as high as 33%.[39,151,152]

Diagnosis of TLN was often difficult and thus delayed. In Lee et al.'s examination of 102 patients with late TLN following conventional 2D-RT,[344] only 31% presented with classic symptoms of TLN (hallucinations, absence attacks, déjà vu), whereas 14% had headaches, confusion, convulsions, or hemiparesis. Thirty-nine percent had vague symptoms of dizziness, poor memory, or sudden changes in behavior, whereas 16% were asymptomatic.

TLN remains a serious concern in patients treated with IMRT, with incidence of 3% to 4% being reported for schedules of 70 Gy at 2.12 Gy/fraction,[180] 66 to 74 Gy at 2 Gy/fraction,[174] and 76 Gy at 2.17 Gy/fraction.[182] Series using larger fractions (70.2 at 2.34 Gy/fraction and 68 Gy at 2.27 Gy/fraction) had incidence rates as high as 12% to 14%.[153,336] According to Bakst et al.,[153] a prospective trial of hypofractionated dose-painting IMRT using 2.34-Gy fractions to deliver a total dose of 70.2 Gy had favorable disease control and survival outcomes; however, 12% of treated patients developed temporal lobe necrosis, with the conclusion that large fractional doses should be avoided to prevent infield brain radiation necrosis.

Cranial Neuropathy

Cranial nerves IX through XII, particularly XII, are the most frequently impaired by radiation.[39,303,345] This is related to marked radiation fibrosis, especially in patients who receive an additional boost dose to the parapharyngeal space. Common symptoms include slurring of speech, twitching of neck muscles, and/or dysphagia. In a study of 31 NPC patients with post-RT dysphagia, Wu et al.[346] found that 77% aspirated after the act of swallowing, raising concerns of fatal aspiration pneumonia.

Cranial nerve VI is also frequently affected, particularly in patients with TLN, whereas isolated palsy of branches of cranial nerve V is less common.[39] Optic neuropathy is rare with careful attention to the RT technique and should be considered when treating lesions with base-of-skull involvement.[347] The possibility of intracranial recurrence may confound the diagnosis of radiation injury, and exclusion of recurrence is necessary.

Oral Complications

Xerostomia is an almost universal complication from treatment with conventional RT and may lead to dental caries. Jen et al.[348] showed that the salivary flow dropped by half with a dose of 7.2 Gy, reached the nadir after 36

Gy, and then further dropped after completion of RT without recovery during the following 2 years.

However, Lee at al.[169] reported marked recovery of salivary function in patients treated with parotid-sparing IMRT (mean parotid dose, 34 Gy); the rate of grade 2 xerostomia decreased from 64% at 3 months to 2.4% at 2 years. Randomized trials comparing 2D-RT and IMRT in patients with T1-2 tumors have confirmed IMRT's advantage in this regard.[349,350] Nevertheless, it is important to rule out tumor invasion of the parotid gland prior to parotid-sparing IMRT, as recurrences have been reported. Cannon and Lee[351] concluded that PET alone may be insufficient for detection of intraparotid lymph node involvement in patients with multilevel nodal disease, including disease in level II nodes. Even with negative PET findings, these patients may require additional evaluation of any benign-appearing parotid nodules before parotid-sparing IMRT by FNA or CT-guided biopsy.

Dental sequelae frequently accompany xerostomia. In a series of 1,758 patients, 2.7% developed osteoradionecrosis at the maxilla and 1.7% at the mandible. Tong et al.[352] reported a 29% complication rate in patients who had post-RT extraction of posterior maxillary teeth, with 10.5% developing osteonecrosis. Prophylactic fluoride treatment should be employed to prevent dental decay, and decayed teeth should be extracted prior to RT to reduce this risk.[352,353]

Aural Toxicity

Hearing loss has always been a common radiation sequela, and the increasing use of cisplatin-based concurrent CRT has resulted in deafness rates as high as 42%.[354]

Sensorineural hearing loss (SNHL), particularly in the high-frequency range, was found in at least 30% of patients assessed with audiograms following RT, with higher rates in patients treated by concurrent CRT.[39,355–357] The primary determinant of high-frequency SNHL is mean cochlea dose, which should be kept below 48 Gy to minimize damage.[39,355–357] Because of the location of the primary tumor in the nasopharynx, pharyngotympanic tube (*Eustachian tube*) damage resulting in otitis media is difficult to avoid. However, lowering the dose to the external auditory canal and mastoid air cells can reduce the incidence and severity of acute external otitis and chronic serous otitis media, respectively.

Carotid Artery Injury

Carotid stenosis is a potentially fatal complication reported in patients who undergo irradiation of the head and neck region. Interval from radiotherapy was a significant independent predictor for severe carotid stenosis. Some have advocated for routine duplex ultrasound screening for high-risk patients (older than 60 years, smoking, hypertension, hypercholesterolemia, cerebrovascular symptoms).[358,359] Severe cases may require carotid endarterectomy or endoplasty.

Massive bleeding from ruptured pseudoaneurysms at the petrous portion of the internal carotid has been reported following IMRT with dose escalation.[182,360] Urgent diagnosis and intervention with endovascular occlusion or stenting may be needed to prevent fatal consequences. Other concerns include severe telangiectasia and hypervascularization in the internal maxillary artery territory, for which emergency embolization may be considered.

Endocrine Dysfunction

The most common endocrine sequelae are amenorrhea and/or galactorrhea from hyperprolactinemia in female patients and followed by hypothyroidism and hypoadrenalism.

Lee et al.[39] observed symptomatic hypothalamic–pituitary dysfunction in 5% of patients, with a median latency of 5 years, whereas a longitudinal study by Lam et al.[361] with detailed endocrine assessment found a 5-year incidence of 62%, with dysfunction detected as early as 1 year following RT.[362] The deficiency of releasing of inhibitory factors indicated that the hypothalamus is the primary location of damage.[363,364] As many of these dysfunctions may be corrected pharmacologically, routine evaluation of hypothalamic, pituitary, and thyroid function should be considered in the follow-up examination of long-term survivors.

Shielding may help lessen endocrine dysfunction when using 2-D technique.[365] The need for maximum conformity to protect normal tissues during radiotherapy is paramount.

Second Malignancies

Radiation-induced malignancy is rare, with an incidence of 0.04% and latency period >10 years. The most common histologic types are maxillary osteosarcoma[366] and soft tissue sarcoma.[79] Surgery presents the only chance of cure, but the prognosis is often poor. Although second primary head and neck cancer is relatively uncommon for NPC patients, Teo et al.[367] reported an

excessive incidence rate of tongue cancer at 0.13% per patient-year. The possibility of radiation carcinogenesis cannot be excluded.

CHAPTER 45

Cancer of the Nasal Cavity and Paranasal Sinuses

Steven J. Frank, Anesa Ahamad, and Carlos A. Perez

This is an update of a previous chapter published by Frank et al. in the 6th edition of Principles and Practice of Radiation Oncology.[1]

ANATOMY

Nasal Cavity

The nasal cavity extends from the hard palate inferiorly to the base of the skull superiorly. It is above and behind the vestibule and is defined anteriorly by the transition from the skin to mucous membrane and posteriorly by the choanae, which open directly into the nasopharynx.[2] The nasal cavity consists of four subsites: the nasal vestibule, the lateral walls, the floor, and the septum.

The *nasal vestibule* is the triangular space located inside the aperture of the nostril as a slight dilation that extends as a small recess toward the apex of the nose. It is defined laterally by the alae; medially by the membranous septum, the distal end of the cartilaginous septum, and columella; and inferiorly by the adjacent floor of the nasal cavity. It is lined by the skin containing hairs and sebaceous glands; therefore, tumors at this location are often those that arise from the skin, usually squamous cell cancers[3], but may occasionally be basal cell carcinoma,[4] sebaceous carcinoma,[5] melanoma,[6] or non–Hodgkin lymphoma.[7]

The *lateral walls* correspond with the medial walls of the maxillary sinuses and consist of thin bony structures that have three shell-shaped projections (superior, middle, and inferior conchae or turbinates) into the nasal cavity. The *floor* extends from the vestibule to the nasopharynx above the hard palate of the maxilla. The *septum* divides the nasal cavity into right and left halves.

Paranasal Sinuses

The paranasal sinuses are named according to the bones in which they are

located: the ethmoid, maxilla, sphenoid, and frontal.

Ethmoid Sinuses

The ethmoid sinuses are composed of several small cavities, the ethmoid air cells, within the ethmoid labyrinth located below the anterior cranial fossa and between the nasal cavity and the orbit. They are separated from the orbital cavity by a thin, porous bone, the *lamina papyracea*, and from the anterior cranial fossa by a portion of the frontal bone, the *fovea ethmoidalis*. They are in close proximity to the optic nerves laterally and the optic chiasm posteriorly. The ethmoid sinuses are divided into anterior, middle, and posterior groups of air cells. The middle ethmoid cells open directly into the middle meatus. The anterior cells may drain indirectly into the middle meatus via the infundibulum. The posterior cells open directly into the superior meatus.

Maxillary Sinuses

The maxillary sinuses, the largest of the paranasal sinuses, are pyramid-shaped cavities located in the maxillae. The lateral walls of the nasal cavity form the base and the roofs correspond to the orbital floors, which contain the infraorbital canals. The floors of the maxillary sinuses are composed of the alveolar processes. The apices extend toward and frequently into the zygomatic bones. Secretions drain by mucociliary action into the middle meatus via the hiatus semilunaris through an aperture near the roof of the maxillary sinus. Ohngren line is a theoretical plane dividing each maxillary sinus into the suprastructure and infrastructure; it is defined by connecting the medial canthus with the angle of the mandible.

Sphenoid Sinus and Frontal Sinuses

The sphenoid bone forms a midline inner cavity that communicates with the nasal cavity through an aperture in its anterior wall. It is directly apposed superiorly to the pituitary gland and optic chiasm, laterally to the cavernous sinuses, anteriorly to the ethmoid sinuses and nasal cavity, and inferiorly to the nasopharynx. The paired, typically asymmetric frontal sinuses are located between the inner and outer tables of the frontal bone. They are anterior to the anterior cranial fossa, superior to the sphenoid and ethmoid sinuses, and superomedial to the orbits. They usually communicate with the middle meatus of the nasal cavity.

EPIDEMIOLOGY

Cancers of the nasal cavity and paranasal sinuses are relatively uncommon. Fewer than 7,500 cases are diagnosed each year in the United States, an incidence of 0.75 per 100,000.[8] Cancers of the maxillary sinus are twice as common as those of the nasal cavity; cancers of the ethmoid, frontal, and sphenoid sinuses are extremely rare. They generally develop after the age of 40 years, except for esthesioneuroblastoma (ENB), which has a unique bimodal age distribution[9] and occurs twice as often in men than in women.[10] These tumors are most common in Japan and South Africa.

The etiologic factors vary by tumor type and location. Adenocarcinomas of the nasal cavity and ethmoid sinus have been reported to occur more frequently in carpenters and sawmill workers who are exposed to wood dust.[11,12] Synthetic wood, binding agents, and glues may also be involved as cocarcinogens.[13] Squamous cell carcinomas (SCCs) of the nasal cavity have been seen more often in nickel workers.[14] Maxillary sinus carcinomas have been associated with radioactive thorium-containing contrast material (thorotrast) used for radiographic visualization of the maxillary sinuses in the past. Occupational exposure in the production of chromium, mustard gas, isopropyl alcohol, and radium also may increase the risk of sinonasal carcinomas.

Cigarette smoking is reported to increase the risk of nasal cancer, with a doubling of risk among heavy or long-term smokers and a reduction in risk after long-term cessation. After adjustment for smoking, a significant dose–response relationship has also been noted between alcohol consumption and risk of nasal cancer.[15]

NATURAL HISTORY

Nasal Vestibule

Nasal vestibule carcinomas can spread by direct invasion of the upper lip, gingivolabial sulcus, premaxilla (early events), or nasal cavity (late events), as shown in Figure 45.1. Vertical invasion may result in septal (membranous or cartilaginous) perforation or alar cartilage destruction. Lymphatic spread from nasal vestibule carcinomas is usually to the ipsilateral facial (buccinator and mandibular) and submandibular nodes. Large lesions extending across the midline may spread to the contralateral facial or submandibular nodes. The incidence of nodal metastasis at diagnosis is approximately 5%.[16,17] Without elective nodal treatment, approximately 15% of patients develop nodal relapse.

Hematogenous metastases are rare.

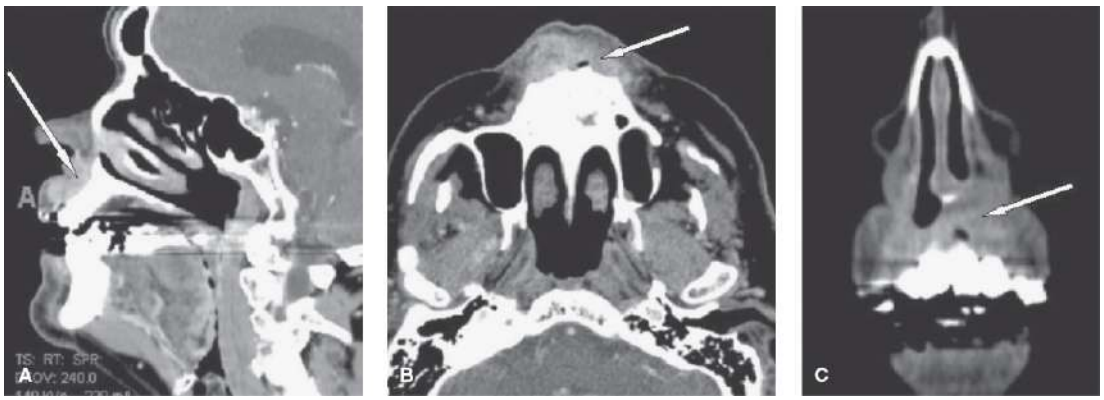

FIGURE 45.1. Computed tomography scans of a nasal vestibule SCC that has spread by direct invasion of the upper lip (*arrow* in **A**) and gingivolabial sulcus and premaxilla (*arrow* in **B** and **C**).

Nasal Cavity and Ethmoid Sinuses

The pattern of contiguous spread of carcinomas varies with the location of the primary lesion. Tumors arising in the upper nasal cavity and ethmoid cells can extend to the orbit through the thin lamina papyracea and to the anterior cranial fossa via the cribriform plate, or they may grow through the nasal bone to the subcutaneous tissue and skin. Lateral wall primaries invade the maxillary antrum, ethmoid cells, orbit, pterygopalatine fossa, and nasopharynx. Primaries of the floor and lower septum may invade the palate and maxillary antrum. Perineural extension (typically involving branches of the trigeminal nerve) is seen most often with adenoid cystic carcinomas.

Lymphatic spread of nasal cavity primaries is uncommon, although spread to retropharyngeal and cervical lymph nodes is possible. In a series of 51 patients reported by the University of Texas MD Anderson Cancer Center, only one patient had palpable subdigastric nodes at diagnosis. Of the 36 patients who did not receive elective lymphatic irradiation, two (6%) experienced subdigastric nodal relapse.[18]

The risk of nodal involvement in patients with cancer of the nasal cavity and paranasal sinuses has not been well defined and may vary depending on the histologic subtype. Current decision-making on whether to cover specific nodal regions is based on interpretation of single-institution retrospective analyses.

Ahn[19] in a review of the SEER database from 2004 to 2009 identified 1,811 patients who had local and nodal staging information, with paranasal sinus cancer as their first cancer diagnosis, defined histology (squamous, melanoma,

adenocarcinoma, sinonasal undifferentiated, and ENB), and defined primary site. Of all the patients examined with information on local and nodal extent, 1,578 patients (87.1%) had no gross nodal involvement at presentation. On presentation, level 1 was involved in 5.1%, level 2 in 6.7%, level 3 in 1.8%, level 4 in 1.2%, level 5 in 1.1%, retropharyngeal nodes in 0.7%, parotid nodes in 0.6%, and facial nodes in 0.2% of all patients. Isolated skip metastases to levels 3 or 4 occurred in 0.7% of patients. On presentation, at least 2.5% presented with bilateral or contralateral disease. In patients with SCC of the nasal cavity, there was a clear gradation in nodal risk among patients with T1 versus T4 disease (4% vs. 23%, $P < .001$); this was not evident in patients with melanoma of the nasal cavity, who had a 5% to 10% risk of nodal involvement regardless of local extension. Local extension of SCC of the maxillary sinus did not predict for nodal involvement in a significant manner, although T1 tumors showed an 11% risk of nodal involvement compared to 21% to 24% for T2+ disease. Squamous cell, small cell, and sinonasal undifferentiated carcinoma had higher rates of nodal dissemination at presentation (14.4%, 19.1%, and 25.3%, respectively), compared to adenocarcinoma, ENB, and melanoma (7.1%, 8.7%, 5.8%, respectively). Although confounded by stage and histology, maxillary sinus carries the highest risk (20.6%), followed by frontal/sphenoid (15.4%), ethmoid (11.9%), and nasal cavity (8.5%, $P < .001$).

The issue of appropriate radiation volumes in the treatment of these patients has not been entirely elucidated, although the data suggest that in some with potential higher nodal involvement, it is advisable to electively irradiate regions at risk. However, as noted by Ahn,[19] in the absence of gross neck disease, the low-neck and retropharyngeal nodes do not need to be treated.

Hematogenous dissemination is rare. In the MD Anderson Cancer Center series, for example, distant metastasis to the bone, brain, or liver occurred in only 4 of 51 patients.[20]

The olfactory region is the site of origin of ENB and, occasionally, adenocarcinomas. ENB constitutes approximately only 3% of all intranasal neoplasms. About 250 cases have been reported between 1924 and 1990.[20] The tumor typically is composed of round, oval, or fusiform cells containing neurofibrils with pseudorosette formation and diffusely increased microvascularity.[21]

Esthesioneuroblastoma may be mistaken for any other “small round cell tumor,” that is, a group of aggressive malignant tumors composed of small and monotonous undifferentiated cells that include Ewing sarcoma, peripheral

primitive neuroectodermal tumor (also known as extraskeletal Ewing's), rhabdomyosarcoma, lymphoma, small cell carcinoma (undifferentiated or neuroendocrine), and mesenchymal chondrosarcoma. The clinical presentations of these entities often overlap, but clinicopathologic features and immunohistochemical staining may help in distinguishing among them.

The route of contiguous spread of ENB is similar to that of ethmoid carcinomas. Lymph node involvement and distant metastasis are uncommon at diagnosis.[22,23]

Maxillary Sinuses

The pattern of spread of maxillary sinus cancers varies with the site of origin. Suprastructure tumors extend into the nasal cavity, ethmoid cells, orbit, pterygopalatine fossa, infratemporal fossa, and base of the skull (Fig. 45.2A–C). Invasion of these structures gives lesions of the suprastructure a poorer prognosis. Their treatment is also associated with greater morbidity as a consequence of craniofacial resection or radiation of intracranial and ocular structures. Infrastructure tumors often infiltrate the palate, alveolar process, gingivobuccal sulcus, soft tissue of the cheek, nasal cavity, masseter muscle, pterygopalatine space, and pterygoid fossa (Fig. 45.2D–J).

The maxillary sinuses are believed to have a limited lymphatic supply[24] and a correspondingly low incidence of lymphadenopathy at diagnosis.[25,26] Only 6 of the 73 patients (8%) in the MD Anderson Cancer Center series had palpable lymphadenopathy at diagnosis. The incidence of nodal spread, however, varies with the histologic type (17%, or 5 of 29 patients with squamous cell or poorly differentiated carcinomas, vs. 4%, or 1 of 27 for patients with adenocarcinoma, adenoid cystic carcinoma, or mucoepidermoid carcinoma). The incidence of subclinical disease, as reflected in the rate of nodal relapse in patients who did not receive elective neck treatment, also varies with histologic type (38%, or 9 of 24 patients with squamous cell or poorly differentiated carcinomas, vs. 8%, or 2 of 26 patients with adenocarcinoma, adenoid cystic carcinoma, or mucoepidermoid carcinoma). The cumulative incidence of nodal involvement (gross and microscopic) for patients with squamous cell and poorly differentiated carcinomas is about 30%. The risk of regional recurrence after treatment is 20% to 30% or higher, depending on the extent of disease and elective neck treatment.[27] Ipsilateral subdigastric and submandibular nodes are most often involved. Hematogenous spread is uncommon.

CLINICAL PRESENTATION

Nasal Vestibule

Carcinomas of the nasal vestibule usually present as asymptomatic plaques or nodules, often with crusting and scabbing. Advanced lesions may extend beyond the vestibule and may cause pain, bleeding, or ulceration. Large ulcerated lesions may become infected, leading to severe tenderness that requires anesthesia for complete clinical assessment.

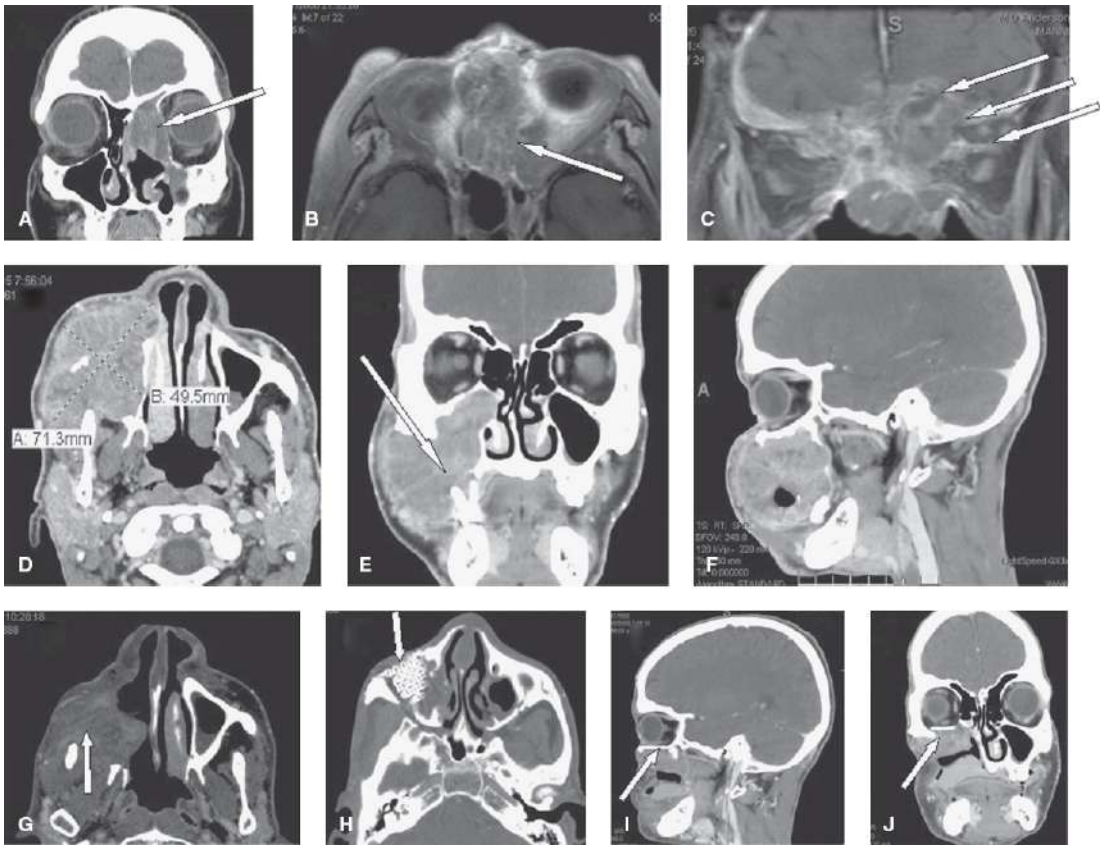

FIGURE 45.2. The pattern of spread of maxillary sinus cancers. **A–C:** Suprastructure tumors are shown, with *arrows* indicating the involvement of the nasal cavity and ethmoid cells **(A)**, the orbit **(B)**, and the base of the skull **(C)**. **D–J:** Advanced tumor is shown, with *arrows* indicating alveolar process destruction with loosening of a tooth **(E)** and abutment of the orbital floor without frank intraorbital invasion **(F)**. The patient had a maxillectomy and orbital floor resection with an anterior–lateral thigh (ALT) flap (*arrow* in **G**), and titanium mesh reconstruction of the orbital floor (**H, I,** and **J**).

Nasal Cavity

Nasal cavity tumors present with symptoms and signs of nasal polyps (e.g., chronic unilateral discharge, ulcer, obstruction, anterior headache, and intermittent epistaxis), hence delaying the diagnosis. Additional symptoms and

signs develop as the lesion enlarges: medial orbital mass, proptosis, expansion of the nasal bridge, diplopia resulting from invasion of the orbit, epiphora because of obstruction of the nasolacrimal duct, anomaly of smell or anosmia from involvement of the olfactory region, or frontal headache because of extension through the cribriform plate.

The common presenting symptoms of ENBs are nasal obstruction and epistaxis. Spaulding et al.[28] found that anosmia could precede diagnosis by many years. Other symptoms are related to contiguous disease extension into the orbit (proptosis, visual field defects, orbital pain, epiphora), paranasal sinuses (medial canthus mass, facial swelling), or anterior cranial fossa (headache) or are due to inappropriate antidiuretic hormone secretion.[28]

Ethmoid Sinuses

The presenting symptoms and signs of ethmoid sinus tumors are central or facial headaches and referred pain to the nasal or retrobulbar region, a subcutaneous mass at the inner canthus, nasal obstruction and discharge, diplopia, and proptosis. In one study of 34 patients with ethmoid sinus cancers treated at MD Anderson Cancer Center between 1969 and 1993,[29] nasal cavity symptoms (nasal obstruction, epistaxis, discharge) were reported in 25 patients (74%), orbital symptoms (diplopia, orbital pain, vision loss, proptosis, inner canthus mass, tearing) in 12 (35%), headache in 6 (18%), and hyposmia or anosmia in 5 (15%).

Maxillary Sinuses

Maxillary sinus cancers usually are diagnosed at advanced stages. Symptoms and signs are facial swelling, pain, or paresthesia of the cheek induced by disease extension to the premaxillary region, epistaxis, nasal discharge and obstruction related to tumor spread to the nasal cavity, ill-fitting dentures, alveolar or palatal mass, unhealed tooth socket after extraction from spread to the oral cavity, and proptosis, diplopia, impaired vision, or orbital pain because of orbital invasion.[30]

DIAGNOSTIC WORKUP

The recommended pretreatment physical, diagnostic, and staging evaluations are listed in Table 45.1.

Physical Examination

Inspection and palpation of the orbits, nasal and oral cavities, and nasopharynx can provide preliminary determination of tumor extent. Bimanual palpation is important in assessing contiguous extension of nasal vestibule lesions and in identifying buccinator and submandibular nodal involvement. Careful examination of cranial nerves is required. Fiber-optic nasal endoscopy after mucosal decongestion and topical analgesia allows assessment of local extent and facilitates biopsy of tumor involving the nasal cavity or nasopharynx.

TABLE 45.1 PRETREATMENT EVALUATION FOR TUMORS OF THE NASAL CAVITY AND PARANASAL SINUSES

General	Complete History and Physical Examination
	Fiberoptic endoscopic examination with biopsies
Radiographic	Computed tomography/magnetic resonance imaging of the primary site and neck
	Chest x-ray; computed tomography of the thorax if adenoid cystic or neuroendocrine carcinoma
Laboratory	Complete blood count
Others	Dental evaluation with extractions/restorations as needed
	Baseline ophthalmologic examination
	Baseline speech and swallowing assessment if surgery is planned

Radiographic Evaluation

Imaging has a crucial role in the staging of sinonasal tumors. Magnetic resonance imaging (MRI) and computed tomography (CT) scans are complementary.[31] MRI is superior at detecting direct intracranial or perineural or leptomeningeal spread.[32] T2-weighted MRI can be helpful in distinguishing tumor (low signal) from obstructed secretions (bright).[33] CT is superior for detecting early cortical bone erosion or extension through the cribriform plate or orbital walls.

MRI, especially T1-weighted with gadolinium contrast, may be used as a supplement or alternative to CT scanning. CT provides the best information about the tumor and its local invasion into surrounding bone structures. MRI allows an estimate of tumor spread into surrounding soft tissue areas, such as the anterior cranial fossa and the retromaxillary space. Bone scintigraphy scan is useful in detecting distant metastases.

The expansile tendency of olfactory neuroblastoma is characterized by bowing of the sinus walls. The destructive aspect is manifested as tumor

replacing the turbinates, septum, and sinus walls with extension into contiguous areas. The density or signal and enhancement characteristics are nonspecific of olfactory neuroblastoma.

Certain features provide clues as to the nature of the tumors in this region. Slowly progressive lesions tend to deform instead of destroy bony structures. Intermediate-grade tumors can cause sclerosis of the adjacent bone. Lymphomas tend to permeate the bone without frank destruction, and carcinomas and sarcomas infiltrate and destroy adjacent bone.

Biopsy

Transnasal biopsy is preferred for tumors arising from or extending into the nasal cavity or nasopharynx. Some paranasal sinus tumors may be more easily sampled using transoral procedures or an open Caldwell-Luc approach.

Laboratory Studies

Complete blood counts and serum chemistries can be used to screen for the presence of distant metastases. Abnormalities of these tests can be further investigated as necessary.

STAGING

The eighth edition of the American Joint Committee on Cancer's (AJCC) *AJCC Cancer Staging Manual* tumor–node–metastasis (TNM) classification includes staging for cancers of the maxillary sinus, the ethmoid sinus, and the nasal cavity.[34] Significant updates from the sixth edition affect classifications of T4 lesions and hence stage IV disease. Specifically, T4 lesions are now considered either T4a (moderately advanced local disease) or T4b (very advanced local disease), which leads to stratification of stage IV disease as either IVA (moderately advanced local or regional disease), IVB (very advanced local or regional disease), or IVC (distant metastatic disease). Definitions of anatomic stage prognostic groupings and TNM classifications are given in Table 45.2.

PATHOLOGIC CLASSIFICATION

Most nasal vestibule cancers are SCCs; the remaining tumors are basal cell or adnexal carcinomas. Most cancers of the nasal cavity and paranasal sinuses are also SCCs, although minor salivary gland neoplasms (adenocarcinoma, adenoid cystic carcinoma, and mucoepidermoid carcinoma) account for 10% to 15% of

lesions in these locations. Melanoma accounts for 5% to 10% of nasal cavity malignancies but is rare in the paranasal sinuses. Neuroendocrine carcinomas of the sinonasal region (including small cell carcinoma, ENB, and sinonasal undifferentiated carcinomas), lymphomas, sarcomas, and plasmacytomas are even less common.

TABLE 45.2 2017 AMERICAN JOINT COMMITTEE ON CANCER STAGING SYSTEM FOR CANCER OF THE NASAL CAVITY AND PARANASAL SINUSES

Definitions of TNM

Primary Tumor (T)	
TX	Primary tumor cannot be assessed
Tis	Carcinoma *in situ*
Maxillary Sinus	
T1	Tumor limited to maxillary sinus mucosa with no erosion or destruction of the bone
T2	Tumor causing bone erosion or destruction including extension into the hard palate and/or middle nasal meatus, except extension to posterior wall of maxillary sinus and pterygoid plates
T3	Tumor invades any of the following: the bone of the posterior wall of maxillary sinus, subcutaneous tissues, floor or medial wall of the orbit, pterygoid fossa, ethmoid sinuses
T4a	Moderately advanced local disease
	Tumor invades anterior orbital contents, skin of the cheek, pterygoid plates, infratemporal fossa, cribriform plate, sphenoid or frontal sinuses
T4b	Very advanced local disease
	Tumor invades any of the following: orbital apex, dura, brain, middle cranial fossa, cranial nerves other than maxillary division of trigeminal nerve (V2), nasopharynx, or clivus
Nasal Cavity and Ethmoid Sinus	
T1	Tumor restricted to any one subsite, with or without bony invasion
T2	Tumor invading two subsites in a single region or extending to involve an adjacent region within the nasoethmoidal complex, with or without bony invasion
T3	Tumor extends to invade the medial wall or floor of the orbit, maxillary sinus, palate, or cribriform plate
T4a	Moderately advanced local disease
	Tumor invades any of the following: anterior orbital contents, skin of the nose or cheeks, minimal extension to anterior cranial fossa, pterygoid plates, sphenoid or frontal sinuses
T4b	Very advanced local disease
	Tumor invades any of the following: orbital apex, dura, brain, middle cranial fossa, cranial nerves other than (V2), nasopharynx, or clivus
Regional Lymph Nodes (N)	

NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single ipsilateral lymph node. 3 cm or less in greatest dimension, ENE neg
N2	Metastasis in a single ipsilateral lymph node, larger than 3 cm but not larger than 6 cm in greatest dimension, or in multiple ipsilateral lymph nodes or contralateral lymph nodes, none more than 6 cm in greatest dimension and ENE neg
N2a	Metastasis in a single ipsilateral lymph node, more than 3 cm but not more than 6 cm in greatest dimension and ENE neg
N2b	Metastasis in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension and ENE neg
N2c	Metastasis in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension and ENE neg
N3a	Metastasis in a lymph node larger than 6 cm in greatest dimension and ENE neg
N3b	Metastasis in any node(s) with clinically overt ENE (ENE positive)
Distant Metastasis (M)	
M0	No distant metastasis
M1	Distant metastasis

PROGNOSTIC FACTORS

Patient-specific factors (primarily prognostic for survival) include age and performance status. Disease-specific factors (primarily prognostic for locoregional control) include location, histology, locoregional extent (reflected in TNM stage), and perineural invasion. Extensive local disease involving the nasopharynx, base of the skull, or cavernous sinuses markedly increases surgical morbidity as well as the risk of subtotal surgical excision. Tumor extension into the orbit may require enucleation, but minimal invasion of the floor or medial

wall may be dealt with through resection and reconstruction, sparing the globe.

GENERAL MANAGEMENT

Nasal Vestibule Tumors

Nasal vestibule tumors can be treated definitively with surgery, primary radiation therapy (RT), or postoperative (adjuvant) RT when indicated because of tumor size or positive surgical findings. For small superficial tumors, standard treatment approaches are surgery or primary RT. Depending on the location and size of the primary tumor, radiation can be delivered as external beam RT, brachytherapy, or a combination of the two. Primary RT may be preferable for nasal vestibule carcinoma for better cosmetic outcome, although surgery can yield high control rates with excellent cosmetic results for selected small superficial tumors. Adjuvant radiation is indicated for cases involving positive surgical margins, positive lymph nodes, or perineural invasion. Cartilaginous invasion is not a contraindication for RT because fractionated treatment carries a low risk of necrosis.[35] For large invasive tumors with extensive tissue destruction and distortion, the combination of surgery and RT, with the radiation given either before or after surgery, is the mainstay of treatment. However, some clinicians favor primary radiation with salvage surgery for this situation.[36] Cosmesis can be enhanced by having experienced prosthodontists design aesthetically satisfactory custom-made nasal prostheses after radical surgery. Patients who are older or who have poor performance status can be treated with RT alone. No role for systemic chemotherapy has been established for tumors of this type.

Nasal Fossa Tumors

Either surgery or primary RT can produce similarly high control rates for early-stage nasal fossa lesions. The choice of treatment modality is generally guided by the size and location of the tumor as well as the anticipated cosmetic outcome. Posterior nasal septum lesions or locally advanced lesions are generally treated surgically, but small anterior–inferior septal lesions (≤1.5 cm) can be treated effectively with interstitial brachytherapy (iridium 192 [^{192}Ir] implant). For lateral wall lesions extending to the nasal ala, primary external beam RT may produce the best cosmetic results.

Paranasal Sinus Tumors

Surgery can produce excellent control rates for T1 and T2 tumors and is generally the mainstay of treatment. The combination of surgery and postoperative RT is the treatment of choice for patients with more advanced but resectable disease who are medically fit to undergo surgery. Maxillary sinus and ethmoid sinus tumors often present as locally advanced disease (large T3 or T4) and are commonly managed with surgery and postoperative RT. Ethmoid sinus carcinomas can be treated with radiation alone or with concurrent chemotherapy to avoid structural or functional deficits. Surgery generally involves medial maxillectomy and en bloc ethmoidectomy; a craniofacial approach is required if tumor extends superiorly to the ethmoid roof or olfactory region.[37,38] Primary RT, with or without concurrent chemotherapy, can be considered for patients who are not fit to undergo surgery owing to significant comorbid conditions or poor performance status or for patients who decline radical surgery.[39]

Early ENB lesions involving the ethmoids with little or no bony destruction or nerve invasion can be treated adequately by high-energy (photon, proton, or electron) RT with good cosmetic and functional results. Those with more extensive local disease benefit from surgery and adjuvant irradiation, although some have advocated against combined surgery and RT because of complications. Patients with locally advanced disease or high-grade tumors should receive aggressive treatment with combined modalities, such as surgery, RT, and chemotherapy. Elective nodal irradiation is not generally recommended for Kadish stage A and B because the incidence of nodal relapse is <15%. Distant metastasis is uncommon (10%) even among patients presenting with locally advanced disease.

CHEMOTHERAPY: NEOADJUVANT AND CONCOMITANT

Neoadjuvant chemotherapy (i.e., chemotherapy given before surgery) can reduce tumor volumes, which may allow a less extensive surgical resection than would be possible otherwise. Similarly, chemotherapy given before primary RT can also reduce tumor volumes and facilitate radiotherapy planning by increasing the distance between tumor borders and critical organ structures such as the brain, chiasm, optic nerve, or spinal cord. Investigations are ongoing to determine whether the response (or lack of same) to neoadjuvant chemotherapy can help in the choice of definitive treatment. For example, if neoadjuvant chemotherapy produces a complete response, then primary RT, with or without chemotherapy, can be considered; a less-than-complete response would prompt surgical

excision of the lesion followed by adjuvant RT.

The optimal treatment strategy for patients with orbital encroachment of sinonasal cancer is controversial. Organ (orbital) preservation with neoadjuvant therapy may determine if patients require an orbital exenteration for locally advanced sinonasal cancer. Yusuf et al.[40] reported on 20 patients determined by a multidisciplinary team to require an orbital exenteration as part of definitive treatment of their sinonasal cancer. Neoadjuvant treatment consisted of concurrent chemoradiation (CRT) in all patients aside from two who refused chemotherapy and underwent RT alone. Six patients received primary surgery followed by adjuvant CRT. Five patients (36%) receiving neoadjuvant therapy had complete disease response at the time of surgery. Fourteen patients underwent orbital preservation (OP). With a median time of follow-up of 18.8 months, actuarial exenteration-free survival was 62% at 2 years for patients undergoing OP. No patients receiving neoadjuvant therapy required an immediate posttreatment orbital exenteration; however, one patient required salvage orbital exenteration when she experienced local failure 35 months after treatment. At 2 years, there were no significant differences in locoregional control (75% vs. 60%, $P = .997$), progression-free survival (40% vs. 36%, $P = .493$), or overall survival (40% vs. 58%, $P = .815$) between patients receiving OP or up-front surgery ($P = .815$). On multivariate analysis, tumor site predicted for locoregional control (maxillary, 86%; nasal cavity, 80%; ethmoid sinus, 40%; $P = .050$). Treatment was well tolerated in both groups. One patient treated with OP experienced grade 3 radiation-related toxicity, developing dysphagia, which improved with medical management. However, one patient developed renal failure following his first dose of cisplatin and subsequently died before completion of treatment.

Concurrent chemoradiation therapy (CRT) can also be used for patients with medical conditions that preclude surgery if those patients have good performance status. Depending on the patient’s performance status and renal function, single-agent cisplatin or carboplatin can be used concurrently with external beam radiation for locally advanced, unresectable SCC. Neoadjuvant chemotherapy or concurrent chemoradiation with etoposide and cisplatin or carboplatin can be used to treat sinonasal undifferentiated carcinoma, neuroendocrine carcinoma, or small cell carcinoma. Chemotherapy is not used routinely for ENB, and its role in the management of this disease is under investigation. Chemotherapy may have a role in the management of Kadish stage C disease, and although responses to chemotherapy have been reported, they are

usually of limited duration.[41] Concurrent chemotherapy during radiation may be considered for inoperable cases.

PALLIATION

Symptoms of incurable sinonasal cancer are particularly distressing. Multidisciplinary input is required even for very advanced cases, as palliation may involve limited surgery, RT, chemotherapy, investigational studies, or best supportive care. The morbidity of each modality must be balanced with the potential benefits in symptom control and improved quality of life. Particular attention is required to address the control of pain and discomfort as a first priority, and the impact of disfigurement and dysfunction, which is often present.

Chemotherapy can be given as single-agent therapy in investigational settings. If RT is given, large doses per fraction are usually given to reduce the duration of treatment. However, if concurrent chemotherapy is added, treatment with 2-Gy fractions should be considered to avoid severe acute effects. Radiation or chemotherapy is often effective in reducing tumor bulk and relieving symptoms associated with disfiguring masses, proptosis, discomfort or neuropathic pain, headache, epistaxis or other bleeding, nasal obstruction or discharge, and trismus.

RADIATION THERAPY TECHNIQUES

Tumors of the Nasal Cavity

Nasal Vestibule Tumors

Target Volumes

For small, well-differentiated lesions that are ≤1.5 cm in diameter, small fields with a 1- to 2-cm margin are appropriate. The initial target volume for all poorly differentiated tumors and well-differentiated primary tumors larger than 1.5 cm without palpable lymphadenopathy should include both nasal vestibules with at least 2- to 3-cm margins around the primary tumor (wider margins for infiltrative tumor) as well as bilateral facial, submandibular, and subdigastric nodes. When lymph node involvement is present at diagnosis, the lower neck is also irradiated. For larger nasal vestibule lesions, the lower half of the nose and the upper lip are treated as well as the regional lymphatics, including the facial lymphatics and upper neck nodes. For postoperative RT, the initial target volume includes the operative bed plus a 1- to 1.5-cm margin and the elective nodal

regions.

Treatment Techniques

External Beam Radiation. Thin superficial nasal vestibule lesions can be treated with orthovoltage x-rays or electrons with skin bolus, whereas thicker lesions are generally treated with electrons, photons, or protons. In definitive therapy, the target volume is treated to a dose of 66 to 70 Gy, with a small reduction in the treatment fields after 50 Gy to boost the dose to the gross disease. For patients presenting with palpable neck adenopathy, the entire neck is treated with at least a subclinical dose of 50 Gy, and the gross disease plus a 1- to 2-cm margin is then treated with an additional 16 to 20 Gy. A technique for external beam irradiation using electrons is illustrated in Figure 45.3. The patient lies supine, immobilized with the neck slightly flexed by using a custom mask to align the anterior surface of the maxilla parallel with the top of the couch. For larger nasal vestibule lesions, the lower half of the nose and the upper lip are treated with an anterior appositional field using 20-MeV electrons and 6-MV photons weighted 4 to 1. Skin collimation is used to minimize scatter irradiation to the eye and reduce the penumbra of the beam and reduce the field size required. Custom beeswax bolus material is prepared to allow a relatively flat surface contour onto which the electron beam is incident, avoiding inhomogeneity because of oblique incidence and surface irregularity. A bolus is also used to fill the nares to avoid the dose perturbation from the air cavity with electron beams. In photon treatments, the bolus is removed to spare the skin unless the overlying skin is involved. An intraoral Cerrobend-containing stent is used to displace the tongue posteriorly and partially shield the upper alveolar ridge. In proton treatments, bolus material is not required and an aperature is used instead of skin collimation to minimize scatter irradiation to the eye and reduce penumbra of the beam.

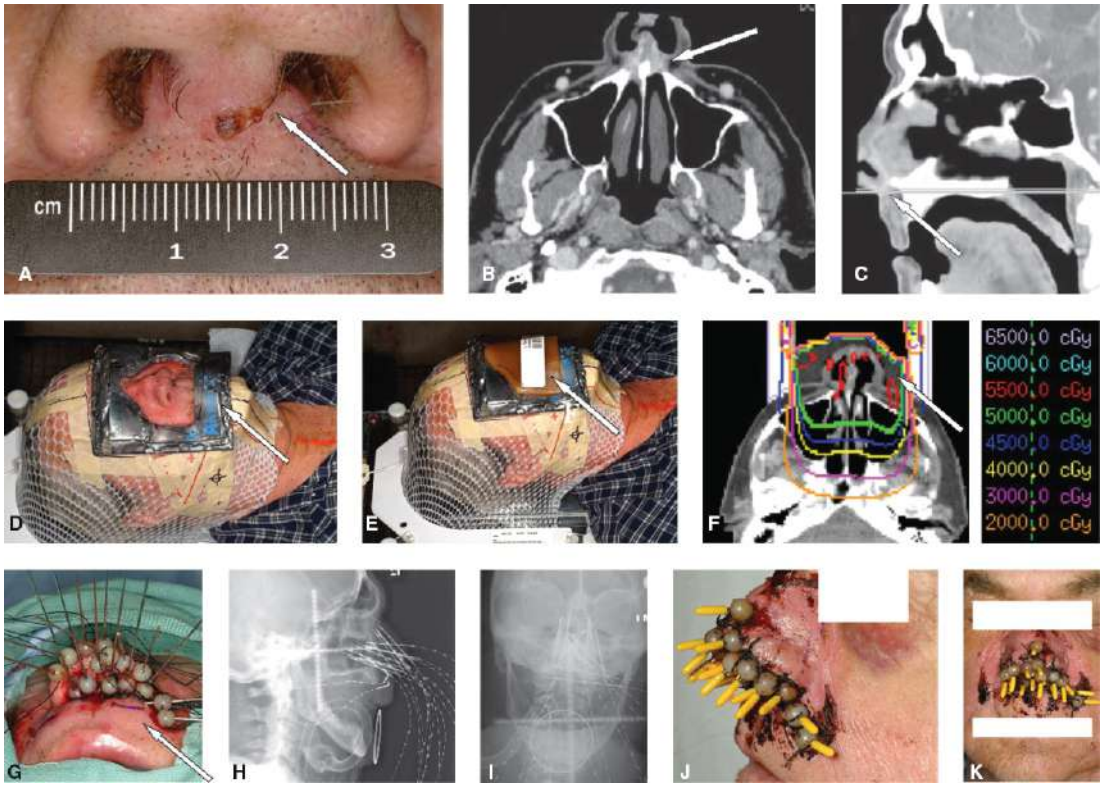

FIGURE 45.3. Nasal vestibule squamous cell carcinoma. **A:** *Arrows* indicate tumor expanding the columella. **B** and **C:** *Arrows* indicate invasion downward into the upper gingivobuccal sulcus on CT imaging. **D:** *Arrow* shows setup for electron-beam phase of therapy with custom lead skin collimation *in situ*. **E:** *Arrow* shows the beeswax bolus *in situ*. **F:** Dosimetry to 50 Gy resulting from an appositional electron beam with beeswax bolus (*arrow*) to compensate for surface obliquity. The primary tumor, facial, and level II nodes were treated with 50 Gy. This was followed by 25 Gy administered by an interstitial low dose rate iridium needle implant at 0.55 Gy/hour. **G:** Dummy wires are inserted into each hollow tube. Each tube has a ball anchor at the distal end of the needles, which is pushed snugly against the skin and sutured to the skin. Note the placement of transverse “moustache” needles. **H** and **I:** Orthogonal x-ray (anterior–posterior, lateral) films taken to document the placement of the needles. CT-based planning was performed. **J** and **K:** Live sources *in situ*.

When indicated, the right and left facial lymphatics are irradiated with appositional fields; these require an approximately 15-degree gantry rotation to the respective side with 6-MeV electron fields, each abutting the appositional primary lesion portal and the upper neck fields. The medial border is matched to the lateral border of the anterior primary field. The anterior border extends down from the oral commissure to the middle of the horizontal ramus of the mandible, whereas the posterior border extends from the upper edge of the anterior field to just above the angle of the mandible. The inferior border splits the horizontal ramus of the mandible and is matched to the upper neck field. The junctions are moved twice during the course of treatment to reduce dose heterogeneity. The

submandibular and subdigastric nodes are treated with lateral parallel-opposed photon fields. For patients with involved nodes, these upper neck fields are matched inferiorly to an anterior portal treating the middle and lower neck nodes.

For definitive treatment, the external beam radiation schedule for lesions up to 1.5 cm in diameter for which a combination of electrons and photons is used is typically 50 Gy in 25 fractions followed by a boost of 10 to 16 Gy in 5 to 8 fractions (prescribed at the 90% isodose line). Larger lesions to be treated by external beam radiation alone receive 50 Gy in 25 fractions plus a boost of 16 to 20 Gy in 8 to 10 fractions. The schedule for elective nodal irradiation is 50 Gy in 25 fractions. Palpable nodes are given a boost to a total dose of 66 to 70 Gy in 33 to 35 fractions, depending on the size. For postoperative treatment, the volume is reduced off the undissected nodal regions after 50 Gy (25 fractions) to deliver an additional 6 Gy to the surgical bed. At 56 Gy, a final “cone down” is done to include a 4-Gy dose to the preoperative tumor bed, for a total dose of 60 Gy. If the excision was limited or positive margins are present, the final cone down dose is 10 Gy for a total dose of 66 Gy.

Brachytherapy. Brachytherapy for small lesions is accomplished by using a ^{192}Ir wire implant or, in selected cases, by using an intracavitary ^{192}Ir mold. Hollow needles for afterloading are inserted under general anesthesia, which allows good exposure of the tumor and protects the airway in the event of bleeding from the vascular Kiesselbach plexus on the anterior nasal septum or from posterior hemorrhages originating from larger vessels near the sphenopalatine artery, behind the middle turbinate. Implantation of a T2 SCC of the columella is shown in Figure 45.3. The recommended doses for low dose rate brachytherapy have evolved empirically and range from 60 to 65 Gy delivered during 5 to 7 days.

Brachytherapy can be used instead of an external beam boost for patients with T1 or T2 nasal vestibule tumors after initial larger-field RT. After delivery of 50 Gy, the patient is assessed, and if the tumor volume has been substantially reduced, a boost of 20 to 25 Gy may be administered in about 2 days by using low dose rate brachytherapy.

High dose rate brachytherapy has also been used to deliver the boost. A custom mold of the nasal vestibule is fabricated, and tumor is marked in the mold. Two to four plastic tubes are inserted in the mold alongside the tumor at 1-cm intervals. For tumors of the lateral part of the vestibule, two catheters are

placed on the inner aspect of the nasal vestibule. For medially localized tumors, catheters are placed on both sides of the vestibule. After external beam radiation to 50 Gy in 5 weeks, high dose rate brachytherapy is delivered in week 6. The dose is typically 3 Gy per fraction, given twice a day, to a total dose of 18 Gy specifically at the center of the tumor. With a median overall treatment time (external beam radiation plus brachytherapy) of 36 days, this technique has been reported to yield 2-year local control rates of 86% and ultimate locoregional control rates of 100%.[42]

Nasal Fossa Tumors

Target Volume

The technique for primary or postoperative external beam irradiation of nasal cavity tumors depends on the depth of the neoplasm. For tumors located <3.5 or 4.0 cm from the skin of the apex of the nose, electrons can be used, as 20-MeV electrons will provide coverage up to 5 cm in depth. A margin of at least 1 cm deep to the posterior edge must be included in the full-dose volume. The technique is as previously described for nasal vestibule carcinoma. CT-based treatment planning is necessary for accurate target localization and dose calculation.

Intensity-modulated radiation therapy (IMRT) with either photons or protons are recommended for tumors of the nasal cavity in which the target volume is more than 5 cm deep or for tumors of the ethmoid sinus[43] (Fig. 45.4). This technique delivers the desired dose to the target volume while minimizing the dose to critical organs such as the cornea, lens, lacrimal glands, retina, optic nerve, optic chiasm, brain, and brainstem. For postoperative RT, the primary clinical target volume (CTV) descriptions are given in Table 45.3. The CTV_1 consists of the primary tumor bed with a 1.0- to 1.5-cm margin. A boost subvolume consisting of high-risk regions (sites of positive margins, gross macroscopic residual tumor) to be treated to higher doses may be outlined. The CTV_2 includes the entire operative bed. For ethmoid sinus tumors, this might include the frontal sinus, maxillary sinus, and sphenoid sinus. The bony orbit is part of the operative bed when orbital exenteration is performed because of tumor invasion. For lesions involving the ethmoid sinuses or olfactory region, the CTV should also include the cribriform plate. A third CTV may be delineated to encompass the tract of cranial nerve V2 to the foramen rotundum if perineural invasion is present. For primary RT given as IMRT, the CTV_1, consisting of the gross tumor volume plus a margin of 1 to 2 cm, receives the full dose of 66 to 70

Gy. For patients receiving neoadjuvant chemotherapy, target volume definition is based on the extent of disease before chemotherapy.

For three-dimensional (3-D) conformal RT, the initial target volume for postoperative radiation consists of the surgical bed with 1- or 2-cm margins, depending on the surgical pathology findings and the proximity of critical structures. The boost volume consists of areas at greatest risk of recurrence, such as close or positive resection margins or regions of perineural invasion, with 1- to 2-cm margins.

For small anterior–inferior septal lesions, brachytherapy can be accomplished by using a single-plane implant of the lesion with 2-cm margins. Elective neck irradiation is not given routinely even for patients with large tumors or early stage Kadish A or B ENB.

Setup and Field Arrangement

For target volumes <5 cm deep, an electron technique similar to that described for nasal vestibule carcinomas is used. Treatment devices include lead skin collimation to obtain a sharp penumbra as well as bolus material in the nasal cavity, in postoperative defects, and on skin scars. An intraoral stent is used to depress the tongue, provide a patent airway, and aid in immobilization. Tungsten internal eye shields may be used if the target volume approaches the orbits (see Fig. 45.3).

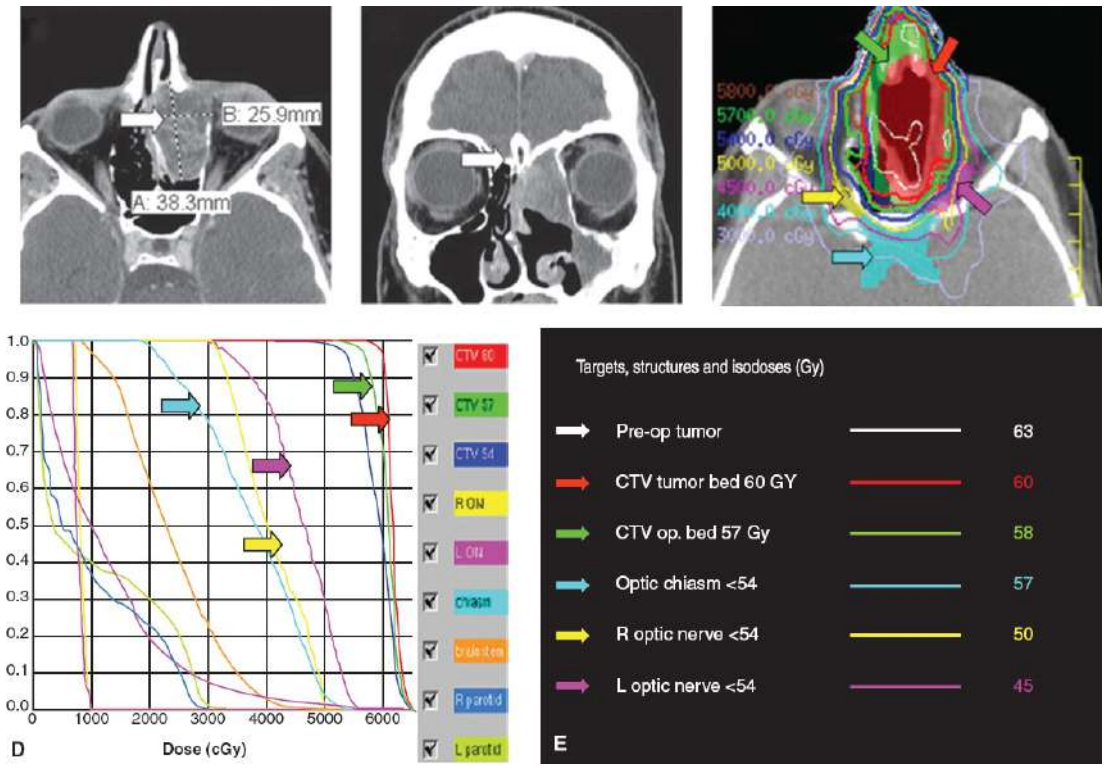

FIGURE 45.4. Intensity-modulated radiotherapy for adjuvant radiotherapy for an adenoid cystic carcinoma of the ethmoid sinus, anterior skull base, nasal cavity, and medial orbit following endoscopic anterior–posterior ethmoidectomy with resection of tumor, left maxillary antrostomy with disease removal, bilateral sphenoidotomy, and frontal sinusotomy with anterior approach to the anterior skull base including a left lateral rhinotomy and medial maxillectomy and extradural resection of anterior cranial base. **A** and **B:** Preoperative CT scans with tumor indicated by *white arrow*. **C:** Transverse section at the level of the orbit that shows sharp dose gradient at the interface of the CTV and the optic nerves and chiasm. **D** and **E:** Cumulative dose–volume (*y*-axis) histogram.

TABLE 45.3 TARGET VOLUMES FOR INTENSITY-MODULATED RADIATION THERAPY OF SINONASAL CANCERS

Target	Description	Dose (33–35 fractions) (Gy)
Primary Radiation Therapy		
GTV	GTV (= prechemotherapy volume)	66–70
CTV_1 (primary CTV)	GTV + 1.0 – 1.5 cm	66–70
CTV_2 (intermediate dose CTV)	Primary CTV + 1.0 – 1.5 cm	59–63
CTV_3 (elective	Nodal volumes, nerve tract, and base of skull margin	54–57

CTV)		
Target	**Description**	**Dose (30 fractions) (Gy)**
Postoperative Radiation Therapy		
CTV_{HR} (high-risk CTV)	Sites of suspected positive margins, gross macroscopic residual tumor, extracapsular nodal disease	66–70[a]
CTV_1 (primary CTV)	Primary tumor bed with 1.0–1.5-cm margin	60
CTV_2 (intermediate dose CTV)	Surgical bed	57
CTV_3 (low dose CTV)	Trigeminal nerve perineural invasion is present, additional skull base margin, elective nodal volume if indicated	54

[a]70 Gy may be given by adding a second boost plan or increasing the number of fractions to 35.
CTV, clinical target volume; GTV, gross tumor volume.

For 3-D conformal therapy or IMRT, the patient is immobilized in a supine position with the head positioned such that the hard palate is perpendicular to the treatment couch. Scars are marked with thin radio-opaque wires, bolus and other devices are positioned, and transverse CT images are obtained from the vertex to the upper mediastinum. For IMRT, rigid immobilization is necessary, including the use of special head and shoulder thermoplastic masks that extend down to the upper thorax. The shoulders can be additionally depressed and fixed by using wrist straps tethered to a footboard. Target volumes are delineated as previously described.

For IMRT, multiple gantry angles are used based on beam optimization algorithms. An example of a 10-field noncoplanar arrangement with two vertex beams is shown in Figure 45.4. The beam angle selections are based on the same principles as for 3-D conformal therapy:

- Preference for the shortest path to the target
- Avoidance of direct irradiation of the critical structures (e.g., avoid beam entry through the contralateral eye after ipsilateral exenteration)
- Use of as large a beam separation as possible

Inverse planning is usually done, and multiple iterations may be necessary to ensure that the following are accomplished:

- Targets are covered.
- Normal tissue constraints are respected.

. Dose is relatively homogenous.

Dose calculations should include heterogeneity corrections because of the significant amounts of air and bone in the sinuses. Radiation oncologists must work closely with physicists and dosimetrists. It is important to realize that the criteria for accepting or rejecting the plan may not be evident from the dose–volume histogram.

For 3-D conformal RT, anterior oblique wedge-pair photon fields are appropriate for lesions located in the anterior lower half of the nasal cavity. Opposed-lateral fields can be used to treat tumors at the posterior part of the nasal fossa, provided the ethmoid cells are not involved. The optic pathway can be excluded from the radiation fields with this setup. For primaries of the upper nasal cavity and ethmoidal air cells, a three-field setup allows coverage of the ethmoid cells while sparing the optic apparatus. CT-based treatment planning is necessary to select beam and wedge angles (usually 45 to 60 degrees) and the relative loading of the fields, as well as to evaluate the dose to critical structures such as the brain, brainstem, and optic structures.

Proton beam therapy techniques for treating nasal fossa tumors are rapidly evolving and include both passive scattering and discrete spot scanning beams. Theoretically, the advantage of proton therapy (PT) derives from the unique physical properties of protons that allow deposition of most of the particle's energy at the end of its range. Descriptions of the various techniques by which PT can be delivered are beyond the scope of this chapter. Nevertheless, with optimization of dosimetry, the conformality and heterogeneity within the target volumes provided by PT should be equivalent to what can be achieved with either electron or photon therapy, with the added advantage of minimizing the unnecessary dose or "dose bath" from IMRT to the surrounding normal tissue structures.

Greenwalt et al.[44] reported on seven adult patients with primary mucosal nasal cavity,[5] ethmoid sinus,[1] and maxillary antrum[1] melanoma treated with external beam PT. Six patients underwent gross total resection before PT, and one patient underwent a biopsy of unresectable disease from intracranial extension. In the postoperative setting, PT was initiated at a median of 53 days after surgery. The primary target volume was defined as the surgical bed plus a margin for microscopic disease and set-up uncertainties. The median PT dose to the primary high-risk planning target volume was 74.4 Gy (relative biologic effectiveness [RBE]) (range, 69.6 to 74.4). Six patients were treated with elective nodal radiation to the neck to a median dose of 50 Gy (range, 48 to 50).

None of the patients had neoadjuvant, concurrent, or adjuvant chemotherapy. Median follow-up was 1.4 years from the end of PT (range, 0.5 to 6.6 years). The cause-specific survival and overall survival rates were equivalent at 83% at 1 year and 67% at 1.5 years. Three patients died of metastatic disease, all died within 25 months of completing PT. One patient who was treated with 69.6 Gy (RBE) recurred locally at 2 months after completing PT and died of distant disease. The locoregional control rates at 1 and 1.5 years were both 86%, whereas the freedom from distant metastases rate was 71% at 1 and 1.5 years. One patient experienced grade 2 epiphora and grade 4 visual toxicity, leading to loss of useful vision in the treated eye. One patient with brain necrosis was found to have developed brain metastases requiring steroids following PT. Two patients reported grade 2 sinusitis, one patient had a grade 2 oral cavity fistula, and one patient reported grade 2 sensorineural hearing loss. No contralateral visual complications occurred.

Radiation Therapy Dose Fractionation Schedule

The dose schedule for low dose rate brachytherapy is 60 to 65 Gy during 5 to 7 days. The external beam regimen for primary RT is 50 Gy in 25 fractions followed by a boost of 16 to 20 Gy in 8 to 10 fractions, depending on the size of the lesion. Postoperative RT consists of 50 Gy to elective tissue, 56 Gy to the operative bed, and 60 Gy to the tumor bed, with an optional boost to close or positive surgical margins, all given at 2 Gy per fraction. Dose regimens for intensity-modulated therapy, whether with photons or protons, are summarized in Table 45.3.

Tumors of the Paranasal Sinuses

Target Volume

Because maxillary cancers are usually diagnosed at a locally advanced stage and surgery is the primary therapy, most patients receive postoperative RT. Delineation of target volumes is based on physical examination, pretreatment imaging, intraoperative findings (tumor extension relative to critical structures such as orbital wall, cribriform plate, cranial nerve foramina, and ease of resection), and pathologic findings (such as positive margin or perineural invasion).

For photon-based treatment delivery, IMRT is the preferred treatment method as it generally yields better dose distribution in terms of both tumor coverage and sparing of normal tissues than can be achieved with 3-D conformal RT.[43,45]

Jeong et al.[46] compared in 10 patients volumetric modulated arc therapy (VMAT) and noncoplanar intensity-modulated radiation therapy (IMRT) for nasal cavity and paranasal sinus cancer with regard to the coverage of planning target volume (PTV) and the sparing of organs at risk (OARs). Planning objectives were (a) to deliver 60 Gy in 30 fractions to 95% of PTV; (b) to ensure maximum dose (D_{max}) of optic nerves, optic chiasm, and brainstem to be <50 Gy, eyes to <40 Gy, and lenses to <10 Gy and the mean dose (D_{mean}) of parotid glands to <25 Gy; and (c) to reduce doses of OARs as much as possible without compromising coverage of PTV.

VMAT plan and each of noncoplanar IMRT (7-, 11-, and 15-beam) plans were evaluated by heterogeneity index (HI) and conformity index (CI) of the PTV, D_{max}, and D_{mean} of the OARs, treatment delivery time, and monitor units (MUs). The HI of PTV was defined as D5% to D95%/D_{mean}, where D5% and D95% are the minimum doses delivered 5% and 95% of the PTV. The CI of PTV was defined as VTV/VPTV, where VTV is the treatment volume enclosed by the prescribed 60-Gy isodose surface and VPTV is the volume of the PTV. The HI and CI of VMAT plan were better than each of 7-, 11-, 15-beam noncoplanar IMRT plans (mean HI, 0.07 vs. 0.10 vs. 0.09 and 0.10, respectively, $P = 0.004$, $P = 0.012$, and $P = 0.005$; mean CI, 1.05 vs. 1.13 vs. 1.10 and 1.10, respectively, $P = 0.002$, $P = 0.008$, and $P = 0.016$). In OAR-sparing effects, VMAT and each of noncoplanar IMRT (7-, 11-, and 15-beam) plans showed equivalent sparing effects for bilateral optic nerves, optic chiasm, brainstem, and bilateral parotid glands. For the eyes and lenses, VMAT achieved equivalent or better sparing effects when compared with each of noncoplanar IMRT plans. For bilateral lacrimal glands, which did not apply constraint during planning, each of the noncoplanar IMRT plans showed better D_{max} and D_{mean} than VMAT. VMAT showed lower MUs and reduced treatment delivery time when compared with noncoplanar IMRT plans. The authors concluded that in the patients with nasal cavity or paranasal sinus cancer, VMAT provided better homogeneity and conformity for PTV than each of 7-, 11-, 15-beam noncoplanar IMRT plans while achieving equal or better OAR-sparing effects and using fewer MUs and lower treatment delivery times.

Proton therapy and intensity modulated proton therapy (IMPT)[47] may offer additional advantages over IMRT in terms of further reducing the dose to normal tissues while achieving equivalent doses to the target volume. The CTV_1 consists of the primary tumor bed with 1.0- to 1.5-cm margin of normal tissue.

The CTV_2 encompasses the operative bed, including the bony orbit after orbital exenteration and the ethmoid, frontal, or sphenoid sinuses if explored during surgery. A third CTV may be delineated to encompass the tract of cranial nerve V2 to the foramen rotundum if perineural invasion is present. A CTV for high-risk areas (CTV_{HR}; see Table 45.3) may also be outlined to cover, for example, gross macroscopic residual tumor or positive margins to which a higher dose may be delivered.

Radiation Therapy Dose Prescriptions

For primary RT using IMRT, VMAT, or IMPT the prescription doses are 66 to 70 Gy to the gross tumor volume (the prechemotherapy volume for those receiving systemic treatment), plus a 1- to 1.5-cm margin of normal-appearing tissue (CTV_1), 59 to 63 Gy to other secondary CTVs such as the rest of the involved sinus and wider region around the primary target, and 54 to 57 Gy to the tracts of nerves (if perineural invasion is present) and to elective nodal regions. An example of an IMRT plan for primary definitive RT of a T4N0 SCC is shown in Figure 45.5.

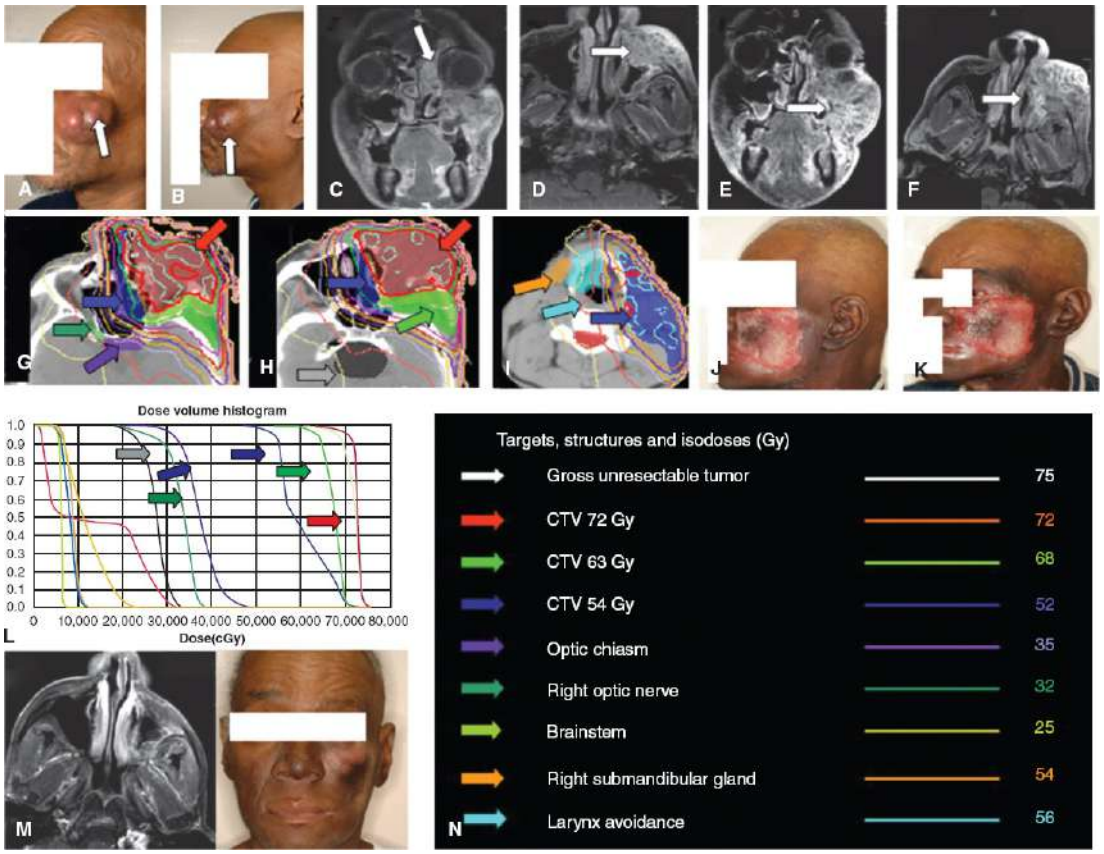

FIGURE 45.5. Intensity-modulated radiotherapy (IMRT) for definitive radiotherapy for

T4N0 SCC of the maxillary sinus. **A** and **B:** Pretreatment photographs showing the skin of cheek involvement. **C** and **D:** Magnetic resonance imaging (MRI) scans with tumor indicated by *white arrow*. **E** and **F:** MRIs following induction chemotherapy showed progressive disease involving the left maxilla, left nasoethmoid region, extending inferiorly into the premaxillary soft tissues. **G–I:** IMRT plan with sections showing coverage of the target volumes. The patient was treated using concomitant boost fractionation. The primary plan delivered 57 Gy and a concomitant boost plan administered an additional 15 Gy. **G** and **H** also show avoidance of the normal tissues, as listed in the key and illustrated further in the cumulative dose–volume histogram in **(L)**. **J** and **K:** The skin reaction during the final week of radiotherapy. **M** and **N:** MRI and patient photo at follow-up, showing healed skin with hyperpigmentation. The tumor was in complete remission at the last visit 7 months after therapy.

For postoperative RT using a 3-D conformal technique, the initial target volume consists of the operative bed with 1- to 2-cm margins. The boost field consists of the primary tumor bed and areas at higher risk of recurrence, such as positive resection margins or perineural invasion. Radiation is administered to the neck after node dissection if multiple nodes are involved or extracapsular extension is present. Elective radiation of ipsilateral submandibular and subdigastric nodes is given for patients with squamous cell or poorly differentiated carcinoma. An example of an intensity-modulated proton plan for postoperative RT is shown in Figure 45.6.

Setup and Field Arrangement

Patients undergoing treatment of paranasal tumors are immobilized in a supine position with the head slightly hyperextended to bring the floor of the orbit parallel to the axis of the anterior field. An intraoral stent is used to open the mouth and depress the tongue out of the radiation field. After palatectomy, the stent can be designed to hold a water-filled balloon to obliterate the large air cavity in the surgical defect to improve dose homogeneity. An orbital exenteration defect can also be filled directly with a water-filled balloon to decrease the dose delivered to the temporal lobe. Marking of the lateral canthi, oral commissures, external auditory canals, and external scars facilitates target volume delineation. The planning CT scan should include the entire head to allow the use of vertex beams. The principles of target delineation and plan evaluation for IMRT of maxillary sinus cancer are the same as those described for nasal cavity and ethmoid tumors.

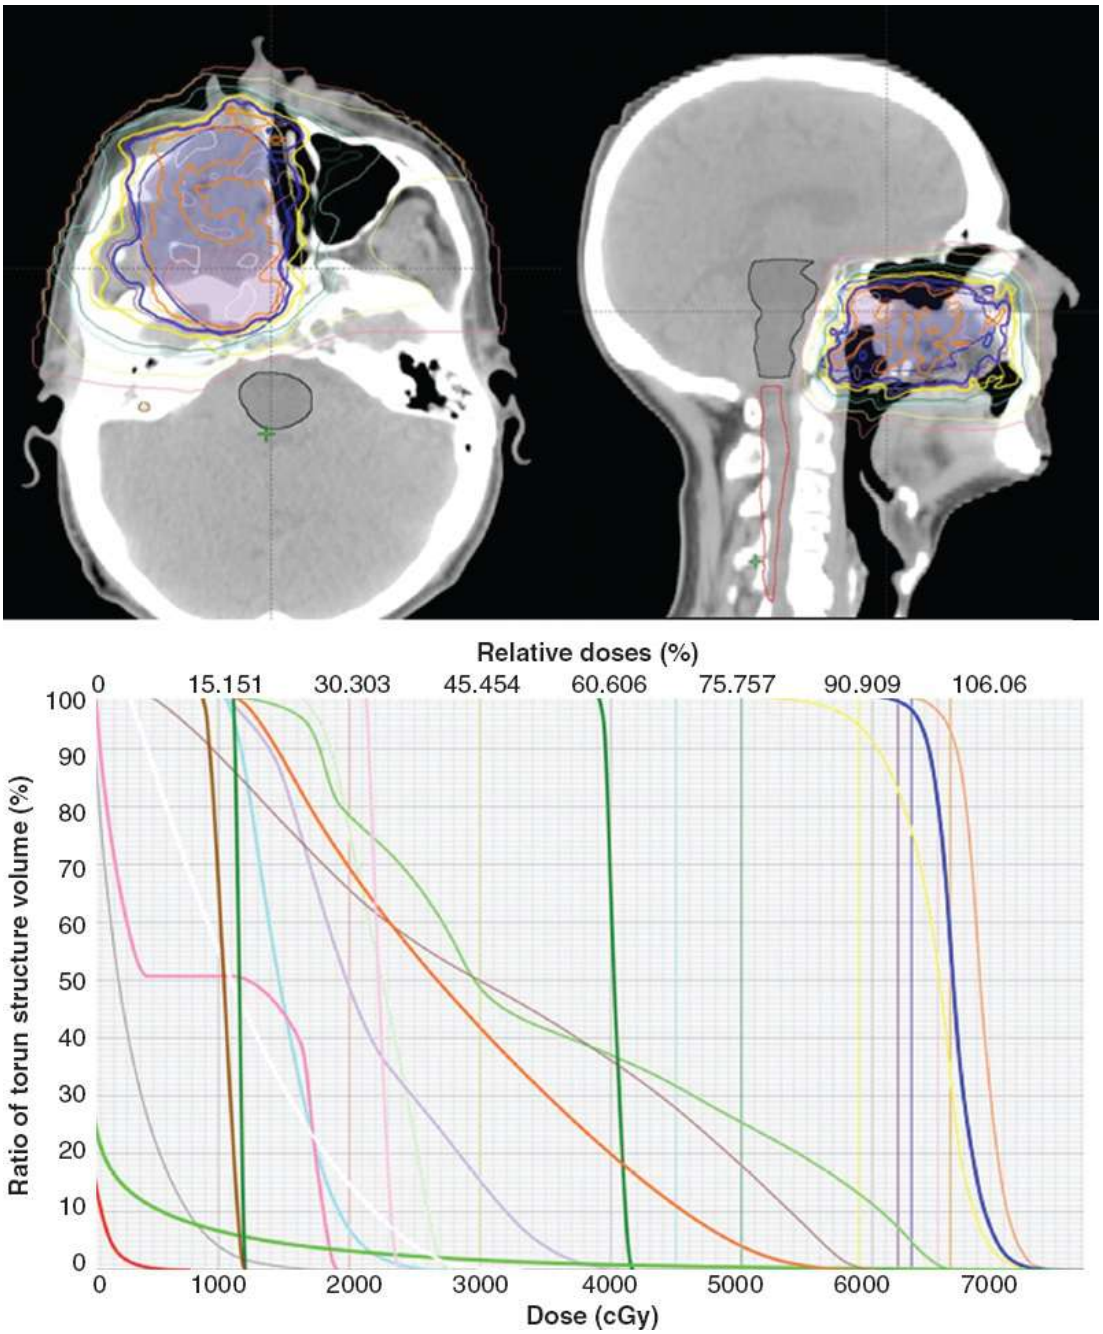

FIGURE 45.6. Proton therapy for recurrent adenoid cystic carcinoma (ACC) of the right hard palate. The patient had a palatectomy with radial forearm free flap reconstruction followed by postoperative external beam RT with IMRT to 60 Gy in 30 fractions. One year later, the ACC recurred with enhancement in right V1 and V2, involvement of the right cavernous sinus, and an enhancing mass in the infratemporal fossa and pterygopalatine fossa. Salvage surgery involved a right total maxillectomy with OP, pterygomaxillary space dissection and resection, and an extracranial dissection of Vidian nerve and cranial nerve 5, V2. With evidence of skull base and cavernous sinus involvement after surgery, he was treated with postoperative chemoradiation with IMPT and cisplatin to a dose of 66 Gy (RBE) in 33 fractions. No evidence of disease was present at 6 months after salvage therapy. The figure represents the axial, sagittal, and dose–volume histogram (DVH) of the IMPT plan.

(DVH for the IMPT plan, from *left* to *right* on the graph: *red*, spinal cord; *green*, whole brain; *black*, brainstem; *pink*, left parotid; *white*, left eye; *brown*, right cochlea; *dark green*, left lens; *sky blue*, right parotid; *brown*, oral cavity; *violet*, optic chiasm; *red*, right eye; *green*, mandible; *light green*, left optic nerve; *soft pink*, right lens; *dark green*, right optic nerve; *yellow*, CTV or CTV_3; *blue*, CTV_2; *orange*, CTV_1.)

For 3-D conformal radiation, a three-field technique consisting of anterior and right and left lateral fields is used for tumors involving the suprastructure or extending to the roof of the nasal cavity and ethmoid cells. The lateral fields may have a 5-degree posterior tilt and 60-degree wedges. The relative loading varies from 1:0.15:0.15 to 1:0.07:0.07 depending on the tumor location and photon energy. For the initial target volume, the superior border of the anterior portal is above the crista galli to encompass the ethmoids and, in the absence of orbital invasion, at the lower edge of the cornea to cover the orbital floor. The inferior border is 1 cm below the floor of the sinus, and the medial border is 1 to 2 cm (or more if necessary) across the midline to cover contralateral ethmoidal extension. The lateral border is 1 cm beyond the apex of the sinus or falling off the skin. The superior border of the lateral portals follows the floor of the anterior cranial fossa, the anterior border is behind the lateral bony canthus parallel to the slope of the face, the posterior border covers the pterygoid plates, and the inferior border corresponds to that of the anterior portal. The boost volume encompasses the tumor bed while sparing the optic pathway.

Anterior and ipsilateral wedge-pair (usually 45-degree wedges) photon fields are used for tumors of the infrastructure with no extension into the orbit or ethmoids. If necessary, the lateral portal can have a 5-degree inferior tilt to avoid beam divergence into the contralateral eye. Lateral-opposed photon fields are preferred for tumors of the infrastructure spreading across the midline through the hard palate. If necessary, the fields can be slightly angled (5-degree inferior tilt from the ipsilateral side and 5-degree superior tilt from the contralateral side) to avoid irradiating the contralateral eye. The use of a half beam with the isocenter placed at the level of the orbital floor and the upper half of the fields shielded further reduces exposure of the eyes by beam divergence.

The eyes and the optic pathway are of particular concern. With 3-D conformal/IMRT/VMAT/IMPT techniques, the cornea can generally be shielded or a planned avoidance structure (to avoid keratitis) in patients with limited involvement of the medial or inferior orbital wall. If the tumor invades the orbital cavity without necessitating orbital exenteration, care should be taken to avoid irradiating the lacrimal gland to prevent xerophthalmia. It is important to

keep the dose to the contralateral optic nerve as well as the optic chiasm below 54 Gy in 27 fractions to prevent bilateral blindness.

Treatment of the Neck

For squamous and undifferentiated carcinoma, elective neck irradiation is recommended. Ipsilateral upper neck treatment can be delivered using a lateral appositional electron field (usually 12 MeV). With conventional radiation techniques, careful matching is required to prevent hot or cold spots. The superior border of the field slopes up from the horizontal ramus of the mandible anteriorly to match the inferior border of the primary portal posteriorly, leaving a small triangle over the cheek untreated. The anterior border is just behind the oral commissure, the posterior border is at the mastoid process, and the inferior border is at the thyroid notch (above the arytenoids). The nodal volume can also be covered by using IMRT with sparing of the parotid gland. Alternatively, the primary tumor bed and the upper neck can be treated with IMRT with the isocenter above the arytenoids and matched to a separate unmodulated lower neck field. This allows the laryngeal structures to be spared by using a larynx block.

If the maxillary sinus is being treated with conventional non-IMRT techniques, the central axes of the primary (sinus) fields and the opposed lateral upper neck fields all are placed in the plane of the inferior border of the maxillary fields (i.e., usually 1 cm below the floor of the maxillary sinus). An independent collimator jaw is used to shield the caudal half of the maxillary fields and the cephalad half of the neck field. The junction between the primary and the neck fields can be moved during the course of treatment to reduce dose heterogeneity in this region. Portals are reduced after 42 Gy, and treatment to the posterior neck continues with abutting electron fields to the desired dose. The middle and lower neck is irradiated with an anterior appositional photon field matched to the inferior border of the opposed-lateral upper neck fields.

Dose Fractionation Schedule

Table 45.3 summarizes the dose regimens for IMRT/IMPT. With 3-D conformal techniques, the dose for postoperative RT at 2 Gy per fraction is 50 Gy for elective nodal treatment, 56 Gy to the operative bed, 60 Gy to the tumor bed if resection margins are negative, and 66 Gy if margins are positive. For primary RT, the total dose to the primary tumor at 2 Gy per fraction is 66 to 70 Gy. The contralateral optic nerve and chiasm are excluded from the field after a dose of

50 to 54 Gy. When the tumor invades structures adjacent to the optic chiasm, a dose of up to 60 Gy to the chiasm may be acceptable because of the higher probability of control and the relatively low risk of visual impairment,[36] after clear discussion with the patient.

FOLLOW-UP AND RECURRENCES

Salvage is possible for some persistent or recurrent lesions. In particular, recurrent cancers of the nasal vestibule remain curable with salvage surgery after primary radiation or occasionally with salvage radiation after primary surgery. Regional recurrences can be treated successfully with neck dissection with or without postoperative radiation depending on the pathologic features. Treatment options are limited for tumors that recur after combined modality therapy, although a few highly selected patients may qualify for reirradiation with curative intent. Cumulative doses of radiation to neural tissues (spinal cord, brainstem, brain, optic structures) are the main limitation to reirradiation.

Most oncologists recommend a second baseline physical examination together with CT, MRI, or positron emission tomography with CT for patients with nasal cavity or paranasal sinus tumors at 3 months after treatment. Common practice is to repeat clinical examination and imaging when indicated every 4 months for the first 3 years after treatment, every 6 months for the fourth and fifth years after treatment, and annually thereafter. In addition to monitoring possible tumor recurrence, these follow-up visits are critical for identifying and managing side effects of treatment.

RESULTS OF TREATMENT

The results of treatment have improved from the 1960s through the 1990s, with overall survival rates increasing progressively from 33% ± 18% in the 1960s to 42% ± 15% in the 1970s, 54% ± 15% in the 1980s, and 56% ± 13% in the 1990s ($P < .001$).[48] In a systematic review of published series spanning 40 years, Dulguerov et al.[49] demonstrated progressive improvements in outcome for all treatment modalities (surgery, surgery with radiation, and radiation). However, a more recent review of the experience at the University of California, San Francisco, showed no significant differences in 5-year overall survival rates or local control rates by a decade of treatment (1960s through 2000s; overall survival, 46% to 56%; local control 55% to 62%) or by radiation technique

(conventional, 3-D conformal, or IMRT; overall survival 47% to 57%; local control 59% to 65%). However, the incidence of severe (grade 3 or 4) side effects declined significantly over time from 50% in the 1960s to 16% in the 2000s.[50]

Tumors of the Nasal Cavity

Nasal Vestibule Tumors

Findings from several retrospective studies of RT for nasal vestibule tumors suggest that either brachytherapy or external beam RT can produce cure rates of up to 90% for small (<2-cm) lesions (Table 45.4).[3,4,16,17,52–60] For 2- to 4-cm lesions, external beam radiation can control 70% to 80% of tumors. Although nodal spread of disease is relatively rare for lesions smaller than 2 cm, up to 40% of patients with larger primary tumors have metastases to the cervical nodes at presentation. With the use of appropriate radiation techniques and fractionation schedules, severe and late complications after RT are uncommon (see Table 45.4).

An analysis by the Groupe Europeen de Curietherapie of 1,676 carcinomas of the skin of the nose and nasal vestibule treated by brachytherapy or external beam irradiation revealed an overall local control rate of 93%.[4] Local control depended on tumor size (<2 cm, 96%; 2 to 3.9 cm, 88%; ≥4 cm, 81%), tumor site (external surface, 94%; vestibule, 75%), and status (new, 95%; recurrent, 88%). Local control was independent of histology for tumors <4 cm, but for those >4 cm, basal cell carcinomas were more often controlled than were SCCs. Complications were rare (necrosis, 2%). The local control rate with surgery was approximately 90%.

Nasal Fossa Tumors

Documentation of treatment outcomes for nasal fossa tumors, like nasal vestibule tumors, comes mostly from retrospective studies.[18,61,62] Results are best for lesions confined to the nasal septum, which are generally small and well controlled with primary RT. Locoregional control rates range from 60% to 85%, and the rate of isolated regional recurrence for patients who did not receive elective nodal irradiation is approximately 5%. The most common complications after RT are soft tissue necrosis, visual impairment, and nasal stenosis, seen in 5% to 11% of patients (Table 45.5).[18,59–61] Ang et al.[18] at MD Anderson Cancer Center reported better primary disease control and survival rates for patients with tumors located in the septum (86%) versus patients with tumors on the

lateral wall or floor of the nasal fossa (68%). In that study, no patients with nasal septum carcinomas who underwent elective nodal irradiation had nodal relapses, whereas two of eight patients who did not undergo nodal irradiation experienced recurrence in the ipsilateral subdigastric nodes. Distant metastasis was more common among patients with lateral wall and floor disease, and ultimately survival rates were best among patients with nasal septum tumors. However, other groups[61] found no differences in results for tumors at various sites within the nasal cavity. Results of treatment for early-stage tumors are excellent after either RT or surgery.

TABLE 45.4 LOCAL AND REGIONAL CONTROL RATES OF NASAL VESTIBULE CARCINOMAS TREATED BY DEFINITIVE RADIOTHERAPY

	Brain necrosis: 1 patient

RT, radiation therapy.

An analysis of 783 patients with nasal cavity cancer included in the Surveillance, Epidemiology, and End Results (SEER) database from 1988 through 1998[62] revealed SCC to be the most common tumor type (49.3%), followed by ENB (13.2%). More than half of the cases presented with a small primary tumor (T1), and only 5% had positive nodes at diagnosis. Overall mean survival time was 57 months and the 5-year survival rate was 40.3%. On multivariate analysis, male sex, increasing age, T status, N status, and poorer tumor grade all adversely affected survival ($P < .05$). RT, given to 50.5% of patients, also independently predicted poorer survival ($P = .03$), probably because those patients had had poor prognostic features such as perineural invasion, positive margins, or poor performance status (medically unfit for surgery). Five-year survival rates by tumor type, T status, and N status are shown in Table 45.6.[62] Five-year survival rates also correlated with extent of tumor dedifferentiation, being 75.3%, 61.9%, 47.6%, and 36.8% for well-, moderately, poorly, and undifferentiated cancers, respectively.

TABLE 45.6 Treatment Results for Nasal Cavity Cancer from the Surveillance, Epidemiology, and End Results Database for 1988 Through 1998[a]

Tumor Type	5-Year Survival Rate (%)	T or N Classification	5-Year Survival Rate (%)
Adenocarcinoma	49.0	T1	66.4
Adenoid cystic carcinoma	59.1	T2	51.8
Melanoma	22.1	T3	45.6
Other tumors	59.5	T4	40.2
Sarcoma	78.0	Overall	56.7
Squamous cell carcinoma	61.6		
Esthesioneuroblastoma	63.6	N0	62.3
SNUC	49.5	N+	28.4

[a]Results are shown by tumor type and by T- and N-stage. Because of rounding, percentages may not total 100.

Esthesioneuroblastoma

Either surgery or primary RT as single-modality therapy can produce locoregional control rates exceeding 90% for tumors that are confined to the nasal cavity (Kadish stage A).[8] Single-modality therapy has also been used for lesions involving the nasal cavity and one or more paranasal sinuses (stage B), as has surgery followed by adjuvant RT. However, the optimal therapy for stage B lesions is not clear because of the heterogeneity of these tumors. Disease that extends beyond the nasal cavity and paranasal sinuses (stage C) seems to be best treated with a combination of surgery and radiation, and the role of chemotherapy, if any, is being investigated. Elective nodal irradiation is not generally recommended because the incidence of nodal relapse is <15%. Distant metastasis is uncommon (10%) even among patients presenting with locally advanced disease. Among 783 nasal cavity cancers identified from the SEER database, 103 (13.2%) were ENBs; the median survival time for patients with these tumors was 88 months, and the overall 5-year survival rate was 63.6%.[62] Tables 45.7[63–68] and 45.8[9] summarize the results of treatment. The prognosis for patients with stage A disease is excellent. Overall, 30% of patients with stage B tumor died of the disease. About 60% of patients with stage C tumors died of the disease, primarily because of failure to control the primary tumor. As noted above, distant metastasis is uncommon (10%) even in locoregionally advanced disease.

TABLE 45.7 OVERALL TREATMENT RESULTS OF ESTHESIONEUROBLASTOMA

[a]Kadish A or B received preoperative RT followed by craniofacial resection; Kadish stage C disease was treated with preoperative chemotherapy and RT followed by a craniofacial resection.
CSS, cause-specific survival; DFS, disease-free survival; DM, distant metastases; OS, overall survival; RFS, relapse-free survival; RT, radiation therapy; S, surgery.

Spaulding et al.[28] reported results for 25 patients treated at the University of Virginia Medical Center from 1959 through 1986 who were followed for 2 years after therapy. Treatment approaches had gradually evolved during that period, with progressive introduction of craniofacial resections, complex field megavoltage radiation, and, for stage C disease, the addition of chemotherapy. Therefore, patients were assigned to two groups, based on treatment era, for comparative analysis. Although this series is relatively small, it revealed two interesting findings on this rare disease: First, that extensive craniofacial resection does not seem to confer a major advantage over wide local excision for patients with stage B lesions, and second, that the addition of chemotherapy to craniofacial resection and RT for patients with stage C tumors may yield higher disease-specific survival rates.

A larger series of 72 patients with sinonasal neuroendocrine tumors treated at MD Anderson Cancer Center between 1982 and 2002[63] included a spectrum of histologies: ENB (31 patients), sinonasal undifferentiated carcinoma (SNUC, 16 patients), neuroendocrine carcinoma (18 patients), and small cell carcinoma (7 patients). The overall survival rates at 5 years were 93.1% for patients with ENB, 62.5% for those with SNUC, 64.2% for neuroendocrine carcinoma, and 28.6% for small cell carcinoma (P = .0029; log-rank test). The local control rates at 5 years also were superior for patients with ENB (96.2%) compared with patients who had SNUC (78.6%), neuroendocrine carcinoma (72.6%), or small cell carcinoma (66.7%) (P = .04). The corresponding regional failure rates at 5 years were 8.7% for patients with ENB, 15.6% for SNUC, 12.9% for neuroendocrine carcinoma, and 44.4% for small cell carcinoma, and distant metastasis rates were 0% for ENB, 25.4% for SNUC, 14.1% for neuroendocrine carcinoma, and 75.0% for small cell carcinoma. Moreover, local therapy alone produced excellent local and distant control rates for ENB. Among eight patients treated for ENB since 2000 with surgery and adjuvant IMRT to 60 Gy (one with stage B disease and seven with stage C [five of whom had intracranial extension]), there were no local recurrences and one nodal recurrence was salvaged surgically. All eight patients were alive with no evidence of disease at the last follow-up. Institutional experiences outcomes from several institutions are reported in Table 45.7.[63–68]

TABLE 45.8 PATTERN OF FAILURE AND RESULTS OF SALVAGE TREATMENT OF ESTHESIONEUROBLASTOMA BY STAGE AND TREATMENT

Kadish Stage	Therapy	Local Control	Nodal Relapse	Salvage by Subsequent RT or S	Distant Metastasis	Died of Disease

RT, radiotherapy; S, surgery.
Modified from Elkon D, Hightower SI, Lim ML, et al. Esthesioneuroblastoma. *Cancer* 1979;44:1087–1094.

Ozsahin et al.[23] described results of treatment in 13 European and North American centers for 77 patients with olfactory neuroblastoma, 11 with Kadish stage A, 29 with stage B, and 37 with stage C; 56 patients had surgery, 44 with total tumor excision. All but 5 patients received RT (50% with 3-D CRT) and 21 had chemotherapy. With median follow-up of 72 months, locoregional tumor control was 62%, disease-free survival 57%, and overall survival 64%. Patients having total tumor resection or receiving ≥54 Gy had better overall survival than those treated with lower doses. Six of the patients treated with RT (56 to 70 Gy) developed grade 3 or 4 late complications (five osteonecrosis and one retinopathy).

Madani et al.[69] published a report on 84 patients (73 with primary and 11 with local recurrent sinonasal tumors), 9 of which were ENB, treated with IMRT (median dose of 70 Gy in 35 fractions). Mean D50 to the optic chiasm was 37.2 Gy, to ipsilateral optic nerve 49.4 Gy, to contralateral optic nerve 47.1 Gy, and to the retina 37.7 and 28.4 Gy, respectively.

Multimodality management has been correlated with improved outcomes.[70]

Modesto et al.[71] described their experience in 43 patients with ENB, 2

groups, 1 of 26 and the other of 17 patients treated at separate institutions. Five patients had stage A at diagnosis (confined to the nasal cavity), 13 stage B (tumor extending into the paranasal sinuses), 16 stage C (beyond the paranasal sinuses), and 9 stage D (cervical lymph node involvement) according to the modified Kadish classification. Neoadjuvant platinum-based chemotherapy was administered to 24 patients, leading to 70.8% response rate (6 CR and 11 PR). A total of 31 patients (72%) were treated by surgery; 39 (90.6%) underwent RT. Among them, 11 patients (28.2%) were treated using IMRT. Median dose was 64 Gy (range 30 to 70 Gy). Twelve patients (28%) received bilateral cervical lymph node irradiation (LNI) (median dose 57 Gy, range 50 to 66 Gy). Twelve patients (21%) received platinum-based CRT. After a median follow-up of 77 months, the 5-year overall survival was 65% and the 5-year progression-free survival 58%.Twelve patients (28%) developed locoregional relapse. The major prognostic factor was the modified Kadish stage with 3-year survival rates of 100% for Kadish A to B versus 48% for stage C and 22% for stage D. After adjustment for tumor stage, neither neoadjuvant chemotherapy nor LNI seemed predictive for locoregional tumor control or survival.

Protons have been used sparingly in the treatment of some of these patients. Nakamura et al.[72] reported on 42 patients with esthesioneuroblastoma treated with proton therapy and 26% receiving chemotherapy. With a median follow-up time of 69 months, the 5-year overall survival and progression-free survival was 100% and 80% for Kadish A, 86% and 65% for Kadish B, and 76% and 39% for Kadish C. Dagan et al.[73] reported on 84 adult patients without metastases receiving primary (13%) or adjuvant (87%) treatment with PT for sinonasal cancers of which 23 % (19) were olfactory neuroblastoma. Advanced stage (T3 in 25% and T4 in 69%) and high-grade histology (51%) were common. Surgical procedures included endoscopic resection alone (45%), endoscopic resection with craniotomy (12%), or open resection (30%). Gross residual disease was present in 26% of patients. Most patients received hyperfractionated PT (1.2-Gy RBE twice daily, 99%) and chemotherapy (75%). The median PT dose was 73.8 Gy (RBE), with 85% of patients receiving more than 70 Gy. The median follow-up was 2.4 years for all patients and 2.7 years among living patients. Local tumor control (LC), neck control, freedom from distant metastasis, disease-free survival, cause-specific survival, and overall survival rates were 83%, 94%, 73%, 63%, 70%, and 68%, respectively, at 3 years. The 3-year LC rate was 61% for primary RT and 59% for patients with gross disease. Late toxicity occurred in 24% of patients (with grade 3 or higher unilateral vision loss in 2%). Akimoto et

al.[74] reported on 339 patients with non–squamous cell cancer in the head and neck, of which 63 were olfactory neuroblastomas, treated with protons. Median follow-up was 64 months. Overall survival, progression-free survival, and local control rate of all patients at 5 years were 61.2%, 36.8%, and 71.2%, respectively, and, for olfactory neuroblastomas, 86.2% and 79.0%. Among all patients, 254 (75%) were not suited for photon RT because doses to OARs exceeded tolerance dose in the evaluation of dose–volume histogram. However, OS at 5 years of these patients was 65.5%. Regarding treatment morbidity, 34 (10%) patients developed grade 3 or 4 late toxicities such as brain injuries and neuropathy. None experienced grade 5 toxicities.

Tumors of the Paranasal Sinuses

Five-year outcomes from studies reported since 1998 continue to illustrate that local control after treatment of paranasal sinus tumors remains problematic[75–82] (Table 45.9). For patients with carcinoma of the maxillary sinuses, the combination of surgery and radiation yields 5-year local control and survival rates ranging from 44% to 80%. These rates are better than those achieved with either surgery or RT alone. For RT alone, the 5-year local control rates range from 22% to 39% and the 5-year overall survival rates from 22% to 40%. Findings from a large multicenter retrospective analysis of 418 patients with ethmoid sinus adenocarcinoma indicated that the size of the lesion (T4), the extent of nodal involvement (N+), and the presence of brain extension were the most significant prognostic factors for overall survival.[83] Although the authors concluded that surgery followed by postoperative RT remains the treatment of choice, they did note that 51% of the patients developed recurrences, 74% of which were local.

C. Side Effects of Combined Surgery and Radiation Therapy in Patients with Paranasal Sinus Cancer	
Vestibulocochlear	Vestibular dysfunction, persistent otitis, tinnitus, hearing impairment
Ophthalmologic (lacrimal gland, eyes, lens, optic nerves, and chiasm)	Retinopathy, xerophthalmia, keratopathy, cataracts, visual impairment
Neurologic (brain, brainstem, spinal cord, temporal lobe)	Neurocognitive impairment, cranial neuropathy, myelopathy, brain necrosis
Endocrine (pituitary gland, hypothalamus, thyroid gland if neck is irradiated)	Multiple endocrine dysfunction: hyperprolactinemia, syndromes associated with decreased GH, FSH, LH, T4, TSH, ACTH, and their downstream hormones
Oral (major salivary glands, oral mucosa, mandible, and temporomandibular joint)	Xerostomia, dental caries, dysgeusia, mandible exposure, necrosis, and trismus
Connective tissue complications (oral cavity, soft palate musculature, pharynx, larynx, skin and subcutaneous tissues, skull bones)	Soft tissue necrosis, skin changes, persistent lymphedema, subcutaneous fibrosis, cartilage necrosis, nasal dryness, choanal stenosis, swallowing and voice dysfunction, bone necrosis

[a]Patients with node-negative disease.

ACTH, adrenocorticotropic hormone; FSH, follicle-stimulating hormone; GH, growth hormone; LH, luteinizing hormone; OS, overall survival; TSH, thyroid-stimulating hormone.

A 1991 review of outcomes after treatment of 73 patients with maxillary sinus carcinomas at MD Anderson Cancer Center reported 5-year local and regional control rates according to pathologic T category as follows: for T1 and T2 tumors, 91% local and 71% regional control; for T3, 77% local and 80% regional; and for T4, 65% local and 93% regional.[30] Five-year regional control rates according to N category were 84% for N0 disease and 82% for N1 or N2 disease. The most common histologic subtypes were SCC (48%) and adenoid cystic carcinoma (27%); 5-year local and regional control rates were 62% (local) and 86% (regional) for squamous cell tumors and 82% (local) and 94% (regional) for adenoid tumors. Perineural invasion and nodal disease at presentation were poor prognostic factors. An update of this report published in 2007[75] showed that increasing the radiation portals to cover the skull base for patients with perineural invasion reduced the risk of local recurrence and that adding elective nodal irradiation for patients with squamous or undifferentiated tumors improved the rates of nodal control, distant metastasis, and recurrence-free survival.

The extent of neuroendocrine differentiation of sinonasal carcinomas also influences the patterns of failure. In one study, the 5-year actuarial rates of local, regional, and distant failure according to tumor histology were as follows: ENB 4% local failure, 9% regional failure, and 0% distant failure; neuroendocrine carcinoma 27% local, 13% regional, and 12% distant; sinonasal undifferentiated carcinoma 21% local, 16% regional, and 25% distant; and small cell carcinoma 33% local failure, 44% regional failure, and 75% distant failure.[63]

IMRT has emerged as the standard of care for tumors of the paranasal sinuses with low toxicity and high local control rates.[43,69,84–87] Madani et al.[69] reported the largest series to date, in which 105 patients (most of whom [56%] had ethmoid sinus tumors) were treated with IMRT. At a median follow-up time of 40 months, the 5-year actuarial local control and overall survival rates were 70.7% and 58.5%. In multivariate analysis, invasion of the cribriform plate was found to predict worse local control ($P < .001$) and lower overall survival ($P < .001$).

The role of proton therapy using passive scattering and IMPT in the management of sinonasal malignancies is rapidly evolving and may be preferred over IMRT when dose limiting structures may be compromised with definitive doses.[47] Resto et al.[88] reported on 102 patients with various histologies receiving surgery and post-operative proton therapy. With a median follow-up of 61 mo, the 5-year local control and overall survival were 95% and 90% for complete

resection, 82% and 53% for partial resection, and 87% and 49% for biopsy-only. Toxicity was not reported. Russo et al.[89] reported on 54 patients with squamous cell carcinoma treated with proton therapy of which 69% had surgery and 39% had chemotherapy. The 5-year local regional control rate and overall survival were 73% and 47%, respectively. Wound site complications (e.g., fistulas) occurred most commonly with 9 Grade 3 and 6 Grade 4 complications. Zenda et al.[90] reported on 90 patients with various histologies of which 18% had surgery and 12% had chemotherapy. With a median follow-up of 57 months the 5-year overall survival and progression free survival rates were 64% and 44%, respectively. Linton et al.[91] reported on 26 patients with adenoid cystic carcinoma of which 77% had surgery and 23% were treated with protons alone. The 2-year local control and overall survival were 95% and 93%, respectively. There were 17 (19%) late Grade 3 and 6 (7%) late Grade 4 toxicities including 2 patients with encephalomyelitis infection and 4 patients with a optic nerve disorder. Takagi et al.[92] reported on 40 patients treated with definitive proton therapy alone for adenoid cystic carcinoma tumors, and with a median follow-up of 38 months, the 5-year local control, progression-free survival and overall survival were 76%, 30%, and 63%, respectively. There were 36 Grade 3 or higher events in 21 patients (26%). High grade toxicities included osteoradionecrosis, vision loss, and nasopharyngeal ulcers resulting in 3 Grade 5 toxicities.

Dagan et al.[93] described their experience in 84 patients treated with PT involving sinonasal sites: nasal/ethmoid (67), maxillary (15), frontal or sphenoid (2). Histologies included squamous cell carcinoma (22), adenoid cystic carcinoma (14), olfactory neuroblastoma (23), adenocarcinoma (8), sinonasal undifferentiated carcinoma (7), neuroendocrine carcinoma (4), mucoepidermoid carcinoma (3), and other histologies (3). Thirty-eight patients had intracranial tumors and 31 had orbital invasion. Eleven patients were treated after biopsy alone, 9 after subtotal resection, and 2 for recurrence after gross total resection. Twenty-two (26%) had gross tumor at the time of proton therapy. Median PT dose was 73.8 CGE (range, 56.8-74.4 CGE) at 1.2 CGE/ fraction twice daily with elective nodal therapy. Sixty-six (78%) of patients were treated to the neck electively. Sixty-three patients (75%) received chemotherapy (mostly concurrent low-dose weekly cisplatin). Median follow-up was 2.4 years (range, 0.4 to 6.7 years) for all patients and 2.7 years for living patients (range, 0.6 to 6.7 years). Three-year local control and nodal controls rates were 83% and 94%, respectively. Freedom from distant mets was 73.2%, cause-specific survival was

70%, and overall survival was 68%. Grade 3-5 toxicities occurred in 24% of patients with 1 fatal central nervous system necrosis.

Truong et al.[94] described their experience with 20 patients with primary sphenoid malignancy who received proton beam to a median dose of 76 CGE with a median follow-up of 27 months. The 2-year local control, regional control, and freedom from distant metastasis rates were 86%, 86%, and 50%, respectively.

Patel et al.[95] performed a meta-analysis summarizing the retrospective data of various histologies and performed comparative effective analysis between charged particle and photon therapy. The median follow-up time was approximately 40 months for both groups, and the pooled overall survival (relative risk 1.51, 95% CI 1.14-1.99; $p = 0.0003$) and disease-free survival (1.93, 95% CI 1.36-2.75, $p = 0.0003$) was higher at 5 years for charged particle than for photon therapy.

Future Directions in Radiation Therapy

IMRT has improved the cancer care in external beam RT for sinonasal malignancies.[43,76–79] Proton beam therapy confers further benefits for nasal and paranasal sinus tumors, and investigators at MD Anderson Cancer Center and others have demonstrated the clinical feasibility of IMPT for this purpose (Fig. 45.6).[96] The additional advantages of this technique over photon-based IMRT are its ability to limit the low dose radiation received by adjacent critical OAR structures and allow escalation of dose to the target volume. Well-designed clinical trials in cooperative group setting will be necessary to provide the evidence required for widespread adoption of PT over IMRT for these rare malignancies. Finally, further improvements in the local control of sinonasal malignancies will require incorporating systemic agents as neoadjuvant or concurrent therapy. Again, the rarity of sinonasal cancer will most likely require international cooperative group trials to facilitate timely analyses of outcomes and design of future trials.

SEQUELAE OF TREATMENT

Soft Tissue and Bone

The formation of nasal cavity synechiae (fibrous mucosal bands causing airway stenosis) can be prevented by intermittent dilation of the nasal passages with a petroleum-coated cotton swab until mucositis has resolved. Dry mucous

membranes can be managed symptomatically with saline nasal spray. Soft tissue or cartilage necrosis is uncommon after therapy, at an estimated incidence of 5% to 10%.[26,66]

Eyes and Optic Pathway

Chronic keratitis and iritis (dry eye syndrome) can develop after RT if tumor extension to the orbital cavity mandates irradiation of the lacrimal gland to doses of more than 30 to 40 Gy.[97,98] Without lacrimal irradiation, fewer than 20% of patients treated with up to 55 Gy to the cornea develop chronic corneal injury. The risk of cataract formation at 5 years is approximately 5% after doses of up to 10 Gy to the lenses using conventional fractionation; this risk increases to 50% at 5 years after 18 Gy.

Radiation retinopathy generally occurs within 18 months to 5 years after treatment.[99] It is rare after doses of <45 Gy, but the incidence increases to about 50% after doses of 45 to 55 Gy.[97,98] Optic neuropathy tends to develop between 2 and 4 years after RT, but it has been reported as late as 14 years after treatment. The reported incidence of optic neuropathy is <5% after 50 to 60 Gy but increases to around 30% for doses of 61 to 78 Gy. Factors that influence the risk of radiation-induced optic neuropathy were reported in 2006 for 273 patients treated between 1964 and 2000 in whom the radiation fields included the optic nerves or chiasm.[27] The likelihood of developing optic neuropathy was primarily influenced by the total dose, but fraction size was marginally significant. The 5-year rates of freedom from optic neuropathy were 95% for doses ≤63 Gy treated once daily, 98% for doses ≤63 Gy treated twice daily, 78% for doses >63 Gy treated once daily, and 91% for doses >63 Gy treated twice daily. On multivariate analysis, the risk of optic neuropathy was found to correlate with increasing total dose (P = .0047) and possibly with increasing patient age (P = .091), once-daily versus twice-daily fractionation (P = .068), and overall treatment time (P = .097). When the target volumes include the optic pathway, special attention must be paid to hot spots and dose per fraction to avoid optic neuropathies.

Optimizing the technique for paranasal sinus tumors is crucial so that the radiation dose to the optic apparatus is limited to the greatest extent possible to minimize the risk of complications. Investigators at the University of Florida, reviewing 464 patients treated from 1964 through 2001,[100] reported a 20% incidence of ipsilateral radiation retinopathy at 5 and 10 years after conventional or 3-D RT. In that study, patients were deemed functionally blind when visual

acuity dropped to 20/100 on the Snellen chart, and neovascularization (rubeosis iridis or neovascular glaucoma) was coincident with radiation retinopathy. Use of IMRT has been shown to limit the doses to the optic apparatus without compromising local control. Indeed, Chen et al.[50] reported findings for 127 patients treated between 1960 and 2005 with a variety of RT techniques that had evolved over that period, namely, conventional, 3-D conformal, and IMRT. They concluded that the incidence of severe (grade ≥ 3) complications depended on the radiation treatment technique used: 54% for conventional therapy, 22% for 3-D conformal therapy, and 13% for IMRT. Specifically, the incidence of grade 3 or 4 late ocular toxicity decreased from 20% with conventional techniques to 0% with IMRT, whereas grade 3 or 4 late auditory toxicity decreased from 15% with conventional to 4% with IMRT ($P < .001$).[50] Moreover, to date, no radiation-induced blindness has been reported among the collective experience, with 308 patients treated with IMRT as either definitive or postoperative therapy for nasal and paranasal malignancies.[43,50,61,69,84,85,87,101]

CHAPTER 46

Salivary Glands

Chris H. J. Terhaard

The salivary glands consist of the three large, paired major glands—parotid, submandibular, and sublingual (Fig. 46.1)—and many smaller, minor glands located throughout the upper aerodigestive tract. Salivary gland malignancies make up only approximately 0.4% of all cancers and account for <5% of the annual incidence of head and neck malignancies in the United States. The international variation in the incidence is between 0.4 and 2.6/100,000 per year, with a mean of approximately 1.2/100,000.[1] In the United States, the incidence of major salivary gland cancer increased from 1977 till 2009 from 1.0 to 1.6/100,000, mainly seen for the smaller tumors.[2]

ANATOMY

Major Salivary Glands

Parotid Gland

The parotid gland is located superficial to and partly behind the ramus of the mandible and covers the masseter muscle. Superficially, it overlaps the posterior part of the muscle and largely fills the space between the ramus of the mandible and the anterior border of the sternocleidomastoid muscle. One or more isthmi that wrap around the branches of the facial nerve connect the superficial and deep lobes of the gland. The nerve enters the deep surface of the gland as a single trunk, passing posterolateral to the styloid process. It usually leaves the gland as five or more branches, emerging at the anterior, upper, and lower borders of the gland. The facial nerve runs superficial to the main blood vessels that traverse the gland but is interwoven within the glandular tissue and its ducts. Thus, removal of all or part of the parotid gland demands meticulous dissection, if the nerve is to be spared.

The parotid gland contains an extensive lymphatic capillary plexus, many aggregates of lymphocytic cells, and numerous intraglandular lymph nodes in

the superficial lobe. Lymphatics drain from more lateral areas on the face, including parts of the eyelids, diagonally downward and posterior toward the parotid gland, as do the lymphatics from the frontal region of the scalp. Associated with the gland, both superficially and more deeply, are parotid nodes. These drain downward along the retromandibular vein to empty in part into the superficial lymphatics and nodes along the outer surface of the sternocleidomastoid muscle and in part into upper nodes of the deep cervical chain. Lymphatics from the parietal region of the scalp drain partly to the parotid nodes in front of the ear and partly to the retroauricular nodes in back of the ear, which, in turn, drain into upper deep cervical nodes.[3]

Submandibular Gland

The submandibular gland largely fills the triangle between the two bellies of the digastric and the lower border of the mandible and extends upward deep to the mandible. It lies partly on the lower surface of the mylohyoid and partly behind the muscle against the lateral surface of the muscle of the tongue, the hypoglossus. The submandibular gland has a larger superficial part, or body, and a smaller deep process. The inferior surface is adjacent to the submandibular lymph nodes, and the deep process of the submandibular gland lies between the mylohyoid laterally and the hypoglossus medially and between the lingual nerve above and the hypoglossal nerve below.[4] Bimanual palpation with one finger in the floor of the mouth and one under the edge of the mandible facilitates clinical detection of masses in this gland.

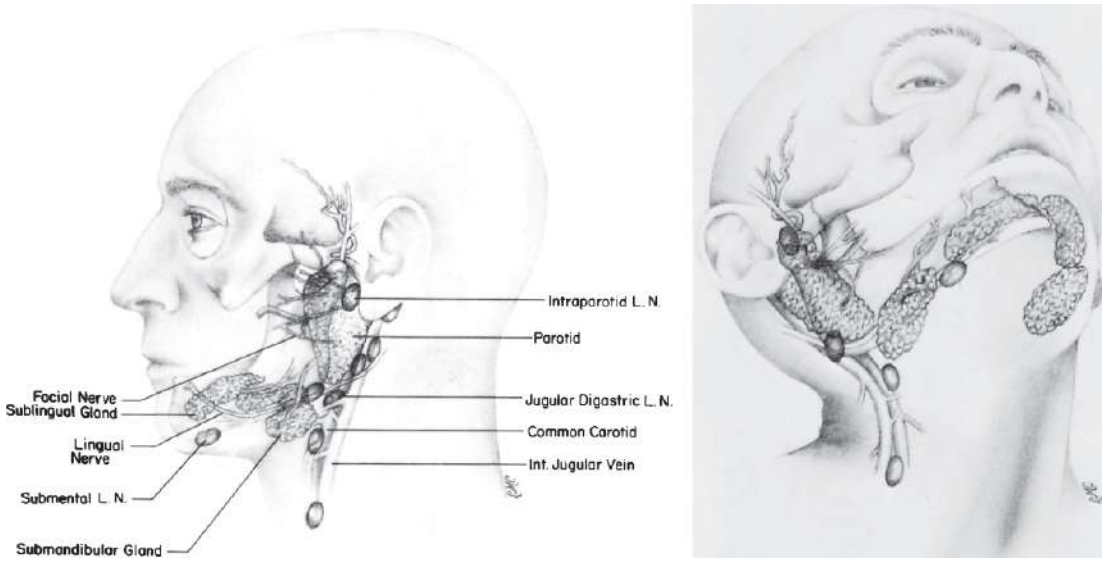

FIGURE 46.1. Anatomy of salivary glands.

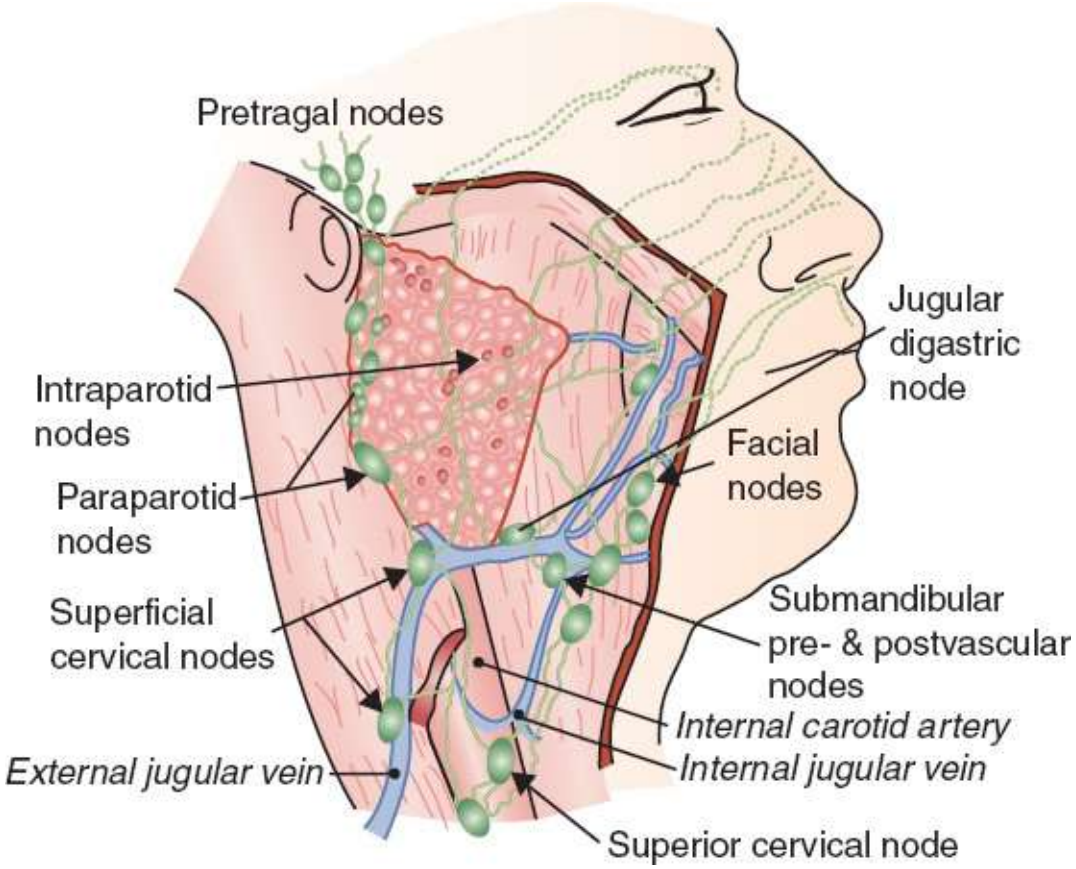

FIGURE 46.2. Lymph node distribution in and around the parotid gland.

A rich lymphatic capillary network lies in the interstitial spaces of the gland (Fig. 46.2). From the lateral and superior portions of the gland, lymph flows to the prevascular or preglandular submandibular lymph nodes. The posterior portion of the gland gives rise to one or two lymphatic trunks, which follow the facial artery and go directly to the anterior subdigastric nodes of the internal jugular chain.[5] The nodes overlying the submandibular gland, followed by the subdigastric and high midjugular lymph nodes, are those involved in nodal metastases.

Sublingual Gland

This smallest of the three major salivary glands, along with many minor salivary glands, lies between the mucous membrane of the floor of the mouth above and the mylohyoid muscle below, the mandible laterally, and the genioglossus muscles of the tongue medially. This is a rare site for malignant neoplasms; they are difficult to distinguish from cancer of the floor of the mouth accounting for fewer than 2% of all reported cases of salivary gland tumors.[1,6] The sublingual gland drains either to the submandibular lymph nodes or more posterior into the

deep internal jugular chain between the digastric and omohyoid muscles. Rarely, the lymphatics of the sublingual gland drain into a submental node or supraomohyoid jugular node.

Minor Salivary Glands

Minor salivary glands are widely distributed in the upper aerodigestive tract, palate, buccal mucosa, base of tongue, pharynx, trachea, cheek, lip, gingiva, and floor of mouth, tonsil, paranasal sinuses, nasal cavity, and nasopharynx.

EPIDEMIOLOGY

Seventy percent of all salivary tumors arise in the parotid gland, 8% in the submandibular gland, and 22% in the minor salivary glands.[6] The proportion of malignant tumors increases from parotid (25%) to submandibular (43%) to minor salivary glands (65%).[6,7] There is a preponderance of benign tumors in women; malignant tumors exhibit an equal sex distribution.[1] Patients with benign tumors are younger (mean age, 46 years) compared with those with malignant tumors (mean age, 54 years), with a trend to an older age for submandibular and minor salivary gland locations.[6] Two to three percent of salivary neoplasms occur in children, in whom half of the tumors are malignant.[8] Two-thirds of the cancers are located in the major salivary glands (parotid gland 53%, submandibular gland 12%, sublingual 1.5%), and one-third in the minor salivary glands, predominantly in the oral cavity.[1] The tumors in children are mostly less advanced, and a 95% 5-year survival is reached.[8]

Etiologic factors are not clearly defined. Nutrition may be a factor because Eskimos in the Arctic, who have low intake of vitamins A and C, have a high incidence. Cigarette smoking and alcohol consumption is in general not related with salivary gland cancer,[9] despite for Warthin tumors. In a study of de Ru et al.,[10] patients with a Warthin tumor had a smoking history in 97%; their mean age at the time of operation was 11 years higher compared to the pleomorphic adenoma group. Irradiation can also be a cause, as evidenced by the increased incidence in survivors of the atomic bombs dropped on Hiroshima and Nagasaki.[11] Saku et al.[11] studied salivary gland tumors in atomic bomb survivors of Hiroshima and Nagasaki. Two-thirds of all cases were parotid, and the remainder was equally distributed between submandibular and minor salivary glands. Mucoepidermoid cancer and Warthin tumor (benign) were particularly elevated compared with nonexposed persons and disproportionately high at high

radiation doses. The incidence of subsequent salivary gland cancer after radiation in childhood is increased compared to the general population.[12] There is a dose–response relationship with an excess relative risk of 0.27 to 0.36 per Gy.[13] The majority of these tumors are mucoepidermoid cancers[12]; however, <1% of salivary gland tumors may be caused by former irradiation.[14]

Workers in various occupations experience an increased risk of salivary gland cancer.[15] For women employed as hairdressers or working in beauty shops, a significant elevated risk was observed in a study by Swanson and Burns.[16]

Women with salivary gland cancer may have a 2.5 elevated breast cancer risk.[17] After treatment for salivary gland cancer, an increased risk for subsequent cancer of the oral cavity hazard ratio (HR 3.5) thyroid (HR 2.7), lung and kidney cancer (HR 1.7), and second salivary gland cancer (HR 10), especially after acinic cell cancer (HR 31) is seen. For adenoid cystic cancer, the risk of developing nasopharyngeal is increased with a factor 17.[18]

NATURAL HISTORY

Local invasion is the initial route of spread of malignant tumors of the salivary glands, depending on location and histologic type. For parotid tumors, this may result in fixation to structures in around 20% of cases.[19] Skin invasion is more often seen in parotid tumors (8% to 10%), compared with submandibular tumors (3%).[20,21]

Approximately 18% to 25% of patients with a malignant parotid salivary gland tumor present with facial palsy from cranial nerve invasion.[6,19,21,22]

A detailed study of the Dutch Head and Neck Oncology Group (NWHHT) concerning patients with a salivary gland malignancy found an overall incidence of clinically positive nodes of 14% and clinically occult, pathologically positive nodes in an additional 11% of patients.[20] This percentage depends on the number of neck dissections performed, the tumor location, histology, and T-stage. The number of elective neck dissections performed varies between the tumor locations. Stennert et al.[23] performed a neck dissection in all malignant *parotid* tumors and found 53% unilateral positive nodes and 0% contralateral nodes. In selected patients in other studies, the percentage positive nodes varied between 20%[24] and 38%.[25] In the large National Cancer Database in 24% of 22.653 parotid cases positive nodes and in 10% occult nodes were found.[26] Three out of four involved lymph nodes in early parotid malignancies (21% occult nodes) were localized in intraparotideal nodes by Stenner et al.[27] Resection of

submandibular tumors is combined with a (partial) neck dissection in most cases. Pathologic neck nodes may be seen in up to 42% of cases.[25] The risk of positive lymph nodes in *minor salivary gland* cancer is depending on four prognostic factors: male gender, T3-T4, pharyngeal site, and histology (high-grade mucoepidermoid and high-grade adenocarcinoma). Based on these factors, a scoring system from 0 to 4 was developed by Lloyd et al.[28] The risk of positive nodes in minor salivary gland cancer is less than 10% for score 0 to 1, 17% for score 2, 41% for score 3, and 70% for score 4. Salivary gland tumors arising in the oral cavity produce an incidence of cervical node metastases of <10%.[7,25,29,30] In nasopharyngeal salivary gland tumors, a risk around 20% has been shown.[30] In general, the risk of positive findings in the neck including *all salivary gland malignancies* may be based on a combination of T-stage, tumor localization, and histology. The highest risk is seen for squamous cell, undifferentiated cancer, and salivary duct cancer.[25,31] There is an intermediate risk for mucoepidermoid cancer and a low risk for acinic cell, adenoid cystic carcinoma, and carcinoma ex pleomorphic adenoma.[25] A 15% risk is found for T1 tumors, 26% for T2, and 33% for T3-T4.[25] An example of a rating scale to estimate the risk of positive neck nodes, based on tumor location, T-stage, and histologic type, is shown in Table 46.1.

Distant metastases overall are encountered in 3% to 4% of patients at presentation and in 33% after 10 years.[20,22] They are fairly common with adenoid cystic, salivary duct, squamous cell, and undifferentiated carcinomas; in the case of adenoid cystic carcinomas, they may occur quite late in the course of the disease, without recurrence of the primary tumor.[20,32,33] Distant metastases are primarily to lung, bone, and occasionally to the liver.[20] Reported incidence of distant metastases in patients with adenoid cystic carcinoma after 10 years of follow-up is around 40%.[20,33,34] Five years after diagnosis of distant metastases of adenoid cystic carcinoma and acinic cell cancer, more than one-third of the patients are still alive; 10% are alive after 10 years. An update of the survival data of the NWHHT study after diagnosis of distant metastases of salivary gland cancer is shown in Figure 46.3.

CLINICAL PRESENTATION

Three of four parotid masses are benign.[6] Patients most often have a painless, rapidly enlarging mass, often present for years before a sudden change in its indolent growth pattern prompts the patient to seek medical attention. Duration

of clinical symptoms before diagnosis may last more than 10 years.[6,20] For malignant tumors, the median duration of clinical symptoms generally is shorter (3 to 6 months)[20,37] compared to that of benign tumors, although for some minor salivary gland tumors, median periods of 2 years have been reported.[29]

Pain is more frequently associated with malignant disease.[6] Although as many as one-third of parotid cancers may have facial nerve involvement, only 10% to 20% of patients complain of pain.[6,19,20] Pain may appear with involvement of deeper structures (masseter, temporal, and pterygoid muscles). Rarely, tumors of the parotid may involve the base of skull and cause intractable pain and paralysis of various cranial nerves. Asymptomatic swelling of the floor of mouth is the primary presentation in sublingual salivary gland cancer, with pain and tongue numbness as symptoms of advanced disease.[38]

TABLE 46.1 RISK ESTIMATION (%) FOR POSITIVE NECK NODES

Summation: T Score + Histologic Type Score	Parotid Gland	Submandibular Gland	Oral Cavity	Other Locations
2	4	0	4	0
3	12	33	13	29
4	25	57	19	56
5	33	60	—	—
6	38	50	—	—

T1 = 1; T2 = 2; T3-T4 = 3; acinic/adenoid cystic/carcinoma ex pleomorphic adenoma = 1; mucoepidermoid = 2; squamous/undifferentiated = 3.

The signs and symptoms associated with tumors of the minor salivary glands vary because of their diverse locations. The distribution of presenting sites and risk of malignancy for 380 cases of intraoral minor salivary gland tumors is shown in Table 46.2.[39] A painless lump is the most common presenting symptom. Almost all extraoral minor salivary gland tumors are malignant.[6] Extraoral minor salivary gland tumors are most frequently seen in the nasal cavity (52%), followed by the larynx (18%), the oropharynx (14%, mostly localized in the tonsil), nasopharynx (8%), and ethmoid (8%).[6] For tumors arising in the nasal cavity or sinuses, facial pain is the most common presenting symptom, followed by nasal obstruction. Laryngeal primary tumors most frequently cause hoarseness or voice change.

Clinical features suggesting a malignant salivary gland tumor are rapid growth rate, pain, facial nerve palsy, childhood occurrence, skin involvement,

and cervical adenopathy.

TABLE 46.2 DISTRIBUTION OF PRESENTING SITES OF INTRAORAL MINOR SALVARY GLAND TUMORS

Site	No. of Patients (%)	Percentage Malignant
Palate	206 (54)	43
Upper lip	64 (17)	9
Buccal mucosa	54 (14)	37
Retromolar region	20 (5)	95
Lower lip	18 (5)	56
Floor of mouth	13 (3)	69
Tongue	5 (1)	60
Total	380	41

DIAGNOSTIC WORKUP AND STAGING

Major Salivary Glands

The diagnostic workup of major salivary gland tumors includes a careful history and physical examination, with particular attention to signs of local fixation or regional adenopathy.

For superficial lesions of the parotid gland, the submandibular gland, and sublingual gland and evaluation of the cervical lymph nodes, ultrasound (US) is the first diagnostic step, combined with fine needle aspiration cytology (FNAC). In US, signs of malignancy are ill-defined borders with heterogonous architecture, internal necrosis, and cystic changes.[40] Benign salivary tumors are well defined and hypoechoic. FNAC is very useful to differentiate between yes or no neoplastic lesions with a specificity of more than 95%. In a systematic review, Colella et al. found, for patients with a histologic diagnosis of a malignant tumor, benign tumor, or nonneoplastic lesion, concordant cytology in 80%, in 96%, and in 94%, respectively.[41] False-negative findings may be seen as a result of lack of representative material or a cyst. The next imaging tool in salivary gland tumors suspected for malignancy is magnetic resonance imaging (MRI). MRI is superior to CT, especially when malignancy is suspected, based on the excellent soft tissue contrast (Fig. 46.4). T1-weighted (W) images are

excellent to assess the margins, extension into the deep tissues, and patterns of infiltration because the (fatty) background of the gland is hyperintensive. With T1-W gadolinium series, tumor infiltration and heterogeneous enhancement may be visualized, as seen in high-grade tumors.[40] With fat-suppressed T2-W images, the fluid content of a tumor is visualized. In general, benign tumors are hyperintensive, and malignant tumors show intermediate or low intensity at T2-W MR images. A low apparent diffusion coefficient (ADC), derived from diffusion-weighted MRI, using high *b*-values, is associated with malignancy.[42] However, Warthin tumors (benign) may also show low ADC values.[43] Perineural invasion of adenoid cystic carcinoma may be evaluated with both CT (foraminal enlargement) and MRI (thickened nerve with enhancement at the fat-suppressed T1-weighted images).[40] The tumor extension along the facial nerve (VII) (foramen styloideum), the cranial nerve V-3 (foramen ovale) or nerve V-2 (foramen rotundum) as seen in tumors of the deep parotid lobe, may be visualized by T1-weighted images.[42] This is of special importance for the delineation of these nerves in case of postoperative radiotherapy for extensive perineural invasion; see Figure 46.5 for the trigeminal and facial nerves. Cortical involvement will be best evaluated by CT.

Fluorodeoxyglucose (FDG) uptake in salivary glands is quite unpredictable, resulting in a low sensitivity of FDG-PET for the diagnosis of malignancy in salivary glands.[44]

The 8th edition of the manual of the American Joint Committee on Cancer and the 8th edition of the classification system of the International Union Against Cancer are identical for major salivary glands[45] (Table 46.3). They are based on size, tumor extension, nodal size, and location, and, different from the 7th edition, extranodal extension. Relative survival rates for major salivary gland cancer according to stage are shown in Figure 46.6.

Minor Salivary Glands

Various radiographic studies may be used, including plain films, to ascertain bone erosion in advanced lesions. CT and MRI scans may be used to evaluate depth, contiguous involvement, and the retropharyngeal nodes. US and FNAC may be used to examine the neck nodes. The definitive diagnostic procedure is an excisional biopsy, particularly if malignancy is clinically expected. Unplanned incisional biopsies should be avoided, and fine needle biopsies are impractical because of the polymorphism of most malignant salivary gland tumors.

A formal staging system has not been developed for minor gland tumors. The same staging system for minor salivary glands as for squamous cell carcinoma in sites other than the parotid or submandibular glands may be used.[45]

PATHOLOGIC CLASSIFICATION

Salivary glands are composed of acinar–ductal units with acinar cells on the inside of the acinic and ductal epithelial cells on the inside of the striated and excretory ducts. Myoepithelial cells are located in the outside of acini and intercalated and striated ducts. Basal (reserve) cells are found on the outside of the excretory ducts.[46] Carcinomas may arise from all these cell types, separately or combined. The histologic classification of these salivary gland tumors is very demanding for the head and neck pathologist. In 1991, the World Health Organization classification for salivary gland tumors of 1972 was expanded from 7 to 20 subtypes. Various types of carcinomas were distinguished based on precise histologic definitions, prognosis, and treatment, discussed more in detail by Seifert and Sobin.[47] In 2005, the WHO classification of malignant salivary gland tumors was extended. Again, 24 subtypes were specified[46] (Table 46.4). Classification may be difficult, as shown in a reevaluation of 101 intraoral salivary gland tumors by experienced pathologists; major disagreement was seen in 8 and there was minor disagreement in 33.[48]

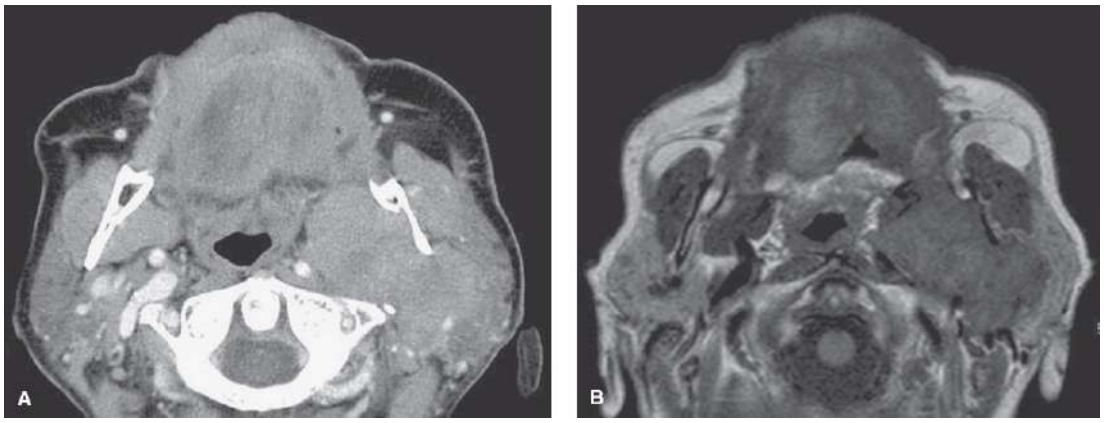

FIGURE 46.4. A patient with acinic cell cancer of the left parotid gland. **A:** Axial contrast-enhanced computed tomography image. **B:** T1-weighted magnetic resonance image. Both images show an infiltrating soft tissue mass involving the deep and superficial lobe. The tumor has widened the left stylomandibular tunnel, with infiltration in the pterygoid musculature. The left internal carotid artery is displaced medially. (Courtesy of Dr. F.A. Pameyer, radiologist, University Medical Center Utrecht.)

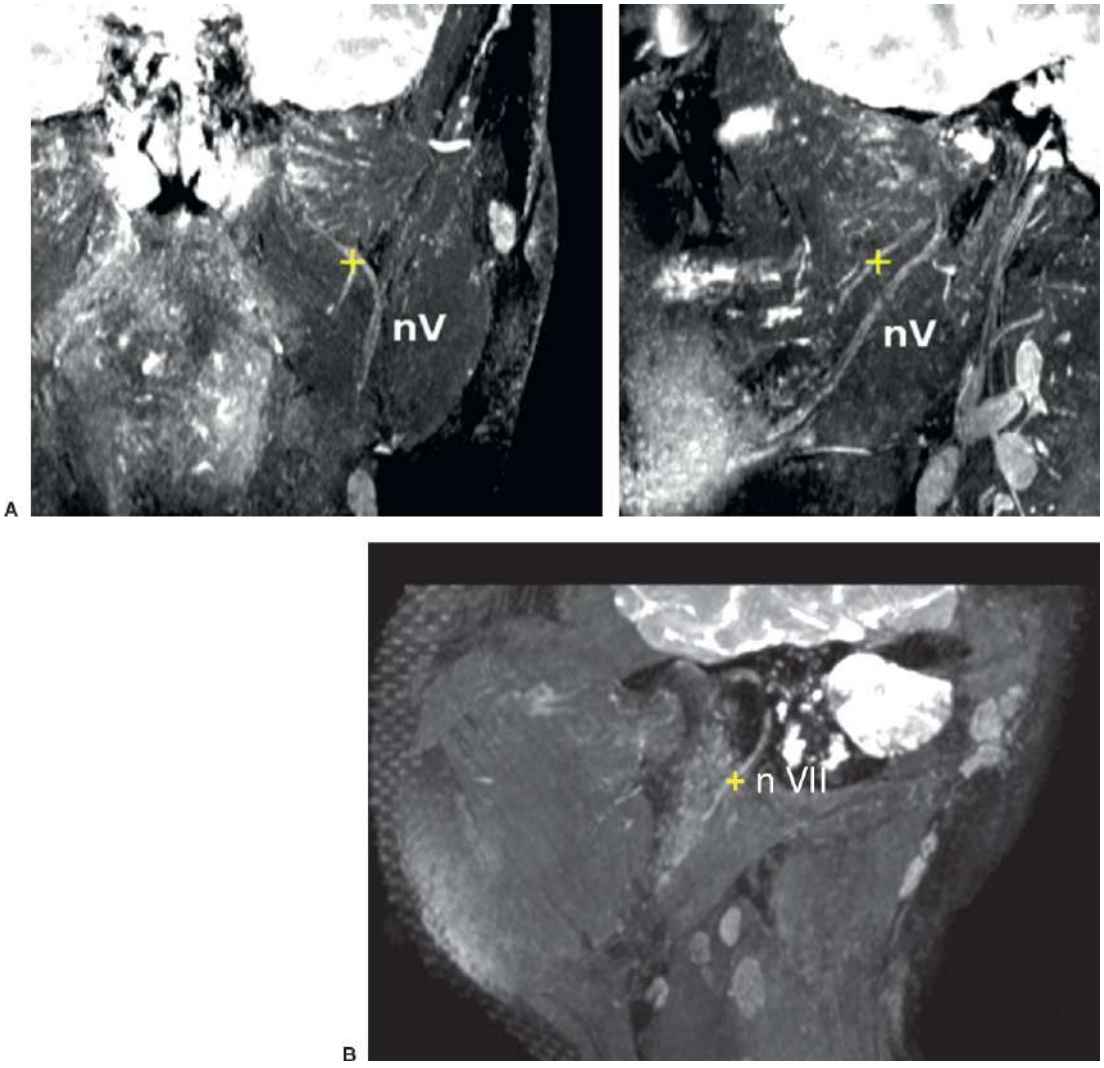

FIGURE 46.5. Three-dimensional magnetic resonance imaging, T2-FFE with binomial RF pulses for water-selective excitation: **(A)** nerve V (nV), **(B)** nerve VII (nVII).

Most salivary gland subtypes are very rare. The percentage of the histologic subtypes varies from series to series and from the localization of the tumor (Fig. 46.7). In 666 patients with a salivary gland carcinoma in a study performed in the Netherlands, for which the pathology was revised, adenoid cystic carcinoma was most frequently diagnosed (27%), followed by mucoepidermoid carcinoma (16%), acinic cell carcinoma (14%), carcinoma ex pleomorphic adenoma (8%), undifferentiated carcinoma (7%), salivary duct carcinoma (SDC) and adenocarcinoma NOS (both 6%), polymorph low-grade adenocarcinoma (PLGA) and squamous cell carcinoma (both 5%), and epithelial–myoepithelial carcinoma in 2%. In this large study, all other subtypes were rarely or not at all diagnosed.[20]

Salivary gland carcinomas may be graded as low and high malignant,

particularly for mucoepidermoid tumors. However, there is a disparity for grading, even among experienced pathologists.[49] Low-grade mucoepidermoid, PLGA, epithelial–myoepithelial, and acinic cell carcinomas comprise a group of low-to-moderate malignancy; high-grade mucoepidermoid, malignant mixed, adenoid cystic, squamous, undifferentiated, and SDCs represent more high-grade malignancies.[49]

Adenoid cystic carcinoma is most common in minor salivary glands, followed by the submandibular gland.[7,20,35,50,51] Perineural invasion is common in adenoid cystic carcinoma.[51–53] The adenoid cystic variety has a tubular pattern that has been associated with the best prognosis, a cribriform pattern with an intermediate prognosis, and a solid pattern with the worst prognosis.[54]

TABLE 46.3 UICC CANCER STAGING SYSTEM FOR MAJOR SALIVARY GLAND CANCER (PAROTID, SUBMANDIBULAR, SUBLINGUAL), 8TH EDITION

Primary Tumor (T)

T1	≤2 cm without extraparenchymal extension[a]
T2	>2–4 cm without extraparenchymal extension
T3	>4 cm and/or extraparenchymal extension[a]
T4a	Invasion skin and/or mandible and/or ear canal and/or facial nerve
T4b	Invasion skull base and/or pterygoid plates and/or carotid artery

Regional Lymph Nodes (N)

N0	No regional lymph node metastasis
N1	Ipsilateral single lymph node, ≤3 cm, without ENE
N2a	Single ipsilateral lymph node >3 cm but <6 cm, without ENE
N2b	Multiple ipsilateral lymph nodes, none >6 cm, without ENE
N2c	Bilateral or contralateral lymph nodes, none >6 cm, without ENE
N3a	Lymph node >6 cm, without ENE
N3b	Single or multiple nodes with ENE

Distant Metastases (M)

MX	Presence of distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

Stage Grouping

I	T1	N0	M0
II	T2	N0	M0
III	T3	N0	M0
	T1, T2, T3	N1	M0

IVA	T1, T2, T3	N2	M0
	T4a	N0, N1, N2	M0
IVB	T4b	Any N	M0
	Any T	N3	M0
IVC	Any T	Any N	M1

ENE, extranodal extension.

In parotid tumors in children and adults, the most common malignant subtype is the *mucoepidermoid* (MEC).[8,55–57] MEC contains squamous cells, mucus-producing cells, and cells of intermediate type. Several grading criteria and cell cycle–based Ki 67 proliferation index of MEC have been published.[46] *Acinic cell* cancer derives from cells of the terminal ducts and intercalated ducts. An extensive update of the literature is published by Vander Poorten et al.[58] Most tumors (86%) are located in the parotid gland.[58] Like in MEC, Ki 67 proliferation index is a prognostic factor for disease-free survival.[46] *Carcinoma ex pleomorphic adenoma* may be localized in all salivary glands, although the majority is found in the parotid gland. In the development of carcinoma ex pleomorphic adenoma, a progressive loss of heterozygosity of chromosome 8q, 12 G, and 17P is seen.[59] The prognosis is poor with a high risk of distant metastases.[20] *Undifferentiated and squamous cell carcinoma* are mainly localized in the parotid gland. The prevalence of comorbidity for patients with squamous cell carcinoma of the salivary gland is comparable to other head and neck cancers, whereas the prevalence of comorbidity in all other malignant salivary gland cancer subtypes is significantly less.[60] Also, patients with squamous cell carcinoma of the salivary glands are mostly older.[1] So squamous cell carcinoma of the salivary gland may be a different entity among salivary gland cancers. The PLGA, salivary duct, and epithelial myoepithelial carcinoma are the most common new subtypes of the World Health Organization 1991 classification. *PLGA* is a solid, ovoid, noncapsulated mass with a highly variable growth pattern (Fig. 46.8A). Most are located in the palate and are slowly growing tumors and 80% are stage I/II. The prognosis generally is good, with a tendency to local and seldom regional recurrences or distant metastases.[61] *Salivary duct carcinoma* resembles ductal breast cancer morphologically (Fig. 46.8B). They derive from excretory duct cells. They are usually located in the parotid gland and are highly aggressive.[62,63] They are frequently positive for androgen receptors and positive for HER2/neu protein.[63] However, the gene

amplification is seen in <50% of the cases.[46] There is also a low-grade subtype, resembling breast atypical ductal hyperplasia and low-grade ductal carcinoma *in situ*. The prognosis is excellent.[64] *Epithelial–myoepithelial carcinoma* is mainly localized in the parotid gland. The tumors are composed of myoepithelial cells, surrounded by epithelial-lined ducts, resembling intercalated ducts. It is a low-grade tumor, and all 14 patients of the Dutch study remained disease free. However, local recurrences may be encountered.[65] *Myoepithelial carcinomas* have exclusive myoepithelial differentiation. They are commonly seen in the parotid gland and the palate. Differentiation with other salivary gland cancers may be difficult. The prognosis is poor with a 40% 5-year disease-free survival.[66] *Basal cell adenocarcinoma* is a low-grade tumor, predominantly seen in the parotid gland, with a high risk on local recurrence but a low risk on regional recurrences or distant metastases.[67] *Malignant oncocytoma* is a high-grade malignant tumor, characterized by oncocytes, with necrosis, perineural spread, vascular invasion, and a high risk on cervical lymph nodes.[68] Most tumors are found in the parotid or submandibular gland. Positive resection margins are a major source of poor overall survival.[68] *Salivary gland cystadenocarcinoma* is a low-grade tumor, predominantly localized in the parotid gland. It has an excellent prognosis.[69] *Mucinous adenocarcinoma* is a high-grade malignancy from the palate and floor of mouth, with a high risk for neck node and distant metastases.[70] Sebaceous carcinoma is mainly localized in the parotid gland and a slow-growing, low-grade tumor.[71] In 2017, four new entities were described by Skalova et al.[72] *Mammary analog secretory carcinoma*, mostly a low-grade tumor, in the past was mainly classified as acinic cell carcinoma. They have specific chromosomal translocations and molecular and immunohistochemical findings. Most cases are seen in the parotid gland and oral cavity. *Cribriform adenocarcinoma* mimics PLGA and is primarily seen in the tongue. It is a very rare tumor, with a high risk on positive cervical lymph nodes. *Sclerosing polycystic adenosis adenoma* involves the parotid gland and is, although benignant, associated with a high risk of local recurrence after surgery. Finally, a new myoepithelioma variant is the *mucinous (secretory) myoepithelioma*, with a benignant to low-grade malignant behavior. It is a very rare subtype mainly seen in the minor salivary glands.

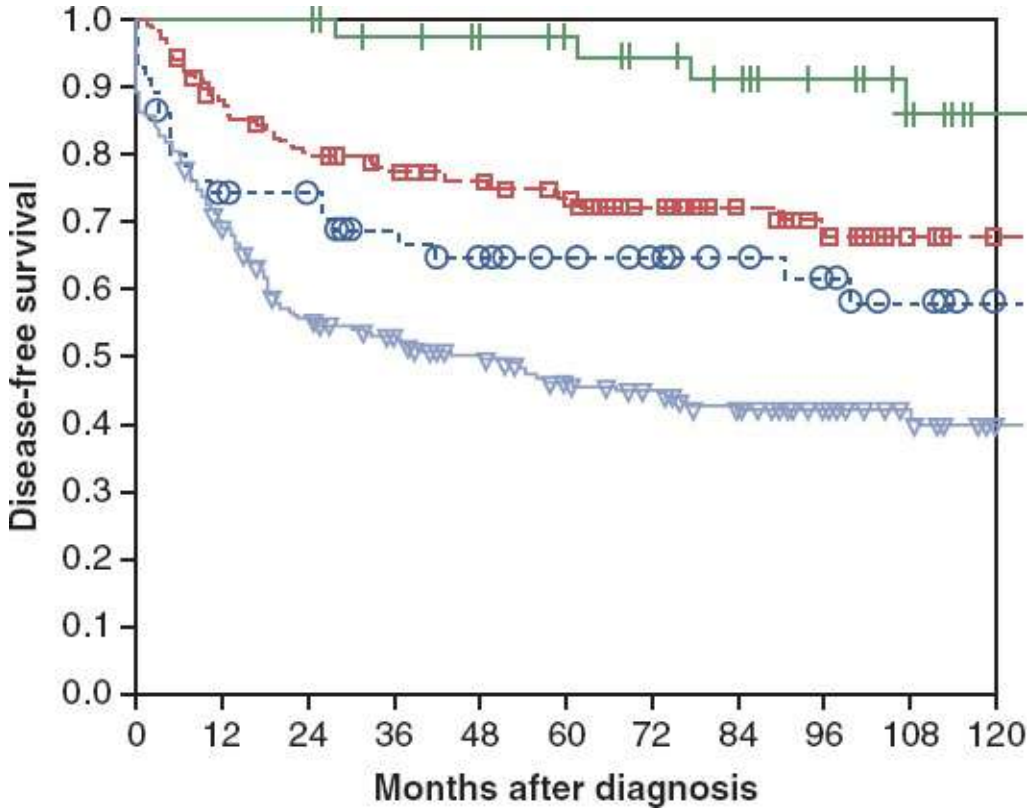

FIGURE 46.6. Disease-free survival for major salivary glands according to the 2002 classification of the American Joint Committee on Cancer. Results of the nationwide Dutch study: +, stage I; □, stage II; ○, stage III; ∇, stage IV.

TABLE 46.4 WHO 2005 CLASSIFICATION OF TUMORS OF THE SALIVARY GLANDS

Malignant Epithelial Tumors	Benign Epithelial Tumors
Acinic cell carcinoma	Pleomorphic adenoma
Mucoepidermoid carcinoma	Myoepithelioma
Adenoid cystic carcinoma	Basal cell adenoma
Polymorphous low-grade adenocarcinoma	Warthin tumor
Epithelial–myoepithelial carcinoma	Oncocytoma
Clear cell carcinoma NOS	Canalicular adenoma
Basal cell adenocarcinoma	Sebaceous adenoma
Sebaceous carcinoma	Lymphadenoma
Sebaceous lymphadenocarcinoma	Sebaceous
Cystadenocarcinoma	Nonsebaceous
Low-grade cribriform cystadenocarcinoma	Ductal papilloma
Mucinous adenocarcinoma	Inverted ductal papilloma
Oncocytic carcinoma	Intraductal papilloma
Salivary duct carcinoma	Sialadenoma papilliferum

Adenocarcinoma NOS	Cystadenoma
Myoepithelial carcinoma	
Carcinoma ex pleomorphic adenoma	**Soft tissue tumors**
Carcinosarcoma	Hemangioma
Metastasizing pleomorphic adenoma	
Squamous cell carcinoma	**Hematolymphoid tumors**
Small cell carcinoma	Hodgkin lymphoma
Large cell carcinoma	Diffuse large B-cell lymphoma
Lymphoepithelial carcinoma	Extranodal marginal zone B-cell lymphoma
Sialoblastoma	

NOS, not otherwise specified.

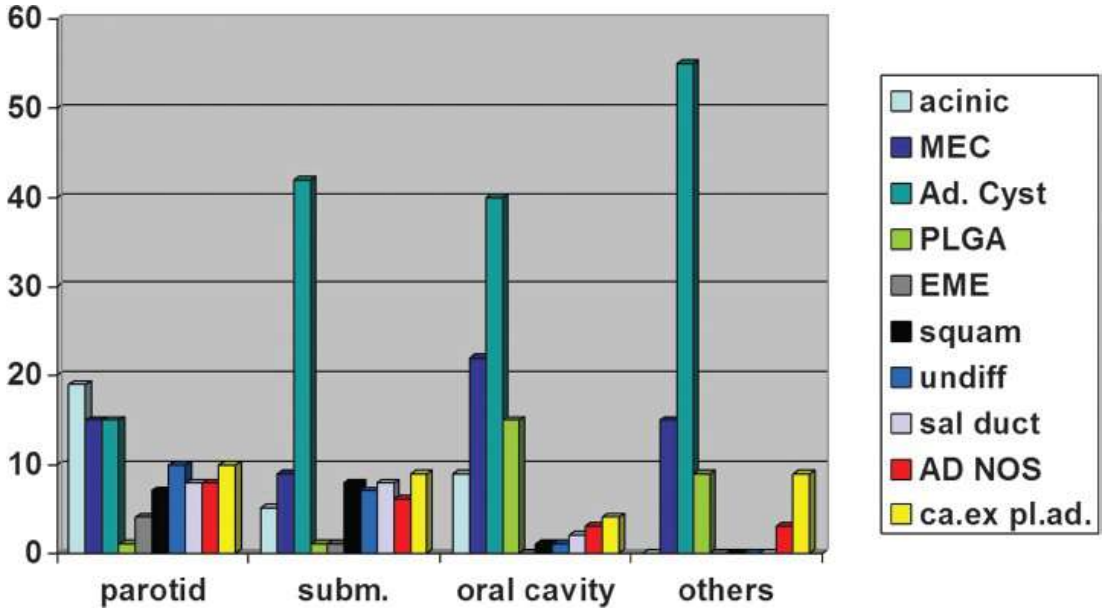

FIGURE 46.7. Distribution of various cell types (%) in series from the Dutch study, depending on site. Ad. Cyst, adenoid cystic; AD NOS, adenocarcinoma not otherwise specified; ca. ex pl. ad., carcinoma ex pleomorphic adenoma; EME, epithelial myoepithelial carcinoma; MEC, mucoepidermoid cancer; PLGA, polymorph low-grade adenocarcinoma; sal duct, salivary duct carcinoma; squam, squamous cell carcinoma; subm, submandibular. undiff, undifferentiated.

So based on the high morphologic diversity of salivary gland carcinomas, the differential diagnosis is a challenging task for the pathologist. Molecular testing may serve as a powerful diagnostic tool.[73]

PROGNOSTIC FACTORS

A number of prognostic variables have been studied in the management of salivary gland cancer. In these studies, multivariate analyses have been performed considering locoregional control, distant metastases, and survival. Results of studies with sufficient number of patients and follow-up have been summarized in Table 46.5. Local control and overall survival is influenced by site, favoring tumors of the oral cavity.[20] T- and N-stages are independent variables for locoregional control, distant metastases, and survival, regardless of site.[7,20,33,55,56,74,75,78–81] As may concluded from Table 46.5 in almost all studies, histologic subtype is not an independent prognostic factor for locoregional control but plays a role in risk on distant metastases and overall survival.[20] The added prognostic value of cytology and/or histologic subtype in salivary carcinoma is limited, largely because of the combined prognostic value of other prognostic factors such as tumor size, N- and M-classification, and comorbidity.[82] Histologic subtypes may be divided into low- and high-grade tumors, although a bit subjective. Grading is associated with risk of recurrence and overall survival.[75,78] Comorbidity is associated with overall survival; however, it is not with disease-free survival.[60]

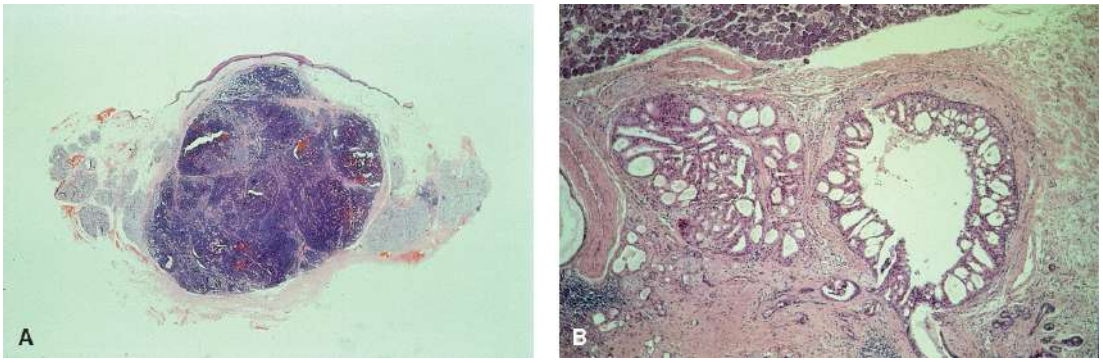

FIGURE 46.8.. Examples of polymorphous low-grade adenocarcinoma **(A)** and salivary duct carcinoma **(B)**. (Courtesy of Prof. Dr. P. Slootweg, pathologist, Radboud University Medical Center, Nijmegen Netherlands.)

Oncogene expression has been evaluated in the search for additional prognostic factors. In a review, Stenman et al. discussed the diagnostics and therapeutic importance of new biologic markers for salivary gland cancer.[83] Overexpression of HER2/neu is related with aggressiveness, distant metastases, and poor survival in salivary gland cancer[84] especially in SDC.[85] It also has been similarly associated with poor prognosis in carcinomas of the breast, ovary, and endometrium. High Ki 67 nuclear antigen and p53 tumor suppressor expression

may be related with poor prognosis. In a study of Finland, comparing both markers, only Ki 67 expression was an independent prognostic factor for overall survival.[86] Another molecular feature studied in relationship to prognosis was the DNA content in adenoid cystic carcinomas. DNA aneuploidy is correlated with the solid type and thus with poor prognosis.[54]

Major Salivary Glands

The survival of patients with submandibular cancers is inferior to that of parotid cancers according to a study by Spiro et al.[57] Extraglandular extension[55,56] and skin invasion[21,79,87] in parotid cancers result in decreased disease-free survival. More advanced age was found to be a negative prognostic factor for locoregional control in some studies[19,31,80] and for disease-free and overall survival in most studies.[21,55,57,79,81] Impairment of function of the facial nerve is a known prognostic factor, not only influencing locoregional control[6,20,87] but also disease-free survival.[79,81,87,88] Pain at presentation may be associated with reduced disease-free survival.[79] Perineural invasion and pain are closely related: not pain, but perineural growth, in some studies, is an independent prognostic factor for distant metastases[20] or disease-free survival.[56,76,89]

The importance of histologic subtype for major salivary gland cancer varies in published studies. In most studies, histologic types are subdivided into low and high grade. The main prognostic significance of grading relates to disease-free survival,[55,75] although grade was not a prognostic factor in most studies. In the large SEER database of major salivary gland carcinomas, higher grade was associated with higher stage and an independent prognostic factor for overall survival in stage II to IV.[90] The best prognosis is seen for acinic cell and (low-grade) mucoepidermoid cancer,[20,57] the worst for undifferentiated[20,87] and squamous cell cancer.[20,57] At the Netherlands Cancer Institute, a prognostic score for patients with parotid carcinoma was developed and validated.[21,79] The preoperative prognostic score was based on a weighted combination of prognostic factors (age, pain, clinical T- and N-stages, skin invasion, and facial nerve dysfunction); histology and grading were not incorporated. Four subgroups were formed with markedly different prognoses. In the postoperative score, perineural invasion and positive surgical margins were also included. In adenoid cystic carcinoma, named major nerve involvement is a prognostic factor; however, this may not be true for microscopic invasion only.[91] Intraneural invasion is a more predominant prognostic factor than perineural invasion.[92]

Positive or close surgical margins result in an increase in local recurrence rate.[20,50,75,77,93] Radiation therapy in addition to surgery improves locoregional control in patients with adverse prognostic factors.[19,25,76,78,87,94,95] Improvement of overall survival by adjuvant radiotherapy has been shown in data from the national cancer database[96] and even in early-stage adenoid cystic carcinoma.[97] In a matched-pair analysis of adjuvant radiotherapy, improved overall survival was found in stage III and IV major salivary glands.[98]

Minor Salivary Glands

Tumors located in the larynx or nasal cavity/paranasal sinus have significant lower cause-specific survival compared to location in the oral cavity.[99] The poorest prognosis is associated with adenoid cystic carcinoma.[29,36] Stage, base of skull involvement, and bone invasion are risk factors for locoregional recurrence and survival in minor salivary gland cancers.[7,29,36] Locoregional control may be improved by adding postoperative radiotherapy.[36]

GENERAL MANAGEMENT

The general management of salivary gland malignancies in most patients includes surgical excision followed by radiation therapy for unfavorable prognostic factors (Table 46.5). Postoperative radiotherapy to enhance local control is recommended for T3-T4 tumors, close or incomplete resection, bone involvement, perineural invasion, high-grade cancer, and recurrent cancer.[20,37,50,56,80,87] Postoperative radiotherapy is indicated for patients with neck node lymph metastases.[20,93] Elective neck radiotherapy prevents nodal relapses in a selected group of patients; however, it is in general not indicated for acinic cell or adenoid cystic carcinoma.[100] According to Chen et al., for carcinoma ex pleomorphic adenoma of the parotid gland and adenoid cystic carcinoma, surgery and postoperative local radiotherapy are the standards.[76,95] Concurrent postoperative platinum- and/or paclitaxel-based chemoradiotherapy for high-risk patients (nodal involvement, microscopic positive margins, T3-T4, perineural involvement) may result in high locoregional control rates, although in the published data, the number of patients is small, the follow-up is short, and the acute toxicity is more severe. However, in general, there is little proof that for salivary gland cancer, concurrent postoperative chemoradiotherapy is superior to postoperative radiation alone[101,102] For advanced, inoperable, and recurrent salivary gland cancers, high linear energy transfer (LET) radiotherapy

like primary neutron therapy[103] may lead to superior local control rates, compared with primary photon therapy, without evidence of improved survival rates[104] Another treatment option in these cases is carbon ions, with the obvious advantage of a higher relative biologic effect on tumor.[105] High local control rates may be achieved with primary treatment with carbon ions or protons in adenoid cystic carcinoma.[106] In Table 46.6, indications for radiotherapy of salivary gland cancer are summarized.

TABLE 46.6 INDICATIONS FOR RADIOTHERAPY: SALIVARY GLAND CANCER

Local Port	Regional Port	Primary RT (≥70 Gy)	High LET RT Consider if Available
AJC Stage T3-T4	pN_+ (60 Gy)	Med. inoperable	R2 resection
High grade	ENE (66 Gy)	Funct. inoperable	Primary RT: T4
Perineural invasion	Elective (Table 46.1) 50 Gy	Irresectable	Reirradiation
Close Res. (1–5 mm) (60 Gy)		Recurrent	
Incomplete Res. (66 Gy)			

ENE, extranodal extension; Funct, functional; Med, medical; PORT, postoperative radiotherapy; Res, resection; RT, radiotherapy.

Major Salivary Glands

Surgical technique depends on location and extent of primary disease and regional adenopathy. Preservation of the facial nerve, at least partially, followed by postoperative radiotherapy is the preferable treatment unless the facial nerve is involved by tumor.[107] Aggressive surgery does not improve disease-free survival. A decrease in extended surgery, resulting in a decrease of sacrifice of the facial nerve, has been shown in the course of years.[57] Cable facial nerve grafting with the greater auricular or sural nerve graft decreases the incidence of facial palsy postoperatively, especially if branches and not the main trunk are involved.[108] Adjuvant postoperative radiotherapy has no negative effect on facial nerve function.[108]

Surgical treatment includes neck dissection in cases of clinically positive nodes, followed by postoperative radiotherapy.[25] The risk of occult nodal disease depends on T-stage and histologic type.[25,100] As shown in the scoring system in

Table 46.1, the decision to treat the neck for parotid tumors will be indicated by a score of at least 4.[25] When local prognostic factors indicate postoperative radiotherapy, no elective neck dissection has to be performed; the neck nodes will also be irradiated.[23,109] Parotid tumors with facial nerve weakness are associated with frequent occult neck nodes; elective treatment is also indicated.[109] The first echelon neck nodes in parotid salivary gland cancer are the intraparotideal,[27,110] followed by level II, III, and IV nodes.[100,111] Involvement of level I nodes is an independent risk factor for disease-free survival.[110] Level I and V nodes are only involved if other levels are positive.[111] Contralateral nodes are not at risk. So in case of prophylactic treatment of the clinical N_0 neck, at least level II and III should be incorporated, followed by postoperative radiotherapy in case of pathologic positive nodes of level I to V. In most cases, elective neck dissection of level I to III combined with a local resection is performed for submandibular tumors. There is no indication for neck dissection for T1 acinic or T1 adenoid cystic tumors (Table 46.1).[25,50,100]

Minor Salivary Glands

The treatment of minor salivary gland tumors varies with location but usually involves an attempt at adequate surgical excision first. Irradiation has been used in surgically inaccessible sites or combined with surgery because of locally aggressive tumor behavior and the occurrence of incomplete resection.[20,37,112] For tumors arising in the palate, tongue, floor of the mouth, oral cavity, or oropharynx, surgical exposure is readily available, and resection usually can be accomplished with acceptable morbidity. Tumors arising in the posterior nasal cavity, nasopharynx, or sphenoid region, however, are relatively inaccessible and are mostly treated with radiation therapy.[112] The indication of elective neck treatment may depend on a prognostic index (score 0 to 4) using four clinicopathologic factors associated with increased risk on positive nodes: 1/male gender, 2/stage T3/T4, 3/pharyngeal location, and 4/high grade (28). For a score of ≥2, elective treatment of the neck nodes is indicated. Adenoid cystic carcinoma is the predominant histologic subtype in minor salivary gland cancer. The risk of occult neck disease is largest for oral cavity or oropharyngeal localizations. When postoperative radiotherapy is indicated, it is advised to treat the ipsilateral neck node levels I to III.[113] Patients with adenoid cystic carcinoma can have a long natural history with late recurrences,[112] and consideration should be given to careful surgical reconstruction and rehabilitation because even patients who are not cured can live many years before dying of disease (Fig.

46.3).[20] Occasionally, a patient may present after simple excision of a lesion, and the pathologic examination shows adenoid cystic carcinoma. If reexcision would cause significant functional or cosmetic sequelae, irradiation alone may be used. However, simple excision is not recommended as the initial management of these tumors because of the potential for a significant volume of residual disease. Surgery alone may be used to treat early-stage hard palate lesions without evidence of positive margins, perineural spread, or bone invasion; simple excision must be avoided.[37]

RADIATION THERAPY TECHNIQUES

Pleomorphic Adenoma

The pleomorphic adenoma (benign mixed tumor) is histologically benign, occurs frequently in a relatively young population, and comprises 65% to 75% of all parotid epithelial tumors.[57] Standard therapy has been conservative (superficial) parotidectomy, with recurrence rates of about up to 6.5% after 2 years.[114–116] Simple excision results in a high recurrence rate of around 25% as focal capsular exposure occurs in virtually all cases.[117] Besides, local recurrence is more frequently encountered in younger patients and positive resection margins.[114,116] Indications for postoperative irradiation may include microscopically positive margins after surgical resection and large, deep-seated lesions that may not allow complete surgical excision with adequate margins or would require sacrificing the facial nerve. The risk of malignant transformation in a large Dutch study was only 0.15%; however, in recurrent cases, it is 3.2%.[116] The mean delay between surgery and the first recurrence was 7 years and only 2 years for the second recurrence. The risk of facial nerve paresis increases after repeated surgery.[117] Most recurrent pleomorphic adenomas are multinodular.[118] In a review of Witt et al., local control after surgery for recurrence was 63% after surgery alone, and 91% after surgery with postoperative radiotherapy.[118] Radiotherapy may decrease the risk of a second recurrence in case of multinodular recurrence only, not for uninodular disease.[119] The entire parotid area should be irradiated with a dose of 50 to 60 Gy in 5 to 6 weeks. In Figure 46.9, an example of a large, multicystic pleomorphic adenoma is shown, with a close safety margin and spillage during parotidectomy; postoperative radiotherapy was indicated.

Parotid Gland

The volume of irradiation is determined by pathologic findings, such as

perineural invasion of a major nerve. Typically, the entire ipsilateral parotid gland is delineated on the postoperative CT scan performed in a custom-made head and neck mold.[56,120] The delineation of the clinical target volume will be individualized based on the extent of the disease and surgery.[56] In case of a tumor of the deep lobe, the parapharyngeal space and the infratemporal fossa have to be covered adequately. In general, it is not necessary to treat the scar to full skin dose because only 1% of the patients have a scar failure.[80] For very superficial localized tumors and in case of skin invasion, a bolus over the scar is required. In tumors with named perineural invasion (e.g., adenoid cystic carcinoma), especially in case of intraneural invasion,[92] the nerve provides a route to the base of skull. So it is important to cover the cranial nerve pathways from the parotid up to the base of the skull.[91] In perineural invasion, postoperative radiotherapy with a dose of 50 Gy, including the base of skull, decreased local recurrence rate from 15% with surgery alone to 5% with combined surgery and radiotherapy in a study of Chen et al.[121] Focal perineural invasion only is not an indication for routine inclusion of the nerve pathways. A clear relationship between dose and local control has only been found by Chen et al.; a dose of ≥60 Gy resulted in significant higher local control rates.[76] In general, a dose of at least 60 Gy postexcision is recommended[24,90,120] and at least 66 Gy (33 fractions) for high-risk patients with positive margins (<1 mm).[56]

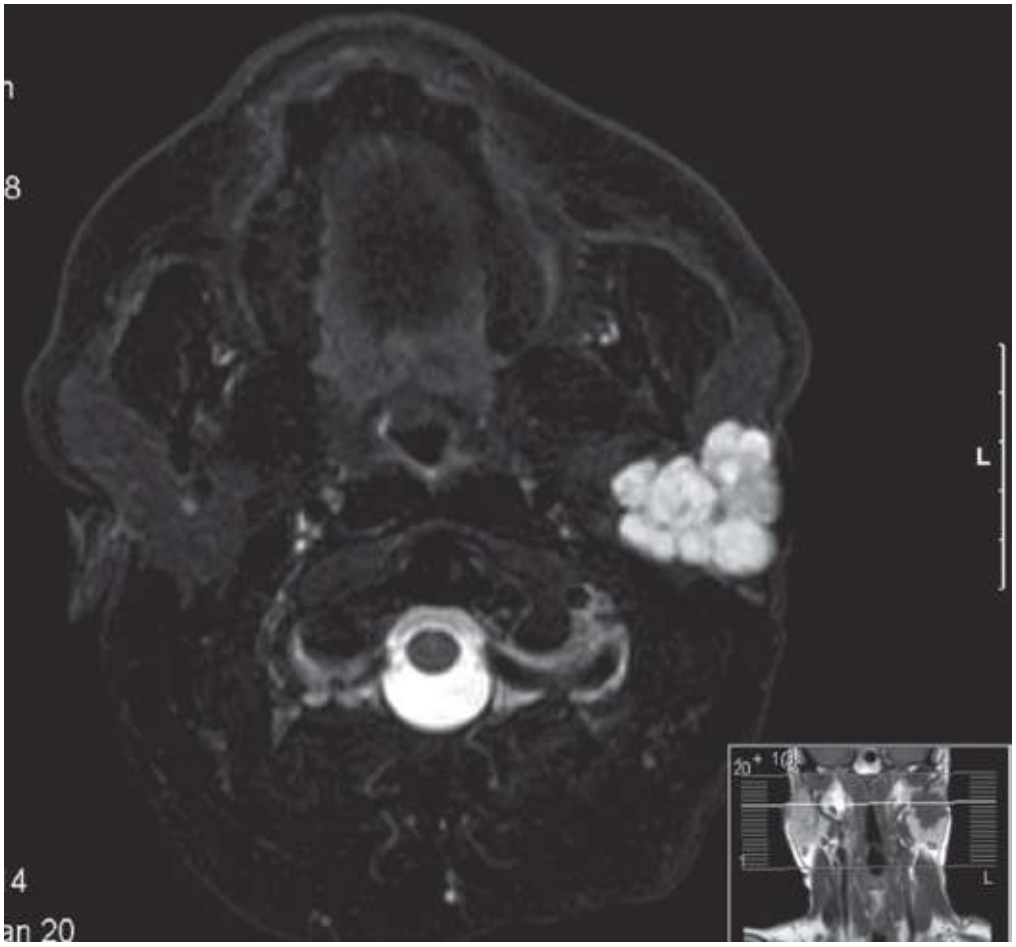

FIGURE 46.9. Multicystic pleomorphic adenoma, T2 STIR, transversal slice.

The ipsilateral neck is treated after a neck dissection has been performed for positive nodes; level I to V should be included.[25] There is no indication for bilateral elective neck treatment.[23,27,100] The recommended postoperative dose for positive nodes is at least 60 Gy (30 fractions) and 66 Gy for extranodal disease.[25] Elective irradiation of the neck should be considered for advanced T-stage, certain histologic subtypes (Table 46.1), facial nerve dysfunction at presentation, and recurrent disease. The intraparotideal nodes should be included.[27,110] At least in early case, high-risk parotid cancer level II and III should be included.[27] Level I and V are seldom positive if only one positive node is diagnosed. However, because in elective treatment the number of possible positive nodes is unknown, most authors advise to treat level Ib to IV prophylactically.[25,109,122] A dose of around 46 to 50 Gy is recommended.[25,56]

Three basic radiation therapy approaches are used, depending on available equipment: conventional, three-dimensional conformal radiation therapy (3DCRT) planning procedure, and intensity-modulated radiation therapy (IMRT)

planning. The first involves unilateral anterior and posterior wedged pair fields using ^{60}Co or 4- to 6-MV photons (Fig. 46.10A). Typical field boundaries are the zygomatic arch superiorly, the masseter muscle anteriorly, the pterygoid muscle and ramus mandibulae laterally, the mastoid process posteriorly, and the posterior belly of the digastric muscle inferiorly.[95] A slight inferior angulation of the beams avoids an exit dose through the contralateral eye. A simpler technique uses homolateral fields with 12- to 16-MeV electrons in combination with photons.[66,123] Usually, 80% of the dose is delivered with electrons and 20% with ^{60}Co or 4- to 6-MV photons to spare the opposite salivary gland, reduce mucositis, and decrease the skin reaction produced by electrons (Fig. 46.10B). Yaparpalvi et al.[123] compared nine conventional treatment techniques. Ipsilateral wedge pair technique with 6-MV photons, wedged anterior–posterior and posterior–anterior and lateral technique with 6-MV photons, and mixed beam using 6-MV photons and 16-MeV electrons (1:4 weighted) were most optimal, considering dose homogeneity within the target and dose to normal tissues. Electron beam (9 to 12 MeV) and tangential photon fields are effective conventional techniques for sparing the underlying spinal cord (from doses more than 45 Gy) and the opposite parotid gland in elective neck irradiation. Conventional techniques do not allow for tissue heterogeneity (air cavity, dense bones, and tissues); underdose and overdose may be seen. So in modern radiotherapy, conformal techniques should be the treatment of choice.

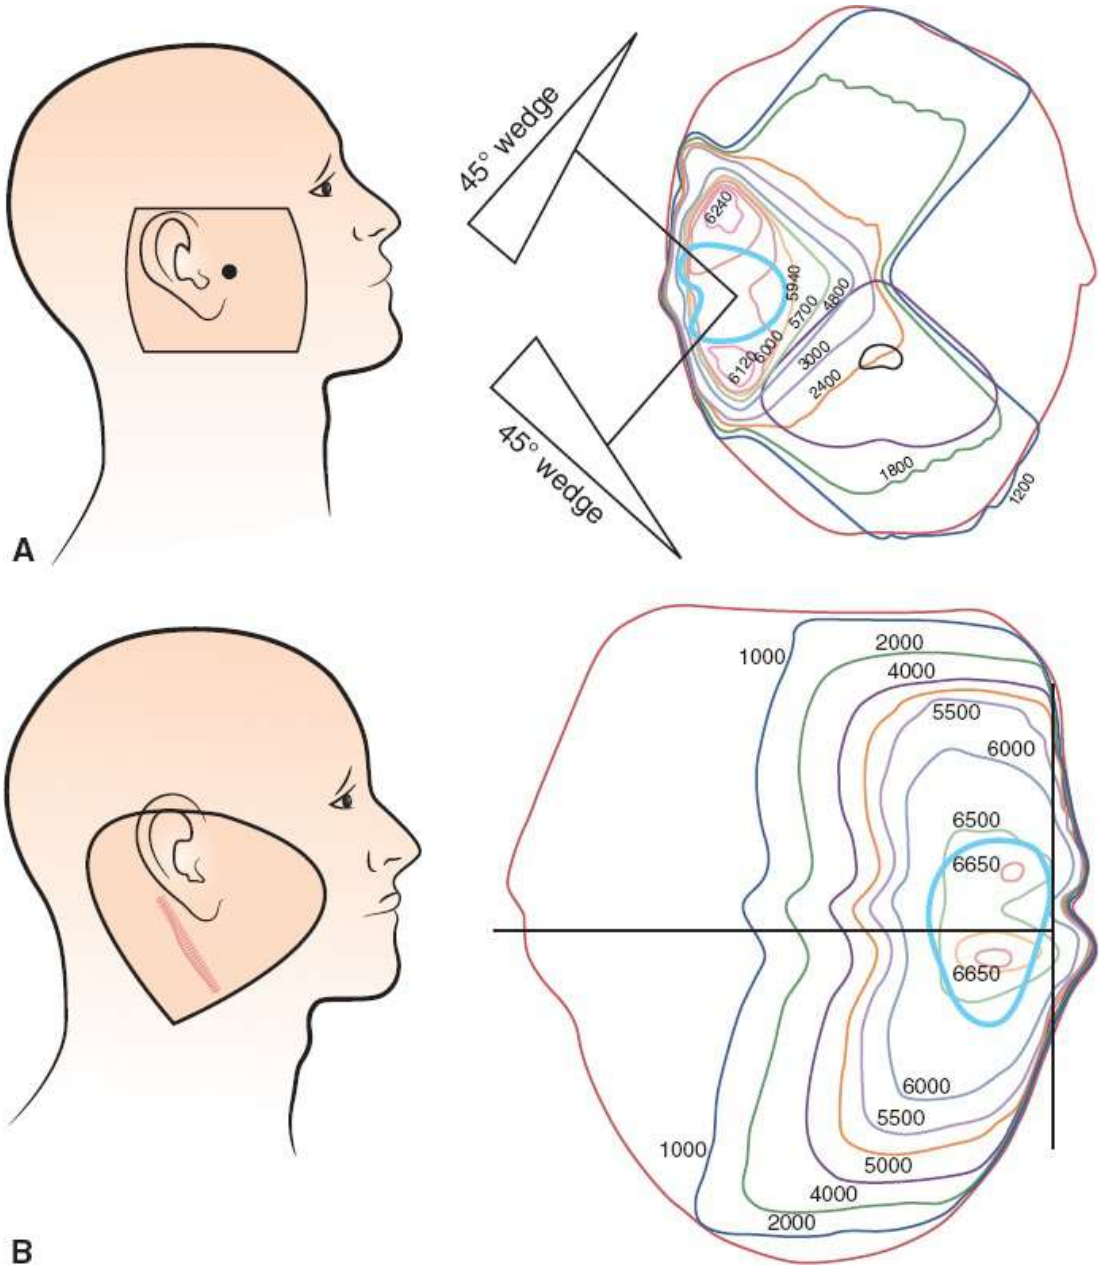

FIGURE 46.10. Conventional radiotherapy for parotid cancer. **A:** Unilateral wedge arrangement and isodose distribution using wedged pair. **B:** Ipsilateral 16-MeV electrons plus ^{60}Co (4:1) electron beam field.

After outlining of the target volumes and critical normal tissues on the planning CT scan, a more conformal 3DCRT plan by the use of geometrically shaped beams of uniform intensity may be reached.[119] More normal tissue may be spared with this technique.[120,124] In case of named perineural invasion, a 3-D FFE T2 MRI technique, performed in treatment position, may be used to delineate the cranial nerves (Fig. 46.5). Probably, the most conformal radiation

technique is IMRT. It can produce convex dose distributions and steep dose gradients. Five- to seven-field inverse IMRT allows excellent coverage of the tumor with sparing of mandible, cochlea, spinal cord, brain, and oropharynx,[125] compared with conformal 3DCRT. Especially the dose to the cochlea and Eustachian tube should stay under 45 to 50 Gy.[126,127] Compared to 3-D conformal radiotherapy, IMRT may spare the inner ear better.[128] In the national cancer database, 5-year overall survival for major salivary gland treated postoperatively with IMRT or 3DCRT was respectively 84.7% and 80.7% (*P* was 0.06).[97] Figure 46.11 shows a comparison of 3DCRT and IMRT planning for a postoperative radiotherapy plan for a parotid cancer, without named nerve involvement, treated with a dose of 66 Gy. The mean dose to the mastoid, meatus acusticus externus, and contralateral parotid gland was 53 and 43 Gy, 57 and 51 Gy, and 1 and 9 Gy, for 3DCRT and IMRT, respectively. The maximum dose to the cochlea was 39 and 32 Gy, respectively. In Figure 46.12, a patient with a recurrent adenocarcinoma of the parotid gland with named perineural involvement, for which a total parotidectomy was performed, is shown. The resection was incomplete. The facial nerve was delineated based on MRI (Figure 46.5B). A unilateral IMRT technique was used.

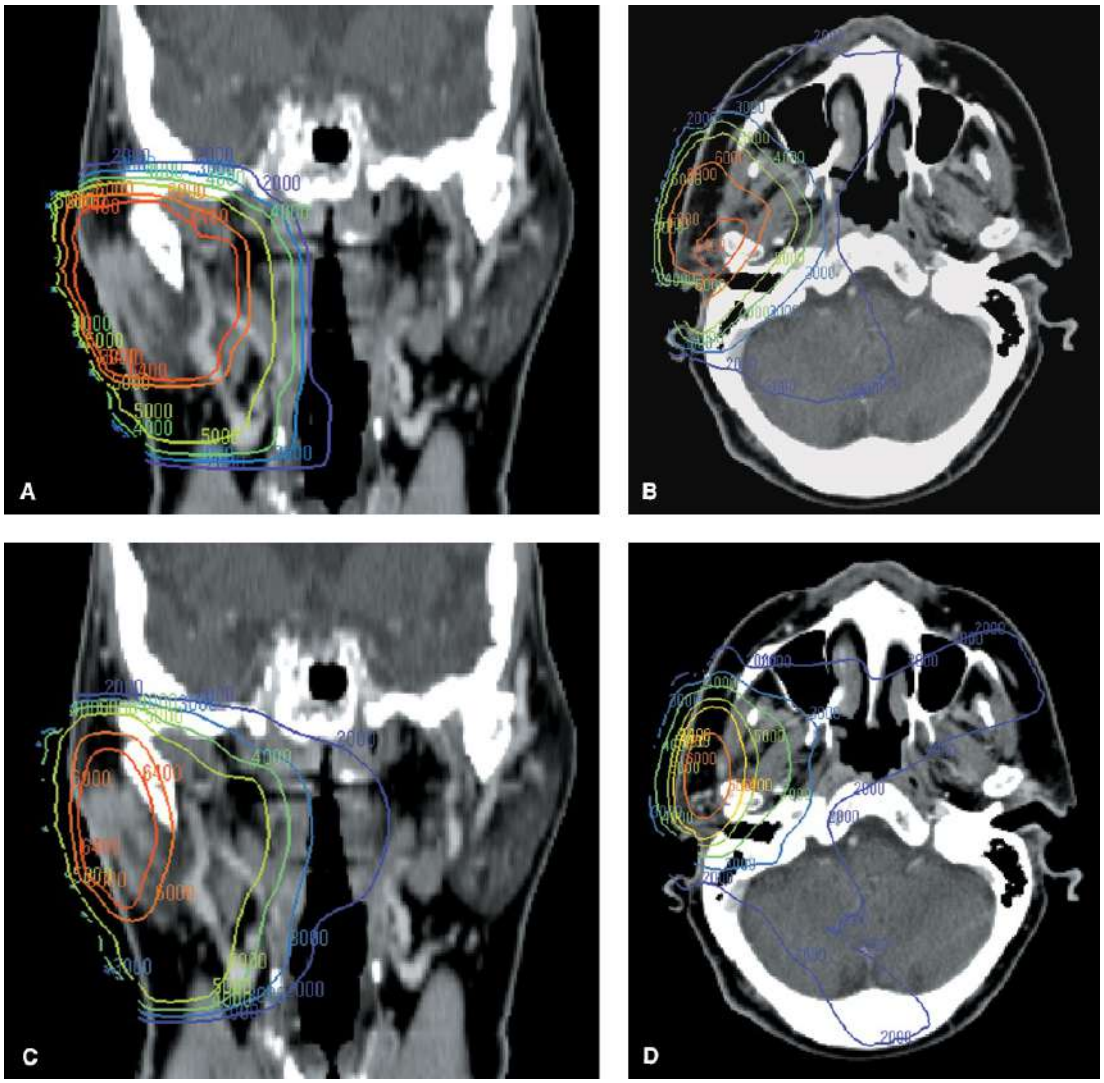

FIGURE 46.11. Postoperative radiation therapy of a parotid cancer, microscopically incomplete resected. Coronal **(A** and **C)** and transversal **(B** and **D)** dose distribution for three-dimensional conformal radiation therapy (25 × 2 Gy primary field, 8 × 2 Gy boost) **(A** and **B)** and intensity-modulated radiation therapy (inverse, 7 fields and 39 segments; simultaneously moderated accelerated radiotherapy (SMART): 33 × 1.6 Gy primary field, 33 × 2 Gy boost) **(C** and **D)**.

Submandibular Gland

Except for small acinic cell and adenoid cystic cancer (Table 46.1), the neck node level I to IV[122] should be irradiated electively, following the indications outlined for parotid tumors; technical considerations are similar. Bilateral fields may be required for tumor extension toward the midline. Five years locoregional control was significantly higher for a dose of more than 56 Gy in a study of Mallik et al.[129] If there is named perineural invasion of a major nerve, a tumor dose of 60 to 66 Gy in 6 to 6.5 weeks is recommended, and the nerve path to the

base of skull should be treated, preferably by IMRT. For an adenoid cystic carcinoma of the submandibular gland with only focal perineural invasion, an attempt to encompass the base of the skull would require a significant change in the treatment volume and may not be warranted because of potential morbidity and the low rate of relapse at that site.[112] An example of 3DCRT for a T2 adenoid cystic carcinoma of the submandibular gland is shown in Figure 46.13.

Sublingual Gland

These tumors are mostly malignant, mostly adenoid cystic carcinoma, mostly advanced disease, and high-grade, however with a low risk of positive neck nodes. Aggressive surgery is required, with postoperative local radiotherapy in almost all cases,[38,130] with elective treatment of level I to III.[130] In case of named nerve involvement, the lingual and/or hypoglossic nerve should be included in the radiation portals.

Minor Salivary Glands

The radiation therapy technique for treating minor salivary gland tumors depends on the area involved and is similar to the treatment for squamous cell carcinomas in these areas, with two significant exceptions. First, when a named branch of a cranial nerve is involved by adenoid cystic carcinoma, the nerve pathways to the base of the skull should be electively treated. Second, for tumors of the paranasal sinuses, the base of the skull is included because of its proximity to the tumor bed. In case of an adenoid cystic carcinoma with perineural invasion, IMRT may reduce the high dose volume, compared to conventional bilateral opposed fields; Figure 46.14 shows an example for a patient with a minor salivary gland cancer of the palate. IMRT is a useful strategy for irradiating minor salivary gland sites such as the ethmoid sinuses while sparing the optic pathways.[131]

Also, because the incidence of lymph node metastases is usually lower than that for squamous cell carcinomas of similar size, the radiation therapy fields are rarely extended to cover such areas if there are no palpable lymph node metastases. Indications for elective treatment of the neck nodes may depend on a scoring system.[25,28] Typically, for male patients with a T_3/T_4 N_0, pharyngeal site tumor neck nodes should be treated prophylactically.[112] In minor salivary gland cancers of the oral cavity, elective radiation of the neck nodes is seldom indicated. Postoperative radiotherapy is indicated after resection of metastatic neck lymphadenopathy.

For patients receiving postoperative irradiation after surgical resection, a dose of 60 Gy is given for close margins and 66 Gy for microscopically positive margins. For gross residual disease after surgery or for lesions treated with irradiation alone, a total dose of 70 Gy is recommended at 2 Gy per fraction. Elective dose to the nodal levels is in the range of 46 to 50 Gy.[25,132]

Three-dimensional conformal radiation therapy, three fields (one right and two left oblique): 25 × 2 Gy, 5 × weekly primary tumor and level I to III nodes, 8 × 2 Gy boost; transversal **(B)**, coronal **(C)**, and sagittal **(D)** planes. Mean dose to contralateral submandibular gland is 27 Gy.

RESULTS OF THERAPY

Surgery Plus or Minus Postoperative Radiotherapy

Tables 46.7 through 46.9 list local control rates and 5- and 10-year survival rates for several series reporting the surgical, irradiation, and combination treatment of carcinomas of the major and minor salivary glands. Little adverse effect of delay between surgery and radiotherapy may be predicted for what are, in general, slow-growing salivary gland cancers. In three studies, one concerning submandibular cancer,[50] one for minor salivary gland,[112] and another for adenoid cystic cancer,[76] impaired locoregional control rates were seen for a delay of more than 6 weeks, which was not confirmed in the Dutch study.[25] The prognosis for children with a malignant salivary gland cancer (mostly mucoepidermoid cancer of the parotid gland) is excellent, with a 5-year overall survival of more than 90%.[8] Most are treated with surgery alone because of the possible risk on radiation-induced malignancies.

Long-term follow-up is recommended because failures may appear after 5 years, especially for minor salivary gland tumors and adenoid cystic cancer.[7,20,22,76] Recurrent tumors in general are more difficult to control than are primary ones, so high initial locoregional control rates should be the goal. Because of high rates of local failure of approximately 40% for parotid, 60% for submandibular, and 65% for minor salivary glands with surgery alone in the past,[6] many institutions have advocated postoperative irradiation especially to reduce the incidence of local failure. Local tumor control appears to be improved by the combination of surgery and irradiation, although randomized, controlled trials have not been performed. Evidence of a positive role of postoperative radiotherapy is based on retrospective studies and a matched-pair analysis. In the study by Armstrong et al.,[76] postoperative radiotherapy significantly improved locoregional control (from 17% to 51% for stage III to IV), not for stage I and II major salivary gland cancer. Locoregional control for patients with positive nodes increased from 40% to 69%. In most studies, an imbalance in prognostic factors is seen comparing surgery alone with combined therapy, favoring surgery alone. Despite this imbalance, locoregional control with combined surgery and postoperative radiotherapy is superior to surgery alone for patients with negative prognostic factors, irrespective of site.[20,25,50,52,74,76,78,95,129] This was also shown for low-grade salivary gland cancer.[133] In the nationwide Dutch study, the relative risk for surgery alone, compared with combined treatment, was 9.7 for local recurrence and 2.3 for regional recurrence.[25] Postoperative radiotherapy is particularly effective if there are close (<5 mm) or microscopic positive resection margins, enhancing local control from around 50% to 80% to 95%.[25,76,77,107]

Comparable results are noted for T3-T4 tumors and pathologically confirmed bone and perineural invasion.[25,52,74,129] For adenoid cystic carcinoma with perineural invasion, postoperative radiotherapy increased 10-year local control rates from 30% to 80% in a study of Chen et al.[76] However, for a T1 or T2 tumor that was completely resected with no bone or perineural invasion, surgery alone will result in more than 90% 10-year local control rate and radiotherapy is not indicated.[25]

Treatment results also may depend on histopathologic status. However, after review, histologic type may change, even among experienced pathologists. In general, the best prognosis is shown for *acinic cell* and *mucoepidermoid* cancer, with a 15% risk of distant metastases after 10 years and a 10-year locoregional control rate of around 85%. Ten-year overall survival is around 80% and 65%, respectively.[6,20,35,58] Postoperative radiotherapy is indicated for the high-risk group.[20,58] *Squamous cell* and *undifferentiated* tumors have been associated with a 10-year overall survival of 35% or less, caused by a high risk of distant metastases (35% and 50%, respectively) and locoregional recurrence.[6,20,77] Postoperative radiotherapy is indicated in all cases to improve locoregional control. The intermediate-risk group consists of *cancer ex pleomorphic adenoma and adenoid cystic cancer*. Distant failure after 10 years is around 35%.[20,33,95] Although the risk of nodal recurrence is low (5% to 10%), local recurrence is diagnosed more often (20% to 50%). Postoperative radiotherapy is indicated in almost all cases. In cancer ex pleomorphic adenoma, 5-year local control rates were 75% and 49% for yes or no postoperative radiotherapy in a study of Chen et al.[95] A precipitous decrease in relapse-free survival is noted among 5 (around 70%), 10 (around 50%), and 15 years (around 45%) for patients with adenoid cystic carcinomas, which are well known for late recurrences.[20,52,76] Significant improvement was reported in local control for adenoid cystic cancer with

combined surgery and irradiation in several studies,[53,76,93,94] regardless of site. Local tumor control rates with combined modality therapy for these tumors approach 85% to 90% at 10 years.

In the World Health Organization classification of 1991, among others, three new subtypes were described that are diagnosed relatively frequently. *PLGA* is situated predominantly in the palate. The vast majority is cured with a wide local excision, without a need for elective treatment of the neck. In the large SEER database, the 10 years disease-specific survival was >95%, only 20% of the patients were treated with postoperative radiotherapy.[61] *Salivary duct carcinoma* is a very aggressive disease, predominantly localized in the parotid gland. Postoperative locoregional radiotherapy is indicated in all cases. Most patients die of disease, despite often successful locoregional combined therapy. Postoperative radiotherapy improves locoregional control.[62,63] Because of a high percentage of distant metastases, 5-year survival is only around 30%.[62] The prognosis correlates with HER2/neu receptor status. HER2/neu overexpression correlates with decreased disease-specific survival.[63] *Epithelial–myoepithelial* cancers have a very favorite outcome with a risk on distant metastases below 5%, and a disease-free survival of more than 80% after 10 years. However, local recurrences may be seen in one out of three; postoperative local radiotherapy is indicated in case of incomplete margin, tumor necrosis, lymphatic invasion, and myoepithelial anaplasia.[65] In *basal cell adenocarcinoma,* postoperative radiotherapy may increase overall survival for T3-T4 cases.[67]

Minor salivary gland tumors of the oral cavity have a more favorable prognosis than paranasal sinus tumors (maxillary and ethmoid sinus and nasal cavity).[112] Patients with hard palate lesions tend to be diagnosed when they have small asymptomatic lumps, which are easily detected on physical examination. On the other hand, paranasal sinus tumors usually do not cause symptoms until they are locally advanced. The surgical approach for these tumors is more difficult, with a greater chance for leaving behind residual disease, leading to high recurrence rates. A combined approach with surgery and postoperative irradiation is recommended, with 10-year local control rates around 85% (see Table 46.9).[36,112,132]

Primary Radiotherapy

The poor results for salivary gland cancer with irradiation alone in several series have been attributed to the use of primary radiotherapy for patients with locally advanced lesions or distant metastases at presentation, who were essentially treated for palliation. Locoregional control rates after conventional photon or electron therapy are around 25%.[101,104] Ten-year locoregional control depended on T-stage in a series of the University of Florida, 72% and 20% for T1-T3 and

T4, respectively.[74] For treatment with photons with curative intent, a clear dose–response relationship has been described.[25,134] A dose of at least 66 to 70 Gy should be adapted, resulting in a 5-year local control of 50% to 70%, although late recurrence was observed. The generally slow rate of regression of advanced salivary gland tumors have made them a logical target for alternative radiation therapy approaches, such as high LET particles and proton therapy.

Particle Therapy

Patients with inoperable primary or recurrent major or minor salivary glands were included in the RTOG-MRC randomized phase III clinical trial. Patients were randomized between 70 Gy for 7.5 weeks or 55 Gy for 4 weeks photon therapy and neutron therapy. The study had to be stopped because of a statistically significant difference in 2-year locoregional control, after inclusion of only 32 patients. The 10-year locoregional control probability was 17% after photon therapy and 56% after neutron therapy.[104] However, survival was identical. Late morbidity was somewhat higher for neutron therapy. Primary neutron therapy in salivary gland disease is reserved for macroscopically residual disease after surgery (R2) and unresected and irresectable tumors. Stannard et al. have published results of 335 patients with neutrons.[103] The 5-year locoregional control was 80% after R2 resection, 55% for unresected cases, and 40% for irresectable cases. The risk of late grade 3 to 4 morbidity was 20%.

In an effort to improve poor results for tumors invading the base of skull, several new techniques have been developed. A combination of neutron therapy with, after a 4-week split, a gamma knife stereotactic radiosurgical boost has been used for tumors invading the base of skull.[135] Compared to a historical control group, treated with neutrons only, in 34 patients treated with combined neutrons and gamma knife, the actuarial local control rate at 40 months was 82% versus 39% for the control group. Complication grades were equal.[135]

Carbon ions have the theoretical advantage of comparable LET as neutrons, however with a higher biologic effectiveness. In Heidelberg, 309 advanced adenoid cystic carcinoma, 60% T4, and 37% paranasal location were treated with a combination of photons (median 50 Gy) and carbon ions (median 24 GyE).[136] Five-year local control for R1 (29%), R2 resection (44%), and inoperable tumors (28%) were ±80%, 56%, and 51%, respectively. Toxicity was moderate. In a subset of R2 resection and inoperable cases (>90% T4, paranasal, parotid gland with base of skull invasion, nasopharynx), combined IMRT with carbon ion boost (n = 58) was compared with IMRT only (n = 37). Although not

randomized, 5-year local control with carbon ion boost was significantly better (60% vs. 40%).[137] In a series from Japan, primary carbon ion therapy (n = 40) was compared with primary proton therapy (n = 40) for advanced adenoid cystic carcinoma. Local control after 5 years for T4 and inoperable cases was equal (68%) for both treatment options.[106] However, the incidence of late grade 3 or more late complications in their study was high (61% for protons and 39% for carbon ions) and dose dependent (>72 GyE).[106] Actually, because of the favorable Brack peak, protons may be used to decrease toxicity. Because of a lower dose to organs at risk, acute toxicity was lower in a retrospective study comparing protons with photons in pediatric salivary gland tumors.[138] However, data concerning proton therapy for salivary gland cancer are scarce, and future studies are needed.

In conclusion, carbon ions or neutron beam therapy should be taken into account, if available, for unresectable, residual, or recurrent salivary gland tumors.[105] Despite high locoregional control, overall survival seems not to be improved and late toxicity is of concern. The value of proton therapy for these indications should be studied.

SYSTEMIC THERAPY

The rarity of these neoplasms and their localized nature provide limited opportunities for trials with chemotherapy. Most published studies concern small series with different histologic subtypes, using a large variety in chemotherapy regimens. Encouraging results are shown for *concurrent* postoperative chemoradiotherapy (paclitaxel, 5FU, hydroxyurea; twice a day 1.5 Gy, mean dose 65 Gy) in high-risk salivary gland cancer by Pederson et al.[139] In 24 patients, a 5-year locoregional progression-free survival of 96% and a 5-year overall survival of 59% was reached. In another small case control study of 24 patients, comparing postoperative platinum-based chemoradiotherapy (63 Gy) with postoperative radiotherapy alone, 3-year overall survival was significantly higher for the combined group (83% vs. 44%, respectively).[140] However, 3-year local progression-free survival was moderate in both groups (61% vs. 44% respectively). In the analysis of the large SEER database, postoperative chemoradiation for resected major salivary gland cancer resulted into worse overall survival compared to postoperative radiation alone, even after propensity score-matched analysis.[101] So in general, there is no proof of superiority for concurrent chemoradiotherapy in the curative setting.[102] Although there might

be a case for postoperative chemoradiation in high-risk salivary gland cancer (T3-T4, positive margins, high grade, perineural extension, positive nodes),[141] this has to be proven in prospective randomized studies, like the ongoing RTOG 1008 trial.

In the *palliative* setting, chemotherapy may be beneficial in patients who have progressive, symptomatic disease with no other treatment options. Cisplatin as monotherapy shows a 20% response rate for locoregional disease and only 7% for distant failures, with duration of 6 to 9 months. In a phase 2 study, chemotherapy alone (platinum and gemcitabine) for advanced, metastatic, or locoregionally recurrent salivary gland cancer showed an objective, modest, response of 25% (n = 30) with a mean duration of 6 months.[142] Comparable response rates were shown for a combination of cisplatin and vinorelbine.[143] In ACC single-agent, vinorelbine, epirubicin, and mitoxantrone are first-line options; for combined regimens, cisplatin and anthracyclines are recommended, however with a response rate of 30% or less.[144]

Molecular targeting therapy is a promising cancer treatment option. A variety of drugs, targeting on specific pathways, are used in the palliative treatment of salivary gland cancer.[73,83] In a large series of 139 patients with primary, recurrent, and metastatic salivary gland cancer, treatment relevant target immunophenotyping has been performed by Locati et al.[145] Tyrosine kinase receptors (TKRs) and EGFR were positive in 70% for all histologic subtypes. C-kit was positive in 78% of the ACC. HER2/neu was positive in 44% in SDC and in 21% adenocarcinoma NOS. Hormonal receptor status was also determined. In SDC and adenocarcinoma NOS, androgen receptor was positive in 43% and 21% respectively.[145] Her2/NEU and EGFR were positive in 26% and 70%, respectively, in a study with 66 SDC.[85] These findings could be exploited for selection of patients for molecular targeting treatment. However, the response rate of the investigated targeted therapy is, until now, limited. A promising role for antiandrogen deprivation has been shown in 17 patients with a recurrent/metastatic androgen receptor expressing salivary gland cancer. The response rate was 67% with even three complete responders and a median progression-free survival of 11 months.[146] In the future, the role of molecular-targeted therapy for these salivary gland cancers has to be further established.[147]

SEQUELAE OF TREATMENT

The most notable complication of treatment of parotid malignancies is facial

nerve paralysis, which is often caused by the initial or a repeated surgical procedure. However, various series have shown that facial nerve sacrifice is rarely necessary, unless the nerve is directly involved by tumor, particularly when postoperative irradiation is given.[57,77] When facial nerve sacrifice is required, facial nerve grafting and postoperative radiation therapy achieve comparable facial nerve function compared with unirradiated graft despite more negative prognostic factors.[107] Other postoperative sequelae, such as salivary fistulae and neuromas of the greater auricular nerve, are sometimes seen. Frey syndrome (i.e., gustatory sweating) may occur in a few patients after parotid surgery, but it is rarely bothersome.[80]

Partial xerostomia after irradiation of the parotid gland is frequently observed and may be permanent. Trismus may result from radiation-induced fibrosis of the temporomandibular joint or the masseter muscles. It usually occurs when there is extensive tumor infiltration of the masseter muscle and high doses are given.

Radiotherapy to the parotid gland may result in complications along the auditory system. As late toxicity, external canal stenosis, dryness, skin atrophy, and chronic otitis externa, resulting in conductive hearing loss, although rare, may be seen. Chronic otitis media has been documented in 35% to 40%, because of damage to the muscles of the tuba of Eustachius. This may lead to conductive hearing loss, and repeated myringotomies may be indicated.[148] Radiation-induced hearing loss mostly is caused by progressive endothelial damage to the vascularization of the inner ear. This will cause sensorineural hearing loss, cognitive impairment, and, at the end, decrease quality of life. However, most hearing loss is seen above 4,000 Hz; for daily use, normal frequency ranges from 1,000 to 3,000 Hz. In a prospective study of patients treated for head and neck cancer, a ≥10 dB hearing loss 2 years after radiotherapy was seen in 40% for 8,000 Hz, and in 50% for 3,000 Hz.[127] A threshold of 45 Gy was seen at ≥2,000 Hz, also depending on age and baseline hearing loss.[127] In published results, the mean threshold dose for the cochlea and tuba of Eustachius for sensorineural hearing loss varies between 40 Gy and 50 Gy.[126,127,148] The latency is around 1.5 to 2 years. After this time, hearing loss stabilizes. The risk of sensorineural hearing loss is depending on radiation technique. From 2-D conventional to 3-D conformal radiotherapy, the mean dose to the cochlea may decrease from above 50 Gy to around 40 Gy,[120,124] and further improvement is noted with the use of IMRT.[120,128] No dose–response relationship has been published for vestibular damage.[148]

Garden et al.[112] reported complications of irradiation in 51 of 160 patients receiving postoperative *conventional 2-D* irradiation for minor salivary gland tumors. The most common complication was decreased hearing in 26 patients, 20 of whom had myringotomies or myringotomy tubes placed for serous otitis media. Bone necrosis or exposure was observed in several patients; however, this complication has been seen infrequently during the past decade with improved radiation therapy techniques and treatment of multiple, as opposed to single fields per day. Complications to the eyes or optic pathways were diagnosed in patients with paranasal sinus primary tumors. At least six cases of contralateral optic atrophy occurred.[112] Other eye complications included dry eye syndrome, nasolacrimal duct obstruction, cataract, retinopathy, and perforated globe.[112] To reduce the incidence of bilateral blindness, the dose to the optic chiasm and contralateral optic nerve is limited to 54 Gy. In patients with extensive tumor involvement of the orbit, it may be preferable to remove the eye surgically rather than to subject the entire orbit to high doses. Radiation-induced injury to the visual pathway is dose dependent. None of the patients receiving a dose of <50 Gy develop optic neuropathy or chiasm injury, whereas the 10-year actuarial incidences of optic nerve chiasm injury is 5% and 30% for patients receiving 50 to 60 Gy and 61 to 78 Gy, respectively.[149]

Radiotherapy of tumors of the pharynx, and less frequently the oral cavity, may result in permanent complaints of xerostomia. In the largest published series, the mean dose to the parotid glands that relates to 50% risk of 1-year xerostomia was 39 Gy, and no threshold was seen.[150] A dose beneath 20 Gy is preferable to reach a low risk on xerostomia.[150] This serious late complication may be significantly reduced by the use of IMRT.[151] Data on quality of life are scarce. In a prospectively scored small series of 36 patients treated for parotid carcinoma with postoperative radiotherapy, quality of life deteriorated during treatment and returned to almost baseline levels from 6 weeks to 1 year after radiotherapy.[152] In general, the risk of late toxicity is much lower using modern radiation techniques like IMRT and Vmat compared to 2 or 3DRT. Based on dose–response models for organs at risk, particle treatment may be preferred in some cases, depending on the estimated lower risk at late toxicity.[153]

TREATMENT OF RECURRENCE

Retreatment usually involves additional surgery, if feasible, and postoperative irradiation in previously irradiated patients (Fig. 46.15). In the retreatment of

parotid neoplasms, preserving facial nerve function and obtaining local control are more difficult than for the initial tumor. Therapy consisting of surgery with postoperative irradiation has demonstrated enhanced local control, and facial nerve sacrifice may be necessary less often if this combination is used. In certain histologic subtypes (e.g., adenoid cystic carcinoma), retreatment of locally recurrent disease yields prolonged survival. Aggressive local therapy for recurrent disease is indicated if the probability of long-term survival is high, as in the case of adenoid cystic carcinoma. Fractionated stereotactic reirradiation, with a dose of 5 times 6 Gy, resulted in a 50% locoregional control in a study by Karam et al.[154] Reirradiation is not advised within 1 year after the first radiotherapy and not for large tumor volumes.[154] Multimodality treatment may be beneficial for recurrence disease of minor salivary gland, if initial tumor classification is $T_{1/2}$.[155]

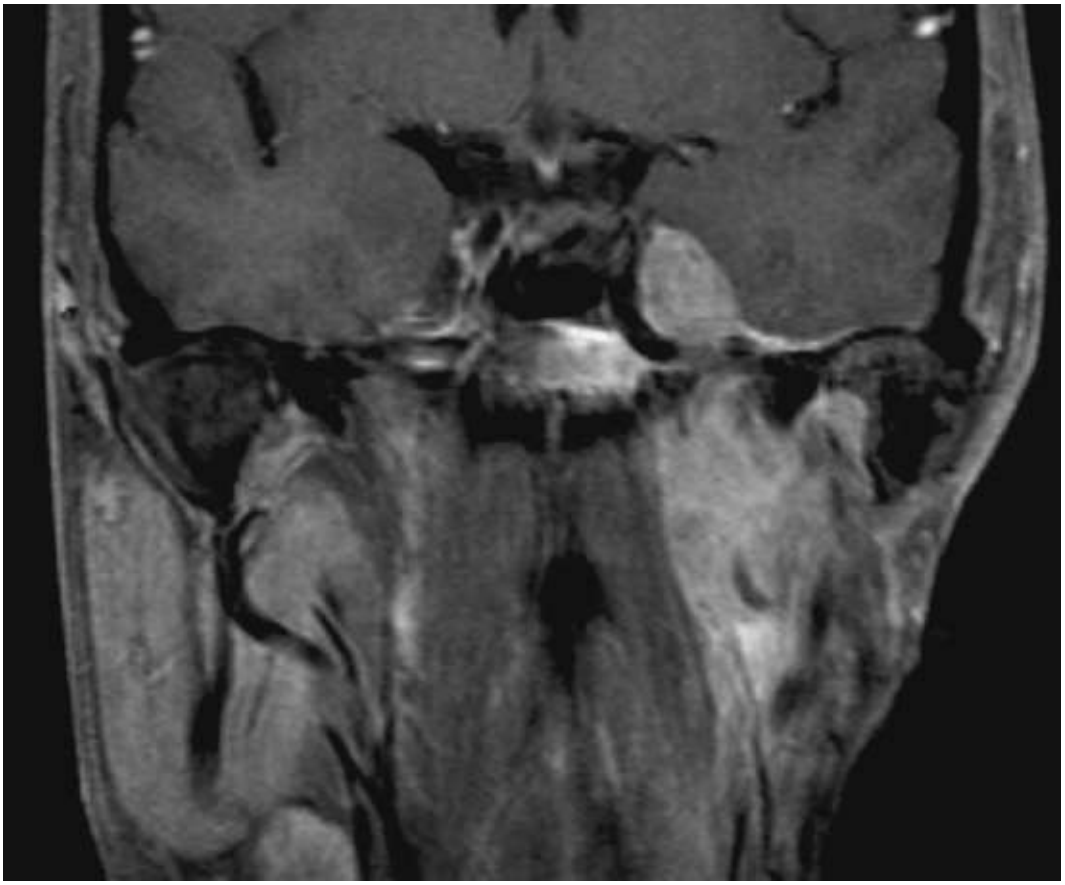

FIGURE 46.15. Coronal fat-suppressed contrast-enhanced magnetic resonance image shows a recurrence of squamous cell cancer of the parotid gland after total parotidectomy. The tumor is centered in the left masticator space with perineural spread along the nV3. Retrograde perineural spread of tumor through foramen ovale on the left side. (Courtesy of Dr. F.A. Pameyer, radiologist, University Medical Center

Utrecht, Netherlands.)

Chemotherapy also has been used for recurrent disease.[143,144] However, in view of its significant toxicity and modest response rates in a population that may have recurrent yet indolent progressive disease, trials of aggressive cytotoxic therapy are recommended only on carefully drafted protocols. In the future, molecular target agents may be tested in selected recurrent salivary gland cancers.

CHAPTER 47

Oral Cavity

Rafael R. Mañon, Jeffrey N. Myers, and Paul M. Harari

GENERAL PRINCIPLES

Squamous cell carcinoma of the lip and oral cavity is primarily a surgical disease. This is reflected by evidence-based practice guidelines in oncology published by the National Comprehensive Cancer Network (NCCN) that provide two clinical pathways for the management of oral cavity and lip squamous cell carcinoma: one pathway for early-stage disease and another for locally advanced disease. The NCCN guidelines recommend surgery as the preferred treatment approach for early-stage T1 or T2N0 lesions of the oral cavity or lip (Fig. 47.1).[1] For more advanced disease (T3/T4a, N0 or T1/T4a, N1/N3), NCCN guidelines recommend a combined modality approach involving surgery followed by adjuvant radiation or chemoradiation (Fig. 47.2). The functional outcomes after primary surgical management are acceptable due to advances in microvascular reconstruction techniques. Thus, particularly for oral cavity carcinoma, organ preservation approaches using primary radiotherapy have largely grown out of favor in North America. Nevertheless, definitive radiotherapy may be a treatment option for patients who are not candidates for surgery because of medical reasons or who refuse surgery.[1] A multidisciplinary approach is paramount in the evaluation and management of patients with oral cavity cancer. A team of health care providers including head and neck surgical oncology, radiation and medical oncology, plastic surgery, nursing, dentistry, dietary, speech pathology, and social work should evaluate the patient before treatment is delivered. Multidisciplinary evaluation prior to treatment disposition helps to ensure that broad consensus treatment recommendations are made and interdisciplinary coordination of care is facilitated. Once treatment has been completed, the multidisciplinary team should provide follow-up to the patient to ensure early detection of recurrent disease and adequate management of treatment sequelae.[1]

INCIDENCE, EPIDEMIOLOGY, AND ETIOLOGY

Oral cancer represents the most common noncutaneous malignancy of the head and neck.[2] Surveillance, Epidemiology, and End Results (SEER) program data estimate 49,670 new cases of cancer of the oral cavity and pharynx and 9,700 deaths for 2017.[3] The incidence rate of oral cancer continues to be more than twice as high in men than in women.[4] The estimated 5-year survival for all stages is 64.5%, whereas survival for cancer localized to the primary site is 83.7%.[3] According to American Cancer Society statistics, mortality rates from carcinoma of the oral cavity and pharynx have been stable in the United States from 2005 to 2014.[4]

Global estimates suggest 300,373 new cases of oral cancer and 145,000 deaths in 2012.[2,5] Worldwide age-standardized mortality estimates for lip and oral cavity cancer were 2.7 per 100,000 during the same year.[2,5] International Agency for Research on Cancer data indicate that the highest rates of oral cancer are found in Melanesia, South-Central Asia, and Eastern Europe, whereas the lowest rates are in Western Africa and Eastern Asia.[5] The incidence of oral cavity cancer seems to be decreasing in many parts of the world, which parallels regional declines in the tobacco epidemic.[6]

The epidemiology of oral cancer strongly reflects exposure to certain environmental agents, particularly tobacco and alcohol. Smoking is identified as an independent risk factor in 80% to 90% of patients who present with cancer of the oral cavity.[7–9] Tobacco users have a 5-fold to 25-fold higher risk of oral cavity and oropharyngeal cancer.[10] Cessation of smoking is associated with a decline in the risk of cancer of the oral cavity.[9] In India, the habit of chewing betel nut leaves rolled with lime and tobacco (mixture known as “pan”), which results in prolonged carcinogen exposure to the oral mucosa, is thought to be the leading cause of oral cancer.[11,12] The combined use of alcohol and tobacco may have a synergistic effect on carcinogenesis.[10] International Head and Neck Epidemiology Consortium (INHANCE) pooled analysis data demonstrate a greater than multiplicative joint effect between tobacco and alcohol on head and neck cancer risk, which is most pronounced in carcinoma of the pharynx and oral cavity.[13]

Ultraviolet radiation has been associated with carcinoma of the lip. In geographic regions where there are long daily periods of sun exposure, cancer of the lip may represent up to 60% of all cancers of the oral cavity. The relationship between HPV and oropharyngeal cancer has been well established.[14,15] However, oral cavity carcinoma, unlike oropharyngeal carcinoma, does not

appear to be typically associated with HPV.[16] Certain syndromes such as xeroderma pigmentosum, Li-Fraumeni, ataxia telangiectasia, Bloom syndrome, and Fanconi anemia, because of inherent genetic instability, have been associated with a predisposition to oral cancer.[17,18]

Overall, there has been a declining trend in the overall incidence of oral cavity squamous cell carcinoma over the past 30 years. However, SEER data suggest an increasing incidence of oral tongue carcinoma in young white individuals ages 18 to 44, which is most pronounced among young white women.[16,19] Past reports suggest that oral tongue carcinoma in this population is associated with a worse prognosis. Recent matched-control studies and national database reviews suggest that outcomes are similar to that in other demographics of oral cancer patients.[16,19] This young population of patients does not seem to have the traditional risk factors of tobacco and alcohol abuse. The increasing incidence of oral tongue carcinoma in young individuals is unlikely due to an HPV-related etiology and may represent a unique and emerging oral cancer patient population.[16]

In patients with cancer of the oral cavity, the risk of developing a second primary cancer is well recognized. Second primary cancers have an adverse effect on prognosis and are the major cause of treatment failure in patients with early-stage disease.[20,21] In an analysis of 851 patients with squamous cell carcinoma of the head and neck, 19% of the study population developed a secondary head and neck carcinoma 5 years after undergoing initial therapy.[21] The probability of developing a second metachronous malignancy at 5 years was 22% (18% for the subset of patients with oral cavity cancer).[21] Quitting tobacco and alcohol use greatly reduces the risk of developing subsequent head and neck squamous cell carcinoma. Individuals that have stopped smoking for 1 to 4 years have a 30% decrease in risk of developing carcinoma of the head and neck compared to those that continue to smoke. For those that quit smoking beyond 20 years, the risk parallels that of never smokers; a similar effect is seen with stopping the use of alcohol.[22] Several chemoprevention strategies have been explored in patients who are at high risk of developing second primary cancer. These strategies include retinoids, COX2 inhibitors, EGFR inhibitors, thiazolidinediones, and green tea polyphenols.[2,22] There is no intervention that can be considered standard of care to date. Therefore, continued efforts toward tobacco and alcohol cessation are a central strategy in the management of patients with oral squamous cell carcinoma.[1,22]

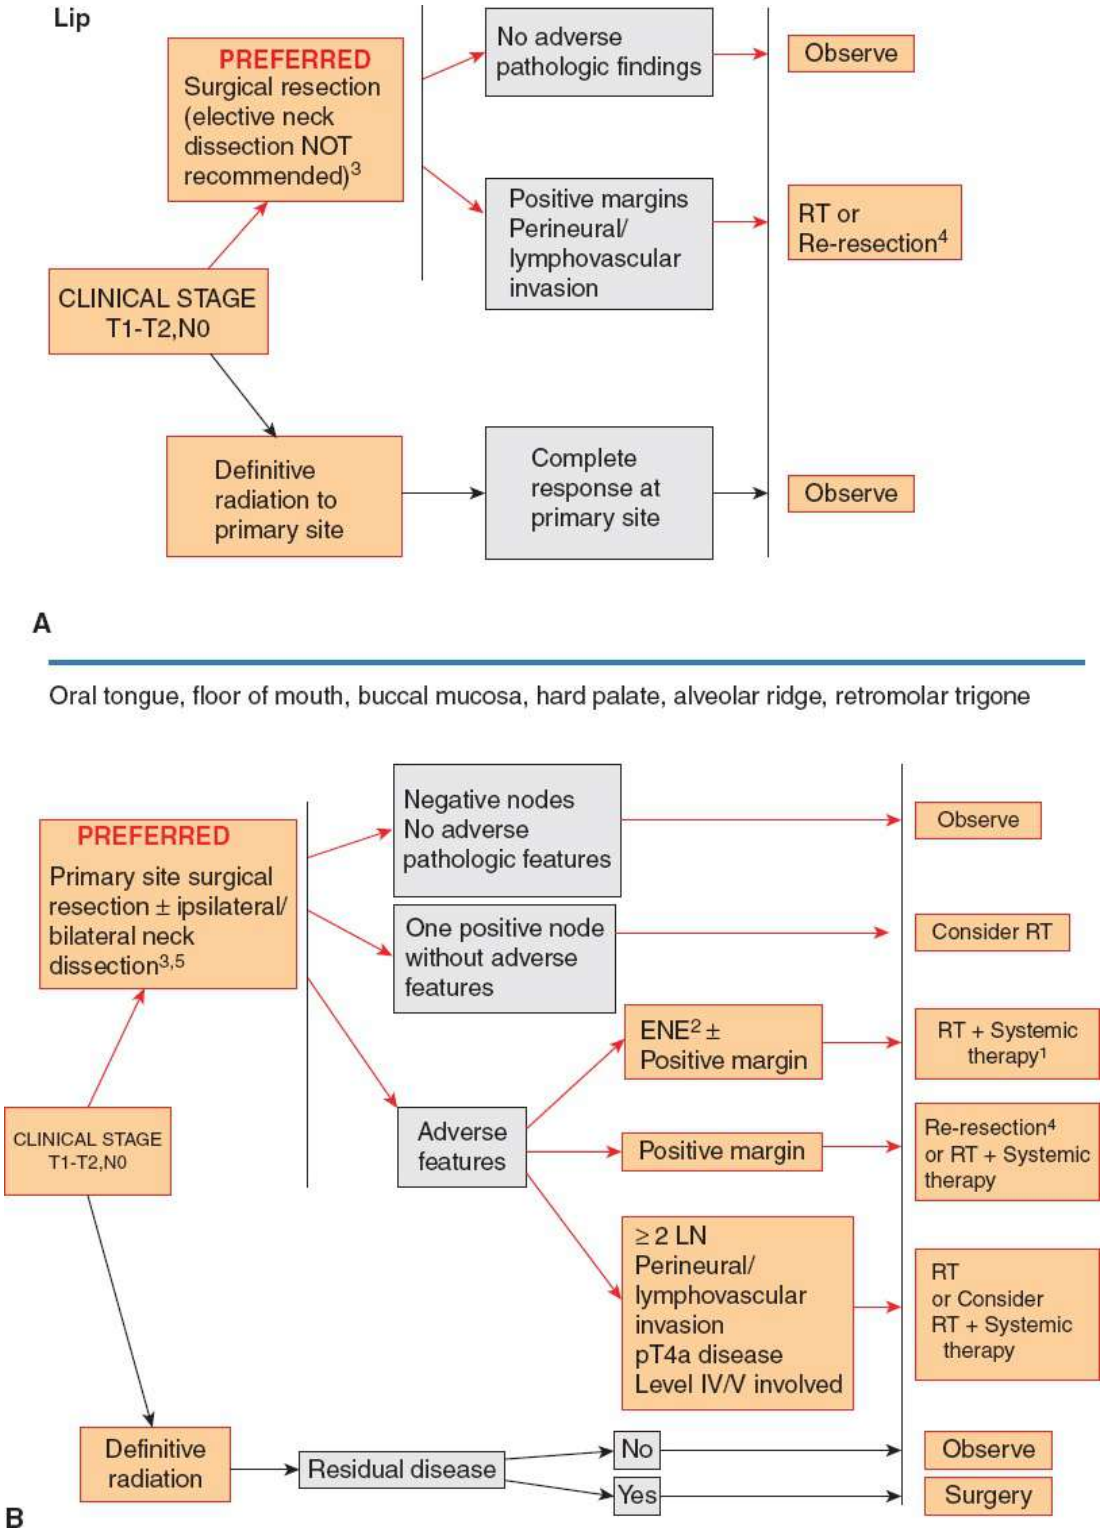

FIGURE 47.1. This treatment algorithm is based on NCCN Guidelines Version 1.2017. **A:** Guidelines for the management of early-stage carcinoma of the lip. **B:** Guidelines for the management of early-stage carcinoma of the oral tongue, floor of mouth, buccal mucosa, hard palate, alveolar ridge, and retromolar trigone. [1]This recommendation is based upon high-level evidence and uniform NCCN consensus.

[2]The acronym “ENE” stands for extranodal extension. [3]Resection of the primary site with sentinel lymph node biopsy is a treatment option. [4]In the event of a positive margin, consider reresection to achieve negative margins. [5]Tumor thickness and location of the primary drive the decision to perform a neck dissection, please refer to the section “Surgical Management of the Neck” in this chapter for details.

ANATOMY

The oral cavity consists of the lips, oral tongue, floor of the mouth, retromolar trigone, alveolar ridge, buccal mucosa, and hard palate (Figs. 47.3–47.5). The anterior boundary of the oral cavity is the skin–vermilion junction. The superior portion of the oral cavity extends posteriorly to the junction between the hard and soft palate, whereas the inferior portion extends to the circumvallate papillae. The specific anatomic subsites of this region are noted below.

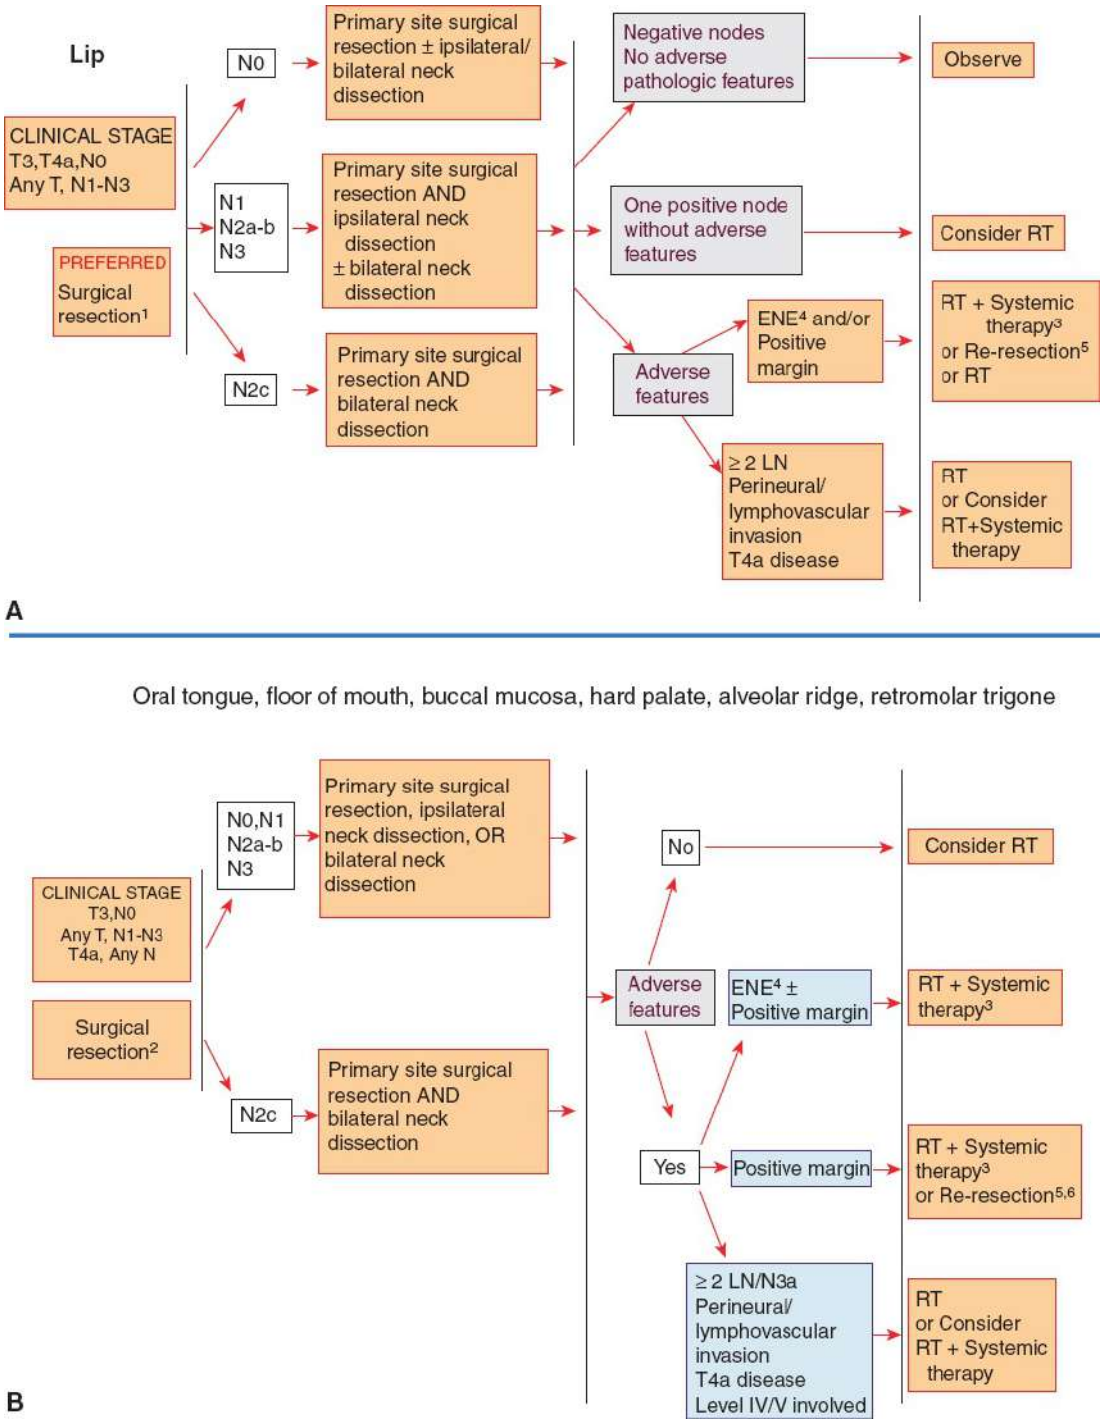

FIGURE 47.2. This treatment algorithm is based on NCCN Guidelines Version 1.2017. **A:** Guidelines for the management of locally/regionally advanced carcinoma of the lip. **B:** NCCN Guidelines for the management of locally/regionally advanced carcinoma of the oral tongue, floor of mouth, buccal mucosa, hard palate, alveolar ridge, and retromolar trigone. [1]Although surgery is the preferred initial treatment, radiation therapy is an option for local control. In the event of primary radiation, the patient will need to undergo response assessment and be evaluated for salvage surgery in the event of incomplete response to therapy. [2]For this population of patients, enrollment clinical trials involving multimodality treatment is an option. [3]This

recommendation is based upon high-level evidence and uniform NCCN consensus. [4]The acronym “ENE” stands for extranodal extension. [5]In the event of a positive margin, consider reresection to achieve negative margins. [6]If negative margins are achieved after reresection, consider adjuvant radiation.

Lip

The lips begin at the junction of the vermilion border with the skin and form the anterior aspect of the oral vestibule. The lips are comprised of the vermilion surface, which is the portion of the lip that comes in contact with the opposing lip. The lips are well defined into an upper and lower. The primary motor control of the lips is provided by the buccal and mandibular branches of the facial nerve.

Oral Tongue

The anterior two-thirds of the tongue is mobile and considered part of the oral cavity. The oral tongue extends anteriorly from the circumvallate papillae to the undersurface of the tongue at the junction of the floor of the mouth. The fibrous septum divides the tongue into right and left halves. The oral tongue can be demarcated into four anatomic areas: the tip, lateral borders, dorsal surface, and undersurface (ventral surface). There are six pairs of muscles that form the oral tongue. Three of these muscles are extrinsic, whereas the other three are intrinsic. The extrinsic muscles include the genioglossus, hyoglossus, and styloglossus. The intrinsic muscles include the lingual, vertical, and transverse muscles. The former primarily move the body of the tongue, whereas the latter alter the shape and conformation of the tongue during speech and swallowing. The blood supply to the tongue is primarily via the lingual artery, tonsillar branch of the facial artery, and the ascending pharyngeal artery with primary drainage by the internal jugular vein. General sensation of the anterior two-thirds of the tongue is supplied by the lingual nerve. Excluding the circumvallate papillae, taste fibers from the anterior two-thirds of the tongue run in the chorda tympani branch of the facial nerve; the glossopharyngeal nerve provides sensation and taste to the posterior third of the tongue and circumvallate papillae.

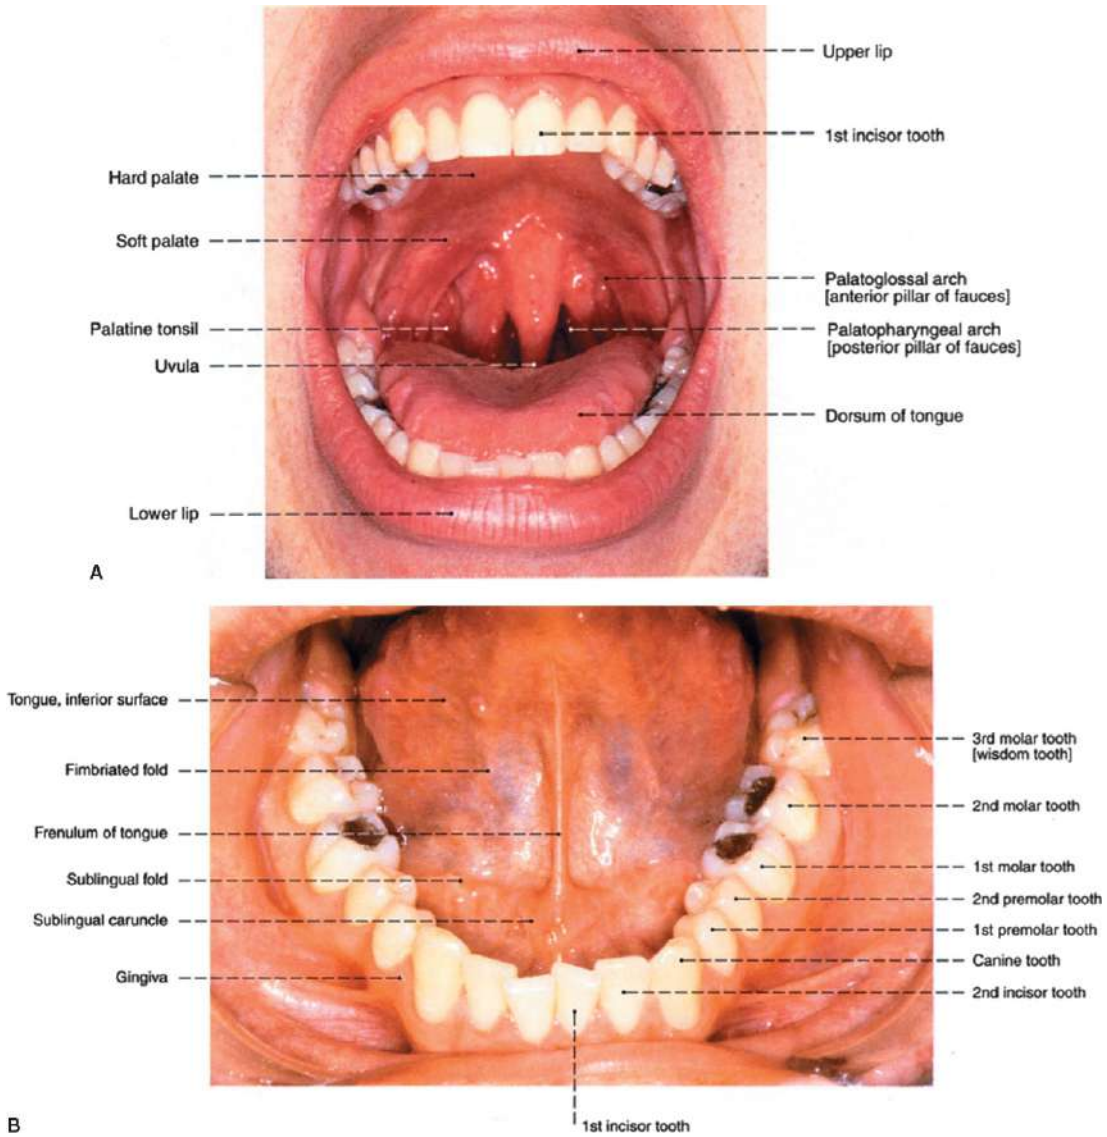

FIGURE 47.3. A: Oral cavity surface anatomy. **B:** Floor of the mouth surface anatomy. (Reprinted from Paulsen F, Waschke J, Sobotta J. *Sobotta Atlas of Human Anatomy*. 15th ed. Munich: Urban & Fischer, 2011. Copyright © 2011 Elsevier GmbH. With permission.)

Floor of the Mouth

The floor of the mouth is a semilunar space extending from the lower alveolar ridge to the undersurface of the tongue. The floor of the mouth overlies the mylohyoid and hyoglossus muscles. The posterior boundary of the floor of the mouth is the base of the anterior tonsillar pillar. This region is divided into right and left by the frenulum of the tongue and contains the ostia of the submandibular and sublingual salivary glands. A sling formed by the mylohyoid muscles medially supports the anterior floor of the mouth, and the hyoglossus supports the posterior floor of the mouth. The lingual and hypoglossal nerves are

lateral to the hyoglossus, whereas the lingual artery is medial to the hyoglossus. Innervation of the floor of the mouth is provided by the lingual nerve.

Hard Palate

The hard palate extends from the inner surface of the superior alveolar ridge to the posterior edge of the palatine bone. This is a semilunar area between the superior alveolar ridge and the mucous membrane covering the palatine process of the maxillary palatine bones.

Alveolar Ridge

The alveolar ridges include the alveolar processes of the maxilla and mandible and the overlying mucosa. The mucosal covering of the lower alveolar ridge extends from the line of attachment of mucosa in the buccal gutter to the line of free mucosa of the floor of the mouth. The lower alveolar ridge extends to the

ascending ramus of the mandible posteriorly. The superior alveolar ridge mucosa extends from the line of attachment of mucosa in the upper gingival buccal gutter to the junction of the hard palate. The posterior margin is the upper end of the pterygopalatine arch.

Retromolar Trigone

The retromolar trigone is the triangular area overlying the ascending ramus of the mandible. The base of the triangle is formed by the posterior most molar, and the apex lies at the maxillary tuberosity.

Buccal Mucosa

The buccal mucosa includes the mucosal surfaces of the cheek and lips from the line of contact of the opposing lips to the pterygomandibular raphe posteriorly. This extends to the line of attachment of the mucosa of the upper and lower alveolar ridge superiorly and inferiorly. Innervation is supplied by the buccal nerve, a branch of the mandibular nerve.

Nodal Levels

The neck is traditionally divided into five primary nodal levels (i.e., levels I–V) plus the retropharyngeal nodes that are relevant to the staging and management of oral cavity carcinoma. The level VI nodal station will not be discussed in this section because it is rarely pertinent for oral cavity cancer. The classification of neck nodal regions, initially popularized by Robbins et al.,[23] has served as a surgical reference system based on visible landmarks. Over the years, there have been several revisions regarding proposed boundaries of nodal stations in the neck, with refinements to include radiologic landmarks.[24,25] Gregoire et al.[26,27] published consensus guidelines for the CT-based delineation of nodal levels in the node-negative neck that were revised in 2014 to serve as a guide in the practice of radiation oncology. In the following discussion, we incorporate radiographic landmarks and anatomic considerations from these guidelines (where relevant) alongside traditional surgical anatomic landmarks.

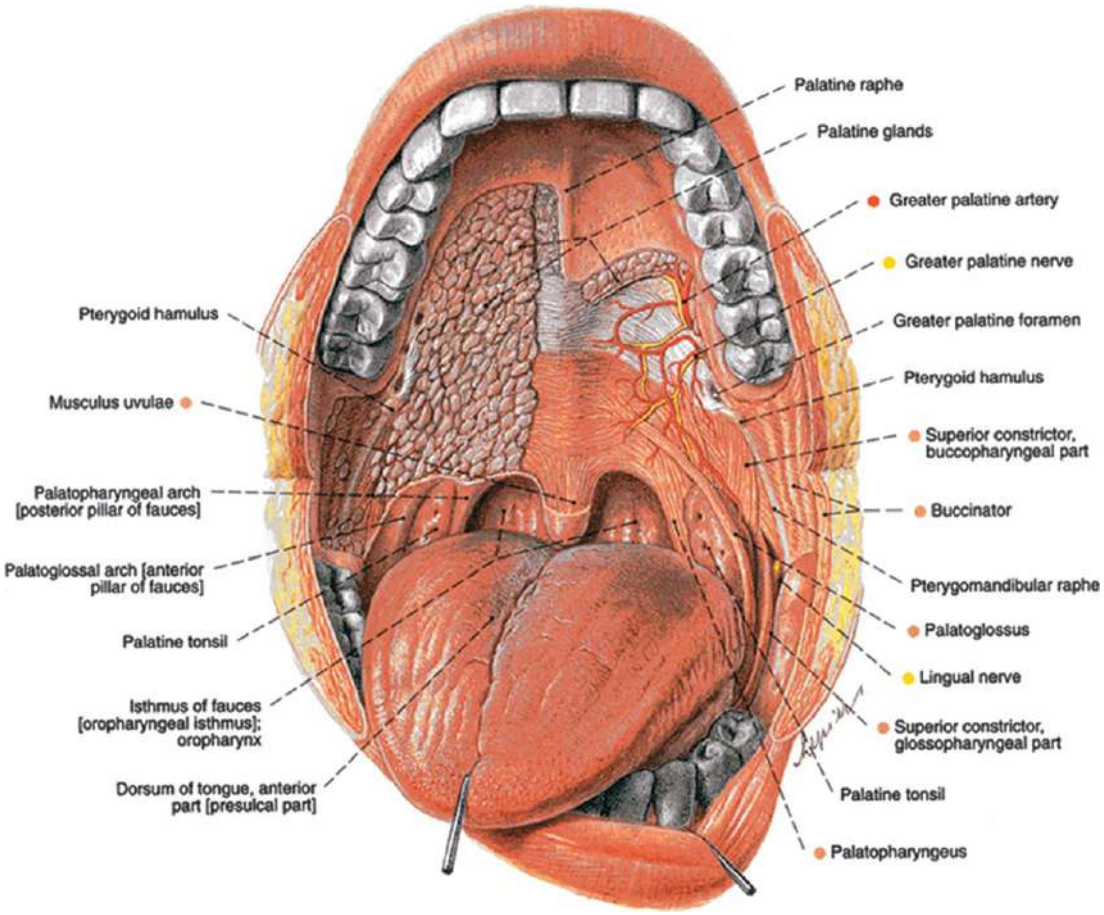

FIGURE 47.5. Oral cavity illustration depicting regional anatomy. (Reprinted from Paulsen F, Waschke J, Sobotta J. *Sobotta Atlas of Human Anatomy*. 15th ed. Munich: Urban & Fischer, 2011. Copyright © 2011 Elsevier GmbH. With permission.)

Level I

Level I includes the submental (Ia) and submandibular (Ib) triangles. Level Ia is limited anteriorly by the mandibular symphysis, posteriorly by the body of the hyoid bone, and cranially by the geniohyoid muscle. The medial border is virtual because this region continues to the contralateral Ia station. Level Ib is located within the space bounded by the inner table of the mandible laterally, the digastric muscle medially, the mandibular symphysis anteriorly, and the submandibular gland posteriorly.

Level II

Level II includes the upper jugular chain lymph nodes from the base of the skull to the carotid bifurcation (surgical landmark) or the caudal body of the hyoid bone (clinical landmark); this nodal station extends from the posterior edge of the submandibular gland anteriorly to the posterior border of the

sternocleidomastoid posteriorly. The level II nodal region is further subdivided into IIa and IIb. The vertical plane defined by the spinal accessory nerve (surgical landmark) or the posterior edge of the internal jugular vein (radiographic landmark) defines each the subdivision within this level; level IIa lies anterior, whereas IIb lies posterior to this plane.

Robbins et al.[23] initially defined the cranial limit of level II as the base of the skull.[23] However, from a practical standpoint, during surgical management of the neck, the cranial border of level II is taken as the insertion of the posterior belly of the digastric into the mastoid.[27] It was later proposed that the bottom edge of C1 serve as the radiographic landmark for defining the cranial border of level II in the node-negative neck.[27] Consequently, the retrostyloid space is considered the cranial continuation of level II from C1 to the skull base.[26,27]

Level III

Level III is the caudal extension of level II. It includes the midjugular nodes, of which the surgical landmarks extend from the carotid bifurcation to the omohyoid muscle inferiorly, the sternohyoid medially, and the posterior aspect of the sternocleidomastoid posteriorly. The corresponding radiographic landmarks are the caudal edge of the hyoid bone superiorly and the caudal edge of the cricoid cartilage inferiorly.

Level IV

Level IV includes the inferior jugular nodes located around the inferior third of the internal jugular vein. Level IV is bounded by the omohyoid muscle superiorly, the clavicle inferiorly, and the posterior aspect of the sternocleidomastoid posteriorly.

Level V

Level V includes nodes in the posterior triangle, which are located posterior to the sternocleidomastoid muscle. This space is bordered by the base of the skull superiorly, clavicle inferiorly, and posterior aspect of the sternocleidomastoid anteriorly. The uppermost part of level V is generally thought to belong to the occipital nodal region.[26] Therefore, from a practical standpoint, the radiolographic cranial border of level V has been accepted as a horizontal plane crossing the cranial edge of the hyoid bone.[27] From a surgical perspective, level V is further subdivided into Va and Vb, and the caudal edge of the cricoid arch is the anatomic landmark denoting this subdivision (Vb lies below this boundary).

Retropharyngeal Nodes

The retropharyngeal space, which contains the retropharyngeal nodes, extends from the skull base (cranially) to the hyoid bone (caudally). The anterior boundary of the retropharyngeal space is the pharyngeal constrictor muscles and the posterior boundary is the prevertebral fascia. The retropharyngeal nodes are further divided into medial and lateral groups. The lateral retropharyngeal nodes lie medial to the carotid artery and lateral to the longus capitis and longus coli muscles, whereas the medial group consists of one or two nodes intercalated along the midline lymphatics.

MOLECULAR BIOLOGY

In parallel to the Fearon and Vogelstein model describing the genetic basis of colon cancer,[28] there are a series of specific genetic events that precede the development of oral squamous cell carcinoma.[29,30] Cancer progression models describe several steps that occur during tumor development: oncogenes become activated and tumor suppressor genes become deactivated, and a series of these alterations are required for carcinogenesis. In the oral mucosa, this genetic progression is reflected histologically by the transformation from normal mucosa to dysplastic epithelium and ultimately to frankly invasive squamous cell carcinoma. Data to support this model come from studies that reveal genetic alterations in histologically normal tissues and in premalignant lesions, including loss of heterozygosity at chromosomes 3p14 and 9p21. Furthermore, mutations in the region of chromosome 17p13, which encompasses the tumor suppressor gene *TP53*, are among early events that contribute to malignant transformation. Indeed, biopsies of normal mucosa from patients with upper aerodigestive tract carcinomas frequently harbor *TP53* mutations.

Comprehensive studies of whole-genome sequencing, gene copy number analysis, and mRNA and protein expression of head and neck squamous cell carcinoma have been performed and have helped to provide an unbiased characterization of the genomic alterations seen in this disease.[31–34] Known tumor suppressor genes and oncogenes were found to be mutated, including *TP53*, *PIK3CA*, *PTEN*, *HRAS*, and *CDKN2A*. It was observed that HPV-positive tumors had a reduction in mutation rate of at least 50% relative to smoking-associated tumors. Moreover, they were inversely correlated with *TP53* mutations, suggesting that HPV-positive tumors are genomically distinct. However, very few oral cavity tumors (~4%) appear to be driven by high-risk

HPV.[35]

The first genomic analyses have identified loss-of-function mutations in *NOTCH1* that suggest that *NOTCH* may act as a tumor suppressor gene in head and neck cancers rather than as an oncogene, as it had been identified in other malignancies.[36] The Cancer Genome Atlas (TCGA) published results validating the initially identified genomic findings[31]in head and neck cancers. Subset analysis of patients with oral cancer has found that reduced copy number alterations and activating mutations in *HRAS* or *PIK3CA* are associated with improved clinical outcomes.

The use of whole-exome sequencing has also been applied to evaluate genomic alterations in younger, nonsmoking patients, and this analysis surprisingly found no significant difference in mutation frequencies, types of mutations, or copy number between younger and older patients with oral tongue cancers.[33] Smoking was seen to have a minimal effect on genomic changes. *FAT1* and *TP53* mutations were not significantly increased in the younger cohort and may represent a novel area of study. Although the genomic characterization has allowed clinicians to better understand the molecular alterations underlying the development of oral cancers, the majority of known mutations represent nontargetable tumor suppressor genes. Therefore, further studies of these alterations as potential prognostic and predictive biomarkers and synthetic lethality approaches are needed to fully realize the immense potential of assessment of the genomic alterations in an individual oral cancer patient's tumor.

More recent analyses have focused on recurrent and metastatic head and neck cancers that suggest the potential for precision approaches to treating these advanced tumors with more than 20% showing "actionable" mutations.[37] Liquid biopsy approaches analyzing tissue fluids including saliva and blood also hold tremendous promise in the early detection of recurrence of oral cancers.[38] Furthermore, immunoprofiling of squamous cancers of the head and neck inclusive of oral cavity tumors indicates that immune-oncologic approaches to treating these tumors should be considered in future clinical investigations.[39]

NATURAL HISTORY AND PATTERNS OF SPREAD

Premalignant Lesions

Leukoplakia

Leukoplakia and erythroplakia are gross clinical descriptors that do not always

correspond directly to specific pathologic entities.[18,40] The World Health Organization defines leukoplakia as a white patch or plaque that cannot be rubbed off or characterized clinically or pathologically as any other disease[40] (Fig. 47.6). Leukoplakia is not related to the presence or absence of dysplasia; however, it is the most common precursor of cancer of the oral cavity. Leukoplakia is primarily a clinical entity, with certain key pathologic features. These features include hyperkeratosis and acanthosis. Leukoplakia may begin as a thin gray or gray/white plaque that may appear translucent, is sometimes fissured or wrinkled, and typically soft and flat. They frequently have sharply demarcated borders but occasionally blend gradually into normal surrounding mucosa.

Homogenous leukoplakia is a uniform white lesion that is prevalent in the buccal mucosa; it is the most common variety of leukoplakia and has a low malignant potential. Conversely, high-risk oral leukoplakia demonstrates abnormal orientation of cells, nuclear hyperchromatism, increased mitosis, and nuclear cytoplasmic ratio.[18] Clinically, these lesions are nonhomogenous, nodular, speckled, or verrucous, with central ulceration or erosion.[40,41] Follow-up studies demonstrate that between <1% and 18% of oral leukoplakias develop into oral cancer, with the latter clinical subtype conferring a higher risk of malignant transformation.[42,43]

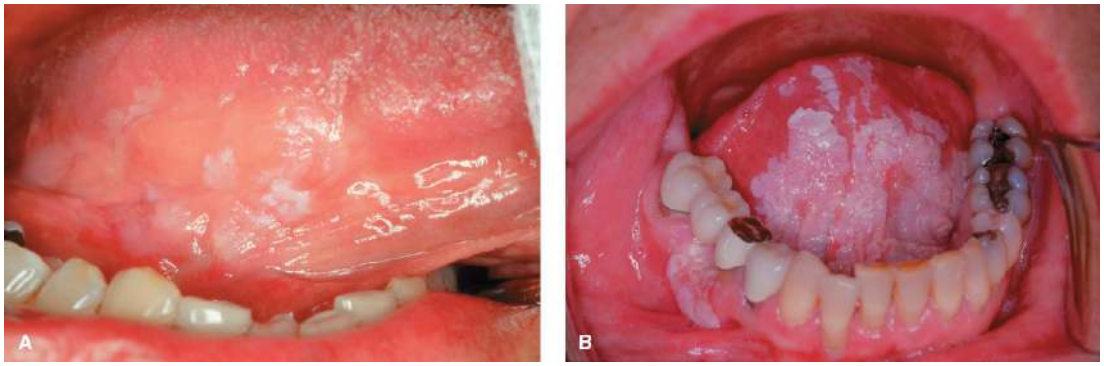

FIGURE 47.6. A: Superficial patches of leukoplakia involving the lateral and ventral surface of the oral tongue. **B:** Extensive leukoplakia involving the ventral oral tongue, floor of the mouth, and mandibular alveolus.

Leukoplakia may regress spontaneously without therapy. A baseline biopsy may be performed to establish diagnosis and rule out malignant transformation. Leukoplakia with clinically or histologically aggressive features, demonstrating dysplasia, should be excised.

Erythroplakia

Erythroplakia describes a chronic, red, generally asymptomatic lesion or patch on the mucosal surface that cannot be attributed to a traumatic, vascular, or inflammatory cause. Erythroplakia, like leukoplakia, is a clinical diagnosis of exclusion that requires the clinician to rule out all other erythematous oral lesions.[44] However, erythroplakia is associated with a higher risk of malignant transformation than leukoplakia. Transformation rates are considered to be the highest among all precancerous oral lesions and conditions.[45] Histopathologically, it has been documented that in homogenous oral erythroplakia, 51% showed invasive carcinoma, 40% carcinoma *in situ*, and 9% mild or moderate dysplasia.[45] The treatment of choice for erythroplakia is surgical excision.

Oral Submucous Fibrosis

The term describes a generalized fibrosis of the oral cavity tissues resulting in marked rigidity and trismus. At early stages, these premalignant lesions are characterized by blanching of the mucosa with a marble-like appearance. At more advanced stages, palpable fibrous bands become evident around the buccal mucosa and the mouth opening. Once oral submucous fibrosis reaches advanced stages, approximately 25% of cases biopsied demonstrate epithelial dysplasia in addition to subepithelial alterations.[10] Oral submucous fibrosis is associated with the use of betel quid (with or without tobacco) or pan masala.[10] In India, it is estimated that as many as 5 million individuals are afflicted with oral submucous fibrosis.[10]

Oral Cavity Cancer

Relative Distribution

The most common subsite for squamous cell carcinoma of the oral cavity (excluding the lip) is the oral tongue.[47] In a review of 3,308 cases of oral cavity cancer treated at the University of Texas MD Anderson Cancer Center between 1970 and 1999, 32% involved the oral tongue.[18] The floor of the mouth is the second most common subsite where oral cavity carcinomas may arise. Carcinoma of the alveolar ridge accounts for approximately 10% of oral cavity carcinomas. Squamous cell carcinoma of the retromolar trigone and hard palate is rare. Similarly, carcinoma of the buccal mucosa is rare in the United States but is the most common carcinoma of the oral cavity in Southeast Asia because of the widespread use of betel nut.[18]

Patterns of Spread

Local Spread

Carcinoma from distinct anatomic subsites may exhibit different tendencies for spread based on natural anatomic barriers and location. For instance, the majority of lip cancers are local growths that do not invade deeply into the tissues of the oral cavity or mandible.[46] However, a select few lip carcinomas may be deeply invasive with perineural involvement, posterior spread to involve cortical bone, extension to the inferior alveolar nerve, or spread to the skin of the face[47]. Squamous cell carcinoma of the floor of the mouth can secondarily involve the ventral tongue, extend along the lingual nerve and submandibular duct, or invade the cortex of the mandible. Tumors in this location can invade deeply, involving the muscles of the floor of the mouth. There is an anatomical gap between the mylohyoid and hyoglossus muscles through which a carcinoma can gain access to submandibular and sublingual areas. Carcinomas of the alveolar ridge and retromolar trigone tend to invade bone early. Tumors of the inferior alveolar ridge may access the mandibular canal and the inferior alveolar nerve, whereas tumors of the superior alveolar ridge may pass into the maxillary antrum or floor of the nose. Infiltrating lesions of the buccal mucosa can invade the buccinator muscle, extend to the buccal fat pad, and invade the subcutaneous tissue. The hard palate has a relatively dense mucoperiosteum that is relatively resistant to tumor invasion. However, the primary and secondary palates are fused at the incisive fossa, where tumors can gain access into the nasal cavity. The greater palatine foramina can allow tumors to spread posteriorly and enter the pterygopalatine fossa and skull base.

Lymphatic Metastases

The oral cavity has an extensive group of lymphatics that manifest a fairly predictable lymph node drainage pattern based on location (subsite) within the oral cavity[47] (Table 47.1).

TABLE 47.1 RELATIVE INVOLVEMENT OF LYMPH NODE REGIONS BY ORAL CAVITY SUBSITE

	Percentage Involved			
	Submaxillary	**Submental**	**Upper Jugular**	**Midjugular**
Oral tongue	18	9	73	18
FOM	64	7	43	0

RMT	25	0	63	12.5

FOM, floor of mouth; RMT, retromolar trigone.

The lymphatic nodal stations most commonly involved include levels I to IV.[48,49] The retrostyloid space is potentially at risk for involvement by metastatic disease when upper level II nodes are grossly positive.[26] The medial retropharyngeal nodes are rarely a site of metastases in head and neck squamous cell carcinoma.[50] The lateral retropharyngeal nodes generally at risk in primary carcinoma of the nasopharynx and oropharynx are rarely involved in oral cavity cancer unless there is oropharyngeal involvement or a significant nodal burden.[51–53] The lymphatic drainage pattern to the upper and lower lip is distinct. The principal lymphatic drainage of the upper lip is to preauricular, periparotid, submental, and submandibular lymph nodes, which secondarily drain to deep jugular lymph nodes. The medial portion of the lower lip drains primarily to the submental lymph nodes, whereas the lateral portion drains to the submandibular triangle.

A classical study by Lindberg[54] demonstrated that the superior deep jugular nodes are most frequently involved by cancers of the oral cavity. The anterior portion of the tongue drains to the submental nodes (level Ia), and the lateral portion drains to the submandibular (level Ib) and deep jugular nodes (level II). The posterior oral tongue drains into the upper jugulodigastric group of lymph nodes (level II). The lymphatics of the oral tongue also have extensive communication across the midline; thus, carcinomas of the oral tongue can metastasize bilaterally. Studies suggest that some carcinomas of the lateral oral tongue may metastasize to level IV lymph nodes without involving levels I, II, or III.[55] This implies that there may be separate lymphatic channels draining from the oral tongue directly to level IV nodes, allowing for apparent “skip metastases.”

Dye injection studies have shown that the floor of the mouth has superficial and deep lymphatic drainage systems.[55] The superficial system crosses randomly in the midline and drains into both the ipsilateral and contralateral submandibular lymph nodes. The deep lymphatic system is thought to penetrate the periosteum and drains into the submandibular and upper jugular lymph nodes. Lymphatics from the buccal mucosa drain into the periparotid, submental, and submandibular nodes. Tumors of the alveolar ridge may drain into the

submental and submandibular triangles, upper deep jugular, and retropharyngeal lymph nodes. Tumors of the inferior alveolus are more likely to metastasize to the neck than tumors of the superior alveolus. The main lymphatic drainage from the retromolar trigone is into the superior deep jugular lymph nodes; however, there may be some drainage into periparotid and retropharyngeal lymph nodes. Lymphatics in the hard palate are few, but drainage is into submandibular, superior deep jugular, and retropharyngeal nodes.

The risk of neck metastases depends on several factors including site and size of the primary tumor. Overall, for patients with squamous cell carcinoma of the oral cavity, cervical metastases occur in approximately 30% of cases.[41] The rate of neck metastases for carcinoma of the lip is approximately 10%.[41] Squamous cell cancer of the oral tongue carries a higher risk of nodal metastases, the frequency ranging from 15% to 75%, depending on the size and depth of the primary lesion.[54,56] Approximately 25% of patients with carcinoma of the oral cavity will have occult nodal metastases, and 3% of patients will have contralateral metastases.[54,56] Contralateral metastases are more common in tumors that approach or cross the midline. Early tumors of the floor of the mouth have approximately a 12% to 30% incidence of occult nodal metastases depending on the thickness of the lesion, whereas larger lesions can have an incidence of nearly 50%.[57] Approximately 15% to 20% of upper alveolar ridge tumors will involve the neck at presentation; the risk of occult metastases in a clinically negative neck is approximately 15% to 20%.[54] The incidence of neck metastases in lower alveolar ridge tumors is higher than for tumors of the upper alveolar ridge.[54] For cancers of the buccal mucosa, the incidence of positive cervical lymph nodes at diagnosis is 10% to 30%; the incidence of pathologically positive nodes in a clinically negative neck is about 15%. Similar rates of occult metastases occur for squamous cell carcinoma of the retromolar trigone; however, patients tend to present with more advanced disease, resulting in a somewhat higher rate of regional metastases.[41] The incidence of lymph node involvement from carcinoma of the hard palate is low, approximately 15%.[46,58]

Distant Metastases

Distant metastasis occurs in approximately 15% to 20% of patients who eventually die of their disease.[41] The risk of distant metastases increases with the degree of lymph node involvement. Patients with recurrent disease are also at higher risk for distant metastases.[59] Patients without clinically appreciable neck disease rarely fail distantly after treatment. In general terms, with respect to head

and neck cancer, 66% of distant metastases are to the lungs, 22% to the bones, and 9.5% to the liver.[60] On rare occasion, the oral cavity will serve as a site for distant metastasis from another anatomic primary tumor site.[47]

PATHOLOGIC CLASSIFICATION

The predominant histopathologic type of cancer in the oral cavity is squamous cell carcinoma. There are several variants of squamous cell carcinoma, including basaloid and verrucous carcinoma. Basaloid squamous cell carcinoma is believed to have a worse prognosis than traditional squamous cell carcinoma. In a retrospective comparison between basaloid squamous cell carcinoma and traditional poorly differentiated squamous cell carcinoma, the former had a higher incidence of advanced disease at presentation, distant metastases, and poorer overall survival rate.[61] Verrucous carcinoma is a less common variant of squamous cell carcinoma. It is generally considered a low-grade malignancy with low metastatic potential and good overall prognosis, although often with challenges for local control in elderly patients.[18] For most cases, adjuvant radiation and elective neck dissection (END) are not indicated. Sarcomatoid carcinomas can be found in the oral cavity and larynx. This variant of squamous cell carcinoma carries a poor prognosis with a mean survival of approximately 2 years.[62]

Less than 10% of neoplasms of the oral cavity have nonsquamous histology. Most of these are minor salivary gland tumors, which tend to arise in the hard palate. Adenoid cystic carcinoma accounts for approximately 30% to 40% of minor salivary gland cancers of the oral cavity.[63] Other histologies that can occur in the oral cavity include adenocarcinomas, melanoma, ameloblastoma, lymphoma, and Kaposi sarcoma.[47] Approximately 50% of acquired immunodeficiency syndrome–related cases of Kaposi sarcoma have oral cavity involvement.[41] Most lymphomas in the head and neck arise in Waldeyer ring (tonsil, base of the tongue, and nasopharynx). Only 2% of all lymphomas are found in the oral cavity.[64] Fortunately, melanoma of the oral cavity is very rare and represents only 0.2% to 8% of all melanomas.[65] Mucosal melanomas generally have a worse prognosis than cutaneous melanomas.

CLINICAL PRESENTATION

The oral cavity is an anatomic region that is readily accessible to visual

inspection and palpation. Despite this fact, many patients with oral cavity tumors present with advanced-stage disease as initial symptoms may be vague and painless. Tumors of the oral tongue often present as small ulcers and gradually invade the musculature of the tongue. Advanced lesions may be either ulcerative or exophytic and are usually quite evident. Some cancers of the oral tongue are painful even in their early stages. Cervical metastases occur early in the natural history of the disease, with 30% to 40% of patients harboring cervical lymph node metastases at diagnosis. Squamous cell carcinomas of the oral tongue most often arise along the lateral borders of the tongue[18] (Fig. 47.7).

FIGURE 47.7. T2N0M0 squamous cell carcinoma involving the right lateral oral tongue.

Lesions of the floor of the mouth are often infiltrative and may invade bone, the muscles of the floor of the mouth, and the tongue. The frenulum is frequently a site of involvement. Clinical fixation of the tumor to the mandible suggests periosteal involvement, which may occur early.

Tumors of the alveolar ridge may present with pain while chewing, loose teeth, or ill-fitting dentures in edentulous patients. These cancers often arise in edentulous areas or along the free margin of the mandibular alveolus (Figs. 47.8 and 47.9). Anesthesia of the lower lip and teeth may indicate involvement of the mandibular canal and inferior alveolar nerve.

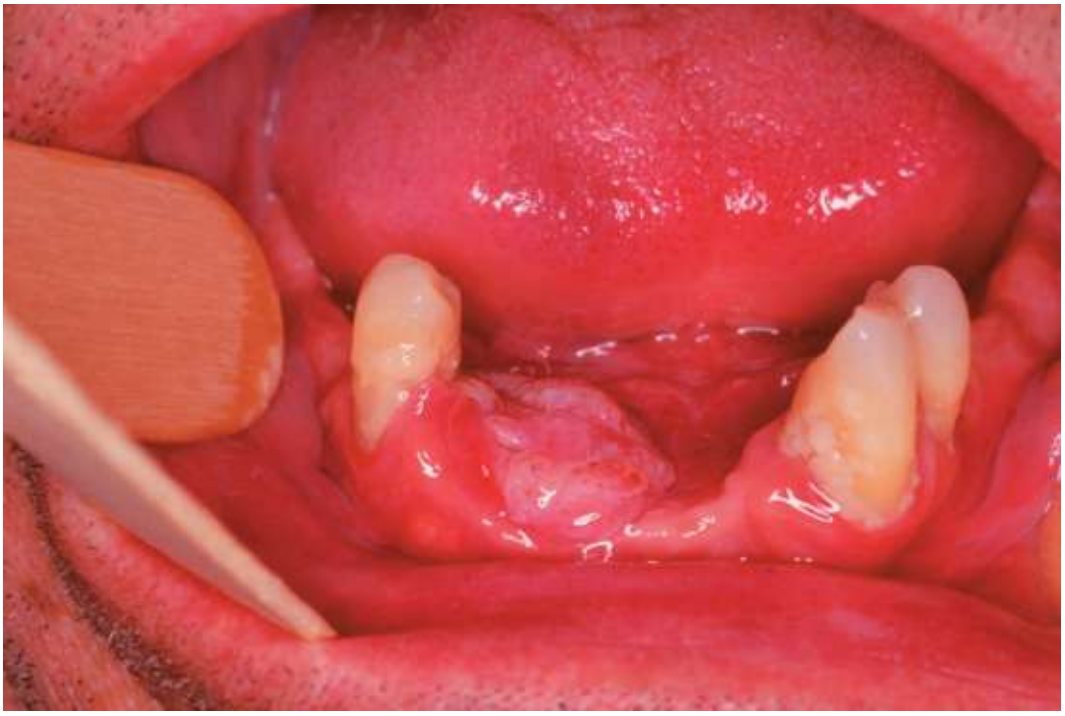

FIGURE 47.8. T1N0M0 squamous cell carcinoma of the mandibular alveolus. No evidence of bone invasion identified on panorex or CT imaging.

FIGURE 47.9. Squamous cell carcinoma involving the mandibular alveolus and buccogingival space.

Tumors involving the retromolar trigone region may present with an exophytic growth pattern and limited involvement of underlying bone (Fig. 47.10), or they may infiltrate cortical bone and spread along regional tissue planes to involve the pterygoid complex and parapharyngeal space. These latter lesions often induce trismus early in the clinical course.

Carcinoma of the buccal mucosa is rarely symptomatic early in its course. Lesions may be papillary or erosive and located near the dental occlusal line. These tumors are often relatively asymptotic and therefore seldom come to medical attention as T1 lesions. Often, these tumors manifest associated leukoplakia. Multiple primary sites and local recurrence are also common. These tumors most frequently arise adjacent to the lower molars along the occlusal line of the teeth.

Carcinoma of the hard palate is often painless, and the sole presenting symptom may be an irregularity in the mucosa or ill-fitting dentures. Other presenting symptoms include nonhealing ulcers of the hard palate, intermittent bleeding, and pain.

DIAGNOSTIC EVALUATION

Patients with oral cavity cancer should undergo a comprehensive history and physical examination. Detailed visual and digital examinations are particularly important for oral cavity tumors. A biopsy of lesions in question should be obtained as well as a thorough dental assessment. Computed tomography (CT) scans, panoramic radiographs, magnetic resonance imaging (MRI), and other imaging studies may also be important for accurate staging of the tumor and in treatment planning.

FIGURE 47.10. Exophytic T3 carcinoma involving the right retromolar trigone, anterior tonsillar pillar, and proximal soft palate with minimal infiltration into the right base of the tongue.

The history of present illness should address the following issues: tobacco and alcohol use; dysphagia; odynophagia; pain; trismus; difficulties with speech; hoarseness; loose teeth; ill-fitting dentures; hypoesthesia of the face, lips, or mandible; weight loss; and malnutrition. Otalgia suggests involvement of the ninth or tenth cranial nerve; facial numbness may suggest involvement of the fifth cranial nerve. Hypoesthesia usually results from perineural invasion, often from penetration of the mandible and perineural spread along the inferior alveolar nerve. The presence of trismus may indicate extension into the pterygoid musculature, signifying locally advanced disease. Other symptoms include a persistent ulcer, bleeding, drooling, or respiratory distress. A patient’s

comorbid illnesses must also be considered in designing the overall treatment strategy.

A detailed examination of the head and neck should be performed, with particular focus on the oral cavity and oropharynx. This usually begins with a full inspection of the oral cavity, including thorough inspection of the teeth. Palpation of the oral cavity can help assess bony involvement, tongue fixation, and depth of involvement. Deviation or fixation of the tongue suggests involvement of extrinsic muscles of the tongue. Bimanual palpation can help assess the depth of tumor invasion into musculature of the tongue and floor of the mouth. A thorough palpation of the neck is important to assess regional nodal disease.

Imaging can complement the physical examination in determining the extent of disease. A chest x-ray should be performed to exclude lung metastases or a second primary cancer. CT is the modality most commonly used to determine the extent of soft tissue and bony involvement and occult disease in the neck (Fig. 47.11). CT may be used to determine the extent of invasion into the deep musculature of the tongue and adjacent structures. Moreover, CT is a valuable modality for visualizing invasion of the mandible, palate, and pterygopalatine fossa. If CT scanning is not available, then panoramic radiographs can be used to demonstrate mandibular invasion. MRI may be used in case of contrast allergy or a lesion that is not well visualized on CT. For instance, MRI may be used if a patient has significant dental artifact that obscures visualization of the primary tumor on CT. MRI provides excellent definition of tumor involving the tongue and is a good modality for evaluating the possibility of perineural spread. Ultrasound may be used to screen for enlarged lymph nodes that are not clinically detectable. In experienced hands, the accuracy of ultrasound when combined with fine-needle aspiration may be superior to CT or MRI for staging the neck.[66]

Positron emission tomography (PET) and PET/CT have been used increasingly in head and neck cancer evaluation for staging disease in the neck, evaluation of perineural and skull base involvement, identification of distant metastases, and detection of recurrence. Several studies suggest that PET is more sensitive and specific in evaluating lymphatic metastases compared to CT and MRI.[67,68] PET/CT may improve the anatomic localization of abnormalities identified on PET and decrease the number of equivocal PET findings.[69] Liao et al.[70] prospectively evaluated 473 patients with oral cavity squamous cell carcinoma and report a sensitivity of 77.7% and a specificity of 58% for PET/CT

after histopathologic correlation of nodal metastases to the neck. Maddipatla et al.,[71] in a prospective study evaluating 552 lymph nodes dissected after oral cancer surgery, report a 97% negative predictive value (NPV) for PET/CT. Pentenero et al.[72] report an accuracy of 66.7%, a specificity of 76.9%, and a NPV of 83.3% for staging of the neck with PET/CT. Despite the improved overall accuracy, clinical application of PET/CT is limited by the suboptimal detection of small metastases. Therefore, the decision to pursue a neck dissection should not be based solely on PET/CT findings.

Reports have indicated that the overall sensitivity and specificity of PET may be superior to CT and MRI for evaluating persistent or recurrent disease, particularly in patients who have received previous radiotherapy.[73,74] The accuracy of PET in detecting disease recurrence or persistence may be influenced by the time post treatment when images are acquired. It is recommended that a PET scan not be performed until 8 to 12 weeks post treatment to minimize the risk of both false-negative and false-positive interpretations.[75–78]

STAGING

The American Joint Committee on Cancer (AJCC) has established a staging system for cancer of the oral cavity. The staging guidelines apply to all forms of carcinoma and are based on the eighth edition of the AJCC Staging Manual (Table 47.2).[79] Nonepithelial malignancies and melanoma of the lip and oral cavity are not included in the staging system. There are several pertinent changes from prior editions of the AJCC Staging Manual: (a) clinical and pathologic depth of invasion are now used in indicating the T category, (b) extrinsic tongue muscle involvement is no longer denoted as T4, (c) separate N staging categories are now present for patients treated with and without neck dissection, and (d) the presence of extranodal extension (ENE) is introduced as a descriptor of HPV-negative squamous cell carcinoma.

FIGURE 47.11. A: Transverse CT image with contrast depicting infiltrative squamous cell carcinoma of the left lateral oral tongue and floor of the mouth with associated bone destruction (*arrows*). There is posterior tumor extension to involve the retromolar trigone and tonsillar complex. **B:** Corresponding CT bone window views demonstrating destruction of the mandibular body.

TABLE 47.2 STAGING OF ORAL CAVITY CARCINOMA

Definition of Primary Tumor

T Category	T Criteria
TX	Primary tumor cannot be assessed
Tis	Carcinoma in situ
T1	Tumor ≤2 cm in greatest dimension, ≤5 mm depth of invasion (DOI)
T2	Tumor ≤2 cm in greatest dimension, DOI > 5 mm and ≤10 mm, *or* tumor >2 cm, but ≤4 cm, and ≤10 mm of DOI
T3	Tumor >4 cm in greatest dimension Any tumor >10 mm DOI
T4	Moderately advanced or very advanced local disease
T4a (lip)	Tumor invades through cortical bone, inferior alveolar nerve, floor of the mouth, or skin of the face (i.e., chin or nose).
T4a (oral cavity)	Tumor invades adjacent structures (e.g., through cortical bone of the mandible or maxilla, maxillary sinus, or skin of the face). *Note:* superficial erosion of bone/tooth socket by a gingival primary is not sufficient to classify a tumor as T4.
T4b	Tumor invades masticator space, pterygoid plates, or skull base and/or encases carotid artery.

Definition of Regional Lymph Node (N)

Clinical N (cN)

N Category	N Criteria
Nx	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastases
N1	Metastases in a single ipsilateral lymph node, ≤3 cm in greatest dimension, ENE (−)
N2	Metastases in a single ipsilateral lymph node >3 cm, but ≤6 cm in greatest dimension and ENE (−); in multiple ipsilateral lymph nodes, none >6 cm in greatest dimension and ENE (−); *or* in bilateral or contralateral lymph nodes, ≤6 cm in greatest dimension and ENE (−)
N2a	Metastases in a single ipsilateral lymph node >3 cm, but ≤6 cm in greatest dimension and ENE (−)
N2b	Metastases in multiple ipsilateral lymph nodes, ≤6 cm in greatest dimension, and ENE (−)
N2c	Metastases in bilateral or contralateral lymph nodes ≤6 cm in greatest dimension and ENE (−)
N3	Metastases in a lymph node >6 cm in greatest dimension and ENE (−) *or* in any node with clinically overt ENE (+)
N3a	Metastases in a lymph node >6 cm in greatest dimension and ENE (−)
N3b	Metastases in any lymph node(s) and clinically over ECE (+)

Definition of Regional Lymph Node (N)

Pathologic N (pN)

N Category	N Criteria
Nx	Regional lymph nodes cannot be assessed

N0	No regional lymph node metastases
N1	Metastases in a single ipsilateral lymph node ≤3 cm in greatest dimension and ENE (−)
N2	Metastases in a single ipsilateral lymph node ≤3 cm in greatest dimension and ENE (+); >3 but ≤6 cm in greatest dimension and ENE (−); in multiple ipsilateral lymph nodes, ≤6 cm in greatest dimension and ENE (−); *or* in bilateral or contralateral lymph nodes, ≤6 cm in greatest dimension and ENE (−)
N2a	Metastases in a single ipsilateral or contralateral lymph node ≤3 cm in greatest dimension and ENE (+), *or* in a single ipsilateral lymph node, >3 but ≤6 cm in greatest dimension and ENE (−)
N2b	Metastases in multiple ipsilateral lymph nodes ≤6 cm in greatest dimension and ENE (−)
N2c	Metastases in bilateral or contralateral lymph nodes ≤6 cm in greatest dimension and ENE (−)
N3	Metastases in a lymph node >6 cm in greatest dimension and ENE (−); in a single ipsilateral lymph node, >3 cm in greatest dimension and ECE (+); *or* multiple ipsilateral, contralateral, or bilateral lymph nodes, any with ENE (+)
N3a	Metastases in a lymph node >6 cm in greatest dimension and ENE (−)
N3b	Metastases in a single ipsilateral lymph node >3 cm in greatest dimension and ECE (+), *or* in multiple ipsilateral, contralateral, bilateral lymph nodes, any with ENE (+)

Note. A designation of “U” or “L” may be used for any N category to indicate metastases above or below the lower border of the cricoid, respectively. Similarly, clinical or pathologic extranodal extension (ENE) should be recorded as ENE (−) or ENE (+).

GENERAL MANAGEMENT

Surgical resection, radiation, chemotherapy, or combined modality approaches are classical treatment options that have been employed for patients with cancer of the oral cavity. The choice of treatment modality, either singly or in

combination, depends on the stage and size of the tumor and relevant patient factors such as toxicity, performance status, comorbid disease, and convenience. The overall health and functional status of the patient are important determinants in choosing between surgical and nonsurgical approaches.

Surgery is most commonly the treatment of choice for lesions of the oral cavity.[1] Surgical resection is expeditious, effective, and often associated with modest morbidity and good functional outcome particularly for patients with small- to moderate-sized lesions. Radiation therapy can be considered for patients with early-stage disease who either are not surgical candidates or refuse surgical management. For patients with advanced lesions of the oral cavity, a combined modality approach is generally recommended. In patients with high-risk pathologic features, the addition of concurrent chemotherapy during the postoperative radiation treatment course may further augment tumor control rates provided the chemotherapy can be tolerated.[80–82] High-risk features commonly include ENE and positive resection margins.[81,83–85]

PRINCIPLES OF SURGERY

All patients with oral cavity carcinoma should be evaluated by a head and neck surgical oncologist.[1] One major reason why surgery is often the primary modality in sequential therapy is that definitive high-dose radiation has been associated with higher rates of osteoradionecrosis and inferior control rates, particularly in the setting of more advanced disease.[86–89] The primary objectives of surgery are complete resection of the primary tumor with negative margins and staging and treatment of the regional lymphatics. Margin status is one of the most important variables associated with survival, as locoregional control is significantly improved with margins of 0.5 cm or greater, relative to margins of <0.5 cm (36% vs. 18%, respectively).[81,84,90]

Surgical Management of the Primary Tumor

In treating cancer of the oral tongue, it is best to obtain adequate margins during initial resection. The outcome of intraoperative positive margins followed by immediate repeat resection revised to negative margins is associated with worse survival compared to negative margins achieved with initial resection (31% vs. 49%, respectively).[91] Several strategies are being developed to enhance the ability of surgeons to detect margins intraoperatively. However, these remain largely experimental and are yet not being used in routine clinical practice.[92–94]

Although surgeons and pathologists agree on the quantified distances for free margins, pathologic findings of margin status can be misclassified because of tissue shrinkage, inaccurate sampling, and improper orientation.[95] Although shrinkage is unavoidable, accurate assessment of all margins can be performed from the main specimen, as opposed to sampling from the tumor bed. How the surgeon takes the margins is also extremely important, and it is recommended that the margins be taken from the tumor specimen rather from the tumor bed, as the latter is associated with higher risks of local recurrence.[96] Furthermore, proper orientation of the specimen and communication with the pathologist are vital to assessing accurate margin status.

The ability to obtain clear, three-dimensional margins is the most important factor in selecting the surgical approach, and this is typically guided by the size and location of the tumor as well as factors related to the patient's dentition as well as the presence or absence of trismus. Most often, lesions of the anterior or lateral oral tongue and floor of the mouth can be resected transorally; however, in cases with significant posterior extent and/or in patients with trismus and/or obstructive dentition, a visor flap with lingual release—sometimes referred to as a pull-through or lip-splitting incision with mandibulotomy—may be required for optimal resection. The visor flap is an approach that avoids a facial incision and is associated with lower rates of oral incompetence and fistula.[97] Buccal resections can often be performed with a transoral approach or with a lip-split incision to allow adequate exposure for mandibular or maxillary resection. Retromolar trigone resections often require mandibulectomy because of the posterior extent and increased rate of bone invasion. The introduction of transoral robotic surgery offers a novel approach for resecting more posterior tumors without mandibulotomy.

Transoral resection is often used for excision of floor of the mouth tumors, and these excisions often involve marginal or segmental mandibulectomy because the presence of mandibular invasion is associated with worsened local control. The decision on whether to perform a marginal versus a segmental resection is based on the preoperative assessment of invasion of the periosteum and cortex.[98] However, this type of assessment remains a challenge because results of preoperative physical examination are predictive of bone invasion only two-thirds of the time. This can be enhanced through the use of imaging that has excellent specificity despite limitations in assessment of microscopic invasion.[99] For the management of small tumors with periosteal involvement, marginal mandibulectomy is associated with outcomes equivalent to those of segmental

mandibulectomy. The major indications for segmental mandibulectomy include pre- or intraoperative findings of bone invasion, tooth loss with low mandibular bone height, and bone that has previously been irradiated. In cases in which both a mandibulotomy and marginal mandibulectomy are contemplated, the risk of postradiation ORN is high and should be considered with caution.[100] Transoral resection can often be employed to resect lesions of the hard palate and maxillary alveolar ridge, though larger tumors that extend into the paranasal sinuses, masticator space, or infratemporal fossa and may require a facial incision to improve access.

Surgical Management of the Neck

The relatively high rate of cervical nodal metastasis associated with oral cavity cancers warrants management of the neck in the vast majority of patients with oral tongue, floor of the mouth, buccal, and retromolar trigone tumors. The selection of type and extent of neck dissection is dependent on whether the patient is clinically node negative based on physical examination and imaging; in clinically node-negative patients, a neck dissection is considered elective. In contrast, patients with nodes that are palpable or detected on imaging require a therapeutic neck dissection. Although neck dissection is a safe procedure, it is not without morbidity; shoulder dysfunction, iatrogenic cranial nerve injuries, and vascular insult remain significant complications of neck dissection.

Therapeutic neck dissection in clinically positive disease is a well-established treatment strategy, and the extent of dissection recommended in this setting has decreased considerably over the past several decades. In the early 1900s, radical en bloc resections according to the surgical oncologic principles advanced by Dr. William Halsted were recommended. Over the intervening years, these relatively morbid operations have largely been replaced by more selective approaches to involve only the nodal basins with expected metastasis with preservation of uninvolved nonlymphatic structures including the internal jugular vein, sternocleidomastoid muscle, and spinal accessory nerve. The contemporary practice of these more limited procedures has been supported with data demonstrating that regional control and survival rates do not decrease with more selective approaches, particularly when adjuvant therapies are used to manage microscopic residual disease in high-risk patients.[101]

For patients whose preoperative examination reveals a cN-positive neck, a selective neck dissection at levels I to IV or I to V is recommended. In these cases, positive pathologic nodes are found in more than 75% with 15.8% having

skip metastasis to level III or IV, without involvement of levels I or II.[47,55,101,102] The use of radical and modified neck dissections is typically reserved for patients with advanced nodal disease (N3), disease extending into level V, or invading critical structures in the neck.

The decision to proceed to END is based on a >20% probability of occult nodal disease being present for patients with early-stage tumors that are clinically node negative (cN0).[103] END can be therapeutic if no positive nodes are found at pathologic review and it can provide important staging information to guide decision about the need for adjuvant therapy in patients found to have pN-positive disease with or without ENE. The depth of tumor invasion has been reported to be the best predictor for regional metastasis in the cN0 neck. Nevertheless, cutoffs for the extent of depth of invasion for which neck dissection is recommended remains ill defined. A meta-analysis identified a depth of 4 mm from the mucosal surface in oral tongue cancers as the cutoff most frequently cited as an indication for END, based on a NPV of 95.5%.[104] Other analyses have shown that depth of invasion >4 mm is associated with increased risk of occult metastasis and late cervical recurrences.[105–107] In floor of the mouth tumors, a depth of invasion >1.5 mm is associated with 33% occult regional metastasis, whereas in buccal carcinomas, tumors of the maxillary alveolar ridge, and tumors of the hard palate, depth has not been extensively studied, and occult metastases are rare, occurring in 9% of patients and most often associated with T4 tumors.[108,109] Therefore, END is not indicated for early-stage buccal, maxillary alveolar ridge, or hard palate cancers in cN0 cases. In addition to depth of invasion, growth type, number of mitoses, PNI, lymphovascular invasion, and poorly differentiated and infiltrative growth patterns are associated with metastasis.[107,109] There is no clear consensus regarding which of these risk factors necessitate END. Once the decision to proceed with END is made, the literature supports dissection of at least the supraomohyoid neck, including levels I to III. The notable exception is cancer of the oral tongue, for which extension to remove level IV can be considered because of the occasional identification of skip metastases, which are difficult to salvage.[55] The need to extend a neck dissection to include level IIB has been questioned because dissection of this nodal level requires dissection of spinal accessory nerve, which in turn is associated with greater morbidity. The results of several prospective studies support the exclusion of level IIB in ENDs for patients with oral cavity cancer as the incidence of nodes with occult regional disease is 11.1% in cN0 patients.[110]

Given that as many as 70% of END are found to have no pathologic lymph nodes at pathologic review and neck dissection can be both morbid and costly, alternatives to END have been explored, and these include observation, elective radiation, or sentinel lymph node biopsy (SLNB). There have been several prospective studies performed to evaluate observation versus END, with one study demonstrating a survival benefit with END.[111] The rate of nodal recurrence in the observation arms in that study performed in Brazil was 41.7% compared with 15% in the END arm. Although successful salvage was higher with observation than with END (57% vs. 16%, respectively), 66% fewer salvage attempts occurred in the END groups. Because the node-related mortality is higher with observation than with END (22% vs. 10%, respectively), END has been the standard of care for most patients with oral cavity cancers.[112]

In a recent landmark study, D'Cruz and colleagues at Tata Memorial Hospital in Mumbai evaluated 500 patients with early-stage oral cavity squamous cell carcinoma who were randomly assigned to undergo END versus observation with therapeutic neck dissection to evaluate survival differences between treatment options.[113] The unadjusted improvement in OS for END was 12.5% (END vs. observation with TND, 80% vs. 67.5%, respectively) and this result was confirmed after the investigators adjusted for other covariates (hazard ratio [HR], 0.63; P<.001). Although no difference was observed in the cohorts when patients had pN0 disease (HR, 1.2; P=.54), among pN-positive cases, significant improvement in survival was noted in the END cohort (HR, 0.52; *P=.008*). In addition, data from this study confirmed that depth >3 mm was a significant independent predictor of regional metastasis (HR, 2.17; P<.001). There was no difference observed for OS when patients with tumor depth <3 mm were compared across the two cohorts (*P=.12*); however, the study was not powered to definitively address this issue. Overall, this study's results support the practice of END for early-stage N0 OCSCC and confirm that depth is an important variable in the decision between END or observation and therapeutic neck dissection.

Another option for managing the clinically node-negative neck is SLNB, which is a less invasive approach used to accurately identify occult metastasis in early-stage oral cancer. SLNB is based on the principle that cancer spreads first to a primary echelon lymph node known as the "sentinel node" that can be readily identified and meticulously evaluated for microscopic disease. This minimally invasive technique to stage regional lymph nodes is well established in melanoma and breast cancer and allows for a more systematic and accurate

pathologic assessment of regional lymph nodes for metastasis without the morbidity of END. There have been several multi-institutional prospective studies that have been performed to assess the efficacy of SLNB in oral squamous cell carcinoma. In a trial completed in Europe, sentinel lymph nodes were identified in 93% of patients with a low false-negative rate.[114] In a study performed in North America (ClinicalTrials.gov identifier: NCT00042926), SLNB was found to have a 96% NPV overall in cancers of the oral tongue.[115] A meta-analysis showed a pooled NPV of 96% in early-stage oral cavity tumors, with no difference in regional recurrence between SLNB and END (6.7% and 6%, respectively). The accuracy and consistent NPV found in most studies indicate that SLNB offers an excellent alternative to END in cN0 patients with early oral squamous cancers. Although this approach has become a standard of care for management of the cN0 neck in oral cavity cancer patient in Europe, its use in the United States has been much more limited. Factors that might explain the slow adaptation of SLNB in this country include the steep learning curve, the additional preoperative workup required, and the need for an experienced multidisciplinary team. There is no level I evidence yet available regarding survival equivalency with END.

Reconstruction

The oral cavity is a complex site made up of several structures critical for speech, swallowing, and appearance, and successful rehabilitation of these functions in patients that have undergone oral cancer extirpative surgery involves meticulous anatomic restoration post resection. A successful, reconstruction should attempt to address all three of these functions, and it must be tailored to the site of the defect. Patients with advanced-stage disease are often best reconstructed with microvascular free tissue transfer, which has become standard in head and neck reconstruction and has improved both oncologic and functional outcomes.[116] In the case of oral tongue reconstruction, which is critical to restoring function, the major goals of reconstruction are to allow obliteration of the oral cavity to minimize dead space, to maintain premaxillary contact for articulation and the oral phase of swallowing, and to optimize the mobility of the tip of the tongue to maximize tongue sweep. Postoperative measures of tongue protrusion and elevation have helped to identify objective targets for favorable speech and swallowing outcomes.[117] Also, for total glossectomy, the volume and convexity of the flap are critical to the achievement of optimal functional outcomes.[118]

For patients with oral cancers requiring mandibulectomy, mandibular reconstruction with bone ensures the best outcomes for speech, swallowing, and cosmesis and also helps to maintain symmetric temporomandibular joint articulation enabling mouth opening and maintenance of an occlusal plane for chewing. The major cosmetic goals of mandibular reconstruction include providing facial height and projection to prevent the “Andy Gump” deformity.[119] Reconstruction of maxillary and hard palate reconstruction can provide oronasal separation as well as a surface necessary for premaxillary contact and obliteration during the oral phase of swallowing. Although prosthetic palatal obturation can also help achieve these objections, the choice between prosthetic obturation and free tissue is based on the size of the defect, the location, and the number of remaining teeth.[120] The major goals for reconstruction of the floor of the mouth include separation of the oral cavity from the neck and provision of soft tissue bulk between the ventral tongue and the mandible that prevents tethering of the tongue as well as provision of a platform for tongue elevation and protrusion. Major objectives of buccal reconstruction include resurfacing the cheek with prevention of cicatricial scaring and trismus. As swallowing function is well established as one of the most important factors associated with improved quality of life, oral cavity reconstruction and swallowing therapy under the guidance of an experienced speech pathologist are the critical elements in the successful functional rehabilitation after oral cavity cancer resection.

PRINCIPLES OF RADIATION THERAPY

Primary Radiation Therapy

In considering primary radiation as a treatment option, it must be borne in mind that the keratinizing, well-differentiated histology of many oral cancers may portend radioresistance. It is also important to consider that the bony structures of the mandible and maxilla may impact the transmission of ionizing radiation. For early-stage disease, a combined approach including both external beam radiation and interstitial brachytherapy is often recommended for optimal outcome. Thus, a course of radiation can require several weeks of daily therapy followed by an interstitial implant. The normal tissue toxicity risks of xerostomia, dental and gum injury, and occasional osteoradionecrosis may render radiation therapy a less attractive option for single modality treatment of patients who are candidates for surgery. For locally advanced disease, definitive radiation or chemoradiation is not advised in patients who are candidates for

surgery.[1]

Historically, sites commonly treated with single modality radiation include the lip, floor of the mouth, and oral tongue.[121,122] Early work indicates that the success rate of radiotherapy is higher if some or all of the treatment is administered with brachytherapy.[123,124] Decroix and Ghossein[125] reported outcomes in 602 patients with cancer of the oral tongue treated with radium implantation or implantation plus external beam radiation. In this series, recurrence at the primary site or at the primary site and neck was 14% and 22% for T1 and T2 lesions, respectively. The Royal Marsden Hospital reported local control rates of 90% at 5 years for T1 and T2 tumors treated with interstitial radiation with or without external beam radiation.[126] Pernot et al.[127] reported local control rates of 96% for T1, 85% for T2, and 64% for T3 lesions of the oral cavity treated with brachytherapy and neck dissection. In this series, locoregional control rates were 83%, 70%, and 44%, respectively. Retrospective studies suggest that control rates at the primary site of early oral cavity lesions treated with brachytherapy alone or a combination of brachytherapy plus external beam radiation range from approximately 70% to >95%.[125–128] For tumors that either involve the mandible or are immediately adjacent to it, definitive radiotherapy is contraindicated because it compromises control and increases the risk of osteoradionecrosis.

Intraoral cone, like interstitial brachytherapy, is a localized radiation therapy technique that has been used to boost the dose to the primary tumor in the oral cavity. Institutions with significant experience with this technique have reported results that rival those obtained by interstitial brachytherapy.[129,130] Either technique for boosting the primary tumor has resulted in improved outcomes compared to high-dose radiation therapy alone.[131,132] In general, external beam radiation therapy followed by either technique is preferable over radiation therapy alone. As with all specialized procedures, the skill and experience of the radiation oncologist are of critical importance to the successful delivery and outcome of interstitial radiation or intraoral cone therapy.

The outcomes for advanced lesions of the oral cavity (T3 and T4) are less than satisfactory with either surgery or radiation alone. In most advanced-stage cancers, single modality therapy is inferior to combined modality therapy.[124,133,134] Adjuvant radiation therapy can be delivered preoperatively or postoperatively.[129,133] Although each strategy has potential advantages and disadvantages, postoperative radiation therapy is generally preferred. Postoperative radiation treatment carries the advantage of no delay in the

implementation of surgical resection and complete pathologic staging of the tumor. However, it must be borne in mind that postoperative wound complications may delay the implementation of radiation therapy.

Adjuvant Radiation

Although surgery has emerged as the preferred initial treatment approach for the majority of patients with tumors of the oral cavity, adjuvant radiation is commonly recommended to enhance the likelihood of locoregional tumor control. Robertson et al.[135] conducted a phase III study in the United Kingdom of 350 patients with T2–T4/N0–N2 oral cavity or oropharyngeal cancers comparing surgery and postoperative radiation versus radiation alone. Because a difference in survival was identified, the study was closed early. The authors found that after 23 months, overall survival, cause-specific survival, and local control were all improved in the surgery plus radiation arm. Traditionally, indications for postoperative radiation therapy include multiple cervical metastases, positive or close margins, extracapsular extension, perineural invasion, advanced T stage, and mandibular bone involvement. A phase III study conducted at the University of Texas MD Anderson Cancer Center established the relative prognostic significance of clusters of two or more clinicopathologic features.[136] The adverse clinicopathologic features in this study included (a) close or positive margins, (b) nerve involvement, (c) ≥2 positive lymph nodes, (d) largest node >3 cm, (e) treatment delay >6 weeks, and (f) Zubrod performance status ≥2. The presence of ENE was the only factor independently predictive of locoregional recurrence. Moreover, the authors concluded that escalation of dose beyond 63 Gy (in 1.8 Gy per fraction) to sites of increased risk did not yield improved locoregional control.

It is well appreciated that head and neck tumors are rapidly proliferating. Several retrospective series have demonstrated an association between diminished outcomes and a delay beyond 6 weeks in initiating postoperative radiation.[137–139] A multi-institutional prospective study by Ang et al. demonstrated that the total treatment time from the completion of surgery to the completion of radiation may affect the likelihood of ultimate disease control.[140] This study illustrated the impact of overall treatment time on 5-year locoregional control: patients with overall times <11 weeks demonstrated a locoregional control rate of 76%, compared to 62% for 11 to 13 weeks, and 38% for times beyond 13 weeks. Hence, it is recommended that adjuvant radiation proceed as soon as surgical wounds are well healed, optimally 4 to 6 weeks after completion

of surgery.

There has been significant interest in the use of intensified radiation fractionation schedules to counter rapid tumor cell repopulation as a means of improving outcomes in head and neck cancer patients treated with radiation. Altered fractionation regimens such as hyperfractionation or accelerated fractionation have been considered for patients being treated with radiation alone, as this approach has been demonstrated to improve the likelihood of locoregional tumor control in the definitive setting.[141] However, the use of altered fractionation in the postoperative setting has not been resolved. Ang et al. reported a trend toward higher locoregional control and survival with a concomitant boost schedule compared to a standard fractionation schedule.[140] However, in a subsequent study, Sanguineti et al.[142] demonstrated no benefit for accelerated fractionation, except in patients for whom postoperative radiation was delayed.

There has been recent interest in postoperative chemoradiation for patients with high-risk pathologic features. The results of two randomized trials suggest that postoperative chemoradiation may be beneficial for improving locoregional control and disease-free survival among selected patients with specific high-risk features.[81,84] The impact of chemoradiotherapy appears to be most pronounced in patients with ENE and/or microscopically involved surgical margins.[83,84]

Radiation Techniques

General Considerations

Historically, carcinoma of the oral cavity has been treated with opposed lateral fields, using either two-dimensional or three-dimensional (CT-based) techniques. However, since the emergence of intensity-modulated radiation therapy (IMRT) at the turn of the millennium, there has been a dramatic shift in the radiotherapeutic management of head and neck cancer. Since that time, IMRT has gained widespread adoption and has become the de facto standard in the management of carcinoma of the head and neck.[1,88,143] The major driver for this dramatic shift away from conventional techniques has been the potential for normal tissue sparing and consequent improvement in functional outcomes, particularly in the realms of salivary function and dysphagia.

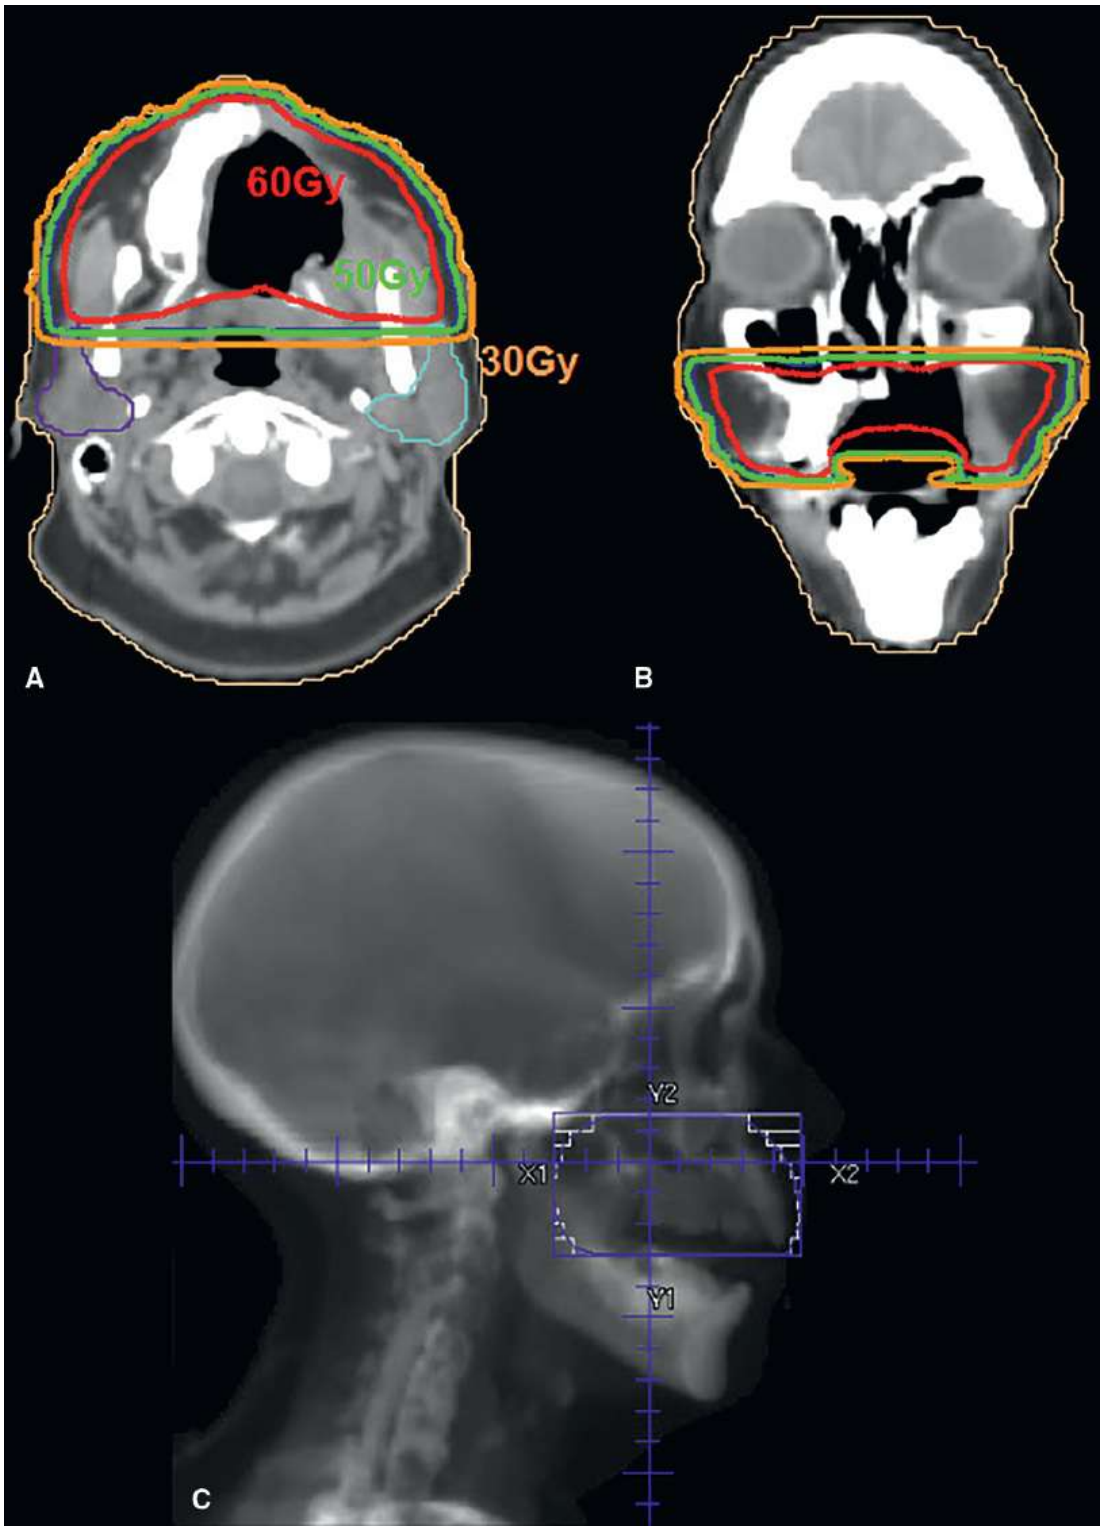

FIGURE 47.12. T4N0M0 squamous cell carcinoma of the maxillary alveolar ridge in a patient who underwent left infrastructure maxillectomy and left selective neck dissection. The figure illustrates postoperative conventional radiation field design with opposed laterals to cover the maxilla and operative bed at risk. Treatment of the neck was omitted in lieu of a negative neck dissection. **A** and **B:** Relevant isodose lines. **C:** Right lateral field DRR. The parotid tissue is nearly completely spared by this field

arrangement.

With respect to oral cavity cancer, the improvements in conformality afforded by IMRT have opened the opportunity to mitigate damage to major salivary glands (xerostomia), the mandible (osteoradionecrosis), and the pharyngeal structures (dysphagia).[50,144–148] However, it is important to bear in mind that there are instances in which IMRT may not provide significant additional benefit in the treatment of oral cavity cancer and conventional techniques may be fully adequate. It is also valuable to consider that practitioner and treating center experience may be important indicators of potential outcomes when IMRT is utilized in the treatment of head and neck cancer patients.[149,150]

Each institution should select appropriate oral cavity cases for treatment with IMRT. For instance, patients with T1/T2N0 carcinoma of the floor of the mouth or alveolar ridge that have undergone surgical staging of the neck may not benefit from IMRT because the bulk of both parotid glands can be excluded from opposed lateral portals (Fig. 47.12). Ideal candidates for IMRT include patients with T1/T4 primary lesions with ipsilateral neck disease. In patients that have ipsilateral positive neck nodes, IMRT may allow dose limitation to the contralateral parotid gland without compromising treatment results.[151] In patients with bilateral neck disease, it may be difficult to effectively spare the parotid glands, particularly when superior level II cervical lymph nodes are involved, because of the coverage of the retrostyloid space in this setting.[152]

Intensity-Modulated Radiation Therapy

The use of more conformal techniques may be associated with a unique set of potential pitfalls. Whereas treatment planning with two-dimensional or three-dimensional techniques does not universally mandate careful interpretation of cross-sectional imaging and attention to anatomic detail, IMRT requires precise target volume delineation. If a target volume is not included within the clinical target volume (CTV), it may receive a subtherapeutic dose of radiation and thus portend marginal recurrence. The quality of conformal radiation therapy is significantly associated with outcomes in the treatment of head and neck cancer.[149,150,153]

Most cases of oral cavity cancer will be treated postoperatively. It is important to consider that neck dissection tends to disrupt the anatomic landmarks defining borders between nodal levels. The task of distinguishing the primary tumor resection bed and adjacent neck dissection poses a significant

challenge in target volume design. Gregoire et al.[26,152] proposed guidelines for target volume delineation in the postoperative patient that are available as a reference. The authors encourage the reader to review these guidelines as they consider more selective coverage of nodal regions during target volume delineation. These guidelines serve in part as the basis for the recommendations presented in this section. Treatment considerations for each oral cavity subsite are presented in the section “Subsite Specific Treatment and Results.”

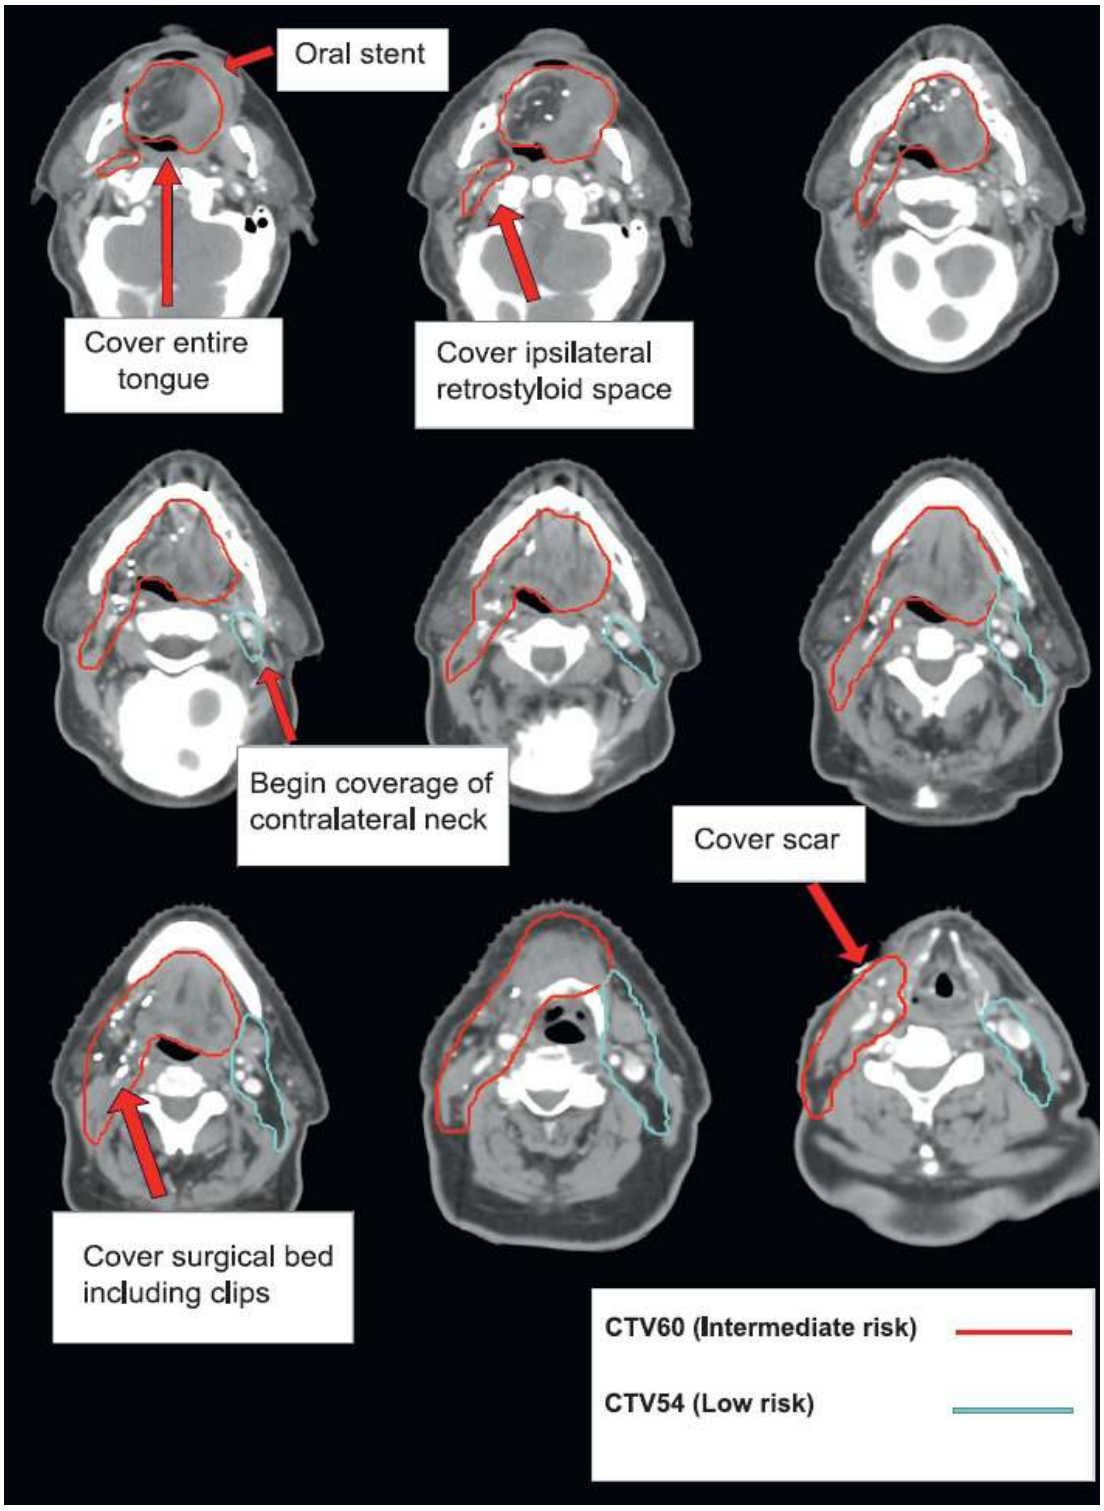

FIGURE 47.13. T3N1M0 squamous cell carcinoma of the right oral tongue. The patient underwent right hemiglossectomy, including resection of the floor of the mouth, and right selective neck dissection. The tumor was 3 cm in size, with a depth of invasion of 1.3 cm, and 1/46 lymph nodes with evidence of carcinoma (no evidence of ENE). Adjuvant treatment was delivered with radiation therapy alone using IMRT with the intent of maximizing coverage to regions at risk while sparing salivary glands and

pharyngeal tissues. Note that the ipsilateral retrostyloid space and entire tongue, intraoral free flap, and dissected neck are included in CTV_{60}. The cranial extent of CTV_{54} in the contralateral neck is the bottom edge of the body of C1. The retropharyngeal nodes are not covered in this setting to allow sparing of the pharyngeal structures.

The discussion to follow is relevant to target volume design in the postoperative setting. Figure 47.13 illustrates relevant target volumes for a typical postoperative oral cavity case. Figures 47.14 and 47.15 provide examples of special considerations for patients with positive margins/ENE and ipsilateral treatment, respectively. There are three classes of CTVs that can be defined based on the practice of a range of North American institutions and cooperative group guidelines.[26,27,51,152,154,155]

- The high-risk CTV (CTV_{66}) is defined as the volume harboring ENE or a positive margin. It is recommended that CTV_{66} receives 66Gy either as a simultaneous integrated boost (SIB) (2.2 Gy per fraction over 30 fractions) or as a sequential boost.
- The intermediate-risk CTV (CTV_{60}) is defined as the volume that includes the primary tumor bed (based on preoperative imaging, physical exam, and operative findings) plus regions of grossly involved adenopathy. The target volume should include the entire primary surgical bed and the pathologically positive hemineck; this frequently requires coverage of nodal levels I, IIa-b, III, and IV for most cases. It is recommended that CTV_{60} receives 60 Gy in 2.0 Gy per fraction.
- The low-risk CTV ($CTV_{54–56}$) usually includes the prophylactically treated neck felt to have a low risk of harboring microscopic disease (e.g., the uninvolved low or contralateral neck) and should receive 54 to 56 Gy as a simultaneous integrated boost in 1.8 to 1.87 Gy per fraction.

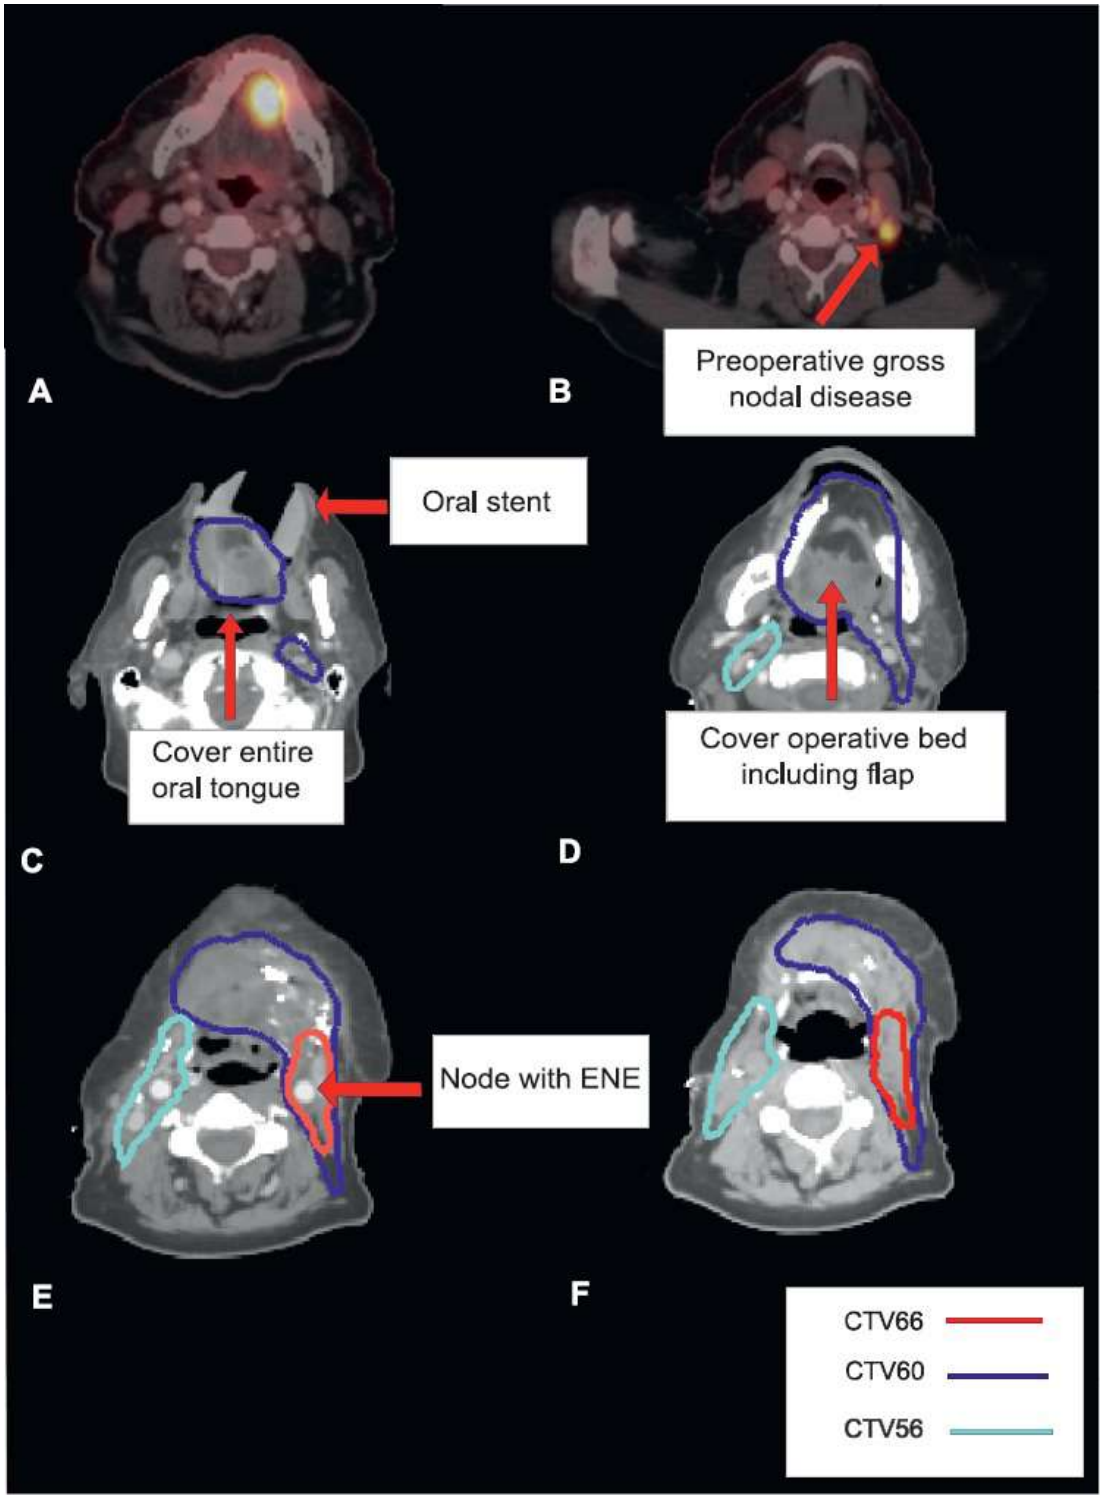

FIGURE 47.14. T4N3bM0 squamous cell carcinoma of the floor of the mouth with evidence of ENE treated on RTOG protocol 1216 (ClinicalTrials.gov identifier: NCT01810913). The patient underwent left mandibulectomy, composite resection of the floor of the mouth, left hemiglossectomy, and neck dissection. The final pathology demonstrated 3 cm primary lesion, with 6/55 lymph nodes positive for carcinoma, and ENE in a lymph node at left level II. The treatment was delivered with IMRT using an SIB concurrently with chemotherapy. The neck region with evidence of ENE received

66 Gy in 2.2 Gy per fraction, whereas the primary site, free flap, and ipsilateral neck received 60 Gy in 2.0 Gy per fraction. The contralateral neck received 56 Gy in 1.87 Gy per fraction. **A** and **B:** Preoperative PET showing primary and nodal disease. **C–F:** Postoperative target volume delineation.

It is common practice for the radiation oncologist to consider selective coverage of the neck and retropharyngeal nodes' order to limit dose to critical organs at risk. This generally involves limiting cranial coverage of the level II neck to the level of C1 in the N0 neck to spare the parotid gland and the upper pharyngeal structures.[51,146,147,152,156] This is an accepted standard in the N0 neck, which may potentially be extended to patients with small N1 disease.[51,152,157] Marginal recurrences near the base of the skull, above this cranial border of level II, have been reported in the node-positive neck.[151] The retrostyloid space represents the cranial extension of level II to the skull base. In cases where involvement of upper level II with one or more lymph nodes is evident, it is suggested that the retrostyloid space be included in the intermediate-risk target volume (i.e., CTV_{60}) (Fig. 47.13).[152] In addition to this principle, there are several target volume design details specific to the postsurgical head and neck cancer patient that should be considered.

- When a metastatic lymph node abuts or infiltrates muscle (most commonly the sternocleidomastoid or paraspinal musculature), it is recommended that the muscle be included in CTV_{60}, at least for the invaded nodal station (Fig. 47.14).[152]
- When a metastatic node lies at the boundary with a nodal level that was not intended to be part of the intermediate-risk CTV, it is recommended that CTV_{60} be extended to encompass this adjacent level.[152]
- If level IV or Vb is involved, it is suggested that CTV_{60} be extended to include the supraclavicular fossa.[152]
- In the event of flap reconstruction of the oral cavity or neck, it is recommended that the entire flap be considered for inclusion in the IMRT field (either CTV_{60} or $CTV_{54–56}$ based on physician discretion), particularly if there is evidence of ENE.[158]
- In the case of extensive perineural spread, it is recommended that the proximal course of the involved nerves be included in the treatment field to the level of the infratemporal fossa or skull base.[159]

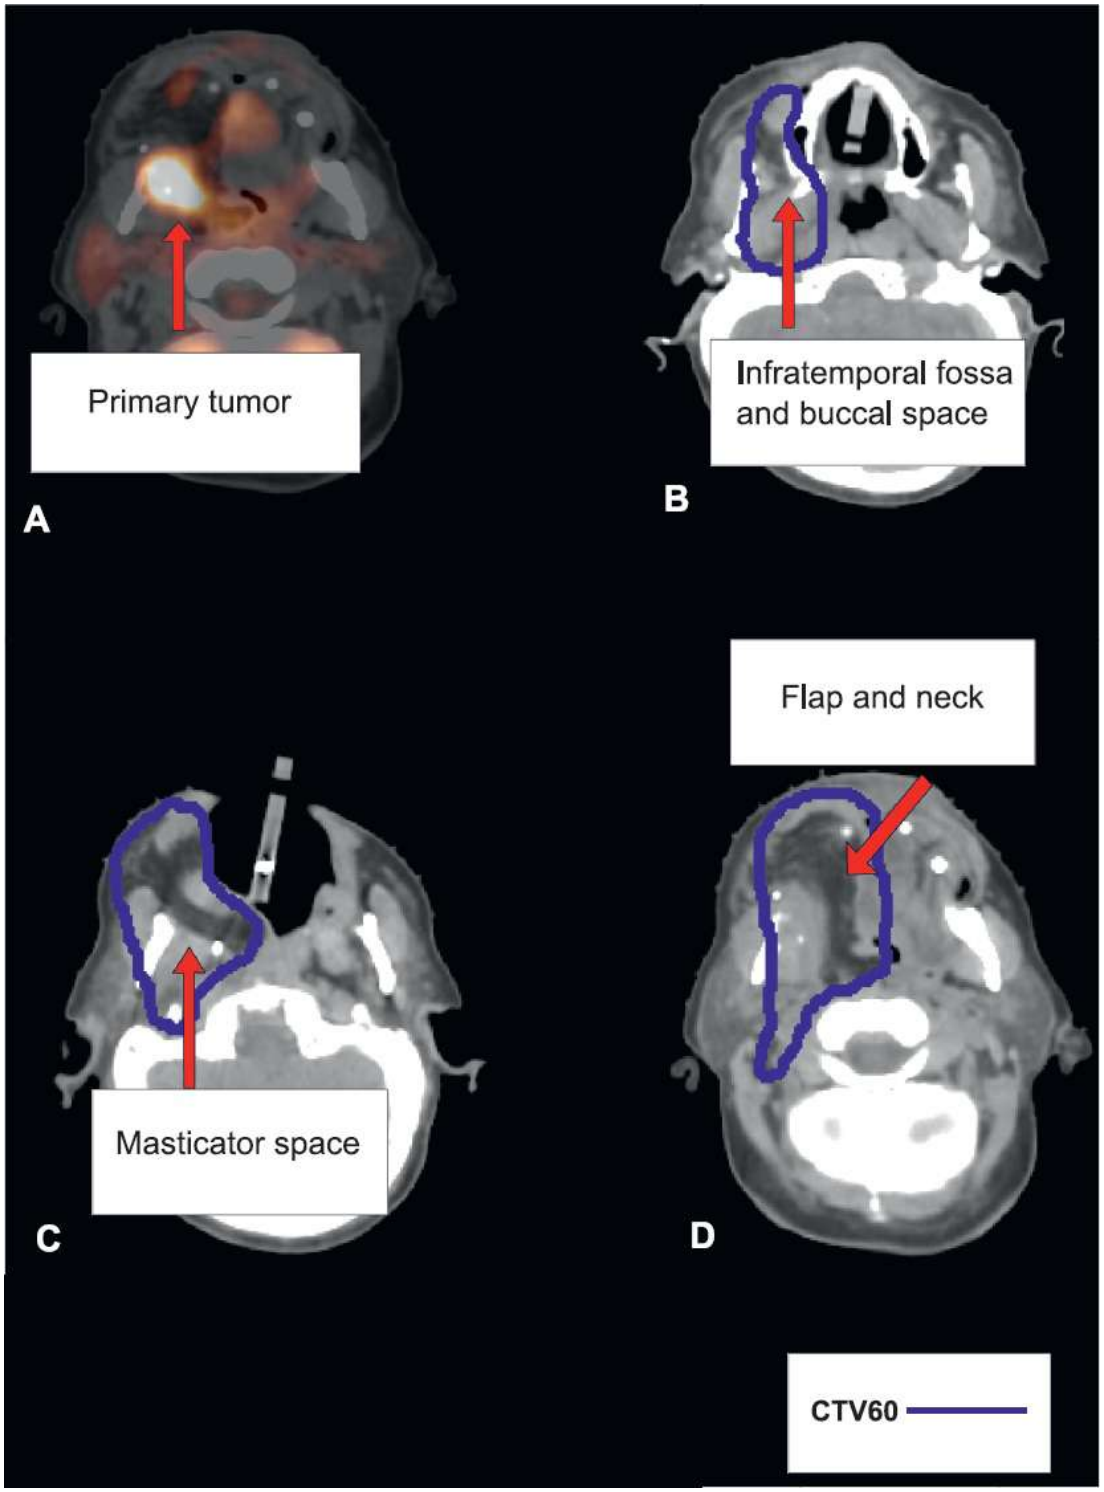

FIGURE 47.15. T2N1M0 squamous cell carcinoma of the right retromolar trigone. The patient underwent composite resection of the right retromolar trigone, buccal mucosa, maxilla, and right neck dissection, followed by anterolateral thigh free flap reconstruction of the defect. **A:** Preoperative PET showing disease at the primary site. **B–D:** Postoperative target volume delineation of the surgical bed, masticator space, infratemporal fossa, free flap, and ipsilateral neck.

Conventional Radiotherapy

For the treatment of oral cavity cancer with either two-dimensional or three-dimensional techniques, the oral cavity tumor bed and upper echelon lymph nodes are included within the initial lateral fields (Fig. 47.16). The upper border of the field is positioned to provide a 1.5- to 2.0-cm border on the tumor bed in attempt to partially spare parotid glands and hard palate without compromising coverage of the tumor bed and regional lymphatics. The inferior border of the field resides at approximately the thyroid notch, just above the true vocal cords. The posterior border is set at the midvertebral body level if level V nodal coverage is not required. The nodal volume should include levels Ia–Ib, II, and III. For patients with more advanced neck disease or positive level V lymph nodes, where the posterior chain requires radiation, the initial fields should be set behind the C1 vertebral body spinous process. The portals are then reduced at approximately 45 Gy to spare high dose to the spinal cord. If patients harbor cervical lymph node metastases, or high-risk disease, then the lower neck will also be treated. In this case, half-beam–blocked anteroposterior (AP) or opposed anteroposterior/posteroanterior (AP/PA) fields can be matched to the inferior border of the opposed lateral fields at the level of the thyroid notch. An anterior larynx block is used, which not only protects the central larynx from unnecessary radiation dose but also protects against spinal cord overdose because of three-field overlap.

Dose and Fractionation

When postoperative radiation is used for oral cavity cancer, the most common dose fractionation in the United States is 1.8 to 2.0 Gy/day. The authors generally recommend 2.0 Gy daily fractions. Dissected tissues that harbored the original tumor should generally receive dose on the order of 60 Gy. However, for close or positive microscopic margins or ENE, either an SIB to 66 Gy (e.g., 2.2 Gy per fraction over 30 fractions) or a sequential 6.0 Gy localized boost should be considered. In the former scenario, the SIB volume should be kept small to minimize normal tissue complications (Fig. 47.14). If there is gross residual disease, either further surgical resection or focal boosting up to 70 Gy may be necessary. Regions of somewhat lesser risk (i.e., clinically or pathologically uninvolved necks) should receive dose on the order of 54 to 56 Gy if treatment is delivered with an SIB.

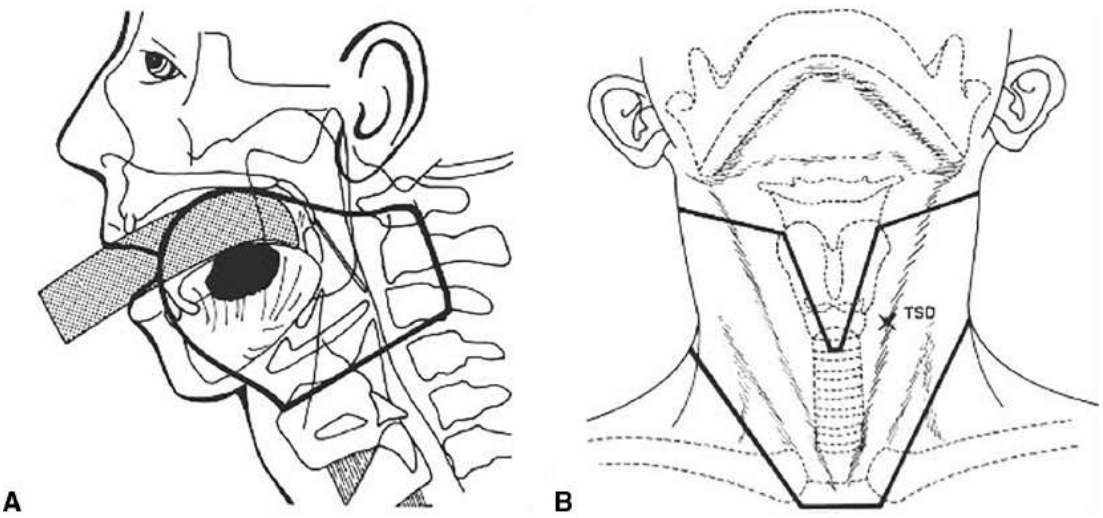

FIGURE 47.16. A: Illustration of field design for treatment of carcinoma of the oral tongue with an N0 neck. **B:** Illustration of field design for treatment of the neck for elective bilateral neck irradiation. (From Million RR, Cassisi NJ, eds. Management of head and neck cancer: *a multidisciplinary approach. 2nd ed. Philadelphia: Lippincott*, 1994. With permission.)

When definitive radiation is used for oral cavity cancer, boosting the primary tumor with either interstitial implantation, submental, or intraoral cone therapy can result in increased tumor control and decreased complications, particularly osteoradionecrosis.[131] When external beam radiation therapy is used as the sole treatment modality, even small lesions that cannot be excised or treated with brachytherapy require doses in the range of 66 Gy in 2.0 Gy fractions for reliable control. For larger tumors, local control rates are generally unacceptable, even with the utilization of IMRT.[88,89]

Simulation and Treatment Considerations

The patient should undergo simulation in the supine position with the neck extended. A thermoplastic mask is generally used to immobilize patients during simulation and treatment. Shoulder immobilization is important during this process, which is accomplished by using either a three-/four-point Aquaplast mask along with a shoulder immobilization device or a five-point mask that also encompasses the shoulders. For most oral cavity simulations, a bite block should be used to depress the tongue away from the hard palate; some institutions use a cork and tongue blade or a custom intraoral stent[160] for this purpose (Fig. 47.17).

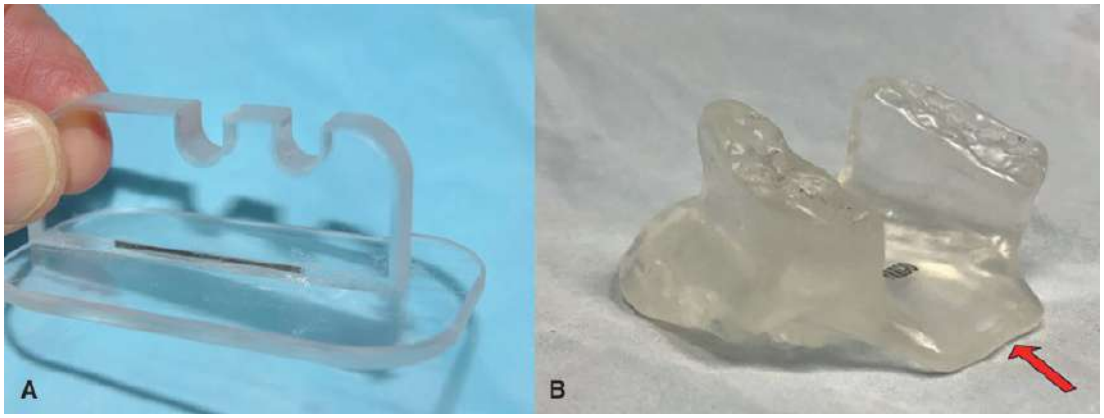

FIGURE 47.17. A: Lucite oral cavity mouthpiece fabricated at the University of Wisconsin for patients with oral cavity carcinomas. Upper dentition or maxillary alveolus links to U-shaped notch and tongue rests beneath smooth undersurface of mouthpiece. Note embedded solder wire in mouthpiece floor to facilitate visualization of tongue positioning at the time of simulation and beam design. **B:** Custom acrylic mouth-opening and tongue-depressing stent utilized at several centers for the treatment of oral cavity carcinoma. The posterior edge (*red arrow*) helps to immobilize the tongue, whereas the superior ridges allow the maxillary teeth to rest and secure the stent in place.

CT simulation should be performed using a slice thickness of ≤3 mm, and i.v. contrast should be utilized in patients that have adequate renal function. The addition of contrast dye during simulation facilitates target volume delineation. The CT acquired during simulation should extend from the top of the head to the carina. During the treatment planning process, the PTV for each region at risk should receive 95% of the prescription dose, and efforts should be made to spare critical structures at risk. Table 47.3 lists normal tissue dose constraints for IMRT treatment planning.

IMRT may be more sensitive to intertreatment setup variations than conventional radiation therapy.[161] Daily imaging and strict immobilization protocols may decrease setup error and improve the fidelity of treatment delivery.[161–163] It is recommended that institutions use daily image-guided radiation therapy (IGRT) to enhance setup reproducibility of IMRT treatment delivery. This may be accomplished with several IGRT techniques including orthogonal kilovoltage films, kilovoltage cone beam CT, or megavoltage CT imaging. With the use of IGRT techniques, planning treatment volume (PTV) expansions on the CTV may be limited to 2 to 5 mm. However, larger margins may be necessary for target volumes subject to significant interfraction variability; examples include the tongue in the absence of an intraoral stent, a large flap in the oral cavity or neck, and some cases where there is significant shoulder motion and the low neck must be included in an extended IMRT

field.[164] For these circumstances, a CTV–PTV expansion margin of 10 mm or greater may be necessary.

TABLE 47.3 Normal Tissue Dose–Volume Constraints[a]

Organ at Risk (OAR)	Dose–Volume Constraint
Spinal cord (*+5 mm*)	Dose to 0.03 cc ≤ 48 Gy
Brain stem (*+3 mm*)	Dose to 0.03 cc ≤ 52 Gy
Parotid glands	*(a)* Mean dose to single gland ≤ 26 Gy
	(b) 20 cc of combined volume of both parotids < 20Gy
	(c) 50% single gland < 30 Gy
OAR pharynx	*(a)* Dose to 33% ≤ 50 Gy
	(b) Mean dose ≤ 45 Gy
	(c) Dose to 15% ≤ 60 Gy
Glottic/supraglottic larynx	Mean dose ≤ 44 Gy
Cochlea	Max dose < 35 Gy
Optic apparatus	Max dose < 54 Gy
Brachial plexus	Max dose < 66 Gy

[a]Dose–volume constraints for IMRT planning adapted based on Qualitative Analysis of Normal Tissue Effects in the Clinic (QUANTEC) recommendations,[217–220] practice standards, and Radiation Therapy Oncology Group protocol guidelines (RTOG 0920, ClinicalTrials.gov identifier, NCT00956007, and RTOG 1216, ClinicalTrials.gov identifier, NCT01810913).

The delivery of a single IMRT plan throughout the course of treatment provides better dose conformality compared to the delivery of several consecutive (sequential) plans.[165] In the absence of low-lying cervical adenopathy, the low anterior neck can be treated with a single AP field or AP/PA fields matched to an upper IMRT field. The advantage of this split-field technique, compared to treating the low neck with an extended IMRT field, lies in the ability to decrease mean dose to the larynx and inferior pharyngeal constrictors.[166]

Brachytherapy

Historically, brachytherapy has played an important role in the treatment of oral cavity carcinoma. Brachytherapy has been used to boost the primary site in the oral cavity before or following external beam radiation (Fig. 47.18). This technique has also been used as a sole modality in the treatment of selected (early-stage) tumors of the oral cavity with good results.[127,128,167] When brachytherapy is used as a sole treatment modality, doses of 65 to 75 Gy are commonly prescribed over 6 to 7 days. Traditionally, radiation has been

delivered using low dose rates of 0.4 to 0.6 Gy/hour to the target volume.[168,169] However, there has been recent interest in high dose rate (HDR) (Fig. 47.19) and pulsed dose rate techniques (PLDR),[170,171] although there is no compelling evidence that these techniques are superior to traditional low dose rate radiation in the treatment of head and neck cancer. There have been several dose and fractionation schedules published for HDR brachytherapy in the treatment of oral cavity cancer.[172–175] Although the American Brachytherapy Society has not provided a consensus as to optimal dose and fractionation,[176] there is concern regarding the potential morbidity with fraction sizes ≥ 6.0 Gy in this setting.[176,177]

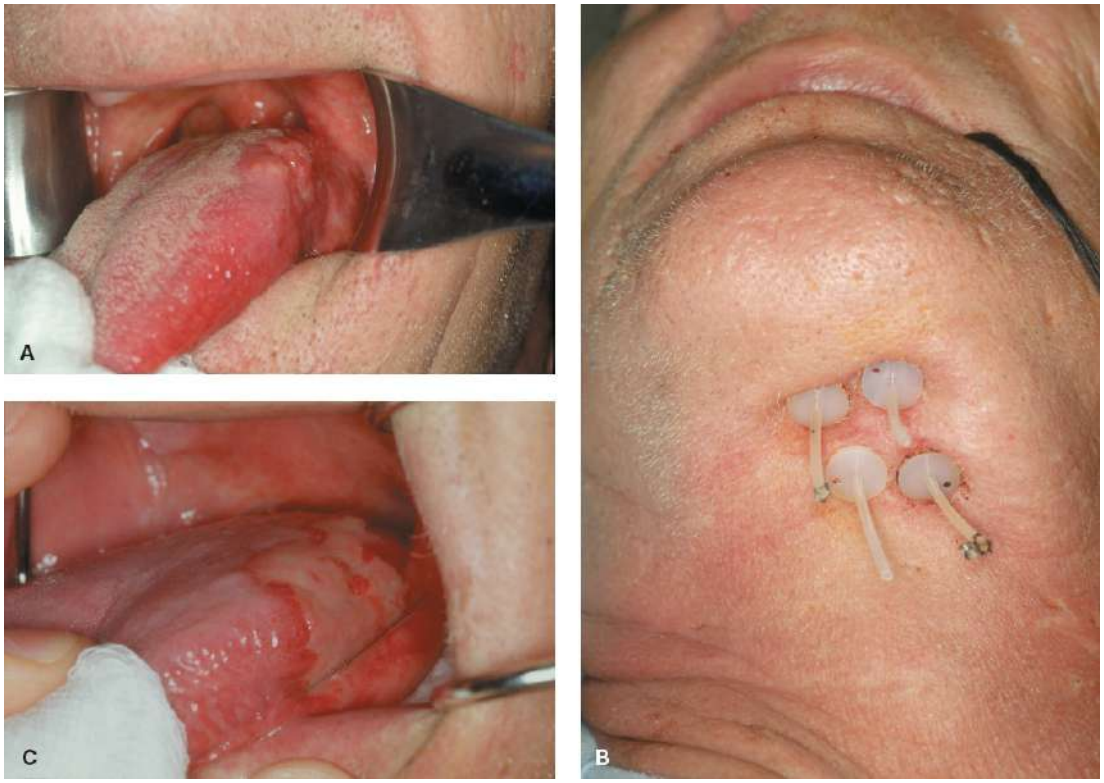

FIGURE 47.18. A: T2N0M0 squamous cell carcinoma involving the left lateral oral tongue. **B:** Submental view of interstitial implantation catheters housing ^{192}Ir seeds for delivery of 25-Gy tumor boost following external beam radiation of 50 Gy. **C:** Implantation bed mucositis conforming to the tumor distribution 7 days following 25-Gy implant boost.

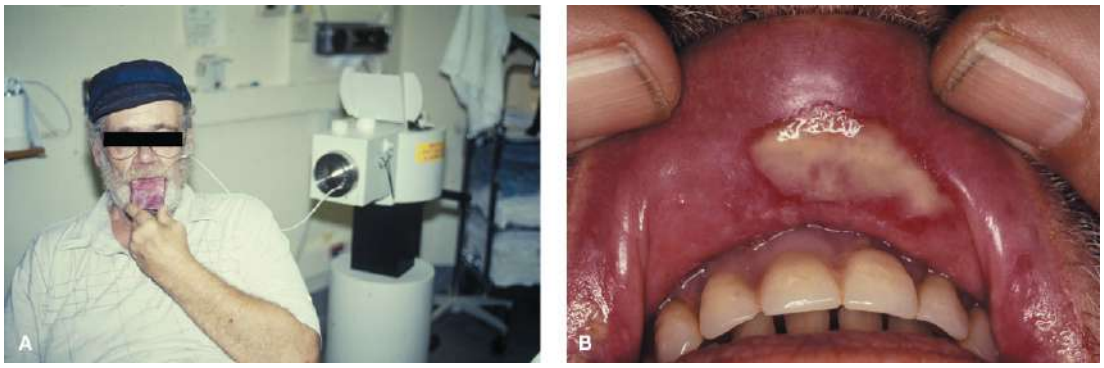

FIGURE 47.19. A: Patient undergoing high dose rate (HDR) brachytherapy for superficial T1 upper lip squamous cell carcinoma (buccal surface) using a single interstitial catheter for source delivery. **B:** Focal mucositis 1 week following completion of HDR brachytherapy treatment course.

Many techniques for brachytherapy in the oral cavity have been described.[178,179] Brachytherapy can be accomplished either with rigid cesium needles or with iridium 192 (^{192}Ir) sources afterloaded into angiocaths. The most common technique is afterloading with ^{192}Ir.[180] Guide needles can be inserted either freehand or with the aid of a custom template to help maintain optimal source spacing.

Depending on the size of the lesion, a single plane, double plane, or volume implant can be used to cover the tumor with a 1-cm margin. For tumors <1 cm in thickness, single-plane implants are adequate. Surface mold radiation can also be considered for small tumors <1 cm depth or superficial lesions of the lip, hard palate, lower gingiva, and floor of the mouth. However, when lesions exceed 2.5 cm, it is difficult to avoid significant cold spots in the implant volume. For this reason, it is recommended that for lesions larger than 2.5 cm, part of the treatment is given with external beam radiation to supplement the dose to the cold spots. In this setting, a combined treatment plan typically gives 50 Gy over 5 weeks with external beam radiation followed by 30 Gy with a brachytherapy implant. What must be borne in mind is that as tumors get too close to the mandible or are large in volume, the risk of osteoradionecrosis increases.[181]

Over the past decade or more, stepwise improvements in reconstructive surgery techniques have diminished the practice frequency of brachytherapy in the treatment of oral cavity carcinoma. In addition, a diminishing percentage of radiation oncologists remain highly skilled and experienced with the requisite implant techniques. Nevertheless, in experienced hands, the expert use of brachytherapy can provide excellent tumor control and high-quality cosmetic and functional results. An example of the use of HDR interstitial brachytherapy

for a patient with an advanced T2N0 lower lip cancer is illustrated in Figure 47.20. Similar comments parallel the use of intraoral cone radiation treatment described further in the section below.

Intraoral Cone

The intraoral cone is another delivery tool to enable boosting of radiation dose to sites within the oral cavity while avoiding direct dose to the mandible (Fig. 47.21). This technique is generally best suited for anterior oral cavity lesions in edentulous patients. However, palatal arch sites can be targeted with the intraoral cone as well. Treatment with intraoral cone involves either 100 to 250 kilovolt (peak) (kvp) x-rays or electron beams in the 6 to 12 MeV range.[129,130,178] Lesions up to 3 cm are amenable to treatment with intraoral cone as long as they are accessible. Intraoral cone therapy requires careful daily positioning and verification by the physician. For this purpose, the device is equipped with a periscope to visualize the lesion. The cone abuts the mucosa and is centered directly over the lesion. Intraoral cone treatment should take place prior to external beam radiation so that the lesion can be adequately visualized. A major advantage of cone therapy is that it is highly focal to the tumor bed but noninvasive. Hence, when available, for suitable lesions, it may be preferred over brachytherapy. However, as noted for brachytherapy delivery, operator experience and dedication are essential to optimize outcome.

PRINCIPLES OF SYSTEMIC THERAPY

Over the decades, the role of chemotherapy has advanced from use only in the recurrent or metastatic setting to use in the definitive treatment setting. The advantage of systemic therapy was explored by the meta-analysis of chemotherapy in head and neck cancer (MACH-NC).[182,183] The study included pooled data from randomized trials of patients with a diagnosis of oral cavity, oropharynx, hypopharynx, and larynx cancer who received chemotherapy in the induction, concurrent, or adjuvant setting.[183] Although the trials included in this analysis vary with respect to radiation dose, fractionation schedule, and chemotherapy regimen, they have in common a randomized comparison between radiotherapy and radiotherapy plus chemotherapy. The updated MACH-NC report of 93 randomized trials identifies an absolute survival benefit of 4.5% at 5 years with the addition of chemotherapy, which is mainly driven by the effect of concurrent chemoradiation (6.5% at 5 years).[183] However, oral cavity patients comprised only 21% of the patient population in the pooled analysis.[86]

Several studies have focused on the use of chemoradiation in patients with high-risk pathologic features following initial surgery. Cooper et al.[81] reported the results of RTOG 9501 comparing radiation alone (60 to 66 Gy) to chemoradiation (same radiation dose plus three cycles of 100 mg/m^2 cisplatin) in patients with head and neck carcinoma demonstrating high-risk features after gross total resection. High-risk disease was defined as any or all of the following: two or more involved lymph nodes, extracapsular extension of nodal disease (ENE), and microscopically involved resection margins. This study demonstrated a benefit in locoregional control and disease-free survival for the

chemoradiation arm, but no overall survival benefit was appreciated. A parallel study, EORTC 2931, reported by Bernier et al.[84] randomized patients to essentially equivalent treatment arms following head and neck cancer surgery. Eligibility criteria included patients with pathologic T3 or T4 disease (except T3/N0), or patients with any T-stage disease with two or more involved lymph nodes, or patients with T1/T2 and N0/N1 disease with unfavorable pathologic findings (ENE, positive margins, perineural involvement, or vascular embolism). Local control, progression-free survival, and overall survival were superior for patients in the chemoradiation arm. In a subsequent comparative analysis using pooled data from these two studies, ENE and/or microscopically involved surgical margins were the risk factors for which the impact concurrent chemoradiation was significant.[83] There was a trend favoring concurrent chemoradiation in the subset of patients with stage III to IV disease, vascular embolism, perineural infiltration, and/or positive lymph nodes at levels IV and V with oral cavity or oropharyngeal primaries.[83] The subset of patients with two or more involved lymph nodes, without evidence of ENE, did not appear to benefit from chemotherapy in this analysis. These studies suggest that the addition of chemoradiation following surgery should be considered in patients with high-risk head and neck cancer features who are able to tolerate treatment.[1]

Neoadjuvant systemic therapy is generally not recommended in the standard management of resectable oral cavity squamous cell carcinoma.[1] In the case of technically unresectable oral cavity squamous cell carcinoma, the concept of neoadjuvant chemotherapy as a means of downstaging disease in order to enable surgical resection has been explored.[184] The engagement of an experienced head and neck surgical oncologist to explore the technical feasibility of resection is paramount due to the potential of disease progression and the consequent risk of compromising the potential for resection in borderline patients. Generally, in this context, a combination of docetaxel, cisplatin, and 5-FU is the preferred induction regimen for clinically fit patients[185] with reported response rates of 17% to 50%.[184] However, it is important to consider that the inherent toxicity of these regimens may compromise the ability to deliver local therapy.[186–188]

The use of molecular targeted therapies has steadily advanced in the field of head and neck oncology. Cetuximab is a monoclonal antibody against the epidermal growth factor receptor (EGFR) that has been approved for the management of locally advanced, recurrent, or metastatic head and neck squamous cell carcinoma.[186,189] In the context of locally advanced head and neck squamous cell carcinoma, Bonner et al. reported the results of a

multinational study demonstrating the superiority of cetuximab plus radiation over radiation alone.[190] However, this study did not include patients with oral cavity squamous cell carcinoma. The RTOG launched a study (RTOG 0920, ClinicalTrials.gov identifier: NCT00956007) to evaluate the impact of cetuximab in the postoperative treatment for intermediate-risk disease. The study defines intermediate-risk disease as perineural invasion, lymphovascular space invasion, close margins, T3/T4a disease, T2 disease with > 5 mm thickness, and single lymph node >3 cm or ≥2 or lymph nodes <6 cm without ENE. After an R0 resection, patients are randomized to radiation or cetuximab plus radiation. A parallel study (RTOG 1216, ClinicalTrials.gov identifier: NCT01810913) was launched to explore the benefit of cetuximab and docetaxel compared to standard platinum-based chemotherapy in the setting of patients with high-risk disease (ENE or positive margins). Both RTOG 0920 and RTOG 1216 are closed to accrual, but results are not yet available. The role of cetuximab in the management of locally advanced oral cavity squamous cell carcinoma remains to be defined.

Prior to the initiation of head and neck radiation, a careful oral and dental evaluation, including a panoramic radiograph, should be performed. Dentition in poor condition should be identified and considered for extraction to minimize the subsequent risk of osteoradionecrosis. Specifically, those teeth that will reside within the high-dose radiation volume that demonstrate significant periodontal disease, advanced caries, or abscess formation or are otherwise in a state of disrepair should be extracted. In addition, impacted teeth, unopposed teeth, and teeth that could potentially oppose a segment of a resected jawbone should be considered for extraction if they are anticipated to reside within the high-dose radiation treatment volume. Extraction of marginal teeth should also be considered in patients who are deemed unable to maintain adequate oral hygiene.

Radiation can induce several chronic effects in the oral cavity that warrant routine surveillance. Radiation can impair bone healing and diminish the capacity for successful recovery following trauma or oral surgery. For this reason, elective oral surgical procedures including extractions must be very carefully considered after radiation. Escalation of dental caries deriving from xerostomia following radiation is well recognized (Fig. 47.22). Radiation of the major salivary glands changes the nature of salivary secretions,[46] which can increase the accumulation of plaque and debris, reduce salivary pH, and reduce the buffering ability of saliva.[191] This creates an environment in the oral cavity,

which predisposes patients to caries. During a course of radiation to the oral cavity, simple techniques such as the use of custom molds or wax to absorb electron backscatter can diminish hot spot mucositis from dental fillings and improve treatment tolerance.[47] Attention to oral hygiene with frequent dental follow-up examinations and cleanings, daily fluoride therapy (Fig. 47.23), flossing, and brushing should be an integral component of the education and postradiation care of patients who undergo radiation to the oral cavity.

FIGURE 47.22. Advanced dental caries in a patient with profound radiation xerostomia and lack of attention to dental hygiene over many years following treatment.

FIGURE 47.23. Custom designed fluoride carrier trays to facilitate daily fluoride application to existing dentition.

PROGNOSTIC AND PREDICTIVE FACTORS

The most significant prognostic factor for outcome in oral cavity carcinoma is the presence of cervical metastases.[192] In patients with positive cervical metastases, the 5-year survival is reduced by approximately 50% compared to those without cervical metastases.[193] The prognosis diminishes further when patients harbor multiple levels of nodal involvement or ENE. In a retrospective review, Myers et al.[192] found that 5-year disease-specific and overall survival rates for pathologically N0 patients were 88% and 75%, respectively; these decreased to 65% and 50%, respectively, if patients were node positive but without evidence of ENE. Patients who were node positive with evidence of ENE had 5-year disease-specific and overall survival rates of 48% and 30%, respectively.

Several histopathologic factors in the primary lesion are associated with adverse prognosis. Tumor thickness and depth of invasion have been shown to confer a higher risk of regional metastases.[18] Perineural invasion has been correlated with cervical lymph node metastases, extracapsular extension, and diminished survival.[194–196] Microvascular invasion has also been correlated significantly with cervical lymph node metastases.[197,198] However, lymphatic

invasion has not been correlated significantly with cervical lymph node invasion.[18] The prognostic significance of grade has also been evaluated.[199] Because of the wide variation in pathologic interpretation, it is difficult to discern the independent value of histologic grading as a prognostic or predictive value.[18]

SURVEILLANCE

The NCCN recommendations for the follow-up of head and neck cancer patients are listed in Table 47.4.[1,200,201] The major goals of surveillance include early diagnosis of recurrence and second primary tumors and management of the ongoing sequelae of head and neck cancer treatment. It is advisable that follow-up be conducted by the multidisciplinary team that provided oncologic management to the patient.[202,203] All patients whom have completed radiation treatment for oral cavity cancer should undergo routine head and neck examination, imaging, and dental evaluation. In addition, it is recommended that the follow-up protocol include an assessment of thyroid function (TSH level) every 6 to 12 months. Radiation-induced hypothyroidism is detected over the subsequent years in 20% to 25% of patients who undergo neck irradiation.[1,204,205] Smoking and alcohol cessation, as well as screening for lung cancer in clinically indicated patients, are also important components of an ongoing follow-up program for all head and neck cancer patients.[1,206]

TABLE 47.4 Follow-Up Recommendations[a]

- History and physical exam (including complete H&N examination, including mirror and fiberoptic exam as indicated)
  - Year 1, every 1–3 mo
  - Year 2, every 2–6 mo
  - Years 3–5, every 4–8 mo; >5 y every 12 mo
  - Baseline imaging of primary and neck within 6 mo of therapy*a*
- Serial reimaging as clinically indicated based on signs/symptoms, continued tobacco use, and areas inaccessible to exam; routine imaging may be indicated in areas difficult to visualize on exam
- Chest imaging as clinically indicated for patient with smoking history for lung cancer screening
- TSH every 6–12 mo if neck irradiated
- Ongoing dental evaluation focused on patient education, prevention/management of caries, xerostomia, osteoradionecrosis, and oral candidiasis
- Supportive care and rehabilitation
  - Speech/hearing and swallowing evaluation as clinically indicated

- Nutritional evaluation and rehabilitation as clinically indicated until nutritional status is stabilized
- Ongoing surveillance for depression*b*
- Smoking cessation and alcohol counseling

- Integration of survivorship care and care plan within 1 y, complementary to ongoing involvement by a head and neck oncologist*c*

*a*Data adapted from NCCN Guidelines for Head and Neck Cancers.[1]
*b*Refer to NCCN Guidelines for Distress Management.[200]
*c*Refer to NCCN Guidelines for Survivorship.[201]

SUBSITE-SPECIFIC TREATMENT AND RESULTS

Lip

The treatment approach for lip cancer is driven by the stage of disease and the expected functional outcome. Surgery is generally the preferred treatment modality for early-stage carcinoma of the lip although radiation therapy is an option for local tumor control (Fig. 47.1). Although the local control of T1 and T2 squamous cancers of the lip is excellent with surgical resection, disruption of the oral sphincter provided by the orbicularis muscle can lead to oral incompetence if not properly reconstructed. Therefore, several reconstructive methods have been developed to help preserve oral sphincteric function even following large excisions for T3 and T4 lesions. For these larger lesions, surgery followed by radiotherapy remains a standard therapy (Fig. 47.2). One possible exception is a superficial cancer that occupies most of the lip, which is best managed with primary radiation therapy because of the potential functional and cosmetic implications of primary surgery.[1]

The successful surgical management of lip cancers includes the eradication of the primary tumor with free margins with preservation of the oral sphincteric function of the lip. For small lesions, excision with primary closure can be highly effective in achieving both of these objectives, whereas resection of larger legions can often require complex local flap repairs to attain satisfactory oncologic, cosmetic, and functional outcomes. SLNB can also prove to be useful in the management of patients of node-negative lip cancers, but further clinical investigation in this area is needed.

When primary radiotherapy is used to treat lip cancer, the target volume should include the primary tumor plus a 1.5- to 2.0-cm margin. For early-stage lesions, photons in the orthovoltage range (100 to 200 keV) or electrons may be used. The electron energy should be chosen based on the thickness of the lesion

(commonly 6 to 9 MeV). Effort should be made to shield the underlying gum, dentition, and mandible as appropriate. This can be accomplished with the use of oral shields or Cerrobend stents. The recommended dose is 50 Gy in 4.5 to 5 weeks for smaller lesions and 60 Gy in 5 to 6 weeks for larger lesions. Some institutions have used an approach where external beam radiation is given to approximately 40 to 50 Gy followed by a brachytherapy boost; however, small to intermediate stage lesions can be treated by primary brachytherapy alone (Fig. 47.20).

An important consideration in managing lip cancer is the risk of regional metastatic disease. Generally, the risk of regional lymph node metastatic disease for T1 and T2 cancers of the lip is lower than for stage-matched tumors of other oral cavity sites. Thus, END is recommended for patients with T3 and T4 carcinomas of the lip; however, it may not be warranted for all T1 and T2 lesions. Some institutions have used a "moustache field" for elective irradiation of the perifacial lymphatics (~50 Gy) for more advanced upper lip lesions.[207]

Oral Tongue

Although primary radiation therapy and surgery are potential treatment options for early-stage carcinoma of the oral tongue, the preferred treatment for most oral tongue cancers in the United States is primary surgery (Figs. 47.1 and 47.2).[18] Surgical resection and reconstruction as appropriate is generally preferred for medically operable patients. Postoperative radiation therapy is recommended for patients with large primary tumors (T3, T4), close or positive surgical margins, evidence of perineural spread, multiple positive nodes, or ENE.[207] Postoperative chemoradiation should be considered for patients with adverse risk factors who are able to tolerate combined modality treatment[81,83–85] (Fig. 47.2). Primary radiotherapy techniques can be used for patients who refuse or are unable to tolerate surgery.

Surgical approaches to oral tongue cancers can either be transoral, transcervical, or alternatively via mandibulectomy to obtain the exposure necessary to achieve adequate margins. Partial glossectomy is the most common procedure performed for oral tongue cancers, and the extent of resection depends on the size and growth pattern of the tumor, as some lesions are relatively infiltrative, while others may be more exophytic. Because the tongue is essentially comprised of skeletal muscle covered by mucosa, the tissue is extremely elastic, and wide margins are encouraged at the onset of resection to avoid retraction of muscle fibers with microscopic tumor cells that could serve

as a source of local recurrence.

Total glossectomy may be indicated for extensive tumors or those that involve the intrinsic tongue musculature. Total glossectomy, even with reconstruction, can result in difficulty with deglutition and maintenance of an adequate airway. Aspiration may be a chronic problem, and, thus, laryngectomy may be necessary in some cases. However, properly selected patients with adequate postoperative rehabilitation can be treated with total glossectomy without laryngectomy. If the larynx is preserved, laryngeal suspension and palatal augmentation may help with the rehabilitative efforts.

Tumor size and depth of invasion are currently the most reliable indicators for predicting cervical metastases in patients with oral tongue squamous cell carcinoma. Because of the high risk of nodal metastases, the neck should be addressed either with surgery or radiation in all but the earliest tumors of the oral tongue. Patients with small oral tongue cancers should be considered for neck therapy, particularly if the primary tumor exhibits extension onto the floor of the mouth or there is increased tumor thickness. Treatment of the clinically negative neck is most often accomplished by supraomohyoid neck dissection. END appears to result in better overall cancer outcome than observation. Potential pitfalls of observation include a salvage rate of only one-third for patients who do not undergo END along with resection of the oral cavity primary.

Superficial T1 lesions can be treated with brachytherapy alone. Commonly, ^{192}Ir temporary implants are used to deliver 50 to 60 Gy with dose rates of 40 to 60 cGy/hour. However, HDR techniques can also be considered. For infiltrating T1 or T2 lesions, a combined approach using external beam and a brachytherapy or intraoral cone boost should be considered. More advanced lesions should be treated with an approach combining surgery and radiation therapy. In patients treated with IMRT, the intermediate-risk CTV (see IMRT section) should include the intrinsic and extrinsic muscles of the tongue, the floor of the mouth, base of the tongue, glossotonsillar sulcus, and the anterior tonsillar pillar (Fig. 47.13). The adjacent dissected neck should also be included in this volume. Patients with advanced lesions and high-risk disease (particularly with multiple positive nodes) should receive radiation treatment to the bilateral necks. In patients with early-stage disease close to midline or patients with well-lateralized disease that is deeply invasive (>4 mm), both sides of the neck should be considered for treatment. For patients with a clinically and radiographically N0 neck, with well-lateralized and superficial disease (<4 mm invasion), 50 to 54 Gy should be considered to the ipsilateral neck as elective nodal irradiation. The appropriate

draining lymphatics (usually levels I to IV unilaterally or bilaterally) should be included in the low- to intermediate-risk CTV (Fig. 47.13 and Table 47.1).

Floor of the Mouth

Surgery is usually preferred in patients who are medically operable because proximity of the tumor to the mandible confers a significant risk of radiation-induced ulceration and osteoradionecrosis. Small lesions of the floor of the mouth are most commonly resected transorally. The surgical defect can be left to heal by granulation or reconstructed with a split-thickness skin graft or local flap. Advanced stage of floor of the mouth cancers is usually managed by a combination of surgery and radiation or chemoradiation.

In the surgical management of floor of the mouth cancer, special attention should be paid to mandibular invasion. A cancer that appears to involve only the periosteum or that only superficially invades the mandible can be removed via a transoral or transcervical approach in which a marginal mandibulectomy is performed. However, segmental mandibulectomy may be necessary for patients with a limited mandibular height when there is no direct bone invasion, because marginal mandibulectomy may leave these patients with insufficient bone, placing them at high risk for radionecrosis or pathologic fracture. A full-thickness segmental resection may be necessary if there is frank bone invasion. For advanced cancers, resection of the anterior arch of the mandible may be necessary. Defects of the anterior segment of the mandible require reconstruction with bone, usually with a free fibular or iliac crest graft.

Management of the neck is similar to that for other tumors of the oral cavity. Patients with lesions <2 mm thick with no adverse pathologic factors and a clinically and radiographically negative neck may be observed after primary resection and observation. Otherwise, most N0 patients should receive either selective neck dissection or radiation therapy. Patients with advanced lesions and high-risk disease (particularly with multiple positive nodes) should receive radiation treatment to bilateral necks.

Small (T1 and T2) lesions may be treated with a combination of external beam radiation and boost with interstitial implant or intraoral cone. For lesions that are very close to the mandible, brachytherapy is contraindicated because of the risk of osteoradionecrosis. Infiltrative lesions that are tethered to the mandible and advanced lesions following surgical resection should receive postoperative radiation. Target volume design considerations for postoperative treatment are similar to that for oral tongue carcinoma. In cases where IMRT is

used, the intermediate-risk CTV (see IMRT section) should include genioglossus and geniohyoid muscles bilaterally, the sublingual and submandibular glands ipsilaterally (bilaterally if the tumor is midline), adjoining alveolar ridge and mandible, the muscles at the root of tongue, and the dissected necks.[157] Because of the close proximity of floor of the mouth lesions to the midline, treatment of both sides of the neck should be considered. The low- to intermediate-risk CTV (see IMRT section) should include the appropriate electively treated necks (Fig. 47.14 and Table 47.1). Another important consideration is the presence of gross perineural invasion of the branches of the inferior alveolar nerve. In the event of extensive perineural involvement, coverage of the mandibular canal to the infratemporal fossa should be considered.[159]

Cases of floor of the mouth carcinoma in which there is no indication for neck irradiation (e.g., a T4N0M0 primary with early mandibular involvement and a negative bilateral neck dissection) may be good candidates for treatment with conventional techniques. In this setting, opposing lateral fields may be used to encompass the oral cavity tumor bed (including the mandible, floor of the mouth, and oral tongue); this volume is commonly treated to 50 to 54 Gy. High-risk areas (primary surgical bed, close margins, perineural spread) may receive additional boost treatment up to 60 to 66 Gy.

Hard Palate and Upper Alveolar Ridge

Tumors of the hard palate are quite rare, accounting for only 0.5% of all oral cancers in the United States. Most carcinomas manifest as a granular superficial ulceration of the hard palate. Initial growth tends to be superficial, although these tumors can extend through the periosteum of bone into regions adjacent to the oral cavity, such as the paranasal sinuses and floor of the nose. Surgery is the preferred modality for treatment of this subsite.

Wide local excision may be adequate to obtain surgical margins. However, infrastructure maxillectomy may in some cases be necessary. For tumors that extensively involve the adjacent bony and soft tissue structures, a total maxillectomy, with or without orbital exenteration, may be required. A defect in the maxilla results in lack of oral/nasal separation that can impair the ability to speak and swallow effectively. An obturator with or without a skin graft is the most common method used to restore oral/nasal separation. The obturator is commonly fabricated from a synthetic polymer and provides oronasal separation that can yield improved speech and swallowing function. Regional pedicled flaps and free tissue transfers may provide alternatives to obturation. One

consideration in the reconstruction of palatal defects with nonremovable flaps is that they can mask local recurrences that can be more readily identified in patients whose defects are obturated.

Postoperative radiation therapy should be delivered when there are adverse features, that is, close/positive margins, perineural extension, vascular invasion, high-grade histology, multiple positive nodes, or ENE. The radiation field should encompass the entire surgical bed. In many cases, it may be feasible to treat with opposed lateral fields to cover the volume at risk (Fig. 47.12). However, for well-lateralized lesions of the upper alveolar ridge, ipsilateral radiation with a wedge pair may be adequate. Conformal treatment techniques, including IMRT, can also be used to tailor the radiation coverage to the high-risk tissue bed, draining lymphatics, surgical flap, and routes of perineural spread along V2 as deemed appropriate.

Elective treatment of the neck is controversial for hard palate region tumors. Although some series have shown lower rates of occult metastases for palatal tumors when compared to other oral cavity sites, preoperative imaging should be performed to evaluate for the presence of metastases to the retropharyngeal nodes because these are difficult to evaluate on clinical examination and are at some risk for spread from primary palatal tumors. Elective treatment of the clinically negative neck should be considered in high-grade tumors or lesions that present with advanced T stage.

Retromolar Trigone

Squamous cell carcinoma of the retromolar trigone is uncommon, and the true incidence is difficult to determine because these cancers often involve both the retromolar trigone and adjacent sites, thereby making it difficult in some cases to identify the original tumor epicenter. Cancers of the retromolar trigone may be advanced at presentation because only a thin layer of soft tissue overlies the bone in this region and invasion of the underlying bone may occur early. In addition, there are multiple pathways for spread from this site including the buccal mucosa, tonsillar fossa, glossopharyngeal sulcus, floor of the mouth, base of the tongue, hard and soft palate, masticator space, and maxillary tuberosity. As patients tend to present with advanced disease of the retromolar trigone, many have regional metastases at the time of presentation.

The treatment of carcinoma of the retromolar trigone has been controversial.[208] Traditionally, surgery and radiation have been felt to be comparable modalities of treatment. However, recent reports suggest that

surgery with adjuvant or neoadjuvant radiotherapy may be associated with better outcomes compared to radiation alone.[209,210] Although early-stage T1 and T2 cancers may be treated equally effectively with surgery or radiation, the probability of osteoradionecrosis is likely higher with definitive radiation.[208] Stage III and IV lesions commonly require combined surgery and radiation. The resection of advanced cancer of the retromolar trigone usually requires a composite resection of soft tissue and bone. Transoral robotic surgery can be helpful in the management of smaller tumors in the retromolar trigone.[211] A limiting factor for the achievement of adequate surgical resection margins for tumors in this area includes extension of tumor posterosuperiorly into the pterygopalatine fossa and/or the base of the skull.

Well-lateralized lesions of the retromolar trigone can be treated by ipsilateral treatment using mixed beam techniques or angled wedge techniques. In the case of more extensive lesions that require free flap reconstruction, IMRT may be beneficial to aid in covering the postoperative tumor bed and neck (Fig. 47.15). For extensive tumors of the retromolar trigone (or those with evidence of perineural spread), the infratemporal fossa should be included in the CTV. Treatment of the contralateral neck is at the discretion of the treating physician. In considering treatment options for carcinoma of the retromolar trigone, it is important to consider that some HPV+ tonsil tumors can largely involve the retromolar trigone and are ideally managed with nonsurgical treatment, highlighting the importance of testing tumors in this area for the presence of high-risk HPV subtypes.

Buccal Mucosa

Verrucous carcinoma accounts for <5% of all oral cavity carcinomas, occurs most often in the buccal mucosa, has a more favorable prognosis, and is considered a low-grade malignancy. Surgical resection remains the preferred mode of treatment for primary lesions of the buccal mucosa. Adjuvant radiation treatment is usually not indicated in the setting of completely excised verrucous carcinoma of the buccal mucosa. Because verrucous carcinomas rarely metastasize, END is often not indicated for patients with this disease. Careful pathology review with clinical correlation is important in the categorization of verrucous carcinomas, as this diagnosis can influence subsequent treatment recommendations.

Squamous cell carcinoma of the buccal mucosa can be an especially aggressive cancer of the oral cavity, as buccal cancers have multiple potential

routes of spread to adjacent areas in the head and neck. Posteriorly, they can extend to involve the pterygoid muscles, and superiorly, they can grow to involve the alveolar ridge, palate, or maxillary sinus. The majority of patients have cancer that extends beyond the buccal mucosa. Metastasis to the cervical lymph nodes most commonly affects the submandibular nodes.

Transoral resection is preferred and is most convenient for small lesions of the buccal mucosa. Tumors approximating the gingiva should be resected with the gingiva and periosteum as an additional deep margin, whereas those that involve the periosteum should be resected with an additional deep margin of bone provided by a marginal mandibulectomy. Cancers that directly invade bone should be resected with a segment of bone. Larger tumors (T3 or T4) may require surgery combined with radiation therapy or chemoradiotherapy.

When considering target volume delineation for carcinoma of the buccal mucosa, it is important to be comprehensive in covering the inner cheek and entire buccal mucosa. The CTV should extend from the orbital rim (superiorly) to the retromolar trigone (posteriorly). Moreover, in the event of extensive disease (i.e., T3/T4 or N2/N3) that is treated postoperatively, the masticator space and infratemporal fossa should be covered within the CTV. As is the case with retromolar trigone carcinoma, treatment of the contralateral neck is at the discretion of the treating physician.

MANAGEMENT OF RECURRENT DISEASE

The recurrence rates after treatment of cancer of the oral cavity are approximately 30% with local recurrence being the most common.[212] Unfortunately, the survival after salvage treatment remains quite poor at 20% to 30%.[212] The appropriate management of recurrent oral cavity cancer depends largely on the extent of disease, the prior therapy administered, and whether the recurrences are local, regional, or both. The disease-free interval between initial treatment and recurrence is among the most important factors associated with survival after salvage surgery, and a disease-free interval of more than 10 months is significantly associated with improved survival.[212] Although surgery and chemoradiotherapy have similar outcomes in the case of early recurrences, surgical salvage has been found to be superior to chemoradiotherapy for late recurrence (84.4% vs. 52% 5-year disease-specific survival, respectively).[212] In the case of small recurrences at the primary site in patients whose index therapy was surgical excision only, further excision with postoperative radiotherapy is

often recommended. For larger recurrences in patients who received radiation as part of their initial management, the rate of surgical salvage is quite low. In some cases, further resection may be considered for palliation or curative treatment attempt, particularly in the setting of a clinical trial. Systemic therapy, reirradiation, and palliative care are other options for this group of patients, and the risks and benefits of each should be discussed with the individual patient.

If there is distant disease recurrence, systemic therapy approaches will likely assume primary importance. A combination of docetaxel, cisplatin, and 5-FU or a platinum doublet (plus a taxane or 5FU) combined with cetuximab are commonly used regimens for first-line treatment.[186,213] Immunomodulating agents targeting the programmed death (PD)-1 receptor and its ligand (PD-L1) represent novel and promising strategies in the treatment of metastatic and recurrent squamous cell carcinoma of the head and neck.[214,215] These agents have demonstrated a survival advantage compared to standard single agent chemotherapy in the setting of platinum refractory head and neck squamous cell carcinoma.[214] Ongoing concepts being investigated include combining these agents with standard cetuximab-containing regimens.[216]

CHAPTER 48

Oropharynx

Joseph K. Salama and David M. Brizel

The incidence of oropharyngeal carcinoma is increasing, which is in contrast to the decreasing incidence of head and neck cancer arising in other anatomic sites. The classic etiologic factors of tobacco abuse and alcohol use continue to play a significant role. However, a significant increase in rates of oropharyngeal cancers in nonsmokers and nondrinkers caused by oncogenic human papillomaviruses (HPVs) is occurring, predominantly among men. Although both HPV-associated and HPV-unassociated malignancies are classified as squamous cell carcinomas, the behavior of these cancers markedly differs as HPV-associated cancers have a significantly more favorable prognosis that is treatment platform independent. The recognition that HPV-associated oropharyngeal cancer is a distinct clinical entity, and the adverse effects of standard therapies on speech, swallowing, degustation, and psychological well-being, has lead to significant multidisciplinary interest in defining different treatment paradigms for HPV-associated and HPV-unassociated oropharyngeal cancers. Treatment recommendations for these two clinical entities currently remain the same, pending the outcomes from ongoing clinical investigations.

Based on the critical role of the oropharynx in speech and swallowing, treatment of oropharyngeal carcinomas can significantly impact patients' quality of life. Appropriate treatment strategies should focus on maintaining high cure rates while minimizing long-term, treatment-induced functional morbidity. Early-stage oropharyngeal cancers are best managed with single modality therapy (radiation or surgery), with the choice based upon anticipated posttherapy consequences. Treatment of locoregionally advanced tumors involves multiple modalities, the most common strategies being either concomitant chemotherapy and radiotherapy or surgery followed by adjuvant radiotherapy with or without chemotherapy based on pathologic risk factors.

Novel approaches to surgical and radiation delivery and the incorporation of molecularly targeted chemotherapeutics are currently the focus of clinical

investigation with an intent to maximize the therapeutic index for HPV-associated oropharyngeal cancers. Transoral surgical techniques including laser and robotic resection have the potential to reduce morbidity. Advances in radiotherapy allow for improved dosing to the primary tumor and involved nodes with reduced radiation exposure of normal tissues, particularly the parotid and submandibular glands and pharyngeal constrictor muscles. Further studies are needed to more completely integrate molecularly targeted agents into the treatment of oropharyngeal cancers. The use of immune-modulating agents has demonstrated improved outcomes in metastatic and recurrent head and neck cancer patients, including oropharyngeal cancer patients, establishing these agents as an integral cancer therapy.

EPIDEMIOLOGY

Oropharyngeal cancers account for approximately 10% of the annual, worldwide incidence of head and neck squamous cell carcinomas. The incidence of oropharyngeal cancer differs significantly by geography.[1] In the United States, the annual incidence of oropharyngeal squamous cell carcinoma is 4.8/100,000,[2] which is similar to other developed countries. This rate has increased by 28% from 1988 to 2004, largely because of the 225% increase in HPV-associated oropharyngeal cancer, whereas HPV-unassociated oropharyngeal cancer has declined by 50% over the same time period.[3] The incidence of oropharyngeal cancer in developing countries is lower at approximately 3/100,000.[1] This rise in developed countries is unique as other mucosal head and neck cancer incidences have decreased over this same time period. The putative cause of this is the increasing incidence of HPV-associated cancers discussed in detail later. Worldwide, the majority of oropharyngeal cancers remain attributable to tobacco smoking and/or the excessive ingestion of alcohol. For these cases, incidence rates are generally higher for men than women (4:1), who are diagnosed more commonly in the sixth and seventh decades of life.

HUMAN PAPILLOMAVIRUS–ASSOCIATED OROPHARYNGEAL CANCER

Human Papillomavirus

The HPV is a circular, double-stranded DNA virus, first determined to be oncogenic when it was found to be the associated with cervical cancer in 1983[4]

and subsequently established as a significant human carcinogen in 1996.[5] To date, approximately 150 HPV types have been identified. HPV subtypes are classified as high or low risk based upon epidemiologic associations with cervical cancer in case–control studies.[6] HPV 16 is the most common HPV type identified in human tumors and is associated with >90% of all HPV-associated related oropharyngeal cancers.[7] Infection with HPV16 confers an approximate 14-fold increase in risk for oropharyngeal cancer.[8]

The HPV genome encodes three oncoproteins (E5, E6, and E7), in addition to regulatory genes (E1 and E2) as well as capsid protein genes (L1 and L2). Oncogenesis is primarily mediated via the E6 and E7 proteins. HPV E6 complexes with E3 ubiquitin ligase and E6-associated protein, promoting ubiquitin-mediated destruction of p53. Loss of cellular p53 function results in dysregulation of the G1/S and G2/M checkpoints. An E7/cullin 2 complex ubiquitinates the Rb protein, resulting in loss of G1/S checkpoint control.[9] E7 is believed to be the major transforming oncogene during early carcinogenesis, with E6 functioning later.[10] A diagram of the pathways affecting the malignant transformation of keratinocytes by HPV is shown in Figure 48.1. Although E6 and E7 oncoprotein function is necessary for development of an HPV-associated malignancy, it is not sufficient. It is believed that as yet undefined genetic events are required for HPV malignant transformation.[11]

A number of different techniques are used to detect HPV in oropharyngeal cancer biopsy specimens. The gold standard is demonstration of HPV E6/E7 in clinical specimens. However, this approach is clinically impractical because it is very difficult to detect viral RNA from cytologic fluid and paraffin-embedded tissues. Polymerase chain reaction (PCR) of HPV DNA is a technique with high sensitivity, but low specificity, as cross-contamination or transcriptionally inactive DNA can be detected. In situ hybridization uses oligonucleotide probes designed to anneal to complementary HPV DNA in the tumor specimen. Advantages of this technique include localization of DNA within the tumor specimen and allow for identification of a single viral copy.[12] A consequence of HPV E7-mediated Rb inhibition is induction of demethylases resulting in expression of $p16^{INK4A}$, an upstream tumor suppressor cyclin-dependent kinase inhibitor.[13] Immunohistochemistry staining for $p16^{INK4A}$ is frequently used as a surrogate for HPV status. There is a small (7%) discordance between HPV ISH and $p16^{INK4A}$ IHC, which is likely related to a combination of infection with non-HPV-16 subtypes or low viral copy numbers not detectable by IHC and true p16-positive/HPV-negative cases.

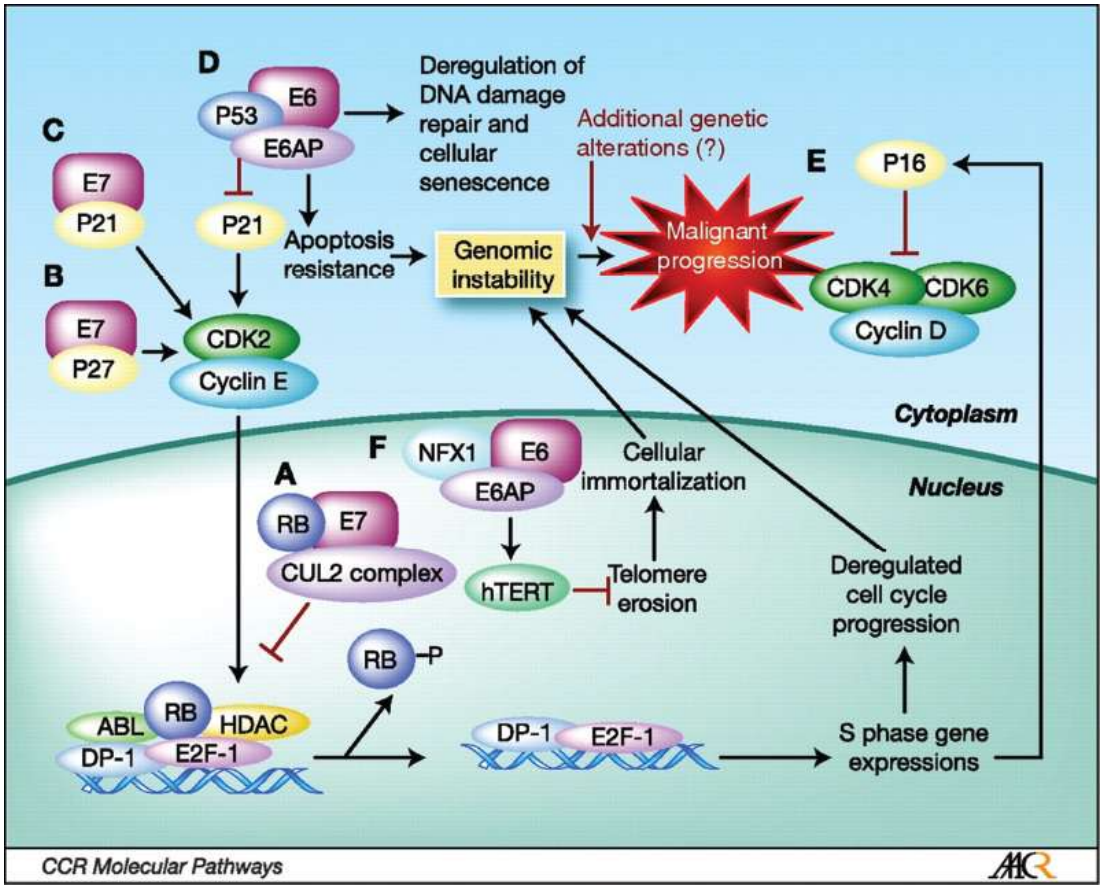

FIGURE 48.1. Diagram of malignant transformation in keratinocytes caused by the HPV oncoproteins, E6 and E7. Clockwise from *A*, ubiquitination by E7 and the cullin 2 ubiquitin ligase complex leading to pRb degradation (23, 25, 56, 57); *B*, interaction between E7 and $p27^{Kip1}$ resulting in inhibition of cell cycle arrest contributing to carcinogenesis (58); *C*, interaction between E7 and $p21^{Cip1}$ resulting in inhibition of cell cycle arrest contributing to carcinogenesis (31, 59); *D*, ubiquitination by E6 and ubiquitin ligase E6AP leading to p53 degradation (19–21); *E*, increased expression of $p16^{INK4A}$ by a consequent of feedback loops from the absence of pRb function (42); and *F*, degradation of NFX1, a transcriptional repressor of hTERT, by association with E6/E6AP resulting in hTERT activation and cellular immortalization.[60] (Reprinted from Chung CH, Gillison ML. Human papillomavirus in head and neck cancer: its role in pathogenesis and clinical implications. *Clin Cancer Res* 2009;15[22]:6758–6762. Copyright © 2009 American Association for Cancer Research. Clinical Characteristics of Human Papillomavirus–Associated Oropharyngeal Cancer

HPV-associated oropharyngeal cancers are more likely to occur among men than women (3:1), most of whom (80%) will not have a smoking history. These cancers are more common among white individuals than other races, are diagnosed in individuals who are 5 to 10 years younger than HPV-unassociated related oropharyngeal cancers, and are associated with higher socioeconomic

status. Furthermore, when compared to patients with HPV-unassociated cancers, these patients are more likely to be married and college educated and have a median income >$55,000. The use of marijuana also elevates odds of HPV-associated oropharyngeal cancer.[14] Analogous to cervical cancers, patients with HPV-associated oropharyngeal cancer have been associated with certain sexual behaviors. These include high number of vaginal or oral sex partners, infrequent condom use, engagement in casual sex, and early age of first intercourse.[15] Whether or not HPV acts in a synergistic manner with tobacco or alcohol exposure in patients to increase risk of HPV-associated oropharyngeal cancer is a matter of ongoing controversy.

HPV-associated oropharyngeal cancers are characterized frequently as poorly differentiated, nonkeratinizing or basaloid in histopathology.[16] HPV-associated and HPV-unassociated carcinomas are also different with regard to molecular alterations. HPV-associated oropharyngeal cancers are associated with wild-type p53, p16 expression, and infrequent amplification of cyclin D, whereas the converse is true for HPV-unassociated cancers. A subset of HPV-associated oropharyngeal cancer patients with more extensive smoking histories will have tumors exhibiting *TP53* mutations and higher epidermal growth factor receptor (EGFR) and Bcl-xL expression and have outcomes similar to those of HPV-unassociated patients.[9]

TABLE 48.1 HPV STATUS AND SURVIVAL OUTCOMES IN PROSPECTIVE TRIALS

Cooperative Group	*N*	Radiotherapy	Induction	Concurrent	% HPV+	Survival HPV+	Survi HPV-
ECOG	96	70 Gy	Paclitaxel 175 mg/m^2 Carboplatin AUC = 6 2 cycles	Weekly paclitaxel 30 mg/m^2	40%	95%	62%
TROG	195	70 Gy	None	CDDP +/− Tirapazamine	28%	94%	77%

DAHANCA	156	62–68 Gy	None	Nimorazole 1,200 mg/m^2/d	22%	62%	26%

Response of Human Papillomavirus–Associated Oropharyngeal

Cancer to Standard Therapy

Patients with HPV-associated oropharyngeal cancers have significantly better outcomes compared to HPV-unassociated oropharyngeal tumors.[17,18] A reanalysis of Radiation Therapy Oncology Group (RTOG) 0129, a randomized study comparing cisplatin administered with either accelerated concomitant boost radiotherapy or conventionally fractionated radiotherapy, HPV status was independently associated with improved outcomes. Three-year overall survival was 82% in HPV-positive patients compared to 54% in HPV negative. Even after adjustment for age, tumor stage, nodal stage, treatment assignment, and tobacco use, HPV status independently predicted for improved survival (Hazard ratio [HR] = 0.42, 95% confidence interval [CI] = 0.27 to 0.66). Additionally, locoregional progression (13.6% vs. 24.8%) and progression-free survival (71.8% vs. 50.4%) were significantly improved in HPV-positive cases. Other large cooperative group studies have demonstrated similar findings.[18,19] It is important to realize that the prognostic significance of HPV was independent of chemoradiotherapy platform and applies to treatment with radiotherapy alone[20] as shown in Table 48.1. In fact, HPV-related tumors have a better prognosis regardless of the treatment modality (surgery,[21] radiation therapy, or chemoradiotherapy) used.

ANATOMY

The oropharynx is contiguous with the oral cavity anteriorly, the larynx and hypopharynx posterior/inferiorly, and nasopharynx superiorly. Three main subregions compose the oropharynx including the tonsil, base of tongue, and soft palate. Normal function of the oropharynx is critical for speech and swallowing.

The tonsillar region contains the anterior and posterior tonsillar pillars and the palatine tonsil. The palatine tonsils are lymphoid aggregates incompletely encapsulated with a keratinized stratified squamous epithelial mucosal lining positioned in the tonsillar bed, a part of the tonsillar cleft between the anterior (palatoglossal) and posterior (palatopharyngeal) tonsillar pillars.

The base of tongue comprises the posterior third of the tongue and is bounded anteriorly by the circumvallate papillae, sitting in front of the sulcus terminalis. It is bounded posterior–inferiorly by the hyoid and epiglottis and laterally by the glossopharyngeal sulci. Underlying the mucosa of the base of tongue are lymphatic nodules collectively known as the lingual tonsil. The vallecula is a 1-cm mucosal strip that serves as a transition between the base of tongue and

epiglottis and is considered a part of the base of tongue. The sensory innervation of the base of tongue is via the glossopharyngeal nerve (CN IX) with a small aspect of the base of tongue supplied by the internal laryngeal nerve (CN X).

The soft palate is a fibromuscular structure bounded anteriorly by the hard palate, laterally coursing into the anterior tonsillar pillars and posterior/inferiorly forming a free edge, and the midline uvula. The soft palate is composed of five muscles (levator veli palatini, tensor veli palatini, palatoglossus, palatopharyngeus, and musculus uvulae) posteriorly and the palatine aponeurosis an expanded tendon of the tensor veli palatini anteriorly. The muscles of the soft palate are supplied through the pharyngeal plexus (which is composed of the pharyngeal branches of cranial nerves IX and X and sympathetic branches from the superior cervical ganglion, except for the tensor veli palatini, which is supplied by cranial nerve V2). The sensory supply is from CN IX.

The oropharynx serves many functions including that of degustation, respiration, and speech. Advanced tumors arising in the oropharynx can infiltrate muscles and nerves, significantly impeding these functions. A major goal of successful therapy is to limit the impact of treatment on long-term function.

TABLE 48.2 ANATOMIC BOUNDARIES OF NECK NODE LEVELS

I	Bounded by posterior belly of digastric, hyoid bone inferiorly, and body of mandible superiorly
II	Bounded by skull base superiorly to level of hyoid bone inferiorly
III	Bounded by hyoid bone superiorly to cricothyroid membrane inferiorly
IV	Bounded by cricothyroid membrane superiorly to clavicle inferiorly
V	Bounded by anterior border of trapezius posteriorly, posterior border of SCM anteriorly, and clavicle inferiorly
VI	Bounded by level of hyoid bone superiorly to suprasternal notch inferiorly, lateral border formed by medial border of carotid sheath

ROUTES OF SPREAD

Primary routes of oropharyngeal cancer spread include direct extension and lymphatic spread, with hematogenous metastases being less common. Oropharyngeal cancers have a predilection for submucosal extension, often visualized as raised erythematous regions without distinct borders or ulceration. This can best be appreciated by direct visualization rather than on radiographic imaging.

Lymphatic Spread of Oropharyngeal Cancer

The lymphatic drainage of the oropharynx and the neck was first described by Rouviere in 1938[22] and has since been refined since by others.[23] Originally described as lymph node chains located in particular anatomic regions, nodal groups are now classified by the level system[24] with the location of lymph nodes in the neck being defined by surgical–anatomic landmarks (Table 48.2). Recently, this system (levels I to VI) was refined with the addition of sublevels (Ia/Ib, IIa/IIb, and Va/Vb) (as shown in Table 48.2), also incorporating radiologically defined landmarks (as shown in Table 48.3 and Fig. 48.2).[25]

The most common location for lymph node metastases from oropharyngeal cancers is ipsilaterally in level II. The probability of lymphatic (regional) metastasis is related to the size and location of the primary tumor within the oropharynx. The typical order of metastatic progression is systematic, from the upper jugular chain nodes superiorly (level I/II; first echelon) to midcervical (level III) and to lower cervical nodes (level IV) inferiorly. In large series of oropharyngeal cancer patients, isolated skip metastases are rare (0.3%); level I or V involvement is usually associated with the involvement of other levels. Additionally, tumors encroaching or crossing midline or involving the posterior pharyngeal wall exhibited a higher propensity for bilateral lymphadenopathy.[26]

TABLE 48.3 RADIOGRAPHIC BOUNDARIES OF NECK NODE LEVELS

Level	Cranial	Caudal	Anterior	Posterior	Lateral
Ia	Geniohyoid m., plane tangent to basilar edge of mandible	Plane tangent to body of hyoid bone	Symphysis menti, platysma m.	Body of hyoid bone	Medial edge of ant. belly of digastric m.

Knowledge of the probability of occult pathologic lymphadenopathy for each involved oropharynx anatomic subsite and extent of disease is critical to modern radiotherapy and surgery planning, as selective neck dissections and limited radiotherapy volumes, designed to preserve function, are the norm. Standardized contouring atlases have been published to aid clinicians in the development of appropriate radiotherapy volumes to cover potential occult microscopic lymphatic spread in the N0 neck.[27–29] Additionally, information regarding probabilities of occult pathologic lymphatic involvement has been compounded from series of patients undergoing elective neck dissection.[30] Use of this knowledge to develop appropriate radiotherapy volumes will be discussed in more detail in the radiotherapy planning section. The rates of pathologic

lymphadenopathy for the pathologically uninvolved and involved neck are outlined in Table 48.4.

Distant Metastatic Spread of Oropharyngeal Cancer

Distant metastatic spread of oropharyngeal cancer is relatively uncommon affecting approximately 15% of all patients during the course of their disease.[31] The most common locations for distant metastatic spread of oropharyngeal cancers are the lung parenchyma[31] followed by the bone and liver. Metastases are more common in patients presenting with locoregionally advanced or recurrent tumors, with the risk increasing with primary tumor stage and the extent of cervical lymphadenopathy (N2-N3 disease).[32] Extranodal extension, lower cervical pathologic lymphadenopathy (level IV), and lymphovascular invasion have also been associated with increased rates of distant metastases.[33]

Lung metastases typically appear radiographically as well-circumscribed, peripherally located nodules. Given different treatment and prognoses, care should be taken to differentiate between pulmonary metastases and primary pulmonary malignancies, characterized as spiculated irregularly shaped masses commonly associated with hilar and mediastinal lymphadenopathy. Often, this distinction is impossible, even after biopsy, as both can be squamous cell histology. In such instances, physically fit patients should be given the benefit of the doubt and treated as if they have two separate primary tumors. In patients with limited pulmonary metastases, who are technically resectable and fit for surgery, resection of pulmonary oropharyngeal cancer metastases may improve survival.[34] For nonsurgical candidates, hypofractionated image-guided radiotherapy to all known metastases can result in long-term disease control and should be considered for patients with limited metastatic disease.[35]

CLINICAL PRESENTATION

Oropharyngeal cancers present with a constellation of symptoms, dependent upon the location of the primary tumor, invasion of nearby organs, and extent of nodal disease. Often, patients will present with a painless neck mass, which is usually mobile, firm, and nontender, but can be fixed, indicating extranodal extension and invasion into surrounding structures. Such masses are frequently treated with an initial course of antibiotics, but persistence or growth in this context mandates further evaluation. Some patients complain of a deep-seated otalgia located within the auditory canal. This is mediated via irritation of the

glossopharyngeal nerve (CN IX) with referral via the Petrosal ganglion to the tympanic nerve of Jacobson. Regurgitation of foods can occur with invasion of the soft palate, inhibiting its ability to elevate during swallowing. Trismus is seen with more advanced tumors and reflects invasion of the pterygoid fossa and/or musculature. Odynophagia and dysphagia are other common presenting symptoms that occur with invasion into the pharyngeal musculature or obstruction by pathologic lymphadenopathy.

DIAGNOSTIC EVALUATION

Physical Examination

A complete examination of all mucosal head and neck sites should be performed in any patient with a known or suspected diagnosis of oropharyngeal cancer. This process not only characterizes the primary tumor but also evaluates for synchronous malignancies given the high propensity for second primary upper aerodigestive tract tumors especially in smokers. A thorough physical examination is essential for diagnosis as understanding of the complete disease extent helps guide the surgeon on the choice of optimal biopsy site. Inspection of the oropharynx should be performed under adequate illumination, be well practiced, systematic, and reproducible. Following examination of the oral cavity, where attention should be directed to the number and health of the teeth and the mucosa, one should closely examine the anterior tonsillar pillars, the tonsillar fossae, and posterior tonsillar pillars followed by the soft palate. Proper exposure can be achieved either with gloved index fingers or two disposable tongue depressors used in unison. Palpation of the tonsillar fossa and the base of tongue should be performed since these locations can harbor occult primary tumors. The base of tongue should be palpated at the completion of the examination because of its propensity to trigger the gag reflex. Direct visualization should be followed by fiberoptic examination because this allows optimal inspection of the base of tongue, posterior-inferior tonsil, and vallecula and can detect spread to laryngeal and hypopharyngeal sites. Fiberoptic examinations should be recorded and compared to assess response during the course of therapy. Indirect mirror examination is much less informative than fiberoptic evaluation but should be performed if fiberoptic capabilities are not available and if the practitioner is skilled in this art.

TABLE 48.4 DISTRIBUTION OF CLINICAL METASTATIC NECK

NODES FROM HEAD AND NECK SQUAMOUS CELL CARCINOMAS

Tumor Site	Patients With N+ (%)	Distribution of Metastatic Lymph Nodes per Level (Percentage of the Node-Positive Patients Ipsilateral/Contralateral)					
		I	II	III	IV	V	Other
Oral cavity (*n* = 787)	36	42/3.5	79/8	18/3	5/1	1/0	1.4/0.3
Oropharynx (*n* = 1,479)	64	13/2	81/24	23/5	9/2.5	13/3	2/1
Hypopharynx (*n* = 847)	70	2/0	80/13	51/4	20/3	24/2	3/1
Supraglottic larynx (*n* = 428)	55	2/0	71/21	48/10	18/7	15/4	2/0

Oropharyngeal tumors often appear as ulcerated masses, with surrounding erythema, neovascularization, and mucositis. Tenderness, evidence of recent bleeding, obstruction of the airway, skin invasion, alteration of gag reflex, and extent of trismus (measured from upper to lower incisors) should be documented. Bulging of the parapharyngeal space should also be noted as this could represent retropharyngeal lymphadenopathy.

Careful examination of the neck is also important for staging and management. Palpation of the neck should focus on neck levels defined by standard anatomic relationships. The neck should gently be turned to the side being examined to relax the sternocleidomastoid muscle, which facilitates the detection of smaller involved lymph nodes. Care should be taken not to palpate too firmly in older patients or those with known vascular disease, as aggressive carotid massage can be associated with syncope. Lymph nodes should be recorded in terms of the level in which they arise, their size, the character of their firmness, as well if they are fixed, and whether or not they penetrate and involve the skin.

Confirmatory biopsy of the primary site should be performed. Adequate exposure is usually possible for in-office biopsies of the proximal oropharynx.

Posterior oropharyngeal tumors are often biopsied under general anesthesia in the operating room, often as part of a comprehensive examination under anesthesia as well as comprehensive endoscopic evaluation (laryngoscopy, bronchoscopy, and esophagoscopy).

Computed Tomography

Computed tomography (CT) imaging of the head and neck with intravenous contrast should be performed for all newly diagnosed oropharyngeal cancer patients to assess the extent of primary tumors and to determine the presence or absence of cervical lymph node metastases. Scan slice thickness <5 mm is necessary to optimize the detection of smaller pathologically involved lymph nodes and to provide the best anatomic delineation of both primary and nodal disease. Pathologically involved lymph nodes are characterized on CT imaging as those that are enlarged, have lost a fatty hilum, enhance with contrast, and/or have a necrotic center. Primary tumors appear as contrast-enhancing masses, distorting normal anatomic relationships. Although ulceration and invasion into surrounding organs are readily assessed, submucosal spread is often difficult to characterize with CT. As multiplanar image reconstruction is routinely available, lymph node and primary tumor size should be measured in cephalad–caudad and axial dimensions to more accurately stage patients. Unfortunately, dental artifact can affect CT imaging and may obscure complete visualization with neutral head position, requiring further scanning with an adjusted head position or use of metal artifact reducing reconstruction algorithms. Thoracic CT should be performed routinely (alone or in combination with a positron emission tomography [PET] scan) to assess for pulmonary spread of oropharyngeal cancer patients with N2 or greater nodal disease and for those with advanced primary tumors, given the risks of pulmonary metastases described above. A diagnostic CT image of a patient with locoregionally advanced head and neck cancer is shown in Figure 48.3.

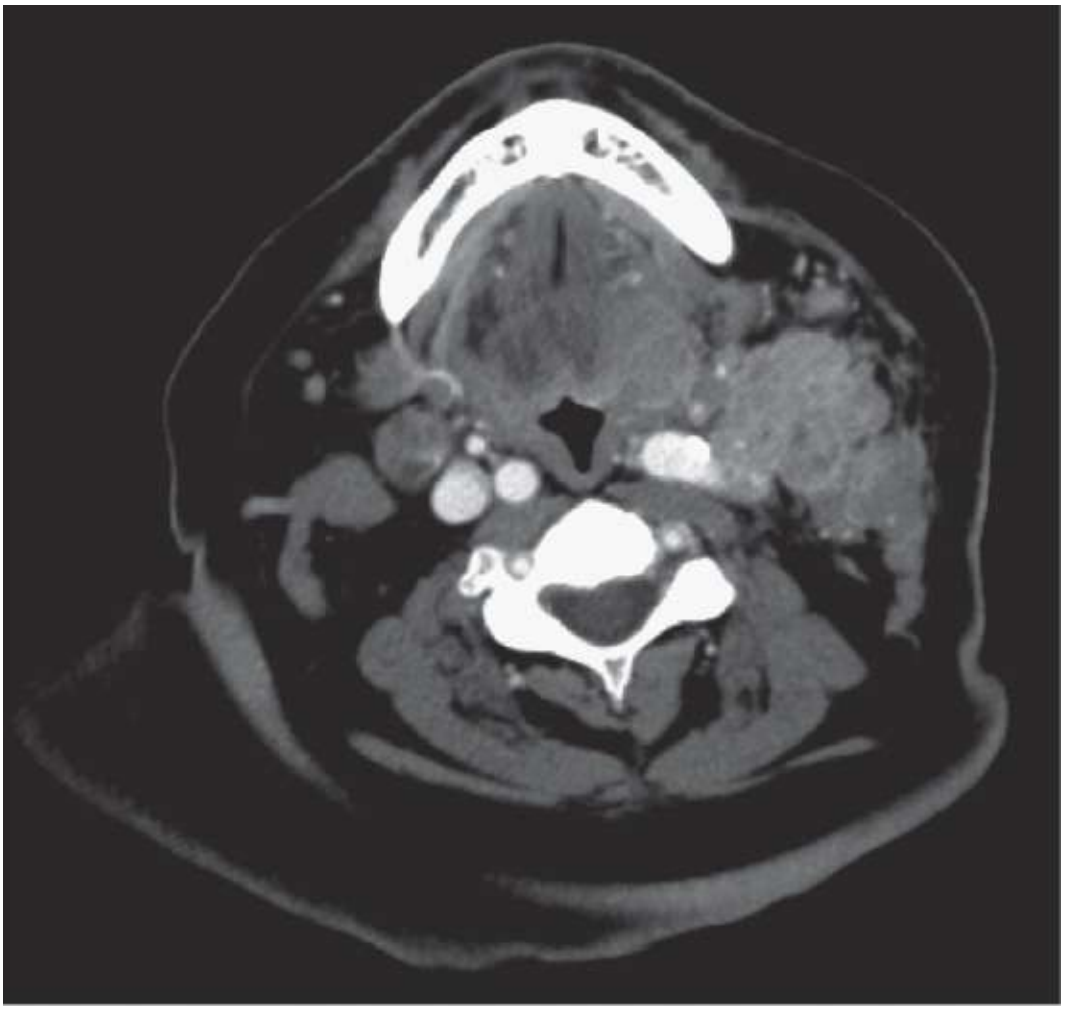

FIGURE 48.3. Diagnostic CT image demonstrating locoregionally advanced oropharyngeal cancer with extensive ipsilateral cervical lymphadenopathy.

Positron Emission Tomography

PET and/or PET/CT imaging incorporating tumor physiology in conjunction with anatomic information is now routinely recommended for the initial staging of oropharyngeal cancer patients. From a practical standpoint, PET-based imaging can assess not only the locoregional burden of disease but also detect and quantify the presence of distant metastases. For oropharyngeal cancer patients, the ability to detect clinically and radiographically occult pathologic cervical lymphadenopathy renders PET a powerful clinical tool, as ipsilateral radiotherapy volumes are commonly used in specific settings.[36] Although usually reported as the maximum standard uptake value (SUVmax), alternative measurements such as SUVmean may have greater prognostic value.[37] The utility of PET/CT for oropharyngeal cancer patients demonstrates high sensitivity approaching 100% but only about 60% specificity for pathologically

proven tumor. Clinical status and knowledge of prior procedures is critical to PET interpretation, as recent biopsies and infections can cause artificially elevated metabolic activity.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) can be a useful imaging tool for oropharyngeal tumors. Squamous cell carcinoma appears as low signal in T1-MRI images and corresponding high signal in T2-sequences. The ability of MRI to differentiate tumor from soft tissues is particularly useful when determination of the extent of base of tongue or oral tongue invasion is needed. Additionally, MRI is useful in patients with compromised renal function who are not able to receive iodinated-based CT contrast agents.

TABLE 48.5 AJCC/IUCC 8TH EDITION TNM STAGING SYSTEM FOR HPV-MEDIATED (P16+) OROPHARYNGEAL CANCER

Primary Tumor (T)	
T0	No primary identified
T1	Tumor 2 cm or smaller in greatest dimension
T2	Tumor larger than 2 cm but not larger than 4 cm in greatest dimension
T3	Tumor larger than 4 cm in greatest dimension or extension to lingual surface of epiglottis
T4	Moderately advanced local disease; tumor invades the larynx, extrinsic muscle of tongue, medial pterygoid, hard palate, or mandible or beyond
Clinical Regional Lymph Nodes (cN)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	One or more ipsilateral lymph nodes, none larger than 6 cm
N2	Contralateral or bilateral lymph nodes, none larger than 6 cm
N3	Lymph node(s) larger than 6 cm
Pathologic Regional Lymph Nodes (pN)	
NX	Regional lymph nodes cannot be assessed
pN0	No regional lymph node metastasis
pN1	Metastasis in 4 or fewer lymph nodes
pN2	Metastasis in more than 4 lymph nodes
Distant Metastasis (M)	
M0	No distant metastasis present
M1	Distant metastasis present

PATHOLOGIC CLASSIFICATION

Squamous cell carcinomas are the most common histological subtype comprising >95% of all oropharyngeal cancers. Uncommonly, minor salivary gland tumors and mesenchymal tumors can affect this region. Given the proportionally high content of lymphoid tissue in the region within Waldeyer ring, malignant Hodgkin, and non-Hodgkin lymphomas also arise in this region. This chapter will discuss only squamous cell and related (poorly differentiated and lymphoepithelioma) histologic subtypes.

STAGING

The staging for oropharyngeal cancer has been significantly revised in AJCC/IUCC 8th edition, shown in Tables 48.5 to 48.9, given the significant differences in prognosis between HPV-associated and HPV nonassociated oropharyngeal squamous cell cancers. Clinical staging is based upon all available history, physical examination, and endoscopic, radiographic, metabolic, and scintigraphic data. For both HPV-associated and HPV nonassociated oropharyngeal cancer, the size of the primary tumor continues to define the T stage, with T1 being <2 cm, T2 >2 cm but <4 cm, and T3 > 4 cm. T4a describes tumors invading the larynx, extrinsic muscles of the tongue, medial pterygoid, hard palate, or mandible. T4b disease describes oropharyngeal tumors invading the lateral pterygoid, pterygoid plates, lateral nasopharynx, skull base, or surrounding the carotid artery.

TABLE 48.6 AJCC/IUCC 8TH EDITION CLINICAL STAGE GROUPING FOR HPV-ASSOCIATED (P16+) OROPHARYNGEAL CANCER

	T0	T1	T2	T3	T4
N0	N/A	I	I	II	III
N1	I	I	I	II	III
N2	II	II	II	II	III
N3	III	III	III	III	III
M1	IV	IV	IV	IV	IV

TABLE 48.7 AJCC/IUCC 8TH EDITION PATHOLOGIC STAGE GROUPING FOR HPV-ASSOCIATED (P16+) OROPHARYNGEAL

CANCER					
	T0	T1	T2	T3	T4
N0	N/A	I	I	II	II
N1	I	I	I	II	II
N2	II	II	II	III	III
M1	IV	IV	IV	IV	IV

Thus, for HPV-associated oropharyngeal cancers, T1-3 is unchanged, and T4 disease is classified as tumor invasion of the larynx, extrinsic muscles of the tongue, medial pterygoid, hard palate, mandible, or beyond. Clinical nodal staging is simplified. N0 remains the absence of lymph nodes, N1 is one or more ipsilateral lymph node all <6 cm, N2 is contralateral or bilateral lymph nodes none <6 cm, and N3 is defined as lymph nodes >6 cm. Pathologic lymph node staging is also simplified to include pN1 with four or fewer lymph nodes and pN2 being more than 4 pathologically involved nodes.

The stage grouping of HPV-associated oropharyngeal cancers is also different from before. Clinical stage 1 now comprises T0-2, N0-1; stage 2 is now T0-2, N2 or T3, N0-2; and stage 3 is comprised of T0-4, N3 or T4, N0-2. Finally, clinical stage 4 is limited to M1 disease. The pathologic staging is similar as shown in Table 48.7.

For p16 negative tumors, the staging is similar to prior AJCC/IUCC 7th edition. The nodal staging in the 8th edition has changed to incorporate the important prognostic significance of extranodal extension. For clinically staged oropharyngeal tumors without extranodal extension, N0 indicates no clinical or radiographic evidence of pathologic lymphadenopathy, N1 indicates a single lymph node <3 cm in the ipsilateral cervical chains, N2a indicates a single lymph node >3 cm and <6 cm in the ipsilateral cervical chain, N2b indicates multiple ipsilateral cervical lymph nodes all <6 cm in size, and N2c indicates bilateral pathologically involved cervical lymph nodes with the largest node <6 cm. N3 status is now divided into two subcategories, N3a and N3b. N3a indicates the presence of at least one lymph node >6 cm and no extranodal extension, while N3b status is attained by the presence of overt clinical evidence of extranodal extension irrespective of number, size, or laterality of pathologic lymphadenopathy.

For pathologically staged nodal disease, the 8th edition now classifies a single LN (ipsilateral or contralateral) <3 cm with ENE as N2a, whereas either a single pathologic LN >3 cm with ENE or multiple lymph nodes with ENE is N3b. The

presence of distant metastatic disease is classified as M1. The stage grouping for HPV nonassociated cancers is unchanged from prior editions and is shown in Table 48.9. Stage I comprises T1N0 tumors and stage II is made up of T2N0 tumors. Stage III includes patients with T3 N0-1 or T1-T2N1. Stage IV is divided into three subgroups. Stage IVa is made up of patients with T4aN0-2a-c, T1-3 N2a-c tumors. Stage IVb disease basically describes patients who are technically unresectable including patients with an extensive primary tumor (T4b) or those with any primary stage who have extensive lymphadenopathy (T any N3). Stage IVc disease is reserved for patients with distant metastases.

MANAGEMENT STRATEGIES

Functional organ preservation with minimal toxicity is the management goal for all oropharyngeal cancer patients. Based on AJCC stage, patients are usually grouped divided into two different treatment groups to help guide therapy decisions. Those with locally confined disease (T1-2, N0 tumors) are considered as early stage, whereas those with stage T3-4 or N1-3 (nonmetastatic) disease are considered as having locoregionally advanced disease. For all subsites, early-stage tumors are usually well controlled with a single local modality either radiotherapy or surgery. This paradigm is in flux for HPV-associated disease as some presentations that would have been considered as advanced stage in AJCC 7th edition, for example, T1N1 and T2N1, are classified as early stage in AJCC 8th edition. Selection of local modality should be based on the primary tumor size, extent of local spread, and subsite involved. Small tumors of the tonsil and small exophytic tumors of the base of tongue can be well managed surgically, whereas the morbidity of surgery on the soft palate typically favors radiotherapy. For locoregionally advanced disease, two appropriate treatment strategies are used: either surgery followed by radiation therapy with or without chemotherapy based on pathologic risk factors or radiotherapy usually given with chemotherapy.

TABLE 48.8 AJCC/IUCC 8TH EDITION TNM STAGING SYSTEM FOR (P16–) OROPHARYNGEAL CANCER

Primary Tumor (T)

TX	Primary tumor cannot be assessed
Tis	Carcinoma *in situ*
T1	Tumor 2 cm or smaller in greatest dimension

T2 Tumor larger than 2 cm but not larger than 4 cm in greatest dimension

T3 Tumor larger than 4 cm in greatest dimension or extension to lingual surface of epiglottis

T4 Moderately advanced or very advanced local disease

T4a Moderately advanced local disease
Tumor invades the larynx, extrinsic muscle of tongue, medial pterygoid, hard palate, or mandible*

T4b Very advanced local disease
Tumor invades lateral pterygoid muscle, pterygoid plates, lateral nasopharynx, or skull base or encases carotid artery

Clinical Regional Lymph Nodes (cN)

NX Regional lymph nodes cannot be assessed

N0 No regional lymph node metastasis

N1 Metastasis in a single ipsilateral lymph node, 3 cm or smaller in greatest dimension and ENE(−)

N2 Metastasis in a single ipsilateral node larger than 3 cm but not larger than 6 cm in greatest dimension and ENE(−);
or metastases in multiple ipsilateral lymph nodes, none larger than 6 cm in greatest dimension and ENE(−);
or in bilateral or contralateral lymph nodes, none larger than 6 cm in greatest dimension and ENE(−)

N2a Metastasis in a single ipsilateral node larger than 3 cm but not larger than 6 cm in greatest dimension and ENE(−)

N2b Metastasis in multiple ipsilateral nodes, none larger than 6 cm in greatest dimension and ENE(−)

N2c Metastasis in bilateral or contralateral lymph nodes, none larger than 6 cm in greatest dimension and ENE(−)

N3 Metastasis in a lymph node larger than 6 cm in greatest dimension and ENE(−);
or metastasis in any node(s) and clinically overt ENE(+)

N3a Metastasis in a lymph node larger than 6 cm in greatest dimension and ENE(−)

N3b Metastasis in any node(s) and clinically overt ENE(+)

Pathologic Regional Lymph Nodes (pN)

NX Regional lymph nodes cannot be assessed

N0 No regional lymph node metastasis

N1 Metastasis in a single ipsilateral lymph node, 3 cm or smaller in greatest dimension and ENE(−)

N2 Metastasis in a single ipsilateral lymph node, 3 cm or smaller in greatest dimension and ENE(+);
or larger than 3 cm but not larger than 6 cm in greatest dimension and ENE(−);
or metastases in multiple ipsilateral lymph nodes, none larger than 6 cm in greatest dimension and ENE(−); or in bilateral or contralateral lymph nodes, none larger than 6 cm in greatest dimension and ENE(−)

N2a Metastasis in single ipsilateral or contralateral node 3 cm or smaller in greatest dimension and ENE(+);
or a single ipsilateral node larger than 3 cm but not larger than 6 cm in greatest dimension and ENE(−)

N2b Metastasis in multiple ipsilateral nodes, none larger than 6 cm in greatest dimension and ENE(−)

N2c	Metastasis in bilateral or contralateral lymph nodes, none larger than 6 cm in greatest dimension and ENE(−)
N3	Metastasis in a lymph node larger than 6 cm in greatest dimension and ENE(−); *or* in a single ipsilateral node larger than 3 cm in greatest dimension and ENE(+); *or* multiple ipsilateral, contralateral or bilateral nodes, any with ENE(+)
N3a	Metastasis in a lymph node larger than 6 cm in greatest dimension and ENE(−)
N3b	Metastasis in a single ipsilateral node larger than 3 cm in greatest dimension and ENE(+) *or* multiple ipsilateral, contralateral, or bilateral nodes, any with ENE(+)
Distant Metastasis (M)	
M0	No distant metastasis present
M1	Distant metastasis present

*Mucosal extension to lingual surface of epiglottis from primary tumors of the base of the tongue and vallecula does not constitute invasion of the larynx

SURGICAL TECHNIQUES, APPROACHES, AND RESULTS

Base of Tongue

Surgery plays a limited role in the management of base of tongue tumors given the inherent morbidity of a near total or total glossectomy, which is required for large and/or midline tumors. For select, well-lateralized or polypoid base of tongue tumors with minimal cervical lymphadenopathy, a partial glossectomy can be performed. Given the high propensity for occult microscopic nodal involvement, bilateral cervical lymph node dissection is often performed. Base of tongue tumors in close proximity to the laryngeal apparatus, such as those arising in the vallecula, often require a supraglottic or total laryngectomy to achieve adequate margins of resection.

Traditional surgical approaches for base of tongue tumors include the midline mandibulotomy (splitting the lip, mandible, and oral tongue midline), the lateral mandibulotomy (dividing the mandible near the angle and approaching the base

of tongue from the side), and the floor drop procedure (elevating the inner periosteum from the mandible from angle to angle, which releases the entire floor of mouth and oral tongue into the neck exposing the base of tongue).

Tonsil Cancers

For small (<1 cm) early-stage tonsil cancers, confined to the anterior pillar, a wide local excision can achieve adequate tumor-free margins, whereas tumors involving the palatine tonsil often require a radical tonsillectomy. For both of these situations, the tonsil is approached transorally, with primary closure. Larger tumors with extension onto the tongue and mandible or into surrounding tissue often require a composite resection, usually including resection of the tonsil, tonsillar fossa, pillars, a portion of the soft palate, tongue, and mandible. For tumors not adjacent or adherent to the mandible, a midline mandibulotomy approach is used. For tumors adherent to the mandible, a partial mandibulectomy is used. Defects are often closed with a myocutaneous flap. Complications from surgery depend on the extent of resection, with impairment in swallowing possible with removal of part of the tongue or soft palate.

Soft Palate Cancers

Surgical resection is rarely recommended as initial therapy for soft palate tumors. Resection of the soft palate is often associated with significant reflux into the nasopharynx during swallowing, even with the use of custom prostheses. Additionally, because of the midline location, primary disease spreads bilaterally to the neck and retropharyngeal lymph nodes with frequency high enough to require elective treatment. However, when surgery is performed, the tumors are approached transorally, and a full-thickness wide local resection is performed for tumors limited to the soft palate. A more extensive composite resection is required if disease extends to surrounding structures. Flaps or prostheses are used to preserve velopharyngeal competence. Nasal speech is also often a consequence.

Transoral Surgical Approaches

Transoral surgical approaches, routinely used for limited tonsillar resections, are increasingly being increasing used for other oropharyngeal cancer operations, as an alternative to open surgical procedures. By limiting the need for open surgical exposure, these operations can have a quicker recovery time and less morbidity. More recently, endoscopic approaches have been adopted to enhance the utility of transoral surgery. However, limited prospective data support the benefit of

transoral operations over traditional approaches. Prospective data are needed to further elucidate the benefits of these surgical advances and better integrate them with the other standard oncologic therapies.

Transoral Laser Surgery

Small series report favorable outcomes for selected patients with stage 1 to 2 oropharyngeal tumors treated with transoral laser microsurgery with or without neck dissection, followed by adjuvant radiotherapy or chemoradiotherapy.[38–40] Positive margin rates are variable (3% to 24%) and appear to vary based on primary site, being more common in base of tongue tumors. Complications include postoperative hemorrhage (5% to 10%). Temporary tracheostomy placement is relatively common (17% to 30%) and needed for exposure, airway control, or aspiration following extensive resection. High rates of locoregional control following this procedure have been reported, primarily for stage 1 to 2 patients (87% to 100%) although for stage 2 to 4 patients local recurrence is more common (20% to 30%). Swallowing outcomes are favorable with series reporting most patients tolerating a normal diet.[40]

Transoral Robotic Surgery

The use of a computer-aided interaction between the surgeon and the patient is commonly referred to as “robotic” surgery. The most common robotic surgical system, the da Vinci Surgical System, is comprised of three surgical instruments and a binocular endoscope controlled by robotic arms and inserted under direct or endoscopic guidance by the surgeon from a patient-side apparatus. The surgeon controls the instruments from a console separated from the patient. The operative environment is visualized virtually in a 3D environment created via a computer, which links the environment provided by the binocular endoscope to the position of the instruments. The surgeon’s movements are translated into the micromovements of the instruments. The advantages of this system include motion scaling, which can increase precision, as well as reducing hand tremor and fatigue. When the system is used for transoral surgeries, an assistant is often positioned by the patient’s head.

There are no prospective randomized studies supporting the use of transoral robotic surgery (TORS) for oropharyngeal tumor resection over conventional surgery. All studies to date are small single institution series. Proponents of TORS highlight an enhanced visualization of the surgical field over traditional transoral techniques. Some have hypothesized that perhaps local control could

be enhanced via TORS debulking with minimal acute sequelae. However, this claim has yet to be tested prospectively. Prospective studies have shown that TORS can be used safely with a low risk of laceration or fracture to a patient.[41] In a series of 27 patients with tonsillar cancer who underwent TORS tonsillectomy, morbidity was "acceptable," including one case of mucosal bleeding and two cases of moderate trismus, while 1 patient required a tracheostomy, and negative margins were obtained in 25/27 patients.[42]

Until mature prospective multi-institutional series and randomized data are available, the true utility of transoral laser microsurgery and TORS remains unknown. Although early results are favorable and associated with shorter hospital stays, long-term data are needed. Additionally, standard oncologic principles limiting the number of modalities used to minimize treatment-related side effects should be carefully considered prior to widespread adoption of the surgical techniques.

ADJUVANT THERAPY FOLLOWING DEFINITIVE SURGICAL RESECTION

Following surgical resection of oropharyngeal cancers, pathologic features including advanced primary T stage (T3 or T4), lymphovascular space invasion, perineural invasion, positive margins, multiple pathologically involved cervical lymph nodes, and extranodal extension place patients at high risk for locoregional recurrence.[41] In these cases, postoperative radiotherapy (PORT) often in conjunction with chemotherapy has been shown to reduce the risk of locoregional relapse.[42,43] Although the study did not specifically include oropharyngeal cancer patients, PORT was shown in RTOG 73-03 to results in superior locoregional control (70% vs. 58%) when compared to preoperative radiotherapy, but did not affect survival.[44]

Adjuvant Chemoradiotherapy for Oropharyngeal Cancer

The addition of cisplatin-based chemotherapy to postoperative radiotherapy has been compared to PORT alone for medically fit head and neck cancer patients of any site in a number of randomized studies.[45–48] All of these studies have demonstrated statistically significant[45–47] or strong statistical trends[48] for improved locoregional control and disease disease-free survival with the addition of chemotherapy to PORT. Additionally, two of these studies have demonstrated statistically significant improvements in overall survival,[48,49]

whereas the other two have shown numerically improved but not statistically significant survival improvements.[50,51] A significant portion of patients in these studies had oropharyngeal cancer (EORTC 30% and RTOG 43%) generalizing these results to oropharyngeal patients with high-risk pathologic risk features.

Concurrent Chemotherapy Regimens for Adjuvant Chemoradiotherapy

The optimal chemotherapy regimen delivered with PORT is currently unknown. Schedules of bolus cisplatin 100 mg/m^2 were tested in two[45,48] randomized studies mentioned above, one tested 50 mg weekly cisplatin,[46] and the other tested cisplatin 20 mg/m^2 and 5 fluorouracil (5-FU) 600 mg/m^2 d1-5 and d29-33.[47] There have been no randomized comparisons of these cisplatin-based schedules. A recently reported study in postoperative head and neck cancer patients compared 30 mg/m^2 weekly cisplatin to 100 mg/m^2 cisplatin every 3 weeks. This study demonstrated improved locoregional control with 100 mg/m^2 cisplatin, which was the primary endpoint. However, given that the weekly regimen was only 30 mg/m^2, which many consider suboptimal and that >90% of patients were postoperative oral cavity cancer patients, the applicability of these results to the postoperative care of oropharyngeal cancer patients is questionable.[49]

Randomized studies have been attempted trying to identify the role of carboplatin-based chemotherapy concurrently with PORT compared to PORT alone.[52] Unfortunately, these studies closed before accrual goals were met, and no significant benefit was found with the addition of carboplatin to PORT. RTOG 0234 randomized high-risk postoperative patients (positive margin, extranodal extension, and/or >2 pathologically involved cervical nodes) to PORT in combination with cetuximab (400 mg/m^2 loading dose followed by 250 mg/m^2 weekly) and weekly docetaxel 15 mg/m^2 or to PORT with cetuximab (400 mg/m^2 loading dose followed by 250 mg/m^2 weekly) and weekly cisplatin 30 mg/m^2. Results of this randomized phase II study are maturing. Currently, no randomized data support the use of taxanes or cetuximab in the postoperative setting although RTOG-1216 is an ongoing randomized phase 3 trial that is designed to determine the effectiveness of both cetuximab and docetaxel relative to cisplatin in the setting of adjuvant PORT.[53] Based on the available data, many consider cisplatin 100 mg/m^2 every 3 weeks as the standard.

Adjuvant Radiation Therapy Dose

The optimal radiation therapy dose for PORT is also not well defined. Most of the randomized studies demonstrating the benefit of concurrent chemotherapy with PORT used radiotherapy doses of 60 to 66 Gy in 2 Gy daily fractions to high-risk areas (primary tumor bed with positive margin or nodal regions with extracapsular spread). Doses of 50 to 54 Gy in 2 Gy fractions were usually given to areas at risk for microscopic involvement. There is little evidence supporting the higher PORT doses used in these randomized trials over those recommended from the PORT-alone dose-finding studies of 63 Gy for extranodal extension and 57.6 Gy for all others. In three of four randomized studies testing the utility of chemotherapy concurrently with PORT, doses >65 Gy were delivered to high-risk areas.[45–47] The fourth study, RTOG 95-01 allowed a dose of 60 Gy with or without an optional 6 Gy boost.[48] As these studies were associated with significant benefits for patients with ECE and positive margins, we recommend similar dosing schedules.

Postoperative Radiotherapy Treatment Volume

The typical treatment volume used in PORT for head and neck cancer includes the bilateral neck and the primary tumor site. However, it is unclear whether both the neck and primary always need to be within the PORT volume. In those with completely resected primary tumors with negative margins whose sole indication for PORT is pathologic cervical adenopathy, some would direct therapy only to the neck. Additionally for patients with a positive margin as the sole indication for treatment in the setting of a comprehensive neck surgery without pathologically involved cervical lymph nodes, some would direct treatment to the primary resection bed only. Additionally for well-lateralized primary tumors, patterns of progression would suggest that PORT to the ipsilateral neck only may be appropriate.[50]

DEFINITIVE RADIATION THERAPY

For early-stage oropharyngeal cancers, the use of radiation therapy as a single modality is associated with good outcomes and functional preservation.[51] Although there is no consensus on the optimal dose fractionation schedule for oropharyngeal cancer patients receiving radiotherapy alone, randomized data[52–54] and meta-analyses[55,56] support an overall survival benefit with the use of accelerated fractionation or hyperfractionated radiotherapy. Therefore, for oropharyngeal cancer treated with radiotherapy alone, strong consideration

should be given to altered fractionation of some sort.

Hyperfractionated Radiation Therapy

The benefit of hyperfractionated radiotherapy for oropharyngeal cancer was clearly demonstrated in EORTC 22791, in which patients with T2-3 N0-1 nonbase of tongue oropharyngeal cancers were randomized to conventionally fractionated radiotherapy at 70 Gy (2 Gy/day) or to 80.5 Gy hyperfractionated at 1.15 Gy twice daily. Hyperfractionated radiotherapy was associated with statistically significant improvements in locoregional control (5-year, 59% vs. 40%) without an increase in long-term toxicity. Additionally, there was a trend toward improved overall survival (P = .08) particularly in stage 3 patients.[54]

Accelerated Radiation Therapy

Accelerated radiotherapy has also been shown to benefit oropharyngeal cancer patients but may depend upon the exact regimen used. For example, a randomized study comparing an accelerated regimen of 66 to 70 Gy delivered in 2 Gy daily fractions 6 days a week to the same dose delivered 5 days a week with oropharyngeal cancer affecting the majority of patients demonstrated improved locoregional control (42% vs. 30%, P = .004), disease-free survival (50% vs. 40%, P = .03), and a trend toward improved overall survival (35% vs. 28%, P = .07). When analyzed as a separate subgroup, pharyngeal primary sites had improved locoregional control (HR = 0.6, 95% CI = 0.41 to 0.86).[53] Of note, accelerated fractionation improved local control for both p16-positive (HR = 0.56 [0.33 to 0.96]) and p16-negative tumors (HR = 0.77 [0.60 to 0.99]).[57] However, when a more intensive accelerated regimen of 1.8 Gy twice daily to 59.4 Gy was compared to 70 Gy in 2 Gy fractions in stage 3/4 head and neck cancer patients, no statistical benefits were seen in terms of locoregional control or overall survival.[58] It is unknown if the lack of benefit seen was due to the regimen used or due to inclusion criteria as the benefit for acceleration in some randomized studies was less significant for those with stage 4 disease as well as those with a larger nodal disease burden.[59]

Accelerated Versus Hyperfractionated Radiation Therapy

For oropharyngeal cancer patients in particular and head and neck cancer patients in general, it is not known if hyperfractionated or accelerated radiotherapy is superior. The meta-analysis of radiotherapy in carcinoma of the head and neck collaborative group pooled 15 randomized studies (including 6,515 patients) comparing conventionally fractionated radiotherapy to either

accelerated radiotherapy or hyperfractionated radiotherapy. Oropharyngeal cancer patients were the largest subsite, representing 44% of all patients (1,585 patients). Altered fractionation radiotherapy regimens were associated with a 3.4% absolute improvement in 5-year overall survival. Heterogeneity in patients included on accelerated and hyperfractionated trials obscure direct comparison, although hyperfractionated patients had an absolute 8.2% improvement in overall survival at 5 years compared to a 2% absolute benefit with accelerated radiotherapy.[56]

One of the studies included in the meta-analysis, RTOG 90-03, compared conventional fractionation (70 Gy in 2 Gy/daily fractions) to hyperfractionation (81.6 Gy [1.2 Gy BID]) and to accelerated fractionation with a split course (67.2 Gy [1.6 BID with a 2-week rest after 38.4 Gy]) to accelerated fractionation with concomitant boost regimen (72 Gy in 1.8 Gy fractions for 14 fractions followed by 1.8 Gy morning and a 1.5 Gy afternoon boost to gross disease). Although all primary sites other than nasopharynx were included, 60% of patients included had oropharyngeal primary tumors. In the initial report, improved locoregional control was seen in both the hyperfractionated and accelerated concomitant boost arms.[60] These improvements resulted in trend toward improved disease-free survival for patients treated with hyperfractionation (37.6% vs. 31.7%, P = .067) and accelerated concomitant boost (39.3% vs. 31.7%, P = .054), which almost reached statistical significance at the P = .05 level. However, with longer follow-up, improved survival was seen with hyperfractionated therapy (HR 0.81, P = .05) when patients were censored at 5 years. Furthermore, less late toxicity was seen with hyperfractionation compared to accelerated fractionation. Specifically in disease-free patients, at 5 years, only 4.8% of HFX patients had feeding tubes versus 13.0% of AFX-C patients.[52] These toxicity data are difficult to interpret in a modern setting because all of the patients were treated with parallel-opposed fields. Blocking techniques were rudimentary and provided minimal sparing of parotid glands and pharyngeal constrictor muscles. Contemporary intensity-modulated radiotherapy (IMRT)/image-guided radiotherapy techniques spare these structures and probably reduce late morbidity significantly.

Simultaneous Integrated Boost Radiation Therapy

With the increasing use of IMRT, simultaneous integrated boost radiotherapy has been investigated for oropharyngeal cancer patients. The RTOG completed a study (00-22) in early-stage (T1-2, N0-2) oropharyngeal cancer patients, treated

with bilateral neck radiotherapy[51] using doses of 2.2, 2, and 1.8 Gy to gross tumor and intermediate-risk and low-risk planning target volumes (PTVs), respectively. The 2-year risk of local progression was 9% and was higher in patients who had significant underdosing of known tumor. Additionally, no local recurrences, distant metastases, or second cancers were seen in never smokers, possibly representing a surrogate for HPV-related disease, compared to 7 locoregional recurrences, 5 second cancers, and 1 case of distant metastases in smokers. The 2-year overall survival was 95% and disease-free survival was 82%. Therefore, it appears for patients with early-stage oropharyngeal cancer treated with radiotherapy alone; simultaneous integrated boost radiotherapy is a viable treatment option.

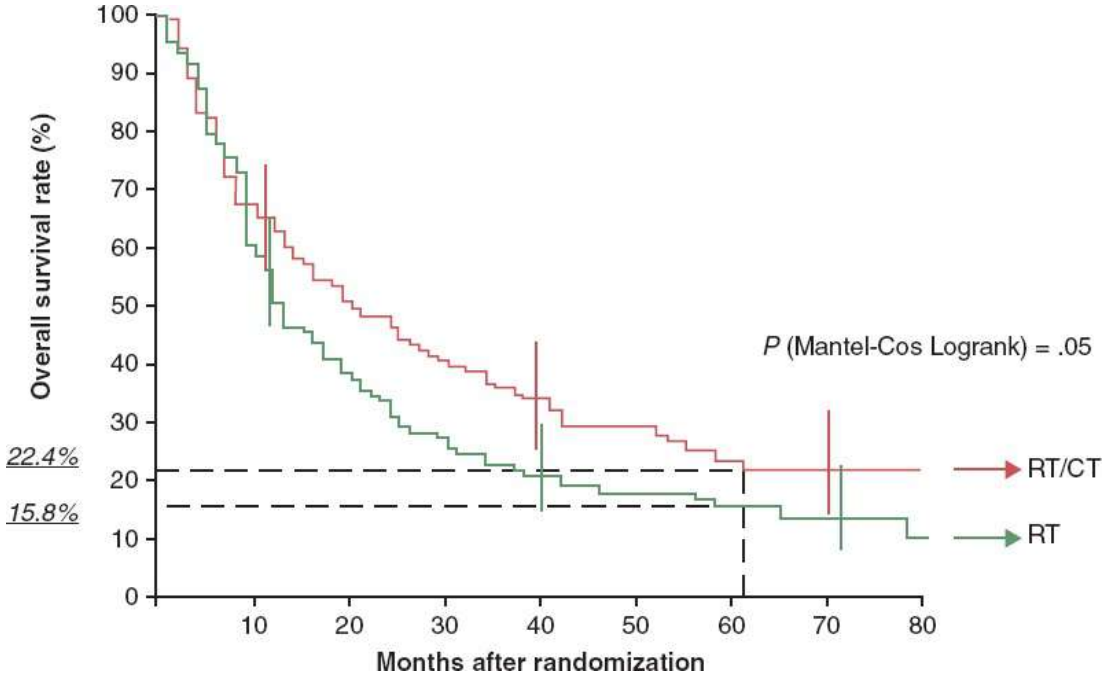

FIGURE 48.4. Overall survival among patients with oropharyngeal cancer treated with radiotherapy alone (RT) or with radiotherapy with concomitant chemotherapy (RT/CT) as analyzed by the Kaplan-Meier method on GORTEC 94-01. (From Denis F, Garaud P, Bardet E, et al. Final results of the 94-01 French Head and Neck Oncology and Radiotherapy Group randomized trial comparing radiotherapy alone with concomitant radiochemotherapy in advanced-stage oropharynx carcinoma. *J Clin Oncol* 2004;22(1):69–76. CONCURRENT CHEMORADIOTHERAPY FOR LOCOREGIONALLY ADVANCED OROPHARYNGEAL CANCER

For patients with locoregionally advanced oropharyngeal cancer, concurrent chemoradiotherapy is the standard treatment. Resection when possible is generally not recommended given the associated surgical morbidity. Additionally, adjuvant chemoradiotherapy is frequently necessary and has similar morbidity to definitive intent chemoradiotherapy. Comparisons of outcomes with radiotherapy with or without neck dissection or surgery with or without adjuvant radiotherapy resulted in similar outcomes with higher complication rates with surgery.[61] With the advent of transoral and robotic surgical techniques, these findings will need to be readdressed.

Evidence for Concurrent Chemoradiotherapy

The use of concurrent chemoradiotherapy for most stages 3 and 4 (nonmetastatic) oropharyngeal cancer patients is based on the results of the meta-analysis of head and neck cancer (MACH-NC), which demonstrated a 6.2% absolute improvement in overall survival at 5 years from the use of concurrent chemoradiotherapy compared to radiotherapy alone.[62] This benefit was also observed in the oropharyngeal cancer subgroup, which showed that concurrent chemotherapy improves 5-year overall survival HR 0.78 (95% CI = 0.72 to 0.85), $P < .0001$.[63]

Additionally, level 1 evidence from multiple randomized studies restricted to oropharyngeal cancer patients supports the use of concurrent chemoradiotherapy for stage 3/4 oropharyngeal cancer.[64,65] The Groupe d'Oncologie Radiothérapie Tête et Cou (GORTEC) compared 2 Gy daily conventional radiotherapy to 70 Gy concomitantly administered with daily bolus carboplatin and continuous infusion 5-fluorouracil 600 mg/m^2/d 5-day 1 to 4 every 3 weeks for three cycles. A total of 222 patients (113 assigned to radiotherapy alone and 109 assigned to combined treatment) were eligible for analysis. With a median follow-up of 5.5 years, absolute 5-year overall survival was significantly higher in the combined modality arm (15.8% with radiotherapy alone to 22.4% with chemoradiotherapy) as shown in Figure 48.4. A five-year locoregional control was also significantly improved with concomitant therapy (from 24.7% vs. 47.6%) for the combined-treatment group ($P = .002$).[66] Combined modality therapy was associated with increased hematological toxicity, increased mucositis, and weight loss. Severe late toxicity was also increased with combined modality therapy (14% vs. 9% radiotherapy alone) including increased mandibular toxicity and cervical fibrosis. These patients were treated with 2D treatment planning, typically including parallel-opposed fields with dosimetric hot spots located in the

mandible and neck soft tissues. The extent to which concurrent chemotherapy contributes to these specific late toxicities in the setting of IMRT is not clearly understood.

Outcomes of locoregionally advanced oropharyngeal cancer have improved in the era of concurrent chemoradiotherapy and modern radiotherapy planning and delivery techniques. This improvement is likely influenced by newer imaging techniques leading to more informed patient selection and radiotherapy planning and the influence of a rise in HPV-related oropharyngeal cancer cases. A recent analysis of over 300 locoregionally advanced oropharyngeal cancer patients treated with primary chemoradiotherapy with a median follow-up of 34 months reported low 2-year rates of local progression (6.1%), regional progression (5.2%), and distant progression (12.2%).[67] Base of tongue cancers have historically been associated with poor outcomes when treated with surgery or radiotherapy alone or in combination (5-year disease specific and overall survival of 27.8% and 40.3%, respectively).[68] However, recent single institution series using chemoradiotherapy highlight high rates of locoregional control with the use of either 3D conformal radiotherapy (5-year 82%) or IMRT (5-year 97.4%),[69] which could represent the influence of HPV-related oropharyngeal cancer. This improvement may reflect the efficacy of chemoradiation, but it may also due to the increased incidence of HPV-associated disease compared to older series.

Acute Toxicity of Chemoradiotherapy

For oropharyngeal cancer patients, a course of concurrent chemoradiotherapy is a life-changing event given the associated toxicities, including fatigue, nausea, emesis, thickened secretions, xerostomia, mucositis, dysphagia, odynophagia, alopecia, dermatitis, anemia, neutropenia, hoarseness, Lhermitte syndrome, and infection. Dysphagia is perhaps the most difficult acute and late complication of chemoradiotherapy for oropharyngeal cancer. Oropharyngeal patients are less likely to be affected than those with laryngeal or hypopharyngeal tumors.[70] Older patients and those with worse performance status are more likely to have worsening of their swallowing following chemoradiotherapy. Those with more advanced tumors are more likely to have swallowing improvement likely due to reduction of tumor bulk.[71] Given the adverse effect of dysphagia on nutritional status, management recommendations include early therapeutic intervention with swallowing exercises designed to strengthen the pharyngeal musculature. Patients should be instructed to swallow as large a volume as possible during and

after treatment and perform exercises shown to improve swallowing ability.[72] Dysphagia has been associated prospectively, with the exceeding of specific dosimetric thresholds to the pharyngeal constrictors or laryngeal apparatus, which should be incorporated into radiotherapy planning as discussed below.[73]

Late Toxicity of Chemoradiotherapy

Late toxicities of chemoradiotherapy for oropharyngeal cancer patients can also be quite significant and can include dysphagia, fibrosis, osteoradionecrosis, trismus, xerostomia, dental caries, feeding tube dependence, and neuritis. Late toxicities of chemoradiotherapy have been catalogued by the RTOG in a pooled analysis of 230 patients treated on three prospective chemoradiotherapy trials with a median follow-up of 3 years. Oropharyngeal primaries affected 34% of all patients. Older patients and those with larger (T3, T4) tumors were more likely to experience late toxicity, as were those who underwent a posttreatment neck dissection.[74] When late toxicity was analyzed by primary tumor site, patients with oropharyngeal and oral cavity primary tumors were statistically less likely to experience late toxicity. Long-term analysis of the aforementioned GORTEC randomized trial demonstrated that 56% of patients treated with chemoradiotherapy had at least one grade 3 to 4 late toxicity compared to 30% treated with radiotherapy alone (P = .12). The small number of long-term survivors probably reduced the power to detect statistically significantly differences between these groups.[66] Recently, a long-term report of HPV-associated oropharyngeal cancer patients treated with chemoradiotherapy demonstrated that development of additional late toxicities beyond those present at 2 years was rare. Furthermore, long-term QOL in all domains was similar to that seen before treatment.[75]

Alternative Concurrent Chemoradiotherapy Regimens

The toxicities of concurrent chemoradiotherapy have stimulated the search for improvements in this platform. Some questions still remain unanswered, including what constitutes the optimal chemotherapy regimen. Cisplatin at 100 mg/m^2 is often cited as a standard regimen. The aforementioned GORTEC randomized study demonstrated an overall survival advantage using a carboplatin/5-FU regimen specifically chosen to avoid cisplatin-related tinnitus, renal dysfunction, and emesis. Randomized studies comparing alternative cisplatin dosing schedules (such as 30 to 40 mg/m^2 weekly, 20 mg/m^2/d, d1-5, 22 to 26) to bolus cisplatin or to other chemoradiotherapy platforms have been

conducted in nasopharyngeal cancer patients or in the postoperative oral cavity setting. However, multiple randomized studies that compared radiotherapy alone to concurrent chemoradiotherapy using nonbolus cisplatin schedules including daily cisplatin (6 mg/m^2/d),[76] weekly cisplatin 40 mg/m^2,[77] or cisplatin 20 mg/m^2/d, day 1 to 5 repeated every 3 weeks[78] had comparable outcomes to bolus cisplatin. The relative merits of various chemoradiotherapy platforms will be discussed in more detail in Chapter 40.

Induction Chemotherapy Prior to Definitive Local Therapy

The use of neoadjuvant chemotherapy prior to surgical resection or radiotherapy for oropharyngeal cancer patients has been tested in randomized studies. In particular, a phase III study restricted to oropharyngeal cancer patients compared three cycles of cisplatin 100 mg/m^2 on day 1 and 5-fluorouracil 1,000 mg/m^2/d, days 1 to 5, repeated every 3 weeks for three cycles followed by definitive local therapy to definitive local therapy alone. At the time of the study, standard local therapies included either radiotherapy alone (70 Gy to the primary, 50 Gy to the neck) or composite surgery with postoperative radiotherapy (50 to 65 Gy based on pathologic findings). Although only 318 of a planned 760 patients were enrolled, a statistically significant improvement in overall survival was seen in the induction chemotherapy arm at 5 years (5.1 years vs. 3.3 years) with a median follow-up of 5 years.[79] This study suggests a benefit to neoadjuvant chemotherapy. The applicability of this trial in the chemoradiotherapy era is questionable, however, because the patients in the control arm of the study received surgery or 70 Gy daily radiotherapy, known to be inferior to accelerated or hyperfractionated radiotherapy. The value of this treatment compared to concurrent chemoradiotherapy is also unknown.

Whether or not induction chemotherapy prior to concurrent chemoradiotherapy improves survival when compared to chemoradiotherapy was an area of active study advocated by some given distant metastases were frequently a site of first failure for patients with locoregionally advanced head and neck cancer in general,[80] This is particularly true for patients with oropharyngeal cancer patients because local regional therapy (chemoradiotherapy) has become so much more effective.[67] However, mature results from multiple randomized studies did not demonstrate improved survival with induction chemotherapy followed by concurrent chemoradiotherapy.[81,82] It is unknown if the lack of demonstrated survival benefit was due to the therapy itself or the fact that these studies were initiated prior to robust knowledge of the

behavior of HPV-associated oropharyngeal cancers. Therefore, inclusion of these patients with their more favorable outcomes was not accounted for in the study design and may complicate interpretation of these studies.

Targeted Agents and Radiation therapy

A randomized study compared radiotherapy 70 to 76.8 Gy with or without weekly cetuximab (loading dose of 400 mg/m^2 followed by 250 mg/m^2), to radiotherapy alone for locoregionally advanced head and neck cancer patients. The combination therapy was found to improve locoregional control, disease-free survival, and overall survival.[83] The majority of patients had oropharyngeal primary tumors (60%). When analyzed alone, patients with oropharyngeal cancer treated with cetuximab had demonstrated improved 2-year locoregional control (50% vs. 41%) and median locoregional disease-free duration and 23 months versus 49 months (HR 0.61) with the use of cetuximab. Furthermore, the median overall survival for oropharyngeal cancer patients treated with cetuximab and radiotherapy was >66 months compared to 30.3 months in those treated with radiotherapy alone HR 0.62, a larger difference than those with laryngeal (32.8 months vs. 31.6 months) or hypopharyngeal (13.7 vs. 13.5) primary sites. Updated analyses show that the addition of cetuximab remains beneficial regardless of p16 status[84] and presence of a prominent rash was a prognostic factor.[85] Therefore, for oropharyngeal cancer patients meeting the inclusion criteria for this study, stage 3/4, nonmetastatic, KPS > 60, and normal hematopoietic, hepatic, and renal function, cetuximab and radiotherapy is an alternative treatment platform. Consideration should be given to the use of altered radiation fractionation with cetuximab because improved overall survival was seen in patients who were treated with accelerated concomitant boost and hyperfractionated radiotherapy.

Cetuximab should be avoided in specific regions (particularly the southeastern United States) where severe anaphylactic reactions mediated by an immunoglobulin E response to the galactose-alpha-1,3-galactose oligosaccharide found on the Fab portion of the cetuximab heavy chain are seen.[86] A fully humanized monoclonal antibody to the EGFR, panitumumab, has a much lower rate of severe allergic reactions, but there is no level 1 evidence to support its equivalent efficacy in this clinical setting. Aside from these geographic limitations, it is unclear which patient populations should receive concurrent chemotherapy and which should receive cetuximab plus radiotherapy. Some physicians use cetuximab plus radiotherapy preferentially over cisplatin plus

radiotherapy in patients with renal dysfunction or overall poor functional status, but there is no level 1 evidence to support this indication. In fact, these same medical conditions constituted exclusion criteria for the randomized trial proving its benefit.

Given the improved outcomes of HPV-associated oropharyngeal cancer with standard treatments, deintensification of therapy is being considered in this patient population. Randomized studies comparing standard chemoradiotherapy to combined EGFR inhibition and radiotherapy are ongoing in the cooperative group setting. RTOG 1016 is comparing bolus cisplatin 100 mg/m^2 d1, 23 with accelerated radiotherapy (70 Gy, 2 Gy/day 6 days per week) to the same radiotherapy and cetuximab 400 mg/m^2 loading dose and 250 mg/m^2 weekly with radiotherapy. This noninferiority study has a primary endpoint of comparable 5-year survival. The NCIC is conducting a similar study but using panitumumab with radiotherapy given the lower rates of dermatologic and anaphylactic reactions. Other investigations are attempting radiation dose reduction aiming to keep locoregional control high while reducing acute toxicity, some using induction chemotherapy before chemoradiotherapy. Mature reports from these studies will help determine how to optimally treat this unique patient population. Need to add in HN002, as well as data from O'Sullivan, and Rad Vac.

Targeted Agents in Combination with Cytotoxins and Radiation Therapy

To date, there are no comparisons of cytotoxic agents and radiation with and without cetuximab for oropharyngeal cancer patients. Oropharyngeal cancer patients comprised 70% of RTOG 0522, which compared two concurrent cycles of 100 mg/m^2 cisplatin and accelerated concomitant boost to 72 Gy radiotherapy with or without the addition of a loading dose of 400 mg/m^2 followed by weekly 250 mg/m^2 cetuximab. The combination of cisplatin, cetuximab, and radiotherapy did not improve locoregional control, disease-free survival, or overall survival. However, this triplet therapy was associated with increased grade 3 to 4 mucositis (43.2% vs. 33.3%, $P = .002$) and skin reactions (25% vs. 15%, $P < .0001$) without increasing grade 3 to 4 dysphagia rates (53% vs. 57%, $P = .27$).[87] Fifty-one percent of oropharyngeal tumor specimens were evaluated for p16 expression, and 73% of these specimens were positive. No differences in outcome were seen as a function of HPV status.

Oropharyngeal cancer patients have also been included in studies evaluating

the addition of bevacizumab to chemoradiotherapy. The addition of bevacizumab to 5-fluorouracil, hydroxyurea, and twice-daily radiotherapy (FHX) did not confer any benefit in a study of locoregionally advanced head and neck cancer patients. The study was terminated early due to toxicity and only 5 of 26 participants had oropharyngeal primary tumors.[88] Bevacizumab has also been integrated with erlotinib (synchronous dual inhibition of vascular endothelial growth factor [VEGF] and EGFR) and cisplatin (33 mg/m^2 cisplatin d1-3 weeks 1 and 5) together with 1.25 Gy twice-daily radiotherapy to 70 Gy. Seventy-one percent of patients had oropharyngeal primary tumors. At a median follow-up of 46 months, 3-year locoregional control and overall survival were promising at 86% and 85%, respectively, compared to historical series.[89] Soft tissue and osteoradionecrosis occurred in both series, and careful attention should be paid to the results of ongoing studies integrating bevacizumab to multiple chemoradiotherapy platforms for locoregionally advanced head and neck cancer patients including those with oropharyngeal tumors.

EXTERNAL BEAM RADIATION THERAPY SIMULATION AND TREATMENT PLANNING

Radiation Therapy Simulation

Prior to a course of radiotherapy or chemoradiotherapy, patients should undergo simulation, preferably CT based to allow for optimal radiotherapy planning. An IV should be placed prior to simulation for the delivery of low osmolar iodinated contrast to optimize the distinction between vascular structures and lymph nodes. Patients are positioned supine, with a rigid head holder cradling the posterior calvarium. Generally, an extended head position is preferable. The shoulders should be positioned as caudally as possible to allow adequate exposure of the neck. This can be achieved either with shoulder pulls or with commercially available devices. Tongue immobilization can be useful for oropharyngeal cancer patients with oral tongue involvement. Bite blocks are also useful as they often elevate the hard palate with its minor salivary glands. This can be achieved either with shoulder-pulls or with commercially available devices. The head should be immobilized with a thermoplastic mask. Care should be taken to ensure that the mask is tight and not allow movement of the nose, chin, or forehead. Images should be taken from above the calvarium to the carina to ensure appropriate volumes can be drawn. The addition of metabolic and magnetic resonance imaging has been found to be complementary for GTV

delineation.[90]

Radiation Therapy Volumes

Radiotherapy volumes for oropharyngeal cancer patients are based on ICRU 50. The gross tumor volume (GTV) includes all known primary and cervical lymph node tumor extension based on clinical, endoscopic, and imaging findings. Care should be taken to look for fat stranding, which could be indicative of extranodal extension. This is usually expanded to include a margin for microscopic extension forming the high-dose clinical target volume. The true clinical target volume (CTV) indicating the margin needed to cover microscopic extension not visible on clinical and imaging modalities is not known. Current RTOG guidelines specify an extension of 0.5 to 1 cm from the GTV to form the high-dose CTV. Nodal regions at risk for occult microscopic spread are usually included in a low-risk CTV. Many studies using clinical presentation data as well as elective surgical series have attempted to define the risk based on primary tumor site and extent of involvement as shown in Table 48.10. In general, this includes at least bilateral level II to IV. Typically, one nodal region beyond those pathologically involved is included. That is for a patient with level II pathologic lymphadenopathy, level IB should be included. The inclusion of the retropharyngeal nodes routinely in the low-risk PTV is controversial as it often increases radiation dose to the pharyngeal constrictors, which has been

associated with dysphagia[91] and should depend on the extent of the primary tumor and cervical lymphadenopathy. The incidence of retropharyngeal lymphadenopathy is demonstrated in Tables 48.11 and 48.12. Coverage of the retropharyngeal nodes up to the base of skull is associated with a low risk of progression,[92] but absence of coverage is not necessarily associated with an increased risk of recurrence. Certainly retropharyngeal coverage (i.e., extending the superior border of level II to include the retrostyloid space) should be considered for oropharyngeal tumors extending into the nasopharynx or pterygoid region, those with gross retropharyngeal nodal involvement, and those with high level II lymphadenopathy.[28]

TABLE 48.11 INCIDENCE OF RETROPHARYNGEAL LYMPH NODES IN HEAD AND NECK PRIMARY TUMORS

Primary Site	Incidence of Retropharyngeal Lymph Nodes (Percentage of the Total Number of Patients)		
	Overall	N0 neck	N+ neck
Oropharynx			
Pharyngeal wall	18/93 (19)	6/37 (16)	12/56 (21)
Soft palate	7/53 (13)	1/21 (5)	6/32 (19)
Tonsillar fossa	16/176 (9)	2/56 (4)	14/120 (12)

Consensus guidelines for contouring the clinically node-negative neck have been published and endorsed by international head and neck cancer cooperative groups, including the RTOG, EORTC, DAHANCA, GORTEC, and NCIC.[29] These guidelines are clinically useful aids for delineating specific nodal treatment volumes. Similar guidelines have been proposed for the node-positive neck and postoperative patients.[28] Specific recommendations for node-positive patients include coverage of the supraclavicular fossa for patients with level IV or Vb lymphadenopathy and inclusion of the entire thickness of muscles invaded by pathological lymphadenopathy in the CTV. Additionally, pathologic lymphadenopathy spanning adjacent levels should trigger inclusion of the full

extent of both levels in the CTV. For postoperative patients, coverage of the entire operative bed in the neck is recommended to account for potential tumor spillage. Coverage of the retrostyloid space was recommended for all patients with pathologic level II lymphadenopathy. Inclusion of the supraclavicular fossa in the treatment volume was recommended for those with involvement of level IV or Vb. Similar to the nondissected node-positive neck, inclusion of muscles invaded by tumor is recommended, as is coverage of all levels spanned by pathologic lymphadenopathy.

CTVs are expanded to account for organ motion and set up uncertainty ideally based on institutional specific data to form the PTV. For oropharyngeal cancer patients, consideration of movement of the base of tongue should be considered (particularly with swallowing) when designing an appropriate PTV margin. The expansion from CTV to PTV should account for imaging methods used to assess daily setup. In general, if more frequent image guidance is performed, the margin needed for setup uncertainty should be less. The RTOG currently recommends 5 to 10 mm for patients treated with standard weekly megavoltage port films and 0.25 to 5 mm if more frequent kV image or cone-beam CT guidance is used. Representative contours for a patient with locoregionally advanced oropharyngeal cancer are shown in Figures 48.5 to 48.7.

Indications for Ipsilateral Radiation Therapy

For well-lateralized tonsillar cancers, not involving the base of tongue and minimal involvement of the soft palate (>1 cm margin between medial extent of tumor and midline), the CTV can be limited to the ipsilateral neck, which will significantly limit the exposure of the contralateral parotid, submandibular gland, and pharyngeal musculature.[26] The ability to forgo treatment to the contralateral neck is based on the extremely low risk of occult contralateral neck lymph node involvement. Surgical series demonstrate that the risk of contralateral cervical lymph node involvement is due to primary tumor size (more common in T3/T4 tumors).[93,94] Additionally, an analysis of tonsillar cancer patients, mostly T1-2 (79%) and N0-1 (88%) who underwent resection of the primary tumor often with ipsilateral lymph node dissection showed that only 5% of patients progressed in the contralateral neck.[95] The low incidence of progression seen in early-stage tonsil cancers is likely due to a lack of invasion of the soft palate and base of tongue, which have richer lymphatic network and access to the contralateral nodes. Patients with contralateral cervical lymph node involvement usually have extensive involvement of ipsilateral cervical lymph nodes[96] or tumors approaching or crossing the midline.

In properly selected tonsil cancer patients, ipsilateral only radiotherapy results in low rates of contralateral neck progression. Large series of patients undergoing ipsilateral RT only demonstrated no contralateral neck progression in patients with T1 tumors and only 1% to 2% in those with T2 tumors. In the few patients with T3 tumors, contralateral nodal progression was 3% to 10%.[97,98] Further analysis of these series shows that contralateral nodal progression was associated with both base of tongue and soft palate involvement (13%), T3 stage (10%), and involvement of the midline of the soft palate (16.5%). No contralateral nodal progression was seen in patients with ≥N2b neck disease, but there were not many patients with this presentation.

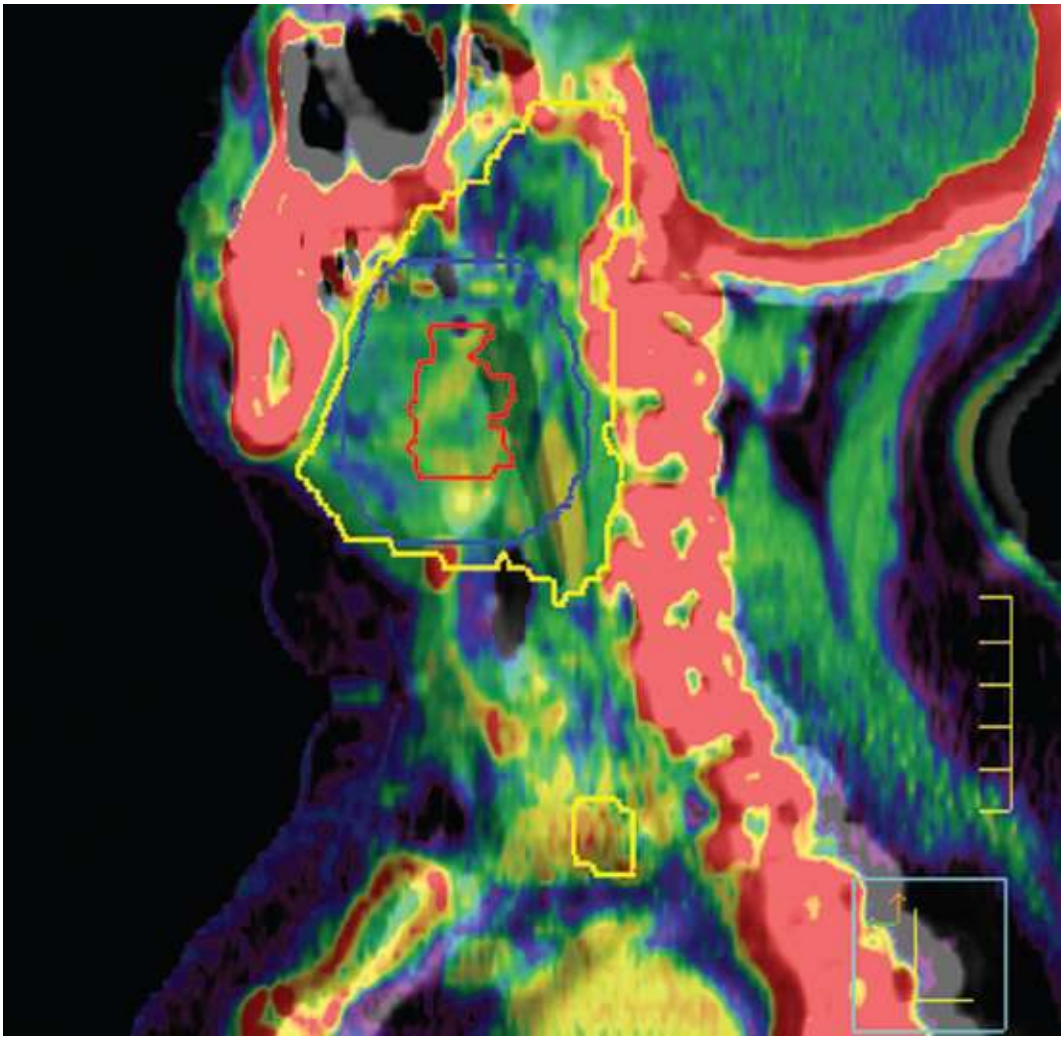

FIGURE 48.7. Sagittal image of a patient with locoregionally advanced oropharyngeal cancer with gross tumor volume and planning treatment volumes.

Studies evaluating the role of ipsilateral treatment in the context of concurrent chemoradiation are sparse. An analysis of tonsil cancer patients treated at MD Anderson Cancer Center from 1970 to 2007 included only three patients who received concurrent systemic therapy for N2b disease. In these patients, there was no contralateral neck progression.[99] An analysis of 20 locoregionally advanced tonsillar cancer patients, with N2b nodal disease, 18 of whom received concurrent chemoradiotherapy, demonstrated high rates of primary and nodal disease control along with a low risk of contralateral nodal progression. A caveat to this study is that all of these patients were staged with a PET scan, and most of these patients underwent surgery at the primary (80%) and/or at the neck

(70%).[100] There appears to be little progression in properly selected patients treated with ipsilateral only radiotherapy, but care should be taken to ensure that patients with more advanced tumors are not treated in this fashion.

Ipsilateral External Beam Radiation Therapy Planning Techniques

Techniques for ipsilateral radiotherapy traditionally include a wedge pair or mixed photon electron field arrangement. The wedge pair technique includes ipsilateral anterior and posterior oblique fields with the head hyperextended to move the orbits out of the treatment field. Adequate sparing of normal tissue with this technique is achieved as the anterior beam spares the oral cavity and the contralateral parotid gland, although usually contributes dose to the spinal cord. The posterior field aperture also spares the contralateral parotid, although it contributes dose to the spinal cord and oral cavity. With the wedge pair technique, hot spots are typically located peripherally near the surface and are between 110% and 115%. These hot spots can be reduced or eliminated if necessary with the addition of a lightly weighted (10%) third, lateral field. The contralateral parotid dose is usually negligible at 0% to 10%.

Alternatively, a combination of photons and electrons can be delivered through two ipsilateral fields. Traditional energies used 14 to 16 MeV electrons and 4 to 6 MV photons but should now be based on optimal 3D planning dosimetry. Bolus is often used to reduce dose to the temporal lobe. Often, an off-cord reduction is used to limit the spinal cord to 45 Gy with low-energy electrons supplementing the region over the spinal cord. Recently, the use of IMRT for ipsilateral only treatment has been increasing.

Bilateral External Beam Radiation Therapy Planning Techniques

Radiotherapy planning should be performed with 3D conformal radiotherapy or IMRT as available. Standard beam arrangements for 3D conformal radiotherapy are opposed lateral upper fields exactly matched to a low neck/supraclavicular field treated with either a single anterior or AP–PA fields. Once spinal cord tolerance is reached, electron fields can be used to increase dose to gross disease as needed. Caution must be exercised to ensure that AP(PA) and lateral fields do not overlap to cause an overdose to the spinal cord. Multiple techniques can be employed to prevent this complication.

Intensity-Modulated Radiation Therapy

IMRT has been widely adopted for the treatment of head and neck cancers.[101] Although theoretical consideration of second cancers exists with IMRT,[102] this

technology has the ability to minimize normal organ exposure to radiation. This is particularly important for oropharyngeal cancer patients as pharyngeal constrictor dose and parotid dose are associated with dysphagia[91] and xerostomia,[103] respectively. In addition, IMRT has the potential to decrease acute dermatitis.

Care should be taken during IMRT to minimize dose to the uninvolved larynx to limit radiation-related speech disorders. Different techniques are available to achieve this objective. The two most commonly used techniques are using IMRT to cover the entire head and neck volume or to use an upper IMRT field matched to a low anterior neck field. Although comparisons of these two techniques have demonstrated reduced mean dose to the larynx and inferior pharyngeal constrictor with the use of a low anterior neck field matched to the IMRT field,[104] controversy persists. Reducing or eliminating fluence from the inferior aspect of posterior and posterior oblique fields should allow median doses to the larynx to be in the 20 to 25 Gy range. Whole-field IMRT is preferable when gross disease is present close to or below the level of the larynx as coverage is better with this technique[105] and in most other cases is simpler to deliver without the inherent difficulties of matching radiation fields.

Impact of Intensity-Modulated Radiotherapy on Xerostomia

The impact of IMRT on reduction of xerostomia in pharyngeal cancer patients (oropharynx or hypopharynx) was prospectively tested in a randomized trial. Patients with pharyngeal squamous cell carcinoma (either oro or hypo) not involving the parotid glands, with good performance status and without distant metastatic spread (T1-4 N0-3), recommended to receive either definitive or adjuvant radiotherapy without concurrent chemotherapy were randomized 1:1 to either conventional radiotherapy or intensity-modulated radiation therapy. The primary endpoint was the proportion of patients with grade 2 or worse xerostomia at 12 months, assessed via the late effects of normal tissues (LENT SOMA) scale.[103] Additionally, salivary flow was assessed preradiotherapy, during week 4 of radiotherapy and then 2, 3, 6, 12, 18, and 24 weeks after radiotherapy. Unstimulated and sodium citrate–stimulated parotid saliva from each parotid orifice and floor of mouth was also collected. Patient reported QL was collected via the EORTC QLQC30 instrument and with the head and neck–specific instrument HN35. Patients could not receive prophylactic pilocarpine or amifostine. Radiotherapy dose was 65 Gy in 30 fractions for definitively treated patients or postoperative patients with macroscopic residual disease

(2.17/fraction) or 60 Gy in 30 fractions (2 Gy/fraction) for postoperatively treated patients without macroscopic residual disease. Uninvolved nodal regions at risk for microscopic spread were treated to 50 Gy (2 Gy/fraction) in the conventional arm and 54 Gy (1.8 Gy/fraction) in the IMRT arm.

Six centers in the United Kingdom participated and recruited 94 patients (47 to each arm). Eighty-five percent of participants had oropharyngeal primary tumors. Eighty-one percent of the patients in the IMRT arm were N0-1 compared to 53% in the conventional arm. This correlated with the statistical difference in stage with 83% of the conventional arm being stage 3 to 4 compared to 68% of the IMRT group. In addition, there were numerically more patients who received PORT in the conventional group (32% vs. 17%).

IMRT significantly reduced mean radiotherapy dose to the ipsilateral (47.6 Gy vs. 61 Gy) and contralateral (25.4 Gy vs. 61 Gy) parotid glands ($P < .0001$). Median follow-up was 44 months. At each planned observation time point, a smaller proportion of IMRT patients reported grade 2 or worse LENT SOMA subjective xerostomia compared to conventional radiotherapy. At 12 months, only 38% of patients treated with IMRT had ≥grade 2 xerostomia compared to 74% in the conventional arm. These were independent of tumor site, radiotherapy indication, stage, and use of neoadjuvant chemotherapy. Additionally, both unstimulated (47% vs. 0%) and stimulated contralateral parotid saliva flow were increased in the IMRT group. Interestingly, ≥grade 2 fatigue was increased in the IMRT group 74% versus 41%. Locoregional progression (IMRT 78% conventional 80%, $P = .34$) and overall survival (IMRT 78% conventional 76%) were similar between the two arms.

These findings in primarily oropharyngeal patients are consistent with those found in studies of nasopharyngeal patients. It is unclear if the benefit of salivary reduction seen with IMRT continues when pharmacologic studies to reduce xerostomia such as pilocarpine and amifostine are employed. Ongoing cooperative group trials recommend limiting the mean dose to the parotids as low as possible and at least < 26 Gy. Furthermore, the mean dose to the submandibular gland is recommended to be limited to 36 Gy (RTOG 1016).

Impact of Intensity-Modulated Radiotherapy on Dysphagia

IMRT planning should also take into consideration the risk of dysphagia. Many studies have attempted to correlate dosimetric parameters with functional swallowing consequences following radiotherapy or chemoradiotherapy. As highlighted in the studies mentioned below, radiation dose to the larynx and

pharyngeal constrictors should be limited as reasonable as possible to limit the risks of aspiration, feeding tube dependence, and stricture. Consensus on dosimetric parameters does not exist as the studies to date have all been retrospective, and their findings are not completely concordant.

Careful correlation of videofluoroscopic findings to radiotherapy dose to normal tissues has been performed in oropharyngeal cancer patients treated with chemoradiotherapy. Based on this analysis, the dose with a 25% or 50% risk (TD 25 or TD 50) of dysphagia to the pharyngeal constrictors was 56 and 63 Gy, respectively. Similarly, TD 25 and TD 50 were 39 and 56 Gy for the glottis and supraglottic larynx.[73] Mean dose to the esophagus was associated with the development of strictures. There were no threshold doses found in this analysis, so it is reasonable to use the TD25 as a planning goal and if not achieved trying to keep the dose to these structures as low as possible.

Others have analyzed radiotherapy doses to normal tissues and correlated to clinical outcomes, persistence use of PEG tube, aspiration rates, and stricture rates.[106] In this analysis, mean dose to the larynx and mean dose to the inferior pharyngeal constrictor predicted for persistent use of PEG tubes and aspiration. Additionally, the volume of larynx receiving 35 to 70 Gy (V_{35} − V_{70}) and inferior pharyngeal constrictor V_{40} through V_{65} was associated with PEG tube dependence and larynx V_{55} through V_{70} and inferior pharyngeal constrictor V_{60} and V_{65} were significantly associated with aspiration. Patients with a mean dose of approximately 50 Gy to the larynx and inferior constrictor all had PEG tubes removed by 12 months.

Concurrent Chemotherapy and Accelerated Radiation Therapy

Two recently reported randomized studies showed that there was no benefit to accelerated radiotherapy over conventionally fractionated radiotherapy when delivered with concurrent platinum-based chemotherapy. GORTEC 99-02 randomized locoregionally advanced head and neck cancer patients to either very accelerated radiotherapy 64.8 Gy (1.8 Gy twice daily), 70 Gy (2 Gy daily over 7 weeks) with concurrent carboplatin 70 mg/m^2 and 5-FU 600 mg/m^2/d d1-4, d22-25, and d43-46 or 70 Gy (2 Gy daily to 40 Gy and then 1.5 Gy twice daily) with carboplatin 70 mg/m^2 and 5-FU 600 mg/m^2/d d1-4, d29-33. Outcome in both chemoradiotherapy arms was similar, and both were superior to very accelerated radiotherapy with lower rates of acute toxicity and percutaneous gastrostomy tube placement during therapy and at 5 years.[107] Similarly, RTOG 0129 randomized patients to 72 Gy accelerated concomitant boost radiotherapy

with two cycles of cisplatin 100 mg/m^2 or to 70 Gy daily radiotherapy with three cycles of cisplatin 100 mg/m^2. Again, there was no benefit to accelerated chemoradiotherapy seen in 8-year overall survival (accelerated 47.6% vs. conventional 47.7%), locoregional progression (36.7% vs. 38.5%), or worst grade 3 to 5 toxicity (37.9% vs. 36.5%).[108] Interestingly on an unplanned post hoc analysis, it appeared that standard fractionation patients who received fewer than three cycles of chemotherapy had worse outcomes than those who received the full-planned dose of chemotherapy. The value of acceleration via the use of a simultaneous integrated boost, a commonly used approach for IMRT delivery, must therefore be questioned when concurrent chemotherapy is being used as part of the treatment program.

Brachytherapy

Brachytherapy, the application of radioactive materials in close proximity to tumors, was developed in the pre-IMRT, preconcurrent chemoradiotherapy era as a means to deliver a tumoricidal dose to gross tumors while minimizing dose to the mandible. The advent of improved radiotherapy planning and delivery techniques in addition to a recognition that osteoradionecrosis secondary to brachytherapy is significantly underreported has corresponded to a major decrease in the utilization brachytherapy for oropharyngeal tumors.

For oropharyngeal tumors, brachytherapy has historically played a role in boosting gross disease following external beam therapy as oropharyngeal tumors have a high propensity for occult nodal spread. Typically, catheters are implanted under general anesthesia in the operating room, with two capable physicians present to handle unexpected events highlighting the fact that brachytherapy is an operator-dependent procedure. Although low–dose rate brachytherapy has previously been the most common type of brachytherapy used, high–dose rate (HDR) and pulsed–dose rate (PDR) techniques are becoming much more common and sometimes preferred given the ability to control dwell times and develop more customized dose distributions. Given the historically poor locoregional control rates for tumors of the base of tongue, intensifying the treatment with brachytherapy makes logical sense. High rates of locoregional control have been achieved using an integrated treatment approach of external beam radiotherapy directed at the primary and bilateral neck, followed by a brachytherapy boost.[109] Complications of brachytherapy for base of tongue tumors include osteoradionecrosis of the mandible. The risk of complication appears to be related to the technique of implantation but may approach 30%.

There is limited information regarding the use of brachytherapy and chemotherapy concurrently; this approach should be avoided outside of a formal trial setting.

When brachytherapy is planned following external beam radiotherapy, care should be taken to delineate the pretreatment tumor extent, as regression is not always uniform. Tattoo and/or gold seed placement along the tumor border have been used to accomplish this. The CTV used is recommended by ESTRO to be 5 mm at minimum and more commonly 1 to 1.5 cm for base of tongue tumors. The PTV is usually equal to the CTV as the implanted catheters move with the tumor. Catheters are typically positioned parallel and equidistant 1 to 1.5 cm apart. Although traditional methods of calculating dose have been used in the past based on the Paris, Manchester, or New York systems, computer-derived brachytherapy plans are now routine.

Brachytherapy Guidelines

The American Brachytherapy Society (ABS) has published guidelines for the use of HDR brachytherapy for head and neck tumors and oropharyngeal tumors in particular. Prophylactic tracheostomy is recommended as posterior and large tumors are at risk to cause airway obstruction. Expert panel evidence, as well as single institution series, recommends external beam radiotherapy doses of 45 to 60 Gy followed by HDR brachytherapy boost of 3 to 4 Gy per fraction for 6 to 10 doses with locoregional control of implanted tumors reaching 82% to 94%.[110]

The European Brachytherapy Group (GEC) and the European Society for Therapeutic Radiology and Oncology (ESTRO) have also published joint guidelines for the use of brachytherapy for head and neck malignancies. Similar to the ABS, these were based on consensus recommendations reflecting limited data.[111] For oropharyngeal tumors, these guidelines recommend 45 to 50 Gy external beam radiotherapy followed by 25 to 30 Gy boost for tonsillar tumors and 30 to 35 Gy boost to base of tongue tumors. The total brachytherapy boost dose is fraction size dependent; 21 to 30 Gy in 3 Gy fractions, and 16 to 24 Gy in 4 Gy fractions. These guidelines were recently updated to reflect standardized use of CT-/MRI-based treatment planning with inhomogeneity corrections.[112] Quality of life analyses comparing a combined regimen of brachytherapy and external beam radiotherapy to surgery and postoperative radiotherapy favored a primary radiotherapy only approach,[113] suggesting that in experienced hands, this is a reasonable treatment method.

Hypofractionated Image-Guided Radiation Therapy for Oropharyngeal Cancer

Hypofractionated image-guided radiotherapy techniques, commonly referred to have stereotactic body radiotherapy (SBRT), have resulted in promising outcomes for the treatment of early-stage lung cancers[114] and limited metastases.[35] Consequently, investigators are attempting to incorporate these techniques into the treatment of oropharyngeal cancer. To date, data are limited,[115,116] and further investigations are needed to determine what role, if any, exists for this approach.

TABLE 48.13 SELECTED SERIES OF HPV-RELATED OROPHARYNGEAL CANCER TREATED WITH REDUCED RADIATION DOSE, LIMITED TREATMENT VOLUMES, OR LIMITED CHEMOTHERAPY

	PMH[a]	Multi-Inst[b]	ECOG 1308[c]	RAVD[d]

DEINTENSIFICATION OF THERAPY FOR HUMAN PAPILLOMAVIRUS–POSITIVE OROPHARYNGEAL CANCER

PATIENTS

Given better outcomes of HPV-related oropharyngeal cancer patients, in combination with the known acute and late effects of surgery, chemotherapy, and radiotherapy, many are investigating strategies to maintain high rates of tumor control and survival while deintensifying curative intent treatment in locoregionally advanced patients. Many different approaches have been investigated in the prospective and pilot study arena with selected studies in Table 48.13. One such approach is altered fractionation radiation alone without chemotherapy. A retrospective analysis of HPV-related oropharyngeal cancer patients treated at a single institution with either altered fractionation radiation alone of chemoradiotherapy demonstrated that RT and CRT outcomes were similar in those patients with < 10 pack-year smoking history (3-year OS RT: 86% vs. CRT: 88%, P = .45).[117] Furthermore, locoregional control and distant metastasis rate were not different between these two approaches.

Other approaches are being investigated. One alternative approach being investigated is tailoring treatment based on response to induction chemotherapy. ECOG 1308 was a single-arm study basing postinduction chemotherapy radiotherapy dose on response to induction chemotherapy. Those with a complete response to cisplatin, docetaxel, and cetuximab induction chemotherapy received 54 Gy with cetuximab, and those with a partial response received 69.3 Gy with cetuximab. In those patients treated with reduced dose RT, 2-year locoregional control was 94%, and 2-year overall survival was 93%.[118] Others have deintensified therapy in patients with a good response to induction chemotherapy by keeping chemotherapy and radiation doses unchanged and instead significantly shrinking or eliminating elective nodal radiation volumes. Following induction cisplatin, paclitaxel, and cetuximab +/− everolimus, patients with >50% reduction in the sum of the tumor diameters were classified as having a good response. Those with a good response went on to receive standard dose chemoradiotherapy to gross disease only, whereas those with less than a good response received standard dose chemoradiotherapy to gross disease as well as the next elective nodal station. Interestingly, in HPV-associated cancer patients, 2-year PFS and OS in good response patients were 93.1% and 92.1%, respectively, compared to those with no response 74.0% and 95.2%, respectively,[119] indicating that this is a potential treatment strategy pending further investigation.

Another alternative is reduced dose RT concurrently with cisplatin chemotherapy. In a single-arm phase II study, HPV-associated oropharyngeal

cancer patients with T0-T3, N0-N2c were treated with concurrent weekly cisplatin 30 mg/m^2 and 60 Gy radiation. The primary endpoint of this study was pathologic CR rate of mandatory biopsy of the primary site and dissection of involved lymph node levels irrespective of imaging response. Remarkably, 86% of patients (37 of 43) had a pathologic complete response and toxicities were reduced compared to standard course chemoradiotherapy.[120]

Although the data above are promising, deintensification of therapy in HPV-associated oropharyngeal cancer remains experimental and should not be considered standard of care. Of note, NRG is conducting HN002 randomizing these patients to 60 Gy radiotherapy with concurrent weekly cisplatin or 60 Gy accelerated radiotherapy alone (NCT02254278).

POSTTREATMENT MANAGEMENT AND SURVEILLANCE

Following definitive therapy for oropharyngeal cancer, patients should be seen regularly for clinical evaluation. Current guidelines suggest examination every 1 to 3 months for the first-year post therapy, every 2 to 4 months in the second-year post therapy and every 4 to 6 months years 3 to 5. The intensity of the examinations within the first 2 years coincides with the likelihood of recurrence in the interval. Given that radiation to the neck commonly causes hypothyroidism, TSH should be evaluated every 6 months.

Following definitive radiotherapy or chemoradiotherapy, follow-up imaging should be performed within the first 3 months of treatment completion for patients with N+ presentations. A radiographic complete response on CT imaging of the neck, defined as nonenhancing, nonnecrotic nodal tissue <1.5 cm, is associated with 100% long-term disease control in the neck, and no further therapy is needed.[121] Surveillance CT imaging of the primary site does not add additional information to physical/fiberoptic examination and should not be routinely performed.[122]

PET/CT is more widely available and is often used as the sole imaging modality following the completion of radiotherapy. An analysis of 121 node-positive predominately oropharyngeal (74%) head and neck cancer patients, prospectively followed with PET/CT at around 12 weeks post therapy (and again 4 weeks later if equivocal residual activity was present on the 12-week scan) with possible neck dissection for metabolic persistence helped to clarify the role of PET/CT scan following chemoradiotherapy. With or without residual CT abnormalities in the neck, a negative PET scan at 12 weeks, defined as the

absence of metabolic activity, was associated with no isolated nodal progression.[123] Additionally, the negative predictive value of PET was 98.1% (95% CI = 93.2% to 99.8%) compared to 96.8% in CT (95% CI = 88.8% to 99.6%) However, more importantly, false-positive readings were seen in only 1.8% of PET scans compared to 38% of CT scans, resulting in a positive predictive value of 77.8% for PET/CT scan and 14% for CT. When the analysis was restricted to p16-positive patients, the results were similar with a negative predictive value of 98.2% (95% CI = 90.4% to 100%) and 66.7% (95% CI = 9.4% to 99.2%) for PET. Long-term follow-up of these patients demonstrated that PET–CT-directed posttherapy management resulted in >90% of patients were adequately spared a neck dissection, with only one patient experiencing a neck recurrence following initial metabolic resolution.[124] Of note, these patients also had a contrast-enhanced CT scan performed 6 weeks after completion of treatment. All patients who had a negative CT scan also had a negative PET. Thus, a 12-week PET may not be necessary for patients who have had a negative CT.

Since these initial evaluations, a randomized study has been reported comparing the utility of postchemoradiotherapy PET-/CT-based neck surveillance versus planned neck dissection in patients with N2 or N3 nodal disease. The trial accrued 564 patients (282 in each arm), 84% having oropharyngeal cancer, and p16 staining was positive in 75%. Patients assigned to the PET-/CT-based neck surveillance arm had 2-year overall survival rate of 84.9% (95% CI = 80.7 to 89.1) compared to 81.5% (95% CI = 76.9 to 86.3) in the planned-surgery group. Furthermore, there were no differences in locoregional control 2-year rate of 91.9% (95% CI = 88.5 to 95.3) in the surveillance group and 91.4% (95% CI = 87.8% to 95.0%) in the planned-surgery group. Finally, PET-/CT-based surveillance was more cost-effective saving an average of $2,190 per patient. Therefore, PET-/CT-based surveillance should be considered standard postchemoradiotherapy.[125]

TREATMENT OF RECURRENT AND METASTATIC OROPHARYNGEAL CANCER

Systemic Therapy for Recurrent and Metastatic Oropharyngeal Cancer

The standard therapy for patients with recurrent or metastatic oropharyngeal cancer is systemic therapy with platinum-based chemotherapy. In phase II

studies, many drugs in addition to platinum agents and methotrexate have shown single-agent activity including paclitaxel,[126] docetaxel,[127] gemcitabine,[128] ifosphamide,[129] vinorelbine,[130] pemetrexed,[131] capecitabine,[132] and irinotecan.[133] Single-agent cisplatin (100 mg/m^2) has been shown to improve overall survival compared to best-supportive care.[134] Cisplatin was also shown to be superior to single-agent methotrexate.[135] Multiple randomized studies have attempted to improve survival with combination cisplatin-based regimens. The combination of cisplatin (100 mg/m^2) with 5-FU (1,000 mg/m^2/d), demonstrated improved response rates (32% vs. 17%), but not improved median survival (5.7 months) over cisplatin alone.[136] Similar results were seen when the combination of cisplatin/5-FU, carboplatin/5-FU, and methotrexate alone was randomly compared. The combination of cisplatin and 5-FU was shown to have increased response rates compared to methotrexate (32% vs. 10%) as was carboplatin and 5-FU compared to methotrexate (21% vs. 10%), but neither had improved median survival (6.6 and 5.6 months, respectively, compared to 5.0 months) to methotrexate.[137] Response rates and survival are similar with cisplatin and paclitaxel versus cisplatin/5-FU, which provides a regimen that is easier to administer.[138] For oropharyngeal cancer specifically, a planned subset analysis of a phase III trial comparing cisplatin and pemetrexed to cisplatin and placebo demonstrated that oropharyngeal cancer patients receiving the combination regimen had improved survival (9.9 months vs. 6.1 months, P = .002) and improved progression-free survival (4 months vs. 3.4 months, P = .047).[139]

The addition of agents targeted to the epidermal growth factor receptor to platinum-based systemic therapy has been shown to improve overall survival compared to platinum agents alone in a phase III study with a large proportion of oropharyngeal cancer patients. The EXTREME study randomized recurrent and metastatic head and neck cancer patients to cisplatin 100 mg/m^2 d1 or carboplatin AUC = 5 d1 along with 5-FU 1,000 mg/m^2/d 5-FU d1-4 every 3 weeks with or without cetuximab 250 mg/m^2 following a loading dose of 400 mg/m^2. Cetuximab was continued until disease progression or patient intolerance.[140] Median overall survival was improved from 7.4 months with chemotherapy alone to 10.1 months with the combination of systemic therapy and cetuximab as was median progression-free survival (3.3 to 5.6 months). No phase III data have suggested a benefit for the addition of tyrosine kinase inhibitors including gefitinib or erlotinib to platinum-based therapy. Ongoing investigations are determining the role of bevacizumab and other targeted agents.

In the platinum refractory setting, immune checkpoint inhibitors have

significantly changed second-line therapy for recurrent and metastatic head and neck cancers in general and oropharyngeal cancers specifically. The checkmate 141 study randomized 361 patients (35.5% pharyngeal cancers) to nivolumab 3 mg/kg every 2 weeks or investigator choice of 40 to 60 mg/m^2 methotrexate, 30 to 40 mg/m^2 docetaxel, or 250 mg/m^2 cetuximab after a loading dose of 400 mg/m^2. Nivolumab treated patients had a longer median (7.5 months vs. 5.1 months) and 1-year overall survival (36% vs. 16.6%) HR = 0.98 (95% CI = 0.51 to 0.96) P = .01. In an exploratory analysis looking at the effect of nivolumab based on p16 status, p16-positive patients had longer median survival (9.1 months vs. 4.4 months) HR = 0.56 (95% CI = 0.32 to 0.99).[141]

Reirradiation for Locoregionally Confined Recurrent or Second Primary Disease

For the subgroup of recurrent oropharyngeal cancer patients with locoregionally confined disease, surgical resection is recommended, although this is possible only in a small proportion of patients.[142] Following surgery[143] in those with high-risk pathologic features or in those who are not surgical candidates,[144] a second course of full-dose radiotherapy with chemotherapy has been shown to result in long-term survival in approximately 20% of patients. Patients who are able to undergo surgery prior to reirradiation, as well as those who have not been exposed to prior chemotherapy and are treated to higher doses, have improved outcomes. Because of the high risk of normal tissue toxicity including up to a 20% carotid rupture rate and 15% fatal toxicity, patients undergoing a second course of chemotherapy and radiation therapy should be managed at experienced centers. It is unknown if systemic therapy alone or chemotherapy and reirradiation is a better therapy for these patients, as a phase III comparison of these modalities failed to accrue.

Recently, data has emerged demonstrating that SBRT is associated with high rates of treated tumor control in previously irradiated head and neck cancer patients with locoregionally confined recurrences.[145] This treatment is attractive as it is a much shorter course (1 to 2 weeks) compared to chemo-reirradiation and has been combined with cetuximab safely.[146] However, similar to chemo-reirradiation, high-grade late toxicities including carotid blowout are possible. Patients with recurrent/second primary tumors arising in the larynx/hypopharynx were more likely to have late high-grade toxicity following SBRT reirradiation. However, the ability to offer SBRT is limited in size and location of the recurrent tumor and should be delivered by those with experience with this technique.

Therefore, treatment decisions will have to be individualized based on extent of disease, performance status, and preference.

CHAPTER 49

Hypopharynx

Matthew E. Witek, Timothy J. Kruser, Henry T. Hoffman, Christopher J. Kandl, and Paul M. Harari

INTRODUCTION

There is a strong association between tobacco use and the development of hypopharynx cancer.[1–3] Because of the rich lymphatic network in this anatomic region, patients commonly present with regional nodal metastases. Many patients with hypopharynx cancer also carry significant medical comorbidities and social issues that present additional challenges to the successful delivery of aggressive cancer therapy. As for all complex tumors of the head and neck (H&N) region, multidisciplinary evaluation and management are critical and should involve the H&N surgeon, radiation oncologist, medical oncologist, nurse, nutritionist, speech or swallow therapist, and social worker. Although a selected cohort of early-stage tumors may be amenable to organ preservation surgery, more radical surgery such as laryngopharyngectomy is often required for patients who undergo a primary operative approach for hypopharynx cancer. This ablative procedure can induce significant cosmetic and functional changes, and postsurgical rehabilitation efforts guided by knowledgeable professionals are very important to assist in patient adaptation. Increasingly, patients with hypopharynx cancer are being considered for nonoperative treatment approaches using definitive radiation or chemoradiation as a means of obtaining tumor control with preservation of organ function. Regardless of the specific treatment approach, all patients require active rehabilitation therapy in an effort to maximize their ultimate speech and swallow function. Despite stepwise advances in the diagnosis and treatment of hypopharynx cancer, the overall outcome for these patients is relatively poor compared with other H&N cancer sites.[4] As with most tumors of the H&N region, there is significant interest in combining molecular targeted therapies with traditional cytotoxic therapy in an effort to further improve outcomes.

ANATOMY

The hypopharynx, sometimes referred to as the laryngopharynx, is contiguous superiorly with the oropharynx and inferiorly with the cervical esophagus (Fig. 49.1). As general landmarks, the superior border of the hypopharynx is demarcated by the hyoid bone and the inferior border by the cricoid cartilage. With regard to cancer diagnosis and staging, there are three primary anatomic subsites within the hypopharynx: the bilateral pyriform sinuses, the postcricoid region, and the posterior pharyngeal wall.

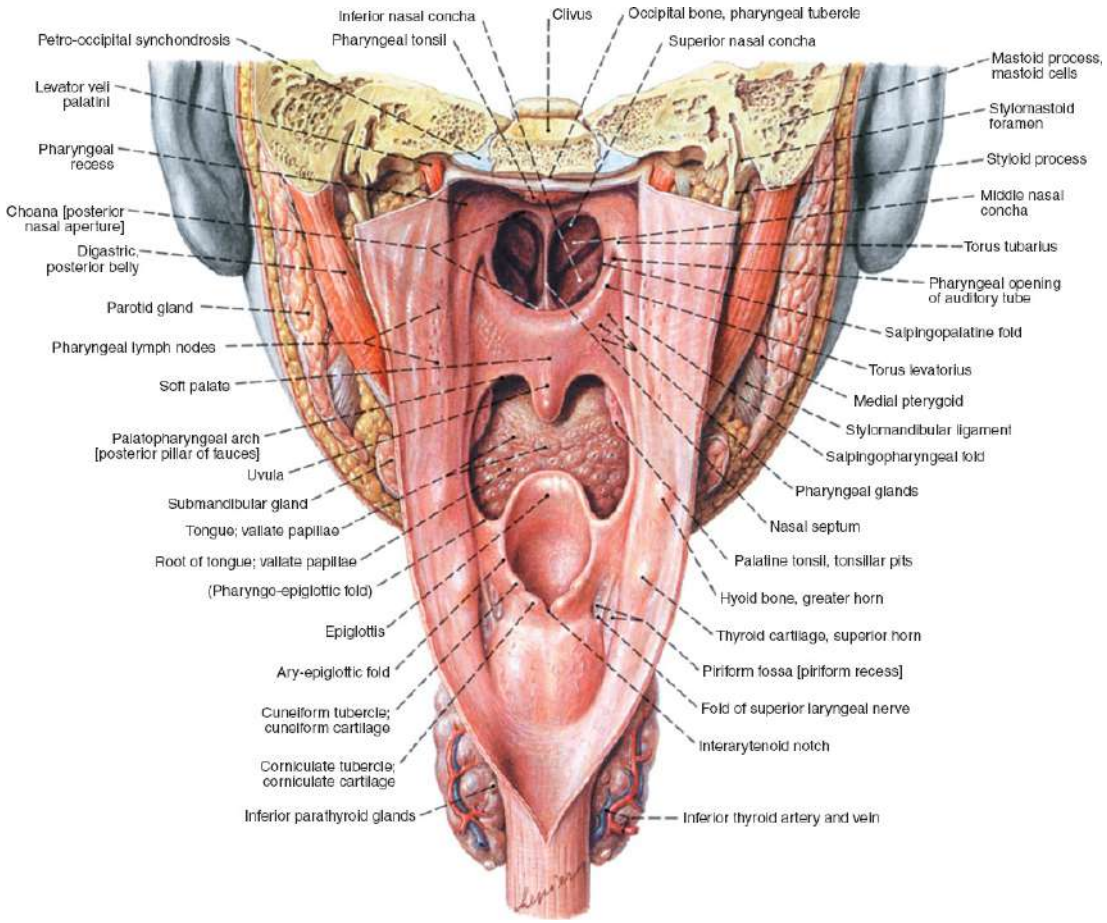

FIGURE 49.1. Posterior view of the hypopharynx shows the relationship of the pyriform sinus, pharyngeal wall, and postcricoid region within the head and neck. (From Putz R, Pabst R. *Sobotta Atlas of Human Anatomy*. 13th ed. Munich: Urban & Fischer, 2001. Copyright ©Elsevier GmbH. With permission.)

The pyriform sinuses are essentially inverted pyramids with the medial, lateral, and anterior walls narrowing inferiorly to form the apices. Posteriorly, the pyriform sinuses are open and contiguous with the pharyngeal walls. Superiorly, the sinuses are surrounded by the thyrohyoid membrane through

which passes the internal branch of the superior laryngeal nerve. Tumor involvement of the sensory branches of this nerve can result in referred otalgia. The postcricoid region is composed of the mucosa overlying the cricoid cartilage, with the arytenoid and esophageal mucosa forming the superior and inferior borders, respectively. The posterior pharyngeal wall predominantly comprises the squamous mucosa covering the middle and inferior pharyngeal constrictor muscles and is separated from the prevertebral fascia by the retropharyngeal space. Typically, the mucosa lining the pharyngeal wall is <1 cm in thickness and provides a minimal barrier to direct tumor infiltration. The posterior pharyngeal wall is contiguous with the lateral wall of the pyriform sinus (Fig. 49.2).

Sensory innervation of the hypopharynx is provided by the internal branch of the superior laryngeal nerve as well as fibers deriving from the glossopharyngeal nerve. The recurrent laryngeal nerve and the pharyngeal plexus provide the primary motor supply. The arterial supply of the hypopharynx is derived primarily from branches of the external carotid artery: superior thyroid arteries, ascending pharyngeal arteries, and lingual arteries.

There is a rich network of lymphatics within the hypopharynx that drain directly through the thyrohyoid membrane and into the jugulodigastric lymph nodes, most commonly involving the subdigastric node. Additionally, there may be direct drainage into the spinal accessory nodes. Tumors involving the posterior pharyngeal wall can also drain to the retropharyngeal nodes, including the most cephalad retropharyngeal nodes of Rouviere.

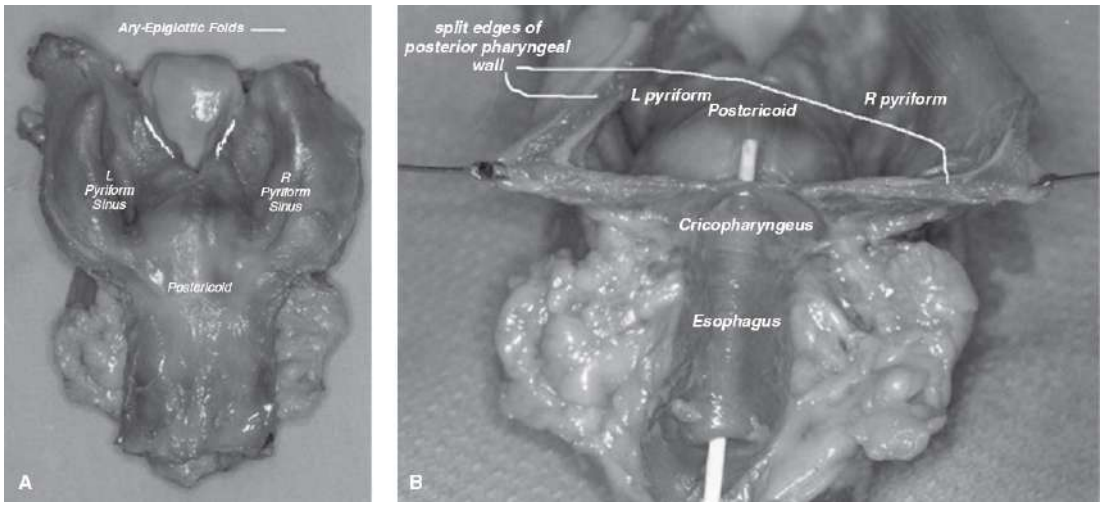

FIGURE 49.2. A: Posterior view of resected larynx and hypopharynx specimen afforded by incision through the posterior pharyngeal wall, cricopharyngeus, and cervical esophagus in the posterior midline. The aryepiglottic folds (*marked*) and

arytenoids separate the pyriform sinuses (hypopharynx) from the larynx. **B:** The three primary anatomic subsites (posterior pharyngeal wall, postcricoid region, and pyriform sinuses) are revealed in this posterior view of the hypopharynx with the posterior pharyngeal wall incised.

EPIDEMIOLOGY AND ETIOLOGY

Hypopharynx cancers are relatively uncommon. Approximately 1,800 cases per year were diagnosed annually in the United States from 1990 to 2004,[4] and the population-adjusted annual incidence rate in the United States was 0.7 per 100,000 from 2000 to 2008, according to the National Cancer Institute's Surveillance, Epidemiology, and End-Results (SEER) database.[5] Hypopharyngeal cancers accounted for 5.2% of upper aerodigestive tract cancers during that time. Approximately three-fourths of hypopharyngeal cancers occur in men, with a mean age of 65 years. Over 90% of patients with hypopharynx cancer report past cigarette use.[6] Alcohol appears to potentiate the carcinogenic effects of tobacco. Additionally, alcohol consumption at medium to high levels for a long period of time can increase the likelihood of hypopharynx cancer in nonsmoking patients.[7] The index hypopharynx cancer often occurs within a field of diseased mucosa characterized by high-grade dysplasia. This "field cancerization" reflects widespread mucosal exposure to carcinogens and is responsible for the high rate of synchronous and metachronous primary tumors identified in patients with hypopharynx cancer. Successful counseling with particular emphasis on smoking cessation can enhance treatment tolerance and diminish the risk of developing subsequent cancers of the upper aerodigestive tract. Patients with occupational exposure to coal dust, steel dust, iron compounds, and fumes have also shown an increased risk for developing hypopharynx cancer.[8,9] Overall, the incidence of hypopharynx cancer has shown some gradual decline in the United States. From 1975 to 2001, the incidence decreased by approximately 35%, perhaps as a result of smoking cessation efforts.[10] Human papillomavirus (HPV) infection is well established as a risk factor for the development of squamous cell carcinoma (SCC) of the gynecologic tract, particularly the uterine cervix. The relation between HPV and H&N cancer is now becoming much better appreciated, particularly for cancers of the oropharynx, where it may approach 60% to 70% in some series. Studies have demonstrated that approximately 20% to 25% of patients with hypopharynx cancer test positive for HPV DNA,[11,12] and seropositivity for antibodies against the HPV-16 E6 and E7 antibodies has been associated with a significantly

elevated risk of hypopharyngeal cancer.[13] The clinical implications of the presence of HPV in hypopharynx cancer are yet to be defined.

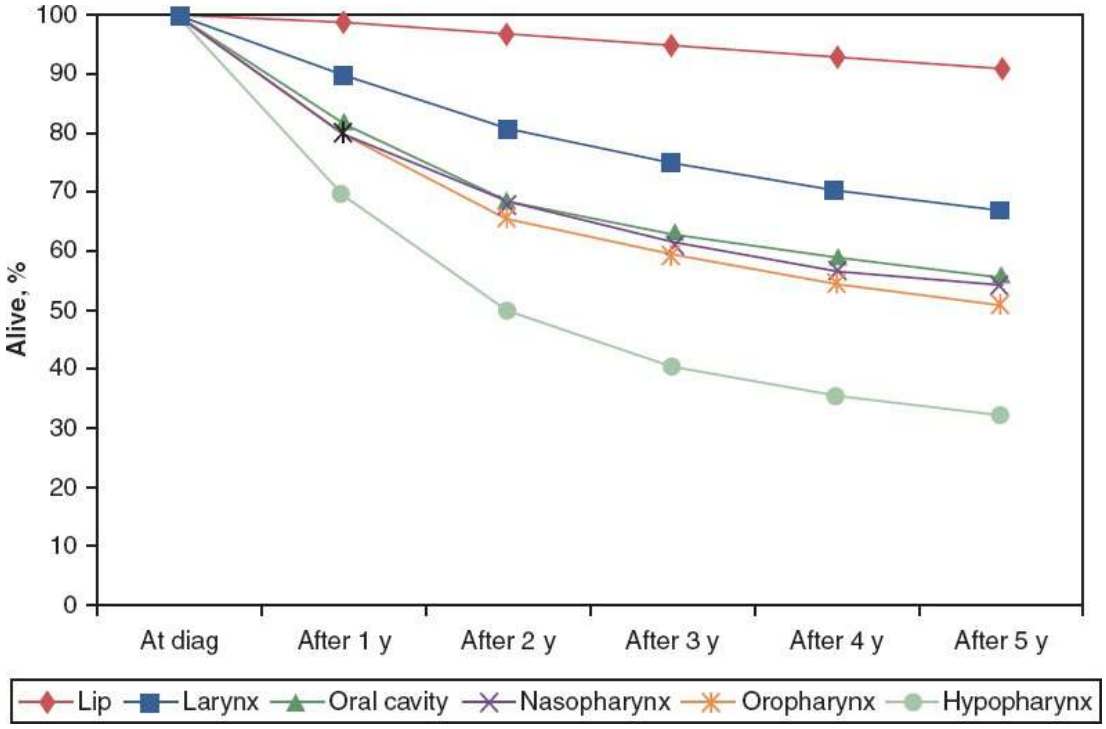

FIGURE 49.3. Five-year survival by mucosal site for head and neck cancers from 1990 to 1999 cases. (From Cooper JS, Porter K, Mallin K, et al. National Cancer Database report on cancer of the head and neck: 10-year update. *Head Neck* 2009;31[6]:748–758. Copyright © 2009 Wiley Periodicals, Inc. Reprinted by permission of John Wiley & Sons, Inc.)

There is a recognized increased risk of developing cancers of the postcricoid region for patients with Plummer-Vinson syndrome, characterized by iron deficiency anemia, hypopharyngeal webs, weight loss, and dysphagia.[7] Favorable changes in the epidemiology of hypopharynx cancer have resulted from changes in nutrition. The addition of iron to flour has made Plummer-Vinson syndrome quite rare in the upper Midwestern United States and Scandinavian countries where it was formerly more common. An associated decrease in hypopharynx cancer involving the postcricoid region has followed.

PROGNOSTIC FACTORS

Several prognostic factors have been identified for patients with hypopharynx cancer. Age, particularly older than 70 years, has been identified as an unfavorable predictor of outcome.[7] This may simply reflect the diminished

likelihood of elderly patients to successfully tolerate the aggressive therapy approaches required for locoregionally advanced cancers of the H&N. Women have been found to achieve somewhat improved outcomes compared to men, although this may in part be a manifestation of earlier-stage disease at diagnosis.[14,15] In addition, tumor location has an impact on outcome, with cancers of the pyriform sinus generally faring better than those arising in the postcricoid or posterior pharyngeal wall regions.[14,15] As a whole, hypopharynx cancer patients fare poorly in comparison with patients harboring tumors from other H&N sites (Figs. 49.3 and 49.4).[4,16] To a lesser extent, tobacco, alcohol, medical comorbidities, and dietary factors may also have an impact on outcome.[17,18]

	DX	1 Year	2 Year	3 Year	4 Year	5 Year
Stage I n=360	100	88.7	75.3	65.8	57.4	50.9
Stage II n=870	100	81	65.6	55.1	47.1	41.1
Stage III n=1,827	100	76.9	59.3	49.7	42.8	37.8
Stage IV n=5,764	100	65.2	43.5	33.8	28.5	25.1

FIGURE 49.4. Observed survival for hypopharyngeal cancer in the United States is calculated for new cases identified in the NCDB as an Aggregate Report from all CoC Hospitals (1233 programs) 2003 to 2009 and includes all pathologic types and the selected anatomic sites: C129, C130, C131, C132, C138, and C139. Staging according to sixth edition of the *AJCC Cancer Staging Handbook.* (From National Cancer Data Base. Commission on Cancer. American College of Surgeons for copyright from the National Cancer Database [NCDB] Survival Reports. Available at: https://m.facs.org/NCDB.SurvivalDS/app/index.html?guid=8989f6dc-9809-4603-8571-7b63548ee64e. Accessed April 17, 2017, with permission from the NCDB.)

Biologic factors have been investigated for their potential role in hypopharyngeal cancer. The presence of p53 gene mutations has been associated with bulkier tumors and younger patients along with higher expression of the epidermal growth factor receptor (EGFR). However, p53 has not shown

correlation with multiple primary tumors, tumor grade, or DNA ploidy.[19,20] Further, there are conflicting data regarding the prognostic significance of EGFR expression for patients with hypopharyngeal cancer.[21] Some studies suggest EGFR overexpression portends a worse prognosis for patients undergoing (chemo)radiotherapy but not for patients treated with primary surgical resection.[22,23]

STAGING

The primary staging system for hypopharynx cancer is the American Joint Committee on Cancer's (AJCC) 2016 eighth edition of the *AJCC Cancer Staging Handbook* and is based on a combination of clinical and radiographic data (Table 49.1).[24] There were no significant changes made between the seventh and eighth editions regarding primary tumor criteria (T-stage) and clinical stage groupings. However, in the eighth edition, the nodal group staging now incorporates extranodal extension (ENE), which constitutes N3b disease regardless of nodal size or laterality. Although AJCC staging is a very useful tool to broadly group similar cancer types, it should not be used as a blueprint for management. Patient factors, including age, comorbid medical conditions, and motivation for organ preservation, are beyond the scope of the staging system but nevertheless represent important factors for consideration with each individual patient.

PATTERNS OF SPREAD

Local Extension

It is sometimes difficult to definitively assign tumor origin to a specific subsite in the hypopharynx when the tumor overlaps more than one subsite. Of the hypopharynx cancer cases recorded in the National Cancer Institute's SEER database between 2000 and 2008, 83% of tumors with a known subsite arose in the pyriform sinus. An additional 9% arose from the posterior pharyngeal wall, and 4% originated in the postcricoid region.[5] Because of the high propensity for advanced primary disease as well as regional nodal involvement, the majority of hypopharynx cancer patients present with stages III and IV disease. In a retrospective study from Washington University, 87% of patients with cancers of the pyriform sinus and 82% of patients with posterior pharyngeal wall tumors presented with stage III or IV disease.[25]

Cancers arising from the pyriform sinus may spread superiorly to involve the aryepiglottic folds and arytenoids and invade the paraglottic and preepiglottic space. Lateral tumor extension can involve portions of the thyroid cartilage, allowing entry into the lateral compartment of the neck. High-resolution computed tomography (CT) or magnetic resonance imaging (MRI) is often useful for optimal assessment regarding the extent of tumor invasion. For tumors arising from the medial wall, the most common site of involvement for pyriform sinus tumors, there is a likelihood of tumor involvement of intrinsic muscles of the larynx resulting in vocal cord fixation. Inferior tumor extension beyond the apex can involve the thyroid gland.

TABLE 49.1 AMERICAN JOINT COMMITTEE ON CANCER 2010 T STAGING FOR HYPOPHARYNX CANCER

T-Stage	Description
T1	Limited to 1 subsite of the hypopharynx and ≤2 cm in greatest dimension
T2	Tumor invades more than 1 subsite of the hypopharynx or an adjacent site, or measures >2 cm but ≤4 cm in greatest diameter without fixation of hemilarynx
T3	Tumor measures >4 cm in greatest dimension or with fixation of hemilarynx or with extension to the esophagus
T4a	Invades thyroid/cricoid cartilage, hyoid bone, thyroid gland, or central compartment soft tissue, which includes prelaryngeal strap muscles and subcutaneous fat
T4b	Tumor invades prevertebral fascia, encases carotid artery, or involves mediastinal structures

From Edge SB, Byrd DR, Compton CC, et al., eds. AJCC cancer staging handbook. 7th ed. New York, NY: Springer, 2010. Copyright © 2010 American Joint Committee on Cancer. Reproduced with permission of Springer International Publishing in the format Book via Copyright Clearance Center.

Cancers arising within the postcricoid region can extend circumferentially to involve the cricoid cartilage or anteriorly to involve the larynx with resultant vocal cord fixation. Tumor involvement of the recurrent laryngeal nerve can also precipitate vocal cord fixation. Primary postcricoid tumors are often quite extensive and can involve the pyriform sinus, trachea, or esophagus. As a result, these tumors generally carry a worse prognosis in comparison to tumors from other subsites of the hypopharynx.[14] Nodal spread to the paratracheal nodes and inferior deep cervical nodes is not uncommon. Tumors arising from the posterior pharyngeal wall can extend to involve the oropharynx superiorly, the cervical esophagus inferiorly, and the prevertebral fascia and retropharyngeal space

posteriorly.

Many cancers of the hypopharynx have a propensity for submucosal spread. It can therefore be difficult to accurately quantify the full microscopic extent of disease. This is particularly true for cancers of the posterior pharyngeal wall and postcricoid regions. Careful study through serial sectioning of surgical specimens has identified that 60% of hypopharynx cancers demonstrate subclinical spread with a range of 10 mm superiorly, 25 mm medially, 20 mm laterally, and 20 mm inferiorly.[26] This extensive pattern of tumor infiltration can present considerable challenge in the effort to achieve clear surgical margins or full dosimetric coverage with radiotherapy.

Regional Disease

Because of the rich lymphatic drainage of the hypopharynx, more than 50% of patients will manifest clinically positive cervical lymph nodes at the time of diagnosis, and ultimately, 65% to 80% of patients will have nodal involvement, as 30% to 40% of N0 necks harbor micrometastatic disease when electively dissected.[27] Jugular chain nodes, levels II to IV, as well as retropharyngeal nodes are all at high risk of harboring regional metastases in patients with hypopharynx cancer. Postcricoid tumors may also spread directly to pre- and paratracheal nodal basins. In light of cross-draining lymphatics, there is a significant risk of bilateral cervical node metastasis (Fig. 49.5).[28,29]

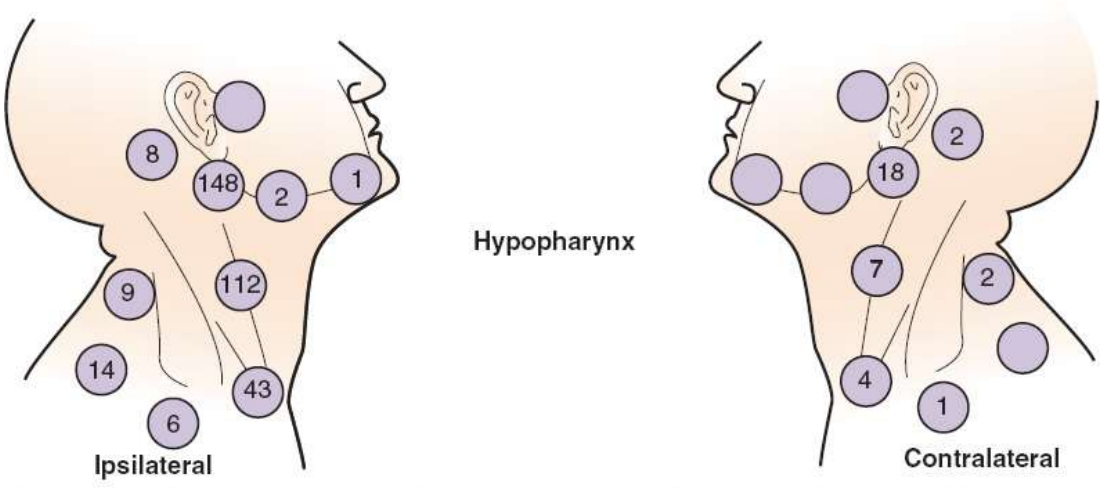
Distant Metastases

The most common site for distant metastasis to develop in patients with cancer of the hypopharynx is the lung. Previously, approximately one-quarter of patients diagnosed with hypopharynx cancer presented with distant metastases, although this incidence in more recent reports is estimated at approximately 16%.[30] For those patients not rendered free of locoregional disease following initial therapy, the incidence of distant metastases increases notably with the length of time following initial treatment.[31]

Field Cancerization

Carcinogens can induce dysplastic changes throughout the mucosa of the upper aerodigestive tract, leading to an increased risk for field cancerization that enhances the likelihood of synchronous or metachronous secondary primary tumors. Approximately 7% of patients with hypopharynx cancer will manifest a second primary tumor at initial diagnosis and between 10% and 20% will develop a secondary primary tumor over time. In fact, this second tumor risk is a

significant cause of mortality in patients who survive more than 2 years following initial treatment.[6]



No	N1	N2A	N2B	N3A	N3B	N1–N3 / Total
65	51	27	45	51	28	202 / 267 = 75%

CLINICAL PRESENTATION

In light of the nonspecific nature of early symptoms, the majority of patients with cancers of the hypopharynx present with advanced local or regional disease. Frequently, there is a delay between presentation and diagnosis as patients are often managed for presumed infectious or gastrointestinal etiology. The majority of symptoms are related to local tumor spread, including dysphagia and odynophagia. There may be frank pharyngeal obstruction, invasion of constrictor muscles, prevertebral space invasion, or strap muscle invasion. Common presenting signs and symptoms include dysphagia, sore throat, hoarseness, weight loss >10 pounds, and neck mass. The majority of patients present with more than one of these signs and symptoms.[32] Roughly 25% of patients will present with clinical stage III disease and 50% with clinical stage IV disease; however, reflux symptoms can be a common presentation leading to diagnosis of stage I or II hypopharyngeal tumors.[6] Selected patients may first come to medical attention with complaints of unilateral ear pain (referred otalgia) due to

tumor involvement of the visceral sensory nerves of the pharynx.

Pretreatment Evaluation and Staging Workup

A comprehensive workup for patients with cancers of the hypopharynx should include a detailed history focusing on the duration of symptoms, amount of weight loss, the presence of otalgia, changes in voice quality, and degree of dysphagia. A previous history of another upper aerodigestive tract malignancy and a history of tobacco smoking are commonly associated. The physical examination should include direct and indirect visualization of the full laryngopharyngeal axis with particular attention to the size, location, and anatomic positioning of the primary tumor as well as the mobility status of the true vocal cords. Dentition and oral health should be assessed. If the patient presents with cervical adenopathy, the size, number, location, texture, and mobility of these nodes should be documented.

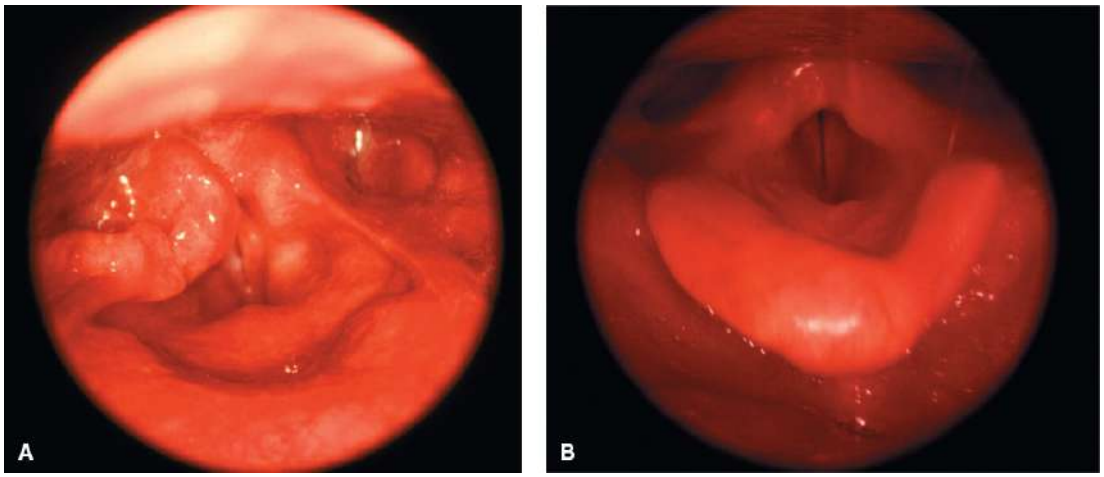

FIGURE 49.6. **A:** Outpatient clinic photograph taken through a rigid endoscope mounted with a 35-mm camera of a newly diagnosed exophytic T2 tumor arising from the right pyriform sinus with involvement of the adjacent aryepiglottic fold. There was no compromise of vocal cord mobility, and clinical staging of the primary lesion was T2. **B:** Photographic examination 1 year following 70-Gy radiation and concurrent cisplatin chemotherapy with complete tumor regression and excellent functional status of the laryngopharynx. Note mild to moderate mucosal edema of supraglottic structures following high-dose radiation.

Although cervical adenopathy associated with hypopharynx cancer may be analyzed with fine needle aspiration (FNA) biopsy, there is little value in this approach, because most patients will receive advanced radiographic imaging to further define the nodal involvement. On rare occasions, FNA may be useful to help distinguish other coexisting causes of lymphadenopathy such as lymphoma.

Most patients will undergo a direct laryngoscopy under general anesthesia in conjunction with esophagoscopy. This panendoscopy allows not only biopsy confirmation of the primary tumor site but also mapping of the extent of the tumor as well as the ability to survey for synchronous primary tumors (Fig. 49.6A). Use of transnasal fiber-optic techniques makes it possible for a panendoscopy to be done for selected patients without anesthesia in the clinic setting.

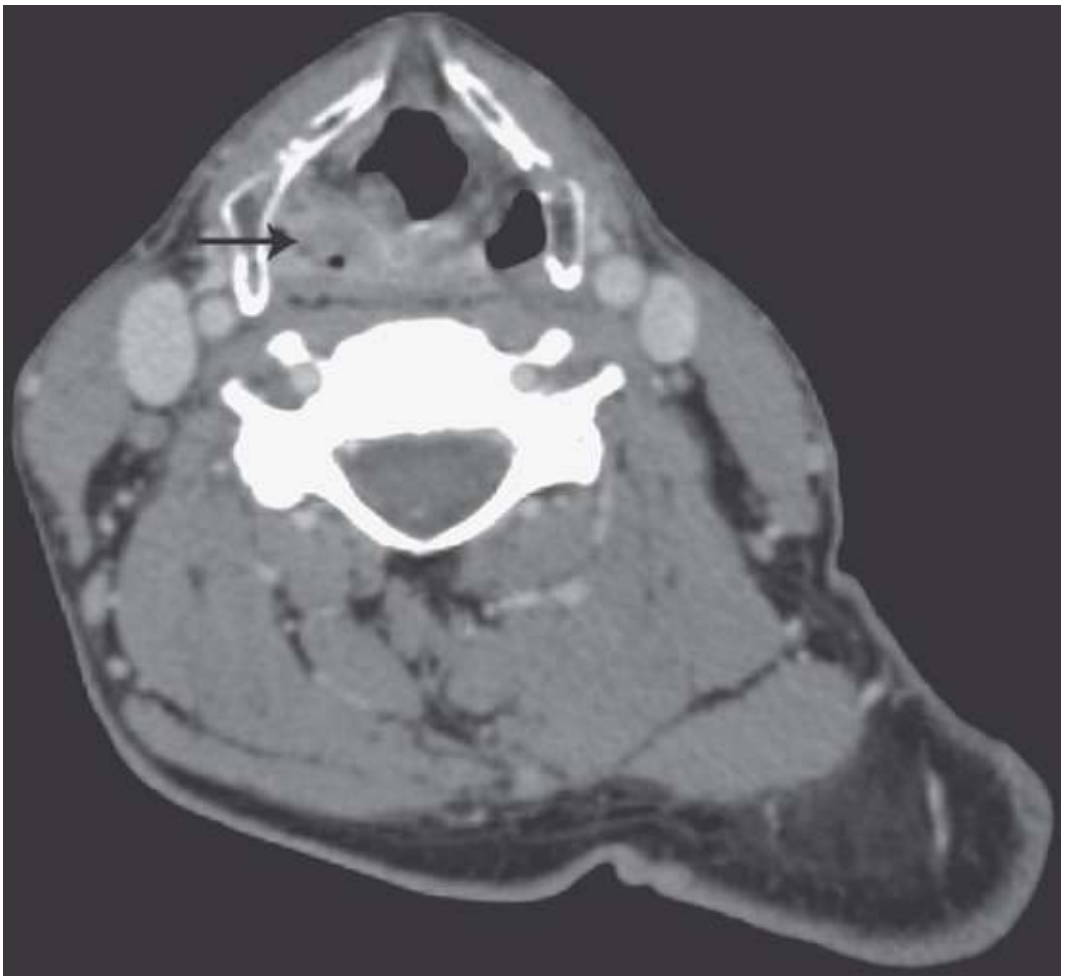

FIGURE 49.7. Axial computed tomography image from the same case as in Figure 49.6, depicting the T2 hypopharynx tumor involving the right pyriform sinus.

In addition to panendoscopy, patients should undergo either high-resolution CT with contrast or MRI extending from the skull base to below the clavicle to help assess the extent of the primary tumor and to quantitatively and qualitatively assess cervical adenopathy (Figs. 49.7 and 49.8).[29] Although a chest x-ray has traditionally been used to assess for the presence of pulmonary

metastasis, 18-fluorodeoxyglucose positron emission tomography (^{18}FDG-PET) imaging (with accompanying CT for coregistration) is increasingly used to assess the extent of regional adenopathy and to survey for the presence of distant metastasis. FDG-PET is becoming an increasingly valuable adjunct to CT or MRI in the radiation treatment planning process, particularly for patients treated with conformal intensity-modulated radiation therapy (IMRT) or tomotherapy techniques. Di Martino et al.[32] compared CT, PET, color-coded duplex sonography, palpation, and panendoscopy in assessment of tumor and nodal status. The results of this study are summarized in Table 49.2 and support the promising sensitivity and specificity of PET scanning in H&N cancers. Schwartz et al.[33] examined standardized uptake value (SUV) of primary and nodal metastasis in H&N cancer patients and their relationship to clinical outcome. A primary tumor SUV >9.0 was associated with a significantly lower local recurrence-free survival and disease-free survival. However, there was no correlation between nodal SUV and clinical outcome.

A recent prospective multicenter study of 233 H&N SCC patients (including 46 hypopharyngeal cancer) highlighted the potential impact of PET imaging on H&N SCC management.[34] TNM staging and therapeutic decisions were first determined based on conventional workup, and then physicians were unblinded to FDG-PET data and asked to restage the patients and reanalyze their therapeutic decisions. PET and conventional workup revealed discordant TNM staging in 100 patients (43%). PET was deemed significantly more accurate than conventional staging and improved the staging in 20% of patients. Incorporation of PET data ultimately impacted management in 32 patients (13.7%) (Table 49.3), supporting the use of FDG-PET in H&N SCC staging.

Many patients with hypopharynx cancer present with concurrent medical and social comorbidities that require consideration before initiating cancer-directed therapy. Commonly, there is a progressive history of dysphagia and odynophagia with associated weight loss. Whether these patients are treated with surgical or nonsurgical approaches, a gastrostomy tube may need to be considered as a temporary measure. It is important to optimize or at least stabilize the patient's nutritional status prior to initiating definitive therapy.

TABLE 49.3 IMPACT OF FDG-PET ON STAGING, MANAGEMENT FOLLOWING CONVENTIONAL WORKUP

End Point	Impact of FDG-PET on 233 Patients
Discordant TNM stage	100 (43%)
PET accurately upstaged	30 (13%)
PET accurately downstaged	17 (7.3%)
PET inaccurately changed stage	13 (5.6%)
No confirmed gold standard TNM	40 (17%)
Impact on Patient Management[a]	
Low	188 patients (80.7%)
Medium	12 patients (5.2%)
High	20 patients (8.6%)

[a]Impact ratings: low, treatment modality and delivery unchanged; medium, change within the same treatment modality (planned procedure, dose, or mode of administration changed); high, change in treatment intent or treatment modality (e.g., curative to palliation, surgery to chemoradiation, and so on).

It is valuable for hypopharynx cancer patients to undergo evaluation by a speech and swallow therapist to determine the degree of dysfunction prior to therapy. This may be done as a bedside study of swallowing capacity, a fiber-optic endoscopic evaluation of swallowing, or (usually preferably) through the more definitive fluoroscopic barium swallow study. This modified barium swallow study is called a cookie swallow, video pharyngogram, or oropharyngeal motility study and is most commonly done with a speech pathologist in attendance. If objective swallowing dysfunction is present, patients may be taught adaptive techniques to improve the effectiveness and safety of their oral intake. Additionally, close follow-up with the same speech and swallow therapist is highly desirable during and after therapy to maximize the patient's long-term functional capabilities.

Because many hypopharynx patients have an active history of alcohol and tobacco use, it is important to counsel accordingly and encourage all patients to take advantage of methods and programs to facilitate smoking and alcohol cessation. All patients should undergo comprehensive dental evaluation and

cleaning as well as basic education regarding oral hygiene. For patients treated with conventional radiation therapy techniques, there is a significant likelihood of long-term xerostomia that can promote dental decay. If existing dentition is in poor condition, dental extractions should be considered prior to therapy, particularly for teeth that will reside within the high-dose radiation region. Typically, 10 to 14 days are required following dental extractions to allow for healing prior to the initiation of radiation therapy. Custom fluoride carrier trays should be fabricated and discussed for long-term use in an effort to diminish the rate of dental decay for patients with chronic xerostomia.

Finally, many patients with hypopharynx cancer will have social issues, including lack of family support, financial limitations, transportation issues, poor nutrition, and hygiene habits that may hamper their ability to successfully receive adequate care. Often, the involvement of a case manager or social worker is of central importance to assist patients who require support both during as well as following cancer therapy.

PATHOLOGIC CLASSIFICATION

In SEER data from 2000 to 2008, 93.9% of hypopharynx cancers were SCC, with lymphoma, sarcoma, adenocarcinoma, and adenoid cystic carcinoma each accounting for approximately 0.5% of cases.[5] Similarly, the National Cancer Data Base (NCDB) Benchmark Reports evaluated 17,654 cases of hypopharyngeal cancer in the United States between the years of 2000 and 2008. Over 90% of cases were SCC.[16]

Management

For patients presenting with early-stage, resectable disease, voice-preserving surgery and definitive radiotherapy alone are viable and acceptable treatment options. The vast majority of patients, however, present with stage III or IV disease and warrant multimodality treatment. Recent analysis of the SEER database reveals a gradual trend away from primary surgery and toward definitive radiation without a decrement in overall survival.[35] A key consideration in determining the favored approach for these patients is the likelihood and motivation to preserve laryngopharyngeal function (Table 49.4).

Primary Surgery

T1 and T2 Tumors

Contemporary indications for primary surgical management of patients with

early cancers of the hypopharynx include those with a history of previous H&N radiation, those in whom organ conservation approaches are deemed possible, and those who refuse radiation. Even for hypopharynx cancer patients who will receive nonoperative treatment approaches, it remains critical for the H&N surgeon to remain actively involved. The role of the surgeon in these cases may include endoscopic biopsy with detailed assessment of tumor extent, methods to secure the airway (tracheotomy or laser debulking), and methods to ensure adequate nutrition (gastrostomy). The surgeon will also play a vital role in multidisciplinary oncologic follow-up after nonoperative treatment.

TABLE 49.4 GENERAL TREATMENT RECOMMENDATIONS BASED ON HYPOPHARYNX TUMOR STAGE

Stage I	Radiation alone or voice preservation surgery if feasible
Stage II	Radiation alone
Stage III and IV with functional laryngopharynx	Concurrent chemoradiation followed by selective neck dissection
Stage III and IV with dysfunctional laryngopharynx[a]	Laryngopharyngectomy with adjuvant RT or CRT

[a]Patients with bulky, destructive tumors that severely compromise the airway or destroy cartilage, bone, and deep soft tissue are often best served with immediate laryngopharyngectomy and postoperative radiation or chemoradiation.
CRT, chemoradiation therapy; RT, radiation therapy.

Selected T1 and T2 hypopharynx cancers may lend themselves to surgical excision. These favorable subsites include the upper pyriform sinus and the posterior pharyngeal wall. The standard supraglottic laryngectomy encompasses the aryepiglottic fold and may be extended to include part of the arytenoids, the base of the tongue, and the upper pyriform sinus. Small cancers isolated to the posterior pharyngeal wall may be removed by endoscopic laser resection or removal using an open approach. Dysphagia requiring nothing by mouth status is common from an open approach, especially if reconstruction of the posterior wall is effected with an adynamic and insensate free flap. Relative contraindications to organ conservation surgery for hypopharynx cancers include cartilage invasion, vocal fold fixation, postcricoid invasion, deep pyriform sinus invasion, and extension beyond the larynx.

Innovations with free flap reconstruction have allowed retention of speech, swallowing, and breathing functions of the larynx despite extensive resection by way of a hemilaryngopharyngectomy. The temporoparietal flap and radial

forearm free flap coupled with rigid cartilaginous support have been employed to retain function in patients with hypopharynx cancers without extension to the postcricoid region or apex of the pyriform sinus.[36]

In recent years, advancements in organ preservation surgery have included the use of transoral laser microsurgery and transoral robotic surgery (TORS). For selected cases, these approaches can achieve oncologic tumor removal while limiting normal tissue disruption, thereby potentially avoiding tracheostomy and the use of feeding tubes.[37–40] This approach may involve concurrent or delayed neck dissection following transoral resection of the primary lesion (to allow for final margin assessment). The necks in some T1N0 patients may be observed with close interval follow-up CT scans. Adjuvant (chemo)radiotherapy is utilized in the majority of patients using this approach (see "Postoperative Radiotherapy" below for indications) and should generally encompass the primary tumor site as well as bilateral necks and supraclavicular fossae. Recent results have demonstrated that appropriately selected T1 or T2 lesions can achieve negative margins by transoral laser microsurgery or TORS.[38] Oncologic outcomes appear similar to open surgical approaches using this technique and are likely accompanied by lower rates of permanent gastrostomy tube or tracheostomy placement (Table 49.5).

TABLE 49.5 FIVE-YEAR ONCOLOGIC OUTCOMES FOR TRANSORAL MICROLASER SURGERY FOR T1 OR T2 HYPOPHARYNGEAL TUMORS

Study (Reference)	T-Stage	N	Node (+)	LC	DSS	OS	Permanent Gastrostomies	Permanent Tracheostomies
Martin et al. (39)	pT1	20	62%	84%	NR	68% (stage I–II)	3.5%[a]	3.5%[a]
	pT2	48		70%	NR			
Karatzanis et al.(38)	pT1	45	56%	90%	78%	NR	0	0
	pT2	74	64%	83%	70%	NR	4%	2.5%

[a]Entire cohort, including T3 and T4 patients.
DSS, disease-specific survival; LC, local control; NR, not reported; OS, 5-year overall survival.

Transoral robotic surgery is currently approved by the Food and Drug Administration (FDA) for treatment of benign and malignant tumors classified as T1 and T2, as well as benign base of tongue resection procedures. Compared

to TLM, it has the advantage of better visualization with a three-dimensional magnified camera, the option to utilized angled endoscopes, and manipulation using “wristed” instruments, which provide the means to resect tumor en bloc. Traditionally, dissection is performed with a grasping instrument and monopolar cautery; however, flexible fiber-optic CO_2 laser delivery may also be utilized via the robotic instrument cart.[41] These instruments provide the means to achieve oncologic tumor removal while limiting tissue disruption, thereby avoiding tracheostomy and feeding tubes. Neck dissection can be done concurrently or staged. Early studies demonstrated oncologic outcomes similar to open approaches.[42]

More recent literature has further supported the efficacy and safety of TORS in treating early-stage hypopharyngeal cancer and continued to demonstrate ability to achieve negative margins in the hypopharynx for T1 and T2 lesions while avoiding tracheostomy and preserving the larynx. The majority of patients in these recent series have functional swallow and voice outcomes as well.[43,44]

The main limitations in TORS are determining whether the tumor is safely resectable, and the ability to gain adequate exposure to visualize the extent of the tumor. As the technology evolves and surgeons build experience with these procedures, additional data will emerge to describe long-term outcome results for patients with early-stage hypopharyngeal cancers.[45]

T3 or T4 Resectable Tumors

Favorable T3 hypopharynx cancers that present in the upper aspect of the pyriform sinus and allow full extirpation by either an extended supraglottic laryngectomy or extended vertical partial laryngopharyngectomy with free flap reconstruction are infrequent. Most T3 and T4 hypopharynx cancers that are treated surgically will require total laryngectomy with efforts to preserve a posterior strip of the hypopharynx spanning the oropharynx to the esophagus. This preserved posterior wall of the hypopharynx may be tubed and closed on itself in selected cases. In the past, it was common practice to accept primary reconstruction of this segment as adequate for swallowing if closure over a nasogastric tube was possible. More recently, primary closure has been discouraged for cases with less than a 3- to 3.5-cm width of posterior pharyngeal wall mucosa to tube on itself. Most commonly superior swallowing results when the anterior and lateral walls of the remaining hypopharynx are reconstructed with a pedicled or free flap.

For more bulky tumors of the hypopharynx, total laryngopharyngectomy,

removal of the larynx and the entire hypopharynx, is required. This procedure creates a gap between the oropharynx and esophagus that must be reconstructed with a tubed fasciocutaneous flap such as the radial forearm free flap or anterolateral thigh flap, a free jejunum, or a tubed pedicled myocutaneous flap. The myocutaneous flaps are technically difficult to tube because of the bulk of the fat and muscle underlying the skin paddle.

Laryngopharyngectomy with esophagectomy may be performed if the hypopharynx cancer extends inferior to the cricopharyngeus to ensure the inferior margin. In this case, gastric pull-up and colon interposition are reconstructive options used to restore the conduit for food and saliva extending from the oropharynx to the stomach.

Palliative Surgery

For patients with incurable, metastatic disease at presentation, or with symptomatic local recurrence not amenable to curative salvage therapy attempts, surgery can play an important role in palliation. If aspiration of secretions (despite nothing by mouth status and enteral feedings) persists, laryngopharyngectomy may afford a reasonable option to discuss with the patient and family members. Similarly, complete stenosis of the pharynx or upper esophagus due to tumor (or following treatment) may leave a patient with the constant need for suctioning his or her own secretions. In selected patients, laryngopharyngectomy with gastric pull-up may be a reasonable palliative option. Finally, gastric feeding tube placement can be considered for patients who do not wish to pursue palliative radiation therapy or surgery.

Postoperative Radiation Therapy

Most advanced hypopharynx cancers that are treated with initial surgical resection have unfavorable features that warrant the addition of postoperative radiation therapy in an effort to enhance locoregional control rates. Classical indications for postoperative radiation include T4 primary tumors, close or positive microscopic margins, cartilage or bony invasion, more than one metastatic lymph node, or the presence of extracapsular extension (ECE). Conventional therapy involves the use of a shrinking field technique to deliver 54 to 63 Gy to all areas at risk and a boost to 60 to 66 Gy to regions of ECE or positive margins. The entire cervical nodal chain from the skull base to the clavicle bilaterally should be included. IMRT techniques may be considered in an attempt to reduce radiation dose to normal tissue structures such as the

contralateral parotid gland and thereby preserve better salivary function.

The Radiation Therapy Oncology Group (RTOG) and European Organization for Research and Treatment of Cancer (EORTC) have evaluated the role of concurrent chemotherapy along with postoperative radiation in prospective randomized trials. Eligibility criteria in the RTOG trial included patients with two or more positive nodes, ECE, or microscopically positive margins. All patients received 60 Gy alone or with concurrent cisplatin 100 mg/m^2 every 3 weeks. This trial demonstrated an improvement in locoregional control and disease-free survival for patients who received concurrent chemoradiotherapy. However, no significant benefit in absolute survival was confirmed (Table 49.6).[46] The EORTC conducted a similar trial that included patients with stage III (except T3N0 larynx), stage IV, and patients with stage I or II with positive margins, lymphovascular invasion, and perineural invasion. All patients received 66 Gy alone or with cisplatin at 100 mg/m^2 every 3 weeks. This trial demonstrated a significant improvement in progression-free survival and overall survival with the addition of chemotherapy (Table 49.7).[47] A subsequently published *post hoc* analysis of the combined data from these trials suggested that patients with ECE and positive margins were most likely to benefit from the addition of chemotherapy, whereas those with two or more involved lymph nodes without ECE as their only risk factor did not appear to benefit from the addition of chemotherapy.[48]

TABLE 49.6 RESULTS OF RTOG POSTOP CHEMORADIATION TRIAL

Although the studies above identify that the addition of cisplatin chemotherapy to postoperative radiation can improve tumor control outcome for specific categories of high-risk patients, it is clear that this modest benefit comes

at the expense of additional toxicity. Careful clinical judgment regarding the selection of patients most likely to tolerate and thereby benefit from this approach is warranted. A recently updated meta-analysis demonstrated similar modest benefit from the addition of concurrent chemotherapy in the postoperative setting as compared to the definitive setting. However, this analysis showed that patients older than 70 years of age derive little to no benefit from the addition of systemic chemotherapy to radiation in H&N cancer.[49] The inadvertent introduction of treatment breaks during the adjuvant radiation course can easily compromise the potential benefits of the combined modality therapy in this setting.

Definitive Radiation Therapy

T1 and T2 Tumors

Curative radiation therapy (RT) is generally the preferred treatment option for patients with T1 or T2 hypopharynx tumors (see Table 46.4). This approach affords good potential for organ preservation without compromise in clinical outcome. A classical course of radiation therapy for hypopharynx cancer lasts 6 to 7 weeks, with treatment delivered 5 days per week. *A review of published clinical results of definitive radiation therapy for H&N cancer suggests a significant loss of local control with prolongation of overall radiation treatment time; therefore, interruptions in treatment once underway should be avoided whenever possible*.[50,51]

Conventional treatment involves a shrinking field technique that initiates with opposed lateral fields encompassing the primary tumor and upper neck lymphatics with a matched anterior field to complete treatment of the lower neck (Table 49.8). One of the most common worldwide fractionation regimens involves the delivery of 2 Gy daily fractions to 70 Gy over 7 weeks. Because of the high likelihood of subclinical nodal metastases even in the clinically N0 neck, patients traditionally receive comprehensive radiation to encompass nodal regions from the skull base to the clavicle. Because of the varying thicknesses of the head and neck, custom compensators or wedges should be used for the lateral fields to improve dose homogeneity. Shrinking field techniques to spare direct spinal cord dose after approximately 45 Gy, as well as final mucosal reductions after 54 to 60 Gy, are often appropriate with posterior neck boosting, with electrons to supplement posterior chain nodal dosing without excessive dose to the spinal cord.

TABLE 49.8 GENERAL ANATOMIC LANDMARKS FOR FIELD DESIGN USING CONVENTIONAL HEAD AND NECK RADIOTHERAPY FOR HYPOPHARYNX CANCER

Border	Description
Superior	Include base of skull
Posterior	Behind vertebral spinous processes (or further if required to cover metastatic cervical lymph nodes)
Inferior	Lower aspect of cricoid cartilage unless extensive caudal tumor extension
Anterior	Flash skin at level of thyroid cartilage

For T1 lesions, classical dose is 66 to 70 Gy in 2 Gy daily fractions. For T2 to T4 lesions, consider altered fractionation regimens or concurrent cisplatin-based chemotherapy, particularly for patients over 70 years of age. Gross disease should generally receive 70 Gy with concurrent chemotherapy.

SCCs of the H&N are rapidly proliferating tumors. There has been significant interest over the past several decades in the use of intensified radiation fractionation schedules to counter rapid tumor cell repopulation as a means of improving outcomes in H&N cancer patients treated with radiation alone. Altered fractionation techniques, including hyperfractionation (e.g., 1.1 to 1.4 Gy twice daily) and accelerated fractionation (e.g., 6 fraction per week or concomitant boost regimens), have demonstrated improved locoregional control rates for H&N cancer patients.[52–54] A meta-analysis examined 15 trials that compared conventional fractionation to altered fractionation, either

hyperfractionation or accelerated fractionation. This meta-analysis demonstrated a small but statistically significant survival benefit of 3.4% at 5 years with altered fractionation. The benefit was higher with hyperfractionation compared to accelerated fractionation and was more pronounced for patients younger than age 50.[55]

Early T-stage hypopharynx patients with N0 or N1 neck disease can be considered for treatment with radiation alone or concurrent radiation plus chemotherapy. In this setting, gross disease should receive 70 Gy and the contralateral neck (N0) should receive 50 to 54 Gy. With T1N0 lesions, patients may achieve 5-year disease-specific survival (DSS) on the order of 90%, whereas T2N0 lesions may achieve DSS above 70% (Tables 49.9 and 49.10).[56–60]

The use of three-dimensional CT-based planning has become routine in the management of H&N cancer patients (Fig. 49.9). CT-based planning allows precise delineation of target volume and visualization of dose distributions (Fig. 49.10). In recent years, there has been significant increase in the use of IMRT in H&N cancer as a means of diminishing normal tissue toxicities, particularly xerostomia resulting from irradiation of major salivary glands. Excellent candidates for IMRT include patients with unilateral T1 to T3 primary lesions with N2b or less neck disease. In light of the high-dose gradients that can accompany highly conformal plans, a critical component of successful IMRT delivery is the use of an accurate and reproducible localization system. At several centers, the optically guided localization system is used to enhance treatment precision for patients undergoing IMRT for H&N cancer.[61] The cephalad margin of the N0 contralateral neck may often be limited to the C1-C2 interspace in an effort to further improve parotid gland sparing.[62,63] A recent randomized trial of conventional radiotherapy versus IMRT in patients with T1-4N0-3 oropharyngeal and hypopharyngeal tumors at high risk for xerostomia highlighted the benefits of IMRT for parotid sparing. Patients were treated either postoperatively or definitively, and the contralateral parotid was constrained to <24 Gy to the whole gland. Grade 2 or worse xerostomia was significantly reduced at both 12 months (74% conventional vs. 38% IMRT) and at 24 months (83% conventional vs. 29% IMRT).[64]

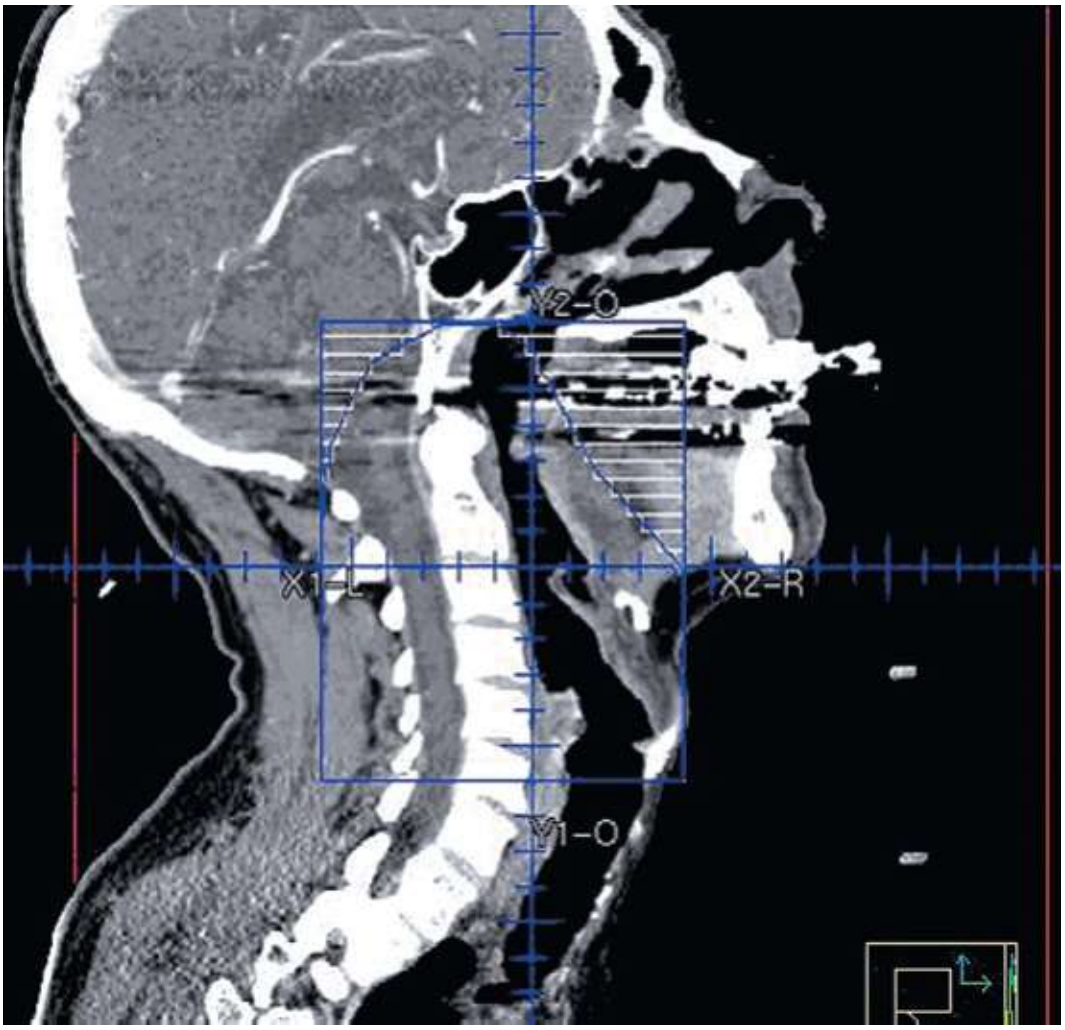

FIGURE 49.9. Digitally reconstructed radiograph depicting a classical lateral field designed to encompass the T2 pyriform sinus cancer from Figures 49.6 and 49.7 plus bilateral cervical lymphatics from skull base to cricoid, with a matching anterior low-neck field to extend the lymphatic coverage to the level of the clavicle.

These benefits translated to significantly better quality-of-life scores in the IMRT group and strongly support a role for IMRT in H&N SCC radiotherapy.

T3 and T4 Tumors

There are several reasons why hypopharynx cancer patients who are technically resectable may not undergo primary surgery. These include age (e.g., patients over 70 to 80 years old), the presence of significant medical comorbidities, or patient unwillingness to accept total laryngectomy. Curative-intent radiation or chemoradiation is often pursued in these settings. Conventional radiation therapy commonly involves a shrinking three-field technique to deliver approximately 70 Gy in 2-Gy daily fractions to areas of gross disease and 50 to 60 Gy to areas

of microscopic disease. If patients are scheduled to undergo postradiotherapy neck dissection, then gross nodal disease can be limited to 60 to 63 Gy. If patients are not candidates for postradiotherapy neck dissection, then gross nodal disease should be carried to 70 Gy. Altered fractionation regimens such as hyperfractionation or accelerated fractionation should be considered for patients being treated with radiation alone given the overall survival benefit observed with these approaches over standard fractionation in meta-analysis.[55]

In patients with adequate performance status, concurrent chemoradiation strategies using platinum-based chemotherapy should be considered. The updated meta-analysis to examine the benefit of chemotherapy in advanced H&N cancer confirms a significant survival advantage for the use of concomitant chemotherapy (6.5%), with the effect of single-agent platin significantly higher than other monochemotherapies.[49] However, this meta-analysis also confirms a steadily decreasing benefit for the use of chemotherapy with advancing patient age, such that no advantage is observed for patients over 70 years of age. This same loss of statistical benefit for patients over 70 years of age is also observed for the outcome gains derived from altered fractionation over conventional fractionation.[55] Therefore, once-daily radiation regimens without concurrent chemotherapy may be quite reasonable for hypopharynx patients over 70 years of age or for those patients with modest performance status.

Another alternative to concomitant chemotherapy or accelerated fractionation is the more recent introduction of molecular targeted therapies in the treatment of H&N cancer patients. The most mature clinical dataset in H&N cancer involves the use of EGFR inhibitors such as cetuximab (monoclonal antibody against the EGFR). An international phase III trial comparing high-dose radiation alone versus radiation plus cetuximab in advanced H&N cancer patients confirmed a locoregional control improvement (10% at 5 years) and overall survival advantage (10% at 5 years) with the addition of cetuximab.[65,66] A relatively small subset of patients with hypopharynx cancer was enrolled in this study of 424 patients, and this subset did not demonstrate a clear advantage with use of the EGFR inhibitor treatment. Ongoing trials to examine the potential value of adding cetuximab to concurrent chemoradiation approaches in advanced H&N cancer are in progress in both the definitive and high-risk postoperative settings.

Management of hypopharynx cancer has gradually evolved over the past decades to reflect the steady advancement of nonsurgical therapy. Data from the

NCDB Benchmark Reports addressing 16,136 cases diagnosed in 2000 to 2008 reveal the combination of radiation and chemotherapy to be the most common initial treatment overall for stage II (32.6%), stage III (47.8%), and stage IV (43.8%) disease (Fig. 49.11).[16] Over 50% of stage III and stage IV cases received initial treatment with chemotherapy in some form—either alone or in combination with radiation or surgery. Radiation as a single-modality therapy was the most common initial treatment for stage I hypopharynx cancer (24.4%), followed by surgery alone (21.0%) as the next most common. It has been reported that approximately 35% to 45% of patients with advanced hypopharyngeal tumors treated with concurrent chemoradiotherapy utilizing IMRT can be expected to live 5 years, with laryngeal preservation in approximately two-thirds of survivors (Table 49.11).[67–69] These survival rates from single institutions utilizing IMRT should be interpreted cautiously in light of less favorable outcomes identified through a cross-sectional analysis of patients diagnosed with hypopharyngeal cancer in the United States in 2003. Review of the NCDB data identified 5-year observed survival for the majority of hypopharyngeal cancers (stage IV) to be only 19.8% (see Fig. 49.4).[16]

The left parotid gland received a mean dose of 22 Gy.

Induction Chemotherapy and Sequential (Chemo)radiation

Recently, there has been renewed interest in the concept of induction chemotherapy approaches for patients with locoregionally advanced H&N cancer. In an effort to examine the potential for organ preservation in patients with advanced cancers of the hypopharynx, the EORTC conducted a randomized trial for patients with tumors that would require total laryngectomy as the surgical approach. This trial randomly allocated patients to induction chemotherapy with cisplatin and 5-florouracil (5-FU) followed by definitive radiation versus primary surgical resection and postoperative radiation. With a median follow-up of 10 years, this trial demonstrated no significant difference in

5- or 10-year overall survival or progression-free survival. Of note, two-thirds of living patients in the chemoradiotherapy arm were able to retain their larynx.[68] More recently, the introduction of taxane-containing regimens have been demonstrated to improve outcomes in patients receiving induction chemotherapy. Three randomized trials have been reported that compare induction 5-FU and cisplatin versus 5-FU, cisplatin, plus a taxane. The EORTC study (TAX-323) randomized patients with locoregionally advanced, unresectable disease to induction cisplatin and fluorouracil (PF) versus induction docetaxel, cisplatin, and fluorouracil (TPF) followed by definitive radiation alone.[70] Treatment with TPF improved the median overall survival from 14.5 to 18.8 months, with a 27% reduction in the risk of death. Similar results were noted in TAX-324, which utilized similar induction chemotherapy arms (TPF vs. PF), followed by concurrent chemoradiotherapy with carboplatin.[71] Five-year survival in the TPF arm was 52% versus 42% receiving PF, while no increased rates of gastric feeding tubes or tracheostomies were noted between groups. A subgroup analysis of larynx and hypopharynx patients demonstrated improved survival in these patients, as well as higher rates of laryngectomy-free survival.[72]

	Stage 0 (N=176)	Stage I (N=1020	Stage II (N=1849)	Stage III (N=3288)	Stage IV (N=9803)
Surg	21%	21.60%	12.30%	6.50%	6.20%

In addition to enhanced survival outcomes, a recent randomized French study demonstrated that TPF induction chemotherapy (compared to PF induction) results in superior tumor response rates (80% vs. 59%) as assessed by laryngoscopy and CT or MRI.[73] Those with response to induction chemotherapy were treated with organ-preserving (chemo)radiotherapy, whereas nonresponders underwent laryngectomy and postoperative (chemo)radiation. The higher response rates in the TPF arm translated into higher rates of laryngeal preservation (70% vs. 57% at 3 years), without a decrease in overall survival (60% at 3 years in both arms). Despite the superiority of TPF chemotherapy over PF, concerns about tolerance of postinduction chemoradiotherapy led to the TREMPLIN trial, which compared induction TPF followed by comprehensive

H&N radiotherapy with either concurrent cisplatin or cetuximab.[74] Indeed, treatment compliance was challenging following completion of TPF with only 43% of patients receiving full-dose systemic therapy on the cisplatin arm and 71% on the cetuximab arm. Patients receiving concurrent cisplatin or cetuximab had similar clinical outcomes with regard to larynx preservation at 3 months (95% and 93%, respectively), larynx function preservation (87% and 82%, respectively), and overall survival at 18 months (92% and 89%, respectively). These aggressive treatment approaches certainly warrant consideration for H&N subsites such as hypopharynx where organ preservation is desirable and overall outcomes are generally poor. Patients with good performance status, no contraindications to taxanes or platins, a high tumor burden and/or advanced nodal disease may be optimal candidates for this approach.[75] Nevertheless, these strategies are toxic and costly, and prospective data support equivalent survival outcomes for patients treated with a 7-week course of concurrent chemoradiotherapy alone.[76] Therefore, careful assessment of tumor control, survival, and long-term functional outcome dovetailed with quality-of-life evaluation are important to place these regimens in best perspective for advanced H&N cancer patients.

Postradiotherapy Neck Dissection

Patients with hypopharynx cancer also require careful evaluation regarding regional nodal metastases. For N0 or N1 patients treated with primary radiation

or chemoradiation approaches, adjuvant neck dissection is generally unnecessary. However, for patients presenting with N2 or N3 neck disease, careful evaluation of tumor response in the neck is important to help gauge the potential value of adjuvant neck dissection following radiation or chemoradiation. An increasing number of reports suggest that detailed imaging of the neck 12 weeks postradiation with FDG-PET can serve as a valuable guide to help select those patients warranting adjuvant neck dissection. One such study from the University of Iowa assessed the value of a postradiation FDG-PET to help select those patients who might benefit most from subsequent neck dissection. For complete clinical responders, the Iowa study concluded that FDG-PET in this setting has a very high negative predictive value. The authors suggest that FDG-PET may be a valuable tool to help determine which patients should undergo adjuvant neck dissection versus observation following the completion of H&N radiation or (chemo)radiotherapy.[77] Despite these emerging data, many institutions mandate adjuvant neck dissection for all patients presenting with N2 or N3 neck disease in an effort to maximize regional disease control.[78–80] Both approaches are readily defendable at present. If neck dissection is performed, this provides an opportunity for the surgeon to reassess the primary tumor site under anesthesia with directed biopsy if suspicious for residual disease. If residual disease at the primary site is highly suspected or confirmed by biopsy several months following completion of radiation or chemoradiation, this will prompt consideration regarding the feasibility and advisability of salvage surgery options.

Palliative Radiotherapy

The management of patients with unresectable locoregional disease without distant metastases is dependent on patient performance status. A patient with a good performance status may be offered definitive radiotherapy, concurrent chemoradiotherapy, or induction chemotherapy with sequential (chemo)radiotherapy, as discussed above. However, patients with poor performance status who are not considered candidates for aggressive radiation or chemoradiation approaches should be managed with palliative intent. This may include short-course radiation regimens such as 4 to 5 Gy x 5 fractions over 1 to 2 weeks with consideration of the same scheme 3 weeks later if the regimen is tolerated and a favorable response is achieved. A recent study suggests using a 3.7-Gy fraction twice daily × 2 consecutive days for 3 cycles every 2 to 3 weeks, as described in RTOG-85-02, may have similar palliative efficacy with less

toxicity as compared to other palliative regimens.[81] Other approaches described include 50 Gy in 16 fractions[82] and 30 Gy in 5 fractions, 2 fractions per week.[83] Systemic chemotherapy alone can be considered, although, for poor performance status patients, best supportive care with medical therapy and airway control may also be appropriate.

Palliative Chemotherapy

As many as one-quarter of hypopharynx cancer patients will develop metastatic disease at some point in their clinical course. In this setting, treatment is palliative and should be delivered to maximize or help maintain quality of life (QOL). If patients are having difficulty with local pain, bleeding, or swallowing, palliative short-course radiation therapy can be delivered, as described above. Surgery may also provide a reasonable palliative option for selected patients who have incurable disease but significant symptoms related to their localized disease, as described above. Many patients in this setting will benefit from narcotic analgesics for pain management.

Patients with adequate or good performance status should be considered for palliative chemotherapy. Median overall survival for patients with metastatic disease is 6 to 10 months.[84] Single-agent cisplatin is usually the first regimen, as it has been shown to improve overall survival.[85] Combinations of cytotoxic chemotherapies have demonstrated improved response rates over cisplatin alone, but have not improved survival and are accompanied by increased toxicity[86] and therefore are uncommonly utilized. However, recent randomized studies have shown efficacy of the anti-EGFR monoclonal antibody cetuximab. In combination with cisplatin as first-line treatment, cetuximab improved overall survival from 7.4 to 10.1 months over cisplatin alone.[87] As second-line therapy in patients who have progressed through platinum-based chemotherapy, cetuximab also has demonstrable activity as either monotherapy[88] or in combination with platinum-based chemotherapy.[89]

COMPLICATIONS

Surgery

The complications from surgery generally fall within the confines of bleeding, infection, reaction to the anesthesia, and damage to structures around or in the field of surgery. The damage to the laryngopharynx that occurs in the course of removing those tissues involved by cancer necessarily interferes with key

laryngeal functions: breathing, swallowing, and speaking.

If an effort is made to preserve laryngeal function, some compromise may be required. A long-term tracheotomy, nothing by mouth status with the use of gastrostomy feedings, and significant dysphonia are not uncommon for patients with hypopharynx cancer treated with conservation laryngeal surgery. These same complications may attend the more comprehensive laryngopharyngectomy as well. Stenosis of the neopharynx, difficulty with alaryngeal speech, and stomal stenosis may compromise the same functions ordinarily ascribed to the larynx. For all open surgical approaches, the risk of a salivary fistula is greatest for those patients previously treated with radiation. Although salivary fistulas are rare with endoscopic approaches, they have occurred in cases requiring aggressive laser resection.

Radiation Therapy

During a course of H&N radiation therapy, there are predictable side effects that are experienced by the majority of patients: mucositis, fatigue, loss of taste acuity, radiation dermatitis, and xerostomia. Typically, patients will begin to experience mucositis during the 3rd week of radiotherapy. This initially manifests as mucosal blanching within the treatment field but can progress to patchy or confluent mucositis. Initially, patients can be treated with an over-the-counter pain reliever, but once patients develop grade II or III mucositis, they will commonly require narcotic analgesics for adequate pain control. The combination of dysphagia and mucositis can result in significant nutritional compromise necessitating intravenous hydration and parenteral nutritional supplementation. Nausea associated with treatment can also further complicate the nutritional status. These acute toxicities can become particularly pronounced in the setting of intensified radiation fractionation schedules or combined chemoradiotherapy. Patients may require prophylactic antiemetics. In patients receiving concurrent radiotherapy and platinum-based chemotherapy, there is clear potential for myelosuppression; therefore, blood counts should be monitored regularly. Signs or symptoms of infection should be addressed promptly. Finally, xerostomia can become problematic during the course of radiation. Ultimately, patients can be reassured that the majority of these side effects, with the exception of xerostomia, are temporary and will resolve several weeks to months following completion of therapy.

As noted, one of the acute side effects of radiotherapy that can become permanent is xerostomia. Chemical and physical modifiers of the radiation

response have been utilized to reduce long-term xerostomia. The free radical scavenger amifostine has the potential to reduce radiation effects on normal tissues if administered just prior to each radiation fraction. A randomized phase III trial demonstrated a reduction in the severity of the acute and chronic grade 2 or higher xerostomia in patients who received amifostine during RT.[90] Dose-limiting toxicities commonly include hypotension and nausea. There has been concern over possible tumor-protective effects of amifostine, but a recent meta-analysis does not suggest this.[91] However, data supporting the use of amifostine to reduce xerostomia have been generated in the setting of conventional radiation, and the magnitude of benefit on xerostomia of parotid-sparing IMRT appears greater than that of amifostine.[62,64] Therefore, the ultimate value of amifostine in patients with advanced H&N cancer, especially in the setting of IMRT, has been called into question.[92] Currently, there is no universal standard recommendation across treatment centers for the use of this radioprotector.

In some cases, hypopharynx cancer patients who complete a course of radiation therapy will be noted to have persistent laryngeal edema on subsequent follow-up visits. Although in the early posttreatment phase (in fact up to 24 months), significant or newfound edema should raise suspicion regarding the possibility of persistent or recurrent disease. The majority of patients who receive high-dose radiation across major segments of the larynx and hypopharynx will manifest some degree of edema, mucosal congestion, and eventual fibrosis (see Fig. 49.6B). Generally, this collateral damage is a tolerable chronic toxicity with modest impact on patient QOL. However, in approximately 10% to 15% of patients, this edema is severe enough to cause significant airway and swallow function compromise requiring tracheostomy. Rarely, more significant complications such as osteoradionecrosis of the cervical spine may occur. In this setting, patients can present with persistent neck pain prompting imaging and biopsy. Most cases can be managed conservatively; however, progression to serious complications including epidural abscess, radiculopathy, and myelopathy has been described. Once neurologic symptoms emerge, they can progress rapidly, indicating the need to maintain vigilance in patients with cervical spine ORN. [93–95]

LONG-TERM FOLLOW-UP

Regardless of whether patients undergo primary surgery or radiation therapy, there is value in close posttreatment surveillance by H&N surgeon and radiation

oncologist in a multidisciplinary fashion. Follow-up care is designed initially to survey for recurrence. As duration from time of intervention to clinic visits lengthen, the focus shifts to surveillance for second primaries (i.e., lung), to address morbidity from treatment, and to provide generalized support.

During the first 6 months after treatment, patients should be followed every 4 to 6 weeks with clinical examination, including fiber-optic nasopharyngoscopy. Recommended guidelines include a follow-up visit every 1 to 3 months during the first year, every 2 to 4 months for the second year, every 4 to 6 months for years 3 through 5, and every 6 to 12 months thereafter. Additionally, if the patient received comprehensive H&N radiation, the serum thyroid-stimulating hormone level should be measured every 6 to 12 months. Imaging evaluation of the neck, most commonly with CT or MRI scan, is obtained at 3- to 6-month intervals during the first 2 years or as indicated based on clinical findings. Functional imaging with ^{18}FDG-PET can sometimes prove valuable to help differentiate posttreatment fibrosis from persistent or recurrent disease.

A study by Hermans et al.[96] examined findings on CT scan of the neck 3 to 4 months following completion of radiation therapy for patients with larynx or hypopharynx cancer to examine correlation with long-term outcome. The authors suggest that in patients achieving complete radiographic resolution of all pretreatment disease, the likelihood of subsequent local failure is very small. These patients might therefore undergo routine clinical examination, with repeat imaging reserved for instances where the clinical examination becomes suspicious for recurrence. For patients who achieved <50% reduction in tumor volume or retained a mass 1 cm or larger on the posttreatment imaging study, the likelihood of local failure was 100% and 30%, respectively. In these patients, repeat CT at 3 to 4 months, FDG-PET, or biopsy is therefore recommended. Preliminary reports indicate that the results of the first post-RT FDG-PET scan may be a strong predictor of developing locoregional disease recurrence.[77]

In the posttreatment setting of hypopharynx cancer patients, the involvement of an experienced H&N radiologist is highly desirable for optimal interpretation of imaging results. Soft tissue changes following ablative surgery and reconstruction, or following high-dose radiation or chemoradiation with resultant edema and fibrosis, can be very difficult to differentiate from tumor, particularly for the inexperienced reader.

MANAGEMENT OF RECURRENCE

After completion of treatment, patients should be followed closely for signs of recurrent or persistent disease. If recurrence is suspected, this should be confirmed by biopsy. If biopsy is confirmatory, then the patient should undergo complete restaging to assess the extent of disease. In the setting of local or regional disease alone, patients treated with initial radiation or chemoradiation can be considered for surgical salvage therapy. Although salvage surgery following comprehensive H&N radiation and chemotherapy presents several resection and reconstructive healing challenges for the surgeon, selected patients may still derive long-term benefit from this approach. Select patients with low-volume localized disease may be candidates for transoral laser microsurgery for recurrent disease following radiation.[97] Recurrent patients who initially received comprehensive H&N radiation have traditionally not been considered good candidates for repeat high-dose radiation in light of normal tissue tolerances. However, two recent prospective RTOG studies have demonstrated that reirradiation to the H&N is feasible.[98,99] With the advent of highly conformal radiation delivery techniques, selected patients may benefit from reirradiation approaches in conjunction with systemic chemotherapy.[100] A retrospective study from Memorial Sloan-Kettering Cancer Center has suggested that IMRT is beneficial for local control in this setting,[101] and a recent prospective trial of reirradiation utilizing IMRT suggests long-term disease control can be achieved in select patients with tolerable toxicity.[102] The use of stereotactic body radiosurgery (SBRT) is becoming more common in the management of head and neck cancer patients who manifest locoregional recurrence. Recent data suggest that patients with laryngeal and hypopharyngeal primaries exhibit significantly more late toxicities compared to those with oral cavity and oropharyngeal primaries, likely related to cartilage in the retreatment region. Therefore, careful consideration should be given to patient performance status, preexisting organ dysfunction, and goals of care prior to delivering ablative doses of radiotherapy in the laryngopharynx.[103]

Many patients with recurrent disease, however, are not good candidates for aggressive surgery or salvage radiation therapy and are best served with systemic chemotherapy or best supportive care approaches.

QUALITY OF LIFE

Assessment of parameters, including functional status, organ preservation, treatment cost, and patient assessment of QOL, plays an increasingly important

role in the evaluation of overall treatment efficacy. For larynx and hypopharynx cancer patients, a focus of contemporary clinical investigation has been the study of treatments designed to preserve laryngeal function for patients traditionally treated with total laryngectomy. A frequently cited but somewhat controversial study by McNeil et al.[104] employed a questionnaire administered to healthy individuals and concluded that some might forgo total laryngectomy in favor of alternative therapy, even if this choice diminished their ultimate chance for cure. A more recent report by El-Deiry et al.[105] evaluated long-term QOL in a matched pair analysis comparing the surgical and nonsurgical treatment of patients with advanced H&N cancer involving the oropharynx, hypopharynx, and larynx. Although patients in the surgery arm demonstrated worse speech outcomes than those treated with chemoradiation, this difference did not carry over to the overall QOL score. These investigators concluded that, although it seems reasonable that organ preservation (nonsurgical) treatment will uniformly result in a higher QOL, the complexities of human adjustment and multitude of potential treatment effects render this assumption invalid for many patients. Alternatively, a study from the Medical University of South Carolina compared swallow-related QOL after surgery or radiotherapy for H&N cancer using a dysphagia symptom survey, the M.D. Anderson Dysphagia Inventory (MDADI). They found significantly better scores on the emotional and functional components of the MDADI for patients undergoing chemoradiation compared to those undergoing surgery followed by radiation.[106]

There have been relatively few prospective assessments of QOL following treatment for H&N cancer. In a subset of locally advanced patients requiring radical surgery, such as total laryngectomy and partial pharyngectomy, the functional deficits are predictable. However, for patients undergoing organ preservation with radiation alone or in combination with chemotherapy, it can be difficult to assess the true extent and quality of organ preservation. Regardless of the primary treatment approach, these patients often require long-term speech, swallow, and dental rehabilitation. A study from Meyer et al.[107] retrospectively assessed speech intelligibility and QOL in survivors of H&N cancer. A total of 64 patients were enrolled; 31 underwent RT alone, 5 underwent surgery alone, and 28 received both. All patients underwent comprehensive subjective and objective testing of speech function and QOL. They found significant subjective and objective deficits in speech and QOL even 5 years after completion of therapy. Terrell et al.[108] reported the results of a self-administered health survey of 570 patients at a Veterans' Administration hospital that demonstrated that the

single most notable event having a negative impact on QOL was placement of a feeding tube. This was followed by medical comorbid conditions, presence of a tracheotomy tube, chemotherapy, and neck dissection.

A prospective study on QOL utilizing the EORTC QLQ-C30 and QLQ-H&N35 questionnaires was conducted in Sweden on 357 patients. This study found that QOL issues were significantly associated with the site of origin, with stage at diagnosis being the most important predictor. Additionally, patients with hypopharynx cancer exhibited the poorest QOL.[109] Similarly, another study prospectively examining swallow function in H&N cancer patients demonstrated that worse swallowing was associated with hypopharyngeal tumor sites.[110] Although the use of IMRT can have a significant impact on xerostomia and QOL measures in H&N cancer patients,[111,112] the intimate approximation of hypopharyngeal tumors to pharyngeal constrictor musculature does not allow for sparing of these structures vital to long-term swallow function, likely contributing to the poorer QOL of hypopharynx patients in comparison to other H&N cancer patients.[113]

CONCLUSION

Patients with cancers of the hypopharynx commonly present with advanced disease associated with varying degrees of compromise in speech or swallow function. Many hypopharynx cancer patients also carry significant medical and social comorbidities. Typically, small T1 or T2 lesions can be managed with either primary radiation or surgery, with similar clinical outcome. For intermediate-stage disease that would require laryngopharyngectomy for the surgical approach, an increasingly preferred treatment option is combined chemoradiation that has demonstrated equivalence to immediate surgery in cancer survival; however, with improved organ preservation and functional outcome. For bulky hypopharynx tumors with significant airway compromise, laryngeal distortion, and cartilage destruction, it is generally best to proceed with definitive surgery with postoperative radiation or chemoradiation.

Despite an aggressive approach in the overall management of hypopharynx cancer patients, ultimate cure rates remain quite poor. There are relatively few early-stage patients; and for many advanced-stage patients, it is difficult to achieve long-term control. Even for those patients with excellent response to therapy, there exists a continuous risk for the development of second malignancies, particularly of the upper aerodigestive track with long-term

follow-up. Posttreatment patients often require aggressive speech and swallow therapy to maximize their functional outcome. There is significant interest in the incorporation of molecular targeted therapies in combination with traditional cytotoxic therapy and radiation in an effort to improve outcomes.

CHAPTER 50

Laryngeal Cancer

William M. Mendenhall, Anthony A. Mancuso, Robert J. Amdur, Brian J. Boyce, and Peter T. Dziegielewski

ANATOMY

The larynx is divided into the supraglottis, glottis, and subglottis. The supraglottis consists of the epiglottis, false vocal cords, ventricles, aryepiglottic folds, and the arytenoids. The glottis includes the floor of the ventricle, interarytenoid area, true vocal cords, and the anterior commissure. The subglottis is located below the vocal cords (Figs. 50.1 and 50.2).[1]

The axial line of demarcation between the glottic and supraglottic larynx is the apex of the ventricle. The demarcation between the glottis and subglottis is ill defined, but the subglottis is considered to extend from a point 5 mm below the free margin of the vocal cord to the inferior border of the cricoid cartilage or 10 mm below the apex of the ventricle.

The vocal cords vary from 3 to 5 mm in thickness and terminate posteriorly with their attachment to the vocal process or the arytenoid cartilage. The posterior commissure is the mucosa between the arytenoids (interarytenoid area).

The shell of the larynx is formed by the hyoid bone, thyroid cartilage, and cricoid cartilage; the cricoid cartilage is the only complete ring of the upper airway. The more mobile interior framework is composed of the heart-shaped epiglottis and the arytenoid, corniculate, and cuneiform cartilages. The corniculate and cuneiform cartilages produce small, rounded bulges at the posterior end of each aryepiglottic fold.

The thyroid and the cricoid cartilages and a portion of the arytenoid cartilage are hyaline cartilage and may ossify with age, particularly in men. The epiglottis is elastic cartilage; ossification does not occur, and even focal calcification is rare.[2]

The external laryngeal framework is linked together by the thyrohyoid, the cricothyroid, and the cricotracheal ligaments or membranes (Figs. 50.3 and 50.4).[1]

The epiglottis is joined superiorly to the hyoid bone by the hyoepiglottic ligament. The epiglottis is joined to the thyroid cartilage by the thyroepiglottic ligament at a point just below the thyroid notch and above the anterior commissure. This area of attachment is the *petiole* of the epiglottis. The arrangement of the ligaments that connect the cricoid and arytenoid cartilages and form the vocal ligaments is shown in Figure 50.2B.[1] The conus elasticus (cricovocal ligament) is the lower portion of the elastic membrane that connects the inferior framework. It connects the upper surface of the cricoid, the vocal process of the arytenoid, and the lower thyroid cartilage; its free border is thickened into the vocal ligament. The quadrangular membrane is the upper

portion of the elastic membrane that connects the superior framework. It connects the false vocal cords, aryepiglottic folds, and the epiglottis.

The vocal ligaments and thyroarytenoid/vocalis muscle complex attach to the vocal process of the arytenoid posteriorly and the thyroid cartilage anteriorly. The intrinsic muscles of the larynx, which primarily control the movement of the cords, are presented in Figures 50.2 and 50.3.[1] The extrinsic muscles are concerned primarily with swallowing. The cricothyroid muscle draws the larynx anteriorly and inferior when contracting. The consequence is increased vocal cord tension leading to increased pitch of the voice. It is innervated by the external branch of the superior laryngeal nerve (Fig. 50.4).[1] The intrinsic muscles of the larynx are innervated by the recurrent laryngeal nerve.

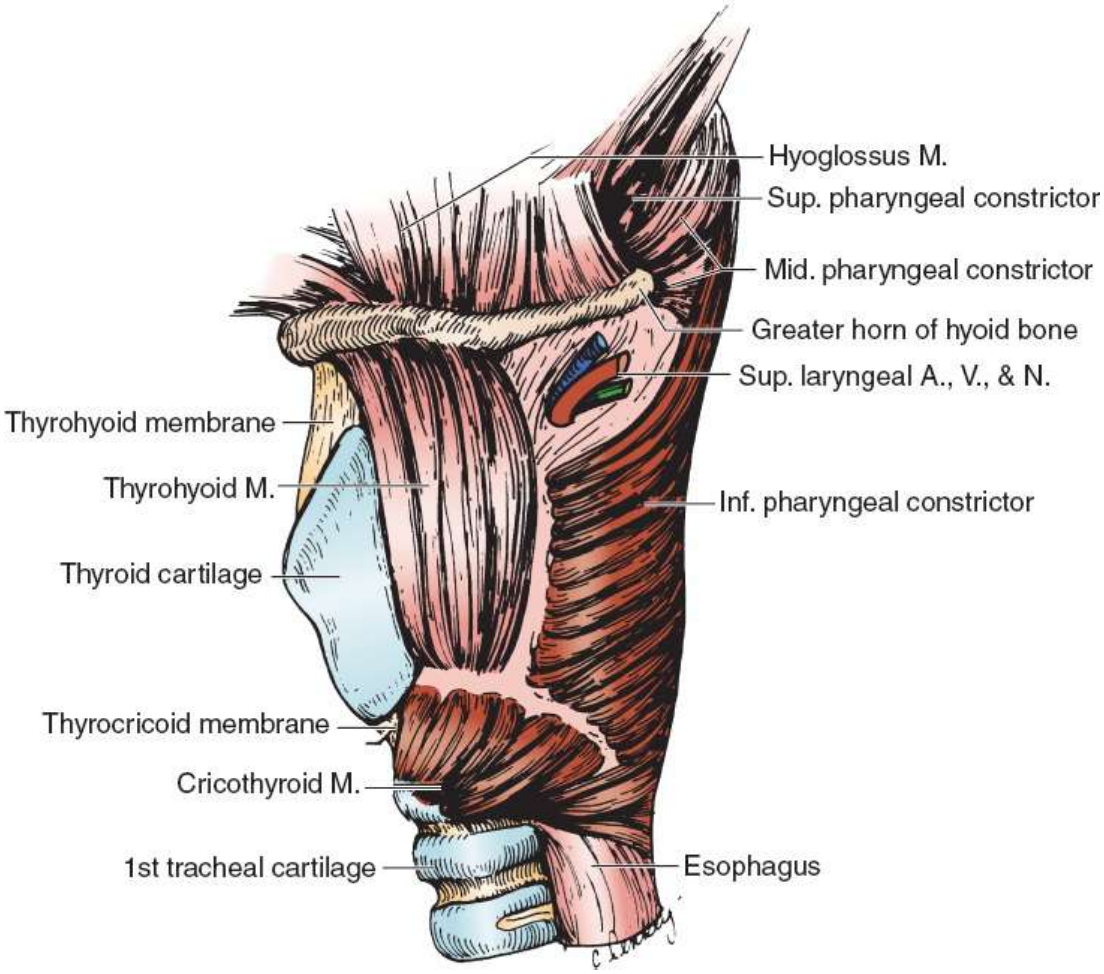

FIGURE 50.4. External view of the larynx. (Reprinted from Paulsen F, Waschke J, Sobotta J. *Sobotta Atlas of Human Anatomy*. 15th ed. Munich: Urban & Fischer, 2011. Copyright © 2011 Elsevier GmbH. With permission.)

The preepiglottic and paraglottic fat spaces are essentially one contiguous

space lying between the external framework of the thyroid cartilage and hyoid bone and the inner framework of the epiglottis and intrinsic muscles. Lam and Wong[3] showed that there are thin membranous septa between the paraglottic and preepiglottic spaces, which produce a barrier to tumor spread to a limited degree. The space is traversed by blood and lymphatic vessels as well as nerves. Because few capillary lymphatics arise in this area, invasion of the fat space seldom leads to lymph node metastases. The fat space is limited by the conus elasticus inferiorly; the thyroid ala, thyrohyoid membrane, quadrangular membrane, and hyoid bone anterolaterally; the hyoepiglottic ligament superiorly; and the fascia of the intrinsic muscles medially. Posteriorly, it is adjacent to the anterior wall of the pyriform sinus.

The laryngeal surface of the epiglottis and the free margin of the vocal cords are squamous epithelium, and the remaining mucosa is usually pseudostratified ciliated columnar epithelium. Beneath the epithelium of the free edge of the vocal cord is the lamina propria, which can be divided into three layers. There is no true submucosal layer along the free margin of the vocal fold.[4] The laryngeal arteries are branches of the superior and inferior thyroid arteries.

The supraglottic structures have a rich capillary lymphatic plexus; the trunks pass through the preepiglottic space and the thyrohyoid membrane and terminate mainly in the jugulodigastric (level II) lymph nodes; a few drain to the middle internal jugular chain (level III) lymph nodes.

There are essentially no capillary lymphatics of the true vocal cords; as a result, lymphatic spread from glottic cancer occurs only if tumor extends to supraglottic or subglottic areas.

The subglottic area has relatively few capillary lymphatics. The lymphatic trunks pass through the cricothyroid membrane to the pretracheal (delphian) lymph nodes in the region of the thyroid isthmus. The subglottic area also drains posteriorly through the cricotracheal membrane, with some trunks going to the paratracheal (level VI) lymph nodes and others continuing to the inferior jugular (level IV) chain.

EPIDEMIOLOGY AND RISK FACTORS

Cancer of the larynx represents about 2% of the total cancer burden and accounts for 0.3% of all cancer deaths. It is the second most common head and neck mucosal cancer. In 2016 in the United States, there were approximately 13,430 new cases of cancer of the larynx (10,550 men and 2,880 women) and about

3,620 deaths from laryngeal cancer.[5] Based on 1973 to 1998 US data, at diagnosis, about 51% of the cases remain localized, 29% have regional spread, and 15% have distant metastases.[6] The ratio of glottic to supraglottic carcinoma is approximately 2:1.

Cancer of the larynx is strongly related to cigarette smoking. The risk of tobacco-related cancers of the upper alimentary and respiratory tracts declines among former smokers after 5 years and is said to approach the risk of nonsmokers after 10 years of abstention.[7] The role of alcohol in provoking laryngeal cancer remains unclear.[8] Some evidence exists that heavy marijuana smoking may be associated with laryngeal cancer in young patients.

PATTERNS OF SPREAD

Local Spread

Although supraglottic and glottic lesions tend to remain confined to their original compartments, there is no anatomic barrier to growth from one area to the next. Glottic lesions tend to be slow growing, but as they increase in size, they extend to the supraglottic and subglottic areas. Supraglottic lesions do not often start near the vocal cords. Involvement of the cords on their external epithelial surface is a late phenomenon, but submucosal extension by way of the paraglottic space occurs earlier.

The fat space is an important avenue of submucosal tumor spread for infrahyoid epiglottis, false cord, and true vocal cord lesions. As the false cord and the true vocal cord lesions penetrate anteriorly and laterally, they quickly encounter the tough perichondrium of the thyroid cartilage and may eventually be shunted by the conus elasticus (lateral cricothyroid membrane) out of the larynx via the cricothyroid space. Thyroid cartilage invasion usually occurs in the ossified section of the cartilage, commonly in the region of the anterior commissure tendon or the junction of the anterior one-fourth and the posterior three-fourths of the thyroid lamina.[9]

Fixation of the vocal cord from laryngeal cancer is usually caused by invasion or destruction of the vocal cord muscle, invasion of the cricoarytenoid muscle or joint, or, rarely, invasion of the recurrent laryngeal nerve. Perineural spread is uncommon.

Supraglottic Larynx

Suprahyoid Epiglottis

A lesion of the suprahyoid epiglottis may produce a large exophytic mass with little tendency to destroy cartilage or spread to adjacent structures. Other lesions may infiltrate the tip and destroy cartilage. The destructive lesions tend to invade the vallecula and preepiglottic space, the lateral pharyngeal walls, and the remainder of the supraglottic larynx.

Infrahyoid Epiglottis

Lesions of the infrahyoid epiglottis tend to produce irregular tumor nodules and simultaneously invade the porous epiglottic cartilage and thyroepiglottic ligament into the preepiglottic fat space and extend toward the vallecula and base of the tongue. The thick hyoepiglottic ligament is an effective tumor barrier. However, the tumor may present in the vallecula and base of tongue without involving the suprahyoid epiglottis.

Lesions of the infrahyoid epiglottis grow circumferentially to involve the false cords, aryepiglottic folds, medial wall of the pyriform sinus, and the pharyngoepiglottic folds. Invasion of the anterior commissure and cords and anterior subglottic extension usually occur only in advanced lesions. Infrahyoid epiglottic lesions that extend onto or below the vocal cords are at a high risk for thyroid cartilage invasion, even if the cords are mobile.[10]

False Cord

Early false cord carcinomas, which are usually submucosal with little exophytic component, are difficult to delineate accurately. They involve the paraglottic fat space early in their development and may spread a considerable distance beneath the mucosa without producing physical signs. These carcinomas extend to the perichondrium of the thyroid cartilage quite early, but cartilage invasion is a late phenomenon. Extension to the lower portion of the infrahyoid epiglottis and invasion of the preepiglottic space are common. Submucosal extension involves the true vocal cord, which may appear normal. Vocal cord invasion is often associated with thyroid cartilage invasion. Submucosal extension to the medial wall of the pyriform sinus occurs early.

Aryepiglottic Fold/Arytenoid

Early lesions of the aryepiglottic fold/arytenoid are usually exophytic. It may be difficult to decide whether the lesion started on the medial wall of the pyriform sinus or on the aryepiglottic fold. As the lesions enlarge, they extend to adjacent sites and eventually cause fixation of the larynx, which is usually a result of involvement of the cricoarytenoid muscle or joint or, rarely, invasion of the

recurrent laryngeal nerve. Computed tomography (CT) may distinguish the cause of fixation. Advanced lesions invade the thyroid, epiglottic, and cricoid cartilages and eventually invade the pyriform sinus and postcricoid area.

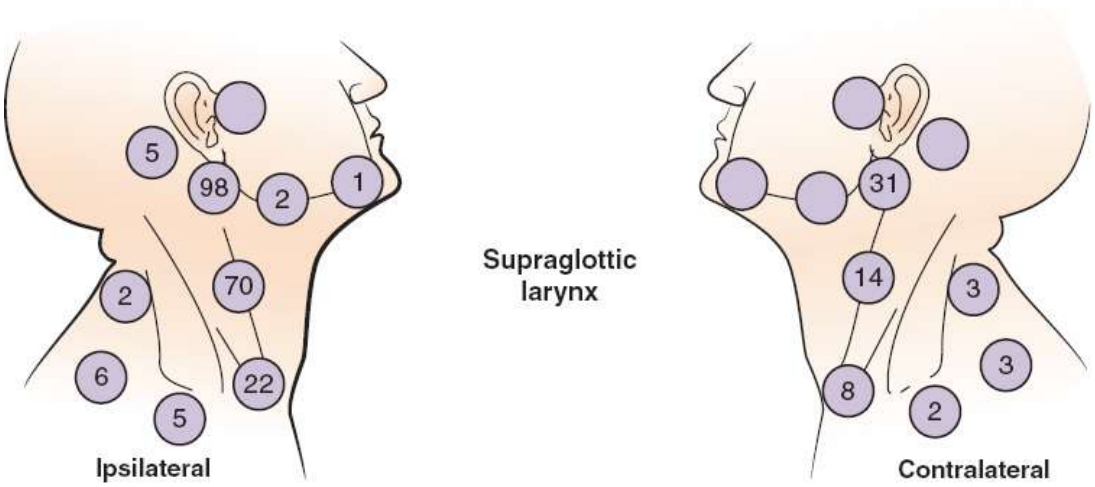
Glottic Larynx

Most lesions of the true vocal cord begin on the free margin and upper surface of the cord. When diagnosed, about two-thirds are confined to the cords, usually one cord. The anterior portion of the cord is the most common site. Anterior commissure involvement, which is common, is said to occur when no tumor-free cord can be seen anteriorly; if the lesion crosses to the opposite cord, anterior commissure invasion is certain. Small lesions isolated to the anterior commissure account for only 1% to 2% of cases. Extension to the posterior commissure is uncommon, occurring only in advanced lesions.

Tumors at the anterior commissure may extend anteriorly via the anterior commissure tendon (Broyles ligament)[11] into the thyroid cartilage. Kirchner,[12] using whole-organ sections, showed that such extension is unusual unless the tumor extends off the vocal cord onto the base of the infrahyoid epiglottis and suggested that the tendon serves as more of a barrier than an avenue of tumor spread. Early subglottic extension is also associated with involvement of the anterior commissure, and tumor may grow through the cricothyroid membrane.

Lesions that arise on the posterior half of the vocal cord tend to extend along the submucosa toward the medial side of the vocal process and invade the cricoarytenoid joint and posterior commissure; this spread is difficult to appreciate by clinical examination.

Subglottic extension may occur by simple mucosal surface growth, but it more commonly occurs by submucosal penetration beneath the conus elasticus. One centimeter of subglottic extension anteriorly or 4 to 5 mm of subglottic extension posteriorly brings the border of the tumor to the upper margin of the cricoid, exceeding the anatomic limits for conventional hemilaryngectomy. Lesions may spread beneath the epithelium along the length of the vocal cord within Reinke space.[13]



No	N1	N2A	N2B	N3A	N3B	N1–N3 / Total
120	49	15	29	11	43	147 / 267 = 55%

FIGURE 50.5. Nodal distribution on admission, MD Anderson Cancer Center, 1948–1965. (From Lindberg RD. Distribution of cervical lymph node metastases from squamous cell carcinoma of the upper respiratory and digestive tracts. *Cancer* 1972;29[6]:1446–1449. Copyright © 1972 American Cancer Society. Reprinted by permission of John Wiley & Sons, Inc.)

As vocal cord lesions enlarge, they extend to the false cord, vocal process of the arytenoid, and subglottis. Infiltrative lesions invade the vocal ligament and muscle and eventually reach the paraglottic space and the perichondrium of the thyroid cartilage. Advanced glottic lesions eventually penetrate through the thyroid cartilage or via the cricothyroid space to enter the neck, where they may invade the thyroid gland. Lesions involving the anterior commissure often exit the larynx via the cricothyroid membrane after they extend subglottically.[13]

A fixed cord that is associated with a lesion having <1 cm of subglottic extension and no false cord involvement does not ordinarily indicate invasion of the thyroid cartilage.[12] If the false cord is also involved, cartilage invasion is likely.

Subglottic Larynx

Subglottic cancers are rare.[14] Most involve the inferior surface of the vocal cords by the time they are diagnosed, so it is difficult to know whether the tumor started on the undersurface of the vocal cord or in the true subglottic larynx. Because early diagnosis is uncommon, most lesions are bilateral or circumferential at discovery. They involve the cricoid cartilages in the early stage because there is no intervening muscle layer. Partial or complete fixation

of one or both cords is common; misdiagnosis or diagnostic delay is frequent.

Lymphatic Spread

The location and stage of neck nodes detected on admission for previously untreated patients with squamous cell carcinoma of the supraglottic larynx are given in Figure 50.5.[15] The disease spreads mainly to the level II nodes. The level Ib nodes are rarely involved, and there is only a small risk of level V lymph node involvement. The incidence of clinically positive nodes is 55% at the time of diagnosis; 16% are bilateral.[15] Elective neck dissection shows pathologically positive nodes in at least 16% of cases; observation of initially node-negative necks eventually identifies the appearance of positive nodes in 33% of cases.[16,17] Spread to the pyriform sinus, vallecula, and base of the tongue increases the risk of lymph node metastases. The risk of late-appearing contralateral lymph node metastasis is 37% if the ipsilateral neck is pathologically positive, but the risk is unrelated to whether the nodes in the ipsilateral neck were palpable before neck dissection.

The incidence of clinically positive lymph nodes at diagnosis for vocal cord carcinoma approaches zero for T1 lesions and is <2% for T2 lesions,[18] *but it* increases to 20% to 30% for T3 and T4 lesions. Glottic spread is typically associated with metastasis to the level II nodes. Anterior commissure and anterior subglottic invasion are also associated with involvement of the midline pretracheal lymph node (level VI).

Lederman[19] reported a 10% incidence of positive lymph nodes in 73 patients with subglottic carcinoma.

CLINICAL PRESENTATION

Carcinoma arising on the true vocal cords produces hoarseness at a very early stage. Odynophagia, otalgia, pain localized to the thyroid cartilage, and airway obstruction are features of advanced lesions.

Hoarseness is not a prominent symptom of cancer of the supraglottis until the lesion becomes extensive. Odynophagia, usually mild, is the most frequent initial symptom, often described as a sore throat. Some patients report a sensation of a “lump in the throat.” Pain is referred to the ear by way of the Arnold branch of the vagus nerve. A neck mass may be the first sign of a supraglottic cancer. Late symptoms include weight loss, halitosis, dysphagia, and aspiration.

DIAGNOSTIC WORKUP

Physical Examination

Flexible fiberoptic endoscopes provide the best view of the larynx, hypopharynx, and posterior oropharynx. The scope is inserted through the nasal passage and passed over the nasopharyngeal side of the soft palate to provide a "bird's-eye" view of the larynx. The mucosal surfaces of the base of the tongue, posterior pharyngeal wall, vallecula, hypopharynx, supraglottis, glottis, and subglottis are examined. Vocal cord mobility is determined by asking the patient to say "ee" (adduction) and sniff in (abduction). Subtle distinctions between paresis and paralysis may require multiple examinations or stroboscopy.

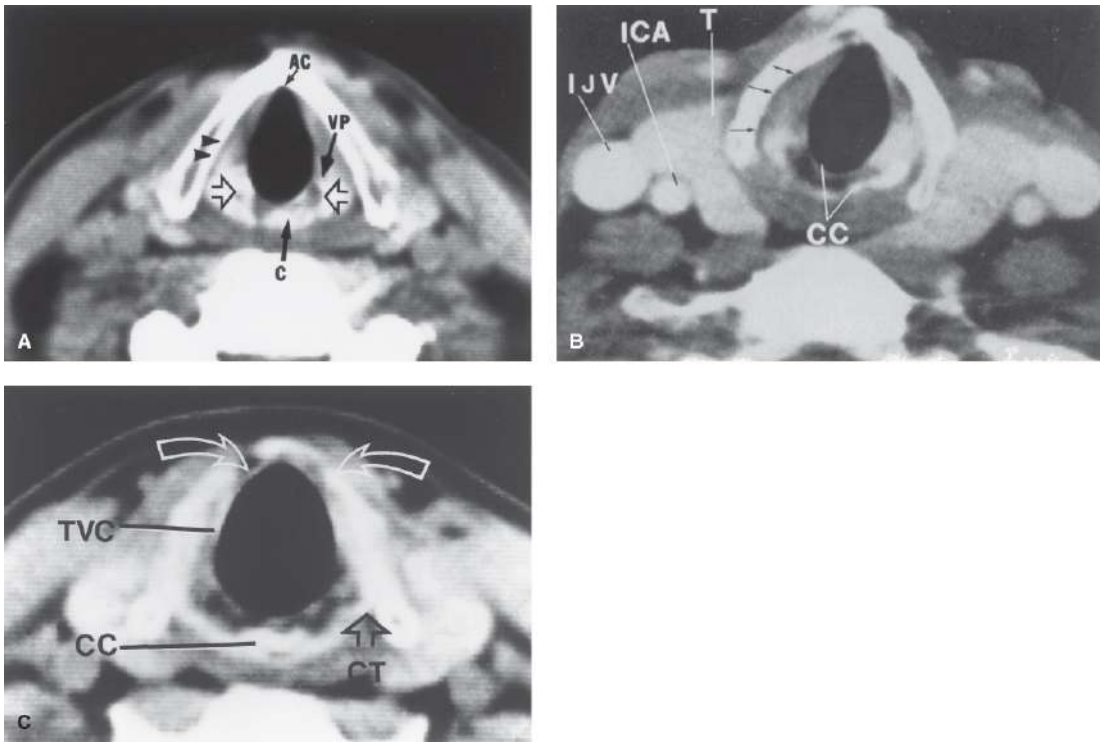


FIGURE 50.6. A: Normal CT anatomy of the midplane of the true vocal cords. *Open arrows* indicate arytenoid cartilages. The top of the cricoid cartilage (*C*) is partially visualized at this level. The vocal process (*VP*) of the left arytenoid cartilage is demonstrated. A narrow, low-density plane is seen between the right true vocal cord and the thyroid lamina (*arrowheads*); this is the inferior part of the paraglottic fat space. Notice the complete lack of tissue at the anterior commissure (*AC*). *Any tissue density here should be considered abnormal*. **B:** Normal CT anatomy just below the midplane of the vocal cords. *Arrows* indicate low-density lower paraglottic fat space. The fibrofatty tissue in this space facilitates separation of the vocal cord and the adjacent thyroid lamina. If this clear space is maintained in the face of the thyroid lamina irregularity adjacent to the tumor, the lamina abnormality can be attributed to uneven calcification rather than tumor destruction. The posterior portion (lamina) of the cricoid cartilage (*CC*) is seen. The outer and inner cortex of the cartilage is

calcified; an intervening marrow space has lower density. The vertical height of the lamina is 2 to 3 cm. There is incomplete calcification of the thyroid cartilage anteriorly. ICA, internal carotid artery; IJV, internal jugular vein; T, thyroid gland. **C:** Normal CT anatomy 5 mm below the free margin of the true vocal cord (*TVC*). The vocal cord appears thin because of abduction during scanning. There is incomplete bilateral paramedian calcification and thinning of the thyroid lamina (*arrows*). Notice the normal lack of tissue density between the airway and the anterior arch of the thyroid cartilage. CC, cricoid cartilage; CT, cricothyroid joint. (From Million RR, Cassisi NJ. Larynx. In Million RR, Cassisi NJ, eds. *Management of head and neck cancer: a multidisciplinary approach*. Philadelphia: JB Lippincott, 1984:315–364. With permission.)

Ulceration of the infrahyoid epiglottis or fullness of the vallecula is an indirect sign of preepiglottic space invasion. Palpation of diffuse, firm fullness above the thyroid notch with widening of the space between the hyoid and the thyroid cartilages signifies invasion of the preepiglottic space. The preepiglottic fat space is a low-density area on the CT scan, and changes resulting from tumor invasion are easily seen.

Postcricoid extension may be suspected when the laryngeal click disappears on physical examination. Postcricoid tumor may cause the thyroid cartilage to protrude anteriorly, producing a fullness of the neck. Invasion of the thyroid cartilage remains a difficult clinical diagnosis. Localized pain or tenderness to palpation or a small bulge over one ala of the thyroid cartilage is suggestive.

Radiographic Studies

CT scan with contrast enhancement is often the method of choice for studying the larynx (Fig. 50.6).[20] The CT scan should be performed before biopsy so that abnormalities that may be caused by the biopsy are not confused with tumor. CT is preferred to magnetic resonance (MR) imaging because the longer scanning time for MR results in motion artifact.[21] CT slices 1 to 2 mm thick are obtained at 1- to 2-mm intervals through the larynx and at 3-mm intervals for the remainder of the study. Thinner sections (1 to 2 mm through the larynx) facilitate high-quality multiplanar reformations. The gantry is angled so that the scan slices are parallel to the plane of the true vocal cords. It is also necessary to obtain a CT scan of the entire neck to detect positive, nonpalpable lymph nodes. Positive retropharyngeal nodes may be present at diagnosis in patients with laryngeal cancer who have advanced neck disease.[22] Retropharyngeal adenopathy will not be apparent on physical examination but is usually appreciated on CT scan. Contrast enhancement helps to outline the blood vessels and the thyroid gland. Tumor is often enhanced, probably because of reactive

inflammatory changes.

The value of MR imaging includes defining subtle exolaryngeal spread or early cartilage destruction as well as the extent of tracheal invasion and esophageal invasion. Sagittal MR may also be useful in detecting early invasion of the base of the tongue.

Vocal Cord Carcinoma

Although the CT scan does not show minimal mucosal lesions and is generally not helpful for well-defined and easily visualized T1 or early T2 vocal cord carcinomas, it is almost always obtained. CT is excellent for determining subglottic extension and is often used in selected T1 and most T2 lesions for this reason alone. CT scanning is useful in the diagnosis of moderately advanced and advanced lesions; it is excellent for demonstrating extension outside the larynx into the soft tissues of the neck and has potential for determining thyroid or cricoid cartilage invasion, which tends to occur at the edges of the cartilage rather than on the faces. Early cartilage involvement is difficult to detect with axial scans, but it may be demonstrated by coronal or sagittal scanning techniques. If the low-density plane of the paraglottic space is intact, cartilage is probably not invaded by tumor.

Archer et al.[23] correlated CT findings with the incidence of cartilage or bone invasion on whole-organ sections. For 12 of 14 patients with pathologic evidence of cartilage invasion, the average diameter of the tumor in two dimensions was >16 mm, and the lesion was located below the top of the arytenoid. Lesions in which the maximum diameter lay above the top of the arytenoid had a low incidence of cartilage invasion.[23]

Supraglottic Carcinoma

The CT scan provides an excellent means for viewing the preepiglottic and paraglottic fat spaces. Soft tissue extension into the neck or base of the tongue can also be seen. The CT scan is also useful for determining extension to the subglottis.[2]

Diagnostic procedures for laryngeal cancer at the University of Florida are summarized in Table 50.1.[24] A CT scan is usually performed for all patients; MR is obtained in a small subset of patients with questionable findings on CT. Positron emission tomography is not routinely obtained; although it may be useful to evaluate suspicious lymph nodes, it would change the treatment. Chest CT is usually obtained to detect pulmonary metastases, particularly in patients

with positive cervical nodes. It may also be useful to identify the occasional synchronous lung cancer. Direct laryngoscopy and biopsy with frozen section are usually performed with the patient under general anesthesia. The ventricles, subglottis, apex of the pyriform sinus, and postcricoid area must be carefully examined because these areas are not consistently seen by indirect examinations. Fiberoptic telescopes (0 and 30 degrees) are introduced through the laryngoscope for inspection of these areas. A generous biopsy specimen is taken from the obvious lesion; additional biopsy specimens may be obtained from suspicious areas and from areas grossly involved. The mucosa of the margin of the cord may be stripped to provide adequate tissue if the lesion is distributed superficially along the cord and is not obviously a carcinoma.

STAGING

The 2017 American Joint Committee on Cancer (AJCC)[25] staging system for laryngeal primary cancer is listed in Table 50.2. T2 glottic cancers are stratified into those with normal (T2A) and impaired (T2B) vocal cord mobility. For lesions arising in the supraglottis, the sites of origin include false cords, aryepiglottic folds, suprahyoid epiglottis, infrahyoid epiglottis, pharyngoepiglottic folds, and arytenoids. Only in the early T stages can one identify the specific site of origin with certainty. As the lesion enlarges, the site of origin is often an educated guess based on the location of the greatest tumor bulk/density. The major difference between the 1998 and 2010 staging systems is that a glottic cancer that invades the paraglottic space is upstaged to T3 in the

latter system, even with mobile vocal cords, resulting in significant stage migration.[26] In addition, T4 has been stratified into T4A and T4B, based on resectability.

TABLE 50.2 STAGING OF LARYNGEAL CANCER

Supraglottis	
TX	Primary tumor cannot be assessed
Tis	Carcinoma *in situ*
T1	Tumor limited to one subsite of supraglottis with normal vocal cord mobility
T2	Tumor invades mucosa of more than one adjacent subsite of supraglottis or glottis or region outside the supraglottis (e.g., mucosa of the base of the tongue, vallecula, medial wall of the pyriform sinus) without fixation of the larynx.
T3	Tumor is limited to the larynx with vocal cord fixation and/or invades any of the following area: postcricoid space, preepiglottic space, paraglottic space, and/or inner cortex of the thyroid cartilage
T4	Moderately advanced or very advanced
T4a	Moderately advanced local disease; tumor invades through the thyroid cartilage and/or invades tissues beyond the larynx (e.g., trachea, soft tissues of the neck including deep extrinsic muscles of the tongue, strap muscles, thyroid, or esophagus)
T4b	Very advanced local disease; tumor invades prevertebral space, encases carotid artery, or invades mediastinal structures
Glottis	
TX	Primary tumor cannot be assessed
Tis	Carcinoma *in situ*
T1	Tumor limited to the vocal cord(s) (may involve the anterior or posterior commissure) with normal mobility
T1a	Tumor limited to one vocal cord
T1b	Tumor involves both vocal cords.
T2	Tumor extends to the supraglottis and/or subglottis with impaired vocal cord mobility.
T3	Tumor limited to the larynx with vocal cord fixation and/or invasion of paraglottic space and/or inner cortex of the thyroid cartilage
T4	Moderately advanced or very advanced
T4a	Moderately advanced local disease; tumor invades through the outer cortex of the thyroid cartilage and/or invades tissues beyond the larynx (e.g., trachea, cricoid cartilage, soft tissues of the neck including deep extrinsic muscle of the tongue, strap muscles, thyroid, or esophagus)
T4b	Very advanced local disease; tumor invades the prevertebral space, encases the carotid artery, or invades mediastinal structures

PATHOLOGIC CLASSIFICATION

Nearly all malignant tumors of the larynx arise from the surface epithelium and therefore are squamous cell carcinoma or one of its variants.

Carcinoma *in situ* occurs frequently on the vocal cords. Differentiating among dysplasia, carcinoma *in situ*, squamous cell carcinoma with microinvasion, and true invasive carcinoma is a problem that the pathologist and the clinician frequently confront.

Most vocal cord carcinomas are well or moderately well differentiated. In a few cases, an apparent carcinoma and sarcoma occur together, but most of these are actually a spindle cell carcinoma (i.e., squamous cell carcinoma with a spindle cell stromal reaction).

Verrucous carcinoma occurs in 1% to 2% of patients with carcinoma of the vocal cord. The histologic diagnosis is difficult and must correlate with the gross appearance of the lesion.

Small cell neuroendocrine carcinoma is rarely diagnosed in the supraglottic larynx, but it should be recognized because of its biologic potential for rapid growth, early dissemination, and responsiveness to chemotherapy.[27]

Minor salivary gland tumors arise from the mucous glands in the supraglottic and subglottic larynx, but they are rare.[28] Even rarer are paragangliomas, carcinoids, soft tissue sarcomas, malignant lymphomas, and plasmacytomas. Benign chondromas and osteochondromas are reported, but their malignant counterparts are rare.

PROGNOSTIC FACTORS

The extent of the primary lesion and neck disease are the major determinants of prognosis. The likelihood of local control is determined primarily by T stage; there are conflicting data pertaining to a possible inverse relationship between N stage and local control. The likelihood of local–regional control is affected primarily by the overall AJCC stage, which accounts for both T stage and N stage. AJCC stage and N stage are the major determinants of cause-specific survival. In addition, within each N stage, patients with positive nodes in the low neck below the level of the thyroid notch tend to have a lower cause-specific survival rate than do those with disease confined to the upper neck. In general, women tend to have a better prognosis than do men.

TREATMENT SELECTION AND TECHNIQUE: VOCAL CORD CARCINOMA

Selection of Treatment Modality

In treating vocal cord carcinoma, the goal is cure with the best functional result and the least risk of a serious complication. Patients may be considered to be in an early group if the chance of cure with larynx preservation is high, a moderately advanced group if the likelihood of local control is 60% to 70% but the chance of cure is still good, and an advanced group if the chance of cure is moderate and the likelihood of laryngeal preservation is relatively low.[29] The early group may be treated initially by radiotherapy (RT) or, in selected cases, by transoral laser microsurgery (TLM) or transoral robotic surgery (TORS).[30] The moderately advanced group may be treated either with RT with laryngectomy reserved for relapse or by total laryngectomy with or without adjuvant postoperative RT. The obvious advantage of the former strategy, which is used at the University of Florida, is that there is a fairly good chance that the larynx will be preserved.[31] Although some patients may be rehabilitated with a tracheoesophageal puncture after laryngectomy, only about 20% of patients use this device long term, and the majority use an electrolarynx.[32] The advanced group is treated with total laryngectomy and neck dissection with or without adjuvant RT or by RT and adjuvant chemotherapy.[33] Data suggest that if patients whose tumors show a partial or complete response to two to three cycles of neoadjuvant chemotherapy are then given high-dose RT, the cure rates are comparable with those obtained with initial total laryngectomy.[34] Another less expensive and less toxic method to select patients likely to be cured by RT alone is to calculate the primary tumor volume on pretreatment CT or MR. Data indicate that primary tumor volume is inversely related to the probability of local control after irradiation.[35,36] Recent data indicate that whereas induction chemotherapy probably does not improve the likelihood of local–regional control and survival, concomitant chemotherapy and RT result in an improved likelihood of cure compared with RT alone.[37–39] There is a subset of patients with high-volume (>3.5 cc), unfavorable, advanced cancers who may be cured by chemoradiation but have a useless larynx and permanent tracheostomy and/or gastrostomy.[35] These patients are best treated with a total laryngectomy, neck dissection, and postoperative RT.[40]

Carcinoma *In Situ*

Lesions diagnosed as carcinoma *in situ* can be treated with TLM. However, it is

difficult to exclude the possibility of microinvasion on these specimens. Recurrence is frequent if the patient continues to smoke, and the cord may become thickened and the voice hoarse with repeated treatments.

Early RT for carcinoma *in situ* often means a better chance of preserving a good voice, especially because many patients with this diagnosis eventually receive this treatment.[37]

Many patients with a diagnosis of carcinoma *in situ* have obvious lesions that probably contain invasive carcinoma. We have often proceeded with RT rather than put the patient through a repeated biopsy procedure.

Early Vocal Cord Carcinoma

In many centers, RT is the initial treatment prescribed for T1 and T2 lesions, with surgery reserved for salvage after RT failure.[18,41,42] However, TLM and TORS have shown comparable cure rates with the possibility of using RT for recurrences.[41,43,44] Supracricoid laryngectomy, as reported by Laccourreye et al.,[45] is a procedure designed to remove moderate-sized cancers involving the supraglottic and glottic larynx. The larynx may be removed with preservation of the cricoid and the arytenoid with its neurovascular innervation; the defect is closed by approximating the base of the tongue to the remaining larynx. The oncologic and functional results of this procedure in selected patients are reported to be excellent. TLM also may provide high cure rates for select patients with small, well-defined lesions limited to the mid one-third of one true cord.[46–50] A small subset of TLM surgeons successfully use this technique for moderately advanced cancers.[41] The major advantage of RT compared with partial laryngectomy is better quality of the voice. The advantages of surgical treatments include avoidance of RT, single treatment, and cost-effectiveness. However, if voice quality is important for the patient, surgery should be avoided. Open partial laryngectomy finds its major use as salvage surgery in suitable cases after RT failure. Even if the patient has a local recurrence after salvage partial laryngectomy, there is a third chance with total laryngectomy, which may still be successful.

Verrucous lesions have the reputation of being unresponsive to RT and, in some instances, converting into invasive, often anaplastic, metastasizing lesions. Partial laryngectomy is recommended for early verrucous carcinoma of the glottis, but RT is recommended if the alternative is total laryngectomy. We have observed typical verrucous lesions that have disappeared with RT and not recurred. O'Sullivan et al.[51] also made this observation. In addition, a variety of

tumors that recur after unsuccessful treatment (with surgery, RT, and/or chemotherapy) are more likely to exhibit more aggressive behavior.

Moderately Advanced Vocal Cord Cancer

Fixed-cord lesions (T3) may be subdivided into relatively favorable or unfavorable lesions. Patients with unfavorable lesions usually have extensive bilateral disease with a compromised airway and are considered to be in the advanced group. Patients with favorable T3 lesions have disease confined mostly to one side of the larynx, have a good airway, and are reliable for follow-up. Some degree of supraglottic and subglottic extension usually exists. The extent of disease and tumor volume are related to the likelihood of control after RT.[35]

The patient with a favorable lesion is advised of the alternatives of RT with surgical salvage or immediate total laryngectomy. Recent data suggest that the likelihood of local–regional control is better after some altered fractionation schedules compared with conventional once-daily RT.[39,52] Follow-up examinations are recommended every 4 to 6 weeks for the 1st year, every 6 to 8 weeks for the 2nd year, every 3 months for the 3rd year, every 6 months for the 4 and 5th years, and annually thereafter. The patient must understand that total laryngectomy may be recommended purely on clinical grounds without biopsy-proven recurrence and that the risk of laryngeal osteochondronecrosis is about 5%.

Evaluation of cord mobility after 50.4 Gy or at the end of RT has not been helpful in predicting local control.[36] Some patients in whom the vocal cord remained fixed have had local tumor control of the disease for 2 years or longer after RT.

The major difficulty in using RT for the more advanced lesions is distinguishing radiation edema from local recurrence during follow-up examinations.[53] Progressive laryngeal edema, persistent throat pain, or fixation of a previously mobile vocal cord frequently signifies recurrent disease in the larynx, although a few patients with these findings remain disease free with long-term follow-up.

Extended hemilaryngectomy has been used by a few surgeons in the treatment of well-lateralized fixed-cord lesions. A permanent tracheostomy is usually required because a portion of the cricoid is resected, but a useful voice may be retained.[54]

Advanced Vocal Cord Carcinoma

Advanced lesions usually show extensive subglottic and supraglottic extension, bilateral glottic involvement, and invasion of the thyroid, cricoid, and/or arytenoid cartilages.[9,23] The airway is compromised, necessitating a tracheostomy at the time of direct laryngoscopy in approximately 30% of patients. Clinically positive lymph nodes are found in about 25% to 30% of patients.

The mainstay of treatment is total laryngectomy, with or without adjuvant RT. The most frequent sites of local failure after total laryngectomy are the tracheal stoma, the base of the tongue, the neck lymph nodes, and/or or soft tissues of the neck. If the neck is clinically negative before surgery and if postoperative RT is planned, neck dissection may be withheld, and RT may be used to treat both sides of the neck. However, in practice, most surgeons prefer to perform elective bilateral selective (levels II to IV) neck dissections in conjunction with a total laryngectomy for T3 N0 or T4 N0 laryngeal cancer, even if postoperative RT is planned. If the lymph nodes are clinically positive, a therapeutic neck dissection is performed at the time of laryngectomy.

The indications for postoperative RT include close or positive margins, significant subglottic extension (1 cm or more), cartilage invasion, perineural invasion, lymphovascular space invasion, extension of the primary tumor into the soft tissues of the neck, multiple positive neck nodes, and extracapsular extension.[55,56] Preoperative RT is indicated for patients who have fixed neck nodes, have had an emergency tracheotomy through tumor, or have direct extension of tumor involving the skin.

Definitive RT is prescribed for the patient who refuses total laryngectomy or is medically unsuitable for major surgery.

As previously stated, there is evidence that two to three cycles of induction chemotherapy followed by RT in patients obtaining at least a partial response may provide a moderate likelihood of larynx preservation without compromising cure.[34] Data suggest that concomitant chemotherapy and RT is more efficacious than RT alone or induction chemotherapy followed by RT.[37,38] The optimal combination of concomitant chemotherapy and irradiation is unclear.[39]

A randomized intergroup trial (RTOG 91-11) compared three treatment arms: arm A, three cycles of induction cisplatin and fluorouracil followed by RT in complete and partial responders; arm B, RT and concomitant cisplatin (100 mg/m^2 on days 1, 22, and 43 of RT); and arm C, once-daily RT (70 Gy in 35 fractions over 7 weeks) alone.[37] Five hundred forty-seven patients were randomized and followed for a median of 3.8 years; 518 patients were evaluable.

The rates of larynx preservation were as follows: arm A, 72%; arm B, 84%; and arm C, 67%. The rates of larynx presentation were significantly improved for arm B; there was no significant difference between arms A and C. The 5-year survival rates were similar for the three treatment groups: arm A, 55%; arm B, 54%; and arm C, 56%. The likelihood of developing distant metastases was lower for the two groups of patients that received adjuvant chemotherapy.

Surgical Treatment

Cordectomy is an excision of the vocal cord and may be performed by a TLM or TORS approach or externally by a thyrotomy. Its use is usually confined to small lesions of the middle one-third of the cord. After cordectomy, a pseudocord is formed, and the patient has a useful, if somewhat harsh, voice.

Vertical partial laryngectomy (i.e., hemilaryngectomy) allows removal of limited cord lesions with preservation of voice. One entire cord with as much as one-third of the opposite cord with the adjacent thyroid cartilage is the maximum cordal involvement suitable for surgery in men; women have a smaller larynx, and usually only one vocal cord may be removed without compromising the airway. Partial fixation of one cord is not a contraindication to hemilaryngectomy; a few surgeons perform a hemilaryngectomy for selected fixed-cord lesions. The maximum subglottic extension suitable for hemilaryngectomy is 8 to 9 mm anteriorly and 5 mm posteriorly; this limit is necessary to preserve the integrity of the cricoid. Tumor extension to the epiglottis, false cord, or both arytenoids is a contraindication to hemilaryngectomy.

Supracricoid partial laryngectomy is used for selected T2 and T3 glottic carcinomas and entails removal of both true and false cords as well as the entire thyroid cartilage. The cricoid is sutured to the epiglottis and hyoid (cricohyoidoepiglottopexy).

Total laryngectomy with or without neck dissection is the operation of choice for advanced lesions and as a salvage procedure for RT failures in lesions that are not suitable for conservation surgery. The entire larynx is removed, and the pharynx is reconstructed. A permanent tracheostomy is required. Speech may be reconstituted with a prosthesis or with an electrolarynx. One hundred four (63%) of 166 patients entered into the surgery and postoperative irradiation arm of the Veterans Affairs Laryngeal Cancer Study Group randomized trial were evaluable for voice rehabilitation at 2 years after treatment.[57] Ninety-six patients had undergone a total laryngectomy and communicated as follows:

tracheoesophageal, 27 (28%); esophageal, 5 (5%); artificial larynx, 47 (50%); nonvocal, 7 (7%); and no data, 10 (10%).[57] One hundred seventy-three patients underwent total laryngectomy and postoperative RT at the University of Florida, and 69 patients were evaluable for 5 years or longer.[32] Voice rehabilitation was accomplished as follows: tracheoesophageal, 19%; electrolarynx, 57%; esophageal, 3%; nonvocal, 14%; and no data, 7%.

Radiation Therapy Technique

RT for T1 or T2 vocal cord cancer is delivered by small portals covering only the primary lesion.[42] The cervical lymph node chain is not electively treated. For T1 lesions, RT portals extend from the thyroid notch superiorly to the inferior border of the cricoid and fall off anteriorly. The posterior border depends on the posterior extension of the tumor.[21] For T2 tumors, the field is extended depending on the anatomic distribution of the tumor. The field size ranges from 4 × 4 cm to 5 × 5 cm (plus an additional 1.0 cm of "flash" anteriorly) and is occasionally 6 × 6 cm for a large T2 lesion. Portals larger than this increase the risk of edema without improving the cure rate. IMRT may be considered for T1–T2 glottic cancers to reduce the dose to carotid arteries.[42] The potential advantages of this technique must be weighed against the potential increased likelihood of a marginal miss.

A commonly used dose fractionation schedule at many institutions is 66 Gy for T1 lesions and 70 Gy for T2 cancers given in 2-Gy fractions. Evidence suggests that increasing the dose per fraction may improve the likelihood of local control.[58–62] Ample data suggest that 1.8 Gy once daily results in significantly lower local control rates compared with 2.0 Gy once daily.[59] Yamakazi et al.[63] reported a prospective trial in which patients with T1 N0 squamous cell carcinoma of the glottic larynx were randomized to definitive RT at 2.0 Gy per fraction or 2.25 Gy per fraction. The 5-year local control rates were 77% after 2.0 Gy per fraction and 92% after Gy per fraction (P = .004); there was no difference in either acute or late toxicity. Patients with T1 or T2 vocal cord cancer treated with once-a-day fractionation at the University of Florida are irradiated with 2.25-Gy fractions; the dose fractionation schemes used are as follows: Tis–T2 A, 63.0 Gy in 28 fractions, and T2B, 65.25 Gy in 29 fractions. Concomitant weekly cisplatin 30 ng/M^2 is considered for patients with T2B cancers.

At the University of Florida, patients are treated in the supine position; the field borders for a patient with a T1 N0 cancer are depicted in Figure 50.7.[21] The

field is checked by the physician at the treatment machine according to palpable anatomic landmarks. This allows the treatment volume to be kept at a minimum and reduces the risk of geographic miss. A three-field technique, using 4- or 6-MV x-rays, is used to deliver approximately 95% of the dose through opposed lateral wedged fields weighted to the side of the lesion; the remaining dose is delivered by an anterior field shifted 0.5 cm toward the side of the lesion (Fig. 50.8).[21] The tumor dose is usually specified at the 95% normalized isodose line.

RT of T3 and T4 lesions requires larger portals, which include the levels II and III lymph nodes (Fig. 50.9).[20,64] The level IV lymph nodes are included in a separate low-neck portal. Patients treated at the University of Florida are irradiated in a continuous course twice daily at 1.2 Gy per fraction to a total dose of 74.4 Gy. The portals are reduced after 50.4 Gy in 42 fractions; the reduced portals cover only the primary lesion.

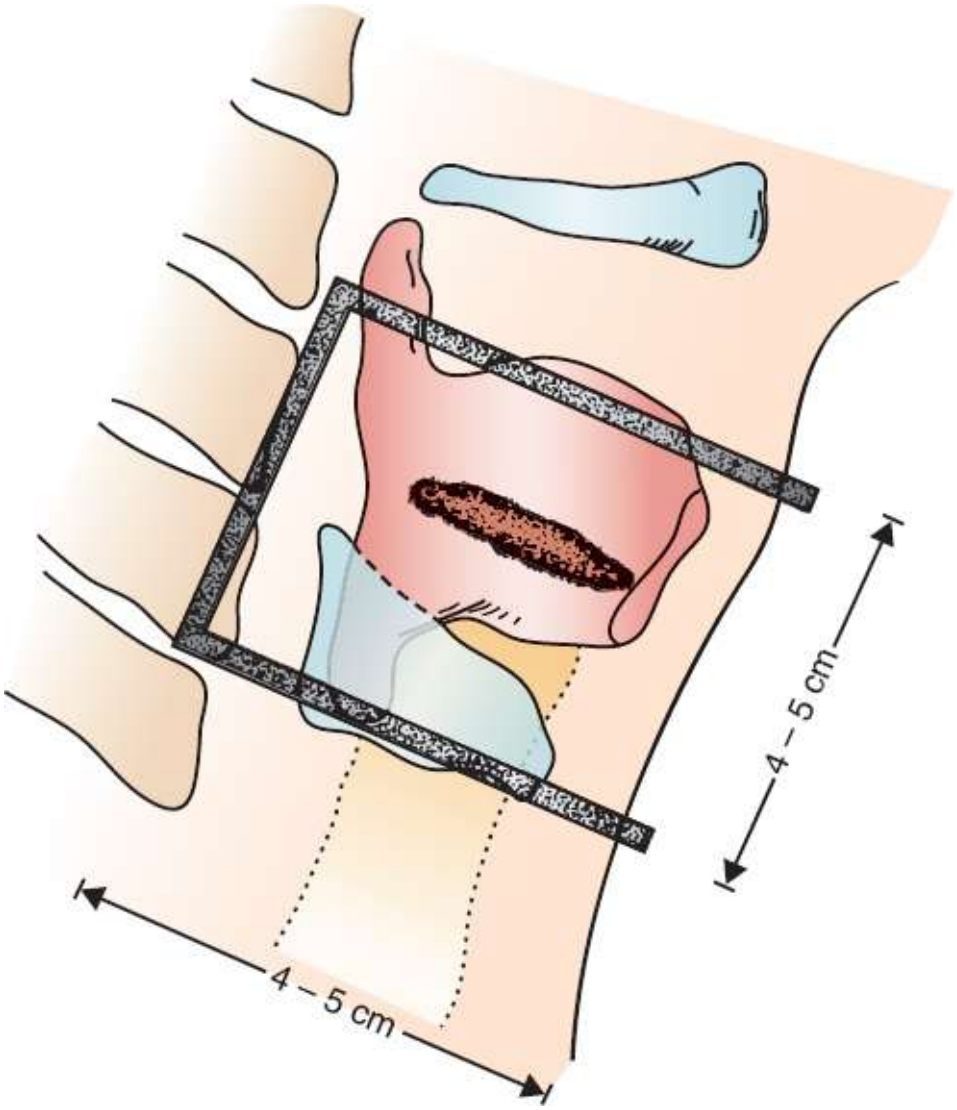

FIGURE 50.7. Conventional treatment portal for early glottic carcinoma. The top border is adjusted according to the lesion. The middle of the thyroid notch is the landmark for very early lesions, and the top of the notch is the marker for larger lesions or those with minimal supraglottic extension. The posterior border is 1 cm posterior to the back edge of the thyroid cartilage if the lesion is confined to the anterior two-thirds of the vocal cord; if the posterior one-third of the vocal cord is involved, the posterior border is placed 1.0 to 1.5 cm behind the cartilage. The inferior border is placed at the bottom of the cricoid cartilage if there is no subglottic extension. (From Million RR, Cassisi NJ, Mancuso AA. Larynx. In: Million RR, Cassisi NJ, eds. *Management head of neck and cancer: a multidisciplinary approach.* 2nd ed. Philadelphia: JB Lippincott, 1994:431–497. With permission.)

Intensity-modulated RT (IMRT) is used if there is a clear advantage associated with this technique. Disadvantages associated with IMRT include increased dose inhomogeneity, increased total body dose, and increased labor and expense.[65] The most common indications for IMRT for laryngeal cancers

would be the occasional patients with a node-positive T3–T4 cancer, where the retropharyngeal nodes would be electively irradiated and the dose to the contralateral parotid gland reduced, and/or a difficult low match between the lateral fields used to treat the primary site and upper neck and the anterior low-neck field in a patient with a short neck and large shoulders. In the latter instance, IMRT could be used to encompass the entire target volume and avoid the problem of field junctioning entirely. IMRT is especially useful for patients with extensive subglottic invasion, where achieving an adequate inferior margin with conventional lateral portals may not be possible.

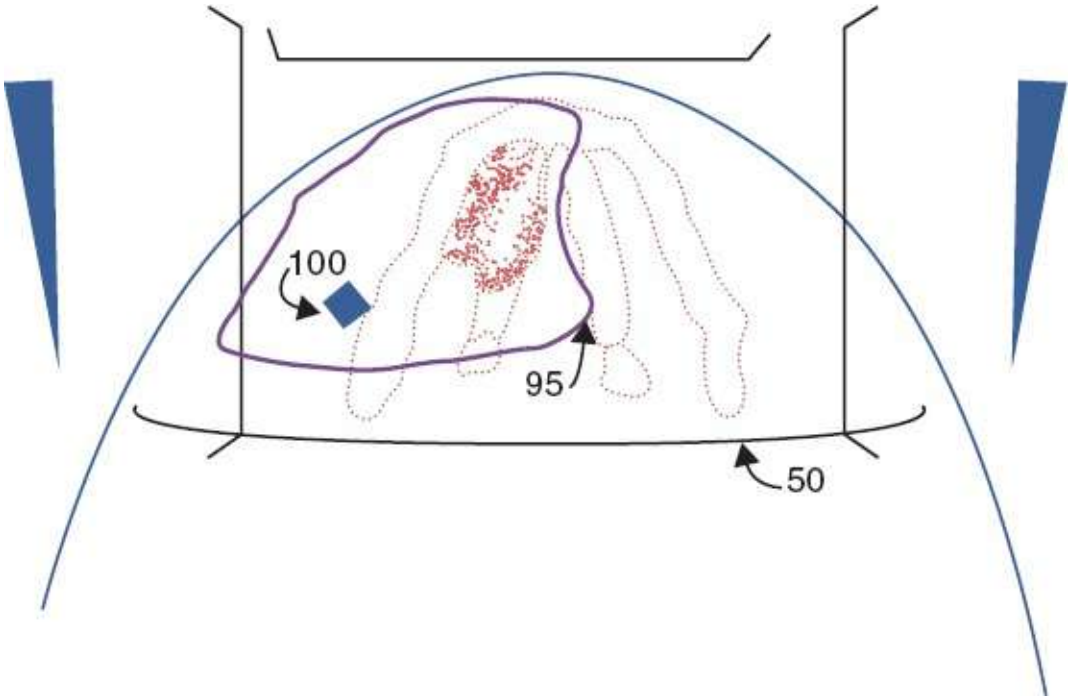

FIGURE 50.8. Normalized isodose distribution for three-field technique for treatment of a tumor involving the anterior two-thirds of one true vocal cord. The dose is specified at the 95% isodose line. (From Million RR, Cassisi NJ, Mancuso AA. Larynx. In: Million RR, Cassisi NJ, eds. *Management head of neck and cancer: a multidisciplinary approach*. 2nd ed. Philadelphia: JB Lippincott, 1994:431–497. With permission.)

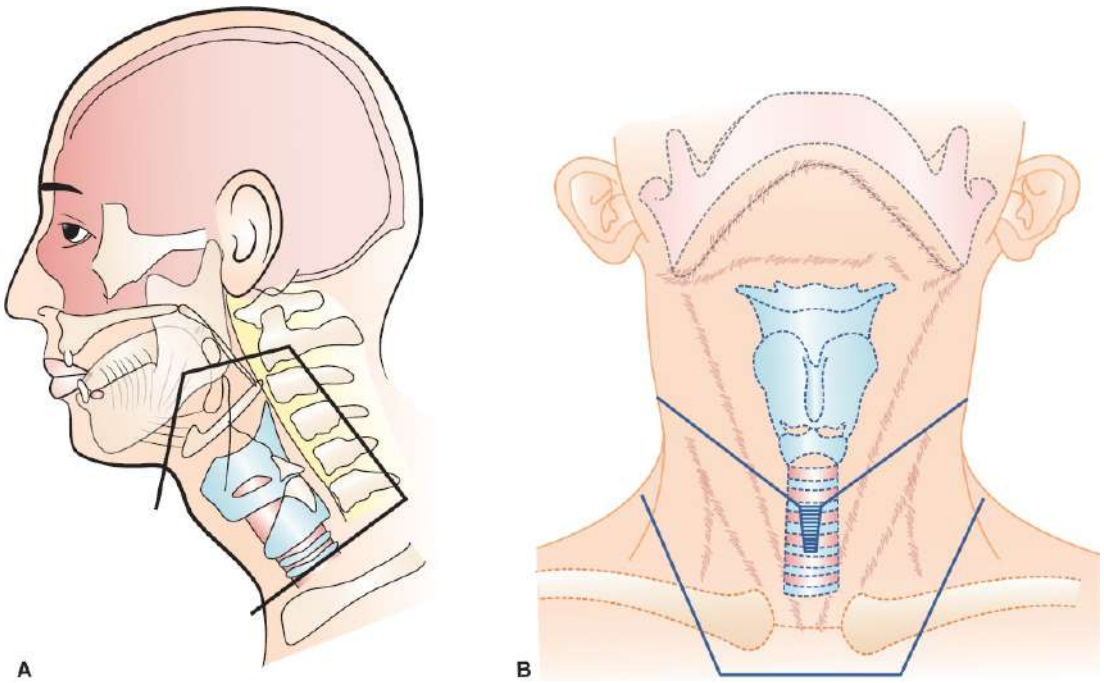

FIGURE 50.9. A: Radiation treatment technique for carcinoma of glottic larynx, stage T3–T4 N0. The patient is treated supine, and the field is shaped with Lipowitz metal. Anteriorly, the field is allowed to fall off. The entire preepiglottic space is included by encompassing the hyoid bone and epiglottis. The superior border (just above the angle of the mandible) includes the jugulodigastric lymph nodes. Posteriorly, a portion of the spinal cord must be included within the field to ensure adequate coverage of the midjugular lymph nodes; spinal accessory lymph nodes themselves are at little risk of involvement. The lower border is slanted to facilitate matching with the low-neck field and to reduce the length of spinal cord in the high-dose field. The inferior border is placed at the bottom of the cricoid cartilage if the patient has no subglottic spread; in the presence of subglottic extension, the inferior border must be lowered according to the disease extent. **B:** Example of a low-neck portal for T3 N0 glottic carcinoma. The main nodes at risk are the low jugular and lateral paratracheal nodes. The delphian node would be in the primary portal. A very narrow and short midline shield is used. (**A**, From Parsons JT, Mendenhall WM, Mancuso AA, et al. Twice-a-day radiotherapy for T3 squamous cell carcinoma of the glottic larynx. *Head Neck* 1989;11[2]:123–128. Management of the neck for squamous cell carcinoma. In: Million RR, Cassisi NJ, eds. Management of head and neck a cancer: *a multidisciplinary approach*. 2nd ed. Philadelphia: JB Lippincott; 1994:75–143. With permission.)

Evidence from both retrospective and randomized trials points to improved therapeutic ratios with altered fractionation schedules.[39] Given that RT is an effective treatment for head and neck primary squamous cell carcinoma, it should not be surprising that higher doses of RT given more intensively would be more effective at providing tumor control. Because most observers have noted no increase in late toxicity with the various regimens, it generally is

concluded that these schedules yield an improved therapeutic ratio. A recently updated Radiation Therapy Oncology Group 90-03 trial reported on 1,073 patients who were randomly selected to receive one of four fractionation schedules[52,66,67]:

- Standard fractionation: 2 Gy per fraction, once a day, 5 days a week, to a total dose of 70 Gy in 35 fractions over 7 weeks
- Hyperfractionation: 1.2 Gy per fraction, twice daily (≥6 hours apart), 5 days a week, to a total dose of 81.6 Gy in 68 fractions over 7 weeks
- Accelerated fractionation with split: 1.6 Gy per fraction, twice daily (≥6 hours apart), 5 days a week, to a total dose of 67.2 Gy in 42 fractions over 6 weeks, including a 2-week rest after 38.4 Gy
- Accelerated fractionation with concomitant boost: 1.8 Gy per fraction, once a day, 5 days a week to a large field, plus 1.5 Gy per fraction once a day to a boost field given 6 or more hours after treatment of the large field for the last 12 treatments days, to a total dose of 72 Gy in 42 fractions over 6 weeks

The 5-year local–regional failure rates were as follows: standard fractionation, 59%; hyperfractionation, 51%; accelerated split course, 58%; and concomitant boost, 52%. Both the hyperfractionation and concomitant schedules boost yielded local–regional control rates that were significantly better than those with standard fractionation. There was a trend toward improved overall survival with hyperfractionation but no difference in cause-specific survival. Acute toxicity was increased with all three altered fractionation schedules; there was a modest increase in late effects with the concomitant boost schedule.

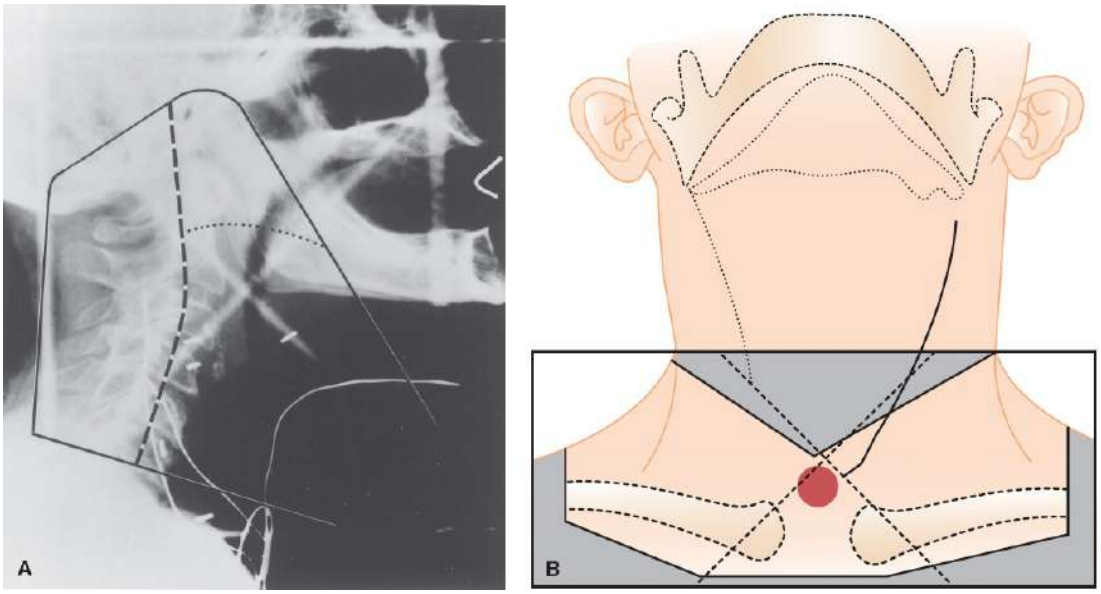

FIGURE 50.10. A: Typical lateral simulation film for postoperative treatment of advanced cancer of the laryngopharynx. If the neck is pathologically negative, the superior field border is lowered to 2 cm above the angle of the mandible. The initial "off-cord" reduction (50 Gy) (*broken line*) and the final reduction (*dotted line*) are indicated. Wires mark the surgical scars and stoma. The slanting line used on the lower border reduces the length of spinal cord treated by the primary field, allows better caudal coverage of the mucosal surfaces while simultaneously bypassing the shoulders, and facilitates matching of the low-neck field. **B:** Schematic diagram of the low-neck field. The rectangle (*solid line*) represents the light field. The shaded areas represent the blocked portions of the field (stacked lead blocks). The superior border of the neck field is the inferior border of the primary field. The actual line is treated only in the primary field. The upper border of the low-neck field assumes a V shape. In the midline of the patient, the apex of the V generally is at or close to the central axis (*broken lines*), so that the portal that treats the spinal cord is not divergent in its upper portion and diverges away from the primary fields in its lower portion. At the junction of the three fields, a short (2 to 3 cm) segment of the spinal cord remains untreated by any of the three fields. (Reprinted from Amdur RJ, Parsons JT, Mendenhall WM, et al. Postoperative irradiation for squamous cell carcinoma of the head and neck: an analysis of treatment results and complications. *Int J Radiat Oncol Biol Phys* 1989;16[1]:25–36. Copyright © 1989 Elsevier. With permission.)

The treatment technique used for postoperative RT after total laryngectomy is depicted in Figure 50.10.[55] The treatment technique for preoperative RT is essentially the same as that used for RT alone. Alternatively, IMRT may be employed for the indications discussed previously.

Treatment of Recurrence

Most recurrences appear within 18 months, but late recurrences may appear after 5 years. The latter are likely second primary malignancies. The risk of metastatic disease in lymph nodes increases with local recurrence.[18]

Recurrence after Radiation Therapy

With careful follow-up, recurrence is sometimes detected before the patient notices a return of hoarseness. There is often minimal lymphedema for 1 to 2 months after RT, which usually subsides or stabilizes. An increase in edema, particularly if associated with hoarseness or pain, suggests recurrence, even if there is no obvious tumor. Fixation of a previously mobile vocal cord usually implies local recurrence, but we have occasionally observed a patient who has experienced a fixed cord with an otherwise normal-appearing larynx and who has not shown evidence of recurrence.

It may be difficult to diagnose recurrence if the tumor is submucosal. Generous, deep biopsies are required. If recurrence is strongly suspected, laryngectomy may rarely be advised without biopsy-confirmed evidence of

recurrence. Positron emission tomography may be useful to distinguish recurrent tumor from necrosis.

RT failures may be salvaged by cordectomy, hemilaryngectomy, supracricoid partial laryngectomy, or total laryngectomy. Biller et al.[68] reported a 78% salvage rate by hemilaryngectomy for 18 selected patients in whom RT failed; total laryngectomy was eventually required in 2 patients. Only 2 patients died of cancer. These investigators offered guidelines for using hemilaryngectomy: contralateral vocal cord is normal, arytenoid is not involved, subglottic extension does not exceed 5 mm, and vocal cord is not fixed. In our experience, 14 patients irradiated for T1 or T2 vocal cord cancers underwent a hemilaryngectomy after local recurrence, and 8 were successfully salvaged.[18]

Recurrence after Surgery

The rate of salvage by RT for recurrences or new tumors that appear after initial treatment by hemilaryngectomy is about 50%. Lee et al.[69] reported 7 successes among 12 patients; one lesion was later controlled by total laryngectomy. Total laryngectomy can be used successfully to treat hemilaryngectomy failures not suitable for RT. RT rarely cures patients with recurrence in the neck or stoma after total laryngectomy.

TREATMENT SELECTION AND TECHNIQUE: SUPRAGLOTTIC LARYNX CARCINOMA

Selection of Treatment Modality

Patients with supraglottic laryngeal carcinoma may be considered to be in an early or favorable group suitable for RT or conservation laryngectomy or an unfavorable group often requiring total laryngectomy.

Early and Moderately Advanced Supraglottic Lesions

Treatment of the primary lesion for the early group is by RT or supraglottic laryngectomy, with or without adjuvant RT.[70] TLM or TORS[71] is effective in experienced hands for small, selected lesions.[47] Total laryngectomy is rarely indicated as the initial treatment for this group of patients and is reserved for treatment failures. RT and supraglottic laryngectomy are highly successful modes of therapy for early lesions.[70]

The decision to use RT or supraglottic laryngectomy depends on several factors, including the anatomic extent of the tumor, medical condition of the

patient, philosophy of the attending physician(s), and inclination of the patient and family. Overall, about 80% of patients are treated initially by RT. Approximately half of the patients seen in our clinic whose lesions are technically suitable for a supraglottic laryngectomy are not suitable for medical reasons (e.g., inadequate pulmonary status or other major medical problems); these patients are treated with RT.

Analysis of local control by anatomic site within the supraglottic larynx shows no obvious differences in local control by RT for similarly staged lesions. Invasion of the preepiglottic space is not a contraindication to supraglottic laryngectomy or RT. Primary tumor volume based on pretreatment CT is inversely related to local tumor control after RT.[35] A large, bulky (>6 cc) infiltrative lesion, especially one with extensive preepiglottic space invasion, is a common reason to select supraglottic laryngectomy.

The status of the neck often determines the selection of treatment of the primary lesion. Patients with clinically negative neck nodes have a high risk for occult neck disease and may be treated by RT or supraglottic laryngectomy and bilateral selective neck dissections (levels II to IV).

If a patient has an early-stage primary lesion but advanced neck disease (N2b or N3), combined treatment is frequently necessary to control the neck disease.[33] In these cases, the primary lesion is usually treated by definitive RT, with surgery added to the treatment of the involved neck site(s). If the same patient were treated with supraglottic laryngectomy, neck dissection, and postoperative RT, the portals would unnecessarily cover the primary site and the neck. If the patient has early, resectable neck disease (N1 or N2a) and surgery is elected for the primary site, postoperative RT is added only because of unexpected findings (e.g., positive margins, multiple positive nodes, or extracapsular extension). We prefer to avoid routine high-dose preoperative or postoperative RT in conjunction with a supraglottic laryngectomy because the lymphedema of the remaining larynx may be considerable, although it eventually subsides. However, Lee et al.[72] from the MD Anderson Cancer Center reported excellent results with combined supraglottic laryngectomy and postoperative RT for moderately advanced lesions.

Advanced Supraglottic Lesions

Although a subset of these patients may be suitable for a supraglottic or supracricoid laryngectomy, total laryngectomy is the main surgical option. Selected advanced lesions, especially those that are mainly exophytic, may be

treated by RT and concomitant chemotherapy,[38] with total laryngectomy reserved for RT failures.

For patients whose primary lesion is to be treated by a total or partial laryngectomy and who have resectable neck disease, surgery is the initial treatment, and postoperative RT is added if needed. If the neck disease is unresectable, preoperative RT is used. The indications for preoperative and postoperative RT have been previously outlined.

Surgical Treatment

Supraglottic Laryngectomy

Supraglottic laryngectomy is voice-sparing surgery that can be used successfully for selected lesions involving the epiglottis, a single arytenoid, the aryepiglottic fold, or the false vocal cord. This can be performed via TLM or TORS.[30] Extension of the tumor to the true vocal cord, the anterior commissure, or both arytenoids, fixation of the vocal cord, or thyroid or cricoid cartilage invasion precludes supraglottic laryngectomy. The supraglottic laryngectomy may be extended to include the base of the tongue if one lingual artery is preserved.

All patients have difficulty swallowing, with a tendency to aspirate immediately after surgery, but almost all learn to swallow again in a short time; motivation and the amount of tissue removed are key factors in learning to swallow again. Preoperatively, adequate pulmonary reserve is evaluated by blood gas determinations, function tests, chest roentgenography, and a work test involving walking the patient up two flights of stairs to determine tolerance to pulmonary stress. The voice quality is generally normal after supraglottic laryngectomy.

Supracricoid Laryngectomy

This procedure is an option for lesions extending from the supraglottis into one or both vocal cords. However, vocal cord fixation is a relative contraindication. At least one arytenoid must be preserved for successful decannulation and phonation. Extension to the cricoid and thyroid cartilage destruction also preclude its use. Phonation and respiratory function are reconstituted by approximating the cricoid to the hyoid (cricohyoidopexy).

Wide-Field Total Laryngectomy

Total laryngectomy is performed as previously described.

Radiation Therapy Technique

The primary lesion and both sides of the neck are treated with opposed lateral portals; wedges are used to compensate for the contour of the neck (Fig. 50.11).[21] The lower neck nodes are irradiated through a separate anterior portal. IMRT may be employed to spare one or both parotids and to avoid a low match line in the occasional patient with a short neck and large shoulders. We currently use either hyperfractionation or simultaneous integrated boost (SIB). The latter schedule delivers 70 Gy in 35 fractions over 30 treatment days in 6 weeks with 1 twice-daily fraction during the last 5 weeks (with a minimum 6-hour interfraction interval). The high-risk clinical target volume (CTV) encompasses the gross disease, the intermediate-risk CTV receives 63 Gy at 1.8 Gy per fraction, and the standard-risk CTV receives 56 Gy at 1.65 Gy per fraction.

In the case of clinically positive nodes, an electron beam portal may be used to increase the dose to the posterior cervical nodes after the fields are reduced to avoid the spinal cord at 45 Gy if parallel opposed fields are employed. CT is obtained 4 weeks after completing RT, and a neck dissection is added if the residual cancer in the nodes is believed to exceed 5%; otherwise, the patient is observed and a CT is repeated in 3 months.[33] Alternatively, a PET-CT is obtained at 3 months, and a neck dissection is added if persistent positive nodes are observed.

Patients experience a sore throat, loss of taste, and moderate dryness during RT. Edema of the arytenoids may occur and give a sensation of a lump in the throat. Tracheostomy is rarely necessary, even for bulky lesions.

Edema of the larynx may persist for several months to a year. Patients who continue to smoke heighten the side effects of dryness, dysphagia, and hoarseness.

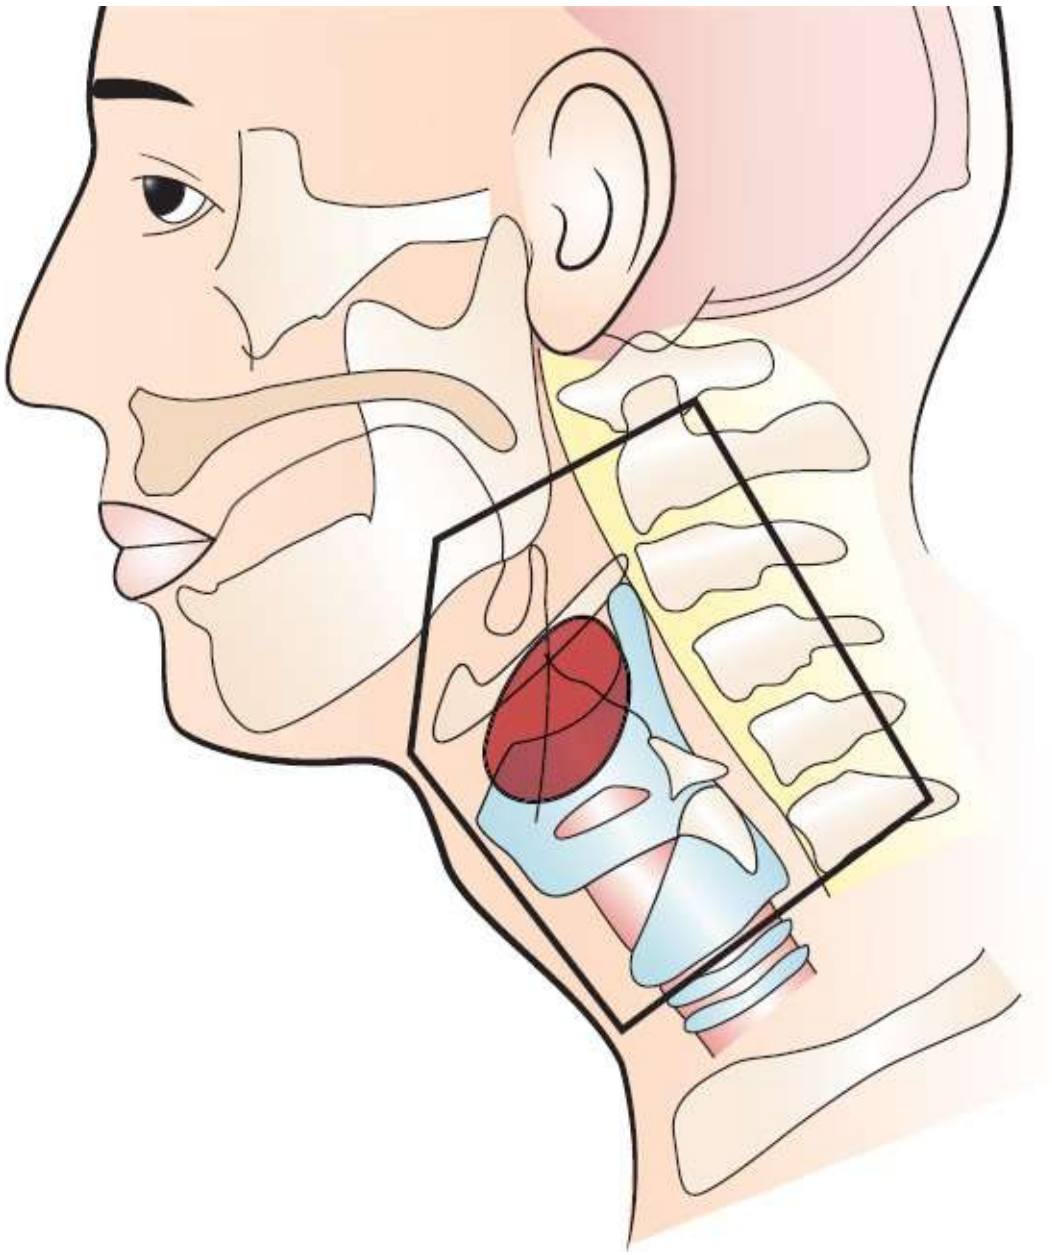

FIGURE 50.11. Example of conventional portal for a lesion of the lower epiglottis or false vocal cord and a clinically negative neck. The subdigastric nodes are included but not the junctional nodes. Depending on the anatomy and tumor extent, the anterior border may fall off (i.e., "flash") or a small strip of skin may be shielded. (From Million RR, Cassisi NJ, Mancuso AA, et al. Management of the neck for squamous cell carcinoma. In: Million RR, Cassisi NJ, eds. *Management of head and neck a cancer*: *a multidisciplinary approach*. 2nd ed. Philadelphia: JB Lippincott, 1994:75–143. With permission.)

Preoperative and Postoperative Treatment Technique

If total laryngectomy is required and the lesion is resectable, postoperative RT is preferred because there is no evidence that preoperative RT produces any better

local–regional control or survival rates than surgery and postoperative RT. Irradiation is added for close or positive margins, invasion of soft tissues of the neck, significant subglottic extension (1 cm or more), thyroid cartilage invasion, multiple positive nodes, and extracapsular extension. The high-risk areas are usually the base of the tongue and the neck.

The dose for postoperative RT as a function of known residual disease is as follows: negative margins, 60 Gy in 30 fractions; microscopically positive margins, 66 Gy in 33 fractions; and gross residual disease, 70 Gy in 35 fractions. All patients are treated with a continuous course, one fraction per day, 5 days per week. The lower neck is treated with doses to 50 Gy in 25 fractions at D_{max}. If there is subglottic extension, the dose to the stoma is boosted with electrons (usually 10 to 14 MeV) for an additional 10 Gy in five fractions. The treatment technique is shown in Figure 50.10.[55] If postoperative RT is added after supraglottic a the laryngectomy, is dose lowered to 55.8 Gy given in 1.8-Gy fractions. This dose produces acceptable rates of local control and laryngeal edema.[72]

The treatment technique used for preoperative RT is essentially the same as that used for patients treated with RT alone, using doses of 50 to 60 Gy at 1.8 to 2.0 Gy per fraction. Thereafter, the dose is boosted to areas of unresectable disease (usually the neck) to total doses ranging from 66 to 70 Gy.

Treatment of Recurrence

Failures after supraglottic laryngectomy or RT can frequently be controlled by further treatment; therefore, recognition of recurrence should be vigorously pursued.[70] Salvage of patients with recurrence after combined total laryngectomy and RT is uncommon. Stomal recurrences are occasionally controlled by RT or surgery; however, the average life span after stomal recurrence is 6.3 months.[73]

RESULTS OF TREATMENT

Vocal Cord Cancer

The local tumor control and survival rates after treatment of early-stage glottic carcinoma are depicted in Tables 50.3 to 50.6.[41] Sengupta et al.[89] recently reported on 37 patients treated at the University of Florida with definitive RT for

carcinoma *in situ* and observed the following 5-year outcomes: local control, 91%; local control with larynx preservation, 91%; and ultimate local control, 91%. Chera et al.[42] reported on 585 patients at the University of Florida for T1–T2 N0 glottic carcinoma and observed the following 5-year local control rates: T1A1, 95%; T1B, 94%; T2 A, 81%; and T2B, 74%. The local tumor control and survival rates are similar for transoral laser excision, open partial laryngectomy, and RT. Larynx preservation rates are also comparable. Voice quality depends on the amount of tissue removed with partial laryngectomy and is probably similar for patients with limited lesions treated with laser to those undergoing RT and poorer for patients undergoing open partial laryngectomy.[41]

Foote et al.[90] reported on 81 patients who underwent laryngectomy for T3 cancers at the Mayo Clinic between 1970 and 1981. Seventy-five patients underwent a total laryngectomy and 6 underwent a near-total laryngectomy; 53 patients received a neck dissection. No patient underwent adjuvant irradiation or chemotherapy. The 5-year rates of local–regional control, cause-specific survival, and absolute survival were 74%, 74%, and 54%, respectively. The results of definitive RT patients with T3 glottic carcinoma are depicted in Table 50.7[64] and are similar to the surgical outcomes reported by Foote et al.[90]

The survival and tumor control rates of patients with T3 fixed-cord lesions treated at the University of Florida are presented in Table 50.8.[97] There was no relationship between subsequent local control and whether the vocal cord remained fixed or became mobile during irradiation. The incidence of severe complications, including those after the initial treatment and any later salvage procedures, was 15% after RT alone and 15% after surgery alone or combined with adjuvant irradiation. The vocal quality varied from fair to nearly normal. Hinerman et al.[31] recently reported an update of the University of Florida experience treating fixed-cord T3 glottic cancers with definitive RT and reported a 5-year local control rate after RT of 63%.

The results of treatment of T4 vocal cord carcinoma in four surgical series and two RT series are summarized in Table 50.9.[58] Hinerman et al.[31] observed an 81% 5-year local control rate in 22 selected patients with favorable T4 cancers treated with definitive RT at the University of Florida.

Parsons et al.[103] reviewed the literature and reported a local control rate of 62% in a series of 87 patients treated with RT alone for T4 glottic carcinoma.

Supraglottic Cancer

The proportion of patients suitable for a supraglottic laryngectomy is depicted in

Table 50.10.[70] Depending on the referral patterns, a modest subset of patients is suitable for this operation. The extent of neck disease for patients treated with either surgery or RT is shown in Table 50.11.[70] In general, patients treated with supraglottic laryngectomy appropriately have earlier-stage neck disease and would be anticipated to have a lower risk of distant failure and improved survival. The local control rates after transoral laser, RT, and supraglottic laryngectomy are summarized in Tables 50.12 to 50.14.[70] In general, the local control rates after transoral laser excision are fairly good for patients with T1–T2 tumors and tend to deteriorate for those with more advanced disease. The local control rate for patients selected for supraglottic laryngectomy is excellent. However, the incidence of severe complications tends to be higher after supraglottic laryngectomy compared with RT and transoral laser excision (Table 50.15).[70,126]

LARYNGECTOMY VERSUS ORGAN PRESERVATION

Treatment of advanced laryngeal cancer carries significant morbidity with deteriorations in quality of life. Thus, many centers and patients have elected to pursue organ preservation strategies. The first major breakthrough in organ preservation came with the Department of Veterans Affairs Laryngeal Cancer Study Group Trial ("The VA Trial").[34] Stage III and IV patients were randomized to total laryngectomy followed by RT versus RT or induction chemotherapy + RT. The conclusion was that induction chemotherapy + RT produced equivalent survival to total laryngectomy + RT. In 2003, the RTOG 91-11 study randomized patients to organ preservation modalities and found that concurrent chemotherapy and RT (CCRT) produced superior survival outcomes. Following these studies, the employment of CCRT for advanced laryngeal cancer has risen significantly.

In 2006, Hoffman et al.[127] used the National Cancer Data Base and found that of all cancer in the United States, laryngeal cancer is the only one with a declining survival rate. Whereas early-stage cancer maintains high survival outcomes, patients with advanced disease have a declining life span. This pattern coincides with the trend of increased use of organ preservation and decreased use of total laryngectomy for advanced laryngeal cancers.

Over the last 15 years, there has been great interest in re-examining the optimal treatment for advanced laryngeal cancers. In 2007, Chen and Halpern[128] analyzed 10,590 patients from the late 1990s and found that total laryngectomy had superior survival outcomes compared to RT or CCRT. In 2009, Gourin et al.[129] analyzed a population of patients treated between 1985 and 2002 and found that patients with stage IV disease had improved 5-year survival compared to organ preservation. In 2012, Dziegielewski et al[130] performed a population-based analysis of survival from 1998 to 2008 and found that T3 and T4a laryngeal cancers treated with total laryngectomy + RT had improved overall and disease-free survival. The 5-year survival rates for T3 cancers treated with total laryngectomy + RT, RT, and CRT were 70%, 18%, and 52%, respectively. For

T4a disease, these figures were 49%, 5%, and 16%. In 2014, Megwalu and Sikora[131] found similar survival outcomes using the SEER database to analyze 5,394 patients with stage III and stage IV laryngeal carcinoma treated between 1992 and 2009. Disease-specific survival rates for surgically treated patients at 2 and 5 years were 70% and 64% versus organ preservation strategies, which yielded rates of 55% and 51%. Multivariate analysis, accounting for year of diagnosis, stage, age, sex, subsite, race, and marital status, continued to show improved disease-specific and overall survival for patients receiving primary surgery.

[a]Includes patients with glottic cancer.
Some values were estimated as closely as possible to fit the table format if the information was not specifically stated in the cited reference.
From Hinerman RW, Mendenhall WM, Amdur RJ, et al. Carcinoma of the supraglottic larynx: treatment results with radiotherapy alone or with planned neck dissection. *Head Neck* 2002;24(5):456–467. Copyright © 2002 Wiley Periodicals, Inc. Reprinted by permission of John Wiley & Sons, Inc.

Since the initial VA trial, advanced laryngeal cancer survival outcomes have deteriorated, prompting debate of whether the results of the trial can be widely applied to all advanced laryngeal cancer.[132] Population-based studies have shown that treatment strategies need to be tailored to the patient and that T stage is a better determinant of survival than overall stage.[129,130] It has become widely accepted that the majority of patients with T4a cancer will experience better survival and functional outcomes when treated with laryngectomy versus organ preservation.[129–131] However, the debate over which T3 tumors can be optimally treated with CRT continues.[133]

FOLLOW-UP POLICY

Follow-up of patients with early lesions is planned for every 4 to 8 weeks for 2 years, every 3 months for the 3rd year, and every 6 months for years 4 and 5, and then annually for life.

Follow-up of patients with vocal cord or supraglottic larynx lesions treated by RT or conservative surgery is almost more important than the treatment itself because early detection of recurrence usually results in salvage that may include cure with voice preservation.

If recurrence is suspected but the biopsy is negative, patients are re-examined at 2- to 4-week intervals until the matter is settled. The value of follow-up CT scans for detecting early local recurrence is investigational.

Wagenfeld et al.[134] studied 740 cases of glottic larynx cancer treated from 1965 to 1974 to determine the incidence of second respiratory tract malignancies. There was a minimum follow-up of 5 years. There were 48 second respiratory tract malignancies, although only 14 were expected. Twenty-five were in the lung, and 23 were scattered among other head and neck sites. Only 7 of the 23 second head and neck primary lesions resulted in death; these second lesions were frequently diagnosed in an early stage during routine follow-up for the glottic lesion.

Because the risk of a lethal lung primary lesion is nearly as great as that of dying of an early glottic carcinoma, it makes sense to obtain annual chest roentgenograms. Approximately 50% of patients who receive moderate- to high-dose RT to the entire thyroid gland will develop hypothyroidism within 5 years, and so thyroid functions are checked every 6 to 12 months and thyroid replacement is initiated if the thyroid-stimulating hormone level begins to rise.[135]

SEQUELAE OF TREATMENT

Surgical Sequelae

Neel et al.[136] reported a 26% incidence of nonfatal complications for cordectomy. Immediate postoperative complications included atelectasis and pneumonia, severe subcutaneous emphysema in the neck, bleeding from the tracheotomy site or larynx, wound complications, and airway obstruction requiring tracheotomy. Late complications included granulation tissue that had to be removed by direct laryngoscopy to exclude recurrences, extrusion of cartilage, laryngeal stenosis, and obstructing laryngeal web.

The postoperative complications and sequelae of hemilaryngectomy include chondritis, wound slough, inadequate glottic closure, and anterior commissure webs.[123] The complications associated with supraglottic laryngectomy and total laryngectomy for supraglottic carcinomas include fistula (8%), carotid artery exposure or blowout (3% to 5%), infection or wound sloughing (3% to 7%), and fatal complications (3%).[123] The risk of complication increased if tumor margins were involved by tumor; there was no change in risk associated with age, sex, race, laryngeal site, stage of primary tumor, size of primary tumor, use of low-dose preoperative RT, or status of the positive nodes.

The incidence of complications after treatment of supraglottic carcinoma is given in Table 50.15.[70]

Radiation Therapy Sequelae

The acute reactions from the treatment of early vocal cord cancer using a tumor dose of 2.25 Gy per day to administer a total dose 63 Gy (4- or 6-MV photons, five fractions per week) are relatively mild. During the first 2 to 3 weeks, the voice may improve as the tumor regresses. The voice generally becomes hoarse again because of RT-induced changes, even though the tumor continues to regress. A mild sore throat develops beginning at the end of the 2nd week, but

medication is usually not required. The voice begins to improve approximately 3 weeks after completion of treatment, usually reaching a plateau in 2 to 3 months. Patients with extensive lesions often recover a normal voice, although not as frequently as those with small tumors.

Edema of the larynx is the most common sequela after RT for glottic or supraglottic lesions. The rate of clearance of the edema is related to the RT dose, volume of tissue irradiated, addition of a neck dissection, continued use of alcohol and tobacco, and size and extent of the original lesion. Edema may be accentuated by a neck dissection and may require 6 to 12 months to subside.

Soft tissue necrosis leading to chondritis occurs in <1% of patients, usually in those who continue to smoke. Soft tissue and cartilage necroses mimic recurrence, with hoarseness, pain, and edema; a laryngectomy may be recommended as a last resort for fear of recurrent cancer, even though biopsy specimens show only necrosis.

Corticosteroids such as dexamethasone (Decadron) have been used to reduce RT-induced edema after recurrence has been ruled out by biopsy. If ulceration and pain occur, administration of an antibiotic such as tetracycline may help. Of 519 patients with T1 N0 or T2 N0 vocal cord cancer treated at the University of Florida, 5 (1%) experienced severe complications,[18] including total laryngectomy for a suspected local recurrence (1 patient), permanent tracheostomy for edema (3 patients), and a pharyngocutaneous fistula after a salvage total laryngectomy (1 patient).

In patients irradiated for supraglottic carcinoma, sore throat persists 1 to 2 months after completion of treatment. There is an associated dry mouth from RT of the salivary and parotid glands, a loss of taste, and a sensation of a lump in the throat. It is unusual for patients to require a tracheotomy before RT unless severe lymphedema develops at the time of direct laryngoscopy and biopsy. However, in patients who have recovered from the direct laryngoscopy and biopsy without obstruction, a tracheotomy has rarely been required during a fractionated course of RT.

Patients treated twice a day with 1.2-Gy fractions (continuous-course technique) to a total dose of 74.4 Gy usually have more brisk acute reactions than those treated once a day with 2-Gy fractions. Approximately 30% treated with twice-a-day RT require temporary gastrostomy feeding tubes because they have difficulty in swallowing.[137]

Examples of acute chondritis requiring discontinuation of treatment have not been seen, although most epiglottic lesions exhibit cartilage invasion.

The epiglottis, both suprahyoid and infrahyoid portions, remains thicker than normal for long periods of time, but this is not often associated with difficulty in swallowing, respiratory obstruction, or aspiration. The patient is cautioned to eat and drink slowly until the edema resolves. The false cord and arytenoids may develop some edema.

Lesions of the suprahyoid epiglottis frequently destroy the tip of the epiglottis, and it may require some time for the exposed cartilage to heal. Successful RT of infrahyoid epiglottis tumors is not associated with a high rate of necrosis, even though most of these lesions penetrate the porous epiglottic cartilage.

The incidence of severe late complications in 274 patients treated with RT alone or combined with neck dissection at the University of Florida was 4%.[70]

CHAPTER 51

Unusual Nonepithelial Tumors of the Head and Neck

Carlos A. Perez and Wade L. Thorstad

GLOMUS TUMORS

Anatomy

Glomus bodies are found in the jugular bulb and along the tympanic (Jacobson) and auricular (Arnold) branches of the tenth nerve in the middle ear or in other anatomic sites (Fig. 51.1). Depending on the location, glomus tumors (GTs) (chemodectoma or paraganglioma) are classified as tympanic (middle ear), jugulare, or carotid vagal or designated as originating from other locations, such as the larynx, adventitia of thoracic aorta, abdominal aorta, or the surface of the lungs (Fig. 51.2).[1]

GT or chemodectomas consist of large epithelioid (smooth muscle) cells with fine granular cytoplasm embedded in a rich capillary network and fibrous stroma with reticulin fibers, which derive from embryonic neural crest cells. Although histologically benign, they may extend along the lumen of the vein to regional lymph nodes, but rarely to distant sites. These tissues are responsive to changes in oxygen and carbon dioxide tensions and pH.

Epidemiology

The mean age at diagnosis has been reported to be 45 years for carotid body tumors and 52 years for glomus tympanicum.[2] These tumors occur three or four times more frequently in women than in men, suggesting a possible estrogen influence.[2–4] Glomus tumors may be familial; they occur in multiple sites in 10% to 20% of patients.[5] Incidence may be influenced by hereditary syndromes including PGL1-5, MEN2, and NF1.

Recent advances in genetics identified three loci associated with hereditary paragangliomas, and genetic screening may detect affected patients.[6] Multiple

paragangliomas of the head and neck are rare, with an incidence of 10% of all patients, but in familial cases, it increases up to 35% to 50%.[5] In the head and neck region, the most common association is bilateral carotid body tumors or carotid body tumor associated with tympanic–jugular glomus.[7]

Clinical Presentation

Glomus tumors may arise along the nerve roots. In the middle ear, they may initially cause earache or discomfort.[8] As they expand, eventually they produce pulsatile tinnitus, hearing loss, and, in later stages, cranial nerve paralysis

resulting from invasion of the base of the skull in 10% to 15% of patients. If the tumor invades the middle cranial fossa, symptoms may include temporoparietal headache, retro-orbital pain, proptosis, and paresis of cranial nerves V and VI. If the posterior fossa is involved, symptoms may include occipital headache, ataxia, and paresis of cranial nerves V to VII, IX, and XII; invasion of the jugular foramen causes paralysis of nerves IX to XI. Chemodectoma of the carotid body usually presents as a painless, slowly growing mass in the upper neck. Occasionally, the mass may be pulsatile and may have an associated thrill or bruit. As it enlarges, the mass may extend into the parapharyngeal space and be visible on examination of the oropharynx. Very rarely, these tumors may be malignant.[9] Metastases occur in 2% to 5% of cases.[3]

Diagnostic Workup

Diagnostic evaluation for glomus tumors of the ear and base of skull is outlined in Table 51.1. In the majority of glomus tympanicum, physical examination demonstrates a red, vascular middle ear mass, although occasionally it may be bluish or white (the latter resembling a cholesteatoma).[2] Audiography may demonstrate conductive hearing loss in the ear involved by tumor as noted in 33 of 49 patients evaluated by Larson et al.[2]; 4 of 33 patients with conductive deficits also exhibited tympanic pulsations. Examination of the neck may occasionally demonstrate a mass in the neck that may be pulsatile or have a bruit or regional lymph node metastases.

Radiographic studies are invaluable in the diagnosis of these tumors. Plain mastoid radiographs never show the soft tissue mass in the middle ear, although they frequently demonstrate clouding of the mastoid air cells, suggesting mastoiditis.[10] High-resolution computed tomography (CT) with contrast has a degree of sensitivity and specificity to diagnose this tumor when located in the middle ear or jugular bulb; masses as small as 3 mm have been demonstrated. Tumor enhancement is similar to that of the temporalis muscle (Fig. 51.3).[2] In 46 patients with glomus tympanicum, there were no instances of local bony erosion; instead, the tumors engulfed the ossicular chain, bulged or protruded through the tympanic membrane, filled the middle ear, or extended into the eustachian tube orifice or aditus ad antrum. This pattern is in contrast to cholesteatomas, which typically destroy adjacent bony landmarks, including the ossicles, and progressively erode the petrous bones as they enlarge.[2]

Magnification angiography is a sensitive and specific means of detecting glomus tympanicum tumors. This procedure is performed after high-resolution

thin-section CT scan (with contrast material), only when there is a question regarding the nature of the lesion or the location of the carotid canal. Findings include a hypervascular middle ear mass that first appears in the middle to late arterial phase, persists through the capillary phase, and quickly disappears in the venous phase without demonstrably early draining veins. Biopsy of an aberrant internal carotid artery can result in major neurologic sequelae or death.

TABLE 51.1 DIAGNOSTIC WORKUP FOR GLOMUS TUMORS OF THE EAR AND BASE OF THE SKULL, HEMANGIOPERICYTOMA, ESTHESIONEUROBLASTOMA, EXTRAMEDULLARY PLASMACYTOMA, AND SARCOMA OF THE HEAD AND NECK

General
Clinical history
General physical examination
Ear, nose, and throat examination
Radiographic Studies
Computed tomography scan (with contrast) to define tumor extent and possible central nervous system involvement)
Magnetic resonance imaging with gadolinium
Arteriography to determine bilateral involvement and collateral cerebral blood flow (optional)
Jugular phlebography (optional)
Laboratory Studies
Complete blood cell count
Blood chemistry profile
Urinalysis
Special Tests
Audiograms to establish baseline hearing loss
Histologic staining to determine presence of catecholamines

FIGURE 51.3. A: Late-phase arteriogram illustrating large glomus jugulare tumor with extension into the neck. **B:** Computed tomography scan with contrast enhancement showing intracranial component of lesion.

Vogl et al.[11] reported on 40 patients with glomus tumors of the skull; diagnostic interpretations were correlated with histologic examination, digital subtraction angiography, CT, and clinical follow-up. Sixteen of eighteen proven tumors were detected with spin-echo images alone. Although four high-flying jugular bulbs were misinterpreted as tumors because of similar signal intensity, combined evaluation allowed differentiation between tumor and sinusal blood flow in all cases.

Drape et al.[12] described magnetic resonance imaging (MRI) findings in 31 patients with a clinical suspicion of glomus tumor; gadoterate meglumine was injected into 19 patients. Twenty-seven of twenty-eight pathologically confirmed glomus tumors were detected with MRI; a peripheral capsule was present in most tumors. The investigators were able to differentiate three subtypes of glomus tumors (vascular, solid, and myxoid) on the basis of relaxation times and enhancement characteristics. Multidetector CT angiography was found to be more accurate in the diagnosis of six glomus tumors, with enhancement in the arterial phase, when compared with MRI.[13]

As GTs show high levels of somatostatin receptor (SSTR) subtypes 2 and 5, fluorine-(^{18}F)-octreotate positron emission tomography (PET) may be useful for diagnostic purposes in a semiquantitative manner and for improving target volume delineation in radiation therapy planning. Astner et al.[14] noted that preliminary findings with two different PET tracers for SSTR imaging have been reported: Gallium-68 (^{68}Ga)-DOTATOC (DOTA-d-Phe(1)-Tyr(3)-octreotide [somatostatin analog]) PET was shown to detect SSTR-expressing tumors with high sensitivity and specificity. A second PET tracer, Gluc-Lys(^{18})F-TOCA, allows fast, high-contrast imaging of SSTR-positive tumors with superior biokinetics and diagnostic performance as compared with indium-111 (^{111}In)-DTPA (diethylenetriamine pentaacetic acid)-octreotide and—as far as can be determined from the literature—comparable to[15] Ga-DOTATOC.[16–18]

Cytochemical techniques demonstrate increased levels of serotonin, epinephrine, and norepinephrine in normal glomus tissue of the carotid body. Histologic staining techniques, including chromaffin and argentaffin reactions, identify patients with hormonally active tumors. This is important because the glomus tumor may coexist with a pheochromocytoma, which requires special preoperative preparation of the patient. Biopsy of glomus tumors may result in

severe hemorrhage.

Staging

The prognosis of these tumors is closely related to the anatomic location and the volume of the lesion, which is reflected in the Glasscock-Jackson classification[19] shown in Table 51.2. An alternative classification proposed by McCabe and Fletcher[20] is presented in Table 51.3.

General Management

Li et al.[21] published a historical perspective of various treatment modalities used to treat glomus tumors over the past 60 years.

TABLE 51.2 GLASSCOCK-JACKSON CLASSIFICATION OF GLOMUS TUMORS

Glomus Tympanicum
I. Small mass limited to promontory
II. Tumor completely filling middle ear space
III. Tumor filling middle ear and extending into the mastoid
IV. Tumor filling middle ear, extending into the mastoid or through tympanic membrane to fill the external auditory canal; may extend anterior to carotid
Glomus Jugulare
I. Small tumor involving the jugular bulb, middle ear, and mastoid
II. Tumor extending under internal auditory canal; may have intracranial canal extension
III. Tumor extending into the petrous apex; may have intracranial canal extension
IV. Tumor extending beyond the petrous apex into the clivus or infratemporal fossa; may have intracranial canal extension

Reproduced with permission from Jackson CG, Glasscock ME III, Harris PF. Glomus tumors: diagnosis, classification, and management of large lesions. *Arch Otolaryngol* 1982;108(7):401–406. Copyright © 1982 American Medical Association. All rights reserved.

TABLE 51.3 MODIFICATION OF MCCABE AND FLETCHER CLASSIFICATION OF CHEMODECTOMAS

Group I: Tympanic Tumors
Absence of bone destruction on x-rays of the mastoid bone and jugular fossa
Absence of facial nerve weakness
Intact eighth nerve with conductive deafness only
Intact jugular foramen nerves (cranial nerves IX, X, and XI)
Group II: Tympanomastoid Tumors
X-ray evidence of bone destruction confined to the mastoid bone and not involving the petrous bone

	Normal or paretic seventh nerve
	Intact jugular foramen nerves
	No evidence of involvement of the superior bulb of the jugular vein on retrograde venogram
Group III: Petrosal and Extrapetrosal Tumors	
	Destruction of the petrous bone, jugular fossa, and/or occipital bone on x-rays
	Positive findings on retrograde jugulography
	Evidence of destruction of the petrous or occipital bones on carotid arteriogram
	Jugular foramen syndrome (paresis of cranial nerves IX, X, or XI)
	Presence of metastasis

Reprinted from Wang M-L, Hussey DH, Doornbos JF, et al. Chemodectoma of the temporal bone: a comparison of surgical and radiotherapeutic results. *Int J Radiat Oncol Biol Phys* 1988;14(4):643–648. Copyright © 1988 Elsevier. With permission.

Surgery

Surgery is generally selected for small tumors that can be completely excised. Glomus tympanicum tumors are particularly well managed with excision via tympanotomy or mastoidectomy. Percutaneous embolization of a low-viscosity silicone polymer has been used, frequently as preoperative preparation of the tumor embolization of feeding vessels allows meticulous microsurgery with virtually complete hemostasis.

Surgical treatment of a glomus tumor arising in the jugular bulb, however, often consists of piece-by-piece removal accompanied by significant intraoperative bleeding with damage to adjacent neurovascular structures and requires more complex surgical approaches involving the base of the skull. Preoperative embolization via a transarterial approach has proved beneficial but is often limited by vascular anatomy and unfavorable locations. Abud et al.[22] reported experience with preoperative devascularization using direct puncture and an intralesional injection of cyanoacrylate (acrylic glue) under fluoroscopic guidance in nine patients with head and neck paragangliomas. Ozyer et al.[23] performed devascularization with intralesional injection of *N*-butyl cyanoacrylate (seven carotid and three jugular paragangliomas). The tumors were subsequently surgically removed.

The local tumor control rate with surgery alone is only about 60%, and there is significant morbidity, particularly cranial nerve injury and bleeding.

In a retrospective review of all skull base surgery cases treated at Baylor University, 175 jugulotympanic glomus tumors and 9 malignant cases (5.1%) were identified.[9] The 5-year survival rate was 72%.

Radiation Therapy

Irradiation is frequently used in the treatment of glomus tumors, particularly for those in the tympanicum and jugulare bulb locations. Tumors with destruction of the petrous bone, jugular fossa, or occipital bone or patients with jugular foramen syndrome are more reliably managed with irradiation.[2,4,24,25] Some surgeons, such as Glasscock et al.,[19] have questioned the effectiveness of radiation therapy in the treatment of chemodectomas because on histologic sections, obtained even many years after irradiation, it is possible to find chromophilic cells remaining in the tumor. However, there is also evidence of fibrosis and decreased vascularity.[26] Suit and Gallager[27] demonstrated in a murine mammary carcinoma model that morphologically intact cells may have lost their reproductive ability after irradiation, which is the ultimate end point of cell killing. Furthermore, it is extremely unusual to observe clinical regrowth of a glomus tumor after irradiation, even if they do not regress completely.

Some reports describe successful combinations of surgery with preoperative irradiation, in an attempt to make an unresectable tumor operable, or postoperatively when obvious tumor could not be resected.

Radiation Therapy Techniques

Radiation therapy techniques are determined by the location and extent of the tumor, which must be defined before treatment.[24,28,29] Limited, usually bilateral, portals were used for relatively localized glomus tumors, whether or not the treatment is combined with surgery (Fig. 51.4). Dickens et al.[30] used a three-field arrangement with a superior–inferior wedged and lateral open field, with a weighting of 1:1:0.33. A superior–inferior 60-degree and 45-degree wedged filtered field arrangement was also used. Electrons (15 to 18 MeV) with a lateral portal or combined with cobalt 60 (^{60}Co) or 4- to 6-MV photons (20% to 25% of total tumor dose) render a good dose distribution (Fig. 51.5). Several prosthetic materials have been used to enhance irradiation dose homogeneity.[31] In patients in whom tumor has spread into the posterior fossa, it may be necessary to use parallel-opposed portals with 6- to 18-MV photons. Treatment is given at the rate of 1.8 to 2 Gy tumor dose per day with five treatments per week for a total tumor dose of 45 to 55 Gy in 5 weeks. Three-dimensional conformal radiation therapy (3DCRT) and image-guided intensity-modulated radiation therapy (IMRT) are highly desirable techniques to treat these tumors, with excellent dose distributions (Fig. 51.5). Table 51.4 summarizes the doses of irradiation recommended by several investigators and the probability of tumor control for each.[24,29,37]

van Hulsteijn et al.[38] performed a meta-analysis of 283 jugulotympanic paragangliomas in 276 patients. Pooled regression proportions for initial, combined, and salvage treatment were respectively 21%, 33%, and 52% in radiosurgery studies and 4%, 0%, and 64% in external beam radiotherapy studies. Pooled local control proportions for radiation therapy as initial, combined, and salvage treatment ranged from 79% to 100%.

Radiotherapy for jugulotympanic paragangliomas results in excellent local tumor control. The effects of radiation therapy on regression of tumor volume remained ambiguous, although the data suggest that complete regression can be achieved in some patients.

Structure	Dose Range (Gy)	Mean Dose (Gy)
Planning target volume (including left neck)	38–77	70
Brain	0–59	2
Brainstem	6–35	12
Spinal cord	0–32	13

Leber et al.[39] reported on 13 patients with glomus tumors treated with radiosurgery in 6, because of recurrences after surgical removal. Histology was not available in 7 patients; diagnosis was made from neuroradiologic features only. With a mean follow-up of 42 months (range 14 to 72 months), there was no tumor progression and no clinical deterioration in any patient; 64% of the patients had improvement of symptoms, and in 36%, the volume of the lesion decreased in size. There was no radiation-related morbidity. In recent years, there have been an increasing number of reports in small series of patients with glomus tumors <2 or 3 cm treated with stereotactic radiation therapy (SRT), with tumor control over 80% and relatively minimal morbidity. The mean single dose is about 16 Gy (range 13 to 20 Gy).[40–45] A report on fractionated stereotactic irradiation (6-MV x-rays) of 17 patients has been published, with a dose of 57 Gy.[46] Pollock[47] reported on 42 glomus tumors (19 primary treatment and 23 recurrences after initial surgery) treated with Gamma Knife (Elekta Corp, Stockholm) stereotactic radiation (12 to 24 Gy single dose at 50% isodose, depending on tumor size). Twelve lesions (31%) decreased in size and 26 were unchanged. The most common complication was hearing loss (19%). Wegner et al.[48] treated 18 patients with carotid or jugular lesions with fractionated stereotactic CyberKnife (Accuray, Sunnyvale, CA) (Fig. 51.6). Fifteen patients (83%) had single glomus jugulare tumors and three patients had bilateral glomus jugulare tumors. Ten tumors were previously untreated, and eight were persistent after previous surgical resection. The median prescribed dose was 20 Gy in 3

fractions (range: 16 to 25 Gy in 1 to 5 fx) The median prescription coverage of the tumor was 93.6% (range: 83% to 98.72%).Median follow-up was 22 months. All the patients were alive at the time of the last follow-up with imaging available for review. The tumor was stable in 17 patients and decreased in size in one patient—yielding a local control rate of 100%. No patients experienced any new or worsening treatment-related neurologic deficits.

for a glomus tympanicum lesion (80% 16-MeV electrons, 20% 4-MV photons). (From Konefal JB, Pilepich MV, Spector GJ, et al. Radiation therapy in the treatment of chemodectomas. *Laryngoscope* 1987;97[11]:1331–1335. Copyright © 1987 The Triological Society. Reprinted by permission of John Wiley & Sons, Inc.)

Results of Therapy

The postirradiation change in tumor size is slow, with an increase in proliferative and perivascular fibrosis and minimal alterations in the chief epithelial cells. Histologic evaluation of tumor cell viability is not reliable.[27] Despite the persistence of tumor both clinically and angiographically, amelioration of symptoms, absence of disease progression, and occasional return of cranial nerve function have been reported. Seventeen patients were treated for glomus tympanicum tumors at Washington University.[3] In five patients, initial treatment consisted of irradiation alone, and all were tumor free at the last follow-up (4.5 years in one patient) or at death. Seven of eight patients irradiated for surgical recurrence were free of disease 4.5 to 19 years after irradiation. The remaining four patients were treated preoperatively or postoperatively; only one had recurrence and was salvaged surgically and tumor free 10 years later. Of six patients with glomus jugulare lesions treated with irradiation, two with extensive lesions died of their disease, whereas the glomus tumor was controlled in four, including two patients with intracranial extension. Irradiation doses ranged from 46 to 52 Gy, with 86% to 100% tumor control with doses over 46 Gy and 50% (two of four) with doses below 46 Gy.

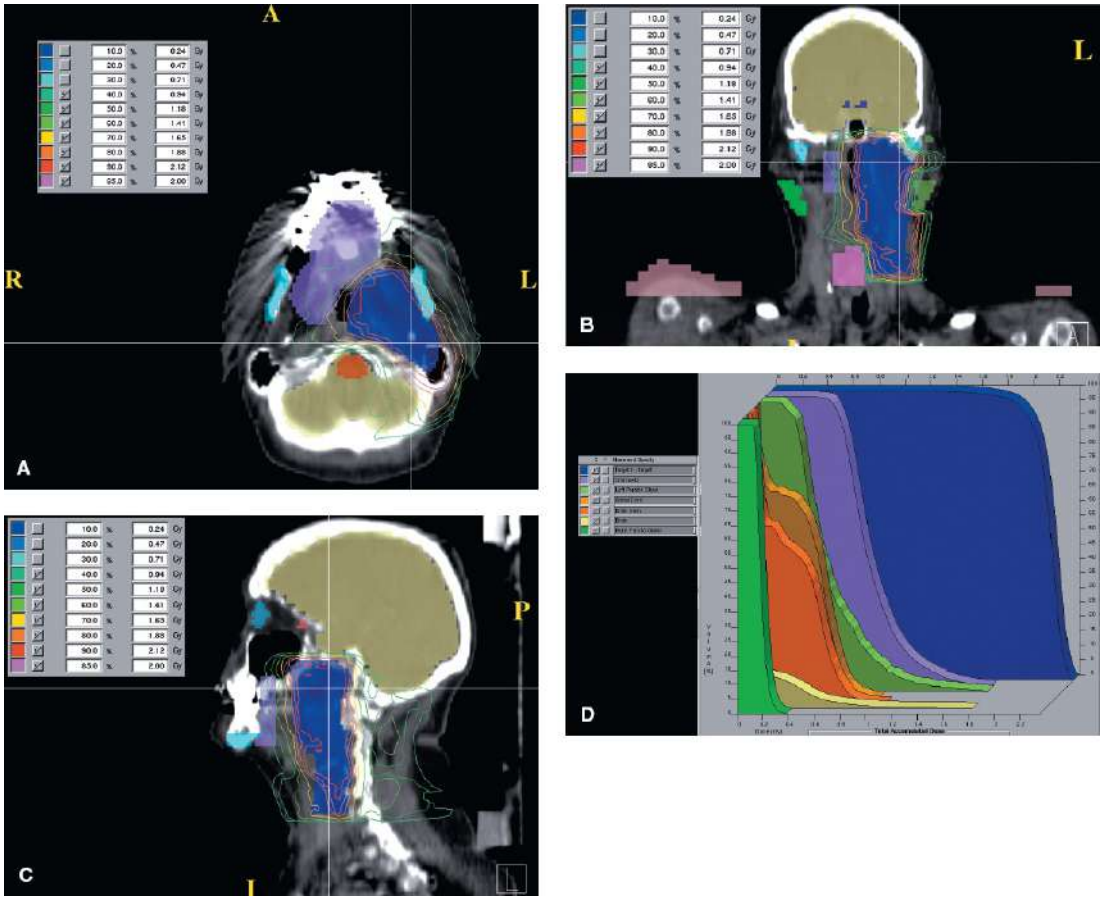

FIGURE 51.5. Fifty-nine-year-old woman with an unusual malignant left glomus jugulare, who had a metastatic left upper cervical lymph node. She was treated definitively with intensity-modulated radiation therapy (66 Gy in 2-Gy fractions). Cross **(A)**, coronal **(B)**, and sagittal **(C)** sections showing dose distributions at primary site and left neck, sparing normal structures. **D:** Dose–volume histogram.

TABLE 51.4 LOCAL CONTROL WITH RADIATION THERAPY FOR CHEMODECTOMA OF THE TEMPORAL BONE (GLOMUS TYMPANICUM AND JUGULARE)

Institution (Reference)	Local Control	Nominal Dosage Schedule
Princess Margaret Hospital[32]	42/45[a]	35 Gy/3 wk

[a]Two patients listed as failures were salvaged with further treatments.
[b]One patient listed as a failure was salvaged with further radiation therapy.
Modified from Wang M-L, Hussey DH, Doornbos JF, et al. Chemodectoma of the temporal bone: a comparison of surgical and radiotherapeutic results. *Int J Radiat Oncol Biol Phys* 1987;14:643–648; and Springate SC, Weichselbaum RR. Radiation or surgery for chemodectoma of the temporal bone: a review of local control and complications. *Head Neck* 1990;12:303–307.

Wang et al.[49] reported on 32 patients with tympanic chemodectomas; 13 are treated with surgery alone, 15 with irradiation alone, and 4 with a combination of both modalities. The initial tumor control rate was 46% with surgery alone; ultimately 84% of patients were tumor free after salvage with additional surgery. Although 78% survived 10 years, 31% developed complications. Of the patients treated with irradiation, 84% had initial local tumor control; 77% survived 10 years, and only 11% developed complications. The doses of irradiation used were slightly higher than those reported by others (mean 58.32 Gy). However, no improvement in tumor control was noted with higher doses. Complications occurred in two patients receiving 66 Gy.

Zabel et al.[50] described results in 22 patients with large chemodectomas of the skull base (8 after primary surgery and 4 after embolization), treated with fractionated stereotactic irradiation (median total dose 57 Gy with median fraction dose 1.8 Gy). With a median follow-up of 5.7 years, 5- and 10-year actuarial tumor control was 90%, with 7 patients (32%) having a partial response and 13 patients with (59%) stable tumors. No patient developed new neurologic deficit.

In a compilation of several studies, Kim et al.[51] noted a 25% local failure rate in 83 patients treated with <40 Gy and 1.4% local failure in 142 patients receiving >40 Gy.

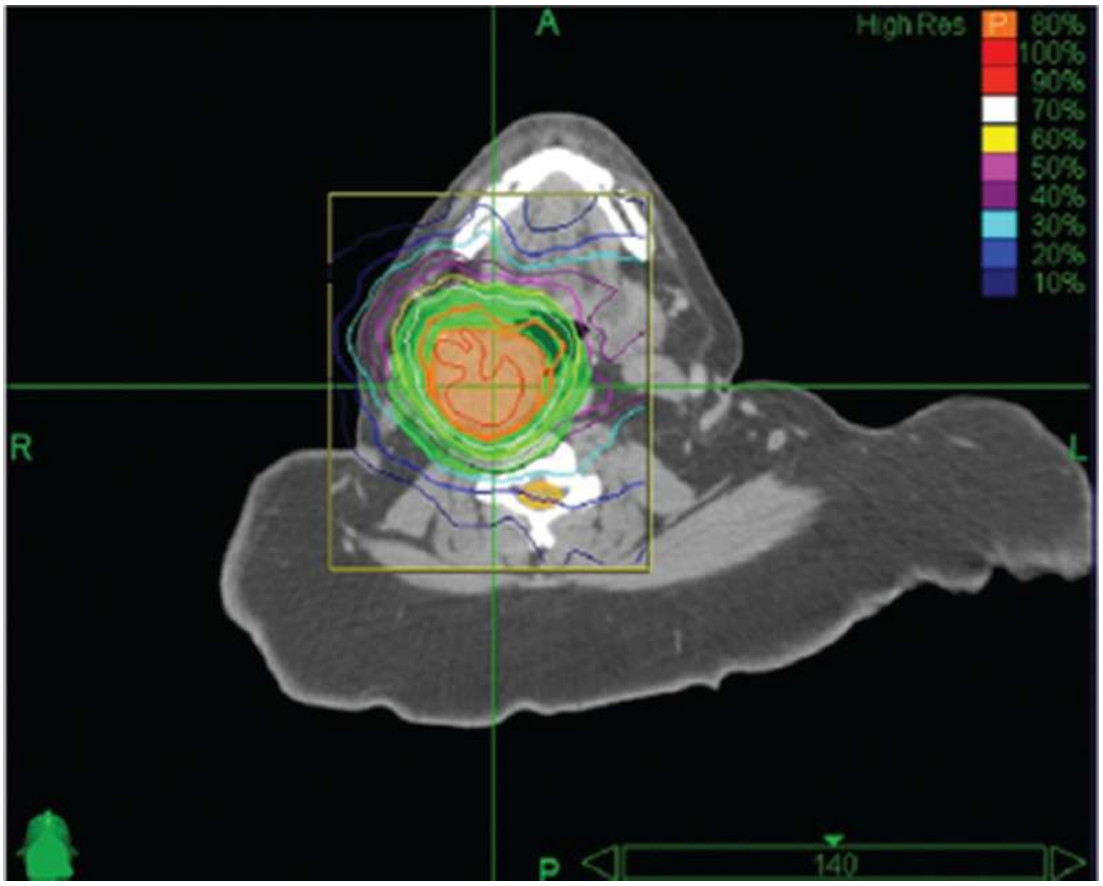

FIGURE 51.6. Dose distribution with stereotactic radiation therapy (radiosurgery) for glomus tumor. Patient was treated with 25 Gy in 5 fractions prescribed to the 80% isodose line; 98% of tumor received the prescribed dose. Thick *orange line* represents the 80% isodose. (Reprinted from Wegner RE, Rodriguez KD, Heron DE, et al. Linac-based stereotactic body radiotherapy for treatment of glomus. *Radiother Oncol* 2010;97[3]:395–398. Powell et al.[25] reported on 84 patients with chemodectoma of the head and neck, 46 of which were in the glomus jugulare and tympanicum, treated with irradiation alone (45 to 50 Gy in 25 fractions). Local control of the lesion was 73% at 5 years. Thirty patients were treated with surgery after irradiation with no recurrences (median follow-up of 9 years). Four patients, treated with surgery alone, developed recurrences by 7 years. Four carotid body and glomus vagal tumors treated with irradiation were locally controlled at 1, 2, 8, and 11 years, respectively. In 13 patients treated with surgery alone, the 15-year local control rate was 54%.

Hinerman et al.[52,53] updated a previous report with 104 patients who had 121 chemodectomas of the temporal bone, carotid bone, or glomus vagal treated with radiation therapy alone in 104 patients or subtotal resection with or without radiation therapy (17 tumors). Seventeen patients had undergone a previous

treatment (surgery 14, irradiation 1, or both 2). Eighty-nine patients were treated with megavoltage radiation therapy, 15 with stereotactic fractionated, 6 with stereotactic single dose, and 11 with IMRT. Median dose with fractionated irradiation was 45 Gy with daily fractions of 1.5 to 2 Gy delivered with[54] Co, 6-MV or 8-MV x-rays, or a combination of different beam energies.[53] There were six tumor recurrences, with a local tumor control of 95%. No severe treatment complications were noted. In the initial report,[52] 18 patients had 25 chemodectomas of carotid body and/or glomus vagal; 15 tumors originated in the carotid body and 10 in the glomus vagal. Pathologic confirmation of chemodectoma was obtained in 10 patients, and diagnosis was based on physical and radiographic findings in the remaining 8 patients. Twenty-two lesions were treated with radiation therapy alone, and two received postoperative radiation therapy after surgical resection for gross residual tumor with malignant changes and lymph node involvement. Patients with benign glomus tumors received 45 Gy in 25 fractions, in most instances, whereas patients with malignant carotid body tumors received 64.8 to 70 Gy in 1.8-Gy fractions. Local tumor control was obtained in 14 of 15 carotid body and 10 of 10 glomus vagal (overall 96% tumor control).[55]

Ivan et al.[56] published a meta-analysis based on 869 patients in 46 studies reported with glomus tumors, with follow-up ranging from 6 to 256 months. The tumor control rates were, for subtotal resection 69%, gross tumor resection (GTR) 86%, subtotal resection and radiosurgery 71%, and stereotactic radiosurgery (SRS) alone 95%. Posttreatment cranial nerve deficit was observed in 26% to 40% of patients treated with GTR and in about 10% of the SRS group. Guss et al.[57] reported on a meta-analysis of 19 studies (335 patients) with glomus tumors treated with SRT (radiosurgery), eight publications with a median follow-up of 36 months; tumor control (unchanged or reduced tumor volume) was 95% to 96%, with various SRT techniques.

In 29 patients with postsurgical recurrent glomus tumors (16 jugular, 7 carotid, 5 tympanic, and 1 thyroid) Elshaikh et al.[58] reported a 5-year tumor control of 100% in 12 treated with radiation therapy and 62% in 17 treated surgically.

Cheesman and Kelly[59] emphasized the importance of evaluating preoperatively the swallowing function of patients with glomus jugulare undergoing surgery, as it is common for these patients to develop postsurgical dysphagia.

The results of primary treatment for temporal bone chemodectoma are

summarized in Table 51.5.

The initial results of treatment for carotid body or glomus vagal are summarized in Table 51.6. Complications were rare in patients treated with chemodectoma of the head and neck.

HEMANGIOPERICYTOMA

Hemangiopericytomas (HPCs) are rare soft tissue neoplasms that account for 3% to 5% of all soft tissue sarcomas and 1% of all vascular tumors. Some 15% to 30% of all HPCs occur in the head and neck, and of these, approximately 5% occur in the sinonasal area. They may resemble meningiomas in the central nervous system (CNS), clinically, and on imaging studies.[66] Vagal paragangliomas originate within the first 2 cm of the extracranial stretch of the vagus nerve and are associated with the inferior ganglion.[67] These tumors are believed to originate from the pericytes of Zimmerman extravascular cells, morphologically resembling smooth muscle, found around the capillaries or from primitive mesenchymal cells. The function of the pericyte is uncertain but is believed to provide mechanical support for the capillaries having contractile function.[68]

Epidemiology

HPC is an unusual tumor; representing approximately 1% of all vascular neoplasms; it occurs in both genders with equal frequency and is found primarily in adults. In the head and neck, the most common sites are the nasal cavity and the paranasal sinuses and, less frequently, the orbital region, the parotid gland, and the neck.[15,69–71] HPCs represent 3% to 4% of all meningeal and <1% of CNS tumors.

Pathology

HPCs are composed of a proliferation of tightly packed pericytes around thin-walled endothelial-lined vascular channels, ranging from capillary-sized vessels to large, gaping sinusoidal spaces.[69] The tumor has a tendency to grow slowly and invade locally into adjacent structures.[15,72] Although they are always well circumscribed and partially or completely surrounded by a pseudocapsule, benign tumors may be difficult to differentiate from malignant tumors. However, prominent mitoses (>4 per high-power field), foci of necrosis, and increased cellularity are suggestive of malignancy; the definitive sign is local recurrence or

development of metastases. In general, tumors of the CNS, lower extremity, and mediastinum tend to be more malignant, with local recurrence occurring in up to 50% of cases.[69]

Kowalski and Paulino[73] reviewed 12 cases of HPCs. The mitotic index per 10 high-power fields varied from 0 or 1 to 15. Proliferation indices using MIB-1 (Ki-67) ranged from 2.6% to 52.5%. Clinical follow-up showed three cases with recurrence all possessing proliferation indices of approximately 10%, indicating a more aggressive subset of HPCs. Vuorinen et al.[74] found proliferation index to be a poor predictor of prognosis. Meningeal HPCs almost always recur, despite seemingly complete removal, because of infiltrative properties of HPC cells and not just higher proliferation potential. They often metastasize.

Clinical Presentation

Soft tissue HPC is a firm, painless, slowly expanding mass that is often nodular and well localized. The skin overlying the mass does not have any discoloration or redness to indicate its vascular origin because the capillaries are emptied of the blood by compression of massive numbers of pericytes surrounding them.[67,69,75])

In the head and neck, the tumor may constitute a polypoid, soft gray or red mass that grows slowly and may cause nasal obstruction. Epistaxis and nasal obstruction are common symptoms. Orbital HPCs account for 3% of orbital malignancies and most frequently occur with painless proptosis.[76] HPC rarely originates in the lacrimal sac; it occurs in a younger age group than that of HPC of other locations. Charles et al.[77] reported on seven cases previously described and added one case.

HPC may occur intracranially. When it arises in the brain, it is a solid mass attached to the meninges that grossly resembles a meningioma. These intracranial HPCs carry a high risk of local failure (80%), as well as higher potential for dissemination. The mean time for local recurrence is 75 months.[75]

The incidence of metastasis, which depends on the site of origin, can be 50% to 80%. Late metastases occurring 10 years after diagnosis are not uncommon.

On plain radiographs, HPC appears as a soft tissue mass in the nasal cavity or other portions of the head and neck. A defect caused by pressure erosion of the surrounding bones may occur, and calcifications are rare. In the neck, the tumor appears as a well-circumscribed, homogeneously and intensely enhancing mass on CT. On MRI, the mass is iso- to slightly hyperintense to muscle on T1- and T2-weighted imaging. Multiple, branching flow voids are typically seen within

the tumor on both T1- and T2-weighted images. On T2-weighted imaging, the punctate black flow voids in cross-section within the relatively bright tumor, creating a characteristic “salt-and-pepper” appearance in tumors >2 cm in diameter. Additionally, flow voids of large feeding arteries are seen at the periphery of the mass. Angiography demonstrates the characteristic appearance of a vascular tumor, with large feeding arteries, intense tumor stain, and early draining veins.[67] On arteriography, according to Yaghmai,[78] HPC is the only vascular tumor that has radially arranged or spiderlike branching vessels around and inside the tumor and a long-standing, well-demarcated tumor stain. Intracranial tumors typically have arterial blood supply from both meningeal and cerebral connections, with one to three main feeders supplying many small corkscrew-like vessels.[75] The most distinctive and constant feature of this tumor is its hypervascularity, which may be demonstrated with contrast-enhanced CT.[70] Intracranially, the diffusely enhancing tumor may closely resemble a meningioma on CT. However, some CT signs may suggest HPC rather than meningioma, such as a lack of calcification, scarce surrounding edema, and ringlike enhancement. Both CT and MRI scans are of special value in the delineation of the full extent of the tumor.

General Management

Complete surgical resection, if possible, combined with preoperative embolization of the tumor, is the treatment of choice. More extensive surgery is required in tumors that show features of malignancy. Many patients undergo surgical treatment after embolization of the feeding artery(ies).

For incompletely resected tumors, postoperative radiation therapy is used.[79,80] The role of chemotherapy in this tumor is not well determined; a few reports have described partial tumor regression in some lesions treated with cytotoxic agents. Doxorubicin, alone or in combination drug regimens, is the most effective agent for metastatic HPC, producing complete and partial remissions in 50% of cases. Other drugs prescribed when metastasis occurs are cyclophosphamide, dacarbazine, vincristine, and actinomycin D.[81] Park et al.[82] reported on 14 patients with soft tissue HPC treated with temozolomide 150 mg/m^2 orally on days 1 to 7 and days 15 to 21 and bevacizumab 5 mg/kg intravenously on days 8 and 22, repeated at 28-day intervals. Median follow-up period was 34 months. Eleven patients (79%) achieved a partial response, with a median time to response of 2.5 months. Estimated median progression-free survival (PFS) was 9.7 months, with a 6-month progression-free rate of 78.6%.

The most frequently observed toxic effect was myelosuppression.

Radiation Therapy Techniques

The role of radiation therapy alone in the management of HPC is controversial. The main role of irradiation is as an adjuvant after complete excision of the lesion or postoperatively for minimal residual disease.[71,83,84] The tumor has been considered relatively radioresistant. Tumor doses of 60 to 65 Gy in 6 to 7 weeks are required to produce local tumor control in postoperative cases.[85] Orbital HPC has been cured by surgery and postoperative irradiation to 65 Gy.[76]

There appears to be a definite role for postoperative irradiation to the brain for primary HPC when radical surgery is performed because these tumors tend to recur after seemingly complete removal. Jha et al.[84] reported local tumor control in all patients treated with adjuvant external beam irradiation postoperatively. Radiation therapy also has been used as a salvage procedure after local recurrence following initial surgery or chemotherapy.

The fields of irradiation should be wide to encompass the tumor bed with a margin of at least 5 cm to safely avoid marginal recurrence. Portal arrangement and beam selection are similar to those used in treatment of malignant brain tumors or soft tissue sarcomas.

Results of Therapy

Billings et al.[86] reported on 10 patients with HPC of the head and neck; seven tumors arose from soft tissue sites and three from the mucosa. All patients underwent wide excision of the primary lesion with a local recurrence rate of 40%. Three patients developed metastatic lung disease 0 to 8 years after initial diagnosis. Each patient who developed metastatic disease had abundant mitoses on pathologic review compared with rare or absent mitoses in the lesions that took a more benign course.

Patrice et al.[87] reported on 18 primary hemangioblastoma tumors (16 had no prior surgical resection and 2 were subtotally resected lesions) and 20 lesions treated after surgical failure with stereotactic irradiation (radiosurgery). Minimum tumor doses ranged from 12 to 20 Gy (median 15.5 Gy). With a median follow-up of 24.5 months (range 6 to 77 months), the 2-year actuarial survival was 88%, and the 3-year freedom from progression was 86%. Four of twenty-two patients died. Thirty-one of thirty-six evaluable tumors (86%) were controlled locally. None of the 18 primary tumors treated with definitive stereotactic irradiation failed. Of the 18 recurrent tumors, 13 (72%) were

controlled. There were no significant permanent complications attributable to the stereotactic irradiation.

Spitz et al. published a report on 36 patients with HPC. The median follow-up was 57 months. Twenty-eight patients (78%) underwent complete and potentially curative resection. Of the nine patients (32%) who had local recurrences, four (44%) had epidural tumors and three (33%) had retroperitoneal tumors, but none had extremity tumors. Ten patients had recurrences at distant sites. Of the 13 patients who experienced any form of disease recurrence, four had recurrences after a disease-free interval of more than 5 years. The 5-year actuarial survival rate for the entire group of 36 patients was 71%.

Carew et al.[88] reviewed the records of 12 patients with HPCs of the head and neck: 5 had high- or intermediate-grade lesions and 7 had low-grade lesions. Nine patients were treated with curative intent; they underwent a variety of surgical resections dictated by tumor location and size. Four patients received postoperative radiation therapy, to a median dose of 60 Gy, for positive surgical margins (two patients), high-grade histology (one patient), or a recurrent lesion (one patient). The 5-year overall survival (OS) rate for patients treated surgically was 87.5%. A single mortality occurred in a patient with a recurrent high-grade lesion who failed at local, regional, and distant sites.

Staples et al.[89] reported on 12 patients with localized HPC, 7 treated with surgery alone (only 1 had long-term tumor control and 2 were salvaged with radiation therapy), 4 with resection and postoperative irradiation (all with long-term tumor control), and 1 with surgery and chemotherapy. Local tumor control was achieved at all sites treated with doses >55 Gy. Mitotic activity was not a reliable predictor of biologic behavior.

Kim et al.[51] evaluated 17 HPCs in nine patients treated with Gamma Knife SRT. Mean and median marginal doses were 18.1 and 20 Gy (range 11 to 22 Gy), respectively, at the 50% isodose line. Mean clinical and radiologic follow-up periods were 49 and 34 months, respectively. Successful tumor control was achieved in 14 of 17 lesions (82.4%). Actuarial local tumor control rate at 5 years was 67%. No adverse effects, such as radiation necrosis or marked peritumoral edema, were observed. Marginal dose (≥17 Gy) was the only statistically significant factor for local tumor control on univariate analysis.

Kano et al.[90] published a retrospective review of 20 patients who had undergone SRT for 29 HPCs after previous surgical resection. In addition, 12 patients underwent fractionated radiation therapy before SRT. Of the 20 patients, 16 patients had low-grade HPCs (20 tumors) and 4 had high-grade anaplastic

HPCs (9 tumors). The median target volume was 4.5 cm^3 and the median marginal dose was 15 Gy (range 10 to 20 Gy). At an average of 48.2 months, the overall survival after radiosurgery was 85.9% and 13.8% at 5 and 10 years, respectively. Follow-up imaging studies demonstrated tumor control in 21 (72.4%) of 29 tumors. The PFS rate after SRT at 3 and 5 years was 89.1% for low-grade HPCs and 66.7% and 0%, respectively, for high-grade HPCs. The factors associated with improved PFS included lower grade and >14 Gy marginal radiation dose.

Olson et al.[91] published a review of 21 patients with 28 recurrent or residual HPCs on whom radiosurgery was performed. Prior treatments included embolization (6 cases), transcranial resection (39 cases), transsphenoidal resection (2 cases), and fractionated radiotherapy (8 cases). The mean prescription and maximum radiosurgical doses to the tumors were 17.0 and 40.3 Gy, respectively. Repeat radiosurgery was used to treat 13 tumors. With a median follow-up of 68 months (range 2 to 138 months), local tumor control was 47.6% (10 of 21 patients). Of the 28 tumors treated, 8 decreased in size on follow-up imaging (28.6%), 5 remained unchanged (17.9%), and 15 ultimately progressed. PFS at 5 years was 28.7%, and it improved to 71.5% after multiple radiosurgery treatments. In 4 of 21 (19%) patients, extracranial metastases developed.

Redmond et al.[92] reported on 118 patients with HPC of the CNS, 9% of whom had distant metastases at the time of initial presentation; 112 patients underwent surgical resection (23% had gross total resection, GTR, 31% had subtotal resection, and 46% had surgery not otherwise specified). Adjuvant RT was received by 31% of patients following GTR, 44% after subtotal tumor resection, and 50% of patients following surgery not otherwise specified. The 5- and 10-year overall survival for all patients was 76.7% and 50.1%, respectively. Patients receiving adjuvant RT (n = 42) had a significantly better overall survival than patients who did not (n = 67; 10-year overall survival was 66.2% vs. 40.7%; P = .05). There was no difference in 5- or 10-year overall survival for patients treated with subtotal resection plus RT (n = 16) compared with those treated with GTR alone (n = 14; 10-year overall survival 75% vs. 57.1%; P = .53)

Shaigany et al.[93] reported on a study of the Surveillance, Epidemiology, and End Results (SEER) database (1973 to 2012) encompassing 121 cases of HPC and compared results with 510 of other body sites with HPC. Head and neck HPC (HN-HPC) was most commonly located in the connective and soft tissue (18.4%), followed by the nasal cavity and paranasal sinuses (8.5%). Head and

neck HPCs were smaller than other HPC and more likely to be of lower histologic grade. Primary treatment modality for HN-HPC was surgery alone 95.8% of cases). The 5-, 10-, and 20-year DSS for HN-HPC were 84.0%, 79.4%, and 69.4%, respectively. Higher histologic grade and the presence of distant metastases were poor prognostic factors. Adjuvant radiotherapy did not appear to confer a survival benefit for any body site.

CHORDOMAS

Anatomy

Chordomas are rare neoplasms of the axial skeleton that arise from the remnant of the primitive notochord (chorda dorsalis). About 50% arise in the sacrococcygeal area; 35% arise intracranially, where they typically involve the clivus, and the remaining 15% occur in the midline along the path of the notochord, primarily involving the cervical vertebrae.[93]

Epidemiology

Chordomas are more common in patients in their 50s and 60s but can occur in all age groups. In children and young adults, the prognosis and long-term survival appear to be better than in older patients. No risk factors have been identified. Male predominance is reported at a 2:1 to 3:1 ratio.

Natural History

Although slowly growing, chordomas are locally invasive, destroying bone and infiltrating soft tissues. Basisphenoidal chordomas tend to cause symptoms earlier and may be difficult to differentiate histologically from chondromas and chondrosarcomas and radiographically from craniopharyngiomas, pineal tumors, and hypophyseal and pontine gliomas. The lethality of these tumors rests on their critical location, aggressive local behavior, and extremely high local recurrence rate. The incidence of metastasis, which has been reported to be as high as 25%, is higher than previously believed and may be related to the long clinical history. The most common site of distant metastasis is the lungs, followed by the liver and bone. Lymphatic spread is uncommon.

Pathology

Chordoma is a soft, lobulated tumor that may have areas of hemorrhage, cystic changes, or calcification. It is frequently encapsulated but may be nonencapsulated or pseudoencapsulated. Histologically, it is composed of cords

or masses of large cells (physaliferous cells) with typical vacuoles and granules of glycogen in the cytoplasm and abundant intercellular mucoid material. Usually, there are few mitotic cells.[94] A chondroid variant of chordoma may exist, being prevalent in the spheno-occipital area. Patients with this type of histologic variant have improved survival.

Aside from the previously mentioned histologic features, the prognostic factors that most influence the choice of treatment are location and local extent of tumor.

Clinical Presentation

Chordomas tend to originate from the clivus and chondrosarcomas from the temporal bone.[95] Clinical symptoms vary with the location and extent of the tumor. In the head, extension may be intracranial or extracranial, into the sphenoid sinus, nasopharynx, clivus, and sellar and parasellar areas, with a resultant mass effect. In chordomas of the spheno-occipital region, the most common presenting symptom is headache. Other presentations include symptoms of pituitary insufficiency, nasal stuffiness, bitemporal hemianopsia, diplopia, and other cranial nerve deficits. Volpe et al.[96] reviewed the clinical features of 48 patients with chordoma and 49 patients with low-grade chondrosarcoma of the skull base. Twenty-five patients (52%) with chordoma and 24 patients (49%) with chondrosarcoma had ocular symptoms (diplopia or visual impairment) as the initial manifestation of the disease. Of the 59 patients (both groups) with diplopia, it was initially intermittent in 25 (42%). Headache and diplopia from abducens nerve palsy occurred in 22 patients (46%) with chordoma and 23 (47%) with chondrosarcoma.

Diagnostic Workup

The diagnostic workup varies with the primary location of disease. Most patients have significant bony destruction, and some may have calcifications in the tumor; hence, plain films and, specifically, CT scans or MRI are very useful (Table 51.7).[97] In most cases, the soft tissue component is much more extensive than initially appreciated, and a CT scan with contrast enhancement is required (Fig. 51.7A). CT and MRI are equivalent for demonstration of the presence and site of these tumors. MRI is inferior to CT in its ability to demonstrate bony destruction and intratumoral calcification (Fig. 51.7B).[98] MRI is superior to CT regarding the delineation of the exact extent of the tumor, which allows for better treatment planning. Because of availability and lower cost, CT appears to be the

technique of choice for routine follow-up of previously treated patients.[98]

Reliable signs of chordoma of the skull base are posterior extension to the pontine cistern; a lobulated, "honeycomb" appearance after gadolinium; the swollen appearance of the bone in the early stages; bone erosion on CT; and frequent extension to critical structures such as the circle of Willis, cavernous sinuses, and brainstem.[98]

General Management

Because of their surgical inaccessibility and relative resistance to radiation therapy, clivus chordomas represent a formidable therapeutic challenge. The general management of the patient is dictated by the anatomic location of the tumor and the direction and extent of spread. A surgical approach is recommended (when feasible), but complete surgical extirpation alone is unusual.[8] Regression of preoperative symptoms without additional postoperative morbidity could be achieved by radical transoral tumor extirpation documented by MRI. Intracranial spread usually requires steroid coverage and therapy directed to correction of neurologic deficits that may be present. Because of the high incidence of local recurrence, combined surgical excision and irradiation is frequently used. No effective chemotherapeutic agent or combination of drugs has been identified.

Radiation Therapy Techniques

Irradiation techniques vary considerably, depending on the location of the tumor along the craniospinal axis. Basisphenoidal tumors usually have been treated by a combination of parallel-opposed lateral fields, anterior wedges, photon and electron-beam combinations, and 3DCRT or IMRT photons or protons, depending on the extent of the neoplasm. Precision radiation therapy planning, using CT and MRI, is required because high doses of external beam radiation

therapy are needed. Three-dimensional CRT or IMRT with photons or protons provides optimal dose distributions.

The tumor usually surrounds the spinal cord and infiltrates vertebral bones. A combined technique using protons or electrons to boost the initial photon fields is generally applied. In the treatment of chordomas surrounding the spinal cord, IMRT can provide high-dose homogeneity and planning target volume (PTV) coverage (Fig. 51.8). Frequent 3-D (cone-beam CT, megavoltage CT) or digital portal image-based setup control reduces random positioning errors for head and neck cancer patients immobilized with conventional thermoplastic masks. Gabriele et al.[99] treated a patient with incomplete resection of a vertebral chordoma surrounding C2-C3 with a total dose of 58 Gy in 2-Gy daily fractions. Beam arrangement consisted of IMRT technique. The mean dose to the PTV was 57.6 Gy covering 95% of the PTV with the 95% isodose. The minimum dose to the PTV (D99) was 53.6 Gy. The maximum dose to the spinal cord was 42.2 Gy and to the spinal cord planning risk volume (8-mm margin) 53.7 Gy. The mean dose to the parotids was 37.4 Gy (homolateral gland) and 19.5 Gy (contralateral gland).

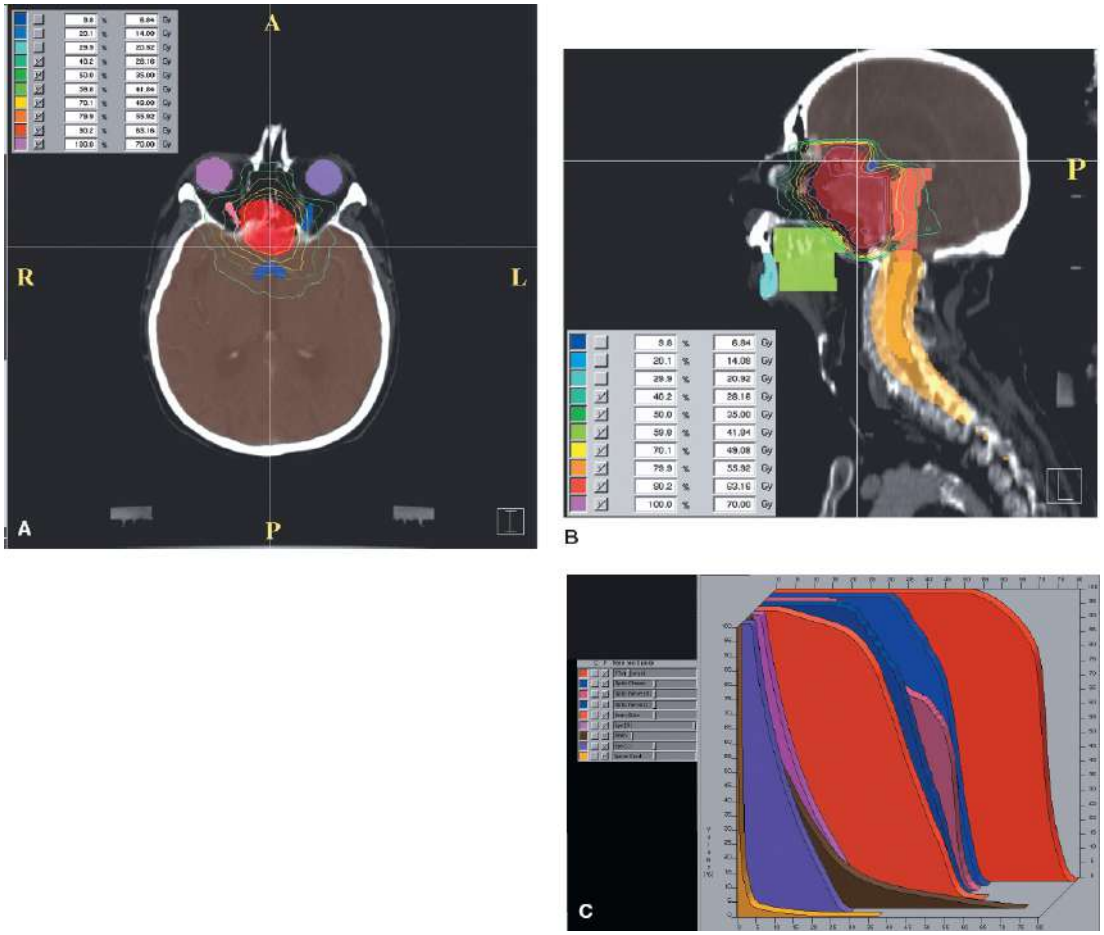

FIGURE 51.8. Chordoma of the clivus in an 81-year-old man treated with 70 Gy in 2-Gy fractions. Example of intensity-modulated radiation therapy plan: **A:** Cross-section in the upper portion of planning target volume (PTV), demonstrating coverage of target volume with sparing of ocular structures. **B:** Sagittal plane dose distribution with excellent coverage of PTV. **C:** Dose–volume histogram.

Because of the slow proliferative nature of chordomas, high linear energy transfer may prove useful in their management, as will be discussed later. Brachytherapy can be used for recurrent tumors of the base of the skull or adjacent to the spine when a more aggressive surgical exposure is offered.

Structure	Dose Range (cGy)	Mean Dose (Gy)
PTV (including left neck)	60–75	70
Optic nerves/chasm	25–50	41
Ocular globe	3–30	12

Results of Therapy

Photons

Although survival in some patients with chordoma may be long term, the salient

feature of this unusual neoplasm is local recurrence with eventual death. The course may be indolent, with multiple treatments for recurrences, but the overall 5-year disease-free survival rate is <10% to 20%. Catton et al.[100] analyzed the long-term results of treatment for patients with chordoma of the sacrum, base of the skull, and mobile spine treated predominantly with postoperative photon irradiation. In 20 base-of-skull chordomas, most of them irradiated with conventionally fractionated radiation to a median dose of 50 Gy in 25 fractions for 5 weeks (range 25 to 50 Gy), median survival was 62 months (range 4 to 240 months) from diagnosis with no difference between clival and nonclival presentations. There was no survival advantage to patients receiving radiation doses >50 Gy (median 60 Gy) compared with lower doses <50 Gy (median 40 Gy). Hyperfractionation regimens did not influence the degree or duration of symptomatic response or PFS. Median survival after retreatment was 18 months.

Forsyth et al.[101] reported on 51 patients with intracranial chordomas (19 classified as chondroid) treated surgically (biopsy in 11 patients and subtotal removal or greater in 40); 39 patients received postoperative irradiation. At the time of the analysis, 17 patients were alive. The 5- and 10-year survival rates were 51% and 35%, respectively; 5-year survival was 36% for biopsy patients and 55% for those who had resection. Patients who underwent postoperative irradiation tended to have longer disease-free survival times.

Gay et al.[102] analyzed the outcome of 46 patients with cranial base chordomas and 14 with chondrosarcomas after extensive surgical resection, 50% of them treated previously and 20% received postoperative irradiation. Nine patients with chordomas and two with chondrosarcomas died during the postoperative follow-up period. The 5-year recurrence-free survival (RFS) for all patients was 76%. Chondrosarcomas had a better prognosis than chordomas (5-year RFS of 90% and 65%, respectively; $P = .09$). Patients who had undergone previous surgery had a greater risk of recurrence than did those who had not undergone previous surgery (5-year RFS rates of 64% and 93%, respectively; $P < .05$). Those with total or near-total resection had a better 5-year RFS rate (84%) than did patients with partial or subtotal resection (64%; $P < .05$). Postoperative leakage of cerebrospinal fluid was the most frequent complication (30% of patients) and was found to increase the risk of permanent disability. Patients who had undergone previous irradiation had a greater risk of death in the postoperative period (within 3 months of operation) and during follow-up.

Tai et al.[103] reviewed the results of irradiation combined with surgery, irradiation alone, and surgery alone in 159 patients reported in the literature. An

analysis of the optimal biologically equivalent dose was performed using the linear-quadratic formula on 47 patients. With conventional photon irradiation, no dose–response relationship was shown. Survival improved in patients undergoing surgery followed by irradiation.

Keisch et al.[104] reported on 21 patients with chordoma treated at the authors' medical center: 5 had clival tumors, 2 had nasopharyngeal tumors, and 1 had a lumbar spine tumor. Nine patients were treated with surgery alone, eight had subtotal resection and postoperative irradiation, and four received irradiation alone after biopsy. The 5- and 10-year actuarial survivals were significantly better in patients treated with surgery alone or surgery and irradiation than in those treated with radiation therapy alone (52%, 32%, and 0%, respectively; P = .02). Disease-free survival of patients with base-of-skull tumors was not significantly different among the treatment groups.

Kim et al.[105] reported 14 clivus chordomas undergoing postoperative IMRT simultaneous integrated boost (SIB). Total and near-total resections were achieved in 11 patients (78.6 %) and partial in 2 patients (14.3 %), and 1 patient (7.1 %) received RT for recurrent tumor after total resection. A moderate hypofractionation schedule was used: Doses to PTV1, PTV2, and PTV3 were 3.9 Gy, 3.15 Gy, and 2.8 Gy through 15 fractions for the first two patients, and the rest received 2.5, 2.2, and 1.8 Gy through 25 fractions. The biologically equivalent dose in 2-Gy fractions (EQD2) was 65 to 68 Gy for PTV1, 52 to 56 Gy for PTV2, and 44.3 to 44.8 Gy for PTV3. Median follow-up was 41 months. Eight patients were free of disease for a median of 42.5 months (range 23 to 91 months), four patients had stable disease for a median of 60.5 months, and 1 patient showed partial response for 38 months after RT. Estimated 5-year progression-free and overall survival rates were 92.9 %. IMRT-SIB was well tolerated without lasting toxicity. Debus et al.[106] reported on 45 patients treated for chordoma or chondrosarcoma with postoperative fractionated 3-D SRT. Median dose at isocenter was 66.6 Gy for chordomas and 64.9 Gy for chondrosarcomas. All chondrosarcomas achieved and maintained local tumor and recurrence-free status at 5-years of follow-up. Local control rate of chordomas at 5 years was 50% and survival was 82%. Clinically significant late toxicity developed in only one patient.

Den et al.[107] described a multi-institutional study of 31 patients, 28 with clivus chordoma or chondrosarcoma, treated with various photon techniques (single-dose stereotactic, fractionated 3DCRT, IMRT). Median fractionated total dose was 65 Gy. Actuarial 3-year local tumor control was 68% and overall

survival 63%. Patients receiving 65 Gy or a higher dose had a 5-year tumor control of 78% and overall survival of 90%. No grade 2 or greater toxicity was observed.

Muthukumar et al.[108] published a report on 15 patients with skull base chordoma and chondrosarcoma treated with SRT (13 had previous surgical resection). Median minimum marginal tumor single dose was 18 Gy (12 to 20 Gy) and the number of isocenters ranged from 1 to 10 (average, 4). Dose to optic nerve or chiasm was ≤9 Gy. With a median follow-up of 40 months, eight patients had clinical improvement, three were stable, and four had died. No significant morbidity was noted.

Protons

The best results in the treatment of chordomas have been obtained with radical surgery followed by high-dose proton irradiation.[109] Berson et al.[110] described 45 patients with chordomas or chondrosarcomas at the base of the skull or cervical spine treated by subtotal resection and postoperative irradiation. Twenty-three patients were treated definitively by charged particles, 13 patients with photons and particles, and 9 were treated for recurrent disease. Doses ranged from 36 to 80 Gy equivalent (GyE). There appeared to be significant benefit for patients with smaller tumor volumes (80% vs. 33% actuarial survival rate at 5 years). Patients treated for primary disease had a 78% actuarial local tumor control at 2 years versus 33% for recurrent disease.

Austin et al.[111] evaluated 141 patients with chordoma and chondrosarcoma of the base of skull and cervical spine treated with proton and photon irradiation. The local disease was controlled in 111 patients. They reviewed 26 patients who had recurrent disease (21 nonchondroid chordomas, 2 chondroid chordomas, and 3 chondrosarcomas). The prescribed doses ranged from 67 to 72 Cobalt Gray Equivalent (CGE). Approximately 25% (6 of 26) of the cases failed in the prescribed dose region. More than half (15 of 26) failed in regions where tumor dose was limited by normal tissue constraints. Approximately 10% of the patients recurred in the surgical pathway and 10% were judged to be marginal misses. Overall, 75% of the patients failed in regions receiving less than the prescribed dose. All tumors that failed in the high-dose region had recurrences (10 of 26) and larger tumors (average volume of 102 cc) than those with base-of-skull disease (16 of 115) with an average volume of 63 cc.

O'Connell et al.[112] reported on 62 patients with base-of-skull chordomas treated with proton-beam irradiation (65 to 73.5 GyE); 29 patients (19 women

and 10 men) experienced local failure, and 14 women (48%) and 7 men (21%) died of disease. On histologic analysis, the presence of >10% necrosis, prominent nucleoli, and tumor >70 mm were significant predictors of short-term disease-specific survival (DSS). Chondroid chordoma and conventional chordomas had equivalent outcomes.

Fagundes et al.[113] updated the Massachusetts General Hospital experience with 204 patients treated for chordoma of the base of the skull or cervical spine. Sixty-three patients (31%) had treatment failures, which were local in 60 patients (29%) and the only site of failure in 49 patients. Two patients had regional lymph node relapse, and three developed surgical pathway recurrence. Thirteen patients relapsed in distant sites (especially lungs and bones). The 5-year actuarial survival rate after any relapse was 7%. Terahara et al.[114,115] reported on 132 patients with skull base chordoma treated with combined photon and proton irradiation; in 115 patients, dose–volume data and follow-up were available. The prescribed doses ranged from 66.6 to 79.2 CGE (median 68.9 CGE). Dose to the optic structures (optic nerves and chiasm), the brainstem surface, and the brainstem center was limited to 60, 64, and 53 CGE, respectively. Local failure developed in 42 of 115 patients, with the actuarial local tumor control rates at 5 and 10 years being 59% and 44%, respectively. In a Cox multivariate analysis, the model's equivalent uniform dose suggested that the probability of recurrence of skull base chordomas depends on gender, target volume, and target dose inhomogeneity; equivalent uniform dose was shown to be a useful parameter to evaluate dose distribution for the target volume.

Hug et al.[116] analyzed efficacy of fractionated proton radiation therapy for 33 skull base chordomas and 25 chondrosarcomas. Following various surgical procedures, residual tumor was present in 91% of patients; 59% demonstrated brainstem involvement. Target doses ranged from 64.8 to 79.2 CGE (mean 70.7 CGE). The range of follow-up was 7 to 75 months (mean 33 months). In 10 patients (17%), the treatment failed locally, resulting in local control rates of 92% (23 of 25 patients) for chondrosarcomas and 76% (25 of 33 patients) for chordomas. All tumors with volumes of ≤25 mL remained locally controlled compared with 56% of tumors >25 mL (P = .02). Of patients without brainstem involvement, 94% did not experience recurrence, whereas with brainstem involvement (and dose reduction because of brainstem tolerance constraints), the tumor control rate was 53% (P = .04). Actuarial 5-year survival rates were 100% for patients with chondrosarcoma and 79% for patients with chordoma. Grade 3 and 4 late toxicities were observed in four patients (7%) and were symptomatic

in three (5%).

Ares et al.[33] treated 42 patients with chordomas and 22 with chondrosarcomas of the skull base using spot-scanning protons (median doses 73.5 and 68.4 Gy, respectively, at 1.8 to 2.0 Gy relative biologic effect). With a median follow-up of 38 months, 5-year tumor control was 81% and 94% and overall survival 100% and 91%, respectively. Late toxicity consisted of one grade 3 and one grade 4 unilateral optic neuropathy and two patients with grade 3 CNS necrosis. No patient experienced brainstem toxicity.

Noel et al.[117] reported on 49 chordomas and 18 chondrosarcomas treated with high-energy photons (two-thirds of dose) and 201-MeV protons (one-third of dose). Median total dose was 67 CGE (60 to 70 CGE). With a median follow-up of 32 months, 3-year local tumor control was 71% for chordomas and 85% for chondrosarcomas and 4-year overall survival 88% and 75%, respectively. Fourteen tumors (21%) failed locally.

Recently, heavy particles have been used to treat some of these patients.[118,119] Hasegawa et al.[81,90] reported on 54 patients with skull base or paracervical tumors (31 with chordomas) treated with carbon ions (escalating doses from 48 to 60.8 GyE in 16 fractions over 4 weeks). In the 31 chordoma patients, 5-year local tumor control and overall survival were 78% and 85%, respectively. Patients were divided into two groups; a low-dose group (n = 10) irradiated with doses ranging from 48 to 57.8 GyE and a high-dose group (n = 21) irradiated with 60.8 GyE. The 5-year local tumor control was 60% for the low-dose group and 93% for the high-dose group, and the overall survival was 90% and 84%, respectively. One late grade 2 brain sequela was noted in a patient treated with 60.8 GyE.

Likewise, Schulz-Ertner et al.[34] treated 24 chordomas and 13 chondrosarcomas with 3-D planning carbon ions (median dose 60 GyE). With a mean follow-up of 13 months, local tumor control at 2 years was 90%. PFS was 83% for chordomas and 100% for chondrosarcomas. No significant toxicity was observed.

Benk et al.[120] described results in 18 children with base-of-skull or cervical spine chordomas who received fractionated high-dose postoperative irradiation using mixed photon and 160-MeV proton beams. Median tumor dose was 69 CGE with a 1.8-CGE daily fraction. With a median follow-up of 72 months, the 5-year survival was 68%, and the 5-year disease-free survival rate was 63%. Patients with cervical spine chordomas had a worse survival rate than did those with base-of-skull lesions (P = .008). Treatment-related morbidity was

acceptable: two cases of growth hormone deficit corrected by hormone replacement, one temporal lobe necrosis, and one fibrosis of the temporalis muscle, improved after surgery.

A report on proton therapy for base-of-skull chordoma published by the Royal College of Radiologists[121] concluded that outcome after proton irradiation is superior to that reported for conventional photon irradiation. Radiation therapy schedules involving a mixed schedule of protons and photons have achieved an approximately 60% local tumor control rate at 5 years.

Sequelae of Treatment

In patients treated with high irradiation doses, as well as with charged particles, there is an increasing probability of sequelae, including brain damage, spinal cord injury, bone or soft tissue necrosis, and xerostomia. In a report by Berson et al.,[110] three patients experienced unilateral visual loss, and four patients had radiation injury to the brainstem.

Santoni et al.[122] reported on the temporal lobe damage rate in 96 patients (75 primary and 21 recurrent tumors) treated with postoperative high-dose proton and photon irradiation for chordomas and chondrosarcomas of the base of the skull. All the patients were randomized to receive 66.6 or 72 CGE with conventional fractionation (1.8 CGE per day, 5 fractions per week) using opposed lateral fields for the photon component and a noncoplanar isocentric technique for the proton component. Of the 96 patients, 10 developed temporal lobe damage (bilateral in 2 and unilateral in 8). The cumulative temporal lobe damage incidence at 2 and 5 years was 7.6% and 13.2%, respectively. CT and MRI scans were evaluated for white matter changes; the MRI areas suggestive of temporal lobe damage in 10 patients were always separate from the tumor bed.

In patients receiving high-dose proton therapy for clivus tumors, Slater et al.[115] observed a 26% incidence of endocrine abnormalities at 3 years and 37% at 5 years, with hypothyroidism being the most frequent sequela. The dose to the pituitary in patients with abnormalities ranged from 63.1 to 67.7 GyE.

LETHAL MIDLINE GRANULOMA

Natural History and Pathology

Lethal midline granuloma (LMG) or midline malignant polymorphic reticulosis (PMR) is a clinical entity characterized by progressive, unrelenting ulceration and necrosis of the midline facial tissues.[123,124] LMG is associated with Epstein-

Barr virus, which has at least two subtypes with different biologic properties that can be identified by their genomic configuration. The occurrence of the rare subtype 2 in LMG may relate to a covert immune defect.[125] Considerable controversy exists regarding various disorders characterized by a necrotizing and granulomatous inflammation of the tissues of the upper respiratory tract and oral cavity. It is now clear that if infections and other known agents such as cocaine use, sarcoidosis, environmental toxins, and various neoplasms can be excluded, three clinical–pathologic entities remain: Wegener granulomatosis, LMG, and PMR.[18] A review of the literature suggests that cases described as idiopathic midline destructive disease and PMR are a large evolutionary spectrum from almost benign to fatal malignant natural killer/T-cell lymphoma.[126,127]

Wegener granulomatosis is an epithelioid necrotizing granulomatosis with vasculitis of small vessels. Systemic involvement of the kidneys and lungs is common.

PMR is an unusual disorder with distinctive clinical and pathologic features. Histologically, PMR is characterized by an atypical mixed lymphoid infiltration of the submucosa with extensive areas of necrosis, sometimes extending to the bone or cartilage. The lesion consists of variable zones of small lymphocytes with scattered immunoblastic forms and abundant plasma cells with occasional eosinophilia and histiocytosis.[127] PMR has been considered a lymphoproliferative disorder; most, if not all, cases are peripheral T-cell lymphomas. Several authorities believe that PMR and systemic lymphomatoid granulomatosis are the same disease, with the latter predominantly involving the lungs.[128]

Idiopathic LMG describes a localized disorder not characterized by visceral lesions but by destruction of the midfacial area, which, if left untreated, is uniformly fatal. The histopathologic findings are nonspecific, with a relatively nondescript inflammatory reaction with acute and chronic inflammation and necrosis. Despite specific clinical–pathologic features, the distinction between LMG and PMR is often difficult; although controversial, they may represent two phases of the same disease, with LMG remaining histologically benign or evolving into PMR. LMG occurs more frequently in men.[99]

Ages range from 21 to 64 years; almost half of the patients are in their 50s at presentation. Most patients have involvement of the nasal cavity (including destruction of the septum) and the paranasal sinuses (particularly maxillary antrum). The primary lesion may extend into the orbits, the oral cavity (palate, gingiva), and even the pharynx.

Characteristics of the three different diseases are outlined in Table 51.8.

Clinical Features and Diagnostic Workup

Clinical manifestations include progressive nasal discharge, obstruction, foul odor emanating from the nose, and, in later stages, pain in the nasal cavity, in the paranasal areas, and even in the orbits.

Examination discloses ulceration and necrosis in the nasal cavity, perforation or destruction of nasal septum and turbinates, and even ulceration of the nose. Edema of the face and eyelids may be noted, and the bridge of the nose may be sunken. Radiographic studies initially show soft tissue swelling, mucosal thickening, and findings consistent with chronic sinusitis.

CT is invaluable in demonstrating the full extent of the tumor, including bone or cartilage destruction. In 13 patients presenting with LMG, CT proved essential for determining the extent of the disease, guiding biopsy, and planning radiation therapy.[129] MRI was also helpful for the latter because it could distinguish fluid retained within the paranasal sinuses from solid masses and tumor from granulation tissue; it was of little value for detecting bone lysis. Eight patients proved to have T-cell lymphoma, two had Crohn disease, in one the lesion was factitious, and two had granulomas without diagnostic histologic features.

General Management and Radiation Therapy Techniques

When treatment of these patients is planned, it is extremely important to exclude the diagnosis of Wegener granulomatosis, a benign process that is commonly treated with antimicrobial agents, steroids, and systemic chemotherapy.[128] *Bona fide* LMG does not respond to steroids; the treatment of choice is radiation therapy.[130–132]

Target volume should encompass all areas of involvement, including adjacent areas at risk (i.e., for a lesion of the maxillary antrum, it will include the antrum as well as all of the paranasal sinuses) with a 2- to 3-cm margin.[133] Because marginal failures are a significant problem, wide margins are necessary for treatment of these patients.[127]

Irradiation techniques are similar to those described for tumors of the paranasal sinuses, nasal cavity, or nasopharynx. Several investigators have described complete responses with doses of 30 to 50 Gy; most patients are treated with 35 to 45 Gy in 3 to 4.5 weeks.[130,134] The authors recommend 45 to 50 Gy in 4.5 to 5.5 weeks in 1.8- to 2-Gy daily fractions.

Results of Therapy

Because of the rarity of this tumor, experience is limited. Fauci et al.[134] reported on 10 patients with extensive midline granuloma treated with irradiation. Three received 10 Gy, and all failed within 2 years (retreated with 40 to 46 Gy). The remaining seven patients received 40 to 50 Gy. Local control of disease was 77%; two patients had local recurrences, one outside the initially irradiated volume.

In a study of 34 patients with PMR treated with primary radiation therapy except for one patient, Smalley et al.[127] found that a minimum dose of 42 Gy or a time–dose factor of 70 was necessary to achieve long-term local control. The most frequent failure site was within the original irradiation field. Systemic failure occurred in 25% of their patients initially presenting with limited disease. The salvage of this subset of patients requires effective systemic chemotherapy. Multimodality treatment using intensive chemotherapy and radiation therapy might improve the prognosis of these patients.

Fauci et al.[134] published a prospective study of 15 patients with systemic lymphomatoid granulomatosis. Of 13 patients treated with cyclophosphamide and prednisone, seven sustained complete remission (mean duration of remission, 5.2 ± 0.6 years). Six deaths were associated with biopsy-proven lymphoma; one was caused by a lymphoma-like illness unproven by biopsy. The eighth death was caused by adenocarcinoma in a patient with lymphoma in remission. None of these patients received radiation therapy.

Chen et al.[135] reported their experience in 92 cases of LMG or centrofacial malignant lymphoma treated with radiation therapy. Twenty-five patients received combination chemotherapy, usually containing doxorubicin, cyclophosphamide, vincristine, and prednisone (CHOP) or other combinations, including CHOP or nitrogen mustard, vincristine, procarbazine, and prednisone (MOPP) in some patients. The nose was the most frequently involved site at initial presentation (85% of patients). Immunophenotyping in 36 patients showed T-cell lineage in 25 (69%) and B-cell lineage in 6 (17%). The irradiation technique consisted of treating all involved and adjacent areas with doses of 30 to 75 Gy. Sixteen patients received neck irradiation (30 to 60 Gy). Daily fractions were 2 to 3 Gy in 5 weekly fractions. Actuarial survival rates were 59.5% at 5 years, 56.2% at 10 years, and 40.5% at 20 years. There was no significant difference in survival in patients receiving <50 Gy. A relapse in the midfacial region was noted in seven patients. Other relapse sites were the lung and skin in three patients, para-aortic or inguinal lymph nodes in two patients,

and brain in one. Survival of patients with recurrences was poor; 73% died within 8 months.

TABLE 51.8 DIFFERENTIAL FEATURES OF THREE CLINICAL–PATHOLOGIC ENTITIES

	Wegener Granulomatosis	Idiopathic Midline Granuloma	Polymorphic Reticulosis
Disease features	Diffuse, inflammatory disease of the upper airway, predominately sinuses and nose	Destructive extension to the palate and facial soft tissues	Destructive lesion with destruction of the bone and extension through soft tissues
Systemic involvement	Lungs, kidneys, small-vessel vasculitis may not have airway involvement	No	No
Associated with lymphoma	No	May remain benign or progress to lymphoma	Usually evolves to lymphoma
Histologic features	Necrotizing vasculitis with epithelioid granulomas, giant cells, and fibrinoid necrosis	Inflammatory reaction, nonspecific; granulomas and giant cells are infrequent	Characteristic atypical and polymorphic lymphoreticular cellular infiltrate; angiocentric growth patterns may simulate vasculitis, but fibrinoid necrosis is absent in vessel walls
Treatment	Chemotherapy	Radiation therapy	Chemotherapy; radiation therapy and chemotherapy

Modified from Bataskis JG. Wegener's granulomatosis and midline (non peeling) granuloma. *Head Neck Surg* 1979;1(3):213–222. Copyright © 1979 Wiley Periodicals, Inc., A Wiley Company. Reprinted by permission of John Wiley & Sons, Inc.

Hatta et al.[136] reviewed 18 patients (15 males and 3 females) with LMG (PMR), about 5.6% of patients with malignant head and neck tumors. Most of the 18 patients underwent both radiation therapy and chemotherapy (cyclophosphamide, vincristine, prednisone [COP], CHOP, methotrexate, leucovorin, doxorubicin, cyclophosphamide, vincristine, bleomycin, and prednisone [MACOP-B]), but, because their disease had reached an advanced stage, three underwent radiation therapy only, three chemotherapy only, and one

received no radical therapy. Of the 18 patients, 13 died of the disease; in 6 patients, progress was confined to the local lesion. The 5-year cumulative survival rate was 15.7%. Fourteen autopsy studies showed that tumor involved the liver (92.8%), lung (92.8%), and spleen (71.4%), and in all cases, it was in leukemic patterns. Five cases were positive for ubiquitin carboxyl-terminal esterase L1 (ubiquitin thiolesterase) (CD45RO), and 10 cases were positive for lysozyme. All cases were positive for Ki-1 (CD30).

Sakata et al.[137] reported on 107 patients with stage I and II non-Hodgkin lymphoma of the head and neck treated with involved field radiation therapy for orbital, nasal, or paranasal lymphoma and extended-field radiation for Waldeyer ring or neck lymphoma (39 to 48 Gy). In the latter half of the study, adjuvant chemotherapy was administered. Of 107 patients, 95 achieved complete response. Of the 12 patients who did not achieve complete response, 9 had nasal T-cell lymphoma of the lethal midline granuloma (LMG-NTL) type. Only one patient who obtained chemoradiation relapsed in a previously irradiated area. LMG-NTL was the most significant prognostic factor on multivariate analysis ($P < .001$). Older patients also experienced a higher relative risk than patients aged ≤60 years ($P = .0063$). Dose of doxorubicin reached borderline significance ($P = .0600$). Radiation therapy is excellent for obtaining local control of head and neck of non-Hodgkin lymphoma and LMG-NTL.

CHLOROMA

Natural History

Chloroma (granulocytic sarcoma, myeloblastoma) is a solid extramedullary tumor composed of early myeloid precursors usually associated with acute myelocytic or nonlymphocytic leukemia. These tumors have predilection for the skin, lymph nodes, and the spine; most common head and neck sites of presentation are in the orbit and other craniofacial bones. The name chloroma (from the Greek *chloros*, meaning green) derives from the green color of affected tissues resulting from the presence of myeloperoxidase. Because not all deposits exhibit the characteristic green tint, the term *granulocytic sarcoma* (GS) seems more appropriate.

GS, an extramedullary proliferation of malignant myeloid precursor cells, was identified in 3% of 478 patients with acute chronic granulocytic leukemia; they can be seen with other myeloproliferative disorders, including polycythemia vera, hypereosinophilia, and myeloid metaplasia. In the absence of acute

leukemia, GS is usually an ominous sign, suggesting imminent conversion to acute myelocytic leukemia or blast crisis. As survival rates for myelogenous leukemias improve, the number of patients who relapse with chloromas is increasing.

Children are affected more often than adults. Of 33 patients with orbital chloromas reported by Zimmerman and Font,[138] 75% were in their first decade of life. Chloromas are found more frequently in children with the M4 and M5 acute myeloid leukemia (AML) subtypes of the French-American-British Cooperative Group Classification and are also associated with the 8:21 translocation. Chloromas may appear during bone marrow remission before an increase in blasts is detected in the bone marrow, so they may herald relapse.

Clinical Presentation and Diagnostic Workup

Intraorbital (retrobulbar) chloroma causes progressive exophthalmos or temporal swelling. CNS involvement causes both local pressure phenomena and generalized elevation of intracranial pressure with headaches, nausea, and vomiting. Intracerebral chloromas may manifest as the rare CNS (parenchymal) involvement of acute nonlymphocytic leukemia.[139,140]

Intracranial chloromas may exhibit intermediate or high attenuation in unenhanced CT scans, with intense, uniform enhancement with contrast material.[141,142] Confusion with meningioma, hematoma, solitary metastasis, and lymphoma may occur on CT scans.[127] MRI of GS is commonly used for a spinal or cranial location that demonstrates isointensity relative to gray matter on TI-weighted images and isointensity to white matter on T2-weighted images. GS demonstrates almost uniform enhancement with gadolinium, which further aids in delineating it.

General Management

Many of these patients are treated with anthracycline-based chemotherapy, although surgical excision or radiation therapy for masses is indicated.

Radiation Therapy Techniques

Chloromas are extremely radiosensitive; however, the optimal dose of irradiation has not been established. Response rates of leukemic infiltrates have been reported with doses as low as 4 Gy, yet the need for higher doses up to 30 Gy in certain locations of extramedullary leukemic infiltrates is well recognized. Although the literature is limited regarding the maximum dose needed for treatment of chloromas, Chak et al.,[143] in a study of 23 patients with GS,

reported that 20 to 30 Gy yielded 85% to 89% local tumor control. In the authors' limited experience, there appears to be a relationship between the size of the chloroma and the total dose of irradiation required for control. The target volume is the tumor mass and an adequate margin (2 to 3 cm). Irradiation techniques depend on the location of the infiltrate. For superficial lesions, electron beam is recommended. Orbital chloroma may constitute a radiation therapy emergency because visual loss is possible if the patient is not treated promptly.

Bakst et al.[142] reported on 38 patients who underwent treatment for chloromas at their institution The majority of the patients that presented with chloroma at the time of initial leukemia diagnosis (78%) did not receive radiation therapy (RT) because the tumor regressed after initial chemotherapy (CT). Yet, most patients that relapsed or remained with chloroma after CT are in the RT cohort (90%). Thirty-three courses of RT were administered to 22 patients, 39% in the head and neck. Median RT dose was 20 (6 to 36) Gy. PFS and overall survival in the RT cohort were 39% and 43%, respectively, at 5 years. The authors recommend irradiating chloromas to at least 20 Gy and propose 24 Gy in 12 fractions as an appropriate regimen.

Kuo et al.[144] described results in 43 lesions treated in 20 patients, the underlying hematologic diseases of the evaluated patients being AML in 14 (70%), chronic myeloid leukemia in 4, myelodysplastic syndrome with myeloid leukemia transformation in 1, and *de novo* GS in 1. Most patients (55%) received RT for GS at the time of relapse following bone marrow transplantation (BMT). The most common cytogenetic abnormality was t(8;21)(q22;q22). The median RT dose of 20 Gy (range, 6 to 35 Gy), administered in 1.5 to 3.5 Gy fractions, provided a 63% CR rate. One case with GS who received a hypofractionation RT regimen of 15 Gy in 5 fractions showed CR.

Hall et al.[145] reported on 90 RT courses administered for chloromas in 41 patients, 6 in the head and neck. Twelve patients were previously treated with systemic chemotherapy only, 13 with at least one prior hematopoietic stem cell transplant without TBI, and 16 with prior transplant with TBI. All patients received RT for chloroma; 27 patients also received systemic chemotherapy, 2 intrathecal chemotherapy, and 7 stem cell transplant, and 5 were treated with RT alone. Median dose was 24 (range 5 to 37) Gy. Median survival (MS) after RT was 3.6 months in patients treated with prior systemic chemotherapy alone, 10.7 months with prior chemotherapy-only transplant, and 3.4 months with prior TBI-based transplant (P = .66). A single course of palliative RT provided local

control (LC) in 89% of patients (95% CI 0.11 to 0.54). MS for patients referred for RT for consolidation was 26.2 months compared to 3.2 months in patients referred for palliation.

ESTHESIONEUROBLASTOMA

Esthesioneuroblastomas (ENBs), first described by Berger and Luc,[146] are rare tumors thought to arise in the olfactory receptors in the nasal mucosa or the cribriform plate of the ethmoid bone. The olfactory nerves perforate grooves in the ethmoid bone in the cribriform plate and continue into the subarachnoid spaces, accounting for the high incidence of intracranial extension.[146]

Epidemiology

ENB constitutes 3% of all endonasal neoplasms. In the United States,[147] according to the data from the SEER program, 84 cases of ENB were registered from 1978 to 1990[145] and about 945 cases have been reported in the world literature.[148] The review authors' cases accounted for 198 and collaborative efforts accounted for 747 cases. Sex distribution was 53.6% male and 46.64% female. Kadish classification was applied to 563 cases: 103 (18.3%) class A, 182 (32.2%) class B, and 278 (49.4%) class C cases.

There appears to be a slight male predominance. The age incidence has a bimodal distribution, with peaks at 11 to 20 years and 40 to 60 years, the highest incidence at 51 to 60 years.

Natural History

Although others thought that ENB were of ectodermal origin, most observers believe the tumor to be of neuroectodermal origin in the olfactory epithelium.[17,146] Most of these tumors occur high in the nasal cavity or in the lateral wall adjacent to the ethmoid. The tumor may spread to the opposite ethmoid bone, superiorly to the frontal sinus and anterior cranial fossa; posteriorly to the sphenoid sinus, nasopharynx, and base of the skull; laterally to the orbits, forward to the frontonasal angle; or inferiorly to the nasal cavity and antrum (Fig. 51.9). Lymphatic spread may be to the subdigastric, posterior cervical, submaxillary, or preauricular nodes, as well as to the nodes of Rouviere. The exact incidence of distant metastases is uncertain; it has been stated to be as high as 50%, but this rate is influenced by the use of chemotherapy in high-risk patients.

FIGURE 51.9. Coronal magnetic resonance imaging scan showing a large soft tissue mass and bone destruction in the right ethmoidal maxillary sinuses and nasal cavity secondary to extensive (Kadish stage C) esthesioneuroblastoma.

Clinical Presentation

These tumors tend to be friable and bleed easily. The most common clinical symptoms are epistaxis and nasal blockage. Patients also may have local pain or headache, visual disturbances, rhinorrhea, tearing, proptosis, or swelling in the cheek.[149] The symptoms may be associated with a mass in the neck.

Diagnostic Workup and Staging

Physical examination may show the inferior aspect of a polypoid friable mass in the nasal cavity. Ocular findings or a mass in the nasopharynx may be present. With early lesions, radiographs or CT or MRI may show only nonspecific

opacification, soft tissue swelling, and occasionally bone destruction.[150] Octreotide is a somatostatin analog that, when coupled to a radioisotope, produces a scintigraphic image of neuroendocrine tumors (NETs) expressing somatostatin type 2 receptors. Octreotide scintigraphy may be useful in confirming the preoperative diagnosis of certain head and neck NETs, such as paragangliomas, Merkel cell carcinomas, medullary thyroid carcinomas, and ENBs. Bustillo et al.[151] carried out a retrospective study that compared the results of octreotide scintigraphy with the histopathologic diagnosis in 74 patients with head and neck NETs. Of the 60 patients undergoing evaluation for suspected paraganglioma, octreotide scintigraphy was correctly positive in 36 of 37 patients with paraganglioma and correctly negative in 19 of 23 patients who did not exhibit paraganglioma (sensitivity of 97% and a specificity of 82%). There were 14 patients in the nonparaganglioma group. Octreotide scintigraphy detected or diagnosed locoregional recurrences in two with ENB.

Table 51.1 outlines the suggested diagnostic workup. MRI, especially with gadolinium contrast, may be used as a supplement or alternative to CT scanning.[47] CT provides the best information about the tumor and its local invasion into surrounding bone structures. MRI allows an estimate of tumor spread into surrounding soft tissue areas, such as the anterior cranial fossa and the retromaxillary space. Bone scintigraphy scan is useful in detecting distant metastases.

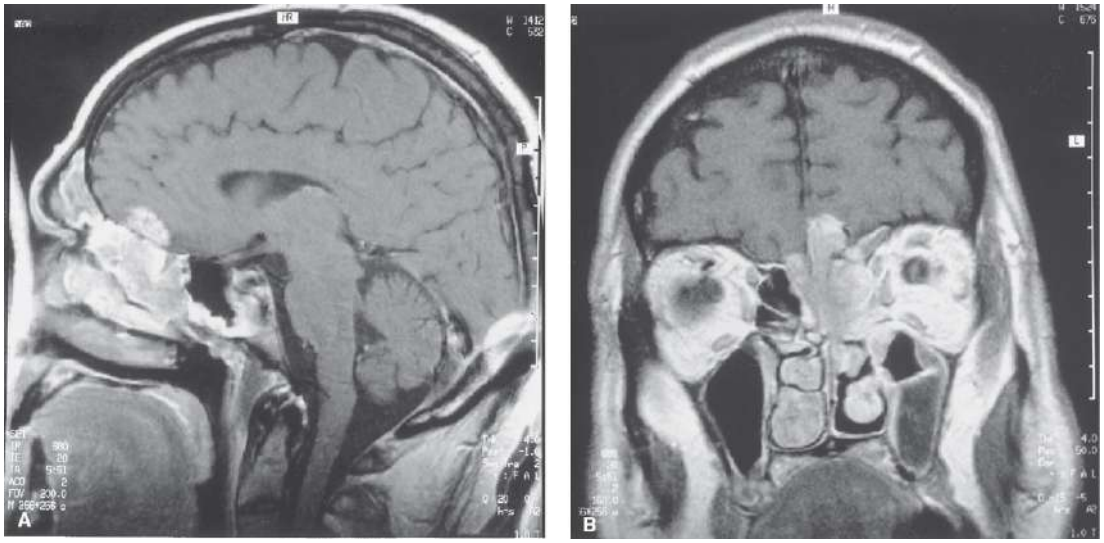

FIGURE 51.10. Sagittal **(A)** and coronal **(B)** views of preoperative magnetic resonance imaging of a 56-year-old patient who was initially seen with a Kadish stage C tumor involving left nasal cavity and extending intracranially. (From Chao KSC, Kaplan C, Simpson JR, et al. Esthesioneuroblastoma: the impact of treatment modality. *Head Neck* 2001;23[9]:749–757. Copyright © 2001 John Wiley & Sons, Inc.

The expansile tendency of olfactory neuroblastoma is characterized by bowing of the sinus walls. The destructive aspect is manifested as tumor replacing the turbinates, septum, and sinus walls with extension into contiguous areas (Figs. 51.9 and 51.10). The density or signal and enhancement characteristics are nonspecific of olfactory neuroblastoma.

Although dopamine β-hydroxylase and catecholamines are produced by these tumors, their measurements or vanillylmandelic acid excretion levels have not proven clinically useful.

A staging system has been proposed by Kadish et al.[149] (Table 51.9).

Pathologic Features and Prognostic Factors

ENBs are polypoid, frequently reddish, soft, and vascular tumors with neuroblasts and neurocytes. ENBs contain epithelial components serving as a supporting stroma and have a nerve component that corresponds to the olfactory cells. Rosettes are the main feature, consisting of several rows of cells arranged around the central area.[17] ENBs may be confused with lymphoma or anaplastic carcinoma and have diffuse, regular distribution. ENBs contain many fibrils, which fill the central space of the rosette (called a pseudorosette). It has been suggested that the presence of chromaffin granules indicates a derivative from primitive neural crest cells. ENB must be distinguished from other poorly differentiated neoplasms, including sinonasal undifferentiated carcinoma (SNUC), which is derived from the Schneiderian epithelium. SNUC lacks rosettes and intercellular fibrils.[17]

TABLE 51.9 KADISH SYSTEM FOR STAGING OF ESTHESIONEUROBLASTOMA

Stage	Characteristic
A	Disease confined to the nasal cavity
B	Disease confined to the nasal cavity and one or more paranasal sinuses
C	Disease extending beyond the nasal cavity or paranasal sinuses; includes involvement of the orbit, base of the skull or intracranial cavity, cervical lymph nodes, or distant metastatic sites

From Kadish S, Goodman M, Wang CC. Olfactory neuroblastoma: a clinical analysis of 17 cases. *Cancer* 1976;37(3):1571–1576.

Extension of the primary tumor based on the Kadish staging system[149] has been identified as the most important determinant of treatment outcome,

although this was not confirmed by Chao et al.[152] High-grade tumors had worse outcome in the reports from the Mayo Clinic and the University of California, Los Angeles (UCLA).[153]

Argiris et al.[154] found that in 16 patients with ENB, 11 of whom had Kadish stage C and 8 (50%) had brain involvement at presentation. Craniofacial resection was performed in 13 patients (81%); 14 received either preoperative or postoperative therapy (radiation therapy in 11 and chemotherapy in 4). The actuarial 5-year survival was 60% and disease-free survival 33%, with a median follow-up of 4.3 years. The first site of failure was locoregional alone in 10 of 12 patients who progressed, and in 6 patients involved the brain or the meninges. Two patients were successfully salvaged.

Hyams[85] proposed a histologic grading system for ENB in which grade I tumors have an excellent prognosis and grade IV tumors are uniformly fatal. The Hyams grading system predated advanced craniofacial techniques, extensive use of immunohistochemistry, and the recognition of SNUC as a distinct entity. Miyamoto et al.,[155] in a retrospective review of 12 patients with ENB and 14 with SNUC, used the Kadish clinical stage and Hyams histopathologic system. Kadish staging was available for 26 patients (2 patients with stage A tumors; 7 with stage B, and 17 with stage C). Of the eight evaluable patients with Kadish stage A or B tumors, six remained disease free for more than 2 years compared with only five of seven Kadish stage C tumors. Slides were available for Hyams grading in 21 patients (2 patients with grade I tumors, 4 with grade II, 4 with grade III, and 11 with grade IV). They concluded that both the Hyams grading and the Kadish staging system can be used as independent predictors of outcome. Papadaki et al.[156] analyzed 18 formalin-fixed paraffin-embedded olfactory neuroblastoma specimens (12 primary tumors and 6 recurrences or metastases) from 14 patients and concluded that p53 point mutation does not play an important role in the initial development of olfactory neuroblastoma; however, p53 wild-type hyperexpression may occur in subsets, show local aggressive behavior, and have a tendency for recurrence.

General Management

Surgery alone (including endoscopic technique) appears to be adequate treatment for small, low-grade tumors confined to the ethmoids in which negative surgical margins can be obtained. An ethmoidomaxillary resection with or without orbital sparing is usually necessary. This procedure is combined with preoperative or postoperative irradiation.[153,157] A complete resection with preservation of vital

structures is achievable by using a craniofacial approach.

Treatment, which could be classified in 898 reported cases in 1997, consisted of surgery alone in 24% (226 cases), radiation therapy alone in 18.4% (165 cases), combined surgery and radiation therapy in 43.2% (388 cases), chemotherapy in 13.2% (119 cases), and in 11 cases (1.2%) bone marrow transplant. In the reported cases, follow-up could be evaluated in 477 cases, whereas in only 234 cases, a 5-year follow-up was done; on these, 20.5% had surgery only, 11.1% radiation therapy, and 68.4% combined surgery and radiation therapy. The best survival rates were obtained by combined therapy, 72.5% versus 62.5% with surgery alone and 53.8% with radiation therapy.[40]

Dias et al.[158] reported on 35 patients with ENB treated with GTR through a transfacial approach with postoperative RT in 11 patients, craniofacial resection and postoperative RT in 7, exclusive RT in 14, craniofacial resection alone in 1, and a combination of chemotherapy and RT in 2 patients. Radiation therapy median dose was 48 Gy. Craniofacial resection plus postoperative RT provided a better 5-year disease-free survival rate (86%) compared with the other therapies (P = .05). The 5-year DSS rate was 64% and 43% for the low- and high-grade tumors, respectively (P = .20). At 5 and 10 years, disease-free survival was 46% and 24%, respectively and overall survival was 55% and 46%, respectively.

Early lesions involving the ethmoids with little or no bony destruction or nerve invasion can be treated adequately by high-energy (photon or electron) radiation therapy with good cosmetic and functional results.[10,83,104] Those with more extensive local disease benefit from surgery and adjuvant irradiation,[158,159] although some have advocated against combined surgery and radiation therapy because of complications. Patients with locally advanced disease or high-grade tumors should receive aggressive treatment with combined modalities, such as surgery, radiation therapy, and chemotherapy.

Monroe et al.[79] described treatment results in 22 patients who received RT for ENB. The modified Kadish stage was stage A in 1 patient, stage B in 4 patients, stage C in 15 patients, and stage D in 2 patients. Treatment modalities included primary RT in 6 patients, preoperative RT in 1 patient, postoperative RT after craniofacial resection in 12 patients, and salvage RT in 3 patients treated for recurrence after surgery. Elective neck RT was performed in 11 of 20 patients (2 patients had cervical metastases at presentation for RT). Rates of local tumor control, cause-specific survival, and absolute survival at 5 years were 59%, 54%, and 48%, respectively. The cause-specific survival rate at 5 years was lower after primary RT (17%) than after craniofacial resection and postoperative RT (56%).

Cervical metastases occurred in 6 of 22 patients (27%). No neck recurrences occurred in 11 patients treated with elective neck RT compared with four neck recurrences in 9 patients (44%) not receiving elective neck RT (P = .02). Their data and review of the current literature suggest a higher cervical failure rate than previously recognized; elective neck RT seems to correlate with improved nodal tumor control and should be considered in the treatment of ENB.

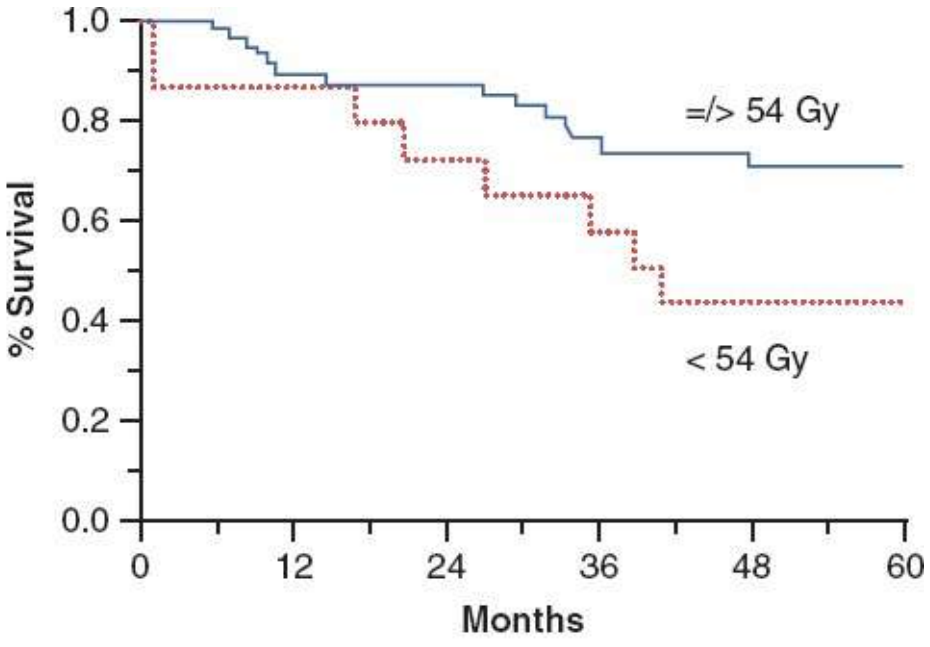
Rosenthal et al.[157] treated 72 adults with nonmetastatic, primary sinonasal NETs (31 with ENB, 16 with SNUC, 18 with neuroendocrine carcinoma [NEC], and 7 with small cell carcinoma [SmCC]). Patients with ENB usually were treated with surgery and/or radiotherapy; only 3 of 31 patients (9.7%) received radiation to regional lymphatics, and only 5 of 31 received chemotherapy. In contrast, patients with non-ENB histologies usually received chemotherapy (10 of 16 patients with SNUC, 12 of 18 patients with NEC, and 5 of 7 patients with SmCC). With a median follow-up for surviving patients of 81.5 months, overall survival at 5 years was 93.1% for patients with ENB, 62.5% for SNUC, 64.2% for NEC, and 28.6% for SmCC (P = .0029). The local control tumor rate at 5 years also was superior for patients who had ENB (96.2%) compared with patients who had SNUC (78.6%), NEC (72.6%), or SmCC (66.7%) (P = .04). The regional failure rate at 5 years was 8.7% for patients with ENB, 15.6% for patients with SNUC, 12.9% for patients with NEC, and 44.4% for patients with SmCC. Additional late events increased the regional failure rate for patients with ENB to 31.9% at 10 years. The distant metastasis rate at 5 years was 0.0% for patients with ENB, 25.4% for patients with SNUC, 14.1% for patients with NEC, and 75.0% for patients with SmCC.

Gruber et al.[160] described 28 patients with ENB treated with RT (median dose 60 Gy). In 13 patients, total tumor resection (recommended by the authors) was performed. Chemotherapy (cisplatin, etoposide, cyclophosphamide, and vincristine) combined with RT was used in five patients. With a median follow-up of 68 months, 54% of the patients were free of local tumor progression (51% at 10 years). Disease-free survival at 10 years was 25%.

Ozsahin et al.[161] described results of treatment in 13 European and North American centers for 77 patients with olfactory neuroblastoma, 11 with Kadish stage A, 29 with stage B, and 37 with stage C; 56 patients had surgery, 44 with total tumor excision. All but 5 patients received radiation therapy (50% with 3DCRT) and 21 had chemotherapy. With a median follow-up of 72 months, locoregional tumor control (LRC) was 62%, disease-free survival 57%, and overall survival 64%. Patients having total tumor resection or receiving ≥54 Gy

had better overall survival than those treated with lower doses (Fig. 51.11). Six of the patients treated with RT (56 to 70 Gy) developed grade 3 or4 late complications (five osteonecrosis and one retinopathy).

Sperry et al.[162] treated 30 patients with ENB (70% with Kadish stage C) with surgery in 27 (52% craniofacial resection), combined with postoperative RT in 75.9% and chemoradiation in 23%. Local tumor failure at 5 years was 43.6% and regional failure 15.7%. The 5-year disease-free survival was 40.7% and overall survival 80%.



Patients at risk						
RT ≥54 Gy	57	49	44	32	28	27
RT <54 Gy	15	13	11	9	7	6

FIGURE 51.11. Overall survival correlated with radiation therapy dose in 72 patients with olfactory neuroblastoma. (Reprinted from Ozsahin M, Gruber G, Olszik O, et al. Outcome and prognostic factors in olfactory neuroblastoma: a rare cancer network study. *Int J Radiat Oncol Biol Phys* 2010;78[4]:992–997. Copyright © 2010 Elsevier. With permission.)

Madani et al.[163] published a report on 84 patients (73 with primary and 11 with local recurrent) sinonasal tumors, 9 of which were ENB, treated with IMRT (median dose 70 Gy in 35 fractions). Mean D50 to the optic chiasm was 37.2 Gy, to ipsilateral optic nerve 49.4 Gy, to contralateral optic nerve 47.1 Gy, and to the retina 37.7 and 28.4 Gy, respectively.

Kased et al.[164] reported on 17 ENB patients treated with IMRT. One patient

had Kadish stage A, three B, and 11 C. Of the 15 surgical procedures, 7 had microscopically positive margins and 4 had gross residual disease. One patient received neoadjuvant chemotherapy, 7 received concurrent chemotherapy, and 4 received adjuvant chemotherapy. The median prescribed radiation dose to the gross tumor volume or clinical target volume (if tumor was grossly resected) was 66 Gy (56.7 to 70 Gy) with 2- to 2.2-Gy daily fractionation. Median follow-up was 44.5 months (7.4 to 117.3). The 5-year estimates of freedom from LRDP, PFS, and OS were 91%, 83%, and 81%. One patient developed local recurrence within the irradiation field at 25 months and died 15 months later. Another patient developed local recurrence at 72 months and was successfully salvaged with surgical resection and SRS. No regional or distant recurrences were observed. Four patients had acute grade 3 infections including meningitis (1), neutropenic sepsis (1), sinusitis requiring surgery (1), and brain abscess (1). Late complications developed in 2 patients (grade 3 brain abscesses requiring surgery.

Sharrett et al.[165] described treatment results in 75 patients with H&N ENB. Median follow-up was 105 months (range 6 to 539). Majority of the patients were men (64%) with a median age of 50.7 years at the time of diagnosis. A total of 77% had advanced-stage disease (Kadish stage C). All patients received radiation therapy (RT); 88% was postoperative and 12% definitive. Median RT dose was 60 Gy (range 42 to 70). Twenty patients (26.6%) received chemotherapy. The 5- and 10-year LC rates were 96% and 93%, whereas the 5- and 10-year locoregional tumor control were 87% and 68%, respectively. Ninety-three percent of patients were free from distant metastasis at 5-year follow-up and 81% at 10 years. Half of the total recurrences were after a 5-year follow-up. The 5- and 10-year OS rates were 87% and 74%; the 5- and 10-year DSS were 93% and 84%, respectively. On univariate analysis, younger age was associated with better RFS, DSS, and OS. On multivariate analysis, younger age was the only independent prognostic factor for improved RFS ($P = .03$), DSS ($P < .0001$), and OS ($P < .0001$).

The authors recommend surgery followed by postoperative RT and chemotherapy for advanced ENB.

Modesto et al.[166] described their experience in 43 patients with biopsy-proven ENB, two groups one of 26 and the other of 17 patients treated at separate institutions. Five patients had stage A at diagnosis (confined to nasal cavity), 13 stage B (tumor extending into paranasal sinuses), 16 stage C (beyond the paranasal sinuses), and 9 stage D (cervical lymph node involvement) according to the modified Kadish classification. Neoadjuvant platinum-based

chemotherapy was administered to 24 patients, leading to 70.8% response rate (6 CR and 11 PR). A total of 31 patients (72%) were treated by surgery and 39 (90.6%) underwent radiation therapy. Among them, 11 patients (28.2%) were treated using IMRT. Median dose was 64 Gy (range 30 to 70 Gy). Twelve patients (28%) received bilateral cervical lymph node irradiation (LNI) (median dose 57 Gy range 50 to 66 Gy). Nine patients (21%) received platinum-based concomitant chemoradiation therapy. Three patients received platinum-based adjuvant chemotherapy. After a median follow-up of 77 months, the 5-year overall survival was 65% and the 5-year progression-free survival 58%.Twelve patients (28%) developed locoregional relapse, mostly within the first two years (five locally, two regionally, and five both locally and regionally). The major prognostic factor was the modified Kadish stage with 3-year survival rates of 100% for Kadish A-B versus 48% for stage C and 22% for stage D. After adjustment for tumor stage, neither neoadjuvant chemotherapy nor LNI seemed predictive for LRC or survival. Interestingly among initial staged B and C patients (N = 29), 2 of them (7%) presented an isolated cervical lymph node relapse, and none occurred among patients previously treated by elective or adjuvant LNI.

Protons have been used sparingly in the treatment of some of these patients. Nishimura et al.[167] reported on 14 patients with olfactory neuroblastoma treated with proton beam (65 CGE in 2.5-GyE fractions) in 6 patients combined with surgery, sometimes combined with chemotherapy. With a median follow-up of 40 months, 5-year local PFS was 84%, disease-free survival 71%, and overall survival 93%.

Dagan et al.[168] reported on 84 adult patients without metastases receiving primary (13%) or adjuvant (87%) treatment with proton therapy for sinonasal cancers of which 23% (19) were olfactory neuroblastoma. Advanced stage (T3 in 25% and T4 in 69%) and high-grade histology (51%) were common. Surgical procedures included endoscopic resection alone (45%), endoscopic resection with craniotomy (12%), or open resection (30%). Gross residual disease was present in 26% of patients. Most patients received hyperfractionated PT (1.2 Gy [relative biologic effectiveness (RBE)] twice daily, 99%) and chemotherapy (75%). The median PT dose was 73.8 Gy (RBE), with 85% of patients receiving more than 70 Gy. The median follow-up was 2.4 years for all patients and 2.7 years among living patients. Local tumor control (LC), neck control, freedom from distant metastasis, disease-free survival, cause-specific survival, and overall survival rates were 83%, 94%, 73%, 63%, 70%, and 68%, respectively, at

3 years. The 3-year LC rate was 61% for primary radiation therapy and 59% for patients with gross disease. Late toxicity occurred in 24% of patients (with grade 3 or higher unilateral vision loss in 2%). Akimoto et al.[169]reported on 339 patients with nonsquamous cell cancer in the head and neck, of which 63 were olfactory neuroblastomas, treated with protons. Median follow-up was 64 months. Overall survival, progression-free, and local control rate of all patients at 5 years was 61.2%, 36.8%, and 71.2%, respectively, and for olfactory neuroblastomas, 86.2% and 79.0%. Among all patients, 254 (75%) were not suited for photon radiation therapy because doses to OARs exceeded tolerance dose in the evaluation of dose–volume histogram. However, OS at 5 years of these patients was 65.5%. Regarding treatment morbidity 34 (10%), patients developed grade 3 or 4 late toxicities such as brain injuries and neuropathy. None experienced grade 5 toxicities.

For advanced lesions, in which disseminated disease is likely, chemotherapy may improve tumor control and decrease the incidence of distant metastases. A combination of thiotepa, cyclophosphamide, doxorubicin, vincristine, nitrogen mustard, and actinomycin D has been used.[170,171] A retrospective review of 10 patients with recurrent ENB treated with chemotherapy at the Mayo Clinic suggested that cisplatin-based chemotherapy is active in advanced, high-grade tumors.[157] Survival from initial chemotherapy treatment was 44.5 months (range 3 to 130 months) in patients with low-grade tumors and 26.5 months (range 2 to 67 months) in patients with high-grade tumors (Table 51.10).

The optimal treatment of ENB demonstrates the benefit of adjuvant therapy, particularly radiation therapy. The largest reported series evaluated neoadjuvant chemotherapy and radiation therapy (50 Gy), resulting in improved resectability and patient survival (156 Polin).

TABLE 51.10 RESULTS OF TREATMENT CORRELATED WITH MODALITY AND STAGE FOR ESTHESIONEUROBLASTOMA

Modality[a]	Stage A			Stage B			
	Initial Treatment	For Recurrence	Total Control Rate (%)	Initial Treatment	For Recurrence	Total Control Rate (%)	Initial Treatn
Radiation therapy alone	2/5	5/5	70	4/7	3/4	64	1/5

Surgery alone	5/9	4/4	69	3/6	1/2	50	1/1
Radiation therapy and surgery	7/10	—	70	12/30	0/1	57	7/15

[a]All results reflect treatment of 78 patients, who were observed for 6 months to 32 years.

Elective Neck Treatment

ENB has been shown to metastasize to the neck and remote sites. Although the sites of metastases are widely variable and often atypical, Beitler et al.[172] found cervical node metastasis to be as frequent as local recurrence. Davis and Weissler[173] compiled a retrospective review of patients and found that the cumulative cervical metastasis rate reached 27% (55 of 207 patients). Noh et al.,[174] in a report of 19 patients with ENB treated with combinations of surgery, RT, and/or chemotherapy, noted that 4 patients with high-risk factors received elective neck RT (45 to 70 Gy). There were no cervical node failures in 5 patients with Kadish stages A and B, 3 of 10 in patients with Kadish stage C treated surgically, and 0 in 9 receiving chemotherapy.

Peacocky et al.[175] reported on 53 patients with ENB in the H&N; 42 (79%) underwent craniofacial resection as the definitive surgical treatment, 28 patients (53%) surgery and adjuvant radiation therapy (ART group) to the primary site only, and 25 (47%) surgery alone as treatment for the primary site (SA group). Median follow-up for the ART group was 84.5 months and for the SA group 93 months. Following initial treatment, the 5-year actuarial survival was 89% for the ART patients and 75% for the SA patients; the 5-year local RFS was 89% for the ART patients and 63% for the SA group. The 5-year cervical lymph node metastasis-free survival was 80% for the ART patients and 75% for the SA patients. Among the 18 patients with delayed cervical lymph node metastases, 10 underwent salvage neck surgery and radiation therapy, 5 had surgery alone, and 3 did not have surgery or radiation therapy, because of distant metastases or other comorbidities. Four patients recurred in the neck at following salvage treatment. With a median follow-up time of 31 months, the 2-year RFS estimate was 85% versus 74% following salvage treatment. Thus, the 5-year delayed cervical lymph node metastasis rate in patients with ENB and a clinically N0 neck undergoing local treatment is 23%. The delayed lymph node metastases

were effectively salvaged in the majority of patients. The authors proposed that patients with ENB and a clinically N0 neck should not undergo elective neck radiation therapy as part of their initial treatment in order to avoid acute and late toxicity.

Yin et al.[176] published a retrospective analysis of 116 patients with naïve ENB treated in China. According to Kadish stage classification, 20% (23 patients) presented with stage B and 79% (92 patients) with stage C. Thirty-two patients showed cervical lymph node metastasis in initial staging. Among 84 patients with N0 disease, the managements of neck in 80 patients with Kadish B/C were available, treatment modalities consisting of primary radiation therapy (RT) in 27 patients, preoperative RT in 10, postoperative RT in 40, and surgery alone in 3. Fifty patients were treated with elective neck irradiation (ENI) and 30 without any prophylactic neck treatment. Thirty-two of 116 (28%) patients were N-positive at the time of initial diagnosis, most frequently involved the level II lymph nodes (81%), followed by level IB (53%), level III (28%), and the retropharyngeal nodes (RPN) (25%). Rates of overall survival, disease-free survival, and regional relapse-free survival at 5 years were 77%, 71%, and 98%, respectively, for patients treated with ENI, compared with 62%, 50%, and 75% for those without neck treatment. The regional failure rate was 2% for patients with ENI compared with 23% without neck treatment, and distant failure rates were 20% in the ENI group versus 27% in the untreated neck group.

Neck recurrence occurred in 7 of 30 patients who were without neck treatment, all relapsed in level IB or level II. The authors concluded that the treatment target of ENI should at least cover the bilateral upper and middle neck, namely, level IB–III and RPNs.

As noted, because of the low incidence of cervical lymph node metastasis (≤10%) in early-stage ENB, elective irradiation of the neck or a dissection is not indicated. However, in patients with Kadish stage C disease, the cervical metastatic rate climbed to 44% (25 of 57 patients). As stated previously, Monroe et al.[79] observed cervical node metastasis in 6 of 22 patients (27%). In 11 patients they treated with elective neck RT, no recurrences were noted, in contrast to 4 of 9 (44%) for patients not receiving elective neck RT. Thus, with advanced-stage disease, cervical nodes may be initially managed by irradiation, radical neck dissection, or a combination of both. Zanation et al.[177] recommend salvage of neck metastases occurring 6 months or more after treatment of the primary site to be treated with combined surgery and radiation therapy. They showed a clear disease-free survival advantage (59 vs. 14%) in patients with

combined modality therapy versus single modality in the salvage setting.

Radiation Therapy Techniques

A combination of photons and electrons with conventional anterior fields provides good coverage for limited ethmoidal disease when the tumor is confined anteriorly. Beam arrangement can be modified for disease extending into the orbit or maxillary sinus. Obturator or bolus may be needed postoperatively to compensate for tissue deficit. When intracranial or posterior extension is present or tumor has spread into the maxillary sinus, a pair of perpendicular (anterior–posterior and lateral) portals with wedges or two lateral wedge fields in conjunction with an open anterior photon field will give good coverage of the treatment volume, with the dose inhomogeneity around 10% to 20%. Incorporation of a vertex field eliminates the high inhomogeneous dose along the junction line of the conventional three-field technique. Treatment techniques are similar to those described for treatment of paranasal sinuses (see Chapter 42). The orbits can be spared or treated as the degree of extension dictates. Occasionally, an anterior electron-beam field may be needed to supplement low-dose areas. When the electron beam is used over air cavities, some dosimetry problems result. Eye blocks must be positioned precisely to avoid undesirable side effects.

When combined therapy is used, preoperative doses of 45 Gy and postoperative doses of 50 to 60 Gy are indicated, depending on the status of the surgical margins. Doses of 65 to 70 Gy are delivered with irradiation alone in patients with inoperable tumors.[164] The usual fraction dose is 1.8 to 2.0 Gy. Contrast-enhanced CT or MRI scans before initiation of treatment are crucial to demarcate extension of the tumor. Treatment planning with CT for determination of tumor extension is extremely important.[178] Because of the proximity of ENB to the optic nerves, the optic chasm, and the brainstem, the precision of treatment setup, target volume definition, and dose homogeneity dictate tumor control and the sequelae of treatment. Treatment techniques similar to those for paranasal sinuses may create “hot spots” along the optic tracks. High doses per fraction (exceeding 2 Gy) increase the possibility of late sequelae, such as blindness and bone and brain necrosis.

Three-dimensional CRT or IMRT provides alternatives to the conventional three-field technique used to treat these tumors (Fig. 51.12). Special attention should be directed to reduce unnecessary irradiation to ocular structures, including optic nerve(s) and chiasma. When occasionally a patient presents with

cervical node metastasis, IMRT is very helpful to optimally treat the primary tumor and the cervical lymphatics (Fig. 51.13).

Structure	Dose Range (cGy)	Mean Dose (Gy)
Planning target volume 1	30–70	65
Planning target volume 2	40–70	58
Optic chasm and nerves	13–42	24

Results of Therapy

Surgery and Irradiation

Platek et al.,[179] in an analysis of SEER data (1973 to 2005) of 135 cases of olfactory neuroblastoma, noted that 59% of the patients were treated with surgery and RT, 23% with surgery only, 12% with RT only, and 6% with neither. No data on chemotherapy administration were available. The 5-year survival with surgery plus RT was 66%, with surgery only 51%, with RT only 26%, and with other therapy 34% ($P = .003$).

Kased et al.[164] reported on 17 patients with ENB (15 undergoing a surgical procedure, 7 receiving concurrent chemotherapy, and 4 adjuvant chemotherapy) treated with IMRT (median dose 66 Gy in 2-Gy fractions). With a median follow-up of 44.5 months, the 5-year freedom of locoregional tumor progression was 91%, PFS 83%, and overall survival 81%. Four patients had acute complications (meningitis, sepsis, sinusitis requiring surgery, and brain abscess), and two patients developed late brain abscess, requiring surgical treatment.

Radiation therapy is an important component in the management of ENB, but the optimal sequence when integrated with surgery is unknown. Eden et al.[180] observed no significant difference in survival whether preoperative or postoperative irradiation was given, but suggested improved local tumor control with preoperative irradiation. Technical factors may have contributed to a higher incidence of postoperative radiation therapy failures because three of five postoperative cases received <50 Gy; all three patients were treated with a single anterior field, which gives less homogeneous dose distribution throughout the treatment volume.

FIGURE 51.13. Patient with Kadish stage C esthesioneuroblastoma of ethmoid cells and nasal cavity who presented with a large left upper cervical lymph node metastasis. Intensity-modulated radiation therapy plans to deliver 70 Gy to primary tumor and cervical lymphadenopathy. Coronal **(A)**, sagittal **(B)**, and cross-section dose distributions illustrate excellent coverage of all target volumes **(C)**.

Foote et al.[153] updated the experience of the Mayo Clinic. Seventeen patients had disease confined to the nasal cavity or paranasal sinuses (Kadish stages A and B), and 32 patients had more advanced disease. Treatment included gross total resection alone or combined with radiation therapy. The 5-year actuarial survival, disease-free survival, and local tumor control rates were 69.1%, 54.8%, and 65.3%, respectively. Local tumor control was improved in patients who received postoperative irradiation (55.5 Gy) even after complete tumor resection.

Levine et al.[181] conducted a retrospective review of 35 patients; 6% of them presented with cervical metastasis, and ultimately 25.7% developed cervical metastases. Fourteen percent of the patients had a local recurrence at an average of 6 years after diagnosis, and in 37%, at least one episode of metastatic disease occurred. The disease-free survival was 80.4% at 8 years. CNS complications occurred in 25.7% of patients, orbital complications in 22.9%, systemic posttreatment problems in 20%, and chemotoxic sequelae in 18%.

Eriksen et al.[182] carried out a retrospective review of 13 patients with ENB (Kadish stage A 1 patient, stage B 5 patients, and stage C 7 patients). The 5-year disease-free survival was 51%. Forty-six percent of the patients experienced relapse, and despite intensive salvage therapy, median survival after recurrence was only 12 months.

Chao et al.[152] reported on 25 patients with ENB (Kadish stage A in 3 patients, stage B in 13 patients, C in 8 patients, and modified D in 1 cervical nodal metastasis patient); 17 patients were treated with surgery and radiation therapy, 6 with irradiation alone, and 2 with surgery only. Eight patients received neoadjuvant chemotherapy. Median follow-up was 8 years. The 5-year actuarial overall survival, disease-free survival, and local tumor control rates were 66.3%, 56.3%, and 73%, respectively. Kadish stage was not a significant prognosticator for local tumor control or disease-free survival. Five-year local tumor control was 87.4% for combined surgery with RT and 51.2% for irradiation alone. Two patients with Kadish stages A and B disease underwent surgical resection alone; both failed locally. In contrast, only three of nine patients with Kadish stage A or B disease who received ART had a local recurrence. With ART, the surgical margin status did not influence local tumor control.

Chemotherapy and Irradiation

Eden et al.[180] described results in 16 patients with stage A or B disease and 24 patients with stage C disease treated with irradiation (median dose 50 Gy) and surgery for stage A and B diseases, with the addition of chemotherapy (cyclophosphamide and vincristine) for stage C disease. Actuarial survival rates at 5 and 10 years were 78% and 71%, respectively. Locoregional failure developed in 15 of 40 patients; 68% of the failures were locoregional (including the brain, neck, facial bone, and sinus). They had no recurrences at the primary tumor bed; all recurrences were either outside the irradiation field or at distant sites.

Preoperative neoadjuvant therapy may provide a valuable complement to radical craniofacial resection.[170]

Forty patients were treated for ENB at Institut Gustave Roussy, France.[146] Three patients had stage T1, 7 patients had T2, 15 patients had T3, and 15 patients had T4 lesions. At presentation, the cervical metastatic rate was 18% and distant metastases were detected by bone marrow biopsy and bone scan in three patients. Treatment modalities included surgery alone in 8 patients, radiation therapy alone in 3 patients, surgery plus radiation therapy in 11 patients, chemotherapy alone in 2 patients, chemotherapy plus radiation therapy in 10 patients, and chemotherapy plus surgery and radiation therapy in 6 patients. The 5-year survival rate was 51%. Multimodality treatment offered better survival (63% at 5 years). Overall local, regional, and distant failure rates were 58%, 15%, and 40%, respectively. Distant metastases commonly occurred in the bone (82%).

Noh et al.[174] summarized reports on patterns of failure of ENB treated with or without chemotherapy. Although the indications for high-dose chemotherapy and BMT must be better defined, it may be a promising alternative for patients with large tumors or those with recurrent tumor to whom no further local therapy (e.g., surgery or irradiation) can be safely given.

Konuthula et al.[183] analyzed 90 patients with Kadish stages C and D ENB in the National Cancer Database (NCDB), 55 % treated with definitive radiation (RT) (median dose 59.4 Gy) and 45 % receiving chemotherapy. Mean follow-up was 57.1 months. There was no difference in 5-year survival between the patients who received RT and those treated with RT and chemotherapy (74.8% vs. 64.4%). There was also no difference in survival between whether or not a clinically node-negative neck was treated with RT (72.9% vs. 67.0%).

Sequelae of Treatment

In a few patients, depending on the dose of irradiation, long-term sequelae include bone necrosis, brain necrosis or abscess, blindness, or painful eye reactions requiring enucleation.[183,184]

Simon et al.,[178] in 13 patients with olfactory ENB treated with surgery and radiation therapy, noted that one patient lost vision as a result of glaucoma and radiation retinopathy after 67.3 Gy in 34 fractions. One patient treated with 61.76 Gy in 34 fractions developed a visual field defect and optic atrophy; she also had a nasal cutaneous fistula. One patient sustained intraoperative rupture of the ocular globe and subconjunctival hemorrhage.

EXTRAMEDULLARY PLASMACYTOMAS

Solitary plasmacytomas are rare tumors of plasma cell origin, making up 4% of all plasma cell tumors. Multiple myeloma occurs about 40 times more frequently than solitary plasmacytoma. Monoclonal extramedullary plasmacytoma (EMP) is a rare, low-grade lymphoma found predominantly in the head and neck region. Only since the introduction of immunophenotyping techniques two decades ago has it been possible to differentiate EMP from benign polyclonal plasma cell proliferation. Hotz et al.[185] reviewed the records of 24 patients with morphologically diagnosed EMP treated at their institution; only 14 patients had true monoclonal plasmacytoma. No EMP-related deaths occurred. Two patients had local recurrence, and two patients developed multiple myeloma. Diagnostic procedures exclude a benign polyclonal plasmacytoma, multiple myeloma, and solitary bone plasmacytoma. The slow natural progression of the disease and the rarity of secondary multiple myeloma favor nonmutilating local surgery whenever possible to avoid the long-term sequelae of radiation.

Epidemiology

The annual incidence of EMP is 0.04 cases per 100,000 population.[186] They constitute only 0.5% of all upper respiratory tract malignancies. Male patients exceed female patients by a ratio of 3:1 to 4:1, and 75% of patients are 40 to 60 years of age.[187]

In a detailed literature search of more than 400 publications between 1905 and 1997, EMP mainly occurred between the 4th and 7th decades of life.[188] Seven hundred fourteen cases (82.2%) were found in the upper aerodigestive tract.

The most common sites in the head and neck are the nasopharynx, nasal cavity, paranasal sinuses, and tonsils.

Clinical Presentation and Diagnostic Workup

EMP of the head and neck area should be considered a separate entity because of its clinical behavior. The most common symptoms are nasal obstruction, local pain and swelling, and epistaxis.

Diagnosis of EMP is based on the exclusion of a systemic plasma cell proliferative disorder (multiple myeloma) and immunohistochemistry results. On light microscopy, EMP must be differentiated from a reactive plasmacytosis, plasma cell granuloma, poorly differentiated neoplasms, immunoblastic lymphoma, or extranodal marginal zone B-cell lymphoma with plasmacytic differentiation. Plasmacytoid lymphoma has a mixture of lymphocytes and plasma cells. Immunoblastic lymphomas show a cytoplasmic IgM heavy chain and express pan B-cell surface antigen, such as CD19 and CD20. Diagnosis of solitary EMP should be made only if studies for disseminated disease are negative. X-ray and/or MRI of the spine, pelvis, femurs, and humerus and bone marrow biopsy should also be within the normal range. There should be no signs of serum urine monoclonal protein, anemia, hypercalcemia, or renal impairment. A prospective study by Schirrmeister et al. has also assessed the accuracy of PET scanning in staging patients with presumed solitary plasmacytoma.

Grossly, plasmacytomas tend to be sessile in the nasal cavity and paranasal sinuses and pedunculated in the nasopharynx and larynx. The masses are soft, pliable, and pale gray. The lesion may remain localized or may infiltrate and destroy the surrounding soft tissue and bone. The usual criteria for solitary plasmacytomas, either medullary or extramedullary, include a biopsy-proven plasma cell tumor with one or, at the most, two solitary foci, absence of Bence Jones protein in the urine, bone marrow taken some distance from the primary site not involved by tumor (<10% of plasma cells), hemoglobin of 13 g/mL or more, and a normal serum protein level or serum electrophoresis at the time of the diagnosis. Basically, the diagnosis of solitary plasmacytoma is made by exclusion, that is, by eliminating the possibility of multiple myeloma.[187] Diagnosis is based on histology along with special immunoperoxidase staining for immunoglobulin-λ and immunoglobulin-κ light chains.[37]

Strict staging criteria, including normal MRI studies of the axial skeleton and the long bones and absence of monoclonal plasma cells detected by flow cytometry or polymerase chain reaction, are required for the diagnosis of solitary

plasmacytoma. Careful microscopic and immunohistochemical studies are also required for the correct diagnosis, because this disease can be confused with other malignancies, particularly lymphomas.

Six patients with primary EMP in the head and neck were examined with MRI[188]; five lesions were oval and sharply demarcated without signs of infiltration, whereas the other lesion filled the parapharyngeal space bilaterally. On T2-weighted sequence, the lesions had moderate signal intensity. On plain T1-weighted sequences, the tumors were isointense or slightly hyperintense with respect to surrounding muscles; after administration of contrast medium, four lesions showed notable enhancement, with distinct central inhomogeneity.

Bone destruction is not a particularly bad prognostic sign, although some investigators report that it adversely affects prognosis.[188] Bony invasion is common in the more malignant types.[17]

Cervical lymph node metastasis from EMP varies with the site of the primary lesion and follows the same pattern of spread as squamous cell carcinoma arising in a similar site. The reported incidence of lymph node metastasis ranges from 12% to 26%. The diagnostic workup for EMP arising in the head and neck region is shown in Table 51.1. The exact relationship between EMP and multiple myeloma is unclear; however, approximately 20% to 30% of EMP cases will convert to multiple myeloma.[185,187]

Modified from Noh OK, Lee S-W, Yoon SM, et al. Radiotherapy for esthesioneuroblastoma: is elective nodal irradiation warranted in the multimodality treatment approach? *Int J Radiat Oncol Biol Phys* 2011;79(2):443–449. Copyright © 2011 Elsevier. With permission.

General Management

The majority of these patients are treated with multimodality therapy. Alexiou et al.[188] reviewed 714 cases in the literature published between 1905 and 1997: Radiation therapy alone was used in 44.3% of cases and surgery alone in 21.9%, with combined therapy (radiation after surgery) in 26.9% of the cases.

Pedunculated EMP lesions may be treated by surgical excision because the chance of local recurrence is low. The treatment of choice for all other lesions is radiation therapy alone or combined with other modalities.[189,190] In a review of 714 cases in the literature, the following therapeutic strategies were used to treat patients with EMP of the upper aerodigestive tract: radiation therapy alone in 44.3%, combined therapy (surgery and irradiation) in 26.9%, and surgery alone in 21.9%. The median overall survival or RFS was longer than 300 months for patients who underwent combined intervention (surgery and irradiation), for surgical intervention alone (median survival time, 156 months), and for radiation therapy alone (median survival time, 114 months). Overall, after treatment for EMP in the upper aerodigestive tract, 61.1% of all patients had no recurrence or conversion to systemic involvement (i.e., multiple myeloma); however, 22% had recurrence of EMP, and 16.1% had conversion to multiple myeloma.

Radiation Therapy Techniques

Irradiation techniques vary with the location of the primary tumor. The techniques are similar to those used for primary tumors in comparable locations (i.e., nasopharynx, tonsil, paranasal sinuses). Solitary plasmacytomas respond well to doses of 50 to 60 Gy in 2-Gy fractions. Hughes et al.[191] suggested that the optimal radiation dose is dictated by the size of the tumor, with doses in the range of 40 Gy in 20 fractions recommended for tumors <5 cm, whereas 50 Gy in 25 fractions was recommended for tumors >5 cm. The local tumor control rate with radiation therapy alone is about 85%. Harwood et al.[190] summarized the literature but could not draw a dose–response curve from the data because of a lack of cases receiving low-dose radiation therapy. Nevertheless, there is a high

risk of local recurrence with tumor doses below 30 Gy and a negligible risk for those treated at or above 40 Gy (Table 51.11).

Wax et al.[37] reported on seven patients, three treated with radiation therapy (31.75 to 60 Gy). All patients have maintained local tumor control and had been followed for a minimum of 1.5 years, with an average of 3 years. One patient, treated with surgical excision, experienced a relapse at a distant site 6 years later.

The response to therapy of 32 patients with localized plasmacytoma was described by Shih et al.[197]; 22 patients had solitary plasmacytoma of the bone and 10 had EMP. Median age for EMP was 63 years. Most EMPs occurred in the oronasopharynx (six cases) and paranasal sinuses (two cases). Seven patients with EMP received radiation therapy (47 to 65 Gy), and all achieved initial local tumor control. There was one local recurrence and multiple myeloma conversion in the EMP group. Local recurrence or dissemination was associated with the appearance of or an increase in myeloma protein.

Holland et al.[198] reported on 14 cases of EMP, 8 of which were in the head and neck. With doses of 46 to 62 Gy, the complete tumor response was 72%. No dose–response effect was observed.

Liebross et al.[199] described results in 22 patients with solitary EMP, in the head or neck in 19 patients, usually in the nasal cavity or maxillary sinuses, and bone destruction was found in 10 of 11 patients. Radiation therapy was the sole treatment in 18 of 22 patients (median dose 50 Gy; range 40 to 60 Gy); 5 of 7 patients with an EMP of the oral cavity, oropharynx, nasopharynx, parotid, or larynx also received ENI. Local tumor control was achieved in 21 of 22 patients (95%), and disease never recurred in regional nodes. Disappearance of myeloma protein occurred in three of five patients with an evaluable abnormality. Multiple myeloma developed in seven patients (32%), all within 5 years. The 5-year rate of freedom from progression to multiple myeloma was 56% and the median survival was 9.5 years. Chao et al.[152] reported on 16 patients with EMP and a median follow-up of 66 months. The head and neck region accounted for the majority of presentations (88%). A serum monoclonal paraprotein was found in three patients, and bone erosion was identified in seven patients. All patients received local RT, although two patients also received elective nodal irradiation. The median RT dose was 45 Gy (range 40 to 50.4 Gy). Local tumor control was achieved in all patients (100%); however, regional recurrence outside the RT fields occurred in 2 of 16. Multiple myeloma developed in five patients (31%) all within 5 years. The 10-year myeloma-free survival was 75% and 10-year overall survival was 54%.

Galieni et al.[200] reviewed 46 cases of EMP most frequently localized in the upper airways (37 of 46 patients, 80%), with the mass being limited to a single site in all but seven patients in whom two contiguous sites were involved. The most frequent form of treatment was local radiation therapy. Thirty-nine patients (85%) achieved complete remission, five (11%) a partial remission, and two (4%) no response to therapy. Local recurrence and recurrence at other sites occurred in 7.5% and 10%, respectively. Seven patients (15%) developed multiple myeloma. The 15-year survival rate was 78%.

Michalaki et al.[186] described 10 patients with EMP treated with radiation therapy. The disease was most frequently localized in the paranasal sinuses (50%). All nine patients who received definitive RT (40 to 50 Gy) achieved a complete response. Median follow-up period was 29 months. Four patients (40%) relapsed; three died of their disease. Two patients with paranasal sinus disease subsequently relapsed with multiple myeloma at 10 and 24 months, respectively. The relapse rate in neck nodes of 10% does not justify elective irradiation of the uninvolved neck.

Miller et al.[201] reported that tumor arose in the sinonasal or nasopharyngeal region in 11 of 20 patients (55%). The primary modality of treatment was radiation therapy (45 to 60 Gy). The mean follow-up was 60.2 months. In 15 to 20 cases, immunohistochemistry staining for immunoglobulin light-chain production was conducted. One of the two cases (50%) classified as medullary plasmacytoma demonstrated conversion to multiple myeloma, whereas only 2 of 18 cases of EMP (11%) converted to multiple myeloma.

Ozsahin et al.[184)] published a compilation of solitary plasmacytoma (42 cases) in the head and neck. There were 258 patients with bone (n = 206) or extramedullary (n = 52) plasmacytomas without evidence of multiple myeloma. Most (n = 214) of the patients received RT alone; 34 received chemotherapy and RT; and 8 had surgery alone. The median radiation dose was 40 Gy. Median follow-up was 56 months (range 7 to 245 months). The median time for multiple myeloma development was 21 months (range 2 to 135 months), with a 5-year survival probability of 45% (Fig. 51.14A). The 5-year overall survival, disease-free survival, and local control rates were 74%, 50%, and 86% respectively (Fig. 51.14B). On multivariate analyses, favorable factors were younger age and tumor size <4 cm for survival; age, extramedullary localization, and RT for disease-free survival; and small tumor and RT for local control. Bone localization was the only predictor of multiple myeloma development. No dose–response relationship was found for doses >30 Gy, even for larger tumors.

Tournier-Rangeard et al.,[119] in a review of 17 patients with solitary EMP in the head and neck, noted a local tumor control of 100% for patients who received ≥45 Gy dose to the CTV versus 50% with doses <45 Gy (P = .034). Prognostic factor for 5-year DSS (81.6%) was local tumor control (P = .058). Prognostic factors for disease-free survival (64.1%) were monoclonal immunoglobulin secretion (P = .008) and CTV dose >45 Gy (P = .056).

[b]Updated, unpublished data of Corwin.

Bachar et al.[189] published outcomes of 68 patients with EMP of the head and neck, 39 treated with radiation (median dose 35 to 37 Gy in 15 fractions), 14 with surgery plus RT, 8 with surgery, and 3 with chemoradiation. With a median follow-up of 8 years, 5-year local RFS was 81% and survival 76%. Local recurrence was equivalent in patients treated with surgery or RT (12.5%). Multiple myeloma developed in 23% of the patients. Sasaki et al.[202,203] described results of radiation therapy in 67 patients with solitary plasmacytoma of the head and neck (in 44 combined with surgery) treated at 23 centers in Japan. Median RT dose was 50 Gy. With a median follow-up of 63 months, the 10-year local tumor control was 87% and overall survival 56%. The 10-year survival was 70% for patients treated with combined RT and surgery and 50% in those treated with RT alone (P = .004). Twelve patients (18%) developed distant metastasis and 8 (12%) converted to multiple myeloma.

Table 51.12 summarizes the doses of irradiation and probability of tumor control reported by various investigators. The authors' limited experience

confirms the efficacy of tumor doses of 45 to 50 Gy for local tumor control. In patients who had extensive disease, a higher dose (50 to 60 Gy) was used, as recommended by several investigators.[208]

NASOPHARYNGEAL ANGIOFIBROMA

Epidemiology

Juvenile nasopharyngeal angiofibroma (JNPAF) is found more frequently in young pubertal boys; it has been shown to contain androgen receptors[209] and occasionally to regress with estrogen therapy. Hwang et al.,[210] in 24 nasopharyngeal angiofibromas, detected androgen receptors in 18 of 24 (75%) cases, whereas only two (8.3%) were positive to progesterone. None of the 24 cases was positive for antibodies to estrogen.

The tumor is believed to originate from the posterior–lateral wall of the nasal cavity where the sphenoidal process of the palatine bone meets the horizontal ala of the vomer and the roof of the pterygoid process because it is always involved.[211,212] Other investigators agree, because involution of tumor after irradiation usually occurs in this direction.[213]

JNPAF comprises <0.05% of head and neck tumors.[163] Patient's age at presentation ranges from 9 to 30 years,[214,215] with a median of 15 years. Females comprise <4% of the total cases.[216] Some investigators have suggested chromosomal studies in affected women because this is mainly a male disease.[212]

Clinical Presentation and Pathology

Symptoms usually occur 2 to 48 months before diagnosis.[214] The most common complaints are nasal obstruction or epistaxis, followed by nasal voice or discharge, cheek swelling, proptosis, diplopia, hearing loss, and headaches.[214] Nasopharyngeal angiofibroma may initially extend into the nasal fossae and maxillary antrum and push the soft palate downward and then through the pterygopalatine fossa and superoanteriorly through the inferior orbital fissure or laterally through the pterygomaxillary fissure to the cheek and temporal regions.[30]

Beham et al.,[203] in a study of 32 cases of JNPAF, noted that most of the tumor vessels, which lacked elastic laminae, were characterized by vascular walls of irregular thickness and variable muscle content. In places, endothelial cells were separated from the stroma by only a single attenuated layer of contractile cells;

in some more fibrotic hyaline areas, the stromal cells displayed reactivity for smooth muscle actin. The irregularity of the vascular walls, together with the lack of elastic laminae and stromal fibers, explains the pronounced tendency for hemorrhage in these lesions.

Differential diagnosis includes fibrosarcoma, rhabdomyosarcoma (RMS), chronic sinusitis, arteriovenous malformation, lymphangioma, neurofibroma, pleomorphic adenoma, lymphoma, pyogenic granuloma, polyps, and hemangioma.

Diagnostic Workup

After the history and physical examination, CT scans with and without contrast should be obtained. Characteristic findings are a mass in the posterior nasal or pterygopalatine fossa and bone erosion in the sphenopalatine foramen and extension to the pterygoid plate.[35] The pattern of enhancement in this highly vascular tumor is diagnostic,[217,218] and many investigators believe carotid angiograms are unnecessary[219] after CT diagnosis of the lesion, unless embolization, which is also controversial, is contemplated.

CT scans are especially helpful in regions involving thin bony structures (paranasal sinuses, orbits), where CT performs better than MRI. In the nasopharynx and parapharyngeal space, MRI is superior to CT. Obtaining tumor volumetric data with spiral CT or MRI facilitates 3-D treatment planning.[220]

Seventy-two patients with JNPAF were evaluated with CT or MRI.[217] Origin of the tumor was in the pterygopalatine fossa at the aperture of the pterygoid (vidian) canal. The tumor extended posteriorly along the pterygoid canal with invasion of the cancellous bone of the pterygoid base and greater wing of the sphenoid in 60% of the patients. The inability to remove the tumor in toto was principally due to deep invasion of the sphenoid; 93% of recurrences occurred with this type of tumor extension.

If intracranial extension is noted and radiation therapy is contemplated, no further studies are indicated. If the lesion is extracranial and surgery is indicated, bilateral carotid angiograms will identify the feeding vessels and delineate the boundaries of the tumor.

Biopsies are not indicated in all patients because of the potential for severe hemorrhage. It is important to perform a biopsy of the lesion when the clinical picture (sex, age, location, and behavior of the lesion) is not consistent with JNPAF because some lesions have proven to be sarcomas or chronic sinusitis.[212] Two cases of fibrosarcoma have been reported in patients in their 40s.[221]

TABLE 51.13 STUDIES REPORTING TREATMENT OUTCOME AND LATE GRADE 3 VISUAL IMPAIRMENT AFTER INTENSITY-MODULATED RADIATION THERAPY FOR SINONASAL TUMORS

Staging and Prognostic Factors

Staging schemes have been proposed by Chandler et al.,[212] a radiographic staging system by Sessions et al.,[213] and a more detailed anatomical system by Radkowski et al.[222] (Tables 51.13 and 51.14). In a retrospective review of 44 cases of JNPAF, invasion of the skull affected two-thirds of the patients, and the rate of recurrence was 27.5%.[228] Extensions to the infratemporal fossa, sphenoid sinus, base of pterygoids and clivus, the cavernous sinus (medial), foramen lacerum, and anterior fossa were correlated with more frequent recurrence. In a review of 97 cases, age at diagnosis, tumor size, and Radkowski classification were significant prognostic factors for recurrence.[229]

General Management

Optimum management of these patients remains controversial,[230] and the decision of whether surgery or radiation therapy should be used depends in part on the initial extent of the disease. In patients with extracranial tumors,[228]

surgery is the treatment of choice and yields near-zero mortality or any long-term morbidity.[231] Tumor extension to the posterior infratemporal fossa or intracranially is associated with a higher risk of recurrence.[232]

Tumor remnants in symptom-free patients should be kept under surveillance by repeated CT scanning, because involution may occur. Recurrent symptoms may be treated by radiation therapy rather than by extended surgery or combined procedures.[212,228,233]. When there is intracranial tumor extension (seen in about 20% of patients), the risk of surgically related death increases. Some investigators recommend preoperative intra-arterial tumor vessel embolization at the time of diagnostic bilateral carotid angiography, claiming a decrease in operative bleeding.[234] Salvage with embolization of polyvinyl alcohol has been described.[235] Others have reported anecdotal evidence of partial regression with the use of estrogens, believed to be the result of feedback inhibition of the pituitary's production of gonadotropin-releasing hormone.

Although radiation therapy is equally effective in extracranial tumors, the low but existing risk of secondary malignancies should limit its use to the more advanced tumors only, such as those involving the orbital apex or the base of the skull.[232,236] In the experience of Cummings et al.[233] covering 20 years, only two radiation-related malignancies were noted (one skin, one thyroid).

TABLE 51.14 STAGING OF NASOPHARYNGEAL ANGIOBROMA

IA	Limited to the nose or nasopharynx
IB	Extension into one or more paranasal sinuses
IIA	Minimal extension through sphenopalatine foramen medial pterygomaxillary fossa
IIB	Involvement of pterygomaxillary fossa displacing anteriorly posterior wall of maxillary antrum. Lateral or anterior displacement of maxillary artery branches or superior extension eroding orbital bones
IIC	Extension through pterygomaxillary fossa into the cheek and temporal fossa or posterior to pterygoid plates
IIIA	Erosion of skull base with minimal intracranial extension
IIIB	Erosion of skull base with extensive intracranial involvement with or without cavernous sinus involvement

Radiation Therapy Techniques

Photon irradiation should be used for these patients, and fields must be individualized to cover the tumor completely with a margin (1 to 2 cm).

Treatment portals are similar to those used in carcinoma of the nasopharynx (without irradiating the cervical lymph nodes) or carcinoma of the paranasal sinuses when these structures or the nasal cavity is involved. Opposing lateral portals are suitable in most patients, with larger fields and compensators used for tumors extending into the nose (Fig. 51.15). More extensive disease requires three-field or wedge-pair arrangements of 3DCRT or IMRT that can yield excellent dose distributions, particularly when there is nasopharyngeal or intracranial tumor extension. In all cases, the eyes are protected as much as possible.

The recommended tumor dose ranges from 30 Gy in 15 fractions in 3 weeks to 50 Gy in 24 to 28 fractions in 5 weeks.[237] A conventional setup uses 6- to 18-MV photons to treat the lesion with parallel-opposed fields to 50 Gy (2-Gy fractions).

The advantages of IMRT for the treatment of extensive or recurrent JNPAF were described in three patients on whom the tumor affected the base of the skull, pterygopalatine, infratemporal fossae, posterior orbit, and nasopharynx.[234] Tumor dose varied from 34 to 45 Gy. Chakraborty et al.[238] treated eight patients with IMRT for stage III tumors (median dose 39.6 Gy). Local control at 2 years was 87.5% and toxicity was minimal (persistent rhinitis in one patient). Significant sparing of the surrounding organs at risk was obtained. No grade 3/4 toxicities were experienced

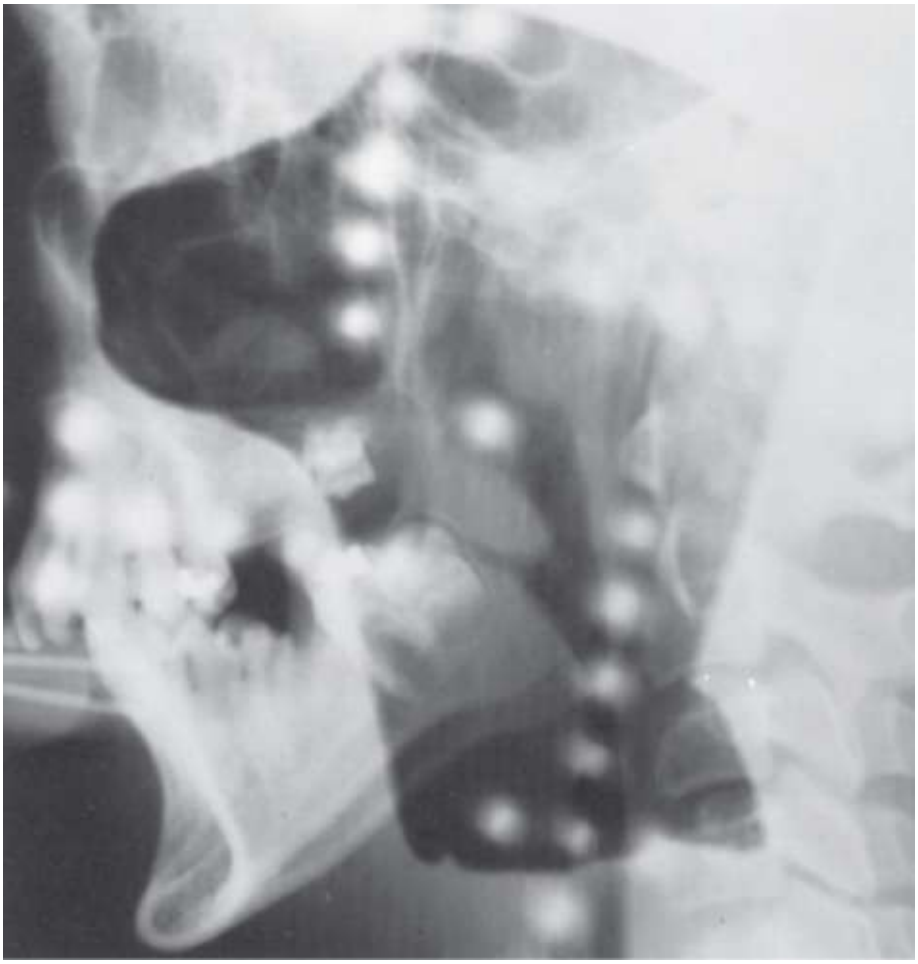

FIGURE 51.15. Example of conventional lateral portal used at the Mallinckrodt Institute of Radiology for nasopharyngeal angiofibroma.

Results of Therapy

In a surgical report, 18 patients were treated with gross tumor excision; 2 cases with intracranial involvement required a combined neurosurgical–otolaryngologic approach.[239] Recurrent intracranial disease was detected by MRI in three patients, who were treated with 35-, 36-, and 45-Gy external beam irradiation. Extracranial tumor recurrences were re-excised in seven patients. All patients (followed up with serial MRI) are living without evidence of active disease.

Cummings et al.[233] treated 42 patients primarily with irradiation and 13 for postsurgical failures; all except 6 had biopsies. Nine had stage IV disease according to Chandler's staging system. Dose was 30 to 35 Gy in 14 to 16 fractions over a 3-week period. Follow-up ranged from 3 to 26 years. The control rate was 80% and was equivalent for all dose ranges. Local control was 89% and 74%, respectively, when three fields versus two fields were used. When

the field size was more than 6 × 6 cm, the control rate was 83% versus 55% for smaller portals, indicating the importance of accurately determining the target volume, including any potential tumor extension. Of 11 recurrences, 8 were controlled by a second course of irradiation and 3 by surgery. These tumors regress slowly, with 50% still present at 12 months. At 24 months, 23% of tumors were still present, and half of those recurred. Of the complete responders, only 1 of 33 had a recurrence. Robinson et al.[240] also found that objective responses after irradiation were noted within 6 months in 60% of patients and within 6 to 20 months in the other 40%. Symptoms, however, resolved in all patients within 6 months of treatment.

At the Mallinckrodt Institute of Radiology, Fields et al.[241] reviewed the authors' experience with 13 patients: 11 surgical failures and 2 primarily treated with irradiation. Intracranial extension was noted in 38% of patients. Follow-up ranged from 40 to 173 months. Doses ranged from 36 to 52 Gy, with a median of 48 Gy (1.8 to 2 Gy per fraction, 5 days a week). The control rate was 85%; patients failing irradiation were salvaged with embolization. Late morbidity was mostly xerostomia and dental decay.

Ungkanont et al.[215] described results in 20 patients treated before 1974 and 23 treated between 1975 and 1993: 31 had surgery (18 with preoperative embolization), 3 had irradiation, 7 received chemotherapy (4 combined with surgery), and 2 were observed. Disease-free survival was 67%; 28% of patients survived with residual tumor, and 4.6% died of surgical complications. Roche et al.[242] treated 15 patients with JNPAF with various maxillofacial surgical resections, combined with Gamma Knife radiosurgery in 2 patients and external RT in 4 patients. With a median follow-up of 108 months, 12 patients were tumor-free and 2 had no progression. All patients had normal or nearly normal quality of life.

Tumor regression usually occurs slowly after either irradiation[233] or chemotherapy[243]; therefore, the presence of tumor up to 2 years after treatment is not an invariable sign of failure unless it is symptomatic or progressing. McAfee et al.[244] treated 22 patients with JNPAF with definitive RT (30 to 36 Gy); with a median follow-up of 12.7 years, 20 patients (91%) had tumor control. The two patients failing were salvaged with surgery. No major treatment morbidity was noted. Kasper et al.,[245,246] in 9 patients treated with RT (30 to 35 Gy), observed 25% to 50% initial tumor regression within 1 year. Eventually, seven of the patients had complete clinical tumor regression, but on CT or MRI, only two of seven had no residual disease.

The management of large JNPAF with intracranial extension is complex. In 18 patients with JNPAF, preoperative MRI, embolization of feeding branches from the external carotid artery, and attempted complete resection were used in seven patients with intracranial disease[239]; serial MRI scans were used for follow-up. Intracranial disease that was persistent or recurrent and demonstrated subsequent growth was irradiated (35 to 45 Gy) or re-excised.

Wiatrak et al.[236] reported on three patients with extensive intracranial extension treated primarily with radiation therapy doses of 36.6, 40.0, and 50.4 Gy, respectively, without surgical tumor resection. Although there was no complete resolution of the tumors, significant improvement of symptoms was obtained without serious sequelae.

Ochoa-Carrillo et al.[218] reported on 31 patients treated with surgery or radiation therapy. Surgery was the treatment chosen in patients with stage II and III diseases, whereas radiation therapy was the treatment in stage IV, but it had low effectiveness, indicating the need to carefully investigate the value of craniofacial approaches in these tumors. Radiation therapy (30 to 55 Gy) was administered to 16 patients; seven with stage III persistent or recurrent tumor, and eight patients as initial treatment for stage IV disease. The disease-free interval of patients with stage III and IV diseases was 80.3% and 19%, respectively, after 36 months of follow-up.

Tranbahuy et al.[247] reported on seven patients with juvenile angiofibroma who underwent direct tumoral embolization. This technique induced marked devascularization and necrosis of the tumor. No neurologic sequelae were encountered.

Goepfert et al.[243] reported on five patients with aggressive nasopharyngeal angiofibromas recurrent after extracranial resection and irradiation who were treated with chemotherapy. Doxorubicin (60 mg/m^2 intravenous push for 1 day) and dacarbazine (250 mg/m^2 intravenous drip for 5 days) were given, with courses being repeated every 3 to 4 weeks. In a second regimen, vincristine, dactinomycin, and cyclophosphamide were administered at usual doses. Excellent tumor regression was noted in all patients. Patients were disease free at 2, 3, 6, and 10 years.

Sequelae of Therapy

Most investigators agree that surgical mortality increases with intracranial extension of the tumor. The most common radiation therapy sequelae include delayed growth secondary to hypopituitarism and decreased bone maturation.[159]

Malignant degeneration in JNPAF undergoing radiation therapy has been occasionally reported,[248,249] and there are several well-documented cases of radiation-induced sarcomas in these patients,[26,233] with doses ranging from 66 Gy to more than 90 Gy. Spagnolo et al.[26] reported on four patients treated with irradiation who later developed sarcoma. Cummings et al.[233] reported two neoplasms developing 13 and 14 years after irradiation, one was a basal cell carcinoma and the other metastatic thyroid carcinoma. Both patients are alive without disease. Two patients developed cataracts.

NONLENTIGINOUS MELANOMA

Malignant melanoma accounts for 11% of primary head and neck malignancies.[250] Of all malignant melanomas, 20% to 35% are located in the head and neck area.[133]

Cutaneous Melanomas

In a review of the literature, Batsakis et al.[251] found that, of all head and neck malignant melanomas, 64% to 78% were cutaneous, 6% to 8% were mucosal, and 14% to 30% were ocular. The superficial spreading and nodular types of malignant melanoma have a metastatic potential of 10% to 30% and 50%, respectively.[252] Prognosis is correlated with location and stage of the tumor.[253] Neurotropic melanoma is an uncommon variant of cutaneous melanoma, with a higher propensity to invade peripheral nerves. A thorough evaluation with CT or MRI scans should determine if there is intracranial or base of the skull involvement.

Whole-body imaging with a CT or PET-CT scan is appropriate only for patients with regional nodal metastases. CT imaging detects occult disease in 0.5% to 3.7% of patients with microscopic nodal metastases on sentinel lymph node biopsy and in 4% to 16% of patients with clinically palpable nodal disease.[254] Only one metastatic lesion was identified in over 500 patients with invasive, node-negative melanoma evaluated in two large studies.[211]

Treatment of cutaneous melanomas has typically been wide excision of the lesion with a minimum 3-cm margin.[250] More recently, margins of at least 2 cm have been used in the head and neck for stage I melanomas, with equivalent success, with local failure rate of 3% to 6%.[211] In the absence of palpable regional lymphadenopathy, the decision to proceed with lymph node sampling after excision of a primary melanoma is frequently based on the probability of

detecting nodal micrometastatic disease, which increases monotonically with the depth of the primary lesion. In several large clinical trials and meta-analyses, nodal metastases were uncommon in patients with melanoma primary lesions under 1 mm thick, with positive nodes seen in only 1% to 5.6% of patients. In contrast, thick lesions with Breslow depths >4 mm were associated with nodal metastases, with estimates ranging from 35% to 45%.[211]

Radiation therapy, combined with surgery, is increasingly used in the treatment of patients with malignant melanoma (cutaneous or mucosal).[255] The Princess Margaret Hospital treated 16 patients with nodular melanomas with local excision and postoperative radiation therapy (50 Gy in 10 fractions over 2 weeks); 14 exhibited local tumor control, and 6 were alive and well 2 to 14 years after treatment. These results were comparable with those with wide local excision alone but with less morbidity and fewer cosmetic alterations. Later, at the same institution, Harwood and Cummings[252] treated five patients with definitive radiation therapy for superficial spreading melanoma of the head and neck area. All five lesions were locally controlled; one patient had a lymph node metastasis that was later controlled, and one died of distant metastases. They recommend treating these patients with 45 Gy in 10 fractions over 2 weeks to 50 Gy in 15 fractions in 3 weeks.[250,256]

Harwood and Cummings[252] also reported results in 74 patients treated with 3 fractions at 8 Gy given on days 0, 7, and 21 with shielding of the spinal cord, brain, and eye. Thirty patients were treated postoperatively after neck dissections if they had extracapsular tumor extension, multiple nodal involvement, a node >3 cm, or residual disease. Tumor control in the neck was achieved in 26 of 30 patients (86.6%) with follow-up of 1 to 4 years. In four patients with microscopic residual disease at the primary site, this postoperative regimen controlled three of four lesions with follow-up of 1 to 3.5 years. The other 40 patients were treated either for gross (13 patients) or recurrent (27 patients) cutaneous melanoma. Complete response was observed in 15 of 40 lesions (37.5%) and partial response in 12 lesions. An update of Harwood's data (personal communication, 1989) showed a neck tumor control rate of 94% in 41 adjuvantly treated patients versus 57% in 48 patients with gross residual or recurrent tumors. He concluded that irradiation alone should be considered for treatment of superficial spreading melanomas when surgery is contraindicated or after a simple excision in all cases of nodular melanoma in which a wide excision may be contraindicated because of age, location, or medical condition. For nodal disease, patients with poor prognostic pathologic factors should

receive postoperative irradiation. Recurrent or unresectable tumors also should be irradiated. Harwood et al.[190] recommended high-dose fractions because the local control rate was 71% when the dose per fraction was >4 Gy and 25% with lower fractions.

Ang et al.[257] reported on 174 patients with head and neck cutaneous melanoma high-risk features (three or more positive nodes, extracapsular tumor extension) who after surgery were treated with elective postoperative RT (30 Gy in 5 fractions of 6 Gy in 2.5 weeks).With a median follow-up of 35 months, LRC was 88%. Lesion thickness strongly affected 5-year survival (100% for <1.5 mm, 72% for >1.5 to 4.0 mm, and 30% for >4 mm). Bibault et al.[258] treated 60 patients with cutaneous melanoma with node dissection (17 in the head and neck) and postoperative RT and 26 (4 in head and neck) with surgery alone. At 5 years, the regional tumor control was better in patients receiving >50 Gy (80% vs. 35% with lower doses), which was reflected on higher overall survival. Grade 2 toxicity was noted in 9% of the patients. In 49 patients with high-risk cutaneous melanoma in the head and neck, Chang et al.[159] used postoperative RT (30 Gy in 5 fractions or 60 Gy in 30 fractions). With a median follow-up of 1.7 and 4.4 years for living patients, the 5-year LRC was 87% (no difference with either RT schedule), cause-specific survival 57%, and overall survival 46%. Two patients in the hypofractionated group developed major complications (osteonecrosis of the temporal bone and brachial plexopathy). Strojan et al.[259] reported on 83 patients with cutaneous melanoma in the head and neck, 40 treated with neck dissection only and 43 with dissection and postoperative RT (30 Gy in 5 fractions or 60 Gy in 30 fractions). In 20 patients, the primary site was included in the irradiated volume. With a median follow-up of 2.1 years, the regional tumor control at 2 years was 56% with surgery alone and 78% with surgery plus RT, with survival 58% and 51%, respectively. Late toxicity was observed in 6 of 34 (17%) of surgery-alone patients and in 10 of 36 (28%) of the surgery plus RT group. Chang et al.[159] summarized reports published on results of postoperative RT in head and neck cutaneous melanoma.

The ANZMTG 01.02/TROG 02.01 randomized controlled trial enrolled 123 patients to receive ART (48 Gy in 20 fractions, given over a maximum of 30 days) and 127 to observation after lymphadenectomy for a palpable lymph node field relapse and who were at high risk of recurrence. This study is registered with ClinicalTrials.gov, number NCT00287196. Median follow-up was 73; 23 (21%) relapses occurred in the adjuvant radiotherapy group compared with 39 (36%) in the observation group. Overall survival and relapse-free survival did

not differ between the two groups. Minor, long-term toxic effects from radiotherapy (predominantly pain, and fibrosis of the skin or subcutaneous tissue) were common, and 20 (22%) of 90 patients receiving adjuvant radiotherapy developed grade 3 to 4 toxic effects. Eighteen (20%) of ninety patients had grade 3 toxic effects, mainly affecting the skin (nine [10%] patients) and subcutaneous tissue (six [7%] patients). Over 5 years, a significant increase in lower limb volumes was noted after adjuvant radiotherapy (mean volume ratio 15.0%) compared with observation (7.7%; difference 7.3%). No significant differences in upper limb volume were noted between groups. Interpretation Long-term follow-up supports our previous findings. Adjuvant radiotherapy could be useful for patients for whom lymph node field control is a major issue, but entry to an adjuvant systemic therapy trial might be a preferable first option. Alternatively, observation, reserving surgery and radiotherapy for a further recurrence, might be an acceptable strategy.

Another approach to the treatment of recurrent or unresectable cutaneous melanomas is combined hyperthermia and high-fraction radiation therapy, as reported by Emami et al.[260] and Engin et al.[261] These data support the use of high fractions for melanoma because Overgaard's complete response rate was 59% when fractions of more than 4 Gy were used and 33% for lower dose per fraction sizes. However, a randomized study by the Radiation Therapy Oncology Group comparing 4 fractions of 8 Gy given on days 0, 7, 14, and 21 and 20 fractions of 2.5 Gy in 5 weekly fractions showed no significant difference in tumor response (24.2% and 23.4% complete response and 35% partial response).[262]

Treatment with high doses of adjuvant interferon or interleukin-2 in high-risk stage II and III melanoma reduced the risk or disease recurrence and increased the median disease-free survival in several large trials; however, the benefits were marginal and toxicity was significant. Recent developments with immune checkpoint inhibition (PD-1 receptor and CTLA-4 inhibition) and targeted therapy (MAPK inhibition) represent a new strategy for patients with metastatic and high-risk melanoma. Clinical trials integrating these treatments into treatment for patients with high-risk, advanced, or metastatic melanoma are in progress.

Mucosal Melanomas

Primary mucosal melanomas of the head and neck area comprise 2% to 8% of the cases seen each year in the United States.[251] They occur more commonly in

countries such as Japan, where mucosal melanoma is found in 22% to 32% of patients with malignant melanoma.[215] Most occur in the fifth to seventh decades of life; they are extremely rare in the first two decades (0.6% of mucosal melanomas).[263] The male-to-female ratio approaches 1 to 1.[263] A review by Batsakis[17] of 204 mucosal melanomas showed 56.4% to be from the upper respiratory tract and 44% from the oral cavity and pharynx. Nasal cavity or paranasal tumors comprise <1% of malignant melanomas and 2% to 9% of head and neck melanomas.[264] Pigmentation may precede the lesion in up to 28% of patients for more than 1 year.[265] In the oral cavity, the most common location is the hard palate (up to 80%), followed in order of decreasing frequency by the upper gingiva and lower gingiva.

Diagnostic Workup

An excisional biopsy should be performed when feasible because some reports have suggested possible local or metastatic spread secondary to a punch or incisional biopsy,[246] although this has not been noted in cutaneous melanomas.[36] Batsakis[17] found that one-third of these lesions were amelanotic, and Hoki et al.[264] noted that 25% were amelanotic.

Metastatic melanoma to the mucosa of the head and neck area is less common. It can be differentiated from primary tumors by the presence of normal tissue between subepidermal tumor and the basal layer of melanocytes.[17] The larynx, tongue, and tonsils are the most common locations for metastases.

Prognostic Factors

Batsakis et al.[251] found >0.5-mm invasion to be a poor prognostic factor. Trapp et al.[266] noted this to be true only in patients with >0.7-mm invasion. Lymph node involvement is not a prognostic factor. Mucosal melanomas fare worse than their cutaneous counterparts,[149] suggesting a lack of immunologic competence.[267]

Management and Results of Therapy

Surgical excision is usually recommended for these lesions. Because of the poor results obtained and because 37% of patients had associated adjacent pigmentation, some investigators recommend prophylactic excision of all melanocytic nevi. Because the results with irradiation are comparable with those of surgical series and because of the poor survival of these patients because of distant metastases and not locoregional failure, irradiation alone, with surgery for salvage, should be seriously considered as the primary treatment for mucosal

melanomas of the head and neck.[256] ENI is not indicated in all patients, as only few develop nodal metastasis.[8]

Patients with nasal cavity or paranasal mucosal melanoma have a median survival of 24 months. Five-year disease-free survival rates of 25% have been reported.[263] Patients with laryngeal melanoma had a 13% 5-year disease-free survival rate.[149] In a review of the Japanese literature, Umeda et al.[268] found a local tumor control rate for stage I and II diseases of 58% (7 of 12) in surgically treated patients with oral melanomas and a minimum follow-up of 3 years. Similar rates of failure have been reported, even with radical en bloc excisions (20% to 42%). Because the main cause of treatment failure is distant metastases and because almost no patient has clinically evident nodal metastases at presentation, an elective neck node dissection is not consistently recommended. This subject is still controversial, as 30% to 60% of patients may later develop nodal disease.[269]

Harwood and Cummings[252] treated 12 cases and added 12 cases from the literature for a total of 24 patients and 25 lesions. Local tumor control was achieved in 11 of 24 (9 to 54 months' follow-up). Six of seven tumors treated with 4-Gy fractions or larger were controlled, versus 5 of 18 treated with smaller fractions. Saigal et al.[8] treated 17 patients with mucosal melanomas (sinonasal tract in 11, oral cavity in 6) with surgery (16 combined with RT) and 1 with RT. Seven patients received adjuvant immunotherapy. With a median follow-up of 35.2 months, local tumor control at 5 years was 81%, disease-free survival 44.5%, and overall survival 51.5%. Krengli et al.[270] reported on 74 patients with upper aerodigestive tract mucosal melanomas (31 nasal and 12 oral), 17 treated with surgery alone, 42 with surgery and RT (median dose 60 Gy, 2-Gy fractions), 11 with RT alone, and 4 with chemoimmunotherapy. At 3 years, the local recurrence was 43% with surgery alone and 29% with surgery plus RT. Grade 3 mucositis was noted in nine patients.

Kingdom and Kaplan[271] described results in 13 patients with mucosal melanoma of the nasal cavity and paranasal sinuses treated with surgical resection. Eight had microscopically negative margins. Seven patients received postoperative irradiation (30 to 62 Gy). The neck was treated in three patients with doses of 30 to 50 Gy. The local tumor recurrence rate was 85% (11 of 13), with a mean interval from primary tumor treatment to recurrence of 16 months. Metastatic neck disease developed in two patients and distant metastases in four. Patients receiving postoperative irradiation had increased disease-free interval and prolonged survival. Negative surgical margins were not predictive of a more

favorable outcome. The investigators recommend resection of tumor with negative margins and postoperative irradiation for the treatment of all patients with mucosal malignant melanoma.

Zenda et al.[254] treated 14 patients with head and neck mucosal melanomas using protons (60 Gy in 15 fractions, 3 fractions per week). With a median follow-up of 36.7 months, the 3-year local tumor control was 85.7% and overall survival 58%. The most frequent failure site was the cervical nodes (six patients). Two patients developed late decreased visual acuity. Carbon ion therapy was used by Yanagi et al.[272] in the primary treatment of 72 patients with mucosal melanomas of the head and neck (dose ranging from 52.8 to 64 GyE in 16 fractions).With a median follow-up of 49 months, local tumor control at 5 years was 84%, cause-specific survival 39.6%, and overall survival 27%. No grade 3 morbidity was observed. Jingu et al.[273] treated 37 patients with head and neck melanomas with carbon ions (57.6 GyE in 16 fractions) and chemotherapy. With a median follow-up of 19 months, the local tumor control at 3 years was 65.3% and overall survival 81%. MRI minimum apparent diffusion coefficient was a prognostic factor for survival.

LENTIGO MALIGNA MELANOMA

Natural History

Lentigo maligna (Hutchinson melanotic freckle[274] or circumscribed precancerous melanosis of Dubreuilh) and its invasive counterpart, lentigo maligna melanoma (LMM), are well-recognized clinical–pathologic entities. LMM comprises about 10% of all melanomas in the head and neck, occurs predominantly on the face and ears of elderly persons, and generally has a very long natural history, frequently reaching a large size before diagnosis. Approximately one-third of lentigo maligna lesions, if left untreated, will eventually transform into invasive LMM.

Tannous et al.[275] hypothesized that lentigo maligna can be divided into two categories: one represents a pigmented lesion that is a precursor to melanoma and the other melanoma *in situ*. Also, they hypothesized that in some patients, there is a progression to malignant melanoma.

Clinical Presentation and Diagnostic Workup

These lesions appear as circumscribed and later as more diffuse areas of hyperpigmentation of the skin. They may develop some superficial nodularity

and eventual ulceration as they become more invasive. In 10% of the latter patients, regional and distant metastases eventually develop. The 10% metastatic spread in LMM contrasts with the 25% metastatic tendency in nodular melanomas arising in superficial spreading melanomas and a 50% metastatic spread in nodular melanomas arising *de novo*.

The diagnostic workup of these patients is similar to that of patients suspected of having malignant melanoma. Biopsies of the lesion are required to obtain histopathologic confirmation of the diagnosis. Careful physical examination must rule out any areas of extension or regional or distant spread.

General Management

The usual treatment of lentigo maligna and LMM has been surgery, with approximately 5- to 10-mm margin of normal skin or Mohs surgery, although larger margins may be required for ill-defined lesions.[276] Radiation therapy is used for more extensive lesions or for postsurgical recurrences.[276] Hill and Gramp[277] reported on 66 cases of LMM, 38% of which required two excisions or more to clear the tumor and 32% of cases showed evidence of invasive melanoma. Only one case has recurred thus far, and none have developed metastatic disease. For larger lesions, wider surgical excision with skin grafting has been reported to give poor cosmetic results.

Cohen et al.[278] reported their experience with Mohs microsurgery, which was performed in 26 patients with lentigo maligna and 19 patients with LMM. After a median follow-up of 58 months (214.3 patient-years), there was one recurrence, in a patient with five prior recurrences before Mohs micrographic surgery. Kuflik and Gage[279] treated 30 patients with cryosurgery. Lesions ranged from 1.3 to 4.5 cm in diameter. Lesions recurred in two patients (recurrence rate of 6.6%) who were successfully retreated with cryosurgery. Eleven patients observed for more than 5 years showed no recurrences.

Because of the low incidence of regional lymph node metastases, elective lymph node dissection is not indicated.

Radiation therapy with various techniques has been frequently used in the treatment of these patients, particularly those with larger lesions, because of minimal morbidity and generally excellent cosmetic results (Fig. 51.16).

Radiation Therapy Techniques

As in other skin lesions, the portals should be carefully designed to include the entire tumor with adequate margin (1 cm for lesions <2 cm and 2 cm for larger

tumors). Because Miescher irradiation technique used very superficial x-rays, with 50% depth dose being at approximately 1 mm, there is the possibility of local recurrence if dermal extension is unrecognized. Therefore, Harwood and Lawson[256] recommend using minimum x-ray energies of 100 keVp and preferably 140 to 175 keVp to treat these patients. Superficial x-rays (100 to 200 keVp) with adequate filtration or electrons (6 to 9 MeV) with appropriate thickness of bolus (1 to 1.5 cm) are adequate for most patients. Doses of 45 to 50 Gy in 15 to 25 fractions delivered over 3 to 5 weeks will control the disease in most patients. The authors recommend delivering 3 to 3.5 Gy, 3 times weekly, every other day, to a total of 50 Gy, depending on the size and thickness of the lesion. Elective irradiation of the regional lymphatics is not necessary. Traditionally, high dose rate (HDR) brachytherapy (BT) scalp molds have been considered the ultimate conformal therapy. Santos et al.[279a] described a new technique, tangential volumetric modulated arc therapy (TVMAT), that gives superior dosimetry to brachytherapy and conventional VMAT (cVMAT). TVMAT treats with the beam tangential to the surface of the scalp. The collimating jaws protect dose-sensitive tissue in close proximity to the PTV. Not all the PTV is within the beam aperture as defined by the jaws during all the beam-on time. TVMAT gave the best homogeneity and conformality; the PTV 98% volume was covered by 99.85% prescription dose. The conformity number for the BT, cVMAT, and TVMAT was 0.30, 0.69, and 0.83 respectively.

FIGURE 51.16. Lentigo maligna melanoma of the face before **(A)** and 6 years after **(B)** 50 Gy in 25 fractions delivered with 9-MeV electrons and bolus.

Careful follow-up with clinical examinations and photographs of the lesion is essential to ascertain the continuing regression of the tumor.

In patients on whom surgical excision is performed, postoperative irradiation is recommended if positive margins are found.[113] Doses are similar to those stated earlier.

Results of Therapy

Harwood and Lawson[256] described 13 patients with lentigo maligna treated with radiation therapy: 11 had local tumor control, 1 had an edge recurrence salvaged by irradiation, and 1 had residual tumor (alive and well 11 years after treatment for the recurrence). One patient alive at 2 years refused further treatment. Of 19 patients irradiated for LMM, 17 had tumor control with radiation therapy alone for periods ranging from 6 months to 6 years. One patient had a central recurrence that was salvaged by surgery (alive and well 5 years after treatment of recurrence). No patient has developed lymph node or distant metastases in either group.

Tsang et al.[263] described results in 54 patients treated with radiation therapy or surgery. Younger patients with smaller lesions were treated with surgical excision (18 patients) and achieved actuarial tumor control of 94% at 3 years. Older patients with larger lesions located in the head and neck area were treated by radiation therapy (36 patients), with an actuarial tumor control rate of 86% at 5 years. No patient developed metastatic melanoma. The late cosmetic appearance was acceptable in the majority of irradiated patients, with 11% showing poor cosmesis because of progressive skin pallor, atrophy, and telangiectasia in the treated area.

SARCOMAS OF THE HEAD AND NECK

Natural History

Sarcomas account for <1% of malignant neoplasms in the head and neck. The most frequent histologic type is malignant fibrohistocytoma (29%), whereas the least common is liposarcoma (1%). The histology is complex and requires immunochemical analysis including angiosarcoma, chondrosarcoma, hemangiosarcoma, leiomyosarcoma, liposarcoma, malignant fibrous sarcoma, neurofibrosarcoma, osteosarcoma, RMS, malignant schwannoma, and synovial sarcoma. Fibrosarcoma, angiosarcoma, leiomyosarcoma, and RMS are the most common types, but this varies in published reports. Distribution of these

sarcomas was 33% in the scalp or face, 26% in the orbit or paranasal sinuses, 14% arising from upper aerodigestive tract including the larynx, and 27% in the neck. Synovial sarcomas are rare soft tissue malignancies in the head and neck region; they account for 3% to 5% of head and neck tumors. Histologic, immunohistochemical, and characteristic chromosomal translocation findings are necessary for diagnosis. The poor prognosis of this sarcoma justifies radical surgery with postoperative radiation.[280]

Radiation-induced sarcoma of the head and neck is a rare long-term complication of treatment. The rarity of this tumor is reflected in the very few series reported in the English language medical literature.[281,282] When they do occur, most appear at least 10 years following radiation therapy. There is a possibility of a postirradiation sarcoma whenever a suspicious lesion is seen, regardless of the amount of time that has passed since radiation therapy was administered. The original pathology should be re-examined to ensure that the original tumor was diagnosed correctly. Electron microscopy can be useful in differentiating sarcomatous-appearing epithelial lesions from true soft tissue sarcomas.

The incidence of radiation-induced sarcomas of the head and neck is, however, likely to increase due to progressive aging of the population combined with improved survival in head and neck cancer patients. This problem can be extremely challenging, and the overall outlook has been reported to be very bleak. Patel et al.[282] reviewed 69 cases reported in the English medical literature since 1966 and pooled this information with their experience in treatment of 10 patients. This group was compared for survival with 124 patients with a diagnosis of head and neck sarcoma registered on the Head and Neck Sarcoma database at the Royal Marsden Hospital. There was no site prediction for radiation-induced sarcoma of the head and neck, but malignant fibrous histiocytoma was the most common pathologic diagnosis. The period of latency between initial radiation therapy and diagnosis ranged from 9 to 45 years, with a median of 17 years. Surgery was the mainstay of treatment, and follow-up ranged from 6 months to 15 years with a median of 48 months. The actuarial 5-year disease-free survival rate in these patients was 60%.

Clinical Presentation and Diagnostic Workup

Clinical presentation varies with the primary site of disease. Tumors arising from the aerodigestive tract usually present with nasal bleeding, a palpable mass in the neck, or difficulty in swallowing or breathing. In tumors arising from the base of

the skull or the nerve sheath, cranial nerve deficit is the most common presentation. Diagnostic workup follows that of soft tissue sarcomas of other sites in the body. With early lesions, radiographs or CT may show only nonspecific opacification, soft tissue swelling, and occasionally bone destruction. Table 51.1 outlines the suggested diagnostic workup. MRI, especially with gadolinium contrast, may be used as a supplement or alternative to CT scanning.[283,284] A CT scan of the chest is also mandatory for staging workup.

The American Joint Committee on Cancer staging system for soft tissue sarcomas is based on histologic grade, the tumor size and depth, and the presence of distant or nodal metastases. The staging system is the same as for sarcomas of the extremities, although specific staging for head and neck sarcomas is not standardized.[216]

Prognostic Factors

Prognostic factors for predicting local recurrence or disease-free survival include anatomic site, treatment modality, tumor histology and grade, tumor size, extension of disease, lymph node metastasis, and surgical margins.[280,285–287]

A report from Royal Marsden Hospital showed anatomic location and treatment modality to be independent prognostic factors for local recurrence; tumors of the head had a better local RFS than did those of the neck.[80] Patients treated with a combination of surgery and radiation therapy had a better RFS than did those treated with surgery or irradiation alone. The only significant independent prognostic factor for overall survival was the implementation of definitive surgery versus biopsy. In the above report, the prognostic impact of tumor stage and grade did not reach statistical significance. In contrast, Tran et al.[288] reported that 90% of patients with low-grade tumors were free of disease versus only 16% with high-grade lesions.

Bentz et al.[10] reviewed 111 head and neck sarcoma patients; median duration of follow-up was 51 months; the actuarial 5-year relapse-free, disease-specific, and overall survivals were 55%, 52%, and 44%, respectively. By multivariate analysis, size and grade significantly influenced all survivals, whereas margin status additionally influenced relapse-free survival.

In 109 soft tissue sarcomas of all sites, a French study demonstrated that quality of the surgery was one of the most important variables for predicting local recurrences. Tumor size, surgical margins, presence of tumor necrosis, and adequacy of the excision correlated with metastasis-free survival.[289]

General Management

Surgery is the preferred initial treatment modality for sarcomas.[237,289a] Unfortunately, it is often difficult to achieve complete resection of the tumor, and a high recurrence rate has been observed with surgery alone.[290] Extracapsular enucleation of the tumor results in 90% local recurrence because of the presence of microscopic pseudopodia, which tend to grow through the pseudocapsule into the surrounding tissue, and the presence of skipped lesions some distance from the main tumor mass. Pathologic analysis of the surgical bed often discloses microscopic extension of tumor. Farhood et al.,[290] in a review of 176 cases of adult head and neck sarcomas, reported that the pathologic margins of surgical specimens obtained by wide local excision were positive in >50% of cases. This resulted in inferior overall survival for sarcomas of the head and neck when compared with extremity sarcomas.[240] Wide local excision, with a 5-cm margin around the pseudocapsule in extremity sarcomas, is associated with better outcome, although approximately 20% will have local recurrence. The criteria for surgical resection are impractical for head and neck sarcomas because of anatomic limitations[216]; wide local excision is rarely possible because the tumors extend beyond the confines of origin and in the proximity of vital neurovascular structures. Some retrospective studies have suggested improved local tumor control when combined surgery and external irradiation are used. In 130 patients with soft tissue sarcomas of the head and neck treated with surgery alone at Royal Marsden Hospital, the overall 5-year survival was 50%; local tumor control was only 47%, and local recurrence was the cause of death in 63% of cases. Patients treated with combined modality treatment (surgery and irradiation) had less extensive surgery, yet local RFS was longer.[286]

Synovial sarcoma in the head and neck is rare. In a report of 36 patients, Al-Daraji et al.[291] noted there was a predilection for the parotid and the temporal regions, and nine involved skeletal muscle. Of 29 patients followed for a median of 14 years after surgical treatment, 11 were alive and tumor free.

A multidisciplinary discussion before the initiation of treatment is required to formulate the best approach for radiation delivery, surgical technique, and mode of reconstruction.

Radiation Therapy

Radiation therapy, by external beam or brachytherapy, plays an important adjunctive role in disease management, especially for tumors where en bloc resection with negative margin is not possible.[287,292] Chemotherapy regimens

are available for soft tissue neoplasms, primarily designed to improve local tumor control.[129] A systematic review of radiation therapy trials was performed by the Swedish Council of Technology Assessment in Health Care.[292] This synthesis of the literature on radiation therapy for soft tissue sarcomas is based on data from five randomized trials. Moreover, data from 6 prospective studies, 25 retrospective studies, and 3 other articles were used. In total, 39 scientific articles were included, involving 4,579 patients. The results were compared with those of a similar overview from 1996, which included 3,344 patients. There was evidence that adjuvant radiotherapy improves local tumor control in combination with conservation surgery with negative, marginal, or minimal microscopic positive surgical margins. There are still insufficient data to establish that preoperative radiotherapy is favorable compared to postoperative radiotherapy in patients presenting primarily with large tumors. The preoperative setting results in more wound complications. There is no randomized study comparing external beam radiotherapy and brachytherapy. These data suggest that external beam radiotherapy and low–dose rate brachytherapy result in comparable local control for high-grade tumors. Some patients with low-grade soft tissue sarcomas benefit from external beam radiotherapy in terms of local control. Brachytherapy with a low dose rate for low-grade tumors seems to be of no benefit, but data are sparse. In two small studies investigating hyperfractionation schedules, there was no indication of improvements compared to daily fractions of 2 Gy.

Mesenchymal chondrosarcoma of the sinonasal tract is a rare, malignant tumor of extraskeletal origin.[95] Thirteen patients with sinonasal mesenchymal chondrosarcoma presented with nasal obstruction (n = 8), epistaxis (n = 7), mass effect (n = 4), or a combination of these. The maxillary sinus was the most common site of involvement (n = 9), followed by the ethmoid sinuses (n = 7) and the nasal cavity (n = 5). All cases were managed by surgery with ART (n = 4) and/or chemotherapy (n = 3). The overall mean survival was 12.1 years, although five of six patients who developed local recurrences died of disease (mean survival, 6.5 years). Six patients were alive and disease free (mean survival, 17.3 years), and two patients were lost to follow-up.

Radiation Therapy Techniques

General principles for radiation therapy of head and neck sarcomas are similar to those of soft tissue sarcomas. Complete coverage of the surgical bed and scar with adequate margins (3 to 5 cm) is required.[293] However, because of the proximity of critical and radiosensitive organs (eyes, spinal cord, brainstem),

selecting optimal portal margins without seriously compromising the functioning of these organs is an art. Techniques similar to those used in epithelial tumors of the head and neck can be applied to sarcomas. In general, 55 to 60 Gy is needed for postoperative adjuvant irradiation, and an additional 10- to 15-Gy boost is recommended if the surgical margins are close (≤3 mm) or involved by tumor. Some institutions prefer preoperative irradiation of 45 to 50 Gy. Special attention should be directed to limiting the dose to critical structures. Use of a 3-D or IMRT treatment technique can be considered as demonstrated in Fig. 51.8.

Results of Therapy

Because of the propensity for sarcomas to invade the surrounding tissues, complete surgical clearance may be difficult. In a series from UCLA, attempted en bloc resection left residual tumor at the surgical margins in 52 of 127 patients.[288] The incidence of local recurrence was high (60%) with surgery alone.

In a retrospective report of 73 patients with sarcomas of the head and neck treated at Princess Margaret Hospital, the 5-year cause-specific survival was 62%, with a local recurrence rate of 41% and a distant metastasis rate of 31%.[283] Extension to adjacent structures, high-grade tumor, and tumor >10 cm were associated with poor survival. Gross residual tumor after surgery was also associated with a high local recurrence rate (75%) despite the addition of radiation therapy. Patients with clear surgical margins or only microscopic involvement fared much more favorably and had a similar local tumor control rate (74% and 70%, respectively), provided adjuvant irradiation was given. Because of the difficulty in obtaining wide surgical margins, 68% of the patients died as a result of uncontrolled local disease. These data substantiate the importance of surgical margins as well as the contribution of adjuvant irradiation.[283]

Colville et al.[216] reported on 41 male and 19 female patients treated with head and neck soft tissue sarcomas, with an overall 5-year survival of 60%. Twenty-five patients had surgery alone, 20 had surgery and pre- or postoperative radiation therapy, and 15 received nonsurgical treatment. With a mean follow-up of almost 4 years, the 5-year local tumor control was 56% in the surgical group and 40% in the nonsurgical group (more advanced and aggressive tumors). The 5-year survival was 70% and 40%, respectively.

Penel et al.[294] recorded their experience with 28 adult head and neck soft tissue sarcomas. The most common subtype was RMS (seven cases). Twenty-

two patients presented with previous inadequate resection performed elsewhere before admission. Nineteen patients had surgery (complete resection in 13 cases). Associated treatments were neoadjuvant chemotherapy, adjuvant chemotherapy, and postoperative radiotherapy in 4, 3, and 10 cases, respectively. The 2-year overall survival rate was 56%. Wolden et al.[295] treated 28 patients with head and neck RMS using IMRT (50 to 55 Gy in 1.8 Gy fractions) combined with chemotherapy. With a median follow-up of 24 months, local tumor control was 95% to 100% and 3-year survival. McDonald et al.[296] treated 20 children with RMS in the head and neck with IMRT (median dose 50.4 Gy, 1.8 per fraction). With a median follow-up of 29 months, the 3-year local tumor control was 100% and survival 76%.

Pandey et al.[297] reported on 22 cases of head and neck sarcomas (the neck, lower jaw, tongue, cheek, scalp, and maxilla were the most common sites affected). None of the patients had palpable neck nodes or distant metastasis at presentation. All the patients were treated with primary surgical resection, followed by adjuvant treatment in 14 cases (63.6%). After a median follow-up of 14.5 months, two patients died, six developed local recurrence, four developed metastatic disease, and another patient developed a second primary sarcoma. The overall 5-year survival was 80%, whereas the 5-year disease-free survival rate was 24.1%.

Barker et al.[16] published a review of 44 patients with nonmetastatic soft tissue sarcoma in the head and neck. The most common tumor histologies included malignant fibrous histiocytoma (15 patients), angiosarcoma (9 patients), fibrosarcoma (6 patients), and leiomyosarcoma (6 patients). The median overall survival for all patients was 79 months. The actuarial 5-year local tumor control was 55% and was highly correlated with the extent of surgical excision: 25% for subtotal resection or debulking, 65% for wide local excision, and 100% for radical excision. Local tumor control at 5 years was 60% for patients treated with both surgery and radiotherapy, 54% for surgery alone, and 43% for radiation alone. ART significantly improved the local control rates (from 25% to 54%) for patients with close (<2 mm) or positive surgical margins. Of 14 patients with locoregional failure in whom salvage was attempted, 9 (64%) were rendered disease free.

Moalikyar et al.[298] reported on 40 patients with head and neck sarcomas, histologies including undifferentiated pleomorphic sarcoma (9), fibrosarcoma (6), chondrosarcoma (6), angiosarcoma (5), spindle cell sarcoma (3), osteosarcoma (3), and others (7). Tumor sites were the scalp or skin (11),

mandible or temporomandibular joint (9), skull base or paranasal sinuses (9), neck (6), or upper airways (6). Histologic grade was low for 13, intermediate for 5, high for 17, and unavailable for 5. All patients underwent gross total tumor resection; 22 treated with surgery alone (57%), whereas 18 patients received surgery and postoperative RT (43%). At a median follow-up of 14.9 months, the 2-year OS, LRC, and distant metastasis control (DC) were 68%, 73%, and 74%, respectively. Positive margins significantly reduced both 2-year LRC (52% vs. 84%; $P = .01$) and OS (42% vs. 81%; $P = .004$). The addition of adjuvant RT did not improve 2-year LC (70% vs. 77%; $P > .05$) or OS (58% vs. 79%; $P > .05$). However, among the subgroup of patients with positive margins, use of RT improved 2-year OS (73% vs. 0%; $P = .03$) without an associated LC benefit. Similarly, improved 2-year OS was identified for high-grade tumors treated with RT (73% vs. 0%; $P = .03$) with no associated LC benefit. Sarcomas of the skull base or paranasal sinuses demonstrated significantly worse 2-year LC (28% vs. 86%; $P = .0002$) and OS (0% vs. 83%; $P = .001$) than other evaluated subsites.

Huang et al.[299] extracted data from 1,525 patients from the Surveillance, Epidemiology, and End Results (SEER) database with diagnosis of head and neck sarcoma treated between 1973 and 2010. Selected patients had no prior malignancies and no distant metastatic disease. The most common histology was fibrohistiocytic tumors (18.6%), followed by unspecified sarcomas (15.5%), blood vessel tumors (14.0%), liposarcomas (12.1%), and leiomyosarcomas (11.6%). Most tumors were nonspecifically coded as connective tissue of the head, face, and neck (60.3%). After that, the most common site was the skin/scalp (19.6%), followed by nasal cavity/paranasal sinus (4.6%) and oral cavity (3.9%). Of the cohort, 576 patients (37.8%) received RT in addition to surgery.

With a median follow-up of 48 months, the 5-, 10-, and 15-year OS rates were 64%, 49%, and 42%, respectively. The median OS in patients treated with surgery and RT was 82 months, which was inferior to that of 139 months in patients with surgery only ($P < .001$). Multivariate analyses showed that age > 60, regional stage, high grade, and tumor size >5 cm were factors associated with worse survival. RT seemed to improve OS, but that result was not statistically significant (hazard ratio 0.90, $P = .247$).

Further analyses showed that patients with high-grade tumors had an improved OS by RT (hazard ratio 0.78, $P = .017$). The median survival was 59 months in patients with RT versus 45 months in those patients without RT. There was no significant difference in OS among patients with low-grade tumors by

RT.

Brandmaier et al.[300] also analyzed the SEER database for local H&N cancers diagnosed between 1990 and 2011 that included an array of 12 sarcoma subtypes totaling 1,046 patients. Tumor size and staging data were limited. For all H&N sarcoma patients, the surgery-alone cohort had a 5-year OS of 65.4% compared to 53.3% for patients receiving surgery and adjuvant RT ($P = .0009$). The 5-year cancer-specific survival (CSS) in the surgery cohort was 82.4% compared to 64% in patients receiving surgery and adjuvant RT ($P < .0001$). Age >75 years was a negative prognostic factor for CSS, relative to age 20 to 39, with a hazard ratio of 1.61 ($P = .033$). High-grade histology was also a negative prognostic factor for CSS; grade 3 tumors had a hazard ratio of 8.0 relative to grade 1 ($P < .0001$). Among patients with grade 3 sarcomas, those receiving surgery alone had a 5-year OS of 48.2% versus 43.7% for those receiving surgery and RT ($P = .81$).

Among a smaller subset of stage T1N0 grade 3 sarcomas, the 5-year OS for surgery alone was 61.1% versus 51.6% for surgery and RT ($P = .89$). The CSS for the two groups was 77.5% and 71.6%, respectively ($P = .99$).

The authors hypothesized that adjuvant RT could be beneficial for grade 3 H&N sarcomas, regardless of tumor stage or margin status.

Mahmoud et al.[301] using the National Cancer Database (NCDB) evaluated radiation therapy (RT) utilization pattern and outcome of adjuvant therapies in 2,096 patients with nonmetastatic H&N sarcomas diagnosed between 2004 and 2012, who underwent tumor resection. Chi-square test assessed the cohort that included 1,366 males and 730 females with a median age of 62 years (range: 18 to 90). Fibromatous sarcoma (20%) and high grades (36%) were the most common histology and grade, respectively. RT delivery was significantly more frequent in high-grade, large tumors with positive surgical margins. At a median follow-up of 36 months, RT use did not impact survival nor did CT, which was delivered in 260 patients. Restricting the survival analysis to 752 high-grade patients, the 5-year OS improved from 43% to 54%, with RT delivery reducing mortality hazards ratio (HR) by 36% ($P < .001$).

TABLE 51.15 TREATMENT RESULTS OF ADULT SOFT TISSUE SARCOMAS OF THE HEAD AND NECK

		5-Year Actuarial Rates
Author	Number of	Local Control

(Reference)	Patients	Modalities	(%)	Survival (%)
Weber et al.[302]	188	S, R, C	—	Overall: 49.4 (<5 cm) Overall: 30.4 (≥5 cm)
Greager et al.[303]	48	S, R, C	—	Disease free: 54
Farhood et al.[290]	176	S, R, C	—	Overall: 55
McKenna et al.[304]	16	S, R, C	75	Disease free: 63
Eeles et al.[286]	103[a]	S, R, C	47	Overall: 50
LeVay et al.[283]	52	S, R, C	59	Cause specific: 63
Tran et al.[288]	164	S, R, C	41	Overall: 66
Willers et al.[287]	57	S, R, C	60	Overall: 66
Chao et al.[152]	33	S, R, C	49	Disease free: 40
Colville et al.[216]	60	S, R, C	50	60

[a]Series based on adults and children, excluding angiosarcomas.
C, chemotherapy; R, radiation therapy; S, surgery.

Their analysis hinted that ART improves survival in high-grade H&N sarcomas and that chemotherapy may not be beneficial.

Reported results of treatment of soft tissue sarcomas are summarized in Table 51.15.

Protons

Protons or heavy ions have been used in selected patients.[305] Hug et al.[306] reported on 27 patients treated at Massachusetts General Hospital in Boston (18 primary and 9 recurrent sarcomas of the head and neck close or abutting critical structures with 160-MeV protons; mean dose 68.5 GyE in 2.1-GyE fractions). Local recurrence was seen in eight patients (29%) and regional recurrence in six patients (22%). Tumor grade had a significant impact on outcome. One patient developed Lhermitte sign and another hypothyroidism.

Jingu et al.[273] described results in 27 patients with head and neck unresectable bone and soft tissue sarcomas, treated with carbon ions (57.6, 64.0, or 70.4 GyE in 16 fractions). The 3-year local tumor control was 91.6% and survival 72%. Therapy was well tolerated. A comparison with historical results showed that local tumor control rate with 70.4 GyE was significantly higher than that with 57.6 or 64.0 GyE (3-year, 91.8% vs. 23.6%, $P < .0001$). Furthermore, the overall survival with 70.4 GyE tended to be higher than that with 57.6 or 64.0 GyE (3-year, 74.1% vs. 42.9%, $P = .09$).

Tumor Characteristics and Prognosis

Several series have shown that tumor grade and size dictate the outcome of patients with head and neck sarcomas such as leiomyosarcoma, RMS, and malignant fibrous sarcoma.[278] Farhood et al.,[290] in a review of 176 adult head and neck sarcomas, found that only 20% of the patients with high-grade tumors were alive 10 years after treatment, compared with 88% of patients with low-grade tumors. Weber et al.[302] described a 45% 10-year survival rate for patients with tumors <5 cm versus 10% for those with tumors ≥5 cm.

Many series have reported that chondrosarcoma is not a radiosensitive tumor, and radiation therapy has no role in its treatment. However, some reports have demonstrated the contribution of radiation therapy in this histology. McNaney et al.[307] described a 65% survival rate at 2 years in 20 chondrosarcoma patients who received primary radiation therapy. Tumor grade was the most important prognostic factor.

Osteogenic sarcoma of the head and neck has a pattern of recurrence different from similar tumors elsewhere in the body. Head and neck osteosarcomas are usually high grade; they have a very high incidence of local recurrence but a lower risk of distant metastases. Several studies have used adjuvant irradiation and chemotherapy, which commonly results in improved locoregional tumor control and survival. Tran et al.[288] reported a 73% 5-year survival rate in patients with osteogenic sarcoma of the head and neck treated with high-dose preoperative irradiation followed by wide surgical excision.

Chemotherapy

Head and neck soft tissue sarcomas frequently metastasize; 25% of patients in a UCLA study had distant metastases.[268] The role of adjuvant chemotherapy to improve disease-free survival in sarcoma of the head and neck is controversial. Unlike with soft tissue sarcomas of the extremities, in which distant metastasis is the most common cause of death, the majority of deaths in sarcomas of the head and neck are associated with local failure. Approximately half of the distant metastases were detected after local recurrence occurred.[283] Chemotherapy did not appear to affect local tumor control.

In a series of 94 patients treated at UCLA,[247] local control was achieved in 52% of patients treated with surgery alone and 90% of those receiving adjuvant irradiation with or without chemotherapy.

For preoperative neoadjuvant chemotherapy, which supplements radiation therapy to downstage disease before surgery, satisfactory results are available only for sarcomas of extremities.[226] With the exception of RMS, postoperative

adjuvant chemotherapy for head and neck sarcomas should be given only in a clinical trial setting.

CHAPTER 52

Neck Cancer Including Carcinoma of Unknown Primary

William M. Mendenhall, Anthony A. Mancuso, Robert J. Amdur, Brian J. Boyce, and Peter T. Dziegielewski

ANATOMY

The locations of the various lymph node groups in the head and neck are shown in Figure 52.1.[1] Under normal conditions, the right and left lymphatic networks do not shunt from one side to the other.[2] The following discussion will focus on mucosal squamous cell carcinomas (SCC) unless otherwise specified.

The internal jugular chain (IJC) lymph nodes lie adjacent to the internal jugular vein and extend from the skull base to the clavicle. The most superior group of lymph nodes in this chain lies near the base of the skull in the posterior aspect of the lateral pharyngeal space and is often referred to as the parapharyngeal or junctional lymph nodes. These lymph nodes lie deep to the sternocleidomastoid muscle, the posterior belly of the digastric muscle, and the tail of the parotid gland. The remaining IJC lymph nodes are artificially divided into the subdigastric, middle jugular, and lower jugular groups.

The spinal accessory chain (SAC) lymph nodes are distributed along the course of cranial nerve XI. The superior nodes of the SAC blend with the upper IJC nodes. The supraclavicular lymph nodes merge laterally with the SAC lymph nodes and medially with the lower IJC lymph nodes.

There are typically three to six submandibular lymph nodes. They may be either preglandular or postglandular; there are no lymph nodes in the substance of the submandibular gland. Adjacent to these nodes are also the perifacial lymph nodes, which lie next to the facial artery and vein around the marginal mandibular nerve. The submental lymph nodes lie in the midline between the anterior bellies of the digastric muscles, anterior and superior to the hyoid bone and superficial to the mylohyoid muscle. There are typically 1 to 3 nodes in this

area. The lateral retropharyngeal lymph nodes lie within the retropharyngeal space, which is bounded anteriorly by the pharyngeal constrictor muscles, superiorly by the skull base, and posteriorly by the prevertebral fascia. They are usually found at the level of the C1 and C2 vertebral bodies but may be found as inferiorly as C3. The medial retropharyngeal nodes are small, inconstant intercalated nodes that are located near midline and empty into the lateral retropharyngeal lymph nodes.

The neck nodes are divided into levels as follows: level I, submental (IA) and submandibular (IB) nodes; level II, upper internal jugular nodes, from the skull base to the level of the hyoid bone divided by the spinal accessory nerve into levels IIa (anterior to the nerve) and IIb (posterior to the nerve); level III, middle internal jugular nodes, from the level of the hyoid bone to the omohyoid muscle; level IV, inferior internal jugular nodes, from the level of the omohyoid muscle to the clavicle; level V, divided by the spinal accessory nerve into levels Va (superior to the nerve) and Vb (inferior to the nerve); and level VI, central neck nodes, bounded by the hyoid bone, the sternum, and the common carotid arteries. Included in level VI are the paratracheal, pretracheal, precricoid (delphian), and tracheoesophageal groove nodes.[3]

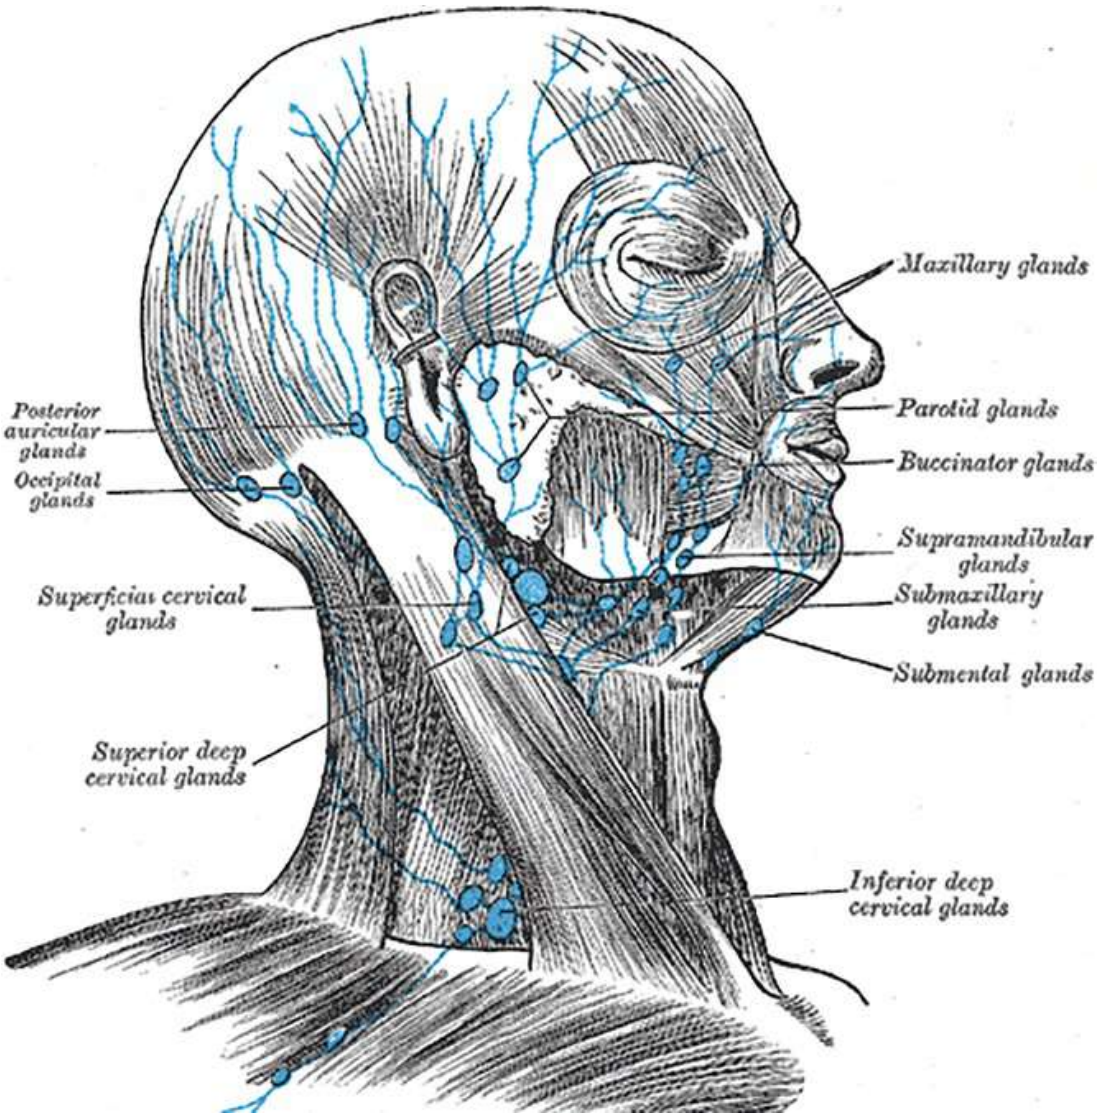

FIGURE 52.1. Arrangement of lymph nodes in the head and neck.

NATURAL HISTORY

The risk of lymph node metastases is influenced by the location of the primary tumor, histologic differentiation, size of the lesion, and the availability of capillary lymphatics.[4–7] The estimated risk of subclinical disease in the clinically negative neck as a function of primary site and tumor (T) stage is shown in Table 52.1.[4] Recurrent lesions have a higher risk of lymphatic involvement than untreated lesions. Moreover, their spread is less predictable.

The relative incidence of clinically positive lymph nodes in the neck by anatomic site and T stage is shown in Table 52.2.[5] The most commonly involved lymph nodes in the head and neck are the level II lymph nodes, followed by the

level III lymph nodes. Lesions that are well lateralized almost always spread first to the ipsilateral neck nodes. Lesions on or near the midline as well as lateralized base of tongue and nasopharyngeal lesions may spread to both sides of the neck.

Patients who have clinically positive lymph nodes on the ipsilateral side of the neck may be at risk for contralateral lymph node spread if the metastatic masses produce significant obstruction of the lymphatic trunks. In addition, patients who have undergone previous surgery on one side of the neck develop shunting of lymph across the submental region to the opposite side of the neck. When contralateral lymph node metastases occur, the level II lymph nodes are most frequently involved, followed by the level III and level IV lymph node groups.

As tumor grows within a lymph node, the node becomes indurated and more rounded, and enlarges. Tumor eventually extends through the capsule of the lymph node and invades surrounding structures. Extension to neurovascular bundles is common and may produce a mass that is fixed to palpation. The incidence of tumor involvement and the likelihood of capsular penetration as a function of lymph node size are shown in Table 52.3.[6]

The risk of lateral retropharyngeal lymph node involvement is related to primary site and neck stage[7]; the medial retropharyngeal nodes are almost never the site of metastatic disease. The incidence of positive retropharyngeal nodes based on pretreatment computed tomography (CT) and, in selected cases, magnetic resonance imaging (MRI) is shown in Table 52.4.[7]

TABLE 52.1 DEFINITION OF RISK GROUPS

Group	Estimated Risk of Subclinical Neck Disease	Stage	Site
I: Low risk	<20%	T1	Floor of the mouth, retromolar gingiva, trigone, palate, buccal hard mucosa
II: Intermediate risk	20%–30%	T1	Oral tongue, soft palate, pharyngeal wall, supraglottic larynx, tonsil
		T2	Floor of the mouth, oral of retromolar tongue, gingiva, trigone, hard palate, buccal mucosa
III: High risk	>30%	T1–4	Nasopharynx, pyriform sinus, base of tongue
		T2–4	Soft palate, pharyngeal wall, supraglottic larynx, tonsil

	T3–4	Floor of the mouth, oral retromolar tongue, trigone, gingiva, hard palate, buccal mucosa

DIAGNOSTIC WORKUP

Physical Examination

The patient is examined in the sitting position, the examiner behind the patient with one hand on the occiput to flex the patient's head forward and the other hand on the side of the neck to be examined. To examine the IJC lymph nodes, which lie deep to the sternocleidomastoid muscle along the internal jugular vein, place the thumb and index finger around the sternocleidomastoid muscle in the form of a "C," and then, gently proceed from the sternal notch to the angle of the mandible. Both sides of the neck should not be examined simultaneously. The level Ib and level Ia nodes may be evaluated by direct palpation of these areas as well as by a bimanual examination with the index finger placed in the floor of the mouth.[12]

TABLE 52.3 Relationship Between Node Size, the Presence of Tumor in the Node, and Capsular Penetration in 519 Nodes[a]

	Size of Node (cm)				
	1	2	3	4	≥5
Number of nodes	177	183	84	17	58
Percentage positive	33	62	81	88	100

Percentage positive capsular with penetration	14	26	49	71	76

The following features of metastatic lymph nodes should be recorded: anatomic location, size, consistency, mobility, and clinical impression as to whether the node is involved with cancer.

Radiographic Evaluation

CT, MRI, fluorodeoxyglucose–positron emission tomography (FDG-PET), and ultrasound may be used to evaluate cervical metastatic disease.[13] At the University of Florida, CT remains the primary method of examination of most carcinomas arising in the upper aerodigestive tract and the regional lymphatic system. MRI is the primary study only in patients with nasopharyngeal malignancies. MRI also may be used in patients who are allergic to intravenous contrast medium. Ultrasound has been used mainly in Europe to evaluate the cervical nodes. FDG-PET may be used to evaluate equivocal suspicious lymph nodes if the results of the scan would alter the treatment plan. Positive nodes <1

cm will not be reliably detected on a PET scan. FDG-PET remains unproven with regard to improving accuracy rates over those available with properly performed and interpreted CT.

Small metastases may be seen as lucent foci in normal-sized nodes. Such metastases have been identified and surgically confirmed in nodes as small as 6 to 8 mm; however, most subclinical disease in normal-sized nodes remains undetected on CT. FDG-PET has a marginal capability to improve on CT in detecting the subclinical disease in small (<1 cm) nodes.

Lucent foci in normal-sized nodes must be differentiated from hilar fat or volume-averaging artifacts. As the metastasis grows, the node becomes more spherical than elliptical. Areas of necrosis are almost always present in nodal metastases larger than 2 cm. As the metastasis enlarges, the capsule of the node becomes hyperemic and is seen radiographically as contrast-enhanced rim. When the capsule becomes indistinct and irregular along its outer margin, it is highly suggestive of early capsular penetration. Continued growth causes obliteration of the fat planes surrounding the nodes. Finally, no clear plane of normal tissue lies between the mass and the adjacent structures, at which point the clinician usually notes fixation (Fig. 52.2). Penetration of the prevertebral fascia and fixation to the scalene muscles are uncommon in untreated patients. Largely necrotic nodes may be negative on FDG-PET examinations.

FIGURE 52.2. T1 squamous cell carcinoma of the lateral wall of the right pyriform sinus (*open arrow*) and a fixed N3B neck node that abuts but does not surround the carotid artery (*solid arrow*). (From Mendenhall WM, Parsons JT, Mancuso AA, et al. Head and neck: management of the neck. In: Perez CA, Brady LW, Halperin EC, et al., eds. *Principles practice and of radiation oncology*. Philadelphia: Lippincott Williams & Wilkins, 2004:1158–1178.)

If a lymph node shows evidence of capsular penetration and envelops more than 50% of the circumference of the carotid artery, clinical evidence of fixation to the artery is likely. Ultrasound and MRI may prove useful in evaluating tumor extension to the carotid, as suggested by CT. MRI tends to be better at excluding extension to the neurovascular bundle when it is suspected on CT, whereas ultrasound can help show invasion of the vessel wall, thus confirming focal extension to the artery.

STAGING

The staging systems shown in Table 52.5 are those of the American Joint Committee on Cancer (AJCC).[14] Because all University of Florida data presented in this chapter were analyzed using the 1983 AJCC staging system,[15] both the 1983 and 2010 systems are outlined in Table 52.5. Stage N3C in the 1983 system is rare and should alert the clinician to search for another primary

lesion. The 2017 AJCC staging system classifies bilateral or contralateral nodes not more than 6 cm in diameter as N2C; N3 is defined as a metastasis in a lymph node more than 6 cm in diameter.[14] The AJCC nodal staging system for head and neck cancer has not changed appreciably since the 1997 edition. The AJCC nodal staging for nasopharyngeal carcinoma differs from other head and neck primary sites and will be discussed in the chapter devoted to that topic.

SURGERY

Historically, surgical treatment of neck lymphatics involved radical neck dissection. This involves the removal of lymph nodes in levels I to V along with the spinal accessory nerve, sternocleidomastoid muscle, and internal jugular vein. This is seldom performed today, as many studies have demonstrated that structures not involved by cancer in the neck can be preserved without sacrificing survival. The only indication to remove nonlymphatic structures in the neck (nerves, muscles, internal jugular vein, etc.) is direct involvement of the structure by a cancerous node.

TABLE 52.5 1983 AND 2017 AMERICAN JOINT COMMITTEE ON CANCER STAGING FOR NECK LYMPH NODES

Stage	Definition
1983 Stage	
NX	Nodes cannot be assessed
N0	No clinically positive nodes
N1	Single clinically positive homolateral node cm 3 or less in diameter
N2	Single clinically positive homolateral node more than 3 cm but not >6 cm in diameter or multiple clinically positive homolateral nodes, none >6 cm in diameter
N2A	Single clinically positive homolateral node >3 cm but not >6 cm in diameter
N2B	Multiple clinically positive homolateral nodes, none >6 cm in diameter
N3A	Clinically positive homolateral node(s), one >6 cm in diameter
N3B	Bilateral clinically positive nodes (in this situation, each side of the neck should be staged separately) N3B (i.e., left, N23; right, N1)
N3C	Contralateral node(s) clinically positive only
2017 Stage	
NX	Regional lymph nodes cannot be assessed
N0	No lymph regional node metastasis
N1	Metastasis in a single ipsilateral lymph node, 3 cm or smaller in greatest dimension and

	extranodal extension (ENE)(−)
N2	Metastasis in a single ipsilateral node larger than 3 cm but not larger than 6 cm in greatest dimension and ENE (−); or metastases in multiple ipsilateral nodes, none larger than 6 cm in greatest dimension and ENE (−); or in bilateral or contralateral lymph nodes, none larger than 6 cm in greatest dimension, ENE(−)
N2a	Metastasis in single ipsilateral or contralateral node larger than 3 cm but not larger than 6 cm in greatest dimension and ENE(−)
N2b	Metastasis in multiple ipsilateral nodes, none larger than 6 cm in greatest dimension and ENE(−)
N2c	Metastasis bilateral or contralateral lymph nodes, none larger than 6 cm in greatest dimension and ENE(−)
N3	Metastasis in a lymph node larger than 6 cm in greatest dimension and ENE(−); or metastases in a single ipsilateral node ENE(+) or multiple ipsilateral, contralateral, or bilateral nodes, any with ENE(+)
N3a	Metastasis in a lymph node larger than 6 cm in greatest dimension and ENE(−)
N3b	Metastasis in a single ipsilateral node ENE(+) or multiple ipsilateral, contralateral, or bilateral nodes, any with ENE(+)

Modified radical neck dissection, or functional neck dissection, involves the removal of lymph nodes in levels I to V with preservation of at least one of the following structures: spinal accessory nerve, sternocleidomastoid muscle, or internal jugular vein. This approach is used when the nodal burden is advanced with high-risk spread to level V or invasion of nonlymphatic structures.

The most commonly performed surgical neck treatment of neck lymphatics is now the selective neck dissection. This approach involves preserving all nonlymphatic structures and only removing the high-risk lymphatic levels. The advantage of this approach is that it maintains function, minimizes morbidity, and does not compromise oncologic treatment. The levels to be removed are determined by site of cancer. Levels I to III are addressed for oral cavity cancers. Levels II to IV are included for treatment of oropharyngeal, laryngeal, and hypopharyngeal cancers. If nodes suspicious for metastases are encountered in areas outside of the planned neck dissection, the selective neck dissection should be converted to a modified radical neck dissection.

Bilateral neck dissections may be performed simultaneously or separately (staged) in patients with bilateral neck disease as long as one internal jugular vein can be preserved. If both internal jugular veins need to be sacrificed, at least one should be reconstructed with a vein graft (e.g., saphenous vain or femoral vein). If both internal jugular veins are left sacrificed, the patient is at high risk of cerebral edema, extreme facial edema, and potentially blindness.

TABLE 52.6 POSTOPERATIVE COMPLICATIONS OF UNILATERAL NECK DISSECTION AFTER IRRADIATION TO THE PRIMARY LESION AND NECK (143 PATIENTS)

Complications	Number of Complications	Number of Second Operations to Repair Complication	Death
Salivary fistula	1	0	0
Wound breakdown	23	15	0
Bleeding	2	1	1
Pneumonia	2	0	1
Orocutaneous fistula	1	1	0
Lymphatic fistula	2	0	0
Pulmonary embolus	1	0	0
Cardiovascular problem	2	0	1
Sepsis	1	0	1
Total complications	35[a]	17	4[b]
Incidence (%)	33/143 (23)	17/143 (12)	4/143 (3)

[a]Thirty-five complications in 33 patients.
[b]Deaths occurred 6, 7, 8, and 35 days after surgery.

Complications of Neck Dissection

Complications of neck dissection include hematoma; seroma; lymphedema; wound infection; wound dehiscence; skin flap necrosis; chyle leak; damage to cranial nerves V, VII, X, XI, and XII; internal jugular vein rupture; and carotid rupture. The incidence of complications is higher when neck dissection is combined with resection of the primary lesion or when it follows a course of radiation therapy (RT). The postoperative mortality rate for unilateral neck dissection after RT was 3% for patients treated between 1964 and 1982.[16] This figure is now <1%.

The incidence of postoperative complications in a series of patients treated with RT to the primary lesion and neck followed by unilateral or bilateral neck dissection(s) is shown in Tables 52.6 and 52.7.[17,18] Two of 10 patients

undergoing a staged bilateral neck dissection experienced a moderately severe complication compared with 4 of 40 patients undergoing a simultaneous bilateral neck dissection. None of the 10 patients who underwent a staged bilateral neck dissection experienced a severe complication, compared with 6 of 40 patients (15%) who underwent a simultaneous bilateral neck dissection (P = .24).[18]

Taylor et al.[17] analyzed the incidence of moderate (2+) and severe (3+) wound complications in a series of 205 patients who underwent a planned unilateral neck dissection after RT at the University of Florida. RT was given once daily in 123 patients, twice daily in 80 patients, and with both techniques in the remaining two patients. The incidence of wound complications increased with total dose and dose per fraction (Fig. 52.3).

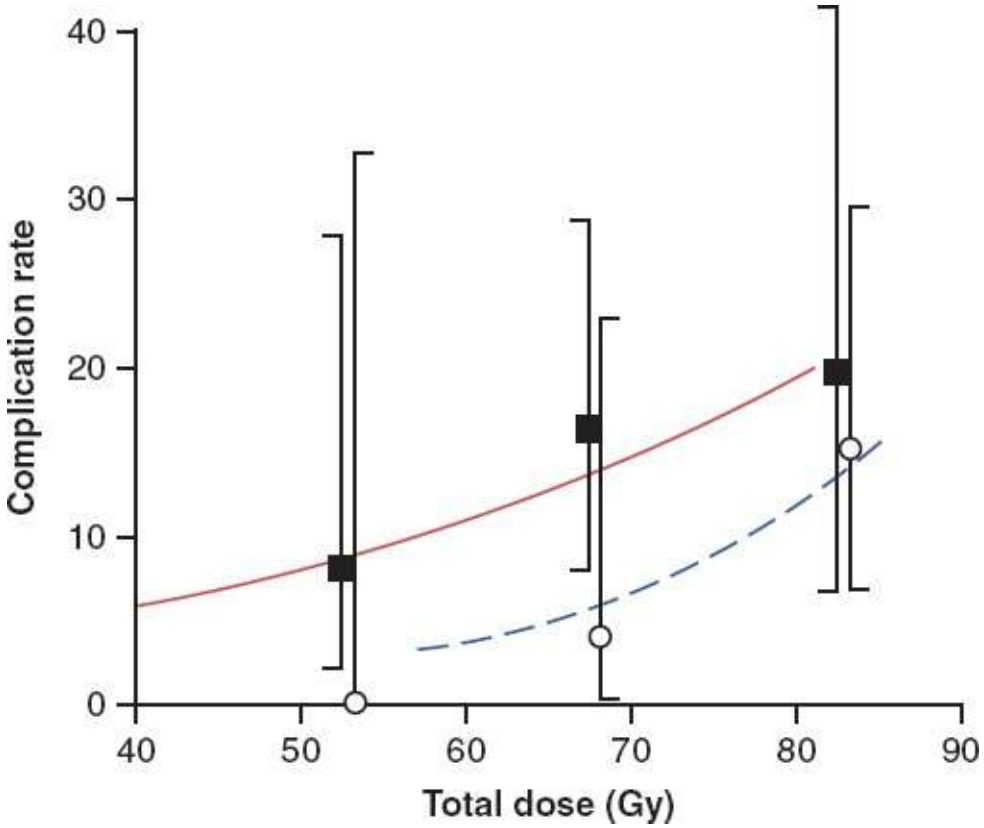

FIGURE 52.3. Complication rate (2+ or 3+) versus total dose. Separate analysis for once a day (*filled square*, *solid curve*) and twice a day (*circle*, *dashed curve*). Data are plotted at the midpoints of the range 45 to 60 Gy, 60 to 70 Gy, and 75 to 90 Gy. Error bars denote 95% confidence intervals. The curves are the results of separate logistic regression analysis. (Reprinted from Taylor JMG, Mendenhall WM, Parsons JT, et al. The influence of dose and time on wound complications following post-radiation neck dissection. *Int Radiat J Oncol Biol Phys* 1992;23[1]:41–46. Copyright © 1992 Elsevier. With permission.)

TABLE 52.7 COMPLICATIONS AFTER RADIATION THERAPY FOLLOWED BY A BILATERAL NECK DISSECTION (*N* = 50 PATIENTS)

Severity	Complication	Number of Patients
Moderate	Wound breakdown	2
	Bleeding	1
	Laryngeal edema	2
	Chyle fistula	1
Severe	Wound breakdown	4

RADIATION THERAPY

RT may be used in the treatment of cervical lymph node metastases as elective treatment when there are no palpable lymph nodes, as the only treatment for clinically positive lymph nodes,[19] or as preoperative or postoperative treatment in combination with neck dissection for clinically positive lymph nodes.[20]

The regional lymph nodes are considered in the treatment planning of the primary lesion. With clinically negative neck nodes, treatment planning depends on the estimated risk of subclinical disease in the nodes. With clinically positive lymph nodes, the plan is influenced by the number of lymph nodes, size, and location.

Elective Radiation Therapy of Cervical Lymph Nodes When the Primary Tumor Is Treated by Radiation Therapy

Factors that influence the decision to irradiate the neck electively are site and size of the primary lesion, histologic grade, difficulty in neck examination, relative morbidity for adding lymph node coverage, likelihood of the patient's returning for follow-up examinations, and suitability of the patient for a radical neck dissection if the tumor appears in the neck at a later date. Patients in whom the primary lesion is to be treated by RT, who have clinically negative nodes, and in whom the risk of subclinical disease is 15% to 20% or greater receive elective neck irradiation to a minimum dose equivalent to 45 to 50 Gy over 4.5 to 5 weeks (see Table 52.1). Patients with lesions arising in the lip, nasal

vestibule, nasal cavity, or paranasal sinuses have a low risk of subclinical neck disease, and the neck is not treated electively unless the lesion is recurrent, advanced, or poorly differentiated. Similarly, the risk of occult neck disease is essentially 0% for T1 and 1.7% for T2 glottic carcinomas, and elective neck radiation therapy is not indicated.[21,22]

The lateral treatment portals used to encompass cancers in the oropharynx, supraglottic larynx, and hypopharynx include the upper jugular and often the midjugular chain lymph nodes. RT portals used for primary lesions of the oral cavity, nasopharynx, glottis, nasal cavity, and paranasal sinuses must be enlarged to include the lymph nodes. The treatment portals for irradiation of the cervical lymph nodes must be designed in such a way as to minimize additional mucosal irradiation. A common error in irradiating oropharyngeal and nasopharyngeal cancers is to enlarge the lateral (primary) portals inferiorly to unnecessarily include all of the larynx in the lateral portals (Fig. 52.4).[23] Because the midneck is smaller in circumference than the upper neck, the total dose and dose per fraction are higher in the larynx than along the central axis of the beam, leading to double trouble. Although a field junction through a positive node(s) may be avoided with intensity-modulated radiation therapy (IMRT), the larynx still receives a substantially higher dose compared with a separate anterior low-neck portal with a midline laryngeal block junctioned at the thyroid notch (Figs. 52.5–52.7).[24] Treating an unnecessarily large field increases the acute and late effects of RT and, by increasing the risk of an unplanned split, reduces the probability of disease control.[23,24]

IMRT may be used to treat patients if there is a goal that can be achieved to reduce the toxicity of irradiation. These goals are usually parotid sparing to reduce the risk of long-term xerostomia, avoiding a low-neck match in patients with a low-lying larynx, and improved coverage of the poststyloid parapharyngeal space in patients with nasopharyngeal cancer.[25] If one or more of these goals cannot be achieved, the patients may be better off being treated with conventional RT because of the disadvantages of IMRT, which include increased risk of a marginal miss, less homogeneous dose distribution, and increased cost and complexity.[25]

Elective neck irradiation for early oral cavity lesions includes the level Ib and level II lymph nodes. The level III and level IV lymph nodes are treated as well by using a narrow anterior field. For primary lesions located in the oropharynx, nasopharynx, supraglottic larynx, and hypopharynx, the lower-neck nodes are also routinely included. The low neck is treated with a single anterior field (Fig.

52.8). A tapered midline larynx or trachea shield is added to protect the spinal cord, the larynx, and the pharynx. For primary lesions lying below the thyroid notch, a small midline tracheal block 1 cm wide is placed in the low-neck field, to shield the trachea, esophagus, and spinal cord.

Treatment of Clinically Positive Cervical Lymph Nodes When the Primary Tumor Is Treated by Radiation Therapy

The dose required to control a clinically positive lymph depends on the size of the lymph node[19,26] and whether concomitant chemotherapy is administered. Relatively recent data suggest that advanced disease has a better chance of cure after altered fractionation or concomitant chemotherapy.[27] Patients treated at the authors' institution routinely receive hyperfractionation on simultaneous integrated boost (SIB) combined with weekly cisplatin 30 mg/m^2. SIB consists of 70 Gy in 35 fractions over 30 treatment days in 6 weeks with 1 twice-daily fraction during the last 6 weeks with a minimum 6-hour interfraction interval. The high-risk planning treatment volume (PTV) receives 70 Gy at 2 Gy per fraction, intermediate-risk PTV receives 63 Gy at 1.8 Gy per fraction, and the standard-risk PTV receives 56 Gy at 1.6 Gy per fraction. Positive nodes receive approximately 70 to 74 Gy, regardless of size or rate of regression.

The decision to add a neck dissection after RT for multiple unilateral positive nodes or bilateral lymph node disease is individualized and is based on the diameter of the largest node, node fixation, and number of clinically positive nodes in the neck. If clinically positive lymph nodes disappear completely during RT, the likelihood of control by RT alone is improved and a neck dissection may be withheld.[28–31] Peters et al.[32] reported on 100 node-positive patients with squamous cell carcinoma of the oropharynx treated with concomitant boost RT between 1984 and 1993 at the MD Anderson Cancer Center (Houston, TX). Sixty-two patients had a complete response in the neck and received no further therapy. Three patients (5%) subsequently developed an isolated recurrence in the neck, and four patients (6%) developed a recurrence in the neck in conjunction with other sites of relapse. The 2-year neck disease control rates did not vary significantly with pretreatment nodal size: ≤3 cm, 87%, and >3 cm, 85%. The incidence of subcutaneous fibrosis was similar following RT alone compared with another group of patients who underwent a neck dissection in addition to RT. Johnson et al.[33] reported on 81 patients with node-positive stages III and IV squamous cell carcinoma of the head and neck treated with concomitant boost accelerated hyperfractionated RT at the Medical

College of Virginia (Richmond). Fifty-eight patients (72%) had a complete response in the neck and were followed; three patients (5%) subsequently developed an isolated recurrence in the neck, and one additional patient developed recurrent cancer in the neck and in the primary site. The 3-year neck disease control rates were 94% for nodes ≤3 cm compared with 86% for those >3 cm.

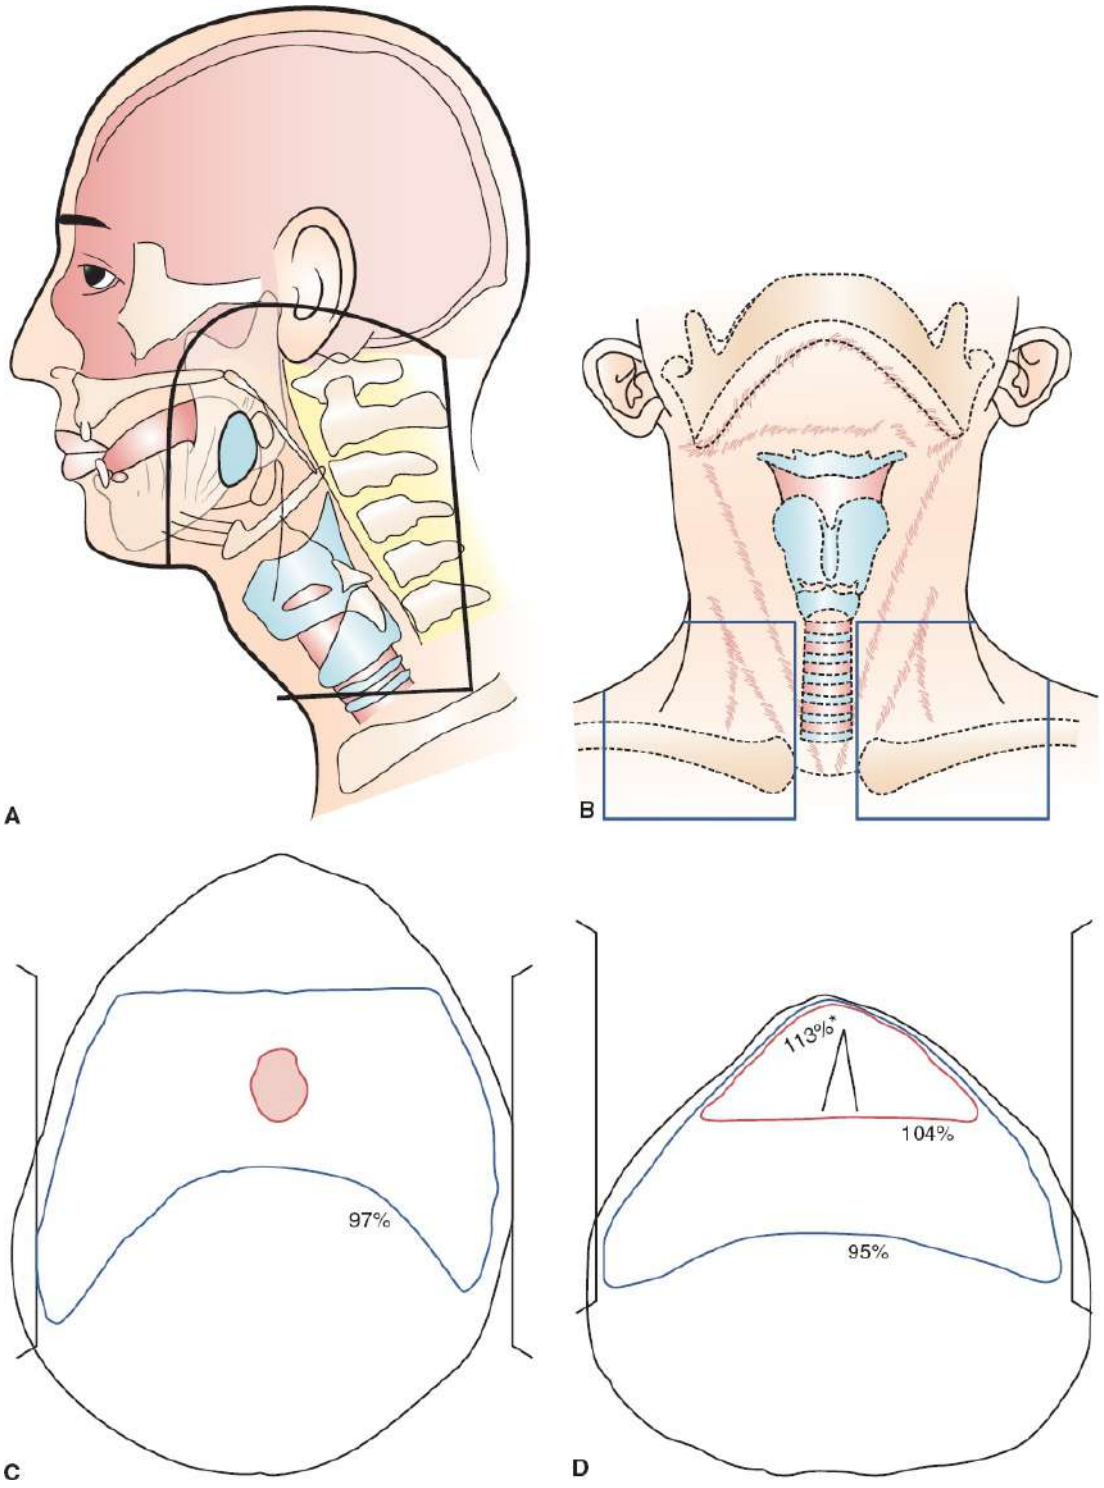

FIGURE 52.4. Carcinoma of the base of the tongue: large conventional radiation portals. **A:** Parallel-opposed lateral portals include the primary lesion, larynx, hypopharynx, most of the cervical spinal cord, and the upper portion of the trachea and cervical esophagus. Treatment through this portal tangentially irradiates the skin of the anterior neck unnecessarily. If an anterior field is not used to irradiate the low neck, the inferior border of the lateral field may be placed near the clavicle (*dashed line*). **B:** Anterior low-neck portal. The wide midline tracheal block partially shields the

low internal jugular lymph nodes, which are located adjacent to the trachea. The supraclavicular lymph nodes, which are less likely to be involved with tumor than the low jugular nodes, are adequately covered. **C:** Central-axis dosimetry at the level of the base-of-tongue primary lesion. The contours were obtained from a RANDO phantom using parallel cobalt-60 fields weighted equally. The base-of-tongue tumor is outlined, and the tumor dose is specified at 97% of maximum dose. **D:** Off-axis contour through the larynx. The minimum dose to the entire larynx is 104% of the maximum dose specified at the central axis, and the maximum dose on this off-axis contour is 113%. If the base-of-tongue tumor dose is specified as 50 Gy at 2 Gy per fraction, the minimum larynx dose is 53.61 Gy at 2.14 Gy per fraction, and the maximum larynx dose is 58.25 Gy at 2.33 Gy per fraction. If the tumor dose is specified as 60 Gy at 2 Gy per fraction, the minimum larynx dose is 64.33 Gy at 2.14 Gy per fraction, and the maximum larynx dose is 69.9 Gy at 2.33 Gy per fraction. (Reprinted from Mendenhall WM, Parsons JT, Million RR. Unnecessary irradiation of the normal larynx [editorial]. *Int J Radiat Oncol Biol Phys* 1990;18[6]:1531–1533. Copyright © 1990 Elsevier. With permission.)

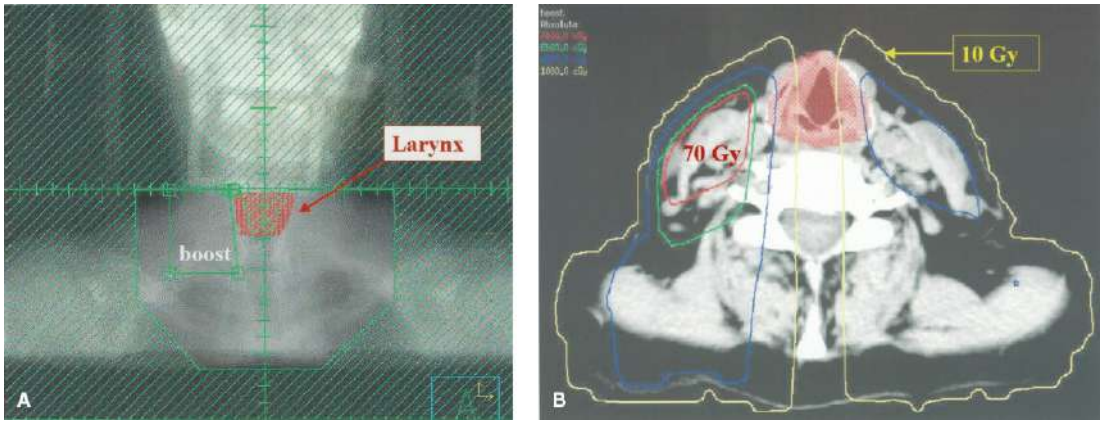

FIGURE 52.5. Laryngeal dose in a model patient with a stage T2N2b carcinoma of the tonsil with positive nodes on the right side at the level of the larynx. The primary site is irradiated with either intensity-modulated radiation therapy or conventional lateral-opposed fields. The cervical lymphatics inferior to the primary site fields are treated with an anterior low-neck field. **A:** Digitally reconstructed radiograph of the low-neck fields. The larynx was contoured and appears as a red color-wash structure. The larynx is shielded with a narrow midline block that does not cover the entire width of the larynx. In this model patient, the entire low-neck field received 50 Gy, and then the field size was reduced to boost the positive nodes on the right of the larynx to 70 Gy. Irradiation was given with a 6-MV photon beam with source to axis distance of 100 cm. **B:** Axial dose distribution at the level of the true vocal cords showing that the dose to the central portion of the larynx is extremely low when the larynx is shielded in the anterior low-neck field. (From Amdur RJ, Li JG, Liu C, et al. Unnecessary laryngeal irradiation in the IMRT era. *Head Neck* 2004;26[3]:257–264. Copyright © 2004 Wiley Periodicals, Inc. Reprinted by permission of John Wiley & Sons, Inc.)

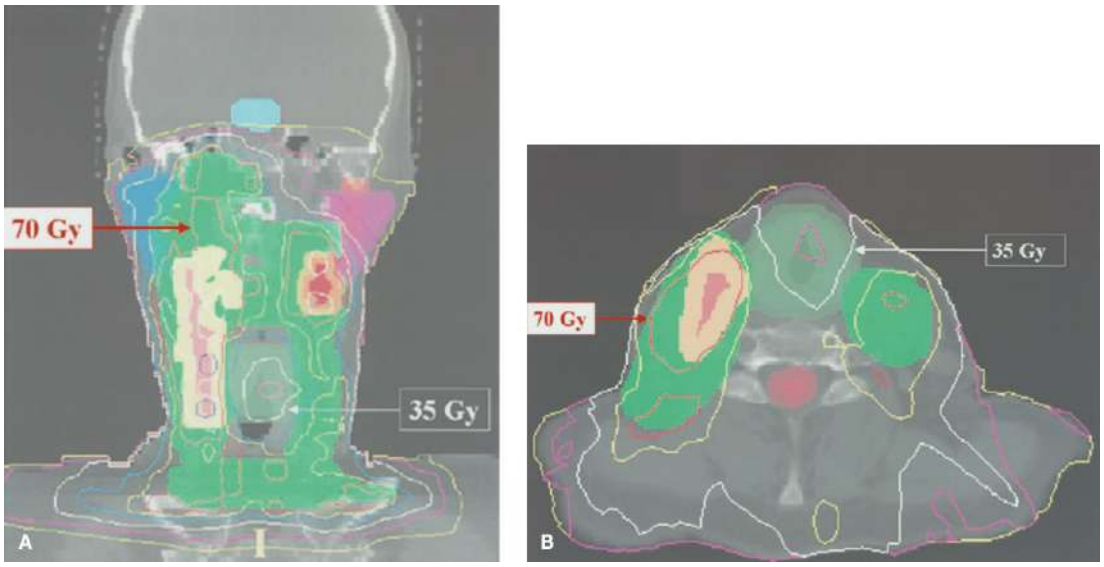

FIGURE 52.6. Dose distribution using intensity-modulated radiation therapy as described in the text to treat the model patient with a stage T2N2b carcinoma of the tonsil with positive nodes on the right side at the level of the larynx. The plan was optimized to minimize the dose to the larynx while delivering 70 Gy to gross disease and 59.4 Gy to areas at risk for subclinical disease. **A:** Coronal projection near the middle of the larynx. **B:** Axial projection at the level of the true vocal cords. A comparison of Figures 52.5B and 52.6B shows that sparing of the central portion of the larynx is shielded in an anterior low-neck field. (From Amdur RJ, Li JG, Liu C, et al. Unnecessary laryngeal irradiation in the IMRT era. *Head Neck* 2004;26[3]:257–264. Copyright © 2004 Wiley Periodicals, Inc. Reprinted by permission of John Wiley & Sons, Inc.)

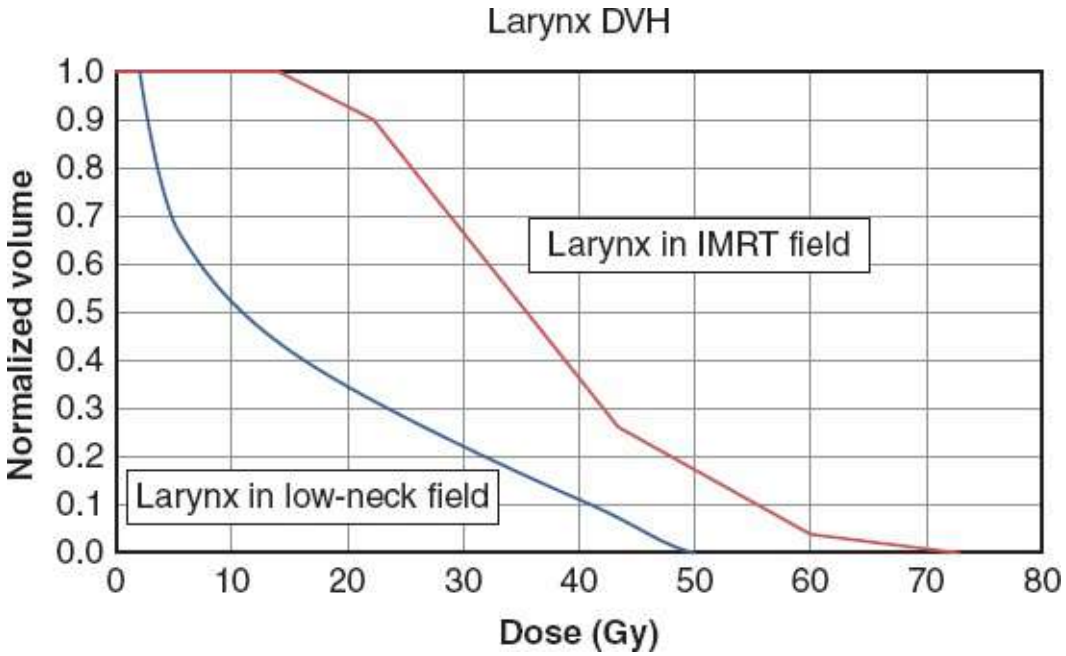

FIGURE 52.7. Dose–volume histogram (DVH) of the larynx for the model patient described in Figures 52.5 and 52.6. The thicker line is the dose–volume histogram when the larynx is included in the intensity-modulated ration therapy (IMRT) fields

shown in Figure 52.6. The thinner line is the dose–volume histogram when the larynx is shielded in the anterior low-neck field shown in Figure 52.5. There is a major difference in the portion of the larynx that receives an extremely low dose. For example, when the larynx is included in the IMRT fields, the entire larynx receives more than 10 Gy, whereas when the larynx is shielded in the low-neck field, approximately 45% of the larynx receives <10 Gy. (From Amdur RJ, Li JG, Liu C, et al. Unnecessary laryngeal irradiation in the IMRT era. *Head Neck* 2004;26[3]:257–264. Copyright © 2004 Wiley Periodicals, Inc. Reprinted by permission of John Wiley & Sons, Inc.)

Both of these series of patients received aggressive altered fractionated RT, and it is unclear whether these data can be broadly extrapolated to patients with head and neck cancer from a variety of head and neck primary sites that are treated less aggressively. It is also unclear whether the addition of concomitant chemotherapy results in a lower likelihood of needing a neck dissection. However, multiple subsequent studies evaluating neck control rates after RT alone or combined with chemotherapy suggest that the likelihood of an isolated failure in the neck is low if there is a complete response after treatment.[20,34–38]

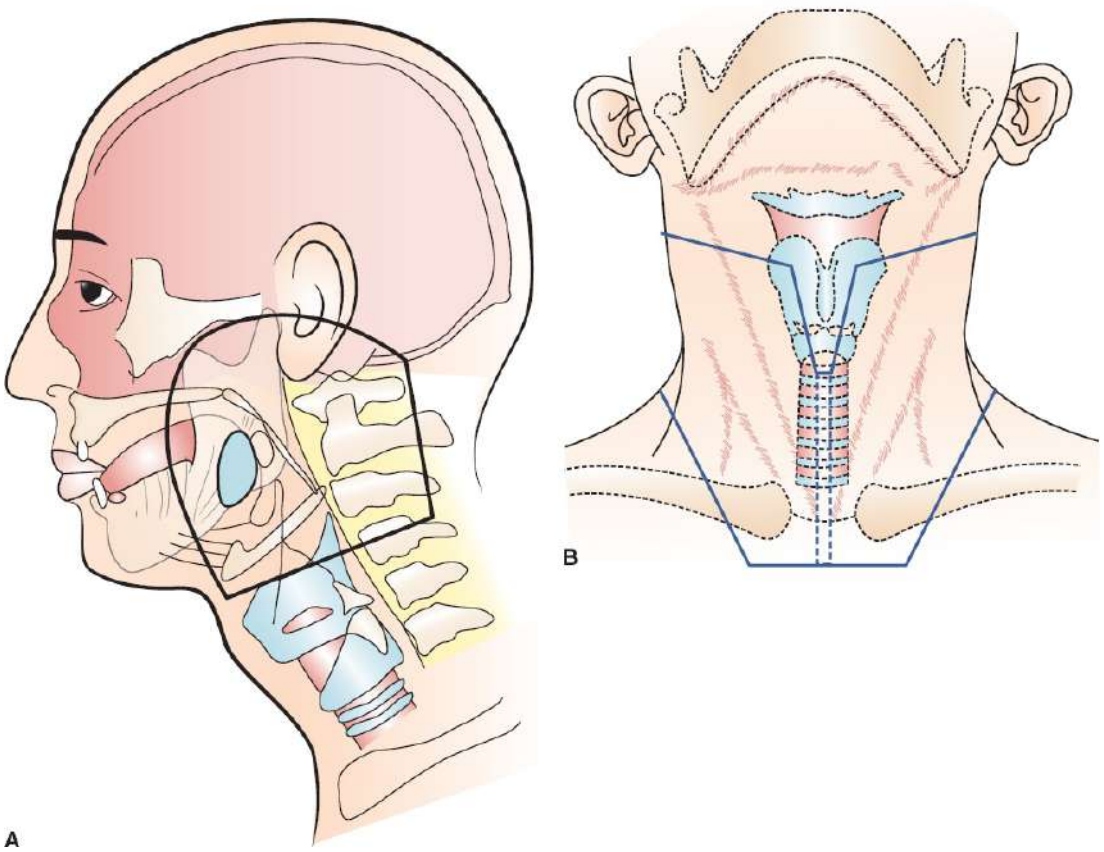

FIGURE 52.8. Lateral and anterior conventional fields are used to irradiate a patient with a carcinoma limited to the base of tongue. **A:** Parallel-opposed fields include the primary lesion with a 2- to 3-cm inferior margin. The lower border of the field is placed

at the thyroid notch and slants superiorly as the junction line proceeds posteriorly. This substantially reduces the amount of mucosa larynx and spinal cord included in the primary treatment portals. **B:** *En face* low-neck portal with tapered midline larynx and tapered midline larynx block. It is not necessary to treat the supraclavicular fossa unless clinically positive nodes are found in that particular hemineck. A 5-mm midline tracheal block may be placed in the low-neck portal (*dashed line*). (Reprinted from Mendenhall WM, Parsons JT, Million RR. Unnecessary irradiation of the normal larynx [editorial]. *Int J Radiat Oncol Biol Phys* 1990;18[6]:1531–1533. Copyright © 1990 Elsevier. With permission.)

The authors' policy at the University of Florida has changed to the extent that we now evaluate patients with clinically positive nodes with CT 4 weeks after RT or a PET-CT at 3 months and withhold neck dissection in the subset of patients with a complete response thought to have ≤5% risk of residual disease.[39–46] Liauw et al.[42] evaluated a series of 550 patients treated with definitive RT at the University of Florida between 1990 and 2002; 341 patients (62%) underwent a post-RT planned neck dissection. CT images obtained at approximately 4 weeks post RT were reviewed for 211 patients; radiographic complete response (rCR) was defined as no nodes >1.5 cm and no focal abnormalities such as focal lucency, enhancement, or calcification.[36] The outcomes are depicted in Table 52.8. Thirty-two patients had an rCR and were followed and did not undergo a neck dissection; the neck control rate was 97%. Recent data published by Yeung et al.[39] suggest that for those who have a partial response to RT, neck dissection may be safely limited to only those levels that remain suspicious after RT. Post-RT selective neck dissection likely results in improved quality of life.[47] PET-CT is obtained 3 months after completion of RT to minimize the risk of a false-positive scan; those with a negative PET-CT are followed; the remainder undergo a neck dissection. Goenka et al.[45] reported on 302 patients with node-positive oropharyngeal SCCs treated with IMRT and concomitant chemotherapy at the Memorial Sloan Kettering Cancer Center between 2002 and 2009. Patients underwent a PET-CT following treatment to assess response. A clinical and radiographic complete response (CR) was observed in 260 (86.1%) patients. The neck control rate was 97.7%. Three of 4 patients who recurred in the neck were successfully salvaged. Patients who underwent a neck dissection had the following rates of pathologically visible tumor: PET-CT positive, 52%, and PET-CT negative, 25%. Mehanna et al.[46] reported on a prospective trial where 564 node-positive patients were randomized to chemoradiation followed by PET-CT and planned either neck dissection (282 patients) or observation in the event of a CR (282 patients). Patients in the latter group underwent fewer neck dissections: the 2-year survival

rates were comparable.

TABLE 52.8 PREDICTIVE VALUE OF POSTRADIOTHERAPY COMPUTED TOMOGRAPHY FINDINGS AT 4 WEEKS IN THE HEMINECK CORRELATED TO NECK DISSECTION PATHOLOGY (*N* = 193 HEMINECKS)

Findings	NPV		PPV	
	Number/Total Number	Percent	Number/Total Number	Percent
Any lymph node >1.5 cm	85/118	72	24/75	32
Any lymph node with focal lucency	49/57	86	49/136	36

If a neck dissection is planned to follow RT in patients with clinically positive lymph nodes, the preoperative dose varies with the size and location of the lymph node, fixation, and response to RT. Preoperative doses of 50 Gy are sufficient for mobile lymph nodes 3 to 4 cm in size, but 60 Gy or more is recommended for 5- to 6-cm nodes and for fixed nodes. Lymph nodes measuring 7 to 8 cm are almost always fixed to adjacent structures and often require doses of 70 to 75 Gy for the surgeon to achieve a complete resection. If the lymph node lies behind the plane of the spinal cord, electrons may be used to boost the dose after the primary fields have been reduced off the spinal cord after 45 to 50 Gy.[16] Patients in whom the decision is made to add a neck dissection after completion of RT receive full-dose irradiation to the clinically positive neck nodes because the decision depends on the response to RT.

Another technique commonly used for boosting the dose to the neck mass

after spinal cord tolerance has been reached, and the treatment to the primary lesion has been completed as opposed anterior and posterior fields with wedges. The final dose to the neck node (not to the entire neck) may be 70 to 80 Gy without exceeding the spinal cord tolerance (Fig. 52.9). The anterior and posterior wedge-pair technique is preferable to an appositional electron boost field because high-energy electron beams increase the skin and mucosal dose.

When the cervical lymph nodes are located superficially, sometimes within 1 cm from the skin or fixed to it, treatment with high-energy photon beams (≥ 6 MV) may underdose these nodes. Treatment should be initiated with cobalt-60 or 4-MV x-rays for the initial 45 to 50 Gy, after which a higher-energy photon beam can be used to continue RT of the primary tumor if the neck nodes are clinically negative or if a neck dissection is planned to follow RT (Fig. 52.10). Parallel-opposed 6-MV x-ray beams may adequately treat the upper neck nodes included in the primary treatment fields; however, the supraclavicular nodes in the en face low-neck field may be underdosed with a 6-MV beam in very thin patients. Although electrons alone may be used to treat cervical nodes, it is preferable to combine them with photons because of the high surface dose with high electron energies. Use of both 20-MeV electrons and 17-MV x-rays is compared with treatment by 20-MeV electrons alone in a patient with a lateralized lesion of the oropharynx (Fig. 52.11).[48] The addition of the 17-MV x-rays to the 20-MeV electrons decreases the surface dose while still adequately irradiating the cervical nodes that are within the primary field. The addition of the x-ray beam also produces a dose distribution that is less affected by bone than that from the electron beam alone.

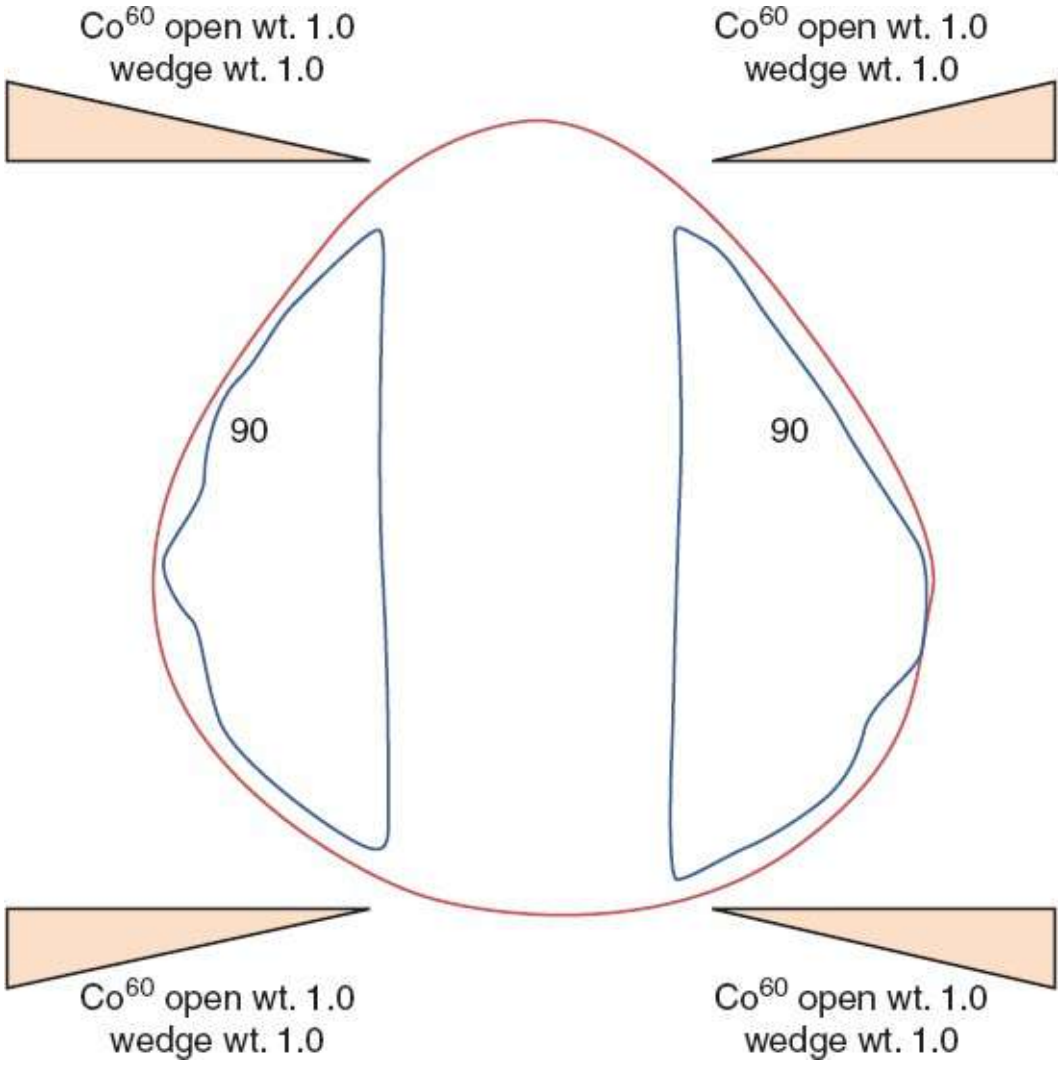

FIGURE 52.9. Dose distribution for anterior and posterior wedge cobalt-60 portals, both fields weighted 1.0.

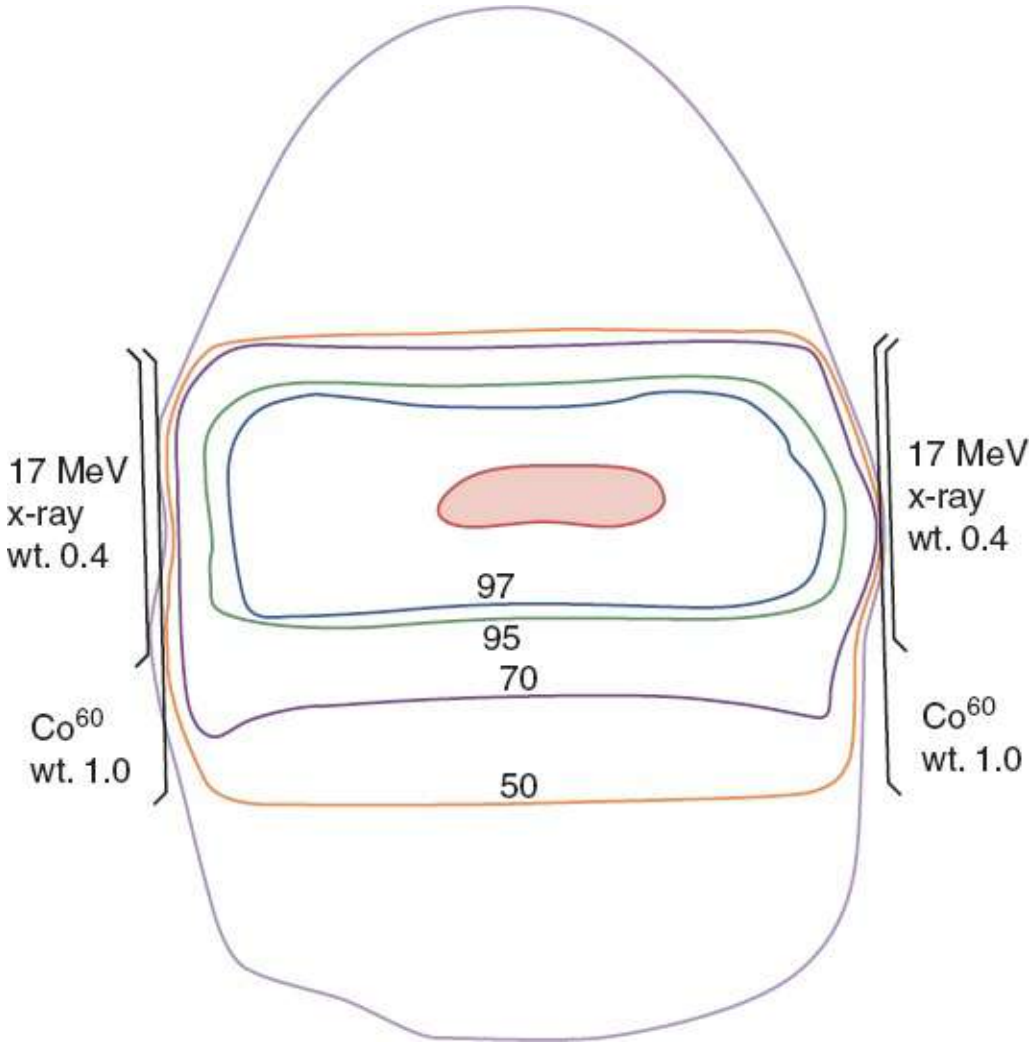

FIGURE 52.10. Dose distribution for parallel-opposed cobalt-60 portals, each weighted 1.0, with reduced 17-MV x-ray portals, each weighted 0.4.

Large lymph nodes may not show much regression during the course of RT but often show significant regression from completion of treatment to the time the patient returns for neck dissection, usually after 4 to 6 weeks. The mass frequently has a thick capsule that facilitates its removal at the time of neck dissection.

Patients with bilateral neck disease require individualized treatment planning jointly by the radiation oncologist and the surgeon. If disease is minimal on one side, RT alone may be used to control the disease on that side of the neck, and a neck dissection may be used on the side with more disease. If major bilateral disease is present, bilateral neck dissection should follow RT.

Complications of Neck Irradiation

The complications of neck irradiation include subcutaneous fibrosis and lymphedema of the larynx and submentum. The latter complications may be minimized by sparing an anterior strip of skin when designing the parallel-opposed lateral portals used to encompass the primary lesion. The probability of complications is directly related to the radiation dose with little, if any, morbidity observed with the doses used for elective radiation therapy of the neck.

Complications of neck treatment in patients who receive RT in conjunction with resection of the primary lesion and a neck dissection are essentially the same as those occurring after neck dissection. However, they occur with an increased incidence depending on the RT dose and extent of surgery.

Treatment of the Neck after Incisional or Excisional Biopsy

Open biopsy of a clinically positive neck node before definitive treatment potentially spills tumor cells along tissue planes that may not be removed with a radical neck dissection. McGuirt and McCabe[49] reported that incisional or excisional biopsy of positive neck nodes before definitive surgery increased the risk of neck failure and worsened the prognosis for patients with squamous cell carcinoma of the head and neck. Parsons et al.[50] reported their experience with incisional or excisional biopsy of positive neck nodes followed by RT as the initial step in the treatment of the patient; these data were updated by Mack et al.[51] After excisional biopsy of a single lymph node, RT alone to the primary lesion and to the neck resulted in a 95% rate of neck control.[51] If residual disease remained in the neck after biopsy, RT followed by neck dissection was more successful than RT alone for controlling neck disease (see Table 52.17).

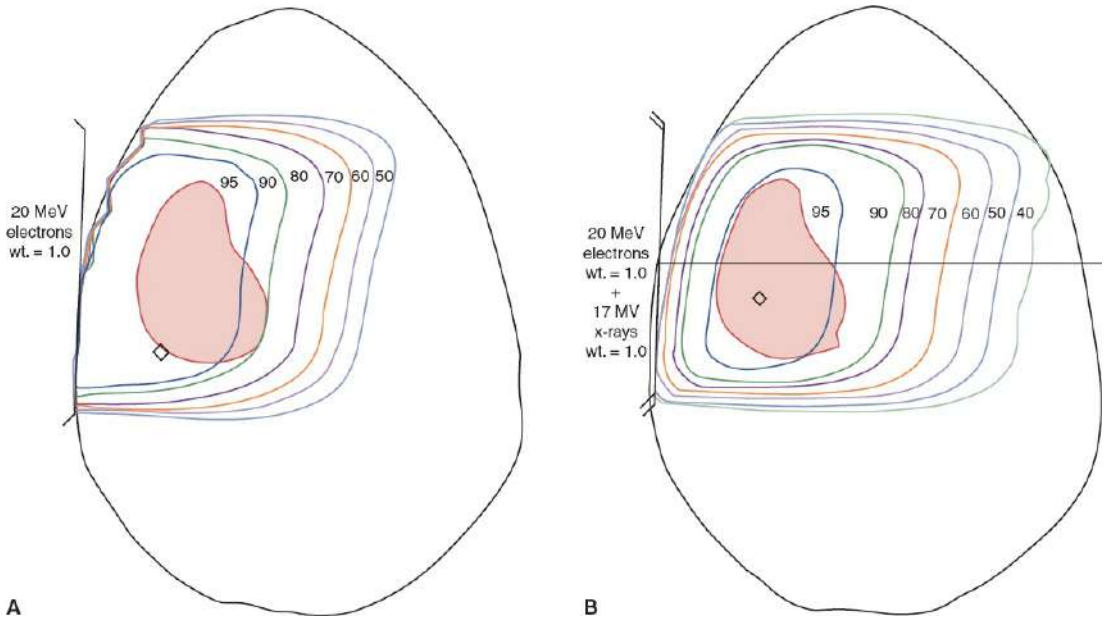

FIGURE 52.11. A: Dose distribution for 20-MeV electrons, field size 8.5 cm by 8.5 cm, SSD 100 cm. **B:** Dose distribution for 20-MeV electrons, field size 8.5 cm by 8.5 cm, and 17-MV x-rays, field size 7 cm by 7 cm, SSD 100 cm for both. The given doses are weighted 1 to 1. The addition of the 17-MV x-ray beam reduces the surface dose and gives a dose distribution that is affected less by bone. (From Bova FJ. Treatment planning for irradiation of head and neck cancer. In: Million RR, Cassisi NJ, eds. Management head of and neck cancer: *a multidisciplinary approach.* 2nd ed. Philadelphia: JB Lippincott, 1994:306. With permission.)

If the primary lesion is to be treated surgically, the patient's neck is typically treated with a completion neck dissection followed by RT. If the primary lesion is to be treated with RT, the patient is treated with RT. If there is no palpable disease remaining in the neck after excisional biopsy of a positive node, the neck may be treated with RT alone. If an incisional biopsy of the node has been performed (leaving gross disease) or if other positive nodes remain after an excisional neck node biopsy, a completion neck dissection is performed with removal of skin over the biopsy site as well as any other structures involved by cancer. RT follows the surgical procedure. The dose of RT preceding a neck dissection depends on the amount of gross disease in the neck and the degree of fixation.[1]

TREATMENT OF THE NECK AFTER SURGERY

Patients treated surgically generally undergo resection of the primary cancer and a unilateral or bilateral neck dissection depending on the location and extent of the primary and presence and extent of positive neck nodes. Indications for

postoperative RT include positive or close (<5 mm) margins, initially positive margins with negative separately submitted margins, extracapsular extension, multiple positive nodes, lymphovascular space invasion, perineural invasion, bone or cartilage invasion, extension into the soft tissues of the neck, invasion of the apex of the pyriform sinus, and subglottic extension of 1 cm or more.[52] The highest risk indications are positive margins and extracapsular extension and require the addition of concomitant cisplatin during the course of postoperative RT. Because of the risk of increased radioresistance due to tumor cells being in potentially hypoxic tissues, the minimum dose is 60 Gy at 2 Gy per once-daily fraction. Areas at higher risk may be boosted to doses in the range of 66 to 70 Gy. Alternatively, patients at particularly high risk may be treated with hyperfractionation at 1.2 Gy per twice-daily fraction to doses up to 74.4 Gy or 70 Gy in 35 fractions over 6 weeks treating twice daily once weekly for the last 5 weeks of RT. Consideration may be given to treating the primary site alone if the neck nodes are pathologically negative. Postoperative RT is not employed for the indication to electively treat the clinically negative neck in lieu of a neck dissection. Patients with a clinically negative neck who will require postoperative RT may forego a neck dissection and the neck irradiated in conjunction with the primary site.

RESULTS OF TREATMENT

Clinically Negative Nodes

Elective neck dissection and elective neck irradiation are equally effective in controlling subclinical disease. The decision whether to use surgery or RT for the purpose of electively treating the neck nodes depends on the method used to treat the primary lesion. Patients with a relatively early primary lesion and clinically negative nodes should be treated with one modality. Patients whose primary lesion is treated surgically may undergo an elective neck dissection, and those whose primary lesion is to be treated with RT should be considered for elective neck irradiation. Patients who develop a local recurrence or a metachronous second primary after RT for an SCC with a cN0 neck in whom the neck has been irradiated may be treated with surgery to the primary site alone and the neck observed because the likelihood of subclinical disease in the cervical lymphatics is <10%.[53,54]

TABLE 52.9 CONTROL OF DISEASE IN THE CLINICALLY

NEGATIVE NECK WITH ELECTIVE NECK IRRADIATION (NUMBER CONTROLLED/NUMBER TREATED)

Risk Group	No ENI (%)	Partial ENI (%)	Total ENI (%)
I (<20%)	13/15 (87)	16/17 (94)	1/1 (100)
II (20%–30%)	6/9 (67)	34/38 (89)	10/11 (91)
III (>30%)	3/4 (75)	32/33 (97)	61/62 (98)

ENI, elective neck irradiation.
Reprinted from Mendenhall WM, Million RR. Elective neck irradiation for squamous cell carcinoma of the head and neck: analysis of time–dose factors and causes of failure. *Int J Radiat Oncol Biol Phys* 1986;12(5):741–746. Copyright © 1986 Elsevier. With permission.

The results of elective neck irradiation at the University of Florida for patients with squamous cell carcinoma of the head and neck in whom the primary lesion was controlled are shown in Table 52.9.[4,55] Patients were divided into three risk categories based on the estimated risk of subclinical disease in the neck as follows: group I, low risk (<20% likelihood of occult disease); group II, moderate risk (20% to 30% risk of occult disease); and group III, high risk (more than 30% likelihood of occult disease). There were 6 neck failures (21%) in 28 patients who did not receive elective neck irradiation and 8 neck failures (5%) in 162 patients who received elective neck irradiation. Of the eight failures in patients receiving elective neck irradiation, two occurred within the irradiation fields, one at the field margin, and five in out-of-field areas. No correlation was found between the rate of tumor control in the first-echelon lymph nodes and the irradiation dose for doses ranging from 40 to 55 Gy or greater.[4] Only one failure occurred in the first-echelon lymph nodes, and this was after 48 Gy in 25 fractions using continuous-course irradiation.[4] The low neck, defined as that part of the neck located below the treatment portals used to treat the primary lesion, received either 50 Gy in 25 fractions or 40.5 Gy in 15 fractions, specified at D_{max} (0.5 cm depth). Both dose fractionation protocols were equally effective in sterilizing subclinical disease in the low neck.[56] Elective neck irradiation is equally efficacious for squamous cell carcinoma arising from various head and neck primary sites.

In patients in whom primary failure occurs in addition to failure in the clinically negative nodes, the chances of surgical salvage are poor. In patients in whom the primary lesion is controlled and in whom failure develops in the initially negative neck, the chances of salvage with neck dissection are approximately 60%.

Although elective neck irradiation significantly reduces the risk of neck

recurrence, there is no definite evidence that it improves survival. It would be necessary to conduct a large randomized trial to detect a survival difference, if one exists. Another problem is that the first-echelon lymph nodes are often included in the treatment portals used to treat the primary lesion so that it is often impossible to avoid at least partial elective neck irradiation. Therefore, such a trial would have to be restricted to primary sites where the portals would have to be enlarged to electively irradiate the neck or to patients treated with elective neck dissection rather than elective neck irradiation. Vandenbrouck et al.[57] and Fakih et al.[58] have conducted randomized trials comparing elective neck dissection with no elective neck treatment for patients with oral cavity carcinoma and oral tongue cancer, respectively. No survival advantage was noted for patients undergoing elective neck dissection in either study. However, because of the small number of patients in both trials, it is likely that even if a survival difference existed, it would have been missed. Subsequently, a randomized trial was conducted at the Tata Memorial Hospital (Mumbai) where 596 patients with T1-T2 N0 SCCs of the oral cavity were randomized to resection of the primary and observation of the neck or to resection of the primary and elective neck dissection. Those in the latter group had significantly improved overall survival at 3 years (80% vs. 68%; $P = .01$).[59]

Dearnaley et al.[60] reported on a series of 148 patients treated with an interstitial implant, alone or combined with external beam RT, for cancer of the tongue or floor of the mouth. Of 131 patients with negative neck nodes at diagnosis, 59 (45%) received elective neck irradiation to a dose of 40 Gy or greater. A multivariate analysis showed that elective neck irradiation significantly improved survival and reduced the risk of dying of cancer. Piedbois et al.[61] reported a series of 233 patients with T1-2N0 carcinoma of the oral cavity treated with interstitial iridium brachytherapy: 123 patients received no elective neck treatment, and 110 patients underwent elective an neck dissection. Patients who received an elective neck dissection tended to have more advanced primary lesions. Although the ultimate rates of neck control were similar, a multivariate analysis showed that elective neck dissection was significantly associated with improved survival.

Clinically Positive Nodes

The incidence of treatment failure in the neck by N stage and treatment category has been reported by the MD Anderson Cancer Center (Table 52.10) and the University of Florida (Table 52.11 and Fig. 52.12).[63,64] In patients in whom the

neck is treated with combined modalities, RT precedes surgery when the primary site is to be treated with irradiation or when the node is incompletely resectable. Surgery precedes RT when the primary site is to be treated operatively and the nodes are resectable.

When the initial treatment is surgery, a neck dissection is sufficient treatment for patients with a single positive lymph node <3 cm unless there is extracapsular spread of disease. RT may be added for control of subclinical disease in the contralateral side of the neck (Table 52.12).[63] The presence of multiple positive nodes in the surgical specimen is an indication for postoperative RT of the neck, especially when positive nodes are found at more than one level.[6,65,66]

Olsen et al.[67] reported a series of 284 patients who underwent neck dissection at the Mayo Clinic for pathologic stages N1 and N2 squamous cell carcinomas of the head and neck; no patient received adjuvant therapy. Neck recurrence–free survival rates at 5 years were as follows: N1, 76%; N2, 60%; and overall, 69%. A multivariate analysis showed that four or more positive nodes (P = .005), invasion of lymphatic or vascular spaces (P = .003), invasion of soft tissue (P = .0008), and a desmoplastic stromal pattern (P = .0001) were significantly associated with an increased risk of recurrence in the neck.[67]

The postoperative dose prescribed is usually 60 Gy in 30 fractions to 65 Gy in 35 fractions over 6 to 7 weeks for patients with negative margins; higher doses may be prescribed when residual disease is present in the neck.[65,68,69] If RT is to be added after surgery, it is usually initiated within 4 to 6 weeks after the operation, although it has been reported that a delay to 10 weeks is not associated with an increased risk of neck failure.[65]

The rate of control for neck nodes treated with RT alone as a function of node size, treatment scheme, and dose is shown in Table 52.13. RT alone is sufficient for patients with N1 (up to 2 cm) disease as long as the fraction size (2 Gy) and the total dose are sufficient.[40] RT followed by neck dissection has provided better rates of disease control than RT alone for patients with more advanced neck disease. The rate of neck disease control for patients treated with twice-daily RT, alone or followed by neck dissection, is shown in Figure 52.12 and shows a significant improvement in the control rates when neck dissection was added in selected cases.[70,71] As shown in a multivariate analysis by Ellis et al.,[72] the addition of neck dissection after RT is independently related to a significantly decreased risk of disease-specific death. At least 50 Gy should be given preoperatively to the lymph nodes, although doses vary according to the

size and degree of fixation of the lymph node. For example, large, fixed lymph nodes require 70 to 75 Gy of preoperative RT (Table 52.14). The likelihood of disease control in each side of the neck treated with irradiation and neck dissection is decreased when the node is fixed before treatment or when residual tumor is found in the pathologic specimen (Tables 52.15 and 52.16).[16] No difference is seen in the rate of control as a function of the interval between RT and neck dissection when comparing patients who have surgery within 6 weeks with those who have neck dissection more than 6 weeks after RT.[16] If a local recurrence occurs, prior combined treatment of the neck does not diminish the chance of successful surgical salvage of the patient.[73] The likelihood of disease control at the primary site was not found to be related to neck stage at diagnosis in patients treated with RT alone or followed by neck dissection at the University of Florida[74]; this finding is different from what others have reported.[75]

Results after Incisional or Excisional Biopsy

Patients who have undergone an incisional or excisional biopsy of a metastatic lymph node before referral do not have an increased risk of neck failure or a decreased cure rate if RT is the next step in treatment.[50] The likelihood of control and the cure rate are probably diminished if an operation without prior RT follows incisional or excisional biopsy of a metastatic neck node because of the risk that the biopsy procedure disseminated tumor cells into tissues not removed by neck dissection.[49]

Ellis et al.[72] reported on 508 patients with 660 positive heminecks treated at the University of Florida with RT alone or followed by a planned neck dissection. Pretreatment node biopsy did not influence outcome when RT was the next step in treatment (Table 52.17).[72] The results of the forward stepwise log-rank tests of prognostic factors for predicting time to recurrence are shown in Table 52.18.[72]

Zenga et al.[76] reported on 45 patients from 1998 to 2012 who underwent open biopsy for HPV-positive oropharyngeal cancer. All patients underwent definitive surgical treatment. Disease-specific survival was 98% versus 99% in a control group who did not undergo an open biopsy. Only 7% of the open biopsy group were found to have dermal metastases in the excised skin. It is known that hypoxic tissues, such as a scar, are increasingly resistant to RT. Thus, excision of the biopsied area along with a neck dissection will improve the efficacy of adjuvant RT. This study questions the idea that previous open biopsy adversely affects patient outcomes in this subset of patients. Neck dissection is an effective primary treatment for previously violated neck nodes. However, an adjuvant dose of RT with 60 to 70 Gy is needed to minimize recurrence rates.

CERVICAL LYMPH NODE METASTASIS WITH UNKNOWN PRIMARY TUMOR

In a small percentage of patients with enlarged cervical lymph nodes, the primary lesion cannot be found, even after extensive evaluation.[77–79] Patients with enlarged lymph nodes in the upper neck have a good prognosis when treated aggressively, compared with those with enlarged lymph nodes in the low internal jugular chain or supraclavicular fossa. The latter patients are more likely to have primary lesions located below the clavicles, which carry a much worse

prognosis. The majority of patients have either squamous cell or poorly differentiated carcinoma. Those with adenocarcinoma almost always have a primary lesion below the clavicles, although if the nodes are located in the upper neck, one must exclude a salivary gland, thyroid, or parathyroid primary tumor. This section deals with patients presenting with squamous cell or poorly differentiated carcinoma in the upper or middle neck.

TABLE 52.18 PROGNOSTIC FACTORS, IN ORDER OF THEIR IMPORTANCE, FOR PREDICTING THE TIME TO OCCURRENCE OF VARIOUS EVENTS

Event	Rank Order	Factor	Level of Significance
Recurrence in the neck (*n* = 660 heminecks)	1	Increasing N stage	*P* = .0001
	2	Treatment of the neck of with RT alone	*P* = .0001
	3	Fixed nodes	*P* = .0001
	4	T-stage[a]	*P* = .0350
Death with disease present (*n* = 508 patients)	1	Recurrence above clavicles	*P* = .0001
	2	Increasing N stage	*P* = .0003
	3	Fixed nodes	*P* = .0053
	4	Treatment of with neck RT alone	*P* = .0121
For occurrence of distant metastasis (*n* = 508 patients)	1	Recurrence above clavicles	*P* = .0001
	2	Increasing N stage	*P* = .0003
	3	Fixed nodes	*P* = .0704
	4	Nodes below the thyroid notch	*P* = .1023

[a]This factor is thought to be correlated with the censoring pattern.

Patients should be evaluated with a thorough physical examination including careful evaluation of the head and neck. A needle biopsy of the lymph node should be performed. After chest roentgenography, a CT or MRI of the head and neck is obtained to detect an unknown primary lesion arising from the mucosa of

the head and neck. It is unclear whether FDG-PET scans may identify primary lesions that would not otherwise be identifiable.[80] The available data suggest that some patients will benefit from these studies. Direct laryngoscopy and examination under anesthesia are performed with directed biopsies of the nasopharynx, tonsils, base of the tongue, and pyriform sinuses and of any abnormalities noted on CT or MRI or suspicious mucosal lesions noted at laryngoscopy. Patients with adequate lymphoid tissue in their tonsillar fossae should undergo at least an ipsilateral tonsillectomy. The likelihood of bilateral tonsillar carcinomas is probably <5% and may prompt some surgeons to perform bilateral tonsillectomy. If a contralateral tonsillar malignancy is missed and the patient is treated with an ipsilateral field arrangement for an ipsilateral tonsillar cancer, salvage treatment would probably be compromised. The diagnostic evaluation for the patient with cervical metastasis from an unknown head and neck primary lesion is summarized in Table 52.19. The results of a diagnostic evaluation for an unknown primary site in 236 patients at the University of Florida are depicted in Table 52.20.[81] Overall, 132 primary sites were discovered in 126 patients (53%) and were most often located in the oropharynx: tonsillar fossa, 59 (45%); base of tongue, 58 (44%); pyriform sinus, 10 (8%); pharyngeal wall, 3 (2%); and supraglottic larynx, 1 (1%).[81]

Some patients may be cured with treatment directed only to the involved area of the neck[82]; however, the authors usually irradiate the nasopharynx and oropharynx as well as both sides of the neck. The hypopharynx and larynx were irradiated as well until 1997 when it was decided to eliminate them because they are rarely the site of the primary cancer and because irradiation of these sites significantly increases the morbidity of treatment. It is not necessary to irradiate the oral cavity unless the patient has submandibular adenopathy, in which case the authors either do a neck dissection and observe the patient or irradiate the oral cavity and oropharynx and not the nasopharynx. Patients are treated with parallel-opposed fields at 1.8 Gy per fraction to a midline dose of 64.8 Gy with reduction off the spinal cord at 45-Gy tumor dose (Fig. 52.13). An alternative is to use IMRT to spare the contralateral parotid gland in patients with ipsilateral neck nodes. The lower neck is treated through a separate en face anterior field. IMRT may be used if patients have unilateral neck disease to reduce the dose to the contralateral parotid.

TABLE 52.19 DIAGNOSTIC WORKUP FOR CERVICAL LYMPH NODE METASTASES: UNKNOWN PRIMARY TUMOR

General
History
Physical examination
Careful examination of the neck and supraclavicular regions
Examination of the oral cavity, pharynx, and larynx (indirect laryngectomy)

Radiographic Studies
Chest roentgenogram
Computed tomography or magnetic imaging resonance scans of the head and neck (special attention to the nasopharynx, pharynx, and larynx)

Laboratory Studies
Complete cell blood count
Blood chemistry profile

Direct and Laryngoscopy-Directed Biopsies
Nasopharynx, tonsils, base of tongue, both pyriform and sinuses, any suspicious abnormal or mucosal areas
Fine needle aspirate core needle or biopsy of the cervical node
Tonsillectomy

Erkal et al.[78] reported on 126 patients treated with curative intent at the University of Florida between 1964 and 1997 with follow-up for at least 2 years. RT was delivered to head and neck mucosal sites and both sides of the neck in 119 patients and to the neck alone in 7 patients. Twelve patients (10%) developed squamous cell carcinoma in a head and neck mucosal site at 0.5 to 10.9 years (median, 1.8 years) after treatment. The 5-year results were as follows: head and neck mucosal failure, 13%; neck node control, 78%; distant metastases, 14%; absolute survival, 47%; and cause-specific survival, 67%. Wallace et al.[8] reported a combined series of 179 patients treated at the University of Florida (139 patients) and the University of Wisconsin (40 patients). The 5-year mucosal control rate was 92%; the head and neck mucosa was irradiated in 174 patients (97%). For the subset of 28 patients where the mucosal RT was limited to the nasopharynx and oropharynx, the 5-year mucosal control rate was 100%. Barker et al.[77] subsequently reported on 17 patients treated with the larynx-sparing technique described above between 1997 and 2002 at the authors' institution; none of these patients developed a head and neck mucosal squamous cell carcinoma after receiving RT.

Colletier et al.[9] reported on 136 patients treated with neck dissection followed by RT to head and neck mucosal sites and bilateral lymph nodes. Six percent of patients developed carcinomas in head and neck mucosal sites within RT portals, and 4% of patients developed carcinomas in head and neck mucosal sites outside the RT portals. The absolute survival rate at 5 years was 60%. The authors recommended RT to head and neck mucosal sites. Reddy and Marks[10] reported on 16 patients with RT to ipsilateral lymph nodes and 36 patients with RT to head and neck mucosal sites and bilateral lymph nodes. The authors concluded that RT reduced the rate of developing carcinomas in head and neck mucosal sites. For patients with no RT to head and neck mucosal sites, the rate of developing carcinomas in head and neck mucosal sites was 46%, and the absolute survival rate at 5 years was 47%. For patients treated with RT to head and neck mucosal sites, the rates were 8% and 53%, respectively. Grau et al.[11] reported on 273 patients treated with curative intent at five cancer centers in Denmark between 1975 and 1995 with surgery alone (23 patients), RT to the ipsilateral neck alone or combined with surgery (26 patients), and RT to the neck and head and neck mucosa alone or combined with surgery (224 patients). The ipsilateral oropharynx unintentionally received some RT in patients treated to the ipsilateral neck alone, depending on the treatment technique. The 5-year rates of freedom from failure in the head and neck mucosa were as follows: surgery alone, 45%; RT with or without surgery to the ipsilateral neck, 77%; and RT to the head and neck mucosa with or without surgery, 87%. The oropharynx, particularly the base of tongue, was the most common location of mucosal site failure.

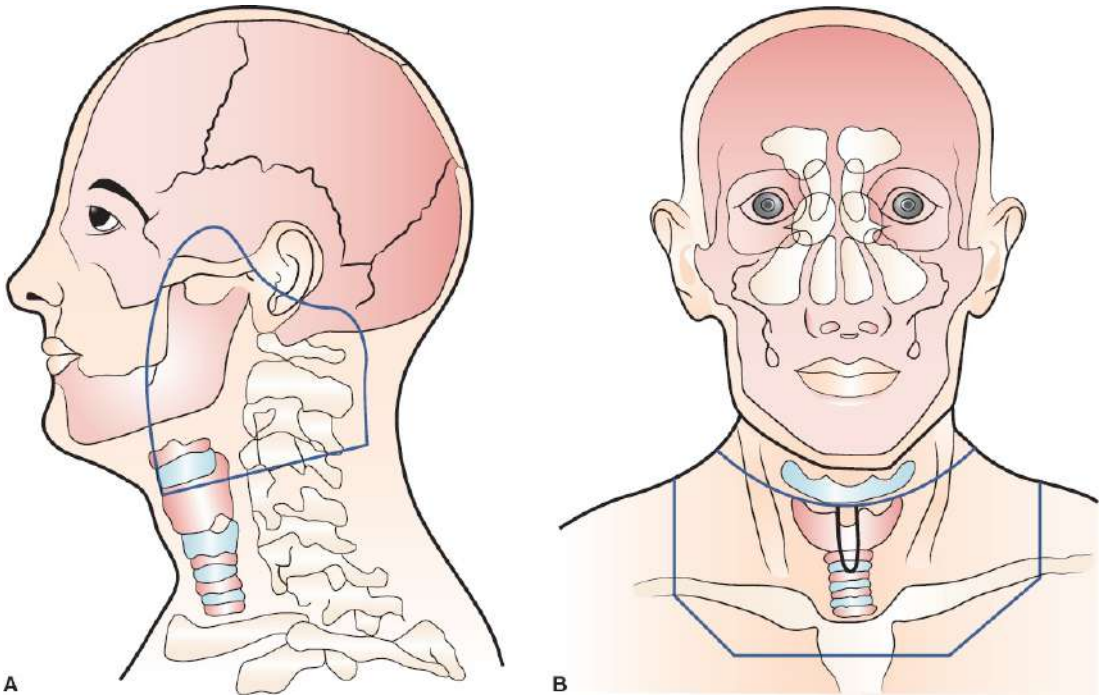

FIGURE 52.13. Conventional radiation therapy portals used starting from 1997 to treat head and neck mucosal sites and upper cervical lymph nodes **(A)** and lower cervical and supraclavicular lymph nodes **(B)**. The inferior border for lateral portals is placed at the superior anterior border of the thyroid cartilage, shielding the hypopharynx and larynx. (Reprinted from Erkal HS, Mendenhall WM, Amdur RJ, et al. Squamous cell carcinomas metastatic to cervical lymph nodes from an unknown head-and-neck mucosal site treated with radiation therapy alone or in combination with neck dissection. *Int J Radiat Oncol Biol Phys* 2001;50[1]:55–63. Copyright © 2001 Elsevier. With permission.)

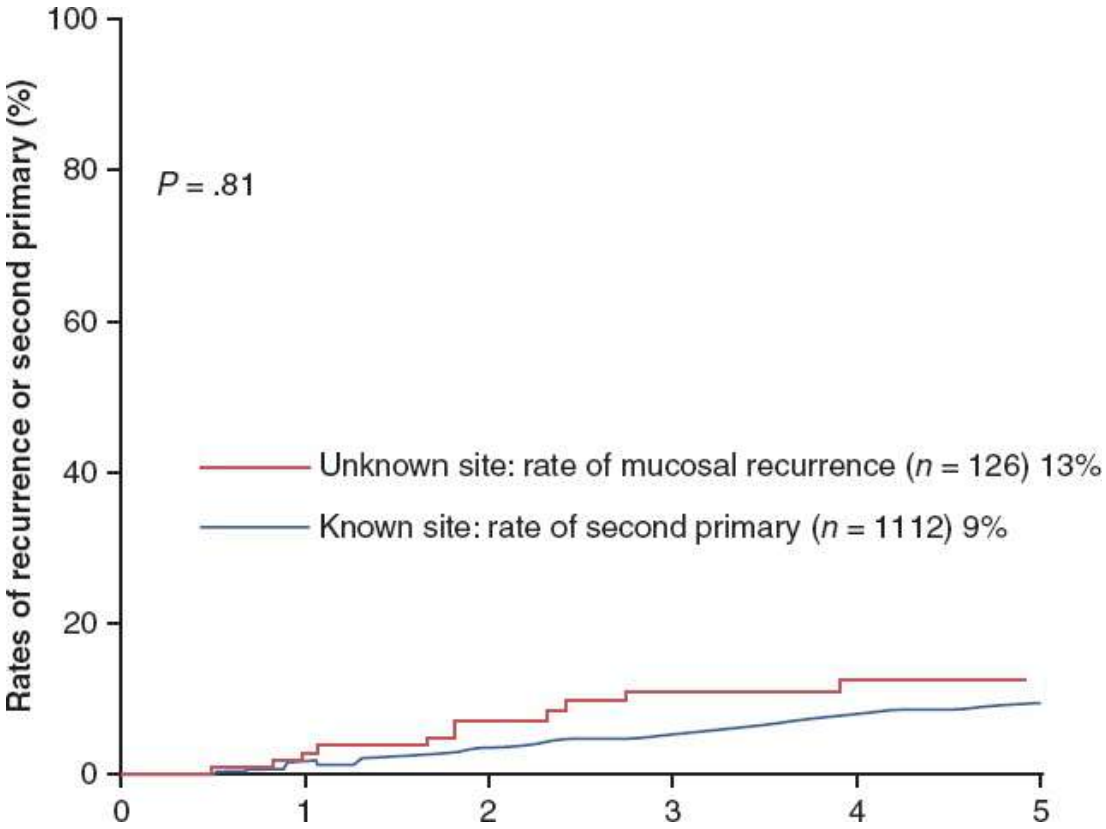

FIGURE 52.14. The rate of developing carcinomas in head and neck mucosal sites for patients treated for carcinomas with an unknown head and neck mucosal site compared to the rate of developing metachronous carcinomas in head and neck mucosal sites for patients treated for carcinomas with a known head and neck mucosal site. (Reprinted from Erkal HS, Mendenhall WM, Amdur RJ, et al. Squamous cell carcinomas metastatic to cervical lymph nodes from an unknown head-and-neck mucosal site treated with radiation therapy alone or in combination with neck dissection. *Int J Radiat Oncol Biol Phys* 2001;50[1]:55–63. Copyright © 2001 Elsevier. With permission.)

The incidence of subsequent mucosal primary lesions was compared by Erkal et al.[11,83] for 1,112 patients with a known primary site (oropharynx, hypopharynx, and supraglottis) and a series of 126 patients treated for an unknown primary site at the University of Florida. The incidence of a subsequent mucosal head and neck cancer was similar for both groups, suggesting either that mucosal irradiation significantly reduced the risk of primary site failure or that patients with unknown primary sites have a much lower risk of a second primary head and neck cancer developing subsequently (Fig. 52.14).[78]

A subset of patients presenting with squamous cell carcinoma metastatic to the neck nodes from an unknown head and neck primary site are treated with palliative intent because of poor medical condition, extensive nodal

involvement, or distant metastases at presentation. Treatment of the neck depends on the extent and location of the adenopathy. Forty of 166 patients (24%) were treated palliatively at the University of Florida between 1964 and 1997.[62] Treatment was delivered to the neck alone to a dose of 30 Gy in 10 fractions over 2 weeks or 20 Gy in 2 fractions with a 1-week interfraction interval. The nodal response rate was 65% and the symptomatic response rate was 57% at 1 year. The 1-year absolute and cause-specific survival rates were 25%.

The main complications of RT for patients treated for an unknown head and neck primary tumor are xerostomia, dysphagia, and neck fibrosis. The complications of treatment of the neck, which have been discussed previously, depend on whether chemotherapy and/or neck dissection is added.[62]

An alternative approach to carcinoma of unknown primary of the neck involves transoral surgery: transoral robotic surgery (TORS) or transoral laser microsurgery (TLM). The TORS approach involves using the surgical robot to access difficult-to-reach areas of the oropharynx to take more thorough directed biopsies. With the robot, the surgeon performs bilateral tonsillectomy/extended tonsillectomy as well as lingual tonsillectomy/base-of-tongue shaves. Moreover, if a primary is found on inspection or frozen section, the surgeon may perform a resection at the same time. Typically, a selective neck dissection (levels II to IV) is performed in conjunctions with the TORS procedure. Durmus et al.[84] reported on the initial experience of this method at the Ohio State University. In 77% of patients, the primary site was identified; 76% tumors were found in the palatine tonsils and 24% in the base of tongue. 77% of these patients underwent complete resection with negative margins. Adjuvant treatment was delivered as indicated with 59% of patients able to avoid chemotherapy. Other studies have demonstrated similar results with the primary being found in 72% to 90% of cases versus 25% to 57% of cases using traditional biopsy techniques.[85] Kang et al. summarized the TORS approach for carcinoma of unknown primary (Fig. 52.15).

Another transoral technique, TLM, utilizes a laser instead of the electrocautery of the TORS approach. Graboyes et al.[86] reported the largest series of carcinoma of unknown primary worked up and treated with TLM. Eighty-nine percent of patients had the primary site identified. The approach also involves palatine tonsillectomy and base-of-tongue resections as well as selective neck dissection. Twenty-six percent of patients who were treated with the TLM approach managed to avoid RT altogether.

There are several advantages to identifying the primary site in patients presenting with carcinoma of unknown primary of the neck. When the primary site is elucidated, RT can be tailored to a smaller field and lower dose, thus reducing the morbidity of RT. Some have contended that conventional RT for carcinoma of unknown primary when the primary site is not found can lead to grade 3 dysphagia in 50% of patients.[87] This has not been our experience when the targeted mucosal sites are limited to the oropharynx.[8,77] If the primary site is completely resected, adjuvant treatment may be avoided or deintensified. However, because the majority of these patients have an oropharyngeal primary, it is likely that the human papillomavirus (HPV)-positive nonsmokers could safely have their treatment deintensified without respecting the primary site. Functional outcomes for this approach are excellent with a 4.5% gastrostomy rate at 1 year and return of quality of life to pretreatment baseline or better.[85] Perhaps even more significant is the potential survival advantage provided when the primary site is identified and treated appropriately.[86,88–90]

CHAPTER 53

Thyroid Cancer

Robert J. Amdur and Roi Dagan

BASIC THYROID ANATOMY AND PHYSIOLOGY

Gross Anatomy

The thyroid gland is located in the central anterior neck at the cervical–thoracic junction (Fig. 53.1). The bulk of the gland is located immediately anterior and inferior to the thyroid cartilage. It has two lateral lobes connected by a central isthmus. Approximately 50% of individuals have a pyramidal lobe that extends superiorly from the central aspect of the gland, which is a remnant of the gland's embryologic origin, the thyroglossal duct. The average adult thyroid gland measures approximately 5 × 5 cm and weighs 10 to 20 g.

The location of the gland in the central neck and its relation to critical structures explain the presenting symptoms of advanced neoplastic processes arising from the thyroid as well as potential complications of thyroid surgery and radiotherapy (Fig. 53.2). The lateral lobes extend superiorly to the level of the midthyroid cartilage overlying the larynx and inferiorly to the sixth tracheal ring. The gland wraps around 75% of the tracheal circumference, posteriorly encroaching on the esophagus. The lateral extent is just medial to the common carotid arteries. The recurrent laryngeal nerves, sympathetic trunks, vagus, and phrenic nerves are all found immediately posterior to the gland, and the gland is anteriorly bound by the strap muscles. Parathyroid glands are located posterior to the thyroid gland and vary in location and number.

Vasculature and Lymphatics

The arterial blood supply to the thyroid gland is provided by the paired superior thyroid arteries (branches of the external carotid arteries) and inferior thyroid arteries (branches of the thyrocervical trunk from the subclavian arteries). Venous blood drains via the paired superior and middle thyroid veins to the internal jugular veins and from the inferior thyroid veins to the subclavian and

innominate veins. There is a dense lymphatic network draining the gland in multiple directions, and bilateral involvement of lymph node metastases is common. According to the American Joint Committee on Cancer's (AJCC) eighth edition of the *AJCC Cancer Staging Manual*, the first-echelon nodes for thyroid cancer metastases are located in level 6 (the central or "visceral" compartment) between the hyoid bone and the thoracic inlet.[1] Specifically, these are the paralaryngeal, paratracheal, and prelaryngeal (delphian) nodes. Second-echelon nodal spread is to the mid- and lower cervical nodes (levels 3 and 4), supraclavicular nodes, upper mediastinal nodes (level 7) and, to a lesser extent, the upper cervical nodes (level 2). Level 1 (submental and submandibular) lymph nodes are rarely involved.

Spread of thyroid cancer to the retropharyngeal nodes is unusual, but we see positive retropharyngeal nodes in patients with many positive nodes in the lateral cervical stations and with advanced-stage disease at the primary site. With thyroid cancer, the positive retropharyngeal nodes are often in the more inferior portion of the station (Fig. 53.3).

Microscopic Anatomy

Microscopically, the normal thyroid gland consists of numerous lobules comprising individual follicles forming the structural and functional unit of the gland (Fig. 53.4). The supporting stoma and vasculature are intertwined around the follicles. Each follicle consists of a single layer of cuboidal surface epithelium comprising thyroid follicular cells surrounding a central lumen-containing colloid, a substance rich in thyroglobulin (Tg). Separate from the follicular epithelium are the parafollicular cells, or C cells, which are neural crest–derived cells containing granules of calcitonin. The thyroid gland is incompletely surrounded by a connective tissue capsule.

Physiology

The primary physiologic role of the thyroid gland is the production of thyroid hormone, which plays an important role in metabolic homeostasis. A secondary role is the production of calcitonin, a hormone involved in calcium homeostasis. The follicular cells of the thyroid gland synthesize and secrete Tg and thyroid hormone in two biologically active forms, thyroxine (3,5,3′,5′ iodothyronine or T_4) and tri-iodothyronine (3,5,3′ iodothyronine or T_3). It is useful to consider T_4 as the storage and transport form of thyroid hormone and T_3 as the metabolically active form. Most circulating thyroid hormone is bound to thyroxine-binding

globulin. In peripheral tissues, where thyroid hormone executes its endocrine function, T_4 is rapidly converted to the more active form T_3 by the action of T_4 monodeiodinase. T_3 is transported to the nucleus where it binds to specific nuclear receptors and interacts with regulatory genes, influencing their expression. The gene products ultimately increase the cell's basal metabolic rate, protein synthesis, catecholamine effects, and growth of long bones and play an essential role in metabolism of proteins, fats, and carbohydrates. Thyroid hormone exerts its endocrine function on virtually all cells in the body.

Iodine is a critical component of thyroid hormone and is essential for thyroid function. The recommended daily intake is 150 μg, and at least 50 μg of daily intake is necessary to prevent deficiency, resulting in a goiter. The follicular cells of the thyroid gland possess a unique ability to actively uptake and concentrate iodine. The sodium iodine symporter (NaIS) actively transports sodium and iodine against an electrochemical gradient across the cell membrane in an energy-dependent fashion. This transmembrane protein is stimulated by thyroid-stimulating hormone (TSH or thyrotropin), which is synthesized in the anterior pituitary. Functional NaIS is present on malignant follicular cells seen in multiple variants of differentiated thyroid cancer (DTC). The unique ability to concentrate iodine within these malignant cells makes radioactive iodine, such as iodine-131 (I-131), a potent targeted therapy. The central role of TSH in driving the internalization of iodine within follicular thyroid cells is exploited in preparation for I-131. To increase the efficacy of I-131 therapy, T_4 deprivation, a low-iodine diet, and administration of recombinant human TSH (rhTSH) can be used to increase the effects of TSH on follicular thyroid cells (see the section on preparing patients for I-131). NaIS is also present in the parotid glands, breast tissues, gastric mucosa, and nasolacrimal ducts, placing them at risk for injury from I-131 therapy.

Upon entering the follicular cells, iodine is transported across the apical membrane and oxidized to a form that binds to tyrosyl residues of Tg, a large (660 kDa) glycoprotein synthesized by the follicular cells. Iodinated Tg becomes the main component of the intraluminal colloid stores of the thyroid follicles. T_3 and T_4 are synthesized by the coupling of iodinated tyrosine. They remain attached to the Tg until leaving the gland. TSH stimulation results in endocytosis of colloid droplets from the lumen into the follicular cells where it is hydrolyzed and releases Tg, T_4, and, to lesser degree, T_3 into the circulation. Malignant differentiated follicular cells retain this function. Thus, serum Tg becomes a

unique tumor marker after thyroidectomy and thyroid remnant ablation.

Basic thyroid anatomy. In: Amdur RJ, Mazzaferri EL, eds. *Essentials of thyroid cancer management*. New York: Springer, 2005:3–6. Copyright © 2005 Springer Science+Business Media, Inc.)

A feedback loop between the thyroid, pituitary, and hypothalamus regulates thyroid hormone synthesis and secretion. Thyrotropin-releasing hormone (TRH) is synthesized in the hypothalamus, and its primary function is to increase the secretion of TSH in the pituitary. Both T_3 and T_4 in turn inhibit TRH release and TSH secretion.

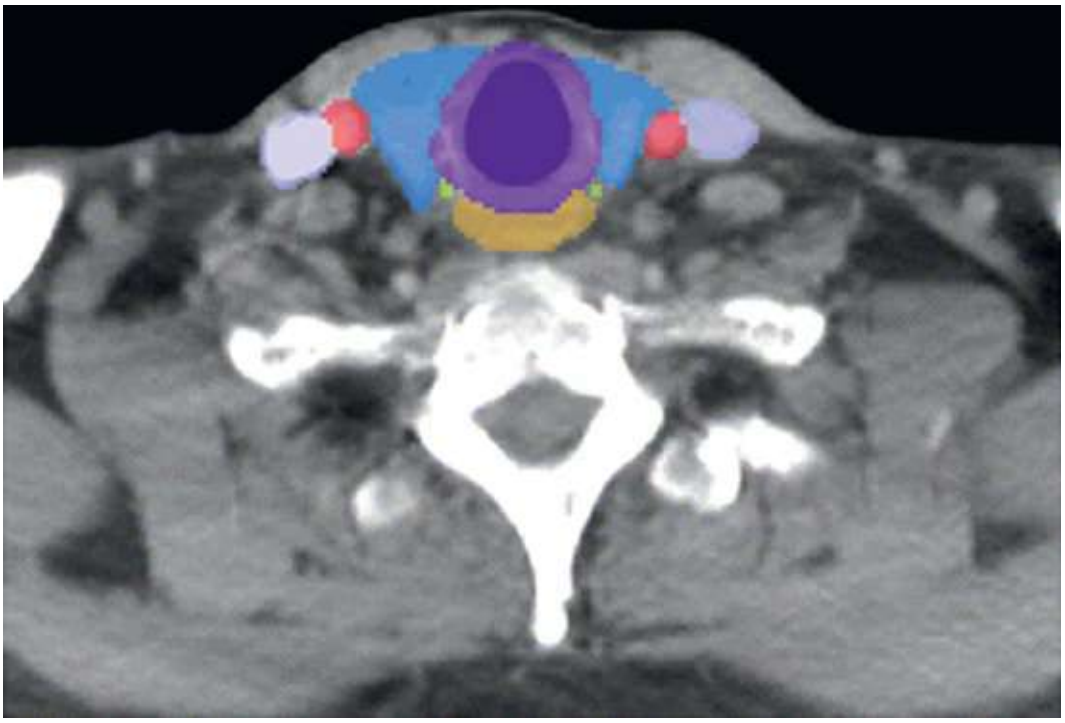

FIGURE 53.2. Anatomy of the thyroid gland. Contrast-enhanced axial CT slice at the level of the bottom of the cricoid cartilage (*purple*) showing the position of the thyroid gland (*blue*) relative to the esophagus (*orange*), carotid arteries (*red*), jugular vein (*lavender*), and the approximate position of the recurrent laryngeal nerves (*yellow-green*).

cords in a patient with papillary thyroid cancer. The *arrow* points to a retropharyngeal node. Metastatic cancer in this node explains the avid enhancement from iodinated contrast.

CLASSIFICATIONS OF THYROID CANCER

Correct pathologic classification of thyroid carcinoma is fundamental to the appropriate clinical management of the malignancy. A system of classification is shown in Table 53.1 and discussed below. The cell of origin, cytologic features, and growth morphology determine the pathologic classification. All carcinomas of the thyroid gland are derived from the follicular epithelium, except medullary thyroid carcinoma (MTC), which is derived from the parafollicular C cells. Capsular invasion is important in the pathologic diagnosis of certain thyroid carcinomas. The diagnosis of papillary thyroid carcinoma (PTC) is entirely predicated on the presence of diagnostic nuclear features and does not require invasive growth, whereas follicular carcinoma (FC) requires the presence of capsular or vascular invasion.[2] Other rarely encountered malignant neoplasms of the thyroid gland include thyroid lymphoma and sarcomas. These two entities will not be discussed in this chapter and are better evaluated and managed under paradigms detailed in the chapters on lymphoma and sarcoma.

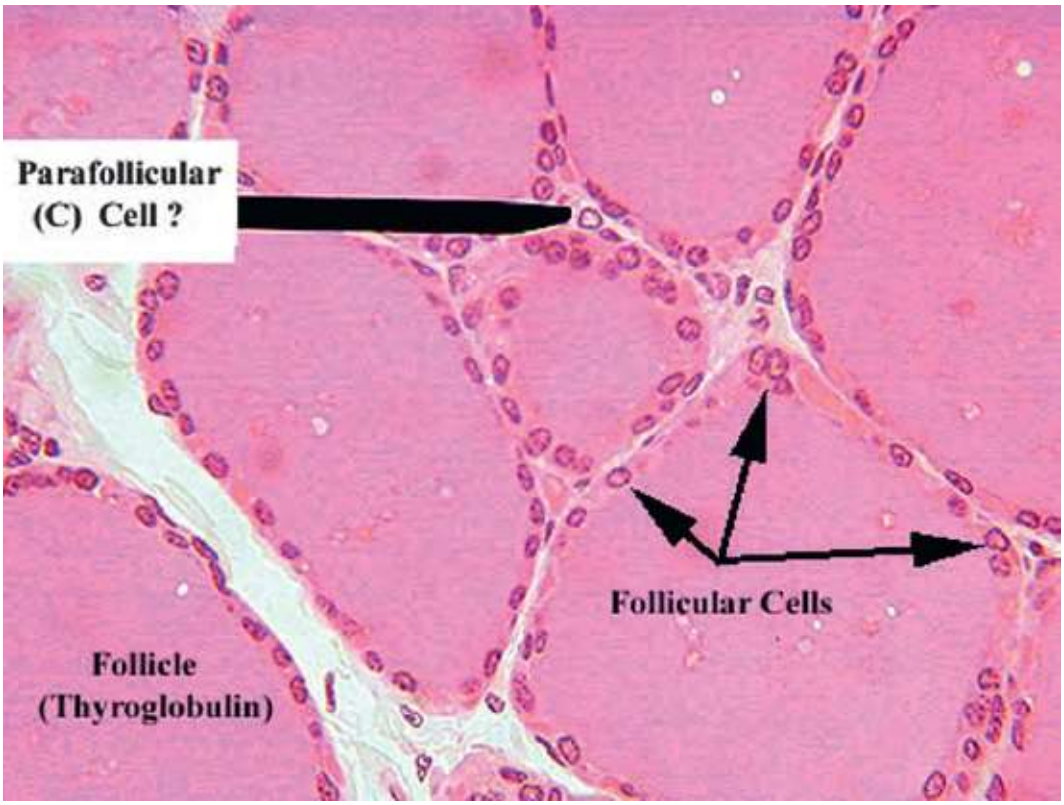

FIGURE 53.4. Thyroid follicle. Thyroid follicular cells produce thyroglobulin and thyroid hormone. Thyroid cells, which are normally located in the thyroid follicles and in perifollicular regions, synthesize and secrete calcitonin. (Reprinted by permission from Springer: Mazzaferri EL, Amdur RJ. TABLE 53.1 CLASSIFICATION OF THYROID CANCER BY CELL OF ORIGIN

Follicular Epithelial Cell

Well-differentiated thyroid cancer (DTC)
- Papillary thyroid carcinoma (PTC)
  - Classic
  - Follicular variant
  - Oncocytic variant
  - Unfavorable variants
    - Diffuse sclerosing
    - Tall cell
    - Columnar cell
    - Hobnail
- Follicular thyroid carcinoma (FTC)
  - Classic
  - Hurthle cell carcinoma

Poorly differentiated thyroid cancer (PDTC): Insular carcinoma

Undifferentiated thyroid cancer: Anaplastic carcinoma

Parafollicular C-cell

Medullary carcinoma

Differentiated (Follicular-Derived) Thyroid Carcinoma

The two major subgroups constituting DTC are PTC and FC. They are distinguished mainly by cytologic features: in PTC, cytology is diagnostic of malignancy whereas in FC, the diagnosis of malignancy requires evidence of tumor invasion through the tumor (not the thyroid) capsule. It is for this reason that PTC is usually diagnosed by fine needle aspiration but diagnosis of FC usually requires at least a lobectomy.

Papillary Thyroid Carcinoma

The distinguishing features of PTC include nuclear enlargement, hypochromasia, intranuclear cytoplasmic inclusions (nuclear pseudoinclusions), nuclear grooves, and distinct nucleoli. After formalin fixation, nuclei may appear pale and optically clear and resemble “Orphan Annie eyes.” PTC is strongly lymphotropic, and multicentric disease within the parenchyma of the gland is

often present secondary to early lymphatic spread. All PTC stain strongly for Tg.[3–5]

In its classic variant, PTC has a tumor architecture comprising branching papillae with fibrovascular cores. The follicular variant of PTC differs from the classic variant by its follicular growth pattern; however, it retains the nuclear features diagnostic of PTC. The oncocytic variant of PTC has the morphology of oncocytomas elsewhere in the body with abundant pink cytoplasm. From the clinical standpoint, the distinction between classic, follicular, and oncocytic subtypes of PTC is not important because they are treated the same way and have similar prognoses. The unfavorable variants of PTC have a worse prognosis than do the above three subtypes.

Diffuse sclerosing is a rare form of PTC, with histologic features of extensive sclerosis, lymphocytic infiltrate, and psammoma bodies. A greater percentage of patients with diffuse sclerosing PTC present with extrathyroidal extension or distant metastases. Likewise, tall cell, columnar, and hobnail variants are commonly associated with poor prognostic features such as advanced age, large tumor size, aggressive histologic features with early invasion, and distant metastases. The distinguishing feature of tall cell PTC is that at least 70% of the carcinoma is composed of cells that are at least twice as tall as they are wide because of abundant cellular cytoplasm. Columnar and hobnail cell variants are rare. These carcinomas histologically show striking nuclear stratification, usually with papillary architecture. However, the usual nuclear features of PTCs may be absent; therefore, some pathologists prefer to classify columnar and hobnail cell variants as poorly differentiated carcinomas.

Follicular Carcinoma

FC, like PTC, is a DTC of follicular cell origin. This malignant thyroid neoplasm lacks the cytologic features of PTC. These carcinomas show evidence of thyroid follicle formation and are usually well circumscribed with a defined tumor capsule. They are grossly indistinguishable from follicular adenomas. The diagnosis of FC is dependent on the presence of one of two histologic features: (a) tumor invasion through the entire tumor capsule or (b) tumor invasion into a blood vessel located in the tumor capsule or immediately outside the tumor capsule. Minimally invasive forms of FC may present a pathologic challenge and often require serial sectioning to find evidence of capsular or vascular invasion, whereas widely invasive forms of FC are obviously invasive tumors on both gross and microscopic evaluation.

Hurthle Cell Carcinoma

Many references classify Hurthle cell carcinoma as a subtype of follicular thyroid cancer, but more recent molecular studies suggest it should be a separate entity.[6] An older name for Hurthle cell carcinoma is oncocytic carcinoma (not to be confused with the oncocytic variant of PTC). Hurthle cells are large and contain abundant granular eosinophilic cytoplasm. Hurthle cells may be seen in both benign and other non–Hurthle cell malignant neoplastic lesions; however, at least 75% of the tumor must be composed of Hurthle cells to designate it Hurthle cell carcinoma. Similar to FC, Hurthle cell carcinoma requires the presence of capsular or vascular invasion to classify it as a malignant neoplasm.

Poorly Differentiated Thyroid Carcinoma (Insular Carcinoma)

These follicular epithelial cell–derived tumors are intermediate between DTC and undifferentiated, or anaplastic, thyroid cancers (ATCs). Both their histologic appearance and biologic behavior are more aggressive than those of DTC. They tend to be widely invasive, and many will extend beyond the gland. Insular carcinoma is characterized by tumor cells that are arranged in discrete nests separated by a fibrous stroma. Microscopically, they are usually solid with some evidence of follicle formation. Mitoses and necrosis are often present. The presence of more differentiated areas of tumor admixed with insular carcinoma suggests that the latter represents “dedifferentiated” tumors.

Undifferentiated Thyroid Carcinoma: Anaplastic Carcinoma

ATC is the most aggressive form of thyroid carcinoma. Most patients are diagnosed at the age of 65 years or older.[7] ATC originates from the thyroid follicular epithelium but shows little to no evidence of histologic differentiation. This tumor is defined as much by its clinical behavior as its histologic appearance. When diagnosed, most ATCs are widely invasive, replacing most if not all of the normal-appearing gland, and freely infiltrate the perithyroidal tissues. They are usually accompanied by bulky metastatic lymphadenopathy and distant metastatic spread. Gross pathologic evaluation is characterized by widely infiltrative disease with areas of necrosis and hemorrhage. Various microscopic patterns have been described, including small cell, spindle cell, giant cell, squamoid cell, and pleomorphic cell. They are hypothesized to be lesions that have dedifferentiated from more benign differentiated follicular neoplasms.

Medullary Thyroid Carcinoma

MTC does not originate from the follicular epithelial cells, but from the parafollicular C cells, which are neural crest–derived cells whose function is to produce calcitonin. Cases are seen sporadically (80%) or in association with familial multiple endocrine neoplasia (MEN IIa, MEN IIb, and pure familial MTC) syndromes. Multifocal and bilateral MTCs are usually seen in patients with MEN, but, otherwise, familial and sporadic MTCs are indistinguishable. Grossly, these tumors are well circumscribed and nonencapsulated. Microscopically, tumors can have different appearances, including patterns that mimic other types of thyroid tumors. The most common pattern is of solid growth or nests similar to insular carcinoma. Amyloid, which is present in approximately 80% of cases, is a characteristic feature of MTC. Calcitonin stains are usually positive and specific for MTC, but up to 20% of cases may not stain for calcitonin; therefore, other neuroendocrine markers such as chromogranin may be useful.

TABLE 53.2 CLASSIFICATION OF THYROID CANCER BASED ON THE ABILITY TO CONCENTRATE IODINE

Usually Concentrate Iodine to a Degree That May Be Curative

Papillary thyroid carcinoma
- Classic
- Follicular variant
- Oncocytic variant

Follicular thyroid carcinoma
- Classic

Often Do NOT Concentrate Iodine to a Degree That Is Curative

Unfavorable variants of papillary thyroid carcinoma
- Diffuse sclerosing
- Tall cell
- Columnar cell
- Hobnail

Hurthle cell carcinoma

Rarely Concentrate Iodine to a Degree That Is Curative

Poorly differentiated thyroid carcinoma: insular carcinoma

Never Concentrate Iodine to a Degree That Is Curative

Anaplastic carcinoma

Medullary carcinoma

Classification Based on the Capacity to Concentrate Iodine

Different pathologic classes of thyroid carcinoma concentrate iodine to various degrees. This characteristic is central to management decisions because the

ability to concentrate iodine presents a useful therapeutic target. Table 53.2 presents a classification system that categorizes cancers based on whether they always concentrate iodine, infrequently concentrate iodine, or never concentrate iodine. Papillary and follicular carcinomas (with the exception of the more aggressive variants) usually concentrate iodine. The follicular variant of papillary cancer has the same avidity for iodine as does papillary cancer with classic morphology. Therefore, from the treatment standpoint, the distinction between these types of DTCs is not important. The aggressive variants of papillary carcinoma and Hurthle cell carcinoma can concentrate iodine, but to a lesser degree than the classic morphologies. In fact, there is often no measurable iodine uptake in metastases of these tumors. Anaplastic and medullary cancers never concentrate iodine to a clinically useful degree.

EPIDEMIOLOGY OF THYROID CANCER

The data in this section come from a recent analysis of the SEER database for the period 1974 to 2013.[8]

DTC accounted for about 90% of total thyroid cancer cases with 90% of these being papillary carcinoma. The approximate distribution of thyroid cancer cases by sex, race, histology, and age was as follows: female, 75%; white, 80%; papillary, 84%; follicular, 11%; medullary, 2%; anaplastic, 1%; and age in years <20, 2%; 20 to 39, 31%; 40 to 59, 42%; 60 to 79, 22%; and ≥80, 3%.

Between 1974 and 2013, the incidence of thyroid cancer tripled, from approximately 4.5 to 14.4 per 100,000 individuals with almost the entire increase attributable to PTC. These findings are explained by the fact that the large increase in thyroid cancer diagnosis is from the detection of early-stage tumor on neck ultrasound and other imaging studies. The extent of cancer at diagnosis was distributed as follows: localized, 59; regional, 33%; and distant, 5%.

Radiation-Induced Thyroid Cancer

Exposure to ionizing radiation is an established risk factor for thyroid nodules and cancer. Well-recognized data come from survivors of atomic bombs in Hiroshima and Nagasaki and the nuclear reactor accident in Chernobyl.[9–15] A recent analysis of the 59,687 atomic bomb survivors in the Life Span Study demonstrated that a total of 24.5% of cases of thyroid cancer in this cohort were attributed to radiation exposure with a strong dose response.[13] Women and young children appeared to be most susceptible. An estimated additional 1,000

cases of thyroid cancer throughout Europe have been attributed to the Chernobyl accident.[15] An increased risk of thyroid cancer has also been attributed to exposure to therapeutic radiation in children treated for Hodgkin lymphoma, tinea capitis, enlarged tonsils, and enlarged thymus.[16–18] Radiation-induced thyroid cancer is pathologically indistinguishable from spontaneous forms of the disease and is not associated with more aggressive biology or poorer prognosis.[19–22]

Familial Medullary Thyroid Carcinoma

Twenty-five percent of cases of MTCs are hereditary. All patients with MTC should be screened for familial disease, and genetic testing is considered the standard of care for all first-degree relatives of patients with newly diagnosed MTC. Heritable forms of MTC are associated with the familial MEN syndromes (MEN IIa, MEN IIb, and pure familial MTC) and have their own unique epidemiology. These disorders are inherited in an autosomal-dominant fashion because of a germline point mutation in the *RET* gene on chromosome 10q11.2. Men and women are affected equally given the pattern of inheritance. These patients typically present with bilateral and multifocal tumors compared to sporadic forms of MTC. The aggressiveness and age of onset of familial MTC differ depending on the specific genetic mutation. Prophylactic thyroidectomies are increasingly being performed on patients at risk for developing MTC.[23]

CLINICAL MANIFESTATIONS OF THYROID CANCER

The most common presentation of thyroid cancer is an asymptomatic thyroid nodule found incidentally by the patient or clinicians or on an imaging study performed for other reasons.[24,25]

Alternatively, locally advanced thyroid cancer presents with symptoms from involvement of the critical structures intimately associated with the thyroid gland, massive cervical lymphadenopathy, or metastatic disease. These patients present with symptoms such as hoarseness from tumor compression of the recurrent laryngeal nerve, airway compromise, dysphagia or respiratory symptoms, and pain and weight loss resulting from metastatic dissemination.

DIAGNOSTIC EVALUATION OF THYROID CANCER

Laboratory Studies

All patients with thyroid nodules should undergo a serum TSH in addition to basic metabolic, renal, and liver function tests and a complete blood count. Other lab tests, such as Tg, T_3, and T_4, are commonly obtained but are rarely useful in the initial management of thyroid cancer. Serum calcitonin can be measured during the initial evaluation of patients with MTC and is essential during follow-up for these patients.

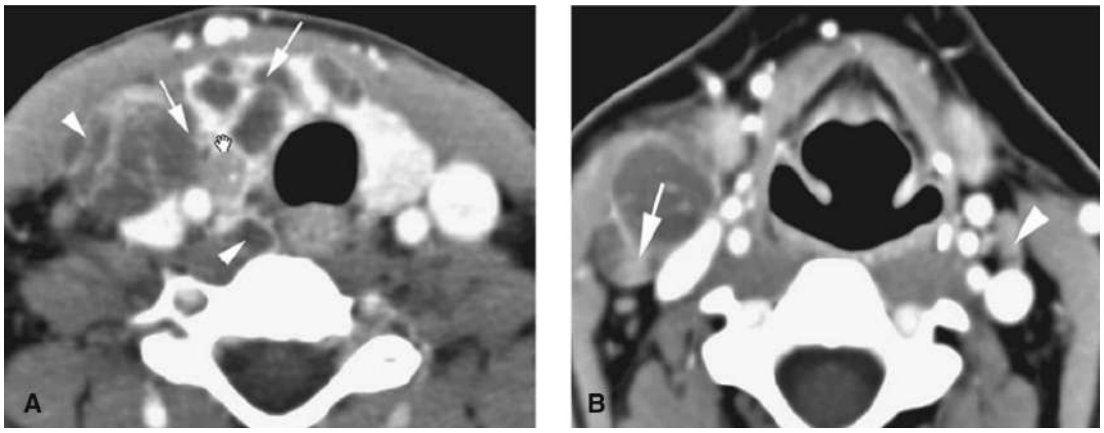

FIGURE 53.5. A patient presenting with a neck mass. **A:** CT image showing the mass to be due to a primary papillary thyroid carcinoma coming into contact with a related level 4 metastatic lymph node (*arrows*). The lymph node at level 4 and in the tracheoesophageal groove is shown by the *arrowheads*. **B:** A section more superiorly shows level 3 adenopathy that is multicystic in a pattern typical but not necessarily diagnostic of papillary thyroid carcinoma. There is upper level 4 cystic adenopathy with an enhancing mural nodule (*arrow*)—a morphology suggesting of thyroid carcinoma. A contralateral enhancing positive node with a focal low-density defect (*arrowhead*) is also present. (From Mancuso AA, Mendenhall WM, Vaysberg M. Thyroid: nodules and malignant tumors. In: Mancuso AA, ed. *Head and neck radiology*. Philadelphia, PA: Lippincott Williams & Wilkins, 2010:1457–1481. With permission.)

Ultrasound and Ultrasound-Guided Fine Needle Aspirate

Neck US with Doppler and US-FNA are the standard diagnostic approaches for evaluating thyroid nodules, both palpable and incidentally detected on imaging. US-FNA has several benefits in the evaluation of thyroid nodules over other means of obtaining a tissue diagnosis: (a) the technique is minimally invasive and is usually performed as an outpatient procedure; (b) the operator can visually verify that the biopsy needle is in the nodule(s) of suspicion; and (c) it allows for evaluation of nonpalpable nodules and, in the setting of cystic lesions, lowers the rate of inadequate specimens.

Cervical US is also an important staging tool because it is effective in identifying lymph node metastases. Cervical lymph node size, presence of

calcification, and irregular diffuse intranodular blood flow are the most important US features suggestive of lymph node metastases.[26,27] Using criteria based on the ratio of largest to smallest lymph node diameter, nodule echogenicity, intranodal structure, and margin irregularity, the sensitivity and specificity of cervical US for identifying malignant cervical lesions were 90% and 82%, respectively, in a study of 112 patients followed for thyroid cancer by high-resolution US with Doppler.[28] Preoperative cervical US identified lymph node metastases that were occult on physical examination in 33% to 39% of patients in a large retrospective series.[29,30] Cervical US findings will alter the surgical approach in 14% to 24% of patients with PTC by identifying nonpalpable cervical lymph node metastases.[26,30]

Computed Tomography and Magnetic Resonance Imaging

Computed tomography (CT) and magnetic resonance imaging (MRI) commonly detect otherwise clinically occult thyroid nodules. Malignancy is likely with either imaging technique when there are findings of a mass with extrathyroidal extension, lymph node metastases, or both. In this setting, the studies are useful in presurgical planning by establishing the extent of extraglandular tumor and helping the surgeon determine the need for extended neck dissections (Figs. 53.5 and 53.6). MRI is superior to CT for establishing the local extent of a known cancer, because it will more clearly show esophageal or tracheal invasion (Fig. 53.6).[31] MRI is indicated in the presence of hoarseness, stridor, dysphagia, or other clinical signs of locally extensive thyroid cancer that cannot be adequately assessed by US.

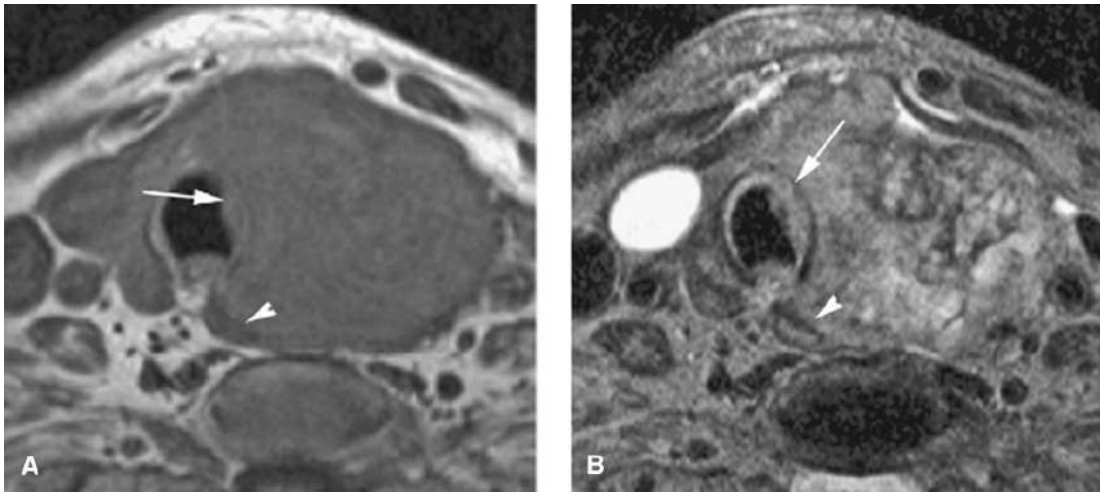

FIGURE 53.6. The value of magnetic resonance in the detection of invasion of the trachea and cervical esophagus, especially as it pertains to treatment planning. This

patient has anaplastic carcinoma of the thyroid gland. In **(A)**, T1-weighted images show distortion of the trachea (*arrow*) and esophagus (*arrowhead*), but it is difficult to determine whether invasion is present. In **(B)**, the T2-weighted image shows obvious growth of tumor replacing the normal signal of cartilage of the trachea with growth on both sides of the cartilage (*arrow*) as well as replacement of the normal muscular wall signal of the cervical esophagus (*arrowhead*), indicating esophageal wall invasion. (From Mancuso AA, Mendenhall WM, Vaysberg M. Thyroid: nodules and malignant tumors. In: Mancuso AA, ed. *Head and neck radiology*. Philadelphia, PA: Lippincott Williams & Wilkins, 2010:1457–1481. With permission.)

A major downside to CT is that useful imaging of the neck requires contrast enhancement, which can interfere with subsequent I-131 therapy. Because of their high concentration of iodine, CT contrast agents can seriously compromise the effectiveness of therapeutic I-131. When patients receiving iodinated contrast agents require I-131, therapy should be delayed in order to achieve adequate efficacy. In selected cases, a noncontrasted CT of the chest may be indicated to evaluate the presence of mediastinal and lung metastases, but, generally speaking, it is not necessary to perform a CT before primary therapy of most DTCs.

Nuclear Medicine Studies

The four major nuclear medicine studies related to thyroid cancer evaluation with iodine isotopes are radioactive iodine uptake (RAIU), thyroid scan, diagnostic whole-body scan (DxWBS), and posttreatment whole-body scan (RxWBS). Table 53.3 summarizes each of these studies.

RAIU tests are used to quantify the RAI iodine-concentrating ability of remnant thyroid tissue after thyroidectomy. This value is required by federal regulation for outpatient I-131 therapy.

Thyroid scans produce images of the thyroid's ability to concentrate iodine and have a historical use in the evaluation of thyroid nodules, characterizing them as functional ("hot") or nonfunctional ("cold"). The authors do not use thyroid scans in the workup or management of patients with thyroid cancer.

The typical DxWBS involves a total-body image several days after administering approximately 3 mCi of I-131 or I-123. The current value of a DxWBS in thyroid cancer management is controversial. Some experts use a DxWBS to determine the therapeutic dose of I-131 in a patient being treated for thyroid cancer. Some experts use a DxWBS as part of the surveillance program following initial treatment. A comprehensive discussion of the issues related to DxWBS is beyond the scope of this chapter. The main arguments against doing DxWBS are low sensitivity, stunning of residual cancer cells, and unnecessary

radiation exposure. The bottom line is that reasonable people will disagree about the role of DxWBS in thyroid cancer management. The authors do not use DxWBS to stage or monitor thyroid cancer patients and have not ordered a DxWBS in over 5 years.

An RxWBS should be done in every patient who receives a therapeutic dose of I-131. The optimal interval between administration and scan in most patients is approximately 7 days. The primary purposes of an RxWBS are to detect gross residual disease in the regional lymphatics or in distant sites and to determine if known disease concentrates iodine.

FDG-PET is another nuclear medicine study that is commonly used to detect metastatic disease, but the predictive value of PET in thyroid cancer is controversial.[32,33]

TSH stimulation increases the accuracy of FDG-PET in most types of DTC. A prospective trial comparing FDG-PET studies during thyroid hormone suppression to studies after administration of rhTSH showed increased detection of occult metastases in the stimulated studies.[34] Some insurers will not reimburse for FDG-PET for thyroid cancer without prior documentation of follicular-derived thyroid cancer with a suppressed or stimulated Tg over 10 ng/mL and a negative DxWBS.[35]

TABLE 53.3 NUCLEAR IMAGING STUDIES USED IN THE MANAGEMENT OF DIFFERENTIATED THYROID CARCINOMAS

TABLE 53.4 AMERICAN JOINT COMMITTEE ON CANCER (AJCC) 8th EDITION (2017) TNM STAGING SYSTEM FOR THYROID CANCER

Papillary, Follicular, Poorly Differentiated, Hurthle Cell, and Anaplastic Thyroid Carcinoma

Primary Tumor (T)		
TX		Primary tumor cannot be assessed
T0		No evidence of primary tumor
T1		Tumor ≤2 cm in greatest dimension limited to the thyroid
	T1a	Tumor ≤1 cm in greatest dimension limited to thyroid
	T1b	Tumor >1 cm but ≤2 cm in greatest dimension limited to the thyroid
T2		Tumor >2 cm but ≤4 cm in greatest dimension limited to the thyroid
T3		Tumor >4 cm limited to the thyroid, or gross extrathyroidal extension invading only strap muscles
	T3a	Tumor >4 cm limited to the thyroid
	T3b	Gross extrathyroidal extension invading only strap muscles (sternohyoid, sternothyroid, thyrohyoid, or omohyoid muscles) from a tumor of any size
T4		Includes gross extrathyroidal extension
	T4a	Gross extrathyroidal extension invading subcutaneous soft tissues, larynx, trachea, esophagus, or recurrent laryngeal nerve from a tumor of any size
	T4b	Gross extrathyroidal extension invading prevertebral fascia or encasing the carotid artery or mediastinal vessels from a tumor of any size
Regional Lymph Node (N)		
NX		Regional lymph nodes cannot be assessed
N0		No evidence of locoregional lymph node metastasis
	N0a	One or more cytologically or histologically confirmed benign lymph nodes
	N0b	No radiologic or clinical evidence of locoregional lymph node metastasis
N1		Metastasis to regional nodes
	N1a	Metastasis to level VI or VII (pretracheal, paratracheal, or prelaryngeal/delphian, or upper mediastinal) lymph nodes. This can be unilateral or bilateral disease.
	N1b	Metastasis to unilateral, bilateral, or contralateral lateral neck lymph nodes (levels I, II, III, IV, or V) or retropharyngeal lymph nodes
Distant Metastasis (M)		

M0		No distant metastasis		
M1		Distant metastasis

OUTCOME AND PROGNOSTIC FACTORS

The AJCC staging system documents the major prognostic factors that determine disease-specific survival after diagnosis of thyroid cancer (Table 53.4 and Figure 53.7). There are major differences in the staging system from prior versions and from the many prognostic models from other groups. The remainder of this subsection will discuss some of the issues that deserve additional explanation.

Recurrence Versus Survival

Many discussions of treatment for thyroid cancer are controversial. A major reason for disagreement is an inability to agree on the outcome endpoint. The

major options are as follows: overall survival (an event is death from any cause), disease-specific survival (an event is death from thyroid cancer), relapse-free survival (an event is cancer recurrence), and locoregional control (an event is cancer recurrence in the thyroid bed or regional neck nodes).

Most types of thyroid cancer have an indolent growth rate such that patients live many years with uncontrolled tumor. An additional complicating factor is that DTC shares with prostate cancer the feature of exhibiting a highly specific serum marker of tumor activity. Serum thyroglobulin (Tg) level is to DTC what prostate-specific antigen is to prostate cancer. Therefore, with most forms of thyroid cancer, there is also the debate about biochemical versus clinical evidence of cancer control.

Most major studies of outcome of thyroid cancer use either overall or disease-specific survival as the outcome endpoint. The major limitation of these survival endpoints is that they do not reflect the morbidity from tumor recurrence that does not cause death. Psychological stress from living with recurrent cancer or uncertainty about cancer cure is substantial,[36,37] and there is physical morbidity that comes from additional diagnostic testing and salvage therapy. This limitation runs through almost every major debate about thyroid cancer treatment because the difference between recurrence and survival results is usually large. Figure 53.8 shows the key figure from a classic study demonstrating this concept.

In this chapter, we do not present specific studies related to a treatment recommendation in a specific situation. Summarizing specific studies would make this chapter unacceptably long and it would not end with definitive answers. For this reason, our approach is to list the major guideline references and to summarize their opinions in some of the major treatment situations. These major guidelines contain a long list of references of the specific studies that inform the discussion topic.

Age

Age is a major prognostic variable in the AJCC staging systems. The current AJCC system dichotomizes staging based on age under 55 years versus 55 years and older. Age is a major factor in all outcome studies because of the consistent finding that younger patients do better than older patients, especially those in the older adult age groups. Of course, the prognostic effect of age is really a continuous variable, but it is more useful for treatment decisions to force a dichotomous breakpoint. But, the major limitation of this approach to age is that

it ignores the data that young children (<12 years old) do worse than young adults.[38] The explanation for this difference may be that young children present with more advanced-stage disease at diagnosis, frequently with distant metastases.[39,40]

Unfavorable Variants of Papillary Thyroid Cancer

The most important prognostic factor for disease recurrence and cancer mortality is the histologic classification. DTC, when diagnosed in an early stage, has a favorable prognosis. However, tall cell variant can have a 10-year mortality of up to 25%.[41] Columnar cell variant and diffuse sclerosing variants likewise carry a poor prognosis relative to other forms of DTC.[42] However, follicular-variant PTC and classic histology have the same prognoses, which is similar to that of follicular thyroid cancer.

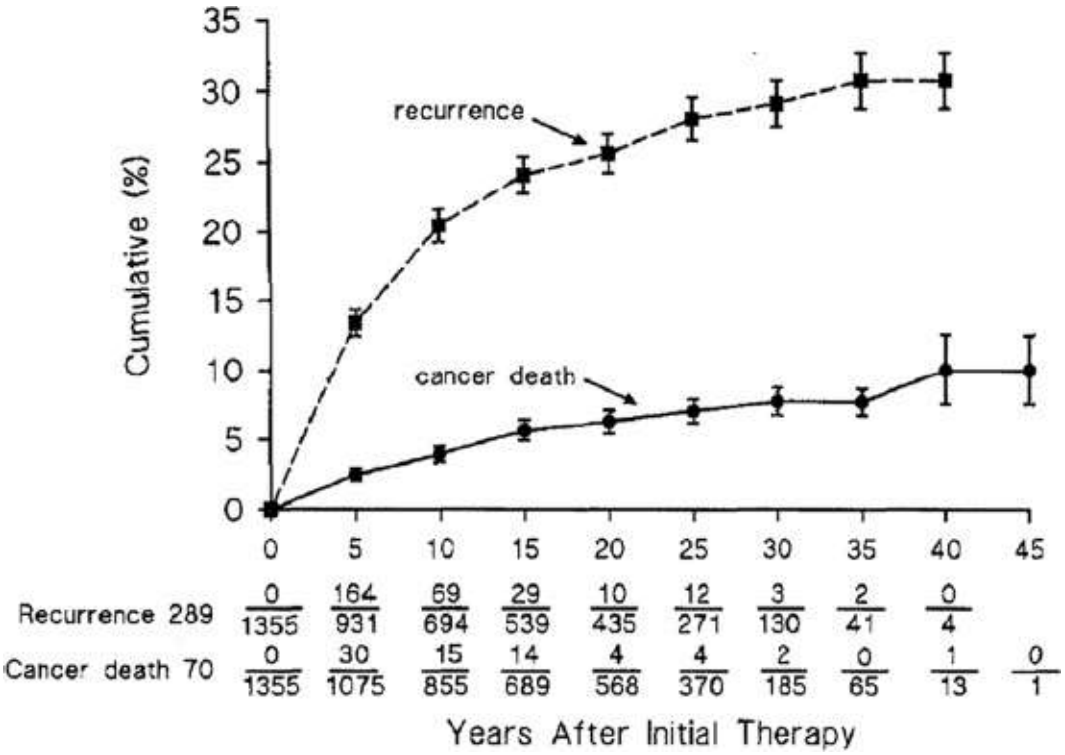

FIGURE 53.8. Tumor recurrence and cancer deaths in 1,355 patients treated for follicular and papillary thyroid carcinoma. (Reprinted from Mazzaferri EL, Jhiang SM. Long-term impact of initial surgical and medical therapy on papillary and follicular thyroid cancer. *Am J Med* 1994;97[5]:418–428. Copyright © 1994 Elsevier. With permission.)

Hurthle Cell Carcinoma

There is major disagreement about the prognosis of Hurthle cell carcinoma relative to other forms of DTC such that some authors recommend a separate staging system. A summary of this debate is beyond the scope of this chapter. A paper from our group summarizes the main issues and presents our data on the subject.[43]

Positive Surgical Margin

A positive surgical margin is an important prognostic factor in most cancer situations. But, microscopic margin status is not a factor in the American Thyroid Association (ATA) and National Comprehensive Cancer Network (NCCN) treatment guidelines (Table 53.5). Data on the independent significance of a microscopic positive margin in DTC are scarce. Some studies suggest that a positive margin warrants more aggressive treatment,[44] but the most respected study on this subject concludes that a positive margin does not affect the recurrence rate following standard treatment.[45] As with many other debates in

thyroid cancer, the studies evaluate different endpoints. In the Memorial Sloan Kettering series, the endpoint is clinical recurrence (visible tumor recurrence) without discussion of biochemical recurrence data.[45] Our view is that a microscopically positive margin should be taken into account such that we are reluctant to recommend observation regardless of other factors (Table 53.7).

Number of Positive Lymph Nodes

The prognostic importance of positive neck nodes from DTC has been a major controversy for decades. The AJCC staging system reflects the conclusion that the distinction between no positive nodes and at least 1 positive node has some importance, but stage does not change based on the number of positive nodes (Table 53.4). Guidelines from the ATA and NCCN do take into account the number of positive nodes by specifying that patients with ≤5 central compartment nodes are still "low risk" (Table 53.5).

Carcinoma

DTC, differentiated thyroid cancer; EBRT, external beam radiation therapy.

Our opinion is that these guidelines undervalue the significance of many positive nodes in predicting outcome and making treatment decisions. Multiple studies show that multiple positive nodes are a powerful negative prognostic factor. For example, in 2015, Adams and colleagues studied this question with the National Cancer Database and SEER database in young patients with an otherwise favorable prognosis.[46] They found that "increasing number of metastatic lymph nodes was associated with decreasing overall survival up to six metastatic nodes." We take the number of positive nodes into account when making treatment decisions (Table 53.7).

Extranodal Extension

Extranodal extension of metastatic tumor is an important prognostic factor in most types of cancer. In thyroid cancer, this factor is not included in the AJCC staging system nor in the factors that determine treatment in the ATA and NCCN guidelines (Tables 53.4 and 53.5). However, there is evidence that extranodal extension predicts a higher recurrence rate in patients with DTC.[47] We take extranodal extension into account when making treatment decisions (Table 53.7).

Distant Metastases

A unique feature of thyroid cancer is that patients with extensive distant metastases from DTC may be cured with I-131 therapy and most experience long-term survival.[48] Treatment of distant metastases depends on the specific situation, and the scenarios vary so greatly that further discussion is beyond the scope of this chapter. The consensus guidelines listed in Table 53.5 address treatment of distant metastases across various situations.

SURGICAL MANAGEMENT OF THYROID CANCER

Surgery is the primary treatment of localized thyroid cancer of all histologies. A total thyroidectomy is the preferred oncologic procedure, but the consensus guidelines listed in Table 53.5 describe scenarios where lobectomy is acceptable.

It is critical to understand that even a total thyroidectomy leaves residual thyroid tissue that will have major implications for subsequent therapy and disease monitoring. The clearest evidence of residual thyroid tissue after total thyroidectomy is seen on postoperative I-131 thyroid studies, which nearly always show uptake in the region of the thyroid bed. The presence of residual

thyroid tissue in this setting is not a sign of incomplete surgery, but a matter of practicality. The ligament connecting the posterior surface of the thyroid capsule to the trachea harbors microscopic nests of thyroid tissue and is rarely completely resected in order to reduce the risk of tracheal injury. Second, the recurrent laryngeal nerve is embedded in thyroid tissue at the point where the nerve enters the larynx, and it is not possible to remove all of this thyroid tissue without injuring the nerve and compromising voice quality and laryngeal function.

Several important complications can arise from thyroidectomy. The most common are recurrent laryngeal nerve injury (temporary 30% and permanent 2%) and hypoparathyroidism (temporary 5% and permanent 0.5%).[49]

Neck Dissection in Differentiated Thyroid Cancer

As with squamous cell carcinomas, a modified radical neck dissection is done for thyroid cancer when there is a visible or palpably positive node. However, elective neck dissection (removal of lymphatic regions at risk for subclinical disease) is generally not performed for DTC, unlike primary surgery for most other head and neck cancers. Despite a high incidence of subclinical lymph node involvement in even small DTCs, elective neck dissection is not included in the initial surgical approach because the results without neck dissection have been good.[50]

An ongoing controversy is the role of central (level 6) node dissection as part of the thyroidectomy procedure. The consensus guidelines listed in Table 53.5 summarize this controversy. In our opinion, thorough dissection of the central compartment is not necessary in the absence of clinically suspicious nodes at the time of surgery.

MANAGEMENT OF DIFFERENTIATED THYROID CANCER WITH RADIOACTIVE IODINE

Bioconcentration of Radioactive Iodine

I-131 for DTC is arguably the most successful targeted therapy in all of oncology. The iodine-concentrating capacity of benign and neoplastic thyroid tissue makes an overwhelming majority of thyroid carcinomas amenable to I-131 therapy. I-131 is taken up by thyroid tissue, including DTC of follicular epithelial origin, at a rate 6.6 times more than most tissues in the body. The biologic half-life in extrathyroidal tissue is merely 12 days compared to 80 days for thyroid tissue (Table 53.6).

TABLE 53.6 PHYSICAL, BIOLOGIC, AND EFFECTIVE HALF-LIVES (T½) OF I-131

Tissue	Physical T½	Biologic T½	Effective T½
Thyroid	8 d	80 d	7.3 d
Extrathyroidal	8 d	12 d	8 h

Radioactive Decay of Iodine-131

I-131 is produced from the fission of uranium atoms during the operation of

nuclear reactors or in the detonation of nuclear bombs. I-131 decays by negatron emission (beta-minus decay) to xenon-131 (Xe-131). A neutron from the I-131 nucleus converts to a proton and an electron (beta particle) is emitted from the nucleus. This first transition results in a beta particle with a range of energies from 250 to 800 keV. These beta particles are core to I-131's ability to deliver targeted cytotoxicity. Because electrons of this energy range will deposit their energy within a millimeter, only the cells taking up the I-131 are affected. In the second decay step, unstable Xe-131 decays to stable xenon, releasing a photon with the energy of 364 keV. This product is therapeutically undesirable, because the photon will travel far from the source where iodine is concentrated. It contributes very little cytotoxicity to thyroid cancer cells and increases the total-body dose; however, it is this property that makes iodine useful for diagnostic imaging, forming the foundation for DxWBS and RxWBS.

Goals of Radioactive Iodine Therapy for Differentiated Thyroid Cancer

Broadly speaking, the two basic purposes of adjuvant I-131 are (a) thyroid remnant ablation and (b) adjuvant therapy for residual microscopic disease. First, I-131 provides potent cytotoxicity by targeting thyroid cancer cells remaining in the operative bed, occult lymph node metastases, and distant metastases. Second, RxWBS provides critical information including staging, prognosis, and determining which patients are likely to require additional treatments. Lastly, ablation of the remaining thyroid tissue facilitates the use of serum Tg as a very sensitive and specific marker for disease persistence after primary therapy. Serum Tg provides a powerful means of monitoring for early disease recurrences that are likely to be amenable to curative retreatment.

Dose of Radioactive Iodine (I-131) to Treat Differentiated Thyroid Cancer

There are two main approaches to selecting the dose of radioactive iodine, or I-131, for remnant ablation or treatment of known residual DTC: empiric and dosimetric. With the empiric method, all patients with the same disease risk factors get the same dose. With the dosimetric method, patients undergo tests of iodine metabolism to customize the dose based on individual physiology. It is beyond the scope of this chapter to discuss the many dosimetric approaches that have been described in the literature. The bottom line is that today most experts recommend empiric dosing in the absence of renal insufficiency or multiple prior

I-131 treatments (Table 53.5).

Table 53.7 summarizes the indications and dose of I-131 that we currently use in our program. There are differences between these guidelines and those of the ATA and NCCN (Table 53.5).

TABLE 53.7 Empiric I-131 Dosing for Treatment of Differentiated Thyroid Cancer: University of Florida Department of Radiation Oncology [a,b]

Adjuvant Treatment Soon after Total Thyroidectomy (No Prior I-131 Treatment and No Visible Tumor)

Observation[c] (No I-131 treatment)	**All must be present:** pT1-2, pN0-1a, M0 ≤3 positive nodes No extranodal extension Negative margin Postop Tg[d] < 1.0 ng/mL
30 mCi	All other scenarios
150 mCi	**If any are present:** pT3b ≥4 positive nodes ENE that is not extensive[e] Positive margin and postop Tg[d] ≥ 1.0 ng/mL
200 mCi	**If any are present:** pT4 Extensive ENE[e] M1(with the exception of large-volume disease)

For Recurrent Tumor Based Only on Serum Thyroglobulin Level (No Visible Disease) Following At least One Prior I-131 Treatment

Observation without additional I-131 is always a reasonable option.

We recommend observation when life expectancy unrelated to thyroid cancer is <5 y or when the risk of additional I-131 treatment is high: renal insufficiency, peripheral blood count deficiency, or substantial dry eye from prior I-131 treatment.

Our usual dose when treating recurrent tumor based only on serum thyroglobulin level is 150 mCi.

Other Situations of Recurrent Tumor Following At least One Prior I-131 Treatment:

The range of scenarios in the category is wide: distant metastasis, small-volume unresectable disease in the neck, and gross total resection of neck disease with a high risk of recurrence based on pathologic findings, positive margin, soft tissue invasion, multiple positive nodes, extranodal extension.

We usually do not give I-131 treatment in this setting when the risk of I-131 treatment is high (major renal insufficiency, peripheral blood count deficiency, or dry eye problems).

When we treat with I-131 in this setting, our usual dose is 200 mCi.

[a]There are differences between these guidelines and those of the American Thyroid Association and National Comprehensive Cancer Network.

[b]8th Edition (2017) of the AJCC staging system.[1]
[c]Observation is always reasonable and we explain this as part of the discussion of treatment options.
[d]Serum thyroglobulin (Tg) value obtained ≥ 6 wk after thyroidectomy with any level of thyroid-stimulating hormone. The 1.0 ng/mL Tg threshold is only applicable in the absence of anti-thyroglobulin antibodies.
[e]ENE, extranodal extension of tumor beyond the node capsule. We do not have a definition of "extensive" in this setting.

Preparing Patients for Iodine-131 Treatment

Appropriate preparation for I-131 therapy is critical to obtaining the optimal desired effect of therapy, whether for remnant ablation or adjuvant therapy residual disease. There are many elements to consider when deciding how thorough to be. Table 53.8 summarizes how we prepare patients in our program. These factors are discussed in detail in the consensus guidelines from the ATA (Table 53.5).

Outpatient Management of Iodine-131

Grigsby et al.[51] described the pattern of radiation exposure in 65 household members of 30 patients treated with I-131. The mean dose to family members was well below regulatory standards at 0.24 mSv and the maximum dose was 1.11 mSv. The Nuclear Regulatory Commission (NRC) has issued guidance on the release of patients following I-131 treatment for thyroid cancer, and a copy of all material related to the issue can be found on the NRC Web site. Major recommendations were issued in 1997 (NRC Regulatory Guide 8.39) and have largely remained in place. Several minor subsequent recommendations have been issued, most recently in early 2011 under 10 CFR 35.75.[52] Overall, the recommendations are intended to keep the exposure to the public "as low as reasonably achievable (ALARA)."

TABLE 53.8 PREPARATION OF PATIENTS FOR I-131: GUIDELINES FROM THE UNIVERSITY OF FLORIDA DEPARTMENT OF RADIATION ONCOLOGY

Component	Description	Comments
Low-iodine diet	A diet that is low in iodine (≤50 μg/d) for 2 wk before, and 2 d after, I-131 administration. Diet instructions are available at www.thyca.org.	The purpose of a low-iodine diet is to deplete the total-body iodine stores to a degree that maximizes the uptake of I-131by thyroid tissue and thyroid cancer.[72,73]
Intravenous	Iodine contrast, as used with CT	In patients who have received

iodinated contrast exposure	scans, results in a large amount of iodine stored in interstitial tissues.	intravenous iodinated contrast within 3 mo of the planned date of therapeutic I-131 administration, we measure the urine iodine level 1–2 wk before the planned date of administration (see below).
Urinary iodine measurement	Total-body iodine level is determined by the amount of iodine in the urine. The gold standard is a 24-h urine specimen, but we use a spot urine sample because it is more convenient for the patient.	Ideally, urine iodine is ≤ 50 μg/L before cancer treatment with I-131. When we suspect inadequate iodine depletion, we measure urine iodine 1–2 wk before the planned date of I-131 administration, on day ≥ 7 of a low-iodine diet. If the urine iodine is ≤150 μg/L, we administer I-131 as planned. If the level is higher, we delay administration, with the patient on a low-iodine diet for as long as we think it will take to adequately deplete total-body iodine stores. It is ideal to recheck the urine iodine concentration, but we do not do this when the initial value was <300 μg/L.
rhTSH instead of T_4 deprivation	rhTSH 0.9-mg intramuscular injection twice (2 d and 1 d) before I-131 administration	Compared to T_4 deprivation, rhTSH injections avoid the problems of hypothyroidism and result in less total-body radiation exposure but may decrease the potency of I-131 cancer treatment. Also, the cost of rhTSH may not be covered by the patient's insurance. We use rhTSH in all adults when the patient can afford the cost. We do not use rhTSH in children as it is not FDA approved in children and because children tolerate hypothyroidism better than adults do.
T_4 deprivation instead of rhTSH	Stop all thyroid hormone (usually levothyroxine, T_4) replacement for as long as it takes to raise the TSH level to ≥30 μU/mL by the day of I-131 administration. Ideally, pretreatment testing and the administration date should be scheduled well in advance. For this reason, our standard program is to stop thyroid hormone replacement 6 wk before the planned date of I-131	Compared to rhTSH, T_4 deprivation may make I-131 treatment more effective because hypothyroidism decreases urinary excretion of I-131 and thus increases biologic half-life. Another advantage of T_4 deprivation is that it does not have the cost of rhTSH injections. But, T_4 deprivation causes the physiologic problems of hypothyroidism and results in a higher total-body radiation dose. We use T_4 deprivation, instead of

	administration because TSH is almost always >30 μU/mL after ~5 wk of deprivation when we check it 5–10 d before the planned date of administration.	rhTSH, in adults that cannot afford rhTSH. We use T_4 deprivation in all children because rhTSH is not FDA approved in children and because children tolerate hypothyroidism better than adults do.
Lithium	The recommended dose of lithium carbonate is ~20 mg/kg/d (usually 300 mg 3 times a day) for 7 d, beginning 5 d before I-131 administration. At this dose, serum lithium concentration should be measured on day 4 and/or 5 (therapeutic range 0.6–1.2 mEq/L). We have found it difficult to get serum lithium results back in a timely fashion. For this reason, in standard-size patients, we often use an empiric dose of 300 mg twice a day and do not check serum levels.	Lithium increases radiation dose in target tissue by increasing iodine retention time preferentially in normal and malignant thyroid cells.[74,75] We use lithium in most patients that do not have a published contraindication, including psychiatric problems, dementia, seizure disorder, cardiac arrhythmia, renal insufficiency, hepatic impairment, hypo- or hypernatremia, and any of these medications: diuretic, antidepressant, nonsteroidal anti-inflammatory drugs, seizure medication, and calcium channel blockers. In patients who are at high risk for tumor recurrence, we often stop contraindicated medications for the week of lithium treatment or administer lithium without stopping the medication.
Stopping T_4 for 4 d with the rhTSH program	Discontinue thyroid hormone replacement 3 d prior to, and the day of, I-131 administration in patients prepared with rhTSH injections	Thyroid hormones contain iodine. Stopping thyroid hormone replacement for a short time before I-131 administration may increase the efficacy of treatment by augmenting the low-iodine diet.[76] We stop T_4 for 4 d in all patients prepared with rhTSH injections.
Scopolamine	Scopolamine transdermal patch of 0.33 mg/24 h. Apply patch behind your ear as soon as you get up in the morning on the day of I-131 administration. Remove patch 48–72 h later. Dispense 1 patch. No refills.	Scopolamine is an antimuscarinic that decreases stimulation of the salivary glands. Less salivary stimulation may decrease iodine uptake and thus decrease radiation dose to the salivary glands from I-131 therapy. We use scopolamine in all patients without major contraindications such as angle-closure glaucoma, pyloric obstruction, or serious dementia.
Sour candy	Do NOT eat sour candy for ~3 d after I-131 administration.	Some programs recommend sucking on sour candy during the first few days after I-131 administration. The

		idea behind sour candy is that stimulating salivary production "washes" iodine out of the saliva glands. One of the few studies on this issue suggested that sour candy INCREASES the radiation dose to the saliva glands.[77] For this reason, we give the patient instructions to NOT chew gum, suck on any type of candy, or eat spicy food for 3 d after I-131 administration.
T_3 during T_4 deprivation	Tri-iodothyronine (T_3, liothyronine sodium) 25 mcg orally twice a day starting the day of discontinuation of T_4 and stopping 2 wk before the day of I-131 administration.	T_3 has a much shorter half-life than T_4. The idea behind administering T_3 is to decrease the fatigue and other symptoms of T_4 deprivation. We do not use T_3 because a formal study failed to show a quality of life benefit.[78]
Diagnostic whole-body scan (DxWBS)	Total-body image ~3 d after administration of I-131 (1–3 mCi) or I-123 (1.5–3 mCi) with TSH ≥ 30 μU/mL.	Some experts use this study to determine the therapeutic dose of I-131. We do not perform this study.

CT, computed tomography; T_3, 3,5,3′ iodothyronine; T_4, 3,5,3′,5′ iodothyronine; TSH, thyroid-stimulating hormone.

TABLE 53.9 SIDE EFFECTS AND RISKS OF I-131 THERAPY: UNIVERSITY OF FLORIDA DEPARTMENT OF RADIATION ONCOLOGY CONSENT DOCUMENT LANGUAGE

The Most Common Temporary Side Effects from I-131 Treatment

Swelling of the saliva glands or neck: It is common to experience mild pain and swelling of the saliva glands that are located near the jawbone. This discomfort usually goes away in 3–5 d.

Taste change: It is common to experience a change in the way food tastes. Taste usually returns to normal within 3 wk after taking I-131.

Nausea: Some patients have nausea—possibly with vomiting—for 1–3 d after taking I-131. Take the nausea medication that we give you as often as you need it.

The Main Serious and Permanent Problems That May Occur after I-131 Treatment

Decrease in saliva and tears causing dry mouth, tooth decay (cavities), and dry eyes:
The risk of these problems depends mainly on I-131 dose and the status of your saliva and tear glands.

Bone marrow damage causing infection, bleeding, and problems from anemia:
The risk of these problems depends mainly on I-131 dose and the status of your bone marrow.

I-131 can cause cancer to develop in the future:
We will try to estimate the risk of cancer from I-131 in your situation.
A publication with a formula is Second primary malignancies in thyroid cancer patients.[79]
A Web site for cancer risk calculation is https://radiationcalculators.cancer.gov/radrat.

Damage to testicles or ovaries: I-131 therapy may cause early menopause if you are a woman and impotence and other problems if you are a man. The chance that you could get these problems depends on your age and dose of I-131.

I-131 therapy may decrease your fertility or ability to produce a normal baby. You should definitely not get pregnant if you are a woman, or get a woman pregnant if you are a man, for at least 6 mo after I-131 therapy.

To Decrease the Change of Problems, Do These Things

Do not wear contact lenses for 3 d after receiving I-131

Stay well hydrated for 3 d after taking I-131: Drink enough fluid so that you need to urinate every few hours. This will decrease radiation exposure to your saliva glands, bladder, and other organs.

Have at least one bowel movement each day for 3 d after taking I-131: Eat prunes or take a laxative, such as Dulcolax 15 mg, as needed.

Avoid things that stimulate saliva production for 3 d after taking I-131: Do not chew gum, use smokeless tobacco, or suck on candy.

Risks of I-131 Therapy

A therapeutic dose of I-131 exposes all tissues in the body to ionizing radiation. For this reason, I-131 may damage any tissue in the body and may cause the formation of all types of benign and malignant tumors. The risk of toxicity from I-131 treatment for thyroid cancer depends on the administered dose, the patient's physiology related to iodine metabolism, the sensitivity of the patient to ionizing radiation, the tumor burden, the tumor location, and the ability of tumor cells to concentrate iodine.

A discussion of all possible acute and late toxicities that have been reported following I-131 treatment will not be useful to most clinicians. Table 53.9 is a version of the consent document that we use to explain the main side effects and complications of I-131 therapy.

EXTERNAL BEAM RADIOTHERAPY FOR THYROID CANCER

Indications for External Beam Radiotherapy for Differentiated Thyroid Cancer

There are no randomized control trials defining the indications for external beam radiotherapy (EBRT) in thyroid cancer. The European Multicentre Study on Differentiated Thyroid Cancer trial was planned as a prospective multicenter trial to evaluate the benefit of adjuvant EBRT in locally advanced DTC. Patients with pT4 disease with or without lymph node metastases and no known distant metastases who underwent total thyroidectomy, I-131, and TSH suppression were to be randomized to EBRT or observation. The trial closed prematurely,

however, as only 16% of patients consented to be randomized to EBRT. The trial was converted to a prospective cohort study, and subsequent results failed to define the role of EBRT in this population.[53–55] Therefore, recommendations for EBRT are based on institutional retrospective experiences. Table 53.10 summarizes indications for EBRT from our department and the major consensus guideline publications.

External Beam Radiotherapy Technique

Techniques for treating metastatic disease will vary by site, tumor burden, and clinical circumstances; therefore, this chapter will only discuss the technique used for treating the primary site and nodal regions.

CT simulation is used for treatment planning with patients positioned supine with arms at their side and the neck extended such that the mandible is at 90 degrees with respect to the treatment couch. An Aquaplast (WFR/Aquaplast Corporation, Avondale, PA) mask, custom head holder, and shoulder straps are used to immobilize the head and neck and to depress the level of the shoulders. Bolus material should be applied over scars in the neck. Intravenous contrast may be helpful in defining target volumes and normal-tissue structures, but this is contraindicated if I-131 is being considered within the next 3 months. Axial CT images are acquired from above the skull base to the middle of the chest. Although not necessary, preoperative image sets may be fused to treatment planning CT scans to aid in target definitions. Historically, conventional anterior posterior/posterior anterior or lateral fields have been described to treat thyroid cancer, often requiring custom bolus materials to ensure homogenous dose distributions. Because the target volume straddles the level of the shoulder and, in nearly all cases, contains concavities with envaginated critical normal tissues, we treat all thyroid cancer cases with intensity-modulated radiotherapy (IMRT). We do not routinely bolus neck scars because the tangential beams in the IMRT plan deliver a high dose to the skin of the low neck.

External Beam Radiotherapy Dose and Target Guidelines

Table 53.11 lists the major publications from the modern era with dose and target volume information related to EBRT with curative intent for thyroid cancer. Table 53.10 summarizes the guidelines that we use.

Sequencing of External Beam Radiotherapy and I-131 Treatment

When there are indications for both EBRT and I-131 treatment, there is the question of sequencing. There is no high-quality study specific to this question.

In the words of the American Head and Neck Society Consensus guidelines: "There is no consensus on the optimal sequence of EBRT and I-131."[56]

The argument for starting with EBRT is that it often minimizes delay to starting adjuvant treatment. The argument for starting with I-131 is concern that EBRT will "stun" cancer cells in a way that decreases uptake of I-131.

We individualize the decision based on projected delay to administering I-131 treatment and the likelihood that I-131 treatment will increase the chance of cure. In most cases, we deliver EBRT first.

TABLE 53.10 INDICATIONS FOR EXTERNAL BEAM RADIOTHERAPY FOR DIFFERENTIATED THYROID CANCER

Age	University of Florida	ATA Guidelines[62,80]	NCCN Guidelines v1.2017[41]	AHNS Guidelines[56]
Age ≤ 18 y	Painful metastases or impending normal tissue damage from a growing tumor not amenable to other treatment	No child-specific guidelines	No child-specific guidelines	No child-specific guidelines
Age > 18 y with visible, unresectable neck disease	Most situations where surgery is not able to remove all visible tumor with acceptable morbidity, but age is a factor Because of the increased risk of complications from EBRT in young patients, we usually treat small-volume (<2 cm^3), unresectable residual tumor in the neck in patients < 55 years old with I-131 without EBRT if the patient is I-131	Recommendation 71 [C22]: EBRT is considered for locoregional recurrence that is not surgically resectable, particularly in patients with no evidence of distant disease.	Consider EBRT for gross disease that is unresectable and/or threatening vital structures.	EBRT is recommended for patients with gross residual or unresectable locoregional disease, except for patients <45 years old with limited gross disease that is I-131-avid.

	naive. We do not use EBRT if I-131 may be curative, or elevated Tg is the only sign of disease.			
Age > 18 y: *Adjuvant treatment soon after thyroidectomy*	Most cases with stage T_4 primary tumor or nodal metastases with extensive extranodal extension, but age is a factor. We often do not give adjuvant EBRT in patients < 55 years old with risk factors for microscopic residual tumor. We do not use EBRT if I-131 may be curative, or elevated Tg is the only sign of disease.	There is no role for routine adjuvant EBRT to the neck in patients with DTC after initial complete surgical removal of the tumor.	No guidelines in the absence of unresectable disease	EBRT should not be used routinely as adjuvant therapy after complete resection of gross disease.
Age > 18 y: *After gross total resection of recurrence following initial therapy*	Same as for adjuvant EBRT after thyroidectomy	No guidelines in the absence of unresectable disease	No guidelines in the absence of unresectable disease	After complete resection, EBRT may be considered in select patients older than 45 y of age with a high likelihood of microscopic residual disease and a low likelihood of responding to I-131. This scenario may occur in the setting of gross extrathyroidal extension or with revision surgery for

	persistent or recurrent disease.

THYROID-STIMULATING HORMONE SUPPRESSION FOR DIFFERENTIATED THYROID CANCER

A common practice in management of DTC is administration of supratherapeutic doses of T_4 in an effort to drive the TSH below detectable limits (<0.1 mIU/L), thereby decreasing stimulation of residual benign and malignant follicular-derived thyroid cells. There is *in vitro* evidence that TSH receptor stimulation is sufficient to initiate thyroid tumorigenesis.[57] A large retrospective series of patients with DTC with 30 years of follow-up showed that, compared with no adjunctive therapy, treatment with TSH suppression with T_4 resulted in a 50% reduction in cancer deaths (6% vs. 12%).[58] Another study showed that the degree of TSH suppression (TSH ≤ 0.05 mIU/L vs. ≥1 mIU/L) was associated

with improved relapse-free survival.[59]

A major limitation to TSH suppression is the associated toxicity as these patients experience subclinical and even overt thyrotoxicosis. As such, these patients are prone to bone demineralization and cardiac abnormalities, including tachyarrhythmia, conduction abnormalities, increased contractility, ventricular hypertrophy, systolic and diastolic dysfunction, and even cardiac death.[60] Nevertheless, a meta-analysis with over 4,000 patients with DTC demonstrated that the relative risk of major adverse clinical events was 0.73 ($P < .05$) favoring a "likely" or "questionable" benefit to TSH suppression in 15 of 17 trials.[61] The authors concluded that TSH suppression is justified following initial therapy for DTC. The authors recommend TSH suppression to just below 0.1 mU/L for high-risk thyroid cancer patients, while maintaining the TSH at or slightly below the lower limit of normal (0.1 to 0.5 mU/L) in patients at low risk of recurring.

CHEMOTHERAPY AND TARGETED AGENTS FOR DIFFERENTIATED THYROID CARCINOMA

There are two settings where chemotherapy or targeted systemic therapy is indicated: adjuvant treatment or treatment for recurrent or metastatic disease for which surgery, EBRT, or I-131 treatment is not a reasonable option.

The ATA's statement summarizes the view of most experts regarding the adjuvant situation: "RECOMMENDATION 61: There is no role for routine systemic adjuvant therapy in patients with DTC (beyond I-131 and/or TSH suppressive therapy using [levothyroxine])."[62]

There is no standard treatment for DTC that is not likely to respond to surgery or radiation therapy. Traditional systemic cytotoxic therapies have no significant role because of poor response rates.[63] Recent advances in targeted therapeutics have opened new doors for effective systemic therapy for recurrent or metastatic disease that is unresponsive to I-131. Most of the agents currently under investigation target specific pathways involved in cellular proliferation through inhibition of tyrosine kinase (TKI) receptors and angiogenesis through inhibition of vascular endothelial growth factor receptors (VEGFRs). This is a rapidly evolving area. Section C41 of the ATA guidelines summarizes the status of this issue as of late 2015.[62] The NCCN guidelines include a brief summary about the most common systemic programs.[41]

MANAGEMENT OF MEDULLARY THYROID CARCINOMA

All patients with MTC should be tested for *RET* mutations, including sporadic cases. Genetic screening and testing is also indicated. Similar to follicular epithelial–derived DTC, initial primary management of localized MTC is total thyroidectomy, which is the only completely effective therapy. Central neck dissection should be performed in all cases, and compartment-oriented lateral neck dissection is indicated when clinically involved. There is no role for adjuvant I-131 therapy. All patients should be followed with serum calcitonin levels as this presents a sensitive and specific marker for extent of residual disease.

MTC is uncommon and most of the time it behaves as an indolent disease where long survival with uncontrolled tumor is common. For these reasons, there are few studies on the role of EBRT. The American Head and Neck Society consensus document is currently the best summary of this issue.[64]

Traditional cytotoxic systemic therapies have been ineffective in the management of metastatic or recurrent MTC; however, recent advances in therapies targeting the *RET*–tyrosine kinase receptors have shown promising preclinical and early clinical results.[65–69]

MANAGEMENT OF ANAPLASTIC THYROID CARCINOMA

The ATA consensus guidelines explain the major issues and relevant literature related to diagnosis and treatment of ATC.[70]

Complete surgical excision should be the goal of initial therapy, when feasible. However, surgery should be avoided when complete excision is not possible as debulking does not improve outcomes. There is no therapeutic role for I-131.

The great majority of patients with ATC present with poor performance status and locally advanced disease such that gross total resection is not possible. For this reason, the goal of treatment in most ATC cases is palliation.

Patients with a good performance status and no evidence of distant metastases should be offered aggressive treatment with maximum safe resection and EBRT, with or without concurrent chemotherapy. There is no consensus on the EBRT fractionation program, but a recent study of the National Cancer Database showed that survival was better when the EBRT total dose was 60 to 75 Gy as compared to lower doses.[71] In our program, we usually use the 70/63/56 Gy program described in Table 53.12.

TABLE 53.12 UNIVERSITY OF FLORIDA EXTERNAL BEAM RADIOTHERAPY NECK TARGET VOLUME AND DOSE GUIDELINES FOR THYROID CANCER

Standard Fractionation with Moderate Risk of Recurrence: 60/54-Gy Prescriptions

We use this program when our indication for EBRT is met and there is NO evidence of visible residual tumor, extranodal extension of tumor, or surgical margin < 0.5 cm.

CTV 60 Gy at 2 Gy = Postoperative areas thought to be at high risk for recurrence. These include areas where recurrent tumor was resected plus a 1-cm margin edited for anatomic boundaries to tumor spread and dissected nodal stations with pathologically positive nodes.

CTV 54 Gy at 1.8 Gy = Undissected nodal stations that we judge to be at > 10% risk of recurrence

PTVs = CTV + 0.3 cm

Standard Fractionation with High Risk of Recurrence: 70/63/56-Gy Prescriptions

We use this program when our indication for EBRT is met and there is visible residual tumor, extranodal extension of tumor, or surgical margin < 0.5 cm

CTV 70 Gy at 2 Gy = Visible residual tumor and/or postoperative areas with close margin or extranodal extension, plus a 1-cm margin edited for anatomic boundaries to tumor spread.

CTV 63 Gy at 1.8 Gy = Dissected nodal stations with pathologically positive nodes

CTV 56 Gy at 1.6 Gy = Undissected nodal stations that we judge to be at > 10% risk of recurrence

PTVs = CTV + 0.3 cm

Stereotactic Body Radiation Therapy (SBRT)

We use neck SBRT for small-volume (<2 cm^3) visible disease in situations where we judge the risk of treating a larger volume to be unacceptable. We do not have criteria for choosing the 50 vs. 35 Gy schedules.

A single target volume: CTV = GTV, PTV = CTV + 0.2 cm

Dose to 95% of PTV = 50 Gy at 5 Gy (10 treatments) or 35 Gy at 7 Gy (5 treatments)

The most aggressive approach is to combine EBRT with chemotherapy involving a taxane, anthracycline, platin, or a combination. In our program, we rarely use chemotherapy with EBRT for ATC because of the high toxicity of combination therapy in this setting.

CHAPTER 54

Lung Cancer

Jing Zeng, Ramesh Rengan, Indrin J. Chetty, Roy H. Decker, Rafael Santana-Davila, Corey J. Langer, William P. O'Meara, and Benjamin Movsas

EPIDEMIOLOGY

Throughout the world, lung cancer accounts for 13% (1.8 million) of the total cases of cancer and 18% (1.6 million) of the cancer-related deaths based on 2012 estimates.[1] Among males, lung cancer is the most commonly diagnosed cancer and leading cause of cancer death. Among females worldwide, it is the fourth most commonly diagnosed cancer and the second leading cause of cancer death.

In the United States, lung cancer is the second most common cancer and the most common cause of cancer-related death in both men and women. The American Cancer Society estimates 155,870 people in the United States died of lung cancer in 2017, including 84,590 men and 71,280 women.[2] More people in the United States die of lung cancer than from breast, prostate, and colorectal cancer combined. The overall 5-year survival rate for lung cancer is approximately 18%.[3]

The overall incidence and mortality rate for lung cancer rose steadily from the 1930s until peaking in the early 1990s. The incidence and mortality rates for men began to drop around 1990, and a slight drop in the incidence and mortality rates for women has only recently been measured. The lag in the trend of lung cancer rates in women compared with men reflects historical differences in cigarette smoking between the sexes; cigarette smoking in women peaked about 20 years later than in men. Gender and racial disparities exist in the incidence and mortality for lung cancer with rates highest in men, particularly those who are African American. In terms of socioeconomics, lung cancer demonstrates the largest disparity of all cancers, with the death rate in men five times higher for the least educated than for the most educated.[2]

Although the lung cancer numbers in the general population are startling, the

main risk of lung cancer is based on exposures to carcinogens; most lung cancer cases are attributable to cigarette smoking. Voluntary or involuntary cigarette exposure accounts for 80% to 90% of all cases of lung cancer. Since the 1964 landmark report by US surgeon general citing smoking as a causal agent for the development of lung cancer, the prevalence of smoking in the United States has declined significantly. More recently, exposure to secondhand smoke has been considered a risk for lung cancer with up to a 30% increase in risk from secondhand smoke exposure associated with living with a smoker. Indoor radon exposure is now considered the second leading cause of lung cancer in the United States. Other known risk factors for lung cancer include exposure to occupational and environmental carcinogens such as asbestos, arsenic, and polycyclic aromatic hydrocarbons.

ANATOMY

In the past, a simplified and relatively superficial understanding of thoracic anatomy provided an acceptable framework for the radiation oncologist to design treatment fields in lung cancer patients utilizing conventional techniques with the carina and bony structures as landmarks. As the field of thoracic radiation oncology has moved toward more conformal therapy, however, a more detailed understanding of thoracic anatomy is essential for proper target delineation and treatment design.

The lungs are situated on each side of the mediastinum, which contains the heart, trachea, esophagus, and great vessels. The lungs are conical in shape with an apex projecting upward into the neck for approximately 2 to 3 cm above the clavicle, a base sitting on the diaphragm, a costal surface along the chest wall, and a mediastinal surface that is molded to the heart and other mediastinal structures. Visceral pleura cover the lungs, and parietal pleura cover the inside of the chest cavity. The lungs are freely suspended but are rooted to the mediastinum by the structures emerging from the hilum.

The lungs are divided into distinct lobes—three lobes to the right lung and two to the left. The right lung is divided into the upper, middle, and lower lobes by the oblique (major) and horizontal (minor) fissures. The oblique fissure runs forward and downward from approximately the level of the fifth thoracic vertebral body to the diaphragm, dividing the lungs into upper and lower lobes. The horizontal fissure separates the right middle from the right upper lobe, fanning out forward and laterally from the hilum. The middle lobe is thus a

small, triangular lobe bounded by the horizontal and oblique fissures and actually rests on the diaphragm. The left lung is divided by only the oblique fissure into two lobes—the upper and lower lobes. The lingula, located in the left upper lobe, is homologous to the right middle lobe and also touches the diaphragm.

The bronchopulmonary segment is the functional unit of the lung and is defined by the segmental bronchi. The trachea bifurcates at the carina, which lies at the junction between the manubrium and body of the sternum, into the right and left main bronchi. Each main bronchus divides into lobar bronchi, each supplying a lobe of the lung. Although the lingula is located in the left upper lobe, the lingular bronchus is considered by many a lobar bronchus. Each lobar bronchus divides into smaller bronchi that form the bronchopulmonary segments. These segments are pyramidal in shape, with an apex toward the lung root and a base at the pleural surface. Structures entering each bronchopulmonary segment (i.e., bronchus and artery) tend to lie centrally. Structures leaving the segment (i.e., veins and lymphatics) lie in the periphery of the segment within the connective tissue that separates the segments. Segmental bronchi divide into bronchioles, continue to branch, and eventually form the alveoli, where blood–gas exchange occurs.

The main lymphatic drainage for each bronchopulmonary segment follows the vasculature and airways toward the hilum, where it ultimately drains into the mediastinum. However, the rich network of lymphatics within the thorax leads to complex variability in drainage patterns.

The International Association for the Study of Lung Cancer (IASLC) developed a lymph node map that reconciles differences among older maps and provides precise anatomic definitions for all lymph node stations.[4] The IASLC lymph node map has been endorsed by the American Joint Committee on Cancer (AJCC) and incorporated into the staging manual. The IASLC lymph node map designates 14 lymph node levels compartmentalized into intrapulmonary, hilar, and mediastinal zones that have prognostic implications and are utilized in common clinical practice.

CLINICAL PRESENTATION AND PATTERNS OF SPREAD

Lung cancer spreads locally by direct extension of the primary tumor, regionally via involvement of the lymphatics, and distantly via invasion into vascular channels leading to hematogenous spread. In a Surveillance Epidemiology and

End Results (SEER) analysis involving all lung cancer histologies, 15% of all cases of lung cancer were localized to the primary site at initial diagnosis; 22% had regional lymph node spread and 56% distant metastasis; and the remaining 7% were stage unknown.[3] In non–small cell lung cancer (NSCLC), half the patients present with localized or locally advanced disease and half with advanced disease. In small cell lung cancer (SCLC), 20% to 30% present with locally advanced disease, and 70% to 80% present with advanced disease. Table 54.1 shows the site of metastasis based on histologic type.[5] Signs and symptoms of lung cancer directly reflect the patient's local, regional, or distant pattern of spread.

Intrathoracic Spread

The intrathoracic spread of lung cancer involves direct extension of the primary tumor or lymphatic spread to regional lymph nodes involving the hilum or mediastinum. There is a wide range of symptoms owing to the intrathoracic effects of lung cancer; the most common include cough, dyspnea, hemoptysis, and chest pain.

TABLE 54.1 SITE OF METASTASIS CORRELATED WITH HISTOLOGIC SUBTYPE IN LUNG CANCER: NECROPSY FINDINGS IN CARCINOMA OF THE BRONCHUS IN 255 PATIENTS WITH METASTASES TO 431 SITES

Site of Metastasis	Squamous	Small Cell	Anaplastic	Adenocarcinoma
Lymph nodes	137 (54%)	163 (85%)	135 (76%)	42 (75%)
Liver	58 (23%)	122 (64%)	67 (38%)	26 (47%)
Adrenals	54 (21%)	84 (44%)	69 (39%)	17 (30%)
Bones	59 (23%)	75 (39%)	53 (30%)	23 (41%)
Brain	26 (17%)	45 (42%)	30 (24%)	13 (39%)
Kidney	39 (15%)	28 (15%)	24 (14%)	11 (20%)
Pancreas	9 (4%)	46 (24%)	25 (14%)	3 (5%)
Lung	31 (2%)	13 (7%)	15 (8%)	8 (14%)
Pleura	18 (7%)	21 (11%)	9 (5%)	3 (5%)
Total	**255**	**191**	**179**	**56**

The central etiology for many symptoms is owing to a growing tumor involving the airway. Cough is present in 50% to 75% of lung cancer patients at

presentation and occurs most frequently in patients with squamous cell and small cell carcinomas because of their tendency to involve central airways. Tumor eroding into a blood vessel or bleeding from the neovasculature supplying the tumor may lead to hemoptysis, which is a presenting symptom in approximately 25% of patients. If tumor blocks airflow through a portion of the lung, shortness of breath may develop and is identified at presentation in approximately 25% of cases.[6] Dyspnea may also be due to the development of atelectasis, postobstructive pneumonia, or a pleural or pericardial effusion.

Chest pain is present in approximately 20% of patients presenting with lung cancer.[6] Pain may be attributed to direct extension to the mediastinum, parietal pleura, or chest wall. Pleuritic pain may also be the result of obstructive pneumonitis or a pulmonary embolus related to a hypercoagulable state. Pleural involvement can also manifest as pleural thickening or pleural effusion. During the course of lung cancer, 10% to 15% of all cases will eventually develop a malignant pleural effusion.

Direct extension of a central primary tumor or mediastinal lymph node involvement may lead to nerve involvement. Involvement of the recurrent laryngeal nerve along its course under the arch of the aorta can result in hoarseness. Irritation of the phrenic nerve may initially produce hiccups, and progressive damage can produce unilateral paralysis of the diaphragm with shortness of breath.

Obstruction of the superior vena cava (SVC) from primary tumor or mediastinal lymphadenopathy causes symptoms that commonly include a sensation of fullness in the head and dyspnea. Physical findings include jugular venous distension and occasionally swelling of the face and arms. SVC syndrome is more common in patients with SCLC than NSCLC. The pathophysiology and treatment options for the management of patients with SVC syndrome are discussed in more detail later.

Primary tumors arising within the superior sulcus may produce the classic Pancoast syndrome manifested by shoulder pain, Horner syndrome, and brachial plexopathy. Pancoast syndrome is most commonly caused by NSCLC and only rarely by SCLC. The treatment of patients with superior sulcus tumors (SSTs) will be discussed later.

Distant Extrathoracic Spread

Once vascular or lymphatic invasion occurs, metastatic dissemination to distant sites is common. Contralateral lung, liver, bone, adrenals, and brain are the most

frequent sites of distant disease; however, lung cancer can spread to any part of the body (Table 54.1).

Asymptomatic liver metastases may be detected at presentation by liver enzyme abnormalities or on staging workup imaging. Pain in the back, chest, or extremity and elevated levels of serum alkaline phosphatase are usually present in patients with bone metastasis. The serum calcium may be elevated owing to extensive bone disease, although the majority of patients with elevated calcium have paraneoplastic parathyroid hormone (PTH)–like syndrome. Approximately 20% of patients with NSCLC and 30% to 40% of patients with SCLC have bone metastases at presentation. An osteolytic radiographic appearance is more frequent than an osteoblastic one, although a mixed picture is common. The most common sites of involvement are the vertebral bodies.

The adrenal glands are a frequent site of metastasis; however, such metastases are only rarely symptomatic. Concern about adrenal metastasis usually occurs when a unilateral mass is found by staging computed tomography (CT) in a patient with a known or suspected lung cancer. Most adrenal masses detected on staging scans are benign. Conversely, a negative imaging study does not exclude adrenal metastases. The lack of specificity of an initial CT scan in identifying an adrenal mass creates a special problem in patients with an otherwise resectable lung cancer. In this situation, positron emission tomography (PET) may be particularly useful in distinguishing a benign from malignant adrenal mass. Other procedures that may be useful in excluding a metastasis include magnetic resonance imaging (MRI) consistent with a benign adenoma or a negative needle biopsy. Involvement of the adrenal glands is more frequent in patients with widely disseminated disease. In autopsy series, adrenal metastases were identified in about 40% of patients with lung cancer.[7] Patients with an isolated adrenal metastasis but otherwise limited thoracic disease seem to have a much better prognosis than other stage IV disease and may be considered for aggressive definitive management.

Symptoms from brain metastasis include headache, vomiting, visual field loss, hemiparesis, cranial nerve deficit, and seizures. In patients with NSCLC, the frequency of brain metastasis is greatest with adenocarcinoma and least with squamous cell carcinoma. The risk of brain metastasis increases with larger primary tumor size and regional node involvement. In patients with SCLC, metastasis to brain is present in approximately 20% to 30% of patients at presentation. An autopsy series of SCLC patients disclosed central nervous system (CNS) metastases in 80% of cases.[8]

Paraneoplastic Syndromes

A paraneoplastic syndrome is a disease or symptom that is the consequence of cancer cells in the body but is not attributable to the local presence of tumor. These phenomena are thought to be mediated by humoral factors secreted by tumor cells or by an immune response against the tumor. Treating the cancer, if successful, usually resolves the syndrome. Some of the more common paraneoplastic syndromes are described next.

Cushing Syndrome

Ectopic production of adrenocorticotropic hormone (ACTH) can cause Cushing syndrome. Patients typically present with muscle weakness, weight loss, hypertension, hirsutism, and osteoporosis. Hypokalemic alkalosis and hyperglycemia are usually present. Cushing syndrome is relatively common in patients with SCLC and with carcinoid tumors of the lung. SCLC patients with Cushing syndrome appear to have a worse prognosis than those without Cushing syndrome.

Syndrome of Inappropriate Antidiuretic Hormone Secretion

The syndrome of inappropriate antidiuretic hormone (SIADH) secretion is frequently caused by SCLC and results in hyponatremia. Approximately 10% of patients who have SCLC exhibit SIADH, and SCLC accounts for approximately 75% of all SIADH. Symptoms include headache, muscle cramps, anorexia, and decreased urine output. If left untreated, cerebral edema can develop, leading to mental status changes, coma, seizures, and respiratory arrest. Besides treating the underlying cancer, demeclocycline is the agent of choice.

Hypercalcemia

Hypercalcemia in patients with lung cancer may be attributable to the secretion of a parathyroid hormone–related protein (PTHrP), calcitriol, or other cytokines, including osteoclast-activating factors. In one study of 1,149 consecutive lung cancers, 6% of patients had hypercalcemia.[9] Among those with hypercalcemia, squamous cell carcinoma, adenocarcinoma, and SCLC were responsible in 51%, 22%, and 15% of cases, respectively. Symptoms of hypercalcemia include anorexia, nausea, vomiting, constipation, lethargy, polyuria, polydipsia, and dehydration. Renal failure, confusion, and coma are late manifestations.

Lambert-Eaton Myasthenic Syndrome

Lambert-Eaton myasthenic syndrome (LEMS) is an autoimmune disorder

characterized by muscle weakness of the limbs that improves with repeated testing, in contrast to myasthenia gravis, which worsens with repetition. Proximal muscles are predominantly affected, and patients complain of difficulty climbing stairs and rising from a sitting position. Approximately 3% of patients with SCLC exhibit LEMS, and SCLC accounts for approximately 60% of all LEMS.[10] The neurologic symptoms of LEMS precede the diagnosis of SCLC in >80% of cases, often by months or years.

Hypertrophic Osteoarthropathy

Hypertrophic pulmonary osteoarthropathy (HPO), most frequently associated with adenocarcinoma, is defined by clubbing and periosteal proliferation of the tubular bones. HPO is further characterized by a symmetrical, painful arthropathy that usually involves the ankles, knees, wrists, and elbows. A radiograph of the long bones shows characteristic periosteal new bone formation. A bone scan or PET typically demonstrates diffuse uptake by the long bones. In a series of 111 lung cancer patients, clubbing was present in 29%.[11]

SCREENING, DIAGNOSTIC STAGING, AND WORKUP

Screening for Lung Cancer

Given the high mortality rate of lung cancer and that the majority of patients are diagnosed at a late stage, lung cancer researchers have theorized that identifying lung cancer at an earlier stage might improve outcomes. Early screening trials involving chest x-rays and/or sputum failed to demonstrate a survival benefit. The role of screening has recently been reinvestigated with the advent of spiral CT scans. Early pilot trials of spiral CT in lung cancer screening looked promising with an increase in the identification of stage I detectable cancer. A subsequent international observational trial using spiral CT screening in a cohort of 31,000 high-risk individuals corroborated the findings, showing that annual spiral CT screening could detect lung cancer at an early, potentially more curable stage, suggesting that the stage I disease detection rate and 10-year survival rate could both exceed 80%.[12] This set the groundwork for the landmark National Lung Screening Trial (NLST).[13] From 2002 to 2004, 53,454 current or former heavy smokers at 33 US medical centers were randomly assigned to three annual screenings with either low-dose CT (26,722 participants) or standard chest x-ray (26,732). Eligible participants were between 55 and 74 years of age with a history of cigarette smoking of at least 30 pack-years and, if former smokers,

had quit within the previous 15 years. Persons who had previously received a diagnosis of lung cancer, had undergone chest CT within 18 months before enrollment, had hemoptysis, or had an unexplained weight loss >6.8 kg (15 lb) in the preceding year were excluded. The findings revealed that participants who received low-dose helical CT scans had a 20% relative reduction in risk of death caused by lung cancer compared with the control radiography group (P = .004). Additionally, the all-cause mortality was reduced in the CT screening group by 6.7% when compared with the control group (P = .02). This is the first randomized trial to demonstrate a reduction in all-cause mortality with screening and has led to the development of lung cancer screening programs throughout the country.

Diagnostic Staging and Workup

When a patient presents with suspected lung cancer, testing is indicated to confirm the diagnosis, identify the histologic type, and determine the disease stage, all in an effort to guide management decisions. The process begins with a thorough history and physical examination to identify signs or symptoms suggestive of locally extensive or metastatic disease, assess pulmonary health status, identify significant comorbidities, and assess overall health status. Each impacts the therapeutic options in a more comprehensive manner than stage alone. A detailed history should also elicit tobacco use and past exposure to environmental carcinogens. Weight loss >5% from baseline has direct prognostic implications for survival in lung cancer.

Physical examination of the chest may detect signs of partial or complete obstruction of the airways, pneumonia, or pleural effusion. Examination of the neck can reveal evidence of supraclavicular lymphadenopathy. Abdominal examination may detect hepatomegaly. Neurologic examination can detect signs of brain metastasis.

Laboratory studies include complete blood count, liver function tests, and serum electrolytes including calcium. Renal function tests should be performed to assess whether the patient can tolerate intravenous contrast for CT examination or subsequent platinum-based therapy. Liver function test abnormalities could be owing to liver metastasis. Elevation of alkaline phosphatase could be due to liver or bone metastasis. Calcium elevation could be from bone metastasis or paraneoplastic syndrome. Anemia could be owing to metastatic disease.

Radiologic Examinations

Computed Tomography

All patients with suspected lung cancer, with or without an abnormal chest x-ray, should undergo a contrast-enhanced CT scan of the chest and upper abdomen to include the entire liver and adrenal glands. Intravenous contrast helps to distinguish vascular structures from mediastinal structures. This not only adds detail to the imaging characteristics of the primary tumor but also is critical to accurately identify suspicious lymph nodes in the mediastinum. CT assessment can establish T-stage by determining tumor size, presence of separate tumor nodules, presence of atelectasis or postobstructive pneumonia, invasion of adjacent structures, and proximal extent of the tumor.

Lymph node enlargement on CT presumes lymph node metastasis in the context of newly diagnosed lung cancer. Most normal mediastinal lymph nodes measure <1 cm, although normal nodes subcarinal lymph can reach a diameter 1.5 of cm. In a patient with known lung cancer, a lymph node is considered suspicious if it measures >1 cm in diameter on its short axis. Unfortunately, many subcentimeter regional lymph nodes may still harbor metastasis. In one study involving pathologic staging, up to 44% of nodes with metastatic deposits were <1 cm in diameter, and 18% of patients with pathologically involved mediastinal nodes did not have any nodes >1 cm.[14]

Positron Emission Tomography or Positron Emission Tomography–Computed Tomography

PET scanning has become standard in the staging workup of lung cancer patients. Although the primary tumor characteristics are usually clearly staged with a CT scan, PET can help distinguish atelectasis from tumor in certain cases. The largest benefit provided by PET is the identification of malignant disease in lymph nodes of normal size or distant metastasis not seen on CT scan. Kalff et al.[15] prospectively evaluated the utility of PET in patients with lung cancer, performing a PET scan on 105 consecutive clinically staged patients with a diagnosis of NSCLC. They found that PET correctly upstaged 26% of patients to palliative from curative intent therapy and appropriately downstaged 10 of 16 patients initially designated for palliative therapy. Integrated PET-CT scanners fuse images obtained in tandem from PET and CT, thus providing both anatomic and metabolic information simultaneously. This is superior to CT or PET alone and can detect malignancy in tumors as small as 0.5 cm.

Although PET has dramatically improved the noninvasive staging of lung

cancer patients, it does have some key limitations. On meta-analysis, the sensitivity and specificity of CT for mediastinal nodal metastasis were estimated to be approximately 59% and 79%, respectively, and the sensitivity and specificity of PET were approximately 81% and 90%, respectively.[16] This same meta-analysis also found a difference in the accuracy of PET based on the CT size of a lymph node with a sensitivity of 91% for enlarged mediastinal nodes and 75% for nonenlarged nodes. Because false positives and false negatives are observed with PET, tissue sampling should be pursued to confirm the presence or absence of regional lymph node involvement before a treatment decision is made. A positive PET should not be considered proof of lymph node metastasis, especially if such a conclusion would otherwise exclude surgery.

With highly conformal radiation therapy for lung cancer becoming commonplace, PET is now being used to aid radiation oncologists in the target delineation process for involved-field radiotherapy (IFRT). Registration of PET with the planning CT scan at the contouring stage has been shown to enhance the accuracy of defining gross tumor volumes (GTVs). The clinician must be mindful that target volumes based solely on 18F-fluorodeoxyglucose (FDG)-PET positivity have their limitations, with the most notable being a false-negative rate of approximately 25% in mediastinal lymph nodes <1 cm in size.[16] Additionally, the optimal windowing algorithm for the purposes of contouring remains to be determined. Depending on the algorithm employed, the volume that is contoured can vary significantly. When benchmarked against the true pathologic volume, at present, the CT-derived contour appears to be more accurate than that derived from FDG-PET regardless of the algorithm employed.

Special Diagnostic Procedures

Percutaneous Fine Needle Aspiration

CT-guided fine needle aspiration (FNA) is an excellent method for establishing a tissue diagnosis from a suspicious peripheral pulmonary nodule that cannot be reached by bronchoscopy. The risk of a pneumothorax from this procedure is 25%. However, most of these are small and asymptomatic and resolve without intervention; only approximately 5% require a chest tube. The overall diagnostic yield is 80%. Indeterminate biopsies must be interpreted with caution. FNA cannot rule out malignancy unless another benign diagnosis can clearly be established. Abnormalities involving bone, liver, and adrenal glands can also be confirmed by CT-guided FNA. Frequently, biopsy of one of these suspected metastatic sites simultaneously establishes tissue diagnosis and stage of the

disease. Increasingly, as we enter the modern era of molecularly guided therapy, core biopsies are displacing FNAs. This increases the risk but also increases the yield.

Bronchoscopy

Fiberoptic bronchoscopy enables visualization of the tracheobronchial tree to the second or third segmental divisions. Cytologic brushings or biopsy forceps specimens can be obtained from identified lesions. Even when no visible lesion is identified, the bronchus draining the area of suspicion can be lavaged for cytologic analysis. Navigational bronchoscopy is a real-time guidance system that combines fiberoptic bronchoscopy with special CT imaging techniques to guide the bronchoscope to specified locations within the bronchial tree. Using this approach, a virtual map of the bronchial tree is generated from a high-resolution CT scan of the chest, enabling the physician to monitor the location of the bronchoscope in real time through feedback from a positional sensor attached to the tip of the bronchoscope. This approach may significantly improve the diagnostic yield for peripheral lesions.

Endoscopic Ultrasound

Fiberoptic endoscopy techniques can also be combined with ultrasound to evaluate mediastinal and hilar lymph nodes. Endobronchial ultrasound-guided needle transbronchial aspiration (EBUS-TBNA) involves FNA sampling of ultrasound-suspicious lymph nodes, especially those located in the paratracheal (lymph node levels 2 and 4), subcarinal (level 7), or hilar lymph node stations (level 10). A prospective study comparing EBUS-TBNA with PET-CT scans revealed an accuracy of 98% and a sensitivity and specificity of 92% and 100%, respectively.[17] An esophageal approach known as transesophageal endoscopic ultrasound-guided fine needle aspiration (EUS-FNA) can perform the same function, especially the sampling of mediastinal nodes that are posterior or inferior, such as the retrotracheal (lymph node station 3p), subcarinal (level 7), paraesophageal (level 8), and pulmonary ligament lymph nodes (level 9).

Thoracentesis

Most pleural effusions in lung cancer patients are owing to tumor and should be evaluated with thoracentesis. In general, a diagnosis of cancer can be established in 70% to 80% of malignant effusions by thoracentesis. Even if cytology fails to identify cancer cells, repeat thoracenteses improve the diagnostic yield. If on multiple taps the fluid is consistently bloody or exudative, it should be

considered malignant. Light criteria[18] can be used to help classify an effusion as exudative or transudative. As an alternative to repeat thoracentesis, thoracoscopy can be used to simultaneously collect pleural fluid for cytology, visualize the pleural space and biopsy suspicious lesions if present, and perform lymph node biopsies if indicated.

Mediastinoscopy and Mediastinotomy

Mediastinoscopy remains the most accurate technique to assess upper and lower paratracheal (lymph node stations 2 and 4), prevascular (station 3a), retrotracheal (station 3p), subcarinal (station 7), and hilar lymph nodes (station 7) in lung cancer patients. Lymph nodes within the aortopulmonary window (lymph node station 5) and along the ascending aorta (station 6) are not accessible by standard mediastinoscopy techniques; however, they can be evaluated by anterior mediastinotomy (also known as the Chamberlain procedure) or video-assisted thoracoscopic techniques. Although considered the gold standard, mediastinoscopy does have a false-negative rate of approximately 10%. Furthermore, the role of mediastinoscopy for lung cancer has evolved recently. Less invasive techniques such as EBUS-TBNA or EUS-FNA are frequently utilized instead to sample lymph nodes found to be clinically suspicious on imaging. Mediastinoscopy should still be considered in situations where less invasive techniques are nondiagnostic. It is reasonable to forgo invasive staging of the mediastinum in patients with clinical stage I peripheral disease, particularly those with PET-positive primary tumors but no mediastinal uptake and no obviously enlarged nodes on CT. Patients with more locally advanced disease being considered for surgery should undergo mediastinoscopy to rule out N3 disease and to identify those with N2 disease for whom induction therapy should be considered prior to surgery.

Thoracoscopy

Video-assisted thoracoscopy is frequently used for the diagnosis, staging, and resection of lung cancer. Peripheral nodules can be identified and excised using video-assisted, minimally invasive techniques. As discussed previously, this technique is also extremely valuable for evaluation of suspected pleural disease when thoracentesis has been nondiagnostic. Thoracoscopy can also be used to reach mediastinal nodes not accessible by standard mediastinoscopy, EBUS-TBNA, or EUS-FNA techniques.

STAGING

The eighth edition of the AJCC *Cancer Staging Manual* was published in late 2016 and will be enacted in January 2018. The IASLC established a Lung Cancer Staging Project in 1998 to bring together larger databases available worldwide. The IASLC lung cancer database is comprised of 94,708 cases available for analysis from 35 sources in more than 16 countries, diagnosed between 1999 and 2000, and treated by all therapeutic modalities.[19] The results of this project were accepted by the AJCC in their staging manual. Definitions of TNM for the eighth edition of the manual are shown in Table 54.2; the stage groupings are shown in Table 54.3. This new staging system more accurately expresses the prognostic significance of both the T and N stages in lung cancer outcome.

TABLE 54.2 AJCC STAGING OF LUNG CANCER, 8TH EDITION

Tx	Primary tumor cannot be assessed, or tumor proven by the presence of malignant cells in sputum or bronchial washings but not visualized by imaging or bronchoscopy
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor 3 cm or less in greatest dimension, surrounded by lung or visceral pleura, without bronchoscopic evidence of invasion more proximal than the lobar bronchus (i.e., not in the main bronchus)
T1mi	Minimally invasive adenocarcinoma: adenocarcinoma (≤3 cm in greatest dimension) with a predominantly lepidic pattern and ≤5 mm invasion in greatest dimension
T1a	**Tumor is ≤1 cm in greatest dimension**
T1b	**Tumor >1 cm but ≤2 cm in greatest dimension**
T1c	**Tumor >2 cm but ≤3 cm in greatest dimension**
T2	Tumor >3 cm **but ≤5 cm** or having any of the following features: **involves the main bronchus but without involvement of the carina**; invades the visceral pleura; or **associated with atelectasis or obstructive pneumonitis that extends to the hilar region, involving part or all of the lung**
T2a	**Tumor >3 cm but ≤4 cm in greatest dimension**
T2b	**Tumor >4 cm but ≤5 cm in greatest dimension**
T3	**Tumor >5 cm but ≤7 cm in greatest dimension** or directly invading any of the following: parietal pleura, chest wall (including superior sulcus tumors), phrenic nerve, parietal pericardium, or separate tumor nodule(s) in same lobe as the primary
T4	**Tumor >7 cm** or tumor of any size of that invades diaphragm, mediastinum, heart, great vessels, trachea, recurrent laryngeal nerve, esophagus, vertebral body, or carina; separate tumor nodule(s) in an ipsilateral lobe different from that of the primary
N0	No regional lymph node involvement

N1	Involvement of ipsilateral intrapulmonary, or peribronchial, hilar lymph nodes
N2	Involvement of mediastinal or subcarinal lymph nodes
N3	Involvement of contralateral mediastinal or hilar lymph nodes. Involvement of ipsilateral or contralateral scalene or supraclavicular nodes
M0	No distant metastasis
M1	Distant metastasis present
M1a	Separate tumor nodule(s) in a contralateral lobe; tumor with pleural or pericardial nodule(s) or malignant pleural or pericardial effusion.
M1b	**Single extrathoracic metastasis**
M1c	**Multiple extrathoracic metastases in one or several organs**

Note: Changes from the 7th edition are in bold.

Given all of the various ways to assess lymph node status, accuracy in determining the nodal stage is essential. In accordance with IASLC recommendations adopted by the AJCC, when pathologic staging of lymph nodes is pursued, sampling of paratracheal (stations 2R and 4R), subcarinal (station 7), hilar (station 10R), and interlobar lymph nodes (station 11R) should be obtained for right-sided tumors, and aortopulmonary window (station 5), ascending aorta (station 6), subcarinal (station 7), hilar (station 10L), and interlobar (station 11L) lymph nodes for all left-sided tumors. Pulmonary ligament lymph nodes (station 9) should also be evaluated for lower lobe tumors. At least six lymph nodes (three from the mediastinum and three from the hilar region) should be examined. If all resected lymph nodes are negative but the number recommended is not met, the patient is still classified as pN0 in the AJCC staging system. For the radiation oncologist, proper staging of nodal disease has taken on increased importance as advances in conformal radiotherapy have resulted in elective mediastinal nodal irradiation being replaced by IFRT.

PATHOLOGIC CLASSIFICATION

The pathologic classification of lung cancer is undergoing significant transformation, driven primarily by recent therapeutic advancements in the management of advanced disease and the movement toward minimally invasive tissue acquisition procedures. The primary charge of the pathologist in the past had been to distinguish between non–small cell carcinoma and small cell carcinoma of the lung. However, since 2000, there are now important therapeutic implications for each of the four major classifications of lung cancer: (a) squamous cell carcinoma, (b) adenocarcinoma of the lung, (c) small cell carcinoma, and (d) large cell carcinoma. Histology is an important determinant in the selection of systemic therapy for advanced NSCLC. Bevacizumab, a monoclonal antibody (MAb) targeting VEGF, resulted in grade 4 and 5 pulmonary hemorrhage in patients with squamous cell histology; however, this agent in combination with standard chemotherapy has yielded a statistically

significant survival advantage in patients with nonsquamous histology.[20] An association between nonsquamous histology (including adenocarcinoma and large cell carcinoma) and improved survival has been observed with pemetrexed in combination with platinum-based chemotherapy.[21] Adenocarcinoma histology is often associated with the presence of epidermal growth factor receptor (EGFR) mutations that confer heightened sensitivity to EGFR tyrosine kinase inhibitor (TKI) therapy and with echinoderm microtubule-associated protein-like 4 (EML4) and anaplastic lymphoma kinase (ALK) translocations that confer sensitivity to the mesenchymal-epithelial transition factor (MET)/ALK inhibitor crizotinib. All of these changes are being incorporated into the pathologic classification scheme for lung and have resulted in modifications to the 2015 World Health Organization (WHO) classification scheme for resected specimens.[22]

PROGNOSTIC AND PREDICTIVE FACTORS

The recent advancements in our understanding of tumor biology have underscored the fact that lung cancer is a heterogeneous cluster of illnesses rather than simply a dual (small cell, non–small cell) disease entity. Given the varied clinical outcomes and significant toxicity of treatment, there is an underlying need for robust prognostic and predictive factors in this disease. Prognostic factors, such as TNM stage, are those that predict clinical outcome independent of therapy, and predictive factors are those that predict response to a particular therapeutic regimen. In general, a discussion of prognostic and predictive factors is divided into two categories: tumor-related factors and patient-related factors. In the near future, these factors may be incorporated into a comprehensive approach to tailor therapy not simply by TNM stage but individualized to the patient and the biology of the patient's tumor.

Tumor-Related Prognostic and Predictive Factors

The past decade has seen significant advances in our understanding of tumor-related prognostic and predictive factors. Sensitizing mutations in EGFR have been demonstrated to be predictive for response to therapy with EGFR inhibitors, such as erlotinib or gefitinib. KRAS mutations are both prognostic of poor survival and predictive for lack of response to EGFR inhibitors. ALK and ROS1 rearrangements are predictive for response to agents such as crizotinib. Other targetable mutations such as RET gene arrangement, BRAF mutations, MET amplification or mutation, and HER2 have also been identified, and

targeted agents have been approved for other malignancies but may be available in the near future or on a clinical trial.

Patient-Related Prognostic and Predictive Factors

Given the significant metabolic toll that lung cancer takes on patients, several patient-related factors have been identified as powerful prognostic indicators of clinical outcome. Performance status, as quantified by either the Karnofsky scale or the Eastern Cooperative Oncology Group (ECOG) scale, and weight loss in the 6 months preceding diagnosis have been shown in large trials to be among the factors most predictive of survival (along with TNM stage).[23] Additionally, age, gender, and marital status have been shown to be prognostic for survival in a number of studies. Movsas et al.[24] reported that baseline quality of life (QOL), as quantified by validated instruments, superseded performance status, age, gender, and other classic prognostic indicators for survival in a prospectively collected dataset in patients enrolled on a Radiation Therapy Oncology Group (RTOG) clinical trial, suggesting that QOL may be one of the most important predictors of long-term survival.[24]

GENERAL MANAGEMENT: NON–SMALL CELL LUNG CANCER

The management of NSCLC presents a formidable challenge. Oncologists not only must account for the stage and extent of disease spread at the time of diagnosis but also must carefully weigh the impact of baseline pulmonary functional status and comorbidities on the patient's ability to tolerate treatment. NSCLC is an aggressive tumor of a vital organ that is poorly functioning at baseline in the majority of patients. Therefore, the final therapeutic approach must be tailored to the individual. The treatment principles presented in this section should be viewed as guidelines and not as a cookbook for the management of this disease.

In general, the standard of care for operable patients with stage I and stage II disease is complete surgical resection with the possible addition of adjuvant chemotherapy. For medically inoperable patients, stereotactic body radiation therapy (SBRT), also known as stereotactic ablative radiotherapy (SABR), is an excellent treatment option. For stage III patients, a significant amount of controversy exists regarding optimal management. For select patients with stage IIIA disease at diagnosis who are candidates for surgical resection, neoadjuvant

chemotherapy or chemoradiotherapy is often used. For patients with unresectable stage III disease, the standard approach is concurrent chemoradiotherapy for fit patients or sequential chemotherapy and radiotherapy for patients who cannot tolerate concurrent treatment. Approximately 50% of patients present with evidence of hematogenous dissemination at the time of diagnosis.[25] For stage IV patients without significant local presenting symptoms or need for urgent radiation, systemic therapy is the standard initial treatment approach. For stage IV patients with significant local presenting symptoms requiring urgent radiotherapy, such as SVC obstruction, hemoptysis, or cord compression, palliative radiotherapy followed by systemic therapy is the preferred treatment approach. For patients with stage IV disease, owing to the poor prognosis, a detailed discussion of the goals of care with consideration of early referral to hospice should be part of the initial treatment approach. Recent evidence suggests that early introduction of palliative care into the standard treatment paradigm in this setting not only improves QOL and reduces inappropriate hospitalization at the end of life but also may improve survival.[26]

Resectable Tumors

Preoperative Assessment

Patient selection is critical when an operative approach is being considered for the management of NSCLC. This includes an assessment by the pulmonologist and operating surgeon of the clinical extent of disease, the predicted postresection pulmonary reserve of the patient, and preoperative cardiac clearance for the intended surgical procedure. Although there are no strict guidelines for operability, traditionally, patients are considered to be suitable for resection if their predicted postoperative forced expiratory volume in 1 second (FEV1) is >60% and diffusing capacity of the lungs for carbon monoxide DLCO > 60%.[27] Patients who do not meet those criteria should undergo additional testing including exercise test or ventilation–perfusion imaging to determine the regional variance in pulmonary function, including the potential loss of functional lung tissue within the planned area of excision.

Stage I and Stage II Non–Small Cell Lung Cancer

The standard of care for a patient with stage I or II lung cancer is surgical resection through either a lobectomy or pneumonectomy with mediastinal lymph node dissection. The Lung Cancer Study Group performed a randomized trial of lobectomy versus limited surgical resection (either wedge resection or

segmentectomy) in patients with T1N0 or T2N0 NSCLC. This trial randomized 276 patients and found a 17% risk of local recurrence with limited resection versus 6% with lobectomy (P = .008) and a trend toward an increase in all-cause and cancer-specific risk of death in patients randomized to limited resection (30% and 50% increased risk, respectively [P = .09], for both). Additionally, the report did not demonstrate any late functional advantages or decreased perioperative morbidity with limited resection.[28] This study firmly established lobectomy as the standard of care for early-stage lung cancer.

There have been several recent series comparing sublobar resection (SR) in appropriately selected early-stage NSCLC with lobectomy, showing comparable oncologic outcomes with the more limited resection. Okada et al.[29] performed a retrospective multi-institutional comparison of 567 patients undergoing either a sublobar (N = 305) or a lobar (N = 262) resection for cT1N0M0 (tumor size <2 cm) disease. With a median follow-up >5 years, they reported a 5-year overall survival (OS) of 89.6% for the SR group and 89.1% for the lobar resection group. The recurrence rate with SR was not inferior to those obtained with lobar resection, and postoperative lung function was significantly better in patients who underwent SR.[29] Results are still pending from Cancer and Leukemia Group B (CALGB) 140,503, a randomized trial of SR versus lobectomy in small, peripheral early-stage operable NSCLC. American College of Surgeons Oncology Group (ACOSOG) Z4032, a prospective randomized trial of sublobar resection (SR) with or without brachytherapy (SRB) for high-risk early-stage NSCLC, reported 224 patients were randomized.[30] Median (range) age was 71 (49 to 87) years; no differences were found in baseline characteristics between the two groups. Adverse events, previously reported, were not different between arms. Median follow-up was 4.38 (0.04, 5.59) years. There was no difference between arms in time to local recurrence, LR (hazard ratio [HR] 1.01; 95% confidence interval [CI] 0.51, 1.98; P = .98), or type of LR. In subgroups of patients with potentially compromised surgical margin (margin < 1cm; margin:tumor ratio <1; positive staple line cytology; wedge resection, nodule size >2 cm), SRB did not reduce LR, although trends favored the SRB arm, especially in the 14 patients with positive staple line cytology (HR 0.11, P = .24). Overall 3-year survival was similar for SR (71%) and SRB (71%) (P = .97). They concluded that there was no impact of brachytherapy on oncologic outcome in these patients.

There is also controversy regarding the role of mediastinal lymph node dissection in early-stage NSCLC. The American College of Surgeons Oncology

Group (ACOSOG) Z0030 trial was a randomized trial of 1,111 patients with N0 or N1 (less than hilar) early-stage NSCLC to either mediastinal lymph node sampling or complete lymphadenectomy during pulmonary resection. The 5-year disease-free survival was 69% in the mediastinal lymph node sampling group and 68% in the mediastinal lymph node dissection group (P = .92). There was no difference in local (P = .52), regional (P = .10), or distant (P = .76) recurrence between the two groups, suggesting that complete lymphadenectomy does not improve survival in patients with early-stage NSCLC.

Based upon the favorable data with SBRT in medically inoperable patients, the possibility of this approach as a treatment option for a subset of resectable early-stage NSCLC patients has been raised. The RTOG (RTOG 0618) initiated a phase II study of SBRT in operable patients with early-stage NSCLC. Of 26 evaluable patients, 23 had T1 and 3 had T2 tumors. Four patients (16%) had SBRT-related grade 3 AEs, whereas 0 had grade 4 to 5 AEs. Median follow-up was 25 months. Two patients have been scored with in-field failure, INF (11.7 and 12.4 months post SBRT), and 1 with marginal failure, MF (32.5 months post SBRT), giving an estimated 2-year primary tumor failure rate of 7.7% (95% CI 0.0%, 18.1%). Two-year estimates of LF (primary tumor plus involved lobe failure), RF, and DF are 19.2% (95% CI 3.7%, 34.7%), 11.7% (95% CI 0.0%, 24.5%), and 15.4% (95% CI 1.2%, 29.6%), respectively. Only one patient was eligible for attempted surgical salvage and underwent lobectomy 1.2 years post SBRT complicated by a grade 4 cardiac arrhythmia. Two-year estimates of progression-free survival (PFS) and OS are 65.4% (95% CI 44.0%, 80.3%) and 84.4% (95% CI 63.7%, 93.9%), respectively. This study suggested that SBRT was associated with a high rate of tumor control, moderate treatment-related morbidity, and infrequent need for surgical salvage in operable early-stage lung cancer patients with peripheral lesions.[31]

As such, three separate prospective randomized trials comparing SBRT with sublobar or lobectomy in resectable early-stage NSCLC were launched, as described in refs[32,33] and [NCT00840749]. These trials have all failed to meet their primary end point because of lack of accrual and therefore are now closed. Two of these trials were retrospectively matched and compared for the primary end point of survival, the STARS and ROSEL trial. In the 2 studies, a total of 58 patients were enrolled and randomly assigned (31 to SABR and 27 to surgery). Median follow-up was 40.2 months for the SABR group and 35.4 months for the surgery group. Six patients in the surgery group died compared with one patient in the SABR group. Estimated OS at 3 years was 95% (95% CI 85 to 100) in the

SABR group compared with 79% (64 to 97) in the surgery group (HR 0.14 [95% CI 0.017 to 1.190], log-rank *P* = .037). Recurrence-free survival at 3 years was 86% (95% CI 74 to 100) in the SABR group and 80% (65 to 97) in the surgery group (HR 0.69 [95% CI 0.21 to 2.29], log-rank *P* = .54). In the surgery group, one patient had regional nodal recurrence and two had distant metastases; in the SABR group, one patient had local recurrence, four had regional nodal recurrence, and one had distant metastases.[34] Although based on a small pooled randomized experience, these data suggest that SBRT may in the future become a viable noninvasive option for selected patients with early-stage operable NSCLC (e.g., who may be at increased risk from surgical resection).

Stage III Non–Small Cell Lung Cancer

Considerable controversy exists regarding the role of surgery in stage III NSCLC. In the 1960s and 1970s, patients with documented N2 disease were generally regarded as incurable and referred for nonoperative approaches. Martini et al.[35] reported the outcome of 1,598 patients who underwent surgical resection, 706 of whom had mediastinal nodal involvement. Of these, 151 patients underwent complete surgical resection with mediastinal node dissection. They reported an OS rate of 74% at 1 year, 43% at 3 years, and 29% at 5 years. Survival in patients with clinical stage I or II (pathologic N2) was favorable at 50% at 3 years. Survival in patients with obvious clinical N2 disease was extremely poor at 8% at 3 years. Martini et al.[35] stated: “Very few patients with gross mediastinal nodal involvement benefit from resection. We believe that this group of patients should not be considered for thoracotomy unless innovative forms of treatment can be offered.” Beyond gross mediastinal nodal involvement, multistation N2 disease and subcarinal nodal involvement are also shown in multiple series to be protend to poor outcomes.[36,37]

Based, in part, on these and similar results with surgical resection alone in stage III disease, neoadjuvant approaches—either preoperative chemotherapy or chemoradiotherapy—were explored in an attempt to facilitate surgical resection. However, significant controversy still exists regarding the role of surgical resection in stage III disease. Van Meerbeeck et al.[38] reported the results of a European Organisation for Research and Treatment of Cancer (EORTC) phase III randomized trial of surgical resection versus radiotherapy after induction chemotherapy in patients with pathologically proven N2 disease. In this study, 579 eligible patients were enrolled and received three cycles of cisplatin-based induction chemotherapy. The 332 patients who responded to induction

chemotherapy were then randomized to surgery (167 patients) or radiotherapy (165 patients). Median and 5-year OS for patients randomly assigned to resection versus radiotherapy were 16.4 versus 17.5 months and 15.7% versus 14%, respectively (HR 1.06, 95% CI 0.84 to 1.35). Rates of PFS were also similar in both groups. The authors concluded that radiotherapy is the preferred approach in these patients owing to lower rates of treatment-related morbidity and mortality.[38]

Neoadjuvant (Induction) Therapy

Preoperative Chemotherapy

The primary rationale for induction chemotherapy is similar to the rationale for preoperative radiotherapy: to facilitate complete surgical resection of disease. Additionally, induction chemotherapy may potentially sterilize micrometastatic disease beyond the thorax. Several early randomized trials compared preoperative chemotherapy versus surgical resection alone in stage III NSCLC and saw a significant survival benefit to the addition of neoadjuvant chemotherapy, causing trials to close early (Table 54.4).[39,41] The Neoadjuvant versus Adjuvant Taxol/Carbo Hope trial (NATCH) randomized 624 patients with stage IA (>2 cm), IB, II, or T3N1 to neoadjuvant versus adjuvant versus surgery alone.[42] Chemotherapy was three cycles of carboplatin–paclitaxel. Neoadjuvant arm had a trend toward better DFS than surgery alone arm, but results were not statistically significant (5-year DFS 38% vs. 34%, HR 0.92, P = .176). One possible explanation for the lack of benefit is due to the proportion of patients with early-stage disease in the trial (75% had clinical stage I disease). With subset analysis of only stage II-T3N1 patients, 5-year DFS was 36.6% in the neoadjuvant arm and 25% in the surgery arm (HR 0.81, P = .07). The adjuvant arm showed less benefit than the neoadjuvant arm, and more patients in the neoadjuvant arm were able to complete their planned chemotherapy (90.4% vs. 60.9% for neoadjuvant vs. adjuvant). Chemotherapy for Early Stages Trial assigned 270 patients with stages IB-IIIA NSCLC to surgery versus neoadjuvant cisplatin/gemcitabine for three cycles.[43] PFS and OS HRs were 0.70 (95% CI, 0.50 to 0.97; P = .003) and 0.63 (95% CI, 0.43 to 0.92; P = .02), respectively, both in favor of chemotherapy. When looking at just stage IIB/IIIA patients, a statistically significant impact of neoadjuvant chemotherapy was seen (3-year PFS rate: 36.1% vs. 55.4%; P = .002).

Preoperative Chemoradiotherapy

The rationale for preoperative chemoradiotherapy is that surgical resection after chemoradiotherapy will optimize local control, thereby improving clinical outcomes in locally advanced disease. A phase II trial by the Southwest Oncology Group (SWOG) of induction chemoradiotherapy followed by surgical resection in 126 patients with stage IIIA/IIIB disease showed a promising 3-year survival of 26%.[44] Motivated by these results, an intergroup randomized phase III trial was initiated to determine the value of adding surgery to chemoradiotherapy in stage III disease with a primary endpoint of OS. Patients with stage T1 to T3 pN2 M0 NSCLC were randomly assigned to concurrent induction platin-based chemotherapy plus radiotherapy (45 Gy). If no progression, patients either underwent resection or continued radiotherapy to 61 Gy.[45] A total of 202 patients were randomized to surgery and 194 to concurrent chemoradiotherapy. The median OS was 23.6 months in the trimodality arm and 22.2 months in the bimodality group (P = .24). For those with pN0 status at thoracotomy, the median OS was 34.4 months. PFS was better in the trimodality arm, median 12.8 months (5.3 to 42.2 months) versus 10.5 months (P = .017).

An unplanned, exploratory analysis suggested that patients who underwent lobectomy in the trimodality arm had improved survival compared to matched patients receiving chemoradiotherapy; however, this result is hypothesis-generating only. One of the most important findings from this trial was the significant toxicity of right-sided pneumonectomy after induction chemoradiotherapy. Among the 29 patients who underwent a right pneumonectomy, there were 11 postoperative deaths (38%).[46] Overall, this trial did not demonstrate a survival benefit for the addition of surgery to chemoradiotherapy in patients with stage IIIA NSCLC.

The German Lung Cancer Cooperative Group (GLCCG) conducted a phase III trial with 558 patients comparing neoadjuvant chemotherapy with cisplatin and etoposide, followed by surgery and postoperative radiation, versus neoadjuvant chemotherapy with cisplatin and etoposide, and then twice-daily chemoradiation with carboplatin and vindesine, followed by surgery and a further radiation boost if positive margins.[47] Mediastinal downstaging (46% vs. 29%) and pathologic response (60% vs. 20%) favored the neoadjuvant chemoradiation arm, but PFS was no different (5-year PFS 16% vs. 14%, P = .87). Pneumonectomy after chemoradiation had a higher mortality rate than chemotherapy (14% vs. 6%).

In conclusion, the role of neoadjuvant chemoradiotherapy in stage III NSCLC remains unclear. Using a multidisciplinary approach, this strategy should be carefully tailored to the individual patient, accounting for his or her performance status, pulmonary function, extent of disease, extent of surgical resection required, and experience of the clinical team.

Adjuvant Therapy

Postoperative Radiotherapy

The predominant pattern of intrathoracic failure after surgical resection is along the surgical stump or in the mediastinal nodes (Fig. 54.1). Concern over locoregional failure led to the idea that postoperative radiotherapy (PORT) in completely resected stages II and IIIA NSCLC might be beneficial based on evidence that it reduced local recurrence.[48] However, the role of PORT was called into question in 1998 when the Medical Research Council published a meta-analysis of nine randomized controlled trials assessing the effect of PORT after resection.[49] The PORT meta-analysis included information on 2,128 patients on and 1,368 deaths. PORT was associated with a decrease in survival for patients with pN1 disease. Given the theoretical benefit of radiotherapy on

local control, the detriment in survival was attributed to excessive radiotherapy-induced morbidity exceeding any benefit. There was no survival difference for pN2 patients, although the incidence of locoregional recurrence was reduced in this group. This analysis has been criticized for many reasons. Twenty-five percent of the patients had pN0 tumors and did not need adjuvant therapy. There was no quality control in the radiotherapy arms, and the nature of the radiation was felt to be inferior to modern standards; many of the patients were treated to large volumes using older cobalt 60 equipment to fields designed under fluoroscopy. A subsequent SEER analysis provided insights to counter some of the findings from the PORT meta-analysis. In this study, over 7,400 patients with stage II/III resected NSCLC were evaluated. PORT showed an improved 5-year OS for pN2 patients (27% vs. 20%) but reduced OS for pN0 and pN1 patients.[50]

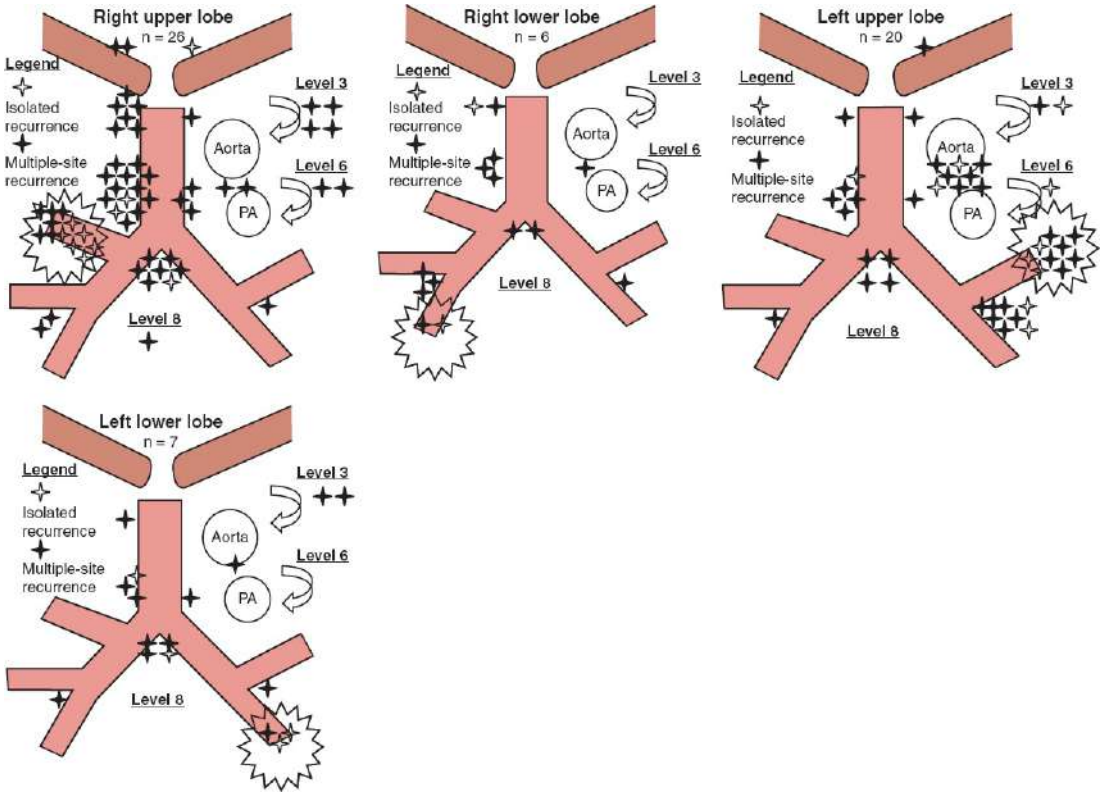

FIGURE 54.1. Patterns of failure. Sites of locoregional recurrence after surgical resection of 26 right upper lobe, 6 right lower lobe, 20 left upper lobe, and 7 left lower lobe tumors. A distinction is made between isolated recurrences (patients with a single recurrent site: *open stars*) and nonisolated recurrences (*filled stars*). (Reprinted from Kelsey CR, Light KL, Marks LB. Patterns of failure after resection of NSCLC. *Int J Radiat Oncol Biol Phys* 2006;65[4]:1097–1105. Copyright © 2006 Elsevier. With permission.)

Additional support for the use of PORT in the modern era can be found in the

Adjuvant Navelbine International Trialist Association (ANITA) trial.[51] This trial randomized 840 patients with stage IB through stage IIIA between 1994 and 2000 to adjuvant chemotherapy with vinorelbine and cisplatin or observation. The use of radiotherapy was not randomized; however, each center decided whether to use PORT before initiation of the study. Radiotherapy doses ranged from 45 to 60 Gy in 2 Gy fractions and were given after completion of chemotherapy. In patients with pN1 disease, PORT led to improved survival in the observation arm (median survival 25.9 vs. 50.2 months) but a detrimental effect in the chemotherapy group (median survival 93.6 months and 46.6 months). In contrast, in patients with pN2 disease, survival was improved both in the chemotherapy (median survival 23.8 vs. 47.4 months) and observation arm (median survival 12.7 vs. 22.7 months). The retrospective evaluation of the ANITA trial supports the findings from the SEER analysis that PORT may confer a benefit in pN2 NSCLC. The Lung Adjuvant Radiotherapy trial (Lung-ART), an intergroup collaborative effort in Europe, randomizes patients with completely resected locally advanced NSCLC with mediastinal nodal involvement to observation or PORT to 54Gy. Adjuvant chemotherapy is allowed on the control arm, and pre- and/or postoperative chemotherapy is allowed on the radiotherapy arm. The trial is ongoing, and results are not yet available.

Postoperative Chemotherapy

Historically, there was little evidence to support the routine use of adjuvant chemotherapy in completely resected lung cancer patients. However, benefits to chemotherapy began to emerge from various clinical trials.

The International Adjuvant Lung Cancer Trial (IALT) reported a statistically significant survival benefit for cisplatin-based adjuvant therapy in patients with completely resected stage I, II, or III NSCLC.[52] In this trial, 1,867 patients were randomized to cisplatin-based adjuvant chemotherapy or observation. With a median follow-up duration of 56 months, patients receiving chemotherapy had a significantly higher survival rate (44.5% vs. 40.4% at 5 years) and disease-free survival rate (39.4% vs. 34.3% at 5 years) compared with observation. However, after 7.5 years of follow-up, the survival curves started to converge and cross, the benefit of chemotherapy decreased over time, and there were more deaths in the chemotherapy group by 7.5 years ($P = .10$).[53]

The National Cancer Institute of Canada JBR.10 trial tested the effectiveness of adjuvant vinorelbine plus cisplatin versus observation in 482 patients with

completely resected stage IB and II NSCLC.[54] Compared to observation, adjuvant chemotherapy significantly prolonged median OS (94 vs. 73 months) and median relapse-free survival (not reached in chemo arm vs. 46.7 months) compared to observation alone. Like the IALT trial, some of the benefit diminished with longer follow-up; however, unlike IALT, the survival difference remained statistically significant beyond 5 years. After 9 years of follow-up, adjuvant chemotherapy was found beneficial for stage II (median survival 6.8 vs. 3.6 years), although not for stage IB patients.[55]

In the ANITA trial, 840 patients with stage IB through stage IIIA NSCLC were randomized to adjuvant vinorelbine plus cisplatin or to observation.[56] Median survival was 65.7 months (95% CI 47.9 to 88.5) in the chemotherapy group and 43.7 (35.7 to 52.3) months in the observation group, and 5-year OS was improved by 8.6%, which was maintained at 7 years (8.4%). On subset analysis, this benefit was limited to node-positive patients (stage II through stage IIIA). The Lung Adjuvant Cisplatin Evaluation (LACE) meta-analysis showed similar results by pooling data from five large randomized trials enrolling 4,584 patients to examine the role of cisplatin-based adjuvant chemotherapy in completely resected patients. They demonstrated a statistically significant 5.4% absolute survival benefit favoring adjuvant cisplatin.[57]

Postoperative Chemoradiotherapy

With the positive early results from adjuvant chemotherapy trials and prior to the publication of the PORT meta-analysis, a few groups began to explore the role of chemoradiotherapy in the postoperative setting.

ECOG 3590 was one of the first multi-institutional randomized trials to investigate postoperative chemoradiotherapy. This trial randomized 488 patients with stage II and IIIA NSCLC and negative margins after surgery to either radiotherapy alone or radiotherapy plus four cycles of EP chemotherapy. Radiotherapy in both arms consisted of 50.4 Gy in 28 daily fractions. There was no difference in local recurrence or survival between the two arms.[58]

Before the results of ECOG 3590 were published, the RTOG embarked on a phase II combined modality study using a newer chemotherapy regimen consisting of carboplatin and paclitaxel. RTOG 9705 included 88 patients with stage II and IIIA NSCLC after surgery who received PORT with concurrent carboplatin and paclitaxel. Radiotherapy consisted of 50.4 Gy in 28 fractions with a boost of 10.8 Gy in extranodal extension or T3 lesions. The radiotherapy was administered during cycles one and two. At a median follow-up of 56.7

months, median OS time was 56.3 months, with 1-, 2-, and 3-year survival rates of 86%, 70%, and 61%, respectively. The 1-, 2-, and 3- year PFS rates were 70%, 57%, and 50%, respectively. Toxicities were acceptable. When compared to previously reported studies, the RTOG concluded that these results might portend an improvement in OS and PFS with chemoradiotherapy in postoperative resected NSCLC patients.[59] In current practice, concurrent chemoradiation is typically recommended in the adjuvant setting if gross disease was left behind at surgery and variably recommended if microscopic disease was left behind at surgery.

Summary

Adjuvant chemotherapy is accepted as standard of care for patients with node-positive (stages IIA, IIB, and IIIA) NSCLC. For patients with N2 disease prior to surgery, neoadjuvant therapy with either chemotherapy or chemoradiation is an option in selected patients. PORT may be beneficial in stage IIIA NSCLC, although it has never been "proven" in randomized testing and is not indicated in completely resected stage I and stage II NSCLC. In practice, a patient who clinically appears to have early-stage NSCLC who undergoes a gross total resection with pathology-confirmed clear margins but is unexpectedly found to have pN2 disease should receive adjuvant chemotherapy first (because of the known survival benefit) and may subsequently be considered for PORT (because of the reported local control benefit) on completion of chemotherapy.

The role of postoperative therapy for NSCLC patients at high risk for local recurrence has not been clearly established. If a patient who is clinically felt to have early-stage NSCLC undergoes surgery that results in a positive microscopic margin or residual macroscopic disease, radiation therapy should start earlier, as local recurrence is the most common cause of failure in this group of patients.[60] Chemoradiotherapy should be considered in this setting if the patient is medically fit.[59,61]

INOPERABLE TUMORS

Stage I/II Non–Small Cell Lung Cancer

The standard of care for a patient with operable early-stage lung cancer remains lobectomy or pneumonectomy with mediastinal lymph node dissection. However, a significant percentage of these patients cannot tolerate invasive procedures because of the comorbidities prevalent in patients with lung cancer,

such as chronic obstructive pulmonary disease and poor cardiovascular health. Historically, the standard therapeutic approach for these patients has been conventionally fractionated definitive radiotherapy alone, with daily fractions delivered over a period of 6 to 8 weeks.[62] More recently, a hypofractionated approach with delivery of a small number of large fractions over a short period of time has gained acceptance. This approach has most commonly been referred to as stereotactic body radiation therapy (SBRT), although recently, there has been a move to rename this approach stereotactic ablative radiotherapy (SABR) to emphasize its distinct radiobiology.[63]

Conventionally Fractionated External Beam Radiotherapy

The RTOG performed a multi-institutional dose escalation study for inoperable NSCLC using three-dimensional conformal radiotherapy (3D-CRT). Patients with small, early-stage tumors were escalated to doses as high as 83.8Gy with acceptable toxicity. The 1-year local control rate for patients treated to this dose was 76%.[64] Hayman et al.[65] performed an adaptive dose escalation trial allowing safe delivery of doses up to 102.9 Gy to small peripheral tumors. However, the OS rates for patients with medically inoperable early-stage NSCLC remain poor when compared to surgery. The 5-year survival for patients treated with definitive radiotherapy range from 10% to 30% and are approximately one-half that reported in surgical series. Several possible explanations exist for this disparity in outcomes, including the poorer overall health of the medically inoperable patient and the fact that most of these patients are clinically, rather than surgically, staged. An additional limitation is the maximum dose that can be delivered to the tumor through conventionally fractionated external beam radiotherapy (EBRT) utilizing currently available techniques. Based on fundamental radiobiologic principles, Fletcher[66] predicted that using conventional fraction sizes of 1.8 to 2 Gy, doses of 100 Gy or higher might be required for the sterilization of most NSCLC tumors. These doses are not routinely achievable with conventionally fractionated radiotherapy in the medically inoperable patient without excessive toxicity.

Stereotactic Body Radiotherapy

SBRT refers to the delivery of large doses of radiation to a small treatment volume, usually employing multiple beams, using a small number of fractions (usually five fractions or less). It has been known for quite some time that this approach is remarkably effective at tumor sterilization, presumably because of

greater radiobiologic efficacy.[67] This treatment approach was initially put to clinical use over a half-century ago by a Swedish neurosurgeon, Lars Leksell, for the treatment of intracranial metastases. However, unlike the cranial vault, the lung is a highly mobile structure. Thus, application of SBRT in lung cancer was impractical until advanced imaging treatment delivery techniques were developed (Fig. 54.2).

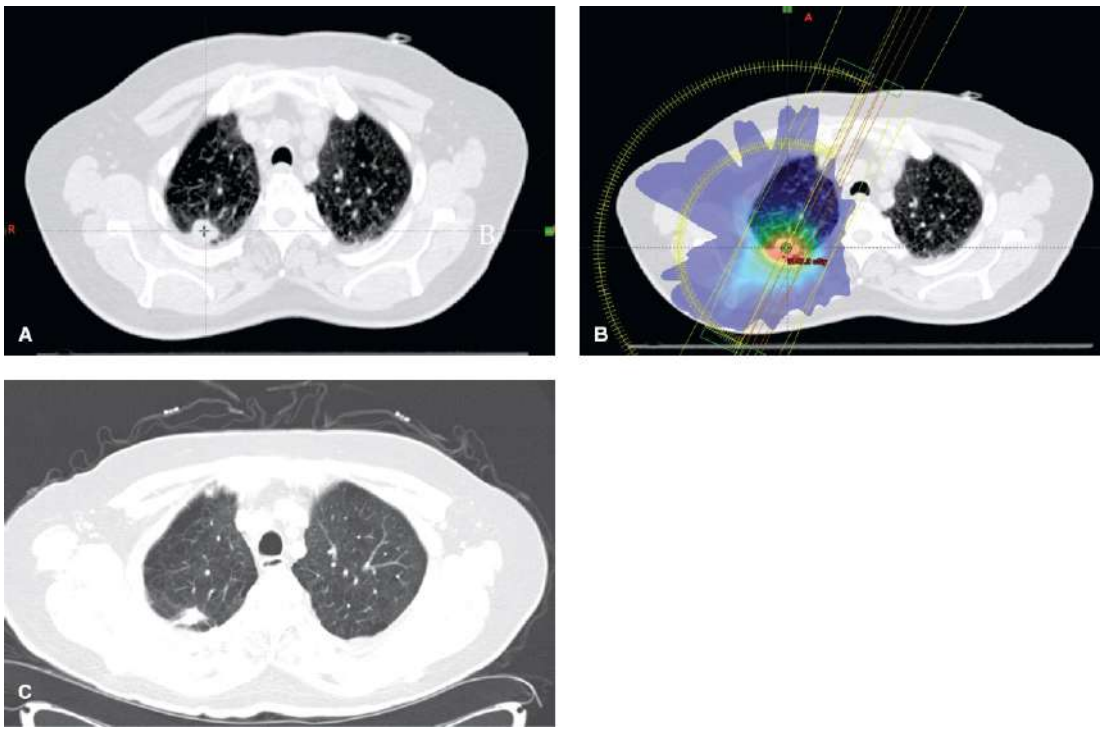

FIGURE 54.2. Stereotactic body radiation therapy (SBRT) in stage I non–small cell lung carcinoma (NSCLC). The patient was diagnosed as having T1N0M0 right upper lobe NSCLC and was treated with SBRT. **A:** Pretreatment tumor volume. **B:** Treatment plan with dose color wash. **C:** CT showing response 6 weeks after treatment.

A phase I dose escalation trial enrolled patients with T1-T2 N0 NSCLC, stratified into three-dose escalation groups based on T-stage and size (T1, T2 <5 cm, and T2 5 to 7 cm). This trial reported a maximally tolerated dose for T2 tumors >5 cm of 22 Gy × 3 and was not reached at 20 Gy × 3 for T1 tumors or at 22 Gy × 3 for T2 tumors <5 cm.[68] There was a loose association between total delivered dose and likelihood of local failure, with 9 of 10 local failures observed in patients treated to the lower-dose levels (<16 Gy × 3). Based on these results, this group moved forward with a phase II trial, utilizing the dose levels identified in the phase I trial. They were able to duplicate the excellent local control results in this expanded cohort of 70 patients. With a median

follow-up of 17.5 months, the local control rate was 95%. However, with such large fraction sizes (of ~20 Gy), the group also identified an association between tumor location and toxicity, with severe toxicity occurring at a median of 10.5 months in 17% of those patients with peripheral lesions versus 46% with central lesions.[69] Data from other institutions suggest that early, central lesions can be treated safely and effectively using a lower dose per fraction (e.g., 10 to 12 Gy × 4 to 5 fractions).[70,71] The initial report from VUMC showed 63 patients with central tumors treated with >90% 3-year local control and no grade 4/5 toxicity, although 9 patients died of cardiopulmonary causes, which might be related to grade 5 toxicity. To further explore the treatment of central tumors, RTOG 0813 is a phase I/II trial for patients with centrally located, medically inoperable stage I (<5 cm) NSCLC. Preliminary results show that 120 patients were dose escalated starting at 10 Gy ×5 fraction, with 7.2% rate of dose-limiting toxicity at the highest dose level.[72,73] The maximum tolerated dose was the highest dose level allowed on the study, 12 Gy/fr × 5 fractions. Seventy-one patients were treated at the two highest dose levels (11.5 Gy and 12 Gy per fraction) with 2-year local control of 88% to 89%, PFS of 52% to 51%, and OS of 70% to 73%. Four patients with grade 5 toxicity were seen, one at 10.5 Gy per fraction, two at 11 Gy, and one at 12 Gy. Optimal dose/fraction and normal tissue constraints in central tumor SBRT remains a topic of ongoing investigation.

A variety of dose fractionation and prescription schemes have been published in SBRT for early (primarily peripheral) lung cancer (Table 54.5). Most studies report 80% to 100% local control, >40% 2- to 3-year survival, and 0% to 4% grade 3 toxicity Timmerman et al. reported the results of RTOG 0236, a phase II trial of SBRT in medically inoperable patients with T1 or T2 tumors treated to 54 Gy in three 18-Gy fractions.[76] In this study, 59 patients were enrolled, with 55 patients having evaluable disease. At a median follow-up of 34 months, they reported a 3-year primary tumor control rate of 97.6% and a 3-year primary tumor and involved lobe (local) control rate of 90.6%. Two patients experienced regional failure; the locoregional control rate was 87.2%. Eleven patients experienced distant recurrence with a 3-year rate of distant failure of 22.1%. The rates for disease-free survival and OS at 3 years were 48.3% and 55.8%, respectively. The median OS was 48.1 months. Protocol-specific treatment-related grade 3 adverse events were reported in seven patients; grade 4 adverse events were reported in two patients. No grade 5 adverse events were reported. Because of the 16% grade 3 and 4 protocol-specified toxicity in RTOG 0236 and an additional six patients with chest wall toxicity for a total of 25% overall

toxicity rate, RTOG 0915 was launched to test two other fractionation regimens that have promising data, 34 Gy in one fraction (arm 1) versus 12 Gy times in four fractions (arm 2).[79] Ninety-four patients with T1-2N0M0 peripheral tumors were accrued and 84 were analyzable. With a median follow-up of 30 months, 4 patients on arm 1 (10.3%) and 6 patients on arm 2 (13.3%) had grade 3+ protocol-specified toxicity. Two-year OS was 61.3% and 77.7% for Arms 1 and 2, respectively. One-year primary control was 97% for arm 1 and 92.7% for arm 2. As results of these trials mature, chest wall toxicity is receiving more attention as patients present with late pain and fractures, with dose constraints for ribs, chest wall, and skin in the more recent trials.[76,79] SBRT, with its advantage of patient convenience and promising local control results, has largely replaced conventionally fractionated radiotherapy as the standard approach in the medically inoperable patient.

Stage III Non–Small Cell Lung Cancer

Definitive Radiotherapy

The majority of patients with inoperable locally advanced NSCLC will receive definitive thoracic radiotherapy as a part of their treatment strategy. The rationale for definitive radiotherapy in patients with inoperable NSCLC is to provide intrathoracic control of disease. Kubota et al.[80] performed a prospective randomized trial in 63 patients with stage III NSCLC comparing chemotherapy alone to chemotherapy plus thoracic radiotherapy. The survival rate in the thoracic radiotherapy group was 58% at 1 year, 36% at 2 years, and 29% at 3 years, compared with 66%, 9%, and 3% at 1, 2, and 3 years, respectively, in the chemotherapy-alone group. The investigators concluded that thoracic radiotherapy "significantly increases the number of long-term survivors as compared with chemotherapy alone and that radiotherapy to bulky disease in the thorax is an important part of combined modality therapy, and a necessary part of further studies in locally advanced disease." At present, definitive thoracic radiotherapy is part of the standard therapeutic approach for patients with unresectable locally advanced NSCLC. However, because of high local failure rates and the significant toxicity associated with this treatment, the optimal dose, treatment volume, and optimal integration scheme with chemotherapy remain to be defined.

Dose and Fractionation with Radiotherapy Alone

The RTOG launched a prospective randomized trial in 1973 to determine the most effective dose and fractionation schedule in patients with inoperable NSCLC. In the initial report of RTOG 7301, 365 patients with T1-T3, N0-N2, M0 unresectable NSCLC were randomized to one of four treatment regimens: 40 Gy given in a split course of 20 Gy in five fractions in 1 week, a 2-week rest, and then an additional 20 Gy in 1 week or 40 Gy, 50 Gy, or 60 Gy given in 2 Gy per fraction continuous course 5 days/week. The split-course group had the poorest survival: 10% at 2 years.[81] The incidence of tumor recurrence in the irradiated volume was 58% for the patients receiving 40 Gy continuous course, 53% for those treated with 40 Gy split course, 49% with 50 Gy continuous irradiation, and 35% in the patients receiving 60 Gy.[82] There were no differences in 5-year survival rates between the four arms. However, based on the differences in local tumor control and short-term survival, this study established 60 Gy as the standard of care.

Motivated by these results, the RTOG moved to explore methods of escalating radiation dose while maintaining the therapeutic ratio through altered

fractionation schedules or improved treatment delivery techniques. RTOG 8311 was a randomized phase I/II trial that delivered thoracic radiation at a dose of 1.2 Gy with twice-daily fractions escalating from a starting point of 60.0 to 79.2 Gy. A total of 848 patients were enrolled and analyzed for outcome. No significant differences in the risks of acute or late effects in normal tissues were found in the five arms. In a subset analysis of good performance status patients (stage III, Karnofsky performance scale [KPS] ≥70, <6% weight loss), there was a dose–response identified for survival with 69.6 Gy yielding improved survival over the lower-dose arms (P = .02). There were no differences in survival among the three high-dose arms; therefore, 69.6 Gy became the standard altered fractionation regimen for subsequent RTOG trials.[83]

The development of 3D-CRT in the early 1990s allowed radiation oncologists to increase the dose distribution to the tumor while restricting the dose to surrounding critical normal structures. Bradley et al.[84] examined 207 patients with inoperable NSCLC and demonstrated by multivariate analysis that GTV was strongly predictive of overall and cause-specific survival, suggesting that large-volume disease might require escalated doses of radiotherapy, if feasible without significantly increased toxicity risk. Rengan et al.[85] examined the value of dose escalation in patients with large-volume stage III disease and found that even in patients with large tumor volumes, local failure rates were significantly reduced when treated to ≥64 Gy.

Seventy-nine patients with NSCLC were enrolled and escalation of dose per fraction was performed according to patients' stratified risk for radiation pneumonitis with total RT doses ranging from 57 to 85.5 Gy in 25 daily fractions over 5 weeks using intensity-modulated radiotherapy. Based upon their protocol-defined criteria, investigators identified 63.25 Gy in 25 fractions (2.53 Gy per fraction) to be the maximally tolerated dose. This was due to late grade 4 to 5 toxicities that was attributable to damage to central and perihilar structures and correlated with dose to the proximal bronchial tree. Although the reported rates of pneumonitis were low, the late toxicities because of damage to the proximal bronchial tree highlights the sensitivity of these structures to hypofractionation. Taken together, these data suggest that dose escalation can be achieved safely in locally advanced NSCLC via novel hypofractionation and treatment delivery approaches. However, caution should be employed when considering hypofractionated regimens.[86]

Volume of Radiation with Definitive Radiotherapy: Involved-Field

Versus Elective Nodal Irradiation in Inoperable Stage III Non–Small Cell Lung Cancer

In the era of two-dimensional (2D) radiation therapy for NSCLC, it was customary to include the elective nodal basin in the radiation portals for any patient receiving curative intent radiotherapy, regardless of stage. There is ample evidence that the elective nodal basins can be safely omitted in stage I NSCLC, as there is low risk of nodal failure after IFRT either with conventionally fractionated radiotherapy or SBRT in this setting in patients who have undergone modern clinical staging.[76,84] Although ^{18}FDG-PET/CT has become an indispensible tool for noninvasive staging of the mediastinum, studies have shown that FDG-PET may carry up to a 25% false-negative rate in lymph nodes <1 cm in the short axis.[16] Therefore, some have argued that although IFRT may decrease toxicity or allow for dose escalation, this may come at the expense of clinical outcome in this disease.[87]

Motivated by this concern, several studies have examined the rate of elective nodal failure in patients treated with IFRT and have shown this to be a relatively rare event.[88] In a study of 524 inoperable patients treated with IFRT, Rosenzweig et al.[89] reported a 2-year elective nodal control rate of 92.4%. Kepka et al.[90] performed a comparative analysis of IFRT, limited elective nodal irradiation (ENI), and extended ENI and reported that substantial incidental radiation dose was delivered to the elective nodal basins even with IFRT; the median dose delivered to these areas ranged from 18 to 45 Gy, depending on the location of the primary tumor and involved nodes as well as the technique employed. Further, there was no significant difference in dose delivered to much of the elective nodal basin between extended and limited ENI. In the only prospective study of ENI versus IFRT, Yuan et al.[91] demonstrated an increase in local control with IFRT of 8% and 15% at 2 and 5 years, respectively. This increase, however, was only statistically significant at the 5-year time point. Additionally, Yuan et al. demonstrated an improved OS rate at 2 years with IFRT (39.4% vs. 25.6%, P = .048) and significantly higher pneumonitis rates in patients treated with ENI (29% vs. 17%, P = .044). Although interesting, this study has been criticized for the imbalances in several factors, including the radiation dose delivered (68 to 74 Gy for IFRT vs. 60 to 64 Gy for ENI) and V_{20} between the two arms, making attribution of the results observed solely to IFRT or ENI problematic. In a single-institution retrospective cohort comparison of patients receiving definitive 3D-CRT for locally advanced NSCLC, Fernandes et al.[92] analyzed 108 consecutive patients treated with either ENI or IFRT. The median follow-up time for

survivors was 18.9 months. The median dose for patients treated with IFRT was 69.9 Gy versus 63.6 Gy for ENI. In a multivariable logistic regression analysis, patients treated with IFRT demonstrated a significantly lower risk of high-grade esophagitis (odds ratio 0.31, *P* = .036). There was a suggestion of improved 2-year local control with IFRT (59.6% IFRT vs. 39.2% ENI); however, this was not significant (*P* = .23). There were no significant differences in elective nodal control (84.3% vs. 84.3%), distant control (52.7 IFRT vs. 47.7% ENI), and OS (43.7% IFRT vs. 40.1% ENI) rates between ENI and IFRT. The authors concluded that IFRT had favorable therapeutic ratio compared with ENI owing to reduced to acute toxicity. Taken together, these data suggest that IFRT can be employed in patients with locally advanced NSCLC without risk of significant compromise in clinical outcome.

Combined Modality Therapy for Inoperable Stage III Non–Small Cell Lung Cancer

Sequential Chemoradiotherapy

Although dose escalation was achievable and appeared to be associated with improvements in local control in locally advanced NSCLC, the dominant pattern of failure in these patients was through distant dissemination in about 75% to 80% of patients.[82] To address the issue of systemic disease in locally advanced cases, the CALGB initiated a phase III randomized trial of 155 patients with unresectable stage III NSCLC with excellent performance status and minimal weight loss either to radiotherapy alone to 60 Gy or to induction chemotherapy with cisplatin and vinblastine followed by radiotherapy to 60 Gy. Median survival was improved with induction chemotherapy to 13.7 months versus 9.6 months with radiotherapy alone (*P* = .0066). The 5-year survival was improved from 6% to 17% with induction chemotherapy.[93] A subsequent intergroup trial was launched randomizing 490 patients with inoperable locally advanced NSCLC to one of the following regimens: (a) standard radiation therapy to 60 Gy, (b) induction chemotherapy followed by standard radiation therapy to 60 Gy, and (c) twice-daily radiation therapy to 69.6 Gy as 1.2 Gy given twice daily. Median survival was improved to 13.8 months with induction chemotherapy compared to 11.4 months with standard radiotherapy and 12.3 months with hyperfractionated radiotherapy (*P* = .03).[94] Overall, these trials established the role of chemotherapy, in addition to radiation, in the management of unresectable stage III NSCLC (Table 54.6).

Concurrent Chemoradiotherapy

The EORTC performed a phase III randomized trial comparing concurrent cisplatin-based chemoradiation to radiotherapy alone and demonstrated a clear survival benefit to this approach.[97] Of note, there was no difference in rate of distant metastases; thus, the authors concluded that the benefit in OS was attributable to an improvement in local control secondary to enhanced radiosensitization of the tumor by low-dose cisplatin. A meta-analysis performed in 2010 to examine the value of concurrent chemotherapy in definitive management of NSCLC by O'Rourke et al.[98] included 19 randomized studies with a total of 2,728 patients with NSCLC (stages I through III), who were randomized to receive either concurrent chemoradiotherapy or radiotherapy alone. Concurrent chemotherapy significantly reduced overall risk of death (HR 0.71) and improved overall PFS at any site (HR 0.69). However, this clinical benefit came at the expense of increased acute toxicity, especially severe esophagitis with concurrent treatment (RR 4.96).

Concurrent Versus Sequential Chemoradiotherapy

Initial phase II trials suggested that concurrent chemoradiotherapy might be an even more effective treatment than sequential chemoradiotherapy.[99] Therefore, Furuse et al.[99] performed a phase III randomized trial comparing concurrent chemoradiotherapy with mitomycin, vindesine, and cisplatin (MVP) given at systemic doses to sequential chemotherapy and radiation therapy. They demonstrated a statistically significant survival advantage to the concurrent approach (median survival of 16.5 months vs. 13.3 months and 5-year survival of 15.8% vs. 8.9%). RTOG 9410 compared two different concurrent regimens (cisplatin and vinblastine with conventional radiotherapy, arm 1, or cisplatin and oral etoposide with hyperfractionated radiotherapy, arm 2) to a "standard" sequential regimen of cisplatin and vinblastine followed by conventional radiotherapy (arm 3). Comparing arm 1 to arm 3 (as per the study design), median survival times improved significantly (17 vs. 14.6 months), as did 5-year survival (15% vs. 10%) with an increase in acute grade 3 through grade 5 nonhematologic toxicities.[100,101] The survival in arm 2 was not significantly better than arm 1, although this intensive regimen was associated with much higher esophageal toxicity. A meta-analysis performed by Auperin et al.[102] evaluated data from six clinical trials involving 1,205 patients. The median follow-up was 6 years. Auperin et al. observed a significant benefit favoring concurrent over sequential chemotherapy and radiotherapy with respect to OS

(HR 0.84, *P* = .004), with an absolute increase in survival of 5.7% (from 18.1% to 23.8%) at 3 years and 4.5% at 5 years. PFS was also improved with concurrent chemoradiotherapy (HR 0.90, *P* = .07). Concurrent chemoradiotherapy decreased locoregional progression (HR 0.77, *P* = .01), although not distant progression. Again, this improvement in locoregional control came at the expense of greater acute toxicity for patients receiving concurrent chemoradiotherapy, with an increase in acute esophageal toxicity (grades 3 and 4) from 4% to 18% with a relative risk of 4.9 (*P* <.001).

Because of the increased toxicity with concurrent chemoradiation, especially acute esophagitis, there are often treatment delays that are potentially detrimental in terms of radiobiologic efficacy. Cox et al.[103] examined the impact of prolonged treatment time in stage III NSCLC treated with radiotherapy alone and documented an association with decreased locoregional control and 5-year survival (15% vs. 0%). To determine whether treatment time had a similar impact in the setting of concurrent chemoradiation, Machtay et al.[104] performed a retrospective study of three prospective RTOG trials (RTOG 9106, 9204, and 9410), all of which included good performance status stage III NSCLC patients treated with cisplatin-based concurrent chemoradiotherapy. The authors defined "short" treatment time as finishing treatment within 5 days of the projected end date. They found that "long" treatment time was significantly associated with acute esophagitis. They also found a nonsignificant trend toward improved median survival for "short" (19.5 months) versus "long" treatment time (14.8 months). This study, although retrospective, indicated that even with concurrent chemoradiation, there could be a detrimental effect on survival with delayed treatment time.[104] Thus, appropriate patient selection and maneuvers to minimize toxicity are increasingly important to minimize the likelihood of treatment delays that can compromise the efficacy of concurrent therapy.

In summary, these prospective data strongly support concurrent chemoradiotherapy as the standard approach for patients with good performance status and minimal weight loss. This therapeutic strategy results in improved OS, likely driven by an improvement in locoregional control in patients with locally advanced NSCLC. Of note, this comes at the expense of greater toxicity to the patient, especially esophagitis, and therefore, patient selection is critical when using this approach.

Cytotoxic Platforms for Concurrent Chemoradiotherapy in Locally Advanced Non–Small Cell Lung Cancer

Several chemotherapy regimens that pair cisplatin or carboplatin with etoposide, vinorelbine, mitomycin, vindesine, irinotecan, paclitaxel, docetaxel, and pemetrexed have each been studied; unfortunately, few head-to-head trials comparing these agents have been conducted. There is no single regimen that could be considered standard. In North America, the most common prescribed regimens are either cisplatin and etoposide (EP) at systemic doses or carboplatin and paclitaxel administered weekly during radiation therapy (XRT). Unlike limited SCLC, where cisplatin is dosed at 60 mg/m^2 every 3 weeks and etoposide at 80 to 120 mg/m^2 daily × 3 both during and after radiation,[105] an alternative dose and schedule is generally used. There are abundant data from the SWOG and RTOG for a schedule that was ultimately phase III tested in RTOG 9309 and later by the Hoosier Oncology Group: specifically, cisplatin 50 mg/m^2 days 1, 8, 29, and 36 and etoposide 50 mg/m^2 intravenously days 1 through 5 and days 19 through 33.[44,45,106] This schedule, while inconvenient, is tried and tested and generally safe. The carboplatin/paclitaxel regimen is

administered weekly during radiation with a carboplatin dose of AUC of 2 and paclitaxel at 40 to 50 mg/m^2. After radiation is completed, two more cycles are usually administered 3 weeks apart using a higher (systemic) dosage of both agents (carboplatin AUC 6 and paclitaxel 200 mg/m^2). Summary of trials involving concurrent chemoradiation can be found in Table 54.7.

Some have argued that carboplatin-based therapy is inferior to cisplatin in the treatment of locally advanced NSCLC. However, data from Japan in a combined modality trial (West Japan Oncology Group Trial WJTOG 0105) evaluating various concurrent chemoradiation regimens failed to show superiority for cisplatin over carboplatin in the context of concurrent chemoradiation.[111] Investigators led by Nobuyuki Yamamoto compared their erstwhile standard of MVP to weekly carboplatin in combination with either irinotecan or paclitaxel during XRT; in each arm, those without disease progression or untoward toxicity went on to receive two cycles of full-dose chemotherapy during the "consolidation" period using the same agents administered during XRT. The paclitaxel/carboplatin regimen resulted in less toxicity, fewer dose reductions or omissions, and equivalent if not superior survival at 5 years: 19.5% versus 17.5% for MVP and 17.8% for irinotecan–carboplatin. In fairness, this study also compared second-generation to third-generation chemotherapy. A Chinese study compared the EP regimen with carboplatin and paclitaxel in a randomized study.[113] Although the 3-year OS was higher in the EP arm, the study failed to meet its primary end point of OS and median survival times were 23.3 months in the EP arm and 20.7 months in the PC arm (log-rank test P = 0.095, HR 0.76, 95% CI 0.55 to 1.05). Furthermore, the trial had some methodologic issues. The role of consolidation treatment as will be detailed below is controversial for patients who receive EP, but standard using carboplatin-based treatments; in this study, half the patients in the EP arm received consolidation treatment, whereas only 35% of patients in the carboplatin arm received it. Therefore, most patients in the carboplatin arm received incomplete treatment, which could potentially account for the decreased survival rate seen in this cohort. In a retrospective analysis of patients treated within the Veterans Health Administration, the outcomes of 499 patients treated with EP and 1,343 treated with CP were compared.[114] No difference in OS was noted between the two regimens, but EP was associated with an increased incidence of toxicities and more hospitalizations. This study has several limitations associated with the inherent biases of retrospective studies; however, it suggests that any difference in survival outcomes between the two regimens is likely to be small. One concern

pertaining to paclitaxel-containing regimens is a potential increase in the incidence of radiation pneumonitis; this was raised after an individual patient meta-analysis identified that elderly patients receiving carboplatin/paclitaxel chemotherapy were at highest risk of developing this complication.[115]

Given its favorable toxicity profile and superiority to gemcitabine in combination with cisplatin in advanced nonsquamous NSCLC, pemetrexed has been widely adopted in the metastatic setting. The PROCLAIM study randomized patients with stage III nonsquamous histologies either to EP or to cisplatin with pemetrexed during definitive thoracic XRT.[116] After 598 patients were enrolled, the study was stopped early because of futility; no difference were observed between the two arms with respect to OS (26.8 vs. 25 months, HR = 0.98 (95% CI: 0.79 to 1.20), *P* = .83), median progression-free survival (11.4 vs. 9.8 months HR, 0.86; 95% CI, 0.71 to 1.04; *P* = .13), and response rates (35.9% vs. 33% *P* = .45). The only clear toxicity difference was a higher incidence of neutropenia for patients treated with EP (54.8 vs. 44.5%, *P* = <.05).

TABLE 54.7 CONCURRENT CHEMORADIOTHERAPY FOR STAGE III NON–SMALL CELL LUNG CANCER

Trial (Reference)	Phase	Number of Patients	Additional Nonconcomitant Agents	Concomitant Chemotherapy	XRT Dose (Gy)	Median PFS (Months)

bid, twice daily; Carbo, carboplatin; CPT-11, irinotecan; DDP, cisplatin; Gem, gemcitabine; MMC, mitomycin C; NR, not reached; OS, overall survival; Pac, paclitaxel; PFS, progression-free survival; VP-16, etoposide; XRT, radiotherapy.

Given the lack of evidence for a “best” or preferred regimen, clinicians and patients need to decide which chemotherapy to choose based on other considerations: these include histology (pemetrexed only useful for patients with nonsquamous histology), potential toxicities (e.g., kidney injury for cisplatin, neuropathy for paclitaxel), and cost (significantly higher for pemetrexed).

In patients with baseline V20s (percentage of normal lung that will receive >20 Gy) >35% or in those with borderline pulmonary function or other comorbidities, many clinicians consider administration of chemotherapy first for two or even three cycles, followed by radiation alone or concurrent chemoradiation if there has been sufficient tumor shrinkage to allow a more reasonable radiotherapy treatment field. In those with minimal or no tumor shrinkage using this approach, some investigators omit concurrent chemotherapy during XRT to avoid untoward toxicity, proceeding with XRT alone. These patients are often much more symptomatic than those with smaller-volume tumors, with postobstructive symptoms including wheezing, pneumonitis, and hypoxia, and often have compromised performance status. However, the one study to isolate the role of induction therapy prior to concurrent chemoradiation with paclitaxel and carboplatin failed to show a survival advantage compared to concurrent chemoradiation alone.[109]

Toxicity mitigation is another major challenge that has been inadequately addressed. Both acute esophagitis and long-term pneumonitis and pulmonary

fibrosis are common complications of combined modality therapy. A recent meta-analysis by Auperin et al.[117] demonstrated a sixfold increase in short-term esophagitis, grade 3 or worse (18% vs. 3%) in those receiving concurrent chemoradiation as opposed to asynchronous or sequential chemotherapy and radiation. A phase III study evaluating amifostine as an esophageal protectant failed to show a significant reduction in esophagitis rates, as determined by objective measures, compared to a control arm that did not feature this agent[118]; however, a subsequent analysis based on patient-reported outcomes (PROs) suggested a modest benefit with reduction in pain and weight loss.[24,107] There is continued interest in evaluating mucosal protectants, including palifermin and other agents, although to date, no prospective randomized phase III trial has demonstrated a palliative benefit. Consequently, the approach to in-field toxicity has generally been reactive rather than pre-emptive. Newer technologies including proton beam may help to reduce the severity and duration of acute and late esophageal and pulmonary effects. This is currently under investigation.

Consolidative Chemotherapy

Consolidative chemotherapy remains highly controversial. A phase II SWOG trial using the EP/XRT regimen as a platform investigated the role of consolidation docetaxel in stage IIIB patients, yielding a 5-year survival rate of nearly 30%, which at the time, was virtually unprecedented in the realm of locally advanced NSCLC.[44] However, in a phase III randomized Hoosier Oncology Group trial, docetaxel consolidation failed to yield a survival advantage compared to standard “observation” in patients who had completed concurrent chemoradiation with EP, in part because the reference arm “outperformed” its historic controls.[106] These results were disappointing. However, there was a borderline significant imbalance in baseline pulmonary function favoring the control arm: Nearly 60% of patients on the arm featuring no consolidation had an FEV1 ≥2 L, compared to slightly >40% in the investigational arm. Similarly, empiric use of gefitinib as maintenance therapy in a SWOG trial led to a paradoxical survival decrement compared to placebo after completion of docetaxel consolidation.[119] A more recent randomized trial in Asia tested consolidation chemotherapy with docetaxel and cisplatin after concurrent chemoradiation with the same agents (vs. no consolidation radiation) and found no difference in OS between the two arms (median OS 20.6 vs. 21.8 months in the observation vs. consolidation arms, HR 0.91, $P = .44$).[120] Hence, based on these trials, there is no proven role for consolidative chemotherapy in patients

who have already received systemically dosed chemotherapy during thoracic XRT. In those who receive a radiosensitizing schedule of chemotherapy during XRT (mainly weekly carboplatin/paclitaxel), the general consensus favors at least two cycles of full-dose chemotherapy after chemoradiation is completed, although its role as consolidation has never been formally tested in phase III trials. Despite the disappointing data thus far, the role of consolidation or maintenance therapy after chemoradiation remains an open question.

Targeted Agents in Locally Advanced Disease

There are no data to support the empiric use of targeted agents such as EGFRs, TKIs, EGFR MAbs, ALK inhibitors, immunotherapy agents, or angiogenesis inhibitors either during or after chemoradiation. RTOG 0617 showed that the addition of cetuximab to standard chemoradiation in an unselected population provided no OS benefit.[121] As described in the previous section, a SWOG trial of adjuvant gefitinib or placedo after chemoradiation led to a paradoxical survival decrement compared to placebo.[119] RTOG 1306/Alliance 31101 is comparing standard chemoradiation versus induction erlotinib or crizotinib for 12 weeks followed by chemoradiation, for patients with EGFR and ALK mutations, respectively. Attempts to integrate bevacizumab into the combined modality approach have been unsuccessful, with adverse events including tracheoesophageal fistulas and pulmonary hemorrhages.[122,123] There is tremendous interest in integrating immunotherapy in the treatment of stage III NSCLC. The randomized START trial looked at whether the MUC1 antigen-specific cancer immunotherapy, tecemotide, improves survival in patients with stage III unresectable NSCLC when given as maintenance therapy after chemoradiation. Out of 1,513 patients randomized, 1,239 were analyzable with median OS of 25.6 months in the tecemotide arm versus 22.3 months in the placebo arm (HR 0.88, $P = .123$). On subset analysis with just patients who received concurrent chemoradiation (65% of patients) and not sequential (35%), median OS was 30.8 months versus 20.6 months in favor of the tecemotide arm (adjusted HR 0.78, $P = .016$).[124] The PACIFIC Trial (NCT 02125461) is looking at a randomization between MED14736, an antibody to PDL-1, and placebo as adjuvant therapy for a year after concurrent chemoradiation for unresectable stage III NSCLC. A Hoosier phase II trial (NCT 02343952) is looking at consolidation pembrolizumab following chemoradiation in patients with unresectable stage III NSCLC. More data on the clinical efficacy of these agents will be forthcoming in the next few years.

Dose Escalation with Concurrent Chemoradiotherapy

Although concurrent chemoradiotherapy has emerged as the standard therapeutic approach for fit patients with unresectable locally advanced disease, this has come at the cost of increased toxicity. It is therefore unclear whether dose escalation in the setting of concurrent chemotherapy will provide meaningful clinical benefit. Although phase II trials showed promise in dose escalation with concurrent chemotherapy,[125,126] RTOG 0617 showed a detriment to 74 Gy compared with 60 Gy, and 60 Gy remains the standard dose in stage III NSCLC treatment. RTOG 0617 was a 2 × 2 phase III randomized trial to simultaneously examine the question of 60 Gy versus 74 Gy and concurrent chemoradiotherapy with or without cetuximab for patients with inoperable stage III NSCLC. A total of 544 patients were randomized to the four arms. Median follow-up for the radiotherapy comparison was 22.9 months (IQR 27.5 to 33.3). Median OS was 28.7 months (95% CI 24.1 to 36.9) for patients who received standard-dose radiotherapy and 20.3 months (17.7 to 25.0) for those who received high-dose radiotherapy (HR 1.38, 95% CI 1.09 to 1.76, P = .004). Median OS in patients who received cetuximab was 25.0 months (95% CI 20.2 to 30.5) compared with 24.0 months (19.8 to 28.6) in those who did not (HR 1.07, 95% CI 0.84 to 1.35, P = .29). Both the radiation dose and cetuximab results crossed protocol-specified futility boundaries. There were no statistical differences in grade 3 or worse toxic effects between radiotherapy groups. By contrast, the use of cetuximab was associated with a higher rate of grade 3 or worse toxic effects (205 [86%] of 237 vs. 160 [70%] of 228 patients; $P < .0001$). There were more treatment-related deaths in the high-dose chemoradiotherapy and cetuximab groups (radiotherapy comparison: eight vs. three patients; cetuximab comparison: ten vs. five patients). There were no differences in severe pulmonary events between treatment groups. A multivariate analysis with OS as an end point revealed that radiation dose (60 Gy), maximum esophagitis grade, planning target volume (PTV), and heart V_5 and V_{30} were all significantly associated with mortality. Emerging studies are testing novel approaches to radiation dose escalation, such as employing functional imaging to decrease the volume to be dose escalated using an adaptive radiation therapy (ART) approach.

Superior Sulcus Tumors and Pancoast Syndrome

SSTs were first described in 1838 and the characteristic accompanying neurologic symptoms in 1932 by Dr. Henry Pancoast. SSTs account for <5% of

all lung cancer.[127]

Signs and Symptoms

The most common symptom among patients with SST is pain in the shoulder, which may radiate down the arm. This can be attributable to direct tumor invasion of the parietal pleura, vertebral body, ribs one through three, or the brachial plexus (Fig. 54.3). Pain radiating down the ulnar aspect of the arm past the elbow indicates involvement of the T1 nerve root, whereas extension to the fourth and fifth digits indicates involvement of the C8 nerve root or more distally the ulnar nerve. There may be weakness or atrophy of the intrinsic muscles of the hand. SSTs that invade the neural foramina may cause spinal cord compression, which can ultimately occur in up to 25% of patients. Involvement of the stellate ganglion may manifest as Horner syndrome: the triad of ptosis, papillary miosis, and hemifacial anhidrosis. Irritation or compression of the adjacent sympathetic chain may cause ipsilateral flushing and sweating of the face or reflex sympathetic dystrophy, a regional syndrome of burning neuropathic pain. Pancoast syndrome is a constellation of signs and symptoms including shoulder/arm pain, Horner syndrome, and unilateral upper extremity weakness.

FIGURE 54.3. A 51-year-old former smoker presented with right shoulder pain and right-sided Horner syndrome and was found to have an adenocarcinoma in the right superior sulcus. **A:** Coronal view with gross tumor volume (GTV) contoured. **B:** An axial view with GTV contoured. A 4-cm tumor is seen invading the mediastinum with displacement of the trachea. He underwent a staging evaluation including mediastinoscopy and was staged as T4N0M0. **C:** Sagittal view with GTV contoured showing vertebral body impingement. The patient was treated with radiotherapy with concurrent cisplatin and etoposide to 50 Gy and underwent resection with negative margins.

Diagnosis and Staging

SSTs are staged in the same way that SCLC and NSCLC are staged elsewhere in the thorax. For patients without metastatic disease, it is important to assess resectability. Surgery typically involves lobectomy with en bloc resection of the chest wall, which may be accompanied by resection of portions of the parasympathetic chain, stellate ganglion, lower trunks of the brachial plexus, subclavian artery, and portions of vertebral bodies.

Management

Determining the feasibility of resection is a critical decision point in the management of NSCLC SSTs. Because of the apical location of the tumor, invasion of the brachial plexus, vertebral bodies, and subclavian vessels are not uncommon and may preclude surgical resection as an option, depending on the extent of invasion. In addition to CT, PET, and bone scan, MRI is useful in documenting the extent of involvement of the brachial plexus, spinal nerve roots, vertebral bodies, and subclavian vessels and is more sensitive than CT for this purpose. Small cell SSTs in patient with good performance status are treated with concurrent chemoradiotherapy for limited-stage disease or chemotherapy for extensive-stage disease.

Multimodality Therapy for Superior Sulcus Tumors

Several large retrospective series and prospective trials have investigated outcomes of multimodality treatment of SSTs. SWOG 9416/Intergroup 0160 included 110 patients with T3-T4, N0-N1 SSTs. All patients were treated with two cycles of EP with radiotherapy (45 Gy in 25 fractions), followed by surgery within 3 to 5 weeks, and then two further cycles of chemotherapy.[128] The study included patients with apical tumors and Pancoast syndrome, or SSTs with chest wall invasion, or involvement of the vertebrae or subclavian vessels. In this study, 88 patients (80%) underwent surgery, and 83 (76%) had complete resection. The 5-year OS was 44%. As well, 61 resected patients (56%) had a pathologic complete response to induction therapy, and their 5-year survival was significantly better at 54%. A Japan Clinical Oncology Group (JCOG) study enrolled 76 patients and used induction MVP with 45 Gy in 27 fractions (split course) followed by surgery.[129] The study included patients with SSTs, staged T3 to 4, N0 to N1, and nonbulky N2 disease; 76% of patients underwent resection, and 68% had complete resection. The 5-year OS was 56%.

In patients who are resectable at diagnosis, surgery may be offered as initial therapy. A prospective trial at the University of Texas MD Anderson Cancer Center enrolled 32 patients with resectable or marginally resectable SSTs.[130] All patients underwent gross total resection initially; 28% had microscopic residual disease. Postoperatively, patients were treated with radiotherapy to 60 in Gy fractions (for 1.2-Gy negative margins) or 64.8 Gy in 1.2-Gy fractions (for positive margins) with concurrent EP. The 5-year locoregional control was 76%, and 5-year OS was 50%. The long-term results of this trial were updated showing the 10-year locoregional control to remain excellent at 76% and the 10-year OS to be 45%.

Chemoradiotherapy

Retrospective evidence suggests that patients who undergo surgery have better local control and survival than those treated with radiation therapy, although such data are subject to significant selection bias.[131] Patients with unresectable localized SSTs and those with stage III disease and bulky N2 (or N3) lymph nodes should be treated with definitive chemotherapy and radiation. Early studies of radiotherapy alone for SSTs show acceptable local control and survival. In a series of 32 patients treated with definitive radiation, 91% of patients with pain reported relief, and 75% of patients with Horner syndrome had symptomatic improvement.[132] The addition of concurrent chemotherapy improves local control and survival in patients with stage III NSCLC—an observation that has led to the widespread use of concurrent therapy in SSTs. Small series in patients with SSTs appear to support this. A retrospective analysis from the Netherlands examined the outcome of patients treated with chemoradiotherapy.[133] In this study, 49 patients with stage II or III SST received 66 Gy with daily cisplatin (6 mg/m^2); 19 patients had sufficient response to undergo resection, and in these patients, there was a 53% pathologic complete response rate. The 5-year OS was 18% in patients who received chemoradiotherapy and 33% in patients who were able to undergo surgery.

RADIOTHERAPY TECHNIQUES AND FUTURE DIRECTIONS

Gross Tumor Volume

The clinically macroscopic disease, as typically identified on any imaging modality, is defined as the GTV. The GTV in the lung cancer patient is usually derived from a treatment planning CT or PET-CT obtained during quiet respiration. Intravenous contrast is usually not required for identification of the primary tumor unless it is located adjacent to the hilum or mediastinum. Studies have shown that the size of the contoured GTV is highly sensitive to the windowing of the CT dataset.[134] Harris et al.[134] reported that measurements of pulmonary nodules using the standard “lung” windowing width of 850 Hounsfield units, with a windowing length of −750 Hounsfield units, resulted in highly accurate sizing of the parenchymal tumor. Therefore, lung windowing should be used for delineation of the primary tumor GTV. An FDG-PET may be of additional value in the setting of atelectasis.[135] However, the optimal standardized uptake value threshold for defining tumor edge remains to be defined.

Identification of the mediastinal nodal GTV may prove more challenging. Intravenous contrast may be valuable in identifying nodal disease and may be used if there are no contraindications such as allergy or renal insufficiency. Chapet et al.[136] at the University of Michigan developed an axial CT-based definition of the thoracic nodal stations for use in radiation treatment planning and nodal identification. On CT, a short-axis diameter ≥1 cm is often employed for identification of pathologically involved nodes. However, this cutoff is unsatisfactory, having a relatively poor accuracy of approximately 60% for correctly identifying the location and size of nodal disease. FDG-PET/CT can add significant value to CT alone in the identification of mediastinal nodal disease. Dwamena et al.[137] performed a meta-analysis of FDG-PET and CT for the identification of mediastinal nodal disease in lung cancer. They reported a mean sensitivity and specificity of 0.79 and 0.91, respectively, for PET and 0.60 and 0.77, respectively, for CT. Although this represents a significant improvement, the gold standard for identification of mediastinal nodal disease is through invasive staging. When feasible, the mediastinum should be pathologically staged through either cervical or mediastinoscopy endobronchial ultrasound with transbronchial needle aspiration; this information should be incorporated into delineating the nodal GTV.

Clinical Target Volume

The clinical target volume (CTV) represents a volumetric expansion of the GTV to encompass microscopic disease. For the primary tumor, pathologically derived correlative data have shown that a 9-mm margin would encompass all microscopic disease in approximately 90% of lung adenocarcinomas.[138] Others have advocated the use of a differential margin based on histology of 8 mm for adenocarcinoma and 6 mm for squamous cell carcinomas to account for 95% of the microscopic extension of disease.[139] For nodal disease, surgical series have shown that a 3-mm margin will encompass 95% of the microscopic extranodal extension of disease in lymph nodes <2 cm. However, larger margins may be required for lymph nodes >2 cm.[140]

Internal Target Volume

The internal target volume (ITV) is defined by International Commission on Radiation Units and Measurements (ICRU) 62 as an expansion of the CTV to account for tumor motion. However, as the CTV includes subclinical disease whose motion cannot be visualized, most clinicians will create an “IGTV,”

which represents the summation of the contoured GTV on all CT datasets obtained in a respiratory-correlated (or four-dimensional [4D]) CT using established methodologies for image acquisition and correlation.[141] In the absence of a 4D CT, a "slow" CT may be used with an extended image acquisition time to encompass a full breathing cycle.[142] The IGTV can then be expanded with a uniform volumetric margin to account for microscopic extension of disease and generation of a CTV.

Planning Target Volume

The PTV is a volumetric expansion of the CTV to account for setup variability. In the past, empiric margins have been used to account for daily variations in patient positioning. However, with the incorporation of image guidance to aid in patient positioning and daily setup, these margins can likely be reduced. Grills et al.[143] showed that calculated population setup margins were reduced from 9 to 13 mm for patients immobilized with a stereotactic body frame and positioned without cone-beam CT to 1 to 2 mm with cone-beam CT. Ideally, with greater integration of image guidance into lung cancer treatment delivery, patient-specific margins will be employed to account for tumor setup uncertainty.[143,144]

Dose Constraints

Normal tissue organs at risk (OARs) should be defined using guidelines outlined in prospective protocols, or using a consensus contouring atlas, so that consistent data can be collected and analyzed. The bilateral lungs excluding the GTV, esophagus, and spinal cord should be defined for all patients; and the heart, pericardium, and brachial plexus should be defined when clinically indicated. For all patients, OAR dose limits should be balanced against adequate coverage of the target volume. A multidisciplinary effort was undertaken—the Quantitative Analysis of Normal Tissue Effects in the Clinic (QUANTEC)—to summarize the published 3D dose–volume/toxicity data in the literature and provide practical guidance for the clinician.[145,146] For SBRT or intermediate hypofractionated schedules, there are less data to recommend dose–volume constraints for most relevant organs. American Association of Physicists in Medicine (AAPM) Task Group 101 provides suggested dose limits in one to five fractions for many parallel and serial organs.[147]

THREE-DIMENSIONAL CONFORMAL RADIOTHERAPY AND INTENSITY-MODULATED RADIOTHERAPY FOR LUNG

CANCER PLANNING AND DELIVERY

Introduction

Accurate treatment planning and delivery of radiation for the treatment of lung cancer are confounded by several technical factors, including proper patient setup and localization, the mobility of lung tumors, and tissue inhomogeneity in the vicinity of the lung, as well as the physical and biologic dose implications of delivering dose in >30 fractions versus ≤5 fractions, as in the case of SBRT. To understand the effects of these factors on the accuracy of treatment, one must look more closely at each of the procedures involved in treatment planning and delivery, including treatment simulation, treatment planning, plan evaluation and quality assurance, and treatment delivery. Among other studies, comprehensive reviews of current techniques for lung cancer treatment planning and delivery have been presented.[148]

Treatment Simulation

The goal of treatment simulation is to acquire an image-based representation of the patient for the purposes of tumor and normal organ delineation for treatment planning. The imaging study is traditionally performed with CT. Serial CT images are acquired of the patient in the same treatment position, using the same immobilization devices as those used during radiation treatment. Slice thickness is typically ≤5 mm; smaller slice thicknesses allow for reconstruction of higher-resolution digitally reconstructed radiographs (DRRs),[148] which may improve localization accuracy during treatment. The anatomic region scanned should include both lungs and often extends from the level of the cricoid cartilage to the second lumbar vertebra. Immobilization refers to the process of "patient fixation" to ensure reproducible patient setup during treatment and between treatment fractions. Custom devices, composed of Styrofoam or other materials that mold to the patient surface, are often fabricated for immobilization. Examples include the Alpha Cradle (KGF Enterprises, Chesterfield, MI) and BodyFIX (Elekta Oncology Systems, Norcross, GA) immobilization systems. In the context of SBRT, the AAPM Task Group Report No. 101[147] recommends the use of 1- to 3-mm axial slice thickness during CT acquisition and the use of standard-of-care immobilization/fixation systems (including stereotactic body frames[149]) for reproducible treatment setup.

Management of Tumor Motion

Motion can result in significant distortion of axial or helical CT scans,

manifested as artifacts in the vicinity of the tumor in the 3D image dataset.[150] Motion-related artifacts not only render it difficult to assess the full extent of motion but also confound the ability to contour the target accurately on the planning CT dataset. As a result of this, the AAPM Task Group Report No. 76 recommends that motion management strategies be considered when the range of tumor motion is >5 mm in any direction. The recommended 5-mm criterion may be reduced for techniques, such as SBRT, where tumor motion may become an accuracy-limiting factor. Several different techniques have been proposed to manage and mitigate the effects of tumor motion.[148] To assess the range of mobility of tumors in the coronal plane, investigators have employed fluoroscopy.[148] Information from fluoroscopy cannot be directly linked to the volumetric simulation CT scan and is also limited by visualization of the target, although the use of implanted markers may overcome this problem. Motion-encompassing methods are utilized to manage the effects of motion during the planning process. These include the generation of 4D CT scans, which contain spatial and temporal information during the CT acquisition process. 4D CT scans are typically reconstructed to generate multiple datasets at different phases of the respiratory cycle, ultimately generating an “envelope” of the moving tumor for treatment planning.[151] The use of “slow” CT scans (4 seconds per slice) acquired during quiet respiration has also been shown to capture reproducible target volumes for peripheral lung cancers.[142] Methods to limit motion, such as shallow breathing that is forced using abdominal compression devices, have shown to be effective in patients who can tolerate these devices. Techniques such as deep inspiration breath-hold, automatic breathing control, respiratory gating, and tumor tracking, although technically challenging to implement, can afford improvement in normal lung sparing, particularly in circumstances where the magnitude of motion is large.[152]

With regard to motion-encompassing approaches, automatic tools have been developed to improve efficiency in the contouring of GTVs on multiple datasets to form an ITV. The maximum intensity projection (MIP) represents the highest intensity value encountered along the viewing ray for each pixel in the volumetric dataset for the respective breathing phase. The summation of MIP images for each breathing phase therefore results in a composite view of the tumor incorporating all phases of motion. Other techniques, such as a color intensity projection (CIP) technique, in which the motion information from the cumulative 4D datasets are composited into a single color image, have also been proposed.[153] Figure 54.4 provides views of variance in GTV position in different

phases of the breathing cycle.

Treatment Planning

The goal of treatment planning is to optimize the therapeutic ratio—that is, to maximize the dose to the target while minimizing dose to surrounding normal organs (Fig. 54.5). As described earlier, target and OAR volumes are defined based on imaging studies, primarily CT and PET. PET can be used to differentiate atelectasis from tumor and to determine nodal involvement for central disease. Respiratory-induced mobility of the tumor is accounted for using the internal margin, which represents the "envelope" encompassing tumor movement determined during the simulation 4D CT acquisition. The internal margin is expanded to form the PTV, which accounts for geometric variation in the CTV owing to day-to-day (interfraction) uncertainties in the patient setup. According to ICRU Report No. 62,[154] a margin (planning risk volume [PRV]) should also be added to an OAR to account for interfraction variation in the OAR position. Margins for the PTV must be designed with an understanding of the random and systematic errors associated with patient setup. For advanced-stage NSCLC, typical margins for the PTV are on the order of 5 to 10 mm if an ITV is used for motion compensation and daily image-guided radiotherapy (IGRT) is employed during treatment. In the absence of motion compensation or IGRT, margins should typically be larger (10 to 20 mm) to minimize the chance of missing the target as a result of motion. Daily IGRT-based setup has been shown to significantly reduce residual errors and, consequently, planning margins.[155] For SBRT-based treatments, where motion management and IGRT are the recommended standard of care,[147] PTV margins can range from 3 to 6 mm.[149]

Beam arrangements for treatment planning can range from simple two-field, parallel-opposed fields (e.g., anterior–posterior, opposed, anterior–posterior/posterior–anterior [AP/PA]) for late-stage NSCLC to complex multiple gantry angle, modulated beams for more focal treatments. Beams are shaped with a multileaf collimator (MLC), which enables conformation of radiation to the target. Treatment plans should be designed to minimize dose to surrounding normal organs and thereby limit the risk of treatment toxicity, implying sharp gradients in the dose falloff outside the target.[147] AP/PA fields may be considered when disease is more extensive and located centrally. The goal in such cases is to produce a homogeneous dose distribution across the treated volume to encompass the extent of the disease. However, AP/PA beams can only

be used for cumulative PTV doses in the range of 40 to 45 Gy (in 1.8 to 2 Gy per fraction) because of spinal cord tolerance. “Off-cord” fields are typically required beyond this dose. When treating large volumes of lung, it is especially important to design treatment plans that adhere to normal lung tolerance doses; dose indices, such as V_{20}, V_5, and MLD, must be closely observed to avoid possible treatment complications.[156] For treatment planning of localized disease, more conformal dose distributions employing multiple beam angles are warranted. Treatment plans can be developed using 3D CRT or IMRT techniques and should include beams from multiple gantry angles, particularly in the context of SBRT.

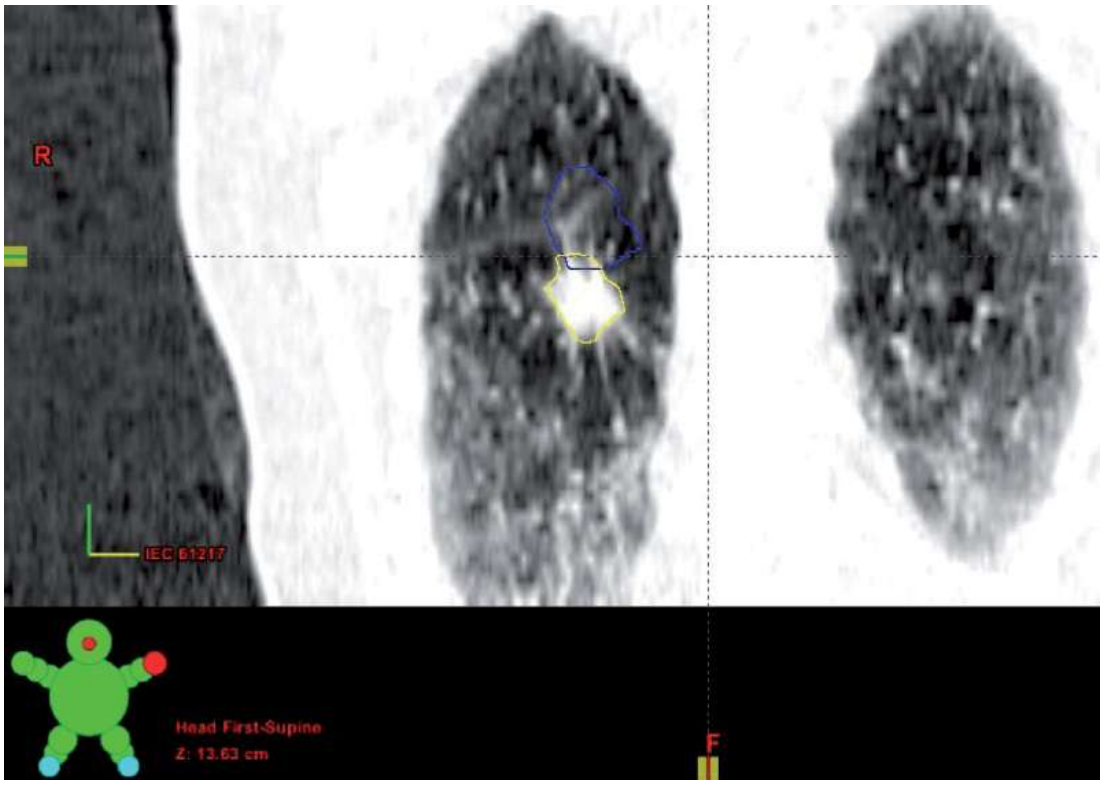

FIGURE 54.4. Tumor motion during a patient’s normal respiratory cycle. The yellow wireframe shows the tumor position at full inspiration. The blue wireframe shows the tumor position at full expiration.

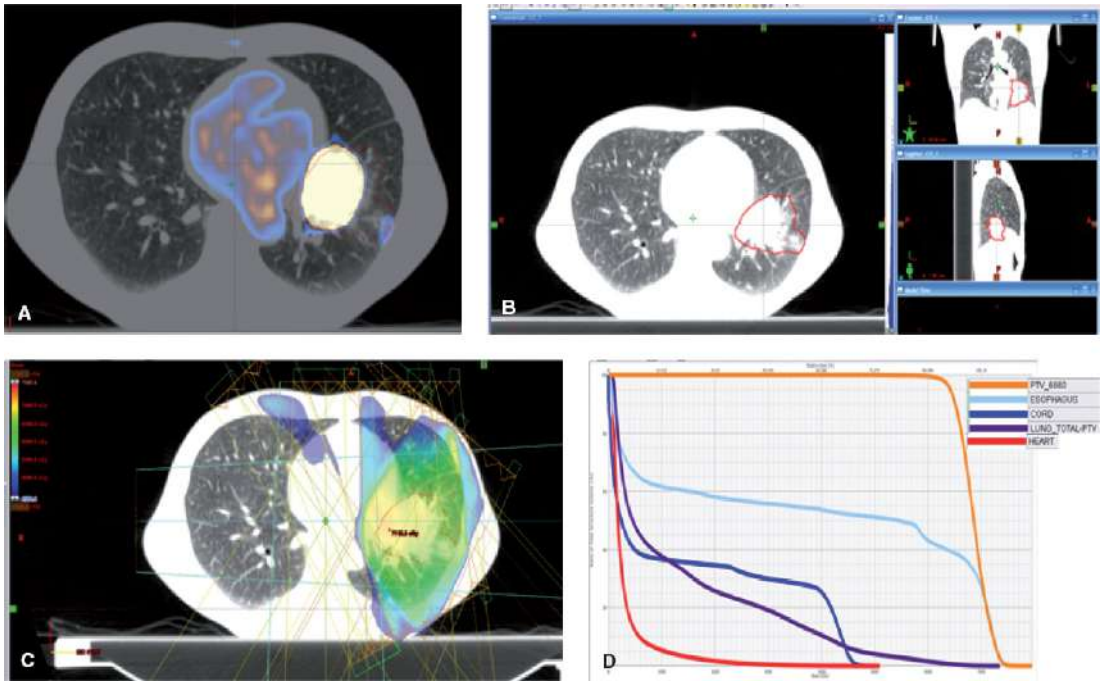

FIGURE 54.5. A: CT- and PET-fused image showing FDG-avid primary tumor. **B:** Axial, coronal, and sagittal views of GTV contour. **C:** Transverse CT image of field arrangement and dose color wash of treatment plan. **D:** Dose–volume histogram showing coverage of the planning target volume (*orange*) and dose to esophagus (*light blue*), spinal cord (*dark blue*), total lung (*purple*), and heart (*red*).

For IMRT-based planning, one must bear in mind the interplay effect, which describes the interplay between a given MLC position and instance of radiation delivery with the position of the tumor in the respiratory-induced motion cycle at the same instance.[157] The interplay effect has been shown to average out over the course of ≥30 treatment fractions.[157] However, in the SBRT setting, where 3 to 5 dose fractions are delivered, the interplay effect may compromise the planned dose distribution, suggesting that IMRT must be used cautiously for SBRT. Planning for SBRT must be done with an understanding of the dose gradients so as to develop dose distributions with sharp gradients. This is typically achieved using multiple nonoverlapping and noncoplanar beams as necessary and a MLC with ≤5 mm leaf width.[147] The dose prescription line can be low (e.g., 80%) with much smaller margins for beam penumbra (“block edge”) than conventional radiotherapy; the motivation is to produce a faster dose falloff and thereby improve sparing of surrounding healthy tissues. The AAPM Task Group No. 101 discourages the use of calculation grid sizes >3 mm for SBRT planning.

Low-density lung tissue in the vicinity of or surrounding thoracic tumors significantly confounds the radiation dose computation problem in lung cancer

treatment planning. Conditions of loss of charged-particle equilibrium are produced when the field size is reduced such that the lateral ranges of the secondary electrons become comparable to (or greater than) the field size; such conditions occur for larger field sizes in lung than in water-equivalent tissues because of the increased electron range in lung. Under such circumstances, the dose to the target is determined primarily by the secondary electron interactions and dose deposition. Because conventional dose algorithms do not account explicitly for transport of secondary electrons, they can be severely limited in accuracy under nonequilibrium conditions. Moreover, in low-density, lung-equivalent tissues, the range of the secondary electrons contributes to the dose "build-down" effect at the edges of the tumor (at the lung–tumor interface), an effect that increases with beam energy. The article by Reynaert et al. and AAPM Task Group No. 105[158] provide examples of numerous studies reporting on the inaccuracies associated with conventional algorithms for dose calculations in the lung. Therefore, for lung cancer treatment planning in general, and especially when dealing with smaller tumors, where the field sizes are $<5 \times 5$ cm^2, more advanced dose algorithms such as convolution/superposition or the Monte Carlo method are necessary—the latter accounts explicitly for electron transport.[147] The AAPM TG Report No. 101[147] and other articles[159] recommend that pencil beam algorithms not be utilized for SBRT-based lung dose calculations.

Plan Evaluation and Quality Assurance

Plan evaluation of IMRT and SBRT treatment plans requires careful evaluation of DVHs and the entire 3D dose distributions.[147] The following items, among others, must be considered to properly evaluate a treatment plan prior to radiation delivery[147]: organ contours and dose–volume–based organ constraints; planning margins for targets and OARs; intrafraction motion and impact on margins; inhomogeneity corrections; dose uniformity and "hot" or "cold" spots in the target region; normal tissue tolerance doses; plan deliverability—that is, the presence of many low-intensity segments that could possibly be removed without compromising plan quality; and unusual beam orientations that might involve collision during gantry rotation. In accordance with national practice guidelines for IMRT[160] and SBRT[147], redundant verification of the patient-specific treatment plan monitor units and verification measurements of the planned isocenter and 2D dose distributions are necessary. When performing patient-specific verification measurements of highly modulated IMRT fields or SBRT plans, special consideration must be given to the detector size and

performance under nonequilibrium conditions.[161] A properly commissioned Monte Carlo dose algorithm may prove valuable for patient-specific verification of IMRT and SBRT treatment plans, given the complexities with accurate measurements under nonequilibrium conditions.[147,161]

Treatment Delivery Technologies

Radiation delivery for lung cancer treatment is generally performed using IGRT-based systems, which can be acquired using megavoltage (MV)- or kilovoltage (kV)-based planar imaging, as well as volumetric, cone-beam CT imaging to localize the patient prior to treatment. Gating or tracking systems, which aim to deliver radiation during a given phase of the breathing cycle or "track" the tumor in real time, respectively, may also be employed. Image-guidance protocols, including type and frequency of imaging, as well as the need for gating or tracking should be decided by the treatment planning team after consideration of factors such as stage of the disease, location of the tumor, degree of tumor mobility, and quality of the IMRT or SBRT treatment plan. Reviews of technologies utilized in the treatment of lung cancer using IMRT and SBRT are provided elsewhere. More recently, volumetric modulated arc therapies (VMATs) have become available for treatment of lung cancers. In one study, an SBRT lung treatment plan performed with VMAT was compared with that of a conventional IMRT plan using the same optimization objective function and constraints.[143] The VMAT plan consisted of a single arc, with partial angles to spare the contralateral lung. The VMAT plan yielded improved target coverage and comparable normal tissue doses compared with the conventional IMRT plan while reducing treatment time by approximately 60%. The faster delivery of radiation with VMAT is likely to substantially mitigate patient movement on the treatment table as a result of discomfort during a long treatment procedure, thereby improving delivery quality. However, as with conventional IMRT, VMAT-based plans are also subject to the interplay effect, which must be considered depending on the mobility of the tumor and the degree of modulation of the MLC fields.

The emergence of linear accelerators with flattening filter free (FFF) beams, in addition to VMAT, has yield much larger gains in treatment efficiency.[162]. Vassiliev et al.,[163] in applying FFF beams to the treatment of early lung cancer patients with SBRT showed a significant improvement in treatment efficiency, with beam-on time being reduced over a factor of 2, from 25 to 11 seconds, on average. They found insignificant differences in target and normal organ doses

with and without the use of FFF beams. They concluded that the increase in treatment efficiency afforded by FFF beams facilitates breath-hold and gated treatments. A recent meta-analysis by Dang et al.[164] comprising 210 studies from 2010 to 2015, involving the use of treatments with and without FFF beams, showed significant improvement in treatment efficiency without compromising target dose coverage or normal tissue sparing. A clinical meta-analysis by Prendergast *et* al. of 64 patients with early-stage NSCLC treated with SBRT using FFF beams showed minimal acute toxicity and reasonable rates of ≥ grade 2 late toxicity.[165]

Particle Beam Radiotherapy for Non–Small Cell Lung Cancer

Because of their physical properties and method of interaction with matter, particle beams, such as protons, neutrons, and heavy ions, have the potential to offer improved dose deposition profiles in tissue when compared with photon beam radiation. Although protons have a similar biologic potency to photons, neutrons and heavy ions such as carbon ions deliver a more biologically effective dose than either photons or protons. A consensus statement was recently issued by the Particle Therapy Co-operative Group (PTCOG) Thoracic Subcommittee task group on the role of proton therapy in NSCLC, reviewing passive scattering proton therapy, pencil beam scanning, available clinical data, and potential for improvement.[166]Further studies are emerging to assess the potential role of particle therapy in the management of lung cancer.

Early-Stage Disease

Loma Linda started treating early-stage lung cancer with proton therapy as detailed by Bush et al.,[167] beginning at 51 Cobalt Gray Equivalent (CGE) protons in 10 fractions and ultimately dose escalating to 70 CGE in 10 fractions. The 4-year local control rate was 96% in peripheral T1 tumors and 75% in T2 tumors. The treatment was well tolerated, with no cases of RP or esophageal or cardiac toxicity. In a smaller series, Hata et al.[168] reported on 21 patients with stage IA/IB treated with a total dose of 50 to 60 CGE at a dose per fraction of 5 to 6 CGE over a median time of 15 days. The 2-year local control and cause-specific survival were 95% and 86%, respectively. There were no grade 3 through grade 5 toxicities in this patient population. Chang et al.[169] reported on a series of 18 patients with centrally located medically inoperable stage I NSCLC treated to 87.5 CGE in 2.5 CGE per fraction with proton beam radiotherapy. With a median follow-up time of 16.3 months, no grade 4 or 5 toxicities were

observed. The most common toxicities observed were dermatitis (grade 2, 67%; grade 3, 17%), followed by grade 2 fatigue (44%), grade 2 pneumonitis (11%), grade 2 esophagitis (6%), and grade 2 chest wall pain (6%). The crude local control in these 18 patients was 88.9%, with 11.1% experiencing regional lymph node failure and 27.8% experiencing distant metastasis. At the time of last follow-up, 12 patients (67%) were still alive with 5 patients dying of distant metastatic disease and 1 patient dying of a cardiopulmonary event unrelated to treatment. Miyamoto et al.[170] reported the results of a four-fraction phase II trial of carbon ion radiotherapy in early-stage NSCLC; 79 patients were enrolled and received either 52.8 cGE (stage IA) or 60 CGE (stage IB). The local control rate for all patients was 90% (T1: 98%, T2: 80%). The patients' 5-year lung cancer–specific survival rate was 68% (IA: 87%, IB: 42%). The OS was 45% (IA: 62%, IB: 25%). Half of the deaths were attributable to intercurrent disease. No toxic reactions in the lung greater than grade 3 were detected. Although these results are promising, whether particle beam therapy provides an advantage over photon-based SBRT is not known at this time.

Locally Advanced Disease

Because of the requirement of delivery of tumoricidal doses of radiation to the mediastinal nodes in locally advanced NSCLC, particle beam radiotherapy may be of particular value in this patient population. There are no prospective data to date examining carbon ion radiotherapy in locally advanced disease; however, there are emerging data with proton beam radiotherapy in this setting. Chang et al.[171] reported the results of the first 44 patients enrolled on a phase II trial of weekly concurrent carboplatin and paclitaxel with proton beam radiotherapy to 74 CGE in patients with inoperable stage IIIA/IIIB NSCLC. With a median follow-up of 19 months, they observed a promising median OS of 29.4 months in these patients. No patient experienced grade 4 or 5 proton-related adverse events. Although these results compare favorably to the 74 Gy arm of RTOG 0617, preliminary results from a phase 2 randomized study to compare passive scatter proton therapy with IMRT in stage III NSCLC treated with radiation therapy to 74 Gy with concurrent carboplatin and paclitaxel was reported in abstract form and found no difference between IMRT and proton therapy.[172] With 255 patients enrolled, patients in the proton group had larger target volumes ($P = 0.07$) and more patients received higher doses to the tumors than the IMRT group. Pneumonitis rates were 8.7% overall, 7.2% in IMRT, and 11% in proton therapy. Median time to local recurrence was 13 months in both

groups.[166] RTOG 1308 is an ongoing randomized trial comparing IMRT with proton therapy in stage III NSCLC with survival as the primary end point.

In addition to conventionally fractionated radiation treatment, Gomez et al.[173] reported the results of a phase I hypofractionation trial for patients with locally advanced NSCLC who are unable to receive concurrent chemotherapy that demonstrated the feasibility of a 3-week regimen of hypofractionated proton beam radiotherapy in this patient population. More clinical trials are ongoing to explore hypofractionation with proton therapy in locally advanced lung cancer.

METASTATIC NON–SMALL CELL LUNG CANCER

Basic Therapeutic Precepts

The treatment of advanced NSCLC has evolved. By the early 1990s, it was clear that platinum-based chemotherapy could prolong survival, improve symptom control, and yield superior QOL compared with best supportive care.[174] In the 1990s, new agents emerged with enhanced therapeutic index. Carboplatin, although no more effective than cisplatin, was considerably safer with less nephrotoxicity, neurotoxicity, and gastrointestinal toxicity. In addition, several new agents, including paclitaxel, docetaxel, gemcitabine, vinorelbine, and irinotecan, were tested and proved compatible with either carboplatin or cisplatin. Phase III studies of these agents partnered with platinum demonstrated no clear preferred doublet.[175] In the early 2000s, histology became an important determinant in the selection of systemic therapy for advanced NSCLC. The antiangiogenic agent, bevacizumab, was proven to be an effective therapy in patients with nonsquamous lung cancer when coupled with carboplatin and paclitaxel.[20] Similarly, for patients with a nonsquamous histology, the combination of cisplatin and pemetrexed had an improved response and survival compared to cisplatin and gemcitabine, whereas the opposite was true for patients with a squamous histology.[21]

In terms of duration of chemotherapy, treatment with a platinum doublet beyond the initial four to six cycles is not a useful strategy as it is associated with an increase in adverse events, a decrease in QOL and a marginal effect on survival.[176] For patients with nonsquamous histologies who receive pemetrexed, continuation of this agent, also known as maintenance chemotherapy, has been demonstrated to achieve an OS advantage.[177]

Treatment of metastatic NSCLC is palliative and invariably patients treated with chemotherapy will acquire resistance to chemotherapy. Second-line

treatment has also shown a survival advantage to best supportive care in phase III trials.[178] Prior to the immunotherapy era, docetaxel and pemetrexed became the standard second-line chemotherapy regimen depending on histology and prior chemotherapy use.[179]

Advent of Immunotherapy

Harnessing the immune system as a tool to treat cancer had long been pursued in a variety of malignancies but with largely disappointing results in the majority of them. The immune system is tightly regulated to avoid immune over activation that could result in harm to healthy tissues. These regulatory mechanisms are exploited by several cancers to escape from immune recognition. T cells, the major effector cell of the immune system, are regulated by a balance between costimulatory and inhibitory signals commonly referred as immune checkpoints. These checkpoints can be dysregulated by tumors as an important immune resistance mechanism.[180] Programmed death 1 (PD-1) receptor is a T-cell coinhibitory receptor that is activated upon its interaction with ligand PD-L1. Blocking this interaction with the use of antibodies against either of these receptors has been proven as successful strategy in a variety of cancers. In NSCLC, treatment with pembrolizumab or nivolumab, both PD1 antagonists, as well as atezolizumab, a PDL1 antagonist, has been shown to improve response rates and OS compared to docetaxel in patients who have progressed through a platinum doublet. Therefore, immune checkpoint inhibition with anti-PD1 or anti-PDL1 agents has become the de facto standard second line for patients who are eligible to receive them.[181]Treatment with these medications have a distinct set of side effect compared to chemotherapy but they are generally better tolerated than cytotoxic agents. Given the success in the second-line setting, these agents have also been studied in patients who are treatment naive. However, in this setting the results have been more challenging to interpret. In patients who have a PDL1 expression in more than 50% of tumors cells, treatment with pembrolizumab is associated with an improvement in OS compared to a platinum doublet in NSCLC (HR 0.6, 95% CI 0.41 to 0.89),[182] establishing pembrolizumab as the new standard of care in this select population of roughly 23% to 28% of all advanced NSCLC patients.

The combination of these immune checkpoint inhibitors with chemotherapy is also being investigated. A phase 2 trials of pembrolizumab with carboplatin and pemetrexed compared to chemotherapy alone in patients with nonsquamous histology showed an increase in response rate (55% vs. 29%) and progression-

free survival (13 vs. 8.9 months, HR 0.53, 95% CI 0.31 to 0.91, $P = 0.010$) in the investigational arm.[183] Overall survival appeared similar but one has to consider that this was not the primary end point and 74% of patients received immunotherapy at progression possibly diluting its effect. The combination arm was accompanied by more toxicities with an increase in the incidence of grade 3 or 4 AEs (40% vs. 25%). Phase III studies asking this question with pembrolizumab and other PD1/PDL1 blockers are underway.

In patients with melanoma, where a longer track record exists with the use of checkpoint inhibitors, 21% of patients are alive a decade after treatment.[184] More time is needed to establish if this is true for patients with NSCLC. Despite this excitement, it is important to remember that currently, only a minority of patients are helped by immunotherapy. Novel immunotherapy combinations with other checkpoint inhibitors and/or other modulators of immune activation such as vaccines or cytokines are being developed and the results of these studies are coming at a pace that we could only have dreamt of a few years ago.

Molecular Determinants of Therapy

Another major advance that dramatically improved the survival of a subset of patients with NSCLC in the last two decades is the discovery that a fraction of patients with mostly adenocarcinomas have a driver genetic abnormality. Pharmacologically inhibiting this abnormality with TKIs is now the standard of care for these patients.

Epidermal Growth Factor Receptor

The presence of EGFR-activating mutations in approximately 10% to 15% of lung cancer patients and their association with heightened sensitivity to EGFR TKIs were first recognized in 2004.[185] However, it is only since 2009 that the association between EGFR mutations and improved response rate and PFS have been confirmed in prospective phase III trials. The Iressa Pan-Asia Study (IPASS), a phase III, multicenter, randomized, study in patients with advanced adenocarcinoma of the lung,[186] randomized treatment-naive East Asian patients ($n = 1{,}217$), either nonsmokers or former light smokers, to gefitinib monotherapy 250 mg/day orally or to combination paclitaxel 200 mg/m^2 and carboplatin (AUC, 5 to 6 mg/mL/minute) every 3 weeks for up to six cycles. Among the overall study population, tumors from 437 patients (35.9%) were evaluable for mutation analysis; approximately 60% carried EGFR mutations. Of those with mutations randomized to gefitinib, the response rate exceeded 70%, whereas

wild-type patients randomized to gefitinib had a response rate of roughly 1%. At 12 months, PFS was significantly longer in mutation-positive patients in the gefitinib group compared to patients in the chemotherapy group (HR 0.48, 95% CI 0.36 to 0.64, *P* <.001). Conversely, PFS was significantly shorter for gefitinib compared to chemotherapy in patients whose tumors did not harbor mutations (HR 2.85, 95% CI 2.05 to 3.98, *P* <.001). Final OS results for the gefitinib and chemotherapy groups were not significantly different, presumably because of crossover to an EGFR TKI in mutation-positive patients randomized to chemotherapy. Despite the absence of a survival benefit, this trial has irrevocably altered the therapeutic paradigm in advanced NSCLC and has laid the groundwork for subsequent phase III trials comparing EGFR TKIs to standard chemotherapy conducted exclusively in patients with an EGFR mutation.

Taken together, the results of these trials, particularly with respect to response rate and PFS, support the use of EGFR TKIs in the first-line setting in patients harboring EGFR-activating mutations. To date, however, largely because of crossover at the time of disease progression, this response rate and PFS benefit has not yet translated into an OS advantage. However, it appears that patients who harbor this mutation live longer than wild-type patients as long as they receive an oral EGFR TKI at some point in their disease course. The choice of which EGFR TKI to use, among those approved in the first-line setting, is a question of debate. Erlotinib, gefitinib and afatinib all have similar activity in this setting. Few studies have conducted head-to-head comparisons of these agents. Erlotinib and gefitinib have been compared in 2 Asian trials and both demonstrate similar response rates, progression free, and OS with similar toxicities.[187,188] Afatinib and gefitinib were compared in a phase IIB study. In a preliminary report, patients treated with afatinib had a slightly longer PFS (11 vs. 10.9 month, HR 0.73 95% CI, 0.57 to 0.95, *P* = 017) and no difference in OS (27.9 vs. 24.5 HR 0.86 95% CI, 0.66 to 1.12, *P* = 258).[189] The incidence and severity of adverse events were higher for patients treated with afatinib with grade 3/4 adverse events reported in 50 (31%) patients given afatinib and 28 (17%) patients given gefitinib, with diarrhea and rash being the most common.

Invariably, patients will acquire resistance to an initial TKI. The most common cause of resistance is the development of a new mutation (T790M) that results in a structural change in the EGFR protein and is present in 50% to 60% of cases.[190] Osimertinib is a third-generation EGFR TKI that still binds to the EGFR receptor despite a T790M mutation. When it was compared to carboplatin and pemetrexed in patients that had progressed after an initial TKI, it was

associated with an increase in the response rate (71% vs. 31%) and an increase in median progression-free survival (10.1 vs. 4.4 months, HR 0.30; 95% CI, 0.23 to 0.41; *P* <0.001).[191] Overall survival has not been reported, but with a 60% crossover rate an advantage may not be apparent. Osimertinib is currently being evaluated in the treatment-naive patients with an EGFR mutation against gefitinib or erlotinib (NCT02296125).

ALK

ALK positivity defines a distinct molecular subset of NSCLC (3% to 7%). Here, the driver molecular abnormality arises because of an inversion in chromosome 2 that juxtaposes the 5′ end of the EML4 gene with the 3′ end of the ALK gene. Nearly all patients have adenocarcinomas, and they are more likely to be nonsmokers. Crizotinib, a selective inhibitor of the ALK and MET tyrosine kinases, was approved for this subset of patients after results of a phase I study in previously treated patients with NSCLC whose tumors expressed EML4-ALK showed remarkable activity.[192] When treatment with crizotinib was compared to a platinum-pemetrexed based regimen, crizotinib was associated with a higher response rate (74% vs. 45%) and longer progression-free survival (10.9 vs. 7 months, HR 0.45; 95% CI, 0.35 to 0.60; *P* <0.001). Similar to what is seen in EGFR-positive cancers, with a crossover rate of about 70%, no difference in OS was noted (HR, 0.82; 95% CI, 0.54 to 1.26; *P* = 0.36).[193] The most common adverse events were mild to moderate and gastrointestinal in nature and included nausea (56%), diarrhea (61%), and vomiting (46%). Other adverse events included liver function test elevations and transient difficulty with light–dark visual accommodation (71%).

Invariably, either resistance to crizotinib develops or patients develop progressive disease within the CNS as crizotinib appears to have modest CNS activity. When resistance occurs, in contrast to the EGFR subset, there is no predominant molecular mechanism that accounts for it. Ceritinib and alectinib are second-generation ALK inhibitors that can overcome resistance to crizotinib and have good CNS activity. In the case of ceritinib, treatment with this agent in patients who had previously been treated with crizotinib resulted in a response rate of 57% (*n* = 92/163) including 3 complete response. In the same study, in 28 patients who had measurable CNS disease that developed while on crizotinib, the intracranial response rate was 36% (*n* = 10) with a median duration of response of 11.1 months.[194] Alectinib has been studied in two phase II trials of patients who developed resistance to crizotinib, and the response rates were 48

and 50% (in 87 and 138 patients) with progression-free survivals of 8.1 months (95% CI 6.2 to 12.6) and 8.9 months (95% CI, 5.6 to 11.3 months).[195,196] In those patients with measurable CNS disease in the first trial, the response rate was an impressive 75% (*n* = 12/16). In the second study of 35 patients with measurable lesions, the CNS response rate was 57%. The most common adverse events of alectinib reported have been constipation (33%), fatigue (26%), and peripheral edema (25%). Ceritinib and alectinib agents have not been compared head to head in a randomized setting and both have been approved for use after progression on crizotinib. Brigatinib and lorlatinib are other second-generation agents that are currently being evaluated. Brigatinib, alectinib, and lorlatinib are being evaluated in treatment-naive patients in randomized controlled trials comparting them against crizotinib in patients with ALK translocations (NCT02737501, NCT02604342, NCT03052608, respectively). The results of these ongoing studies may change the current standard of care in the near future.

ROS1

The translocation between *ROS1* and other genes, the most common of which is *CD74*, occurs in 1% to 2% of NSCLC.[197] These fusions lead to the constitutive activation of *ROS1*. This activation can be inhibited with crizotinib. In an open-label study of 50 patients treated with crizotinib, the objective response rate was 72 percent (3 complete and 33 partial responses) with a PFS of 19.2 months.[198] Crizotinib is currently approved for this indication. Little is known about the mechanisms of resistance is this setting and early phase trials are currently evaluating brigatinib and lorlatinib.

BRAFV600E

BRAF can also act as an oncogenic driver in the presence of an activating mutation, the most common one of which is V600E, observed in 1% to 2% of lung adenocarcinomas.[199] A BRAF inhibitor, dabrafenib, has been found to have activity in these patients with a response rate of 33% (*n* = 26/78) and a PFS of 5·5 months.[200] Vemurafenib, another BRAF inhibitor, also has activity with a response rate of 42% (*n* = 8/19) and a PFS of 7.3 months.[201] In patients with melanoma where the BRAFV600E mutation is more prevalent, studies using a MEK inhibitor along dabrafenib is synergistic. A phase II of the combination of dabrafenib and the MEK inhibitor, trametinib, reported that in 57 previously treated patients, the response rate was 63% with a PFS of 9.7 months (95% CI 6.9 to 19.6). The most common adverse events were pyrexia (44%), nausea

(40%), vomiting (35%), and diarrhea (32%). These were typically mild and manageable; the most common grade 3/4 adverse events were neutropenia (9%) and hyponatremia (7%).[200] A study of this combination in previously treatment-naive patients is ongoing.

Role of Radiation in Oligometastatic/Oligoprogressive NSCLC

Although survival for patients with metastatic NSCLC remain poor with 5-year OS of <10%, there is a subset of patients who have better prognosis and may benefit from aggressive local therapy. The challenge has been to identify those patients. One subgroup that has consistently shown superior outcome is patients with limited systemic disease burden (oligometastatic disease), and this has been incorporated into the AJCC 8th edition staging system, with M1b being patients with a single site of extrathoracic metastasis.[19] The exact definition of oligometastatic is still evolving and varies based on studies. An international analysis of 757 NSCLC patients with 1 to 5 synchronous or metachronous metastases and a controlled primary (treated with curative intent local therapy including surgery, SBRT, curative dose radiation, or some combination) showed 5-year OS of 29.4% for the entire population, with 5-year OS of 47.8% for the best risk group on recursive partitioning analysis in patients with metachronous disease and 5-year OS of 13.8% in the worst risk group for patients with synchronous metastases and N1/N2 disease.[202] Beyond treating the primary lung tumor, aggressive radiation may also have a role in managing the oligometastatic sites. A multicenter, phase II trial randomized patients with metastatic NSCLC with 3 or fewer metastatic lesions after first-line systemic therapy to either local consolidative therapy to all sites of disease +/- maintenance treatment or to maintenance treatment alone.[203] Local consolidative therapy included surgery or radiation, and radiation was given with curative intent when possible. SBRT, hypofractionated radiotherapy (e.g., 15 fractions to the mediastinum), and concurrent chemoradiotherapy were allowed. The study was terminated early after randomization of 49 patients because of improved median PFS in the local consolidative therapy group (11·9 months (90% CI 5·7 to 20·9) versus 3·9 months (2·3 to 6·6) with HR 0·35 [90% CI 0·18 to 0·66], log-rank P = 0054). Adverse events were similar between groups, with no grade 4 adverse events or deaths because of treatment. A single arm, phase II study in 24 patients who progressed through platinum-based chemotherapy but were eligible to receive erlotinib and SBRT to 6 or less sites of extracranial disease showed it was possible to achieve median OS of 20.4 months with median PFS of 14.7 months,

and most patients progressed in new distant sites, with only 3/47 measurable lesions recurring inside a prior SBRT field.[204] This was an unselected group of NSCLC from the standpoint of EGFR mutation status, with 0/13 tested patients positive for EGFR mutation.

As systemic therapies improve, there is also a category of patients with "oligoprogressive" disease, who may have many sites of metastasis that are all responding to systemic therapy (usually targeted agents), but one or a few sites of disease that are progressing. In this scenario, aggressive radiation therapy, such as with SBRT, to the sites of oligoprogressive disease can give patients more time on the targeted agent before having to switch systemic therapies. In published series of patients on erlotinib or crizotinib with four or fewer sites of extracranial progressive disease, ablative local therapy such as SBRT to the oligoprogressive sites can provide an additional 6 months or more of PFS on the same targeted agent.[205,206]

Conclusion

These are very exciting times for the treatment of metastatic NSCLC as significant advances have become available that are dramatically changing the paradigm of how we treat this disease. Chemotherapy remained the standard of care for several decades, and although it is still the predominant first-line treatment in the majority of patients, a growing subset of patients can be more effectively treated with either targeted therapy when an actionable molecular driver exists or with immunotherapy when they have a strong expression of PDL1. As systemic therapies improve, there may also be an increasing role for local therapy in providing durable disease control.

PALLIATIVE RADIOTHERAPY

Given the propensity of lung cancer for locoregional recurrence and/or distant metastatic disease, radiotherapy plays an important role in the palliation of symptomatic disease in many lung cancer patients. The most common sites of disease that require palliative radiotherapy include the thorax, bone, and brain. Intrathoracic disease and bone metastasis will be covered here. The reader is referred to the CNS section (see Chapter 94) for management of brain metastasis from lung cancer.

Palliation of Intrathoracic Disease

Symptoms from progression of intrathoracic lung cancer that may benefit from a

course of palliative radiotherapy include cough, hemoptysis, chest wall pain, SVC syndrome, dyspnea from airway obstruction, and hoarseness from involvement of the recurrent laryngeal nerve. The rate of palliation of local symptoms is high for chest pain and hemoptysis at 60% to 80%, whereas cough and dyspnea are improved in only 50% to 70%.[207] For intrathoracic disease with an obstructive component, 30 to 45 Gy in 2.5- to 3-Gy fractions over 2 to 3 weeks is generally recommended. For patients with poor performance status or for whom daily radiotherapy over 2 to 3 weeks is logistically difficult, hypofractionated regimens (of one to two fractions) have been utilized with good palliative results. The use of concurrent chemotherapy in the palliative setting is not supported by the current medical literature.

Endobronchial brachytherapy provides relief for patients with endobronchial lesions causing obstruction or hemoptysis. The lesion to be treated should be visible by bronchoscopy and generally located in the trachea, main stem, or lower lobe bronchi. This procedure requires the combined efforts of an interventional pulmonologist and brachytherapist. The pulmonologist performs fiberoptic bronchoscopy, placing an afterloading catheter within the airway adjacent to the tumor under direct visualization. In a retrospective study from MD Anderson Cancer Center involving 175 patients with lung cancer who received high–dose rate brachytherapy for metastatic or locally recurrent lung cancer, 115 patients (66%) demonstrated symptomatic improvement.[208] Endobronchial brachytherapy is primarily indicated in patients with obstructive endobronchial lesions who have already received EBRT. It can also be combined with other interventions that can acutely relieve symptoms related to airway obstruction such as stenting or debulking procedures.

Superior Vena Cava Syndrome

Lung cancer is the most common cause of SVC syndrome and accounts for approximately 80% of cases at diagnosis. If the SVC becomes obstructed because of an extrinsic mass, blood returns to the heart through collateral vessels to the azygos vein or inferior vena cava. Venous collaterals dilate over weeks so that the upper body venous pressure and resulting edema of the arm and face decrease over time. The severity of the symptoms is therefore attributable not only to the degree of SVC narrowing but also to the rapidity with which it develops. The characteristic signs include cyanosis, plethora, distension of subcutaneous veins, and edema of the head, neck, and arm. Patients may report dyspnea or cough. Rarely, severe and acute obstruction can result in cerebral

edema or laryngeal stridor. The clinical course may be exacerbated by the development of a thrombus or the simultaneous tumor mass effect on the bronchi or heart.

Traditionally, SVC syndrome was viewed as a medical emergency. Accumulating experience, however, demonstrates that the course of SVC is rarely life threatening.[209] In malignant SVC syndrome, immediate intervention is warranted when the symptoms are life threatening (e.g., cerebral edema leading to altered mental status, stridor, or clinically significant hemodynamic compromise). When urgent intervention is indicated, intravascular stenting provides the most immediate relief and can be accomplished even when there is complete obstruction. In the absence of life-threatening symptoms, the patient should be appropriately staged and biopsied and the underlying malignancy treated in a manner appropriate for its stage and presentation. The majority of patients with SVC syndrome attributed to SCLC will respond to systemic therapy, and patients with extensive-stage SCLC and SVC syndrome should start chemotherapy after a staging evaluation. Similarly, patients with limited-stage SCLC and SVC syndrome with bulky disease should respond rapidly to a cycle of chemotherapy, after which radiation can be added, treating the smaller, postchemotherapy volume to spare normal lung tissue. Patients with NSCLC and SVC syndrome are less likely to respond to chemotherapy, thus the threshold for starting radiation or placing an endovascular stent should be lower. In patients with metastatic NSCLC, palliative radiotherapy is commonly recommended as part of initial therapy.

SMALL CELL LUNG CARCINOMA

In the United States in 2011, approximately 28,000 patients were diagnosed with SCLC, constituting approximately 13% of all lung cancer diagnoses. Over the past several decades, the proportion of SCLC among all lung cancer histologies has been decreasing, perhaps because of smoking cessation and the proliferation of low-tar cigarettes. Although there has been a modest but statistically significant improvement in 2- and 5-year survival in both limited- and extensive-stage diseases in recent decades, the outcomes are still extremely poor, particularly because the majority (~60%) of patients present with extensive-stage disease with an expected 2-year survival of only 4%.

Pathology

The establishment of a firm pathologic diagnosis distinguishing SCLC from NSCLC variants such as carcinoma with neuroendocrine features and carcinoid is extremely important in this disease, as it can have a significant impact on management and clinical outcome. Histologically, SCLC is one of the small, round, blue cell tumors (along with neuroblastoma, rhabdomyosarcoma, Merkel cell carcinoma, etc.) with scant cytoplasm and indistinct nucleoli. Cells are often molded together, and crush artifact is commonly noted after needle biopsy but is not pathognomonic. Almost all SCLC samples are immunoreactive to keratin and epithelial membrane antigen, and approximately 80% express thyroid transcription factor-1 (TTF-1).[210] The majority of tumors will stain for neuroendocrine markers including synaptophysin, neuron-specific chromogranin A, enolase, and CD56. Immunohistochemistry alone, however, cannot distinguish SCLC from small cell cancer of nonthoracic origin or from NSCLC with neuroendocrine differentiation. The WHO recognizes that SCLC can occur in a pure type or mixed with NSCLC in up to 30% of cases.

Prognostic Factors in Small Cell Lung Cancer

The most clinically important prognostic factor in SCLC is stage (limited vs. extensive), with a median survival of approximately 23 months for patients with limited disease versus 8 to 9 months for those with extensive disease.[105] Other clinical factors consistently reported to correlate with improved survival include good performance status, female gender, and normal lactate dehydrogenase levels at baseline.[211]

Staging Workup

As in patients with NSCLC, patients with SCLC should undergo a timely and efficient history, physical exam, and laboratory and radiographic evaluation. The history and physical should be performed with particular attention to signs and symptoms of paraneoplastic syndromes, including SIADH and elevated ACTH. Laboratory evaluation should include a complete blood count and comprehensive chemistry panel. Radiographic studies should include a CT scan of the chest and abdomen with intravenous contrast, with PET/CT for suspected limited-stage disease. All patients with SCLC, regardless of stage, should undergo a brain MRI with gadolinium or a head CT with contrast to evaluate for brain metastases. A diagnostic thoracentesis should be performed for any identified pleural effusion to determine the presence of malignant cells. The TNM staging system adopted by the American Joint Commission for Cancer

(AJCC) is applicable to both NSCLC and SCLC. Most historical studies and ongoing prospective trials, however, classify patients as having limited or extensive disease based on the 1973 Veteran's Administration Lung Group staging scheme.[212] In this system, limited stage is defined as disease confined to the ipsilateral hemithorax, which can be safely encompassed within a tolerable radiation portal. Virtually all studies in limited disease exclude malignant pleural effusions. From a practical standpoint, hemithoracic radiotherapy to encompass the entire ipsilateral pleura has little justification because it would confer a significant risk of pulmonary toxicity in a high-risk patient population with little chance of cure. As such, patients with malignant pleural effusions are classified as having extensive-stage disease.

Paraneoplastic Syndromes

Paraneoplastic syndromes are commonly encountered in lung cancer; however, the spectrum of paraneoplastic syndromes in SCLC is distinct from that observed in NSCLC. Neurologic paraneoplastic syndromes are more commonly encountered in SCLC and are thought to be primarily autoimmune in nature. LEMS is seen in 3% of all SCLC patients at presentation and is characterized by proximal muscle weakness that improves with continued activity. This syndrome occurs when autoantibodies are generated against voltage-gated calcium channel receptors on the presynaptic membrane, impeding release of acetylcholine into the neuromuscular junction and resulting in muscular weakness. A wide variety of other rare autoimmune neurologic paraneoplastic syndromes have been described in SCLC, including encephalomyelitis, cerebellar degeneration, and retinopathy. SCLC can also elaborate hormonally active peptides including ACTH and vasopressin leading to Cushing syndrome and SIADH, respectively. Although SCLC is the most common tumor associated with SIADH, only 10% of patients meet the clinical criteria for SIADH. Similarly, only 5% of SCLC patients present with Cushing syndrome. Despite the fact that paraneoplastic syndromes may lead to early identification and diagnosis of SCLC, some of these syndromes, such as Cushing's, have been associated with poorer survival.[213] Treatment of the cancer will often, although not always, ameliorate the paraneoplastic syndromes.

General Therapeutic Precepts

Early-stage (i.e., T1 to T2, N0) SCLC is diagnosed in <5% of incident cases. For these patients, definitive surgical resection is a potential therapeutic option. In a

population-based study, lobectomy without adjuvant radiation was associated with an approximately 50% OS.[214] Given the propensity for early nodal dissemination with SCLC, invasive staging of the mediastinum should be performed prior to surgical resection. After surgical resection, the primary mode of failure for these patients is distant dissemination. Tsuchiya et al.[215] reported the results of JCOG9101, a JCOG Lung Cancer Study Group multi-institutional phase II prospective trial evaluating adjuvant EP after complete surgical resection of stage I through stage IIIA SCLC. The majority of patients enrolled had clinical stage I disease (44/62). Three-year survival was 61% overall, 68% in patients with clinical stage I disease, 56% in patients with stage II disease, and 13% in patients with stage IIIa disease. These data suggest a possible role for surgical resection in select patients with pathologically proven stage I or II SCLC.

The majority of patients present with evidence of nodal or distant dissemination at the time of diagnosis. Multiagent chemotherapy, usually a platinum-based combination, is an essential part of therapy for these patients. For patients with limited-stage disease, the addition of thoracic radiation significantly improves survival and therefore is an integral of part their treatment regimen. Two meta-analyses have demonstrated not only an improvement in thoracic control but also a significant increase in OS of about 5% (and relative improvement of about 50%) in patients with limited-stage disease treated with combined modality therapy compared to those with treated chemotherapy alone.[216,217] For select good performance status patients with extensive-stage disease who have complete resolution of their extrathoracic tumor burden, consolidative thoracic radiotherapy may be of benefit to reduce the risk of intrathoracic failure.[218,219] Patients with limited-stage disease selected (and with patients extensive-stage disease) who respond to initial therapy should be offered prophylactic cranial irradiation (PCI), as this has been shown to provide a significant improvement in absolute survival for these patients.[220,221]

Combining Radiation and Chemotherapy for Limited-Stage Disease

A randomized trial by the JCOG evaluated concurrent versus sequential chemotherapy and thoracic radiation in patients with limited-stage SCLC.[222] All patients received 45 Gy in 1.5-Gy fractions twice daily and were randomized to receive four cycles of cisplatin (80 mg/m^2 on day 1) and etoposide (100 mg/m^2 days 1, 2, and 3) every 4 weeks concurrent with radiotherapy (beginning day 2) or every 3 weeks sequentially before radiotherapy. Patients treated concurrently

had longer median survival compared to patients treated sequentially: 27 months versus 20 months. A second randomized trial by the National Cancer Institute of Canada compared early with late concurrent chemoradiotherapy.[223] In this trial, 308 patients received cyclophosphamide, doxorubicin, and vincristine alternating with EP and were randomized to 40 Gy in 15 daily fractions given with either the first cycle of EP (week 3) or the last (week 15). The median survival improved to 21 months with radiotherapy early 16 versus months with treatment late (P = .008). These two trials were included in a meta-analysis by Fried et al.[224] that included >1,500 patients from seven randomized trials evaluating the timing of radiotherapy when given concurrently with multiagent chemotherapy. The use of early thoracic radiotherapy, with cycle one or two of chemotherapy, was associated with improved 2-year OS compared to delayed or sequential chemotherapy and radiation. The benefit was more pronounced when the radiotherapy was given with platinum-based chemotherapy. The chemotherapy most commonly prescribed in the curative setting is cisplatin and etoposide.

Dose and Fractionation

The optimal dose and fractionation scheme for concurrent chemoradiation for limited-stage small cell is an area of active investigation. SCLC is highly radiosensitive, suggesting that hyperfractionation could be employed to reduce late normal tissue toxicity. It also has a high proliferative rate, arguing for accelerated treatment to counteract repopulation. Between 1989 and 1992, 417 patients were enrolled in a randomized, intergroup trial of concurrent accelerated hyperfractionated radiotherapy versus standard daily radiotherapy in patients with limited-stage SCLC.[105] All patients received four cycles of cisplatin (60 mg/m^2 on day 1) and etoposide (120 mg/m^2 on days 1, 2, and 3), and radiotherapy began with cycle 1. In the once-daily arm, patients received 45 Gy in 1.8-Gy fractions over 5 weeks. In the twice-daily arm, patients received 45 Gy in 1.5-Gy fractions over 3 weeks. Patients who achieved a complete response were offered PCI. OS was significantly higher in the twice-daily arm, 26% versus 16% at 5 years, and local recurrence was significantly lower, 36% versus 52%. There was a significant increase in grade 3 acute esophagitis, 26% versus 11%, in the twice-daily arm, with no difference in late toxicity.

The high intrathoracic relapse rate observed in both arms of the Turrisi study highlights the inadequacy of these modest doses to achieve meaningful local control.[105] Dose escalation, either through an altered fractionation or

conventionally fractionated approach, has been explored with a goal of improving intrathoracic control of disease. In 2005, the RTOG reported the results of a phase I dose escalation trial in which 64 patients were enrolled and dose escalated in a stepwise fashion from 50.4 Gy to 64.8 Gy in 1.8 Gy per fraction.[225] The lowest dose cohort received 1.8 Gy once daily for 20 fractions, followed by 1.8 Gy twice daily on the final 3 days. Dose escalation was achieved by the addition of a second daily fraction on the last 5, 7, 9, or 11 days, retaining the 5-week treatment duration. The maximum tolerated dose was determined to be 61.2 Gy in 5 weeks using this scheme. In a follow-up phase 2 study, RTOG 0239,[226] 72 patients were treated to 61.2 Gy in 5 weeks, with twice-daily radiotherapy for the last 9 treatment days. With 19 months median follow-up, 2-year OS was 37% and 2-year locoregional control was 80%.

Dose escalation has also been examined utilizing a daily fractionation scheme. Choi et al.[227] conducted a phase I dose escalation study with both twice-daily and once-daily arms. In the twice-daily arm, 45 Gy in 30 fractions over 3 weeks was the maximum tolerated dose. In the once-daily arm, the dose was escalated to the maximum of 70 Gy in 35 fractions over 7 weeks without dose-limiting toxicity. CALGB 39808 tested the feasibility of this approach with concurrent platinum and etoposide.[228] In this study, 63 patients were treated with two cycles of induction paclitaxel (175 mg/m^2 day 1) and topotecan (1 mg/m^2 days 1 through 5), followed by concurrent thoracic radiation with carboplatin (AUC 5) and etoposide (100 mg/m^2 days 1 through 3). Thoracic radiation consisted of 44 Gy to the mediastinum and primary tumor delivered in 2 Gy per fraction, followed by a cone down to encompass the involved nodes and primary tumor alone for an additional 26 Gy, totaling 70 Gy in 35 fractions over 7 weeks. The OS at 2 years was 48%. Results of the Concurrent Once-daily Versus Twice-daily Radiotherapy (CONVERT) trial were reported in 2016. This study enrolled 547 patients between 2008 and 2013 at 88 centers worldwide, randomizing patients with limited-stage disease to 45 Gy twice daily or 66 Gy once daily. The 2-year OS was not significantly different (56% for twice daily, 51% for once daily), and the rate of grade 3 or greater esophagitis was 19% in both arms. The authors concluded that once-daily radiation is an acceptable alternative to twice-daily radiation.[229]

An ongoing intergroup effort (CALGB 30610, RTOG 0538, NCT00632853) continues to compare 45 Gy in 30 fractions over 3 weeks versus 70 Gy in 35 fractions. A third arm was closed, which administered 61.2 Gy in 5 weeks per RTOG 0239. All patients receive concurrent EP, and radiotherapy begins with

cycle 1 or cycle 2.

Radiotherapy Volume

Limited-stage SCLC is frequently bulky at presentation, requiring large treatment fields to encompass all sites of intrathoracic disease. Therefore, induction chemotherapy has been employed to achieve cytoreduction of disease prior to initiation of thoracic radiotherapy. This approach raises the concern of potentially increasing the risk of marginal treatment failure if the postchemotherapy volume alone is included in the radiation portal. To address this question, the SWOG conducted a randomized study, enrolling 191 patients who had a partial response or stable disease after 6 weeks of induction chemotherapy. They were randomized to receive radiotherapy (48 Gy split course) to either the preinduction or postinduction volume.[230] There was no difference in local recurrence rates: 32% in the preinduction versus 28% in the postinduction arm. Careful retrospective studies of patients treated with preinduction or postinduction thoracic radiotherapy show that local failure is not significantly higher if smaller fields are used. Furthermore, most intrathoracic failures occur in the smaller postchemotherapy radiation field, arguing, as in locally advanced NSCLC, against the use of ENI.[231,232]

Thoracic Radiotherapy for Extensive-Stage Disease

Systemic therapy is the essential element in the treatment of patients with extensive-stage SCLC with good performance status; however, thoracic radiotherapy may play a role in selected patients. Based on the observation that patients have high rates of thoracic relapse after systemic therapy alone, a single-institution prospective randomized trial was undertaken in Yugoslavia.[218] In this trial, 209 patients with extensive disease were enrolled and treated with three cycles of EP. Of those, 110 patients who had a partial response in the chest and a complete response outside the chest were randomized to receive thoracic radiation with concurrent carboplatin and etoposide, followed by two cycles of EP, versus four further cycles of EP alone. All eligible patients received PCI. The thoracic radiation was delivered in 54 Gy in 36 fractions over 12 days. At 5 years, the OS was higher in the arm that featured thoracic radiation: 9% versus 4%.

RTOG 0937 was a randomized phase II study in patients with metastatic SMLC with 1 to 4 extrathoracic sites of disease (excluding brain metastasis); patients were randomized to receive 45 Gy in 15 fractions to all sites of disease

followed by PCI, versus PCI alone, after chemotherapy. The trial was closed for futility after an interim analysis of 86 patients.[233] With a median follow-up of 9 months, there was no significant difference in 1 year OS: 60% for PCI versus 51% for PCI and RT to thoracic and metastatic sites. Yet, the Chest Irradiation in Extensive Stage Small Cell Lung Cancer (CREST) trial, conducted by the Dutch Lung Cancer Study Group suggests a benefit of thoracic radiation in this setting. In this study, 498 patients with extensive-stage disease who responded to chemotherapy were randomized to thoracic radiotherapy (30 Gy in 10 fractions) and PCI versus PCI alone. The dose of thoracic RT was 30 Gy in 10 fractions. The primary end point was OS at 1 year, and there was no significant improvement at this time point (33% for TRT vs. 28%). At 2 years, however, there was a significant improvement in OS, 13% versus 3%, favoring TRT.[219] Overall, these results suggest that TRT may benefit a subset of patients with extensive disease after chemotherapy.

Prophylactic Cranial Irradiation

Brain metastases are present at diagnosis in approximately 20% of patients with SCLC. The brain is also a frequent site of failure after chemotherapy for extensive disease or chemoradiotherapy for limited-stage disease. Several randomized trials have addressed the value of PCI following a response to initial therapy and have consistently demonstrated a decrease in the incidence of brain metastases. A meta-analysis reported the results of 987 patients treated in seven randomized trials enrolling between 1977 and 1995.[221] Here, 85% of these patients had limited stage and 15% extensive. All were randomized either to PCI or to observation following a complete response to initial therapy, although response was most commonly assessed by chest x-ray rather than CT scan. PCI regimens varied from 8 Gy in a single fraction to 40 Gy in 20 fractions. At 3 years, PCI was found to significantly decrease the incidence of brain metastases (59% vs. 33%) and significantly improve OS (21% vs. 15%). There was trend toward improved brain control when PCI was administered earlier and at higher dose. The publication of this study demonstrated the value of PCI in limited-stage SCLC.

PCI in extensive-stage SCLC was addressed separately in a randomized trial conducted by the EORTC.[220] In this study, 286 patients with extensive-stage SCLC were randomized to either PCI or observation after any response to four to six cycles of chemotherapy. Those assigned to the PCI arm were treated within 4 to 6 weeks of completing systemic therapy. Of note, this study did not

require brain imaging prior to initiation of PCI. The 1-year cumulative incidence of brain metastases was significantly decreased in the PCI arm at 15% versus 40%, and 1-year OS was significantly increased in the PCI arm at 27% versus 13%. Six different PCI regimens were permitted, with biologically effective dose ranging from 25 to 39 Gy. A similar Japanese randomized trial did not replicate these results; the trial was terminated after enrollment of 163 patients when an interim futility analysis determined that no benefit was possible. Patients were randomized after any response to chemotherapy, but unlike the EORTC study, brain imaging was done before enrollment. The median OS was not significantly different between the two arms with a trend toward worse survival in the PCI arm: 11.6 months for patients who received PCI versus 13.7 months for those who did not (HR 1.27, CI 0.96 to 1.68, $P = 0.094$).[234] Thus, the role of PCI in extensive-stage SCLC remains an ongoing controversy.

Despite the survival benefit reported in the Auperin meta-analysis and the EORTC trial in extensive-stage disease, a variety of dose and fractionation schemes were employed to treat the patients enrolled in the trials. To help define the optimal dose and fractionation for PCI, a multi-institutional intergroup trial was launched to examine standard-dose PCI versus high-dose PCI. Patients with limited-stage SCLC who had achieved a complete response to chemoradiotherapy were randomized to receive PCI in standard dose, 25 Gy in 10 daily fractions, or high-dose, 36 Gy in either 18 daily fractions or 24 twice-daily fractions.[235] In this study, 720 patients were randomized; at 2 years, the cumulative incidence of brain metastases was not significantly different between the two arms: 29% in the standard-dose arm versus 23% for high dose. Surprisingly, there was poorer OS in the high-dose arm: 2-year survival was 42% in the standard-dose arm versus 36% for high dose. This was attributed to a higher cancer-related mortality in the high-dose arm. Patients enrolled in this trial participated in baseline and follow-up neuropsychologic test batteries along with QOL assessments. Wolfson et al.[236] recently reported the results of these assessments and observed an increased incidence of chronic neurotoxicity at 12 months after PCI in the 36-Gy cohort ($P = .02$). Taken together, these results establish 2.5 Gy in 10 fractions as the current preferred regimen to deliver PCI.

Extensive-Stage Disease

For patients with extensive-stage disease, treatment is largely palliative, and for patients with adequate performance status, systemic chemotherapy is the cornerstone of treatment. Given a more favorable toxicity profile, cisplatin is

often substituted by carboplatin. A meta-analysis of four trials concluded that in the metastatic setting, there was no differences in efficacy between cisplatin and carboplatin.[237] Other drug partners aside from etoposide have been tested with no clear advantage. Recurrence is inevitable and few effective options exist at the time of progression. The only US Food and Drug Administration (FDA)–approved regimen in this setting is topotecan. Treatment with this agent in the second-line setting has been associated with a slower deterioration of QOL and better symptom control compared to best supportive care despite having a response rate of only 7%.[238]

After decades with no major advance in the treatment of patients with extensive-stage SCLC, two new developments provide hope that a breakthrough maybe in the horizon. On one hand, immunotherapy has gained considerable interest. In a phase 1/2 study, patients who have progressed after chemotherapy were treated with immune checkpoint inhibitors in different cohorts.[239] Nivolumab alone had an objective response rate of 10% in 98 patients. The combination of nivolumab and ipilimumab proved to be more efficacious with a response rate of 23% in the cohort using nivolumab 1 mg/kg plus ipilimumab 3 mg/kg (n = 14/61) and 19% (n = 10/54) in the nivolumab 3 mg/kg plus ipilimumab 1 mg/kg cohort. The use of combination immunotherapy was associated with increase toxicity, with an incidence of grade 3/4 adverse events of 24% versus 13% in monotherapy. Immunotherapy is currently being explored in several clinical trials in this setting.

The second exciting development is targeted therapy. The delta like 3 gene (*DLL3*) is highly expressed in neuroendocrine tumors, including approximately 80% of SCLC.[240] Rovalpituzumab tesirine is an antibody drug conjugate directed against *DLL3* that is linked to a pyrrolobenzodiazepine (PBD) dimer toxin. This agent was evaluated in a phase 1 study with 74 patients with previously treated metastatic SCLC. In patients who had an *DLL3* expression of >50% of neoplastic cells (n = 29), 10 (35%) had a confirmed objective response and 26 (90%) achieved disease control. The most common grade 3 or higher toxicities were serosal effusions (11%) and thrombocytopenia (11%). This agent is currently being evaluated in the relapsed setting in a single arm phase 2 trial (NCT02674568) and in a phase 3 trial.

NORMAL TISSUE TOXICITY

The risk and severity of radiation toxicity in normal tissue are related to the dose

and volume irradiated, as well as the functional organization of the OAR. In serial tissue such as spinal cord, esophagus, and trachea and bronchi, injury of any one organ subunit may result in total organ dysfunction. Therefore, high dose to even small volumes can lead to significant toxicity. In parallel tissues, such as lung, dysfunction of any one organ subunit leads to partial organ dysfunction. In this case, the volume irradiated, even to lower doses, plays a larger role.

Emami et al.[241] published partial-volume organ tolerances for normal tissue that served for more than a decade as the standard source for radiation dose limits. Dose limits were defined for specific toxicity endpoints, using a 5% complication rate at 5 years ($TD_{5/5}$) or 50% complication rate at 5 years ($TD_{50/5}$). These parameters were based predominantly on clinical data from 2D radiotherapy planning. More recently, a multidisciplinary effort was undertaken, the QUANTEC, to summarize the published 3D dose–volume/toxicity data in the literature, review NTCP modeling, and provide practical guidance for the clinician[145,146] (Table 54.8).

Lung

Clinically significant pneumonitis occurs in 5% to 20% of patients receiving radiation for lung cancer and is one of the key dose-limiting factors in radiation planning for patients with locally advanced disease. RP may occur during fractionated treatment or up to 18 months afterward, with a peak incidence at 2 to 6 months posttreatment. The most clinical common presentation includes a persistent nonproductive cough, dyspnea, low-grade fever, and fatigue. Chest x-ray or CT scan may be normal, or, depending on the time course, there may be ground-glass opacification (within 2 to 6 months), patchy consolidation (4 to 12 months), or fibrosis (10 months or more) that loosely corresponds to the radiation field. Pulmonary function testing shows reduced lung volumes, tidal volumes, and diffusion capacity.

TABLE 54.8 DOSE–VOLUME CONSTRAINTS FOR NORMAL TISSUES USING STANDARD FRACTIONATION TO TARGET VOLUME AND TRADITIONAL ESTIMATES OF NORMAL TISSUE TOLERANCE OF THERAPEUTIC IRRADIATION

Chemo, chemotherapy; Fx, fractions; Max, maximum; MLD, mean lung dose; RT, radiation therapy; SBRT, stereotactic body radiation therapy; TD, tolerance dose; Vol, volume.

[a]Hypofractionation dose constraints not validated by long-term follow-up.

[b]$TD_{5/5}$ and $TD_{50/5}$ represent the estimated dose for each organ volume or partial organ volume resulting in a 1% to 5% risk and a 50% risk, respectively, at 5 years.

[c]The chance of spinal cord damage is increased as treated volume is increased. Physicians should consider off cord earlier if a significant amount of spinal cord has received constraints dose. In general, spinal cord should not receive dose >60 Gy even in very limited volume. Higher fraction size of radiation or higher daily dose will decrease the tolerance. If the patient is treated with 3 Gy per fraction, the cord constraint should be around 40 Gy (based on biologic effective dose calculation).

[d]Consider a kidney scan if the large volume of one kidney will be treated to a high dose.

[e]Less than 50% of combined both kidneys, or <75% of one side of kidney if another kidney is not functional.

[f]First constraint applies to bilateral kidney hilum and vascular trunk. Second parenthetical constraint applies to bilateral kidney cortices.

[g]For patients receiving concurrent chemo/RT, V_{15} may also be an important parameter to be

considered. V_{20} = effective lung volume (total lung volume – GTV) received ≥20 Gy.

A variety of dose–volume models have been evaluated as predictive metrics of RP, including threshold volumes (i.e., V_{dose}), MLD, and Lyman–Kutcher–Burman NTCP models. MLD and dose–volume threshold models are more widely used because of their simplicity, and MLD-based risk assessment for RP correlates closely to that calculated using NTCP modeling. A logistic regression of RP versus MLD and the cross-correlation of various V_{dose} parameters suggest a gradual increase in dose–response, with no safe threshold dose below which the risk of RP is zero.[242]

From collected data in the QUANTEC effort, the risk of RP is <20% when the MLD is less than approximately 20 Gy with conventional fractionation. With regard to V_{dose} threshold models, where the volume of lung outside of the GTV or PTV receiving a threshold dose is quantified, individual datasets have found different thresholds to be optimal, reflecting the interdependence of the dosimetric parameters as well as differences in technique and the specific clinical endpoint used. The risk of RP is <20% for V_{20Gy} <35% or V_5 <60% with conventional fractionation.

All models of conventional fractionation are extrapolated from datasets using standard, simple planning techniques and may have lower predictive power for IMRT, proton therapy, or hypofractionated radiotherapy. Caution is warranted when using IMRT and absolute dose–volume thresholds, because planning algorithms may meet strict dosimetric constraints at the cost of higher dose at other, unconstrained cut points. However, in an analysis of patients treated with IMRT for locally advanced NSCLC on the RTOG 0617, V20 remained the most accurate predictive metric of RP.[243]

RP occurs less commonly after SBRT in comparison to conventionally fractionated radiation.[69] The risk of symptomatic RP does seem to follow a similar relationship to dose and volume irradiated as seen in conventionally fractionated treatment, although specific dose thresholds corresponding to risk thresholds have not yet been fully elucidated. In one large series, the risk of grade 2 or greater RP was 17% when the MLD was >4 Gy versus 4% for lower values and 16% when the V_{20} was >4% versus 4% for lower values.[244] The AAPM Task Group 101 report included a first approximation of tissue dose tolerances for SBRT.[147] For bilateral lung, they recommended maximum dose to 10 and 15 cc of lung of 7.4 and 7 Gy for single-fraction SBRT, 12.4 and 11.6 Gy for three-fraction SBRT, and 13.5 and 12.5 Gy for five-fraction SBRT.

Radiotherapy-induced dyspnea may have several contributing causes, including not only RP but also radiotherapy to other thoracic OARs. Emerging evidence suggests an interaction between cardiac dose and RP,[245] or there may be additive dyspnea owing to pleural and pericardial effusions, restrictive pericarditis, cardiomyopathy, and bronchial stenosis or bronchiectasis. Bronchial toxicity has been reported with conventional radiotherapy after dose escalation,[246] and QUANTEC recommendations include the caution that doses >80 Gy to the major airways should be avoided.[242] For SBRT, the risk of bronchial stenosis is felt to be higher because of the higher biologically effective dose delivered, and this may be one cause of the reported higher risk of pulmonary toxicity when lesions near the proximal bronchi are being treated. The AAPM Task Group 101 recommends maximum doses to 4 cc and maximum point doses to the proximal tracheobronchial tree of 10.5 and 20.2 Gy for single-fraction SBRT, 15 and 30 Gy for three-fraction SBRT, and 16.5 and 40 Gy for five-fraction SBRT.

Several patient- and treatment-related factors impact the risk of RP, independent of dose and volume. In a large dataset derived from patients treated on RTOG trials, the risk of RP was significantly higher for tumors in the lower lung fields.[247] Older age may increase the risk of RP, and patients who continue to smoke through their radiotherapy may be at decreased risk, although the benefits of smoking cessation far outweigh any potential benefit in terms of reduction of risk of RP.[242] Several chemotherapy agents that are commonly administered to lung cancer patients are associated with an increased risk of RP, including docetaxel, gemcitabine, and immune checkpoint inhibitors.

Glucocorticoids are commonly used to treat developing RP, although this has not been evaluated in a prospective fashion, and the starting dose and tapering schedule are undefined. A starting dose of approximately 60 mg or 1 mg/kg of prednisone may be given for 1 to 2 weeks, followed by a slow taper over 4 to 8 weeks. Symptoms may recur when steroids are discontinued, and although it is hoped that treatment may mitigate the development of lung fibrosis, this has not been established. Prophylactic antibiotics or anticoagulants do not appear to effect the development of RP. Pentoxifylline is a xanthine derivative that improves microvascular blood flow; it was used in a single randomized trial of 40 patients undergoing breast or lung irradiation.[248] The proportion of patients with grade 2 or 3 pulmonary toxicity was significantly lower in the patients who received pentoxifylline (20% vs. 50%), as was the measured diffusion capacity. Captopril is an angiotensin-converting enzyme inhibitor that has been shown to

reduce the development of radiation-induced fibrosis in rats, although no such protective effect has been demonstrated in humans.[249]

Esophagus

Acute esophagitis is often the most prominent symptom during fractionated radiotherapy for thoracic malignancy, leading to inpatient admissions, dehydration, weight loss, and treatment interruption. Late esophageal toxicity may include stricture, perforation, or fistula formation. Grade 3 or greater acute esophagitis (symptoms requiring hospitalization, endoscopic intervention, surgery, or treatment breaks) occurs in 15% to 25% of patients during or shortly after chemoradiation. Acute esophagitis may coexist with, and be exacerbated by, comorbid conditions such as candidiasis or reflux disease. Severe late toxicity is less common, occurring in <5% of patients,[250] and manifests as stenosis or, more rarely, fistula formation.

Several dose–volume metrics have been evaluated as predictors of severe esophagitis. The maximum esophageal dose correlates with symptoms, as do multiple absolute dose and volume thresholds. These are highly cross-correlated, and no consensus has been reached regarding the optimum parameter for radiotherapy planning. Circumferential measures (i.e., limits to the length of entire esophageal circumference treated to threshold dose) have also been significantly correlated with symptoms, as has the mean esophageal dose.[251] QUANTEC analysis concludes that volumes treated above 40 to 50 Gy correlate with acute esophagitis and further suggests that no dose above prescription be allowed to even small volumes of esophagus, to reduce the risk of severe ulceration or fistula. This latter information is especially important for heterogeneous IMRT planning.

Esophageal toxicity is related to both dose and volume of irradiation, and the risk and severity are therefore also a function of the size, anatomic arrangement, and proximity of target structures. Other factors identified as increasing the risk or severity of acute esophagitis include the use of accelerated fractionation,[105] older patient age, and the use of concurrent chemotherapy.[93,99] Recently, an unexpectedly high risk of tracheoesophageal fistula formation was reported after radiotherapy with concurrent chemotherapy and bevacizumab.[122]

Treatment of acute esophagitis is primarily supportive care, frequently requiring topical agents, dietary changes, and narcotic pain medication. It is often prudent to evaluate patients for viral or candidal esophagitis. Patients may be treated empirically with antifungal agents or with proton pump inhibitors for

comorbid reflux disease. When esophageal stricture develops, it is usually reversible with repeated dilations. An esophageal fistula can be life threatening, although stenting or surgical management may restore function.

Heart

The cardiotoxicity of radiotherapy has been primarily studied after treatment for breast cancer or mediastinal lymphoma. In these patients, the excess cardiac mortality manifests years after thoracic radiotherapy and depends on the dose, volume, and the patient's existing cardiac risk factors. More recently, analysis of the RTOG 0617 demonstrated that heart dose correlated with worse OS.[121] Acute toxicities include pericarditis, which uncommonly may progress to chronic pericardial fibrosis, effusion, or even more rarely a constrictive pericarditis. Ischemic changes in the cardiac muscle can manifest after a long latency and may lead to late cardiac events. Valvular abnormalities have been reported, presumably owing to late fibrotic changes.

Most of the data regarding dose and volume tolerances for the heart are derived from patients treated for breast cancer or lymphoma, typically with distinct beam arrangements that have limited application to 3D conformal or IMRT treatment of lung malignancies. The risk of pericardial toxicity has been correlated with treatment of >50% of the heart contour in 2D planning and to the volume receiving ≥30 Gy in 3D planning. NTCP modeling has been done using both breast and lymphoma patient data; the derived parameters differ, reflecting the significant differences in technique-related cardiac exposure and underlying patient risk factors. Recommendations made as part of the QUANTEC effort reflect a conservative interpretation of the existing literature: If the V_{25} is <10%, then the excess risk of cardiac mortality attributable to ischemic changes is <1% at 15 years. The risk of pericarditis can be minimized by keeping the mean pericardial dose <26 Gy or the pericardial V_{30} <46%. Heart and pericardial exposure should otherwise be minimized without compromise of target coverage.

Other clinical risk factors for cardiac mortality increasing the risk of radiotherapy-induced cardiac toxicity include hypertension, diabetes, obesity, and genetic predisposition. The risk of cardiac mortality from radiotherapy has been specifically demonstrated to be increased in patients >60 years old and by tobacco use.[252]

Brachial Plexus

Radiation brachial plexopathy is relatively poorly described with a low incidence. There are case reports of an early, transient plexopathy that occurs during or within weeks to months of radiation at relatively low dose and may resolve spontaneously.[253] Late radiation plexopathy is more clinically significant; it manifests years after radiation to the supraclavicular area with hypesthesia, paresthesia, and weakness of the affected arm and shoulder. It may progress to total paralysis of the affected arm and severe pain.

The dose tolerance of the brachial plexus is less defined than other thoracic organs, partly because of the difficulty in contouring and defining the OAR. A consensus contouring atlas has been created so that more robust clinical data can be collected.[254] Peripheral nerves respond as a serial organ; thus, it is thought that the maximum point dose should be predictive of plexopathy. Late plexopathy is rare in patients who have received ≤60 Gy. Proposed brachial plexus dose limits for standard, fractionated radiotherapy planning vary considerably; RTOG 0617 suggests a point maximum limit of 66 Gy.

For SBRT, brachial plexopathy has been reported after treatment of apical tumors. In a series of 37 apical tumors in 36 patients treated with SBRT at Indiana University, 7 patients developed plexopathy at a median of 7 months posttreatment.[255] The cumulative risk of grade 2 to 4 plexopathy was 46% when the plexus received >26 Gy versus 8% when the plexus received ≤26 Gy. AAPM Task Group 101 recommends maximum dose to 3 cc and maximum point dose of 14 and 17.5 Gy for single-fraction SBRT, 20.4 and 24 Gy for three-fraction SBRT, and 27 and 30.5 Gy for five-fraction SBRT.[147]

Reirradiation

As systemic therapy improves, more patients are presenting with locally recurrent lung cancer without systemic progression of disease, such as in stage III NSCLC previously treated with chemoradiation. This presents a challenge in management as local therapy is indicated, but surgery is usually not feasible, and we are still just beginning to understand normal tissue dose constraints in the setting of reirradiation. With conventional radiation techniques such as 3D conformal radiation, it is often not feasible to give a second, curative (i.e., >45 Gy) dose of radiation to the same thoracic region without exceeding dose constraints of nearby organ. Many small series have been published on using SBRT for reirradiation, both after prior SBRT as well as conventional radiation.[256] There is also increasing interest in using proton therapy in thoracic reirradiation because of the dosimetric advantages of proton therapy. There is a

lot of variability in terms of efficacy, with median time to disease progression of typically 6 to 12 months with mean OS usually of about 18 months. Significant toxicity can be seen, including pneumonitis, esophagitis, fistulas, chest wall toxicity, and potentially fatal bleeding. Many studies do not publish detailed dosimetric analysis, which makes it difficult to apply the results clinically. A series of 102 patients from MD Anderson treated with proton therapy or IMRT for thoracic reirradiation reported acceptable toxicity rates with 7% grade 3+ esophageal toxicity and 10% grade 3+ pneumonitis.[257] Median initial dose was 70 EQD2Gy and median reirradiation dose was 60.48 EQD2Gy. At a median follow-up of 6.5 months, 41% had a local failure and 49% distant metastasis. Most local failures (88%) were within the original or reirradiation field or margins. Median OS was 14.7 months. Patients tended to have better OS with concurrent chemotherapy and higher EQD2, and worse OS with higher T-stage, poor performance status, squamous histology, and larger reirradiation volumes. Reirradiation appears feasible, but it is important to carefully select patients who are likely to benefit from this potentially high-risk treatment.

Patient-Reported Outcomes In Lung Cancer

A PRO is defined as any report of the status of a patient's health condition provided directly by the patient (such as QOL), without interpretation of the patient's response by others. Examples of validated QOL instruments that include both generic and site-specific lung modules are the Functional Assessment of Cancer Therapy-Lung (FACT-L) and the EORTC QOL Questionnaire Core-30 (QLQ-C30) and QLQ-LC13. The Lung Cancer Symptom Scale (LCSS) is a shorter (9-item) QOL instrument that is specific for lung cancer.

There are many compelling reasons to study PROs in lung cancer patients. When used to assess the impact of clinical regimens, PROs can often identify meaningful differences that may not have been anticipated.[258] For example, Temel et al.[26] assessed the impact of early palliative care on QOL (using FACT-L) among patients with newly diagnosed metastatic NSCLC randomized to early palliative care or to standard care. They found that patients in the early palliative care arm not only had significant improvement in QOL, with less depression or anxiety, but also had longer median survival (P = .02), despite receiving less therapy.

Another clinically relevant aspect of QOL is its ability to serve as an independent prognostic factor for survival. Movsas et al.[24] reported that the

baseline QOL score independently predicted for 5-year survival in patients with stage III NSCLC treated with chemoradiation on RTOG 9801. Similarly, in RTOG 0617, every 10 points higher on the FACT-TOI instrument at baseline corresponded to a 10% decreased risk of death.[259] Moreover, although RTOG 0617 was not randomized by radiation technology, significantly fewer patients who received intensity-modulated radiation therapy (vs. 3D conformal radiation) had a clinically meaningful decline in QOL a full year after treatment (P = 0.005). Interestingly, studies are beginning to elucidate the biologic underpinnings supporting the relationship between QOL and outcomes.[260]

Studies have highlighted a critical "disconnect" between PROs and provider-reported observations.[261] In light of the above, a PRO measurement system has been developed by the NCI as a companion to the Common Terminology Criteria of Adverse Events (CTCAE), termed the PRO-CTCAE.[262] The PRO-CTCAE is novel in that it integrates the patient perspective directly into the toxicity reporting using a validated methodology that can guide future treatment recommendations. Indeed, randomized data have demonstrated that incorporating PROs into the clinical setting can improve physician–patient communication.[263] Ultimately, PROs should become a routine tool in the clinical care for our patients with lung cancer.

CHAPTER 55

Mediastinum and Trachea

Shervin M. Shirvani, Daniel R. Gomez, Clifton David Fuller, and Charles R. Thomas Jr.

MEDIASTINAL TUMORS

The mediastinum is a trapezoidal structure in the center of the thoracic cavity. It is bound by the sternum anteriorly, the vertebral column posteriorly, and the lungs and pleura laterally (Fig. 55.1). The diaphragm forms the floor of the mediastinum, whereas the thoracic outlet at the first thoracic vertebra, its rib, and the manubrium form the roof.[1] Conceptually, it is helpful to divide the mediastinum into anterior, middle, and posterior compartments, but no anatomic barriers specifically separate these regions.[2–4] The anterior mediastinum is the space anterior to the pericardium and great vessels and is occupied by the thymus, lymph nodes, and small vessels. The middle mediastinum is composed of the heart, proximal great vessels, central airway structures, and lymph nodes. The International Thymic Malignancy Interest Group (ITMIG) has codified these anatomic boundaries into a series of computed tomography (CT)-based radiographic standards for aiding clinical diagnosis and research.[5]

Tracheal anatomy is depicted in Figure 55.2. The posterior mediastinum is posterior to the heart and great vessels and contains the sympathetic chain ganglia, vagus nerve, thoracic duct, and esophagus. Given the number of structures within the mediastinum, it is not surprising that a heterogenous group of malignancies can arise in this location. Thymic, neurogenic, germinal, and mesenchymal tissues may all give rise to neoplasms. The malignancies that occur within the various compartments in the mediastinum are listed in Table 55.1.

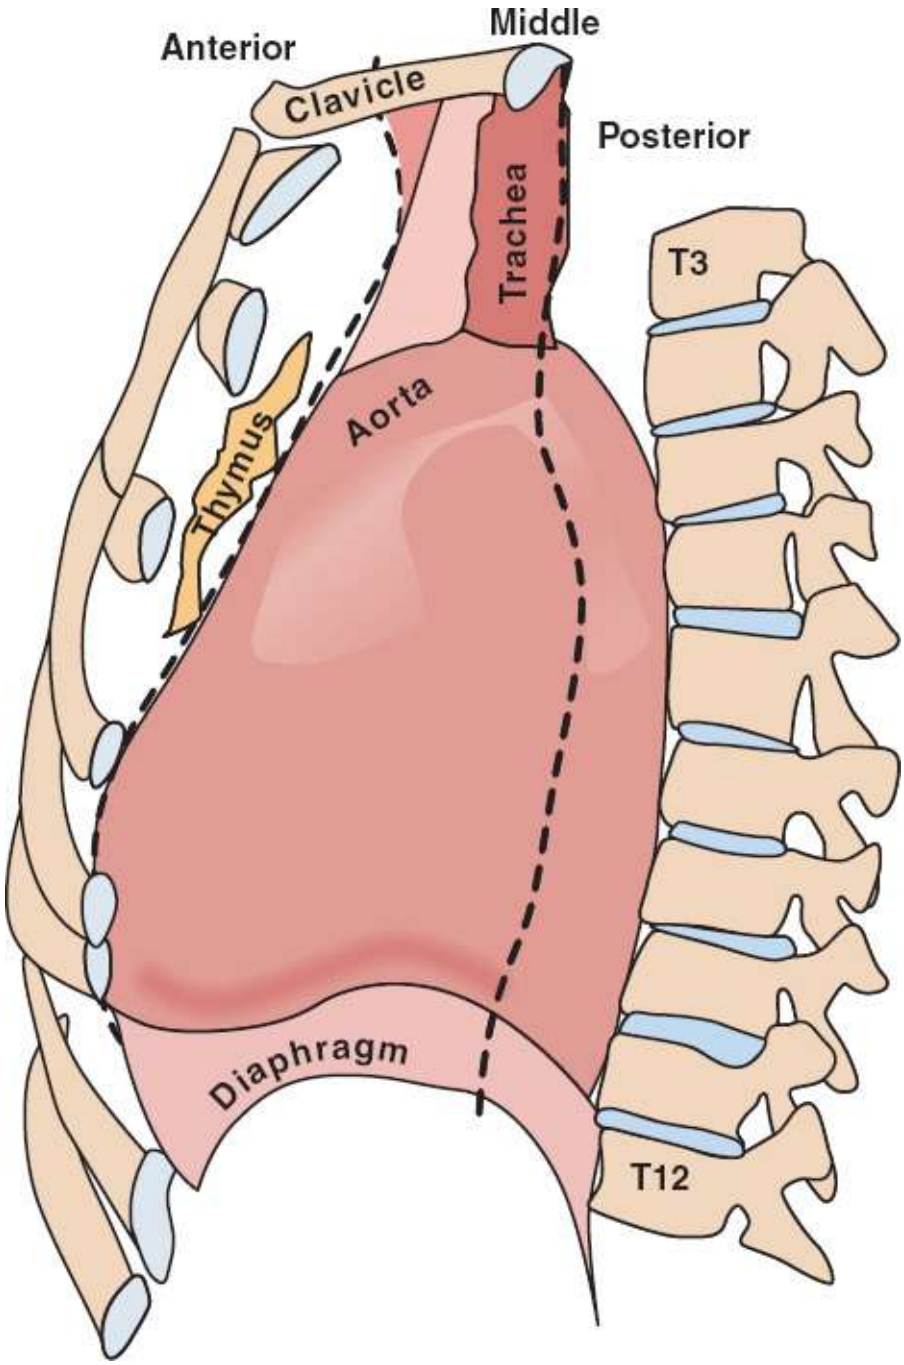

FIGURE 55.1. Anatomy of the mediastinum.

Incidence of Primary Mediastinal Tumors

Lymphomas represent the most common type of mediastinal tumor. The malignancies with the next highest incidence—tumors of thymic origin—are rare and represent about 0.2% to 1.5% of all malignancies.[6] Thymic carcinomas are especially rare and account for only 0.06% of all thymic neoplasms.[7] The frequency and prevalence of primary mediastinal tumors seem to be increasing

over time.[8–11] Adults generally develop thymic tumors and lymphomas, but they can also develop germ cell tumors and carcinomas.[11,12] Neurogenic tumors are usually seen in children.[9,13,14]

THYMOMAS

The thymus gland is an irregular lobulated lymphoepithelial organ in the anterior mediastinum. Embryologically, the thymus is derived from the endoderm of the lower portion of the third pharyngeal pouch and involutes during adulthood, gradually being replaced by adipose tissue. Its blood supply is from the internal mammary arteries, and its venous return drains to the innominate and internal thoracic veins. Its lymphatics drain into the lower cervical, internal mammary, and hilar lymph nodes.

The vast majority of thymic tumors are thymomas, 90% of which are found in the anterosuperior mediastinum; other variants occur in the middle and posterior mediastinum or neck.[15] Thymomas are epithelial tumors associated with an exuberant lymphoid component composed of immature cortical thymocytes. Although lymphomas, carcinoid tumors, and germ cell tumors can all arise within the thymus, only thymomas, thymic carcinomas, and thymolipomas arise from true thymic elements.

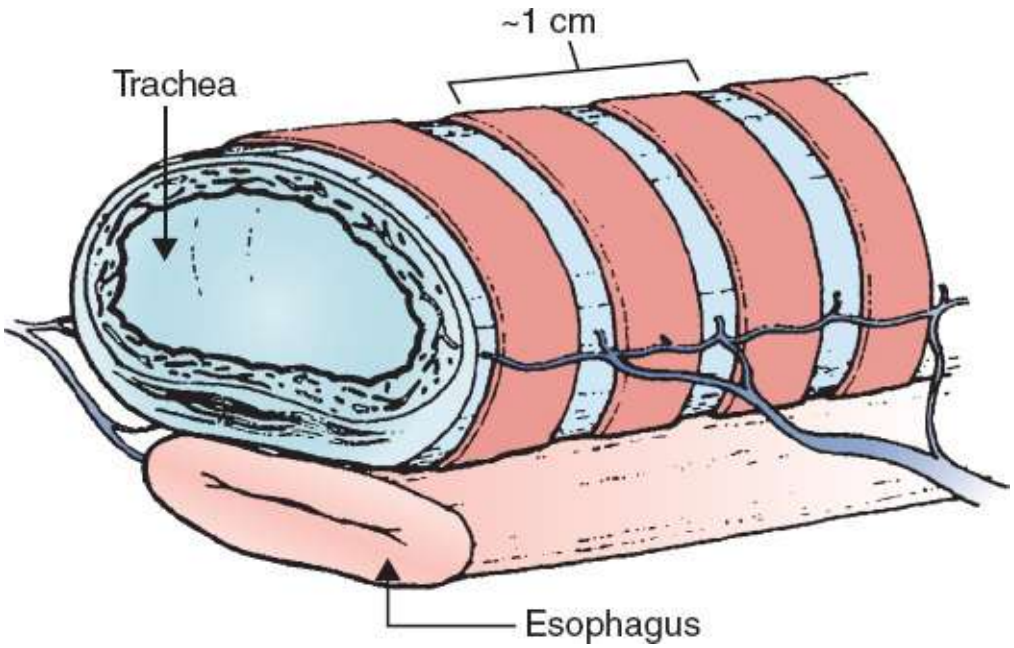

FIGURE 55.2. Representative schema of the trachea. Note the lateral longitudinal anastomotic artery running parallel to the organ and the intercartilaginous branches feeding each tracheal segment. The trachea resides in close proximity to the

esophagus.

TABLE 55.1 HISTOLOGIES OF TUMORS APPEARING IN THE VARIOUS COMPARTMENTS OF THE MEDIASTINUM

Anterior (Anterosuperior)	Middle	Posterior
Thymic tumors	Lymphomas	Lymphomas
Thymomas	Cysts	Neurogenic tumors
Thymic carcinomas	Bronchogenic	Peripheral nerves
Thymic cysts	Foregut	Malignant peripheral nerve sheath tumors
Carcinoids	Pericardial	Schwannomas
Thymolipomas	Thoracic duct	Neurosarcomas
Lymphomas	Meningoceles	Sympathetic ganglia
Hodgkin disease	Mesenchymal tumors	Ganglioneuroblastomas
Non–Hodgkin lymphomas	Tracheal tumors	Ganglioneuromas
Undifferentiated	Carcinomas	Neuroblastomas
Germ cell tumors	Cardiac and pericardial tumors	Paraganglia
Seminomas	Hernias	Paragangliomas
Nonseminomas	Hiatal	Mesenchymal tumors
Embryonal carcinomas	Morgagni	Endocrine tumors
Choriocarcinomas	Vascular tumors	Esophageal tumors and cysts
Mixed germ cell tumors	Ascending aortic	Hiatal hernias
Teratomas (dermoid cysts)	Transverse arch	Lateral thoracic meningoceles
Endocrine tumors	Descending aortic	
Parathyroid adenomas	Great vessels	
Thyroid tumors	Lymphadenopathy	
Mesenchymal tumors	Inflammatory	
Amyloid tumors	Granulomatous	
Castleman disease	Sarcoidosis	
Chordomas		
Extramedullary hematopoiesis		
Fibromas, fibrosarcomas, malignant fibrous histiocytoma		
Hemangiomas, hemangioendotheliomas, hemangiopericytomas		
Intrathoracic meningioma		
Lipomas, liposarcomas		
Leiomyomas, leiomyosarcomas,		

leiomyoblastomas
Lymphangiomas, lymphangiosarcoma, lymphangiomyomatosis
Mesotheliomas
Mesenchymomas
Myxomas
Rhabdomyosarcomas, rhabdomyomas
Xanthogranulomas
Morgagni hernias

Epidemiology

Thymomas are exceedingly rare. The Surveillance, Epidemiology, and End Results (SEER) project reported the thymoma incidence to be 0.13 per 100,000 person-years.[16] For patients with associated myasthenia gravis, the peak age is in the 4th decade, whereas for patients without myasthenia gravis, the peak age is in the 7th decade or later.[17–22] According to the SEER data, the incidence of thymoma increases into the 8th decade of age and then decreases.[23] Thymomas are more common in men than in women (P = .007) and are most common among Asians/Pacific Islanders (0.49 per 100,000 person-years).

Thymomas represent 20% of all mediastinal tumors in adults[4,12,24,25] and 15% in pediatric populations.[15] Furthermore, they are the most common tumor of the anterior mediastinum, accounting for about 30% of all such masses.[9–11,15,26,27] Though a precise causative factor has not been identified, associations of thymomas with Epstein-Barr virus, lymphoepitheliomas, radiation exposure, and cytogenetic abnormalities have been suggested.[28–34]

Natural History

Thymomas are generally characterized by an indolent growth pattern that can be locally invasive. The vast majority of thymomas are cytologically bland tumors, and approximately half of them are noninvasive.[11,22,35–45] Roughly one-third of thymomas are asymptomatic and found incidentally on chest x-rays.[41,42,46] Of the symptomatic thymomas, about 40% of cases present with symptoms relating to impingement by the intrathoracic mass, ranging from cough, chest pain, dyspnea, hoarseness, superior vena cava obstruction, and even tumor hemorrhage.[47] The remainder of symptomatic patients present with one of several parathymic syndromes, the most common of which are myasthenia gravis, benign cytopenias, hypogammaglobulinemia, and polymyositis.[17,20,48–51]

Myasthenia gravis has the highest incidence among the parathymic syndromes and occurs in approximately 45% of patients with thymomas, with

the reported prevalence in studies involving more than 100 patients ranging from 10% to 67%.[18,19,21,22,52,53] Conversely, only 10% to 15% of patients with myasthenia gravis have a thymoma; 60% of myasthenia patients will have thymic lymphoid hyperplasia, and roughly 25% will have a normal thymus.[19,54–57] Thymectomy results in clinical improvement in most cases even when the thymus is normal.[58]

Myasthenia gravis is characterized by the presence of antibodies that react with nicotinic acetylcholine receptors in muscle and disrupt transmission at the neuromuscular junction.[54] The cardinal features are weakness and fatigability of skeletal muscles, with most patients first experiencing fatigue in the ocular muscles followed by ptosis and diplopia, and later developing generalized weakness. More severe cases involve the proximal limb girdle muscles and, in the worst cases, respiration can be limited.[59–61]

Other systemic symptoms occur in 5% to 10% of patients with thymomas as part of a constellation of autoimmune disorders. Souadjian et al., in reviewing more than 500 cases of thymoma, noted that 71% were associated with systemic disease.[51] These include erythroid and neutrophil hypoplasia, pancytopenia, Cushing syndrome, DiGeorge syndrome, carcinoid syndrome, Lambert-Eaton syndrome, pernicious anemia, nephrotic syndrome, SIADH [syndrome of inappropriate antidiuretic hormone hypersecretion], Whipple disease, lupus erythematosus, pemphigus, myotonic dystrophy, scleroderma, polymyositis, polyneuritis, myocarditis polyarthropathy, myotonic dystrophy, Sjogren syndrome, Addison disease, panhypopituitarism, sarcoidosis, hypogammaglobulinemia, ulcerative colitis, rheumatoid arthritis, Hashimoto thyroiditis, hyperthyroidism, hyperparathyroidism, and thyroid carcinoma.[15,62–65] Other miscellaneous diseases include hypertrophic osteoarthropathy and chronic mucocutaneous candidiasis.[64]

Several studies have also reported an excess risk of developing a second primary malignancy of approximately 15% among thymoma patients.[48,49,51,66–68] An aberrant immune system is postulated to be a mechanism for the development of these metachronous malignancies.[69] The highest excess risk of subsequent malignancy appears to be for non-Hodgkin lymphoma, but thymoma patients are also at risk for digestive system malignancies and soft tissue sarcomas.[23] Patients with higher-grade and advanced stage tumors seem to have the highest risk of metachronous extrathymic malignancies.[69]

The vast majority of thymomas are indolent, but if the tumors spread, they

most commonly implant on regional pleural surfaces (so-called drop metastases), which can progress to malignant pleural effusions.[17] Other mechanisms for metastases are uncommon for this histology. The rate of lymphogenous metastasis in a large database of 1093 patients with thymomas was 1.8%, with 90% of positive lymph nodes located in the anterior mediastinum.[70] Only rarely do thymomas spread hematogenously, though metastases have been reported in the liver, lung, and bone.[71]

Diagnosis

The radiographic presence of an anterior mediastinal mass is suggestive of a thymic tumor as these histologies account for the majority of masses in this location (see Table 55.1).[11] A clinical diagnosis of thymoma can sometimes be made based on the presence of an anterior mediastinal mass in conjunction with clear evidence of a parathymic syndrome such as myasthenia. The absence of symptoms suggestive of lymphoma (fevers, weight loss, adenopathy) or tell-tale radiographic findings for rare histologies such as teratoma are further clues suggestive of a thymic malignancy.

Nonetheless, histologic confirmation is usually required to establish a definitive diagnosis. Biopsy can be performed via a fine needle aspiration, bronchoscopy, mediastinoscopy, video-assisted thoracoscopy, or open biopsy. Historically, biopsies were assumed to be relatively contraindicated because of a concern for tumor spillage into the pleural space when the capsule was breached.[72,73] However, no cases of seeding of a needle tract or the biopsy site have been reported, and only three recurrences in thoracotomy scars have been reported.[74,75] In fact, multivariate analysis in one series of 136 patients being treated for thymomas showed better survival among patients who underwent biopsy before surgery (P = .056).[49] Therefore, many centers routinely obtain biopsy samples of anterior mediastinal tumors for histologic assessment.[19,48,74,76–79]

When thymoma is suspected or confirmed, the diagnostic workup begins with a careful evaluation for myasthenia gravis. Routine blood work for common associated syndromes should be done, with serum alpha-fetoprotein and beta-human chorionic gonadotropin in men to rule out a germ cell tumor.[80] In addition to laboratory studies, imaging is a hallmark of thymoma diagnosis and treatment planning.

Plain film chest x-rays were historically the main diagnostic modality for identifying and measuring thymic tumors. Thymomas tend to appear as ovoid,

smooth, and unilateral masses occupying the space between the thoracic inlet and the cardiophrenic angle.[81] More advanced presentations may present an irregular border between the mediastinum and the lung, suggesting lung invasion, or elevation of the diaphragm if the phrenic nerve has been infiltrated.

CT is the most common technique for visualization of thymomas and other anterior mediastinal masses.[44,82–84] Magnetic resonance imaging (MRI) can provide more detail when needed, delineating the musculoskeletal anatomy and neurovascular structures of the mediastinum.[85–87] MRI may also improve sensitivity for defining the soft tissue extent of the mass in addition to providing information regarding tumor grade and invasiveness beyond that which can be gleaned from CT. Common features indicative of a high-grade tumor include low T2-signal foci within the mass, the presence of mediastinal lymphadenopathy, an incomplete capsule, and inhomogeneous enhancement.[88,89]

The use of ^{18}F-fluorodeoxyglucose positron emission tomography (PET) is expanding for visualizing several types of malignancies, including thymoma. In the mediastinum, the results of PET can be confounded by the physiologic uptake of fluorodeoxyglucose by the thymus in children and young adults.[90–93] Nevertheless, this imaging modality has continued to show promise for disease detection and for evaluating prognosis. Recent studies have shown that PET not only can improve the sensitivity of diagnosis but also can be helpful for establishing the grade of the disease and for distinguishing thymoma from thymic carcinoma, which tends to have significantly higher metabolic activity.[94–98] In terms of distinguishing among lower- and higher-risk thymomas, maximum standardized uptake value may lack sensitivity, though some emerging data suggest that homogenously distributed uptake is more characteristic of lower-risk thymomas (types A, AB, and B1).[99]

In one provocative study in which 49 patients with thymic tumors underwent PET imaging, the rate of fluorodeoxyglucose uptake was compared with the expression of several biologic markers, including GLUT1, GLUT3, HIF-1α, vascular endothelial growth factor (VEGF), microvessel density, CD31 and CD34, p53, and bcl-2. The authors found a direct correlation between fluorodeoxyglucose uptake on PET and expression of GLUT1, HIF-1α, VEGF, and p53 as well as microvessel density, and several of these markers also correlated with tumor grade.[100] Predicting the presence of HIF-1α may also be germane to therapeutic strategies that seek to match radiation dose to the presence of hypoxia and its associated radioresistance in the tumor microenvironment.[99]

These findings are important because they imply that metabolic response may be a viable marker for measuring treatment efficacy. Figure 55.3 demonstrates PET findings from a patient with locally advanced thymoma treated with trimodality therapy. Indium 111-octreotide, carbon-11 methionine, and gallium-67 citrate, three other nuclear medicine agents, have also been reported to show some activity for thymic malignancies, but utilization of these modalities has been limited by their lack of sensitivity in distinguishing benign conditions such as thymic hyperplasia from frank neoplasia.[81,101]

Pathologic Classification

The varied appearances and the frequent absence of classic malignant features have made thymomas challenging to classify pathologically. Disagreements on the prognostic importance of certain pathologic features have led to multiple proposed classification systems (Table 55.2). Indeed, even simple terminology such as “invasive versus noninvasive” or “benign versus malignant” has not accurately captured clinical behavior. Recurrences and metastases after resection have been reported in all large series[18,19,102–104] regardless of disease stage or histologic subtype.[17–19,21,22,43,48,49,103–111] Ultimately, even bland-appearing, noninvasive thymomas have the fundamental characteristics of a malignant tumor in their ability to recur and metastasize.

A historical perspective of thymoma classification systems is illustrative of the challenges of pathologic classification for thymoma. The earliest system, proposed by Bernatz, identified four categories based on the predominant cell type: lymphocytic, epithelial, mixed, and spindle cell.[112] In practice, this classification system poorly correlated with clinical prognosis. Verley and Hollman later also identified four categories: spindle or oval, lymphocyte-rich, differentiated epithelial cell–rich, and undifferentiated epithelial.[103] The first three types are cytologically bland, whereas the fourth category includes pleomorphic tumors with high numbers of mitoses and atypia, which are also considered thymic carcinoma. Unfortunately, this categorization also did not correlate well with prognosis.

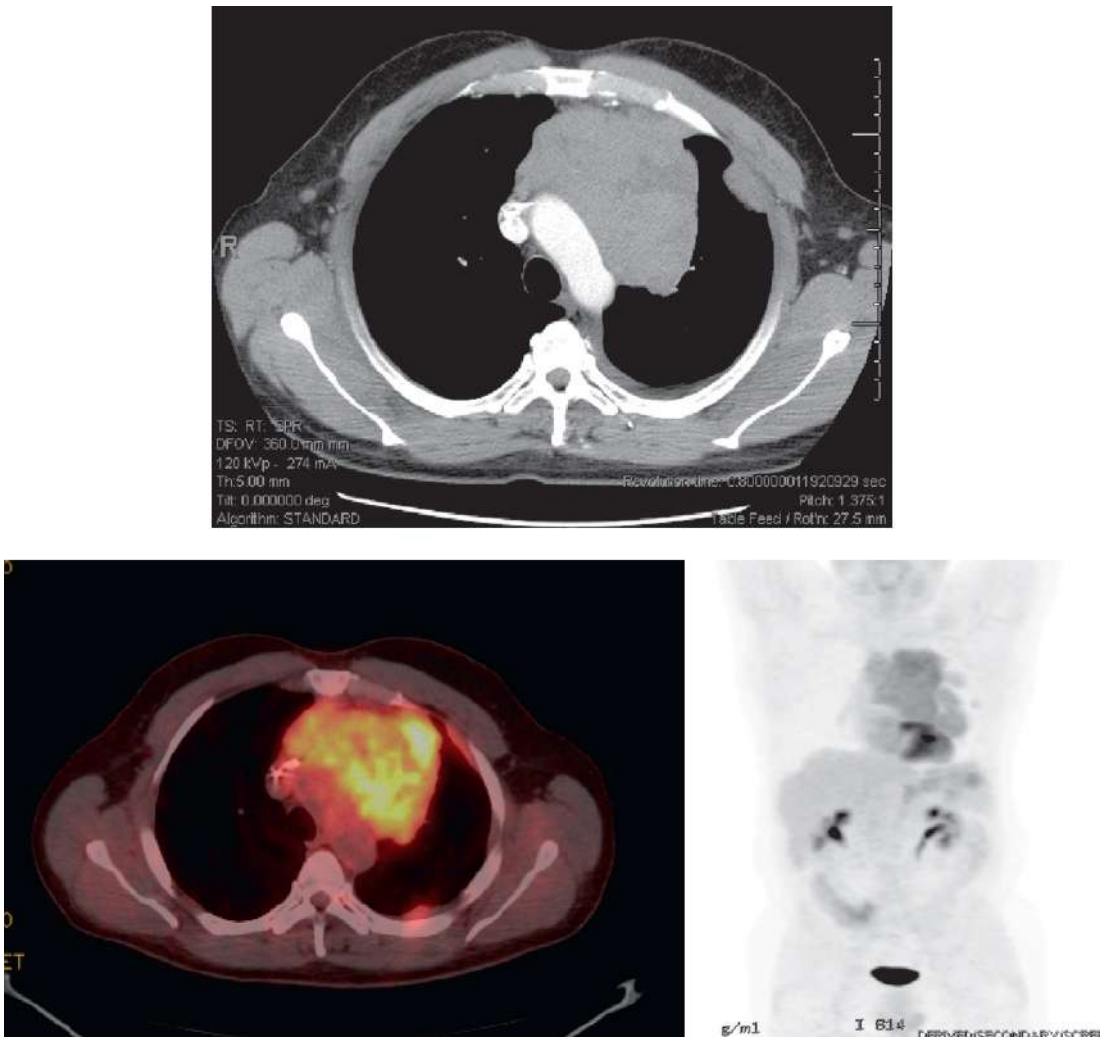

FIGURE 55.3. PET scanning in thymic malignancies. PET imaging has been shown to aid in delineating the extent of disease and assessing for metastases.

A third classification system based on work by Müller-Hermelink et al. based classification on the different subsets of epithelial cells found in the thymus: cortical, medullary, mixed cortical and medullary, and well-differentiated.[113] Although this system was widely used, again a strong like between epithelial cell morphology and clinical prognosis has not been validated.[116] Although some associations have been found, such as cortical thymomas behaving more aggressively and being more often associated with myasthenia gravis, several multivariate analyses have shown that the Müller-Hermelink classification system is not an independent predictor of survival, casting doubt on the link between this histologic classification and prognosis.[17,20,76–78,103,107,116–120] Another confounder for these classification schemes is that they do not consistently correlate with other schemes.[116] Concordance rates for thymomas

classified independently by a panel of pathologists were often as low as 35% within one system, although two small studies demonstrated 78% concordance when using the Müller-Hermelink classification system.[121,122] The poor correlation between the histopathology of thymomas and their potential for aggressive malignant behavior or systemic syndromes underlines the need for a consistent and predictive classification system.[44] The current system—the World Health Organization (WHO) classification—represents an important step in this direction though further refinement that perhaps includes a molecular component will likely be required.

TABLE 55.2 THYMOMA CLASSIFICATION SYSTEMS

Bernatz et al. (1961)[112]	Müller-Hermelink and Kirchner (1985)[113]	Suster and Moran (1999)[114]	WHO (1999)[115]
Spindle cell	Medullary	Thymoma, well-differentiated	Type A
—	Mixed		Type AB
—	Predominantly cortical		Type B1
Lymphocyte-rich Lymphoepithelial	Cortical		Type B2
Epithelial-rich	Well-differentiated thymic carcinoma	Atypical thymoma	Type B3
—	High-grade thymic carcinoma	Thymic carcinoma	Type C

The WHO classification, first proposed in 1999 and updated in 2004, is similar to the Müller-Hermelink system but recognizes six different types of thymic tumors (A, AB, B1, B2, B3, C; see Table 55.2).[115,123,124] Type A tumors are composed of neoplastic oval or spindle-shaped epithelial cells without atypia or lymphocytes. Type AB is similar to type A, but with foci of lymphocytes. Type B tumors consist of plump epithelioid cells that can be subdivided into three subtypes defined by increasing proportions of epithelial cells and increasing atypia. Type B1 tumors resemble normal thymic cortex with areas similar to thymic medulla. Type B2 have scattered neoplastic epithelial cells with vesicular nuclei and distinct nucleoli among a heavy population of lymphocytes; perivascular spaces are prominent and a palisading effect of tumor cells along the perivascular spaces may be present. Type B3 is composed of predominantly round or polygonal epithelial cells exhibiting mild atypia admixed with a minor component of lymphocytes; thus, this type resembles what others have described as well-differentiated thymic carcinoma. Thymic

carcinomas are designated type C tumors and have cytologic atypia and a cytoarchitecture resembling carcinoma that is distinctively unlike normal thymus tissue.[125]

TABLE 55.3 MASAOKA STAGING SYSTEM FOR THYMOMAS

Stage		Description
I		Macroscopically completely encapsulated, with no microscopic capsular invasion
II	a	Macroscopic invasion into surrounding mediastinal fatty tissue or mediastinal pleura
	b	Microscopic invasion into the capsule
III		Macroscopic invasion into surrounding organs
IV	a	Pleural or pericardial implants/dissemination
	b	Lymphogenous or hematogenous metastases

Adapted from Masaoka A, Monden Y, Nakahara K, et al. Follow-up study of thymomas with special reference to their clinical stages. *Cancer* 1981;48(11):2485–2492. Copyright © 1981 American Cancer Society. Reprinted by permission of John Wiley & Sons, Inc.

Concordance rates among different pathologists using the WHO system were reported to be 90% and 95% in two independent studies.[126,127] The most clinically distinct subtypes are type B3, formerly known as well-differentiated thymic carcinoma, and type C, thymic carcinomas. The clinical characteristics associated with the other WHO subtypes still vary considerably, but the WHO system at least seems to correlate well with Masaoka stage (Table 55.3) in studies in which patients were analyzed with the WHO system.[125] The vast majority of type A and AB tumors are Masaoka stage I or II, and the B subtypes tend to resemble the higher Masaoka stages.[125]

With regard to prognosis, the WHO system has been found to have independent prognostic value for disease-specific survival, with only two small studies indicating that stage was the only prognostic variable.[125] Most of the prognostic value of the WHO classification is attributable to type C having distinctly worse survival,[128–130] but even studies that excluded type C could demonstrate WHO type as having independent prognostic value.[130,131]

More recent pathologic studies have provided intriguing insights on prognostic histologic features. In one such study by Shim et al. that involved assessing the effect of stromal lymphocytic infiltration in thymic carcinoma,[132] patients with low levels of CD4+ lymphocytes and CD20+ lymphocytes within the tumor stroma were found to have lower survival rates, and various combinations of CD4+, CD8+, and CD20+ cells were particularly predictive of

worse survival outcomes. These authors concluded that these lymphocytes may work together to suppress cancer progression and that combinations of them may be useful for stratifying patients in terms of long-term prognosis.[132]

Molecular Characterization

During the past several years, pathologic classification systems for several thoracic malignancies have been refined by the incorporation of molecular markers. Likewise, there has been vast interest in clinical studies targeting these molecular markers with specific therapeutic agents. These innovations have been explored in thymomas as well, albeit at a smaller scale than non–small cell lung cancer (NSCLC).

Several studies have shown elevated expression of the epidermal growth factor receptor (EGFR) in large percentages of thymic malignancies, similar to what is observed among NSCLC and other epithelial cancers.[133–136] However, among thymic malignancies, the elevated EGFR levels have rarely been associated with accompanying mutations.[137–139] Therefore, targeted EGFR inhibitors have not shown consistent improvements in thymic tumor response or control rates.[140–142] Other signaling pathways that often show overexpression are the VEGF,[143] IGF-1R,[144] and KIT pathways,[145,146] although again in most circumstances the overexpression takes place mainly in thymic carcinomas rather than thymomas.

More recent studies utilizing genomic, proteomic, and transcriptomic technologies have revealed new discoveries with regard to the molecular biology of thymomas. For instance, Radovich et al. used RNA sequencing to compare the transcriptomes of thymic malignancies to normal thymus tissue and found that large microRNA cluster on chromosome 19 is a hallmark of type A and AB thymoma; this cluster was associated with the PI3K pathway, suggesting a potential role for the use of PI3K inhibitors in this disease.[147] Similarly, Badve et al. conducted whole-genome expression of 34 thymoma patients and identified 4 clusters of thymic tumors that appeared to correlate with histologic classification.[148]

These efforts have recently culminated in a project by the Cancer Genome Atlas Project to molecularly subtype thymic epithelial tumors using a dataset of 120 patients using a robust approach that incorporated DNA mutational analysis, mRNA expression, and somatic copy number alterations.[149] This tour de force analysis identified four distinct subtypes. The first two were characterized, respectively, by general transcription factor II-I mutation or mRNA clusters

associated with T-cell signaling expression. The next two subtypes were characterized by the presence or absence of chromosomal stability based upon somatic copy number. These subtypes were associated with disease-free and overall survival. As in other malignancies like breast cancer, the identification of molecular subtypes holds promise for testing of thymomas for their genetic type in the clinic and then selecting treatments or clinical trials based upon the result.[150]

Staging

The most commonly used staging system for thymomas was published by Masaoka et al. in 1981 (Table 55.3).[105] Staging is based on the extent of either macroscopic or microscopic invasion into structures including the thymoma capsule and surrounding mediastinal structures at the time of surgery. Other groups have tried to improve upon the Masaoka system. For example, the French Groupe d'Etudes des Tumeurs Thymiques (GETT) classification (Table 55.4) incorporates completeness of resection, which may be of prognostic value but does not allow patients to be compared independent of treatment factors.[151]

It is a testament to the robustness of Masaoka's classification system that it has persisted nearly unchanged for 30 years. But despite its popularity, areas of ambiguity have persisted, especially with regard to the Masaoka system's tendency to incorporate both clinical and pathologic data. For instance, some clinicians have questioned the precision with which one can assess that a "tumor is adherent to but not breaking through mediastinal pleura." After all, the mediastinal pleura is not typically in the pathologic specimen.[152] Therefore, a group headed by the ITMIG proposed a new staging classification in 2013 based upon TNM staging principles.[153] The T-stage—which still drives staging—has been more finely characterized as pathologically observed microscopic invasion into mediastinal fat (T1a), mediastinal pleura (T1b), pericardium (T2), "more resectable" organs (T3), and "less or unresectable" organs (T4).[154] Although it remains to be seen whether this staging system can provide better prognostic information above historical staging systems, at the very least it provides a standard template for communication among physicians and for the design of collaborative trials, an essential contribution by the staging system for the investigation of a rare disease like thymoma.

TABLE 55.4 GROUPE D'ETUDES DES TUMEURS THYMIQUES (GETT) THYMOMA STAGING SYSTEM

Stage		Description
I	a	Encapsulated tumor, completely resected
	b	Macroscopically encapsulated tumor, completely resected
		Surgeon suspects mediastinal adhesions and potential capsular invasion
II		Invasive tumor, completely resected
III	a	Invasive tumor, subtotal resection
	b	Invasive tumor, biopsy only
IV	a	Distant pleural implants or supraclavicular metastasis
	b	Distant metastasis

Prognostic Factors

The two factors that have consistently demonstrated prognostic value in multivariate analyses in large studies are tumor invasiveness (i.e., disease stage) and completeness of resection.[17,18,20,21,35–37,42,48,49,76,102,105,155–159] Disease stage has proven important for prognosis in every large study.[17–19,21,22,43,48,49,102,105,160] Mean overall survival rates at 15 years are 78% for those with stage I disease, 73% for stage II, 30% for stage III, and 8% for stage IV (Table 55.5).[18] At 10 years, mean disease-free survival rates are 92% for those with stage I disease, 87% for stage II, 60% for stage III, and 35% for stage IV (recurrence rates are summarized in Table 55.6).[18,21,102,117,159]

The extent of resection is the other major factor consistently identified as being prognostic in thymic malignancies.[18,48,49,166–168] Patients for whom complete (R_0) resections can be done have significantly better survival than do those with R_1 or R_2 resections.[105,169] R_0 resections are almost always possible for stage I tumors, but resectability rates decrease on average to 50% for stage III tumors.[19,22,43,105]

As mentioned previously, the WHO histology classification was found to be independently associated with prognosis. Major studies reporting analyses of stage, histology, and resection status as independent predictors of survival in thymic tumors are summarized in Table 55.7. Other potential prognostic factors are tumor size and the presence of symptoms.[17,48,107] Interestingly, although bulky tumor size was classically defined in terms of a 10-cm threshold, a more recent publication of 154 consecutive patients with thymic epithelial tumors treated in the modern era (2000–2014) demonstrated that a size >4 cm was associated with worse relapse-free survival, even among patients with stage I disease.[170] With regard to symptoms, older series reported that patients with parathymic syndromes such as myasthenia gravis and other autoimmune diseases fared worse than those without such syndromes,[45,48,159] but this finding has not been replicated in newer series.[18,21,22,49,77,78,105,107,157,171–173] Indeed, some studies have found survival to be better for patients with myasthenia gravis,[19,49,174] perhaps because of earlier detection of thymomas.[48,175–177] A study published in 2005 indicated that myasthenia gravis, present in 25% of 1,089 patients from Japan,[53] did not affect 5-year overall survival rates among

patients with stage III disease. For patients with stage IV disease, 5-year overall survival rates were 85.1% for patients with myasthenia gravis versus 63.9% for patients without. R_0 resection was accomplished in a significantly higher proportion of patients with myasthenia gravis (60%) than those without it (38%).

Another potential prognostic factor is patient age. Patients older than 30 to 40 years may have a better prognosis than younger patients.[17,76,159] Thymomas in children seem to follow a more malignant course than those in adults.[181] Fortunately, malignant thymomas in children are extremely rare.[182]

[a]Type C excluded.
[b]Overall survival instead of disease-free survival.
MGH, Massachusetts General Hospital; NS, not statistically significant; R_0, complete resection.

General Management

Treatment modalities that have shown activity for thymoma are numerous and include surgery, radiation, cytotoxic chemotherapy, and targeted agents. The optimal utilization and sequencing of these treatments is not well defined by randomized prospective trials. Therefore, treatment selection for these tumors can be daunting. The ITMIG advocates that patients with thymic epithelial tumors are best served in a setting in which multimodality consultation can occur prior to initiation of treatment.[183] The authors agree that multidisciplinary consultation is critical to achieve best outcomes.

Surgery

Surgical resection is the mainstay of treatment for thymomas. A complete en bloc surgical resection (R_0) remains the treatment of choice for all thymomas regardless of invasiveness, except in rare advanced cases with extensive intrathoracic or extrathoracic metastasis. Fortunately, the vast majority (90% to 95%) of thymomas are localized.[184] Operative mortality rates average 2.5% (range 0.7% to 4.9%).[17–19,22,43,48,102,164] Resectability rates for stage I thymomas should approximate 100%, but those rates vary widely for higher-stage thymomas: 43% to 100% (mean 85%) for stage II, 0% to 89% (mean 47%) for stage III, and 0% to 78% (mean 26%) for stage IV.[102]

Because the completeness of resection is such an important prognostic factor, an aggressive surgical approach is justified to remove as much of the lesion as possible at surgery. If residual microscopic disease is suspected of being present (an R_1 operation), metallic clips should be placed to help delineate the radiation

field. Whether subtotal resections are beneficial is controversial, with some authors demonstrating better survival when debulking takes place before adjuvant radiation therapy[19,22,52,105,106,159] and others finding no benefit from debulking over biopsy alone.[18,19,22,48,76,151,159,174,185] One large study found significant differences in 5-year survival rates among patients undergoing subtotal resection versus biopsy only (64% vs. 36%) but little difference in 10-year survival rates, suggesting that any benefit may only be in intermediate-term survival.[52]

Traditional surgical techniques for patients with stage I thymic tumors produce 5-year survival rates in excess of 90%, with survival rates decreasing slightly at 10 years,[19,22,65] and with local recurrence rates of <5%. For stage II and III disease, recurrence rates after surgery alone range from 10% to 47%. In a study of more than 100 patients previously treated for thymoma, causes of death were as follows: 38% were related to thymoma (range 19% to 58%), 9% to postoperative causes (range 2% to 19%), 22% to myasthenia gravis (range 16% to 27%), 9% to other autoimmune diseases (range 2% to 19%), and 29% to unrelated causes (including other cancers) (range 8% to 47%).[17–19,21,22,43,49,103,106,117,159] Recurrence rates are summarized in Table 55.6.
