Neuroblastoma has the highest spontaneous remission rate of any human neoplasm, usually by maturation to ganglioneuroma.[9] Microscopic neuroblastomas have been found in the autopsy material of the adrenal glands of young infants at >40 times the expected rate. It has been suggested that most potential neuroblastomas remain clinically silent, because of spontaneous regression.[10] Despite these peculiarities, clinically obvious neuroblastoma is frequently a progressive and relentless disease.

CLINICAL PRESENTATION

Pain is the most common presenting symptom. This frequently is caused by bone, liver, or bone marrow metastases or local visceral invasion by the primary tumor. Other constitutional symptoms may include weight loss, anorexia, malaise, and fever. Respiratory distress may accompany massive hepatomegaly, especially in infants with stage IV-S disease.[8] Horner syndrome can accompany a primary tumor originating in the neck. Spinal cord compression with paralysis of the lower extremities can accompany the so-called dumbbell-shaped tumor that extends from its origin along the sympathetic ganglia through the adjacent neural foramina. Orbital metastases are not uncommon and can cause proptosis and ecchymosis. Skin metastases may have a bluish tinge, giving the classic “blueberry muffin” sign. When pressed, the release of catecholamine into the tissue causes transient blanching of the adjacent skin. An unusual presentation of localized neuroblastoma is the opsoclonus–myoclonus syndrome, manifested by truncal ataxia and cerebellar encephalopathy. This syndrome typically indicates a favorable prognosis from the tumor, but patients may have persistent neurologic sequelae after successful tumor therapy.[11,12]

DIAGNOSTIC WORKUP

As in the case of any suspected malignant neoplasm in children, the diagnosis of neuroblastoma must be established by pathologic evaluation. Tumor tissue may be obtained from the suspected primary tumor site or from involved lymph nodes by excision (if the tumor is resectable) or incisional biopsy. Bone marrow aspirate and biopsy frequently show metastatic tumor deposits that can establish the diagnosis. Pathologic evaluation of bone marrow is also a requirement for staging of neuroblastoma. Characteristically, neuroblastoma in bone marrow

appears in clumps and pseudorosettes. The absence of pseudorosettes does not eliminate the possibility of neuroblastoma.

Laboratory studies should include measurement of urinary catecholamines and their metabolites. Either HVA or VMA (metabolites of dopa/norepinephrine and epinephrine, respectively) is elevated in >90% of patients with stage IV neuroblastoma. A ratio of VMA to HVA of >1.5 is associated with a favorable prognosis in patients with metastatic neuroblastoma. An assay for urinary VMA is the basis for screening studies of infants in Japan, Europe, and North America. Anemia secondary to bone marrow involvement with tumor can be evaluated with a complete blood cell count. Serum ferritin, lactate dehydrogenase (LDH), and other liver function indicators should be assayed routinely.

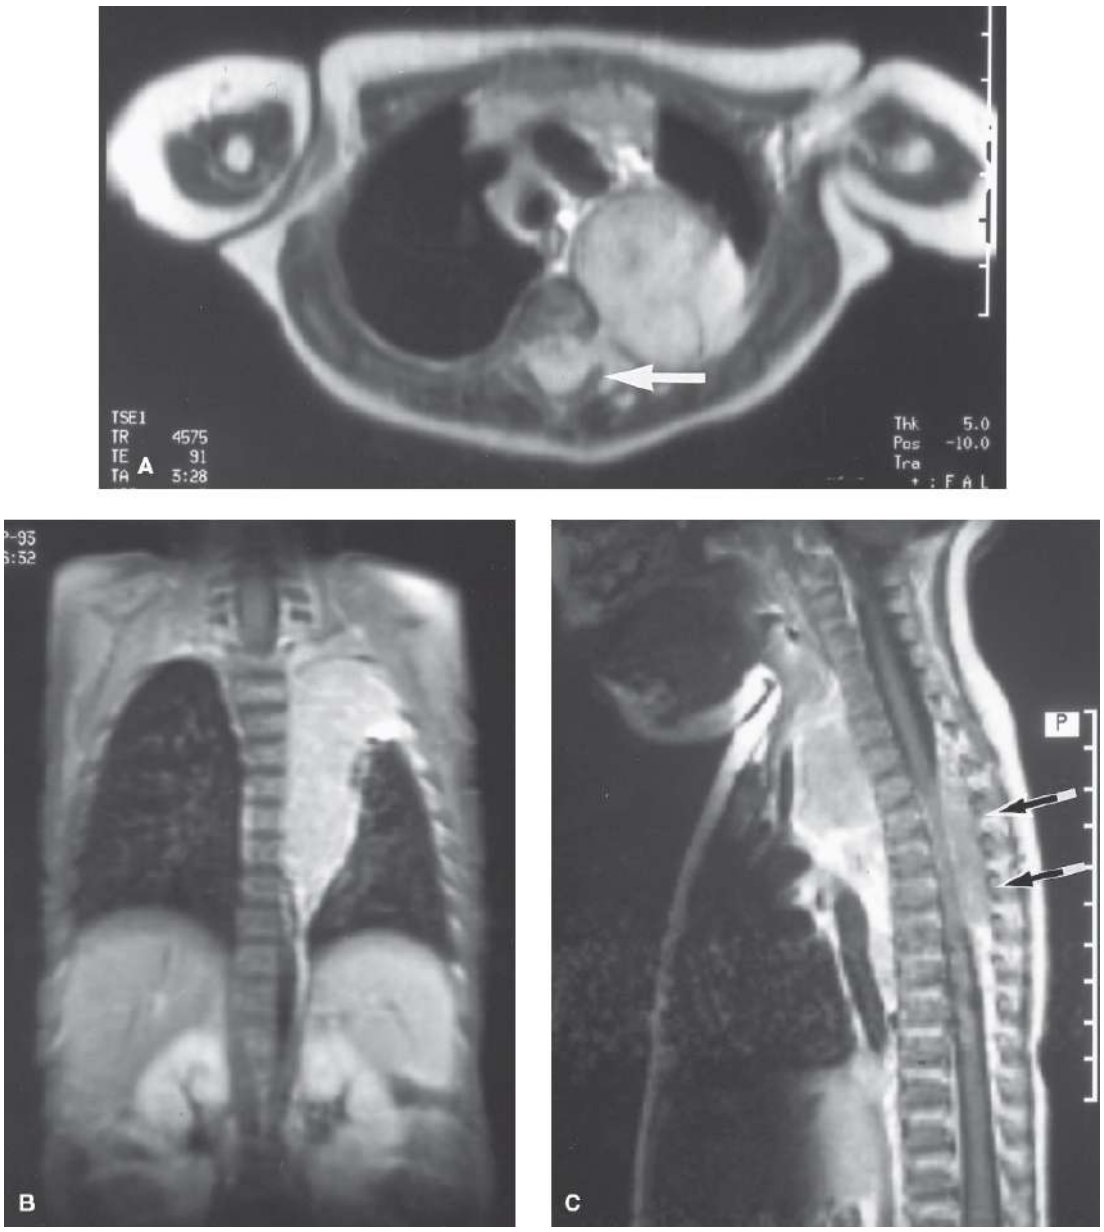

FIGURE 90.1. Magnetic resonance imaging scans of a 4-month-old child with a thoracic neuroblastoma. The dumbbell shape of the paraspinal mass can be appreciated on axial **(A)**, coronal **(B)**, and sagittal **(C)** images. The intraspinal component is indicated by *arrows*. The three views of this child's tumor are helpful in radiation therapy field design.

Appropriate use of imaging studies assists in staging and in planning an approach to therapy. X-ray studies demonstrate intrinsic speckled calcifications in 85% of neuroblastomas. Computed tomography (CT) of the abdomen with intravenous contrast is more sensitive than intravenous pyelography and provides more information about lymph node or hepatic metastases as well as tumor resectability.[13] High-quality magnetic resonance imaging (MRI) scans are

being used to better evaluate blood vessel encasement, intraspinal extension (dumbbell tumors), diffuse hepatic replacement, and bone marrow involvement (Fig. 90.1). Each of these findings improves staging accuracy and facilitates the decision-making process regarding appropriate surgical interventions.[14–17]

Nuclear medicine scans are helpful in determining the extent of metastatic disease. Because neuroblastoma has a predilection for bony metastases, a radionuclide bone scan has been part of routine workup. A recent study from Boston questions the value of a bone scan when *meta*-iodobenzylguanidine (MIBG) scan is used.[18] In this report, 132 patients underwent both MIBG and bone scans. In the 78 cases with metastatic disease, 74% were both skeletal MIBG and bone scan positive. Only 3 had a negative skeletal MIBG and positive bone scan, but all 3 had other sites of metastatic disease. In no case did a positive bone scan alone determine a stage 4 designation. MIBG is concentrated by neurosecretory granules of both normal and neoplastic tissues of neural crest origin and can be used to image primary and metastatic sites of neuroblastoma. MIBG labeled with either ^{131}I or ^{123}I has a sensitivity of 85% to 90% and a specificity of almost 95% in the detection of metastatic neuroblastoma.[19] Poor scintigraphic response on ^{123}I-MIBG scans after induction chemotherapy has been shown to predict for a poor event-free survival in patients undergoing high-dose chemotherapy with stem cell rescue.[20] Like other neural crest–derived neoplasms, neuroblastoma can express somatostatin receptors. The long-acting somatostatin analog octreotide labeled with ^{123}I has been used to image neuroblastoma with a sensitivity comparable to that of ^{131}I-MIBG.[21] The expression of somatostatin receptors by neuroblastoma tissues is a favorable prognostic factor.[22]

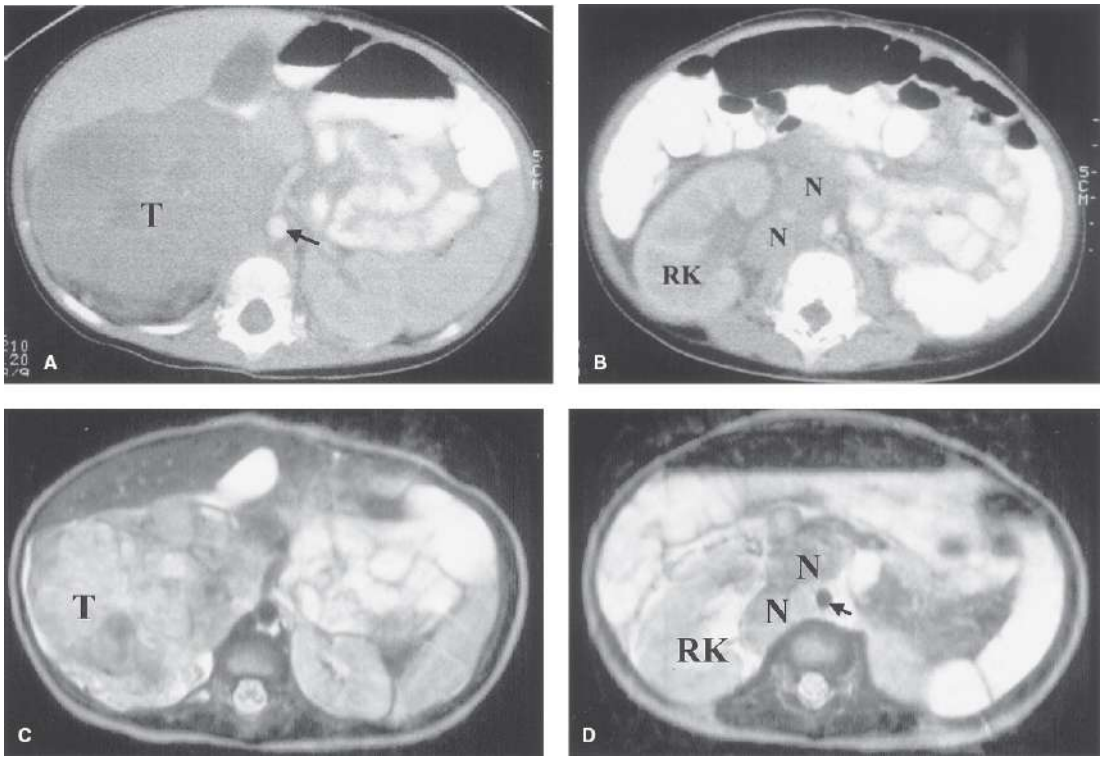

FIGURE 90.2. Neuroblastoma with nodal involvement in a 3-year-old boy. **A:** Computed tomography (CT) through the upper abdomen shows a large soft tissue mass (*T*) arising in the right adrenal gland and extending to the midline (aorta, *arrow*). **B:** A CT scan several centimeters lower shows several small nodes (*N*) in the right pararenal area. **C:** T_2-weighted axial image shows a high–signal intensity tumor (*T*) in the right suprarenal area. **D:** T_2-weighted image at a lower level shows enlarged, mildly enhancing paracaval lymph nodes (*N*). *RK,* right kidney. (Courtesy of Dr. Marilyn Siegel, *Mallinckrodt Institute of Radiology*, St. Louis, MO.)

The Radiology Diagnostic Oncology Group enrolled 96 children with newly diagnosed neuroblastoma in a multicenter prospective cohort study prior to surgery. CT, MRI, and bone scintigraphy were used to evaluate tumor stage. The results show that MRI is more accurate than CT for detection of stage 4 disease (sensitivities 0.83 and 0.43, respectively). When combined with bone scintigraphy, both imaging tests have high accuracy for the detection of metastases. Figures 90.2–90.4 illustrate the value of CT and MRI in staging patients with metastatic disease. The prevalence of determinants of local disease was relatively low in this study because patients who had extensive disease at the time of entry underwent delayed surgery after induction chemotherapy. Although the numbers are small, the data suggest the following: (a) In stage 1 tumor, abdominal extent was more likely to be staged correctly with CT than with MRI, which often overstaged tumor; (b) for stage 2 and 3 tumors, both CT and MRI were more likely to understage than overstage tumor; and (c) for stage

2 tumor, understaging was more likely with CT than MRI (Fig. 90.5).

STAGING

The most commonly used staging system is the International Neuroblastoma Staging System (INSS). It is based on clinical, radiographic, and surgical findings.[23] The INSS integrates many of the concepts of previous staging systems promoted by the Children's Cancer Group (CCG) and Pediatric Oncology Group (POG)[24,25] and unifies them into a single system. Because the INSS is a postsurgical staging system, the International Neuroblastoma Risk Group (INRG) Classification System was established to stage patients before any treatment. The INRG staging system is based on clinical criteria and image-defined risk factors.[26] Each of these systems is summarized in Table 90.1.

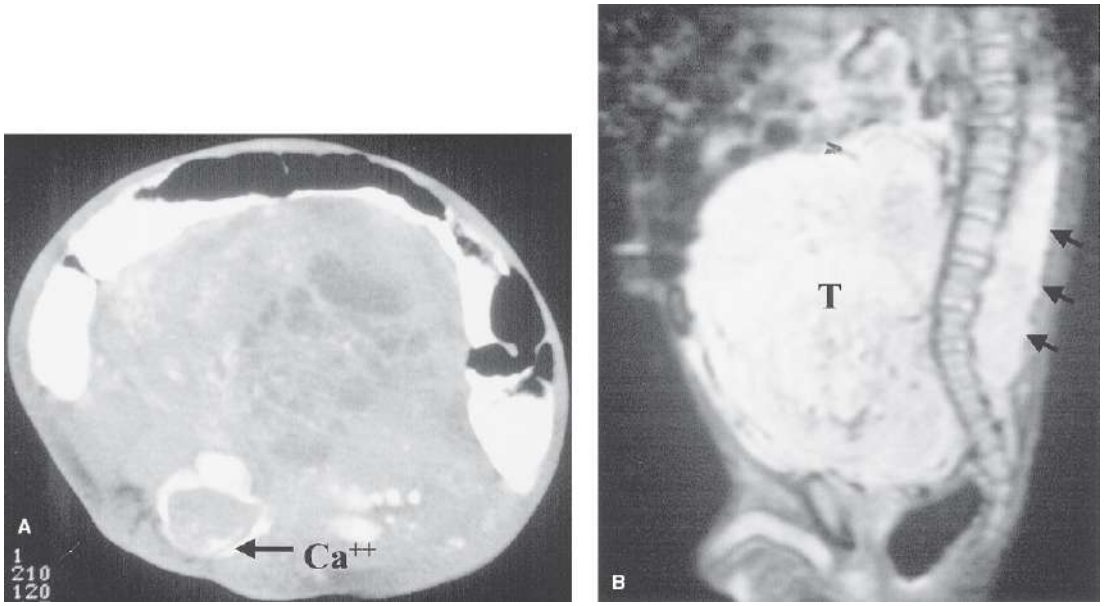

FIGURE 90.3. A 1-year-old child with constipation and a palpable mass, also noted to have lower leg weakness. **A:** Computed tomography shows a large soft tissue mass with calcifications and necrosis filling the retroperitoneum. Tumor calcification (*arrow*) is noted in the spinal cord. **B:** Sagittal, short tau inversion recovery image shows the large prevertebral mass (T) displacing bowel loops superiorly. Intraspinal tumor extends from the lower thoracic level through the lumbar level. The patient underwent emergent resection of the intraspinal tumor (*arrows*). (Courtesy of Dr. Marilyn Siegel, *Mallinckrodt Institute of Radiology*, St. Louis, MO.)

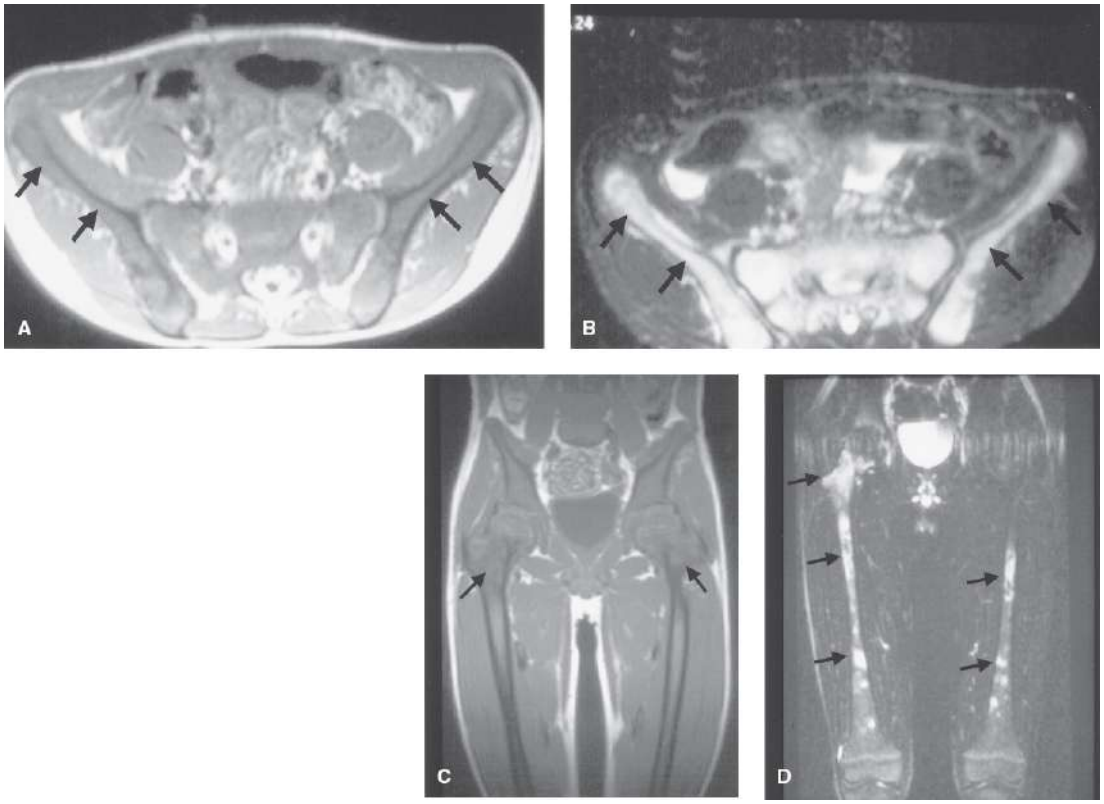

FIGURE 90.4. A 6-year-old boy who presented with bone pain. Axial **(A)** and coronal **(B)** T_1-weighted images of the pelvis and femurs show diffusely low–signal intensity marrow from metastases (*arrows*). **C:** Fat-saturated T_2-weighted image of the pelvis. The involved marrow has increased in signal intensity and is now hyperintense to adjacent fat and soft tissue (*arrows*). **D:** Fat-saturated T_2-weighted coronal image of the pelvis and femurs. Multiple high-signal foci are noted throughout the long bones (*arrows*). By comparison, normal marrow has a signal intensity similar to that of muscle on fat-saturated images. (Courtesy of Dr. Marilyn Siegel, *Mallinckrodt Institute of Radiology*, St. Louis, MO.)

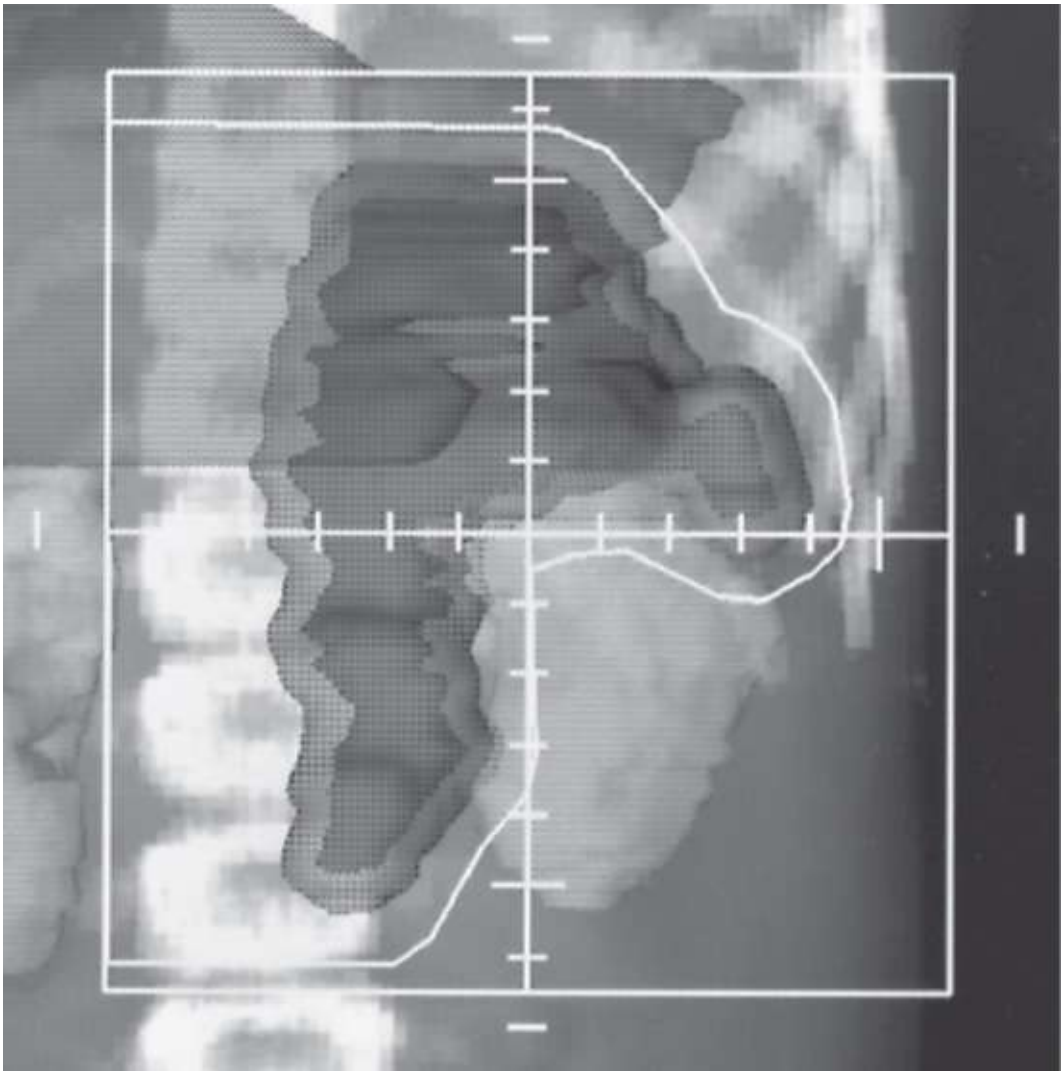

FIGURE 90.5. Radiation therapy treatment field for a child with a left adrenal primary neuroblastoma and para-aortic lymph node metastases. The beam's-eye–view display with a digital reconstructed radiograph allows for adequate coverage of the target volume and lymph node region with sparing of the ipsilateral kidney and liver while homogeneously irradiating the adjacent spine.

PATHOLOGIC CLASSIFICATION

Neuroblastomas are derived from primitive neural crest cells arising from within sympathetic ganglia. Three types of tumors, representing different degrees of differentiation, are recognized. *Ganglioneuroma* consists of mature ganglion cells, Schwann cells, and nerve bundles and is benign in appearance and nature. It frequently is calcified and may represent a matured neuroblastoma.[26] Cases of maturation of proven neuroblastomas to ganglioneuromas, either spontaneously or after therapy, have been reported.[9] *Ganglioneuroblastoma* is the intermediate

form between ganglioneuroma and neuroblastoma. Both mature ganglion cells and undifferentiated neuroblasts are evident.

Neuroblastoma is at the undifferentiated end of the spectrum of neural crest tumors. It is a small, round, blue cell tumor composed of dense nests of hyperchromatic cells. Homer Wright rosettes with a central fibrillary core can be present. Areas of necrosis, hemorrhage, and calcium are frequently present. Immunohistochemical stains may help distinguish neuroblastoma from other undifferentiated malignant neoplasms of childhood. Neuroblastoma characteristically stains positive for neurofilaments, neuron-specific enolase (NSE), synaptophysin, and chromogranin A and negative for muscle and leukocyte common antigens. The use of electron microscopy to demonstrate neurosecretory granules is required infrequently to establish the diagnosis.

A grading system has been proposed by Shimada et al.[27] and its significance has been confirmed by the CCG.[28,29] This clinicopathologic staging system evaluates tumor specimens for stromal development (i.e., stromal-rich and stromal-poor tumors), neuroblastic differentiation, and mitosis–karyorrhexis index of neuroblastic cells. These three histologic features and the patient's age at diagnosis divide children into favorable and unfavorable prognostic groups. The stroma-rich tumors are characterized by an extensive Schwann cell stroma. The well-differentiated stroma-rich tumors may correspond to ganglioneuroma, and the "intermixed" stroma-rich tumors may correspond to the ganglioneuroblastomas. To be reliable, the Shimada classification requires pretreatment evaluation of the entire primary tumor specimen. However, primary tumors often are not completely resectable, or the presence of widespread metastases makes thorough tumor resection inappropriate before introduction of initial systemic therapy, thereby limiting the usefulness of this system.

PROGNOSTIC FACTORS

Patient age and stage at initial presentation remain the two most important factors that influence outcome (Table 90.2). In general, >75% of infants and children <2 years old survive, as do 90% to 100% of children with INSS stages 1 and 2.[30–40] The presence of tumor in regional lymph nodes is a poor prognostic factor and was recognized as such by the POG in their staging system.[41] Infants <12 months old with metastatic disease confined to the liver, bone marrow (not bone), or skin (stage IV-S) have a remarkably good prognosis; <75% of these children survive with little or no treatment.[8,42] Treatment should be directed at

relief of the acute presenting event (often respiratory distress secondary to hepatomegaly), and the temptation to aggressively treat these patients in the absence of other bad prognostic factors should be avoided.

Patients with more differentiated tumors (e.g., ganglioneuroma, ganglioneuroblastoma) fare better than do children with poorly differentiated or undifferentiated neuroblastomas. A favorable Shimada stage is associated with 90% survival, compared with 22% with unfavorable Shimada stages. Elevated serum ferritin (>142 ng/mL), NSE (>100 ng/mL), and LDH (>1,500 IU) are all associated with advanced disease and a poor prognosis.[32,43–46]

MYCN (N-*myc*) is a proto-oncogene that resides on the short arm of chromosome 2. An amplification of *MYCN* gene is associated with an extremely poor prognosis (5% survival).[46,47] *MYCN* amplification has been associated with the multidrug resistance gene, which may account for this tumor's notorious resistance to therapy.[48] A tumor with a DNA index of 1 (diploid or near-diploid) paradoxically gives a worse prognosis than tumors that are aneuploid.[49] Hyperdiploid tumors occur more often in lower stages and are associated with better chemotherapy responsiveness. Allelic loss of the short arm of chromosome 1 represents a loss of heterozygosity of a tumor suppressor gene and is also associated with a poor prognosis independent of age and stage. It reliably identifies patients with stage 1, 2, or 4S disease who have a high risk of relapse and require aggressive therapy.[50] Mutations in *ALK* (encoding anaplastic lymphoma kinase) have also been described in neuroblastoma and have been identified as the predisposition gene for familial neuroblastoma. About 14% of high-risk neuroblastoma will have somatic mutations in *ALK*.[51]

GENERAL MANAGEMENT

Because of the biologic heterogeneity of neuroblastoma, the following treatment recommendations should be considered as guidelines. The prognostic implications of a tumor's biologic indices, such as *MYCN* amplification and DNA index, may warrant more aggressive therapy in young patients with otherwise a favorable stage (Table 90.3).

TABLE 90.1 NEUROBLASTOMA STAGING SYSTEMS

Evans and D'Angio	Pediatric Oncology Group	International Staging System	International Neuroblastoma Risk Group

Stage I Tumor confined to the organ or structure of origin	**Stage A** Complete gross resection of primary tumor, with or without microscopic residual; intracavitary lymph nodes, not adhered to and removed with primary (nodes adhered to or within tumor resection may be positive for tumor without upstaging patient to stage C), histologically free of tumor; if primary in the abdomen or pelvis, liver histologically free of tumor	**Stage 1** Localized tumor with complete gross excision, without microscopic residual disease; representative ipsilateral lymph nodes negative for tumor microscopically (nodes attached to and removed with the primary tumor may be positive)	**L1** Localized tumor not involving vital structures as defined by the list of image-defined risk factors and confined to one body compartment
Stage II Tumor extending in continuity beyond the organ midline; regional lymph nodes on the ipsilateral side may be involved	**Stage B** Grossly unresected primary tumor; nodes and liver same as stage A	**Stage 2A** Localized tumor with incomplete gross excision; representative ipsilateral nonadherent lymph nodes negative for tumor microscopically	**L2** Locoregional tumor with presence of one or more image-defined factors
Stage III Tumor extending in continuity beyond the midline; regional lymph nodes may be involved bilaterally	**Stage C** Complete or incomplete resection of primary, intracavitary nodes not adhered to primary histologically positive for tumor; liver as in stage A	**Stage 2B** Localized tumor with or without complete gross excision, with ipsilateral nonadherent lymph nodes positive for tumor; enlarged contralateral lymph nodes must be negative microscopically	
Stage IV Remote disease involving skeleton, bone marrow, soft tissue, distant lymph node groups, etc. (see stage IV-S)	**Stage D** Any dissemination of disease beyond intracavitary nodes (i.e., extracavitary nodes, liver, skin, bone marrow, bone)	**Stage 3** Unresectable unilateral tumor infiltrating across the midline,[a] with or without regional lymph node involvement; or localized unilateral tumor with contralateral regional lymph node involvement; or midline tumor with bilateral extension by infiltration (unresectable) or by lymph node	**M** Distant metastatic disease (except stage MS)

		involvement	
Stage IV-S Patients who would otherwise be stage I or II but who have remote disease confined to the liver, skin, or bone marrow (without radiographic evidence of bone metastases on complete skeletal survey)	**Stage DS** Infants <1 year of age with stage IV-S disease (see Evans and D'Angio)	**Stage 4** Any primary tumor with dissemination to distant lymph nodes, bone, bone marrow, liver, skin, and/or other organs (except as defined for stage 4S)	**MS** Metastatic disease in children younger than 18 months with metastasis confined to the skin, liver, and/or bone marrow
		Stage 4S Localized primary tumor as defined for stage 1, 2A, or 2B with dissemination limited to skin, liver, and/or bone marrow[b] (limited to infants <1 year of age)	

Multifocal primary tumors (e.g., bilateral adrenal primary tumors) should be staged according to the greatest extent of disease, as defined in the table, and followed by a subscript letter M (e.g., 3_M).

[a]The midline is defined as the vertebral column. Tumors originating on one side and crossing the midline must infiltrate to or beyond the opposite side of the vertebral column.

[b]Marrow involvement in stage 4S should be minimal, that is, <10% of total nucleated cells identified as malignant on bone marrow biopsy or on marrow aspirate. More extensive marrow involvement would be considered to be stage 4. The *meta*-iodobenzylguanidine scan (if performed) should be negative in the marrow.

Low-Risk Disease

Low-stage, resectable tumors (INSS stage 1, 2, or 3 with negative nodes) have an excellent prognosis after complete gross surgical excision. Adjuvant chemotherapy or irradiation has not improved the outcome in children with completely resected tumors with favorable biologic features.[38,52–54] Positive surgical margins or microscopic residual disease does not uniformly require more aggressive therapy. Patients with *MYCN* amplification or low DNA index may require adjuvant therapy and should be enrolled in clinical trials.[49]

Unresectable tumors that are otherwise of low stage (INSS stages 1 to 3 with negative lymph nodes) may require preoperative chemotherapy and occasionally radiation therapy to convert them into a resectable status. Second-look surgery is performed to remove a previously unresectable primary tumor and achieve a complete remission after induction chemotherapy. Complete resection can be achieved in almost two-thirds of previously unresectable stage III to IV primary tumors.[55] The CCG reported that eventual complete resection of the primary tumor in advanced disease may have a favorable impact on outcome.[55] The benefit to complete resection in patients with advanced disease has not been uniformly established. Patients with biologically favorable tumors may be more amenable to surgery after chemotherapy, and the apparent benefit of complete resection may be a result of patient selection.[56] POG-8104 enrolled patients with INSS stage 1 (POG stage A) disease. In that trial, *MYCN* amplification and DNA index were not evaluated uniformly. Treatment was surgery only. Regardless of the presence of residual microscopic disease, the 2-year disease-free survival rate was 89%.[25] In the CCG experience (CCG trial 3881) with stage 1 disease,

the 4-year event-free and overall survival rates for children treated initially with surgery alone were 93% and 99%, respectively. For patients with stage 2 disease, the event-free and overall survival rates were 81% and 98%, respectively. In that trial, only 13% of patients with stage 2 disease received any chemotherapy or radiotherapy, despite the fact that 104 patients had INSS stage 2b disease. The authors ascribe the favorable results to improved surgical management and better staging with MIBG scanning.[57]

TABLE 90.3 NEUROBLASTOMA RISK ASSESSMENT

Risk	Stage	Age	*MYCN*	Ploidy	Histology	Other
Low	1	Any	Any	Any	Any

amp, amplified; DI, DNA index; FH, favorable Shimada histology; UH, unfavorable Shimada histology.

Intermediate-Risk Disease

Locally advanced and regionally metastatic tumors (INSS stage 2b to 3 with positive lymph nodes) require more intensive therapy. Infants <1 year of age should undergo complete resection of the primary tumor and receive adjuvant

chemotherapy.[56,58–60] In unresectable cases, chemotherapy may be administered at diagnosis followed by surgical resection after response to systemic treatment. In older children with lymph node metastases, adjuvant radiation therapy to the primary and regional lymph nodes has improved the disease-free and overall survival rates. A prospective, randomized trial of postoperative chemotherapy or chemotherapy plus regional irradiation demonstrated 31% disease-free survival in children treated with chemotherapy, compared with 58% in those who also received radiation therapy.[61] However, the value of radiation therapy in intermediate-risk patients is not universally accepted. De Bernardi et al.[62] failed to demonstrate a benefit from the addition of radiotherapy in 29 children >1 year of age with postoperative residual tumor or positive regional lymph nodes. Children in that randomized study received two cycles of Peptichemio with or without radiation. Progression-free survival was 64% in the radiotherapy arm and 73% in the arm without radiotherapy.[62] Coupled with the risk of late effects from even moderate radiotherapy doses, this small trial provided an argument that systematic radiation therapy, even for POG stage C patients, may not be necessary. Current COG trials reflect this bias because the use of radiation therapy is decreasing.

Patients with intraspinal extension of neuroblastoma pose a unique problem. They frequently have severe neurologic compromise resulting from spinal cord compression. Historically, these patients were treated with laminectomy and surgical debulking with or without radiation therapy and chemotherapy.[63] Because the morbidity of this approach is significant, with a high rate of spinal growth deformity, a number of investigators have proceeded with treatment of these patients using primary chemotherapy.[55] A prospective series of 42 patients treated with primary chemotherapy demonstrated a 92% improvement in neurologic deficits, allowing children to avoid neurosurgical decompression in >60% of cases when receiving courses of carboplatin and etoposide alternating with cyclophosphamide, vincristine, and doxorubicin.

The POG experience (POG trials 8742 and 9244) with stages 2b to 3 disease demonstrates an 85% event-free survival with completely resected tumors at diagnosis, compared to 70% with incomplete resection at diagnosis ($P = .259$). In both of these studies, patients underwent maximum safe tumor resection followed by five courses of induction chemotherapy. In POG-8742, they received cis-platinum and etoposide alternating with cyclophosphamide and doxorubicin. In POG-9244, they received alternating cycles of vincristine, cis-platinum, etoposide, and cyclophosphamide (OPEC) and vincristine, carboplatin,

etoposide, and cyclophosphamide. After second-look surgery, the same chemotherapy was given as maintenance. Radiotherapy was given to patients with viable residual tumor discovered at the time of the second-look operation. Children age 12 to 24 months at the time of radiation therapy received 24 Gy in 1.5-Gy fractions to the primary tumor site. Older children received 30 Gy in 1.5-Gy fractions. Of the 37 patients on these two protocols who survived "event free," 11 (30%) received radiotherapy. Patients with favorable Shimada histology tumors had a 92% event-free survival, compared with 58% with unfavorable tumors (P = .009). Patients with *MYCN* amplification did poorly, with outcomes comparable to those for stage D patients.[27]

Based on CCG and POG data, patients with intermediate-risk neuroblastoma have an estimated 3-year survival of between 75% and 98%. Cyclophosphamide, doxorubicin, carboplatin, and etoposide are the four most active agents.[64–66] Surgery plays a critical role in the primary management of neuroblastoma. The goals of surgery are to establish a diagnosis; provide tissue for evaluation of prognostic biologic markers; stage the disease according to INSS criteria; and attempt to totally excise the primary, if feasible. The extent of surgery has an important impact on outcome. O'Neill et al.[67] reported that 55 of 59 patients with a complete or near-complete resection were alive and free of disease 2 years after surgery, compared to only 13 of 24 cases with a subtotal resection. Just as Haase had reported, Grosfeld and Baehner[34] found evidence for improved outcome in stage 4 patients attaining complete resection of primary tumor at delayed second-look procedures.

High-Risk Disease

The majority of patients with neuroblastoma present with metastatic disease. Many clinical trials have sought to intensify treatment of metastatic neuroblastoma through the use of high-dose myeloablative chemotherapy with stem cell rescue or bone marrow transplantation (BMT). The French Lyon-Marseille-Curie East group reported a 40% progression-free survival at 2 years and 20% at 5 years in 62 patients proceeding to autologous bone marrow transplant (ABMT).[68] The CCG reported a 43% 2-year event-free survival in 43 children undergoing consolidation melphalan, cisplatin, teniposide, doxorubicin, and total-body irradiation (TBI) to 10 Gy in 3 fractions of 3.3 Gy/day. The toxic death rate was 22%.[69] Australian investigators tested a less intense preparative regimen with a TBI regimen consisting of 12 Gy in 6 twice-daily fractions.[70] Of 28 patients registered, 19 achieved complete remission after induction

chemotherapy. Seventeen of these nineteen patients underwent ABMT and fifteen (87%) remained free of disease at 5 years from ABMT. Of the 28 patients registered, 50% have survived 5 years.

Uncertain that ABMT could be studied successfully in a cooperative group, the CCG conducted two pilot studies for children with stage 4 disease. In CCG-321, patients received induction chemotherapy consisting of cisplatin, etoposide, doxorubicin, and cyclophosphamide. Of 207 patients, 159 remained disease free during induction chemotherapy. Of these patients, 67 received myeloablative chemotherapy and ABMT, whereas 74 continued conventional chemotherapy for a total of 13 cycles. The patients receiving the ABMT had a higher event-free survival than patients continuing standard chemotherapy (40% vs. 19%, P = .019).[71] Because they are not randomized trials, these studies potentially may have allowed a biased allocation of patients to one arm based on clinical concerns or prognostic risk factors. The POG failed to show a benefit to BMT in high-risk metastatic neuroblastoma (POG 8340).[45]

The European Neuroblastoma Study Group studied the role of consolidative ABMT with high-dose melphalan versus no further treatment following induction chemotherapy with the OPEC regimen in patients with stage 3 and 4 diseases.[72,73] With a median follow-up of 14.3 years for surviving children, they report an improvement in event-free survival (38% vs. 27%) and overall survival (47% and 30%) for the high-dose melphalan arm, but these differences did not reach statistical significance. The subset of patients with stage IV disease who were >1 year of age, however, did show statistically significant improvement in event-free survival (33% vs. 17%, P = .01) and overall survival (46% vs. 21%, P = .03).

The CCG conducted a randomized trial comparing continued chemotherapy with myeloablative therapy (including 10 Gy TBI in 3 daily fractions) and ABMT in children with high-risk neuroblastoma. All patients received radiation therapy to the primary site and select metastatic sites. A second randomization following cytotoxic therapy included 6 cycles of 13-*cis*-retinoic acid or no further therapy. Initial results demonstrated an event-free survival advantage to both BMT and 13-*cis*-retinoic acid therapy, but no overall survival advantage.[74] However, after a median follow-up of more than 7 years, a statistically significant advantage to overall survival was demonstrated for the cohort treated with both myeloablative therapy and 13-*cis*-retinoic acid therapy.[75]

Berthold et al.[76] in Germany reported results of a prospective, randomized trial in children with high-risk neuroblastoma comparing myeloablative therapy

with melphalan, etoposide, and carboplatin and autologous stem cell rescue with maintenance chemotherapy with cyclophosphamide. When analyzed as-treated, statistically significantly improved 3-year event-free survival (53% vs. 30%) and overall survival (68% vs. 53%) were seen with myeloablative therapy.

Immunotherapy with ch14.18, a monoclonal antibody against tumor-associated disialoganglioside GD2, has been shown to have activity against neuroblastoma. A randomized trial comparing 6 cycles of isotretinoin versus immunotherapy (6 cycles of isotretinoin and 5 concomitant cycles of ch14.18 in combination of alternating GM-CSF and interleukin-2) resulted in a 2-year event-free survival (47% vs. 67%) and 2-year overall survival (76% vs. 86%) with the use of immunotherapy.[77]

A recent trial compared single autologous stem cell transplant (ASCT) with carboplatin, etoposide, and melphalan (CEM) or tandem ASCT with thiotepa, cyclophosphamide ACST followed by a modified CEM regimen. For single and tandem transplant without immunotherapy, there was improvement in 3-year event-free survival (49% vs. 62%). For single and tandem transplant with immunotherapy, there was improvement in 3-year event-free survival (55% vs. 74%) and 3-year overall survival (76% vs. 86%).[78]

Local control of the primary tumor in stage 4 neuroblastoma is an important element of patient management. The role of surgical resection in metastatic disease remains controversial. Many authors have reported more favorable outcome in patients undergoing complete resection.[79] There is a strong association between chemotherapy dose intensity and surgical resectability, which reduces the significance of aggressive resection as an independent favorable factor. It can be assumed that tumors that are amenable to resection may have an inherently less aggressive biology.

In the CCG-321-P3 pilot, there was a 33% rate of local relapse in patients not undergoing a complete resection at their initial surgery, irrespective of their ultimate surgical resection status, including second-look operations.[80] This high local failure rate suggests that there is a role for local radiation therapy. In that pilot study, patients received radiotherapy only if they had gross residual disease after second-look surgery. Although the local control in patients receiving radiotherapy was the same as in unirradiated patients, one should note that only patients with gross residual disease received this local treatment, suggesting that the radiotherapy (RT) was beneficial.

In a reanalysis of CCG-3891, Hass-Kogan et al.[81] compared locoregional control rates in patients on the non-ABMT arm who received 10 to 20 Gy to

gross residual disease after induction therapy to patients in the ABMT arm who received similar RT to residual disease but also received 10-Gy TBI in 3.33-Gy daily fractions in their conditioning regimens The patients in the ABMT arm had a lower locoregional recurrence rate (33% vs. 51%, P = .004). Although this effect may be due to the higher dose of RT delivered in this group of patients, it is not possible to separate the RT effect from that of the more intense systemic therapy also given to these patients in the ABMT arm.

Laprie et al.[82] analyzed locoregional control in MYCN-amplified INSS stage 2 and 3 patients treated with different regimens over different eras. Their approach varied from conventional chemotherapy and RT only to gross residual disease after surgery in patients >1 year of age, to high-dose chemotherapy with ABMT, to local radiation therapy to all patients. They noted an improvement in event-free survival with ABMT and RT (83% vs. 25%, P = .001). Again, conclusions regarding the effect of RT independent of the intensified systemic therapy are difficult to make because this was not a randomized comparison.

Multiple studies have shown that locoregional control rates with RT for high-risk neuroblastoma range from 84% to 100%, utilizing doses of 21 to 24 Gy.[83–85] For patients who have an incomplete resection, it is unclear whether a higher dose of RT is warranted. Some studies show a worse local control rate with 21 to 21.6 Gy for patients with gross disease at the primary site. A German trial showed better event-free survival and locoregional progression-free survival for patients receiving RT; in this study, a subset of patients who had subtotal resection received a median dose of 36 Gy, whereas others including those who had gross total resection did not receive RT[86]

Local therapy to the primary tumor and metastatic sites may be beneficial in the curative therapy of children with disseminated disease. Surgical resection of the primary tumor has been associated with improved survival and local control after aggressive systemic therapy.[55,80] There is a predilection for recurrence in previous sites of disease, and it is conceivable that additional local therapy with irradiation to the primary tumor site and distant metastases may enhance tumor control and cure rates.[80,84,87] Currently, patients with MIBG-avid metastatic sites after induction chemotherapy and surgery are treated with RT to 21.6 Gy. In one study, children with two or more postinduction MIBG-avid sites have a worse progression-free and overall survival despite RT to sites of persistent distant metastasis.[84]

Radiation therapy plays an extremely important role in the palliative management of patients with end-stage symptomatic neuroblastoma. Pain from

bone or other visceral metastases often can be relieved with external beam radiation therapy. Mass effect from a rapidly enlarging tumor can respond dramatically to radiation therapy. In a series of 10 patients treated at Duke University Medical Center, Halperin[88] reported 7 complete responses to radiation therapy, either alone or in conjunction with chemotherapy. Radiation doses ranged from 4 to 24.4 Gy at a rate of 1 to 1.5 Gy/fraction. The seven patients with complete response survived without recurrence.

Systemic radionuclide therapy with ^{131}I-MIBG has been tested in several European and US centers with early encouraging results. This radioactive agent produced objective responses in previously treated and chemoresistant stage 4 neuroblastoma.[89,90] These early positive results prompted some investigators to test this agent in previously untreated metastatic neuroblastoma. De Kraker et al.[91] reported that a combination of ^{131}I-MIBG and second-look surgery produced response rates comparable to those of multidrug chemotherapy. Preliminary research on the combination of ^{131}I-MIBG with systemic chemotherapy and/or TBI with BMT demonstrated that this is a safe treatment and worthy of more investigation.[92–94]

The current approach by the Children's Oncology Group for patients with high-risk disease is to combine induction chemotherapy, surgical resection, autologous stem cell rescue, and radiation therapy to the primary site and select metastatic sites13-*cis*-retinoic acid and immunotherapy in an attempt to improve outcome in these patients. The current protocol utilizes a higher radiation total dose of 36 Gy for patients with gross residual disease at their primary sites.

RADIATION THERAPY TECHNIQUES: TREATMENT PLANNING AND FIELD DESIGN

Treatment of children with neuroblastoma can be challenging because of their young age and immature tissues. Most tumors will be located in the abdomen with the kidneys, liver, and spine as the usual dose-limiting organs. AP/PA fields have been previously recommended for well-lateralized lesions because of lower dose to the contralateral kidney and more homogeneous dose to the spine, whereas intensity-modulated radiation therapy (IMRT) may be more advantageous for midline tumors.[95] Recently, proton therapy has been used and may have a dosimetric advantage to minimize dose to anterior structures beyond the retroperitoneum and posterior mediastinum.[96]

When defining the volume for the tumor bed, the postinduction

chemotherapy, preoperative CT, or MRI scan is used for tumor volume delineation. Unlike other pediatric solid tumors, the initial tumor volume tumor bed is not treated with RT. The clinical target volume (CTV) is the tumor bed and residual tumor with a 1- to 1.5-cm margin, with attention to anatomic barriers of spread. A planning target volume of 0.5 cm may be used depending on the institutional experience. The CTV and PTV are typically treated to 21.6 Gy in 12 fractions. The question of whether a higher dose is needed for patients with residual tumor is currently being investigated in COG ANBL12P1 study where patients with residual disease receive a boost of 14.4 Gy in 8 fractions to the residual tumor with a 1-cm margin (CTV boost). An additional margin of 0.5 to 1 cm beyond the CTV boost is used for the PTV boost.

Persistent activity in metastatic sites after induction therapy can be treated with radiotherapy as long as the patient can tolerate the treatment. The dose is 21.6 Gy in 12 fractions over 2.4 weeks and follows the same CTV and PTV guidelines for the primary site.

Low-dose TBI has been used with variable success in the curative management of children with metastatic neuroblastoma.[97,98] In the past, TBI was part of the preparative regimen for patients undergoing BMT for high-risk metastatic disease. The patterns of failure in high-risk neuroblastoma were analyzed by Li and colleagues.[99] In this multi-institutional report, patients who had TBI were less likely to have relapse in prior sites of disease compared to those who did not have TBI. The authors conclude that radiopharmaceutical therapies may be helpful and needs to be further investigated.

Other investigators have used intraoperative radiation therapy (IORT) in patients with high-risk neuroblastoma. Haas-Kogan[100] described the results of IORT in 23 patients with high-risk disease. A single fraction of 7 to 16 Gy (median 10 Gy) to the primary tumor bed was associated with a local control rate of 100% in patients who had gross total resection, whereas IORT was unable to control any patients with gross residual disease.

Radiotherapy can also be used for palliation of painful and/or enlarging bone and soft tissue metastasis[35,101,102] with about two-thirds or more of patients having symptomatic response. Low-dose, short-fractionation schedules are appropriate if the child is not expected to live beyond 6 to 12 months. In these instances, minimizing a child’s visits to the radiation therapy facility while rapidly relieving symptoms is a worthwhile goal. If the likelihood of long survival is small, 5 to 20 Gy in 1- to 5-daily fractions can allow rapid palliation.

RESULTS OF THERAPY

Low-Risk Disease

Survival rates after surgery alone of 85% to 90% or better can be expected.[25,52,53,57] Additional therapy usually is not indicated unless unfavorable biologic features are present.

Intermediate-Risk Disease

Children with large, initially unresectable tumors often respond to primary chemotherapy with combinations of drugs, including cyclophosphamide, vincristine, cisplatin, etoposide, doxorubicin, or teniposide. Children with unresponsive, unresectable gross residual disease may require external beam irradiation. Frequently, these children can undergo resection of the tumor at a second-look operation[55] and achieve a survival rate of 60% to 90%.[54]

High-Risk Disease

Children >1 year of age with metastatic neuroblastoma continue to have an unfavorable prognosis, with expected 3- or 4-year survival rates of 30%. For patients who have not progressed after induction therapy and surgery, tandem transplant with immunotherapy was associated with 3-year EFS of 74% and 3-year overall survival of 86%.[78]

Infants with metastatic disease confined to the liver, skin, and bone marrow have a uniquely favorable outcome. In stage 4S, survival rates can be as high as 75% to 90%.[60,103,104] In these patients, the goal of therapy should be limited to the relief of acute presenting symptoms. Halperin[88] reported 7 complete responses to hepatic radiation in 10 infants with symptomatic liver metastases. All 7 of these children survived. The recommended dose for symptomatic liver metastasis is 4.5 to 6 Gy in 3 to 4 fractions.

SEQUELAE OF TREATMENT

Early Complications

Acute side effects of radiation therapy depend on tumor site and fields of treatment. The short-term effects are those that can be expected for any patient receiving radiation therapy. Acute effects, especially skin reactions and mucositis, may be enhanced if concurrent chemotherapy or a hyperfractionated irradiation schedule is used.

Late Effects

Long-term effects depend on the site irradiated and the total dose of both radiation and chemotherapy agents used. Age at the time of treatment may influence the risk and severity of skeletal anomalies,[105] which may include spinal deformities such as kyphosis, scoliosis, or limb shortening. Generally, younger children are more prone to late radiation injury than older children. In one study, children irradiated at <6 months have more musculoskeletal abnormalities.[106] Both laminectomy and RT dose >17.5 Gy were risk factors for development of scoliosis in children with abdominal neuroblastoma.[105] A report from Memorial Sloan Kettering Cancer Center showed no cases of chronic renal insufficiency in 266 patients treated with techniques minimizing RT dose to bilateral kidneys.[107] A report from the Childhood Cancer Survivor Study showed the 20-year cumulative incidences of neurologic, sensory, endocrine, and musculoskeletal toxicities were 29.8%, 8.6%, 8.3%, and 7.8%. The cumulative incidence of secondary malignancies was 3.5% at 25 years after diagnosis.[108]

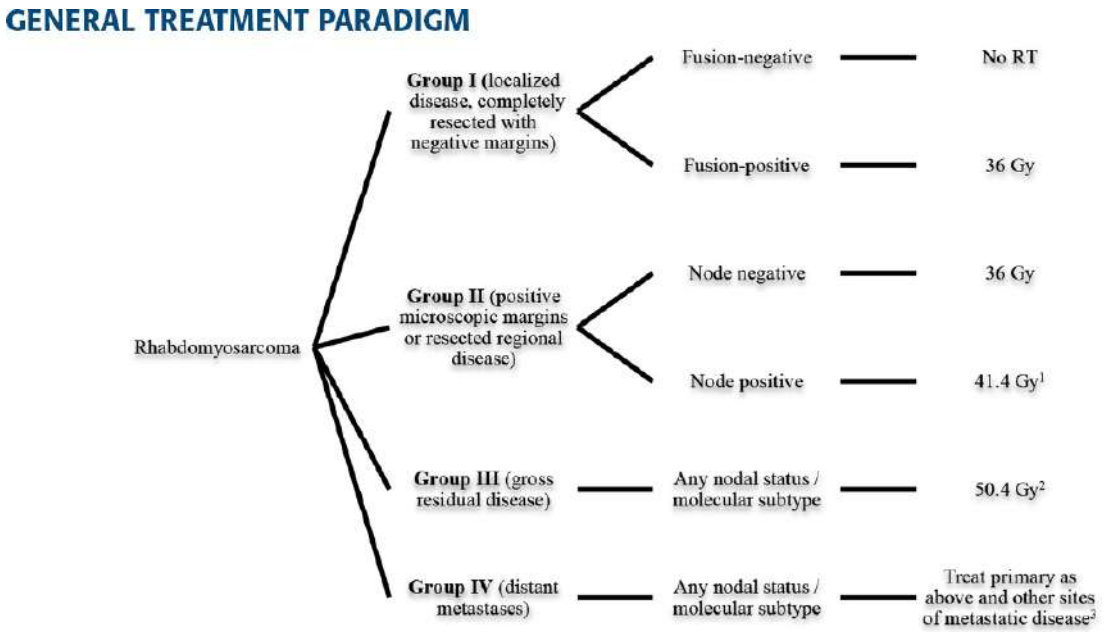
CHAPTER 91

Rhabdomyosarcoma

Dana L. Casey, John C. Breneman, Sarah S. Donaldson, and Suzanne L. Wolden

GENERAL TREATMENT PARADIGM



Ongoing Investigations

- Reducing the dose to 36 Gy for patients with group II node-positive disease.
- For patients with group III disease, treating the prechemotherapy volume to 36 Gy followed by a boost to 50.4 or 59.4 Gy if the initial size is >5 cm.
- Treating bone metastases with stereotactic body radiation therapy.

ANATOMY

Rhabdomyosarcoma (RMS) is a highly malignant soft tissue sarcoma that arises from unsegmented, undifferentiated mesoderm or myotome-derived skeletal

muscle. It may occur at any site in the body, but the most frequently involved sites are the orbit (9%); head and neck (excluding parameningeal tumors) (7%); parameningeal (25%); genitourinary (31%); extremity (13%); trunk (5%); retroperitoneum (7%); and other sites (3%).[1]

Epidemiology and Risk Factors

RMS is the most common of the childhood soft tissue sarcomas, with an annual incidence of 4.4 per 1 million whites and 1.3 per 1 million blacks. The male-to-female ratio is approximately 1.5 to 1.0, and males may have slightly better overall survival.[2]

The great majority of patients are <10 years of age at the time of diagnosis, and approximately 5% are <1 year of age. There are two peak age frequencies, at ages 2 to 6 and in adolescence. Tumors in the younger age group are likely to be of embryonal histology. About 25% of patients are ≥10 years at diagnosis and their tumors are more commonly of alveolar histology. Age has been identified as an independent predictor of prognosis, with children <1 year and >10 years having inferior survival.[3] Adults with RMS have been reported to have poor outcomes, although there is evidence that when they are treated aggressively using pediatric-type protocols, the prognosis may be similar to that of younger patients.[4–6]

The cause of RMS is unknown; however, it is associated with disorders in development, including central nervous system, genitourinary, gastrointestinal, and cardiovascular anomalies, and with congenital disorders including congenital pulmonary cysts, Gorlin basal cell nevus syndrome, and neurofibromatosis. In addition, RMS is the most frequently occurring childhood cancer in families with Li-Fraumeni syndrome, and its incidence is increased in children with neurofibromatosis type 1, Beckwith-Wiedemann syndrome, and Costello syndrome.

Recent developments in cytogenetics and molecular genetics now provide a more comprehensive understanding of the origin and biologic behavior of RMS. The classic distinction of embryonal versus alveolar histology has been largely replaced by the PAX/FOXO1 fusion status (fusion-negative vs. fusion-positive) for both prognostic and therapeutic decision-making. These details are discussed in more detail later.

NATURAL HISTORY AND PATTERNS OF SPREAD

There are unexplained associations of site of primary tumor with age at diagnosis and tumor histology. For example, tumors arising in the urinary bladder and vagina occur primarily in infants and often are of the embryonal or botryoid histologic type. Tumors arising in the trunk and extremity occur in adolescents and are often alveolar. Tumors of the head and neck area occur throughout childhood and are commonly of the embryonal type.

RMS, a locally invasive tumor often with a pseudocapsule, has the potential for local spread along fascial or muscle planes, lymphatic extension, and hematogenous dissemination. The overall risk of regional lymphatic spread is approximately 15% but varies with the site of the primary lesion. Lymph node metastases are rare in orbital tumors, but they occur in approximately 15% of tumors at other head and neck sites, most commonly the nasopharynx. Accounting for staging inaccuracies, regional lymph node extension occurs in approximately 25% of children with paratesticular, extremity, and truncal tumors and in approximately 50% of children with perineal and perianal tumors.[7,8] The risk for lymph node involvement also correlates with primary tumor invasiveness and large tumor size.

Hematogenous metastases are detected at the time of presentation in approximately 15% of patients, particularly those with truncal and extremity primary tumors. The most common sites of hematogenous dissemination are lungs, bone marrow, and bone. Malignant pleural and peritoneal effusions may also accompany tumors primary to the chest and abdomen or pelvis, respectively.[9]

CLINICAL PRESENTATION

Because RMS occurs in multiple primary sites, there are many site-specific clinical signs and symptoms. It usually presents, however, as an asymptomatic mass. When symptoms are present, they relate to mass effect on associated organs and tissues. Tumors of the orbit may cause proptosis and ophthalmoplegia. Patients with parameningeal tumors often present with nasal, aural, or sinus obstruction; cranial nerve palsy; and headache. Genitourinary tumors may cause hematuria, urinary obstruction, or constipation.

DIAGNOSTIC WORKUP

Determination of tumor extent is best done with a multidisciplinary approach by

a radiation oncologist, pediatric oncologist, and appropriate subspecialty surgeon. An expeditious local and systemic workup is essential because these tumors have the potential to grow rapidly. The initial assessment by all members of the team permits accurate staging and the formation of a uniform treatment plan. Table 91.1 provides recommendation for diagnostic workup at various sites. Early experience with combined positron emission tomography (PET) and computed tomography (CT) scanning indicates this modality may be a valuable component of staging[10] and may in fact provide more accurate staging than conventional imaging.[11] PET-CT may be especially valuable in assessing response to therapy and in predicting outcomes, as conventional imaging has not shown a good correlation of tumor response to long-term clinical outcome.[12–14] Some children whose tumors exhibit characteristic fusion transcripts can be shown to have micrometastatic disease using reverse transcriptase polymerase chain reaction techniques, even when there is no evidence of metastases from routine diagnostic procedures. The clinical significance of this is, however, unknown.[15]

TABLE 91.1 RECOMMENDED WORKUP FOR TUMORS AT VARIOUS SITES

All Patients	Optional
All sites	
History	
Physical examination by several observers (including a pediatric oncologist, surgical oncologist, and radiation oncologist)	Examination under anesthesia for infants and youngsters
Laboratory studies Complete blood count Liver function tests Renal function tests Urinalysis	Plain films of bones abnormal on scans Abdomen/pelvis CT, MRI, or ultrasound
Imaging studies PET-CT (this study can likely replace chest/abdomen/pelvis CT and bone scan studies) MRI or CT of primary tumor	
Bone marrow biopsy and aspirate	
Head and neck	
MRI or CT of primary tumor (with contrast)	Plain films of area
Lumbar puncture with cytologic examination of fluid (in parameningeal primary tumors)	Dental evaluation and x-rays Paranasal sinus and skull films MRI of spine if cerebrospinal fluid

	is positive or patient is symptomatic
Genitourinary	
CT of MRI of abdomen/pelvis (with contrast)	Ultrasound of pelvis
Pelvic examination under anesthesia	Cystoscopy
Extremity and truncal lesions	
MRI or CT of primary lesion (with contrast)	Plain films of primary site
	Ultrasound
	Barium gastrointestinal contrast studies

CT, computed tomography; MRI, magnetic resonance imaging; PET, positron emission tomography.

STAGING SYSTEMS

The clinical grouping classification used extensively by the Intergroup Rhabdomyosarcoma Study Group (now known as the Children's Oncology Group Soft Tissue Sarcoma [COG STS] committee) investigators is somewhat of a misnomer because it actually requires surgical pathologic evaluation (Table 91.2). It is not a staging system and does not accurately reflect the biology of the disease; rather, it reflects the surgical procedure selected for an individual patient. It is, however, useful for guiding decisions for radiotherapy, based on the amount of residual tumor after the initial surgical procedure. A more valid pretreatment staging system uses a TNM (tumor, node, metastasis) approach, which emphasizes characteristics of the primary tumor, size and invasiveness, nodal status, and systemic spread. Noninvasiveness, small size, and an absence of metastases have been shown to influence prognosis.[16] The site of primary tumor also has a significant impact on survival.[17,18] The Intergroup Rhabdomyosarcoma Study IV (IRS-IV) prospectively demonstrated the validity of a staging system incorporating TNM classification along with primary tumor site (Table 91.3). Three-year failure-free survival was 86% for stage 1 tumors, 80% for stage 2, 68% for stage 3, and 25% for stage 4.[1,9] Of note, the clinical grouping did not correlate as well with survival. In fact, failure-free survival for clinical group II patients in the IRS-IV study was superior to that for clinical group I patients (86% vs. 83%), probably reflecting the routine use of radiotherapy for group II patients.

TABLE 91.2 INTERGROUP RHABDOMYOSARCOMA STUDY CLINICAL GROUPING CLASSIFICATION

Group I	Localized disease, completely resected
A	Confined to organ or muscle of origin
B	Infiltration outside organ or muscle of origin; regional nodes not involved
Group II	Compromised or regional resection
A	Grossly resected tumor with microscopic residual disease
B	Regional disease, completely resected, in which nodes may be involved or extension of tumor into adjacent organ may exist
C	Regional disease with involved nodes, grossly resected, but with evidence of microscopic residual disease
Group III	Incomplete resection or biopsy with gross residual disease
Group IV	Distant metastases at diagnosis

TABLE 91.3 INTERGROUP RHABDOMYOSARCOMA STUDY PRETREATMENT STAGING SYSTEM

Stage	Site[a]	Invasiveness	Size	Nodal Status	Metastases
I	Favorable	T1 or T2	a or b	N0 or N1	M0
II	Unfavorable	T1 or T2	a	N0	M0
III	Unfavorable	T1 or T2	b	N0	M0
			a or b	N1	M0
IV	Any site		T1 or T2	N0 or N1	M1

[a]Favorable sites: orbit, head and neck (nonparameningeal), genitourinary (non–bladder–prostate); unfavorable sites: genitourinary (bladder–prostate), extremity, parameningeal, other.
T1, tumor confined to site or organ of origin; T2, regional extension beyond the site or organ of origin; a, ≤5 cm; b, >5 cm; N0, no evidence of regional node involvement; N1, evidence of regional node involvement (enlargement of nodes on radiographic imaging is considered evidence of involvement, although histologic confirmation is recommended when possible); M0, no distant metastasis; M1, evidence of distant metastasis.

PATHOLOGIC CLASSIFICATION

The histogenesis of RMS can be traced from mesoderm to mesenchyme and ultimately to striated muscle tissue. The classification of RMS initially used by the IRS investigators consisted of four histologic subtypes: embryonal, botryoid subtype of embryonal, alveolar, and pleomorphic. Embryonal histologies constitute approximately two-thirds of all cases, with most of the rest having

alveolar histology.[19] Other variants including a “solid” alveolar pattern, considered a subtype of alveolar RMS, a spindle cell subtype of embryonal RMS, and a diffuse anaplastic variant have also been described.[20]

To improve reproducibility of pathologic subtyping and prognostic utility, pediatric pathologists developed an updated classification system: the International Classification of Rhabdomyosarcoma. This system is based on a review of IRS-II data, and it groups pathologic subtypes into distinct prognostic groups. The International Classification of Rhabdomyosarcoma system appears to be predictive of outcome and has been reproduced by several reference pediatric pathologists.[20,21] The superior prognosis group, consisting of two subsets (botryoid and spindle cell), carries a projected 5-year survival rate of 88% to 95%.[21] The botryoid subtype, a polypoid variant of embryonal RMS, has a grapelike appearance. The stroma consists of loose cellular tissue with a myxoid appearance. Under the superficial stroma is a hypercellular zone of tumor cells called the cambium layer of Nicholson. Botryoid tumors are usually noninvasive and localized and occur in mucosal-lined organs such as the vagina, urinary bladder, middle ear, biliary tree, and nasopharynx. The spindle cell subtype of embryonal RMS has a spindled appearance, often with a storiform pattern. It is frequently found in paratesticular sites.

Patients with embryonal RMS have an intermediate prognosis, with an 83% failure-free survival at 3 years.[17] The embryonal type consists of blastemal mesenchymal cells that tend to differentiate into cross-striated muscle cells. There is often a considerable variation in degree of cytoplasmic development, ranging from primitive mesenchymal to highly differentiated muscle tumor cells. Most of the tumor cells have eosinophilic cytoplasm, which is positive by periodic acid–Schiff staining. Immunohistochemistry may demonstrate actin- or desmin-positive reactions. Ultrastructural studies exhibit evidence of myogenesis with the presence of thick and thin cytoplasmic intermediate filaments or Z-band material. Ribbon or strap-shaped cells and tadpole cells are characteristic. The presence of cross-striations confirms the diagnosis. The embryonal form may be distinguished from the other subtypes by specific structural abnormalities. A consistent loss of heterozygosity at the chromosome 11p15.5 locus suggests that this site is specific for the embryonal subtype,[22] although, unlike alveolar histology, no characteristic translocation has been identified. Immunohistochemical presence of epidermal growth factor receptor and fibrillin-2 appears to be highly specific for embryonal histology and is predictive of a favorable outcome.[23,24] Dysregulation of the RAS pathway has also been

found in some patients and may be involved in the pathogenesis of this subtype.[25] The embryonal histology is found most commonly in the orbit, head and neck, and genitourinary sites.

The group with poor prognosis includes alveolar, diffuse anaplastic, and undifferentiated sarcomas. With routine use of immunohistochemistry and molecular genetic analysis, about one-third of RMSs are now classified as alveolar; it is most commonly found in adolescents with truncal, retroperitoneal, and extremity tumors. The alveolar subtype is characterized by a pseudoalveolar pattern of connective tissue trabeculae, lined by large rhabdomyoblasts and multinucleated giant cells. The “solid” variant of alveolar RMS grows as solid nests of closely aggregated tumor cells with less alveolar pattern. Alveolar histology is strongly associated with hyperdiploid content.[26] Approximately 75% of children with alveolar RMS exhibit a characteristic translocation involving chromosomes 2 and 13, t(2;13)(q35;q14), and occasionally a 1;13 translocation.[22,27] These translocations correspond to abnormal fusion genes involving *PAX3-FKHR* and *PAX7-FKHR*, respectively, and are probably the initial oncogenic events in these tumors.[28,29] Immunohistochemical presence of AP2-β and P-cadherin is also highly specific for alveolar histology.[23,24] The projected 3-year failure-free survival for children with the alveolar subtype is 66%.[1]

Undifferentiated sarcoma is largely a diagnosis of exclusion; it consists of a diffuse cell population of primitive, noncommitted mesenchymal cells. The 3-year failure-free survival rate of patients with undifferentiated sarcoma is 55%.[1] Today, sarcomas that lack characteristics of differentiation are most appropriately managed as non-RMS soft tissue sarcomas, though their outcomes have been similar to alveolar RMS.

The pleomorphic type is extremely rare; many cases formerly classified as pleomorphic RMS are currently considered to be malignant fibrous histiocytoma. Previously, tumors classified as extraosseous Ewing sarcoma were treated using guidelines for RMS. These are more appropriately considered in the Ewing family of tumors and are managed as such.

As more is learned about the molecular biology of RMS, fusion status rather than histology may be the more important driver of clinical outcomes. Recent data suggest that fusion-negative alveolar RMS is more similar to embryonal histology both clinically and molecularly.[30] On COG D9803, there was a trend toward improved event-free survival (EFS) among patients with fusion-negative alveolar RMS when compared to those with embryonal RMS (EFS 90% vs.

77%).[31] Other studies have confirmed that fusion status may be more important prognostically than histology.[30,32] As such, modern COG clinical trials account for fusion status in addition to histology for risk stratification.

PROGNOSTIC FACTORS AND THERAPEUTIC CONSIDERATIONS

Because RMS is protean in presentation, factors such as age, site, stage, extent of disease, and pathologic characteristics of the tumor influence therapeutic decisions. These prognostic factors are interrelated and are best discussed as a function of the specific site (Fig. 91.1). Although most treatment failures occur within 3 years of diagnosis, about 10% of children who are free of disease at 5 years will subsequently experience disease recurrence.[33]

Orbit

The orbit has long been recognized as a favorable prognostic site. In addition to prompt recognition of the tumor, the paucity of lymphatics in this area means that lymphatic extension is rare. Most tumors in this site have embryonal histology, and hematogenous metastasis at the time of diagnosis is uncommon. Approximately 10% are alveolar histology, however, and the prognosis for these children is more guarded.[34]

When treatment for orbital tumors is individualized, it is generally agreed that no surgical procedure should be used that may compromise vision or loss of function. In most patients, this means that biopsy only should be performed to provide the diagnosis. Primary treatment typically consists of vincristine, actinomycin-D, and cyclophosphamide (VAC) or vincristine and actinomycin-D (VA) chemotherapy with local radiotherapy beginning after the 12th week of treatment. Radiation doses of approximately 50 Gy are often used. Dose reduction to 45 Gy was tested on D9602, resulting in a local failure rate of 13% (compared to 5% seen on IRS IV).[35,36] A dose of 45 Gy was shown to result in unacceptable rates of local control for orbital RMS again on ARST0331 in those without a complete response to chemotherapy. As discussed later, orbital tumors should be treated with similar doses as other primary sites.

Chemotherapy without irradiation has resulted in local relapse and inferior EFS.[37] Although salvage radiotherapy for these patients can still be curative, functional vision in this setting is often poor.[38] Orbital exenteration should be reserved for salvage treatment and enucleation for management of posttreatment

ocular complications.

With a combined-modality approach, radiotherapy can be directed to the tumor plus a margin without necessarily irradiating the entire orbit. Technique is very important for minimizing corneal and lacrimal gland dose and for preserving useful vision, ocular function, and appearance. Photon irradiation with the eyelid open can minimize the corneal dose when an anterior field is used and may be associated with improved long-term functional outcome.[39] Three-dimensional conformal or intensity-modulated radiotherapy technique is optimal for treating the target volume and sparing normal structures, and proton radiation has also been used successfully.[40]

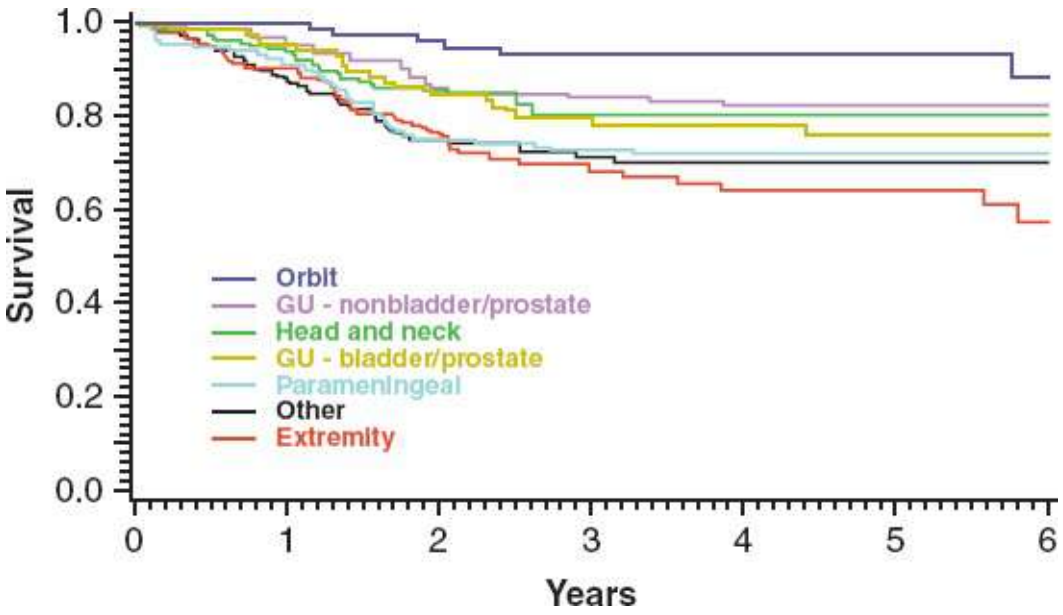

FIGURE 91.1. Survival curves for 883 children with nonmetastatic disease entered into the fourth Intergroup Rhabdomyosarcoma Study are shown by anatomic site of the primary tumor. GU, genitourinary. (Adapted with permission from Crist WM, Anderson JR, Meza JL, et al. The Intergroup Rhabdomyosarcoma Study-IV: results for patients with non-metastatic disease. *J Clin Oncol* 2001;19[12]:3091–3102. Head and Neck: Parameningeal Sites

Nonorbital RMS of the head and neck is grouped into parameningeal sites (nasopharynx, nasal cavity, paranasal sinuses, middle ear, pterygopalatine fossa, and infratemporal fossa) and nonparameningeal sites based on differences in natural history, treatment, and prognosis. Parameningeal RMS represent the majority of nonorbital head and neck RMS, and radiotherapy is essential for maximizing the chance of cure.[17,41] These tumors have a propensity for invading the base of the skull, creating a potential for cranial nerve palsy and direct

extension into the central nervous system, a pattern of spread that is seen in as many as 41% of these patients.[42] Historically, as many as 35% of children with tumor arising in a parameningeal site would later have meningeal extension, and previous irradiation regimens called for whole-brain irradiation as part of central nervous system prophylaxis.[43] However, the prognosis of these patients is markedly improved with appropriate imaging, multiagent chemotherapy, and adequate irradiation of the primary tumor and adjacent meninges, and studies demonstrate that whole-brain irradiation is not necessary, even in the presence of direct intracranial tumor extension.[44] Patients with known meningeal dissemination should receive craniospinal irradiation. A radiation dose of 50.4 Gy in 28 fractions to the primary site is commonly used. Data from the IRS studies show improved local control in patients with intracranial tumor extension when radiotherapy is started within 2 weeks of diagnosis,[42] although other reports show no disadvantage with delayed radiotherapy.[45]

Aggressive surgery is rarely indicated because complete resection usually is not possible, does not obviate the need for high-dose radiation therapy, and often results in a delay of systemic chemotherapy because of postoperative complications. Surgical approaches to these tumors have been described by proponents of multispecialty skull base surgery, but the efficacy of these approaches has not been firmly established.[46] Delayed surgical resection has been proposed as beneficial for children with residual tumor after completing chemotherapy and radiotherapy but is not considered standard of care.[47,48] The role of postradiation surgical resection is being investigated in select intermediate-risk patients enrolled onto IRS-V.

Five-year survival for patients with parameningeal RMS is approximately 75% with adequate radiotherapy.[49] For the subset of parameningeal tumors arising in the nasopharynx or nasal cavity, middle ear, and parapharyngeal locations, survival may be even higher,[44] and functional and cosmetic outcome can be good in spite of an aggressive treatment regimen (Figs. 91.2 and 91.3).

Head and Neck: Nonparameningeal Sites

Children with tumors in nonparameningeal head and neck sites tend to have a better outcome than their parameningeal counterparts (80% 5-year failure-free survival in IRS-IV) and require less-intensive chemotherapy.[1,17] These sites include the scalp, parotid, oral cavity, larynx, oropharynx, and cheek. These tumors may be more amenable to complete gross surgical excision compared with their parameningeal counterparts. Approximately 15% of these patients

present with regional lymph node metastases. Radiotherapeutic management is based on the amount of residual tumor after surgery. Draining regional lymph nodes are not routinely irradiated unless they are considered to be involved with tumor by clinical or pathologic assessment.

FIGURE 91.2. This 12-year-old girl was treated at age 3 years for an embryonal rhabdomyosarcoma of the nasal cavity. Her treatment consisted of excisional biopsy, followed by VAC (vincristine, actinomycin-D, and cyclophosphamide) chemotherapy and 41.4-Gy radiotherapy. Slight hypoplasia of the midface is evident, but overall cosmesis is excellent.

Pelvis

Pelvic tumors usually are divided into anatomic subgroups because the natural history, treatment, and prognosis are different for each site. Some children present with locally advanced pelvic tumors for which an exact site of origin cannot be determined. These large tumors are associated with an unfavorable prognosis.

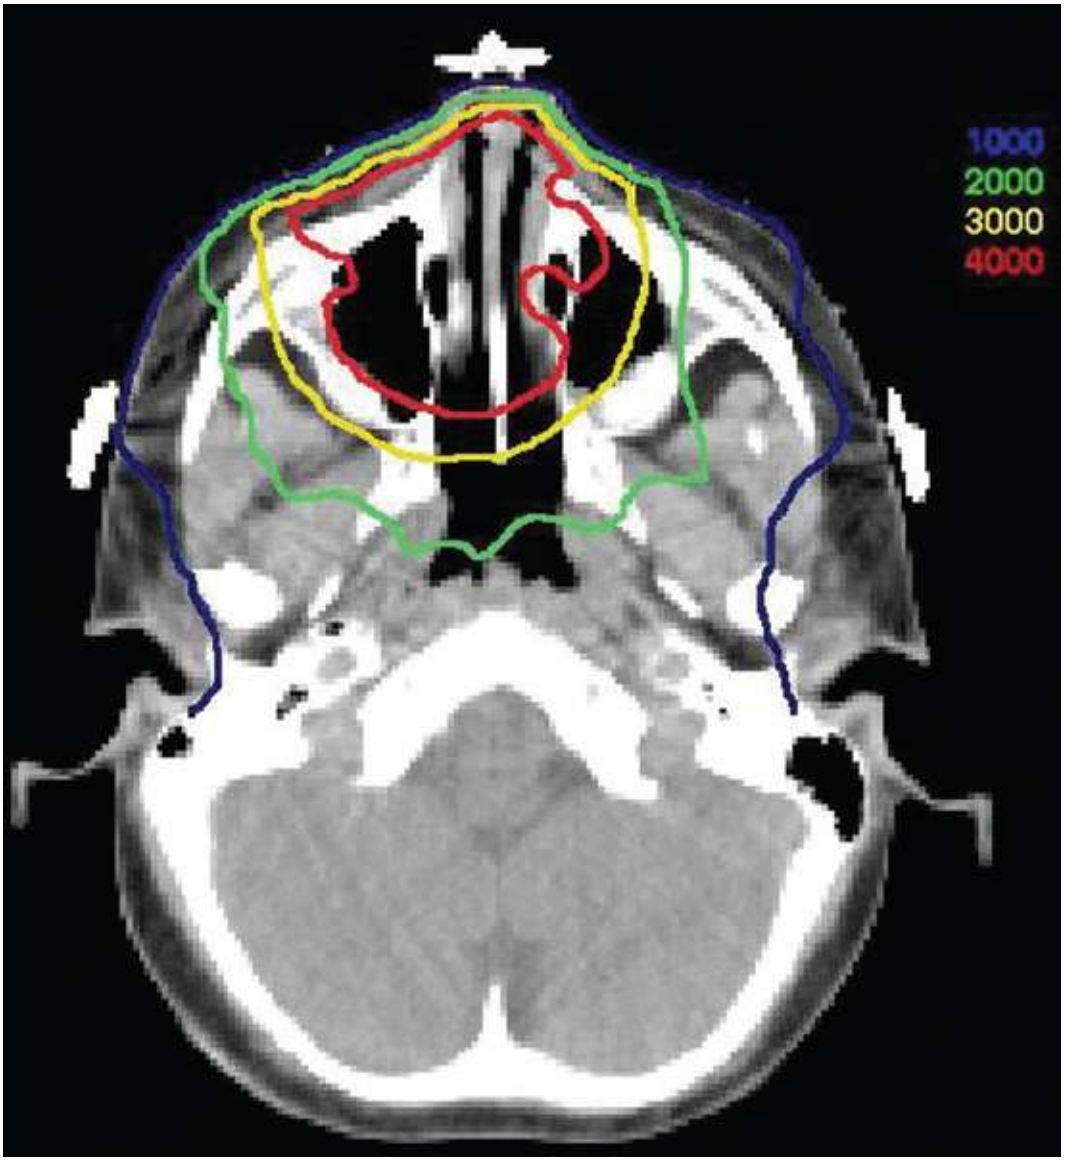

FIGURE 91.3. Isodose distribution from the treatment of the child in Figure 91.2 (doses in cGy).

Bladder and Prostate Tumors

Bladder and prostate primary tumors account for about half of all pelvic RMS[41]; 75% of patients are age <5 years at presentation, and more than 90% of these tumors are of the embryonal histologic subtype, with approximately one-third having a botryoid morphology. In boys, it is often difficult to differentiate a tumor of prostatic origin from one of bladder origin because disease usually involves both structures. However, patients with tumors arising in the prostate have significantly inferior survival compared with those with tumor confined to the bladder.[50]

Historically, anterior pelvic exenteration (or partial cystectomy for small tumors arising from the dome of the bladder) combined with chemotherapy and irradiation for microscopic or gross residual disease has been associated with a survival rate of approximately 70%.[18] More recently, emphasis has been on limited surgery to preserve bladder function. The IRS-II study treated these patients primarily with chemotherapy followed by delayed surgery or radiation therapy when there was residual or recurrent disease. This approach resulted in an inferior 3-year disease-free survival rate of 52%, compared with 80% for a primary radical surgical approach and only 22% of patients survived with intact bladders.[51] Subsequently, IRS-III intensified the therapy with systematic use of planned irradiation 6 weeks after the start of treatment and added cisplatin and doxorubicin (Adriamycin) chemotherapy.[52] The 5-year survival rate for patients with locoregional disease was 82%, with 64% of surviving patients retaining functional bladders, demonstrating the necessity of routine radiation therapy early in treatment.[53] Survival of patients with locoregional bladder or prostate tumors treated on IRS-IV was similar, with 40% of all enrolled patients reporting normal bladder function at follow-up.[54] A more recent analysis showed maintenance of continence in 69% treated with conservative surgery in a multimodality treatment program.[55]

The German Cooperative Weichteilsarkom Studiengruppe CWS-96 protocol treated children with bladder or prostate RMS using multiagent chemotherapy followed by response-adapted radiotherapy and surgery. Children with complete resection did not have radiotherapy, whereas others received 32 to 44.8 Gy using 1.6 Gy twice a day, depending on the tumor's IRS group and response to chemotherapy. Five-year EFS was 70%.[56]

A pooled analysis of patients treated prospectively on several cooperative group trials from North America and Europe showed improved local control for those who received radiotherapy as part of their initial treatment, but this did not translate into improvement in overall survival.[57]

Paratesticular Tumors

Paratesticular tumors represent approximately 7% of all RMS and may arise anywhere along the spermatic cord, from the intrascrotal area through the inguinal canal.[58] At presentation, the tumor usually is a painless scrotal or inguinal mass that does not transilluminate. Most boys with paratesticular RMS present with early-stage disease that is amenable to complete resection and is associated with cure rates approaching 90%. As with prostatic primary tumors,

the lymphatic network is rich, draining directly to the retroperitoneal nodes along the external iliac and spermatic vessels, the aorta, and the vena cava. The incidence of retroperitoneal lymph node involvement varies with the age of the patient and method of staging (surgical vs. nonsurgical). In the IRS-III study, retroperitoneal lymph node sampling was done in most patients, showing a 14% incidence of node involvement for children <10 years of age and a 47% incidence for those ≥10 years. In IRS-IV, thin-cut CT without surgical sampling was used for staging, and the incidence of detected nodes dropped to 4% and 13% for the two age groups, respectively.[58]

The recommended surgical procedure for the primary tumor is inguinal orchiectomy. If there is no evidence of invasion into the scrotum and the proximal spermatic cord is free of tumor, this procedure is considered equivalent to an amputation, and no further local therapy is necessary. Surgical staging of retroperitoneal lymph nodes is controversial. European investigators do not recommend retroperitoneal lymph node sampling for these patients, preferring to treat with intensified chemotherapy in high-risk patients and salvage radiotherapy, if necessary.[59,60] In the IRS, the high risk of nodal involvement in certain subsets of these patients has led to the recommendation for ipsilateral retroperitoneal nerve-sparing node dissection for staging of all children ≥10 years of age.[58] In the absence of histologic documentation, enlargement of retroperitoneal lymph nodes on thin-section CT imaging is considered evidence of tumor involvement.

Patients with nodal disease have a 5-year survival rate of 69%, compared with 96% for those without regional nodal disease ($P < .001$). Regional lymph node irradiation to the periaortic and ipsilateral iliac nodes is recommended when there is nodal involvement.[61] Surgical violation of the scrotum or tumor extension to the structure is an indication for hemiscrotectomy or, less commonly, scrotal irradiation. If scrotal irradiation is used, orchiopexy should be considered prior to treatment to protect the remaining testes. Treatment programs must be planned to reduce morbidity, particularly among this group with high likelihood of cure.

Gynecologic Tumors

Tumors arising in the vulva, vagina, cervix, and uterus are about one-third as common as bladder and prostate primary tumors and account for 4% of all RMS.[62] Within this group, the vagina is the most common site of origin.

Patients with vaginal tumors are often much younger than those with other

pelvic RMS, with most girls diagnosed before the age of 3 years. Most present with a vaginal mass or discharge; botryoid morphology is common. Initial surgery is used primarily for diagnosis, although gross tumor resection is occasionally possible without cosmetic or functional deformity. These tumors are often quite sensitive to chemotherapy, and treatment regimens have previously used a strategy of chemotherapy only, reserving surgery and radiotherapy for persistent or recurrent tumor.[62–64] However, analysis of data from the IRS-IV and IRS-V studies have revealed high rates of local failure for vaginal tumors when local control with surgery or radiotherapy is omitted.[36,65] Current guidelines from the COG STS committee call for radiotherapy in all patients with postsurgical microscopic or macroscopic tumor.

Uterine, cervical, and vulvar tumors receive chemotherapy and radiotherapy based on the amount of tumor present after initial surgery. Intracavitary and interstitial brachytherapy are useful irradiation techniques in some of these patients.[66] Data are limited, but with proper patient selection, disease control is excellent and late normal tissue effects may be significantly less with brachytherapy than is seen with external beam techniques.[67] Permanent implants with iodine-125 and temporary low dose rate and high dose rate brachytherapy have all been used, and there are no clear differences among these techniques in terms of disease control or late effects. When temporary implants are used, high dose rate brachytherapy has the practical advantage of minimizing radiation exposure to the family and medical personnel caring for the child.

Survival after treatment is excellent. Children aged 1 to 9 years have a 98% 5-year survival. Survival for infants and adolescents approaches 90%, although these patients may require more intensive systemic therapy for cure.[62]

Other Pelvic Sites

These tumors include perianal, perirectal, and perineal primary sites. The location of these primary tumors creates surgical and irradiation challenges. Combined chemotherapy and radiation therapy programs are favored over primary surgical procedures if excision requires exenteration with urinary and fecal diversion procedures or is associated with organ or sphincter dysfunction. In general, tumors in these locations are associated with poor prognostic features, high rates of regional nodal involvement, and dismal outcomes, especially in children >10 years of age.[8]

Extremity

Tumors arising in the extremity are often of the alveolar or undifferentiated subtypes, large, deeply invasive, and associated with a high probability of lymphatic and hematogenous metastasis.[68] Complete surgical resection is difficult to achieve, usually requires extensive dissection, and is associated with a high risk of residual disease. Because radiation therapy and multiagent chemotherapy have been shown to provide excellent local control, it is advisable to avoid disfiguring and mutilating surgical procedures, with their attendant functional disabilities, and to recommend limb-salvage procedures including irradiation and chemotherapy.

Regional lymph node involvement is present in approximately 24% of patients and confers a more guarded prognosis.[68] Aggressive surgical staging of draining lymph node basins is important to define extent of involvement, although if lymph node dissection is performed, it is for the purpose of staging, not for treatment. Sentinel lymph node mapping and biopsy are being investigated for their diagnostic and prognostic value.[69,70] Radiotherapy of involved regional lymphatics is mandatory, and aggressive treatment of in-transit nodal sites may improve overall local control.[71]

Radiation therapy for extremity primary tumors requires careful immobilization techniques, sparing of nonirradiated skin for lymphatic drainage, and use of shrinking fields. Routine physical therapy during and after radiation therapy is important for obtaining an optimal functional result. Overall survival at 3 years for these patients is about 70%, although failure-free survival is only 55%.[72]

Other Sites

Patients with tumors arising in sites such as a paraspinal, retroperitoneal, or intrathoracic location have a poor outcome compared with other patients.[17] Most patients with tumors in these locations are unable to undergo complete resection of the tumor. Both local and distant relapse are common. These patients should be treated aggressively with high-dose radiation therapy and multiagent chemotherapy.

Metastatic Disease

Hematogenous or distant lymph node metastasis at the time of diagnosis is an ominous finding, although not all these children do poorly. The subset of patients who are <10 years of age and have only one or two sites of metastatic disease may have long-term survival chances of >50%.[9] Intensive multiagent

chemotherapy plays a major role in the treatment of these patients, although marrow ablative techniques have not improved efficacy compared with conventional chemotherapy approaches.[73,74] Local control of the primary tumor is site specific, as previously described. Metastatic sites should be treated with radiotherapy whenever feasible and control rates after radiation are similar to local control rates at the primary site.[75] The role of stereotactic body radiotherapy (SBRT) for bony sites of metastatic disease is currently being explored. Whole lung irradiation for lung metastases is currently the standard of care, although SBRT for lung metastases is also an area of active investigation.[76,77]

GENERAL MANAGEMENT

A multidisciplinary approach using surgery, irradiation, and chemotherapy is important in the management of RMS; however, the optimal sequence and specific application of each modality continue to be investigated. Although the primary goal remains long-term cure, improvement in therapeutic results necessitates considerations of quality of life, with particular attention to maximization of functional and cosmetic results.

Surgery

Before the era of multidisciplinary therapy, surgical ablation resulted in a long-term survival rate of approximately 20% of those patients able to undergo resection.[78] Certain primary sites represented exceptions to these data; for example, approximately 50% of those with localized disease of the orbit survived after orbital exenteration.[79] However, with the introduction of effective adjunctive treatment, preservation of function and appearance became major goals. The concept of reasonable surgery has evolved. It involves removal of the bulk of tumor with maximal conservation of anatomic structures, including preservation of bladder, bowel, and sexual function in patients with tumors of genitourinary origin; limb function in patients with extremity tumors; and vision, voice, deglutition, and appearance in patients with head and neck tumors.

Resection of RMS from normal surrounding tissues is often technically challenging. Only 20% of tumors are located in sites where complete excision can readily be accomplished without an undesirable loss of function or cosmesis.[17] An additional 20% of patients have compromised surgical procedures, leaving microscopic residual disease. Sixty percent of patients have

tumors amenable to biopsy only or present with metastatic disease and are not candidates for primary resection. When the IRS surgical grouping system is used, patients with tumor amenable to complete excision fare better than those who have subtotal resection or biopsy alone. However, the tumors that are most accessible to surgical excision are small and noninvasive and are confined to the organ or structure of origin. Assessment using a TNM system demonstrates that prognosis is dictated by tumor size and invasiveness rather than by the initial surgical approach.[80] Furthermore, combined-modality therapy provides good local control of the primary tumor, even after subtotal excision.[81] For these reasons, the trend has been toward less-aggressive surgical resection, with more reliance on radiation therapy and chemotherapy to provide local control.[17]

In cases of suspected RMS, the initial surgical procedure should be an incisional biopsy. Surgical excision is indicated if it can be done without compromise of function or cosmesis. Normal tissue margins of at least 5 mm around the tumor are usually required to consider the resection complete (IRS group I), although this is sometimes not feasible in some anatomic sites and smaller margins may suffice. If microscopic disease remains after initial resection, a primary re-excision can be considered prior to beginning chemotherapy. Those children who can be rendered microscopically free of disease by this procedure have an improved outcome, compared with children who remain in clinical group II following initial surgery.[82,83] Amputation of an extremity, orbital exenteration, mutilating surgery of the head and neck area, therapeutic lymphadenectomy, and radical neck dissection are procedures reserved in case initial therapy fails.

Second-look operations (also termed delayed primary excisions, DPE) may be useful for converting partial responses after chemotherapy into complete responses, and there is evidence that these procedures may improve survival.[48] However, data regarding efficacy of second-look operations are mixed, with some finding no benefit with this procedure.[12] The IRS-V study evaluated whether DPE might allow a reduction in the amount of radiotherapy that is necessary to provide local tumor control; local control following DPE and reduced-dose radiation for bladder dome, extremity, and trunk tumors was similar to historic results after higher doses of definitive radiation. Some investigators have used second-look operations in an attempt to eliminate radiotherapy, although this approach has resulted in inferior local control and survival.[84] Second-look operations may be used to evaluate therapeutic response after chemotherapy or radiation therapy. In the IRS-III study, 28% of patients

categorized as having clinical partial response and 43% of those scored as having no response to induction chemotherapy were reclassified as having pathologic complete response after second-look operation.[85] These children enjoyed a survival rate similar to that of children who were able to undergo complete surgical excision at the time of initial diagnosis. Therefore, a clinical or radiographic evaluation indicating residual tumor after initial therapy may be misleading and is not associated with worse outcomes.

CHEMOTHERAPY

Chemotherapy is necessary in all cases. Several drugs have demonstrated single-agent activity measured as a percentage response rate, including vincristine (59%), dactinomycin (24%), cyclophosphamide (54%), cisplatin (15% to 21%), dacarbazine (11%), mitomycin-C (36%), etoposide (15% to 21%), ifosfamide (86%), irinotecan (23%), and topotecan (46%).[86–88] Agents with known activity against central nervous system tumors, such as the nitrosoureas and methotrexate, have not shown activity against RMS.

The most extensive experience in combination chemotherapy is with VAC or VAC plus doxorubicin (VACA). Some studies have suggested that patients with embryonal histology tumors in favorable sites who have no gross residual disease or lymph node involvement after the initial surgical resection may be adequately treated with VA for 1 year, provided that irradiation is given for microscopic residual disease.[17] However, data from the recently completed IRS-V study suggest that local control may be compromised when alkylating agents are omitted.[35,36] Patients with unresectable pelvic tumors may benefit from the addition of doxorubicin and cisplatin to VAC, but tumors in other sites do not seem to benefit from the addition of these drugs compared with an intensive regimen of VAC alone.

Some subsets of patients, such as those with tumors of unfavorable histology or unfavorable site and those with extensive tumor burden, continue to fare poorly. Some of these patients with embryonal histology may benefit from intensification of the cyclophosphamide or ifosfamide component of their chemotherapy, although there are conflicting data regarding this.[89,90] Patients with metastatic RMS benefit from the addition of ifosfamide and etoposide to the standard VAC regimen.[91] High-dose chemotherapy with total-body irradiation and autologous bone marrow transplantation has not improved the outcome in these high-risk patients.[73,74]

Initial intensive chemotherapy has been used as a means of pharmacologic debulking, potentially allowing for a more conservative surgical approach or less-aggressive radiation therapy.[51,92,93] However, data fail to consistently show that response to induction chemotherapy predicts ultimate outcome.[14,94] When chemotherapy alone is used for tumors in sites such as the head and neck or pelvis, most children require radiation therapy with or without a follow-up surgical procedure because of incomplete response or local recurrence.[18,37,95,96] Omission of radiotherapy in these patients may result in inferior survival.[84,97] Even patients with only microscopic disease after initial resection (group II) require radiotherapy to achieve optimal local control.[98] In patients with group II disease who routinely receive radiotherapy, local control is 92%.[99] The approach of initial chemotherapy followed by limited irradiation or less radical surgery may be appropriate in the management of infants and very young children, in whom late effects of aggressive surgery or high-dose, large-volume irradiation are particularly severe, although this may lead to inferior local control and survival.

Radiation Therapy

Adequate irradiation implies careful attention to volume and dose. It is essential to evaluate the soft tissue extent of the primary lesion by CT scan or magnetic resonance imaging. Because RMS tends to infiltrate tissue planes widely, tumors often extend beyond a fascial compartment and beyond the obvious visible margins. Careful examination by a radiation oncologist at the time of initial diagnosis, even if the treatment plan calls for neoadjuvant chemotherapy, is essential to establish the appropriate tumor volume.

Treatment portals are designed to encompass the involved region at the time of presentation (before chemotherapy) with margins that encompass surgical sites and biopsy tracts. A biopsy should be performed of clinically suspicious lymph nodes, or they should be included in the radiation therapy portal. Prophylactic lymph node irradiation is not necessary in children with clinically negative findings who will be receiving combination chemotherapy. The gross tumor volume is defined as the tumor as seen at the time of initial diagnosis. A clinical target volume of 1 cm is added and can be modified to account for anatomic barriers to tumor spread (such as the bony orbit in primary orbital tumors) or to account for regression of “pushing” the tumor border after chemotherapy, such as may occur in large pelvic tumors that initially displace contents of the peritoneal cavity. The planning target volume adds a patient-

specific margin, which is typically about 5 mm. Many current treatment protocols use a cone down boost or simultaneous integrated boost to any gross posttreatment tumor volume after a microscopic tumor dose has been delivered. Patients with tumors at parameningeal sites (middle ear, paranasal sinuses, nasopharynx, nasal cavity, infratemporal fossa, and parapharyngeal area) have developed meningeal extension of tumor when inadequate irradiation portals were used.[44] Radiation therapy portals that cover the adjacent meninges in these patients can prevent meningeal relapse.[17,42]

Three-dimensional conformal and intensity-modulated radiotherapy treatment planning techniques are valuable for ensuring adequate treatment of the tumor volume and minimizing acute and chronic toxicity from the irradiation of uninvolved, adjacent structures.[42,100–102] Proton-beam radiotherapy is being increasingly utilized as access to this form of therapy increases,[40] and dosimetric studies consistently demonstrate decreases of integral dose to normal structures compared to photon-based techniques for many children with RMS (Fig. 91.4).[103,104] Local control and survival outcomes appear similar after proton radiation compared to historical cohorts treated with photon radiation. In addition, acute and early late toxicity rates with protons appear quite promising, especially for tumors in the head and neck region.[105] Follow up is limited, though, and long-term toxicity data are necessary to follow for adverse events that may take >4 years to develop.

Immobilization techniques that ensure reproducible portals are essential. Sedation or anesthesia may be necessary to ensure adequate implementation of the treatment plan. These complex programs are best conducted in regional centers by an experienced team of physicians, including a pediatric surgeon, pediatric anesthesiologist, pediatric oncologist, and radiation oncologist.

Radiation is necessary to ensure local tumor control in patients who are unable to undergo complete surgical resection. Local control of gross disease in most anatomic sites requires doses of 50 to 55 Gy. In the IRS-IV study, investigators studied the efficacy of a higher radiation dose, 59.4 Gy, given in 1.1-Gy fractions twice daily at 6-hour intervals for children with gross residual disease.[106] This hyperfractionated regimen was compared in a prospective, randomized fashion to a standard radiotherapy regimen consisting of 50.4 Gy given as 1.8 Gy once daily. There was no difference in locoregional disease control, failure-free survival, or overall survival between the two groups. Therefore, the standard of care for group III RMS continues to be conventionally fractionated radiation with chemotherapy.

Ninety percent of patients with microscopic residual tumor achieve local control with 41.4 Gy, and the D9602 study results suggest that 36 Gy may be adequate for microscopically positive margins that are not associated with lymph node involvement as described in more detail below. Investigators have been unable to generate a strict dose–response curve but have observed an association with age that suggests that lower doses, often given to infants and youngsters, are associated with higher relapse rates.[107] They also suggest that local tumor control is greater for tumors <5 cm in diameter than for larger lesions, supporting the adult experience with soft tissue sarcomas.[108–110]

Results of the IRS-I study had indicated that radiotherapy was not needed for patients whose tumors were completely resected at diagnosis (group I). Subsequently, a reanalysis of data from the IRS-I to IRS-III studies suggested that the subset of group I patients with alveolar or undifferentiated histology had improved overall and failure-free survival when radiotherapy was given to the primary tumor site.[111] A more recent analysis using data from IRS-IV did not, however, show a significant advantage for radiotherapy in group I alveolar tumors. This practice is currently under review for the next generation of RMS protocols, with fusion status playing a critical role in risk stratification.[112]

Interstitial radiation therapy may play a role as primary treatment or as a boost after external beam therapy for selected sites.[46,67] The advantages of precise shaping of the dose distribution, sharp falloff of radiation dose, and

shortening of overall treatment time are especially attractive in dealing with infants and young children. Some investigators report a decrease in late normal tissue effects when compared with external beam techniques.[113] There are no data regarding comparative efficacy or toxicity between high dose rate and low dose rate techniques. However, high dose rate remote brachytherapy may be particularly attractive in this patient population for logistical reasons. These children often require extensive care from family members and medical personnel during their treatment, and high dose rate techniques can eliminate radiation exposure to these caregivers.

The timing of radiation therapy must be carefully coordinated with planned surgical intervention and combination chemotherapy scheduling to optimize local control and ensure optimization of drug doses and unimpaired postoperative healing. Although radiation therapy is often delayed for several weeks to allow administration of neoadjuvant chemotherapy, some data suggest that earlier irradiation, particularly in high-risk patients, may provide better local tumor control and survival.[42,114,115] Interaction between radiation and some of the commonly used chemotherapeutic drugs can produce undesirable early and late effects. This is particularly true of dactinomycin and doxorubicin. Radiation therapy given concurrently with these agents is usually avoided. In contrast, systemic treatment with drugs such as vincristine and cyclophosphamide can usually be continued concurrently with the administration of irradiation.

Retrieval Therapy

Salvage after recurrence of RMS is difficult, which probably accounts for the inferior survival seen with treatment approaches that do not maximize therapy at the time of initial diagnosis.[97,116] Because local recurrence is the most common pattern of failure, surgery and radiotherapy play especially important roles in the treatment of these children. Aggressive treatment programs utilizing radical resection and brachytherapy have had success in selected patients with head and neck RMS.[46] There is evidence that salvage is more successful if radiotherapy was not used in the initial treatment and can be maximized for salvage therapy. Care must be taken when evaluating patients for local recurrence. Residual masses can be seen in as many as 40% of children who are shown to be pathologically free of tumor.[117]

RESULTS OF THERAPY: SUMMARY OF CLINICAL TRIALS

Because of the low incidence of RMS, much of what has been learned about its treatment has come from cooperative group trials performed in North America and Europe. Various cooperative groups have used different philosophies of treatment. In general, the North American IRS studies have emphasized the role of local control measures and European studies have focused more on chemotherapeutic approaches.

Intergroup Rhabdomyosarcoma Studies

The IRS began intergroup clinical trials for RMS in 1972 and has enrolled several thousand children with this disease since then. A primary goal has been to test the efficacy of chemotherapy and radiation therapy as a function of surgical stage. In the first IRS study (IRS-I), radiation therapy was given initially for patients with group I and II disease and was delayed until week 6 for those with group III and IV disease. All patients received multiagent chemotherapy for 2 years. This study made several important observations[118]:

- For localized tumors amenable to complete resection (IRS group I), postoperative radiation therapy is unnecessary if the patient is given 2 years of VAC. For these patients, the relapse-free survival rate in IRS-I at 5 years was 80%, and the 5-year survival rate was 81% to 93%. Subsequent analysis has shown a benefit to postoperative radiation therapy for patients with group I tumors of alveolar or undifferentiated histology.[111]
- VAC failed to improve results obtained with intensive VA for patients with group II disease if postoperative radiation therapy was given. For these patients, the relapse-free survival rate at 5 years was 65% to 72%, and the overall 5-year survival rate was 72%.
- VACA provided no advantage over VAC for patients with group III disease (gross residual) or group IV disease (metastasis) if routine radiation therapy was used in addition. The complete remission rate for group III patients was 69%, and for group IV patients, it was 50%. Those who achieved complete remission had a 60% chance of staying in remission for 5 years in group III and a 30% chance in group IV. The survival rate at 5 years was 52% for group III and 20% for group IV patients.
- The 5-year survival rate for the entire group was 55%.
- Survival after relapse was poor—32% at 1 year and 17% at 2 years.
- The risk of distant metastasis was much greater than the risk of local recurrence.
- Primary tumors of the orbit and genitourinary tract carried the best prognoses, and tumors of the retroperitoneum had the worst.

- The alveolar histologic subset had a poor prognosis, especially in extremity lesions.

A second IRS study (IRS-II) was built on the findings of IRS-I.[41] The results from this study include the following:

- The 5-year survival rate for the IRS-II group was 62%, a 7% improvement over the IRS-I rate.
- Patients in group I (excluding alveolar extremity patients) had better disease-free status with VAC (82%) than did those who received only VA (68%), but they had similar survival rates (82% and 88%) at 5 years. Cyclophosphamide could not be withdrawn safely from the standard VAC regimen if irradiation was omitted from patients with group I disease.
- Intensive (cyclic-sequential) VA therapy was as effective as repetitive pulse VAC therapy for patients with group II disease, if all patients received postoperative irradiation. At 5 years, 68% to 75% remained disease free and 77% to 90% were alive, with no differences between the two therapy groups.
- Repetitive pulse chemotherapy for 2 years increased survival in children with group III disease but not in those with group IV disease; doxorubicin and dactinomycin had comparable efficacy in the pulse regimens used. The complete remission rates were 72%. At 5 years, 70% remained in complete remission and 64% were surviving.
- In IRS-I, patients having tumors in parameningeal sites with high-risk factors (cranial nerve palsy, erosion of the base of the skull, or intracranial extension) had a high incidence of central nervous system relapse. In IRS-II, whole-brain radiotherapy irradiation, with or without intrathecal chemotherapy, was introduced. This prevented meningeal recurrence and increased survival in these patients with high-risk parameningeal primary tumors.
- Primary repetitive pulse VAC for patients with special pelvic primary tumors (i.e., bladder, prostate, uterus, vagina) did not reduce the frequency of total cystectomy or produce durable bladder salvage, although survival was not compromised.
- Survival after relapse was only 17% at 5 years.

The third IRS study (IRS-III) covered the period 1984 to 1991. This study revealed the following[17]:

- The 5-year survival rate for the IRS-III group was 71%, an 8% improvement over the IRS-II rate. The 5-year progression-free survival rate was 65%, a 10% improvement over IRS-II.
- Patients with group I favorable-histology tumors fared as well on a 1-year

regimen of VA as did a comparable group treated with VA plus cyclophosphamide. The 5-year progression-free survival rates were 83% and 76%, respectively (P = .18).

- Results for patients with group II favorable-histology tumors, excluding orbit, head, and paratesticular sites, were not improved with the addition of doxorubicin over VA chemotherapy × 1 year and radiation therapy.
- Patients with group III tumors, excluding those in special pelvic, orbit, and other selected head sites (scalp, parotid, oral cavity, larynx, oropharynx, and cheek), fared better on the more intensive regimens of IRS-III than on pulsed VAC or VAC vincristine and doxorubicin (VADR) in IRS-II; the 5-year progression-free survival rates were 62% and 52%, respectively. The intensive regimen from IRS-III included multiple agents (VAC + doxorubicin + cisplatin + etoposide) plus radiation therapy plus second-look surgery. There were no differences in outcome among the three chemotherapy programs on IRS-III.
- Patients with group IV tumors did not benefit from the aggressive therapy of IRS-III.
- Patients with tumors in the bladder, vagina, and central pelvis in clinical group III had significantly improved outcome as compared with IRS-II patients, primarily because of the routine administration of early radiation therapy, which improved the bladder salvage rate from 25% in IRS-II to 60% in IRS-III.
- Patients with unfavorable histology, in clinical groups I and II, who received VADR-VAC + cisplatin and radiation therapy had improved outcome over patients in IRS-II receiving VA or VAC and irradiation.
- Patients with favorable-histology group II paratesticular tumors and those with favorable-histology orbit and head tumors in groups II and III do not require cyclophosphamide when VA × 1 year plus radiation therapy is used.
- Whole-brain radiotherapy was omitted for patients with parameningeal primary tumors and cranial nerve palsy or base of skull erosion (although patients with intracranial extension of tumor still received this treatment). Risk of central nervous system relapse and survival were not compromised by this change if adequate local fields were used.

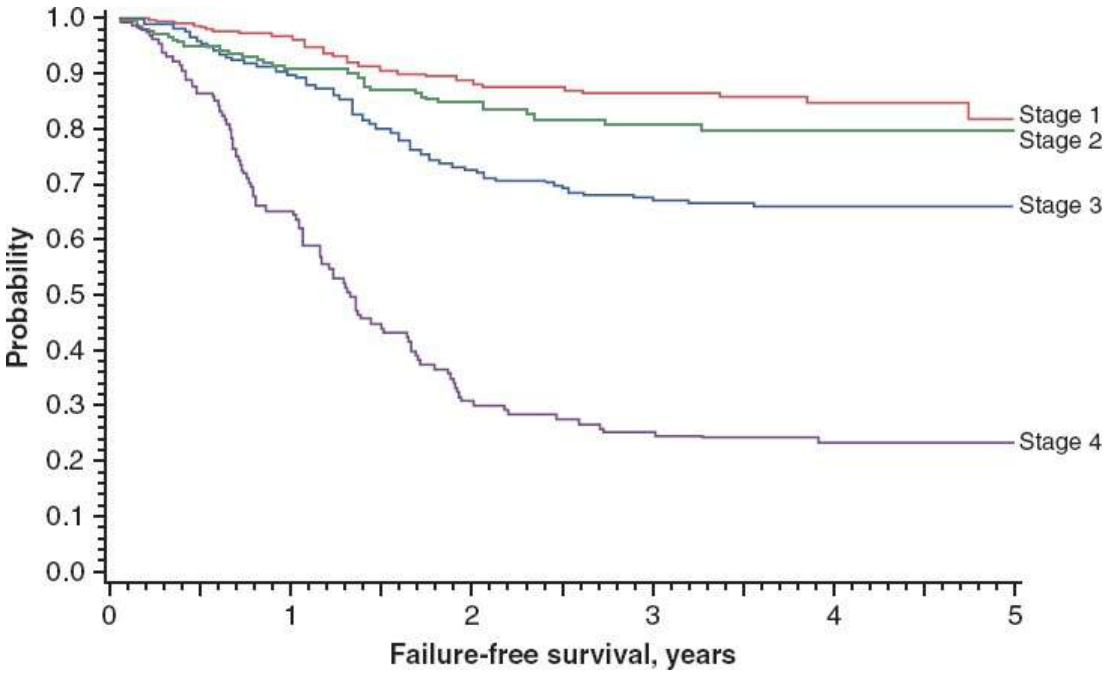

FIGURE 91.5. Survival curves of 1,010 children with rhabdomyosarcoma entered into the fourth Intergroup Rhabdomyosarcoma Study are shown by stage. (Adapted from Breneman JC, Lyden E, Pappo AS, et al. Prognostic factors and outcome in children with metastatic rhabdomyosarcoma: a report from the Intergroup Rhabdomyosarcoma Study IV. *J Clin Oncol* 2003;21:78–84; and from Crist WM, Anderson JR, Meza JL, et al. The Intergroup Rhabdomyosarcoma Study-IV: results for patients with non-metastatic disease. *J Clin Oncol* 2001;19:3091–3102.)

The fourth IRS study (IRS-IV) was conducted from 1991 to 1997 (Fig. 91.5).[1] Results from this study are as follows:

- For patients with group III tumors, hyperfractionated radiotherapy was no more effective than conventional radiotherapy for tumor control and survival.
- There was no difference in survival between VAC and vincristine/actinomycin/ifosfamide and vincristine/ifosfamide/etoposide in children with nonmetastatic disease.
- Failure-free survival at 3 years for patients with embryonal histology was superior to results seen in IRS-III (83% vs. 74%), but no difference was seen for alveolar or undifferentiated subtypes.
- Survival for patients with group I or II orbit or eyelid tumors was excellent when treated with VA and radiotherapy for group II disease.
- Prognostic subsets of patients based on histologic subtype, stage, and group could be identified as follows: low-risk patients had embryonal histology and were stage 1 (all groups), or stage 2 or 3 and group I or II. All other patients with locoregional disease were intermediate risk.
- Survival for patients with metastatic disease was superior with the drug pair

ifosfamide/etoposide when compared with vincristine/melphalan.[91]

- Whole-brain radiotherapy was omitted for all patients with parameningeal primary tumors except when there was cytologic evidence of cerebrospinal fluid involvement. Survival was not compromised by this approach.

The fifth IRS studies (IRS-V) were conducted from 1997 to 2005. They studied a number of questions that included the following:

- Can a subset of the most favorable patients be treated without alkylating agents?
- Can radiation dose be reduced to 36 Gy for microscopic disease and 45 Gy for gross tumor in the subset of patients with orbital primaries?
- Can radiation be omitted in patients with vaginal tumors who achieve a complete response?
- Can radiation dose be reduced for group III patients after induction chemotherapy and second-look operation?
- What is the activity of topotecan and irinotecan in the treatment of RMS?

Results from some of these studies are now available and show that failure-free survival for low-risk patients (treated without cyclophosphamide and given decreased radiation doses as described above) was similar to results seen in IRS-III, which also did not use cyclophosphamide, but was inferior to results from IRS-IV where cyclophosphamide or ifosfamide was given. The conclusion of this study was that reduced radiotherapy doses with 36 Gy for microscopic disease did not appear to compromise local control, but the inclusion of an alkylating chemotherapy agent in the treatment regimen may be important for maximizing outcomes in these patients.

For group III orbital tumors, dose reduction to 45 Gy resulted in an unacceptably high rate of local failure rate at 13% (compared to 5% seen on IRS IV). As such, 50.4 Gy remains the standard of care for orbital tumors with gross disease, though 45 Gy may be sufficient if there is a complete response to induction chemotherapy.[35,36] For vaginal tumors treated without radiation, local failure rates were also unacceptably high (26% on D9602 and 43% on ARST003).[65] Omission of radiation therapy for these children is not advisable, and intravaginal brachytherapy may be the preferred modality of treatment given the high dose gradient and subsequent sparing of surrounding normal tissue.

For patients who undergo second-look surgery after induction chemotherapy, radiation dose can be successfully reduced to 36 Gy for negative margins and 41.4 Gy for microscopically positive margins without compromising local

control.[119] For patients with intermediate-risk disease, the addition of topotecan to the standard VAC regimen did not improve failure-free survival.[120]

Societe Internationale D'oncologie Pediatrique Studies

SIOP (the French acronym for the International Society of Pediatric Oncology) began multi-institutional trials for RMS in 1975 and has reported results from three studies to date.[95,121,122] The focus of these studies has been to minimize local therapy by using risk-adapted intensification of chemotherapy, with attempted salvage of patients who fail locally.

The first SIOP study (RMS-75) used VAC chemotherapy plus doxorubicin. Group III patients were randomized to early local therapy versus response-based delayed local therapy (surgery preferred over radiotherapy) after maximal chemotherapy response. No survival difference was seen between these arms, although overall survival was only 40%.

The second SIOP study, MMT-84 (malignant mesenchymal tumor), used a similar strategy of limited radiotherapy only when there was residual tumor after chemotherapy and surgery. Overall survival at 5 years was 68%, although EFS was only 53%, and 29% of patients had isolated local relapse.

The third SIOP study, MMT-89, concluded that alkylating agents can be omitted for patients with the most favorable prognosis. The use of radiotherapy was again limited, resulting in a local failure rate of 34%.

The SIOP and IRS studies differ significantly in their use of local therapy, with IRS studies emphasizing early introduction of radiotherapy for patients with residual tumor after surgery, and SIOP studies avoiding radiotherapy except for proven residual tumor after chemotherapy and surgery. A comparison of the results of the two studies has been performed, and although it is clear that some children can be cured without radiotherapy, the routine use of radiotherapy for residual tumor after initial surgery as used in the IRS studies results in higher survival rates for most subsets of patients.[97]

Cooperative Weichteilsarkom Studiengruppe Studies

The German-based CWS studies have taken an approach to local control that is intermediate between that of the IRS and SIOP trials. The CWS-81 trial used response-adapted radiotherapy after chemotherapy and second-look surgery with children receiving no radiotherapy, 40 or 50 Gy depending on tumor status. Results of this study showed that children who have a complete response to chemotherapy have a prognosis equal to those who have an initial complete

resection of their tumor. However, those patients who do not have a complete response to chemotherapy by week 9 should have early surgery or radiotherapy. Overall disease-free survival after 5 years was 68% for children with nonmetastatic disease.[92,123] Local recurrence was the most common cause of failure.

The CWS-86 study used ifosfamide for all patients, with an abbreviated course of chemotherapy for favorable patients with early-stage disease, and altered the way radiotherapy was given.[124] Patients who had an early complete response to chemotherapy did not receive radiotherapy. Most received hyperfractionated accelerated radiotherapy of 1.6 Gy twice daily concurrent with ifosfamide and doxorubicin containing chemotherapy, using 32 Gy after a good response and 54.4 Gy after a poor response. Conclusions from this study were as follows:

- Duration of chemotherapy can be reduced to as little as 16 weeks for the most favorable patients.
- Ifosfamide gives improved response rates compared with cyclophosphamide.
- Hyperfractionated accelerated radiotherapy concurrent with chemotherapy as used in the study is tolerable and provided acceptable local control.

Like CWS-81, the majority of failures in this study were local, with an especially high local recurrence rate in those group II and III patients who did not receive radiotherapy.

The CWS-91 study continued the strategy of risk-adapted therapy.[125] Patients were initially stratified for treatment according to IRS group, tumor site, and histologic subtype. After induction chemotherapy, second-look surgery was encouraged, and those with a complete resection and no high-risk features did not receive radiotherapy. Others received 32 or 48 Gy (1.6 Gy twice daily) depending on risk factors and response to initial chemotherapy. Outcomes were compared to historical controls from the CWS-86 study. Major findings were as follows:

- Local control and EFS were improved in those patients who received radiotherapy when compared to those who did not receive radiotherapy, in spite of more unfavorable risk factors in the former group.
- Results for patients receiving 32 or 48 Gy on CWS-91 were similar to results in similar patients treated with higher radiation doses on the CWS-86 study.
- Patients with group I and group II tumors and favorable risk factors had equivalent outcomes with decreased intensity chemotherapy compared with

similar patients treated in CWS-86.

SEQUELAE OF TREATMENT

Acute Effects

Acute side effects from surgery are primarily postoperative complications that are usually reversible and not serious. The acute toxicity from chemotherapy includes nausea, vomiting, mucositis, alopecia, and hematopoietic suppression. Drug-induced granulocytopenia significantly increases the risk of fever and infection, although the routine use of granulocyte colony–stimulating factor has lessened these risks. Newer protocols using more aggressive therapy, including topoisomerase inhibitors, ifosfamide, etoposide, and other agents, have other acute side effects, including renal and electrolyte imbalance, which demand close monitoring.

Acute radiation toxicity is related to the regions irradiated and the dose administered. It can be especially pronounced for tumors of the head and neck, abdomen, and pelvis. The synergistic effect of chemotherapeutic drugs such as dactinomycin and doxorubicin can be severe and may require modification of the treatment plan. Both dactinomycin and doxorubicin are known to accentuate a “recall” of radiation injury if given during or immediately after the course of radiation therapy.

Prompt attention to skin care is important. Moisturizers and steroid creams are effective symptomatic treatments for erythema and dry desquamation. Moist desquamation may be treated with aluminum acetate soaks or hydrocolloid dressings. Occasionally, a delay in radiation therapy is necessary to permit healing.

After orbital irradiation, an acute inflammatory reaction of the cornea and conjunctiva may be seen within weeks of completion of treatment. This can result in pain and photophobia. Topical steroids should be administered under the direction of an ophthalmologist for these symptoms.

Acute otitis externa or media with hyperemia and swelling of the membranes of the eustachian tube is common during or soon after treatment of head and neck areas. Decongestants are helpful in reducing the swelling. Erythematous mucositis, leading to a patchy, fibrinous exudate, is seen after head and neck irradiation, after drug therapy, and almost universally if the two are used simultaneously. Mouthwashes such as baking soda, 1% hydrogen peroxide, or combinations of diphenhydramine elixir, hydrocortisone, and antibiotics partially

alleviate the reaction. Bacterial or fungal superinfection requires specific drug management. Pretreatment evaluation by a dentist is important to correct pre-existing problems and help guide preventive therapy such as dental hygiene and fluoride applications.

Acute gastrointestinal sequelae, such as vomiting and diarrhea, are usually managed by supportive care. Parenteral nutritional support may be necessary to prevent protein or calorie malnutrition.

Late Effects

Life-threatening late events occur in approximately 9% of survivors after treatment.[33] A higher percentage experience lesser degrees of late morbidity, with the risks dependent on factors such as primary tumor site, disease stage, and the treatment modalities employed.

Long-term sequelae related to specific chemotherapy drugs are usually site specific, and the morbidity may be accentuated by radiation therapy. Cyclophosphamide may induce hemorrhagic cystitis, and doxorubicin is implicated in late myocardiopathies.[126] Cisplatin carries a high incidence of hearing impairment. Alkylating agents and topoisomerase inhibitors are associated with the development of secondary neoplasms, particularly acute myeloid leukemia.[127,128]

Late radiation effects are related to the irradiated site, the dose of radiation, and the age of the child at the time of treatment. Effects include bone and soft tissue growth disturbances, dental abnormalities, cataract, hypopituitarism, gonadal dysfunction, induction of second malignant tumors (particularly bone sarcomas), and chronic organ dysfunction.[55,127,129–131] Long-term follow-up and treatment are important to minimize the impact of these, particularly for endocrine and dental complications.[132] Combined-modality treatment programs are significantly implicated in many of these complications.

Late surgical complications depend mainly on the choice of surgical procedure for primary treatment of the tumor. They include disfigurement and loss of function. Serious late effects of surgical treatment include the consequences of fecal and urinary diversion as well as ejaculatory impotence after retroperitoneal lymph node dissection.

FUTURE DIRECTIONS AND RESEARCH

Advances in molecular biology are providing a more comprehensive

understanding of the biologic behavior of RMS and direct new research initiatives.

Chromosome aberrations are common in RMS. A consistent loss of heterozygosity at 11p15.5 is seen in embryonal RMS. Cytogenetic studies of alveolar RMS often demonstrate a translocation involving chromosomes 2 and 13, which affects the *PAX3* gene in band 2q35 and the *FKHR* gene in band 13q14.[133,134] The reciprocal translocation t(2;13) fuses *PAX3* to the *FKHR* gene, resulting in a chimeric structure that functions as an oncoprotein, resulting in dysregulation of cell growth and transformation.[135] Similarly, t(1;13) juxtaposes the *PAX7* gene on chromosome 1p36 with the *FKHR* gene on chromosome 13q14, again producing a chimeric transcript. These findings suggest that there may be a set of target genes involved in the pathogenesis of RMS, and work is currently under way to engineer vaccines against the resulting fusion proteins.[29] The identification of genes in alveolar RMS has permitted the development of molecular diagnostic assays, including reverse transcriptase polymerase chain reaction and fluorescence *in situ* hybridization, for improved detection of alveolar RMS cells.[136]

Proto-oncogene research has focused on nuclear transcription factors. Embryonal RMS does not reveal amplification of either N-*myc* or c-*myc*; however, the majority of alveolar cases do have N-*myc* amplification. Survival among N-*myc*–amplified patients is poor.[137] Recent investigations link N-*myc* regulation to the *PAX3-FKHR* fusion gene present in many patients with alveolar RMS and may suggest targets for biologic manipulations.[138] Overexpression of the histone H3 lysine 9 (H3K9) methyltransferase KMT1A has been shown to block differentiation of alveolar RMS by repressing a myogenic gene expression program and is a potential target for novel therapies.[139]

The hedgehog pathway has been found to be activated in a subset of patients with embryonal and fusion-negative alveolar RMS.[140] These children have a significantly worse outlook than those with similar phenotypes without hedgehog activation. Inhibitors of the hedgehog pathway may offer therapeutic options in this group of patients. STAT3 is also an important signaling pathway in the oncogenesis of RMS, and targeting of this cascade is also being explored.[141]

Increased expression of the insulinlike growth factor 1 receptor (IGF1R) has been demonstrated in several RMS cell lines, and IGF1R inhibitors have shown significant preclinical antitumor activity.[142] Future studies will examine the efficacy of these drugs in the clinical setting.[143] Antibodies to the death receptor

DR-5, present on many RMS cells, have also shown significant preclinical activity.[144]

What is a Fusion Gene?

Fusion genes, such as the PAX3-FOXO1 fusion gene discussed in this chapter, play a critical role in tumorigenesis. A fusion gene forms from the combination of two genes secondary to chromosomal aberrations including translocations, insertions, inversions, and interstitial deletions. As a result, fusion transcripts and proteins are created that can lead to the abnormal proliferation of cells and subsequently oncogenesis. Gene fusions are thought to be responsible for the pathogenesis of approximately 20% of cancer cases.[1]

The first fusion gene discovered was the BCR-ABL1 fusion gene characteristic of chronic myeloid leukemia (CML). This fusion results from the translocation between chromosomes 9 and 22 (the Philadelphia chromosome) and results in a constitutively active tyrosine kinase that acts as the driver mutation for CML. Since the initial characterization of the Philadelphia chromosome in the 1960s, there have been over 10,000 fusion genes identified, including the reciprocal translocation between chromosomes 2 and 13 (t2;13, or occasionally t1;13) that fuses the PAX3 (or PAX7) gene to the FOXO1 (FKHR) gene in alveolar RMS; the interstitial deletion on chromosome 21 that results in the formation of the *TMPRSS2-ERG fusion gene seen in approximately 50% of patients with prostate cancer*; the translocation between chromosome 8 and 21 (t8;21) that is characteristic of acute myeloid leukemia; the EWSR1-FLI1 fusion in Ewing sarcoma; *and the ELM4-ALK fusion seen in a small percentage of patients with lung cancer*.[2]

Fusion genes are important not only for oncogenesis but also for clinical utility. The detection of fusion genes may be used for diagnostic purposes; for example, urine *TMPRSS2-ERG can be used for screening and diagnosing prostate cancer*.[3,4] For tumors in which there is heterogeneity with respect to gene fusion status (such as RMS), fusion genes play a significant role in risk stratification. Importantly, therapeutic agents targeted at fusion proteins have changed the treatment paradigm and outcomes for many tumors (e.g., imatinib for CML and crizotinib for ALK fusion-positive lung cancer). In alveolar RMS, vaccines targeted against the PAX-FOXO1 fusion protein are currently under development.[5]

In summary, fusion genes can serve as the driver mutation for different cancer types and can play a critical role clinically for diagnosis, prognostication, and as a target for therapy. As molecular techniques continue to advance, the role of fusion genes in cancer development and therapy will continue to grow.

Alteration of tumor suppressor genes is described in RMS, although their significance is unclear. Investigators have reported that >50% of both alveolar and embryonal RMS in established cell lines contain a mutant *p53* tumor suppressor gene.[145] However, more recent data indicate that the actual incidence of mutant *p53* in tissue derived directly from patient biopsies is much lower, and data regarding its predictive value for survival are mixed.[146,147] Studies of multiple drug–resistant genes, which encode P-glycoprotein, suggest that in RMS, high levels of P-glycoprotein lead to tumor resistance. In these tumors, there appears to be a correlation between P-glycoprotein positivity and poor outcome.[148]

The current generation of COG STS studies tests a number of clinical hypotheses. These include testing the ability to reduce the duration of chemotherapy for favorable prognosis of tumors, studying the effect of delivering radiotherapy at week 13 of treatment concurrently with temsirolimus for intermediate-risk patients, boosting tumors initially measuring >5 cm to 59.4 Gy total, and evaluating the prognostic value of early treatment response as assessed by PET imaging.

Future directions and research in RMS are being driven by many exciting molecular biologic and technologic advances. Such new findings provide hope for more refined risk-based therapy in RMS and potentially for gene therapy to be added to the therapeutic armamentarium.

CHAPTER 92

Ewing Tumor

Line Claude, Ronan Tanguy, and Marie-Pierre Sunyach

EPIDEMIOLOGY

Ewing sarcoma family of tumor (ESFT) is the second most common primary tumor of the bone in childhood. ESFT primarily afflicts adolescents/young adults and is uncommon before 8 years and after 25 years.[1] The incidence is estimated to be 3/1,000,000 per year in White Caucasian population[2] but is rarer in Africans and Asians.[3]

Overall survival (OS) has improved mainly in localized disease since a few decades, thanks to a multidisciplinary approach. Five-year OS in localized ESFT increased from about 45% to 60%–68% after the 1990s. Five-year OS in metastatic disease has also increased but remains quite poor, about 30% to 40%,[3] especially for patients with other metastasis than isolated lung lesions.

PATHOLOGY AND CYTOGENETICS

Light microscopy shows a tumor of small, round blue cells that lack markers for lymphoma, neuroblastoma, or rhabdomyosarcoma. Cytogenetics has shown that ESFTs of the bone and soft tissue are the most undifferentiated members of a tumor family that shares a common neuroectodermal precursor cell, arrested at different stages of differentiation.[4] Cells are periodic acid–Schiff (PAS) positive, vimentin positive, and also often cytokeratin positive.[5,6] Approximately 95% of ESFTs have a translocation between the EWS gene on chromosome 22 and the FLI1 gene on chromosome 11 (t[11;22][q24;q12]) or the ERG gene on chromosome 21 (t[21;22][q22;q12]). In an analysis of 222 consecutive tumors at the Rizzoli Institute in Italy with a presumptive diagnosis of Ewing tumor, an occasional other translocation was noted.[7] The translocations are present only in tumor cells and occur in bone and soft tissue ESFT, primitive neuroectodermal tumors of the bone and soft tissue, peripheral primitive neuroectodermal tumors,

Askin tumors, some esthesioneuroblastomas in children, and some central nervous system (CNS) tumors.[8]

The t(11;22) juxtaposes the EWS gene with the FLI gene (EWS/FLI gene), which seems to act as an aberrant transcription factor, resulting in tumorigenesis.[9] The t(11;22) breakpoint location has been reported as prognostic factor in some publications,[10] but both recent reports from EURO-EWING 99 (EE99) study and Children's Oncology Group (COG) study have not confirmed this impact.[11,12]

More recently, other translocations were identified involving EWS gene and non-ETS genes (NFATc2, SMARCA5, PATZ1, SP3). Moreover, CIC-DUX4 fusion transcript positive or BCOR-CCNB3 fusion with an X chromosomal inversion has been also identified in ESFT. These translocations may be associated with different mechanisms of oncogenesis and may have different clinical impacts, which are currently studied.[13,14]

CLINICAL PRESENTATION

Locoregional pain is the most common presenting symptom in patients with ESFT, reported in about 90% of cases. Pain can be intermittent and variable in intensity. Pain often does not completely disappear during the night.[15] As the majority of ESFT patients are in their second decades of life and physically active, pain is often mistaken for "bone growth" or injuries. Tumor growth eventually leads to a visible or palpable swelling of the affected site. The tumor bulk, however, may be indiscernible for a long time in patients with pelvic, chest wall, or femoral tumors. Significant limitation of movement has been described in 25% of presentations.[15]

As ESFT may arise in virtually any bone and in soft tissue, additional symptoms, depending on the affected site, may vary considerably. Patients with chest wall or pelvic primaries may experience significant complaints only at a very late stage. Neurologic symptoms or signs occur in 15% of children, either as spinal cord compression or as peripheral nerve compression.

Unlike other bone sarcomas, constitutional symptoms such as fever, weight loss, and fatigue are occasionally noted at presentation mostly on more advanced and/or metastatic stages, affecting about one-third of patients.[16]The duration of symptoms prior to the definitive diagnosis can be weeks to months, or rarely even years, with a median of 3 to 9 months.[17]

DIAGNOSTIC WORKUP: LOCAL AND SYSTEMIC

Local Workup

The initial imaging investigation when an osseous lesion is suspected is usually a simple radiograph. ESFTs are defined as a destructive lesion of the bone. Tumor-related osteolysis, detachments of the periosteum from the bone (Codman triangle), and spiculae of calcification in soft tissue tumor masses suggest the diagnosis of a malignant bone tumor. Diaphyseal location suggests an ESFT, as compared with the metaphyseal location more common in osteosarcoma.[18]

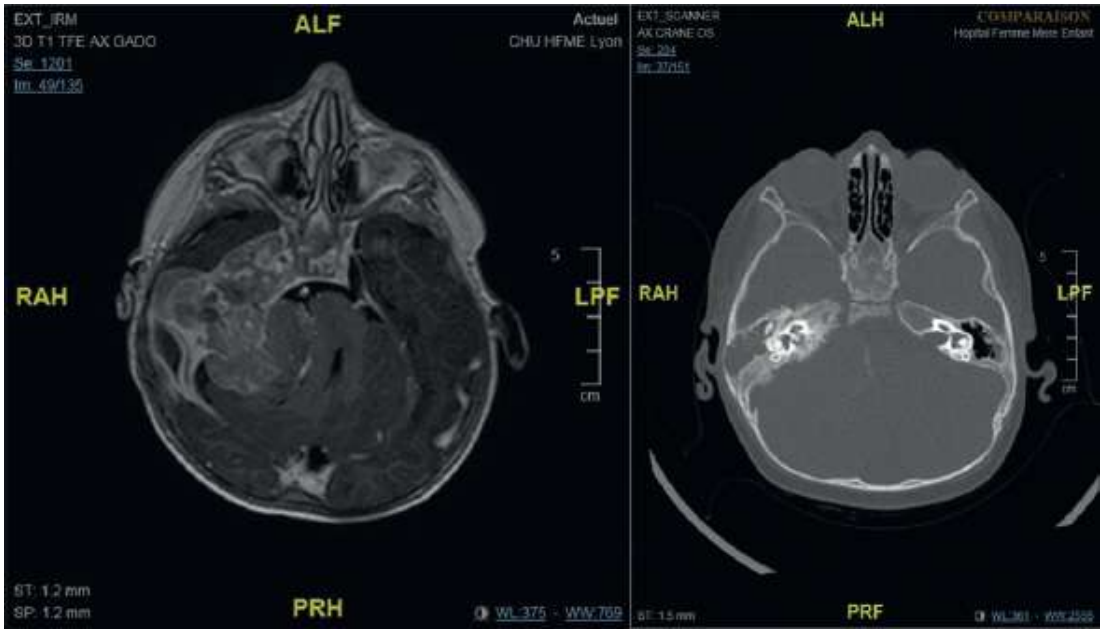

FIGURE 92.1. Ewing sarcoma of the right bone rock in a 2-year-old boy.

Local computed tomography (CT) and magnetic resonance imaging (MRI) are needed and complementary (Figs. 92.1 and 92.2). CT outlines better the bone and soft tissue extent of central ESFT. The most precise definition of the local extent of disease, including the intramedullary portion and the relation of the lesion to adjacent blood vessels and nerves, is provided by MRI.[19]

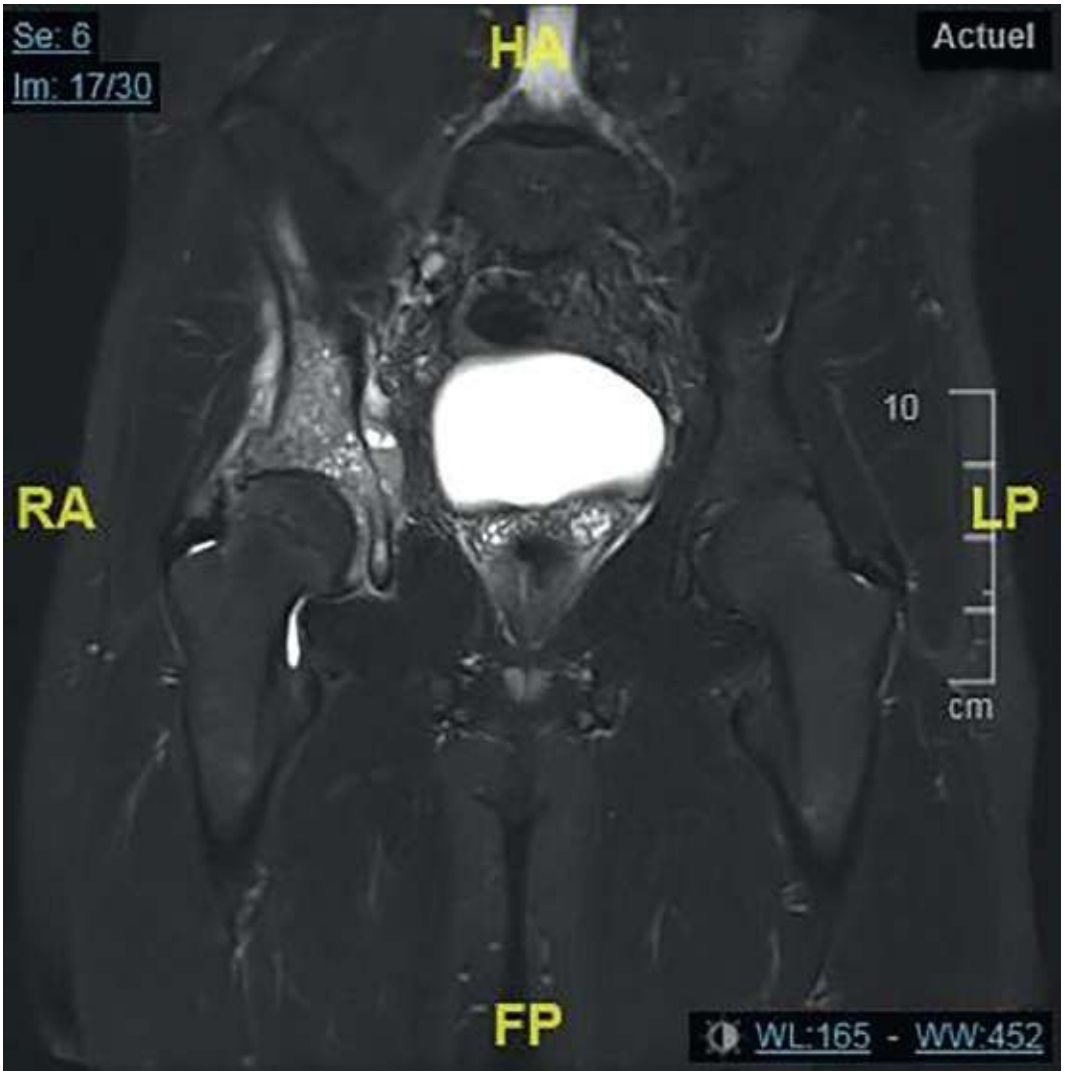

FIGURE 92.2. Localized Ewing sarcoma of the right acetabulum cup in a 16-year-old boy on magnetic resonance imaging (MRI)—Example of the planning treatment using TomoTherapy for exclusive radiotherapy (patient refused surgery).

Systemic Workup

Nonspecific signs of tumor or inflammation may be noted, such as an elevated erythrocyte sedimentation rate, moderate anemia, or leukocytosis. The pretreatment serum lactate dehydrogenase (LDH) rate is a prognostic factor.[20]

Whole-body MRI has also been reported to be superior to bone scan in detecting bone metastases in patients with Ewing tumors, particularly diffusion-weighted images or short-time inversion recovery (STIR) images.[19]

Currently, fluorodeoxyglucose positron emission tomography (FDG-PET-CT) is still an optional staging modality but is used more and more frequently. It has demonstrated high sensitivity and specificity in ESFT. FDG-PET-CT has been shown to detect more bone metastases than traditional bone scans do, both at

diagnosis and at recurrence.[21] Because few lesions <8 mm are not detectable using FDG-PET-CT imaging, CT scans are still more accurate for the screening of lung metastases.[21]

The EWS-FLI1 transcript can sometimes be detected in the peripheral blood or bone marrow, where it may indicate residual occult disease.[22]

In conclusion, the systemic workup should include blood studies including LDH, a chest CT scan, bone marrow aspirate/biopsies, and a bone scan, or better if available a FDG-PET-CT.

Results of Workup

Approximately 53% of ESFT have a primary site in an extremity, and 47% have central primaries.[2,23] ESFT can be localized everywhere, but the most frequent sites are the pelvis (23% to 25%), femur (16% to 18%), below the knee (10% to 16%), ribs (12% to 13%), spine (8%), and humerus (5%).[24]

On the whole, the proportion of metastatic patients at diagnosis is about 20% to 25% in large prospective studies. Metastasis is more frequent in pelvic primaries as compared with tumors of the extremities or ribs.[2,25,26]

Most frequent metastatic sites are the lungs (40%) and bones (40%), with less common disease involving the bone marrow, lymph nodes, soft tissue, and visceral sites. Rarely, the CNS is involved.[2,20]

PROGNOSTIC FEATURES

Metastatic Situation

Metastatic status at diagnosis is the strongest prognostic factor across different treatment strategies, whereas the 5-year disease-free survival (DFS) remains <30% for metastatic patients. However, patients with only lung metastasis have a better clinical outcome than those with metastases in other sites (EFS 29% to 52%).[27] In addition, other prognostic factors were identified to build a prognostic score in the EE99-R3 study.[25] After a median follow-up of 3.8 years on 281 patients, event-free survival (EFS) and OS at 3 years were still disappointing (27% and 34%, respectively). Cox regression analyses demonstrated increased risk at diagnosis for patients older than 14 years, a primary tumor volume over 200 mL, more than one bone metastatic site, bone marrow metastases, and additional lung metastases. An up-front risk score based on these factors identified three groups with EFS rates of 50% for score <3 (82 patients), 25% for score more than 3 to <5 (102 patients), and 10% for score >5

(70).

Metastases to uncommon sites (i.e., brain, liver, spleen) were associated with a worse prognosis in a retrospective study of 30 patients.[28]

Localized Disease

Most important parameters of favorable prognosis include a distal/peripheral site of primary disease, tumor volume <200 mL (or/and maximum tumor size <8 cm), normal LDH level at presentation, and a younger age at diagnosis.[2,23,29–34]

Poor histologic/radiologic response to chemotherapy has also been identified as a major adverse prognostic factor, even when chemotherapy was followed by R0 resection.[34–37]

ESFTs in the spine and sacrum are associated with significantly worse outcome and prognosis than primary ESFT in other sites,[37] but multidisciplinary approach is encouraging.[38] Similarly, the results of the Intergroup Ewing's Sarcoma Study (IESS) show that patients with primary tumors in pelvic bones have lower survival rates compared with patients with lesions in distal bones of the extremities.[39]

Ewing tumors with p53, p16/p14ARF alterations, or the presence of vascular endothelial growth factor respond poorly to chemotherapy and have a poor prognosis.[40–42] The matricellular protein CCN3, which plays an important role in bone formation, has been reported to be associated with a worse prognosis if fully expressed.[42]

Although in the past the type 1 fusion abnormality, which is the EWS-FLI1 transcript created as a result of fusion between exons 7 of *EWS* and 6 of *FLI1*, has been reported to have a favorable prognosis, more recent analyses do not confirm this. A reexamination of this association in a prospective cohort of patients with ESFT treated according to current COG protocols using more intensive chemotherapy shows no advantage.[11] In a report from the EE99 trial, no type of translocation impacted disease progression or relapse.[12]

GENERAL MANAGEMENT

Effective local *and* systemic therapy is necessary for the cure of ESFTs. Most chemotherapy regimens combine cyclophosphamide, doxorubicin, vincristine, dactinomycin, ifosfamide, and etoposide.[20,24,43–48] Induction chemotherapy is often preferred over starting the systemic therapy and local therapy concomitantly. There are several advantages to this approach:

- Administering the chemotherapy first allows an evaluation of the effectiveness of the regimen, to adapt postoperative chemotherapy and radiotherapy.
- Shrinkage of the soft tissue mass may help the surgeon or radiation oncologist decrease the volume of the local therapy.
- Shrinkage of the soft tissue mass may allow the surgeon to achieve better margins.
- Some bone healing takes place during the chemotherapy, which may diminish the risk of pathologic fracture if radiation therapy is used to treat the primary lesion.

Response rates to induction chemotherapy are high, with radiologic complete response and partial response rates of up to 90% reported.[49–51] For institutions that use surgery for the treatment of the primary lesion, excellent necrosis rates have been reported in many patients.[30,45]

The biopsy should be performed at the same institution where the treatment will be performed, and the biopsy specimen should only be taken from the soft tissue component, if present. Enough tissue should be collected for light and electron microscopy as well as cytogenetics. In experienced hands, a large-needle biopsy may be sufficient, although usually a larger sample is preferred, particularly because cytogenetics is becoming increasingly important.

Considering local treatment, the strategy has gradually moved from exclusive radiotherapy (RT) to surgery with or without RT.[2] For example, the Italian experience reports a percentage of patients treated with surgery increasing from 32% in the first protocols to 72% in the most recent studies. During the same period, RT followed an inverse evolution from 68% to 28% ($P = .0001$).[52,53]

There are no randomized studies to confirm the superiority of surgery compared to RT, but lots of retrospective studies demonstrate better local control (LC) and EFS after complete surgery (+/− followed by radiotherapy) as compared with RT alone.[29,37,54–56] Patients treated with exclusive RT often come from older protocols and generally have a lower prognosis: larger tumors, more pejorative sites, and poor response to chemotherapy.[56–58]

Currently, tumor resection is performed whenever a marginal or wide resection seems possible. Intralesional resection or debulking procedures followed by RT do not offer increased LC or DFS compared with definitive RT and should be avoided.[56] Limb-salvage surgery is preferable over amputation, but amputation may be an option especially for younger patients with lesions of the fibula, tibia, and foot. In older patients, lesions of the proximal fibula, ribs, scapula, clavicle, and wing of the ilium are easier to resect than other sites. Other sites may be resectable with major reconstructive procedures and significant morbidity.[59]

However, exclusive RT is a reasonable alternative if complete surgery is difficult, especially in case of small volume. In the German series, for example, central tumors, volume <100 cm^3, have a local recurrence rate after RT similar to tumors operated, with or without postoperative RT: 12.3% versus 15.9% and 11.1%.[56] In contrast, tumors larger than 100 cm^3 have a local relapse rate of 26.4% after exclusive RT versus 15.4% and 6.6% after surgery with or without RT.

RADIOTHERAPY TECHNIQUES

Radiation Indication and Doses

Exclusive RT

For gross disease, standard treatment is a total dose of 55.8 to 59.40 Gy and 1.8 Gy/day. A dose of 45 to 50.4 Gy is usually recommended, although 36 Gy may be adequate for the initial field, including microscopic disease.[60–63] Local control rates of 53% to 93% have been reported with these doses (Table 92.1). Local control at doses <40 Gy is significantly worse, even for small lesions.[73] An example of exclusive RT is shown in Figure 92.3

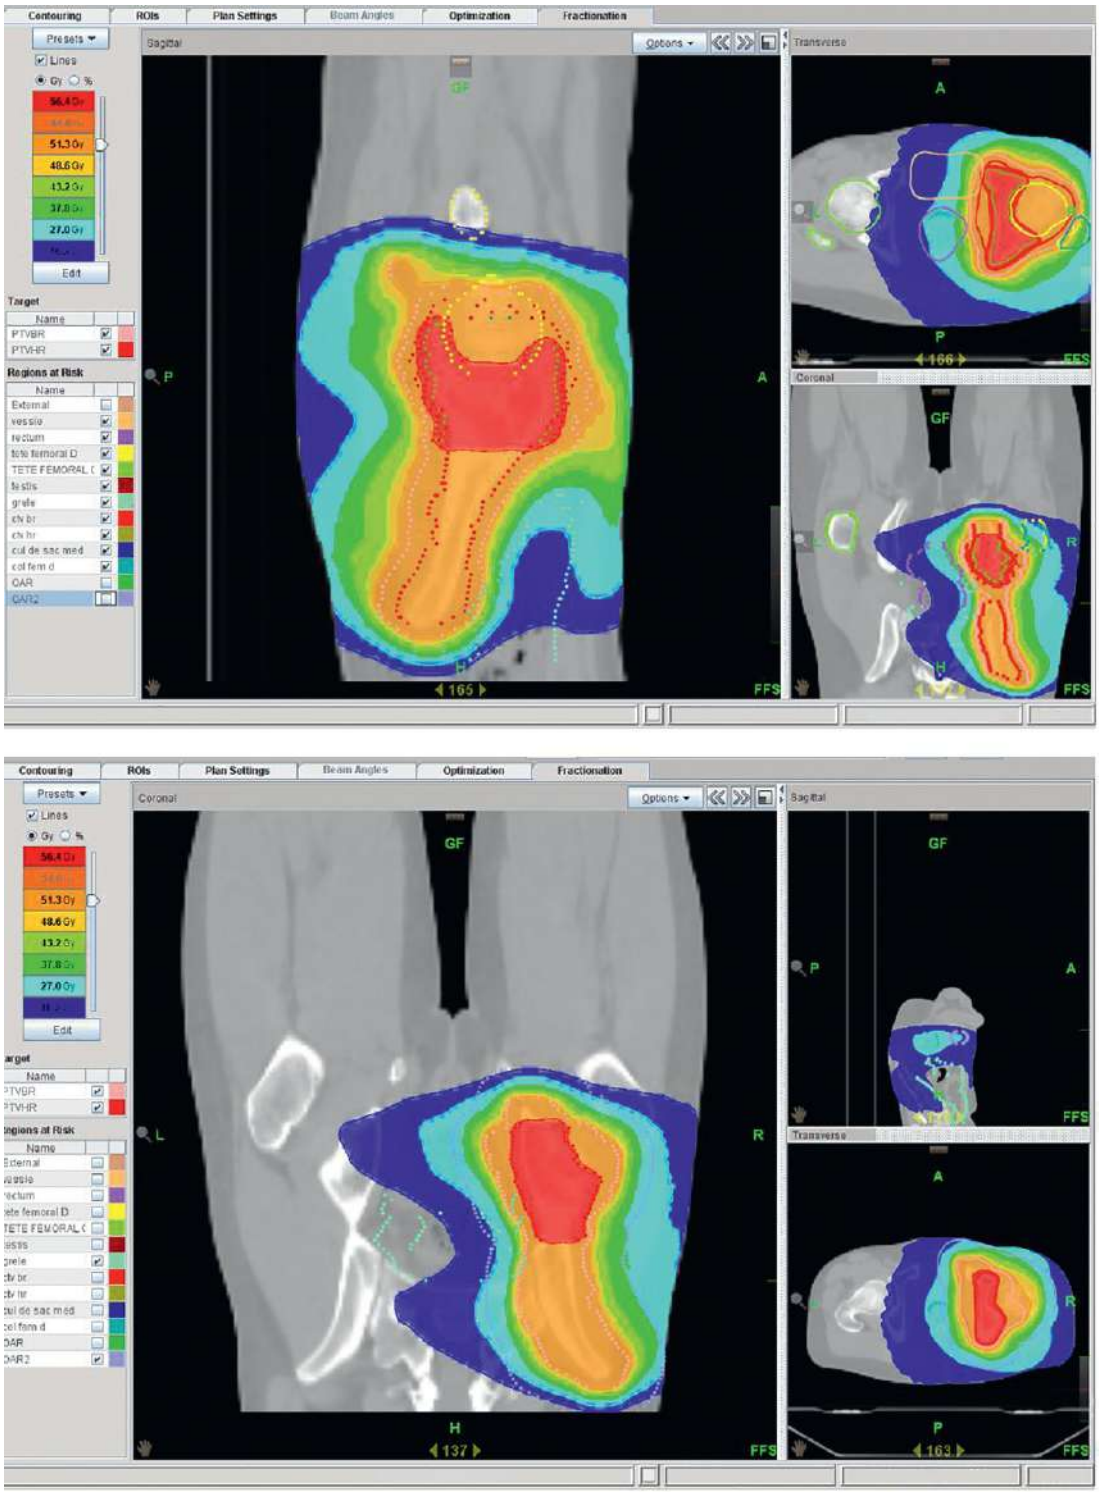

FIGURE 92.3. Example of the planning treatment using TomoTherapy for exclusive radiotherapy (patient refused surgery).

Adjuvant Radiotherapy

Jereb et al.[74] found that the local recurrence rate after conservative surgery was

high without RT. Ozaki et al.[75] also reported a slight advantage for adding postoperative RT for patients with inadequate margins. Dunst and Schuck[76] reported that patients with a wide resection alone but a poor histologic response had a local failure rate of 12%, in comparison with 6% for similar patients who received postoperative RT.

As a consequence, all patients with marginal margins and all patients with a poor histologic response receive RT.

In addition, taking into account competing events, a recent analysis of the EE99 trial showed that adjuvant RT improves LC for all the patients, even after good response to induction chemotherapy.[77] With a median follow-up of 6 years, 8-year local relapse incidence was 12%. A statistically significant reduction of local relapse was shown in patients treated with surgery and RT compared to surgery alone (P = .02). The benefit of RT was particularly marked for tumors larger than 200 mL at diagnosis and 100% necrosis. A nonsignificant trend for benefit associated with postoperative RT for DFS, EFS, and OS was reported.

As a consequence, in the currently ongoing EE2012 protocol, postoperative RT is considered for all patients except for those who have had a wide local excision, defined as negative resection margins of at least 1 mm, and a good histologic response (>90% necrosis) to preoperative chemotherapy and with removal of all tissues originally involved by the prechemotherapy tumor volume.

Postoperative RT is however not recommended for those in whom the anticipated adverse side effects of RT are sufficiently high to outweigh the additional benefit of RT for local control. Reasons for deciding against RT include young age, risk of surgical complications following RT, and predisposition to cancer.

Further studies are required to assess the balance between adjuvant RT benefit and risks, especially in patients with complete R0 resection and good histologic response.

For the dose, in the COG trials, a dose of 50.4 Gy (1.8 Gy once a day) is given if postoperative RT is indicated. Doses in the range of 30 to 44.8 Gy at 1.8 Gy a day have also been reported to be effective for subclinical disease.[75,78] Intralesional resections should be treated to the same dose as in patients receiving radiotherapy alone, with doses to residue or microscopic resection up to 54 to 59.4 Gy.

Table 92.2 lists the recommended doses and fields for different clinical situations.

In a review of 153 patients treated with surgery followed by postoperative RT

from Cooperative Ewing Sarcoma Study (CESS) 86 and EICESS 92, Schuck et al. showed that the interval between surgery and RT did not influence survival, although there was a slight trend for improved local control in patients receiving RT < 90 days postoperatively.[79]

TABLE 92.2 RECOMMENDATIONS FOR RADIATION THERAPY FIELDS AND DOSES

Clinical Situation		Total Dose (%)	Dose Per Fraction (%)	Volume
Gross target volume = GTV (after biopsy only or intralesional resection)				
Treatment once a day	Microscopic involvement (CTV)	36–50.4 Gy	1.8–2 Gy/fraction	Original bone and soft tissue mass
	Boost field (GTV, residue)	5.4–18 Gy[a] (total dose 54–59.4 Gy to GTV)	1.8–2 Gy/fraction	Original bone and *residual* soft tissue mass
Treatment twice a day	Initial field	36 Gy	1.2 bid	Original bone and soft tissue mass
	Boost field	14.4–19.2 Gy	1.2 bid	Original bone and *residual* soft tissue mass
Postoperative radiation (especially after marginal resection and/or poor histologic response at surgery)		45–54 Gy	1.8 qd	Original bone and soft tissue mass plus surgical scars and drains if feasible
Preoperative radiotherapy		45–50.4 Gy	1.8 qd	Original bone and soft tissue mass
	(Doses as low as 35 have been successful)			

[a]Depending on initial dose.

bid, twice a day; CTV, clinical target volume; GTV, gross target volume; qd, once a day.

Neoadjuvant RT

Good results have also been reported with preoperative RT for patients with a poor response (<50% reduction of the evaluable soft tissue mass) after two cycles of chemotherapy.[75,80] Doses of 36 to 63 Gy have been used.[75]

The total dose for preoperative RT is usually 50.4 Gy (1.80/fr) in a single phase to the PTV. If there are concerns about organ tolerance or wound healing, then this dose can be reduced to 45 Gy.

RT After High Dose Chemotherapy with Busulfan

Because of the high risk of toxicity of the association of RT and high dose chemotherapy (HDCT) including busulfan (HDCT-BuMel), both indications should be early discussed in multidisciplinary meetings.

In case of patients receiving HDCT-BuMel before RT, the total dose will often be limited (generally at 45 Gy), whereas the dose constraints to major critical organs have to be strictly respected to avoid severe toxicity. Using conventional fractions, RT doses will not exceed 30 Gy to the spinal cord[81] and 45 Gy on a small volume of the gastrointestinal tract, including the bowel, colon, rectum, stomach, and duodenum.[82] Large irradiated lung volumes should be also avoided. Hemithoracic lung or whole-lung RT is not recommended in first intention after HDCT-BuMel, because of the risk of respiratory toxicity. Spacer devices can be discussed in the pelvis to displace the bowel away from treatment volumes.

Intensity-modulated radiotherapy (IMRT) techniques or proton therapy should be used to spare critical organs as much as possible in this situation. For patients who receive HDCT-BuMel, RT should begin later. EE2012 protocol recommends to begin RT at least 10 weeks after HDCT delivery.

Fractionation

Standard fractionation delivers 1.8 to 2 Gy per fraction, 5 days a week. In very young children, fractionation using 1.6 Gy/day may be considered.

Twice-a-day RT has been used in several trials. To treat ESFTs, radiation oncologists at the University of Florida used 1.2 Gy twice a day to a total dose of 50.4, 55.2, or 60 Gy, depending on the tumor response to induction chemotherapy, and showed that late effects could be decreased while maintaining good LC, even for large primary tumors.[62,63] In CESS 86, doses of 1.6 Gy twice a day to a total of 60 Gy were given, although not in a continuous

course. The Italian SE-91 trial also used 1.6 Gy twice a day to a total of 60.8 Gy, but in a continuous course. The CESS 86 trial showed no advantage for the accelerated hyperfractionated approach, but the early results of SE-91 are promising with regard to local control.[66,76] Both of the latter regimens would be theoretically expected to increase late effects.

Radiation Volumes

The Pediatric Oncology Group (POG 8346) trial showed, in a randomized fashion, that the traditional approach of irradiating the entire marrow cavity was not necessary.[54] Although "tailored" fields are the standard of care today, attention to the requisite volume is critical to obtaining maximal control rates; geographic miss has been a frequent source of failure in cooperative group studies.[54,64] Three-dimensional treatment planning is essential.

Growth tumor volume (GTV) is defined as the visible tumor on imaging at its maximal extent (using CT, FDG-PET-CT, bone and MRI scans, as available) prior to any chemotherapy or surgery.

Clinical target volume (CTV) 1 should encompass any sites of potential microscopic extension of GTV, or of contamination by GTV, including metallic prostheses, drain sites, and surgical scars (if feasible), and should be at least GTV + 1 cm.

Planning target volume (PTV) 1 is defined from CTV1, with a margin to account for day-to-day set-up variation and, if relevant, internal organ motion. This will vary according to tumor location in the body and is specific to individual institutions. PTV1 will be typically CTV1 + 0.5 to 1.0 cm.

The boost is delivered to the residual tumor volume (GTV) at the time of RT plus a 1-cm margin to CTV2. Any initial bone or bone marrow abnormalities in the primary bone should be included in GTV. CTV2 does not need to include scars and drain sites. It should take into account anatomical barriers to tumor spread such as facial boundaries and bone. PTV2 will be typically CTV2 + 0.5 to 1.0 cm. These margins are much tighter than in previous studies, and only additional follow-up will show whether they will be adequate.

The use of MRI is essential to identify the tumor extent, at the diagnosis and after the induction chemotherapy. PET-CT may be helpful for planning.

Extremity lesions require sparing at least a 1- to 2-cm strip of tissue to prevent lymphedema, which can be very difficult at times, particularly in arm lesions, although the arm is less likely to develop lymphedema than the leg. It may be necessary to consider surgery as an alternative if a strip of tissue cannot

be spared. It is more important to cover the tumor adequately than to spare adjacent growth plates and joints.[83]

With the high doses of cyclophosphamide or ifosfamide given in chemotherapy regimens for Ewing tumor, it is important to minimize the dose to the bladder. Radiation cystitis can be a significant risk even at doses as low as 20 Gy. Because pelvic lesions rarely infiltrate into the tissues around the bladder, but instead tend to push aside those structures, neoadjuvant chemotherapy allows additional bladder to be spared if good shrinkage is obtained. A 1-cm medial margin on the residual disease at the time of treatment is adequate from the beginning of radiation therapy.

Radiation therapy doses are shown in Table 92.2.

RT in Special Sites

Ribs

Rib lesions should be treated conformally with a minimum of lung and heart in the high dose field. However, rib primary tumors often present with pleural effusions. In the EICESS 92 trial, the 7-year rate of EFS was 63% with hemithorax RT versus 46% without.[84] Claren et al. recently confirmed that pleural effusion at diagnosis and incomplete resection were both independent risk factors for survival in localized tumor of the rib. Eighty-two French patients, median age 13.6 years and median follow-up 8.4 years, were treated in EE99 protocol and reviewed. Five-year DFS was 69%. Pleural effusion and incomplete surgical resection (R1 or R2) were independent prognostic factors for DFS and OS. In case of initial pleural effusion, documented or not, OS was 27% without RT versus 68% after RT ($P = .01$).[85]

Spine

The type of local treatment remains a pending question in this site. A large-scale retrospective study on patients diagnosed with ESFT of the spine in the Surveillance, Epidemiology, and End Results (SEER) registry from 1973 to 2012 was recently published. Age, surgical resection, tumor size, and extent of disease (OS $P < .001$, DSS $P < .001$) were independent factors of survival. RT trended toward improved survival but did not achieve statistical significance.[86]

A French cohort of 75 patients with localized spinal ESFT treated between 1988 and 2009 was reported. Seventy-nine percent presented initial neurologic compression and 69% had inaugural decompressive surgery. Local treatment modality was surgery and RT in 50 patients, RT alone in 19, and surgery alone in

6. After a 7-year median follow-up, the 5-year LC, EFS, and OS were 78.0%, 57.0%, and 70.0% (95% CI: 59.1–81.0), respectively. Vertebral compartment involved was the only prognostic factor.[38]

The standard dose for vertebral lesions is usually 45 Gy, but modern techniques including protons or dynamic IMRT allow nowadays to increase the dose of RT in many situations while sparing the spinal cord. The average dose used in the CESS 81, CESS 86, and EICESS 92 trials was 49.6 Gy, although sometimes spinal shielding was used.[80,87] In these trials, neurologic late effects were seen in 1 of 47 patients irradiated, occurring at a dose of 44.8 Gy at 1.6 Gy twice a day.

Sacral lesions should be treated to the full dose. The Scandinavian Sarcoma Group confirmed recently a better prognosis for sacral lesions on 29 patients. Seventy-nine percent received exclusive RT, with a 5-year DFS of 66%.[88]

Doxorubicin and dactinomycin given during the course of RT will often cause moist desquamation, particularly with beams of 6 MV or less, tangential irradiation, or skin folds. These drugs may also cause a “recall” phenomenon of the dry or moist desquamation when given after the end of radiation therapy. HDCT-BuMel should not be given before RT for spinal lesions if RT dose to the spinal cord is expected to be over 30 Gy, because of the risk of myelitis.[81]

RESULTS OF THERAPY

The majority of studies reported in the literature reflect the results of therapy only for ESFT of the bone, because before 1991 soft tissue ESFTs were treated on Intergroup Rhabdomyosarcoma Study (IRS) Group protocols. The addition of chemotherapy to local therapy increased the survival for ESFT of the bone from <10% to >40% at 5 years for patients with localized disease at diagnosis.[94] Modern protocols show better results and SEER data confirm this gradual improvement in survival rates over time. Five-year survival improved from 36% for patients treated from 1973 to 1977 to 59% for patients treated from 1993 to 1997.[3] However, late recurrences and deaths from complications continue to occur for years, yielding 10- and 15-year survival rates 10% to 15% lower than 5-year rates.[51,95]

LC and survival rates are shown in Table 92.1 for patients treated with different LC strategies in cooperative group trials that reported appropriate data. Surgery has become the treatment of choice for the primary lesion at most centers, and many series report superior local control for patients receiving

surgery as a component of their local treatment, particularly if RT compliance was poor.[54,64] The influence of different LC strategies on survival is less certain. In CESS 86, with good RT compliance, survival rates were not influenced by the method of therapy to the primary tumor,[96] nor was there an advantage for surgery in pelvic primary lesions treated in Intergroup 0091.[67] Other trials show an advantage for surgery or a combination of surgery and RT. With no randomized studies addressing this question and considerable selection going into the choice of local treatment, conclusions regarding the relative influence of different local therapies on survival are based more on opinion than fact.[64]

However, systemic therapy does influence the rate of detectable local relapse. The first Intergroup Ewing's Sarcoma Study (IESS-I) reported that the addition of doxorubicin improved local control.[97] The first Children's Cancer Group/Pediatric Oncology Group (CCG/POG) intergroup study showed an improvement in survival in the intensified arm for patients with localized disease and large primary or pelvic tumors. The improvement with the more intensive regimen resulted from a decrease in the rate of local relapse; the rate of distant metastases was similar in both arms.[24] The time interval between initiation of chemotherapy and start of RT has also been reported to influence survival (local control was not evaluated), with early RT preferable to late RT.[76]

RESULTS OF CLINICAL TRIALS FOR PATIENTS WITH LOCALIZED DISEASE AT DIAGNOSIS

The first reports of drug treatment of ESFT come from the 1960s with cyclophosphamide-based protocols. In 1974, Rosen et al. published the first results of a trial of RT given with a four-drug regimen consisting of vincristine, actinomycin D, cyclophosphamide, and doxorubicin used in combination rather than sequentially, leading to long-term survival in 12 patients with EFST.[98] The VACA scheme then became a standard therapy in numerous clinical trials.

IESS-I showed that VACA chemotherapy (vincristine, dactinomycin, cyclophosphamide, and doxorubicin) produced superior results over a VAC (vincristine, dactinomycin, and cyclophosphamide) regimen alone in terms of effectiveness of local control (96% vs. 86%) and EFS (60% vs. 24%). The third arm combined bilateral whole-lung irradiation (WLI) with VAC and produced survival rates better than VAC alone, but less than VACA, indicating that bilateral WLI is an effective adjuvant, although it has not been studied in any subsequent trial except in patients with lung metastases at diagnosis.[20]

Intensifying systemic therapy in IESS-II improved the results for pelvic tumors. IESS-II also showed that induction chemotherapy was a viable option.[46] A trial at St. Jude Children's Research Hospital (Memphis, TN) confirmed this approach, and it has since been the standard of care.[49]

Based on data from previous trials, both the University of Florida and the German Cooperative Ewing Sarcoma Study (CESS) stratified ESFTs by tumor size and intensified treatment for large localized tumors. Although neither approach was randomized, both the University of Florida studies and CESS 86 found that intensifying treatment improved survival.[35,51,63]

On the basis of phase II results achieved with the combination of ifosfamide and etoposide (IE),[99] in the Pediatric Oncology Group–Children's Cancer Group (POG-CCG) study, INT-0091 patients were randomized to receive either VACD or VACD-IE. The VACD arm achieved a 5-year EFS rate of 54% in patients with localized disease versus a 69% EFS rate in the experimental arm with the addition of IE.[24] This first CCG/POG intergroup study starting in 1988 showed that adding etoposide–ifosfamide improved the survival rates, particularly for patients with primary tumors of the pelvis.

The United Kingdom Children's Cancer Study Group trials ET-1 and ET-2 showed a better survival rate in the ET-2 trial if ifosfamide was substituted for most of the cyclophosphamide used in ET-1; however, the dose intensity in ET-2 was also higher.[65]

The first COG trial used the more standard doses but decreased the interval of chemotherapy to 2 weeks if there was blood count recovery. In this randomized trial for patients younger than 50 years with localized ESFT (n = 568), Womer et al. reported that VAC-IE given on an every-2-week schedule was found to be more effective than VAC-IE given on an every-3-week schedule, with no increase in toxicity; median 5-year EFS was 73% and 65%, respectively.[72]

Because of the results of the interval compression study, the five-drug standard of vincristine, cyclophosphamide, doxorubicin, ifosfamide, and etoposide with interval compression is now considered the standard ESFT regimen in North American institutions.

The EICESS 92 study investigated whether cyclophosphamide has a similar efficacy as ifosfamide in patients with standard-risk ESFT (small localized tumors) and whether the addition of etoposide to a regimen already containing ifosfamide improves survival in patients with high-risk disease (large tumors or metastatic disease at diagnosis).[100]

Patients with standard-risk disease were randomly assigned to VAIA

(vincristine, dactinomycin, ifosfamide, and doxorubicin; *n* = 76) followed by either VAIA or VACA (vincristine, dactinomycin, cyclophosphamide, and doxorubicin; *n* = 79). The 3-year EFS rates were 73% and 74%, respectively, for VACA and VAIA, suggesting that cyclophosphamide has the same efficacy as ifosfamide in this group of patients. Patients with high-risk disease were randomly assigned to VAIA or VAIA plus etoposide (EVAIA). The 3-year EFS rate was not significantly different between the two treatment groups (52% and 47%, respectively, for EVAIA and VAIA). However, there was some evidence that the addition of etoposide was associated with a greater survival benefit in the subgroup of patients without metastases (*P* = .18) than in those with metastases (*P* = .84).[101] So, the EICESS 92 trial showed that for standard-risk patients (<100 mL and no metastases at diagnosis), a regimen substituting cyclophosphamide (VACA) for ifosfamide (VAIA) was equivalent.

As a follow-up to the EICESS 92 study, the EE-R1 trial evaluated cyclophosphamide as a replacement for ifosfamide as a part of consolidation therapy that also included vincristine and dactinomycin (VAC vs. VAI) after VIDE (vincristine, ifosfamide, doxorubicin, and etoposide) induction chemotherapy in 856 patients with standard-risk ESFT. VAC was statistically not inferior to VAI, but was associated with a slight increase in events (-2.8% decrease in 3-year EFS). The proportion of patients experiencing severe hematologic toxicity was slightly higher in the VAC arm, but renal tubular function impairment was more significant for patients receiving VAI.[101] The comparative evaluation of long-term renal and gonadal toxicity is ongoing and will be crucial to decisions regarding future patients.

Raney et al.[102] reported the results of treating extraosseous ESFT on the IRS until 1991. Long-term survival of these patients was probably better than for patients with bony primaries, with 10-year survival of 62%, 61%, and 77% for IRS-I, IRS-II, and IRS-III therapeutic protocols, respectively. Survival rates were better for patients with primary lesions of the head and neck, extremities, and trunk and for those with gross tumor removal. Extraosseous primary lesions are now treated on the same protocol as osseous lesions.

RESULTS OF CLINICAL TRIALS FOR PATIENTS WITH METASTATIC DISEASE AT DIAGNOSIS

Patients with metastatic disease at diagnosis have a poor prognosis. In a report from the EICESS, the 5-year EFS for patients with lung metastases only was

29%; for patients with bone and bone marrow metastases, it was 19%; and for patients with both lung and bone metastases at diagnosis, it was only 8%.[2] Although there was an improvement in survival rates in patients with localized disease treated in the first intergroup CCG/POG trial, adding ifosfamide–etoposide did not improve survival for patients with metastatic disease at diagnosis.[103]

WLI improved survival in the CESS 81, CESS 86, and EICESS 92 trials for patients with lung metastases as the only site of metastatic disease at diagnosis.[104] The CESS 81 and 86 studies also showed increasing survival rates with an increasing RT dose to the lung fields, particularly with a dose of >18 Gy (corrected for lung transmission) at either 1.5 Gy once a day or 1.25 Gy twice a day. Bölling et al. reported 99 patients from EICESS 92 with pulmonary metastasis. WLI was performed with a dose between 12 and 21 Gy. Seventy patients were treated with WLI, thirteen of them received a further boost to their primary tumor in the thorax up to a cumulative dose of 54 Gy. OS showed a trend toward better results for patients with WLI (5-year OS 61% vs. 49% without WLI, $P = .36$).[105] Some institutions only use WLI in patients with lung metastases who respond poorly to chemotherapy.[106]

In patients with disseminated disease, results are better with adequate treatment of the primary as well as all the metastases. EE99 showed that the 3-year EFS was better (47%) for patients receiving both surgery and radiation to the primary lesion versus either surgery alone (25%) or radiation therapy alone (23%). Without local therapy, the EFS was 13%.[107] Obviously, selection bias cannot be excluded. At Memorial Sloan Kettering Cancer Center (New York, NY), LC was worse for patients with metastatic disease (61%) than those with localized disease (84%)[108] although in a large series from St. Jude Children's Hospital, the LC in the two groups was equal.[29]

TABLE 92.3 SURVIVAL IN METASTATIC EWING SARCOMA: MOST RECENT PROSPECTIVE STUDIES

BuMel, busulfan/melphalan; HDCT, high dose chemotherapy; IE, ifosfamide–etoposide; N, number of patients; OS, overall survival; PFS, progression-free survival; TBI, total-body irradiation; VAC, vincristine, dactinomycin, and cyclophosphamide; VACA, vincristine, actinomycin D, cyclophosphamide, doxorubicin; VAI, vincristine, dactinomycin, ifosfamide; VAIA, vincristine, dactinomycin, ifosfamide, and doxorubicin; VDC-IE, vincristine, doxorubicin, cyclophosphamide, ifosfamide–etoposide; VIDE, vincristine, ifosfamide, doxorubicin, etoposide; WLI, whole-lung irradiation.

Recent evidence shows improved survival in patients with disseminated bone metastases if all the lesions are treated. Of 120 patients enrolled on arm R3 of EURO-EWING, which suggested but did not mandate local therapy (RT, surgery, or both) to all sites of disease, 40% received local therapy (either surgery or RT) or both to all sites of metastatic disease, and 60% received no local therapy. Three-year EFS was 35% in those patients who received RT to metastatic sites compared to 16% in those who received no local therapy.[107] Paulino et al. show similar results with local therapy to all sites of metastatic disease.[28] It is acceptable to delay the RT until close to the end of chemotherapy if a significant amount of bone marrow would be treated.

HIGH DOSE THERAPY WITH STEM CELL RESCUE

Many institutions have investigated end-intensification with HDCT and stem cell

rescue with and without total-body irradiation (TBI), concerning patients with high-risk localized disease, in metastatic situations, or for recurrence. TBI has been largely abandoned as part of the conditioning regimen. Many different regimens have been used, mostly a combination of melphalan with etoposide, busulfan, carboplatin, and thiotepa.[109]

Metastatic Tumors

Table 92.3 presents results of the most recent studies in metastatic situations. Patients with metastatic disease treated on EICESS studies between 1990 and 1995 had a superior 4-year EFS when HDCT was added to the end of therapy, but CCG-7951 showed no improvement with this approach over a matched cohort from other Ewing tumor studies for patients with bone or bone marrow metastases.[90,110] Some institutional pilot studies without strict selection criteria show promising but not conclusive results.[48,51,91,111–113]

The survival of patients with bone metastases at diagnosis appears much better than with standard therapy in some reports. EFS rates as high as 43% have been reported in a French monocentric study. In patients with lung metastasis, EFS reached 52%.[91] The use of whole-body MRI to detect bone metastases followed by compartmental irradiation to doses up to 54 Gy and HDCT has also been reported to produce a 5-year survival rate of 45%.[113] Although it was a small series, over half the patients had lung metastases and multiple bone metastases.

The Italian Sarcoma Group and the Scandinavian Sarcoma Group designed a joint prospective study for 102 patients with metastatic ESFT (lungs, pleura, or single bone).[92] Intensive combination chemotherapy, surgery, and/or RT and consolidation treatment with HCDT-BuMel and WLI were planned. Only 71 patients on 102 received the whole therapeutic program, mostly because of disease progression. With a median follow-up of 62 months, 5-year OS and PFS for the whole group were 52% and 43%. However, for the patients with only lung metastases who completed the therapeutic program, 5-year OS and PFS were 66% and 53%, respectively.[92]

The EE99-R2 (lung) trial evaluated in a randomized way the question of the best consolidation treatment after initial chemotherapy with VIDE, comparing WLI with conventional VAI chemotherapy versus HDCT-BuMel. Two hundred and sixty-five patients were randomized: 132 received VAI-RT and 133 received HDCT. Three-year EFS was 56% after HDCT versus 50.3% for conventional arm patients (P = .21). Significantly, more patients in HDCT experienced severe

acute toxicities than in the standard arm. The authors concluded that in ES with lung metastases, there is no clear benefit associated with HDCT-BuMel compared to conventional chemotherapy combined with WLI.[93]

The EURO-EWING 99-R3 study also evaluated the efficacy of induction chemotherapy (six courses of VIDE), local treatment (surgery and/or RT), and HDCT in 281 patients with ESFT with primary disseminated disease. After a median follow-up of 3.8 years, the 3-year EFS for the entire study cohort was disappointing (27%), but the EFS rates were 57% and 25% for patients with complete and partial response after HDCT, respectively. The comparison of the outcome of patients with and without HDCT was not possible because of the bias introduced in the nontransplant group: 82% of patients without HDCT died after a median time of 1 year.[25]

High-Risk Localized Tumors

A few institutions have used a single transplant to treat high-risk patients (large primary tumors or tumors of the pelvis or trunk) with localized disease. Five-year survival rates of 48% to 71% have been reported.[48,51,114] Although the results are clearly better than standard treatment for similar high-risk groups treated historically, recent intensified regimens without end-intensification appear to give similar results[24,30,51] showing that intensifying systemic therapy for patients with high-risk localized disease has improved survival rates, whether the intensification is with an ablative approach or more intensive conventional chemotherapy.

Two cooperative groups used HDCT-BuMel as consolidation treatment for high-risk localized ES, defined by poor histologic response to induction chemotherapy,[68,115] which have reported encouraging results. These studies were the basis of EE99-R2 (localized disease). Results of this trial were present in ASCO 2016.[116] Between 2000 and 2013, from 477 patients classified as high-risk patients, 216 were randomized to VAI or HDCT-BuMel. Some patients requiring RT to the primary site were excluded to avoid excess organ toxicity from interaction between RT and busulfan. In an intention to treat analysis, the risk of an event was significantly decreased by HDCT-BuMel compared to VAI: 3-year EFS was 67% using BuMel versus 53% after VAI (P = .023). OS was also significantly better after HDCT-BuMel.

TREATMENT AFTER RELAPSE

The prognosis after relapse is poor, with a 5-year OS of only 13% for patients recurring after treatment in the CESS 81, CESS 86, and EICESS 92 studies. Patients experiencing either late (>2 years) strictly localized relapses fared slightly better.[2,117] Relapse occurring only at the local site warrants aggressive attempts at salvage.[117] To date, no standard treatment has been defined in such situation. Patients who relapse only with lung metastases can sometimes be salvaged with additional chemotherapy and WLI. Resecting the lung metastases, if there are fewer than four lesions, may also be beneficial.[118] Patients with late pulmonary relapses fare better than those with early relapses.[65] Patients who relapse with bone metastases, however, are essentially incurable with standard therapy.

Interesting response rates have been reported in retrospective studies or in phase II trials, including topotecan–cyclophosphamide,[119] temozolomide–irinotecan,[120] gemcitabine–docetaxel,[121] and high dose ifosfamide.[122] The role of HDCT for tumors, which respond to second-line therapy, is controversial, with both positive and negative results reported in retrospective and single-arm studies.[123]

SEQUELAE OF TREATMENT

ESFT has been reported to have an actuarial complication rate of 70% at 35 years.[124] Paulino et al. reported that 10 (53%) of 19 patients receiving RT alone, 4 (25%) of 16 receiving surgery alone, and 2 (40%) of 5 undergoing combined surgery and RT therapy had significant late effects.[41]

More recently, a retrospective chart review of 101 pediatric patients reported the most common complications were musculoskeletal abnormalities (50%) and cardiac toxicity (28%).[125]

Neither study included loss of function related to planed surgical resection as a complication.

The most common skeletal complication of RT is abnormal growth and development of the irradiated tissues. RT can cause premature closure of active epiphyses, producing growth deficits and limb-length discrepancies. The degree of discrepancy depends on the RT dose, patient’s age, and epiphysis radiated. Because 65% of leg growth is from the distal femoral (37%) and proximal tibial (28%) epiphyses, typical RT doses to the knee in boys younger than 14 years of age and girls younger than 12 years of age will usually cause a severe enough leg-length discrepancy to require intervention.[126] Deficits of 2 to 6 cm can

usually be managed by a shoe lift; larger deficits require surgical treatment.

Approximately 15% of long bone lesions develop pathologic fractures at some time in their course, 5% at diagnosis, and 10% after RT, although approximately one-third of the latter are caused by tumor recurrence or occasionally a secondary malignancy.[127] Whether the fracture is disease or treatment related, the most common site is the femur, particularly the proximal femur. RT-related fractures usually occur within 24 months after treatment, but can be much later. Doses below 40 Gy using once-a-day doses of 1.8 to 2.0 Gy appear to have a very low risk, as does a hyperfractionated approach using 1.2 Gy twice a day from 50.4 to 55.2 Gy.[60,127]

Extremity weakness, decreased range of motion secondary to fibrosis, pain in the extremity (particularly in the early morning), discoloration of the skin, and lymphedema can also occur after RT, even with careful planning and sparing of an adequate strip of tissue.

The risk of secondary neoplasia at the site of the primary lesion is related to RT dose, with an increased risk at doses >60 Gy. Sarcomas, often osteosarcoma, are the most common second tumor, and the risk for megavoltage treatment has been reported as 1% to 5% at 20 years.[20,125,128,129] The Italian Sarcoma Group Experience was reported, following 543 patients with ESFT, treated between 1983 and 2006. Fifteen patients (2.8%) experienced a secondary cancer. The cumulative 10- and 20-year incidence was 3.4% ± 0.9% and 4.7% ± 1.6%. The most common SMN in the ESFT group was RT-induced osteosarcoma (n = 6).[130]

In a recent paper, the British Childhood Cancer Survivor Study reported cause-specific mortality and risk of secondary neoplasms for 664 bone sarcoma survivors.[131] Beyond 25 years of follow-up, the risk of dying from all causes was comparable to the general population. In contrast, before 25 years, the risk was 12.7-fold than expected. Survivors were four times more likely to develop a secondary cancer than expected (bone and breast mainly), but the excess was restricted to 5 to 24 years post diagnosis.

The quality of life of 618 long-term survivors of ESFT was recently reported. Median observation time was 12.9 years from primary diagnosis. Survivors were less active than control subjects, but the recommended level for an active lifestyle was achieved. Pelvic tumor location was the major inferior disease-specific prognostic factor as well as older age at diagnosis and female sex.[132]

FUTURE CONSIDERATIONS

Although the 5-year survival rate of patients with ESFT appears to have improved since 1970, almost half of all patients diagnosed with Ewing tumor die of it within 10 years.[3] Outcomes for patients with metastatic disease and recurrent ESFT especially remain poor with current strategies.[125] Several randomized trials are ongoing for localized ES. The VIDE induction chemotherapy is considered the standard chemotherapy for ES in Europe, whereas the compressed VDC-IE is the standard in North America. The ongoing EE2012 trial is comparing those two regimens to define the international standard chemotherapy for ESFT. The benefit of adding zoledronic acid to maintenance conventional chemotherapy is also randomized in this trial, as well as in the Ewing 2008 study by GPOH.

The COG-AEWS1031 trial is currently evaluating the addition of cyclophosphamide/topotecan to the compressed VDC-IE. The Italian group ISG/AIEOP EW-1 trial randomizes a prolonged treatment versus a shorter dose-intense treatment.

For high-risk patients, HDCT has proven better results for patients with high-risk localized disease at diagnosis, but the limits of intensification have probably been reached with the presently available drugs. Other drugs are being tested for metastatic patients and recurrences.

The Ewing family of tumors is characterized by the t(11;22)(q24;q12) translocation that generates the EWS-FLI1 fusion transcription factor producing the malignant EWS cell. Because continued expression of EWS-FLI1 is believed to be critical for ESFT cell survival, clinically effective small molecule inhibitors have been sought.

Mithramycin has been reported to inhibit expression of EWS-FLI1 downstream targets at the messenger RNA and protein levels.[133] YK-4-279, a small molecule found by researchers at Georgetown University (Washington, DC) in a library of small molecules supplied by the National Cancer Institute, stops EWS-FLI1's fusion protein from sticking to RNA helicase A, inducing apoptosis in ESFT cells, and reduces the growth of tumor cells.[134] The most promising targeted therapies are those acting on the microenvironment and are under research.[27]

With regard to local therapy, the focus should be on improving function and decreasing the incidence of long-term sequelae. The use of IMRT therapy and proton therapy, as well as smaller margins, should spare significantly more normal tissues than older techniques, probably decreasing late effects. However, it is unlikely that refinements in local therapy with RT or surgery will

significantly improve the cure rate for patients with apparent localized disease, although treating all metastases with RT or surgery appears to be promising for high-risk patients. Stereotactic body radiation therapy (SBRT) may help treat some patients, especially in case of oligometastatic situation. Feasibility and toxicity are currently under evaluation in pediatric patients (ongoing French National protocol 2013-A01176-39).

CHAPTER 93

Lymphomas in Children

Avani Dholakia Rao, Louis S. Constine, Stacy Lorine Cooper, and Stephanie A. Terezakis

INTRODUCTION

Childhood lymphomas, a broad spectrum of cancers, have become increasingly curable as treatment regimens have evolved in tandem with improvements in radiation and chemotherapy, pathology, and imaging. The challenge has been to optimally balance treatment intensity with its attendant toxicity. Treatment with adult regimens, although effective, caused unacceptable morbidities in children, such as impaired musculoskeletal development, increased risks of secondary benign and malignant neoplasms, cardiopulmonary toxicities, and other organ toxicities. Consideration given to mitigation of therapy toxicity is paramount to the design of modern pediatric trials. Although there is a focus on intensification of therapy in children with unfavorable prognosis, the field is also moving to refine and even deescalate treatment in children with a favorable prognosis. In addition, recent data have established early response to therapy as a tool to identify patients with more sensitive disease in whom therapy can be reduced or patients with more aggressive disease in whom therapy should be escalated.

Commensurate with the identification of prognostic and predictive factors, widespread use of modern imaging techniques, and the increasingly effective use of chemotherapy has been a more restrictive role for radiotherapy. Our recognition of the long-term sequelae of therapy has led to the refinement of both chemotherapy and radiation therapy (RT) strategies.

HODGKIN LYMPHOMA

Hodgkin lymphoma (HL) constitutes a class of diseases that arise in both children and adults. Although histologic similarities between adult and pediatric subtypes exist, there are a number of differences to suggest that the biology is

only partially shared. For example, the clinical presentations vary in terms of the gender ratio, distribution of histologic subtypes, hypotheses of etiology, and the role of Epstein-Barr virus (EBV), as well as the potential for cure.[1] Historic therapies, though successful in adults, caused substantial morbidities in children.[2,3] As patients were often cured, children with pediatric HL have served as models for understanding the long-term toxicity of RT and chemotherapy. High dose extended field RT causing musculoskeletal hypoplasia and cytotoxic therapy with certain alkylating agents prompted the first generation of studies examining combined modality therapy using lower doses and/or smaller fields during RT with the expectation that cycles of multiagent chemotherapy could eradicate microscopic foci of disease in children staged with laparotomy.[4–9] The unacceptable rates of secondary malignancies attributed to the offending alkylating agents led to the second generation of investigations using doxorubicin-containing chemotherapy regimens to replace more toxic alkylating agents. Overall, recent 5-year survival rates of children and adolescents with HL have increased to 97% from 87% in the late 1970s.[10]

TABLE 93.1 RECOMMENDATIONS FOR TREATMENT APPROACH IN CLASSIC PEDIATRIC HODGKIN LYMPHOMA

Clinical Presentation	Stage	Recommended Treatment Approach
Low risk Localized disease involving <3–4 nodal regions in the absence of "B" symptoms, bulky disease, or extranodal extension.	IA, IIA	**Recommended therapy** 2–4 cycles non–cross-resistant chemotherapy (OEPA, VAMP, COPP–ABV, AV–PC). Response-based low dose ISRT (1,500–2,550 cGy). **Other considerations** If complete response after 2 cycles of OEPA, no need for ISRT.
Intermediate risk Localized disease involving ≥3–4 nodal regions in the presence of bulky lymphadenopathy (mediastinal ratio ≥33%; lymph node mass ≥6–10 cm) and extranodal extension.	IA, IIA, IIB[a] IIIA	**Recommended therapy** 3–6 cycles compacted, dose-intensive, non–cross-resistant chemotherapy (OEPA/COPP, ABVE–PC) plus low dose ISRT (1,500–2,550 cGy). **Other considerations** ABVE–PC x 4 without RT for rapid early responders after 2 cycles and complete response after cycle 4.
High risk	IIB[a]	**Recommended therapy**

Stage II patients with constitutional symptoms of fevers or weight loss or any patient with advanced disease.	IIIB IV	4–6 compacted, dose-intensive cycles of non–cross-resistant chemotherapy (COPP/OEPA, ABVE–PC) plus low dose ISRT (1,500–2,550 cGy). **Other considerations** 8 cycles non–cross-resistant chemotherapy alone (BEACOPP) for high-risk, poor early response.

Note: In treatment centers where prechemotherapy, postchemotherapy, and radiation simulation imaging are all obtained in the same position with the radiation simulation immobilization device, then involved-node radiation therapy (INRT) can be considered instead of ISRT.

[a]Stage IIB patients have been variably treated as intermediate or unfavorable risk. Some studies use associated factors, for example, weight loss, bulk disease, and extranodal extension, for further risk stratification.

ABV, doxorubicin, bleomycin, and vinblastine; AV–PC, doxorubicin, vincristine, prednisone, and cyclophosphamide; BEACOPP, bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, prednisone; COPP, cyclophosphamide, vincristine, procarbazine, prednisone; ISRT, involved-site radiation therapy; OEPA, vincristine, etoposide, prednisone, and doxorubicin; VAMP, vinblastine, doxorubicin, methotrexate, and prednisone.

Today's treatment of children with lymphoma employs thoughtful chemotherapy regimens and nuanced radiation approaches in an effort to mitigate long-term toxicity (Table 93.1). Decisions for treatment are determined using a risk-adapted approach in which patients receive varying intensities of multiagent chemotherapy and low dose involved field RT, with the most recent studies using treatment response to guide elimination of RT in certain patients.[5,6,8,9,11–36] Future directions will aim to identify and subsequently integrate biologic factors to guide therapy in patients with very good or very poor outcomes.

Epidemiology

Pediatric HL has unique epidemiologic presentations that vary based on age, geography, gender, and socioeconomic status. The most common subtype, nodular sclerosing or classic HL, is separated into childhood HL, which occurs in patients ages 14 years or younger and young adult HL, which affects patients ages 15 to 34. In the United States, childhood HL is the eighth most common cancer in children (ages 0 to 14), and young adult HL is the most common malignancy of adolescence (ages 15 to 16).[10] Although the incidence of non-Hodgkin lymphoma (NHL) is slightly more common than childhood HL in children younger than 14, comprising 6% versus 4% of all cancer diagnoses, young adult HL constitutes 15% of new cancer diagnoses compared to 8% being

NHL in adolescents.

The childhood form of classic HL is rare in children < 4 years of age, usually occurring in children >10 years. Incidence is associated with male gender, increasing family size, and decreasing socioeconomic status.[37–40] In the United States, although whites have the highest overall incidence rates for both males and females, the male gender association of childhood HL is strongest in black males (M:F ratio 4:1). There is a marked variation in international incidence of HL, with an inverse relationship between the occurrence of childhood and young adult forms of the disease.[41–43] Countries with a high incidence of childhood HL demonstrate a low incidence of young adult HL and vice versa. Early and intense exposure to an infectious agent has been speculated to increase the risk for the childhood form of HL.[44,45]

In contrast to childhood HL, young adult classic HL is associated with a higher socioeconomic status, smaller family size, and later birth order.[37,38,45] There is a roughly equal incidence between older adolescent males and females.[46] Similarities between HL and paralytic poliomyelitis suggest that delayed exposure to an infectious agent may be a risk factor for the development of young adult HL, with the risk of oncogenesis increasing with later age of infectious exposure.[38] Interestingly, there also seems to be an association of early exposure to children at nursery school and day care decreasing the risk of young adult HL, most likely by facilitating childhood exposure to common infections and promoting maturation of cellular immunity.[45]

A less common subtype, nodular lymphocyte-predominant HL (NLPHL), represents approximately 5% of pediatric HL diagnoses. It is associated with a much higher incidence in males, Caucasians, and younger children (<10 years) and does not have a strong association with income or birth order. The other subtypes of HL, such as mixed cellularity (MC), lymphocyte-rich, and lymphocyte-depleted, are extremely rare in children and young adults.[47]

Pathologic Classification

As in adults, pediatric HL follows the same WHO classification into two major groups of HL: classic HL and NLPHL. Distinctions between groups are made according to their biologic and clinical features, which will be discussed later in following sections.[48,49] Classic HL is further subclassified into nodular sclerosing (NS), MC, lymphocyte-rich (LR), and lymphocyte-depleted (LD) histologies based on their unique morphology. NLPHL appears to have a better outcome, and treatment typically varies from those with classic HL.

The relative distribution of the subtypes differs in younger children compared with adolescents and adults.[40,50] Although NS is the most common subtype in all age groups, it constitutes a significantly larger proportion of cases of adolescent (77%) and adult (72%) HL than in children < age 10 (44%). Conversely, MC subtype is more common in younger children (33%) than in adolescents (11%) or adults (17%). Similarly, NLPHL is more common (13%) in children younger than 10 years than in adolescents (8%) and adults (5%). LD subtype is rare in all age groups.[40]

Biology

Similar to adult HL, both pediatric HL and NHL are neoplasms arising from the germinal center of lymph nodes. HL is unique among the lymphomas because the malignant Hodgkin and Reed-Sternberg (HRS) cells, lymphocytic and histiocytic (L and H) cells, and their variants account for <1% of the tumor cell population. Identical immunologic gene rearrangements in HRS and L and H cells support their origin from a single transformed B cell that subsequently undergoes monoclonal expansion.[51–53] There are two distinct immunophenotypes of HL, which distinguish the differentiation of HL into World Health Organization's classifications of classic HL and NLPHL.[48] The first immunophenotype associated with classic HL is characteristic of HRS cells that consistently express CD30 and often express CD15 but lack J chain expression.[48,54] The second immunophenotype associated with NLPHL is characteristic of L and H cells that consistently express CD20 and J chain and do not express CD30 and CD15.[53,55]

Considerable evidence suggests an etiologic role of the EBV in the pathogenesis of both childhood and young adult HL.[56,57] Early serologic studies linked EBV to HL.[56,57] Delayed early adolescent exposure to EBV is frequently associated with development of infectious mononucleosis, and studies show an increased risk of HL in patients diagnosed with infectious mononucleosis.[58–63] Additionally, increased EBV antibody titers have been observed in patients with HL several years prior to HL diagnosis.[64] The incidence of EBV-associated HL varies by age, gender, ethnicity, histologic subtype, and regional economic level.[57] EBV-positive tumor genomes are more frequent in children <10 years of age and in those who live in low-income countries.[57] EBV positivity is most common in the MC and lymphocyte-depleted HL subtypes, observed in approximately 80% of children ages 0 to 14 with these subtypes of HL. Tumors of children with nodular sclerosing HL were found to be EBV-positive in nearly

40% (childhood HL) and 20% (young adult HL) of cases.[57] A detailed description of the histologic subtypes of HL is discussed below.

HL is also associated with congenital (e.g., ataxia-telangiectasia)[65] and acquired (e.g., human immunodeficiency virus [HIV]) immunodeficiencies, and EBV appears to be an important cofactor in the development of HL in these patients.[66] Concordance of HL has been observed in first-degree siblings to have a 3-fold increase risk in HL[67] with other studies suggesting as high as a 9-fold increased risk in siblings of the same gender. As high as a 99-fold increased risk in monozygotic twins of patients with HL has been reported, with no increased risk in dizygotic twins.[68] These familial cases of HL suggest a genetic predisposition to the disease or a common environmental exposure.

Clinical Presentation

Typical presenting signs and symptoms include lymphadenopathy, mediastinal mass, or systemic symptoms. Up to 90% of patients will demonstrate contiguous lymphatic spread with 80% of pediatric HL patients presenting with cervical lymphadenopathy.[69] The lymph nodes are often fixed, firm, rubbery, and painless. Mediastinal involvement is present in 76% of adolescents but only in 33% of children aged 1 to 10 years.[69] If mediastinal lymphadenopathy is present, it may be associated with a nonproductive cough, respiratory distress, or other symptoms of tracheal or bronchial obstruction. Isolated infradiaphragmatic HL is rare, occurring in <5% of patients.

As a result of cytokine production by the HRS cells, one-third of patients may have one or more of the so-called B symptoms at diagnosis. These include recurrent unexplained fevers >38.3°C during the previous month, drenching night sweats, or weight loss of more than 10% in the 6 months preceding diagnosis.[69,70] Other cytokine-mediated systemic symptoms may also include anorexia, pruritus, fibrosis, eosinophilia, thrombocytosis, plasmacytosis, and immunodeficiency.[71]

Diagnostic Workup

The diagnosis of HL is made based on morphology, immunohistochemistry, and flow cytometry reviewed by experienced lymphoma pathologists. When appropriate, molecular studies may be needed for further characterization. The diagnosis is facilitated through an excisional lymph node biopsy to provide adequate tissue for evaluation of the malignant HRS and L and H cells and the characteristic architectural changes associated with the specific histologic

subtypes. Although less desirable, core needle biopsy can be considered when excisional biopsy is not possible; however, lack of adequate tissue sampled and inappropriate tissue sampling are common causes of failure of this diagnostic approach.[72] Fine needle aspiration (FNA) is neither helpful nor cost-effective and may even misguide treatment as diagnoses based on FNA often do not correlate with evaluations on subsequent excisional biopsies.[73]

A detailed history should evaluate the age, sex, and absence or presence of B symptoms, each of which may alter the management of a child with HL. Fatigue, pruritus, and alcohol-induced pain should be noted. Though these symptoms do not direct treatment, their recurrence may be an early indication of disease relapse. Physical exam involves a detailed lymph node exam, including assessment of Waldeyer ring, as well as measurement of the liver and spleen. Laboratory evaluation should include a complete blood count with white blood cell differential and platelet count, erythrocyte sedimentation rate, albumin, renal and liver function tests, and lactate dehydrogenase.

An upright posterior–anterior chest radiograph is required for assessment of mediastinal bulk defined as mediastinal adenopathy measuring 33% or more of the maximum intrathoracic cavity. Chest radiograph is highly concordant with chest computed tomography (CT),[74] although chest radiograph is still required to define bulk in the majority of protocols including those run by the Children's Oncology Group (COG). Contrast-enhanced CT is recommended for evaluation of the thorax as it can detect lymphadenopathy involving the subcarinal, hilar, and cardiophrenic angles as well as extranodal sites including the pleura, chest wall, or pericardium, which may change management.[75]

Infradiaphragmatic disease is best assessed by CT scan with oral and intravenous contrast to distinguish lymphadenopathy from other structures. CT evaluation of the abdomen and pelvis may be limited, however, with suboptimal contrast administration or in children who lack retroperitoneal fat. In such cases, magnetic resonance imaging (MRI) may provide better assessment of disease involvement in the retroperitoneal lymph nodes.

Essentially all cases of HL demonstrate (18)fluorine-fluorodeoxyglucose ([18]F-FDG) avidity,[76] and thus [18]F-FDG positron emission tomography (PET) is included as standard staging for HL.[77] [18]F-FDG-PET scans lead to a change in stage in 10% to 30% of patients, more often upstaging.[78] [18]F-PET-CT is furthermore critical in monitoring treatment response, particularly in cases with persistent radiographic abnormalities[79] or "rebound" thymic growth after completion of therapy.[80] Splenic and hepatic involvement by HL is suggested by

the presence of enlarged organs with areas of abnormal density on CT or MRI scans, as well as increased [18]F-FDG uptake on PET scan.

Traditionally, bone marrow biopsy was standard in lymphoma staging; however, given the low rate of bone marrow involvement at initial presentation, particularly in the setting of a negative [18]F-PET-CT for bone marrow involvement, bone marrow biopsy can be restricted to patients with B symptoms or stage III or IV disease.[77]

TABLE 93.2 REVISED ANN ARBOR STAGING SYSTEM

Stage	Involvement	Extranodal (IE) Status
Limited		
I	One node or a group of adjacent nodes	Single extranodal lesions without nodal involvement
II	Two or more nodal groups on the same side of the diaphragm	Stage I or II by nodal extent with limited contiguous extranodal involvement
II Bulky[a]	II + "bulky" disease[a]	
Advanced		
III	Nodes on both sides of the diaphragm Nodes above the diaphragm + spleen involvement	
IV	Additional noncontiguous extralymphatic involvement	
Modifications	If Present	If Absent
B symptoms	*B*	*A*
Bulky disease[a]	*X*	—
Extranodal spread	*E*	—
Splenic involvement	*S*	—

Positron emission tomography–computed tomography used to define extent of disease in HL. Tonsils, Waldeyer ring, and spleen are considered nodal tissue.
[a]Bulky definition varies across protocols but most commonly as a mass of more than one-third of the maximum intrathoracic diameter or extramediastinal mass >6–10 cm.

Staging Systems

As for adults, children with HL are staged according to the system devised at the Ann Arbor Staging Conference in 1970 and revised at the Cotswolds meeting.[81] Patients are typically treated based on limited (stages I and II, nonbulky) or advanced (stages III or IV) disease, with stage II bulky considered limited or

advanced based on other prognostic factors as shown in Table 93.2.

Prognostic Factors

A discussion of prognostic factors in pediatric HL is complicated for several reasons. First, prognostic factors such as disease stage, bulk, and biologic aggressiveness are frequently codependent.[82] Second, identification of prognostic factors is confounded by the impact of therapy, with higher-intensity therapies negating previously determined adverse risk factors.[83] Third, different institutions and different cooperative groups have various risk stratification schemes within pediatric HL protocols,[33,35,36,84–90] and within these determinations, patients with early-stage disease have different prognosticators than patients with advanced-stage disease.[82]

The following are some generalizations regarding prognostic variables derived from both adult and pediatric data:

- *Stage of disease* is the most significant prognosticator of treatment outcome. Advanced-stage disease, particularly stage IV disease with multiple organ involvement, confers an exceptionally poor prognosis when managed with conventional therapy.[91,92]
- *Bulk of disease* is reflective of both the number of disease sites and the volume of involvement at each site. Patients with several sites of involvement, typically three or more, have an inferior relapse-free (RFS) and overall survival (OS) in some, but not all, reports.[93] Bulky mediastinal adenopathy and nonmediastinal sites have historically been associated with an increased risk of disease recurrence, particularly when managed with RT alone.[93–96] Bulky mediastinal adenopathy has been defined using a variety of definitions, most commonly as a mass of more than one-third of the maximum intrathoracic diameter.[96–99] Other common definitions include a ratio of greater than 1/3 of the mediastinal mass to the intrathoracic width at T5-6[100] or an absolute mass of >10 cm,[101] ≥5 cm,[102] or ≥6 cm[103,104] depending on the protocol. In Europe, a volume definition of bulk is used, recently defined as 200 mL estimated using an ellipsoid volume formula where $V = (xyz)/2$ where x, y, and z are the diameters of the mass in three dimensions.[105]
- *Presence of systemic symptoms* (B symptoms), which result from cytokine secretion, reflects biologic aggressiveness and correlates with an increased risk of relapse compared with the absence of such symptoms (A disease).[70,92]
- *Abnormally high levels of certain serum markers*, including ESR, hemoglobin, serum albumin, and white blood cell count, have been reported to be negative prognostic factors.[82,92] As these are confounded by increased tumor volume, it

is unclear if elevated serum markers are independently prognostic for more malignant biology of disease.[82,92]

- *Histologic subtype* may correlate with prognosis. Patients with NLPHL have a unique biology and improved outcomes compared to other classic HL histologies. LD histology confers a worse outcome than do the other subtypes, but it is exceedingly rare.[96] Patients with LP histology are more commonly early stage and have an excellent outcome.[106] A recent COG study reported a survival advantage for patients with mixed cellularity HL,[107] however, most moder combined modality trials do not show any histology survival differences.[27,92]
- *Patient age* appears to be a determinant of patient outcome with children <10 years of age seemingly faring better than older patients with 5- and 10-year survival rates of 94% and 92%, respectively, compared with 93% and 86% for adolescents and 84% and 73% for adults.[40,50] This may be due to the higher prevalence of stage "A" disease in children compared to adults.[50]
- *Response to initial therapy* has recently been identified as a prognostic factor, observed in pediatric patients with advanced-stage HL treated on Pediatric Oncology Group (POG) 8725, where 93% of patients who attained a complete response after three cycles of chemotherapy remained disease free.[8] A similar finding was also observed in low-risk patients.[108] Early treatment response has since become the foundation for new trials and recommendations for response-based therapy that are discussed separately in the section "Risk-Adapted Combined Modality Therapy for Classic Hodgkin Lymphoma" to follow. As this is an emerging prognostic factor and stratification for treatment, definitions for complete response, partial response, and progressive disease based on CT or PET-CT are varied across studies.[33,35,84,109–111] Recently, a visual five-point score known as the Deauville criteria has been shown to be a reproducible approach to score response on PET-CT in adult HL and is being applied as a standard reporting criterion in clinical trials and practice in both pediatric and adult HL.[112,113]

In efforts to define a prognostic risk scoring group for pediatric HL patients treated with modern-era combined modality therapy, a retrospective analysis of the most recent COG study AHOD0031, which analyzed response-based therapy in intermediate-risk patients, was introduced. The Childhood Hodgkin International Prognostic Score (CHIPS) is a new scoring system that allocates one point each for fever, stage IV disease, albumin < 3.5, and large mediastinal adenopathy (defined as mass of more than one-third of the maximum intrathoracic diameter).[114] CHIPS was highly predictive of event-free survival

(EFS), and the scoring system identified a subset (CHIPS 2 or 3) that comprised 27% of intermediate-risk patients with inferior outcomes (EFS < 80%) who may benefit from early intensification of therapy.

The use of prognostic factors is reflected in the risk grouping that various pediatric trials employ for assignment of therapy. Such stratifications are discussed below in the “Risk-Adapted Combined Modality Therapy for Classic Hodgkin Lymphoma” section and are reflected in the summary of treatment recommendations.

General Management

Pediatric HL is a highly curable disease. Given the longevity of patients with pediatric HL, treatment is complicated by their increased risk for adverse treatment-related side effects over time.

For patients with early-stage disease, RT to extended fields to a curative dose range of 30 to 40 Gy produced the first cures in patients with HL, and similar treatment paradigms were used for adults and children. In children undergoing surgical staging with early-stage disease, 5-year disease-free survival (DFS) rates following extended-field RT ranged from 60% to 80% when treated with RT alone.[6,12,13,115] For patients with advanced-stage disease, the development of non–cross-resistant chemotherapy combinations provided the first effective therapy; however, the specific chemotherapeutic combinations have changed as their gonadotoxic and leukemogenic properties have become better understood. Although treatment approaches of the past involving large radiation fields, including total lymphoid RT, and toxic alkylating chemotherapy are archaic, the observed late morbidity and mortality as a result of second malignancies, cardiopulmonary disease, musculoskeletal growth retardation, and gonadal toxicity caused by these treatments have steered the management of pediatric HL to balance the efficacy and morbidity of treatments to children at this critical time in their development.[16,94,115–126]

A summary of chemotherapy-alone and combined modality therapy trials for the treatment of pediatric HL is summarized in Tables 93.3 and 93.4. Current management paradigms for pediatric HL involve a risk-adapted and an emerging response-adapted approach to treatment. Therapy typically involves multiagent chemotherapy followed by low dose RT for slowly responding, bulky, residual, or recurrent disease. The development of this treatment approach with the refinement of combination chemotherapy regimens and reduced-field, low dose RT is discussed in the sections to follow.

Combination Chemotherapy

The first effective systemic therapy for HL was MOPP (mechlorethamine, vincristine, procarbazine, prednisone),[144–146] although treatment was associated with ovarian failure in women, infertility in both sexes, and a high rate of secondary acute myeloid leukemia (s-AML).[147,148] The cumulative risk of secondary malignancy is 4% to 8% after MOPP-based therapy,[149] with incidence peaking 5 to 10 years after treatment and plateauing to a cumulative risk of 2% more than 10 years following treatment.[150] A regimen substituting cyclophosphamide for mechlorethamine (COPP) has been associated with a lower incidence of s-AML.[149]

Subsequently, an alternative regimen using ABVD (doxorubicin, bleomycin, vinblastine, and dacarbazine) was shown to result in superior disease control compared to MOPP chemotherapy.[151,152] Despite improvements in chemotherapeutic side effects, bleomycin and doxorubicin cause pulmonary and cardiovascular damage, respectively, each enhanced when combined with RT to the lungs and heart.[14,95,119,153] One approach to reduce the risk of cardiomyopathy caused by doxorubicin, an anthracycline agent, is to limit the cumulative dose of anthracyclines for pediatric HL patients to a maximum cumulative of 250 mg/m^2, particularly in the case of favorable risk disease. Bleomycin-induced pulmonary toxicity is manifested as a chronic pneumonitis or pulmonary fibrosis and typically occurs at doses higher than 400 U/m^2.[154] Most modern pediatric HL regimens use doses in the range of 60 to 100 U/m^2. Although such doses typically result in subclinical pulmonary restriction and diffusion defects, toxicity can be exacerbated by thoracic RT. Serial pulmonary function tests during therapy are recommended, and if a compromise in function of 20% or more from baseline is observed, bleomycin can be held.[155]

To reduce the treatment-related toxicities associated with six cycles of either MOPP or ABVD, strategies alternating the two regimens, and using fewer cycles of each, have been developed. The combined ABVD and MOPP regimens used for children have produced excellent disease control with apparent diminished toxicity.[26,68,156]

Etoposide, a topoisomerase II inhibitor, has been incorporated into the treatment regimens for advanced and unfavorable HL to intensify therapy and as an alternative to alkylating agents to reduce gonadal toxicity (e.g., ABVE–PC, doxorubicin, bleomycin, vinblastine, etoposide, prednisone, cyclophosphamide).[19,24,35,88,138,142] The secondary malignancy risk with topoisomerase II inhibitors is due to a unique pathogenesis from the alkylator-related s-AML described above,[157] and the risk is compounded with the use of multiple topoisomerase II inhibitors as seen in the POG trial of dexrazoxane

(topoisomerase II inhibitor) as a cardiopulmonary protectant during treatment with ABVE or ABVE–PC with unacceptably high rates of s-AML attributed to the use of multiple topoisomerase II inhibitors.[158] Risk of s-AML is low when etoposide is limited to 5.0 g/m^2 or less. Although chemotherapy intensification may be justifiable in intermediate- and unfavorable-risk patients, the risk of secondary malignancies raises questions about its appropriateness for treatment of children with favorable-risk HL.

Not only is the patient's risk level an important consideration for the balance of toxicity for disease control in the selection of chemotherapy regimens, but gender-adapted therapy has been considered given the differing susceptibility to infertility caused by procarbazine in boys compared to girls. The German Society for Paediatric Oncology and Haematology (GPOH) evaluated a gender-adapted therapy approach using an OEPA (vincristine, etoposide, prednisone, doxorubicin) regimen for boys to limit alkylator exposure, whereas girls received OPPA (vincristine, procarbazine, prednisone, doxorubicin) substituting procarbazine for etoposide.[156,159] The gender-adapted regimen is more commonly utilized in Europe.

Contemporary therapy for pediatric HL using chemotherapy alone or combined modality therapy produces long-term DFS in 85% to 100% of patients with localized disease and 70% to 90% of patients with advanced disease.[5,8,9,11,14–17,19–24,26,28–31,86,87,90,108,117,143,160–162] Multiagent chemotherapy alone is an effective treatment approach for the treatment of pediatric HL.[8,9,11,14,20,24,29,132,163] A chemotherapy alone paradigm eliminates the risk of radiation-specific toxicities such as musculoskeletal complications, thyroid and cardiopulmonary dysfunction, and solid tumor carcinogenesis; however, regimens typically require more cycles and/or higher doses of chemotherapy, and thus, patients are at an increased risk of cardiopulmonary toxicity, infertility, and s-AML. Furthermore, chemotherapy alone may be less effective than combined modality therapy for treatment of bulky and intermediate- or unfavorable-risk disease.[9,87]

In total, three trials in North America have evaluated chemotherapy alone compared to combined modality therapy in pediatric HL patients.[6,7,84,90] Two studies, the first a Children's Cancer Study Group (CCG) study evaluating 12 cycles of alternating MOPP/ABVD versus 6 cycles of ABVD plus low dose (21 Gy) RT[7] and the second POG trial of four cycles alternating MOPP and ABVD with or without low dose RT,[8] failed to show a significant advantage in EFS and OS with the addition of RT. The third study was a CCG-randomized controlled

trial comparing outcomes in patients treated with contemporary risk-adapted combined modality therapy with COPP/ABV (cyclophosphamide, vincristine, prednisone, procarbazine/doxorubicin, bleomycin, vinblastine) hybrid chemotherapy and low dose, involved field RT to those treated with COPP/ABV chemotherapy alone. The study was closed early based on a significantly higher 3-year EFS in patients randomized to also receive RT.[90] However, longer follow-up did not demonstrate a significant difference in OS among the groups because of the successful treatment of relapsed patients following intense, salvage therapy.

In the European experience, the German HL-DAL-90 protocol treated intermediate- and high-risk patients with two cycles of OPPA or OEPA (girls or boys, respectively), followed by two to four cycles of COPP. All patients received 20- to 35-Gy involved field radiation therapy (IFRT). Five-year EFS in the intermediate- and high-risk groups was 93% and 86%, respectively, which was comparable to that seen in the low-risk group. Five-year OS for all three risk groups was ≥94%.[23,26,87,164] In the subsequent HL-95 trial, which employed the same chemotherapy but omitted IFRT in complete responders, the EFS for intermediate- and high-risk patients who did not receive radiotherapy dropped to 79% compared to 91% for those who did get radiotherapy.[87]

Newer agents are emerging and are under evaluation for use in patients with high-risk classic HL, relapsed HL, or NLPHL. Rituximab is an anti-CD20 monoclonal antibody that is being evaluated for its role in NLPHL[165] and NHL.[166,167] Brentuximab vedotin is a conjugate antibody that combines an anti-CD30 antibody with a synthetic tubulin disruptor, has been evaluated for salvage HL and certain NHLs, and is currently being evaluated for its role in the up-front setting in the treatment of high-risk HL in a current COG study.[168]

Thus, although the current consensus regarding the optimal therapy for children and adolescents with HL has not been firmly established, contemporary practice of low dose IFRT (and now involved-site or involved node RT) has substantially reduced the risks of many of the undesirable radiation-associated toxicities while limiting the cycles of chemotherapy through a combined modality treatment. Still, the field is gaining success in identifying select patients who may be treated with multiagent chemotherapy alone using modern refined regimens with reduced s-AML and infertility risks.[33] The current generation of COG studies in pediatric HL evaluates risk- and response-adapted approaches to intensify or deescalate based on risk factors at presentation and response to therapy.

Techniques of Radiation Therapy

Commensurate with the increasingly effective use of chemotherapy has been a more tailored approach to radiation utilizing significant reductions in prescription dose and irradiation volume, particularly over the recent years. Still, RT remains an important component of pediatric HL treatment to complement chemotherapy for slowly responding, residual, or bulky disease and to reduce chemotherapy intensity in selected patients where the predicted late toxicity risk for RT is small.

Unlike the treatment of most adults with HL, children are typically treated at academic or tertiary care centers, often as part of or per the protocol of a clinical trial. Studies have shown that outcomes of patients with HL treated with RT alone were superior at institutions with higher volumes[99] and when patients were treated in compliance with radiation protocols.[169,170] Thus, it is the responsibility of the treating radiation oncologist to confirm the workup, to review and comply with protocol requirements, and to seek experienced guidance when necessary to achieve the best outcomes for patients.

The technique of RT has long since progressed from extended fields, which included total lymphoid, mantle field, and pelvic radiation to IFRT volumes over the last few decades because of concerns of cardiac toxicity and secondary malignancies. Additionally, over the past few years, there has been an even more dramatic shift to involved-node (INRT) or involved-site radiation therapy (ISRT) as the new standard approach for defining the irradiation volume (Fig. 93.1). Instrumental in this progression toward smaller volumes is a balance of the increasing recognition of the late effects of early radiation fields and the high curability and salvage rates of pediatric HL.

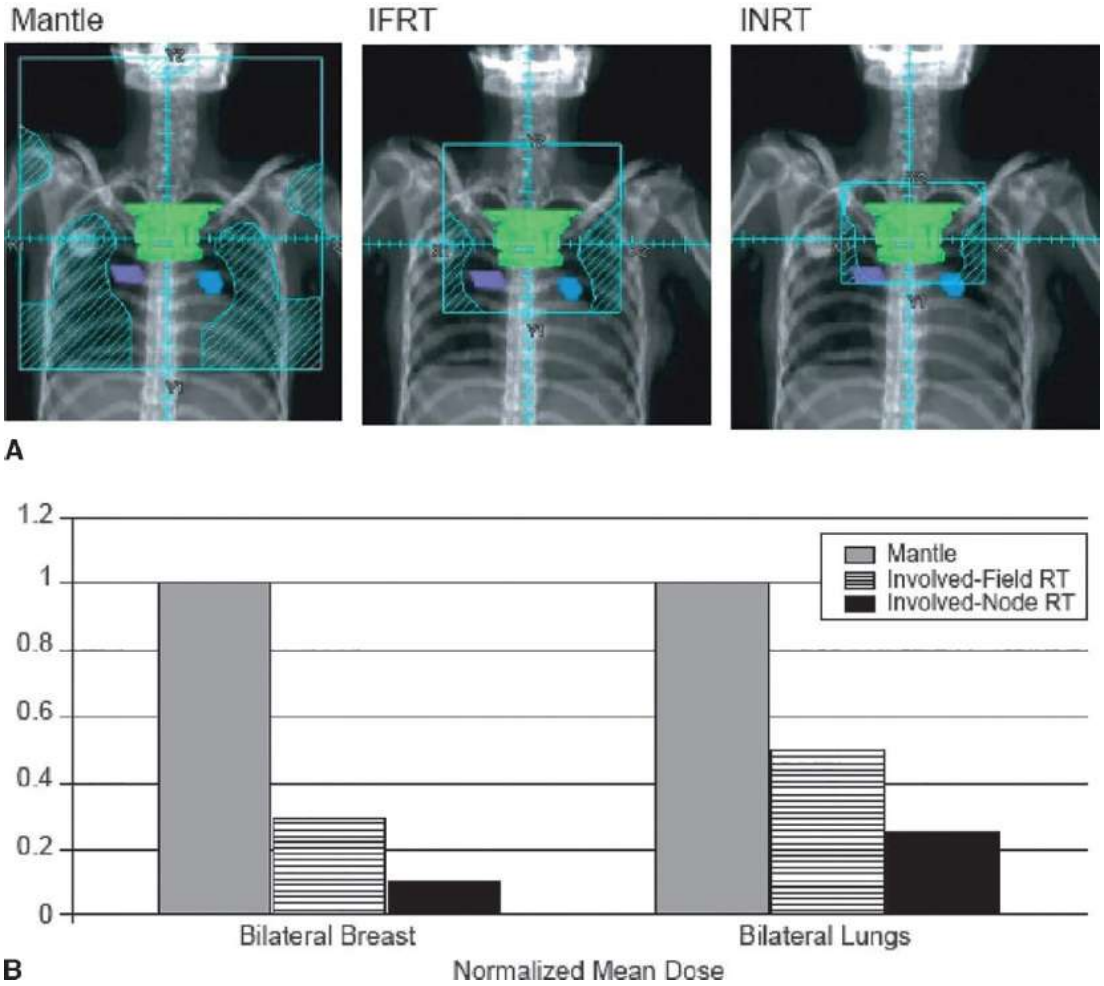

FIGURE 93.1. A: Digitally reconstructed radiographs showing typical RT fields for historic mantle RT, contemporary involved field RT (IFRT), and involved-node RT (INRT) for a patient with stage I disease involving the upper mediastinum. The postchemotherapy volume of initially involved mediastinal nodes is shown in green. Hila are shown in *blue* and *violet*. **B:** Reduction in dose to breast and lung for the female patient shown in **A**. For each volume, the prescribed dose to the CTV is the same. The resulting mean dose to breast and lung tissue with mantle RT is a set value = 1. The proportional reduction in normal tissue dose occurs as a result of the reduction in treated volume with IFRT and INRT. (Reprinted with permission from Hodgson DC, Hudson MM, Constine LS. Pediatric Hodgkin lymphoma: maximizing efficacy and minimizing toxicity. *Semin Radiat Oncol* 2007;17[3]:230–242. Copyright © 2007 Elsevier. With permission.)

The new field designs take into consideration modern technology, including the use of staging PET-CT scans, 3-D and 4-D treatment planning with CT scanning, conformal treatment techniques, and image guidance, replacing IFRT based on 2-D treatment planning and bony anatomy. Historically, IFRT included not just the involved lymph nodes but also the entire lymph node region containing the involved nodes and adjacent uninvolved lymph nodes.[171] These

fields are no longer appropriate for modern, more focused RT aimed at reducing normal tissue exposure.

In an effort to rationally reduce the treatment fields of RT, a review of relapses in patients with HL has shown that recurrence occurs most often in initially involved nodes.[172–174] This suggests that chemotherapy is sufficient to treat microscopic disease in lymph nodes that do not appear abnormal on imaging, and RT is needed to treat sites of gross involvement. Thus, with sophisticated imaging techniques, a concerted effort to scan patients in the radiation treatment position, and more accurate RT delivery, the practice of INRT emerged as an effort by the European Organisation for Research and Treatment of Cancer and Group d'Etude des Lymphomes de l'Adulte (EORTC-GELA) investigators to customize delivery of RT to the radiographically involved regions.[175,176] Such reduction in treatment volumes is feasible largely because of FDG-PET scanning. FDG-PET has been shown to identify involved lymph nodes that were radiographically occult on CT scan in a study of patients with early-stage HL. As such, prechemotherapy FDG-PET can delineate the full extent of disease.[177] Although clinical outcomes with the use of INRT are only just emerging, a study of patients with limited-stage HL treated with INRT revealed no marginal or locoregional recurrences when margins of ≤5 cm were used.[178] Importantly, these margins are significantly larger than those prescribed in the present-day INRT practice. Currently, INRT is being practiced on both the standard and experimental arms of HL studies in Europe,[175] and INRT is being compared to IFRT in a randomized fashion in the German Hodgkin Study Group HD17 trial in unfavorable, early-stage disease in adults.

Paramount to successful INRT is the acquisition of prechemotherapy and postchemotherapy CT and FDG-PET scans with the patient in the treatment position for RT. In North America, ISRT, in contrast to INRT, has recently been introduced and readily accepted as the standard conformal therapy. Although ISRT has not been as formally evaluated as INRT, it is more conservative, designing fields and margins to account for suboptimal imaging information.

Radiation Simulation

When possible, CT simulation for the treatment of children with HL should be carried out with intravenous contrast to best delineate nodal stations and differentiate vessels. Oral contrast may be helpful for treatment of certain abdominal and pelvic tumors. Four-dimensional CT can help assess for target motion and aid in the selection of appropriate margins because of respiratory

movement. If the patient is able to participate with breathhold techniques, deep inspiration breath hold at the time of simulation and treatment can allow for significant sparing of the heart and lung.[179]

Careful consideration of immobilization to be used at the time of simulation can offer significant advantages of increasing the set-up reproducibility, translating into smaller margins needed for set-up uncertainty with the planning target volume (PTV). Additionally, thoughtful patient positioning with the arms above the head to move the axillary lymph nodes away from the lungs, allowing greater lung shielding, may aid in reducing the dose to normal structures. When treating the axilla of patients who are still growing, positioning of the arms above the head may not be recommended because the axillary lymph nodes then move into the vicinity of the humeral heads, which should be blocked in growing children. Thus, the position chosen involves weighing concerns regarding tumor volume coverage and dose delivered to the lung and humeral heads.

Radiation Therapy Target Delineation

Guidelines for INRT and ISRT have been recently published to aid the radiation oncologist in defining treatment volumes.[175,180] The principles of target volume delineation for INRT and ISRT are largely the same, with differences in the quality and accuracy of prechemotherapy imaging suggesting that the margins for ISRT are larger to allow for uncertainties in contouring the clinical target volume (CTV). For both approaches, the pre- and postchemotherapy FDG-PET and CT, if possible obtained in the treatment position using the planned immobilization devices, should be ideally fused with the simulation CT (or simulation PET-CT if available) in the RT planning system. The gross tumor volume (GTV), CTV (and internal target volume [ITV] when relevant), and PTV should be delineated as follows using all the available imaging information on contrast-enhanced CT and PET-CT as shown in Figure 93.2 and described below:

- Prechemotherapy GTV: Gross tumor volume contoured on prechemotherapy CT and PET scans.
- Postchemotherapy GTV: Gross tumor volume contoured on postschemotherapy CT and PET scans.
- CTV: A volume encompassing the superior and inferior extent of the prechemotherapy GTV with the radial extent respecting overtly uninvolved, normal structures (i.e., lungs, kidneys, muscles) based on clinical judgment. The CTV should also take into account the quality and accuracy of imaging,

pattern or spread of disease, changes in the volume of disease since imaging, risk of subclinical involvement, and nearby structures. Nodal volumes that are more than 5 cm apart can be treated as separate fields and do not need to be connected volumes. The CTV for ISRT will generally be larger than that for INRT because of the lack of optimal imaging information. Furthermore, if RT is being used as the sole treatment modality as in NLPHL, the CTV should be more generous as microscopic disease is likely more extensive in the absence of treatment with chemotherapy.

- ITV: Target motion should be accounted for using an ITV as defined in the ICRU Report 62 as the CTV with a margin to consider organ motion for an individual patient.[182] A 4-D CT simulation can be useful to obtain the ITV margins. If unavailable, 1.5- to 2-cm margins may be necessary in the chest or upper abdomen where respiratory movements are significant.
- PTV: This margin should account for uncertainty in setup based on patient factors or immobilization that varies across institutions.

Radiation Therapy Dose

The dose of RT prescribed is in part determined by the intensity and regimen of chemotherapy used in the combined modality approach. Typical doses in the current era of low dose RT are 15 to 25 Gy, with doses rarely exceeding 25 Gy in the pediatric setting.[17,19,31,36,90,115,136,143,155] In North America, the COG has set the standard dose as 21 Gy in 14 fractions.[33,107,183]

Radiation Therapy Planning

Although the anterior–posterior/posterior–anterior (AP/PA) beam arrangement is still commonly utilized in the delivery of RT for pediatric HL, 3-D conformal RT using nonopposed beams, intensity-modulated RT (IMRT), or proton therapy may be considered when the increase in conformality or the unique dose distribution may be favorable for the specific clinical scenario. IMRT and proton therapy may be particularly useful in cases of prior RT or radiation to the thorax to spare dose to the heart, lungs, and developing breast tissue or the abdomen and pelvis to reduce dose to the reproductive organs. IMRT remains controversial in the treatment of children as a result of the concerns that increased integral dose and radiation scatter within the smaller body habitus of a child could lead to an increase in the development of secondary malignancies.[184,185] Proton therapy may offer the advantage of both reduced mean dose to normal surrounding tissue without the increase in volume of normal tissue receiving integral dose through IMRT.[186]

As always, we should strive to achieve dosimetric parameters that are as low as reasonably achievable. Data suggest that the volume getting 5 Gy or more (V5) to the breast and lung tissue may be important in the treatment of young patients with HL.[187] A mean lung dose < 15 Gy has also been shown to result in low rates of radiation pneumonitis.[188]

Gender-based use of RT has been considered, given the predisposition of females to secondary radiation-related cancers. The CCG 59704 high-risk study did include a gender-based consolidation phase with all patients receiving escalated BEACOPP up front. Slow responders received four additional cycles of BEACOPP and IFRT, but rapidly responding males were treated with ABVD with IFRT, whereas females received four cycles of COPP/ABV without radiotherapy to avoid the risks of breast cancer with mantle fields and infertility with pelvic radiation fields.[189–191]

Complications of Radiation Therapy

Acute Effects

The acute side effects of RT are related to the involved site treated. Because of the lower doses used in pediatrics, the most common toxicities include temporary loss or change in taste, xerostomia, esophagitis, low posterior scalp epilation, skin erythema, and occasionally dyspepsia, nausea, and vomiting, all depending on the location treated. Acute effects of para-aortic irradiation include early-onset nausea and vomiting, which usually abates after the second or third treatment without antiemetic therapy. Patients who receive larger fields may be subject to bone marrow suppression, the severity of which may be influenced by the systemic regimen preceding radiation.

Long-Term Effects

Musculoskeletal

Height reduction is a potential long-term consequence of irradiation, most frequently with doses > 20 Gy and most severe in prepubertal children. Growth arrest or delay is modest with the low doses currently used in modern pediatric HL treatment strategies.[192–194] Interclavicular shortening and hypoplasia of the neck muscles may occur in children irradiated before puberty, which is particularly dependent on dose delivered. Avascular necrosis of the femoral or humeral heads is rare if appropriate shielding is provided. Radiation doses of 20 to 40 Gy to the mandible may result in dental abnormalities, such as stunted tooth development, incomplete calcification, premature apical closure or eruption, and root tapering with apical constriction if in the irradiated field.[195]

Cardiovascular

Radiation-associated pericardial and myocardial diseases are related to dose (including fraction size) and volume and are complicated by the use of anthracyclines. Cardiac sequelae, including pericarditis and effusion, valvular thickening, biventricular dysfunction, and coronary artery disease, all are observed with irradiation to the heart.[26,116,119,135] Increase in mortality risk, because of premature coronary artery disease and acute myocardial infarction, has been demonstrated in patients who received mediastinal radiation in doses > 30 Gy before 20 years of age.[117]

Conversely, modern treatment approaches based on tailored low dose radiation and less cardiotoxic chemotherapy, sometimes including cardioprotectants, will optimistically reduce such effects. Radiation doses of <30 Gy and techniques that use adequate cardiac shielding and avoid anterior weighting of the treatment fields appear to reduce the risk of cardiac complications, particularly pericarditis and myocarditis.[116,119] The 45-fold excess mortality risk historically reported from acute myocardial infarction associated with higher radiation doses has diminished substantially with current approaches.[155] Also, dose to the heart can now be calculated using advanced radiation techniques, and dose can be constrained using conformal techniques in order to keep the risk of long-term development of cardiac injury to a minimum. Unfortunately, the impact of low dose RT to the heart may not become apparent until larger cohorts of survivors treated with modern combined modality regimens have longer follow-up.

Pulmonary

Use of bleomycin can increase the risk of acute pulmonary pneumonitis and late

pulmonary fibrosis in patients receiving pulmonary RT. In a report from the CCG, 9% of children treated with ABVD and 21 Gy of mantle irradiation exhibited clinically significant pulmonary damage.[5] These results were confirmed recently in a study evaluating pediatric patients with any chest RT who developed radiation pneumonitis. The incidence was found to be low and most often related to therapies including bleomycin.[196]

Thyroid

Thyroid dysfunction may result from neck or upper mediastinal irradiation and most often is manifested by an elevated serum concentration of thyroid-stimulating hormone (TSH). The incidence of hypothyroidism varies, but it appears to be directly related to irradiation dose. Constine et al.[197] noted an increased serum TSH in 4 of 24 (17%) children who received mantle irradiation of ≤26 Gy and in 74 of 95 (78%) who received >26 Gy. Approximately one-fourth of these children had a concomitant low thyroxine level. In this series, 36% of children experienced spontaneous improvement in thyroid function.

In a Childhood Cancer Survivor Study, thyroid abnormalities were self-reported by 34% of patients surveyed. Hypothyroidism was the most common thyroid disturbance, with a relative risk of 17.1 ($P < .0001$) compared with sibling controls. Risk factors for hypothyroidism include increased dose of radiation, older age at diagnosis of HL, female sex, and Caucasian race.[198] The estimated actuarial risk of hypothyroidism for survivors treated with ≥45 Gy was 50% at 20 years from diagnosis. Other thyroid abnormalities identified in excess from sibling controls included hyperthyroidism (8-fold excess risk), thyroid nodules (27-fold excess risk), and thyroid cancer (18-fold excess risk).[199]

Pelvic Late Effects

Gonadal injuries, including infertility and impaired secretion of sex hormones, are potential complications of pelvic RT.[200] In women, irradiation of the pelvis can affect the ovaries, resulting in premature menopause or fertility impairment.[173] In a report of female HL survivors by the Late Effects Study Group, 42% of women treated with alkylating agent chemotherapy and subdiaphragmatic radiation had experienced menopause by age 31 years, compared with 5% of control subjects.[201] In childhood cancer survivors who continued to have spontaneous menses more than 5 years after their cancer diagnosis, the cumulative incidence of nonsurgical menopause was 8% by age 40 years, representing a 13-fold higher risk compared with a sibling control

group. Risk factors for premature menopause include exposure to increasing doses of ovarian radiation, increasing exposure to alkylating agents (based on the number of agents and cumulative dose), and diagnosis of HL.[199] Normal pregnancies, without increased risk of fetal spontaneous abortion or birth defects, have been reported after pelvic irradiation.[200] In an effort to preserve ovarian function, the ovaries can be transposed via oophoropexy to a shielded area laterally or inferomedially near the uterine cervix prior to the initiation of radiation.

In boys irradiated to the pelvis, oligospermia is common, but it is reversible (usually by 18 to 24 months) in most cases if the radiation dose scattered to the shielded testes is small.[3,148,202] Permanent oligospermia may occur, however, after full-dose pelvic irradiation.[202] Several investigations have demonstrated that fertility is compromised in boys treated with gonadotoxic chemotherapy combinations like COPP, even when cycles of alkylating agent chemotherapy are limited.[156,203] Anthracycline-based regimens such as ABVD (or a similar hybrid) are associated with recovery of spermatogenesis after a temporary period of azoospermia.[204,205] In the modern treatment era, risk-adapted strategies seek to reduce or eliminate gonadotoxic treatments, resulting in excellent potential to preserve fertility in boys.[156]

Secondary Malignant Neoplasms

The 15-year actuarial risk of second malignant neoplasms ranges from 8% to 15%.[117,150,155,187,206–214] Patients are at risk for developing secondary malignancies including leukemias (e.g., acute myeloblastic leukemia) and solid tumors, most commonly breast, thyroid, bone, and soft tissues. The risk of leukemia, which exhibits a peak frequency in the first 5 to 10 years after treatment, is associated primarily with the use of alkylating agents.[206,207] In contrast to secondary hematopoietic malignancies, the risk of developing a second solid tumor increases with time after therapy, with a latency usually exceeding 10 years from diagnosis.

Several studies reveal an increased ratio of observed to expected risk of second tumors for girls compared with boys, with a median follow-up of 10 to 16 years.[189,215,216] A portion of this risk results from breast cancer, which is the most common solid second malignant neoplasm following the treatment of children. The increased risk of breast cancer is a significant concern for women treated for HL at a younger age. This increase in risk of breast cancer is related to the patient’s age at the time of RT and has also been shown to decrease with a

decrease in radiation dose.[217,218] In a large case-control study of 105 women who developed breast cancer from a cohort of more than 3,800 female survivors diagnosed with HL at age ≤ 30 years, the relative risk of breast cancer for a HL survivor treated at age 25 with chest radiation of at least 40 Gy without alkylating agents, the estimated cumulative risks of breast cancer by age 35, 45, and 55 years were 1.4%, 11.1%, and 29.0%.[217]

Multiple studies have now demonstrated that lower RT dose and smaller treatment fields should translate into a reduction in late effects when used judiciously.[123,125,219,220] Historical extended-field treatments included a substantial amount of breast tissue in the field design, which were then exposed to full-dose RT. Interestingly, breast tissue exposure was most significant when the axillae were irradiated in a typical mantle field as opposed to the mediastinal and hilar region. The practice of prophylactically irradiating the axillae is no longer performed, and, thus, the volume of breast tissue exposed to RT using involved-site or involved-node radiotherapy approaches is substantially less.[123] Using CT-based planning, the breast tissue can also be contoured as an avoidance structure and thereby shielded appropriately when designing RT fields in the region, a practice that was not used 30 years ago.

Current recommendations for the screening of late effects of therapy after childhood cancer can be found in the long-term follow-up guidelines developed by the COG, which are frequently updated (http://www.survivorshipguidelines.org).

Risk-Adapted Combined Modality Therapy for Classic Hodgkin Lymphoma

The sequence of therapy in the setting of combined chemotherapy and irradiation generally utilizes chemotherapy as the first modality. This allows assessment of drug response, maximization of the amount of drug treatment, and shrinkage of disease with more limited fields of irradiation. Rarely, focal irradiation prior to chemotherapy is necessary because of significant symptomatic compromise such as airway obstruction.

Current recommendations for therapy follow a risk-adapted approach based on features at presentation including B symptoms, mediastinal and peripheral lymph node bulk, extranodal extension of disease, number of involved nodal regions, Ann Arbor stage, and gender.[27,50,70,82,91–98,100,106,107] The most recent COG risk stratification defines patients into risk groups as follows:

- Favorable risk: stages IA and IIA without bulk

- Intermediate risk: stages I to IIA with bulk, I to IIAE, I to IIB, IIIA, and IVA
- High risk: stages IIIB and IVB

In Europe, an integrated EuroNet cooperative group most recently has categorized patients into treatment groups (TGs) based on risk as follows[105]:

- TG-1: stages IA/B and IIA, without bulk ≥200 mL, and ESR < 30 mm/h
- TG-2: stages IEA/B, IIEA, IIB, or IIIA and stages IA/B and IIA with bulk ≥200 mL or ESR ≥ 30 mm/h
- TG-3: stages IIEB, IIIEA/B, IIIB, or IVA/B

The response to chemotherapy as assessed on CT and FDG-PET has been found to be a significant prognostic factor.[8,108] As a result, it has prompted the most recent series of trials to determine if response, either early during chemotherapy or after its completion, can be used to guide a reduction or intensification of therapy.[9,33,35,84,108–111,140,221,222] Although final reports for low- and high-risk groups have not yet been published, response-based therapy is now the standard approach for treatment of children with intermediate-risk HL as discussed below.[33]

Favorable Risk

Favorable-risk disease is defined differently by various clinical trial groups, but for the most part, favorable-risk disease encompasses patients with localized stage I and II disease without adverse prognostic features. Treatment typically involves two to four cycles of chemotherapy and low dose ISRT. In some regimens, the RT dose has been reduced or eliminated based on a favorable response to chemotherapy.

Response-based therapy involves either intensification of RT, chemotherapy, or both for patients with slow early response (SER) or poor response to chemotherapy while omitting RT for patients with rapid early response (RER) or good response to chemotherapy. Low-risk patients are the natural group in which to consider de-escalation of therapy because of their excellent outcomes. Early investigations of response-based therapy in the French Society of Pediatric Oncology MDH90 trial included 202 children with stage I/II HL.[19] Patients were treated with four cycles of vinblastine, bleomycin, etoposide, and prednisone (VBEP), and CT was obtained to assess response to therapy. A good response was defined as either complete remission or more than a 70% reduction in tumor size. Good responders received 20 Gy of RT to initially involved fields. The remaining patients (poor responders) were given one or two cycles of OPPA and

were evaluated after each cycle. If no response was obtained after one cycle of OPPA, RT was administered to 40 Gy. If the response after the first or the second cycle exceeded 70%, the patient received 20 Gy to involved fields. Eighty-five percent of patients were good responders, and the overall 5-year OS and EFS of the entire cohort were 97.5% and 91.1%, respectively. These results were comparable to the prior French Society of Pediatric Oncology (MDH82) in which all patients received chemotherapy consisting of alkylating agents and anthracycline followed by low dose RT.[143]

The GPOH pioneered the use of risk- and gender-adapted therapy featuring the OEPA regimen for males in order to limit the amount of alkylators, whereas females received OPPA. In the GPOH-HD 95 trial, RT was successfully omitted in patients achieving complete response to chemotherapy with early-stage disease.[87] Complete response was defined as a volume reduction of ≥95% and ≤2 mL of the initial volume or unconfirmed complete response if volume reduction was ≥75% or <2 mL; fewer than 30% of patients fell into this category of good responders. There was no difference in outcome between favorable-risk patients treated with chemotherapy alone and those treated with combined modality therapy. Notably, the cohort consisted of classic HL and NLPHL. These outcomes were confirmed in the GPOH-HD 2002 study that excluded NLPHL patients in which all patients were treated with IFRT to 19.8 Gy except early-stage (IA/B and IIA without extranodal involvement) patients with complete response as defined in the prior GPOH-HD 95 study.[32] If <75% response was noted, a boost to 30 Gy was delivered, and residual disease >100 mL was boosted to 35 Gy.

Several North American investigators have demonstrated excellent treatment results using combined modality therapy for favorable-risk HL. Investigators from Stanford University Medical Center, St. Jude Children's Research Hospital, and Dana-Farber Cancer Institute reported results using a nonalkylator regimen, VAMP (vinblastine, doxorubicin, methotrexate, and prednisone), for children with clinical I/II, nonbulky HL.[137] Following four cycles of VAMP, patients were treated with 15-Gy IFRT if they achieved a complete response or 25.5 Gy for those with a partial response after two cycles of VAMP. At a median follow-up of 9.6 years, 5- and 10-year EFS rates were 92.7% and 89.4%, respectively. The POG evaluated the feasibility of combined modality therapy using four courses of DBVE (doxorubicin, bleomycin, vincristine, and etoposide) followed by IFRT to 25.5 Gy to treat stage IA, IIA, and IIIA HL.[135] At a median follow-up of 8.4 years, nearly all patients (98%) achieved complete remission after

completion of therapy, and 6-year OS and EFS rates were 98% and 91%, respectively. This DBVE regimen was used by the POG and the COG to support reduction of chemotherapy via an early-response–based treatment algorithm evaluated on P9426.[133] Patients received only two courses of DBVE if they achieved an early complete response (45% of all patients) versus four courses of DBVE if they were slower responders. All patients were treated with IFRT to 25.5 Gy. Five-year OS and EFS were 98% and 88%, respectively.

To compare a chemotherapy-alone regimen to a risk-adapted combined modality treatment approach with low dose IFRT in low-risk patients achieving a complete response, the CCG trial 5942 treated patients with COPP/ABV. Those achieving a complete response to chemotherapy were randomized to receive low dose IFRT or no further therapy. Given a significantly higher number of relapses in patients who were treated with chemotherapy alone, the trial was terminated early. Although 3-year OS estimates were no different between groups, salvage therapy is a known risk for neoplastic complications and early mortality.[16] This trial was compromised by the use of less intensive chemotherapy than is used in most contemporary trials.

To better select low-risk patients who may benefit from the omission of RT, the COG AHOD0431 single-arm study incorporated interim PET-CT when possible to assess disease response and identified a group of very early responders (negative PET scan after one cycle) who may have favorable outcomes even without adjuvant RT. Two hundred and eighty-seven stage IA/IIA patients were treated with three cycles of AV–PC (doxorubicin, vincristine, prednisone, and cyclophosphamide). Those who achieved a complete response after three cycles received no further therapy, whereas partial responders received 21-Gy IFRT. Two-year OS was 100%; however, 2-year EFS for those with complete response to chemotherapy and no RT was 80% compared to 88% of those with partial response who received IFRT (P = .11). A subset analysis suggested the utility of interim PET-CT after one cycle (PET1) of chemotherapy in identifying patients who may be treated without RT after three cycles of AV–PC. Of the patients with complete response who did not receive RT, the 2-year EFS rate for those with a positive/equivocal PET1 versus those who had a negative PET1 was 65% compared to 87%, respectively (P = .005). Similarly, 2-year EFS in partially responding patients with a positive/equivocal PET1 versus a negative PET1 was 82% versus 96%, respectively (P = .047).[84] These data highlight the importance of the added information gained by the interim FDG-PET scan when evaluating low-risk patients for response-adapted therapy. We

await final publication of this study with long-term results.

Intermediate Risk

Patients with localized stage IA and IIA disease with unfavorable features including bulk and extranodal extension are grouped into an intermediate-risk category that also includes patients with stage IIIA disease. Treatment typically involves four cycles of chemotherapy and low dose ISRT. As in low-risk disease, RT dose generally has been reduced or eliminated based on a favorable response to chemotherapy.

In the GPOH-HD 2002 study, all patients were treated with two cycles of chemotherapy (OEPA for males and OPPA for females) with intermediate- and high-risk treatment group patients (TG-2 and TG-3) receiving two cycles of COPP for females and COPDAC for males in order to spare fertility by reducing alkylator exposure.[134] All patients were treated with IFRT to 19.8 Gy except early-stage (IA/B and IIA without extranodal involvement) patients with complete response as discussed above. If <75% CT response was noted, a boost to 30 Gy was delivered, and residual disease >100 mL was boosted to 35 Gy. The two regimens, procarbazine-free OEPA–COPDAC in boys and the standard OPPA–COPP in girls, had comparative effectiveness supporting the use of a reduced gonadotoxic regimen for boys.

The COG has completed two trials to evaluate a response-based approach. The first, POG9425, evaluated the prospect of reducing the number of chemotherapy cycles based on response to therapy.[35] The second trial, AHOD0031, evaluated a regimen to omit RT in patients with a rapid early response and complete response to chemotherapy and to intensify therapy for those with a slow response.[33]

In POG9425, intermediate- and high-risk patients received three and five cycles of ABVE–PC followed by 21-Gy regional (mantle, para-aortic, or pelvic) RT for RER and SER, respectively. There was no difference in EFS between the two groups.[35] This study provided encouraging clinical outcomes using response-based therapy.

The recently published COG AHOD0031 study[33] was the first randomized trial to compare standard and response-based treatment arms in order to risk stratify selected groups of patients for omission of RT or augmentation of systemic therapy (Fig. 93.3). Early response to therapy was determined by CT scan, and complete response status was determined by CT and gallium or FDG-PET scanning. Functional imaging was obtained after two cycles (at the time of

early-response assessment), and as the availability of PET scanning increased, more patients were able to obtain interim PET-CT scans as well. All 1,712 patients received two cycles of ABVE–PC followed by response assessment. Patients with RER received two additional cycles of ABVE–PC followed by a second response assessment. Those with a CR were randomized to receive 21-Gy IFRT or no further therapy. Patients with a RER who did not have a CR were all assigned to receive IFRT. SER patients were all randomized to either two additional cycles of ABVE–PC or dexamethasone, etoposide, cisplatin, and cytarabine (DECA) followed by an additional two cycles of ABVE–PC. All SER patients received 21-Gy IFRT after chemotherapy. Four-year EFS rates were 85% overall and 86.9% for RER patients versus 77.4% for SER patients ($P < .001$). The 4-year OS for the entire cohort was 97.8% and 98.5% for RER patients versus 95.3% for the SER patients ($P < .001$). The 4-year EFS rate was 87.9% for RER/CR patients randomized to receive IFRT versus 84.3% for those randomized to no IFRT ($P = .11$).[33]

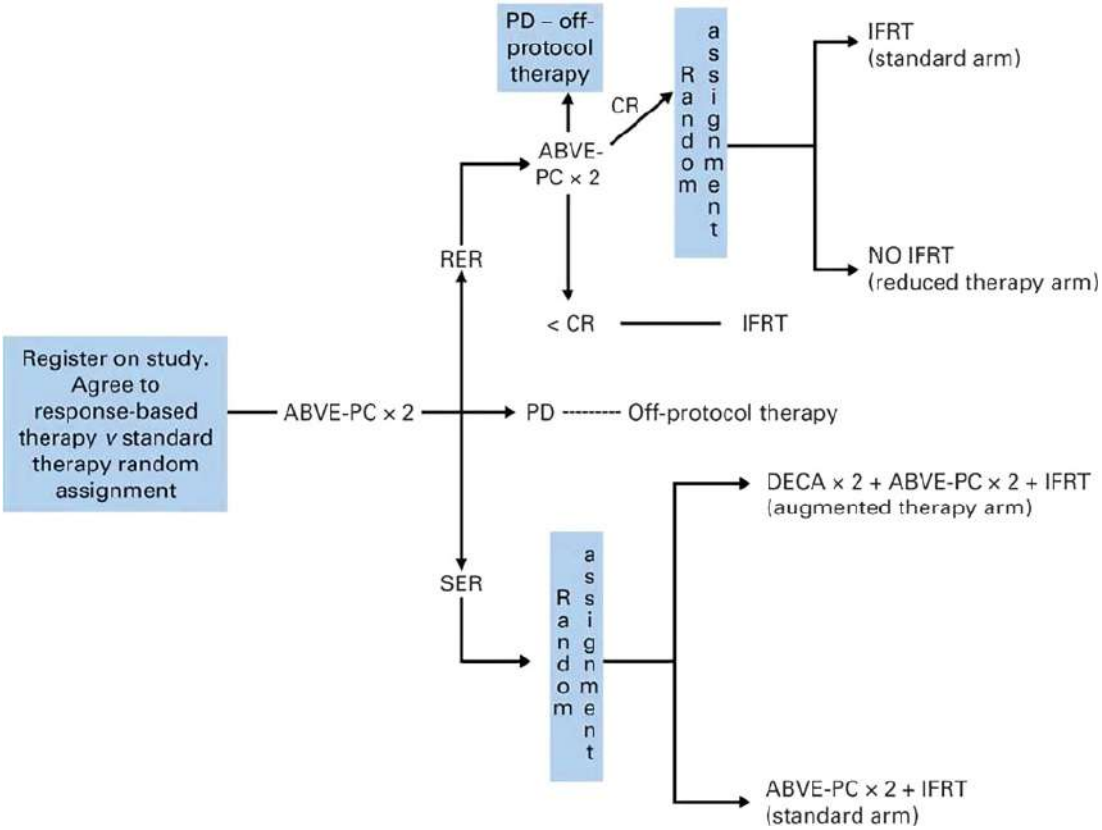

FIGURE 93.3. Study schema of COG AHOD0031, a phase III study of dose-intensive response-based chemotherapy and radiation therapy for children and adolescents with newly diagnosed intermediate-risk Hodgkin disease. RER was defined as a 60% or greater reduction in the product of perpendicular diameters (PPD) for all target

lesions, or there was a return to normal size after two ABVE–PC cycles on CT scan. CR was defined as an 80% or greater reduction in the PPD or a return to normal size for all target lesions and a negative gallium or FDG-PET scan. A 50% or greater increase in the PPD of any nodal mass or organ lesions or a new lesion(s) was considered progressive disease. ABVE–PC, doxorubicin, bleomycin, vincristine, etoposide, cyclophosphamide, and prednisone; CR, complete response; DECA, dexamethasone, etoposide, cisplatin, and cytarabine; IFRT, involved field radiation therapy; PD, progressive disease; RER, rapid early responder; SER, slow early responder. (From Friedman DL, Chen L, Wolden S, et al. Dose-intensive response-based chemotherapy and radiation therapy for children and adolescents with newly diagnosed intermediate risk Hodgkin lymphoma: a report from the Children's Oncology Group Study AHOD0031. *J Clin Oncol* 2014;32[32]:3651–3658. Reprinted with permission. Copyright © 2014 American Society of Clinical Oncology. All rights reserved.)

Because of the study era, FDG-PET was not required for early-response determination, but interim PET after two cycles of ABVE–PC (PET-2) was obtained in 1,135 (66%) patients of whom 746 were eligible for the two random assignments in the study. Of the 550 patients with available PET-2 imaging that had a RER/CR, there was no difference in EFS with and without IFRT to those with a negative PET-2 (86.7% vs. 87.3%, respectively; $P = .87$). Among patients with PET-2–positive results, there was also no difference in EFS with and without IFRT (83.1% vs. 78.1%, respectively; $P = .80$). Of the 196 patients with SER with available PET-2 results, there was no difference in EFS in patients treated with or without DECA when PET-2 was negative (90.1% vs. 85.6%, respectively; $P = .54$). However, among patients with SER with PET-2–positive results, EFS with DECA was marginally superior to those treated without DECA (70.7% vs. 54.6%, respectively, $P = .05$).[33]

In a secondary analysis of the patterns of failure of AHOD0031, first relapses rarely occurred outside of the irradiated field only, and relapses commonly occurred in previously involved disease sites (94% of relapses), suggesting that INRT or ISRT may be sufficient to determine irradiation volumes without compromising local control.[221] Additionally, recurrences occurred both in bulky and nonbulky initial sites of disease, suggesting that in intermediate-risk HL, irradiation of bulky sites alone may not be a recommended treatment strategy.[221]

The results of AHOD0031 suggest that early response to chemotherapy defined by early reduction (60%) in tumor size based on CT after two cycles can be a powerful predictor of outcome and help optimize subsequent treatment. A secondary analysis of PET response after two cycles of ABVE–PC demonstrated that PET may further assist with treatment optimization. If validated, a pediatric-specific prognostic score, CHIPS, proposed using the data from AHOD0031

discussed in the “Prognostic Factors” section may also guide early therapy reduction or augmentation as the components of this score are known at diagnosis.[223] As a result of the primary outcomes of AHOD0031, response-adapted treatment is the current standard of care of patients with intermediate-risk HL.

High Risk

The criteria for high-risk clinical presentation are typically restricted to stage III or IV disease with “B” symptoms and may also include extranodal extension to contiguous structures. Combined modality therapy is the standard approach to treatment. Historically, chemotherapy was administered over the course of 6 to 8 months on a twice-monthly schedule.[7,8,35,85,90,224] An alternative strategy condenses the chemotherapy component of treatment into 3 to 5 months to enhance dose intensity and reduce the risk of developing resistant disease. RT for high-risk HL is variable and protocol dependent.

Dose-intensified treatment regimens may increase the risk of acute and late side effects. The GOPH-HD 2002 study discussed above included patients with high-risk disease and demonstrated that a procarbazine-free regimen of OEPA–COPDAC administered to boys yielded comparable outcomes as those observed in girls receiving the standard OPPA–COPP regimen.[134] The European Network for Pediatric Hodgkin Lymphoma (EuroNet-PHL)-C1 trial is testing whether equivalent results can be achieved with the procarbazine-free regimen in a non–gender-stratified approach. All patients on the trial received OEPA, and intermediate- and high-risk groups (TG-2 and TG-3) were randomly assigned to receive COPP or COPDAC. Interim results of the TG-2 and TG-3 patients randomized between the COPP and COPDAC regimen showed no difference in 4-year EFS rates between the two groups.[225] Final results will definitively inform if the less gonadotoxic regimen results in equivalent results.[105]

As in the cases of other risk groups, there is increasing interest in developing a response-adapted treatment approach for children with high-risk HL. In the GPOH-HD 95 trial outlined previously, RT was omitted in patients achieving complete response after OEPA–COPP chemotherapy.[86] Progression-free survival (PFS) for intermediate- and high-risk patients who experienced a complete response and did not receive RT was significantly lower than observed in patients without a complete response who received RT (69% and 83%, respectively, $P = .01$). This study highlighted the need for more refined criteria and modalities for response assessment than those used on GPOH-HD 95 to

successfully identify intermediate- and high-risk patients for whom treatment without RT may suffice.[86]

A recent assessment of a dose-intense, response-based regimen using BEACOPP (bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone) in children with high-risk disease was reported by the COG 59704 trial. Females with a rapid response received four cycles of COPP/ABV following BEACOPP without IFRT, and males received two cycles of ABVD and IFRT. All patients with a slow response received four additional cycles of BEACOPP and IFRT. A high 5-year EFS rate of 94% was achieved, and the 5-year OS rate was 97% with significant acute hematologic toxicity and two patients developing secondary leukemia.[85]

AHOD0831 was the first COG trial for high-risk patients evaluating a risk-adapted approach to chemotherapy intensification and RT volumes based on early response to chemotherapy.[226] Patients were treated with two cycles of ABVE–PC and then assigned to one of two consolidation therapy regimens based on response to induction therapy. Patients with rapid early response received two more courses of ABVE–PC. Those with slow early response received intensification of therapy with the addition of two cycles of ifosfamide/vinorelbine followed by two courses of ABVE–PC. Patients with a continued response after completion of chemotherapy proceeded to risk-adapted RT (21 Gy in 14 fractions of IFRT) delivered only to initial sites of bulky disease in rapid responders and to PET-avid sites and sites with >2.5 cm of residual disease in slow responders. Although the study has closed, final results have not yet been reported. Preliminary analysis revealed that the approach did not meet the predefined high goal of 95% EFS.[227]

The current ongoing high-risk HL study with the COG is AHOD1331 that is evaluating the role of brentuximab in the up-front setting based on its effectiveness in the salvage setting. The trial also incorporates a response-adapted approach to RT.[226] Patients are treated with five cycles of AVE–PC with or without brentuximab with interim PET-CT after two cycles. RT of 21 Gy in 14 fractions will be given to patients with sites of disease that do not show a rapid response after two cycles of chemotherapy and to all patients with bulky mediastinal disease. The RT being administrated on this trial incorporates ISRT and allows for protons and IMRT. Although not a study question, the approach to radiation therapy varies from the established standard for pediatric RT including dose escalation from 21 to 30 Gy for patients with residual FDG-avid disease at the end of chemotherapy and delivery of RT to large mediastinal adenopathy

regardless of response to chemotherapy. The results of this trial will be enlightening not only with regard to its primary study question on the role of brentuximab in the up-front setting but also in the outcomes using a refined approach to RT for children with high-risk HL.

The ongoing EuroNet-PHL-C2 trial is also evaluating a risk-stratified and response-adapted approach in children with high-risk HL.[228] Using the Deauville score (DV) for PET response assessment,[112] patients with adequate response after two cycles of initial OEPA chemotherapy (i.e., PET-negative DV 1 to 3) will not receive RT, and those with inadequate response to chemotherapy (i.e., DV ≥ 4 or <50% volume reduction in bulky site) will receive a modified IFRT to 19.8 Gy with 10-Gy boost to sites with DV3 or higher PET avidity at the end of all chemotherapy. All intermediate- and high-risk patients will receive consolidation chemotherapy based on randomization between two and four cycles of standard COPDAC-28 (cyclophosphamide, vincristine, prednisone, dacarbazine) or intensified DECOPDAC-21 (doxorubicin, etoposide, cyclophosphamide, vincristine, prednisone, dacarbazine). This study will evaluate (a) whether intensified DECOPDAC-21 consolidation chemotherapy improves EFS as compared to standard COPDAC-28 in early responders and (b) if DECOPDAC-21 combined with radiotherapy restricted to sites that remain FDG-PET positive at the end of all chemotherapy has comparable EFS compared to COPDAC-28 plus RT as in the C1 trial.

Therapy for Lymphocyte-Predominant Hodgkin Lymphoma

NLPHL is considered indolent with a favorable prognosis with OS rates of close to 100%, typically presenting as a localized, early-stage disease. Relapses are typically late and curable with 10- and 15-year cumulative relapse rates of 4.8% and 8.3%, respectively, with similar OS rates in patients with relapsing and nonrelapsing patients.[229] Historically, patients with NLPHL have been treated on protocols for patients with classic HL; however, there are several reports in the adult and pediatric literature suggesting that they can be cured with less aggressive therapies. Adult patients are typically treated with RT alone to 30 to 40 Gy.[230,231]

Given the concern for late toxicity of RT to curative doses in children, resection has been considered as a treatment approach for localized pediatric NLPHL. A meta-analysis of French, United Kingdom, and German trial series showed that surgery alone was a feasible option for localized disease and yielded a long-term relapse-free survival of 67%.[232] The COG AHOD03P1 study

prospectively evaluated 52 stage IA patients who were observed after surgery only.[222] Five-year EFS was 77% with 13 patients experiencing relapse. Twelve of the relapses were stage IA, occurring at the site or in adjacent nodes or nodal regions; one relapse was stage IIA. Nine of these patients received salvage chemotherapy with AV–PC, all achieving a complete response. Four patients relapsed after the salvage chemotherapy arm was closed and received chemotherapy per institutional choice.

The EuroNet is conducting a clinical trial to prospectively validate this "watch-and-wait" approach for children with completely resected disease and low dose chemotherapy for patients with residual disease after resection (EuroNet-PHL-LP1).[233,234]

Therapy for Refractory or Relapsed Hodgkin Lymphoma

Treatment failures in pediatric HL patients typically develop within the first 3 years, although late relapses have been reported, particularly in patients with NLPHL. The most common site of relapse following risk-adapted therapies remains the primary site of disease.[216] Generally, favorable prognostic factors include the site of relapse (nodal better than extranodal), stage at relapse (early better than advanced), histology, and response to first-line salvage chemotherapy.

Treatment options include standard-dose chemotherapy (with or without RT), RT alone, or high dose chemotherapy (with or without RT), followed by stem cell transplant, clinical trials, or palliative therapy. When pursuing transplant, RT may also be used pre- or posttransplant depending on the clinical scenario. The selection of the most appropriate salvage regimen is based on whether a complete remission was achieved, the durability of the remission, the extent of disease at relapse, and the intensity of the frontline therapy given.

Because of the excellent outcome for the majority of children and adolescents with HL, investigations regarding salvage strategy have been limited. For higher-risk relapses, a combination of ifosfamide and vinorelbine for pediatric patients in first relapse was studied by the COG (AHOD00P1). This regimen showed a very good overall response rate (CR/PR) of 78% and achieved good stem cell mobilization for future autologous stem cell transplant once remission is achieved, because studies have shown that patients undergoing autologous stem cell transplant with active disease have a worse outcome.[235] Claviez et al.[236] reported observations of 91 pediatric patients with relapsed or refractor HL treated with allogeneic hematopoietic stem cell transplantation. Relapse at 2 and

5 years is 36% and 44%, respectively. PFS rates were 40% and 30% and OS rates were 54% and 45% at 2 and 5 years, respectively.

Patients with primary refractory disease (i.e., those unresponsive to initial therapy or who relapse within 1 year of primary therapy) have a very poor prognosis. Intensive cytoreductive chemotherapy followed by myeloablation and autologous hematopoietic stem cell transplantation is reported to salvage 30% to 60% of these patients, but relapses after 5 years have been observed, and long-term treatment complications may predispose to early mortality.[237–239]

Newer targeted agents promise great efficacy with less toxicity. Brentuximab vedotin, an antibody drug conjugate that targets CD30 and is bound to an antitubulin agent monomethyl auristatin E, has shown excellent results in early clinical trial in relapsed and refractory Hodgkin lymphoma.[240,241] Given promising results, brentuximab vedotin is being incorporated in larger studies and in the up-front setting in combination with multiagent chemotherapy.[168] mTOR inhibitors, histone deacetylase inhibitors like panobinostat,[242] and nivolumab (programmed death-1 pathway inhibition)[242] are currently under investigation and may prove to be active alone or when used in combination with other agents.

Future Investigations

To build on the current era of risk- and response-adapted trials in pediatric HL, future studies should focus on refining our ability to better stratify therapies at diagnosis by validating pediatric-specific prognostic factors and identifying patients at high risk of serious toxicity from treatment.[35] Preliminary data suggest a genetic risk factor for the development of radiation-associated breast cancer in patients treated with thoracic RT for HL,[243] whereas other investigators have identified genetic variants associated with anthracycline-induced cardiotoxicity in children.[244] Such exemplary research will enable future clinicians to develop personalized treatments for patients based on risk profiles informed by both stage of disease and individual genetic presentations.

Newer drugs also promise great efficacy with less toxicity. Future studies are likely to move targeted agents, such as brentuximab vedotin, histone deacetylase inhibitors, and immunotherapy agents such as PDL-1 inhibitors into the up-front treatment of patients, starting with patients with high-risk disease. These evaluations of new agents and the applications of genetic information in future studies are novel approaches to achieve the same decade-old goal of balancing the toxicity and efficacy of treatments for children with HL.

NON-HODGKIN LYMPHOMA

Childhood NHLs are a heterogeneous group of malignancies with variable histopathology, site of origin, and clinical manifestations. Childhood NHLs are diffuse, high grade, and poorly differentiated; extranodal involvement is common, and dissemination occurs early and often.[245] This is in striking contrast to adult NHL, in which low- and intermediate-grade nodal disease predominates.[245,246] The common low-grade lymphomas seen in adults, such as follicular and marginal zone lymphomas, are rare in children. These differences in pathology and clinical behavior observed between children and adults explain the markedly different presentations, staging practices, and treatment strategies for these age groups.

Epidemiology

In the United States, NHL is diagnosed in approximately 800 children and adolescents younger than 20 years of age, each year. According to the Surveillance, Epidemiology, and End Results Program of the National Cancer Institute, NHL accounts for about 8% of all cases of childhood cancer.[247] The incidence increases with age, being rare in the child <3 years old; incidence is higher in males than in females (ratio of 3 to 1) and higher in Caucasians than in African Americans (ratio of 1.5 to 1). In younger children, NHL is more frequent than HL, whereas the reverse is true for adolescents.

Although NHL is related to several genetic and environmental factors, its cause and pathogenesis remain unclear.[245,248] A small proportion of cases are seen in association with inherited immunodeficiencies (e.g., Wiskott-Aldrich syndrome, X-linked lymphoproliferative disease, ataxia-telangiectasia, and common variable immunodeficiency)[249,250] or acquired immunodeficiencies (e.g., HIV infection or immunosuppressive therapy in patients receiving solid organ or bone marrow transplants).[251,252]

There is geographic variation in the incidence and pathogenesis of NHL. In equatorial Africa, evidence of EBV infection has been demonstrated in the majority of endemic Burkitt tumors, but in only 10% to 15% of sporadic cases (outside of Africa). This suggests a significant role for the EBV virus in lymphomagenesis through unknown mechanisms that leads to the same oncogenic chromosomal translocations as those seen in non–EBV-associated sporadic cases of Burkitt lymphomas.[253–255] EBV infection has also been associated with the development of posttransplant lymphoproliferative disease (PTLD), a B-cell lymphoproliferative disorder seen in patients after solid organ

or hematopoietic stem cell transplantation.[256,257]

Pathologic Classification

Pediatric NHL cases are divided into four major histopathologic subtypes based on morphology and immunophenotype in the order of frequency: (a) Burkitt lymphoma (BL); (b) lymphoblastic lymphoma (LL), including B-cell LL and T-cell LL; (c) large B-cell lymphoma including the subtypes diffuse large B-cell lymphoma (DLBCL) and primary mediastinal (thymic) large B-cell lymphoma (PMBL); and (d) anaplastic large-cell lymphoma (ALCL).[49,247,248,258] The distribution of histologies is shown in Table 93.5.

The classification of NHL by the WHO was updated in 2016.[48,49] It increasingly incorporates immunophenotyping and cytogenetics in important diagnostic, prognostic, and therapeutic distinctions. A few notable changes with respect to pediatric NHL exist in the updated WHO classification. Pediatric follicular lymphoma (FL) became a distinct subtype, now known as pediatric-type FL.[48,258,260] It is characterized by large expansile highly proliferative follicles that often have prominent blastoid follicular center cells rather than classic centroblasts and a lack of MYC, BCL6, and BCL2 rearrangements; however, BCL2 protein may be expressed. Large B-cell lymphoma with IRF4 rearrangement, which commonly occurs in children and young adults, was added as a new provisional entity. Most have IG/IRF4 rearrangements, some with BCL6 rearrangements, but uniformly lack BCL2 rearrangements. These lymphomas typically occur in Waldeyer ring and/or cervical lymph nodes and are more aggressive than other pediatric-type FL. Burkitt-like lymphoma with 11q aberration was added as a provisional entity to distinguish a subset of lymphomas that have more complex karyotypes and lack MYC rearrangements with lower levels of MYC expression than Burkitt lymphomas. Instead, this subtype is notable for chromosome 11q changes with proximal gains and telomeric losses.[261,262] The clinical course seems similar to that of BL.

TABLE 93.5 CLINICAL CHARACTERISTICS OF CHILDHOOD NON-HODGKIN LYMPHOMA

Histologic Subtype	Proportion of Cases (%)	Most Common Sites of Presentation
Burkitt lymphoma	35–40	Abdomen or head and neck
T-lymphoblastic lymphoma	15–20	Mediastinum
B-lymphoblastic lymphoma	3	Cutaneous masses, isolated nodes,

		and bone
Diffuse large B-cell lymphoma	15–20	Nodes, abdomen, and bone
Mediastinal large B-cell lymphoma	1–2	Mediastinum
Anaplastic large-cell lymphoma	15–20	Skin, nodes, and bone

Adapted from Sandlund JT. Childhood lymphoma. In: Abeloff MD, Armitage JO, Lichter AS, et al., eds. *Clinical oncology*. 2nd ed. New York: Churchill Livingstone, 2000:2438. Copyright © 2000 Elsevier. With permission.

Overall, identification of large numbers of monoclonal antibodies directed against surface antigens has allowed subclassification of the NHLs according to immunophenotype (Table 93.6).[263] Thorough and efficient evaluation of histology and immunophenotype is key to the determination of diagnosis, prognosis, and appropriate course of treatment because pediatric NHLs are usually aggressive. Cytogenetic analysis and identification of molecular markers provide a more precise means of characterization of these tumors and will likely contribute to the understanding of pathogenesis as well as the development of novel therapeutic approaches.[264–266]

Clinical Presentation

In many cases, clinical manifestations and sites of disease correlate with NHL subtype. A mediastinal mass, which can cause wheezing, stridor, cough, or dyspnea, is present in 25% of children with NHL, commonly associated with DLBCL or T-lymphoblastic lymphoma.[267] Clinical presentation is different between endemic and sporadic BL. The abdomen is the most common site of disease in sporadic BL, which presents with abdominal pain, distension, palpable mass, nausea, vomiting, and gastrointestinal bleeding, followed by head-and-neck region involvement. Bone marrow involvement is seen in about 20% of patients with sporadic BL and LL sporadic disease.[268] However, in endemic BL, jaw involvement is the most common, and bone marrow involvement is rare.[269]

The majority (50% to 70%) of children with precursor T-cell LL present with rapidly enlarging neck and mediastinal lymphadenopathy.[248,264] Mediastinal masses can cause respiratory symptoms (e.g., cough, wheezing, shortness of breath, and orthopnea) by compressing airways or cause neck, face, and upper extremity swelling because of obstruction of the superior vena cava (SVC). Hemodynamic compromise because of pericardial effusions may also occur. However, children and adolescents with precursor B-cell LL tend to have limited

disease in sites including the skin, bone, and peripheral lymph nodes.[270,271]

DLBCL usually presents with nodal disease, especially in the abdomen, although the bone (single or multiple sites) is also a relatively common site.[272,273] Primary mediastinal large B-cell lymphoma can be locally invasive and may present with SVC syndrome.[31]

The most frequent sites of involvement in systemic ALCL are peripheral nodes, mediastinal lymph nodes, and extranodal sites such as the skin, soft tissue, and bone.[274,275] Spontaneous regression or waxing and waning of disease has been observed.

Diagnostic Evaluation

Tissue diagnosis and investigation to determine the clinical extent of disease should be completed expeditiously. It is important that appropriate therapy be initiated promptly because of the extremely rapid growth rate of pediatric NHL.[245] Histology, immunophenotype, karyotype, and molecular studies are vital for implementation of an optimal treatment plan.[258,276] Thus, it is critical that an adequate amount of tissue be obtained at biopsy by performing either open biopsy or core needle biopsy. The use of irradiation or steroids before biopsy in the case of a symptomatic mass may result in rapid shrinkage and subsequent improvement in symptoms, but may jeopardize the ability to establish a tissue diagnosis.[277,278]

Bone marrow biopsy (BMB) has been a standard in lymphoma staging (Table 93.7).[81] Bone marrow biopsies are superior to a single aspirate or biopsy for identifying bone marrow involvement, which is often patchy in distribution in NHL.[248] In DLBCL, FDG-PET-CT has been shown to be more sensitive than BMB, but does miss low-volume diffuse involvement of 10% to 20% of the marrow.[279–281] Thus, in pediatric patients with DLBCL, FDG-PET-CT indicating bone marrow involvement is typically sufficient, and BMB is not required. If FDG-PET-CT is negative in patients with DLBCL, BMB is indicated if relevant for a clinical trial or in cases where identifying a discordant histology is important for patient management. For all other NHL histologies, a 2.5-cm unilateral BMB, along with immunohistochemistry and flow cytometry, is still

standard practice because of lack of conclusive data guiding the utility of FDG-PET-CT. [77]

TABLE 93.7 INVESTIGATIONS REQUIRED FOR ACCURATE STAGING AND DIAGNOSIS OF CHILDHOOD LYMPHOMAS

FDG-PET-CT should be used for staging FDG-avid NHLs.[282] Contrast-enhanced CT is indicated for all nonavid histologies. The avidity of the different NHL subtypes is reported in Table 93.8. Data in adults with HL and NHL and children with HL suggest that PET scanning to assess the rapidity of response may be prognostic.[195,283] However, further confirmation is needed to determine whether FDG-PET response has predictive value for detecting recurrence of pediatric NHL.

Laparotomy is generally no longer performed for staging as combination chemotherapy is part of the primary treatment. MRI may be helpful in detecting disease at specific sites, particularly the nervous system, but it is not routinely used.

Staging Systems

Pediatric NHL is currently staged using the Murphy/St. Jude's Children's Research Hospital system from 1980, which incorporates extent of disease and clinical patterns.[246] Since the introduction of the St. Jude staging system, the pathologic classification of NHL has changed significantly. New subtypes of

pediatric NHL, some of which display unique patterns of organ involvement, including mucosal sites, skin, bone, ovary, and kidney, have been identified. The Ann Arbor staging system[81] (commonly used in adult NHL) has proved to be of limited use in pediatric NHL because of the unique clinical presentation and course of the disease in children with predominant involvement in the extranodal primary sites and a tendency to evolve into leukemia and to involve the central nervous system (CNS).

The Lugano lymphoma staging classification similarly focuses on adult lymphomas.[77] As a result, a Revised International Pediatric NHL Staging System Classification was recently developed by a multidisciplinary multinational consortium, incorporating new histologic entities, extranodal dissemination, improved diagnostic methods, and advanced imaging techniques (Table 93.9). The revised staging will enable more precise, reproducible comparisons of efficacy of treatment strategies across cooperative groups.[284]

TABLE 93.9 STAGING AND GROUPING SYSTEM FOR CHILDHOOD NON-HODGKIN LYMPHOMA

Stage/Group	Description	
	Murphy Staging System	International Pediatric Non-Hodgkin Lymphoma Staging System
I	Single EN tumor or single anatomic N area, excluding the mediastinum or abdomen	Single tumor excluding the mediastinum or abdomen (N; EN; B or S: EN-B, EN-S)
II	Single EN tumor with regional lymph node involvement Two or more N areas on the same side of the diaphragm Two single EN tumors + regional node involvement on the same side of the diaphragm Primary GI tract tumor (usually in ileocecal area), + involvement of associated mesenteric nodes only	Single EN tumor with regional node involvement Two or more N areas on the same side of the diaphragm Primary GI tract tumor (usually in ileocecal area), + involvement of associated mesenteric nodes, that is completely resectable (if malignant ascites or extension of tumor to adjacent organs, it should be regarded as stage III)
III	Two single EN tumors on opposite sides of the diaphragm Two or more N areas above and below the diaphragm All primary intrathoracic tumor (mediastinal,	Two or more EN tumors (including EN-B or EN-S) above and/or below the diaphragm Two or more N areas above and

	pleural, thymic) All extensive primary intra-abdominal disease including disease with spread via lymphatics to para-aortic and retroperitoneal nodes via intraperitoneal dissemination to form implants and plaques along the mesentery or peritoneum or by direct infiltration of structures adjacent to primary tumor. Ascites may be present, and complete resection of all gross tumor is not possible All paraspinal or epidural tumors, regardless of other tumor sites	below the diaphragm Any intrathoracic tumor (mediastinal, hilar, pulmonary, pleural, or thymic) Intra-abdominal and retroperitoneal disease, including liver, spleen, kidney, and/or ovary localizations, regardless of degree of resection (except primary GI tract tumor [usually in ileocecal region] involvement of associated mesenteric nodes that is completely resectable) Any paraspinal or epidural tumor, regardless of whether other sites are involved Single B lesion with concomitant involvement of EN and/or nonregional N sites
IV	Any of the above with initial CNS or BM involvement (<25% blasts)	Any of the above findings with initial CNS involvement (stage IV CNS), BM (stage IV BM), or both (stage IV combined) based on conventional methods
Group Classification in the B-Cell Lymphomas		
A	Completely resected stage I or completely resected abdominal stage II lesions	
B	All cases not eligible for group A or group C (Murphy stage III and non-CNS stage IV)	
C	Any CNS involvement and/or bone marrow involvement ≥25% blasts. For CNS involvement, one or more of the following applies: (1) Any L3 blasts in CSF (2) Cranial nerve palsy (if not explained by extracranial tumor) (3) Clinical spinal cord compression (4) Isolated intracerebral mass (5) Parameningeal extension: cranial and/or spinal	

B, bone; BM, bone marrow; CNS, central nervous system; CSF, cerebrospinal fluid; EN, extranodal; N, nodal; S, skin.

Revised International Pediatric Non-Hodgkin Lymphoma Staging System. *J Clin Oncol* 2015;33(18):2112–2118.

Prognostic Factors

The most important factor in determining prognosis in childhood NHL is stage,

which takes into account other known prognostic variables such as tumor burden, site, and extent of involvement.[285–287]

Other clinical prognostic factors in NHL include LDH level and CNS involvement. Biologic characteristics including the presence of 13q abnormalities, MYC/8q24 rearrangement in DLBCL, and minimal disseminated disease (MDD) and minimal residual disease (MRD) in BL seem to be of prognostic relevance.[286–288] Prospective validation of these prognostic factors in patients with B-cell NHLs is planned in the ongoing Inter-B-NHL Ritux 2010 study.[166,167]

As most cases of pediatric NHL are of the diffuse, high-grade, and aggressive subtypes, only few reports support the role of histologic subtype as a prognostic factor. Response to therapy is also being investigated as a prognostic factor,[289] and attempts are being made to incorporate a standardized international pediatric NHL response criteria to facilitate communication and future investigations.[290]

Treatment of Non-Hodgkin Lymphoma

The OS of children with NHL was poor before the advent of multiagent chemotherapy in the mid-1970s.[285] Even in cases in which the disease apparently was localized, cure rates as low as 20% were reported. Failure, in most cases, was caused by early systemic dissemination of disease. In modern regimens, chemotherapy is the primary therapeutic modality for all histologies and stages of childhood NHL. The dramatic improvement in the overall rate of survival of those with childhood NHL can be attributed not only to the development of highly effective, multiagent chemotherapy regimens but also to the systematic evaluation of these diseases and their treatment by pediatric cooperative group clinical trials. Cure rates of 85% to 95% in patients with limited disease (Table 93.10) and 70% to 90% in those with extensive involvement (Table 93.11) have been reported.[291,292,295,298–321]

TABLE 93.10 MODERN TREATMENT OUTCOMES FOR LIMITED-STAGE NON-HODGKIN LYMPHOMA BASED ON RECENT TRIALS

Burkitt Lymphoma

As a result of several consecutive prospective trials, outcomes for BL have dramatically improved.[289,291,292,295,298,309,312,322,323] Treatment consists of 2 to 6 months of multiagent, cyclophosphamide-based chemotherapy. Relapses tend to occur within the first year. The current paradigm has been established through collaborative efforts across consortiums such as the French Society of Pediatric Oncology and French-American-British (FAB), Lymphomes Malins B (LMB), and the oligonational Berlin-Frankfurt-Munster (BFM) studies.[289,291,292,295,298,309,312,322,323] As BL frequently occurs in resource-deprived countries, treatments have been adapted in some regions to balance toxicity, efficacy, and cost. Still, over half of patients are cured with suboptimal, resource-adapted protocols.[324,325]

TABLE 93.11 MODERN TREATMENT OUTCOMES FOR ADVANCED-STAGE NON-HODGKIN LYMPHOMA BASED ON RECENT TRIALS

In health systems with available resources, the current standard frontline therapy for advanced BL is based on the FAB/LMB96 regimen.[289] Patients received cyclophosphamide, vincristine, prednisone, high dose methotrexate, doxorubicin, and cytarabine. Although 20% to 25% of patients present with advanced-stage disease involving the bone marrow and/or CNS, the current treatment approach results in EFS of approximately 90%. Of note, involvement of >25% of the marrow by Burkitt is classified as Burkitt leukemia, but should still be treated using a high-risk lymphoma treatment paradigm, and not therapy for acute lymphoblastic leukemia. High dose methotrexate with or without high-dose cytarabine and intrathecal methotrexate with or without cytarabine can effectively serve as CNS prophylaxis or treatment of CNS-positive disease, eliminating the need for CNS irradiation.[289,291,292,295,298,309,312,322,323] Testicular involvement at diagnosis is uncommon but does occur in about 5% of children with disseminated BL and Burkitt-like NHL.[326] Testicular disease does not seem to confer a poor prognosis, and it is curable with intensive combination chemotherapy alone. Local treatment (i.e., surgery or radiation) is avoidable; therefore, gonadal function can be preserved.

Both DLBCL and BL express CD20. As such, the most recent era of studies involves incorporating the anti-CD20 monoclonal antibody (rituximab) into a conventional multiagent chemotherapy regimen. In 2004, the COG implemented ANHL01P1, a pilot study evaluating the toxicity of adding rituximab to standard therapy for patients with newly diagnosed, pediatric BL and DLBCL.[327] Survival rates were similar to the 4-year reported EFS in patients treated on FAB/LMB96, the current standard therapy.[289] In a multicenter European phase II

study, 136 pediatric patients with newly diagnosed B-cell NHL received 1 dose of rituximab in an up-front window prior to starting standard chemotherapy to assess the possibility of a future phase II trial to test if rituximab could substitute for chemotherapy. An ambitious response rate of higher than 65% was set for classification of favorable activity of rituximab; however, only 41% of patients experienced disease improvement after a single dose of rituximab.[297] The current phase II/III intergroup trial, ANHL1131, will test the efficacy of frontline rituximab therapy in pediatric patients with B-cell NHL.[328] The phase II component of the study has closed and the target accrual of the phase III component is 600 patients. No data are available to date.

Large B-Cell Lymphoma

Diffuse Large B-Cell Lymphoma

The treatment of DLBCL follows the same protocols as that for BL. Follow-up for patients with DLBCL, however, should be focused on the possibility of comparatively later relapses, occurring up to 3 years following treatment.[295,309,323] The role of frontline rituximab therapy in DLBCL, as well as BL, is being investigated in the studies outlined above.

Primary Mediastinal B-Cell Lymphoma

Primary mediastinal B-cell lymphoma (PMBL) has a significantly inferior EFS approaching 70% using standard FAB/LMB96 chemotherapy.[329] It typically presents in adolescents and young adults, and therefore, pediatric-specific protocols have not been established. As the biology of disease appears similar across age groups, a reasonable alternative regimen to rituximab, cyclophosphamide, doxorubicin, and prednisone (R–CHOP) with good outcomes in adults is dose-adjusted etoposide, doxorubicin, and cyclophosphamide with vincristine, prednisone, and rituximab (DA–EPOCH–R) and may obviate the need for RT therapy in patients with PMBL.[330] This DA–EPOCH–R regimen is currently being investigated in children with PMBL.[331]

Lymphoblastic Lymphoma

Lymphoblastic lymphoma consists of both precursor T-cell (T-LL) and B-cell (B-LL) NHLs, with the majority (80% to 90%) being T-LL. T-LL typically presents at an advanced stage with a mediastinal mass and occasionally bone marrow involvement. B-LL is typically localized and presents in various locations including the bone, skin, soft tissue, and peripheral nodes.[332] Treatment approach follows an ALL-based paradigm with the addition of high-

dose methotrexate and/or intrathecal injections for CNS prophylaxis,[300,333,334] rather than CNS RT.[299,335] Overall, regimens include early intensified multiagent chemotherapy consisting of vincristine, prednisone, L-asparaginase, doxorubicin, cytarabine, cyclophosphamide, and high dose methotrexate, followed by maintenance chemotherapy for 2 years.[294,299,300,315,316,333,334,336–339] Long-term EFS with current treatment protocols approaches 85%. The prognostic value of extent of disease dissemination at diagnosis and MRD identified using advanced PCR and flow cytometry technologies is being evaluated as a basis of treatment stratification in the ongoing COG study ALL0932.[340,341]

Anaplastic Large-Cell Lymphoma

Anaplastic large-cell lymphoma presents in either a systemic or primary cutaneous form. Systemic ALCL is frequently associated with "B" symptoms and extranodal disease. Advanced systemic ALCL has been treated with short-pulse chemotherapy, proven effective in B-cell lymphomas, or with modifications of high-risk ALL protocols.[302,303,321] Long-term EFS ranges from 65% to 75%[301–303,319,342,343]; however, recurrences are comparatively more responsive to salvage therapies than relapsed disease in other NHL subtypes.[258] Treatment of recurrent ALCL involves chemotherapy followed by hematopoietic stem cell transplant or weekly vincristine and yields survival rates of >90%.[301,302,344–347]

Role of Radiation Therapy

With the development of effective multiagent chemotherapy regimens, RT for local control of primary disease[305,348] (exclusive of primary bone lesions) or for CNS prophylaxis has been virtually eliminated.[298,299,349] Indications for cranial irradiation are currently limited to patients with overt symptomatic CNS lymphoma at diagnosis, particularly when unresponsive to initiation of chemotherapy or dexamethasone or when there is CNS relapse.[350]

Historically, radiation was incorporated as standard in the treatment of primary lymphomas of the bone. Localized RT to the involved bone was included as part of standard management in early chemotherapy trials.[305] In a prospective randomized trial evaluating the need for local RT in early-stage NHL, all patients with primary lymphoma of the bone received 37.5 Gy and were not included in the randomization to "no radiation."[305] Given the rarity of these entities, the patterns of failure of all early-stage primary lymphomas of the bone treated on three consecutive POG studies were examined to determine the

impact on outcome of radiotherapy as an adjuvant treatment in children receiving chemotherapy. Across the three studies, a total of 31 patients with primary lymphoma were analyzed. Seven patients had both chemotherapy and radiation, whereas the remaining 24 were treated with chemotherapy only. There were no local relapses identified in this subset analysis.[348] With these data, it is reasonable to treat patients with primary lymphoma of the bone with chemotherapy alone without adjuvant RT.

Radiation is used for some cases of relapsed or refractory disease, either as palliation or consolidation, for emergency treatment of mediastinal disease or symptomatic neurologic compromise such as spinal cord compression, palliation of pain, and treatment of overt symptomatic CNS lymphoma at diagnosis or relapse.

For persistent disease after chemotherapy or relapse disease, children are often treated with high dose chemotherapy with stem cell rescue.[351] RT to the site of residual or relapsed disease can be considered pre- or posttransplant, typically to at least 20 to 30 Gy. One must take into account potential preparatory regimens for transplant particularly if total-body irradiation (TBI) will be incorporated. Persistent disease after chemotherapy is overall rare in NHL; however, it is more common in PMBL. Consolidative ISRT in the case of residual disease following induction chemotherapy for PMBL is debated, but should be strongly considered.[330,352,353]

Emergent palliative radiation for superior vena cava syndrome, airway compromise, or spinal cord compression can produce dramatic and rapid responses, typically within 48 hours of treatment. Treatments can be daily with 1.5 to 2 Gy per fraction or hyperfractionated with twice-daily treatments of 1.2 to 1.5 Gy per day. For palliation, total doses as low as 4 Gy in 2-Gy fractions can result in rapid relief from symptoms associated with such conditions as SVC syndrome, acute respiratory distress, spinal cord compression, and orbital proptosis.[354] Local radiotherapy delivered at a dose range of 20 to 30 Gy may be more appropriate for palliation of cranial nerve deficits.[355] Steroids, ideally after confirmation of a histologic diagnosis, can also cause dramatic shrinkage of the tumor. Every attempt at biopsy should be made before steroids are administered given the potential to reduce yield in diagnosis. If steroids must be started emergently, then biopsy should be obtained within 48 hours to have the greatest chance at yielding a diagnosis in this setting.

Future Investigations

Given the high overall success rates of the current multiagent chemotherapy regimens, future trials will aim to develop more targeted therapeutic regimens that include new types of active chemical agents, monoclonal antibodies, and molecularly targeting agents. The obstacle that exists for improving NHL therapy for children is the small number of relapsed or refractory pediatric patients available to participate in early-phase trials. Given the diversity of histologies in pediatric NHL, the population is further limited given the relative rarity of the entities. Still, over the last decade, there has been progress in identifying potential targets and utilizing novel therapies for pediatric NHL. For example, ALCL tumor cells strongly express CD30 on their surface, making them a target for antibody therapy. Brentuximab vedotin, a conjugate antibody that combines an anti-CD30 antibody with a synthetic tubulin disruptor, has been evaluated in a phase II study of adults and pediatric patients with relapsed or refractory ALCL with good response rates.[356] Targeted therapy using crizotinib may also be an area of future interest in patients with ALCL as the majority demonstrate rearrangements involving the *ALK* gene. Early studies show tolerability of crizotinib in a small cohort of pediatric ALCL patients, paving the path for future efficacy studies.[357]

CD20 is expressed on the surface of cells with DLBCL and BL. Currently, most clinical experience with monoclonal antibodies in adult and pediatric B-cell NHLs exists with rituximab (anti-CD20). Several second- and third-generation anti-CD20 monoclonal antibodies are in development and undergoing trials in adult patients with NHL but with no pediatric experience. Future studies with these newer anti-CD20 antibodies should be evaluated in pediatric patients if adult trials are promising.[358]

Immunotherapeutic approaches also show promise in some subtypes of NHL. Specifically, blockage of the PD-1 (programmed death) pathway in PMBCL recently demonstrated good tolerability and efficacy in the relapsed/refractory setting.

Such new targeted treatments hold promise for improving outcomes in children with refractory and relapsed lymphoma. If successful, it may be possible to move therapies to the frontline and possibly reduce treatment intensity and chemotherapy-related toxicities.

CHAPTER 94

Unusual Tumors in Children

Zachary Buchwald and Natia Esiashvili

INTRODUCTION

Many rare childhood tumors are comparable to those that occur in the adult population and require the similar therapeutic strategy, with particular attention given to late sequelae. There are groups of rare tumors, however, diagnosed predominantly in children and require specific treatment strategies including radiotherapy.

NASOPHARYNGEAL CARCINOMA IN CHILDHOOD

Nasopharyngeal carcinoma (NPC) is a rare malignant tumor in childhood and adolescence (<1% of pediatric malignancies). The frequency differs greatly by geographic area: 1 case per 100,000 in Europe, the United States, and Australia; 10 per 100,000 in North Africa; and 80 per 100,000 in South China, Malaysia, and Greenland. Interestingly, although the absolute numbers are lower in nonendemic countries (United States, Turkey, Israel), childhood NPC is 6% to 18% of all cases compared to <1% to 2% in endemic countries/regions (southern China, Southeast Asia, Mediterranean basin).[1] A study from 2016 found that NPC in children has different demographic distribution relative to adults and is associated with low socioeconomic status, rural location, and more advanced disease at presentation.[2] The World Health Organization formerly divided NPC into three distinct classification groups: type I, keratinizing squamous cell carcinoma; type II, nonkeratinizing carcinoma; and type III, undifferentiated carcinoma. A recent change in terminology instead divides them into two broad categories: keratinizing and nonkeratinizing with the latter subdivided into differentiated and undifferentiated. Most pediatric NPC cases are type III (undifferentiated).[3] As in older patients, Epstein-Barr virus is associated with this type of NPC in addition to certain human leukocyte antigen (HLA)

haplotypes/alleles (A2 Bsin2, Aw19, Bw46, and B17). The virus is found in the tumor cells and not in the surrounding lymphocytes. Antibody and antigen titers are useful for both diagnosis and follow-up (Table 94.1).[4] The association between dietary factors and NPC has been suspected in China and seems to be confirmed in a case–control study published by Jia et al.[5]

TABLE 94.1 ANTIGEN AND ANTIBODY EPSTEIN-BARR VIRUS TITERS

	IgG VCA	Ig EA	IgM VCA	IgA VCA	IgA EA	EBNA
Naive patient	0	0	0	0	0	0
Immune patient	Mild	0	0	0	0	Mild
Burkitt lymphoma	Raised	Raised	0	0	0	Raised
AIDS	Very raised	Raised	0	0	0	0
NC	Very raised	Very raised	Mild	Raised	Raised	Very raised

AIDS, acquired immunodeficiency syndrome; EA, early antigen (active disease); EBNA, EBV-associated nuclear antigen (cellular immunity); Ig, immunoglobulin; NC, nasopharynx carcinoma; VCA, vision capsid antigen (immune status).

Clinical Presentation

The mean age at presentation is 13 years, and it has a male (1.8:1) and black predominance.[6] Typically, the initial presentation is a painless mass in the upper neck. There can be associated nasal obstruction, epistaxis, otitis, and neck and facial pain. The tumor usually originates in the fossa of Rosenmüller, followed early on by locoregional extension, including extensive pharyngeal involvement and often bone, lung, and cervical lymph node metastases.

On clinical examination, bilateral lymphadenopathy and cranial nerve palsies are found; a nasopharyngeal mass can be seen by direct or indirect nasopharyngoscopy, and sometimes, a protruding mass can be seen in the oral cavity.

The diagnostic workup must include a cranial and neck computed tomography (CT) scan with contrast, magnetic resonance imaging (MRI), and a positron emission tomography-computed tomography (PET-CT). Pathologic confirmation is obtained by biopsy. Commonly used staging systems are the tumor-node-metastasis (TNM)/American Joint Committee on Cancer (AJCC), Kyoto, and Ho classifications. The Ho and Kyoto systems are based on topographic extension; the more commonly used TNM/AJCC classification is based on tumor volume and CT information.[7]

Treatment

In adult NPC, concomitant radiotherapy (RT) and chemotherapy (cisplatin and 5-fluorouracil) are the standard of care.[8,9] Because of the scarcity of pediatric NPC cases, it is difficult to perform randomized studies in this age group. Based on adult trials, multimodality treatment is generally accepted as the standard of care for children for stage II or greater with potentially RT alone for stage I.[10] Usually, two courses of 5-fluorouracil/*cis*-diamminedichloroplatinum II (cisplatin) are given on weeks 1 and 5 of RT, whereas others prefer the standard adult regimen of three cycle.[11,12] Others have used neoadjuvant cisplatin-based chemotherapy, followed by radiation or chemoradiotherapy.[13] A recent phase II study comparing two cisplatin-based induction regimens (docetaxel plus cisplatin and 5-fluorouracil vs. cisplatin and 5-fluorouracil) did not demonstrate a difference in toxicity or efficacy.[14]

Radiation Therapy

A dose–response relationship for local control with a threshold at 60 Gy has been reported in a number of series.[11,15,16] However, Habrand et al.[17] reported interesting results with lower doses of radiation therapy (50 Gy) in patients with a good response to chemotherapy. These results are in accordance with the reports of Polychronopoulou et al.[18] and Orbach et al.[19] In this series, 70% of children achieved local control with doses of <60 Gy (50% received only 52 Gy). A study from St. Jude also reported a better outcome for patients receiving cisplatin and doses of radiation >50 Gy.[20] Techniques include three-dimensional (3D) dosimetry, customized blocking, and, if possible, MRI/CT scan image fusion for intensity-modulated radiotherapy (IMRT). Proton beam therapy is appropriate where available.

The target volume encompasses the tumor site and the neck (even in N0 disease) because of the severity of late sequelae after standard techniques. The standard of care for radiotherapy is IMRT, if available.[20] A 2017 retrospective analysis comparing 2D-CRT to IMRT demonstrated that IMRT has improved overall survival with reduced grade 2 to 4 xerostomia and hearing loss.[21] High dose rate, pulsed low dose rate, or conventional low dose rate intraluminal brachytherapy is used for the boost at some institutions. For some physicians, hyperfractionated radiotherapy is believed to be standard of care. One publication examining hyperfractionated radiotherapy showed an increased rate of neurologic complication.[22] The overall survival for T1-T2 disease is 70% to 90% at 5-years. The survival for T3-T4 disease using combined modality is 50%

to 60%. For advanced stage, innovative targeted therapies are being evaluated. These include induction of the lytic viral cycle with ganciclovir, gene therapy, antitumor vaccination against the viral protein LMP2, and more recently other immunomodulatory approaches including the adoptive transfer of EBV-specific T cells.[23–25]

Late Effects

Xerostomia is the main side effect of treatment, followed by dental caries, trismus, muscular atrophy, nerve palsies, and endocrine dysfunction resulting from pituitary irradiation. Significant auditory late toxicity and sporadic cases of visual morbidity, secondary to radiotherapy with or without cisplatin-based chemotherapy, have been reported.[26] The St. Jude retrospective analysis reported a rate of 8.5% of subsequent malignancies 8.6 to 27 years after treatment.[20]

New techniques such as IMRT have been shown to decrease the late sequelae including xerostomia.[21]

OTHER HEAD AND NECK TUMORS

Carcinoma of the Oropharynx and Salivary Glands

Schwaab et al.[27] reported the largest pediatric series, with only 2% squamous cell carcinoma among 380 head and neck tumors. The more frequent sites of disease are the tongue, lip, tonsil, palate, and salivary glands. Cigarette smoking or use of smokeless tobacco has been shown to be an etiologic factors for adolescent tongue carcinoma.[28] For other sites, passive smoking, poor oral hygiene, or genetic predispositions (xeroderma pigmentosum or retinoblastoma) have been suggested.

Special attention must be paid to larynx carcinoma because some of the cases may develop from juvenile papillomatosis, a benign condition of the aerodigestive tract that may undergo malignant degeneration. Guidelines for surgery and radiation therapy are the same as those for adults. Combined chemotherapy and radiation can be attempted for organ conservation.[29] The node area to treat does not differ from adults and must follow the Gregoire definition.[30] Psychological support and rehabilitation programs are an essential part of the comprehensive treatment for children who undergo major surgical resection.

HPV-positive oropharyngeal cancer is not a significant problem in this age group as HPV exposure is associated with sexual activity. However, in one

series, the HPV prevalence in the oral cavity/oropharynx of children was 1.9%.[31] This should help guide vaccine recommendations that may help reduce the incidence of HPV-positive disease in the future.

Esthesioneuroblastoma

Esthesioneuroblastoma is a malignant tumor arising from the olfactory nerve in the upper nasal cavity. Intracranial extension is common at the time of diagnosis. Esthesioneuroblastoma is mostly seen in patients in their 20s or 60s. Positive S100 and neuron-specific enolase stains combined with negative epithelial markers strongly suggest a neurogenic origin.[32] The clinical presentation includes nasal obstruction, loss of smell, epistaxis, and, sometimes, enlarged cervical lymph nodes. Bony structures are often involved, as well as the ethmoid and maxillary sinuses. The most commonly used staging/grouping system is by Kadish et al.[32] and is based on degree of local tumor extension. Tumors are also graded according to the Hyams system.[33]

There is no universally agreed-upon standard of care. For localized disease, tumors are resected, if possible. Because of a high risk of recurrence, postoperative radiotherapy is usually offered and has been shown to reduce recurrence risk. Earlier studies have shown local control can be obtained in >75% of cases.[34] Eich et al.[35] and Broich et al.[36] recommend combined surgery and radiotherapy in all stages. Demiroz et al.[37] reviewed 26 patients treated between 1995 and 2007. The relapse rate for patients treated with surgery alone was 29% versus 0% for those treated by surgery and postoperative radiotherapy. The recommended dose is 50 to 60 Gy.

More recently, for previously untreated disease, Hollen et al. showed local control rates at 5 years of 79%. The age range for these 26 patients was 3 to 82 years.[38] One large retrospective study from China examined long-term outcomes for 113 patients from 1979 to 2014. The majority of patients were Kadish stage C, and they were treated with multimodality therapy and different sequencing including 51 who received preoperative radiotherapy. The local control for preoperative radiotherapy followed by surgery was 91% at 5-years.[39]

Elective neck irradiation or dissection is not typically advocated because <10% of early-stage cases exhibit nodal involvement. However, node metastases are frequent if the tumor extends beyond the paranasal sinuses, and Hollen et al.[38] show that elective nodal irradiation reduces the risk of regional relapse for stage B and C disease. Therefore, lymph node dissection or prophylactic irradiation may be considered under certain clinical circumstances.

Chemotherapy has yet to be accepted as part of routine first-line treatment for early-stage disease, although responses to chemotherapy have been reported.[40] It can reduce tumor volume prior to surgery or radiotherapy and can be used for palliative purposes in advanced cases. Promising results with cyclophosphamide, doxorubicin, vincristine, *cis*-platinum, and etoposide, combined with radiotherapy and stem cell support, have been reported by Mishima et al.[41] They obtained 8 complete responses in 12 Kadish stage C and D patients. Neoadjuvant concurrent chemoradiotherapy as preoperative treatment for locally advanced esthesioneuroblastoma has been reported by Sohrabi et al.[42] with very promising results.

Recently, data evaluating the role of proton therapy have begun to accumulate. Lucas et al. retrospectively evaluated eight patients (4 to 21 years old), the majority of whom were treated with different surgery, chemotherapy, and radiotherapy sequencing; however, all received proton treatment (59.4 to 70 GyE). The results are encouraging with a 5-year overall survival of 87.5% and local control of 100% with acceptable toxicities.[43]

Juvenile Nasopharyngeal Angiofibroma

Juvenile nasopharyngeal angiofibroma (JNA) is a malignant vascular tumor most often arising from the posterior lateral wall of the nasopharynx in adolescent males. The lesion tends to extend into the nasal cavities, maxillary and sphenoid sinuses, orbit, and infratemporal fossa. Several classifications have been proposed, but the classification of Radkowski et al.[44] appears to be the most appropriate, at least for surgical purposes (Table 94.2). Common symptoms are epistaxis, cheek swelling, a visible orbital tumor, and cranial nerve palsies. JNA is more frequent in familial adenomatous polyposis patients. A mutation in the cluster region of the APC gene was reported in several studies, suggesting that JNA is perhaps a familial adenomatous polyposis tumor.[45,46]

Treatment consists of surgery for small lesions, often with preoperative embolization or hormone therapy. Surgery carries a risk of significant operative blood loss. For localized JNA, the cure rate obtained by surgery alone can be as high as 90%. Resection with negative margins is required because inadequate margins will result in a high local failure rate.[47] Minimally invasive endoscopic resection has been proposed for early-stage JNA. Lesions limited to the nasal cavity and/or nasopharynx or lesions with minimal extension through the sphenopalatine foramen are suitable for this procedure. A craniofacial approach is recommended for lesions extending into the pterygoid plates.[48,49] For tumors

with intracranial extension, there are recent data demonstrating near-total tumor resections with good outcomes.[50] Radiation therapy is used either as adjuvant treatment or as sole treatment in locally advanced lesions extending into unresectable areas. IMRT have been successfully applied in unresectable and recurrent tumors.[51] A wide range of doses have been used, but there is no evidence that doses of >36 Gy are advantageous. Chakraborty et al.[52] treated eight patients with IMRT with a median dose of 39 Gy. The local control rate was 87% with a mean follow-up of 2 years. Mallick et al.[53] looked at long-term outcomes for patients treated with radiotherapy for refractory residual or unresectable disease from 1990 to 2012 with a median dose of 30 Gy and showed a 10-year progression-free survival of 70.7%. There is no role for cytotoxic chemotherapy in JNA. The role of antiangiogenic agents is speculative, although a recent complete molecular profile suggests other potential targets.[54]

TABLE 94.2 STAGING CLASSIFICATION FOR JUVENILE NASOPHARYNGEAL ANGIOFIBROMA

Stage	Description
Ia	Limited to the nose and/or nasopharynx
Ib	Same as Ia, but with extension into one or more paranasal sinuses
IIa	Minimal extension through the sphenopalatine foramen, into and including a minimal part of the medialmost part of pterygomaxillary fossa
IIb	Full occupation of the pterygomaxillary fossa, displacing the posterior wall of the maxillary antrum forward; lateral and/or anterior displacement of branches of the maxillary artery; superior extension may occur, eroding orbital bones
IIc	Extension through the pterygomaxillary fossa into the cheek and temporal fossa or posterior to the pterygoid plates
IIIa	Erosion of the skull base with minimal intracranial extension
IIIb	Erosion of the skull base with extensive intracranial extension with or without cavernous sinus invasion

Based on the classification of Radkowski D, McGill T, Healy GB, et al. Angiofibroma. Changes in staging and treatment. *Arch Otolaryngol Head Neck Surg* 1996;122:122–129.

LUNG CANCER

Bronchogenic Carcinoma

Pediatric bronchogenic carcinoma is extremely rare, and its management does not differ from that of adults. Most of the tumors occur during adolescence.

Histology is more frequently undifferentiated adenocarcinoma or carcinoid tumors rather than squamous cell carcinoma.[55]

Of 230 cases of primary pulmonary neoplasms of childhood reviewed by Hartman and Shochat,[56] <25% were bronchogenic carcinoma. The survival rate was very similar to that of adults, stage for stage. Treatment strategies of these patients should be similar to adults.

Pleuropulmonary Blastoma

According to the International Pleuropulmonary Blastoma (PPB) Registry (IPBBR), there have been 425 confirmed cases of PPB. This tumor can occur from the neonatal period up to 12 years of age and is the most common primary malignancy of the lung in childhood.[57] PPB was often mixed with pulmonary blastoma until it was accepted that PPB is purely a pediatric tumor. The main histologic difference between pulmonary blastoma and PPB is the absence of epithelial carcinomatous components in PPB; PPB consists of mesenchymal stroma only. The tumor usually begins in pulmonary tissue, but it can also originate in the pleura or mediastinum.[58] According to the Dehner et al.[59] classification, three pathologic features can occur: cystic (type I), mixed (type II), and solid (type III). According to the IPPBR, the 5-year overall survival rates are 91%, 71%, and 53% for types I, II, and III, respectively, with the PPB type shown to be strongest predictor of outcome.[60,61] A germ-line mutation in DICER1 is the known cause of the majority of PPB cases,[62] and Messinger et al. concluded that surveillance of DICER1 carriers may be reasonable to detect PPB before it progresses. Some reports described PPB association with a preexisting pulmonary cyst.[63] It is unclear whether PPB arises in preexisting malformation or whether PPB induces cystic lesion formation. The report from the IPPBR showed that great vessel or cardiac extension is present at diagnosis in 3% of cases.[64]

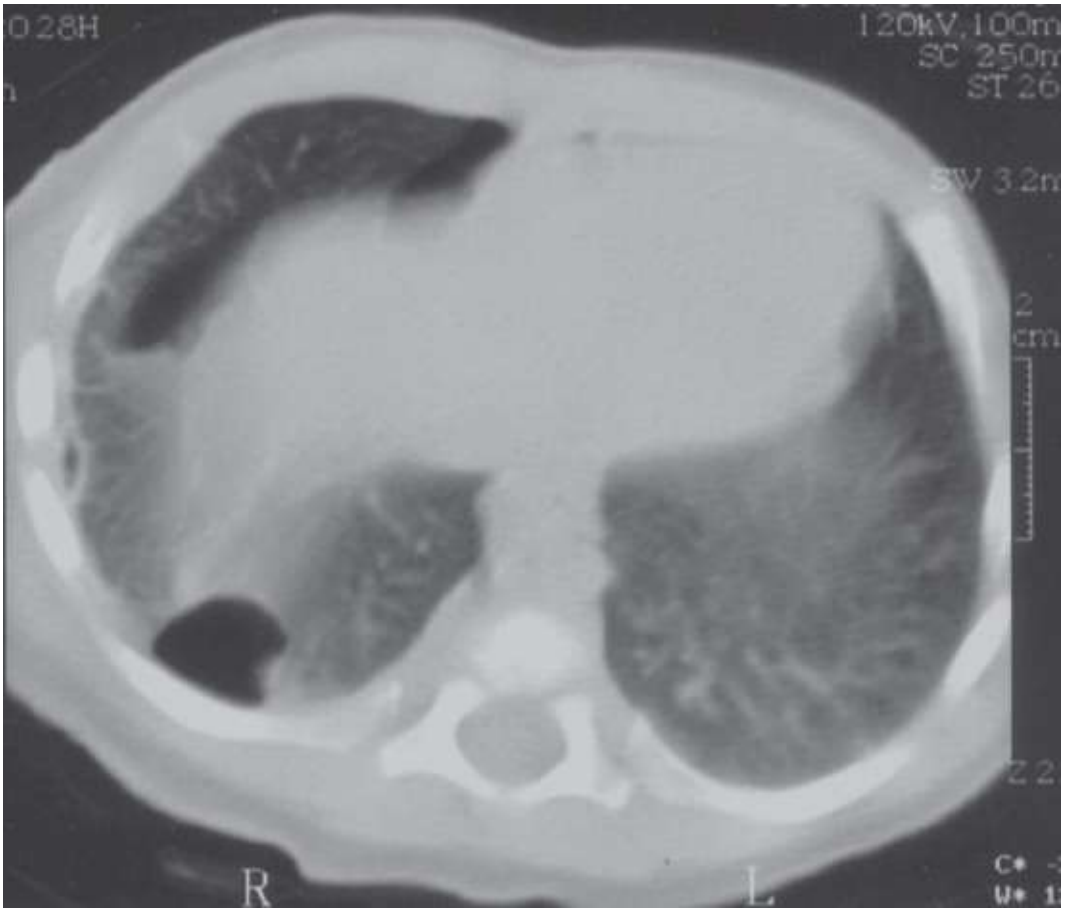

FIGURE 94.1. Pleuropneumoblastoma in a 1-year-old girl.

Clinically, PPB exhibits no specific symptoms. The usual presentation is cough, thoracic pain, and fever. Respiratory impairment is unusual. Radiologic findings depend on the extent of the cystic component (Fig. 94.1). The standard treatment is surgery alone with chemotherapy included and radiotherapy used in a minority of cases.

Priest et al.[57] reported an only 8% survival rate at 5 years among 50 patients[65]; however, large cohorts described earlier showed superior outcomes. Multimodal therapy with surgery followed by chemotherapy and radiotherapy (10.5 Gy) has been reported[66]; however, the IPPBR study examining the largest patient cohort demonstrated no benefit from adjuvant radiotherapy.[61] The value of chemotherapy is somewhat controversial for type I PPB. Because of higher metastatic potential, multiagent combinations such as actinomycin D, cyclophosphamide, cisplatin, etoposide, doxorubicin, and vincristine have been used in type II and III PPB.[58,67–70] Long-term survival can be achieved for patients treated with surgery and chemotherapy; however, the optimal combination of chemotherapy drugs or their direct impact on outcomes is less

clear.

BREAST TUMORS

Malignant breast tumors account for <1% of all childhood cancers and <0.1% of all breast cancers.[71–74]

A review of adolescents seen at the MD Anderson Cancer Center during a 40-year period identified breast cancer in 16 patients <20 years of age. Ten patients had primary adenocarcinoma of the breast, four had cystosarcoma phyllodes, and two had breast metastases from other primary tumors. Four of the 16 patients had a family history of breast disease.[75] Roisman et al.[76] reported seven female patients, ages 14 to 17 years, who were treated in various hospitals in Israel for malignancy of the breast between 1967 and 1989. There were two cases of undifferentiated carcinoma with positive axillary lymph nodes, two cases of cystosarcoma phyllodes, one case of rhabdomyosarcoma, and two cases of malignant lymphoma, one of them Burkitt type. Umanah et al.[77] reported 1 case (1.2%) of an invasive ductal carcinoma among 84 breast tumor materials from patients aged 10 to 19 years in a Nigerian city.

Ultrasonography is the most appropriate initial investigation in any adolescent patient with a breast mass because dense breast tissue adversely affects the quality of mammography.[78] MRI is recommended for diagnosing breast cancer when conventional imaging is complex and indeterminate, especially in young patients with dense mammographies.

Juvenile secretory carcinoma of the breast is rare and was first described by McDivitt and Stewart[79] in 1966 in seven girls ages 3 to 15 years, all of whom had a benign clinical course. The tumor cells are characterized by abundant mucin- and mucopolysaccharide-containing materials.[80] Hormonal receptors are generally negative.[81] Local tumor excision alone may be adequate therapy, although simple and radical mastectomies have also been used.[81–83]

The histology and patterns of spread of adenocarcinoma of the breast in children and adolescents are similar to those in adults. Because most publications refer to isolated cases, neither a consensus of opinion nor specific guidelines exist with regard to treatment. In general, principles of clinical management established for adults should be adopted. Because recurrences were found in 25% of patients treated with excisional biopsy alone, this seems inadequate, and a simple mastectomy with axillary lymph node dissection should probably be performed.[84] Sentinel lymph node biopsy offers an approach to

stage the axillary lymphatic drainage with a lower complication rate than formal dissection.[85] On the other hand, McDivitt and Stewart[79] believed that the disease tends to run a relatively favorable course and that radical therapy is therefore unnecessary. Hartman and Magrish[86] considered it important to avoid radiotherapy in young children, and instead, they recommended radical mastectomy.

Inflammatory carcinoma of the breast is extremely rare in children.[87,88]

There have been case reports of primary lymphoma, rhabdomyosarcoma, adenoid cystic carcinoma, radiation-induced sarcoma, and cystosarcoma phyllodes of the breast in children.[89–94]

Cystosarcoma phyllodes appears as a large breast mass; in 25% of cases, it is bilateral. Norris and Taylor[93] were the first to separate benign from malignant lesions in this disorder. The distinction is based on tumor size, stromal invasion, cellular atypia, degree of mitotic activity, focal calcification, and/or patterns of infiltration. Metastases occur in the lungs and bones. Lymph node metastases are extremely rare. Simple or wide local excision or simple mastectomy, with rare local recurrences, may adequately treat histologically benign lesions. In malignant cystosarcoma phyllodes, some authors recommend radical mastectomy with or without axillary lymph node dissection, and others are in favor of simple mastectomy.[95–99] The use of radiotherapy and postoperative chemotherapy in cystosarcoma phyllodes is controversial. These modalities should be reserved for locally advanced, palliative, and disseminated cases.

Rhabdomyosarcoma of the breast, either primary or metastatic, is rare. Billroth[100] reported the first case of primary rhabdomyosarcoma in a 16-year-old girl in 1860. In a series of 108 patients <20 years of age with this malignancy, Howarth et al.[101] reported 7 patients who had metastatic tumors to the breast with primary rhabdomyosarcoma located on an extremity or buttock. Six of the seven patients had alveolar histology. Rhabdomyosarcoma of the breast and other sarcomas of the breast are treated primarily by surgery followed, in most cases, by adjuvant radiation and chemotherapy.

Breast metastases in the pediatric age group include hepatocarcinoma, non-Hodgkin lymphoma, rhabdomyosarcoma Hodgkin disease, neuroblastoma, and adenocarcinoma.[102]

GASTROINTESTINAL TUMORS OF CHILDHOOD

Gastrointestinal tract malignant tumors are relatively rare in children. Carcinoid

and hepatobiliary tumors are the most common.[103] Others are adenocarcinoma, lymphoma, and leiomyosarcoma. More common are benign tumors such as hamartoma, leiomyoma, neurofibroma, and hemangioma.

Esophagus

In most cases, an esophageal tumor is of epithelial origin, either squamous cell carcinoma or adenocarcinoma. Rarely, sarcomas may develop in the esophagus (leiomyosarcoma, carcinosarcoma, malignant schwannoma). Malignization of a chemical injury to the esophagus has been described.[104] Carcinoma of the esophagus may develop in association with Barrett esophagus and Cornelia de Lange syndrome.[105,106] McGill et al.[107] reported on a 16-year-old 3-year survivor of gastroesophageal junction cancer following resection and chemotherapy. The most common benign tumor of the esophagus in the pediatric age group is leiomyoma; desmoid and teratoma may also occur.[108–110] The management of esophageal cancer in the pediatric age group follows the same guidelines of treatment as in adults.[111]

Stomach

Adenocarcinoma is extremely rare representing <0.05% of pediatric gastrointestinal malignancies; it may arise in association with Peutz-Jeghers syndrome.[112] *Helicobacter pylori* infection also appears to be a risk factor.[113] In children, the prognosis is exceedingly poor with a median survival of 5 months.[114] A report from 2015 describes an *H. pylori*–positive antral tumor in a 16-year-old boy.[115]

Non-Hodgkin lymphoma is the most frequent gastric malignancy in the pediatric age group, followed by leiomyosarcoma and leiomyoblastoma.[116] The management of non-Hodgkin lymphoma follows the treatment guidelines of non-Hodgkin lymphoma in adults. There is also some evidence that primary gastric Burkitt lymphoma may also be associated with *H. pylori*.[117]

Leiomyosarcoma of the stomach is treated primarily with surgery. Postoperative irradiation is given to patients with a high risk of local recurrence (such as positive surgical margins or extension into the retroperitoneum).

As in the adult age group, subtotal gastrectomy with resection of associated lymph nodes is the treatment of choice for children with gastric carcinoma. No data are available on adjuvant radiation–chemotherapy in the pediatric age group. In adults, there are multiple randomized studies that show a benefit to adjuvant chemoradiotherapy compared to chemotherapy alone if the patient has

a D2 dissection with positive lymph nodes.[118] A sandwich regimen of chemo, surgery, and chemotherapy has also demonstrated a progression-free and overall survival benefit.[119]

Radiotherapy guidelines are similar to those for the adult age group. At the time of radiotherapy planning, attention should be given to vital structures such as spinal cord, kidneys, small bowel, and liver. During treatment, acute side effects may occur, such as nausea, weight loss, and fatigue.

Several combination chemotherapy regimens have been used in the adjuvant setting and for locally advanced or metastatic gastric carcinoma. More than 20% of gastric cancers and up to 33% of gastroesophageal junction tumors show HER2 overexpression.[120] A phase II trial examining the role of trastuzumab demonstrated encouraging efficacy.[121]

Small Bowel

According to the Surveillance, Epidemiology, and End Results (SEER) data, the incidence of malignant small intestine tumors is low in patients <30 years of age.[122] The most common malignancy of the small intestine in children is non-Hodgkin lymphoma.[123] Sarcomas of the small bowel and carcinoids may also develop in children. Small intestine adenocarcinoma may develop spontaneously or in association with Peutz-Jeghers syndrome.[124]

Treatment guidelines are similar to those of the adult age group. Adjuvant radiation can be given after surgery for duodenal sarcomas or adenocarcinomas arising in the segment fixed to the retroperitoneum or for palliative purposes such as for pain or bleeding.

Colorectal Cancer

Carcinoma of the rectum and the large bowel is rare in children and adolescents. Recent SEER data for 2014 record a rate of around 0.4 per 100,000 for patients <20 years of age.[125] Young patients with long-standing ulcerative colitis have an increased risk of developing colorectal cancer.[126,127] Several genetic conditions may also be associated with colorectal carcinoma in childhood and adolescence. These include familial polyposis, Turcot syndrome, Oldfield syndrome, and Gardner syndrome.[120,122–126,128–134] The genetic events associated with the development of colorectal carcinoma in familial adenomatous polyposis syndrome, from epithelial proliferation, through formation of adenomas, to the sequential development of colorectal malignancy, have been described by Vogelstein et al.,[135] and more recently, the associated mutations have been well

characterized.[136]

Similar to the adult age group, signs and symptoms of colorectal cancer are related to the segment of the large bowel where the tumor is located. Because of its rarity in the pediatric and adolescent age groups, diagnosis of colorectal carcinoma is often delayed, and patients usually present with acute symptoms that necessitate urgent laparotomy. Colorectal cancer in the young is usually diagnosed at an advanced stage with metastases involving the omentum, peritoneum, mesenteric lymph nodes, liver, ovaries, and sometimes lungs, brain, and bones, and therefore, it carries a poor prognosis.[137]

Colorectal carcinoma is diagnosed by direct fiberoptic colonoscopy. Radiographic studies include barium enema with air contrast, CT scan, and radioisotope studies (fluorodeoxyglucose–positron emission tomography [FDG-PET]) to determine metastatic spread. Preoperative carcinoembryonic antigen (CEA) level is important both as a prognosticator and for follow-up purposes. CA19-9 has been less valuable, although some tumors produce CA19-9 without CEA production.

Adenocarcinoma of the colorectum may be well, moderately, or poorly differentiated. The mucinous variety and signet cell types are associated with an extremely poor prognosis. Mucinous adenocarcinoma is the most common histotype in the pediatric age group.[138] Unlike adult patients, in whom 60% of colonic cancers are located within 25 cm of the anus and in whom the rectum and sigmoid are also common sites for mucinous adenocarcinoma, tumors in children are probably more evenly distributed in all parts of the colon.[109,139,140] In a series reported by Andersson and Bergdahl,[141] the most common area was the transverse colon (39%). In a series of 20 patients reported by Karnak et al.[142] from Turkey, the rectosigmoid area was the most frequent site of location of the primary tumor (65%, the same as in adults). Another series from St. Jude's evaluated 24 adolescents with colorectal, 21 of whom had poorly differentiated mucin-producing adenocarcinoma. The disease-free survival reported was extremely poor.[143]

Surgery alone is the primary and most effective treatment for early-stage colorectal carcinoma. Because of late diagnosis, the rate of complete resection has been less than optimal in children. In the series of Karnak et al.,[142] complete resection was possible in only 6 of 20 patients. The surgical guidelines are similar to those of adult patients. Similarly, the use of chemotherapy and radiotherapy follows the guidelines of the adult age group with the Sauer et al.[144] demonstrating superiority for preoperative chemoradiotherapy for T3, T4, or

node-positive rectal cancer. Special attention should be given to radiochemotherapy sequelae on the reproductive system, as both the ovaries and testes are exquisitely radiosensitive.

Appendix

The most frequent malignant tumors of the appendix in the pediatric age group are carcinoids. These tumors are usually diagnosed incidentally during surgery for acute appendicitis or during other abdominal surgery. Complete surgical removal is the treatment of choice.[145,146]

Pancreas

Pancreatic tumors are rare in children. The most important types are the functional tumors, pancreatoblastomas, and solid papillary epithelial neoplasms.[147,148] The adult form of pancreatic adenocarcinoma rarely occurs in children.

Functional islet cell tumors are characterized by their hormonal activity. The diagnostic procedures and management follow the same guidelines set for adults.

Pancreatoblastoma, a rare tumor, accounting for 25% of pancreatic cancer in children <10 years old, has an annual incidence of 0.004 per 100,000 persons.[149] The mean age of diagnosis is 5.[150] The European Cooperative Study Group for pediatric rare tumors analyzed 20 patients diagnosed between 2000 and 2009.[151] The tumor is characterized by adenocarcinomatous tissue with ductal cells, acinar cells, squamoid corpuscles, and sometimes islet cell differentiation. These tumors stain positively by periodic acid–Schiff, α-trypsin, and α-keratin and in many cases can be associated with increased levels of α-fetoprotein (AFP).[152–154] Familial adenomatous polyposis and Beckwith-Wiedemann syndrome are associated with neonatal cases.[150] The SEER database from 1973 to 2004 reports 10 cases, and the United Kingdom National Registry of Childhood Tumors reports 11 cases.[155]

In most cases, the tumor is located in the head of the pancreas. In patients with a solitary noninfiltrative tumor, complete local resection without radical pancreatoduodenectomy is recommended. Unlike patients with local disease, in whom local resection can be curative, in many other cases, the tumor is clearly malignant, with porta hepatis or vascular invasion, local recurrences, and nodal and disseminated metastases. The prognosis for these patients is very poor.[156,157] For unresectable disease, neoadjuvant chemotherapy may be recommended with adjuvant chemotherapy to follow resection.

Radiation therapy is used in the postoperative setting, in locoregional recurrences, and in the neoadjuvant setting. A dose of 40 to 50 Gy is recommended.[154,158] Technical guidelines of radiotherapy planning are similar to those of the adults. Intraoperative radiotherapy for recurrent disease has also been used.

Chemotherapy has been used for unresectable tumors, to treat metastatic disease, or in the adjuvant setting. 5-fluorouracil, cyclophosphamide, actinomycin D, vincristine, vinblastine, mitomycin C, bleomycin, ifosfamide, etoposide, cisplatin, doxorubicin, and gemcitabine, alone or in combination, have been used with very modest results.[150,159,160] Because the disease is so rare, it is impossible to set firm guidelines and treatment policies for chemotherapy in pediatric pancreatoblastoma; however, there are case reports of long-term survival and tolerance of aggressive surgical and chemotherapy regimens for locally advanced disease.[161] There is also evidence that a combination of vinorelbine and oral cyclophosphamide may be effective for relapsed disease.[162]

Papillary cystic tumors of the pancreas, also known as Frantz tumors or solid pseudopapillary tumors, are usually encapsulated lesions that can develop throughout the pancreas. They are characterized by cystic or pseudocystic spaces surrounded by residual solid tissue. Only 15% of these tumors are malignant, and they usually occur in female patients at a mean age of 24 years at diagnosis.[163]

These tumors usually present as an upper abdominal mass. Unlike other malignant pancreatic tumors, their prognosis is excellent after complete surgical excision.[164] In a retrospective analysis, Hwang et al. showed that CT scan findings of an increased solid component indicated the disease was more likely to be malignant and a more radical resection should be recommended.[165]

The adult type of pancreatic adenocarcinoma is extremely rare in the pediatric and adolescent age groups. Signs and symptoms are similar to those of adult carcinoma of the pancreas.[158] These tumors are managed according to guidelines of treatment set for adult patients with surgery for resectable disease.

Hepatobiliary Tumors

Hepatobiliary tumors are the most common neoplasms of the gastrointestinal tract to occur in children. They constitute 0.5% to 2% of pediatric cancer in Europe and in the United States. Hepatocellular carcinoma (HCC) occurs more frequently in Saharan Africa and the Asia.[77,166,167] This geographic clustering may be explained by the high rates of hepatitis B infection and hepatitis B serum

antigen positivity.[168] This is supported by the dramatic decrease in the rate of HCC in Taiwan from 10% to 1% 10 years after a nationwide hepatitis B vaccination program was launched.[169]

Benign hepatic tumors are more frequent than malignant tumors in young children. In older children, malignant tumors become more common. Benign tumors are classified according to the cell of origin: mesenchymal (hemangioma, hemangioendothelioma, hamartoma, peliosis hepatis) or epithelial (cysts, focal nodal hyperplasia, adenoma).[170] On rare occasions, radiation therapy may be used for the treatment of hemangiomas.

Malignant tumors of the liver are classified according to the tissue of origin, with hepatocellular tumors (hepatoblastoma [HBL] and HCC) most common, constituting 75% to 90% of primary hepatic malignant tumors of childhood. Other tumors include malignant mesenchymoma, undifferentiated embryonal sarcoma, primary hepatic malignant tumors with rhabdoid features, leiomyosarcoma, angiosarcoma, hepatic sinusoid tumors, carcinoid, and non-Hodgkin lymphoma.

Bile duct adenocarcinoma (cholangiocarcinoma) is extremely rare before the age of 30. This tumor has been associated with certain rare congenital biliary anomalies, ulcerated colitis, cystic fibrosis, and sclerosing cholangitis.[170,171] The liver is also a common site for metastatic disease.

Of the malignant tumors of the liver in childhood, HBL is the most common. HBL occurs almost exclusively in small infants, although isolated instances in older children and in young adolescents have been reported. These tumors occur more frequently among males.

HBL is associated with Beckwith-Wiedemann syndrome, familial adenomatous polyposis, and congenital anomalies like hemihypertrophy and cleft palate, Wilms tumor, and glycogen storage diseases.[172–174] Although the association between HBL and Beckwith-Wiedemann syndrome indicates abnormalities on chromosome 11 and loss of heterozygosity of 11p, increased incidence of HBL in families with familial adenomatous polyposis indicates abnormalities of chromosome 5q.[174,175] More recently, it has been shown that familial adenomatous polyposis cases with HBL are associated with germ-line mutations of APC, located on 5q. However, the sporadic cases of HBL instead demonstrate mutations in the Wnt–β-catenin pathway.[176] Others have shown that activation of the telomerase gene, TERT, and MYC expression are associated with the more aggressive HBL phenotypes.[177]

The presenting signs and symptoms are distension of the abdomen, anorexia,

vomiting, anemia, fever, and jaundice. Isosexual precocity secondary to human chorionic gonadotropin (HCG) secretion or testosterone production by the tumor can be seen in some cases.[178]

Serum AFP produced by the embryonal endoderm is increased in 84% to 90% of patients with HBL.[179] HCG and cystathionase may also serve as tumor markers.[180] Histologically, HBLs (Fig. 94.2) are classified into five subtypes (Table 94.3). These subtypes can occur together in varying proportions, but present definitions do not take this into account, which makes it difficult to relate a specific histologic subtype with prognosis. Pure fetal histology has a better outcome, but the histologic definition of "pure fetal" is not clear.[182] The prognosis of the rare (3%) small cell undifferentiated subtype is poor. In long-term survivors of HBL, the most common histologic variant is the conventional type with predominantly fetal cell patterns. A German study (HB 89–94)[183] identified several poor prognostic factors in HBL: metastatic disease, AFP > 1,000,000 ng/mL, extrahepatic and intrahepatic vascular invasion, multifocal disease, involvement of both liver lobes, stage (TNM), and poorly differentiated epithelial histology. More informative molecular data have begun to accumulate.[176] Sumazin et al. performed whole-exome sequencing, mRNA and miRNA expression arrays, and high-resolution copy number arrays. They found three distinct molecular clusters with prognostic biomarkers including NOTCH1 and NFE2L2.[184] They demonstrate, from clustering of mRNA profiles, the high-risk group has a difference in cumulative survival relative to the low- and intermediate-risk groups.

HCC is the second most common primary malignant liver tumor in the pediatric age group and accounts for about one-fourth to one-third of hepatic malignancies. Although reported in children as young as 21 months, most reports indicate that HCC usually develops in early adolescence.[185,186] This is in contrast to HBL, which occurs primarily in infancy and is seldom seen in children older than 3 years. Similar to HBL, HCC occurs mainly in males.[187,188] The fibrolamellar carcinoma variant of HCC occurs mainly in young adults around the age of 20 years but has also been reported in childhood.[189,190]

Approximately 25% of HCC cases in childhood are associated with cirrhosis secondary to biliary atresia, Fanconi anemia, glucose-6-phosphatase deficiency, and hereditary tyrosinemia.[191] The most important known etiologic factor for HCC is the high incidence of maternal transmission of the hepatitis B surface antigen in Africa and Asia.[192,193] Other etiologic factors include exposure to aflatoxins, hepatic fibrosis, anabolic steroids, inherited disorders of metabolism,

membranous obstruction of the inferior vena cava, and possibly ethanol abuse.[167,188,194] However, these etiologic factors apply mostly to HCC in the adult age group. In adult black South African patients, deletions of alleles on chromosome 17p and P53 (codon 249) have been identified[195,196]; the exact molecular mechanisms responsible for the development of HCC are not known.

Similar to HBL, two-thirds of children with HCC have an elevated AFP.[197] AFP levels are high in the healthy newborn and drop rapidly by the age of 1 month and should not be detectable by age 2 years.[198] Initial AFP level is a significant prognostic factor: In a study performed by the Radiation Therapy Oncology Group,[199] the mortality in HCC was 1.8 times higher in patients with strongly positive AFP. AFP is an indicator of tumor growth and can serve as a valuable marker of response to therapy. After complete tumor resection, AFP level should return to normal within 2 months.[200] Increasing levels of AFP during the follow-up period after surgery indicate local recurrence or metastatic disease.[197]

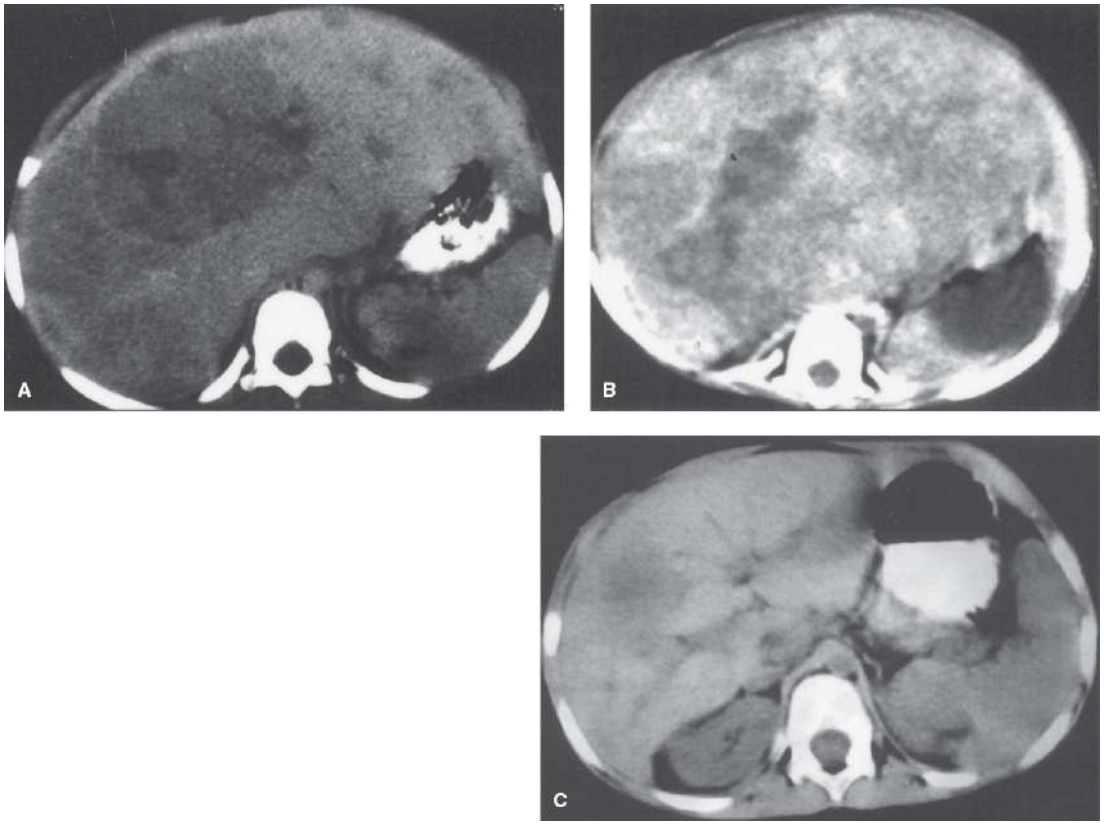

FIGURE 94.2. A 7-year-old girl with hepatoblastoma at diagnosis **(A)**, after one cycle of chemotherapy **(B)**, and after four cycles of chemotherapy before right hepatic lobectomy **(C)**.

The Children's Cancer Study Group (CCSG) intergroup and Pediatric Oncology Group (POG) staging systems for primary malignant liver tumors are based on resectability and on the histologic subtype (Table 94.4[201] and Table 94.5[203]).

Successful therapy of localized HBL or HCC depends mainly on the feasibility of complete surgical excision.[183] Up to two-thirds of HBL patients have resectable tumors at presentation because these tumors are usually unifocal and encapsulated. Cure can be achieved in one-third of the successfully operated patients, typically those with fetal HBL.[172,182,204]

TABLE 94.3 HISTOLOGIC CLASSIFICATION OF HEPATOBLASTOMA

Epithelial type (56%)	Mixed epithelial and mesenchymal type (44%)
Fetal pattern (31%)	Without teratoid features (34%)
Embryonal and fetal pattern (19%)	With teratoid features (10%)
Macrotrabecular pattern (3%)	
Small cell undifferentiated pattern (3%)

TABLE 94.4 CHILDREN'S CANCER STUDY GROUP STAGING SYSTEM FOR PRIMARY MALIGNANT LIVER TUMORS

Stage	Description
I	Complete excision
A	Favorable histology (fetal HBL)
B	Unfavorable histology (embryonal HBL, HCC)
II	Microscopic residual disease
A	In liver
B	Extrahepatic
III	Gross residual disease ± node involvement ± spilled tumor
A	Tumor completely removed; tumor spilled, residual gross disease in nodes, or both
B	Gross tumor not completely removed ± positive nodes ± spill
IV	Metastatic disease
A	Primary tumor completely excised
B	Primary tumor not completely excised

HBL, hepatoblastoma; HCC, hepatocellular carcinoma.
Data derived from Cohen MD, Bugaieski EM, Haliloglu M, et al. Visual presentation of the staging of pediatric solid tumors. *Radiographics* 1996;16:523–545.; Perilongo G., S.D., Meadown A.T.,

et al. *Liver tumors*. New York: Wiley-Liss, 1992. References 201 and 202.

In contrast, only 30% of the cases of HCC are suitable for complete resection at the time of diagnosis because of the multifocal involvement or size. From 50% to 75% of the fibrolamellar variant of HCC is amenable to complete resection at the time of presentation.[205,206] In principle, tumor resectability is determined by the tumor size, the existence of bilobar involvement necessitating the resection of more than three liver segments, vascular invasion, or metastatic spread. Patients with advanced disease who are not suitable for primary surgery may be considered for neoadjuvant preoperative cytoreductive chemotherapy. In these cases, the diagnosis can be based on clinical presentation; on imaging findings, including FDG-PET scan[207] and tumor markers; or on tissue diagnosis obtained via open biopsy or CT/ultrasound-guided needle biopsy, although there are some concerns that a needle biopsy may cause a significant hemorrhage. Preoperative cytoreductive chemotherapy can reduce the size of the tumor in the majority of HBL patients and in a significant percentage of HCC patients, rendering them resectable. A variety of chemo regimens exist including cisplatin, vincristine, and 5-fluorouracil,[208] the camptothecin analogues topotecan and irinotecan; oxaliplatin; and liposomal doxorubicin (Doxil).[183] Sorafenib, a tyrosine kinase inhibitor, is available for unresectable HCC. In animal models of pediatric HCC, sorafenib has shown promising efficacy.[209] A phase II trial also demonstrated a good toxicity profile for sorafenib in children.[210] Bevacizumab has shown a survival benefit in a phase II trial.[211,212] In one center's experience, bevacizumab plus conventional platinum-based chemotherapy was effective and safe.[213] If resectability cannot be achieved using chemotherapy, there is still a chance to render unresectable tumors resectable by radiotherapy.[205] The perioperative mortality of hepatic lobectomy is on the order of 5% to 10% in specialized centers applying improved surgical techniques, modern methods of anesthesia, and state-of-the-art postoperative intensive care.[214]

TABLE 94.5 PEDIATRIC ONCOLOGY GROUP STAGING SYSTEM FOR PRIMARY MALIGNANT LIVER TUMORS

Stage	Description
I	Complete resection achieved
II	Microscopic residual tumor remaining
III	Gross residual tumor remaining
IV	Metastatic disease present at diagnosis

Modified from Bowman LC, Riely CA. Management of pediatric liver tumors. *Surg Oncol Clin N Am* 1996;5(2):451–459. Copyright © 1996 Elsevier. With permission.

Surgical resection of pulmonary metastases can be attempted if they persist after chemotherapy and if the primary tumor can be completely resected. Patients who are successfully operated on for stage I disease and later develop a solitary lung metastasis are also suitable for metastasectomy.

Total hepatectomy and liver transplantation can be attempted in unresectable HBL (about 10% after chemotherapy) and HCC (>50% are unresectable at diagnosis) with tumor confined to the liver without penetration of the capsule and in the absence of lymph node and distant metastases. The overall survival is between 50% and 83%, with a minimum follow-up of 2 years. The best outcome was achieved in patients with a good response to chemotherapy who had a "first-line transplant" (i.e., not after an unsuccessful attempt at resection).[183,215–217]

Although it has been used preoperatively and postoperatively in children with HBL and HCC, radiation therapy has a limited role in curative management.

Preoperative radiation was given to children who remained unresectable after initial chemotherapy.[205,218,219] In the postoperative setting, it has been shown that patients with residual disease after surgery may benefit from postoperative irradiation. In a combined POG-CCSG protocol,[182] patients with microscopic residual disease after surgery received postoperative chemotherapy and limited field irradiation, 45 Gy to the tumor bed. Their 3-year progression-free survival was 60%. Patients who were unable to undergo complete resection after preoperative chemotherapy received whole-liver irradiation, 30 Gy. Their 3-year progression-free survival was 22%.

According to the Institut Gustave Roussy protocol,[205] children were treated with preoperative chemotherapy followed by surgery. If there was evidence for microscopic or gross persistent tumor at surgery, more chemotherapy was given and limited field irradiation was administered to the site of residual tumor, 25 to 45 Gy. Fifteen patients were reported by Habrand et al.,[205] 11 with HBL, 2 with HCC, and 2 without tissue diagnosis. Nine patients who underwent surgical resection of the primary tumor received either preoperative or postoperative chemotherapy consisting of vincristine, doxorubicin, and cyclophosphamide, alternating with vincristine, cyclophosphamide, and *cis*-platinum. Radiotherapy with a median dose of 40 Gy was given to eight incompletely resected patients. Six of eight patients were alive at a median of 45 months from the time of diagnosis. One inoperable patient was rendered operable by whole-liver irradiation (24 Gy) and concurrent 5-fluorouracil and *cis*-platinum. This patient

was alive at 68 months after radiation therapy. Of four unresectable primaries, one was controlled by radiotherapy. Two children received whole-lung irradiation, 18 to 20 Gy, for pulmonary metastases; neither of them was controlled. One of these two patients underwent pulmonary metastasectomy and was alive without evidence of disease 41 months after surgery.

When radiotherapy is given to children with HBL or HCC, careful assessment of the tumor volume is essential to reduce the amount of normal liver tissue irradiated. Parallel-opposed high-energy beams or multiple-field techniques, using 3D treatment planning systems or IMRT, should be employed. When limited irradiation volume is administered, a dose of 35 to 45 Gy is appropriate for bulky disease and 25 to 45 Gy for microscopic residual disease. For children treated with a palliative intent, whole-liver irradiation, 20 to 25 Gy in 2 to 2.5 weeks, is adequate.

The results of whole-lung irradiation for macroscopic pulmonary metastases are discouraging. A total dose of 12- to 13-Gy whole-lung irradiation might be considered in patients with microscopic residual pulmonary metastatic disease after chemotherapy or surgery and chemotherapy.

A number of multicenter trials have been performed by cooperative study groups to test the value of preoperative and postoperative combination chemotherapy in HBL and HCC. In some of the studies, radiotherapy was included as part of the treatment protocol. It has been demonstrated that a significant number of initially unresected tumors could be surgically removed after chemotherapy and that complete resection followed by adjuvant chemotherapy was superior to surgery alone.

In CCG trial 831,[220] patients with residual disease in one lobe after surgery received actinomycin D, vincristine, and cyclophosphamide combination chemotherapy and involved-field irradiation. Patients with disseminated tumors received chemotherapy alone. Of 40 children entered into the study, there were only 7 long-term survivors: those with either stage I disease or minor residual tumor who received irradiation.

In CCG trial 881,[220] doxorubicin and 5-fluorouracil were added to the actinomycin D, vincristine, and cyclophosphamide combination used in CCG 831. A response rate of 44% was observed in patients with measurable disease, and 83% of patients receiving the drug combination as an adjuvant treatment were disease-free at 30 months.

In CCG trial 823F,[220] patients with HBL (33 children) or HCC (14 children) confined to the liver received doxorubicin and cisplatin prior to definitive

surgery. Although only 2 of 14 HCC patients survived, 78% of 25 HBL patients who completed chemotherapy and were eligible for surgery were alive without evidence of disease. In 16 patients, complete resection was performed, and no viable tumor was found in 9 of them at the time of surgery. Fifteen of these patients were alive and disease free. It was found that, for children with unresectable or metastatic HBL entered into this study, early changes in AFP levels were a reliable predictor of outcome and could identify poor responders to therapy. The authors suggested that if the AFP level failed to decrease by two logs prior to surgery, a surgical approach should probably not be attempted.[221]

In a trial performed by the Pediatric Hepatoma Study Intergroup (CCG 8881/POG 8945),[222] patients were allocated to receive either cisplatin, vincristine, and 5-fluorouracil or cisplatin and doxorubicin. Both chemotherapy regimens were equally effective in terms of overall and disease-free survival; however, the cisplatin plus doxorubicin combination was significantly more toxic.

POG study 8,679[223] enrolled children with stage I to IV HBL. Children with stage I favorable histology received surgery alone. Children with stage I unfavorable histology or stage II disease received surgery and adjuvant cisplatin, vincristine, and 5-fluorouracil. Children with stage III or IV disease received five cycles of chemotherapy, after which they were evaluated for surgery. Unresectable patients received limited field irradiation, 33 to 39 Gy, and additional chemotherapy. The 3-year disease-free survival for stage I unfavorable histology and stage II patients was 91; for stage III, it was 67; and for stage IV patients, it was 13. Three of five irradiated patients underwent complete resection and were free of disease.

The International Society of Pediatric Oncology (SIOP) designed a series of clinical trials based on a risk-adapted treatment approach philosophy. In the SIOPEL-1 trial, patients underwent a preoperative cisplatin–doxorubicin (PLADO) regimen.[224] The investigators concluded that the extent of pretreatment hepatic disease and the presence of pulmonary metastases were significant prognosticators of 5-year event-free survival. Survival for HCC patients was significantly inferior to that of children with HBL, and complete tumor excision remained the only realistic chance of cure. A novel staging system was developed called *PRETEXT* (pretreatment extent of disease), and two risk clusters for treatment failure were identified: a “standard-risk” group, comprising patients with disease confined to the liver and involving up to three hepatic sectors, and a “high-risk” group, with disease extending to all four

hepatic sectors or with extrahepatic spread. It was suggested that PLADO chemotherapy followed by delayed surgery and a short course of postoperative chemotherapy used in the SIOPEL-1 trial should be regarded as best treatment for children with HBL and that future treatment programs should be measured against this standard.[225,226]

In the SIOPEL-2 trial, patients were stratified according to standard- and high-risk groups. For high-risk HBL patients, treatment was intensified by adding carboplatin to the cisplatin/doxorubicin regimen used in the SIOPEL-1 trial, in a rapidly alternating sequence of administration. For standard-risk HBL patients, 3-year overall and progression-free survivals were 91% and 89%, and for the high-risk HBL group, they were 53% and 48%, respectively. Despite chemotherapy intensification, only half of the high-risk HBL patients were long-term survivors.[227]

SIOPEL-3 standard-risk HBL trial compared doxorubicin plus cisplatin versus cisplatin alone with cisplatin monotherapy achieving similar rates of complete resection and survival[228]. For the high-risk patients, they were treated with alternating cycles of cisplatin and carboplatin plus doxorubicin and delayed tumor resection with results showing an improved survival compared to previous results.

Finally, SIOPEL-4, a prospective single-arm trial for high-risk HBL, evaluated a dose-dense cisplatin regimen with results showing feasibility and efficacy for this cohort. Complete resection of all tumor lesions was achieved in 74% with 3-year event-free survival of 76%.[229]

SIOPEL-5 was focused exclusively on HCC and was closed because of poor accrual, and SIOPEL-6 is a randomized trial evaluating the efficacy of STS in reducing ototoxicity for standard-risk HBL patients receiving cisplatin. Final results are pending although there were no adverse outcomes related to STS reported.[230]

An ongoing phase III COG trial, AHEP-0731, has the primary objective of evaluating survival for HBL based on the stage treated with surgical resection followed by two cycles of cisplatin, 5-FU, and vincristine. The guidelines of the study recommend surgical resection only for PRETEXT I and II tumors and specific imaging findings with the intention of more effectively systematizing surgical decisions rather than relying on individual practitioners.[231]

Investigators from the United States analyzed the effectiveness of intrahepatic chemotherapy[232] and intrahepatic chemoembolization.[233] They concluded that these treatment modalities can halt the progression and possibly downstage

advanced hepatic malignancies.

Japanese investigators used transarterial chemoembolization with Lipiodol and cisplatin/etoposide, concluding that this treatment modality was particularly useful in potentiating the cytoreductive effect of antitumor drugs and also useful in reducing toxicities.[234]

Other Japanese investigators analyzed the survival outcome for patients with HBL treated by preoperative and/or postoperative chemotherapy using a combination of cisplatin and tetrahydropyranyl–Adriamycin.[235] They concluded that preoperative chemotherapy resulted in an improved resectability of the tumor, whereas postoperative chemotherapy played an important role in the increased cure rate of patients with an incomplete tumor resection or metastasis.

In the prospective, multicenter, single-arm German Liver Tumor Study HB94, children undergoing primary surgery received ifosfamide, cisplatin, and Adriamycin (IPA) chemotherapy and/or etoposide and carboplatin. Treatment was risk stratified according to stage: stage I patients receive IPA ×2; stage II patients receive IPA ×2 to 3; and stage III or IV patients receive carboplatin/etoposide plus IPA. Growth pattern of the liver tumor, vascular tumor invasion, occurrence of distant metastases, initial AFP level, and surgical radicality were found to be pretreatment prognostic factors.[236]

In an interim analysis of the German Liver Tumor Study HB 99, it was shown that adding high-dose carboplatin and etoposide to the regimen for high-risk HBL patients was highly efficient and induced a remission in the majority of patients with advanced and metastasized high-risk HBL.[237]

LANGERHANS CELL HISTIOCYTOSIS

Langerhans cell histiocytosis (LCH), a dendritic disorder, is believed to affect fewer than 1 in 200,000 children; however, any age group can be affected.[238]

Other terms for LCH include histiocytosis X, eosinophilic granuloma, Letterer-Siwe disease, and Hand-Schüller-Christian disease; however, the preferred term is LCH.

The pathogenesis is not completely understood, but excessive production of interleukin-1, interleukin-17a prostaglandin, and metalloproteases MMP9 and MMP12,[239] as well as of prostaglandin E_2, has been demonstrated in affected bone. These factors can play a major role in osteoclast activation. Controversy exists regarding whether the clonal proliferation of LCH cells results from a malignant transformation or is the result of an immunologic stimulus. Regardless

of the mechanism responsible for the clonal proliferation, the primary treatment, if necessary, involves chemotherapeutic agents. Select chemotherapeutic drugs also have immunomodulatory activity. The diagnosis of LCH is based on a histologic and immunophenotypical examination of tissue. The main feature is the morphologic identification of the characteristic Langerhans cells. In addition, positive staining of the lesional cells with CD1a, langerin (CD207), or both are required for a definitive diagnosis. The expression of langerin confirms the presence of Birbeck granules, the cytoplasmic organelles typically found in Langerhans cells.[240]

In children older than 2 years, the disease is less aggressive, with widespread bone granulomas causing pain, otitis, diabetes insipidus (42%), and exophthalmos. Eosinophilic granuloma is characterized by bone involvement only and with symptoms related to the location of the granuloma. Central nervous system (CNS) involvement is possible; most frequently, meningeal and pituitary lesions occur, but intraparenchymal lesions, especially hypothalamic and cerebellar, can also be encountered.

Staging procedures include a skeletal survey (rather than isotopic bone scan). Many prognostic scores have been proposed, all based on the extent of disease, age at diagnosis, and demonstrable organ dysfunction.[241] Patients are classified into the following groups:

Single system	Unifocal or multifocal organ system involvement Unifocal or multifocal bone involvement Skin Lymph node Hypothalamic/pituitary/CNS Other (e.g., thyroid)
Multisystem	Involvement of ≥2 organs or systems[242]

Treatment decisions are based on whether the high- or low-risk organs are involved and whether the disease is single system or multisystem. Many cases of LCH are indolent or resolve spontaneously. Aggressive treatment therefore should not be given if there is no organ dysfunction. International efforts during the last 20 years have shown that combination therapy with vinblastine/prednisone is an effective therapy for multisystem LCH. Trials conducted by the Histiocyte Society confirmed this regimen as standard therapy for multisystem LCH with and without risk organ involvement.[243,244]

Risk organs and their involvement were defined according to modified Lahey criteria as follows:

- Hematopoietic: Anemia and/or leukopenia and/or thrombocytopenia
- Liver: Enlargement >3 cm below the costal margin, dysfunction, or both

- Spleen: Enlargement >2 cm below the costal margin
- Lung: Typical changes via high-resolution CT, histopathologic diagnosis, or both[245]

Local Therapy

The POG 8047 study demonstrated that a similar control rate can be achieved (70% to 90%) with biopsy, curettage, or tumor excision.[246] Wide excision is recommended for expendable bones (clavicle, ribs) and biopsy for other sites. Curettage is not indicated if there is a risk of instability (cervical vertebra, femoral neck) or if a poor cosmetic or orthopedic outcome is likely.

Radiation therapy was widely used in the 1960s but is no longer indicated in the large majority of cases. Radiation therapy could be discussed in a case of resistant cerebral location. Tumors are very radiosensitive; however, wide range of dose has been reported for treatment of LCH (3 to 50 Gy).[247–251]

It appears that 9 Gy for bone lesions and 15 Gy for soft tissues will result in very high response and local control rates; however, they may be still consequential for children and should be only considered in selected cases.

Systemic Treatment

In Situ Injection of Steroids

The procedure is performed under general anesthesia and fluoroscopic guidance. Methylprednisolone is injected directly into the granuloma.[252] It has not been proven whether the steroid or the local trauma is responsible for the effects.

Chemotherapy

The exact point in the course of the disease at which chemotherapy should be considered is controversial. There is little agreement on the factors that should be considered as bad prognostic signs. Only organ dysfunction and/or multiorgan disease have been generally accepted as indications for chemotherapy. Initially, high-dose steroids are used and followed, when necessary, by vinblastine. The international study LCH2 compared vinblastine and etoposide, with no benefit seen for the latter. Thus, because of the risk of etoposide-induced leukemia, the drug should not be used as first-line therapy.[253] The LCH3 protocol failed also to find any advantage for methotrexate.[244] There is no proof that a multidrug regimen is more effective than single-agent chemotherapy as first-line therapy. Furthermore, it is unknown whether early treatment prevents the development of diabetes insipidus at a later stage.[254,255] Recently, promising results were reported using thalidomide for treatment of disseminated LCH.[256]

For resistant disease (especially in infants), a more aggressive approach, including cyclosporine, liver transplantation, bone marrow transplantation, and/or monoclonal antibody therapy, is under investigation.[257,258] Pamidronate has been shown to be effective in reducing bone pain secondary to skeletal involvement by LCH.[259]

The reported overall incidence of the long-term consequences of LCH ranges from 20% to 70%. The reason for this wide variation is due to sample size, therapy used, duration of follow-up, and method of data collection. Children at low risk for organ involvement have approximately a 20% likelihood of developing long-term sequelae.[260] The most commonly reported permanent consequences are diabetes insipidus, orthopedic abnormalities, hearing loss, and neurologic issues.

Rosai-Dorfman disease (RDD), also known as sinus histiocytosis with massive lymphadenopathy, is nonmalignant histiocytic disorder. Histology and immunohistochemistry help differentiate RDD from malignant disorders such as lymphoma and LCH.

Patients typically present with fever, leukocytosis, and nonpainful cervical lymphadenopathy. Although the disease has a predilection for the lymph nodes in the head and neck, RDD can also present in any extranodal site, with common sites including the skin and soft tissue, the CNS, and, less commonly, the gastrointestinal tract.

RDD is usually self-limiting and eventually recedes, making systemic therapy rarely required. In patients with RDD requiring systemic treatment, steroids are a first-line therapeutic option.

In patients with RDD, radiation can be used for symptomatic steroid-resistant disease. Although no standard radiation guidelines have been established for patients with RDD, lymphoma-like approaches with total doses ranging between 30 and 50 Gy have been employed.[261]

ENDOCRINE TUMORS

Adrenocortical Carcinoma

Adrenocortical carcinoma (ACC) accounts for 0.2% of childhood cancer and in 75% of the cases occurs in children younger than 5 years, more commonly in females.[262–267] ACC is sometimes associated with Beckwith-Wiedemann syndrome and hemihypertrophy.[268]

Children with ACC may present with abdominal pain and a palpable mass.

More than 75% of the tumors are functional, secreting one or more hormones: androgens, cortisol, aldosterone, or estrogens. The most common presenting sign is virilization, with deepening of the voice, hirsutism, premature pubic hair, clitoromegaly, phallumegaly, excessive muscular development, and advanced bone age. Pure Cushing syndrome (moon face, plethora, hypertension, striae, weight gain, acne, and "buffalo hump") is rare in children. Feminization or aldosterone-secreting tumors are also rare.[266]

Urinary 17-ketocorticosteroids and 17-hydroxycorticosteroids are usually elevated, with steroid production not influenced by adrenocorticotropic hormone suppression.

Diagnostic imaging studies include CT and/or MRI. It is sometimes difficult to separate ACC from adenoma. However, at presentation, most carcinomas are >6 cm and calcified, whereas benign adenomas are small and nonfunctional. A characteristic echogenic star pattern can be seen on ultrasonography, and CT scan shows an inhomogeneous tumor with irregular contrast material. Recently, the use of 18-FDG-PET has been shown to be effective in discriminating between benign and malignant adrenal lesions.[269,270] Because both benign adenomas and ACC may exhibit abnormal mitoses and cellular and nuclear pleomorphism, malignancy is determined by the finding of capsular penetration, invasion of the inferior vena cava up to the right atrium, lymph node, and distant metastases.[262]

Generally, the prognosis of ACC is poor.[271–273] Small, well-encapsulated, and easily excised tumors can be cured by surgery alone. In locally advanced cases, there is a significant risk of locoregional and metastatic relapse.[266,267] Repeat complete resection of local recurrences and discrete metastatic lesions can improve survival.[274]

The literature on adjuvant radiation therapy after resection of ACC is scarce and relatively old and consists of small series or case reports. Postoperative whole-abdominal irradiation (15 to 30 Gy) was administered by Stewart et al.[275] Three of four irradiated patients were long-term survivors. Percarpio and Knowlton[276] used preoperative irradiation, 45 to 50 Gy, to treat two patients and postoperative irradiation to treat four patients with unresectable tumors or spillage at the time of surgery. One patient who was treated preoperatively was rendered operable; three of four postoperatively treated patients relapsed in the field of radiation and one outside the field.

Magee et al.[277] reported a series of 15 patients with ACC, 9 of whom received postoperative irradiation. Three of the irradiated patients were girls

under the age of 2 years, who received 30 Gy in 4 weeks. Two of these girls died as the result of a second malignancy arising in the irradiated volume.

Based on these results and the results of similar small retrospective series,[263,278–280] it is difficult to make any firm recommendations on the role of radiotherapy in ACC. Investigators from the United Kingdom reported a relatively high frequency of second, fatal, primary tumors, especially if radiotherapy was part of the treatment protocol.[281]

Mitotane (o,p-DDD) is the most frequently used chemotherapeutic agent for recurrent or metastatic ACC, with a response rate of approximately 20%. Other agents include suramin, doxorubicin, 5-fluorouracil, streptozotocin, cisplatin, and etoposide, alone or in combination, with response rates of 20% to 30%.[282] The administration of adjuvant chemotherapy is controversial. Some investigators advocate the use of adjuvant mitotane after surgery[278]; however, the administration of this drug is associated with significant gastrointestinal, neuromuscular, and skin toxicity, as well as with abnormal platelet aggregation and prolongation of bleeding time. There is also a significant decrease in urinary 17-hydroxysteroids and 17-ketosteroids. The response rates to mitotane are highly dependent on obtaining adequate serum levels (>10 to 14 mcg/mL), and the therapeutic window between toxicity and efficacy is quite narrow. Hence, most authorities agree that in the absence of solid data based on randomized, well-controlled clinical trials, it is difficult to justify the administration of radiation or chemotherapy in the adjuvant setting.[187,281,283]

PHEOCHROMOCYTOMA AND PARAGANGLIOMA

Pheochromocytoma and paraganglioma are rare tumors of childhood and adolescence.[284–288] Pediatric pheochromocytoma occurs usually between 8 and 14 years of age, more frequently in males. More than 90% of all pheochromocytomas in adults, and 70% of pheochromocytomas in children, originate in the adrenal gland, but the tumor can occur at any site in the sympathetic chain, most commonly below the diaphragm. The most common sites of occurrence of extra-adrenal pheochromocytoma are the superior paraaortic region, between the diaphragm and the lower renal poles, in the paraganglia, the organs of Zuckerkandl, and the bladder. Extra-abdominal tumors may develop in the brain, thorax, and the bladder.[284,287,289,290] Approximately 10% of all patients with pheochromocytoma are children, but several characteristics distinguish them from their adult counterparts. Unlike

pheochromocytomas of the adult age group, children with pheochromocytoma have a higher incidence of bilaterality, a higher association with the multiple endocrine neoplasia (MEN) syndromes, and a lower incidence of malignant neoplasms.[284,289,291,292]

Familial pheochromocytoma is associated with other endocrine tumors in the MEN IIA and IIB syndromes.[289,293–295]

In addition to the familial syndrome of isolated pheochromocytomas, pheochromocytomas in the pediatric age group can be associated with other inherited diseases, such as von Hippel-Lindau disease (retinocerebral angiomatosis), tuberous sclerosis, and von Recklinghausen neurofibromatosis.

Malignant pheochromocytomas occur in 10% of the pediatric cases of pheochromocytoma. The definition of malignancy is based on biologic and clinical behavior and not on histologic features alone.

Pheochromocytoma is responsible for 1% of cases of childhood hypertension, which, unlike the situation in adults, is sustained and not paroxysmal. Other signs and symptoms include diaphoresis, flushing, fatigue, headache, and convulsions.[296]

Adrenal pheochromocytomas produce epinephrine and norepinephrine, but most extra-adrenal pheochromocytomas produce only norepinephrine.

Urinary epinephrine, norepinephrine, metanephrine, and vanillylmandelic acid values remain the gold standard for biochemical screening of pheochromocytoma. On some occasions, urinary catecholamine levels may be normal, whereas serum levels are elevated. Imaging studies include ultrasonography, CT scan, and/or MRI. Iodine-131 metaiodobenzylguanidine (MIBG) scan provides the most accurate and direct method of diagnosing adrenal, extra-adrenal, or metastatic pheochromocytoma because MIBG, which has a molecular structure similar to that of norepinephrine, is actively concentrated and stored in catecholamine storage vesicles of pheochromocytoma cells.[284,289,297–299]

Surgery is the definitive therapy. The most significant reduction in preoperative and postoperative mortality has come from the control of perioperative hypertension using alpha- and beta-blockers.[34,300]

External beam irradiation is used for palliation of lymph node, bone, brain, and spinal cord metastases. High-dose iodine-131 MIBG has been used with modest results in metastatic disease. Streptozotocin or cyclophosphamide, vincristine, and dacarbazine may produce modest decreases in catecholamine secretion in patients with malignant pheochromocytoma.[282] Patients with

malignant pheochromocytoma require chronic medical control of their elevated blood pressure by alpha and beta blockade or inhibition of catecholamine synthesis with α-methyl-para-tyrosine.[301–303]

THYROID CARCINOMA

Thyroid carcinoma accounts for 1% to 1.5% of all cases of cancer in the pediatric and adolescent age groups, with between 0.4 and 1.5 cases per million, two to three times as frequent in girls as in boys.[304] After the April 26, 1986, Chernobyl nuclear reactor accident, a remarkable incidence increase was observed in children exposed to radioactive iodine (RAI) fallout.[305,306] The incidence of thyroid cancer in Belarus and Ukraine began to rise sharply in 1989 to 1990: in adults, the number of new cases increased twofold to threefold; and in children <20 years of age, and particularly during the first 5 years of life, the number of new cases increased 20- to 30-fold.[305] Almost all new pediatric cases were papillary tumors (94% to 98%), with a relatively high incidence of lymph node (65%) and lung (5%) metastases at presentation (Table 94.6). Lubin et al.[307] reported pooled data from nine cohort studies of childhood external radiation exposure and thyroid cancer with individualized dose estimates, ≥1,000 irradiated subjects or ≥10 thyroid cancer cases, with data limited to individuals receiving doses <0.2 gray.

TABLE 94.6 HISTOLOGIC TYPES OF CHILDHOOD THYROID CANCER

Type	Frequency (%)	Characteristics
1. Differentiated carcinoma		
A. Papillary carcinoma	70–80	Infiltrative and multicentric; lymph node metastases in 70%–90% of cases; hematogenous spread (mainly lung) in 5%–10% of cases
B. Follicular carcinoma	16–20	Vascular invasion
2. Medullary carcinoma	Rare	Occurs in isolation, but more frequently associated with one of the MEN syndromes; usually aggressive and can be fatal
3. Undifferentiated carcinoma	Rare	Aggressive, usually fatal within 6 months of diagnosis
4. Insular carcinoma	Very rare	A variant of the poorly differentiated carcinoma; aggressive, poor prognosis

Estimates of threshold dose ranged from 0.0 to 0.03 gray, with an upper 95% confidence bound of 0.04 gray. The increasing dose–response trend persisted >45 years after exposure, was greater at younger age at exposure and younger attained age, and was similar by sex and number of treatments.

Follicular carcinoma accounts for 16% to 20% of cases and usually has favorable behavior and outcome. The papillary thyroid carcinoma (PTC) is a tumor named for its papillary growth pattern, although the defining diagnostic criteria are actually the nuclear features of neoplastic cells. In addition to enhanced screening, the important factor contributing to increased incidence of PTC is the increase in diagnosis of a variant of PTC known as the follicular variant of PTC (FVPTC). Among two main subtypes, infiltrative (or nonencapsulated) and encapsulated, encapsulated FVPTC (EFVPTC) has increased in incidence by an estimated two- to threefold over the past two to three decades and makes up 10% to 20% of all thyroid cancers currently diagnosed in Europe and North America.[308,309] In a recent international, multidisciplinary, retrospective study of patients with thyroid nodules diagnosed as EFVPTC, including 109 patients with noninvasive EFVPTC observed for 10 to 26 years and 101 patients with invasive EFVPTC observed for 1 to 18 years found that thyroid tumors currently diagnosed as noninvasive EFVPTC have a very low risk of adverse outcome and should be termed as noninvasive follicular thyroid neoplasm with papillary-like nuclear features (NIFTP).[310] This reclassification will affect a large population of patients worldwide and result in a significant reduction in psychological and clinical consequences associated with the diagnosis of cancer.[311]

Medullary carcinomas are rare and tend to be more aggressive than the differentiated carcinomas and can be fatal. They are associated with the immunoreactive thyrocalcitonin marker. Because of the aggressive clinical course, experts advocate genetic testing to identify affected individuals with specific mutations in the ret oncogene that predict for MEN syndromes. Those individuals could be candidates for prophylactic thyroidectomy at an earlier age than if the increase in serum calcitonin was used to identify C-cell hyperplasia or early carcinoma. At present, genetic testing should be performed at birth in children suspected of having the MEN IIA syndrome and no later than 1 year of age for those with possible MEN IIB.[312–314]

Children with thyroid cancer are commonly euthyroid and usually present with a thyroid nodule or palpable cervical lymph node. Conventional

radiographs may show calcifications in the region of the thyroid gland (psammoma bodies). Iodine radionuclide scan may show a cold nodule.

Paradoxically, despite the fact that 70% to 80% of patients present with regional lymph node involvement and approximately 20% have distant metastases at diagnosis, the prognosis of differentiated thyroid cancer in children and adolescents is excellent.[3,314–316]

Thyroid carcinoma is treated primarily by surgery. The extent of surgery for the primary tumor (subtotal lobectomy, lobectomy, total thyroidectomy) and involved lymph nodes (node picking, modified or radical neck dissection) is controversial.[317]

The arguments in favor of total thyroidectomy include the multifocality of the tumor, decrease in neck recurrences, the ability to use serum thyroglobulin as a tumor marker after radical surgery, and the ability to detect pulmonary metastases by RAI scan earlier. The arguments for more limited surgery are mainly the increased complication rate of radical surgery, with apparently no clear survival advantage.[3,313–315,318–323]

The use of RAI for routine ablation of remaining thyroid tissue after surgery in patients without any known metastatic disease is another area of controversy. However, many support the administration of RAI in this setting because of the high incidence of nodal and systemic metastases of thyroid cancer in the young.[324]

RAI is indicated in patients with cervical lymph node involvement or distant metastases. The radiopharmaceutical is taken up by 50% to 80% of well-differentiated tumors and is able to deliver high focal doses of irradiation to any remaining thyroid tissue.

Side effects of RAI include nausea, xerostomia, taste alterations, increases in caries, stomatitis, candidiasis, glossalgia, hypogeusia, thyroiditis, and gastrointestinal discomfort.[325,326] Potential and rare long-term complications include myelosuppression, leukemia, bladder cancer, salivary cancer, gastric cancer, breast cancer, and infertility. These complications occur rarely with today’s treatment doses and protocols.[324]

Exogenous thyroid hormone is given to suppress thyroid-stimulating hormone production and to decrease the probability of tumor recurrence. Exogenous thyroid hormone is also given as replacement therapy to keep the patients euthyroid despite thyroidectomy.[318,327,328]

External beam irradiation in children with differentiated thyroid cancer is indicated for unresectable primary tumor or cervical or mediastinal lymph nodes

that do not take up RAI. It also has a role in advanced locoregional disease, with extensive extrathyroid extension, or where there is gross residual tumor after attempted surgical excision, or when definitive resection has not been possible. Although external beam irradiation is useful for palliative therapy of advanced or metastatic disease, the lack of randomized controlled studies makes its role as part of initial adjuvant treatment controversial, and it is rarely indicated for microscopic residual disease. Radiotherapy, with or without chemotherapy, can be administered in children with anaplastic thyroid carcinoma.[316]

The volume of irradiation is designed according to operative and pathologic findings and can range from whole-neck and upper mediastinal irradiation to just treating the thyroid gland or thyroid bed. CT-based planning, 3D treatment planning, or IMRT is advocated to allow the administration of curative doses (in the range of 55 to 65 Gy) to the target volume without compromising spinal cord tolerance. This can be achieved by a variety of techniques.[329]

In the Mayo Clinic series, survival rates for children did not differ significantly from those of matched controls at 20 to 30 years.[330] In the Royal Marsden series,[318] the median overall survival was 53 years, and the median survival for patients who developed recurrence was 30 years. The only presenting feature predictive of poorer survival was the presence of metastases at diagnosis. According to a study reported by the Surgical Discipline Committee of the Children's Cancer Group, the overall survival for children presenting with distant metastases was 100% at 10 years. The progression-free survival rate was 76% at 5 years and 66% at 10 years. In a series of 14 children with papillary thyroid cancer and pulmonary metastases treated at the Mayo Clinic[328] by various surgical procedures, RAI, external beam irradiation (one patient), and suppressive hormone therapy, at a mean follow-up time of 19.3 years, 50% were alive completely free of disease and 50% were alive and asymptomatic with residual pulmonary disease.

GERM CELL TUMORS

Gonadal or extragonadal germ cell tumors (GCTs) represent <2% of pediatric cancer. The tumor is the result of neoplastic transformation of primitive germ cells or totipotent embryonal cells (Fig. 94.3).[331] The GCTs can arise from the brain to the sacrococcygeal region with the most common site presentation in the testis, ovary, sacrococcygeal region, retroperitoneum, and mediastinum. Aberrant migration can explain unusual tumor sites.[332] The Children's Oncology

Group evaluated the link between a family history of cancer and pediatric GCT in a case–control study of 274 cases. The risk of GCT decreased among female cases with a family history with onset before 40 years but increased for boys, especially for those with a family history of melanoma.[333] The most frequent cytogenetic abnormality is the isochromosome 12p for both gonadal and extragonadal GCT, except for children <3 years of age at diagnosis. Klinefelter syndrome can be associated with GCT in boys.[305] Intracranial germ cell tumors are discussed in Chapter 84.

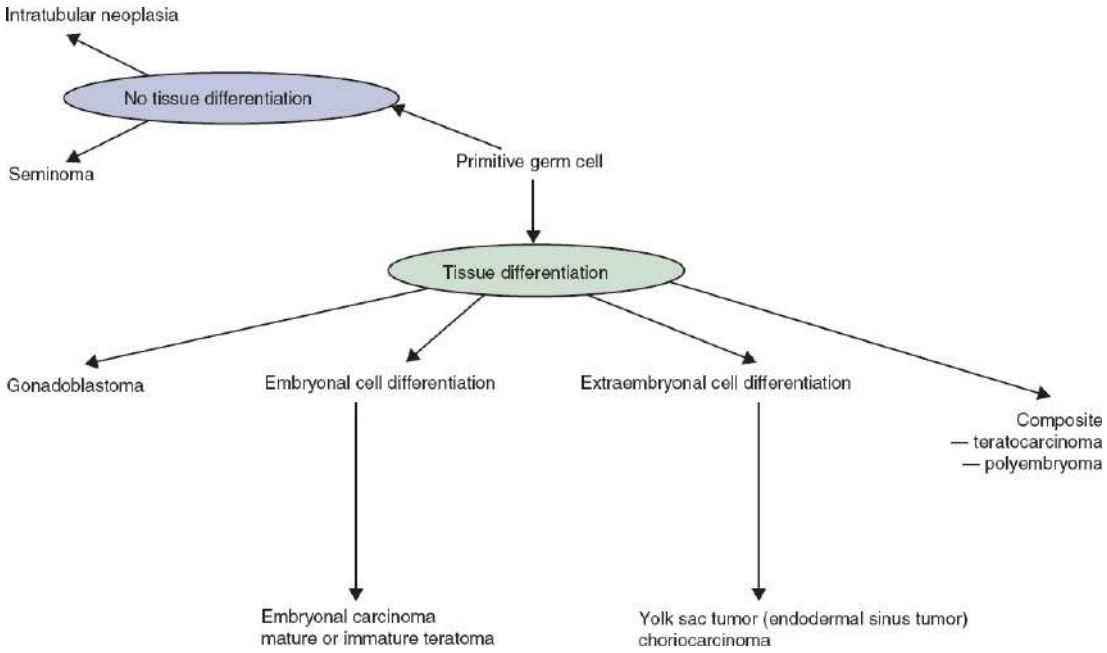

FIGURE 94.3. Classification of germ cell tumors.

TABLE 94.7 GERM CELL TUMOR AND CLINICAL MARKERS

Tumor Type	β-HCG	AFP	LDH	CEA	PLAP
Embryonal carcinoma	+	+		+	
Mature teratoma					
Immature teratoma	+	+	+	+	
Yolk sac tumor		+++	+	+	
Choriocarcinoma	+++		+		
Germinoma	+		+	+	+++

AFP, α-fetoprotein; β-HCG, beta-human chorionic gonadotropin; CEA, carcinoembryonic antigen; LDH, lactate dehydrogenase; PLAP, placental alkaline phosphatase.

Clinical Presentation

Abdominal pain, abdominal distension, and sacrococcygeal or buttock swelling are the frequent presenting signs.[334] Staging includes imaging both of the primary tumor and most frequent sites of metastatic dissemination (lungs, liver, brain, and bone). Serum AFP, β-HCG, lactate dehydrogenase, CEA, and placental alkaline phosphatase levels are mandatory prior to the initiation of any treatment. Serum AFP level must be interpreted according to patient age (level >1,000 mg/mL is normal until the age of 1 month). Clinical markers are strongly correlated with some histologic features (Table 94.7); however, high AFP levels can be detected in infectious diseases of the liver, and increased β-HCG level can be associated with malignancies other than choriocarcinoma. The half-life time of AFP is 5 to 7 days and that of β-HCG is 24 to 36 hours. Both are very useful tools for predicting and monitoring treatment response, progression of disease, and relapse.[335]

Treatment

Their cure rate is high and strongly correlated with adherence to strict treatment guidelines.

Surgery is the standard treatment for mature teratomas and sacrococcygeal tumors (with complete removal of the tumor and the coccyx), but it may be combined with chemotherapy to limit the extent of irradiation. Surgery is often the first treatment for malignant gonadal GCT: orchiectomy with high inguinal ligation or ovariectomy with careful peritoneal cavity exploration. Lymph node dissection is not recommended in early-stage GCT, especially in germinomas. Second-look surgery can be indicated in cases of residual disease (clinical or biochemical) after chemotherapy.

Since the introduction of cisplatin-based chemotherapy, the survival rate of GCT has risen from 60% to 90%,[336] and regimens used are similar to those used in the adult age group. There is now a trend to use carboplatin in order to reduce late toxicities.[337] The rate of decline of serum tumor markers has demonstrated prognostic significance and must be used in the management of poor-risk patients.[225] Radiotherapy is rarely indicated except for some cases of early-stage ovarian germinoma in adolescents (dose, 20 to 25 Gy). The use of radiotherapy for ovarian germinoma in the young, however, must be compared with salvage chemotherapy after surgery alone. In advanced cases of ovarian dysgerminoma, careful surgical staging followed by conservative resection and chemotherapy without radiotherapy results in an overall survival rate as high as 85% without compromising the possibility of future pregnancy.[65] There is no indication for

radiotherapy after complete response in extragonadal GCT. For stage IA ovarian dysgerminoma, conservative surgery is the gold standard, even in a case of incomplete staging, and chemotherapy is given only in the event of relapse, according to the last Italian group report.[338]

BENIGN VASCULAR TUMORS

Hemangiomas

Infantile hemangiomas, congenital hemangiomas, and kaposiform hemangioendotheliomas constitute vasculoproliferative tumors. They are subdivided on the basis of presence or absence of endothelial cell glucose transporter 1 (GLUT1) isoform protein. Infantile hemangioma is the most common benign vascular tumor in children and affects approximately 40% of all infants. The skin, subcutaneous, and soft tissue of the head and neck are the site of origin in 60% of patients, followed by the trunk, extremities, and viscera (e.g., liver, lung, gastrointestinal tract).

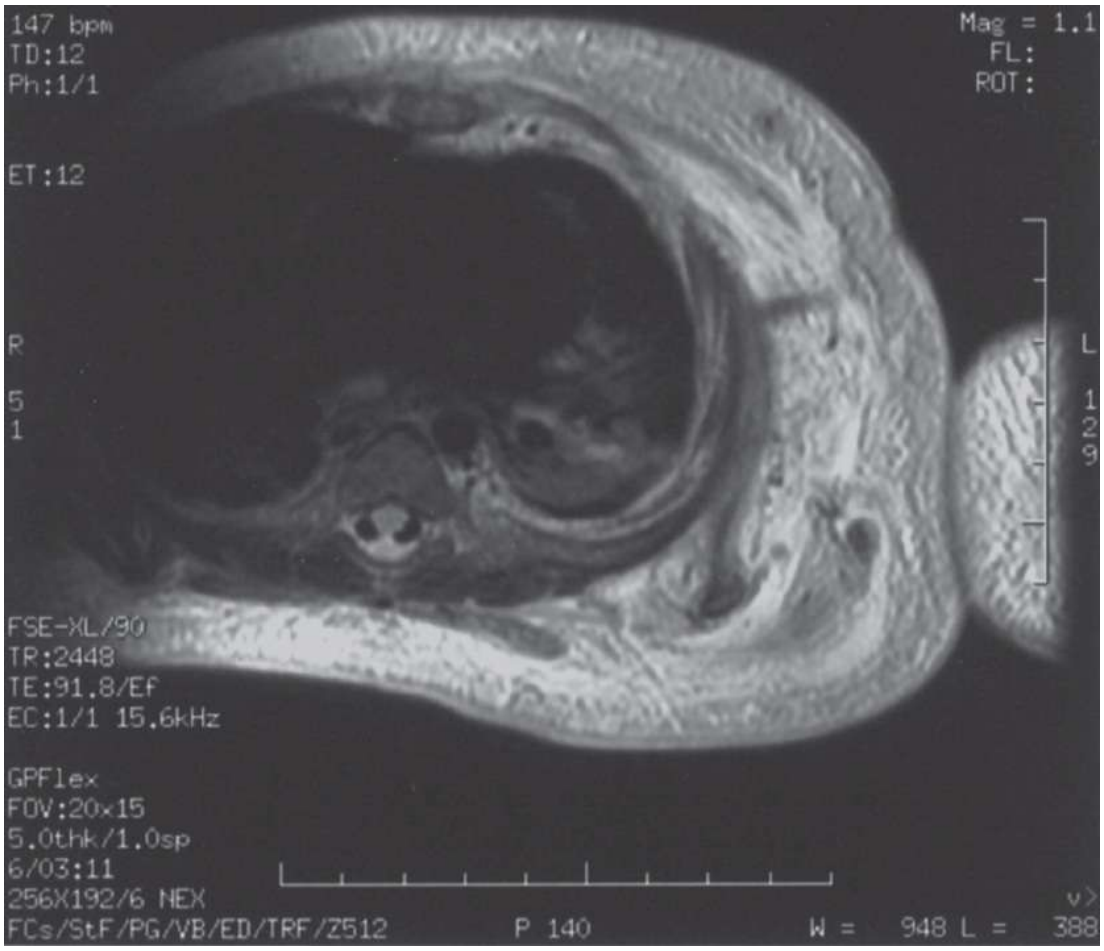

FIGURE 94.4. Kasabach-Merritt syndrome. Massive left hemithorax infiltration and involvement of the left arm.

In some cases, their development can be associated with adverse cosmetic effects, unacceptable symptoms, and organ compression that in certain cases could be life threatening. Such cases require therapy. There are two distinct types of hemangiomas[339]: dynamic lesions, which include cellular hemangiomas, capillary hemangiomas, and cavernous hemangiomas; and adynamic lesions, which include port-wine stains, telangiectasias, and venous lakes. Vascular malformations are subdivided into two major groups, low or slow flow and high or fast flow.[340]

Radiation therapy is very rarely used in the treatment of hemangiomas. Treatment of infantile hemangiomas depends on the location and number of lesions as well as associated symptoms. Laser therapy is available for skin ulceration, the most frequent complication. For hemangiomas with symptoms, including thrombocytopenia or hypothyroidism, as well as heart failure caused by numerous hepatic hemangiomas, treatment is typically started with

antiangiogenic drugs (propranolol, steroids, and less often vincristine) followed by gradually more aggressive treatments, such as embolization and rarely surgery. External beam radiotherapy was used in the past for patients not responding to steroids or interferon. Total doses of 300 to 750 cGy, and rarely exceeding 1,000 cGy, at 10 to 20 cGy per fraction could achieve good local control.[341]

Recently, radiotherapy fell out of favor because of concerns for potential late effects, like scarring, bone growth abnormalities, dental and periodontal problems, and secondary neoplasms.[342–345 346,347]

Higher doses (30 to 40 Gy) are used in older patients for large and progressive lesions for achieving lasting local control.[348]

Special attention must be given to the Kasabach-Merritt syndrome (KMS) (Fig. 94.4), which is defined as combination of cutaneous vascular abnormalities with or without visceral involvement and thrombopenia because of intravascular coagulopathy. KMS is associated only with Kaposi-like hemangioendothelioma or tufted angioma. Kaposi-like hemangioendothelioma must be distinguished from infantile hemangioma, which disappears spontaneously.[349,350] These are alarming hemangiomas with life-threatening lesions (mediastinum, lower extremities, abdomen) either because of compression or secondary to a thrombocytic coagulopathy or high-output cardiac failure. Cavernous hemangiomas can be located in the epidural space and cause spinal cord compression. Surgical resection is the standard treatment.[351]

Radiotherapy is used in a rare setting for unresectable cases and should be considered very cautiously because of its late effects. A dose of 10 Gy in 10 fractions can be given; it is not mandatory to encompass the whole hemangioma in the target volume.[352,353]

Lymphangiomas

Histologically, lymphangiomas are a benign proliferation of lymph vessels. Four types are recognized: (a) capillary lymphangiomas, (b) cavernous lymphangiomas, (c) cystic hygromas, and (d) lymphangeal hemangiomas. Surgery is the treatment of choice.

Special attention must be given to the Gorham syndrome, also known as the bone-vanishing syndrome or massive osteolysis of bone.[354] Gorham syndrome is a bone hamartoma with various percentages of lymphangioma and hemangioma, characterized by well-margined osteolytic scattered lesions that progressively affect the cortex, with no respect for joint boundaries (Fig. 94.5). All bones can

be affected (vertebrae, ribs, scapula). Progression is unpredictable, from spontaneous remission to bone absorption and sometimes even death. The prognosis is very poor when pleural or visceral involvement develops. Some encouraging results have been reported using antiresorptive therapy such as calcitonin or biphosphonates.[355] Although radiotherapy is the last resort for the patient, encouraging results have been reported for patients with chylothorax and in patients with rib, thorax, and vertebral body involvement. The usual dose is approximately 18 Gy to the hemithorax. Affected bones have been treated to approximately 40 Gy with good response.[356]

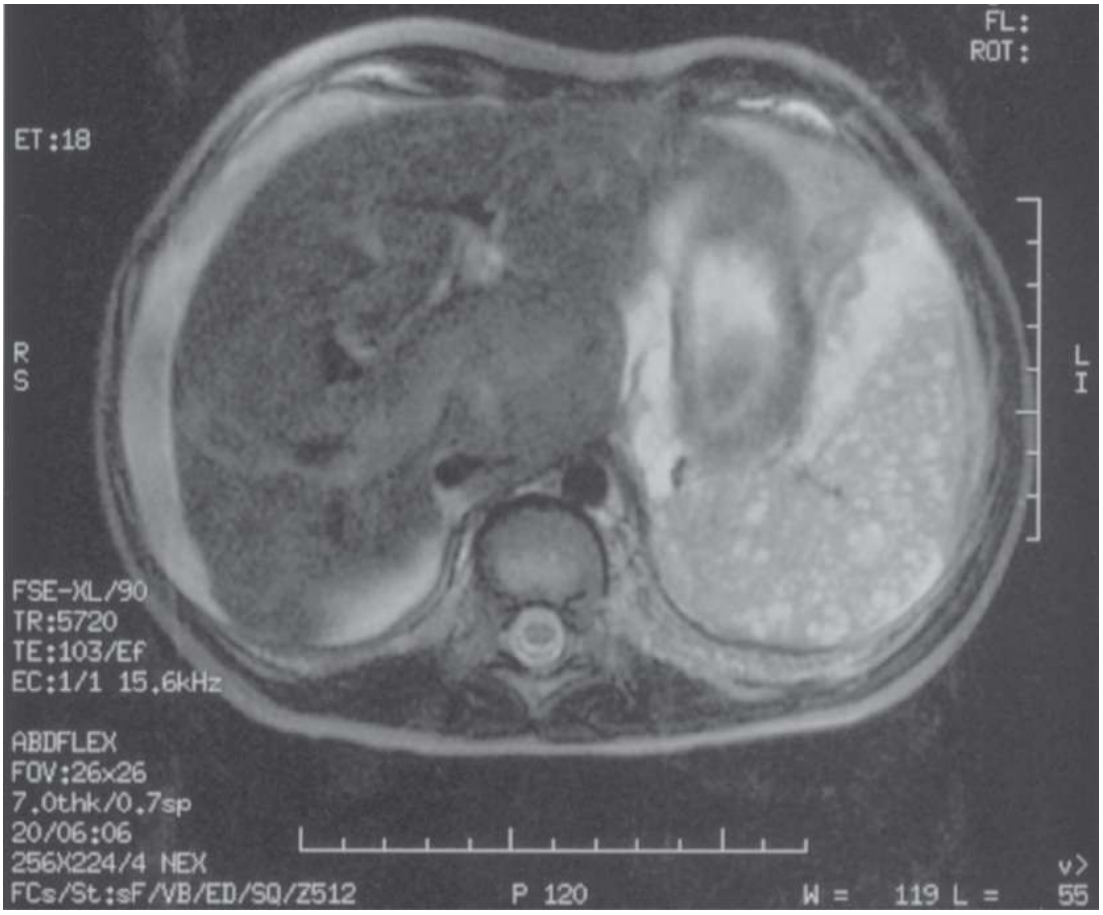

FIGURE 94.5. Gorham disease in a 3-year-old girl. Diffuse lymphangiomatosis affecting pelvic bones, ribs, spleen, and liver.

DESMOPLASTIC SMALL ROUND CELL TUMOR

Desmoplastic small round cell tumor (DSRCT) was first described in 1989.[357] It is a rare aggressive neoplasm with typical clinical, histologic, karyotypic, and biologic characteristics. DSRCT mainly affects male adolescents and young

adults, but it sometimes occurs in young females. Clinically, patients present with a bulky abdominal or pelvic mass, but intracranial, testicular, renal soft tissue, and bone DSRCTs have also been described.[358–361]

The tumor is characterized by a desmoplastic stroma with circumscribed tumor cells and encased nests of primitive undifferentiated cells. The tumoral cells express epithelial (keratin, EMA), conjunctival (vimentin), muscular (desmin), and neuroendocrinal markers.

Reciprocal translocation (11:22) (p13:q12) has been described, which results from a fusion between the terminal part of the Ewing sarcoma gene (EWS) and the carboxy terminus part of the Wilms tumor gene (WT1).[362]

The DSRCTs are highly chemosensitive, but the prognosis is still poor. Kretschmar et al.[363] reviewed 101 cases of DSRCT: after 2 years, only 2 patients were still alive, and the median survival was 17 months.

More recently, investigators from the Memorial Sloan Kettering Cancer Center reported a series of 66 patients treated with high dose alkylating agent–based chemotherapy with autologous bone marrow transplantation, surgical debulking, and whole-abdominopelvic radiotherapy. The dose to the whole abdomen was 30 Gy (1.5 Gy twice daily), and patients with gross residual disease received a boost of 6 to 15 Gy. The 3-year overall survival was 48%, but the progression-free survival was only 35% in the first report.[363] In a more recent publication, a slightly better survival rate at 3 years (55%) was reported.[364] Survival at 3 years was only 27% when the three modalities were not used, with only 10 patients surviving without evidence of disease at a median follow-up of 2.4 years.

The MD Anderson Cancer Center published an outpatient and home chemotherapy program, including neoadjuvant chemotherapy, continuous hyperthermic peritoneal perfusion with cisplatin, and abdominal radiation (30 Gy) with simultaneous temozolomide with an overall survival at 3 years of 71% among eight patients.[365,366]

NONMELANOMA SKIN CANCER

Basal and squamous cell carcinomas are rare in children and adolescents. When they occur in the pediatric and adolescent age groups, there is usually an underlying predisposing genetic disorder, such as basal cell nevus syndrome (BCNS) or Gorlin-Goltz syndrome and xeroderma pigmentosum. Basal and squamous carcinomas have also been reported to arise in nevus sebaceous[367] and

after radiation for benign or malignant conditions.[368,369]

BCNS or Gorlin-Goltz syndrome[370–372] is an autosomal dominant disorder with variable penetrance characterized by a "coarse face" with hypertelorism and frontal bossing, multiple basal cell carcinomas presenting at a young age, pits on the palms and soles, skeletal abnormalities (e.g., bifid ribs, hemivertebrae, fusion of vertebral bodies), jaw cysts, epidermic cysts and hamartomas, oculoneurologic abnormalities, and ectopic calcification of the falx cerebri and other structures. Skin lesions located in the head and neck tend to invade the deep structures. Several patients with BCNS were reported to have developed medulloblastoma at early childhood and ovarian fibromas.[164,370,373–377]

Mutation of the human homologue of *Drosophila*-patched (PTC) gene is considered the molecular defect in BCNS.[377,378] The Gorlin-Goltz syndrome is a unique example of the genetic–environmental interaction for the production of malignancies: children treated for medulloblastoma by craniospinal irradiation developed multiple skin cancers in the irradiated area, an unusual and special illustration of multihit mutagenesis, suggesting that radiotherapy should probably be omitted or limited in children with BCNS.[377]

Xeroderma pigmentosum (XP) is an extremely rare, autosomal recessive inherited disease characterized by abnormal pigmentation and >1,000-fold increase in nonmelanoma skin cancer (basal cell carcinoma and squamous cell carcinoma) on sun-exposed skin. XP patients are also at a significant risk to develop melanoma.[379,380] Neurologic abnormalities such as areflexia and mental retardation are sometimes associated with XP.

The genetic abnormality underlying XP leads to defects in nucleotide excision repair of ultraviolet-induced DNA damage.[379,381,382]

Skin cancer in affected children is treated by standard techniques (such as surgery, cryosurgery, chemosurgery). There should not be any contraindication to using radiotherapy to treat skin cancer or any other malignancy in XP patients because ionizing radiation damage is normally repaired in these patients.[383]

MALIGNANT MELANOMA

Childhood melanoma can sometimes be associated with large congenital nevocytic nevi, dysplastic nevus syndrome, immunosuppression, transplacental malignant melanoma, and xeroderma pigmentosum.[384–389] Pediatric malignant melanoma should be distinguished from the juvenile melanoma or Spitz nevus characterized by a relatively benign course and long-term survival.[390–392]

The management of childhood melanoma follows the guidelines set for adult patients.[393] The prognosis is related to the Breslow or Clark thickness of the primary lesion and nodal status. Chemotherapy regimens usually have a poor activity against melanoma in adults. However, St. Jude Children's Research Hospital (SJCRH) has reported a complete or partial response in 8 of 18 (44%) pediatric patients receiving cyclophosphamide, vincristine, and dacarbazine.[394] Immunotherapy has been explored with promising results. Given the favorable results with the use of interferon α-2b in adults, 15 patients <18 years of age with stage III melanoma, defined as having a primary tumor thickness >4 mm or having lymph node or in-transit metastases, were included in a SJCRH feasibility study.[395] Another group from Toronto used the high dose interferon in children with metastatic disease.[396] Most of the patients in both studies did complete their therapy with some alterations in dosage because of toxicity. Intergroup Study of Cancer and Leukemia Group B, Children's Oncology Group, Eastern Cooperative Oncology Group, and Southwest Oncology Group (S0008) studied the role of biochemotherapy, which provided statistically significant improvement in RFS but no difference in OS patients with high-risk melanoma.[397] Targeted therapies, such as BRAF and MEK inhibitors that are approved for the treatment of patients with advanced melanoma who harbor *BRAF* V600E mutation–positive tumors, result in a significant survival advantage compared to chemotherapy.[398]

Recently, drugs blocking immune checkpoints, such as cytotoxic T-lymphocyte–associated antigen 4 (CTLA-4) and the programmed cell death protein 1 (PD-1) have been used to enhance antitumor immunity and have drawn huge interest.[399,400] Overall, the pediatric age group represented a very small proportion of patients studied for systemic therapy. Therefore, treatment plans for children are mainly extrapolated from adult studies.

Radiotherapy has a role mainly for palliation of metastatic disease or in locally advanced lesions. Again, data here should extrapolate from the adult literature; however, high dose per fraction regimens will need to be evaluated with caution because of toxicity concerns.

PART N

Benign Diseases

CHAPTER 95

Nonmalignant Diseases

Simon A. Brown, Jerry J. Jaboin, Tony Y. Eng, Jose G. Bazan, and Charles R. Thomas Jr.

Benign diseases generally include a class of localized tumors or growths that have a low potential for progression and do not invade surrounding tissue or metastasize to distant sites. Pathologically, they are composed of well-differentiated cells that are considered nonmalignant and usually do not require any treatment. However, clinically, not all benign diseases have benign consequences. Some untreated benign diseases can produce bothersome mass or secretory effects. Others can be locally aggressive and cause secondary debilitating symptoms. For example, Graves ophthalmopathy can lead to local pain and visual impairment without therapeutic intervention[1]; a hormonally active pituitary adenoma may cause growth abnormality in addition to blindness[2]; desmoid tumors can be locally persistent even after surgical resection and grow uncontrollably similar to their malignant counterparts.[3]

Documented empirical use of radiation in imaging and the treatment of benign diseases or conditions occurred soon after the discovery of x-rays by Wilhelm Röntgen in 1895.[4] Between 1920 and 1960, over a million Americans, mostly young adults and children, received x-ray treatments to the head and neck region for benign conditions.[5] The efficacy of painless x-ray treatment led to the treatment of many benign conditions with radiation: acne, body hair, scalp ringworm, enlarged tonsils, enlarged thymus, enlarged neck lymph nodes, whooping cough, and others. Radiation therapy was used in some instances because of a lack of effective alternative therapies.

Over the past decades, advances in medical and surgical therapies have provided new treatment options for many diseases. With improved awareness of late radiation sequelae on normal tissue, particularly radiation carcinogenesis, use of radiation therapy for treatment of benign conditions has gradually declined. However, with modern radiation therapy techniques and better understanding of radiobiology, judicial use of radiation provides good local

control with minimal toxicity and relief of associated symptoms.

RADIOBIOLOGIC EFFECTS ON BENIGN DISEASES

The precise radiobiologic mechanisms of radiation effects on benign diseases are not well defined. Radiation is believed to work through a complex of multicellular interactions that affect different cell types in our body system.[6,7] Specific cellular and functional mechanisms depend on the specific disease and site. Although most benign lesions have no known stimuli or causes, some benign lesions may be triggered by trauma as seen in keloid formation after body piercing or heterotopic bone formation after surgery. In conditions that arise following trauma, local inflammation and repair occur, which is often characterized by stimulation of growth factors and accelerated cellular proliferation. For example, in the development of keloids, fibroblast proliferation is responsible for most of the hyperproliferative process. Even with the lower doses commonly used in benign diseases, radiotherapy is clinically effective in inhibiting cell proliferation and suppressing cell differentiation without inducing cell death as is typically seen with tumoricidal doses of radiation. Yet, radiation can induce apoptosis in selected target cells by influencing the expression of cytokines in macrophages, leukocytes, endothelial, and other cells and thereby modulating the inflammatory cascade.

Among the major sites of radiation effects are the blood vessels; vascular endothelial cells respond rapidly to radiation damage by up-regulating the cytokine-mediated cellular reactions responsible for inflammatory tissue response. Low-dose irradiation (total dose <12 Gy using 1.0 Gy or less per fraction) exerts anti-inflammatory effects on the endothelial cells of capillaries and mononuclear cells of the immune system.[8]

Cell adhesion molecules, selectins, are mobilized to the cell membrane and change the capillary permeability allowing the inflammatory cells (lymphocytes, macrophages, monocytes) to migrate into interstitial space. The anti-inflammatory effect is attributed to the modulation of cytokine and adhesion molecule expression on the activated endothelial cells and leukocytes. These cells are known to be radiosensitive. They express proinflammatory cytokines (e.g., interleukin-1, interleukin-6) or necrosis factors (e.g., tumor necrosis factor-α), which influence the complement cascade and enzymes of inflammatory reaction. Interleukin-1 stimulates the production and release of proinflammatory prostaglandins leading to a change in synthesis of inducible nitric oxide

synthetase.

The radiation-induced modulation of nitric oxide production and oxidative burst in activated macrophages and native granulocytes lead to modification of the immune response and inflammatory process as well as clinical analgesic effects. Although endothelial cells possess a high proliferative potential and are sensitive to radiation damage at high doses, they are not prone to rapid mitotic radiation death at low doses.

Chronic inflammatory processes are triggered by antigen–antibody reactions and mediated by mononuclear peripheral blood cells in the immune system. Ionizing radiation helps suppress some of these cell populations, such as T lymphocytes, in the inflammation process or modulate their effects. Although low doses of radiation can exert an anti-inflammatory response, high doses of radiation as used in malignant tumors can elicit proinflammatory effects and fibrotic change in normal tissue.[9] At higher single or total doses, endothelial cell damage can lead to sclerosis and obliteration of blood vessels. In vascular disorders such as hemangiomas or arteriovenous malformations, high radiation doses may induce occlusion of pathologic vessels. In addition to inhibition of cell proliferation, cell killing may play a part in the management of benign meningiomas, pituitary adenomas, or neuromas where higher, tumoricidal doses of radiation may be required.

RISK OF SECOND MALIGNANCIES

The induction of cancer or genetic defects by radiation exposure is attributed to stochastic effects where there is no threshold level of radiation exposure below which cancer induction or genetic effects will not occur. Increasing the radiation dose or the volume of exposure will increase the probability that a cancer or genetic effect will occur. Sometimes, the radiation effects are difficult to separate from inherent genetic effects. For example, in patients with retinoblastoma, the *Rb1* gene plays an important role in the development of radiation-induced sarcomas.[10,11] In a study of 384 retinoblastoma patients treated with radiation, the actuarial risk for developing a sarcoma in the treatment field 18 years after treatment was 6.6%.[10] In another study of 693 patients, the cumulative risk for any sarcoma 50 years after radiotherapy was 13.1%.[11] Although most sarcomas were within the irradiated fields, 18 out of 69 sarcomas developed outside of the treatment fields. *Rb1* mutations appear to confer a genetic predisposition to developing sarcomas especially after radiation exposure.

The risk of the induction of secondary tumors was overestimated in the past.[12] Trott and Kamprad used the epidemiologic data from long-term follow-up studies on patients treated with radiotherapy for benign diseases to estimate the risk of cancer induction.[13] Taking all known modifying and organ-specific factors into account, including doses of radiation and volume irradiated, the estimated absolute lifetime risk for sarcoma induction was <0.0001% for 1 Gy and a 100-cm^2 field. Table 95.1 lists the absolute lifetime risk for other malignancies.

Jansen et al.[14] applied the effective dose concept and estimated the carcinogenic risk in patients after radiotherapy of benign diseases (heterotopic ossification [HO], omarthrosis, gonarthrosis, heel spurs, and hidradenitis suppurativa). Special risk-modifying factors, including age at exposure and gender, were taken into account. For an average-aged population, the estimated number of radiation-induced fatal tumors was between 0.5 and 40 persons per 1,000 patients treated. The range of effective doses was also found to be large (5 to 400 mSv). In addition to age and gender, the individual risk also depends on individual inherent sensitivity, anatomic site, type of disease, and treatment techniques, such as dose and fractionation. The International Commission on Radiological Protection estimates the incidence of cancer from ionizing radiation increases linearly and is about 5.5%/Sv.[15] Thus, for a patient exposed to 20 mSv—the typical limit for radiation workers per year—irradiation increases the lifetime cancer risk by about 0.020 × 5.5/Sv = 0.1%.[7]

TABLE 95.1 THE ESTIMATED ABSOLUTE LIFETIME RISK FOR MALIGNANCIES AFTER RADIATION THERAPY FOR BENIGN DISEASES

Types	Absolute Lifetime Risk
Skin (basal cell carcinoma)	0.1% for 100-cm^2 field
Osteosarcoma	<0.0001% for 1 Gy and a 100-cm^2 field
Leukemia	1% for 1-Gy TBI
Brain tumor	0.2% after 20 Gy for endocrine orbitopathy
Thyroid carcinoma	1% per Gy for children <10 yr
Breast carcinoma	5% for one breast, 1 Gy, age <35 (<3% for age 35–45)
Lung carcinoma	1% within 25 y after a mean lung dose of 1 Gy

INDICATION FOR RADIOTHERAPY

The majority of benign diseases can be classified as inflammatory, degenerative, hyperproliferative, or functional. Therefore, therapeutic approaches vary widely and are regionally customized, in part because of geographic traditions and differences in clinical training. Radiation treatment of benign diseases is less commonly used in the United States than in some other parts of the world where variations in indications and treatment schedules are institutionally based.[16] Within Germany, a pattern of care study revealed significant geographic and institutional differences.[17] Although most radiation treatments for benign disease are delivered in the low-dose range (<10 to 15 Gy), the prescribed dose varied widely and inconsistently within geographic regions and between institutions.

Degenerative processes in tendons, ligaments, and joints can cause pain by chronic inflammation and trigger secondary functional impairment of the involved musculoskeletal system. Although radiation does not halt the degenerative process, it may reduce the inflammation and provide partial or complete pain relief. This clinical effect is well established in reports of osteoarthritis, synovitis, and bursitis, where low-dose radiation therapy has improved the function of affected joints.[17,18]

Benign diseases may have a significant effect on self-image and self-esteem because of cosmetic appearance (e.g., facial keloids, juvenile angiofibroma) or lasting impact on quality of life because of chronic pain or other secondary symptoms (e.g., heterotopic bone, macular degeneration). When benign diseases become locally invasive with aggressive growth, therapeutic intervention can prevent or limit functional loss of organs. In rare cases of large hemangioma with associated thrombocytopenia and consumption coagulopathy (Kasabach-Merritt syndrome [KMS]), potentially fatal complications can occur, and timely therapeutic intervention can be life-saving.[19]

Despite lack of an international consensus, the German Working Group on Radiotherapy of Benign Diseases published their consensus guidelines for radiation therapy of nonmalignant diseases. The guidelines were to serve as a starting point for quality assessment, prospective clinical trials, and outcomes research.[7,18,20–22] In brief, treatment is indicated when benign diseases are symptomatic or potentially symptomatic. When other methods are unavailable or have failed, radiation therapy should be considered. As medical professionals, we remain mindful of therapeutic gain and potential treatment side effects and complications. A thorough risk–benefit analysis is always pertinent. Organ-specific acute and chronic toxicities including potential effects on fertility and induction of secondary tumors in the future must be explained to and discussed

with patients, especially those who are young and have a long life expectancy. Informed consent that is required for all medical interventions is certainly required for treatment of benign diseases and should be obtained prior to the delivery of radiation therapy.

The current chapter covers some of the more common benign conditions that we still encounter in the practice of radiation oncology. Details on the therapeutic approaches and data on radiation dose regimens for different benign diseases are summarized in the individual corresponding sections.

BENIGN NEOPLASMS OF THE BRAIN, HEAD, AND NECK

Nonmalignant tumors of the central nervous system (CNS) and neck can lead to severe, life-threatening symptoms because of pressure and mass effect on critical structures from tumor growth. However, depending on growth rate and location, the surrounding tissue may adapt leading to a delay in the clinical diagnosis.

Meningioma

Background and Clinical Aspects

Meningiomas are the most common tumors of the CNS. The incidence peaks in the seventh decade of life with a 2 to 3:1 female-to-male predominance. The lowest incidence is among those of American Indian/Alaskan Native backgrounds, approximately 35% greater for Whites and Asian and Pacifica Islanders and nearly double for Blacks.[23] The majority (>90%, Central Brain Tumor Registry of the United States (CBTRUS) 2008–2012) of meningiomas are benign and classified by the World Health Organization (WHO) as grade I tumors.[24] They can be heritable in some genetic syndromes (e.g., neurofibromatosis type 2; SMARCE1-related meningioma, multiple endocrine neoplasia type 1), which present in childhood but make up a minimal percentage of these tumors.[25] These WHO grade II meningiomas (4.6% by CBTRUS) have a higher tendency for local recurrence, and WHO grade III/malignant meningiomas (anaplastic, rhabdoid, papillary) are exceedingly rare.

The most common presenting symptom is headache, but patients may present with other localizing symptoms depending on the tumor location. The radiographic diagnosis of meningioma is often made on computed tomography (CT) or magnetic resonance imaging (MRI) based upon the appearance of a homogeneously and intensely enhancing extra-axial mass with or without the presence of a dural tail.

Surgical Management

Surgical resection is the treatment of choice for most patients with dual benefits of symptomatic relief and pathologic diagnosis. The primary goal of surgery is to remove as much tumor burden as possible while minimizing the risk of neurologic deficits (maximal safe resection). Gross total resection (GTR) is generally attempted for patients with tumors in locations such as the convexity and olfactory groove.[26,27] After GTR, the relapse rate is as low as 10%, but depends upon the Simpson classification, which grades tumors according to extent of resection and degree of dural involvement (Table 95.2).[28] Local recurrence rates are as high as 40% for patients with incomplete resection,[28] though these rates can be substantially reduced with the use of adjuvant radiotherapy. Notably, endoscopic endonasal approaches have allowed for access to anterior cranial base tumors with reasonable morbidity rates.[29]

Meningiomas tend to be highly vascularized tumors. In select patients, preoperative embolization is used to decrease blood loss and improve the extent of resection.[30,31]

TABLE 95.2 SIMPSON GRADING SYSTEM FOR POSTOPERATIVE MENINGIOMAS WITH ASSOCIATED RATES OF RECURRENCE

Simpson Grade	Description	Recurrence Rate
I	Complete macroscopic tumor removal with adherent dura as well as the possibly affected part of the cranial calotte	8.9% (8/90 patients)
II	Complete macroscopic tumor removal with adherent dura via diathermia	15.8% (18/114 patients)
III	Complete macroscopic tumor removal without adherent dura or possibly additional extradural parts	29.2% (7/24 patients)
IV	Partial macroscopic tumor removal while leaving intradural tumor parts	39.2% (20/51 patients)
V	Simple decompressive and bioptic removal of tumor	88.9% (8/9 patients)

Active Surveillance

Asymptomatic patients with small meningiomas may be observed clinically. At the time of tumor growth or the development of symptoms, patients can be treated with surgery or radiation therapy. The safety and reasoning for this

approach were established in a large retrospective series from Japan that demonstrated that the majority of patients do not require intervention in the short-term.[32]

Systemic Therapy

Interest in the use of medical therapy to treat meningiomas stems from the observation that up to 67% of meningiomas express the progesterone receptor or androgen receptor and approximately 10% express the estrogen receptor.[33] However, response rates to antihormonal agents are low. Overall, studies that have investigated the role of chemotherapy, such as hydroxyurea, in the management of recurrent disease have demonstrated little efficacy.[33]

Radiotherapy

Primary radiotherapy (RT) is indicated for tumors in locations in which complete resection is not feasible (i.e., optic nerve, cavernous sinus, major venous sinus) or for patients who are poor surgical candidates. Adjuvant RT is indicated for patients with STR, recurrent disease, or WHO grade II/III tumors. RT techniques include conventionally fractionated three-dimensional conformal radiotherapy (3DRT), conventionally fractionated intensity-modulated radiation therapy (IMRT), frame-based or linear accelerator–based fractionated stereotactic radiotherapy (FSRT), stereotactic radiosurgery (SRS), or protons and heavy ions.

The MRI sequences that best delineate the gross tumor volume (GTV) should be coregistered with the treatment planning CT scan for optimal treatment planning and delivery. Particularly for patients receiving FSRT or SRS, it is important that a neuroradiologist and neurosurgeon be involved in assisting with GTV delineation, as enhancement from residual tumor versus postoperative change is often difficult to ascertain.

For 3DRT or IMRT treatments, the clinical target volume (CTV) is constructed by adding a symmetric margin (0 to 1 cm for WHO grade I; 1 to 2 cm for WHO grade II/III) around the GTV, respecting normal tissue boundaries and accounting for the imaging characteristics of the tumor. An additional 3 to 5 mm is added for the final planning target volume (PTV). These margins may be modified based on institutional policy and other considerations, such as the availability of daily image guidance (i.e., kV imaging or cone-beam CT).

For benign meningiomas, the typical dose prescription to the PTV is 50 to 54 Gy given in 1.8- to 2-Gy daily fractions. Retrospective data suggest that local control is inferior for patients treated with doses of <52 Gy.[34] For patients with

more aggressive histology (WHO grade II/III tumors), a higher dose prescription in the range of 59.4 to 63 Gy is used. Several modern series of radiotherapy show 5-year local control rates ranging approximately 89% to 98%, with three-dimensional conformal therapy demonstrating local control rates >95% (Table 95.3).[34–38] Although there is still no consensus on the benefits of adjuvant radiotherapy for WHO grade II meningioma, a National Cancer Database (NCDB) analysis demonstrated a survival benefit for adjuvant radiotherapy in patients with subtotal resection.[39]

SRS and FSRT are increasingly being used in the treatment of meningiomas. The decision to fractionate depends largely upon tumor size and proximity to critical structures, such as the optic apparatus or brainstem. Typical dose prescriptions for frame-based SRS range from 12 to 16 Gy prescribed to the 50% isodose line (IDL) and 14 to 18 Gy prescribed to the 80% IDL for a frameless robotic radiosurgery platform. In patients with tumors that require fractionated treatment, dose prescriptions vary and are dependent upon the individual case. Additionally, a select group of perioptic tumors, including meningiomas, can be treated with a prescription of 24 to 30 Gy in 3 to 5 fractions (to the 80% IDL) resulted in high rates of tumor control and visual preservation (Fig. 95.1).[40] There is nonrandomized, prospective evidence indicating that FSRT should be the treatment of choice for optic nerve sheath meningiomas because of the high rate of preservation of visual acuity.[41]

TABLE 95.3 CLINICAL OUTCOMES OF STEREOTACTIC RADIOSURGERY OR EXTERNAL BEAM RADIOTHERAPY (WITH OR WITHOUT SURGERY) FOR MENINGIOMAS IN MODERN SERIES

Study (Year)	No. of Patients	Radiation	S + R/R	Dose (Median or Mean)	Local Control (%)
Ganz et al. (2009)[44]	97	SRS	NA	12 Gy	100 (2 y)
Takanashi et al. (2009)[50]	101	SRS	24%/76%	13.2 Gy	97 (1 y)

Iwai et al. (2008)[47]	108	SRS	NA	12 Gy	93 (5 y) 83 (10 y)
Kondziolka et al. (2008)[49]	972	SRS	49%/51%	14 Gy	87 (10 y)
Davidson et al. (2007)[42]	36	SRS	100%/0%	16 Gy	100 (5 y) 95 (10 y)

Feigl et al. (2007)[43]	214	SRS	43%/57%	13.6 Gy	86.3 (4 y)
Hasegawa et al. (2007)[46]	115	SRS	57%/43%	13 Gy	87 (5 y) 73 (10 y)
Kollova et al. (2007)[48]	368	SRS	30%/70%	12.5 Gy	98 (5 y)
Zachenhofe et al. (2006)[51]	36	SRS	70%/30%	17 Gy	94 (9 y)
Goldsmith et al. (1994)[34]	117	EBRT	100%/0%	54 Gy	89 (5 y) 77 (10 y)
Mendenhall et al. (2003)[35]	101	EBRT	35%/65%	54 Gy	95 (5 y) 92 (10 y)
Nutting et al. (1999)[37]	82	EBRT	100%/0%	55–60 Gy	92 (5 y) 83 (10 y)
Vendrely et al. (1999)[38]	156	EBRT	51%/49%	50 Gy	79 (5 y)

EBRT, external beam radiotherapy; R, radiation; S, surgery; SRS, stereotactic radiosurgery. Adapted from Minniti G, Amichetti M, Enrici RM. Radiotherapy and radiosurgery for benign skull base meningiomas. *Radiat Oncol* 2009;4:42.

Reported results with SRS are excellent, with 5-year local control rates as high as 98% to 100% (Table 95.3).[42–51] DiBiase et al.[52] demonstrated that male gender, conformality index <1.4, and size >10 mL predict for worse outcome after SRS. Improved disease-free survival in patients was also noted for coverage of the dural tail as part of the target volume, though benefits should be weighed against toxicity.[52] In Ferraro et al.,[53] additional poor prognosticators included high mitotic rate, nuclear atypia, spontaneous necrosis, and WHO grade III pathology.

Because of their physical properties, protons and heavy ions (i.e., carbon) are attractive choices for the treatment of meningiomas, particularly for those located near critical structures. Several studies have shown excellent local control rates with the combination of protons and photons or protons alone.[54–56]

Pituitary Adenoma

Background and Clinical Aspects

Pituitary adenomas are the second most common intracranial tumors with a US incidence of 11,700.[23] Approximately 65% to 70% of these tumors are functional (secretory), thereby producing increased amounts of hormones. Prolactinomas and growth hormone (GH)–secreting adenomas are the most frequently encountered. Functional adenomas are more common in women, whereas nonfunctioning and GH-secreting adenomas are more common in men.

Adenomas are often classified by size with a picoadenoma <0.3 cm,

microadenoma <1 cm, and macroadenoma >1cm. Clinical presentation can vary, but nonfunctional adenomas (mostly consisting of gonadotrophs) are most commonly with visual symptoms (often bitemporal hemianopsia from compression of the optic chiasm). Less commonly, patients complain of headaches (~20%), and with larger tumor extent, there can be cranial nerve involvement or hypopituitarism (second to hypothalamic extension).

Patients with functional adenomas present with signs and symptoms that correspond to the excess hormone: galactorrhea, amenorrhea, diminished libido, and infertility in patients with prolactinomas, acromegaly or gigantism in patients with GH-secreting adenomas, Cushing disease in adrenocorticotropic hormone (ACTH)-secreting adenomas, and hyperthyroidism in patients with thyroid-stimulating hormone (TSH)-secreting adenomas. In patients who have had bilateral adrenalectomy, up to 40% will develop Nelson syndrome, which is characterized by an ACTH-secreting adenoma and increased skin pigmentation secondary to increased release of alpha-melanocyte–stimulating hormone.

In addition to history and detailed physical examination (H&P), workup of a pituitary tumor includes laboratory analysis of pituitary hormone levels, contrast-enhanced MRI with thin slices through the pituitary (Fig. 95.2A and B), and tissue diagnosis to rule out other causes of pituitary masses including craniopharyngioma, meningioma, suprasellar germ cell tumor, metastatic disease, or a benign lesion (i.e., cyst).

Surgical Management

Transsphenoidal surgery is generally the treatment of choice for pituitary adenomas, providing immediate relief of compressive symptoms and potentially decreasing hormone secretion. In some cases, a more aggressive surgery (i.e., extended transsphenoidal approach, frontal craniotomy) may be indicated for patients with extensive intracranial and skull-based involvement. Overall, local control rates range from 50% to 80% after surgery alone for both functioning and nonfunctioning adenomas.[57] In patients that continue to have abnormally elevated hormones after surgical resection, adjuvant treatment with pharmacotherapy and/or radiation therapy is pursued.

Pharmacotherapy

For unsuccessful or contraindicated surgeries, pharmacotherapy, such as bromocriptine and cabergoline for prolactinomas, octreotide for GH adenomas and TSH adenomas, and ketoconazole for ACTH adenomas, has been used as an

adjunct for patients with functioning adenomas. The SEISMIC study, a 24-week multicenter open-label trial after failed multimodality therapy, demonstrated that mifepristone could produce significant clinical and metabolic improvement in patients with Cushing syndrome with an acceptable risk profile.[58] However, with the exception of prolactinomas, the use of these drugs as monotherapy is generally not curative. Prolactinomas can often be managed with pharmacotherapy alone, but a high proportion of patients are unable to tolerate bromocriptine for long periods of time because of nausea, headache, and fatigue.

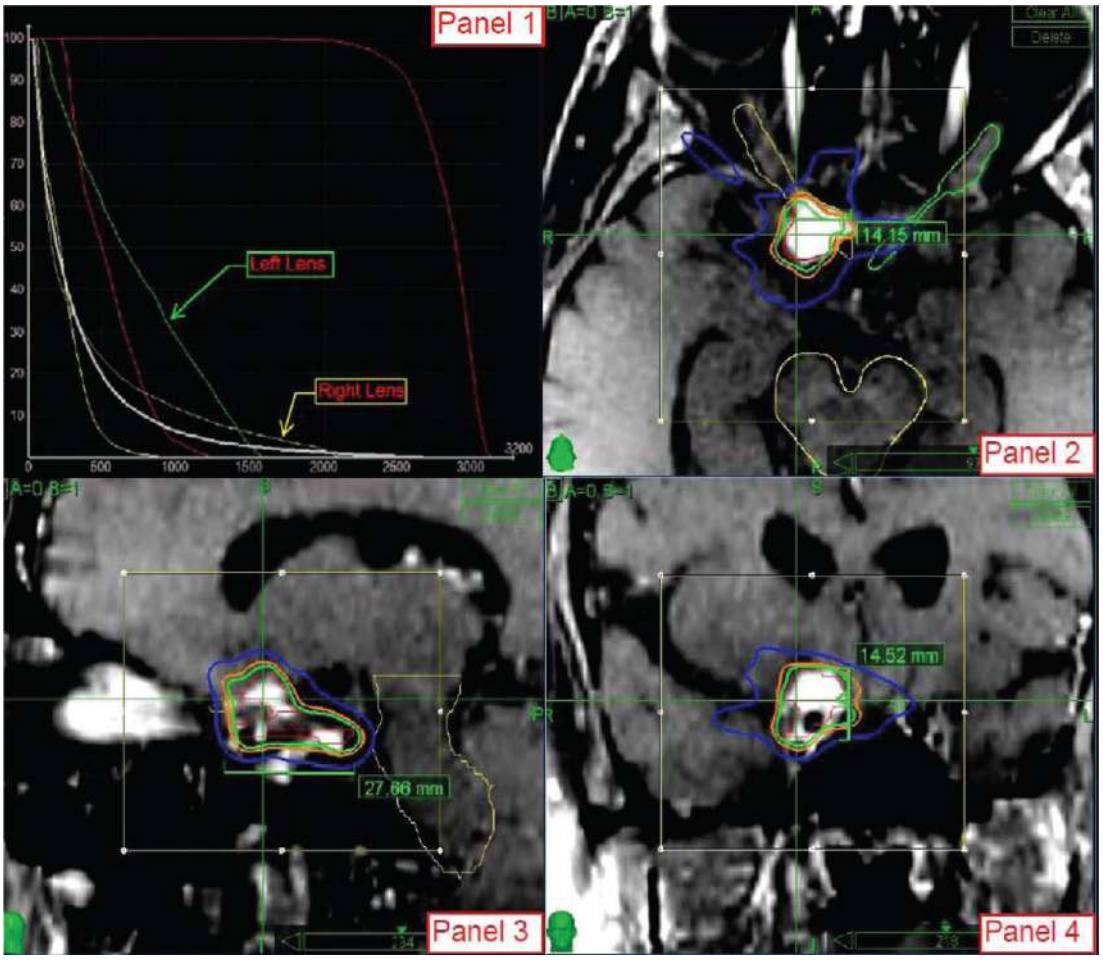

FIGURE 95.1. Radiosurgery treatment plan of a patient with a right optic nerve sheath meningioma treated to a dose of 24 Gy in 3 fractions. The lesion is intensely enhancing on the postcontrast stereotactic MRI sequences. *Panel 1* demonstrates the dose–volume histogram for the patient. The maximum dose to the ipsilateral optic nerve was 22.3 Gy. *Panels 2 to 4* demonstrate the isodose curves for the treatment in the axial, sagittal, and coronal planes. The 100% (24 Gy) isodose line is *green*, the 88% (21 Gy) isodose line is in *orange*, and the 50% (12 Gy) isodose line is *blue*.

Radiotherapy

Except for medically inoperable patients in which RT is used in the primary setting, the role of RT is generally in the adjuvant setting with the following indications: recurrent tumor after surgery, persistence of hormone elevation after surgery, and residual disease after STR/debulking procedure. Tumor growth control is excellent, particularly for patients with nonfunctioning adenomas.[59–61] Endocrine control after treatment of functioning adenomas, as demonstrated by normalization of pituitary hormone levels, takes years to develop. At a median of 2 years after RT, growth hormone levels stabilize quickest; normalization is slowest for TSH-secreting adenomas.[62] Pharmacologic therapy should be discontinued 1 to 2 months prior to the initiation of RT based on evidence demonstrating lower RT sensitivity with concurrent medical treatment.[63]

RT techniques include 3DRT, IMRT, single-fraction SRS, SBRT (or HSRT), and FSRT. Delineation of the GTV (or preoperative GTV in the case of GTR) should be performed by coregistration of the postoperative MRI to the treatment planning CT scan. CTV is the gross disease and subclinical extent of the tumor; an additional 3 to 5 mm is added to the CTV to create the PTV. These margins may be modified based on institutional policy and other considerations, such as the availability of daily image guidance. Nonfunctional adenomas are typically prescribed a dose of 45 to 50.4 Gy given in 1.8- to 2.0-Gy daily fractions (Fig. 95.2C–E). Higher doses in the range of 50.4 to 54 Gy are recommended for secretory adenomas, as these are felt to be more locally aggressive and less radioresponsive. Prolactinomas, in particular, rarely achieve biochemical normalization with radiation monotherapy.

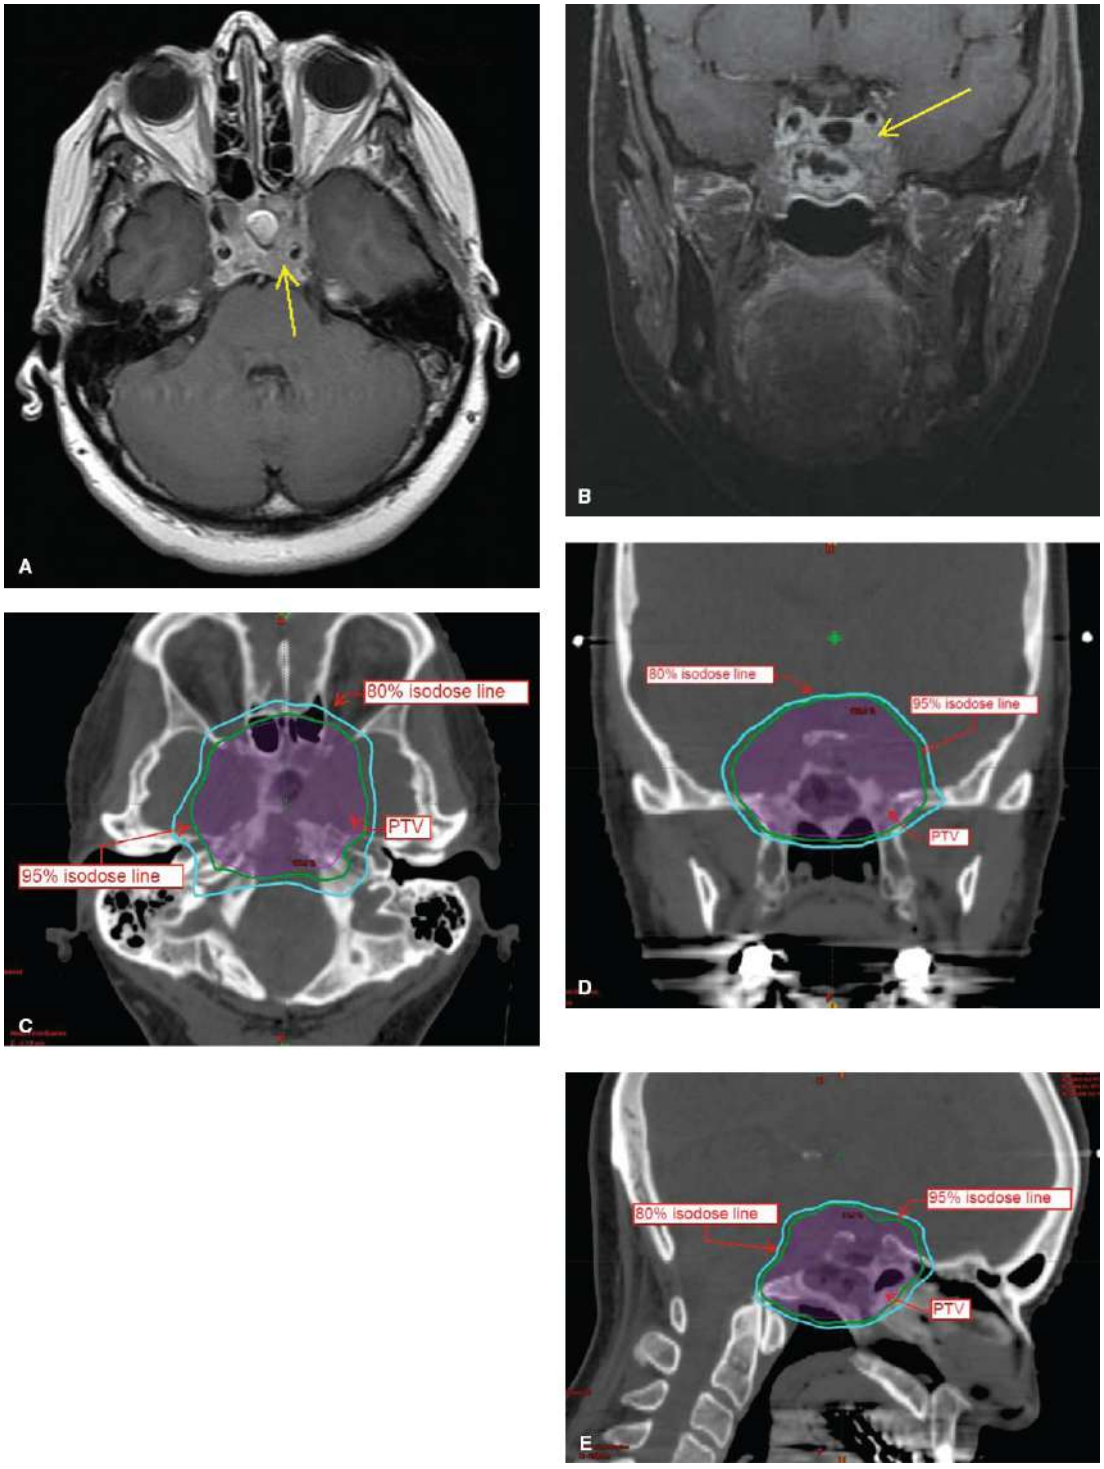

FIGURE 95.2. A and **B:** A recurrent nonfunctioning pituitary adenoma 7 years after surgical resection in the axial **(A)** and coronal **(B)** planes. The *yellow arrows* denote invasion into the left cavernous sinus. **C–E:** Rapid arc intensity-modulated radiotherapy treatment plan for the same patient in the axial **(C)**, coronal **(D),** and sagittal **(E)** planes. The PTV (*purple-shaded area*) was prescribed 50.4 Gy in 28 fractions.

SRS has become the more attractive option for the treatment of pituitary adenomas. General principles apply in that FSRT is used over SRS for large lesions (i.e., >3 cm) or lesions near critical structures (i.e., <1 to 2 mm from the chiasm). Similar to 3DRT/IMRT, higher doses are needed for functional adenomas compared to nonfunctional adenomas. Numerous retrospective studies have demonstrated excellent local control rates of 92% to 100% for nonfunctional adenomas using doses of 14 to 25 Gy (at the edge of the tumor) in a single fraction.[64] Commonly used prescriptions are 16 to 20 Gy in a single fraction for nonfunctional adenomas and 20 to 25 Gy in a single fraction for functional adenomas using a frameless robotic radiosurgery platform. Hypofractionated regimens can also be applied. In a 25-year experience of 1,837 patients undergoing SRS for benign tumors, there were neither radiation-induced tumors nor malignant transformation noted in the 188 pituitary adenomas identified.[65]

Craniopharyngioma

Background and Clinical Aspects

Craniopharyngiomas make up 6% to 10% of pediatric CNS tumors, or approximately 350 to 400 cases per year in the United States.[23] The median age of diagnosis is 5 to 10 years with a second peak in patients >40 years old and an equal male:female ratio.

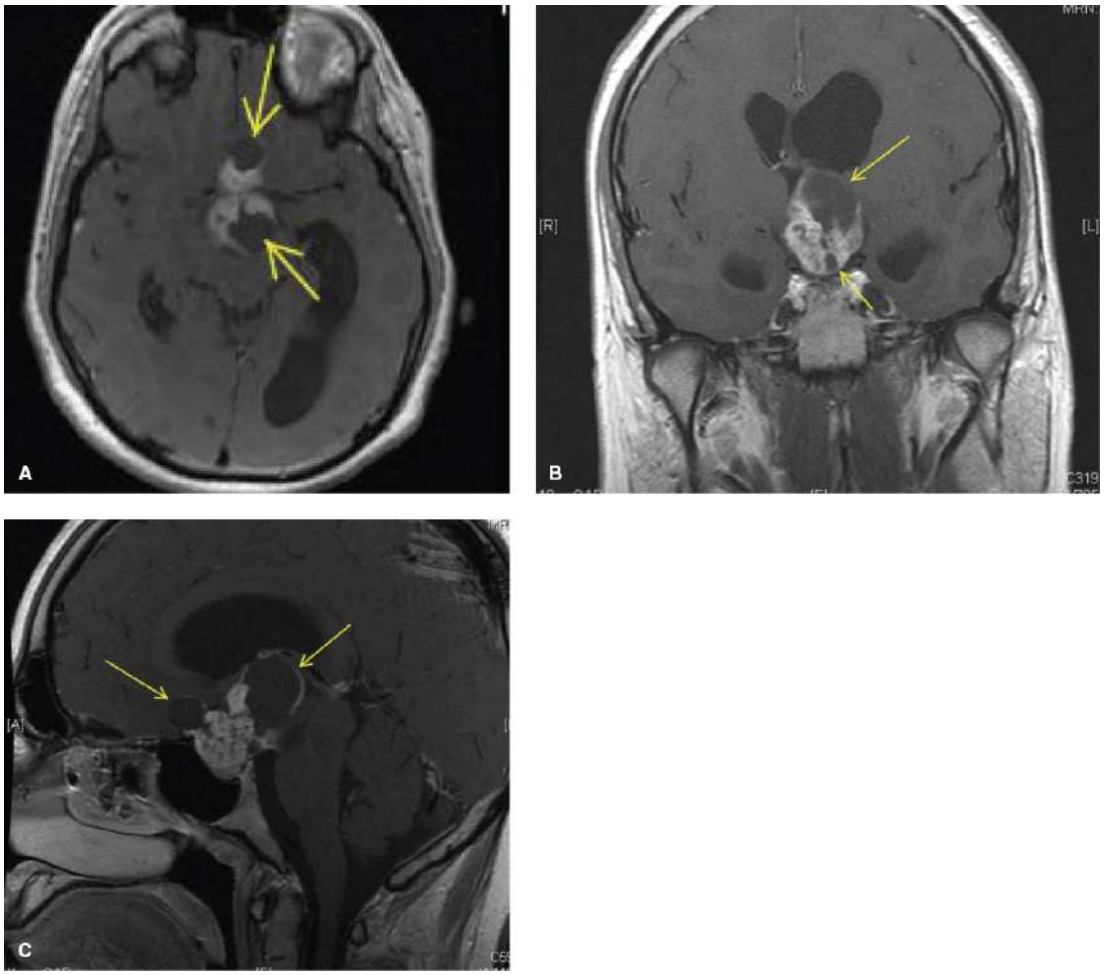

FIGURE 95.3. Axial **(A)**, coronal **(B)**, and sagittal **(C)** MRI images of a patient with multicystic (*yellow arrows*) craniopharyngioma prior to treatment.

These benign tumors are epithelial, arising from remnants of Rathke pouch (hypophyseal–pharyngeal duct), and are most commonly located in the suprasellar region, though they may be found in the sella proper. Craniopharyngiomas generally abut the hypothalamus and third ventricle. Histologically, they are divided into the adamantinomatous and squamous subtypes. The adamantinomatous subtype is characterized by a solid and cystic pattern with the well-known description of “machine oil–like” cystic fluid.

Presenting signs and symptoms include headache, nausea and vomiting, bitemporal hemianopsia, and endocrine dysfunction (diabetes insipidus [DI], dwarfism, fat tissue disturbance, adrenal cortical insufficiency). The most common hormone deficiency is lack of GH. The workup is similar to that of pituitary adenoma and includes H&P, pituitary hormone levels, and brain MRI with thin slices through the sella (Fig. 95.3).

Surgery

The primary goal of surgery is complete resection. However, GTR may be associated with high rates of neurologic sequelae including visual impairment and panhypopituitarism. In order to minimize morbidity, most patients are treated with maximal safe resection followed by adjuvant RT.

Intracavitary Therapies

Intralesional bleomycin may be directly injected into the cyst to decrease the rate of cyst recurrence.[66] Cystic craniopharyngiomas may also be managed by the use of intralesional radioactive isotope injection using a beta emitter (yttrium 90, phosphorus 32). Typical prescriptions range from 200 to 250 Gy prescribed to the cyst wall. Optimal results are seen in patients whose tumors have one cyst and lack a large solid component.[67,68]

External Beam Radiotherapy

External beam radiation therapy is often used in the adjuvant setting. In select patients (i.e., <3 years old), observation following STR may be an option as local control rates are similar with RT at the time of relapse ("salvage" RT) compared with adjuvant RT with no compromise in overall survival.[69]

RT techniques include 3DRT, IMRT, FSRT, proton therapy, and intralesional RT with beta-emitting isotopes. The GTV is the postoperative residual tumor volume, including the cyst wall, if present. The postoperative MRI should be fused with the treatment planning CT scan for optimal target delineation. The CTV includes the gross tumor and subclinical disease with a GTV for set-up margins. Dose prescriptions for 3DRT and IMRT are typically at least 54 Gy given in 1.8-Gy daily fractions.

Fractionated proton radiotherapy has demonstrated excellent results. The Loma Linda series treated 15 patients to a total dose of 50.4 to 59.4 gray equivalents (GyE) given in 1.8 GyE daily fractions.[70] Local control was achieved in 14 out of 15 patients with few long-term complications. In a series from the Massachusetts General Hospital (MGH), no failures were seen in 24 patients that received fractionated proton radiotherapy to a total dose of 52.2 to 54 GyE in 1.8 GyE per fraction.[71] Overall survival and recurrence outcomes have been mixed when comparing proton to conformal photon radiotherapy.[72]

It has been well established that cysts may regrow during the several weeks of fractionated treatment. The MGH proton study recommends that reimaging (CT or MRI if cyst is not well visualized on CT) be performed within 2 weeks of the

treatment planning scan and every 2 weeks thereafter; for large cysts or those that demonstrate growth during RT, weekly reimaging is recommended.[71] Image-guided radiotherapy techniques now allow for the convenient monitoring of cyst regrowth with cone beam CT scans while patients are on the treatment table.

SRS and FSRT have been used with success in the treatment of craniopharyngioma. In one series from Stanford using a frameless robotic platform,[73] 16 patients were treated postoperatively with doses of 18 to 38 Gy given over 3 to 10 fractions prescribed to mean IDL of 75%. Local control was 91% in this cohort of patients with no visual or neuroendocrine complications. Similar results have been demonstrated with use of a frame-based platform.[74–77]

Vestibular Schwannoma (Acoustic Neuroma)

Background and Clinical Aspects

Acoustic neuromas (AN) are derived from the neurilemmal of the vestibulocochlear nerve (CN VIII) and represent 5% to 8% of primary CNS brain tumors. The vast majority of cases (90%) are unilateral and sporadic, and when bilateral (10% of cases), they are associated with neurofibromatosis type II (NF-2).

Clinical presentation can include symptoms of sensorineural hearing loss, tinnitus, and vertigo. Hearing loss is correlated with tumor location (intracanalicular) rather than tumor size. In a minority of patients (5%), facial nerve symptoms may be present. As the AN grows, it may affect the trigeminal nerve (CN V) and brainstem.

During the initial workup, physical examination should include the Rinne test (air conduction > bone conduction on the affected side) and Weber test (vibratory sound louder on the unaffected side) to test for sensorineural hearing loss, as well as detailed examination of CN V and CN VII. All patients should undergo audiometry when the diagnosis of AN is suspected; this will often reveal asymmetric hearing loss more prominent at high frequencies as well as impairments in speech discrimination score. Imaging should include a contrast-enhanced MRI with thin slices through the internal auditory canal. The entire neuraxis should be imaged in patients with NF-2.

Surgery

Surgery is the mainstay of management of vestibular schwannomas, particularly for patients with large, symptomatic lesions. The standard approaches are

retromastoid suboccipital, translabyrinthine, and middle fossa with each providing unique advantages and risks. Most patients can undergo a complete resection and have low recurrence risk. Though cases of subtotal resection are associated with an approximately 15% risk of recurrence, surgical mortality is approximately 0.5% based on a NCDB analysis of 10,136 patients.[78] Hearing preservation is approximately 50% to 60% after surgery, and facial nerve preservation ranges from 80% to 90%.[79,80]

Active Surveillance

Observation is appropriate management for some individuals; indications include age >60, multiple comorbidities, small tumor size, and risk of hearing loss. Serial MRI and audiometry (every 6 to 12 months) should be performed in this patient cohort for surveillance. Treatment is initiated when the lesion demonstrates rapid and significant growth or when the patient becomes symptomatic. Overall, a growth rate of <1 mm/year is expected for most patients.[81]

Radiotherapy

RT in the form of SRS or FSRT is an option for the primary treatment of AN, often with higher rates of hearing preservation and facial nerve presentation compared with surgery. Proton therapy has also been used to treat AN.

SRS doses using frame-based platforms are generally 12 to 13 Gy prescribed to the 50% IDL. Although earlier studies demonstrated lower hearing preservation rates with higher SRS doses,[82] current results are significantly improved at these lower margin doses. Flickinger demonstrated local control rate of 98.6%, hearing preservation rate of 70.3%, 4.4% rate of trigeminal neuropathy, and no incidence of facial nerve dysfunction.[83] Using a frameless robotic radiosurgery platform to treat 383 ANs to a dose of 18 to 21 Gy given in 3 fractions, Stanford demonstrated 98% local control, 76% hearing preservation, 2% incidence of trigeminal nerve dysfunction (transient in 4 of the 8 affected patients), and no facial nerve dysfunction.[84]

Common dose prescriptions employing FSRT include 25 Gy in 5 fractions, 30 Gy in 10 fractions, and 50 to 55 Gy in 25 to 30 fractions. A nonrandomized, prospective trial compared SRS (10 to 12.5 Gy) to FSRT (20 to 25 Gy in 5 fractions). This study demonstrated comparable rates of local control, hearing preservation, and CN V and CN VII preservation between the two groups.[85]

Proton beam SRS has also been used to treat AN, though with low rates of

hearing preservation compared to other RT techniques. In a series from MGH, 88 patients were treated to a median dose of 12 GyE given in a single fraction prescribed to a median IDL of 70%. Tumor control rates at 2 and 5 years were 95.3% and 93.6%, respectively. Facial and trigeminal nerve preservation rates were 90%. Only 33% of patients retained serviceable hearing.[86] In a study of FSRT using proton beam, local control was excellent, but the hearing preservation rate was also poor at 42%.[87]

Chordoma

Background and Clinical Aspects

Chordomas are rare, representing <1% of intracranial lesions. They are slowly growing and locally aggressive midline tumors originating from the embryonal notochord remnants. Hence, they occur along the axial skeleton in the skull base (35%), vertebral column (15%), or sacral regions (50%).[88] The most common sites of skull-based tumors include the clivus, dorsum sella, and nasopharynx.

Patients typically present with signs and symptoms attributable to the primary site of the tumor. Workup includes MRI with contrast enhancement. CT may complement MRI to assess local bony destruction. A biopsy is necessary primarily to distinguish chordoma from chondrosarcoma, which has a better prognosis, and other malignancies. In children, biopsy is essential to distinguish chordoma from rhabdomyosarcoma, which can frequently present in the same location.

Surgery

Complete surgical resection is the mainstay of treatment. However, because of their location, GTR is often not possible. Relapse rates are as high as 50% even after surgical resection with negative margins.[89] Poor prognostic factors include large tumors, recurrent tumors, older age, clinical visual deficits, and presence of necrosis on biopsy.[90–92]

Systemic Therapy

Approximately 25% of chordomas metastasize to the lungs, liver, or bone. In these patients, or in patients with recurrent disease after surgical resection and radiation therapy, molecularly targeted agents may be considered. Several small studies have demonstrated some benefit to the use of sorafenib and imatinib or the combination of imatinib and sirolimus in this situation.[93–96]

Radiotherapy

Adjuvant radiation therapy is indicated to reduce recurrence rates for skull-based chordomas regardless of resection status. Retrospective data suggest that salvage RT is inferior to adjuvant RT with 5- and 10-year overall survival rates of 50% and 0%, respectively, for those treated with salvage RT compared to 80% and 65%, respectively, for patients treated with adjuvant RT.[97] RT techniques for treatment of skull-based chordomas include conventionally fractionated EBRT and IMRT, fractionated charged particle therapy (protons, carbon ions), and FSRT.

Determination of the GTV should be made by coregistration of the preoperative and/or postoperative MRI to the treatment planning CT scan. Particularly for pediatric cases in which IMRT will be used with tight margins, a neuroradiologist should be available at the time of treatment planning to assist in creating the GTV. Margins for CTV should be 1 to 2 cm with an additional 3 to 5 mm for the PTV. Dose prescriptions to the PTV for patients receiving photon-based treatment should be at least 60 Gy given in 1.8 to 2.0-Gy daily fractions.

Proton-based therapy can achieve higher doses with good results. In a series of 195 chordomas treated at the MGH, 5-year PFS was 70% with doses of 63 to 79.2 GyE given in 1.8 to 2.0 GyE daily fractions.[98] Among the 28 patients with primary spinal chordomas who underwent preoperative RT and en bloc resection, no local recurrences were seen.[99] Loma Linda examined 33 cases of chordomas treated with a median of 70 GyE and found 76% 5-year local control and 79% 5-year overall survival.[91]

In a report of 96 chordomas treated using carbon ion therapy at the University of Heidelberg with median total dose of 60 GyE (range, 60 to 70 GyE) delivered in 20 fractions within 3 weeks, good local control rates of 81% at 3 years and 70% at 5 years were observed.[100] In a recent report of 188 patients who received >60 GyE, the 5-year local control, overall survival, and disease-free survival rates were 77.2%, 81.1%, and 50.3%, respectively.[101]

FSRT and SRS are less well established than charged particle therapy. The North American Gamma Knife Consortium published the experience of 71 patients that underwent gamma knife SRS as primary, adjuvant, or salvage therapy for skull base chordomas.[102] The median dose to the tumor margin was 15 Gy (range, 9 to 25 Gy). Five-year local control was 66% for the entire cohort (69% for the no prior RT group and 62% for the prior RT group). Debus et al.[103] reported on 37 patients with chordomas treated with FSRT to a median dose of 66.6 Gy given in 1.8-Gy daily fractions; the target volume was encompassed by 90% of the dose. Local control was 82% at 2 years and 50% at 5 years.

Glomus Tumor/Chemodectoma/Paraganglioma

Background and Clinical Aspects

Glomus tumors are rare, benign tumors that originate from chromaffin-negative chemoreceptor cells derived from the embryonic neural crest. They occur particularly along the carotid artery near the bifurcation (carotid body tumor), the jugular bulb (glomus jugulare), or the middle ear (glomus tympanicum). The peak age is in the fifth decade of life. Bilateral or multiple tumors occur in 10% to 20% of affected patients.

Symptoms include headache, cranial nerve dysfunction, dysphagia, pulsatile tinnitus, vertigo, and large, pulsating masses in the neck. In rare cases, patients present with episodic hypertension, which may be related to the secretion of vasoactive substances by the tumor. In this situation, urine and serum metanephrines should be measured. The clinical presentation coupled with imaging (high-resolution CT, MRI, and/or angiography) often establishes the diagnosis. In patients in which multiple tumors are suspected, imaging with metaiodobenzylguanidine (MIBG) may be useful.

Surgery

In the carotid region, primary tumor resection after previous embolization is the therapy of choice. At the skull base or tympanum, neurosurgical intervention is often deferred because of the high rates of complications, including stroke and cranial nerve injury.[104]

Radiotherapy

RT is indicated for patients with tumors in unsuitable locations (i.e., skull base), as adjuvant therapy after STR, or as salvage therapy at the time of relapse after surgery. A retrospective comparative analysis of 41 patients with jugular paraganglioma treated by conventional radiotherapy and 47 patients by surgery showed similar outcomes, 96% and 86%, local control rates, respectively, but the radiotherapy patients achieved tumor control with less morbidity.[105] RT techniques include conventionally fractionated 3DRT/IMRT, SRS, and FSRT.

The diagnostic MRI should be coregistered with the treatment planning CT scan. The GTV is delineated, and 1 to 1.5 cm is added for clinical and set-up margin. With conventional techniques, doses are often 45 to 55 Gy given in 1.8- to 2-Gy daily fractions with local control rates near or >90% in several series.[106–108]

Results with SRS have been comparable to that of conventionally fractionated

RT. Using a frame-based platform, reported tumor margin doses range from 12.5 to 20 Gy prescribed to the 50% IDL [109–111] and 15 to 25 Gy for LINAC-based SRS.[104] Local control rates in these series range from 90% to 100%. A recent meta-analysis of SRS published by the Johns Hopkins Hospital reviewed 335 patients treated with SRS across 19 different studies.[112] In the eight studies with median follow-up of >3 years, clinical control was 95% and tumor control was 96%. The control rates were equal among patients treated with LINAC-based platforms and frame-based platforms. Complications were rare and often transient in each of the studies examined. On the basis of these findings, the authors advocate for the use of SRS as primary treatment of glomus jugulare tumors.[112]

TABLE 95.4 Chandler Staging System for Juvenile Nasopharyngeal Angiofibroma[a]

Stage	Description
I	Confined to nasopharynx
II	Extension into nasal cavity and/or sphenoid sinus
III	Extension into ≥1 of the following: cheeks, infratemporal fossa, pterygomaxillary fossa, ethmoid sinus, maxillary antrum
IV	Intracranial extension

[a]Please see references for the Fisch[114] and Radkowski[115] staging, respectively.

Juvenile Nasopharyngeal Angiofibroma

Background and Clinical Aspects

Juvenile nasopharyngeal angiofibroma (JNA) is a rare, benign, vascularized tumor in the head and neck, affecting mostly male adolescents. It originates from the first branchial arch artery. JNAs typically occur in the sphenoethmoidal suture and spread from the nasal cavity to the sphenopalatine foramen and pterygopalatine fossa. Other routes of local spread include the paranasal sinuses, infratemporal fossa, orbital space, and middle cranial fossa.

Symptoms initially include recurrent epistaxis and impaired nose breathing. As local extension occurs, patients may develop facial swelling, orbital symptoms (blindness), cranial nerve deficits, and headaches from intracranial extension.

Diagnosis is often made with the clinical presentation and CT- or MRI-based

imaging. Biopsy may cause massive bleeding. Several staging systems are used to categorize the tumors based on extent of local extension (Table 95.4).[113–115]

Surgery

Surgery combined with embolization is the preferred treatment. Through surgery, most JNAs without intracranial extension have local control rates of near 100%. In patients with intracranial extension, complete resection is often not possible.

Radiotherapy

Tumors with intracranial extension or tumors in patients that are medically inoperable are generally treated with RT as the primary modality. Indications for postoperative RT include relapse after surgery. Fractionated IMRT is currently the RT technique of choice to limit collateral radiation to critical structures near the target volume.

The PTV is generally treated to 30 to 50 Gy given in fraction sizes of 2 to 3 Gy/day. In modern series, local control rates range from 85% to 100% (Table 95.5).[116–119] After RT, JNA remission is slow, and late recurrences may occur.

TABLE 95.5 CLINICAL RESULTS OF RADIOTHERAPY IN JUVENILE NASOPHARYNGEAL ANGIOFIBROMA

Study	No. Patients	Study Period	Dose (Gy)	Local Control	Side Effects
Chakraborty et al. (2011)[116]	9	2006–2009	30–46	87.5% (2 y)	No late toxicity
Mcafee et al. (2006)[118]	22	1975–2003	30–36	90% (10 y)	Cataracts (6), transient CNS syndrome (2), “in-field” BCC (2)
Lee et al. (2002)[117]	27	1960–2000	30–55	85% (5 y)	15% late toxicity (growth retardation, panhypopituitarism, TLN, cataracts)
Reddy et al. (2001)[119]	15	1980–1991	30–35	85% (5 y)	Cataracts (3), CNS syndrome (1), BCC (1)

BCC, basal cell carcinoma; CNS, central nervous system; TLN, temporal lobe necrosis.

Langerhans Cell Histiocytosis (Histiocytosis X)

Background and Clinical Aspects

Langerhans cell histiocytosis (LCH) is a rare disorder that affects approximately 300 individuals with a higher incidence in children (3 to 5 per million) than

adults (1 to 2 per million). Age is an important prognostic factor with children having better outcomes than adults. In the past, it was felt that children younger than 2 years old had a poor prognosis, but recent data from the LCH-II study now refute that point.[120]

The disease is due to an accumulation and/or proliferation of cells that phenotypically resemble the Langerhans skin cell and can cause tissue damage by production of cytokines and infiltration. The actual Langerhans cell is a myeloid dendritic cell that expresses the same antigens (CD1a and CD207) as the Langerhans skin cell.[121] On electron microscopy, Birbeck granules are the classic finding.

LCH can affect a variety of organ systems. Patients are typically stratified into groups based on the extent of disease: single-system disease at a single site, single-system disease involving multiple sites, or multisystem disease. The clinical presentation is dependent upon the sites of disease. Involvement of the skeletal system is the most common site for children and may manifest as pain, palpable mass, or motion deficit or chronic otitis in the case of mastoid or middle ear involvement. Bony lesions from LCH are predominantly lytic in appearance, and the skull is the most frequently involved bony structure.

Cutaneous involvement affects primarily the skin of the scalp and groin and resembles a seborrheic dermatitis. Patients with cranial involvement (posterior pituitary or hypothalamus) may present with DI. The disease may also involve the cervical lymph nodes. Pulmonary involvement is more typically seen in adults. Hepatomegaly, splenomegaly, bone marrow infiltration, and involvement of the gastrointestinal tract are further potential sites of disease.

Evaluation of the patient with suspected LCH should include complete history and physical examination. Routine laboratory work should include CBC with differential. Patients that have symptoms of DI should also undergo a water restriction test. A skeletal survey with or without bone scan should be performed to assess for potential lytic lesions. Further imaging with CT of the head should be performed in patients with skull, orbital, or mastoid involvement. MRI of the head is indicated for patients with DI and those suspected of having brain parenchymal disease involvement. CT of the chest is performed to evaluate patients with pulmonary involvement. An MRI abdomen should be performed for patients with palpable hepatomegaly or splenomegaly.

Surgery

Treatment of LCH depends upon the site and extent of disease. Asymptomatic

lesions may be observed. For patients with involvement of only the skeletal system, treatment options include curettage, excision, or intralesional steroid injection. Response rates with curettage or excision alone range from 70% to 90%.[122] Single-system multifocal bone disease may be effectively treated with corticosteroids or chemotherapy, such as vinblastine. For skin-only disease, topical nitrogen mustard and methotrexate are considered effective treatments.

Systemic Therapy

In patients with multisystem disease with symptoms (fever, pain, failure to thrive) or organ dysfunction, treatment with systemic therapy is indicated. In LCH-II, all patients received initial treatment with prednisone and vinblastine and were randomized to intensification with or without etoposide.[120,123] The patients treated with intensification demonstrated superior rapid response rates and decreased mortality rates compared to the standard arm.[123] Exogenous ADH (vasopressin) is used to treat children with DI.

Radiotherapy

Because of the excellent response rates to nonradiotherapeutic measures, the role of RT in the treatment of LCH bony lesions has decreased. Indications for radiation therapy to bony sites include relapse after surgery, no signs of clinical healing after other interventions, pain relief, potential compromise of critical structures from an expansile lesion (i.e., cord compression), or if the bony site is not amenable to other local therapies. Collapsed vertebral lesions should not be irradiated unless they are painful. Controversy still remains regarding the role of RT in the management of DI. In a retrospective series from MGH, 14 of 17 patients with DI received irradiation to the hypothalamic–pituitary axis.[124] Only two of these patients had a complete response (cessation of ADH therapy), and no patients had a partial response. When the decision is made to treat, 3DRT should be the technique of choice.

The target volume for patients with bony disease should encompass the abnormality seen on imaging with a small margin. For children, low doses on the order of 5 to 10 Gy given in 1.5- to 2-Gy daily fractions should be sufficient to control most bony lesions. Higher doses can be used in adults. In a study of 80 patients who were irradiated up-front or as salvage therapy with a median total dose of 15 Gy, 77% achieved a complete remission and 12.5% achieved a partial remission. The long-term control rate was 80%.[125] UCLA found local control rates of 88% with doses in the range of 6 to 15 Gy for previously untreated

lesions and 8 to 15 Gy for recurrent lesions.[126]

The target volume for patients receiving treatment for DI should encompass the hypothalamus and pituitary gland. The recommended prescribed dose is 15 Gy in 1.5-Gy daily fractions. In a report from the Mayo Clinic, 36% of 28 evaluable patients responded to radiotherapy.[127] The response rates were 60% (3 of 5 patients) in those treated with more than 15 Gy compared to 30% (7 of 23 patients) treated with doses of <15 Gy. Six patients had a complete response to therapy, five of whom received treatment within 14 days from diagnosis of DI.

VASCULAR DISORDERS

Vascular disorders are broadly categorized into vascular tumors, most commonly benign hemangiomas, and vascular malformations, including arteriovenous malformations (AVMs) and cavernous hemangiomas. Radiosurgery has emerged as an important and common treatment option for AVMs. Although radiation was used commonly in the past to treat hemangiomas in children, the recognition of late effects associated with radiotherapy, especially secondary malignancies, has rendered this practice less common.

Arteriovenous Malformations

Background and Clinical Aspects

Intracranial AVMs are congenital vessel abnormalities consisting of conglomerations of dilated arteries and veins with a resultant lack of a normal capillary bed. The nidus is a tangle of vessels connected by one to several fistulas with risk of rupture. The overall prevalence is low, affecting approximately 18 in 100,000 individuals with age at presentation typically between 20 and 40 years old.

Clinical concern comes from the high risk of bleeding, estimated to be 2% to 4% per year. Approximately 50% of patients present with hemorrhage and 50% present with nonfocal (headache, nausea) symptoms or incidentally found focal neurologic deficits. The risk of death per bleed is up to 10% and approximately 30% have serious morbidity associated with each bleed.

Diagnostic imaging includes angiography, which is invasive but allows for full grading of the AVM according to the Spetzler-Martin scale, which is predictive of hemorrhage risk. MRI, MR angiography, and CT angiography are noninvasive and complementary studies that may be used to visualize the AVM.

Surgery

The goal of any therapy for AVM is to completely obliterate the nidus. Partial obliteration of the nidus does not decrease the bleeding risk. Complete surgical excision provides immediate cure but carries a risk of intraoperative bleeding, ischemic cerebrovascular accident, infection, and death. Surgery is particularly indicated for AVMs in superficial, noneloquent regions of the brain. Endovascular therapy (embolization) is not curative, but may be used to decrease the risk of intraoperative bleeding or to decrease the size of the nidus before planned radiotherapy. There is a theoretical increased risk of hemorrhage or neurologic complication postembolization.

Radiotherapy

SRS is the radiation modality of choice for the treatment of AVMs. SRS is indicated mostly for lesions in deep or eloquent regions of the brain and is particularly safe and successful for lesions that are <3 cm. Unlike surgery, the time to obliteration ranges from 1 to 4 years after SRS, so the patient remains at a continued bleeding risk. Even with time, Maruyama et al.[128] demonstrated that the bleeding risk is not completely eliminated, but reduced by approximately 88%. Overall, the obliteration rate is 80% by 3 years for lesions that are 3 cm of smaller. For larger lesions, the angiographic obliteration for large AVMs is significantly reduced, with a mean approximating 66%.[129]

Based on the Flickinger dose–response data, typical prescriptions for treatment of AVM are 21 to 22 Gy prescribed to the 50% IDL for frame-based radiosurgery (Table 95.6).[130] The prescription should be lowered for AVMs near the brainstem or larger lesions (>3 cm). For LINAC-based SRS, prescriptions generally range from 16 to 24 Gy in a single fraction to 20 to 22 Gy in 2 fractions for spinal AVMs (Fig. 95.4).[131]

Hemangioma/Kasabach-Merritt Syndrome

Background and Clinical Aspects

Hemangiomas are dynamic vascular tumors characterized by a proliferative phase followed by an involution phase. Approximately 20% of hemangiomas are present at birth, whereas the remaining 80% usually form within the first few weeks of life. Most hemangiomas present no problems to the patient and require no treatment. The spontaneous involution rate is approximately 10% per year.[132] However, potential complications that may require treatment include obstruction of vision (eyelid hemangioma), ulceration and infection, cosmetic deformity from a facial hemangioma, and high-output cardiac failure.

TABLE 95.6 FLICKINGER'S PREDICTED RATES OF IN-FIELD AVM OBLITERATION BASED ON THE MINIMUM DOSE WITHIN THE TARGET VOLUME

Minimum Dose to Target (Gy)	Predicted AVM Obliteration Rate (%)
27	99
25	98
22	95

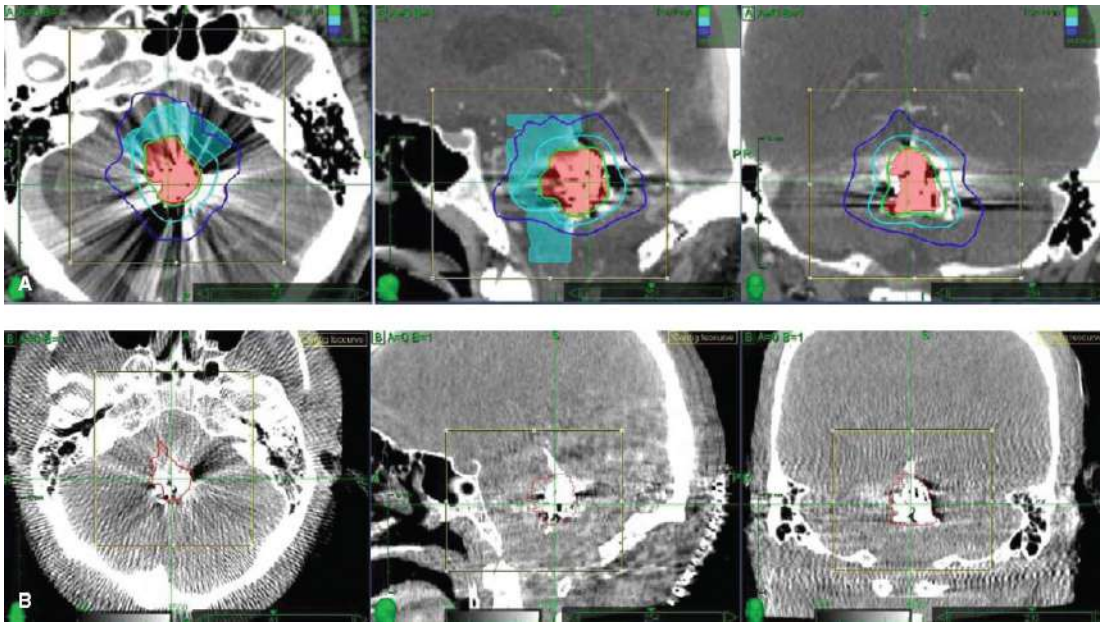

FIGURE 95.4. A: Stereotactic radiosurgery plan for an AVM (*red*) in the dorsal pons treated with 22 Gy in 2 fractions. The prominent streak artifacts are present because of embolization 1 year prior to treatment. **B:** CT angiogram of the same patient used to assist in defining the AVM nidus (*red contour*).

Previously, it was felt that extremely large hemangiomas predisposed patients to the KMS. This syndrome consists of platelet trapping and destruction within the vascular tumor with a resultant consumptive coagulopathy (disseminated intravascular coagulation) that can be life-threatening. It is now recognized that this phenomenon is associated with a type of vascular tumor known as the

kaposiform hemangioendothelioma and not the classical infantile hemangioma.[133]

Systemic Therapy

Treatment options for hemangiomas include local and systemic pharmacotherapy, laser therapy, and surgery. Glucocorticoids have been the mainstay of systemic treatment for patients with hemangiomas. However, long-term use of steroids in children leads to many complications, including growth retardation, metabolic disorders, cushingoid facies, personality changes, and increased risk of infections. Recently, propranolol has been recognized as a potential therapeutic agent for hemangiomas. The first report of its use was published in the New England Journal of Medicine in 2008 when two patients with hemangiomas with resultant heart failure were treated with propranolol and were noted to have softening, change in color, and ultimately regression of the lesions.[134] Both of these children were able to sustain a clinical response even after being weaned off of steroids. Additional studies of propranolol have shown promising results with most children exhibiting significant regression of their lesions and the ability to wean off of steroids without a rebound effect.[135]

For patients with KMS, vincristine and interferon-α have been used, particularly in situations in which a quick clinical response is needed or when the disease has become refractory to steroids and propranolol. Patients with KMS should also be managed with supportive measures, such as blood and/or platelet transfusions, as needed.

Patients with small lesions may be candidates for local therapy, such as intralesional or topical steroids. Topical timolol is also being investigated, given the promising results seen with propranolol.[136] Select patients may be candidates for treatment with pulsed-dye laser or excisional surgery.

Radiotherapy

Radiotherapy is indicated only in patients that have exhausted all other treatment options. When RT is used, responses are often quick and dramatic. RT can improve platelet counts in patients with KMS when they fail to respond to other treatments.[137] With low-dose RT (i.e., <10 Gy), scarring should be minimal, but patients must be followed closely for secondary malignancies.

The CTV should include the clinically visible and palpable lesion with margin. Imaging of the affected area with MRI is useful to delineate the depth and full extent of disease. Although there are no prospective trials to guide total

dose and daily dose, most reports have used fractionation schedules of 100 to 300 cGy/day to a total dose of 10 Gy or less.[19,138] When patients have not responded to low-dose RT, higher doses may be used to achieve a response.

FUNCTIONAL DISORDERS

SRS is widely used for the treatment of benign tumors. However, a significant number of patients benefit from the use of SRS to treat functional disorders such as trigeminal neuralgia (TN), tremors, and epilepsy. Over the past several years, there have been increasing reports of the use of SRS for the treatment of refractory psychiatric disorders including obsessive–compulsive disorder (OCD) and major depressive disorder.

Trigeminal Neuralgia (Tic Douloureux)

Background and Clinical Aspects

TN is a common problem that affects approximately 15,000 patients each year in the United States. There is a slight female predominance (1.5:1). The disorder is currently classified into type I TN and type II TN, which is based on pain characteristics, as opposed to the traditional classification system, which divided patients into idiopathic TN versus secondary TN.[139–141] The classic form of the disease, type I TN, is described as sudden shocks of sharp, lancinating facial pain lasting anywhere from a few seconds to minutes with pain-free intervals. Patients with type II TN predominantly experience constant burning, aching, or throbbing pain, generally of lower intensity.[142] This system also carries prognostic significance, with type I TN patients more likely to be pain-free and have longer disease control than patients with type II TN after decompression.[139]

The classic clinical feature is recurrent episodes of sudden, brief, severe, stabbing, or lancinating pain in the area of the trigeminal nerve sensory distribution. It is most commonly unilateral, but some cases are bilateral. Common triggers for attacks include talking, chewing, brushing teeth, and cold air. The diagnosis is often suspected on the basis of the above clinical symptoms, but an MRI brain should be performed to rule out structural abnormalities that may be causing secondary TN.

Medical Therapy

TN is first treated with pharmacotherapy, with carbamazepine being the most common and extensively studied agent. Oxcarbazepine is an option for patients who are unable to tolerate carbamazepine. Numerous other agents have been

used to treat carbamazepine-refractory patients including lamotrigine, neurontin, pimozide, tizanidine, and topiramate.

Surgery

In patients that have medically refractory disease, microvascular decompression is the treatment of choice for immediate relief of symptoms. Other options include rhizotomy with radiofrequency ablation, glycerol injection, or balloon compression.

Radiotherapy

SRS has emerged as a successful and minimally invasive procedure to treat classical TN. Treatment planning involves fusion of a contrast-enhanced MRI with thin cuts to the treatment planning CT scan. The target for SRS varies along the track of the trigeminal nerve. Potential targets described in the literature include the anatomical emergence of the trigeminal nerve from the pons—proximal dorsal root entry zone (DREZ), the prepontine cistern slightly anterior of the DREZ—the retrogasserian target, and the semilunar ganglion.[143–151] Typical doses using a frame-based radiosurgery platform range from 70 to 90 Gy, prescribed to an isodose range varying from 50% to 100% prioritizing low doses to the brainstem for minimal toxicity. This dose range is largely based on a composite of trials originating from Kondziolka et al. prospectively assigning patients to low-dose (60 to 65 Gy) or high-dose (70 to 90 Gy) SRS and demonstrating higher rates of pain relief in the high-dose arm (72% vs. 9% for patients treated with ≥70 Gy vs. <70 Gy).[145,151]

The durability of treatment and time to response depend on the dose distribution. The median time to treatment response varies from 2 to 4 months with higher doses yielding better treatment response but increased chances of sensory neuropathy (facial numbness).[128,142,152,153] Flickinger et al.[154] prospectively randomized patients to 75 Gy targeted to a shorter (1 isocenter) or longer (2 isocenters) segment of the trigeminal nerve demonstrating that treating larger segments of the nerve with higher doses is associated with delayed onset of facial numbness. The rates of pain relief were surprisingly identical between the two groups. There was a trend toward a higher incidence of numbness or paresthesias in the two-isocenter patients, and overall, the nerve length irradiated was significantly correlated with the development of numbness and paresthesias. However, in a report by Adler et al.,[155] 46 patients received treatment with a frameless robotic radiosurgery platform to a 6-mm segment of the trigeminal

nerve with a mean marginal prescription dose of 58.3 Gy and mean maximal dose of 73.5 Gy. In this cohort of patients, 85% experienced a complete response and, at a mean follow-up of 15 months, 96% reported excellent or good outcomes. Only 15% of patients experienced ipsilateral facial numbness.[139]

Epilepsy

Background and Clinical Aspects

Epilepsy is a disorder characterized by recurring seizures. It affects 0.5% to 1% of the population, and its etiology is unknown in the vast majority of cases. The clinical presentation of patients with seizures is broad, depending on the type of seizure and the area of the brain involved. Seizures are generally classified into simple versus complex (loss of consciousness) and generalized versus partial (affecting only one focus in the brain).

Nonradiotherapeutic Treatment

Antiepileptic drugs are the treatment of choice for patients with epilepsy. Surgery is an option for patients that develop medically refractory disease, particularly for temporal lobe epilepsy.[156]

Radiotherapy

SRS may be an alternative to surgery in medically refractory epilepsy for patients that are not surgical candidates. In a multi-institutional study, Regis et al.[157] treated 20 patients with SRS for intractable mesial temporal lobe epilepsy. The mesial temporal lobe was treated to a dose of 24 to 25 Gy in a single fraction with gamma knife. At a follow-up of 2 years, 65% of the patients were seizure-free. However, there was a 1-year lag between treatment and maximal effect, and there was a transient increase in seizures before the seizures started to diminish. In a study by Barbaro et al.,[158] 30 patients were randomized to low-dose (20 Gy) or high-dose (24 Gy) radiosurgery targeting the amygdala, hippocampus, and parahippocampal gyrus. At 3 years, the seizure-free rate was 67% among all patients with a trend toward a higher response rate (77% vs. 59%) and earlier responses in the high dose compared to the low-dose group of patients. No serious toxicity was reported in the study.

In general, the use of SRS to treat epilepsy is not routine, and nonradiosurgical options should be employed first. Further study is needed to establish the long-term safety and efficacy of SRS in the treatment of epilepsy.

Parkinson Disease

Background and Clinical Aspects

Parkinson disease (PD) results from the loss of dopaminergic neurons in the substantia nigra. It is a debilitating and progressive neurodegenerative disorder that affects approximately 1 million people in the United States. The hallmark clinical symptoms include masked facies, resting tremor, slow movements, shuffling gait, and muscle rigidity. Some patients also develop dementia as part of the disorder.

Nonradiotherapeutic Treatment

Pharmacotherapy with dopamine agonists and other compounds is the treatment of choice for patients with PD. Once refractory to medical therapy, surgery (thalamotomy or pallidotomy) may be used to remove the overactive brain nuclei. Deep brain stimulation is another invasive procedure done under stereotactic guidance that can be used in medically refractory PD.

Radiotherapy

Patients that are poor candidates for surgery may receive SRS for the treatment of medically refractory PD. To relieve tremor, the target is the nucleus intermedius (thalamotomy) with a dose in the range of 120 to 180 Gy. Evidence demonstrates long-term success rate of 80% to 90% in relieving symptoms from PD tremor, as well as essential and other types of tremors with a very low rate of permanent complications.[145–147,159–161]

Although radiosurgery has proven beneficial for tremors, mixed results have been found with regard to the treatment of PD-related akinesia/dyskinesia/rigidity. Treatment entails targeting the globus pallidus internus (pallidotomy) with doses in the range of 120 to 180 Gy. Rand et al.[162] reported that four of eight patients received relief in rigidity with no serious complications. However, Friedman et al.[163] achieved a response in only one of four patients while causing dementia and psychosis in the only patient responder. Young et al.[164] treated 29 patients with SRS pallidotomy with 80% success rate at mean follow-up of 2 years and only 1 (3.4%) complication at 9 months (homonymous hemianopia).

Psychiatric Disorders

Background and Clinical Aspects

Psychiatric disorders such as OCD, bipolar disorder, and major depressive disorder are debilitating illnesses. Radiosurgery has been used for the treatment of some of these psychiatric illnesses, with the majority of the experience in

patients with OCD. OCD is characterized by intrusive thoughts (obsessions) that lead to repetitive behaviors (compulsions).

Nonradiotherapeutic Treatment

The combination of pharmacotherapy (i.e., selective serotonin reuptake inhibitors) and behavior therapy is the treatment of choice for patients with mood disorders and OCD. Surgical management and deep brain stimulation are used for extreme and severe cases.

Radiotherapy

Patient selection for the use of SRS to treat psychiatric disorders is complex. Friehs et al.[165] recommend that such patients must be enrolled on an institutional protocol after carefully being evaluated by a multidisciplinary team. Similar strict criteria were used by Kondziolka et al.[166]

The treatment of OCD involves targeting the bilateral anterior capsules to a total dose of 120 to 140 Gy (Fig. 95.5). Kondziolka et al.[166] delivered a maximum dose of 140 or 150 Gy to the anterior limb of the internal capsule in three patients. At a minimum follow-up of 28 months, all patients noted significant functional improvements with no treatment-related complications. In a pilot study by Lopes et al.,[167] five patients were treated with SRS to a maximum dose of 180 Gy to the anterior limb of the internal capsule. At 3 years, three patients had a complete response to treatment, and one patient had a partial response based on changes in scores on an OCD assessment tool. Based on these findings, the group has opened a double-blind, randomized controlled study on the use of SRS to treat refractory OCD.[167]

Cardiac Arrhythmias

Cardiac arrhythmias are common complications that cause significant morbidity and mortality. Atrial fibrillation is the most common arrhythmia with an estimated 2.3 million cases diagnosed in the United States each year.[168] Most treatment methods are aimed at rate and rhythm control via medications and invasive intracardiac ablation procedures, both associated with adverse effects and complications, respectively.[169]

Recent interest has been directed toward animal and theoretical treatment planning for cardiac radioablation via SRS.[170–175] In most series, a dose of at least 25 Gy was delivered in a single fraction to the causative ectopic site identified via electroanatomic maps. Based on these models, accurate targeting of an arrhythmic heartbeat is challenging to achieve while simultaneously

sparing dose to adjacent critical structures including the esophagus and/or bronchial tree. Furthermore, different phases of cardiac contraction and relaxation during respiration must be taken into account.[168] Only two independent case reports document successful treatment of ventricular arrhythmia via stereotactic radioablation without definite acute or late complications.[176,177] The number of in-human treatments of cardiac arrhythmias using stereotactic radioablation is limited, and further study is needed to establish the long-term safety and efficacy.

Summary

SRS is a well-established, safe, and effective treatment modality for TN. Its use in the treatment of PD, epilepsy, psychiatric disorders, and cardiac arrhythmias remains an active area of investigation with limited data to support the widespread use of SRS in these situations. In particular, patients with psychiatric disorders and cardiac arrhythmias should only be treated with SRS as part of a strict institutional protocol.

Sialorrhea

Background and Clinical Aspects

Sialorrhea, from excess saliva production or inadequate saliva clearance, affects up to 80% of patients with Parkinson's and approximately 30% of patients with amyotrophic lateral sclerosis (ALS). The neurodegenerative process of ALS affects upper motor neurons of the anterior horn of the spinal cord with bulbar involvement seen in the later stages of the disease. A pseudobulbar palsy resulting in dysphagia and inability to control swallowing causes drooling and subsequent facial and skin irritation. Furthermore, use of noninvasive ventilation (NIV), which has been shown to increase life expectancy and quality of life for ALS patients, is limited because of risk of choking and pulmonary aspiration.[176,178]

Nonradiotherapeutic Treatment

Medical management is not always effective and can come with side effects, which have the potential to further complicate an already progressively debilitating disease state. Treatment consists of postural changes, repetitive swallowing, suctioning, botulism injections, surgery, and/or radiation.[177,179]

Anticholinergic drugs are the primary medications deployed in the management of sialorrhea. Scopolamine patches are thought to be the most effective and well-tolerated anticholinergic drugs in the management of

sialorrhea. Oral anticholinergics are often discontinued due to systemic side effects such as sedation and delirium. Glycopyrrolate has been shown to have a more favorable toxicity profile regarding central side effects and can also be administered subcutaneously.[176–179]

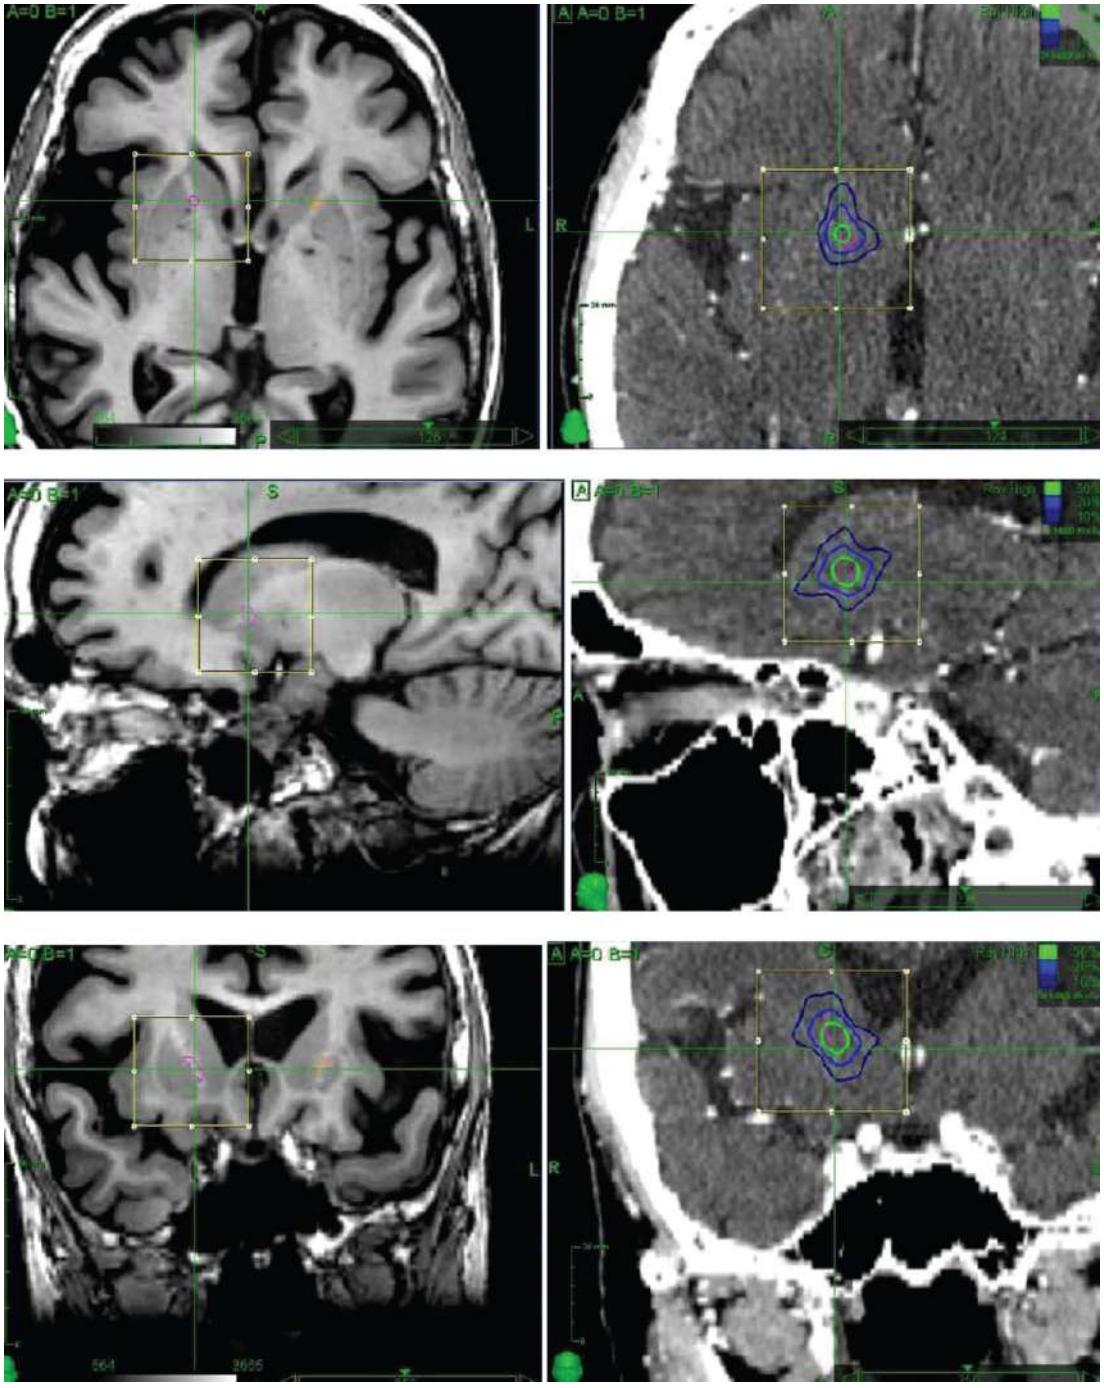

FIGURE 95.5. Stereotactic MRI sequences (**Left**) demonstrating the contoured anterior limbs of the internal capsule bilaterally and the corresponding treatment plan for the right internal capsule (**Right**) for a patient with refractory OCD. The right

internal capsule was prescribed 70 Gy to the 50% IDL (140-Gy maximum dose) in a single fraction.

Botulism can be injected into the submandibular or parotid glands under ultrasound guidance. Because the duration of effect can range from 3 to 7 months, the need for repeat injections is often necessary.[178,180]

Radiotherapy

Electron-based and photon therapy are both techniques deployed in delivering radiotherapy for sialorrhea. Photon therapy is typically delivered with parallel opposed radiation targeting the inferior two-thirds of the bilateral parotids and the entire bilateral submandibular glands. Most common electron field arrangement targeted the entire bilateral submandibular and parotid glands. The durability of treatment effect is variable, but the side effects of treatment are characteristic of patients receiving head and neck radiation. Guy et al.[181] compared the two treatment techniques and demonstrated longer durability and less acute toxicity (oral pain and mucositis) among patients treated with electron therapy. A systematic review demonstrated median time to symptomatic improvement was 2 months with efficacy ranging from 3 months to over 5 years.[179] Assouline et al.[182] treated 50 patients with 6MeV photons to a regimen of 20 Gy in 4 fractions or 10 Gy in 2 fractions with 92% of patients achieving a complete response with no difference in toxicity.[168] In this cohort eight of nine patients receiving a second RT course were treated initially with the lower-dose (10Gy) regimen. Optimal treatment is likely a 3-D conformal plan with a combination of mixed photon–electron beams using an oral cavity avoidance to minimize toxicity.

DISEASES OF THE EYE AND ORBIT

Pterygium

Background and Clinical Aspects

Pterygium is a chronic fibrovascular and degenerative process that arises from the conjunctival–corneal border that extends from the nasal corner of the eye to the cornea. Its name (“pterygium”) refers to the shape of the tissue, which is winglike. The exact prevalence of this problem is unknown, but it is well established that the frequency is higher in tropical regions. Most patients are asymptomatic and present for medical attention on the basis of cosmetic concerns, but symptoms may include redness and irritation of the eye. Pterygium

may impair vision by producing an irregular astigmatism as it grows onto the cornea.

Surgery

Treatment is indicated when vision is threatened and less commonly to improve cosmesis. The treatment of choice for pterygium is surgical excision with an adjunct to help improve local control rates (i.e., sliding conjunctival flap; rotational conjunctival autograft; free conjunctival or limbal autograft). Intraoperative or postoperative mitomycin C has also been used to improve local control rates, though this leads to increased risk of scleral ulceration, secondary glaucoma, iritis, and cataracts.

Radiotherapy

Local radiation therapy with strontium 90 plays an important role as an adjunct to surgery to prevent relapse. Fractionation schemes of 3 Gy × 10 to 6 Gy × 10 once per week have been commonly used with rates of local recurrence after surgery ranging from 5% to 12%.[183,184] In the most recent randomized study, Nakamatsu et al.[185] evaluated 73 pterygia in 71 patients and compared 30 Gy/3 fractions versus 40 Gy/4 fractions. The 2-year local control rate was nonsignificantly higher in the 30-Gy arm (85% vs. 75%). In a prospective randomized trial of single-dose postoperative radiotherapy (25 Gy × 1) delivered within 24 hours of surgery compared to sham RT, patients that received radiotherapy had a local control rate of 93.2% compared to 33.3% in the placebo.[186] In another randomized study, Viani et al.[187] compared low fractionation dose (2 Gy in 10 fractions) to high fractionation dose (5 Gy in 7 fractions) beta radiotherapy in the postoperative settings. Control rates were similar between the two groups (93.8% vs. 92.3%) with a significantly lower incidence of poorer cosmesis, photophobia, eye irritation, and scleromalacia in the low fractionation dose arm.

Choroidal Hemangioma

Background and Clinical Aspects

Choroidal hemangiomas (CH) are rare vascular tumors that arise from the choroid. CH can be classified as circumscribed, which occur in older patients or diffuse, which are associated with the Sturge-Weber syndrome.[188]

Clinically, these lesions are often asymptomatic, but patients may present with a visual disturbance by several mechanisms, including retinal detachment, macular edema, and retinal pigment changes.[189] Lesions are detected on

fundoscopic exam. Further workup includes ultrasonography, angiography with fluorescent dyes, and CT or MRI.

Surgery

Among the surgical treatment options available, CH that are not near the central visual structures (macula and papilla) are often treated with photodynamic therapy (PDT) with a low rate of complications.[188] Other treatment modalities include laser photocoagulation and transpupillary thermotherapy. In general, radiation therapy is preferred over PDT for the treatment of diffuse CH, though several small studies have reported encouraging results with the use of PDT.[188]

Radiation Therapy

RT is indicated to treat lesions near the macula and papilla and in cases that did not respond to other therapeutic maneuvers. RT techniques to treat CH include conventional 3DRT, proton beam therapy, and brachytherapy. Data for the use of radiosurgery for this condition are scarce[190].

Typical dose prescriptions for 3DCRT are 18 to 20 Gy for circumscribed CH and 30 Gy for diffuse CH given in 1.8- to 2-Gy daily fractions. Schilling irradiated 36 circumscribed CH with 20 Gy in 10 fractions.[191] Retinal reattachment occurred in 64% of the cases with improved vision in 50% and stable vision in 50%.

Fractionated proton radiotherapy doses range from 16.4 to 30 Gy in four fractions.[192–194] In the study by Zografos et al.,[194] all 54 cases experienced retinal reattachment and visual acuity was improved in 70%. Levy-Gabriel et al.[195] demonstrated a 100% rate of retinal reattachment and substantial improvement in visual acuity using proton beam therapy.

Plaque brachytherapy using cobalt 60, iodine 125, or ruthenium 106 has been used to treat circumscribed lesions.[189,194,196,197] Typical doses prescribed to the apex of the lesion range from 25 to 50 Gy. Each isotope has advantages and disadvantages depending on the physical properties (i.e., energy, half-life), and there is no evidence to support the use of one over the other.

Age-Related Macular Degeneration

Age-related macular degeneration (AMD) is the leading cause of blindness in the developed world.[198] The development of AMD is dependent on age, with a prevalence of up to 35% in the eighth decade of life. External beam radiotherapy with photons or protons and brachytherapy have been used in the past to treat macular degeneration. Overall, results of radiotherapy in the management of this

disease have been mixed. A Cochrane meta-analysis in 2010 analyzed 14 randomized trials utilizing RT as a treatment for AMD and concluded that the review "does not provide convincing evidence that radiotherapy is an effective treatment for neovascular AMD."[199]

However, there is renewed interest in radiation therapy for AMD based on results of the IRay in Conjunction with Anti-VEGF Treatment for Patients with Wet AMD (INTREPID) trial.[200] In this study, 230 participants that had received at least 3 injections with anti-VEGF therapy were randomized to 16 Gy, 24 Gy, or sham SRT. The primary endpoint was mean number of pro re nata (PRN) intravitreal ranibizumab injections over 52 weeks. With 2 years of follow-up, patients that received 16 or 24 Gy had fewer PRN treatments compared to the sham SRT group. SRT was found to induce microvascular change, but this affected vision in only 1% of patients.[200] This trial supports SRT as a potential method to stop or slow down the visual loss associated with continued intravitreal injections of anti-VEGF therapy.

Graves Ophthalmopathy

Background and Clinical Aspects

Graves ophthalmopathy (GO), also referred to as Graves orbitopathy or thyroid eye disease, is an autoimmune disorder affecting the musculature of the orbits. The presence of activated T lymphocytes leads to an inflammatory reaction secondary to the release of cytokines. It is estimated that up to 50% of patients with Graves disease will develop orbitopathy, but 10% of patients are euthyroid and some are hypothyroid at presentation.[1] Smoking is the greatest risk factor for the development of GO and also predicts for a poorer response to therapy.[1]

A multidisciplinary team including an ophthalmologist, endocrinologist, and radiation oncologist should be involved in the evaluation of the patient with GO. Clinical features of patients with GO include proptosis (measured by the Hertel exophthalmometer on physical exam), photophobia, upper eyelid retraction, periorbital edema (because of the accumulation of collagen and hyaluronan, which attract water), conjunctival erythema, and tearing and visual impairment (Fig. 95.6A and B). Patients may complain of a "gritty" sensation in their eyes. Several classification systems are available to document the extent of disease, though the one favored at our institution is the SPECS Ophthalmic Index (Table 95.7), which assigns a score of 1 to 3 on the basis of six categories: *S*oft tissue involvement, *P*roptosis, *E*xtraocular movements, *C*orneal involvement, and *S*ight (visual acuity).

Imaging studies, such as CT or MRI, will demonstrate abnormalities, including enlargement of the extraocular muscles and fatty infiltration, in 70% to 80% of cases.[1] The most commonly involved muscles include the inferior and medial rectus muscles.[201]

FIGURE 95.6. A and **B:** A 50-year-old woman with Graves ophthalmopathy before **(A)** and after **(B)** treatment with corticosteroids and radiotherapy for prominent eyelid edema and strabismus. **C:** 3-D conformal radiotherapy treatment plan for a patient with Graves ophthalmopathy. The isocenter (*yellow arrow*) is placed a few mm posterior to the lenses (*magenta*), and the opposing fields are beam split anteriorly (*white arrows*). The extraocular muscles are contoured in *red*. The color wash display demonstrates that <10% of the dose reaches the lens.

TABLE 95.7 SPECS CLASSIFICATION SYSTEM FOR GRAVES OPHTHALMOPATHY

Clinical Feature	Grade 1 (1 Point)	Grade 2 (2 Points)	Grade 3 (3 Points)
S (soft tissue involvement)	Minimal objective symptoms: redness, chemosis, slight periorbital edema	Moderate objective symptoms: redness, chemosis, moderate periorbital edema	Severe objective symptoms: conjunctival exposition, prominent periorbital edema
P (proptosis)	>20–23 mm	24–27 mm	>27 mm

E (eye muscle dysfunction)	Rare diplopia; none in primary position	Frequent diplopia; moderate mobility impairment	Severe constant muscular dysfunction
C (corneal involvement)	Slight corneal changes and no symptoms	Prominent corneal changes and moderate symptoms	Keratitis or other severe eye symptoms
S (sight loss)	20/25–20/40	20/45–20/100	>20/100

Management Overview

Treatment options for GO include glucocorticoids, orbital radiotherapy, and surgery (orbital decompression, eye muscle surgery, eyelid surgery). Smokers should be encouraged to quit. Prior to the initiation of treatment, the patient's thyroid function should be normalized. Radioiodine therapy, but not antithyroid drugs, may cause worsening of GO.[202] Once thyroid function is stabilized, the treatment of GO depends upon the severity of the disease.

Medical Management (Glucocorticoids)

Glucocorticoids (GCs) are a mainstay of treatment for GO. Immediate treatment with high-dose steroids (IV or oral) is required for patients whose vision is threatened by optic neuropathy.[203] GCs may also be used to treat patients with moderate to severe active ophthalmopathy.[203]

Surgery

In the event that GCs fail to improve optic neuropathy, urgent orbital decompression is necessary.[204,205] Another indication for urgent orbital decompression is exposure keratopathy not relieved by local measures.[204] In order to improve extraocular muscle function and cosmesis, other procedures such as strabismus surgery and lid surgery may be performed. It is recommended that the GO be inactive for at least 6 months before pursuing these procedures.[204]

Radiotherapy

Indications for RT in the management of GO have been outlined by Donaldson et al.[206] and include (Table 95.8) inducing clinical regression, improving functional deficits, improving cosmesis, and avoiding side effects of other treatments.

RT is generally administered with 3DRT. Both orbits, including the entire length of the extraocular muscles, are treated to a total dose of 20 Gy in 2-Gy fractions using opposed lateral fields with the isocenter placed a few millimeters

posterior to the lenses using a beam-split technique (Fig. 95.6C).

For patients with progressive GO, retrospective data suggest that orbital RT is an effective treatment modality. Marquez et al.[207] reviewed the records of 197 patients treated at Stanford, all of whom received 20 to 30 Gy to the bilateral retrobulbar region. Outcomes assessed included SPECS score and patient satisfaction. There was a 96% overall response rate and 98% patient satisfaction rate with the largest improvements in soft tissue findings (89%), extraocular muscle dysfunction (85%), and corneal abnormalities (96%). In a more recent study, Matthiesen et al.[208] reported on 211 patients that received orbital RT between 2000 and 2010 for GO. Overall, 97% of patients had stabilization of disease and 84% reported symptomatic improvement. Steroids were discontinued in 98% of patients who received them as initial therapy. A subset of 14 patients received orbital reirradiation for persistent symptoms, with 5 achieved a complete response and 9 had disease stabilization. These 14 patients did not experience increased toxicity compared to the rest of the cohort.[208]

TABLE 95.8 CLINICAL GUIDELINES FOR USE OF RADIOTHERAPY IN GRAVES OPHTHALMOPATHY (GO)

Radiotherapy Goal	Precondition/Indications	Contraindications
Induce clinical regression	*Pretherapeutic diagnostics*: evidence of autoimmune thyroid disease; CT/MRI	Stable GO without clinical progression
Reduce/eliminate functional deficits	*Ophthalmologic diagnostics*: documented progressive disease	Lack of euthyrosis
Improve cosmetics/esthetics	*Subjective/objective findings*: evidence of functional deficits and disorders	"Cosmetic" indication alone without functional impairment
Avoid/decrease undesired effects of other measures	*Exclusion of risk factors*: no other eye disease (i.e., diabetic retinopathy)	No consent to planned therapy

Smitt MC, Donaldson SS. Radiation therapy for benign diseases of the orbit. *Semin Radiat Oncol* 1999;19(2):259–264.

Reactive Lymphoid Hyperplasia/Orbital Pseudotumor

Background and Clinical Presentation

Disease of the lymphoid tissue in the orbit is rare and may include orbital pseudotumor (OP) or malignant lymphomas. OP is an inflammatory condition of unclear etiology that affects the soft tissue of the orbits, most often unilaterally.[201] Most patients present between the fifth and sixth decades of

life.[209]

Clinical features of OP include periorbital edema, retrobulbar pain, extraocular muscle dysfunction, palpable mass, and exophthalmos.[201] Symptoms usually develop acutely. Imaging with CT or MRI of the orbits should be obtained for further evaluation. Imaging findings include enlarged extraocular muscles, optic nerve thickening, and infiltrates in the retrobulbar adipose tissue with enhancement after administration of iodinated contrast or gadolinium.[201] Biopsy should be obtained to establish the diagnosis, especially for lesions that are easily accessible.

Medical Therapy

Corticosteroids are the treatment of choice for the majority of patients. Response rates for optic neuropathy are as high as 92% with an overall response rate of 78%.[201] However, only 33% of patients experience long-term control with a single course of steroids.[210]

Surgery

Surgical excision may be used for easily accessible lesions. Relapses are common after surgery.

Radiation Therapy

Indications for RT include recurrent lesions after surgery, steroid-refractory lesions, and lesions not amenable to other treatments. The RT technique of choice is 3DRT.

A planning CT should be obtained and coregistered with the diagnostic MR or diagnostic CT to delineate the target volume, when visible. Unilateral treatment is typically performed with a single lateral field or with an anterior and lateral field, weighted more heavily laterally. Bilateral orbital involvement is treated in a manner similar to GO. Occasionally, superficial lesions may be treated with electrons. Typically, the prescription dose is 20 Gy given in 10 fractions.[201]

Two modern series demonstrate the efficacy of orbit RT on OP. In a study by Matthiesen et al.,[211] 20 orbits in 16 patients were treated with RT for OP. With a mean dose of 20 Gy in 10 fractions, 87.5% of the patients experienced a response (clinical improvement and/or tapering of corticosteroid dose). Corticosteroid use was stopped or reduced in 81% of the patients. No significant late effects were reported. Similarly, Prabhu et al.[212] reported on 26 orbits affected with OP in 20 patients treated with radiation therapy (25.2 to 30.6 Gy) between 2002 and 2011. The majority (85%) demonstrated a response to RT, and

70% of the patients initially on steroids were completely off steroids by the last follow-up visit. Long-term complications occurred in seven patients, the majority of which were cataracts.[212]

BENIGN DISEASES OF SOFT TISSUE AND BONES

General Overview of Inflammatory Conditions of Joints and Tendons

The role of radiation therapy in the treatment of benign inflammatory conditions involving the joints and/or tendons is controversial. Osteoarthritis (OA), tendonitis, bursitis, rotator cuff syndrome, and tennis elbow are examples of inflammatory conditions for which radiation therapy has been used in the past. These soft tissue syndromes may result from repetitive activities that cause overuse or injury to the joint areas, incorrect posture, stress on the soft tissues because of an abnormal or poor positioned joint or bone, or other diseases, such as autoimmune diseases or infection.

Although the cause of each disorder may be different, the clinical presentation and general treatment plan are frequently similar. Symptoms include pain, swelling, or inflammation in the tissues and structures around a joint, such as the tendons, ligaments, bursae, and muscles. Treatment generally involves a combination of exercise, lifestyle modification, and analgesics. If pain becomes debilitating, joint replacement surgery may be used to improve the quality of life. In rare instances, low-dose radiation therapy (<10 to 15Gy) can be employed. The low dose required to improve symptoms suggests the possible mechanism of action for radiation therapy (Table 95.9).

Osteoarthritis

Osteoarthritis (OA), the most common joint disorder, is a chronically debilitating musculoskeletal disorder, which predominately affects older people. It presents with pain associated with cartilage destruction, bone modification, and structural changes of capsule and synovia. Symptoms are caused by reactive inflammation of joint surface and joint capsule lining (synovia). Risk factors include age, genetic predisposition, bone fracture or joint injury whether by an accident of overuse from work or sports, and increased BMI.[213] The incidence of OA is expected to rise worldwide because of an aging population and the increasing prevalence of obesity compared to previous decades.

TABLE 95.9 RADIATION THERAPY MECHANISM OF ACTION DOSE CONCEPTS

Mechanisms of Action	Single Dose (Gy)	Total Dose (Gy)
Cellular gene and protein expression (e.g., eczemas)	<2.0	<2
Inhibition of inflammation in lymphocytes (e.g., in pseudotumor orbitae)	0.3–1.0	2–6
Inhibition of fibroblast proliferation (e.g., in keloids)	1.5–3.0	8–12
Inhibition of proliferation in benign tumors (e.g., in desmoids)	1.8–3.0	45–60

Nonradiotherapeutic Treatment

Hunter et al.[214] provide a general overview of the diagnosis, investigation, and treatment of OA. The treatment of early OA is intended to reduce the primary symptoms of joint pain and stiffness with the goal of maintaining and improving the functional capacity of the affected joint(s).[215] Exercise, weight reduction, and joint braces, among other measures, have shown some success at unloading damaged joints and improving symptoms.[216] For osteoarthritis of the hip and knee, exercises that strengthen muscles and improve aerobic condition are most effective.[217]

Oral analgesics are the mainstay of treatment for OA. Although acetaminophen is frequently offered due to its relative safety and effectiveness, a nonsteroidal anti-inflammatory drug (NSAID) may be added or substituted.[218] NSAIDs can be used in patients with symptomatic OA of the hand, hip, or knee. The goal is to administer the lowest effective dose for the shortest duration. The use of stronger analgesics, such as weak opioids and narcotic, may be considered when other methods have been ineffective or if certain drugs are contraindicated.[216] Glucosamine and chondroitin sulfate are over-the-counter remedies that are frequently used to reduce pain, but their efficacy has not been proven.[219] Corticosteroids and other analgesics may be injected directly into the joint; injections may temporarily reduce swelling and pain. Acupuncture and other complementary and alternative treatment modalities have been used, but their efficacy has yet to be proven.[220]

Surgery is reserved for patients with severe OA and those who have not responded to noninvasive therapies. Total or partial joint replacement is most commonly used for OA involving the knee, hip, and shoulder and is considered when structural damage is visible on x-rays. However, there are modern surgical procedures that can obviate or delay the need for joint replacement, including

osteotomies, and joint resurfacing.[221] Joint fusion or arthrodesis may be used to treat arthritis of the spine, ankles, hands, and feet. Arthroscopy, or arthroscopic surgery, is a minimally invasive surgical procedure that can be used to examine and treat the interior surface of a damaged joint. Arthroscopic procedures can help relieve pain for a short time and allow the joints to move better. Although arthroscopy may delay the need for joint replacement surgery, it does not improve the arthritis itself.[222]

Radiotherapeutic Options

In nonsurgical candidates, low-dose RT may be considered if pharmacotherapy has failed. RT can lead to primary freedom from pain and secondary to improved joint function.[223] Several single-institution studies have been published that report long-term pain relief and functional gain in 50% to 75% of patients. In Germany, a pattern of care study investigated the use of RT for the treatment of OA of the knee (gonarthrosis) from the years 2006 to 2008.[224] Almost 80% of institutions in Germany have used RT to treat OA in the 2-year period analyzed. Treatment of 4,544 patients was performed annually at 188 institutions. The median total dose was 6 Gy (range 3 to 12 Gy), with a median single dose of 1 Gy (0.25 to 3 Gy). Long-term clinical outcomes were available in 5,069 cases. The majority of patients experienced pain reduction for at least 3 months, but pain management for up to 12 months was reported. In 30% of patients, a second course of RT was used for inadequate pain response or early pain recurrence.[224] Micke et al.[225] published a prospective study on elderly patients with gonarthrosis using a similar RT regimen demonstrating a good analgesic effect of low-dose RT with minimal side effects.

As with arthroscopy, radiation may reduce pain and pain-related dysfunction, but it does not improve the arthritis itself. Because of its efficacy and relative safety, RT may provide an alternative to conventional conservative treatment for patients who are not surgical candidates.

Gorham-Stout Syndrome

Gorham-Stout syndrome, also known as disappearing bone disease or massive osteolysis, is a rare bone disorder of unknown etiology. It is characterized by progressive proliferation of small blood or lymph vessels resulting in destruction and resorption of the bone matrix. The symptoms are nonspecific, but include muscular weakness, limb tenderness, and pathologic fracture occurring minimal trauma. Involvement of the cervical spine or skull base could be fatal. Case

reports indicate limited efficacy of systemic therapies such as zoledronic acid and interferon-α.[226,227] Radiation therapy has also been used.[228] Heyd et al.[229] completed a national patterns-of-care study and literature review that summarizes the scant data available for this rare disorder. The 38 articles listed therein provide evidence from treatment of 44 patients that conventionally fractionated external beam RT (total dose of 36 to 45 Gy) may prevent disease progression in 75% to 80% of cases.

Pigmented Villonodular Synovitis

Pigmented villonodular synovitis or tenosynovial giant cell tumor is a rare proliferative disorder of synovial tissue. Symptoms include sudden onset, unexplained joint swelling and pain that frequently involves a single joint. The knee and foot are most commonly affected, but there are reports of shoulder, hand, and hip involvement.[230] Decreased motion, joint stiffness, and increased pain occur as the disorder progresses. Surgical resection with either synovectomy or joint replacement is the treatment of choice.[231]

Radiation therapy is indicated in cases of diffuse disease, bulky disease resulting in bone destruction, or in the rare instance of multiple recurrences after resection. Although intrasynovial injection of radioactive isotopes postoperatively has been used in the past for high-risk patients,[232] most institutions use external beam radiation therapy. RT to a dose of 36 to 50 Gy has been effective.[21,233,234] MRI is essential for delineating disease pre- and postoperatively. Final dose of RT should be tailored to the amount of residual disease.[235]

Vertebral Hemangiomas

Hemangiomas are benign proliferations of blood vessels that can affect any tissue and are typically asymptomatic. About 50% of hemangiomas involving the vertebral body are associated with pain and therefore may require treatment. Treatment options include surgical resection or more conservative interventions such as transarterial embolization, vertebroplasty, or intralesional injections.[236] Radiation therapy either alone or postoperatively has been successful in reducing pain caused by vertebral hemangiomas.[237] In a German multicenter trial, a total of 84 patients with 96 symptomatic lesions were irradiated for a symptomatic vertebral hemangioma. At a median 68-month follow-up, 90% of patients had either complete or partial pain relief. Radiation doses ≥34 Gy resulted in significantly improved pain relief. A total radiation dose of 36 to 40 Gy

delivered in 2 Gy per fraction has been recommended.[238]

DISEASES OF CONNECTIVE TISSUE AND SKIN

Desmoid Tumors

Background and Clinical Aspects

Desmoid tumors (also called aggressive fibromatosis or deep musculoaponeurotic fibromatosis) are benign tumors of connective tissue tumors that arise from muscle fascias, aponeuroses, tendons, and scar tissue. They are slightly more predominant in females and tend to occur during the third and fourth decades of life, although children and the elderly can be affected. In the general population, desmoids are rare; the estimated incidence is 2 to 4 per million per year. Genetic factors, trauma, and/or surgery predisposes the development of desmoids. Most desmoids arise sporadically, with 85% of cases associated with CTNNB1 gene mutation in the Wnt/β-catenin signaling pathway. Mutations in the APC genes result in desmoid tumors affecting 10% to 20% of patients with familial adenomatous polyposis (FAP) and are a manifestation of Gardner syndrome.[239,240]

Tumors can develop anywhere in the body, but most commonly involve in the trunk/extremity, abdominal wall, and intra-abdominal sites, including the bowel and mesentery. Approximately 30% of patients with desmoid tumors have a history of prior desmoid tumors.[241,242] Sporadic cases commonly involve the extremities, the shoulder girdle, and the buttock.[242] In patients with FAP, intra-abdominal desmoids predominate and tend to be associated with surgical sites and anastomoses following colectomy.[243] Desmoid tumors in women can occur during or after pregnancy and therefore may be associated with high estrogen states. Women who have been pregnant are more likely to have abdominal desmoid tumors that develop within 10 years of the last pregnancy.[244]

Although desmoids have no known potential for metastasis or dedifferentiation, they are locally aggressive and commonly have a high rate of recurrence even after complete resection. Diagnostics workup with MRI helps to estimate size and infiltration into other organs and should be obtained prior to incisional biopsy that is obtained to confirm diagnosis.

Nonradiotherapeutic Treatment

Observation is a viable option for stable, asymptomatic desmoids. Treatment is indicated for symptomatic patients, if there is risk to adjacent structures, or to

improve cosmesis. Complete surgical resection of the tumor with negative microscopic margins is the treatment of choice for most desmoid tumors. Because of the size and infiltrative nature of extra-abdominal desmoids, resection may result in significant morbidity requiring skin grafting or flap reconstruction. Desmoid tumors have a high rate of recurrence following even complete surgical removal. Recent meta-analysis of 1,295 patients demonstrated that risk of recurrence in patients with positive surgical margins was almost twofold higher.[245] Although resection does not alter survival in most patients, given the histologically benign nature of desmoids, the overall surgical strategy should still be an attempt at complete removal using function-preserving surgical approaches to minimize major morbidity (functional and/or cosmetic).[246]

Although extra-abdominal desmoid tumors can generally be treated effectively with local therapy, surgical intervention tends to be counterproductive in intra-abdominal variants, especially the ones associated with FAP. In some instances, systemic therapy may achieve significant and durable cytoreduction, obviating the need for resection. Patients with desmoid tumors have been treated with NSAIDs. The most widely used NSAID for treatment of desmoid tumors is sulindac. Hormonal agents such as tamoxifen, raloxifene, and progesterone have been used, often in combination with NSAIDs. Tamoxifen has been used most widely and is typically prescribed at doses similar to those used for breast cancer (10 mg daily). Much higher doses (120 mg daily) have been recommended,[247] but high-dose tamoxifen is difficult to tolerate, and there is no evidence to suggest that higher doses of tamoxifen are better than lower doses.

A variety of palliative chemotherapeutic regimens have been used.[248–251] With the waxing and waning natural history of desmoids, it is difficult to say whether systemic therapy provides much benefit over observation. In one series, 142 patients presented with either a primary (n = 74) or recurrent (n = 68) desmoid tumor. Eighty-three patients were treated with observation along, and fifty-nine received either hormone therapy or chemotherapy. There was no statistically significant difference in progression-free rates between the two groups.

Desmoid tumors also respond to the tyrosine kinase inhibitor imatinib.[252,253] The response is thought to be due to expression of one of Gleevec's molecular targets, PDGF receptor, on desmoid tumors.[254] Phase II clinical trials have demonstrated efficacy of imatinib in the treatment of progressive and recurrent aggressive fibromatosis. Although response rates are low, the 2-year progression-free rate in responders is about 50% with a favorable toxicity

profile.[253,255] Kasper et al.[255] prospectively administered imatinib (800 mg/daily) to patients with desmoid tumors not amenable to R0 resection without significant function loss and demonstrated a 2-year progression arrest rate of 45%.

Intralesional injections[256] and radiofrequency ablation[257] have also been used. Although the techniques led to some tumor shrinkage, the experience to date is limited and the long-term results are not yet known.

Radiotherapeutic Options

Radiation therapy is a viable option for inoperable patients and may also be used in combination with surgery or chemotherapy. Spear et al.[258] retrospectively compared the efficacy of surgery-alone, radiation-alone, and combined modality therapy (radiation and surgery) in the treatment of desmoid tumors. Five-year local control rates among surgery, radiation therapy, and combined modality groups were 69%, 93%, and 72%, respectively. More recently, Janssen et al.[245] performed a meta-analysis on the influence of surgical margin and adjuvant RT on local recurrence and found that RT reduces the risk of recurrence in patients with microscopically positive resection margins. The association of adjuvant RT benefit was even stronger for resection of recurrent tumors with positive margins. Of note, adjuvant radiotherapy for patients with negative margins did not affect recurrence rates.

The general recommended radiation dose for inoperable or recurrent desmoids is 60 to 65 Gy.[21] However, long-term results at another institution show increased posttreatment toxicity in patients who receive RT doses >56 Gy.[246,259]

Young age (≤30 years) was also associated with increased late toxicity. In a retrospective study of 30 patients under the age of 30, younger age (<18) is associated with inferior locoregional control following RT. Although actuarial control rates were better with RT doses of ≥55Gy, almost 50% of patients experienced grade III and IV complications, including pathologic fractures, impaired range of motion, pain, and in-field skin cancers.[260] Because long-term results suggest that unresectable tumors respond to 56 Gy with a 75% expectation of local control, the lower dose may be more appropriate in this population.

When an R0 resection is not possible, doses of 50 to 60 Gy postoperatively should be given to improve local control. RT is often not considered for intra-abdominal tumors because of the dose and increased field size required increase

risk of bowel injury. Because of the complexities involved in managing the disease, a multidisciplinary approach must be taken.[261]

Peyronie Disease

Background and Clinical Aspects

Peyronie disease (also known as “induratio penis plastica”) is a chronic inflammatory connective tissue disorder involving the penile tunica albuginea that results in tissue proliferation and the development of hard plaques, most commonly on the dorsal surface of the penis, which may cause a curvature and changes in the length or circumference of the penis while erect. Symptoms may lead to difficult intercourse, penile pain, and erectile dysfunction.

Peyronie disease (PYD) affects up to 10% of men, although a recent population-based study suggests the condition may be underreported in the United States.[262] Although PYD can affect teenagers, men between the ages 40 to 70 are mostly affected, with a peak incidence at 50 years of age. The cause is unknown, but is often associated with prior penile trauma. Diabetes mellitus and arterial and venous vascular disease are risk factors, along with an assumed genetic predisposition. PYD results in pain, abnormal curvature, erectile dysfunction, indentation, loss of girth, and shortening. Slow progression over several months is typical, with spontaneous remission occurring in <15% of men.[263]

Nonradiotherapeutic Treatment

Results of nonsurgical treatment of PYD are mixed and controversial.[264,265] Some success has been reported with vitamin E supplementation, but results have not been confirmed in larger studies.[266] A combination of vitamin E and colchicine may delay disease progression.[267] Other agents that specifically target inflammatory pathways have also shown mixed benefit, including TGFβ1 inhibitors,[268] coenzyme Q10,[269] and sildenafil, among others.[270] Topical therapies have largely been ineffective, but penile injection with verapamil or collagenase, intended to break up scar tissue formed by the inflammation, has shown some efficacy.[271] Physical therapy and extracorporeal shock treatments have also had limited benefit.

Surgical options for PYD are complex procedures that should only be performed by experienced urologists and are reserved for patients not responding to other therapies.[272] Although the nonsurgical treatments discussed may not reliably treat the disease, they can be used to stabilize the scarring process and

may result in some reduction of deformity. A combination of nonsurgical techniques may have even more efficacy.[273]

Radiotherapeutic Options

The largest experience with the use of RT in the treatment of PYD has been in Europe. Retrospective studies report varied symptom improvement with the use of RT in terms of pain, curvature reduction, plaque volume, and sexual functioning.[274] These data also suggest that any benefit of RT is best in the treatment of early stages of disease, when radioresponsive inflammatory cells and fibroblasts are still active in the disease. RT in later stages of PYD once the plaques have fully formed is thought to yield worse outcomes.

The current recommendation for RT in PYD is a total dose of 10 to 20 Gy in daily single fractions of 2 to 3 Gy using a direct ventral field with the penis laying on the scrotum and a lead or polyethylene layer between the scrotum and testes. Orthovoltage, low-energy photons and/or electrons may be used. One retrospective study from the Netherlands indicated that low-dose RT, either 13.5 Gy (9 × 1.5 Gy, 3 fractions per week) or 12 Gy (6 × 2 Gy, daily fractions), resulted in pain relief in the majority of the 179 patients evaluated.[275] Sexual dysfunction was a reported side effect, although this is confounded by the underlying disease.

As experimental models improve our understanding of the pathogenesis of PYD, the use of RT for plaque development in this highly complex vascular organ may further decline given concerns regarding radiation-induced vascular fibrosis, and more effective therapies emerge.[276,277]

Dupuytren Contracture

Background and Clinical Aspects

Dupuytren contracture, also known as Morbus Dupuytren (MD) and Morbus Ledderhose (ML) depending on involvement of the hands or feet, respectively, is a connective tissue disorders that affects the palmar or plantar fascia. Some authors estimate a global prevalence of Dupuytren disease to be between 3% and 6%. Incidence increases after the age of 40 and the condition affects men more often than women. A genetic predisposition along with a number of environmental factors (smoking, alcohol use) can lead to local ischemia and free radical release, which, in turn, stimulates fibroblast proliferation and cytokine production, particularly IL-1.

In the early stage, subcutaneous nodules appear, which may be fixed to the

overlying skin. As the disease progresses, cords develop and become visibly predominant. With further progression, the cords reach the periosteum of the bones and lead to the characteristic appearance of palmar or plantar contraction. The fourth/fifth phalanges of the hand (MD) or the first/second toes of the foot (ML) are most commonly affected digits (Fig. 95.7). With increased thickening of the fascia and progressive contracture, the fingers and toes begin to curl, resulting in significant functional deficits, for example, difficulty grabbing (MD) or walking (ML).

Nonradiotherapeutic Treatment

Excision of diseased cords and fascia via limited or selective fasciectomy is widely considered the gold standard treatment for Dupuytren contracture.[278,279] A 20-year review of open surgery for Dupuytren contracture showed that major complications occurred in 15.7% of cases and wound complications were seen in 22% of cases.[280] Even with excellent surgical resection, relapse is common, with 30% to 50% recurrence rate at 3 years.

FIGURE 95.7. Dupuytren contracture of both hands and the left foot.

Modern minimally invasive techniques have substantially reduced the complication rates. Percutaneous needle fasciotomy is a technique where cords

are weakened through the insertion and manipulation of a small 25-gauge needle mounted on a 10-mL syringe.[281] The procedure is performed under local anesthesia and patients may return to full usage of the affected limb within 24 hours. Because the cords and nodules are not fully excised, minimally invasive surgery has an even higher recurrence rate than surgical excision. A randomized study comparing percutaneous needle fasciotomy with limited fasciectomy showed an 85% recurrence rate after 5 years with the minimally invasive procedure.[282]

During the early stage of Dupuytren's, medication (steroids, allopurinol, nonsteroidals, vitamin E) may provide benefit, but the effects are temporary. Collagenase *Clostridium histolyticum* (CCH) injections are an FDA-approved nonsurgical treatment option for adult Dupuytren contracture patients with a palpable cord. Injections of this collagenase enzyme weaken the cords through breakdown of the peptide bonds in collagen, which subsequently allows for finger manipulation and release of contractures.[283–285] Although CCH has proven to be a useful minimally invasive technique for patients with later-stage DC, recurrence rates of 35% at 3 years of follow-up have been reported.[285,286]

Radiotherapeutic Options

Radiotherapy is currently used in the treatment of Dupuytren's exclusively for early-stage patients (who have a <10-degree deformity) and is considered standard of care for prevention of Dupuytren progression. Low-dose radiotherapy hinders fibroblast proliferation and the cascade of inflammatory markers that induce collagen formation and fibroblast differentiation into fibronectin. Many studies have demonstrated patient-reported effectiveness of radiation preventing further Dupuytren progression with minimal toxicity.[287–290] Adamietz et al. reviewed 176 hands treated with low-dose radiotherapy. Of those patients with <5-degree deformity, 82% had a patient-hand–reported disease progression-free survival at 10-year follow-up. Betz et al. retrospectively reviewed 208 hands treated with low-dose radiation and found that patients with <5-degree deformity had an 87% patient-hand–reported disease progression-free survival at 13-year follow-up. Most recently in 2015, a prospective study by Schuster et al. published the largest US patient-reported outcomes after low-dose radiation for early-stage Dupuytren's. In this study, 45 patients had received low-dose radiation via electrons directed en face. After 31 months, 94% of surveyed patients reported the RT was successful with minimal toxicity.

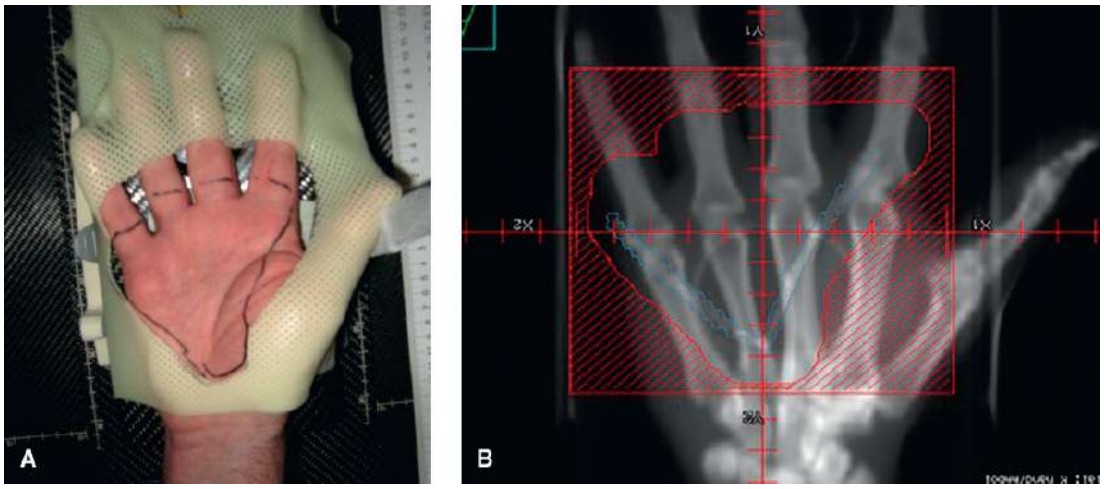

FIGURE 95.8. A: Immobilization for treatment of Dupuytren contracture with electrons. **B:** Block formation with clinical margin. (Courtesy of Barbara Agrimson CMD, RT (R) (T) Oregon Health & Science University.)

Seegenschmiedt et al.[290] performed a randomized clinical trial comparing the safety and efficacy of two different dose regimens with an untreated control group.[21] Group A received 10 × 3 Gy (30 Gy) via a split course (5 × 3 Gy) repeated at intervals of 12 weeks; in Group B, patients were treated with 7 × 3 Gy (21 Gy) delivered over 2 weeks. Regardless of the dose regimen, approximately 90% of treated patients had stable or improved disease. After a mean follow-up of 8 years, the extension deficit increased in 35% of the control group, in 7% of the 21-Gy group, and in only 4% of the 30-Gy group. Acute toxicity was more pronounced in group B, but long-term toxicity was comparable and included dryness, desquamation, skin atrophy, and altered sensation. The results of this study indicate that the prophylactic RT is well tolerated by patients and effective at preventing disease progression, and the 30-Gy regimen may be superior.[21] Irrespective of dose regimen, the target volume should include palpable or detectable nodules and cords surrounded by a 3- to 5-mm margin; and appropriate immobilization and shielding of unaffected joints are required (Fig. 95.8).

Keloids and Hypertrophic Scars

Background and Clinical Aspects

Keloids are an excessive tissue proliferation after scars after skin injury from surgery, heat, chemical burns, inflammation (e.g., acne), or even spontaneous proliferation. They differ from hypertrophic scars by their typical infiltrative growth pattern, causing local pain and inflammatory reactions, and sometimes

long-term progression; hypertrophic scars show thickening without surrounding reaction and can flatten spontaneously. Keloids appear mostly in the upper body and in regions with high skin tension (e.g., sternum, ear lobes). The cause is still unknown, although there is a genetic and race-specific predisposition that is already noted during adolescence. Keloids at the ear lobe after piercing are typical. In some patients, the resulting lesions are severely disfiguring and painful (Fig. 95.9). Recurrence is common after treatment.

FIGURE 95.9. A: Keloid behind left ear lobe. **B:** Status of keloid following resection plus 4 × 4-Gy radiotherapy.

Nonradiotherapeutic Treatment

Silicone bandages, pressure dressings, and cryosurgery have all been used to treat for keloids with varying efficacy.[291,292] Intralesional injections remain the first-line therapy for most keloids. Corticosteroids, 5-FU, and verapamil have all been directly injected into keloid lesions with symptom improvement. Up to 70% of patients respond to intralesional corticosteroid injection with flattening of keloids, although the recurrence rate is high in some studies (up to 50% at 5 years).[293]

Surgical excision may be indicated if injection therapy alone does not result in improvement. In patients treated with excision alone, recurrence rates range from 45% to 100%[294]; therefore, excision is typically combined with

perioperative and postoperative injections of either triamcinolone or interferon.[293]

Radiotherapeutic Options

Radiotherapy should be considered in cases of repeat recurrences postoperatively or where there is a high-risk of recurrence (e.g., marginal resection, large lesion, unfavorable location). Primary RT can be considered in instances where resection would result in functional impairment and in actively proliferating disorders within about 6 months after the triggering trauma. Because proliferating fibroblasts and mesenchymal and inflammatory cells are the target cells for RT, fully matured keloids have minimal response to RT alone. Prophylactic RT immediately following excision (within the first 24 hours) is most effective and reduces the risk of recurrence to 15% to 25% in most series.

Among different modalities for postexcisional radiotherapy, brachytherapy was found to have a lower recurrence rate when compared to electron and x-ray therapy by meta-analysis.[295] The target volume is limited to the scar plus a 1-cm margin; lead shielding can be constructed to protect normal tissue. An analysis of multicenter data on the use of postoperative RT for earlobe keloids shows that higher dose per fraction and use of deeper-penetrating electrons are preferable to standard 2-Gy fractionation schemes.[296] Achieving a BED of 15 to 22.5 Gy (at α/β of 10) with 10, 12, or 20 Gy delivered within 1 week over 2, 3, or 4 fractions, respectively, is sufficient for efficacy evaluated by relapse rate and good cosmesis. Common side effects include erythema and changes in skin pigmentation.

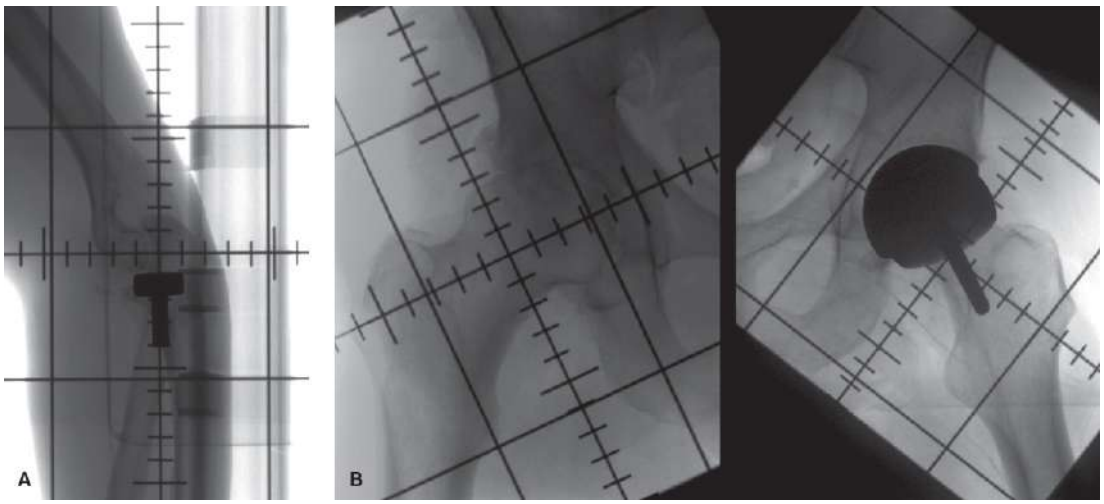

FIGURE 95.10. Typical treatment field for HO. **A:** Field set up for elbow after radial head replacement. **B:** Field setup of acetabulum with active HO and after hip

arthroplasty.

Heterotopic Ossification

Background and Clinical Aspects

Heterotopic ossification (HO) is a common complication of total hip arthroplasty, hip trauma, or acetabular fracture. HO occurs when the soft tissues around the hip become ossified. Following trauma, primitive mesenchymal cells in the surrounding soft tissues are transformed into osteoblastic tissue that then forms mature bone. The hip is the most common joint affected; HO typically occurs around the femoral neck and adjacent to the greater trochanter. The risk factors for development of HO are unknown, but the incidence is greater in men and occurs in more than 80% of patients who have a history of ipsilateral or contralateral HO. It is also more common in patients with a known history of osteoarthritis, ankylosing spondylitis, and Paget disease.[297] Hip stiffness is the primary symptom and the diagnosis is made radiographically. Pain is typically not associated with HO.

Nonradiotherapeutic Treatment

The treatment for HO is surgical excision followed by some form of HO prophylaxis. Prophylaxis is only applied to patients at high risk for developing HO. A meta-analysis showed that NSAIDs are effective in reducing the risk of postoperative HO.[298] Indomethacin is the most commonly used nonselective NSAID for HO prophylaxis. Indomethacin is a prostaglandin synthase inhibitor that also suppresses mesenchymal cells. The limited data available have not shown a clear benefit to the use of selective cyclooxygenase-2 (COX-2) inhibitors in HO prophylaxis.[299,300] Kan et al. performed a meta-analysis comparing selective NSAIDs (COX-2 inhibitors) and nonselective NSAIDs versus placebo in HO prevention. Efficacy was the same among the two classes with similar rates of discontinuation from gastrointestinal side effects.[301] Bisphosphonates have been used for prophylaxis because they delay mineralization of osteoid and appear to have some efficacy in preventing HO if used at the appropriate time. In one study, the cost of bisphosphonate use was prohibitive for routine use when compared to indomethacin.[302]

Radiotherapeutic Options

External beam radiation is an effective method for prevention of HO after total hip arthroplasty. Prophylactic radiation therapy for the prevention of HO has been used since the 1970s. A single fraction of 700 or 800 cGy to the at-risk

region (Fig. 95.10) is recommended and should be delivered in the perioperative period, either preoperatively (within 4 hours) or postoperatively (within 72 hours).[22] Typically, an AP-PA field size measures 14 × 14 cm with the cranial field border approximately 3 cm above the acetabulum and the caudal field border encompassing two-thirds of the proximal implant. The dose is prescribed to the body midplane.[22]

When comparing radiation therapy and NSAIDs, there is no clear benefit for use of one modality over another. A prospective, randomized study demonstrated that radiation therapy and indomethacin are both effective in the prevention of postoperative HO.[303] Although one meta-analysis of seven randomized studies concluded that radiotherapy is more effective than NSAIDs for HO prophylaxis,[304] a more recent analysis of 9 studies involving 1,295 patients found no statistically significant difference between the two.[305] An economic analysis using the same nine studies and the meta-analysis suggest that radiation therapy is not cost-effective when compared to use of NSAIDs.[306] This analysis has yet to be validated.

Section IV

Palliative and Supportive Care

CHAPTER 96

Palliation of Brain and Spinal Cord Metastases

Arpit Chhabra, Mark Mishra, Roy A. Patchell, William Regine, and Young Kwok

BRAIN METASTASIS

Brain metastasis is a very common diagnosis, with an annual incidence of approximately 170,000 to 300,000 cases. Brain metastasis represents the most common intracranial lesion in adults, occurring at a median time of 8.5 to 12 months from primary diagnosis. The rising incidence of brain metastasis is likely in part from a combination of increasing survival from recent advances in therapy and a greater availability and use of magnetic resonance imaging (MRI). The most common primary site is the lung followed by breast (Table 96.1).[1–4]

Clinical Presentation, Diagnosis, and Prognosis

The majority of patients present with neurologic signs and symptoms (Table 96.2).[1,5] Although differential diagnoses such as an abscess or a stroke must be considered, new-onset neurologic symptoms in a known cancer patient should always be presumed to be from brain metastasis until proven otherwise.

Patients presenting with acute neurologic signs and symptoms will likely undergo an initial noncontrast CT because of its ease of completion and ability to rule out life-threatening etiologies. However, contrast-enhanced MRI represents the most sensitive imaging modality to detect brain metastases, especially for identifying small lesions, which can have a significant effect on the patient's prognosis and treatment course. The majority of brain metastases will be located in the cerebral hemisphere (80%) at the junction of gray-white matter. Although there is no pathognomonic MRI characteristics of brain metastases, they generally tend to be T1 iso- or hypointense, T2 hyperintense and enhance with contrast administration.[6,7] Full systemic workup (e.g., positron emission tomography [PET] and CT) should be promptly initiated if brain metastasis is

the presenting event.

Performance status and extracranial disease status have consistently been shown to impact prognosis. Gaspar et al.[8] reported on the Radiation Oncology Therapy Group (RTOG) experience of 1,200 patients. This analysis revealed three recursive partitioning analysis (RPA) classes, with the RPA class I (Karnofsky performance score [KPS] ≥ 70, controlled primary, age < 65 years, no extracranial metastases), II (not meeting requirements of classes I or III), and III (KPS < 70) having median survivals of 7.1, 4.2, and 2.3 months, respectively. This class scheme has subsequently been validated using the patient cohort from RTOG 91-04.[9] Contemporary series have further refined the class division by incorporating disease-specific prognostic factors, thereby creating and validating a diagnosis-specific graded prognostic assessment (DS-GPA) index to estimate survival outcomes with brain metastases.[10]

TABLE 96.1 EPIDEMIOLOGY OF BRAIN METASTASIS

Primary Site	
Lung	20%–50%
Breast	5%–20%
Small cell lung cancer	15%
Melanoma	7%–10%
Renal cell carcinoma	4%–6%
Colon	2%–5%
Relevant Facts	
Median survival	<1 yr
Mean age	60 yr

Corticosteroids

Initial therapy for suspected or confirmed brain metastases should promptly start with corticosteroids (e.g., dexamethasone or methylprednisolone), which

effectively improve edema and neurologic deficits in approximately two-thirds of patients within 24 to 48 hours.[11] The only randomized trial evaluating steroid dosage was reported by Vecht et al.[12] This trial included two successive groups of patients. The first group (n = 47) evaluated 8 mg per day versus 16 mg per day initial dexamethasone doses, with tapering schedules over 4 weeks. The second group (n = 49) evaluated 4 mg per day versus 16 mg per day of initial dexamethasone, with continuation of these doses for 28 days before tapering. The patients were scheduled for whole-brain radiotherapy (WBRT) and concurrent ranitidine. All arms had similar KPS improvements at 7 days (54% to 70%) and 28 days (50% to 81%). The study concludes that 4 mg per day of dexamethasone (with a taper over 4 weeks) is the preferable regimen. One should be cautious, however, in interpreting the results of this study. Patients in the 4 mg per day arm had to have the medication be reinstituted at a higher rate than the patients in the 8 or 16 mg per day arms. Furthermore, the arm with the greatest improvement in the KPS was the 16 mg per day arm when this was tapered over 4 weeks, compared with any of the other arms. It can be argued that higher KPS improvement arose from the maximal anti-inflammatory effects of the initial higher doses, with the 4-week taper minimizing the late toxicity associated with corticosteroids.

TABLE 96.2 CLINICAL PRESENTATION OF BRAIN METASTASIS

Symptom	Percentage of Patients
Headache	24–53
Mental disturbance	14–32
Motor weakness	20–40
Cerebellar dysfunction	7–26
Seizures	12–22
Speech problems	14

From Lagerwaard FJ, Levendag PC, Nowak PJ, et al. Identification of prognostic factors in patients with brain metastases: a review of 1292 patients. *Int J Radiat Oncol Biol Phys* 1999;43(4):795–803 and Posner JB. Brain metastases: 1995. A brief review. *J Neurooncol* 1996;27(3):287–293.

A reasonable corticosteroid regimen in patients with brain metastases is a 10 mg intravenous (IV) or oral bolus, followed by a 4 to 6 mg every 6 to 8 hours of dexamethasone equivalent dose (with a concurrent proton-pump inhibitor [PPI]), before this is tapered in a clinically cautious manner. The trial by Vecht et al., however, did demonstrate that 4 mg per day (e.g., 2 mg BID) of dexamethasone

is probably acceptable in select, symptomatic patient's minimal mass effect. In asymptomatic patients with little peritumoral edema or mass effect, initial corticosteroids may be reserved until the first sign of neurologic symptoms.

Anticonvulsants

Patients may present to the radiation oncologist already started on prophylactic anticonvulsants. This represents one of the most preventable causes of neurocognitive decline in brain tumor patients given the known negative impact on quality of life and neurocognition with anticonvulsants. In a study of 156 patients with low-grade glioma (85% experiencing a seizure), Klein et al.[13,14] analyzed the impact of antiepileptic treatment on quality of life and neurocognitive function. This study convincingly demonstrates the significant

correlation between the use of anticonvulsants (even with lack of seizures) and a decrease in quality of life and neurocognitive function.

Based on four negative randomized trials, the American Academy of Neurology in 2000 recommended that prophylactic anticonvulsants not be initiated in newly diagnosed brain tumor patients who have not experienced a seizure.[15] This recommendation continues to be relevant as there has now been a fifth randomized trial that has shown no benefit in newly diagnosed brain tumors.[16]

Whole-Brain Radiotherapy

WBRT continues to be a standard of care in select patients with diffuse brain metastasis (≥5 brain metastases). WBRT is well known to provide improvement in neurologic symptoms with overall response rates of 70% to 93%.[17] Unfortunately, there exists no agreement on the optimal dose and fractionation schedule for WBRT, despite numerous studies are designed to determine the optimal delivery. Table 96.3 summarizes selected randomized fractionation studies.[18–22] A total of 30 Gy in 10 fractions or 37.5 Gy in 15 fractions continue to remain the standards for a vast majority of patients receiving WBRT.[2] As reported by Nieder et al., the radiographic overall response rate with this fractionation scheme is 59% (24% CR and 35% PR).[23]

For patients with poor performance status, and/or uncontrolled extracranial disease burden, a shorter fractionation scheme (e.g., 20 Gy in 5 fractions) can be considered. For this patient cohort, a supportive care–alone strategy may also be considered. Most recently, a phase III randomized, noninferiority study, the QUARTZ (Quality of Life after Treatment of Brain Metastases) trial, compared the Quality Adjusted Life Years (QALY) between optimal supportive care (OSC) alone and OSC + WBRT (20 Gy in 5 daily fractions) for NSCLC patients with brain metastases unsuitable for resection or stereotactic radiotherapy. OSC consisted of dexamethasone titrated based on patient's symptoms as well as patient access to palliative care clinicians and nurses. Results revealed a difference in mean QALY of 4.7 days (46.4 QALY days for OSC + WBRT vs. 41.7 QALY days for OSC), which was within the prespecified noninferiority margin of 7 days. Overall survival was not significantly different between randomization arms (OSC + WBRT: 9.2 weeks vs. OSC alone: 8.5 weeks). Subgroup analysis suggested a survival benefit in favor of OSC + WBRT for patients younger than 60, KPS ≥ 70, and controlled extracranial primary.[24] However, serious concerns about patient selection, methodology, and trial design

have been pointed out.[25,26] Therefore, although WBRT may be omitted in select patients with very poor prognosis, it still remains an important therapeutic strategy.

Historically, WBRT has been frequently cited as the major cause of neurocognitive decline in cancer patients. One of the most misinterpreted studies on this subject is the Memorial Sloan-Kettering Cancer Center experience reported by DeAngelis et al.[27] who reported an 11% risk of radiation-induced dementia in patients undergoing WBRT for brain metastasis. The 11% figure is very misleading. Of the 47 patients who survived 1 year after WBRT, 5 patients (11%) developed severe dementia. When these 5 patients were examined, all were treated in a fashion that would significantly increase the risk of late radiation toxicity (i.e., large daily fractions and concurrent radiosensitizer). Three patients received 5 and 6 Gy daily fractions, whereas a fourth patient received 6 Gy fractions with concurrent Adriamycin. Only 1 patient received what is considered a standard radiation fractionation scheme (i.e., 30 Gy in 10 fractions), but this patient received a concurrent radiosensitizer (lonidamine). No patient who received the standard 30 Gy in 10 fractions WBRT alone experienced dementia.

Additionally, this trial did not address the potential neurocognitive changes in WBRT patients resulting from any underlying disease progression. Li et al. have attempted to further elucidate the true incidence of WBRT-related neurocognitive changes while controlling for brain metastasis response. All patients received WBRT in 30 Gy in 10 fractions and were subjected to a battery of neurocognitive tests monthly for 6 months and then every 3 months thereafter until death. The neurocognitive tests covered domains of memory, verbal fluency, and executive function. Additionally, patients underwent serial MRI with the summed volume of up to six brain metastases used for assessment of good or poor response. Good or poor response was defined as reduction of the summed volume at 2 months being >45% or <45%, respectively. Results revealed that volume regression was associated with preservation of neurocognitive function, primarily in the domains of executive function and fine motor coordination. Tumor volume changes, however, had weaker association with preservation of memory function (recall and delayed recall), which were domains most susceptible to changes from WBRT use.[28]

The RTOG subsequently completed RTOG 0933 and 0614, evaluating the role of hippocampal avoidance WBRT (HA-WBRT) and use of WBRT + memantine, respectively, in an effort to preserve memory-related dysfunction as

was identified by Li et al.[28] RTOG 0933 was a phase II trial comparing the 4-month decline in HVLT-delayed recall scores with HA-WBRT (30 Gy in 10 fractions) relative to a historical control group receiving standard WBRT (30 Gy in 10 fractions). HA-WBRT resulted in a mean decline of 7% in HVLT-DR scores from baseline to 4 months, which was significantly lower than the mean decline of 30% for historical controls.[29] RTOG 0614 was a phase III placebo-controlled trial randomizing patients to WBRT (37.5 Gy in 15 fractions) with or without 24 weeks of memantine administration. The primary end point was the effect of memantine use on delayed recall at 24 weeks, which trended in favor of memantine use, though was not statistically significant (P = .059). Use of memantine, nonetheless, resulted in superior results in various other domains including delayed recognition, executive function, and processing speed.[30] These results have prompted the ongoing trial (NRG-CC001) evaluating the role of WBRT with or without hippocampal avoidance in patients all of whom receive memantine. Until there are mature data from this trial, it is hard to justify the routine use of memantine or HA-WBRT.

Targeted Agents as an Alternative to WBRT in NSCLC

Historically, the use of systemic chemotherapy for control of NSCLC brain metastasis has been limited by the poor penetration of these agents through the blood brain barrier (BBB). However, with a greater understanding of the BBB and the many oncogenic drivers present in NSCLC, contemporary targeted therapies have begun to pay a larger role in the management of brain metastases. Epidermal growth factor receptor (EGFR) mutations as well as anaplastic lymphoma kinase (ALK) rearrangements, which occur in 15% to 20% of advanced NSCLC cases,[31] represent two commonly targeted mutations. Zimmerman et al. identified a brain metastasis response rate of 74% to 89% with the use of EGFR tyrosine kinase inhibitors (TKIs).[32] Similarly, Rusthoven et al. note response rates of 36% to 67% with next-generation TKI's, such as alectinib, in ALK-positive NSCLC brain metastases.[33] Magnuson et al. have reported the largest pooled multi-institutional analysis to date evaluating the optimal sequencing of EGFR-TKI's and radiation therapy in patients with EGFR-mutant NSCLC brain metastases. TKI naive patients who had developed brain metastases underwent one of three treatment regimens: SRS followed by EGFR-TKI, WBRT followed by EGFR-TKI, or EGFR-TKI followed by SRS or WBRT at a time of intracranial progression. At baseline, patients receiving upfront EGFR-TKI had smaller (<1 cm) and less symptomatic intracranial disease.

Median OS for the upfront SRS, WBRT, and EGFR-TKI arms was 46, 30, and 25 months, respectively ($P < .001$). Both upfront SRS and WBRT use were independently associated with improved OS relative to upfront EGFR-TKI. Use of upfront SRS or WBRT was also associated with a trend toward lower risk of intracranial progression, highlighting the potential for inferior outcomes with deferral of early radiotherapy.[34] On the contrary, Gerber et al. found equivalent survival outcomes with use of upfront EGFR-TKI or WBRT in patients with EGFR mutant brain metastases.[35] As such, prospective trials remain critically warranted at this time to address the role of targeted agents.

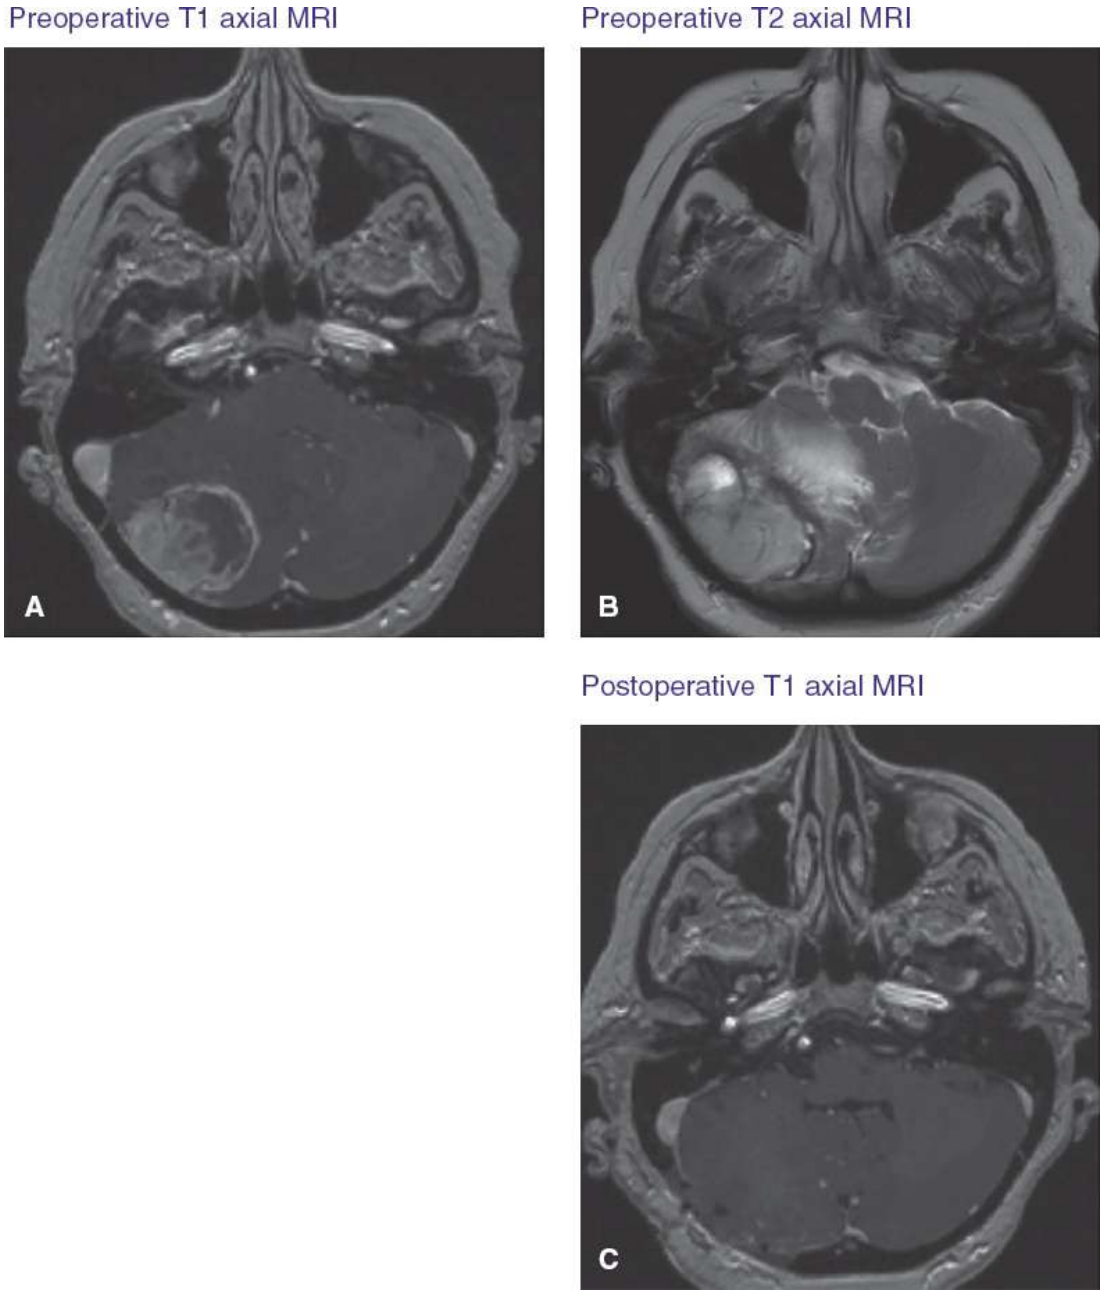

FIGURE 96.1. A: Six months after definitive therapy for stage IIIB non–small-cell lung carcinoma (NSCLC), a patient presented with progressively worsening headache, nausea, vomiting, and coordination difficulties. T1-gadolinium-enhanced axial magnetic resonance imaging (MRI) demonstrates a large, necrotic right cerebellar mass. **B:** T2-axial MRI reveals large area of vasogenic edema, with resultant mass effect causing fourth ventricular compression and hydrocephalus (not shown). **C:** Patient was taken immediately for a craniotomy, and a gross total resection was achieved. Pathology revealed metastatic NSCLC. Postoperative T1-gadolinium-enhanced axial MRI reveals no residual tumor, decompression of the mass effect, and reexpansion of the fourth ventricle.

Surgical Resection

Surgical resection can aid in obtaining a pathologic diagnosis of intracranial lesions, provide immediate relief of tumor mass effect (Fig. 96.1), and may cure a small percentage of patient with single or solitary lesions. On the other hand, radiation typically takes several days to work. Radiobiologically, 30 Gy in 10 fractions to a solid tumor (excluding radiosensitive tumors) is not adequate to achieve long-term tumor control.

Given that up to 50% of brain metastases can present as a single lesion, there has been historical interest in evaluating the role of surgery in the management of brain metastases.[36] There have now been three phase III trials testing the hypothesis that surgical resection to single brain metastasis is potentially beneficial. All three trials included patients with either a single lesion, defined as the presence of only one intracranial lesion regardless of the extracranial disease status, or a solitary lesion, defined as the intracranial lesion being the only site of metastatic disease. Table 96.4 summarizes the three trials.[37–39] The studies by Patchell et al.[37] (KPS ≥ 70) and Noordijk et al.[38] (World Health Organization grade ≤ 2) included better performance status patients compared with the Mintz et al.[39] study (KPS ≥ 50), which may have contributed to the differences in the outcomes between these studies. Additionally, 45% of patients in the study by Mintz et al. had extracranial metastases, as compared to 37.5% and 31.7% in the studies by Patchell et al. and Noordijk et al., respectively. Similarly, as highlighted by Noordijk et al., the survival benefit to the addition of surgery to WBRT was most pronounced in the patient with inactive or stable extracranial disease, with no survival benefit present for patients with active or progressive extracranial disease. The results of these studies suggest that surgical resection should be reserved for lesions causing life-threatening complications, requiring pathologic confirmation or in patients with good performance status (i.e., KPS ≥ 70) with controlled extracranial disease burden.

Radiosurgery Boost Trials

Radiosurgery provides a suitable alternative to conventional surgery. The three aforementioned randomized trials of surgical resection were all performed before the widespread availability of stereotactic radiosurgery (SRS). Although no randomized trials have been performed comparing surgery with SRS, SRS boost appears to provide at least comparable, if not improved, local control rates (80% to 90% when combined with WBRT). Therefore, in the setting of limited intracranial disease burden, unless emergent surgery is warranted, SRS alone or as a boost can serve as a noninvasive alternative. Additionally, although two of the three aforementioned surgery trials have shown a survival benefit in single brain metastasis, there have been no randomized trials addressing the role of surgery for multiple lesions. In contrast, three randomized trials have assessed the efficacy of SRS boost in the treatment of multiple metastases (Table 96.5).

The first randomized trial was reported by Kondziolka et al.[41] from the

University of Pittsburgh. This small study was stopped early at a planned interim analysis of 60% patient accrual because the authors reported having found a large difference in the primary end point of 1-year local control in favor of SRS (92% vs. 0%; $P = .0016$). Unfortunately, the study used nonstandard end points to measure recurrence, defining it as *any* increase in the lesion size on MRI. Furthermore, no attempt was made to control for steroid use, radiation changes, or other factors that might produce small fluctuations in the lesion size on MRI. Median overall survival was not significantly different between arms (WBRT alone: 7.5 months vs. WBRT + SRS: 11 months, $P = .22$). Therefore, this study is difficult to interpret.

Chougule et al.[42] from Brown University reported the second trial, although this has to date only been published in abstract form. This trial had three treatment arms and randomized patients to treatment with SRS alone, SRS plus WBRT, or WBRT alone. This trial suffers from several methodologic problems. Although the authors conclude that the survival times among the treatment arms were similar and that patients treated with SRS experienced superior local control, no probability values are given. Furthermore, 51 of the patients had surgical resection for at least one symptomatic brain metastasis prior to entry into the study, and no attempt was made to stratify for previous surgery. The inclusion of the surgically resected patients effectively made this a six-arm trial and, therefore, the size of this trial was not large enough to support a meaningful analysis. Finally, the radiation doses used in the SRS arms cannot be considered conventional because the peripheral dose was not individualized based on the tumor size or volume.

In the third study, RTOG-95-08, inclusion was limited to 1 to 3 metastases, with maximum diameter of 4 cm for the largest lesion with additional lesions not exceeding 3 cm. WBRT dose was 37.5 Gy in 15 fractions, whereas SRS boost dose was lesion size based in accordance with the results of RTOG 90-05. The primary end point was overall survival, which was not statistically different between the WBRT plus SRS and WBRT-alone arms (6.5 and 5.7 months, respectively; $P = .1356$), although the SRS boost improved the survival in the subgroup (planned analysis) of patients with single metastasis.[40] For secondary end points, the local control and performance measures were higher in the SRS boost arm, but this did not translate into a lower death rate from neurologic progression. Multiple unplanned subgroup analyses were completed, and an overall survival benefit with SRS boost was found in several subgroups that included patients with RPA class 1, tumor size ≥2 cm, and non–small cell lung

cancer or metastatic squamous histology from any site. Unfortunately, these subset analyses were not planned or prespecified, and the probability values needed for significance should have been adjusted for inflation of the type I error. When this was done, none of these subgroup analyses showed a positive benefit for SRS. On the other hand, this trial did demonstrate that SRS boost is associated with lower edema and corticosteroid use, countering a commonly held notion that SRS actually increases the edema risk. However, regarding the major end points for multiple metastases, this study should be considered a negative trial.

fx, fraction number; KPS, Karnofsky performance score; NS, not significant; NSCLC, non–small-cell lung cancer; RPA, recursive partitioning analysis; RT, whole-brain radiotherapy; SRS, stereotactic radiosurgery.

More recently, Sperduto et al. completed a secondary analysis of RTOG 95-08 to determine the efficacy of SRS boost with patients restratified by DS-GPA scores. Their secondary analysis predominantly included lung cancer primaries (84%). Results revealed an overall survival benefit to SRS boost in patients with DS-GPA score of 3.5 to 4, irrespective of number of metastases (WBRT alone: 10.3 months vs. WBRT + SRS: 21 months, $P = .05$). No survival benefit for SRS boost was observed with DS-GPA scores <3.5. These results should be interpreted with caution, however, given the small sample size and potential nonrandom selection of patients in the secondary analysis.[43]

In conclusion, although SRS boost is indicated (from RTOG-95-08 and from the extrapolation of surgical resection data) in patients with a single metastasis, it is difficult to justify its routine use in patients with multiple metastases in light of the equivocal phase III SRS boost trials.

Postoperative or Postradiosurgery Radiotherapy

An ongoing controversy in the treatment of brain metastasis is the role of WBRT

postoperatively or post-SRS. In a multiinstitutional retrospective SRS study, Sneed et al.[44] argue for the omission of upfront WBRT because this does not compromise overall survival. Unfortunately, only an overall survival analysis was performed, and no local control or detailed retreatment data were given. In an earlier study by Sneed et al.[45] on the University of California–San Francisco SRS experience, patients who were initially treated with SRS alone without WBRT experienced worse freedom from new brain metastasis and overall brain freedom from progression despite the imbalance of the prognostic factors that favored the SRS-alone group, although the overall survival was not different. Because of the equivalency of overall survival, many have advocated withholding upfront WBRT with salvage therapies including repeat SRS or delayed WBRT for failures. One caveat to this approach is that recurrent brain failure can lead to unacceptable consequences and symptoms. For example, Regine et al.[46] reported on 36 patients with planned observation after initial SRS alone. Even with close follow-up with examinations and high-resolution MRIs, 47% of patients experienced brain failure, with 71% and 59% experiencing symptomatic relapse and neurologic deficits, respectively.

The omission of upfront WBRT may have even more serious consequences for patients with more radioresistant tumors such as renal-cell carcinoma (RCC). The SRS dose given is typically limited by tumor size and volume, not by whether the patient received additional dose with WBRT. Therefore, a patient treated with WBRT plus SRS receives much higher tumor dose than SRS alone. It is then not surprising that the Eastern Cooperative Oncology Group protocol E6397 demonstrated very disappointing results.[47] In this phase II trial that evaluated SRS alone in radioresistant tumors (RCC, melanoma, sarcoma), Manon et al.[47] reported a 6-month total brain failure rate of 48.3% with 6-month local failure within the SRS volume of 32.2%, which is elevated relative to other histologies. The authors correctly conclude that routine avoidance of WBRT should be approached judiciously.

Fortunately, there have been seven phase III trials that have assessed the use of postoperative or postradiosurgery radiation (Table 96.6). Patchell et al.[48] evaluated upfront WBRT (50.4 Gy in 28 fractions) versus observation in resected metastatic lesions with a primary end point comparing local and distant intracranial control rates. Results demonstrated that surgical resection without WBRT led to a failure rate at the original site and distant brain/leptomeningeal recurrence of 46% and 37%, respectively. In comparison, surgical resection with upfront WBRT led to a significantly lower failure rate at the original site and

distant brain/leptomeningeal recurrence of 10% and 14%, respectively, More importantly, 44% of the patients in the surgery-alone arm died as a result of neurologic sequelae from brain failure as compared to 14% of patients receiving upfront WBRT (P = .003). Overall survival was not significantly different between arms (surgery alone: 43 weeks vs. surgery + WBRT: 48 weeks, P = .39). The results of this study have been frequently misinterpreted in the literature. Some have justified the withholding of upfront WBRT based on the fact that this study demonstrated equivalent survivals. In fact, this study was designed with brain tumor recurrence rate as the primary end point and not overall survival. To show an overall survival difference, this trial needed to enroll over 2,000 patients. This study met its primary end point and confirmed the importance of postoperative WBRT in preventing brain failure and death from neurologic causes.

Given the long-term cognitive impact attributed to WBRT, however, contemporary series have evaluated the efficacy of postoperative SRS as an alternative to upfront WBRT. No phase III trials have been published to date, though two prospective trials have recently completed and reported in presentation form. Mahajan et al. prospectively evaluated local tumor control rates of resected metastases receiving postoperative cavity SRS vs. observation in 1 to 3 brain metastases. All lesions not resected received definitive SRS. Secondary objectives included distant brain control and overall survival. Results revealed 1-year local control rates for observation and postoperative SRS of 45% and 72%, respectively (P = .01). One-year freedom from distant brain failure with observation and postoperative SRS was 33% and 43%, respectively (P = .29). Similarly, overall survival did not differ with use of postoperative cavity SRS (observation: 17 months vs. postoperative SRS: 17 months, P = .37).[53]

Additionally, Brown et al. recently reported the results of NCCTG N107C/RTOG 1270, which randomized patients to postoperative SRS vs. postoperative WBRT in a prospective trial. This trial included 1 to 4 brain metastases with surgical resection of one lesion, and subsequent randomization to postoperative cavity SRS vs. postoperative WBRT with all unresected metastases receiving SRS in both arms. Preliminary results reveal that 77% of enrolled patients had single brain metastasis with 59% being of lung primary. Primary end points were cognitive deterioration-free survival and overall survival. Use of postoperative WBRT resulted in a shorter cognitive deterioration-free survival vs. SRS (median 2.8 vs. 3.2 months, respectively, P < .0001) with 6-month cognitive deterioration rates of 85.7% and 53.8% for WBRT and SRS, respectively. However, long-term follow-up in the WBRT group will be critical to assess the percentage of patients in whom these early neurocognitive changes are transient and resolve over time. Additionally, limitations to these results include that the WBRT sample size (numbers at risk) in whom cognitive impact was evaluated was significantly smaller with time than the sample size randomized to WBRT and that factors known to result in

cognitive decline, such as antiepileptic and corticosteroid use, were not reported as stratification variables. Use of WBRT did, however, provide improved 1-year intracranial control rates of 78.6% and 54.7% for WBRT and SRS, respectively ($P < .0001$). Although median surgical bed relapse-free rates were similar (WBRT: 7.7 months vs. SRS: 7.5 months, $P = .04$), use of WBRT trended for improved long-term surgical bed control. Median overall survival rates did not differ between arms (WBRT: 11.5 months vs. SRS 11.8 months, $P = .65$).[54] Complete analyses of these trials remain pending and will further elucidate the role of postoperative SRS an alternative to WBRT, though postoperative WBRT continues to remain the standard of care. Furthermore, it remains difficult to justify the current routine use of surgery with postoperative cavity SRS for lesions not causing significant mass effect, as these patients should be strongly considered for SRS treatment alone.

There have now been four phase III trials that have evaluated the role of SRS alone versus the addition of WBRT. In the Japanese Radiation Oncology Study Group JROSG-99-1 phase III trial of one to four lesions, the SRS-only arm experienced increased 1-year total brain recurrence rate ($P < .001$), increased 1-year rate of distant brain relapse ($P = .003$), and increased 1-year local tumor failure ($P = .002$). This resulted in more frequent use of salvage therapy ($P < .001$) in the SRS-alone arm.[49] Furthermore, the average time until Mini-Mental State Examination (MMSE) deterioration was significantly longer for the WBRT plus SRS arm (16.5 months vs. 7.6 months; $P = .05$), in large part due to increased recurrence in the SRS group.[55] Median overall survival did not differ between groups (WBRT + SRS: 7.5 months vs. SRS alone: 8 months, $P = .42$). Despite, no overall survival benefit for the entire group, this study demonstrates the importance of WBRT in decreasing brain failure, corroborating the findings of the Patchell et al.[48] study.

Subsequently, this group has performed a secondary analysis evaluating the outcomes of post-SRS WBRT in non–small-cell lung primaries restratified by DS-GPA. Significantly increased median overall survival was observed with DS-GPA score of 2.5 to 4 (WBRT + SRS: 16.7 months vs. SRS alone: 10.6 months, $P = .04$), whereas no survival differential was observed with DS-GPA scores <2.5. No significant difference in neurocognitive function, as assessed by the MMSE, was observed at baseline or during follow-up for WBRT + SRS or SRS-alone arms for either DS-GPA scores <2.5 or >2.5.[56] The results of the secondary analyses of the RTOG 95-08 and JROSG-99-1 trials therefore indicate that patients with brain metastases from NSCLC primary with favorable DS-GPA

scores may benefit more from combined treatment (WBRT + SRS) than either treatment alone. Future prospective examination of this conclusion is warranted.

Muacevic et al.[50] randomized single brain metastasis patients (KPS ≥ 70, size ≤ 3 cm, stable systemic disease) to SRS alone versus resection plus WBRT. Although this trial is not exactly an SRS ± WBRT trial, it addresses the benefit of WBRT to local therapies. Those randomized to SRS alone experienced worse distant (P = .04) recurrences, but there were no differences in neurologic death rates or overall survival.

The results of EORTC-22952-26001 have been reported with the primary end point of evaluating duration of functional independence.[51] In this study, patients with one to three brain metastases underwent local therapy with either surgery or SRS and were then randomized to the addition of WBRT versus observation. WBRT did not improve duration of functional independence or overall survival but was associated with a significant decrease in 2-year local and distant brain relapse rate versus observation with either surgery or SRS. This resulted in a 16% decrease in the risk of neurologic death. Although there was no difference in duration of functional independence between the two arms, the authors conclude that this is likely because of a variety of factors, including the subjective definition of functional independence, the routine use of MRI imaging rendering the majority of recurrences as asymptomatic, and the potential impact of systemic progression on performance status.

Chang et al.[52] reported on a series of 58 patients with one to three brain metastases randomized to SRS with or without WBRT. The primary end point of the study was neurocognitive function, which was assessed using the Hopkins Verbal Learning Test-Revised at 4 months after therapy. They found that patients receiving combined therapy were more likely to have a decline in learning and memory function at 4 months compared with patients who did not receive WBRT. The median survival was 15.2 months for the SRS-alone group and 5.7 months for the WBRT/SRS group (P = .003). However, the local (100% vs. 67%; P = .012) and distant (73% vs. 45%; P = .02) brain control rates were worse in the SRS-alone group compared with the WBRT/SRS group. There are multiple criticisms of this study worth noting.[57] First, because the primary end point was neurocognitive function, the authors did not stratify by baseline neurocognitive function or other factors known to impact neurocognition. Second, the authors chose a single test at a single time point. Ideally, a whole battery of tests should be performed at multiple time points to adequately assess the trend of something as complex as neurocognition. Most importantly, the

combined arm inexplicably had a shorter survival, contrary to the four previously mentioned trials that demonstrated equivalent survivals. The median survival of 5.7 months was within 2 months of the primary end point mark, which classically falls within the time point of progressively worsening cognition seen in terminally ill patients.[58,59] The superior survival in spite of inferior local and distant brain control is unprecedented and can possibly be explained by an improper randomization, which is possible in a small study.

In summary, four of the five phase III local with or without WBRT trials unequivocally show a meaningful benefit of WBRT in terms of preventing neurologic deaths or brain failure. It is difficult to ignore the level I evidence provided by these phase III trials. Adjuvant WBRT, therefore, should be strongly considered after local therapy with surgical resection or SRS. However, this has become very controversial. Therefore, it is critical for radiation oncologists to help patients navigate through the risks and benefits of additional WBRT.

Repeat Whole-Brain Radiotherapy

Occasionally, patients will fail in the brain after initial WBRT. Salvage surgery, SRS, or repeat WBRT should strongly be considered. Wong et al.[60] reported on a series of 86 patients who underwent repeat WBRT. The median dose for the first course was 30 Gy in 10 fractions, whereas the median dose for the second course was 20 Gy. A total of 70% experienced neurologic improvement, with 27% experiencing complete neurologic resolution whereas 43% had partial improvement after repeat WBRT. Median survival was 4 months after second course of WBRT, with a retreatment dose of >20 Gy associated with a significantly longer survival. Clinically significant radiation-related complications were rare.

Son et al.[61] similarly reported on a series of 17 patients who underwent whole brain reirradiation. The median RT dose for the first course of treatment was 35 Gy in 14 fractions and for the second course 21.6 Gy in 1.8 Gy per fraction. The median survival time for all patients after retreatment WBRT was 5.2 months. In patients with stable extracranial disease, the median survival time after retreatment was 19.8 months compared with 2.5 months in patients with progressive extracranial disease. Eighty percent of patients experienced improved symptoms, with acute mild to moderate adverse reactions seen in 70.5% of patients.

Therefore, repeat WBRT is relatively safe and highly effective for recurrent or progressive brain metastases after initial WBRT. A minimum of 20 Gy in 1.8

to 2 Gy fractions should be given.

Concurrent Radiosensitizers

Although a majority of patients with brain metastases ultimately succumb to systemic progression, a significant percentage will die from neurologic progression. Multiple randomized trials of concomitant radiosensitizers have been performed in an attempt to optimize brain control (Table 96.7).[62–70] No trial has demonstrated a survival advantage, although a few have demonstrated an increased response rate. The trials with temozolomide show promise. Temozolomide is an oral alkylating agent with excellent CNS penetration. However, the findings of these relatively small trials need to be confirmed in a larger trial. Otherwise, a patient should be treated with a concomitant radiosensitizer only on a prospective trial.

Causes of Neurocognitive Decline in Brain Tumor Patients

Historically, brain radiation has been frequently cited as a major cause of neurocognitive decline in cancer patients. As previously discussed, the experience reported by DeAngelis et al.[27] initially reported an 11% risk of radiation-induced dementia in patients undergoing WBRT for brain metastasis. The accuracy of this dementia rate is questioned by the nature of the statistical interpretation utilized. Although the study included 232 patients in the initial analysis, it only examined the 47 patients who survived at least 1 year. The principles of conditional probability dictate that the 11% risk is accurate only if a patient survives 1 year, which is significantly longer than most reported series. Therefore, a radiation-induced dementia risk of 2% (5 of 232) would reflect the true probability *ab initio* for patients presenting with brain metastasis. Indeed, in a separate study of a larger cohort, DeAngelis et al.[71] estimated the risk of radiation-induced dementia to be 1.9% to 5.2% for all patients presenting with brain metastasis.

Additionally, the increased local control achieved with use of adjuvant WBRT may actually improve neurocognition in a significant number of patients, as brain recurrence or progression is associated with a decrease in neurocognitive function.[72] In a neurocognitive analysis of RTOG-91-04, Regine et al.[73] demonstrated that approximately one-third of patients treated with WBRT experienced improvement in their MMSE; most importantly, those who had uncontrolled brain metastases had an average decrement of 6 points on the MMSE, which was a significantly greater drop than those with controlled brain metastases ($P = .02$).

Although it is certainly possible that subtle neurocognitive decline may result from WBRT, evaluating these changes will require more sophisticated battery of testing than has historically been employed. Additionally, appreciating the baseline cognitive dysfunction in patients with brain metastases will provide the most accurate assessment of the decline resulting from additional WBRT. In the large phase III motexafin gadolinium study, the neurocognitive battery examined

memory recall, memory recognition, memory delayed recall, verbal fluency, pegboard hand coordinate, and executive function.[74] This study demonstrated that 21.0% to 65.1% of patients had impaired functioning *at baseline* before treatment with WBRT. Furthermore, patients who progressed in the brain after treatment experienced significantly worse scores in all of these individual tests.

There are now strong data that other confounding factors, such as anticonvulsants, benzodiazepines, opioids, chemotherapy, surgery, and tumor progression, contribute significantly to the neurocognitive decline of patients with brain tumor. It will be vital to control for these factors when interpreting ongoing studies evaluating alternative WBRT strategies (e.g., HA-WBRT, concurrent memantine).

SPINAL CORD COMPRESSION

In the United States, more than 20,000 cases of metastatic spinal cord compression (MSCC) are diagnosed annually, and it is estimated to develop in approximately 5% to 10% of all cancer patients.[75,76] MSCC is a devastating complication of cancer. It is considered a true medical emergency, and immediate intervention is required. Even with aggressive therapy, results can often be unsatisfactory. Although most patients with MSCC have limited survival, up to one-third will survive beyond 1 year.[77] Therefore, aggressive therapy should always be considered to preserve or improve the quality of life.

Pathophysiology

MSCC develops primarily in one of four ways: (a) continued growth and expansion of vertebral bone metastasis into the epidural space; (b) neural foramina extension by a paraspinal mass; (c) destruction of vertebral cortical bone, causing vertebral body collapse with displacement of bony fragments into the epidural space; or (d) rarely primary hematogenous seeding to the epidural space. Although complex, the most significant damage caused by MSCC appears to be vascular in nature as opposed to mechanical. Epidural tumor extension causes epidural venous plexus compression, which leads to intramedullary edema. This increase in vascular permeability and edema cause increased pressure on the small arterioles. Capillary blood flow diminishes as the disease progresses, leading to white matter ischemia. Prolonged ischemia eventually results in white matter infarction and permanent cord damage.[78]

Clinical Presentation, Diagnosis, and Prognosis

The vast majority of patients with MSCC have a cancer diagnosis history. As highlighted by Prasad et al.,[79] the most common tumor types are breast cancer, lung cancer, and prostate cancer, accounting for 15% to 20% of all cases. This reflects the high natural incidence of these tumors and their propensity for osseous metastasis. New-onset back pain in cancer patients needs to be taken seriously and worked up. Even without a prior cancer diagnosis, MSCC should be suspected in anyone who presents with progressively worsening back pain, incontinence, or paraplegia, especially in the high-risk population such as long-time smokers. The most common level of the MSCC involvement is in the thoracic spine (60% to 80%), followed by lumbar (15% to 30%) and cervical spine (<10%), whereas multiple levels can be involved in up to half of the patients.[79] Back pain is the most common presenting symptom (70% to 94%), followed by weakness (61% to 91%), sensory deficits (46% to 90%), and autonomic dysfunction (40% to 57%).[79]

MRI is the standard modality for spine imaging. It has a very high sensitivity, specificity, and accuracy in diagnosing MSCC.[80,81] Because patients can have synchronous, multifocal MSCC, an MRI of the entire spine with and without contrast should be promptly performed in anyone suspected of having MSCC. High-resolution CT scan or CT myelogram of the spine should be performed for those with contraindications to MRI.

One of the most important prognostic factors predicting ambulatory outcome is the rapidity of symptom onset. Other important prognostic factors include radiosensitive histology (e.g., multiple myeloma, germ cell tumors, small cell carcinoma) and pretherapy ambulatory function. In a prospective study of 98 patients with MSCC reported by Rades et al.,[82] the single strongest predictor for ambulatory status after therapy on multivariate analysis was time to development of motor deficits before radiation ($P < .001$) from the start of any symptoms. This cohort was separated into three groups according to the time to motor deficits before radiation therapy: 1 to 7 days (group A), 8 to 14 days (group B), and >14 days (group C). The ambulatory rates after therapy for groups A, B, and C were 35%, 55%, and 86% ($P < .001$), respectively. The symptom improvement rates for groups A, B, and C were 10%, 29%, and 86% ($P = .026$), respectively. The other factor significant on the multivariate analysis for post-therapy ambulatory status was favorable histology ($P = .005$), and there was a trend regarding pre-therapy ambulatory status ($P = .076$). Acute, rapid deterioration is predictive of irreversible spinal cord infarction. Only 10% of the patients in group A had symptom improvement; therefore, prompt diagnosis and

treatment of MSCC are essential.

Corticosteroids

Corticosteroids must be started as soon as possible in anyone suspected of having MSCC, even before radiographic diagnosis, because this can be rapidly discontinued if a negative diagnosis is obtained. Corticosteroids effectively decrease cord edema and serve as an effective bridge to definitive treatment. Although multiple retrospective studies have demonstrated their clinical efficacy, Sorensen et al.[83] reported the only randomized controlled study (n = 57) on the utility of high-dose corticosteroids before definitive radiotherapy in MSCC from solid tumors. The treatment arm consisted of 96 mg of IV bolus of dexamethasone followed by 96 mg oral per day for 3 days and a 10-day taper versus no corticosteroid therapy. This study demonstrated 3-month and 6-month ambulatory rates of 81% versus 63% and 59% versus 33% (P < .05), respectively, in favor of high-dose dexamethasone.

The optimal maintenance dose of corticosteroids is unknown. Vecht et al.[84] reported the only randomized study (n = 37) comparing corticosteroid doses in patients with MSCC, but this study only evaluated the IV loading dose. It compared IV loading doses of 10 mg versus 100 mg, followed in both arms by the same oral regimen of 16 mg per day. Both arms demonstrated significant reductions in pain from baseline (P < .001); however, there was no difference between the two arms with respect to pain reduction, ambulation, or bladder function.

Very high doses of corticosteroids are associated with significant side effects. The Sorensen et al.[83] phase III study reported an 11% incidence of serious side effects for patients in the treatment arm, whereas Heimdal et al.[85] reported a 14.3% incidence of serious gastrointestinal (GI) side effects in 28 consecutive patients treated with 96 mg of IV dexamethasone per day. The toxicities in the Heimdal et al. report included one fatal ulcer hemorrhage, one rectal bleeding, and two bowel perforations. Subsequently, the dexamethasone dose was decreased to 16 mg per day for the next 38 consecutive patients, and there were no incidences of serious side effects (P < .05). Most importantly, the ambulatory rates were not different between the two dexamethasone doses.

Based on these data, a loading dose of 10 mg of IV dexamethasone followed by a maintenance dose of 4 to 6 mg every 6 to 8 hours should be sufficient before being tapered. Patients can be safely switched to an oral regimen after 24 to 48 hours because there is good oral bioavailability of corticosteroids.

Furthermore, patients should be started on a PPI for GI prophylaxis. Although here has been no randomized trial utilizing PPIs in patients receiving corticosteroids, there have been multiple studies demonstrating the protective effects of PPIs against peptic ulcers in patients receiving chronic nonsteroidal anti-inflammatory drugs (NSAIDs).[86] NSAIDs and corticosteroids both cause GI mucosal injury by decreasing mucosal-protective prostaglandin levels. Therefore, it is not an unreasonable extrapolation to assume that PPIs provide a similar mucosal protective effect with corticosteroids, especially considering that the morbidity of GI toxicity can be life-threatening. Additionally, multiple comparative series reveal the superiority of PPI's to histamine H2 receptor antagonists for ulcer prophylaxis.[87] Use of oral antacids is not recommended as they have not been shown to protect against injury.[86]

Surgery

Radiation for nonradiosensitive tumors typically takes several days to have an effect and does not stabilize the spine, whereas surgery allows for immediate cord decompression and provides an opportunity to stabilize the spine intraoperatively. At some institutions, surgery was used infrequently because several retrospective studies and one small randomized study showed no benefit to surgery plus radiation over radiation alone. Young et al.[88] randomized 29 patients with MSCC to decompressive laminectomy followed by radiation versus radiation alone. Although this trial showed no benefit to surgery in terms of pain relief, ambulation, or sphincter function, it is difficult to draw any conclusion because of the small sample size. All of these studies used posterior laminectomy in conjunction with radiotherapy; however, most of the lesions in MSCC involve the anterior portion of the vertebral body. Therefore, a laminectomy may not effectively relieve the compression simply by opening the spinal canal and may actually worsen the stability of the spine.

Therefore, authors have advocated the use of direct surgical decompression, tumor debulking, and spinal stabilization via instrumentation to improve on the results from radiation alone. Patchell et al.[89] reported the first phase III randomized trial testing the efficacy of direct decompressive surgery in patients with MSCC (Table 96.8). The study compared radiation alone (standard 30 Gy in 10 fractions) versus circumferential decompressive and stabilization surgery within 24 hours of diagnosis followed by the same radiotherapy (within 2 weeks of surgery). The trial was terminated early when early-stopping rules were met regarding the primary end point of ambulation after treatment. This trial

definitively demonstrated an advantage to surgery for every end point at statistically significant levels. For nonambulatory patients, the combined treatment patients had a significantly higher chance of regaining the ability to walk after therapy. Maintenance of continence, maintenance of American Spinal Cord Injury (ASIA) and Frankel scores (measures of spinal function after injury), median overall survival, and median mean daily dexamethasone and morphine equivalent doses all favored the surgery arm.

TABLE 96.8 KEY FINDINGS OF A PHASE III STUDY OF PATIENTS WITH METASTATIC SPINAL CORD COMPRESSION[89]

	Surgery + Radiation (*n* = 50)	Radiation Alone (*n* = 51)	*P*
Primary end point			
Ability to walk post treatment			
Rate	84% (42/50)	57% (29/51)	.001
Time[c]	122 days	13 days	.003
Secondary end points[c]

If operable, patients should undergo surgical decompression and stabilization followed by radiotherapy. Even for radiosensitive tumors, surgery can often stabilize the spine. Therefore, all patients with MSCC should be evaluated by a surgeon. Effective multidisciplinary teamwork is critical to the rapid evaluation and management of patients with MSCC.

Radiotherapy

Palliative radiotherapy has been the standard of care in the treatment of patients with MSCC. Although a total of 30 Gy in 10 fractions is the most frequently employed fractionation schedule, multiple fractionation schemes have been reported, which undoubtedly reflects the heterogeneity in the patient population and tumor histology. In one of the largest studies to date, Rades et al.[90] reported a retrospective series of 1,304 patients with MSCC. The patients were separated into five schedules: 8 Gy × 1 in 1 day (n = 261, group 1), 4 Gy × 5 in 1 week (n = 279, group 2), 3 Gy × 10 in 2 weeks (n = 274, group 3), 2.5 Gy × 15 in 3 weeks (n = 233, group 4), and 2 Gy × 20 in 4 weeks (n = 257, group 5). All of the groups had similar posttreatment ambulatory rates (63% to 74%) and motor function improvements (26% to 31%). However, in-field recurrence rates were much lower for the protracted schedules. The 2-year in-field recurrence rates for groups 1, 2, 3, 4, and 5 were 24%, 26%, 14%, 9%, and 7% ($P < .001$), respectively. They recommend that a single fraction of 8 Gy should be used in MSCC patients with limited survival expectations and that 30 Gy in 10 fractions should be used for all other patients.

Maranzano et al. have reported on two randomized trials evaluating short, radiation schedules. However, it is very difficult to interpret these results because neither trial included a fractionation that would be considered a standard of care.[77,91] A more relevant randomized trial was reported by Rades et al.[92] comparing a short course regimen (4 Gy × 5) to 30 Gy × 10 in patients with poor to intermediate survival prognosis, defined as having an estimated 6-month survival of 14% to 56% based on a validated scoring system. Primary end point was motor function response rate showing improvement or no progression of motor deficits at 1 month. Seventy-five percent of patients survived > 1 month. One-month response rates were similar for both radiation regimens (87.2% to 89.6%, $P = .73$). Both regimens also had similar RT effects on motor function at 3 and 6 months post treatment. Ambulatory status at 1, 3, and 6 months was not significantly different between regimens. Local progression-free survival and overall survival (median: 3.2 months) were also similar for both arms. Based on

this trial results, 4 Gy × 5 was deemed noninferior to 30 Gy × 10 and should be strongly considered for patients with poor prognosis in whom limiting treatment time and discomfort should be a high priority.

For patients receiving radiotherapy for MSCC from solid tumors, 30 Gy in 10 fractions is considered the standard of care. Shorter fractionation schedules, such as 8 Gy × 1 or 4 Gy × 5, should only be reserved for those with clear evidence of progressive disease refractory to systemic therapy in whom survival expectations are poor. These short schedules should be clearly avoided in newly diagnosed, chemotherapy naive patients because the clinical course can be quite variable and prolonged. Chemotherapy may be considered in select, newly diagnosed patients with excellent neurologic functional status and very chemosensitive tumors (e.g., lymphoma, multiple myeloma, germ cell tumors), but this is still considered outside the accepted standard as these tumors also respond very effectively to radiotherapy. If the patient is found to have a good performance status, oligometastatic disease, and controlled primary disease, then consideration should be made to escalate the total dose beyond 30 Gy because in an effort to achieve greater long-term gross tumor control while respecting dose constraints. Special techniques such as intensity-modulated radiation therapy (IMRT) or fractionated stereotactic body radiation therapy (SBRT) should be considered to safely escalate the total dose (Fig. 96.2).

Caution against Short, Hypofractionated Radiotherapy

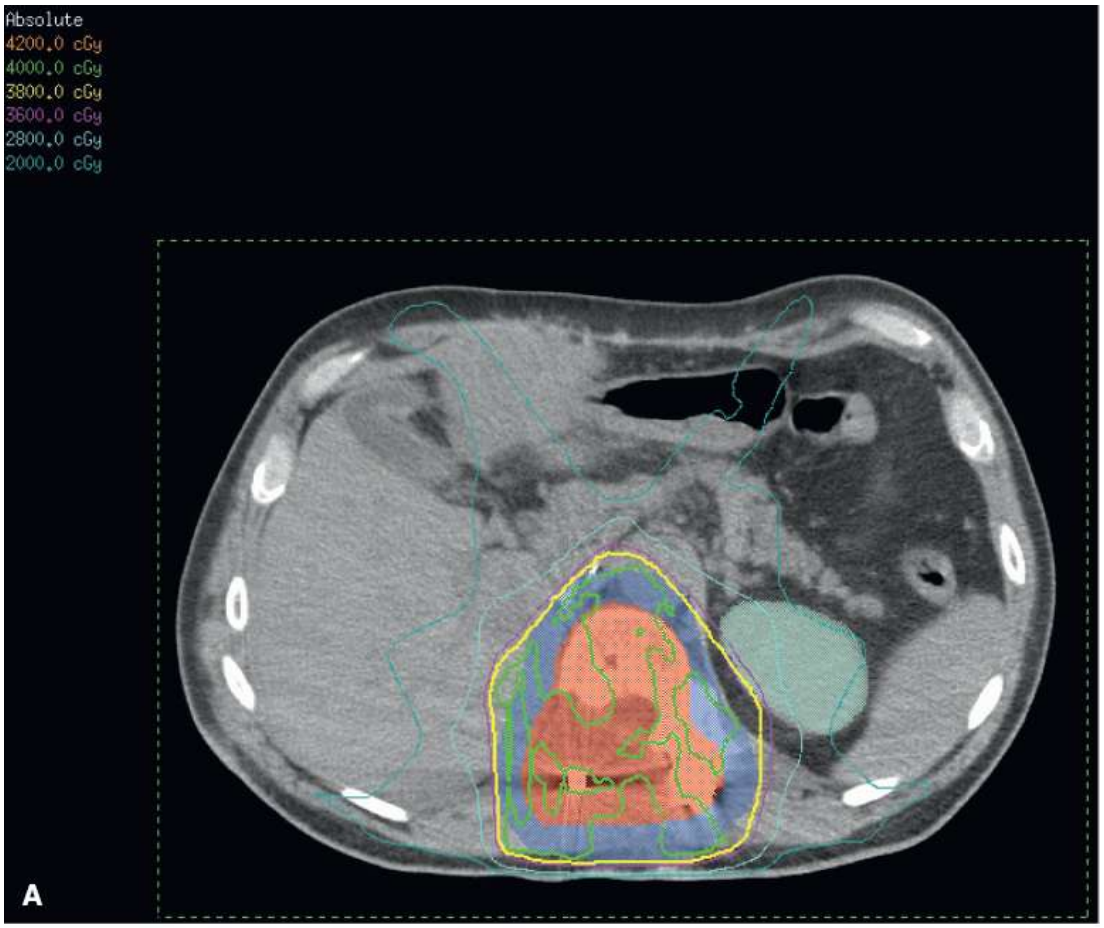
A common mistake made by those who advocate a short hypofractionated regimen (e.g., 8 Gy × 1 to 2 or 4 Gy × 5) for MSCC is equating the safety and equivalency of these abbreviated schedules in bone and lung metastases trials as a justification for the safety of such regimens in MSCC. The consequence of progression of a bone metastasis despite prior radiotherapy (i.e., 8 Gy × 1) is an increase in pain, which leads to an increased need for pain medications and usually reirradiation. By contrast, the consequences of MSCC progression despite prior radiotherapy are an increase in pain, paralysis, and incontinence, which usually contribute significantly to the direct demise of the patient. Because some studies, but not all, suggest that single fraction radiotherapy for bone metastasis is associated with a higher retreatment rate than fractionated therapy, a note of caution is appropriate for single fraction radiotherapy for MSCC.[93]

Therefore, these abbreviated schedules should be routinely avoided unless the patient is refractory to multiple lines of systemic therapy and has convincing

evidence of progressive systemic disease with limited expected survival.

Pediatric Spinal Cord Compression

MSCC in the pediatric population differs from adult MSCC. Histologic subtypes commonly encountered in children (e.g., neuroblastoma, Wilms tumor, and Ewing sarcoma) rarely occur in adults. In adults, most cases of MSCC are caused by direct invasion into the epidural space by metastatic vertebral body tumors, although, in children, most are caused by direct neural foraminal invasion, causing the characteristic “dumbbell” tumor. Chemotherapy plays a central role in the treatment of pediatric MSCC.[94]



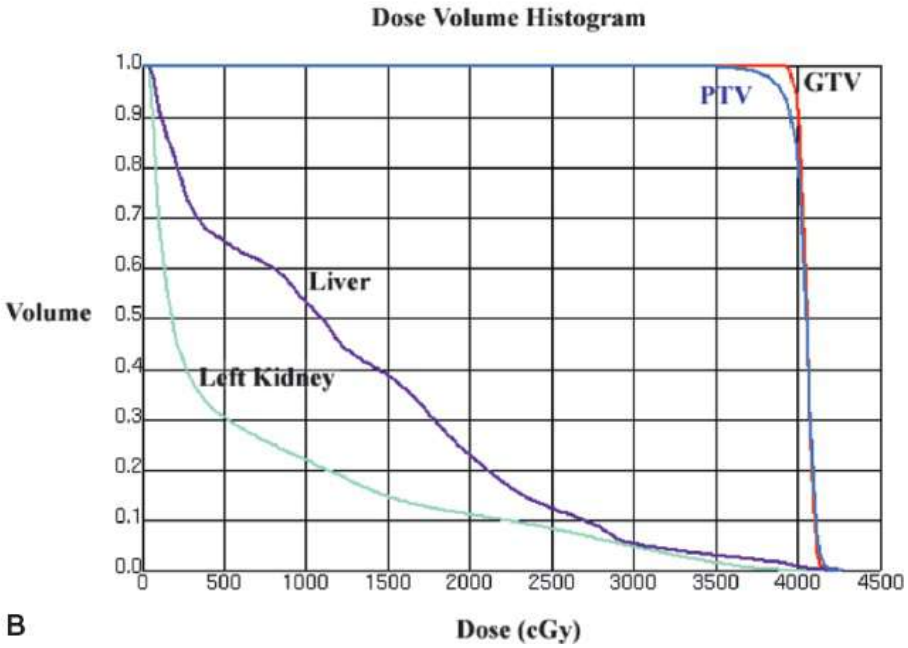


FIGURE 96.2. A: Five years after undergoing a right nephrectomy for a stage I renal call carcinoma (RCC), patient presented with progressively worsening midback pain. Magnetic resonance image of the spine revealed a T11–12 right-sided paraspinal

mass invading the right lateral T12 vertebral body and neural foramina causing T12 spinal cord compression. Patient underwent a gross total resection and instrumentation to stabilize the spine. A full metastatic workup revealed the vertebral disease as the solitary site of recurrent RCC. Chemistries revealed a mild chronic renal insufficiency, with a creatinine level of 2.1 mg/dL. Intensity-modulated radiation therapy (IMRT) was used to minimize the dose to the left kidney. The figure shows an axial computed tomography image of the IMRT plan generated, with the *red* and *blue* color washes representing gross tumor volume (GTV) and planning target volume (PTV), respectively. **B:** The dose–volume histogram of the IMRT plan is shown. A total of 40 Gy in 20 fractions was delivered to the PTV (GTV + 1 cm). The PTV was modified so the margin was decreased to 8 mm along the left lateral edge of the vertebral body next to the left kidney.

Neuroblastoma is the most common histology of pediatric MSCC. Hayes et al.[95] (nine cases of neuroblastoma and five cases of Ewing sarcoma) and Sanderson et al.[96] (four cases of neuroblastoma) demonstrated that chemotherapy alone allowed complete recovery of spinal cord function in all cases. The French Society of Pediatric Oncology protocol NBL-90 included 42 nonmetastatic neuroblastoma patients with intraspinal extension and consequent MSCC.[97] All were treated with initial chemotherapy, and this resulted in intraspinal tumor shrinkage, avoidance of surgery, and neurologic deficit improvement in 58%, 60%, and 92% of the patients, respectively. Severe neurologic sequelae occurred in only six patients (15%).

Emergent surgery should be offered to any pediatric patient with rapid neurologic progression at initial presentation or while on chemotherapy. In most circumstances, this should be followed by definitive chemotherapy. In stable or mildly symptomatic patients, chemotherapy can obviate the need for surgery, which is often associated with long-term skeletal deformities. Radiation should be reserved only for those who require palliation for progressive disease after failure of multiple systemic regimens, those who progress neurologically despite the initial treatment with chemotherapy or surgery, and those who present with primary vertebral tumors (e.g., primary vertebral Ewing sarcoma) in which definitive surgery is rarely feasible.

Intramedullary Spinal Cord Metastasis

Intramedullary spinal cord metastasis (ISCM) is rare, representing only 1% of all intramedullary tumors but being more greatly recognized as an entity given enhanced radiographic techniques. According to a review by Kalayci et al.,[98] ISCM is most commonly secondary to a lung primary (54%), followed by breast cancer (11%). Although back pain is common in >90% of MSCC patients, back or neck pain was seen in only 38% with ISCM. However, high sensory deficits

(79%), sphincter dysfunction (60%), and weakness (91%) are more common in ISCM. The most striking difference between ISCM and MSCC is the high incidence of synchronous brain metastasis (41%) in patients presenting with ISCM. This is not surprising when one considers the route of spread and the high incidence of lung primaries in patients with ISCM. An MRI of the brain should be obtained.

The treatment of ISCM should be approached very similarly to MSCC, except for the role of surgery. Most surgeons are reluctant to operate in ISCM because surgery carries a high morbidity rate. Corticosteroids as well as radiation therapy should be promptly initiated. Unfortunately, a diagnosis of ISCM portends a poor prognosis with median survival of 1 to 5.5 months.[99]

Leptomeningeal Carcinomatosis

Leptomeningeal carcinomatosis (LCM) is a rare complication of multiple cancers, occurring in approximately 5% of metastatic cancer. A diagnosis of LCM portends a poor prognosis with medial survival of 2.3 to 4.7 months in modern series.[100] The most frequent cancers associated with LCM are lung and breast. In breast cancer, it is often seen in patients who have *HER2-neu* overexpression or infiltrating lobular histology.[101] In lung cancer, it is most commonly involved by NSCLC with adenocarcinoma histology accounting for 50% to 78% of cases.[102]

The majority of patients present with signs and symptoms. According to the review by Gleissner and Chamberlain,[103] spinal symptoms (>60%) are the most common, followed by cerebral (50%) and cranial nerve symptoms (40%). Contrast-enhanced MRI is the radiographic modality of choice. The entire neuroaxis must be imaged if LCM is clinically suspected in a patient with a known malignancy as multifocal involvement is common. In most patients, the MRI will reveal leptomeningeal enhancement that is frequently associated with cranial nerve enhancement and gross tumor deposits. MRI can provide a diagnosis of LCM with a sensitivity and specificity of 76% and 77%, respectively.[104] A radiographic diagnosis of LCM may be limited, however, in the setting of hematopoietic tumors as the rate of positive neuroimaging is approximately 50%, thereby requiring CSF cytology for confirmation.[100]

CSF cytology is also warranted in a setting when suspicion for LCM is high but MRI is equivocal. Multiple samples may need to be obtained because the initial yield of a lumbar tap may be only 50%.[103] Neurosurgery must be consulted to evaluate the need for (a) shunting if hydrocephalus is suspected and

(b) placement of Rickham or Ommaya reservoir for possible intrathecal (IT) chemotherapy. Gleissner and Chamberlain[103] argue that CSF flow studies should be performed with indium-111 or technetium-99, because up to 40% of patients have abnormal CSF flow from gross tumor deposits that may disrupt adequate IT chemotherapy delivery. However, flow studies are not performed by many centers because gross tumor nodules, most likely to cause flow disruption and not effectively treated by IT chemotherapy, are treated with radiation anyway. Thus, CSF flow studies typically do not change the overall management of patients with LCM who require treatment decisions to be made in an expedient manner.

TABLE 96.9 RANDOMIZED TRIALS OF SOLID TUMOR PATIENTS WITH LEPTOMENINGEAL CARCINOMATOSIS

Study (Ref.)	*N*	Histology	Arms[a]	RR[b] (%)	Median Survival	Survival (*P*-value)
Hitchins et al. (1987)[107]	44	Solid tumors	IT MTX 15 mg	61	12 wk	.08
			IT MTX + Ara-C 50 mg/m^2	45	7 wk	
			Concurrent RT (not randomized)	75		
			No concurrent RT	35		<.05
Grossman et al. (1993)[108]	52	Nonleukemic[c]	IT MTX 10 mg	0	16 wk	NS
			IT thiotepa 10 mg	0	14 wk	
Glantz et al. (1999)[109]	61	Solid tumors	IT MTX 10 mg	20	2.6 wk	.15
			IT DepoCyt 50 mg	26	3.5 wk	
Kim et al. (2003)[110]	55	Solid tumors	IT MTX 15 mg	14	10 wk	.03
			IT MTX + Ara-C 30 mg/m^2 + hydrocortisone 15 mg/m^2	39	19 wk	
			Concurrent RT (not randomized)	82	19 wk	
			No concurrent RT	50	11 wk	.47
Boogerd et al. (2004)[111]	35	Breast	IT chemotherapy[d]	41	18 wk	.32
			Non-IT chemotherapy	39	30 wk	

[a]All studies allowed palliative radiation when necessary.
[b]RR determination by neurologic and CSF improvements as predefined by each study.
[c]Fourteen patients (19%) had lymphoma and the rest had solid tumors.

[d]All patients started with MTX and switched to Ara-C if no response.
Ara-C, cytarabine; DepoCyt, sustained-release cytarabine; IT, intrathecal; MTX, methotrexate; NS, not significant; RR, response rate.

There is no consensus on the optimal management of patients with LCM. This is mainly because of the lack of large published experiences, limited number of randomized trials, nonuniform treatment regimens in single institution experiences, and inclusion of various primary tumor histologies in the clinical trials. However, most would agree that an aggressive treatment with radiation (either WBRT or focal spinal radiation to symptomatic sites) and IT chemotherapy are indicated in patients with good performance status. The optimal dose and fractionation schedule of radiation therapy delivered in the setting of LCM remains unknown; however, similar to WBRT and MSCC, 30 Gy in 10 fractions is the most typical scheduled used. In patients with poor performance status, larger fractions may be more advantageous because these patients will rarely live long enough to experience late radiation toxicity and larger fractions may result in a faster symptomatic response. In a large published experience on LCM from small cell lung cancer (n = 36), the dismal median survival of 1.3 months is a direct result of only 14 patients being offered some kind of therapy (n = 9 for radiation, n = 5 for chemotherapy).[105] In contrast, Chamberlain and Kormanik,[106] in a series of patients with LCM from non–small-cell lung cancer (n = 32), treated patients prospectively with radiotherapy followed by IT chemotherapy. The median survival for the entire cohort was 5 months, while patients with normal CSF flow had a significantly longer median survival compared with patients with interrupted CSF flow (6 months vs. 4 months; $P < .05$). This suggests that an aggressive multimodality approach can produce survival times that are comparable to patients with multiple brain parenchymal metastases.

All of the randomized clinical trials on patients with LCM from solid tumors have included IT methotrexate (MTX)-based regimens (Table 96.9).[107–111] The only trial that compared IT versus non-IT (i.e., systemic) chemotherapy was reported by Boogerd et al.[111] However, this negative trial only included patients with breast primaries. Glantz et al.[109] reported that IT DepoCyt (cytarabine liposome injection) led to a greater median time to neurologic progression (8 weeks vs. 4 weeks; $P = .007$), although the overall survival was not statistically different. The only positive trial reported to date has been by Kim et al.[110] from Seoul National University. Patients randomized to IT MTX, Ara-C (arabinofuranosyl cytidine), and hydrocortisone had a significantly longer

survival than those randomized to IT MTX alone (18.2 weeks vs. 10.4 weeks; *P* = .029). Patients with adenocarcinoma of the lung in the multiagent arm had a significant, longer survival (23.9 weeks vs. 10.4 weeks; *P* = .038). Multiple other agents have been studied, but none have demonstrated significant responses.

There is ample evidence that focal radiation, such as WBRT or spinal radiation, provides added benefit to IT chemotherapy. This is particularly true in patients with bulky meningeal disease because IT chemotherapy only penetrates 2 to 3 mm. In the randomized IT chemotherapy trial reported by Hitchins et al.,[107] patients who received concurrent CNS radiation had a higher response rate compared with those who did not (73% vs. 35%; *P* < .05). Likewise, in the randomized trial reported by Kim et al.,[110] those who received concurrent CNS radiation had a significant higher neurologic response rate (81.5% vs. 50.0%; *P* = .014). There is a concern that concurrent radiation and IT chemotherapy could potentially increase toxicity. However, the vast majority of patients do not survive long enough to see the late neurologic toxicity manifest.

CONCLUSION

A significant percentage of cancer patients will require palliative radiation therapy at some point during their natural history. On the basis of randomized data, patients with a limited number of brain metastases should be treated with local therapy such as surgery or SRS with or without whole-brain irradiation whereas those with numerous brain metastases should be treated with whole-brain irradiation alone. In patients with spinal cord compression, surgical decompression should be strongly considered in patients with single-level disease and good performance status followed by radiation therapy. Radiation therapy alone can also be considered for all patients with spinal cord compression with the most common fractionation scheme being 30 Gy in 10 fractions. Leptomeningeal carcinomatosis continues to have an unfavorable prognosis, and the use of radiation therapy should be based on the palliation of individual signs and symptoms.

CHAPTER 97

Palliation of Bone Metastases

Alexander A. Harris and William F. Hartsell

BACKGROUND AND INCIDENCE

Metastatic disease to the bone is a common cause of pain and other significant symptoms that are detrimental to quality of life. The exact incidence of bone metastases is difficult to determine, but estimates are that >100,000 people in the United States will develop osseous metastatic disease annually.[1,2] The incidence of bone metastases varies significantly, depending on the primary site, with breast and prostate cancer accounting for up to 70% of patients with metastatic disease.[3] Bone metastases may be found in up to 85% of patients dying from breast, prostate, or lung cancer. Other primary sites with a propensity for bone metastases include thyroid, melanoma, and kidney. On the other hand, gastrointestinal sites of primary malignancy give rise to bone metastasis in only 3% to 15% of patients with metastatic disease.[4] Some hematologic malignancies, including myeloma and lymphoma, can also cause significant pain and bone destruction.

The ultimate prognosis for patients with bone metastases is poor, with median survival typically measured in months rather than years. Overall survival depends on the primary site and the presence or absence of visceral metastases. Patients with bone metastases from lung cancer have short median survival durations of 6 months. However, patients with bone metastases from breast or prostate primary sites may have significantly longer survival times. In patients with bone-only metastatic prostate or breast cancer, median survivals of 2 to 4 years have been reported.[3,5,6] Whether the survival time is only a few months or extends to multiple years, these patients will often require active treatment because of pain, difficulty with ambulation and immobility, hypercalcemia, pathologic fractures, neurologic deficits, anxiety, depression, spinal cord or nerve root compression, fatigue, insomnia or sleep disturbances, and general deterioration of quality of life.[4,7,8]

The axial skeleton is the most common site of bone metastasis, with metastasis most frequently occurring in the spine, pelvis, and ribs. The lumbar spine is the most frequent site of bone metastasis.[9–12] In the appendicular skeleton, the proximal femurs are the most common site of metastatic disease, and humeral lesions also occur frequently. The acral sites (feet and hands) are rarely involved. Certain skeletal sites are associated with specific types of metastatic cancer. For example, scapular metastases are seen more frequently from renal primaries.[13] Involvement of the skull is more common with breast primaries. The distal appendicular skeleton (tibia, fibula) and acral sites (especially the hands) are more common with lung primaries, and involvement of the toes is seen more commonly with genitourinary primaries.

The most common symptom of bone metastases is slowly progressive, insidious pain that is fairly well localized. The pain may be worse at night. Pain from the femur or acetabulum may worsen with weight bearing or ambulation. In contrast, pain from the inferior ischium or sacrum may be worse with sitting but less bothersome with ambulation. Although the pain is frequently localized, pain may radiate to other areas. This is most frequently seen with pain in the lower back, pelvis, or hips that may radiate down the legs. Pain that radiates does not necessarily indicate nerve impingement because radicular pain can also be caused by spasm of muscles that originate or insert near the area of disease (e.g., pain in the hip radiating to the knee).

The concept of “oligometastases” was proposed by Hellman and Weichselbaum in 1995.[14] This has been used as a justification for aggressive treatment of a small number of visceral metastases, and there is some evidence of benefit in certain patients with a few lung, liver, or brain metastases. This principle has also been applied to bone metastases, primarily in the setting of stereotactic body radiotherapy. Although some patients have achieved long-term disease-free survival, there is a question as to whether this simply is a factor of patient selection rather than a separate and distinct subgroup of patients.[15] The treatment for bone metastases remains in the realm of palliative and supportive care, but as more studies are performed with long-term follow-up, it is possible that the goals of treatment may change to curative in a subset of patients.

PATHOPHYSIOLOGY

There are primarily three types of cells within mature bone: osteocytes, osteoblasts, and osteoclasts. Osteoblasts originate from osteogenic cells, found in

the periosteum or endosteum. The osteogenic cells differentiate into osteoblasts when there is a mechanical or chemical stimulus for remodeling or repair. The osteoblasts build bone by depositing collagen type I into the extracellular space. An inorganic complex of calcium and phosphate (hydroxyapatite) is laid down within this organic matrix to provide the strength and density of the bone. The osteoblasts then mature into osteocytes, which maintain the bone structure. Osteoclasts are multinucleated giant cells that originate from pluripotent hematopoietic bone marrow cells and adhere to the bone surface.[16] These cells create an acidophilic environment that causes dissolution of the hydroxyapatite crystals and proteolysis of the bone matrix.

The differentiation and activation of osteoclasts occur because of the effects of a group of proteins that are related to tumor necrosis factor; including osteoprotegerin, receptor activator of nuclear factor-κB (RANK), and the RANK ligand (RANKL). Osteoblasts, stromal cells, and activated T cells express and release RANKL. The RANKL binds to the RANK receptor on osteoclast precursors, which then induces the formation of mature osteoclasts. This may occur through up-regulation of RANKL expression in osteoblasts via a hedgehog signaling pathway.[17] Osteoprotegerin is a decoy receptor for RANKL and inhibits the differentiation and activation of osteoclasts.[16] The destruction of bone by osteolytic metastases is mediated by the osteoclasts, not by the tumor cells. However, the factors that activate the osteoclasts are likely produced by the tumor cells, including RANKL, interleukin-1, interleukin-6, parathyroid hormone-related peptide (PTHrP), transforming growth factor β (TGF-β), and macrophage inflammatory protein 1α.[18–20]

Normal bone is constantly being remodeled in a cycle lasting about 120 to 200 days (3 to 6 months). For the first 20 to 40 days of the cycle, the bone is resorbed by osteoclasts. The bone is then rebuilt by osteoblasts during the next 100 to 150 days.[21]

The structure of the bone changes during growth and development. At the time of birth, all bones are immature, woven bone. Woven bone is more cellular, with no organized orientation to the collagen fibers of the bone. As bones age, the woven bone is absorbed and is replaced by lamellar bone. The lamellar bone is organized circumferentially around neurovascular canals. This cylindrical structure provides much more strength than the haphazard orientation of woven bone. Most adult bone is lamellar.

Adult bone has three distinct layers; cortical, cancellous, and bone marrow. The cortical bone is the dense, compact exterior portion of the bone. This portion

of the bone comprises most of the mass and strength of the skeleton. Internal to the cortical bone is the porous, haphazard network of bone tissue known as cancellous bone, which is also known as trabecular or spongy bone. Inside the porous cancellous bone is the bone marrow. There are two different types of bone marrow, red marrow and yellow marrow. Red marrow produces red blood cells, white blood cells, and platelets. Red marrow is highly vascular. Yellow marrow produces fat, cartilage, and bone. Yellow marrow is scantly vascular. At birth, all marrow is red marrow, but as bone ages, red marrow is slowly replaced by yellow marrow.

In the adult body, there are five different types of bone: long, short, flat, sesamoid, and irregular bone. Long bones consist of the epiphyses, metaphyses, and a diaphysis. The diaphysis is the long shaft of the bone, consisting of a hard cortical exterior encapsulating a central cavity consisting of cancellous bone and bone marrow, known as the medullary cavity. The epiphyses are at the ends of the bone. These are composed of hyaline cartilage initially, which becomes ossified during puberty. The metaphysis is the area between the epiphysis and diaphysis. Most of the bones of the limbs are made of long bones. Short bones are cuboid in shape and make up the bones of the wrist and ankle. Flat bones are thin and curved bones. They make up the skull and sternum. Sesamoid bones are found suspended in tendons, such as the patella. Irregular bones are oddly shaped bones that contain a thin layer of cortical tissue surrounding an interior of active cancellous and bone marrow. The majority of the axial skeleton, including the spine and pelvis, is made up of irregular bones.

Metastases to the bone most often occur in the red marrow, which is found in highest concentration in the skull, irregular bones of the axial skeleton, and the medullary portion of the appendicular skeleton. This most often occurs by hematogenous spread but may occur by direct extension as well. Involvement of adjacent bone by direct extension (e.g., mandibular involvement from an oral cavity cancer) does not necessarily imply that there is a higher likelihood of distant bone metastases, and its management is very different from that of bone metastases from hematogenous spread.

The relatively high proportion of hematogenous metastasis to bone compared with other sites in the body cannot simply be explained by blood flow, which is >30 times greater in the lung than in red bone marrow.[22] The predilection of certain tumor sites to metastasize to bone may be related to local growth factors in the bone such as TGF-β, insulin-like growth factors I and II, fibroblastic growth factors, platelet-derived growth factors, preferential adherence to

endothelial surfaces in certain bones by cell adhesion molecules, or chemotactic attraction from bone cells by osteocalcin or type I collagen.[4,16,23]

Bone metastases are often described as either osteolytic or osteoblastic. However, these are different representations of abnormalities in the normal bone-remodeling process. Breast and lung cancers more commonly cause osteolytic-appearing lesions. Prostate and thyroid cancers more often have osteoblastic-appearing lesions. Only myeloma is associated with purely osteolytic lesions.[16] Most other tumors have a combination of osteolytic and osteoblastic components.

The mechanism of pain from bone metastases is not clearly understood. Possible mechanisms include mechanical instability, irritation of periosteal stretch receptors, tumor-directed osteoclast-mediated osteolysis, tumor cells themselves, tumor-induced nerve injury, production of nerve growth factor, or stimulation of other cytokine receptors.[2,3,24,25] Because the mechanisms of pain may be multifactorial, a combination of therapies may be superior to any one therapy alone.[24]

EVALUATION

The most common symptom associated with bone metastasis is pain. Therefore, the physical examination is an important step in evaluating a patient with bone metastases. The physical examination may help make decisions regarding appropriate subsequent imaging studies. Firm palpation will often elicit the specific area of pain, with “point tenderness” often pointing directly to the affected area in the bone. It is important to carefully evaluate the entire skeletal system with examination because intense pain at one site often masks subjective reports of pain at other sites. A careful physical examination may reveal hidden pain in other locations. A thorough neurologic examination is also important, especially in patients with spinal metastases, to carefully evaluate for the possibility of spinal cord, cauda equina, or nerve root compression.

Technetium-99m bone scintigraphy (nuclear medicine bone scan) is the best method for screening patients at risk for bone metastasis who may not present with bone pain. It is also useful to evaluate the extent of metastatic disease in the bone (Fig. 97.1). Bone scintigraphy is an indicator of osteoblastic activity. Because multiple myeloma is frequently purely osteolytic, bone scans are less useful for evaluating extent of disease in myeloma. Bone scintigraphy is not specific for metastatic disease, and positive findings must often be confirmed

using other imaging studies. A confirmatory study is especially important in a weight-bearing bone such as the proximal femur. False-positive readings may be seen in areas of arthritis, trauma, prior fractures, or Paget's disease. In addition, the osteoblastic activity in healing bone after treatment may give the appearance of progressive disease. False-negative readings may occur in fast-growing, highly aggressive tumors, especially if these are mainly osteolytic.

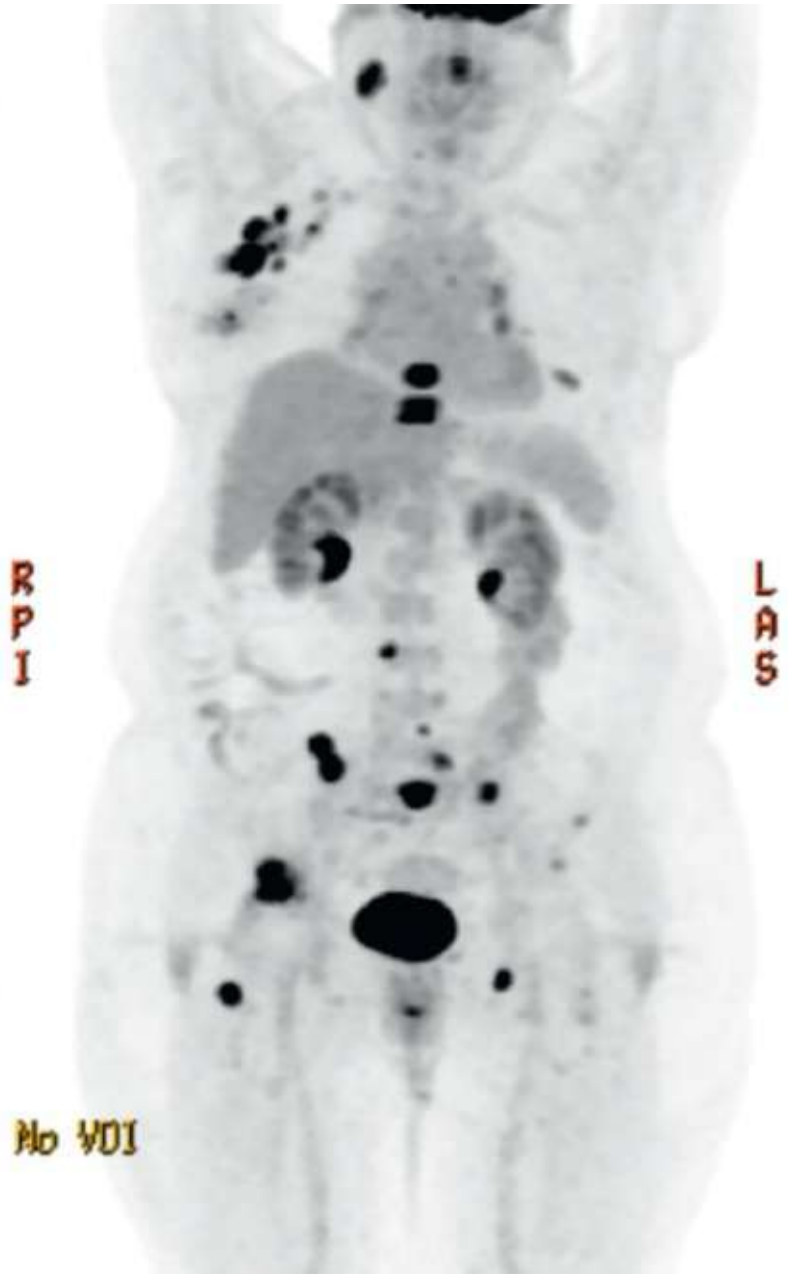

FIGURE 97.1. Nuclear medicine bone scan from a woman with metastatic breast cancer. The bone scan shows the abnormality in multiple osseous sites, as well as in the right breast and axilla.

For symptomatic patients with point tenderness or for patients with an abnormal bone scan, plain radiographs are typically the most appropriate first or next imaging study.[26] Radiographs are easy to obtain and inexpensive. The appearance of bone metastases on x-rays varies depending on the primary site and histology, with some appearing osteolytic and some osteoblastic. However, nearly all bone metastases have components of both osteolytic and osteoblastic processes. The primary disadvantage of plain radiographs is that small lesions are rarely seen. Approximately 30% to 50% of the bone mineral content must be lost before the lesion will be apparent on x-rays.

Computed tomography (CT) scans are more sensitive than plain radiographs and may be better able to localize the lesion within the bone. However, CT scans are more expensive and more time-consuming and may not be useful as a screening tool for skeletal metastasis. The CT may be useful in defining the extent of cortical destruction and helping to assess the risk of a pathologic fracture.[27] In addition, the CT scan may be used to guide needle biopsies to obtain a tissue diagnosis (Fig. 97.2A and B). CT scans have limited usefulness in detecting marrow involvement but are much better than plain radiographs at evaluating soft tissue extension of disease.

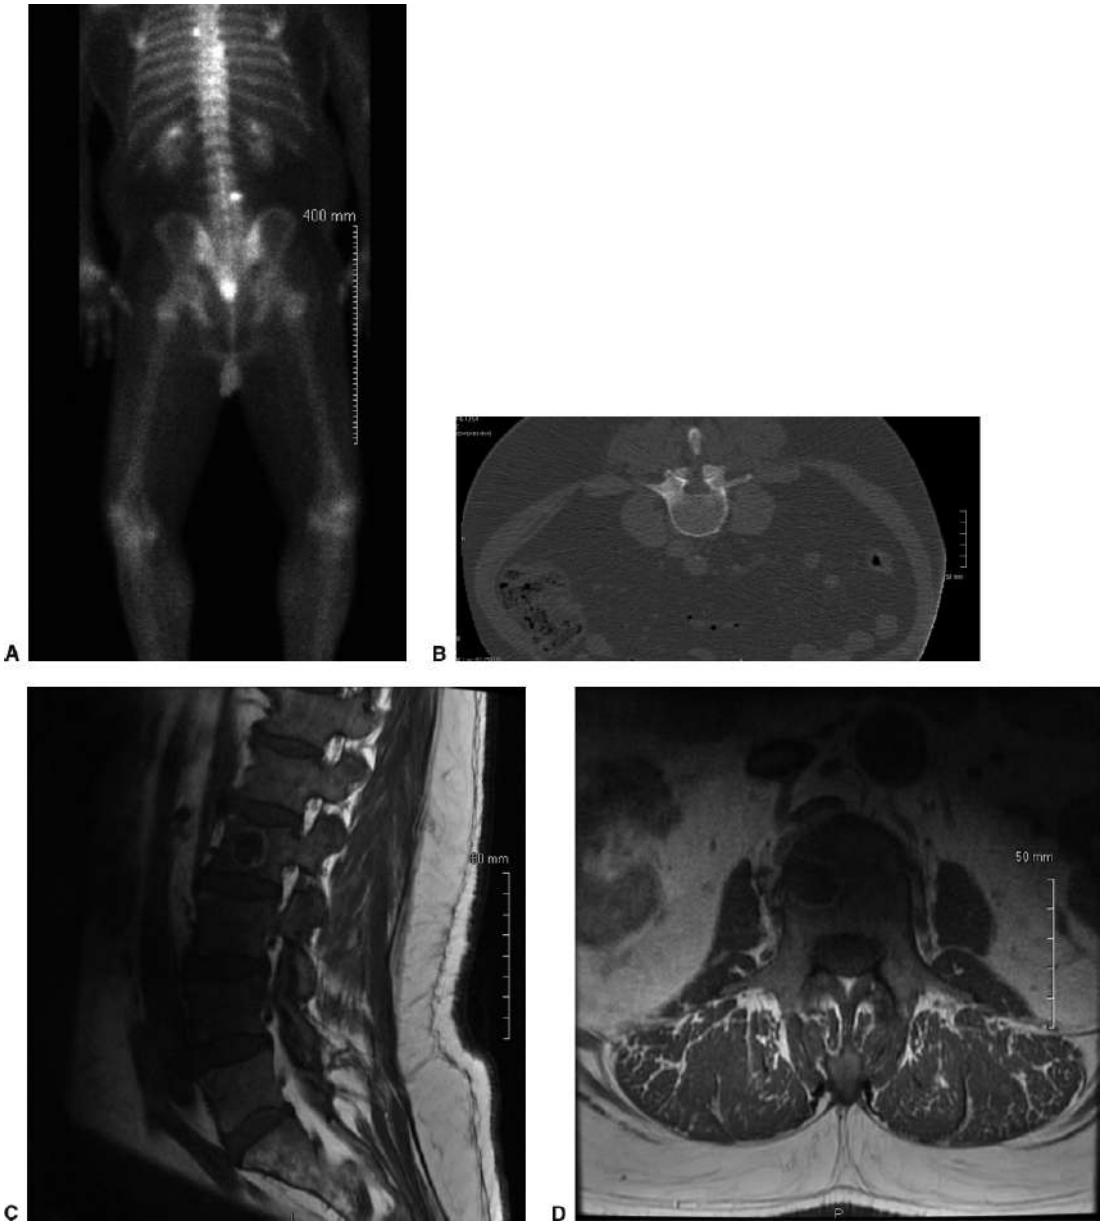

FIGURE 97.2. Images from a patient with metastatic prostate cancer. Nuclear medicine bone scan **(A)** shows uptake in the right pedicle of L4, seen as an osteoblastic lesion on axial CT **(B)**. This was biopsy confirmed as metastatic prostate cancer. The bone scan does not demonstrate the lesion in the L2 vertebral body, which is demonstrated on the sagittal **(C)** and axial **(D)** magnetic resonance images.

Magnetic resonance imaging (MRI) is better than plain radiography or nuclear medicine bone scintigraphy at assessing the involvement of trabecular bone and bone marrow, especially in the vertebral bodies (Fig. 97.2C and D). The findings are typically best seen on T1 contrast-enhanced images and short-tau inversion recovery (STIR) images. Metastatic prostate cancer is visible as high-intensity lesions on the STIR images and is visible prior to its appearance

on bone scintigraphy.[28] In addition, MRI scans are useful in determining the involvement of neurovascular structures. MRI scans are not useful as a screening tool for bone metastases because of the high cost and lengthy time of the exam. However, MRI scans may be more sensitive than bone scintigraphy in the vertebral body region. The sensitivity of MRI scanning has been reported as 91% to 100%, compared with 62% to 85% for bone scintigraphy.[28,29] In addition, MRI images can help distinguish whether a vertebral body compression fracture is from malignancy or from osteoporosis.

Positron emission tomography (PET) scanning evaluates areas of increased metabolic activity, most commonly using the 18-fluorodeoxyglucose (FDG) isotope. These scans are useful in detecting highly metabolic osteolytic bone metastases but are less sensitive for the less metabolically active osteoblastic metastases. In addition, precise determination of the location of lesions is difficult with PET scans, but the use of simultaneous CT scans allows for much better localization of the abnormal FDG uptake.[30] PET scans may be useful as a whole-body screening tool.[30,31] Comparative studies have shown PET scans to be more sensitive than Tc-99m scintigraphy or whole-body MRI scans in detecting bone metastases.[32,33] There may be limitations in the sensitivity of PET scanning in certain areas such as the skull, where the intense physiologic metabolic uptake from the adjacent brain parenchyma may obscure small skull metastases. 18-FDG-PET scans have been used for many epithelial tumor types, but less frequently for prostate cancers. There are multiple new PET scan isotopes, which may be more sensitive and more specific for metastatic prostate cancer, including ^{18}F-NaF, ^{11}C-choline, ^{11}C-acetate, and ^{18}F-fluciclovine.[34]

PAIN MANAGEMENT

The majority of patients with bone metastases will experience pain during their disease course, and pain control can significantly improve their quality of life. Pain management may be achieved either by debulking disease using cytotoxic therapy or by symptomatic control with pharmacologic interventions.

Despite increasing understanding about the effective treatment of pain, patients with pain from bone metastases frequently have inadequate pain management. Barriers to pain treatment include physician underestimation of the patient’s pain and reluctance by the patient to report pain.[35] In addition, concerns about opioid abuse and dependence may lead to undertreatment of cancer pain. There is a significant discrepancy between the physician estimate of pain and the

pain level reported by the patient.[36] The use of a validated pain scale, such as the Brief Pain Inventory, gives the patient an opportunity to describe both the severity of pain and the interference it has with daily functioning in a manner that can be understood both by the patient and the physician.[35] This also allows for distinguishable comparisons of pain levels over time, to better assess the effectiveness of treatments.

Pain control can be achieved in the majority of patients using the World Health Organization analgesic ladder. Step I uses nonopioid analgesics such as acetaminophen or nonsteroidal anti-inflammatory drugs; step II uses weak opioids such as codeine; step III uses strong opioids such as morphine or oxycodone. These medications are increased as necessary until the patient is free of pain. Typically, the medications are given on a routine schedule ("by the clock") rather than waiting until a certain level of pain is reached ("on demand"). Using this schedule, 70% to 76% of patients will have good pain relief.[37,38] Adjuvant medications such as gabapentin, pregabalin, or amitriptyline may be added for neuropathic pain. Antianxiety or antidepressant medications may also be of benefit in selected patients.

The opioid-based pain medications frequently cause constipation and may cause nausea. Patients using opioid medications should routinely be administered a fiber medication with or without a stool softener to minimize constipation. Other side effects of the opioid analgesics may include sedation, mental status changes, and mood changes.

SURGICAL MANAGEMENT

Surgical management of bone metastases is performed primarily to prevent or treat pathologic fractures. The goals of surgical intervention are to prevent or relieve pain, improve motor function, and improve overall quality of life. Treatment techniques are simpler and more effective when the procedure is performed prophylactically for an impending fracture rather than after the occurrence of a pathologic fracture. The risk of pathologic fracture depends on multiple factors, including location and extent of the lesion; whether the lesion is osteolytic, osteoblastic, or mixed; and the primary cancer site.

Fractures of the weight-bearing bones are the most likely to cause significant functional deficits. The proximal femur may have a higher propensity for fracture than other sites, but some authors have suggested that the fracture risk in upper limbs is similar to the risk in the femur. Whether or not there is a

difference in the risk of fracture, the peritrochanteric femur is the site most likely to cause serious morbidity, and therefore, the threshold for prophylactic intervention should be relatively low. The femur accounts for 65% of pathologic fractures requiring surgical intervention.[39] The humerus and vertebral bodies are also sites that require special attention because of the potential functional deficits from pathologic fractures.

The size of the bone metastasis is an important predictor of risk of fracture, especially with regard to the extent of cortical destruction. Various models have been used to predict the risk of pathologic fracture based on the size of the lesion. In series using plain radiographs, lesions ≥2.5 cm in the cortex of the femur were significantly more likely to fracture.[40] The proportion of cortical destruction is important as well. The risk of pathologic fracture of the femur begins to significantly increase when there is destruction of >50% of the cortex; the risk of fracture is 80% when >75% of the cortex is destroyed.[41] Femoral lesions with axial cortical destruction >30 mm had a 23% risk of pathologic fracture, compared with 3% risk of fracture for cortical destruction ≤30 mm.[42] The location within the bone is important as well. An experimental model has shown that the greatest reduction in strength of the femur occurs with lesions in the inferior and medial aspect of the femoral neck, and posterior lesions have the least impact (Fig. 97.3).[43]

A scoring system proposed by Mirels[44] has a 12-point scale based on the location of the lesion, pain, extent of cortical destruction, and radiographic appearance (Table 97.1). The risk of fracture is 15% for a score of 8 and 33% for a score of 9. He proposed that prophylactic fixation is indicated for a score of ≥9.

The decision to proceed with surgery should be based on a number of factors, which include but are not limited to the estimated risk of pathologic fracture and overall life expectancy. For patients with a very limited life expectancy, surgery may not be indicated even if the risk of pathologic fracture is relatively high.[39] Clinical prediction of survival may be more accurate than relying on specific parameters such as diagnosis (primary site), performance status, number of bone metastases, presence of visceral metastases, and hemoglobin level.[45]

FIGURE 97.3. Anterior–posterior **(A)** and oblique **(B)** radiographs of the right femur in a patient with metastatic breast cancer. Note the significant destruction of the posterior cortex from the proximal to mid diaphysis of the femur, in a "moth-eaten" appearance.

Femoral fractures are the most common site of surgical correction. Fractures of the femoral neck can be managed either by total hip arthroplasty (which replaces both the femoral head and acetabulum) or a proximal femoral endoprosthesis alone.[39] Fractures of the intertrochanteric area may be managed by open reduction and internal fixation without the use of a prosthesis. This may allow for better long-term gait because of preservation of the hip flexor and adductor strength.[39] Lytic disease that extends below the intertrochanteric area is treated with a long intramedullary rod that provides stability throughout the length of the femur. If there is significant destruction of the greater trochanter and femoral neck or head in addition to subtrochanteric involvement, a prosthetic replacement would be more appropriate than a reconstruction nail.[46] Fractures of the distal femur may be managed either with a plate and compression screw or with an intracondylar nail and screws augmented by intramedullary methyl methacrylate cement. The latter method may reduce the risk of late failure of the repair, especially in patients receiving postoperative radiation therapy.[39]

TABLE 97.1 MIRELS' SCORING SYSTEM OF PREDICTION OF

PATHOLOGIC FRACTURE RISK

Score	Pain	Location	Cortical Destruction	Radiographic Appearance
1	Mild	Upper limb	<1/3	Blastic
2	Moderate	Lower limb	1/3–2/3	Mixed
3	Severe	Peritrochanteric	>2/3	Lytic

A score is assigned for each of the four categories, and the sum of those scores is used to estimate the risk of pathologic fracture.
Reprinted from Mirels H. Metastatic disease in long bones: a proposed scoring system for diagnosing impending pathologic fractures. *Clin Relat Orthop Res* 1989;249:256–264. With permission.

Repair of pathologic fractures of the humerus may be more problematic because of the small intramedullary canal and because of the proximity of the radial nerve, which may require extensive dissection.[39] Pathologic fractures of the proximal humerus will frequently require prosthetic replacement.[39] Fractures in the diaphysis may be repaired with a compression plate and screws. An alternative is to use a segmental diaphyseal replacement prosthetic device, which involves a prosthetic device than can be cemented into an allograft.[46] Supracondylar fractures are difficult to manage because the shape of the bone is not conducive to a plate and screws; these lesions may require intramedullary rods inserted in a retrograde manner through both the medial and lateral condyles, supplemented by intramedullary cement.[39]

Most pathologic fractures of the pelvis do not require surgical intervention, except for those involving the acetabulum.[39] Repair of acetabular fractures may involve the use of a total hip acetabular prosthesis, but more extensive lesions may require reconstruction that transfers the load-bearing stresses into more structurally intact bone in the iliac bone or sacroiliac joint.[39]

INTERVENTIONAL TECHNIQUES

Vertebroplasty is an effective method of palliating pain from vertebral body metastases, even in patients who have received prior radiotherapy.[47] Most patients experience pain relief within 48 hours. The procedure involves percutaneous injection of methyl methacrylate under CT or fluoroscopic guidance. Retropulsion of bone, epidural tumor, or collapse of the bone to less than one-third of its original height are relative contraindications to percutaneous vertebroplasty because of the risk of extrusion of the cement into the spinal canal, potentially causing neurologic complications. In some patients with

epidural tumor, percutaneous vertebroplasty can be performed safely and effectively with a relatively low risk of serious complications.[48,49] However, the procedure should be considered with some caution; in a systematic review of 987 patients, there were 5 deaths and 19 other serious complications.[50]

Kyphoplasty involves percutaneous placement of a balloon-like device into a symptomatic spinal metastasis (most commonly into a fractured or compressed vertebral body).[51] The balloon is then inflated to restore the height of the vertebral body, and methyl methacrylate is subsequently injected into this cavity. This procedure may provide significant relief of pain and improve overall functioning, especially in patients with mechanical instability of the vertebral body.[52,53] Kyphoplasty may be a better option than vertebroplasty in patients with vertebral wall deficiency.[52]

An ablative procedure is frequently coupled with vertebroplasty or kyphoplasty.[54] Radiofrequency ablation (RFA) may be used to ablate the tumor but is most effective for tumors that are osteolytic or mixed osteolytic and blastic. The RFA may not be as effective in tumors that are primarily sclerotic. Cryoablation may be used for larger lesions or those that are sclerotic. For both of these procedures, special attention to cord and nerve temperatures is required to minimize the risk of complications.

SYSTEMIC TREATMENT

The rationale for using systemic therapy in the management of bone metastasis is compelling. The pathophysiology of bone metastasis involves hematogenous dissemination, and most patients with bone metastasis suffer from multiple synchronous sites of disease. In theory, administering systemic cytotoxic therapy should deliver palliative benefit by simultaneously addressing all sites of bone metastasis. A localized therapy such as external-beam radiation may be most appropriate for palliation if symptoms are localized. On the other hand, systemic chemotherapy may offer palliative benefit if symptoms are diffuse or constitutional and disease is widespread. The chemotherapy drugs are frequently given with bisphosphonates and corticosteroids, which may affect the response rates.

Measurement of response to systemic therapy has generally been with the same criteria used for solid metastatic tumors: a measurable radiographic change. This works well for lung and liver metastasis but not as well for bone metastasis. For bone metastases, the definition of a complete response is

complete disappearance of all lesions on radiographs for at least 4 weeks. This is unlikely to occur even if all tumor cells are eradicated. A partial response requires some recalcification of lytic lesions, which may not be evident for 6 months or more.[55] PET scans may be more accurate at assessing response in a timely manner but are too expensive to be used as a routine follow-up evaluation for bone metastases. Markers of bone resorption may be a good way to detect response to therapy but are not clinically available at this time. Response to therapy for other modalities (i.e., radiotherapy, bisphosphonates) is measured in terms of pain relief and quality-of-life measures. Unfortunately, there is not much literature on accurate and reliable response criteria to palliative systemic therapy for bone metastasis. Most of the studies of chemotherapy for metastatic disease involve patients with visceral as well as osseous metastases. The responses in terms of pain are typically reported for all patients, not just those with bone metastases, so pure bone metastatic pain is difficult to ascertain. There is more information regarding response to chemotherapy for patients with metastatic prostate cancer because this more frequently involves bone-only metastatic disease.

Tannock et al.[56] recommended using more relevant end points of palliation. They performed a randomized trial of mitoxantrone plus prednisone versus prednisone alone for patients with hormone-refractory prostate cancer and pain. Improvement in pain was seen in 29% of patients receiving the chemotherapy, compared with 12% of those who received prednisone alone. In a subsequent study, they compared mitoxantrone and prednisone plus or minus clodronate for a similar group of patients. Most had mild pain at study entry (160 of 209; 77%), and the remainder had moderate pain scores. The patients with moderate pain who received chemotherapy and clodronate had a 58% response rate (≥2-point improvement in pain score) compared with 26% for those who received chemotherapy alone. The median duration of pain response was 6 months. The TAX327 phase III trial was conducted in 1,006 men with hormone-resistant metastatic prostate cancer and randomized patients to receive prednisone combined with either docetaxel or mitoxantrone. The docetaxel arm showed an improvement in overall survival, lower cancer-induced bone pain, and better objective tumor response.[57]

In patients with bone metastasis, there is seldom reason to combine chemotherapy with concurrent radiation therapy because of the potential for increased toxicity when both modalities are delivered concurrently.

A number of hormonal therapies are available in the management of

metastatic prostate and breast cancer. In properly selected patients, hormonal therapy has the potential for providing excellent palliation of metastatic disease with limited morbidity. In 1984, the Medical Research Council started a prospective, randomized trial in which 938 patients who either had asymptomatic metastatic prostate cancer or were not medical candidates for definitive therapy were randomized to immediate versus delayed hormone ablation therapy. Hormone ablation was achieved using either a luteinizing hormone–releasing hormone agonist or by orchiectomy. This study showed that immediate versus delayed initiation of hormone ablation therapy in the subset of patients with metastatic prostate cancer helped to prevent serious complications from metastatic disease. Serious complications including pathologic fracture, spinal cord compression, development of extraskeletal metastases, and ureteral obstruction were twofold more frequent in patients whose hormonal therapy was deferred compared with patients who received immediate hormone ablation therapy.[58]

Osteoclast inhibitors are also often used in conjunction with other systemic treatments. The bisphosphonates are pyrophosphate analogs that bind to calcium phosphate with high affinity and are potent agents affecting bone resorption through osteoclast inhibition.[59] The nitrogen-containing bisphosphonates inhibit the key enzyme farnesyl diphosphate synthase in the mevalonate pathway.[60] This prevents the action of several additional enzymes required for bone resorption. The bisphosphonates include pamidronate, alendronate, ibandronate, risedronate, and zoledronic acid. Zoledronic Acid is much more potent than the other bisphosphonates, in part because it also inhibits tumor cell adhesion to the extracellular matrix. There is evidence that the bisphosphonates also induce apoptosis in cancer cells.[61]

The initial studies of bisphosphonate usage were primarily in women with metastatic breast cancer. Pamidronate was evaluated in multiple randomized, prospective studies of women with osteolytic bone metastases from breast cancer. The Aredia Breast Cancer Study Group Protocols 18 and 19 enrolled women receiving either chemotherapy (P19) or hormonal therapy (P18). In the P18 study, 372 women were randomized to receive either placebo or pamidronate 90 mg as a 2-hour infusion every 4 weeks for 24 cycles.[62] The primary end point was the prevention of “skeletal-related complications” (pathologic fractures, spinal cord compression, hypercalcemia, or the requirement for surgery or radiation therapy on bone). There were fewer skeletal-related complications in the pamidronate arm (475 events vs. 648 in the

placebo group), but the benefit in reducing pathologic fractures and hypercalcemia was not significant until 18 to 24 months of treatment. The primary difference was that twice as many placebo patients required radiation therapy for palliation of pain, most often in the first 6 to 12 months. There was no difference in survival, although pain levels and serum markers of bone resorption were significantly lower in the group receiving pamidronate. In the P19 study, women with stage IV breast cancer who were receiving chemotherapy and had lytic bone metastasis were given placebo or pamidronate for 12 monthly cycles.[63] Patients in the pamidronate arm suffered fewer overall skeletal complications and had a greater median time to first skeletal complication when compared with patients in the placebo arm of the study. Women treated with pamidronate maintained better performance status and had less bone pain secondary to metastasis.

Rosen et al.[64] evaluated 773 patients with bone metastases from solid tumors, including lung cancer, renal cell carcinoma, head and neck cancers, thyroid, and other primary sites (exclusive of breast and prostate cancer). They compared placebo with zoledronic acid in doses of either 4 or 8 mg given every 3 weeks for 9 months. The primary end point was proportion of patients developing a skeletal-related event (SRE), including pathologic fracture, spinal cord compression, or the need for surgery or radiation therapy. The proportion of patients developing an SRE was 44% in the placebo group compared with 38% in the 4-mg zoledronic acid group (P = .127) and 35% in the 8-mg group (P = .023). The time to development of an SRE was significantly longer with zoledronic acid compared with placebo (230 vs. 163 days; P = .017). The dose of the 8-mg group was reduced to 4 mg during the latter part of the study because of safety concerns, and thus 25% of patients in the 8-mg treatment arm actually received only 4 mg per dose. In addition, only 25% of patients received the full 9-month course of treatment because of death (27%), adverse events (21%), patient decision to discontinue (15%), or “insufficient efficacy” (7%). There was no improvement in two specific events—surgery to bone and spinal cord compression—in the patients receiving zoledronic acid compared with placebo. In addition, the need for analgesics gradually increased and functional capacity decreased from baseline to month 9 in all groups, with no differences between zoledronic acid and placebo.

The Medical Research Council PRO4 and PRO5 were two prospective, randomized trials conducted to evaluate sodium clodronate in men with prostate cancer. Long-term data showed that sodium clodronate improved overall

survival in men with metastatic prostate cancer who were starting hormone therapy, but there was no improvement in overall survival for men with nonmetastatic disease.[65]

Complications of supportive therapy with bisphosphonates include osteoradionecrosis (particularly of the jaw) and renal insufficiency.[66] The mechanism of bisphosphonate-induced osteoradionecrosis is not known. Risk factors include the intravenous use of pamidronate and zoledronic acid, duration of treatment of 36 months or longer, older age in patients with multiple myeloma, and need for periodontal procedures.[67] Bisphosphonates are not metabolized by the body and are excreted by the kidneys. Bisphosphonate therapy can lead to renal toxicity. The incidence of renal toxicity is 9% to 15% in trials when 4 mg of zoledronic acid is delivered intravenously during 15 minutes.[66] Moreover, the rate of renal toxicity depends on underlying renal disease, dose of bisphosphonate used, and duration of the infusion.

Another form of systemic therapy is the use of agents that target the RANK pathway. Denosumab is a human monoclonal antibody specific for the RANKL. The antibody binds to RANKL and thus inhibits the formation, activation, maturation, and survival of osteoclasts.[68] In randomized, prospective comparisons of denosumab with zoledronic acid in patients with metastatic breast or prostate cancer, denosumab was superior to zoledronic acid in delaying or preventing the time to skeletal-related events.[69,70]

RADIATION THERAPY

Radiation therapy has been reported to be effective in palliating painful bone metastases, with partial pain relief seen in 60% to 90% of patients and complete pain relief in 30% to 50% of patients. These data are primarily from meta-analyses of studies using physician evaluation of pain. When patient evaluation of pain is used, pain improvement is seen in 60% to 80% of patients and complete pain relief is seen in 15% to 40% of patients.[71] The response to treatment depends on a large number of factors, including sex, primary site and histology, performance status, type of lesion (osteolytic vs. osteoblastic), location of the metastases, weight-bearing versus non–weight-bearing site, extent of disease, number of painful sites, marital status, and level of pain prior to treatment. The effectiveness of the treatment also depends on the goal: palliation of pain, prevention of pathologic fracture, avoidance of future treatments, or local control of the disease. The doses required and volumes

treated may be quite different for each of these goals. In addition to pain relief, other symptoms may also be relieved by radiotherapy. Patients who have improvement in pain after radiotherapy may also have improvement in emotional functioning, decreased insomnia, decreased constipation, and overall improvement in quality-of-life scores.[72] Radiation therapy should be an integral part of palliative treatment for bone metastases to treat pain and prevent other symptoms.[73]

Local-field external-beam radiation therapy is typically used for palliation of a few discrete areas of painful metastases (Fig. 97.4). The first large randomized study evaluating different dose and fractionation schemes was the Radiation Therapy Oncology Group (RTOG) 74-02 trial.[74] Patients with solitary bone metastases were randomized to 40.5 Gy in 15 fractions versus 20 Gy in 5 fractions. Patients with multiple painful metastases were allocated to one of four treatment schedules: 30 Gy in 10 fractions, 15 Gy in 5 fractions, 20 Gy in 5 fractions, or 25 Gy in 5 fractions. The initial analysis by Tong et al.[74] in 1982 showed no statistically significant difference in response rates between any of the treatment arms, with complete responses in 49% to 61% of patients. These results were questioned by Blitzer,[75] who reanalyzed the data using different criteria for complete response, which excluded patients who received repeat treatment, and defined complete response as no pain and no analgesic usage. With this adjustment in response definition, there was a significant difference in response favoring the longer treatment courses: 40.5 Gy in 15 fractions for the solitary metastases and 30 Gy in 10 fractions for multiple metastases. This was offered as evidence that higher doses were necessary for optimal palliation, even though one of the highest biologic doses for multiple fractions (25 Gy in 5 fractions) had one of the lower response rates. This reanalysis highlighted the importance of retreatment in this group of patients, especially in those given lower total doses during the initial course of radiation therapy.

There have been multiple randomized, prospective trials evaluating different dose and fractionation schemes.[74,76–88] Most of the earlier studies evaluated different multifraction treatment regimens (Table 97.2). No significant difference was seen between longer-course treatments and the shorter-duration, lower-total-dose treatment courses. Two randomized studies evaluated single doses of radiation therapy for palliation of bone metastases. Hoskin et al.[89] randomized patients to 4 versus 8 Gy, and Jeremic et al.[90] randomized patients to one of three dose levels, 4 versus 6 versus 8 Gy. In both of these studies, the 8-Gy arm was superior to 4 Gy, indicating that there is a threshold dose necessary to achieve

adequate palliation. Most of the randomized trials during the last 15 years used a multiple-fraction treatment scheme as the control arm and a single dose of 8 to 10 Gy as the study arm (Tables 97.3 and 97.4).

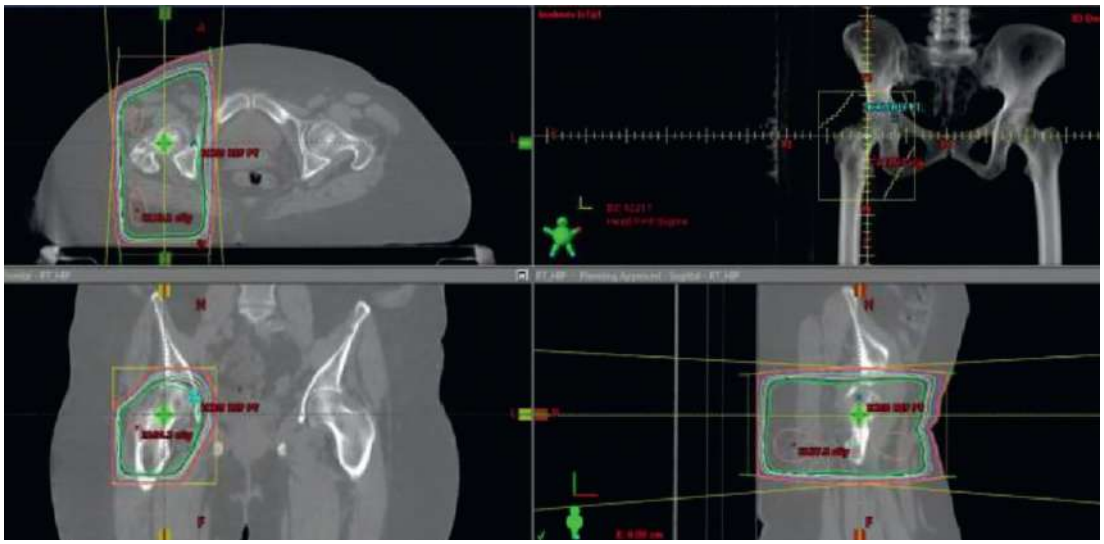

FIGURE 97.4. Isodose plan for a patient receiving radiation therapy to the right hip, showing axial and coronal projections of the doses as well as a digitally reconstructed radiograph of the treatment fields.

Two large studies compared single-dose treatment to longer courses of radiation therapy. The Dutch trial evaluated patients with bone metastases from solid tumors, primarily breast (39%), prostate (23%), and lung (25%); patients with metastatic melanoma and renal cell carcinomas were excluded.[88] The primary end point was patient-assessed pain relief, evaluated on an 11-point scale (0 = no pain, 10 = worst imaginable pain). A total of 1,171 patients were randomized to either 8 Gy in a single fraction or 24 Gy in six fractions. The painful areas had to be included in a single-treatment volume. The spine (36%) and pelvis (30%) were the two most common sites of treatment. The median pain score was 6.3, with a minimum score of 2. About half of the patient were receiving narcotic pain medications prior to randomization, and slightly more than half (53%) were receiving systemic therapy. The median survival after treatment was 30 weeks, with no difference between the two treatment groups. There was no difference in overall or complete response rates between the single-dose versus longer-course treatment arms. Overall, 71% of patients achieved a response to therapy during follow-up, with 35% achieving a complete response. Most of the responses occurred within the first 4 to 6 weeks after treatment. Complete response rates were higher for patients with breast and

prostate primaries than with lung or other primary sites (44% and 41% vs. 21% and 16%, respectively).

TABLE 97.2 RANDOMIZED TRIALS WITH ≥100 EVALUABLE PATIENTS COMPARING MULTIPLE-FRACTION TREATMENTS FOR PALLIATION OF BONE METASTASES

Study	Number of Patients (Number Evaluable)	Dose (Gy)/Number of Fractions	Complete Response[a] (%)	Overall Response[a] (%)	Pathologic Fractures (%)
Tong et al.,[74] 1982, U.S. (solitary treatment site)	266 (146)	20/5	53	82	4
		40/15	61	85	18
Tong et al.,[74] 1982, U.S. (multiple sites)	750 (613)	15/5	49	87	5
		20/5	56	85	7
		25/5	49	83	9
		30/10	57	78	8

[a]Response rates listed are for pain relief.
Number of patients entered on study and number of patients evaluable for response; dosage schedule; complete and overall responses; and proportion of patients with pathologic fractures after treatment. NA, not available from published report.

There were two significant differences between the two treatment groups: retreatment rates and pathologic fracture rates. The rate of pathologic fracture in the treated area was 4% for the 8-Gy single-treatment arm compared with 2% for the 24 Gy/six fraction group. The median time to fracture was similar for the two groups at 21 and 17 weeks. Although there was a significant difference in pathologic fracture between the two groups, these rates are still relatively low. There was also a significant difference in retreatment rates between the two arms of the study, with a much higher likelihood of a second course of treatment in the single-treatment group. The group of patients receiving 24 Gy in six fractions initially was given a second course of treatment 7% of the time, whereas 25% of

the 8-Gy single-fraction group was given retreatment. Retreatment occurred more commonly with lung/other tumors than with breast/prostate primaries. In addition, the retreatment was given at a lower pain score (median 6.8 for 8-Gy single-fraction compared with 7.5 for the multiple-fraction group) and at an earlier time (14 weeks after initial treatment compared with 23 weeks). This may indicate a greater willingness to reirradiate after a single dose of 8 Gy or more reluctance to give retreatment after a higher initial dose of radiation therapy.

[a]Time from study entry to assessment of response.
[b]Proportion of patients with severe pain scores at the time of study entry.
C, cervical; L, lumbar; NA, not available from published report; T, thoracic.

The second large study of single-dose versus longer-course treatment for palliation of bone metastases was RTOG study 9714, which was conducted in the United States and Canada.[79] This was limited to patients with painful bone metastases from breast or prostate primaries, with up to three painful sites allowed. Pain was evaluated using the Brief Pain Inventory, an 11-point scale. At the time of randomization, the patient was required to have a minimum pain score of 5 or a high narcotic pain medication requirement of the equivalent of >60 mg of morphine per day. More than 70% of the patients had severe pain at study entry (pain scores of 7 to 10). Patients were randomized to 8 Gy in a single fraction versus 30 Gy in 10 treatments. The median survival was 9.3 months. Overall toxicity rates were low, with fewer patients in the 8-Gy treatment group experiencing acute toxicity. There were no significant differences in complete (17%) and partial pain response rates (49%) between the two treatment groups. Complete pain and narcotic response (0 pain score and no narcotic pain medication use) was seen in 11%; these responses were all determined at the 3-month posttreatment evaluation. As in the Dutch trial, the rate of retreatment was higher in the 8-Gy treatment group, with 18% in that group receiving retreatment compared with 9% in the 30-Gy group. This disparity in the rate of retreatment

occurred despite nearly identical rates of stable (26% vs. 24%) or progressive pain scores (9% vs. 10%) and similar rates of narcotic use between the two groups.

[a]Proportion of patients with pathologic fractures after treatment.
[b]Response rates listed are for pain relief.
[c]A regimen of 30 Gy/10 was also allowed; 98% of patients received 20 Gy/5.
NA, not available from published report; NS, not statistically significant.

In contrast to the Dutch trial, there was no difference in the rate of pathologic fractures between the two groups (5% for 8 Gy vs. 4% for 30 Gy). Further analysis of this study has shown that certain subgroups may benefit from the longer course of palliative radiation therapy. Konski et al.[91] showed that although married men and both single and married women were more likely to receive retreatment after receiving 8 versus 30 Gy of palliative radiation therapy, there was no difference in retreatment rates among single men. The authors suggest that social support factors may significantly affect the ability of some patients to access repeat therapies for painful bone metastasis, especially as their health declines. Such subgroups of patients may benefit from the longer 10-fraction course of therapy.

These two large prospective, randomized trials comparing single-fraction to multiple-fraction palliative radiation therapy have similar results and help to clarify the role of palliative radiotherapy for bone metastases. The assessment of pain was performed by the patients rather than by physicians or other health care providers. The studies with the highest response rates generally used physician assessment of pain response (e.g., the RTOG 7402 study). Even with patient assessment of response, the single-fraction treatment yields similar response rates to the longer-course treatment. The patients in the Dutch trial were treated when their pain was in the moderate range, with only half on narcotic pain medications, compared with severe pain and high dose narcotic pain medication for most of the patients entered on the RTOG trial. This may account for the higher rates of complete response on the Dutch trial. In the RTOG trial, the group of patients with a single area of pain or with moderate pain scores at the time of study entry had higher complete response rates. Thus, it appears that the outcome is much better if patients are treated with palliative radiotherapy earlier in the course of their bone metastases rather than waiting until pain is severe or narcotic pain medication requirements are significant. There was no difference in pain response whether the treated bone metastases were in the spine or in extremity sites. The rates of pathologic fracture after treatment are relatively low, but it is not clear whether higher doses provide greater protection from fractures. The rates of retreatment are significantly higher with the single-dose schedules, but there may be some physician bias partially accounting for this difference because the retreatment tends to be offered at an earlier time and at lower levels of pain following the single-dose treatment.

There have been multiple randomized, prospective trials in the last 40 years comparing shorter-course, lower–total-dose treatment to the more “standard”

longer-course, higher-dose treatment. Several conclusions are clear from these studies:

- Single-dose treatments of 8 Gy provide similar pain relief to longer treatment regimens (30 Gy in 10 fractions or 20 to 24 Gy in five to eight treatments).
- The retreatment rates are higher after short-course treatment by a factor of two to three.
- Response rates are lower when scored by the patient instead of by the treating physician.
- Response rates are better when the initial pain scores are lower, that is, when the patients are treated for moderate pain rather than severe pain.
- There is no consistent dose–response relationship for palliation of bone metastases.

The lack of a dose–response relationship suggests that the mechanism of initial pain relief is not a reduction in tumor burden but more likely a change in the local environment that has caused activation of bone resorption by osteoclasts.[2] This helps to explain the seeming paradox of similar pain improvement with single-dose treatment compared with higher–total-dose, longer-course treatment. The treatment paradigm for bone metastases may be more analogous to treatments for certain benign conditions such as prevention of heterotopic ossification or keloid formation. In those conditions, a single or few treatments are given to diminish the activation of osteoblasts or fibroblasts.

This mechanism of pain relief may also help to explain the higher rates of retreatment after single-dose 8-Gy treatment because there will be less cell kill with this dose compared with 30 Gy in 10 fractions. Thus, for patients with a longer life span, there is a greater opportunity for regrowth of the tumor, which may again affect the local milieu, causing osteoclast activation.

For patients with a poor performance status, difficulty making multiple trips for treatment, extensive nonosseous metastases, and/or a short life expectancy, the most appropriate treatment is a single fraction of 8 Gy. Even with a limited expectancy (<3 months), the majority of patients experience pain relief, and palliative radiotherapy should still be considered for those patients.[92,93] For patients with a longer life expectancy, bone-only metastases, and good performance status, a longer course of treatment (30 Gy in 10 fractions) may be more appropriate to minimize the risk of retreatment. For selected patients with a solitary bone metastasis (“oligometastasis”), an even higher dose of treatment may be indicated, although this must be tempered by potential weakening of surrounding normal bone.

The single large-fraction treatment may be more likely to cause a “flare” reaction, with a temporary increase in pain at the site of the metastases.[94] The risk of this side effect may be diminished by the use of anti-inflammatory medications, either corticosteroids or nonsteroidal anti-inflammatory medications. Although the risk of significant acute toxicity has been low in the randomized trials, another potential concern is the risk of nausea or emesis if a significant portion of the stomach is within the treatment field (e.g., with a field covering the lower thoracic spine). It may be beneficial to give prophylactic antiemetics 1 to 2 hours before the treatment to minimize the possibility of this side effect.

For select patients that do not respond to the initial treatment course or for those with pain recurrence after an initial successful treatment, reirradiation to the painful metastatic sites can be administered.[95] Approximately 60% of retreated patients experienced an improvement of their pain, with 16% to 28% of patients experiencing a complete resolution of pain.[96] Patients also experienced an improved overall quality of life, and decrease in pain associated functional limitations after retreatment of a painful bone metastasis.[97] A randomized, controlled, noninferiority study compared single-dose treatment to longer courses of radiation therapy for the retreatment of previously irradiated painful metastatic bone cancer. 425 patients were randomized to receive either 20 Gy over multiple fractions or 8 Gy over one fraction. The single-fraction course was found to be noninferior to the multiple-fraction course, and resulted in a lower frequency of acute toxicity. There was no difference in pathologic fracture or spinal cord compression between these two groups.[95]

An economic analysis comparing shorter course treatment plans (8 Gy x1) to longer-course treatment plans (30 Gy x 10) was done in order to assess whether the longer treatment course is cost-effective in treating patients with bone metastasis by preventing further retreatment. The mean cost of the single-fraction treatment group was $998 with a quality-adjusted survival of 7.26 months, as compared to mean cost of $2316 and a quality-adjusted survival of 9.53 months for the longer treatment group. The incremental cost-effectiveness ratio was found to be $6972.95 per quality-adjusted life year. This study showed that the short, single-fraction treatment course with potential subsequent retreatments is both the less expensive, and more cost-effective treatment course for treating painful bone metastasis.[98]

Stereotactic radiosurgery has also been evaluated for the treatment of bone metastasis, particularly in the spinal region. A prospective, nonrandomized

cohort study conducted at the University of Pittsburgh in 500 cases of spinal metastasis treated with single-fraction radiosurgery to a maximum intratumor dose of 12.5 to 25 Gy demonstrated long-term pain level improvement in 86% of cases. Long-term tumor control was demonstrated in 90% of cases when radiosurgery was used as the primary treatment modality.[99]

The Radiation Therapy Oncology Group (RTOG) 0631 is a phase II/III study evaluating the role of stereotactic radiosurgery for patients with spine metastasis. Patients on this trial are randomized to either single-fraction external-beam radiation to 8 Gy or to single-fraction image-guided stereotactic radiosurgery to 16 Gy. The primary end point of this study is assessment of pain control at the treated site(s). The phase II portion of this study demonstrated the feasibility and accurate use of stereotactic radiosurgery to treat spinal metastases.[100] The primary end point of the phase III portion of the study will compare the pain relief at the treated site(s) and improvement in quality of life between the two groups. The results of the phase III portion of the study are pending.

The use of bisphosphonates with external-beam radiotherapy may further improve the outcome in terms of both pain and bone healing. A prospective trial by Vassiliou et al.[101] evaluated 45 patients who received both external-beam irradiation and monthly ibandronate for painful bone metastases from solid tumors. All of the patients had improvement in pain, with 57% complete responses and 43% partial responses when using the same response criteria as RTOG 9714. The average pain score decreased from 6.3 to 0.8, and opioid pain medication use decreased from 84% of the patients before treatment to 24% after treatment. Bone density in the area of the metastases increased by 73% by 10 months after treatment. A similar study using pamidronate and 30 Gy of external-beam radiotherapy in women with painful bone metastases from breast cancer found that 88% of patients had complete radiographic response by International Union Against Cancer criteria.[102]

The majority of patients with osseous metastases have multiple lesions. Although radiation therapy is effective at palliating pain in a few sites, it cannot be used to treat widespread disease. Two techniques that have been used to treat more-diffuse metastases are hemibody irradiation (HBI) and intravenous radiopharmaceuticals.

Hemibody Radiation Therapy

HBI, or wide-field radiation therapy, refers to the technique of treating a large portion of the body with external-beam irradiation. Although the term *hemibody*

irradiation is used, typically the field does not cover half of the body, but more accurately treats about one-third of the body. The treatment has been used for palliation of symptoms and as an adjuvant to prevent the development of new bone metastases. The treatment for palliation of pain is most useful in patients who have diffuse, widespread bone metastases.

The treatment volumes have been divided into upper, middle, and lower HBI. The fields for upper HBI cover the thorax and abdomen from the neck to the top of the iliac crests. For midbody HBI, the fields include the abdomen and pelvis from the diaphragm to the ischial tuberosities. For lower HBI treatment, the field borders are from the top of the pelvis to the inferior portion of the femurs. The toxicities from each of the fields depend on the critical structures included. The most problematic of these is the risk of radiation pneumonitis with upper HBI. This is the dose-limiting toxicity for upper HBI, and dose-inhomogeneity corrections for the lung are necessary to minimize the risk of fatal pneumonitis. A lower total dose can be given to the upper hemibody fields compared with the middle or lower hemibody areas.

RTOG 78-10 was a dose-searching prospective protocol evaluating the maximum tolerated dose (MTD) for single-dose HBI.[103] The MTD for middle and lower hemibody treatment was 8 Gy. The MTD for the upper HBI was 6 Gy if the lung dose was uncorrected and 7 Gy if lung corrections were used. Improvement in pain was noted in 80% of patients with breast cancer and 90% of patients with prostate cancer. Overall, the response rate in terms of pain relief was 73%, with complete relief of symptoms seen in 19%. Pain relief was seen relatively rapidly, with 50% of responses occurring within 2 days and 95% of responses within 2 weeks. The subsequent study RTOG 82-06 evaluated the use of HBI in addition to local radiotherapy to determine whether the HBI would prevent the development of new sites of disease.[104] All of the patients received involved-field irradiation to one or more painful sites, and half of the patients were randomly assigned to receive single-dose HBI as well. The median time to progression was 6.3 months in the local-treatment-only group compared with 12.6 months for those receiving HBI. Fewer patients receiving HBI required additional treatment. The incidence of severe hematologic toxicity was low and transitory but was seen only in the group receiving HBI.

Both the RTOG and the International Atomic Energy Agency performed trials evaluating multifraction courses of HBI.[105,106] The doses per fraction ranged from 2.5 to 4 Gy to a total of 8 to 20 Gy. The maximum tolerated dose on the RTOG 88-08 study was 17.5 Gy in seven fractions. On the International Atomic

Energy Agency study, 3 Gy twice daily for 2 days (12 Gy total) or 3 Gy daily for 5 days (15 Gy total) was more effective than 4 Gy daily for 2 days. The primary toxicities were hematologic and gastrointestinal. The rationale for these doses was to decrease the acute toxicity. However, each of these regimens requires multiple treatments during several days, and the acute toxicities are not appreciably different than the single-dose treatment. With the use of appropriate antiemetic premedications and with cytokines to aid in hematologic recovery, there does not appear to be any appreciable benefit to the fractionated HBI compared with the single dose.

Premedication with antiemetics and anti-inflammatory medications significantly reduce the acute side effects of treatment. Before the development of the 5-HT3 receptor antagonists, nausea was a significant side effect of treatment, even with pretreatment and posttreatment use of steroids, prochlorperazine, and intravenous hydration. With the use of ondansetron, granisetron, or other 5-HT3 receptor antagonists, the incidence of acute nausea and emesis has been minimized and HBI is well tolerated.[107] A typical premedication regimen consists of dexamethasone, 8 to 16 mg, and ondansetron, 8 to 16 mg, 1 hour before treatment with HBI.[108]

Radiopharmaceuticals

The concept of radiopharmaceutical treatment is compelling.[109] Calcium (and to a lesser extent phosphorous) analogs will preferentially accumulate in bone, especially in areas of active bone turnover. A radioactive isotope that is a β-emitter or low-energy γ-source will allow localized treatment in the areas in which the radiopharmaceutical accumulates, thus minimizing side effects and giving an excellent therapeutic ratio. The radiopharmaceuticals are given in a single injection that is easily administered. The treatment can be combined with other modalities, including chemotherapy or external-beam radiation therapy.

The first radiopharmaceutical used for treatment of bone metastases was phosphorous-32 (P-32). Treatment with P-32 for diffuse bone metastases was successful in giving subjective pain relief but with unacceptable bone marrow toxicity. Other radioisotopes have been used for the palliation of diffuse osseous metastases with a better therapeutic ratio than P-32. Strontium-89 (Sr-89) is chemically similar to calcium and is deposited in the bone matrix, preferentially in sites of active osteogenesis. Sr-89 is a pure β-emitter with an energy of 1.4 MeV and a half-life of 50.6 days.[110] Samarium-153 (Sm-153) is primarily a β-emitter but also has a component of gamma emission, which is useful for

imaging purposes. The Sm-153 ethylenediamine tetra-methylenephosphonic acid (EDTMP) is concentrated in areas of high bone turnover, accumulating in areas of hydroxyapatite. The physical half-life of Sr-153 is 46.3 hours, but the biologic half-life is much shorter because about half of the compound is excreted in the urine within 8 hours of injection.[111] These two isotopes have been evaluated in multiple prospective trials. There are other, newer isotopes that are being evaluated, including rhenium-186, rhenium-188, and tin-117m. All of these isotopes accumulate in areas of osteoblastic activity, especially in areas of increased uptake on bone scintigraphy; for this reason, most of the patients entered on prospective trials have metastatic prostate cancer.

Strontium-89

The first study of Sr-89 with substantial numbers of patients was a randomized, prospective trial of Sr-89 versus placebo in 126 men with metastatic prostate cancer, reported by Porter and McEwan[112] in 1993. The patients were randomized after involved-field radiation therapy in a double-blind fashion to 400 MBq of Sr-89 versus placebo. Although there was no statistically significant difference in the primary end point of pain relief, there were several secondary end points that were improved with the Sr-89. More patients were able to discontinue pain medications (17% vs. 2%), and there were fewer sites of new pain requiring additional radiotherapy in the patients who received Sr-89. Smeland et al.[113] reported on a similar study of Sr-89 versus placebo after involved-field radiation therapy, which showed no difference in outcome between the two groups. In this study, the dose of Sr-89 was only 150 MBq.

There have been two randomized trials of Sr-89 versus external-beam radiation therapy. A study by Quilty et al.[114] from the United Kingdom evaluated Sr-89 given in a dose of 200 MBq compared with external-beam radiotherapy. For patients with a few bone metastases, the randomization was Sr-89 versus local-field radiation therapy. Patients with more widespread metastases were randomized to Sr-89 versus HBI of 8 Gy to the lower hemibody or 6 Gy to the upper hemibody. There was no difference in pain relief, toxicity, or median survival between the groups. In the patients with diffuse disease, there were fewer new pain sites after Sr-89 than HBI. The trial by Oosterhof et al.[115] evaluated 203 patients with hormone-refractory metastatic prostate cancer, randomly assigning patients to receive local-field radiation therapy or 150 MBq of intravenous Sr-89. There was no difference in pain relief or toxicity between the two treatment arms.

Sr-89 can be given concomitantly with chemotherapy. Two randomized, prospective trials evaluated concomitant chemotherapy with Sr-89 for patients with hormone-refractory metastatic prostate cancer. In the trial by Sciuto et al.,[116] 70 patients received 148 MBq of Sr-89 on day 0. They were randomly assigned to receive cisplatin, 18 mg/m^2 intravenously on day 0 and 16 mg/m^2 on days 10 and 11, or placebo on the same days. The group that received cisplatin and Sr-89 had significantly more patients with pain relief (91% vs. 63%), longer duration of pain palliation (120 vs. 60 days), longer median survival (9 vs. 6 months), and a significantly greater proportion of patients with improvement in performance status (66% vs. 26%), with no significant difference in toxicity. Tu et al.[117] performed a phase II randomized study of doxorubicin, 20 mg/m^2 per week given intravenously, with randomization between 2.035 MBq/kg of intravenous Sr-89 versus placebo. Neutropenia and anemia were common in the combined Sr-89 plus doxorubicin group compared with doxorubicin alone, but the median survival was also significantly better (28 vs. 17 months).

An economic evaluation of the Trans-Canada randomized study found Sr-89 treatment to be cost-effective.[118] The patients who received the Sr-89 had significantly lower subsequent costs for palliative medications, hormonal therapy, and subsequent radiation therapy. However, Oosterhof et al.[115] found that Sr-89 was associated with higher costs than external-beam radiotherapy.

Samarium-153

Samarium-153 is chelated with ethylenediamine tetra-methylenephosphonic acid to form Sm-153 EDTMP, a compound that is preferentially taken up in newly formed bone. The unbound remainder of the drug is rapidly cleared via urinary excretion. Phase I/II studies showed that doses of >2.5 mCi/kg are associated with neutropenia. In a dose-escalation study, Collins et al.[119] evaluated doses from 0.5 to 3.0 mCi/kg. There was no significant difference in clinical response between 1.0 and 2.5 mCi. There have been at least five randomized, prospective evaluations of Sm-153 for metastatic cancers (primarily for prostate cancers).[111,120–123] Two of these studies used a placebo arm in comparison to 1.0 mCi/kg[122] or 0.5 and 1.0 mCi/kg.[111] In both of these studies, the 1.0-mCi/kg dose gave significant improvement in pain relief compared to placebo. The average opioid dose decreased for the patients receiving Sm-153, compared to an increase in the patients receiving placebo. Transient marrow suppression was seen, with a nadir at 4 to 6 weeks and recovery by 8 weeks; this primarily manifested as grade ≥3 neutropenia (14% compared with 0% for placebo).

The other phase III study evaluated three dose levels of Sm-153 (0.5, 1.0, and 1.5 mCi/kg). Olea et al.[120] reported no difference in response rates among the different dose levels, with an overall pain relief response rate of 73%. Two randomized phase II studies compared doses of 0.5 with 1.0 mCi/kg, with no placebo arm.[121,123] In these two studies, there was no significant difference between the two dose levels for response or toxicity. There was no difference in response by primary site, although the numbers of patients were small for each primary site. The study by Tian et al.[123] is the only one in which metastatic prostate cancer patients did not comprise the majority of patients included.

Radium-223

Radium-223 dichloride is a pharmaceutical that emits alpha particles and selectivity targets bone metastases. The ALSYMPCA trial was a phase III, prospective randomized study of men with castrate-resistant prostate cancer with bone metastases. Patients were randomized to receive 6 injections every 4 weeks of either radium-223 or placebo. The randomization was 2:1, with 614 patients receiving Ra-223 and 307 patients receiving placebo. The primary end point of the study was survival, which was significantly greater in the patients treated with Ra-223 (14.9 months) compared to placebo (11.3 months).[124] Multiple secondary end points were improved with the Ra-223 compared to placebo: (1) time to first symptomatic skeletal event (15.6 vs. 9.8 months), (2) decreased risk of spinal cord compression, (3) lower use of external radiation therapy for bone pain, and (4) decrease in certain biomarkers (total alkaline phosphatase and lactic dehydrogenase, although there was not a statistically significant difference in prostate specific antigen).[124,125] There was no difference between the groups in pathologic bone fractures or the need for orthopedic intervention. The rates of significant adverse events were low, as was the risk of myelosuppression, in the patients receiving Ra-223.[125] Radium-223 has been used concomitantly with abiraterone, enzalutamide, and denosumab in an open-label prospective but nonrandomized study, with relatively low significant toxicity rates (grade ≥ 3 hematologic toxicity was <10%).[126] Radium-223 is the only bone-directed radionuclide, which has shown improvement not only in pain and quality of life but also in overall survival.

Patient Selection

Radiopharmaceuticals, specifically Ra-223, Sr-89, and Sm-153, are effective in providing pain relief for patients with diffuse osseous metastases. This is

primarily true for metastases that have an osteoblastic component. In general, if a Tc-99m nuclear medicine bone scan shows localized areas of increased uptake, then radiopharmaceutical treatment is likely to be of benefit. An advantage of radioisotope treatment is that it can be combined with other modalities, such as external-beam radiation therapy or chemotherapy. Because the targets of treatment are similar, treatment with bisphosphonates should not be given simultaneously with radioisotopes because this may reduce the efficacy of both medications. However, there is evidence that the Radium-223 can be given concomitantly with denosumab. Relative contraindications to therapy would be impaired renal or hepatic function or inadequate hematologic reserve.

Radiopharmaceuticals: Summary

The primary advantages of Sm-153 compared with Sr-89 are reduced radiation safety issues (because of the much shorter half-life) and the ability to image the distribution of the Sm-153. Although there has not been a randomized comparison of Sr-89 and Sm-153, there does not appear to be a significant difference in the incidence, severity, onset, or duration of hematologic toxicity, despite the short half-life of the Sm-153. Both radiopharmaceuticals appear equally effective at palliating pain from bone metastasis. Radium-223 offers not only palliation of pain but also the possibility of improved overall survival, at least in patients with castrate-resistant metastatic prostate cancer. These radiopharmaceuticals add to the growing armamentarium of therapies designed to palliate pain and improve the quality of life of patients with bone metastasis from cancer.

CONCLUSION

Palliative radiation therapy is of significant benefit to patients with painful bone metastasis, with most patients experiencing relief in the magnitude of pain following treatment. Response rates to palliative radiation therapy for localized sites of pain are consistently higher than response rates from palliative systemic therapy, and palliative external-beam radiation therapy remains the mainstay of treatment for clinically localized painful bone metastasis. Providing shorter, single-fraction palliative treatment schedules (i.e., 800 cGy × one fraction) for properly selected patients with bone metastasis can help better integrate palliative radiation therapy into the multidisciplinary management of patients with metastatic cancer and offer equivalent palliation compared with longer

courses of palliative radiation therapy. Systemic targeted therapies including Ra-223, Sm-153, and Sr-89 offer yet another means to target painful sites of bone metastasis without limiting the ability to use localized external-beam radiation therapy and systemic chemotherapy.

CHAPTER 98

Palliation of Visceral Recurrences and Metastases and Treatment of Oligometastatic Disease

Alexander A. Harris and William F. Hartsell

INTRODUCTION

The 5-year survival and overall cure rates for many cancers have significantly improved over the past 40 years. Unfortunately, there is still a substantial minority of patients who develop recurrent or metastatic disease. The most common sites of metastatic disease are bones, brain, lungs, and liver. In addition, there are other visceral sites of recurrence or metastatic disease that may cause significant symptoms. Palliative radiation therapy for treatment of bone and brain metastases is well established, with multiple randomized prospective trials evaluating best treatment practices. However, there is less information on treatment of visceral metastases, although radiation oncologists recognize that radiation therapy is frequently effective at palliating symptoms from visceral metastases.

The specific goals of treatment will depend on the symptoms, treatment site, functional status of the patient, and other patient-specific factors. The indications for treatment may include pain, visceral obstruction, bleeding, or other symptoms that negatively impact the quality of life. In general, this treatment is given with the goal of improving the quality of life, not the quantity of life. For some disease sites, this can be done with a very short course, low-dose treatment. For other sites, this will require higher doses given to control the local disease.

Some visceral metastases will cause pain. For example, liver or adrenal metastases may cause significant pain. Splenic metastases from hematologic metastases may cause abdominal pain, early satiety, and abdominal distention. In contrast, pulmonary metastases rarely cause pain. Instead, these lesions may

cause airway obstruction or hemoptysis. Metastatic lesions in the gastrointestinal system may cause bleeding or obstructive symptoms (esophageal obstruction, gastric outlet obstruction, gastric bleeding, biliary obstruction, rectal obstruction). In addition to rectal obstruction, pelvic masses may cause ureteral obstruction, bleeding (vaginal, bladder, or rectal), or pain from involvement of the sacrum or sacral nerves.

There has been a revolution in the understanding of the metastatic process in the past decade. Traditionally in solid tumor biology, cancer cells are thought to undergo some genetic change that potentiates them to grow into tumors and cause daughter cells to spread through the lymphatic or circulatory system to lymph nodes and distant sites. However, recent understanding of the epithelial–mesenchymal transition demonstrates that cancer cells develop embryonic stem cell–like properties that allow them to disseminate to distant sites. The microenvironment surrounding the primary tumor and metastatic sites can regulate the metastatic process. In addition, metastasis occurs much earlier than clinical detection of lymphadenopathy and radiographic or symptomatic evidence of the development of distant visceral disease.[1] Treatment of visceral metastases in the oligometastatic setting may allow for improved palliation and may also improve the overall survival in carefully selected patients.

MALIGNANT LOWER AIRWAY OBSTRUCTION

The lower airway is generally defined as being below the first tracheal ring. Upper airway obstructions can be emergently treated with a tracheostomy. The lower airway can become compromised from either primary or metastatic malignancy. Patients may have intrinsic compression caused by an endobronchial tumor or extrinsic airway compression by a tumor mass in the lung parenchyma or bulky lymphadenopathy during the course of their illness. Clinical symptoms, bronchoscopy, and radiographic imaging are used to determine the extent of luminal obstruction. It is important to determine whether the airway obstruction is endobronchial or from external compression of the airway in order to select the most appropriate treatment. For intrinsic compression of a tumor mass growing inside the bronchial lumen, interventional bronchoscopy techniques offer immediate benefit in many patients. These interventional techniques can result in relief of dyspnea, decreased risk of postobstructive pneumonia, and improved functional status.[2–4] Either laser resection of tumor or endobronchial stent placement, along with radiation

therapy, is effective in maintaining the patency of the lower airway.[5,6] The additional treatment of the airway can be given with either external-beam radiation therapy, endobronchial brachytherapy, or photodynamic therapy. Brachytherapy is typically the best option in patients who have recurred after prior external-beam radiation therapy. For endobronchial therapy, the recommended doses are 7.5 Gy × 3 or 10 Gy × 2.[7] In a prospective observational study, de Aquino Gorayeb et al. utilized high-dose-rate endobronchial brachytherapy for palliation of malignant airway obstruction. The study protocol consisted of three fractions of 7.5 Gy weekly or biweekly, with over half of the patients having been previously treated with external beam radiation. Of the 78 patients treated, 70% reported an improvement in performance status and 87% noted improvement of one or more of their presenting complaints (dyspnea, cough, infection, and/or hemoptysis). Of the patients who presented with one or more of the above symptoms, 57% noted improvement in their dyspnea, 34% noted improvement in their cough, 80% noted improvement in their infection symptoms, and 100% noted improvement in their hemoptysis.[8]

External-beam radiation therapy is typically used for treatment of airway compromise caused by extrinsic compression of a bronchus. Endobronchial brachytherapy typically does not improve symptoms when there is external compression of the airways.[9,10] The highest doses from brachytherapy will be given to the (relatively) normal mucosa of the airway, with a much lower dose to the extrinsic tumor that is causing the compression.

There is no standard fractionation scheme or total dose for palliative external-beam treatment for lung cancer. A review by Fairchild et al.[11] found the best results, in terms of palliation of symptoms, are achieved with relatively high doses of radiation therapy: 3 Gy per fraction to a total of 30 to 45 Gy, or 2 Gy per fraction to 50 to 60 Gy. The trade-off is that there is a higher rate of acute esophagitis with these higher doses. The American Society for Radiation Oncology clinical practice guideline consensus statement recommends doses equivalent to 30 Gy in 10 fractions or greater.[12] For patients with a poor performance status or who have difficulty traveling for multiple treatments, shorter fractionation schemes such as 20 Gy in 5 fractions can be used. Very short regimens (17 Gy in 2 fractions or 10 Gy in 1 fraction) may be useful in certain situations; however, there are reports of radiation myelopathy with these regimens (17 Gy in 2 fractions).[12]

In most patients who receive radiation therapy for palliation of pulmonary symptoms, there is no benefit to the addition of chemotherapy. Combined

chemotherapy and radiation therapy may improve response rates slightly, but with significantly greater acute toxicity.[12]

LIVER METASTASES

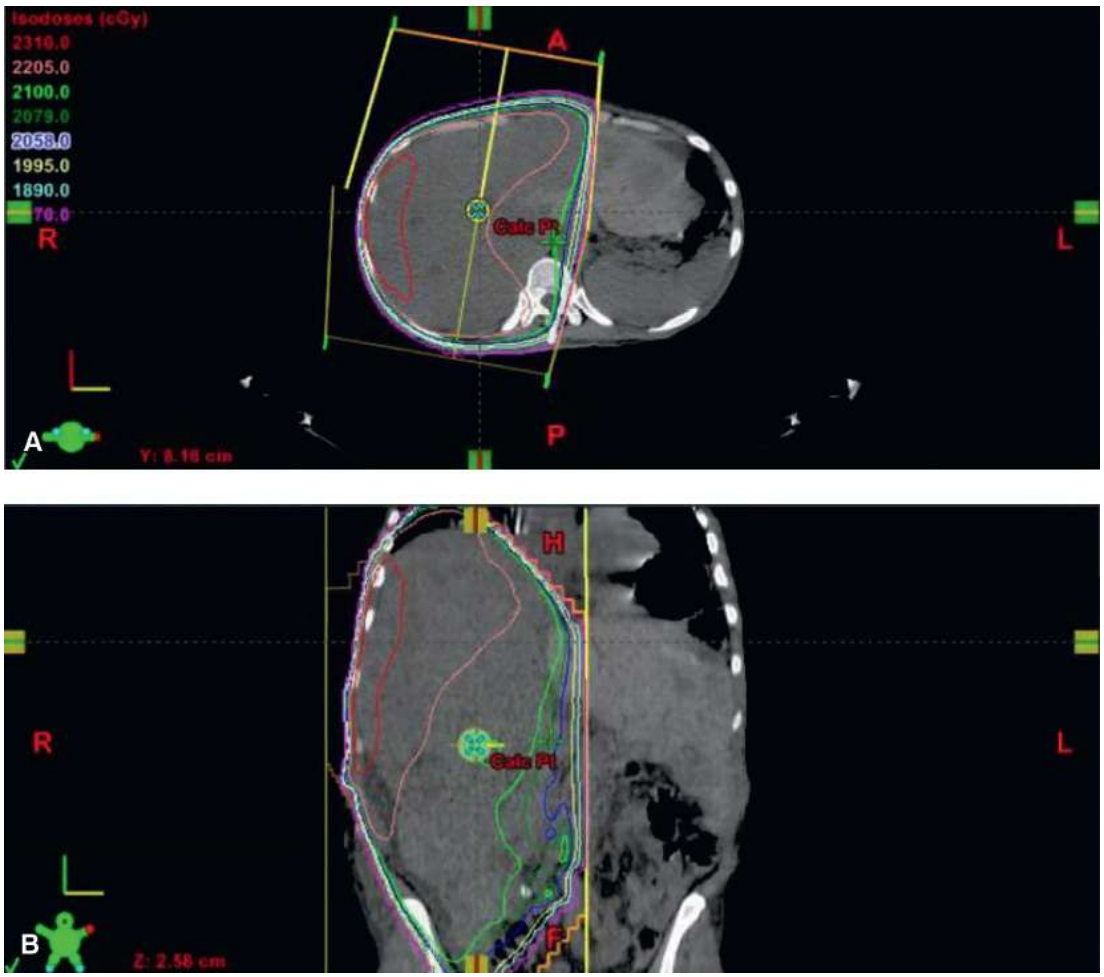
The liver is a common metastatic site. It is the most frequent site of distant metastatic disease from gastrointestinal tumors, especially colorectal, but also including esophageal, stomach, and pancreatic cancers. The liver is also a frequent site of metastases from lung cancer, breast cancer, and melanoma. A patient with liver metastases may have symptoms of anorexia or early satiety, weight loss, nausea, right upper quadrant or epigastric pain, jaundice, and fever.

For patients with few metastatic lesions in the liver and no evidence of extrahepatic metastases, 12% to 36% may be cured with surgical resection.[13] The risk factors associated with the best outcome are clear resection margins, low levels of carcinoembryonic antigen, a single metastatic deposit, metachronous presentation of the liver metastasis, and node-negative disease (with the original primary).[13] There are multiple other treatments that can be used for patients with one or a few hepatic metastases, including radiofrequency ablation, microwave coagulation therapy, transarterial chemoembolization, and stereotactic body radiotherapy (SBRT).[14]

Most patients with liver metastases are found to have multiple lesions, extrahepatic disease, or other risk factors that make them unsuitable for these surgical or interventional procedures. It is common for these patients to undergo multiple courses of systemic therapy prior to being seen and evaluated by a radiation oncologist. For many years, the only viable chemotherapy option for metastatic gastrointestinal tumors was 5-fluorouracil, often given in combination with leucovorin. More recently, multiple drug regimens including oxaliplatin or irinotecan have significantly improved the response rates and increased the median duration of survival. Targeted agents such as cetuximab or bevacizumab may improve the response rates even further. These new combinations have changed the goal of treatment from palliation to prolonging survival; with this new paradigm, the multiple drug regimens are given as neoadjuvant therapy with the goal of downsizing tumor bulk in order to facilitate a resection.[15] Hepatic arterial infusion of chemotherapy gives higher local concentrations of the chemotherapy agents and also gives higher response rates. A meta-analysis of hepatic arterial infusion chemotherapy for liver metastases demonstrated a significantly higher response rate but showed no improvement in survival

duration.[16]

The group of patients who are referred to a radiation oncologist for palliation of liver metastases tend to be the patients who have more medical comorbidities, a greater tumor burden, and who have been previously treated with multiple other therapies. Despite these poor prognostic factors, radiation therapy can be effective in palliating symptoms (Fig. 98.1).[17]



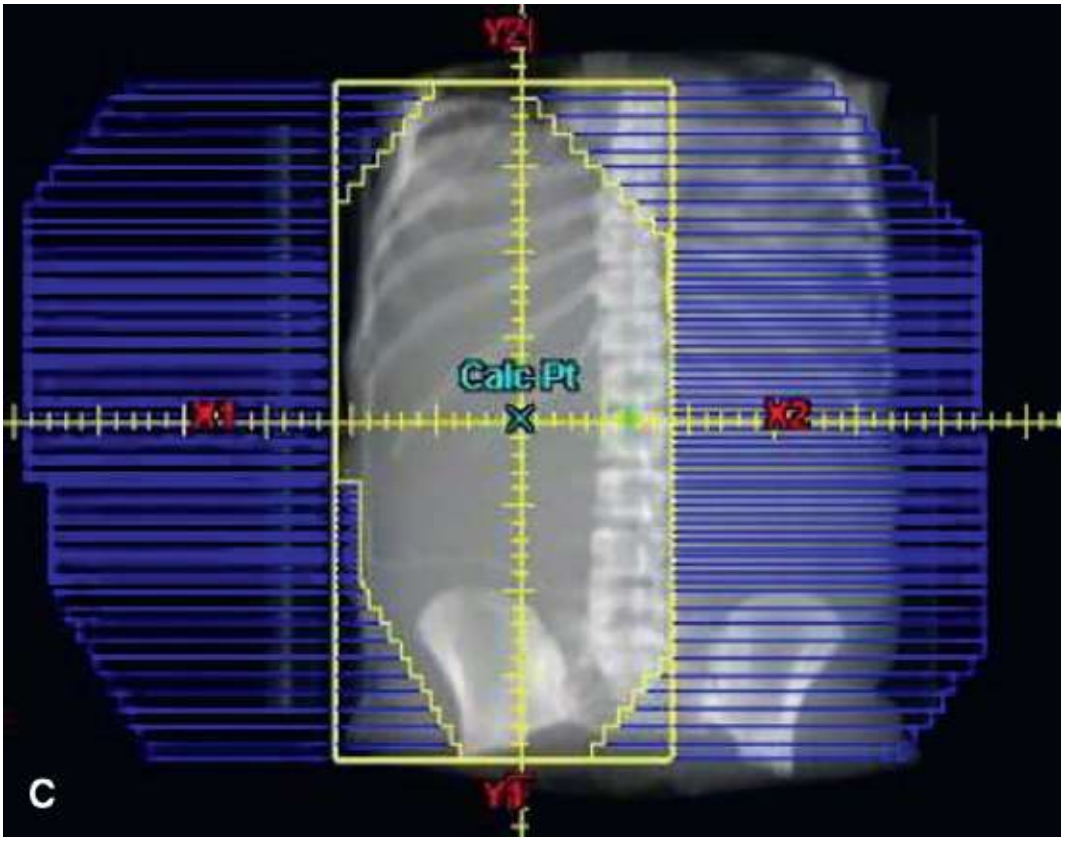


FIGURE 98.1. Axial **(A)** and coronal **(B)** isodose plots in a patient with diffuse metastases in an enarged liver, causing significant pain. Treatment field is shown in **(C)**. This patient was given 21 Gy in 7 fractions, and had significant improvement in pain within 4 weeks.

Palliative treatment of the liver is limited by radiation-induced liver toxicity (RILD). This toxicity becomes apparent 1 week to 3 months after treatment and may result in liver failure and death.[18] Both dose and volume of liver irradiated are important in avoiding RILD. For treatment of the whole liver, the threshold for RILD is approximately 30 Gy in 2 Gy fractions or 33 Gy in 1.5 Gy twice daily fractions.[19,20] The Radiation Therapy Oncology Group's trial RTOG-7605 evaluated multiple regimens in patients with multiple liver metastases: 30 Gy in 15 fractions, 25.6 Gy in 16 fractions, 20 Gy in 10 fractions, and 21 Gy in 7 fractions.[21] Improvement in symptoms was seen in 55% of the patients, with no difference among the four treatment regimens. A subsequent RTOG trial evaluated whole-liver radiation therapy with a dose of 21 Gy in 7 fractions; patients were randomized to receive the radiation alone or with the addition of misonidazole to the radiation.[22] There was minimal toxicity and a rapid symptomatic response in the majority of patients. Complete pain relief was reported in 54% of the patients, and 80% of the patients noted an improvement

in pain following treatment. Overall, there was no significant benefit with the addition of misonidazole. The best response rates were seen in patients with colorectal primaries. Bydder et al.[23] reported on a series of 28 patients treated with a hypofractionated regimen of 10 Gy in 2 fractions to the whole liver. The overall response rate was 54%, with 2 patients experiencing grade 3 toxicity (emesis and diarrhea).

If a smaller portion of the liver is irradiated, higher doses can be given with low risk for RILD. A 5% risk of RILD is associated with 90, 47, and 31 Gy with uniform irradiation of one-third, two-thirds, and the whole liver, respectively. If the effective liver volume irradiated is <25%, doses >100 Gy can be given with little risk of RILD.[24,25]

Selective internal radiation therapy (SIRT) is another option for patients with diffuse liver metastases. This technique involves the use of yttrium-90 (^{90}Y) glass or resin microspheres that are given through intra-arterial infusions into the liver. A phase III trial of patients with liver metastases from colorectal cancer evaluated intra-arterial floxuridine alone compared to intra-arterial floxuridine plus SIRT with ^{90}Y resin microspheres.[26] The patients who received SIRT had a significantly better overall response rate, time-to-tumor progression, and overall survival. The addition of SIRT did not increase grade 3 or 4 toxicity.

In summary, patients with multiple symptomatic liver metastases may be palliated by whole-liver radiation therapy. Relatively low doses of 21 Gy in 7 fractions or 30 Gy in 15 fractions are generally well tolerated and provide symptomatic relief for the majority of patients.[17–22] Treatment to high doses can be done if a smaller percentage of the liver is radiated.

BILIARY OBSTRUCTION

Malignant biliary obstruction may be caused either by a tumor mass causing extrinsic compression onto the bile duct or intrinsic compression from tumor progression within the bile duct lumen. This obstruction can lead to hyperbilirubinemia and jaundice, which can cause pruritus, anorexia, and weight loss. The biliary obstruction may be a life-threatening emergency. Emergent drainage of the bile duct is achieved initially by external stent. These stents are later converted to internal endoprostheses; however, these catheters typically only remain patent for 4 to 8 months.[27] The patency of these stents can be extended with the use of intraluminal brachytherapy, photodynamic therapy, or external-beam radiation therapy. Intraluminal brachytherapy extends stent

patency and lengthens survival duration in patients with inoperable cholangiocarcinoma.[28,29] Although there are few data specifically for the use of external-beam radiation therapy for palliative treatment of metastatic biliary obstruction, it may be of benefit especially for treatment of extrinsic bile duct compression by a tumor mass.[30]

PAINFUL ADRENAL METASTASES

The adrenal glands are a common site of metastatic disease from many types of cancer, primarily due to the rich blood supply of the adrenal gland. Lung cancer is the most common source of adrenal metastases. These metastases are frequently asymptomatic, but occasionally may cause pain. For patients with a good performance status and few sites of metastatic disease, surgical management may be appropriate. Radiation therapy is also appropriate for palliative treatment.

Palliative radiotherapy typically has been given with conventional external-beam techniques. Soffen et al.[31] reported the results in 16 patients with painful adrenal metastases treated with palliative radiation therapy. The majority of the patients received 30 Gy in 10 to 12 treatments. A response was seen in 12 of 16 patients (75%), with 6 of those patients having complete response for the duration of their survival. Nearly half of the patients (44%) experienced nausea, which may have been related to the technique of treatment with anterior and posterior fields. No late toxicity was seen, but the median survival was only 3 months. A multicenter retrospective study assessed results from 134 patients treated with 3D conformal (88%), intensity-modulated radiation therapy (IMRT) (6%), or SBRT (6%) for adrenal metastasis from hepatocellular carcinoma. Treatment regimens ranged from 20 to 60 Gy (median of 45 Gy) with dose per fraction of 1.8 to 15 Gy (median 2.5 Gy). A complete response was seen in 6 patients, a partial response seen in 48 patients, for an objective response rate of 39%. Seventy-eight patients (55%) were noted to have stable disease.[32]

There are multiple recent reports evaluating the use of intensity-modulated radiation therapy techniques or stereotactic body radiation therapy techniques for treatment of adrenal metastases. Most of these patients were treated for asymptomatic adrenal metastases, rather than for palliation of symptoms. These treatments appear to provide a high rate of local control. SBRT studies have shown local control rates ranging from 73% to 100% after 1 year, with minimal toxicity.[33–35] These newer radiotherapy treatments may be appropriate for

patients with limited volume disease (oligometastases) (Fig. 98.2). In the palliative setting, there is a benefit with a dose of 30 Gy in 10 to 12 treatments using conventional techniques.

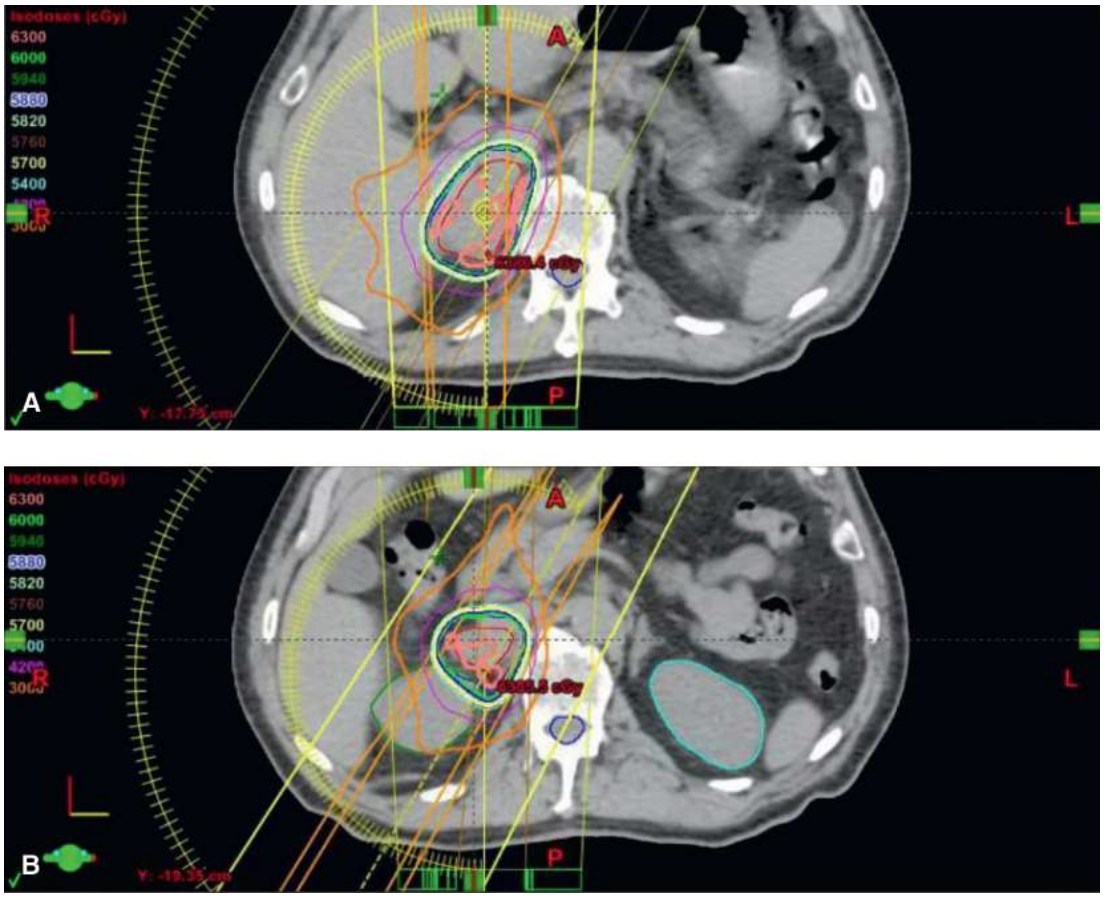

FIGURE 98.2. Axial isodose plots from superior **(A)** and inferior **(B)** aspect of SBRT fields for an adrenal metastasis. This patient was given 50 Gy in 5 fractions.

SPLENIC METASTASES

It is relatively uncommon for solid tumors to metastasize to the spleen. Splenomegaly is more often associated with hematologic malignancies and disorders such as leukemia or myeloproliferative diseases. The spleen can become massively enlarged, causing pain, early satiety, nausea, or emesis. These symptoms may also occur when the spleen is enlarged because of extramedullary hematopoiesis due to marrow failure.[36]

Treatment with radiation therapy can be very effective at reducing the size of the spleen and palliating the other symptoms associated with splenomegaly. The doses required for palliation of symptoms are much lower than the doses

typically used for palliation of other visceral metastases. The response may be quite rapid as well, which necessitates evaluation of the field sizes on a frequent basis. The regimens frequently used include doses of 0.25 to 1 Gy given two to three times per week. It is important to evaluate blood counts on a frequent basis, since anemia and thrombocytopenia may occur rapidly with precipitous drops in the counts over a very short period. A typical regimen is the one reported by McFarland et al.[37] Their patients were treated twice-weekly beginning at 0.5 Gy per fraction the first week, increasing to 0.75 Gy per fraction in the 2nd week and 1 Gy per fraction on the 3rd week. A complete blood count was obtained prior to each treatment. The total dose was typically <5 Gy. Even with these low doses, 14 of 16 patients had subjective improvement in their symptoms, and 12 of 16 patients had objective decrease in the splenomegaly.

A recent systemic review of palliative splenic radiation for the treatment of splenomegaly in the setting of hematologic malignancy showed that the treatment was effective at reducing splenic size, splenic pain, and improving cytopenias. Over the 27 articles reviewed, the average partial response rate was 85%, with 72% of the treatment courses resulting in splenic size reduction, 59% resulting in pain relief, and 78% resulting in improvement in cytopenia. Of the total of 766 treatment courses assessed, 33% resulted in acute toxicities, with the most common being a grade 3 to 4 leukopenia/neutropenia or thrombocytopenia. No long-term toxicities were noted.[38] Treatment of the spleen may cause an abscopal effect as well, with decrease in size of involved lymph nodes distant to the treated spleen.[37]

VAGINAL BLEEDING OR DISCHARGE

Vaginal bleeding is a common symptom at diagnosis in several gynecologic tumors, especially cervical, uterine, and vaginal tumors.[39] The initial treatment should be with vaginal packing.[40] Radiation therapy is also effective at controlling this type of vaginal bleeding. A hypofractionated treatment course is typically used, usually with 2.5 to 4 Gy per fraction. A typical course of treatment would be 30 Gy in 10 fractions.[39] Often, the bleeding will slow or stop after 3 to 5 treatments. The treatment can be continued to definitive doses at that point, using more standard fractionation of 1.8 to 2.0 Gy per fraction (Fig. 98.3). An alternative method of palliating bleeding and vaginal discharge is to use a single large fraction of 10 Gy.[41–43] This will result in a high likelihood of reducing or stopping the bleeding, often within 24 to 48 hours of the first dose.

This dose of 10 Gy can be repeated at 1-month intervals. The risk of complications increases when this dose is repeated a third or fourth time, so this should be limited to one to two fractions.[44]

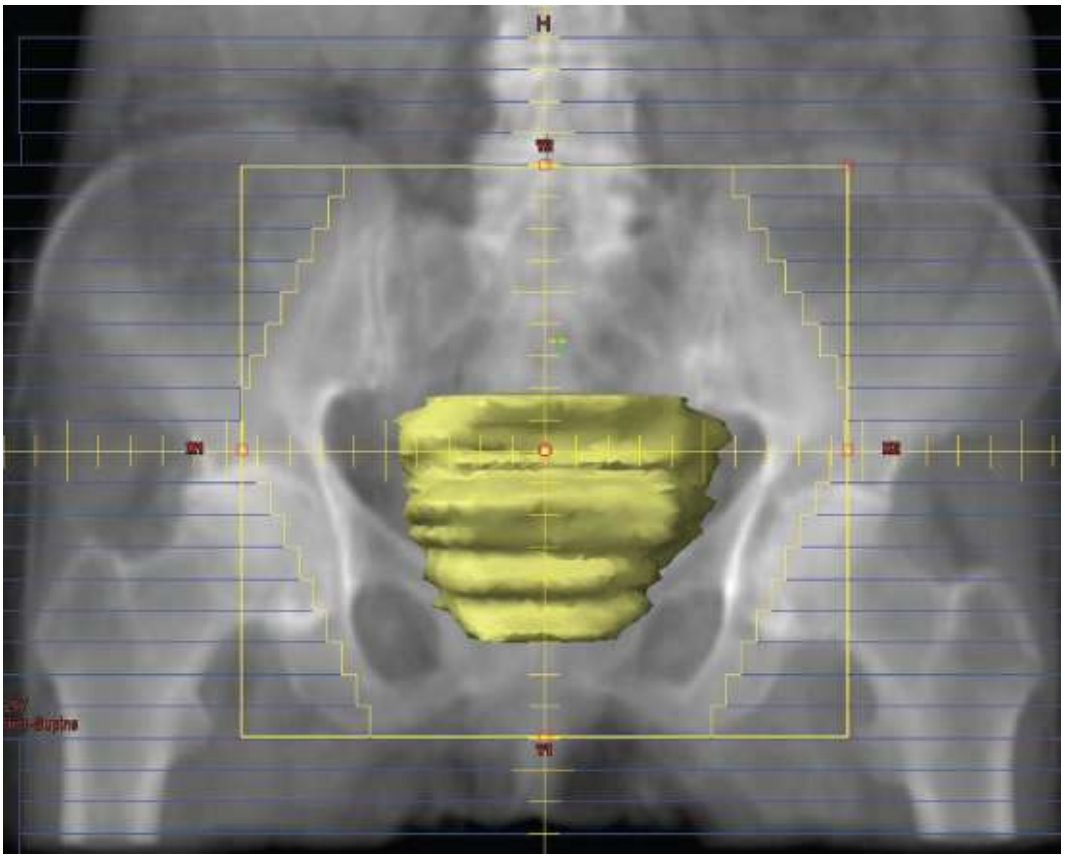

FIGURE 98.3. Digitally reconstructed anterior-posterior radiograph of a palliative pelvic field. This palliative field arrangement would be appropriate to treat a patient with hemorrhage from a cervical or bladder cancer.

PELVIC RECURRENCE

Recurrent pelvic malignancies may cause significant symptoms, including pain, bleeding, or obstruction. The choice of the appropriate palliative treatment depends on multiple factors, including the type and amount of prior treatment. In contrast to palliative treatment of other sites of recurrent disease, aggressive combined modality treatment may provide the best chance of palliation of symptoms for recurrent pelvic malignancies.

Recurrent colorectal cancer may cause life-threatening problems from bowel obstruction. For most patients in this circumstance, surgical intervention is the most appropriate treatment. This may involve complete surgical removal of the

disease, if possible, or a diverting colostomy to alleviate the symptoms of obstruction.[45] There is a high risk of perioperative complications in this group of patients, primarily because it is frequently difficult to perform an adequate bowel preparation prior to surgery.

Hydronephrosis and severe pain may be signs of a more advanced tumor and are relative contraindications to surgical resection.[46] The majority of patients with recurrent rectal cancers have posterior or posterolateral involvement of the pelvis, which makes surgery more difficult.[47] The presence of severe pain may indicate invasion of the sacrum or sacral nerve roots. Tumors that invade these structures are more difficult to resect completely. Melton et al.[48] and Wells et al.[49] reported that patients who underwent an aggressive surgical resection of locally recurrent rectal cancers had a high risk of significant complications. Patients who had sacral resection as part of the surgical treatment had a 42% risk of significant complications.[49]

Patients with bulky pelvic recurrences who have not previously received radiation therapy are appropriate candidates for combined chemotherapy and radiation therapy. A prospective randomized Danish trial evaluated radiation therapy alone (50 Gy in 25 fractions, with a boost of 10 to 20 Gy in 5 to 10 fractions) compared with the same radiation therapy with concomitant weekly bolus dose of 5-fluorouracil.[50] This treatment was given to patients with locally recurrent or inoperable rectal cancers. There was no improvement in survival with the addition of chemotherapy, but there was a higher rate of acute complications (33% with chemotherapy vs. 13% with radiation alone). In several retrospective studies, the addition of chemotherapy was beneficial. Ito et al.[51] reported on 30 patients with symptomatic intrapelvic recurrent rectal cancers. They noted a higher pain relief rate in the patients receiving chemotherapy (100% vs. 77% for radiation alone) and a near doubling of the median survival time (7.8 vs. 4 months). For these patients with locally recurrent rectal cancers, combined modality therapy is usually recommended to improve the likelihood of local control.

Relatively high doses of radiation therapy are required for palliation of symptoms. A review by Wong et al.[52] showed that total dose was important in achieving a response, with the highest responses seen in patients receiving ≥50 Gy. In their series, the patients with the best prognostic factors received higher doses, but the dose–response relationship was still predictive of local control and survival in a multivariate analysis. Bae et al.[53] also found improvement in the rate and duration of symptom control in patients who received higher doses.

They recommended a biologic effective dose >40 Gy_{10} when possible.

Patients who have received prior irradiation and subsequently develop locally recurrent rectal cancer are frequently treated with surgery, chemotherapy, or a combination of the two. However, there are circumstances in which additional radiation therapy may be beneficial. The radiation therapy may be given as hyperfractionated external-beam radiation, intraoperative radiation therapy (IORT), or brachytherapy. Lingareddy et al.[54] utilized hyperfractionation with 1.2 Gy twice a day to a median dose of 30.6 Gy for reirradiation of patients with locally recurrent rectal cancer; these patients had received full-dose pelvic radiation therapy as part of their initial treatment. They used limited fields for the reirradiation, excluding the bladder and small bowels. Most of the patients (90%) received concurrent 5-fluorouracil chemotherapy. There was improvement in pain in 65% of these patients and cessation of bleeding in 100%. The late toxicity of treatment was significantly lower in patients who received hyperfractionated treatment compared to single daily treatments (18% vs. 47%). The most frequent late toxicities were small bowel obstruction (17%) and fistula formation (8%). An Italian prospective study evaluated patients with recurrent rectal cancer who had previously received radiation therapy.[55] Patients with biopsy-proven recurrent disease were given preoperative combined modality treatment, with hyperfractionated radiation therapy (30.6 Gy using 1.2 Gy twice a day, followed by a 10.8 Gy boost also with 1.2 Gy twice a day) and continuous infusion 5-fluorouracil. The patients were then evaluated for resection, and surgery was performed at 4 to 6 weeks following the chemoradiotherapy, when feasible. Fifty-one (86%) of the patients completed the preoperative treatment as planned, and 30 (50.8%) underwent resection. The overall median survival was 42 months, and the 5-year survival was 39%. Seven patients had late grade 3 toxicity, and there were no grade 4 toxicities.

SBRT has shown promising results for treating previously irradiated pelvic cancers; however the majority of the literature is limited to small, single institution studies.[56,57] Dewas et al.[57] reviewed 16 patients with lateral pelvic recurrences of anal, rectal, endometrial or bladder cancer. The patients received reirradiation of 36 Gy over 6 treatments to the lateral pelvic recurrence. The 1-year local control rate was approximately 50%, with a median disease free survival of 8 months, with toxicities limited to ≤grade 2. Defoe et al.[58] reported on 14 patients with presaccral tumors from rectal cancer who received SBRT treatment after prior radiotherapy. The patients were retreated to a dose of 36 Gy over 3 fractions. Local control rates were 91% at 1 year, and 68% at 2 years,

with overall survival of 90% and 79%, respectively. Toxicities were limited to ≤grade 2. Jerezek-Fossa et al. treated 34 patients with recurrent prostate cancer, localized to pelvic lymph nodes. The patients were retreated on average to 30 Gy over 4.5 fractions. About half of the treated patients received androgen deprivation therapy.[59] Biochemical response was noted in 84% of cases. In patients that received SBRT without androgen deprivation therapy, the biochemical response rate was 81%, with a complete prostate-specific antigen (PSA) response rate of 56%. Most toxicity was acute, with 18% of treated patients experiencing acute urinary toxicity, and 3% experiencing acute rectal toxicity. Late urinary toxicity occurred in 20% of patients, and late rectal toxicity in 6%.

Intraoperative radiation therapy may be useful in some patients with locally recurrent rectal cancer. The patients who may benefit from this treatment are those with locally advanced recurrent rectal cancer who have no evidence of metastatic disease. Haddock et al.[60] reported on a series of 51 previously irradiated patients with recurrent rectal cancer who underwent maximal resection followed by intraoperative radiation therapy using electrons. The dose given was 10 to 30 Gy, with a median of 20 Gy. Thirty-seven patients received additional external-beam radiation therapy (median 25.2 Gy) following the surgery and IORT. The 2-year survival rate was 48%, but the 5-year survival rate was only 12%. The local control rate was 60% at 2 years, with a trend toward better local control in patients who received ≥30 Gy external-beam treatment in addition to the IORT (81% local control vs. 54% for those who received no external-beam treatment or doses <30 Gy). The toxicity included peripheral neuropathy in 32% of patients and ureteral narrowing or obstruction in 14%.

Brachytherapy is another alternative method to deliver radiation dose to a relatively limited volume. Alektiar et al.[61] reported on 74 patients with locally recurrent colorectal cancers. The patients underwent surgical resection of the recurrence, followed by high-dose-rate intraoperative brachytherapy, with doses of 10 to 18 Gy. The 5-year overall survival rate was 23% with a 5-year local control rate of 39%. The primary toxicity was peripheral neuropathy, which occurred in 16% of the patients. Patients with negative margins of resection had a higher likelihood of local control compared to those who had positive margins (43% vs. 28%). Kolotas et al.[62] evaluated palliative interstitial high-dose-rate brachytherapy in a group of 38 patients. Only four of the patients had the catheters implanted intraoperatively; most were placed using computed tomography guidance, with the catheters implanted through the perineum or

sacrum. This group of patients had bulky disease at the time of implant. The median survival was 15 months following brachytherapy, with most deaths caused by distant metastases. There was stable disease in 28 of 38 patients, with pain relief in 89.5% of patients.

In summary, palliative radiation therapy is effective in reducing pain or bleeding from recurrent pelvic malignancies. Because of the location and nature of pelvic recurrences, combined modality treatment with chemotherapy, radiation therapy, and surgery may be needed. Relatively high doses of radiation may also be needed to provide the palliative benefits of treatment.

RADIATION THERAPY IN THE SETTING OF OLIGOMETASTATIC DISEASE

As reviewed in the preceding sections, the radiotherapeutic management of metastatic disease has historically been limited to palliation, typically utilizing relatively low overall doses and abbreviated treatment schedules. The goal of this approach has been to provide short- to moderate-term palliation, while limiting treatment-related toxicity and minimizing duration of therapy. Until recently, this paradigm has been generalized to nearly all patients staged as metastatic, with an essentially uniform treatment strategy applied to a widely heterogeneous group of patients, presentations, and disease biology. The paradigm shift of “curative” local therapy, including radiation therapy for select presentations of “oligometastatic” disease, was first proposed by Weichselbaum and Hellman in a 1995 editorial.[63] According to this concept, select patients with controlled locoregional disease and a limited number of metastatic sites may theoretically be cured with definitive local therapy, especially in the setting of effective systemic therapy. During the era of Weichselbaum and Hellman’s writing, limitations in radiotherapy technique precluded effective ablation of most sites of oligometastatic disease without significant toxicity. Furthermore, available systemic therapy was largely ineffective in eliminating microscopic systemic disease. However, interval advances in highly conformal image-guided radiotherapy and the increased efficacy of systemic and molecular therapies have allowed for the translation of this theoretical concept into clinical investigation and practice.

Early investigations of definitive radiation therapy for metastatic disease included isolated metastatic liver disease.[64] Investigators at the University of Michigan first pioneered the paradigm of high-dose three-dimensional conformal

radiation therapy in a cohort of patients that included both primary hepatocellular carcinoma and hepatic metastasis, achieving acceptable local control and toxicity (Fig. 98.4). With the advent of image-guided SBRT, the definitive treatment of isolated hepatic metastasis has been the focus of intense clinical investigation and practice.[65] A multi-institutional phase I and II trial of 47 patients with one to three liver lesions (each <6 cm in size) tested dose-escalated SBRT of 36 to 60 Gy in 3 fractions, reporting a 2-year local control of 92% for all lesions. Local control rates of 100% for lesions ≤3 cm and 77% for lesions >3 cm were also achieved in the 60-Gy cohort. With a median follow-up of 16 months, an overall survival of 20.5 months was reported, with no documented radiation-induced liver disease and grade ≥3 toxicity of 2%.[66] A pooled analysis of 65 patients from three institutions has also demonstrated an excellent efficacy and toxicity profile for SBRT in the definitive treatment of colorectal liver metastasis, recommending a prescription dose of at least 48 Gy for a 3-fraction regiment for optimal local control.[67] More recently, Goodman et al. evaluated the long term safety and efficacy of SBRT treatment for oligometastatic liver disease. Eighty-one patients, with 1 to 3 liver metastases were treated with a median dose of 54 Gy in 3 to 5 fractions. They found that local control was 94% after 33 months, and a partial or complete response was observed in 69% of lesions treated. Grade 3 liver toxicity occurred in 5% of the cases.[33]

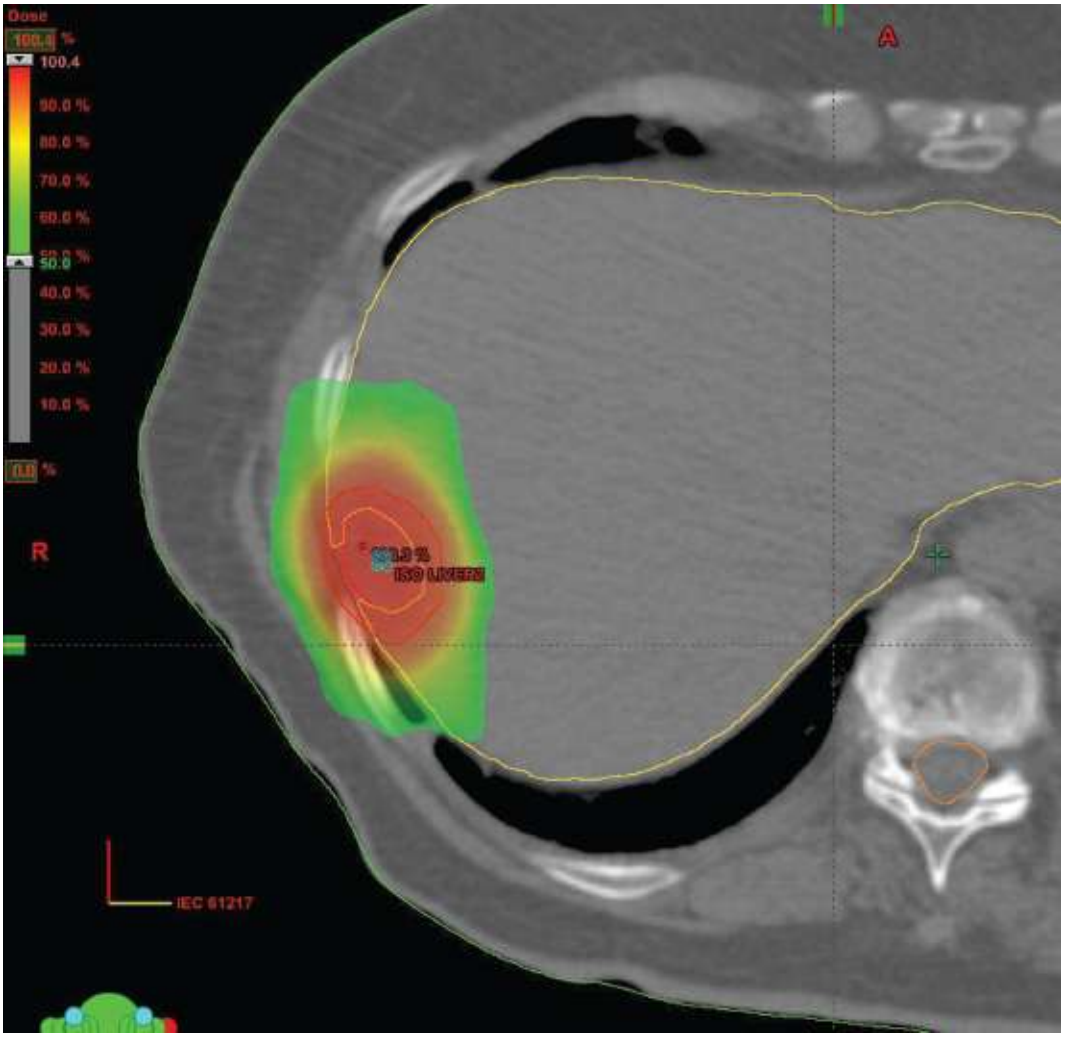

FIGURE 98.4. Axial computed tomography images showing the dose distribution from stereotactic body radiotherapy treatment of a liver metastasis.

With rapid advances in SBRT technique and experience in the definitive treatment of primary lung malignancies, the definitive SBRT treatment of oligometastatic disease involving the lung has also been the subject of numerous clinical reports.[68,69] A multi-institutional phase I and II trial of SBRT for lung metastasis dose-escalated 38 patients with one to three lesions and cumulative maximal tumor diameters of <7 cm from 48 to 60 Gy in 3 fractions. A median survival of 19 months and local control rate of 96% at 2 years were achieved, while symptomatic radiation pneumonitis was uncommon (2.6%) and grade ≥3 toxicity was reported as 8%.[70] A German multi-institutional pooled database of 700 patients with oliogmetastic lung cancer treated with SBRT showed a 2-year local control rate of 81.2% and overall survival rate of 54.4%. Radiation-induced pneumonitis grade 2 or higher was observed in 6.5% of patients.[71]

The curative treatment of oligometastatic sites in addition to lung and liver has also shown promise in published clinical reports. In most series, the oligometastatic state has been defined as one to five sites of metastatic disease, with inconsistent application of primary disease status, overall disease volume, or maximal lesion size as constraints for oligometastatic disease (Fig. 98.5). Investigators from the University of Chicago have reported a dose-escalation trial of 29 patients with one to five sites of metastatic disease, concluding that there was minimal toxicity and potential clinical benefit from this approach.[72] Another prospective study of 121 curative-intent SBRT with five or fewer oligometastatic lesions yielded 4-year survival rates of 28%, progression-free survival of 20%, and local control of 60%.[73] Twenty-nine patients were alive and with no evidence of disease at last follow-up, leading the authors to conclude that “oligometastatic disease is a potentially curable state of distant cancer spread.”

Other investigators have also examined the curative role of oligometastatic disease for specific primary sites of disease. Milano et al.[74] examined the role of curative SBRT for 51 metastatic breast cancer patients, concluding prolonged survival and possible cure for select patients with limited metastatic disease, as well as the utility of palliative-intent SBRT for symptomatic or potentially symptomatic sites. International guideline statements have also addressed the management of select oligometastatic breast cancer patients in consensus recommendations, stating “a small but very important subset of metastatic breast cancer patients, for example those with a solitary metastatic lesion, can achieve complete remission and a long survival.”[75] Similarly, the role of curative SBRT for the treatment of limited metastatic prostate cancer shows promise. Prospective studies have shown good rates of local and PSA control in limited boney and nodal metastatic disease.[76,77]

While these studies show promising results, toxicity from SBRT remains a

significant concern. To address this, an NRG trial (NRG-BR001) is currently underway to investigate recommended treatment doses for oligometastatic non-small cell lung cancer, breast cancer, and prostate cancer. The study is accruing patients with less than or equal to four metastatic lesions, limited to the abdomen and pelvis, central and peripheral lung, mediastinal and cervical lymph nodes, liver, bone, or spine. Results are pending.[78]

Early reports have also documented the potential utility of curative SBRT for oligometastatic disease from gynecological and non–small cell lung primary sites, as well as involved oligometastatic sites such abdominal nodal metastases and adrenal gland metastasis.[79–84]

In summary, SBRT may be beneficial in selected patients with a small number of metastatic sites; these patients should be treated on prospective trials in order to obtain a better understanding of the appropriate use of this technology.

CHAPTER 99

Cancer Pain: Assessment and Management

Esther Yu, Paul Koffer, and Tracy A. Balboni

INTRODUCTION

The most common cancer-related symptom that radiation oncologists are called upon to assess and manage is cancer-related pain. More than half of patients undergoing radiotherapy (RT) experience pain.[1] Notably, majorities of patients and physicians feel that patients' pain is suboptimally controlled[2] highlighting the need for oncologists to have a comprehensive understanding of and facility with cancer pain assessment and management.

PAIN AS A MULTIDIMENSIONAL CONSTRUCT

Pain is a complex symptom that is dynamically related to physical, emotional, social, and spiritual aspects of illness and quality of life. For example, the young parent with metastatic cancer who is struggling emotionally with concerns of how this will impact his/her young children may experience bone pain heralding progressive disease with much greater intensity than a patient who has experienced acceptance of his/her illness. Dame Cicely Saunders, founder of the modern hospice movement, termed this comprehensive concept, "total pain" (Fig. 99.1).[3] Such an approach is critical to holistic pain assessment and management, addressing the multidimensionality of pain and drawing upon multidimensional resources for its mitigation. In the patient examples above, physical strategies to address pain, such as pharmacologic agents and palliative radiation therapy, should be considered together with psychosocial/spiritual assessment and care as part of a comprehensive approach to pain management, an approach discussed further in Chapter 100. Such an approach is fostered by multidisciplinary management of patients with cancer pain, including palliative and psychosocial specialists, social work, and chaplaincy.

PHYSICAL ETIOLOGIES OF CANCER-RELATED PAIN

Though cancer can be asymptomatic within the normal tissues, symptoms arise once sufficient disruption of normal tissues has occurred, with pain being the most common manifestation. Cancer pain has been hypothesized to be multifactorial in its etiology (Fig. 99.2).[4] It is hypothesized to arise from induction of local inflammatory cytokines within the microenvironment with recruitment of inflammatory cells. These in turn promote sensitization and activation of primary afferent neurons. Additionally, cancer pain can arise from mechanical disruption and/or mass effect on normal tissues. This includes normal tissue destruction resulting in pain, such as lytic disease causing bone instability as well as local tissue compression or expansion resulting in pain, such as back pain from malignant spinal cord compression or capsular stretch pain from extensive liver metastases.

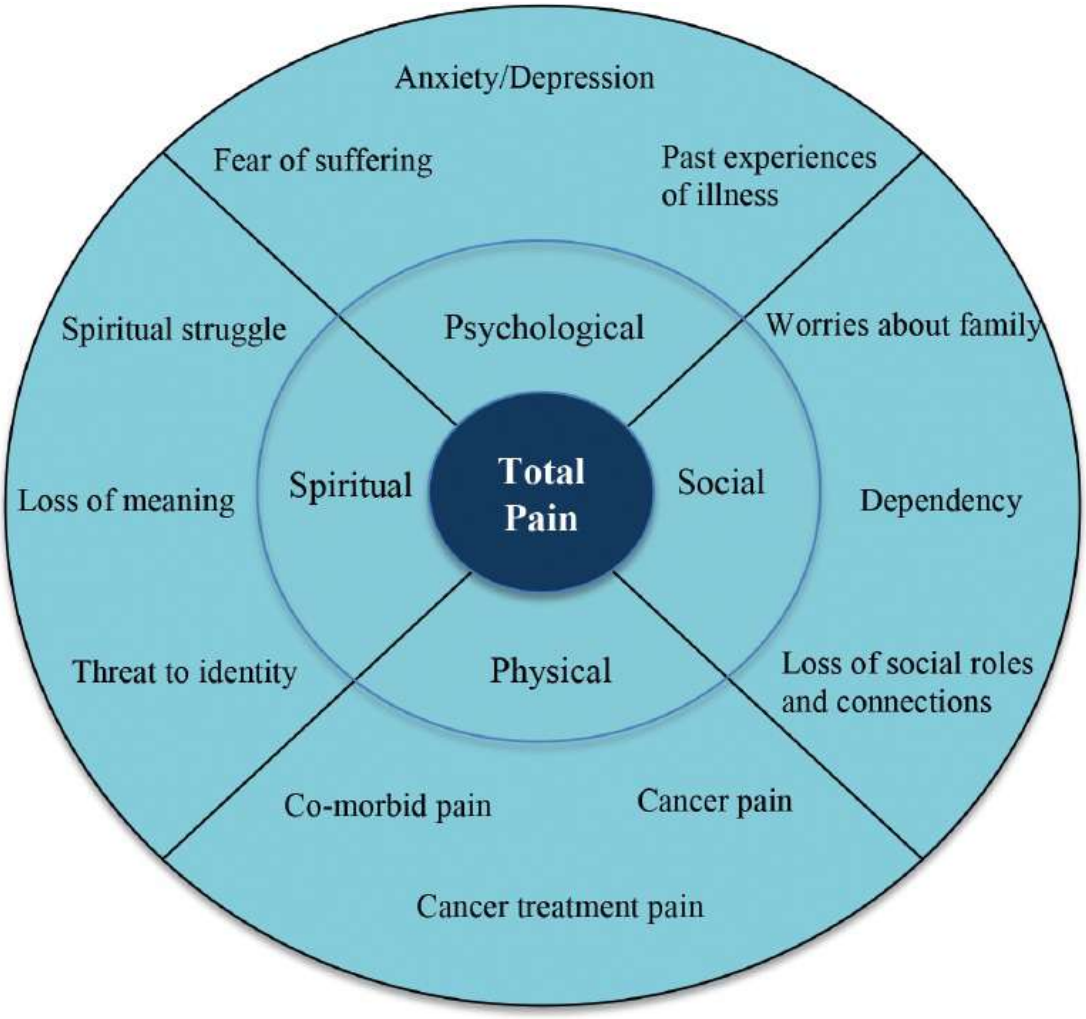

FIGURE 99.1. Dame Cecily Saunders[3] conceptual model of total pain, with examples

of factors contributing to the physical, psychological, social, and spiritual pain domains. (Reprinted by permission from Saunders C. The treatment of intractable pain in terminal cancer. *Proc R Soc Med* 1963;56:195–197. Copyright © 1963 SAGE Publications.)

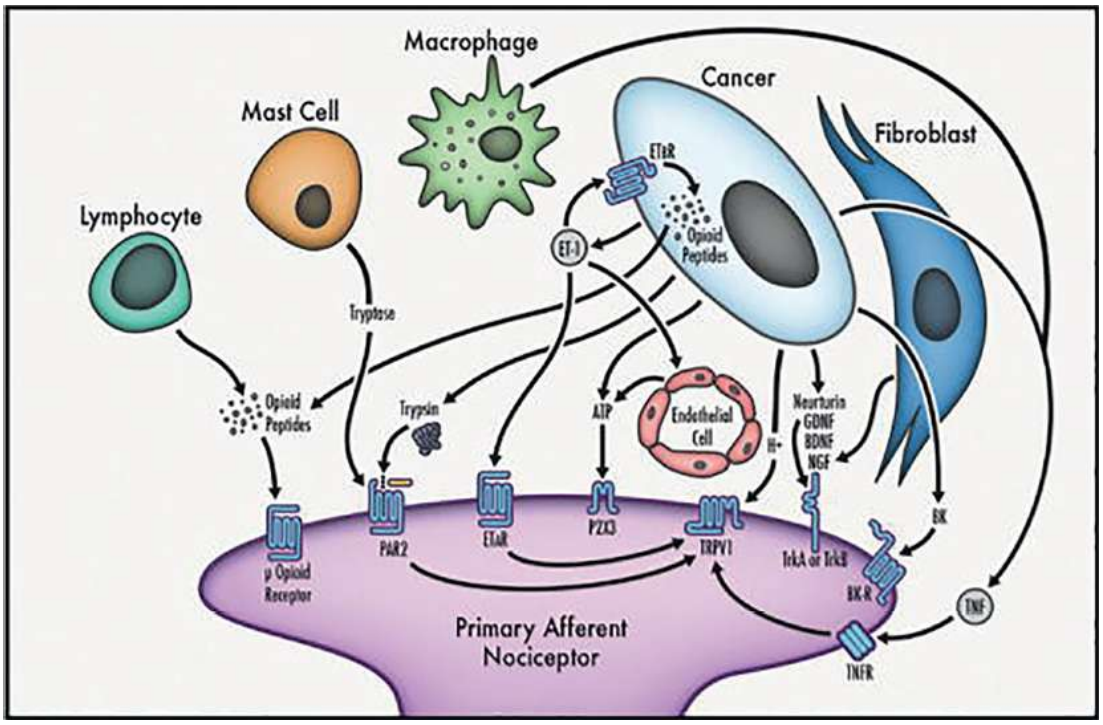

FIGURE 99.2. Schmidt[4] model of the mechanisms of cancer pain. Cancer cells are hypothesized to secrete mediators that sensitize and/or activate primary afferent neurons within the local microenvironment. Cancer cells are posited to secrete chemoattractants that recruit lymphocytes, mast cells, macrophages, and fibroblasts that secrete mediators modulating cancer pain. (Reprinted by permission from Schmidt BL. The neurobiology of cancer pain. *Neuroscientist* 2014;20[5]:546–562. Copyright © 2014 SAGE Publications.)

Cancer-related pain can also result from the delivery of RT and subsequent complications to normal tissues. Acutely, irradiation of normal tissues with a rapid growth rate causes cell death and triggers a cascade of cytokines and thrombotic and growth factors, propagating local painful reactions.[5,6] Examples include RT-related mucositis and dermatitis. RT can also cause pain because of late or chronic tissue damage such as fibrosis and damage to local microvasculature. Pain management in the setting of acute RT toxicities typically requires a strategy conducive to dynamic pain management needs, including

rapid uptitration with gradual downtitration of pain interventions, as symptoms resolve. In the setting of pain related to the long-term effects of RT, pain management strategies should reflect the frequent long-term nature of these pain syndromes given that they often are caused by permanent damage to normal tissues.

This chapter provides an overview of cancer pain assessment, management, and guidelines critical to the practice of radiation oncology. RT is often a valuable component of a treatment plan for cancer-related pain given its efficacy in palliating symptomatic cancers involving bone, nerves, and other soft tissues.[7] The application of RT for the palliation of cancer-related pain and other symptoms is covered in their respective chapters elsewhere in this book.

Types of Cancer-Related Pain

Pain is generally classified as nociceptive or neuropathic or can present as a combination of these pain types. For example, lumbar vertebral body involvement at L1 with tumor compressing the L1 exiting nerve root can cause both local somatic pain (e.g., mid to lower back pain) because of bone involvement by tumor as well as referred neuropathic pain down the L1 dermatomal distribution to the lateral hip. Nociceptive pain refers to the nervous system response that is proportional to the tissue damage initiating the response. Nociceptive pain is subcategorized into somatic pain and visceral pain depending on the location and symptoms of the painful stimulus. Somatic pain generally is a local response to damage to normal tissues such as skin, muscle, or connective tissue. It often presents as a dull or achy pain that is localizable to its source. Conversely, visceral pain is typically due to irritation of viscera (e.g., colic from gallstones) and may be difficult to localize, though it can also have a somatic component. Visceral pain often is characterized as a dull, sharp, and/or cramping pain.

Neuropathic pain results from irritation and activation of peripheral or central nerves. Patients may complain of burning, shooting, tingling, or numbness, which generally occurs along a nerve distribution.[8] Neuropathic pain can result in pain out of proportion to the pain stimulus where there is abnormal pain processing by the peripheral or central nervous system.

Cancer Pain Assessment

All patients should be screened for pain at each point of clinical contact. Typically, screening is performed with the 0 to 10 pain intensity scale. A

comprehensive pain assessment should be performed at initial consultation and at each subsequent evaluation of their ongoing pain management.[9] A comprehensive pain assessment is critical for determining the etiology of pain and for informing strategies for symptom management, both pharmacologically and with local interventions such as radiation therapy. Each type of pain syndrome is amenable to treatment with different modalities. For example, localized, somatic pain may be better treated with nonsteroidal anti-inflammatory drugs (NSAIDs) and/or with opioid medications, whereas neuropathic pain may be more effectively managed with anticonvulsants or antidepressants with or without opiates.

Comprehensive pain assessment should include assessment of the following factors, captured in the acronym “PAINED” to aid in application to clinical practice. Place (P) is assessment of the location of pain, including any pain radiation. Activators (A) are determining factors that make the pain worse, such as positions (e.g., lying down), actions (e.g., walking), or time of day. Intensity and interval (I) are assessment of the intensity of the pain, typically assessed with the 0 to 10 pain scale from 0 (none) to 10 (worst possible pain) together with the interval of time the pain has been present; this includes assessment of changes in pain intensity over time. Asking about the range of pain intensity and intensity changes with aggravating factors can also be informative. Nullifier (N) is assessment of those factors that reduce pain, including analgesics (with full assessment of analgesic types used and quantity), positions and activities reducing pain, or other practices (e.g., meditation). Effect (E) is assessment of the effect of pain on daily activities, including activities of daily living and additional activities important to the patient (e.g., being able to pick up a grandchild). Finally, description (D) is assessment of the quality of the pain in the patient’s own words (e.g., dull, stabbing, aching, burning).

Assessment of the patient goals for pain management (e.g., activity goals) and evaluation of risk factors for opioid misuse and diversion are also important to determine an optimal strategy for pain management. Risk factors include a prior history of drug or alcohol abuse, family history of substance abuse, history of psychiatric disorders (e.g., anxiety, depression, posttraumatic stress disorder [PTSD]), history of legal problems or incarceration, and age < 45 years.[9] In patients with risk factors, referrals to clinicians with experience in managing pain in high-risk patients, such as palliative medicine specialists, should be considered. All patients given opiates should be educated regarding safe use, storage, and disposal of opiates.

Cancer Pain Management

A comprehensive pain assessment guides the application of workup and treatment strategies. For example, a patient with metastatic cancer and low back pain radiating to the lower extremities should have a magnetic resonance imaging (MRI) of the spine to assess for possible etiology of cord/cauda compression, with the treatment strategy based on the etiology. Wherever possible, the etiology of the pain should be addressed (e.g., radiation therapy for bone metastasis–related pain) in addition to pharmacologic intervention. The roles of radiation therapy in alleviating cancer-related pain are addressed elsewhere. Herein, guidelines to approach pharmacologic and other non–cancer-directed therapies to alleviate pain are outlined.

GUIDELINES FOR PAIN MANAGEMENT

Many national and international organizations have developed guidelines for pain management. Despite variations in the details, the principles and approaches are consistent across guidelines. The World Health Organization (WHO), American Pain Society (APS), and National Comprehensive Cancer Network (NCCN) guidelines are discussed here.

WHO Pain Ladder. The WHO guidelines for analgesic management of cancer pain, first described in the early 1980s,[10,11] consist of a three-step approach that has been validated in clinical trials.[12] Despite some debate on its effectiveness,[13] it establishes a widely practiced, stepwise approach in the treatment of various levels of pain severity.

TABLE 99.1 GUIDE TO COMMON NONOPIATE MEDICATIONS AND STARTING DOSES FOR ADULTS

Medication	Starting Dose (Maximum Daily Dose in mg)
Acetaminophen	500, 3–4 × day (4,000)
Nonsteroidal anti-inflammatory drugs	
Aspirin	325, 3–4 × day (4,000)
Ibuprofen	200, 3 × day (2,400)
Naproxen	250, 2 × day (1,250)
Ketorolac	IV 15–30 up to 4 doses
Diclofenac	50, 3 × day (150 mg)
Specific COX-2 inhibitors	
Celecoxib	100, 2 × day (400–800)

COX-2, cyclooxygenase-2; IV, intravenous.

The first tier involves the use of nonopiate medications, primarily NSAIDs (Table 99.1). These medications include acetaminophen, nonspecific cyclooxygenase inhibitors (including ibuprofen, diclofenac, aspirin), and cyclooxygenase-2 inhibitors (celecoxib).[14] NSAIDs are considered the first group of medications to administer. If the patient's pain persists or worsens, the second tier adds a weak opioid in addition to the nonopiate. Finally, continued treatment for worsening pain includes the addition of a strong opioid to replace the weak opiate, the third tier (Table 99.2).

Five simple principles are recommended to make the pharmacologic treatments effective: (a) Oral administration of analgesics should be used whenever possible; (b) analgesics should be given at regular intervals; (c) analgesics should be prescribed according to pain intensity as evaluated with a pain scale; (d) dosing of analgesics should be adapted to the individual; and (e) analgesics should be prescribed with a constant concern for detail.[17]

Over time, adaptations of the WHO ladder have been proposed. In refractory pain or crises of chronic pain, a fourth step may be considered. This fourth step includes invasive techniques such as nerve blocks, neurolysis, or surgical or other interventions.[10,18] Adjuvant medications including steroids, anxiolytics, antidepressants, hypnotics, anticonvulsants, antiepileptic-like gabapentinoids (gabapentin and pregabalin), membrane stabilizers, sodium channel blockers, *N*-methyl-D-aspartate receptor antagonists, and cannabinoids may be used in the treatment of neuropathic pain.[19,20]

APS and NCCN Guidelines. Although the WHO guidelines are a good initial step in pain management, other organizations have expanded these strategies to improve treatment for cancer pain. These guides provide initial medication dosages, the addition of adjuvant medications, and information on appropriate dose increases, allowing the radiation oncologist to further develop pain management skills.

TABLE 99.2 Guide to Common Weak and Strong Opioid Medications and Potential Starting Doses[a]

Opioid	PO Starting Dose (mg)	PO Conversion (mg)	IV Conversion (mg)
Weak			
Tramadol	50, 2–3 × day	—	—
Codeine	30, 4–6 × day	—	—

Hydrocodone	5, 4–6 × day	—	—
Strong			
Morphine	15, 4–6 × day	30	10
Hydromorphone	2–4, 4–6 × day	8	2
Methadone	2.5–5, 2–3 × day	2	1
Fentanyl	Transdermal 25 μg/d	NA	0.2
Oxycodone	5–15, 4–6 × day	20	NA

[a]Opiate medication must be titrated for adequate pain relief and minimal side effects. For the strong opiates, equivalent doses for conversion are given, with methadone IV as the base dose of 1 mg.[9,15,16] The conversion factors can be used to change PO or IV doses among the different opiates (i.e., 2 mg of PO methadone is roughly equivalent to 30 mg of PO morphine). Similarly, 2 mg of PO methadone is equivalent to 1 mg of IV methadone. When changing from one opiate to another, a reduction factor is sometimes applied (usually 25% to 50% of the original medication's dose) because of less tolerance to the new medication. For example, if a patient is using 60 mg of PO morphine every 4 hours, an equivalent oxycodone dose may be 40 mg × a 50% reduction, leading to 20 mg every 4 hours.
IV, intravenous; NA, not applicable; PO, by mouth.

The 2005 APS *Guideline for the Management of Cancer Pain in Adults and Children* contains detailed discussions of cancer pain management algorithms, pharmacologic strategies, coanalgesics, psychological strategies, supportive therapy, integration of nonpharmacologic and pharmacologic treatments, physical strategies, nerve blocks, surgical strategies, radiation therapy, chemotherapy, and pain management in special populations. It also discusses patient education and the importance of patients' adherence to the pain management plan as well as how to improve quality of care in pain management.[21]

The latest (2017) NCCN guidelines[9] for adult cancer pain outline the following management principles: (a) Patients should be screened for pain at each point of contact; (b) pain intensity must be quantified and quality described by the patient whenever possible; (c) a formal comprehensive pain assessment must be performed for new or worsening pain; (d) reassessment of pain intensity must be performed at specified intervals to ensure that the therapy selected is having the desired effect; (e) education must be provided to the patient to ensure safe use and disposal of opiates and other analgesics; and (f) all patients should be screened for potential opiate misuse, abuse, or diversion. The guidelines provide specific suggestions for dosing of NSAIDs, opioids, and coanalgesics, as well as titrating and rotating of opioids, escalating of opioid dosage, managing opioid adverse effects, and deciding when and how to proceed to other techniques/interventions for the management of cancer pain.

Role of Oncologists and Pain Specialists in Managing Cancer-Related Pain

Radiation oncologists, together with other oncology clinical practitioners, are responsible for assessing and managing pain for their patients by utilizing the guidelines as noted above. However, this raises the question of when to call upon palliative medicine or acute pain specialists in pain management. Randomized trials have shown a quality of life benefit of early involvement of palliative medicine clinicians in the care of cancer patients, and hence, American Society of Clinical Oncology recommendations call for the early integration of palliative care into standard oncology care.[22] Oncologists should have a low threshold to call upon palliative care providers to guide pain management strategies, particularly in the setting of refractory pain, complex pain syndromes, and/or difficult-to-manage side effects. Integration of palliative medicine into oncology care, and when to refer patients to palliative medicine specialists, is discussed in more detail in Chapter 100.

Routes of Administration

Chemotherapy, surgery, and RT often produce significant side effects that can limit oral administration of pain medications. Furthermore, cancer-related pain can be so severe that acute pain management requires hospital admission and intravenous (IV) pain medication administration. Both opiate and nonopiate pain medications come in formulations that can be delivered via nonoral routes such as transdermal, IV, or rectal. When changing from oral to another delivery mode, care must be taken to give equipotent analgesic doses. Conversion charts for opioids are readily available in the literature.[23] When switching opiate agents, a 25% to 50% dose reduction should be applied to account for incomplete cross tolerance between distinct opioid agents. Such complicated pain management scenarios may require an inpatient stay and/or the assistance of pain management specialists.

Opiate Side Effects

Treating a patient's pain is a balance of maximizing analgesic effects and minimizing side effects.[24] Common opioid side effects include gastrointestinal (constipation, nausea, and emesis), respiratory (decreased respiratory rate), dermatologic (pruritus and dry mouth), and peripheral/central nervous system (myoclonus, sedation, hallucinations, and seizures) effects.

General management strategies include the pharmacologic treatment of the

side effects. These include the standard inclusion of strategies to mitigate constipation such as high water intake, dietary fiber, and a daily regimen of stool softeners and laxatives. Consideration of peripherally acting opioid antagonist methylnaltrexone is made in the case of constipation refractory to these measures. Nausea can be mitigated through the use of antiemetics, though care must be taken in the use of antiemetics that can cause constipation such as ondansetron. Another important opiate side effect mitigation strategy is to reduce the dose of opiates required to achieve analgesia through the use of adjunctive medications for pain management, including agents such as glucocorticoids, anticonvulsants, and antidepressants. These medications are discussed further in the next section. A third strategy is opioid rotation as some opiate side effects such as pruritis and myoclonus can be mitigated by rotating to another opioid agent. Opioid rotation should follow the principles of an approximate 25% to 50% dose reduction based on an equianalgesic table given incomplete cross-tolerance of different opiate agents.[9]

Adjuvant Therapies and Interventions for Pain Management

Using the WHO ladder, pain related to cancer can be managed with oral medications in 70% to 85% of patients.[12,25] At any point on the WHO analgesic ladder, adjuvant therapy can be initiated to supplement NSAIDs and opioid treatment. Benefits of adjuvant therapy include use of medications tailored to specific causes of nociceptive responses (i.e., neuropathic pain) and reduction of opiate side effects.

Adjuvant Therapies in Neuropathic Pain

Because neuropathic pain often is not responsive to opioid medications unless high doses are applied, other classes of medications often are prescribed.[26] Glucocorticoids (e.g., dexamethasone) are effective for the short-term management of tumor-related neuropathic pain and often are the initial agent of choice when managing neuropathic pain while awaiting an anticipated response to palliative RT. If glucocorticoids are insufficient to control neuropathic pain, and/or palliative RT does not sufficiently resolve neuropathic pain symptoms, typically anticonvulsants or antidepressants are considered.

Anticonvulsants such as gabapentin, carbamazepine, and pregabalin are effective in managing neuropathic symptoms.[8] Both gabapentin and pregabalin are renally excreted and have minimal drug–drug interactions, which renders these medications effective first-line treatments for neuropathic pain.[8] Like

anticonvulsants, antidepressants are a broad category of medications that stabilize neurons involved in neuropathic pain. Tricyclic antidepressants in low doses, such as amitriptyline, have been well-studied and can be effective for pain relief.[27] Serotonin reuptake inhibitors and newer classes of antidepressants, including selective serotonin and norepinephrine reuptake inhibitors (milnacipran, duloxetine, and venlafaxine), are less well-studied but are often prescribed for neuropathic pain. Because many patients with neuropathic pain experience depression or anxiety, antidepressants may play a dual treatment role and improve efficacy of pain control.[27]

Topical agents can also be effective in management of neuropathic pain and often have minimal side effects. These include capsaicin cream and transdermal lidocaine, both found to be effective in the management of neuropathic pain.[28–30]

Muscle relaxants are another class of agents that can be used both in neuropathic pain and other pain syndromes. Because painful muscle spasm can add to the pain etiology in both neuropathic and other pain syndromes (e.g., somatic pain from vertebral body fracture), muscle relaxants can have a role in mitigating pain in this setting. Agents typically used include baclofen and cyclobenzaprine.

TABLE 99.3 COMMON ADJUVANT MEDICATIONS WITH STARTING DOSAGES AND COMMON SIDE EFFECTS

Medication	Starting Dose (PO unless Otherwise Specified; mg)	Significant Side Effects
Antidepressants		
Amitriptyline	10–25 at night	Cardiac, CNS
Nortriptyline	10–25 at night	Cardiac, CNS
Venlafaxine	37.5 every day	CNS
Duloxetine	60 every day	Nausea, somnolence
Anticonvulsants		
Gabapentin	100, 3 × day	CNS, sedation
Carbamazepine	100, 2 × day	Bone marrow, liver, CNS
Pregabalin	75, 2 × day	CNS, sedation
Topicals		
Lidocaine 5%	1–3 patches for 12 h	CNS, cardiac
Capsaicin	0.025% cream	Burning
Muscle relaxants		
Baclofen	5, 3 × day	CNS

Cyclobenzaprine	5, 3 × day	Drowsiness, dry mouth
Tizanidine	2 every night (4 mg tid)	Weakness, dry mouth
N-Methyl-D-aspartate antagonist		
Ketamine	Intravenous infusion	Hallucinations, CNS

PO, by mouth; tid, three times a day.

Finally, agents that antagonize the NMDA (*N*-methyl-D-aspartate) receptor are also considered in the management of neuropathic pain; however, prescription of these medications is typically limited to pain specialists. The NMDA receptor has a role in modulating pain signals throughout the nervous system. Methadone is a long-acting opioid receptor antagonist, which is hypothesized to also act as an NMDA receptor antagonist, preventing morphine tolerance and NMDA hyperalgesia effects.[31] Ketamine, a specific NMDA receptor antagonist, is also employed by pain management specialists to relieve cancer and neuropathic pain, especially refractory pain.[32]

Other adjuvant analgesic drug classes used in cancer therapy include local anesthetics, steroids, muscle relaxants, benzodiazepines, α-adrenergic agonists, and bisphosphonates.[32] In recent years, there has been a resurgence in clinical trials of cannabis extracts and analogs in the treatment of refractory cancer pain.[33] Many of these medications are used in specific pain syndromes, which may be useful for the radiation oncologist (Table 99.3).

INTERVENTIONAL PAIN MANAGEMENT STRATEGIES

Although most cancer pain can be managed medically, some patients require interventional procedures to achieve pain relief. Such interventions include neuroablative techniques and implantable neuroaxial drug delivery devices. These strategies should be considered in patients with refractory pain despite pharmacologic management via traditional administration routes (e.g., oral) escalated according to WHO guidelines or among patients with severe side effects despite optimization of pharmacologic agents.

Neuroablative Techniques

Neuroablative techniques can be excellent options for patients who have pain along discrete nerve distributions when chronic and/or insufficiently controlled by conventional systemic pharmacologic management. Interventional pain management specialists offer a myriad of neurolytic procedures that can be

highly efficacious and can reduce or even obviate the need for systemic pharmacologic pain medications.

Common nerves targeted include intercostal nerves for thoracic chest wall or abdominal wall pain, maxillary and mandibular nerves for facial pain, and median branch nerves for facet arthropathy.[34] Cryoanalgesia techniques apply subzero temperatures to induce wallerian degeneration of neurons while allowing normal regrowth of axons. Radiofrequency techniques use heat to induce nerve damage. Chemical neurolysis can be achieved with phenol or alcohol preparations.

Pain signals initiating from the perineal, pelvic, and abdominal regions may be transmitted via visceral afferents following the sympathetic nervous system. Along with these fibers, the sympathetic nerves coalesce at specific ganglia (impar, superior and inferior hypogastric, and celiac plexus). At these sites, image-guided neurolytic procedures can be performed.[35] When pain fibers are destroyed in this process, the associated region is also sympathetically denervated.

Implantable Neuroaxial Drug Delivery Devices

Implantable neuroaxial drug delivery devices are indicated when oral opioid doses are escalated without sufficient pain relief and/or when side effects are intolerable.[36] Either semipermanent epidural systems or permanent intrathecal delivery systems can be used to deliver local anesthetic and opiate medications in low concentrations to appropriate spinal cord root levels.[37] The benefits of these methods include decreased side effects than systemic pain pharmacologic agents and often superior pain control.[38]

Electrostimulation techniques also may be applied to disrupt the flow of pain signals in the spinal cord. Transcutaneous electrical nerve stimulation, spinal cord stimulation at thoracic and lumbar regions, and deep brain stimulation at the thalamus or motor cortex can interfere with the conduction of pain signals.[39] The stimulation of large motor fibers inhibits the conduction of pain signals by small nerve fibers and has shown efficacy for various pain syndromes.[40]

Neurosurgical techniques are generally reserved for refractory pain and specific indications. Plexus root avulsions may be responsive to dorsal root entry zone lesioning, but the indications and success rates are limited.[41] More specific lesions at the spinal cord and central nervous system (e.g., thalamotomy and deep brain stimulation) have also been used with variable success and significant side effects.[42] Finally, various chemoneurolytic medications can be delivered

intrathecally for destruction of specific nerve roots or parts of the spinal cord for the treatment of refractory cancer pain.[43]

COMPLEMENTARY THERAPIES

Conventional medical regimens may not satisfactorily treat cancer-related pain syndromes. Several complementary modalities such as hypnosis, biofeedback, massage, music therapy, mind–body exercises, and dietary supplementation have been shown to reduce anxiety and chronic pain,[44] yet more multi-institutional, randomized, controlled trials are needed to confirm their efficacy in this setting.[45]

Acupuncture is perhaps the most extensively studied alternative method for pain control.[46] Acupuncture can relieve both acute pain (e.g., postoperative dental pain) and chronic pain (e.g., headache, osteoarthritis).[47–49] Acupuncture also appears effective against cancer-related pain. A randomized, placebo-controlled trial tested auricular acupuncture for patients with cancer pain despite medication. Pain intensity decreased by 36% at 2 months from baseline in the treatment group, a statistically significant difference compared with the two control groups for whom little pain reduction was seen.[50] Most patients in this study had neuropathic pain, which is often refractory to conventional treatment. Neurophysiologic studies show that acupuncture-induced analgesia appears to be mediated by endogenous opioids and other neurotransmitters.[51] Functional brain imaging studies suggest that acupuncture also modulates the affective–cognitive aspect of pain perception.[52] Correlations between functional magnetic resonance imaging signal intensities and analgesic effects induced by acupuncture have been reported.[53]

SPECIFIC SCENARIOS FOR THE RADIATION ONCOLOGIST

The following section identifies some common pain scenarios and syndromes specific to the setting of radiation oncology and proposes strategies for their management. As previously noted, radiation oncologists are generalist palliative care providers who should readily reach out for the expertise of pain specialists (e.g., palliative medicine and anesthesia pain services) to ensure optimal pain control and quality of life for their patients.

Pain during Radiotherapy Planning and Treatment

Radiation oncologists regularly encounter patients who cannot tolerate RT

positioning secondary to pain. The first goal should be to optimize treatment positioning and to decrease time on the treatment table to minimize pain. Often, simple modifications in treatment setup (e.g., cushion under the knees and/or neck), where feasible without compromising radiation delivery, can greatly mitigate incident pain. Next, overall pain management using the aforementioned guidelines should be optimized. Premedication with additional dosing of the breakthrough pain agent such as short-acting opiates approximately 1 hour prior to the simulation or treatment should be performed to anticipate incident pain. Not infrequently, patients will require IV pharmacologic management as an inpatient and hence IV premedication can be given. For such inpatients with severe pain, pain specialists should be involved to optimize pain management using specialized strategies. Among patients with pain that is severe only with the positioning and who may become overmedicated with traditional short-acting opiates, fast-acting opiates can also be considered. For example, transmucosal preparations of fentanyl are optimal because of their pharmacologic properties of fast onset and resolution of effect.

Mucositis and Proctitis

Pain associated with mucositis (up to 75% of patients treated with radiation) can be debilitating and, if not sufficiently controlled, may result in treatment delays and/or dose limitations of RT.[54] Pain control strategies for patients with mucositis follow the aforementioned pain management guidelines, but with some adaptations given the particular needs of this patient population. Topical analgesics, such as viscous lidocaine preparations (e.g., 1:1:1 solution of magnesium and aluminum hydroxide, diphenhydramine, and lidocaine), can provide relief from incident pain when swallowing.[55] When systemic pain management is required, often liquid short-acting opiate preparations and transdermal long-acting agents (e.g., fentanyl patch) are required given difficulty swallowing pills. Mucositis prevention and management will be discussed in greater detail in Chapter 100.

Similar to oral mucosa, the rectum is susceptible to acute and chronic proctitis, with patients typically presenting with tenesmus and rectal pain. In addition to systemic pain control, topical-directed therapies are often used in this setting, including hydrocortisone topical preparations and the use of sucralfate.[56] Management of constipation and diarrhea is also critical in these patients as either can worsen local irritation. Acute proctitis in the setting of RT most often heals within several weeks of RT completion without clinical sequelae, but

particularly among patients receiving high-dose RT to the rectum, chronic proctitis can occur. These patients have chronic mucosal irritation that can be painful with rectal mucosal thinning and aberrant blood vessel formation that can result in rectal bleeding. Novel therapies, including hyperbaric oxygen and laser therapy, have been used successfully to heal rectal mucosa and reduce associated symptoms.[57–59]

Plexopathy

Nerve plexopathies are a frequent problem encountered by radiation oncologists, often because of tumor involving the nerve plexus. This scenario is typically managed with radiation therapy directed at the culprit tumor site for palliation together with the aforementioned pharmacologic processes for managing neuropathic pain. Though less common, radiation therapy can also cause plexopathies. Similar to muscle fibers, nerve bundles exposed to dose equivalents of more than approximately 60 Gy in 2 Gy fractions undergo significant decreases in large nerve fiber density.[60] Significant pain may ensue months to years after RT, especially in the brachial plexus distribution.[61] Rates of radiation-induced plexopathy range from 1% to 5% in selected patient populations. Among these patients, 10% will have complicated pain syndromes.[62] Treatments involve physical and occupational therapy, together with pain management strategies, generally overseen by a pain specialist. Typical strategies include multimodality pain regimens (opioid and neuropathic pain medications as previously discussed), with consideration of interventional pain procedures and other novel interventions.[63]

Radiation-Related Muscle Spasm

Muscle fibers, once thought to be radioresistant, may undergo significant change, especially months to years after radiation exposure.[64] One-time muscle exposures to 10 to 20 Gy or fractionated doses >55 Gy are associated with myokymia, pain, and decreased muscle strength and range of motion.[64] Specific cancer locations susceptible to muscle complications include head and neck cancers and soft tissue cancers (e.g., Ewing sarcoma).[64] Treatment regimen includes early physical therapy and orthopedic exercises and pharmacologic therapy such as muscle relaxants such as baclofen or cyclobenzaprine. Novel treatments involve the use of botulinum toxin injected in small doses (15 to 25 units) into the muscle to relieve contracture or spasm.[65,66]

Summary

Pain is a common problem in patients with advanced cancer. RT is frequently utilized to treat pain caused by the underlying cancer. A multimodal management approach should be applied, starting with oral analgesics administered according to clinical practice guidelines, with simultaneous attention to the psychosocial and spiritual aspects of pain and illness. For patients who experience refractory pain despite medical management according to pain management guidelines, pain specialists (e.g., palliative medicine and/or anesthesia pain services) should be involved and specialty pain interventions (e.g., interventional procedures) considered, where applicable. Complementary therapies may be helpful in some patients, although their efficacy has not been definitively established.

CHAPTER 100

Palliative and Supportive Care

Paul Koffer, Esther Yu, and Tracy A. Balboni

INTRODUCTION: PALLIATIVE AND SUPPORTIVE CARE IN ONCOLOGY

Definitions

The National Consensus Project defines palliative care as "patient and family-centered care that optimizes quality of life by anticipating, preventing, and treating suffering. Palliative care throughout the continuum of illness involves addressing physical, intellectual, emotional, social, and spiritual needs and to facilitate patient autonomy, access to information, and choice."[1] Palliative care may be delivered in a variety of settings including inpatient and outpatient care as well as throughout the patient's disease course, from initial diagnosis to the end of life. The National Consensus Project has defined eight domains of palliative care (Table 100.1) critical to quality palliative care provision.

Palliative care delivered in definitive cancer care settings is at times separately referred to as "supportive care." Furthermore, in some cancer care settings, regardless of the treatment intent, the term "supportive care" is used. To ensure clarity and comprehensiveness, this chapter defines "palliative and supportive care" as care that addresses the biopsychosocial and spiritual dimensions of patient quality of life throughout the cancer care continuum.

TABLE 100.1 Domains from the National Consensus Project Guidelines[a]

NCP Domain	Domain Description
Domain 1: Structure and Processes of Care	This domain addresses interdisciplinary team engagement and collaboration with patients and families, with an emphasis on coordinated assessment and continuity of care across healthcare settings. Clarity and specificity of interdisciplinary composition, team member qualifications, necessary education, training, and support are described. This section includes quality assessment process and improvement according to the mandates under

	the Patient Protection and Affordable Care Act.
Domain 2: Physical Aspects of Care	This domain addresses the assessment of physical symptoms with appropriate, validated tools and the multidimensional management of symptoms with pharmacological, interventional, behavioral, and complementary interventions. Explicit policies for the treatment of pain and symptom management and safe prescribing of controlled medications are recommended.
Domain 3: Psychological and Psychiatric Aspects of Care	This domain addresses the collaborative assessment process for psychological concerns and psychiatric diagnoses. Essential elements are described and include patient–family communication on assessment, diagnosis, and treatment options for common conditions in context of respect for goals of care of the patient and family. The domain also includes description and required elements of a bereavement program.
Domain 4: Social Aspects of Care	This domain addresses interdisciplinary engagement and collaboration with patients and families to identify, support, and capitalize on patient and family strengths. The essential elements of a palliative care social assessment are defined. The role of the professional social worker (e.g., with a bachelor's or master's degree) is described.
Domain 5: Spiritual, Religious, and Existential Aspects of Care	This domain defines spirituality and describes assessment, access, and staff collaboration in attending to spiritual concerns throughout the illness trajectory. Requirements for staff training and education are set forth, and responsibility of the interdisciplinary team—including a chaplain—to explore, assess, and attend to spiritual issues of patients and families are discussed. Spiritual and religious rituals and practices to promote comfort are promoted.
Domain 6: Cultural Aspects of Care	This domain defines culture and cultural competence for the interdisciplinary team, with culture understood as a source of resilience and strength for patients and families. This domain accentuates cultural and linguistic competence using plain language, literacy, and linguistically appropriate care delivery.
Domain 7: Care of the Patient at the End of Life	This domain highlights communication and documentation of signs and symptoms of the dying process for the patient, the family, and involved health providers. Meticulous assessment and management of patient pain and other symptoms and attention to family guidance as to what to expect in the dying process and post death period are emphasized. Bereavement support, beginning with anticipatory grief, is emphasized, together with social, spiritual, and cultural aspects of care throughout the dying process.
Domain 8: Ethical and Legal Aspects of Care	This domain is subdivided into advance care planning, ethics, and legal aspects of care. Under advance care planning, the responsibilities of palliative care teams to promote ongoing discussion regarding goals of care together with completion and documentation of advance care planning. In ethical issues, the frequency and complexity of ethics issues are acknowledged and team competencies in identifying and resolving commonly encountered ethical issues are described. The importance of seeking guidance from ethical committees is also emphasized. Finally, under legal issues, the complex legal and regulatory issues in palliative care are acknowledged, together with an emphasis on team members understanding scope of practice within the provision of palliative care. There is also an emphasis on the necessity of and access to expert legal counsel that are essential to navigating the intricate and sensitive legal and

regulatory issues in palliative care.

EVIDENCE AND CLINICAL GUIDELINES: PALLIATIVE CARE IN ONCOLOGY

In the oncology setting, there is a strong body of evidence supporting the integration of specialty palliative care into oncology care. The American Society of Clinical Oncology (ASCO) set forth the 2012 ASCO Provisional Clinical Opinion based on the randomized controlled trial by Temel et al.[2] This study of 151 advanced lung cancer patients randomized to receive either concurrent palliative care at the time of diagnosis or usual care showed that integration of palliative care into oncology care resulted in better quality of life and fewer depressive symptoms. Additionally, despite receiving less aggressive medical interventions, patients randomized to early palliative care had longer median survival.[2] A survival benefit was also seen in the ENABLE III trial, which randomized patients to early or delayed palliative care. Survival at 1 year was 63% for patients who enrolled early versus 48% for those who enrolled 3 months later.[3] Caregivers may also experience lower levels of depression and stress burden with early enrollment.[4] In the realm of everyday life, early consultation can improve symptom severity and ongoing quality of life for patients.[5] These studies clearly demonstrate that early initiation of palliative care has wide-ranging benefits for patients and caregivers.

Based on these findings and others, ASCO set forth the 2017 ASCO Clinical Practice Guideline Update.[6] These guidelines call for the early integration of palliative care in the treatment of advanced cancer patients and incorporation of palliative care for patients across the cancer care trajectory with attention to triggers based on regular screening for palliative and supportive care needs.

The ASCO Clinical Practice Guidelines call for oncologists to act as generalist providers of palliative and supportive care.[6] Specific to radiation oncology, radiation oncologists provide specialty expertise in the use of radiation therapy for the management of cancers, both definitively and palliatively. Together with this specialist role, radiation oncologists must have a basic competency in addressing the aforementioned domains of palliative and

supportive care that can arise at all phases of cancer treatment. Palliative medicine teams may then be viewed as corresponding specialist providers working in tandem with the oncology team. Notably, some cancer care centers do not have ready access to palliative care teams. In this setting, the oncology care team is called upon to gain more in-depth facility in providing palliative and supportive care. Though advocacy for establishment of palliative medicine resources is needed, care teams in those settings are encouraged to seek out continuing medical education experiences that deepen palliative and supportive care knowledge. Organizations such as the American Society for Radiation Oncology, the American Society of Clinical Oncology, and the American Academy of Hospice and Palliative Medicine sponsor educational opportunities for oncology clinicians using a variety of formats such as online or conferences.

As generalist providers of palliative care, oncologists have a role in the initial screening, assessment, and management of several palliative care domains including physical, psychological, social, and spiritual aspects of quality of life. To this end, patient-reported outcome measures (PROMs) are surveys that allow patients to comprehensively and systematically report and rate their symptoms and psychosocial/spiritual distress. PROMs aid in informing when clinicians are needed to provide additional supportive care and interventions to improve symptom control and overall patient well-being.[7] A recent trial of electronic integration of PROMs in patients with metastatic cancer demonstrated improved measures of quality of life[8] and a significant survival benefit with the addition of PROMs, with results guiding supportive care intervention.[8] These findings point to the need for the standard integration of PROMs in oncology settings as a means of screening patients for palliative and supportive care needs.

In the ensuing sections, we will review common palliative and supportive care issues that arise in the radiation oncology setting and strategies for their management. These include fatigue (both cancer and radiation related), weight loss and cachexia, radiation-induced salivary gland injury, radiation-related mucosal injury, radiation-induced nausea and vomiting, radiation-related diarrhea and other intestinal injury, radiation-induced skin injury, and radiation-related genitourinary injury, including male and female sexual function. Given its frequency and complexity, cancer pain management is addressed with a dedicated chapter (Chapter 99). Radiation oncology clinicians can be expected to provide more in-depth expertise and management for common palliative supportive care issues that arise among their patients. Palliative and supportive care issues with which radiation oncologists have less familiarity (e.g.,

psychosocial and spiritual issues) should be addressed with established screening tools such as PROMs that provide thresholds to prompt referrals to specialty providers for intervention.

Cancer-Related Fatigue

Cancer-related fatigue (CRF) affects a majority of patients with a cancer diagnosis including those receiving active treatment as well as cancer survivors.[9] The National Comprehensive Cancer Network (NCCN) defines CRF as "a distressing, persistent, subjective sense of physical, emotional, and/or cognitive tiredness or exhaustion related to cancer or cancer treatment that is not proportional to recent activity and that interferes with usual function." CRF is often multifactorial and can be related to the cancer treatments themselves (including radiotherapy and chemotherapy), tumor burden, and up-regulation proinflammatory cytokines including Il-1, Il-6, and TNF-α.[10,11]

The most recent NCCN guideline at the time of this publication (Version 2.2017) recommends screening for CRF in all patients undergoing treatment for cancer at regular intervals with the simple question, "How would you rate your fatigue on a scale of 0 to 10 over the past 7 days?" For those with fatigue scores of 4 or greater, a more focused history should be obtained with an emphasis on possible contributing or related factors including pain, medication side effects, emotional distress, sleep disturbances, hypothyroidism, anemia, and nutritional deficits.[12] Primary management of CRF should be focused on correcting any of these contributing factors. Nutrition deficits and imbalance often occur and may be overlooked in these patients. Weight, caloric intake, fluid intake, electrolyte abnormalities, and micronutrient deficiency from an imbalanced diet should be identified and nutritional counseling provided. One of the most common causes of fatigue is inadequate and/or poor-quality sleep. Control of stimulus, optimizing sleep environment, and promotion of sleep hygiene are all important. Massage therapy to reduce tension and stress is often helpful. Patient should be counseled on self-monitoring of fatigue levels, energy conservation techniques, and the use of distraction. Simple behavioral changes in daily life, such as setting priorities, pacing daily activities, delegating as much as possible, scheduling activities at times of peak energy, and structuring a daily routine to promote quality of sleep, can go a long way to reduce fatigue.

Many nonpharmacologic interventions have proven successful in managing CRF. A meta-analysis of 113 studies examined the effect of exercise, psychological interventions, and pharmacologic interventions for CRF.[13] This

analysis showed significant reduction in fatigue scores in cancer patients with both exercise and psychological interventions but not with pharmacologic interventions. Specifically, there is randomized evidence in support of the use of yoga in reduction of CRF in patients being treated for breast and colorectal cancer.[14,15] Cognitive behavioral therapy (CBT) has also been found to be effective in the treatment of CRF in a randomized trial of cancer survivors.[16]

Pharmacologic interventions can also be implemented in carefully selected patients for whom nonpharmacologic interventions are not effective.[17] Short-term uses of glucocorticoids such as dexamethasone and methylprednisolone have been evaluated in several randomized trials. Dexamethasone 4 mg/twice daily for 14 days was compared to placebo in 84 patients with advanced cancer showing short-term improvement in fatigue scores, quality of life, and physical well-being.[18] A separate randomized trial of methylprednisolone 32 mg/daily for 14 days was also compared to placebo again showing short-term improvement in fatigue.[19] However, long-term use of glucocorticoids is limited by their significant side effect profile including hyperglycemia, psychological symptoms including anxiety and agitation, insomnia, GI bleeding, and adrenal insufficiency upon withdrawal.[20,21]

Psychostimulants such as methylphenidate and modafinil have also been evaluated in CRF with conflicting results. A meta-analysis of 5 randomized controlled trials (298 patients) in the treatment of CRF showed improvement fatigue scores with methylphenidate over placebo but not in cognition or quality of life and with increased rates of vertigo, anxiety, nausea, and anorexia.[22] Modafinil was compared to placebo in 208 patients with advanced lung cancer showing no difference in fatigue, depression, sleepiness, or quality of life.[23] In general, these medications should only be considered in patients refractory to more established treatment modalities, and a referral to palliative care should be strongly considered in these cases.

Radiotherapy-Associated Fatigue

Radiotherapy can also be directly responsible for worsening fatigue in cancer patients. Radiation-related fatigue is often difficult to distinguish from generalized CRF resulting from multiple aforementioned etiologies. Radiotherapy fatigue has been demonstrated in patients treated to multiple different body sites including treatment for prostate, breast, and head and neck cancer. Radiation-associated fatigue typically is short lived and less severe than chemotherapy-generated fatigue. Compared with women who received adjuvant

radiation, women receiving adjuvant chemotherapy were more than twice as likely to develop fatigue during the course of therapy.[24] In a prospective study of 28 men receiving radical external beam radiation for prostate cancer, the prevalence of moderate to severe fatigue increased from 7% at baseline to 32% at completion of radiation. Fatigue significantly interfered with walking ability, normal work, daily chores, and enjoyment of life, but only at the end of radiation. Improvement occurred after completion of treatment, but remained higher than baseline at 6.5 weeks of follow-up.[25] Similar results are seen in studies of breast cancer patients. In 38 women alive with no evidence of disease 2.5 years after adjuvant radiation for localized breast cancer, there was no significant difference between chronic fatigue levels after radiation and pretreatment values.[26] In another cohort of breast cancer patients, during and for 3 months after adjuvant radiation for breast cancer, fatigue increased from 33% to 93% and gradually improved during the following 3 months.[27] In patients with advanced cancer, fatigue levels initially worsened with radiation, stabilized at week 8, and returned to baseline by week 27.[28]

The size of the radiotherapy field also relates to the likelihood of developing fatigue. For example, patients treated with whole-breast radiotherapy are more likely to experience fatigue compared to those treated with partial breast radiotherapy.[26] In addition, in a survey of patients with brain metastases treated with whole-brain radiation or radiosurgery, 69% of patients receiving whole-brain radiation experienced severe fatigue and problems with cognition. Only 5% of radiosurgery patients reported fatigue.[29]

Cancer-Related Weight Loss and Cachexia

Weight loss and anorexia are a commonly encountered problem among cancer patients and has been associated with poor overall survival.[30] Cancer-related cachexia is a distinct category within weight loss and anorexia categorized by a metabolic syndrome associated with a proinflammatory state resulting in loss of muscle with or without associated loss of fat. This syndrome can occur even in the absence of decreased caloric intake or malabsorption.[31] Increases in Il-1, Il-6, and TNF-α have all been associated with increased protein catabolism resulting in skeletal muscle breakdown and a worsening cachexia syndrome.[32] The exact definition and diagnostic criteria for cancer-related cachexia have been previously ill-defined. An international panel of experts published a definition and classification of cancer-related cachexia in 2011 defining cachexia as “patients who have more than 5% loss of stable body weight over the past 6

months, or a body mass index (BMI) less than 20 kg/m^2 and ongoing weight loss of more than 2%, or sarcopenia and ongoing weight loss of more than 2%."[33]

The data regarding the optimum treatment of cancer-related cachexia are limited. Patients with cachexia should be managed by a multimodality approach with emphasis on identifying potentially reversible factors. Although there is mixed evidence on intensive nutritional intervention, all patients with cancer-related cachexia should be evaluated by a nutritionist for advice on diet modification and liquid meal supplementation.[33,34] Dietary counseling has been shown to improve outcomes in selected populations.[35] Patients should be encouraged to take in multiple smaller, calorie-dense meals throughout the day.[34] Liquid meal supplements seem to have the greatest impact if they are taken in between, rather than with meals, with reduction in early satiety and improved overall caloric intake.[36]

Cancer patients tend to have a higher protein turnover. Adequate protein intake is critical in patients undergoing cancer treatment. Daily intake of 1.5 to 2.0 g of protein per kilogram of ideal body weight generally maintains a positive nitrogen balance. Caloric intake helps maintain the weight. Between 30% and 90% of total calories can come from carbohydrates. Fat provides energy, serves as a vehicle for other nutrients, and performs other important biologic functions. It usually makes up around 30% of the content in enteral formulas. Vitamins, minerals, and other micronutrients should be included. Sufficient water intake is required to offset the 2.5-L daily fluid loss. Body weight and serum markers (albumin, transferrin, and prealbumin) can be monitored to assess whether the nutritional support is adequate.[37–39]

In patients with moderate to severe radiation-induced oral mucositis or esophagitis, oral nutritional support can be challenging. Tube feeding bypasses the injured tissues and provides direct access to the absorption surface. Nasogastric or nasojejunal tubes enable short-term access. For longer-term access (>30 days), gastrostomy, gastrojejunostomy, and jejunostomy tubes can be placed endoscopically, radiologically, or surgically. Percutaneous endoscopic gastrostomy is increasingly the method of choice, often placed prophylactically when severe upper GI toxicity is anticipated.[40–43] Gastrostomy tube placement is not without risk. Some series suggest a 17% morbidity rate. In 3% of patients, serious complications such as peritonitis, sepsis, perforation, and dislodgement were reported.[44,45] For patients with reflux esophagitis, gastroparesis, aspiration pneumonia, or limited stomach volume, a jejunostomy tube may be placed instead. The feeding tube should be cared for properly to prevent displacement

or malfunctioning such as clogging.

When adequate nutrition intake can be achieved, enteral intake is preferred over parenteral support because it uses and helps maintain the existing alimentary functions. It is less expensive, safer, and associated with fewer side effects. However, in patients without a functioning GI tract because of obstruction, poor GI motility, intractable vomiting, severe diarrhea, short bowel syndrome, or severe pancreatitis, total parenteral nutrition may be appropriate. Implementation of total parenteral nutrition requires special expertise and is done in a concerted manner between the cancer-treating team and the nutrition support team.[46,47]

Pharmacologic interventions have also been studied to improve appetite, weight gain, and quality of life in patients with cancer-related cachexia, particularly those who have failed intensive nutritional support. Short-term uses of glucocorticoids (such as prednisone and dexamethasone) have shown modest benefits in improving appetite and weight gain, but do not seem to improve quality of life and can result in significant side effects such as hyperglycemia, psychological side effects such as anxiety and agitation, insomnia, adrenal insufficiency, and gastrointestinal bleeding.[20,21] Megestrol acetate, a progestin with antiandrogen activity, has also been shown to modestly improve appetite compared to placebo in randomized trials at a dose of 800 mg/daily.[48] A head-to-head comparison of megestrol acetate and dexamethasone showed them to be equivalent in the induction of weight gain.[21] Dronabinol, a cannabinoid, which has been examined for treatment of nausea and anorexia, has not been shown to be superior to placebo in inducing weight gain in cancer patients and has been shown to be inferior to megestrol acetate.[49] In general, short-term use of glucocorticoids and more sustained use of megestrol acetate can be considered for management of cachexia in patients who have failed conservative nutritional management.

SALIVARY GLAND INJURY: XEROSTOMIA

Xerostomia, the subjective experience of dry mouth, is among the most common complaints experienced by cancer patients treated with radiotherapy to the head and neck area. It is caused by salivary gland dysfunction as a result of damage in the field of radiation. Histologically, irradiated salivary glands demonstrate acinar atrophy and chronic inflammation. Inflammatory changes and fibrosis are observed in periductal and intralobular areas, whereas the ductal system remains

relatively intact.[50,51]

Salivary dysfunction develops immediately and predictably. A 50% to 60% decrease in salivary flow occurs during the first week. As radiotherapy continues and the total radiation dose increases, salivary function decreases accordingly in a dose-dependent fashion. After initial deterioration, a recovery phase may be seen, with patients reporting reduced xerostomia even though salivary flow remains depressed. This may result from adaptation to the sensation of xerostomia and compensatory response from surviving functional glandular tissues. However, salivary function usually continues to decline for 6 to 8 months after therapy, and many patients show no recovery even at 12 months.[52,53] In some patients, xerostomia may be permanent.

In addition to oral discomfort, radiation-induced salivary gland injury contributes to systemic problems, including loss of appetite, chronic esophagitis, gastroesophageal reflux, and sleep disruption because of the need for frequent mouth moistening and subsequent polyuria.[54] The lubricating, buffering, and antimicrobial effects of saliva maintain the integrity of oral tissue (dental and mucosal). Saliva also assists in speech, taste perception, mastication, bolus formation, and swallowing.[55] Decreased salivation can lead to dental caries, periodontal diseases, a shift of oral flora, poor tolerability to dental prosthesis and inflammation, and atrophy and ulceration of mucosa. As a result, radiation-induced xerostomia has a debilitating impact on health and overall quality of life in head and neck cancer patients and survivors.[56]

Xerostomia Prevention

The extent of radiation-induced salivary dysfunction is influenced by radiation field, radiation dose, and initial volume and function of the salivary gland. Several approaches have been developed to prevent or minimize injury to salivary glands. They include salivary gland transplantation, intensity-modulated radiation therapy, and amifostine therapy.[57] In several earlier studies, surgical transfer of submandibular glands into the submental space prior to radiation therapy resulted in prevention of xerostomia.[58–61] A 2-year follow-up showed that 83% to 92% of patients reported no or minimal xerostomia.[61,62] Advances in three-dimensional conformal radiation therapy and intensity-modulated radiation therapy make it possible to conduct gland-sparing radiotherapy. Several studies showed that both subjective and objective measures of salivatory function are preserved. Limiting the mean dose of the parotid glands to ≤26 Gy decreases the risk of long-term xerostomia. Local treatment failure rates do not appear to be

compromised by the use of salivary gland-sparing intensity-modulated RT.[63–68]

Intravenous (IV) amifostine, a thiol-containing radioprotectant, administered at 200 mg/m^2 daily 15 to 30 minutes before irradiation, reduced acute and chronic xerostomia in an open-label phase III study.[69] Antitumor treatment efficacy was preserved; however, oral mucositis was not reduced. Nausea, vomiting, hypotension, and allergic reactions were the most common side effects.[70] Subcutaneous administration of amifostine has been explored for reduced side effects.[71–73] A multicentered phase III randomized trial failed to show that subcutaneous amifostine is superior to IV amifostine in terms of patient compliance or efficacy.[74] Other agents are less promising. Pilocarpine during radiation therapy was compared to salivary gland transfer in the prevention of xerostomia and found to be inferior.[75,76] Cevimeline, a muscarinic agonist, was evaluated in randomized controlled trial with conflicting results.[77,78]

Management of Radiation-Induced Xerostomia

Current treatment of radiation-induced xerostomia includes dietary and oral hygiene, saliva substitution, or stimulation of salivation by moistening agents or medications.[57,79,80] Cold, tepid, soft food and beverages are preferred. Hard, spicy foods should be avoided. In patients without residual salivary function, saliva substitutes are used to relieve xerostomia. Water is commonly used and preferred by patients. Other types of mouthwash such as saline, bicarbonate, glycerol, or commercial formulations are available. Artificial saliva has been designed to mimic natural saliva. It may contain carboxymethylcellulose, porcine and bovine mucin, or xanthan gum. In patients with residual salivary function, increased flow of natural saliva can be achieved by stimulation with chewing gum, sucking ointment, sugarless candies, menthol, acid, vitamin C, or lozenges developed to provide antimicrobial enzymes.

Several sialogogues, defined as systemic salivary gland stimulants, have been tested with mixed results. They are typically muscarinic agonists such as pilocarpine, bethanechol, carbachol, or cevimeline. Other classes of agents include neostigmine, physostigmine, nicotinic acid, potassium iodide, bromhexine (a mucolytic), and anethole trithione.[51] Current data support the use of pilocarpine. Further studies are needed to determine the long-term efficacy and safety of cevimeline and bethanechol.[57]

The most extensively studied pharmacologic treatment for xerostomia is pilocarpine. Oral administration at 5 to 10 mg, three times daily, is the standard

regimen. Several randomized, double-blind, placebo-controlled trials have shown clinical efficacy and safety of pilocarpine in treating radiation-induced xerostomia.[81,82] In a multicenter study, 54% of the 207 study subjects reported reduction in the overall severity of xerostomia. Only 25% of those receiving placebo reported improvement. Speaking ability improved in 33% of patients receiving pilocarpine versus 18% of those receiving placebo. Saliva production also improved, but this did not correlate with subjective symptom relief.[81] In another multicenter trial that involved 162 patients, both subjective symptom and objective measurement of saliva flow improved significantly in those receiving pilocarpine versus placebo. Best results were obtained with continuous treatment for 8 to 12 weeks.[83]

Some patients require pilocarpine treatment for 2 months or longer to achieve maximum effect. Sweating, the most common side effect, is experienced by 37% to 65% of patients. In one study, 6% and 29% of patients in the 5- and 10-mg groups, respectively, dropped out because of the adverse effects.[81] Because of the cholinergic activity of pilocarpine, it is not recommended for patients with cardiovascular disease, and it is contraindicated in patients with narrow-angle glaucoma and uncontrolled asthma.[84]

Acupuncture has been shown to stimulate saliva production.[85–87] It even shows some benefit in pilocarpine-resistant xerostomia.[88] Patients with more severe symptoms appear to benefit more from acupuncture treatment.[89] Acupuncture given concurrently with radiotherapy was shown to significantly reduce xerostomia and improve quality of life.[90] Yet, an acupuncture-like transcutaneous electrical nerve stimulation given concomitantly with radiation failed to do the same.[91] Acupuncture appears to modulate the function of the autonomic nervous system, which may stimulate salivary gland function and induce salivary flow.[92–95] Functional magnetic resonance imaging changes in the brain were associated with acupuncture treatment.[96] In summary, acupuncture appears to be a low-risk intervention that offers a potential future treatment for radiation-induced xerostomia.[57,97]

MUCOSAL INJURY: ORAL MUCOSITIS, NAUSEA AND VOMITING, DIARRHEA, AND OTHER GASTROINTESTINAL TOXICITY

Radiation therapy causes mucosal injury. When such injury occurs in the oral cavity, as commonly seen in patients irradiated at the head and neck area, it is

called *stomatitis* or *oral mucositis*. When the injury occurs in nonoral alimentary tract mucosa, it presents as esophagitis, gastritis, enteritis, colitis, or proctitis. These injuries manifest as pain, dysphagia, odynophagia, nausea, vomiting, and diarrhea, typically described as GI toxicity. Mucosal injuries by radiation appear to share the same underlying molecular pathogenesis, regardless of anatomic location.[98–100] Some favor the terminology of *alimentary mucositis* to describe the hierarchy and constellation of toxicity to the oral and GI mucosa.[101] Depending on the site of irradiation, dosage, and fractionation, patients' risks of mucositis vary. More than 50% of patients receiving radiation to the head and neck, abdomen, or the pelvis will experience moderate to severe mucositis. Stem cell transplant recipients who received total-body irradiation have more severe and prolonged symptoms.[102]

Recent research indicates that the pathogenesis of mucositis is not simply the result of nonspecific epithelial cell death. Rather, it may involve a more complex pan–tissue process.[103–105] The complexity of the pathogenesis of mucositis reflects the dynamic interactions of all of the cell and tissue types that comprise the epithelium and submucosa. Genetic predisposition, circadian variables, epithelial type and characteristics, and local microbial environment all play a role in determining the risk of mucosal injury.[106–108] Novel therapies are being developed based on these new findings.[107,109]

A practice guideline developed in 2004 by the Multinational Association of Supportive Care in Cancer and International Society of Oral Oncology was updated in 2014.[104,110] These guidelines provide an excellent and evidence-based reference in the prevention and management of chemotherapy and radiotherapy-related mucositis.

Oral Mucositis Prevention

Topical benzydamine, a drug with anti-inflammatory, analgesic, and antimicrobial effects, has been shown to reduce the frequency and severity of oral ulcers and pain in a randomized controlled trial.[111] It inhibits the production of proinflammatory cytokines, including tumor necrosis factor-α.[111,112] Chlorhexidine failed to prevent radiation-induced oral mucositis (Fig. 100.1).[113–115]

Basic oral care is the foundation of care for oral mucositis. There is a lack of evidence supporting one protocol over another. Therefore, feasibility, adherence, performance, and outcomes are more important than the use of specific agents. Three randomized and three nonrandomized trials showed that implementation

of a systematic protocol improved outcome.[116–121] Protocols consisting of brushing, flossing, bland rinses, and moisturizers should be implemented for all patients. An interdisciplinary approach to oral care (nurse, physician, dentist, dental hygienist, dietician, pharmacist, and others as relevant) is preferred. Dental examinations and treatment are important prior to the start of cancer therapy, especially for those with head and neck cancer, and should continue throughout active treatment and follow-up.[122]

Studies testing amifostine for oral mucositis have been disappointing. Although it appeared useful in the prevention of xerostomia, inconsistent results have been reported for its use for oral symptoms.[123] New classes of agents are being investigated. Recombinant human keratinocyte growth factor-1 (rhuKGF-1, palifermin) was shown to reduce mucositis in patients with hematologic malignancies receiving high-dose chemotherapy and total-body irradiation with autologous stem cell transplantation.[124] Palifermin reduces incidence of severe oral mucositis in head and neck cancer patients receiving definitive chemoradiotherapy and delays the onset of severe symptoms when compared to placebo. Yet, the differences are not significant after multivariate analysis.[125] Its use in non–stem cell transplantation settings is not recommended based on current data.

On the other hand, a local granulocyte–macrophage colony–stimulating factor mouthwash should *not* be used in efforts to prevent oral mucositis in the transplant setting. Other growth factors and cytokines are in early stage of development, including epidermal growth factor, transforming growth factor-β, glucagonlike peptide-2, lactoferrin, anti-inflammatory amino acid decapeptide, recombinant human interleukin 11, and insulinlike growth factor 1.[126] Natural product and dietary supplements such as glutamine, PV701 (milk-derived protein extract), several vitamins (A, B_{12}, E), folate, aloe vera (a plant extract), probiotics, and curcumin, an extract from turmeric, were shown to hold promise in reducing radiation-induced mucositis. Most of the studies are not of sufficient quality to support a recommendation.

Oral Mucositis Treatment

Pain management is an important component of the management of oral mucositis. Most studies were done in the setting of chemotherapy-induced mucositis, instead of radiation-induced oral mucositis. Systemic and topical analgesics are used, as are coating agents. The use of opioids, nonopioids, and adjuvant medications is covered in more detail in Chapter 99. These agents can

be given via oral, transmucosal, transdermal, or IV routes. Use of topical agents is widespread in practice, with practices and institutions using their own favorite formulation. Typically, these are compounded mixtures with nicknames such as “magic mouthwash.” Common ingredients include viscous lidocaine, diphenhydramine, and Maalox. Despite their popularity, there is little evidence supporting their effectiveness.[115,127–132] Doxepin rinses have also been evaluated for the treatment of oral mucositis. In a randomized, placebo-controlled trial of 155 patients being receiving head and neck radiotherapy, doxepin was found to modestly improve painful mucositis.[133] The MASCC/ISOO 2014 guideline currently suggests doxepin 0.5% solution or 2% morphine mouthwash for the treatment of radiotherapy-associated oral mucositis but provide no guidance on the use of lidocaine-based mixtures.[110]

FIGURE 100.1. A, B: Radiotherapy-induced oral mucositis.

Gastrointestinal Mucositis Prevention

Several medications have been shown to significantly reduce the frequency and severity of radiation-induced GI mucositis, which usually presents as diarrhea and pain. Depending on the location, the GI mucositis may be termed *esophagitis*, *enteritis*, *colitis*, *proctosigmoiditis*, or *proctitis*. External beam irradiation to the pelvis as part of treatment for prostate, rectal, or cervical cancer produces lower GI injury in the majority of patients.

In a randomized, controlled trial of pelvic irradiation, sulfasalazine 1 g orally twice daily reduces GI toxicity from 93% to 80% and diarrhea from 86% to 55% when compared with placebo. Grade 4 diarrhea was reduced from 16% of the patients to none.[134] Amifostine is an antioxidant that appears to protect normal cells from radiation injury preferentially to cancer cells.[135] Amifostine was shown in several studies to prevent proctitis in patients receiving standard-dose radiation for rectal cancer.[123] The frequency, onset, and duration of acute rectal

toxicity were reduced.[136–138] When used in patients receiving combined chemoradiation for non–small cell lung cancer, amifostine significantly reduced the need for morphine to control pain from severe esophagitis,[139] but its efficacy was mixed in other settings.[136,140,141] IV amifostine is not without side effects. Other routes of administration that might reduce side effects are under study.

Other agents that did not show significant benefit include glutamine,[140] oral sucralfate,[142,143] rectal administration of sucralfate,[144] and other anti-inflammatories commonly used in ulcerative colitis, such as 5-aminosalicylates,[145] mesalazine,[146] and olsalazine.[147] They should not be used to prevent radiation GI toxicity.

Gastrointestinal Mucositis Treatment

Nausea and Vomiting

In addition to measures discussed here that aim to treat the underlying pathology of radiation-induced mucosal injury, symptomatic treatment should also be provided. Radiation-induced nausea and emesis tend to be undertreated. Factors that influence radiation-induced emesis include single and total dose rate, fractionation, field-size and irradiated volume, site of irradiation and organs included in the radiation field, patient positioning, radiation technique, energy and beam quality, previous or simultaneous influencing therapy, and general health status of the patient.[148] Evidence-based practice guidelines developed by national organizations differ in specific recommendations and in, when recommendations apply, reflecting the limited amount of high-level evidence available to date. The updated guidelines from the Multinational Association of Supportive Care in Cancer[149] American Society of Clinical Oncology,[150] and NCCN[151] are summarized in Table 100.2.

Diarrhea

Symptomatic management of radiation-induced diarrhea is similar to that of chemotherapy-induced diarrhea.[152,153] Diarrhea usually occurs during the third week of fractionated abdomen or pelvic radiotherapy. Guidelines were developed by an expert panel and updated in 2004.[154]

For mild to moderate diarrhea, the initial management should include dietary modifications.[155] Patients should eat small, frequent, protein-rich meals. Adequate fluid intake (35 mL/kg/day) is necessary. Liquids should be taken primarily between meals. Soluble fibers such as oats, pectin, guar, and psyllium help retain stool consistency. Spices, alcohol, caffeine, high-osmolar beverages,

and high-lactose food should be avoided.[155]

Loperamide remains the mainstay of pharmacologic treatment. It should be started at 4 mg followed by 2 mg every 4 hours or after every unformed stool (maximum 16 mg per day). Unlike in chemotherapy, where loperamide may be discontinued after initial response, standard doses of loperamide should be continued for the duration of radiation. This is because the long duration of fractionated radiation may cause repeated injury to the intestinal mucosa. The dose is increased to 2 mg every 2 hours if the diarrhea persists for more than 24 hours.

If diarrhea has not resolved after another 24 hours on the higher dose of loperamide, the drug should be continued and a second-line agent, such as tincture of opium (paregoric), an antimotility agent, can be added. Diphenoxylate and atropine can also be used, although they do not have as favorable a side effect profile as loperamide. Patients with diarrhea may require outpatient evaluation and IV fluid. Antibiotics and complete stool and blood workup are usually not necessary in the absence of signs of dehydration or infection. Octreotide and glutamine have been studied and found of no benefit.[156,157] Probiotic supplementation showed beneficial effect in the prevention and treatment of radiation-induced diarrhea in animal studies, but high-quality clinical studies are lacking. If diarrhea is severe, persistent, or complicated, hospitalization may be considered.[154]

TABLE 100.2 GUIDELINES FOR PREVENTION AND TREATMENT OF RADIATION-INDUCED NAUSEA AND VOMITING

	Risk

SKIN INJURY: ACUTE DERMATITIS AND CHRONIC SKIN CHANGES

Radiation-induced skin injury can lead to acute dermatitis or chronic skin changes.[158,159] These changes can occur at both the entrance and exit sites of the irradiation beam. Severity is determined by the dose, fractionation, beam, volume, and surface area. Patient-specific factors such as poor nutrition status, preexisting vascular condition or connective tissue disease, excessive skin folds, and genetics also play a role.[160] The pathophysiology is a combination of direct radiation injury and a subsequent inflammatory response. Free radicals from ionizing radiation cause alteration of DNA, proteins, lipids, and carbohydrates. Epithelial basal cells, vascular endothelial cells, and Langerhans cells are damaged. A cascade of proinflammatory cytokines, thrombotic factors, growth

factors, and other molecules is activated.[161]

Acute skin changes may become visible after 10 to 14 hours. Grade 1 changes include mild generalized erythema and dry desquamation, pruritus, scaling, dyspigmentation, and hair loss. After 4 or 5 weeks of radiotherapy and radiation doses to the skin of 40 Gy or greater, grade 2 dermatitis may develop, with tender or edematous erythema, moist desquamation in skin folds, and considerable pain. They tend to peak 1 to 2 weeks after the last treatment and start healing 3 to 5 weeks after radiation. Complete healing may take 1 to 3 months. Occasionally, dermatitis may progress to grade 3, characterized by confluent moist desquamation, or even grade 4, with ulcers, hemorrhage, and necrosis.[158,162] Chronic changes may develop months or years after the initial exposure. Postinflammatory hypo- or hyperpigmentation, textural changes (xerosis and hyperkeratosis), loss of hair follicles and sebaceous glands, atrophy, telangiectasia, or subcutaneous fibrosis are among the manifestations. Fibrosis can result in tissue retraction, pain, and limitation of movement. The scalp appears more tolerant to radiation injury than the skin of the face, neck, trunk, and extremities. The affected skin can be predisposed to ulcers and skin breakdown.[163,164] In some patients, radiation recall dermatitis may occur. This happens when a patient who has completed radiation encounters a drug and develops skin reaction similar to an acute radiation dermatitis. The offending drugs are usually cytotoxic agents. Radiation recall dermatitis is probably due to local cutaneous immunologic responses to the challenging agent.[165]

Mild acute dermatitis is treated symptomatically. Washing with water, gentle cleansing with a mild agent, wearing loose, nonbinding clothing, and avoidance of irritants, antiperspirants, and ultraviolet exposure all help. When erythema and dry desquamation occur, creams or ointments (petrolatum-based, castor oil, balsam of Peru, trypsin, trolamine) can be used. Topical sucralfate or hyaluronic acid was shown to be efficacious in some controlled studies.[166,167] In a phase III study in breast cancer patients receiving postoperative radiotherapy, an extract from the calendula plant significantly reduced the occurrence of moderate to severe acute dermatitis from 63% to 41% when compared with trolamine, a nonsteroidal agent.[168] Other topical agents containing aloe vera, D-panthenol, almond, or chamomile can also be tried. The use of these agents is supported only by uncontrolled studies or anecdotal evidence.[169,170]

The value of topical antioxidants has not been established, and topical steroids are controversial, with research producing conflicting results. There are concerns of infection and skin atrophy, known side effects of topical steroids. At

best, steroids may ameliorate the symptoms, but they do not prevent the dermatitis.[171] Topical ascorbic acid lotion (vitamin C) did not show discernible benefit for the prevention of radiation dermatitis.[172]

When acute dermatitis becomes severe, usual wound care should be applied to the erosions and ulcerations. Key measures are keeping the site clean and moist, pain management, protection from contamination, debridement, and infection control.[164,173] During radiation treatment, hydrogel dressings, hydrocolloid dressing, burn pads, or foam dressings can be applied. If the wound is infected, ionic silver powder, topical antibiotics, cadexomer iodine, or maltodextrin powder can be added. Referral to wound care specialists should be made in these cases.[169] In recent years, more specific agents have been investigated, such as topical granulocyte–macrophage colony–stimulating factor, tacrolimus, pimecrolimus, and platelet-derived growth factor, though these are not included in the standard of care.[158]

Chronic skin changes from radiation injury are harder to treat. Chronic fibrosis is associated with high incidence of skin breakdown and infection. A team approach should be adopted that includes wound care, physical therapy, deep massage, and pain management to address cosmetic and quality of life issues. Pentoxifylline appears to have an antifibrotic effect. Oral pentoxifylline (800 mg/day) and vitamin E (1,000 IU/day) for 6 months significantly reduce radiation-induced fibrosis.[174] Prophylactic use of pentoxifylline significantly reduces late skin changes, fibrosis, and soft tissue necrosis in a randomized controlled study, possibly through its protective effect against vascular pathology.[175] Intramuscular liposomal copper or zinc superoxide dismutase, subcutaneous interferon-γ, or hyperbaric oxygen therapy has also been used.

GENITOURINARY TRACT INJURY

Urinary Symptoms

Irradiation to the pelvic region as part of treatment for cancer of the prostate, uterus, ovary, cervix, rectum, or urinary bladder can cause urinary problems because of injury to mucosa, vasculature, and smooth muscles.[176,177] Acute reactions occur within 3 to 6 months of treatment. Chronic changes occur later. Acute reactions present as dysuria, frequency, and urgency. They are usually not as severe as some of the cystitis caused by chemotherapy. Strictures or fistula can develop during the years following radiotherapy.[178,179]

Once infection is ruled out, symptomatic relief with phenazopyridine is

usually the first-line treatment for acute symptoms. It is given at 200 mg orally, three times a day. Phenazopyridine accumulates in the urine essentially unchanged and acts as a topical analgesic within the bladder. Patients should be warned that phenazopyridine turns the urine into a bright orange color and can stain clothing. If the symptoms are not adequately relieved, antispasmodics can be added. Oxybutynin or flavoxate help relax the smooth muscles and reduce urinary urgency and frequency.[180] Tolterodine is a cholinergic antagonist that is also effective for overactive bladder. It causes less dry mouth, but its response rate is lower.[181] Trospium was documented to improve symptoms in radiation-induced cystitis and is significantly better tolerated than immediate-release oxybutynin.[182]

Intravesical infusion of hyaluronic acid or chondroitin sulfate, injection of botulinum toxin A into bladder wall, and hyperbaric oxygen therapy have shown benefit.[183–186] Intravenous WF10 (tetrachlorodecaoxide), an immunomodulator, was reported to be beneficial.[187,188] In patients with severe pain, aggressive pain control with opioids may be needed.

Symptomatic management of chronic changes is similar to that of acute reactions. Dilatation or placement of a permanent catheter may be required for significant obstruction. Patients not responding to less aggressive treatment may be candidates for reconstructive surgery to repair the stricture, sphincter failure, or fistula.

Female Sexuality

High-dose radiation to the pelvis causes varying degrees of sexual dysfunction related to injury to the ovaries and vagina.[189,190] Ovarian failure as a result of pelvis irradiation leads to postmenopausal changes. Acute injury occurs during the course of radiation therapy and the following few months. It usually presents as vaginal and vulvar mucositis, pain, and ulceration. Chronic changes are less frequent than acute changes, which can develop more than 3 months after the completion of treatment. Chronic changes include fibrosis, loss of elasticity and sensation, susceptibility to trauma and infection, postcoital bleeding, and dyspareunia.[191–193]

Maintenance of local hygiene, aggressive treatment of infection, and regular dilatation of the vaginal canal help reduce the acute reaction. Hormone replacement therapy and application of lubricants for mucosal dryness can be used to treat acute injury. To prevent chronic changes, uses of vaginal dilators, lubricants, and supplemental estrogen were shown to be helpful. When fibrosis

is established, treatment may require more drastic measures, such as hyperbaric oxygen therapy or surgical reconstruction. Although these are common options in clinical practice, the level of evidence supporting their use varies.[189]

Most studies of use of topical estrogen showed benefit.[194,195] Radiation causes damage to the epithelium, which may persist for another 3 to 6 months after therapy. Topical estrogen promotes epithelial regeneration. Benzydamine is an anti-inflammatory that also has analgesic, local anesthetic, and antimicrobial effects. It can be applied topically to achieve a higher local tissue concentration. It reduced both subjective symptoms and objective observation of vaginal mucositis.[196,197] There have been several uncontrolled studies of hyperbaric oxygen therapy in the treatment of established necrotic wound resulting from perineal and vaginal radiation; the strength of evidence is modest.[198,199] In women with severe radiation damage, such as perineal defect or obliteration of the vagina, reconstructive surgery may be considered. All reported studies are retrospective.[189]

Male Sexuality

When planning radiation for prostate cancer, its effect on male sexual function must be considered and discussed with the patient. Although the rate of erectile dysfunction (ED) is lower in patients receiving radiotherapy versus radical prostatectomy, sexual dysfunctions remain one of the most important posttreatment quality of life issues.[200,201] A survey showed that 68% of men aged 45 to 70 years were willing to trade off a 10% or greater advantage in 5-year survival to maintain sexual potency.[202] Onset of ED is gradual, usually beginning about 6 months posttreatment and continuing to deteriorate for 4 years.[203]

Radiation does not appear to reduce testosterone production or cause pelvic nerve injury.[204] In addition to psychological reasons, vascular changes after radiation appear to be the predominant cause of postradiation male sexual dysfunction. As such, smoking and hypertension are risk factors.[205,206] With external beam radiation, the rates of ED vary from 7% to 72%, a wide range attributed to the differing study populations. Brachytherapy is associated with 2% to 89% of ED.[207] Diminished sexual desire, decreased orgasmic pleasure, and a reduced ejaculation volume are other problems reported by patients.[208]

The rising use of androgen deprivation therapy (ADT) for the treatment of intermediate-risk, high-risk, and metastatic prostate cancer has also had a dramatic impact on male sexuality. Rapid drops in testosterone brought on by the

initiation of ADT can cause decrease or result in the complete loss of libido and sexual desire in up to 90% of men being treated for prostate cancer as well physical and emotional changes such as weight gain, gynecomastia, genital shrinkage, depression, and emotional lability.[209] Sexual side effects related to ADT can begin almost immediately and can last for several years after completion of therapy. A quality of life analysis of a prospective, definitive prostate cancer trial demonstrated that at 2 years after completion of the therapy, 75.4% patients receiving 4 to 8 months of ADT in conjunction with definitive radiotherapy stated that their ability to function sexually was poor or very poor versus only 44.0% treated with radiotherapy alone.[210] Patients and their partners are often unprepared for the profound side effects related to ADT. In a survey of 79 patients and their partners recently prescribed ADT, 30% to 50% were unaware that low of libido, erectile dysfunction, and genital shrinkage were possible side effects of ADT. Care should be taken by physicians to communicate all of these side effects to both patients and their partners and to facilitate consultation with couple counseling, sex therapy, and men's health clinics when appropriate.

Treatment of postradiotherapy sexual dysfunction should take a multidisciplinary approach, including psychosocial evaluation and counseling, pharmacologic intervention, and exploration of the use of mechanical devices.[207,211] The mainstay of pharmacologic treatment is phosphodiesterase inhibitors in patients with arteriogenic ED. A randomized double-blinded, placebo-controlled crossover trail suggests a positive response to sildenafil. Yet, the overall response rate is low. Only 21% of patients improved during sildenafil treatment but not during placebo treatment.[212] Tadalafil is found beneficial in these patient populations too.[213,214]

Intracavernosal injection of prostaglandins or phentolamine papaverine is also effective. For patients who are refractory to pharmacologic intervention, implantation of a penile prosthesis can be considered. Minimal intraoperative and postoperative complications and an excellent patient satisfaction rate were reported.[215] Vacuum devices are another option.

Economics, Education, Ethics, and Technology Assessment

CHAPTER 101

Technology Assessment, Outcome Analysis Research, Comparative Effectiveness, and Evidence-Based Radiation Oncology

Peter A. S. Johnstone, Carlos A. Perez, Edward C. Halperin, Yolande Lievens, and Andre A. Konski

INTRODUCTION

Concern over the magnitude and continued growth of expenditures for health care in the United States has led to economic pressure on all parties involved to contain costs. In radiation therapy (RT) in particular, powerful forces affect the introduction of new technologies. Inventors and developers, medical equipment manufacturers, corporate stockholders, and equipment salespeople seek rapid entry of new technologies into the marketplace at a minimum cost for as rapid a financial return as possible. Radiation oncologists desire new technology either for a real or perceived improvement in health care, career development, competitiveness with other practitioners, and/or personal profit. Patients and family members hope to see an improvement in clinical outcomes. Third-party payers seek cost reductions or stabilization, stable budgetary expenditures, and a plausible explanation of the "medical necessity" of the new technology. Finally, policy makers seek to balance the competing pressures that they feel from medical equipment manufacturers, physicians, and patients and the overall need for cost containment.[1]

Historically, regulatory approval of new drugs and devices was reliant on well-funded developers with a significant revenue stream conducting and funding randomized, prospective clinical trials. Many new technologies in RT, however, are introduced by small startup companies that are smaller, less well capitalized, and often single-product vendors. They are not capable of funding

randomized, prospective trials, and they have a powerful financial impetus to bring their product to market as quickly and as profitably as possible.

In 1985, the Blue Cross Blue Shield Association adopted the criteria that required “adequate scientific evidence” to determine that technology improved health outcomes. This approach quickly became the norm among public and private payers. In an interesting development, in 2005, the Centers for Medicare and Medicaid Services (CMS) posted on its website draft guidelines describing a new approach to the determination of coverage policies called Coverage with Evidence Development.[1] This proposal argued that Medicare coverage of promising technologies or services could be linked directly to a requirement that the beneficiary be a participant in a trial or registry and that the CMS had statutory or regulatory authority for that requirement. In the United Kingdom, there was a similar proposal for funding “only-in-research” programs. Such programs were used for the evaluation of laparoscopic surgery for colorectal cancer, photodynamic therapy for age-related macular degeneration, the National Emphysema Treatment Trial to determine whether lung reduction surgery was superior to pulmonary rehabilitation without surgery, a comparison of balloon angioplasty plus carotid artery stenting versus carotid endarterectomy in patients at high risk for stroke, and the role of positron-emission tomography scanning in suspected dementia.[2]

ECONOMIC EVALUATION IN HEALTH CARE

Economic evaluation is routinely becoming an important criterion for evaluation of therapeutic strategies. Unfortunately, consistent criteria are not followed for evaluation of the economics of treatment, which reduces the usefulness and credibility of comparative cost and other financial data/statistics across studies or over time.[3]

The potential contribution of more complex and expensive procedures to the outcome of cancer therapy thus must be carefully evaluated.[4] Obviously, a significant portion of the increase in health care costs is linked to new technology. Although much of this technology is welcome, cost–benefit should be demonstrated. Some technologic advances improve health care and can be justified economically if we document a positive impact on tumor control, patient survival, morbidity of treatment, and quality of life. The efficacy of diagnostic and therapeutic procedures can be related to outcome studies, and costs should be carefully evaluated based on both monetary and health-related

considerations. Doubilet et al.[11] cautioned against the indiscriminate use of "cost-effectiveness" as the criterion on which medical decisions should be made, and thus we must carefully define the end points on which these studies are based.

Models can be constructed using a Markov model and available data on the natural history of a tumor, prognostic factors, efficacy, and morbidity of a given therapeutic modality (based on outcome analysis) and reimbursement data for treating a specific patient population. When patterns-of-failure data are used, the cost differential can be calculated for a patient treated successfully in contrast to one who fails in a specific anatomic site (locoregional failure, distant metastasis, or combination), incorporating expenditures related to management of the treatment failure. The model can be made more complete (and complex) by adding costs of the morbidity of therapy. With the information and epidemiologic data currently available in the United States, annual costs of care can be computed and compared for various therapeutic modalities. Using Monte Carlo simulation, sensitivity analysis of cost-effectiveness may be performed.

Total cost-of-care projections should be carried out using a Markov-type analysis based on clinical experience, which will provide more accurate cost data for different management options. Providing cost–benefit information to patients (consumers) will be necessary when evaluating diagnostic and treatment options, particularly in carcinoma of the breast and prostate, in which great controversy exists regarding the merits of various modalities.

A full economic evaluation typically involves quantitative examination of both costs and outcomes, or consequences, of competing possible options, including no intervention. An appropriately performed economic evaluation is incremental, that is, it measures the extra cost incurred to obtain the incremental improvement in outcome. Drummond et al.[6] identified different types of full economic evaluation based on the denominator chosen (Table 101.1).

TABLE 101.1 LEVELS OF EVIDENCE AND GRADING OF EVIDENCE FOR RECOMMENDATIONS

	Type of Evidence
Level	
I	Evidence obtained from meta-analysis of multiple, well-designed, controlled studies or from high-power randomized, controlled clinical trials
II	Evidence obtained from at least one well-designed experimental study or low-power randomized, controlled clinical trial

III	Evidence obtained from well-designed, quasi-experimental studies such as nonrandomized, controlled, single-group, pre/post, cohort, time, or matched case–control series
IV	Evidence from well-designed, nonexperimental studies, such as comparative and correlational descriptive and case studies
V	Evidence from case reports and clinical examples
Grade	
A	There is evidence of type I or consistent findings from multiple studies of type II, III, or IV
B	There is evidence of type II, III, or IV and findings are generally consistent
C	There is evidence of type II, III, or IV but findings are inconsistent
D	There is little or no systematic empirical evidence

Adapted from Drummond M, Sculpher MJ, Torrance GW, et al. *Methods for the economic evaluation of health care programmes*. 3rd ed. Oxford, UK: Oxford University Press, 2005:105. Reproduced by permission of Oxford University Press.

In evaluating medical care, the term *efficacy* is not interchangeable with *effectiveness*. The maximum possible reduction in a disease because of the use of medical intervention is properly termed efficacy, which is generally measured with randomized, controlled trials, which will achieve the maximum possible benefit when patients are carefully selected and stratified, randomization arms are properly designed, compliance is high, and trial participants are often free of other diseases or conditions that might interfere with the intervention being evaluated. The benefits established in a randomized, controlled trial are only partially applicable to day-to-day practice in a general population. The value of a medical intervention in the general population is termed effectiveness. The difference between efficacy and effectiveness can be very large, and obtaining a realistic measurement of effectiveness is often difficult.[7]

There are four approaches to health economic evaluation for comparing two therapies: (a) incremental cost-effectiveness; (b) cost minimization, in which one assumes or observes no difference in effectiveness; (c) cost–utility analysis (CUA); and (d) incremental cost–benefit analysis. The last can be expressed in units of either effectiveness or costs. When analyzing data from a clinical trial, expressing incremental net benefit in units of cost allows the investigator to examine all the approaches in a single graph, complete with the corresponding statistical inferences.

The most widely used approach, *cost-effectiveness analysis* (CEA), compares the incremental costs of a new technology or intervention to the incremental gain or loss of clinical outcome of the new intervention, ideally measured in life years gained (LYG). Other potential denominators in a CEA are disease-free survival or number of cancers prevented or detected, but the use of such intermediary

outcome measures hampers comparison among different CEAs and should therefore be discouraged. The evaluation will result in a ratio of the cost/outcome, for example, cost/life year gained ($/LYG, €/LYG), called the incremental cost-effectiveness ratio. Assuming a well-defined comparison of two RT approaches and a sufficiently long follow-up, LYG may be measured, but it can be questioned whether this metric has most relevance to patients.

When the outcome of the evaluated interventions is expected to be the same, the economic evaluation will be limited to a cost comparison called cost-minimization analysis (CMA). Provided that there is sufficient evidence that the outcome of interest for the experimental treatment or intervention does not differ from the standard treatment, a CMA is undertaken. This simply requires a cost comparison, with the intervention resulting in the lower cost being favored from a health economics perspective.

The third type of full economic evaluation, *cost–utility analysis* (CUA), acknowledges quality of life after an intervention by weighting the LYG with a "utility factor" typically ranging from 0 (death) to 1 (perfect health). For example, if a patient had a utility or preference for a health state of 0.5 and he survived in that state for 1 year, then he would have had a quality-adjusted survival of 6 months. A CUA employs quality-adjusted life years (QALYs) in the denominator, with the result expressed as cost/QALY. Utilities or patient preferences for a certain health outcome can be measured with instruments such as the Health Utilities Index III[8] and EuroQol[9] or tests such as Time Trade-Off or Standard Gamble.[10] CUAs are helpful in trying to compare nonsimilar health interventions, such as a prostate cancer–screening program with a child immunization program. CUA calculates the value of an intervention as the ratio of its incremental cost divided by its incremental survival benefit, with survival weighted by utilities to produce QALYs. Many studies are at variance with current standards; only 20% of studies took a societal perspective, more than one-third failed to discount both the costs and QALYs, and utilities were often simply estimates from the investigators or other physicians. There remains much room for improvement in the methodologic rigor with which utilities are measured. Considering quality of life effects by incorporating utilities into economic studies is particularly important in oncology, when many therapies obtain modest improvements in response or survival at the expense of nontrivial toxicity.

The last type of full economic evaluation is *cost–benefit analysis*, in which both cost and outcome are valued in terms of currency. Where the benefit in

monetary units is greater than the cost, the medical intervention is considered worthwhile. Putting a dollar value on the quantity and quality of a life is, however, a highly specialized and controversial area. Full economic evaluation in RT, requiring detailed input on short- and long-term costs and outcomes, can be difficult to perform. One such approach addresses costs and outcomes separately and leads to cost and outcome descriptions, respectively.[6] However, there are dangers with separating costs and outcomes, and one must be cautious that the information generated will not be misused.

Stinnett and Mullahy[11] introduced the concept of net health benefit as an alternative to cost-effectiveness ratios for the statistical analysis of patient-level data on the costs and health effects of competing interventions. Net health benefit addresses a number of problems associated with cost-effectiveness ratios by assuming a value for the willingness to pay for a unit of effectiveness. Willan[12] extended the concept of net health benefit to demonstrate that standard statistical procedures can be used for the analysis power and sample size determines cost-effectiveness data. He showed that by varying the value of the willingness to pay, the point estimate and confidence interval for the increment cost-effectiveness ratio can be determined.

The most useful descriptions of outcome of a new treatment strategy, particularly from the patient's perspective, result from the conduct of clinical trials. Randomized and controlled phase III trials have been categorized as efficacy or effectiveness evaluations.[6] It can be argued, however, that such comparisons may indirectly lead to the increased cost of health care as funders come under pressure to broadly adopt new interventions with only marginal clinical benefit and no consideration of the opportunity cost. A pure cost comparison, in contrast, entails the opposite risk. If the tendency to reduce health care spending is strong, this might result in the simple choice of the cheapest approach, which may, in turn, lead to reduced quality, hence inferior outcome.

There are many reasons why data and conclusions from cost-based studies may be suspect. For example, in a computerized literature search of >14,000 articles published since 1994 having *cost* as a keyword, critiques focused on three areas:

- Costs are not measured correctly[13–15] because most studies use charge or reimbursement dollars as a proxy for cost. This is an incorrect measure because neither value is representative of the resources consumed or foregone in the process of providing a good service. Neither is a cost: the former is a construct, and the latter is the result of a negotiation between a payer and a

provider.

- Costs are not compiled using a proper perspective and scope.[14,16] Most studies only tabulate the cost to the health care provider and not that to the patient, the family, or society.
- There is a lack of consistency in reporting results,[13,17,18] which prevents interstudy and interinstitutional comparison.[19]

Clearly, a better costing method is required. Russell[20] emphasized that to serve its purpose, a model must produce accurate predictions and low probability for substantial variation in the factors that influence costs and effects. He identified three aspects of modeling: validating effectiveness estimates, modeling costs, and the implications of common statistical forms. Validation procedures similar to those for effectiveness estimates are proposed for costs. Modelers need to ensure that the events described by a model represent costs and effects. Modelers can also help improve the epidemiologic and clinical research on which cost-effectiveness analyses depend by showing the implications for resource allocation of the statistical forms conventionally used in these fields.

Comparative effectiveness research (CER) aims to improve the quality, effectiveness, and efficiency of health care and to help patients, health care professionals, and purchasers make informed decisions regarding various treatment options, particularly for chronic illnesses or cancer. CER is moving forward, with recently defined priorities and a newly funded Patient-Centered Outcomes Research Institute (PCORI). Economic analyses are most valuable to health policy analysts and health care managers who must allocate resources and establish benefit packages. An economic health care analysis tries to directly relate the incremental cost of an intervention to its potential benefit. The intervention is always evaluated relative to an alternative form of treatment.[3]

CER must be focused on patient outcomes. One cannot assume that a higher dose of radiation to a target field or a more conformal dose distribution will result in better survival or improved tolerance. Outcomes of significance to the patient such as survival, disease-free survival, quality of life, or specific side effects must be the focal points of research.[21] It is particularly important for radiation oncologists to remember that an improved dose distribution achieved through intensity-modulated radiotherapy (IMRT), conformal techniques, or particle therapy is not the same as an improved outcome. The presence of an improved outcome as the result of a difference in dose distribution must be proven, not assumed.

TYPES OF COST IN HEALTH CARE

The numerator in economic analysis is cost. A number of studies on the costs of treating cancer patients with RT[22–25] used either relevant costs defined in a number of ways or different proxies for actual costs (billed charges, revenue received, Medicare allowable). Recent reviews illustrate the wide variety of cost information and cost methods used in the literature and call for a consistent method for estimating site- and intent-specific treatment costs.[3,15,16,19,26] In estimating costs of health care interventions, several decision tools, including cost analysis, cost-effectiveness, and cost–utility and cost–benefit analysis, seek to define a unit of health outcome per unit input of cost. Before employing any of these decision tools, proper definition and calculation of cost are essential. Cost of medical care can be calculated in many different ways as highlighted below.

Costs during Treatment

Direct medical costs include the value of all the goods and services consumed in the provision of an intervention or dealing with the side effects of treatment. These costs include the consumption of all capital and human resources such as professional time, diagnostics, treatment, and medications.

Direct non–health care costs include all costs as a consequence of undergoing a treatment but not related to the treatment itself. Examples are the cost of transportation while patients are receiving treatment. Other costs sometimes included are *changes in the use of informal caregiver time* (including the cost of family or other providers to provide health care in the home or continuous nursing care for disabled individuals) and *patient time costs* (referring to the time patients spend receiving care, including the value of the time consumed in receiving the treatment as well as travel and waiting time).

Indirect medical costs include all costs in the time after the treatment has been terminated and include costs of late toxicity or related diseases. In RT, these costs can differ quite substantially between different approaches if the side effects are very different or if one of the interventions has a higher curative potential. Typically, however, these costs occur many years after termination of the treatment.

Indirect nonmedical costs refer to costs that are important for society, in that they measure loss of productivity because of long-term disability or premature death. Costs to the family or society can be substantial. These include the patient’s travel costs, the patient’s or care provider’s time off from work, and the

considerable strain on caregivers. There may also be “downstream” effects. If a caregiver is devoting time to an ill spouse, he or she is taking time away from work or child care responsibilities, for example.

Global cost estimates of the cost of RT are the aggregate costs of the human and capital resources consumed in the delivery of an RT service. They do not contain the fine detail required when comparing, say, one RT protocol with another. However, they can have value as a background to allocating national health care budgets between different classes of medical intervention.

Data reveal that even in countries with optimal infrastructure, the budget assigned to RT is roughly 5% of the total amount spent on cancer care.[27] In the early 1990s, the European Union estimated the average cost per course of RT at about 3,000€, compared to roughly 7,000€ and 17,000€ for surgical and chemotherapy treatments, respectively. However, in spite of the perception of high capital costs, it is the personnel cost that dominates the cost of the provision of the service (about 70%), with capital investment typically representing <30% of the total RT budget.[10,28,29]

Reimbursement-Based Costs

Although economic evaluation theoretically advocates the use of cost figures that reflect actual resource consumption, this is frequently not achievable, and charges for service are used as a proxy. It should, however, be realized that large discrepancies may exist between the reimbursement of treatments and the costs of resources consumed while delivering a treatment. Because of the fact that reimbursement often lags behind the introduction of novel technologies, in many countries, there is a tendency for high-tech treatments to be underreimbursed. The inverse seems to hold for the United States, where the reimbursement is likely to be higher for new technologies, although it decreases with time.

Besides numerical differences between costs and charges, other, more practical and theoretical problems may arise when utilizing reimbursement figures for economic evaluation. This was observed by the Radiation Therapy Oncology Group when performing an economic evaluation based on combining clinical trial data with cost data obtained from Medicare for each patient.[30] The first problem was that Medicare-managed care products do not have individual claims because managed care companies receive capitated payments and therefore may not record and/or report individual claims to Medicare. A more accurate estimation of costs would result from using administrative claims data to calculate costs, provided that they contain all claims of care a patient received.

Another potential problem is that an underestimation of costs could occur if codes with only a cancer diagnosis were used, thus neglecting costs related to treatment toxicity or indirect medical costs occurring in the further follow-up of the patient. It may also be difficult to generalize the results of an analysis based on Medicare patients older than 65 years to the general population. Finally, it is apparent that obtaining administrative claims data from Medicare can be a costly procedure in itself.[31]

ACTIVITY-BASED COST ANALYSIS

Activity-based costing (ABC) is a system widely used in manufacturing but rarely in health care. ABC dissects the process of providing patient care into a series of microlevel tasks and assigns costs to these tasks. As a result, ABC directly identifies resources consumed by cost objects (treatments, patients, or health care providers).[8] Tabulating these tasks and resources consumed allows for comparison of cost values across institutions and time in a consistent and credible way. From this, the economic impact of differences in operating policies can be quantified, and the comparison of cost to health outcome will be improved.

The traditional cost models that hospitals have used are outdated and ill equipped to provide accurate information on costs of a specific medical procedure or global cost of medical care for a patient from initial diagnosis to death. Cost models break organizations into departments for financial oversight and budgetary control. The focus of these cost models is departmental budgets, and they are not specific for a patient or a procedure, although patients and procedures (not the department) trigger costs. For example, the accounting system of a hospital may be able to provide a fair assessment of the total budget (cost) of its radiation oncology department. However, the same system is of little help in assessing the actual cost of treating a patient with prostate cancer using RT. This lack of applicability of cost information at the patient or the procedure level often leads to faulty decision-making because analysis of the whole department does not necessarily translate into data about an individual patient.

ABC is concerned with measuring resource consumption by an individual patient. There are two general advantages of using ABC: increased accuracy of cost measurements and transparency of cost-incurring sections. The latter advantage—increased accounting transparency—means that there is a more lucid and readily apparent correlation between costs and actions. This allows

managers to evaluate each step of the process, perceive inefficiencies in the system, and quantify economic benefits of process improvements.

The cost data of any technology should reflect the facilities and equipment costs (including depreciation and replacement), space (including housekeeping and utilities), and recorded time and effort of all professional staff on hospital payroll treating patients. Specific technical approaches should be identified, for example, in patients undergoing definitive RT, standard two-dimensional (2-D) or three-dimensional (3-D) conformal RT (CRT) or IMRT or image-guided RT (IGRT). Time and effort observations for multiple tasks must be recorded by the respective staff members as they take place. The numbers of observations provide a representative sample of treatment procedures.

Technical cost is defined as the actual expenditures recorded in hospital accounting records. The total technical cost of a course of therapy includes staff time and effort, compensation including fringe benefits, space, utilities, maintenance, equipment depreciation, supplies, support services, liability cost, and administrative overhead. The ABC method[32–35] was used to derive technical (hospital) resource utilization costs for treatment procedures in treating localized prostate cancer.[3,24] The costing method consists of four major steps:

- Creating a process flow map that identifies and defines all of the activities and steps associated with the treatment of patients with standard irradiation or with 3DCRT (Fig. 101.1).
- Collecting and recording the staff time expended on each activity
- Identifying and accumulating all hospital costs from the general accounting ledger system related to the patients treated at a radiation oncology center in a given period
- Allocating actual cost to each activity to derive total specific costs of technical resource utilization for a course of 2D- or 3DCRT, IMRT, or IGRT

An example of an ABC cost calculation model is the one developed in by Lievens et al.[29] Because it was felt that current RT protocols, with a shift toward more complex treatment planning and delivery techniques and more thorough quality assurance procedures, were no longer accurately captured within the original model, a novel version has recently been developed.[36] Because evolving technology over the last decade was more complex, it was found that the introduction of IMRT compared to 3DCRT translated into an almost doubling of procedure costs. ABC analysis allowed the authors to identify exactly where these extra costs were incurred. It was shown that the cost increase was the consequence not of the IMRT technique as such but of the combined effect of

IMRT using more fields and delivering dose escalation and the introduction of more frequent online imaging guidance for position verification.

If, however, techniques such as IMRT or gated radiotherapy delivery make it possible to reduce the number of fractions using simultaneous integrated boosts or accelerated hypofractionation, the resulting costs may decrease while yielding potentially improved treatment outcomes.[31] This phenomenon has been discussed in some detail by Konski and colleagues.[37]

Time and Effort Analysis

An integral phase of ABC is identifying process flow, listing each individual involved in the process, and recording the actual amount of time spent to perform an activity by each person involved using electronic or paper daily activity logs. Determining the participant's task time should follow the monopolizing rule: Timing begins when a specific patient requires the participant's attention and stops when he or she is no longer doing so. Whether or not the patient is still present in the activity area is immaterial. For example, for an office visit, the nurse's time to prepare the patient's paperwork should be attributed to the patient, even before the patient arrives or after he or she has left the office. The actual activity time may be adjusted upward to recognize some normal unproductive time of activity participants, such as time spent in work breaks. Tables are generated to show the time and effort involved in each of the functions necessary to register and evaluate the patient, perform treatment planning, deliver external beam irradiation, and supervise the management, as well as in preparation of the appropriate records to document all information, including quality assurance requirements.

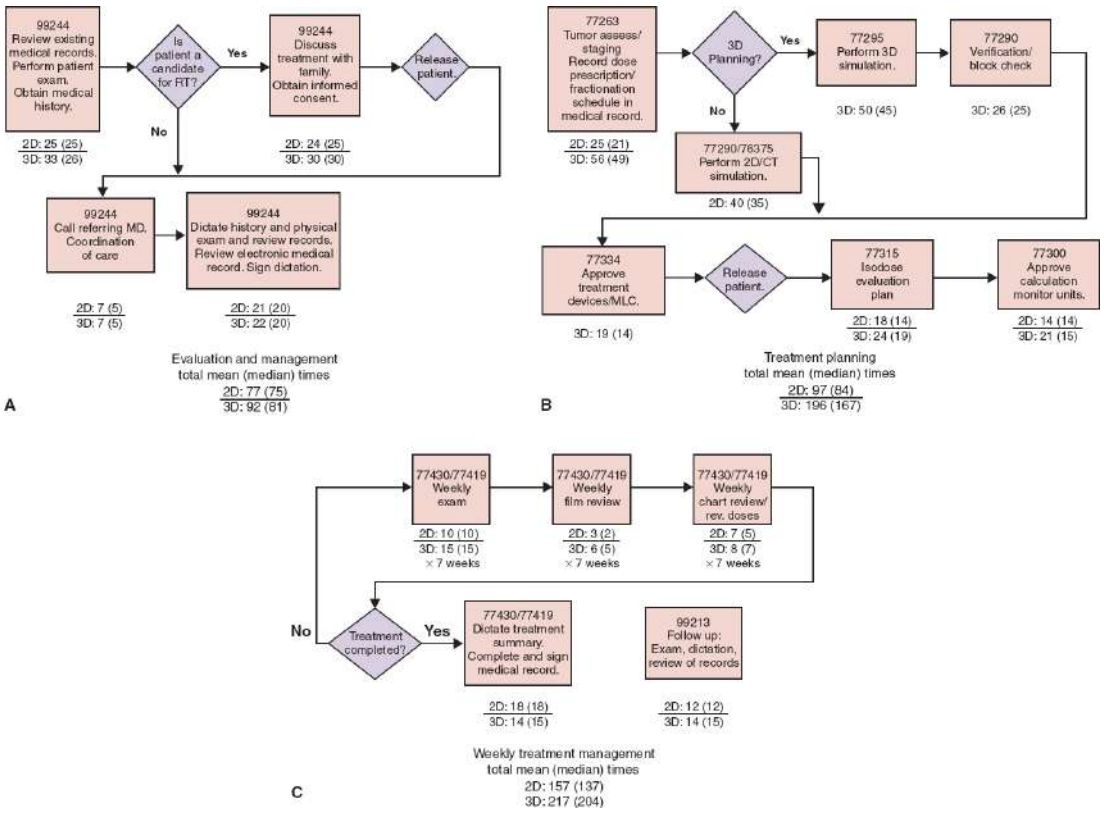

FIGURE 101.1. Process flow chart. Activity map and corresponding mean (median) times for definitive irradiation of cancer of the prostate. **A:** Evaluation and management. **B:** Treatment planning. **C:** Weekly management. MLC, multileaf collimator.

Times are collected for each activity in the treatment process beginning with the initial consultation through the first follow-up visit after full treatment. These data points are analyzed and used to generate average times for patients treated with a specific technique along with the standard deviation of times.

RESOURCE UTILIZATION COSTS

Four types of resources should be catalogued and measured for each task:

- Activity participants (e.g., radiation oncologists, physicists, therapists, dosimetrists, nurses, receptionists)
- Physical resources (e.g., space, equipment, machines)
- Supplies (e.g., x-ray films, office supplies)
- Support services (e.g., administration, centralized information system)

Patient-related expenses include salaries and fringe benefits of the staff, Social Security contributions, retirement annuities, health, life disability and

long-term care, dental insurance, tuition and child care benefits, and disability insurance. Average hourly salary and related costs for each staff member are computed.

There are many supplies, such as office paper and latex gloves, for which the cost is trivial, and it is not economically worthwhile to track their specific use for individual patients. An average cost rate can be computed for such supplies by dividing their total cost by the total number of patients, which is applied to each patient. However, supplies used only by patients with specific diseases or procedures (e.g., contrast material, immobilization devices) need to be recorded for individual patients.

For hospital-based departments, indirect operating costs are classified into general hospital operating expenses and administrative overhead, which includes hospital liability insurance and administrative costs such as shared activities (administrative personnel for purchasing and payroll functions, human resources, public relations, and financial operations). The allocation of indirect operating costs among different departments of the hospital is complex. Models include allocating them as a proportion of personnel costs and many others.

The allocation of cost among various units in a hospital can also be the source of discord between different units. In many hospitals, allocation of costs is a mechanism of cross-subsidization among different departments (e.g., the surgery department subsidizing primary care). Administrative cost can be determined by computing prorated allocation, dividing the total hospital indirect expenses by the proportion of the radiation oncology center technical budget to the total hospital annual budget.

Technical equipment expenses for treatment of patients are included using American Hospital Association standard depreciation schedules. The cost of depreciation of all equipment involved in the management of these patients, including treatment planning and delivery, should be accounted for on a prorated basis.

Because an increasing proportion of the health insurance market is being controlled by managed care, with its cost-cutting pressures, there may be a tendency to de-emphasize the importance of quality of care. Under such conditions, it is critical to document any decreased morbidity of treatment with advanced technology in comparison with conventional external beam RT (see Chapters 69 and 70 for prostate cancer). This potential benefit is of great financial significance because treatment of major therapy complications may be costly.

Owen et al.[38] conducted economic studies for two phase III Radiation Therapy Oncology Group (RTOG) studies comparing different irradiation fractionation schedules: 1-04 and 90-03 (brain metastasis and head and neck cancer, respectively). Expected numbers of current procedural terminology codes and relative value units (RVUs) were modeled. Institutions retrospectively provided procedure codes, quantities, and components, which were converted to RVUs used for Medicare payments. The median and mean RVUs were within the range predicted by the model for all arms of one study and above the predicted range for the other study. The model predicted resource use well for patients who completed treatment per protocol. Some institutions experienced difficulty collecting retrospective data; prospective collection of data is necessary to validate such studies.

This information also will be very helpful in contract negotiations with health care organizations and third-party payers and in setting policies for establishing therapy guidelines and justification of health care expenditures.

OUTCOMES IN ECONOMIC ANALYSIS

Outcomes, such as survival or year of life gained, are the denominator in economic analyses. Ways to identify outcomes are highlighted below.

OUTCOME RESEARCH

Outcome research focuses on identifying variations in medical procedures and associated health outcomes. Figure 101.2 illustrates the interplay of outcome research and clinical trials with clinical and policy decision-making.

The term *outcome* is frequently used to describe a variety of end points or products of health care. Areas of specific focus of outcome analysis include the following:

- Structure of care (such as features of health care facilities, staffing, equipment)
- Process of care (such as type of studies performed, services provided)
- Patient characteristics (gender, age, race, ethnic group)
- Disease focus (such as location and type of tumor, histology, pathologic features)
- Treatment-related factors (type of treatment, tumor response, disease-free survival, overall survival, morbidity of therapy)
- Socioeconomics (such as cost–benefit, quality of life, financial impact of the

disease, recovery, and rehabilitation)

Meta-analysis is another mechanism to systematically research and collect published/unpublished randomized clinical trial data and quantitatively summarize results to obtain objective assessment of efficacy. The process should be (a) hypothesis driven, (b) protocol based, and (c) reproducible and comprehensive. However, meta-analysis has some potential shortcomings, such as uncontrolled testing conditions, sample heterogeneity, unrecorded interventions, ambiguous end points, lack of independence of determinant factors, synergistic interactions, and sometimes contradictory experimental results.

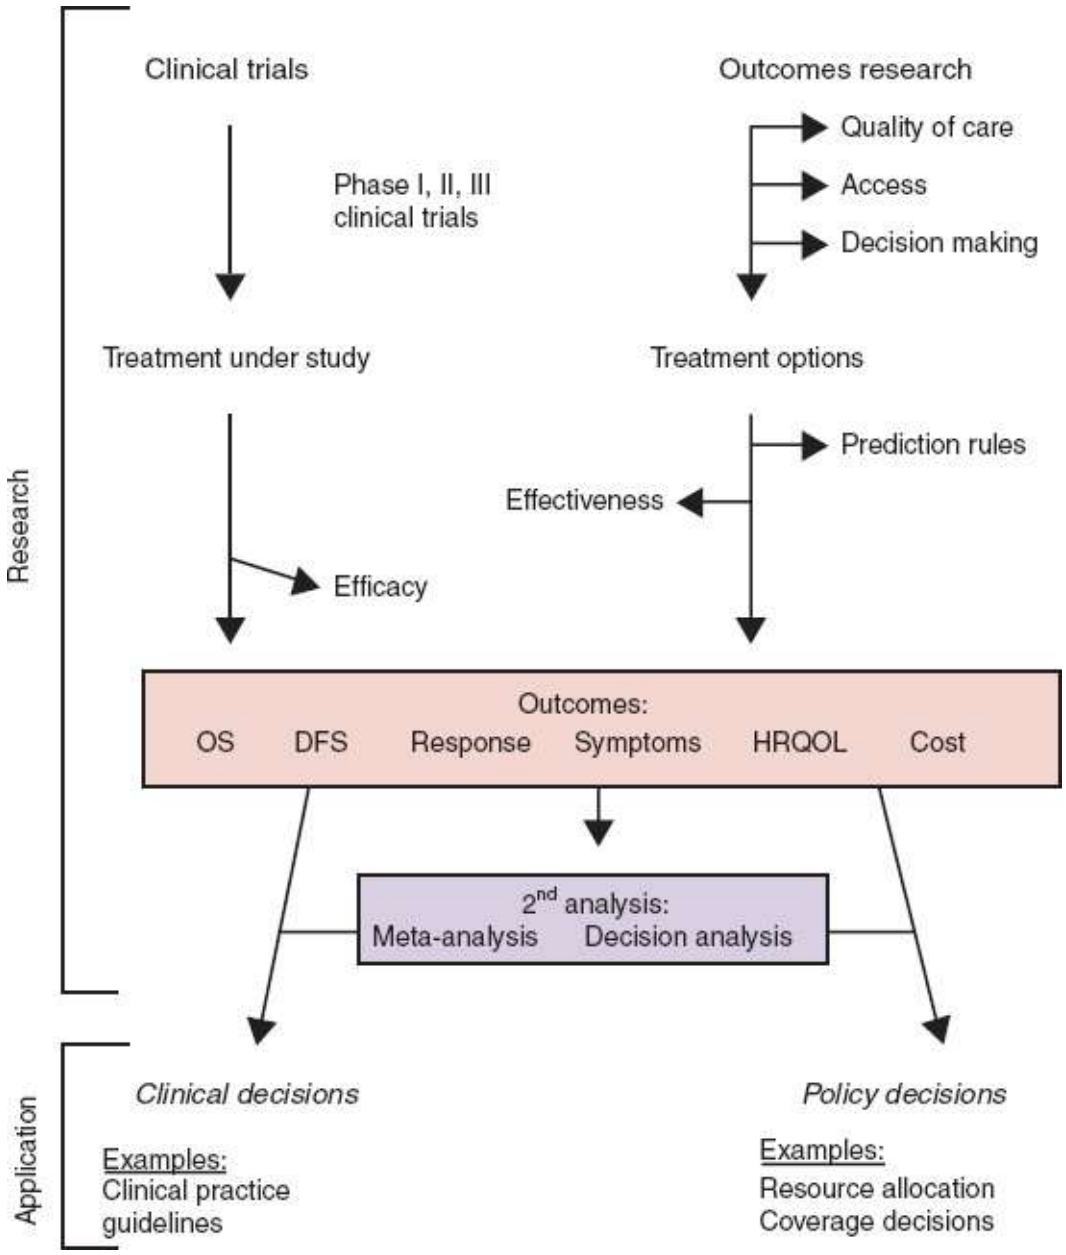

FIGURE 101.2. Conceptual framework of outcome research. Interaction is shown between research topics, end points, analytic techniques, and applications in defining outcomes research. Depicted in the upper left corner are the classic clinical trials and analytic techniques that are not outcomes research. In the upper right corner are shown the study topics, end points, and analytic techniques that are considered to be outcomes research. Outcomes depicted in the center box may or may not constitute outcomes research, depending on the context. For example, overall survival as measured in a phase III trial is not an outcomes study (efficacy), whereas it is if observed in a large community cohort (effectiveness). Symptoms have both efficacy and outcomes influences. Applications are indicated in italics and may emanate from either clinical trials or outcomes research. See text for further details. (From Lee SJ, Earle CC, Weeks JC. Outcomes research in oncology: history, conceptual framework, and trends in the literature. *J Natl Cancer Inst* 2000;92[3]:195–204. Reproduced by permission of Oxford University Press.)

Efforts have intensified during the last 20 years to promote outcome research in oncology, and there is a critical need to continue to support randomized, controlled studies. Patient and physician acceptance of participation in outcome research studies must be improved because only 10% to 20% of patients with newly diagnosed cancer participate in these important studies.[39] There is considerable variation in participation of patients in research studies as a function of patient age and disease site. In general, compliance with participation in studies is much higher among pediatric patients than adults.

Among the most commonly used data are those of the Surveillance, Epidemiology, and End Result (SEER) program. SEER is a continuing project of the biometry branch of the U.S. National Cancer Institute. The program draws data from several population-based cancer reporting systems covering approximately 14% of the total population of the United States. When linked to Medicare and other insurance administrative files, it has been extremely valuable in assessing the quality of care of the elderly and other insured populations. Although an excellent data source, SEER has been criticized as being inadequate to represent the diversity of systems of care throughout the country and in general does not have data that may more accurately define patient- or tumor-specific prognostic characteristics or treatment details.

The National Cancer Database, a joint project of the American College of Surgeons' Commission on Cancer and the American Cancer Society, holds information on more than half of all newly diagnosed cases of cancer in the United States and includes many of the demographic, clinical, and health systems data elements necessary to assess quality of care. A serious limitation of the National Cancer Database is the absence of complete information on outpatient care; its data have not been widely used to assess quality of care, but it has great potential for doing so.

An effective national system to collect this type of information should be established in the United States to collect data about the following:

- Demographics of individuals with cancer (e.g., age, ethnic group, socioeconomic status, and insurance or health plan coverage)
- Type of cancer (stage, histologic type, grade, comorbid conditions)
- Treatment, including outcome of procedures, such as adjuvant chemotherapy and RT
- Specialty training of care providers
- Site of care delivery (such as community hospital or specialized cancer center)
- Type of care delivery system (such as managed care, fee for service,

government agency)
- Outcomes (tumor control, survival, complications of treatment, quality of life, satisfaction with services provided)

WAYS TO MEASURE OUTCOMES INDICATIVE OF SURVIVAL AND TUMOR RESPONSE

Survival can be measured as overall survival, disease-free survival, progression-free survival, or event-free survival. It is clearly the most important outcome in cancer treatment. It is also clear, however, that survival alone is insufficient as a measure of outcome. The quality of survival and the cost of maintaining and improving survival must also be assessed.[40]

Making a choice between alternative treatment approaches often involves a tradeoff between length of survival and quality of life. A survival measurement alone might not answer the question of whether gains in survival justify toxicity. Quality-adjusted survival attempts to adjust the absolute length of life to reflect the patient's quality of life. Quality-adjusted survival provides a framework within which tradeoffs that influence treatment choices can be defined as in decision and cost-effective analysis to assess the effectiveness of alternative therapies.[41,42]

Quality of Life Outcome Measures

Quality of life considers the impact of cancer and its treatment on the physical, psychological, and social components of patient's lives. Cancer-related quality of life is a family of outcomes including the global quality of life as well as physical, psychological, and social dimensions, each one of which is a potentially separate outcome. Because of its subjective nature, the assessment of quality of life generally should include an evaluation by the patient. Quality of life measures should be characterized by reliability and validity.[42–44]

Toxicity Measures of Outcome

Toxicities are subjective, objective, or both. An example of a subjective toxicity would be a symptom such as nausea that is often not associated with overt signs or laboratory abnormalities. Evaluation of toxicities of this sort rests with the patient's report. Objective toxicities are measured by physical examination or laboratory tests. The common toxicity criteria use a system for categorizing toxicity from cancer treatment according to its severity. Such systems are widely used in cooperative group trials.

Measures of Cancer Response Outcomes

Measures of tumor response include complete response, response to radiation, and time to progression. Response may also be measured by biomarkers and changes in cancer-induced abnormalities and common blood tests. Some studies demonstrated the positive relationship between response rate and quality of life, but others did not. It is clear that freedom from progression may not be a convincing indication of the benefits of treatment if it does not predict significantly improved survival or cure. Freedom from progression is therefore not an adequate measure of quality of life.[39]

Cost-Effectiveness as a Cancer Outcome

Cost is not an outcome. It is, instead, what we spend to produce an outcome. Cost-effectiveness, in contrast, is often an important outcome. Cost-effectiveness may be reported in terms of cost per year of life saved or cost per quality-adjusted year of life saved. Clinical practice guidelines are generally informed by cost-effectiveness considerations.[41,42] If all that matters is minimizing expense, then the lowest-cost treatment—or no treatment in some cases—would be preferred. However, cost–benefit, which incorporates the incremental impact of a new technology on outcome, and cost–utility, which also relates additional costs to impact on survival as well as on the patient's quality of life and productivity, are important parameters in the assessment of new technology.[3] The projected cost of treating a patient who initially has control of the local tumor and no distant metastases is about one-third of that for a patient who develops a treatment failure.[45]

Health technology assessment (HTA) plays an essential role in modern health care by supporting evidence-based decision-making in policy and practice. HTA involves addressing five questions[46]:

- Can a health care intervention achieve its expected goal when used in optimal circumstances? (Efficacy)
- Does the intervention do more good than harm when used in routine practice? (Effectiveness)
- What is the balance between the health outcome obtained and the resources required to deliver the intervention? (Efficiency or Cost-Effectiveness)
- Is the supply of services matched to locations where they are accessible to persons that need them? (Availability)
- Who gains and who loses by choosing to allocate resources to one health care program instead of another? (Distribution)

Technology assessment, cost–benefit outcome analysis, clinical trials supported by evidence-based medicine (EBM), and comparative effectiveness together can enhance the rationale and quality of medical care provided to patients at a competitive cost.

TECHNOLOGY ASSESSMENT

Technologic change is the key driver of health care expenditure growth because it is generally associated with increased rather than reduced cost. As the economist Henry Aaron is quoted as saying, “Rapid scientific advance always raises expenditures even as it lowers prices. Those who think otherwise need only to turn their historical eyes to automobiles, airplanes, television, and computers. In each case, massive technologic advance drove down the price of services, the total outlay soared.”[47] A good example in medicine of this phenomenon is laparoscopic cholecystectomy. Although the price of a laparoscopic procedure is less than the price of an open cholecystectomy, after the introduction of the new technology, the rates of both types of surgery increased, and the growth in the quantity of services overwhelmed the impact of per unit reduction in price. Similar examples can be found in the widespread use of magnetic resonance imaging, computed tomography, coronary artery bypass grafting, angioplasty, cardiac intensive care units, neonatal intensive care units, and positron-emission tomography and the growth of radiation oncology facilities. Technology may also increase costs by either premature adoption of the technology without adequate evidence that it improves outcome or overuse of technology, regardless of value, to provide a competitive market advantage or to generate revenues.[48]

Technology assessment is undertaken to determine (a) the appropriateness of adopting a new procedure consistent with the health care organization’s mission and strategic plan; (b) the safety, efficacy, and cost-effectiveness of the new technology; (c) distinctions between appropriate and inappropriate use of the new technology; and (d) quality improvement methods to optimize the use of the new technology.[49] Technology assessment is a complex process that involves financial considerations; a given therapeutic outcome; treatment-induced morbidity; quality of life; impact on caregivers, family, and coworkers; and lost opportunity costs.

When new technology emerges and priorities for allocation of increasingly scarce resources are considered, it is imperative to carry out economic analyses

and also to assess the positive effects to the population who will benefit from the new technology compared with standard treatment techniques. The U.S. Centers for Medicare Management concluded that cost-effectiveness should be considered in approving reimbursement by Medicare for new technology procedures.

Halperin[50] pointed out the importance of technology assessment in determining the merits of new devices or modalities and the impact they may have on the cost of health care. In a provocative editorial, Lee[51] pointed out that although technology is ubiquitous in radiation oncology, it is our professional responsibility to critically evaluate the merits of new technologic developments. Yet, technology assessment can be a thorny and complex subject. Many of the technologic advances in radiation oncology have not undergone a strict test of worthiness in formal clinical trials. Simulation, positioning techniques, computed tomography scanning for treatment planning, online imaging, intensity-modulated RT, adaptive planning, and daily image guidance have had multiple dosimetric validations, but no randomized trial has documented their impact on outcome of large numbers of patients. However, lack of this evidence would not lead us to discontinue any of these procedures, which have been shown to improve in some way (i.e., less toxicity) the quality of care provided to patients.

Many nations have agencies to conduct HTA, and there is an international network of agencies for HTA that can share such data. The United States, however, has no national coordinating body on HTA. Assessments are conducted through organizations such as the Veterans Administration, the Blue Cross Blue Shield Association, and professional organizations like the American College of Radiology, the Medicare Coverage Advisory Committee, and HMOs.

Health care organizations use a variety of models to assess and acquire technology, some of which include outcome. Reliable data for such benchmarking are frequently scarce. Some compare new and emerging technology against existing technology, although reliable outcome data are rare. Most institutions or individuals buy what physicians, advocacy groups, philanthropists, or governing boards want and use manufacturers and physicians as the primary sources of technology information. Cowan and Berkowitz[48] pointed out several key mistakes that occur during the diffusion of technology:

- Technologies are adopted simply because they are new, without assessing their impact on outcomes.
- Equipment is replaced solely because of its age. To avoid overuse of

technology, health care organizations must carefully match the capacity of existing technology with projected utilization in a world of limited resources.

- Applications of technology expand without adequate justification based on outcome or cost considerations.
- Numerous vendors are used, and numerous models of products with duplicative specifications are purchased. Reducing the number of brands and models of devices used may provide an opportunity to reduce purchasing and inventory costs, as well as maintenance and repair costs. On the other hand, competitive pressures in the marketplace may provide downward pressure on equipment prices and favor multiple vendors.
- Economies of scale in regionalizing technology decisions are missed because of lack of consolidation of services. This is sometimes related to inadequate systems for patient transport to treatment centers.

Duplication of services may add cost without significant increase in work volume.

The benefit of 3DCRT, IMRT, or IGRT is hypothetically linked to (a) improved local tumor control because of better coverage of the target volume with a specific dose of irradiation, (b) less acute and late morbidity, and (c) the possibility of carrying out dose escalation studies if morbidity is held to an acceptable level, resulting in improved survival.[45] Several institutions, the RTOG, and 10 institutions under cooperative agreement with the National Cancer Institute conducted phase I/II dose escalation studies in carcinoma of the prostate and are carrying out a study on carcinoma of the lung. Depending on the results, the cost–benefit of 3DCRT, IMRT, or IGRT must be further evaluated in dose escalation and in larger multi-institutional phase III studies, comparing it with standard techniques to justify its somewhat higher initial cost. Cases most likely to benefit from 3DCRT, IMRT, or IGRT include patients with (a) tumors in sites with complex anatomy, (b) irregular-shaped tumors, (c) tumors adjacent to radiation-sensitive normal structures, (d) tumors that undergo significant changes in volume during treatment, and (e) small-volume or high-dose treatment.

A recent workshop convened by the National Cancer Policy Forum in July 2015[52] specifically concerned itself with “value” as the relationship between clinical effectiveness and cost. The panel described the rapid market saturation of IMRT with only small, recent randomized trials assessing moist desquamation in breast cancer[53] and xerostomia in head and neck cancer.[54] This was due in large part to consensus among radiation oncologists of the dosimetric advantages provided by the technique. Nevertheless, Medicare expenses for IMRT were

estimated to increase fourfold between 2002 and 2010, from about $200B to about $800B.[55]

Another example is the recent adoption of particle therapy—most commonly proton therapy in the United States. The literature on the cost-effectiveness of particle therapy for cancer is scarce, studies are often not comparable, and many studies are not performed according to standard health assessment criteria. Evidence on the cost-effectiveness of particle therapy is, therefore, limited.

Consensus also exists for some proposed uses for proton therapy such as pediatrics, again absent randomized data. In this case, initial centers were built not only by university-based cancer programs but by regional or venture capital–based entities. Because early centers were quite expensive, protons became a convenient example of rampant health care costs,[56] and in some cases, the accusations were valid. Clearly, despite the value of protons in complex and pediatric cases, most centers required a large number of "simple" treatments for which no clinical benefit could be proven simply in order to service debt.[57] The ultimate result of proton facility locations being driven by available venture capital, geographic ego, and academic marketeers is that the expansion became unsustainable,[58] evidenced by closing of the Indiana University Health Proton Therapy Center in 2014. Although smaller proton facilities and vendor competition have greatly reduced entrance costs, more upheaval is expected within the proton space in the United States before settling.[59] Given limited success with existing grant systems in the United States, it is unclear that adequate reimbursement will be found to support such innovative and costly treatments to learn whether it is truly more efficacious.

The introduction of protons and heavy ions (hadrons) into the RT armamentarium has brought additional controversy in technology assessment because of the higher cost of facilities, equipment, and operation, with much dispute as to the cost-effectiveness of these innovative modalities. A 2008 review of the literature showed that only 17 publications (out of 777 on particle therapy) dealt with economic aspects, and only 5 of them were on cost-effectiveness.[60] Many articles have been published on the physical advantages of protons or heavy ions in comparison with photons, resulting in better dose distribution in the target volume with less radiation administered to normal tissues, which may decrease morbidity and eventually the risk of second malignancies.[61,62] However, there is a lack of randomized trials documenting superior clinical outcomes with these particles.

Opinions on the need for or ethical considerations to subjecting patients to

prospective trials have been expressed.[63,64] Perrier et al.[65] used an ABC approach similar to the examples discussed previously to evaluate the cost of carbon ion therapy. It allowed an in-depth definition of the cost of treatment preparation and the actual irradiation, depending on various parameters such as actual treatment time and patient setup time. The approach of Peeters et al.,[66] conversely, was more aggregate, using a spreadsheet model that assumes that treatment costs scale linearly with the number of fractions. This, obviously, is a somewhat simple approximation of reality, which results in less accurate estimates.[29]

The American Society for Radiation Oncology maintains the position that new technologies and modifications of existing technologies representing significant paradigmatic shifts in treatment approach should be implemented into clinical practice in such a manner as to ensure safety, efficacy, and, ideally, cost-effectiveness.[67]

EVIDENCE-BASED MEDICINE AND EVIDENCE-BASED ONCOLOGY

There have been significant scientific advances in biologic sciences and health care. At the same time, there has been increased accountability and in some instances attempts to ration services; as a mechanism to accomplish this, arbitrary clinical practice guidelines have been promulgated. A more rational effort to define optimal heath care should be based on identification of innovative approaches, outcome analysis in properly designed clinical trials, and careful assessment of current practice; more importantly, we have a dire need for solid and credible clinical research and evidence-based decision-making in medicine.

The growth in basic and translational research data to guide medical practice has made it critical for clinicians to appraise and use published data for medical decisions. EBM is the compelling idea that any recommendation of a specific medical procedure should be supported by empirical evidence for its superior efficacy/toxicity ratio compared with alternative treatment options in a patient with a given presentation.[68–70]

EBM helps correct an imbalance in contemporary medicine in which clinicians are being trained to maintain high standards of critical consciousness in methodologic domains but not in the broader historic and sociocultural domains that surround them.[71]

Evidence-based health care is the conscious use of current best evidence in making decisions about the care of individuals or the delivery of health services. Current best evidence is up-to-date information from relevant valid research about the effects of different forms of health care, the potential for harm from exposure to particular agents, the accuracy of diagnostic tests, and the predictive power of prognostic factors.

Evidence-based clinical practice is an approach to decision-making in which the clinician uses the best evidence available, in the context of consultation with the patient, to decide on which option suits the patient best. EBM is a conscientious, explicit, and judicious use of current best evidence in making decisions about the care of individual patients.

Such evidence-based practice aims to apply the best available evidence gained from the scientific method to clinical decision-making. It seeks to assess the strength of evidence of the risks and benefits of treatment or lack of treatment and diagnostic tests. Evidence quality will range from more rigorous—meta-analysis and systematic reviews of double-blind, placebo clinical trials—to less (conventional wisdom).

The systematic review of published research is the major method used for evaluating particular treatments. The Cochrane Collaborations are among the best known and respected examples of systematic reviews. Like other collections of systematic reviews, it requires authors to provide a detailed and repeatable plan of literature search and evaluation of the evidence. Once all the evidence is assessed, treatment is categorized as “likely to be beneficial,” “likely to be harmful,” or “evidence did not support either benefit or harm.”

EBM categorizes different types of clinical evidence and rates or grades them according to the strengths of their freedom from the various biases that have beset medical research. The strongest evidence for therapeutic intervention is provided by systematic review of randomized, triple-blind, placebo-controlled trials with allocation concealment and complete follow-up involving a homogeneous patient population and medical condition. In contrast, patient testimonials, case reports, or even expert opinion has little value as proof because of the placebo effect, the biases inherent in observation in reporting cases, and difficulty in ascertaining who is an expert.

Randomized, controlled trials are highly desirable to answer questions about technology assessment, but there are alternatives. Carefully controlled observational studies are good predictors of the outcome of randomized trials as long as enough essential information is collected to ensure that the patients are

standardized. It is equally important in an observational series to understand which patients have been excluded.[21]

The American College of Radiology (ACR) has created a product named Appropriateness Criteria. These are exceptional medical practice guidelines that have been used by the Agency for Healthcare Research and Quality as designated by the Institute of Medicine. The ACR adopted the AQA's[72] definition of appropriateness: "The concept of appropriateness, as applied to health care, balances risk and benefit of treatment, test, or procedure in the context of available resources for an individual patient with specific characteristics. Appropriateness criteria provides guidance to supplement the clinician's judgment as to whether a patient is a reasonable candidate for the given treatment, test, or procedure." Specifically for radiation oncology treatments and procedures, there are published ACR appropriateness guidelines that one can consult to garner an opinion about the "consensus view."[72]

The Delphi methodology is a technique used to arrive at appropriateness ratings. A series of surveys is conducted to elicit members of the expert panel's interpretation of the evidence concerning the appropriateness of a therapeutic procedure for specific clinical scenario. The panelist receives a survey with an evidence table and narrative. Each panelist is asked to interpret the available evidence and rank each procedure. The survey is completed by each panelist without consulting fellow panel members. Ratings are done on a scale of 1 through 9, which is further divided into three categories: 1 to 3 is defined as usually not appropriate; 4 to 6 is defined as maybe appropriate; and 7 to 9 is defined as usually appropriate. Each panel member assigns one rating for each RT procedure or intervention per survey round. Surveys are collected and the results are tabulated, deidentified, and redistributed after each round. A maximum of three rounds is conducted. This modified Delphi technique enables each panelist to express individual interpretations of the evidence and his or her expert opinion without receiving bias from fellow panelists in a simple, standardized, and economical process. A consensus is defined as 80% agreement within a rating category.

Practicing EBM requires recognition that, in most encounters with patients, questions arise that should be answered to provide the patient with the best available medical care. Appropriate and relevant clinical questions contain four elements: (a) a patient or problem, (b) an intervention, (c) a comparison intervention (if necessary), and (d) an outcome. Important practical steps in practicing EBM include the following:

- Formulation of the patient's clinical problem
- Search of literature for relevant and reliable data
- Evaluation of validity and usefulness of data
- Integration of critical evaluation of evidence with clinical judgment
- Implementation of useful information
- Assessment of outcome to improve medical practice

Once the right questions have been formulated, the best source for finding most types of best evidence is by searching Medline (National Library of Medicine), PubMed (National Library of Medicine), OVID, the Cochrane Database, or a similar database by computer.

The quality (strength) of evidence is based on a hierarchy, proceeding from the most reliable results of systematic reviews of well-designed prospective clinical trials to results of one or more well-designed meta-analysis studies, results of large retrospective case series, expert opinion, and personal experience.[73] Once the best data have been found, the EBM approach involves critically appraising the quality of the evidence, determining its magnitude and precision, and applying it to a specific patient.[74,75]

The Cochrane Collaboration was established in 1993 as an international network to help health care providers, policy makers, patients, their advocates, and their caregivers make well-informed decisions about health care by preparing, updating, and promoting the success of Cochrane reviews. More than 4,500 such reviews have been published so far online in the Cochrane Library.[76]

The Cochrane Collaboration traces its origins to a 1972 publication by the British epidemiologist A. Cochrane entitled *Effectiveness and Efficiency: Random Reflections on Health Services*.[77] This book called attention to the collective ignorance concerning the effects of health care. In 1979, Cochrane published an essay in which he suggested that "it is surely a great criticism of our profession that we have not organized a critical summary, by specialty or subspecialty, adapted periodically, of all relevant randomized controlled trials."[78] Responding to Cochrane's charge, the Cochrane Collaboration undertook such a crucial but enormous undertaking.

There are >28,000 people working within the Cochrane Collaboration in >100 countries. Its central functions are funded by royalties of its publisher, which comes from sales from subscription to the Cochrane Library. The individual entities of the Cochrane Collaboration are funded by a large variety of governmental, institutional, and private funding sources and are bound by organization policy limiting uses of funds from corporate sponsors.

EBM promotes rule-based behavior on the part of physicians in an effort, among other things, to eliminate variations in medical practice. However, professionals do not follow rules per se; they intuit what is right in a situation, including, sometimes, that it is right to defer to a rule.[79]

The practice of EBM (careful clinical judgment in evaluating the "best available data") should be differentiated from the special collection of data regarded as "suitable evidence." The new collection of best available information has major constraints for the care of individual patients; derived almost exclusively from randomized trials and meta-analyses, the data do not include many types of treatments or patients seen in clinical practice, and the results show comparative efficacy of treatment for an "average" randomized patient, not for pertinent subgroups formed by such cogent clinical features as severity of symptoms, illness, comorbidity, and other clinical nuances. The intention-to-treat analyses in clinical trial reporting do not reflect important postrandomization events leading to altered treatment, and the results seldom provide suitable background data when therapy is given prophylactically rather than remedially. The authoritative aura given to the "collection of data" may lead to abuses that produce inappropriate guidelines or poorly supported doctrinaire dogmas for clinical practice.[80]

There are a variety of mechanisms to apply EBM to clinical practice, including formulation of treatment pathways, practice guidelines, appropriateness criteria, consensus conferences, patterns of care, and institutional peer review. A fundamental part of EBM is the filtering of evidence through the clinical skill of the clinician. It is not easy to determine which level of evidence is required, and it is estimated that only 20% of medical procedures currently in practice can be justified by evidence-based medical standards. When does a new cancer therapy cease being experimental and become a component of the standard of care? This distinction is subject to powerful influences for for-profit pharmaceutical companies and medical equipment manufacturers wanting to increase their sales and financial return to shareholders, advocacy groups, politicians, and a public anxiously awaiting the next "cancer breakthrough." A dispassionate set of systems for technology assessment of cancer therapies is essential to evidence-based oncology practice.

In 1993 in the United States, the American Society of Clinical Oncology (ASCO) formed a Health Services Research Committee (HSRC) to perform technology assessments and to develop guidelines for cancer treatment. The committee is composed of clinical researchers and clinicians from academic

centers and private practice and performs technology assessment after hearing from expert advisors. The committee does not develop guidelines; it assembles expert panels to develop guidelines.[41]

Among the most important initial tasks of the HSRC was to create an outcome working group to define the outcomes of cancer treatment that should be considered for technology assessment in forming cancer treatment guidelines. Not surprisingly, patients, physicians, researchers, payers, and policy makers all have different ideas about which outcomes of cancer treatment are important. The main purpose of ASCO's technology assessments and guidelines is to define what constitutes the best cancer treatment, not to inform policy development and payment decisions. The working group on outcomes, therefore, considered outcomes primarily from the perspective of the clinical investigators who produced evidence for the guidelines, individual doctors and patients who have to make decisions about treatment, and health service researchers who evaluate the quality and cost of care produced by the guidelines. Because it is clear that there are health policy implications of ASCO's technology assessments and guidelines, the working group also considered outcomes that would convince health policy makers that ASCO's technology assessment was sound and that its guidelines represented worthwhile treatment.[41,49] For technology assessment, the ASCO working group is composed of members of the Health Services Research Committee and selected members. They conduct a literature review and analyze the outcome-based evidence. Testimony is collected from invited experts and interested parties. After evaluating the information, the working group defines specific questions and provides a report outlining conditions under which the proposed procedures are warranted to assist both physicians and patients in making informed decisions regarding the technologist or procedures.

The working group identifies specific questions to be addressed by the technology assessment, develops a strategy for completing the assessment, and reviews the available literature and evidence. The process may include face-to-face meetings of available working groups and members, circulation of draft forms of the technology assessment, and opportunities for comment. Working groups do not attempt to codify established practice. They review the available evidence and add their best clinical judgment to make final recommendations.

Making a treatment selection involves defining the patient's condition, identifying management options and outcome, collecting and summarizing evidence, and applying value judgments or preferences to arrive at an optimal course of action.[81] The randomized, controlled clinical trial has become the

“gold standard” for evaluating the efficacy of health care intervention. In the 30-year period starting in 1966, >80,000 journal articles from randomized, controlled trial results were registered in the Medline database. The first 5 years of that period contributed <1% of the total number of articles, whereas the last half decade contributed more than the previous 25 years combined. (For more detailed review of the principles of design in clinical trials, the reader is referred to Bentzen.)[92] A proposal for structured reporting of randomized clinical trials was described in the consolidation of standards for reporting trial guidelines[42] that have been accepted by many medical journals. For instance, the journal *Radiotherapy and Oncology* adopted a set of guidelines for reporting clinical research (Table 101.2).[82] Linking management options to known outcomes in clinical trials or obtained through systematic reviews is becoming a common procedure (Fig. 101.2).

Clinical decisions are complex and based on many sources of information (Fig. 101.3).[42] Patient management decisions are always a function of both scientific evidence and individual preferences (physicians, health care providers, patients). A development to improve the basis for clinical decision-making is an international movement to improve the reporting of clinical research results, particularly in randomized, controlled trials and method analyses. New data on current molecular biology and genetics investigations have broadened the scope of evidence-based oncology.

Hunt et al.[83] reported on an analysis of 68 controlled medical trials, 40 of which were published since 1992, to assess the effects of computer-based clinical decision support systems on physician performance and patient outcome. They observed that, in 43 of 65 studies (66%) on physician performance, a benefit was found, including drug dosing systems, use of diagnostic aids, preventive care assistance, and other medical care procedures. Only 6 of 14 studies assessing patient outcome found a benefit, indicating that the impact of clinical decision support systems on patient outcome has been insufficiently studied. Furthermore, very few reports dealt with cancer-related treatment issues; most reports centered on prevention, activities, and cancer screening.[84,85]

Although oncologists, patients, and national organizations recognize that communication is very important in cancer care, evidence-based data on the subject are scarce. Oncologists should use a patient-centered interview approach, ask patients what level of involvement they want in medical decision-making, develop a caring attitude, and consider that patient–physician encounters should provide both cognitive data of patient understanding and feelings.[86]

TABLE 101.2 Guidelines for Reporting Clinical Outcome Studies in the Journal *Radiotherapy and Oncology*

Heading	Subheading	Item	Was It Reported? Yes/No/NA[a]	If Yes, on What Page Number?
Title		1. Identify the study as a randomized trial	_____	_____
Introduction		2. State the prospectively defined hypothesis, clinical objectives, and planned subgroup or covariate analyses	_____	_____
Methods	Study design	3. Define the patient population, inclusion and exclusion criteria	_____	_____
		4. Planned treatments and their timing	_____	_____
	Radiotherapy	5. Radiotherapy dose prescription method, dose planning procedure	_____	_____
		6. Target volume definition, critical organs considered, simulation and verification procedures	_____	_____
		7. Dose fractionation details	_____	_____
		8. Planned radiotherapy quality assurance procedures	_____	_____
	End points and analysis	9. Primary and secondary end points, specific follow-up procedures, the minimum clinically relevant difference, the target sample size and how it was decided	_____	_____
		10. Statistical analyses, their purpose and methods used, and whether the intention-to-treat principle was used	_____	_____
		11. Trial monitoring, early-stopping rules	_____	_____
	Randomization	12. Method used for randomization	_____	_____
		13. Method of concealment and time of randomization	_____	_____
		14. Method to separate the generator of random treatment assignments from the treating physician	_____	_____
Results	Masking patient flow and follow-up analysis	15. Describe any blinding procedures (if relevant)	_____	_____

	16. Provide an overview of number of patients randomized, compliance with treatment, radiotherapy quality assurance results	_____	_____
	17. State the effect of treatment on primary and secondary tumor outcome measures, including effect estimates with confidence intervals	_____	_____
	18. Describe the incidence and grade of treatment-induced early and late toxicity by treatment group	_____	_____
	19. State frequencies as absolute numbers when feasible (e.g., 10/20 and not just 50%)	_____	_____
	20. Present summary data with appropriate statistics to permit alternative analyses or interpretations and comparisons with other trials on the same problem	_____	_____
	21. Describe prognostic variables by treatment group, check if they were balanced, and if not describe attempts to adjust for them	_____	_____
	22. Describe protocol deviations from the study as planned, together with reasons	_____	_____
Discussion	23. State the interpretation of the study findings, including sources of bias and imprecision, and discuss how this trial compares with other similar studies	_____	_____
Conclusion	24. State the general interpretation of the trial in view of all available evidence in the literature	_____	_____

These guidelines meet the minimum criteria defined in the CONSORT statement for reporting of randomized clinical trials.

[a]NA, not applicable; certain items apply to randomized studies only.

QUALITY OF MEDICAL CARE AND EVIDENCE-BASED MEDICINE

Continuous quality improvement emerged from the industrial sector as an effective means of reducing production errors. The quality of health care can be precisely defined and measured with a degree of scientific accuracy comparable to that of most measures in clinical medicine.[87] Health care quality problems can be classified into three categories:

- *Underuse* is the failure to provide a health care service when it would have produced a favorable outcome for a patient, such as not administering irradiation in breast-conserving therapy.
- *Overuse* occurs when a health care service is provided under circumstances in which its potential for harm exceeds the possible benefit—for example, prescribing postoperative pelvic irradiation to a patient with stage IA G1 endometrial carcinoma.
- *Misuse* takes place when an appropriate service has been selected but a preventable complication occurs and the patient does not receive the full

potential benefit of the service; avoidable complications of surgery, medications, or irradiation are important misuse problems.[88]

Other issues influencing the inadequate use of services include geographic variation in the rate of use, training of general practice or specialist physicians, the makeup of the nonphysician health care workforce, and the effect of organization of medical services as a determinant of quality.

In health care, continuous quality improvement is most effective when used as an integral part of a scientific approach to improving clinical practice. A potential strength is the ability of motivate good performers to excel and to place emphasis on generating new methods for achieving improvement. Among its limitations are a too-narrow focus on administrative (as opposed to clinical) aspects of care and a lack of attention to problems of overuse or underuse. Several major strategies have been advocated to move the health care delivery system toward improving quality. The challenges are (a) to always provide effective care of those who could benefit from it, (b) to always refrain from providing inappropriate services, and (c) to eliminate all preventable complications.[89] Skeptics point out that no health care market currently competes on the basis of improving quality, and there is little theoretical basis in economics to predict that this success will occur.[88] Mendelson et al.[43] noted that there are many parties involved in outcome and effectiveness research (Fig. 101.4) and that payers and providers of health care may in the future use outcome research as a basis for coverage of services, including procedures, devices, or drugs.

HOW ONE MIGHT USE OUTCOMES FOR TECHNOLOGY ASSESSMENT AND GUIDELINE DEVELOPMENT

Priority of Outcomes

Patient outcomes are more important than cancer outcomes for technology assessment and development of cancer treatment guidelines. If a new technology or therapy is not ultimately shown to make patients live longer or feel better, then its use cannot be justified. Gathering the necessary data is not easy. Randomized, controlled trials are the gold standard for these comparisons but often fail to accrue enough patients. The reasons for failure to accrue include physicians who refuse to enroll patients because they believe one technology is superior, patients who refuse to be randomized because they have a treatment/technology preference, and the extra work necessary to enroll a patient

in a trial.[21]

The Need to Use Multiple Outcomes

There is no single outcome that can represent the results of cancer treatment. Each of the various outcomes provides a unique perspective on treatment and has its own limitations. In general, multiple outcomes should be used for technology assessment.

Barriers to Progress in Cancer Outcome Research

Despite growing interest, there are numerous obstacles to overcome in health care outcome research, including the need to apply scientific disciplines that are different from the biomedical sciences (survey research, psychology, health services research, statistics, economics), the need for resources to collect additional data and information beyond that of standard clinical care, and limited coordination and collaboration among researchers working in the field. Other barriers are intrinsic to a specific cancer, including heterogeneity of patients, type of tumor, phases of the disease, and ethnic and socioeconomic characteristics. Furthermore, many institutions do not give a high priority to or adequately fund outcome research because this activity is considered a cost, not a revenue center, and there is a lack of conviction that this effort will reduce health care spending.[88,90]

Data sharing and increased collaboration in data collection and analysis should be promoted among health care providers and the various groups conducting outcome research. Creative approaches to educating providers and patients about outcome studies are needed, as well as mechanisms to ensure that patients and health professionals have ready access to the results of outcome research.

Making a treatment selection involves defining the patient's condition, identifying management options and outcome, collecting and summarizing evidence, and applying value judgments or preferences to arrive at an optimal course of action.[4] The randomized, controlled clinical trial, the first of which was published in 1952, has become the "gold standard" for evaluating the efficacy of health care intervention.

Clinical decisions are complex and based on many sources of information (Fig. 101.3).[29] Patient management decisions are always a function of both scientific evidence and individual preferences (physicians, health care providers, patients).

Although oncologists, patients, and national organizations recognize that communication is very important in cancer care, evidence-based data on the subject are scarce. Oncologists should use a patient-centered interview approach, ask patients what level of involvement they want in medical decision-making, develop a caring attitude, and consider that patient–physician encounters should provide both cognitive data of patient understanding and feelings.[41]

The Complexity of Randomized, Prospective Clinical Trials

Randomized, prospective, controlled trials are held forth as the gold standard for determining the appropriateness of introducing technology into clinical practice. One must be cognizant, however, of adverse influences upon the generalizability of randomized, controlled trials. If the age, gender, severity of the disease, risk factors, comorbidity, ethnicity, or socioeconomic status of the patients in the randomized, prospective trial is not representative of the general population, it may be inappropriate to generalize the results of the clinical trial to that population. Similarly, if the dose, timing of administration, duration of therapy, quality of care, or comedications of the patients in the trial are not similar to those of the general population, the results may not be applicable.[20]

There is a long-standing joke that one does not need a randomized, prospective trial to ascertain the efficacy of a parachute. In medicine, there are long lists of new technologies that were introduced into general practice based on historical controls without randomized, prospective trials. These include, for example, the use of thyroxin for myxedema, insulin for diabetes, vitamin B12 for pernicious anemia, sulfonamides for puerperal sepsis, penicillin for lobar pneumonia, streptomycin for tuberculosis, defibrillation for ventricular fibrillation, and cisplatin, vinblastine, and bleomycin for disseminated testicular cancer. The analysis of a randomized clinical trial has traditionally been based on a hypothesis that presumes that there is no difference between treatments. The hypothesis is tested by estimating the probability of obtaining a result as extreme as or more extreme than the one observed if the hypothesis is true. The hypothesis may be irrelevant if there had been previous studies demonstrating that the treatment had some benefits. Those who criticize randomized, prospective trials will quickly argue that “no one ever did a randomized trial to prove that a linear accelerator was better than a cobalt machine, that port films were necessary, or that simulation was preferable to a clinical setup.” These arguments are, to some extent, true. One must remember, however, that there is a considerable financial difference between using and not using a port film

compared to using a linear accelerator versus a $200 million proton apparatus.[85]

Nonetheless, prospective, randomized clinical trials have come to occupy a prominent role in clinical research in radiation oncology. The most commonly used clinical end points are summarized in Table 101.3. Unfortunately, many published reports have unclear definitions or lack some of the fundamental end points.

Clinical trials are time consuming and costly. Randomization is the only method that may guarantee that comparisons of treatment outcome are, on average, unbiased. Not all clinical trials yield positive results, and not all new therapies are improvements compared with the standard therapy.[69,74] As an example, a recent analysis of outcome data from 57 randomized, controlled trials, including a total of 12,734 patients, conducted between 1968 and 2002 by the RTOG[73] showed that overall, experimental and standard radiotherapies were equally successful (odds ratio for survival, 1.01; $P = .5$); however, treatment-related mortality was significantly greater in the experimental arm of the trials (odds ratio, 1.76; $P = .008$). A drawback of randomized trials for the evaluation of a new technology in radiation oncology is that to detect small improvements in morbidity from, for example, an alleged improved dose distribution, an enormous number of patients will need to be accrued and followed for a considerable length of time. Radiation oncologists must, therefore, give serious consideration to the development of novel paradigms for HTAs without meeting, in some cases, the ideal requirement of randomization.[73]

TABLE 101.3 MOST COMMONLY USED CLINICAL END POINTS IN RADIATION THERAPY TRIALS

End Point	Definition of Event	Comments
Local control	No evidence of disease at the primary site (T position)	Statistically, this is the absence of an event (i.e., local recurrence); estimated at a given time as the local recurrence–free rate
Local failure rate	Recurrence in T position	Estimated as 1 minus the local recurrence–free rate
Locoregional control	No evidence of disease in T and N positions	See above, but for T or N recurrence, whichever comes first; sometimes defined as in-field control (i.e., control within the treated volume)
Survival or overall survival	Death irrespective of cause	—
Cancer-specific survival or	Death of cancer	Often defined as death of cancer or with active disease

cause-specific survival		
Disease-free survival	Any recurrence or death from any cause, whichever comes first	A composite end point combining survival and disease control
Local recurrence–free survival	Local recurrence or death from any cause, whichever comes first	As above, but with local recurrence as the relevant event
Disease-free rate	Any recurrence	Death without recurrence is a cause of censoring
Local relapse-free rate	Local recurrence	As above
Early reactions	Signs or symptoms of a specific early reaction; defined by measuring scale	Typically defined inside a time window; actuarial methods normally not used
Late reactions	Signs or symptoms of a specific late reaction; defined by measuring scale	Actuarial methods should be used
Palliation	Typically defined by measuring scale	May require special statistical considerations
Quality of life	Typically defined by measuring scale	May require special statistical considerations

All definitions involving local recurrence are defined for nodal recurrence (N position) or distant recurrence (M) by analogy.

Practice Guidelines

Guidelines for health services resulting from valid and appropriate outcome studies have the potential to promote consistency and quality of care. In the United States, clinical practice guidelines have been promulgated by the American Cancer Society, the American College of Radiology, the American Society of Clinical Oncology, the National Cancer Centers Network, and other professional organizations (Table 101.4).[21,44] Sisk[90] observed that for such guidelines to be successful, it is very important to involve local physicians in the process, to get their views and ultimately their support. The values of practice guidelines in medicine include minimizing inappropriate practice variations, providing reference points for education/practice, improving patient care and outcomes, providing criteria for self-evaluation, setting indicators for external quality review, assisting with service coverage and reimbursement, and decreasing overall cost of medical care. Perceived drawbacks to such guidelines

include overregulation and loss of autonomy for both physicians and patients. The conflicting needs and motivations of physicians, patients, third-party carriers, and society bring into play a variety of ethical perspectives. Although contrasting ethical foundations likely will lead to significantly different solutions to the health care resource problem, it is only through educated and reasoned discussion that this problem can be tackled.[91]

Courts in the United States have ruled that guideline developers can be held liable for faulty guidelines and that doctors cannot pass off their liability by claiming that adherence to guidelines corrupted clinical judgment. Protocols and guidelines provide the courts with examples of clinical standards across a wide range of medical practice. However, adherence to guidelines has not automatically been equated with reasonable practice, and the courts seem unlikely to follow the standards enunciated in clinical guidelines without critically evaluating their authority, flexibility, and scope of application.[92]

TABLE 101.4 AMERICAN COLLEGE OF RADIOLOGY APPROPRIATENESS GUIDELINES LITERATURE EVIDENCE TABLE KEY

Strength of recommendation (quality of the study design)
- *Good* evidence to support recommendation that procedure be performed
- *Fair* evidence to support recommendation be performed
- *Poor* evidence to support recommendation but may be made on other grounds
- *Fair* evidence to support recommendation not be performed
- *Good* evidence to support recommendation not be performed

CONCLUSIONS

Technology assessment, outcome analysis, cost–benefit, comparative effectiveness, and clinical trials supported by EBM should be strengthened and fostered to enhance the rationale and quality of medical care provided to patients at a competitive cost. Basic and translational laboratory research and properly designed, relevant, and timely prospective clinical trials should be strongly promoted, and patient participation must be increased to acquire more accurate information to develop innovative therapeutic strategies in oncology. Methods for accurate cost accounting of medical care and comparative effectiveness studies need further development. Technology assessment will substantially

contribute to better utilization of scarce health care resources and will be invaluable in determining the potential value of innovative therapeutic approaches.

CHAPTER 102

Error Avoidance*

Bhishamjit S. Chera, Lukasz Mazur, Prithima Mosaly, and Lawrence B. Marks

INTRODUCTION

Improving the quality of health care is garnering enthusiastic support in the current social and political environment. The Institute of Medicine (IOM) published two seminal reports highlighting that (a) there is a large gap between what we know to be good quality care and what actually exists in practice and (b) patient safety is an urgent quality problem.[1,2] The IOM defines quality as the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge and that health care should be (a) safe, (b) effective, (c) patient centered, (d) timely, (e) efficient, and (f) equitable.

The concept of safety in health care is not new. The ethical standard of *first, do no harm*, given to us by Hippocrates in the 5th century BC[3] and mandated as a key principle in the practice of medicine by Florence Nightingale[4] in the late 19th century has been taught in medical education for years.[5] However, patients suffer iatrogenic harm from medical treatment every day. In 1999, the IOM reported that 44,000 to 98,000 people die each year in the United States as a result of preventable medical errors, which roughly equates to 3 jumbo-jet crashes every 2 days.[1,5]

Public awareness of radiation delivery errors has increased in a number of developed countries such as the United States, because of articles in *The New York Times*, a World Health Organization report,[6–10] and an accident in Épinal, France.[11] Society (e.g., patients, politicians, attorneys) is demanding *safe* health care. Highly publicized medical errors are driving our profession to prioritize quality and safety. Our professional societies responded by publishing numerous quality and safety publications, such as the ASTRO-sponsored *Safety is no Accident*, and holding several safety-focused meetings.[12] Serious accidents have

also been reported in the 1990s in the United Kingdom, triggering a strong response by their National Health Service. One result was the publication of the report “An Organisation with a Memory.”[13] Similarly, the European Radiation Oncology Safety Information System (ROSIS) project started in the early 2000s to promote safety through systematic incident reporting and analysis.[14]

Furthermore, it is also known that the quality of radiation delivery affects patient outcomes. Post hoc analyses of noncompliance with clinical protocol radiotherapy guidelines show associations between deviations, disease control, and overall survival in patients treated on clinical trials.[15–17] Ohri et al.[15] analyzed 8 clinical trials and observed that deviations in the radiation plans were associated with decreases in overall survival (HR = 1.74, 95% CI = 1.28 to 2.35, $P < .001$). In addition, spreading treatment protocols from the research environment to the broader, routine clinical setting is affected by a systematic loss of efficacy, chiefly because of a relaxation of the tight constraints in schedule, treated volumes, doses, etc. that prevail in the research setup (i.e., efficacy in clinical trial vs. effectiveness in clinical practice).[18] Thus, quality assurance (QA) of radiotherapy plans is important to ensure the delivery of effective care.

Radiation oncology is a modest-sized field with approximately 4,000 practicing radiation oncologists in the United States. Nevertheless, the clinical impact of radiation therapy (RT) is large. Approximately 50% of patients with cancer receive RT, with ≈ 600,000 patients treated annually in the United States alone. A reasonable estimate is that there is an incident during the course of treatment in ≈1% to 3% of patients, but the vast majority of these are not clinically relevant (Table 102.1). However, ≈1 in 1,000 to 10,000 treated patients is affected by a reportable event with potentially serious consequences. This rate may compare unfavorably with highly reliable industries such as commercial aviation (≈1 death in 4.7 million passenger flights) or other areas of medicine such as anesthesiology (≈1 death in 200,000 procedures).

RT is a highly technical field and the inappropriate application of radiation can have severe consequences. There is a broad understanding of the need for strict technical standards (e.g., defining the accuracy of the planning and delivery systems). The American Association of Physicists in Medicine (AAPM) and other professional groups provide many guidelines (e.g., Task Group reports) to help guide the technical aspects of our work. However, technical accuracy alone is not enough to ensure quality and safety. The practice of radiation oncology is a human endeavor that requires the coordinated efforts of many people with diverse, yet synergistic, skills. For example, numerous handoffs are routine in our work; thus, there is great need for clarity in our communications. Other industries facing similar challenges have learned that quality and safety require addressing both the technical and human aspects of their processes. As the technical aspects are largely understood and accepted, our focus here will be on the human-based aspects (see Fig. 102.1). This emphasis is not intended to minimize the importance of these technical aspects nor the leadership role of physicists and other “technically focused” team members. We acknowledge the critical importance of these technical components but believe the human-based aspects deserve special highlighting at this time.

In this chapter, we discuss the practical application of error-avoidance strategies from nonmedical high-reliability organizations (HROs). As a primer, Table 102.2 defines several keywords and terms formally utilized among safety experts. In the vernacular, this specificity is often lost, and the overall meaning and understanding of these keywords may broadly overlap.

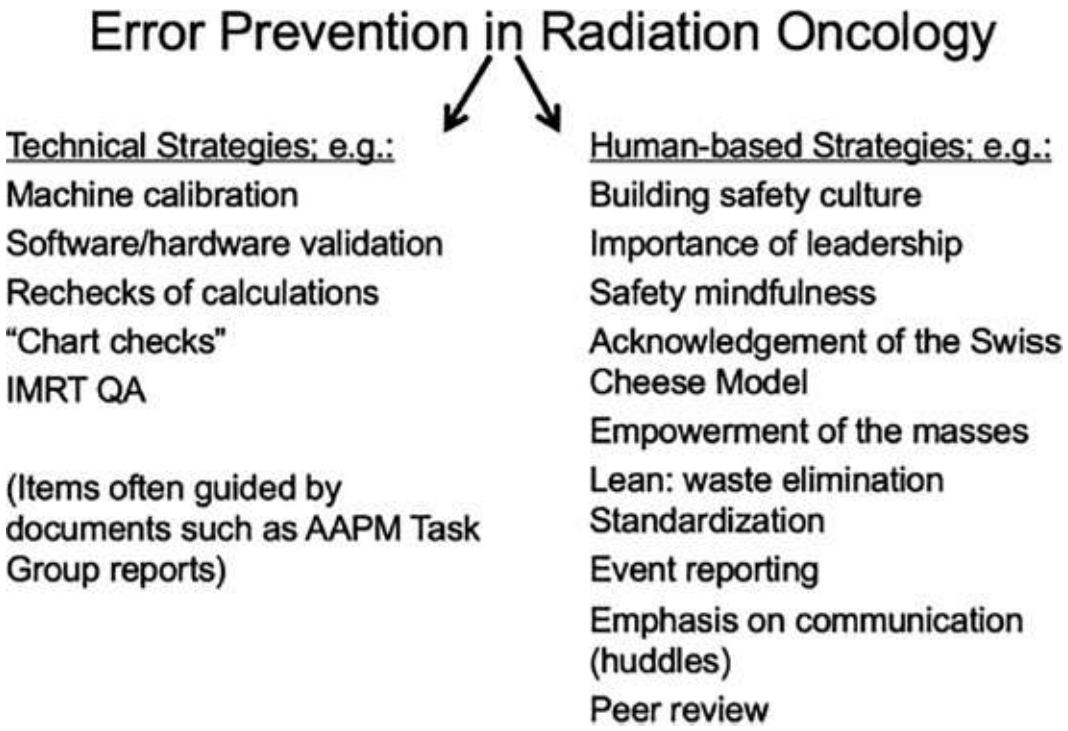

FIGURE 102.1. There are many technical-based strategies to prevent errors in radiation oncology (e.g., AAPM Task Group reports). In this chapter, we focus on human-based strategies.

PHYSICIAN LEADERSHIP

Transformational physician leadership is absolutely necessary for error avoidance strategies to be successful.

Traditionally, the quality of radiation delivery has been the responsibility of the "technical personnel," for example, physicists, dosimetrists, and radiation therapists. QA has historically been largely focused on the mechanical performance of the radiation therapy devices, the accuracy of the treatment planning system, and the physical and mental tasks of the radiation therapists. This is clearly insufficient as the experience from HROs demonstrates that quality can only be achieved by a multipronged effort to define robust and consistent procedures, the monitoring of quality indicators to assess reliability of these procedures, and a culture to support these ongoing activities.

TABLE 102.2 COMMON TERMS, KEYWORDS, AND VERNACULAR OF ERROR AVOIDANCE/PREVENTION

Keyword/Term	Definition/Explanation
Quality	The IOM defines quality as "the degree to which health services for individuals

	and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge”
Safety	Safety (or patient safety) is the prevention of errors and adverse effects to patients associated with health care
Error	An error is a preventable adverse effect of care, whether or not it is evident or harmful to the patient. Slips, lapses, and mistakes are all considered forms of error, mainly human error
Near-error	An event or situation that could have resulted in an accident, injury, or illness but did not either by chance or through timely intervention
Quality control	All planned operational techniques necessary to retrospectively verify if a provided product or service met the requirements of quality
Quality assurance	All planned proactive (i.e., prospective) processes, techniques, and actions necessary to ensure adequate confidence that a product or service meets the requirement for quality
Incident reporting system	A program/system by which any individual of an organization can report incidents (safety events, error, near-errors, etc.) that occur in their daily work for analysis and shared learning in a secure and nonpunitive environment with the goal of improving quality and safety
Hierarchy of effectiveness	Human factors engineering concept for error reduction strategies
Lean	A systematic approach to identify and eliminate waste (non–value-added activities) through continuous improvement
Human factors engineering	An engineering knowledge domain that covers three main areas: (1) physical ergonomics concerned with physical activity, (2) cognitive (or information processing) ergonomics concerned with mental process, and (3) organizational (or macroergonomics) ergonomics concerned with sociotechnical system design
Normal accident theory	Theory that hypothesized that systems in which elements are tightly coupled and interactively complex would be subjected to accidents in the normal course of operations
Swiss cheese model	A conceptual error causation model based on four failure domains: organizational influences, supervision, preconditions, and specific acts

Radiation oncologists’ participation in continuous quality improvement (CQI) has generally been limited. Though the majority of radiation oncology clinic and department leaders are radiation oncologists, CQI has not been a priority in their work. This current arrangement will not support the culture needed to build robust and sustainable improvements. Radiation oncologists have unique clinical perspectives that are needed during CQI initiatives, and as leaders, they must be actively involved to motivate others and build an optimal culture to support this work.[19] Furthermore, the expanding complexity of the broader health system and the rapid adoption of increasingly complicated radiotherapy technologies compel radiation oncologists to be involved in the CQI effort.[19]

Changing organizational culture in medicine is difficult and impossible without physician engagement and leadership. Physician leadership is a key

element to designing, fostering, and nurturing a culture of safety.[19–22] Physician engagement in quality improvement is fundamental for successful organizational cultural change.[21,22] Physicians must be identified as champions of safety and be involved in CQI initiatives from the beginning.[21,22] To create a healthy culture of safety, physicians must adopt a "no-blame" environment that fosters open communication in which all team members are free and responsible to raise concerns about quality and safety. Getting "buy-in" and support from team members for a quality/safety agenda is difficult. First and foremost, physicians must publicly declare and support quality and safety and empower and motivate others to continuously improve quality and safety. At departmental faculty and staff meetings, at educational conferences, and within the clinic, physicians should dialogue about the importance of quality and safety and celebrate those who are actively engaging in initiatives and improvements. Physicians should not be on the "sidelines" as observers but should visibly and actively serve as leaders of quality and safety.

According to change management experts, successful CQI efforts require that physician leaders demonstrate a blend of *transactional* and *transformational* leadership behaviors.[23,24] Transactional leadership is a task-oriented, command-and-control approach emphasizing what needs to be done and how to do it. This approach seems to be most useful when organizations are operating within well-defined constraints and seek to further efficiencies within existing structures. Transformational leadership focuses on the relationship between the leader and follower and is largely concerned with motivating and inspiring followers to do more than expected. It is contingent on followers' strong levels of trust, admiration, loyalty, and respect for the leader. This approach is most useful when organizations are attempting to adapt, innovate, and change in order to address new opportunities and challenges. Transformational leadership appears to result in greater job satisfaction and a more collaborative/helpful environment among workers as well as higher trust in the leader.[25]

In summary, physician leaders must actively work with others to promote quality and safety with high levels of urgency for change, charisma, vision, et cetera. The behaviors, actions, and words of physician leaders can carry great weight as others may emulate them. A physician leader who does not consistently and overtly espouse these principles may inadvertently discourage others from embracing these concepts. Physician leaders need to continuously inspire people to go beyond their regular duties and identify ways to improve quality and safety.

SYSTEMS THINKING

The effective and safe application of radiotherapy requires many team members, technologies, and processes to function reliably. The ever-present risk of errors including unforeseen errors and interactions in our systems is complex, for example, failure patterns are not always predictable. Sustainable advances in quality and safety require that we adopt a *systems-based approach* for error avoidance and prevention.[26–29]

The Problem with Systems Thinking in Medicine

Medical training and education have developed a culture with a powerful tenant that quality and safety are the personal responsibility of the physician. Physicians are taught that if we work and study hard enough, we won't make a mistake. Thus, many physicians believe that quality and safety improvements are a personal endeavor to be conducted in their autonomous microsystem. This credence does not allow for a system-based perspective and naturally leads to a "blame culture." Physicians are socialized in medical school and residency to strive for error-free practice, are taught that mistakes are unacceptable, and thus condition themselves to be infallible. Physicians are motivated to not commit errors, in part, for fear of punishment via social/peer disapproval. Errors are seen as character flaws and as someone's fault, and blame is used to encourage proper performance. This desire to be infallible may result in physicians not reporting errors, because of embarrassment/shame by colleagues, fear of patient reaction, and fear of litigation. Also, as errors are not discussed, potential lessons learned are not shared with team members and processes and systems are not improved.

Unfortunately, the culture of medicine is based on individuals not making errors rather than (appropriately) acknowledging that they will, that is, that physicians are humans performing in imperfect systems. Dr. Lucian Leape has stated that "The single greatest impediment to error prevention is…that we *punish* people for making mistakes."[5]

Errors Will Occur and Are Due to System Flaws, Not Character Flaws

Professors Popper and McIntyre published an enlightening paper in 1983 entitled "The critical attitudes in Medicine: The need for a new ethics," including the following principle assertions: (a) "Errors by doctors are common," (b) "We (physicians) are all fallible, and it is impossible for anybody to avoid all mistakes, even avoidable ones. The old idea that we must avoid them, has to be

revised. It is mistaken and it has led to hypocrisy," and, (c) "But whereas doctors may acknowledge this responsibility in principle, there is little evidence that they spend much time analyzing their error, either in clinical practice or even during their training."[30]

Radiation oncologists must understand that errors will occur (as part of the human condition) and that we must design systems to minimize errors, identify them efficiently, and prevent them from reaching the patient. Error-free performance is unachievable and the mentality of infallibility will inevitably result in system failure. From the cognitive psychology viewpoint, making mistakes is, in fact, a "normal" behavior, a condition for learning which gains experience on how to interact with the world. Remember the saying "good judgment comes from experience, experience comes from bad judgment."

In addition, the belief that an error-free practice is a realistic objective is a source of great stress and ultimately results in professional burnout. Expecting errors to occur and realizing that they are a manageable part of everyday practice allow us to practice in a no-blame culture focusing on the underlying root causes of system failures. Although the proximal error is often a human error, the root causes of the error are often due to poor system and organizational design. Workers are not so much the actors of their own errors; rather, they are victims of a poorly designed environment. Errors are indicative of system flaws rather than character flaws. The medical approach to error avoidance has been with superficial investigations of the often downstream causes of errors resulting in solutions to prevent specific individuals from repeating the error. This approach often results in work-arounds that may only temporarily prevent errors. Understanding the underlying root causes and creating system solutions will lead to sustainable improvements. For example, though a radiation delivery error may be immediately attributed to a performance issue with a radiation therapy technologist, the underlying root cause may be due to inadequate supervision or training, workload (too much or not enough), nonstandardized/ambiguous communications, or poorly designed human–machine/computer interfaces. Management decisions can have unintended consequences creating workplace situations that predispose team members to errors, that is, "accidents waiting to happen." Systems should be designed to incorporate a series of safety barriers that make it difficult for an individual to err. In other words, our systems and environment should make it easy to do the right thing. This concept does not imply that character flaws are nonexistent. Repeated mistakes by the same individual should raise concerns regarding his or her ability to carry such a

function but only after the root cause problems have been honestly and properly addressed. Furthermore, team members should be held accountable for participating in quality improvement work (e.g., reporting errors, participating in improvement discussions) and in fostering a safety culture (e.g., not ostracizing others for reporting or making errors).

Focusing on Making Better Systems ("It's the Process, Not the Person")

Human error has been extensively studied by psychologists and engineers in HRO (e.g., aviation, nuclear power, automobile manufacturing). Two theories that are particularly instructive to medicine are the Swiss cheese model (SCM) and normal accident theory (NAT).

Swiss Cheese Model

Although errors are often attributed to human error, their root causes are often poor system and organizational design (James Reason, Swiss cheese model [SCM][31]) (Fig. 102.2). The successful practice of radiation oncology relies on people and their ability to repeatedly perform diverse tasks in a reliable and accurate manner. However, people do not perform tasks in a vacuum. From the SCM perspective, peoples' actions (Fig. 102.2) are influenced by "upstream" latent failure pathways (contributory factors that may lie dormant for long periods of time) at the organizational, workplace, and people levels (e.g., policies, programs, schedules, workflows, training, perceptions). The worker's action that is linked to the incident (e.g., forgetting to do something) is often referred to as the "active failure." Often, during root cause analyses, too much emphasis is placed on the person's active failure and not enough attention to the "upstream" layers of the SCM.

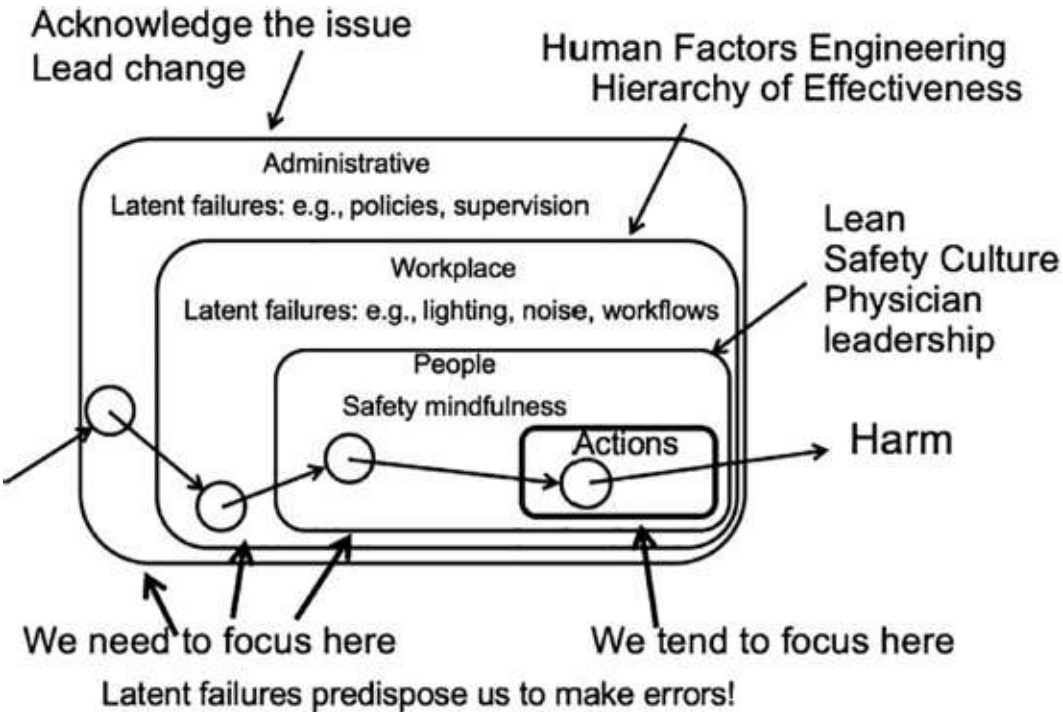

FIGURE 102.2. Adaptation of James Reason's Swiss cheese model. Human Factors Analysis and Classification System

From a system thinking perspective, it is critical to analyze both the active and latent failure pathways to fully understand root causes of patient harm. The human factors analysis and classification system (HFACS) model is perhaps the most widely used method, having been applied in civil and military aviation,[32,33] helicopter maintenance,[34] coal mining,[35] rail transportation,[36] maritime,[37] construction,[38] health care,[39] and road transportation.[40] HFACS was developed by Shappell and Wiegmann,[32] based on Reason's SCM (Fig. 102.3). HFACS investigates events using 4 main levels of failure and 12 additional sublevels (Fig. 102.3).[31] To classify an event into the various categories of the HFACS model, a user starts at the first level (unsafe act, mandatory to select) and then proceeds to the corresponding sublevels (e.g., unintended vs. intended violation), followed by the nanocodes (unintended violation, skill based vs. decision-based vs. perceptual; intended violation, routine violation vs. exceptional violation). Although these categorizations are somewhat arbitrary and inexact, they can help drive improvement work by providing a framework to better analyze and understand system behaviors.

We will apply this approach to an incident that occurred in our clinic. The patient was scheduled to receive a bilateral lung treatment: first to the left lung and then the right lung. When the radiation therapist downloaded the patient's right lung treatment plan, the digital reconstructed radiograph for the right lung plan was the same as the digital reconstructed radiograph from the left lung plan. Using HFACS at the action level, the failure investigation team identified an *unintended action* where the planner demonstrated an attention failure as one of the causes (forgot to change the right lung digital reconstructed radiographs). At the precondition for unsafe act level, the team found the planner was under an increased workload. At the unsafe supervision level, the team identified both the physician and planner failed to check digital reconstructed radiographs before approving the plan. Finally, at the organization influence level, the team identified the lack of a formal policy for digital reconstructed radiograph checks. In summary, application of the HFACS model may help identify and foster discussion on latent failures and their pathways, reduce the temptation for finger pointing, and develop a culture of safety.

Normal Accident Theory

Substantial work in non–health care settings has been performed to better understand the causes of accidents and investigate potential mitigation strategies. One of the nation's leading theorists in the area of safety, Dr. Charles Perrow, coined the term normal accident theory (NAT, Fig. 102.4).[41] He argues that failures in systems occur often and are indeed expected and part of the normal operations (hence the name *normal*). He categorizes systems based on how these failures interact within the larger system and lead to major accidents. Systems in which failures propagate and interact predictably are considered *linear* and those where failures behave unpredictably are *interactively complex*.

He further categorizes systems in their ability to detect and respond to failures. Systems that are relatively slow with more opportunity to detect and respond to failures are termed *loosely coupled*, whereas those that are fast with less opportunity to detect and respond to failures are termed *tightly coupled*.

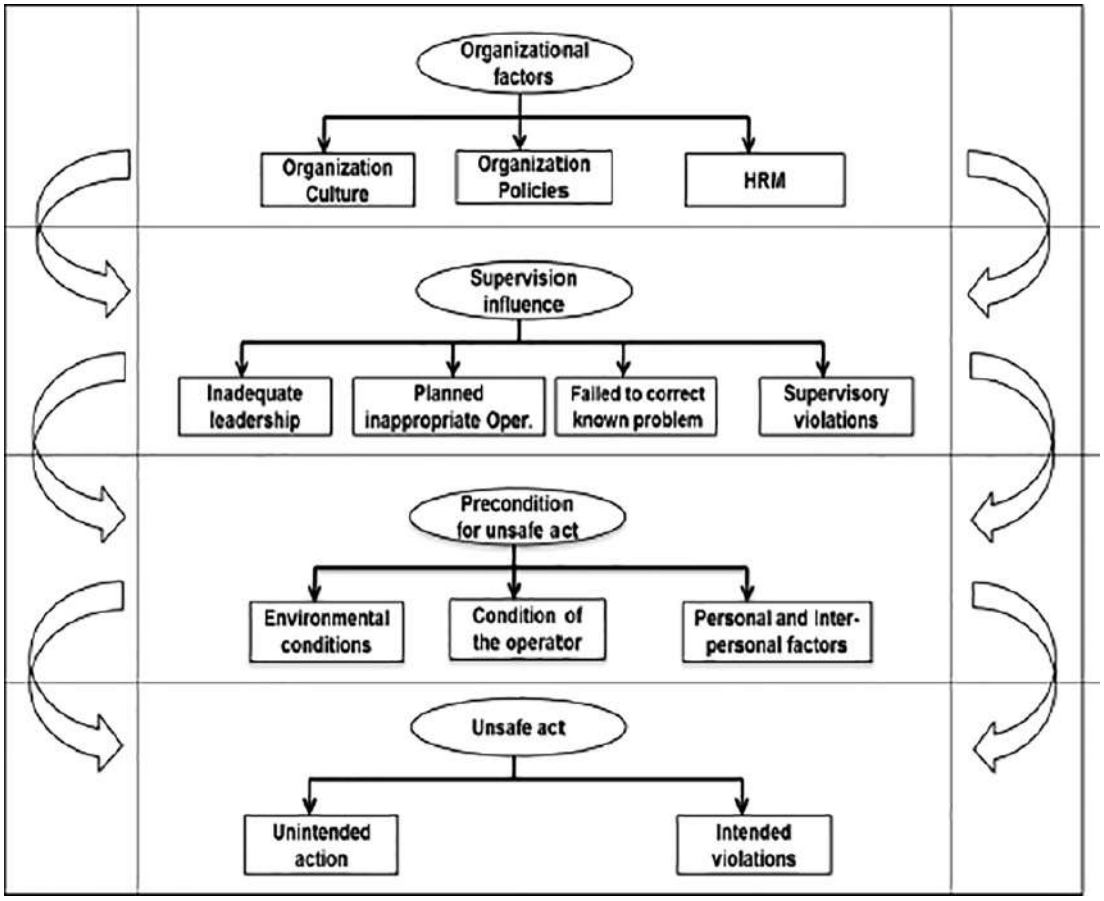

FIGURE 102.3. HFACS model with categories, subcategories, and hierarchy. (Reprinted from Mosaly P, Mazur LM, Burkhardt K, et al. Application of Human Factors and Classification System [HFACS] Model to Event Analysis in Radiation Oncology. *Pract Radiat Oncol* 2015;5[2]:113–119. Copyright © 2015 Elsevier. With permission.)

For example, the post office is linear (failures have predictable consequences) and is loosely coupled (failures are largely corrected and most of the mail ultimately gets delivered). Dams are also linear, but are tightly coupled. A dam breach will likely lead to a flood because the time scale required to fix the breach is too long to mitigate the (literally) downstream effects. Universities are interactively complex because events in their varied components (e.g., multiple departments, schools, social events, athletics, etc.) interact in unforeseen ways (Fig. 102.4).

Perrow argues that systems that are both interactively complex and tightly coupled have a particular propensity for catastrophic failure. Failures in these subsystems are assuredly going to occur, and because these will propagate in unforeseen ways that cannot be mitigated, major global system failures are probable. In other words, complex systems cannot be fully understood and their

behavior will always have some element of chaos. He argues that only a change in their structure such as reducing coupling, or reducing interactive complexity, can help reduce the probability of a catastrophic event.

Applying NAT Constructs to Radiation Oncology

Is radiation oncology linear or nonlinear (Fig. 102.4)? From the provider's perspective, workflow in the clinic might be broadly simplified as:

- Evaluate the patient and medical records.
- Make treatment recommendations.
- Perform radiation treatment planning.
- Review treatment plans (often iterate).
- Initiate therapy.
- Conduct treatment management (i.e., monitor/continue therapy, repeat).

Similarly, on the technical side (e.g., physicist/dosimetrist/therapist), workflow for a radiosurgery case might be broadly simplified as:

- Gather planning images.
- Fuse planning images with diagnostic images.
- Generate image segmentations.
- Review desired dose/volume parameters with the provider.
- Perform treatment planning.
- Perform plan QA.
- Bring patient to the machine.
- Perform pretreatment QA/alignment verification.
- Deliver treatment.

These are largely forward or linear processes with failures typically propagated from one step to the next. However, these are idealized presentations of the workflow. There are many nonlinear components (e.g., iterations in the treatment planning process and the repeats in the treatment management). Some of the newer technologies (e.g., image-guided radiation therapy [IGRT], adaptive therapy) also introduce nonlinearity and interactive complexity. Thus, for the most part, the flow of information and the impact of associated failures are orderly and in the forward (likely predictable) direction. However, with some of the newer technologies (e.g., adaptive therapy, IGRT), there is information flow in the reverse direction, essentially causing some procedures to be repeated. Further, some of the processes are long, with many steps (e.g., intensity-modulated radiation therapy [IMRT] planning and delivery), thus increasing the

possibility of unexpected interactions of different failures.

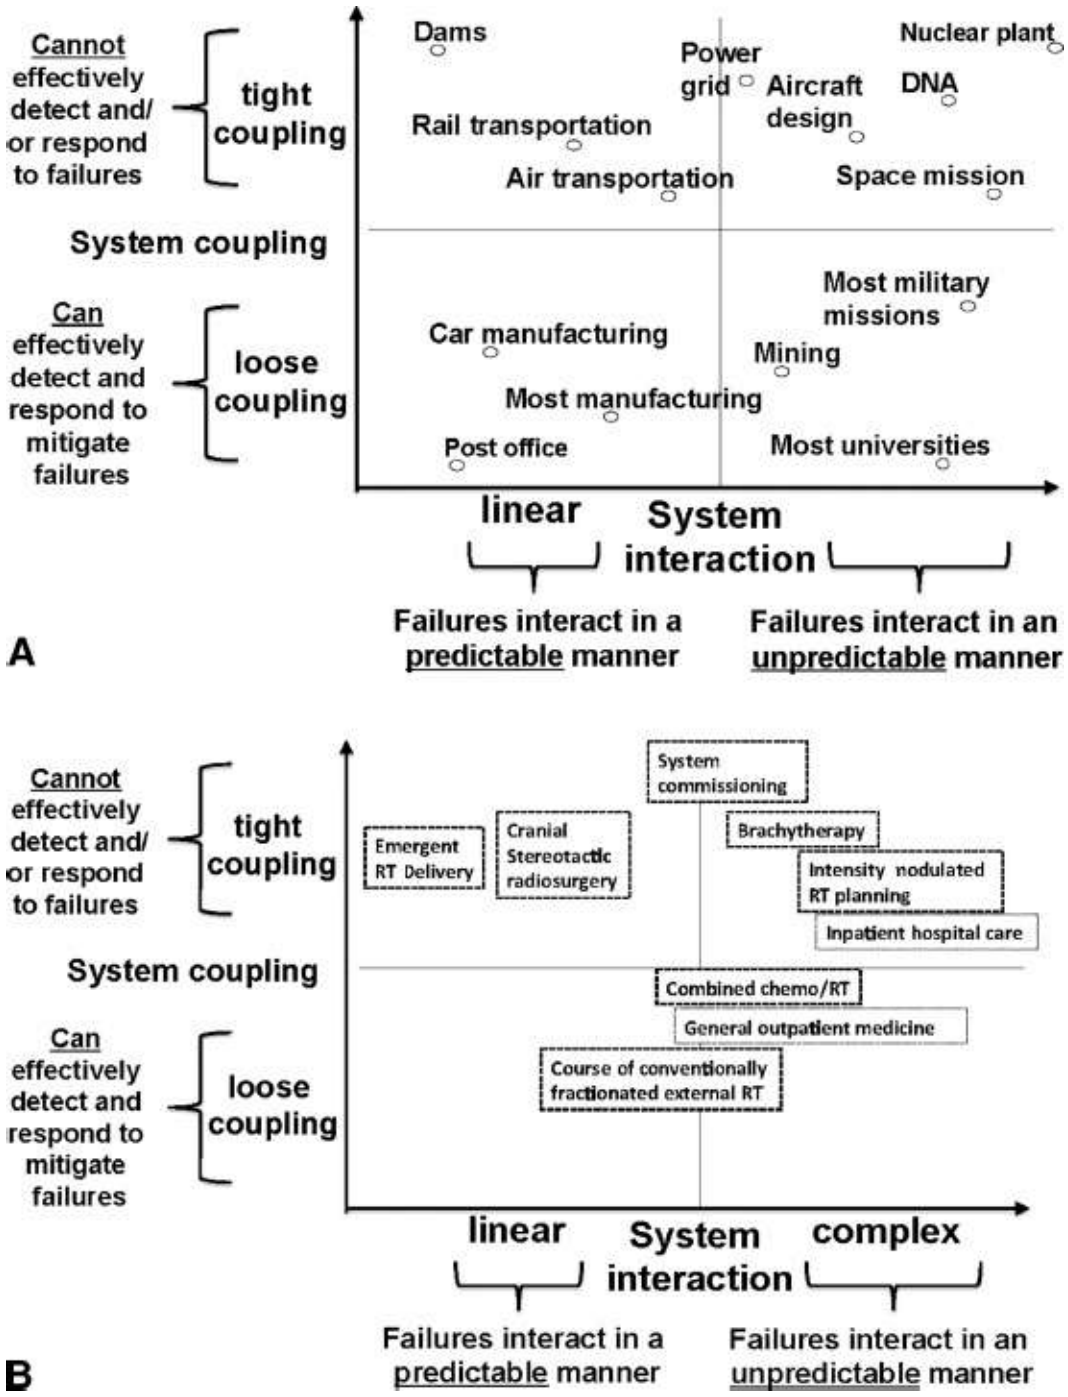

FIGURE 102.4. Normal accident theory concepts of loose versus tight coupling (*y*-axis) and linear versus interactively complex **(A)**. Several nonmedical systems from Perrow's original description are plotted according to normal accident theory concepts. (Adapted from Perrow C. *Normal accidents: living with high-risk technologies*. Princeton paperbacks. Princeton, NJ: Princeton University Press, 1999.) Car manufacturing processes (assembly lines) are considered as linear and loosely coupled systems. Things tend to happen in an orderly fashion (linear), and

failures can often be detected and corrected in a timely fashion. Water dams are thought of as linear and tightly coupled systems. A failure at one dam (e.g., a breech) typically has predictable downstream (quite literally) consequences (linear). The system is tightly coupled because this is almost certainly going to manifest (e.g., cause a flood). Even though the breech is readily apparent, it is usually not humanly possible to prevent the flood (the time scale for corrective action is much slower than the flow of the water). Universities are seen as complex and loosely coupled systems. Decisions in broad areas of the university often affect each other (interactively complex). The unforeseen impacts of these complex interactions are often detected and can be addressed and averted in a timely fashion (loosely coupled). Nuclear power plants are examples of interactively complex and tightly coupled systems. The interactions between the various components are hard to predict; things can happen very fast, much faster than the response time of a human monitoring the system (tightly coupled). In **B**, we map several radiation oncology processes to approximate locations on the normal accident theory grid. (Adapted from Marks L, et al. *Engineering patient safety in radiation oncology: University of North Carolina's pursuit for high reliability and value creation*. Boca Raton, FL: Taylor & Francis, 2015.)

Is radiation oncology coupled or uncoupled (Fig. 102.4)? Broadly speaking, most radiation oncology processes are modestly coupled. The pace of the work is generally slow enough for unexpected interactions between failures to be evident. For example, suboptimal decisions about patient positioning and immobilization are typically evident early in the course of therapy and can be addressed. In many areas of radiation oncology, as well as other areas of medicine, the relatively slow pace tends to soften the impact of failure (i.e., reduce their clinical impact).

Are there parts of our practice that are tightly coupled (Fig. 102.4)? Yes, consider intraoperative radiotherapy, brachytherapy, and radiosurgery settings where the entire procedure is often compressed into a few hours. In these instances, some steps have near-immediate impacts on other steps. Furthermore, portions of our routine processes are very fast. Consider the setup and delivery steps for each individual fraction of radiation: patient identification, setup, image verification, and treatment delivery. This sequence of steps occurs very rapidly, which leaves the potential for many human errors. Also, failures in some processes can be difficult to detect and may affect many treatments or patients downstream (e.g., system commissioning) and thus may be considered tightly coupled. As we introduce more components to the processes such as combined chemoradiotherapy and adaptive therapy, the number of steps and people involved increases. Interactions become more complex (unusual interactions between failures become more likely) and coupling becomes tighter. It may become more difficult to detect and address these failures.

So, what is the relevance of this discussion? Can we use these constructs to

guide QA strategies? Safety experts suggest there are global optimal QA strategies applicable to all types of systems (e.g., leadership-driven safety mindfulness, the application of automation and forcing functions wherever able, etc.). However, there are particular QA considerations for different systems depending where they lie on this paradigm of linear versus interactively complex and loosely coupled versus tightly coupled.

For example, a course of conventionally fractionated external RT (mostly linear, modestly coupled, and generally slow) might be amenable to employee-based CQI strategies. For interactively complex systems that are loosely coupled, their behavior is less predictable than the linear systems. Failures and their interactive effects can be detected, but corrective actions often have further unforeseen effects. Thus, to assure quality, a strategy of continuous comprehensive monitoring (perhaps with forcing functions) is best. Any changes or interventions need to be carefully considered as they may result in unexpected consequences. CQI-based improvement cycles may be useful in some areas but may be more challenging because there are more stakeholders and interactive effects can be difficult to predict. Thus, these systems may appear to be sometimes chaotic, as leadership responds to continual iterations. Because their pace is somewhat slow, observers have the luxury to analyze system behavior retrospectively and to second-guess previous actions (because interactions may seem obvious in hindsight). Processes that are both interactively complex and tightly coupled can be unpredictable. Failures and their interactive effects are often not detected until they manifest as a catastrophic event given that their character may be unknown (e.g., it is hard to monitor and thus detect an unforeseen type of failure). Even if failure effects are detected, human-based corrections are unreliable as system behavior is interactively complex. Thus, quality is best assured by rather strict adherence to process standardization in all areas. System performance needs to be comprehensively monitored because the nature or type of a failure cannot be reliably predicted. Ideally, this monitoring process should be automated to assure compliance; human intervention is too slow and often misguided. Vigilant testing and verification are needed before any changes in the system or its processes are made. The adoption of automation and forcing functions (where possible), end-to-end testing, strict QA, and redundant checks for IMRT planning, brachytherapy, and system commissioning reflects our field’s recognition that these systems are interactively complex and tightly coupled. These processes are made safe for clinical use through QA initiatives. Further, our field embraces automated technologies aimed to enhance

accuracy and patient safety (e.g., automatic tracking, gating). If this is copied verbatim, that is fine; we just need to be sure that we say so in the acknowledgments and be sure that we get permission from the publisher of our book.

TABLE 102.3 SIMPLISTIC EXAMPLE OF FAILURE MODES AND EFFECTS ANALYSIS (FMEA)

Steps in the Process	Failure Mode	Failure Causes	Failure Effect	Likelihood of Occurrence (1–10)	Likelihood of Detection (1–10)
3Ps (pacemaker, pregnancy, prior radiation)	Increase in patients treated without accounting for 3Ps	Information entered in an electronic medical record by the nurse cannot be transferred automatically into the planning system	Damage to the pacemaker thus leading to cardiac complications, miscarriage, or excess radiation toxicity	6	5

Failure Modes and Effects Analysis

Failure Modes and Effects Analysis (FMEA) is a prospective way to conduct failure analysis and is based on trying to predict where failures will occur (vs. HFACS, a retrospective approach). The FMEA technique is a well-established and widely used tool for safety and improvement in many industries[42] including health care[43–45] and, specifically, radiation therapy.[46,47] The FMEA technique consists of three steps. First, it requires generating or selecting process steps for analysis. Second, it lists all possible failure modes per each process step. Third, a numeric value is assigned for each failure mode based on (a) likelihood of occurrence, (b) likelihood of detection, and (c) potential severity. The numeric values usually range from 1 and 10, with 1 meaning “very unlikely to occur/detect” and 10 meaning “very likely to occur/detect.” Finally, a risk priority number (RPN) for each failure mode is calculated by multiplying the three scores. The lowest possible score could be 1 and the highest 1,000.

Identifying the failure modes with highest RPNs should help teams prioritize improvement opportunities (e.g., see Table 102.3).

Ford et al.[47] applied this FMEA approach to processes within their radiation oncology clinic. Only approximately 50% of the actual incidents occurring in their clinic were predicted by the formal FMEA analysis. This observation highlights the complex nature of our systems, that is, failure modes cannot always be predicted as there are often unforeseen failures and failure interactions. The utility of FMEA for error avoidance and prevention in radiation oncology requires further study.

CONTINUOUS QUALITY IMPROVEMENT

Processes in many HROs and in most areas of medicine are continually evolving. Even if systems were "perfect" at one instance in time, they will assuredly drift toward imperfection as workflows change. Further, given the complexities of these systems, changes in processes may have unforeseen consequences. For these reasons, it is generally understood that continuous incremental improvements are needed to adapt to evolving systems and to carefully evaluate the consequences of any changes as well as minimize the risk of unforeseen problems. A cornerstone of quality improvement work is improvement *cycles* with ongoing monitoring informing additional cycles in a never-ending iterative manner. This approach continually drives change forward and ensures that proposed improvements are implemented, sustained, and modified (as needed) over time. Often, this cycle is referred to as Plan–Do–Study–Act, or PDSA.

Radiation oncology departments are highly complex entities that require numerous subsets of employees working simultaneously to achieve the common goal of treating patients safely, effectively, and efficiently. Within these groups are numerous opportunities to improve workflow and outcomes. Although any improvement may have a positive effect within its specific group, there is a real possibility that other groups will develop unforeseen problems as a result of changes made in order to achieve that improvement. The PDSA cycle, when correctly implemented, takes into account the complexity of the interrelationships between these groups and considers the unintended consequences that suggested improvements might have on the system as a whole instead of just one part. The major steps in the PDSA cycle are:

- *Plan*: This is the start of the cycle. In the planning stage, a problem within the

system is identified and described in detail so that a set of goals and expected outcomes can be determined.

- *Do*: This is the initial implementation stage. Corrections that result from the planning step are implemented, and data are collected that relate to the efficacy of these corrections.
- *Study*: This is the step of the cycle that takes the data collected in the previous step and analyzes how well everything is working. Here, the outcomes of the changes are compared to expectations, that is, if the changes made were actually the ones intended. Analyses completed here are carried forward to the next step.
- *Act*: This is sometimes considered the "adjust" phase of the cycle. The focus is to assess the analyses from the study phase and determine what adjustments can or should be made in order to better address the identified problem.

Transforming Individuals into Effective Problem Solvers

The challenge is *how* radiation oncology professionals will respond to latent and active failures when they occur, not *whether* they will respond. Radiation oncology professionals are dedicated employees who take pride in the safety of their patients. Human nature and working conditions often predispose radiation oncologists to develop quick fixes and work-arounds when faced with latent and active failures. Prospective PDSA problem-solving behavior is difficult to cultivate in individual workers, but this type of problem-solving is the most effective and most likely to result in long-term quality improvement. Furthermore, empowerment of frontline staff (i.e., nonphysician staff) is crucial to the CQI process. Given that there are more nonphysician staff than physician staff in a radiation oncology department, there are a greater number of ideas that can be generated for problem-solving and PDSA cycles if they are given the support to participate in and/or lead quality improvement efforts. In addition to supportive and engaged leadership and a strong culture of safety, additional driving forces acting on individuals transforming their behaviors include the following[32]:

- *Standard operating procedures*: Support employees with detection of failures. When standard operating procedures continuously "fail," this should conflict with the desire to conform to existing ways of operating. This, in turn, should spur individual motivation for change.
- *Positive feedback*: Employees need to know their improvement efforts are valued even under circumstances of suboptimal final results. If feedback is positive, employees are more likely to invest in future improvement efforts.

- *Role models*: Employees need to see that problem-solving behaviors are rewarded. The exact nature of the reward, that is, monetary, title, or other nonmonetary recognition, is not as important as the reward's meaning to the recipient and the value placed by the members of the organization. This creates tangible examples for others to emulate.
- *Job-related autonomy*: Without a sense of autonomy, employees tend to follow the rules, especially if the rules are perceived to be good enough and do not openly cause harm. Without autonomy, conformance is viewed as a safe choice.
- *Support from direct supervisor*: This is needed to create an appealing work environment for problem-solving behaviors. Employees must be empowered by supervisors to take action.
- *Individualized attributes of the employee*: Employees with a strong sense of care and concern for patients, coworkers, and the organization are more likely to break free from the status quo and take improvement actions based on problem-solving behaviors.
- *Critical thinking skills*: Employees must be trained to skillfully conceptualize and assess situations, question assumptions, determine options for responding to the situation, apply improvement tools, and make intelligent decisions.
- *Organizational accountability*: This accountability refers to becoming a continuous improvement organization. In the presence of failures, it is leadership's role to set improvement expectations at a high but attainable level. In the absence of failures, leadership must develop a sense of urgency to improve and communicate its importance.

Although understanding, developing, and promoting the driving forces for positive change is of high importance, careful consideration must also be given to restraining forces, which can act as barriers to the transition to problem-solving behaviors.

- *Low staffing levels and high work efficiency requirements*: If employees are to become initiators or enhancers, they must have time in their workdays to take necessary actions for improvements. If staffing levels are low and the demands for efficiency and productivity are high, the perception is there is not sufficient time to institute real improvements. Thus, making quick fixes, expediting, or conforming is more likely to happen.
- *Burdensome defect reporting systems*: When reporting systems are too administratively burdensome, employees are less inclined to report a defect, which, in turn, decreases an organizations ability to learn.
- *Concerns related to psychological safety*: Employees' ability to think and act

freely without fear of negative consequences to self-image, status, or career is repeatedly identified as a significant restraining force. Prior research has demonstrated that higher psychological safety increases the willingness of individuals to engage in failure reporting and improvement behaviors even though such efforts are inherently risky and can have negative personal and career consequences.[48,49]

- *Gratification and burnout*: Naturally, initial reactions to quickly fixed problems or procedural shortcuts under time pressure can bring some satisfaction. This feeling of instant gratification can be a powerful motivator for continuing to use work-arounds to get rapid resolution of problems. Such "firefighting behavior" becomes the norm and the desire for true improvement is dampened. However, in the long run, when employees find themselves solving the same problems, a more insidious restraining force arises due to personal burnout.
- *Culture of conforming to work procedures*: When organizational pressure to conform to work procedures is strong, employees will not be motivated to engage in process improvement efforts. Note that this force does not imply abandoning efforts to develop standard operating procedures. Rather, it implies that the desire to comply with work procedures may motivate employees to keep doing their jobs in the same way.
- *Suboptimal training on improvement philosophy*: If employees have not been exposed to an improvement philosophy at work, they are less likely to know the mechanics of how to continuously improve. The specialized methods, tools, and mind-set required to succeed at initiating and enhancing behaviors must be disseminated to frontline workers. This requires dedicated training and a sustained commitment by the leadership team.
- *Lack of dedicated improvement time*: Without time to invest in problem-solving behavior, employees may find it difficult to sustain this behavior over time.
- *Lack of knowledge of improvement methods/tools*: Those who are effective at initiating and enhancing need to be trained in these areas and gain experience over time in applying tools and methods.
- *Lack of operational visibility*: Certain systems in radiation oncology centers are tightly coupled where the actions of one professional group tend to affect or be affected by actions of other professional groups. The lack of visibility of how their local work areas are connected to the larger operating system can limit employees' ability to be effective at problem-solving behaviors. Without sufficient visibility and understanding, it is difficult for employees to identify sources of defects and make system-wide improvements.

- *Lack of employee's social network for improvement*: Outside of senior leadership, direct supervision, and explicit continuous improvement role models, potential initiators and enhancers need a support system of colleagues. Employees who strive to enhance will experience inevitable setbacks and challenges. The support and encouragement of colleagues can be invaluable to continuous improvement initiatives.

"Lean" Approach to CQI

Lean is a management philosophy derived from the Toyota Production System.[50,51] The heart of Lean is preserving value with less work by the identification and elimination of "waste" and developing highly reliable processes. This is performed in a context of connectedness, respect, and growth of all employees who are trained to identify waste and errors and suggest possibilities for improvements that will be tested using scientific methods. Categories of waste include defects, overproduction, waiting, overprocessing, excessive inventory and motion, and (most damaging) failure to use employees to their highest potential. Waste reduction results in quality improvement and reduction in time and cost. The Institute for Healthcare Improvement believes that Lean principles can and are being successfully applied to the delivery of health care. Hence, it makes sense to take a closer look at Toyota to learn how they have developed their processes.[52] A few of the more common process engineering practices are:

- *Just-in-time*: Producing only what is needed, when it is needed, and in only the necessary quantities; reducing work-in-process inventory.
- *Kanban*: A card that signals production of a set quantity of goods once that number of goods has been used by a customer process.
- *Production leveling (or heijunka)*: Spreading production evenly over time; reducing batch sizes to one.
- *Set-up time reduction*: Reducing the time to changeover between producing different products; required to make production more even.
- *Standardized work*: Documented and detailed work procedures strictly followed by everyone doing the job such that the work is performed the same way every time.
- *Multiskilled workers*: Workers trained in multiple job tasks so work can be assigned flexibly to balance the line dynamically.
- *Kaizen*: An activity with a purpose to remove the waste ("muda") and to humanize the workplace by eliminating overly hard work ("muri").

At the operational level, Lean is equipped with two basic tools: *value-stream mapping*[53] and the *A3 problem-solving tool*.[54,55] Value-stream maps graphically represent key people, material, and information required to deliver a product or service. They are designed to distinguish value-adding from non–value-adding steps. A3s are a problem-solving tool where the user documents the problem area, current state, root cause analysis of the problem, target condition, countermeasures, implementation plan (who, what, when, outcome, metrics), and follow-up plan (30-, 60-, 90-day assessment) on a sheet of paper (the name "A3" is derived from the paper size). These basic tools are often used during Kaizen events, which are usually 1- to 4-day activities where employees engage in small cycles of improvement that promote Lean thinking and behavior. Kaizen events are a critical component in implementing lean because they directly eliminate unnecessary waste and bring the organization closer to desired performance outputs.

Six-Sigma Approach to CQI

Six Sigma is a business management philosophy for quality improvement that originated in the US manufacturing industry. It seeks to improve efficiency and reliability of processes by identifying and removing the causes of failures and minimizing process variability. The approach is heavily dependent on quantitative data; thus, the process can take many months to quantitatively assess the multiple components of the current state, design an improvement plan, and assess its impact. The term Six Sigma reflects the desire for critical errors to occur at a rate approximating six standard deviations away from the desired performance. Six-Sigma approaches require experts in data generation, analysis, and associated statistical knowledge. It uses the DMAIC process (define, measure, analyze, improve, and control) to conduct improvement projects:

- **Define:** To clearly articulate the problem under investigation while focusing on the voice of the customer (VOC) and critical to quality (CTQs) drivers. In addition, to establish project goal, potential resources, project scope, and project timeline and milestones.
- **Measure:** To objectively establish baselines as the basis for improvement. This data collection step establishes process performance baselines.
- **Analyze:** To identify, validate, and select root causes for elimination.
- **Improve:** To identify, test, and implement a solution to the problem, in part or in whole. Lean and Six Sigma are often combined at this step, especially when the goal is to reduce operational waste.

- **Control:** To sustain gains and monitor improvements to ensure continued and sustainable success. Control charts are often used during this stage to assess the stability of the improvements over time.

Compared to Lean, there is relatively little empirical research on the utility of Six Sigma to effectively improve quality and safety, other than "best practice" studies by consultants or practitioners. Further, Six Sigma is a more time-consuming and complicated process compared to Lean-based approaches and, when applied to complex systems within health care, can be particularly challenging because quantitative data may be needed from *many* interactive areas, thus complicating analysis. In practice, the length and difficulty of this approach can make physicians and other stakeholders disillusioned with and resistant to CQI work. Nevertheless, this "ultra–data-driven" approach can be very helpful in settings where the simpler Lean-based approaches cannot be applied. This may include settings where iterative trial-and-error approaches are not safe (e.g., where any failure can be catastrophic such as with nuclear power plants or NASA) and where such detailed multifaceted data are needed to even understand the current state.

PATIENT SAFETY CULTURE

The concept of safety culture originated in HROs such as nuclear power, aviation, and manufacturing. High-reliability organizations maintain a commitment to safety at all levels from frontline workers to managers. The safety culture of an organization is defined "…as the product of individual and group values, attitudes, perceptions, competencies, and patterns of behavior that determine the commitment to, and the style and proficiency of, an organization's health and safety management".[56] Creating a patient safety culture is a critical component of any type of safety improvement program. Outside of health care, a strong safety culture is noted as a critical underpinning in other high-reliability organizations.[56–58]

The key features of a culture of safety are (a) acknowledging the high-risk nature of processes, (b) having a blame-free environment where workers can report errors/near-errors without fear of punishment, (c) encouraging collaboration across ranks and disciplines to improve safety, and (d) organizational/leadership commitment of resources to address safety concerns. In non–health care high-reliability organizations, the safety of workers themselves is the focus of the safety culture. In health care, a culture of safety

for health care professionals is pertinent as is prioritizing the safe delivery of health care to the patient, hence the concept of *patient* safety culture. Assessing the safety culture in an organization can be challenging. The Agency for Healthcare Research and Quality (AHRQ) administers a patient safety culture survey that is generally regarded as a reasonable measure.[59] Interestingly, there are some data, albeit limited, to support the notion that centers with better safety culture scores, as assessed by their own staff, have lower rates of severe adverse events.[60]

The following are some of the key components of the safety culture within commercial aviation[61–65]:

- *Training*: Most commercial airline carriers encourage, reward, and pay staff to attend required quality/safety training. If an employee misses or fails training/proficiency checks, they usually face restrictions until their underperformance has been rectified. Training focuses on the inevitability of errors and the importance of culture, teamwork, and communication in avoiding errors as well as containing their spread and mitigating their effects before they lead to serious or catastrophic harm.
- *Policies and procedures that enforce safe operations*: There must always be two physiologically and psychologically sound pilots to fly a plane. This minimum safety requirement *always* applies. No exceptions are granted. This is often audited by random drug and alcohol tests. Further, during the safety-critical phases of a flight such as flying below an altitude of 10,000 feet, the pilots and cabin crew must adhere to strict standard operating procedures and refrain from all nonessential activities (e.g., reading newspapers or chatting idly). This safety requirement is known as the sterile cockpit rule. Crew members are taught how to call, without awkwardness, for implementation of the sterile cockpit rule at additional times when particular concentration becomes necessary. The entire crew is informed about the enforced rule through warnings or alert systems. Adoption of comparable policies in radiation oncology centers would be controversial, but they might better ensure patient safety.
- *Flight recorders*: These recorders, also known as black boxes, monitor key flight parameters throughout each flight. This data is analyzed by computers *after every flight*. Readings outside of predetermined acceptable ranges trigger warning signals that can initiate an investigation. The full exploration of flight recording is only conducted in catastrophic circumstances, but pilots and staff know that all of their actions are being monitored and that everything they do and say is being recorded.

How do we build an infrastructure to support a culture of safety in radiation oncology centers? Where do we start? Perhaps, not with flight recorders right away. However, one could consider posttreatment assessments of the quality of patient setups by a computer-based analysis of pretreatment images (e.g., cone beam CT or surface mappings) as analogous to flight recorders. More importantly, we believe that our field (and frankly all of medicine) needs to develop and maintain a high level of urgency toward change and innovation to improve quality and safety. We need to acknowledge our challenges and build a robust set of tools to drive improvement work as well as nurture the culture to support and apply these tools. Several examples of our initiatives include:

- *Incident learning*: Many HROs have incident learning systems in which any individual can report errors/incidents that occur in the processes they work with, and these incidents are studied and analyzed to identify targets for process improvement. Learning from these errors/incidents plays a key role in improving quality and safety. The *Good Catch Program* is our departmental incident reporting system. In effect since 2012, it is custom-built, enabling users to easily report any types of system failures (e.g., waste, work-arounds, incidents reaching the patients). Reporting can be done anonymously, if desired, if people are reluctant/anxious about reporting. Over time, with a "just culture," very few of our reported issues are anonymous. Reporting is encouraged and celebrated; the person(s) reporting the "best" good catches each month are publicly celebrated with their names and pictures posted in several places throughout the department. They are given a modest gift certificate for our hospital's eatery, and they are asked to sign the department basketball that is on display in our trophy case. The event reporting system is purposefully named "Good Catch" to provide a positive connotation to participation.[66,67] The American Society of Radiation Oncology launched the Radiation Oncology Incident Learning System (RO-ILS) in 2014 to provide a standardized system for analyzing incidents/errors and providing shared learning across the radiation oncology profession.
- *Safety rounds*: Departmental leaders speak with frontline employees about their work, for example, what is good, what can be better, how we can improve things for them, and do they have the tools they need to work safety, efficiently, and reliability? These discussions occur *at their workstations*, not in a conference room or office, as a sign of respect for the workers, and so leadership can better appreciate the issues being discussed. The goal is to improve performance of the overall system, empower workers to think about how they can make improvements, and help build a culture of respect and

improvement. Safety rounds, with visits to several locations in our department, occur every 3 months with the goal of reaching all areas at least annually.[48,68]

- *Huddles*: Suboptimal communication is one of the most common factors implicated in root cause analyses of critical events. Huddles, brief meetings among various members of work teams, held at regularly scheduled times, is an approach attempting to improve communication. For example, we ask our clinical teams (e.g., nurses, residents, and faculty) to briefly huddle at the start of a clinic day to review the schedule and identify any anticipated challenges (e.g., conflicts, double-bookings) that may be mitigated or accommodated. We also have a daily department-wide huddle where that day's planned clinical work is reviewed, again to identify and plan for anticipated challenges. The daily list of patients due for treatment planning and CT simulation is reviewed. Staff have the opportunity to seek clarifications regarding ambiguities in any of the directives, and the names of the doctor, resident, physicist, and dosimetrist "of the day" are reviewed. It is a time for announcements, introductions of visitors, and brief discussions of any items of broad interest or concern. These daily departmental huddles serve a social function, can help improve interpersonal and organizational communication, and break down unnecessary hierarchies.[56,69,70]
- *Time-outs*: These are formal standardized methods to help review the most crucial aspects of the radiation planning and delivery process (similar to a presurgery checklist in an operating room). Our dosimetrists and faculty perform a time-out at the time of signing the treatment plan and prescription to review the dose per fraction, number of fractions, treatment site, and the presence or absence of receipt of prior radiation, which aids in identifying possible overlap issues. Our radiation therapists perform a similar time-out on the first day of a patient setup on the treatment machine.[71–73]
- *Peer review*: Peer review can be loosely defined as the process whereby providers evaluate the quality of their colleague's work to ensure that prevailing care standards are met. Typically, peer review is most valuable for the somewhat subjective aspects of work that are not readily amenable to objective assessment. In medicine, this is often done retrospectively through chart review *after* patients complete their treatment. This retrospective approach can be helpful to detect shortcomings that can be addressed or to reinforce positive actions to improve care for future patients. However (obviously), for an individual patient's case, peer review done *prior* to therapy or early during the course of therapy is better than peer review done later or after therapy is completed.

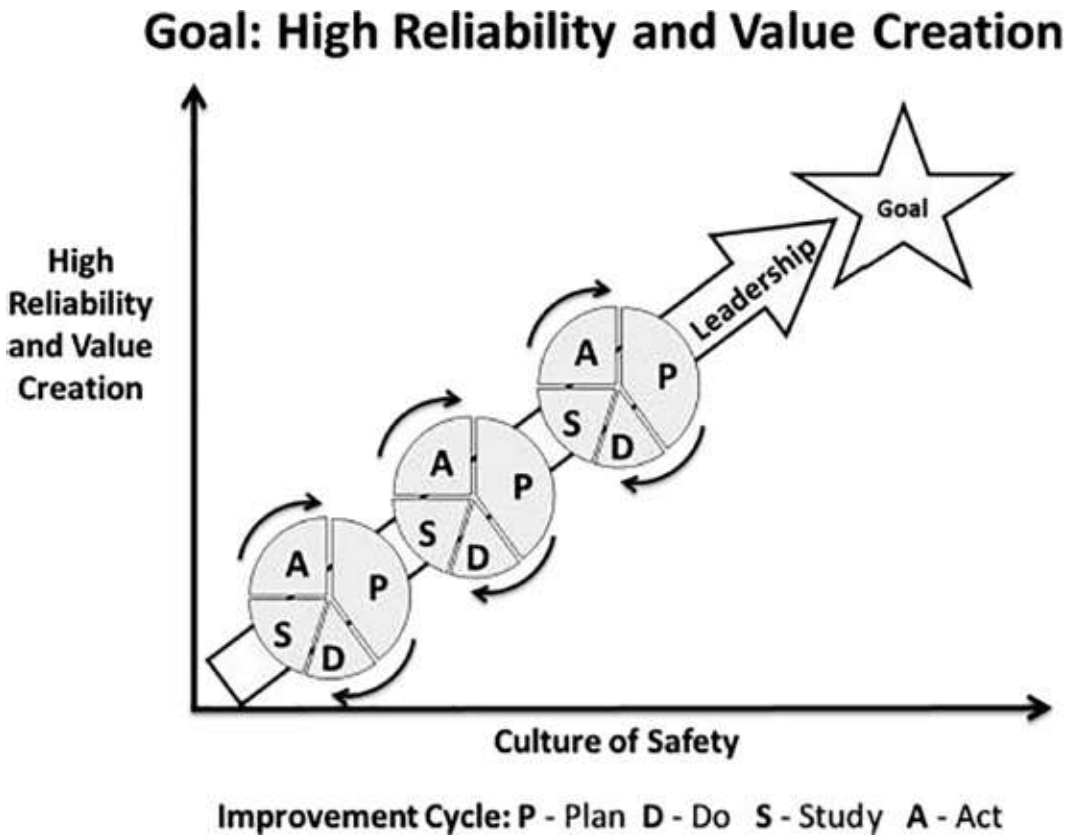

FIGURE 102.5. This conceptual figure illustrates the symbiotic relationship between the culture of safety (*x*-axis), high reliability and value creation (*y*-axis), and continuous improvement cycles (PDSA). Each of these components is mutually dependent and reinforces the other. As such, the relative positions of the three components are somewhat arbitrary. At the organization level, leaders must be the driving force behind improvement cycles, which promote the culture of safety (e.g., safety mindfulness among the staff and robust systems). Similarly, there must be some degree of a culture of safety in order to successfully perform the PDSA cycles. Building a culture of safety and systematically improving processes through the PDSA approach will increase reliability and value creation. The sizes of the pie charts on the leadership arrow pointing toward the goal (shown using a star symbol in the top right corner) are deliberate, with Plan (P) being the largest, indicating the need for thoughtful planning and readiness of all stakeholders before relatively rapid improvements, Doing (D), Studying (S), and Acting (A), as no major improvement can be typically achieved in one leap. (The figure is conceptually adopted from teaching of Mark Chassin, President and Chief Executive Officer at Joint Commission, 2012 Institute for Healthcare Improvement (IHI) Annual Conference.)

Peer review in radiation oncology appears to be a useful tool to improve patient care[74–76] and has been strongly endorsed by several national and international organizations.[72] As in medicine in general, peer review done prior to, or early in the course of radiation treatment, is likely to be most useful. Indeed, radiation treatment plans that deviate from standard protocols are associated with inferior patient outcomes (i.e., cancer control and survival), and

prospective peer review holds promise to improve patient outcomes.[15,16]

Despite the promise of peer review, our field has not broadly embraced its full potential. For example, a recent survey of North American academic radiation oncology centers noted marked variation in the use of peer review.[77] Further, based on discussions with colleagues nationally, it is our impression that most peer review is done after treatment has been initiated, rather than prior to treatment. Because there is much effort required to make adjustments after therapy has been initiated, many suggested adjustments may not be made (or perhaps some suggestions are not even offered because the potential associated rework is so high). To address this issue in our clinic, we perform pretreatment peer review of essentially all cases. For patients undergoing conventional 3-D or IMRT planning the broad treatment plan and goals are discussed. All image segmentations are reviewed prior to planning, for the IMRT cases. This work is performed daily, immediately prior to our department huddle, and both meetings are often blended together (e.g., if the treatment planning computers are slow in bringing up the next patient for peer review, we will perform parts of the huddle during that hiatus).

CONCLUSIONS

Our field is highly technical and errors can result from technical failures. However, the practice of radiation oncology is largely a human endeavor, and most errors are strongly linked to “human-based aspects” (e.g., workflows, communication, human–machine interactions). Our systems currently behave somewhat unpredictably (because of many interactive variables), and the resulting complexity requires an ongoing robust embrace of CQI; there are no easy fixes. Our field can only achieve very high levels of reliability if we acknowledge these complexities and our challenges as human beings working in a complex system. We need to embrace a culture of safety, where leaders and workers together openly identify existing waste or shortcomings and generate improved systems that are more reliable and efficient (Fig. 102.5). For example, we can, and should, more systematically standardize our processes as a means to reduce complexity. A greater understanding is needed of the multifaceted causes of errors as well as systematically and openly discussing and addressing our latent failures. They occur all around us and are currently tolerated given they largely do not lead to major problems (except when they do). The many strategies outlined in this chapter, proven successful in many industries, can be

more broadly applied in our field to reduce the risks of errors. We owe this to our patients and to ourselves.

CHAPTER 103

Radiation Oncology Education

Daniel W. Golden and Paris-Ann Ingledew

INTRODUCTION

Radiation oncology is a unique specialty that requires a broad knowledge base, as it is one of the few specialties that deliver care to patients from all age groups and all genders and interfaces with a multitude of medical specialties. The radiation oncologist must have the requisite clinical skills necessary to evaluate a new patient at the time of consultation, appropriately stage a tumor,[1] assess treatment planning scans for extent of tumor to delineate target volumes and organs at risk accurately,[2] and evaluate patients during and after treatment for radiation toxicities and signs of tumor recurrence.[3] In order to do this, radiation oncologists must not only have a solid foundational knowledge of oncology, tumor biology, physics, and radiation delivery but also be versed in a variety of additional areas including communication, collaboration, patient advocacy, and health system management.[4,5] Other professions that work as part of the radiation oncology care team, including medical physics,[6,7] dosimetry,[8] radiation therapy,[9] nursing,[10,11] social work,[12] and physical therapy,[13] also have specific skill sets that are acquired during training and continue to develop while working in the radiation oncology clinic. Although the focus of this chapter is education for radiation oncologists, to provide optimal patient-centered care, the educational process for all of these professions ideally is coordinated in a complementary fashion, with each member of the interprofessional and interdisciplinary radiation oncology team optimally trained to deliver high-quality, effective, and compassionate patient care (Fig. 103.1).

Descriptions of radiation oncology educational training programs can be found in the literature dating from the 1950s,[14] and currently, radiation oncology training programs exist worldwide.[15–23] Despite the abundance of established training programs, there is little literature discussing the core aspects of medical education and its application to radiation oncology. The goals of this chapter

therefore are to describe fundamental educational theory and processes necessary to develop an effective radiation oncology educational curriculum, to review current educational practices in radiation oncology, and to identify potential areas for radiation oncology educational scholarship. Physician training at the undergraduate (medical school), graduate (residency and fellowship), and continuing medical education (CME) (attending physician) levels primarily will be used to frame this discussion, but the concepts, theory, and methods described can be applied to education of other health professions involved in radiation oncology clinical care.

BACKGROUND

The day-to-day practice of medical education in radiation oncology needs to be considered within the broader context of learning theories. It is essential to look beyond the oncology literature, and even outside of the medical literature, to understand the best practices for medical education and curriculum development.

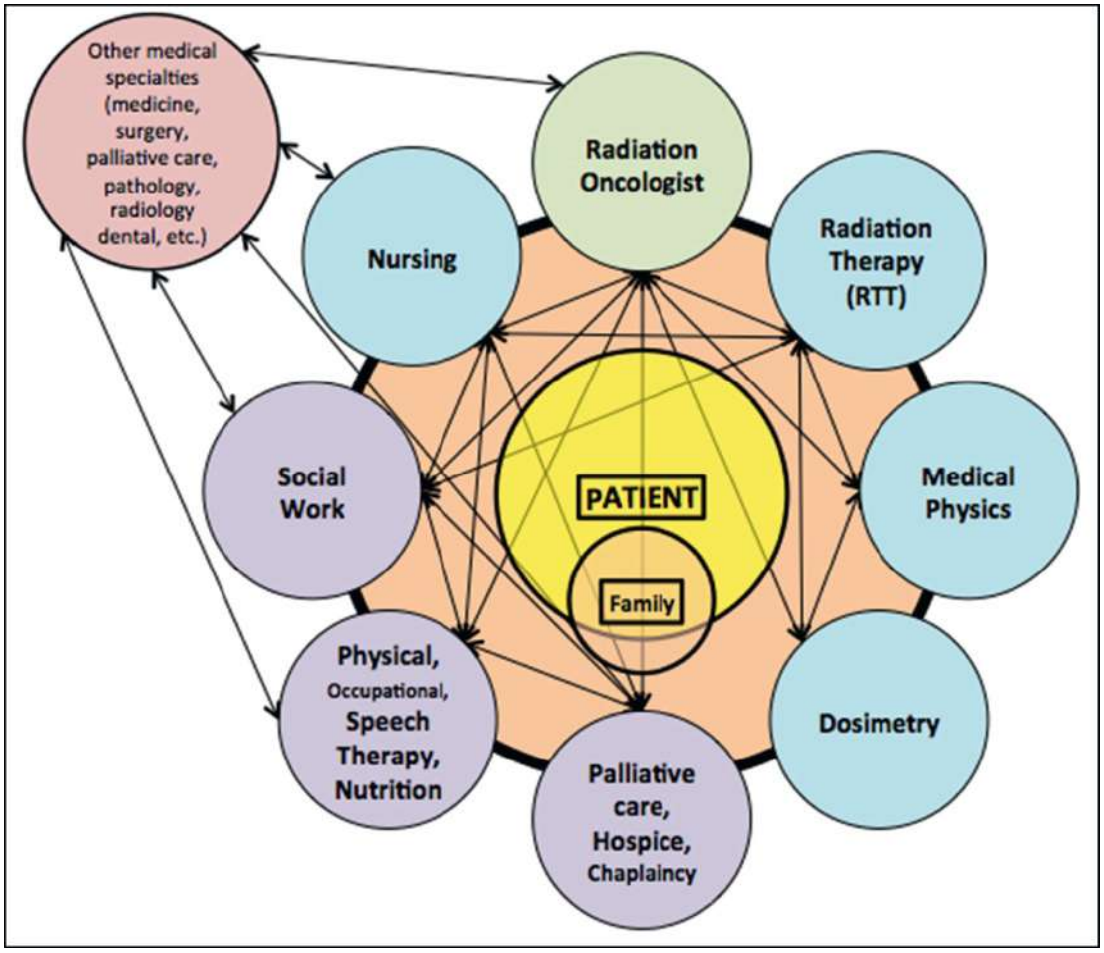

FIGURE 103.1. Interprofessional care of the radiation oncology patient.

Learning Theory

Much of the literature surrounding learning has differentiated between "andragogy," or adult learning defined as "the method and practice of teaching adult learners," viewed as unique from "pedagogy," which is defined as "the method and practice of teaching" but which literally means "leading children." There is considerable debate surrounding this differentiation. Rather than present a detailed discussion of the history and controversies in learning theory, concepts of learning theories will be discussed in relation to the range of adult learners in radiation oncology from medical student to practicing radiation oncologists. The basic concepts of most learning theories are based on behavioral change and transformative experiences. The goal of any educational intervention is to effect a behavioral change in the learner through some form of experience. Examples within radiation oncology include improving physician–patient interactions (behavior) through an objective simulated clinical exam (experience),[24] improving brachytherapy technique (behavior) through simulation-based education (experience),[25] and improving contour accuracy (behavior) through a simulated contouring workshop (experience).[2]

To help understand the process by which educational interventions can result in changes in behaviors, learning models can be informative. Kolb's experiential learning model (Fig. 103.2) describes a four-step cycle of learning that includes a concrete experience, reflective observation, abstract conceptualization, and active experimentation.[26] Similarly, Merriam et al.[27] describe three keys to transformational learning including (a) experience, (b) critical reflection, and (c) development. Collins[28] frames adult learning in the context of studying theory and applying it to practice. Others propose that the two fundamental components of adult learning are critical thinking and self-directed learning.[29,30] Taken together, educational opportunities that allow for concrete experiences, application, and the opportunity for reflection are best aligned with these principles.

Learning theory can be enhanced by an understanding of the six assumptions regarding characteristics of the adult learner as defined by Knowles et al.[31] (Fig. 103.3). These six assumptions can be applied to learning in radiation oncology. For example, in the case of a radiation oncology residency training program, the residents must understand why, what, and how they are going to learn their chosen profession. They need to have some autonomy and control over their

learning within the structure of the residency training program. Therefore, when the radiation oncology educator is developing an adult learning experience, consideration should be given to Knowles' six assumptions, what behavior the curriculum or educational intervention intends to change, and how the learning experiences will stimulate critical thinking, self-directed learning, and transformation.

Lastly, to optimize learning, it is important for medical educators to consider the learning environment when designing an educational program. The Hebbian version of the Yerkes-Dodson law suggests that learners have an optimal level of arousal, or stress, that will promote optimal learning (Fig. 103.4).[32,33] At very low levels of stress and arousal, the learner is not stimulated enough to learn. An example is an early morning resident lecture with no postlecture knowledge assessment. The stakes for the resident learner are low, and the resident may not engage with the presentation to learn. As arousal increases, an optimal point is encountered on the learning curve where stress optimally enhances learning without negatively impacting it. As stress continues to increase, learning begins to decline because of stress impeding higher-level cognitive process such as attention, working memory, and problem-solving. Thus, the radiation oncology educator must consider stressors on the trainees (both positive and negative) and determine if the amount of stress within a given learning environment will facilitate optimal learning. Examples of pertinent stressors include medical student anxiety about securing a residency position, resident anxiety about certification boards, presenting in front of a group versus a single listener, or a multiple-choice test with a minimum score required to obtain credit as a component of a self-assessment CME module. Educators should work to minimize undue (negative) stressors while emphasizing the rationale for planned positive stressors such as postlecture knowledge assessments.

SCHOLARSHIP OF RADIATION ONCOLOGY EDUCATION

Methods for successful curriculum development and implementation draw from both social sciences and business theory. The research methodology for scholarship of radiation oncology education incorporates qualitative research, an approach that may not be familiar to radiation oncology educators, whose training is focused in the biologic and physical sciences. This section reviews the concepts of scholarship as relevant to radiation oncology education and provides an introduction to qualitative methods and conceptual frameworks useful to radiation oncology educational scholarship.

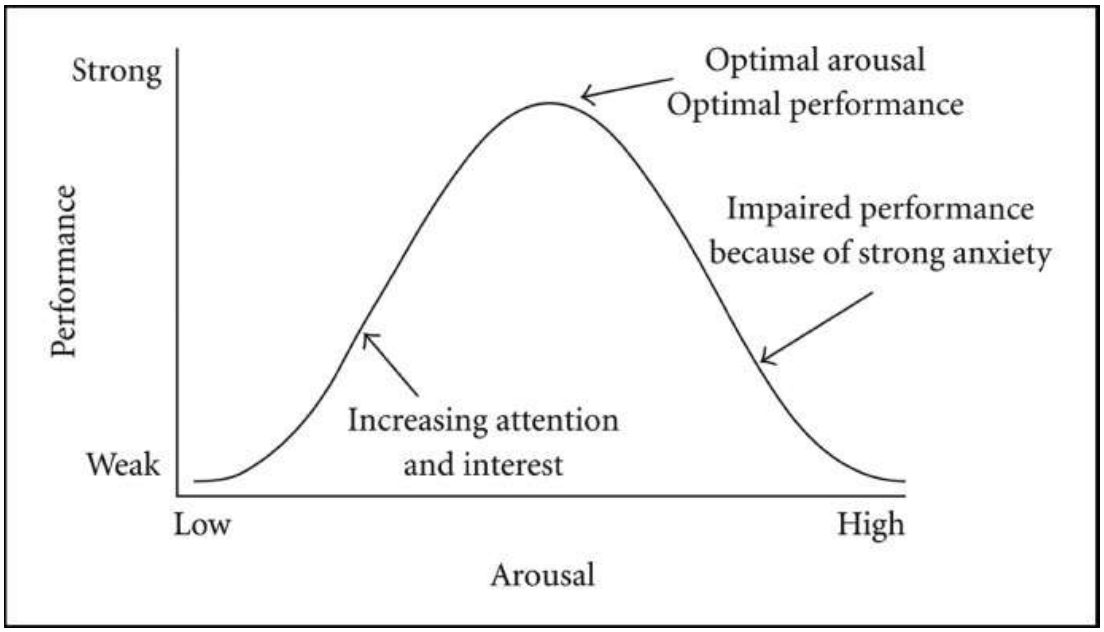

FIGURE 103.4. Hebbian version of the Yerkes-Dodson law correlating arousal with performance.

Scholarship in Medical Education

When undertaking any medical education intervention, careful attention should be given at the outset for opportunities for scholarship.[34] Boyer[35] defines four types of scholarship including the scholarship of discovery, the scholarship of application, the scholarship of integration, and the scholarship of teaching. The scholarship of discovery refers to scholarly activities for the purpose of finding new knowledge and best encompasses our traditional view of research.[35,36] The scholarship of integration refers to scholarship that draws on other research and draws across disciplines or extends research to new areas and beyond boundaries helping to illuminate relationships.[35,36] The scholarship of application takes knowledge and applies it in new and practical ways.[35,37] Finally, the scholarship of teaching refers to teaching practices approached with a scholarly lens. This

expanded definition of scholarship allows for many activities in medical education to be viewed as grounds for scholarship outside of research projects.

Scholarship is defined as a tangible product of knowledge or its presentation that is peer-reviewed and disseminated publicly.[38] Hutchings and Shulman[39] define the following three essential criteria for scholarship:

- The work must be made public.
- The work must be available for peer review and critique according to accepted standards.
- The work must be able to be reproduced and built on by other scholars.

Criteria for excellence in scholarship can be applied to educational scholarship and help to assess the quality of scholarship. Glassick[40] defines six criteria to assess scholarship:

- Clear goals
- Adequate preparation
- Appropriate methods
- Significant results
- Effective presentation
- Reflective critique

Application of these criteria assists the radiation oncology educator to evaluate the potential to turn a medical education project into a work of scholarship. For example, a novel resident training curriculum implemented at a single institution and not disseminated in peer-reviewed literature does not qualify as scholarship based on the above definition. However, if the residency program director publishes learner assessment and program evaluation data in a peer-reviewed journal or disseminates the curriculum materials using MedEdPORTAL, the implementation and evaluation of the curriculum qualify as scholarship.

The difference between scholarly teaching and the scholarship of teaching must also be defined. Fincher and Work[41] define three levels of teaching (Fig. 103.5). The first level is basic teaching. In radiation oncology, basic teaching examples include giving a lecture, facilitating a case conference, demonstrating proper history-taking technique or brachytherapy technique to trainees, or educating patients regarding the radiation treatment process and potential toxicities.

The next level is scholarly teaching. This implies that the instructor is using evidence-based practices when teaching trainees. Examples in radiation

oncology could include using best practices when delivering a PowerPoint presentation,[42] providing patient educational materials at or below the sixth grade reading level,[43] or using the 1-minute preceptor model to teach a clinical pearl to a resident after an initial consultation.[44]

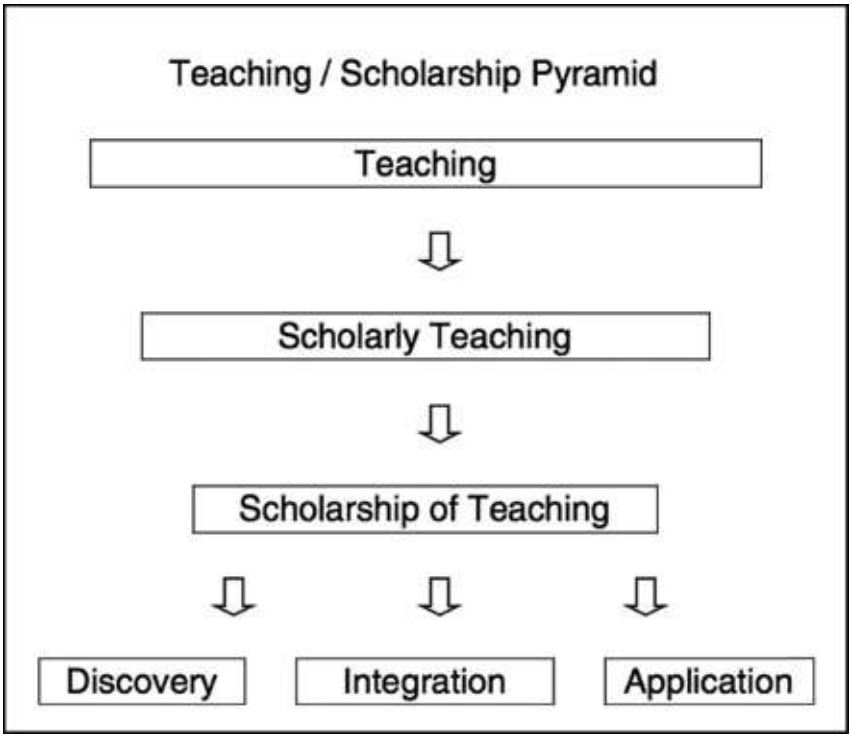

FIGURE 103.5. Fincher and Work's pyramid of teaching and scholarship. (From E Fincher R-M, Work JA. Perspectives on the scholarship of teaching. *Med Educ* 2006;40[4]:293–295. Copyright © 2006 Blackwell Publishing Ltd. Reprinted by permission of John Wiley & Sons, Inc.)

The third tier is scholarship of teaching, which includes developing and disseminating new knowledge through discovery, integration, or application. Drawing from Boyer,[35,40] discovery refers to obtaining new knowledge in a discipline. Scholarship examples in this context include the evaluation of new innovations or interventions. Examples in radiation oncology include demonstrating that students who participate in a radiation oncology clerkship with a didactic curriculum report increased confidence to function as a resident,[45] utilizing a novel Internet-based contouring tool that can improve target delineation accuracy,[46] and demonstrating that inclusion of a radiation oncology lecture in the medical school curriculum is feasible and increases objective knowledge of the specialty.[47]

Scholarship of integration refers to making connections across scholarship

and synthesizing data across studies.[40] Examples include a literature review of radiation oncology teaching in the undergraduate setting[48] or a Best Evidence in Medical Education systematic review on faculty development initiatives aimed to improve teaching effectiveness.[49] The scholarship of application bridges theory with practice often drawing together fields and disciplines.[35,50] In the context of radiation oncology, this could include assessing the value of simulation in brachytherapy training,[25] bringing simulation which is well utilized in other specialties to radiation oncology, and evaluating the impact on learner performance.

Without scholarship in radiation oncology education, educational programs will advance slowly. Individual training programs will be unaware of the best practices implemented at other training programs and may develop redundant educational material, which introduces inefficiency in a process that is already limited in resources. Just as clinical oncology and basic science research is disseminated as manuscripts in peer-reviewed journals, novel radiation oncology educational initiatives must be rigorously developed and evaluated in preparation for dissemination to the international radiation oncology community.[34] However, because of limitations of journal publication alone in effecting change,[51] programs such as the Radiation Oncology Education Collaborative Study Group[52] have been established to improve dissemination and implementation of educational research and programs. These processes allow other institutions to adopt or adapt novel educational initiatives and subsequently build on them for further dissemination.

Qualitative Versus Quantitative Research

For health profession educators, scholarly research comes from both quantitative and qualitative sources, and many studies benefit from the use of both simulatenously.[53] Some studies refer to the term “mixed methods,” which is a reference to the use of both quantitative and qualitative methods. While many radiation oncologists are familiar with quantitative research, they may be less aware of qualitative research methods. Qualitative methods are distinct from quantitative methods in their research paradigm, research design, method of data collection, types of data collected, and methods of data analysis.

With respect to research design, most quantitative research is hypothesis driven with the researcher developing research methods and collecting data to support or refute the hypothesis. In the case of qualitative methods, researchers start at the observational level and then move to explanation by building a

theory. Several strategies for qualitative inquiry are commonly used, and a complete description is beyond the scope of this chapter. Some of the more commonly referenced terms in qualitative methods include ethnography, narrative inquiry, and grounded theory approach. Ethnographic research encompasses a variety of research techniques aimed at characterizing the authentic everyday experiences of subjects through observation and interviews.[54,55] An example of ethnographic research is a study utilizing detailed interviews with teaching faculty and observations of their teaching patterns on the ward to identify the characteristics of effective clinical teachers.[56] Narrative research is the study of participants through the analysis of documents.[55] Usually the participant describes one or more pivotal life events and the researcher looks to describe these events. Finally, grounded theory is a term used in qualitative methods to describe the process in which a "theory" is generated from data of the experiences of the participants.[55] Unlike quantitative research that starts with a theory, the grounded approach uses data to generate theory by looking for emerging themes through a process of constant comparative analysis.[54] Data are collected through interviews, document analysis, and focus groups. In a grounded theory approach, as data are collected, a theory is generated, then more data are collected, and the theory is revised as needed, continuing the process until it appears that the theory is relatively robust. An example of grounded theory methodology in radiation oncology is the use of focus groups and in-depth interviews to develop a four-step learning process for implementation of high-precision radiation technology: (a) Anxiety as new skills are acquired, (b) learning to interpret new imaging and findings while continuing to experience uncertainty, (c) questioning assumptions and critical reflection resulting in new understanding, and (d) constructing new knowledge through research, development, and dialogue.[57]

The processes and methods used in qualitative studies include distinguishable methods that help to build observations to support explanations.[58] Methods of data collection include focus groups, one-on-one interviews, surveys with open-ended questions, observations of behaviors, and document analysis (e.g., themes in portfolios). Unlike quantitative data that are numeric, the data collected in a qualitative study are usually text or words. For example, data may be collected in the form of words, or even pictures, rather than numbers. The analysis of qualitative data is an iterative process to conceptualize and reduce data, analyze it to develop themes, elaborate on categories, and find relationships.[54] Common to qualitative methods, steps are taken to ensure reliability of the themes

developed through stages of analysis. This may include having coraters of themes, peer review from others not involved in the study, checking the themes with study participants, and triangulation with established literature. Ultimately the goal of qualitative research is to develop hypotheses, building theory through descriptions of observations, and to describe and explain complex phenomena by analyzing data for themes and relationships. Table 103.1 summarizes key differences between quantitative and qualitative methods.

TABLE 103.1 SUMMARY OF DIFFERENCES BETWEEN QUALITATIVE AND QUANTITATIVE RESEARCH

	Quantitative Research	Qualitative Research
Research paradigm	– Deductive Research – Collect data to test hypothesis	– Inductive Research – Observations to explain and then develop theory
Research method examples	– Closed-ended surveys (i.e., demographics of current radiation training programs) – Observations of time taken to complete a task (i.e., contouring)	– Open-ended surveys (i.e., resident descriptions of current challenges in training programs) – Observational study (i.e., observations of differences of learner's contouring abilities at different stages of training) – Document analysis (i.e., analysis of learner's portfolio reflections on dealing with difficult cancer patients)
Data	– Numeric data	– Words as data

Qualitative research is important to medical education. There are certain educational research questions that are best approached using qualitative research methods[59] such as:

- "How does charting influence the quality and quantity of communication between different health care professionals?
- How do health care professionals learn to teach on the job?
- What constitutes "professional competence" and how is that different from "professional identity"?
- What influences patients' adherence with their doctor's suggestions?"

Qualitative methods can be used specifically for radiation oncology scholarship in multiple settings (Table 103.2). For example, qualitative methods can be used to develop and evaluate a program to teach radiation oncology residents communication skills with elderly cancer patients. One-on-one interviews, focus groups, and surveys with open-ended questions could be used

to conduct a targeted needs assessment of learners (see curriculum development below) prior to developing a new educational program. The results would inform the development of the program. Later, reflections on the new training program, collected through repeated one-on-one interviews, surveys, and analysis of reflective writing exercises, could be used to systematically evaluate the program once implemented. Years later, the clinical behaviors of oncologists in practice could be observed to reflect on the retention of skills in learners and the impact of the program on their communication skills. Utilizing both qualitative and quantitative methods for program development facilitates development and improvement of a training program in a scholarly manner.

TABLE 103.2 EXAMPLES OF USE OF QUALITATIVE METHODS IN RADIATION ONCOLOGY EDUCATION

Educational Issue	Qualitative Approach
Analyzing "memorable" in-training experiences of medical students on radiation oncology rotations[248]	Thematic analysis of written narratives to describe the training experiences of learners in a clinical education program
Needs assessment for development of a radiation oncology curriculum for medical students[174]	Analysis of written responses to open-ended surveys to analyze for gaps and strengths in current training Thematic analysis of one-on-one interviews with stakeholders
Establishing needs and priorities in a global radiation oncology training programs[249]	Facilitated group discussion with analysis of themes to develop consensus on possible goals and objectives for a training program
Evaluation of a contouring boot camp[18]	Thematic analysis of open-ended survey questions to provide evaluation data
Evaluation of a didactic curriculum for a radiation oncology medical student clerkship[181]	Thematic analysis of open-ended survey questions to provide evaluation data

Conceptual Frameworks

When approaching radiation oncology medical education endeavors through a scholarly lens, it is critical to define one or more conceptual frameworks used to guide the educational process. While medical education scholars often employ conceptual frameworks in curriculum development and program evaluation, it is helpful to be able to identify them. A systematic review found that a lack of a conceptual framework is one of the most common reasons education scholarship is rejected for publication.[60]

Conceptual frameworks are "ways of thinking about a problem or a study, or

ways of representing how complex things work the way they do. Different frameworks will emphasize different variables and outcomes, and their inter-relatedness."[61] Conceptual frameworks are not mutually exclusive, and there is the potential to apply multiple conceptual frameworks to a single curriculum development endeavor. For example, a radiation oncology educator developing a simulation-based education curriculum to train residents how to perform interstitial breast brachytherapy may use the six-step approach to curriculum development[62] to guide the overarching curriculum development process, the theory of deliberate practice from Ericsson et al.[63] when developing the specific educational method to develop adequate breast brachytherapy psychomotor skills, and Kirkpatrick's four-step framework[64] when developing a plan for program evaluation. Bordage defines 11 key points pertaining to conceptual frameworks (Table 103.3) that clarify the critical nature of conceptual frameworks to educational scholarship, both to guide curriculum development and move the field of radiation oncology education forward in a logical and coherent manner.[61]

There are numerous conceptual frameworks in the medical education and general education literature that can be applied to radiation oncology educational scholarship. If an applicable conceptual framework is not available for a particular curriculum development program, existing conceptual frameworks can be modified and adapted to fit, or a new conceptual framework can be developed and reported in the peer-reviewed literature. To help guide the development of new literature in radiation oncology education, Table 103.4 provides examples of conceptual frameworks that may be applied when approaching common radiation oncology education issues. In summary, the radiation oncology educator should be able to identify the conceptual framework that applies to their educational intervention.

TABLE 103.3 KEY POINTS REGARDING CONCEPTUAL FRAMEWORKS

1. Conceptual frameworks help understand (illuminate) problems.
2. Different conceptual frameworks emphasize (magnify) different aspects of the problem or elements of the solutions.
3. More than one conceptual framework may be relevant to a given situation.
4. Any given conceptual framework, or combination of frameworks, can lead to a variety of alternative solutions.
5. Conceptual frameworks can come from theories, models, or evidence-based best practices.
6. Scholars need to apply the principles outlined in the conceptual framework(s) selected.
7. Conceptual frameworks help identify important variables and their potential relationships; this

also means that some variables are disregarded.
8. Conceptual frameworks are dynamic entities and benefit from being challenged and altered as needed.
9. Conceptual frameworks allow scholars to build upon one another's work and allow individuals to develop programs of research.
10. Programmatic, conceptually based research helps accumulate deeper understanding over time and thus moves the field forward.
11. Relevant conceptual frameworks can be found outside one's specialty or field.

Adapted from Bordage G. Conceptual frameworks to illuminate and magnify. *Med Educ* 2009;43(4):312–319. Copyright © 2009 Blackwell Publishing Ltd. Reprinted by permission of John Wiley & Sons, Inc.

TABLE 103.4 EXAMPLES OF CONCEPTUAL FRAMEWORKS APPLICABLE TO DOMAINS OF RADIATION ONCOLOGY EDUCATION

Education Domain	Conceptual Framework Examples
Curriculum development	*Six-step approach to curriculum development*[62] 1. Problem identification 2. Needs assessment of the learners 3. Goals and objectives 4. Educational strategies 5. Implementation 6. Evaluation and feedback
Goals and objectives	*Bloom's revised taxonomy of learning objectives*[109,110] 1. Knowledge → Remember 2. Comprehension → Understand 3. Application → Apply 4. Analysis → Analyze 5. Synthesis → Evaluate 6. Evaluation → Create
Educational methods/learning theory	*Miller's pyramid of clinical competence*[116,117] – Knows – Knows how – Shows – Does *Kolb's experiential model*[26] – Concrete experience – Reflective observation – Analysis and integration – Application to new situations *Ericsson's theory of deliberate (mixed) practice with feedback*[63] – Motivate through improvement in real-life performance – Take into account the learner's pre-existing knowledge (difficulty of the task tailored to the individual) – Allow repetition of the skills multiple times – Accompanied by feedback that is constructive and timely *Merrill's first principles*[250]

	Learning is facilitated when: 1. Problem—Learners are engaged in solving real-world problems 2. Activation—Existing knowledge is activated as a foundation for new knowledge 3. Demonstration—New knowledge is demonstrated to the learner 4. Application—New knowledge is applied by the learner 5. Integration—New knowledge is integrated into the learner's world
Skills acquisition/simulation-based education	*Mastery learning*[251] – Baseline testing – Clear objectives – Engagement in educational activities – Clear minimum passing standards – Formative testing – Advancement dependent on achievement – Individualized time frame *Features of effective simulation education*[252] – Feedback to the learner – Repetition – Simulation integrated into the overall curriculum – Learners practice with increasing difficulty and complexity – Simulations adapted to multiple learning strategies – Clinical variation built into the sessions – Control of the environment – Individualized learning options – Defined outcomes, benchmarks – Simulation closely represents practice *Kneebone's evaluation criteria for simulation programs*[253] Simulations should: – Allow for sustained, deliberate practice within a safe environment, ensuring that recently acquired skills are consolidated within a defined curriculum, which assures regular reinforcement – Provide access to expert tutors when appropriate, ensuring that such support fades when no longer needed – Map onto real-life clinical experience, ensuring that learning supports the experience gained within communities of actual practice – Provide a supportive, motivational, and learner-centered milieu, which is conducive to learning
Assessment	*National Council on Measurement in Education (NCME) standards: 5 sources of validity evidence*[130,254] 1. Content 2. Response process 3. Internal structure 4. Relationship to other variables 5. Consequences *Criteria for good assessment*[255] 1. Validity or coherence 2. Reproducibility or consistency 3. Equivalence 4. Feasibility 5. Educational effect 6. Catalytic effect

	7. Acceptability
Evaluation	*Kirkpatrick's four levels of program evaluation*[64] 1. Reaction 2. Learning 3. Behavior 4. Results *Grant's ACTION model for evaluating new technologies for learning*[256] – Access – Cost – Types of learning – Integration – Organization – Novelty
Continuing medical education	*Davis' characteristics of effective (best practice) CME programs*[239] 1. Needs assessment that can be either subjective (e.g., questionnaires) or objective (e.g., literature review) 2. Focused initiative to meet the needs of the physician 3. Interactive educational programs 4. Multiple educational strategies 5. Multiple sessions 6. Time for feedback and practice 7. Outcome evaluation *Harden's Crisis Criteria for effective CME*[238] 1. Convenience 2. Relevance 3. Individualization 4. Self-assessment 5. Independent learning 6. Systematic
Interprofessional education	*Ivey's categorization of interprofessional practices*[257] – Parallel practice – Coordination – Consultation – Collaboration – Multidisciplinary teams – Interdisciplinary teams *Parsell and Bligh's elements of interprofessional education*[258] – Relationships – Collaboration and teamwork – Roles and responsibilities – Benefits *MUSC spiral theory*[259,260] Teamwork—Prepare–think–practice Transforming ways of knowing—Absolute–transitional–independent–contextual Ever-increasing acquisition, application, demonstration
Professionalism	*Assessment of professionalism*[261] – Evaluations by faculty supervisors – Nurses and patients – Peer evaluation

– Self-evaluation
– Standardized patients
– Longitudinal observations

CURRICULUM DEVELOPMENT

Using the background medical education theory and key principles to medical education scholarship, the radiation oncology educator can begin curriculum development. The objective of this section is to discuss the educational theory relevant to curriculum development, review curriculum development models, and then explore approaches to curriculum development with application to radiation oncology.

A curriculum can be defined as any planned educational experience.[62] In this context, radiation oncology curriculum examples include a 1-hour lecture on the history of radiation oncology for medical students, a residency training program's annual clinical rotation and didactic lecture schedule, a patient seminar on late effects of radiation oncology, or a national meeting on hands-on brachytherapy simulation workshop. The common thread through all of these examples is that the educator has a goal for the curriculum—that is, some type of knowledge transfer.

Curriculum theory proposes three types of curricula in any educational setting (Table 103.5). The first type of curriculum is the "set" or explicit curriculum. The set curriculum is what the educator defines a priori as the instructional plan. A radiation oncology clerkship will have goals and objectives defined for participating medical students to orient them to the experience. The overarching goal of the clerkship is likely "to learn the fundamentals of clinical radiation oncology." A syllabus may be prepared, and the educational strategies employed are chosen to reach the explicit curricular goal.

The second curriculum in any educational setting is the "hidden" or implicit curriculum. The hidden curriculum is what the learner comes to "know" based on interactions that occur outside of formal learning environments.[65] Examples in radiation oncology could include a medical student in a resident workroom overhearing a resident disparaging a referring service or a department choosing not to allocate resident education time to quality and safety or communication skills. The hidden curriculum often is referred to with a negative connotation, but there are positive effects of the hidden curriculum. For example, a resident may observe their attending physician during a particularly compassionate patient encounter and take away a positive lesson on how to interact with a

similar patient in the future. Radiation oncology educators must consider their departmental and institutional hidden curriculum when developing a novel set of curriculum. Individual educators may be encouraged to view their behaviors as modeling and note the potential impacts on the hidden curriculum. Areas to consider relating to the hidden curriculum include policy development, evaluation, resource allocation, and institutional slang.[65] These four areas within a radiation oncology department can teach trainees both positive and negative lessons without the trainee ever being exposed to a formal learning environment.

TABLE 103.5 EDUCATIONAL THEORY'S THREE COEXISTING CURRICULUM TYPES

Type of Curriculum	Radiation Oncology Examples
Set, formal, or explicit curriculum	– Medical student clerkship lecture series – Residency lecture series and rotation schedule – Goals and objectives for society meeting educational session
Hidden or implicit curriculum	– Radiation oncology resident disparages a referring specialty in front of a medical student – Radiation oncology attending models superb compassion when counseling a patient regarding terminal diagnosis – Radiation oncology attending belittles a dosimetrist in front of a resident and medical student
Null curriculum	– Medical school does not include any radiation oncology in their formal curriculum – Residency program director decides to forgo a formal treatment planning rotation because of training time constraints – Society does not include a session on palliative radiation because of space constraints at conference center

The third type of curriculum is the "null" curriculum, which is defined as what is not taught.[66] The classic example in childhood education is removing art class from a grammar school curriculum, which results in a negative impact on the children by sending a message that art is not important and can therefore be ignored. Medical educators within radiation oncology are faced with limited time for education. Thus, during the curriculum planning process, radiation oncology educators must strive for a balance of including material that is important to their learners while not overburdening the learner or institutional resources. Topics that are important to functioning as a radiation oncologist but are often not taught formally during training because of resource constraints include (but are not limited to) treatment planning and plan evaluation, diagnostic radiology interpretation skills, communications, collaboration, and

leadership skills. The Accreditation Council for Graduate Medical Education (ACGME) permits residency programs to count resident attendance at multidisciplinary tumor boards as adequate training in medical oncology, radiology, and pathology in place of formal clinical rotations.[4] Because of training time constraints, this capitulation is necessary, but it may send a message to US radiation oncology residents that knowledge pertaining to these specialties is less important. This may lead to the long-term detriment of patient care.[67] Radiation oncology itself suffers from the consequences of the null curriculum. Radiation oncology's status as a subspecialty means the formal medical school curriculum frequently does not include radiation oncology material leading to reduced knowledge of the specialty[68,69] and residency training programs outside of radiation oncology frequently do not provide formal lectures or training pertaining to radiation oncology.[70,71] Radiation oncology educators must carefully consider the institutional and departmental educational milieu when deciding on which educational initiatives to pursue or cut.

Curriculum Development Models

Curriculum development should be a logic and rational process. Often in medical education, curriculum development is a haphazard process or occurs in a reactive, rather than proactive, manner. Multiple curriculum development models are proposed. These include empirical/analytical/systematic curriculum inquiry, deliberative curriculum inquiry, and reconceptualist curriculum inquiry.[72]

Systematic curriculum inquiry is perhaps the most commonly utilized curriculum development model. Systematic curriculum development has been in the literature for over 60 years with multiple educators, medical and nonmedical, contributing to the current iteration.[62,73,74] The six-step approach to medical education curriculum development[62] provides a systematic approach to curriculum development and, if followed, helps medical educators ensure critical components necessary for effective curriculum planning are not missed. One criticism of the systematic approach is that it can be a top–down process with curriculum deans, residency program directors, or clerkship directors dictating curriculum content and structure.

Deliberative curriculum inquiry focuses on the process of curriculum planning, implementation, and evaluation.[75] To be effective, deliberative curriculum inquiry requires a structure for "deliberation."[76] Curriculum stakeholders are given an opportunity to evaluate the curriculum goals and

objectives, propose modification to educational methods, and suggest methods for assessment and evaluation. For example, a radiation oncology residency program choosing to employ deliberative curriculum inquiry would create an opportunity for stakeholders within the program (residency, chairperson, program director, department faculty, institution, and patients) to provide feedback on the program. The ACGME now requires US radiation oncology residency programs to have a program evaluation committee conduct an annual evaluation of the program.[4] Members of the program evaluation committee must include department faculty and residents. To improve the deliberative nature of this process, inclusion of other stakeholders can be considered (e.g., patients, institution, etc.).

The final curriculum development model is reconceptualist curriculum inquiry.[77] This model of curriculum inquiry aims to explore how the curriculum relates to society. How does the curriculum interact with economic, cultural, and political institutions? An example of reconceptualist curriculum inquiry in radiation oncology is a program director's decision whether to include formal education (e.g., a lecture) on health economics in a radiation oncology residency program. By choosing to educate the program's trainees about the economic implications of different radiation treatment modalities, the residency program can have a future societal impact on economic and political institutions.

The systematic, deliberative, and reconceptualist models of curriculum development are not mutually exclusive. Rather, these models can be used simultaneously to achieve the most effective radiation oncology curriculum possible that is properly structured, includes consideration of stakeholder viewpoints, and has potential for societal impact. Further discussion of curriculum development will focus on the systematic model,[62] but implications of the deliberative and reconceptualist models should be considered as well.

Systematic Curriculum Development

Systematic curriculum development for medical education is most clearly defined by the "six-step approach" from Thomas et al.[62] The six steps are (a) problem identification and general needs assessment, (b) needs assessment of targeted learners, (c) goals and specific objectives, (d) educational strategies, (e) implementation, and (f) evaluation and feedback (Fig. 103.6). Although these six steps are presented in a sequential order, in practice they often are occurring simultaneously. Each step can have effects on or be affected by the other steps. The following discussion will focus on each of the six steps with relevant

examples from radiation oncology cited where applicable.

Problem Identification and General Needs Assessment

When beginning to develop an educational intervention, an initial problem identification and general needs assessment is done. With respect to radiation oncology, sample problems could include variability in the delineation of radiation target volumes between radiation oncologists[78–81] or lack of exposure to oncology training in medical school curriculum.[82] In either case, once the problem is identified, a general needs assessment is done. This includes determining the current approach to the problem and defining the ideal approach. Often, an educator may identify a problem in their local educational and clinical environment but on review of the literature discovers that another institution or organization is addressing the problem adequately. Rather than develop a new curriculum for the identified problem, the educator can adopt or adapt the existing curriculum to their local needs.

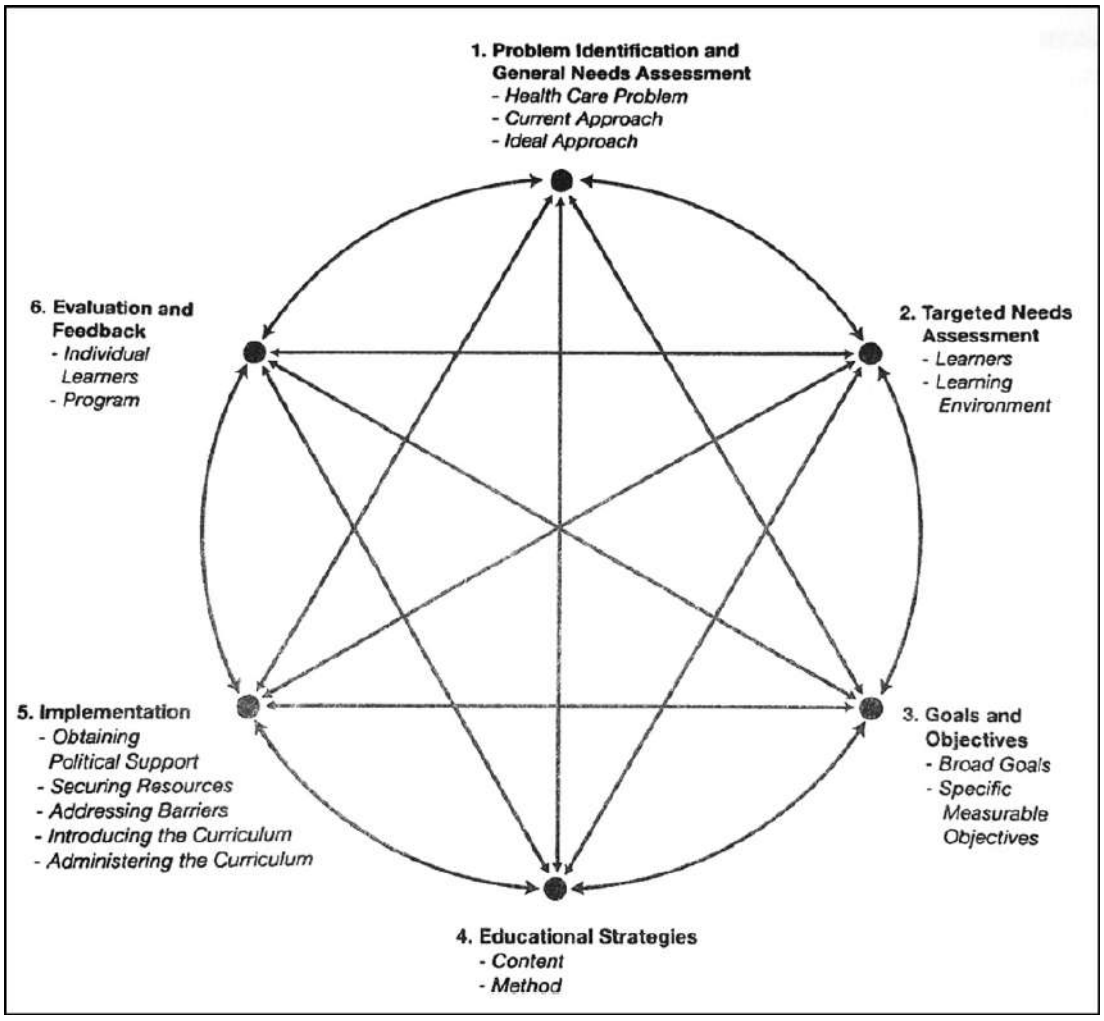

FIGURE 103.6. The six-step approach to systematic curriculum development. (From Thomas PA, Kern DE, Hughes MT, et al. *Curriculum development for medical education: a six-step approach*. 3rd ed. Baltimore: Johns Hopkins University Press, 2016: Figure 1, p. 7. © 1998, 2009, 2016 Johns Hopkins University Press. Reprinted with permission of Johns Hopkins University Press.)

A systematic literature review is an excellent method to identify the current approach to a problem. A systematic literature review may not identify any published approach in which case there is no curriculum precedent for the educator to follow. Conversely, the systematic review may identify other approaches to the identified problem and thereby provide the educator with a starting point for their curriculum development process. When conducting a medical education systematic review, it is necessary to review resources beyond the usual peer-reviewed literature databases (e.g., MedEdPORTAL[83]) to ensure approaches to the identified problem are not previously published. Methodology for systematic reviews is defined in the Preferred Reporting Items for Systematic

Reviews and Meta-Analyses (PRISMA) statement[84] and the Institute of Medicine's "Finding What Works in Health Care: Standards for Systematic Reviews"[85] and is beyond the scope of this text. A systematic review of the medical education literature for curriculum development should follow the same rigorous approach used for a systematic review of clinical research.

Subsequent to identifying the current approach to the problem, the ideal approach should be defined. This is an opportunity to incorporate aspects of deliberative and reconceptualist curriculum inquiry. Stakeholders representing the targeted learners (e.g., medical students or residents), patients, health care professionals, medical educators, and society can be included in this step of curriculum development to ensure all relevant parties agree with the proposed ideal approach. In the previous examples (i.e., variability in contouring and lack of oncology undergraduate education), there would be different stakeholders. The contouring variability example could include residents, faculty, and dosimetrists. For the undergraduate oncology education, stakeholders could include medical students, university faculty, teaching faculty, and accreditation bodies. Educators in radiation oncology must also consider accreditation bodies (e.g., Liaison Committee on Medical Education [LCME], ACGME, Accreditation Council for Continuing Medical Education [ACCME]) and certifying organizations (e.g., American Board of Radiology (ABR), the Royal College of Physicians and Surgeons of Canada (RCPSC), Canadian Medical Education Directions for Specialists (CanMEDS), the Royal Australian and New Zealand College of Radiologists (RANZCR), and the Royal College of Radiologists in the United Kingdom, etc.) when considering the ideal approach to a problem. Training program requirements from these accrediting and certification bodies may direct the ideal approach to an educational problem. New information can be obtained from stakeholders through in-person interviews, focus groups, and questionnaires or surveys. Qualitative and quantitative methods can be used to collect date to define the problem and define goals for the ideal approach to achieve.

By obtaining input from all stakeholders, the educator minimizes the chance of overlooking a key component of the ideal approach to the problem and can begin to generate momentum with the stakeholders for eventual implementation of their new curriculum. The identified differences between the current and ideal approach to a specific health care problem should be the target of any subsequent curriculum development.

Lastly, based on the problem identification and general needs assessment, the

educator can decide the amount of time and effort to dedicate to curriculum development. If the potential for a positive impact on targeted learners, patients, and society is high, then more time and effort may be devoted to curriculum development. Conversely, if there is a low likelihood of significant impact on learners, patients, or society, less time and effort may be necessary to obtain an acceptable curriculum.

Problem identification and general needs assessments in the radiation oncology literature include surveys identifying a deficiency in medical student knowledge of radiation oncology,[68,69] an analysis of average volume of brachytherapy cases performed by resident volume,[86] studies showing failure of practicing physicians to implement best practices based on high-level evidence,[87,88] or evaluation of critical safety events.[89] These studies identify a problem and indicate a general need for curricular development to solve the problem. However, they do not provide detailed information regarding how best to design the curriculum to solve the problem.

Targeted Needs Assessment

Once the educational problem is identified and the differences between the current and ideal approach are realized, the educator should conduct a targeted needs assessment of the learning environment and learners. In radiation oncology, the targeted learner could be a medical student, resident, attending physician, patient, nurse, dosimetrist, physicist, etc. The learning environment may be a clerkship, residency program, society meeting, or any other myriad learning environments. The goal of this step in systematic curriculum development is to determine the specific needs of the radiation oncology educators, learners, and environment that differ from the ideal approach identified in the prior step. For example, the physics curriculum proposed by the American Society for Radiation Oncology (ASTRO) for radiation oncology residents[90] may not be feasible in a specific training program's learning environment. Alternatively, the literature reviewed in the general needs assessment may not be current, and educational methods will require updating and modification to be relevant to current learners. For example, a radiation oncology residency program developed in 2002 in Singapore[91] may not cover all aspects of radiation oncology training necessary in 2017. Additionally, the program was designed to satisfy accreditation requirements of RANZCR and may need to be modified if implemented by a program in the United States or Canada because of different accreditation requirements set forth by the ACGME

or RCPSC, respectively. However, the design and implementation of the Singapore residency program can provide a starting point for a new residency program followed by a targeted needs assessment within the new program's educational milieu.

Detailed information about the targeted learners and the targeted environment is necessary to develop an effective curriculum. Table 103.6 summarizes characteristics about the targeted learner and environment that are necessary to understand before proceeding further with curriculum development. For example, if the targeted learner is a junior radiation oncology resident, understanding that they have limited or no prior education about contouring a prostate fossa will lead to a different curriculum design compared to if the targeted learner is an attending physician attending a refresher course. Similarly, the resources available within a targeted learning environment dictate how a curriculum is structured. A residency program with a proton center and busy pediatric service will design their resident rotation schedule differently than a training program that does not have a proton center and refers all pediatric cases to an out-of-area proton facility.

TABLE 103.6 CONTENT RELEVANT TO A TARGETED NEEDS ASSESSMENT

Content About Targeted Learners

Expectations regarding the scope of knowledge and skills needed
Previous training and experiences relevant to the curriculum
Already planned training and experiences relevant to the curriculum
Existing characteristics/proficiencies/practices
- Cognitive: knowledge, problem-solving abilities
- Affective: attitudes, values, beliefs, role expectations
- Psychomotor: skills/capabilities (e.g., history, physical examinations, procedures, counseling, current behaviors/performance/practices)

Perceived and measured deficiencies and learning needs
Attitudes and motivations of learners to improve performance
Preferences and experiences regarding different learning strategies
- Synchronous (educator sets time, such as noon lecture)
- Asynchronous (learner decides on learning time, such as with e-learning)
- Duration (amount of time the learner think is needed to learn or that he/she can devote to learning)
- Methods (e.g., readings, lectures, online learning resources, large and small group discussions, problem-based learning, team-based learning, peer teaching, demonstrations, role-plays/simulations, supervised experience)

Content About Targeted Learning Environment

Related existing curricula
Needs of stakeholders other than the learners (course directors, clerkship directors, program

directors, faculty, accrediting bodies, others)
Barriers, enablers, and reinforcing factors that affect learning by the targeted learners
Barriers (e.g., time, unavailability, or competition for resources)
Enablers (e.g., learning portfolios, electronic medical record reminders)
Reinforcing factors (e.g., incentives such as grades, awards, recognition)
Resources (e.g., patients and clinical experiences, faculty, role models and mentors, information resources, access to hardware and software technology, audiovisual equipment, simulation center)
Informal and collateral curriculum

Thomas PA, Kern DE, Hughes MT, et al. *Curriculum development for medical education: a six-step approach*. 3rd ed. Baltimore: Johns Hopkins University Press, 2016: Table 3.1, p. 32. © 1998, 2009, 2016 Johns Hopkins University Press. Reprinted with permission of Johns Hopkins University Press.

Given the critical nature of the targeted needs assessment to developing an effective curriculum, methods to obtain the necessary information must be carefully considered. Results of the National Resident Match Program (NRMP), Association of Residents in Radiation Oncology (ARRO) chief resident survey, and the ASTRO workforce survey can provide a starting point for curriculum development. These surveys can provide information on past experiences of targeted learners, work environment, and intrinsic and extrinsic motivation. In addition, these surveys frequently include information on the learning environment in residency programs for graduate medical education (GME) curriculum development or practice settings for CME curriculum development. An educator must consider how broadly they want their curriculum to be applicable. If the curriculum is developed specifically for a problem identified within their own institution, it may not be applicable to other institutions or educational programs. Thus, reviewing national survey data of training programs[22] and practice environments[92] will inform the radiation oncology educator how they can develop their curriculum in a manner such that it satisfies the needs at their local institution and will be beneficial to other educators in need of a similar curriculum. Table 103.7 summarizes methods commonly employed when conducting a needs assessment of targeted learners.

Surveys represent the most common method for a radiation oncology targeted needs assessment published in the literature. Numerous resources are available to guide a radiation oncology educator designing a survey or questionnaire for a targeted needs assessment including resources from the Association for Medical Education in Europe (AMEE)[93,94] and textbooks.[62,95,96] Surveys include interviews, focus groups, and questionnaires. Radiation oncology educators should decide which method best suits the needs of their curriculum development process. Advantages and disadvantages and basic techniques of

each method are summarized elsewhere.[62] General considerations when designing a survey include paying careful attention to the goal of the survey (questions should have clear justification for inclusion) and avoiding subjective questions, sensitive questions, or lengthy surveys as the response rate will decrease with increasing survey length or sensitivity of questions asked. The survey population should be informed of the purpose of the survey and whether responses are confidential. Surveys represent research, and therefore local Institutional Review Board (IRB) approval or exemption should be obtained prior to survey dissemination. A survey should be pilot-tested to ensure clarity and understandability.[62] In addition, the pilot data should be analyzed to determine if the data collection format would allow the educator to obtain the desired needs assessment results.

TABLE 103.7 METHODS FOR NEEDS ASSESSMENT OF TARGETED LEARNERS

Needs Assessment Method	Radiation Oncology Example
Informal discussion or interviews with individual learners, supervisors, or other stakeholders (in person, over the phone, or by e-mail)	Development of an integrated interdisciplinary oncology elective[174]
Focus group discussions	Focus group discussions with oncologists on patient- and family-centered care[262]
Formal interviews	Interviews of radiation oncology professions regarding uptake of high-precision radiotherapy[57]
Formal questionnaires	Targeted needs assessment for radiation oncology medical student clerkship curriculum[45,98]
Direct observation of targeted learners	Mini-CEX[263]
Pretests of knowledge, attitudes, or skills	Pretest of prostate fossa contouring ability[2]
Audits of current performance	Analysis of brachytherapy procedure volume at US residency programs[86]
Strategic planning sessions for the curriculum	Development of medical school oncology educational goals and objectives[176]

Thomas PA, Kern DE, Hughes MT, et al. *Curriculum development for medical education: a six-step approach*. 3rd ed. Baltimore: Johns Hopkins University Press, 2016: Table 3.2, pp. 37–38. © 1998, 2009, 2016 Johns Hopkins University Press. Reprinted with permission of Johns Hopkins University Press.

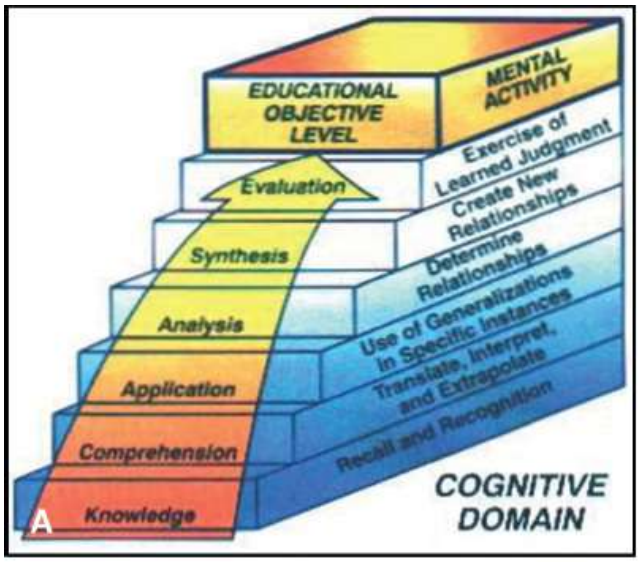
Survey response rate is critical to obtaining representative data. Survey responses can suffer when either the targeted learner does not receive the survey (e.g., requesting that a residency program coordinator forward survey invitations on to residents) or when the targeted learner elects not to complete the survey because of length, sensitivity of question topics, unclear questions, or other factors that inadvertently discourage responses. Methods by which to improve survey responses (unit response rate) and question responses (item response rate) are summarized elsewhere.[94]

Targeted needs assessments at the undergraduate medical education (UGME), GME, and CME levels are frequently reported in the literature, although many do not identify themselves as such. At the UGME level, targeted needs assessments provide perspective and guidance on radiation oncology education in the general medical school curriculum[68,97] and for radiation oncology clerkships.[45,98] At the GME level, examples of needs assessments include those investigating general residency experiences,[22,99] resident education in IMRT,[100] resident knowledge of caring for elderly patients with cancer,[101] palliative care training,[102,103] brachytherapy experience,[86,104] radiation physics education,[105] and radiobiology education.[106] Numerous other GME needs assessments for specific educational goals are reported in the literature. Finally, at the CME level, surveys of practicing physicians can inform educators regarding deficiencies in clinical knowledge that should be addressed. An example of a CME targeted needs assessment is assessing expert consensus on involved-site radiation for lymphoma and determining that there is a lack of consensus.[79] Although these studies provide some guidance, it is critical to incorporate alternative methods for the needs assessment including focused interviews, discussion with multiple stakeholders, and evaluation of available resources.

Goals and Objectives

Once the radiation oncology educator has defined the health care problem, performed a general needs assessment, and conducted a targeted needs assessment, they can begin to formulate goals and objectives for the curriculum. Alternatively, the educator may begin the entire curriculum development process with a general goal or specific objective for their targeted learners. Goals and objectives are key to curriculum development because they help guide the choice of curricular content, educational strategies, learner assessment methods, and curriculum evaluation methods and communicate to others what the curriculum addresses and aims to achieve.[62] Curriculum goals are broad and general.

In contrast, curriculum objectives are Specific, Measurable, Attainable, and Relevant and have a Time frame (SMART).[107] Specific and measurable objectives help to refine the curriculum content and guide learner assessment and curriculum evaluation methods. Objectives should contain five basic elements: "(a) *Who* (b) *will do* (c) *how much (how well)* (d) *of what* (e) *by when*?"[108] By defining specific measurable objectives, the radiation oncology educator can determine the ideal educational, assessment, and evaluation methods that will demonstrate efficacy of the curriculum.



EDUCATIONAL OBJECTIVE LEVEL

C
PSYCHOMOTOR DOMAIN

FIGURE 103.7. A–C: Taxonomy for cognitive, affective, and psychomotor learning domains.

Learner objectives can be in one of three learning domains: cognitive, affective, or psychomotor. Within the three learning domains, cognitive refers to "knowledge," affective to "attitudinal," and psychomotor to "skill" or "behavioral" objectives.[62] Bloom's taxonomy for the cognitive domain defined six levels of the cognitive domain: knowledge, comprehension, application, analysis, synthesis, and evaluation (Fig. 103.7A).[109] The cognitive domain taxonomy was subsequently modified to remembering, understanding, applying, analyzing, evaluating, and creating.[110] One of the modifications included changing the domains to verbs rather than nouns to emphasize the active nature of the learning process. The cognitive taxonomy was further refined to four levels: retrieval of knowledge, comprehension, analysis, and use of knowledge.[111] Taxonomies for the affective domain[112] (Fig. 103.7B) and psychomotor domain[113–115] (Fig. 103.7C) are also defined in the literature. Another conceptual framework used to define progressive levels of learning objectives is Miller's pyramid of clinical competence, which progresses through four phases: Knows, Knows how, Shows, and Does (Fig. 103.8).[116,117]

When writing objectives, verbs that are open to fewer interpretations should be used. For example, "to list" or "to demonstrate" is better than "to know" or "be able to." Examples of action verbs that can be used to define objectives for the cognitive, affective, and psychomotor domains can be found in medical education texts.[117a] The action verb used in the objective can guide what type of assessment method is used to determine if the learner meets the objective. The radiation oncology educator should not overlook the critical nature of writing specific and measurable objectives. These represent the linchpin of any curriculum. Unfocused, unattainable, or unclear objectives will lead to confusion regarding educational, assessment, and evaluation methods.

Learner objectives are generally written to the highest order expected of the learner. However, the radiation oncology educator needs to consider any enabling objectives at lower levels on the pyramid that are required to achieve the higher-order target objective.[62] In addition to learner objectives, the curriculum designer may also define process objectives in relation to curriculum implementation. Table 103.8 provides examples of learner and related process objectives relevant to radiation oncology. Finally, outcome objectives can be specified that relate to patient or societal outcomes.[62] Demonstrating a positive

effect of an educational curriculum on patient or societal health outcomes is the ultimate goal for any medical educator. However, measuring the direct effect of an educational intervention for medical trainees on outcome objectives can be challenging because of the numerous variables that determine health outcomes.

Within the context of educational goals and objectives, competency-based education is gaining popularity. Competency-based education is defined as:

> … *an approach to preparing physicians for practice that is fundamentally oriented to graduate outcome abilities … It deemphasizes time-based training and promises greater accountability, flexibility, and learner-centeredness and focuses on the competencies required of learners driven by needs of the health care system*.[118]

With respect to radiation oncology competency-based education, national accrediting bodies have developed structured guidelines to assist with defining goals and objectives for program graduates. In the United States, as a component of the Next Accreditation System,[119] the ACGME worked with a number of stakeholder groups, including the ABR, to develop the Radiation Oncology Milestones. The Milestones define competency levels for residents within the six competency domains of Patient Care, Medical Knowledge, Systems-Based Practice, Practice-Based Learning and Improvement, Professionalism, and Interpersonal and Communication Skills.[120] Competency objectives for levels of training are defined within the six domains. Level one is the knowledge or skill level expected of an incoming resident, level four is that of a graduating resident, and level five is above that of a graduating resident. The ACGME currently mandates that a program's clinical competency committee assess residents using the Milestone framework semiannually. The learner objective is to achieve or outperform the ACGME Milestone commensurate with their training level, and the process objective is to have all residents at or above their training level.

Similarly, the RCPSC has developed the Canadian Medical Education Directions for Specialists (CanMEDS) framework.[5,121] The CanMEDS competencies include Medical Expert, Communicator, Collaborator, Scholar, Health Advocate, Leader, and Professional. Currently the RCPSC is defining the CanMEDS competencies within the constructs of Entrustable Professional Activities and Milestones in the Competency by Design Project.[122] Similar to the ACGME Milestone project, there will be specific Entrustable Professional Activities (EPAs) and milestones for four levels of residency training including transition to discipline, foundations of discipline, core of discipline, and

transition to practice.

TABLE 103.8 SAMPLE LEARNER AND PROCESS OBJECTIVES FOR RADIATION ONCOLOGY EDUCATION

Domain	Level on Domain Taxonomy	Learner Objective	Process Objective
Cognitive	Remembering	The medical student will correctly identify three radiation emergencies at the end of the lecture	80% of medical students will correctly identify three radiation emergencies at the end of the lecture
	Applying	The resident will correctly compute the appropriate number of monitor units to treat an emergency spinal cord compression at the end of the workshop	100% of residents will correctly compute the appropriate number of monitor units to treat an emergency spinal cord compression at the end of the workshop
	Evaluating	The radiation oncologist will correctly revise incorrect head and neck target volumes at the end of the interactive contouring workshop	80% of radiation oncologists will correctly revise incorrect head and neck target volumes at the end of the interactive contouring workshop
Affective	Receiving	The medical student will acknowledge the importance of using	100% of medical students will acknowledge the importance of using

		nonmedical jargon with patients at the end of the clerkship	nonmedical jargon with patients at the end of the clerkship
	Valuing	The resident will demonstrate a willingness to use nonmedical jargon during patient consultations at the end of their first year of clinical training	100% of residents will demonstrate a willingness to use nonmedical jargon during patient consultations at the end of their first year of clinical training
	Characterization	The radiation oncologist will modify their discussions with patients to minimize use of medical jargon after completing the communication workshop	100% of radiation oncologists will modify their discussions with patients to minimize use of medical jargon after completing the communication workshop
Psychomotor	Perception	The medical student will correctly identify the bevel side of a brachytherapy needle after observing a permanent prostate implant	100% of medical students will correctly identify the bevel side of a brachytherapy needle after observing a permanent prostate implant
	Guided response	The resident will correctly reproduce the attending physician's needle placement technique after a lecture on technique and observing a complete permanent prostate implant	80% of residents will correctly reproduce the attending physician's needle placement technique after a lecture on technique and observing a complete permanent prostate implant
	Origination	The brachytherapy fellow will correctly and independently construct a new HDR catheter implant pattern after encountering pubic arch interference by halfway through their 1-year fellowship	100% of brachytherapy fellows will correctly and independently construct new HDR catheter implant patterns after encountering pubic arch interference by halfway through their 1-year fellowship

Instruction/Educational Strategies

As discussed in the learning theory section of this chapter, effective learning can be facilitated by addressing preconceptions, building expertise, and developing a metacognitive approach to learning.[123] Learners have prior experiences that shape their attitude and motivation toward learning new knowledge or a new skill. These experiences lead to preconceptions that may need to be addressed prior to engaging the learner. Building expertise requires repeatedly exposing learners to specific conceptual frameworks so they can develop fluency of

retrieval known as “automatism.”[62] As the learners gain experience, they improve their ability to utilize the specific knowledge or skill until they have achieved expertise. Metacognition refers to the learners’ ability to recognize what they know or need to know in a specific problem-solving situation. This concept is related to the learner’s ability for self-reflection.[62] If a curriculum is able to lead learners to identify their preconceptions, build expertise, and improve their metacognition, the curriculum is successful in achieving transformative learning where the learner changes in a meaningful way. Learners may resist this type of change because it challenges their assumptions, beliefs, and values.[62]

Educational strategies for a radiation oncology educational curriculum should match the goals and specific measurable objectives defined previously. Educational strategies refer to both the content and methods by which the goals and objectives will be achieved.[62] A simple method by which to choose the content of a curriculum is to refer to the nouns in the specific measurable objectives. For example, if the objective is “the resident will demonstrate the ability to contour the prostate fossa by the end of the workshop,” then the content of the curriculum will focus on the “prostate fossa.” Although this seems obvious on the surface, a large curriculum such as that of a clerkship or residency program may have numerous subgoals and specific objectives. There is a risk of bias toward easily implementable and assessable content. If each specific objective is not considered when choosing content and educational strategies, the educator risks omitting content critical to one or more of the specific objectives. To prevent omission of content in a larger educational program with multiple goals and objectives, curriculum mapping can be pursued. A detailed discussion of curriculum mapping is beyond the scope of this text and can be found elsewhere.[62]

Educational methods to relay specific content must also be matched to the learning styles of individual learners. Multiple learning style theories exist in the literature.[124] An example of a learning style conceptual framework is Dunn and Dunn’s visual, auditory, kinesthetic, and tactile categorization.[125] It is not usually feasible to create a specific curriculum for each individual learner’s preferred learning style. In addition, most learners will learn from multiple different educational strategies. Thus, radiation oncology educators should include multiple educational methods that will allow learners with different learning styles to achieve the learning objective. For example, utilizing only slide-based didactic lectures to teach radiation oncology residents about radiation physics

and radiation biology may hinder learners who prefer a problem-based format. When choosing educational methods available, resources must also be considered. The ideal approach identified after the problem identification and general needs assessment may not be feasible based on resources available (time, money, etc.).

Commonly used educational methods in relation to radiation oncology include readings, lectures, online learning resources, small group discussion, problem-based learning, peer teaching, real-life supervised clinical experiences, role models, demonstration, simulation, and artificial models. Other methods less commonly employed in radiation oncology because of restrictive resource requirements for development or implementation, limited numbers of faculty or learners, or lack of knowledge in the radiation oncology educator community of the educational method include large group discussion, team-based learning, reflection on experience, role-play, standardized patients, audio/video review of the learner, and behavioral/environmental interventions.[62]

Educational methods can be divided based on the domain objectives they aim to achieve. Cognitive objectives may be best achieved through readings, lectures, or discussion; affective objectives through standardized patients, reflection on experience, and role-play; and psychomotor objectives may be best achieved through real-life and supervised clinical experiences, simulation and artificial models, or demonstration.

Radiation oncology educators face unique challenges when choosing appropriate educational methods. At the UGME and GME training levels, the number of learners is often small. Medical school clerkships may have one to three students rotating at any given time. Residency training programs also have limited numbers of trainees, often at different training levels. The limited number of trainees translates into limited resources (faculty time, money, space, clinical volume) that can be dedicated to educational methods. Thus, radiation oncology educators must utilize educational methods that efficiently utilize limited resources while achieving the goal and specific objectives of their curriculum.

To overcome the challenge of limited resources, individuals, collaborative groups, societies, and certifying organizations have developed curriculum proposals and specific educational methods to assist individual radiation oncology educators in achieving their local educational goals and objectives. Table 103.9 summarizes selected curricula and educational methods. In addition, educational methods utilized by other medical specialties to teach knowledge

and skills that are not specific to radiation oncology (e.g., breaking bad news, diagnostic radiology knowledge, etc.) should be adopted or adapted by radiation oncology educator so as not to reinvent the wheel.

Implementation

Once a curriculum is developed with content and educational methods are selected to accomplish the specified goals and objectives, implementation must occur. All too often, well-designed educational interventions are unsuccessful because of barriers encountered during the implementation phase. Consideration of barriers to successful implementation should start at the outset of the curriculum planning process. The general and targeted needs assessment phase of curriculum development is a useful opportunity to begin establishing rapport with stakeholders who will need to provide support for successful implementation. For example, during the development of a new 1-month international clinical experience for radiation oncology residents, a program director must consider stakeholders (e.g., the chairman, teaching faculty, GME office, and residents) for a needs assessment but also use the opportunity to develop relations that will be important for successful implementation. For example, if early in the development of the 1-month international clinical experience the residency program director fails to discuss the required funds with the chairman and/or international rotation requirements with the GME office, the resulting decrease in available residents for service coverage or the requirements for an international rotation with the GME office may present insurmountable barriers at the time of implementation. Additionally, if the residents themselves were not made aware of the proposed experience prior to an attempt at implementation, they may choose not to participate, thus negating the effort put into the curriculum development.

Resources for successful implementation must be identified and obtained. These include personnel, time, facilities, and funding.[62] Successful implementation requires appropriate resources, and as Figure 103.6 demonstrates, barriers to implementation must be considered during the earlier phases of curriculum development. Table 103.10 provides a checklist that can be used early in the curriculum development process to streamline the implementation phase.

TABLE 103.10 CHECKLIST FOR IMPLEMENTATION

- Identify resources
  - Personnel: faculty, audiovisual, computing, information technology, secretarial and other support staff, patients
  - Time: curriculum director, faculty, support staff, learners
  - Facilities: space, clinical sites, clinical equipment, educational equipment, virtual space (servers, content management software)
  - Funding/costs: direct financial costs, hidden or opportunity costs, faculty compensation, costs of scholarship
- Obtain support
  - Internal
    From: those with administrative authority (dean's office, hospital administration, department chair, program director, division director, etc.), faculty, learners, other stakeholders
    For: curricular time, personnel, resources, political support
  - External
    From: government, professional societies, philanthropic organizations or foundations, accreditation bodies, other entities (e.g., managed care organizations), individual

donors
For: funding, political support, external requirements, curricular or faculty development resources
- Develop administrative mechanisms to support the curriculum
  - Administrative structure: to delineate responsibilities and decision-making
  - Communication
    Content: rationale; goals and objectives; information about the curriculum, learners, faculty, facilities and equipment, scheduling; changes in the curriculum; evaluation results; etc.
    Mechanisms: websites, social media, memos, meetings, syllabus materials, site visits, reports, etc.
  - Operations: preparation and distribution of schedules and curricular materials; collection, collation, and distribution of evaluation data; curricular revisions and changes, etc.
  - Scholarship: plans for presenting and publishing about curriculum; human subject protection considerations; IRB approval, if necessary
- Anticipate and address barriers
  - Financial and other resources
  - Competing demands
  - People: attitudes, job/role security, power and authority, etc.
- Pilot
  - Phase-in
  - Full implementation
- Plan for curriculum enhancement and maintenance

Any new or modified educational curriculum represents a change in the status quo, and therefore radiation oncology educators must become familiar with methods to effect successful change. Kanter's six steps to leading positive change[126] (Table 103.11) and Kotter's eight steps to leading change[127] (Fig. 103.9) are two examples of conceptual frameworks that can be employed to garner support from necessary stakeholders and successfully develop and implement a new curriculum or changes to an existing curriculum. One unifying

theme in both conceptual frameworks is that to effect change, others must be involved in the process of change. Further discussion of leadership theory[128] and organizational culture[129] is beyond the scope of this text.

Evaluation

Per the six-step framework,[62] evaluation is a final step in curriculum development. Evaluation takes place both at the learner and the program level. In education parlance, "assessment" refers to a test or survey to provide feedback to the learner, whereas "evaluation" refers to methods used to evaluate the educational program. These can include stakeholder surveys, review of aggregate assessment data to determine if the specific and measurable objectives were achieved, etc. In this section, assessment of the individual learner is referred to as distinct from the evaluation of an educational program, although both are intimately linked.

Learner Assessment. Key to the delivery of any educational intervention is a clear plan for learner assessment. Assessment is defined as "any systematic method of obtaining information from tests and other sources, used to draw inferences about characteristics of people, objects of programs."[130] The purposes of learner assessment are multifold.[131] Many of the educational attributes or traits that educators assess are hypothetical concepts. Assessments allow educators to assign a measure or degree of quantification to such attributes. Assessments aim to document achievement of what was learned or taught, which is helpful to assess the competency of learners and generate learner feedback for areas of improvement. Assessments can also be useful to measure aptitude to gauge learner performance, assign grades or provide ranking, and predict future performances or suitability for certain educational programs (i.e., MCAT for admission to medical school). Ultimately, in many settings, assessments are a requirement for accreditation and can inform decisions about the effectiveness of medical education programs and be integral to a programmatic evaluation (see below). To be meaningful, learner assessment must be clearly linked to objectives, define standards for performance, and include measurements that are reliable.

Assessments may be formative or summative. Formative assessments provide the learner with feedback with the intent to allow the learner to identify what they have learned and areas for improvement.[131,132] Formative assessments should occur at multiple defined points throughout a training program or course. In radiation oncology residency programs, formative assessments could include

in-house written exams for physics or radiation biology, objective structured clinical examinations (OSCEs) to assess communication skills and end-of-life discussions administered midway through a clerkship rotation in medical school, or annual in-service training exams to assess clinical knowledge. Summative assessments are intended to provide an overall summary of a learner's achievement. They are generally done at the end of a defined curricular period. With respect to radiation oncology, this may include licensing exams at the end of residency such as those administered by the ABR or RCPSC. Assessments can be "low stakes" and "high stakes." These are often linked, but not always, to formative and summative evaluations, respectively. The consequences of the exam define the stakes of the exam. High-stakes exams have "a serious impact on the examinee," whereas low stakes have significantly lower potential for impact on the trainee.[132,133] Assessments can also be norm-referenced (e.g., percentile determines performance) or criterion-referenced, which are interpreted in the context of specific objectives or learning standards (e.g., "Pass/Fail" or "Meets Standard, Standard in Progress, Does not Meet Standard"). The annual in-service training exam is an example of a norm-referenced test, whereas competency-based assessment is usually criterion-referenced. Methods to set the pass threshold including the Angoff Method (used for the ABR certifying exams) are discussed elsewhere.[132]

FIGURE 103.9. Kotter's eight steps to leading change. (From Kotter JP. *Leading change, with a new preface by the author*. Boston, MA: Harvard Business Review Press, 2012. Reprinted by permission of Kotter International.)

Assessment Methods. There is a wide range of assessment methods reported in the medical education literature.[62,133,134] Although not an exhaustive list, the following provides a sample of assessment methods. Downing and Yudkowsky[132] propose that there are four major types of assessment methods. Table 103.12 summarizes these methods with examples relevant to radiation oncology. The four groups include written tests, performance tests, clinical observations, and miscellaneous or other forms not classified. Written tests are among the most commonly used forms of assessment. Written tests may include open-ended (a.k.a. constructed responses, short or long answer, essay) responses or closed-ended (a.k.a. selected responses, matching, true or false, multiple

choice). Closed-ended multiple-choice questions offer the advantage of being easy to administer and grade but may lack the ability to assess diagnostic reasoning. Well-constructed written tests may overcome this problem and allow for more detailed assessments of knowledge and reasoning.[133,135,136]

Performance tests are those assessments that allow for direct observation of the learner. They allow the learner to demonstrate "what they can do."[132] The most common examples are the OSCEs or simulations. An OSCE consists of a series of stations with a distinct focus on a clinical task.[133] Many OSCEs use standardized patients trained to portray a patient and relevant medical scenario.[134] For the purposes of assessment at an OSCE station, an observer will assess the performance of the learner based on a checklist or global rating tool. Although this type of assessment can be constructed to be realistic and reliable, they can be expensive and highly dependent on checklist quality and observer consistency. The term simulation refers to a realistic representation of a real-world task.[132] High-fidelity simulations can be used to assess procedural skills or teamwork scenarios. They provide a relatively low-risk environment to assess high-risk and low-frequency scenarios.[137] Simulations can be realistic and provide reliable assessments. However, they can be expensive and do not provide a "real-time/real-world" assessment.

Clinical observations are assessments made based on performance in the clinical setting.[132] The clinical performance evaluation or global assessment rating is one of the most common methods utilized during training. The ACGME toolbox distinguishes the global rating from other assessment methods in that "A rater judges the general categories of ability instead of specific skills or behavior and the ratings are completed retrospectively based on general impressions collected over a period of time derived from multiple sources or information."[138] These are easy to carry out for the rater and usually done in real time. There has been considerable literature, however, on the subjectivity of the raters and the variability in the assessments coupled with issues with rating tools.[139]

The final category of assessment includes tools not well positioned in any of the categories above. These include assessment tools such as portfolios, formal oral exams, and bedside oral exams. A portfolio is a purposeful sampling of work to support attestation of meeting a required level of training or competency. Portfolios are combined with self-reflection and allow the learner to demonstrate areas of strengths and potential areas for improvement.[133,140] Portfolios can include a broad sampling of a learner's experiences including dictations, procedure logs, sample contouring logs, quality improvement projects, and even

videos of procedural techniques or consults. Mentoring is integral to the interpretation of the portfolio. Portfolios can provide a broad sampling to support assessment but can be labor intensive and dependent on faculty development.

Selection of Assessment Methods. Numerous resources provide guidance on the selection of specific assessment methods. From a conceptual perspective, the ACGME defined five characteristics integral to an assessment instrument or approach including that the approach should provide valid and reliable data, be feasible, apply to the assessment circumstances, and finally provide valuable information.[141] Van Der Vleuten and Schuwirth[142] developed a conceptual model that mirrors these criteria. Their model describes five criteria to help select an appropriate assessment tool. The criteria included are validity (if the assessment measures what it is intended to measure), reliability (does the tool reproducibly measure what it is intended to measure), educational impact (what are the effects of using the tool on learners and the educators), acceptability to learners and faculty, and costs. This model proposes that each of the criteria are weighted depending on the intended purpose of the assessment data and that all factors are multiplied together. For example, if the assessment would be for a certifying exam (e.g., ABR licensing exam), then more weight may be given to reliability and validity as opposed to an in-house physics exam intended to provide the learner with formative feedback where more weight may be given to costs and educational impact. This model is useful to conceptualize that each assessment method has inherent advantages and disadvantages and many factors should be both considered and relatively weighted in choosing a method appropriate to the educational context.

TABLE 103.12 COMMON ASSESSMENT METHODS AND RELEVANT RADIATION ONCOLOGY EXAMPLES

Assessment Method	Example	Radiation Oncology Example with Relevant Literature if Applicable
Written exam	Multiple-choice exam Essay exam Short-answer exam	– American College of Radiology (ACR) Radiation Oncology In-Training (TXIT) Exam[196] – Pre- and Posttest Written Exams after e-learning module[271] – American Board of Radiology Qualifying Exam – Royal College of Physicians and Surgeons of Canada Radiation Oncology Written Exam
Performance Test	OSCE Simulation	– Cancer Pain Management OSCE for Medical Students[272] – Standardized Patients to Assess Communication Skills in Radiation Oncology Residents[24]

		– Prostate Fossa Contouring Simulation[2] – Prostate or Gynecologic Brachytherapy Insertion Simulation on Phantom
Clinical observation	Structured clinical observation	– Mini-CEX – Direct Observation of Medical Student and Resident in Radiation Oncology Clinic rotations
Miscellaneous	Portfolio review Chart simulation	– Portfolio review to include clinical encounter notes, collection of clinical evaluations, sample of contouring tasks, quality improvement projects[273]

In the context of selecting an assessment method that measures what it is intended to, Miller's pyramid of clinical competence can help to provide a framework.[116,132] As discussed previously, Miller's pyramid (Fig. 103.8) progresses through four levels of clinical competence: knows, knows how, shows, and does. It can be useful to map assessment methods to each of these levels. At the base level of "know," a learner may be asked to simply demonstrate factual knowledge of a concept. At this level, assessment methods examine the ability of the learner to recite knowledge. Examples of assessment methods include traditional written tests such as true or false. "Knows how" implies that learner can use factual knowledge for the purposes of interpretation or application. This level may be assessed by more detailed written tests including short or long written answers or oral exams where the learner is required to show not only their knowledge but its application. The "shows" level implies an ability to demonstrate learned skills. Assessment methods include simulations or OSCEs. Finally, the "does" level moves the learner's performance into clinical practice. Assessments in this setting take place in the "real world" and include direct observations in a clinical setting and multisource feedback. Figure 103.10 depicts the selection of assessment methods in radiation oncology based on Miller's pyramid.

Although a multitude of assessment methods exist, the role of the medical educator is to select methods that provide a broad sampling of performance and are reliable, reproducible, and free of bias. No single assessment can give a perfect measure of performance or knowledge, and the application of several methods will provide the most reliable data. Assessment should be mapped to the objectives and instructional methods within a curriculum map (see objectives section).[143,144] A purposeful discussion of assessment methods should happen at the time of curriculum development with the intent of clearly defining what needs to be measured, how this will be measured, who will measure (and how will their skills be developed to support this), and how will the data be

used.[133,137] Table 103.13 summarizes some of the practical questions a radiation oncology educator could ask themselves when developing an assessment plan.

TABLE 103.13 PRACTICAL QUESTIONS TO ASK WHEN DEVELOPING AN ASSESSMENT FRAMEWORK

Question	Subset of Questions
What is the goal of assessment?	What is the intended purpose of the assessment data? Is the data meant to be formative or summative?
What are you trying to assess?	Where does the entity being assessed exist on the Miller's pyramid[116]? How best can the learner demonstrate what you are trying to measure (i.e., written test or clinical observation)? How many measurements and methods would provide an adequate sampling of the entity to be measured?
When will you assess?	How often should assessments take place? If the assessments are formative, what frequency is needed for the learner to improve their performance? Are assessments too frequent and thus not feasible or sustainable?
Who will conduct the assessments?	How will you ensure the assessments are similar and reproducible? Will you need faculty development? How many assessments do different observers need?
Who will manage the assessment data?	Where will the assessment data be kept? Who will collate, distribute, and review the assessment data? How will the security of the assessment data be maintained? How will feedback be given in a timely fashion?

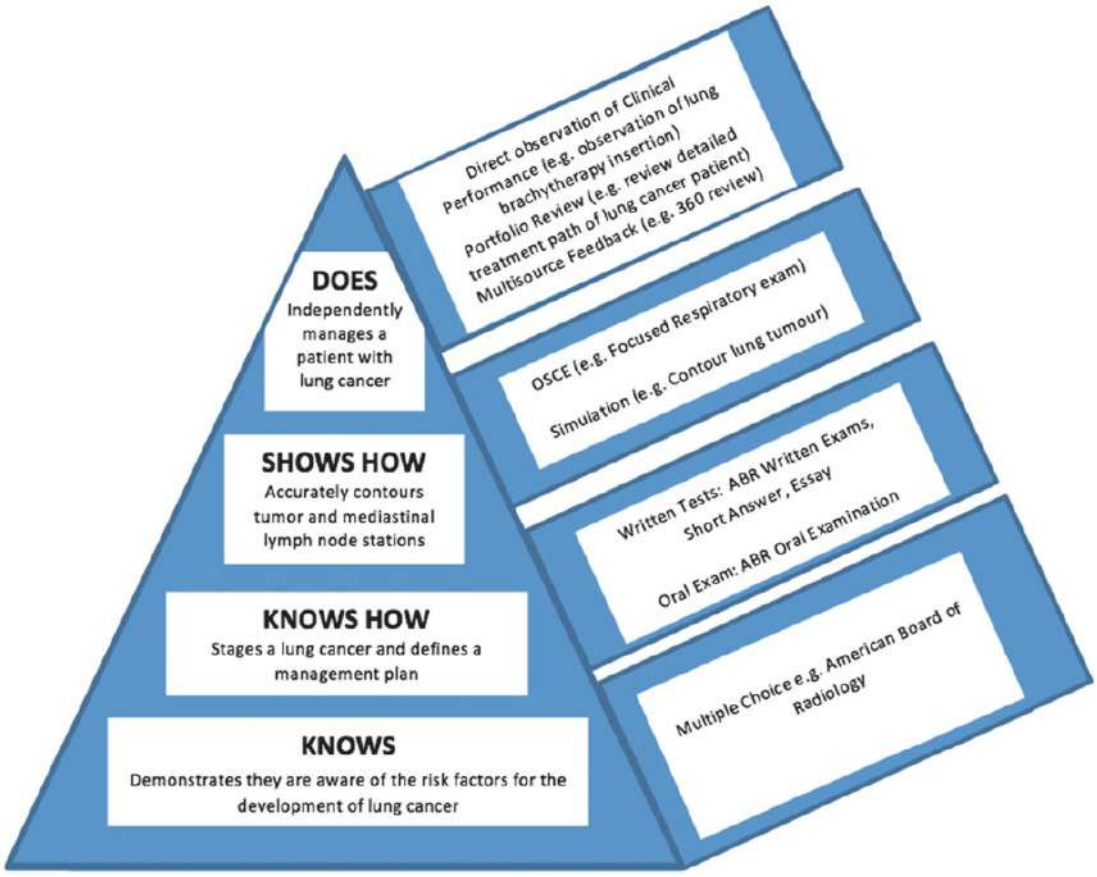

FIGURE 103.10. Miller's pyramid[116] applied to assessment methods in radiation oncology.

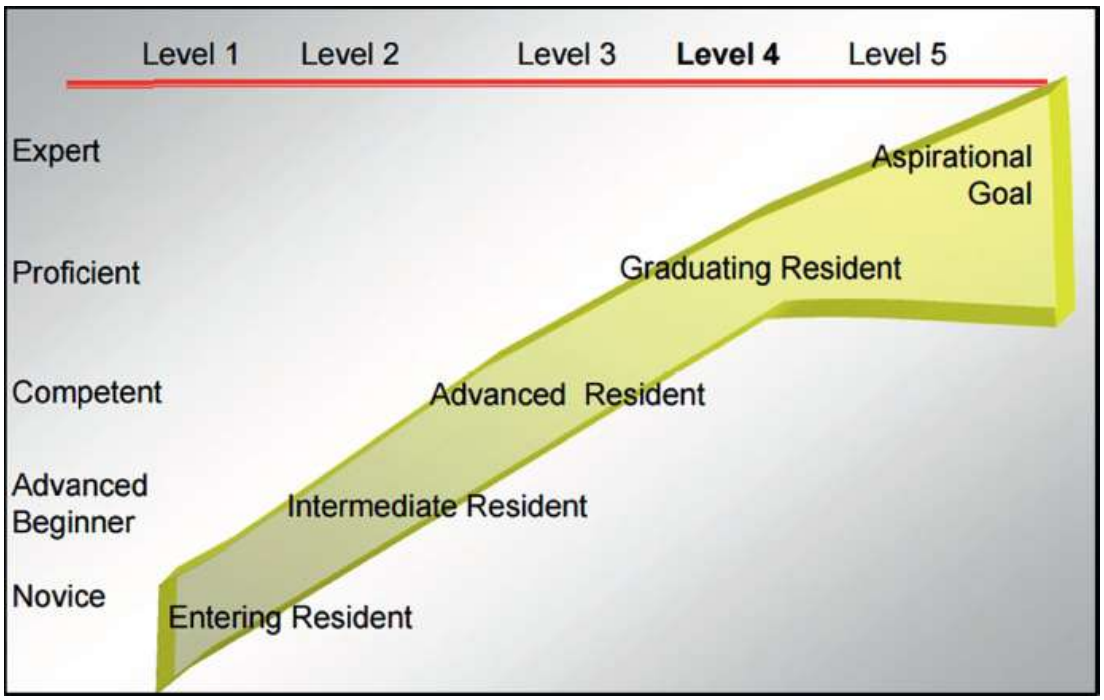

FIGURE 103.11. ACGME milestone levels of expectation. (From Ling L, Derstine P,

Cohen N. *Implementing milestones and clinical competency committees*. 2013. Reprinted with permission of Accreditation Council for Graduate Medical Education.)

Competency and Assessment. As discussed previously in the Goals and Objectives section, medical training is shifting to competency-based frameworks.[118] Within radiation oncology GME, relevant frameworks include the RCPSC CanMEDS framework[5] and ACGME/ABR Radiation Oncology Milestone.[120] In Canada, the RCPSC is developing specialty-specific competency frameworks for all specialties including radiation oncology through the Competence by Design project.[122,145] Both the ACGME Milestone Project (Fig. 103.11) and the Radiation Oncology Competence by Design (Fig. 103.12) define competencies related to the various roles (i.e., Communicator, Collaborator, etc.) and specific to level of training. By the end of a specific level of training, a learner is expected to demonstrate competency through the accomplishment of a number or training level–specific EPAs.[146] An EPA is a clinical task that is demonstrable and typically includes multiple milestones.

Each of the competency-based frameworks in the United States (ACGME) and Canada (CanMEDS) has toolboxes that may help the educator to select assessment methods by competency.[138,147] With the evolving competency-based curriculum, there will be changes to these toolboxes, but the foundations will likely remain similar. Although these toolboxes divide assessment methods by competency, it is well established that many of the competencies overlap and their assessment on an individual level is artificial at best. Competencies are not stable through training and develop with experience.[148] The most robust assessment of competencies will rely on features mentioned previously and will include broad, purposeful, and frequent sampling with reliable and reproducible methods. In the context of competency-based assessments, the assessment data can be used both “for learning” and allow self-reflection and to “assess learning” to ensure accountability to training programs and society.[149] Lastly, both the RCPSC and the ACGME mandate the involvement of a clinical competence committee to review competency assessments on a regular basis and help to provide feedback to the learner and the program. With a shift to competency-based training and assessment, a considerable amount of faculty development will need to occur to ensure that the assessments are performed in a consistent and reliable manner and accomplish the intended outcomes.

Program Evaluation. Program evaluation is a key step in curriculum development. The purposes of evaluation are multifold. Program evaluation can

be performed[150,151]:

…to determine the effectiveness of the curriculum for learners
…to document that curricular objectives have been met
…to enable faculty to make changes to improve the program
…to provide data to track program management, evaluate efficiency, to support accountability and dissemination

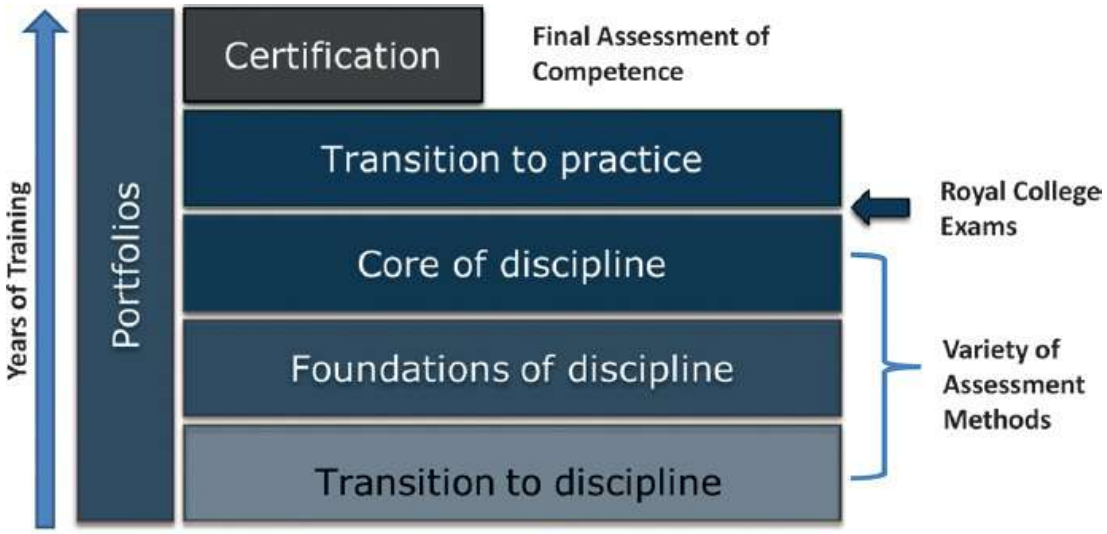

FIGURE 103.12. College of Physicians and Surgeons of Canada Competence by Design Conceptual Framework for Residency Training. (Adapted from Royal from The Royal College of Physicians and Surgeons of Canada. Accessed May 16, 2018.)

Eight practical steps adapted from the six-step curriculum approach,[62] Fitzpatrick,[152] and AMEE guides[151,153] are proposed to guide program evaluation:

- Identification of users: As a first step, the stakeholders should be identified. Stakeholders refer to the likely users of the evaluation data. This will often include the learners, the faculty, the curriculum developers, the funders, the university, and the accreditation bodies when appropriate.
- Determine the purpose of the evaluation: The purpose of the evaluation should be clearly defined. It is here that the approaches to evaluation and the dimensions should be reviewed as discussed above. Key questions to ask are what approach is this evaluation? Will this evaluation be summative or formative? How will the results of this evaluation impact the program and how will the data specifically be used?
- Identify resources and select and an evaluation team: Resources will need to be allocated to conduct an evaluation. Such resources can include personnel, time,

equipment (e.g., computers, access to secure databases), and funding. Many medical schools and residency programs may have existing evaluation units, and it can be useful to identify this at the outset. With respect to choosing an evaluation team, it is useful to consider if an evaluation team is best composed of internal or external reviewers. Additionally depending on the approach to evaluation, it may be useful to include participants, faculty, learners, and health care consumers, among others.

- Determine the evaluation questions: The evaluation questions depend on the approach to the evaluation. With respect to an objective-oriented approach, evaluation should be linked to the process and outcome objectives of a curriculum (see Goals and Objectives). As such, the evaluation will examine the *who will do how much of what* and *when*. It is best when writing program objectives that a lens is given to the evaluation questions to ensure they are in fact measurable and clear. If a participant-oriented approach is taken, evaluation questions could be directed to participants, and the questions asked are related to the perceived effectiveness of the program and the relative strengths and weaknesses.
- Select an evaluation design: A variety of evaluation approaches can be taken. For the most part, these are dependent on the approach to evaluation and are well summarized elsewhere.[151] Some of the most common evaluation designs relate to an objective approach to document that learning objectives have been met. These can include a posttest design, a pre-posttest design, or a controlled pre- and posttest design (i.e., where an experimental group is exposed to a curricular intervention). As the degree of control increases, the complexity to administer also increases. There are well-known limitations to each design approach.[62]
- Select a measurement method and relevant instruments to collect data: It is essential that the measurement method be aligned with the questions identified in the evaluation. Similar to the section on assessment, evaluation methods should be chosen to provide reliable and reproducible data that evaluate questions relevant to making appropriate judgments. In part, Kirkpatrick's hierarchy of evaluation[64] (Table 103.14) can help to frame the possible methods one might use to evaluate a program examining learner outcomes. At the lowest level of the hierarchy, one could simply evaluate the participation and reaction of learners. One could use rating forms or conduct individual interviews to gain information on the satisfaction of learners (or stakeholders). To demonstrate that learning had taken place, one could examine the results of written or oral exams. With respect to documenting a change in behavior, this would likely be best done in the context of direct observation. Finally,

improved patient care could be done through direct observation and performance audits. The most robust evaluation data would be both quantitative and qualitative.

- Collect and analyze the data: The data must be both collected and analyzed. As part of curriculum design, it is essential to define the frequency with which evaluations will be done and how the data will be stored and analyzed. Data may require analysis with both descriptive statistics and qualitative analysis. When established standards are in existence, the data may be compared to these or the literature can be reviewed to relate the experience to other programs or institutions.
- Dissemination and feedback: The last stage of program evaluation is the act of collating the results and dissemination. Evaluations should be timely and distributed to the relevant stakeholders. It is useful to review the purposes of the evaluation in order to assess who should receive the results and in what format.

TABLE 103.14 Kirkpatrick's Hierarchy of Evaluation[64] in Relation to Radiation Oncology Education

Level 1: Reaction	Are participants satisfied with the educational experience? Example: Medical students rate a clerkship curriculum as useful.[82]
Level 2: Learning	Has learning taken place? Example: Medical students demonstrate improved knowledge on an objective assessment after a single lecture on radiation oncology.[165]
Level 3: Behavior	Is there a measurable change in professional behavior? Example: Learners demonstrate improved contouring accuracy after a teaching intervention.[46]
Level 4: Results	Is there an improvement in patient care? Example: Implementation of a contouring atlas to educate physicians on contour accuracy demonstrates improved tumor control probability and decreased normal tissue complication probability.[274]

Overall, program evaluation is a key component of curriculum development. Table 103.15 provides specific examples of radiation oncology program evaluation.

Dissemination

To qualify as scholarship, any curriculum development project must be disseminated to the public.[39] Dissemination of a novel curriculum can help address a health care problem, stimulate change, provide feedback to curriculum developers, increase collaboration, prevent redundant work, and help curriculum

developers achieve recognition and academic advancement.[62] Dissemination of a curriculum should be considered during all phases of curriculum development to develop a coherent strategy for dissemination, address ethical and legal issues related to protection of the participants and intellectual property, identify what curriculum material and data will be disseminated, identify the target audience, and identify venues for dissemination.[62] Innovations are more likely to be adopted if there is a perceived relative advantage over existing practice; compatibility with previous experience, beliefs, and values; simplicity of the innovation; trial ability allowing the innovation to be implemented in a stepwise fashion; and observability.[154] Ethical and legal issues include consideration of whether local IRB exemption or approval is required prior to disseminating the curriculum. In the United States, many educational projects qualify as "exempt" from IRB review based on Health and Human Services Office for Human Research Protections guidelines for exemption.[155] Projects that are exempted include:

TABLE 103.15 EXAMPLES OF EDUCATIONAL EVALUATION STUDIES IN RADIATION ONCOLOGY

Study Summary	Evaluation Approaches	Evaluation Methods
Evaluation of a Radiation Safety Initiative for Nurses[275]	Objectives oriented	Pre- and postwritten tests to assess for changes in knowledge and attitudinal objectives
Evaluation of Theoretical Radiation Oncology Training Programs[23]	Participant oriented	Written user satisfaction surveys
Evaluation of a Contouring Bootcamp[18]	Objectives oriented Participant oriented	Pre- and post written tests Written learner satisfaction surveys
Longitudinal Study to Assess Adherence to Clinical Pathways[276]	Objectives oriented	Pre- and post written tests using Clinical Performance and Value Vignettes
10-Year review of student accomplishments in rapid response radiotherapy program[277]	Objectives oriented/management oriented Participant oriented	Number of first authored papers produced by students in the program Written learner satisfaction surveys

Category 1: Research conducted in established or commonly accepted educational settings, involving normal educational practices, such as (i) research on regular and special education instructional strategies or (ii)

research on the effectiveness of or the comparison among instructional techniques, curricula, or classroom management methods.

Category 2: Research involving the use of educational tests (cognitive, diagnostic, aptitude, achievement), survey procedures, interview procedures, or observation of public behavior, unless (i) information obtained is recorded in such a manner that human subjects can be identified, directly or through identifiers linked to the subjects, and (ii) any disclosure of the human subjects' responses outside the research could reasonably place the subjects at risk of criminal or civil liability or be damaging to the subjects' financial standing, employability, or reputation.

Radiation oncology educators are encouraged to speak with their institutional IRB representatives to obtain advice on whether IRB exemption or full review is required for an educational project. Professional ramifications for not obtaining proper IRB approval of a scholarship project can be significant.

Consideration of intellectual property issues is also important. Images, figures, and tables used in lectures may be subject to copyright protection. Publishers can be contacted for permissions, or more simply, when developing an educational product, care can be taken to avoid copyrighted materials. In addition, institutions may have copyright protections for patient images or photographs, and the curriculum developer is advised to discuss possible copyright issues with the appropriate institutional representative.

Multiple components of the curriculum development process can be disseminated including a systematic review performed as a general needs assessment, a survey focus group done as the targeted needs assessment, the curriculum materials themselves including goals and objectives with educational methods (e.g., lecture, workshop, small group), and then the assessment and evaluation data. Methods for dissemination include presentations at national meetings, publication in peer-reviewed journals, and dissemination via the Internet (e.g., MedEdPORTAL[83]). A more detailed discussion of curriculum dissemination strategies is available elsewhere.[62]

Curriculum Maintenance, Renewal, and Reform

Radiation oncology educational programs must adapt and evolve to accommodate changes in accrediting body requirements, learner preferences, turnover of faculty and staff, and changes in clinical practice. Additionally, novel systemic therapies and radiation oncology techniques are continually being

developed and implemented. As such, training programs must continually address these changes. A seminal paper by Abrahamson describes nine "diseases" of the curriculum. Examples include "carcinoma of the curriculum" characterized by uncontrollable growth of one segment or component of the curriculum, "iatrogenic curriculitis" where the curriculum suffers from excessive tampering or meddling, "curriculum hypertrophy" with an increasingly crowded curriculum due to more and more content crammed into limited educational time, bad teaching leading to "idiopathic curriculitis," and "curriculum ossification" where the curriculum is "cast in concrete" and is characterized by comments such as "What do you want to change anything for?" or "Well, we've always done it this way."[156] These "diseases," although humorous on the surface, affect many radiation oncology educational programs including medical school clerkships, residency training programs, educational sessions at society meetings, and CME programs. To prevent or treat Abrahamson's diseases of the curriculum, radiation oncology educators should routinely re-evaluate their curriculum for deficiencies and areas in need of improvement. A curriculum is never "done" and can be re-evaluated utilizing the six-step model[62] or by applying Harden's ten questions.[74] Without regular re-evaluation, radiation oncology educators are at risk for curricular ossification or any of Abrahamson's other diseases of the curriculum.

To achieve success when revising or reforming an existing curriculum, methods discussed previously for implementation should be employed. In particular, utilizing a deliberative curriculum development model that includes as many stakeholders as possible will help to garner political support for curriculum reform.[157]

CURRENT PRACTICES IN RADIATION ONCOLOGY TRAINING

Having a basic understanding of the principles of medical education can help to facilitate the careful development, implementation, and evaluation of a new curriculum and educational scholarship. The following section focuses on the real-world application of medical education principles to UGME, GME, and CME in radiation oncology. This review will focus on the current educational landscape in each setting and identify areas for potential future educational development and scholarship.

Undergraduate Medical Education in Radiation Oncology

Radiation oncology education as a specific discipline begins during the undergraduate phase of medical training. Students enter medical school with varied experiences and preconceptions about which specialty they plan to pursue. As a small specialty, radiation oncology may be relatively unknown to medical students relative to larger core clerkship specialties (internal medicine, pediatrics, surgery, obstetrics and gynecology, psychiatry, family medicine) or specialties that are commonly portrayed in popular culture (surgery, emergency medicine, etc.). Therefore, radiation oncology educators must work to ensure that the specialty is represented in their institution's core curriculum. In one US needs assessment for radiation oncology education, only 30% of respondents reported receiving a lecture in their medical school on radiation oncology, and 1% reported a mandatory radiation oncology educational experience.[45] A survey of students, primary care providers, and radiation oncology attendings at seven US medical schools demonstrated persistent misconceptions regarding radiation oncology.[97] For example, 23% of fourth year medical students and 19% of primary care providers responded that radiation oncologists "push a button to deliver RT every day," indicating a lack of knowledge regarding the daily clinical duties of a radiation oncologist. Similarly, in a survey at two US medical schools, medical students reported increasing comfort regarding their knowledge of medical oncology, surgical oncology, and hospice/palliative care, but not radiation oncology or survivorship care.[69] A survey of Canadian medical schools demonstrates similar deficiencies in radiation oncology education with 17% of students reporting no radiation oncology training, a majority reporting ≤2 hours of radiation oncology teaching, and 19% reporting they were deterred from considering radiation oncology as a career choice because of lack of knowledge about the specialty.[158] Combined, these data indicate that medical students are not being adequately exposed to clinical aspects of radiation oncology during their core medical school curriculum and are uncomfortable with their radiation oncology knowledge. This deficiency may lead to potential negative consequences. First, students who may otherwise choose radiation oncology as their specialty are not being exposed early and in enough depth in medical school to consider pursuing the specialty. Second, for the majority of students who pursue specialties other than radiation oncology, lack of a basic understanding of the specialty may negatively impact future patient care, including recognizing the need for a radiation oncology consultation or toxicities commonly caused by radiation.

Radiation Oncology Education for All Medical Students

Multiple efforts to develop radiation oncology educational experiences for the general UGME curriculum are reported.[158–171] General exposure to radiation oncology can be achieved through development of a preclinical oncology interest group[172] or through tumor board shadowing experience.[171]

Hirsch et al.[47,163,165] at Boston University developed a 1.5-hour didactic lecture on radiation oncology during the radiology clerkship. All students at their institution received the lecture. A pre- and postclerkship multiple-choice exam was administered to assess objective knowledge improvement. The average exam score increased, most significantly on the radiation oncology scores (56.5% to 71.8% correct, $P < .001$), demonstrating that a single lecture can have a significant impact on knowledge of radiation oncology. The same group has developed the Oncology Education Initiative for preclinical students that includes a radiation oncologist-led oncology education block for second year medical students.[173] Students rate the oncology block favorably and specifically report that the oncology block "was effective in contributing to [their] overall medical education."

The group at Thomas Jefferson University has taken a different approach offering an optional 3-week radiation oncology elective during the third year surgery clerkship.[166,168] Overall objective test scores improved after the rotation (64% to 82%) and within the subdomains of clinical (63% to 79%), biology (70% to 77%), and physics (62% to 88%) knowledge (all values $P < .001$).[166] On a follow-up survey, an average of 1.5 years after completion of the elective, improvements in knowledge persisted, with some decay seen for clinical and physics knowledge. Students felt that the elective helped them to understand when to consult a radiation oncologist, identify emergent situations where radiation is needed, and how to take care of patients with cancer, among other benefits.[168]

At the University of British Columbia, other approaches have been used to increase medical student exposure to radiation oncology. During the third year surgery clerkship rotation, only 10% to 15% of medical students partake in radiation oncology electives. As a result, upwards of 85% to 90% of graduating medical students receive no clinical exposure to radiation oncology. A targeted needs assessment of learners identified that, relative to other areas of clinical training, medical students felt unprepared to take care of cancer patients and that supplemental online resources were needed.[174] Based on the six-step method for curriculum development,[62] Ingledew and colleagues developed and implemented

a series of online modules, supported by virtual patient vignettes and educational whiteboard videos to provide basic oncology instruction to medical students. User satisfaction surveys demonstrated that medical students completing the modules feel more prepared to deal with oncology in clinical scenarios.[175] The online modules are now being examined for impact on knowledge. The online materials are being utilized throughout Canada and in selected universities in the United States and elsewhere. New modules are being added to meet the objectives of the Canadian Oncology Education Goal and Objectives for medical students.[176]

The aforementioned programs represent methods by which a radiation oncology educator can include a radiation oncology educational experience in their school's core curriculum. Other institutions worldwide report strategies to include radiation oncology in the medical school curriculum.[167,169,177] Radiation oncology primers are available to supplement a course or lecture.[3] Oncology curricula for medical schools have also been proposed that include radiotherapy.[164,176] The primary challenge to implementing radiation oncology education within the core curriculum of a medical school is resource scarcity, in particular student time. Thus, it is critical that the radiation oncology educator utilize the methods discussed above to ensure successful implementation.

Education for Students Pursuing a Career in Radiation Oncology

Medical students interested in pursuing a career in radiation oncology represent a different group of learners than the general medical student population. Prior to their first formal rotation in a radiation oncology department, the majority of US medical students spend time in a radiation oncology department shadowing physicians (69%), work in a radiation oncology department conducting research (clinical, translational, or basic science) (60%), or had a lecture on radiation oncology during the first or second year of medical school (30%). Only 26% report no prior radiation oncology clinical or research experience.[45] However, 23% of fourth year medical students who have not completed a rotation in radiation oncology still believe that radiation oncologists push a button every day to deliver radiation.[97] Thus, the radiation oncology clerkship is a critical educational experience for students considering radiation oncology as a specialty choice to ensure they understand what their clinical activities and professional responsibilities will entail once they complete residency training. Additionally, the clerkship likely represents the student's first significant formal radiation oncology educational experience and is thus the beginning of their radiation

oncology training.

The traditional radiation oncology clerkship in the United States and Canada employs the apprenticeship model. Students spend time working with attending and resident physicians in the clinic observing daily clinical activities including consultations, simulations, treatment planning, contouring, plan review and approval, management of on-treatment patients, and follow-up visits to manage acute and late toxicities. Students report opportunities to participate in clinical care including performing an oncologic history and physical independently without resident or faculty supervision (90%), write or dictate a consult (73%), contour at a planning station for a clinical case (78%), participate in a brachytherapy case (60%), participate in a stereotactic radiosurgery case (57%), participate in a stereotactic body radiation therapy (SBRT) case (49%), and review port films (52%).[45] However, merely participating in these clinical experiences does not mean the medical student is learning the basic background knowledge associated with the experience. For example, participating in a plan review of a base of tongue squamous cell carcinoma being treated with intensity-modulated radiation therapy (IMRT) does not mean the student learns the clinical, radiobiologic, and physics aspects of external beam radiation treatment. Students are encouraged to read primary and secondary literature outside of clinic, but as discussed previously, students will have different learning styles,[124] and thus educational strategies other than clinical observation and outside reading should be incorporated into the clerkship experience.

Students may attend resident-level didactics (clinical, physics, radiation biology) and shadow physicians at tumor boards, but the majority of clerkships did not include formal didactics at the medical student training level.[45,98] This apprenticeship model is not unique to radiation oncology and is frequently used in other subspecialty clerkships where there are limited students at any one time.

These clerkships are also sometimes referred to as “audition rotations” where one of the student’s goals for the clerkship is to secure a competitive residency position. There are multiple critiques of the practice of audition rotations. First, audition rotations potentially waste valuable educational time during the final year of medical school when the student could be broadening their medical education before focusing on radiation oncology. Second, audition rotations outside of the geographic location where the medical student resides require the student to have sufficient funds to travel and pay for room and board during the elective clerkship. Therefore, wealthier students may be more likely to take audition rotations. Because in the US economic status correlates with race,

selecting students for residency positions based on performance during an audition rotation may discriminate against minority groups. Lastly, audition rotations may be difficult to arrange for students with significant home and family responsibilities, thus discriminated against married students or students with children. Residency training programs must be cognizant of the pitfalls of using audition rotations to select future residents and, rather, should holistically evaluate each applicant's medical school performance, letters of recommendation, and personal statement for potential fit with the training program.[178]

In a national radiation oncology clerkship needs assessment in the United States, students reported giving a departmental talk on a topic of their choice at 87% of clerkship experiences, whereas 72% of clerkships had no medical student lectures, and 52% of clerkships had no formal lecture, case discussion, or hands-on didactic session at the medical student training level.[98] This disparity suggests that clerkships may place an emphasis on the audition aspect of the experience rather than the educational experience.

Based on these data demonstrating a lack of structured didactics for the medical student clerkship, the Radiation Oncology Education Collaborative Study Group (ROECSG) developed a structured, didactic curriculum for the radiation oncology medical student clerkship. Using the six-step model for curriculum development,[62] a series of targeted needs assessments were conducted to determine the target learners' (medical students) needs and preferred learning methods (Fig. 103.13).[45,98] Based on these data, a structured, didactic curriculum was developed incorporating three lectures (Introduction to Radiation Oncology, Radiation Biology and Physics, and Simulations/Radiation Emergencies) and a hands-on treatment planning workshop.[179] The needs assessment demonstrated that students want the opportunity to give a lecture to the department (perhaps for the purposes of auditioning for residency) and to give formal case presentations. These activities were not removed from the clerkship but rather supplemented by the addition of the formalized lectures and a treatment planning workshop. The curriculum was piloted at 2 institutions in 2012[180] and subsequently expanded to 11 academic medical centers in 2013.[82,181] 88 students completed the curriculum in 2013 and subjective evaluation of the curriculum was positive. All lectures and the treatment planning workshop were rated as "quite" to "extremely" useful. Students rated the curriculum as helping them to better understand radiation oncology as a specialty, increase their comfort with their specialty decision, and help the

transition to radiation oncology residency.[82] The curriculum subsequently expanded to 22 academic medical centers with 146 students completing it in 2017. Mean objective multiple-choice question test scores pre- and postcurriculum were 63% and 80%, respectively ($P < .01$). Postscores for students rotating de novo at ROECSG institutions ($n = 30$) were higher compared with prescores for students with 1 or more prior rotations at non-ROECSG institutions ($n = 55$) (77% vs. 69%, $P = .01$).[181a] This exploratory analysis showing students completing a clerkship at ROECSG institutions perform objectively better when compared with students who completed clerkships at non-ROECSG institutions supports a structured didactic curriculum as a standard component of a radiation oncology clerkship.

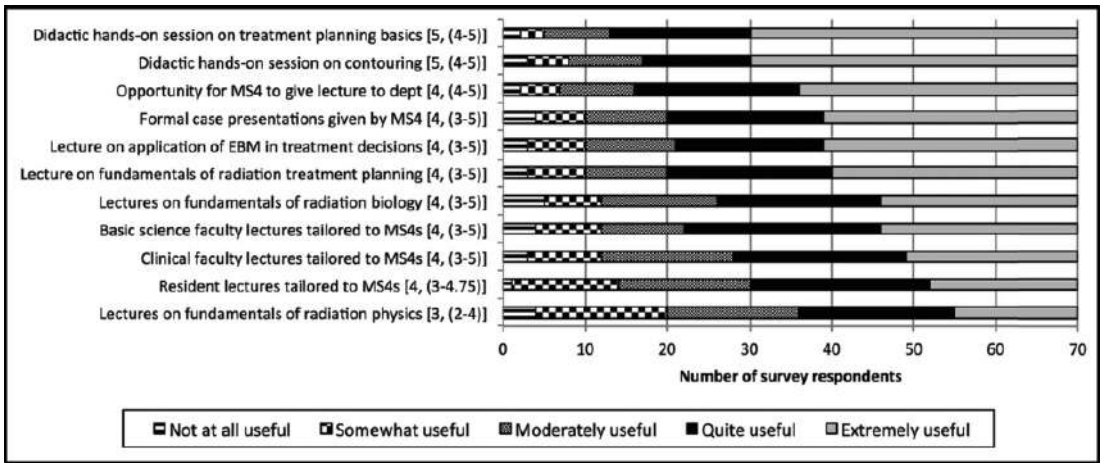

FIGURE 103.13. Survey respondent perspectives on the utility of specific curricular components of an ideal radiation oncology clerkship: median Likert scale (interquartile range). Based on the needs assessment indicating students desired hands-on training for contouring,[45] an additional module was developed that teaches fundamental concepts of atlas-based contouring of the prostate fossa.[182] Using a treatment planning station, students first contoured the prostate fossa on a standardized CT scan with no prior instruction. Utilizing Kolb's experiential learning model[26] (Fig. 103.3), this represents the concrete experience. The student then receives a lecture on the CT anatomy of the prostate fossa and how to follow atlas-based instructions for contouring the target volume (reflective observation and abstract conceptualization). The student then repeats the contouring exercise using the

atlas and their new knowledge from the lecture (active experimentation and concrete experience). Finally, the student turns on a “gold standard” contour as determined by experts in genitourinary radiation oncology (reflective observation). Students reported subjective improvements in comfort contouring a prostate fossa, ability to find references for contouring, knowledge of CT prostate/pelvis anatomy, and ability to use contouring software tools. In addition, objective analysis of contour accuracy when compared to the gold standard showed significant improvements after the educational intervention.[2]

Formal UGME curriculum development remains nascent in radiation oncology. Implementation of a formal didactic curriculum and hands-on planning and contouring workshops represent methods by which the UGME radiation oncology educator can ensure medical students are making the best career choice while enhancing the students’ clinical knowledge to ease the transition to residency training.

Graduate Medical Education in Radiation Oncology

Clinical training in radiation oncology primarily occurs during GME after graduation from medical school. Many countries including the United States,[4] Canada,[121] Australia, New Zealand,[16] and others[15,19–21] train radiation oncologists and medical oncologists as distinct medical specialties. Trainees in these countries complete medical school and a variable amount of nonradiation oncology clinical training followed by 3 to 4 years of full-time radiation oncology clinical training. A small minority of trainees in the United States complete postgraduate fellowships,[183] whereas in Canada, a majority of trainees pursue a postgraduate fellowship.[184] In the United States, these fellowships are not accredited by the ACGME. This discrepancy in fellowship training is likely due to a restricted job market in Canada and associated difficulty securing employment after residency.[184] In contrast to the radiation oncology–specific training system, clinical oncology trainees in the United Kingdom[185] and other countries train as nonsurgical oncologists and learn to manage both systemic chemotherapy and radiation therapy.

Although certain disease sites such as pediatric malignancies and treatment techniques such as interstitial brachytherapy have relatively few numbers of cases and are nonuniformly geographically distributed, trainees in the United States continue to be certified to treat all disease sites. This raises a dilemma of whether these trainees are adequately prepared to treat rare diseases or use specialized treatment modalities. US residency program directors address this

problem by allowing residents to train at other centers that see higher volumes of rare cases or use specialized treatment procedures. Although in an ideal training environment all trainees would see high volumes of rare cases or specialized procedures, analysis of radiation oncology training programs suggests that subspecialty certification is unlikely in radiation oncology.[186] Thus, programs must continue to develop novel training methods including simulation-based education and case-based education to provide sufficient training for rare cases and techniques. By ensuring trainees are competent in the clinical and technical fundamentals of radiation oncology as applied to any disease site or therapeutic technique, training programs will ensure that their graduates are competent to treat rare tumors (e.g., pediatric malignancies) or use specialized techniques (e.g., interstitial brachytherapy) when required.

Regardless of whether trainees focus solely on radiation oncology or learn radiation and medical oncology as in the UK system, during residency, trainees must become competent in all aspects of clinical radiation oncology including obtaining a focused radiation oncology history and physical, the treatment decision process, simulation, contouring, treatment planning, plan review, and treatment and toxicity management. Residents must learn fundamental scientific knowledge of radiation biology and physics, research methods, and biostatistics. Residents in the United States are assessed semiannually by their department's clinical competency committee using the ACGME Radiation Oncology Milestones,[120] which, as described previously, are divided into the ACGME core competencies including Patient Care, Medical Knowledge, Systems-Based Practice, Practice-Based Learning and Improvement, Professionalism, and Interpersonal and Communication Skills. In Canada, an almost analogous set of core competencies is represented by the CanMEDS framework and include Medical Expert, Communicator, Collaborator, Scholar, Leader, and Health Advocate.[5] Finally, residents must be responsible to themselves, their chosen profession, society, and the patient. Based on these complementary learning goals, a conceptual framework of GME radiation oncology education is presented (Fig. 103.14). Educational scholarship related to the clinical care path outlined in this conceptual framework is discussed henceforth.

History and Physical

Trainees entering radiation oncology GME should be competent in obtaining a focused history and physical. However, obtaining a history and physical specific for radiation oncology requires further development and refinement of skills

developed during medical school and internship. A trainee must learn how to obtain information in the history of the patient that is relevant to radiation oncology including the complete chronologic oncology history, family cancer history, past radiation and systemic therapy, history of connective tissue disease or other contraindications for radiation, and other radiation oncology–specific history items. Trainees acquire this skill through clinical observation of attending physicians, feedback on the trainee's case presentations and clinical notes, and lectures on specific disease sites that include a review of relevant history information.

Physical examination is also a skill that is developed during the undergraduate medical training process. Similar to obtaining a history, obtaining a radiation oncology physical exam requires additional skill refinement. For example, trainees must learn to carefully examine the supraclavicular fossa in a patient with cervical cancer and periaortic lymphadenopathy on imaging, whereas patients with anal cancer must be assessed for inguinal lymphadenopathy, and patients with nasopharyngeal squamous cell carcinoma should have a thorough cranial nerve exam. Similar to the patient history, these skills are most commonly taught through faculty clinical observation and lecture format.

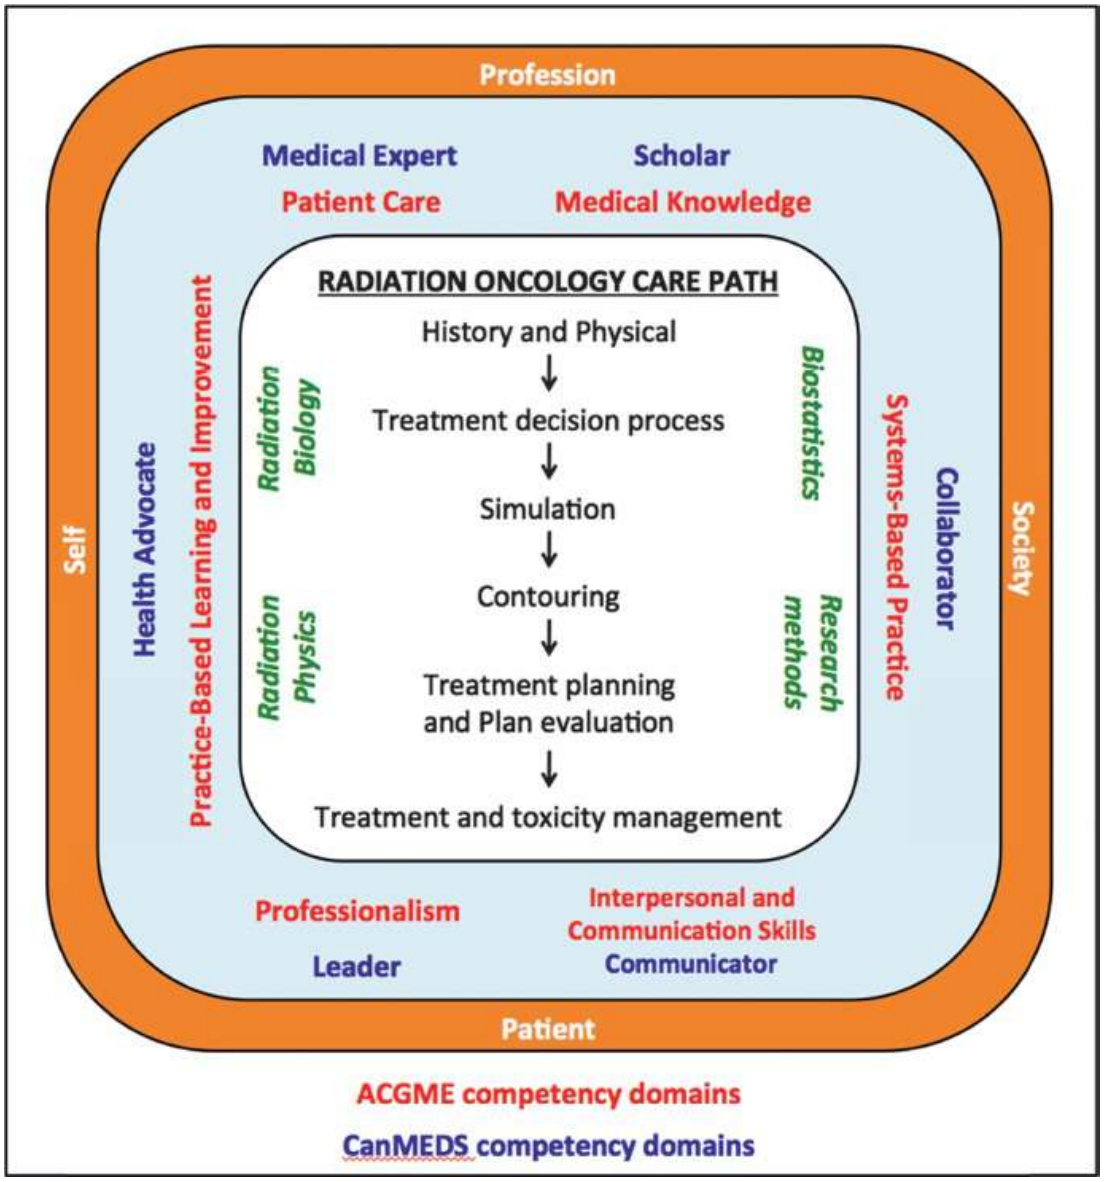

FIGURE 103.14. Conceptual framework for radiation oncology clinical education structured on learner obligations, Accreditation Council for Graduate Medical Education (ACGME) and Canadian Medical Education Directives for Specialists (CanMEDS) core competencies, fundamental knowledge of physics/radiation biology and research methodology knowledge, and the patient's clinical care path.

To perform an appropriate physical exam, anatomic knowledge relevant to oncology is critical.[187] Time spent learning about anatomy is heavily frontloaded in the UGME curriculum with minimal time allotted during residency training, whereas the need for applied anatomy knowledge increases drastically at the start of residency training (Fig. 103.15). To address this need for applied anatomy knowledge, Duke University developed an oncoanatomy course for resident trainees that included a 1-hour didactic session followed by a 1-hour

session in the gross anatomy lab with cadaveric prosections. Implementation of this course demonstrated a significant improvement in objective anatomic knowledge, and residents rated the course as highly effective.[188]

Communication skills are also necessary during the history and physical process. The University of Pennsylvania developed a novel OSCE with the goal of improving resident skills with regard to breaking bad news.[24] Residents were presented with two case scenarios and given the opportunity to work through the cases with standardized patients. Residents worked through an initial case and then underwent an evaluation by and feedback from the standardized patient, faculty, and residents themselves using the Kalamazoo Essential Elements Communication Checklist—Adapted.[189,190] The residents then completed a second case scenario. Although there was no difference demonstrated in resident performance between scenarios 1 and 2, barriers to developing strong interpersonal relationships were revealed including perceived lack of empathy, absence of shared decision-making, and use of excessive medical jargon. Resident feedback included the suggestion to allow the resident to review the video recording of the encounter and then repeat the same encounter to try new wording.[24] An OSCE encounter represents a novel method by which radiation oncology trainees can be taught methods to develop strong interpersonal relationships with their patients at the first clinical encounter.

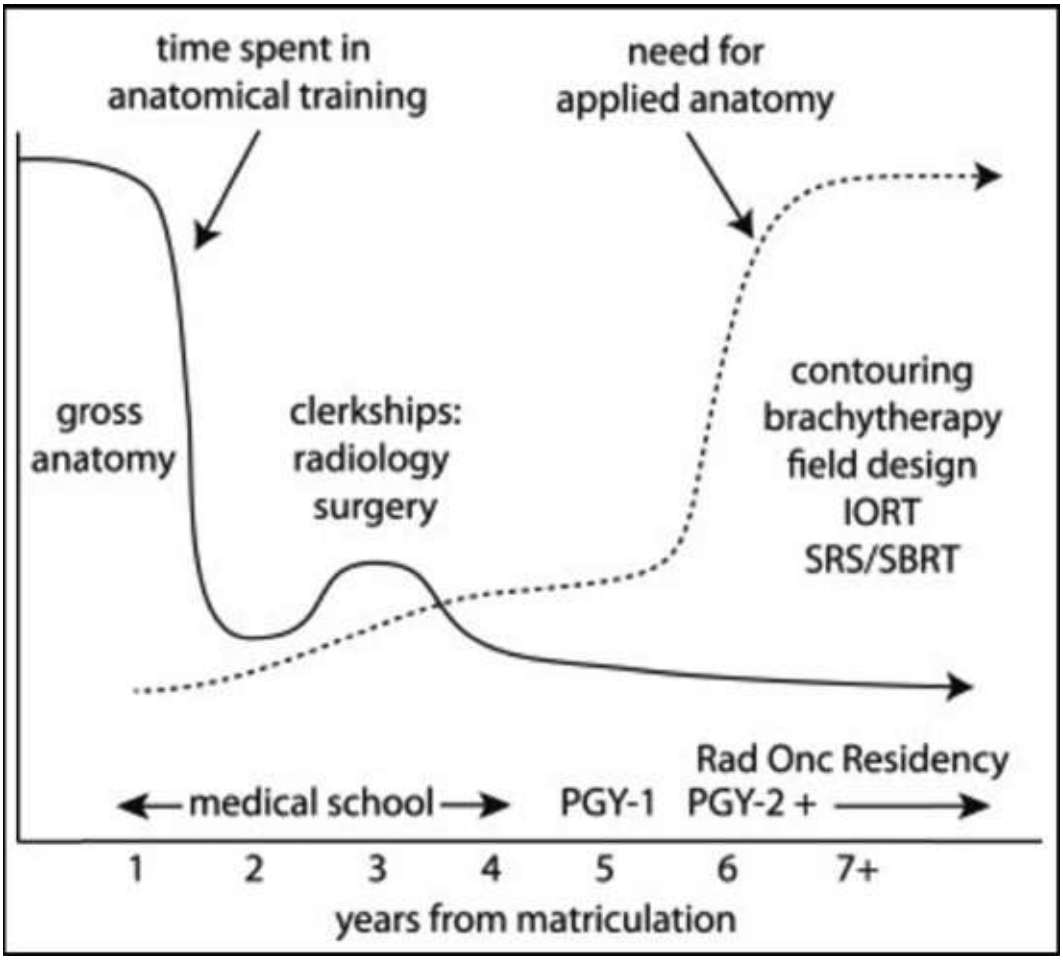

FIGURE 103.15. Schematic of time spent in anatomic instruction and the need to apply knowledge of anatomy for the radiation oncologist in training. Clinical Decision-Making

Once the trainee obtains a focused radiation oncology history and physical, they must make a treatment decision. Determining a treatment recommendation requires a strong fund of medical knowledge and clinical reasoning skills. Ensuring that graduating trainees obtain the requisite fund of medical knowledge required of a competent radiation oncologist is perhaps the most important role of residency training program. Without knowledge of treatment guidelines and the primary literature supporting those recommendations, a radiation oncology trainee will have difficulty determining the optimal treatment approach for a specific clinical scenario.

Trainees most commonly learn medical knowledge through a variety of methods including readings, lectures, online learning resources, peer teaching, and real-life supervised clinical experiences (personal observations of authors). Other teaching methods such as small group discussions and problem-based learning are less commonly employed and represent novel educational methods that may provide trainees with varying learning styles and additional opportunities to assimilate the material. Outside of radiation oncology, there is a substantive body of literature on clinical decision-making[191–194] with recommendations to clearly define critical thinking objectives in a course or curriculum.[195]

Trainee knowledge and clinical decision-making skills for radiation oncology are unique compared to internal medicine, surgery, or other core specialties. However, the same principles for teaching clinical decision-making in these specialties apply to radiation oncology. The most important clinical decision made by the radiation oncologist is whether or not a patient should receive radiation therapy. The radiation oncologist must evaluate clinical data to determine if radiation therapy is indicated and how best to integrate it with other forms of therapy. However, radiation oncologists also utilize clinical decision-making skills on a daily basis when determining the threshold to order a magnetic resonance imaging (MRI) of the brain in a patient with locally advanced node-positive breast cancer complaining of headaches midway through adjuvant breast radiation, whether a complaint of dysuria during prostate radiation should prompt a urinalysis or if a patient who completed radiation for lung cancer and is complaining of shortness of breath should be started on steroids for possible radiation pneumonitis. Clinical decision-making for radiation oncology trainees is assessed in the United States with formative methods via the American College of Radiology In-Service Exam.[196] Programs in Canada and the United States use internal assessment methods including case-based skills assessment (colloquially known as “mock oral boards”), case presentations, and faculty feedback. Summative assessment in the United States is through the ABR board exams and through the Royal College of Physicians and Surgeons of Canada Radiation Oncology Certifying Exams. Studies evaluating methods to teach clinical decision-making specific to radiation oncology, however, are lacking.

Simulation

Subsequent to making a treatment recommendation, the vast majority of

radiation oncology patients undergo a radiation therapy simulation scan (e.g., CT simulation). Literature regarding formal resident education specifically regarding the simulation process is unavailable. Knowledge and skills pertaining to the simulation process are taught via lectures, clinical experience and observation, and informal peer teaching. At the UGME level, a formal lecture regarding the simulation process is included in a structured, didactic curriculum.[82] One study evaluated the efficacy of an educational program for residents on the use of intravenous contrast media as a component of CT simulation.[197] Resident knowledge regarding use of IV contrast improved with the intervention, although this effect was not sustained 1 year afterward. Additionally, given the low incidence of IV contrast reactions, the study was unable to demonstrate a clinical effect of the educational intervention. Given the critical nature of the simulation process to the quality of effectiveness of radiation delivery, radiation oncology educators must consider how this is taught and assessed in their local training program.

Contouring

After a patient undergoes simulation, a trainee must be able to accurately and efficiently contour target volumes and adjacent critical structures. “Imaging literacy” for radiation oncologists likely requires collaboration from specialists outside of radiation oncology alone.[198] An imaging literacy curriculum was developed using an international two-round Delphi process with four thematic groups of key competencies emerging: (a) imaging fundamentals, (b) clinical application, (c) clinical management, and (d) professional practice.[199] Perhaps the most pertinent competency to the specific technical skill of “contouring” is “Delineate on any imaging modality the radiation therapy target and organs at risk in all cancer disease sites and identify targets in 2D, 3D, and 4D image guidance modalities.”[199] Radiation oncology educators should review this proposed curriculum to determine where their local program may be deficient.

Multiple educational methods are reported to improve radiologic interpretation skills and contouring skills. Trainee daily clinical activities should include contouring to allow residents to gain a hands-on “concrete” experience per the Kolb experiential learning model.[26] If a program requires trainees to spend significant amounts of time seeing patients in clinic while attending physicians or dosimetrists complete contouring duties, the trainees may graduate deficient in this skill.

To address this curriculum gap, based on a pilot study at a single

institution,[200] a two-and-a-half-day National Anatomy and Radiology Contouring Boot Camp was implemented in Canada with significant improvements in knowledge assessment scores and Dice similarity coefficients comparing contour accuracy.[18] In the United States, Memorial Sloan Kettering Cancer Center developed a contouring training module for head and neck cancer demonstrating improvements in contouring accuracy, although there were still significant deviations in contours indicating a need for repeated exposure and possibly refinement of the curriculum.[201] This is similar to the prostate fossa contouring module developed for medical students.[2] Other contouring educational interventions are also published.[202–205]

Web-based educational methods are also under development. EduCase[206] (access with subscription at EduCase.com) was demonstrated to have a high usability as assessed by resident trainees for head and neck nodal station educational modules.[207] In a randomized study, the use of eContour[208] (access free with registration at eContour.org) compared with any other available contouring materials improved objective assessment of target delineation of the high-risk volume and contralateral parotid gland.[46] Of note, the high-risk volume showed consistently high variability in the Memorial Sloan Kettering study[201] suggesting that the eContour educational format might further enhance the learning experience. Residents using eContour demonstrated greater knowledge of contour delineation and radiographic anatomy on an objective knowledge assessment, and the mean usability score was high.[46]

Treatment Planning and Treatment Plan Evaluation

Subsequent to accurately delineating contours, a radiation oncology trainee must become proficient in treatment planning and treatment plan evaluation. Working collaboratively with dosimetrists and physicists, the trainee must learn to create a treatment plan, and evaluate treatment plan quality, specifically, to determine when it is not meeting appropriate dosimetric constraints or adequately covering the target volume. Although the treatment plan will nearly always be created by the dosimetrist or physicist in clinical practice, an understanding of how the plan is created, along with the limitations and uncertainties involved, will be exceptionally valuable to the resident when he/she enters clinical practice. In the United States, the current ACGME program requirements state that the educational program must include “regularly scheduled didactic sessions” with “instruction in medical physics that includes practical demonstrations of … the use of state-of-the-art treatment planning systems.”[4] In the ACGME Radiation

Oncology Milestones, each “patient care” milestone includes a competency stating that the resident “critically evaluates treatment plan options.”[120] Similarly, the Royal College of Radiologists in the United Kingdom calls for “comprehensive teaching of radiotherapy planning … including simulation, virtual simulation, three-dimensional conformal planning, image fusion and IMRT, Volumetric Modulated Arc Therapy (VMAT) and image-guided radiation therapy (IGRT),”[185] and similar content is found in the Royal College of Physicians and Surgeons of Canada Radiation Oncology Objectives of training documents.[121]

Currently, treatment planning and treatment plan evaluation concepts are taught in the course of regular clinical duties, didactic lectures,[90] and peer-to-peer teaching. The ASTRO physics curriculum developed by the ASTRO Physics Core Curriculum Subcommittee recommends 7 hours dedicated to “Photon beam characteristics and dosimetry,” 2 hours dedicated to “Electron beam characteristics and dosimetry,” 3 hours dedicated to “Intensity modulated radiation therapy,” and 1 hour dedicated to “Prescribing, reporting, and evaluating radiation therapy treatment plans.”[90] Training programs may include a treatment planning rotation for their residents, but given the competing demands for resident time, most programs do not offer a formal dosimetry rotation.[105] In the recent ARRO chief resident survey, only two-thirds of graduating residents reported receiving adequate experience in treatment planning.[22]

Given the critical nature of radiation treatment plan evaluation for all modalities (three-dimensional conformal radiation, intensity-modulated radiation treatment, SBRT, radiosurgery, etc.), there are limited reports of formal educational methods to teach treatment plan evaluation. A series of self-directed modules teaching fundamentals of dosimetry and plan evaluation including AP/PA spine, three-field breast, and intensity-modulated radiation were developed at the University of Chicago.[179] These modules provide an opportunity for “active experimentation” within Kolb’s experiential learning model.[26] Completion of the modules by the resident physicians was associated with improved resident comfort with AP/PA treatment planning, three-field breast treatment planning, and IMRT planning. Resident understanding of dosimetry concepts including dose grid, beam energy selection, calculation point, iterations, segments, optimization, and ring structure was also significantly improved.[209] Additional structured educational methods to teach and assess competence with treatment planning and dosimetry are needed to

ensure that trainees are graduating with the skills necessary to adequately evaluate and constructively critique treatment plans in independent practice. The ASTRO physics curriculum provides an outline for additional dosimetry module development.[90]

Treatment and Toxicity Management

Once a patient begins radiation treatment, the trainee must be proficient in evaluating portal images as well as volumetric image data and images from other modalities for image-guided radiation, adjusting treatment plans as needed, managing acute toxicity of treatment, and coordinating care with other specialties including medical oncology and surgical specialties. Similar to how other steps in the clinical care path are taught, treatment and toxicity management is primarily taught through a combination of clinical experience, lectures, and reading. Investigations of novel educational methods to teach skills necessary for treatment and toxicity management are limited. A review of methods by which to assess residents' clinical skills proposes the use of OSCEs, standardized patients, and patient management problems in addition to the standard assessment methods of "ward" evaluation, multiple-choice question tests, and oral examinations.[210] An OSCE to teach residents communication skills was developed at the University of Pennsylvania.[24] Two cases representing treatment or toxicity management were developed including telling a patient 2 months out from radiation treatment that there is a tumor recurrence and telling the family of an 8-year-old patient that the proton machine is out of commission and the remainder of treatment will be IMRT. Residents received formative feedback from standardized patients and faculty observers. Educational strategies such as OSCEs and standardized patients represent novel and effective methods by which to teach radiation oncology trainees about management of patients receiving radiation and management of acute and late toxicity, which is essential as toxicities from modern treatments become less common. Further development of teaching material for this component of the care path is needed.

Medical Physics

Medical physics is a key component of training in radiation oncology with the ACGME,[4] RCPSC,[121] and Royal College of Radiologists (RCR)[185] including medical physics as a required training. According to a recent survey of residency program directors in the United States, 100% of residency programs provide a didactic course in radiation physics,[211] and >85% of US residents report

adequate formal courses in radiation biology and physics.[22] Didactic lectures represent one of many educational strategies to teach the concepts and knowledge required of a practicing radiation oncologist. Medical physics training for radiation oncology residents in the United States is heterogeneous with a median of 42 lectures but a range from 10 to 90 per year and only approximately one-third of programs reporting physics rotations.[105] Additional educational strategies should be considered to allow optimal adult learning to occur. Providing an opportunity for hands-on experiences allows for learning in the context of Kolb's experiential learning cycle.[26] Didactic lectures alone cannot accomplish this.

The ASTRO Physics Core Curriculum Subcommittee developed a comprehensive recommended curriculum for medical physics education consisting of 56 hours of didactic sessions.[90] The curriculum also provides recommended references, a set of suggested practical clinical radiation oncology physics modules, and a set of suggested practical modules for radiation therapy treatment planning. The group recommends that training programs ensure residents complete the course at least twice during their training. A detailed physics curriculum for proton therapy is also proposed.[212]

A novel medical physics educational strategy is used at one training program in the UK where radiation oncology registrars (the equivalent of residents in the United States) spend 6 months completing a medical physics rotation.[213] These trainees continue to spend 1 day per week in clinic to maintain their clinical skills. The goal of the program is that by the end of the 6-month block, the trainee is competent in planning any case with the exception of total-body irradiation. This novel educational strategy utilizing a combination of continued clinical training and hands-on medical physics training could be adapted at other training programs. Importantly, the emphasis on advanced dosimetry over basic physical interactions has become more relevant to clinical practice in the setting of robust modern treatment planning systems.

Radiation Biology

Similar to radiation physics, radiation biology is a key component of training in radiation oncology with the ACGME,[4] RCPSC,[121] and RCR[185] requiring a fundamental understanding of radiobiologic concepts. All US radiation oncology training programs report formal radiation biology courses[211] with residents reporting sufficient training in radiation biology.[22] A survey of US and Canadian radiation biology educators indicates that many are not completely familiar with

relevant radiation biology materials, some do not receive adequate departmental support, and more than 50% are not routinely provided with resident radiation biology performance on the in-training exam.[106] Many residents use the ASTRO radiation biology study guide as a learning resource.[214] In addition, the American College of Radiology in-training exam can be used as a teaching and assessment tool.[215] In recent years, incorporation of mechanisms of systemic therapies, some of which are delivered concurrent with radiation therapy, represents information that is more applicable to daily practice.

Continuing Medical Education in Radiation Oncology

For the practicing radiation oncologist, lifelong learning to ensure clinical knowledge and skills are up to date is critical. Perhaps even more so than some other areas of medicine, radiation oncology is constantly evolving due to the development of new technologies and treatment techniques and new treatment paradigms for cancer. The continued maintenance and acquisition of skills in radiation oncology is a complex process, and the implementation of new techniques and maintenance of competency can be challenging.[57] Evidence supporting the efficacy of CME for the maintenance of competency is mixed. Early studies suggested CME has a positive impact on physician performance and patient outcomes.[216] More recent studies failed to demonstrate a significant improvement in patient outcomes for physicians engaging in ongoing maintenance of competency activities.[217,218] A series of Cochrane literature reviews suggest that the impacts of CME may be linked with the type of CME activity, with isolated didactic lectures less effective as compared to interactive sessions, well-planned educational meetings, and quality improvement activities.[219–221] Within radiation oncology, the role for maintenance of certification programs administered by certification organizations remains controversial.[222] However, maintaining an up-to-date fund of clinical knowledge and ensuring clinical skills remain current are characteristics of any good physician. In addition, effective education of practicing physicians to drive a change in practice patterns to high-quality and high-value care is needed.[87,88] Thus, programs that educate practicing radiation oncologists are valuable, regardless of whether they are mandated by certifying organizations.

To encourage practicing radiation oncologists to engage in lifelong learning, certifying organizations such as the ABR and RCPSC has established maintenance of certification standards. In the United States, the ABR maintenance of certification process includes four parts: (a) Professional

Standing, (b) Lifelong Learning and Self-Assessment, (c) Cognitive Expertise, and (d) Practice Quality Improvement.[223] Professional Standing requires a valid, unrestricted licensure in all states of practice. CME applies most directly to Lifelong Learning and Self-Assessment and Cognitive Expertise components of the ABR's maintenance of certification process. Lifelong Learning and Self-Assessment requirements include completing 75 American Medical Association Category 1 CME credits every 3 years. Twenty-five of these credits must be "Self-Assessment" CME (SA-CME) credits. The general CME credits can be obtained by attending local tumor boards, CME-accredited resident lectures, or any other AMA Category 1 accredited activity. The SA-CME credits can be completed at approved lectures or through journal CME offerings. A by-product of the SA-CME requirement is that residency training programs are now certifying resident didactics for SA-CME to encourage faculty to attend the resident lectures.[224] Cognitive expertise was traditionally assessed by the ABR with a multiple-choice question recertification exam every 10 years. Because radiation oncology does not have any ACGME accredited subspecialty fellowships, the exam covered all disease sites. In 2015, the ABR began to allow practicing physicians to select specific disease sites for the recertification exam to satisfy cognitive expertise, but this ended in 2017.[225] The ABR is currently transitioning to an ongoing longitudinal assessment that will replace the 10-year recertification exam. This will include weekly multiple-choice questions that aim to test "walking around knowledge" in response to the efficacy demonstrated by the Maintenance of Certification in Anesthesiology (MOCA) Program referred to as the MOCA Minute.[226] Finally, to satisfy the requirement for practice and quality improvement (PQI), a practice quality improvement project or other participatory quality improvement activity must be completed every 3 years.

CME requirements in the RCPSC construct are similar to the ABR lifelong learning and self-assessment. CME in Canada represents the culmination of the Competence by Design competence continuum.[227] In contrast to the United States (until recently), in Canada, there is no recertification exam. The RCPSC maintenance of certification program requires radiation oncologists to obtain 400 credits and a minimum of 25 credits in each maintenance of competency program section per 5-year cycle. RCPSC maintenance of competency credits fall into one of three categories/program sections including (a) group learning, (b) self-learning, and (c) assessment.[228] With a transition to Competence by Design (Fig. 103.12), the RCPSC maintenance of competency system will likely undergo significant changes. As such, the maintenance of competency will need

to allow for continuous ongoing demonstration of competency with ongoing feedback to facilitate learning in practice.[229]

CME activities cover a broad range of educational strategies including didactic learning, interactive sessions, and practice audit and feedback. These activities often mirror those discussed previously for UGME and GME education. Some of the most commonly recognized CME activities include didactic learning activities at educational meetings (e.g., American Society for Radiation Oncology [ASTRO], European Society for Radiotherapy and Oncology [ESTRO], and Canadian Association of Radiation Oncology [CARO] annual society meetings). A variety of interactive activities including large contouring workshops,[230] provided through national societies, are also used in CME. Many national society meetings include seminars and workshops and allow for the discussion of or dissemination of new techniques. In Europe, the ESTRO School has developed the Fellowship in Anatomic Delineation and Contouring (FALCON), which incorporates web-based contouring into their educational programs.[230] CME can also be delivered in a small group learning environment such as weekly tumor boards, simulation-based education, or local grand rounds and lectures.[231,232] Despite the frequency with which such activities are offered, there is a relative paucity of scholarship. Very few publications have robust program evaluation from these CME activities, and the majority evaluate user satisfaction[232] as opposed to change in knowledge or behavior.

Although historically CME was designed to deliver educational content to individual physicians, a primary goal of CME is now systems-based or quality improvement.[233] Quality improvement and “audit with feedback” CME programs are becoming more common.[220] Shakespeare et al.[234] examined the effects of audit with feedback for practicing radiation oncologist’s changes in behavior. Their audit included an assessment of patient charting and radiation plans. Radiation oncologists were provided individualized feedback. The audit with feedback resulted in improvements in some aspects of patient charting and documentation and radiation planning. These effects were retained through time and demonstrated that audit with feedback may be a useful CME exercise. As peer-review and quality assurance programs are developed at radiation oncology centers,[235,236] careful attention should be paid to not only improve consistency and quality in radiation plans[237] but also design programs that allow for continuous practice improvement. By educating individual physicians, CME can drive organizational change and overall improvements in health care delivery.

Additionally, when deficiencies are noted through the process of peer-review, individual or group educational programs may be required, and review of medical education principles previously discussed may be helpful.

In order to develop CME activities, similar to other areas of radiation oncology education, guiding principles and frameworks can help to provide valuable perspective. CME activities include a broad range of educational interventions. These can include, among others, didactic programs (e.g., lectures and journal clubs with question and answer session), interactive instruction (e.g., interactive case discussion, group role-play), audit and feedback, and academic detailing (i.e., individual education delivered by a trained professional to education on evidence-based techniques). Harden describes six criteria for effective CME: (a) convenience, (b) relevance, (c) individualization, (d) self-assessment, (e) independent learning, and (f) systematic.[238] The development of effective curriculum for CME programs can be based on the six-step model[62] and enhanced by Davis et al.'s[239] description of the seven characteristics of effective CME programs including (a) needs assessment, (b) focused initiative, (c) interactive educational programs, (d) multiple educational strategies, (e) multiple sessions, (f) time for feedback and practice, and (g) outcome evaluation. The application of established frameworks to any CME activity or program should allow for robust development, implementation, and evaluation.

Although there is a significant body of literature examining the best practices in development, implementation, and outcomes of CME activities in a variety of other areas in medicine, radiation oncology remains ripe for educational scholarship. Work can be done to improve existing CME curricula and to develop novel CME educational strategies. Potential areas for scholarship include the application of established educational frameworks to CME development and evaluation outcomes linked to changes in knowledge, behavior, and clinical outcomes.

Areas for Further Scholarship in Radiation Oncology Education

Radiation oncology education at the UGME, GME, and CME levels continues to evolve. There remain a myriad of scholarship opportunities to rationally and methodically improve radiation oncology education. Examples include further developing and validating competency frameworks such as the ACGME Milestones[120] and CanMEDS Competence by Design.[5,122] Development of EPAs also represents an opportunity to move radiation oncology forward.[240] Looking beyond the medical profession, there is ample opportunity to develop

interprofessional educational activities at all training levels.[241,242]

Simulation-based medical education is no longer a new concept[243] and is being rapidly adopted by other specialties. Within radiation oncology, there is ample evidence that increasing experience can improve outcomes for brachytherapy[244] and head and neck treatment, particularly in the IMRT era.[80] Reports of decreasing case volume for brachytherapy,[86] reports of limited pediatric cases,[186] and reports from graduating residents of inadequate training in intraoperative radiation, brachytherapy, and proton therapy[22] suggest that development of simulation-based education specific to radiation oncology may provide a solution to the dilemma of how to safely train residents and assess competency for case scenarios or procedures that are less common or require high technical skill. Many educational reports within radiation oncology represent simulation-based medical education, even though they are not identified as such. For example, there are multiple reports of contouring training on a standardized case.[2,46,201,202,207,230] This represents simulation-based education because the trainee is working in a simulated environment with no real-world consequences when making an error, though reports in radiation oncology less often self-identify as simulation-based medical education, with the few examples including brachytherapy training,[25] interprofessional team simulation,[245] and preparation for on-call emergencies.[246]

CONCLUSION

Radiation oncology is a unique field within medicine. Although much of the essential cognitive, affective, and psychomotor knowledge acquired during medical school is useful to a radiation oncology trainee, the knowledge and skills required of a competent and compassionate radiation oncologist are unique and iterative. Curricula to teach this radiation oncology knowledge and skill set must be developed in a logical and rational manner to ensure desired goals and objectives of the learning process are achieved. Furthermore, curricula must be continually updated to meet changes in modern radiation oncology. For example, training in radiographic anatomy and treatment plan evaluation is critical in the modern era but often is relegated to the null curriculum in UGME, GME, and CME. Meanwhile, the approach to educational programs must reflect changes in information technology, with the potential to increase simulation-based training over traditional didactic lectures and for longitudinal assessments to replace exams performed once every decade. Dissemination of curricular innovations is

essential to ensure the radiation oncology educational community is aware of the progress and can further build and improve radiation oncology education while ensuring the educator receives appropriate academic recognition. The radiation oncology profession must place value on medical education scholarship to encourage the advancement of the entire discipline.

Radiation oncology educators must critically evaluate the local, national, and international training milieu and consider disruptive innovation to ensure vigorous and active curriculum revision and renewal. Disruptive innovation is defined in the business sense as follows:

> *"Dominant players in most markets focus on sustaining innovations… That makes a market ripe for upstart companies seeking to introduce disruptive innovations… more convenient products or services."*[247]

The concept of disruptive innovation can be applied to radiation oncology education. Current radiation oncology curricula across the globe evolved to satisfy the requirements set forth by accrediting bodies but are not necessarily the most effective and efficient methods for teaching a particular radiation oncology topic or concept. Educational innovations that are demonstrated as effective through rigorous curriculum inquiry, learner assessment, and program evaluation and are disseminated have the potential to disrupt the status quo radiation oncology curriculum on a large scale with the ultimate goal of improving the quality of patient care.

CHAPTER 104

Ethics, Professional Values, and Legal Considerations in Radiation Oncology

Brian D. Kavanagh, Laurel J. Lyckholm, and Jeremy Sugarman

INTRODUCTION

Although progress in medical science has improved the quality and duration of life for some patients with cancer and other serious illnesses, technical expertise alone does not fully account for the upsurge in the societal standing of medical doctors during the past 100 years.[1]

High regard for physicians is contingent on the trust that doctors act unselfishly in a patient's best interests, a role sometimes called moral fiduciary.[2] Essential to this role are medical knowledge and a firm grasp of ethics. Derived from the Greek *ήθος* (*ethos*), meaning *character,* ethics refers to the process of applying values and principles in professional interactions and particularly in medical decision-making on behalf of patients. Although not a routine requirement for admission, many medical schools encourage undergraduate applicants to take an introductory course in ethics, and the curriculum of most medical schools now includes coursework in ethics.

To foster an appreciation for the intellectual underpinnings of modern medical ethics, this chapter begins with an overview of scholarly approaches to ethics. Next is a discussion of selected proclamations and codes of ethics published by professional societies, federal commissions, and other authorities as guidelines for medical practice and research. Finally, common practical ethical issues in radiation oncology are addressed, including relevant medicolegal considerations.

CONCEPTUAL APPROACHES USED IN BIOMEDICAL ETHICS

The term bioethics, coined in the early 1970s, refers to the academic inquiry and

public policy movement addressing the application of science and medicine from a humanistic perspective.[3] Medical ethics may be most accurately viewed as a branch of bioethics, but the terms are commonly used interchangeably. Among the more influential theoretical approaches that are used in bioethics are *utilitarianism, deontology, casuistry, virtue theory, principlism, and feminism*.

Utilitarianism is based on the premise that, in any situation, the best course of action is the one that produces the maximum net positive value (or least negative value). Utilitarianism can be applied to an individual patient's case or to matters of health policy, in which decisions might be made to achieve the greatest overall benefit for the largest number of people.

Unlike utilitarianism, deontology is an ethical theory based on the morality of actions themselves rather than their net result. Deontology, sometimes called Kantianism in recognition of the influence of Immanuel Kant,[4] calls for consistent standards of behavior at all times, regardless of the consequences. One simple example of the difference between utilitarianism and deontology is the issue of educating patients about their diagnosis, especially if the prognosis is very poor. Whereas a deontologist would always feel obliged to tell the truth even at the risk of causing distress, a utilitarian considers whether telling a patient the complete truth about the disease does or does not really benefit the patient. In daily practice, finding the right balance between purely utilitarian and purely deontologic perspectives in a situation like this one requires consideration of case-specific factors. Respect for the patient's autonomy, for example, is one of the *prima facie* ethical principles discussed in the next section. Truth-telling is an integral component, and overriding this principle requires justification.

Casuistry is an approach to ethics that emphasizes inductive reasoning based on established precedents, and it is a common practice in both law and medicine. The proper course of action in any individual case is decided by recalling decisions made in prior similar cases. The major weakness of casuistry is the lack of a reference benchmark or settled opinion on novel technologies.

Virtue theory focuses on the character of moral agents, in this case physicians and other health care providers, focusing less on actions or outcomes. As such, virtue theory captures the way in which correct moral actions occur. For example, it is not only important to tell patients the truth about their diagnoses, but it is also critical to do so in a compassionate manner. In this case, the virtue is compassion. Accordingly, although virtue is a critical part of assessing moral action, virtues themselves have little guiding force.

Principlism is a system of applied ethics through which core principles ideally

govern behavior in the absence of compelling reasons to override them. Principlism can be integrated with the other philosophical approaches already mentioned and serves as a unifying influence.

Feminism concentrates on the concerns of those who are vulnerable and marginalized, as well as categorized unjustly according to particular hierarchies. Frameworks such as structural violence aid in analyzing various practices and policies that perpetuate oppression and injustice. Narrative practice provides a voice to those who may be marginalized on the basis of sex, race, gender, age, disability, susceptibility or presence of stigmatized diseases, imprisonment, health status, and other social categorizations. As such, feminism does not focus solely on women's issues, but on those who are traditionally subject to discrimination.

ETHICAL PRINCIPLES IN BIOMEDICAL ETHICS

A *prima facie* obligation may be defined as one that is "binding unless overridden or outweighed by competing moral obligations."[4] Four *prima facie* principles of bioethics are highlighted here: *respect for autonomy, beneficence*, *nonmaleficence*, and *justice.*

Respect for a patient's autonomy is based on respect for the right to individual liberty. A patient's voluntary decision to seek medical care or comply with referral to a specialist is the starting point of most patient–physician relationships, and competent patients should remain free to forgo therapy or change physicians at any time. The responsibility to respect patients' autonomy is established not only in ethics but also in law. An example is the requirement to obtain a patient's informed consent for proposed medical therapy. In a landmark case involving postmastectomy chest wall radiation therapy, a patient who sustained soft tissue necrosis won a lawsuit against her radiation oncologist for negligence and for lack of proper disclosure regarding possible treatment-related toxicity. The Kansas Supreme Court ruled that doctors should explain "in language as simple as necessary" the side effects associated with any recommended therapy.[5]

The principle of *beneficence* is intertwined with that of *nonmaleficence*. Some authors have offered nuanced distinctions between the two principles,[4] but the key point is that physicians should act for the benefit of patients and should not harm their patients. Beneficence and nonmaleficence are typically concordant objectives, but sometimes an intervention that is helpful also entails a high risk

of adverse treatment-induced sequelae. For example, administering high dose morphine to a patient severely dyspneic from an incurable lung malignancy can relieve symptoms but at the same time risks fatally suppressing respiratory drive. Here the quality of remaining life might be improved by a measure that also hastens death. Such an action can sometimes be justified by the principle of double effect, the earliest expression of which is generally attributed to St. Thomas Aquinas.[6]

In recent years, a number of states in the United States have enacted so-called Death with Dignity legislation that permits physicians to prescribe life-ending medications to certain patients with terminal illness when pain or other distress from the illness becomes intolerable to the patient. Generally, there is a stipulation that the patient must be able to self-administer the medication, and there is also a requirement that the patient is competent to make the decision to end his or her life. Individual hospitals and health systems retain local administrative authority regarding whether these statutes are implemented within the institution and, if so, what specific local regulatory requirements apply.

The principle of justice refers to fairness, typically the equitable distribution of health care resources. Justice-related questions often arise concerning matters of public policy. One specific example is the challenge of determining the means to allocate scarce organs for transplantation. A more global problem faced by all governments is the calculus of distributive justice implies that persons ought to be afforded medical care according to their medical needs and the ability of the system to provide.

FORMAL OATHS AND CODES OF ETHICS

There are many published declarations of medical ethics authored by physicians. Not surprisingly, the tone and language of each reflect the social mores and sometimes historical events of the era in which it was composed.

The Hippocratic Oath

> *I will prescribe regimen for the good of my patients according to my ability and my judgment and never do harm to anyone*

The *Corpus Hippocraticum* is a collection of medical treatises dating from around the fifth century BCE, believed to be the work of philosopher–physicians from the Greek island of Cos (Fig. 104.1). Contained within the *Corpus* is the

well-known oath of Hippocrates, an ancient physician's pledge of professionalism. Curiously, the oath is inconsistent with some other sections of the *Corpus,* perhaps because it was added later. Comments about abortion and surgery, for example, are at variance with teachings elsewhere in the collected works.[7] Nevertheless, timeless themes are included, and the oath has survived in various modernized versions. The oath is often recited by medical students at the time of graduation—even if its contents are not always well remembered.[8,9]

FIGURE 104.1. Early19th-century engraving depicting a likeness of Hippocrates, closely resembling images of ancient coins found on the island of Cos bearing his likeness. (Image Courtesy of the U.S. National Library of Medicine.)

Percival's Medical Ethics

Hospital physicians and surgeons should minister to the sick, with due impressions of the importance of their office, reflecting that the ease, the health, and the lives of those committed to their charge depend on their skill, attention, and fidelity.

Thomas Percival (1740–1804) (Fig. 104.2) published *Medical Ethics* at a time when there were considerable tension among clinicians in his community.[10] In the 1760s, Manchester, England, was a prosperous urban society that comfortably supported public health initiatives, including an infirmary serving as a charity hospital and teaching institution. But as the city grew and became crowded by the 1790s, tensions arose between rival groups in the medical community. Percival was prompted to draft a code of ethics after a contentious dispute about enlarging the infirmary's staff, a threat to the controlling physician faction.[11]

When he began writing *Medical Ethics,* Percival was already a well-known writer and moralist whose *A Father's Instructions to His Children*, published in 1775, included essays promoting personal virtues and social awareness to young readers. While completing *Medical Ethics,* Percival suffered devastating personal tragedies, bereaving the untimely deaths of two of his own sons. The finished work was dedicated to a third son studying medicine at the time.

Ultimately, *Medical Ethics* provided a template for the codes of ethics adopted by the American Medical Association (AMA) and other societies in the 19th century. Early 20th-century pundits criticized Percival's work as merely a book of medical *etiquette* rather than medical *ethics.* However, revisionist historians have subsequently argued that although Percival focused on interprofessional relationships, he also taught that a physician's duty toward the patient outweighs obligations of civility toward other health care professionals. Furthermore, Percival advanced the enlightened view that indigent patients should receive the same quality of care as affluent patients.[12]

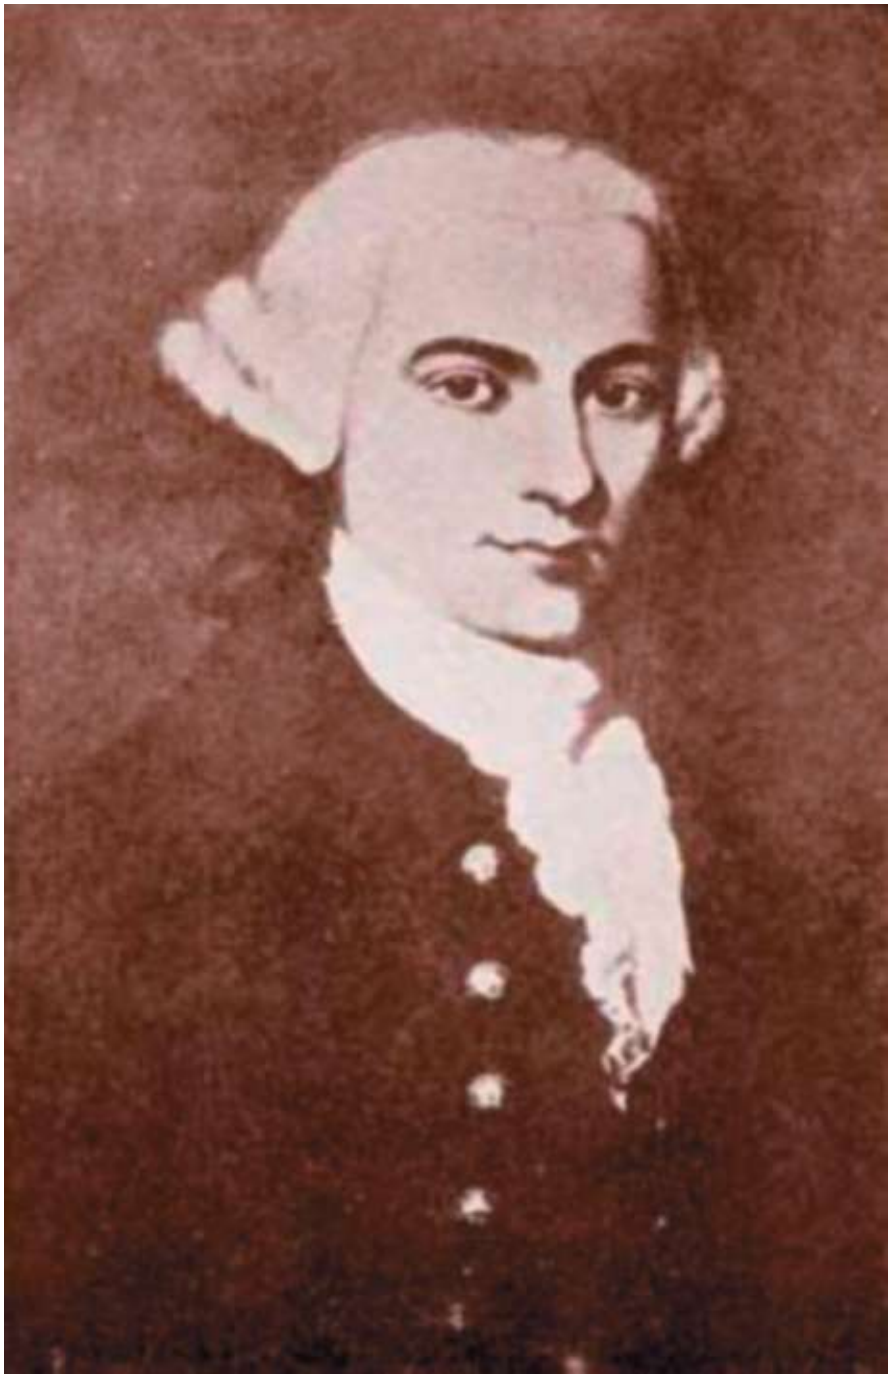

FIGURE 104.2. Thomas Percival (1740–1804). (From Brockbank EM. *Sketches of the lives and work of the honorary medical staff of the Manchester Infirmary, from its foundation in 1752 to 1830 when it became the Royal Infirmary*. Manchester: Manchester University Press, 1904.)

The American Medical Association Code of Ethics

The AMA first adopted a code of ethics at its inaugural meeting in 1847. The initial code was modeled on the work of Percival, but subsequent updates have

reflected societal changes and technologic progress. The 2016 update begins with an articulation of basic principles[13]:

I. *A physician shall be dedicated to providing competent medical care, with compassion and respect for human dignity and rights.*
II. *A physician shall uphold the standards of professionalism, be honest in all professional interactions, and strive to report physicians deficient in character or competence, or engaging in fraud or deception, to appropriate entities.*
III. *A physician shall respect the law and also recognize a responsibility to seek changes in those requirements, which are contrary to the best interests of the patient.*
IV. *A physician shall respect the rights of patients, colleagues, and other health professionals and shall safeguard patient confidences and privacy within the constraints of the law.*
V. *A physician shall continue to study, apply, and advance scientific knowledge; maintain a commitment to medical education; make relevant information available to patients, colleagues, and the public, obtain consultation; and use the talents of other health professionals when indicated.*
VI. *A physician shall, in the provision of appropriate patient care, except in emergencies, be free to choose whom to serve, with whom to associate, and the environment in which to provide medical care.*
VII. *A physician shall recognize a responsibility to participate in activities contributing to the improvement of the community and the betterment of public health.*
VIII. *A physician shall, while caring for a patient, regard responsibility to the patient as paramount.*
IX. *A physician shall support access to medical care for all people.*

Among the numerous topics discussed in more detail in the eleven chapters of the code are conflicts of interest in patient care. The AMA code states that "Under no circumstances may physicians place their own financial interests above the welfare of their patients…Treatment or hospitalization that is willfully excessive or inadequate constitutes unethical practice."

The Nuremberg Code and the Declaration of Geneva

During World War II, odious crimes were committed by Nazi physicians who conducted horrific experiments on concentration camp prisoners who were coerced to submit. The Nuremberg Code was a formal response to these World War II–era human rights atrocities disguised as medical experiments.[14] Issued

from the military tribunal that tried some of the Nazi doctors who conducted these experiments, the Nuremberg Code acknowledges that medical investigations are important. However, for a medical experiment to be morally permissible, it must meet 10 criteria, paraphrased as follows:

- Voluntary consent of the human subject
- Necessity to yield results helpful to society
- Appropriate design based on knowledge of the disease under study
- Avoidance of unnecessary physical and mental suffering and injury
- Absence of reason to believe that death or disabling injury will occur
- Overall degree of risk in proportion to the nature of the problem to be solved
- Adequate precautions against the possibility of the subject's injury, disability, or death
- Qualified persons conducting the study
- Unrestricted freedom of the subject to end the experiment if he or she reaches the physical or mental state where continuation of the experiment seems impossible
- Willingness of the investigator to discontinue the study at any time if there is reason to believe that continuing the experiment is likely to result in injury or death to the subject.

In the aftermath of the war, the international medical community was especially sensitized to the need for universal adherence to high standards of ethical behavior. The Declaration of Geneva was adopted in 1948 by the World Medical Association and has been updated since then. The text includes the physician's vow to ignore "considerations of age, disease or disability, creed, ethnic origin, gender, nationality, political affiliation, race, sexual orientation, or social standing" in the treatment of a patient and to uphold "even under threat … the utmost respect for human life."

Case Study

Despite publicity about the Nuremberg Code and the Geneva declaration, controversial large-scale, government-sponsored medical studies took place in the years following World War II. Experimentation on the effects of radiation exposure on humans was conducted in the United States during the Cold War, when fears of nuclear warfare prompted inquiry into the carcinogenic and other adverse health effects of environmental exposure to ionizing radiation. In response to public concern about thousands of federally funded studies conducted from the 1940s through 1970s without consent of the subjects, in

1994, President Bill Clinton established the Advisory Committee on Human Radiation Experiments (ACHRE). ACHRE was comprised of ethicists, radiation oncologists, and others with relevant expertise. It was charged with evaluating the experiments' ethical and scientific standards and recommending actions to ensure that any mistakes of the past would not be repeated. ACHRE reviewed all available documentation and also conducted an oral history project in which scientists described prevailing sentiments regarding human research ethics during the era of interest.

ACHRE found that government officials and investigators were in some cases culpable "for not having had policies and practices in place to protect the rights and interests of human subjects who … could not possibly derive direct medical benefit."[15] One example was the observational study of uranium mine workers exposed to radon levels known to be hazardous, without warning and without efforts to reduce the radon levels by ventilating the mines. As a result, lung cancer developed in hundreds of workers, and appropriate compensation was recommended for the individuals affected.

The Belmont Report

In 1972, Jean Heller exposed the injustices of the U.S. Public Health Services (USPHS) Study of Untreated Syphilis in the Negro Male that was conducted in Tuskegee, Alabama.[16] During a 40-year period beginning in the 1930s, 399 indigent African American sharecroppers with syphilis and 200 without syphilis were subjects in a natural history study of the disease. The men mistakenly believed that diagnostic blood tests and lumbar punctures composed treatment for their "bad blood" when in reality, these were done solely to monitor the course of the infection. Moreover, years later when penicillin was discovered and found to be effective in the treatment of syphilis, it was withheld intentionally from the men. Subsequently, public awareness of the USPHS study likely contributed to enduring reluctance among some members of minority groups to participate in clinical trials,[17,18] and the political backlash provoked action by the federal government.

The 1974 National Research Act established the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research. The commission met at the Belmont Conference Center in Maryland to develop ethical guidelines for the conduct of biomedical and behavioral research. In 1979, the commission published *Ethical Principles and Guidelines for the Protection of Human Subjects of Research*, commonly known as the Belmont

Report.[19]

In the Belmont Report, a clear distinction is made between medical research and clinical practice. The term *practice* describes interventions intended "to enhance the well-being of an individual patient … that have a reasonable expectation of success," whereas *research* is "designed to test an hypothesis, permit conclusions to be drawn, and … contribute to generalizable knowledge." Sometimes, a clinician uses good judgment and departs from standard methods for the benefit of an individual patient in special circumstances. However, if major innovations are proposed as replacement for standard techniques, then a formal investigation should be conducted to assess safety and efficacy. The National Commission embraced a principlist perspective in drafting the report, emphasizing in particular respect for persons, beneficence, and justice. The Belmont Report's definition of respect for persons incorporates respect for autonomy and special concern for individuals with diminished capacity to exercise their autonomy. Involving prisoners in research activity is cited as an example. Although it is inappropriate to deny prisoners the possible benefit of experimental interventions, any direct or indirect pressure on prisoners to participate in clinical studies must be avoided. For instance, a promise of clemency in return for study enrollment is unacceptable. The report also addresses the nature of justice in medical research, emphasizing that the process of selecting subjects for a research study must be carefully examined. Investigators should minimize the chance that socioeconomically disadvantaged groups are represented disproportionately as a result of a vulnerability to manipulation in the health care environment.

National Electrical Manufacturers Association Code of Ethics

The makers of equipment and software used in the practice of radiation oncology are not required to demonstrate clinical efficacy of a new device or software through the same sort of clinical testing that is required by the U.S. Food and Drug Administration (FDA) for approval of a new drug or implantable medical device. Rather, most treatment devices are approved after demonstration of safety and substantial equivalence to an approved device that is already commercially available. A company that wishes to sell a new device submits a premarket notification to the FDA at least 90 days before commercial distribution is to begin, in accordance with Section 510(k) of the FDA Modernization Act of 1997. Because devices may be introduced into the market without proof of superiority in any given clinical situation, manufacturers may

promote their products to physicians by emphasizing intuitively attractive features that might or might not provide meaningful clinical advantage to patients.

On January 1, 2005, members of the National Electrical Manufacturers Association (NEMA) adopted a code of ethics regarding interactions between makers of medical imaging and treatment equipment and physicians (www.nema.org). Individual sections of the NEMA code address member-sponsored product training and education, support for third-party educational conferences, sales and promotional meetings, arrangements with consultants, gifts, provision of reimbursement and other economic information, charitable donations, and research grants. The guidelines are essentially consistent with the AMA policy on gifts and applicable federal regulations. NEMA members are allowed to support educational conferences and advertise their wares in these venues, and also they may provide educational support for individual customers in the safe use of their products. However, hospitality provided by NEMA member at conferences and meeting should be "modest in value and … subordinate in time and focus to the purpose of the meeting." When it is necessary to demonstrate nonportable equipment, members may pay for reasonable travel costs of attendees with a *bona fide* professional interest but not for their guests.[20]

COMMON ETHICAL ISSUES IN RADIATION ONCOLOGY

> *Doctors wear a lot of hats these days; besides the usual physician role, we are expected to be a researcher, financial counselor, administrator, gatekeeper, patient advocate in the medicolegal system, ethicist, and Lord knows what else.*
>
> *—Thomas J. Smith*[21]

Financial Relationships with Hospitals and Referring Physicians

Reimbursement for radiation oncology services or other procedure-intensive subspecialties can be a major revenue source for hospitals. At the same time, subspecialists depend on other physicians to refer patients for evaluation and management. These situations can tempt hospital administrators to reward subspecialists for practicing in their facility and might tempt the subspecialists to induce referrals with financial incentives. In either case, a conflict of interests

emerges: Treatment recommendations can be influenced not only appropriately by patient-centered beneficence but also inappropriately by the physician's interest in personal gain. In the United States, the Anti-Kickback Statute and the Stark Law make it illegal to engage in such unscrupulous medical business practices.

The Anti-Kickback Statute (42 U.S.C. §1320a-7b) includes criminal penalties for acts involving Medicare or state health care programs. Section (b) makes it a felony punishable by a fine up to $25,000 and up to 5 years in prison to solicit or receive "any remuneration (including any kickback, bribe, or rebate) directly or indirectly … in return for referring an individual to a person for … any item or service" reimbursed in whole or in part through Medicare or a state health care program. The Anti-Kickback Statute also bans other fraudulent transactions supported through the same funding sources.

Named for its leading congressional author, Rep. Pete Stark of California, the Stark Law (42 U.S.C. §1395nn; "Limitation on certain physician referrals") bans other misconduct involving Medicare and Medicaid patients. The Stark Law prohibits a physician from referring a patient for a "designated health service" to a clinic or other facility with which the physician or an immediate family member of the physician has a financial relationship. Radiation therapy is considered a designated health service, but it is clarified that a request by a radiation oncologist for radiation therapy is considered integral to the consultation request from the (nonradiation oncologist) referring physician and does not constitute a self-referral *per se* in most situations. Sanctions for violations of the numerous Stark Law regulations may include civil prosecution.

Self-Referral for Radiation Oncology Services

In addition to being considered a designated health service per Stark Law language, radiation therapy is also considered in the category of in-office ancillary service exemptions for Medicare coverage. The implication is that radiation therapy is grouped with a number of less complex services such as simple blood tests or antibiotic injections that a physician might reasonably do in his or her office for the convenience of rendering a quick diagnosis or managing a simple medical problem on an outpatient basis. Because of this classification for radiation therapy, nonradiation oncologists may own linear accelerators and derive profit from the utilization of this technology on patients referred for treatment. One of the most contentious issues to emerge in recent years is the debate over the legitimacy and ethics of business arrangements in which

nonradiation oncologists own radiotherapy delivery technology and derive profit from self-referring patients for treatment.

In 2013, Jean Mitchell reported a study in *The New England Journal of Medicine* in which patterns of IMRT utilization for prostate cancer were analyzed. Urologists were grouped according to whether they purchased radiotherapy equipment. For those who purchased equipment (the self-referring group), the use of IMRT in the periods before and during ownership were compared. To account for the changing baseline trends in prostate cancer management, the use of IMRT among patients seen by non–self-referring urologists who did not own radiotherapy equipment was also analyzed, and a "difference-in-differences" methodology was employed. It was observed that men treated by self-referring urologists, as compared with men treated by non–self-referring urologists, were significantly more likely to be treated with IMRT rather than less expensive options.[22] Other similarly constructed studies have yielded concordant results.[23,24]

Terry Wall offers a perspective on both the legal and ethical aspects of this issue.[25] He points out that advocacy efforts by the American Society for Radiation Oncology (ASTRO) over the last decade to remove radiation therapy from the list of in-office ancillary service exemptions have been unsuccessful, and there is unlikely to be a legislative resolution. Dr. Wall poses the question of whether an individual radiation oncologist who is the potential recipient of a self-referral is "eating fruit from a poisonous tree." He offers guidance for the individual practitioner to ensure that self-referral arrangements put the patient's interest first, including a mandate to disclose the financial interests to the patient and inform patients of their alternative to receive care elsewhere.

Electronic Record-Keeping and Billing Practices

The principles of respect for autonomy and nonmaleficence oblige confidentiality in physician–patient communications. Publicizing private details of a patient's condition can create social and economic harms for the patient. With the advent of electronic medical records and Internet communication, there is a greater need for vigilance in this respect.

In the United States, the Health Insurance Portability and Accountability Act of 1996 (HIPAA) empowered the Department of Health and Human Services to codify standards for storage and transmission of an individual patient's health information. Penalties for violations vary in proportion to their severity. In the worst case of wrongful disclosure of information with intent to sell it, a fine of

up to $250,000 and a prison term of up to 10 years can be imposed.

Submitting fraudulent claims to the government for reimbursement of health care services is illegal. The False Claims Act (31 U.S.C. §3729) provides that any person who knowingly presents fraudulent claims to the US government may be fined $5,000 to $10,000 and may be liable for three times the amount of any damages sustained by the government.

Applications of New Technology

Innovative treatment delivery methods such as stereotactic body proton therapy (SBRT), proton therapy, adaptive therapy, and other new treatment techniques can be intuitively appealing but cannot be assumed to provide meaningful clinical benefit unless tested properly against existing standard treatment methods. A recent example underscoring this need is the lack of benefit of proton therapy over photon therapy for non–small cell lung cancer in the first randomized trial comparing these modalities.[26] Ideally, it is best that such innovations are tested in formal research protocols in which a clinical problem is identified and the new technology is proposed as a solution so that toxicity and efficacy can be monitored closely. A prospective clinical trial approved and monitored by an institutional review board affords the opportunity to advance knowledge in the field with ethical oversight.[27]

Clinical Trial Conduct

Instances of flagrantly improper clinical research taint the annals of medical history. The USPHS study of syphilis mentioned earlier and the human radiation experiments conducted during the Cold War without the consent of the participants are dark reminders of the need for ethical oversight of research.

Obtaining a participant's informed consent is of paramount importance in conducting most clinical research. Despite the recognized importance of informed consent, precisely how much information should be conveyed to a potential clinical trial participant is debatable. The Belmont Report offers this criterion: "the extent and nature of information should be such that persons, knowing that the procedure is neither necessary for their care nor perhaps fully understood, can decide whether they wish to participate" in the study. In certain situations, the nature of a study requires that there is incomplete disclosure of information to the participant to sustain the integrity of the study. The Belmont Report condones such research only when "i) incomplete disclosure is truly necessary to accomplish the goals of the research, ii) there are no undisclosed

risks to subjects that are more than minimal, and iii) there is an adequate plan for debriefing subjects, when appropriate, and for dissemination of research results to them." The federal rules governing research (45 CFR 46) reflect these arguments.

Advances in the biosciences, such as stem cell research, cloning, and manipulations of the human genome, have been associated with contentious public debate. Federal government and professional policies on such matters have sometimes been constructed as a compromise between scientific opportunity and political ideology.[28] Extra safeguards have been imposed in some settings; for example, the federal government requires an extra level of review for gene-transfer experiments.[29]

Genetics

The management of some cancer patients can involve assessment of genetic markers that might predict treatment response and reveal a predisposition to the development of certain cancers among the patient's family members. The National Society of Genetic Counselors has published a guideline concerning genetic cancer risk assessment, counseling, and testing.[30] It is recommended that the process of obtaining informed consent for genetic testing should include, among other considerations, an explanation to the patient of possible implications on the ability to obtain health or disability insurance in the future.

Relationships with Industry Sponsors

Incentives from industry representatives to prescribe pharmaceuticals or purchase equipment threaten the fiduciary obligations physicians have to their patients. The AMA code of ethics states that physicians should decline cash gifts in any amounts from any entity with a financial interest in the physicians' treatment recommendations.[13] The AMA code allows for accepting an in-kind gift that will directly benefit patients and is of minimal value and allows for support for educational programs with certain restrictions.

Advertising items such as patient education pamphlets and anatomic models bearing a sponsor's name are commonly found in radiation oncology clinics.[31] Physicians should be aware of any real or perceived influence on the patient–physician relationships resulting from their tacit compliance with such marketing activities.

Pharmaceutical companies may be prosecuted for kickback schemes or other illegal enticements to physicians, and the civil and criminal penalties paid by the

corporations held responsible have ranged up to hundreds of millions of dollars.[32] Brennan et al.[33] contend that voluntary self-regulation by physicians, industry, and government is an insufficient safeguard against the conflict of interests nurtured by close relationships between practicing doctors and sellers of pharmaceuticals and medical products. These authors argue that academic medical centers should set an example for the rest of the medical community by establishing policies that forbid gifts to physicians, funds for travel, unjustified consulting fees, participation in speakers' bureaus, and the practice of "ghostwriting" medical articles, among other things. Substantial attention has focused on implementing policies related to these issues.[34,35]

Prasad and Rajkumar recommend a forward-looking strategy of transparency and full disclosure to as a means of minimizing the impact of conflict of interest in academic publications and presentations.[36] Their suggestions include excluding authors of reviews, editorials, and practice guidelines from having any financial interest that exceed a reasonable threshold[37]; stopping the practice of having professional medical writers funded by industry serve to prepare manuscripts; and open disclosure of the amount of support given to professional organizations by individual industry sponsors.

CASE-SPECIFIC DILEMMAS: THE ROLE OF AN ETHICS CONSULTANT OR COMMITTEE

The radiation oncology–related ethical issues discussed thus far relate primarily to general practice and research guidelines. However, individual cases can also pose uncertainties regarding the proper choice of action for a specific patient.

Case Study

A 37-year-old woman undergoes modified radical mastectomy for a pathologic T3N2M0 breast cancer; postoperative chemotherapy and locoregional radiation therapy are recommended. The patient wishes to receive the therapy only if she can periodically interrupt it to alternate with what she calls a "natural herbal" therapy.

In this case, respect for a patient's autonomy conflicts with what is believed to be in the patient's best interests, but a physician cannot ethically abrogate the fiduciary responsibility to a patient simply for reasons of unfamiliarity with alternative medicine or prejudice against its worth.[38] Similar situations may arise when patients do not adhere to standard treatment recommendations because of a

particular religious faith or cultural heritage. Although physicians must respect patients' choices, there is no strict obligation for a physician to accept a particular individual as a patient, especially if there are foreseeable personal conflicts that might adversely affect the patient–physician relationship, unless the treatment is needed urgently and/or there are no other physicians with the same skills or knowledge to treat the patient.

Pediatric oncology also requires special considerations. Parents are the chief decision makers, but sometimes their wishes can seem discordant with the best interests of the child. In a different context, what should be done if the adult children of a patient with a heritable trait for malignancy inquire of the patient's diagnosis, but the patient has instructed the physician not to reveal any information to them? The obligation to patient–physician confidentiality conflicts with a potentially overriding obligation toward the family members who might benefit from guidance toward screening.

In cases such as these in which it is difficult to choose between two defensible courses of action, individuals and committees with experience in clinical medical ethics can provide the expertise needed to sort through the ethical, legal, and social issues involved.[39]

PALLIATIVE MEDICINE

Palliative medicine has become a well-established component of clinical practice, and numerous academic medical centers offer accredited fellowship programs in this field. Palliative medicine places emphasis on symptom management and on the goals of care, not only at the end of life but also in the treatment of serious illnesses. An exclusively palliative approach is ethically justified when fully aggressive therapy might be intolerable or futile, but the use of early concurrent palliative care can also be beneficial for patients with metastatic cancer or cancer with high symptom burden who are still receiving aggressive anti-cancer therapy.

Case Study

A 92-year-old woman presented with stage IVa maxillary sinus cancer. She complained of sinus fullness and a painful 4-cm neck node. Radical radiation therapy to the primary and neck was recommended, and the patient underwent placement of a percutaneous gastric feeding tube and full dental extraction. Midway through the course of treatment, the patient required a lengthy

hospitalization for failure to thrive and severe mucositis.

In retrospect a less aggressive course of radiation therapy intended to reduce the sinus and neck symptoms would have likely been a better choice for this patient, who was frail and unable to withstand intense treatment. Palliative medicine pays careful attention to a patient's individual needs, quality of life, and a discussion of goals of care. A recent randomized study demonstrated improved quality of life and overall survival when palliative care was given early alongside standard cancer treatment for metastatic lung cancer.[40] In many cases, aggressive symptom management and good communication among patient, family, and provider may result in better quality and, perhaps, quantity of life than would antineoplastic therapy that has little expectation of efficacy but significant risk of morbidity.[41]

ETHICS AND MEDICAL ERRORS

Soon after the discovery of x-rays by Wilhelm Röntgen more than 100 years ago, the first cases of malpractice involving the clinical use of radiation therapy were tried in the US court system.[42] During the early 20th century, severe dermatitis was a frequent plaintiff's complaint—not surprising in view of the physical limitations of the low-energy machines available at the time.

In 1999, the Institute of Medicine published a report on medical errors, elevating the level of public awareness and stimulating inquiry into this topic.[43] One recent study has suggested that medical errors might be the third leading cause of death in the United States.[44]

Physicians are often reluctant to discuss errors. It has been suggested that doctors and patients "harbor deep within themselves the expectation that the physician will be perfect."[45] Other reasons for reticence include uncertainty about whether an event really is an error, concern for the patient's well-being, and fear of litigation.[46]

If a patient has an undesirable treatment outcome, careful review of the case can help distinguish error from untoward but unsurprising occurrence. For example, severe pneumonitis after breast radiation therapy is uncommon but not necessarily proof of negligence. Concern that disclosing an error causes a patient undue anxiety is contradicted by studies revealing that patients prefer physicians to acknowledge errors[47] and that they might even sue for lack of apology.[48] In cases of alleged or suspected error leading to injury, the institutional risk management service should usually be contacted for advice. However, fear of

litigation should be mitigated by the fact that a low overall percentage of patients who suffer negligent injuries actually file malpractice claims.[46]

Nondisclosure of error can weaken the trust at the core of the patient–physician relationship. The argument for disclosure is especially strong when there is a specific preventive intervention that might lessen the severity of possible future injury. Nevertheless, the question still remains: Are physicians ethically obliged to disclose an error, even if there is no immediate harm to the patient?

Case Study

A patient with T3N1M0 squamous cell carcinoma of the left retromolar trigone received concurrent cisplatin plus intensity-modulated radiation therapy to the gross disease, with elective coverage of adjacent nodal echelons. The intent was to give 54 Gy to adjacent uninvolved lymph nodes at a rate of 1.8 Gy/day and 66 Gy to the gross disease at a rate of 2.2 Gy/day using a synchronous integrated boost technique, with all treatment completed in 30 fractions. After the spinal cord was contoured as an organ at risk, the structure was inadvertently deleted on all planning computed tomography slices below the level of the gross disease. As a result, when the intensity-modulated radiation therapy inverse planning software optimized the dose distribution according to the constraint of limiting the maximum dose to the spinal cord to 50 Gy, the entire cross-section of a 6-cm length of cervical spinal cord received the full prescription dose. The error was not detected until 1 week after the patient completed treatment, during a routine quality assurance check.

In this example, no injury has yet occurred, but the patient is at increased risk for radiation myelitis. Although there is currently no available proven preventive measure, if the escalated risk of myelitis is unknown to the patient, he or she might later undergo misguided management by another physician if symptoms develop. For instance, if the patient develops arm and leg weakness, a magnetic resonance imaging scan showing nonspecific enhancement and edema in the cervical spinal cord might be interpreted as evidence of metastatic intramedullary or epidural tumor rather than radiation change. Unaware of the prior treatment error, the patient would be unable to inform the other physician involved about the high risk for radiation injury. As a result, the patient might be given only minimal supportive care on the assumption of incurable recurrent disease rather than appropriate efforts toward rehabilitation.

Evans and Decker[49] have offered practical suggestions on how to address the

issue of a medical error in radiation oncology once the event has been recognized. They advise disclosure for any errors that result in a perceptible clinical effect, change in diagnosis or treatment course, or a chance of future harm. Their two-phase response recommendation involves initial attention to the patient's immediate needs and an apology that avoids giving an impression of defensiveness. Later, after a more thorough analysis of the situation has been completed with the involvement of the hospital's risk management team, a carefully prepared discussion with the patient and other interested parties can occur.

Toward the goal of fostering a culture of safety across the field of radiation oncology and facilitating the identification of preventable systematic errors with different treatment delivery platforms, ASTRO and the American Association of Physicists in Medicine (AAPM) have created a national Radiation Oncology Incident Learning System.[50] This program allows for anonymous, privacy-protected self-reporting of incidents and near misses. The information can be used locally to inform root cause analysis projects that identify ways of improving patient safety. Industrial engineering-based principles for minimizing errors in a busy radiation oncology clinic are now becoming widely implemented, and entire texts devoted to this topic are available.[51,52]

CONCLUSION

Society's view concerning medical ethics has shifted over time to adapt to the forces of advancing knowledge. Ethical guidelines have sometimes been constructed as formal documents or mandated as law, but no single system comprehensively predicts and resolves all situational dilemmas. The core principles of medical ethics remain essential foundations for the practice of medicine.

CHAPTER 105

Health Economics and Health Policy

Ann C. Raldow, Eric M. Chang, and Michael L. Steinberg

INTRODUCTION

The 21st century has been marked by a continued increase in health expenditure in the United States, estimated at 16.9% of the country's gross domestic product (GDP) in 2015—the highest ranked in data collected from the Organization for Economic Cooperation and Development (OECD) member countries and nearly twice the OECD average[1] (Fig. 105.1). Furthermore, national health spending is only expected to continue its rise in the coming years, with the Centers for Medicare and Medicaid Services (CMS) National Health Expenditures projecting health spending to grow 1.2% points faster than GDP per year over the 2016 to 2025 period, amounting to 19.9% share of GDP by 2025.[2] The cost of cancer care is escalating precipitously, estimated at $24.7 billion in 1987 (in 2007 US dollars) versus $48.1 billion in the 2001 to 2005 period.[3] Although the double-digit growth rates in US cancer expenditures observed prior to the Great Recession began to decline substantially in 2007, associated costs of cancer care are still projected to rise from $124.57 billion to $157.77 billion from 2010 to 2020 (in 2010 US dollars) assuming constant incidence, survival, and cost.[4,5]

There are many factors contributing to this rise in costs, including aging of the population, with anticipated increases in both the number and the percentage of elderly patients and commensurate increases in new diagnoses, magnified by persistence of risk-increasing behaviors and earlier diagnoses via improved cancer screening.[6,7] These demographic factors warrant discussion regarding the allocation and prioritization of resources. Yet, the increasing cost to the individual patient merits further consideration as well. Driven partly by innovation—new advances in systemic therapies, radiotherapy techniques, surgical devices, and diagnostic tools—these investments pose a particular dilemma, as efforts to cut costs would potentially slow the development of lifesaving medications and technologies. However, in the setting of limited

resources, these rising costs are not benign. In 2011, roughly 40% of expenditures in cancer care were publicly funded (34.1% by Medicare and 5.3% by Medicaid), and by 2030, more than 70% of cancer diagnoses will be made in persons eligible for Medicare.[6,8] Thus, from a societal perspective, we must consider whether our expenditure in cancer care is reasonable when balanced with other priorities in medical care and other areas. Furthermore, substantial out-of-pocket costs directly impact patients' ability to access medical care and to afford other nonmedical life necessities, with having insurance often not enough to protect patients from the impact of the high costs of treatment.[9] Estimates by the Congressional Budget Office (CBO) indicate that aging explains less than half of the estimated increase in spending for major health care programs as a share of GDP from 2016 to 2046, with the majority resulting from rising health care costs per person—indicating that these challenging questions and the need for the transformation of health care delivery will not go away.[10]

In this setting of mounting health care costs, interest in health policy and health economics has flourished in the past decades. Broadly, health policy as a discipline encompasses questions of access, cost, and quality of health care.[11] As a function of health policy, health economics addresses difficult questions regarding the appropriate and efficient allocation of resources in the health care setting as well as the behavior of stakeholders in the face of competing choices for financial resources. In his seminal article, "Uncertainty and the Welfare Economics of Medical Care," Kenneth Arrow, often credited with the birth of health care economics, distinguishes between health and other goods, noting that health care, in contrast with other goods and the free market ideal, is marked by uncertainty on behalf of the patient in evaluating the quality of care provided by their physician, leading to asymmetric information.[12] Physicians, serving as agents for their patients, are expected to act in their patients' best interests, though this system, based on trust, permits for misaligned incentives. Moreover, health care is awash in externalities or costs and benefits externally imposed by the purchaser on others not party to the transaction. Given these notable exceptions, it is imperative that health policy ensures symmetric access to quality health care. As defined by Steinberg, ideal health policy should ensure (1) that all patients get all necessary care, (2) that equivocal and nonindicated treatment be excluded, (3) that cost of care be socially responsible, (4) that variation in the quality of care be so small from a technical perspective that does not matter from which facility or provider a patient receives treatment, and (5) that when competition occurs, it should be over the quality of the art of care,

such as how patient centered it is and how well staff and physicians communicate with patients.[11]

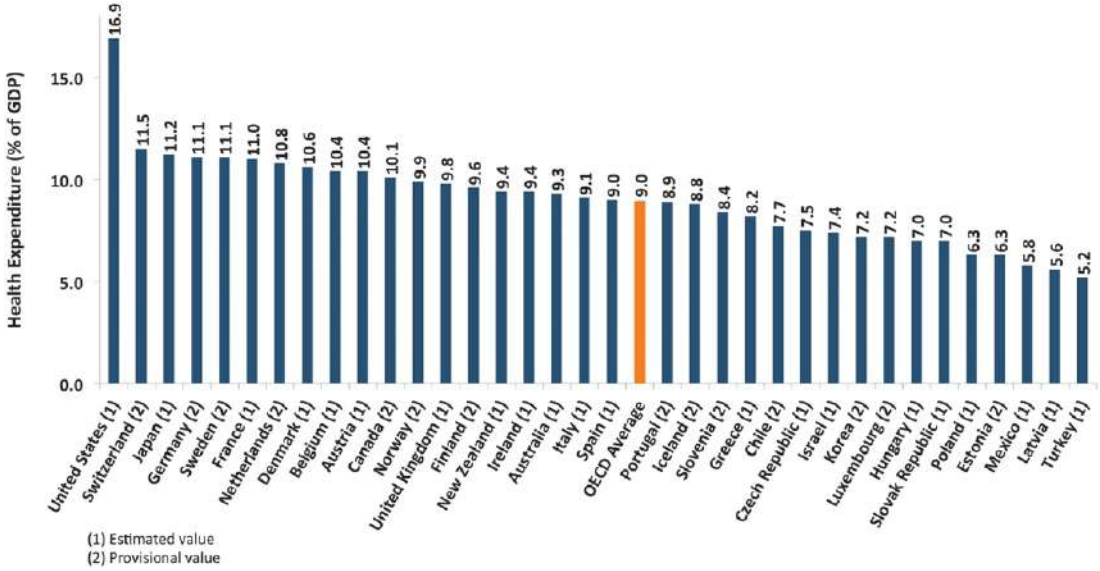

FIGURE 105.1. Health expenditure expressed as a percentage of gross domestic product (GDP) among the Organization for Economic Cooperation and Development (OECD) member countries. (Source: OECD Health Statistics 2016.)

Radiation oncology, in particular, has been labeled as an outlier in its contribution to health care spending and as such has often been targeted in policy discussions. Though Medicare's sustainable growth rate (SGR) formula for physician payment was permanently repealed in April 2015, radiation oncology was notable for exceeding its SGR target over the 2003 to 2009 period by nearly 300% expressed as a percentage of 2002 expenditure.[13,14] Between 2000 and 2009, the total Medicare expenditures for external beam radiation therapy (RT) increased from $256 million to $1.08 billion, mainly owing to reimbursement for intensity-modulated radiation therapy (IMRT).[15] Additionally, the code for IMRT demonstrated the fourth highest percent increase of all Medicare codes between 2010 and 2011.[16] Although there are likely multiple underlying causes for the field's disparate contributions to health care spending, including the employment of advanced technologies and the complex teams required for their safe and effective use, they were at least in part secondary to our primarily resource-based payment system, in which hospitals and clinics are reimbursed for discrete elements of care.[17] In this system, there is incentive to maximize billable units, such as by using advanced treatment modalities when not clinically indicated and by dividing dose over an increased number of fractions

—all facilitated by the technologic and complex nature of radiation oncology. This engenders further inefficiency as payers invest in the creation of guidelines to restrict payments and providers in turn require significant resources to guarantee appropriate billing. Although radiation oncology's role as a beneficiary of this system could be interpreted as cause for blame, it may also be seen as a charge for leadership by the field in health care reform discussions and in the development and use of modern methods for assessing quality of care and the comparative effectiveness of various treatment modalities.

RT plays a fundamental role in the curative and palliative treatment of cancer. Its continued value in cancer care will depend on the advancement of not only clinical evidence but also health services research. Toward this end, this chapter will provide an overview of the value proposition in health care as it relates to radiation oncology, with a focus on modern methods for assessing comparative and cost-effectiveness, including decision analysis and cost-effectiveness analysis. These techniques provide an alternative method for approaching clinical questions not readily answered with standard data analyses and aim to maximize the value of each health care dollar spent. Thus, understanding their employ will be of importance in the establishment of the value of RT in health policy discussions moving forward.

VALUE IN RADIATION ONCOLOGY

Remarkable advances in RT have been made in the past decades, allowing for extraordinary precision in treatment delivery and the attainment of dose escalation paired with decreased morbidity to surrounding normal tissues. In particular, IMRT achieves highly conformal dose distributions using computer-based treatment planning and delivery. The advent of stereotactic body radiation therapy (SBRT) has further provided the ability to deliver large doses of radiation with extreme precision using complex methods of patient immobilization and tumor localization, at times supplanting or offering an alternative definitive treatment to surgery in multiple disease sites. Coupled with RT, concomitant advances in oncologic surgery, medical oncology, and diagnostic testing have ushered in an era of personalized medicine, with the promise of more effective, tailored therapy with reduced toxicity. However, historically in cancer care, as in most fields of medicine, doing more for patients has not always equated to improved outcomes. Rising health care spending has not necessarily met with a proportional improvement in outcomes, with the US

ranking 13th out of 32 OECD countries in mortality from cancer per 100,000 persons in 2013, leading to calls for an increased focus on "high-value care" by policy makers, providers, professional societies, payers, and patient groups in the context of health care reform.[18–20] The value proposition in health care is not merely an exercise in cost containment, but it also strives toward a delivery system that incentivizes high-quality, evidence-based, and cost-effective treatments.[21] In this section, we will discuss the value proposition as it applies to the specialty of radiation oncology, describing current challenges and future directions in the advancement toward value-based care. Given the many stakeholders involved, it is important to note that the patient's voice is a highly valued component of value-based health care delivery. We therefore address these issues with a focus on the patient perspective of high-value care.

DEFINING VALUE IN RADIATION ONCOLOGY

In order to discuss value and the metrics used to measure it, we must first establish a mutual understanding of what is meant by the term *value*.[21] Outside of the world of health care, a "good value" can be described as a desirable product or service that can be purchased for a fair price.[22] Definitions of *value* from the Merriam-Webster dictionary center on the fair return in goods, services, or money for something exchanged, with clear parallels in the definition of value as it applies to medicine in terms of relative worth, cost, and quality of care.[23] These issues are reflected in the definitions of value as put forth by multiple governing bodies in health care from around the world, including the European Observatory on Health Systems and Policies, which describes value to include "patient preferences, quality, equity, efficiency, and product acceptability among a wide range of stakeholders," and the United Kingdom's National Institute for Health and Clinical Excellence (NICE), which defines value as "based on scientific value judgments, including clinical evaluation and an economic evaluation, and social value judgments, including considerations of efficiency and effectiveness."[24,25]

THE VALUE EQUATION

In order to unify the often-conflicting goals of the numerous stakeholders in health care delivery, Michael Porter and Elizabeth Olmsted Teisberg established a working definition of value in health care as health outcomes achieved per

dollar spent (value = outcomes/cost)[26,27] (Fig. 105.2). Outcomes in this equation are specified to include both near-term and longer-term health in order to cover the ultimate results of care and are noted to be condition-specific and multitiered, with adequate measurement of risk factors and baseline condition to enable for risk adjustment. Costs are defined to include the total costs of the complete cycle of care as opposed to individual services; as Porter notes, narrowly targeted cost containment efforts may not maximize value for the patient, with at times the best approach to increasing value being spending more on some services to reduce the need for others.[27] As both outcomes and costs are dependent on results as opposed to inputs, the challenge in value-based care is to shift focus away from the volume of services as is typical in traditional fee-for-service systems.

$$Value = \frac{Outcomes}{Cost}$$

FIGURE 105.2. The value equation as defined by Porter. (From Porter ME. What is value in health care? *N Engl J Med* 2010;363[26]:2477–2481. Copyright © 2010 Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society.)

As described by Porter, "Value should always be defined around the customer, and… the creation of value for patients should determine the rewards for all other actors in the system."[27] Recognizing the importance of the patient in the value proposition, Teckie and colleagues, in setting forth a framework for value in the field of radiation oncology, further expanded the numerator toward a more comprehensive definition of quality to include structure and process along with outcomes, in line with the classic Donabedian model[22,28] (Fig. 105.3). The Donabedian model is a conceptual framework for evaluating the quality of medical care, in which assessments are drawn from three dimensions of care: structure, process, and outcomes. Structure encompasses the context in which care is delivered, including the physical facility, human resources, organizational characteristics, and, of particular importance in radiation oncology, the equipment and technology. Process includes all acts of health care delivery, including interactions between the patient and physician and the technical delivery of care. In the Donabedian model, outcomes include not just objective measures, such as survival and functional status, but also subjective measures, such as quality of life and patient satisfaction. By this expanded framework (value = quality/cost), efforts to improve structure, process, and outcomes can all

be seen as strides toward improving value.

STRUCTURE

Donabedian defines structure as "concerned with such things as the adequacy of facilities and equipment; the qualifications of medical staff and their organization; the administrative structure and operations of programs and institutions providing care; fiscal organization and the like."[28] Radiation oncology, as a field, has become increasingly complex in recent years, with advances in treatment modalities involving multifaceted structural elements requiring multidisciplinary teams and state-of-the-art technology for adequate delivery. This complexity has allowed for wide variation in structural practices. Although at times this variation is indicated based on an individual patient's needs, critics have noted that deviations may not be associated with increased quality of care, with an opportunity for enhancement of value via standardization.[8] In 2010, the American Society for Radiation Oncology (ASTRO) convened a total of 12 multidisciplinary societies to develop a guidance document describing the elements necessary for the safe delivery of RT. This document, entitled "Safety is No Accident," was published in 2012 and sets forth specific requirements for a radiation oncology facility in terms of structure, personnel, and technical process.[29] In 2014, in an effort to expand adoption of these principles and further unify variations in care delivery, ASTRO launched the ASTRO Accreditation Program for Excellence (APEx), which provides impartial third-party review of practices' personnel, equipment, treatment planning, medical records, patient safety policies, and quality control/quality assessment activities against an established set of performance standards with focus on structure and process elements.[30] Radiation oncology practices (including freestanding single facilities, multisite organizations, and practices that are part of a hospital facility) that apply undergo a process of self-assessment and third-party review against a set of 16 established standards with accreditation granted for a 4-year cycle. The Commission on Cancer (COC) and the National Accreditation Program for Breast Centers (NAPBC) both accept APEx accreditation as fulfilling the RT component of their accreditation programs. Accreditation ideally demonstrates achievement of a threshold level of quality and safety to referring physicians, peers, prospective patients, regulatory agencies, and payers. However, it remains to be seen whether these various stakeholders value accreditation or understand what the evaluation

process involves. Moreover, without appropriate economic incentives to pursue and maintain accreditation, it is unclear how many radiation oncology practices will elect to participate. At the time of writing (April 1, 2017), 36 facilities have obtained APEx practice accreditation, though more are undergoing the painstaking application and accreditation process.[31]

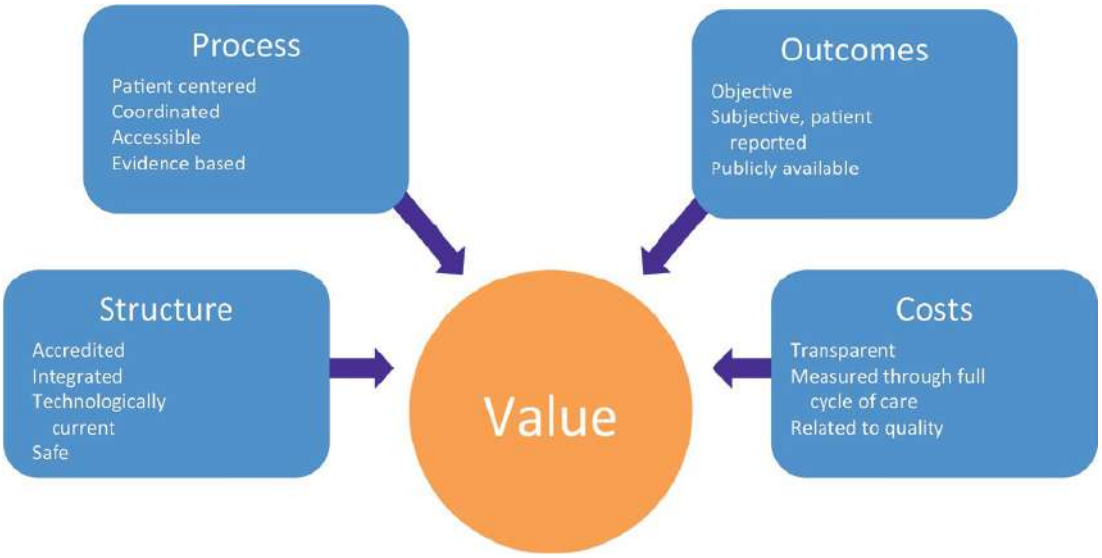

FIGURE 105.3. Components of value as defined by Teckie and colleagues, adapted from the Porter equation including elements from the Donabedian model. Integration of Care

In traditional organizational structure of medical care, delivery of care is siloed according to separate medical specialties or departments. However, in the past decades, there has been a shift toward medical practices centered around the patients' perspective of their medical condition integrated across the continuum of care; additionally falling under the realm of structure, this strategy has received attention for promoting high-value care.[32] In the integrated practice unit (IPU) model, clinical and nonclinical personnel deliver care according to evidence-based care pathways and treatment directives with responsibility for the full cycle of care, including inpatient, outpatient, rehabilitative care, and supporting services, such as nutrition and social work. Importantly, the team measures outcomes, costs, and processes for each patient with feedback mechanisms for refinement of care delivery, economic efficiency, and patient convenience, all relevant to the value proposition. This integration promotes

value not only by limiting overuse of tests and procedures but also by increasing use of patient-centered shared decision-making. Specific to oncology, the multidisciplinary clinic model centers a team of multiple specialties, including medical oncologists, radiation oncologists, radiologists, surgical oncologists, and pharmacists, around a specific tumor site.[33] While requiring significant reorganization and reassessment of traditional interactions between subspecialists and ancillary staff, adaptation of these models has been successful at many high-volume centers, with suggestion of both improved outcomes and reduced costs compared to similar community groups.[34,35] For instance, comparison of a consecutive sample of 104 melanoma patients with localized disease treated in the Michigan community with 104 blindly selected patients treated at the University of Michigan Multidisciplinary Melanoma Clinic during an identical time period matched for Breslow depth and melanoma body site indicated cost savings of $1,600 per patient for patients treated in the multidisciplinary clinic.[34] Via coordination between multiple specialties in complex decision-making, the multidisciplinary model may allow for higher attainment of benchmark measures for quality care in accordance with national practice guidelines. For example, a study of 609 patients with nonmetastatic breast cancer treated in the University of California, Los Angeles multidisciplinary breast clinic indicated increased appropriate referral rates for genetic testing for family history–based (62% vs. 92%) and overall (80% vs. 96%) indications after the inclusion of a genetic counselor in the multidisciplinary clinic.[36] Although limited primarily to observational studies because of difficulty in recruiting patients from practices in which the multidisciplinary model is not standard of care and confounded by parallel improvements in therapies, multiple studies have demonstrated potentially increased survival in patients treated in the multidisciplinary care setting.[37,38] Variations of care for complex patients and for those from underserved backgrounds or rural areas would ideally be minimized in the multidisciplinary setting.[39]

Alternative Payment Models

Newer coverage models, under the umbrella of the Donabedian definition of structure, offer an opportunity to incentivize value by linking reimbursement to quality metrics as well as encouraging patients to select high-value centers or providers. Traditional fee-for-service reimbursement, in linking payment to the volume of services provided, has been criticized for incentivizing overutilization

of care, often without proportionate benefit. The technologic focus of radiation oncology, in particular, allows for a surplus of discrete billable units per treatment episode.[17] Pure prospective payment, proposed as an alternative to the traditional fee-for-service payment, reimburses providers a fixed amount independent of the volume of services provided, with aim of promoting efficiency via incentivizing providers away from costly treatments.[40] However, by shifting the marginal cost of care—and associated financial risk—to providers, pure prospective payment may incentivize providers to select patients with lower risk of complications ("cherry picking"), or to provide less care than would best treat the patient ("stinting on care"), and to avoid treating patients whose optimal treatment involves costly interventions.[40] Thus, the ideal reimbursement system would fall in between these two extremes, with payment linked to value while still allowing for evenly distributed access to high-quality care.[41]

Unfortunately, even with an established definition of value, deriving applicable metrics for quantifying value in oncology remains elusive. Although there are widely accepted measurements of outcomes (e.g., prostate-specific antigen progression-free survival in prostate cancer) and toxicities associated with treatment (e.g., the Common Terminology Criteria for Adverse Events [CTCAE]), adequately assessing these metrics may require multiple years of follow-up, impractical for adaptation to a reasonable payment cycle. Likewise, it is often difficult to assess whether adverse effects are the result of surgery, chemotherapy, radiation, or something unrelated to treatment.[17] As noted before, linking payment to outcomes metrics without accurate risk adjustment algorithms could also discourage providers from treating sicker patients. In the field of medical oncology, the American Society of Clinical Oncology (ASCO), the European Society for Medical Oncology (ESMO), and the National Comprehensive Cancer Network (NCCN) have each put forth frameworks for the evaluation of value, with notable overlap in their attempts to quantify the gradients of benefit associated with drug regimens, toxicity, and quality of life, though formal cost-effectiveness analyses are deemphasized.[42] Radiation oncology has been late in the development of its own value metrics, with many measures of quality advanced through more broadly focused organizations. In parallel with the efforts of the American Medical Association's Physicians Consortium for Performance Improvement and other similar organizations to develop, implement, and validate quality metrics, the National Quality Forum (NQF) was funded by Congress with aim of evaluating quality measures for

transmission to the CMS for inclusion in eventual value-based penalties and bonuses. ASTRO has endeavored to establish a series of best practice guidelines, based on evidence and expert review, as well as determining a list of five interventions to only be used in specific situations because of proven lack of value as part of the American Board of Internal Medicine Foundation's *Choosing Wisely* initiative[43] (Fig. 105.4). Although admirable steps toward the value proposition, early quality indicators have been criticized for representing little more than enforcers of current standard of care, with persistence of many low-bar measures such as documentation of stage of disease or presence of normal tissue dose constraints. These measures are further debilitated by minimal correlation with reimbursement, without tracking by payers or accrediting bodies, thus effectively having limited impact on patients or society with call to focus metrics on true gaps in care.[44] Furthermore, care must be taken to ensure adherence to guidelines does not limit patients whose unique clinical situations call for individualized care or slow clinically meaningful advancement if innovation outpaces updates to guidelines.[17]

1	Don't initiate whole breast radiotherapy as a part of breast conservation therapy in women age ≥50 with early stage invasive breast cancer without considering shorter treatment schedules.
2	Don't initiate management of low-risk prostate cancer without discussing active surveillance.
3	Don't routinely use extended fractionation schemes (>10 fractions) for palliation of bone metastases.
4	Don't routinely recommend proton beam therapy for prostate cancer outside of a prospective clinical trial or registry.
5	Don't routinely use intensity modulated radiotherapy (IMRT) to deliver whole breast radiotherapy as part of breast conservation therapy.

FIGURE 105.4. The American Society for Radiation Oncology's list of five radiation oncology–specific treatments that are commonly ordered but may not always be appropriate as part of the national American Board of Internal Medicine Foundation's Choosing Wisely campaign. With clear quality metrics still under development, payment reform thus far has mostly occurred in the form of narrow or tiered networks offered by health plans, often based on price or provider relationships with the larger market-dominant entity.[22] However, several alternative payment schemes, such as population-based shared savings arrangements, clinical pathways, and bundles of

care and episodes of care payments, have been examined in oncology, accelerated by their inclusion in accountable care organizations (ACOs).[17] In population-based shared savings arrangements, providers are reimbursed via similar fee schedules though are rewarded when their fee-for-service payments are below a predefined target, often via the provider receiving a percentage of the savings. These risk-sharing arrangements have been implemented as elements of oncology-focused ACOs with report of decreased spending growth and high scores on quality metrics. In the clinical pathway approach, best practices are established for each clinical scenario with providers rewarded for adherence with higher fee-for-service payments, bonuses, or other incentives. Providers are expected to adhere to pathways for 60% to 80% scenarios to allow for individualization of care. This has demonstrated success in reducing treatment variation, drug trend, and hospitalizations in medical oncology; however, its application has been criticized as ill-suited to radiation oncology given the field's anatomic and technologic focus, which allows for potentially larger number of branch points in the decision-making process with a greater role for patient preference in the selection of treatment modality. Lastly, bundled or episodic payment has been described as a middle ground between fee-for-service and pure prospective payment, in which providers are reimbursed upfront based on the expected costs for a clinically defined episode of care thereby incentivizing efficient use of resources. CMS has devoted significant focus to experiments in episodic payment systems, though with focus in oncology primarily on comprehensive bundles that include medical, surgical, and radiation services as well as the complications of care. Multiple companies have experimented with specialty-specific episodic bundles in radiation oncology with reported improvements in administrative efficiencies, though in this model attention to quality measurement will be necessary to ensure implementation actually yields higher-value care without incentivizing providers away from high-risk populations. Likewise, to properly incentivize high-value care, bundled payment schemes will likely require context-specific models for different clinical scenarios as well as cost calculations based on updated RT codes that more accurately reflect current clinical practice.[45]

In July 2015, Turning the Tide Against Cancer, an initiative convened by the American Association for Cancer Research, the Personalized Medicine Coalition, and Feinstein Kean Healthcare to identify policy solutions that will sustain medical innovation while addressing the issue of rising health care costs, held a roundtable consisting of a multidisciplinary group of stakeholders to

review key considerations for oncology-focused alternative payment models.[46,47] Noting reliance on annually calculated spending benchmarks and only intermittently updated episode-of-care definitions, the panel highlighted the importance of having alternative payment models keep pace with emerging science via incentivizing adoption of innovative medicine and technologies that have the potential to improve patient outcomes and make health care more efficient. Toward this end, it stressed the avoidance of unintended barriers to patient access to novel therapies, particularly those that may be expensive in the short term but that may result in savings in the long term. Given the trend toward more personalized medicine, the roundtable acknowledged that a critical step in this is the coverage of diagnostics that will enable identification of patients that respond best to targeted therapies and thus avoiding the cost of treating patients who will not benefit or will be harmed by adverse effects or delays in initiating more effective treatments. Likewise, the participants suggested that alternative payment models incentivize the physician's ability to appropriately tailor treatment to an individual patient's needs and preferences, furthermore noting that there is no one-size-fits-all model, with the impact of a payment system at times dependent on geographic region, practice characteristics, setting, and other factors. Finally, the panel indicated that alternative payment models should include mechanisms to encourage participation in clinical trials and ongoing postmarket clinical research. Given the potential for models to incentivize patients toward rigorous care protocols or clinical pathways, the panel indicated that care should be taken to make it financially feasible for practices to enroll patients and participate in clinical trials to support continued development of cancer treatment.

PROCESS

Process includes all components of health care delivery, including both the technical processes in how health care is delivered as well as the interpersonal processes that describe the manner in which care is delivered, with focus on patient-centered, accessible, and coordinated care.[28] As defined by Donabedian, process can be measured via review of medical records, interviews with patients and providers, and direct observation of health care visits with measurement intrinsically tied to metrics of quality. In a technologically focused specialty such as radiation oncology, the measurement of process goes beyond those components immediately noticeable by patients, such as the quality of the

patient–physician interaction and the timeliness of care, to include less tangible components, such as physician expertise and medical physics quality assurance oversight for treatment planning and delivery.[22] Thus, structural efforts to establish patient-centered and safety-focused process standards, such as the previously mentioned APEx accreditation program, are directly linked with process improvement. The Radiation Therapy Oncology Group (RTOG) cooperative group clinical trials, which specify treatment planning specifics such as contouring guidelines, dose constraints, and planning techniques as enforced by centralized review processes, are another example of process standardization, with evidence suggesting protocol deviations are associated with poorer outcomes.[22] In this light, ASTRO's previously mentioned best practice initiative, which establishes clinical practice guidelines based on the RAND/University of California Los Angeles appropriateness criteria, looks beyond defining guidelines to support the indication of radiation to include evidence-based and expert panel–devised assessment of the technical processes underlying the delivery of therapy.[48]

Physician Expertise

Regarding physician expertise, similar to surgical procedures, multiple studies have described the presence of a learning curve in the application of advanced radiation oncology techniques, including IMRT volume delineation, technical IMRT delivery, and brachytherapy procedures. For instance, in a single-institution study from the Department of Radiation Oncology at CancerCare Manitoba, the number of prostate cancer patients treated with I 125 interstitial implant with D90 < 140 Gy, a metric for the dosimetric quality of the brachytherapy implant, which correlates with decreased biochemical relapse-free survival, declined with increasing experience at the program, with brachytherapy team experience found to be a more important predictive factor of implant quality than size of the prostate.[49] Furthermore, with regard to IMRT, a population-based analysis by Boero and colleagues identified radiation providers from Medicare claims of 6,212 Medicare beneficiaries with head and neck cancer treated between 2000 and 2009 and found that among patients undergoing IMRT, those treated by higher-volume providers had increased survival compared with those treated by lower-volume providers. Specifically, for every five additional patients treated per provider per year, the risk of all-cause mortality decreased by 21%.[50] Patients treated by higher-volume physicians additionally had decreased head and neck cancer–specific mortality and

decreased risk of aspiration pneumonia. Of note, no significant relationship between provider volume and patient survival or toxicity was observed among patients treated with conventional RT. Such results highlight the importance of improved training or novel educational resources for practicing physicians, with focus on skills-based education, in the establishment of value in radiation oncology, particularly as technology continues to advance at a rapid rate. Other advancements, such as in semiautomated target delineation, knowledge-based planning, and telemedicine, may also assist toward this end without necessitating physician or patient travel.

OUTCOMES

Outcomes span all of the effects of health care on patients or populations. These include objective outcomes providers and payers have traditionally assessed, such as survival, disease control, functional status, disease recurrence, and complications of treatment. Subjective outcomes, such as patient-reported outcomes, psychosocial ramifications of disease or treatment, ability to maintain employment status, and patient's understanding of disease, although considered by some as more difficult to assess via traditional scientific methods, are also included and hold equal import in the value discussion. Of the components in the value equation, the medical community is best at assessing objective outcomes, with wide support for furthering our understanding of the objective impact of particular interventions via high-level clinical research. However, given the expense of such research, there is a need for additional methods to assess objective outcomes at the population level in real-world settings, with multiple specialty-based and multidisciplinary real-time observation registries under development to meet this need.[51] The advancement of accurate methods for risk stratification is of particular importance if these outcomes are to be reported on an individual provider level to enhance patient selection of providers or if they are to be connected with reimbursement. This consideration is also relevant for comparisons between treatment modalities, with wider use of multiple research methods for comparative effectiveness in oncology; some of these methods will be detailed in this chapter's section on research methods.

The Outcome Measures Hierarchy

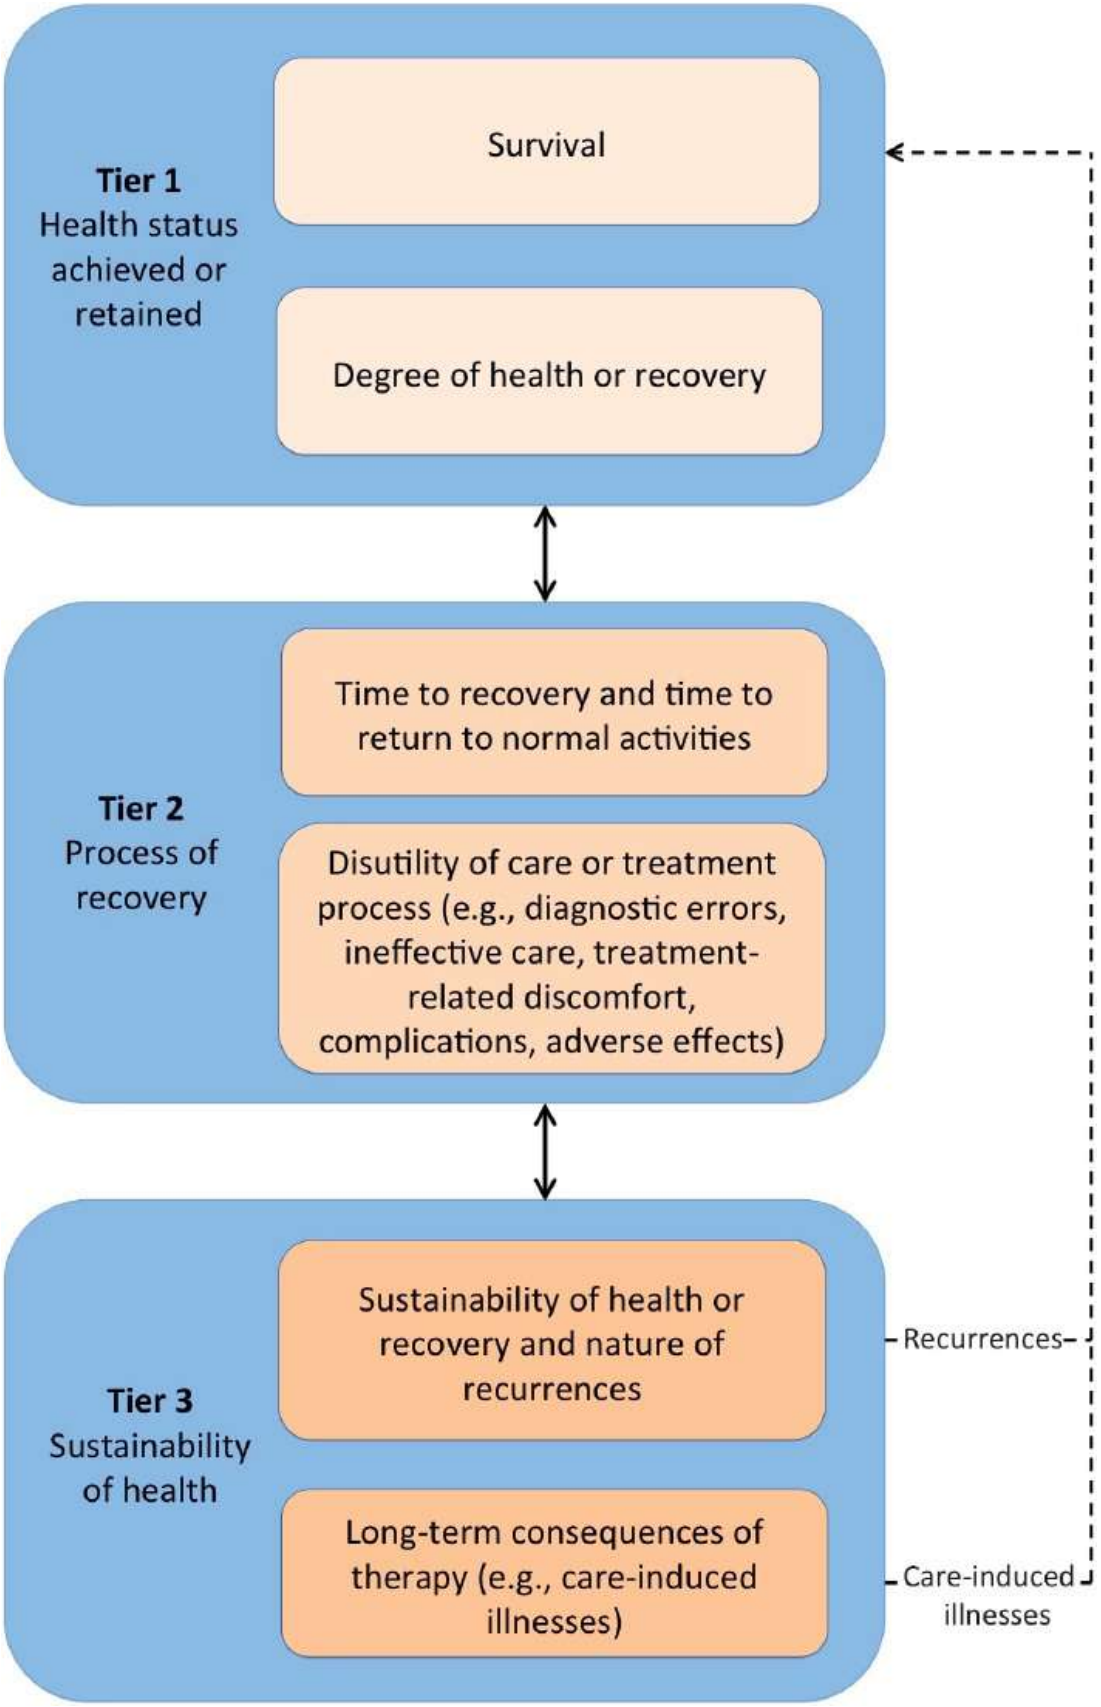
As described by Porter, the outcomes for any medical condition can be arranged in a three-tiered hierarchy[27] (Fig. 105.5). Each tier includes two levels, each

described by one or more distinct outcomes dimensions, with success for each dimension measured through specific metrics. In this hierarchy, Tier 1 represents the health status achieved or retained, and it includes levels of survival and degree of health or recovery. Specific to cancer care, common metrics in Tier 1 include 5-year overall survival and functional status. Tier 2 relates to the recovery process and includes levels of time required to achieve recovery and disutility of care. Common metrics specific to cancer care include time to remission and rates of adverse effects related to the treatment process. Lastly, Tier 3 describes the sustainability of health and includes the levels of recurrence of the original disease and associated complications as well as new health issues caused by treatment. Common metrics in cancer include cancer recurrence and incidence of second primary cancers. In this hierarchy schema, Tier 1 is generally considered the most important with lower-tier outcomes dependent on success at higher tiers. However, trade-offs between tiers may exist—such as sacrificing survival benefit in favor of a less morbid treatment modality—and mapping these trade-offs is an important part in furthering innovation in care.

Patient-Reported Outcomes

The study of subjective outcomes, by comparison, is less mature in its development than traditional clinical research in radiation oncology. While initially falling under the purview of dedicated health services research, patient-reported outcomes are increasingly included in clinical research in oncology, in part spearheaded by the RTOG, which has developed a model for the inclusion of patient-reported outcomes as endpoints in clinical trials.[52] The U.S. Food and Drug Administration (FDA) provides a broad definition of patient-reported outcomes as “any report of the status of a patient’s health condition that comes directly from the patient, without interpretation of the patient’s response by a clinician or anyone else.”[53] With respect to their inclusion in clinical trials, however, patient-reported outcomes typically include health-related quality of life (HRQOL) instruments, with hundreds of validated generic and disease-specific instruments available and radiation oncology-specific instruments currently in development.[54,55] For instance, the National Cancer Institute (NCI) developed a patient-reported outcome measurement system for use in cancer clinical trials, named the Patient-Reported Outcomes version of the Common Terminology Criteria for Adverse Events (PRO-CTCAE). Designed to be used as a companion to the CTCAE, the PRO-CTCAE includes an item library of 124 items representing 78 symptomatic toxicities drawn from the CTCAE and has

been tested in a consortium of academic- and community-based cancer treatment sites in the NCI-sponsored clinical trial network.[56] Many challenges exist regarding the optimal application of such instruments, including refining the validation process, establishing the clinical meaningfulness of their results, and deciding how to handle missing data; further research to understand their utility in drawing conclusions in the trial setting, such as with regard to dose-limiting toxicity and overall/comparable tolerability, is necessary as well. Nevertheless, these tools offer an opportunity to inform translational and comparative effectiveness research, health care technology assessment, and quality assurance, as well as to quantify value from the patient perspective. Another patient-reported outcome commonly measured is patient satisfaction, which refers to the patient's perception of the quality of care received.[57] Although limited by patients' relative inability to assess the technical quality of their care and inevitable dependence on patients' initial expectations, patient satisfaction remains an important part of the patient experience, and its inclusion in the value proposition reflects the greater shift in mindset in health care toward patient-centered care.



Tier 1
Health status achieved or retained
Survival
Degree of health or recovery
Tier 2
Process of recovery
Time to recovery and time to return to normal activities
Disutility of care or treatment process (e.g., diagnostic errors, ineffective care, treatment-related discomfort, complications, adverse effects)
Tier 3
Sustainability of health
Sustainability of health or recovery and nature of recurrences
Long-term consequences of therapy (e.g., care-induced illnesses)
Recurrences
Care-induced illnesses

FIGURE 105.5. The outcome measures hierarchy as defined by Porter. (From Porter ME. What is value in health care? *N Engl J Med* 2010;363[26]:2477–2481. Copyright © 2010 Massachusetts Medical Society. Adapted with permission from Massachusetts Medical Society.)

VALUE: A PATIENT-CENTERED APPROACH

Paralleling the rise of value-based care, patient-centered cancer care has received increasing focus in recent decades, as advocated by the Institute of Medicine (IOM), patient groups, and professional societies.[58] Patient-centered care, as defined by the Picker Institute, describes care that address multiple dimensions of patient care including patient preference, emotional support, physical comfort, information and communication needs, continuity and transition, care coordination, involvement of family and friends, and access to care.[59] Patient-centered care, while inherently aligned with value-based care via a shared focus on high-quality care, has distinct attributes not typically included in discussions of value, such as patient experience and preference measures as well as conceptions of cost that are payer–as opposed to patient-focused[20] (Fig. 105.6). Patients themselves appear to intuit these contradictions: in a series of focus groups, interviews, and online surveys of health care consumers undertaken by the American Institutes for Research, respondents in general were unfamiliar with concepts related to evidence-based care, believing medical guidelines to reflect an “inflexible, bargain-basement approach” to treating unique individual patients.[60] Thus, for the transition to value-based care to be accepted and effective on a population level, patients—as recipients, codecision-makers, and cofinanciers of this care—will need to be included in the discussion, with patient-centered outcomes, perspectives, and preferences explicitly incorporated into the definitions and metrics of quality and cost.[61]

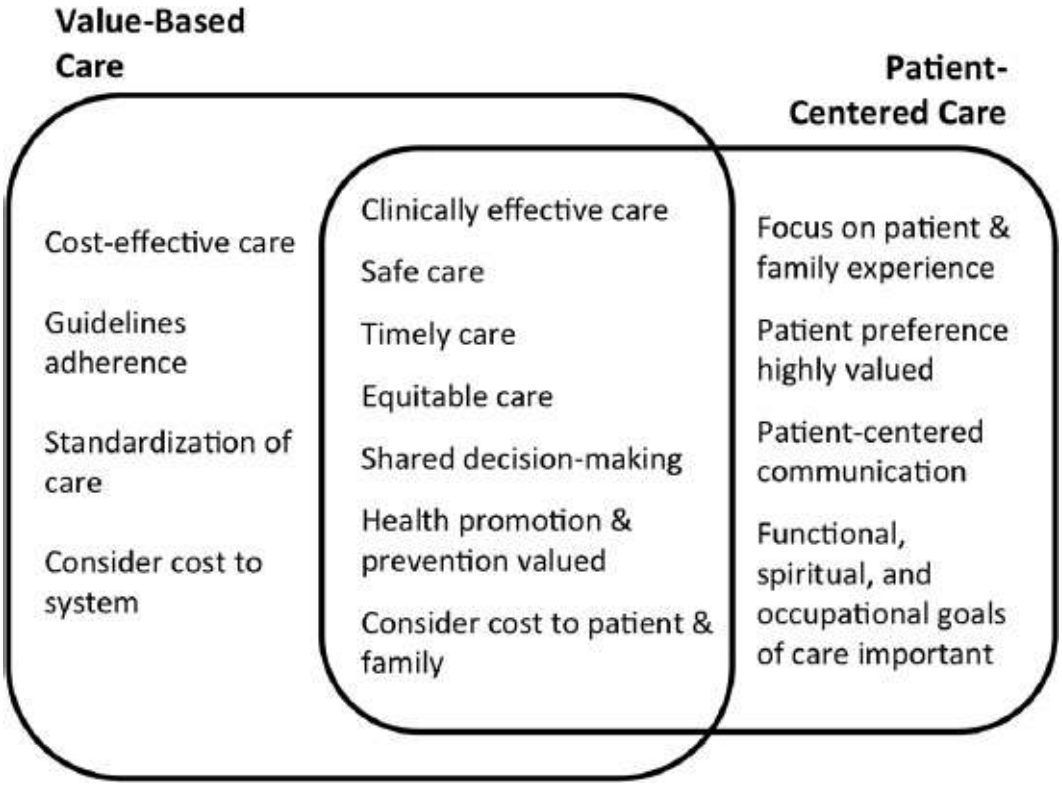


FIGURE 105.6. Attributes of value-based care and patient-centered care. (Adapted by permission from Springer: Tseng EK, Hicks LK. Value based care and patient-centered care: divergent or complementary? *Curr Hematol Malig Rep* 2016;11[4]:303–310. Copyright © 2016 Springer Science+Business Media New York.)

Aligning Patient-Centered and Value-Based Care

Challenging the alignment of patient-centered and value-based care is the relative inability to assess cost in health care. Under the traditional fee-for-service–based system, although providers and administrators may have knowledge of individual billing charges and the direct costs of running a radiation oncology clinic, it is more difficult to calculate the total cost of care administered at a patient level. Furthermore, in our free market system, the charge for the same procedure can vary widely between providers, with no consistent correlation with the quality or outcome of care.[22] In comparison with how their purchasing decisions are made outside of health care, patients are left to make important health care decisions with a relative deficiency of information, unable to assess the real costs or quality of care offered by different providers; this is exacerbated in a system where the majority of patients are insured by a third party and bear only a small fraction of the total cost of care. Patients thus cannot function as “utility maximizers,” choosing products that provide the highest utility for the lowest dollar. This discrepancy in effect

removes the market pressure toward high-value care, in part contributing to increased cost, over- and underutilization, and decreased quality in health care. In effort to recreate this market pressure on patients, health plans have responded by increasing cost sharing via higher deductibles and copays. This practice, however, can counteract the achievement of value by preventing patients from pursuing necessary, high-cost sharing treatments, ultimately worsening patients' health and increasing the overall cost of care.

The Financial Burden of Cancer Care

Oncology care, in particular, has been presumed to be relatively shielded from the downward pressure of cost on demand, though evidence suggests that even cancer patients consider treatment cost in their decision-making, suggesting that the cost of care should receive greater emphasis in assessments of value from a patient perspective.[62] Multiple studies have reinforced the detrimental effect that out-of-pocket costs have on patients' access to medical care as well as ability to pay for other nonmedical life necessities, with a report from the NCI indicating between 33% and 80% of cancer patients depleting their savings to finance medical expenses.[22,63] In a population-based study from Western Washington State, a cancer diagnosis was associated with a 2.65-times greater likelihood of declaring personal bankruptcy. Upon further analysis, cancer patients declaring personal bankruptcy additionally demonstrated a 79% greater mortality risk than those who did not.[64] This relationship between extreme financial distress and greater mortality risk is likely multifactorial, partly explained by overall poorer well-being, impaired health-related quality of life, or subpar quality of care.[65] Likely, further exacerbating the patient's sense of well-being, the burden of financial hardship for cancer care is not borne by the patient alone, with between 2% and 34% of patients borrowing money from friends or family to pay for care.[63] Unfortunately, as multiple forms of cancer are currently incurable with many patients eventually succumbing to disease, at least a portion of these expenses are likely exhausted on futile care at the end of life. Although the administration of chemotherapy in patients in their last weeks of life has been well documented—indeed, chemotherapy administered the last 2 weeks of life is an emerging quality indicator employed by the ASCO Quality Oncology Practice Initiative—evidence indicates that the field of radiation oncology is not immune to potential contributions to futile care, with a population-based study of Surveillance, Epidemiology, and End Results (SEER) Medicare and Texas Cancer Registry Medicare databases indicating an increase in use of advanced

RT techniques in patients in the last 30 days of life from 2000 to 2009, with the proportion of patients treated with IMRT increasing from 0% to 6.2% and with stereotactic radiosurgery from 0% to 5.0%.[66–68] Although further research is necessary to determine whether these shifts in practice patterns improve palliative outcomes and to better identify patients that may benefit from advanced techniques in the palliative setting, consideration should be given toward the potential impact of the cost of these therapies on patients and their families.

Financial Toxicity

Building evidence describing the deleterious effect of the cost of cancer care on patient well-being has led to a push for the inclusion of "financial toxicity," described as the harmful personal financial burden faced by patients receiving cancer treatment, in physicians' discussions with patients of the side effects associated with a particular treatment, with both the IOM and ASCO categorizing cost of care discussions as an essential component of high-quality care.[26,69–71] Clearly, numerous potential obstacles currently preclude effective cost of care discussions between patients and physicians, including uncertainty about the appropriateness of the topic and inability to accurately assess the cost of care.[72] Comprehensive intervention will likely require further research on the measurement of the material, psychological, and behavioral effects of financial toxicity and the identification of potential modifiable risk factors as well as further inclusion of these metrics at a policy level.[73] Composite scores using summary measures of multiple components of financial hardship, such as the Comprehensive Score for Financial Toxicity (COST) and Personal Financial Wellness Scale (PFW Scale), have been employed in clinical studies as a patient-reported outcome though results can be difficult to interpret with unclear application to the general population.[63]

Decisional Regret

As previously discussed, the effective measurement of more subjective outcomes in radiation oncology remains an area in need further research, and their greater inclusion in assessments of value is a critical challenge in the alignment of value-based and patient-centered care.[20] Validated metrics of patient-reported outcomes, in which patients report directly on perceptions of their own health, have been developed and are now more broadly included in clinical trials, providing essential patient-centered data on the impact of interventions;

likewise, development of validated instruments to assess patient-reported experience measures, or their perception of their experience with health care delivery, is underway. An intriguing example of a validated and well-studied patient-reported outcome with applications to radiation oncology is decisional regret, defined as the negative emotion experienced when we suspect that an alternative course of action would have resulted in a better outcome.[74] Cancer-related decision-making is complex, requiring an understanding of both the medical and psychosocial impacts of treatment in the context of one's personal values and beliefs; given the complexity and multifactorial nature of these choices, decisional regret offers a broad measure of a patient's treatment experience and quality of life and has been shown to be a more sensitive outcome than patient satisfaction in certain settings. In prostate cancer, multiple factors have been associated with treatment regret, including poor health-related and global posttreatment quality of life. Interestingly, specific treatment modalities have also been associated with increased posttreatment regret. For example, at the University of California, Los Angeles, survey of patients with localized prostate cancer treated with IMRT, SBRT, or high dose rate (HDR) brachytherapy suggested that patients treated with SBRT experienced significantly less treatment regret compared with patients treated with IMRT or HDR.[75] Thus, when comparing modalities—particularly with equivalent long-term survival and comparable toxicity profiles—further understanding of the patient experience is informative in assessing the value of specific medical interventions.

VALUE IN RADIATION ONCOLOGY: CONCLUSIONS

Regardless of the volume of ongoing debate surrounding health care reform, in many ways, the transition to some form of value-based care is inevitable. Enacted in April 2015, the Medicare Access and CHIP Reauthorization Act (MACRA) repealed the SGR to establish the Quality Payment Program to encourage physician participation in alternative payment models that utilize value-based payment; in response to unsustainable rising health care costs, multiple private payers have begun experimenting with alternative payment models already.[17,76] This transition offers an opportunity to serve patients, providers, society, and shareholders alike through better alignment of incentives among stakeholders and reduced administrative costs. Whatever method of payment reform ultimately takes ahold will arise from iterative experimentation;

radiation oncologists and the patients they treat will be best served by taking an active role in this collaborative process, both via participation in health care advocacy and contribution to novel health services research.

HEALTH SERVICES RESEARCH: RESEARCH METHODS

The field of health services research, often referred to as outcomes research, refers to the study of access to care, costs of care, and quality of care. Access to care concerns factors that expedite or hinder the use of medical services. Costs of care include payments by insurers and patients for medical services as well as the cost of lost productivity because of time away from work and decreased wages. As previously discussed, quality of medical care incorporates elements of structure, process, and outcomes. Although there are several methods of analysis relevant to health services research, decision analysis and cost-effectiveness analysis, in particular, are standard techniques used to evaluate and compare medical therapies. As the costs of oncologic care rise, it is vital to evaluate the cost-effectiveness of RT. Cost-effectiveness analyses assess the costs relative to health outcomes for a particular medical intervention. This chapter section will explain the theoretical aspects of decision and cost-effectiveness analyses.

DECISION ANALYSIS

Although randomized clinical trials are the “gold standard” for gathering evidence, they have several limitations.[77] For instance, randomized trials often necessitate lengthy follow-up before showing differences between various treatments, and their results may not be available until the therapy itself is out of date. In addition, randomized trials report the best treatment for the “average person”; patient preferences are not considered.[78]

Decision analysis uses a set of mathematical tools designed to determine the most favorable outcome with regard to a particular endpoint (such as overall survival or time without recurrence) for individuals with a given starting situation under many different sets of circumstances, using existing data or assumptions regarding the effectiveness and toxicities of treatments. Decision models can help outline the trade-offs for different treatments in clinical situations when no good evidence is available.

METHODOLOGY OF DECISION ANALYSIS

To make a model, a decision tree is created to symbolize the results of clinical choices. The model requires making simplifying assumptions while still being sufficiently complex to correctly illustrate the important aspects of the decision. Figure 105.7 depicts a scenario in which a patient is faced with the treatment dilemma of whether or not to undergo RT for illness X.[78] Decision nodes are signified by squares in the decision tree, chance nodes by circles, and terminal nodes by triangles.

Subsequent to choosing a treatment, there is a chance node after which all potential events are shown as branches. The probability of a particular outcome following a chance node is determined from data from the literature or expert opinion. The probabilities of events at each chance node must add to 1. In Figure 105.7, if the patient with illness X chooses RT, he has a 90% chance of surviving the treatment and a 10% chance of dying from the treatment. If the patient survives the treatment, he then has an 80% chance of remaining alive and a 20% chance of dying. If the patient forgoes treatment, he has a 70% chance of living and a 30% chance of dying.

The terminal nodes depict the final outcomes states of each pathway. Next to each of the terminal nodes is a value associated with that state. In our example, the only two outcome states are living and dying. Being alive and dead are associated with values of 1 and 0, respectively. When calculating the expected survival rate for RT, we see that if a patient survives treatment, he has an 80% chance of living (outcome of 1) and a 20% chance of dying (outcome of 0). The value at this chance node is calculated by multiplying the probability of the outcome with the associated value, resulting in a value of 0.80. We then substitute the value of 0.80 as the value associated with surviving treatment and multiply this value by its probability of 0.90. The resulting value (0.72) is then combined with that of dying from treatment (outcome of 0 with probability of 0.10), for an expected value of 0.72. The expected survival rate for no treatment is calculated by multiplying the likelihood of living (0.70) with its outcome of 1 and combining that to the product of the likelihood of dying (0.30) and its outcome of 0, to obtain a value of 0.70.

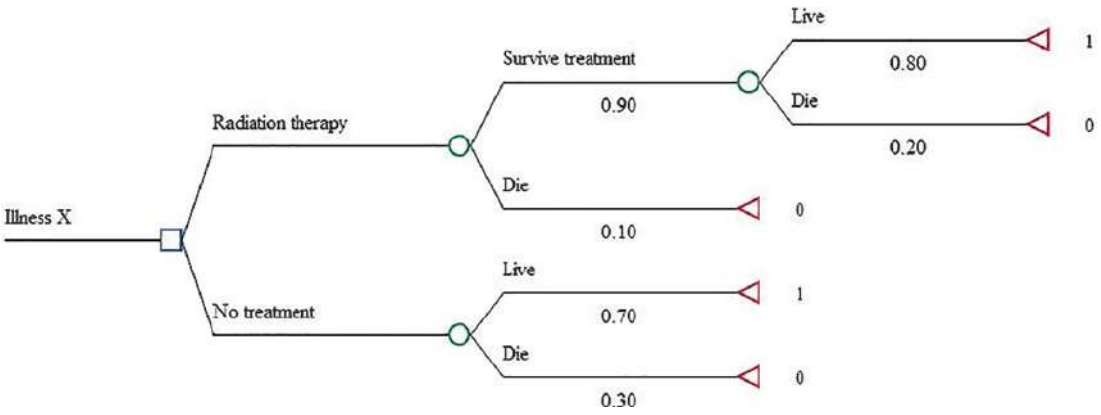

FIGURE 105.7. Decision tree of a patient with illness X. (Adapted from Sher DJ, Punglia RS. Decision analysis and cost-effectiveness analysis for comparative effectiveness research: a primer. *Semin Radiat Oncol* 2014;24[1]:14–24. Copyright © 2014 Elsevier. With permission.)

OUTCOME VALUES

In our simple example, the outcome value was the likelihood of survival with or without treatment for illness X. However, decision analyses can also model values associated with different health states. A utility is an econometric construct that describes how an individual values a given health state versus death (0) and perfect health (1).[79] The worse the health state, the worse the utility. For instance, experiencing a rectal toxicity may be associated with a utility of 0.7, and living with distant metastasis may be associated with a utility of 0.6. This ability to describe utilities for different outcomes states allows modelers to incorporate side effects of treatments into their model, an important consideration given that many cancer treatments affect a patient's quality of life. The benefit associated with various cancer treatments depends on the trade-offs between the fear and consequences of recurrence versus the inconvenience and potential toxicity of treatment.

Utilities are different from more familiar, descriptive quality of life measures as they reflect how a respondent values a state under conditions of *uncertainty*. Although there are several techniques for assessing utilities, the most firmly grounded in expected utility theory is the standard gamble. The standard gamble assesses the utility for a health state by asking how high a risk of death a participant would accept to improve it (Fig. 105.8). The respondent is asked to choose between a certain life in an intermediate health state and a gamble between optimal health and immediate death. The probabilities in the gamble are varied systematically until the respondent feels that the two choices (life in an intermediate health state and the gamble) are equally desirable. At the "point of

indifference," the respondent's utility for the health state is given by the probability of optimal health in the gamble. The utility of the health state is given by the probability of perfect health in the gamble such that the respondent is indifferent between the gamble and the certain intermediate outcome.

Utilities can also be used to calculate quality-adjusted life-years (QALYs), an index of survival that is adjusted to account for the patient's quality of life during a specific period. The quality-adjusted life-year (QALY) is the standard effectiveness measure.[80] A QALY is determined by multiplying the time spent in a certain health state with the utility associated with that state. For example, 2 years of time spent in a state whose utility is 0.5 would be the equivalent of 1 QALY.

SENSITIVITY ANALYSIS

The published literature and expert opinion provide the basis for probabilities at the nodes of a decision tree. However, these estimates are often quite uncertain. Sensitivity analyses are therefore usually a critical part of decision models. Sensitivity analyses vary a certain parameter (e.g., the probability of recurrence of prostate cancer) over the entire plausible range of its values and then study the effect of varying the parameter on the outcome. Sensitivity analyses provide a measure of the robustness of a conclusion in a similar way to confidence intervals and *P* values in biostatistics. They may also increase the level of confidence by confirming the lack of significant dependence of an outcome on a certain transition parameter. In addition, sensitivity analyses may also identify areas where further research may be valuable by revealing dependence of an outcome measure on the variable studied.[78] One-way sensitivity analyses provide threshold values. Two-way and three-way sensitivity analyses systematically vary two to three parameters simultaneously; the outcomes for each combination of variables can then be assessed.

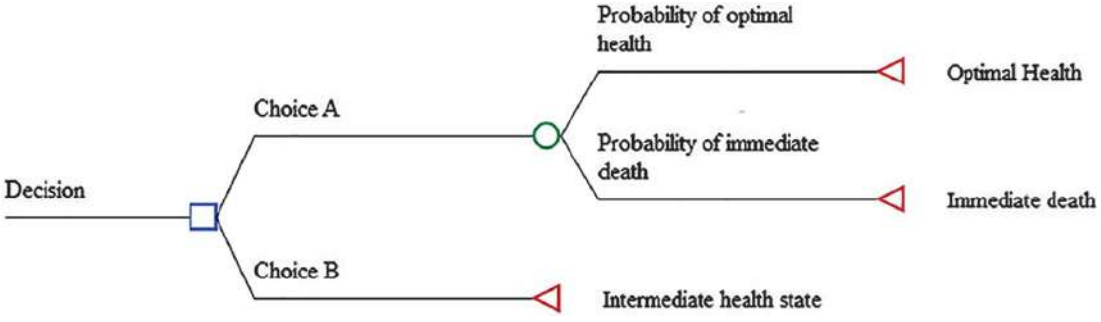

FIGURE 105.8. The standard gamble assesses the utility for a health state by asking

how high a risk of death a participant would accept to improve it.

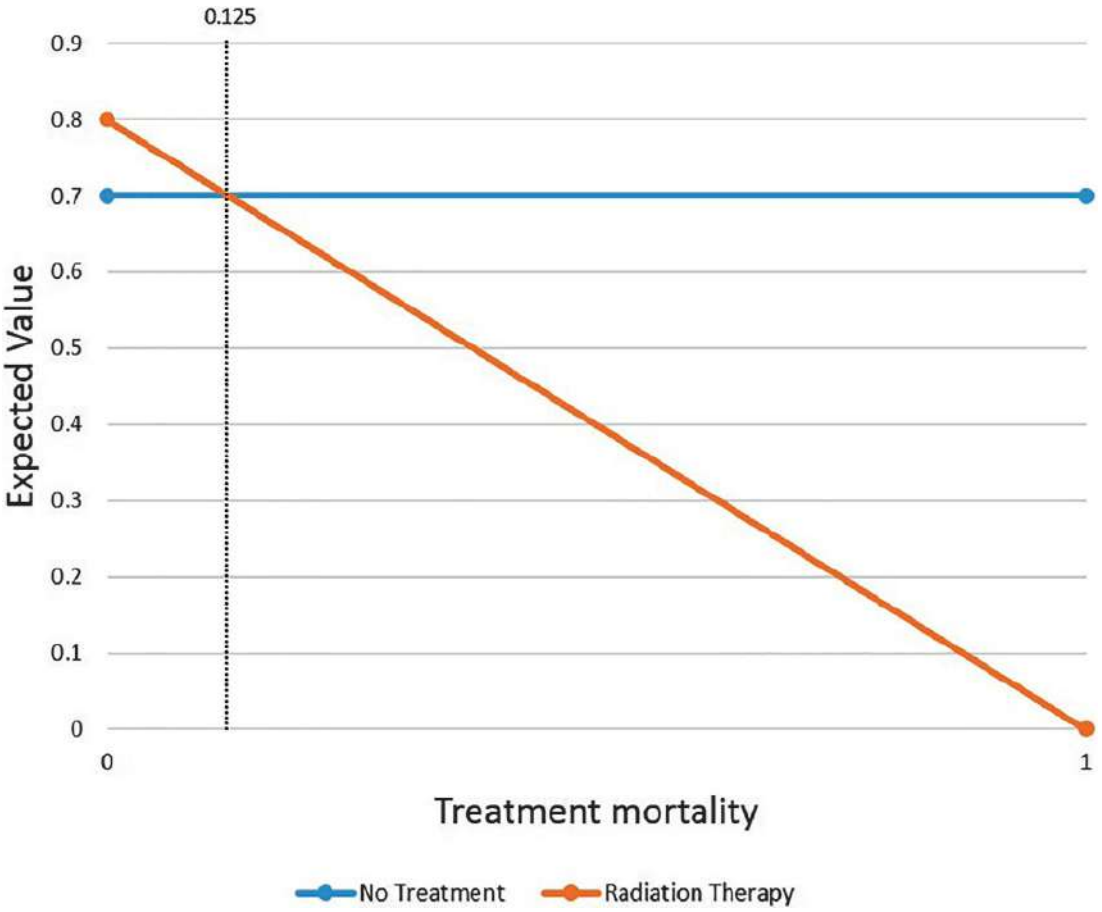

FIGURE 105.9. Sensitivity analysis of mortality from treatment for illness X. (Adapted from Sher DJ, Punglia RS. Decision analysis and cost-effectiveness analysis for comparative effectiveness research: a primer. *Semin Radiat Oncol* 2014;24[1]:14–24. Copyright © 2014 Elsevier. With permission.)

In the example shown in Figure 105.7, we may not know the likelihood of treatment mortality for illness X. It may also vary by physician or with patient characteristics. In order to determine the optimal treatment strategy for a given treatment mortality, we can conduct a one-way sensitivity analysis. As shown in Figure 105.9, the expected value of RT decreases as the treatment mortality increases. The threshold mortality at which RT and no treatment yield equivalent expected outcomes is 0.125. Below this mortality threshold, RT is associated with the best expected value, but no treatment becomes the optimal strategy above this value.

MARKOV MODELS

Markov models are useful when time needs to be incorporated into a decision model. They allow the study of outcomes by describing events as discrete states. They are particularly helpful in modeling clinical situations where a patient is at risk for a given event over an extended period of time (e.g., recurrence of prostate cancer). Markov modeling works by making a number of assumptions. First, a patient is always in one of a finite number of discrete health states. Second, all events are represented as transitions from one state to another. Third, time is divided into equal increments referred to as Markov cycles, which may be days, months, or years depending on the clinical situation. Fourth, transitions between health states occur only once per cycle. Finally, all patients in a given health state face the same transition probabilities, no matter when they entered that particular health state.[78] Patients start the model in a single health state. As the model cycles, the patients travel through time and may remain in their previous health state or transition to a different health state with a certain transition probability.

Figure 105.10 shows a simplified prostate cancer model.[78] Patients who have completed initial therapy start in the “no-disease” health state. At each cycle, the patients may either remain in the “no-disease” health state, have a finite probability of having a recurrence and transition to the “recurrence” health state, or have a finite probability of dying of causes unrelated to their cancer and transition to the “death” health state. Once in the “recurrence” health state, patients may remain there or with a certain probability die from their recurrent disease and enter the “death” health state. Once the patients enter the “death” health state, they may not exit. (This is an example of an “absorbing” health state.) A type of a Markov model called an absorbing model runs until all patients are in the “death” health state and can be used to calculate residence times in transient states allowing for life expectancy and time spent without recurrence.

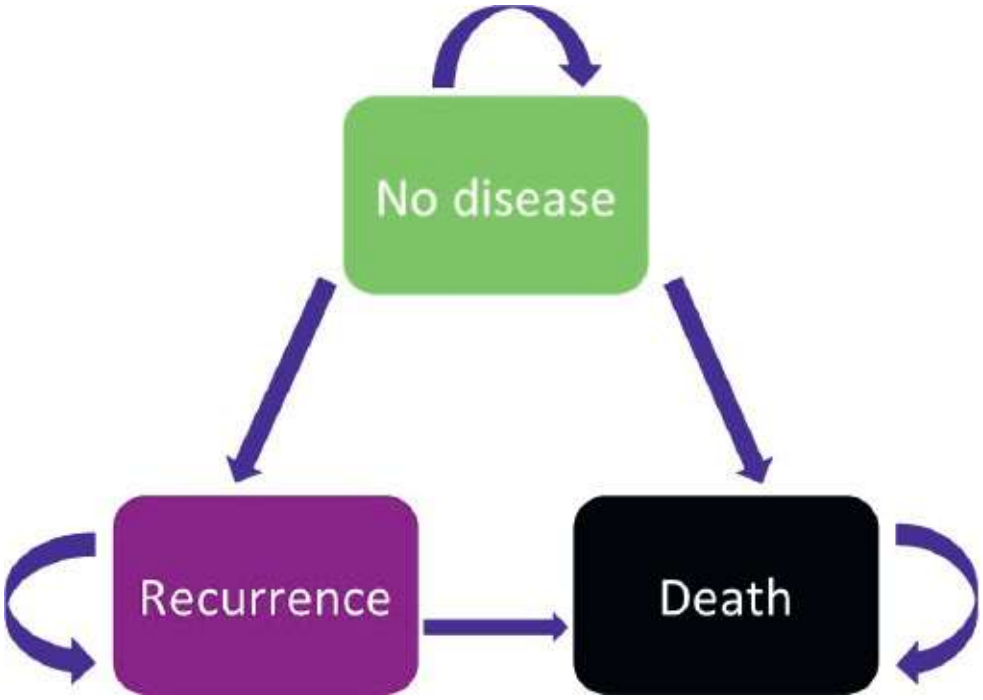

FIGURE 105.10. Markov model with three health states. (Adapted from Sher DJ, Punglia RS. Decision analysis and cost-effectiveness analysis for comparative effectiveness research: a primer. *Semin Radiat Oncol* 2014;24[1]:14–24. Copyright © 2014 Elsevier. With permission.)

One common method to evaluate a Markov model is the Monte Carlo simulation, where simulated patients enter the model one by one. The computer program then randomly selects a value for a variable in the decision analysis using a probability distribution and tracks the outcome. The process is repeated thousands of times (simulating thousands of patients), and the mean and standard deviation for a result (e.g., mean overall survival) are obtained.

COST-EFFECTIVENESS ANALYSIS

Cost-effectiveness analysis is a set of mathematical tools designed to compare the relative costs and benefits of treatment alternatives. The most common type of cost-effectiveness analysis uses a model-based study, which is nearly identical to a classic decision analysis. A Markov model is created, and QALYs are accumulated over the time scope of the study. Costs are also accumulated during each stage, such that by the end of the analysis, there is a cost and QALY associated with each strategy. One then orders the strategies by effectiveness.

The end result of any cost-effectiveness analysis is reported as an incremental cost-effectiveness ratio (ICER), which is the ratio of the change in costs to

incremental benefits of a therapeutic intervention or treatment.[81] The ICER is usually reported as a cost per QALY (e.g., $55,000 per QALY). Treatments are considered "cost-effective" or not based on whether or not the ICER passes a particular threshold, the societal "willingness to pay" (WTP). $50,000 per QALY is a commonly accepted value above which treatments are not considered cost-effective in the United States.[82] A new treatment is said to "dominate" the standard treatment if is more effective and less costly.[81]

COSTS

Costs included in a cost-effectiveness analysis depend on the perspective of the analysis. In the societal perspective, every cost needs to be measured, including capital expenses and the lost economic productivity of both the patient and caregivers.[81] In the payer perspective, only costs paid by the payer are pertinent. Analyses from the payer perspective primarily take health care reimbursements into account. Costs associated with RT can be divided into fixed costs and variable costs. Fixed costs consist of costs of the facility, physics and engineering maintenance of the machine, and salaried labor.[83] The capital cost of purchasing a linear accelerator or building a proton therapy center makes up a substantial fraction of the fixed costs. The estimated cost of a linear accelerator is approximately $4 million. The market price of a proton unit is estimated to be on the order of $120 million.[84]

The variable costs of RT vary substantially by radiation treatment modality. They can be broken down into three basic categories: treatment simulation, treatment planning, and treatment delivery.[83] IMRT and three-dimensional conformal radiation therapy (3D-CRT) simulations involve a CT simulation, which necessitates more effort on the part of physicians, physicists, and therapists than a two-dimensional (2D) simulation, which is done using a simple fluoroscopic simulator. Whereas the planning process for a 2D plan involves calculations that can be performed using a calculator, a three-dimensional (3D) plan requires more work by the dosimetrist. An IMRT plan is even more complex and, for that reason, more costly. Moreover, quality assurance programs for IMRT plans often entail "dry runs" to guarantee that the planned dose approximates the delivered dose, adding to costs.[85] Because each Lucite compensator is custom-made for each proton patient, compensators used in proton beam therapy (PBT) are more expensive than the wedges used in conventional RT. By the same token, delivering a simple 2D plan is considerably

less expensive than a 3D-CRT or IMRT treatment, and PBT is even more expensive (producing protons in a cyclotron is more resource-intensive than producing photon from a linear accelerator). In addition, the daily image guidance associated with IMRT incurs additional costs.

WHAT TYPES OF COST-EFFECTIVENESS QUESTIONS ARE THERE WITHIN RADIATION ONCOLOGY?

There are three types of questions that can be answered within the field of radiation oncology with cost-effectiveness models.[78] First, what is the cost-effectiveness of using RT, compared to other types of treatments, such as surgery? Second, what is the cost-effectiveness of using RT, as compared to observation? Finally, what is the cost-effectiveness of using different RT modalities or fractionation regimens?

Examples of Cost-Effectiveness Studies within Prostate Radiation Oncology

These questions (particularly the last category) have inspired research within the field of prostate cancer, as the explosion of new and expensive technologies such as IMRT, SBRT, and PBT calls for careful analyses of their cost-effectiveness. For example, Konski and colleagues developed a Markov model comparing PBT with IMRT for a 70-year-old man with intermediate-risk prostate cancer from the payer perspective.[86] Their model included four health states: alive without disease, alive on hormonal therapy, alive on chemotherapy, and death. The model assumed that the conformality of proton therapy would permit dose escalation with the same risk of toxicity as IMRT, resulting in 5-year freedom from biochemical relapse for patients treated with IMRT and PBT of 83% and 93%, respectively. Utilities for a patient treated with IMRT were obtained from patients with intermediate-risk prostate cancer undergoing IMRT (without hormone therapy) randomly assigned to treatment in a phase III clinical trial at Fox Chase Cancer Center (Philadelphia, PA). Utility values for patients receiving hormone therapy and chemotherapy were obtained from the literature. Costs for the technical component of the treatment were obtained from ambulatory payment classification rates for 2005. Physician-expected reimbursement was calculated from the corresponding resource value units multiplied by the 2005 conversion factor. The cost of hormones was obtained from the Drug Red Book, and the cost of chemotherapy in the last year of life was estimated based on the

literature. Even with the unproven assumption of improved biochemical response with a 10-Gy dose escalation, proton therapy was not cost-effective. For a 70-year-old man, the ICER was US$63,000 with a 15-year time window. The probabilistic sensitivity analysis revealed that there was only a 49% likelihood that PBT was cost-effective at a societal WTP of US$50,000/QALY and there was only an approximately 60% chance of cost-effectiveness at a WTP of US$100,000/QALY. If the cancer outcomes were assumed to be identical between IMRT and PBT, there was only 24% likelihood that PBT was cost-effective. One limitation of this study is that the assumption that dose escalation using PBT results in a 10% reduction in 5-year freedom from biochemical relapse and equal toxicity as compared to IMRT is unproven. In addition, the study was performed from the payer's perspective, and costs of building the facilities were not included in the calculation.

In another study, Sher and colleagues developed a Markov model comparing the cost-effectiveness of robotic (R-) and nonrobotic (NR-) SBRT to IMRT for a 65-year-old man with low-risk prostate cancer from the payer perspective.[87] Their model included the six health states of alive with no evidence of disease, alive with asymptomatic local recurrence, alive with symptomatic local recurrence, alive with distant metastases, death from unrelated causes, and death from prostate cancer. Over time, the patient could also experience toxicity. Patients were allowed to have any combination of sexual, rectal, and urinary toxicities, with the assumption that the development of any toxicity was independent of the others. All toxicities from treatment were assumed to occur within 5 years of therapy; after 5 years, they assumed no new onset of toxicity. Given the lack of robust follow-up, it was assumed that the recurrence risk after SBRT was the same as the recurrence risk after IMRT. Each health state was associated with a cost and a utility derived from the published literature. Patients were followed until death. The baseline costs of each radiotherapy treatment were defined by the 2012 Medicare payment schedule for hospital-based practice. The total costs of IMRT, NR-SBRT, and R-SBRT were $27,564.21, $10,108.93, and $19,275.41, respectively. Costs after local or distant recurrence were taken from Bayoumi and colleagues, and costs for the management of proctopathy, bladder toxicity, and impotence were extracted from the Institute for Clinical and Economic Review. Quality-adjusted life expectancy after IMRT was slightly higher than after SBRT, because worse toxicity was assumed after SBRT. The ICERs for IMRT over R-SBRT and NR-SBRT were $285,000 and $591,100/QALY, respectively. On sensitivity analysis, SBRT was almost always

the cost-effective therapy, in which the ICER for IMRT was generally over $100,000/QALY. Treatment efficacy, rectal toxicity, and impotence and the potential for unforeseen SBRT late effects were the most critical parameters in the model. When including these uncertain parameters in a probabilistic sensitivity analysis, SBRT was still most likely to be cost-effective at a WTP of $100,000/QALY. The authors concluded that SBRT clearly contained more value than IMRT for external beam treatment. One limitation of this study is that although outcomes are well established after IMRT, they are less mature after SBRT, with prospective trials reporting recurrence and toxicity data at relatively short follow-up.

In a third cost-effectiveness study, Hayes and colleagues developed a Markov model comparing observation versus initial treatment for men aged 65 and 75 years with newly diagnosed low-risk prostate cancer using the societal perspective.[88] Brachytherapy (BT), IMRT, radical prostatectomy (RP), active surveillance (AS), and watchful waiting (WW) were modeled. Men were aged 65 or 75 years on model entry, and they exited at death. The AS strategy comprised PSA tests every 3 months, digital rectal examinations every 6 months, and biopsies at 1 year and every 3 years thereafter. Men who progressed to more aggressive disease or selected treatment received IMRT. Ten percent of men who developed a Gleason score of 7 had “unfavorable risk” disease and received 6 months of androgen deprivation therapy with IMRT. The WW strategy reproduced the Prostate Cancer Intervention Versus Observation Trial (PIVOT) experience.[89] Men were followed with visits and PSA tests every 6 months and bone scans every 5 years, and 20.4% of men were treated over 10 years (49% with RP, 39% with IMRT, and 12% with BT). Model inputs were generated from a systematic review and from PIVOT; probabilities were estimated using a random effects model from a meta-analysis.[89,90] All men treated initially were assumed to have the hazard ratio (HR) point estimate of 1.48 reported in PIVOT for prostate cancer–specific death, compared with WW.[89] The publication assumed that AS would provide 25% additional benefit compared with WW in preventing prostate cancer–specific death and used an HR for prostate cancer–specific death for treatment compared with AS of 1.85. The annual probability of Gleason progression on AS was 2.3%, and the annual probability of developing other signs of disease progression was 5.2%.[90] Adverse effects of treatment were classified as short term (occurring and resolving within 90 days) and long term (occurring or persisting at least 90 days after treatment and persisting for life). Utilities for health states were elicited using a time–trade-off method from men

without prostate cancer.[90] Costs were derived from Medicare reimbursements and average wages for age-matched men. Observation was more effective and less costly than initial treatment. Compared with AS, WW provided 2 additional months of quality-adjusted life expectancy (9.02 vs. 8.85 years) at a savings of $15,374 ($24,520 vs. $39,894) in men aged 65 years and 2 additional months (6.14 vs. 5.98 years) at a savings of $11,746 ($18,302 vs. $30,048) in men aged 75 years. BT was the most effective and least expensive initial treatment. Treatment became more effective than observation when it led to more dramatic reductions in prostate cancer death (HR 0.47 vs. WW and 0.64 vs. AS). Active surveillance became as effective as WW in men aged 65 years when the probability of progressing to treatment on AS decreased below 63% or when the quality of life with AS versus WW was 4% higher in men aged 65 years or 1% higher in men aged 75 years. WW remained least expensive in all analyses. The authors concluded that, for men aged 65 and 75 years with newly diagnosed low-risk prostate cancer, observation is more effective and costs less than initial treatment and WW is most cost-effective. One important limitation of the study is that the base-case results depend on a HR for prostate cancer–specific mortality of 1.48 for treatment versus WW, which was obtained from a subgroup analysis of the low-risk patients in PIVOT. However, the 95% confidence interval on this HR was large (0.42 to 5.24) because only 10 deaths from prostate cancer occurred in this subgroup.

HEALTH SERVICES RESEARCH: CONCLUSIONS

Although randomized clinical trials are the gold standard for obtaining level I evidence, the dearth of long-term data directing therapeutic choices is one reason to perform decision analysis, which allows assumptions to be made and then varied over a wide range to determine their effects on results. To date, only a handful of properly constructed cost-effectiveness analyses studying radiation have been reported in the literature. There is a pressing need for additional cost-effectiveness studies within the field of radiation oncology. As our treatments become more technical and expensive, it is our responsibility to prove that these treatments lead to benefits (either better survival or improved quality of life) that warrant the increased cost.

Kenneth J. Arrow, MA, PhD
(August 23, 1921–February 21, 2017)

Kenneth J. Arrow, MA, PhD, was an American scholar, world-renowned for his work in economic theory and often credited with inventing the field of health economics. Although he had not previously written about health care, in 1963 Arrow was invited by the Ford Foundation to apply his theories to medical markets as part of a larger effort to address policy areas with significant public–private overlap, such as health, education, and welfare. The resultant paper, entitled "Uncertainty and the Welfare Economics of Medical Care," was published in *The American Economic Review* and first described the ways in which health care delivery fundamentally differs from the classical free market. The article has since become one of the most cited articles in the field of health economics, and its principles—such as asymmetric information, in which consumers and sellers do not share mutual information—have been broadly applied to fields outside of health and have served as an influence in widely impacting legislation. Outside of health care, Arrow's 1951 book *Social Choice and Individual Values* was credited with serving as the basis of social choice theory, which addresses matters of collective decision-making. For his contributions to general equilibrium analysis and welfare theory, Arrow was awarded the Nobel Memorial Prize in Economic Sciences in 1972—at age 51, the youngest Laureate in Economic Sciences to date.

Arrow earned a bachelor's degree from the City College of New York and master's degree and doctorate from Columbia University. He served on the economics faculties at the University of Chicago, Stanford University, and Harvard University, prior to retiring from Stanford in 1991. He served as the president of the American Economic Association in 1973 and was the recipient of numerous honorary degrees and awards, including the National Medal of Science in 2004.
