External surrogates, such as the RPM system, are advantageous because they are noninvasive, easy to use, and well-tolerated by patients and don't require

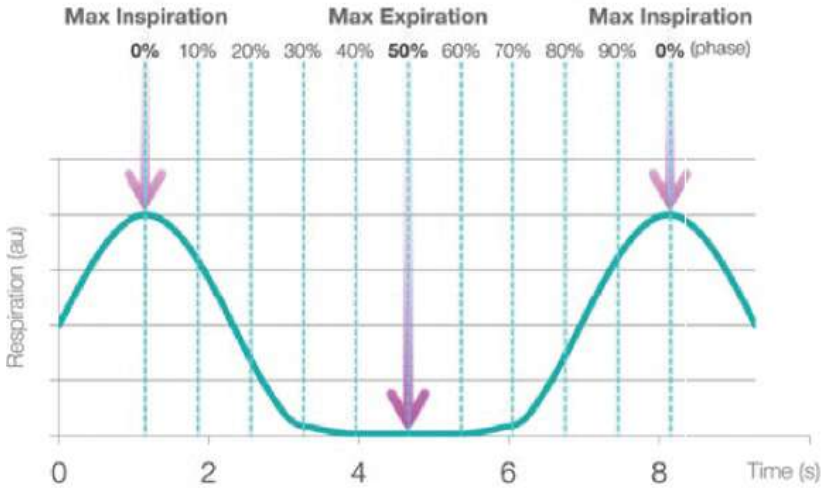
additional imaging radiation dose. However, because only an external respiratory signal is acquired, the correlation between tumor motion and patient respiration must be closely monitored throughout treatment. Other systems, such as the ExacTrac X-Ray Monitoring System (BrainLAB, Westchester, IL), combine x-ray imaging of internal anatomy with an external respiratory signal.[129] This technique allows the correlation between tumor position and patient respiration to be continuously updated at a reasonable frequency, keeping patient x-ray exposure in mind.

Regardless of the gating system, patient respiration is typically divided into ten discrete time points per period. These time points, typically referred to as phases, are used to assess tumor motion and determine a gating strategy. An example of a respiration period is illustrated in Figure 12.8 (top), where the 0% phase corresponds to maximum inspiration and the 50% phase corresponds to maximum expiration. On average, most patients spend more time in expiration than they do in inspiration, which creates a beneficial scenario for respiratory gating around expiration (Fig. 12.8, middle). More specifically, if no respiration is occurring, no respiration-induced tumor motion is occurring, providing a large window to treat the tumor with limited motion. On the other hand, if a patient is a candidate for deep inspiration breath hold (DIBH), they can be asked to hold their breath for an extended amount of time, creating a large window to treat the tumor with little motion (Fig. 12.8, bottom). Both of these respiratory gating strategies are contingent on the ability to generate the necessary four-dimensional treatment planning images during simulation.

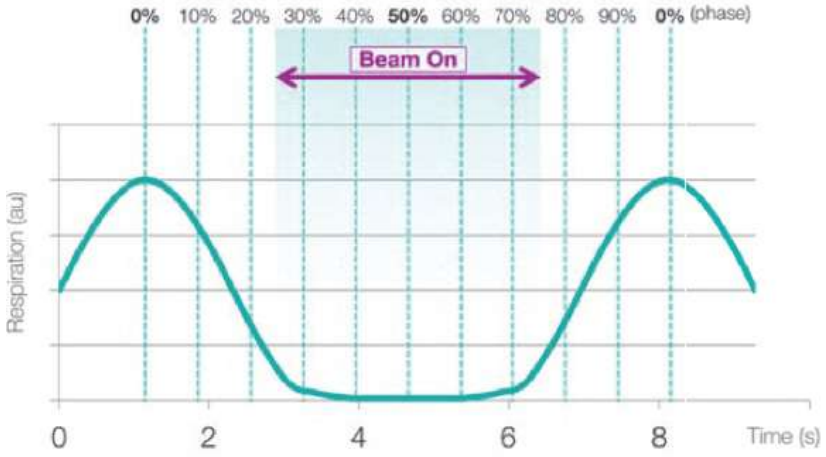
Four-Dimensional Imaging

Four-dimensional (4-D) imaging combines three-dimensional (3-D) spatial information with the time-dependent motion resulting from respiration. Although 4-D MRI[130] and PET[131] techniques currently exist, 4-D CT is currently the most prevalent imaging technique utilized in radiation oncology.[132,133]

Respiration Phases



Gating Around Expiration



Deep Inspiration Breath Hold

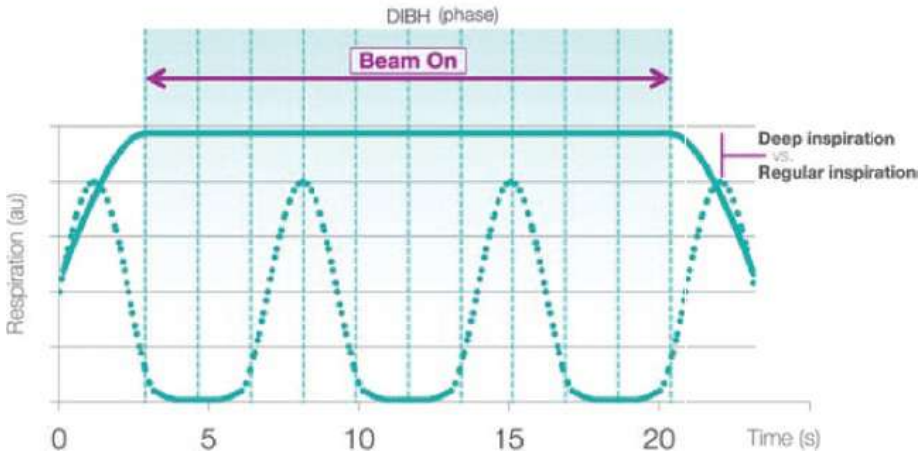


FIGURE 12.8. **Top:** A sample period of patient respiration, with ten phases labeled (0% to 90% phases). **Middle:** An illustration of respiratory gating around expiration (30% to 70% phases). **Bottom:** An illustration of deep inspiration breath hold gating.

Motion artifacts can occur in free-breathing CT scans for a variety of reasons. If the scan speed is slower than the tumor motion speed, the image of the tumor is blurred. If the scan speed is faster than the tumor motion speed, the tumor image represents an arbitrary phase of respiration. If the scan speed is comparable to the tumor motion speed, the tumor image is distorted (shape and/or position). All of these scenarios present significant challenges for motion management and treatment planning.[123,124,134]

Four-dimensional CT provides a solution to these imaging problems by correlating the CT data acquisition with patient respiration. By associating each position of interest along the patient's superior–inferior axis with the corresponding breathing phase, multiple 3-D datasets can be generated (typically ten) that represent the patient's anatomy throughout respiration. During the CT scan, real-time breathing phase information can be obtained through a variety of methods: RPM system, surface imaging, pressure belts, or spirometry. After completion of the scan, images are sorted using the corresponding breathing phase or amplitude signals. However, this additional information comes at a cost. By acquiring redundant information to generate multiple phase images, the patient is exposed to more radiation dose. Figure 12.9 illustrates the motion of a simulated lung tumor (top) and the corresponding CT slices (bottom) during the various phases of respiration.

Four-Dimensional Target Delineation

Creating an internal target volume (ITV) or an internal gross tumor volume (IGTV) for a moving lung tumor can be done in multiple ways.[135–140] Simplistic techniques such as "slow" CT scanning or forced shallow breathing have shown to be beneficial when compared to free-breathing CT-derived ITV techniques alone.[136] However, more sophisticated techniques, utilizing 4-D CT imaging, are preferred for target delineation.

Four-dimensional CT-based target delineation techniques for lung tumors are most commonly broken up into two approaches: maximum intensity projection (MIP)-based or individual phase-based.[138–140] The MIP-based technique is popular because of its simplicity. By creating a single 3-D image that represents the maximum intensity of all phases of interest, the target can be visualized in all positions simultaneously. This allows for easy target delineation, if the MIP was

created from accurate phase images and the target is not abutting a structure with a similar electron density (e.g., the diaphragm). However, as treatment planning systems have become more sophisticated and computationally powerful, visualizing multiple 3-D phase images as a movie has become the gold standard for 4-D lung tumor target delineation. This technique allows for the full range of tumor motion to be evaluated while also inspecting each individual phase image for artifacts or distortions. This method also provides all of the information necessary to choose the optimal gating strategy for a given set of images. Figure 12.10 illustrates the potential dangers of using a MIP-based alone, without examining the individual phase images for a lung tumor in the right lower lobe.

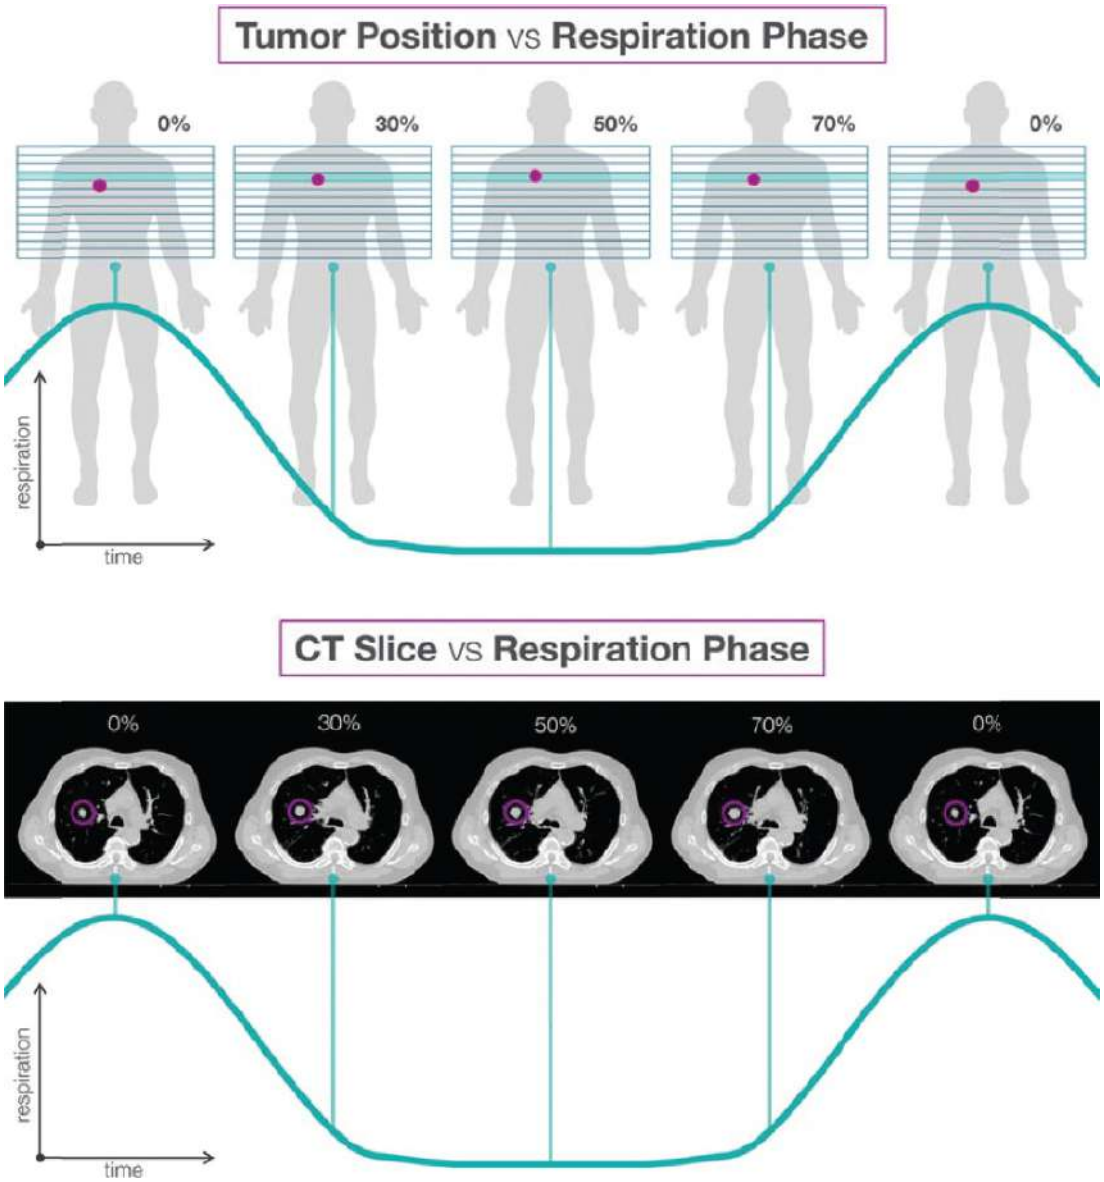

FIGURE 12.9. Top: Motion of a simulated lung tumor (magenta circle) during the

various phases of respiration. In the 50% phase (max expiration), the tumor is in the most superior position. In the 30% and 70% phases, the tumor is pushed slightly inferior as the lungs expand, but the majority of the tumor is in the corresponding slice as the 50% phase (*blue shading*). In the 0% phase (max inspiration), the tumor is pushed greatly inferior, leaving only a small cross-section of the tumor in the corresponding slice. **Bottom:** Computed tomography (CT) slices of the above scenario, illustrating the changing tumor cross-section with respiration.

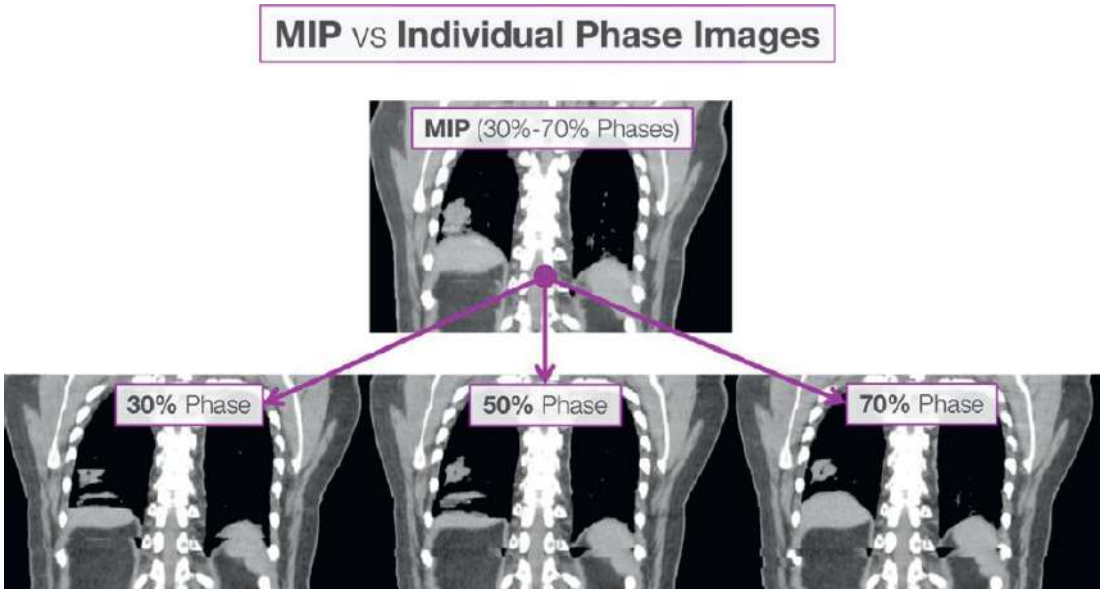

FIGURE 12.10. Top: A maximum intensity projection (MIP) image of a right lower lobe lung lesion around expiration (30% to 70% phases), which appears to illustrate a large lesion abutting the diaphragm. **Bottom:** The 30%, 50%, and 70% phase images (*left to right*) used to create the MIP image. All of these individual phase images contain significant motion artifacts that could lead to overestimating the size of the lung tumor in the MIP image.

For moving tumors outside of the lung, target delineation can be more difficult because of the similarities between the tumor electron density and that of the surrounding soft tissue. In these cases, the use of surrogates can be extremely valuable. When available, implanted metal fiducials, stents, and surgical clips are all effective options for quantifying target motion. If the surrogate is stable (i.e., is not migrating) and is located in or near the tumor, the aforementioned techniques can be used to determine the extent of motion and choose the optimal gating strategy. For liver cancers specifically, the electron density of the tumor is generally lower than that of the surrounding liver tissue. Therefore, the minimum intensity projection (MIN) image can also be valuable for deriving the ITV.

Treatment planning and dose calculation for moving tumors should be approached differently than target delineation. Although MIP and MIN images

both provide useful information for contouring, they do not provide an accurate depiction of the tumor for dose calculation. Instead, the average intensity projection (AVG) image is recommended for treatment planning because of the fact that it more closely represents the time-averaged patient anatomy than any other composite image. Figure 12.11 illustrates an image comparison between a free-breathing CT image, a MIP image, and an AVG image for a lung tumor. As the field of radiation oncology continues to evolve, and the computational resources for commercial RT products continue to increase, the field will move toward 4-D planning as the gold standard (i.e., calculating dose on each individual phase image and accumulating the dose).[141,142]

FIGURE 12.11. A comparison of a free-breathing computed tomography (CT) image, a maximum intensity projection (MIP) image, and an average intensity projection (AVG) image (*left to right*) for a lung tumor. The free-breathing image provides a snapshot of the tumor in an arbitrary phase. The MIP image illustrates the position of the tumor in all 10 phases. The AVG image illustrates the time-averaged position of the tumor.

IN-ROOM IMAGING

Ultrasound

Ultrasound (US) remains a clinically available IGRT modality in modern radiation oncology; however, the technique is typically confined to prostate cancer.[142,143] US systems work by first transmitting high-frequency sound waves into the body from a probe and then waiting for the sound waves to reflect back to the probe from a tissue boundary. This information can then be used by the US system to calculate the distances from the probe and the tissue or organ (boundary) of interest. Furthermore, anatomical images can be generated by sweeping the probe across an entire region of interest. Readers interested in a

more in-depth description of US technology are referred elsewhere.[144]

IGRT using US requires a system to map the US image coordinate system to the linear accelerator coordinate system and subsequently the simulation images. This is typically done in one of two ways: tracking the position of the stereotactic arm holding the probe or tracking the position of the probe itself via infrared imaging. An example of tracking the position of the stereotactic arm is the B-mode acquisition and targeting (BAT) transabdominal system (NOMOS, North American Scientific, Chatsworth, CA). In this system, the stereotactic arm is attached to the linear accelerator gantry, providing information on the probe location. An example of tracking the location of the probe itself is the SonArray system (Varian Medical Systems, Palo Alto, CA). In this system, an optical guidance platform provides real-time feedback of the US probe position in the treatment room. Using either of these techniques, the target location can be determined in the treatment room prior to treatment, and the necessary shifts can be calculated to move the target into the correct position for treatment.

Very little information has been published regarding the use of US IGRT for nonprostate patients. Most notably are studies to confirm bladder volume and position in gynecologic patients[145] and evaluate intracavitary brachytherapy treatment planning for perforations.[146,147] However, there is an extensive amount of research regarding the use of US IGRT for prostate cancer. Numerous studies have been published comparing US-based patient set-up methods versus conventional set-up methods (i.e., utilizing external skin markers),[148–152] and several studies have been published comparing US-based patient set-up versus implanted fiducial markers.[152–154]

As newer IGRT approaches continue to develop, the role of US-based IGRT is likely to continue to decrease.[143] However, US will likely always have a role in prostate cancer care because of the fact that it offers an IGRT solution that does not require additional ionizing radiation.

Video and Surface Imaging

Video and surface imaging techniques for radiation therapy were first introduced over 30 years ago. Early versions of this technology were based on the ability of closed circuit cameras to compare an image of the patient's setup to a stored reference image[155] or for image subtraction techniques to automatically determine differences in patient set-up images.[156,157]

An example of a modern surface imaging technology is the AlignRT system (Vision RT Ltd., London, UK). This system is designed to aid in initial patient

setup as well as patient position monitoring. Through the use of three 3-D stereo camera units mounted to the ceiling of the treatment vault, the patient surface can be constantly monitored and compared to the ideal position (determined from the treatment planning CT) with submillimeter accuracy. This system can also be incorporated into the linear accelerator management system to automatically trigger the beam to turn off when a patient is out of position.

Although this technology has been used for many IGRT applications, one of its most popular applications involved breast cancer. AlignRT has been used to assess interfraction variation for whole breast radiotherapy,[158,159] as well as to examine positioning accuracy for left-sided breast DIBH techniques.[160,161] In addition to breast, the AlignRT system has also shown value when used for intracranial SRS cases with minimal immobilization. Cerviño et al. have shown that an open-mask approach (i.e., leaving the face exposed) provides enough surface area to accurately detect head motion in real time.[162,163] Figure 12.12 illustrates the use of AlignRT for an intracranial SRS case.

As surface and video imaging technologies continue to evolve, the uses for these IGRT techniques are expected to expand. Building on the success of frameless radiosurgery, other novel uses for this nonionizing IGRT technique will likely appear in the future.

Planar Imaging

Megavoltage (MV) and kilovoltage (kV) planar imaging techniques are the most common in-room IGRT approaches used in radiation therapy today. These systems have proven valuable for nearly all disease sites and are incorporated into a variety of linear accelerator-based treatment systems.[143,164] As the field of radiation oncology has evolved, so has the quality and performance of these planar imaging systems, making them a staple in modern radiation oncology.

Electronic Portal Imaging Devices

Electronic portal imaging devices (EPIDs) utilize the therapeutic beam (MV) to generate an image on a movable flat-panel detector. These devices have entirely replaced portal films in most cases, by providing higher-quality 2-D digital images of the treatment field with the patient in the treatment position. Although EPID design has gone through numerous iterations, most commercial systems today consist of amorphous silicon (aSi) detectors. These systems work by first converting the x-rays to visible light using a scintillator and then converting the visible light to electrons using a photodiode array. In the last step, the electrons

activate pixels in a layer of aSi to generate an image. For a more comprehensive overview of EPID technology and development, readers are referred elsewhere.[165,166]

EPID-based planar imaging is often used for patient setup when the size and shape of the treatment field need to be verified in reference to the patient anatomy (i.e., 3-D conformal techniques). Although different energy beams are available for treatment and imaging, EPID-based imaging is limited by the lack of contrast available for the Compton interactions that dominate the 2.5- to 18-MV therapeutic energy range. Because of this, EPIDs are most beneficial when the region of interest contains boney anatomy or implanted fiducial markers.[167–170] However, as more sophisticated IGRT techniques become commonplace, the use of EPID-based imaging is decreasing for complex IMRT/VMAT treatments.

kV Imaging Devices

Utilizing the therapeutic treatment (MV) beam for IGRT has two main limitations: increased patient dose and decreased image quality. Because of this, kV-based imaging systems have become the standard for modern IGRT. Diagnostic kV imaging systems are incorporated into treatment delivery systems in a variety of ways, but regardless of the implementation, all are designed to provide high-quality 2-D pretreatment digital images of the patient anatomy.

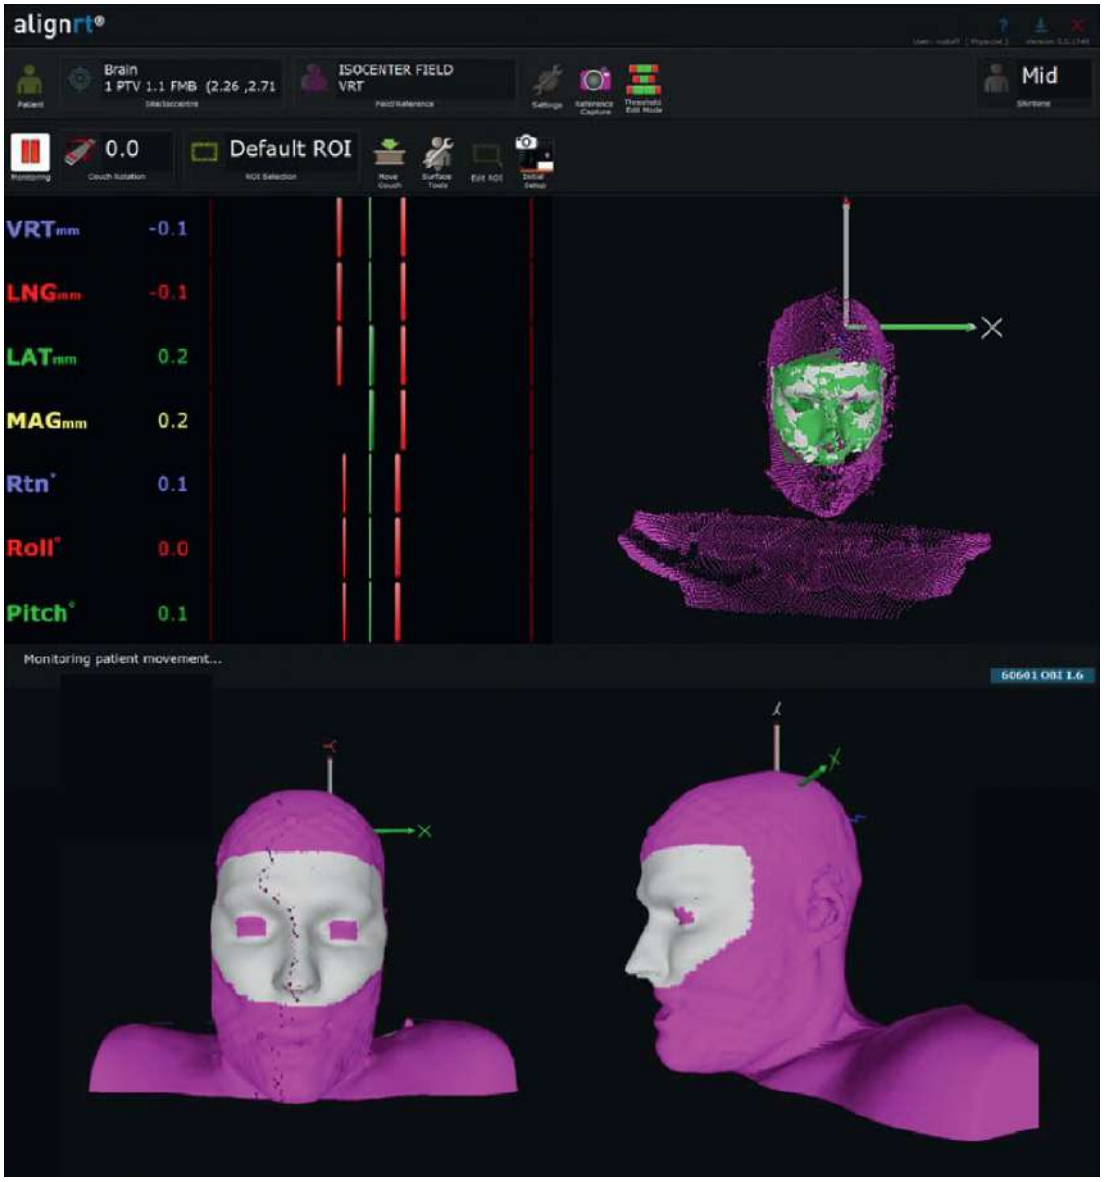

FIGURE 12.12. The use of AlignRT during an intracranial stereotactic radiosurgery case. **Top:** AlignRT monitoring the alignment of a patient's surface (face in an open mask), with deviations from the intended position listed in a column on the *left*. **Bottom:** The chosen surface to monitor (*white*), selected from the simulation computed tomography body contour (*pink*).

The On-Board Imager (OBI) system (Varian Medical Systems, Palo Alto, CA) is a popular example of a linear accelerator equipped with gantry-mounted kV imaging. This system incorporates a retractable diagnostic quality kV imaging tube and a movable flat-panel aSi detector perpendicular to the treatment beam (i.e., offset by 90 degrees). The OBI system allows high-quality and low-dose images to be compared to digitally reconstructed radiographs (DRRs) of the patient anatomy for orthogonal pairs of images, taken at any

angle. Fox et al. presented a comprehensive overview of the OBI software and hardware implementation and performance.[171] An example of the Varian gantry–mounted OBI system is illustrated in Figure 12.13.

Although gantry-mounted kV imaging systems are the most popular design, other implementations also exist. CyberKnife (Accuray Inc, Sunnyvale, CA) consists of a linear accelerator attached to a robotic manipulator with 6 degrees of freedom. In this system, diagnostic x-ray tubes are mounted to the ceiling and nearly orthogonal aSi flat-panel detectors are mounted to the floor. The Novalis system (BrainLAB Inc, Westchester, IL) is a more conventional gantry-mounted linear accelerator design, but the diagnostic x-ray tubes are mounted on the floor of the treatment room, and the nearly orthogonal flat-panel detectors are located on the ceiling. In both systems, images are automatically compared with DRRs from the treatment planning CT to verify and adjust patient alignment.[172–174]

Volumetric Imaging

Cone-beam computed tomography (CBCT) systems (both MV and kV) offer the natural progression from planar 2-D IGRT to volumetric 3-D IGRT. Over the past several years, CBCT systems have quickly become the standard of care for a variety of disease sites and have been incorporated into numerous linear accelerator-based treatment systems.[144,164] As IGRT continues to progress, the use of CBCT will most likely continue to play an integral role.

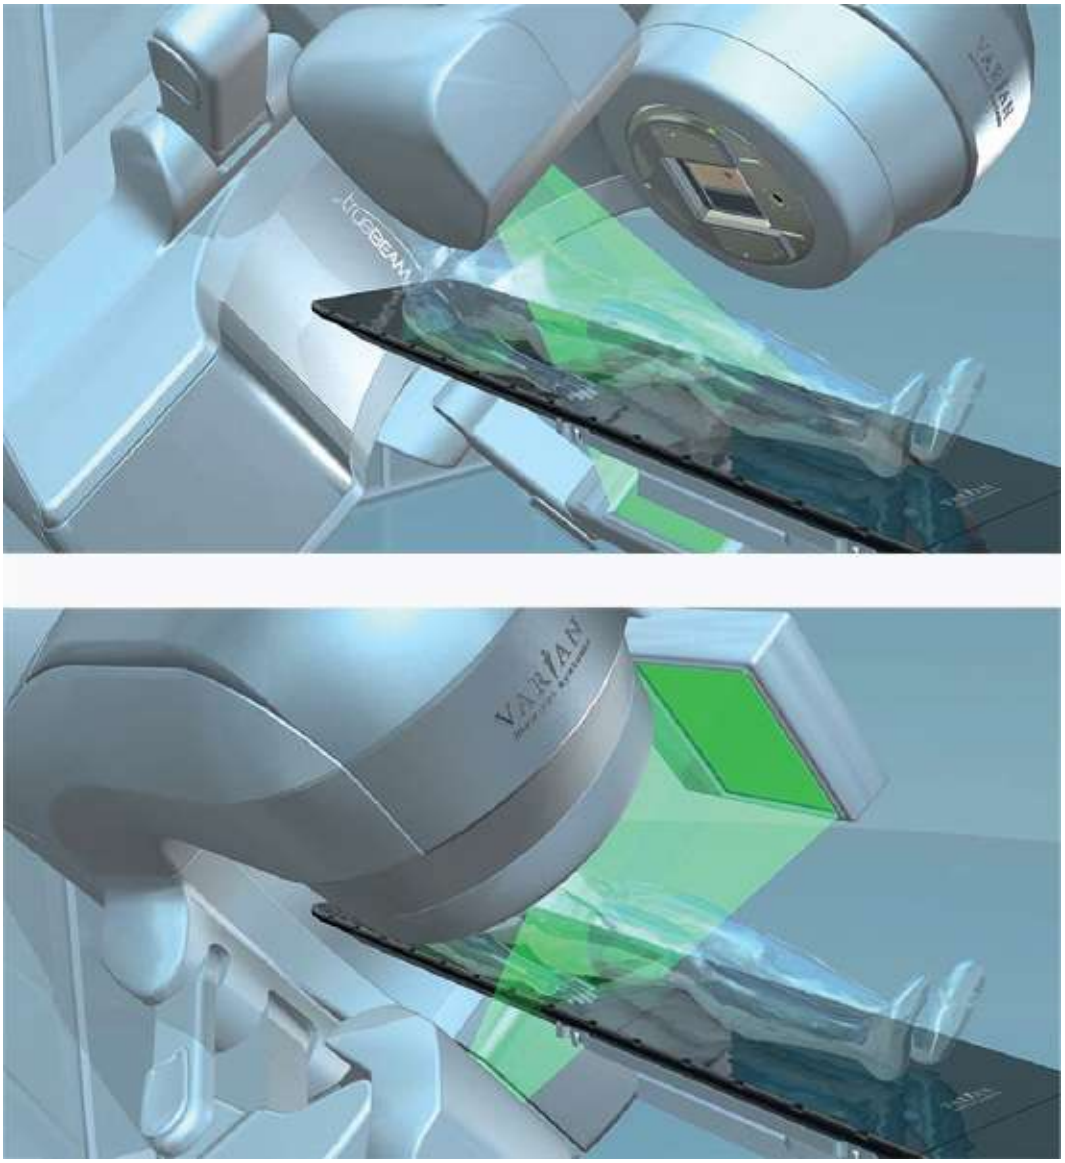

FIGURE 12.13. An illustration of the gantry-mounted Varian On-Board Imager system. Planar kilovoltage images (*green* overlay) are being taken at two orthogonal positions (*top and bottom*). (Courtesy of Varian, Palo Alto, CA.)

MV CBCT

MV CBCT systems utilize the treatment beam and the EPID to generate a 3-D image that is comparable to the treatment planning CT. MV CBCT images are created by collecting a series of 2-D projections, followed by reconstruction of the 3-D dataset in a process similar to that of conventional CT imaging. MV CBCT has the same limitations as that of MV planar imaging. When compared to kV techniques, MV CBCT is associated with a higher patient dose and lower contrast. An example of a MV CBCT is illustrated in Figure 12.14.

Multiple studies have evaluated the usefulness of MV CBCT, with the largest

number of publications coming from UCSF utilizing a Primus linear accelerator (Siemens Oncology Systems, Concord, CA).[175–178] Although many of these studies illustrate the utility of MV CBCT imaging for a variety of cancers, most vendors have moved away from this technology because of the aforementioned downsides. One unique exception is the Halcyon system (Varian Medical Systems, Palo Alto, CA), which offers integrated MV planar and CBCT imaging, with the imaging dose accounted for in the treatment planning system. Although kV imaging is available for Halcyon systems, MV imaging–only systems are available at a lower price point.

kV CBCT

Most large linear accelerator manufacturers currently offer gantry-mounted kV CBCT systems. For example, the previously discussed Varian OBI system, consisting of a diagnostic x-ray tube mounted across from a flat-panel aSi detector, is also capable of generating high-quality kV CBCT images. The OBI system, along with the Elekta Synergy system (Elekta Oncology Systems, Norcross, GA), acquires kV projections through a full 360-degree gantry rotation or smaller 180-degree rotation, which are then reconstructed into a 3-D dataset.[179] An example of a kV CBCT is illustrated in Figure 12.15.

Similar to MV CBCT imaging, multiple studies have evaluated the utility of kV CBCT imaging systems.[179–182,182a] However, unlike MV CBCT imaging, kV CBCT imaging has become the standard of care for modern IGRT. Higher-contrast high-quality kV CBCT images allow users to identify important anatomy for a variety of cancers throughout the body, creating the best 3-D–3-D registration possible with the treatment planning CT. As kV CBCT techniques continue to evolve, image quality will continue to improve as advances such as 4-D CBCT will become the norm.

MRI

As discussed earlier, MRI provides superior soft tissue visualization compared to other CT and other clinically available in-room imaging modalities. Until recently, there have been technical barriers making it difficult to combine MRI with clinical radiation therapy devices. However, there are now clinically available hybrid machines capable of real-time MR imaging during radiotherapy. One of the first of these devices of its kind developed by ViewRay Inc. (Oakwood Village, OH) utilizes a 0.35-T MR, 3-KCi cobalt sources, and three double-focused MLCs (Fig. 12.16). This system was developed using cobalt

sources rather than a linear accelerator to overcome some of the technical issues that arise due to electron interactions with high-strength magnetic fields.[183]

Chen et al.[184,185] recently reported on their initial clinical experience in the use of MR-guided radiotherapy. Using an integrated MR–cobalt system, they treated 31 patients with newly diagnosed or recurrent HNC with MRI-guided IMRT (Fig. 12.17). The results were promising with excellent rates of locoregional control in both newly treated and recurrent patients as well as modest rates of toxicity consistent with previously published literature. Of note, the authors commented that only a small subset of these patients were treated with adaptive replanning, and they felt that expanded use of this approach would be feasible and provide potential to improve the therapeutic ratio.

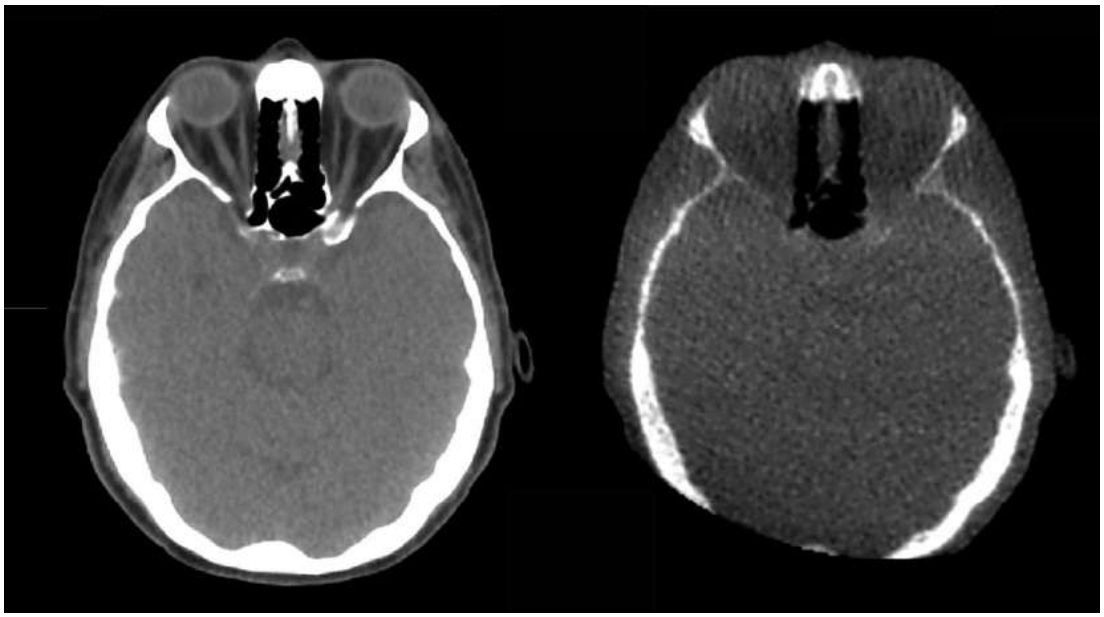

FIGURE 12.14. Comparison of a megavoltage cone-beam computed tomography (*right*) with the treatment planning computed tomography (*left*). The axial slice shown includes the brain, skull, and optic structures.

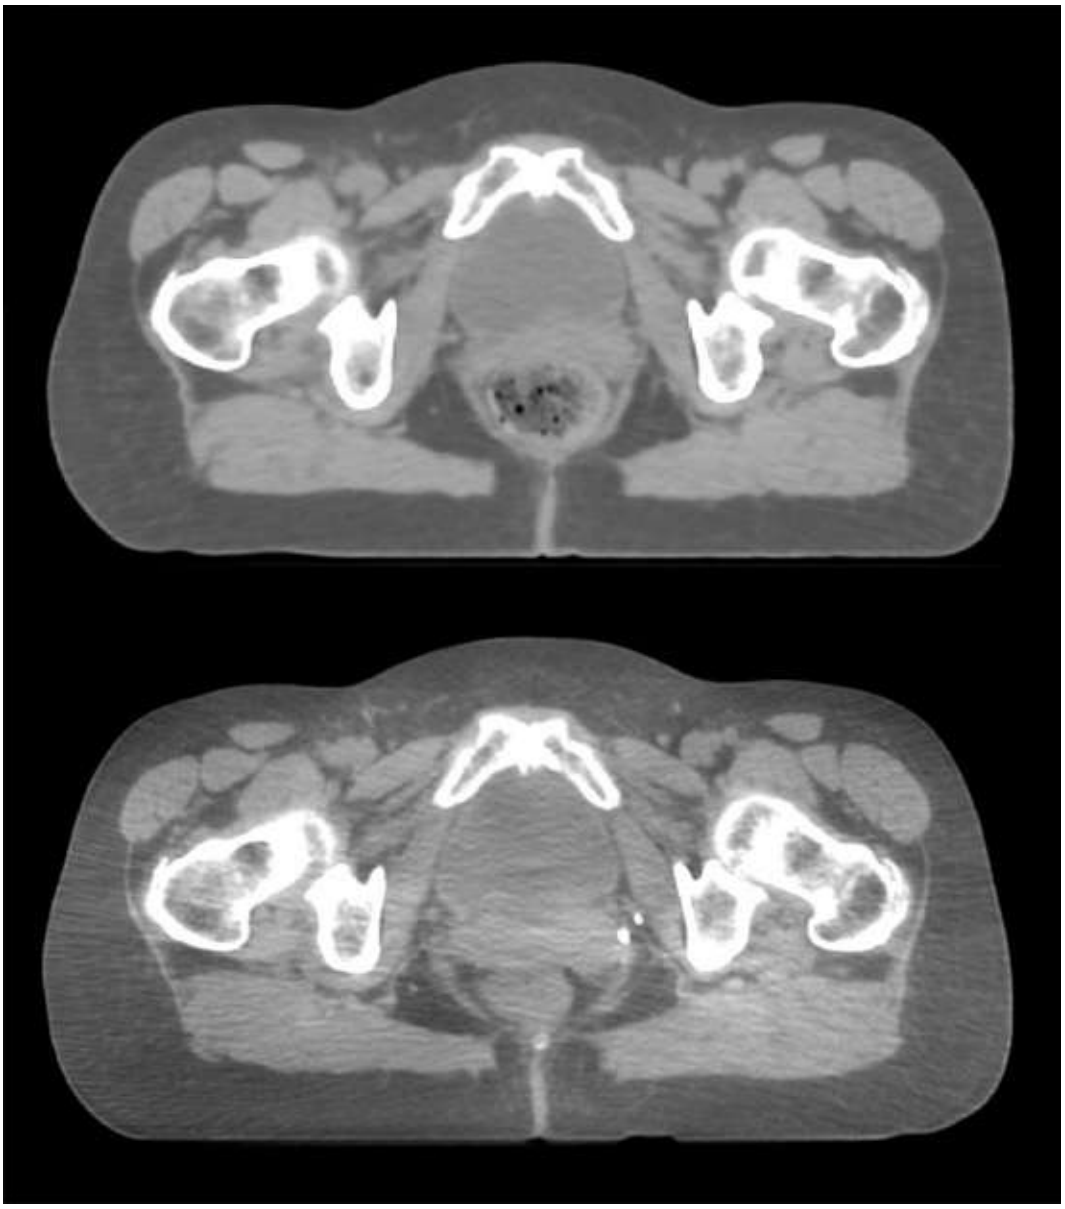

FIGURE 12.15. Comparison of a kilovoltage cone-beam computed tomography (*bottom*) with the treatment planning computed tomography (*top*). The axial slice shown includes the femoral heads, bladder, rectum, etc.

In an attempt to overcome some of the technical limitations of cobalt therapy, several centers worldwide have begun development of MR-LINAC prototypes. Investigators at the University of Utrecht and Cross Cancer Institute in Alberta are pioneers in this area and have been working for over a decade to development hybrid MR-LINAC prototypes.[186,187] There are now multiple other MR-LINAC systems currently under development, but to date these have not been employed in routine clinical use.

FIGURE 12.16. ViewRay cobalt-magnetic resonance imaging system. (Courtesy of Viewray, Oakwood Village, OH.)

Radiofrequency Localization Systems

Electromagnetic localization systems typically consist of a magnetic dipole source and multiple sensors to detect the magnetic field created by the dipole. When a radiofrequency (RF) pulse excites the dipole, a magnetic field is created. When the RF signal is removed, it results in an oscillating magnetic dipole. The dipole sources in clinical RF localization systems are typically referred to as transponders, where each transponder is approximately the size of a gold fiducial. These transponders are implanted directly into the tissue of interest. Electromagnetic localization systems have several benefits. The transponders can be implanted directly into the target area, no ionizing radiation is used, and the system provides real-time positional feedback. The Calypso system (Varian Medical Systems, Palo Alto, CA) is an example of a commercially available RF localization system.[188]

Although most of the research published with RF localization systems is focused on prostate cancer localization and continuous monitoring during treatment,[189–193] other treatment sites such as pancreatic cancer have also shown potential.[193a] As a whole, RF localization systems such as Calypso are a valuable

IGRT tool for performing real-time monitoring of target position for sites in which intrafraction motion is a concern.

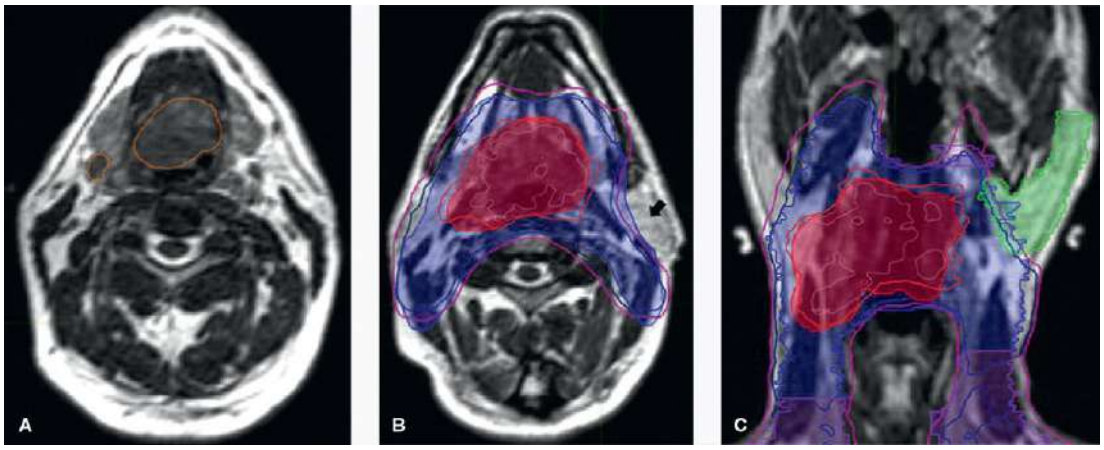

FIGURE 12.17. Axial and coronal magnetic resonance images (MRI) from an MRI-guided intensity-modulated radiation therapy plan in a patient with locoregionally advanced head and neck cancer. The gross tumor volume **(A)**, planning tumor volume (PTV) receiving 70 Gy (PTV70) (**B** and **C**; *red line*), PTV59.4 (**B** and **C**; *blue line*), PTV54 (**B** and **C**; *purple line*), and parotid gland (**C**; *green line*) are shown. The *arrow* demonstrates sparing of the contralateral parotid gland. (Reprinted by permission from Springer: Chen AM, Hsu S, Lamb J, et al. MRI-guided radiotherapy for head and neck cancer: initial clinical experience. *Clin Transl Oncol* 2018;20[2]:160–168. Copyright © 2017 Federación de Sociedades Españolas de Oncología [FESEO].)

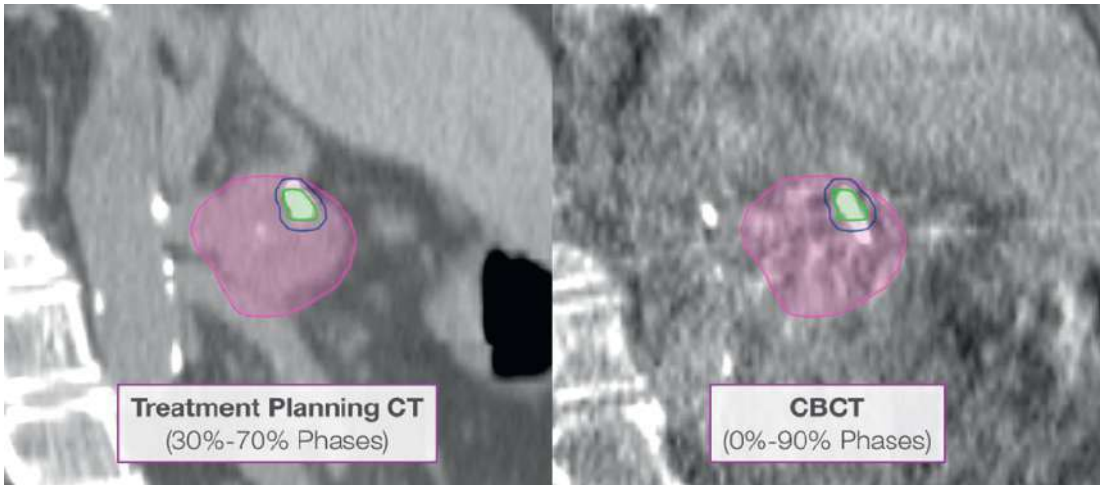

FIGURE 12.18. A comparison of the treatment planning computed tomography (CT) (*left*) created from the phases around expiration (30% to 70%) and a cone-beam CT (*right*) created from all 10 respiratory phases (0% to 90%). In both cases, the *pink* contour represents the planning target volume, and the *green and blue* contours represent the fiducial and a 1-mm margin, respectively.

Four-Dimensional Imaging and Motion Management

Regardless of the respiratory-induced motion management strategy utilized for target delineation and treatment planning, effective in-room imaging is a necessity to ensure proper treatment delivery. For free breathing, abdominal compression, respiratory gating, and real-time tumor tracking techniques, in-room imaging must be used to verify that that the treatment planning conditions are appropriately replicated.

2-D, CBCT, and Fluoroscopic Imaging

Two-dimensional and 3-D (CBCT) imaging have well-defined roles in patient setup and treatment verification. However, in 4-D motion management cases (e.g., gating around expiration or DIBH), the use of these technologies becomes more complex and crucial. Although orthogonal kV images are the standard for initial patient alignment, little attention is paid to the breathing phase at this stage of the patient set-up process. This is not the case for CBCT imaging, which has proven to be valuable for tumor and soft tissue alignment in both gated and nongated treatments. In nongated cases, the 3-D–3-D matching process is relatively straightforward. However, the lack of commonplace 4-D CBCT imaging creates a significant 3-D–3-D registration problem for gated cases. For example, when gating around expiration, the treatment planning CT is generated from the phases around expiration only (i.e., 30% to 70%), but most in-room CBCT systems only have the capability to generate images from all respiratory phases (i.e., 0% to 90%). When substantial motion is present, this results in the target or surrogate appearing larger or elongated in the CBCT image. Figure 12.18 illustrates a common registration issue where the CBCT image of an implanted fiducial appears much larger than the contour from the treatment planning CT. This is the result of the CBCT image including the phases around inspiration, where the fiducial is pushed inferiorly. As 4-D CBCT systems become more commonplace, the problems associated with motion-induced blurring will become less prohibitive.

Fluoroscopic imaging is a unique and beneficial tool for gated treatment verification. Unlike static kV imaging, this technique provides a “live” look at the target anatomy and/or surrogate throughout the patient’s respiratory cycle. This allows the position of the target to be compared to an aperture representing the correct breathing phase (e.g., around expiration or DIBH), allowing the position of the target and the gating window to be determined simultaneously. The diagrams in Figure 12.19 illustrate how fluoroscopic imaging can be used to determine that the target is in the correct location for a gated treatment delivery.

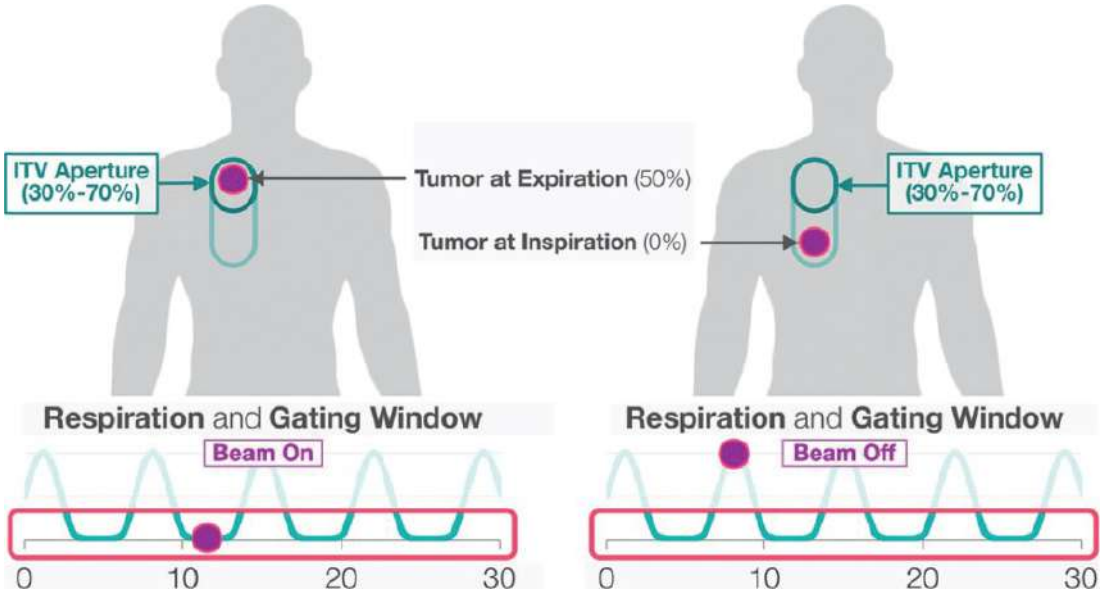

FIGURE 12.19. Simulated fluoroscopic images (anterior–posterior) of a lung tumor (*purple circle*) in the correct phase (*left side*—within the internal target volume [ITV] aperture) and in the incorrect phase (*right side*—outside of the ITV aperture).

Tumor Tracking

Tumor tracking is a sophisticated motion management strategy that provides a technologically intense alternative to respiratory gating, DIBH, or abdominal compression. Instead of limiting target motion or treating at specific phases of respiration, tumor tracking utilizes real-time tumor localization to continually reposition the treatment beam, thus decreasing residual target motion and increasing delivery efficiency. However, this ideal motion management strategy has several technical hurdles that are currently preventing widespread clinical adoption of this technology. One of these limitations is treatment planning. All of the actual tumor positions, relative to the surrounding tissues, cannot be known at the time of treatment planning. Therefore, treatment planning for tumor tracking is typically done on an average patient geometry or 4-D simulation data, and an adaptive scheme is applied throughout the treatment course. Although some specialized commercial systems are already available, more LINAC-based systems are currently investigating ways to obtain real-time 3-D tumor position information and to decrease system latency.

CONCLUSIONS

IGRT has become ubiquitous in radiation oncology clinics, and new applications are constantly being developed to improve treatment accuracy with the ultimate

goal of improving clinical outcomes. Although numerous studies have shown dosimetric benefits with implementation of IGRT, only a handful have tested the use of IGRT in a prospective fashion and reported clinical outcomes. Additional research is still needed to test the clinical impact and safety of various IGRT applications. Furthermore, the question of cost-effectiveness of routine use of IGRT needs to be addressed. There are numerous ongoing trials analyzing the utility of image-guided radiation therapy in a variety of cancer types.[194] The results of these studies should help to guide clinical decision-making in radiation oncology in regard to IGRT implementation and provide further hypotheses for incorporation of novel imaging modalities into prospective clinical trial design.

SECTION II

Techniques, Modalities, and Modifiers in Radiation Oncology

CHAPTER 13

Altered Fractionation Schedules

Anthony E. Dragun

INTRODUCTION

Conventionally fractionated radiotherapy (CFRT) is typically defined as the delivery of doses of 1.8 to 2 Gy, once daily, 5 days/week. This chapter discusses the history of and rationale and evidence for altered radiotherapy fractionation schedules for some of the most common cancers seen in clinical practice. The first section addresses background radiobiology. The second section reports outcomes of clinical studies of hyperfractionated radiotherapy (HyperRT), as well as new results of hypofractionated radiotherapy (HypoRT) for prostate and breast cancer, which have been added to this edition. The purpose of this chapter is to explore the experience of altered fractionation in cases where the traditional target and delivery technique remains (e.g., tangential whole-breast radiotherapy portals), but the dose per fraction is changed. Altered radiation schedules using special treatment procedures such as stereotactic radiosurgery (SRS) or stereotactic body radiotherapy techniques (SBRT), partial breast irradiation, or brachytherapy are discussed in dedicated chapters elsewhere in this book.

BACKGROUND RADIOBIOLOGY

The most important consideration of altered fractionation is the sensitivity of late effects to changes in dose per fraction.[1] Alternatively, acute reactions are more dependent on changes in total dose.

The traditional understanding of early and late reactions is couched in terms of target cell killing. This description is better characterized for acute effects, where direct connections can be made between cell loss and measurable injury, than with late effects, where that association is less well understood[2] (see also Chapter 3 of this book). Nonetheless, the conventional understanding of the potential risks and benefits of altered fractionation is framed within this target

cell concept.

Time–Dose Parameters

The time–dose parameters that determine normal tissue tolerance are total dose, dose per fraction, fraction frequency, and duration of treatment. Fraction size and frequency determine rate of dose accumulation, sometimes referred to as the *weekly dose rate.* The intensity of acute reactions in tissues that are organized into stem cell, maturation, and functional compartments (e.g., epithelium, bone marrow) reflects the balance between cell killing by irradiation and the rate of regeneration of surviving stem cells, driven primarily by the weekly dose rate. After an acute reaction has peaked (e.g., moist desquamation of the skin), further stem cell killing cannot produce an increase in *intensity* of the acute reaction but manifests as a delay in healing, which may ultimately result in a *consequential* late injury.[3]

Late reactions differ in that they are thought to occur in tissues characterized by slow cellular turnover, such as mature connective tissues and the parenchymal cells of various organs. Because cellular depletion in such tissues does not manifest until well after the completion of the course of radiation, weekly dose rate would be of minor significance in determining the severity of late reactions. Therefore, late reactions would depend more on size of dose per fraction, and interfraction interval.

The understanding of late effects, however, does not lend itself well to simplification. For example, we have already mentioned evidence that the frequency of some late reactions correlates with the weekly dose rate and intensity of acute reactions (consequential late effects).[4–6] Moreover, there is evidence that late effects can be modified by pharmacologic intervention. For example, amifostine administration protects lung tissue and the esophageal mucosa in the treatment of lung cancer,[7] and other agents have been shown to affect the development of radiation-induced nephritis (captopril) and breast fibrosis (pentoxifylline and vitamin E).[8]

Size of Dose per Fraction and Length of Interfraction Interval

The influence of fraction size on radiation therapy outcome is manifest through the slope of fractionated dose response curves, and this is a reflection of cellular *repair capacity*. In Chapter 3 of this book, Figure 3.18 shows that changes in isoeffect doses for late effects with changing dose per fraction (solid curves) are steeper than for acute effects (dashed curves).[9] Therefore, for tumors with

fraction sensitivity similar to acutely responding normal tissues, a gain in therapeutic ratio can be realized by significantly reducing the fraction sizes and escalating the total dose (hyperfractionation). It is convenient to mathematically estimate fractionation sensitivity, and this is most easily done using the linear quadratic (LQ) model. Assuming that the target cell hypothesis is correct and that the LQ model correctly describes the target cell survival curves, the ratio α/β of the LQ model becomes a quantitative measure of sensitivity to changes in fraction size[9]: low ratios signify high fractionation sensitivity, and high ratios signify low fractionation sensitivity. The implication is that the tolerance dose for late effects can be increased more by the use of smaller fraction sizes than the tolerance dose for tumors and acute effects (hyperfractionation). The α/β ratios for some animal normal tissues are set out in Chapter 3 and clinical data inhuman tissues and tumors in Table 13.1.

In general, the estimated values of α/β for early and late reactions in human normal tissues are consistent with results from experimental animals. With regard to tumors, squamous cell carcinomas of the head and neck, cervix, and skin and non–small cell lung cancers (NSCLCs) are characterized by high α/β ratios, in agreement with rodent models. However, data from melanomas and sarcomas suggest somewhat lower α/β ratios for these tumor types. The α/β ratio for breast adenocarcinomas may be lower than those for other carcinomas listed in Table 13.1.[42] The situation is different with prostate tumors, which contain unusually small fractions of cycling cells.[43] Prostate tumors might not respond to changes in fractionation in the same way as do other cancers,[44,45] and respond to changes in fractionation more like a late-responding normal tissue.[36,46–48] There is evidence both from animal[44,49–54] and from human[5,55–57] studies that for late rectal sequelae a value of α/β of >4 Gy is higher than for most other late sequelae. And so, if the α/β value for prostate cancer (range: 1 to 3) is indeed less than that for this adjacent late-responding normal tissue, then hypofractionation would be expected to yield increased tumor control for a given level of late complications or decreased late complications for a given level of tumor control.

TABLE 13.1 ESTIMATES OF α/β FOR HUMAN TISSUES AND TUMORS

Tissue/Tumor	Reference	Estimate/Bound of α/β in Gy (95% CI)

Acutely Responding		
Skin		
Desquamation (time ≤ 29 d)	Turesson and Thames[6]	11.2 (8.5–17.6)
Erythema	Turesson and Thames[6]	8.8 (6.9–11.6)
	Bentzen et al.[10]	12.3 (2–23)
Mucous membrane—ulcer	Rezvani et al.[11]	15 (0–45.2)
Lung—acute	Cox[12]	>8.8
Late Responding		
Supraglottic larynx—late sequelae	Maciejewski et al.[13]	3.8 (0.8–14)
Larynx—cartilage necrosis	Henk and James[14]	~3.4
	Horiot et al.[15]	≤4.4
	Fletcher et al.[16]	
	Stell and Morrison[17]	≤4.2
Larynx—pharynx	Taylor et al.[18]	7.8 (3–∞)
	Rezvani et al.[11]	3.5 (1.1–5.9)
Oropharynx—late sequelae	Horiot et al.[15]	~4.5
Skin		
Subcutaneous fibrosis	Bentzen et al.[10]	1.9 (0.8–3)
Telangiectasia	Turesson and Thames[6]	3.9 (2.7–4.8)
	Bentzen et al.[10]	3.7 (0.2–4.7)
	Bentzen and Overgaard[19]	2.8 (0–8.1)
Mucosal ulceration (consequential effects)	Withers et al.[20]	21.3 (5.2–∞)
Shoulder—impaired movement	Bentzen et al.[21]	3.5 (0.7–6.2)
Rib—fracture	Overgaard[22]	1.8–2.8
Bone—exposure/necrosis	Withers et al.[20]	0.8 (0–2.4)
Lung		
Pneumonitis	Cox[23]	≤3.8
Computed tomography density	van Dyk et al.[24]	3.3 (0.5–6.5)
Spinal cord—myelopathy	Dische et al.[25]	≤3.3
Brachial plexus—plexopathy	Powell et al.[26]	≤5.3
Bowel—stricture/perforation	Bennett[27], Edsmyr et al.[28]	$2.2 \le \alpha/\beta \le 8$
Tumors		
Tonsil	Withers et al.[20]	14.7 (4.4–∞)
Vocal cord	Harrison et al.[29]	>9.9

Larynx	Rezvani et al.[30]	T2[a]: 18 (0–42), T3[a]: 13 (3–23)
Oral cavity/oropharynx	Maciejewski et al.[31]	~25
	Byhardt et al.[32]	>6.5
	Cox et al.[23]	~10.3
	Handa et al.[33]	>7
Lung—non–small cell carcinomas	Cox et al.[23]	50–90
Cervix	Watson et al.[34]	>13.9
Skin	Trott et al.[35]	8.5 (4.5–11.3)
Prostate	Brenner et al.[36]	1.2 (0.03–4.1)
	Brenner and Hall[37]	1.5 (0.8–2.2)
	Fowler et al.[38]	1.5 (1.3–1.8)
	King and Fowler[39]	1.8–2.8
Melanoma	Bentzen et al.[40]	0.6 (0–2.5)[b]
Liposarcoma	Thames and Suit[41]	0.4 (0–5.4)[b]

CI, confidence interval.
[a]American Joint Committee on Cancer staging system.
[b]Lower confidence limit is negative but is listed as 0 because a negative α/β has no biologic meaning.

Repair Kinetics

During altered fractionation schedules, the time interval between the dose fractions becomes crucial for allowing adequate repair of normal tissue. If doses are too closely spaced, injury will accumulate between dose fractions, and successive doses will become increasingly more damaging. This concept is described as *repair kinetics*, which is quantified by the half-time for repair. Of tissue models in which repair kinetics have been studied, half-times for repair tend to be longest (1 to several hours) in the skin, kidney, and spinal cord, shortest (~1/2 hour) in the jejunal mucosa, and intermediate in the lung and colon.[2,58–67] The exact values vary according to the experimental protocol, and considerable overlap exists in the confidence limits of repair half-time. The important point is to ensure an adequate interfraction interval during hyperfractionation.

Repair kinetics is of particular importance in determining the response of the spinal cord to fractionation schedules of more than one daily fraction. In rats, experimental data showed that repair is best described by a biexponential function in which the slower component has a half-time of 3.8 hours.[68] This would imply that any fractionation schedule using more than one fraction per day is associated with some degree of incomplete repair in the spinal cord. A clinical report of radiation myelopathy occurring in four patients whose spinal

cords received 45 to 48 Gy in 28 fractions of 1.5 Gy three times a day with a 6-hour interval over 9 consecutive days supports this observation.[69,70] Two reports from the Radiation Therapy Oncology Group (RTOG)[71,72] showed an increased rate of other late complications in patients treated with HyperRT when the mean interval was <4.5 hours.

Bentzen et al.[73] analyzed late complications in the Continuous, Hyperfractionated, Accelerated Radiation Therapy (CHART) randomized trial, estimated repair half-times, were 4.9 hours (95% CI, 3.2 to 6.4) for laryngeal edema, 3.8 hours (95% CI, 2.5 to 4.6) for skin telangiectasia, and 4.4 hours (95% CI, 3.8 to 4.9) for subcutaneous fibrosis. These results are consistent with observations from two other randomized altered fractionation trials: European Organization for Research and Treatment of Cancer (EORTC) 22791 and EORTC 22851.[74,75] For clinical practice, it is crucial to be mindful of compounding effect of incomplete repair, and a minimum 6-hour interval between dose fractions is typically advised.[76]

Overall Time

The cure rates of some cancers (particularly squamous cell carcinomas) are highly dependent on overall treatment time. Decrease in tumor control with longer treatment times is thought to be due to accelerated repopulation of tumor cells.[77] After a variable lag period, surviving tumor clonogens regenerate rapidly during fractionated radiation therapy to the extent that each additional day of treatment requires approximately 0.6 Gy, to offset potential regeneration, again. This hypothesis suggests a clonogenic cell doubling time of 3.5 to 5 days.[78–80]

Conversely, reduction of the overall treatment time may increase the probability of local tumor control. Molecular marker profiles (TP53, E-cadherin, Ki 67, and EGFR) may aid in the selection of patients likely to benefit from reduction in overall treatment time.[81]

Isoeffect Formulas

The commensurate adjustment of total dose to account for the effect of changes in dose fractionation in the production of a desired is approximated by isoeffect formulas. The first clinical isoeffect curve was produced by Strandqvist.[82] This was followed by other studies,[83–86] culminating in the nominal standard dose formula of Ellis[87]: $D = N^{0.24} \times T^{0.11}$, where D is the dose, N is the number of dose fractions, and T is the overall time. None of these explicitly included dose per fraction.

In the early 1980s, it was recognized that isoeffect doses for various late effects in normal tissues are more sensitive to changes in dose per fraction than are corresponding doses for acute effects. With the widespread use of the LQ model to quantify the fractionation sensitivity, the following model has gained in popularity: $D_1 = D_2(\alpha/\beta + d_2)/(\alpha/\beta + d_1)$, where D_2 is the reference total dose given in fractions of size d_2, and it is desired to calculate the total dose D_1 in fractions of size d_1 that would be isoeffective. This basic formula assumes complete repair between dose fractions, and no time factor is incorporated in it (see Chapter 3 for a detailed discussion). Whereas the LQ-based isoeffect model is remarkably consistent for a wide range of clinical applications, it is limited by at least two factors. First, there is the lack of precision of estimates of α/β. In both animal and human studies, estimates of α/β show large confidence intervals (Table 13.1). Second, as discussed earlier, the severity of complications can be modulated by various agents, including growth factors, radioprotectors, and pharmacologic agents. In the end, the isoeffect formula is neither perfect nor sufficiently reliable to substitute for sound judgment, and each new fractionation schedule must be tested clinically to establish its safety and efficacy.

Rationale for Hyperfractionated Radiotherapy

Hyperfractionation employs small-dose fractions to allow higher total doses to be delivered within the tolerance of late-responding normal tissues, thus enabling a higher biologically effective dose to the tumor. For this rationale to hold, the α/β ratio for both tumor cells and acute responding tissues must be greater than that for the dose-limiting normal tissue. Other rationales for HyperRT include radiosensitization through cell cycle redistribution and lesser dependence on oxygen effect.[88]

HyperRT has been tested in more than 20 randomized trials, and these are summarized in the data presented in Table 13.2. Regimens are classified as either hyperfractionated or accelerated. In hyperfractionation, the total dose and number of fractions are increased whereas the size of dose per fraction is reduced, and overall time is relatively unchanged. In accelerated fractionation, overall time is significantly reduced.

Rationale for Accelerated Fractionation

The rationale for accelerated fractionation is that reduction in overall treatment time decreases the opportunity for tumor cell regeneration, thereby increasing the probability of tumor control for a given total dose. Because overall treatment

time has little influence on the probability of late normal tissue injury, a therapeutic gain should be realized, provided the interval between dose fractions is sufficient for complete repair to take place.

Strategies to accelerate radiation can be divided into two categories: (a) *pure accelerated fractionation* regimens, with reduced overall treatment time without concurrent changes in the fraction size or total dose (Table 13.3), and (b) *hybrid accelerated fractionation*, with reduced overall treatment time in conjunction with changes in other parameter(s), such as the fraction size, total dose, and time distribution (Table 13.4). The categories are further described as follows (Figs. 13.1–13.3):

Type A: There is drastic reduction of the overall time, with substantial decrease in the total dose.

Type B: Duration of treatment is more modestly reduced, with total dose kept in the same range, and there is a break in treatment.

Type C: Duration of treatment is more modestly reduced, with total dose kept in the same range, with a concomitant boost phase.

CLINICAL STUDIES

This section summarizes the results of hyperfractionated (HF) radiotherapy trials and accelerated fractionation (AF) radiotherapy trials. A new subsection summarizes results of pure hypofractionated radiotherapy (fraction size of >2 Gy). There is also a summary of combined altered fractionation with concurrent chemotherapy, critical fractionation issues to consider when intensity-modulated radiotherapy (IMRT) is used, common clinically practiced fractionation schedules, and future directions in combining molecular targeting with altered fractionation.

Results of HyperRT Trials

The key findings of HyperRT include the following:

- HF offers better locoregional control than standard fractionation when radiotherapy alone is used in the treatment of locally advanced head and neck carcinoma. This was also associated with an improvement in survival in three trials.[78]
- Reducing the fraction size from 2 Gy to 1.1 to 1.2 Gy permits a 7% to 17% total radiation dose escalation without increase in late complications. This supports the existence of differential fractionation sensitivity (variable α/β

ratios) between human late-responding normal tissues and head and neck carcinomas.

Altered fractionation radiotherapy improves survival in patients with head and neck squamous cell carcinoma (HNSCC).[120] Comparison of the different types of altered radiotherapy suggests that hyperfractionation provides the greatest benefit. An individual patient data meta-analysis was conducted to see the effect of altered fractionation radiotherapy. It revealed a significant absolute survival benefit of 3.4% at 5 years with altered fractionation radiotherapy (hazard ratio [HR], 0.92; 95% confidence interval [CI], 0.86 to 0.97; $P = .003$) among 6,515 patients with nonmetastatic HNSCCs in 15 randomized trials comparing conventional radiotherapy with altered fractionation. The survival benefit at 5 years with HyperRT was 8%, with accelerated radiotherapy was 2% (without total dose reduction), and was 1.7% (with total dose reduction; $P = .02$). Locoregional control was better with altered fractionation (6.4% at 5 years; $P < .0001$), with particularly effect improved local control and less benefit for nodal control. The benefit was significantly higher in the youngest patients, <50 years old.

Table 13.2 summarizes reported prospective, randomized trials addressing hyperfractionation for the treatment of patients with head and neck, bladder, lung, and brainstem tumors; whole-brain radiotherapy for pediatric acute lymphoblastic leukemia; whole-brain radiotherapy for brain metastases or prophylactic whole-brain radiotherapy; and rhabdomyosarcoma. The most striking results are from trials in HNSCC, for which HyperRT was accompanied by an increase in dose.

Head and Neck

In all four head and neck trials,[75,89–92] HyperRT allowed a higher total dose to be delivered, which produced improved locoregional control by 8% to 20%. In three of these trials, HyperRT improved overall survival by 10% to 19%. In all four studies, HyperRT produced more severe acute mucositis but no increase in late morbidity. A Brazilian group[89] tested HyperRT of 70.4 Gy at 1.1 Gy twice daily and showed improved local response by 20% and 3.5-year overall survival from 8% to 27%. The EORTC tested 80.5 Gy HyperRT at 1.15 Gy/fraction twice per day for 7 weeks.[75] The 10-Gy increase in dose improved locoregional control from 38% to 56% and overall survival.[78,90] The Princess Margaret Hospital (Toronto, Canada) tested 58 Gy at 1.45 Gy twice per day over 4 weeks versus 51 Gy at 2.55 Gy/fraction once daily (a standard fractionation at that

institute).[91] The 7-Gy increase in dose improved locoregional control from 37% to 45% and improved 5-year overall survival from 30% to 40%.

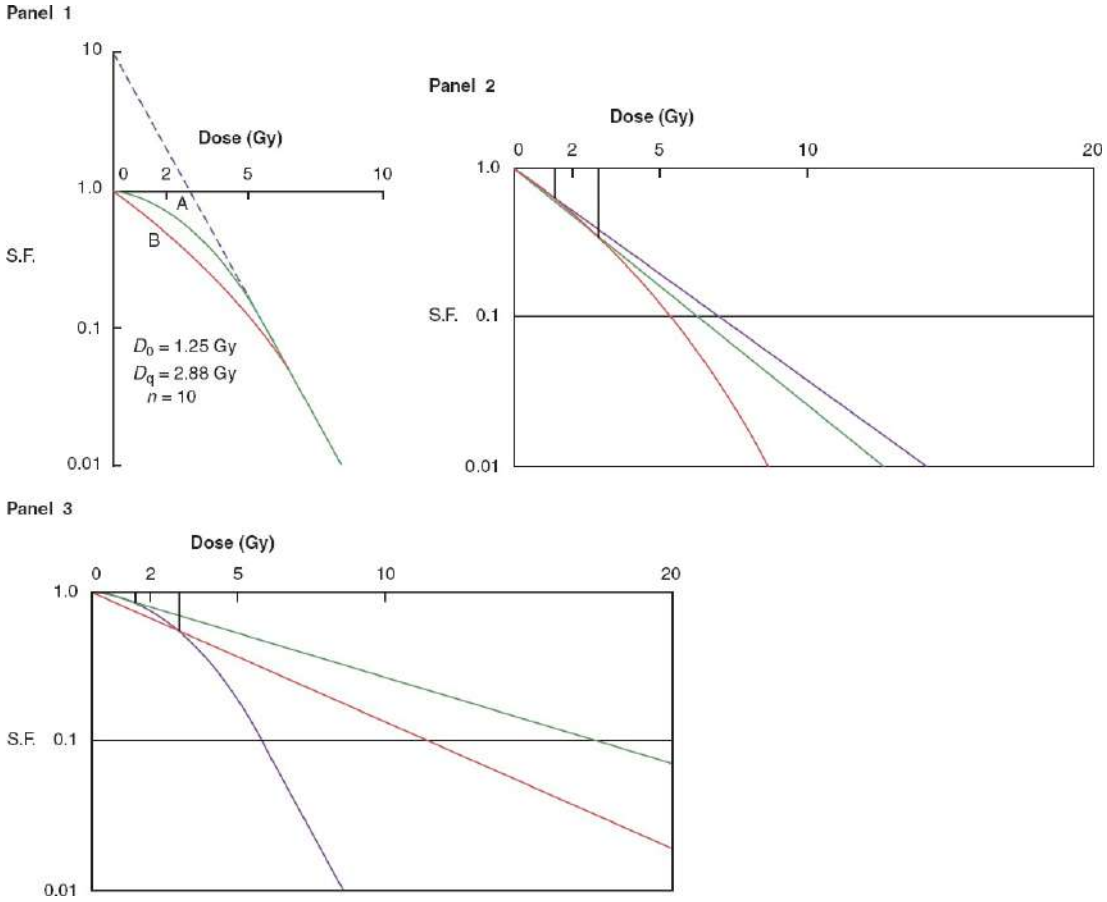

FIGURE 13.1. The importance of survival curve shoulder *shape* rather than width for the response to fractionated irradiation. *Panel 1:* Two survival curves with the same D_0, D_q, and n but with different initial slopes and shoulder curvatures. In terms of the linear quadratic model of cell survival, the α/β ratio is lower for curve A than for curve B. *Panels 2 and 3:* Effect of change in fraction size on the dose required for a given effect. *Panel 2:* When the shoulder has a steep initial slope and little curvature (high α/β), a change in dose per fraction from 3 to 1.5 Gy would only slightly increase the total dose needed to produce a given survival fraction. *Panel 3:* When the shoulder has a shallow initial slope and marked curvature (low α/β), a much greater increase in total dose is necessary to produce a given survival fraction when the same change in dose per fraction is made. (From Peters LJ, Brock WA, Travis EL. Radiation biology at clinically relevant fractions. In: DeVita V, Hellman S, Rosenberg SA, eds. *Important advances in oncology*. Philadelphia: JB Lippincott, 1991:65–83. With permission.)

The RTOG 9003 trial[92] tested 81.6 Gy at 1.2 Gy/fraction HyperRT twice per day over 6 weeks versus 70 Gy at 2 Gy/fraction versus two accelerated regimens (a continuous and a split-course accelerated regimen), as shown in Tables 13.2 and 13.4. HyperRT improved locoregional control from 46% to 54.4% (similar to the improvement by AF with the concomitant boost arm of the trial). This trial gives strong evidence that total dose and treatment duration are important to outcome. Locoregional control was significantly improved by an increase of the total dose without changing overall time using HyperRT or by accelerated overall treatment time without changing total dose using concomitant boost fractionation.

Meta-analysis of HyperRT and accelerated radiotherapy in unresected locally advanced squamous cell carcinoma of the head and neck showed a substantial prolongation of median survival (14.2 months; $P < .001$) for HyperRT compared to CFRT.[121] Of the four hyperfractionation trials,[75,90,122] one from Barcelona[122] has been criticized for questionable quality.[123] All four trials showed a statistically significant survival benefit. Studies testing HyperRT without dose escalation did not show a survival advantage.[124,125] Overall, HyperRT is a useful tool to enable dose escalation without an increase of severe late toxicity.

Bladder Cancer

In the study by Edsmyr et al.,[28] T2–T4 bladder tumors were randomized to either three 1-Gy daily fractions 4 hours apart with interfraction intervals to 84 Gy or a single daily fraction of 2 Gy to total dose of 64 Gy, both given in a split course over 8 weeks. Cystoscopic complete response rate increased from 36% to 65% with HyperRT ($P < .001$), and the 5-year survival rate also significantly increased. However, severe late complications were higher in the hyperfractionated arm, indicating that the dose chosen might not be equivalent for late normal tissue injury. An updated analysis revealed that the survival benefit persisted for 10 years, but there was a trend for higher bowel complications requiring surgery in the HyperRT group.[93]

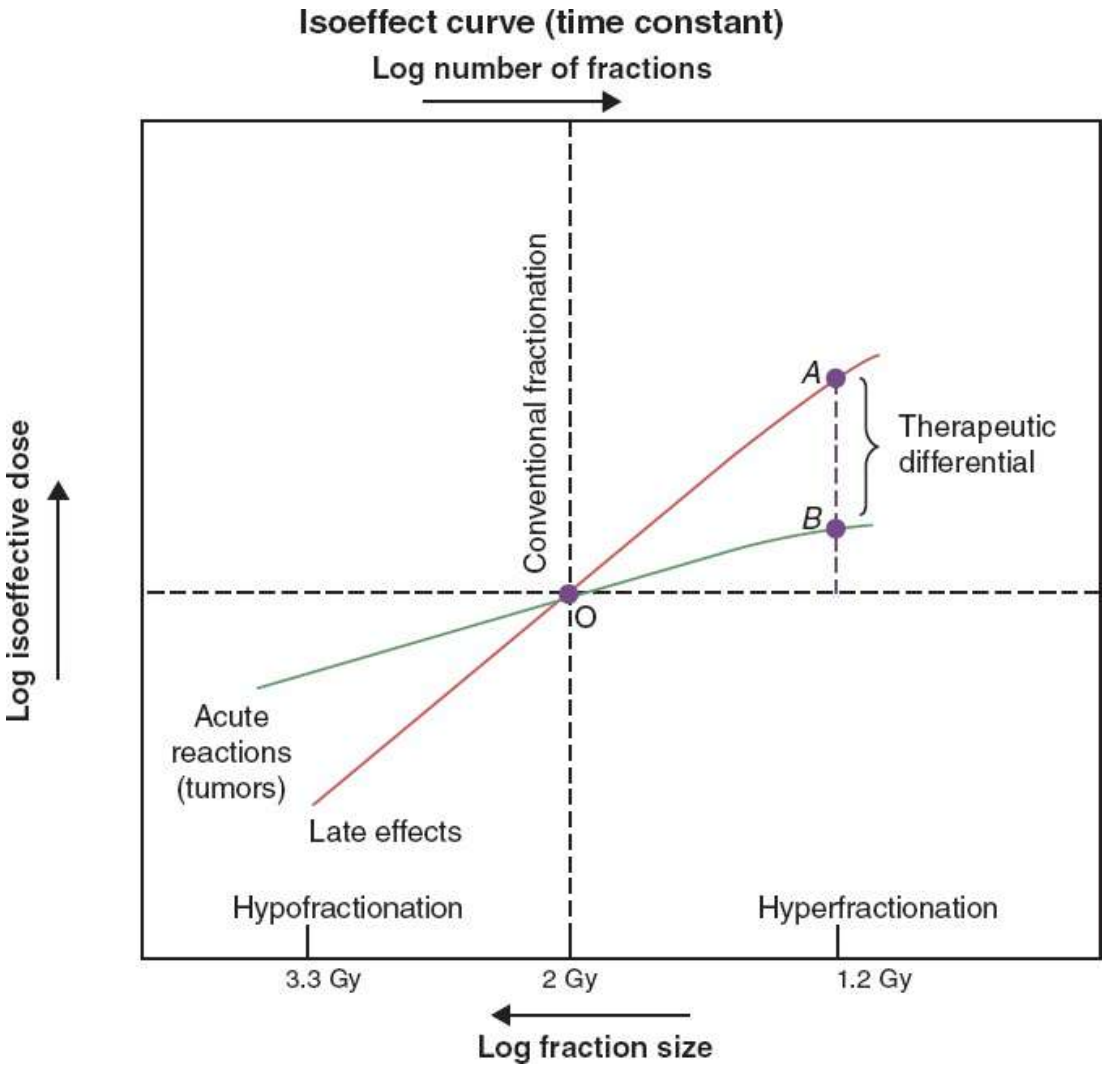

FIGURE 13.2. Effect of change in size of dose fraction (with overall time held constant) on the total dose necessary to produce a given level of acute and late effects. The curves are normalized to the "conventional" 2 Gy/fraction. Changes in fraction size have a relatively greater effect on the isoeffective doses for late reactions than for acute reactions and for the response of tumors with high α/β ratios. Consequently, by reducing the dose per fraction—for example, from 2 to 1.2 Gy—the total dose for equivalent late effects can be increased from O to *A,* which is greater than the increase (O to *B*) required to achieve an equivalent tumor response. The increment in dose from *B* to *A* represents the therapeutic differential achieved by hyperfractionation.

Non–Small Cell Lung Cancer

The joint Intergroup trial[94] of the RTOG, the Eastern Cooperative Oncology Group (ECOG), and the Southwest Oncology Group compared induction chemotherapy (cisplatin and vinblastine) plus 60 Gy in 2-Gy fractions or HyperRT (69.6 Gy in 1.2-Gy fractions) with CFRT (60 Gy in 2-Gy fractions). Though considered slightly more effective, HyperRT did not significantly

improve survival over CFRT.

Two concurrent regimens with standard or HyperRT were tested as part of three arms of RTOG 9410, a phase III trial. Six hundred ten patients had either neoadjuvant cisplatin and vinblastine or the same chemotherapy concurrent with 60-Gy standard fractionation versus concurrent cisplatin and etoposide with HyperRT (69.6 Gy delivered as 1.2-Gy twice-daily fractions). Median survival times were 14.6, 17.0, and 15.6 months, respectively. Five-year survival was statistically significantly higher for patients treated with the concurrent regimen with once-daily radiotherapy (TRT) compared with the sequential treatment (5-year survival: sequential, arm 1, 10% [20 patients], 95% CI = 7% to 15%; concurrent, arm 2, 16% [31 patients], 95% CI, 11% to 22%, *P* = .046; concurrent, arm 3, 13% [22 patients], 95% CI, 9% to 18%). Late toxic effects were similar.[95]

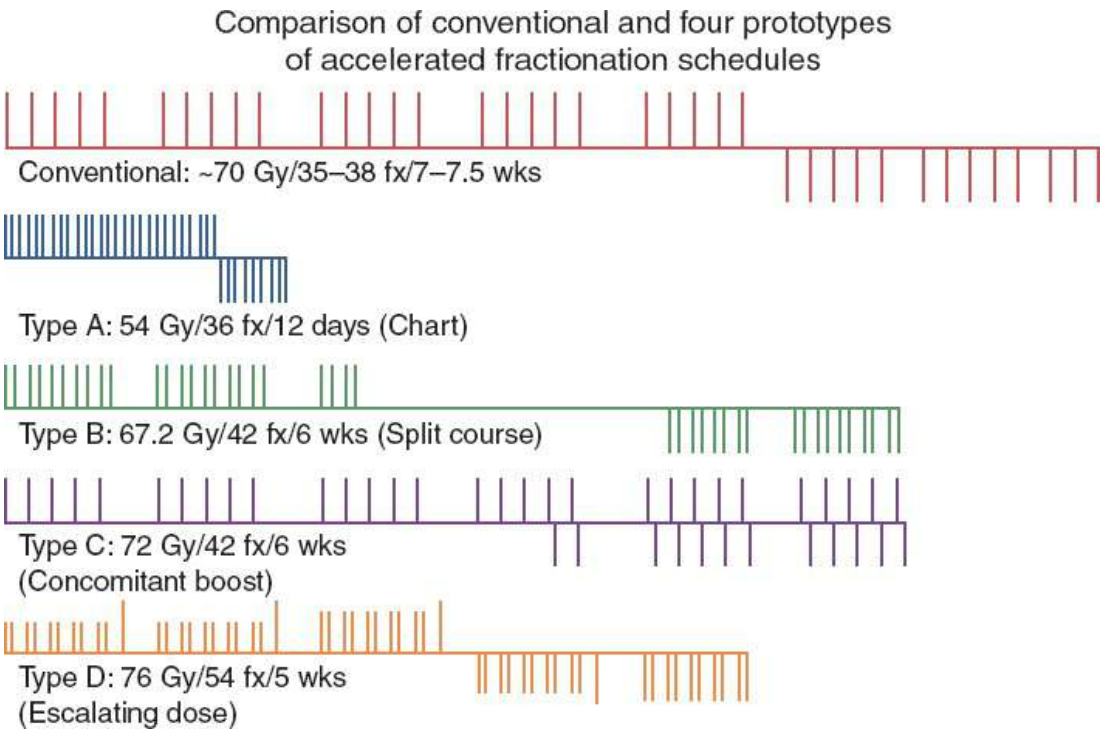

FIGURE 13.3. Conventional and accelerated fractionation schedules. For each regimen, the large-field treatment is depicted by the bars above the horizontal line and the boost-field irradiation by the bars below the line. The dotted bars represent treatment omitted in the lower ranges of total dose. fx, fraction.

Childhood Brainstem Tumor

The trial of the Pediatric Oncology Group[96] compared the efficacy of 70.2 Gy given as 1.17 Gy/fraction versus 54 Gy in 1.8-Gy fractions, both in combination

with 100 mg/m^2 cisplatin. This study showed no difference in the median time to disease progression, median time to death, or survival rates at 1 and 2 years, with no significant difference in toxicity.

Cranial Radiation Therapy for High-Risk Acute Lymphoblastic Leukemia

To test whether HyperRT could reduce incidence and severity of late toxicities associated with 18-Gy prophylactic cranial radiotherapy, 369 children on two consecutive Dana-Farber Cancer Institute Consortium protocols were randomized to 18 Gy delivered in ten 1.8-Gy fractions once daily over 2 weeks versus 18 Gy delivered in twenty 0.9-Gy fractions. No benefit was seen in terms of cognitive late effects, and the results suggested that HF may compromise antileukemic efficacy.[97,98]

Group III Rhabdomyosarcoma

A total of 490 children with group III rhabdomyosarcoma (RMS) were randomized to HyperRT (59.4 Gy in fifty-four 1.1-Gy twice-daily fractions) versus CFRT to 50.4 Gy in the Intergroup RMS Study IV. This trial showed that HyperRT did not improve local/regional control, failure-free survival, or overall survival compared with CFRT and that HyperRT actually produced more acute toxicity.[99] Unlike studies in HNSCC showing positive results with dose-escalated HyperRT, an escalation of dose by 9.5 Gy did not improve outcome for RMS.

Unresected Brain Metastasis

RTOG 9104 compared 1-year survival and acute toxicity rates between an accelerated HyperRT (1.6 Gy twice a day) to a total dose of 54.4 Gy and an accelerated hypofractionated (HypoRT) arm of 30 Gy in 10 daily fractions in patients with unresected brain metastasis. Of 429 analyzable patients, the median survival time was 4.5 months in both arms. The 1-year survival rate was 19% in the HypoRT arm versus 16% in the HyperRT arm. Grade III or IV toxicity was equivalent in both arms. In spite of an escalated dose, HyperRT was of no benefit.[100]

Prophylactic Cranial Irradiation for Limited-Stage Small Cell Lung Cancer

To test whether higher-dose prophylactic cranial irradiation (PCI) would reduce brain metastases, 720 patients with limited-stage small cell lung cancer (SCLC)

who were in complete remission after chemotherapy and thoracic radiotherapy were randomized to standard 25 Gy in 10 daily versus 36 Gy either as 18 daily 2-Gy fractions or accelerated HyperRT as 24 twice-daily 1.5-Gy fractions in 16 days. There was no significant difference in the 2-year incidence of brain metastases and a lower overall survival in the higher-dose group. PCI at 25 Gy was recommended as the standard of care in limited-stage SCLC.[101]

Results of Accelerated Radiotherapy Trials

Key findings of accelerated regimens include the following:

- Modest acceleration by 1 week by delivering six fractions of 2 Gy/week or a concomitant boost regimen without dose reduction or treatment break yields superior locoregional control of head and neck carcinomas without increase in late toxicity but without clear impact on survival. Acceleration by more than 3 weeks with a 10% total dose reduction (<6 to 7 Gy) also improves the locoregional control without demonstrable increase in late complications. However, a further 5% to 8% total dose reduction abrogates the gain in tumor control but appears to reduce the severity of some late normal tissue complications, such as fibrosis and edema.
- Mucositis per se or its consequential late toxicity prevents delivery of more than 12 Gy/week when given in two fractions of 2 Gy/day for 5 days a week or daily fractions throughout weekends to a total dose of 66 to 70 Gy (pure acceleration).
- Acceleration achieves significantly improved local control for well-differentiated tumors and advanced primary mucosal site tumors but may be of little benefit to advanced nodal disease and poorly differentiated tumors. This supports the existence of the accelerated proliferation phenomenon in mucosa-derived tumor cells.

The trials are classified into either pure accelerated, with same total dose, or hybrid accelerated, of which there are three types: (a) accelerated with dose reduction, (b) accelerated with split course, and (c) accelerated with concomitant boost.

Pure Accelerated Fractionation

Table 13.3 summarizes the radiation regimens and outcomes of six reported randomized trials of pure AF for the treatment of patients with NSCLC lung and head and neck carcinoma.

Non–Small Cell Lung Cancer

A study of 204 patients randomized them to 60 Gy in 3 weeks versus 60 Gy in 6 weeks, both with and without concurrent carboplatin.[102] The results showed no survival advantage with either acceleration or concurrent carboplatin. The study showed that 60 Gy in 3 weeks induced a significantly greater esophagitis than did 60 Gy in 6 weeks.

Head and Neck Cancer

The first two HNSCC studies shown in Table 13.3[103,104] induced unacceptable toxicity, leading to early termination, and these two fractionations have been abandoned. However, two of the other three trials showed positive results,[105,107] whereas one[106] showed no benefit and similar late toxicity.

The Polish Cooperative Group compared 66 Gy given in 33 fractions over 38 days (two fractions every Thursday) as compared with a conventional regimen of 66 Gy given in 33 fractions over 45 days. In the study, 395 patients with T1–T3, N0, M0 glottic, and supraglottic laryngeal cancer were randomized. There was no difference in terms of locoregional control ($P = .37$).[106]

The Danish trial, one of the largest trials of altered fractionation,[105] accrued 1,485 patients with larynx, oropharynx, and oral cavity carcinomas of all stages. Six versus 7 weeks of treatment was achieved by giving a sixth fraction each week. Overall 5-year locoregional control rates improved (70% vs. 60%; $P = .0005$). The benefit of shortening treatment time was seen for primary tumor control (76% vs. 64%; $P = .0001$) but not for neck node control. Acceleration from 7 to 6 weeks improved voice preservation in laryngeal cancer (80% vs. 68%; $P = .007$) and improved disease-specific survival (73% vs. 66%; $P = .01$) but not overall survival. Multivariate analysis of 754 larynx cancers showed that AF was beneficial in tumors that were moderately and well differentiated, with no benefit for those that were poorly differentiated. This effect suggests that the mechanism of repopulation in the primary tumor may be similar to the response in the original normal mucosa and in its functional mechanism of regeneration. This capacity to respond to the trauma of irradiation is more likely to exist in well-differentiated tumors, and the process may be facilitated by signaling from the surrounding normal mucosa. Accelerated proliferation may, therefore, be a response of the primary tumor and not the nodal metastases.[126]

Nasopharynx

Pure acceleration for nasopharynx cancer was tested in Guangxi, China. In the

study, 416 patients were randomized to three arms: all had 7,400 to 7,600 cGy given as accelerated six fractions per week with or without concurrent cisplatin and 5-fluorouacil versus the conventional five 2-Gy fractions per week. The local recurrence rates were 16.7% in the accelerated group, 13.6% in the accelerated-concurrent group, and 27.3% in the CFRT group ($P < .05$). The 5-year survival rates were 53.6%, 57.6%, and 43.8% ($P < .05$), respectively. The interesting finding was that acceleration had a similar effect as concurrent chemotherapy with acceleration for nasopharynx cancer.[107]

Hybrid Accelerated Fractionation

Table 13.4 summarizes the details of regimens and outcomes of reported prospective, randomized trials addressing the role of types A to C hybrid accelerated fractionation (Fig. 13.4).

Type A

Accelerated fractionation regimens (with dose reduction) were addressed in trials shown in Table 13.4, including a trial in HNSCC (definitive and postoperative), brain metastases, and NSCLC. It includes trials by the British Medical Research Council (MRC), the Trans-Tasman Radiation Oncology Group (TROG), the French Radiotherapy Oncology Group for Head and Neck Cancer (GORTEC), and the ECOG.

Head and Neck

As shown in Table 13.4, two trials for HNSCC—the MRC CHART[126] and TROG regimens[109]—did not yield improvement in locoregional control and disease-free and overall survival rates. In contrast, the GORTEC regimen[110] for locally advanced head and neck carcinoma, with a 3.5-week acceleration and only 7-Gy (10%) dose reduction, significantly improved the locoregional control, with no gain in the overall survival rate.

Based on the potential for accelerated proliferation after surgery, Awwad et al.[111] in Cairo explored acceleration in postoperative radiotherapy of locally advanced HNSCC. Seventy patients with T2/N1–N2 or T3–T4/any N squamous cell carcinoma of the oral cavity, larynx, and hypopharynx were randomized to accelerated HyperRT of 46.2 Gy in 12 days versus CFRT (60 Gy per 6 weeks). The 3-year locoregional control rate was better with accelerated treatment (88% ± 4%) versus CFRT (57% ± 9%; $P = .01$), with no difference in survival (60% ± 10% vs. 46% ± 9%; $P = .29$). As expected, acute mucositis was more severe in the accelerated group, and fibrosis and edema also tended to be more frequent;

this finding contrasts with the results in two postoperative studies of type C (concomitant boost) described later and in Table 13.4.[115,118]

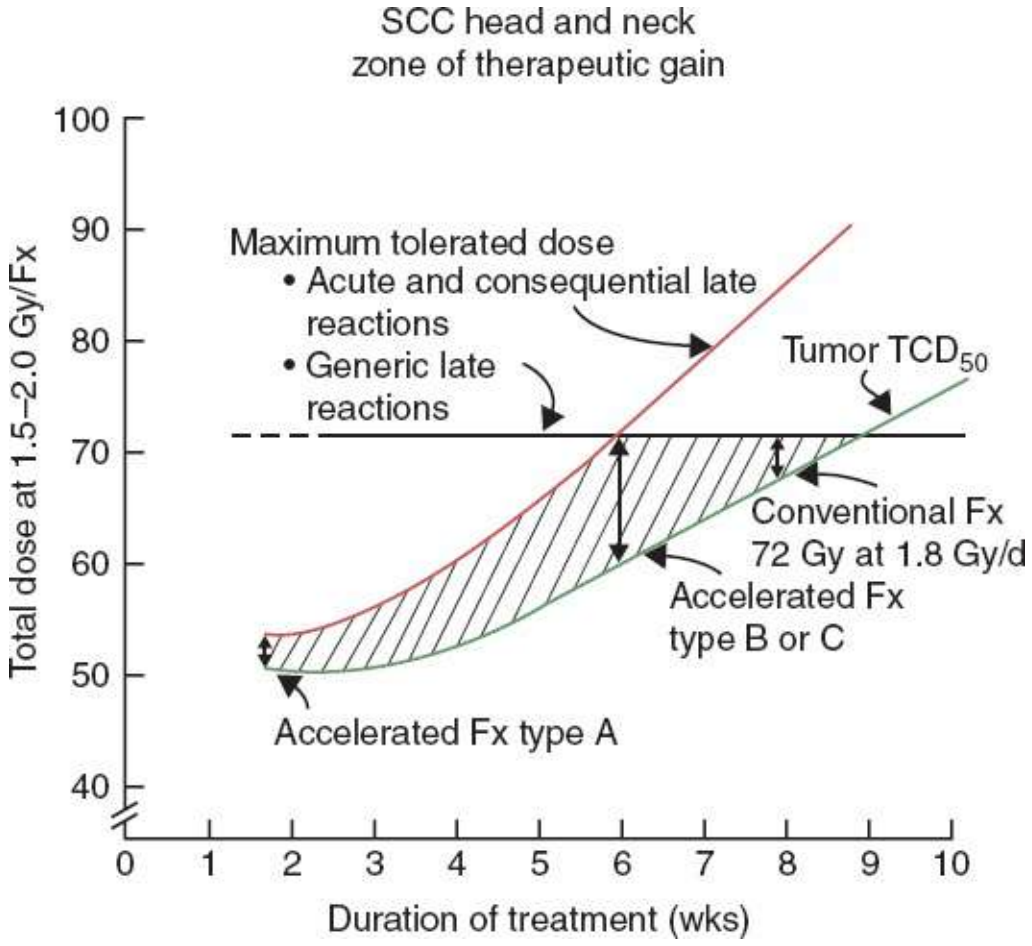

FIGURE 13.4. Zone of therapeutic gain in squamous cell carcinomas (SCCs) of the head and neck for different accelerated fractionation schedules. Type A is 54 Gy in 36 fractions over 12 days, type B is 67.2 Gy in 42 fractions over 42 days, and type C is 72 Gy in 42 fractions over 40 days. For explanation, see text. (From Peters LJ, Brock WA, Travis EL. Radiation biology at clinically relevant fractions. In: DeVita V, Hellman S, Rosenberg SA, eds. *Important advances in oncology*. Philadelphia: JB Lippincott, 1991:65–83. With permission.)

Non–Small Cell Lung Cancer

One randomized, controlled trial showed that CHART improves survival over standard radiotherapy of 60 Gy in 30 fractions in patients with locally advanced, unresectable stage III NSCLC. This MRC trial[112] showed that CHART with a 4-week acceleration and 6-Gy (10%) dose reduction decreased the risk for local progression and improved the overall survival significantly without increasing short- and long-term morbidity. These patients are now routinely given concurrent chemotherapy. However, in some countries, selected patients who are

not fit for chemotherapy or patients who prefer radiotherapy only may be considered for CHART. The ECOG tested accelerated radiotherapy after induction chemotherapy (two cycles of carboplatin plus paclitaxel) in stage IIIA and B NSCLC. Acceleration was achieved with 57.6 Gy (1.5 Gy three times a day for 2.5 weeks) versus CFRT (64 Gy in 2 Gy/day). Of 141 patients enrolled, 83% were randomly assigned—60 accelerated and 59 conventional. The median survival was 20.3 and 14.9, respectively (P = .28). With the acceptance that concurrent chemoradiation is more effective than sequential treatment, this trial closed early.[113]

Further acceleration to 2.5 weeks was tested in a trial of CHARTWEL (CHART weekend less), in which 406 patients with NSCLC were randomized to receive three-dimensional planned radiotherapy to 60 Gy/40 fractions/2.5 weeks (CHARTWEL) or 66 Gy/33 fractions/6.5 weeks (conventional fractionation [CF]). Overall survival (OS; primary endpoint) at 2, 3, and 5 years was not significantly different after CHARTWEL (31%, 22%, and 11%) versus CF (32%, 18%, and 7%; HR, 0.92; 95% CI, 0.75 to 1.13, P = .43). Local tumor control rates and distant metastases did not significantly differ.[114]

Split-Course Accelerated Fractionation Regimen (Type B)

Split-course accelerated regimens (type B) are also shown in Table 13.4. This was addressed by EORTC[74] and RTOG,[92] by a study from Florence, Italy,[116] of patients with locally advanced head and neck carcinomas, and by the Royal Marsden NHS Trust, Institute of Cancer Research, London, for bladder cancer.[117] The EORTC regimen consisted of 28.8 Gy over 7 days, followed by a 2-week break, then 43.2 Gy over 11 days to a cumulative dose of 72 Gy in 45 fractions over 5 weeks. Although the 2-week acceleration improved locoregional control, it produced twice as many grade 3 to 4 acute morbidities, more late toxicity (P < .001), seven cases of permanent peripheral neuropathy, and two cases of myelopathy. This regimen has been abandoned.

The RTOG split regimen was comparable to that of the Massachusetts General Hospital study[127]: two fractions of 1.6 Gy/day to a total dose of 67.2 Gy in 6 weeks, including a 2-week break in treatment after 38.4 Gy, with the standard 70 Gy in 7 weeks. This 1-week acceleration with a 3.8-Gy (5%) dose reduction increased acute mucositis without improving the locoregional control rate, with the concomitant boost and hyperfractionation arm being superior. Fallai et al.[116] reported an Italian multicenter randomized trial that treated 192 patients with advanced carcinoma of the oropharynx with CFRT (arm A: 66 to

70 Gy in 33 to 35 fractions for 5 days a week over 6.5 to 7 weeks) versus accelerated split-course radiotherapy (arm B: 64 to 67.2 Gy in two fractions of 1.6 Gy for 5 days a week with 2-week split at 38.4 Gy) versus concomitant chemoradiation (arm C: same radiotherapy as arm A plus concomitant carboplatin and 5-fluorouracil). Although the results did not reach statistical significance, chemoradiation almost doubled the 5-year overall survival (21%, 21%, and 40% for arms A, B, and C, respectively) and relapse-free survival (15%, 17%, and 36% for arms A, B, and C, respectively). There was a slight trend toward better 5-year locoregional control (P = .07) for the combined arm: patients without locoregional relapse in arm C, 21%, 18%, and 48% for arms A, B, and C, respectively. The occurrence of persistent G3 xerostomia was comparable in the three treatment arms.

The Royal Marsden study in London evaluated the efficacy and toxicity of an accelerated regimen to treat T2 or T3, N0 or N1 muscle-invasive bladder cancer. The 229 patients were randomized into two groups and given 60.8 Gy in 32 fractions over 5 weeks with a 1-week treatment gap after the first 12 fractions versus 64 Gy in 32 fractions over 6.5 weeks. Acceleration was achieved by two fractions per day of 1.8 and 2.0 Gy. RTOG grade 2 or 3 bowel toxicity in the accelerated arm was 44% versus 26% in the CFRT arm (P trend = .001), with no difference is acute grade 2 or 3 bladder toxicity or late RTOG grade 2 toxicity equivalent. There was no significant difference in disease-free survival and overall survival at 3 and 5 years.[117]

Concomitant Boost Accelerated Fractionation Regimen (Type C)

Concomitant boost acceleration (type C) was also addressed by the RTOG[92]; this regimen was designed at the MD Anderson Cancer Center[128] and delivers 54 Gy of wide-field irradiation in 1.8-Gy fractions over 6 weeks and 18 Gy of boost dose given in 1.5-Gy fractions as second daily fractions during the last 2.5 weeks. This regimen was found to improve the locoregional control rate, with a strong trend for a higher disease-free survival rate and with more severe mucositis but no detectable increase in late complications.

Concomitant boost-type fractionation was also tested for postoperative radiation therapy in two phase III trials.[118,128] Ang et al.[129] randomized patients with high-risk pathologic features to 63 Gy given in 35 fractions over either 5 weeks (daily fractions for 3 weeks and then two fractions per day for 2 weeks) or 7 weeks. This study showed that the cumulative time of the combined treatment was a significant determinant of locoregional control and overall survival.

Concomitant boost partially offsets the detrimental effect of a delay in initiating radiation therapy beyond 6 weeks after surgery without inducing a detectable increase in late complications. These findings were confirmed by Sanguineti et al.[118] in Genoa, Italy, who randomized patients from four institutions with one or more high-risk features after surgery to CFRT (60 Gy in 6 weeks) versus 64 Gy in 5 weeks with twice-daily treatment in the first and last weeks of treatment. Once again, there was no difference in outcome between the two arms; however, there was a trend for improved locoregional control for patients who had a delay in starting radiotherapy and who were treated with acceleration compared with those with a delay who were treated with CFRT (HR, 0.5; 95% CI, 0.2 to 1.1). Acceleration does not seem worthwhile postoperatively for carcinoma of the head and neck, although it might be an option for patients who delay starting radiotherapy.

A phase III trial in patients with glioblastoma multiforme (GBM) assessed the role of a combined accelerated, hyperfractionated regimen with a 2-week reduction of therapy duration and a dose increment of 11 Gy (18%).[119] This radiation regimen, with or without difluoromethylornithine, was found to yield no better progression-free and overall survival rates.

Pure Hypofractionated Radiotherapy (HypoRT) for Breast Cancer

Elective mastectomy rates among breast conservation candidates are consistently highest among underserved patients with limited access to radiotherapy services.[130,131] For such a common disease, the commitment to daily CFRT has significant barriers, mainly related to the inconvenience of a 3- to 7-week regimen and the cost of treatment—both direct health care expenditures and opportunity costs to the patient and society due to time away from home and work.[132] Hypofractionated radiotherapy (HypoRT) for breast cancer has therefore been seen as a logical solution to these disparities, but has a long and controversial history dating back to the 1960s.[87,133–135] Early understandings of radiobiology (inadequate reductions of total dose to compensate for increased fraction size) along with limitations in technology (high skin doses, gross off-axis inhomogeneities) contributed to poor outcomes in the mid-to-late twentieth century.[136] Fortunately, perseverance to better understand the biologic dose–response of breast cancer and normal tissue as well as the desire to improve access and cost of adjuvant radiotherapy led to a modern renaissance of HypoRT in the late 1990s.

Modest HypoRT

Although 2.0-Gy fraction size has been considered standard since the beginning of the breast conservation era, modest, daily hypofractionation with fractional doses between 2.5 and 3.3 Gy has been common practice in countries with centralized healthcare systems such as the United Kingdom and Canada, where reduction in total treatment time represents significant cost savings. Long-term data are now available from multiple randomized hypofractionated trials in breast cancer and these are summarized in Table 13.5.

TABLE 13.5 RECENTLY PUBLISHED PROSPECTIVE, RANDOMIZED TRIALS OF MODESTLY FRACTIONATED BREAST HYPOFRACTIONATED RADIOTHERAPY

Study	Enrollment	Number of Patients	Dose/Fx (Gy)	Total Dose (Gy)	Overall Time (wk)	Follow-up (y)	Tumor Control	T

control; RMH, Royal Marsden Hospital.

Phase III trials from the United Kingdom began with the Royal Marsden Hospital (RMH) study and progressed to include the two multi-institutional Standardisation of Breast Radiotherapy Trials (START A and B). All of these studies used 50 Gy in 25 fractions as the standard arm and tested multiple iterations of modest hypofractionation schemes over 3 to 5 weeks in an endeavor to determine the most appropriate biologically equivalent dose for both efficacy and toxicity. The RMH study accrued 1,410 patients from 1986 to 1998 and used an every-other-day schedule to test two HypoRT regimens (39.0 or 42.9 Gy in 13 fractions).[137] In this study, all patients had undergone BCS and nearly 75% of patients were prescribed an additional tumor bed boost. At 10 years follow-up, there were no differences in local control among the treatment arms. The 39-Gy HypoRT arm of the RMH study exhibited cosmetic outcome that was equivalent to CFRT, and so it was chosen as the "standard-experimental" arm of the START A Trial.

START A (1999 to 2002) tested two dose levels of a 13-fraction schedule, again every other day, against the sCFRT with the aim of measuring the sensitivity of normal and malignant tissues to fraction size.[138] Two thousand two hundred thirty-six women with early breast cancer (pT1-3a, pN0-1, M0) were randomized to receive after primary surgery (85% BCS) standard 50 Gy in 25 fractions versus 41.6 Gy or 39 Gy in 13 fractions of 3.2 Gy or 3.0 Gy over the same 5 weeks. Over 60% of patients who had BCS as primary surgery received an additional tumor bed boost. After a median follow-up of 9.3 years, the rate of locoregional tumor relapse was at 7.2% after 50 Gy, 6.3% after 41.6 Gy, and 8.8% after 39 Gy. There was a lower rate of late adverse effects after 39 Gy than with 50 Gy in terms of breast induration, telangiectasia, and edema. The START B Trial (1999–2001) ran concurrently with START A and randomized 2,215 women with pT1-3a, pN0-1, M0 breast cancer to 50 Gy in 25 fractions over 5 weeks versus 40 Gy in 15 fractions of 2.67 Gy, (this time once daily) over 3 weeks.[138] A total of 92% of patients had undergone BCS of which 43% received an additional tumor bed boost. After a median follow-up of 9.9 years, treatment with daily HypoRT 40 Gy in 15 fractions produced the same rates of locoregional tumor relapse as that with 50 Gy in 25 fractions (4.3% vs. 5.5%). The rates of late adverse effects (breast shrinkage, telangiectasia, and edema) were lower after 40-Gy than after 50-Gy treatment by photographic and patient self-assessments.

Similar to START B, a Canadian study in 1,234 stage I, postmenopausal

women tested daily HypoRT (42.5 Gy in 16 fractions, 3 weeks) versus CFRT (50.0 Gy in 25 fractions, 5 weeks). All patients in this study underwent BCS with clear resection margins and none received an additional boost.[139] At 10 years, the risk of local recurrence was similar: 6.7% with standard fractionation versus 6.2% with hypofractionated regimen and the rate of women with a good or excellent cosmetic outcome was also similar. A meta-analysis of nearly 8,200 patients included in the four abovementioned trials as well as nine additional published studies showed that for early breast cancer, there are no significant differences in local failure, regional failure, or survival in patients treated with HypoRT versus CFRT.[140] In addition, HypoRT is associated with significantly less acute toxicity while providing equivalent late cosmetic outcomes.

There are differing opinions as to whether routine use of HypoRT should be restricted to patients that represent the majority of subjects enrolled in these clinical trials (postmenopausal, stage I, post-BCS) or whether they should be considered studies of biologic equivalence to be reasonably extrapolated to underrepresented subgroups. The American Society for Radiation Oncology therefore developed an evidence-based guideline to provide direction for clinical practice.[141] The panel considered the data sufficient to support the use of hypofractionated whole-breast irradiation for patients with early-stage breast cancer who were of age 50 years or older, had disease stage pT1-2, pN0, and did not receive chemotherapy. However, it remains highly unlikely that separate clinical trials on the scale and scope of those described above will ever be practical or feasible for patients with earlier (DCIS) or more advanced disease. In the United Kingdom, where the published experience of HypoRT remains the longest and broadest, the view is that modest HypoRT should be available to any identifiable subset of subclinical breast cancers.[136] The National Institute for Health and Clinical Excellence (NICE) in the United Kingdom has adopted a much more broad view of modest HypoRT and endorses it as standard of care for the majority of patients (either BCS or postmastectomy) with early breast cancer.[142] Although NICE acknowledges that the use of HypoRT in the treatment of DCIS is a matter of debate, it seems paradoxical to insist on CFRT for this more favorable subset of breast cancers. It is likely that in the coming years, multi-institutional collaboration and registry studies will continue to shed light on the efficacy of HypoRT for the treatment of subsets of patients not fitting the mold of those in the original clinical trials.

Large-Fraction HypoRT

The accumulation of sufficient modest HypoRT experience has allowed investigators to further push the limits of hypofractionation in order to eliminate the requirement of daily therapy. Large-fraction HypoRT, which delivers approximately 30 to 33 Gy in 5 to 6 Gy/fraction, once or twice weekly, was initially tested in small, institutional nonrandomized studies in Europe and the United Kingdom. First employed only for elderly patients, early studies have shown toxicity, cosmesis, and outcomes comparable to CFRT regimens.[143–148] A summary of studies that used once-weekly hypofractionated breast irradiation (WHBI) published in the modern era is listed in Table 13.6.

TABLE 13.6 RECENTLY PUBLISHED TRIALS OF LARGE-FRACTION BREAST HYPOFRACTIONATED RADIOTHERAPY

Study	Enrollment	Number of Patients	Dose/Fx (Gy)	Total Dose (Gy)	Overall Time (wk)	Follow-up (y)	Tumor Contro

G/E: good–excellent; HypoRT: hypofractionated radiotherapy; NR: breast-conserving surgery; NR:

not reported.
[a]Reported as “significant photographic change,” cosmetic outcome was statistically significantly better in the 28.5-Gy HypoRT arm.

The first prospective phase III randomized study of large-fraction HypoRT against CFRT is the UK FAST trial.[147] This trial (n = 915) tested 50 Gy in 25 fractions of CFRT against two different regimens of HypoRT delivered in a five-fraction schedule over 5 weeks (30 Gy or 28.5 Gy/fraction). The two experimental arms represented the most commonly used regimen to date (30 Gy per 5 fractions) and a dose-reduced regimen (28.5 Gy per 5 fractions) based on radiobiologic estimations derived from the outcomes of the UK START trials. The first published report of this trial, which was open to node-negative postmenopausal women, showed an overall rate of grade 2 or higher skin toxicity of 23.9%, with a lower rate found in both experimental arms (14.4% and 10.4%) versus those treated with CFRT (46.4%).[147] At 3 years’ follow-up, there were only 5 local recurrences, 3 in the CFRT arm and 2 in the HypoRT arms. The rate of significant photographic cosmetic change was slightly higher (17.3%) for patients treated with 30 Gy compared to 28.5 Gy or CFRT (11.1% and 9.5%, respectively). A phase II trial from the United States, which had a broader eligibility criteria and used the same large-fraction HypoRT dosing schemes, showed similar results for both toxicity and local control.[148]

Longer-term follow-up from these studies will ultimately provide clarity before large HypoRT regimens can be considered for routine use outside of a clinical trial. In the meantime, the investigators in the United Kingdom have proceeded with the FAST-Forward study aims to further reduce treatment times.[149] Patients on this trial are randomized to modest HypoRT (40 Gy in 15 fractions, 3 weeks) versus one of two large-fraction HypoRT arms (27 or 26 Gy, 5 fractions, 1 week). Fortunately, this study includes patients outside of traditionally targeted low-risk (i.e., postmenopausal, node-negative, no chemotherapy) populations. This will prove vital to facilitate reasonable extrapolation of alternative fractionation so as to improve access to care among women with breast cancer.

Concerns Related to Dosimetry and Organs at Risk

Despite the level of evidence described above, widespread, wholesale changes in practice patterns away from CFRT have been slow, especially in the United States.[150] The reasons for this are multifactorial and include health care physician reimbursement economics as well as a general risk aversion based on historical reports. Given the superb and predictable outcomes achieved with

CFRT, physicians in practice must balance the improved convenience of HypoRT versus the more rigorous attention to dosimetric criteria in order to deliver it safely. In terms of dose heterogeneity within the breast, “hot spots” in a dose plan that receives a higher dose per fraction carry more significance and will ultimately be penalized more severely.[136] Therefore, it is generally advised that distributions within the breast are kept within 95% to 107% of the reference isodose, where the risk of additional adverse effects is predicted to be clinically insignificant.

As with any breast radiotherapy plan, it is also vital to limit the exposure of the underlying heart and lung tissue using customized physical dose sculpting and shielding. Lung volumes exposed in modern, CT-based tangential field arrangements are minimal, but doses to lung tissue exceed tolerance no matter which fractionation scheme is employed. One prospective, randomized study of CFRT versus HypoRT used spirometry, plethysmography, and hemoglobin-corrected diffusing capacity at baseline and post treatment.[151] Investigators found that although mild lung restriction could be detected within 3 years of treatment completion, there were no differences between the two fractionation regimens. In terms of cardiac risk, the priority is to protect the heart from exposure using custom blocking or respiratory management techniques. Radiation exposure to the heart in the modern era therefore is less from direct irradiation and more from low-dose internal scatter. Because it is widely accepted that there is no “safe” heart dose, and because the most robust risk models are based on “mean heart dose,”[152] it is unclear if or how altered fractionation might confer an additional risk. In a large prospective registry of over 5,000 women treated with CFRT or HypoRT for left-sided breast cancer, there were no differences in 15-year cardiac mortality (4.2% vs. 4.8%).[153] Future studies may shed light on risks associated with changes in dose per fraction when it comes to specific cardiac substructures.

Pure HypoRT for Prostate Cancer

Similar to breast cancer, hypofractionation schedules are particularly attractive because of the sheer impact of cost and convenience benefits for the treatment of the most common cancer seen in men. Moreover, prostate cancers are slow proliferating with estimated α/β ratios of 1 to 3 Gy—even lower than those for breast cancer.[36,46] Early results for HypoRT for prostate cancer are somewhat mixed, as they differ in structure (superiority vs. noninferiority hypotheses) and inconsistencies regarding conventional doses delivered in the standard arm. As

of now, there is no clear consensus to replace conventional fractionation with a new “gold standard”; however, the most recent data offers more favorable evidence for the present use and future growth of HypoRT as a very valid option for many prostate cancer patients. A summary of the largest, most modern randomized trials of HFRT in prostate cancer is shown in Table 13.7.

TABLE 13.7 RECENTLY PUBLISHED PROSPECTIVE, RANDOMIZED TRIALS OF PROSTATE HYPOFRACTIONATED RADIOTHERAPY

Study	Enrollment	Number of Patients	CFRT Arm	HypoRT Arm	Follow-up Time (y)	Tumor Control	Tox
Fox Chase Cancer Center[154]	Low–high risk	303	76 Gy/38 Fx	70.2 Gy/26 Fx	5y	No significant differences, HypoRT not superior	No
MDACC[155]	Intermediate risk	203	75.6 Gy/42 Fx	72 Gy/30 Fx	6y	No significant differences, HypoRT not superior	No

NRG 0415[158]	Low risk	1092	73.8 Gy/41 Fx	70 Gy/28 Fx	5.5y	No significant differences, HypoRT not inferior	Inc
CHHiP[159]	Low–intermediate risk	3216	74 Gy/37 Fx	60 Gy/20 Fx or 57 Gy/19 Fx	5y	60 Gy/20 Fx HypoRT not inferior	No

PROFIT[160]	Intermediate risk	1206	78 Gy/39 Fx	60 Gy/20 Fx	6y	No significant differences, HypoRT not inferior	No

Early trials of HypoRT for prostate cancer were conducted before dose escalation benefits were fully understood. For instance in 2005, a Canadian study of 936 low-risk patients could not exclude the possibility that HFRT might be inferior to the standard regimen.[161] However, the two arms (66 Gy in 33 fractions versus 52.5 Gy in 20 fractions) were both less biologically effective than what we consider standard today. Recently there have emerged smaller, randomized studies from two highly regarded US cancer centers that employed more modern radiotherapy doses and techniques. The Fox Chase Cancer Center tested 76 Gy in 38 fractions versus 70.2 Gy in 26 fractions in 303 patients, whereas investigators at the MD Anderson Cancer Center tested 75.6 Gy in 42 fractions versus 72 Gy in 30 fractions. Both centers employed IMRT, and both found the efficacy and toxicity of HFRT schedules to be comparable to conventional treatment.[154,155]

In the last few years, there has been a rising tide of data from larger, cooperative group organizations from all over the world. The first of these reports came from the European HYPRO study involving 820 intermediate- to high-risk patients.[156,157] This randomized phase 3 trial treated patients to 78 Gy in 39 fractions or 64.6 Gy in 19 fractions (every other day) and hypothesized that HypoRT would increase 5-year relapse-free survival by 10% over CFRT (80% vs. 70%). After a median follow-up of 5 years, the actual RFS for patients treated with HypoRT versus CFRT was 80.5% versus 77.1% (P = .36). What was statistically significant, however, was grade 3 late GU toxicity in the HypoRT arm (P = .021).

In contrast to the HYPRO study, three larger cooperative group endeavors were structured as noninferiority trials. The NRG Oncology group in the United States randomized 1,092 low-risk patients to 73.8 Gy in 41 fractions versus 70 Gy in 28 fractions.[158] This study found that the hazard ratio for DFS was 0.85 (95% CI, 0.64 to 1.14), consistent with its predefined noninferiority benchmark of <1.52 (P < .001). Late grade 2 to 3 GI and GU toxicities were higher for

patients treated with HypoRT in this study, which employed both 3D conformal radiation therapy and IMRT techniques. The Conventional or Hypofractionated High-Dose Intensity-Modulated Radiotherapy in Prostate Cancer (CHHiP) trial in the United Kingdom randomized 3,216 patients to receive either CFRT (74 Gy in 37 fractions) or HFRT in one of two regimens (57 Gy or 60 Gy in 3 Gy/fraction).[159] This study featured a more heterogeneous enrollment, with 12% of patients having high-risk disease. At a median follow-up of over 5 years, failure-free rates were 88.3% for CFRT, 85.9% for 57 Gy HypoRT, and 90.6% for 60 Gy HypoRT. The 60-Gy experimental arm was judged to be noninferior to CFRT; however, noninferiority could not be established for the 57-Gy schedule. Patterns of toxicity were different with higher acute symptoms seen in HypoRT and higher late reactions noted after CFRT, but these differences were not statistically significant. Finally, the international PROFIT trial compared 78 Gy in 39 fractions to 60 Gy in 30 fractions for 1,206 patients with intermediate-risk disease.[160] This noninferiority study allowed either 3D conformal radiation therapy or IMRT but mandated strict, centrally reviewed radiation quality control. At 5 years, the study found no difference in biochemical failure or grade 3 or higher late GI or GU toxicity.

These studies have contributed greatly to our understanding of the efficacy of altered fractionation in the treatment of prostate cancer and provided cautionary tales along the way. Although the optimal fractionation regimen has yet to be revealed, enough evidence exists for clinicians to discuss HypoRT as an alternative to standard fractionation with a wide variety of patients. As with breast cancer, the cost and convenience drivers for patients must be accompanied by an even greater attention to quality of radiation dosimetry and technique on the part of the treating physician who offers HypoRT.

The Combination of Altered Fractionation with Concurrent Chemotherapy

In a meta-analysis conducted at the Institut Gustave Roussy (Villejuif, France), an absolute benefit of 3% (from 36% to 39%; HR, 0.92; 95% CI, 0.87 to 0.97; *P* = .004) was observed at 5 years in favor of the altered fractionation regimens.[162] In light of the data in support of the superiority of altered fractionation to standard radiotherapy alone and findings of improved local control and survival with the addition of concurrent chemotherapy to radiotherapy in several randomized studies[163–165] and two recent meta-analyses,[166,167] at least 11 studies reported on investigation of addition of chemotherapy to altered fractionation

(Table 13.8). These studies did not explore chemotherapy results with varying fractionation regimens, except for one study,[146,174] which tested the addition of chemotherapy to radiation in patients with unresectable squamous cell HNSCC by adding chemotherapy to either standard fractionation or a complicated prolonged split-course regimen.

Key Findings of Combined Altered Fractionation with Concurrent Chemotherapy

Although the magnitude of its effect was less marked for survival indices than for locoregional control, the addition of chemotherapy to altered fractionation regimens results in a clear improvement compared with hyperfractionated or accelerated regimens alone; however, the effect on late toxicity of normal tissues is not fully known.

In nasopharynx cancer, the benefit of concurrent chemotherapy is similar to that of acceleration without chemotherapy. The potential biologic interactions between chemotherapy and radiotherapy by the addition of radiation can be summarized as follows[147]:

- Shift of cell survival curves toward higher cell-killing levels and lower cell-surviving fractions for a given dose of irradiation
- Cooperation to prevent the emergence of resistant clones
- A decrease in tumor mass and reoxygenation
- Specific toxicity for hypoxic cells
- Selective toxicity depending on cell cycle phase
- Cytokinetic cooperation
- Inhibition of DNA repair
- Increased apoptosis

Table 13.8 summarizes the results of randomized studies investigating the efficacy of concurrent chemotherapy regimens with altered fractionation.

Acceleration Versus Chemoradiation or with Chemotherapy

An Austrian three-arm trial tested the addition of mitomycin C (MMC) on day 5 of treatment to the Vienna variation of continuous, hyperfractionated, accelerated radiotherapy (V-CHART): 55.3 Gy in 17 days. The three arms were 70 Gy of conventional fractionation alone versus V-CHART and versus V-CHART with concurrent MMC on day 5 (V-CHART plus MMC).[148] Two hundred thirty-nine patients were randomized. Locoregional tumor control was 31% after conventional fractionation, 32% after V-CHART, and 48% after V-CHART plus

MMC, respectively ($P < .05$). Overall, crude survival was 24% after conventional fractionation, 31% after V-CHART, and 41% after V-CHART plus MMC, respectively ($P < .05$). Therefore, reducing the treatment time from 7 weeks to 17 consecutive days and dose of radiotherapy from 70 to 55.3 Gy produced identical results, whereas the addition of MMC on day 5 to the accelerated fractionated treatment produced a significant improvement in local tumor control and survival. This supports an argument for adding chemotherapy to AF.

TABLE 13.8 PHASE III TRIALS ADDRESSING CONCURRENT CHEMOTHERAPY AND ALTERED FRACTIONATION IN PATIENTS WITH HEAD AND NECK CANCER

Reference	Tumor Site and Stage	Number of Patients	Therapy Regimen	Tumor Response	Complication

Hugeunin et al.[173]	Squamous cell carcinomas of the head and neck	224	74.4 Gy; 1.2 Gy b.i.d. + Cis 20 mg/m^2 (on 5 d wk 1 and 5) 74.4 Gy; 1.2 Gy b.i.d.	Failure-free rate at 2.5 y was 45% and 33%; LRC was significantly improved, log-rank test (*P* < .039).	Late toxicity w comparable.
Hyperfractionated Accelerated Chemoradiation with Concurrent Chemotherapy Versus Dos Escalated Hyperfractionated Accelerated Radiation Therapy Alone in Locally Advanced He and Neck Cancer					
Budach et al.[121]	Various sites, stage III–IV	384	70.6 Gy in 6 wk (30 Gy, 2 Gy/d + 40.6 at 1.4 Gy b.i.d.) + 5-FU (600 mg/m^2) +	5-y LRC 49.9% vs. 37.4% (*P* = .001) 5-y OS: 28.6% vs. 23.7% (*P* = .023)	Maximum acut mucositis, m desquamati and erythem were higher dose-escala

	mitomycin (10 mg/m^2) 77.6 Gy (14 Gy at 2 Gy/d + 1.4 Gy b.i.d.): dose-escalated radiotherapy	radiotherapy no difference in late reactions.

5-FU, 5-flourouracil; b.i.d., twice-a-day irradiation; CB, concomitant boost; CF, conventional fractionation; Cis, cisplatin; DMFS, distant metastasis–free survival; DSS, disease-specific survival; G-CSF, granulocyte colony–stimulating factor; LC, local control; LRC, locoregional control; LRPFS, locoregional progression-free survival; MMC, mitomycin C; NS, not significant; OS, overall survival; PFS, progression-free survival; RFS, relapse-free survival; V-CHART, Vienna variation of continuous hyperfractionated accelerated radiotherapy.

A German Cooperative Group compared a concomitant boost radiation regimen with or without carboplatin and 5-fluorouracil.[149] The addition of chemotherapy produced a trend for better locoregional control and survival rates, but it induced a significantly higher incidence of chronic dysphagia, resulting in feeding tube dependence (51% vs. 25%). A secondary randomization to receive or not receive granulocyte colony–stimulating factor to reduce mucositis produced the startling finding that *the administration of granulocyte colony–stimulating factor significantly reduced the probability of locoregional control in both treatment arms.*

The French Cooperative Group GORTEC tested the combination of 62 to 64 Gy given in 5 weeks with cisplatin and 5-fluorouracil but terminated the trial prematurely because of unacceptable toxicity.[89] The nasopharynx trial from China gave a very interesting finding that accelerated radiotherapy provides the same benefit as adding concurrent chemotherapy; this was discussed earlier in the section on accelerated radiotherapy.[56]

Alternating chemoradiotherapy was studied in Italy by Corvo et al.[170] and compared with high-dose accelerated radiotherapy. The 136 patients with unfavorable stage II or stage III to IV head and neck carcinoma were randomized to alternating cisplatin and 5-fluorouracil with three 2-week courses of radiotherapy (20 Gy at 2 Gy/day: 60 Gy vs. 75 Gy at 40 fractions in 6 weeks) using a concomitant boost technique. At 60 months, there were no differences in overall survival, progression-free survival, or locoregional control.

Split-course altered fractionation with or without concurrent chemotherapy was tested in two trials. Both added cisplatin and 5-fluorouracil to split-course AF schedules (70 Gy in 42 to 51 days).[143,151] Both showed that a chemotherapy regimen improved locoregional control versus altered fractionation alone.

However, a split-course accelerated regimen is now known to be no more effective than standard fractionation. The locoregional control improved, with an 18% to 26% increase in late effects. The larger trial showed improved overall survival.

Adelstein et al.[171] reported on the Head and Neck Intergroup's trial to test the addition of chemotherapy to radiation in patients with unresectable squamous cell HNSCC by adding chemotherapy to either standard fractionation or a prolonged split-course regimen. The 295 patients were randomized into three arms: 70 Gy at 2 Gy/day (radiation [RT] only) versus the same radiation therapy with concurrent bolus cisplatin (RT + chemotherapy [C]) versus a third arm: split-course radiotherapy with chemotherapy during the break in radiotherapy (split RT + C) from week 9. They did not meet the accrual goal. Grade 3 or worse toxicity occurred in 52% of patients in the RT-only arm, 89% in the RT + C arm ($P < .0001$), and 77% in the split RT + C arm ($P < .001$). The 3-year projected overall survival for patients in the RT-only arm was 23%, compared with 37% for the RT + C arm ($P = .014$) and 27% for the split RT + C arm (P = not significant). The addition of concurrent high-dose, single-agent cisplatin to conventional radiation significantly improves survival and increases toxicity; however, multiagent chemotherapy did not offset the loss of efficacy resulting from prolongation by split-course radiation.

Concurrent Chemotherapy in Addition to Hyperfractionated Radiotherapy

A randomized trial by Jeremic et al.[175] tested the addition of low-dose daily cisplatin to 77 Gy at 1.1 Gy/fraction twice daily over 7 weeks. Daily cisplatin improved the results of HF radiation, with better locoregional progression-free survival (50% vs. 36%; $P = .04$), 5-year progression-free survival (46% vs. 25%; $P = .007$), 5-year distant metastases–free survival (86% vs. 57%; $P = .001$), and 5-year overall survival (46% vs. 25%; $P = .008$). This was a true therapeutic gain because there was no difference in late side effects.

A study conducted in Zurich reported similar results.[173] The 224 patients with squamous cell carcinomas were randomized to two cycles of concurrent cisplatin 20 mg/m^2 on 5 days of weeks 1 and 5 with HF radiotherapy (median dose, 74.4 Gy; 1.2 Gy twice daily) versus the same radiotherapy. Locoregional control and distant disease–free survival were significantly improved with cisplatin (log-rank test; $P = .039$ and .011, respectively) with no difference in overall survival and similar late toxicity. The therapeutic index of HyperRT was improved by

concomitant cisplatin.

A third trial, reported by the German Cancer Society with an even greater number of patients, confirmed this outcome, using a nonplatinum regimen with HyperRT-accelerated radiation versus dose-escalated HyperRT-accelerated radiation.[176] The 84 patients with stage III (6%) and IV (94%) oropharyngeal (59.4%), hypopharyngeal (32.3%), and oral cavity (8.3%) cancer were randomized to concurrent chemotherapy and accelerated radiation therapy to 70.6 Gy in 6 weeks versus accelerated radiation therapy alone to 77.6 Gy. Chemotherapy was 5-fluoroucil (600 mg/m^2, 120-hour continuous infusion) days 1 through 5 and mitomycin (10 mg/m^2) on days 5 and 36. At 5 years, the locoregional control was 49.9% versus 37.4% (P = .001), and overall survival was 28.6% versus and 23.7% (P = .023), respectively. Progression-free and metastases-free rates were 29.3% and 51.9% versus 26.6% and 54.7%, respectively (P = .009 and .575, respectively). There were no differences in late reactions. They concluded that concurrent chemotherapy with accelerated HyperRT to 70.6 Gy is superior to dose-escalated HyperRT to 77.6 Gy, with less acute reactions and equivalent late reactions, indicating an improvement of the therapeutic ratio.[176]

Results of Radiation Therapy Oncology Group Trial of Concurrent Chemotherapy to Select Fractionation Schedules

The RTOG conducted a randomized trial to determine whether accelerated fractionation improves the outcome of concurrent cisplatin chemotherapy (i.e., whether the benefit of altered fractionation remains true in the setting of concurrent chemotherapy).[177] Acceleration of radiotherapy did not improve outcome in the setting of concurrent cisplatin chemotherapy. Seven hundred forty-three patients with stage III or IV squamous cell carcinoma of the oral cavity, oropharynx, hypopharynx, or larynx were randomized into two arms: *standard radiation* (70 Gy in 35 fractions once daily over 7 weeks [SFX]) with three cycles of concurrent cisplatin (100 mg/m^2 given every 3 weeks during radiotherapy) versus accelerated *fractionation with concomitant boost* 72 Gy in 42 fractions in 6.5 weeks (AFX-C) with *two cycles* of the same chemotherapy. Seven hundred twenty-one cases were analyzable (360 for AFX-C; 361 for SFX). Two arms were balanced by site, stage, performance status, and age. At analysis, 418 patients were alive with median follow-up of 4.8 (0.3 to 6.5) years. First analysis of this trial showed that, when combined with concurrent cisplatin, AFX-C did not improve outcome or increase late toxicity. No differences were

observed in OS (5 years: 59% vs. 56%; HR, 0.90; CI = 0.72 to 1.13; *P* = .18), disease-free survival (45% vs. 44%; *p* = .42), locoregional failure (31% vs. 28%; *P* = .76), or metastasis (18% vs. 22%; *P* = .06). There were also no differences in the overall grade 3 to 4 acute mucositis (33% vs. 40%) and worst grade 3 to 4 late toxicity (26% vs. 21%). Feeding tube rates were 22% and 25% pretreatment, 67% and 69% at therapy end, and 28 and 29% at 1 year, respectively, but declined later to 5% to 15%. When analyzed for the effect of radiotherapy duration and cisplatin dose, they both affected survival significantly. Cisplatin improved OS more by reducing locoregional progression, but it also increased toxicity. The effect of AFX-C approximated the third cisplatin dose, suggesting that cisplatin acted, in part, by inhibiting clonogen repopulation.

This finding suggests that for patients undergoing standard fractionation and who are unable to have their full planned concurrent chemotherapy, acceleration of the remaining course of radiotherapy may be of benefit. This may be achieved by treating two fractions per day on one of their treatment days each week.

As a continuous variable, each day of radiotherapy delay in RTOG 0129 was associated with compromised OS, progression-free survival, and locoregional progression by 5%, 4%, and 4% (*P* = .001, .006, and .02), respectively.[178]

Critical Fractionation Issues to Consider When Intensity-Modulated Radiation Treatment Is Used

There is great diversity in IMRT fractionation. A survey of international practice of IMRT fractionation showed that among 14 international centers, 12 different dose fractionations were practiced: conventional daily 2 Gy/fraction was used in 3 of 14 centers with concurrent chemotherapy, whereas 11 of 14 centers used altered fractionation, including a 6-fractions/week Danish Head and Neck Cancer Group regimen in 3 centers, ≤2.2 Gy/fraction in 3 centers, dose-escalated hypofractionation (≥2.3 Gy/fraction) in 4 centers, hyperfractionation in 1 center, continuous acceleration in 1 center, and concomitant boost in 1 center. Reasons for fractionation practice included (a) dose escalation, (b) total irradiated volume, (c) number of target volumes, (d) synchronous systemic treatment, (e) shorter overall treatment time, (f) resources availability, (g) longer time on treatment couch, (h) variable gross tumor volume margins, (i) confidence in treatment setup, (j) late tissue toxicity, and (k) use of lower neck anterior fields.[179]

The new era of high-precision radiation therapy brings two major advantages: improved coverage of tumor volumes by the prescribed dose without the use of

multiple matched fields and increased sparing of normal tissues, such as parotid gland, spinal cord, brainstem, brain, and optic using IMRT. However, there are two important fractionation issues to be considered:

- If a single plan is used, all targets are treated in the same overall number of fractions. This may result in treating secondary targets to a lower dose per fraction. This has to be corrected by alteration of the total dose to the secondary targets to avoid the potentially serious disadvantage of delivering a lower biologically effective dose.
- IMRT may allow an increased dose to be delivered if the dose-limiting toxicity can be spared by organ avoidance. This may be delivered as additional fractions with prolongation of the duration of treatment or by giving more than one fraction per day. Alternatively, the dose per fraction may be increased and the total escalated dose delivered in the same or shortened treatment time.

Potential Delivery of Lower Biologically Effective Dose to Targets and Lower Probability of Cure

Classic non-IMRT techniques for HNSCC deliver doses at a fixed dose per fraction to all targets. A large initial field delivers an initial dose to the entire volume, and the field is reduced sequentially to boost additional regions to a higher dose (shrinking-field technique). For example, a classic head and neck three-field plan uses opposed lateral photon fields and abutting electron fields to deliver 50 Gy at 2 Gy/fraction to gross disease at the primary site and nodes, elective nodal regions, and regions around the tumor that may contain microscopic tumor cells. Smaller fields are then used to deliver an additional 16 to 20 Gy in 8 to 10 fractions to boost the gross tumor and nodal disease to 66 to 70 Gy, depending on the size of the gross tumor. A posterior electron field may be added to bring the dose adjacent to the gross nodal tumor to 56 to 60 Gy. This type of fractionation is used especially with concurrent chemotherapy. This contrasts with IMRT, with which the dose prescribed to various portions of the treatment volume is delivered simultaneously. Each fraction delivers a specific constant dose per fraction throughout the treatment to each target. All targets are treated in the same number of fractions. For example, 70 Gy in 35 fractions prescribed to the gross tumor will deliver 2 Gy/fraction to this volume. The 56 and 50 Gy prescribed to secondary target volumes will also be delivered in 35 fractions in 7 weeks using IMRT at a 1.6 and 1.43 dose per fraction over 7 weeks, respectively. The biologically effective dose to 56 and 50 Gy in 35 fractions in 7 weeks is lower using IMRT because of the effect of the smaller

dose per fraction and longer treatment time. This must be compensated for by increasing the total dose to the elective and intermediate dose targets, as suggested in Table 13.9.

TABLE 13.9 COMMONLY USED FRACTIONATION REGIMENS FOR HEAD AND NECK CANCER

The biologically isoeffective dose for tumor control to targets in the third and fourth columns with IMRT takes into consideration the effect of reduced dose per fraction and the effect of prolonged overall treatment time. b.i.d., twice a day; Fx, fraction; Gy, gray; GTVs, gross tumor volumes; IMRT, intensity-modulated radiotherapy; N, nodal stage; PMH, Princess Margaret Hospital; s.i.d., once per day; T, tumor stage; wk, week.
[a]Single-phase treatment schedule.

Prospect for Improving the Therapeutic Ratio by Dose Escalations to Targets without Increased Dose to Normal Tissues

The experience and conclusions of altered fractionation studies are based entirely on results of traditional radiotherapy techniques and conventional conformal techniques. These techniques deliver the boost dose to a much larger volume of tissue of normal tissues, which inevitably receive the full boost dose. However, IMRT delivers much reduced doses to normal structures with potential for less toxicity. For example, IMRT produced significant reduction in incidence and severity of xerostomia with parotid-sparing head and neck.[180–182] However, a further advantage of IMRT may be its potential for dose escalation. Preclinical comparative dosimetry studies suggested that dose escalation may be feasible using simultaneous boosts to tumor subvolumes.[183] Further work is ongoing to explore whether the boost volume may be localized using metabolic or hypoxic imaging.[184]

Common Standard Clinical Practice

An analysis by the Meta-Analysis of Chemotherapy on Head and Neck Cancer Collaborative Group revealed that concurrent chemoradiation yielded a larger survival benefit than that achieved with altered fractionation regimens.[167] This benefit is seen predominantly in more locally advanced (i.e., stage IV) HNSCC, and concurrent chemoradiation is often recommended for patients with large T3 or T4 tumors or with N2–N3 nodes usually given with standard fractionation.

Because accelerated regimens seem to preferentially benefit local control at the primary site and not nodal control, it is reasonable to choose altered fractionation for patients with T2, exophytic T3, or N0–N1 disease who are not routinely given chemotherapy and those with more advanced locoregional tumor who are unfit to receive chemotherapy.[185]

In much of the United States and Europe, standard fractionation remains 2 Gy/day. However, there is considerable variation in common practice, and

despite the results of randomized studies, institutions tend to adhere to dose fractionation schedules with which they are experienced. Examples of commonly used schedules in Manchester (United Kingdom), Canada, Denmark, and the United States are shown in Table 13.9.

FUTURE DIRECTIONS: COMBINING THE GAINS OF MOLECULAR IMAGING AND MOLECULAR TARGETING WITH ALTERED FRACTIONATION

Up to the present day, the choice of fractionation scheme for a particular cancer has been based largely on mathematical estimations based on tissue models and clinical experience. Our understanding of the effects of radiation on crucial cellular processes and DNA repair mechanisms is largely based on conventional fractionation. There may be significant differences in gene expression response patterns resulting from the various forms of altered fractionation. Further investigation into these differences may reveal targetable pathways to enhance tumor response to fractionated radiotherapy. Molecular profiling of tumors in preclinical studies has revealed an array of targetable molecules (such as NF-κB and STAT1), the presence of which varies with dose and fractionation.[186] Advances in the understanding of molecular biology, immunotherapy, and genomics have opened exciting possibilities and broadened our ability to identify subgroups of tumors that will best respond to—as well as patients who will best tolerate—altered fractionation.

ACKNOWLEDGMENT

I gratefully acknowledge the work of Anesa W. Ahmad, M.D., whose previous work on this chapter served as a framework for this updated version.

CHAPTER 14

Late Effects and QUANTEC

John P. Kirkpatrick, Michael T. Milano, Jimm Grimm, Louis S. Constine, Zeljko Vujaskovic, and Lawrence B. Marks

INTRODUCTION

Modern cancer therapy is largely predicated on the safe intensification of radiation, chemotherapy, and biologic and, now, immunologic adjuvants. This has resulted in a markedly increased survivorship, which now exceeds 64% overall, and for some malignancies, such as breast and prostate cancer, is much higher. Malignancies resistant to therapy may demand an aggressive treatment approach that often resides at the limit of, or even exceeds, normal tissue tolerance to some “acceptable” degree. Clearly, the potential to ameliorate or prevent such normal tissue damage, or to manage and rehabilitate affected patients, requires an understanding of tissue tolerance to therapy. Because “late effects” manifest months or years after cessation of treatment, therapeutic decisions intended to obviate such effects can be based only on the probability, not the certainty, that such effects will develop. In making such decisions, the balance between efficacy and potential for toxicity should be considered, as well as the influence of host, disease, and treatment-related risk factors.

Historically, radiation therapy fields and doses were selected empirically, based largely on physicians’ clinical experience and judgment. They understood that these empiric guidelines were imprecise and did not completely reflect the underlying anatomy, physiology, molecular biology, and dose distributions. The introduction of three-dimensional (3D) treatment planning offered the promise of quantitative correlates of doses/volumes with clinical outcomes. This promise was partly delivered. When 3D dosimetric information became widely available, guidelines were needed to help physicians predict the relative safety of proposed treatment plans, although only limited data were available.

In 1991, investigators pooled their clinical experience, judgment, and information regarding partial organ tolerance doses and produced the “Emami

paper."[1] As discussed later, this paper clearly stated the uncertainties and limitations in its recommendations, and it is rightly admired for addressing a critical clinical need. Over the past two decades, numerous studies have reported associations between dosimetric parameters and normal tissue outcomes. In 2007, a joint task force of physicists and physicians was formed, with the support of the American Society for Therapeutic Radiology and Oncology (ASTRO) and the American Association of Physicists in Medicine (AAPM), to summarize the available data in a format useful to clinicians and to update/refine the estimates provided by Emami et al.

The resulting QUANTEC reviews[2] (*qu*antitative *a*nalysis of *n*ormal *t*issue *e*ffects in the *c*linic), published in a special issue of the *International Journal of Radiation Oncology, Biology and Physics* in March 2010, are summarized in this chapter.

HISTORICAL BACKGROUND

The relationship between dose–volume parameters and outcome has been the focus of numerous investigators for decades. A brief summary of historical landmarks is provided to follow, along with our opinion regarding the key contributions and shortcomings of these reviews (Fig. 14.1 and Table 14.1).

THE INCORPORATION OF 3D DOSE–VOLUME INFORMATION INTO CLINICAL GUIDELINES

The pre-Emami reports[3] were novel in that there were typically no good tools available (to either the authors or clinicians) to accurately quantify the fraction of various organs that were being irradiated. Thus, the dose/volume/outcome information presented consisted largely of estimates based on expert opinion. Similarly, clinicians needed to estimate the partial volumes of different organs that were being irradiated in their patients in order to apply the provided information.

In the late 1980s and early 1990s, 3D planning systems were providing clinicians with a plethora of information. However, systematic dose/volume/outcome data to guide clinical decisions based on this information were limited. There was an urgent need for clinicians to have some guidance in making clinical dose–volume decisions. The report by Emami et al.[1] met this critical need. This report was, and remains, a landmark summary of decades

worth of data for a wide variety of organs, supplemented with expert opinion where data were lacking. This article remains a required reading for all trainees in our field.

During the 1990s and 2000s, a large number of studies related dose–volume data to clinical outcomes. The QUANTEC review was an attempt to refine the guidelines based on the available 3D dose/volume/outcome data.

DOSE–VOLUME HISTOGRAMS AND ASSOCIATED FIGURES OF MERIT

Three-dimensional dose–volume data can be difficult for clinicians to readily digest. Visualizing isodose distributions is challenging, and comparing competing distributions is almost impossible. Therefore, dose–volume histograms (DVHs; essentially two-dimensional [2D] representations of the 3D data) were embraced as a rapid way to summarize the dose distribution. Note that DVHs discard information regarding the spatial character of dose as well as (usually) variations in fraction size. However, DVHs can also be challenging for clinicians to consider and compare. Therefore, it has become attractive to extract "figures of merit" from the DVH, such as the V_x (the percent of an organ receiving $\geq x$ Gy). Thus, DVHs and their associated figures of merit are necessary tools to enable clinicians to readily apply 3D information clinically. They are excellent tools but obviously have their shortcomings.

MODEL-BASED ESTIMATES OF OUTCOMES

The Emami et al. report systematically used the same DVH-based construct across many organs, for example, the $TD_{5/5}$ and $TD_{50/5}$ for the uniform irradiation of one-third, two-thirds, and the whole volume of an organ. This uniform approach enabled the application of "single unifying models" of dose/volume/outcome across organs. For example, the dose/volume/outcome estimates from Emami et al. were used by Burman et al.,[4] Kutcher et al.,[5] and Lyman et al.[6] to generate a set of organ-specific model parameters. Such a uniform approach is attractive to modelers and busy clinicians.

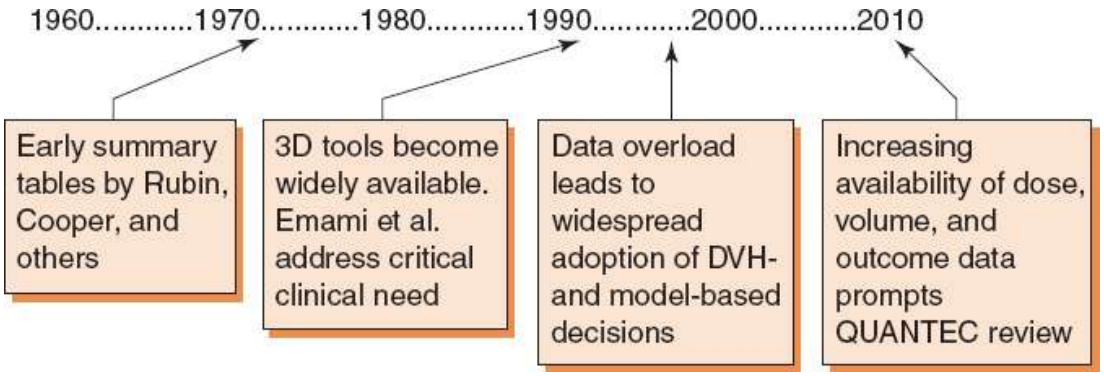

FIGURE 14.1. Key events in the development of dose–volume and normal tissue toxicity relationships in radiation oncology.

During the last two decades, many clinical dose/volume/outcome reports computed parameters for these "unifying models" (e.g., Ten Haken et al.).[7–9] Other investigators have suggested alternative models that appeared to be better suited to specific organs (*vide infra*).

The dose/volume/outcome data available for the QUANTEC review were not of a uniform format. Outcomes across organs were correlated with a diverse array of dose–volume metrics (e.g., threshold volumes [V_x], threshold doses [D_x], mean doses). Therefore, the QUANTEC review included model-based parameters for just a few organs, and not always in a systematic fashion.

MAJOR DIFFERENCES BETWEEN THE QUANTEC AND EMAMI REVIEWS

Emami et al.[1] provided information for 26 organs, judged necessary to support protocols for "three-dimensional treatment planning for high-energy photons (RFP #NCI-CM-36716-21)." Conversely, the QUANTEC review was focused on organs for which the steering committee thought that there were meaningful dose/volume/outcome data (Table 14.2).

Emami et al. addressed a wide variety of clinical outcomes and thus provided the reader with a set of dose–volume parameters for *essentially* all clinical situations. Conversely, the QUANTEC review was focused on end points where there were dose/volume/outcome data. In this regard, the Emami tables are more complete. For example, consider the QUANTEC summary for the small bowel. A volume restriction is provided for the end point of acute grade ≥3 toxicity. No guidance is provided for late small bowel injury, as the authors did not believe that there was meaningful dose/volume/outcome data for late injury. This is a

shortcoming of the QUANTEC review as it is not “complete.” When evaluating a proposed 3D treatment plan, one obviously must consider both acute and late injury.

TABLE 14.1 HISTORICAL OVERVIEW OF SUMMARIES OF DOSE/VOLUME/OUTCOME INFORMATION

Report	Key Contributions	Key Shortcomings
Rubin, 1975[3]	Introduced the concept of $TD_{5/5}$ and $TD_{50/5}$	Minimal dose–volume data
Emami, 1991[1]	Concise summary addressing most clinically meaningful end points in a uniform manner Based on available data and expert opinion	Dose–volume relationship based on limited data and, thus, much expert opinion
QUANTEC, 2010[2]	Driven largely by the available 3D dose/volume/outcome data. Systematic review addressing many challenges such as organ delineation and confounding factors such as chemotherapy	Because dose/volume/outcome data on all meaningful clinical outcomes are *not* available, the summary is not able to guide all clinical practice.

Emami et al. presented information in a systematic/uniform manner, facilitating interorgan comparisons and model-based parameter estimates. The QUANTEC review presented dose/volume/outcome data in the diverse manner in which they were available in the literature.

MOLECULAR MECHANISMS OF LATE RADIATION DAMAGE

The design of optimal radiation treatment plans and identification of therapeutic strategies to prevent radiation-induced damage would benefit from an understanding of the underlying late effects from ionizing radiation. Both of these issues are further complicated by the variability in sensitivity to radiation observed across disease types and between patients, as well as the current absence of identifiable factors that predict a propensity for radiation-induced toxicity.[10–13]

An early theory for describing the development of acute and late side effects after radiation exposure was based on the target cell hypothesis. This hypothesis is focused on radiation as a direct cause of cell killing in tissues and organs, thus depleting crucial cell populations and resulting in functional deficiency.

Radiation is thought to cause irreversible damage to predominantly rapidly proliferating cell populations. These damaged cells in turn lose their ability to replicate and induce a regenerative response. The latent period between radiation exposure and repopulation appears to depend on both tissue turnover time and radiation dose. Both parenchymal cell loss and vascular endothelium damage occur; vascular hyperpermeability and venous exudation follow and have been theorized to contribute to clinically devastating toxicities, such as radiation myelopathy. Although the target cell hypothesis may explain some of the mechanisms by which acute side effects occur, it does not appear to fully explain the development late side effects. Recent research has shown a complex interaction between multiple cell types, leading to persistent overexpression of reactive oxygen species (ROS), activation of signaling pathways, and production of proinflammatory and profibrotic cytokines.

Although the initial damage done to the DNA, proteins, and membrane lipids of cells by exposure to ionizing radiation is well known, the mechanisms behind the sustained changes in gene expression and signaling pathways that contribute to latent and permanent tissue injury are less clear. This section will focus on the established mechanisms of radiation-induced tissue injury and identify areas in which further efforts are needed to determine the mechanisms driving tissue injury and prognostic markers for the development of radiation injury.

TABLE 14.2 COMPARISON OF THE CHARACTER/CONTENT OF EMAMI ET AL. AND QUANTEC

Characteristic	Emami et al.[1]	QUANTEC[2]
Number of organs	26	16
3D data available	Minimal	More/moderate (18-y interval)
Format dose–volume limits	Uniform $TD_{5/5}$ and $TD_{50/5}$ for one-third, two-thirds, whole organ	Nonuniform
End points	Specific, complete	Specific, incomplete
Expert opinion	Dominant	Much less
Impact of chemotherapy	Not explicitly discussed	Addressed individually for each organ

Early Cellular Effects of Radiation

Exposure to ionizing radiation causes direct DNA damage through linear energy transfer as well as indirect damage by radiolytic cleavage of water, yielding

hydroxyl radicals capable of abstracting hydrogen from the backbone of DNA to cause double-stranded breaks.[14,15] This damage to genomic DNA causes cell death by apoptosis or mitotic catastrophe. Although the ability of hydroxyl radicals to cause DNA damage is significant, the initial increase in hydroxyl radical and other ROS attributable to radiation exposure is negligible compared to the baseline presence of ROS in the cell.[15] Within a few hours of radiation exposure, however, the cell responds by increasing ROS production, creating a cellular environment capable of exacerbating the initial injury by causing oxidative damage to proteins and lipids.[16] This is thought to occur via ROS-mediated activation of mitochondria-dependent and mitochondria-independent metabolic enzymes, including nitric oxide synthases (NOSs) and oxidoreductase enzymes.

Sources of Reactive Oxygen Species

NADPH Oxidases

Nicotinamide adenine dinucleotide phosphate (NADPH) oxidases are a family of broadly distributed oxidoreductase enzymes. Membrane-associated NADPH oxidases are the primary source of ROS in nonphagocytic cells.[17] Under normal conditions, NADPH oxidase–derived superoxide anion is a mediator of maintenance and smooth muscle tone of the vasculature.[18] When these enzymes are induced to begin pathologic overproduction of ROS, however, they can contribute to the development of oxidative stress, resulting in cell damage and disruption of signaling pathways.[19] Nox4, a hydrogen peroxide–producing isoform, is of particular interest, as overproduction of hydrogen peroxide by Nox4 has been shown to be a necessary element of transforming growth factor-β1 (TGF-β1)–mediated cell death.[20]

Mitochondria

Under normal conditions, electrons from the electron transport chain can leak into the mitochondrial matrix and react with oxygen to form superoxide anion.[21] Following radiation, Leach et al.[22] observed that mitochondria in squamous carcinoma cells undergo a permeability transition, causing release of high levels of ROS into the cytoplasm. They further showed that inhibition of this transition not only attenuates the increase in cytoplasmic free radicals but also prevents radiation-induced activation of mitogen-activated protein (MAP) kinase, suggesting a causal link between mitochondrial ROS/reactive nitrogen species (RNS) generation and a large group of signal transduction pathways. The role of

mitochondrial-generated ROS/RNS in radiation injury is further supported by the radioprotective effect of Mn porphyrin superoxide dismutase (SOD) mimetics, which accumulate preferentially within the mitochondria.[23]

Augmentation of Reactive Oxygen Species from Other Sources

Superoxide anion from any source can react with nitric oxide to form peroxynitrite (ONOO–), itself a powerful oxidizing species capable of reacting with other molecules and cellular elements to perpetuate free radical overproduction and cause oxidative damage to the cell.[24]

Free Radicals and the Tissue Response to Radiation

When the increase in ROS production exceeds the antioxidant capacity of the cell, the intracellular environment becomes strongly oxidizing. This change results in altered gene expression as a part of the response to oxidative damage to genomic DNA, modification of redox-sensitive protein activity, and membrane lipid oxidation.[25] All of these insults can affect the structure, function, and signaling capacity of the cell. Of particular importance to the radiation response is the persistent upregulation of transcription factors, including hypoxia-inducible factor-1α (HIF-1α) and nuclear factor κB (NFκB), and cytokines, including TGF-β, which contributes to the development of radiation-induced tissue injury.[16,26] These molecules all contribute to the vascular changes, inflammation, and cell death observed in response to radiation, but their roles in complex signaling pathways suggest that early changes in the activity of these molecules may also contribute to the disease process of latent injury. The role of ROS in radiation-induced tissue injury has been confirmed by the finding that SOD overexpression and the use of SOD mimetics can mitigate tissue injury following ionizing radiation exposure.[11,23,27–30]

The Role of Inflammation in the Response to Radiation

Although the manifestations of radiation injury can be divided into early and late effects, irradiated tissues show a dynamic population of different inflammatory cell types throughout the “latency” period, suggesting that, on a cellular level, radiation injury is an ongoing disease process.[31] Localization of inflammatory cells is mediated by vascular adhesion markers, and preferentially blocking intercellular adhesion molecule-1 (ICAM-1) does indeed reduce the inflammatory response to radiation in the lungs of C57BL/6 mice.[32,33] The resulting reduction in inflammation was, however, not sufficient to suppress development of latent pulmonary damage, suggesting that there are other

mechanisms at work during this latent period that contribute to disease processes.[32] With the changing inflammatory cell populations come changes in cytokine activity, specifically interleukins, tumor necrosis factor-α (TNF-α), TGF-β, monocyte chemoattractant protein-1 (MCP-1), and keratinocyte chemoattractant (KC).[31,34,35] Expression of interleukin-1 (IL-1) messenger RNA (mRNA), together with a two-part upregulation of TGF-β expression, is known to coincide with the development of fibrosis in C57BL/6J mice, suggesting that the inflammatory response does indeed contribute to the development of latent tissue injury.[36] This idea is further supported by the finding that early inhibition of TGF-β reduces radiation-induced pulmonary fibrosis and improves lung function.[37–39] Further studies indicate that administration of exogenous SOD following thoracic radiation reduced the early upregulation of IL-1, TNF-α, and TGF-β and extended postradiation survival.[40] The apparent link between ROS, inflammatory signaling, and latent injury development suggests that early changes in ROS production do affect delayed tissue damage through ongoing perturbations of signaling pathways.

Radiation-Induced Vascular Changes

Exposure to ionizing radiation causes damage to endothelial cells and vascular structural elements, causing increased vascular permeability.[41] This vascular dysfunction results in edema as well as decreased perfusion, which can lead to development of hypoxic regions within the affected tissues.[42] Hypoxia exacerbates the initial injury by increasing recruitment of inflammatory cells that, in the process of undergoing the respiratory burst, produce ROS and increase tissue hypoxia by consuming the available oxygen.[43] Hypoxia also results in activation of HIFs. HIF-1α is an ROS-stabilized transcription factor that, under hypoxic conditions, forms a heterodimer with HIF-1β. This heterodimer is translocated to the nucleus where it binds the hypoxia response element (HRE), inducing transcription of genes involved in migration proliferation, apoptosis, and angiogenesis.[44] This element of the hypoxia response contributes to endothelial cell damage, increasing vascular permeability and, as a result, leakage of fibrin into the extracellular matrix.

Vascular endothelial growth factor (VEGF) is an HIF-mediated growth factor. Under hypoxic conditions, VEGF expression is increased, resulting in aberrant vascular network formation, which leads to irregular perfusion.[45] The resulting cycles of hypoperfusion and reperfusion contribute to oxidative stress, further damaging tissue.[38]

Macrophage accumulation further contributes to the self-perpetuating nature of radiation-induced tissue injury. Accumulation of macrophages is known to occur in areas of low perfusion and inadequate supply of oxygen and is observed in tissues following radiation exposure.[46,47] When activated, these cells produce HIF-1α in order to initiate angiogenesis to correct low perfusion.[47] This response on the part of macrophages increases the level of oxidative stress, continuing the spread of damage through inappropriate continuation of wound healing mechanisms.

Possible Metabolic Changes

Carbonic anhydrase-9 (CA-9) is commonly used as a hypoxia marker because CA-9 transcription is dependent on HIF-1α. Because carbonic anhydrases act to catalyze the conversion of metabolically produced carbon dioxide to bicarbonate,[48] this increase in CA-9 suggests that cells may also be undergoing a metabolic shift in response to their hypoxic environments. The observed changes in mitochondrial activity would support altered metabolism in postradiation cells, but further work is necessary to determine the nature of such a change.

Implications

Exposure to ionizing radiation disrupts DNA, causing cell death, but it also causes increased production of ROS in viable cells. The oxidizing environment that results from ROS production exceeding the antioxidant capacity of the cell causes further damage by disrupting cell function and signaling pathways. This disturbance results in changes in vascular integrity, an ongoing inflammatory response, and aberrant angiogenesis. Because overproduction of ROS is self-perpetuating, these effects are amplified, increasing the area and severity of damage.

Though many of the mechanisms through which ROS production affects the development of late radiation effects remain unclear, it is likely that these early changes initiate disease processes that progress over time to cause the observed late injury.

SUMMARY BY ORGAN SYSTEM

To provide a consistent summary of the extensive information in the individual organ reviews, the following outline is utilized:

. Clinical Significance

- End points
- Challenges Defining Volumes
- Dose/Volume/Toxicity Data
- Factors Affecting Risk
- Mathematic/Biologic Models
- Special Situations
- Recommended Dose–Volume Limits
- Future Studies
- Toxicity Scoring Criteria

Note that the brief summaries for each review do not substitute for reading and understanding the original papers and, as necessary, the underlying literature. In addition, the dose–volume limits described in the QUANTEC reviews are intended to supplement, not supplant, clinical judgment.

CENTRAL NERVOUS SYSTEM

Brain

Clinical Significance

The acute and late effects of radiotherapy on the brain are common and represent a significant source of morbidity.[49] In particular, patients with tumor-related neurocognitive dysfunction may exhibit exacerbated deficits after radiotherapy. In addition, the radiation fields used to treat the upper aerodigestive tract (e.g., sinuses and pharynx) often include a portion of the brain.

End Points

The acute side effects of radiation therapy (RT) to the brain include nausea, vomiting, and headache; seizures, visual disturbances, and vertigo are less common.[49] These symptoms are typically transient and generally respond well to medication. The end points for assessing long-term radiation-induced complications are typically radiation necrosis or asymptomatic radiologic changes as seen on serial magnetic resonance imaging (MRI) scans.[49] Other measures have included steroid usage, preservation of performance status, and neurocognitive function.[50–52]

Challenges Defining Volumes

Contouring the entire brain is straightforward, and with appropriate immobilization, there is little intra- or interfraction motion. However, delineation

of subregions (e.g., the border between the brainstem and thalamus) and functional segments (e.g., Broca area) of the brain is challenging, and the utility of defining such areas has not yet been proven.[49]

Dose/Volume/Toxicity Data

For fractionated radiotherapy to the brain, the relationship between dose and radiation necrosis for partial brain irradiation is shown in Figure 14.2 for various fractionation schemes.[53–60] Lawrence et al. compared different fractionation schemes by calculating the biologically effective dose (BED),[61] with an α/β ratio of 3 Gy.[49] For standard fractionation, a dose–response relationship appears to exist, such that an incidence of side effects of 5% and 10% occurs at a BED of 120 Gy_3 (range, 100 to 140) and 150 Gy_3 (range, 140 to 170), respectively (corresponding to 72 Gy [range 60 to 84] and 90 Gy [range, 84 to 102] in 2-Gy fractions). For twice-daily fractionation, a steep increase in toxicity is apparent when the BED exceeds 80 Gy. For daily large-fraction sizes (>2.5 Gy), the incidence and severity of toxicity are unpredictable. Lawrence et al. caution against overinterpreting this analysis given the heterogeneity of the data pool (i.e., different target volumes, end points, sample sizes, and brain regions).

In children, whole-brain radiotherapy appears associated with neurocognitive decline. With central nervous system prophylaxis for acute lymphoblastic leukemia, the addition of 24-Gy radiation to the whole brain (to a chemotherapy regimen) is associated with a median 13-point intelligence quotient reduction at 5 years after radiotherapy, as well as poorer academic performance and greater psychological distress.[62] Reported toxicities have been lower when 14 to 18 Gy was used.[63–65] In medulloblastoma, the post-RT intelligence quotients were 10 to 15 points higher for a total whole-brain dose of 23.4 versus 36 Gy.[66,67] In adults, the neurocognitive effects of whole-brain irradiation are less clear. The RTOG 0933 phase II study of hippocampal sparing (which required that 100% dose and maximum dose not exceed 10 and 17 Gy, respectively) analyzed 113 patients with brain metastases. With hippocampal sparing, memory preservation at 4 and 6 months was significantly better than that in historical controls.[68]

With permission.)

In stereotactic radiosurgery (SRS) of brain lesions, normal tissue toxicity appears to be a function of dose, volume, and location in the brain. The Radiation Therapy Oncology Group (RTOG) conducted a dose escalation study (RTOG 9005) of radiosurgery to recurrent brain metastases and primary tumors in patients who previously received whole or partial brain irradiation.[69] The goal of this study was to determine the maximal tolerated dose as a function of

maximum diameter of the lesion. Unacceptable toxicity was defined as acute irreversible severe neurologic symptoms, requiring inpatient or outpatient medications, any life-threatening neurologic toxicity, or death. This study found a maximum tolerated prescription dose to the tumor margin of ≥24, 18, and 15 Gy for tumors with a maximal diameter of ≤2.0, 2.1 to 3.0, and 3.1 to 4.0 cm, respectively. The rates of acute and late unacceptable toxicities in patients treated at these doses were 0% and 10%, 0% and 14%, and 0% and 20%, respectively. The dose limits appear to be validated by the results of the RTOG 9508, a randomized study of SRS + whole-brain radiation therapy (WBRT) versus WBRT alone in 333 patients with brain metastases.[50] Using the dose constraints developed in RTOG 9005, this study found a 3% and 6% rate of grade 3 and 4 acute and late toxicities, respectively, in the group of 167 patients receiving radiosurgery.

The results of dose–volume studies of the development of "radionecrosis" following single-fraction radiosurgery are shown in Table 14.3.[49,70–79] Although a common element in many of these studies is the volume receiving a dose of 10 or 12 Gy or more (V_{10} or V_{12}, respectively), there is a broad variation in the crude rate of radionecrosis as a function of volume irradiated. This is likely due to difference in the definition of *radionecrosis*, the location irradiated, the proximity to and sparing of critical structures, and the length and intensity of clinical follow-up.

These results suggest that the rate of complications increases rapidly as the V_{12} increases beyond 5 to 10 cm^3. Note, however, that V_{12} will far exceed these limits for lesions 2 cm or greater in mean diameter when the RTOG guidelines are utilized. For example, assume that spherical lesions 1, 2, 3, and 4 cm in diameter are treated under the RTOG guidelines with single-fraction radiosurgery with the plans yielding V_{12}'s of six, five, four, and three times the lesion volume, respectively. Then, the calculated V_{12}'s are 3, 21, 57, and 101 cm^3, respectively.

The location of the lesion is important as the severity of expressed damage is greater in the more eloquent parts of the brain. For example, for a V_{12} of 10 cm^3, Flickinger et al.[72] found a <5% symptomatic postradiosurgery injury for arteriovenous malformations (AVMs) in the frontal, temporal, and parietal lobes versus >20% for AVMs in the brainstem, thalamus, and basal ganglia.

Factors Affecting Risk

Younger age is associated with a higher risk of neurocognitive decline in children undergoing cranial irradiation.[80,81] Other risk factors include female gender, neurofibromatosis-1 (NF1) mutation, extent of surgical resection, hydrocephalus, concomitant chemotherapy (especially methotrexate), location, and volume of brain irradiated.[82] No evidence has shown that children are at particular risk of radiation necrosis,[83,84] however.

Mathematic/Biologic Models

Although the linear-quadratic model appears useful in comparing dose/fraction for conventionally fractioned radiotherapy schemes, its utility at high doses per fraction (≥8 Gy) is controversial. In general, quantitative dose/volume/clinical toxicity relationships have not been established for neurocognitive function in partial brain irradiation. The apparent increased risk of radionecrosis in twice-daily partial brain irradiation suggests that the time constant for repair of radiation-induced damage may be longer than the typical interfraction interval, but this has not been modeled for this specific system.

Special Situations

Reirradiation of the whole brain is frequently performed in the setting of recurrent, multiple brain metastases. A meta-analysis of whole-brain reirradiation (interval between courses, 3 to 55 months) found no cases of necrosis when the total radiation dose was <100 Gy (normalized to 2 Gy/fraction with an α/β ratio = 2 Gy).[85] In primary central nervous system lymphoma, whole-brain radiotherapy has been associated with an atypically high risk of cognitive decline, especially in those >60 years old.[86,87] The heightened sensitivity of this population to irradiation might be explained by the tumor's highly diffuse, angiocentric growth pattern and that most patients receive high-dose methotrexate, a potent neurotoxin. As a result, up-front full-dose RT is now often avoided in elderly patients with this disease. A lower radiation dose of 23.4 Gy delivered in 1.8-Gy daily fractions appears to be associated with minimal

cognitive toxicity, even in older patients.[88]

Recommended Dose–Volume Limit[49]

For partial brain irradiation at a conventional dose per fraction, there is a predicted 5% and 10% risk of symptomatic radiation necrosis at a BED of 120 Gy_3 (range, 100 to 140) and 150 Gy_3 (range, 140 to 170), respectively, which corresponds to 72 Gy (range 60 to 84 Gy) and 90 Gy (range 84 to 102 Gy) for 2-Gy daily fractions. This is a less conservative estimate than the 5% risk of radionecrosis for one-third of the brain irradiated to 60 Gy in the Emami paper.[1] The authors stress that for most cancers, there is no clinical indication for partial brain dose above 60 Gy and that, in some scenarios, an incidence of 1% to 5% radiation necrosis at 5 years would be unacceptably high. The brain appears especially sensitive to fraction sizes >2 Gy and, surprisingly, twice-daily irradiation.

For radiosurgery, the available data suggest that it is prudent to minimize the volume of normal brain receiving >12 Gy in a single fraction and to consider both target diameter and anatomic location when prescribing dose. However, the QUANTEC authors admit that “the substantial variation between the reported treatment parameters and outcomes from different centers has prevented [more] precise toxicity risk predictions.”

Future Studies

Key questions that would benefit from systematic study include the following:

- What is the dose/volume/location/clinical toxicity relationship for brain metastases and other common lesions treated with single-fraction SRS?
- What is the rate of local and distant failure for the aforementioned sets of patients as a function of prescribed dose?
- How does the gross tumor volume (GTV) to planning target volume (PTV) expansion influence the incidence of normal tissue toxicity and failure rates in single-fraction SRS?
- How is the incidence of normal tissue toxicity affected by previous large-field irradiation to the brain, particularly the combination of WBRT and SRS in the treatment of brain metastases?
- How do systemic treatments affect the incidence of normal tissue toxicity?
- What is the time interval for repair of radiation-induced damage in the brain?

Toxicity Scoring Criteria

Studies of brain radiotherapy should report detailed dosimetric and outcome data, including neurocognitive and neurologic dysfunction (e.g., per the Common Terminology Criteria for Adverse Events, version 4.0 [CTCAE v. 4.088]), the prescription dose, dose/fraction, target volume, V_{12}, anatomic location treated, and clinical outcome data (e.g., adverse events, patterns of failure).

Optic Apparatus

Clinical Significance

The optic nerves and chiasm frequently receive a substantial dose during therapeutic irradiation of the brain, base of the skull, and head and neck targets, and the optic apparatus is frequently the dose-limiting structure in these cases. While rare, damage to the optic apparatus can produce devastating and, at present, irreversible visual deficits.[89]

End Points

The primary end point for radiation-induced optic neuropathy (RION) is visual impairment, defined by visual acuity and the size/extent of visual fields.[90] Of course, damage to the lens (development of cataracts), retina (retinitis), and lacrimal apparatus and trigeminal nerve (dry eye syndrome) can also produce impaired vision.[91] Although toxicity may be objectively scored using CTCAE version 4[92] and late effects of normal tissues and subjective, objective, medical management, and analytical (LENT–SOMA) evaluation of injury criteria,[93,94] it is important to obtain a comprehensive ophthalmologic examination of patients with suspected RION.

Challenges Defining Volumes

The optic nerve originates roughly at the posterior center of the globe and is bracketed by the rectus muscles as it tracks posteriorly through the orbit to pass through the optic notch, just medially to the anterior clinoid process. The optic nerves join and decussate to form the optic chiasm, an X-shaped structure that sits just superiorly to the sella turcica with the center immediately anterior to the pituitary stalk.[95] The optic nerves and chiasm are thin (<5 mm diameter), and visualization is best performed using thin-cut (≤3 mm) T1- or T2-weighted MRI. Contouring the optic nerves/chiasm is challenging, and it is important to ensure that these structures are drawn in continuity (i.e., there is no gap in the contours). Appropriate contouring of these structures is facilitated by visualizing this region

in multiple planes and using fused imaging modalities (e.g., utilizing the magnetic resonance images in the axial and coronal planes to track the optic nerves/chiasm and sagittal computed tomography [CT] views to see the sella turcica).

Dose/Volume/Toxicity Data

The data for the incidence of RION with conventional fractionation for selected studies[96–103] are summarized in Figure 14.3. The risk of RION appears to rise steeply past 60 Gy. None of the patients in the study by Parsons et al.[96] with a maximum point dose (D_{max}) to the optic nerves/chiasm <59 Gy developed RION. In the study by Martel et al.,[97] the average maximum chiasm and nerve dose was 53.7 Gy (range 28 to 70 Gy) and 56.8 Gy (range 0 to 80.5 Gy) for patients without RION. The optic nerves had received a D_{max} of 64 Gy with 25% of the volume receiving >60 Gy for patients with moderate to severe complications. Jiang et al.[98] reported no incidence of ipsilateral RION for a dose <56 Gy and a <5% incidence at 10 years for a dose <60 Gy at approximately 2.5 Gy/fraction.

The risk of RION appears to be related to the fraction size. Parsons et al.[96] reported 15-year actuarial rates of RION for total doses of 60 to <70 Gy of 50% versus 11% at ≥1.9 versus <1.9 Gy dose/fraction, respectively. No patients treated twice daily with 1.2 Gy/fraction developed RION. At total doses of 70 to 83 Gy, the incidence was 33% versus 11% for ≥1.9 versus <1.9 Gy/fraction and 12% for 1.2 Gy twice-daily fractions. Bhandare et al.[104] noted reductions in RION rates for twice- versus once-daily treatment.

Results from proton treatments appear consistent with those utilizing photons.[103,105–107] Note that the proton doses are reported as cobalt gray equivalent (CGE), reflecting their greater biologic effect, and that photons were often used in combination with protons. Most proton series have reported a very low incidence of RION, and in the few cases of reported RION, a threshold dose in the range of 55 to 60 CGE has been observed, consistent with the photon experience. As with photons, many patients exceeding this threshold did not develop RION. Wenkel et al.,[107] Noel et al.,[105] Weber et al.,[103] and Nishimura et al.[106] used a D_{max} constraint to the optic structures of 54, 55, 56, and 60 CGE, respectively.

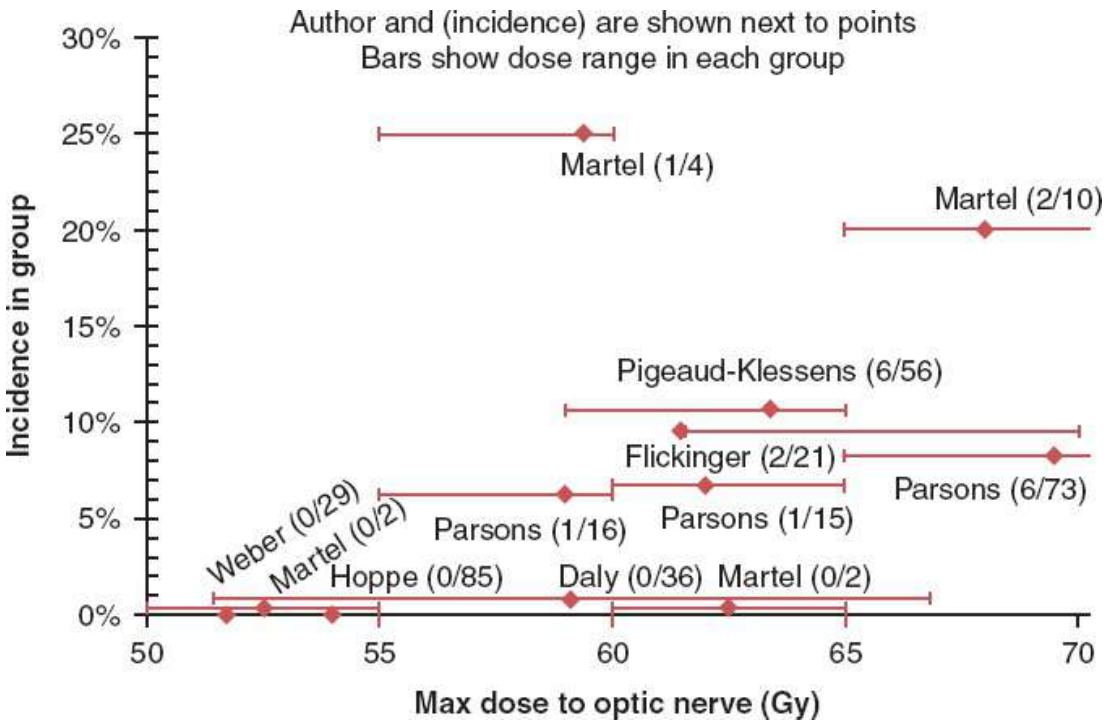

FIGURE 14.3. Incidence of radiation-induced optic neuropathy (RION) in selected studies.[96–103] Points offset from 0% to 1% were shifted to clearly show range bars. The single patients in the studies by Parsons et al.[96] and Martel et al.[97] with events in the 55 to 60 Gy range were treated to 59 Gy and 59.5 Gy, respectively. (Reprinted from Mayo C, Martel MK, Marks LB, et al. Radiation dose-volume effects of optic nerves and chiasm. *Int J Radiat Oncol Biol Phys* 2010;76[3 Suppl]:S28–S35. Copyright © 2010 Elsevier. With permission.)

Because of the small size of the optic nerves/chiasm and steep dose gradients in radiosurgery, most studies of RION involving SRS use the D_{max} to the optic nerves/chiasm as the critical dose metric.[89] As shown in Table 14.2, single-fraction SRS studies describe a range of threshold D_{max} for RION. In analyzing their early experience with radiosurgery, Tishler et al.[108] reported RION at D_{max} as low as 9.7 Gy and recommended 8 Gy as the dose limit for the optic nerves/chiasm in SRS. Stafford et al.[109] found RION in 4 of 215 patients receiving a median D_{max} of 10 Gy. The D_{max} in the patients ranged from 0.4 to 16 Gy, and 3 of the 4 had received previous external beam radiotherapy to this area. They estimated a 1.7%, 1.8%, 0%, and 6.9% incidence of RION for D_{max} of <8, 8 to 10, 10 to 12, and >12 Gy, respectively.

Pollock et al.[110] observed no cases of RION in 62 patients with nonfunctioning pituitary adenomas receiving a median D_{max} of 9.5 ± 1.7 Gy to the optic apparatus during single-fraction SRS, using a 12-Gy D_{max} as the dose constraint for the optic apparatus. From a study of 50 patients with benign base

of the skull tumors treated with single-fraction SRS and a median follow-up of 40 months, Leber et al.[111] estimated a 0%, 27%, and 78% risk of RION for D_{max} of <10, 10 to <15, and ≥15 Gy, respectively. No data for dose–volume and RION were available for hypofractionated stereotactic radiotherapy (HFSRT) (4 to 8 Gy/fraction).[89]

Factors Affecting Risk

There appears to be an increased risk of RION with increasing age.[96] Parsons et al.[96] reported that none of the 38 patients in the 20- to 50-year-old range developed RION, even though the reported optic nerve doses were >60 Gy for 58% and >70 Gy for 26%. In contrast, for patients with doses >60 Gy, the incidence was 26% and 56% for the 50- to 70- versus >70-year-old age groups. RION in children is poorly characterized, but treatment of the developing optic apparatus should be approached cautiously. Reports on the effect of other factors such as adjuvant chemotherapy, diabetes mellitus, and hypertension have been inconsistent. Minimal data are available on reirradiation of the optic apparatus and the effect of the interval between courses on RION. Flickinger et al.[112] found that one of 10 patients undergoing reirradiation of the optic apparatus developed RION—the affected received an initial 40 Gy and, after a 7.5-year interval, an additional 46 Gy, both at 2 Gy/fraction.

Mathematic/Biologic Models

The original Lyman-Kutcher-Burman normal tissue complication probability (NTCP) volumetric modeling[4] estimated TD_{50} = 65 Gy, n = 0.25, and m = 0.14. The dose–response data from Jiang et al.[98] (1.5 to 2.2 Gy/fraction) suggest TD_{50} ≈ 72 to 75 Gy. Martel et al.[97] and Brizel et al.[113] estimated TD_{50} at 72 and 70 Gy, respectively. Extrapolation of the Parsons dose–response data[96] suggests that TD_{50} exceeds 70 Gy.

Special Situations

There is a suggestion that RION may occur at lower doses in patients with pituitary tumors, as complications at doses as low as 46 Gy at 1.8 Gy/fraction have been reported.[101,114,115] Mackley et al.[101] and van den Bergh et al.[114] constrained the optic structure D_{max} to 46 and 45 Gy, respectively. The RION latency also appeared shorter in patients with pituitary tumors. The average latency was 10.5 and 31 months (range 5 to 168 months) in patients with pituitary targets and nonpituitary targets, respectively.[101,115] The apparent

increased sensitivity in these patients might be related to tumor-associated compression and/or postsurgical trauma of these nerves.

Recommended Dose–Volume Limits

The estimate by Emami et al.[1] of a 5% risk of blindness within 5 years of treatment for a dose of 50 Gy appears inaccurate. The QUANTEC review[89] suggests that the incidence of RION was unusual (<2%) for D_{max} < 55 Gy, particularly for fraction sizes <2 Gy. The risk increases (3% to 7%) in the region of 55 to 60 Gy and becomes more substantial (>7% to 20%) for doses >60 Gy when dose per fraction of 1.8 to 2.0 Gy is used. The patients with RION treated in the 55 to 60 Gy range were typically treated to doses in the very high end of that range (i.e., 59 Gy). For particles, most investigators found that the incidence of RION was low for a D_{max} < 54 CGE. One exception to this range was for pituitary tumors, in which investigators used a constraint of D_{max} < 46 to 48 Gy for 1.8 Gy/fraction.

The aforementioned studies suggest that the incidence of RION in single-fraction radiosurgery is rare for D_{max} < 8 Gy, increases in the range of 8 to 12 Gy D_{max}, and becomes >10% when D_{max} exceeds 12 Gy. Though the QUANTEC paper presents isoeffect curves for RION over a range of 2 to 12 Gy/fraction using various radiobiologic models, the authors emphasize that there are no data in the hypofractionated range and caution that the curves should not be used to predict toxicity in this regimen.

Future Studies

In addition to reporting detailed dose–volume data for patients with and without RION receiving radiation to the optic apparatus, investigators must consistently, completely, and accurately contour the optic apparatus.

Toxicity Scoring Criteria

Visual deficits should be scored using the CTCAE v. 4.0.[37]

Brainstem

Clinical Significance

As with the optic apparatus, irradiation of the brain, base of the skull, and the neck can deliver a significant dose to the brainstem, which is frequently the dose-limiting structure.

End Points

Radiation-induced damage to the brainstem may be manifest as specific cranial neuropathies; focal motor, sensory, or balance deficits; or mild to life-threatening global dysfunction. This is reflected in the CTCAE,[92] which scores brainstem-related toxicity on the basis of symptoms. The study of radiation-induced brainstem injury is challenging because (a) the reported incidence of injury is low, (b) survival time is short for many patients, (c) formal grading of brainstem effects is subjective and is often characterized categorically (i.e., "yes–no") for cranial neuropathy, and (d) for patients with intracranial tumors, it is often difficult to distinguish between side effects and disease progression.[116]

Challenges Defining Volumes

Contouring the brainstem on axial MRI is usually straightforward, although it requires special attention to the superior extent and interfaces at the cerebral and cerebellar peduncles where the borders are indistinct. Coronal and sagittal views, in addition to axial images, are frequently helpful in visualizing the brainstem and its interfaces. The adult brainstem volume is on the order of 35 ± 8 mL.[117]

Dose/Volume/Toxicity Data

Studies of potential radiation-induced brainstem toxicity in conventionally fractionated partial brain, base-of-skull, or neck irradiation variably report crude radiographic and functional toxicities over typically short follow-up periods.[100,103,105–107,118–127] Reported toxicities attributable to radiation of the brainstem and dose constraints are presented in Table 14.4. Uy et al.[127] reported brainstem necrosis in one of 40 adult meningioma patients treated with intensity-modulated radiation therapy (IMRT). For this patient, the D_{max} was 55.6 Gy, and the absolute volume of brainstem that exceeded 54 Gy was 4.7 mL. Jian et al.[122] noted a grade 1 neurologic deficit in three of 48 patients with nasopharyngeal cancer treated with 1.2 Gy twice-daily photons to 74.4 Gy and concomitant chemotherapy.

TABLE 14.4 SELECTED STUDIES OF RADIATION-INDUCED BRAINSTEM TOXICITY WITH CONVENTIONAL FRACTIONATION OR HYPERFRACTIONATION

Reference	Patients/Disease	Modality	Dose Constraint	Radiation-Induced Brainstem Toxicity
Jian et al.[122]	48	Photons	V_{65} < 3 mL, V_{60}	3 grade 1

	Adults/nasopharyngeal cavity		< 5 mL	neurologic toxicities
Hoppe et al.[121]	85 Adults/nasal cavity and/or paranasal sinus	Photons	D_{max} < 50 Gy	
Daly et al.[100]	36 Adults/nasal cavity and/or paranasal sinus cavity	Photons	$D_{1\%}$ < 54 Gy	
Schoenfeld et al.[126]	100 Adults/pharynx or larynx	Photons	V_{55} < 0.1 mL	
Uy et al.[127]	40 Adults/intracranial meningioma	Photons	Unknown	1 BS necrosis @ D_{max} 55.6 Gy, V_{54} 4.7 mL
Merchant et al.[123]	68 Children/infratentorial ependymoma	Photons	No separate brainstem constraint	1 BS necrosis @ D_{mean} 59 Gy
Freeman et al.[120]	136 Children/brainstem glioma	Photons	Prescribed 54–60 Gy at 2 Gy once daily or 75.6 Gy at 1.26 Gy twice daily	None reported
Packer et al.[124,125]	98 Children/brainstem glioma	Photons	Prescribed 72 or 78 Gy total @ 1 Gy twice daily	One treatment-related death at 72 Gy total @ 1 Gy twice daily and concurrent β-IFN
Weber et al.[103]	29 Adults/chordoma, chondrosarcoma	Protons	Surface ≤ 63 CGE Center ≤ 54 CGE	None reported
Nishimura et al.[106]	14 Adults/olfactory neuroblastoma	Protons	Surface < 64 CGE Center < 53 CGE	None reported
Noel et al.[105]	45 Adults/BOS tumors	Photons + protons	Surface ≤ 63 CGE Center ≤ 54 CGE	
DeBus et al.[118,119]	367 Adults/BOS tumors	Photons + protons	Surface ≤ 64 CGE Center ≤ 53 CGE	19 BS toxicities, including 3 deaths
Wenkel et al.[107]	46 Adults/BOS meningiomas	Photons + protons	Surface ≤ 64 CGE Center ≤ 53 CGE	1 BS injury, 2 neurologic toxicities

β-IFN, recombinant β-interferon; BOS, base of skull; BS, brainstem; CGE, cobalt gray equivalent.

In the largest study, Debus et al.[118,119] reported on 367 patients with base-of-skull tumors with a combination of conformal photon and proton radiation therapy. Nineteen late brainstem-related toxicities were observed, including three

deaths. On univariate analysis, significant predictors of toxicity were D_{max} > 64 CGE, V_{50} CGE > 5.9 mL, V_{55} CGE > 2.7 mL, V_{60} CGE > 0.9 mL, two or more skull-based surgeries, diabetes, and high blood pressure. On multivariate analysis only V_{60} > 0.9 mL, two or more skull-based surgeries, and diabetes were predictive. In a study of 46 patients with recurrent base-of-skull meningiomas, treated to a median brainstem D_{max} of 58.0 CGE, Wenkel et al.[107] found that one patient developed brainstem injury at a dose that exceeded an unspecified constraint value by 10%. Two others with neurologic toxicities had brainstem doses that exceeded the constraints as shown in Table 14.4.

In pediatric patients with brainstem glioma (treated with opposed lateral fields that encompassed the majority of the brainstem), no toxicity was reported at doses of 54 to 60 Gy at 2 Gy/fraction, 75.6 Gy at 1.26 Gy twice daily,[120] or 78 Gy at 1 Gy twice daily.[124] The primary limitation of these studies was the short median survival, <12 months. Of 32 patients treated to 72 Gy twice daily in combination with recombinant β-interferon, there was at least one treatment-related death.[125]

Most pediatric protocols for central nervous system tumors recommend doses >54 Gy, and separate brainstem dose constraints are often absent. Merchant et al. studied 68 patients with infratentorial ependymoma treated with surgery and conformal RT (54 to 59.4 Gy).[123] In patients with full recovery, a considerable portion of the brainstem received over 60 Gy (V_{60} = 7.8 ± 1.4 mL). There was no difference in brainstem recovery based on absolute or percent volume of the brainstem that received more than 54 Gy. Differences in these values for patients without full recovery were not statistically significant. One patient died with autopsy-confirmed residual tumor and focal areas of brainstem necrosis. The mean brainstem dose was 59 Gy, and he also exhibited severe perioperative morbidity after two surgeries.

A limited number of studies report brainstem toxicity in single-fraction SRS or HFSRT.[128–132] A broad range of prescription isodose levels and dose metrics are reported, making it difficult to develop a predictive dose–volume model for brainstem toxicity.[116] In the study with the largest number of patients, Foote et al.[128] analyzed the outcome in 149 vestibular schwannoma patients treated with SRS between 1988 and 1998; 41 were treated before 1994, when radiosurgery was primarily based on CT imaging, and 108 after 1994, when planning was MRI based. Large single-fraction doses (10 to 22.5 Gy) were used. Their analysis revealed a “learning curve,” with a 5% and 2% actuarial 2-year rate of

facial and trigeminal neuropathies, respectively, for patients treated after 1994 compared with 29% for both neuropathies for the earlier patients. This study found a significant difference, with a 2-year actuarial rate of facial and trigeminal neuropathies of 29% and 7% for patients treated before and after 1994, respectively. The authors ascribe this difference to the use of MRI rather than CT-based imaging and lower prescription doses in the latter years. A univariate analysis showed an incidence of cranial nerve neuropathy of 2% for <12.5 Gy versus 24% for >12.5 Gy ($P < .0003$). On multivariate analysis, the prescription dose >12.5 Gy, prior surgery, and treatment prior to 1994 were significant variables.

Mathematic/Biologic Models

The Emami review estimates a 5-year, 5% rate of complications, defined in that study as "necrosis/infarct," at 50, 53, and 60 Gy delivered to the whole, two-thirds of, and one-third of the brainstem, respectively.[1] The corresponding Lyman-Kutcher-Berman (LKB) parameters for calculation of the NTCP were $n = 0.16$, $m = 0.14$, and a tolerance dose for 50% probability of these complications (TD_{50}) equal to 65 Gy.[26] These estimates and model parameters appear overly conservative. For example, the LKB model estimates a 12% risk of severe complications for 54 Gy to the whole brainstem or a 3% risk of complications when the proton dose constraints (Table 14.4) are utilized. The clinical data would suggest that a larger TD_{50}, smaller m, or larger m values might produce more reasonable estimates of toxicity. For example, an LKB model with a larger TD_{50} (72 Gy) or smaller m (0.1) would reduce the predicted risks to <5% or <1%, respectively. However, there are insufficient existing dose/volume/complication data to generate a more accurate model estimate at this time.

Recommended Dose–Volume Limits

The QUANTEC study concludes that the entire brainstem may be treated to 54 Gy using conventional fractionation with limited risk of severe or permanent neurologic effects.[116,123] Although the precise dose–volume relationship is unclear, partial volumes of the brainstem (1 to 10 mL) may be irradiated to a maximum dose of 59 Gy for dose fractions ≤2 Gy. The risk appears to increase markedly at doses >64 Gy. In radiosurgery, it appears that a maximum brainstem dose of 12.5 to 13 Gy is associated with a low (<5%) risk of cranial neuropathy in patients with vestibular schwannomas treated with single-fraction SRS. The

risk appears to increase rapidly when the marginal prescription dose is >15 Gy or when the target volume exceeds 4 mL.[116,128,133] However, doses of 15 to 20 Gy have been used to treat brainstem metastases with a low reported rate of complications, potentially because of the limited survival time for these patients.[130,134]

Future Studies

Uniform, complete reporting of patient-specific dose/volume/outcome data for patients with and without complications are required.

Toxicity Scoring Criteria

Patients should undergo a complete history and physical examination at regular intervals with particular attention to the neurologic exam. Toxicity should be scored and reported using the CTCAE v. 4.0.[92]

Auditory Apparatus

Clinical Significance

Radiation therapy to brain tumors and head and neck cancers may damage the cochlea and/or acoustic nerve, leading to sensorineural hearing loss (SNHL) and compromised quality of life.[135]

End Points

SNHL following conventionally fractionated radiotherapy is typically measured by a decrease in the bone conduction threshold (BCT) at 0.5 to 4 kHz,[135] the primary range for human speech, using pure-tone audiometry (PTA). Although the technique is well established and standardized, a broad range of specific audiometric parameters are used to characterize SNHL, including the frequency (range) used for testing, the threshold chosen for a clinically significant change in the BCT (10 to 20 dB), and the control/standard used for comparison. In stereotactic radiosurgery, SRS, or HFSRT, hearing status is more commonly evaluated using the Gardner-Robertson scale, which is based on both PTA and speech discrimination. Hearing loss after SRS/HFSRT may be characterized by changes in Gardner-Robertson hearing grade or retention of serviceable hearing (i.e., functional hearing with the aid of a hearing aid) or any measurable hearing. In addition, the length of follow-up will influence reported hearing loss, as deficits may develop more rapidly following single-fraction SRS than HFSRT, and hearing loss increases over time in both situations.

Challenges Defining Volumes

Contouring of the acoustic nerve and brainstem is best accomplished on high-resolution, contrast-enhanced T1-weighted and fast imaging with steady-state precession MRI. The cochlea and associated bony anatomy are better delineated on fine-cut (≤1 mm slice thickness) CT scans. Both the acoustic nerve and cochlea are small structures, and the dose gradient at the latter structure is often quite steep. Moreover, the acoustic nerve anatomy is distorted by the tumor, significantly increasing its apparent diameter. Thus, the dose to these structures is typically characterized by an average or maximum dose, rather than a dose–volume distribution. In many studies, the primary dose metric was the dose to the acoustic neuroma, rather than the normal tissue structures per se, which is not unreasonable as the dose to the tumor appears to be correlated with the dose received by the acoustic nerve.[45]

Dose/Volume/Toxicity Data

SNHL at key frequencies following radiotherapy for head and neck cancer with conventionally fractionated radiotherapy[135–142] is summarized in Figure 14.4. Pan et al.[136] prospectively studied the BCT in 31 patients after unilateral RT with standard fractionation using changes seen in the contralateral ear as standard (0.25 to 8 kHz). Changes in BCT > 10 dB were rarely observed unless the corresponding difference in mean cochlear dose was >45 Gy. The dose to the contralateral cochlea ranged from 0.5 to 31.3 Gy (mean, 4.2 Gy). Honore et al.[141] retrospectively estimated mean cochlear doses in 20 patients treated with radiation therapy for head and neck cancer.[143–145] A dose–response relationship was observed at 4 kHz, but not at other frequencies.

Chen et al.[137] retrospectively studied 22 patients treated with RT for nasopharyngeal cancer (with fraction sizes from 1.6 to 2.3 Gy and concurrent/adjuvant chemotherapy) and studied BCT 12 to 79 months post RT. A significant increase in hearing loss (change in BCT of >20 dB at one frequency or >10 dB at two consecutive frequencies) was observed for all frequencies (0.5 to 4 kHz) when the mean dose received by the cochlea exceeded 48 Gy. Van der Putten et al.[142] retrospectively evaluated changes in BCT after head and neck radiotherapy in 21 patients with unilateral parotid tumors (fraction sizes 1.8 to 3.0 Gy). Using the contralateral ear as a control, SNHL, defined as a >15 dB difference in BCT at three or more frequencies between 0.25 and 12 kHz, was seen when mean doses received by the cochlea were >50 Gy. Oh[140] prospectively studied changes in BCT (0.25 to 4 kHz) post RT in 25 patients

with nasopharyngeal cancer (fraction size 2 Gy). In that study, inner ear doses were high (63 to 70 Gy), and hearing loss (a >15 dB decrease in BCT from baseline) correlated with total dose received by the inner ear.

Table 14.5 summarizes the reported incidence of hearing loss for single-fraction SRS and fractionated stereotactic radiotherapy (FSRT) in the treatment of vestibular schwannomas.[143,144,146–155] The range of hearing loss reported is broad, in part because of the variation in the definition of hearing preservation and the length of follow-up. Nonetheless, several studies suggest that there is a relationship between the volume/length of acoustic nerve irradiated and/or the dose to the nerve and cochlea with hearing loss. In a study of 82 patients treated to a marginal dose of 12 Gy in single-fraction SRS, Massager et al.[156] found that increased intracanalicular tumor volume (<100 vs. ≥100 mm^3) and volume-averaged intracanalicular dose were significant predictors of increased hearing loss. Pollock et al.[157] reported that hearing preservation was more likely when tumors <3 cm versus >3 cm in diameter were treated with single-fraction SRS.

Niranjan et al.[158] found that the dose extending beyond the intracanalicular tumor volume and the prescription dose were the most important factors adversely affecting hearing. In that study, serviceable hearing was preserved in 100% of patients treated with a marginal tumor dose of ≤14 Gy in single-fraction SRS versus 20% in those receiving >14 Gy. Similarly, Kondziolka et al. and Lunsford et al. reported significantly improved hearing preservation rates when the marginal dose was reduced from 16–20 to 12–14 Gy.[150,151]

Several studies suggest that the rate of hearing preservation is improved with FSRT versus single-fraction SRS.[143–145] However, there is an issue of selection bias in that patients are frequently selected for fractionated treatment because their hearing is good. Meijer et al.[154] found no significant difference in hearing preservation in acoustic neuroma patients treated with four to five fractions of 5 Gy HFSRT versus 10 to 12.5 Gy single-fraction SRS (61% vs. 75%), though trigeminal nerve preservation was significantly higher with HFSRT (98% vs. 92%).

Factors Affecting Risk

Although the mean total dose to the cochlea during fractionated radiation therapy to the head and neck and to the acoustic nerve in SRS for vestibular schwannomas is a dominant factor in affecting hearing loss postradiotherapy

(see earlier), the effects of fraction size and twice- versus once-daily treatment are not well characterized. Cisplatin, administered during or after radiotherapy, may exacerbate SNHL.[137,159,160]

Mathematic/Biologic Models

The results of SNHL in conventionally fractionated radiotherapy of head and neck cancers have been fit using multivariate regression models, as discussed in the QUANTEC paper.[135]

Special Situations

The QUANTEC analysis applies only to adult patients; hearing loss after radiotherapy may be more problematic in pediatric patients, particularly in combination with chemotherapy.[161] In patients with neurofibromatosis type 2, treatment of vestibular schwannomas by SRS appears to result in increased hearing loss, as well as poorer tumor control, compared to patients with sporadic tumors.[162–164]

Recommended Dose–Volume Limits

For conventionally fractionated RT, the mean dose to the cochlea should be limited to ≤45 Gy (or more conservatively ≤35 Gy) to minimize the risk for SNHL.[135] Because a threshold for SNHL has not been established, the dose to the cochlea should be kept as low as possible to prevent hearing loss. To minimize hearing loss while maintaining adequate control of vestibular schwannomas, the QUANTEC authors recommend a marginal dose of 12 to 14 Gy for single-fraction SRS.[128,135,165] Though data for hypofractionated regimens are quite limited, the authors speculate that a total dose of 21 to 30 Gy, presumably delivered in three 7-Gy, five 5-Gy, or ten 3-Gy fractions, would provide an acceptable balance of hearing preservation and tumor control.[135]

Future Studies

The effects of concurrent chemotherapy in radiotherapy for head and neck cancer, of acoustic nerve length irradiated and fractionation in vestibular schwannomas, and of the absolute dose to the cochlea in all settings would benefit from prospective, multi-institutional studies.

CT, computed tomography; FSRT, fractionated stereotactic radiotherapy; fx, fraction; HFSRT, hypofractionated stereotactic radiotherapy; MRI, magnetic resonance imaging; NF2, neurofibromatosis type 2; SRS, stereotactic radiosurgery.

Toxicity Scoring Criteria

An audiometric evaluation should be performed for both ears immediately before radiotherapy and biannually thereafter. The QUANTEC authors recommend that a “clinically significant hearing loss” should be defined as an

increase in the threshold of 10 dB in postradiotherapy BCT or a decline of 10% in a speech discrimination evaluation.[135]

Spinal Cord

Clinical Significance

Although the spinal cord proper is from the base of the skull through the top of the lumbar spine, individual nerves continue down the spinal canal to the level of the pelvis. Thus, portions of the spinal cord and canal are often included in radiotherapy fields during treatment of malignancies involving the neck, thorax, abdomen, and pelvis.[166] In addition, metastatic disease to the bony spine is encountered in approximately 40% of all cancer patients,[167] and this disease is often treated with radiotherapy. Though rare, radiation-induced spinal cord injury (i.e., myelopathy) can be severe, resulting in pain, paresthesias, sensory deficits, paralysis, Brown-Séquard syndrome, and bowel/bladder incontinence.[168]

End Points

Myelopathy is defined as a grade 2 or higher myelitis, per CTCAE v. 4.0.[92] Under this definition, asymptomatic changes in the cord detected radiographically and mild signs/symptoms, such as the Babinski sign or Lhermitte syndrome, would not be classified as myelopathy. Consequently, a diagnosis of myelopathy is based on the appearance of signs/symptoms of sensory or motor deficits, loss of function, or pain, now frequently confirmed by MRI. Radiation myelopathy rarely occurs <6 months after completion of radiotherapy and, in most cases, appears within 3 years.[169]

Challenges Defining Volumes

In conventional external beam RT, the field generally encompasses the entire circumference of the cord, vertebral body, and spinal nerve roots, and precise organ definition is not critical apart from correctly identifying the level of the involved cord. Delineation of the cord in radiosurgery is unsettled, with various studies contouring the critical organ in the axial plane as the spinal cord, the spinal cord expanded 2 to 3 mm, the thecal sac and its contents, or the entire spinal canal.[170] As the volume receiving a high dose often extends superiorly and inferiorly to the target, several studies expand the critical organ volume above and below the target volume. For example, RTOG protocol 0631, a study of image-guided radiosurgery of spine metastases, defines the cord as the unexpanded cord itself visualized in MRI and extends the volume of the partial

spinal cord 5 to 6 mm above and below the target volume.

Dose/Volume/Toxicity Data

Schultheiss[166,171] compiled and analyzed published reports of radiation myelopathy in 335 and 1,946 patients receiving radiotherapy to the full circumference, previously unirradiated cervical[169,172–175] and thoracic[176–187] spines, respectively (Fig. 14.5A and B). Although a small number of these patients received relatively high doses per fraction, none were treated using stereotactic techniques to exclude a portion of the circumference of the cord. Note that the dose to the cord is the prescribed dose reported in those studies; typically, dosimetric data were not available to calculate the true cord dose. As discussed later, the rate of myelopathy appears very low below total doses of 50 Gy for conventional radiation delivered at 2 Gy per fraction.

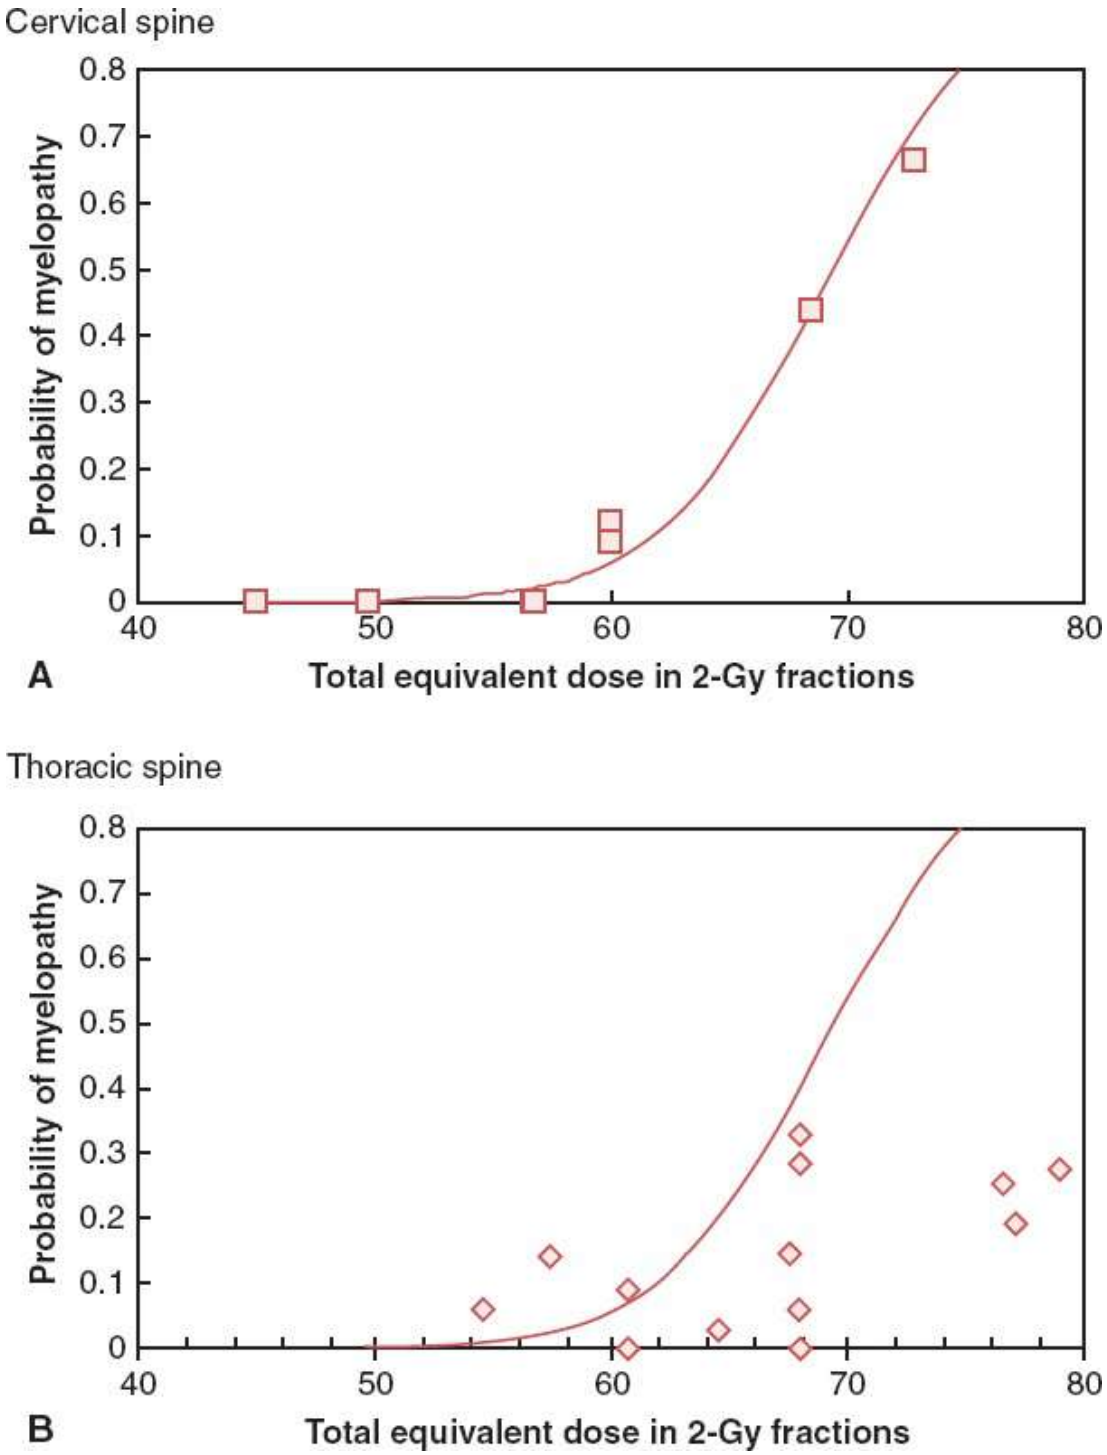

FIGURE 14.5. Incidence of transverse myelopathy from selected studies. **A:** Cervical cord: data for selected studies[169,172–175] shown by □ with probability of myelopathy corrected for estimated survival and *solid line* fit to these data by the method of Schultheiss. **B:** Thoracic cord: data for selected studies[176–187] shown by ◊ with probability of myelopathy corrected for estimated survival. *Solid line* is the best fit to the cervical cord data, as thoracic cord data were insufficient to permit an adequate fit. (Adapted from Schultheiss TE. The radiation dose-response of the human spinal cord. *Int J Radiat Oncol Biol Phys* 2008;71[5]:1455–1459. Copyright © 2008 Elsevier.

With permission.)

Published reports of radiation myelopathy from radiosurgery to the spine are summarized in Table 14.6.[188,190–196] Of the exactly 1,400 cases of spinal radiosurgery presented in the published literature, there are only 12 reported instances of radiation-induced myelopathy, equaling a crude rate of 0.8%. Because the survival is generally short for most of these patients, this may be an underestimate of the true rate of injury. Given the small number of reported cases of myelopathy, as well as the variation in published dosimetric parameters, it is not feasible to construct a quantitative model for the risk of myelopathy as a function of cord dose in spinal radiosurgery. In fact, most of the cases of myelopathy involved cord doses well within the range of doses *not* associated with myelopathy, as discussed later.

Factors Affecting Risk

Animal studies suggest that the immature cord is somewhat more susceptible to radiation-induced complications and the time to manifestation of damage is shorter.[197–200] Though the literature on radiation-induced myelopathy in children is sparse, care should be exercised in irradiating a child's spine because of the increased sensitivity of the developing central nervous system and bone to ionizing radiation.[201] There are a handful of reports of myelopathy at relatively low radiation doses to the spine postchemotherapy.[202–205] Many chemotherapeutic agents are directly neurotoxic[206] and should be used with caution during irradiation of the central nervous system.[207]

Mathematic/Biologic Models

Schultheiss[171] calculated the risk of myelopathy as a function of dose using a probability distribution model, using the data for cervical and thoracic spinal cord myelopathy adjusted for estimated overall survival. A good fit to the combined cervical and thoracic cord data was not possible, and separate analyses were performed. For the cervical cord data, D_{50} = 69.4 Gy and α/β ratio = 0.87 Gy provided a reasonable fit of the data, as shown in Figure 14.5. The 95% confidence interval was 66.4 to 72.6 Gy for D_{50} and 0.54 to 1.19 Gy for α/β ratio. At 2 Gy per fraction, the calculated probability of myelopathy is 0.03% at a total dose of 45 Gy and 0.2% at 50 Gy. Because of the dispersion of the thoracic data, it was not possible to obtain a good fit to those data. As shown in Figure 14.5B, the data points for the thoracic cord generally lie to the right of the dose–response curve generated from the cervical cord. This suggests that the thoracic cord may be less radiation sensitive than the cervical cord.

At the high doses per fraction encountered in radiosurgery, the applicability of the linear-quadratic model is controversial, and the biologically equivalent doses presented in Table 14.6 should be used solely for making rough comparisons of the different dose regimens. In particular, data obtained at a low dose per fraction should not be extrapolated to regimens employing doses of 10 Gy or more per fraction.[166,208] Applying the Schultheiss model[171] to spinal radiosurgery appears to overestimate the risk of myelopathy. For example, using the α/β ratio of 0.87 Gy, the model yields an estimated risk of myelopathy of 0.8%, 13.6%, 50%, and 73% for 12, 13, 13.7, and 14 Gy, respectively, delivered in a single fraction. In contrast, Ryu et al.[189] found only one case of myelopathy in 86 patients treated with single-fraction spine radiosurgery at a mean cord D_{max} of 12.2 Gy (±2.5 Gy standard deviation) and no cases in the subset of 39 lesions prescribed 18 Gy and treated to a mean cord D_{max} of 13.8 Gy. Note that the Medin et al.[209] study of single-fraction irradiation of the swine spinal cord shows a steep dose–response curve with a median effective D_{max} of 20 Gy.

Special Situations

The need to reirradiate previously treated cord is often encountered in the setting of recurrent spine metastases following spinal irradiation or new spine lesions within, for example, a previously treated lung, pancreas, or esophageal field. In evaluating reirradiation of the spinal cord, the dose regimen for each course, the volume and region (re)irradiated, and the time interval between the courses of radiation therapy must be considered.[210] Animal studies support a time-dependent model of repair for radiation damage to the spinal cord.[197,211–215] For

example, Ang et al.[197] treated the thoracic and cervical spines of rhesus monkeys to 44 Gy and then reirradiated these animals with an additional 57 Gy at 1 to 2 years or 66 Gy at 2 to 3 years, yielding aggregate doses of 101 and 110 Gy, respectively. Of 45 animals evaluated, 4 developed myelopathy by the end of the observation period. The reirradiation tolerance model developed from these and similar data[211] estimates a recovery of 34 Gy (76%), 38 Gy (85%), and 45 Gy (101%) at 1, 2, and 3 years, respectively. Under conservative assumptions, an overall recovery of 26 Gy (61%) was calculated.

Table 14.7 summarizes published reports involving reirradiation of the spinal cord in humans using both conventional and full circumference external beam radiotherapy.[210,216–228] For purposes of comparing different regimens, an α/β ratio of 3 Gy was used to calculate the biologically equivalent dose in Gy_3. In all of these studies, the median interval between courses was at least 6 months, and only a small number of cases were treated at intervals <6 months. Note that few cases of myelopathy are reported despite large cumulative doses, with essentially no cases of myelopathy observed for cumulative doses <60 Gy in 2 Gy equivalent doses. These observations are consistent with the predictions of postradiotherapy repair observed in the animal models.

As discussed earlier, radiosurgery at a high dose per fraction is increasingly employed in the treatment of spinal lesions. Though reports of toxicity are rare, the follow-up time is short and patient numbers small. Prudence should be observed when prescribing the dose and every reasonable effort made to limit the dose to the cord by immobilization, image guidance, and attention to patient comfort. Estimates of toxicity based on conventional fractionation should not be applied to such treatments without further careful study.

Recommended Dose–Volume Limits

With conventional fractionation of 2 Gy/d including the full cord cross-section, total doses of 50 Gy, 60 Gy, and approximately 69 Gy are associated with a 0.2%, 6%, and 50% rate of myelopathy. The level of acceptable risk will depend on the clinical scenario; that is, a 5% risk of myelopathy may be acceptable in treatment of a primary spinal cord tumor but not in irradiation of a lung lesion. For reirradiation of the full cord cross-section at 2 Gy per daily fraction after prior conventionally fractionated treatment, cord tolerance appears to increase at least 25% 6 months after the initial course of RT. In spine radiosurgery, a maximum cord dose of 13 Gy in a single fraction or 20 Gy in three fractions appears associated with a <1% risk of myelopathy. In comparison, Sahgal et al.[229] recommend a *de novo* single-fraction maximum point dose to the thecal sac of 10 Gy to avoid myelopathy entirely, and RTOG protocol 0631 specifies a cord D_{10} and $D_{0.35\ mL}$ of 10 Gy and D_{max} of 14 Gy for the involved spine.

Future Studies

A model of dose/volume/outcome for spinal cord toxicity will require that more extensive and detailed data be collected over many years, including data on entire cohorts of patients treated with radiotherapy and radiosurgery, not just those with myelopathy. Extensive dosimetric parameters should be collected, specifically D_{max}, D_1, D_{10}, D_{50}, $D_{0.1\ mL}$, $D_{0.35\ mL}$, and $D_{1\ mL}$, and the volume of the involved segment of the spinal cord, as well as the prescribed total dose, dose per fraction, involved spinal level(s), portion of the vertebral body irradiated, irradiation technique, and patient characteristics/demographics. In addition, preclinical studies identifying the fundamental mechanisms of radiation-induced toxicity would be valuable.

Toxicity Scoring Criteria

Toxicity should be scored and reported using CTCAE v. 4.0.[92]

NECK

Larynx and Pharynx

Clinical Significance

Radiation therapy is often utilized as the primary treatment of early-stage laryngeal cancers in an effort to preserve speech and swallowing. However, radiation-induced progressive edema and associated fibrosis can lead to long-term problems with phonation and swallowing.[230] Irradiation of the pharynx and larynx, particularly in combination with concurrent chemotherapy, can produce severe dysphagia, compromising nutrition, protection of the airway, and quality of life.

End Points

The critical larynx-specific end points examined were laryngeal edema and vocal function.[231] Dysphagia, resulting from laryngeal and/or pharyngeal dysfunction, may be assessed by instrument-based swallowing studies,[232] by observer-based criteria (e.g., CTCAE v. 4.0[92]), or by patient-reported quality of life questionnaires.

Challenges Defining Volumes

Phonation and swallowing are complex processes involving multiple anatomic structures in close proximity to one another. The relative importance of various

normal tissue structures affecting vocal function and swallowing is controversial. In studying vocal dysfunction, doses to the epiglottis, base of tongue, lateral pharyngeal walls, preepiglottic space, aryepiglottic folds, false vocal cords, upper esophageal sphincter, and cricoid cartilage have been considered.[231,233,234] Radiation-induced dysphagia has been correlated with the dose to the pharyngeal constrictor muscles and specific points in the supraglottic and glottic larynx.[233,235–238] Precise identification of these structures for treatment planning requires a high-resolution, contrast-enhanced CT scan.

Dose/Volume/Toxicity Data

On multivariate analysis, Sanguineti et al.[234] found that the mean laryngeal dose or percentage of volume receiving >50 Gy and neck stage were the only independent predictors of grade 2 or greater laryngeal edema. Vocal function is usually well preserved after radiotherapy for stage T1 laryngeal cancer[231] (typically 60 to 66 Gy). Less information is available regarding voice quality after treatment of more locally advanced laryngeal cancers. However, Dornfeld et al.[233] found a strong correlation between speech quality and the doses delivered to the aryepiglottic folds, preepiglottic space, false vocal cords, and lateral pharyngeal walls at the level of the false vocal cords. In particular, a steep decrease in vocal function was observed when the dose to these structures exceeded 66 Gy.

In a prospective study using intensity-modulated radiotherapy to reduce dysphagia in patients undergoing chemoradiation, Feng et al.[236] observed a strong correlation between the mean doses and the dysphagia end points (Fig. 14.6). Aspiration was observed when the mean dose to the pharyngeal constrictors was >60 Gy and the dose–volume threshold for the pharyngeal constrictor volume receiving ≥40, ≥50, ≥60, and ≥65 Gy was 90%, 80%, 70%, and >50%, respectively. For aspiration to occur, the glottic/supraglottic larynx dose–volume threshold was >50% of volume receiving ≥50 Gy. In a retrospective study of conventional radiotherapy, Jensen et al.[237] found that doses <60 Gy to the supraglottic area, larynx, and upper esophageal sphincter were associated with a low risk of aspiration. Dornfeld et al.[233] found that swallowing difficulties increased progressively with radiation doses >50 Gy to the aryepiglottic folds, false vocal cords, and lateral pharyngeal walls near the false cord.

Levendag et al.[238] reported that a median dose of 50 Gy to the superior and middle pharyngeal constrictor muscles predicted a 20% probability of dysphagia

and that this increased significantly beyond a mean dose of 55 Gy. The $V_{60–65}$ and mean inferior pharyngeal constrictors were most predictive of gastrostomy tube dependence in one study,[239] whereas V_{50}[240] and mean dose[240,241] of the middle pharyngeal constrictors were most predictive of dysphagia in other studies. In an analysis of 96 patients from Dana-Farber, the inferior pharyngeal constrictor V_{50} and larynx V_{50} were significantly associated with aspiration and stricture risk.[242] MDACC recommends a $V_{55} < 80\%$ and $V_{65} < 30\%$ for superior pharyngeal constrictors,[243] whereas UAB recommends $V_{60} < 12\%$ to the inferior pharyngeal constrictors, $V_{65} < 75\%$ to the middle pharyngeal constrictors, and $V_{65} < 33\%$ to the superior pharyngeal constrictors.[244]

Factors Affecting Risk

The addition of concurrent chemotherapy to high-dose RT appears to at least double the risk of laryngeal edema and dysfunction.[231] Severe laryngeal dysfunction secondary to tumor will often persist following radiotherapy, and a laryngectomy may be preferred to chemoradiation in this setting.

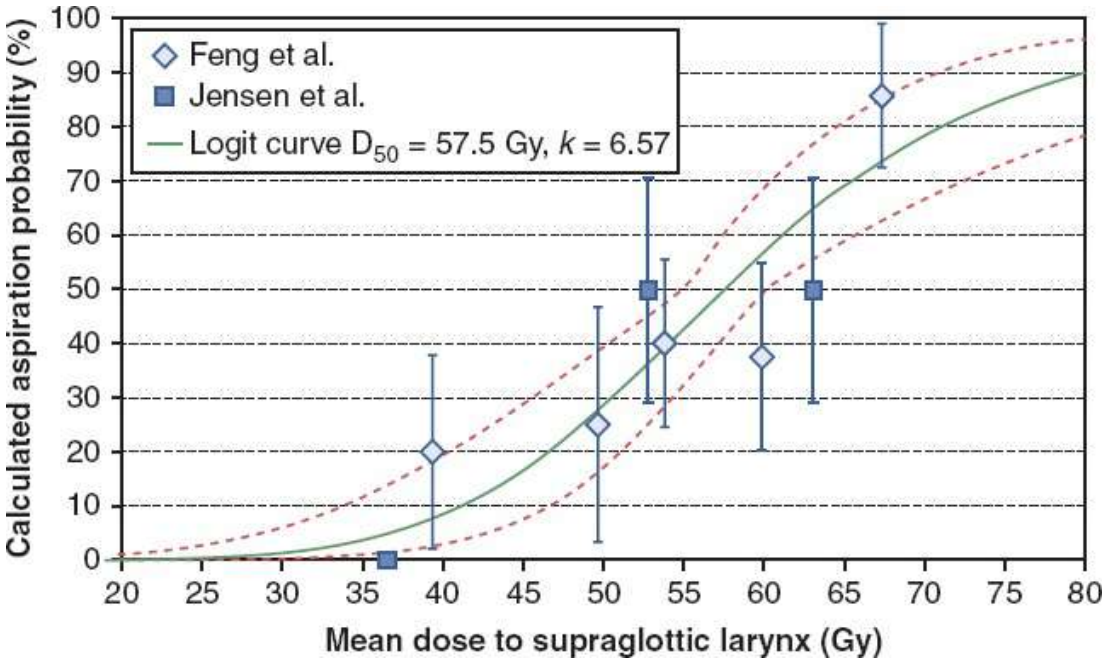

FIGURE 14.6. Probability of aspiration (proxy for dysphagia) versus larynx dose for selected studies.[236,237] *Solid line* fit of logit model to combined data; *dotted lines* represent 68% confidence area. (Reprinted from Rancati T, Schwarz M, Allen AM, et al. Radiation dose-volume effects in the larynx and pharynx. *Int J Radiat Oncol Biol Phys* 2010;76[3 Suppl]:S64–S69. Copyright © 2010 Elsevier. With permission.[69])

Mathematic/Biologic Models

Rancati et al.[245] fit dose–volume data for grade 2 to 3 laryngeal edema using the Lyman-Kutcher-Burman model and the logit model with the DVH reduced to the equivalent uniform dose (EUD). Both models fit the clinical data well. The best fit parameters for the Lyman-Kutcher-Burman model were $n = 0.45 \pm 0.28$, $m = 0.16 \pm 0.05$, and $TD_{50} = 46.3 \pm 1.8$ Gy. Based on these findings, the investigators suggested an EUD of <30 to 35 Gy to reduce the risk of grade 2 to 3 laryngeal edema. The Feng et al. study[236] suggests that a 50% NTCP is observed at mean doses of 50 to 60 Gy to the pharyngeal constrictors and the larynx (Fig. 14.6).

Special Situations

Pretherapy vocal and swallowing function should be considered when assessing the functional response to radiation therapy of the larynx and pharynx.[246]

Recommended Dose–Volume Limits

To minimize the risk of laryngeal edema, the QUANTEC authors recommend limiting the mean noninvolved larynx dose to 40 to 45 Gy and the maximal dose to <63 to 66 Gy, if possible, according to the tumor extent.[231] Minimizing the volume of the pharyngeal constrictors and larynx receiving >60 Gy and reducing, when possible, the volume receiving >50 Gy is associated with reduced dysphagia/aspiration.[231] Of course, the impact of any such dose reduction on tumor control must be considered, given the uncertainties in target delineation.

Future Studies and Toxicity Scoring Criteria

Prospective studies that include pretherapy assessments of vocal and swallowing function should be conducted to correlate observer-rated scores such as the CTCAE v. 4.0 system,[92] patient-reported quality scores, and objective swallowing.[231] Such studies should focus on patients receiving concurrent chemoradiation, as this population is at the greatest risk of laryngeal/pharyngeal toxicity. Although CTCAE-based scoring is simple and widely utilized, objective measurement by a speech pathologist is often necessary to quantify swallowing dysfunction following radiotherapy.

Salivary Glands

Clinical Significance

In radiotherapy of head and neck tumors, the parotid, submandibular, and minor salivary glands often receive substantial doses of radiation. Reduced salivary

production is a common toxicity and adversely affects the patient's quality of life. Inadequate salivary function leads to multiple problems, including poor dental hygiene, a propensity to oral infections, sleep disturbances, pain, and difficulty chewing and swallowing.[247] The majority of stimulated salivary production comes from the parotid glands, whereas resting (unstimulated) salivary production is due primarily to the submandibular, sublingual, and numerous small oral salivary glands.[248]

End Points

Xerostomia (dry mouth secondary to inadequate saliva production) can be assessed based on the patient's symptoms (altered taste or sensation of dryness) and/or quantitative saliva production.

Challenges Defining Volumes

Parotid and submandibular salivary glands can be adequately delineated on contrast-enhanced CT scans. However, during irradiation, parotid glands typically shrink during RT, potentially resulting in decreased gland sparing. For example, Robar et al.[249] found that while the medial position of the parotid gland was stable over a course of radiation therapy, the lateral borders shrank approximately 1 mm/wk, yielding total displacements of 4 to 6 mm.

Dose/Volume/Toxicity Data

A variety of dose–volume parameters have been correlated with salivary end points, including subjective xerostomia and objective stimulated/unstimulated salivary flow. In particular, mean parotid gland dose[249–252] appears associated with whole-mouth or individual gland salivary production. Table 14.8 summarizes the reported dose–volume predictors for salivary flow, the incidence of complications, and salivary function recovery. Minimal reduction in flow is observed at mean doses <10 to 15 Gy, decreases gradually over the range of 20 to 40 Gy, and is markedly reduced above 40 Gy.[250,254] The risk of xerostomia is reduced when at least one parotid gland or submandibular gland is spared.[255] In the study by Portaluri et al.,[256] patients receiving <30 Gy to the contralateral parotid reported either no or mild subjective xerostomia.

Some recovery of salivary function occurs over time, with the dose required to obtain an equivalent reduction in salivary flow increasing at longer follow-up times (Fig. 14.7).[252,255,257–260] The whole-mouth or ipsilateral salivary measurement-based tissue dose required for a 50% response (TD_{50}) tends to be

lower than the scintigraphy-based TD_{50}, yielding a higher TD_{50} compared with those derived from salivary flow data. The wide variation in the reported TD_{50} values may be the result of several factors, including variations in dose distributions, salivary measurement methods, segmentation, and inherent tissue sensitivity.

TABLE 14.8 DOSIMETRIC PREDICTORS OF XEROSTOMIA

Reference	Patients (*n*)/Follow-Up	Total Prescribed Target Dose (Gy)[a]	Dose–Volume Parameters	
			Unstimulated	Stimulated
Eisbruch et al.[253]	88/1–12 mo	58–72	Mean dose ≤ 22–25 Gy[b] V_{15} < 66% V_{30} < 43% V_{45} < 26%	Mean dose ≤ 25–26 Gy[c] V_{15} < 67% V_{30} < 45% V_{45} < 24%

[d]Corresponds to probability of 70% that loss of salivary excretion fraction was <50%.
V_x, percentage of gland volume receiving >*x* Gy.

Factors Affecting Risk

Patient factors (e.g., gender and age) and the use of chemotherapy have typically not correlated with xerostomia risk. However, pretreatment salivary function and medications affecting salivary function can influence the risk of xerostomia.[247]

Mathematic/Biologic Models

As noted earlier, there is a wide variation in the observed dose/volume/toxicity relationship, depending on the patient population, treatment technique, and end point selected. Thus, models predicting the risk of xerostomia as a function of dose–volume parameters have yielded a broad range of parameters.[247,250,254,259,262,263] Because the glands seem to respond

independently to irradiation, the function of the parotid glands should be modeled separately. NTCP modeling of 178 patients treated with IMRT showed that baseline salivary function and mean contralateral parotid gland dose were predictors for xerostomia and that mean contralateral submandibular gland dose, mean sublingual dose, and mean dose to minor salivary glands in the soft palate were predictive for sticky saliva.[264,265]

Attempts to predict the effect of fraction size on toxicity using the linear-quadratic model have returned low to high α/β ratios, perhaps because the different end points examined represent acute versus late effects.[247]

Special Situations

Submandibular gland sparing appears to reduce the risk of both stimulated and unstimulated xerostomia.[255] A Finnish study found that mean unstimulated salivary flow was 60% of the pretreatment function among patients who had one submandibular gland spared versus 25% in those who did not (P = .006),[266] whereas a study from Shanghai showed that intentional sparing of submandibular glands (average mean dose of 20.4 Gy and V_{30} of 14.7%) versus no submandibular gland sparing (average mean dose 57.4 Gy), resulted in a nonsignificant trend toward better recovery of salivary flow.[267]

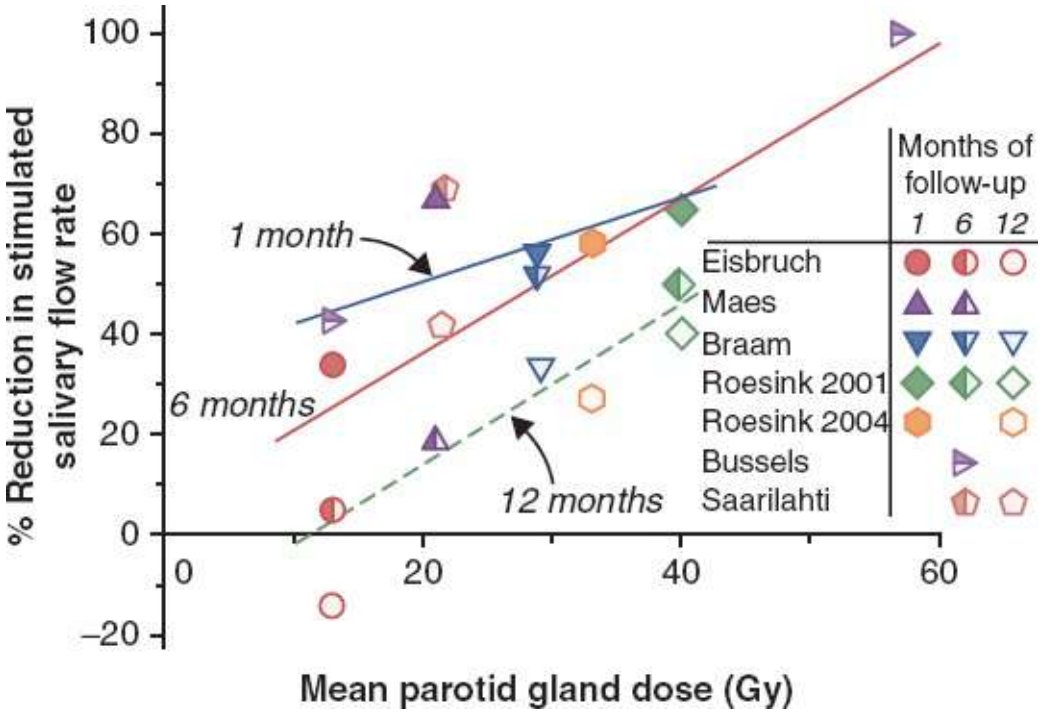

FIGURE 14.7. Mean percentage of reduction in stimulated salivary flow rate versus mean parotid gland dose for selected studies[252,255,257–261] using different follow-up

durations. Nominal follow-up intervals of 1, 6, and 12 months represent ranges of 1 to 1.5, 6 to 7, and 12 months, respectively. *Lines* represent least-squares fit of data for each nominal follow-up interval. (Reprinted from Deasy JO, Moiseenko V, Marks LB, et al. Radiotherapy dose-volume effects on salivary gland function. *Int J Radiat Oncol Biol Phys* 2010;76[3 Suppl]:S58–S63. Copyright © 2010 Elsevier. With permission.)

The mean dose to the oral cavity (which contains minor salivary glands) has also been found to be an independent risk factor in some studies[261,268] but not others,[269] probably because of differences in technique. Although quantitative data are admittedly sparse, amifostine has been shown to increase the functional tolerance of the parotid and submandibular glands to therapeutic radiation.[270] Much of the existing data is derived from patients with oropharyngeal cancers being treated to ≈70 Gy. With the increasing incidence of HPV-associated oropharynx cancers, which appear to be more sensitive to therapy, lower doses of radiation (e.g., 60 Gy) are sometimes being used. Because the dosimetric parameters such as mean dose and V_x are likely surrogates for more complex 3D dose/volume distributions within the glands, the appropriate dose/volume constraints in the setting of a prescribed dose of 70 Gy may or may not be appropriate in the setting of a prescribed dose of 60 Gy.[271]

Recommended Dose–Volume Limits

Severe xerostomia (long-term salivary function <25% of baseline) can usually be avoided if at least one parotid gland receives a mean dose of less than about 20 Gy or if both glands receive a mean dose of less than approximately 25 Gy.[272,273] In patients with head and neck cancer treated with IMRT, the mean dose to each parotid gland should be kept as low as possible, taking into account the desired target coverage. Similarly, keeping the dose to the submandibular glands to modest levels (<35 Gy) may reduce the severity of xerostomia.[247]

Future Studies

Key questions on radiation-induced salivary gland dysfunction and xerostomia include the following:

- Does partially sparing the submandibular glands or salivary minor glands have a positive impact on quality of life (QOL)?
- Is the (arbitrary) 25% salivary threshold the best quantitative measure with respect to QOL?
- Should parotid gland shrinkage during RT explicitly be accounted for in functional predictions?
- How should submandibular sparing be incorporated into predictive salivary

function models?
- How does oral cavity sparing quantitatively affect xerostomia?
- Does the radioprotector amifostine provide a clinically significant benefit for whole-mouth salivary function?
- How does the use of lower tumor target doses (as are being increasingly suggested in patients with HPV-associated cancers) impact the dose/volume limits?

Toxicity Scoring Criteria

The QUANTEC authors recommend that an observer-based system (e.g., CTCAE v. 4.0) be supplemented by a validated quality of life instrument (e.g., the xerostomia questionnaire[261]) and/or quantitative salivary measurements.

CHEST

Lung

Clinical Significance

The lung's primary function is the exchange of oxygen for carbon dioxide. Radiation-associated lung injury is one of the most common side effects seen in clinical oncology, and its risk limits the dose of radiation that can be used for treatment of thoracic tumors.

End Points

Radiation damage to the lung can result in symptomatic pneumonitis and fibrosis. Symptomatic radiation pneumonitis is characterized by dyspnea, cough, and occasionally a low-grade fever, typically occurring several weeks to months after radiation. Long-term lung fibrosis can lead to respiratory insufficiency. It is often challenging to distinguish radiation-related pulmonary symptoms from comorbid illnesses (e.g., exacerbation of chronic obstructive pulmonary disease, infection, cardiac events).[274] Objective reductions in the lungs' ability to move and exchange gas can be measured by formal pulmonary function tests (PFTs). The various end points shown in Table 14.9 are arbitrarily segregated by their manifestation (clinical vs. subclinical) and whether they reflect regional or global lung function.

Challenges Defining Volumes

Because the lungs move and their volume changes with respiration, there are inherent inaccuracies when defining the lung volume. As the mass of the lung is

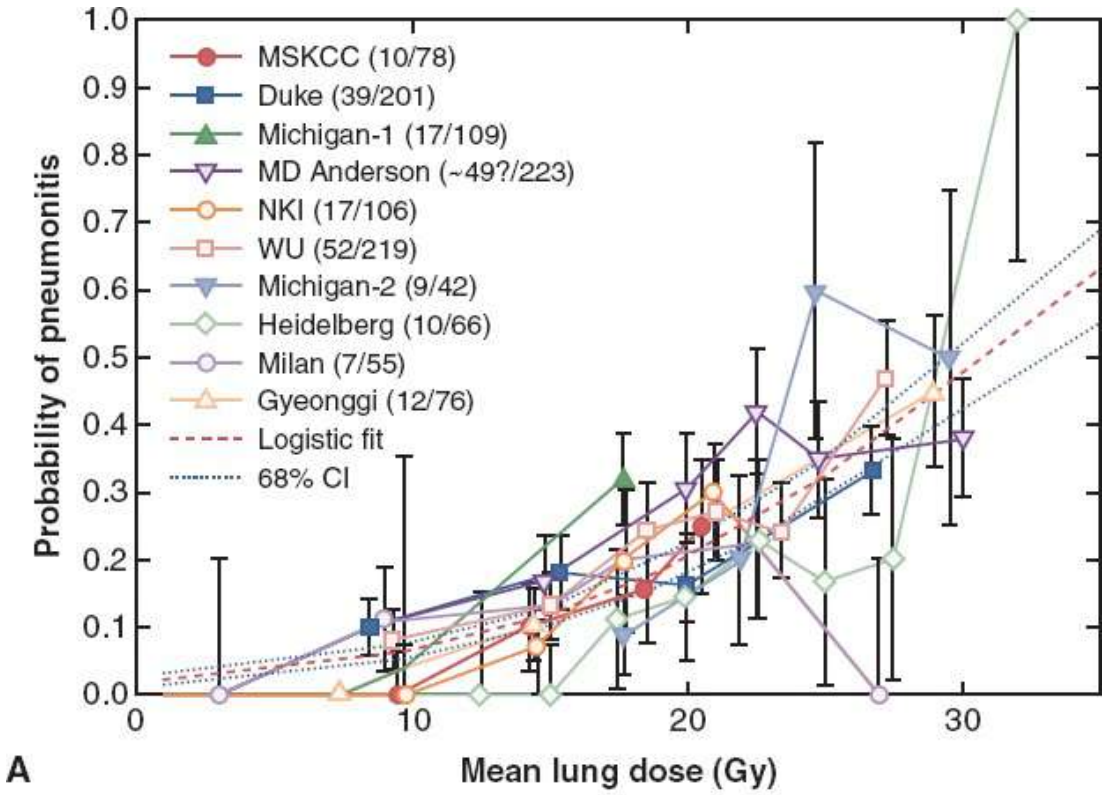
relatively constant during respiration and its density must decline with increased lung volumes, one could consider using dose–mass histograms rather than DVHs. To our knowledge, this approach has not been widely applied. Because of this variation in volumes with respiration, it is very likely that the dose/volume/outcome data are dependent on the type (if any) of respiratory control. The vast majority of dose/volume/outcome data are derived from free-breathing scans/treatment. These may not apply to patients being treated under, for example, breath hold techniques. Further, there are uncertainties in defining the lung borders in the vicinity of the central airways. Variable inclusion of the conducting airways in the "defined lung" can influence interpatient/institutional comparisons.

TABLE 14.9 END POINTS FOR RADIATION-INDUCED LUNG INJURY

	Geographic Distribution	
Manifestation	**Regional**	**Global**
Clinical	Symptomatic bronchial stenosis	Respiratory symptoms (dyspnea, cough)
Subclinical	Radiologic abnormalities (computed tomography, perfusion/ventilation scans)	Pulmonary function tests, exercise testing results

Dose/Volume/Toxicity Data

Several parameters have been shown to be associated with the risk of radiation pneumonitis, including V_5 to V_{70}, mean lung dose (MLD), and model-based parameters.[9,275] These dosimetric parameters are mutually correlated, accounting for the fact that in most studies examining a range of V_x's, many appear statistically significant.[276–291] Figure 14.8 summarizes the studies discussed here.



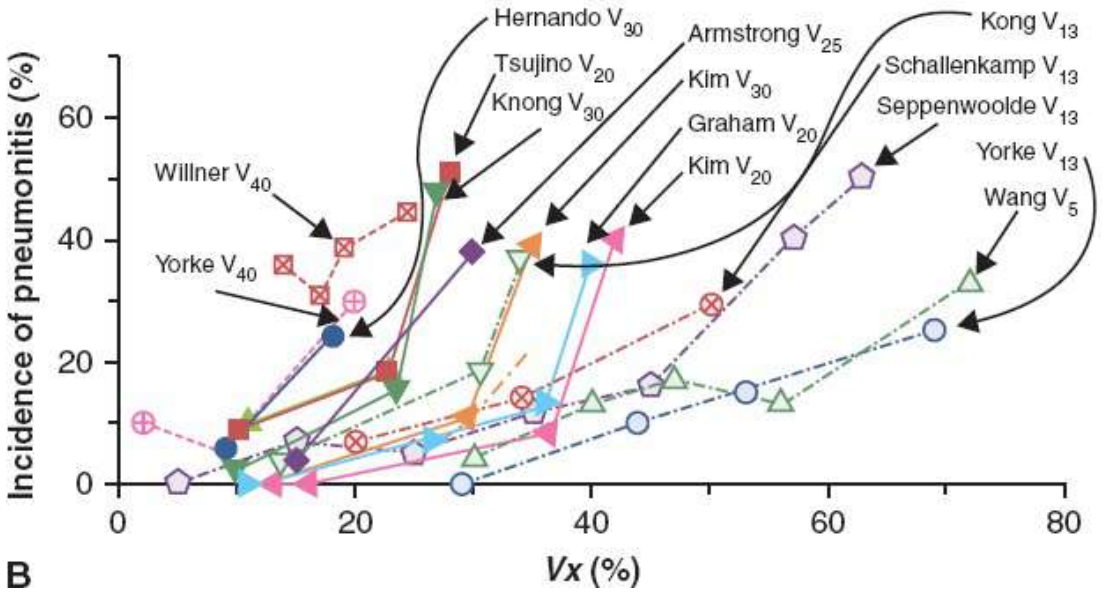


FIGURE 14.8. The rate of radiation pneumonitis after fractionated partial lung radiotherapy as a function of **(A)** mean lung dose (MLD) and **(B)** lung volume receiving *x* Gy (V_x). **A:** MLD: Confidence intervals (*bars*) represent ± 1 standard deviation. Results from Memorial Sloan-Kettering Cancer Center (MSKCC),[290] Radiation Therapy Oncology Group (RTOG) grade 3 or higher pulmonary toxicity at 6 months; Duke,[279] Common Terminology Criteria for Adverse Events (CTCAE) grade 1 or higher at 6 months; Michigan,[292] Southwest Oncology Group (SWOG) grade 2 or

higher at 6 months; M.D. Anderson Cancer Center,[287] CTCAE grade 3 or higher, 1 year actuarial—includes concurrent chemotherapy patients; Netherlands Cancer Institute (NKI),[293] SWOG grade 2 or higher at 6 months; Washington University (WU),[280] SWOG grade 2 or higher; Michigan,[294] SWOG grade 1 or higher; Heidelberg,[295] RTOG acute grade 1 or higher; Milan,[296] SWOG grade 2 or higher, no time limit, patients without chronic obstructive pulmonary disease, includes induction chemotherapy patients; Gyeonggi,[281] RTOG grade 3 or higher at 6 months, includes concurrent chemotherapy patients. Dashed line is best fit of these data fit to the logistic expression of the form [$f/(1 + f)$], where $f = \exp(b0 + b1 * MLD)$. Best fit values (95% confidence intervals) are b0 = −3.87 (−3.33, −4.49) and b1 = 0.126 (0.100, 0.153), corresponding to TD_{50} = 30.75 (28.7, 33.9) Gy and γ_{50} = 0.969 (0.833, 1.122), where γ_{50} represents the increase in response (measured as percentage) per 1% increase in dose around the 50% dose–response level. **B:** V_x: Data from Yorke,[290] Willner,[288] Hernando,[279] Tsujino,[298] Kong,[292] Armstrong,[299] Kim,[281] Graham,[275] Seppenwoolde,[285] Wang,[287] and Schallenkamp.[284] Some of the above data were modified or derived from the original publications, as described in Marks et al.[300] (Reprinted from Marks LB, Bentzen SM, Deasy JO, et al. Radiation dose-volume effects in the lung. *Int J Radiat Oncol Biol Phys* 2010;76[3 Suppl]:S70–S76. Copyright © 2010 Elsevier. With permission.)

A NTCP analysis from the Netherlands, in collaboration with the University of Michigan, suggests that using the MLD (linear function) is more predictive than using V_x (step function).[285] However, V_{13} tended to be more predictive in situations where the MLD exceeded 20 Gy or V_{13} exceeded 50%. The TD_{50} values in this study were an MLD of 30.8 Gy, $V_{13} > 77\%$, and $V_{20} > 65\%$, similar to the MLD of 31.8 Gy reported in an earlier multi-institutional study.[282] From a study at the Memorial Sloan-Kettering Cancer Center (MSKCC),[291] a MLD of approximately 26 Gy, V_{13} of >80% to the ipsilateral lung, or V_{40} of >32% to the lower lung results in a 50% risk of developing late complications. A MLD of approximately 12 Gy or a V_{13} of >40% to the ipsilateral lung results in a 5% late complication risk. A V_{13} of 36% to the lower lung, 42% to the total lung, or 62% to the ipsilateral lung results in a 20% risk of developing late grade 3 or higher complications.

Another study from MSKCC of patients treated with radiation alone reported a significantly increased risk of grade 3 or higher pulmonary toxicity, 38% for $V_{25} > 30\%$ versus 4% for $V_{25} < 30\%$ ($P = .04$).[276] In subsequent studies from this same group, significant variables for predicting grade 3 or higher pulmonary toxicity include MLD, the range of V_5 to V_{40} of total lung, V_5 to V_{40} of ipsilateral lung, and V_5 to V_{50} of lower lung.[290,291] The range of V_5 to V_{20} ipsilateral lung was most predictive.

Washington University was another of the early investigators to show that the

risk of pneumonitis significantly correlates with the V_{20}; the 2-year incidence of grade 2 or higher radiation pneumonitis was 36%, 13%, 7%, and 0% with a V_{20} of >40%, 32% to 40%, 22% to 31%, and <22% (P = .0013), respectively.[275] In another study by Washington University, radiation pneumonitis was significantly correlated with V_5 to V_{80}, with peak significance in the V_5 to V_{15} and V_{70} to V_{75} ranges; radiation pneumonitis was also significantly correlated with the dose delivered to 5% to 100% of the lung (D_5 to D_{100}), with peak significance in the D_{30} to D_{40} and V_{90} to V_{95} ranges.[280]

A study from Duke, in which 18% of patients received concurrent chemoradiotherapy, found that a V_{30} of >18% versus <18% was associated with a risk of grade 1 or higher radiation pneumonitis of 24 versus 6% (P = .0003).[279] MLDs of <10, 10 to 20, 21 to 30, and >30 Gy were associated with risks of 10%, 16%, 27%, and 44%, respectively. A Japanese study of patients treated with platinum-based chemoradiotherapy found a 6-month risk of grade 2 or higher radiation pneumonitis to be 85%, 51%, 18.3%, and 8.7% (P < .0001) with a V_{20} of ≥31%, 26% to 30%, 21% to 25%, and ≤20%, respectively.[298] In a University of Michigan study, a 10% risk for grade 2 or higher pneumonitis and fibrosis was associated with a V_{20} of >30% and an MLD of >20 Gy. These thresholds provided a positive predictive value of 50% to 71% and a negative predictive value of 85% to 89%.[292] In a study from M.D. Anderson Cancer Center (MDACC), the MLD and V_5 to V_{65} were highly correlated with risk of pneumonitis, and V_5 was the most significant factor in a multivariate analysis.[287] For a $V_5 \leq 42\%$ versus >42%, the risk of grade 3 or higher pneumonitis at 1 year was 3% versus 38% (P = .001). In a Mayo Clinic study, V_{10} to V_{13} was most predictive of radiation pneumonitis; a V_{10} = 32% to 43%, V_{13} = 29% to 39%, V_{15} = 27% to 34%, and V_{20} = 21% to 31% resulted in a 10% to 20% risk of pneumonitis.

Several dose escalation studies have used V_{20}, V_{eff}, and/or NTCP to stratify the risk of toxicity as a function of dose.[301–304] In the RTOG 9311 dose escalation study,[301] patients with a V_{20} of <25% experienced a 7% to 16% 18-month actuarial rate of grade 3 or higher late lung toxicity with prescribed doses of 70.9 to 90.3 Gy; the absolute risk of grade 2 or higher late lung toxicity was 30% to 45%, with one fatal lung complication at the 90.3 Gy dose level. Patients with a V_{20} of 25% to 36% treated to doses of 70.9 to 77.4 Gy experienced 15% grade 3 or higher late toxicity at 18 months and a 40% to 60% risk of grade 2 or

higher late lung toxicity. D_{15} was the most predictive variable for radiation pneumonitis.[277]

Factors Affecting Risk

Recent meta-analyses have shown that patient-related adverse risk factors for radiation pneumonitis among NSCLC[305–307] and breast cancer[308] patients include older age,[305,306] history of chronic lung disease, or diabetes.[307] Smoking was an adverse risk factor in one meta-analysis,[307] whereas not being an active or prior smoker[305] was an adverse risk factor in another, a discrepancy that is attributed to the complexity of the relationship between smoking, chronic lung disease, and pneumonitis.[307] Chemotherapy concurrent with radiation therapy,[307] particularly carboplatin/paclitaxel chemotherapy,[306] has been reported to increase the pneumonitis risk.

The effect of dose to regions of the lung was investigated in a Dutch study,[293] dividing the lung into central and peripheral, ipsilateral and contralateral, caudal and cranial, and anterior and posterior subvolumes. The mean regional doses to the posterior, caudal, ipsilateral, central, and peripheral lung subvolumes were significantly correlated with the incidence of steroid-requiring radiation pneumonitis. In a similar study from MSKCC, the risk of radiation pneumonitis was better correlated with the radiation dose to the inferior, as opposed to the superior, aspect of the lung.[291]

Tumor location within the chest may also be a factor affecting risk of pneumonitis. In the study from Washington University,[280] inferior tumor location was the most significant predictor of radiation pneumonitis. Tumor location was not a strong correlate with radiation pneumonitis in RTOG 9311, perhaps attributable, in part, to differences in treatment (with RTOG 9311 treating smaller volumes to higher doses) and differences in tumor size and location (the RTOG 9311 tumors tended to be smaller and more superiorly located).[277] Using a combined dataset of patients from RTOG 9311 and Washington University, tumor location and MLD were significant predictors of toxicity.

Mathematic/Biologic Models

Most of the aforementioned studies used NTCP models to fit the toxicity data. In the QUANTEC analysis,[300] a fit of the data for radiation pneumonitis as a function of MLD to the logistic expression (see Fig. 14.7) yields a predicted TD_{50} = 30.8 Gy (95% confidence interval [CI], 28.7 to 33.9 Gy) and γ_{50} = 0.97 (0.83 to 1.12). The latter parameter represents the percent increase in radiation

increase in response per 1% increase in dose at the 50% dose–response level. A fit using the probit response function (equivalent to a fit of the Lyman model with $n = 1$) yields $TD_{50} = 31.4$ Gy (95% CI, 29.0 to 34.7 Gy) and $m = 0.45$ (0.39 to 0.51), with the result essentially identical to that of the logistic fit in the region occupied by the data.

Special Situations

IMRT provides unique dose distributions for some patients with advanced-stage non–small cell lung cancer,[309] potentially reducing the risk of normal tissue injury. Investigators at MDACC compared rates of lung toxicity in their patients treated with IMRT versus 3D planning and noted a reduction in toxicity with the use of IMRT.[310] A $V_5 > 70\%$ was associated with a 21% risk of grade 3 or higher pneumonitis versus a 2% risk with $V_5 \leq 70\%$ ($P = .017$). Similarly, a study from MSKCC found a low rate of clinical lung injury in patients with non–small cell cancer treated with IMRT.[311]

In a study from Dana-Farber,[312] in which patients received thoracic IMRT after pneumonectomy for mesothelioma, 6 of 13 patients developed fatal pneumonitis. The median V_{20}, V_5, and MLD for patients who developed pneumonitis was 17.6%, 98.6%, and 15.2 Gy, respectively, versus 10.9%, 90%, and 12.9 Gy for those who did not develop pneumonitis. Although these differences were not significant, the severity of the toxicities suggests caution in treating patients to large volumes after a pneumonectomy. In a study from Duke,[313] 1 of 13 patients treated with IMRT for mesothelioma died from pneumonitis, and two others developed symptomatic pneumonitis. The median V_{20}, V_5, and MLD for patients developing pneumonitis were 2.3%, 92%, and 7.9 Gy, respectively, versus 0.2%, 66%, and 7.5 Gy for those who did not develop pneumonitis and 6.9%, 92%, and 11.4 Gy for the patient who developed fatal pneumonitis. In a study of mesothelioma patients treated at MDACC,[314] 6 of 63 died from pulmonary-related causes (including two patients with fatal pneumonitis). The V_{20} was significant on univariate and multivariate analyses ($P = .017$), with $V_{20} > 7\%$ corresponding to a 42-fold increase in the risk of pulmonary death.

Stereotactic body radiotherapy (SBRT) generally involves a few large fractions (e.g., three 18-Gy or five 10-Gy fractions) given over 5 to 20 days.[315–317] Typically, the high-dose volumes in SBRT are small and dose gradients steep, minimizing dose to surrounding critical structures. However,

because multiple beams are used, large volumes of lung receive low to medium doses.[317] Consequently, the dose–volume characteristics of lung SBRT are quite different from those of conventional RT and deserve special consideration. Radiation pneumonitis is relatively uncommon after SBRT, usually <10%[316,318,319] but as high as 25% in one study.[320] Bronchial injury/stenosis, an unusual complication with conventional dose fractionation,[321] has been associated with SBRT to perihilar/central tumors.[316]

A recent review from Zhao et al.[322] suggests that the risk of RT-associated lung injury was <10% to 15% after lung SBRT with a MLD of the combined lungs <8 Gy, and the percent of total lung volume receiving more than 20 Gy (V_{20}) <10% to 15%. Patients with interstitial lung disease appear to be especially susceptible to severe radiation-associated lung toxicity.

Recommended Dose–Volume Limits

Individual studies note a dose–response relationship for radiation pneumonitis based on a variety of metrics. However, the QUANTEC analysis[300] of the pooled data shows that there is no specific threshold for pneumonitis, with risks increasing gradually as dose increases. Because many dose–volume parameters of the lung (i.e., V_5 through V_{30}, MLD) are correlated with each other, there likely is not an "optimal" parameter. For patients with non–small cell lung cancer, it is prudent to limit the V_{20} to <30% to 35%, and the MLD to <20 to 23 Gy, in order to reduce the risk of pneumonitis to <20%. In patients irradiated after pneumonectomy for mesothelioma, it is prudent to limit the V_5 to below 60%, V_{20} to <4% to 10%, and the MLD to <8 Gy.

Future Studies

Radiation-induced pneumonitis appears more commonly in patients with lower versus upper lobe tumors and may be better correlated with radiation doses to the lower versus upper lung. The cause of this correlation is presently unknown and requires further investigation, though it may be related to heart irradiation. Additional work is needed to better understand the impact of clinical factors (e.g., preradiotherapy functional status, tobacco use) and systemic agents (e.g., chemotherapy) on the risk of lung injury. Studies aimed at determining and exploiting the ability of biomarkers such as TGF-β (measured before and/or during lung radiotherapy) on radiation pneumonitis would be valuable.

Toxicity Scoring Criteria

The LENT–SOMA system should be used for scoring toxicity as it explicitly captures symptomatic, functional, and radiographic end points. A global score can be generated, but the granular data should be recorded and maintained.

Heart

Clinical Significance

The heart is a muscular organ typically located in the left hemithorax, which, via continuous rhythmic contraction, pumps blood throughout the blood vessels. The functional and structural complexity of the heart places it at risk for a spectrum of radiation and chemotherapy injuries that can manifest months to years following therapy.[323]

End Points

All components of the heart and pericardium are susceptible to radiation damage. Radiation-induced cardiac injury includes pericarditis, congestive heart failure, restrictive cardiomyopathy, valvular insufficiency and stenosis, coronary artery disease, ischemia, and infarction.

Challenges Defining Volumes

The substructures of the heart, as well as the intersection/border of the heart, great vessels, liver, diaphragm, and stomach, can be challenging to delineate on CT imaging. The heart moves during the respiratory and cardiac cycles, with different regions moving to different degrees. The uncertainties that accompany these anatomic/physiologic realities must be considered when contouring targets and normal tissue structures and when interpreting DVHs.

Dose/Volume/Toxicity Data

Multiple studies show an increased risk of cardiac morbidity following left-sided versus right-sided thoracic radiation in patients undergoing treatment for breast cancer. It is generally recognized that reducing the dose prescribed to the mediastinum and reducing the volume of heart in the radiation field reduce the risk of late toxicity.[324–326] Recent studies from Duke demonstrated that an increased percentage of the left ventricle irradiated correlates with a greater risk of cardiac perfusion defects.[327–329] Even over the range of low-dose exposure (~8 to 20 Gy) to small volumes of the cardiac apex, an increased risk of heart disease has been reported.[330]

A study from Stockholm used NTCP modeling to predict the risk of late heart toxicity in women treated for breast cancer.[331] The models predicted a TD_{50} of

52 Gy for dose to the myocardium. A 5% risk of excess cardiac mortality at 15 years was associated with a myocardial dose of approximately 30 Gy, V_{33} > 60%, V_{38} > 33%, *or* V_{42} > 20%. Calculations using the whole-heart volume (as opposed to myocardium) yielded equivalent results.

The same group from Stockholm used a similar analysis to assess cardiac risk in Hodgkin disease patients.[332] Patients were stratified based on a V_{38} > 35% versus <35%. The excess mortality risk at 15 years was 7.9% and 4.7%, respectively. The TD_{50} was calculated to be 70 Gy. Heart doses of 42 and 53 Gy resulted in a 5% and 10% risk of cardiac complications, respectively. The corresponding values in the breast cancer patients were 37 and 44 Gy, respectively (lower threshold doses and steeper gradient). The differences in complication probabilities and TD_{50} between the breast cancer and Hodgkin disease cohorts (Fig. 14.9) suggest that radiation exposure to different portions of the heart results in differences in cardiac risk, though there may be other confounding variables (i.e., patient age at treatment, overlapping breast cancer, cardiac disease risk factors, etc.).

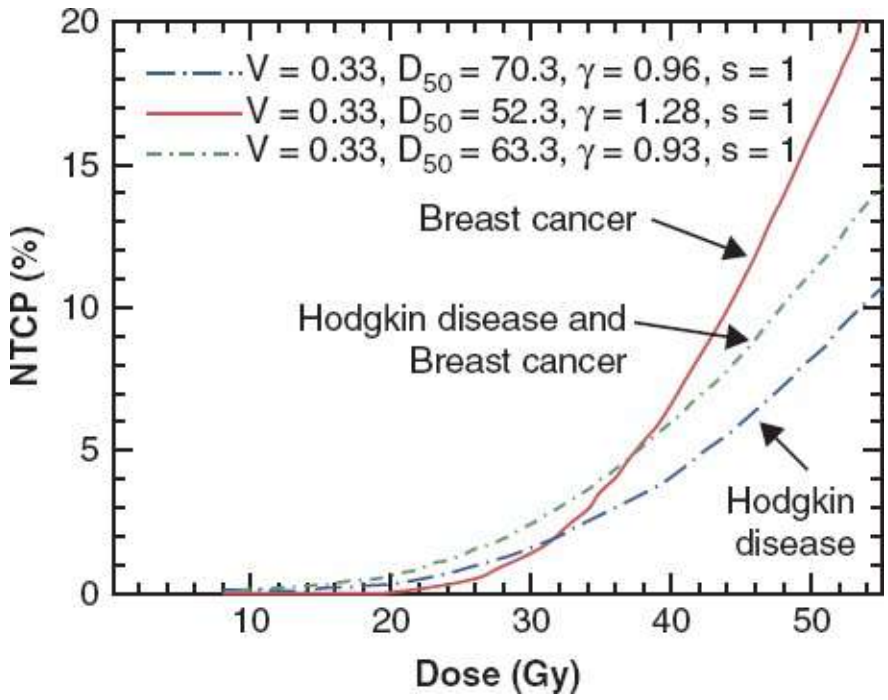

FIGURE 14.9. Dose–response curves for long-term cardiac mortality in patients with Hodgkin disease (HD) and breast cancer treated with thoracic radiotherapy. NTCP = normal tissue complication probability, defined in that study as the excessive risk of ischemic heart disease. *Curves* were obtained by fitting data from breast cancer trials, a cohort of patients with Hodgkin disease, and the combined dataset. *Plotted curves* correspond to uniform irradiation of one-third of the heart volume. (Reprinted from

Eriksson F, Gagliardi G, Liedberg A, et al. Long-term cardiac mortality following radiation therapy for Hodgkin's disease: analysis with the relative seriality model. *Radiother Oncol* 2000;55[2]:153–162. Copyright © 2000 Elsevier Science Ireland Ltd. With permission.)

A study from MDACC described the risk of pericardial effusions in patients treated for esophageal cancer.[333] A mean dose >26 Gy and relative volumes of the pericardium treated at doses >3 to 50 Gy (V_3 to V_{50}) showed the greatest risk, with the association strongest at V_{30}. For V_{30} < 46% versus >46%, the rate of pericardial effusion was 73% versus 13% (P = .001) 18 months postradiation. For a mean pericardium dose <26 versus >26 Gy, the rate of pericardial effusion was 73% versus 13% (P = .001). A study from the University of Michigan[334] also demonstrated that a mean dose >27 Gy and a maximum dose of 47 Gy correlated with risk of pericardial effusion. However, only patients treated with 3.5-Gy fractions developed pericardial effusions.

The incidence of valvular disease has been related to mediastinal radiation doses >30 Gy and younger age at irradiation.[335] Subclinical valvular disease has been detected at 2 to 20+ years postradiation, but it appears to take much longer for clinical symptoms to become apparent (median interval 22 years from radiation to symptoms). For patients treated for Hodgkin lymphoma more than 10 years prior with radiation, aortic disease, usually consisting of mixed stenosis and regurgitation, is more common than mitral and right-sided valvular disease.[335,336]

Factors Affecting Risk and Special Situations

Anthracycline chemotherapy can exacerbate radiation-elated cardiac toxicity. In Hodgkin disease patients, radiation exposure, in conjunction with anthracyclines, may impair ejection fraction and increase risk of myocardial infarction, congestive heart failure, and valvular disorders. A Dutch study[337] of 1,474 Hodgkin lymphoma survivors showed that risks of myocardial infarction and congestive heart failure were significantly increased, with standard incidence ratios of 3.6 and 4.9, respectively, for these survivors versus the general population. Mediastinal radiation alone increases the risks of myocardial infarction, angina pectoris, congestive heart failure, and valvular disorders (two- to sevenfold). The addition of anthracyclines further elevated the risks of congestive heart failure and valvular disorders, with hazard ratios of 2.81 and 2.10, respectively. The 25-year cumulative incidence of congestive heart failure following combined radiation and anthracycline chemotherapy was 7.9%.

Other risk factors for cardiac disease, particularly coronary artery disease, also must be considered. For example, a University of Rochester study[338] assessed the risk of coronary artery disease in survivors of Hodgkin lymphoma and also the prevalence of cardiac risk factors. The relative risk of cardiac death was 3.1 for males versus 1.8 for females. Other risk factors were more common than in the general population; among patients with Hodgkin lymphoma experiencing morbid cardiac events, 72% smoked, 72% were male, 78% had hypercholesterolemia, 61% were obese, 28% had a positive family history, 33% had hypertension, and 6% had diabetes.

Evolving data from patients irradiated for breast or lung cancer suggest that RT-associated cardiac injury may occur earlier than previously believed (i.e., within a few years of RT).[339–342] For example, in patients with non–small cell lung cancer prescribed to receive >70 Gy, the mean heart dose and preexisting cardiac disease have been implicated as predictors for cardiac injury[342]; the 2-year competing risk–adjusted cardiac event rates for patients with heart mean doses <10 Gy, 10 to 20 Gy, or ≥20 Gy were 4%, 7%, and 21%, respectively.

Mathematic/Biologic Models

There are no well-accepted models for cardiac toxicities. Nevertheless, several authors have computed model parameters for various cardiac end points, as summarized in the QUANTEC review.[323]

Recommended Dose–Volume Limits

A heart V_{30} to V_{40} of approximately 30% to 35% is associated with an approximately 5% excess risk of cardiac death at approximately 15 years. A heart V_{30} of >45% and a mean cardiac dose of >26 Gy are associated with a higher risk of pericarditis. In patients with breast and lung cancer, it is recommended that the irradiated heart volume be minimized as much as possible without compromising target coverage. In patients with lymphoma, the whole heart should be limited to 30 Gy if treated with radiation alone and to 15 Gy for patients also receiving anthracycline chemotherapy. Although there is no direct evidence that eliminating traditional cardiac risk factors alters the natural history of radiation-associated cardiac disease, it seems prudent to minimize such factors.[323,343,344]

Future Studies

Issues that would benefit from further systematic study are the effects of

radiation on specific subvolumes of the heart, the impact of modern radiotherapy techniques on cardiac toxicity, the relationship between heart irradiation and baseline cardiovascular risk factors on the development of cardiac disease, the effect of hypofractionation encountered in thoracic SBRT, and the global physiologic effects of thoracic radiotherapy (e.g., interactions between simultaneous heart and lung irradiation).[323]

Toxicity Scoring Criteria

The QUANTEC authors recommend that the LENT–SOMA system[94,345] be considered to describe cardiac toxicity, as it explicitly includes clinical, radiologic, and functional assessments of cardiac dysfunction.

Esophagus

Clinical Significance

Acute esophagitis is very common and often severe in patients receiving radiation for intrathoracic malignancies (e.g., primary lung cancer and esophageal cancer). Patients with severe esophagitis may require a feeding tube and/or treatment interruptions.

End Points

Because most patients with thoracic cancers have a poor prognosis, acute toxicity may be considered more clinically relevant than late injury. Late esophageal complications include dysphagia, stricture, dysmotility, odynophagia, and rarely necrosis or fistula.

Challenges Defining Volumes

The esophagus can be challenging to visualize on axial imaging, and the use of dilute oral contrast can assist in its identification. Also, the esophagus often has folds such that its external contour as seen on an axial image may not accurately represent its true circumference. Indeed, in CT imaging, the circumference of the esophagus appears highly variable on different axial levels, when in fact the esophagus has a relatively uniform circumference. One study has suggested that the dosimetric parameters that apply this prior anatomic knowledge are better predictors of acute and late esophageal injury than are traditional dosimetric parameters.[346]

Dose/Volume/Toxicity Data

A variety of dose–volume parameters have been associated with the incidence of

esophagitis.[333,347–384] Although a continuous dose–response curve for acute esophagitis is observed based on a range of dosimetric parameters, as shown in Figure 14.10, there is no consensus as to the optimal dosimetric predictors of esophageal injury.

In a series from Washington University, grade 3 to 5 esophageal toxicity (acute and late) was associated with a maximal dose (D_{max}) of >58 Gy, a mean dose of >34 Gy, and the administration of concurrent chemotherapy.[353] The V_{55} was not significant. A study from China reported that maximal dose >60 Gy, as well as the use of concurrent chemotherapy, was a significant factor for esophageal toxicity (acute and late).[352] In a study from Duke, V_{50}, the surface dose receiving ≥50 Gy (S_{50}), the length of esophagus receiving >50 to 60 Gy, and a circumferential D_{max} > 80 Gy were significant predictors of late esophageal toxicity.[351] A V_{50} > 32% or an S_{50} > 32% resulted in crude rates of approximately 30% late esophageal toxicity versus 7% below these thresholds. With >3.2 cm of the esophagus receiving >50 Gy, late toxicity occurred in approximately 30%, versus 4% in those with <3.2 cm receiving >50 Gy (P = .008).

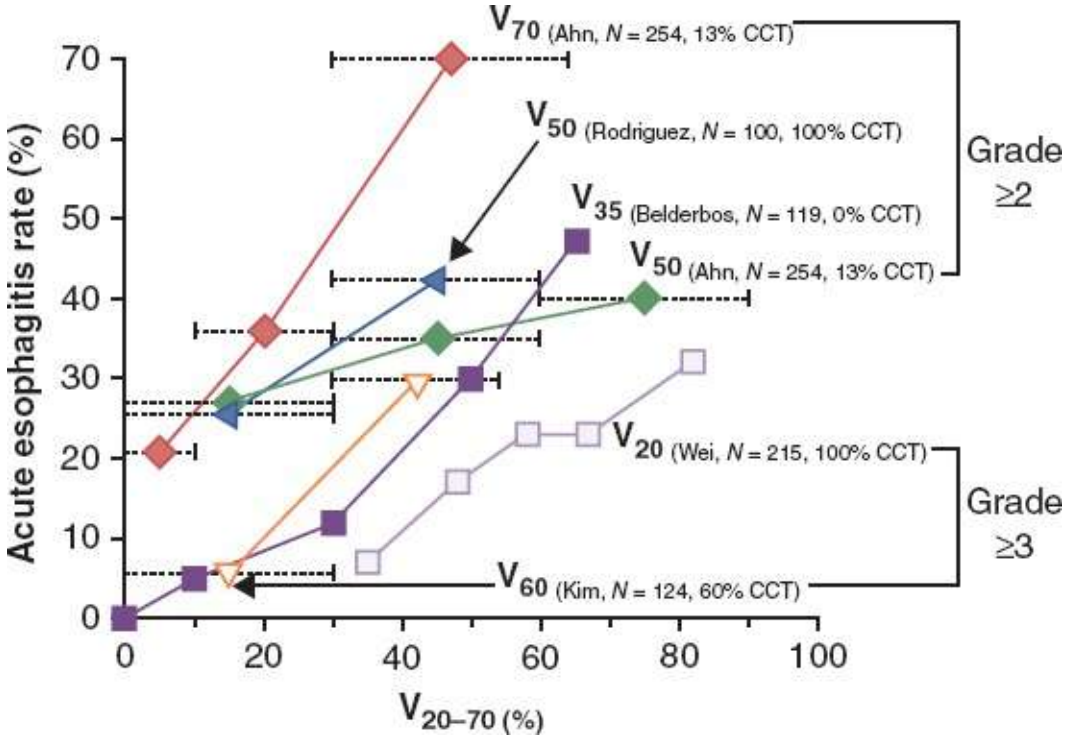

FIGURE 14.10. Incidence of acute esophagitis according to V_x (volume receiving more than x Gy) for selected studies. X-axis values estimated from range of doses reported. Datasets annotated as follows: V_{dose} (investigator, number of patients,

percentage with concurrent chemotherapy [CCT]). (Reprinted from Werner-Wasik M, Yorke E, Deasy J, et al. Radiation Dose-Volume Effects in the Esophagus. *Int J Radiat Oncol Biol Phys* 2010;76[3]:S86–S93. Copyright © 2010 Elsevier. With permission.)

In another study from Duke, grade 1 or higher late toxicity was correlated with several dose parameters: the entire circumference receiving ≥50 Gy and ≥55 Gy; 75% of the circumference receiving ≥70 Gy; and maximal percentage of circumference receiving ≥60 to 80 Gy.[347] The rate of grade 1 or higher late toxicity was approximately 5% in patients with a V_{50} to V_{70} of 0% to 30% versus approximately 25% in those with a V_{70} of 31% to 64% and approximately 10% in those with a V_{50} > 60% (nonsignificant). Acute esophageal toxicity was the greatest predictor of late toxicity. In two studies, most of the patients who developed late grade 3 or higher toxicity had developed acute grade 3 or higher toxicity, though roughly 25% to 40% of patients who developed grade 3 or higher late toxicity had only grade 0 to 2 acute esophageal toxicity.[352,353]

A 2013 meta-analysis (published after QUANTEC) of 1,082 NSCLC patients treated with chemoradiation analyzed esophageal V_5 to V_{70} parameters (in 5 Gy increments); all significant predictors of grade ≥2 esophagitis and on multivariate analyses V_{60} proved to be the most significant predictor of grade ≥2 to 3 esophagitis (PMID 24035329). Recursive partitioning identified 3 risk groups: low (29% and 4% risk of grade ≥2 and ≥3 esophagitis with V_{60} < 0.07%), intermediate (41% and 10% risk of grade ≥2 and ≥3 esophagitis with V_{60} 0.07% to 17%), and high (59% and 22% risk of grade ≥2 and ≥3 esophagitis with V_{60} ≥ 17%).

Factors Affecting Risk

Greater rates of acute esophagitis have been observed with more aggressive radiotherapy regimens (e.g., hyperfractionation, concurrent boost), the addition of concurrent chemotherapy, increasing age, and several other clinical factors (e.g., preexisting dysphagia, increasing nodal stage). The incidence of grade 3 or higher acute esophagitis is approximately 1% for patients treated with once-daily radiotherapy alone versus as high as 49% with concurrent gemcitabine. Several studies have assessed the putative radioprotector amifostine. Three single-institution phase III studies suggested a benefit for amifostine in reducing the rate of grade 2 or higher esophagitis, but this result was not confirmed in a large cooperative group phase III randomized trial (RTOG trial 9801).[355–358]

Mathematic/Biologic Models

Using data on grade 2 or higher acute esophagitis, two studies obtained relatively consistent estimates of Lyman-Kutcher-Burman model parameters, including TD_{50} of 47 to 51 Gy.[7,348] Note that these parameters differ significantly from those derived from the Emami data,[4] which examined a more clinically severe end point (stricture and perforation).

Special Situations

Esophageal toxicity data for hypofractionated treatments in SBRT to central thoracic lesions are quite limited,[359] and long-term data in this and other altered fractionation settings (e.g., accelerated fraction and concomitant boosts) have not been comprehensively reported.[360]

Recommended Dose–Volume Limits

Given the available data, there are no strict dose–volume limits for the esophagus. Several parameters are associated with the risk of adverse events, and clinicians can apply these data as seems reasonable for the clinical situation. Unfortunately, the anatomic reality for many patients with locally advanced non–small cell lung cancer is that the PTV (and certainly the GTV) is often immediately adjacent to the esophagus, and thus, it is not possible to limit the doses as desired without compromising target coverage. The ongoing phase III intergroup trial, RTOG 0617, has recommended (but has not mandated) that the mean dose to the esophagus be kept to <34 Gy.

Future Studies

IMRT may provide increased flexibility in sparing the esophagus during lung irradiation,[385] and outcome as function of dose–volume should be systematically studied for this treatment technique. As in other organ systems, detailed outcome and dosimetric data should be reported, based on clearly defined methods of contouring the target and organs at risk.

Toxicity Scoring Criteria

Esophageal toxicities should be scored using the CTCAE v. 4.0.[37]

ABDOMEN/PELVIS

Liver

Clinical Significance

The liver is a vital organ, involved in the metabolism of ingested nutrients, detoxification, protein synthesis, bile production, glycogen storage, and red blood cell decomposition. The liver may be incidentally irradiated during radiation therapy of abdominal or thoracic tumors and will be irradiated in patients undergoing partial hepatic radiation for liver metastases or hepatocellular carcinoma. There is no effective treatment to reverse the process of radiation-induced liver disease (RILD); therefore, prophylaxis and prevention are best. Anticoagulants, paracentesis, and diuretics can be used to mitigate symptoms, whereas liver transplantation is required for frank radiation hepatopathy.

End Points

RILD generally presents as vague to intense right upper abdominal pain followed by abdominal swelling because of hepatomegaly and ascites, resulting in weight gain. Anicteric ascites often develops 2 to 4 months after irradiation; chemoradiation-induced liver disease may occur more rapidly (e.g., 1 to 4 weeks post radiation therapy in a bone marrow transplantation setting). Other sequelae of RILD include elevation of liver enzymes, jaundice, asterixis (tremor), encephalopathy, or coma.

The basic pathophysiologic sequelae of classic RILD is central vein thrombosis at the lobular level, which results in retrograde congestion leading to hemorrhage and secondary alterations in surrounding hepatocytes. This often occurs between 2 weeks and 3 months after therapy. Severe acute hepatic changes often progress to fibrosis or cirrhosis and liver failure.

Nonclassic RILD implies dramatic elevations of liver transaminases (greater than five times the upper limit) or decline in liver function in the absence of classic RILD. The underlying pathology of nonclassic RILD is unclear.[361]

Challenges Defining Volumes

The liver is readily identified on CT and MRI. For radiation planning, it must be recognized that the liver moves with the respiratory cycle.[361]

TABLE 14.10 RADIATION-INDUCED LIVER DISEASE IN PARTIAL LIVER IRRADIATION

Reference	*n*/% C-P A	Diagnosis	Dose Fractionation	Crude Rate of RILD	Mean Normal Liver Dose in Patients with vs. without RILD

Michigan[363,364]	203/100%	PLC + LMC	1.5 Gy bid	9%	37 vs. 31.3 Gy
Taipei[365]	89/76%	HCC	1.8–3 Gy qd	19%	23 vs. 19 Gy
Shanghai[366,367]	109/85%	PLC	4–6 Gy qd	16%	24.9 vs. 19.9 Gy
Guangdong[368]	94/46%	HCC	4–8 Gy qd	17%	Not stated
S. Korea (Seong et al.)[369]	158/74%	HCC	1.8 Gy qd	7%	Not stated
S. Korea (Kim et al.)[370]	105/81%	HCC	2.0 Gy qd	12%	25.4 vs. 19.1 Gy

% C-P A, percent of patients with baseline Child-Pugh A score (in all studies, patients were either A or B); bid, twice-daily treatment; HCC, hepatocellular carcinoma; LMC, metastatic disease to the liver; PLC, primary liver cancer; qd, once-daily treatment; RILD, radiation-induced liver disease. Dose/Volume/Toxicity Data

The liver parenchyma is composed of innumerable, redundant, parallel functional subunits, which allows the liver to potentially tolerate focal injury without clinical sequelae if adequate normal liver parenchyma can be spared.

In a study of 79 patients treated with liver radiotherapy at the University of Michigan, 9 of 33 patients who received whole-liver radiotherapy developed late radiation toxicity versus none of 46 who underwent partial liver radiation.[362] Several studies have explored partial liver radiation in more detail, many of which used mean liver dose as a dose–volume metric (Table 14.10). In a series from Taipei, patients with irradiated hepatocellular carcinoma who developed late liver toxicity had received a mean hepatic dose of 25 Gy (vs. 20 Gy in patients without toxicity, $P = .02$).[371] In a Korean study of 105 patients with hepatocellular carcinoma, the mean dose and V_{20} to V_{40} parameters to total liver and normal liver (total liver minus GTV) were investigated.[370] The total liver V_{30} was the only significant parameter ($P < .001$). Grade 2 or higher liver toxicity was observed in only 2.4% of patients with a total liver V_{30} of approximately 60% and 55% of patients with a total liver V_{30} of >60% ($P < .001$).

Factors Affecting Risk and Mathematic/Biologic Models

A wide variety of agents have been reported to elevate liver enzymes: nitrosoureas (BCNU), methotrexate, and some combinations of chemotherapy agents such as cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) and proMace-MOPP (prednisone, methotrexate, doxorubicin,

cyclophosphamide, etoposide, and MOPP). In bone marrow transplantation, preparatory regimens can be toxic.

As described earlier, the dose to partial liver volumes can impact the risk of RILD. Several studies have used NTCP modeling to help predict risks. In a study from University of Michigan, no late liver toxicity was observed with a mean liver dose <31 Gy, with NTCP models being optimized with a TD_{50} of 43 Gy and TD_5 of 31 Gy for whole-liver radiation; the risk of complications was strongly dependent on volume of liver irradiated.[363] Other risk factors for late toxicity included primary hepatobiliary carcinoma (as opposed to metastatic disease), use of bromodeoxyuridine chemotherapy (as opposed to fluorodeoxyuridine), and male gender. The NTCP models predict a TD_5 in excess of 80 Gy if less than one-third of the liver is irradiated. With irradiation of two-thirds of the liver, the TD_5 is on the order of 50 Gy and TD_{50} on the order of 60 Gy.

In the series of hepatocellular carcinoma patients from Taipei (discussed earlier),[371] the TD_{50} for whole-liver, two-thirds liver, and one-third liver radiation was modeled to be approximately 43, 50, and 67 Gy, respectively. The TD_5 for whole-liver, two-thirds liver, and one-third liver radiation was modeled to be approximately 25, 28, and 38 Gy, respectively. The volume effect of liver radiation was less in this series. In another study from the same group, the mean liver dose and hepatitis B virus positivity were significant predictors of radiation toxicity; with NTCP modeling, the TD_{50} was approximately 50 Gy.[365]

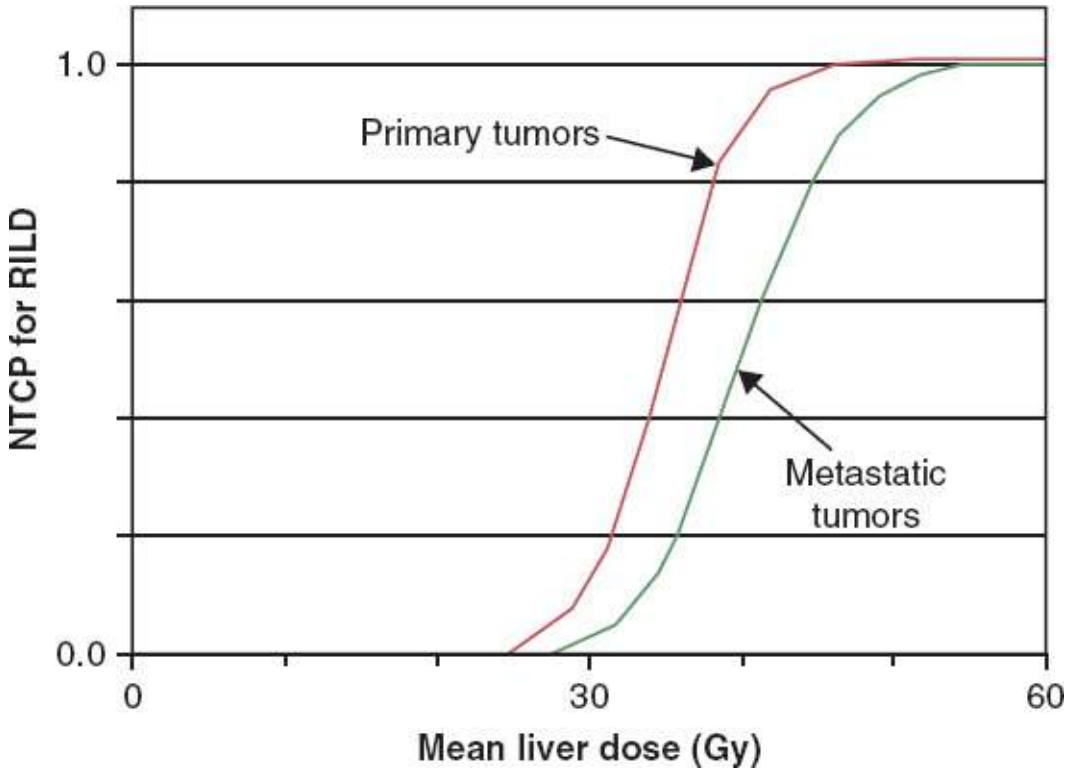

FIGURE 14.11. Mean liver dose, corrected with linear-quadratic modeling for 2-Gy fractions versus Lyman normal tissue complication probability (NTCP) of classic radiation-induced liver disease (RILD) for primary and metastatic liver cancer. (Reprinted from Pan CC, Kavanagh BD, Dawson LA, et al. Radiation-associated liver injury. *Int J Radiat Oncol Biol Phys* 2010;76[3 Suppl]:S94–S100. Copyright © 2010 Elsevier. With permission.)

The data from Asia differs from that in the West, perhaps reflecting differences in the treated malignancy (mostly metastases in the West vs. primary liver cancer in Asia, which often occurs in the setting of liver cirrhosis), as shown in Figure 14.11. In addition, radiation fractionation, concurrent therapies delivered with radiation, and the fact that the majority of patients with hepatocellular carcinoma from Asia have hepatitis B viral infections may impact liver tolerance.[361] Poor preexisting liver function is also predictive of poorer tolerance to radiation.[361]

Special Situations

The hypofractionated delivery of radiation, using novel techniques such as SBRT and/or image-guided radiation therapy (IGRT), for primary and metastatic liver lesions presents a unique situation in which small volumes of normal liver receive very high doses of radiation per fraction. In a collaborative phase I study, the University of Colorado and Indiana University enrolled 18 patients with one

to three liver metastases treated with three fractions of SBRT.[372] No patients developed grade 2 or higher toxicity. Late radiographic changes of well-circumscribed hypodense lesions were commonly seen, corresponding to the 30-Gy dose distribution. In a follow-up analysis, including an additional 18 patients treated in a phase II study of three fractions of 20 Gy, one patient developed subcutaneous tissue breakdown; no radiation-related liver toxicity occurred.[373] In a subsequent study, in which ≥700 mL of normal liver was required to receive <15 Gy in three fractions, no patient experienced RILD.[374]

Princess Margaret Hospital treated 41 patients with primary hepatocellular or intrahepatic biliary cancer in a phase I study of 24 to 60 Gy in six fractions.[375] Using normal tissue complication modeling, patients were stratified into three different dose escalation groups, based on the effective liver volume to be irradiated. Acute (<3 months) elevation of liver enzymes occurred in 24%, acute grade 3 nausea occurred in 7%, and acute transient biliary obstruction occurred in 5% of patients. In contrast, among 68 patients with liver metastases treated similarly with SBRT, two patients (3%) developed grade 3 liver enzyme changes, but no RILD or other grade 3 or higher liver toxicity was reported.[376]

Recommended Dose–Volume Limits

For patients with liver metastases undergoing partial volume liver radiation, the risk of radiation-induced liver toxicity appears to be more dependent upon the volume of liver irradiated. Partial volumes of liver can tolerate relatively high doses. Liver tolerances, however, are lower for patients with primary liver cancer (who are more apt to have underlying liver disease). For whole-liver radiation, doses ≤28 to 30 Gy in 2-Gy fractions (28 Gy for liver metastases and 30 Gy for primary liver cancer) and ≤21 Gy in 3-Gy fractions are recommended. For partial liver radiation, treated with standard fractionation, the mean dose to normal liver (liver minus GTV) is suggested to be <30 Gy for liver metastases and <28 Gy for primary liver cancer.

Future Studies

Studies that better correlate dose–volume parameters with long-term clinical/objective outcomes are needed. The impact of treatment-related (including fractional dose and systemic therapies) and host-related variables should be better defined.

Toxicity Scoring Criteria

The CTCAE v. 3.0 grades hepatobiliary toxicity according to clinical criteria of

jaundice, asterixis, and encephalopathy or coma for grades 2, 3, and 4, respectively. The much more commonly occurring alteration in liver enzymes, in the absence of symptomatic manifestations, is classified under the CTCAE metabolic/laboratory category of elevations of alanine aminotransferase (ALT) and aspartate aminotransferase (AST). The use of CTCAE criteria for elevations of AST and ALT and other metabolic effects is advisable to promote consistency of reporting.

Small Bowel/Stomach

Clinical Significance

The stomach and small bowel aid in the digestion and absorption of food and nutrients. Symptoms from radiation-related late toxicities include dyspepsia, gastric ulceration, diarrhea, bowel obstruction, and ulceration, fistula, or perforation.[377]

End Points

Nausea and vomiting can occur immediately or within hours after RT to the stomach or small bowel. The radiosensitivity of the gastric mucosa is reflected in the early depression of hydrochloric acid and pepsin secretion after modest radiation doses of 15 to 20 Gy. Although some recovery of cellular structure occurs, suppression can continue for 6 months to many years after irradiation. Usually, at total doses at or above 50 Gy, cellular and functional recovery is never complete. Ulcers are the most common complication of gastric irradiation and present clinically with dyspepsia, significant pain, and sometimes hemorrhage. An ulcer in this anatomic setting can lead to hemorrhage and perforation, which, although rare, can be fatal. Ulcerations have been described as typically antral, perhaps because of placement of radiation therapy fields, and develop as early as 2 to 12 months after treatment. Pyloric obstruction may be a late development because of fibrosis after ulcer healing.

The early onset of malabsorption of fat and hypermotility after modest doses of radiation illustrates the radiosensitivity of the small intestine. Usually, recovery at dose levels below 40 to 45 Gy occurs, although some persistence of small bowel dysfunction and mesenteric cramping may be noted. Surgical intervention and adhesions can precipitate a more serious course of events. Higher doses result in diarrhea, malabsorption of fat, and leakage of albumin into the bowel. If an obliterative arteritis develops, the risk of infarction and perforation remains despite recovery. The underlying lesion is one of ulceration

and segmental enteritis that can lead to stenosis of the bowel lumen, with varying degrees of obstruction during the chronic period.

Challenges Defining Volumes

The stomach and small bowel are well visualized, particularly with the use of intravenous contrast and/or oral contrast. The stomach and small bowel position can be variable, and it is therefore recommended that patients avoid large meals or carbonated beverages prior to simulation and treatment.

Dose/Volume/Toxicity Data

Because the stomach and small bowel are mobile and distensible, determining accurate dose–volume (or dose–surface) constraints is challenging. A 2013 systematic review of women undergoing extended field radiation suggested a point dose maximum of 55 Gy to small bowel would yield a 10% toxicity risk within 5 years.[386] In a study of women undergoing posthysterectomy IMRT, the V_{40}/small bowel volume ratio (optimal threshold of 28%) and maximal dose (optimal threshold of 55.9 Gy) were significant prognostic factors for chronic grade 1 to 2 toxicity.[387]

Late radiation-induced stomach injury has been reported to occur with increasing frequency with increasing doses. In a study from Walter Reed, the rates of gastric ulceration were 4% and 16% after treatment of <50 versus >50 Gy, respectively. Similarly, the rates of perforation were 2% and 14% in the same dose cohorts, respectively. Overall, the dose of approximately 50 Gy to the stomach is associated with about a 2% to 6% incidence of severe late injury. The volume effect for late stomach injury is not well defined. For late small bowel toxicity, doses of approximately 50 Gy are associated with obstruction/perforation rates that are approximately 2% to 9%. There is a paucity of good quantitative data on dose–volume metrics that predict for gastric or bowel late toxicity. Nevertheless, there are data that demonstrate a volume effect. The risk of bowel obstruction among patients with rectal cancer whose fields extended to L1 or L2 was 30% versus 9% in those treated with pelvis-only fields.[378] The University of Michigan investigated gastric and duodenal bleeding after radiation of patients with liver tumors.[379] Normal tissue complication modeling was consistent with a dose threshold (~60 Gy) for bleeding without a large volume effect.

Two studies of locally advanced pancreatic cancer patients correlated small bowel toxicity risks with dose–volume metrics. After concurrent gemcitabine

and radiotherapy, duodenal V_{35} > 20% was associated with a 41% risk of grade ≥3 small bowel toxicity (acute or late) versus 0% for a V_{35} < 20%.[388] In another study, V_{55} ≥ 1 mL versus <1 mL was significantly correlated with grade ≥2 toxicity (47% vs. 9%, *P* = .0003).[389]Among patients treated with neoadjuvant radiation for rectal cancer, a 10% risk of grade ≥3 small bowel toxicity was correlated with a V_{15} < 275 cm^3 for contoured bowel loops and <830 cm^3 for the peritoneal space.[390]

Factors Affecting Risk

Factors affecting risk of late toxicity include total dose (with doses in excess of 40 to 50 Gy increasing the risk of late complications), fractional dose, prior abdominal surgery (which increases the risk of bowel obstruction), and concurrent chemotherapy use. In the European Organisation for Research and Treatment of Cancer (EORTC) Hodgkin lymphoma study, the rate of complications was 3% without prior abdominal surgery versus 12% with prior abdominal surgery.[380]

Mathematic/Biologic Models

The University of Michigan analyzed gastric bleeding among patients treated with radiation for liver tumors.[379] Variables significantly impacting bleeding risk included NTCP, mean dose to stomach, and presence of cirrhosis. Data from William Beaumont Hospital has suggested that the volume of bowel exposed to radiation doses of >5 to 40 Gy correlates with risk of acute grade 3 toxicity; their studies[381,382] and others have shown small bowel V_{15} to be highly significant (*P* < .0001).[383] The model results are graphically depicted in Figure 14.12. Using NTCP modeling for patients undergoing preoperative radiation for rectal cancer, IMRT has been shown to reduce the anticipated rate of grade 2 or higher diarrhea from 40% to 27% (with further reductions if IGRT is also used).[377]

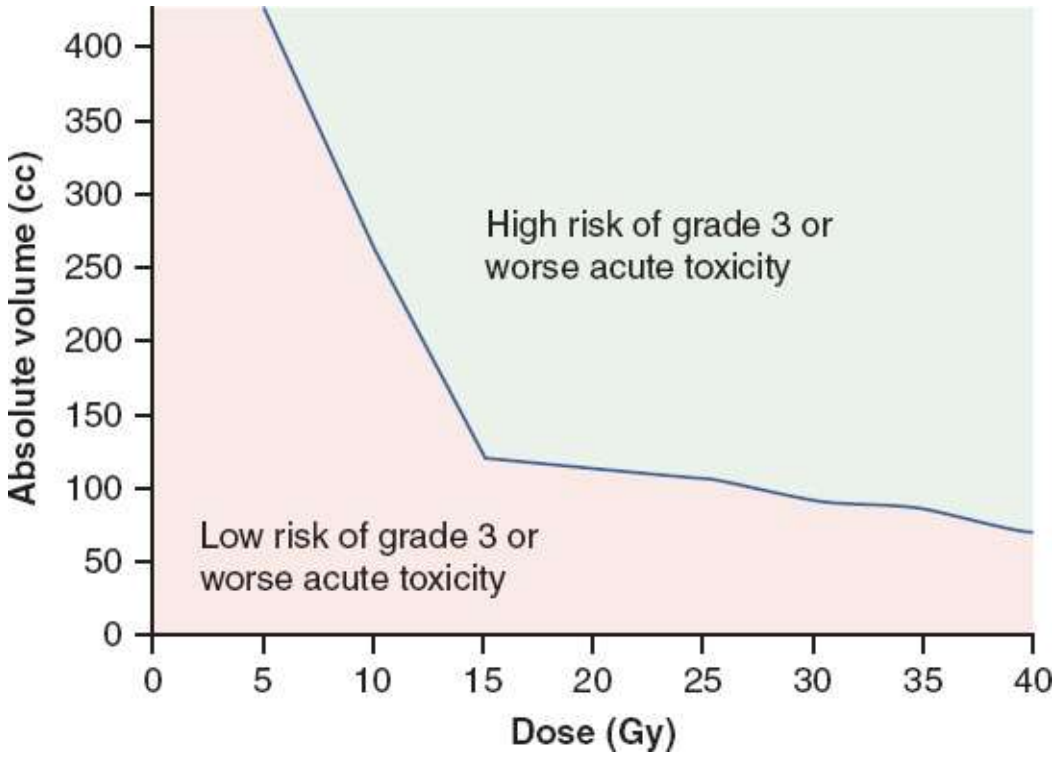

FIGURE 14.12. Graphic representation of the Baglan–Robertson[381,382] threshold model for acute small bowel toxicity. "Low risk" implies <10% and "high risk" >40% grade 3 toxicity. Absolute volume is based on contouring individual bowel loops, not the entire peritoneal space. (Reprinted from Kavanagh BD, Pan CC, Dawson LA, et al. Radiation dose-volume effects in the stomach and small bowel. *Int J Radiat Oncol Biol Phys* 2010;76[3 Suppl]:S101—S107. Copyright © 2010 Elsevier. With permission.)

Special Situations

High-grade small bowel mucositis, ulceration, and perforation, as well as acute gastroparesis, have been reported in patients undergoing hypofractionated SBRT for pancreatic malignancies,[384] though the reported rate of such grade 3 to 4 toxicities (albeit in a patient population with poor survival) has been relatively low in US studies.[391–393] Among patients undergoing three- to five-fraction SBRT for liver metastases, bowel toxicity has been reported to occur with maximal doses to the bowel of >30 Gy.[361]

Recommended Dose–Volume Limits

Using the entire potential small bowel space, it is suggested that the small bowel exposed to V_{45} to V_{50} should be <195 mL to reduce acute toxicity (not discussed earlier)[377,394]; while using the visualized loops of bowel, it is recommended that the V_{15} should be <120 mL.[377,381] Although these dose constraints were derived from acute toxicity data, they do provide guidelines that should help minimize

risk of late toxicity as well. For the stomach, it is recommended to maintain the dose to the whole stomach to <45 Gy; a maximum point dose might be an important predictor of toxicity, but more data are needed to confirm this hypothesis.

Future Studies

More detailed dose–volume effects for late bowel toxicity are needed, particularly for altered fractionation (i.e., SBRT). As many gastrointestinal cancers are treated with chemotherapy, data on the impact of chemotherapy on acute and late stomach and bowel toxicity are needed.

Toxicity Scoring Criteria

The CTCAE v. 4.0 is used to grade gastric and small bowel toxicity.[92]

Kidneys

Clinical Significance

The kidney functions to remove wastes; regulate electrolytes; produce erythropoietin, which stimulates red blood cell production; and modulate blood pressure through the renin–angiotensin pathway as well as through fluid/electrolyte balance. Radiation nephropathy is an uncommonly reported toxicity, not because kidneys are radioresistant, but because clinicians carefully respect renal tolerance doses.

End Points

Five distinct clinical syndromes may overlap in symptoms, signs, and time sequence: acute radiation nephropathy, chronic radiation nephropathy, benign hypertension, malignant hypertension, and hyperreninemic hypertension secondary to a scarred encapsulated kidney (Goldblatt kidney). The signs (i.e., decreased glomerular filtration rate) and symptoms of radiation nephropathy are not distinguishable from other causes of renal damage, and these should be excluded. Acute (within 6 months) radiation-induced kidney injury is generally subclinical. Urinary findings consist of microscopic hematuria, proteinuria, and urinary casts. Blood alterations in β_2-microglobulin correlate linearly with both inulin and creatinine clearance and with later elevations of blood urea nitrogen (BUN). There is a 6- to 12-month latency period before the clinical expression of acute radiation nephropathy. In this subacute phase, the signs and symptoms include dyspnea, headaches, ankle edema, lassitude, anemia, hypertension, albuminuria, papilledema, elevated blood urea, and urinary abnormalities

(granular and hyalin casts, red blood cells). Death may occur from chronic uremia or left ventricular failure, pulmonary edema, pleural effusion, and hepatic congestion. Chronic radiation nephropathy and hypertension do not develop until after 12 to 18 months. When chronic nephropathy is severe, death may result.

Challenges Defining Volumes

The kidneys are readily defined on contrast and noncontrast CT imaging. Ideally, the "functional" kidney parenchyma as opposed to the collecting system should be contoured.

Dose/Volume/Toxicity Data

Several studies have investigated whole-kidney dose tolerance, either after whole-abdominal radiation or total-body irradiation (TBI) (generally delivered with lower fractional doses). Renal toxicity can occur after bilateral kidney doses ≥10 Gy, and the risk is quite high (50% to 80%) after 20 Gy. Thus, the kidneys have a relatively low threshold for damage. The dose–volume effect on the kidneys has been long recognized, even prior to the planning CT era, because kidneys are well visualized on plain simulation films. From these studies, when greater than half of the kidney receives doses >20 to 30 Gy, or greater than one-third receives >30 to 40 Gy, patients are at increased risk of developing renal atrophy, decreased kidney function, and hypertension.[1,297,395,396]

There is little published on dose–volume parameters to predict late renal toxicity, in part because clinicians make an effort to minimize the volume of kidney exceeding the accepted tolerance dose. Low doses, 10 to 15 Gy, to large volumes of kidney increase the risk of nephrotoxicity,[78,397,398] whereas smaller volumes of kidney with doses exceeding approximately 20 to 25 Gy can result in late renal toxicity.[78,397,399,400] In a series from Heidelberg, normal tissue complication modeling was used to estimate the risk of late complications.[399] A median dose of approximately 17.5 to 21.5 Gy and 22 to 26 Gy corresponded to a 5% and 50% late complication risk (anemia, azotemia, hypertension, and edema), respectively. In another German study, reduced kidney function, as measured by scintigraphy changes, was analyzed as a function of dose and volume.[397] After irradiation of 10% to 30%, 30% to 60%, and 60% to 100% of the kidney volume to 20 Gy, the incidence of reduced activity was <10%, approximately 40%, and >70%, respectively. After irradiation of 10% to 30%, 30% to 60%, and 60% to 100% of the kidney volume to 30 Gy, the incidence of reduced activity was approximately 35%, >90%, and >98%, respectively. In a

Dutch study of patients with gastric cancer (treated with concurrent radiation and cisplatin or capecitabine), the left kidney V_{20} of ≥64% and mean left kidney dose of ≥30 Gy were associated with a significant decrease in left kidney function as compared to the right.[400]

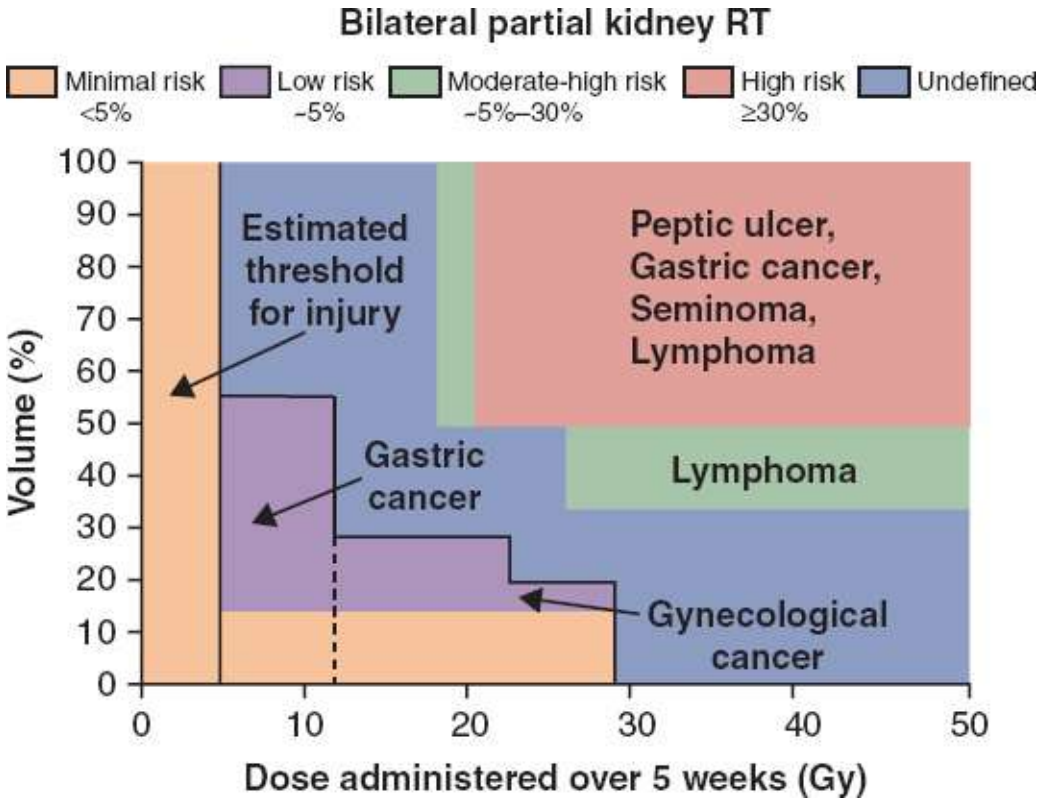

FIGURE 14.13. Schematic diagram of bilateral kidney dose–volume histogram from selected studies, represented as regions associated with minimal (<5%), low (~5%), moderate to high (~5% to 30%), high (>30%), or undefined estimated risk of toxicity. Clinical situation that yielded risk estimates for each region is also indicated. Actual risks are patient and plan specific and are associated with substantial uncertainty. (Adapted from Dawson LA, Kavanagh BD, Paulino AC, et al. Radiation-associated kidney injury. *Int J Radiat Oncol Biol Phys* 2010;76[3 Suppl]:S108–S115. Copyright © 2010 Elsevier. With permission.)

Recognizing the limitations described earlier, the QUANTEC study summarized the toxicity data for bilateral kidney irradiation in Figure 14.13.

Factors Affecting Risk

A variety of agents have been implicated as toxic or as radiosensitizers (i.e., retinoic acid, cisplatin, BCNU, actinomycin D), administered either singly or in combination chemotherapy. Of note, angiotensin-converting enzyme (ACE) inhibitors and angiotensin II receptor blockers have been shown to delay the

progression of radiation injury in the experimental setting.[401] TBI dose rates (≤6 cGy/min vs. ≥10 cGy/min) have been shown to significantly impact risk of renal toxicity.[402] Patient-related factors may include underlying renal insufficiency, diabetes, hypertension, liver disease, heart disease, and smoking.[403]

Special Situations

Several reports have described the use of SBRT in the treatment of medically unresectable kidney cancer and/or in patients with only one functioning kidney. With limited follow-up, SBRT with high dose (≥10 Gy) has been reportedly well tolerated.[403]

Recommended Dose–Volume Limits[403]

For whole (bilateral) kidney radiation, doses <10 Gy delivered over five to six fractions (at a <6 cGy/min dose rate) and <15 to 18 Gy for radiation delivered over ≥5 weeks are recommended. For partial kidney radiation, the volume of kidneys receiving >20 Gy predicts risk of renal toxicity. The recommendation for partial kidney radiation is to maximally spare the kidneys and maintain a mean dose of <18 Gy to both kidneys, or maintain a V_6 < 30% if one kidney cannot be adequately spared.

Future Studies

Studies are needed to better define partial kidney tolerance to radiation, investigating the impact of underlying kidney function, dose–volume exposure (accounting for regional variation), fractionated dose delivery, and radiation protectors.

Toxicity Scoring Criteria

The CTCAE v. 4.0 can be used to grade renal toxicity.[92] Severity of injury can also be graded according to the glomerular filtration rate, serial urine protein, serum BUN, creatinine clearance, blood pressure, and symptoms of renal failure.

Rectum

Clinical Significance

The rectum is the terminal portion of the large intestines that functions as a temporary storage for feces, as well as providing the urge to defecate. A portion of the rectum is irradiated in patients undergoing radiation for prostate cancer, gynecologic cancers, and other pelvic tumors (such as sarcomas).

End Points

Acute rectal toxicity includes diarrhea or loose stools, tenesmus, proctitis, and rectal urgency and/or frequency. The most common late radiation-related rectal complication is bleeding. Rectal ulceration and fistula are much less common. Other late injuries include stricture and decreased rectal compliance, which can result in frequent small stool and/or tenesmus. The anus is also at risk of late complications including stricture and laxity, leading to fecal incontinence.

Challenges Defining Volumes

The rectum extends from the rectosigmoid junction to the anus, with the inferior extent variably defined as the level of the anal verge the ischial tuberosities or 2 cm below the ischial tuberosities, or above the anus (the most inferior 3 cm of the intestines). The rectum should be segmented from above the anal verge to the turn into the sigmoid colon, though the superior and inferior borders of the rectum are not always easy to define on CT imaging, and definition of the cranial and caudal extents is variable.[404] The rectum is mobile and distensible, and therefore, its position and volume can vary between and during radiation fractions.

The percentage of rectum or rectal wall receiving a given dose can be somewhat subjective (i.e., based on how much of the rectum is segmented); using the absolute volume of rectum[405] or rectal wall is less subjective, though defining the rectal wall is not standardized. William Beaumont Hospital demonstrated that the rectal volume as well as rectal wall V_{50} to V_{70} values predict late toxicity, with the rectal wall being more predictive of grade 2 to 3 late effects; acute toxicity is also predictive of late toxicity.[406] MDACC has also shown the rectal wall to be better predictive of late rectal bleeding.[407]

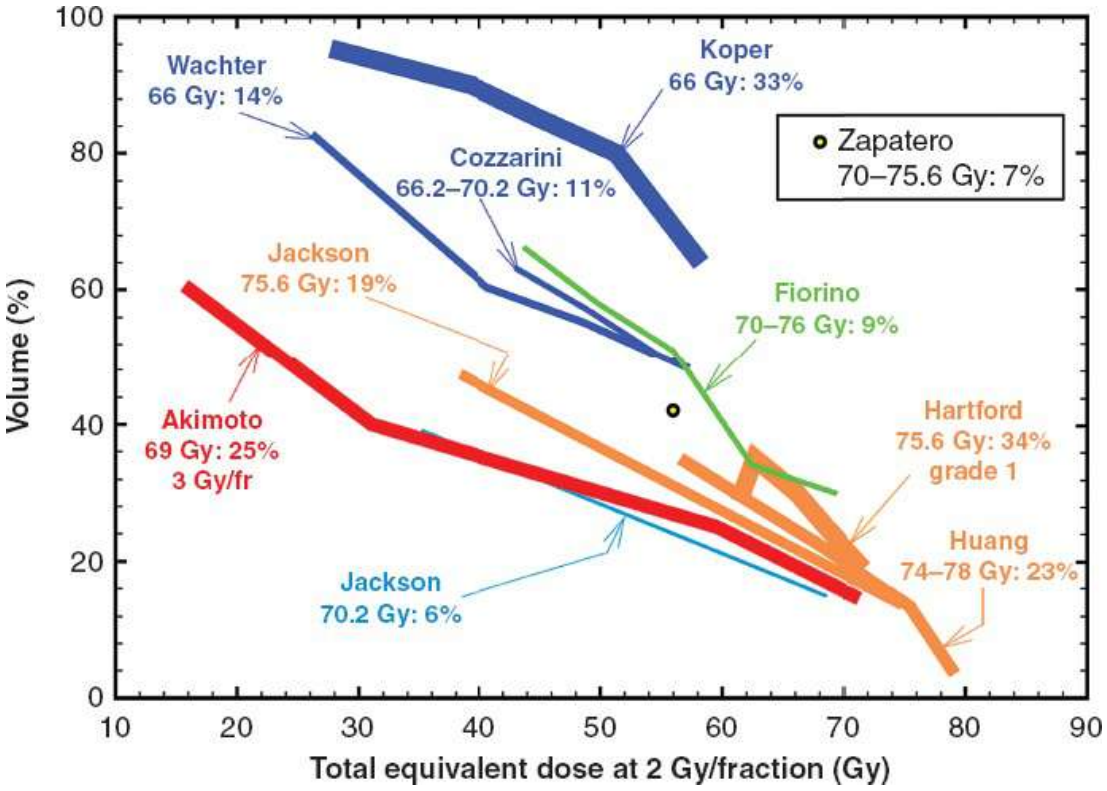

FIGURE 14.14. Dose–volume histogram thresholds for grade 2 or higher rectal toxicity from selected studies.[408–416] *Thicker lines* indicate higher rates of overall toxicity (percentages are indicated on the figure along with the physical prescription dose). Threshold doses are expressed as the total equivalent dose delivered in 2-Gy fractions, adjusted using the linear-quadratic model with α/β = 3 Gy. The associated equivalent prescription doses are coded by color spectrum from lowest (*blue*) to highest (*red*). Volumes shown in the graph are based on the full length of the anatomic rectum. Note that these curves converge in the high-dose range, implying that doses in this range are more consistently associated with rectal toxicity. (Reprinted from Michalski JM, Gay H, Jackson A, et al. Radiation dose-volume effects in radiation-induced rectal injury. *Int J Radiat Oncol Biol Phys* 2010;76[3 Suppl]:S123–S129. Copyright © 2010 Elsevier. With permission.)

Review of Dose/Volume/Toxicity Data

Abundant dosimetric data have shown a correlation of risk with rectal volume and surface/rectal wall doses among patients undergoing radiation for prostate cancer. Figure 14.14 summarizes many of the studies discussed here.

MSKCC has shown a significant difference in the DVHs between patients who developed rectal bleeding versus those who did not after conformal radiation for prostate cancer.[408] The percent rectum exposed to 62% and 102% of the prescription dose (70.2 or 75.6 Gy) was significant; the rectal wall being encompassed by the 50% isodose line, higher maximal dose to the rectum, and smaller rectal volume were also significantly adverse risk factors.[408,417] In a

recent study of 1,571 patients treated at MSKCC, the use of IMRT and the lack of acute rectal toxicity predicted for lower risk of late rectal toxicity.[418]

In a randomized trial of 70 versus 78 Gy from MDACC in the treatment of early- to intermediate-risk early-stage prostate cancer, the risk of grade 2 or higher late rectal complications was significantly greater with a rectal $V_{70} \geq 25\%$ versus $V_{70} < 25\%$ (46 vs. 16%, $P = .001$).[419] A retrospective analysis from MDACC showed that the risk is a continuous function of dose and volume, with suggested cutoff points for lowering the complication risk: $V_{60} \leq 41\%$, $V_{70} \leq 26\%$, $V_{76} \leq 16\%$ or 3.8 mL, and $V_{78} \leq 5\%$ or 1.4 mL.[409] At 6 years, the risk of grade 2 or higher late rectal complications was 54% for patients with a rectal $V_{70} \geq 26\%$ versus 13% for a $V_{70} < 26\%$.

Among patients treated in the Dutch randomized trial of 68 versus 78 Gy for prostate cancer,[420] the mean anal dose (as well as V_5 to V_{60}) significantly predicted the rate of grade 2 or higher gastrointestinal toxicity (at 4 years, 16% vs. 31% for a mean dose of <19 vs. >52 Gy).[421] The mean dose (as well as V_5 to V_{70}) also predicted the risk for use of incontinence pads (at 5 years, <5% vs. >20% for a mean dose <28 vs. >46 Gy). The anorectal V_{65} (as well as V_{55} to V_{60}) was significantly predictive of rectal bleeding (4-year risk <1% and >10% for a $V_{65} < 23\%$ vs. >29%).[421] Several other studies have shown that the volume of rectum receiving >50 to 70 Gy has been shown to significantly correlate with late rectal toxicity.[410,411,422,423] From a 1998 Dutch study, recommendations for the volume of rectal wall (vs. rectal volume) exceeding 65, 70, and 75 Gy are <40%, <30%, and <5%, respectively.[424] Data from the Cleveland Clinic[405] and William Beaumont Hospital[406] showed a significantly increased risk of grade 2 or higher rectal toxicity with rectal or rectal wall V_{70} to V_{78} of ≥15 versus <15 mL (~20% to >30% vs. ~5% to 10%).[406] V_{75} was the only dosimetric measure significantly associated with late rectal toxicity in a phase I/II RTOG 9406 study of 1,009 prostate cancer patients.[425] In an analysis of 748 patients randomized to the 79.2-Gy arm of the RTOG 0126 protocol, rectal $V_{70} \geq 15\%$ was associated with grade 2+ rectal toxicity ($P = .034$ on multivariate analysis). At 3-years, $V_{70} \geq 15\%$ was associated with an approximately 24% risk of late gastrointestinal toxicity versus 12% for $V_{70} < 15\%$.[426] In a study of 1,285 prostate cancer patients who received proton therapy, the rectal ($P = .010$) and rectal wall ($P = .0017$) V_{75} were significant for risk of rectal bleeding on multivariate analysis.[427]

Women undergoing radiation for gynecologic malignancies are also susceptible to rectal toxicity. From historical data, the incidence of severe proctitis in patients with cancer of the cervix is dependent on the prescribed point A dose, with a <4% incidence with doses of <80 Gy, a 7% to 8% incidence after 80 to 95 Gy, and a 13% incidence for doses of ≥95 Gy.[428,429] With modern radiation delivery, particularly with IMRT planning, the rate of severe gastrointestinal toxicity is low. In a University of Chicago series of 183 patients treated with conventional radiation and brachytherapy, 9% developed grade 1 to 2 rectal toxicity and 7% developed grade 3 toxicity; a history of diabetes, point A dose, and the pelvic external beam radiotherapy dose were most significantly correlated with rectal toxicity. Among patients experiencing diarrhea or loose stools after pelvic radiotherapy, rectal toxicity becomes difficult to differentiate from small bowel toxicity. In another report from the University of Chicago, of 50 women treated with pelvic IMRT for gynecologic malignancies, acute gastrointestinal toxicity was correlated with small bowel dose (see above), but not rectum receiving 25% to 110% of the prescription.[251] However, the rectum was constrained to receive <40 Gy to >40% with a maximum dose of 49 Gy.

Factors Affecting Risk

Several patient-related variables, such as history of diabetes and/or vascular disease, inflammatory disease, and age, may impact the risk of late toxicity.[420,430,431] Prior abdominal surgery is also relevant.[432] From 1,010 prostate cancer patients enrolled in the RTOG 9406, cardiovascular disease was significantly (P = .015) associated with a higher rate of late rectal toxicity, whereas diabetes, hypertension, rectal volume, rectal length, neoadjuvant hormone therapy, and prescribed dose per fraction (1.8 vs. 2 Gy) were not significant factors.

Mathematic/Biologic Models

Rectal toxicity has been modeled using the Lyman-Kutcher-Burman NTCP model, mostly from patients treated with 3D conformal radiation. Most data are suggestive of a small volume effect, meaning that small volumes receiving high dose are most predictive for late effects.[404] The TD_{50} of grade 2 or higher late rectal toxicity is estimated to be around 77 to 79 Gy (with 95% CIs of ~74 to 82 Gy).[404] From the largest study to date of 1,010 patients enrolled in the RTOG 9406, the TD_{50} was 79 Gy; the fit based on dose-wall histogram data was not significantly different. EUD has also been modeled as a predictor of late rectal

toxicity.[433]

Special Situations

SBRT for prostate cancer is under investigation. In one study, 67 patients were treated with 7.25 Gy × 5, in which rectal DVH goals were $V_{18.1\%} < 50\%$, $V_{29\%} < 20\%$, $V_{32.6\%} < 10\%$, and $V_{36.3\%} < 5\%$.[434] Grade 3, 2, and 1 rectal toxicities were seen in 0%, 2%, and 12.5% of patients, respectively. Persistent rectal bleeding was not observed. In another study, after SBRT (9.5 Gy × 4), acute grade 1 to 2 and 3 rectal toxicity occurred in 33% and 0% of patients, respectively, and late grade 1 to 2 and 3 acute genitourinary toxicity occurred in 8% and 0%, respectively.[435] For patients treated with permanent interstitial brachytherapy[436,437] or afterloaded high-dose rate brachytherapy[438] for prostate cancer (either as monotherapy or as a boost), the dose–volume exposure of rectum has been correlated with late rectal toxicity. Combined external beam radiation and brachytherapy may lower the threshold for rectal toxicity after prostate brachytherapy.[439]

Recommended Dose–Volume Limits

For patients undergoing radiation therapy in which the rectum is irradiated, it is recommended to limit the rectal V_{50}, V_{60}, V_{65}, V_{70}, and V_{75} to <50%, 35%, 25%, 20%, and 15%, respectively. Although the data supporting these dose constraints primarily are from prostate cancer patients treated with conventional radiotherapy, studies of patients undergoing IMRT for prostate cancer suggest similar dose constraints.[440]

Future Studies

Future studies should be directed at achieving accurate dose–volume distributions for the rectum, which is a mobile, distensible structure, and correlating these dosimetric characteristics with toxicity. More robust data are needed for hypofractionated radiation delivery to the rectum, as with SBRT or HDR brachytherapy, as well as with low-dose brachytherapy and combined modality approaches.

Toxicity Scoring Criteria

The CTCAE v. 4.0[92] or RTOG scoring criteria can be used to grade rectal toxicity.

Urinary Bladder

Clinical Significance

The bladder is a highly distensible organ that collects urine. Symptoms from late radiation-related toxicities include increased urinary frequency, hematuria, and dysuria. Necrosis, contracted bladder, and hemorrhage are less common, severe effects. Perhaps, late bladder toxicity is underreported due to its long latency as well as toxicity being attributed to more common causes.

End Points

Bladder injury can be broadly classified as focal damage (e.g., bleeding) or more global injury (e.g., reduced bladder capacity with secondary urinary frequency). Acute side effects from incidental bladder irradiation are common and include urinary frequency, urgency, and dysuria (symptoms that may also reflect acute urethral toxicity). Late effects attributable to global injury include dysuria, frequency, urgency, contracture, spasm, reduced flow, and incontinence. In contrast, late effects arising from focal injury include hematuria, fistula, obstruction, ulceration, and necrosis.

Challenges Defining Volumes

The bladder is a mobile and distensible structure, depending upon the volume of urine within the bladder. Postvoid residuals may vary due to variable emptying and constant filling. In contouring the bladder, either the volume of the bladder and contents or the bladder wall alone can be segmented (with the latter more representative of a surface).

Dose/Volume/Toxicity Data

Because the bladder is mobile and distensible, determining accurate dose–volume (or dose–surface) constraints is challenging. Detailed dose–volume (or dose–surface) constraints have not been published, in part because of the complexities of assigning dose–volume or dose–surface metrics to a mobile, distensible structure. Whole-bladder tolerances have been mostly studied in patients with urinary bladder cancer, whereas partial bladder tolerances have been mostly studied in patients with genitourinary (mostly prostate) and gynecologic cancers.[441]

For whole-bladder irradiation, doses in excess of 60 Gy, particularly with fraction sizes >2 Gy and/or accelerated radiation regimens, result in a significant risk of grade 3 or higher late toxicity. Risks are lower when the whole bladder receives 45 to 55 Gy followed by a boost to >60 Gy to a portion of the bladder,

though toxicity risk has not been correlated to dose–volume metrics. With prostate cancer treated to high doses (≥72 Gy), the inferior portion of the bladder (e.g., trigone area) also receives ≥70 Gy. This tends to be well tolerated with respect to bladder toxicity. Arguably, the urinary toxicity that does develop after radiation is due in part to the prostatic urethra receiving suprathreshold doses.

Mean bladder dose and area under the DVH were significant predictors of grade ≥2 genitourinary toxicity in a study of 503 prostate cancer patients.[442] In a study of 296 prostate cancer patients (in whom the bladder was contoured as whole organ, after drainage and infusion of 120 mL of saline), no bladder dose–volume relationships were associated with the risk of grade ≥2 genitourinary toxicity.[440]

Factors Affecting Risk

Prior pelvic surgery can result in increased risk of bladder toxicity as a direct result of bladder or urethral trauma and/or denervation of the bladder, which can cause urinary hesitancy or retention, resulting in overflow incontinence.[441] Patients receiving anticoagulants may be at greater risk of hematuria. Cytoxan, independently or with radiation, can cause chronic hemorrhagic cystitis, incontinence, contractions, and vesicoureteral reflux. Radiation-sensitizing chemotherapy may increase risk of acute and late bladder toxicity, though data supporting this are lacking.

Mathematic/Biologic Models

Quantitative mathematic modeling of bladder toxicity is lacking.

Special Situations

SBRT for prostate cancer is an emerging investigative approach. In one study, after SBRT (7.25 Gy × 5), grade 1 to 2 genitourinary toxicity occurred in 28%, and grade 3 toxicity was reported in 3% of patients (two patients required cystoscopies and dilation procedures for dysuria).[434] Urinary incontinence, complete obstruction, or persistent hematuria was not observed. In another study, after SBRT (9.5 Gy × 4), acute grade 1 to 2 and 3 acute genitourinary toxicity occurred in 71% and 0% of patients, respectively, and grade 1 to 2 and 3 late acute genitourinary toxicity occurred in 11% and 5%, respectively; grade 3 toxicity included temporary urinary catheterization and intermittent self-catheterization.[435]

Recommended Dose–Volume Limits

For whole-bladder radiation, the reported risks of grade 3 or higher toxicity in doses of 50 to 60 Gy range from ≤5% to 40%. This variation is likely attributable to the challenges of correlating toxicity with dose delivered to a mobile structure, which is even more problematic when correlating partial volume exposures to toxicity. With the caveat of these issues, bladder constraints of approximately 15%, 25%, 35%, and 50% receiving ≥80, ≥75, ≥70, and ≥65 Gy, respectively, as recommended in the RTOG 0415 study of prostate cancer, are suggested. The protocol advises an empty bladder at the time of simulation and treatment; the bladder is segmented from the base to the dome.

Future Studies

Studies that incorporate the changing size and shape of the bladder may provide a better understanding of the dose–volume tolerance of the bladder. Incorporating day-to-day variation with adaptive planning DVHs and/or use of deformable modeling would be informative. More detailed studies are needed to assess regional variation in radiation susceptibility (i.e., trigone vs. dome).

Toxicity Scoring Criteria

The CTCAE v. 4.0 or RTOG scoring criteria can be used to grade genitourinary toxicity.

Penile Bulb

Clinical Significance

Radiation dose to the penile bulb can affect erectile function, as a direct result either of damage to this structure or of damage to surrounding structures, whose radiation-induced damage is correlated with the dose exposure of the penile bulb. The most common scenario in which the penile bulb is irradiated is in the treatment of prostate cancer. IMRT is often used to minimize the dose to the penile bulb.[443,444]

End Points

Erectile dysfunction reported by the patient can be the result of treatment or other confounding factors including age, medications (particularly hormonal therapy), or comorbid conditions (e.g., diabetes, peripheral vascular disease, hypertension). Objective diagnostic tests can be performed to help establish the etiology of erectile dysfunction; these include nocturnal penile tumescence, somatosensory-evoked potentials, bulbocavernosus reflex latency, penile electromyography, color duplex Doppler ultrasound, dynamic infusion

cavernosometry, and pharmacologic testing.

Challenges Defining Volumes

The anatomy of the pelvic floor is challenging to visualize on CT or MRI, and hence, definition of the penile bulb is somewhat subjective. The QUANTEC authors recommend defining the penile bulb as the most proximal portion of the penis sitting immediately caudal to the prostate.[445]

Dose/Volume/Toxicity Data

Several studies have investigated dose–volume parameters to predict risk of erectile dysfunction. In several studies, no correlation was discerned for penile bulb dose and erectile function.[443,446,447] In one study, attempts were made to reduce the dose to the penile bulb (mean dose of 25 Gy), and thus, few patients received high dose to the penile bulb.[443] In another study of 70 patients, no correlation was found for mean dose or maximal dose to the penile bulb, penile crura, or superior most 1 cm of the penile crura; DVHs were also compared and found to be similar.[447]

In a small (21 patients), early study from University of California, San Francisco, patients receiving a D_{70} of <40%, 40% to 70%, and >70% to the penile bulb had a 0%, 80%, and 100% risk, respectively, of experiencing radiation-induced impotence.[448] In a study (29 patients) from Thomas Jefferson University, several dose–volume metrics were analyzed; a $D_{30} > 67$ Gy, $D_{45} > 63$ Gy, $D_{60} > 42$ Gy, and $D_{75} > 20$ Gy to the proximal penis were correlated with increased erectile dysfunction as well as decreased ejaculatory function.[449] In a study from Royal Marsden Hospital, a $D_{90} > 50$ Gy to the penile bulb was associated with significantly worse erectile function, whereas D_{15}, D_{30}, and D_{50} showed a similar (albeit not significant) trend toward increased doses in impotent versus intermediately potent versus potent patients.[450] The largest study (158 patients) to date to investigate penile bulb dose is an analysis of the RTOG 9406 dose escalation study.[451] A median dose of ≥52.5 Gy was associated with a greater risk of impotence (50% vs. 25% at 5 years).

Factors Affecting Risk

The etiology of erectile dysfunction following radiation is likely multifactorial. In additional to radiation effects, pretreatment erectile function, diabetes, smoking history, and a history of hypertension have been implicated as important factors affecting risk, though the data to date have been somewhat

conflicting.[450]

Special Situations

Hormonal therapy, which is commonly used in patients with early-stage intermediate- to high-risk prostate cancer or advanced-stage prostate cancer, in and of itself can result in erectile dysfunction. However, the interaction (if any) of hormonal therapy and dose–volume delivery to the penile bulb is not well established.[445] Proton therapy is a well-established treatment approach for prostate cancer and is becoming more widely utilized as more proton centers are developed. Although proton therapy can reportedly lower penile bulb dose, the impact on erectile dysfunction is unknown.[452] Proton therapy may reduce postradiation testosterone suppression.[453] Interstitial brachytherapy (either with high-dose rate sources using afterloaded catheters or with permanent low-dose rate seeds) is a standard radiation modality as well. Data correlating erectile function with penile bulb dose from brachytherapy are sparse. In one study, there was no correlation between the penile bulb dose and postbrachytherapy erectile dysfunction.[454] SBRT for prostate cancer is an emerging investigative approach. The impact of hypofractionated SBRT on erectile dysfunction or the dose–volume parameters predictive of risk after prostate SBRT are not well studied. In one small study of 32 patients, penile bulb dose did not correlate with erectile dysfunction.[455]

Recommended Dose–Volume Limits

Based on published data for photon external beam radiation, the QUANTEC authors recommend keeping the mean dose to 95% of the penile bulb below 50 Gy and limiting D_{70} and D_{90} to 70 and 50 Gy, respectively.[445]

Future Studies

Studies should be directed at better anatomic definition of the putative anatomic sites impacted by erectile dysfunction and rigorous prospective correlation of dose–volume parameters with erectile dysfunction.

Toxicity Scoring Criteria

Pre- and posttreatment assessment of erectile dysfunction should be performed using the International Index of Erectile Function Scale.[445]

COMPOSITE SUMMARY OF DOSE/VOLUME/OUTCOME DATA

Table 14.11 summarizes the dose/volume/outcome findings in the QUANTEC reviews. Note that clinicians must understand the clinical situations from which the QUANTEC recommendations were derived, and there is no substitute for reading the original QUANTEC papers. At the same time, clinical judgment as applied to a specific patient is essential. In addition to the QUANTEC papers, the Emami paper continues to play an important role in estimating normal tissue toxicity during radiotherapy. Finally, as more comprehensive dose/volume/outcome data are developed—particularly in combination with emerging and evolving chemotherapy regimens—the radiation oncologist will need to continually and critically keep abreast of the clinical literature on normal tissue toxicity. There is an ongoing effort to perform a similar dose–volume outcome summary for organs that are of particular interest for pediatric patients (PENTEC), but no information is available from that initiative.

CLINICAL APPLICATION, LIMITATIONS, AND IMPLICATIONS OF QUANTEC

Implications for Understanding the Underlying Mechanisms of Radiation-Induced Normal Tissue Injury

The consistent structure of the Emami dose–volume limits, and the application of that information to predictive models, may be taken to imply a uniform mechanism of radiation-induced injury. The diversity of the structure of the information obtained in the QUANTEC review suggests a more diverse mechanism of radiation-induced injury. An interorgan comparison of dose–response functions from the QUANTEC review is interesting (Fig. 14.15) and may have implications for our understanding of radiation-induced normal tissue injury.

- There are marked variations in the dose–response curves for different organs, suggesting that there are different mechanisms for radiation-induced injury in different organs and/or that the end points selected for the different organs reflect a varied type of injury.
- Organs that are classically considered structured in series (e.g., spinal cord, optic nerve, and small bowel, analogous to electrical circuits in series) have

steep dose–response curves at doses beyond an apparent critical threshold. This is expected based on our understanding of the structure/anatomy of the series of organs: damage to a functional subunit can render the entire structure dysfunctional.

- Several neural structures exhibit a similar threshold dose for injury: ≈55 to 60 Gy (corresponding to a BED of ≈100 for an α/β ratio of 3 Gy) for the brain, brainstem, optic nerve, and spinal cord. This suggests that there may be a common mechanism of injury in these structures. Because all of these organs are dependent on the vasculature, it is tempting to implicate vascular injury as the common target for these organs.
- Organs that are classically considered structured in parallel (e.g., lung, liver, parotid, and kidney, analogous to electrical circuits) experience injury at far lower doses and have more gradual dose–response curves compared to series organs. The presence of injury at lower doses suggests that a different mechanism of injury is occurring in these organs as compared to series organs. It appears that these organs each have critical components that are more sensitive to the radiation than are the critical components within the neuronal tissues. It is thus tempting to conclude that subunits such as hepatocytes, nephrons, and alveoli are relatively radiation sensitive.
- During heterogeneous organ irradiation, the predictive value of mean organ dose in some parallel-structured organs is interesting but counterintuitive. Consider the lung. Relatively uniform fractionated whole-lung doses as high as 15 to 23 Gy have a very low risk of symptomatic pneumonitis. Thus, the lung's "functional subunit" must generally be able to tolerate these doses. However, heterogeneous lung irradiation to a MLD of ≈15 to 23 Gy is associated with a 10% to 25% risk of symptomatic pneumonitis. Thus, during heterogeneous lung irradiation, it is likely that the mean dose is merely a surrogate for the percent of lung exposed to various other doses of radiation. The same may be true in other parallel organs as well.

TABLE 14.11 QUANTEC SUMMARY: CLINICAL DOSE/VOLUME/OUTCOME DATA

Organ	Volume Segmented	Irradiation Type (Partial Organ Unless Otherwise Stated)[a]	End Point	Dose (Gy), or Dose–Volume Parameters[a]		R (%
Brain	Whole organ	3DCRT	Symptomatic necrosis	D_{max}	<60	<

	Whole organ	3DCRT	Symptomatic necrosis	D_{max}	72	5
	Whole organ	3DCRT	Symptomatic necrosis	D_{max}	90	1
	Whole organ	SRS (single fraction)	Symptomatic necrosis	V_{12}	<5–10 mL	<
Brainstem	Whole organ	Whole organ	Permanent cranial neuropathy or necrosis	D_{max}	<54	<
	Whole organ	3DCRT	Permanent cranial neuropathy or necrosis	$D_{1–10\ mL}$	≤59	<
	Whole organ	3DCRT	Permanent cranial neuropathy or necrosis	D_{max}	<64	<
	Whole organ	SRS (single fraction)	Permanent cranial neuropathy or necrosis	D_{max}	<12.5	<
Optic nerve/chiasm	Whole organ	3DCRT	Optic neuropathy	D_{max}	<55	<
	Whole organ	3DCRT	Optic neuropathy	D_{max}	55–60	3
	Whole organ	3DCRT	Optic neuropathy	D_{max}	>60	>
	Whole organ	SRS (single fraction)	Optic neuropathy	D_{max}	<12	<
Spinal cord	Partial organ	3DCRT	Myelopathy	D_{max}	50	0
	Partial organ	3DCRT	Myelopathy	D_{max}	60	6
	Partial organ	3DCRT	Myelopathy	D_{max}	69	5
	Partial organ	SRS (single fraction)	Myelopathy	D_{max}	13	1
	Partial organ	SRS (hypofraction)	Myelopathy	D_{max}	20	1
Cochlea	Whole organ	3DCRT	Sensory neural hearing loss	Mean dose	≤45	<
	Whole organ	SRS (single fraction)	Sensory neural hearing loss	Prescription dose	≤14	<
Parotid	Bilateral whole	3DCRT	Long-term parotid	Mean dose	<25	<

	parotid glands		salivary function reduced to <25% of pre-RT level			
	Unilateral whole parotid gland	3DCRT	Long-term parotid salivary function reduced to <25% of pre-RT level	Mean dose	<20	<
	Bilateral whole parotid glands	3DCRT	Long-term parotid salivary function reduced to <25% of pre-RT level	Mean dose	<39	<
Pharynx	Pharyngeal constrictors	Whole organ	Symptomatic dysphagia and aspiration	Mean dose	<50	<
Larynx	Whole organ	3DCRT	Vocal dysfunction	D_{max}	<66	<
	Whole organ	3DCRT	Aspiration	Mean dose	<50	<
	Whole organ	3DCRT	Edema	Mean dose	<44	<
	Whole organ	3DCRT	Edema	V_{50}	<27%	<
Lung	Whole organ	3DCRT	Symptomatic pneumonitis	V_{20}	≤30%	<
	Whole organ	3DCRT	Symptomatic pneumonitis	Mean dose	7	5
	Whole organ	3DCRT	Symptomatic pneumonitis	Mean dose	13	1
	Whole organ	3DCRT	Symptomatic pneumonitis	Mean dose	20	2
	Whole organ	3DCRT	Symptomatic pneumonitis	Mean dose	24	3
	Whole organ	3DCRT	Symptomatic pneumonitis	Mean dose	27	4
Esophagus	Whole organ	3DCRT	Grade 3 or higher acute esophagitis	Mean dose	<34	5

	Whole organ	3DCRT	Grade 2 or higher acute esophagitis	V_{35}	<50%	<
	Whole organ	3DCRT	Grade 2 or higher acute esophagitis	V_{50}	<40%	<
	Whole organ	3DCRT	Grade 2 or higher acute esophagitis	V_{70}	<20%	<
Heart	Pericardium	3DCRT	Pericarditis	Mean dose	<26	<
	Pericardium	3DCRT	Pericarditis	V_{30}	<46%	<
	Whole organ	3DCRT	Long-term cardiac mortality	V_{25}	<10%	<
Liver	Whole liver—GTV	3DCRT or whole organ	Classic RILD	Mean dose	<30–32	<
	Whole liver—GTV	3DCRT	Classic RILD	Mean dose	<42	<
	Whole liver—GTV	3DCRT or whole organ	Classic RILD	Mean dose	<28	<
	Whole liver—GTV	3DCRT	Classic RILD	Mean dose	<36	<

	Whole organ	3DCRT	Severe erectile dysfunction	D_{90}	<50	<
	Whole organ	3DCRT	Severe erectile dysfunction	$D_{60–70}$	<70	<

Clinically, these data should be applied with caution. Clinicians are strongly advised to use the individual QUANTEC articles to check the applicability of these limits to the clinical situation at hand. These end points largely do not reflect modern IMRT.

[a]All at standard fractionation (i.e., 1.8–2.0 Gy per daily fraction) unless otherwise noted.

[b]For optic nerve, the cases of neuropathy in the 55–60 Gy range received ~59 Gy (see optic nerve paper for details). Excludes patients with pituitary tumors where the tolerance may be reduced.

[c]Severe xerostomia is related to additional factors including the doses to the submandibular glands.

[d]Nontraumatic brain injury.

[e]With combined chemotherapy.

3DCRT, three-dimensional conformal radiotherapy; D_x, minimum dose received by the "hottest" *x*% (or x mL) of the organ; RILD, radiation-induced liver disease (characterized by anicteric hepatomegaly and ascites, typically occurring between 2 weeks and 3 months after therapy; classic RILD also involves elevated alkaline phosphatase, more than twice the upper limit of normal or baseline value); RTOG, Radiation Therapy Oncology Group; SBRT, stereotactic body radiotherapy; SRS, stereotactic radiosurgery.

NEXT STEPS: HYTEC (HIGH DOSE PER FRACTION, HYPOFRACTIONATED TREATMENT EFFECTS IN THE CLINIC)

A similar methodology to QUANTEC is now being applied to SBRT, in a multidisciplinary effort termed HyTEC: High Dose per Fraction, Hypofractionated Treatment Effects in the Clinic,[457,458] addressing hypofractionated treatments versus the predominantly conventionally fractionated regimens in QUANTEC. In addition, whereas QUANTEC focused primarily on normal tissue tolerance, HyTEC will also address tumor control. This collaboration of physicians, physicists, radiobiologists, and biomathematicians is officially organized as the SBRT Working Group (WGSBRT) within the American Association of Physicists in Medicine (AAPM). The working group received the following charge from AAPM:

> *The radiobiology of hypofractionated treatments may differ considerably from that of standard fractionated treatments, in regards to repair,*

reoxygenation, dose-rate effects, volume effects, fraction size effects, etc. The working group will generate reports, including but not limited to, critically surveying the published data regarding: 1. Tumor response: review of the effect of hypofractionation on local control. 2. Normal tissue response: review of the effect of hypofractionation on normal tissue tolerances. 3. Radiobiology of hypofractionated treatments. 4. Clinical rationales for the diverse prescription schemes in current use (e.g., 20Gy x 3 fractions vs 24Gy x 1 fraction). 5. Standards for reporting outcome, including end points, defining/contouring of target and normal structures, dose definitions.

These studies are well underway, and peer-reviewed publication is expected in late 2017. In an independent effort outside of HyTEC (which includes only existing peer-reviewed data), a series of articles[459,460] presented hypofractionated dose–response models for 10 critical structures: optic pathway, cochlea, oral mucosa, aorta/major vessels, esophagus, chest wall, bronchi, small bowel, and spinal cord.

In the Emami paper,[1] all dose tolerance limits were specified in terms of TD 5/5 and TD 50/5, the dose at which a complication rate of 5% and 50%, respectively, was expected 5 years post radiotherapy. This standardized definition was important for establishing the concept of dose tolerance limits and normal tissue injury. Today, however, we recognize that the rate of normal tissue complications encountered in practice is much lower, typically well under 10% for serious adverse events. In addition, using the profile likelihood[461] or bootstrap methods,[462] it was apparent that the lack of clinical data at doses producing a 50% complication resulted in broad confidence intervals at these high-dose/high-risk levels. In contrast, the confidence in the models was reasonably good at the low complication rates encountered in clinical practice. Specific details regarding the models for each of the 10 critical structures are presented, although the focus is on simplicity and clinical utility, as in the Emami study and QUANTEC.

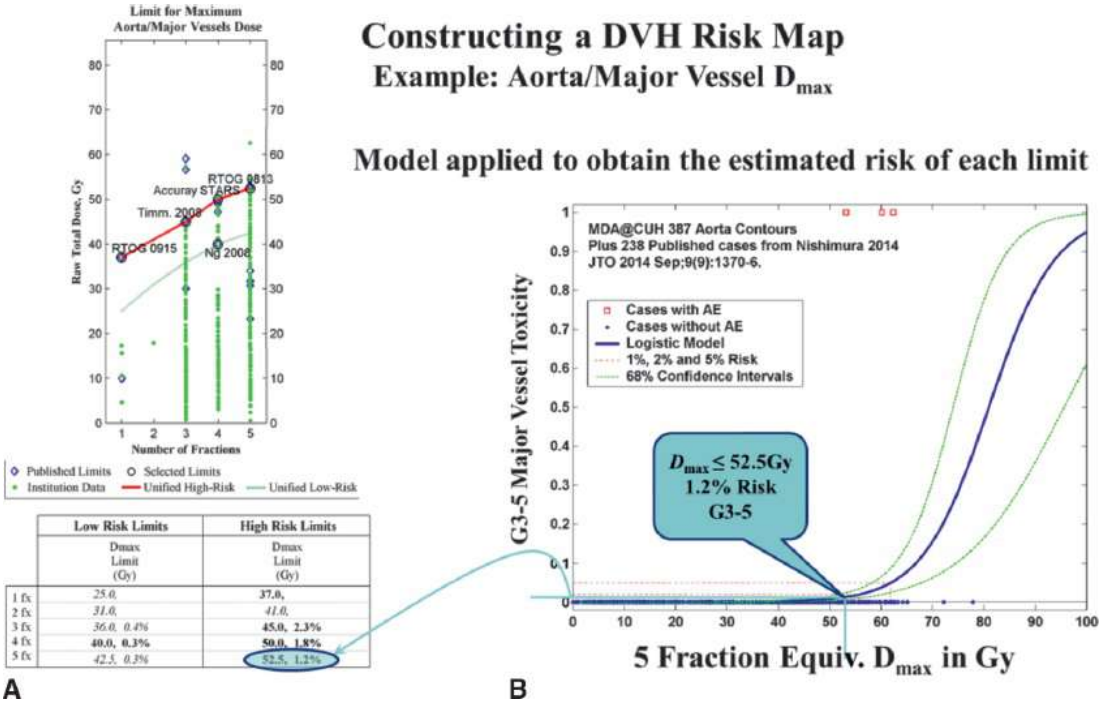

FIGURE 14.16. Construction of the DVH Risk Map for maximum point dose of aorta/major vessels in 1 to 5 fractions. **A:** The portion of the DVH Risk Map corresponding to aorta/major vessel maximum point dose; datapoints in this figure are only from the newer dataset.[463] **B:** The dose–response model. The red squares represent the D_{max} doses corresponding to the grade 3 to 5 complications, whereas the *green* and *blue dots* correspond to the noncomplications. All published dose tolerance limits are shown as *blue diamonds*, and a selected subset is circled and labeled to show a high-risk (*solid red line*) and low-risk trend (*dashed green line*). The tabular portion of the figure shows the numerical values of each selected dose tolerance limit, as well as the corresponding risk estimate from the logistic model. Because the median number of fractions was 5, the model was constructed in terms of 5-fraction equivalent dose with the linear-quadratic model and α/β = 3 Gy and converted back to effective dose in 1 to 5 fractions for the 5 rows in the table. No risk estimates were provided for 1 and 2 fractions because that data were too sparse. In light of the extremely low-risk values for the low-risk trend line (all less than half a percent), an alternate low-risk trend line was selected in Figure 14.17, which is closer to 1% to 2% risk.

FIGURE 14.17. DVH Risk Map for aorta/major vessels in 1 to 5 fractions, including dose–volume data from 625 aorta or other major vessel contours, combined from both datasets.[463,464] From left to right, the 5 panels present data for V_{25Gy}, $D_{4\ cc}$, $D_{1\ cc}$, $D_{0.05\ cc}$, and D_{max}. All other annotations are the same style as described in the legend of Figure 14.16. In comparison to the Emami TD 5/5 and TD 50/5, these low-risk levels are about 1%, and the high-risk levels are about 2%, reflecting the evolution over the past 25 years, from the notions of 5% and 50% risk toward lower levels of around 1% to 2% risk encountered in today's clinical practice. Caution must be advised as these data are from only two institutions, and the outcomes may depend strongly on the exact treatment techniques employed; the goal of HyTEC is to generalize results such as these by combining many such datasets and to determine insights into the factors affecting outcomes by detailed comparisons of the studies.

As an example of this approach, Figures 14.16 and 14.17 present the results for radiation-induced damage to the aorta/major vessels. Nishimura et al.[464] provided full DVH data for the entire portion of 238 aorta or major vessel contours that received 25 Gy or higher dose. Among the 133 patients whose lung tumor was treated with SBRT in 5 fractions, 3 developed late grade 3 to 5 toxicity in the pulmonary artery. These data were combined with major vessel contours from 387 additional patients who were treated with CyberKnife at the M.D. Anderson Cancer Center at Cooper University Hospital.[463] Logistic dose–response models were generated from the aggregate dataset, and all information was organized into a DVH Risk Map[460] as shown in Figures 14.16 and 14.17.

The actual dose–volume major vessel data points planned for each patient are shown as the green dots in these figures, and the dose–volume points corresponding to the grade 3 to 5 complications are shown as the red squares. These are overlaid onto the published dose tolerance limits (blue diamonds), also including a selected representative low-risk and high-risk subset of those, denoted as the black circles with text descriptions. A high-risk trend line is depicted as the red solid line and the low-risk trend line as the dashed green line; these selections were somewhat arbitrary but now using the clinical datasets, the estimated risk level for each selected limit is interpolated from the dose–response model, as illustrated in Figure 14.16. The upshot is that, although the dose tolerance limits were extracted from a variety of publications, each with its own unique characteristics, the estimated risk levels are all from the aggregate data of these two institutions. Clinical application must carefully consider the relevance of the particular treatment techniques of those two manuscripts as compared to an institution's own patient population. The goal of the HyTEC effort is to combine all appropriate published datasets to more fully characterize the general principles for broad classes of patients while identifying the unique aspects of each dataset to determine factors that affect outcomes.

CONCLUSIONS

The QUANTEC effort is one further step in our field's decades-long effort to better quantify the relationship between dose–volume parameters and clinical outcomes. As the scope of the QUANTEC review was largely limited to organ systems with meaningful dose/volume/outcome data, the review, by itself, is an incomplete tool to guide clinical care. Consistent and clear reporting of dose/volume/outcome data[465] will enable further refinements in clinical guidelines and will hopefully improve patient care.

CHAPTER 15

Methodology of Clinical Trials

Abigail T. Berman, Erin F. Gillespie, Clifton David Fuller, Yiyi Chen, and Charles R. Thomas Jr.

In this chapter, we discuss the design, conduct, and analysis of oncology clinical trials, along the way pointing out particular areas of interest to radiation oncology and reviewing some recent ideas in clinical trials and related research studies. This chapter provides only a brief and essentially nontechnical sketch of the main concepts and current research areas, and we refer the reader to comprehensive texts on clinical trial conduct in oncology for further details. Excellent recent texts, the *Handbook of Statistics in Clinical Oncology*,[1] *Clinical Trials in Oncology*,[2] and *Oncology Clinical Trials: Successful Design, Conduct and Analysis*,[3] provide the fundamentals, as well as up-to-date discussion of new challenges and active research in statistical methods for oncology clinical trials.

Clinical trials enable physicians to advance medical care in a safe, scientific, and ethical manner. Formally defined, clinical trials are a set of procedures in medical research conducted to allow safety and efficacy data to be collected for health interventions.[4] A more detailed definition for our purposes would describe a clinical trial as a prospective study that includes an active intervention, carried out in a well-defined patient cohort and producing interpretable information about the action of the intervention.[5] Although in some ways similar to a well-designed laboratory experiment, the involvement of living human subjects demands adherence to strict ethical principles while also adding to the complexity of interpretation of the results. The last 60 years has witnessed an unprecedented appreciation of the importance of clinical trials and a consequent surge in the number of clinical trials performed. In the field of radiation oncology alone, according to a PubMed search, 376 clinical trials were published in 2010, of which 65 were phase III trials.

Over the course of less than a century, the evidence upon which medicine is practiced has evolved from being entirely empirical to a highly regulated scientific process based upon vigorously designed clinical trials tightly overseen

by numerous scientific and governmental agencies. Cardinal chapters in the history of clinical trial design and implementation include:

- 1747—James Lind's work on the effect of citrus fruits in the prevention of scurvy among sailors in the Royal Navy
- 1863—Austin Flint's use of a placebo group for comparison with an experimental treatment in the treatment of rheumatic fever
- 1947—Nuremburg Codex, a result of the appreciation that much of the medical experimentation performed by physicians in Nazi Germany was both ethically wrong and scientifically uninterpretable
- 1948—The first double-blind trial, performed by the British Medical Research Council, to assess the value of streptomycin in the treatment of tuberculosis
- 1964—Declaration of Helsinki, ethical guidelines for the performance of clinical trials developed by the World Medical Association and frequently updated since
- 2000—Creation of ClinicalTrials.gov Web site, a registry of clinical trials under the auspices of the National Institute of Health (NIH)

The performance of high-quality cancer clinical trials involves the cooperation of multiple bodies, so-called stakeholders, including cancer patients and their families, physicians (who accrue the patients), their operating environment (academic institution or practice), the research team (who run the trial on a day-to-day basis), sponsors (who oversee and fund the trial), independent monitors (to ensure the correct performance of the research team), government regulatory agencies, contract research organizations (CROs, who may carry out specific aspect of the trial such as auditing), and medical insurance companies. Modern clinical trials may often require involvement of translational scientists, clinical psychologists, and experts in quality of life, cost-effectiveness, and other disciplines. The complexity of clinical trials adds to the regulatory work involved; for instance, a multi-institutional federally sponsored clinical trial protocol will require the approval of at least three different research ethics oversight committees (Institutional Review Boards or IRBs): within the group coordinating the trial, at each institution that opens the trial to accrue patients, and at the sponsor.

Although many phase I and phase II trials are carried out by investigators within a single institution, many larger phase II and most phase III trials are generally multi-institutional. Thus, clinical trial investigator networks have emerged as essential players in the performance of large phase II and III clinical trials. The U.S. National Cancer Institute–sponsored cancer cooperative group

program is an example,[6] as are similar groups such as the European Organisation for Research and Treatment of Cancer (EORTC). One cooperative group, the Radiation Therapy Oncology Group (RTOG), founded by Simon Kramer in 1968, is dedicated to trials involving radiation therapy, has activated 460 protocols, and has accrued approximately 90,000 patients to its trials. Early studies sought to answer questions regarding radiation dose and fractionation. As cancer therapy became multimodal, the group addressed questions relating to combining systemic chemotherapy with radiation therapy. The majority of recent trials seek to combine targeted agents with contemporary radiation therapy techniques.[6]

Clinical trials are extremely expensive to perform, with costs continuing to rise as a result of both increased regulatory oversight and greater trial complexity. For instance, it has been estimated that implementation of the European Union's Clinical Trials Directive (laws and regulations relating to implementation of good clinical practice [GCP] in the conduct of clinical trials) led to a doubling of the cost of running noncommercial cancer trials in the United Kingdom.[7] Large phase III trials can cost in excess of $100 million, and as a result, clinical trials are frequently financed by the pharmaceutical industry. An unfortunate consequence is that clinical trials are rarely performed on established "generic drugs" where there is little commercial interest in establishing new indications. Conversely, the performance of rigorous clinical trials contributes significantly to the costs involved in the development of new pharmaceutical agents, which are subsequently reflected in the commercial pricing of the product.

RESPONSIBILITIES OF THE PRINCIPAL INVESTIGATOR

Although much progress has been made over the past several decades since the Tuskegee Study and other shoddy research debacles came to widespread public attention, there persists an inconsistency in the conduct of rigorous research, both preclinical and clinical, to the extent that it is becoming well known that a significant portion of research results are not readily reproducible.[8] The radiation oncology research community is not immune to this quandary and must be committed to improving the research climate on multiple levels.

High-quality research involving human subjects demands accountability on multiple levels, starting foremost with the *responsibilities* of the principal investigator (PI). Although we recommend that prospective PIs proactively

enroll in courses that have been developed by one's IRB, we will briefly summarize some of the essential elements.

All clinical trials must be based on testable objectives that are based upon a sound hypothesis. There should be appropriate end points that can actually measure whether the objectives have been met (or not). The eligibility, trial design, and statistical power (including estimate of the effect size, accrual, specimen availability, imaging interpretation, etc.) must be defined up-front. Bioassays and imaging should be performed by qualified personnel who do not have any knowledge of the outcome for patients enrolled onto the study. The study data must be maintained in a secure database at a recognized institution (not at the PIs' private home server).

The PI is responsible for making sure that research is conducted in a manner that is consistent with the guidelines of the International Council for Harmonisation of Technical Requirements for Pharmaceuticals for Human Use (ICH) by using accepted best practices, also known as good clinical practice (GCP). To participate in the conduct of clinical trials, the PI will need to review and sign the investigator statement (form FDA 1572), which basically is a voluntary commitment to follow the IRB-approved protocol and related requirements, including all applicable federal, state, and institutional regulations. The PI is responsible for controlling all investigational devices and/or agents for a protocol. For the radiation oncologist, this requires a cadre that may include—nurse, research associate, protocol coordinator, regulatory and budget coordinator, medical physicists, dosimetrists, lead radiation therapists, and other oncology coinvestigators. Finally, the PI must be committed to protecting the rights, safety, benevolence, and overall welfare of patients who are evaluated and eventually enrolled onto the trial.

There are core *qualifications* of the PI. Primarily, the PI should possess the necessary qualifications with respect to educational training and experience to make sure that research, including a clinical trial, can be conducted properly and ethically. The PI should be cognizant of the essentials of GCP and be committed with complying. Although intuitive to most readers, it is necessary to reiterate that the PI should be familiar with the use of investigational treatment approaches, including devices and/or agents. The PI should have a serious time commitment to successful execution of the trial. This commitment includes reading and approving the protocol as well as being involved in a rational plan to identify and enroll patients, proactively addressing barriers to the conduct of increasingly common ancillary or translational research components of trials

such as procurement of blood, tissue, and/or novel imaging tests. The PI should have an assessment plan to make sure that the end points are set up to measure the objectives of the trial, especially the primary objective. The PI needs to have a team and the necessary resources to conduct the trial; if not, then it is not ethical to open a trial regardless of the scientific enthusiasm or merit. The PI needs to understand that certain tasks are delegated to qualified members of the research team. There should be an expectation that routine auditing, and expectation by sponsoring organizations as well as government and institutional regulatory bodies, is normal. Finally, it is critical that the PI is committed to evaluating the results and dissemination to the scientific community via a peer-reviewed manuscript submission. Presenting meeting abstracts alone undermines the credibility and impact of cancer research.

All patients must submit truly *informed consent* that includes both verbal and written components. The consent *process* is not purely transactional, but part of a relationship between the patient and the PI. The phases of the consent process include: (a) prestudy review and approval by the IRB; (b) during the recruitment of subjects with a number of caveats that the patient must understand, primarily that any conflict of interest (COI) on the part of the PI is proactively disclosed and that subjects can withdraw from the study at any time without prejudice; (c) prior to beginning the trial, a signed copy of the consent must be given to the patient (or qualified surrogate such as a parent in the case of a pediatric radiation oncology trial) and also remain on file in the official medical record as well as the protocol office; and (d) during the trial, any revised consent form must have IRB approval, and new information that can impact the outcome for patients must be proactively shared.

Earlier, we mentioned the concept of GCP. The essential values of GCP are listed below[9]:

- Comply with ethical principles.
- Minimize risk to human subjects.
- Maintain dignity, welfare, and human rights.
- Accurate investigational study product information.
- Rigorous peer-reviewed protocol.
- IRB review and approval of protocol.
- Bioethics review (either separate or in concert with IRB approval).
- PI must be qualified.
- Research team must be qualified to carry out delegated responsibilities.
- Enrolled patients must sign uncoerced and voluntary informed consent (written

and verbal).

- Data generated must be accurate and verifiable.
- Study records must be kept confidential in a secure environment and readily made available to auditing and/or regulatory authorities.
- Investigational produce functionality and manufacturing standard should be verifiable.
- Quality assurance (QA) and quality control must be in place.

Essential Questions for the PI to Consider (adapted with permission from Lillian Siu, MD and Patricia LoRusso, DO)

1. It is absolutely critical that the PI be clear on why it is of value to perform the trial and what the rationale is. The scientific insights, including the robustness of the preclinical and other published data, must be understood. Is there a gap in theranostic efficacy?
2. If the trial is positive, will a meaningful vertical impact and penetration in the field result? Some trials may prove a proof of concept and others may have a clinical impact. In the latter case, is the PI testing a low-risk strategy in incremental steps such that a new standard of care may result? In radiation, this might be the addition of Manuka honey to prevent radiation-induced oral mucositis. Or, is a higher-risk strategy being tested, which may involve a significant step forward. An example of this would be the addition of pembrolizumab to chemoradiation for locally advanced lung cancer, which is currently a trial concept being developed by the NRG.
3. Where does the trial concept lay within the innovation spectrum? If a low-risk question, will the field really care about the results and is the research question worth the investment in resources (i.e., time, money, and patients)? If a high-risk question, will the feasibility and dissemination be limited to a few very specialized centers?
4. Does the study have a primary clinical end point and what are the pros/cons of candidate end points? It is important to have an idea as to how quick one can determine an early end point (i.e., response rate), reliability (i.e., overall survival), clinical significance, and impact of subsequent factors on the end point (i.e., PFS vs. overall survival). Because no end point will be perfect to show an increase in the therapeutic ratio, the PI should have a rational justification for choosing it.
5. The study must be feasible with respect to scientific, pragmatic, financial, and ethical boundaries.
6. Are you able to assemble the nonphysician investigative team, beginning with an experienced biostatistician? Other component personnel include imaging

and basic science investigators, research nurses, study coordinator, pharmacist, regulatory affairs, and IRB.

- The PI must have dedicated (protected) time to remain engaged in the study.
- Barriers always exist. It is important that the PI learn, early on, which barriers are permanent versus temporary, which require a doable work-around versus a fatal flaw. A mentor who is committed to helping navigate the oncopolitical landscape is valued.
- It should be clear who and what are competing in this research space. Is a more capable investigator at another institution actually more capable of executing your original idea? Are your colleagues as enthusiastic about your concept as you are? Is there a competing institutional and/or multi-institution trial that will limit patients? If so, is this a temporary concern?
- The PI needs to discern if they are ready to start working on the protocol immediately or perhaps at a time in the future. Time management is paramount.

OVERVIEW OF ETHICAL CONSIDERATIONS

Medical ethics are based upon the principles of autonomy (the patient's right to refuse or choose their treatment), beneficence (a practitioner should act in the best interest of the patient), nonmaleficence (first, do no harm), justice (fairness and equality), dignity, and honesty. Without due diligence, physicians may infringe upon these principles when encouraging patient participation in clinical trials. Are the physicians confident that the proposed treatment is beneficial and not harmful? Are the potential subjects fully aware of the implications of participation? Do all segments of the population have equivalent chance to participate and receive potentially better treatment? Despite the universal acceptance of these principles, there have been numerous examples of grossly unethical research being performed in the Western world within living memory. Documents seeking to address these issues include the Nuremberg Code, the Declaration of Helsinki, and the Belmont Report. Emanuel has listed seven requirements that provide a systematic and coherent framework for determining whether clinical research is ethical.[10]

Ethical principles themselves, and the creation of guidelines, are insufficient to ensure the ethical conduct of medical research. Physicians within Nazi Germany performed atrocities despite the existence of German guidelines published in 1931,[11] reflecting the need for legislation. The International Council for Harmonisation of Technical Requirements for Pharmaceuticals for Human

Use (ICH) brought together the regulatory authorities of Europe, Japan, and the United States and experts from the pharmaceutical industry to regulate scientific and technical aspects of pharmaceutical product registration. The ICH guidelines are legally binding in many countries (although not in the United States) and are updated every few years, reflecting the increasing sophistication of the field. An example of a recent addition is the introduction of data and safety monitoring committees (DSMCs), an independent group of experts who monitor patient safety and treatment efficacy data while a clinical trial is ongoing. Another recent advance is the requirement for the registration of clinical trials, at sites such as *ClinicalTrials.gov*. Such registration both improves transparency concerning what clinical trials have been or are being performed and empowers patients to find relevant clinical trials.

OVERVIEW OF TRADITIONAL CLINICAL TRIAL DEVELOPMENT

Traditionally, a new anticancer agent is tested in a three-step process, starting with a small dose-finding trial (phase I), followed by a pilot efficacy trial (phase II), and culminating with a large comparative randomized (phase III) trial. Although this development paradigm was created and established in the era of cytotoxic chemotherapies, it continues to be used today in the era of often less toxic (and possibly not dose dependent) targeted therapies, with some adaptations and innovations that we will discuss later. Here, we review the traditional paradigm without technical details, which can be found in many excellent sources for clinical trial design and conduct.[2,5]

Phase II

The primary purpose of the phase II trial is to determine the response rate of the treatment, seeking early evidence of clinical activity. An important secondary purpose is to gather more robust adverse event (AE) information at the established dose. The primary efficacy end point of the phase II trial has traditionally been tumor response, but duration of response, progression-free survival (PFS), and site-specific activity such as locoregional control are all relevant and increasingly used. Measures of patient survival are usually secondary end points in phase II trials, because of the limited sample size and follow-up duration of these trials. In general, phase II trials usually are not designed to provide definitive evidence that the test treatment is superior to

current options. In fact, phase II trials have traditionally been single-arm studies comparing against a benchmark historical response rate. Reliance on this nonconcurrent external control rate can be problematic.[12–14] Furthermore, patient selection factors can influence the results, for example, overall response rates in a single-institution phase II trials can be significantly higher than in multicenter studies or subsequent phase III controlled trials.[15] Randomized phase II trials have historically had a role in multiarm trials aimed at selecting the best treatment(s) to take forward for further testing[16] and have more recently become favored as a means of providing more reliable pilot efficacy data.[17] However, the preferred approach is changing as described later.

Phase III

Phase III trials are randomized comparisons between a new treatment regimen that has already shown promise in phase I/II trials and the current best standard of care (i.e., the control). Randomization offers a critical advantage over nonrandomized studies. Specifically, randomization balances the distribution of prognostic factors between treatment arms and assures that treatment is assigned independent of these factors, thereby minimizing or eliminating these effects when comparing outcomes by treatment. When randomization is combined with treatment blinding of patients, researchers, or both, then even subjective outcomes can be assessed with minimal bias. Also, in multicenter studies, randomization can balance any systematic bias of the treating physicians or institutions.

Phase III trials can address one of several types of primary questions. For example, a study can be designed to determine if standard treatment is better than the best supportive care. More often, phase III studies are designed to compare a new treatment with the current standard treatment. Phase III studies can also compare two or three different regimens with each other, as well as with standard treatment. Finally, a trial may be designed to demonstrate that a given treatment option is not worse than another by more than a tolerable margin. These “equivalence” trials, more accurately referred to as noninferiority trials, play an important role in the development of less invasive or less burdensome treatment regimens.

The primary end point of a phase III trial is most typically overall survival (time to death from any cause), but other important clinical end points such as disease-free survival (DFS) are increasingly justified. Because these trials aim to definitively demonstrate benefit with respect to these end points, the number of

participants and follow-up period required for the phase III trial is much longer than in phase II trials. Important secondary end points can include locoregional control and other site-specific failure end points, AE profiles, and quality of life measures.

Phase IV

Phase IV trial is also known as postmarketing surveillance trial. Phase IV trials involve the safety surveillance of a drug after it receives regulatory approval for standard use. The safety surveillance is designed to detect any rare or long-term adverse effects over a much larger patient population and longer time period than was possible during the phase I to III clinical trials.

Phase 0 or Window Studies

The goal of phase 0 trials is to evaluate the pharmacodynamics (PD) and/or pharmacokinetics (PK) of an antitumor modality prior to traditional phase 1 studies (see Fig. 15.1 from Murgo et al.[18]).

PD is considered to represent "what the modality does to the body," whereas PK measures "what the body does to the modality," be it radiation and/or a systemic agent.[19] PD parameters may include nadir hematologic counts, nonhematologic toxicity, molecular correlates, and/or imaging end points. PK parameters such as C_{max}, AUC (area under the curve drug exposure), half-life, and clearance all help to quantitate absorption, distribution, metabolism, and/or excretion of an agent. This can impact the bioavailability of an agent that is intended to sensitize radiation. Phase 0 studies can help to refine a target or biomarker assay for drug impact in human samples by incorporating methods developed and validated in representative preclinical models.

Therapeutic clinical trials in radiation oncology typically involve the introduction of new technologies (e.g., the use of stereotactic body radiation for a new indication) or more frequently the novel combination of radiation therapy with a systemic agent. There are unique challenges—biologic and clinical—that characterize clinical trials in radiation oncology compared to those not involving radiation.

Response rate is frequently used in early-phase medical oncology trials to indicate activity; however, because radiation therapy itself is highly effective at shrinking tumors, this end point is not useful in radiation trials. A more appropriate "activity" end point for radiation trials may be PFS, but this itself is often difficult to objectively assess. Modern imaging end points (such as FDG

uptake) show promise as early readouts of activity, but still require vigorous validation for individual disease sites. Furthermore, efficacy and toxicity end points in radiation trials are dependent on multiple biologic factors including size of the target, proximity of tumor to sensitive normal tissues, accuracy of target volume definition, degree of patient immobilization, dose of radiation, and fractionation scheme. Consequently, quality assurance measures are an essential feature of radiation trials, especially in the multi-institutional setting.[20] Inadequate QA and lack of consistency in radiation delivery have led to the conclusions obtained from large expensive clinical trials being questioned.[21–27] As a recent example in the RTOG trial 9704, which evaluated postoperative adjuvant chemoradiation treatment of pancreatic cancer, subtle protocol violations in target definition influenced both toxicity and survival.[28]

In medical oncology trials, AEs typically occur during or within days of completing treatment. In contrast, toxicity following radiation therapy follows a biphasic course, early (within 3 months of starting treatment) and late (months to years later). Late toxicity is typically irreversible and hence important in determining the tolerability of an experimental treatment. Although utilizing long-term toxicity as the primary end point in clinical trials is not practical, it is nonetheless imperative to collect and report robust information on long-term outcomes from radiation therapy trials. In fact, even in phase I radiation therapy trials, the follow-up period can be significantly longer than for those evaluating chemotherapy. A recent approach to dose escalation in phase I trials that considers late toxicities when deciding whether to advance to the next dosing level is discussed later.[29]

A further difference relates to the population studied. In medical oncology early-phase trials, participants have often received several lines of treatment and lack further therapeutic options. In contrast, patients on phase I radiation trials typically receive full-dose radiation treatment and subjects may be treatment naïve. Furthermore, phase I trials in medical oncology are frequently “first-in-human” experience for the agent; toxicity is unpredictable and PK studies are essential. Conversely, most multimodality phase I trials in radiation oncology involve systemic agents that have already been through extensive clinical testing; systemic toxicity is known and PK studies are unnecessary. The purpose of the trial is to define the extent of local toxicity within the radiation field; consequently, radiation oncology phase I trials are organ specific. A recent study demonstrated that in reality, radiation phase I trials rarely utilize “first-in-human” agents, are associated with qualitatively predictable toxicity, and are

comparatively safe.[30]

STATISTICAL ISSUES IN CLINICAL TRIAL DESIGN

Patient Population Definition and Stratification

A key issue in a clinical trial is a well-defined patient population to which the potential therapy applies. This is typically defined in terms of traditional disease characteristics reflecting putative prognosis, such as stage or its components. Increasingly, tumor pathology or marker features may be included. In any case, these must be unambiguously defined. Because factors defining eligibility are often critically related to prognosis, any randomized comparative study may use a stratified randomization approach in order to ensure equal representation of prognostic risk among treatment arms. Stratification factors need to be limited to a reasonable number, because the total number of strata equals the product of the number of categories for each. For example, in a recently completed RTOG for prostate cancer, stratification factors consisted of two levels of PSA (<4 vs. 4 to 20), three cell differentiation categories (well, moderate, poor), and nodal status (N0 vs. NX). The possible combinations of these variables create $2 \times 3 \times 2 = 12$ strata within which treatments are to be balanced in allocation.

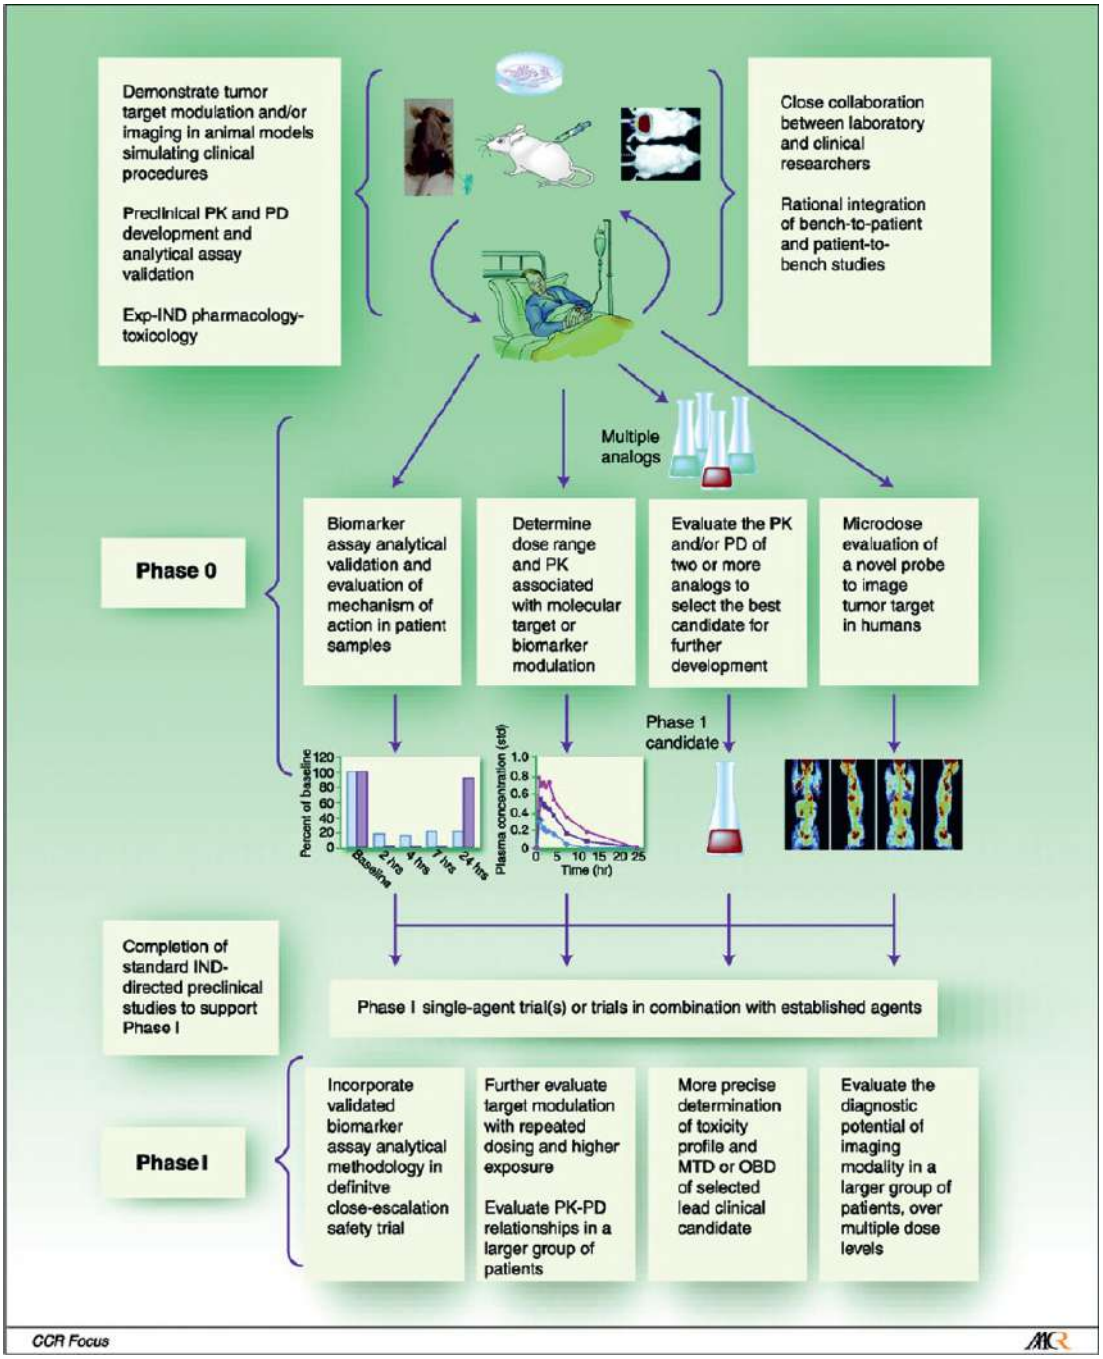

FIGURE 15.1. Preclinical, phase 0, and phase 1 clinical trial development. (From Murgo AJ, Kummar S, Rubinstein L, et al. Designing phase 0 cancer clinical trials. *Clin Cancer Res* 2008;14:3675–3682.)

Randomization

Randomization is used differently in different phases of development, but serves a similar purpose, which is to render treatment groups similar with respect to factors other than treatment that can influence outcomes. In phase I trials, there

typically are not comparative groups, although there are situations where parallel cohorts of patients are being evaluated, and thus randomization into cohorts assures that these groups can be compared later for response biomarkers or other factors of interest. In phase II trials, randomization has been used in two similar but distinct ways. First, so-called selection designs have been used to help decide which of several potential candidate treatments to take forward to further definitive testing.[16] In these trials, interest is not in statistically significant differences between treatments but rather the ability to nominally rank candidates in terms of best potential efficacy. It can be shown that this approach has high probability of identifying the most likely superior arm but at the cost of false-positive findings, particularly if misused.[31] A second and more recent role of randomization in phase II trials is to provide evidence, albeit at a less stringent criteria, that a test treatment is indeed promising.[17] In phase III, randomization is critical for definitive unbiased evaluation.

With regard to implementation, randomization assignments can be simple or, more commonly, implemented using blocking or dynamic approaches with respect to balancing treatment arms by key factors, such as stratification variables mentioned above. A number of proven methods are available.[5]

It is important to note that investigators must protect against practices that can erode or nullify the benefits of randomization. Any breach of the random assignment process has an irreparable effect on the validity of the trial. Second, a large number (or differential number per treatment arm) of patient withdrawals can make the validity of the comparison suspect. Similarly, differential follow-up and consequently ascertainment of patient status between treatment arms can bias the treatment effect estimate. Third, bias in assessment of outcomes can have a major impact on the estimated treatment effect, and thus objective outcome measures and blinding of treatment assignment become important. Treatment assignment blinding is not feasible for radiotherapy and most chemotherapy regimens, but can be used for many agents. In either case, and in particular for studies that cannot be blinded (among patients or caregivers), unambiguous, objectively defined end points are essential. In cases where determination of the end point involves possible observer subjectivity, such as when reading a diagnostic scan to determine disease progression, keeping assessors unaware of treatment assignment may be necessary.

Phase 1 Studies

The phase team includes the patients, caregivers, biostatisticians, oncologist

investigators, clinical trial nurses, research associates and data coordinators, pharmacologist and/or pharmacists, and imaging and pathology specialists, along with sponsoring agencies (government, industry, academic, or combinations thereof).

There are multiple types of phase 1 trials. They may be testing an investigational agent plus another investigational agent, investigational agent plus an approved modality (i.e., RT) or agent(s), an approved modality (i.e., RT) or agent plus another approved agent(s), an approved or investigational agent with a PK focus (i.e., adding a PARP inhibitor), or an approved or investigational agent with a PD focus (e.g., evaluation using functional imaging).

If RT is tested with a systemic agent, there should be a preclinical rationale to pursue an early-phase human trial. Ideally, there should be convincing preclinical data that indicate the combination is either efficacious (radiation sensitization) or show no overlapping toxicities (toxicity independence). There should be evidence of *in vitro* radiosensitization in human tumor cell lines, *in vivo* radiosensitization in human tumor models, lack of sensitization of normal tissues, and preclinical use of clinically relevant doses and schedules of agents and RT (add Blackstock oxaliplatin/RT preclinical scheduling paper).

The primary objective is to determine the maximum tolerated dose (MTD) based on scientifically defined dose-limiting toxicities (DLTs). The MTD found in phase I stage is often used as the recommended phase II dose(s) (RP2D). DLT is often defined as a toxicity that is considered serious, typically based on standard criteria CTCAE (most recent version). The DLT must be defined in advance prior to beginning the trial, is protocol-specific, and is usually based, in the case of a systemic agent, on toxicity seen in the first cycle. The MTD is a dose level that yields reasonable rate of DLTs in targeting patient populations. It is a dose that is believed to be efficacious and adequately safe. A dose higher than the MTD is unacceptable. The secondary objectives of phase I studies are to define toxicity profile of new therapy(s) or schedule of an existing modality, such as radiotherapy, under evaluation. The PK and PD effects in tumor and/or surrogate tissues can be determined along with a preliminary assessment of antitumor activity.

Phase I

The main objective of the phase I trial is to determine the maximum tolerable dose of an agent to be subsequently used in testing for efficacy. Although initially developed in the setting of drug testing, this concept has been adapted to

test radiation alone and combined drug/radiation regimens. The basic conceptual approach is that of sequential dose increases, or escalation, in small patient cohorts until the treatment-related AE rate reaches a predetermined level or unexpected toxicity is seen. This stepwise testing in phase I trials determines what is known as the MTD, which is putatively the most effective level at which to evaluate efficacy.

The key parameters to be defined at the outset of a phase I trial include patient eligibility criteria, starting dose and the schedule of dose escalation (which should frame the expected MTD), events comprising the AE/toxicity response and the expected MTD, and finally the escalation design plan.[32] By far, the dominant design has been the so-called 3 + 3 approach, where cohorts of 3 patients are exposed to a given dose, and based on the outcomes in that cohort, either de-escalation, escalation, or additional enrollment takes place. There are a large number of other designs, one of which may be particularly suited for radiation therapy trials, as we will discuss shortly. It should be appreciated that the MTD is a relative concept that can change over time. For example, hematologic toxicity may be less dose limiting today than it was before the development of bone marrow stimulators such as erythropoietin and filgrastim.

Design Challenges

When setting up an early-phase RT trial, it is absolutely critical to think about the next step in development. There are several considerations that are paramount, including the following: What should the starting dose be? How many patients should each cohort include? What is the standard therapy for the tumor site being treated? How quickly can doses be escalated? What is the role of conventional chemotherapy? How should surgery (if appropriate) be integrated? How should chemotherapy be integrated? Can the validation of biomarkers be assessed? Is it possible to avoid an unselected subject population in the follow-up phase II to III study?

A phase 1 trial can include RT as the single modality undergoing testing. Often, a second modality, such as concomitant systemic therapy, is included. In the latter case, data that will be helpful for the design of the study should include single-agent PK data from a pragmatic and relevant scheduling regimen such as consideration of continuous dosing during RT versus once-a-week dosing. Single-agent PD data including the agent’s affect (if known) on a molecular target that is relevant to the interaction between RT and radiation are necessary as are safety data.

Dose escalation guidelines have been developed and refined in order to effectively identify the RPTD. Basic principles of dose escalation include starting with a safe starting dose, minimizing the number of patients treated at subtoxic (and thus maybe subtherapeutic) doses, escalating dose rapidly in the absence of toxicity, and escalating dose slowly in the presence of toxicity.

The Fibonacci sequence typically includes three patients per cohort until the DLT is reached; then, additional three patients are accrued at the dose level. Some of the accelerated titration designs attempt to minimize patients within the early dose levels. Typically, a single patient is enrolled at each cohort until ≥grade 2 toxicity, and then the number of patients accrued at the dose level increased to 3 (or perhaps a total of 6 if that turns out to the MTD). Standard dose escalation rules are acceptable especially if multiple agents are being used (including conventional chemotherapy). The *M*aximum *A*dministered *D*ose (MAD) and *M*aximum *T*olerated *D*ose (MTD) can be confusing, and these phrases vary with country. More importantly, the RP2D is often one dose level below that which the DLT occurred in a prespecified proportion of patients (e.g., ≥33%) (Fig. 15.2)

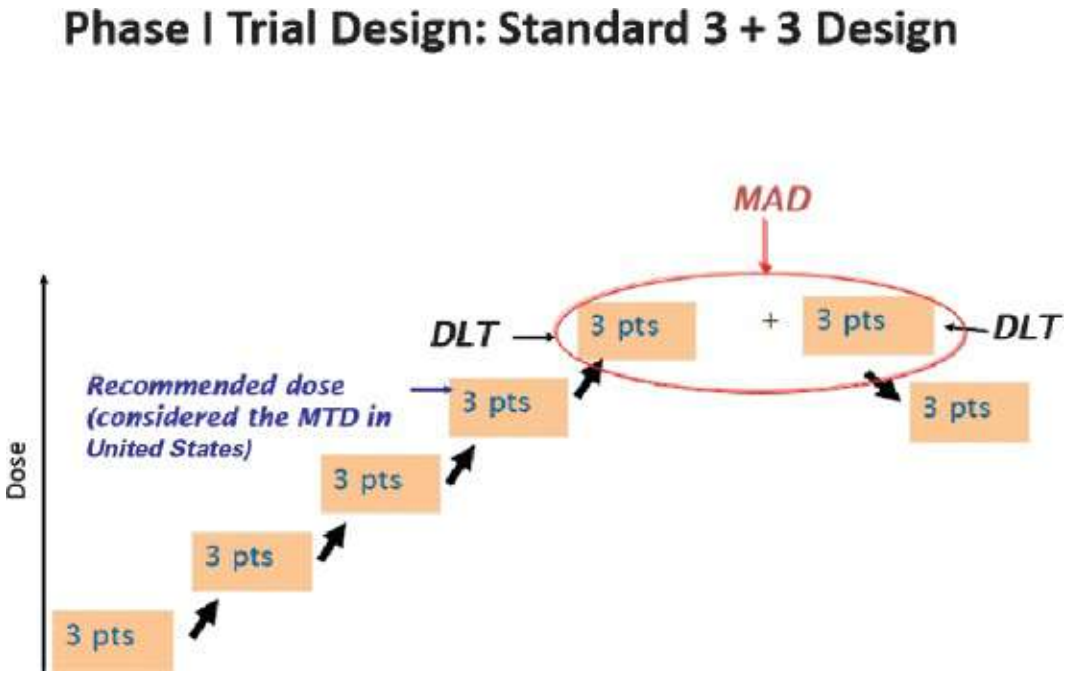

FIGURE 15.2. Example of standard 3 + 3 phase I design.

It is recommended to consider using a toxicity assessment in association with clinical or biologic end points. With targeted small molecular agents, it may be necessary to define the optimal biologic dose (OBD) as opposed to MTD. The

OBD is the *dose associated with a prespecified desired effect on a biomarker. For example, it may be the* modality dose at which ≥20% of patients have inhibition of a key target in tumor/surrogate tissues. It may also be the modality dose at which ≥20% of patients achieve a prespecified immunologic parameter. Caution is advised because the biologic end point is often considered a surrogate for therapeutic effect, and this may not be completely understood during the early drug development period.

Patient selection is important in early-phase study design. For example, the tumor site(s) to be studied needs to be defined because this will impact the assessment of toxicity. Not all normal tissue is equal (as discussed in more detail in Chapter 14). The selection of tumor site may also be impacted by the agent being used in combination with RT, such as the choice to study the epidermal growth factor receptor monoclonal antibody, cetuximab, with radiotherapy in the head and neck setting. Also, are the patients being enrolled onto a phase 1 study going to receive curative or palliative radiotherapy? This will affect total radiation dose and fractionation utilized. This will affect the patient population and perhaps the ability to tolerate combined modality therapy. In general, phase I data are generated from studies that are cancer specific and/or site specific.

Starting dose and schedules of the modality under investigation will need to be defined. If the goal is radiosensitization, then delivery of the agent during as many fractions of radiation is desirable. Timing may be critical. A typical approach especially in the curative setting is to start with a standard radiation dose; however, escalation (or even de-escalation) of the radiation dose may be desirable in certain clinical situations.

A limited dose escalation design is more commonly being used. DLTs may include, though not limited to, the following: grade IV hematologic toxicity, grade III nonhematologic toxicity with exceptions for grade III GI (nausea and emesis) in the setting of upper abdominal RT, unscheduled breaks during the RT course, inability to administer systemic agent, and/or surgical morbidity for trials where the dose escalation component occurs in the preoperative setting.

As stated earlier, not all normal tissues are equal. A parallel track dose escalation design may allow one to test the combination of one (or more) agent(s) plus different doses of RT for different anatomical disease sites. After the RP2D of the dual-targeted agents is identified and thereafter fixed, then the RT dose is escalated.

Lead-in administration of a novel agent, prior to piggybacking onto a standard combined modality backbone, may allow for independent assessment of

toxicity as well as evaluation of a biomarker with respect to proof of principal preliminary exploration of possible mechanisms of target inhibition (see Fig. 15.3).

In addition, this approach may be particularly helpful in selecting patients for phase II studies. Furthermore, an expanded cohort at final dose may allow for a more precise evaluation of biomarker.

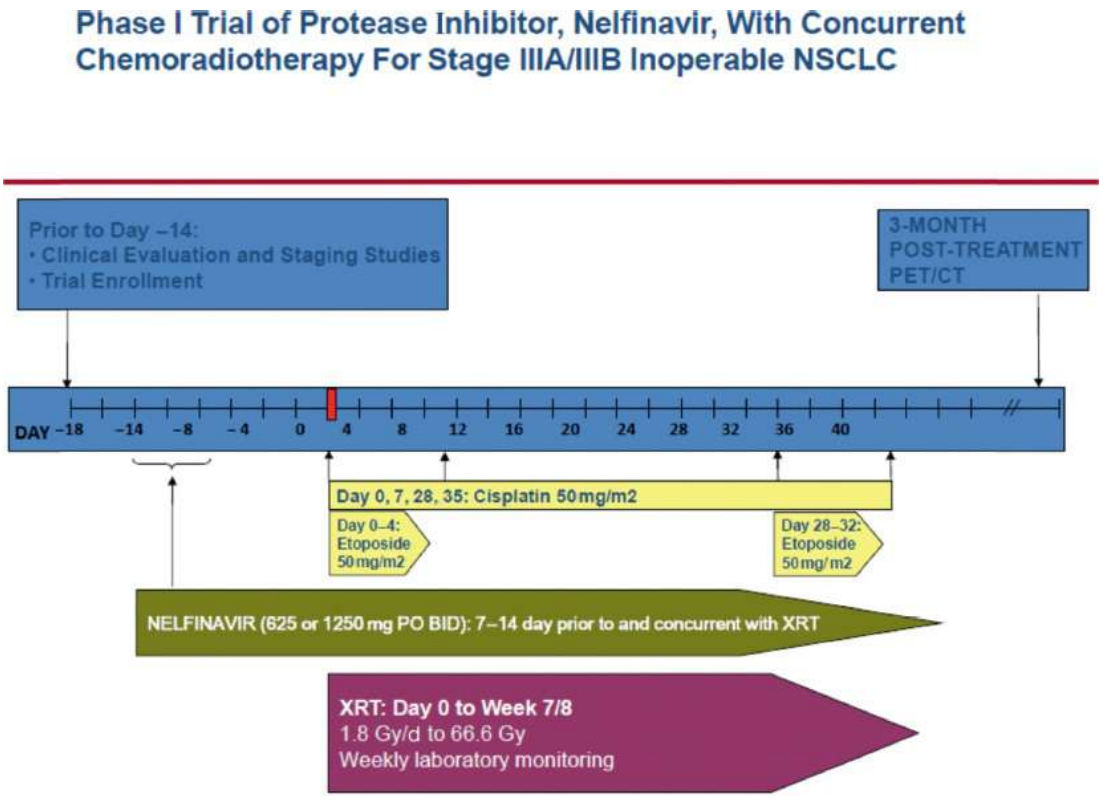

FIGURE 15.3. Example of lead-in administration of a novel agent, which may allow for independent assessment of toxicity as well as evaluation of a biomarker. (Courtesy of Ramesh Rengan.)

End Points

In clinical trials, end points must be unambiguously defined, be assessable and reproducible, and reflect the action of the intervention. Typically, there is a single primary end point in a clinical trial, but there may be numerous secondary end points.

Traditionally in phase II cancer trials, treatment activity has been defined in terms of reduction in tumor burden. The most recent criteria for measuring activity are known as the Response Evaluation Criteria in Solid Tumors, or RECIST.[33] The criteria require the identification of target and nontarget lesions at baseline and their largest single dimensions. Categories of response are then

defined, for example, complete response (CR, disappearance of all target and nontarget lesions and no new lesions), partial response (PR, 30% or greater decrease in the sum of the longest diameter of all target lesions, no progression of nontarget lesions, and no new lesions), and progressive disease (PD, 20% or greater increase in target lesions, progression of nontarget lesions, or the occurrence of new lesions). A patient not satisfying either response or progression criteria is classified as having a stable disease (SD). Those achieving either a CR or PR are typically defined as objective responders, and the proportion of patients responding is then the primary end point of interest. Although widely used, there has long been concern that response defined this way is an inadequate substitute for more clinically relevant and objective end points such as survival time. In one study, <25% of agents that produced tumor response were eventually found to extend survival in comparative trials,[34] whereas another suggested that tumor response is a reasonable surrogate for survival extension.[35] Additional problems with the use of response rates in phase II trials include subjectivity and lack of reproducible assessments.[36]

As mentioned earlier, response is not as frequently used when radiation therapy is the test question, and in any case, other discrete binary end points can readily be used. For example, the proportion free of a given event (i.e., proportion alive, proportion recurrence-free, etc.) at a fixed time landmark, such as 2 years, is a common and straightforward end point.

A more informative end point that is used in many phase II and most phase III trials is the elapsed time from trial entry until occurrence of some event. The most straightforward of these is overall survival time, or time to death from any cause. This simple end point does not depend on adjudication of cause of death and its attendant complexities and naturally corrects for both favorable and unfavorable consequences of treatment. Although it can be verified or even ascertained from public records because of its simplicity, active follow-up per protocol remains of paramount importance. Cause-specific survival end points may also be considered, although as mentioned, assigning cause of death is not simple, and one must account for “other cause” of deaths and whether these have any relationship to treatment. Also, whenever cause-specific deaths or other site-specific failure end points are used, methods for appropriately dealing with competing risks are required.[37,38]

Other commonly used time-to-event end points include DFS (time to recurrence or death from any cause) or PFS (time to disease progression, possibly determined via imaging or other assessments at regular intervals),

although definitions of these are not standardized (e.g., see Hudis et al.[39]), and the specific failure events comprising a given end points should be carefully specified. The main advantage of using DFS or PFS is the more rapid rate of events, leading to a smaller required sample size. In many cancer types, benefit with respect to these end points does not necessarily imply subsequent lengthened survival, although they may still represent clinical benefit for patients. For other disease settings (e.g., adjuvant therapy in colon cancer), DFS is a reliable and well-accepted primary end point that is strongly correlated with survival.[40] This raises the topic of so-called surrogate end points, which are end points upon which treatment benefits can be reliably measured. Various biomarkers and clinical end points have been studied and have been proposed as surrogate end points in clinical trials. Prentice specified the criteria that a surrogate end point must fulfill if it is used to substitute for a clinical end point: The therapeutic intervention must exert benefit on both the surrogate and the clinical end points; the surrogate and clinical end point must be associated; and the effect of intervention on surrogate end point must mediate the clinical effect.[41] An example of a widely studied surrogate marker is prostate-specific antigen (PSA), applied either as a static measure or as dynamic measures (PSA velocity; PSA doubling time; time to PSA nadir, particularly useful after radiation therapy of the intact prostate), to assess time to biochemical failure in patients with nonmetastatic adenocarcinoma of the prostate.[42,43] This continues to be a developing area, and there remain many caveats and cautions regarding surrogate end points in clinical trials.[44]

Statistical Power and Sample Size

The overarching design consideration in clinical trials is to obtain sufficient information about an intervention so that a reliable decision can be made regarding its further development or use. In the classical (e.g., frequentist) statistical hypothesis testing paradigm, one sets up a null hypothesis of no treatment effect and an alternative hypothesis (which one hopes to validate) indicating a treatment effect. The type II or β error equals the probability that a statistical test fails to produce a decision in favor of a treatment effect when in fact the treatment is superior in the population. The complement of this probability ($1 - \beta$) is referred to as *statistical power* and equals the probability of correctly deciding in favor of a treatment benefit. Statistical power depends on the other principal parameters considered when planning the trial, specifically the probability of incorrectly finding in favor of a difference when none exists

(type I or alpha error, usually set to 0.05 or 0.01 by convention), the *a priori* specification of a treatment effect that is considered both realistic and clinically material, and of course the sample size. It is imperative that trials be designed to achieve adequate statistical power; typically, 0.80 to 0.90 is desirable, so as not to obtain equivocal findings concerning the potential worth of new treatments under consideration. Studies with low statistical power can cause delay or even abandonment of the development of promising treatments, and waste valuable resources, not least of which is the participation and goodwill of patients.[45] In contrast, a "negative" trial that does not find the test treatment to be superior, if adequately powered, is informative, in that resources can be directed into other more promising alternatives.

Thus, sample size to satisfy the power desired for the specified effect of interest is the key calculation in phase II and III clinical trials (phase I trials do not rely on hypothesis-driven sample size calculations, and the sample size derives from the specific design used). The specific sample size calculation depends on the end point, and technical details will not be provided here, but the two most common types of end points can be summarized as follows.

For a discrete binary end point in a phase II trial, for example, responded/did not respond, sample size calculations are straightforwardly performed using formulas for comparison of proportions. In a single-arm study, one aims to compare the observed response rate for the new agent to some historical response proportion, p_0—the response rate achievable with standard therapy in the target population. The main objective is to determine whether there is sufficient evidence to conclude that the response rate for the new regimen is greater than p_0. We designate p_A a response rate, which, if true, would be clinically material. We test the null hypothesis H_0: $p = p_0$ against the alternative hypothesis H_0: $p = p_A$. The values of p_0 and p_A (and more importantly the difference), along with the sample size, will determine the power of the study. Note that to detect a small improvement (say, ≤10%) requires a large sample size. For example, to detect an improvement from a historical value of 20% to 30% with 85% power, over 120 subjects are required. Also, the value for both p_0 and p_A must be realistic; it is of little value to design and carry out a study to detect an effect size $p_A - p_0$ that is unlikely to be realized, simply because it is compatible with the number of patients that can be recruited.

For two-arm randomized phase II trials with discrete end points, the above is simply redefined in terms of two-sample comparisons of proportions, and the

sample size is consequently much larger. Finally, if the end point is a fixed time landmark such as proportion event-free or alive at one year, then the estimates of the proportions may be derived from survival analysis methods to appropriately account for losses to follow-up.

In many randomized phase II and nearly all phase III trials, the time from randomization until occurrence of the event is of principal interest, rather than the event status at some fixed time landmark. In larger phase II trial and phase III trials, recruitment may take place over a lengthy interval, and each patient will have a different follow-up duration, and the use of follow-up time per patient is more efficient than waiting until all patients have reached some fixed time. The treatment effect measure is then specified in terms of failure *hazards*, which can be thought of as failure rates per unit of time. Hypotheses are thus usually formulated in terms of the hazard ratio (HR) as H_0: λ_A/λ_B = HR = 1.0 where λ_A and λ_B are the hazards for treatments A and B versus alternative H_A: HR < 1.0, for some value of the HR that represents a clinically important difference in outcomes. Under the assumption that this ratio is relatively constant over time, a given HR can be converted to an absolute difference between groups in proportions remaining event-free at a specific follow-up time. For example, a new/standard HR equals to 0.75, or a 25% reduction in failure rate in the experimental group relative to the standard group may translate into an absolute difference in the proportion of patients remaining free of the event between groups of 4.6% at 5 years, if the standard group 5-year survival percentage is 80%.

From the specification of difference of interest or effect size, then the sample size in terms of number of *events* required to detect this difference with desired statistical power and significance level is determined. Depending on the anticipated accrual rate and the prognosis (e.g., rapidity of failure events) in the control treatment group, the number of *patients* required can then be approximated. The number of events required depends strongly on the HR, becoming dramatically larger as the HR approaches 1.0. The number of patients required and total duration of the trial depend on the rate of patient accrual and the failure rate in the control group, both of which contribute to the determination of how rapidly the requisite events will be observed. The accrual rate is typically estimated from previous experience and may also involve querying investigators to project the accrual rate per unit of time. Similarly, the failure rate for patients under standard therapy is derived from available data. The final computations are straightforward but generally require computer

programs,[46] but, under certain assumptions, can be approximated.[47] Sample size methods have been extended to take into account other factors that will influence power, such as patients withdrawing from treatment (dropout), switching from the assigned treatment to the other group (crossover), or deviating from protocol treatment (noncompliance).[48–50]

Interim Analysis and Stopping Rules

Primarily for ethical considerations but also to make best use of resources, interim analysis plans are used in all phases of clinical trials. These plans provide for early decision-making in a trial regarding continuation, disclosure of findings, or modification of the trial while preserving integrity of the study with respect to power and type I error control described earlier. These methods are needed because with repeated hypothesis tests, the probability of at least one test resulting in an erroneous rejection of the null hypothesis increases.

Phase I trials have stopping rules that are integral to the design, in that termination of enrollment to a given dose is based on observed cumulative AE rates at a given time. We refer to a review of the designs for more details.[1]

Phase II trials more formally incorporate stopping rules, usually restricted to “futility stopping”, or discontinuation when results do not appear promising. For trials with discrete end points such as tumor response, this is accomplished through multistage study designs, whereby a cohort of patients is enrolled and assessed for response, and if a specific minimum response proportion is observed, the trial continues to full accrual; otherwise, it discontinues enrollment. The most commonly used designs are those proposed by Simon,[51] although there are other similar approaches. In trials with time-to-event end point, futility rules similar to those for phase III trials (discussed next) can be used to discontinue after a period of follow-up if results appear unpromising. Early stopping of single-arm phase II trials for extraordinary efficacy is unusual but certainly not prohibited.

Phase III trials use repeated testing strategies derived from an area of statistics known as group sequential methods. Briefly, the primary hypothesis is evaluated at predefined increments (typically 3 to 5 looks) of the total information (usually in the form of failure events) needed for definitive analysis. The individual tests are designed to (a) protect against spurious early stopping because of the unstable nature of “early” results and (b) correct for the effect of repeated testing on type I error, which can also lead to spurious declaration of treatment effects that may not be reliable. Commonly used approaches include

the Haybittle-Peto approach, for which each test through the penultimate look requires a constant highly significant result, such as $P < .0001$, in order to stop,[52,53] and the O'Brien-Fleming approach and its subsequent approaches,[54] in which the required significance level decreases over the looks, becoming less extreme as more information accumulates. There are many variations and extensions of the latter approach, with different properties and advantages in special circumstances. In addition to efficacy monitoring rules, phase III trials increasingly also incorporate formal futility-stopping rules, although methods such as conditional power calculations have been available and used for some time.[55,56] Futility-stopping rules similarly involve setting a boundary such that when the test statistic falls beyond it, then one considers stopping because the new treatment will not ultimately prevail. Stopping for futility is a complex decision requiring careful consideration,[57] and methods continue to be studied and developed.[58,59]

Definitive Analysis and Secondary Analyses

When the trial reaches maturity either as planned or earlier as a result of the monitoring plan, then definitive analysis takes place. Prior to this, it is not conventional or recommended to disclose any results from the trial,[60] and this policy is adhered to in NCI Cooperative Group trials.

A critical aspect of clinical trial analysis is the definition of the analyzed cohort. The concept of analysis by *intention to treat* is often cited, but the definition of this term can sometimes be unclear, so it is best to explicitly describe which patients are included.[61] In the strictest sense, the intention-to-treat cohort includes all patients randomized, regardless of eligibility, adherence to assigned treatment, or any other postrandomization deviations from protocol. However, it is often the case that patients found ineligible for the trial after randomization because of having been incorrectly staged or for other reasons are excluded from the primary analysis, and this practice (used with caution) is sometimes advocated, as it allows for evaluation of the therapy in the population for whom it was intended.[2] A rarely acceptable practice involves exclusion of patients who did not or could not comply with assigned therapy regimens or received nonprotocol therapy or other postrandomization conditions. Such exclusions can easily lead to biased comparisons, and in general, any post hoc analysis of treatment benefit by dose received is fraught with interpretational difficulties and should be avoided in primary analysis.[62]

The primary analysis methods follow naturally from a well-written protocol

(see below) and thus should be straightforward. Given that major journals increasingly require that study protocols be provided at the time of publication, and that regulatory agencies and public sponsors do likewise, it behooves the trialist to outline the analysis plan in the protocol and then carry it out at study conclusion. This does not suggest that additional analyses cannot be carried out, but having a framework for the planned analysis adds credibility to the findings.

Secondary prognostic factor analysis using statistical models or other techniques often follows primary analysis of phase III trials. Of particular interest is whether there are particularly responsive or nonresponsive subsets of patients, in an attempt to render the findings more relevant to practice. The modeling process, which entails deciding which factors to include, determining the correct way to represent a given factor (i.e., in categories, on a continuous scale, etc.), consideration of interrelationships (e.g., interactions) among factors, and many other issues, can be complex, and it should be recognized that these analyses will be largely viewed as exploratory. Although possibly worth exploring, true differential effects of treatment by other factors usually require a large sample size, unless the effects are very large.[63] A comprehensive review of current modeling methods applied to oncology data is provided by Schmoor et al.[63]

PRACTICAL ISSUES IN THE DESIGN, CONDUCT, AND REPORTING OF CLINICAL TRIALS

Protocol Document and Study Conduct

The goal of a clinical trial is to answer a well-formulated question that will change clinical practice. To achieve that, the investigators must know the current state of knowledge on the studied disease, clearly describe the eligibility criteria of the studied population, understand the number of patients who will be eligible in their institution/cooperative group, choose simple and achievable end points, establish statistical assumptions based on thorough review of preexisting data, and collaborate with a biostatistician to decide on study design, sample size, and power.

The clinical trial protocol document must contain the title, investigators and sponsor’s name, phase (I, II, or III), protocol synopsis, background knowledge, study design and schema, objectives, methodology, subject selection criteria, registration procedures, treatment plan, dosing modifications, AE reporting, data and safety monitoring plan, study calendar, outcome measures, data reporting,

statistical considerations, and the informed consent.[64]

Choosing the right study end points is crucial, as it needs to reflect the primary goal of the trial. Any number of end points may be of suitable scientific and clinical value, but if there is interest in regulatory approval, then obviously the end point must reflect the requirements of those parties involved. Overall survival largely remains the "gold standard" for a registration trial designed to gain marketing approval. However, survival length may be affected by effective salvage therapies or by patient's "crossing over" to the other study arm. End points such as DFS and PFS have been used for either expedited drug approval or regular approval, depending on the disease site.[65] If end points subject to assessment bias are to be used (e.g., PFS or tumor response), then appropriate bias reduction measures are needed. One approach to circumvent this problem is an independent review panel (e.g., radiologists reviewing baseline and follow-up images to quantify tumor responses and note the moment of tumor progression), consisting of experts not associated with the trial and unaware of the arm to which the patient was enrolled. One must also consider validity of modern end points even under unbiased review. For example, the phenomena of pseudoprogression and pseudoresponse have made imaging-based end points, including overall radiographic response and PFS, problematic.[66]

Successful completion of a clinical trial requires constant attention to its practical aspects. Sufficient personnel are necessary in order to assure the smooth running of the study and safety of the participating subjects. Clinical research nurses, clinical research associates, data managers, and investigational pharmacists are crucial components of the research team.[67] Of particular importance are careful and immediate recording and attribution of all AEs. Severe AEs have to be reported promptly to appropriate regulatory agencies (IRB in the institution where the study is open, FDA, and others) and to the study sponsor. Because most protocols have amendments added during their lifetime and new toxicities are reported from other studies, the research protocol commonly evolves over several successive versions. As a result, new versions of consent forms must be created as well, and IRB approval may again be required. It is imperative that patients enrolled to the study sign the most current version of the consent form. All the prescribed follow-up tests (imaging, blood work, etc.) have to be scheduled ahead of time and coincide with the study calendar. Departures from any of the procedures are scored as protocol deviations during periodic audits and will impact adversely on the study's validity. Additionally, designated independent medical monitors are assigned to high-risk trials (such as

most single-institution investigator-initiated trials) to continuously review any reported events, which are later evaluated periodically by the institutional data safety monitoring committee.

Data and Safety Monitoring Committees

The decision to alter clinical trial in progress, including discontinuation of accrual and/or treatment, depending on its current state, and early release of findings is typically vested in an independent DSMC. In addition to evaluating according to the monitoring rules described earlier, the DSMC considers the information available from the trial as well as external information that bear on treatment for the disease under study. Specifically, it should be noted that the early stopping rules described above are meant to serve as guidelines, and there may at any decision point be additional considerations that must be taken into account.[68] The policies and procedures for U.S. National Cancer Institute–sponsored Cooperative Group trials provide a good overview of DSMC structure and function.[69]

Trial Reporting

Once the study is completed and the data are fully analyzed, its results should be reported promptly. Publication of the results of the trial in a scientific journal represents culmination of the investigators' efforts and allows wide distribution of the findings. However, lack of precise requirements of reporting may lead to inaccurate or biased result presentation. The CONSORT (Consolidated Standards of Reporting Trials) statement is used worldwide to improve the quality of reporting of randomized controlled trials.[70] It provides a 25-item checklist of all required elements and a flow diagram to assure that all patients enrolled are accounted for. Many journals require the authors to follow the CONSORT guidelines, because "diligent adherence by authors to the checklist items facilitates clarity, completeness, and transparency of reporting."[70] The ICMJE (International Committee of Medical Journal Editors) similarly publishes guidelines on uniform requirements for manuscripts submitted to biomedical journals.[71] There have also been calls for improvements in reporting of phase I and II trials.[72,73] In addition to quality with respect to content, a full disclosure of the financial COI by the investigators to the readers is necessary as well. Redundant publications (repeating the same results in several journals) are discouraged and there is an obligation to publish negative studies. Study of the publication rate of cancer cooperative group trials regardless of findings shows

there is room for improvement with respect to responsible approach to clinical trial conduct.[74]

In the United States, reporting requirements are currently trending toward an expansion to more "open access" sources, based on mandates arising from recently enacted legislation. ClinicalTrials.gov is the largest clinical trial database in the world, run by the National Library of Medicine in the National Institutes of Health. Initially including information only on NIH-sponsored studies, NILM now also contains studies sponsored by the pharmaceutical companies and demands "basic results" information not later than one year after the study's primary completion date (ClinicalTrials.gov). The requirements for results reporting were prompted by removal of several drugs from the market because of earlier unrealized toxicity, knowledge about which was obscured by lack of publication or other public documentation.

RECENT APPROACHES TO CLINICAL TRIAL DESIGN

An Alternative Phase I Trial Design for Radiation Oncology Trials

As mentioned earlier, phase I trials in radiation therapy present a unique challenge in that toxicities may occur long after treatment and need to be incorporated into dose evaluation. The traditional stepwise designs do not accommodate this, and thus an extension of the Continual Reassessment Method[75] that incorporates the time-to-event (i.e., time to toxicity) information for each patient was developed.[76] Designated the TITE-CRM approach, a dose–response model is first posited that identifies the starting dose and range to be considered, along with a time frame for events occurring anywhere up to T time units from administration of therapy. Rather than waiting for each cohort of patients to be followed for this length of time, however, one can enter new patients at, say, half-month intervals. As in the original CRM, the first patient is assigned to a dose level based on prior information or, as in the modified CRM, to the lowest candidate dose. At the time the next patient(s) is (are) to be enrolled, the observed toxicities and follow-up times of patients already entered are used to form an updated estimate of the β parameter that defines the dose–response curve and the dose level for the next patient(s) selected according to the usual CRM or modified CRM criteria. In simulation studies, the TITE-CRM produced results comparable to its CRM counterpart while significantly reducing the average duration of the trial. However, the TITE-CRM method was

associated with slightly more toxicities, particularly in situations where events tend to occur near the end of the observation period, because escalation to the next dose may have already occurred before toxicities were observed.[76] Another problematic issue is rapid accrual, where premature escalation of dose may be indicated. A recent review and suggested modifications may make this approach even more suitable for radiation oncology trials.[77]

Alternative Phase II Trial Designs

As indicated earlier, the value of traditional single-arm phase II trials has been called into question in terms of providing a reliable basis for further pursuit of promising treatments. The currently favored design is a randomized phase II trial with a standard of care comparison group.[13,17,78] This approach and the goal of accelerating development have led to consideration enhancements to the phase II design, including adaptive randomization, where one favors enrollment to the arm(s) that seem to be prevailing while reducing probability of enrollment on other arms and even dropping some treatment arms. This is an idea with a long history,[79] but recent innovations in computing and Bayesian methods, as well as a newfound interest in accelerated development, have brought it to wider use in some settings.[80] In some instances, it may offer advantages but must be weighed against simpler approaches with similar or even greater efficiency.[81]

Changes in therapeutic approaches also suggest design changes. Because primarily cytostatic agents (i.e., most biologic drugs) are not expected to necessarily result in tumor response in the traditional sense, there is a need to consider alternative phase II designs based on end points other than response rates. For trials enrolling patients who have failed prior therapy, Mick et al.[82] propose a method that uses each patient as his/her own control, comparing the time to progression (possibly censored) under the new agent with the time to progression under prior therapy. Rosner et al.[83] propose a randomized discontinuation design to evaluate cytostatic drugs in which all patients are initially treated with the experimental agent. After a specified interval, responders remain on drug and those who progress discontinue, whereas those patients with SD are randomized to either continued active treatment or placebo. This randomized comparison allows one to assess whether the drug is truly slowing the rate of growth of the tumor, as opposed to the investigators having simply selected patients with slow-growing tumors. Because the patients with SD form a more homogeneous subgroup, this design also requires a smaller sample size than would a trial that randomized all patients at entry. It is

important to note that the purpose of this design is to determine whether the drug is active in an explanatory sense. Whether the percentage of patients exhibiting SD is high or low has bearing on the efficiency of the approach, because in the latter case the total sample size required may be quite large and any demonstration of activity in the randomized component would only be relevant to a small subset of the population. Korn et al.[84] point out other caveats with this design. For example, patients may find it unattractive to potentially discontinue a treatment that they perceive to be helping their disease.

Using Biomarkers as Inclusion Criteria

It is increasingly understood that the response of tumors to targeted agents is highly dependent on their molecular subtype. Consequently, trials increasingly screen for molecular characteristics of tumors to use as eligibility criteria or, at a minimum, stratification factors. For example, recent and currently accruing RTOG brain tumor trials require MGMT status, whereas the head and neck cancer trials are now requiring HPV status to be determined at entry. When studies enroll sufficient numbers of patients, then treatment by marker synergisms, referred to statistically as interaction effects, can be investigated. Robust evaluation of true differential benefit according to markers requires that treatments be randomized, and so randomized phase II and phase III trials are ideal setting for developing tailored treatments.

In many instances, potentially responsive subsets of patients may be small and may also be identified after trials have initiated enrollment. For instance, ALK inhibitors are highly effective, but only in the 3% to 5% of lung cancers that have *ALK* gene rearrangements. It may simply not be feasible to perform separate phase III trials for each lung cancer subtype. One possible alternative is “adaptive randomized” trial designs in which the data gathered as the trial progresses are used to change some aspect of the trial as it progresses. Some recent examples are the Biomarker-Integrated Approaches of Targeted Therapy for Lung Cancer Elimination (BATTLE) trial in lung cancer[85] and the I-SPY trials in breast cancer.[86] However, there are limitations and challenges to these complex trial designs. For example, in order to be able to acquire information rapidly enough to undertake weighted randomization favoring more promising arms or eliminate nonresponsive arms, surrogate end points such as “disease control rate at 8 weeks” must be used. It is not clear such short-term end points are relevant to radiation oncology where local control is very frequently achieved.

A number of recent papers in the clinical literature have provided excellent reviews of the opportunities and challenges involved in incorporating modern molecular medicine into clinical trial design.[87,88]

MOVING BEYOND CLINICAL TRIALS

Comparative Effectiveness Research

The randomized phase III clinical trial is considered the most robust method of comparing the efficacy of a new treatment with the standard of care. Grading systems for evaluating clinical evidence universally place "randomized controlled trials" above observational trials.[89] More recently, this hierarchical approach to scientific evidence has been attacked by[20] criticisms including the high fiscal cost of clinical trials, the length of time that it takes to obtain a conclusion (by which time the results are frequently no longer relevant because the standard of care has changed), and the large number of trials with negative results.

A specific criticism relates to clinical protocols that typically allow enrollment of only the fittest patients that lack comorbidities and have good performance status, criteria that subsequently limit the generalizability of the results. Studies have indeed shown that, for example, older patients are excluded unnecessarily out of concern for potential AEs.[90–92] There have indeed long been calls for simpler and more inclusive eligibility criteria.[93]

In some sense, the desire to reduce exclusivity and broaden trial enrollment to more closely match the population is antithetical to "personalized medicine" and more focused trials as mentioned above. However, there are some ways in which the two concepts can possibly work in concert. Larger trials that can robustly support subset analysis according to biologic, clinical, and health history/behavior factors can at once be more inclusive and address questions about particularly responsive subgroups.

Another response to the criticism of phase III trials has been a reappreciation of the importance of population-based retrospective studies as a way to appreciate a treatment's effectiveness in the "real world." Even more useful are well-designed prospective cohort studies, such as the Cancer of the Prostate Strategic Urologic Research Endeavor (CaPSURE) study in prostate cancer, which will provide information both on factors driving treatment choice and the effects of specific intervention strategies for which randomized trial evidence is currently lacking.[94] Another key strategy is conducting trials in parallel with

concurrent registries of patients treated according to physician and patient choice and/or common convention, such as the **T**rial **A**ssigning **I**ndividua**L**ized **O**ptions for Treatment (**Rx**) (TAILORx) trial.[95] In this trial, 7,000 women with breast cancer are screened using a molecular profiling tool, and for those with profiles in the range where the utility of the tool is uncertain, randomization between "hormonal therapy alone" and "hormonal therapy plus chemotherapy" is performed. Patients obtaining scores below or above this range are registered in order to accurately record treatment choices and ensure that good follow-up data are obtained. This trial will both serve to determine the utility of the profiling tool in the uncertain range and provide high-quality data on the validity of treatment decisions based upon it.

Meta-analysis

A formal quantitative means of combining evidence from multiple clinical trials is by meta-analysis, a widely used analytic tool in many areas of social and medical science. Meta-analysis refers to a process whereby data from independent studies are combined to form a quantitative summary estimate of a given effect. Meta-analyses are considered by some to be a level I evidence source along with large randomized clinical trials. A meta-analysis combines results of several studies, all of which ask a similar research question, but may be individually too small to have enough statistical power to definitively answer the question. Performing a systematic analysis of data from all identified randomized trials can define a modest but real advantage associated with a new therapeutic approach. The goals of combined modality phase I studies are similar to single-agent studies. However, the design and application often differ. The primary end point is usually an assessment of toxicity and to identify a RP2D. The investigation of biomarkers can also occur, although some investigators have tended to attach this end point as part of a phase 0 trial design.

Toxicity assessment is typically during the entire radiation course and some defined period of time afterward, for example, 30 to 60 days. It is frankly impractical to wait an extended period of time for late and/or chronic RT toxicity to be assessed. The TITE-CRM Bayesian methodology may allow for more prompt dose escalation and continuous inclusion of new toxicity data from prior patients enrolled onto the trial.[29,96]

TIME-TO-EVENT CONTINUAL REASSESSMENT METHOD (TITE-CRM)

The TITE-CRM was initially described by Cheung and Chappell[76] where the time to toxicity was incorporated for each patient. This allows both acute and late toxicities to be accounted for, all while patient enrollment continues. Studies have shown that the TITE-CRM design is usually more efficient, treating more patients closer to the MTD and shorter trial durations.

Statistically, the TITE-CRM design assumes that the hazard of developing toxicity is constant over time. In radiotherapy, that is often not the case. For example, pneumonitis is a subacute toxicity after thoracic radiotherapy that occurs 1 to 6 months after the end of radiotherapy, but not before or after. Therefore, assuming a constant risk for pneumonitis after time is inaccurate.

In radiotherapy, where late toxicity is a major concern, the TITE-CRM has multiple advantages. Normolle et al. performed a Monte Carlo simulation and found that, compared with a traditional 3 + 3 design, it can produce more accurate estimates of the MTD and not expose patients to significant excess risk.[29]

One concern in chemoradiotherapy trials is that with fast patient accrual and late toxicities, the TITE-CRM could lead to overdose. Polley et al.[77] have proposed a modification to the TITE-CRM using accrual suspension. Bekele et al. proposed yet another variation on the TITE-CRM using time to toxicity. In this model, if the anticipated risk to patients while conducting a trial becomes too high, but then normalizes, the trial is restarted. The authors propose that this affords greater safety than the classic TITE-CRM, although the trial may take longer (Fig. 15.4).[97]

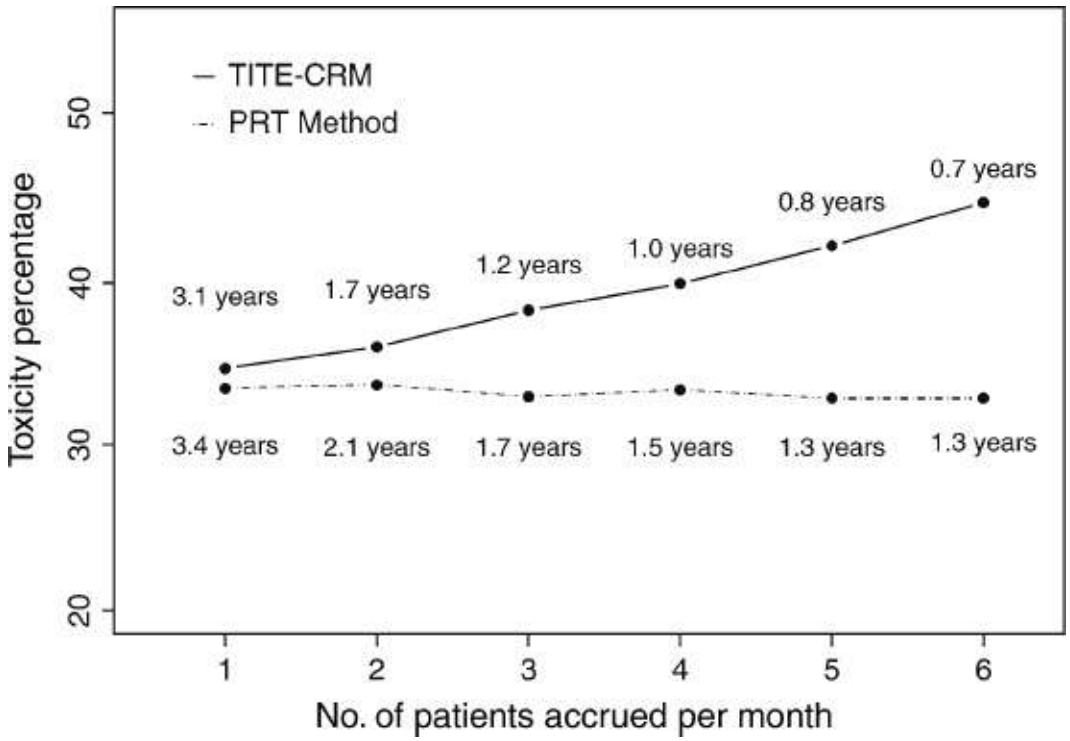

FIGURE 15.4. Comparison of toxicities seen using both methods with different accrual rates. (From Bekele BN, Ji Y, Shen Y, Thall PF. Monitoring late-onset toxicities in phase I trials using predicted risks. *Biostatistics* 2008;9[3]:442–457. Reproduced by permission of Oxford University Press.)

A radiotherapy-specific model-based method has also been developed. Mehta et al.[98] reported on an alternative Bayesian methodology, which determines the probability of pneumonitis as a function of mean normalized lung dose, and the dose per fraction is escalated accordingly.

Despite the advantages of CRM design, Rogatko et al.[99] have shown that only 1.6% of 1,235 phase I cancer trials published between 1991 and 2006 used Bayesian designs. Le Tourneau et al.[100] found that only 3.3% of 181 evaluable phase I trials performed in 2007 to 2008 used CRM design (5 modified CRM, 1 TITE CRM).

Multiple CMT studies have used the TITE-CRM design. For example, in pancreatic cancer, TITE-CRM has been used in a phase I/II to dose escalate the radiotherapy dose with fixed-dose gemcitabine.[101] It has been used to dose escalate both oxaliplatin and gemcitabine with fixed-dose radiotherapy.[102] And, lastly, it has been used to escalate cisplatin with fixed-dose gemcitabine and radiotherapy.[103]

Lawrence et al.[104] published on the early-stage development of radiosensitizers. They advocated for the use of the TITE-CRM design in its

ability to enroll new patients while simultaneously monitoring for the development of late toxicity and incorporating that data into the model. They specifically note that intrapatient dose escalation is likely not appropriate in trials that use radiotherapy because of the cumulative nature of radiation toxicity. Likewise, TITE-CRM has been used to dose escalate radiotherapy when combined with radioprotectants, for example, in liver radiation and concurrent amifostine.[105]

Accordingly, there is an urgent need for predictive biomarkers of normal tissue toxicity. Finding such biomarkers is an area of fruitful research. One example that appears promising in the cardio-oncology arena is troponin and/or N-terminal pro–B-type natriuretic peptide (NT-proBNP) blood levels along with strain analysis of 2-D speckle-tracking echocardiography.[106–109]

Pitfalls

Chronic and cumulative toxicities usually cannot be assessed and may be missed, because most patients do not stay on trial beyond 2 cycles if systemic agent is being added onto an RT backbone. Furthermore, uncommon toxicities will be missed, because few patients are enrolled onto early-phase trial. Finally, the variations in target delineation by different investigators have the potential to inadvertently impact the toxicity profile. The use of anatomic atlases may help mitigate this critical variable. Chronic and cumulative toxicities usually cannot be assessed and may be missed, because most patients have been lost to follow up.

History of Phase 1 RT–Drug Trials

Over the past 3 decades, most of these clinical trials (N = 162 phase 1 only, N = 66 phase 1 to 2) have utilized a rule-based design for dose escalation, usually a 3 + 3.[110] RT has only been tested for dose escalation approximately one-eighth of the time (27 trials) when combined with a drug. In these trials, RT was the only modality being tested for dose escalation two-thirds of the time. Only a single anatomical site has been usually studied (98%), with head and neck (20%), lung (18%), brain (11%), and pancreas (10%) being the most common. Over 90% of published studies did report grade 3 to 4 AE, with two-fifths (42%) comprising hematologic AEs and 50% nonhematologic (with plurality being mucositis). The mean number of events described as DLT per number of grade 3 to 4 AE was reported to be 4, and the description of the DLT period (mean of 69 days) was only described in only nearly two-thirds (62%) of

the studies. This published benchmark although helpful cannot account for the much larger number of trials that were never written up in full manuscript form. With the increasing cadre of radiation oncologist learning how to design prospective clinical trials as part of dedicated career development course, including the ASCO (American Society of Clinical Oncology)/AACR (American Association for Cancer Research) Methods in Clinical Cancer Research Vail Workshop, the ECCO (European CanCer Organisation) Methods in Clinical Cancer Research Zeist (formerly Flims) Workshop, and other smaller courses developed exclusively to training radiation oncologist, this future may be brighter.

Phase 2 Trials

The decision to proceed with a combined modality phase II study is dependent upon the safety and early efficacy results from the phase I trial. A major goal of a combined modality study is *efficacy* or clinical activity, as defined as increasing the therapeutic window (or therapeutic ratio).[111,112] These trials can screen out suboptimal treatments and identify promising strategies worthy of further validation in a more definitive or confirmatory trial setting. Phase 2 trials can also provide a more extended safety profile than may have been possible in the phase 1 trial.

Design

When designing phase 2 trials involving RT, there are a number of challenges, some of which are unique to the modality and others are compounded by combined modality therapeutic designs. These include that fact that (a) many phase II studies are of unselected patient populations, (b) they are often introduced in the curative setting (i.e., plus/minus boost for ductal carcinoma *in situ*) such that the interval for observation may be extended (i.e., years), (c) recent data on RT/immunotherapy are promising for some metastatic scenarios resulting in both a redefinition of the classic mantra of spatial cooperation between modalities and considering whether RT may be a vaccine or primer for novel immunotherapy agents such as checkpoint inhibitors, (d) combination with classic cytotoxic-based chemotherapy, (e) difficulty in assessing late effects, and (f) the low prioritization from the drug development industry. As a consequence of this latter reality, there is a prolong delay (median 6 years, interquartile range 5 to 8 years) between the opening of the phase I trial without RT and the opening of the phase I with RT.[113] In addition, the median lag time P between the

published phase I trial without RT and the *opening* phase I with RT was 3 years (interquartile range of 1 to 6 years).

An important consideration is to be cost-efficient in the design of the trial, as the PI should seek to minimize the number of patients exposed to an ineffective treatment by enrolling as few patients as "necessary" to show benefit or failure.

One of the most important design decisions is to determine if a single-arm study will suffice or whether a multiarm trial is preferable. The latter may be required if the historical data for comparison are lacking or considered generally weak. Single-arm studies may include a two-stage design with early stopping rules for futility or lack of response. The most common single-arm trial designs are the Simon two-stage,[51] the balanced design,[114] Gehan two-stage,[115] and the Fleming two-stage.[116] These are considered frequentist approaches (as opposed to Bayesian designs). A multiarm phase 2 trial may include a (a) phase 2 selection design (prioritization) or (b) phase 2 design with a reference control am (control). The former involves parallel single-arm studies that do not directly compare the arms to each other. They compare each to the "null rate." The Simon "pick-the-winner" design is an example.[16] This approach is useful when there are more than one candidate new drugs, new schedules, new doses, or even combinations of different drugs, schedules, and doses to be evaluated. It is not powered to directly compare the treatment efficacies, and hence, the number of patients needed to complete the study is smaller. On the other hand, a randomized phase 2 design with a reference control arm directly compares the new treatment with the control treatment. The randomization is effective to remove potential bias that is often unavoidable in single-arm trials where treatment effect of the new treatment (represented by efficacy end points, e.g., local control, response rate, colostomy-free survival, nodal failure, etc.) is indirectly compared with the historical controls. The comparison is indirect in that the point estimate from historical controls is often treated as the null hypothesis in the single-arm trials. Therefore, the uncertainty associated with the estimate is neglected in the testing. As a consequence, the single-arm trials often require one-third or smaller a sample size compared to randomized two-arm trials with the same hypothesis to be tested. As a trade-off, the findings in the single-arm trial are often much unreliable compared with randomized trials.[117]

Phase 2 studies may often include patients for whom RT is a standard and definitive therapy. In these instances, the savvy radiation oncology investigator has an opportunity to carefully define goals, strategic diagnostic, and/or therapeutic interventions, to achieve a well-defined and clinically meaningful

end point for the patient's benefit. Adaptive designs are becoming more common in cancer medicine, including radiation oncology–based trials (Bhatt). For instance, the definition of response rate is important to consider. There are emerging data to suggest that a well-defined, *a priori* change in metabolic response rate via functional imaging assessment with FDG-PET (positron emission tomography) may harbor useful imaging biomarkers of tumor response or resistance much earlier than classic pure anatomic imaging using conventional CT scanning.[118–120] Adaptive trials will need to incorporate serial data inputs, including though not limited to imaging, -omic (genomic and proteomic), and anatomic changes during treatment in order to enhance response and get ahead of the tendency of tumors to develop radioresistant phenotypes (Fig. 15.5).

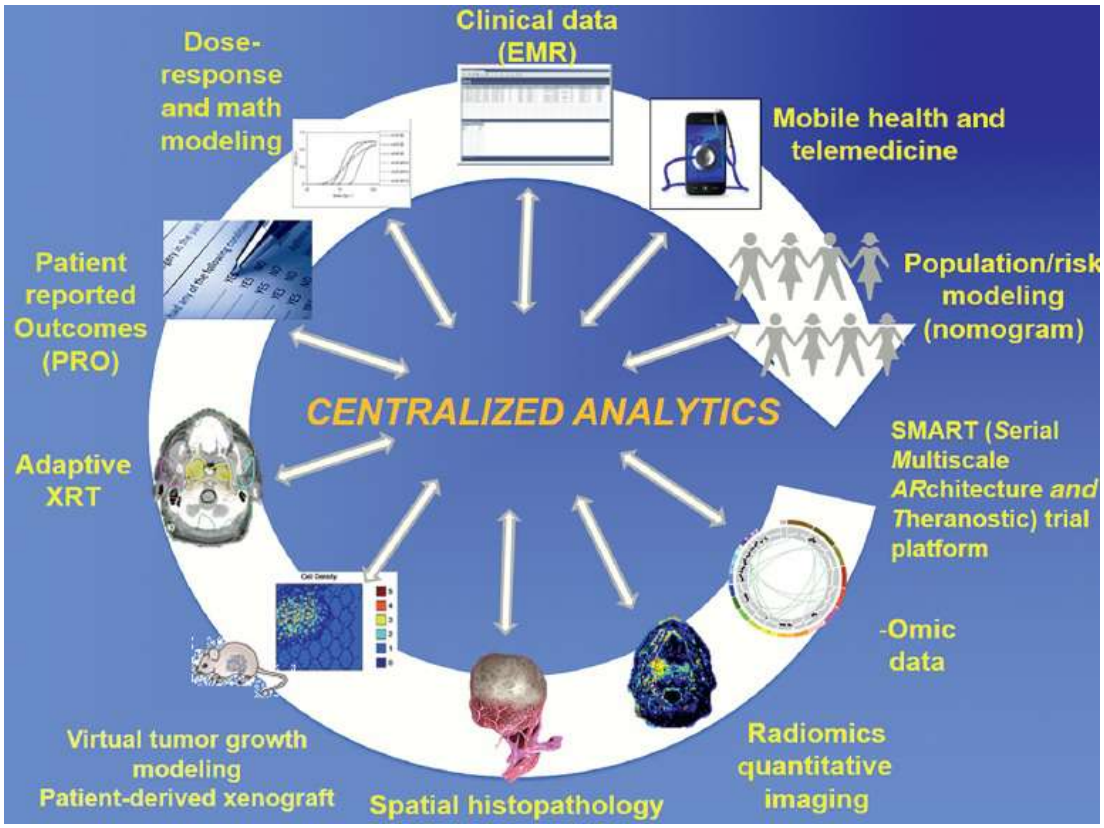

FIGURE 15.5. Centralized analytics allows for phenotyping using all patient and tumor-specific data.

In order to exploit the promise of precision medicine, alternative phase 2 designs have emerged in the form of umbrella and basket trials.[121] The umbrella trial is set up to test one type of cancer (i.e., lung), which may harbor multiple mutations, some of which may be actionable with various therapeutic interventions. The basket trial can include patients with multiple anatomic types

of cancer though each tumor must harbor a common genetic mutation for which the same candidate therapy is tested.

End Points

Response rates alone may be challenging for selecting efficacious regimens, because of several factors including (a) delayed time to response with RT, (b) residual unevaluable masses versus scarring or fibrosis, (c) progressive disease outside of the RT field, and/or (d) underlying high local response rates to RT.

Response rate is commonly measured by the RECIST and sometimes the PRECIST (Positron Emission Tomography Response Criteria in Solid Tumors) criteria. A CR plus a PR is added together to determine the overall objective response rate. If patients whose best response is SD or no change, that may also be important because many of the targeted agents (sometimes called cytostatic agents) inactivate a driver tumor target though no objective shrinkage of tumor may be noted by conventional imaging.

Efficacy end points commonly used include (a) CR rate, (b) pathologic CR rate based on examination of tissue, (c) undetectable blood biomarkers such as circulating tumor DNA and/or circulating tumor cells, (d) local or locoregional control rates, (e) time to progression, (f) survival, and/or (g) a decrease in toxicity. In the instance of the latter end point of decreased toxicity, RTOG 0529 is a good example of a clinical trial that was primarily designed to show that the way that RT was delivered (i.e., IMRT) may yield a preferable therapeutic window compared to historical experience for invasive anal cancer.[122,123] The end point selected will depend upon the tumor and the current standard therapy.

Robust documentation of both acute and late toxicities is essential. In particular, collection of late toxicity data will be helpful as the phase III study is designed. This should involve provider assessment via the usual tools such as the next-generation CTC profile, as well as validated patient-related outcome (PRO) tools. There are emerging data that the concordance of AE documentation between patients and providers on cancer cooperative group setting could even improve overall survival.[124]

Summary

Phase II trials are designed to generate a signal of antitumor activity and to inform the phase III decision. The ideal phase II trial uses a good PK/PD drug against a validated disease target and shows convincing antitumor activity. Results of phase II trials must be interpreted cautiously, in the context of the

availability of other therapies. It does, however, estimate clinical activity and provide further safety information, which is important in the "go/no-go" decision for a phase III trial. A phase II randomized trial is still considered exploratory and does not obviate the need for a larger more definitive phase III trial. Adaptive designs can be very efficient for selection, but require more maintenance.

Phase 3 Trials

These trials usually involve two or more arms, including one that is considered a standard of care. The goal is to show superiority of a new therapeutic approach, such as the addition of postoperative (adjuvant) chemoradiotherapy for resected gastric cancer[125] or perhaps to demonstrate noninferiority, the latter which can lead to a more cost-effective treatment approach, such as hypofractionated radiotherapy for breast cancer.[126] The essential components to consider for phase III trials are study design, randomization approach, blinding strategy, and monitoring of end points. The CONSORT 2010 checklist (www.consort-statement.org) summarizes information that must be considered when analyzing phase III trial reports.[127]

Design

The design is randomized in most phase III trials, and the patients enrolled should all have the disease to be studied as well as comparable pretreatment characteristics. A *parallel* design involves randomization to a standard (or control) intervention versus an experimental (new) intervention. The experimental intervention may include ≥1 arm, such that the variable between the experimental arms may be the number of radiation fractions and/or fraction size, with a theoretically equal BED. *Factorial* designs, such as utilized in the ACT II anal cancer trial, allow for more multiple intervention variables to be compared to a single gold standard or control.[128] Crossover designs allow for patients randomized to arm A to undergo crossover therapy to arm B after the efficacy end point of arm A has been measured. This occurs when the efficacy end point is PFS.[129]

Randomization

This is a process that provides each patient an equal chance of being assigned to an intervention arm or a control arm, unless it has been predetermined that an unequal randomization allocation (i.e., 2:1) is warranted to enhance accrual. Ideally, the patient and the PI should not influence or be aware of which arm the

former will be randomized to prior the decision has been made to provide informed consent to participate in the study. This requires equipoise on the part of the investigator, an area of active controversy among the radiation oncology community when deciding how to study new and expensive technology, such as particle therapy. *The following section on Statistical Issues will provide a more in-depth discussion on randomization and blinding considerations in clinical trials*.

Superiority, Noninferiority, and Equivalence Designs

A superiority design is fairly common and seeks to show that a new radiation approach (i.e., higher dose of radiotherapy) is superior to that standard of care, such as was tested in RTOG-0123.[130]

A noninferiority design is often used to show that a less aggressive (or potentially toxic) approach (i.e., lower dose of radiotherapy or less intense systemic therapy) is not worse to a clinically meaningful degree compared to the standard intervention. The difference or delta (Δ) in the *a priori* defined end point should only be slightly worse (or inferior) to the standard. Confidence intervals estimate the difference in outcome between the control and experimental arms as an approach to confirm the hypothesis. Sample sizes of noninferiority trials are often bigger than superiority trials.[131] Several studies have been *a priori* designed and reported on for localized prostate cancer,[132] resectable rectal cancer,[133] and brain metastases.[134] Some trials combine noninferiority and superiority testing into one study. This is because the noninferiority and superiority can both be evaluated at 0.05 significance level without a need to adjust for multiple testing because of the closed testing principle.[131] Two things need to be paid attention to when conducting such combination testings: (a) the study needs to be powered for noninferiority and (b) the noninferiority needs to be tested before testing for the superiority.

An equivalence design seeks to show that the control and the experimental arm(s) are equal with respect to the primary outcome. Equivalence can be defined as the treatment effect residing between −delta (−Δ) and delta (Δ) (two-sided problem). This design *is not* the same as a noninferiority design. RTOG 9704 was a phase III trial that sought to show that by excluding mitomycin C (an antitumor antibiotic with a well-known profile of significant hematologic and renal toxicity) from a backbone of fluorinated pyrimidine chemotherapy (5-fluorouracil) and external beam radiotherapy for anal canal cancer, the therapeutic outcomes would remain equal, whereas the therapeutic ratio would

be increased by lessening the toxicity.[135] This study showed that the doublet, including mitomycin C, was actually superior. It is problematic to routinely relay on null hypothesis testing of equality if statistical significance of the *a priori* differences is not met.

Quality Assurance/Contouring

In the era of highly conformal radiation treatment, safe and effective treatment planning depends increasingly on precisely identifying tumor and normal tissues through contour delineation, with evidence from clinical trials emerging that correlates poor contouring with inferior outcomes. In head and neck cancer, both TROG 02.02 and RTOG 0129 found a 20% decrease in overall survival for patients with radiation protocol violations.[136,137] Similar trends have been identified in pancreatic cancer and Hodgkin lymphoma.[28,138] Although multiple aspects of the radiation planning process can lead to protocol violations,[139,140] between 13% and 83% of protocol violations have been attributed to contouring.[28,136,138,141] In response, an increasing emphasis is being placed on trial QA programs that actively perform contour evaluation and train providers.

First, development of a visual atlas for anorectal cancer was shown to reduce contour variation[142] and improve predicted toxicity[143] among providers that intended to enroll patients on a SWOG-sponsored study (SWOG S0713). This atlas was initially developed for RTOG 0529 in response to the observation from the first five cases submitted with coverage of the mesorectum and elective nodes.[122] Visual atlases have been duplicated in contouring studies performed outside of the clinical trial setting for disease sites that have a well-defined high-risk clinical target volume such as prostate fossa[144] and nasopharyngeal cancer.[144] However, RTOG 1106 recently reported that development of a visual atlas for lung cancer, which relies primarily on identification of gross tumor, did not reduce variation in contours submitted through its trial QA credentialing process.[145]

Given the limitations of a visual atlas, disease sites such as lung cancer have been moving toward prospective centralized contour review prior to patient treatment. However, the administrative burden and potential for treatment delays warrant consideration by the QA committee when determining feasibility of their contouring QA program. Multiple trials show that radiation protocol deviations are more frequent among low-accruing treatment centers,[136–139,146] so perhaps a risk-stratified approach should be considered. It is important to keep in mind that the more strict the trial QA, the less generalizable the results may be to routine

practice. Instead, development of robust resources and training processes that could be implemented and easy to use in routine practice would be ideal.

STATISTICAL ISSUES IN TRADITIONAL CLINICAL TRIAL DESIGN

Patient Population and Subject Eligibility

Defining patient population is an essential step in the design of clinical trial. The inclusion and exclusion criteria of subject should be carefully defined and specified for any clinical trial before study initiation. Several aspects need to be considered when defining the subject eligibility of enrollment to specific trials: (a) generalizability, (b) feasibility, (c) competing risks, (d) projected AEs, and (e) homogeneity. The patient inclusion and exclusion criteria of a trial should be the result of a nice balancing of all the above five aspects.

Generalizability and Feasibility

To begin with, investigators should first think about the targeting patient population to which the new treatment will be adopted. Ideally, a phase III clinical trial should relax the exclusion criteria as much as possible to mirror the target patient population. Less restricted eligibility criteria will make the findings in the trial more generalizable to the targeting population. In addition, relatively relaxed inclusion criteria are likely to lead to quicker accrual and make the study treatment more available to a broader patient population who may benefit from it.

Adverse Events, Competing Risks, and Homogeneity

Although inclusive eligibility criteria will boost the generalizability and feasibility, it can be risky and harmful to include subjects who should be excluded. For instance, if subjects with HIV/AIDs are suspected to have exceptional high risk of experiencing treatment-related toxicity in a pancreatic cancer trial, they should better be excluded. Otherwise, not only the subgroup of patients are exposed to high risk of toxicity, including them may put the whole trial to the risk of closure for excessive toxicity. Even if the trial continued as planned, these subjects are likely to add complexity to the efficacy and toxicity analysis of the trial.

Another thing to keep in mind is the competing risk. For example, if a trial is to evaluate the response rate after six cycles of radiation therapy, then including

subjects with high risk of dying before completing the six cycles is undesired. In this example, the competing risk is death of cancer or other disease before treatment completion or before the primary end point becomes available.

The last thing to aware is the homogeneity of subjects as defined in the eligibility criteria. Exclusive eligibility criteria often help to pick more homogeneous subjects, which could add power in detecting a true treatment effect if the certain type of subjects as defined in the eligibility criteria has a good response to the treatment. However, as we discussed previously, findings of a trial with exclusive eligibility criteria lack generalizability, and exclusive eligibility criteria may also jeopardize the speed of accrual. Therefore, it is typically acceptable to have more exclusive eligibility criteria in phase I and phase II trials, but the criteria should be relaxed to be more inclusive in phase III trials. A relatively heterogeneous patient population in a phase III trial will also allow the detection of efficacy difference in subgroups of subjects, which is an added bonus of having inclusive eligibility criteria in a clinical trial with relatively large sample size.

Historically, there are not much guidelines to follow for determining the inclusion and exclusion criteria of a clinical trial. Starting August 2016, ASCO and Friends of Cancer Research (Friends) had a joint effort to form four working groups to develop consensus recommendations on clinical trial eligibility criteria that are both scientifically and clinically appropriate.

Randomization

Randomization is an effective way to assign patients to treatment groups without systematic imbalances in important factors and patient characteristics. A well-designed and implemented randomized trial is often viewed as the “gold standard” for evaluating an experimental treatment when compared with either placebo or standard treatment.

In this section, we introduce a few randomization schemes that are most well-known or widely used for implementing random treatment assignments.

Simple Randomization

Considering a randomized controlled study where subjects are to be 1:1 assigned to either an experimental treatment or a control group, the simple randomization is no different from flipping a fair coin and assigning subjects to the experimental group if “head” and to the control group if “tail.” Although, in theory, the assignment can be quite balanced in treatment assignment and in

patient characteristics between groups on average; very few trials choose to use simple randomization in practice. This is because reasonable balance can only be achieved using simple randomization if the sample size is large. However, large clinical trials often are multisite and have interim analyses. A multisite trial typically requires stratified randomization by site, and interim analyses require balance in assignment be achieved with relatively smaller sample size.

Permuted Block Randomization

One easy way to address the unbalanced group size at interim analysis or at other time points during the trial is to use permuted block randomization (PBR), which imposes a balance restriction by blocks. The size of the block can be a prefixed or be selected at random. If we again consider a 1:1 randomized controlled trial, implementing PBR with block size of 4 will ensure balance in group size for every four subjects. That means for every four subjects, two must be assigned to the experimental group (E) and two must be assigned to the control group (C). We can easily permute the potential sequences for assignment of two treatments for block size of 4: EECC, CCEE, CECE, ECEC, CEEC, and ECCE. The same can be done essentially for any block size. Common choices of the block size are 2, 4, 6, and 8. We may randomly pick one of the generated sequences for any block if using PBR with fixed block size. For using PBR with random block size, one additional random pick needs to be made before starting any block: Randomly pick the block size for the coming block from all available choices, say 2, 4, or 6. Once the size of coming block is determined, we can use the same procedure as PBR to implement the randomization.

We discourage using a block size of 2 for PBR with fixed block size because that adds too much restriction on randomization. We also discourage using a block size of 8 or more for any PBR as the imbalance can still be substantial with larger block sizes. A well-known and criticized drawback of PBR with fixed block size is that it may hinder blinding. With relatively small block size, there is a good chance for physicians or researchers to figure out who are assigned to which treatment although they should be blinded of such assignment. Therefore, we suggest using PBR with random block size over PBR with fixed block size whenever appropriate and necessary.

Stratified Randomization and Covariate-Adaptive Randomization

Achieving balance in the number of subjects assigned to each arm throughout the duration of the trial is often not sufficient for most randomized clinical trials

in oncology. It is also important to ensure balancing on known covariates that may affect outcomes. If the covariates to be balanced are all categorical variables and the number of covariates is less than 3, stratified randomization is often appropriate for achieving balance in covariates. The idea of stratified randomization is simple: We first create different strata based on the covariates to be stratified and then conduct PRB or simple randomization within each stratum. The number of strata is jointly determined by the number of stratifying covariates and the levels of each covariate. For k stratifying covariates with levels of each covariate denoted by $l_1,l_2,\ldots,l_k$, the number of strata is $l_1 \times l_2 \times \cdots \times l_k$. For example, if a randomized trial has two stratifying covariates, site (three participating sites) and type of cancer (breast and prostate cancer), then the number of strata is 6. The number of strata increases quickly with more stratifying covariates. Once the number of subjects in each stratum becomes too small, there is an increased chance of imbalanced assignment within each stratum, which influences the balance of the whole trial. Therefore, when the number of stratifying factors exceeds 3, or if one or more continuous covariates are to be balanced, we suggest using covariate-adaptive randomization, also called minimization. The covariate-adaptive randomization assigns treatment to a new subject for minimizing the covariate imbalances within treatment groups. There are multiple ways of doing so, such as Zelen's rule, the Pocock-Simon procedure, and Wei's marginal urn design.[147]

Response-Adaptive Randomization

Most adaptive clinical trials that use Bayesian design adopt response-adaptive randomization, which has a changing probability of assigning a new patient to treatments based on the observed data from previously treated patients in the trial. The response-adaptive randomization allows more subjects be assigned to the more promising treatment arm and thus is viewed as a more ethical design. The response-adaptive randomization is preferred for many trials, but not all, because it typically requires an added complexity in designing, implementing, and analyzing the trial and often has slightly reduced power in detecting treatment difference for a fixed sample size.

Statistical Power and Sample Size

All clinical trials require the computation and justification of sample size, because the number of subjects evaluated in the trial is a key factor that determines the quality of scientific findings in the study. A clinical trial with too

small a sample size fails to yield meaningful scientific results, whereas a trial with too large a sample size will waste resources in finding a result and may expose more subjects than necessary to inferior treatment.

We need to know the design of a clinical trial and the variable type of the primary end point before doing sample size computation. In general, if a hypothesis testing is going to be conducted, we should specify the desired power, the null and the alternative hypothesis, the statistical test procedure to be conducted, and the type I error rate. The type I error is the probability of rejecting the null hypothesis when the null hypothesis is true. In other words, it is the chance of claiming a new drug is effective although it actually is not. As type I error can be a very serious error for all clinical trials, it is typically controlled at a low rate (α) of 0.05 or less. Another error we take into consideration when computing sample size is the type II error, the probability of not rejecting the null hypothesis when the alternative hypothesis is true. It can be viewed as the chance of incorrectly determining a therapy is not effective although it actually is. Although type II error is also critical, it is often not as serious error as the type I error. Therefore, it is acceptable for a trial to have 20% or less type II error rate (β). The power is simply $1 - \beta$. Therefore, clinical trials are typically designed to have 80% or more power.

For some early-phase pilot studies, the major goal may not be to determine whether a treatment is effective or not but to gain preliminary information on the level of effectiveness for planning future studies. For such a trial, it makes sense to plan the sample size based on the precision of a confidence interval. The precision of an estimate is directly based on the width of a confidence limit. The smaller the width, the narrower is the confidence interval, and the better precision is the estimate. For example, if we want to gain preliminary information on the 6-month objective response rate for a new radiation therapy in a single-arm phase II pilot trial, and we believe a 95% confidence limit ±0.15 is narrow enough no matter what the estimated response rate locates, we can then propose a sample size of 47 evaluable subjects to ensure the computed width of confidence interval is within 0.3.

Figure 15.6 shows the relationship between width of confidence limit, sample size, and the estimated proportion computed using Clopper-Pearson exact method (produced by Power Analysis and Sample size Software, 2017, NCSS, LLC, Kaysville, Utah, USA, http://ucss.com/software/pass). We can tell the width of confidence limit monotonically gets smaller as the sample size increases, and the width of confidence is also influenced by the point estimate of

the response rate. The width is always the widest at point estimate of 0.5 and gets narrower as the point estimate moves away from 0.5 in either direction.

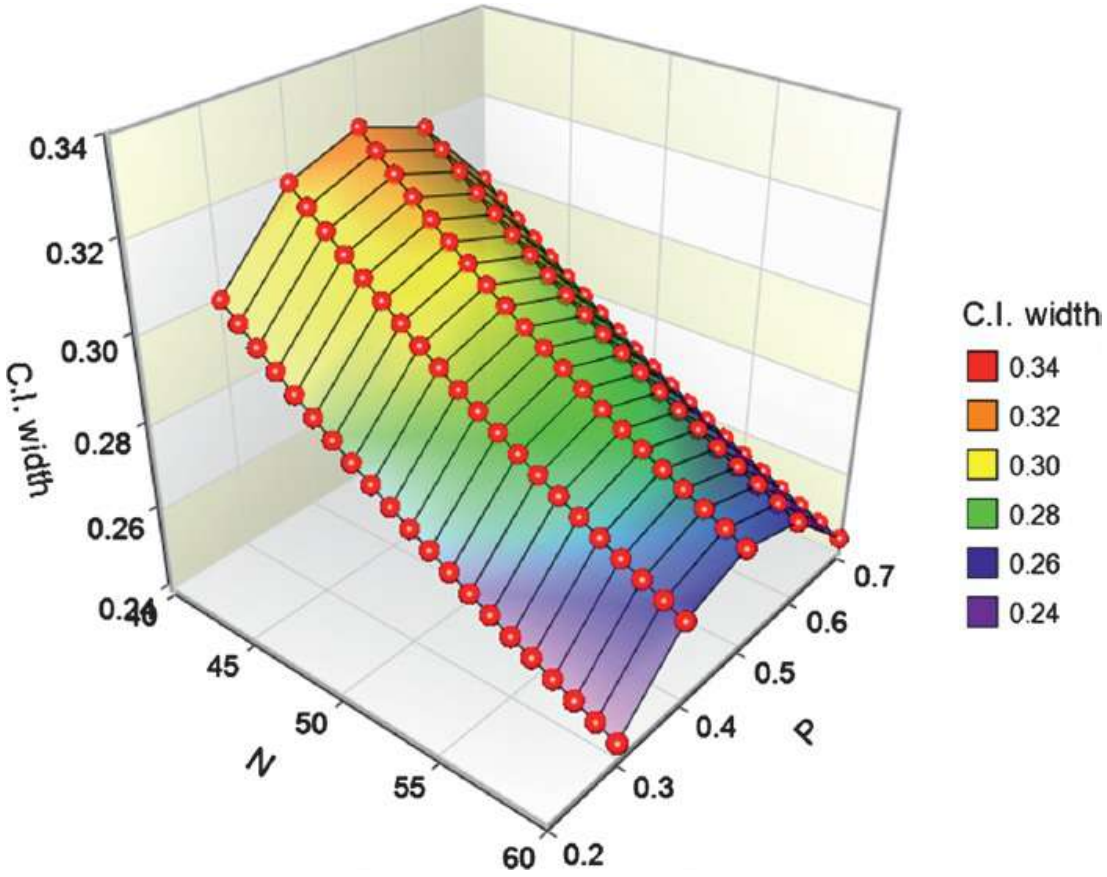

FIGURE 15.6. Relationship between width of confidence limit, sample size, and the estimated proportion.

We should keep in mind that the proposed sample size of enrollment in a clinical trial typically is larger than the computed sample size, because it is likely for patients to either drop off or become invaluable after enrollment. The proposed sample size should be inflated accordingly to make sure the final evaluable sample size has adequate power.

Although most trials require a predetermined fixed sample size at the design stage, some allows flexible total sample size depending on the findings during the trial. For example, the well-known 3 + 3 design, continual reassessment design, and Simon's two-stage design all allow flexible total sample size. Any clinical trials with interim looks and associated stopping rules allow flexible total sample size. However, the procedures of determining the sample size based on findings in the trial and the potential range of the trial need to be specified clearly in the protocol at the design stage.

Interim Analysis and Stopping Rules

Most phase III clinical trials and some phase II trials are designed to have interim analyses that allow the trial to be stopped early based on the findings in the interim analysis. A major purpose of a stopping rule is to protect patients from unsafe and/or ineffective drug. Many trials with interim analysis only allow early stopping because of evidence of futility or excessive toxicity. For example, the famous Simon's two-stage design only stops the trial for futility. In the design, n_1 subjects are enrolled to stage 1. If only r_1 or fewer subjects had successes, the trial will be stopped early. Otherwise, it will continue to enroll another n_2 subject. The final analysis is based on all $n_1 + n_2$ subjects. In general, the decision on whether to stop early for futility is predetermined based on the conditional power, the conditional probability of having statistically significant result if the trial continues to the end given the accumulated data in the interim analysis.[148] If such a probability is very low, lower than a preset threshold, then the trial may be terminated early because of futility.

Many other trials with interim looks allow early stopping for clear evidence in efficacy of the treatment. For such trials, it is extremely important to make sure the overall type I error rate is not inflated by the interim looks. For example, the well-known Pocock group sequential design[149] and the O'Brien-Fleming group sequential design proposed stopping boundaries for interim looks with appropriate α spending functions.[54] The Pocock design makes the interim looks equally spaced and requires the same level of evidence (i.e., using the same z, the boundary of rejection for the test statistic) for early and late interim looks. These requirements can be too restricted. Therefore, O'Brien and Fleming proposed a group sequential design that makes it harder to stop in early interim looks by letting the boundaries of early stopping decrease with the number of looks being conducted before the interim look.

Many other sequential or group sequential designs have been proposed and implemented. The key requirements for such trials are as follows: (a) the end point for interim analysis is relatively quick to evaluate. It is not desirable to use an end point that requires longtime follow-up (e.g., 10-year overall survival), because the trial will be halted for each interim look. (b) The number of interim looks, when to take the looks, and under which condition the trial will be stopped early should all be clearly specified in the protocol before the initiation of the trial. (c) An appropriate spending function is used to control for the overall type I error rate.

In general, unplanned interim looks are not allowed for any clinical trials. The

exception is that when the unplanned interim look is proposed by data safety monitoring board for protecting patients. In such situation, stopping boundaries can be constructed and modified for the added looks.[150]

Many sequential and group sequential clinical trials are designed using Bayesian methods. Unlike the frequentist methods that completely rely on the data in the current trial to make inferences and decisions, Bayesian methods incorporate outside information (e.g., published similar studies, pilot data, expert's opinion, etc.) into the procedure. A Bayesian method typically starts with specifying a prior distribution for the parameters of interest and updates the distributions using data from the trial. The updated distribution is called the posterior distribution, and the updates can be applied as many times as necessary in theory. The stopping rule of a Bayesian group sequential design is based on the posterior probability of efficacy or futility, which is computed combing the prior and the current data of the trial.

SURVIVAL ANALYSIS AND CATEGORICAL DATA ANALYSIS

Many oncology clinical trials include overall survival or time to PFS as primary or secondary end points. Such end points are called time-to-event end points, and statistical analysis for time-to-event end points is called survival analysis. Patients are followed sufficiently long so that a subset of subjects will experience the event of interest during the trial. The event of interest is death for overall survival and is progression or death for time to PFS.

Without loss of generalizability, we use overall survival as the event of interest from now on. The method is exactly the same for all other time-to-event end points.

The survival end point is actually a combination of two measures: (a) a binary variable indicating whether the subject died by the end of the study or at the last follow-up of the subject and (b) a continuous variable measuring time from a common starting point (e.g., the initiation of a treatment or at the time of randomization) to death if the subject has died. For those subjects who are still alive by their last follow-up time, the component of the survival time is not known and is thus treated as missing. Noticed that the information is only partially missing for these subjects because we do know they were still alive by the time of their last follow-up. A special terminology is used in survival analysis for such partial missingness—censored.

For most survival data, the first step is to use Kaplan-Meier estimate to

describe the distribution of survival time.[151] The Kaplan-Meier method utilizes the information of all subjects, including those who had observed death and those who censored, to describe the cumulative survival over time, which is the product of survival ratio of the number of subject still alive to those who are at risk.

Let us illustrate the computation and the plot of Kaplan-Meier curve using a simple example.

Suppose that we have 20 patients randomized to 2 arms. The observed survival time for subjects in each arm is as follows:

A: 8+, 11+, 16+, 18+, 23, 24, 26, 28, 30, 31.
B: 9, 13, 13, 14, 14, 16, 19+, 22+, 23+, 29+.
The unit was in month, and "+" indicates a censored observation.
Figure 15.7 shows the plot of the Kaplan-Meier curve.

Using arm A as example, we show step by step how the Kaplan-Meier curve was determined. Before plotting, the data should be sorted from low to high, regardless of whether the subject is censored or not. The Kaplan-Meier plot is a step function with steps formulated at one of more observed death. Starting at baseline, all 10 patients are alive, so the initial ratio of subject still alive to those who are at risk is 1 (=10/10). This is also the cumulative survival at baseline. At 8 months, one subject had censored, so the ratio of subject still alive to those at risk remains the same 1 (=9/9). As the baseline cumulative survival is 1, the cumulative survival at 8 months is still 1 (=1*1). Afterward, 3 more subjects are censored, which did not change the ratio, whereas the number of subjects at risk dropped to 6. The fifth subject died at 23 months. This makes the ratio dropped to 0.83 (=5/6). The cumulative survival at 23 months is still 0.83, because the cumulative survival at 18 months (the previous time point) is 1; thus, 0.83*1 = 0.83. The ratio was further dropped to 0.8 (=4/5) at 24th month, making the cumulative survival to be 0.664 (=0.8*0.83). The seventh subject died at month 26, with the computed ratio being 0.75 (=3/4) and the cumulative survival being 0.498 (=0.75*0.664). The ratio for the last subject at 31 months was 0 (=0/1), making the cumulative survival to become 0 as well. For a Kaplan-Meier plot, the cumulative survival is always 0 if the last subject is an observed death, as shown in the plot for arm A. Otherwise, if the last subject is censored, the Kaplan-Meier plot is flat with a positive cumulative survival, as seen in the plot for arm B.

The Kaplan-Meier plot can be used to compute the median survival time, a

common statistic of interest showing the estimated time that half of the patients will have died. Again, using the arm A plot as example, the median survival is month 26, when the cumulative survival first fell under 0.5. The median survival time is often reported with a confidence interval because this is an estimate. We omit the computation of the confidence interval here because of limited space. The median survival time and its associated confidence interval typically can be computed by almost all software for survival analysis. However, sometimes, the median survival is not estimable. This is because the Kaplan-Meier curve never fell below 0.5 for the study or for the particular arm under evaluation.

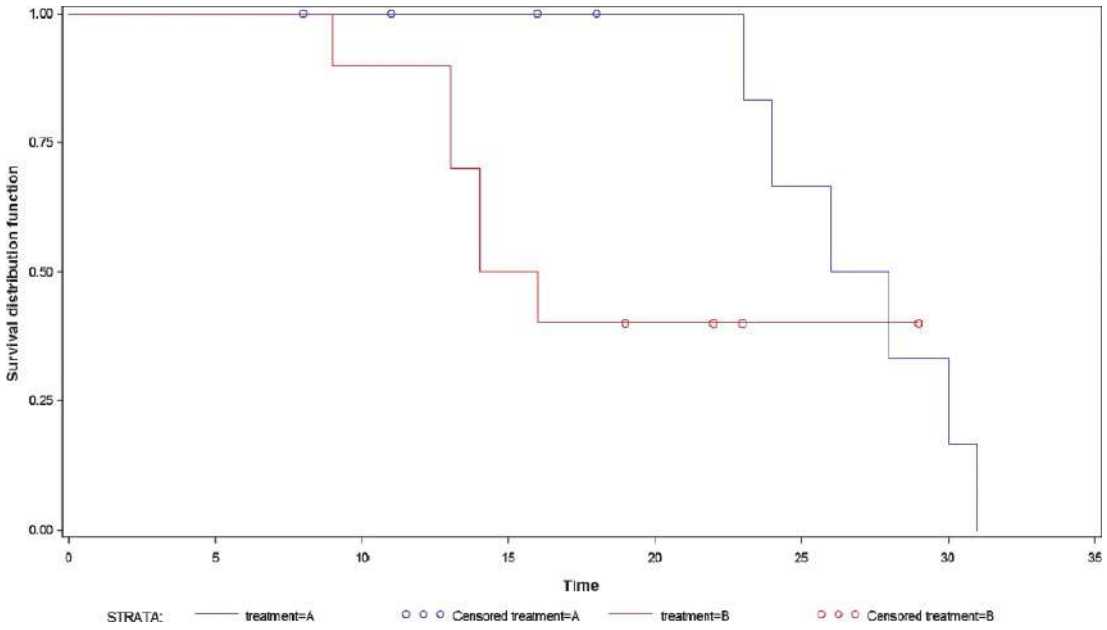

FIGURE 15.7. Plot of a Kaplan-Meier curve.

As the observed survival data rely a lot on the length of follow-up, it is important for any clinical trial with survival analysis to report the follow-up time.

The Kaplan-Meier plot is often accompanied by a log-rank test, a nonparametric test for comparing the survival distribution in two treatment groups. A significant log-rank test suggests the survival distribution in the Kaplan-Meier plot differs significantly for the two treatment arms.

The log-rank test only compares the survival distribution of the two arms without considering and controlling the effect of other influential factors, potential confounder, and effect modifiers. In order to control for those covariates, a Cox regression model is typically used to estimate the HR of the two treatments. In survival analysis, the hazard rate is the instantaneous risk of

death at a given time and can be thought of loosely as the probability of death at time *t* given that the patient is alive just before time (t^2). The Cox regression model is also called proportional hazards model because it assumes the HR for two specified strata are constant over time.

Another type of end points often seen in oncology clinical trial is the categorical end points, such as tumor response. The first thing to describe for categorical end points is the response rate and the associated confidence interval in each arm if this is a randomized trial. Pearson's chi-square test is the most often used test to evaluate the difference in response rate for two treatments without controlling for other factors. When the sample size is small, *P* values from Fisher's exact test are often reported instead. Logistic regression model is the most common choice for comparing treatment effects using statistical modeling. It provides estimation to the odds ratio of treatment after controlling for important covariates other than the treatment.

In addition to traditional statistical modeling, machine learning methods can also be used to analyze survival end point and categorical end points.

PRACTICAL ISSUES IN THE DESIGN, EXECUTION, AND REPORTING OF CLINICAL TRIALS

The Institutional Review Board

Several different groups share responsibility for the monitoring and oversight of ethical and safety issues in clinical trials. According to U.S. Federal Regulations, the role of the IRB is primarily to ensure that "risks to subjects are minimized" and "risks to subjects are reasonable in relation to anticipated benefits."[90] This involves review of the study protocol, informed consent document, background information, and proposed research plan.

Data and Safety Monitoring Committees

Once trials are initiated, ongoing monitoring of accumulating data regarding safety, effectiveness, and trial conduct is required. In the late 1960s, federal agencies (such as the National Institutes of Health and the Department of Veterans Affairs in the United States) began to mandate an *external* review by a DSMC, because investigators may not be fully objective in their interim data analysis. Meanwhile, industry-sponsored trials have been slower to incorporate this practice.[81] However, not all trials warrant the cost of a DSMC, including trials of short duration or those that have end points such as relief of symptoms

(rather than survival or severe toxicity). For this reason, the IRB review serves to inquire about the safety monitoring plan and can request establishment of a DMSC, if warranted because of perceived potential risk to patients.

Conflict of Interest

Industry sponsorship of clinical trials in oncology has increased over the past 2 decades. Compared to the pharmaceutical industry, radiation oncology is limited to a small number of equipment vendors. Nonetheless, one study found that among clinical trials led by radiation oncologists and reporting conflicts of interest, over half of COI was related to industry sponsorship.[152] A literature review of COI in radiation therapy trials for breast cancer from 2004 to 2014 found that 13% of studies reported funding from profit organizations, whereas an additional 49% of trials were supported by not-for-profit organizations.[153] They found that funded trials and those with a positive conclusion were more likely to be published in journals with a higher impact factor, but the presence of COI did not influence study conclusions. In a randomized survey of internal medicine physicians, the perceived impact of trial results from industry-sponsored studies was lower than that from NIH-sponsored studies.[154] Nonetheless, any financial support should be reported given the potential for conflicts of interest to arise.

Role of Cooperative Groups

Clinical trials are truly only ethical if the foreseeable risks outweigh the benefits. It is considered unethical to launch a trial if it is unlikely to enroll enough patients to ensure statistically significant results. This has led to the initiation of trials by multicenter cooperative groups, such as the European Organisation for Research and Treatment of Cancer (EORTC), and more recently the combination of the National Surgical Adjuvant Breast and Bowel Project (NSABP), Radiation Therapy Oncology Group (RTOG), and Gynecologic Oncology Group (GOG) into the NRG. Meanwhile, the Human Health Division of the International Atomic Energy Agency (IAEA) supports coordinated research activities (CRAs) between their member states, which aims to support well-designed trials that maximize impact.[155] Important randomized trials have been conducted under the auspices of the IAEA including the evaluation of the safety and efficacy of hypofractionated radiation in elderly patients with GBM[156] and brachytherapy boost in nasopharyngeal cancer.[157] One ongoing IAEA trial randomizes patients to SBRT versus transarterial chemoembolization (TACE) for hepatocellular carcinoma, with practical components of trial design that include training on

treatment techniques and use of novel QA phantoms in credentialing processes.[89]

Register on ClinicalTrials.gov

Maintained by the National Institutes of Health, ClinicalTrials.gov serves to inform researchers, physicians, and patients of ongoing and completed clinical trials both in the United States and around the world. The Web site was created as part of the Food and Drug Administration Modernization Act of 1997, which mandated that both federally and privately funded trials conducted under investigational new drug applications be registered in a publicly accessible platform. Although requirements for registration were expanded in 2007, still many clinical trials do not require registration, though it is strongly encouraged to improve transparency. As of April 2017, ClinicalTrials.gov reported 41,919 registered trials, of which 56% represented exclusively non-US trials from 197 countries. The trial sponsor or PI is responsible for registering trials at ClinicalTrials.gov at study initiation, as well as providing timely updates and submitting summary results.

Consolidated Standards of Reporting Trials (CONSORT)

By the early 1990s, medical journal editors and clinical trialists identified a need for a scale to assess the quality of randomized controlled trials. Groups of these experts meeting separately in Canada and the United States created the SORT and Asilomar reports, respectively, which merged in 1996 into a single, coherent, evidence-based recommendation known as the CONSORT Statement (http://www.consort-statement.org/). Most notably, this guideline statement includes both a checklist and flow diagram (Figure: http://www.consort-statement.org/consort-statement/flow-diagram) to enable readers to understand a trial's design, conduct, and analysis and to encourage adherence and transparency by authors.[158]

NOVEL APPROACHES TO CLINICAL TRIAL DESIGN

Seamless Phase I to II Trial

As have been discussed thus far, typically, phase I trials evaluate toxicity and phase II efficacy. However, seamless phase I/II trials—or trials that achieve the goals of both phases I and II in one umbrella protocol—have been developed to address both of these questions.[22] In these two-stage designs, information from the initial phase I study is incorporated into the phase II study. Different variations on this have been developed. Figure 15.8 from the manuscript by Berry et al.[159] shows the concept behind a seamless phase I/II trial using two drugs, A and B, given either concurrently or sequentially in one of the 10 dose combinations indicated by the yellow dots. This adaptive randomization takes into account the toxicity and efficacy of these combinations.

Another Bayesian adaptive phase I to II clinical trial has been designed for evaluating efficacy and toxicity with delayed outcomes,[160] which, as previously discussed, is crucial in radiotherapy trials. This approach evaluates both efficacy and toxicity as binary outcomes, both as time-to-event models. The authors' simulations showed that this method significantly reduces the study duration.

Pan et al.[161] propose a phase I/II seamless dose escalation/expansion with adaptive randomization scheme (SEARS). There are three critical components to this model: First, it applies the modified toxicity probability interval (mTPI) method as a way of monitoring toxicity. Then, in the phase II portion, it

adaptively randomizes, based on efficacy, patients to any doses showing promising efficacy and safety. Posterior probabilities are calculated using both the phase I and II information (Fig. 15.9 from Pan et al.[161]).

REDEFINING THE APPROACH TO CLINICAL TRIALS

The randomized phase III clinical trial is considered the most robust method of comparing the efficacy of a new treatment with the standard of care. Grading systems for evaluating clinical evidence universally place RCTs above observational trials. However, multiple features of modern medicine challenge the feasibility of this traditional approach. First, as medicine progresses through incremental improvements in treatment as well as earlier detection, the potential effect size of the next intervention decreases, whereas the time to event increases. The result of increasing trial size and duration of follow-up increases the cost. The age of the patient population diagnosed with cancer continues to increase, as mortality from cardiac diseases decreases. Because this population of elderly patients with comorbidities is often excluded from clinical trials, the applicability of trial results to this population is difficult. Meanwhile, technologic advances in imaging and treatment as well as incorporation of molecular profiling can cause the question being addressed to become obsolete by the time trial results have matured. Specifically in radiation therapy, rapidly evolving technology has often led to increasing complexity of treatment, such as with improvements in treatment conformality through intensity-modulated radiation therapy (IMRT) and stereotactic body radiation therapy (SBRT). Increasing complexity often warrants more strict QA mechanisms to ensure that the intervention is applied appropriately in order to adequately test its utility, thereby reducing the ability to generalize the results to routine clinical practice.

Pragmatic Clinical Trials

The concept of pragmatic clinical trials arose out of the concern that clinical trials were being optimized to determine efficacy while potentially overestimating benefit and underestimating harm when applied to the general population.[162] Pragmatic trials thus focus on applicability of a new intervention to general practice, whereas explanatory trials aim to address questions of biologic mechanism. In 2009, a tool called the PRagmatic-Explanatory Continuum Indicator Summary (PRECIS) was published to provide clinical trialists with a guide to understanding how different components of design would impact the applicability, or pragmatism, of the trial.[163] An updated version (PRECIS-2) was published in 2013 in which 9 domains get scored on a Likert-type scale (1 = most explanatory, 5 = most pragmatic).[164] The primary goal of PRECIS-2 is to match the trial design to the intended application of trial results.

Meanwhile, CONSORT published an "extension for pragmatic trials" that specifies that trial publications include all the information on the context of their conducted trial so that future readers can judge applicability of the results to their own clinical context, where they may be considering implementing the intervention tested in that randomized trial.[165] So although PRECIS-2

encourages appropriate trial design, CONSORT ensures trial results and information are reported adequately for health system decision-makers to determine applicability of trial results to their clinical setting.

A study design often employed in pragmatic trials is cluster randomization. This allows the intervention to be implemented at the group level rather than the individual level, which affords more opportunity for training of interdisciplinary teams of professionals and assurance that implementation is appropriate for the clinical context. Furthermore, as a result, all patients within a center are treated uniformly, which improves efficiency and reduces the risk of errors. The comparator arm, meanwhile, is generally usual care, which is not always the case on explanatory trials. By facilitating training, cluster designs also help to address differences in provider experience, which have been shown in radiation oncology to influence outcomes and must be considered such as to avoid confounding. Although pragmatic trials often include providers with a representative mix of experience levels to increase generalizability, trial quality must always be closely monitored. A pragmatic trial conducted poorly is of no use for decision support.

Pragmatic trials rely more heavily on electronic health records (EHRs) and patient registries to collect patient information, as this reduces cost of trial coordinators. Of note, many registries were established prior to implementation of EHRs, so they often collect data in parallel, with work ongoing to synchronize the system. Some health systems have developed robust national quality registries that are disease-based or intervention-based, which has facilitated large clinical trials. For example, the Thrombus Aspiration in ST-Elevation Myocardial Infarction in Scandinavia (TASTE) trial was a multicenter, prospective, open-label, randomized, controlled clinical trial that used the infrastructure of a population-based registry in 29 Swedish centers and 1 Icelandic center, to facilitate enrollment and long-term data collection on 11,709 patients treated for heart attacks from 2008 to 2009.[166]

Comparative Effectiveness Research

The 1999 Institute of Medicine's report "To Err Is Human" called attention to serious concerns about patient safety in the United States. The Agency for Healthcare Research and Quality (AHRQ) was established to address these concerns by focusing on the safety and quality improvement in health care delivery. The AHRQ defines comparative effectiveness research (CER) as that which is "designed to inform health-care decisions by providing evidence on the

effectiveness, benefits, and harms of different treatment options."[87] Then, in 2010, an independent nonprofit, nongovernmental organization called the Patient-Centered Outcomes Research Institute (PCORI) was authorized by Congress to further address the need for information to guide better-informed health decisions by patients, providers, and policy makers. PCORI is the single largest public funder of CER in the United States, supporting primarily large pragmatic studies and large-scale observational studies.[88]

Over the past few decades, government agencies, professional societies, and private corporations have established patient registries that collect standardized data from patients diagnosed and treated in a variety of settings, in order to provide data regarding patterns of care and patient outcomes.

The Surveillance, Epidemiology, and End Results (SEER) Program of the National Cancer Institute was established in 1974 to provide cancer statistics in order to reduce the burden of cancer.[86] SEER is a population-based registry representing 17 regions and 28% of the US population. It is therefore a useful epidemiologic tool for calculating incidence (new cases per population), prevalence (existing cases per population), and mortality (deaths per population) for different cancers, and it documents tumor-specific information. SEER, a clinical database, is often linked to the Medicare claims data, in order to provide more detailed indirect information regarding treatment of cancer (including number of fractions of radiation) as well as diagnosis codes and interventions that could relate to toxicity (such as cystoscopy, colonoscopy, coronary angioplasty). Use of Medicare linkage restricts the data to over 65 years, however. This is similar but distinct from the Medicare Chronic Conditions Warehouse (CCW), which is an administrative database that can be used independently to investigate broader patterns of care than SEER-linked data, though it lacks detailed cancer information that is available in SEER, such as stage.

The National Cancer Database (NCDB) is jointly sponsored by the American College of Surgeons and the American Cancer Society. It includes patients from 1,500 Commission on Cancer (COC)-accredited programs, representing 70% of cancer diagnoses.[85] The initial goal of NCDB was to monitor patterns of care at the local hospital level and provide feedback regarding quality measures. NCDB requires COC accreditation and therefore does not represent all patients in a population. It is therefore technically not a population-based database and thus not appropriate for incidence/prevalence but can be used to assess outcomes after diagnosis. NCDB includes details of margin status, radiation dose, and

technique, which are not captured in the SEER database. Although NCDB enables important patterns of care studies, it lacks robust outcome data, including cancer-specific survival, and recently has been used extensively to assess efficacy of radiation treatment with overall survival as the primary end point, which has significant limitations. Because of the observational nature of this registry, confounders exist in treatment selection (including patient performance status), which can bias the perceived efficacy of the treatment. In a retrospective database, one can never fully control for this selection bias and therefore should interpret overall survival results with extreme caution.

A major limitation of SEER, NCDB, and CCW, however, is the lack of patient-reported outcomes. The CaPSURE represents a prostate-specific registry that was initiated in 1995 to enable prospective cohort studies in men with prostate cancer that focused on incorporating patient-reported outcomes.[167] Approximately 40 urology practices, primarily community-based, enroll patients in a database that tracks over 1,000 clinical and patient-reported variables. Though this is not a population-based sample, it provides much richer clinical detail than SEER. Given the long natural history of prostate cancer, CaPSURE is regarded as a cost-effective alternative to randomized trials that reflects "real-world" practice and has resulted in nearly 200 peer-reviewed publications.

Newer registries are being developed to address the limitations of current databases and therefore include a robust interface for data collection that facilitates prospective clinical trials (such as the Swedish TASTE trial) and incorporation of radiation-specific information (including that captured in Digital Imaging and Communications in Medicine (DICOM) files). Cancer Learning Intelligence Network for Quality (CancerLinQ) is a national initiative sponsored by the American Society for Clinical Oncology (ASCO) that involves a cloud-based platform that communicates nightly with the EHR at each individual practice to collect, deidentify, and update patient information, which serves as both a database to evaluate quality metrics and also real-time decision support tool that recommends guideline-concordant therapies.[168] As of October 2016, CancerLinQ had registered over 1 million patients treated at 70 clinics by 1,500 oncologists, and shortly thereafter, the American Society for Radiation Oncology (ASTRO) announced partnership to incorporate critical radiation-specific data into the database.[84] Developing a DICOM-based registry for radiation oncology requires first standardizing naming conventions to enable harmonization of the digital information. This process is in progress in the United States, with AAPM Task Group 263 defining the naming convention and

the Radiation Oncology Institute developing the National Radiation Oncology Registry and piloting it in prostate cancer at 30 centers. Meanwhile, Sweden has successfully implemented the naming convention and is collecting RT data in DICOM files through their Medical Information Quality Archive at the majority of their radiation centers.[169]

Meta-analysis

A formal quantitative means of combining evidence from multiple clinical trials is by meta-analysis—a widely used analytic tool in many areas of social and medical science. Meta-analysis refers to a process whereby data from independent studies are combined to form a quantitative summary estimate of a given effect.

Meta-analyses are considered by some to be a source of level I evidence along with large randomized clinical trials. A meta-analysis combines results of several studies, all of which ask a similar research question but may be individually too small to have enough statistical power to definitively answer the question. Performing a systematic analysis of data from all identified randomized trials can define a modest yet real advantage associated with a therapeutic approach, such as overall survival associated with radiation in breast cancer[170] and concurrent chemotherapy with radiation in head-and-neck cancer.[171] To address the likelihood of publication bias (i.e., a greater representation of trials with positive results appearing in the literature), a meta-analysis should include unpublished studies as well, though assessing quality is critical given the lack of peer review.

Meta-analyses can be performed with or without access to the raw data, though the methods employed are critical to ensuring quality results. Cochrane is an independent, nonprofit, nongovernmental organization consisting of a group of more than 37,000 volunteers in more than 130 countries that aims to improve access to high-quality reviews that guide decision-making.[82] Researchers interested in undertaking meta-analyses are encouraged to contact the Cochrane Methods Groups, which provide access to methodologists that can assist with responsible conduct of meta-analyses (http://methods.cochrane.org/methods-groups).

Clinical trials in radiation therapy often restrict access to raw patient data, including detailed treatment planning information in DICOM files, much of which is not reported or even investigated in the primary publication. For example, multiple trials have reported the presence of a major protocol deviation

predicting inferior overall survival.[146] Even determining the reason for the deviation can be difficult to find, because the process has been retrospectively defined until only recently. Access to the original images, treatment plans, and setup images could elucidate important information regarding details in QA that could better explain the differences in patient outcomes. An ideal system would promote the public availability of trial data to facilitate further research, with a currently available resource including figshare (https://figshare.com/).

NEXT-GENERATION RADIATION ONCOLOGY TRIALS

Next-generation trials will need to include iterative, adaptive designs that are not *a priori* committed to studying uniform fraction intervals (i.e., q daily, Monday to Friday, *or* qod, Mon, Wed, Fri), but are based on the constant incorporation of serial imaging and liquid biopsies, which can serve as surrogates of early response and/or resistance for most or a small component of the tumor. All patients will have omic information available, and all patients will likely have their tumors growing in an avatar to generate patient-derived xenografts (PDX). There is increased evidence that immunotherapy radiation may enhance the therapeutic capacity of immunotherapy, as shown in Fig. 15.10.

Furthermore, the emerging field of radiomics[172] and mathematical modeling,[173] an outgrowth of evolutionary biology, will provide personalized radiotherapy prescriptions that may change multiple times during a course of treatment.[174–176]

Although the patient and providers may not know the length and schedule of the prescription at the time of the initial consultation, positive results will demand that trials incorporate disruptive algorithms in order to test promising and disruptive treatment paradigms. Figure 15.11 provides a snapshot of the next-generation clinical trial approach for radiation-based cancer research.

CHAPTER 16

Stem Cell Transplantation and Total-Body Irradiation

Sarah Jo Stephens, Kenneth B. Roberts, Zhe (Jay) Chen, Stuart Evan Seropian, and Chris R. Kelsey

INTRODUCTION

Historically, total-body irradiation (TBI) was used without stem cell support for palliation of radiation-sensitive diseases such as chronic lymphocytic leukemia and follicular lymphoma. Currently, TBI is primarily performed in the context of hematopoietic transplantation for its cytotoxic and immunologic effects. The patient's hematopoietic system is reconstituted after high-dose chemotherapy, with or without TBI, from either the patient's own stem cells (autologous) or stem cells from a donor (allogeneic). In the case of donor stem cells from an identical twin, the term syngeneic transplantation is appropriate. This chapter will also briefly address hemibody irradiation (HBI), which is occasionally utilized for palliation of diffuse metastatic disease. Stem cell support is not required in this setting.

RATIONALE FOR STEM CELL TRANSPLANTATION

Hematopoietic stem cell transplantation (SCT), while utilized in a variety of settings, is primarily pursued for patients with high-risk or relapsed/refractory hematologic malignancies to decrease the risk of disease recurrence. Multipotent stem cells have the capacity to differentiate into all blood cell lineages and can be obtained from several sources including bone marrow, peripheral blood, and umbilical cord blood. Stem cells can be harvested directly from the marrow or through apheresis of the peripheral blood following administration of granulocyte colony-stimulating factor (G-CSF). The conditioning regimen for hematopoietic SCT has several important functions and depends on the type of transplant—autologous (auto-SCT) or allogeneic (allo-SCT). For the former, the

sole purpose of the conditioning regimen is cytotoxicity. For allogeneic transplants, the conditioning regimen also facilitates immunosuppression, so the host does not reject the donor stem cells, and to create space in the bone marrow for the graft. Conditioning regimens can consist of chemotherapy alone or a combination of chemotherapy and TBI.

Autologous Transplantation

Autologous transplantation relies upon higher doses of chemotherapy to overcome the resistance of malignant cells with subsequent reinfusion of stem cells to reconstitute the hematopoietic system. The most common indications for auto-SCT are multiple myeloma, relapsed diffuse large B-cell lymphoma, and relapsed Hodgkin lymphoma. Peripheral blood stem cells are the graft product of choice for auto-SCT and are associated with improvements in rates of engraftment, quality of life, and reduced cost when compared with cells derived from bone marrow.[1,2] Patients undergoing auto-SCT must be reasonably fit to tolerate high-dose chemotherapy/TBI. With modern supportive care and increasing experience with this procedure, the risk of mortality from auto-SCT is quite low (~1%).[3]

The timing of auto-SCT depends on the underlying disease. For most patients with relapsed aggressive lymphomas, auto-SCT is preceded by a salvage chemotherapy regimen. If the patient has chemotherapy-sensitive disease, ideally demonstrated by achievement of a negative positron emission tomography/computed tomography (PET-CT) scan, then the patient proceeds with high-dose chemotherapy and auto-SCT. The high-dose chemotherapy regimen is based on the underlying disease. For example, in the setting of relapsed Hodgkin lymphoma, BEAM (carmustine, etoposide, cytarabine, melphalan) or CBV (cyclophosphamide, carmustine, and etoposide) is often utilized. High-dose melphalan is the most common conditioning regimen for multiple myeloma.

When adjunctive radiotherapy is indicated, the optimal timing is not well characterized. Historically, radiotherapy has been given after auto-SCT, but there is increasing experience of giving it before. Some concern exists for radiation therapy (RT) to the chest prior to auto-SCT having an undue risk of pneumonitis, as initially reported by a Toronto group.[4] Other investigators, such as from Memorial Sloan Kettering Cancer Center, dispute this and prefer to give RT prior to high-dose therapy and transplant.[5]

Allogeneic Transplantation

As opposed to auto-SCT, which relies completely on cytotoxicity from high-dose chemotherapy/TBI to eradicate persistent tumor clones, allo-SCT relies in part on an immunologic graft-versus-tumor effect to eradicate malignant cells. The most common indication for allo-SCT is high-risk and relapsed acute leukemia, particularly acute myelogenous leukemia (AML) and acute lymphocytic leukemia (ALL). Allo-SCT may be preceded by full-dose (myeloablative) conditioning designed to have maximal antitumor effect and also to condition the patient for the infusion of the donor cells as an immunologic therapy. Increasingly, allo-SCT is preceded by a nonmyeloablative or reduced intensity conditioning program. In this latter situation, the major antitumor effect is postulated to derive from the infused donor stem cells, and the intensity of the condition regimen is modified to allow the procedure in patient populations previously ineligible because of age or medical condition. Nonmyeloablative allogeneic transplants are associated with lower treatment-related morbidity compared with myeloablative allogeneic transplants.[6,7] Most transplant centers utilize peripheral blood progenitor cells, as opposed to bone marrow, for allo-SCT.

Thus, allo-SCT is largely an immunologic therapy. Allogeneic hematopoietic cells must be matched with the recipient for the majority of the major histocompatibility antigens to avoid rejection and minimize graft versus host disease (GVHD). Differences in minor human leukocyte antigens (HLA) facilitate the graft-versus-tumor effect that enhances transplantation efficacy. Early studies demonstrated improved leukemia control with allogeneic bone marrow cells as compared to syngeneic (identical twin) donor cells.[8] Further evidence for graft-versus-tumor effect derives from the efficacy of donor lymphocyte infusions after relapse of leukemia following allo-SCT.[9,10]

Despite HLA matching, allo-SCT is limited by GVHD. GVHD results from the release of inflammatory cytokines as a result of activation of mature donor T cells that recognize recipient HLA alloantigens, presented as peptide molecules by antigen-presenting cells (APCs). Normally, mature T cells express “tolerance” to these peptides derived from self-proteins because of thymic depletion or peripheral suppression of autoreactive T cells.[11] However, in the setting of allo-SCT, despite HLA matching, a repertoire of peptides displayed on recipient cells can be recognized as minor histocompatibility antigens by donor T cells because of polymorphisms in genes outside of the HLA system.[12] The activation of donor T cells after contact with specialized APCs leads to

differentiation to effector cells that produce cytokines such as interferon gamma (IFN-γ) and tumor necrosis factor (TNF) as well as mediate cytotoxicity against normal recipient organs. Acute GVHD includes clinical damage to the skin, GI tract, and liver, but other organs can also be involved. GVHD may evolve, or develop de novo, later after transplantation with distinct clinical features resembling sporadic autoimmune diseases (termed chronic GVHD). Common presentations include sicca syndrome, sclerotic or lichenoid skin disease, and immune hepatitis. Fasciitis/myositis and bronchiolitis obliterans syndrome (BOS) are less common presentations, which may cause significant morbidity.

Despite the prophylactic use of immunosuppressive agents such as cyclosporine, tacrolimus, methotrexate, sirolimus, and mycophenolate mofetil, HLA-matched sibling hematopoietic transplants result in some degree of GVHD in approximately 60% of patients.[13,14] Increased immunosuppression may ameliorate symptoms from GVHD but may also abrogate the graft-versus-tumor effect and place patients at higher risk for posttransplant infections.[15] Acute GVHD can be effectively prevented by T-cell depletion of the donor cells prior to stem cell infusion, but this may also lead to an increased risk for infections as well as the concern that the desirable graft-versus-tumor effects will be diminished or lost. Nevertheless, there has been clinical success with T-cell–depleted allo-SCT in reducing GVHD. Such techniques require more intensive immunosuppression to prevent graft rejection and therefore often employ TBI in the conditioning regimens.[16,17]

Myeloablative Allogeneic Stem Cell Transplantation

TBI has been a central part of allo-SCT for leukemias since the pioneering work of Thomas and associates beginning in the late 1950s. Historically, a single dose of 10 Gy utilizing a low dose rate (~10 cGy/min) was used. The premise that TBI had to be given as a single fraction was challenged in the late 1970s when Peters et al. demonstrated the marked sensitivity of most normal tissues to altered fractionation and dose rate with minimal effects on bone marrow progenitors and leukemic cells.[18,19] It was concluded that with the same total dose, an improved therapeutic ratio would be expected from a reduction in the dose rate of single-fraction TBI or by TBI fractionation. Calculations of various fractionation schemes and dose rates have been published based on the linear quadratic model.[20–22] O'Donoghue et al. calculated that for very low dose rate single-fraction TBI to be equivalent radiobiologically to the more common fractionated TBI schedules, an unreasonable radiation time of 20 to 24 hours

would be necessary.[22] With concepts of both radiobiology and practicality in mind, a large variety of fractionated TBI schedules have been used. After a generation of clinical investigation, no one regimen is clearly superior to another. Currently, most myeloablative TBI programs use a twice or three times a day fractionation scheme over 3 to 5 days to deliver a total dose of 12 to 15 Gy.

Nonmyeloablative or Reduced Intensity Allogeneic Stem Cell Transplantation

In the past decade, growing recognition of the immunotherapeutic potential of allografts has led to a reconsideration of the need for high-dose myeloablative conditioning regimens traditionally administered prior to transplantation. Pioneering work of Storb et al. and others in canine models established that highly immunosuppressive, but nonmyeloablative, regimens could establish stable mixed hematopoietic chimerism in major histocompatibility complex–matched littermates using one-sixth of the usual ablative dose of TBI in combination with postgrafting immunosuppressive drugs.[23,24] Subsequently, numerous clinical trials have established that a spectrum of subablative conditioning regimens of varying intensity may allow engraftment of donor cells with reduction in transplant-related toxicity, permitting transplantation of patients traditionally excluded from allo-SCT because of age or medical comorbidities.[25,26] The primary purpose of a nonmyeloablative preparatory regimen is to suppress the patient's immune system sufficiently to allow the engraftment of donor cells with minimal host toxicity. The graft-versus-tumor effect is relied upon to eradicate tumor cells.

Common to these regimens is sufficient immunosuppression to overcome host resistance to engraftment using either antimetabolites such as fludarabine, TBI, or both, in combination with other agents. Other factors, such as patient age, HLA disparity with the donor, tumor burden, and prior therapy may also affect the degree of engraftment. A series from the Seattle transplant group, for example, demonstrated that a single 2-Gy fraction of TBI, in combination with postgrafting cyclosporine and mycophenolate, is sufficient to achieve a high rate of donor engraftment in patients with a prior history of auto-SCT, but additional immunosuppression in the form of fludarabine is necessary to assure engraftment in less heavily pretreated patients or patients receiving unrelated donor grafts.[27]

Reduced intensity transplants now account for roughly 25% of all allo-SCTs. Efficacy is difficult to evaluate in the absence of randomized trials, but reduced

intensity conditioning regimens have allowed for an expanded use of transplants in high-risk populations. As an example, elderly patients with acute leukemias in first remission have long-term survival rates over 40% with reduced intensity transplants, which would be considered a remarkable achievement compared to historical experience in which very few patients would be expected to survive.[28] Toxicity is significantly lower than traditional myeloablative transplants. The Seattle group has reported a 1-year non–relapse-related mortality of allo-SCT of 30% for ablative regimens compared to 16% for reduced intensity conditioning regimens (P = .04).[29] The toxicity of a single-fraction 2-Gy TBI, for example, should be minimal. Most transplant centers delivering this dose of TBI would dispense with the complexities of lung blocks as well as compensating filters for dose homogeneity.

PURPOSES OF CONDITIONING

The purpose of high-dose chemotherapy, with or without TBI, prior to auto-SCT is simply to give a higher intensity of treatment to overcome intrinsic tumor resistance, thereby decreasing the risk of a relapse. The purpose of conditioning in the setting of allo-SCT is more complex and serves three key functions: (a) to provide sufficient immunosuppression in the recipient to prevent rejection of the graft, (b) to create space in the bone marrow for donor stem cells, and (c) to provide further cytoreduction to achieve a minimal residual disease state prior to transplant. Myeloablative regimens address all three whereas reduced-intensity regimens provide immunosuppression and create space for the donor stem cells but with variable, and lesser degrees of, further cytoreduction.

The choice of conditioning regimen prior to transplantation depends upon a variety of factors that include the type of transplant (allogeneic vs. autologous), conditioning intensity (myeloablative vs. nonmyeloablative), disease type (AML vs. ALL), expected patient tolerance, and disease status.

TBI-Based Conditioning Regimens

There is wide variability between centers in regard to the techniques utilized for TBI including total dose, fractionation scheme, dose rate, lung shielding, and patient positioning (see below for further discussion). Some aspects have been formally evaluated with randomized studies, whereas many others have not.

In regard to total dose, two randomized trials have compared 12 Gy versus 15.75 Gy in patients with AML and chronic myelogenous leukemia (CML). In

the AML study, patients randomized to the higher-dose arm were noted to have improved relapse-free survival (RFS) (P = .06) but at the cost of increased transplant-related mortality (P = .04) and moderate to severe GVHD (P = .02).[30] There was no difference in overall survival (OS). In the CML series, a disease that is rarely transplanted anymore given the efficacy of tyrosine kinase inhibitors, the investigators also noted improvement in RFS (P = .008) with a nonsignificant trend toward increased transplant-related mortality (P = .13) and moderate to severe GVHD (P = .15) in patients receiving the 15.75-Gy regimen.[31] As OS was not improved in either study, more moderate total doses seem preferable.

Several studies have evaluated single-fraction compared with multifraction regimens. Deeg et al. evaluated 75 patients with acute nonlymphoblastic leukemia in first remission. The first 22 patients enrolled on the study received 9.2 Gy in a single fraction at 4 to 6 cGy/min utilizing opposed cobalt sources. The remaining patients were randomized to either 10 Gy in a single fraction or 12 Gy in 6 fractions. Survival was improved in the patients receiving either 9.2 Gy in a single fraction or 12 Gy in 6 fractions compared to 10 Gy in a single fraction (P = .04). There was an increase in early toxicity, particularly veno-occlusive disease or sinusoidal obstructive syndrome (VOD/SOS), in patients receiving 10 Gy in a single fraction. Pneumonitis appeared more common in single fraction (both 10 Gy and 9.2 Gy) compared to the fractionated regimen.[32] Girinsky et al. randomized 160 patients to either 10-Gy single-fraction (12.5 cGy/min instantaneous dose rate, 4.5 cGy/min average dose rate) or hyperfractionated TBI to 14.85 Gy in 11 fractions (25 cGy/min instantaneous dose rate). They noted no difference in OS or cause-specific survival. There was an increase in incidence of VOD/SOS in patients who received single-fraction TBI (P = .044).[33] In a study from the Hôspital Tenon in Paris, 157 patients were randomized to single-fraction TBI with variable dose rate (6 vs. 15 cGy/min) or fractionated TBI with variable dose rate (3 vs. 6 cGy/min). No significant differences were noted between the single-fraction and fractionated TBI schedules, or by dose rate.[34] The preponderance of data favors a fractionated regimen using a low dose rate approach.

The choice of chemotherapy agents used in conjunction with TBI depends on the underlying disease. For AML, and in many other settings, high-dose cyclophosphamide is utilized given its effectiveness in both immunosuppression and cytotoxicity. A typical dose is 120 mg/kg over 2 days. In other settings, agents such as etoposide, melphalan, and fludarabine are combined with TBI.

Reduced intensity or nonmyeloablative transplant regimens using low-dose TBI are often combined with fludarabine.[35]

Chemotherapy and TBI are given sequentially rather than concurrently to avoid any potential increase in normal tissue toxicity. Whether chemotherapy should be given before or after TBI is unclear. One study of 1,769 patients undergoing myeloablative allo-SCT for acute leukemia did not show any differences in outcomes with cyclophosphamide given before or after TBI.[36] Typically, TBI over 3 to 5 days is best delivered during the regular work week, when the full technical support staff is available. TBI may be better tolerated if given first when the patient is less fatigued and not experiencing the side effects of chemotherapy. The risk of nosocomial infections may be marginally lower when the patient travels to the radiotherapy department before becoming neutropenic later in the conditioning course. Alternatively, TBI at the end of the preparative regimen allows the stem cell transplant to proceed immediately thereafter. Unlike chemotherapy, there is no washout period needed for TBI, theoretically decreasing the time the patient spends neutropenic prior to engraftment.

Chemotherapy-Alone Conditioning Regimens

Although the evolution of TBI has led to significant reduction in toxicities, the initial concern about the risk of fatal radiation pneumonitis led to the development of non-TBI regimens. For example, Santos at Johns Hopkins and other groups began administering busulfan in place of radiotherapy.[37] These approaches were initially developed for use in the auto-SCT setting but have been expanded for use in the allo-SCT, as well. The hope was that these regimens would result in less toxicity compared to TBI-containing regimens. In addition, conditioning with chemotherapy alone can be used in practice settings where TBI is unavailable. Combinations have been developed based on biologic activity of a particular drug, drug tolerability, and nonoverlapping drug toxicities. The most commonly used ablative regimens to condition patients with AML are the combination of busulfan and cyclophosphamide (BuCy) or busulfan and fludarabine.[38,39] A regimen utilizing carmustine, etoposide, cytosine arabinoside, and melphalan (BEAM) or carmustine, etoposide, and cyclophosphamide is commonly used to treat patients with non-Hodgkin and Hodgkin lymphoma.[40] Single-agent high-dose melphalan is also used frequently prior to auto-SCT for treatment of multiple myeloma. For patients with aplastic anemia, the combination of cyclophosphamide and antithymocyte globulin is

often used for immunosuppression while avoiding excessive myelotoxicity.[41] There is interfacility variation in dosing and drug delivery schedules making it somewhat difficult to make direct comparisons between these regimens.

Most of the initial trials using BuCy used high-dose oral busulfan, which has highly variable pharmacokinetics, poor gastrointestinal tolerability, high rates of VOD/SOS, and increased frequency of seizures.[42] An intravenous formulation of busulfan has been developed, which is much better tolerated, has more predictable pharmacokinetics, and has been associated with less toxicity.[43] Some chemotherapy agents are associated with pulmonary toxicity, which may be a significant issue in patients with a prior history of chest radiotherapy.[44,45]

TBI-Based Versus Chemotherapy-Alone Conditioning Regimens

Randomized studies comparing chemotherapy-alone conditioning regimens to TBI-based regimens are few, often enrolled multiple leukemia subtypes, included a variety of patients (e.g., first complete remission, relapse, etc.), and used antiquated TBI and chemotherapy platforms. These limitations make it difficult to reach firm conclusions.

A French randomized trial compared BuCy to TBI-Cy before allo-SCT for adult AML in first remission.[46] TBI-Cy was superior for disease-free survival (DFS) ($P < .01$), leukemia relapse ($P < .04$), and transplant mortality ($P < .06$). Long-term follow-up also demonstrated worse OS and leukemia-free survival (LFS) in the patients receiving BuCy compared to TBI-Cy, felt to be the result of higher transplant-related mortality and relapse rates.[47]

Bunin et al. published a randomized series of patients with ALL treated with either etoposide–cyclophosphamide–TBI or etoposide–BuCy. The authors found an improvement in event-free survival ($P = .03$) for patients in the TBI arm.[48]

A randomized study from the Southwest Oncology Group (SWOG 8612) compared fractionated TBI plus etoposide versus high-dose BuCy in patients who had failed prior conventional therapy for ALL, AML, or CML. Patients were stratified as “good risk” (second complete remission for acute leukemia or accelerated phase CML) or “poor risk” (more advanced stages of leukemia). There was no difference noted in OS or DFS between the two treatment groups.[49]

Ringdén et al. of the Nordic Bone Marrow Transplantation Group compared BuCy to TBI-Cy in patients with AML, CML, and ALL. Patients treated with BuCy had higher rates of VOD/SOS ($P = .009$), hemorrhagic cystitis ($P = .003$), transplant-related mortality in those with advanced disease ($P = .002$), seizures

(P = .03), high-grade chronic GVHD (P = .04), and death associated with GVHD (P = .003). There were similar rates of acute GVHD between the two groups. RFS was similar upon analysis of all patients, but in the subgroup of adult patients (P = .05) and advanced disease (P = .005), TBI-containing regimen appeared superior.[50] Long-term follow-up of this study demonstrated a 7-year relapse rate of 29% in both groups. In patients with advanced disease, there was a significant increase in transplant-related mortality in patients who received BuCy (P = .004). There was no difference in LFS in patients with early disease, but there was an improvement in LFS in patients with advanced disease receiving TBI (P < .01).[51]

A randomized trial from the French Society of Bone Marrow Graft (SFGM), which also evaluated the impact of single fraction versus fractionated TBI, showed no difference in overall 5-year survival or DFS for patients with CML treated with BuCy versus TBI-Cy.[52] Similarly, the study by Clift et al. showed no significant difference for 3-year OS, relapse, event-free survival, or speed of engraftment for BuCy versus TBI-Cy for CML.[53]

Socié et al. published long-term follow-up of 4 randomized controlled trials. For patients with AML, there was a strong trend toward improved survival (P = .068) and DFS (P = .051) with TBI-Cy.[54] A meta-analysis by Hartman et al. evaluated 5 prospective randomized control trials with 652 patients treated from 1966 to 1996 and showed trends not reaching statistical significance in favor of TBI for both OS and DFS.[55] Another meta-analysis by Shi-Xia et al. evaluated 18 trials with a total of 3,172 patients. For patients with ALL or AML, TBI-Cy was associated with lower rates of leukemia relapse, lower transplant-related mortality, and higher rates of DFS. However, for patients with CML, the TBI-Cy regimen was associated with higher rates of leukemia relapse, lower transplant-related mortality, and similar DFS. The risk for cataracts (P = .01), pneumonitis, and growth/developmental problems (P = .008) was higher with a TBI-containing regimen. Alternatively, the risk of VOD/SOS (P < .00001), hemorrhagic cystitis, and transplant-related mortality appeared higher for patients treated with BuCy.[56]

Given the conflicting randomized studies, a number of retrospective series, most using registry data, have evaluated TBI-based versus chemotherapy-alone conditioning regimens in AML. The majority of retrospective analyses demonstrate equivalent outcomes when comparing oral busulfan-containing regimens compared to TBI-Cy.[57–60] A single-institution retrospective series from Duke showed superior LFS and OS in patients with AML treated with TBI-Cy

compared to BuCy, at the expense of increased pulmonary toxicity.[61] Intravenous busulfan has the added advantage of better tolerability and pharmacokinetics. The data are inconsistent whether intravenous busulfan with cyclophosphamide is more effective than TBI-Cy regimens.[57,62,63]

To summarize, limited randomized data, with obvious limitations, have not demonstrated any difference in outcomes with TBI and non–TBI-based regimens for CML. For ALL, TBI appears to be an important component of the conditioning regimen. For AML, the available randomized studies and meta-analyses favor TBI-Cy, though this is controversial given negative findings from nonrandomized registry studies (Table 16.1).

TABLE 16.1 CONDITIONING REGIMENS FOR AML

Study	*N*	Conditioning Regimen	Leukemia-Free Survival	Comments
Randomized Trials				
Blaise et al.[47]	101	TBI–Cy BuCy	55% 35% (*P* = .02)	PO busulfan
SWOG 8612[49]	122	TBI-etoposide BuCy	NS (*P* = .69)[a]	PO busulfan
Ringdén et al.[51]	69	TBI–Cy BuCy	56% 59% (*P* = .7)	PO busulfan Increased incidence of VOD/SOS, hemorrhagic cystitis, chronic GVHD, and obstructive bronchiolitis with BuCy. Cataracts more frequent with TBI/Cy[a]
Meta-Analysis				
Socié et al.[54]	172	TBI–Cy BuCy	57% 47% (*P* = .051)	PO busulfan
Shi-Xia et al.[56]	1,289	TBI–Cy BuCy	OR 1.49 (1.01, 2.20) in favor of TBI	PO busulfan Higher rates of cataracts, interstitial pneumonitis, and developmental problems for patients receiving TBI–Cy. Higher rates of VOD/SOS and hemorrhagic cystitis in patients receiving BuCy
Registry Studies				
Nagler et al.[57]	1,659	TBI–Cy BuCy	64% 61% (*P* = .27)	Intravenous busulfan Lower incidence of acute GVHD (grades 2–4) and chronic GVHD in IV BuCy group
Copelan et al.[62]	1,230	TBI–Cy BuCy	RR 0.70 (0.55,	Examined both IV and PO busulfan formulations

			0.88) (*P* = .003) in favor of IV busulfan	No statistically significant difference between oral busulfan and TBI-based regimens
Litzow et al.[59]	581	TBI–Cy BuCy	58% 54% (*P* = .438)	PO busulfan Higher rates of VOD/SOS with busulfan-based regimen
Ringdén et al.[60]	824	TBI–Cy BuCy	66% 64% (NS)	PO busulfan Higher rates of VOD/SOS and hemorrhagic cystitis with busulfan-based regimen
Institutional Series				
Stephens et al.[61]	206	Cy-TBI BuCy	43% 30% (*P* = .12)	PO busulfan LFS improved with Cy-TBI on multivariate analysis Higher rates of pulmonary toxicity in TBI-based regimen

ALL, acute lymphocytic leukemia; AML, acute myelogenous leukemia; Bu, busulfan; CML, chronic myelogenous leukemia; Cy, cyclophosphamide; DFS, disease-free survival; LFS, leukemia-free survival; TBI, total-body irradiation.
[a]Included data from patients with ALL/CML.

The side effect profile of different conditioning regimens is also an important consideration. Although there can be significant overlap in treatment-related toxicities between chemotherapy and TBI-based conditioning regimens, such as fatigue and nausea, some toxicities are more common with one modality versus another. Although both chemotherapy and TBI can cause lung toxicity, TBI-based regimens appear to be associated with a higher risk of pneumonitis and other lung complications.[46,50,54,55] Prior thoracic radiotherapy may increase the risk of fatal pneumonitis. One study demonstrated a 32% risk of fatal pneumonitis after TBI in patients with prior chest radiation doses above 20 Gy.[64] Avoiding TBI may be prudent in such patients. One contemporary series of allo-SCT documented a 33% risk of severe pulmonary toxicity after TBI-based conditioning, with the number of prior chemotherapy regimens being the only independent risk factor for lung toxicity.[65] Cataracts and endocrine deficiencies are also more common with TBI.

In contrast, hepatic VOD/SOS[66] and hemorrhagic cystitis are more common with BuCy.[55,67] The Nordic Bone Marrow Transplantation showed a VOD/SOS incidence of 12% in patients treated with busulfan compared to 1% for the TBI-treated patients (P = .009). Hemorrhagic cystitis risk was 24% for busulfan-based therapy versus 8% for TBI (P = .002).[50] Oral busulfan-conditioning regimens also have an appreciable risk for seizures.[68]

A relative advantage in using TBI for SCT is that the dose delivery throughout the body is highly controllable. In contrast to chemotherapy, dose distribution is independent of such factors as blood supply, and there are no concerns about agent activation, metabolism, excretion, or dose modifications based on liver or kidney function. TBI may also reach chemotherapy sanctuary sites, which is of particular concern in patients at risk for testicular or CNS involvement.

GRAFT FAILURE

Failure to engraft is a potential life-threatening complication of allo-SCT. Historically, approximately 6% of patients fail to engraft with myeloablative conditioning.[69] Given the expanded use of alternative donor transplants and nonmyeloablative regimens, more recent estimates of failure to engraft are between 12% and 15%.[70–72] Not surprisingly, graft failure is associated with worse outcomes.[73] For those patients who fail to engraft, salvage allo-SCT with a TBI-based regimen is possible. Several small, single-institution studies have described using a nonablative regimen in this setting,[74–76] although use of a second myeloablative regimen has also been described.[77] Second myeloablative transplants are generally associated with increased risk of severe toxicity. Reduced intensity regimens can be used to escalate host immunosuppression and increase the probability of successful engraftment.[78]

TOTAL-BODY IRRADIATION—RADIOBIOLOGY

Radiobiologic Effects on the Normal Hematopoietic System

Successful hematopoietic stem cell engraftment requires (a) eradication of the recipient bone marrow, (b) immunosuppression to prevent rejection of donor stem cells in the case of an allo-SCT, and (c) relative sparing of the recipient's bone marrow stromal cells. The use of the classic radiobiologic parameter D_0 gives a rough indication of the radiosensitivity of various cell populations. The reported D_0 values of bone marrow stem cells usually range from 0.5 to 1.4 Gy, indicating intrinsic radiosensitivity.[79,80] Although conventional wisdom assumes that recipient marrow cells must be removed to leave space for donor cells in the stem cell microenvironment to favor competitive repopulation, this concept has been challenged. In fact, mixed bone marrow chimerism resulting from less cytotoxic, nonmyeloablative transplantation may be acceptable or even

desirable.

Immunosuppression in the setting of allo-SCT is necessary to avoid rejection of donor stem cells. TBI is a very efficient immunosuppressant. In animal work by Storb and colleagues, equivalent doses of fractionated TBI were significantly less effective than single-dose TBI to condition dog leukocyte antigen (DLA)-identical littermate dogs before bone marrow transplantation.[24,81] The investigators concluded that significant repair of DNA damage by lymphoid cells occurs during interfraction intervals. In a murine model, Salamon et al. looked at 3 TBI schemas from schedules that had been developed for human TBI therapy (8.5-Gy single-fraction TBI, 2 Gy × 6 fractions of TBI, and 1.2 Gy × 12 fractions of hyperfractionated TBI).[82] In terms of the immunosuppressive effects, the results favored single-fraction TBI. A marked initial shoulder on the dose survival curve has been reported for T-lymphocyte precursors[83] and for a human lymphoblastoid cell line.[84] The immunosuppressive effects of TBI show marked fractionation sensitivity, leading one to conclude fractionated TBI might be associated with more graft rejections than the same dose delivered in a single fraction.

If bone marrow stromal cells and their progenitors (colony-forming unit fibroblasts) are damaged, delayed engraftment or even graft failure may follow.[85] Progenitors of human bone marrow stromal cells have been found to have a D_0 of 1.46 Gy.[86] They are also sensitive to dose rate effects and fractionation. Thus, fractionated TBI spares bone marrow stromal cells and their progenitors better than does single-fraction TBI.[87]

Radiobiologic Effects on Leukemia

In the setting of SCT, TBI achieves significant leukemia cell killing in conjunction with chemotherapy and the subsequent graft-versus-tumor effect, leading to eradication of malignant clones in a significant portion of cases. Most D_0 values for both animal and human leukemia cell lines range from 0.8 to 1.5 Gy,[88–91] although extreme values range from 0.3 to >5 Gy. Leukemic cell lines frequently show a minimal initial shoulder in radiation cell survival curves, leading to the hypothesis that fractionation (or reduced dose rate exposure) should have only a minor effect on cell survival. Split-dose radiation experiments lend further support to this hypothesis. Greater repair capacity is seen with more differentiated leukemias or lymphocytes (e.g., B- or T-cell phenotypes).

TOTAL-BODY IRRADIATION—TECHNIQUES AND DOSIMETRY

Basic Requirements

Historically, radiation oncologists have aimed to deliver a relatively homogenous dose of TBI throughout the whole body given the concern that leukemias are systemically distributed. Because microscopic disease burden during remission may not be uniform throughout the body, the importance of homogeneous dose delivery is unclear. Some TBI programs use photon energies above 20 MV, which may theoretically deliver higher marrow doses because of increased pair production and higher bone absorption.[92] Many correct for skin-sparing effects of megavoltage irradiation with the use of beam spoilers, although this is probably not necessary for low-energy photons in the absence of leukemia cutis or a tropism for skin involvement such as in monocytic leukemias. Where there is concern for a higher burden of disease, boost radiation fields may be added to TBI. Augmented doses of radiation may be delivered to the brain in the setting of CNS involvement or to the testes in males with ALL, for example.

To ensure the planned dose distribution is accurately delivered, all TBI techniques must undergo a rigorous and comprehensive dosimetric characterization. Because of large variations in body geometry and tissue density between patients, it is recommended that dose homogeneity remain within a specified window of ±10% of the prescribed dose, though ±5% is typically attainable. For TBI and HBI, there is evidence that a 5% change in lung dose could result in 20% change in the incidence of radiation pneumonitis, a complication that is sometimes fatal.[93,94] Therefore, the basic dosimetry of TBI (and HBI) techniques should be performed as precise as readily achievable. Accurate dosimetry coupled with an effective quality assurance program, including adjustments to dose delivery after *in vivo* measurements on the first day of treatment, will ensure not only safe delivery of TBI treatments but also accurate dosimetry data for meaningful dose–response analysis. Once a patient begins a course of TBI, within a comprehensive conditioning program, the timing of successive fractions becomes critical to the outcome of the procedure. It is imperative to have a backup TBI system either within the same institution or in a nearby radiation therapy department when establishing a TBI program. When the primary system is down, a fully commissioned backup TBI system can be utilized to complete the remaining treatments.

Total-Body Irradiation Techniques

Many TBI techniques have been described, and improvements in both the irradiation technique and physical dosimetry continue.[95–98] Much of the early clinical experience with TBI was obtained at centers with facilities designed specifically for large-field irradiation.[99] Although a few dedicated systems still exist, current TBI procedures are largely performed with techniques established on linear accelerators that are also used for conventional radiotherapy. Common to these TBI techniques is the use of radiation fields that are larger than the maximum field size (~40 by 40 cm) available at standard source-to-surface distance (SSD) by treating TBI patients at extended SSDs of 200 to 600 cm. For treatment rooms large enough to accommodate an SSD of 5 m or more, a single square field at maximum collimator opening is usually sufficient to completely encompass patients of typical height placed along the diagonal of the field (Fig. 16.1A–E). At shorter SSDs, multiple abutting fields may be necessary, and irradiation of the whole body can be achieved by translating the radiation field[100] or the patient[101] or by sweeping the radiation field over a stationary patient (Fig. 16.1F–H).[102] For these irradiation techniques, patients are typically treated with two parallel-opposed fields. When a single radiation source is used, this can be accomplished by rotating the patient 180 degrees along the patient's longitudinal axis between the two fields. In a dedicated system with two radiation sources mounted opposite to each other, the treatment can be accomplished by irradiating the two fields simultaneously without changing the patient's position. Various patient positions, ranging from sitting, standing upright, to lying horizontally in a supine or lateral decubitus positions, have been used (Fig. 16.1A–H).

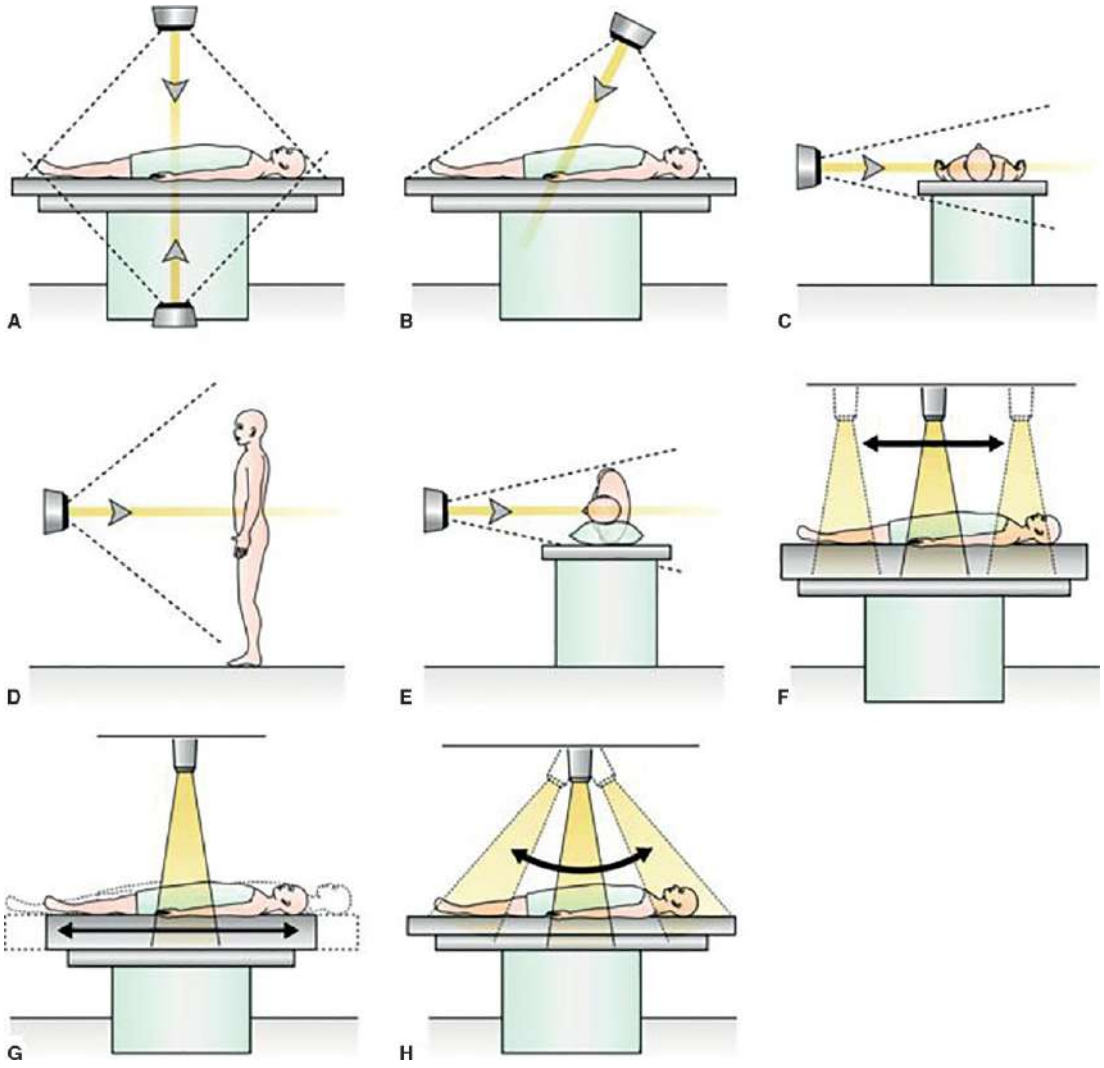

FIGURE 16.1. **A–E:** Some of the current large-field total-body irradiation (TBI) techniques in which patient and beams are stationary: **A:** Two vertical beams. **B:** One vertical beam. **C:** One horizontal beam, patient in supine position. **D:** One horizontal beam, patient standing or sitting. **E:** One horizontal beam, patient in lateral decubitus position. **F–H:** Some of the small-field TBI techniques in which patient or beam moves. **F:** Source scans horizontally. **G:** Patient moves horizontally. **H:** Sweeping beam.

The technique using a single large field encompassing the entire patient at extended SSD is by far the simplest and the most prevalent TBI technique used today. The treatment is typically delivered with a horizontal field directed toward the primary shielding wall. It eliminates the dosimetry complications occurring in the junctions of multiple abutting fields. It also alleviates the concern that cells circulating through the body may potentially receive a reduced dose when abutting fields are delivered sequentially.

Recently, with the introduction of intensity-modulated radiation therapy

(IMRT) and other advanced IMRT delivery systems, such as volumetric modulated arc therapy (VMAT) on conventional linear accelerators and spiral TomoTherapy on dedicated treatment units, the possibility of delivering TBI-type treatments at SSDs similar to that of conventional radiotherapy has been explored by several research groups.[96–98] In addition to obviating the need for using extended SSDs, these new techniques open the possibility to design and deliver customized dose distributions throughout the whole body. Their ability to seamlessly deliver integrated boost dose to total marrow and/or the lymphatic system while reducing dose to uninvolved critical organs has the potential to further improve the therapeutic ratio of TBI. At present, only limited clinical experience has been reported with these techniques.[103] More carefully designed and controlled clinical testing of these new techniques is needed to fully establish their clinical utility and efficacy.

Dosimetric Characterization of Total-Body Irradiation Techniques

Once an irradiation technique is chosen, a careful characterization of the dosimetric properties of the technique should be performed by a qualified medical physicist. The dosimetric data needed to model the treatment planning system for accurate planning of TBI for individual patients should be carefully measured and validated. The technical issues and method of radiation dosimetry for TBI have been reviewed in several reports.[99,104,105] In particular, a report from the American Association of Physicists in Medicine (AAPM) task group 29 (TG-29) on the physical aspects of TBI and HBI provides a comprehensive discussion on dosimetry issues and techniques specific to large-field TBI.[99] It is a good resource for medical physicists charged to commission a large-field TBI technique.

Since publication of the TG-29 report, the reference dosimetry protocol for external beams at standard treatment SSD, known as the TG-21 protocol, has been updated by a new calibration protocol (TG-51). For photon beams at standard SSD, the TG-51 protocol produces similar results as the TG-21 protocol. However, the TG-51 protocol cannot be applied directly for large fields at extended SSD as encountered in TBI. The calibration of a TBI beam can be established with direct traceability to TG-51 by using an approach similar to that proposed by Curran et al.[106] In this approach, the photon source of the TBI beam is first calibrated under the TG-51 reference condition at standard SSD. The dose per unit beam-on time at a reference point of the TBI beam under TBI treatment conditions is then related to the dose per unit beam-on time of the same photon

source at the TG-51 reference point by a correction factor that accounts for the TBI setup geometry and scattering conditions. This correction factor, as well as the relative dose factors that characterize the spatial distribution of the TBI beam, such as the percent depth dose (PDD) or tissue maximum ratio (TMR) along the central axis, can be measured directly under the TBI treatment conditions using a phantom with size similar to that of a typical patient. In-phantom off-axis beam profiles at various depths, especially along the diagonal near the corners of the field, should also be measured at TBI treatment distances to evaluate the dose variation across the radiation beam. Independent verification of the TBI calibration should be performed after the initial commissioning. The modeling of the treatment planning system should also be verified on an anthropomorphic phantom.[107–109] A thermoluminescent dosimeter calibrated on an independent linear accelerator can be used to verify TBI calibration and doses at other points of interest. Ion chamber and film may be used to assess dose distributions.[110]

Skin Surface Dose

Although skin sparing is often a desirable feature of megavoltage irradiation in conventional radiotherapy, for TBI, it may be desirable to have skin surface receive close to full prescription dose as leukemia may circulate through or infiltrate the skin. When needed, the skin dose can be increased by using either bolus placed on the skin or a beam spoiler positioned between the source and the patient.[111] In the latter technique, a large plastic screen (e.g., 2-cm-thick acrylic plastic sheet or acrylic resin) covering the whole body is placed approximately 10 cm from the patient. As photons of the TBI beam pass through the beam spoiler, scattered electrons are produced, which deposit most of their energy at shallow depths near the skin surface. The use of a beam spoiler alters the depth-dose characteristics of the TBI beam in the buildup region. The magnitude of this modifying effect depends on the photon energy of the beam, the composition and thickness of the scatter screen, and the distance between the screen and the patient. It should be carefully evaluated as part of the commissioning task for the TBI technique. The dosimetric effect of the beam spoiler can be treated separately or included in the TBI beam calibration. When the beam spoiler is included in the calibration, choice of the calibration depth becomes an important consideration. Calibration measurements performed at a depth of 5 cm or greater decrease the influence of beam spoiler-generated electrons significantly.

Dose Rate

As discussed in preceding sections, the rate of TBI dose delivery could have an impact on the clinical outcome after TBI.[112] Many clinical protocols require low dose rate treatment at the rate of 0.05 to 0.20 Gy/min.[99] Modern linear accelerators offer a wide range of dose rates (e.g., from 1 to 6 Gy/min in increments of 1 Gy/min), to the depth of maximum buildup at standard SSD. At extended SSD, the nominal dose rate will be smaller because of inverse-square falloff of photon fluence with SSD. The dose rate at the TBI treatment distance is dependent on the combination of SSD and the nominal dose rate programmed at the LINAC console. If a given combination of SSD and nominal LINAC dose rate does not produce a desired dose rate, a custom-made attenuator can be placed in the beam path to help achieve a desired dose rate. TBI calibration and dosimetry characterization should be performed with the desired treatment dose rate to ensure accurate dose delivery.[99]

Patient Positioning

As treatment times may last up to 30 or 40 minutes for each fraction of a TBI protocol (even longer for single-fraction protocols), patients must be placed in a comfortable and reproducible position. When a pair of parallel-opposed fields is used, irradiation along the anteroposterior/posteroanterior (AP/PA) direction is advantageous as the body thickness in the AP/PA direction is usually smaller than in the lateral direction, which results in better dose uniformity along the beam path for a given photon energy. As depicted in Figure 16.1A and B, this may be accomplished with the patient lying in the supine/prone position under a vertical beam arrangement or with the patient lying on the side in a lateral decubitus position when a horizontally directed beam is used (Figs. 16.1E and 16.2A and B). Irradiation with the patient lying supine using a horizontally directed beam (Figs. 16.1C and 16.2C) is also a reasonable technique, especially for patients with small lateral separations, such as pediatric patients, or when a higher-energy photon beam is employed. Because of clinical problems associated with patient fatigue and orthostatic hypotension, special patient stands are used in some institutions to facilitate upright patient positioning (Fig. 16.1D).

Treatment Planning

The calculation of radiation beam-on time for a prescribed TBI dose is often performed with a specialized in-house program or by manual computation. This is because most commercial treatment planning systems are designed and

commissioned using standard datasets for conventional radiotherapy, which do not automatically apply to a TBI configuration. Some newer versions of commercial treatment planning systems can be adapted for isodose planning of TBI at extended SSDs by using depth dose, beam profiles, and other parameters measured directly under TBI conditions. For example, a special TBI beam model was successfully commissioned on the Theraplan Plus 3D system and used in routine TBI treatment planning at Yale. Others have commissioned and evaluated an extended SSD photon model on the Pinnacle[3] planning system for TBI.[113] Newer techniques for total marrow and/or lymphatic irradiation using TomoTherapy or VMAT at standard treatment distances can take advantage of the beam models already commissioned in an existing treatment planning system, although the dosimetric accuracy must undergo a careful validation for irradiating large and complex target volumes demanded by TBI and total marrow irradiation (TMI).

In addition to TBI beam characteristics, an accurate description of patient geometry is needed for patient-specific treatment planning. The external body contour of a TBI patient in treatment position can be reconstructed from the measurements of body thickness at representative anatomic points judiciously distributed over the patient's body. A CT scan of the entire body provides the best description of patient geometry and is required for IMRT-based TBI/TMI techniques. For extended SSD, TBI techniques using two parallel-opposed beams, dose variation over the patient's body arises primarily from (a) photon attenuation along the beam path, (b) the changing body contour across the patient, and (c) variations in tissue density.

The dose variation caused by photon attenuation along the beam path is dependent upon both the beam energy and the body thickness. It decreases with decreasing body thickness and increasing photon energy. Because the body is typically thinner in AP direction, treating patients using an AP/PA technique with higher photon energy will improve the dose uniformity along the beam path. Using lateral-opposed beams will usually result in greater dose variation compared to AP/PA treatments, especially for adult patients. The dose variation caused by changing body contour may be reduced by using missing-tissue compensators or tissue-equivalent bolus material placed directly on the patient. The ability to compute isodose distribution across the body is highly desirable for compensator design. Missing-tissue compensator for TBI is typically constructed to even out the variation of body thickness along the head to toe direction. Such a one-dimensional compensator can be constructed manually

using multiple thin copper (or material) plates. As the compensator is usually mounted at the head of the linear accelerator, small variations in the placement of compensating plates will be magnified at extended SSD distance. Care must be exercised in constructing these compensators. For example, when compensating plates are used for the head and neck region, mounting the compensator too far inferiorly could result in a lower dose to the shoulders. In addition, careful alignment of the patient to the planned position becomes important to achieve the desired missing-tissue compensation.

Dose variation caused by tissue heterogeneity in the thoracic region requires special attention because the lungs are a critical dose-limiting structure in TBI. Without compensation for air density, particularly for AP/PA treatments, dose inhomogeneity can exceed the prescribed dose by 10% to 24%, depending on the energy of beams used.[99] In order to reduce lung toxicity, correction for lung air density should be taken into account. Further, many institutions attenuate the dose to the lungs using lung shielding. This can take many forms including customized lung blocks (typically in the setting of AP/PA fields; Fig. 16.2B and E) or attenuation using brass compensators (typically in the setting of lateral fields; Fig. 16.2D). The use of lung blocks increases the complexity of the TBI procedure, and accurate repositioning of lung blocks can be a challenge for fractionated treatments. Several techniques have been reported to increase the repositioning accuracy of lung blocks.[114–116] At Yale, individualized thin lung blocks (with ~85% photon transmission) are mounted close to the patient on an acrylic resin tray using a hook and loop fastener system that allows easy repositioning of lung blocks for each fraction (Fig. 16.2B). Verification of correct lung block positioning is carried out by using customized online electronic portal imaging. For the lateral technique, the arms can be used, in addition to shielding using brass compensators, to decrease dose to the lungs (Fig. 16.2C). For pediatric patients, the arm may not be large enough laterally to cover the entire lung.

Dose Description and Reporting

Because there is no standard treatment technique for TBI, significant differences in dose distributions can exist with different treatment methods. Two institutions can prescribe the same dose at some selected prescription point, but dose to other points could vary considerably if different treatment techniques are used. Without supplemental information on the dose distribution, it would be difficult to assess the clinical effectiveness of different TBI programs based on the

reported prescription dose alone. To facilitate treatment comparison among institutions, various methods for prescribing the dose for TBI treatments have been reported.[117,118] One method uses a single-point prescription dose supplemented with the specified limits of highest and lowest dose levels acceptable for any point within the body. In addition, dose limits are also set for certain tissues, such as the lungs. An example of such a TBI prescription is given in AAPM TG-29, which uses the midpoint at the level of the umbilicus as the prescription point. A prescription would read as follows: “The dose to the midpoint at the level of the umbilicus is 14 Gy to be delivered in 8 fractions with 2 fractions on each day separated by at least 6 hours. All points in the body should receive doses within the limits of −5% and +10% of prescription dose. The dose to lung should be no more than 85% of the prescription dose.” When reporting results from a TBI-based conditioning regimen, ideally, the actual values of the corresponding dose descriptors would be provided. When CT-based TBI treatment planning is available, dose–volume histogram of the target volume and critical organs should be reported.

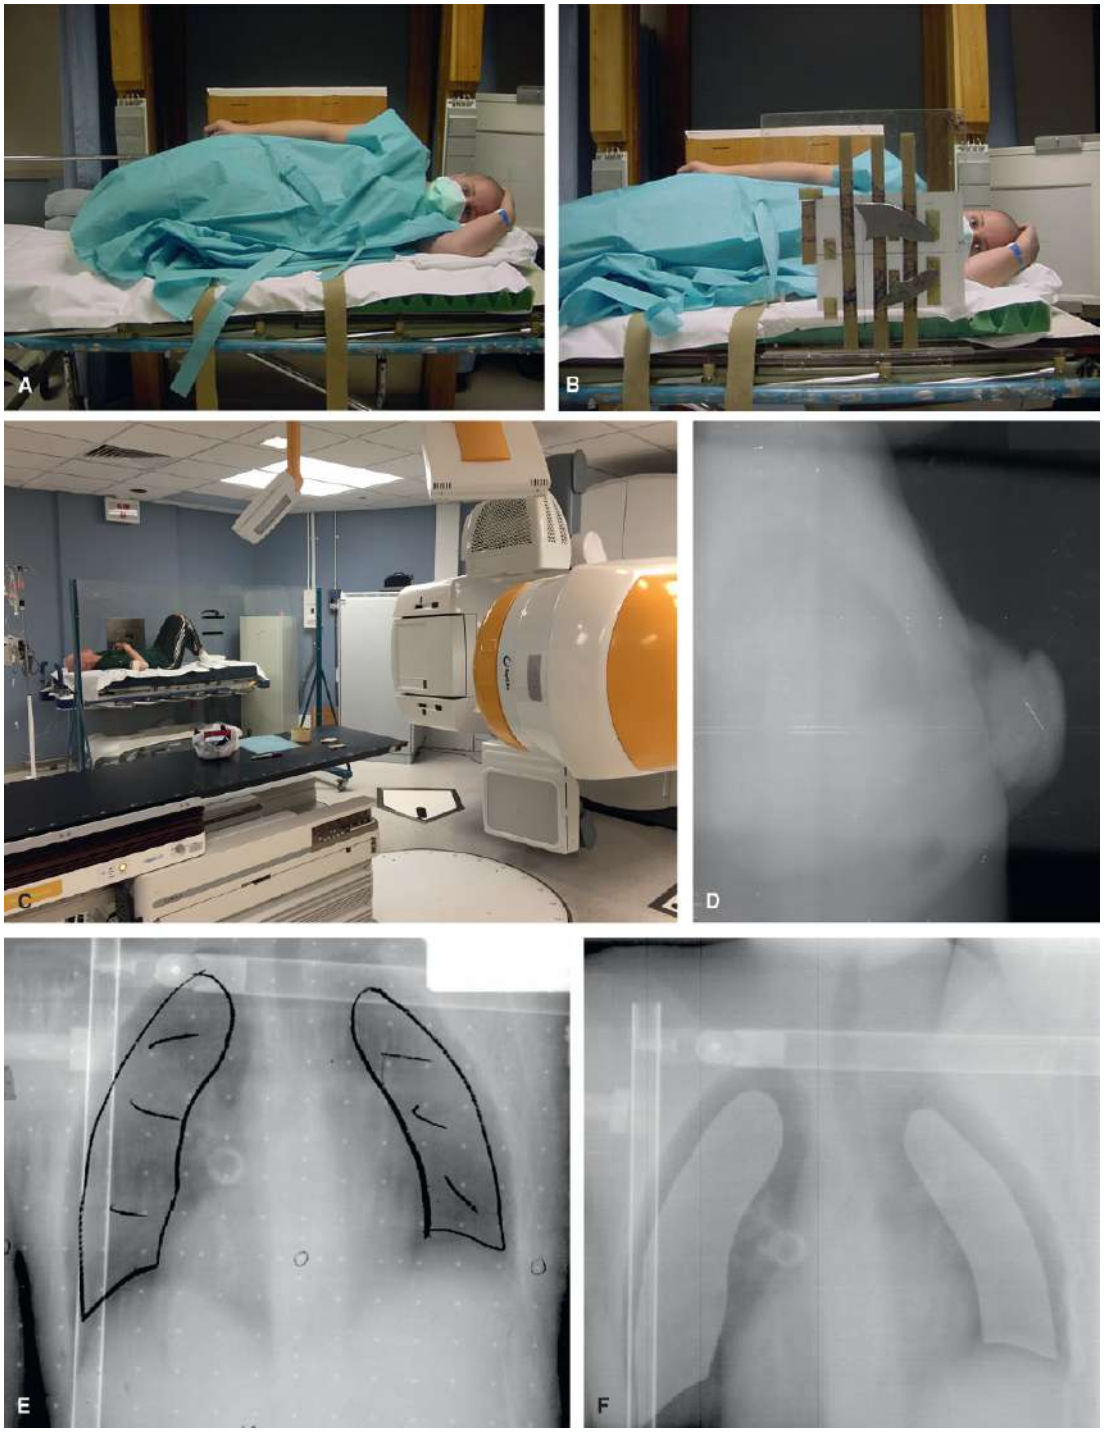

FIGURE 16.2. **A:** Patient in decubitus position for total-body irradiation (TBI), anterior beam. **B:** Thin lung blocks placed close to the thorax using a Velcro–plexiglass system to reposition blocks with each fraction. **C:** Patient in supine position for TBI using lateral fields. **D:** A megavoltage port film confirming position of brass compensators to attenuate the dose to the lungs when lateral fields are utilized. **E:** A megavoltage simulation film taken in decubitus position. **F:** Treatment portal imaging taken in decubitus position.

Quality Assurance

To improve dosimetric accuracy and consistency, periodic assessment of TBI calibration and beam characteristics should be performed as part of an ongoing quality assurance program. Each patient's treatment plan, including the design of customized tissue compensators when used, should be checked by an independent physicist. In addition, *in vivo* dosimetry verification of the treatment plan should be performed during the first fraction for all TBI patients. Changes in patient body shape (e.g., due to weight loss between the time of simulation and treatment delivery) and positioning can alter the dose distribution. Adjustment of radiation beam-on time and tissue compensators may be needed for subsequent treatments based on the *in vivo* verification (assuming the accuracy and confidence of *in vivo* measurement have already been established). Thermoluminescent dosimeters and diode detectors are typical choices for *in vivo* monitoring of doses delivered to patients.[110,119] These detectors should be calibrated in the TBI beam under the treatment condition prior to commencing patient treatment. A diode dosimetry system with multiple diode detectors is especially convenient for these types of measurements because they allow simultaneous measurement of doses at multiple anatomic sites in nearly real time.

Lung (and Other Organ) Dose Attenuation

Many transplant centers use lung blocks or lung shielding during TBI in order to correct for the dosimetric effects of lung density or to specifically reduce the dose to lung tissue, thereby reducing the risk for pneumonitis. This is particularly important in patients who have baseline lung dysfunction.[120] Lung shielding will reduce the risk of pneumonitis, all other factors being equal.[121] Overcompensation, however, risks an increase in leukemia recurrence. A study from the Institut Gustave Roussy delivering 10 Gy as a single fraction of TBI over four hours showed a higher incidence of relapse in patients whose lung dose was reduced to 6 Gy with lung blocks compared with 8 Gy.[122]

There are many techniques to attenuate the dose to the lungs. The technique at Yale utilizes 1/8-inch lead filters that attenuate the dose by 10% to 15%, in essence a slight overcorrection for the dosimetric effects of pulmonary air density[123] (Fig. 16.2E and F). At Duke University, where lateral TBI fields are utilized, the dose to the lungs is attenuated to 8 to 10 Gy, based on baseline lung function and other clinical factors, using brass compensators (Fig. 16.2D). The Memorial Sloan Kettering Cancer Center (MSKCC) group utilizes lung

shielding with the use of electron boosts to the chest wall under the blocks.[124] There are considerable dosimetric challenges with this technique: electron treatments are planned in a supine position yet delivered standing; overlap issues of photon and electron fields; surface contour variability, especially from breast tissue in women; and delivering unwanted radiation dose to some limited volume of the lungs. The Institut Gustave Roussy has reported no clinical benefit to electron boosts to the chest wall under such lung blocks.[125] The Johns Hopkins group has reported using thick (7 HVL) blocks for just 1 fraction of their TBI course over several days.[126] The Seattle group uses 1 or 2 HVL blocks for half of the TBI fractions without a chest wall boost. Other transplant groups such as the University of Minnesota have reported using partial transmission blocks to the liver and kidneys to reduce the risk of hepatic VOD/SOS or nephropathy.[127,128]

When TBI is used for nonneoplastic diseases (e.g., aplastic anemia), where the main objective is immunosuppression, one may also consider shielding radiosensitive structures such as the gonads or eyes (i.e., the lens).[129]

Boosting of Selected Organs with TBI

A relative advantage of TBI is the treatment of chemotherapy sanctuary sites. This is particularly important when treating diseases with a propensity to involve the CNS or testes. Theoretically, regions of the body where there is a higher burden of disease at the time of transplant may be boosted with additional radiation to supplement TBI. In selected patients with acute lymphoblastic leukemia, CNS-preventative therapy may include cranial irradiation. When such patients are determined at diagnosis to be best managed with an allo-SCT, it is reasonable to defer prophylactic cranial irradiation until the time of TBI. Augmented doses of radiation may be delivered to the CNS bringing the cumulative cranial dose to approximately 18 Gy (a current standard in children and many adults with ALL). Higher total doses to the brain and perhaps the spine can be considered in patients being managed with overt CNS leukemia. Boost doses to the brain using lateral fields may be given in 1.8- to 2.0-Gy fractions. Caution is necessary for additional CNS boost treatments when patients have received prior cranial irradiation because of toxicity concerns. Similarly, the testes in males with ALL may be boosted to a cumulative dose of approximately 16 to 18 Gy. The scrotum may be treated with en face electrons of appropriate energy or a single superior/anterior/oblique photon field. Because the incremental toxicity of such testicular irradiation is low regardless of fraction

size, and the fact that some programs have not observed testicular relapses after TBI, dose prescriptions for testicular boosting vary from 0 to 4 Gy.

TOTAL-BODY IRRADIATION—ACUTE AND LATE TOXICITIES

Side effects from TBI used with SCT have complex interactions with cytotoxic drugs and posttransplant immunosuppressive agents. In addition, GVHD has its own unique toxicities, which have complex interactions with the conditioning regimen. Infectious complications are also prevalent after transplant. Isolating which toxicities are strictly related to TBI is not always straightforward.

Low-Dose TBI (Nonmyeloablative Regimens)

With TBI-based nonmyeloablative regimens, 2 Gy in a single fraction being commonly employed, the chief side effect after treatment is nausea and vomiting, which can be ameliorated using prophylactic antiemetics. The primary long-term risk is cataract development, which can be corrected surgically. The risk of injury to other normal organs with a single 2-Gy fraction is very low.

Full-Dose TBI (Myeloablative Regimens)

Acute Toxicity

Nausea, vomiting, and diarrhea are the most common early side effects when a single fraction of 8- to 10-Gy TBI is given. Xerostomia, headaches, fevers, and hypertension were historically reported in roughly half of patients receiving single-fraction TBI.[130] The use of fractionated TBI reduces the incidence, as well as the severity of these and other side effects. Moreover, fever and hypertension are rarely seen with fractionated TBI.[131,132] Patients can also develop a transient xerostomia, reduction in tear formation, and mucositis within 10 days. Reversible alopecia develops at approximately 2 weeks in all patients.[19] Parotiditis, which usually occurs after the first day of irradiation and subsides within 24 to 48 hours, is unique to TBI and is very common with single-fraction RT but occurs in <10% of cases with fractionated regimens.[131]

Nausea may be controlled with the use of serotonin receptor-3 antagonists, as shown in several small randomized trials.[133,134] Mucositis resulting from both radiation and chemotherapy may be ameliorated by good dental hygiene[135] along with a variety of topical agents. Adjunctive agents that have been studied include topical chlorhexidine digluconate,[136,137] calcium phosphate slurry,[138]

sucralfate,[139] and clarithromycin.[140] Amifostine was studied in one trial of allo-SCT showing a reduction in duration of mucositis with fewer severe infections but no effect on hepatic toxicity, renal toxicity, or hematopoietic engraftment.[141] Recombinant human keratinocyte growth factor was found to reduce mucositis after TBI and intensive chemotherapy resulting in reduced narcotic and parenteral nutrition usage in one auto-SCT study.[142] Despite such supportive care, parenteral nutrition and narcotics are often necessary.

Late Toxicity

Lung

Interstitial pneumonitis is the major dose-limiting toxicity for TBI. The lung-sparing effect for fractionation has been shown to be important down to approximately 1 Gy.[143] This dose roughly corresponds to the lowest fraction size in some hyperfractionated TBI schedules. The marked lung-sparing effect of fractionation, or of a decrease in dose rate, has been confirmed by the work of Penney and colleagues showing a progressive sparing of the lung with increased fractionation for both early pneumonitis and late fibrosis.[144] The rate of lung repair between fractions was reviewed by Travis et al., indicating the presence of two significantly different repair rates corresponding to a fast repair half-time of 0.40 hours and a slow repair half-time of 4.01 hours.[145] The slow repair component needs to be kept in mind when designing TBI schedules that include 2 or 3 fractions per day.

Reduction in the risk of pneumonitis by fractionation is supported by the previously described randomized clinical trial comparing single-fraction TBI (9.2 or 10 Gy) with fractionated TBI (12 Gy in 6 fractions over 3 days) for patients with AML in first remission. This study demonstrated a significant improvement in event-free survival with fractionation, primarily due to a reduction in early mortality. Interstitial pneumonitis was decreased from 26% to 15% with fractionation.[32] Other studies have confirmed that fractionated TBI regimens markedly reduce the incidence of interstitial pneumonitis to <20% without increasing the rate of tumor recurrence.[124,132,146] Within a range of conventional fraction sizes of 1.5 to 2 Gy given once or twice daily, no significant increase in the incidence of interstitial pneumonitis is noted up to total doses as high as 15 Gy.[30,31,146] Nevertheless, total dose delivered to the lung is a key determinant of pneumonitis risk.[93,147]

Another radiobiologic approach to reduce the incidence of interstitial pneumonitis is to lower the radiation dose rate. Within the context of

fractionated TBI schemes, instantaneous dose rates of 5 to 20 cGy/min have been generally employed and are often determined by the available output of linear accelerators at extended treatment distances. It is unclear whether or not higher instantaneous dose rates are detrimental despite theoretical concerns in this regard. One small study that compared dose rates of 7.5 cGy/min versus 15 cGy/min in context of a TBI prescription of 12 Gy in 6 fractions reported a pneumonitis risk of 13% versus 43%, respectively, although there were many confounding covariates.[148] Other studies have not shown dose rate to be an important predictor of pneumonitis from fractionated TBI, but rather total dose to the lung is the more critical determinant.[121]

Pneumonitis in the transplant setting has a multifactorial etiology, reflecting not only the effects of radiation but also the effects of chemotherapy,[149] performance status,[150] GVHD, lung injury from tumor, baseline lung function, opportunistic infections, patient age, and other risk factors.[121,147,151] Many chemotherapy drugs are known to injure the lung. GVHD may cause lung injury directly and the drugs used to control GVHD may also cause pulmonary toxicity.[152] T-cell–depleted transplants tend to have lower risk for pneumonitis.[153]

Lens

The lens of the eye is one of the most radiation-sensitive structures in the body. Schenken and Hagemann derived an alpha/beta ratio of 1.2 Gy (0.6 to 2.1), suggesting a high fractionation and/or dose rate sensitivity for cataract induction.[154] In the Seattle experience, >75% of patients developed cataracts 5 years or more after single-fraction TBI.[155] The risk is markedly reduced with fractionation. Ozsahin et al. calculated a difference in the 5-year estimated cataract incidence between single-fraction TBI (39%) and fractionated TBI (13%) while also showing a beneficial effect of lower dose rate.[156] Tichelli et al. reported that the probability of requiring cataract surgery was 85% after single-fraction TBI and 20% after fractionated TBI.[157] This has been confirmed in the Seattle long-term analysis showing the risk of cataracts to be 85%, 50%, 34%, and 19% after 10-Gy single-fraction TBI, >12-Gy fractionated TBI, 12-Gy fractionated TBI, and no TBI, respectively.[158] Steroid therapy is an independent risk factor for cataract formation after bone marrow transplantation, even in the absence of TBI. Lens shielding during TBI is not recommended because of the risk of retro-ocular relapse of leukemia but is a consideration in aplastic anemia and other nonneoplastic diseases managed with SCT.

Growth and Gonadal and Endocrine Effects

Almost all children who undergo bone marrow transplantation with TBI experience decreased growth velocity, which is less with fractionated than single-dose TBI.[159,160] Growth hormone deficiency may be detected in 34% of adults who received TBI in their childhood. Other endocrine effects in this setting include Leydig cell dysfunction in 23% and primary hypothyroidism in 34%.[161] High-dose TBI produces primary gonadal failure in almost all patients, but recovery may occur in females.[160] In children, puberty is usually delayed but can be induced by appropriate hormone replacement.[162,163] Thyroid dysfunction is reported in as many as 43% of patients after TBI.[159,164] Subclinical hypothyroidism is the most common picture, with raised thyroid-stimulating hormone and normal thyroxine levels. The incidence of thyroid dysfunction is lower when hyperfractionated TBI is used.[165]

Liver

Hepatic veno-occlusive disease (VOD) has been renamed sinusoidal obstructive syndrome (SOS) given the recognition that this clinical problem, principally seen in myeloablative transplants, is an endothelial injury to hepatic sinusoids and this hepatocyte injury and hepatic thrombosis are secondary late-stage effects.[166–168] This syndrome accounting for significant morbidity and mortality in high-dose transplant regimens is characterized by hepatic enlargement, ascites, jaundice, encephalopathy, and weight gain in 10% to 40% of patients.[131,169] This disease, which needs to be distinguished from cholestatic drug injury and acute GVHD, is best diagnosed by transvenous hepatic biopsy where an elevated hepatic venous pressure gradient is documented along with characteristic histology showing hepatic sinusoidal and central vein fibrosis and accompanying hepatocyte necrosis. The etiology of VOD/SOS is thought to be related to acrolein, a cyclophosphamide metabolite also implicated in causing hemorrhagic cystitis, which acts as an endothelial toxin. Other toxic agents give rise to this disease, but in the transplant setting, TBI, busulfan, cytosine arabinoside, and preexisting or concomitant liver disease are risk factors, possibly due to depletion of intracellular glutathione levels or matrix metalloproteinase activity. Radiobiologically, hepatocytes respond to dose fractionation (or dose rate) in a manner similar to late-responding tissues with large variations in the isoeffect dose when fraction size (or dose rate) is modified.[170,171] An alpha/beta ratio of 1 to 2 Gy has been estimated.[172]

The incidence of VOD/SOS has been minimized by fractionating TBI and

keeping total doses below 13.2 Gy. The Seattle group has reported considerably more VOD/SOS after 10-Gy single-fraction TBI than after 12-Gy fractionated TBI in a randomized trial.[32] A nonrandomized retrospective study found that fractionated TBI resulted in less VOD/SOS disease but with borderline significance.[173] Barrett showed a decrease in the incidence of VOD/SOS with a lower dose rate.[174] Others have shown that modifications of chemotherapy dosing and scheduling based on individual pharmacodynamics may also lower the risk.[50,168] Other prevention strategies for VOD/SOS include the administration of low molecular weight heparins and ursodiol as part of the pretransplant supportive care regimen.[168] In one well-designed clinical trial, ursodiol prevented cholestatic liver injury and GVHD, but had no effect on VOD/SOS.[175] Treatment is mainly supportive care, but there is some limited evidence that defibrotide, a single-stranded polydeoxyribonucleotide drug with antithrombotic and anti-ischemic properties, may be helpful.[176]

Kidney

Renal toxicity has been underreported as a major late complication of SCT. A report by Tarbell et al. in 1988 showed a 35% rate of renal dysfunction in ALL patients receiving transplants.[177] More contemporary reports place this risk at 17%, influenced by the use of TBI, cyclosporine for immunosuppression, and presence of significant GVHD.[178] Alpha/beta ratio calculations for kidney in a variety of animal and human models have consistently shown relatively low values indicative of fractionation and dose rate radiosensitivity.[179–181] A protracted value of the half-time for repair ($t½$) for late damage of 2.10 hours (1.90 to 2.34) was found by VonRongen.[182] Because transplant patients also receive various nephrotoxic drugs (etoposide, teniposide, amphotericin B, aminoglycoside antibiotics) before, during, and after intensive cytoreductive therapy, the contribution of TBI to renal dysfunction is not clearly established.[183] GVHD also has complex interactions with TBI in affecting the risk of transplant-related nephritis.[184] Helenglass reported a trial comparing cyclophosphamide-TBI with melphalan-TBI. The benefit obtained from melphalan in reducing the relapse rate was offset by its nephrotoxic effect.[185] Other studies suggest that use of TBI and chronic GVHD are risk factors for posttransplant chronic kidney disease.[178,186] Some transplant programs have used partial transmission blocks over the kidneys or limiting the total dose, suggesting that kidney doses over 12 Gy are associated with increased risks of nephropathy.[128] This is not done at our institutions.

Secondary Cancers

The risk for development of a second tumor 15 years after intensive chemoradiation and SCT is estimated to be 13% to 20%.[163,187–190] The risk for a secondary malignancy is approximately 4 times higher than the general population.[191] Increasing TBI doses has been associated with increased risk of solid cancers in one study[187] but has not been observed in others.[192] The largest series of secondary malignancy from combined registries of the International Bone and Marrow Transplant Research Centers and the Fred Hutchinson Cancer Research Center has observed 189 solid cancers among 28,874 transplant patients, more than 6,000 of whom had survived >5 years.[192] Two-thirds of this cohort received radiotherapy as part of their conditioning and was a major determinant for a secondary cancer along with chronic immunosuppression. Common posttransplant nonsquamous cell cancers include melanoma, cervical or uterine cancer, thyroid cancer, breast cancer, and gliomas.[191] Patients < 30 years of age at the time of treatment have an approximately 9-fold increased risk for nonsquamous cell cancers over those who did not receive radiotherapy. Myelodysplastic syndrome and AML are the most common secondary tumors in patients treated for lymphoid malignancies. Patients who are older, who experienced acute GVHD, who were treated with antithymocyte globulin or anti-CD3 antibodies, or who receive TBI are at greatest risk.[189,190] Some lymphoproliferative disorders that occur after allo-SCT are associated with Epstein-Barr virus and may be successfully managed with anti–B-cell antibodies,[193,194] adoptive immunotherapy,[195–197] or donor lymphocyte transfusions.[196] Chronic GVHD and male age increase the risk for squamous cell cancers. Other studies have documented an increased risk for skin cancers and oral cavity cancers, the latter related to chronic lichenoid oral lesions and the historical use of azathioprine for GVHD immunosuppression.[198]

HEMIBODY IRRADIATION

HBI has been used for many years to palliate widely metastatic solid tumors, often very late in the course of the disease.[199–201] As the field of medical oncology has developed a larger array of systemic therapies for disseminated cancers, this form of radiotherapy has been less frequently employed.

Applications

Patients with osseous metastases tend to have multiple sites of disease, often

with multiple painful areas that can be challenging to treat with conventional RT. The pain relief produced by single-fraction HBI for skeletal metastases is prompt, with nearly 50% of all responding patients doing so within 48 hours and 80% within 1 week after treatment.[202,203] More than 70% of treated patients experience pain relief as documented in a number of studies including various RTOG trials from the 1980s.[202,204–207] The duration of pain relief persists for at least 50% of the patient's remaining life.[199,202] The most effective HBI doses found by the RTOG were 6 Gy for upper HBI and 8 Gy for lower and middle HBI. Doses beyond these levels do not appear to increase pain relief, duration of pain relief, or rapidity of response.[202]

When treatment of the other half of the body is also indicated, it is advisable to wait 6 to 8 weeks to allow sufficient recovery of blood cells and irradiated marrow.[199] Planned sequential upper and lower HBI 6 to 8 weeks apart has been used to treat multiple myeloma, malignant lymphoma, and other widely disseminated tumors.[199,208–212] HBI appears to be capable of delaying the progression of existing asymptomatic metastasis and the clinical development of new metastases,[204,208,209,213] which eliminates or reduces the need for patients to spend a substantial portion of their remaining lives commuting to treatment centers. At least for multiple myeloma, however, a randomized trial did not support routine use of hemibody radiotherapy.[212] In this trial, patients were initially treated with chemotherapy. Eligible patients were then randomized to 1 year of vincristine, melphalan, cyclophosphamide, and prednisone (VMCP) versus sequential HBI with vincristine and prednisone (VP). RFS and OS were better with VMCP than with HBI (P = .04 and P = .018, respectively).

Technique

The physical considerations for HBI are similar to those for TBI. The field size required for HBI is much smaller than that for TBI, and HBI can often be delivered on a conventional linear accelerator, albeit using extended distances. By convention, subtotal-body irradiation is usually divided into upper HBI, lower HBI, and middle HBI.[202,214] An arbitrary line at the bottom of L4 is commonly used to separate upper and lower HBI,[214] although this may be modified based on individual circumstances. Treatment is delivered using AP/PA parallel-opposed fields. The patient is positioned with a vertical beam allowing coverage of the hemibody, and the treatment table is lowered to the appropriate level or to the floor. Shielding of previously irradiated areas or other body regions to reduce toxicity, such as the salivary glands and the lungs, may be

employed. The dose is prescribed to the midplane of the patient at the central axis of the beam.

Complications

In general, HBI is well tolerated. The most common side effects associated with single-dose HBI are nausea and vomiting, mainly when the abdomen is included within the fields. These occur shortly after radiation administration and last a few hours.[199,202,203] Premedication with steroids and antiemetics is highly recommended. As these patients are frequently anorexic or cachectic from their underlying illness, dehydration and need for intravenous fluids are common with HBI, and hospitalization for supportive care may be desirable.[214] A series from the University of Maryland examined single-fraction HBI with escalating doses of 4 to 10 Gy, split-course HBI with two 4-Gy fractions separated by 2 weeks, and daily fractionated HBI with 15 Gy given in 5 fractions. Fractionated HBI was found to be more acutely tolerable, similar to the experience with TBI.[215] Diarrhea occurs commonly when a significant volume of the intestines are irradiated and may last for several days. The severity of this side effect can be reduced by limiting the dose to the abdomen to 6 Gy.[202] The risk of pneumonitis is very low if the single-fraction dose to the whole lungs is limited to 7 Gy (uncorrected for air density). If 8 Gy is delivered to the upper body, partial transmission lung blocks to limit the lung dose at 6 to 7 Gy is recommended. Hematologic recovery usually occurs in 4 to 6 weeks.

CHAPTER 17

Stereotactic Radiosurgery

John C. Flickinger

INTRODUCTION

Stereotactic radiosurgery (SRS) and stereotactic radiotherapy (SRT) are techniques to administer precisely directed, high-dose irradiation that tightly conforms to an intracranial target to create a desired radiobiologic response while minimizing radiation dose to surrounding normal tissue. These techniques exploit the fact that the radiation tolerance of normal tissue is volume dependent. Compared to conventional radiotherapy with standard 1- to 2-cm treatment margins allowing for patient movement and setup error, stereotactic techniques reduce complication risks for any radiation dose delivered by minimizing or eliminating normal tissue treatment margins. The term radiosurgery is used when all of the irradiation is done in 1 to 5 sessions or fractions, whereas the term stereotactic radiotherapy (SRT) is appropriate when 6 or more radiation fractions are administered. Table 17.1 lists the key requirements for successful stereotactic irradiation. Advances in imaging, computers, and treatment planning in the last two decades have led to the development of a variety of different stereotactic radiosurgery/radiotherapy techniques and their wider applications. Successful clinical experience with intracranial radiosurgery for a variety of applications has lead to a reexamination of radiobiology and exploration of both fractionated approaches and extracranial applications. Margin reduction with radiosurgery and fractionated stereotactic irradiation techniques makes target definition accuracy more critical. Drawing contours from different imaging techniques or by different physicians are approaches to reduce target definition error (Fig. 17.1).

TERMINOLOGY

Stereotactic refers to using a precise three-dimensional mapping technique to

guide a procedure. The terminology used in stereotactic irradiation can be confusing. The term radiosurgery or stereotactic radiosurgery (SRS) is best used for stereotactically guided conformal irradiation of a defined target volume in a single session but may be also used for 2 to 5 sessions, although fractionated stereotactic radiosurgery (FSR) is a clearer description for that use. Radiosurgery or SRS can be delivered with Gamma Knife, modified LINAC radiosurgery systems (including CyberKnife and image-guided radiotherapy systems), TomoTherapy, or proton beam systems. The terms stereotactic radiation therapy (SRT), stereotactic body radiotherapy (SBRT), and stereotactic ablative radiotherapy (SABR) can be used to refer to stereotactically guided delivery of highly conformal radiation to a defined target volume in 6 or more fractions, typically using noninvasive positioning techniques, although they are often used with treatment courses with 2 to 5 fractions as well. While SRT could potentially refer to precision image-guided radiotherapy used with the same doses and schedules used for conventional radiotherapy, SABR is normally reserved for high, ablative doses of radiation usually with hypofractionated schedules. Adding specific references to intensity-modulated radiation therapy (IMRT) to the nomenclature can further complicate or confuse the terminology. Any radiation treatment plan that uses individual treatment beams that irradiate only part of the target at a time is IMRT. Strictly speaking, multiple-isocenter radiosurgery (of a single target volume) meets the criteria for IMRT or stereotactic IMRT (SIMRT), although the term SIMRT is usually only used when multileaf collimators are employed. The terminology is useful to distinguish when the same linear accelerator is equipped to treat with either fixed circular collimators for radiosurgery (SRS or SRT mode) or to deliver IMRT using multileaf collimators (SIMRT mode).

TABLE 17.1 KEY REQUIREMENTS FOR OPTIMAL STEREOTACTIC IRRADIATION

Requirement	Rationale
Small target/treatment volume	Reducing the volume of normal and target tissue irradiated to high doses improves tolerance
Sharply defined target	Sharply defined targets can be treated with little or no extra margin of surrounding normal tissue and/or without unintentional underdosage of the target (marginal miss)
Accurate radiation delivery	No margin of normal tissue needed for set-up error and/or reduced chance of underdosing target

High conformality	Reduces the treatment volume to match the target volume
Sensitive structures excluded from target	Dose-limiting structures (optic chiasm, spinal cord, etc.) should be able to be defined and excluded from the target volume to limit the risk of radiation injury

RADIOBIOLOGIC CONSIDERATIONS

Prior to the introduction of radiosurgery, essentially all clinical irradiation was administered with radiation dose fractions between 1.2 and 3 Gy for intracranial targets. Extracranial targets were usually treated with 1.2- to 4-Gy fractions with 6- to 8-Gy fractions used occasionally for treatment of bone metastases or malignant melanoma. Before the rapid adaption of radiosurgery into the clinic in the late 1980s, most radiation oncologists and radiation biologists believed that fractionating radiation treatment lessens the relative risk of injury to normal tissue compared to tumor in essentially all circumstances. Radiobiologic analysis of a limited number of malignant tumors in cell culture and clinical experience with conventionally fractionated radiotherapy of fast-growing malignant tumors established this radiobiologic dogma. Increasing the fractionation of radiotherapy for slow-growing benign tumors may not necessarily improve the balance between tumor control and radiation complication. Slow-growing benign tumors are difficult to study in either cell culture or animal models, so the effect of fractionation has not been well delineated. Stereotactic radiosurgery allowed clinicians to administer high single doses of radiation to intracranial targets with relative safety, thereby leading to a new appreciation of the underlying radiobiology. Laboratory studies suggest that the radiation response for the high-dose single fractions used in radiosurgery is predominantly related to the supporting endothelial cells.[1] Pathology studies of benign and malignant tumors treated by radiosurgery also support a vascular response dominated by the response of endothelial cells.[1,2]

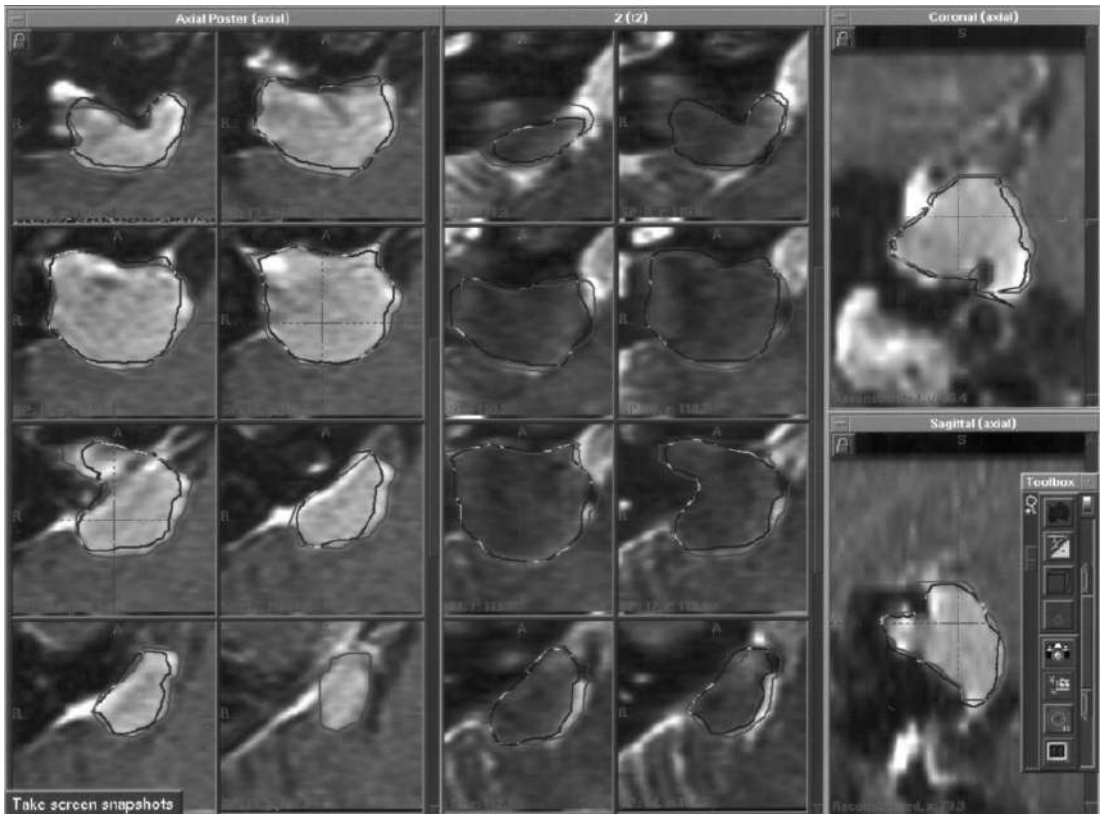

FIGURE 17.1. Comparisons of acoustic schwannoma contours drawn from T1-contrast MR images (eight axial images on the left side with coronal and sagittal images on the right side) with contours drawn from T2 MR images (the darker eight axial images in the center). T1 contours can sometimes slightly overestimate extension into the internal auditory canal and unnecessarily include adjacent blood vessels.

Analysis of clinical data from radiosurgery to delineate dose–response relationships and define radiobiologic parameters is fraught with difficulties. Typical radiosurgery treatment plans use inhomogeneous dose distributions with the prescription isodose covering anywhere from 90% to 100% of the target volume. The absolute minimum dose to the target typically is 5% to 30% lower than the prescription dose. Contours of the same tumor/target volume or critical structures may vary slightly from one clinician to another. Using the linear-quadratic formula to extrapolate from experience with conventional radiotherapy experience with low-dose fractions to high-dose single fractions for radiosurgery appears problematic. Using single-fraction radiosurgery dose–response curves for arteriovenous malformation (AVM) obliteration, radiation injury to brain parenchyma and cranial nerves to calculate α/β ratios yields values of negative 30 to negative 60 rather than 2 to 3 as expected from conventional fractionated radiotherapy data.[3,4] Comparing dose–responses for fractionated stereotactic

radiotherapy to radiosurgery is hampered by limited data with dose–response curves that have insufficient slopes for accurate comparison.

There are several reasons that radiosurgery/SABR might potentially be better than conventional radiotherapy for combined treatment with immune modulation. The immune responses from cells within the additional margin of normal tissue irradiated around the tumor with conventional radiotherapy could potentially be dampened within that margin but should be less affected with SRS/SABR. Also, the higher proportion of tumor cells killed with ablative doses of radiation used in SRS/SABR should expose more tumor antigens to stimulate immune responses both against the irradiated tumor and also possibly against more distant nonirradiated tumor (referred to as the abscopal response). Dewan et al.[5] looked at three schedules of ablative radiotherapy (20 Gy × 1, 8 Gy × 3, or 6 Gy × 5 fractions in consecutive days) delivered to one out of a pair of identical implanted mouse tumors in combination with immunotherapy using a 9H10 monoclonal antibody against CTLA-4. The immunotherapy alone had no effect on either tumor, whereas radiotherapy alone caused growth delay in only irradiated tumor. The combination of immunotherapy with either 3- or 5-fraction radiotherapy increased tumor response at the irradiated site ($P < .0001$) and, unlike the mice treated to 20 Gy in 1 fraction, inhibited growth of unirradiated tumor (which correlated with CD8+ T cells showing tumor-specific IFN-γ production). Marconi et al.[6] performed a meta-analysis of abscopal effects in preclinical animal models that correlated abscopal tumor responses with increasing biologic effective dose (BED) assuming an α/β ratio of 10 for the tumors. Abscopal effects were detected in 50% occurred with BED (10) doses of 60 Gy (such as with 10 Gy × 3 fractions).

RADIOSURGICAL TECHNIQUES

Radiosurgery was originally envisioned to treat intracranial lesions by delivering a high dose of ionizing radiation in a single treatment session using multiple beams precisely collimated to a target inside the cranium. Advances in both imaging and computer technologies resulted in wider applications of radiosurgery. There are now a variety of different radiosurgery and stereotactic radiotherapy techniques available for intracranial and extracranial use.

Gamma Knife Radiosurgery

After Leksell’s initial experiences with stereotactic treatment using orthovoltage

radiotherapy in 1951 and proton beam irradiation in 1957, Leksell and Larson created the first prototype of the Gamma Knife in 1967. The Gamma Knife uses a relatively hemispherical array of multiple fixed Co-60 beams (201 in most models) that are sharply collimated to create small relatively spherical treatment volumes of varied diameter with sharp dose falloff. The earlier model originally was referred to as the U (for university) style and contained cobalt sources arranged in hemispherical array including sources at the pole of the hemisphere. These units present challenging loading and reloading issues with the cobalt-60 sources, particularly with radiation protection. To eliminate this problem, the B-unit (named after Bergen, Norway, the first site) was redesigned so that sources were arranged in an annular section of a hemisphere, similar to the northern hemisphere with the Arctic Circle excluded. In 1999, the Model C version of the Gamma Knife was introduced with the option to use robotic positioning to set treatment coordinates. This expedited execution of multiple-isocenter treatment plans. Manual positioning was still needed for some targets away from the center of the head. The Model 4-C introduced in 2005 was equipped with enhancements designed to improve workflow, increase accuracy, and provide integrated imaging capabilities. The Perfexion model introduced in 2006 uses a larger patient aperture and internally mounted secondary collimators that can be blocked or treated with different diameters of 4, 8, or 16 mm for any of eight different sectors around the circumference of the unit. Because of the larger patient aperture, the Perfexion unit is able to treat all intracranial and even C1-2 level spine targets quickly and efficiently with robotic positioning. The latest version, the ICON unit, is similar to a Perfexion but equipped with a cone-beam CT scan for use with a frameless thermoplastic mask system with infrared patient position monitoring to facilitate FSR. Figure 17.2 shows the infrared monitor tracking of patient movement within an ICON unit during treatment. Clinical experience with the ICON unit has found that despite the relatively tight thermoplastic immobilization mask used, patient motion exceeding 1.0- or 1.5-mm total deviation (requiring repeat cone-beam CT for realignment) tends to occur more frequently with treatments over 30 minutes and in patients who fall asleep during treatment. Patients requiring longer treatments or sedation are more easily treated with stereotactic frame-based techniques with this unit. In addition to reducing patient motion, another advantage of radiosurgery using a magnetic resonance (MR)-compatible stereotactic frame is the elimination of any error (though usually small) from MR to CT image coregistration.

FIGURE 17.2. Infrared motion tracking on an ICON model Gamma Knife displaying real-time maximum combined position deviation within a thermoplastic immobilization mask during radiosurgery.

Rotating Gamma System

A radiosurgery device called the rotating gamma system (RGS) was developed in China. The RGS (OUR International Inc., Shenzhen, China) employs thirty cobalt-60 radiation sources in a revolving hemispherical shell. The secondary collimator is a coaxial hemispheric shell with six groups of five different collimators to produce spherical treatment volumes of different diameter. The experience with this system is somewhat limited.

Proton Radiosurgery

The chief advantage of charged proton radiosurgery is that the beams stop at a depth related to the beam's energy. Electron beams also use charged particles but lack the sharp beam edge of the proton beam. The lack of an exit dose and the sharp beam profile of protons allow target irradiation with lower integral doses than are delivered with photon (LINAC x-ray or cobalt-60 gamma) irradiation. An unmodified proton beam irradiation deposits increased energy in the last couple millimeters of the path length. This area of increased ionization, where cell killing is even higher because of an increased radiobiologic effect, is termed the Bragg peak or Bragg-Gray peak. To allow homogeneous irradiation of targets greater than a millimeter or two, the Bragg peak is normally modulated or spread out throughout the target, essentially eliminating its effect. The first treatment of a malignant tumor by irradiation with a proton beam Bragg peak

was carried out in 1957 followed by functional neurosurgery done for advanced Parkinson disease in 1958. Presently, proton beam irradiation is available at a limited number of centers because of high cost of equipment and maintenance. If technical improvements and increased competition lead to continued cost reductions, proton beam irradiation will become increasingly used because of its dosimetric advantages

LINAC Radiosurgery

The pioneering work of many researchers in the 1980s led to the gradual modifications of linear accelerators (LINACs) designed for conventional radiotherapy to be used for radiosurgery. LINAC technologies were modified by incorporating improved guiding (stereotactic) devices and methods to measure and improve accuracy of various components. Unmodified LINACs for conventional radiotherapy tend to deviate from isocenter alignment at different gantry angles. Most early LINAC-based radiosurgery techniques used multiple radiation arcs with circular secondary collimators to create spherical dose distributions for stereotactically defined 3-D targets. Improved hardware and advanced dose planning software have been developed to enhance conformity. These include beam shaping with micromultileaf collimators and intensity modulation with inverse treatment planning algorithms. Many LINAC-based systems are commercially available. Most are modifications of standard linear accelerators equipped with more precise treatment couches (some capable of alignment with three degrees of rotation) and highly stable treatment isocenters, usually with cone-beam CT scans for targeting and often with patient monitoring system. The CyberKnife combines a miniaturized LINAC mounted on an industrial robot with a system for orthogonal x-ray target tracking and beam realignment. This system utilizes a 6-MeV LINAC with different-sized circular collimators attached to a six-axis robotic manipulator. Stereotactic frames are not normally used for targeting. CyberKnife plans use multiple fixed beam positions and multiple isocenters. Before the radiation is delivered from any beam position, the target position is tracked using an integrated x-ray image processing system (IPS), consisting of two orthogonal diagnostic x-ray cameras and an optical tracking system. During treatment, the IPS acquires x-ray images of the patient’s body multiple times throughout the treatment, while stealth tracking software compares the actual images with the target images to correct alignment of the beam. The tracking interval is set by the user with many CyberKnife centers usually using 1-minute intervals. There are some other LINAC

radiosurgery systems that have capability for intratreatment patient movement monitoring and correction and others that do not. Respiratory gating/tracking is necessary for optimal treatment (with minimum treatment volumes) of SBRT targets that move with respiration.

The combination of diagnostic 3-D imaging with highly conformal treatment delivery in a single unit to maintain accuracy is the basis of various treatment techniques and processes collectively known as image-guided radiation therapy (IGRT). Most IGRT techniques add CT imaging capability to a LINAC radiotherapy unit equipped for stereotactic and IMRT use. Because any patient movement between image acquisition and treatment delivery (or during treatment delivery) can introduce error, these IGRT systems utilize noninvasive immobilization devices and patient position tracking systems. Several manufacturers currently offer IGRT using LINAC technology capable of delivering stereotactic radiosurgery and radiotherapy. Equipping LINAC units with image guidance from the addition of positron emission tomography (PET) scanning and MR imaging are other possible developments.

TomoTherapy

TomoTherapy, literally “slice” therapy, is a new form of radiotherapy that modifies the design of a diagnostic CT (computerized tomography) scan into a treatment delivery machine, thereby combining the precision of CT imaging with the radiation treatment. This is done by adding a LINAC megavoltage treatment beam to the rotating x-ray source and moving table design of a diagnostic CT unit, which normally uses only a kilovoltage diagnostic x-ray beam. Unlike traditional radiation therapy systems with a slow-moving external gantry designed for positioning individual beams onto the tumor from a few different directions, TomoTherapy rapidly rotates the beam around the patient (and inside the housing of the unit), thus allowing the beam to enter the patient from many different angles in succession. Beam intensity modulation (IMRT) is possible through the use of a multileaf collimator system. The inclusion of CT imaging technology within the TomoTherapy unit allows precise localization of the target before and during treatment.

NORMAL TISSUE TOLERANCE IN SRS AND SRT

Radiosensitivity

Estimating the risks of a proposed treatment plan with various doses is an

essential part of treatment planning and dose prescription for SRS and SRT. The ability of normal tissue to tolerate radiation without injury depends on the radiation dose administered, the volume of tissue irradiated, the sensitivity of the tissue affected, history of any prior radiation treatment to the region, as well as any individual variation in radiation sensitivity between different people. At present, with the exception of patients with known increased radiation sensitivity, such as those with ataxia–telangiectasia, there is usually no information routinely available to modify treatment plans for individual differences in radiosensitivity. Prior fractionated radiotherapy appears to have limited effects on the risks of developing postradiosurgery parenchymal edema and neurologic sequelae after radiosurgery but has been observed to effect optic nerve tolerance.

Location Effects

Analysis of postradiosurgery injury reactions in AVM patients revealed no difference in the likelihood of postradiosurgery injury imaging changes (increased signal developing in surrounding brain on long relaxation time or T2 images) in different regions of the brain.[6,7] Dramatic differences were seen in the rates of developing persistent neurologic sequelae after AVM radiosurgery between the brainstem, thalamus, and other regions of the brain as shown in Table 17.2.

TABLE 17.2 PREDICTED RISKS OF DEVELOPING ANY SYMPTOMATIC (AND PERMANENT) NEUROLOGIC SEQUELAE AFTER AVM RADIOSURGERY ACCORDING TO 12-GY VOLUME AND LOCATION FROM 755 PATIENTS WITH 2-YEAR MINIMUM FOLLOW-UP

12-Gy Volume	Brainstem	Thalamus	Other
0.1 cm^3	11% (8%)	5% (3%)	1% (0.3%)
10 cm^3	28% (15%)	15% (7%)	4% (1%)
20 cm^3	55% (30%)	37% (15%)	10% (2%)
30 cm^3	79% (50%)	64% (28%)	27% (5%)
40 cm^3	92% (69%)	84% (48%)	53% (12%)

From Kano H, Flickinger JC, Tonetti D, et al. Estimating the risks of adverse radiation effects after Gamma Knife radiosurgery for arteriovenous malformations. *Stroke* 2017;48(1):84–90.

Radiosurgery Dose Escalation Studies

The RTOG Radiosurgery Dose-Escalation Study (95-05) established tolerance doses for radiosurgery of recurrent brain metastases and high-grade gliomas not involving the brainstem.[8] They administered radiosurgery to 156 patients with brain metastases or primary brain tumors that recurred or progressed after conventional radiotherapy following a dose escalation protocol. Starting with initial doses of 18, 15, and 12 Gy for diameters <20, 21 to 30, and 31 to 40 mm, respectively, they escalated prescription doses in 3-Gy intervals until irreversible toxicity was seen in over 20% of patients within 3 months. The exception was with tumors <20 mm in diameter where dose-limiting toxicity was not reached and investigators were reluctant to escalate above 24 to 27 Gy. The recommended tolerance doses from that protocol were 24, 18, and 15 Gy for diameters of <20 mm, 21 to 30, and 31 to 40 mm, respectively. The data with longer follow-up beyond 3 months to assess late toxicity were fitted to individual logistic dose–response curves in Figure 17.3. These tolerance doses have been widely used as dose guidelines for single-fraction radiosurgery of malignant tumors, often with interpolation for tumors close to 20 and 30 mm in diameter (e.g., 20 Gy for 18- to 22-mm diameter and 16.5 Gy for 28- to 32-mm diameter treatment volumes).

Murai et al.[9] performed a limited dose escalation study of CyberKnife radiosurgery of 48 brain metastases 2.5 to 4 cm in average diameter with 18 to 30 Gy in 3 fractions and 13 metastases >4-cm diameter with 21 to 35 Gy in 5 fractions. They reported grade 2 brain necrosis developing in 1/19 patients at the penultimate level of either 22 to 27 Gy/3 fractions or for >4 cm 25 to 31 Gy/5 fractions and 3/23 patients (two grade 2 and one grade 3) at the highest level of 27 to 30 Gy/3 fractions or for >4 cm 31 to 35 Gy/5 fractions.

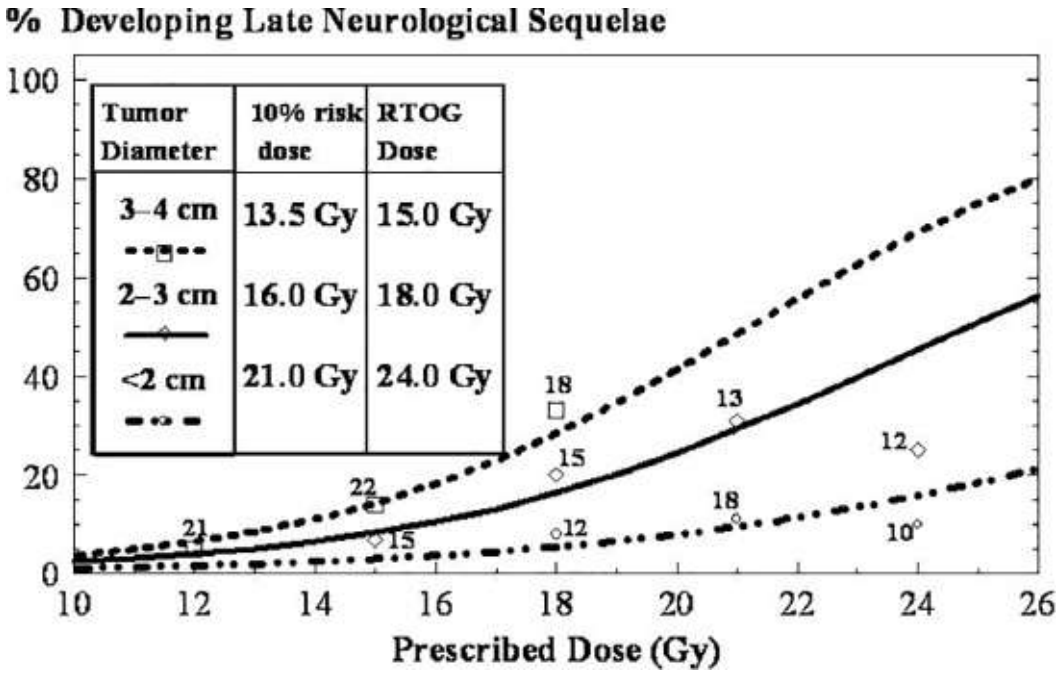

FIGURE 17.3. Phase 1 RTOG dose escalation data for radiosurgery of recurrent brain metastases and glioblastoma fit to logistic dose–response curves. The numbers at each data point indicate the number of patients in each dose/diameter group. (From Dewan MZ, Galloway AE, Kawashima N, et al. Fractionated but not single-dose radiotherapy induces an immune-mediated abscopal effect when combined with anti-CTLA-4 antibody. *Clin Cancer Res* 2009;15[17]:5379–5388.)

Schwer et al.[10] performed a 3-fraction SRS dose escalation study from 18 to 36 Gy in 15 patients with recurrent gliomas treated in combination with gefitinib. With a median treatment volume of 41 cm^3 (8 to 151 cm^3), three patients were treated at the 18, 24, and 30 Gy levels and 16 at 36 Gy. They failed to identify any radiation-related toxicity.

Clarke et al.[11] reported a dose escalation study of 3 fractions of radiosurgery delivered with 10 mg/kg bevacizumab q2 weeks to doses of 27, 30, and 33 Gy in groups of 3, 5, and 7 patients, respectively, with recurrent glioblastoma and anaplastic astrocytoma after prior conventional chemoradiotherapy. They identified no cases of clearly symptomatic radionecrosis, but one patient in the 33-Gy level exhibited cognitive deterioration and grade 3 fatigue, which they counted as treatment-related toxicity. Three patients underwent subsequent resections for presumed local progression with viable tumor and substantial radiation necrosis found in each, one of which had necrosis in >90% of the specimen.

Pollom et al.[12] also reported a somewhat unenlightening dose escalation trial of 5-fraction radiosurgery to doses of 25, 30, 35, and 40 Gy delivered with a 5-

mm margin along with concurrent and adjuvant temozolomide in 30 patients with newly diagnosed supratentorial glioblastoma. Six patients were entered at each of the 4 lower-dose levels and 12 at the highest level of 40 Gy. With a median follow-up of 13.5 months (0.4 to 62.4 months) and 10.4 months for quality of life (QOL) assessment, 8/30 showed evidence of adverse radiation effects (ARE), which were symptomatic in 6 of those patients, but no dose/volume breakdown of the toxicity was reported nor was a maximum tolerated radiation dose. The 12-month ARE rate was 38% with 4/5 survivors with >2 years of health-related QOL follow-up developing ARE. Survival and tumor control seemed similar to that expected with standard chemoradiotherapy. ARE did not significantly affect health-related QOL, possibly because all patients developing ARE were treated with bevacizumab.

Optic Nerve Tolerance for Radiosurgery

The first analysis of optic nerve tolerance to radiosurgery, a combined Harvard/University of Pittsburgh study of patients with cavernous sinus meningiomas, craniopharyngioma, and pituitary adenomas, recommended 8 Gy as a safe maximum dose limit for the optic nerves/chiasm, although most centers now use 10 Gy.[13] The lowest optic chiasm dose at which optic neuropathy developed in that study was reported as being 9.7 Gy. Optic nerve/chiasm doses were estimated from isodose distributions overlaid on CT images, unlike the present day when the entire optic system is usually outlined on detailed MR images and maximum doses are assessed from dose–volume histograms. It is highly likely that the true maximum doses to the optic system were higher and lay in portions of the nerve that were poorly visualized.

Stafford et al.[14] reported a later analysis of four cases of optic neuropathy occurring out of 215 Mayo clinic radiosurgery patients with a median dose of 10 Gy to the optic chiasm. One case developed after an optic nerve/chiasm dose of 12.8 Gy with radiosurgery alone, at which the risk level appeared to be approximately 3%. The other cases developed in patients with prior fractionated radiotherapy (7 Gy after 58.8 Gy, 9 Gy after 45 Gy and two procedures delivering 9, and later 12 Gy to the optic system after 50.4 Gy).

Leber et al.[15] analyzed optic nerve injury risks in 50 patients with 24- to 60-month follow-up (median 40 months) who underwent Gamma Knife radiosurgery for benign skull base tumors. Their risks of optic neuropathy were 0% with <10 Gy, 27% with 10 to 15 Gy, and 78% with >15 Gy. They found no cavernous sinus nerve injury with doses of 5 to 30 Gy.

Hiniker et al.[16] found <1% risk of optic neuropathy with 12 Gy in 1 fraction, 19.5 Gy in 3 fractions, and 25 Gy among 262 patients with perioptic tumors treated with SRS.

What is not clear at this point is what doses of repeat radiation can be delivered for 1%, 5%, and 10% risks of injury to the optic system nerves and chiasm to 6 months or more after they have received standard tolerance doses of 10, 18, or 25 Gy in 1, 3, or 5 fractions, respectively.

Tolerance of Other Cranial Nerves

From clinical experience with fractionated conventional radiosurgery and radiosurgery, it appears that special sensory nerves (optic and auditory) are the most radiosensitive, followed by somatic sensory nerves (trigeminal) and finally the motor nerves (cranial nerves II, IV, VI, VII, and IX to XII). After acoustic schwannoma radiosurgery to doses of 12 to 13 Gy, FSR to 18 Gy in 3 fractions, or SRT to 45 to 50 Gy in 25 to 28 fractions, decreased hearing develops in 30% to 50% of patients, facial numbness in 2% to 3%, and facial weakness in 0.5% or less. Single-fraction radiosurgery with present techniques for meningiomas involving the cavernous sinus is associated with a risk of trigeminal neuropathy of approximately 3% of patients with radiation injuries to cranial nerves III, IV, or VI more uncommon.[17–21] The risk of injury correlates with the length of nerve irradiated.[22]

CLINICAL USES OF SRS AND SRT

Table 17.3 lists the most commonly used indications for radiosurgery with representative references. Except for functional radiosurgery, there are varied levels of experience with SRT for each of these indications.

TABLE 17.3 COMMON INDICATIONS FOR RADIOSURGERY OR HYPOFRACTIONATED STEREOTACTIC RADIOTHERAPY

Indication	Experience	Value	References
Functional			
a. Trigeminal neuralgia	a. Extensive	1. Less numbness than rhizotomy	a. 18–22
b. Unilateral tremor	b. Moderate	2. In poor candidates for deep brain stimulation	b. 23–26
Vascular			a. 4,27–29
a. AVM	a. Extensive	a. High	b. 30–32
b. Cavernous	b. Moderate	b. Controversial	

Benign tumors: schwannoma, pituitary adenoma meningioma, etc.	Extensive	High tumor control, acceptable morbidity for selected small tumors	11–13,33–64
Brain metastases	Extensive	Control rates ≥ surgery for small mets	65,66
Primary malignant brain tumors	Extensive for GBM. Limited with other uses	Initial SRS appears ineffective for GBM. Helpful for recurrent tumors, possibly initial pilocytic, neurocytoma	67–75
Spinal metastases	Moderate	High for recurrent tumors. No phase 3 comparison with conventional XRT for initial treatment	16,17

Functional Radiosurgery

The most widely used functional application for radiosurgery is in the management of typical trigeminal neuralgia refractory to medical therapy.[23–27] Atypical or constant pain does not respond. Other alternatives for managing typical trigeminal neuralgia are medication, open surgery with microvascular decompression, and rhizotomy procedures using glycerol injection, balloon compression, or radiofrequency injury to the nerve. Typically 4-mm collimators are used for radiosurgery to a maximum dose of 80 to 90 Gy. Response rates reach approximately 85%, typically 1 week to 4 months after the procedure, but can develop as late as 6 months afterward. Approximately 50% of typical trigeminal neuralgia patients remain pain-free and off medication 5 years following radiosurgery. A typical radiosurgery plan for trigeminal neuralgia is shown in Figure 17.4. Kotecha et al.[25] analyzed the dose response for trigeminal neuralgia in 352, 85, and 433 patients undergoing SRS with maximum doses of ≤82, 83 to 86, and ≥90 Gy. They found 4-year pain responses of 79%, 82%, and 92% and 4-year rates of BNI class 3 to 4 numbness developing in 25%, 49%, and 40% of patients at maximum doses of <82, 73 to 86, and >90 Gy, respectively. The numbness in nine patients (1%) was classified as anesthesia dolorosa, all of whom with maximum doses ≤86 Gy.

Recent studies have suggested that radiosurgery within 3 years of onset of trigeminal neuralgia lead to better long-term pain control and that selective dose reduction to 70 to 75 Gy may reduce risks of radiation-induced trigeminal neuropathy in patients with larger treatment volumes resulting from having thicker trigeminal nerves.[26,27]

A small destructive lesion in the ventralis intermedius nucleus of the thalamus can be created either invasively with a needle equipped with a radiofrequency

generator or noninvasively with radiosurgery using 4-mm diameter collimators and a maximum dose of 130 Gy to alleviate medically refractory unilateral tremor in patients with essential tremor and/or Parkinson disease.[28–31] Nondestructive management through insertion of a deep brain stimulator is preferred in most patients, but not all patients are acceptable candidates and radiosurgery appears more cost-effective.[31] Although targeting the globus pallidus for bradykinesia, rigidity, and dyskinesia from Parkinson's has been successful with deep brain stimulation, limited early radiosurgical pallidotomy has not achieved established success.[32,33] There is limited experience with bilateral radiosurgical capsulotomy (targeting the anterior limb of the internal capsule) for managing severe, refractory obsessive–compulsive disorder, including a small randomized controlled study that was retracted after it was found that only 2/8 patients responded to radiosurgery (vs. 3/8 as originally thought) compared to 0/8 without radiosurgery.[34] Radiosurgery to hypothalamic hamartomas may help control refractory gelastic seizures.[35] The use of radiosurgery as an alternative to extensive surgery in medically refractory mesial temporal lobe epilepsy shows promise and continues to be investigated.[36] Improvements in functional imaging such as MR tractography should eventually lead to improvements in functional neurosurgical interventions including radiosurgery. Another recent development is the substitution of focused ultrasound as a substitute for radiation to create focal areas of necrosis.[65]

FIGURE 17.4. Typical radiosurgery plan for right trigeminal neuralgia. The right trigeminal nerve is outlined in white. The 30% and 50% isodose volumes from treating a single isocenter with 4-mm diameter collimators with a gamma unit are shown. A maximum dose of 80 Gy will deliver 40 Gy to the 50% isodose value and 16 Gy to the 20% volume.

Vascular Malformations

Untreated intracranial AVMs have a bleeding risk of approximately 2% to 3% per year or higher if prior bleeds have occurred.[66–68] This results in an average of 1% of untreated AVM patients dying per year from hemorrhage. Management options include observation, surgical resection, embolization, and radiosurgery. The ARUBA trial for AVMs with no prior bleeds compared observation to treatment intervention with institutional choices of embolization, resection, and/or radiosurgery.[69] Because the initial morbidity from intervention by surgery, embolization, and/or radiosurgery was compared to the relatively low annual bleeding risk of unruptured AVM with observation, the ARUBA trial

identified observation as the best management option for their relatively short 33-month mean follow-up period. Although this trial could be used to justify observation for older patients with low-risk AVMs, the relatively short follow-up ARUBA trial was inadequate to see the long-term benefits from definitive management of AVM with surgery or radiosurgery in younger patients.

After 3 to 5 years, radiosurgery can dramatically reduce the risk of hemorrhage. Radiosurgery obliterates the AVM nidus in approximately 75% of patients within 3 years of the procedure.[3,70,71] Individual obliteration rates vary from 50% to 88% depending upon marginal dose administered as shown in the dose–response curve illustrated in Figure 17.5. Although AVM obliteration rates appear to be optimized with marginal doses of approximately 23 Gy, lower doses are selected for most patients to minimize complications. The risk of neurologic sequelae from radiosurgery averages approximately 3% but varies with treatment volume, dose, and location (Fig. 17.2). The risk of hemorrhage while waiting for complete obliteration to develop seems unaltered.[66] All of these risks and benefits of radiosurgery need to be considered together to optimize management of individual AVM patients.

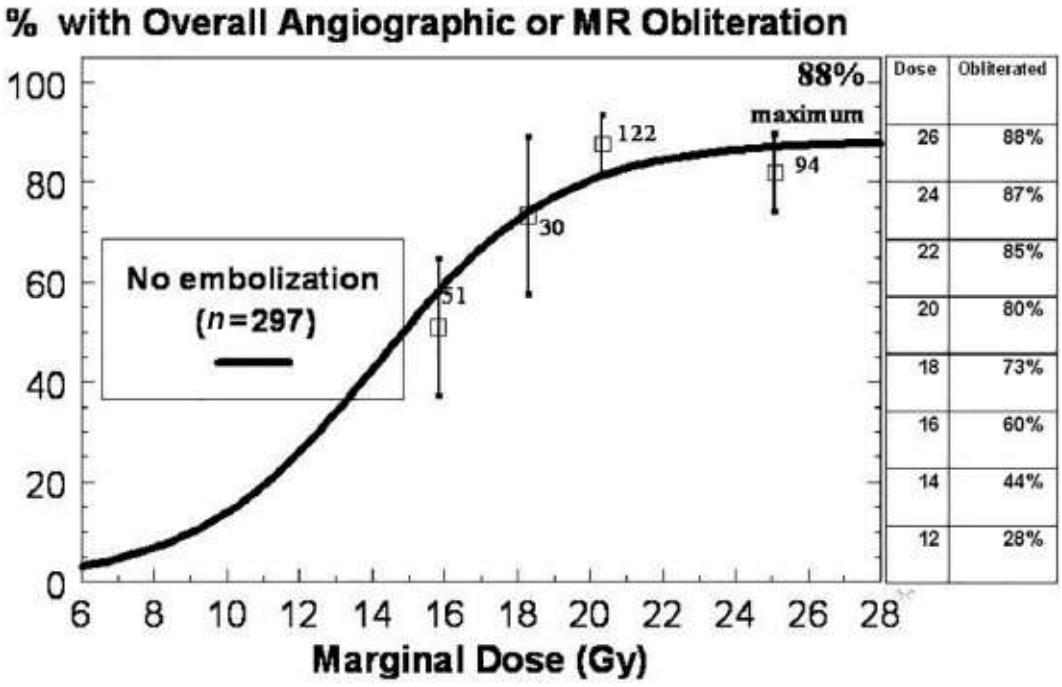

FIGURE 17.5. Dose response for obliteration of AVM after radiosurgery from 297 patients treated at the University of Pittsburgh without embolization. (Reprinted by permission from Flickinger JC, Kondziolka D, Lunsford LD. Radiobiological analysis of tissue responses following radiosurgery. *Technol Cancer Res Treat* 2003;2[2]:87–92. Copyright © 2003 SAGE Publications.[72])

When an AVM nidus fails to completely obliterate by 3 years after radiosurgery, irradiation can be repeated with acceptable morbidity.[73,74] Although some residual radiation injury effect would be expected within the previously irradiated unobliterated AVM nidus vasculature, re-treatment appears to require similar, if not higher doses to achieve similar rates of complete obliteration as initial radiosurgery.[73,74]

Management of large AVMs is presently difficult because radiosurgery may be associated with high complication risks and low obliteration rates. Recent improvements in embolization with liquid glue or onyx polymer can sometimes help reduce the target volume but add to the total risks of the overall management.[75] Another promising approach is staged radiosurgery, in which large AVMs are treated in two or three sections separated by 4- to 6-month intervals to reduce acute toxicity. Whether there is any benefit to fractionating stereotactic irradiation of AVMs is presently unclear.[76]

Cavernous malformations do not show detectable flow on angiography but nevertheless are vascular lesions with annual hemorrhage risks of 0.5% per year with no prior bleed, 4.5% with one prior hemorrhage, and approximately 32% per year after a history of two or more hemorrhages.[77–81] Lower pressures in these lesions lead to smaller bleeds than are typically seen with AVM. Repeated bleeds from brainstem cavernous malformations can cause considerable neurologic morbidity. Symptomatic surgically accessible lesions should be resected. Radiosurgery of brainstem cavernous malformations with a history of two or more prior hemorrhages appears to reduce the risk of subsequent bleeds to approximately 1% per year with acceptable morbidity.[82–88]

Benign Tumors

Most small benign intracranial tumors are well managed with radiosurgery, FSR, or SRT. Radiosurgery control rates are high with radiosurgery with single-fraction prescription doses on the order of 12 to 14 Gy or their equivalent with hypofractionation.[17–21,37–62,89–98] Kondziolka et al. evaluated long-term tumor control in 285 consecutive patients who underwent radiosurgery for benign intracranial tumors between 1987 and 1992 with a median follow-up period of 10 years.[17] This included 157 patients with vestibular schwannomas, 10 with other cranial nerve schwannomas, 85 with meningiomas, 28 with pituitary adenomas, and 5 with craniopharyngiomas. 44% had prior surgical resection and 5% had prior fractionated radiotherapy. They found that 95% of the 285 patients had imaging-defined local tumor control (63% had tumor regression, and 32%

had no further tumor growth). The crude tumor control was 95% (271/285 patients) with a 15-year actuarial tumor control rate of 93.7%. In 5% of the patients, delayed tumor growth was identified. Resection was performed after radiosurgery in 13 patients (5%) for tumor growth.

Vestibular Schwannomas

Vestibular schwannomas, also known as acoustic neuromas, are benign tumors arising from Schwann cells. They are associated with loss of genetic information on chromosome 22.[93] Vestibular schwannomas either occur on one side as spontaneous mutations or bilaterally as the hallmark of type 2 neurofibromatosis (NF-2). Vestibular schwannomas usually arise within the internal auditory canal and later extend intracranially into the cerebellar–pontine angle. Because these tumors lack the ability to invade bone, the portion of tumor outside the canal in the cerebellar–pontine angle eventually grows into a globular extension that is larger than the intracanalicular portion (Fig. 17.1). The differential diagnosis of a cerebellar–pontine angle tumor includes vestibular schwannoma (90%), meningioma (close to 10%), cholesteatomas, facial or trigeminal schwannoma, and rare primary or metastatic malignant tumors. Cerebellar–pontine angle meningiomas (which can be managed similarly to vestibular schwannomas) also may involve the internal auditory canal, but usually be distinguished by a broad, flat, dural attachment that is lacking in vestibular schwannomas.

Observation and surgical resection were essentially the only management strategies offered to acoustic schwannoma patients until favorable experiences with Gamma Knife radiosurgery were reported in the 1980s. Observation may be appropriate in selected NF-2 patients and some elderly patients with small, minimally symptomatic vestibular schwannomas, but early intervention appears to be the best strategy for long-term hearing preservation for most patients.[94,95] Surgery appears to be the best initial strategy in patients with vestibular schwannomas large enough to cause symptomatic brainstem compression with obstructive hydrocephalus. For small to medium vestibular schwannomas, tumor control rates with radiosurgery or SRT are comparable to surgical resection.[37–58,94–98]

Early radiosurgery series including patients treated during the 1980s with higher doses (14 to 18 Gy) and less conformal treatment plans had higher rates of postradiosurgery cranial neuropathies (15% to 20% trigeminal and/or facial and 67% with a drop in their Gardner-Robertson hearing level).[98] This prompted some groups to pursue SRT for vestibular schwannomas, whereas others pursued

radiosurgery with refined techniques and lower doses. Both approaches lead to improved results.[37–55,94–98] The University of Pittsburgh reported on 313 previously untreated unilateral acoustic schwannoma patients that underwent Gamma Knife radiosurgery doses of 12 to 13 Gy between February 1991 and February 2001.[38] Median follow-up was 24 months and maximum follow-up 115 months, and 36 patients had >60 months of follow-up. The actuarial clinical tumor control rate, free of surgical intervention, was 98.6% at 7 years. One patient's growing tumor was subsequently completely resected. The only other failure required a partial resection because of an enlarging adjacent subarachnoid cyst, despite control of the irradiated tumor. The 7-year actuarial rates for unchanged facial strength, unchanged facial sensation, unchanged hearing level, and useful hearing preservation were 100%, 95.6%, 70.3%, and 78.6%, respectively. Eight patients developed new trigeminal neuropathy, six of whom developed numbness (7-year actuarial rate = 2.5%), whereas the other two developed new typical trigeminal neuralgia (7-year actuarial rate = 1.9%). The risk of developing postradiosurgery trigeminal neuropathy was associated with increasing tumor volume (P = .038). Similar results with low-dose radiosurgery of vestibular schwannomas were reported by Iwai et al.[41], Paek et al.,[44] Muacevic et al.,[42] and Rowe et al.[46]

Various fractionation schemes (18 Gy/3, 20 Gy/4 to 5, 25 Gy/5, 45 to 50 Gy/25, and 54 Gy/30) have been used with vestibular schwannoma with minor differences in results. After accounting for length and quality of follow-up treatment, results seem similar to radiosurgery with 12 to 13 Gy, but an advantage for fractionation can't be excluded entirely.[43] UCLA reported unusually good hearing preservation (93%) for their experience with 50 unilateral acoustic schwannoma patients irradiated to 54 Gy in 30 fractions to a 90% isodose treatment volume including a 1- to 3-mm margin around gross tumor.[56] All tumors were controlled with a median follow-up of 36 months (range: 6 to 74 months). They defined useful hearing preservation as the ability to talk on the telephone with the affected ear. New facial numbness developed in one patient (2%) and facial weakness also in one patient (2%) after radiotherapy.

Andrews et al. analyzed the Jefferson vestibular schwannoma experience, comparing 69 radiosurgery patients to 50 SRT patients who received 50 Gy/25 fractions.[50] Their first 25 vestibular schwannoma patients were treated using a linear accelerator, whereas later radiosurgery patients were treated with Gamma Knife radiosurgery. The authors reported similar facial and trigeminal neuropathy rates for the radiosurgery and fractionated radiotherapy groups, but

the rate of hearing loss was significantly higher in their radiosurgery group. There were only a small number of patients with serviceable (useful) hearing in each group prior to irradiation (12 in the radiosurgery and 21 in the FSRT groups), and follow-up was limited. Meijer et al., from Amsterdam, also reported a single-institution comparison of radiosurgery (LINAC to 10 or 12.5 Gy) and SRT (20 Gy/4 to 5 fractions) for vestibular schwannoma.[49] They selected 49 edentulous patients (mean age = 63 years) for radiosurgery and 80 patients (mean age = 43 years) with intact dentition for SRT. They found a higher rate of trigeminal neuropathy following radiosurgery (8%) than SRT. (2%) at 5 years (P = .048), but similar hearing loss with radiosurgery (25%) than SRT (39% FSRT, $P > 0.05$), similar, but higher than usual rates of new facial neuropathy (7% radiosurgery vs. 3% FSRT, $P > 0.05$) and similar 5-year actuarial tumor control rates (100% with radiosurgery vs. 94% with SRT). Combs et al.[53] compared the results of vestibular schwannoma management with single-fraction radiosurgery to a median dose of 13 Gy in 169 patients to FSRT at 1.8 Gy/fraction to a median dose of 57.6 Gy in 291 patients with a median follow-up of 67 months. Local control rates were similar at 95% and 94% at 5 and 10 years. Useful hearing preservation rates were also similar at 84% and 86% in the SRS and FSRT groups, as was trigeminal and facial neuropathy were similar at approximately 1% for both. Akpinar et al.[58] reported the results of hearing preservation after single-fraction radiosurgery with a median dose of 12.5 Gy (11 to 13 Gy) to a median volume of 0.72 cm^3 (0.11 to 12.8 cm^3) in 88 University of Pittsburgh patients with vestibular schwannomas with no subjective hearing loss at the time of diagnosis with 75 months of median follow-up. For the 57 patients who underwent SRS ≤2 years from diagnosis, the serviceable hearing (class 1 to 2) and normal hearing preservation rates (class 1) at 5 years after SRS were 88% and 77%, whereas those for the 31 patients who underwent late SRS (>2 years after diagnosis) were 55% and 33%, respectively ($P = 0.006$ and $P < .001$).

Nonacoustic Schwannomas

Schwannomas may occasionally involve other cranial nerves, particularly V, VII, and XI-XII in the jugular foramen. Tumor control rates are similar, but postradiosurgery neuropathies seem less common as somatic sensory and particularly motor nerves seem less sensitive to radiation injury than special sensory nerves like VIII.[59–63] Kano et al.[63] reported on 92 jugular foramen schwannomas managed at multiple institutions with a median single-fraction dose of 12.5 Gy (10 to 18 Gy) to volumes of 0.8 to 22.6 cm^3 (median = 4.1 cm^3).

Tumor control rates at 5 and 10 years were 87% and 82%. Preexisting cranial neuropathies improved in 32% and 37% of patients. Because spinal schwannomas involving motor nerves are difficult to completely resect without causing motor deficits, they are often managed with radiosurgery. Shin et al.[64] reported one of the larger series of neurogenic spinal nerve root tumors (47 schwannomas, 7 neurofibromas, and 4 malignant peripheral nerve sheath tumors managed with radiosurgery). Local control for the schwannomas was 86%.

Meningiomas

Radiosurgery and SRS are both excellent management options for most small benign meningiomas with infield tumor control rates well above 90%, as has been seen with most other benign tumors.[17,89] Marginal recurrences rates as high as 25% may develop because of the tight margins used for radiosurgery or SRT treatment volumes limited to small recurrences or residual tumor after resection of large parasagittal meningiomas.[17,89,99–101] Marginal recurrences are far less of a problem with unresected (and usually unbiopsied) meningiomas. A University of Pittsburgh study[89] analyzed 219 imaging diagnosed (unbiopsied) meningiomas managed with single-fraction Gamma Knife radiosurgery to a prescription dose of 8.9 to 20 Gy (14 Gy median) and treatment volumes of 0.47 to 56.5 mL (median 5.0 mL) with 2 to 164 months of follow-up (median 29 months). Tumors progressed in 7 patients, two of which proved to be different tumors (metastatic nasopharyngeal adenoid cystic carcinoma and chondrosarcoma). Another patient with locally control of the lesion developed a subsequent brain metastasis, changing the diagnosis of the first lesion to the same. The actuarial tumor control rate was 93.2% at both 5 and 10 years. The actuarial rate of identifying a diagnosis other than meningioma was at both 5 and 10 years. No pretreatment variables, including dose, correlated with tumor control in univariate or multivariate analysis. The actuarial rate for developing any postradiosurgical injury reaction was 8.8% at 5 and 10 years. The risk of postradiosurgery sequelae was lower (5.3%) after 1991 (with stereotactic MRI and lower doses; $P = .0104$).

Atypical and malignant (anaplastic) meningiomas have higher rates of local and marginal recurrence after therapeutic intervention. Complete surgical resection is advocated whenever possible followed by a full course of conventional radiotherapy with at least 1-cm margins around the tumor volume. Radiosurgery has been recommended to improve local control of unresectable tumor.[101–104] Malik et al. reported 5-year actuarial control rates of 87% for

typical meningiomas, 49% for atypical, and 0% for malignant meningioma in the Sheffield Gamma Knife experience.[101] Harris et al. reported on the Pittsburgh Gamma Knife experience in 12 malignant and 18 atypical meningiomas.[103] Their 5-year local tumor control was 72% for malignant and 83% for atypical meningiomas; however, 10-year actuarial survival rates were only 59% and 0%, respectively. Katz et al. could not substantiate that either accelerated fractionated radiotherapy or a radiosurgery boost improved tumor control or survival in their analysis of 27 atypical and 9 malignant meningioma patients managed at the University of Florida.[104]

One controversy in radiosurgical management of meningiomas is whether an additional dural margin or dural tail needs to be routinely included in the treatment volume. Dibiase et al.[105] analyzed a series of 162 benign meningioma patients treated to a median single fraction of 14 Gy and found improved tumor control with treatment of the dural tail (96% vs. 78%). Most centers do not follow this policy and other authors[106] have argued against this policy with WHO grade 1 meningiomas. Outlining the tumor target volume with T2 imaging sometimes discloses gross tumor extension into what otherwise appears to be normal dura adjacent to the tumor. Any WHO grade 2 or 3 meningioma should be treated with a 1-cm margin of additional normal dura whenever possible.

Pituitary Adenoma

Management of pituitary adenomas requires a multidisciplinary approach to properly select which patients are suitable for different approaches with medical therapy, surgery, fractionated radiotherapy and radiosurgery, or combinations of these. Most patient with visual compromise, particularly with a hemianopsia or greater, will do better with initial surgical decompression. Prolactinomas are usually initially managed with medical therapy.[90] Most other small pituitary adenomas, where the target volume can be separated from the optic nerves, are reasonable candidates for radiosurgery.[17,90–92]

Sheehan et al.[92] performed a review of 35 peer-reviewed reports of radiosurgery for pituitary adenoma, which included 1,621 patients. Most studies reported a >90% control of tumor size (range: 68% to 100%). His weighted average tumor control rate for all published series (encompassing 1,283 patients) was 96%. In eight published series with mean or median patient follow-up periods of 4 or more years, tumor growth control rates varied from 83% to 100%.

Twenty-two series results published radiosurgery results for 314 Cushing

disease patients. The mean radiosurgical prescription (margin) doses for these series varied from 15 to 32 Gy. In those series with at least ten patients and a median follow-up of 2 years, endocrinologic remission rates range from 17% to 83%. Many of the patients in older series were treated in the pre-CT and MRI era of radiosurgery sometimes as often as many as four times before their Cushing disease went into remission. Mehta et al.[93] reported a multi-institutional experience with SRS to a mean single-fraction dose of 23.7 Gy in 278 Cushing disease patients with a mean follow-up of 5.6 years (0.5 to 20.5 years). Cumulative initial control of hypercortisolism was 80% at 10 years with a mean time to cortisol normalization of 14.5 months. Recurrences after initial cortisol normalization developed in 18% of patients, which made the overall rate of durable hormonal control to 64% at 10 years and 68% among patients who received SRS as a primary treatment. AREs included hypopituitarism (25%) and cranial neuropathy (3%). Development of visual deficits correlated with tumors involving the suprasellar cistern ($P = .01$), whereas both visual ($P < .0001$) and nonvisual cranial neuropathies ($P = .02$) were related to prior pituitary irradiation. The North American Gamma Knife Consortium series[94] of 512 nonfunctioning pituitary adenoma patients reported 5- and 10-year tumor control rates of 91% and 85% with a mean dose of 16 Gy (range: 5 to 35 Gy) to a mean volume of 3.33 Gy (range: 0.08 to 33 cm^3). Higher tumor control rates were found in tumors <5 cm^3 and those without suprasellar extension. Tumor control rates in patients receiving <12 Gy, 12 to 20 Gy, and >20 Gy were 73.5%, 95.5%, and 92%. New or progressive cranial neuropathies developed in 9% of patients (including 6.6% optic). Decreasing age, increasing volume, history of prior radiation therapy, and history of prior pituitary axis deficiency correlated with new or worsening cranial neuropathy.

Malignant Tumors

Management of brain metastases with radiosurgery is discussed elsewhere in this book. The most important controversies in brain metastasis radiosurgery involve the management of larger brain metastases. For brain metastasis radiosurgery, both local tumor recurrence rates and complication rates increase with increasing tumor target volume, particularly for tumors >3 cm in diameter. Strategies to improve the radiosurgical management of brain metastases include switching from single fraction to different forms of fractionated SRS or SRT and also combining radiosurgery with surgical resection.

Two different overall types of fractionation strategies have been used. One

strategy is to fractionate the radiation treatment for a single treatment plan over a short time period, usually within 1 to 2 weeks to limit tumor repopulation. The other approach is a two-staged adaptive radiosurgery with the fractions separated by approximately 1 month. This allows tumor to shrink before the second fraction is delivered and so requires reimaging with a second treatment plan. Cho et al.,[107] for example, compared the outcome of treating 81 small brain metastases with a median volume of 1.0 cm^3 (range: 0.12 to 4.4 cm^3), with single-fraction radiosurgery to a median dose of 22 Gy to that with 38 larger brain metastases with a median volume of 17.6 cm^3 (range 12.8 to 23.7 cm^3) treated with 3 to 5 fractions to a median dose of 35 Gy. Tumor control rates at 1 year for single versus 3 to 5 fractions were similar at 89.7% versus 87% as were radiation necrosis rates at 12.3% versus 15.8%, respectively. The second strategy for radiosurgery of large brain metastases is a two-staged adaptive radiosurgery with time in between to allow for tumor shrinkage. Angelov et al.,[108] for example, treated 63 brain metastases with a median volume of 10.5 cm^3 in 54 patients with a median initial dose of 15 Gy (12 to 18 Gy) and to a median second dose of 15 Gy (range 12 to 15 Gy) to a median volume of 7.0 cm^3(1.0 to 29.7 cm^3) and a median of 34 days later. Tumor control was 88% at 6 months and only 11% adverse radiation effects.

The other approach for dealing with large brain metastases is combining surgical resection with radiosurgery to the tumor bed. Patel et al.[109] compared the results of surgical resection of brain metastases with radiosurgery delivered either preoperatively to a median dose of 14.5 Gy with no margin in 66 patients or postoperatively with 2-mm margin in 114 patients. Although no significant differences were found in overall survival ($P = .1$), local recurrence ($P = .24$), or distant brain recurrence ($P = .75$), patients undergoing postop SRS developed significantly more leptomeningeal disease (16.6% vs. 3.2%) and symptomatic radiation injury (16.4% vs. 4.9%) at 2 years despite a higher proportion of breast cancer with similar median gross tumor volumes (9.2 vs. 8.3 cm^3) and a higher proportion of breast cancer cases in the preoperative group (27.2% vs. 10.5%). Atalar et al.[110] had previously reported higher risks of leptomeningeal seeding with postop SRS for brain metastases from breast cancer (24% vs. 9% at 1 year) than other primaries.

Brain Metastases

Brain metastases are the most common and best studied of the indications for radiosurgery.[103] Early clinical investigations found impressive tumor control

with radiosurgery for brain metastases that progressed after prior whole-brain radiotherapy (WBXRT). RTOG's phase I dose escalation trial in recurrent brain tumors to some degree standardized dose prescription for brain metastasis radiosurgery.[72] Because of the success of radiosurgery in controlling brain metastases after WBXRT and the high rate of eventual local tumor progression in brain metastases after conventional WBXRT, radiosurgery has been increasingly used in initial management of brain metastases.[72] RTOG's subsequent phase III randomized trial, RTOG 95-08, established that radiosurgery immediately following standard WBXRT (37.5 Gy in 15 fractions) improves local control and quality of life for patients with one to three brain metastases while also improving overall survival for patients with solitary metastasis, all compared to patients initially managed with only WBXRT.[36]

Although RTOG 95-08 established radiosurgery's role after WBXRT in managing one to three brain metastases, questions remained about managing brain metastases with radiosurgery alone and preserving full-dose WBXRT as an option for later managing cases with subsequent progression. Aoyama published the outcome of a prospective randomized controlled trial to evaluate whether initial WBXRT provides better outcomes when added to stereotactic radiosurgery (SRS) compared to using SRS alone.[1] Aoyama's 11 hospital study randomized 132 patients with one to four brain metastases <3 cm in diameter to radiosurgery either with or without initial WBXRT. They found that the median survival time and the 1-year actuarial survival rates were not significantly different with or without WBXRT.[35] The 1-year brain tumor "recurrence rate" (corresponding to the development of additional brain metastases) was higher in the SRS-alone group compared to the patient group who received both WBRT and SRS. Earlier retrospective studies had similar observations. The most common primary site in these studies was the lung. Separate analyses of brain metastases radiosurgery of different histologies with and without whole-brain radiosurgery found that WBXRT reduced subsequent development of brain metastases in lung cancer patients but not in patients with melanoma or renal cell carcinoma. Administering initial WBXRT and waiting a month before radiosurgery for subsequent tumor shrinkage are a reasonable strategy to limit radiation injury reactions and/or improve tumor control for brain metastases >3 cm in diameter and for brainstem metastases >2 cm in diameter.

There is no clear limit to how many metastases and what total volume of metastases can or should be treated by radiosurgery. RTOG 9508 was limited to 1 to 3 metastases, whereas Aoyama's trial and a smaller University of Pittsburgh

trial included patients with up to four brain metastases.[104] Bhatnagar et al.[111] analyzed 205 patients who underwent radiosurgery for 4 to 18 brain metastases (median = 5). They reported a median survival of 8 months after radiosurgery and found that survival correlated with the total volume of metastases, age, and RTOG-RPA class, but not the total number of brain metastases. Presently, many centers use WBXRT alone to initially manage patients with five or more metastases and subsequently consider radiosurgery for patients who are unable to be withdrawn from steroid medication and for patients whose brain metastases progress after WBXRT.

Radiosurgery has also largely supplanted WBXRT for postoperative radiotherapy following initial resection of brain metastases. Luther et al.[112] reported the outcome for 120 brain metastasis patients undergoing tumor resection bed radiosurgery. Although overall tumor control was satisfactory at 85.8%, the 2-year local control for target volumes ≥8 cm^3 was only 65% (compared to 86%) for <8 cm^3. Soltys et al.[113] recommended adding a 2-mm margin to the postoperative cavity radiosurgery treatment volume. In their experience, it improved local control from 70% (n = 79) to 100% (n = 10), though not significantly (P = 0.15). Minnetti et al.[114] reported on 101 solitary brain metastases >3-cm diameter resections managed with postoperative SRS to 27 Gy in 3 fractions with a 2-mm margin added to resection cavity volumes of 12.6 to 35.7 cm^3. The 1- and 2-year rates of local control rates were 93% and 84%, whereas those for radiation necrosis (developing in 9 patients) were 7% and 16%.

Patel et al.[115] compared the results of surgical resection of brain metastases with radiosurgery delivered either preoperatively to a median dose of 14.5 Gy with no margin in 66 patients or postoperatively with 2-mm margin in 114 patients. Although no significant differences were found in overall survival (P = 0.1), local recurrence (P = .24), or distant brain recurrence (P = .75), patients undergoing postop SRS developed significantly more leptomeningeal disease (16.6% vs. 3.2%) and symptomatic radiation injury (16.4% vs. 4.9%) at 2 years despite a higher proportion of breast cancer similar median gross tumor volumes (9.2 vs. 8.3 cm^3) and a higher proportion of breast cancer cases in the preoperative group (27.2% vs. 10.5%). Atalar et al.[116] had previously reported higher risks of leptomeningeal seeding with postop SRS for brain metastases from breast cancer (24% vs. 9% at 1 year) than other primaries.

Glioblastomas

During the late 1980s and 1990s, many centers that had been using brachytherapy for recurrent high-grade gliomas and as boosts after conventional radiotherapy switched to radiosurgery.[69,106] Although retrospective series appeared to show that initial brachytherapy or radiosurgery boosts after conventional radiotherapy improved survival of glioblastoma patients, prospective randomized trials of both modalities used prior to conventional radiotherapy of glioblastoma patients were negative[69,106]. Radiosurgery appears to be a reasonable option for small well-circumscribed high-grade gliomas that recur after prior conventional large-field radiotherapy and chemotherapy. Clark et al.[117] reported dose-escalated radiosurgery delivered with 10 mg/kg bevacizumab q2 weeks to 27, 30, and 33 Gy for recurrent glioblastoma and anaplastic astrocytoma in 3, 5, and 7 patients with no cases of clearly symptomatic radionecrosis but with one patient in the 33-Gy level exhibiting cognitive deterioration and grade 3 fatigue. Three patients underwent subsequent resections for presumed local progression with viable tumor and substantial radiation necrosis found in each, one of which with necrosis in >90% of the specimen.

Summary

Stereotactic radiosurgery and radiotherapy techniques have become a dominant way of managing a large number of benign and malignant tumors and other conditions in the brain and central nervous system. The safety and effectiveness of these techniques continue to improve along with technical improvements in radiation targeting and delivery as well as improvements in our understanding of radiobiologic responses.

CHAPTER 18

Stereotactic Irradiation of Tumors Outside the Central Nervous System

Brian D. Kavanagh, Jeffrey D. Bradley, and Robert D. Timmerman

INTRODUCTION

Departing from the established traditions of conventionally fractionated external beam radiotherapy, in the late 1980s and early 1990s, investigators in the United States, Sweden, and Japan began to explore the use of extremely brief hypofractionated radiation treatment regimens for the spine, lung, liver, and selected other malignant extracranial tumors.[1–3] In essence, these clinical researchers were modifying techniques proven clinically valuable in the context of cranial and spine stereotactic radiosurgery in an effort to exploit the efficiency and biologic potency of high–dose per fraction irradiation.[4] This idea was soon appreciated for its clinical promise by other researchers in numerous countries across the world.

Pioneers in the field initially used customized ancillary equipment constructed in their own institutions to immobilize patients and to adapt ordinary linear accelerators for the task of precise internal tumor targeting. Now, however, the administration of high-dose, tightly focused external-beam radiation therapy is greatly facilitated by a wide assortment of commercially available systems that immobilize patients, address the problem of respiratory motion during treatment, and ensure accurate treatment with the use of image guidance. The newest generation of linear accelerators from several manufacturers is either exclusively dedicated to cranial or extracranial stereotactic radiotherapy or is equipped with a built-in package of features that provide an easy means of administering this type of treatment.

Stereotactic body radiation therapy (SBRT) is the term applied in the United States by the American Society of Therapeutic Radiology and Oncology (ASTRO) for the management and delivery of image-guided high-dose radiation

therapy with tumor-ablative intent within a course of treatment that does not exceed 5 fractions.[5] Other descriptive terms have been occasionally applied to describe what is officially called SBRT, including the acronym SABR, an abbreviation for *s*tereotactic *ab*lative *r*adiotherapy.[6]

BIOLOGIC AND ONCOLOGIC RATIONALE FOR SBRT

The appeal of SBRT is based on the nonlinear relation between radiation dose and cytotoxic effect, whereby one or a few large individual doses of radiation therapy may have substantially more cell-killing effect than the same dose of radiation given in smaller individual doses. Traditionally, the expected relation between radiation dose and tumor cell kill has been commonly estimated by the well-known linear-quadratic (LQ) model of radiation dose response, often relied on for the purpose of comparing the biologic potency of different schedules of conventionally fractionated radiation therapy. In the range of dose per fraction used in SBRT, however, there has been an emerging appreciation that the LQ model overestimates the potency of fraction sizes on the order of 8 to 10 Gy or higher.

A variety of alternative mathematical models have been proposed to account for the observed inaccuracy of the LQ model for doses in this range. For example, Guerrero and Li[7] have proposed a modification of Curtis's[8] lethal-potentially lethal model that accounts for ongoing repair processes occurring during the time of an individual radiation treatment, thus predicting lower cytotoxicity from high doses administered over time intervals resembling typical clinical treatment times. Experimental data modeling cranial radiosurgery offer support for this concept.[9] Alternatively, Park et al.[10] have offered the universal survival curve formalism, which combines the LQ model for doses in the range used in conventional fractionation with a multitarget model for doses in the range used for SBRT. This piecewise function effectively achieves the same key mathematical result as other departures from the LQ model applied to SBRT, namely, a more linear slope in the relation between dose and log cell kill in the high-dose region.

In the special case of prostate cancer, the rationale for evaluating SBRT for prostate cancer has also included an additional LQ model-based hypothesis. Retrospective outcomes comparisons that involve a variety of doses and schedules of treatments had suggested that if the LQ model was applicable, the α/β ratio for prostate cancer might be very low, likely in the range of 1.5 to 3.0

Gy.[11,12] If this estimate of α/β ratio for prostate cancer were correct, then higher doses per fraction should provide a more favorable therapeutic ratio than a conventionally fractionated regimen. Accumulating evidence from randomized clinical trials comparing conventional daily fractions of 2 Gy with hypofractionated regimens using fractions sized on the order of 2.5 to 3 Gy/d offer conflicting evidence in this regard, raising some questions about the initial parameter estimates.[13–15] Clinical reports involving SBRT for prostate cancer have involved doses that are higher than 3 Gy and are discussed later in the chapter.

None of the aforementioned models of high–dose per fraction tumor cell–killing effects explicitly incorporate a mechanism of tumor cell kill that might be of equal or greater importance than tumor DNA damage-based injury, namely, the antiangiogenic effect of endothelial cell apoptosis occurring above an apparent threshold dose on the order of 8 to 10 Gy. First observed preclinically and reported by Garcia-Barros et al.,[16] clinical evidence indirectly supporting the importance of this mechanism includes measures of an increase in serum markers of apoptosis post-SBRT.[17] Challenging the importance of this mechanism, however, is the work of Kirsch and colleagues, who used a genetically engineered mouse model to evaluate the influence of endothelial cell apoptosis in a mouse sarcoma model,[18,19] observing minimal impact on tumor radiosensitivity from the degree of endothelial apoptosis achieved. The impact of high–dose per fraction radiotherapy upon immune responses is a topic of current high interest. One early preclinical study demonstrated that a single dose of 20 Gy, unlike a fractionated regimen of lower dose per fraction, can trigger a strong T-cell response that enhances the cytotoxic effect in a preclinical melanoma model.[20]

Beyond its uses as primary therapy for selected early-stage cancers, SBRT can also be used as a noninvasive and efficient means of eradicating discrete tumors in the setting of oligometastatic disease. As articulated by Hellman and Weichselbaum,[21] the spectrum theory or theory of oligometastases proposes that there is a subgroup of patients with metastatic disease that is intermediate between completely absent and widely metastatic. For such patients, the entire systemic disease burden is contained within the finite number of individual sites of gross disease recognized by the relevant imaging studies. This condition would reflect an intermediate point in the natural history of that individual’s cancer; therefore, these patients might be cured if their limited numbers of metastatic sites are eradicated. There have been numerous reports of patients

enjoying a high rate of 3- to 5-year survival following various forms of aggressive local treatment (e.g., surgical resection, radiofrequency ablation, cryotherapy) for limited metastases in the liver or lung from an assortment of solid tumor types.[22] SBRT is a valid, noninvasive substitute for other local modalities if it can provide similar efficacy and the same or less toxicity. Among the many examples of studies lending indirect support to the theory of oligometastases and the potential value of SBRT in this setting would be the report by Stinauer et al.[23] involving patients treated with SBRT for metastases from melanoma or renal cell carcinoma, where there was significantly longer survival for patients with oligometastatic disease, there defined as three or fewer sites, than for patients with more extensive disease.

The indications for SBRT in the setting of metastatic disease might be alternatively couched in terms of a patterns-of-failure model. Rusthoven et al.[24] reviewed a large series of patients who received chemotherapy for metastatic non–small cell lung cancer and observed, not surprisingly, that patients are most likely to suffer tumor recurrence in sites initially involved prior to chemotherapy. The hypothesis that eradicating all known sites of non-small cell lung cancer present in patients with limited metastatic disease can extend disease-free survival was tested in a clinical trial by Gomez et al.[25] After appropriate induction systemic therapy (at least four cycles of platinum doublet therapy or at least 3 months of erlotinib/crizotinib for patients with EGFR mutations/ALK fusions, respectively), patients were randomized to either local consolidative therapy (LCT) or systemic therapy alone. LCT could be radiotherapy, chemoradiotherapy, or surgical resection. The study was closed early on advice from the data safety monitoring committee because of significant efficacy benefit observed in the LCT arm. At a median follow-up time of over 16 months, the median progression-free survival time in the LCT arm was 14.4 months, compared to 3.9 months in the no-LCT arm (hazard ratio = 0.36, $P = .013$).

Numerous studies of similar structure to the Gomez trial have been launched. For example, Palma and colleagues have conducted a multicenter randomized phase II trial to assess the impact of a comprehensive oligometastatic SBRT treatment program on overall survival and quality of life in patients with up to five metastatic cancer lesions, compared to patients who receive standard of care treatment alone.[26] Patients are stratified by the number of metastases (1 to 3 vs. 4 to 5) and then randomized between Arm 1: current standard of care treatment, and Arm 2: standard of care treatment + SBRT to all sites of known disease. Patients will be randomized in a 1:2 ratio to Arm 1:Arm 2, respectively. Salam

and Milano have provided a thorough review of the use of ablative-intent radiotherapy for extracranial oligometastases.[27]

Especially intriguing is the possibility that stereotactic irradiation can initiate immunologic responses that can trigger an abscopal responsive to novel agents such as ipilimumab, as described in a number of case reports.[28,29] Additional indirect evidence for a favorable relationship between the use of radiotherapy and another immunotherapeutic agent, pembrolizumab, has emerged from a secondary single institutional analysis of the KEYNOTE-001 trial.[30] Among 98 patients who were enrolled and received their first cycle of pembrolizumab, 42 (43%) had previously received any radiotherapy for the treatment of NSCLC before the first cycle of pembrolizumab. Overall survival with pembrolizumab was significantly longer in patients who previously received any radiotherapy than in patients without previous radiotherapy (P = .026; median overall survival 10.7 months [95% CI 6.5–18.9] vs. 5.3 months [2.7–7.7]) and for patients who previously received extracranial radiotherapy compared with those without previous extracranial radiotherapy (P = .034; median overall survival 11.6 months [95% CI 6.5–20.5] vs. 5.3 months [3.0–8.5]). The optimal timing of immunotherapeutic agent and dose prescription for radiotherapy given in combination is a topic of active investigation at numerous centers.

STEREOTACTIC BODY RADIATION THERAPY GUIDELINES, PHYSICS OVERVIEW, AND SAFETY CONSIDERATIONS

ASTRO and the American College of Radiology (ACR) have published guidelines that characterize the personnel qualifications and responsibilities, documentation, quality control, and clinical operations recommended for the safe and proper administration of SBRT and follow-up care for patients treated.[5] The ASTRO-ACR guidelines advise that the following components should be in place within and institution’s SBRT program:

. Qualified personnel:

   a. Board-certified radiation oncologist
   b. Qualified medical physicist
   c. Licensed radiation therapist
   d. Other support staff as indicated (dosimetrists, oncology nurses, and so forth) Ongoing machine quality assurance program

- Documentation in accordance with the *ACR Practice Guideline for Communication: Radiation Oncology*
- Quality control of treatment accessories
- Quality control of planning and treatment images
- Quality control of treatment planning system
- Simulation and treatment systems that account for systematic and random errors associated with setup and target motion in a manner that is based on actual measurement of organ motion and setup uncertainty.

The American Association of Physicist in Medicine Task Group 101 (TG101) moved forward from the ASTRO-ACR guidelines to generate a report that considers additional important nuances in the planning and treatment delivery of SBRT.[31] Included within the TG101 report are discussions of potential imaging artifacts and their impact on treatment planning, the challenges of small-field dosimetry, and the importance of using an acceptable dose calculation algorithm, among other issues.

Proper patient repositioning, target localization, and management of breathing-related motion are essential for SBRT. A variety of patient immobilization devices are available, including several types of body frames with external fiducial markers. So-called frameless systems incorporate ultrasound, kilovolt-range imaging, or near real-time computed tomography (CT) scanning to verify the location of internal targets relative to the beams to be used. Because SBRT treatment sessions are lengthier than conventional external-beam treatments, patient comfort is an important issue.

Breathing-related motion control devices and systems fall into three general categories: (a) dampening, (b) gating, and (c) tracking or “chasing.” Respiratory dampening techniques include systems of abdominal compression intended to diminish one of the largest contributors to breathing-related motion, namely, diaphragmatic excursion, by obliging the inspiratory–expiratory lung motion pattern to involve more intracostal expansion and shallower breathing overall. Also included in this category are the systems employing breath-holding maneuvers to stabilize the tumor in a reproducible stage of the respiratory cycle (e.g., deep inspiration). Gating systems for SBRT, as for any radiotherapy application, follow the respiratory cycle using a surrogate indicator for respiratory motion, for example, chest wall motion, and employ an electronic beam activation trigger allowing irradiation to occur only during a specified range of expected tumor locations. Tracking or “chasing” systems move the radiation beam or patient to follow the movement of the tumor.

Regardless of the system employed, the procedure of treatment planning must include the same consideration for respiratory motion management to be used during treatment. Despite available motion control equipment, some positional uncertainty will remain. The planning target volume (PTV) margins used to account for this residual motion of the gross tumor volume (GTV) will typically range from 3 to 5 mm.

The word *stereotactic* has heretofore usually implied that some sort of external reference markers indexed to internal structures facilitate internal target relocalization, but the definition has expanded to include systems of image-guided radiation therapy (IGRT) that relate the position of internal targets to a three-dimensional coordinate geometry registered to the treatment machine without the use of external markers on the patient. SBRT always involves some form of IGRT to guide for treatment delivery.

Most reports describing SBRT published to date have employed high-energy photons (x-rays) as the source of therapeutic radiation, although other particles can also be used. There is no absolute standard for the combination of beam or arc angles ideal for any given clinical situation, and each case can present unique challenges. In general to achieve a tightly focused high-dose distribution within the PTV and rapid dose falloff outside the PTV, a combination of multiple (often 10 or more) noncoplanar beams or multiple arcs are required. Intensity modulation across the individual beams or arc segments can be incorporated within SBRT.

As part of ASTRO's Target Safely campaign, the Multidisciplinary Quality Assurance Subcommittee of the Clinical Affairs and Quality Committee of ASTRO commissioned a white paper on the topic of cranial radiosurgery and SBRT titled "Quality and Safety Considerations in Stereotactic Radiosurgery and Stereotactic Body Radiation Therapy."[32] Of particular importance within the white paper are sections emphasizing the importance of creating a proactive culture of safety with procedural checkpoints and error analysis mechanisms.

CLINICAL EXPERIENCE WITH STEREOTACTIC BODY RADIATION THERAPY IN SELECTED SITES

Liver

The two major reasons for considering SBRT for hepatocellular cancer (HCC) is that underlying severe liver disease often renders patients medically inoperable and that other nonsurgical therapies have generally achieved at best rather

modest success in that setting. The natural history of untreated HCC has been reported to involve a median survival in the range of 3 to 8 months,[33–35] and so a safe and effective therapy is needed in this setting.

The earliest observations following SBRT for HCC were reported by a group at Karolinska Hospital,[2] and more recent formal prospective studies have followed. The Princess Margaret Hospital group utilized a 6-fraction regimen in a prospective phase I study in patients with HCC (n = 31) or intrahepatic cholangiocarcinoma (n = 10).[36] Prescription doses were selected according to a normal tissue complication probability (NTCP) model based on conventionally fractionated radiotherapy to the liver. The median dose to the tumor was 36 Gy (range, 24 to 54 Gy). The NTCP model overestimated the chance of radiation-induced liver disease, and it is possible that the dose could have been escalated to a higher level in most cases. Nevertheless, in this group of heavily pretreated patients (over 60% had had at least one prior therapy for HCC), a remarkable median survival of 12 months was observed.

Méndez Romero et al.[37] at Erasmus University Medical Center treated eight patients with 11 separate lesions of HCC in 3 to 5 fractions to a dose of 25.0 to 37.5 Gy. A 1-year survival of 75% was observed. Choi et al.[38] at the Catholic University of Korea treated 23 patients with 32 individual lesions in a 3-fraction regimen to a median dose of 36 Gy (range, 30 to 39 Gy). No patient experienced severe toxicity, although follow-up was limited (median 11 months). Interestingly, in a subsequent analysis of predictors for decline in liver function after SBRT, on multivariate analysis the only predictor for a decrease in Child-Pugh classification (CPC) from baseline level was the volume of normal liver receiving 18 Gy or more (V18). The rate of negative impact on CPC rose sharply when the V18 exceeded 800 cc.[39] This latter observation favors a model of SBRT effect on normal liver in line with a critical volume model, whereby it is important to preserve a certain minimum level of function by sparing an adequate volume of normal liver from receiving a dose above a certain threshold.

The group from the Korea Institute of Radiological and Medical Sciences treated a prospectively registered cohort of 38 patients with inoperable HCC with SBRT, all of whom had failed prior transarterial chemoembolization.[40] The median tumor volume was 40.5 cc (range, 11 to 464). The SBRT dose was 33 to 57 Gy in 3 or 4 fractions. Minimal grade 3 toxicity (<3%) was observed, and the 2-year overall survival was 61%.

Cardenes et al.[41] from Indiana University and the University of Colorado

reported a multi-institutional phase I dose escalation study of SBRT given in 3 fractions for HCC. Eligibility requirements were CPC-A or -B, medical or technical inoperability, and three or fewer lesions of cumulative tumor diameter 6 cm or less. The study enrolled 17 patients with 25 individual lesions. Dose was escalated from 36 to 48 Gy (16 Gy per fraction) in CPC-A patients without dose-limiting toxicity (DLT); however, two patients with CPC-B status at baseline developed grade 3 hepatic toxicity at the 42 Gy (14 Gy per fraction) dose level. Consequently, the dose for CPC-B patients was reduced to 40 Gy in 5 fractions. There were no local failures within the treated volume, and six patients proceeded to liver transplantation. The 2-year overall survival for the entire group was 60%.

The Indiana University group has separately reported their single institution experience involving a total of 60 patients: 34 CPC-A, 25 CPC-B, and 1 CPC-C.[42] The median number of fractions, dose per fraction, and total dose, was 3, 14, and 44 Gy, respectively, for those with CPC-A cirrhosis and 5, 8, and 40 Gy, respectively, for those with CPC-B. With a median follow-up time of 27 months, the 2-year local control rate was 90%. Two-year overall survival was 67%. SBRT served as a bridge to liver transplant for 23 patients who underwent transplant at a median time of 7 months following SBRT. A progression in CPC was observed in 20% of patients within 3 months of treatment.

Numerous other series have been reported in the last several years. Among the larger is the experience of Bibault et al., who treated 75 patients with 96 liver-confined HCC with SBRT.[43] There were 67 patients with Child-Turcotte-Pugh (CTP) Class A and eight patients with CTP Class B. Treatment was administered in three sessions. A total dose of 40 to 45 Gy to the 80% isodose line was delivered. The local control rate was 89.8% at 1 and 2 years. Overall survival was 78.5% and 50.4% at 1 and 2 years, respectively. Toxicity mainly consisted of grade 1 and grade 2 events. Higher alpha-fetoprotein (aFP) levels were associated with less favorable local control, and a higher dose was associated with better local control. A Child-Pugh score higher than 5 was associated with worse overall survival.

A provocative analysis has been reported by Su et al.[44] A propensity matching technique was used to pair 82 patients who received SBRT with a group of 35 patients who underwent liver resection. Before propensity score matching, the 1-, 3-, and 5-year OS was 96.3%, 81.8%, and 70.0% in the SBRT group and 93.9%, 83.1%, and 64.4% in the resection group, respectively (P = NS). After propensity score matching, 33 paired patients were selected from the SBRT and

resection groups. The 1-, 3-, and 5-year OS was 100%, 91.8%, and 74.3% in the SABR group and 96.7%, 89.3%, and 69.2% in the resection group, respectively (*P* = NS). There was a similarity of hepatotoxicity between the 2 groups. The SBRT group experienced more acute nausea but suffered lower rates of complications such as hepatic hemorrhage, hepatic pain, and weight loss.

Outcomes following SBRT for liver metastases have also been reported by numerous groups[45–53] and are summarized in Table 18.1. Regimens of 1 to 5 fractions have been employed, and total doses up to 60 Gy to the PTV have been administered. Taken together, the results show good survival outcomes achieved in heavily pretreated individuals and a trend toward improved local control with increasing dose.

Chang et al.[54] reported a pooled analysis from three institutions with the use of liver SBRT for liver metastases from colorectal primary cancers. The combined experience from Stanford, Princess Margaret Hospital, and the University of Colorado included 65 patients with a total of 102 individual liver metastases from colorectal cancer treated. More than half of the patients had had at least one prior systemic therapy regimen, and over 40% of the patients had had two or more prior systemic regimens. The analysis indicated that to achieve durable local control of treated lesion, a 3-fraction total dose on the order of 48 Gy is needed. Sustained local control after SBRT was closely associated with improved survival on multivariate analysis (*P* = .06).

Technical issues and posttreatment imaging follow-up considerations unique to liver SBRT have been included in these reports and in review papers.[55,56] Briefly, target delineation and image guidance can be difficult, because liver metastases are not well visualized on CT scans or in-room volumetric imaging used for IGRT. In many centers, radiopaque fiducial markers are place in or near the metastases to facilitate IGRT. In all centers, the PTV is an expansion of the GTV in consideration of the setup and intrafraction motion to be expected with the particular setup and delivery system employed. Typically, the margin used to expand a GTV into a PTV is on the order of 5 mm axially and 5 to 10 mm craniocaudally.

TABLE 18.1 STEREOTACTIC BODY RADIATION THERAPY FOR LIVER METASTASES

Institution	Patients/Lesions	SBRT Dose and Fractionation	Results

Heidelberg[45]	37/60	11–21 Gy × 1	18-month LC: Low dose (<16): 0% High dose (>16): 81%
Würzburg[46]	39/51	7 Gy × 4 10 Gy × 3 12.5 Gy × 3 26 Gy × 1	2-year LC: Low dose (28–30): 58% High dose (others): 82%
Aarhus-Copenhagen[47]	44/not stated	10 Gy × 3	2-year LC: 79% All pts CRC 3 ulcers with intestinal dose >30 Gy
Erasmus[48]	17/34	10 Gy × 3 12.5 Gy × 3	54% 15 pts CRC; 1 late portal hypertension in multiply treated patient
Colorado/multi-institutional[49]	47/63	12–20 Gy × 3	2-year LC: ≤3 cm: 100% >3 cm: 75%
Princess Margaret Hospital[50]	68/141	Variable, NTCP based Median 7 Gy × 6	1-year LC: 71% Better for higher dose, smaller volume
Stanford[51]	19/35	18–30 Gy × 1	1-year LC: 77% Combined with 7 patients with primarily liver cancer; maximum tolerated dose not reached
University of Texas—Southwestern[52]	26/35	6–12 Gy × 5	2-year LC 56%, 89%, 100% for total dose 30, 50, 60 Gy, respectively
Humanitas Clinical and Research Center[53]	42/52	Mean dose 75 Gy in 3 fractions	2-year LC 91%, 2-year OS 65%

CRC, colorectal cancer; LC, local control; NTCP, normal tissue complication probability; OS, overall survival; PTV, planning target volume.

The Colorado group first applied the critical volume approach to normal liver dose constraints in their initial phase I study[57] and subsequent phase II study. Noted above in relation to the observations of the Catholic University of Korea in their treatment of primary liver tumors, the critical volume model liver SBRT is an adaptation of the early work of Yeas and Kalend.[58] Applicable for organs of radiobiologically parallel structure, the crux of this application is to work backward, in a sense, from an estimate of how much volume of the organ is essential and must be protected from functional ablation. The estimate for liver that at least 700 cm^3 should receive <15 Gy during a 3-fraction SBRT course was derived from a combination of prior reports of outcomes after partial hepatectomy documenting approximate minimum volumes required and

estimates of the effects of that dose of radiation extrapolated from prior reports of conventionally fractionated treatment.

One feature of the normal tissue effect of liver SBRT consistently observed within the first few months after SBRT is a zone of hypodensity observed on follow-up CT scans corresponding to the volume that received approximately 30 Gy.[57] This phenomenon, first described by Herfarth et al.[59] following single-dose liver SBRT, is likely related to local veno-occlusive effects.[60] There is no known clinical consequence associated with the finding per se, but it can cloud the assessment of tumor response within the first few months after liver SBRT.

CASE STUDY

Liver Stereotactic Body Radiation Therapy

A 45-year-old female had been diagnosed with stage IV breast cancer 2 years previously. Biopsy-proven liver metastases were present at the time of diagnosis. Numerous systemic agents had been given, most recently gemcitabine and trastuzumab. Although all other measurable or assessable sites of disease were stable or regressing, a mass in the liver had progressed from 2.5-by-2.9 cm to 6.0-by-4.2 cm within the past 3 months. Because the patient was tolerating the regimen well and apparently having a response in most sites, she was offered SBRT in an effort to eradicate tumor in the liver.

The lesion diameter (>6 cm) rendered the patient ineligible for an ongoing phase II trial of SBRT for liver metastases, and the dose given was lower than the protocol doses (Fig. 18.1). The 53 cm^3 GTV was expanded by 5 mm radially and 10 mm in the superior–inferior direction to generate the PTV. The dose distribution shown was administered in 3 fractions within 1 week using multiple dynamic conformal arcs and a controlled breath-holding device. The nominal prescription dose was 45 Gy. The maximum point dose was 59 Gy, and the equivalent uniform dose was 54 Gy. The volume of normal liver receiving <15 Gy was 1,800 cm^3. The portion of the right kidney receiving above 15 Gy was 13%. Follow-up scans at 6 and 10 months show a Herfarth type 2 reaction with hyperdensity in the treated normal liver.[59] There is also volume loss in the nearby normal liver parenchyma surrounding the lesion, a phenomenon that has also been described.[60] The lesion remained controlled for the duration of the patient's life; she eventually died of complications related to central nervous system metastases.

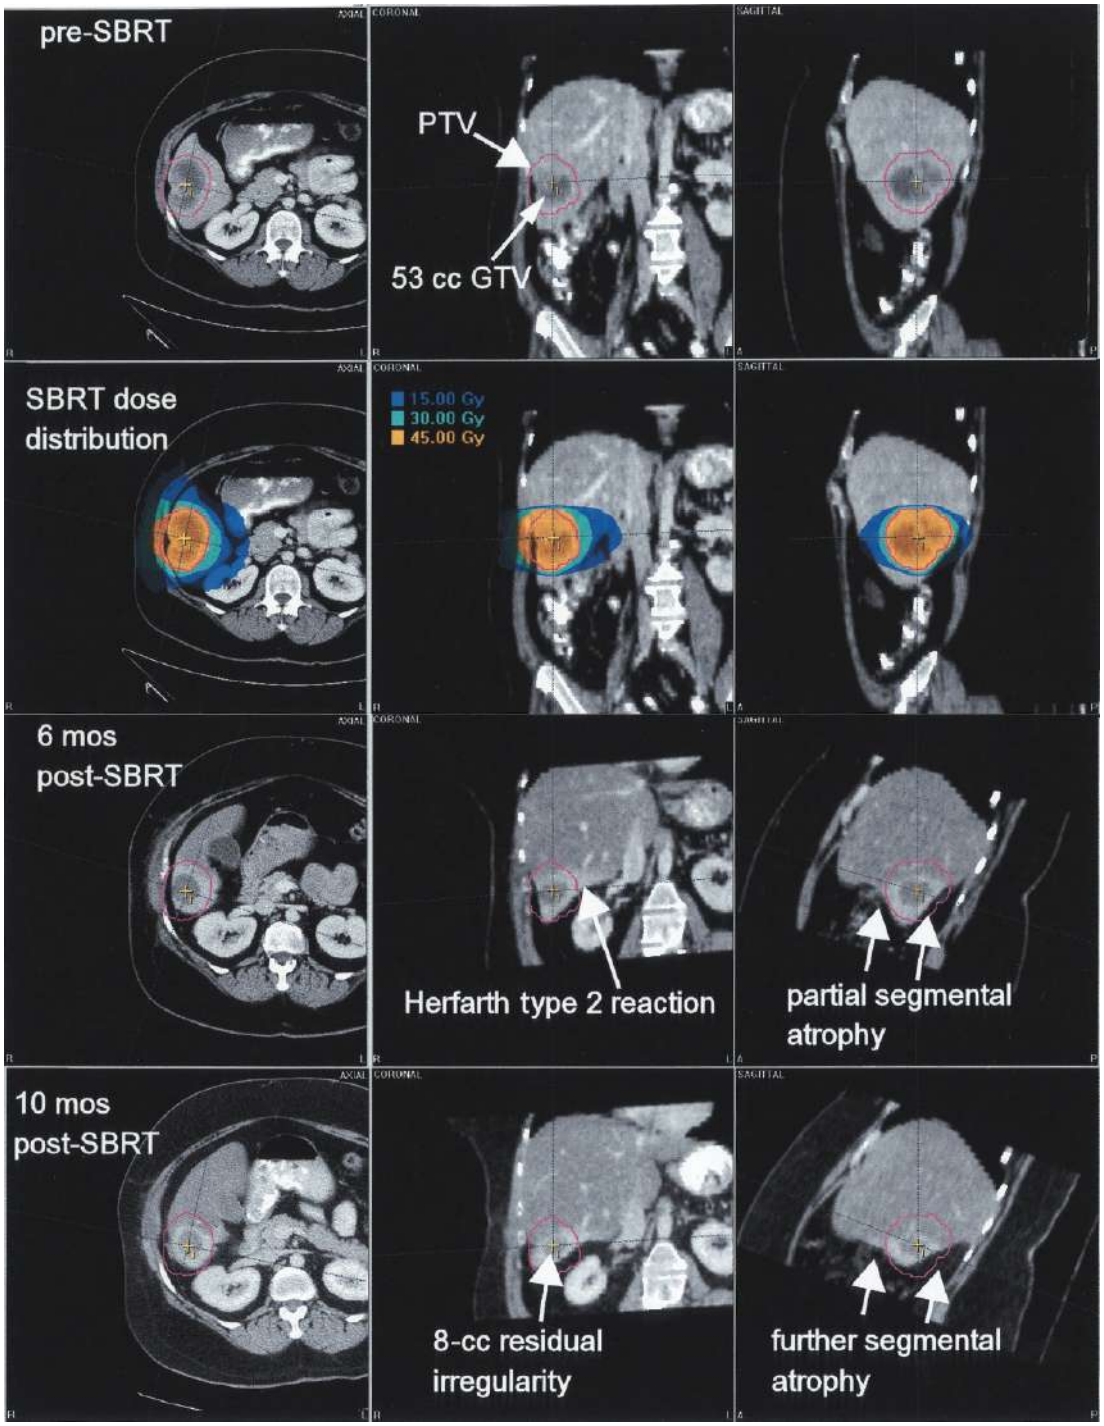

FIGURE 18.1. Example of liver stereotactic body radiation therapy (SBRT). **Top panel:** Pre-SBRT planning computed tomography images with *thin arrow* pointing to the gross tumor volume (GTV) and *wide arrow* showing the planning target volume (PTV), which is outlined. **Second panel:** SBRT composite dose distribution. **Third panel:** Images obtained 6 months post-SBRT illustrating a Herfarth type 2 reaction in adjacent parenchyma and partial segmental atrophy. **Bottom panel:** Shows images 10 months post-SBRT, indicating continued tumor regression as the ablated liver volume continues to recede.

Lung

Medically inoperable early-stage lung cancer has historically provided a substantial management challenge. Conventionally fractionated radiotherapy has yielded generally unsatisfactory outcomes with high rates of local failure and 3-year survivals in the range of approximately 30%. For this reason, medically inoperable early-stage lung cancer was the first clinical indication for which SBRT was studied in prospective clinical trials. Following the early exploratory studies of lung SBRT for stage I non–small cell lung cancer at the Karolinska Hospital in Stockholm[61] and National Medical Defense Hospital in Saitama,[3] numerous formal prospective studies of SBRT for medically inoperable non–small cell lung cancer have been now been reported. Table 18.2 lists the major prospective studies (N = 50 or more) with a minimum median follow-up of 24 months at the time of reporting, along with local control and overall survival at 3 years.[62–65] The consistent observation is that 3-year survival on the order of 50% to 60% has been achieved. A randomized clinical trial comparing SBRT (66 Gy in 3 fractions) to conventionally fractionated radiotherapy (70 Gy in 35 fractions) in this setting revealed equivalent overall survival despite slightly worse prognostic features in the SBRT arm. Patients who received SBRT also had lower rates of pulmonary toxicity and better self-reported quality of life.[66]

One important observation from the Indiana University studies was that although the treatment was generally well tolerated, tumor location near large airways in the vicinity of the pulmonary hilum (called the zone of the proximal bronchial tree) was associated with a markedly higher risk of toxicity. For this reason, in the Radiation Therapy Oncology Group's (RTOG) study RTOG-0236 of SBRT for medically inoperable non–small cell lung cancer, patients with tumors located in the zone of the proximal bronchial tree were excluded.[64] The RTOG launched a separate dose escalation study (ROTG-0813) in which tumors near the proximal bronchial tree were treated to doses in the range of 50 to 60 Gy in 5 fractions.[67] Protocol specified DLT rate were low, though some late toxicity outside those definitions occurred. The American Society for Radiation Oncology (ASTRO) has issued a guideline on SBRT for early-stage lung cancer that addresses key questions of patient selection and dose regimen for peripheral and central tumors.[68]

TABLE 18.2 MAJOR PROSPECTIVE STUDIES OF STEREOTACTIC BODY RADIATION THERAPY FOR MEDICALLY INOPERABLE NON–SMALL CELL LUNG CANCER

Institution	Number of Patients	SBRT Dose and Fractionation	3-Year Results
Indiana University[62]	70	60–66 Gy/3 fractions	LC 88%, OS 43%
Nordic Group[63]	57	45 Gy/3 fractions	LC 92%, OS 60%
RTOG[64]	55	54 Gy/3 fractions	LC 98%, OS 56%
University of Torino[65]	62	45 Gy/3 fractions	LC 88%, OS 57%

LC, local control; OS, overall survival; RTOG, Radiation Therapy Oncology Group.

Although many retrospective studies of lung SBRT contain a mixture of both primary and metastatic lesions, a few prospective studies exclusively focused on SBRT for lung metastases have been reported. In the University of Colorado phase I SBRT trial for lung metastases,[69] eligible patients had one to three pulmonary metastases from a solid tumor, cumulative tumor diameter <7 cm, and adequate pulmonary function (forced expiatory volume in the first second of expiration [FEV_1] >1.0 L). The PTV was typically constructed from the GTV by adding a 5-mm radial and 10-mm craniocaudal margin. The first cohort received 48 Gy to the PTV in 3 fractions. The SBRT dose was escalated in subsequent cohorts up to a preselected maximum of 60 Gy in 3 fractions. The percentage of normal lung receiving more than 15 Gy (V15) was restricted to <35%. DLT included acute grade 3 lung or esophageal toxicity or any acute grade 4 toxicity. No patient experienced a DLT, and the SBRT dose was escalated to 60 Gy in 3 fractions without reaching a maximum tolerated dose. No consistent significant effects on pulmonary functions tests were noted.

The phase II study of SBRT for lung metastases the Colorado study group included 38 patients with 63 lesions.[70] Most had received at least one prior systemic regimen for metastatic disease, and approximately one-third had received two or more prior regimens. The incidence of any grade 3 toxicity was 8% (3/38), and no grade 4 toxicity was seen. Symptomatic pneumonitis occurred in one patient (2.6%). For 50 lesions assessable for local control, the median follow-up was 15.4 months. The median GTV was 4.2 cc. The actuarial 2-year local control was 96%. Median overall survival was 19 months.

CASE STUDY

Lung Stereotactic Body Radiation Therapy

A 74-year-old female had undergone wedge resection for a pT1N0M0 non–small cell cancer of the right lung 7 years previously. She had a right pneumonectomy 3 years later as salvage treatment for a locoregional recurrence. She was later observed to have developed a left lung nodule on a surveillance chest x-ray, and needle biopsy proved it to be a non–small cell lung cancer, presumed to be a second primary. Staging studies revealed no other sites of disease. She was given systemic therapy and enjoyed a transient minor response and then regrowth of the lesion (Fig. 18.2).

The patient used supplemental oxygen, 2 L/min at bedtime and occasionally during the day. She was offered SBRT as potentially curative therapy for a new T1N0M0 lung cancer. The 4 cm^3 GTV was expanded by 5 mm radially and 10 mm in the superior–inferior direction to generate the 29 cm^3 PTV. The dose distribution shown was administered in 3 fractions within 1 week using multiple dynamic conformal arcs. The patient did not comfortably tolerate a breath-holding technique because of her supplemental oxygen requirements; therefore, an abdominal compression technique was used during simulation and treatment. The nominal prescription dose was 60 Gy. The maximum point dose was 79 Gy, and the equivalent uniform dose was 72 Gy. The portion of normal lung receiving <15 Gy was 12.7%. The lesion remained controlled for the duration of the patient's life; she died of unrelated causes more than 2 years after SBRT.

Spine

The earliest investigation into what would now be termed spine SBRT was that of Hamilton et al.,[1,71] who used a rigid immobilization with a device surgically attached to the spinal column. Conservative doses in the range of 8 to 10 Gy were given in 1 fraction to nine patients with recurrent lesions in the spine following prior conventional radiotherapy. Spinal cord doses were very low using this technique (0.5 to 3.2 Gy). Limited follow-up suggested a favorable clinical effect in some patients, and no complications were observed. More recently, less invasive techniques have been investigated.

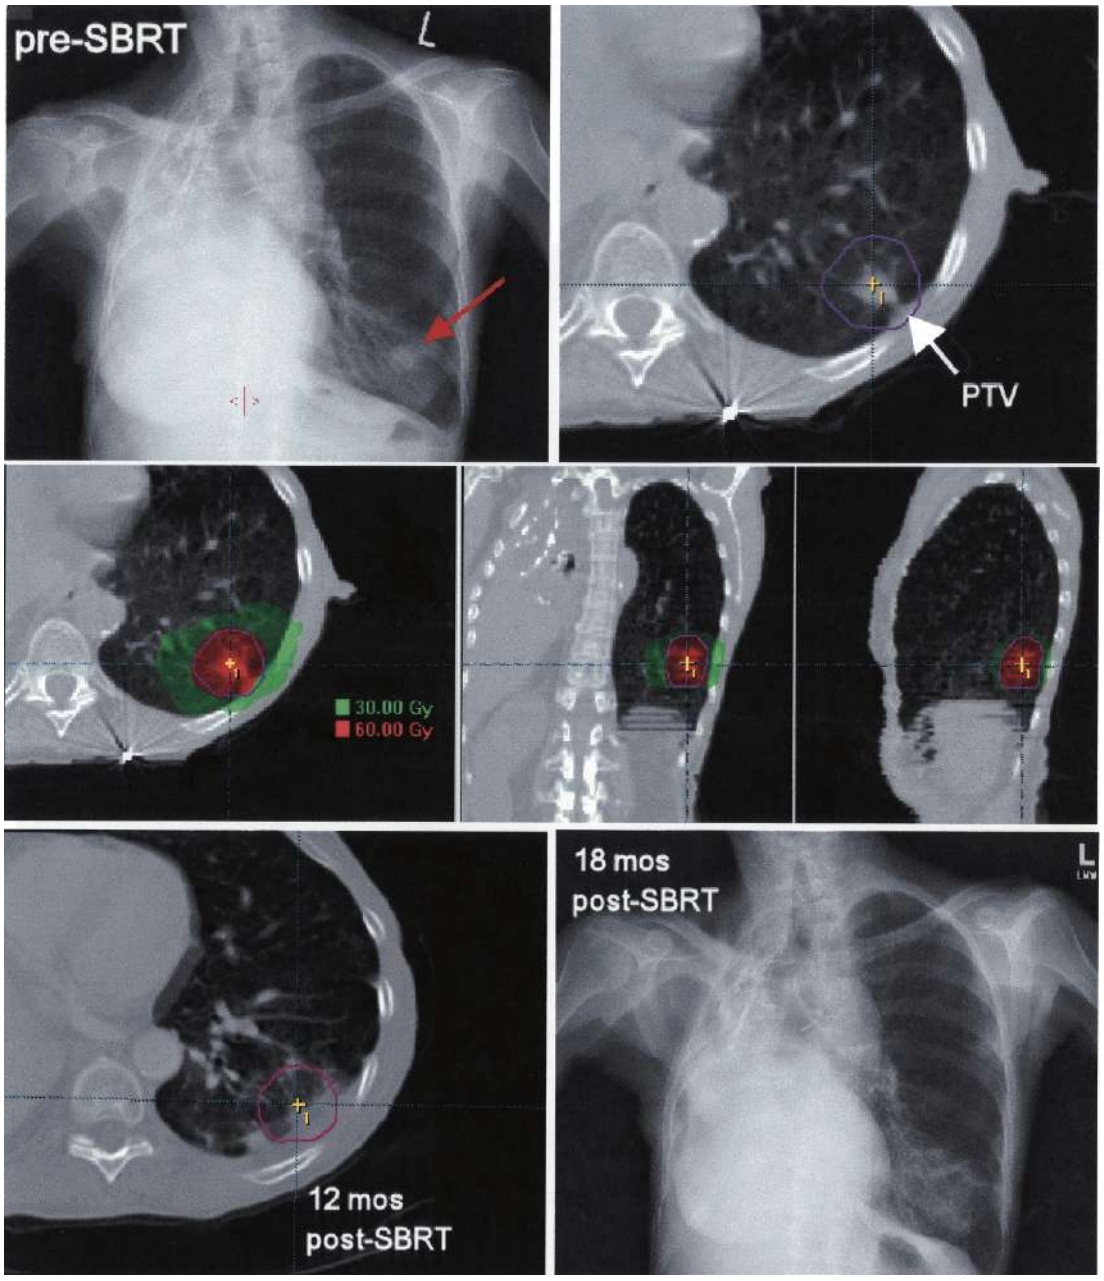

FIGURE 18.2. Example of lung stereotactic body radiation therapy (SBRT). **Top panel:** Pre-SBRT chest x-ray showing the left lung nodule (*red arrow*) and axial planning computed tomography (CT) image with *white arrow* pointing to the planning target volume (PTV), which is outlined. **Middle panel:** SBRT composite dose distribution shown in axial, coronal, and sagittal perspectives. **Bottom panel:** Follow-up CT scan axial image obtained 12 months post-SBRT illustrating stable patchy fibrosis in the high-dose region (*left*) and chest x-ray obtained 12 months post-SBRT, indicating minimal residual haziness in the region treated.

Ryu et al.[72] at the Henry Ford Hospital initially studied the treatment of spine metastases with initial fractionated radiotherapy followed by a spinal radiosurgery boost (6 to 8 Gy), observing prompt relief of pain in nearly all 10

treated patients. In a subsequent study of single-fraction spinal radiosurgery alone (10 to 16 Gy), this group observed complete or partial pain relief in 85% of the 49 patients treated.[73] Perhaps even more importantly, pain relief was rapid after SBRT, sometimes within hours of treatment.

Chang et al.[74,75] at the M.D. Anderson Cancer Center performed a prospective phase I dose escalation study in treating spinal metastases and later updated their institutional experience. The equipment used included a "CT on rails" that allowed for imaging immediately to guide patient repositioning. Sixty-three cancer patients underwent near-simultaneous CT-guided SBRT. Spinal magnetic resonance imaging was conducted at baseline and at each follow-up visit. The median tumor volume of 74 spinal metastatic lesions was 37.4 cc. Approximately half the patients received 30 Gy in 5 fractions, and the other half received 27 Gy in 3 fractions. A conservative constraint of 9 to 10 Gy maximum dose to the spinal cord was applied. No neuropathy or myelopathy was observed during a median follow-up period of nearly 2 years. The actuarial 1-year tumor progression-free rate was 84%. The investigators noted two characteristic patterns of failure: (a) recurrence in the bone adjacent to the site of previous treatment and (b) recurrence in the epidural space adjacent to the spinal cord. A low rate of any grade 3 toxicity was observed.

Similar observations of good tumor control and minimal toxicity have been reported from other centers.[76–81] For example, Gerszten et al.[78] of the University of Pittsburgh analyzed a cohort of 500 cases of spinal metastases. The maximum intratumoral dose ranged from 12.5 to 25 Gy (mean, 20). Tumor volume ranged from 0.20 to 264 mL (mean, 46). Durable pain reduction was achieved in 86% of patients, and durable tumor control was demonstrated for approximately 90% of the lesions treated. The vast majority of patients with a progressive neurologic deficit before treatment experienced at least some clinical improvement.

Regarding normal tissue toxicities, the Memorial Sloan-Kettering Cancer Center group reported that post-SBRT vertebral fracture is common when there is metastatic lytic disease involving more than 40% of the vertebral body and location at or below T10.[81] The MD Anderson Cancer Center group also analyzed the risk of fracture after spine SBRT and noted that fractures were more common among patients of age over 55 years, those with a pre-existing fracture, and pain at the time of treatment,[82] suggesting that patients at very high risk might appropriately be considered for prophylactic vertebral stabilization or augmentation procedures. Fortunately, spinal cord toxicity has only rarely been observed after SBRT. Case-control comparisons offer some suggestions of

parameters that might elevate the risk, but the paucity of events evaluable make it difficult to draw firm conclusions.[83,84] Constraints used to guide spine SBRT have included maximum point dose to the cord in the range of 10 to 14 Gy and limiting the volume of adjacent spinal cord receiving more than 10 Gy in a single fraction to 10% or less.

The International Spine Radiosurgery Consortium group has published guidelines to inform target definition and response assessment after spine SBRT.[85] The SPIne response assessment in Neuro-Oncology (SPINO) Group has likewise issued guidance on response assessment.[86]

Prostate Cancer

The first publication on SBRT for prostate cancer was the work of Madsen et al.,[80,87] who recently updated their observations. In a prospective trial, 40 patients with low-risk cancer (Gleason score ≤6 and prostate-specific antigen [PSA] ≤10 ng/mL) were treated to a dose of 33.5 Gy in 5 daily fractions The median age was 69 years (range, 50 to 82), and the median follow-up period was 5 years. The overall 5-year Phoenix definition (nadir plus 2 ng/mL) biochemical relapse-free survival (bRFS) rate was 93%. No patients died of prostate cancer. Late grade 3 genitourinary toxicity was rare, occurring in only one patient, and no late grade 3 or higher gastrointestinal was observed.[88]

The groups at Winthrop University and the University of California–San Francisco have also reported trials of SBRT for early-stage prostate cancer.[89,90] Using doses of 35 to 38 Gy in 4 or 5 fractions, both groups reported similarly low rates of grade 3 or higher toxicity of any kind (<1% in aggregate between the studies) after a median follow-up of 1 year. King et al.[91] from Stanford University reported a prospective trial in which 67 patients with clinically localized low-risk prostate cancer were treated with SBRT to a dose of 36.25 Gy, administered in 5 fractions. The 4-year bRFS was 94%, and no grade 3 or higher rectal toxicity was observed. There were only two cases (3%) of grade 3 or higher bladder toxicity, both of which were believed to have been caused or exacerbated by procedures performed for dysuria (cystoscopies or dilatation).

The combined observations from multiple prospective trials at eight institutions were pooled and reported.[92] SBRT to a median dose of 36.35 Gy in 4 to 5 fractions was given to 1,100 patients with clinically localized prostate cancer. Most patients were low-risk, though nearly 40% had intermediate-risk or high-risk disease. A minority (14%) received a short course of androgen deprivation therapy. The 5-year bRFS rate was 93% for all patients; 95%, 83%,

and 78% for GS ≤6, 7 and ≥8, respectively (P = .001), and 95%, 84%, and 81% for low-, intermediate- and high-risk patients, respectively (P < .001). For 135 patients with a minimum of 5 years follow-up, the 5-year bRFS rate for low- and intermediate-risk patients was 99% and 93%, respectively. A parallel quality of life analysis in the same group of patients indicated a transient decline in the urinary and bowel domains within the first 3 months after SBRT, which typically returned to baseline status or better within 6 months and remained so beyond 5 years.[93] Sexual quality of life decline was predominantly observed within the first 9 months

Boike et al.[94] from the University of Texas–Southwestern have completed a dose escalation for prostate SBRT, aiming for a more aggressive regimen potentially suitable for patients with intermediate- or high-risk disease. At the highest dose level, 6.6% of patients treated (6 of 91) developed high-grade rectal toxicity, 5 of whom required colostomy.[95] Grade 3+ delayed rectal toxicity was correlated with volume of rectal wall receiving 50 Gy >3 cm^3 (P < .0001) and treatment of >35% circumference of rectal wall to 39 Gy (P = .003). Grade 2+ acute rectal toxicity was significantly correlated with treatment of >50% circumference of rectal wall to 24 Gy (P = .010). The anticipated incorporation of hydrogel spacers inserted between the rectum and prostate is expected to reduce bowel toxicity after prostate SBRT and allow the evaluation of dose escalation in high-risk patients in the future.[96]

Pancreas Cancer

The role of conventionally fractionated radiotherapy in combination with chemotherapy for locally advanced pancreas cancer remains unresolved. An effect on overall survival is not seen consistently, though there is likely at least a moderate benefit in terms of achieving treatment-free intervals in this challenging clinical scenario.[97,98] SBRT would be an appealing alternative if equivalent or better survival could be achieved with lower rates of toxicity related to the reduction of the volume of normal tissue exposed to a high dose of radiation.

SBRT regimens for pancreas cancer have included treatments given in 1 to 5 fractions. The relation of risk of toxicity to the volume of normal tissue receiving a high dose is illustrated by the Danish cooperative group study. Here, a dose of 45 Gy in 3 fractions to a volume that included generous margins around the GTV, such that the median volume receiving more than 30 Gy, was 136 cc.[99] The toxicity from this high-volume treatment was unacceptably high.

More recent studies have incorporated tighter planning margins around the primary tumor and achieved reduction in toxicity and improvement in survival. The Stanford experience included 55 patients treated with a single 25 Gy fraction to the GTV plus 3-mm margin, with gemcitabine (GEM) given for 1 cycle prior to and 4 to 6 cycles after SBRT.[100] A median survival of 13 months was observed. The San Bartolo Hospital group gave 30 Gy in 3 fractions to a similar target volume, again with GEM given before and after SBRT, and observed an 11-month median survival.[101] The Beth Israel Deaconess group used a dose of 24 to 36 Gy in 3 fractions, with the GEM given after SBRT for 6 cycles, and observed a 14-month median survival.[102] The incidence of grade 3 or higher SBRT-related toxicity was very low for each study. In the San Bartolo Hospital and Beth Israel Deaconess studies, the rates of grade 3 or higher nonhematologic toxicity were 0% and 14%, respectively.

The Stanford group analyzed potential dosimetric factors that predicted for a risk of duodenal toxicity after single-fraction SBRT for pancreatic cancer.[103] Among 73 patients evaluable, 6 patients experienced grade 2 toxicity and 6 experienced grade 3 or 4 toxicity. Numerous interrelated metrics proved to be able to distinguish groups of lower versus higher risk of toxicity. For example, the volume of duodenum receiving a dose of 15 Gy or higher (V15) was significant: for V15 ≥ 9.1 cc, the rate of toxicity was 52%, whereas for V15 < 9.1 cc, the rate was 11% ($P = .002$).

In a more recent phase 2 multi-institutional study, 49 patients with locally advanced pancreas cancer received up to 3 doses of gemcitabine (1,000 mg/m^2) followed by a 1-week break and then SBRT (33.0 gray [Gy] in 5 fractions).[104] After SBRT, patients continued to receive gemcitabine until disease progression or toxicity. The median overall survival was 13.9 months (95% confidence interval, 10.2 to 16.7 months). Freedom from local disease progression at 1 year was 78%. Rates of acute and late (primary endpoint) grade ≥2 gastritis, fistula, enteritis, or ulcer toxicities were 2% and 11%, respectively. QLQ-C30 global quality of life scores remained stable from baseline to after SBRT (67 at baseline, median change of 0 at both follow-ups; $P > .05$ for both). Patients reported a significant improvement in pancreatic pain ($P = .001$) 4 weeks after SBRT on the QLQ-PAN26 questionnaire. The median plasma carbohydrate antigen 19-9 (CA 19-9) level was reduced after SBRT (median time after SBRT, 4.2 weeks; 220 vs. 62 U/mL [$P < .001$]). Freedom from local disease progression at 1 year was 78%.

CONCLUSIONS

SBRT has emerged as a versatile strategy with a wide range of applications for many different types and stages of cancer. As with any form of radiation therapy, careful attention to matters of patient selection and technical quality assurance is essential for the effective and safe implementation of SBRT. Future advances will refine our understanding of the biologic mechanisms and optimal integration and sequencing of SBRT with other anticancer therapies.

CHAPTER 19

Stereotactic Radiation Therapy Techniques

Mark J. Amsbaugh and Shiao Y. Woo

AN INTRODUCTION TO STEREOTACTIC RADIOSURGERY

> The tools used by the surgeon must be adapted to the task, and where the human brain is concerned they cannot be too refined.
>
> —Lars Leksell (Stereotaxis and Radiosurgery)

The tools of radiosurgery have been constantly refined and adapted from their humble beginnings to some of the most precise and impressive in all of modern medicine. Remarkably, at the time of their conception, many techniques we take for granted in modern stereotactic radiosurgery treatment planning and delivery had not yet been developed. Parts of the planning process as integral as 3D imaging were not available to early adopters of this new treatment modality. Therefore, both the capabilities and applications of stereotactic radiosurgery have evolved over its history and continue to change as technology and our understanding of these tools improve.

A Definition for Stereotactic Radiosurgery

Stereotactic radiosurgery and its various derivations, such as fractionated stereotactic radiotherapy (fSRT), stereotactic body radiotherapy (SBRT), and stereotactic ablative body radiotherapy (SABR), are treatment techniques, which require precise localization of the patient and the target, combined with the ability to safely deliver large biologically effective radiation doses.[1] When Lars Leksell conceptualized radiosurgery, he saw a role for this new therapy to minimize the toxicity of traditional neurosurgical techniques of the day by causing “the non-invasive destruction of intracranial tissues that may be inaccessible or unsuitable for open surgery.”[2] This definition has evolved and a

modern consensus was formulated in 2007:

> *(a) Stereotactic radiosurgery is a distinct discipline that utilizes externally generated ionizing radiation in certain cases to inactivate or eradicate a defined target(s) in the head and spine without the need to make an incision. The target is defined by high-resolution stereotactic imaging. To assure quality of patient care the procedure involves a multidisciplinary team consisting of a neurosurgeon, radiation oncologist, and medical physicist.*
>
> *(b) Stereotactic radiosurgery typically is performed in a single session, using a rigidly attached guiding device, or other immobilization technology and/or a stereotactic image-guidance system but can be performed in a limited number of sessions, up to a maximum of five.*
>
> *(c) Technologies that are used to perform stereotactic radiosurgery include linear accelerators, particle beam accelerators, and multi source Cobalt 60 units. In order to enhance precision, various devices may incorporate robotics and real time imaging.*
>
> *—AANS Position Statement*[3]

Despite this comprehensive definition put forward, the role of stereotactic radiosurgery continues to evolve as the pace of clinical and technologic innovation increases. The first stereotactic radiosurgical procedure was the treatment of trigeminal neuralgia using an orthovoltage x-ray tube by Lars Leksell.[4] Many of the first patients to receive radiosurgery were similarly treated for nonmalignant purposes including trigeminal neuralgia, pituitary adenomas, and refractory pain (Fig. 19.1). In contrast, today, the majority of patients in the United States receiving intracranial radiosurgery are undergoing treatment for metastatic cancer to the brain (Fig. 19.1).[5]

The History and Development of the Stereotactic Method for Radiotherapy Delivery

In addition to increasing computational power and dose planning algorithms, technical advances have been made in two main areas: development and improvement of stereotactic localization, and transformation and specialization of known radiotherapy sources for radiosurgical applications. These two paths of development began very separately but have, over the last 50 years, been

integrated into complete systems with incredible precision, accuracy, and efficacy for treating human disease.

The first devices for stereotactic localization were developed by Victor Horsley and Robert H. Clarke for the purpose of precisely localizing electrodes in the primate brain by relying on external fixation referenced to a coordinate systems in the early 1900s.[6,7] Expanding on this work, Ernest A. Spiegel and Henry T. Wycis developed a stereotactic localization device for use in humans in the 1940s.[8] By 1947, this headframe was being used to guide surgery on the thalamus and other deep brain structures in an effort to limit the toxicity by traditional, nonstereotactic approaches. It was clear by the 1950s that Speiegel's stereotactic localization device and others like it were allowing neurosurgeons to reduce the operative morbidity and mortality of traditional open approaches.[9] However, neurosurgeons of the day soon realized that any invasive approach had significant morbidity and mortality associated with it, and some began to search for a way to accomplish the same disease control rates while improving toxicity.

Lars Leksell, the father of stereotactic radiosurgery, began experimenting with a 250-kVp x-ray tube attached to a stereotactic headframe for the treatment of function brain disorders in the early 1950s.[10] The first patient was treated by Leksell in 1951 to the gasserian ganglion for trigeminal neuralgia.[10,11] Although his work showed promise, the application of this new treatment technique was limited by the poor dosimetry of such a low-energy beam.[10] Despite this limitation, the radical concept of inactivating or obliterating a target but not removing it would prove extremely provocative to many neurosurgeons of the time.

Leksell's desire was to develop a system that could be used by general neurosurgeons in a hospital operating room, similar to other surgical tools.[2] Although cross-fired protons were tried for a short time, they were dismissed due to difficulty of use in the clinic.[12,13] It was Kurt Liden, head of the Department of Radiation Physics at Lund University, who recommended a 10- to 20-MV photon source for future radiosurgery applications after performing a preliminary analysis of the physical possibilities. Although linear accelerators were briefly considered, because of the limited precision that was achievable at the time, ^{60}Co sources were ultimately chosen for this new surgical tool.[11]

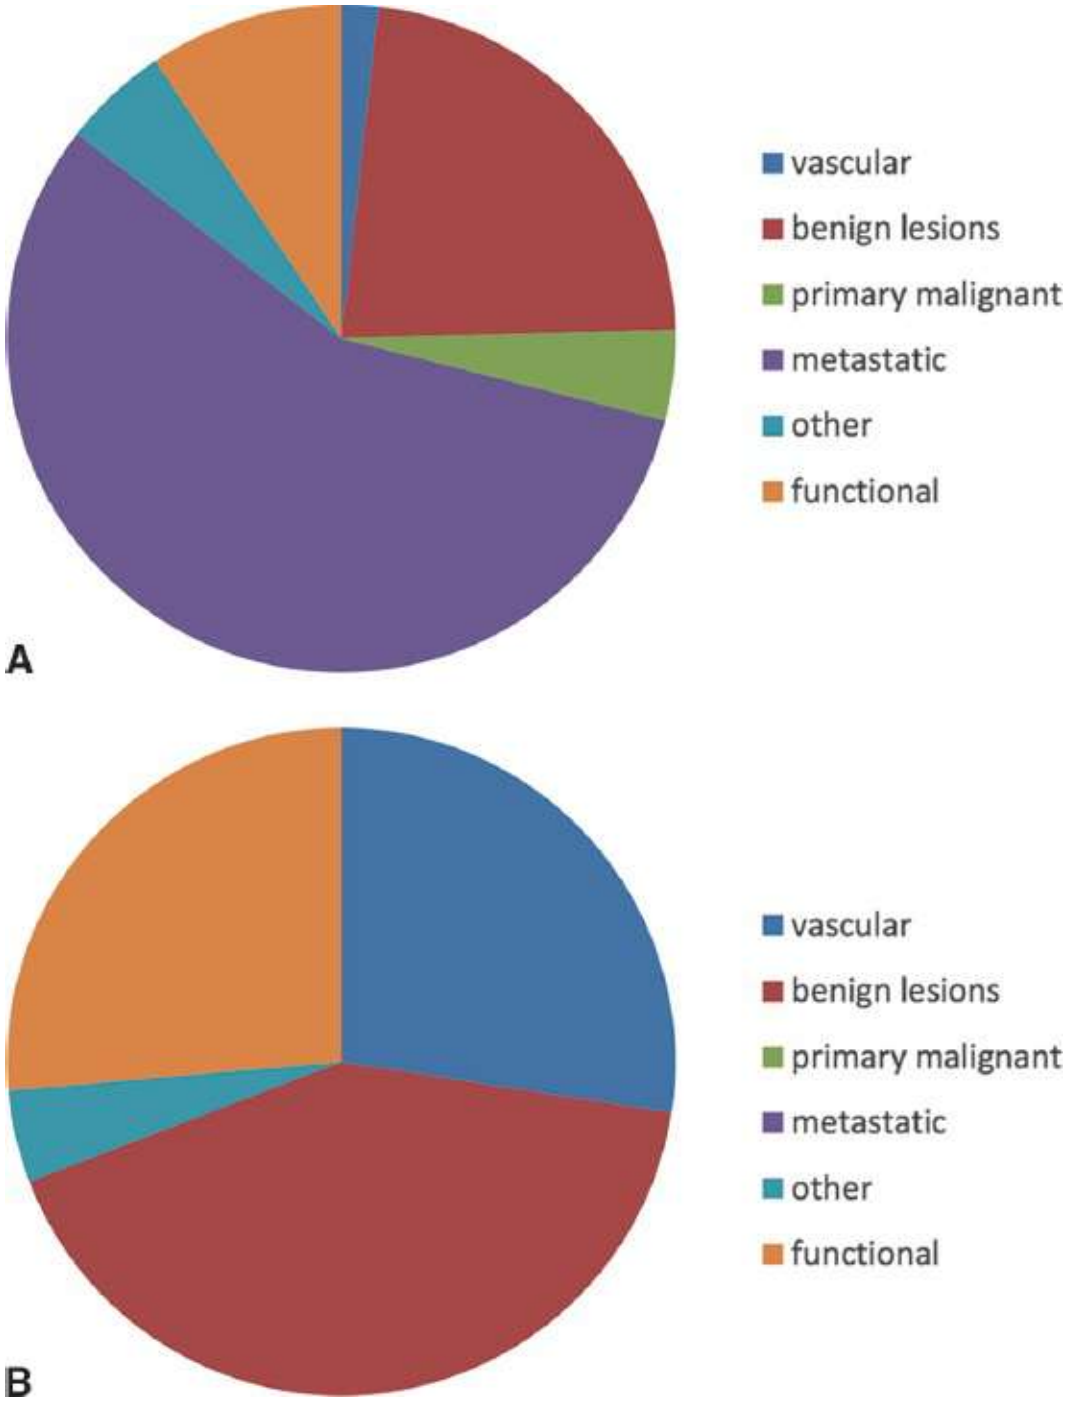

FIGURE 19.1. Indications for radiosurgery **(A)** in the RSSearch Registry from 2008 through 2013[5] and **(B)** at the Karolinska from 1968 through 1982.[2] (Reproduced from Leksell L. Stereotactic radiosurgery. *J Neurol Neurosurg Psychiatry*. 1983;46[9]:797–803, with permission from BMJ Publishing Group Ltd.)

Leksell's first "gamma unit" was built in 1967 and treated the first patient with ^{60}Co-based radiosurgery in November of 1967.[14] After improvements to the design were made, the second "gamma unit" was installed in 1974 at the

Karolinska Hospital in Stockholm.[2] From 1968 to 1982, 762 patients were treated with radiosurgery using the "gamma unit." By the early 1980s, radiosurgery was offering an outstanding alternative to traditional surgery for many patients with small tumors. Dade Lunsford and others completed the installation of the first American Gamma Knife for clinical use (the fifth in the world) at the University of Pittsburgh in 1984.[15] This new gamma knife model U held 201 ^{60}Co sources, weighed 22 tons, and had many targeting improvements over earlier models.[15] There was increasing international interest in this new technique; however, many investigators began to look for alternatives to a cobalt-based system, which could be heavy and have high cost resulting in limited availability.

By the 1980s, great advances had been made in the precision of linear accelerators. Additionally, with the clinical availability of computed tomography (CT) and later magnetic resonance (MR), increasing target localization was now much easier. This combination of technical advantages increasingly made linear accelerator systems more attractive for radiosurgery.[16] Groups in Italy and Argentina independently developed and implemented linear accelerator–based systems in the early 1980s.[17,18] Many other groups quickly developed their own systems, but there was a lack of standardization across the field. This was addressed by Ken Winston and Wendell Lutz who described a radiosurgical system using a commercially available stereotactic frame in 1988,[19,20] resulting in the increasing adoption of radiosurgery by confirming safety through a rigorous description of a proven quality assurance and testing process with commonly available technology. Shortly after publication of their techniques and others, linear accelerator–based radiosurgery began gaining acceptance as a reliable alternative to ^{60}Co-based techniques.[21]

TABLE 19.1 INDICATIONS FOR EXTRACRANIAL RADIOSURGERY FROM 2008 TO 2013 IN THE RSSEARCH REGISTRY

Indication	Number (%)
Lung/bronchus	1,973 (30.9)
Prostate	1,165 (18.3)
Pancreas	108 (1.7)
Liver	50 (0.8)
Metastatic site	1,722 (27)
Other	1,359 (21.3)

Davis JN, Medbery C 3rd, Sharma S, et al. The RSSearch Registry: patterns of care and

outcomes research on patients treated with stereotactic radiosurgery and stereotactic body radiotherapy. *Radiat Oncol* 2013;8:275.

With the gaining popularity of intracranial radiosurgery and the ability to deliver fractionated treatment with some linear accelerator–based systems, interest began moving toward delivering radiosurgery outside of the cranium. After spending a fellowship year with Lars Leksell in 1985, the neurosurgeon John Adler began to develop a method for delivering radiosurgery without a stereotactic frame at Stanford University.[16] The first patient was treated with the CyberKnife in 1994, as Adler's creation was named. This system used a 6-MV linear accelerator mounted on an industrial robot allowing a theoretically infinite number of beam angles for treatment of a target.[22] Other systems were being developed or modified to allow for extracranial radiosurgery at the same time. Hamilton and colleagues described the first spine radiosurgery system in 1995, the first truly extra cranial site treated with radiosurgery.[23]

Although the system described by Hamilton and colleagues was the first designed for extracranial treatments, it required the patient to be placed prone and a clamp to be placed on the spinous process.[16] There was increasing desire to develop a system that allowed for treatment of sites outside of the central nervous system. Ingmar Lax developed a mobilization frame that incorporated stereotactic fiducial markers, which allowed for targeting of thoracic and abdominal tumors using axial CT imaging. The device was subsequently commercially produced by Elekta.[11] This frame was quickly adopted as investigators such as Robert Timmerman began to use it for the treatment of early-stage lung tumors at Indiana University.[24] The indications for extracranial radiosurgery have continued to expand (Table 19.1).

MODERN TECHNOLOGIES FOR THE DELIVERY OF HIGHLY CONFORMAL RADIOTHERAPY

A multitude of modern systems exist, with new systems constantly under development, for the delivery of radiosurgery to both intracranial and extracranial targets. Although specifics may vary significantly, and each system has comparative advantages and disadvantages, the current systems can be grouped into similar types that have common guiding principles.

Gamma Knife

Common Principles for Gamma Knife Radiosurgery

The gamma knife's development has been closely tied with the evolution of the field of radiosurgery since its inception. In essence, any gamma knife facilitates the positioning of a target at the focal point of many ^{60}Co beams for the delivery of high doses of radiation. This focal point is known as an isocenter.

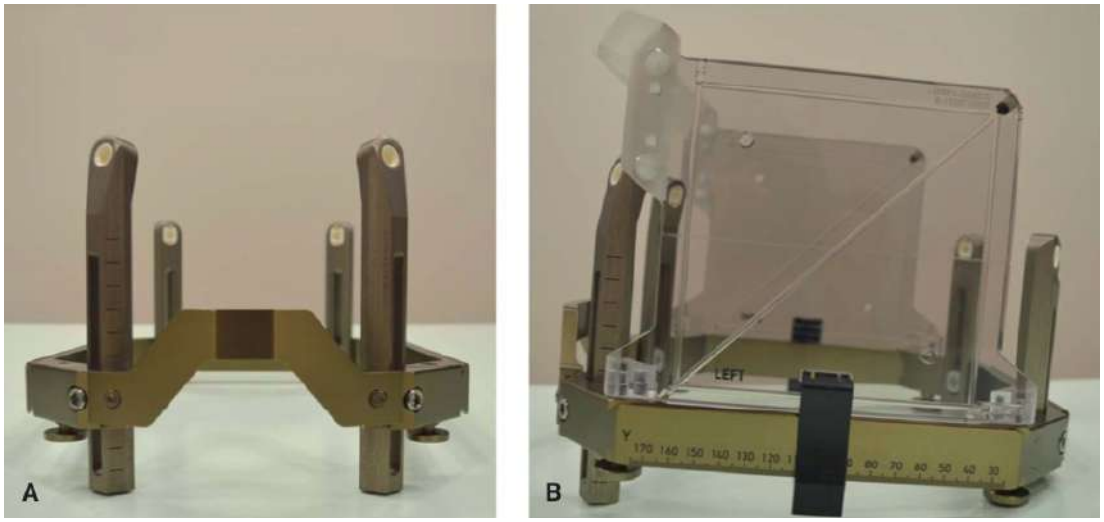

FIGURE 19.2. The Leksell headframe **(A)** and the Leksell headframe with an attached fiducial box for imaging **(B)**. (From Rojas-Villabona A, Miszkiel K, Kitchen N, et al. Evaluation of the stability of the stereotactic Leksell Frame G in Gamma Knife radiosurgery. *J Appl Clin Med Phys* 2016;17[3]:75–89.)

The primary components of gamma knife treatment are precision and conformality of radiation delivery. This requires an accurate radiation field, immobilization of the region of interest, and reproducible localization. The stereotactic headframe developed by Lars Leksell[25] (Fig. 19.2) when appropriately attached to the head can immobilize patients with a high level of certainty.[26,27] This immobilization combined with high-quality axial imaging allows for reproducible localization using a three-dimensional coordinate system.

Once the target is localized and the patient is immobilized, both accurate and precise radiation delivery is essential. This is accomplished using collimated ^{60}Co sources in all gamma knife models. Depending on the model, 192 to 201 ^{60}Co sources are positioned around the head with an isocenter that is aligned with the target and then shifted to the next target after that portion of the treatment is complete. The accuracy and reproducibility of the alignment of the machine isocenter with the target is essential for successful radiosurgery. The use of small collimators combined with multiple beam angles results in a high-dose fall of at the 50% isodose line. This allows the treatment of targets to high doses

while respecting the tolerance of the surrounding brain and critical structures. Much of the technical development and improvement of various gamma knife units has been related to the ability to better spare critical structures by creating more conformal isodose distributions surrounding the target, from selective blocking to now more sophisticated techniques.[28]

Gamma knife systems use ^{60}Co sources, which emit two photons, one with an energy of 1.17 MeV and one with an energy of 1.33 MeV. The resulting average energy of 1.25 MeV is relatively low when compared to modern day radiotherapy machines, and the dose rate is ultimately determined by the source activity, which degrades according to a half-life of 5.27 years.[29] The initial dose rate is around 3 Gy per minute[28] and decreases as the source continues to decay. This combined with the time required to move the patient into the correct position, change out collimators, and the use of a number of isocenters can result in long treatment times. Recent gamma knife systems have been able to minimize this by reducing the setup and patient positioning times despite using a similar source activity for radiotherapy.[28]

All gamma knife systems must conform to radiation safety principles and limit unnecessary dose both to other parts of the patient's body and to radiosurgery staff. Using radioactive sources is a potential disadvantage of a radiosurgical system because of the continuous radioactivity, but gamma knife systems seek to mitigate this disadvantage by appropriate collimation and shielding. Newer models also automate some functions, which in the past have required staff to enter the room where the unit is housed. This has further reduced the unnecessary exposure of radiosurgical staff.

Early Units

The first larger production gamma knife unit was branded as the Model U. There was also a similar model called the B model, which had a slightly different helmet shape and positioning. These units arranged 201 sources in a hemispheric array and later a circular configuration. In these early gamma knife units, a frame was affixed to the patient's head, a helmet with various collimators was placed on the frame, which was then attached to an adapter through a trunnion system or, later, an automatic positioning system, resulting in movement of the target to the focal point of the machine.

Gamma Knife Perfexion

The gamma knife Perfexion makes several key improvements over previous

gamma knife units. Launched in 2006, it contains an array of 192 ^{60}Co sources arranged in a configuration differing from the previous hemispheric arrangement behind a solid tungsten collimator with multiple holes drilled directly into it (Fig. 19.3). As a result, no helmet is needed to attach the headframe and patient to the gamma knife. The patient positioning system uses the headframe attached to the motorized treatment couch, which moves the target into the planned treatment position.

This system has improvements in speed and isocenter reproducibility over previous gamma knife units.[28,30,31] A new method for collimator selection has been developed as well. The 14 mm and 18 mm collimators that existed in the previous models have been replaced with a 16 mm collimator. Beam collimation can be set to intermediate values by alternating selection of different size collimators. This is accomplished by moving the radiation sources between one of five positions by servo-motors (home position, 4 mm collimator, 8 mm collimator, 16 mm collimator, off position) (Fig. 19.3).[29] By generating a single isocenter made of different beam diameters, a composite shot is formed, and each isocenter can be planned to an optimized shape increasing dose conformality.[28] The ability to block sectors that contain beams passing through these volumes at risk has improved treatment conformity around critical structures.[31]

FIGURE 19.3. Leksell Gamma Knife® Perfexion™ unit with tungsten collimator shown from the side **(A)** and from the treatment couch with the shielded doors closed **(B)**. The tungsten collimator is shown removed from device **(C)**. (Reprinted with permission from Elekta AB, Stockholm, Sweden.)

Procedure of a Gamma Knife Treatment

The first step is application of the Leksell headframe to the patient's head. Before attachment, previous imaging should be reviewed to determine the optimal location for the headframe. The headframe should be attached with the target closest to the center of the frame as possible using one of several described techniques.[16] This can be difficult for the case of multiple brain

metastases, especially with cerebellar metastases, but is made less critical by the improvements in newer models that allow for treatment in larger range of area. It is also essential to place the frame in a way that allows for the fiducial box to be firmly affixed.

After frame placement, stereotactic imaging must be performed in order to aid in target identification and delineation. The most common modern imaging modalities used with radiosurgery are CT, MR, and angiography. CT is often used with other methods because of the additional three-dimensional information when combined with angiography and because of the concern of image distortion with 1.5 and 3.0 T MR scanners. Although the reported variations are less than a millimeter in the center of the field, more peripheral lesions have been shown to have clinically significant distortion.[32] However, MR, especially with fine cut sequences, is the usually preferred imaging modality because of improved target delineation.

Following imaging, treatment planning occurs while the patient waits with the headframe intact. Many experienced physicians proceed with planning immediately, but target definition and identification of any at risk structures nearby are highly recommended. Often for difficult to define targets such as arteriovenous malformations, the input of a radiologist or other specialized personnel is needed. Once the target is defined, the planning process can occur.

After the final plan has been created, reviewed, and approved, the patient is brought into the treatment vault and docked to the machine. The therapists will then perform the quality assurance process to ensure collisions do not occur and that the plan will proceed with as few interruptions as possible. Following plan delivery, the stereotactic headframe is removed and the patient is discharged from the clinic.

Gantry-Mounted Linear Accelerator–Based Systems

Common Principles for Radiosurgery with Gantry-Mounted Systems

Linear accelerator systems use multiple beam entry points to sufficiently spread out the dose in a way that geometrically sums to a high dose with as rapid dose falloff as possible. With linear accelerator–based radiosurgery, 4 to 5 rotational arcs are chosen based on the target location. The gantry will rotate through an entire arc, the couch will rotate to a new plane, and another arc will be delivered by a gantry rotation. These arcs can be circular collimators, shaped conformal collimators with or without microleaf collimators, or even intensity-modulated fields.[11]

As frameless systems continue to develop, these systems now have precision approaching traditional frame-based approaches.[33,34] One of the major advantages of a gantry-based system is the availability of onboard imaging for localization and monitoring of both intrafraction and interfraction movement. Various systems exist using orthogonal kV radiographs, cone beam CT, electromagnetic transponders, infrared markers, or skin contours. Each of these imaging options are combined with immobilization techniques to ensure treatment accuracy. A very common immobilization approach is a custom thermoplastic mask with a stiffness intended for radiosurgery applications. Sometimes, a bite block to further immobilize the skull is used.

An advantage of omitting an invasive headframe is the ability to deliver fractionated radiosurgery treatments. Although there is significant controversy regarding fractionation of intracranial radiosurgery, there seems to be a clinical benefit for large lesions that may be difficult to control with doses that can be safely delivered in a single fraction such as brain metastases.[35] Fractionation combined with the open nature of linear accelerators also allows for the delivery of high biologic effective doses to extra cranial targets such as lung tumors.[24]

Development of Modern Linear Accelerator–Based Systems

One of the first linear accelerator systems developed was reported by Oswaldo Betti and colleagues in 1984.[18] A 10-MV photon linear accelerator was used with a secondary collimator system with circular inserts ranging from 6 to 25 mm. The patient was seated in a chair while attached to a rotating headframe. Working separately and at the same time Frederico Columbo and colleagues reported their technique using a modified 4-MV photon linear accelerator using multiple converging arcs.[17]

The first reports of linear accelerator–based radiosurgery were soon followed by an explosion of different solutions for delivering intracranial radiosurgery using a modified linear accelerator. Some degree of standardization was introduced when Winston and Lutz described a radiosurgical system using a 6-MV linear accelerator equipped with a special collimator. A Brown-Roberts-Wells (BRW) stereotactic headframe was affixed to the patient and photon beam arcs were used in four positions. Although this system was able to deliver very conformal treatment plans, the most significant advance was a system of extensive testing and quality assurance, which later became standard for many clinics.[19]

With the increasing accuracy in many systems, it soon became clear that

circular collimators originally designed for small regular shaped targets were severely limited when larger or grossly irregular targets were treated. To address this, Dennis Leavitt first described a method of dynamic field shaping for arc-based radiosurgery. A circular collimator was chosen for a target lesion and four independent vanes were used to trim the circular field to a trapezoidal shape, which was more conformal to the target projection in that arc increment. This resulted in an ability to reduce irradiation of normal brain tissue surrounding an irregular target.[36]

Soon after the development and implementation of dynamic field radiosurgery, a new company, founded by Stefan Vilsmeier named Brainlab, partnered with Varian to produce small micromultileaf collimator system that could be added on to existing linear accelerator–based systems or used with the purpose to build 6-MV linear accelerator called Novalis.[11,37] The addition of micromultileaf collimators to radiosurgery systems allowed for radiation to be delivered with static fields or dynamic arcs. These principles would later be expanded to allow for intensity modulation during radiosurgery treatment deliver, leading to even more conformal treatment plans for linear accelerator–based radiosurgery.[38]

Procedure of Linear Accelerator–Based Radiosurgery

The procedure of radiosurgery starts with imaging to identify a target. This usually occurs with MR imaging, angiography, or CT imaging. This imaging, regardless of modality, will need to be coregistered to images taken at the time of CT simulation for most systems.

After CT simulation and target localization imaging are coregistered, segmentation of targets and at risk structures occurs. The quality of coregistration should always be checked before beginning this process as it is a common source of error in radiosurgical planning. Once target structures and organs at risk are identified, the treatment planning processes begins. This process can take several hours.

Following the creation and approval of a treatment plan, a quality assurance process ensuring the “tightness” of the isocenter is usually performed. After that the patient returns to the clinic and is placed in the treatment position on the couch with the head immobilized. Once the patient is determined to be in the appropriate position, the treatment is delivered. Following treatment delivery, the patient is discharged from the clinic.

Robotic Linear Accelerator–Based Radiosurgery

After the explosion of radiosurgery centers in the early 1990s, there was a significant interest in developing a system, which preserved the ability to deliver very conformal high doses of radiation but allowed patients to avoid the placement of a rigid headframe. John Adler a neurosurgeon from Stanford developed the CyberKnife, a radiosurgical system that integrated treatment delivery and localization in an innovative way.[22,39] The radiation delivered by the CyberKnife is generated by a lightweight 6-MV linear accelerator, which is mounted on a robotic arm with 6 degrees of freedom. The robotic arm moves the linear accelerator in three-dimensional space to any of 100 nodes for delivery of radiation beam resulting in an extremely conformal dose distribution. At those nodes, the radiation beam is collimated in several ways. A traditional cone-based secondary collimator can be used (12 cones are included with sizes from 5 to 60 mm). Additionally, an iris-based collimator is included in the linear accelerator to reduce the treatment time attributed to cone switching. Newer models offer the option of a true multileaf collimator that can increase the ability to collimate the beam and higher dose rates to help decrease treatment times.

Traditional gantry-mounted linear accelerator–based radiosurgical systems and the gamma knife deliver radiation to a fixed isocenter usually in a spherical pattern. This is extremely effective for simple spherical targets, but different approaches must be used for more complex target shapes. The CyberKnife allows for isocentric and nonisocentric treatment modes to help improve the conformity and dose delivery to these targets (Fig. 19.4).[40]

The CyberKnife has two primary onboard imaging systems. Orthogonal kV x-ray tubes are used with a real-time, flat panel amorphous silicon digital x-ray imager.[41,42] This system establishes initial patient position and ensures tracking of intrafraction movement by comparing the images captured at the time of treatment with previously generated digitally reconstructed radiographs. When small movement of the target is detected, the robotic arm can adjust the position of the linear accelerator to a new position in order to reduce inaccuracy by compensating for the movement. The second imaging system uses infrared markers to track patient chest wall movement caused by respiration and is called Synchrony. This system starts by constructing a model predicting the location of the tumor in real time based on chest wall movement with respiration correlated to x-ray verification of target at eight different points in the respiratory cycle.[43]

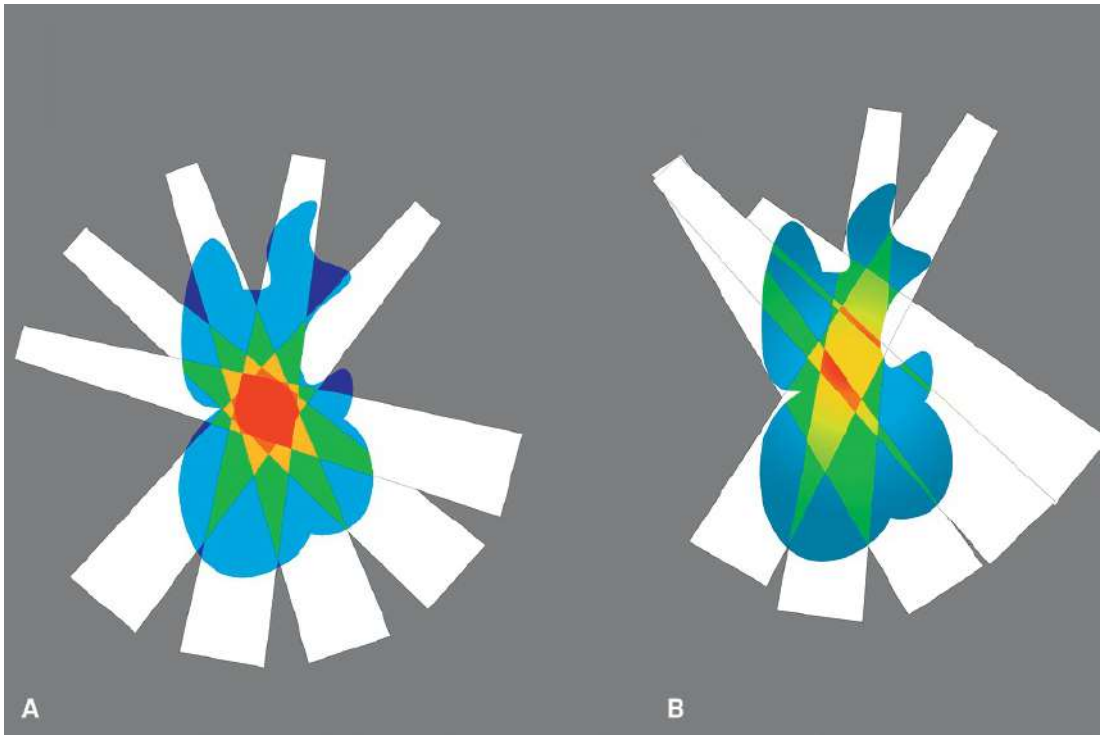

FIGURE 19.4. A: With standard radiosurgery-dispersed isocentric beams, all beams intersect a common region. Because multiple spherical volumes are needed to cover irregular lesions, the resulting dose distributions tend to be inhomogeneous. **B:** Nonisocentric beams from various directions. Beams do not all cross in a single point; therefore, dose distributions tend to be less inhomogeneous than in **A**.

TREATMENT PLANNING FOR RADIOSURGERY

Target Delineation and Dose Selection for Radiosurgery

Target Delineation for Intracranial Radiosurgery

Target delineation and the segmentation of organs at risk are an essential part of modern planning for traditional fractionated external beam radiotherapy. By identifying both targets and avoidance structures, beam angles can be selected, and dose tolerances can be evaluated for conformal radiotherapy plans. For intensity-modulated radiotherapy and other techniques, which utilize an inverse planning method, segmentation of these structures is required for planning.

The original radiosurgery techniques were developed by neurosurgeons in collaboration with medical physicists,[11] and it can be helpful to conceptualize the treatment planning process including target delineation for radiosurgery as a surgeon would think of any other minimally invasive surgical technique. The concepts of gross tumor volume (GTV), clinical target volume (CTV), and planning target volume are interpreted somewhat differently in radiosurgery than in traditional fractionated external beam radiotherapy. Typically, a tumor is

contoured as target, and for well-defined tumors, no expansion is made for subclinical tumor spread.[44]

Intracranial radiosurgery has always made the assumption that targets retained a fixed position in relation to skull anatomy. Systems using this principle have continued to be refined, so now, errors are typically on the order of 1 to 2 mm.[45] This is further improved to submillimeter accuracy with kV imaging and a robotic couch[33] or with a rigid headframe.[26] Therefore, intrafraction motion management has primarily been accomplished by either attaching a fixed rigid headframe to the skull or by imaging the bony structures of the head. Many physicians do not place a margin for motion on intracranial targets in an attempt to lower the risk of subsequent toxicity by making the target as small as possible and allowing dose falloff to account for slight variations in patient positioning. Still others have included a margin on some targets including brain metastases in an attempt to improve local control by ensuring all of the lesion is included in a high-dose region.[46]

Target Delineation for Extracranial Radiosurgery

The concept of delivering ablative doses to areas outside of the cranium is a relatively new one and its implementation is often more technically difficult. Unlike for intracranial radiosurgery, there is rarely an opportunity to use rigid fixation for extracranial body sites. As a result of high-dose gradients next to radiosensitive structures and large doses required to ablate target lesions, fractionation is often employed when treating patients with Stereotactic Ablative Body Radiotherapy (SABR).

Target delineation varies significantly by body site for SABR. Gross tumor is of course contoured on simulation scans. For most body sites, a CTV is not added. It is instead assumed that dose falloff from the prescription isodose line will cover the areas of microscopic disease spread.[47] Although margin is not typically added for subclinical tumor spread, motion must be accounted for in the process. This is accomplished by the addition of an internal target volume (ITV). These can be relatively small for sites such as prostate, but very large for other sites such as lower lobe of the lung. The effect of motion can be reduced or eliminated by using techniques such as gaiting; however, assuming these techniques are not used, most physicians will segment the tumor on multiple phases of a four-dimensional CT scan and combine contours to make an ITV.

Because the majority of body radiosurgery is fractionated, unlike single-fraction intracranial radiosurgery, most physicians will add an additional margin

on the GTV or ITV to account for setup uncertainty. This is especially true when time passes from simulation for body sites that do not allow for rigid fixation where targets or organs at risk may have moved or changed in size. Treatments can take course over three to five fractions, which may be delivered over 10 days or longer. Expansions therefore should be as small as possible to minimize the normal tissue exposed to ablative doses of radiation therapy while covering setup uncertainties that would lead to underdosing the target.[44] Ideally, these expansions would be based on measured uncertainties specific to the individual radiosurgery system, technique, and clinic where the radiosurgery is being delivered.

Prescribing Doses for Radiosurgery

There is a clear and convincing dose–response and dose–toxicity relationship for radiosurgery.[48,49] This fact underlines the importance of dose selection when planning radiosurgery. In early cases, radiosurgery was used for functional neurosurgery, and there was often no predefined lesion to target.[50–52] Furthermore, because of the limited number and type of systems designed to deliver radiosurgery, dose was commonly described as a single maximum dose because doses were prescribed to the isocenter with the dose distributions commonly known in the community.[4] As treatment systems continued to evolve and multiply in both number and complexity, it was apparent that describing dose to the isocenter was not sufficient for reporting radiosurgery procedures. Other dose statistics were soon adopted as it became clear that some, such as peripheral lesion dose, mattered as much or more than maximum dose.[53]

Traditionally, the peripheral isodose is normalized to value that corresponds with the steepest portion of the dose curve. This is typically around the 80% isodose line for one isocenter plans[4] but can range between 90% and 40%.[54] With multiple isocenter, lower prescription isodose lines are used, resulting in higher maximum doses. Because of the heterogeneity, conformality of dose is a significantly more important metric than it is for traditional fractionated radiotherapy.

It is also important to note that body sites often have large tissue inhomogeneity adjacent to the target. Heterogeneity corrections can therefore have significant effect on the calculated dose and generally should be used when treating body sites with body radiosurgery. Furthermore, when referencing doses used in clinical trials from the literature, great care must be taken to determined whether heterogeneity calculations were employed or not, for example, the

original Indiana University lung SBRT data.[24]

This is not to say that common dose prescriptions do not exist for radiosurgery; many of the doses used in the modern era are based on clinic outcome data painstakingly collected over the last several decades. These dosing guidelines however can be somewhat complicated and difficult to interpret. For example, the Radiation Therapy Oncology Group performed a phase I dose escalation trial to determine the maximum tolerated dose for single-fraction radiosurgery in patients with recurrent brain tumors.[55] This trial described peripheral dose for brain tumors by lesion size; targets 20 mm or less received 24 Gy as a maximal tolerated dose, targets between 21 and 30 mm received 18 Gy, and targets between 31 and 40 mm received 15 Gy. As discussed earlier, however, the prescription isodose line was left up to the discretion of the treating physician, so resulting maximum doses did differ even within set dose arms. Given that dose and control of brain metastases are tightly correlated with radiosurgery,[35] today, larger lesions are treated with fractionated radiosurgery at many institutions.[56]

Developing the Treatment Plan

Common Principles of Treatment Planning

The single isocenter technique was the first used for stereotactic radiosurgery. Originally used on the gamma knife platform, this technique involves the geometric summation of multiple beams in a small “focal point” at the isocenter of the machine. This can also be accomplished on gantry-mounted linear accelerator systems using multiple rotating arcs with circular collimators, producing a sphere of high dose with extremely quick dose falloff outside of the isocenter. The size of the sphere is determined by the diameter of the collimators used for the individual beams; larger collimator sizes result in larger high-dose spheres. These spherical dose distributions are often viewed in a cross-sectional axial plane and appear as circles. Therefore, the single isocenter technique is ideal for small spherical targets for which conformality and equal dose falloff are desired for planning. Treatment systems, which have multileaf collimators, are able to add additional conformality to single isocenter techniques by collimating the beam using either conformal collimation or intensity modulation.

For irregular targets, the single isocenter approach without multileaf collimators requires a much larger dose sphere than would normally be necessary to provide adequate target coverage. Therefore, these cases are usually planned out using different techniques. One such technique is known as sphere

packing.[57] Sphere packing provides more conformal dose coverage of an irregular target by using multiple single isocenter techniques to pack the target with spherical dose (Fig. 19.5). Typically, the largest diameter sphere that will fit within a target is chosen first. Additional smaller isocenters are added, and the dose is summed over the entire target to produce the final dose distribution. Gamma knife uses the Leksell GammaPlan software for planning radiosurgery. A sphere-packing plan can be created either by contouring the target and using an inverse dose planning algorithm, which can be manually adjusted at the end of the process, or by a completely manual process. The gamma knife Perfexion allows for several newer treatment planning modes including an automatic dynamic shaping ability to shape the dose in a way to protect structures contoured as avoidance structures. Also, beam shape can be changed as the system now allows for single isocenters composed of different collimated beam diameters including completely blocked.

Although linear accelerators are capable of a single isocenter dose distribution as described above, using multiple rotational arcs with cone-based collimators, several other isocentric techniques can be used for irregularly shaped or large targets using linear accelerators using either fixed or rotational fields. For simple targets, fixed noncoplanar fields with multileaf collimators can be used for a deliver that is analogous to 3D conformal radiotherapy. Each field is shaped to a conformal beam's eye view of the target, and with sufficient beams, plans can be adequate for treatment delivery. Conformality can be an issue with this technique[58]; however, using intensity-modulated radiotherapy methods can significantly increase the conformality. Rotational techniques include combining the dosimetric advantages of arc-based therapy with the increased conformity of multileaf collimator techniques by using dynamic conformal arcs and volume-modulated arc therapy, which additionally uses intensity-modulated radiotherapy. These can produce plans with similar conformality as traditional ^{60}Co-based multisource techniques but at the cost of low-dose spillage.[59,60]

Irregular targets can also be conformally treated using nonisocentric techniques. Used primarily by the CyberKnife robotic radiosurgery system but also by other linear accelerator based systems, this technique uses narrow beams from multiple noncoplanar directions to cover the target (Fig. 19.4). Because the beams do not cross in a single point, the dose does not become heterogenous, which can occur with other techniques such as sphere packing. This approach allows for a virtually limitless number of beam positions and can produce very

conformal homogenous dose distributions over irregular targets. This further allows for specific shaping of where the hot spot occurs.[61] Given the complexity and sheer number of iterations that exist using nonisocentric techniques, inverse planning is nearly always used. The CyberKnife uses the multiplan software for treatment planning. Although over 300 possible linear accelerator positions are possible, most CyberKnife plans choose between 110 nodes arranged in a hemisphere surrounding the target.[16] For isocentric plans, the linear accelerator is pointed toward the isocenter at each node position; however, for nonisocentric plans, there are 12 discrete pointing directions at each node called vectors. The treatment plan is formed from a combination of different nodes and vectors and by weighting each of the resulting beams accordingly. By designating the treatment site, the system selects a group of nodes, which is ideally used to treat that body site called paths.[16] Different collimator sizes can be used for each beam,[62] and in addition to traditional circular collimators, the CyberKnife has a variable collimator that can change the aperture size between 5 and 60 mm. After contouring, a sequential optimization algorithm is commonly employed, which performs a series of individual optimization steps in a defined order.[63]

Extracranial radiosurgery treatment planning is similar to that used for intracranial targets with several key differences. Although conformality is extremely important for both intracranial and extracranial radiosurgery, extracranial targets can often be positioned next to sensitive structures in one direction with considerable distance to sensitive structures in other directions. In this case, avoidance of dose-limiting structures is prioritized above strict uniform conformality. Geometry of the patient, couch, and treatment machine much more frequently come into play with the multiple beams or multiple dynamic arcs that are used for the majority of extracranial radiosurgery. Care must be taken to avoid choosing beam angles or positions, which are not deliverable in the actual patient without causing a collision. Finally, although intracranial targets are rarely deep enough to prompt the selection of high-energy beams, body sites sometimes lead themselves toward treatment with higher-energy beams for better dosimetry at depth. This should be avoided in radiosurgery given neutron contamination and increasing penumbra size with higher-energy photon beams.

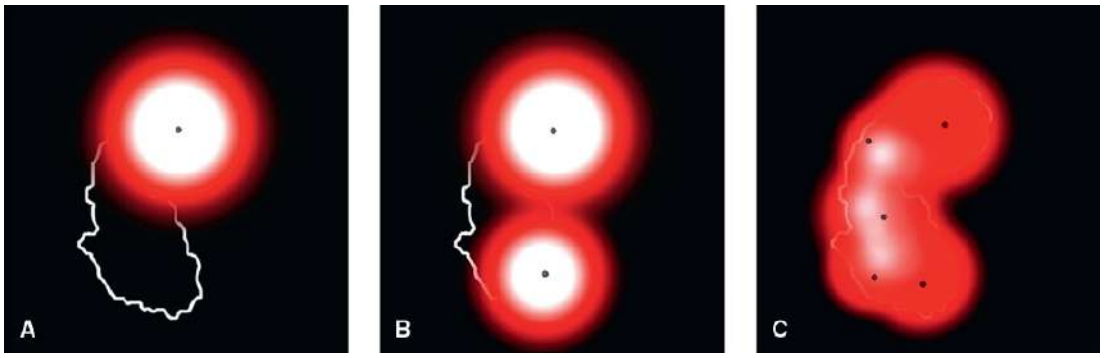

FIGURE 19.5. With an irregularly shaped target, the process of adding shots to construct a multi-isocenter treatment is shown. Panels **A** through **C** demonstrate the reduced heterogeneity and increasing coverage with the addition of more shots.

Dose calculation was originally performed for the gamma knife system using a standard beam profile combined with the inverse square law and the linear attenuation of the beam. By summing all beams at the focal point, a dose calculation can be completed.[57,64] A similar approach can be used for arc-based linear accelerator radiosurgery. Individual arcs can be estimated as individual beams, calculated, and then summed for the total contribution of a specific arc. The density of the medium for intracranial radiosurgery is usually assumed to be that of water, and heterogeneity corrections are not typically employed where the magnitude of error from not taking in to account the skull is generally <1%.[16] Even older dose calculation algorithms appear to be sufficient.[65] For extracranial targets, differences can be more pronounced, even >10% depending on what algorithm is used for dose calculation.[66] Older algorithms can overestimate dose in low-density tissues.[67] These differences can have clinically significant effects and can vary depending on beam energy, technique, and geometric position of beams. Today, the Monte Carlo algorithm is being increasingly used for dose calculation, especially for extracranial radiosurgery as computing power becomes more available in reducing the computational time needed for this extremely accurate dose calculation method.[68,69]

Radiosurgery Plan Evaluation

Once the plan has been created, it must be reviewed by the radiosurgery team before delivery. Confirmation of the dose prescription should be followed by a visual inspection of the isodose lines of the plan on the target imaging. Coverage of the target should be confirmed. The isodose lines should be visualized in the axial, coronal, and sagittal plane through all slices in and surrounding the target. Careful attention should be paid to the relationship of these isodose lines to the

target and other critical structures surrounding. Following visual inspection of the plan in the treatment planning system, a dose–volume histogram should be generated and reviewed. The dose–volume histogram is a way to convey three-dimensional information in two dimensions by plotting target and avoidance structure volume against dose received. Doses and volumes can be either relative to the total or absolute. Both these methods for plotting the dose–volume histogram can be useful in evaluating a radiosurgery plan. This can be used to determine target coverage, ensure any hot or cold spots are within plan tolerances, and determine volumetric doses to avoidance structures. It is important to note, however, that a limitation of the dose–volume histogram is that it does not provide spatial information for where these things occur in the plan, for that the actual isodose lines are needed. A sample radiosurgery plan is shown in Figure 19.6.

In addition to visually inspecting the isodose plot and the dose–volume histogram, a number of additional parameters are available to determine the quality of a given radiosurgical plan. It is important to remember, however, that in actual patient's plans, it will often not be able to meet all dose parameters and often compromises will have to be made. It is the role of an experience radiosurgical team to determine when and how these compromises are made in order to best serve the patient.

The most basic parameter is coverage. Coverage is a measure of what isodose line completely encompasses the target. Generally, it is desirable to have 90% of the prescription isodose line encompass the target whenever possible.[1] Another parameter of radiosurgical plans is the homogeneity index. This index measures how high the maximum dose is compared to the prescription for a given plan and is calculated by dividing the global maximum dose by the prescription isodose line. Ideally, the homogeneity index is <2.0 (or another way to think of this is that the prescription isodose line is normalized to 50% or higher).[1] The conformity index is used to measure the conformality of the dose distribution. This is calculated by dividing the prescription isodose volume by the target volume. Ideally, this will range from 1.0 to 2.0.[1] Other dose indices have been reported,[30,70–72] but are not commonly used outside of specific clinical scenarios.

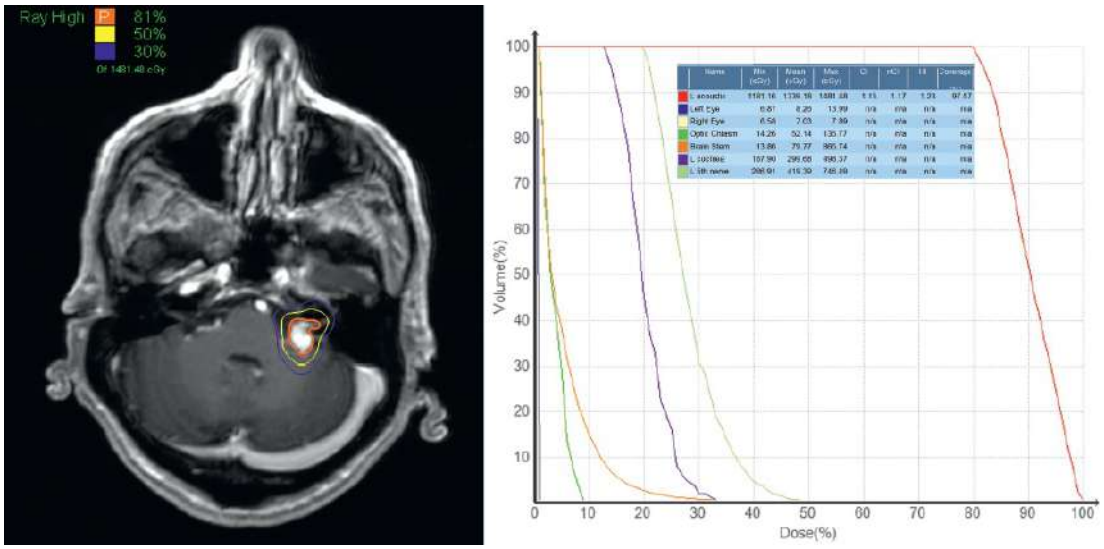

FIGURE 19.6. A radiosurgery plan for delivery using the CyberKnife robotic linear accelerator to an acoustic neuroma. Shown in *left panel* are the isodose curves for the 12-Gy prescription normalized to 81% and delivered using a nonisocentric technique. In *right panel*, a dose–volume histogram is shown.

LOCALIZATION AND MOTION MANAGEMENT TECHNOLOGIES

Localization of target lesions is of the upmost importance for stereotactic radiosurgery. Regardless of how precisely and conformally the radiation can be delivered, if it is delivered to the wrong location, the patient can suffer significant harm. In fact, mechanical accuracy of modern radiosurgical systems is submillimeter making imaging the largest source of radiosurgery error.[42,64,73] Devices for stereotactic localization of targets in the brain have been in use since the early 1900s for research purposes[7] and since the 1940s for therapeutic use.[8] Today, the tools for stereotactic localization continue to evolve, but the general goal remains the same as when the first devices were designed and implemented. Any system used for stereotactic localization in radiosurgery must use a reproducible system for knowing the precise location of objects in three-dimensional space from the time of lesion localization through the delivery of treatment using one of several methods.[74]

Stereotactic Localization with a Rigid Headframe

Stereotactic localization for the gamma knife has historically been based on the use of a rigid headframe, which was developed by Lars Leksell[25] (Fig. 19.2). The Leksell stereotactic headframe is attached to the skull with four pins, which provide relatively fixed position throughout the treatment planning and delivery

process, with submillimeter immobilization.[26,27] The frame has a three coordinate positioning system comprised of an *x*, *y*, and *z*-axis. The *y*-axis runs from posterior to anterior, the *x*-axis runs from side to side, and the *z*-axis runs superior to inferior. By convention, zero for each of the planes is placed right, posterior and superior. A frame cap is used for the Perfexion model to ensure no collisions will occur with the patient or the headframe once affixed. Other headframes exist for use with the linear accelerator–based radiosurgery. The BRW system was developed at the University of Utah in 1977.[75] This was later improved by Wells and Cosman as the Cosman-Roberts-Wells (CRW) frame by simplifying the design. Other frame systems exist for radiosurgery including some that allow for fractionated stereotactic radiosurgery such as the TALON system.[76]

Many systems that use rigid headframes for patient immobilization and stereotactic localization make use of an "N-localizer."[77] This is an essential piece of equipment for these systems, which allows for imaging to be performed with the headframe in place and fiducial markers to be present in that imaging. Each axial slice of imaging has three fiducials visualized in a line. The outer two fiducials do not appear to move in relation to one another as the axial slice changes, but the middle fiducial is always in a different place (with a different distance between the anterior and posterior fiducial) depending on the axial slice. Because the size and location of the N-localizer is known, the location of a target lesion can be measured precisely in three-dimension space and related to the coordinate system of the particular stereotactic frame (Fig. 19.2). The N-localizers also allow distortion to be measured and corrected before radiosurgical planning occurs.

Frameless Stereotactic Localization

There has always been a desire to combine the high ablative doses of stereotactic radiosurgery with the benefits of fractionation that are seen with traditional external beam radiotherapy.[78] One of the largest hurdles to making fSRT a reality in clinics was the development of stereotactic guidance that does not rely on the placement of an invasive headframe. This has now been accomplished for multiple systems including linear accelerator–based systems[22,34,39,79,80] as well as ^{60}Co systems.[81,82] In addition to the benefits of reduced patient discomfort, better workflow, and less procedural time, this development finally allowed for multiple radiosurgery treatment to be given to the same target lesion in a patient on different days without the need for repeat headframe placement.

Intracranial Sites

Image-guided radiosurgery without a stereotactic frame for intracranial targets relies on concept of a fixed position of intracranial lesions with the skull anatomy. Therefore, it is the bony anatomy of the skull that is of primary importance. Cone beam CT can be used to accurately position the patient, as can infrared light–emitting diods,[83,84] but the advent of dedicated radiosurgical systems such as the CyberKnife and Novalis allows for a quicker method.[85,86] Computed tomography scans with fine cuts taken at simulation time are reconstructed into a digitally reconstructed radiograph. This digitally reconstructed radiograph is then used as a reference for orthogonal kV x-rays taken before treatment. By comparing the orthogonal kV x-rays, which are taken from a fixed position in the room, a stereotactic coordinate system is formed.[58,87] The patient can therefore be shifted to the desired position, and the treatment can proceed. This method has been demonstrated to be extremely accurate, with average setup errors <1 mm.[34,42,58,87] When a frame is not used for stereotactic localization, a thermoplastic mask or other immobilization device is typically used to limit patient movement after correct positioning and during the delivery of radiotherapy. This technique has shown to be extremely effective for limiting motion during treatment.[88]

Extracranial Sites

For radiosurgery outside of the skull, there are several approaches that can provide stereotactic guidance information. The traditional technique is to implant radiopaque fiducial markers. These markers, which are present at the time of simulation, can be used to compare orthogonal kV images at the time of treatment with the original planning images much in the same way that kV imaging is compared to digitally reconstructed radiographs of the skull for the creating of stereotactic space.[41,89] For extracranial sites near the spine, some radiosurgery systems have specific techniques that can be used to improve accuracy and allow for the delivery of radiosurgery without the implantation of fiducial markers.[90] The CyberKnife Xsight system uses deformable modeling of bony spinal anatomy with a hierarchical mesh tracking system to create the stereotactic information needed to localize a target lesion in three-dimensional space.[41,91]

Imaging Techniques During the Delivery of Radiosurgery

Motion does not cease after initial stereotactic localization. Both patient motion

and internal motion (from the heart beat, respiration, and bowel peristalsis) contribute to intrafraction motion. Although patient motion can be limited with immobilization, internal motion can significantly contribute to the target motion, especially respiration.[92] Targeting is further complicated as this motion is often irregular[93] and is overestimated using imaging defined at respiratory extremes.[94] With increasing adoption of frameless techniques and proportion of extracranial sites making up delivered radiosurgery cases every year, there has been increasing interest in extending the concept of image-guided stereotactic localization to intrafraction imaging and motion management. Several of the methods previously discussed can be used to establish stereotactic guidance for radiosurgery and monitor movement during the delivery of radiosurgery.

Techniques using orthogonal kV imaging are perhaps the most commonly used way to monitor patient motion during treatment. This approach used technology previously discussed for stereotactic localization but will continue intermittent assessment during the delivery of radiosurgery. The frequency of assessment can be changed by the therapists during treatment delivery, so less frequent imaging can be used if minor corrections are being made or the frequency can be increased if more motion is observed. In addition to orthogonal kV imaging, some systems make use of an infrared bite block for intracranial stereotactic radiosurgery.[79,80,83,95] These systems can track motion using an optical camera focused on several optical tracking spheres fixed to a bite block inserted into the mouth, much in a similar way to optical guidance for invasive otolaryngology and neurosurgery procedures. Benefits to these systems include more frequent position determination and no need to use ionizing radiation to determine position.

The ideal system for intrafraction motion management provides near instantaneous location information constantly without the need to use ionizing radiation. In an effort to meet these goals, the Calypso system has been used to monitor motion during radiosurgical treatment.[96,97] Calypso uses an electromagnetic transponder fiducial implanted in or near the target that is monitored by an electromagnetic detector. The detector’s position is monitored by optical cameras tracking infrared fiducials placed on the detector to discern its position in the room. This allows for the benefits of near real-time continuous tracking without using ionizing radiation but requires an invasive procedure for implantation. Furthermore, although various sites are undergoing active investigation, electromagnetic transponder–guided radiosurgery is not available for many of the common body sites treated with radiosurgery.

Perhaps the greatest contribution to intrafraction motion during radiosurgery procedures when appropriate immobilization devices are used is respiration. One of the first systems clinically used for this purpose relied on kV imaging connected to the linear accelerator that would image up to 30 times a second and shut the beam off when fiducial markers placed in the tumor were outside a predefined volume.[98] Therefore, the beam is delivered in a "gated" manner, only during specific phases of the respiratory cycle. Similar systems can be combined with infrared monitoring of the chest wall as a surrogate marker for respiratory tumor movement.[42,99] These systems use infrared light–emitting diodes or passive markers. Some systems are able to take this tumor tracking data and update a dynamic model to continuously deliver a radiosurgery treatment. The CyberKnife has the ability to track respiratory movement using the Synchrony system. This system creates a model from kV imaging taken at the time of treatment combined with chest wall movement seen using infrared makers and then uses external infrared imaging to allow the linear accelerator to target different positions in the lung automatically within a specific tolerance. The model is continuously updated with information from the kV imaging, which can verify the internal position.

THE FUTURE OF RADIOSURGERY IS BRIGHT

Advances in radiosurgery over the last 60 years have been astounding. Many conditions that were unable to be treated using standard surgical techniques because of size or location are now common in radiosurgery programs across the world. Designers continue to innovate, constantly improving machine tolerances and quality of delivered treatment. These new and improved technologic systems allow for investigators to continue pushing the limits for what is able to be accomplished.

Advances will continue to be made in localization and tracking of the target. It is likely that methods not involving ionizing radiation for localization will continue to grow in popularity, especially those that can provide multiple verifications per second and help form predictive models for motion. By decreasing treatment times as a result of more "beam-on" time, and potentially limiting toxicity by reducing margin for uncertainty, the patient's experience will continue to improve.

As systemic therapies continue to improve survival for a patient with metastatic disease and radiosurgical systems become easier to use by traditional

radiation oncology clinics, it is likely that the number of patients receiving radiosurgery will increase. Hopefully as the numbers of patients receiving radiosurgery increase, it will only serve to spark innovation and development. The future of radiosurgery is bright. Many of the advances that are now essential to the field could not even be conceptualized by Leksell when he first described the technique. Hopefully, similar gains will be made within the next 60 years, thereby increasing our ability as physicians to care for our patients.

CHAPTER 20

Intraoperative Radiotherapy

Timothy J. Kinsella

INTRODUCTION

Intraoperative radiotherapy (IORT) involves the delivery of radiation during surgery using various types of radiation sources/technologies, including intraoperative electron radiation therapy (IOERT), high dose rate brachytherapy (HDR-IORT), and electronic brachytherapy/low-kilovoltage x-rays (KV-IORT). The major advantage of IORT is the potential for delivery of higher effective radiation doses to a tumor or, more ideally, to the bed of a grossly resected tumor, while limiting the radiation dose to adjacent, dose-limiting, normal tissues or organs. This normal tissue sparing is accomplished by the dosimetric features of these different IORT technologies and by surgical approaches and/or customized lead shielding to exclude/limit normal tissues during IORT. Although IORT may be used alone following resection of certain primary or recurrent cancers, it is more often (and ideally) combined with external beam radiotherapy (EBRT), typically administered preoperatively with or without concurrent chemotherapy. Indeed, based on clinical IORT data generated over the last three decades, one can conclude that the acute and late normal tissue toxicities and local tumor control rates are quite acceptable in patients with a variety of solid cancers treated with curative intent combining EBRT (± chemotherapy) with gross total resection and IORT. Effective use of IORT requires a multidisciplinary approach, including close cooperation with surgical oncology, medical physics, and surgical nursing personnel. However, despite encouraging clinical data and more widespread use of IORT throughout the world over the last decade, level 1 evidence based on large phase III trials is lacking, with the possible exception of its use in the treatment of breast cancer.

This chapter begins with an overview of the radiobiology of IORT, based largely on comprehensive preclinical experiments using canine models that established normal tissue and organ-specific guidelines, principally for IOERT ±

EBRT. Using American foxhounds and beagles as models, acute and late normal tissue responses to IOERT ± EBRT were categorized using experimental designs that mimicked thoracic and abdominal cavity surgeries where IOERT was anticipated to be used clinically. Next, the physics and technical applications of IORT are described with details regarding the specific uses of IOERT, HDR-IORT, and KV-IORT. Finally, a summary of the available clinical IORT data is presented for some tumor sites where IORT has shown efficacy as a component of multimodality treatment. A discussion of potential future clinical uses of IORT is also presented in this final section.

RADIOBIOLOGY PRINCIPLES AND EXPERIMENTAL STUDIES OF IORT

Radiobiologic Modeling for the Determination of Equivalent Single-Fraction IORT Doses

The principal advantage of IORT is the ability to maximally exclude adjacent normal tissues by surgical mobilization and/or the use of customized lead wafer shielding in the cases of IOERT and HDR-IORT. However, the clinical application of IORT to treat minimal gross (R_2 resection) or suspected microscopic residual disease (R_1 resection) in a resected tumor bed necessitates inclusion of partial volumes of adjacent normal tissues or organs based on tumor location, tumor size, and extent of infiltration of adjacent normal tissues, including regional lymph node basins. Based on typical *in vitro* clonogenic studies and *in vivo* small animal studies, where large single doses of 5 to 20 Gy have often been used, it is evident that IORT doses of 15 to 25 Gy could provide a theoretical disadvantage with respect to IORT-related tumor cell kill (or local control) versus normal tissue toxicities.

Typically, the radiation dose–response curve for acute-reacting normal tissues, such as gastrointestinal epithelium and bone marrow, is very steep, and a small change in the radiation dose near the tissue tolerance level can result in a significant risk of toxicity. In contrast, the radiation dose–response curve for late-reacting normal tissues, such as heart muscle, peripheral nerve, large arterial blood vessels, and bone, is less steep and correlates directly with the volume of tissue included within the irradiated field. Extrapolating from the linear-quadratic model using clonogenic survival data, one can extrapolate the shape of the radiation survival curve for tumor and normal tissues using the α/β ratio. A late-reacting normal tissue has a low α/β ratio (usually <5 Gy), whereas acute-

reacting normal tissues, as well as most solid tumors, have α/β ratio of >7 Gy. Using these α/β ratios, one can estimate the single-fraction IORT dose (compared to conventional fractionated EBRT) to control tumor while limiting specific normal tissue toxicities. For example, for a squamous cell carcinoma with minimal residual disease following surgery, an EBRT dose of 60 Gy using 2-Gy fractions (D_{2Gy} = 60) is required, and the α/β ratio for squamous cell carcinoma cells is 10 Gy. We can use the linear-quadratic (LQ) formula to calculate the equivalent D_{IORT} to be 22.3 Gy, which is supported by multiple single-institution IORT clinical studies that included patients with recurrent or locally advanced head and neck cancers.[1] Similarly, such an equivalent IORT dose can be calculated for a late-reacting normal tissue, such as peripheral nerve, using D_{2Gy} = 70 and α/β ratio = 2 Gy. The calculated D_{IORT} is 16 Gy, which is again supported by experimental canine and human clinical data.[2]

Although the D_{IORT} calculation has some clinical utility, as these two examples illustrate, many other clinical variables are not factored into the calculation, such as prior or recent EBRT ± chemotherapy, the inclusion of multiple types and volumes of acute- and late-reacting normal tissues within the IORT field, and other patient-specific comorbidities, for example, cardiovascular disease, diabetes, and connective tissue disease. Indeed, in patients treated with preoperative or postoperative EBRT ± chemotherapy, the IORT boost dose calculation should include these additional treatment effects, particularly with regard to both acute- and late-reacting normal tissues. There are experimental canine data, specifically from the beagle dog model, to assist in the $D_{IORT\ boost}$ calculation, which is often in the 10- to 15-Gy range. In addition, from a radiobiologic perspective, it is recognized that tumor cell hypoxia is the major factor determining tumor radioresponse, as other biologic factors, such as repair, reoxygenation, and repopulation, are not operative with single-fraction treatment.

Another radiobiologic effect that is not included within the D_{IORT} calculation for normal tissue toxicity is the risk of a radiation-induced cancer. Radiation-induced cancers are typically a late effect, often occurring a decade or more after radiation therapy. For an IORT-induced cancer, the cancer should arise within the IORT field and should have a different histology than the original primary. In the canine studies of normal tissue tolerance to varying IORT doses, long-term follow-up (up to 5 years) demonstrated IORT-induced sarcomas of bone and soft tissue, evident at autopsy, in up to 20% to 25% of animals receiving >25 Gy.[3] No

IORT-induced cancers have been reported in humans, although many IORT-treated patients have very aggressive primary or recurrent cancers and often die from progressive metastatic disease within 1 to 2 years after IORT without autopsy evaluation of the IORT volume. Because IORT is being used for some pediatric oncology cases, it will be especially important to follow these patients closely for the potential risk of an IORT-induced cancer as a late effect.

Experimental Studies of IOERT with or without EBRT to Establish Normal Tissue Tolerance Guidelines

Comprehensive studies of acute and late normal tissue responses to IOERT ± EBRT were performed using two canine models. The American foxhound model was principally used for IOERT studies at the National Cancer Institute (NCI), whereas a beagle dog model was used for IOERT ± EBRT studies at Colorado State University (CSU). Both canine species are large enough to allow surgical procedures in the thoracic and abdominal cavities that mimic surgeries for human cancers for which IORT may be applied. The goal of these studies was to establish dose guidelines of IOERT alone (NCI) and IOERT ± EBRT (CSU) to reduce acute and late normal tissue toxicities in selected intact and surgically manipulated tissues that mimicked clinical situations in which IOERT might be used. After IOERT ± EBRT, dogs were closely followed clinically and by various sequential diagnostic studies for up to 5 years. All dogs were subjected to complete autopsy with detailed histologic analyses of irradiated tissues.

A description of the NCI IOERT studies is presented in Table 20.1. A more comprehensive overview of these studies is summarized in two reviews.[4,5] A total of 13 sites or target tissues were studied using escalating IOERT doses and a fixed IOERT volume based on the target site. In total, these NCI studies involved 227 dogs, with 196 receiving IOERT and 31 receiving sham IOERT (0 Gy). At CSU, adult beagles were randomized to receive IOERT alone (5 × 8-cm field; 6 MeV; dose range 17.5 to 55 Gy), EBRT alone (5 × 10-cm field; 6-MV photons; dose range 60, 70, and 80 Gy in 30 fractions of 2, 2.33, and 2.67 Gy, respectively), or initial EBRT (5 × 10-cm field; 6-MV photons; dose 50 Gy in 25 fractions of 2 Gy) followed by IOERT (5 × 8-cm field; 6 MeV; dose range 10 to 45.5 Gy). A summary of the clinical and pathologic data regarding normal tissue tolerance from these collective NCI and CSU canine studies is presented in Table 20.2 and briefly described below.

Vascular Tissues

Because the vasculature determines, in large measure, the viability and functionality of all normal tissue systems, an understanding of the tolerance thresholds of IORT on blood vessels is critically important. Intact large vessels (aorta, vena cava) appear to tolerate large single IOERT doses without significant clinical sequelae, based on serial follow-up radiographic studies for up to 5 years.[6] At autopsy, no pathologic changes were found following a 20-Gy dose, and only mild to moderate subintimal fibrosis was found after 30- and 40-Gy doses, respectively. However, the combination of 50-Gy EBRT and >20-Gy IOERT resulted in an IOERT dose–related luminal narrowing with thrombus formation and moderate mural fibrosis pathologically, with up to 2 years of follow-up.[7] To evaluate the IORT tolerance of intraoperatively mandated vascular repairs and anastomoses, a transection and end-to-end reanastomosis of the infrarenal abdominal aorta was performed, followed by IOERT doses of 20 to 45 Gy.[6] Pathologically, moderate medial wall fibrosis was found at doses >30 Gy. Although anastomotic integrity was maintained at all doses, follow-up arteriograms showed anastomotic occlusion at doses >30 Gy within 6 to 12 months. However, occlusion was sufficiently slow to allow formation of arterial collaterals around the occlusion, preventing any clinical or pathologic signs of ischemia distal to the anastomosis. At 45 Gy, development of a late arteriovenous fistula at the anastomotic site in one dog suggested the potential for IORT dose–limiting, clinically relevant, toxicity.

The tolerance of vascular grafts to IORT was investigated in beagles, for which a segmental resection of the infrarenal aorta was performed with reconstruction using a polyfluorotetraethylene graft.[8] IOERT up to 30 Gy was immediately delivered following the prosthetic grafting, and half of the dogs were randomized to receive postoperative EBRT to 36 Gy in 10 fractions over 4 weeks. Arterial graft occlusion occurred acutely in both treatment groups but was correctable by thrombectomy. During clinical follow-up, most dogs receiving ≥30-Gy IOERT ± EBRT developed late graft occlusion (within 12 months) but again showed evidence of progressive collateralization by arteriography, preventing distal ischemia–related complications.

TABLE 20.1 NATIONAL CANCER INSTITUTE INTRAOPERATIVE ELECTRON RADIATION THERAPY STUDIES OF NORMAL TISSUE TOLERANCE

	IOERT Field; Electron	Dose Range

Sites	Surgical Procedure	Energy (MeV)	(Gy): Number Treated
Retroperitoneal soft tissues, aorta, vena cava, left ureter, lower pole left kidney	LAP; exposure to unilateral retroperitoneum	4 × 15 cm; 11	0:4; 20:4; 30:4; 40:4; 50:4
Aortic anastomosis and small bowel suture line	LAP; transection and reanastomosis of aorta; Roux-en-y with blind loop	4 × 15 cm; 11	0:1; 20:1; 30:1; 45:1
Aortic anastomosis	LAP; transection and reanastomosis	4 × 15 cm; 11	0:1; 20:4; 30:3; 45:3
Small bowel suture line; retroperitoneal soft tissues	LAP; Roux-en-y with small bowel blind loop	4 × 15 cm; 11	0:1; 20:5; 30:5; 45:5
Intact extrahepatic bile duct	LAP; mobilization of biliary tree	5-cm circle; 11	0:1; 20:3; 30:2; 45:2
Extrahepatic bile duct with jejunal anastomosis	LAP; biliary–jejunal anastomosis	5-cm circle; 11	0:2; 20:3; 30:2; 45:2

Spinal cord	LAP; exposure of retroperitoneum over lumbar spine	4 × 15 cm; 11	0:3; 20:7; 25:7; 30:8
Right upper lobe lung and mediastinum including right atrium	Right thoracotomy	5-cm circle; 9	0:3; 20:7; 30:7; 40:7
Left bronchial stump, pulmonary artery and vein, left atrium	Left pneumonectomy	5-cm circle; 13	0:3; 20:4; 30:4; 40:4
Esophagus	Right thoracotomy and mobilization of the esophagus	6-cm circle; 9	0:1; 20:7; 30:5

IOERT, intraoperative electron radiation therapy; LAP, laparotomy.

TABLE 20.2 TOLERANCE DOSES TO INTRAOPERATIVE RADIOTHERAPY IN CANINE MODELS

	Maximum Tolerated IORT Dose	Maximum Follow-up Period

System	Organ	(Gy)	(Months)	Comments
Cardiothoracic	Aorta	30	60	Threshold for fibrosis, patency to 60 Gy
	Vena cava	30	60	Threshold for fibrosis, patency to 60 Gy
	Arterial anastomosis	30	36	Threshold for stenotic occlusion
	Arterial graft	30	24	Threshold for occlusion
	Heart	30	60	Threshold for fibrosis, no clinical effects to 40 Gy
	Tracheobronchus	30	60	Threshold for fibrosis, no clinical effects to 40 Gy
	Bronchial suture line	40	60	Intact to 40 Gy, bronchovascular fistulae at 20 Gy
	Lung	20	60	Threshold for fibrotic pneumonitis, no clinical effects to 40 Gy
	Esophagus	20	60	Ulceration and stricture with full-thickness exposure, no sequelae to 40-Gy partial thickness
Gastrointestinal	Duodenum	18	6	Threshold for ulceration, obstruction, or perforation
	Small intestine diverted loop	45	60	Defunctionalized bowel loop, no clinical effects, fibrosis at ≥20 Gy
Hepatobiliary–pancreatic	Bile duct	20	60	Threshold for fibrosis and stenosis
	Bile duct anastomosis	<20	12	Dehiscence at all doses ≥20 Gy
Urinary	Kidney	15	60	Threshold for tubular loss
	Ureter	30	60	Threshold for fibrosis and stenosis
	Bladder	30	60	Threshold for ureterovesical junction stenosis, normal contractility to 40 Gy
Nervous	Peripheral nerve	15	60	Threshold for motor neuropathy

IORT, intraoperative radiotherapy.

Gastrointestinal Tissues

Because of its rapidly proliferating mucosa and rich blood supply, the small and large intestines are among the most radiosensitive normal tissues. As such, the

intestine needs to be surgically mobilized and excluded from IORT portals. NCI investigators assessed the IORT tolerance of small intestinal suture lines where a jejunal blind loop was created surgically and intestinal continuity maintained by distal jejunojejunostomy.[9] The IOERT field encompassed the suture line and the full thickness of the intestinal wall, and doses of 20 to 45 Gy were delivered. No immediate histologic changes were seen, and no clinical evidence of suture line dehiscence was found with 5 years of follow-up. However, internal interloop fistulae occurred following 45 Gy. Thus, whereas acute IOERT tolerance of a defunctionalized bowel loop was acceptable to 45 Gy, chronic complications suggest a maximum of 30 Gy. However, functional small and large bowel showed clinical and pathologic manifestations of ulceration, stricture, and perforations following doses as low as 15 to 20 Gy.

Hepatobiliary Tissues

Bile duct tolerance to IOERT was studied at the NCI using a 5-cm IORT portal to the subhepatic space, which encompassed the extrahepatic bile duct.[10] When using a dose range of 20 to 45 Gy, no acute complications were noted, but progressive and IOERT dose–related chemical evidence of partial biliary obstruction was seen within 2 to 8 months of follow-up. Frank biliary cirrhosis developed in one-half of dogs receiving 30 Gy or more that were followed for a minimum of 12 months. The tolerance of biliary–enteric anastomoses was also studied using a similar IOERT dose range. After laparotomy and formation of a jejunal biliary loop, the bile duct was transected and anastomosed to the jejunal loop, followed by immediate IOERT to the anastomotic site. All animals developed acute complications within several weeks, with either anastomotic disruption or subacute anastomotic obstruction, resulting in cholangitis or bile duct necrosis. Thus, although the intact bile duct may tolerate doses of up to 20 Gy, a bile duct anastomosis cannot be included within an IORT field.

Urinary Tract Tissues

In the IOERT study involving the intact unilateral retroperitoneum,[6] a 12-cm segment of ureter, as well as the inferior pole of one kidney, was irradiated to IOERT doses as high as 50 Gy. Dogs were followed clinically with renal function testing and radiographic pyelography. The kidney showed dose-related fibrosis and hyalinization. Acute obstructive nephropathy secondary to ureteral obstruction was evident with 50 Gy, whereas subacute obstructive nephropathy was evident at 2 to 3 months of follow-up in the 40-Gy dogs and at 6 to 12

months following 30 Gy. In the 20-Gy–treated dogs, no clinical or pathologic changes in the irradiated ureter were evident. A CSU study showed that shorter (≤4 cm) segments of the ureter would tolerate doses of 30 Gy.[11] Typically, the ureter can be surgically mobilized and excluded from the IORT field, but segments at high risk of residual microscopic disease may be included, and prophylactic ureteral stenting may reduce the risk of narrowing/obstruction as a subacute complication.

Bladder tolerance to IOERT was studied using the foxhound model at the NCI.[12,13] Following laparotomy and cystotomy, a 5-cm circular IORT portal, including the trigone and both ureteral orifices, was treated with doses of 20 to 40 Gy. Dogs were then followed for up to 5 years with clinical evaluation, kidney function tests, intravenous pyelography, and cystometry. Although no acute complications were noted, some dogs who received 25 Gy or greater developed fibrotic strictures at the ureterovesical junction within 2 years, which became more frequent at 5 years in the ≥30-Gy–treated dogs. Whereas pathologic changes of fibrosis and microvascular changes in the bladder wall were evident at 30 Gy or greater, follow-up cystometric studies showed little difference in post-IOERT bladder contractility from baseline at all IOERT doses.

Cardiothoracic Tissues

In the NCI studies of IOERT to the canine mediastinum, atrial appendages of the heart received doses up to 40 Gy.[14,15] Dense fibrosis of the myocardium was found pathologically following IOERT doses of 30 Gy or greater, with early (within 1 month) medial hyaline degeneration followed by radiation vasculopathy and infarction within 12 months. However, because of the limited irradiated volume of cardiac muscle, no clinical signs of cardiac failure were evident with up to 5 years of follow-up.

Segments of the trachea and mainstem bronchi also received IOERT of 20 to 40 Gy in the NCI mediastinal IOERT studies.[14,15] Pathologic changes of fibrosis in the tracheobronchial wall were evident at doses of 30 Gy or greater, with infrequent development of chondronecrosis of the tracheal rings at doses of <40 Gy; however, most animals showed no clinical respiratory symptoms. In addition, the canine pneumonectomy study found normal healing of the bronchial stump following IOERT to 20 to 40 Gy, and no clinical sequelae were observed through 5 years of follow-up.[16] However, when limited amounts of lung tissue received IOERT, acute confluent pneumonitis progressing to interstitial fibrosis and pulmonary arteriolar sclerosis developed at all doses

within 12 months.[14,16]

IOERT tolerance of the esophagus was also evaluated in the NCI mediastinal studies, with both full-thickness and partial-thickness (<50% of circumference) treatment.[14,15] Clinical examinations, barium swallows, and esophagoscopies were performed for up to 2 years following doses to 30 Gy for full-thickness irradiation and to 40 Gy for partial-thickness irradiation. With full-thickness esophageal IOERT, all animals receiving 20 Gy or more showed acute clinical toxicity with signs of dysphagia and weight loss. Acute, but transient, inflammatory changes to esophageal mucosa were found at 20 Gy, but progressive severe inflammatory changes leading to ulceration and stricture by 2 to 3 months were found following 30 Gy. With partial esophageal wall IOERT, no severe clinical or radiographic sequelae occurred at doses up to 40 Gy, with dose-related fibrosis but no mucosal ulcers or strictures.

Nervous Tissue

Whereas peripheral nerves were traditionally considered to be relatively radioresistant, clinical IORT trials at the NCI reported a significantly increased risk of lumbosacral neuropathy following IOERT + EBRT in patients with localized but technically resectable retroperitoneal sarcomas.[17] In this clinical trial, patients were randomized to receive postoperative EBRT alone (initial 40 Gy, followed by a 14- to 16-Gy boost) or IOERT (20 Gy using multiple abutting fields based on tumor bed size/location) followed by postoperative EBRT (36 Gy). Subacute (within 1 to 3 months) and late (>6 months) clinical motor and/or sensory neuropathies to the lower trunk and/or lower extremity were found in 9 of 15 patients randomized to IOERT + EBRT and in 1 of 20 patients randomized to postoperative EBRT alone ($P < .01$).[18]

To further establish the tolerance of peripheral nerve trunks to IORT, a series of studies was conducted at the NCI and CSU.[2,19] In the initial NCI study using foxhounds, the lumbosacral plexus was surgically exposed and IOERT doses of 20 to 75 Gy were delivered. Hind limb motor changes developed in 90% of treated dogs within 12 months, ranging in severity from slight motor strength weakness to complete motor paralysis, with an approximately inverse relationship between IOERT dose and the time to onset and severity of neurologic signs. However, no threshold dose for neuropathy was found, even with the use of nerve conduction times as a measure. Pathologically, loss of large nerve fibers and perineural fibrosis with radiation vasculopathy in perineural connective tissue were seen. A follow-up NCI trial attempted to establish a

threshold dose for IORT-induced neuropathy in the lumbosacral plexus. No animal receiving IOERT doses of up to 15 Gy developed clinical neuropathy by exam and nerve conduction testing for more than 3 years following IOERT, whereas all animals receiving 20 Gy developed hind leg paresis with lower nerve conduction testing within 12 months. With up to 5 years of follow-up, dogs treated with IORT doses of up to 15 Gy showed continued lack of neurotoxicity.[18]

Studies assessing lumbar nerve injury following IOERT alone, EBRT alone, and combined IOERT plus EBRT were performed at CSU using a beagle dog model.[19] Similar neurologic and nerve conduction testing as used in the NCI studies was performed for up to 2 years of follow-up. Although no neurologic complications were found using EBRT alone, dose- and time-related neuropathy was seen in IOERT alone and in IOERT + EBRT–treated dogs with an IOERT dose threshold of 15 Gy. Radiation-induced changes to Schwann cells and nerve vasculature were found, similar to the NCI findings, and ultrastructural studies suggested microvascular damage causing regional hypoxia and subsequent nerve fiber loss. Thus, peripheral nerve appears to be a dose-limiting tissue for IOERT, in contrast to the relative radioresistance of peripheral nerves to EBRT.

IORT-Induced Malignancies

As mentioned previously, radiation-induced malignancies are infrequent following conventionally fractionated EBRT and are most commonly seen several to many years after the successful treatment of childhood cancers. Although IORT-induced cancers have not been reported in humans, the canine data support a potential risk in humans. Again, an IORT-induced cancer should fulfill several criteria, including occurring within the IORT field, developing after an appropriate latency period (e.g., a few years in canines), and being histologically confirmed and of a histologic type that develops infrequently in the particular dog species.

In studies of IOERT-related toxicity to the bone at CSU, a 21% incidence of osteosarcoma was noted, with at least 4 years of follow-up following IOERT alone to >25 Gy with or without EBRT.[20] In dogs treated with EBRT alone for spontaneous soft tissue tumors, a 3% incidence of osteosarcoma within the EBRT volume was seen. IOERT-induced tumors were also seen in the NCI canine trials.[3,21] Among 59 animals followed for 2 or more years, 12 tumors were pathologically confirmed at complete necropsy. Three tumors did not meet the criteria for being radiation induced, including 2 benign fibrous tumors and a

mammary carcinoma. The 9 IORT-related tumors included a bladder rhabdomyosarcoma, a soft tissue malignant fibrous histiocytoma, and 7 sarcomas of the bone or cartilage. In dogs receiving >25-Gy IOERT, the overall incidence of radiation-induced neoplasms was 25%, consistent with the CSU data.

In summary, the validity of the canine tissue tolerance models as described in this section and Table 20.2 as representative of the human tissue response to IORT is supported by clinical IORT data from human trials. Although the tolerance to IORT-induced acute and late toxicities can vary considerably between tissues, doses up to 20 Gy are generally tolerated. The general principle providing the rationale for IORT should always be practiced, that is, maximize the radiation dose to the tumor or, ideally, the bed of a grossly resected tumor while minimizing dose exposure to adjacent normal tissues.

PHYSICS AND TECHNICAL ASPECTS OF IORT

Definition of Techniques

IORT involves the use of a single fraction of radiation therapy delivered while the patient is under anesthesia. Three different technologies can be used to deliver IORT, including electrons (IOERT), high dose brachytherapy with iridium 192 (^{192}Ir; HDR-IORT), and low-kV x-rays (KV-IORT). IOERT is delivered by a linear accelerator electron beam in the 6- to 15-MeV dose range. Although the use of a conventional linear accelerator in the radiation oncology department was the standard for IOERT delivery in the 1970s and early 1980s, the subsequent development of mobile linear accelerators that are transported to the operating room (OR), or the installation of a dedicated accelerator in an OR, improved the efficiency and use of IOERT, no longer requiring the patient to be transported under anesthesia. At present, there are three commercial mobile linear accelerators designed for IOERT, including the Mobetron (4- to 12-MeV electrons; IntraOp Medical, Sunnyvale, CA), the Novac 7 (4- to 10-MeV electrons; NRT SpA, Rome, Italy), and the LIAC (4- to 10-MeV electrons; Sordina SpA, Saonara, Italy). HDR-IORT uses a high dose rate afterloader with ^{192}Ir that decays via β or electron capture, and the daughter isotopes are short lived, emitting γ-rays of various energies. The β decay is absorbed by the source capsule, and the average photon energy emitted is 370 keV with a 74-day half-life. HDR-IORT is feasible only after a near gross total resection, as the maximum depth of coverage is typically 0.5 cm deep from the surface of the

resected tumor bed. Several ^{192}Ir HDR remote afterloaders are commercially marketed by Nucletron (Veenendaal, Netherlands) and by Varian Medical Systems (Crowley, United Kingdom). A shielded OR is required for HDR-IORT. Over the last decade, mobile IORT devices using low-kV x-rays (KV-IORT) have been developed. Low-kV x-rays (20 to 50 kV) have the advantage of a steep dose gradient, not requiring specially shielded ORs, but have a major disadvantage in that the target (tumor bed) should ideally be spherical in shape with a maximum tissue treatment radius of 1 to 2 cm. Two commercial low–KV-IORT devices are available, including the Zeiss Intrabeam (Zeiss Surgical, Oberkochen, Germany) and the Xoft S700 Axxent System (Zoft, Medford, MA).

IOERT: Physics and Technical Applications

With the development of mobile linear accelerators as described earlier, no permanent OR shielding is required, unlike a fixed OR-based linear accelerator, because the maximum electron beam energy is 12 MeV or less and these mobile linear accelerators are designed without bending magnets. In addition, neutron contamination is not a problem for OR personnel or patients. The Mobetron has a fixed beam stopper, whereas the Novac 7 and LIAC accelerators are equipped with mobile beam stoppers. The 90% depth dose in water ranges from 1.1 cm for 4-MeV electrons to 3.5 cm for 12-MeV electrons. A variety of applicator shapes (e.g., circular, rectangular) and sizes are available from the manufacturers. However, to commission a machine for IORT, a minimum set of dosimetry measurements is required for each applicator and each electron energy including percentage depth dose, beam profiles in two orthogonal planes, isodose curves in two orthogonal planes, and applicator ratios. The applicator ratios are compared to a reference applicator for which the accelerator output is calibrated.

Quality assurance (QA) procedures for mobile IOERT linear accelerators are outlined in detail in the reports of the American Association of Physicists in Medicine (AAPM) Radiation Therapy Task Groups 48 and 72.[22,23] Because any malfunction of these mobile accelerators could result in a patient not receiving the scheduled IOERT treatment or in having a patient’s surgery delayed, a high level of QA requires calibration of all electron energies early on the day of surgery, in addition to a rigorous process of periodic checks similar to the QA for a standard linear accelerator. Unique factors to the mobile IOERT linear accelerators are the lack of adjustable collimators and bending magnets. QA checks are necessary of the alignment of the soft docking system as used in the Mobetron and of a hard docking system for the two other mobile accelerators.

Although *in vivo* dosimetry using TLDs or silicon diodes is not feasible for placement in a sterile surgical resection bed during IOERT, offline procedures such as the use of radiochromic films or real-time methods such as the use of metal oxide semiconductor field-effect transistors are being applied to breast cancer.[24,25] IORT may be applied to other tumor sites.

Mobile IOERT accelerators, however, have limited mobility, requiring the patient and OR table to be moved to the accelerator in the OR and sometimes requiring a change in the patient's position. The use of special OR tables with fine movement capabilities superiorly, inferiorly, laterally, and pitch and roll positioning, as well as Trendelenburg and reverse Trendelenburg movements, makes IOERT patient positioning and docking much easier and faster. The soft docking process required for the Mobetron is facilitated by a set of lasers in the accelerator head. The hard docking system used with the Novac 7 and LIAC accelerators involves a two-part applicator. Once the appropriate field size and applicator shape are determined, the superior part of the applicator is fixed to the linear accelerator head and then physically mated with the inferior part, which is in contact with the target (tumor bed). Once aligned, a rigid interlocking of the two parts is made prior to IOERT delivery. Typically, the process of soft or hard docking requires <10 to 15 minutes.

However, prior to docking, a detailed determination of the IOERT treatment volume is required, involving close collaboration between the surgical oncologist and the radiation oncologist. Typically, surgical sutures or clips are placed by the surgeon to better visualize the tumor bed, and at least a 1-cm margin is added. Next, the size, shape, and degree of bevel for the suitable applicator are determined, as well as determining whether one or more IOERT fields are necessary to cover the tumor bed. Although the IOERT applicators can function as a normal tissue retractor, additional surgical packing is often required to further exclude certain normal tissues, for example, bowel. In the clinical situation in which sensitive normal tissues cannot be physically displaced from the IOERT field, secondary shielding using sterilized lead sheets can be placed with appropriate thickness to attenuate 90% or more of the dose. Lead shielding is also essential to prevent any dose overlap, if multiple IOERT fields are required to cover the tumor bed with at least 1-cm margins. Finally, to reduce the accumulation of serous fluid in the tumor bed during IOERT (which would attenuate the dose), placement of suction adjacent to the IOERT applicator is recommended.

HDR-IORT: Physics and Technical Applications

HDR-IORT involves the use of an ^{192}Ir HDR afterloader to deliver a large single fraction of brachytherapy to a grossly resected tumor bed with necessary retraction and physical shielding of adjacent normal tissues, similar to the guidelines for IOERT as described. Because of the high activity of ^{192}Ir afforded by computer-controlled remoter afterloading, HDR-IORT treatment times of 30 to 60 minutes can be accomplished, based on the target (tumor bed) size. The desired dose distribution is generated by superimposing a large number of single-source radiation distributions at different locations and different dwell times. Two AAPM publications from Task Group 43 summarize in detail the dose calculations for ^{192}Ir in air and water.[26,27] A recent review of HDR-IORT is also recommended.[28]

Construction of an HDR-IORT–dedicated facility requires a shielded OR equipped with door interlocks, room radiation monitors, and additional adjacent space for the OR team (surgeon, radiation oncologist, nurses) to remain sterile during HDR-IORT, should any emergency reentry be needed. Anesthesia and surgical monitoring via video cameras must also be available in this adjacent OR space. Ideally, construction of a HDR-IORT facility in the hospital OR complex allows for most efficient use of OR personnel and equipment. The QA program for HDR-IORT follows guidelines outlined by AAPM task groups.[29] Typically, a series of QA checks is performed 24 hours prior to each HDR-IORT procedure and involves determination of source positioning and source strength, verification of proper functioning of room radiation monitors, and checking of equipment for use in the event of emergency source retraction.

For HDR-IORT, the applicator must be rigid enough to secure the afterloader catheters in a fixed and reproducible position while also conforming to the tumor bed contour. The applicator design must provide adequate thickness to maintain a 0.5-cm distance between the source plane and the treatment surface.[28] Prior to HDR-IORT delivery, the radiation oncologist must confirm that the applicator is in direct contact with the tissue surface throughout the entire target area, as a separation of only 0.5 cm can reduce dose delivery by up to 30%. Treatment planning for HDR-IORT is greatly facilitated by creating a plan atlas of clinically anticipated tumor volumes.[30] Plans incorporating optimized dwell times enhance efficiency and reduce risks of error. However, a plan atlas cannot anticipate the need to spare an adjacent normal tissue in certain patients, but customized lead wafers of 0.3 cm thickness can be used at the applicator–tissue interface.

KV-IORT: Physics and Technical Applications

The Zeiss Intrabeam has a miniature x-ray source at the end of a 10-cm-long, 3-mm-wide probe, where electrons are accelerated at a gold target in the probe tip, resulting in a nearly isotronic distribution of low-kV x-rays in the 30- to 50-kV range. Because these x-rays are of such low energy, no special shielding is required in a standard OR, which normally has adequate shielding for the intraoperative use of diagnostic radiology equipment. The Intrabeam is small, lightweight, and designed with a floor stand and can be easily accommodated in a standard OR. A dose rate of 2 Gy/min at 1 cm in water from the center of the target is possible with a 50-kV setting. However, the dose decreases in tissue as the inverse cube of the distance. It has an extended lifetime of over 10 years.

The Xoft S700 Axxent System is an electronic brachytherapy apparatus with a Wolfram target that operates at x-ray energies of 20 to 50 kV. As with the Intrabeam, the 50-kV energy is most commonly used. A miniature x-ray tube is located within a flexible, disposable sheath, which permits water cooling of the x-ray tube. The Xoft source is more adaptable in the OR compared to the Intrabeam source and has a higher depth–dose rate of 0.6 Gy/min at 3 cm in water. In addition, because of heavier filtration, the dose falls off less slowly in tissue than the Intrabeam source. However, the typical Xoft source lifetime is only 2.5 hours, and it has been used clinically for a much shorter time period, compared to more than a decade for Intrabeam.

A recent comprehensive review of these two KV-IORT systems is available.[31] Both units are potentially suited for IORT treatment of breast cancer, either as a boost or as definitive treatment, although most of the current clinical data involve the use of the Intrabeam. Both manufacturers are expanding the clinical use of their respective low–kV-IORT systems to superficial skin tumors and vaginal applications for endometrial cancers. The main applicators for the Intrabeam are spherical, with diameters ranging from 1.5 to 5 cm, and are composed of solid biodegradable material with a 2.8-mm central cavity where the source is placed. A homogeneous surface dose is generated with the addition of an aluminum flattening filter for applicators >3.5 cm in diameter. The Xoft system uses inflatable balloons, similar to MammoSite (Hologic, Bedford, MA) for breast irradiation, with spherical or ellipsoidal balloon shapes. The balloon sizes vary from 3 to 6 cm for spherical balloons and 5 × 7 cm and 6 × 7 cm for ellipsoidal balloons. Both systems have a number of safety features to alert the user to the emission of x-rays and allow monitoring of the output dose. QA procedures involving pretreatment checks, monthly checks, and yearly checks

are reviewed.[32]

Comparison of IORT Technical Applications

A comprehensive comparison of the technical applications of the three IORT approaches is published.[32] The potential advantages of IOERT compared to HDR-IORT include better dose homogeneity, faster treatment times, requirement for less OR shielding, and the ability to treat gross residual disease based on depth-dose characteristics. Potential disadvantages include surface dose of <90% with 6- to 9-MeV electrons (compensated with the use of bolus) and difficulty in treating anatomic areas such as the low pelvis, abdominal side walls, retropubic areas, subdiaphragmatic areas, thoracic side walls, and skull base. Low–kV-IORT requires a small target (tumor) volume, where the depth in tissue at risk is 0.5 to 1.0 cm or less from the surface of the applicator.

CLINICAL RESULTS OF IORT WITH OR WITHOUT EBRT: AN OVERVIEW

A comprehensive review of the clinical experience of IORT ± EBRT (± chemotherapy) is beyond the scope of this chapter, and the reader is referred to a published textbook of IORT in which the clinical data by tumor site are presented in detail.[33] In addition, some of the IORT clinical data are discussed in this textbook in chapters devoted to specific cancers and tumor sites. The general conclusions from these mostly nonrandomized studies in selected cancers will be discussed here, in addition to a brief overview of the limited clinical data from a few prospective, randomized trials. A general conclusion is that IORT, as a component of a multidisciplinary approach for typically locally advanced primary and recurrent cancers, is feasible and appears to improve local control, as well as overall survival in some cancers, with acceptable acute and late toxicities based on the normal tissue tolerance guidelines previously presented (Table 20.2). The clinical use of IORT in a larger number of institutions across the world over the last 10 to 15 years has been aided by improvements in IORT technology as described in the last section. The more widespread use and the promising nonrandomized, generally single-institution, clinical data, as well as data from a few prospective, randomized trials, will, it is hoped, facilitate the design and implementation of prospective, randomized trials in specific tumor sites in the next decade.

Colorectal Cancer

The clinical experience with the use of IOERT and HDR-IORT as part of a multidisciplinary approach to locally advanced colorectal cancer was recently summarized.[34,35] More than 900 patients have been treated with IOERT and 59 patients with HDR-IORT, usually following preoperative combined modality treatment with EBRT (45 to 54 Gy) and concomitant infusional 5-fluorouracil (5-FU). These data are derived from multiple, nonrandomized, single-institution studies in the United States and Europe. No randomized, prospective studies are available or ongoing. Most patients had clinical T4 or tethered T3 lesions in these IORT studies, making direct comparison to large prospective, randomized trials, such as the German Rectal Cancer Study, difficult, because, certainly, the clinical T4 lesions would not be included in the phase III trial. The 3- to 5-year local control rates for IORT-treated patients were, respectively, 85% to 90% for R_0 patients and 50% to 75% for R_1/R_2 resections, with a 5% to 10% risk of grade 2 or 3 normal tissue toxicities to peripheral nerve or ureter. The 3- to 5-year disease-free survivals were in the 50% to 60% range for R_0 patients but dropped to 25% to 35% for R_2 patients. Thus, these data suggest some benefit to IORT in these clinically tethered T3 and T4 patients, but systemic relapse remains a major problem.

A similar general conclusion can be reached for the use of IORT in patients with recurrent colorectal cancer, based on a recent summary of the literature.[36] For this patient group, many will have already received EBRT ± 5-FU–based chemotherapy at the time of presentation, making the use of further EBRT (± chemotherapy) somewhat limited. The largest experience with IOERT in this patient group is from the Mayo Clinic. In a group of 140 patients with prior EBRT, the subsequent use of 30-Gy preoperative EBRT followed by IOERT (10 to 20 Gy based on extent of resection) resulted in a 3-year local control rate of 70% and overall survival rate of 30%. Again, no randomized, prospective data are available to more accurately assess the role of IORT in this patient group, but the single-institution data are encouraging.

Gastric Cancer

The clinical data regarding the integration of IORT as a component of combined modality treatment of resectable gastric cancer were recently summarized in detail.[37,38] Three randomized prospective trials of IOERT have been reported. In 1988, M. Abe from Kyoto University, Japan, reported a trial in which more than 200 patients with stage I to IV stomach cancer (using the Japanese Surgical

Staging System) were randomized to surgery alone versus surgery + IOERT (28 to 35 Gy).[39] A nonstatistically significant trend toward improved 5-year overall survival was seen in stage II to IV patients. However, two smaller phase 3 studies did not show a survival benefit. At the NCI, 40 stage III and IV (American Joint Committee on Cancer) patients were randomized to surgery + IORT (20 Gy) versus surgery + EBRT (50 Gy), whereas at the University of Freiburg (Freiburg, Germany), 115 patients were randomized to surgery versus surgery + IORT (28 Gy).[40,41] Data from other single-institution, nonrandomized studies suggest a benefit to IORT or IORT + EBRT compared to surgery alone.[37] The present standard of care for locally advanced (node positive and/or margin positive) gastric cancer includes postoperative chemoradiation or perioperative chemotherapy alone, based on recent phase 3 trial experience.[42] Thus, any future trial testing the integration of IORT in locally advanced gastric cancer must include these approaches.

Pancreatic Cancer

The results of many single-institution, nonrandomized clinical trials in patients with pancreas cancer were recently summarized.[43,44] For patients found to have localized but technically unresectable disease, the use of IORT ± EBRT ± chemotherapy is associated with better long-term epigastric pain control but with no effect on median or overall survival. In patients with resectable pancreatic cancer, the combination of preoperative EBRT (± chemotherapy) followed by IORT appears to increase local control and overall survival modestly. Any future trials of IORT in pancreatic cancer will require the integration of more effective systemic therapy.

Sarcomas

IORT has played a role in the management of adult soft tissue sarcomas arising in the retroperitoneum, trunk, and extremities as a component of combined modality treatment.[45] IORT has also been used in the treatment of some primary bone sarcomas in adolescents. Both IOERT and HDR-IORT techniques have been used.

Retroperitoneal soft tissue sarcomas, although rare, are an appropriate tumor for using IORT because these tumors are typically large (>10 to 15 cm) and locally invasive, making wide excisions with negative margins very difficult to achieve. A comprehensive review of the IORT studies in retroperitoneal sarcomas is published.[46] In the only randomized, prospective trial, a small group

of 35 patients with technically resectable retroperitoneal sarcomas were randomized to receive postoperative EBRT (50 to 55 Gy; control group; 20 patients) or IOERT (20 Gy to multiple abutting fields) plus reduced-dose postoperative EBRT (30 to 35 Gy; study group; 15 patients).[17] With a minimum follow-up of 5 years, in-field local recurrences occurred in 20% of the study group and in 80% of the controls ($P < .001$). However, there were no differences in overall survival or risk of distant metastases, which were correlated primarily with pathologic stage. Differences in the type of acute and late normal tissue complications were found with significantly increased gastrointestinal toxicities in the control group and significantly increased peripheral nerve toxicities in the study group. Multiple nonrandomized, single-institution studies support an improved local control rate with less peripheral nerve toxicities using IOERT doses of 15 Gy or less.[46] Two institutions have published their experience using combinations of EBRT and HDR-IORT for primary or locally recurrent retroperitoneal sarcomas. A prospective, nonrandomized trial at Memorial Sloan-Kettering Cancer Center (MSKCC) included 32 patients (12 with primary disease and 20 with recurrent disease) who each received 14 Gy at 0.5 cm deep to the resected tumor bed using HDR-IORT. The MSKCC group reported a 5-year local control rate of 74% and 54% and a 5-year overall survival rate of 55% and 30%, respectively, in the primary and recurrent tumor patient groups.[47] A second series of 46 patients with primary or recurrent retroperitoneal sarcomas from the Curie Cancer Center in France received 20-Gy HDR-IORT following a gross total resection (30 patients with R_0 resection and 16 patients with R_1 resection). These patients experienced actuarial 5-year overall survival and local recurrence survival rates of 55% and 51%, respectively.[48]

The IORT literature for extremity and truncal soft tissue sarcomas is summarized.[49] Although local recurrence risks using surgery and EBRT (either preoperative or postoperative) are low (5% to 8%) with R_0 resections, patients with positive margins or gross residual disease require higher EBRT doses, with an increased risk of acute and late normal tissue toxicities. For these patients, IOERT or HDR-IORT treatments have been used as a treatment boost while maintaining the EBRT dose at 45 to 50 Gy. In general, local control is excellent (≥85%), and normal tissue complications and functional outcomes are acceptable.[50]

The more limited experience with IORT in bone sarcomas is also reviewed.[51] Typically, IOERT has been used for marginally resected Ewing sarcomas and osteosarcomas in adolescents at centers in Germany, Spain, and Japan. Although

local control is excellent in these high-risk patients, the risks of late normal tissue complications, including IORT-induced second cancers, are of concern, and long-term follow-up is needed before an endorsement of the role of IORT in these patient groups can be made.

Breast Cancer

IORT is playing a major role in the curative treatment of early-stage breast cancer throughout the world, as reviewed.[52] Based on several prior single-institution, nonrandomized studies, two large phase III studies have been designed for patients with early-stage disease to test the concept of IORT as full-dose, single-dose partial breast irradiation treatment compared to standard, conventionally fractionated whole-breast radiation therapy (WBRT). In addition, the concept of using IORT as a boost followed by WBRT for patients with adverse pathologic features is being evaluated by the European Group of the International Society of Intraoperative Radiotherapy (ISIORT Europe). A brief description of the two large phase III studies of definitive IORT and the ongoing single-arm IORT boost study is given later. A more detailed discussion of these trials is provided in the chapter of this book on breast cancer.

The Targeted Intraoperative Radiotherapy Trial enrolled and randomized more than 2,200 early-stage (T1, T2; N0) breast cancer patients with invasive ductal carcinoma without evidence of lobular carcinoma and older than 45 years of age to single-fraction, orthovoltage IORT to 20 Gy (surface dose) or conventionally fractionated WBRT to 50 Gy.[53] Only in the case of specific risk factors was the IORT complemented with WBRT. An interim analysis, published in February 2014, with a median follow-up of 5 years, reported a higher local recurrence risk at 4 years (3.3% in IORT arm vs. 1.3% in the WBRT arm, P = .042).[54] Longer follow-up is needed before definitive conclusions may be drawn. Although TARGIT-IORT is included in national guidelines for breast cancer treatment in Europe and Asia, it is not considered a national guideline in the United States. Two recent editorials have presented arguments that support or criticize the TARGIT-A trial design and data interpretation.[55,56]

Other Cancer Types

The clinical data regarding the use of IORT for lung cancers, head and neck cancers, CNS malignancies, and pediatric cancers were recently reviewed in detail,[33] and the reader is referred to chapters in this textbook on specific tumor sites for additional information. No prospective, randomized trials of IORT for

these cancers are available or in development.

CHAPTER 21

Proton Therapy

Nancy P. Mendenhall and Zuofeng Li

INTRODUCTION

The potential to improve the therapeutic ratio in radiation therapy has fueled interest in proton therapy. This chapter will touch on the rationale, evolving technology, applications and outcomes, and current challenges associated with proton therapy.

RATIONALE

Therapeutic Ratio

With any medical intervention, there is an optimal balance between the potential to benefit and the potential to harm a patient, known as the therapeutic ratio. In radiation oncology, it is the balance between radiation effects on the tumor and radiation effects on normal, nontargeted tissues. This ratio informs every physician and patient decision. Different priorities may drive different decisions in certain clinical situations. One physician might recommend a treatment that results in a lower probability of disease control but minimizes the risk of optic nerve damage, whereas another physician might recommend a treatment that results in a higher probability of disease control but carries a greater risk of optic nerve damage. In another example, the potential risks of low-dose radiation exposure to a large volume of the brain tissue may be of great concern to the parents of a young child, but not of concern to an elderly patient with a short life expectancy. In evaluating new radiation modalities, the first question is whether there exists a potential to improve the therapeutic ratio.

The Impact of Dose Distribution on the Therapeutic Ratio

Many factors influence radiation effects and the therapeutic ratio: total dose, dose intensity (the overall time and number of fractions), relative biologic

effectiveness (RBE), and modifying factors, such as chemotherapy, patient age, and comorbidities. No factor is as important as dose distribution—the dose to the target compared with the dose to nontargeted normal tissues—because radiation therapy is a nonspecific intervention that affects both normal and cancerous cells. A basic principle in radiation oncology is that the higher and/or more intense the radiation dose, the greater the probability of tumor control. Similarly, the higher and/or more intense the radiation dose to a normal tissue, the greater the probability of injury. A second less well-understood principle is that the volume of tumor or normal tissue exposed to various radiation dose levels impacts the effect. For example, a higher dose of radiation to an organ may be tolerated if the absolute or relative volume of exposure to the organ at risk (OAR) is limited. In addition, there may be critical components of either an OAR or a tumor that require a higher or lower dose for a clinical response. For example, the hypoxic section or the positron-emission tomography (PET)-avid portion of a tumor may require a higher dose than the rest of the tumor for disease control. These principles of dose and volume response relationships have been observed in both malignancies and normal tissues but may not always be apparent if effective doses are not delivered to critical volumes (of tumor or a normal tissue), if adequate tools for measuring response (toxicity or functional compromise) are not available, or if observation time is insufficient for manifestation of the effect.

The primary barrier to maximizing local tumor control through dose escalation or intensification is the risk of damaging normal tissues, either by delivering too high a dose to a critical tissue or by exposing too great a volume of the critical normal tissue to a potentially harmful dose of radiation. *The most direct means of improving the therapeutic ratio is by reducing radiation dose and exposure to nontargeted tissues, which both reduce toxicity and facilitate dose escalation for increased tumor control: herein lies the rationale for proton therapy.*

The Problem with Photons (X-Rays) and the Promise and Challenge of Protons

The pattern of dose deposition with photon-based external beam radiotherapy (Fig. 21.1) is problematic because the dose to tissues along the beam entrance path is always higher than the dose to the target and additional dose is deposited in nontargeted tissues along the exit path of the beam. *Thus, most of the radiation dose with photon-based therapy is deposited outside the target.*

Many elegant strategies have been developed for offsetting this basic problem (4-field box technique, stereotactic radiosurgery and stereotactic radiation therapy [SRT], three-dimensional conformal radiation therapy [3DCRT], intensity-modulated radiation therapy [IMRT], tomotherapy, volumetric modulated arc therapy [VMAT], etc.), but with these technologies, radiation to nontargeted tissues is primarily redistributed rather than reduced. Because the total dose to a given tissue is one of the key determinants of toxicity, certain toxicities are reduced when using these sophisticated techniques. It is likely, however, that other toxicities will increase owing to methods that redistribute integral dose and expose greater volumes of normal tissue to lower doses of radiation. Some effects from low-dose exposure may require more time for clinical manifestation (second malignancies), and some may require more subtle tools for detection (neurocognitive testing), leading to an early underestimation of toxicity with these sophisticated photon delivery methods.

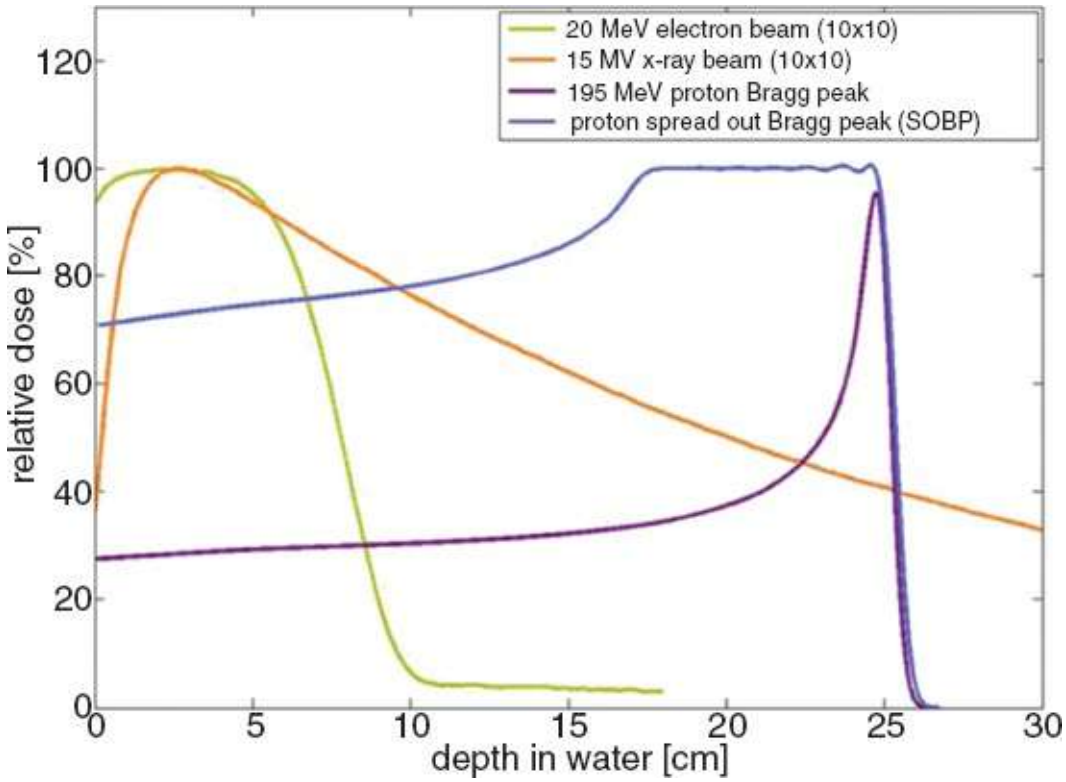

FIGURE 21.1. As shown here, the shapes of the depth-dose curves for electrons (*tan*), photons/x-rays (*orange*), a pristine proton Bragg peak (*purple*), and an SOBP comprised of multiple pristine Bragg peaks (*blue*) differ significantly. Compared to photons or electrons, the entrance dose with protons is constant and reduced relative to the target dose and there is no exit dose. The depth of penetration is much greater and the dose falloff at the end of the proton range much sharper for protons than for electrons. The depth of the proton Bragg peak can be varied according to

acceleration energy; current cyclotrons and synchrotrons accelerate protons to energies sufficient to place the Bragg peak at 30- to 35-cm depth in tissue for coverage of deep-seated tumors. Because of the entrance and exit doses with photons, most of the radiation energy is deposited outside of the target, whereas with protons, most of the radiation energy is deposited inside of the target.

The pattern of dose deposition with protons differs significantly from that of photons. A proton carries a positive charge, which means it can be accelerated and directed by magnets; the proton has mass, which means it will not travel an infinite distance but rather only to the range or depth in tissue determined by its acceleration energy. In a patient, protons can be made to stop at a depth corresponding to the tumor depth. As protons traverse matter, they lose energy primarily through interactions with atomic electrons. Because of the significantly larger mass of protons (~1800×) relative to electrons, protons lose only a small portion of their energy in each interaction (in contrast to x-rays) and experience only small directional changes.

As protons traverse matter, the rate of energy loss in electronic interactions is described by the linear stopping power, $S(E)$, defined as dE/dx, where dE is the mean energy lost by a proton in electronic collisions over a distance of dx in media. A more commonly used function is the mass stopping power, $s = S(E)/\rho$, which denotes the energy loss dE when protons travel through a distance of dx in a media of mass density ρ.[1]

Linear energy transfer (LET) is closely related to stopping power. Although stopping power indicates energy lost by the protons, LET denotes the energy transferred to a medium as the protons traverse it. LET therefore represents the density of energy deposition in media and is directly related to the local RBE of the radiation. At higher energies (e.g., along the beam's entrance path), protons have a small stopping power and low LET values; their LET values increase sharply by up to two orders of magnitude as the protons' energy decreases just before coming to a complete stop. This phenomenon creates a characteristic pattern of dose deposition with protons known as the Bragg peak: a small, nearly constant rate of dose deposition along the entrance path followed by a sharp peak immediately before the protons stop in media. Because RBE values are related to LET values, the RBE values also rise sharply near the end of a proton-beam range. Much work has been done to determine *in vitro* and *in vivo* proton-beam RBE values.[1] Currently in proton therapy treatment planning, an RBE multiplicative factor of 1.10 is uniformly applied to the physical dose[2] without explicitly accounting for the increased RBE values near the end of a proton-

beam range. The actual RBE-corrected dose at the very end of the range may exceed the physical dose by up to 25%, thus producing an RBE value up to 1.3 at the very end of the proton range.[3] Enhanced RBE effects are more significant in heavier ions like carbon, and nascent carbon ion treatment planning systems are attempting to account for these variations in RBE along the carbon beam path.[4] Efforts to account for LET and RBE variations along the beam path in proton treatment planning are developing as well.[5]

In addition to energy loss through electronic collisions, high-energy protons also experience nuclear interactions in media. Such interactions remove protons from the initial proton fluence and produce secondary protons, neutrons, and heavier particles, such as deuterons, tritons, He, and α; these particles contribute only a small percentage of the dose along the beam path.[6] Although negligible, most of the dose from the neutrons produced in these nuclear interactions is deposited downstream from the stopping point of the proton beam, beyond the Bragg peak. The neutrons produced by protons within the patient, as well as those produced in the beam delivery mechanical components, have been under intense investigation for their potential secondary cancer-inducing effects. Hall[7] raised concern that such scattered neutrons may increase the incidence of secondary tumors in patients treated with historical proton therapy systems, similar to the transition from conventional 3DCRT to IMRT.[8] Much research has been performed to estimate secondary cancer risks from contemporary proton therapy systems using either scattering beam techniques or scanning-beam techniques.[9] Consistent reductions in secondary cancer induction have been predicted with protons compared to photons in studies of medulloblastoma, prostate cancer, and liver cancer.[10–12] A clinical outcome study comparing actual secondary cancers between a cohort of patients treated with protons at the Harvard Cyclotron and a cohort of photon-treated patients matched by age and tumor type from the Surveillance, Epidemiology, and End Results database has shown nearly twice as many secondary cancers in the photon cohort.[13] Modern proton therapy equipment produces fewer neutron contaminants than the early proton therapy sources in physics research laboratories, so it appears that neutron production should be of much less concern for late effects than excess integral dose from photons.

The primary rationale for an improved therapeutic ratio with protons, compared with photons, is thus the significant reduction in integral dose (dose to nontargeted tissues) related to a significantly reduced entrance path dose and the absence of any exit path dose, which should translate into a lower risk of

complications for a given target dose and greater probability of tumor control. A lower risk of complications could also be leveraged to permit dose escalation or intensification (yielding higher disease control in certain settings) or to facilitate hypofractionation (reducing patient inconvenience and treatment costs in other settings).

There is emerging evidence of another difference between proton and photon radiation therapy, which may provide a second rationale for an increased therapeutic ratio from proton therapy. The predominant pattern of DNA damage with photon therapy is isolated double-stranded DNA breaks; however, after proton radiation, most DNA lesions are clustered double-stranded breaks, which may be more difficult to repair and require slower repair processes, possibly homologous rather than nonhomologous repair pathways. It is possible that these differences in DNA damage and tissue repair responses provide part of the explanation for apparent RBE differences and a rationale to expect higher disease control rates but also potentially higher complication rates with proton therapy.[14–18] Some tumors and host conditions may have genetic variations that impact responses to radiation in general and proton therapy specifically.[18]

TECHNOLOGY

Beam Production and Transport

Protons are produced either from hydrogen gas obtained from electrolysis of deionized water or from commercially available high-purity hydrogen gas. Application of a high-voltage electric current to the hydrogen gas strips the electrons from the hydrogen atoms, leaving positively charged protons. The protons are then accelerated to energies applicable for clinical proton therapy with either a cyclotron or a synchrotron (Fig. 21.2). Energies on the order of 230 MeV are required for penetrating approximately 32 cm into a tissue. Cyclotrons produce a continuous beam of nearly monoenergetic and unidirectional protons. The beam must then be degraded to meet specific requirements for each treatment field in each patient. This process takes place shortly after the beam exits the cyclotron in a device known as the “energy degrader,” which is composed of a material of variable thickness with a low atomic number. The proton beam exiting the energy degrader will have a spread of energies centered around the final energy spread necessary for coverage of the target. An energy selection system (ESS), consisting of energy slits, bending magnets, and focusing magnets, is then used to eliminate protons with excessive

energy or deviations in angular direction. Cyclotrons can produce a large proton-beam current of up to 800 nA and thus deliver proton therapy at a high dose rate using either a double-scattering technique or a scanning technique.

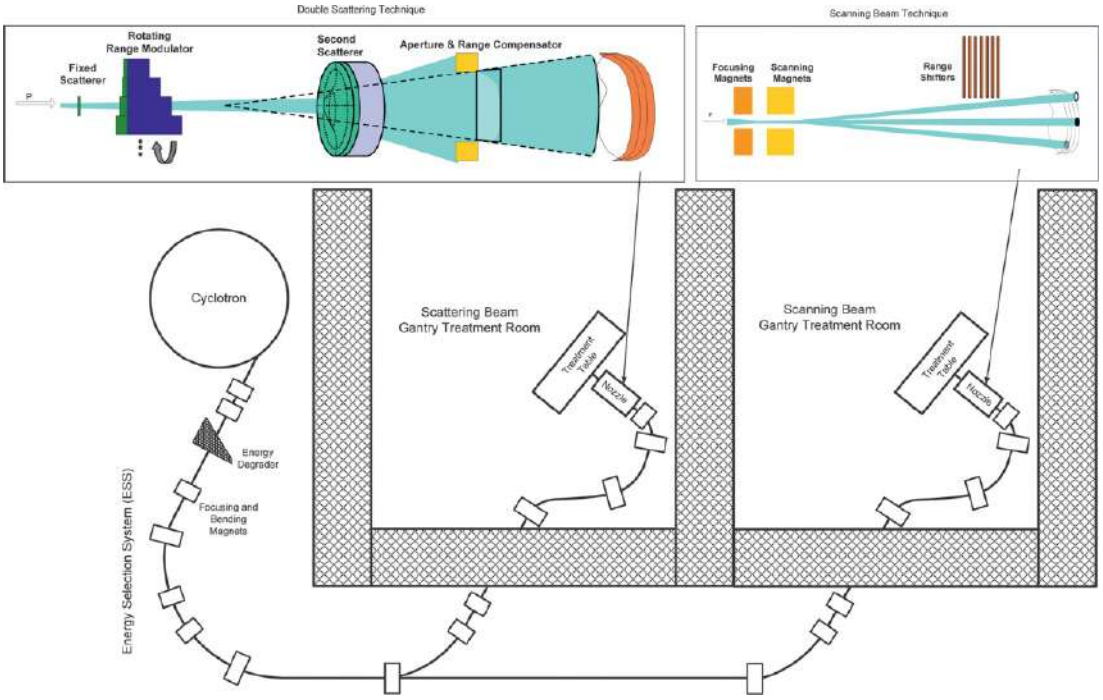

FIGURE 21.2. A proton therapy system with a cyclotron, ESS, beamline, gantry, and nozzle. Scattering is illustrated in the nozzle on the left and scanning in the nozzle on the right.

Synchrotrons, however, produce proton beams of varying energies, which can be selected, thereby eliminating the need for the energy degrader and energy selection devices. A proton pulse exiting a preaccelerator, with energy typically up to 7 MeV, is injected into the ring-shaped accelerator. Each complete circuit of the proton pulse through the accelerator ring structure incrementally increases the proton pulse energy. When the desired beam energy is reached, the proton pulse is extracted from the accelerator. The time segment between pulses depends on the final energy required of the proton beam, ranging from subseconds to several seconds for the highest beam energy. The pulsed nature of the beam introduces additional complexity in certain treatment delivery scenarios, such as gated treatment of mobile targets and intensity-modulated proton therapy (IMPT).[19] Beam currents from synchrotrons are typically much lower than with cyclotrons, thus limiting the maximum dose rates that can be used for patient treatment, especially for larger field sizes. The maximum dose rate available from a commercially available synchrotron-based proton therapy

system for a 25 × 25-cm^2 field has been specified at 0.8 Gy/min.[20] The elimination of the energy degrader and selection system removes a major source of neutron production and thus subsequent activation of beamline components in the accelerator vault. A synchrotron vault is therefore accessible immediately after the beam is stopped for maintenance, whereas for a cyclotron vault, approximately 30 minutes is necessary to allow the neutron-activated parts of the accelerator and ESS to "cool down" before maintenance can be performed, sometimes longer if access to internal parts of the cyclotron is required. The shielding requirements for cyclotrons are also higher than for synchrotrons because of the higher neutron radiation produced by the ESS. However, the overall footprint of a cyclotron vault, including the additional shielding required, is actually similar to or smaller than that of a synchrotron vault because of the smaller physical dimensions of cyclotrons.

The proton beam, on exiting the ESS for a cyclotron-based system or exiting the accelerator for a synchrotron-based system, is transported to the treatment room(s) via the beam transport system. Maintenance of beam focusing, centering, spot size, and divergence throughout the beam transport system is critical to maintaining a high-quality proton beam for treatment delivery. Paganetti et al.[21] performed Monte Carlo calculations of the dosimetric effect of proton-beam energy spread, spot size, and angular energy spread on the shape of the Bragg peak. They found that small deviations in these parameters from their nominal values result in a widening of the Bragg peak and increased entrance doses. Beam transport systems in clinical proton facilities therefore include bending and focusing magnets and beam profile monitors so that the proton-beam quality may be monitored and adjusted ("tuned") as it is transported through the beam transport system.

Recent progress in accelerating and control technologies has led to new designs of proton therapy systems in the form of single-treatment room systems with small cyclotrons that may be mounted on a gantry, as well as dielectric wall accelerators and laser-accelerated accelerators.[22] Single-room proton therapy systems are currently available from a number of commercial vendors, each with its own strengths and weaknesses. Dielectric wall accelerators and laser-accelerated systems are currently under development. One of the primary drivers for development of these single-room proton therapy solutions is facility cost reduction (see "Challenges" below).

Beam Delivery

The proton beam exiting the transport system (Fig. 21.2) is a pencil-shaped beam with minimal energy and direction spread. The beam has a small spot size in its lateral direction and forms a narrow Bragg peak in its depth direction in water. Two basic techniques have been developed to convert this narrow pencil beam into a dose distribution suitable for treatment of a 3D target, broadly categorized into the "scattering technique" and the "scanning technique." These techniques are implemented in the machine treatment head or "nozzle."

The scattering technique produces a dose distribution with a flat lateral profile, similar to what is achieved in linear accelerator–produced 3D conformal photon beams, but a depth dose curve with a low entrance dose and a plateau region, followed by the sharp falloff of doses to zero. The plateau is produced by summing a number of Bragg peaks, each with progressively reduced maximum energy and range, to a sufficient width to cover the thickness of the target. The weights of the individual Bragg peaks are optimized to achieve a flat top region of the depth-dose curve. A proton beam that produces a constant energy may be used for such treatments, with range-reducing materials inserted into the beam path to create a series of Bragg peaks of reduced ranges. Range modulation wheels consisting of variable thicknesses of "acrylic glass" (polymerized methyl methacrylate) or graphite steps are traditionally used for this purpose.[21] The proton beam travels through the variable thickness steps, with each step creating a Bragg peak of a precalibrated range. The widths and thicknesses of the modulation wheels are calibrated to achieve a flat depth dose or "spread-out Bragg peak" (SOBP). When the desired width of the SOBP is reached, the beam is turned off. Alternatively, a "ridge filter" may be used to create an SOBP[23] with the advantage of eliminating sensitivity to organ motion in the formation of the SOBP but with the added complexity that each ridge filter is designed to achieve a single SOBP width.

The scattering technique produces a large, flat lateral dose profile through physical scattering filters placed in the proton-beam path.[21] One scattering filter may be used, which creates a wide beam with a Gaussian dose profile known as a single scattering beam. A single scattering beam, with limited field sizes, is used primarily in dedicated eye treatment rooms for proton therapy of eye tumors, such as choroidal melanoma, and proton stereotactic radiosurgery treatments of brain lesions. Alternatively, and more often, a second scattering filter can be added into the beam that flattens the lateral dose profile, known as a double-scattering beam. Apertures fabricated out of brass or other metals are used to confine the treatment field to the target. A tissue-equivalent range

compensator, or bolus, is designed to adjust the beam range within the field to conform to the distal profile of the target.[24] With the scattering technique, it is not possible to achieve conformity of the dose distribution to the proximal contour of the target.

In the scanning technique, as the pencil beam exits the transport system, it is magnetically steered laterally to deliver dose to the treatment field.[25–27] The proton-beam intensity may be modulated as the beam is moved across the field, resulting in *i*ntensity-modulated *p*roton beam *t*herapy, or IMPT, technique delivery. Current implementation of IMPT uses the "spot-scanning" technique, in which the beam is moved from one spot, where a prescribed dose is delivered, to the next spot. In the beam axis direction, IMPT treatments are delivered using a layer-stacking technique. A pencil beam with a pristine peak is scanned through the deepest layer of the target to deliver the intensity-modulated dose distribution for the layer before a range shifter—effectively an energy degrader of predetermined thickness—is inserted into the beam path to deliver dose to a depth immediately proximal to the deepest layer. Doses to each subsequent layer are delivered by inserting additional range shifters. The size of the spot, represented by the sigma of the Gaussian function describing the pencil beam profile, is a critical parameter of the pencil beam. Smaller beam sigma values allow intricate sculpting of the intensity-modulated dose distribution but require increased control system complexity and delivery time; larger beam sigma values result in faster dose delivery but produce a greater lateral penumbra and a reduced dose gradient at interface regions of target and critical organs.

Similar to the interplay effect reported for IMRT,[28–30] scanning techniques are sensitive to organ motion because time is required for moving the pencil beam across the treatment field for dose delivery to a given layer and inserting range shifters for dose delivery to subsequent layers; over the delivery time, organ motion can occur, resulting in under- and/or overdosage of parts of the target. A potential strategy for mitigating this interplay effect is to deliver divided doses to each spot either by "repainting" each layer multiple times before changing the beam energy to scan the next layer (layer repainting) or by scanning each consecutive layer of a given target volume once, followed by rescanning of the entire target volume several additional times during each treatment fraction (volumetric repainting), rather than scanning each layer and the entire volume only once.[31] Standard motion mitigation measures, such as breath holding, gated therapy, and abdominal compression, may also be necessary to minimize the dosimetric effects of organ motion.

The advantages of pencil beam scanning over double scattering are its increased proximal target conformity and decreased need for apertures and compensators A disadvantage of pencil beam scanning over double scattering with current technology is its longer delivery time per field, which may enhance sensitivity to organ motion and complicate system operations with multiroom, single cyclotron or synchrotron systems. The advantages of IMPT over IMRT are the absence of exit dose, the significant reduction in integral dose, and the necessity for fewer beam angles permitting increased sparing of critical organs.

Treatment Planning

Treatment planning for proton therapy requires a volumetric patient computed tomography (CT) scan dataset. The CT Hounsfield unit numbers are converted to proton stopping power values for calculating the proton range required for the treatment field.[32,33] Unlike the relatively reliable conversion of CT numbers to relative electron density for photon dose calculations, errors and uncertainties in the conversion of CT numbers to proton stopping power in proton dose calculations translate linearly into proton range calculation uncertainties and errors. In clinical practice, these uncertainties are handled during the treatment planning process by bracketing the intended SOBP with a distal margin beyond the target and a proximal margin before the target in the range calculation of each treatment field.[34] Other considerations in determining the values for distal and proximal margins include target motion, daily setup errors, beam delivery uncertainties, and uncertainties in patient anatomy and physiology changes throughout treatment that could affect the water-equivalent depth of the target. It is worth noting that the concept of PTV, as defined in the various International Commission on Radiation Units and Measurements reports,[35,36] does not strictly apply to proton therapy. Generally, a planning target volume (PTV) expansion, with either uniform or nonuniform margins, is used for photon planning, which accommodates maximum target motion and setup error in each of the patient axes (longitudinal, lateral, and anterior/posterior). In contrast to photon planning, the PTV for proton therapy is specific for each treatment field. In the lateral direction of the beam’s eye view of a proton field, margins are identical to traditional definitions, but the distal and proximal margins along the beam axis are calculated to account for proton-specific uncertainties. The lower entrance dose and absence of exit dose of a proton beam afford additional flexibility in selection of beam angles for which lateral target motion and setup error are minimal; thus, the PTV expansion margin may be less for a given proton-beam

angle than would be required with IMRT to account for uncertainties for all beam angles. Commercial proton treatment planning systems have been designed to allow for the definition of beam-specific PTV volumes such that the range and modulation width (or SOBP width) of each beam may be calculated with adequate consideration of the varying distal and proximal target margins.

The pencil beam scanning treatment technique, with its additional ability to modulate dose intensity within and outside of the target region, requires additional considerations in treatment plan optimization. The single-field uniform dose (SFUD), or single-field optimization technique, allows the treatment planning system optimizer algorithm to optimize the treatment plan on a field-by-field basis, so that each field will deliver a nearly uniform dose that covers the target to the extent that OAR protection constraints permit. The SFUD technique provides the most plan robustness after a proper passive-scattering treatment plan, despite various physical and physiologic uncertainties that may significantly perturb dose delivery accuracy, including the interplay effect of moving organs, with potential compromises in plan quality of conformity and OAR protection. The multifield uniform dose (MFUD) optimization technique, on the other hand, allows each treatment field to deliver a heavily modulated dose distribution to a subvolume of the target and relies on the accurate delivery and combination of all fields to achieve plan goals. This MFUD optimization technique can therefore achieve the highest plan quality, but potentially increases sensitivity to the effects of delivery uncertainties, and should therefore be applied judiciously. IMPT plans may use either SFUD or MFUD or a combination of the two. Pencil beam treatment plans can additionally be optimized with consideration for various sources and magnitudes of delivery uncertainties, such as range uncertainties and setup errors, resulting in the so-called robust optimization, which allows optimization of a treatment plan over the 10 breathing phases of a four-dimensional CT scan of a moving target. The effectiveness of these newer optimization techniques must be carefully evaluated, disease site by disease site, before they are broadly accepted for treatment planning.

State-of-the-art proton therapy dose calculations use pencil beam algorithms,[37–40] which model proton interactions and scattering in various media of the beam path, including the nozzle, range compensators, and patient. Monte Carlo calculations have been used to study the accuracy of such dose calculation algorithms, with results indicating errors near tissue interfaces, particularly near interfaces of media differing in density and composition, such as the air cavity

and bone in head and neck treatments.[41,42] Several fast Monte Carlo calculation algorithms have been proposed to improve proton therapy dose calculation accuracy,[43–46] which will soon be available in commercial proton treatment planning systems.

As of yet, there are no clear class solutions to treatment planning, although it is agreed that beams that stop at the interface of a critical organ should generally be avoided because of range uncertainties and our current inability to account for changes in RBE at the end of the range. Concerns regarding dose delivery time, intrafraction organ motion, potential changes in beam path length and composition, and adjacency of critical organs impact decisions regarding the number of fields to use, overall plan robustness, scanning versus scattering delivery modes, single-field versus multifield optimization of the treatment plan with scanning modes, and clinical operations.

Even with strategies to account for proton range uncertainties, comparisons of treatment plans involving proton and photon techniques generally demonstrate a striking advantage with protons for reducing the volume of nontargeted normal tissue receiving low- to medium-range radiation doses. In some cases, the volume of nontargeted tissue receiving moderate- to high-dose irradiation is also reduced. With double-scattered proton delivery modes currently in common usage, the target dose homogeneity and conformality index can sometimes, but not always, be inferior to that of IMRT. With scanned proton delivery modes, IMPT plans can, in addition to reducing low and moderate integral doses, also improve dose homogeneity and conformality indexes when compared with IMRT. However, depending on spot size and specific machine characteristics, the penumbra of scanned proton beams may be greater than that of double-scattered proton beams, making IMPT less useful, particularly in patients with adjacent critical structures. This concern can be addressed with beam collimating apertures, identical to those used in passive-scattering proton therapy, to reduce the beam penumbra. Each case within each tumor type is different, and until comparative plans are performed, it remains unclear whether protons are preferable to IMRT, VMAT, or 3DCRT and, further, whether IMPT would be more beneficial than double-scattering proton delivery. The clinical impact of improvements in physical dose distribution achievable with proton therapy may not be fully appreciated or even anticipated at this time; therefore, how to achieve the maximum benefits from proton therapy will require time, careful trial design, and detailed outcome assessments to define.

Applications and Outcomes

Many publications have reported significant differences in dose distribution between proton treatment plans and photon-based treatment plans in a wide range of malignancies and benign lesions throughout the body, including the eye,[47] brain,[48–55] skull base,[56,57] advanced head and neck sites,[58] sinonasal structures,[59,60] oropharynx[61,62] and nasopharynx,[63,64] lung,[65–68] lymphoma,[69–73] pancreas,[74–76] esophagus,[77–79] rectum[80] and anal canal,[81,82] seminoma,[83] prostate,[12,84,85] cervix,[86–91] breast,[92–95] sarcomas,[96] and standard target volumes, such as pelvic lymph nodes[97] and craniospinal irradiation,[98] and complex cases requiring reirradiation.[99]

Despite the existence of only a few facilities with technology capable of proton delivery to most cancers, the efficacy and safety of proton therapy have already been demonstrated in a variety of malignancies including retinoblastomas[100]; melanomas of the eye[101–107] and other sites[108,109]; bone and soft tissue sarcomas of the base of skull, lumbosacral, spine, extremities, and retroperitoneal space[110–124]; brain[125–129] and spinal cord tumors[130]; head and neck cancers including paranasal sinus tumors[108,109,131–139]; oropharyngeal carcinoma,[140–142] nasopharyngeal cancer,[143,144] ipsilateral head and neck tumors,[145] and adenoid cystic carcinoma[146–148]; gastrointestinal malignancies including esophageal cancer[78,149–153]; thoracic malignancies including early- and advanced-stage lung cancer,[154–164] thymoma,[165,166] and mesothelioma[167]; urologic malignancies including bladder cancer[168] and low-, intermediate-, and high-risk prostate cancer[169–182]; breast cancer[183–186]; Hodgkin and other lymphomas[69,73,187–196]; upper abdominal malignancies including hepatocellular carcinoma[197–204]; pancreatic cancer[205–209]; cholangiocarcinoma[201,210]; liver metastases[211]; cervical cancer[212]; a variety of pediatric brain tumors,[213–227] and other pediatric malignancies[123,195,196,228–237]; benign lesions like pituitary tumors[238]; acoustic neuroma,[239,240] age-related macular degeneration,[241–243] non–age-related macular degeneration choroidal neovascularization[244]; and hemangiopericytoma,[245] craniopharyngiomas,[224,226] paragangliomas,[246] and meningioma.[247,248] In addition, protons have been used in situations requiring re-irradiation.[249,250]

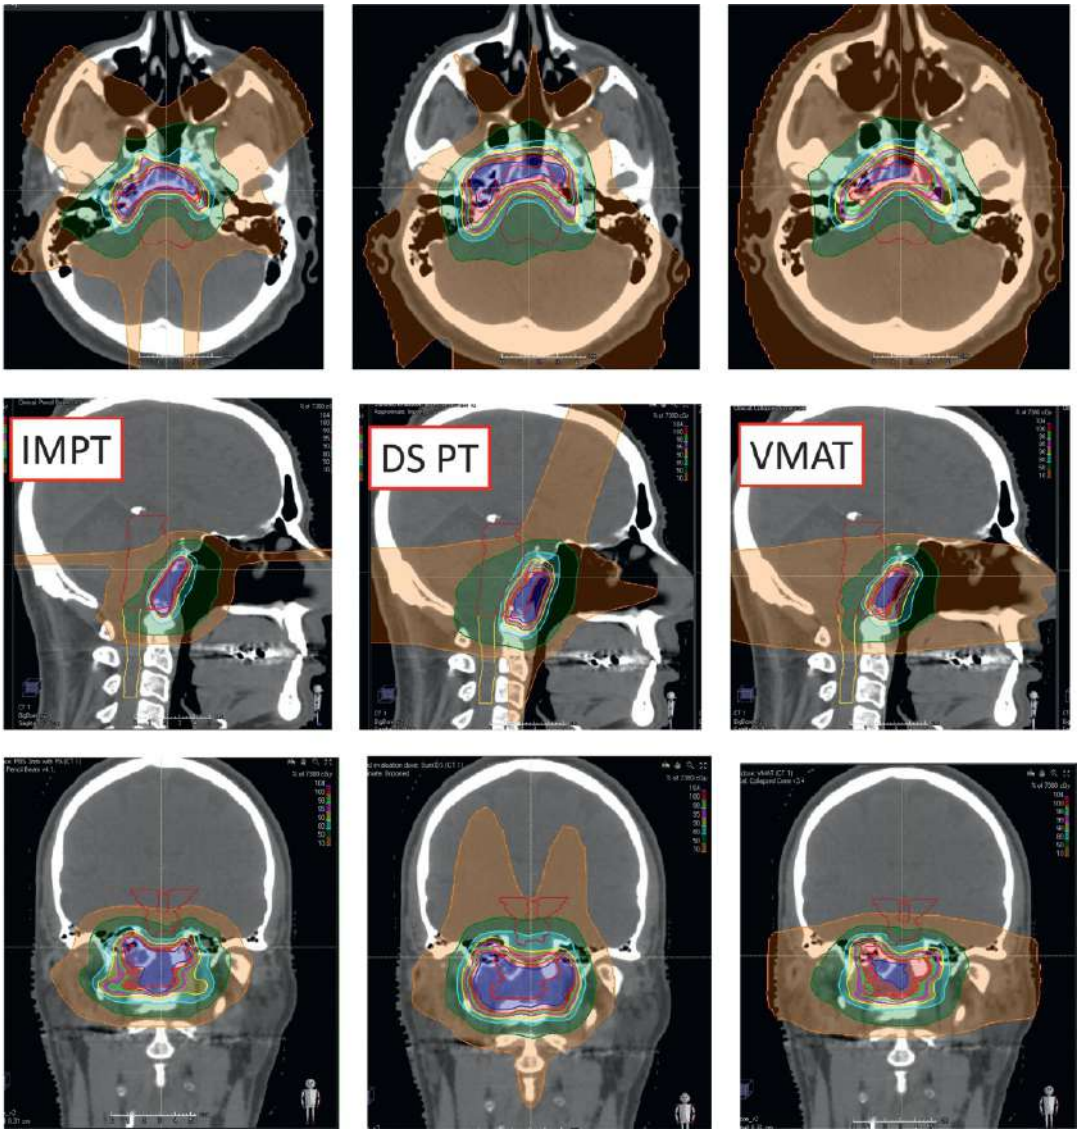
Figures 21.3 through 21.12 illustrate comparative treatment plans for 10 examples of clinical settings that could benefit from proton therapy. The examples are not comprehensive but representative. Currently, some proton facilities provide only double-scattering proton therapy (DS PT), some provide only pencil beam scanning proton therapy, and a few provide both. Where

differences between IMPT and DS PT were anticipated, both plans were provided. The term “IMPT” used in examples below refers to PBS using SFUD and/or multifield optimization. Treatment planning techniques, particularly with IMPT and VMAT, are rapidly evolving. Current methods of dose prescription and treatment planning are not standardized across the field, so it may be possible to improve upon some of the treatment plans depicted below with other techniques, delivery modes, and better treatment planning systems.

Skull Base Sarcomas

Skull base sarcomas typically are not amenable to complete resection and require very high-radiation doses for disease control. Their adjacency to the brainstem, optic chiasm, and optic nerves often precludes delivery of optimal tumor doses for fear of fatal or severe functional radiation injuries. Proton therapy in these cases can achieve dose distributions that often provide better target coverage and permit the delivery of potentially curative doses of radiation to the tumor with minimal risk of brainstem necrosis or blindness; in some cases, proton therapy may offer the patient the only realistic chance of cure. Outcomes from several institutions suggest that up to 81% of chordomas and 94% of chondrosarcomas of the skull base can be controlled with proton therapy with a low risk of serious toxicity like brain necrosis.[111,113,118,119]

Figure 21.3A shows axial, coronal, and sagittal color wash displays of the dose distributions for IMPT, DS PT, and photon-based VMAT treatment plans for a skull base chondrosarcoma. Figure 21.3B shows an analysis of dose–volume histogram data for the three plans. The IMRT plan delivers low-dose irradiation to a much larger volume of nontargeted tissue than either proton plan, specifically to the nose and posterior fossa, and provided inferior target coverage compared with the proton plans. With a goal of delivering ≥70 Gy (RBE) to the gross residual tumor volume, the doses achieved were 71 Gy (RBE) with IMPT, 69 Gy (RBE) with DS PT, and 60 Gy with photons (VMAT). Sparing of all OARs was best with IMPT. Conformality was similar between IMPT and VMAT, whereas homogeneity was similar between DS PT and VMAT.



A

Targets	Goal Value	IMPT	DS PT	VMAT
PTV1	V50.4 Gy ≥95%	99.40%	99.97%	99.76%
PTV1	D95% ≥50.4 Gy	54.52	59.77	54.62
PTV2	V73.8 Gy ≥95%	65.4%	74.6%	46.0%
PTV2	D95% ≥73.8 Gy	66.33	66.39	62.11
GTV	V73.8 Gy ≥99%	96%	92%	79%
GTV	D99% ≥70.1 Gy	71.31	69.09	60.52

OARs	Goal Value	IMPT	DS PT	VMAT
Brainstem	D0.1 cc ≤55 Gy	59.32	64.22	62.74
Brainstem	Max dose ≤60 Gy	67.85	68.12	68.16

B

FIGURE 21.3. A: Axial, sagittal, and coronal displays of the dose distributions achieved with pencil beam scanning proton therapy, also known as IMPT, with a 3-mm spot size, double-scatter delivery of proton therapy (DS PT), and photon-based IMRT using the volumetric arc treatment planning system (VMAT) for a **skull base chondrosarcoma of the clivus**. The *thick red line* indicates the target volume containing gross residual tumor (GRTV), the *thin yellow line* indicates the spinal cord, and the *thin red line* indicates the brainstem. The color wash indicates the radiation dose levels achieved with each treatment plan; the inner bright blue wash and line indicate the isodose volume receiving 104% of the prescribed radiation dose. The colored shaded areas indicate the following volumes: *red*, isodose volume receiving the prescribed dose of 73.8 Gy (RBE); *bright green*, volume receiving 98% of the prescribed dose; *magenta*, volume receiving 95% of the prescribed dose; *yellow*, volume receiving 90% of the prescribed dose; *aqua*, volume receiving 80% of the prescribed dose; *dark green*, volume receiving 50% of the prescribed dose; and *orange*, volume receiving 10% of the prescribed dose. **B:** Dose distribution goals for skull base tumors. Different institutions use different dose distribution goals for evaluating skull base tumor plans. In this case, the target coverage goals were to deliver a dose of 50.4 Gy (RBE) to at least 95% of the planning target volume PTV1, a dose of 73.8 Gy (RBE) to at least 95% of the PTV2, and a dose of 73.8 Gy (RBE) to at least 99% of the GTV. As is apparent in the goal sheet above, target coverage goals for the PTV1 were met with all three plans, but target coverage goals for PTV2 could not be achieved with any of the plans. The goals for the GTV likewise were not achieved with any of the plans but were better met with the proton plans than the

VMAT plan and best met with the pencil beam scanning proton therapy plan, with the GTV receiving 96%, 92%, and 79% of the prescribed dose with IMPT, DS PT, and VMAT plans, respectively. With respect to OARs, several parameters must be considered simultaneously, including “hot spots” reflected by the D0.1 cm^3 and max dose, mean organ doses, and various relative or absolute volumes of an organ receiving certain doses. The DS PT plan involved the use of matched “patch” fields that treat partial target volumes to achieve better coverage of the target but can result in hot spots or higher mean organ doses in some cases. In this case, all three plans produced “hot spots” in the brainstem that exceeded the very conservative planning goal of D0.1 $cm^3 \leq$ 55Gy. Using a volumetric definition of the outer 3-mm rim of the brainstem as the “brainstem surface” and the remaining volume inside the brainstem surface as the “brainstem core,” it was felt that all plans would carry only a very small risk of brainstem injury, because the “hot spots” were small. None of the plans could avoid a significant risk of injury to the right cochlea, but both proton plans provided a good chance of preserving the left cochlea, with mean doses to the left cochlea of 18 Gy (RBE), 31 Gy (RBE), and 41 Gy (RBE) with IMPT, DS PT, and VMAT, respectively. Considering both target coverage and OAR protection, the best plan for this patient was the IMPT plan. Although mean and maximum doses of some structures were better with VMAT than DS PT, the improved target coverage with DS PT would generally warrant selection of the DS PT plan over VMAT, if IMPT were not available. (GTV, gross tumor volume visible on treatment planning imaging; CTV [not shown], GTV plus expansion including area at risk for subclinical disease; PTV1, planning target volume for the first phase of a sequential treatment involving more than one treatment volume, in this case a volume that included not only the GTV but also the CTV, as well as a margin or expansion to account for daily setup variations; PTV2, the planning target volume for the second phase of treatment, which, in this case, includes only the GTV plus a margin or expansion for daily setup variation; V, volume; D, dose; Gy, gray [RBE], a dose prescribed for protons intended to be radiobiologically equivalent [RBE] to the prescribed photon dose and to the physical photon dose divided by a factor of 1.1; IMPT, pencil beam scanning delivery of proton therapy using single-field uniform dose [SFUD] optimization and/or multifield uniform dose [MFUD] optimization treatment planning techniques; DS PT, double-scatter delivery of proton therapy; OARs, organs at risk; VMAT, photon-based intensity-modulated volumetric arc treatment planning; IMRT [not shown], photon-based intensity-modulated radiation therapy; V50.4 Gy and V73.8 Gy, the percentage of a target volume or OAR receiving a dose of 50.4 Gy [RBE] or 73.8 Gy [RBE]; D95% and D99%, the doses to 95% and 99%, respectively, of a target or OAR.)

Additional factors in comparing plans include the complexity of delivery, the robustness of the treatment plan, and the number of fields and time required for delivery. DS PT generally requires more fields and treatment delivery time; “through and patch” fields, which cover only parts of the target volume, are often necessary, with some fields treating “through” the target whereas others are “patched” in to fill gaps in dose coverage. Care must be taken to avoid placing potential hot spots in critical structures.

Advantages of IMPT over DS PT proton therapy are the avoidance of patch fields, less need for apertures and compensators, increased dose homogeneity within the target, and reduced utilization of room time; however, depending on

spot size, the penumbra of the scanned beams for IMPT may preclude its use in some cases. In this case, with minimal concern for organ motion, IMPT provided the best treatment plan. In other skull base sarcomas, the benefits from proton therapy may differ or differ in degree.

Paranasal Sinus Tumors

Paranasal sinus tumors frequently extend into the orbit or anterior cranial fossa adjacent to critical optic structures, such as the chiasm, optic nerves, retinae, lacrimal glands, cornea, and lens. With photon-based therapy, it is often difficult to deliver adequate doses to the entire tumor target without injury to at least one of the critical optic structures.[251] The physician often must choose between prioritizing tumor control and preserving vision. Figure 21.4 shows a comparison of IMRT and proton plans with both DS PT and IMPT delivery in a patient with a paranasal sinus tumor. All three plans were specified to deliver the prescribed dose of 50.4 Gy to the volume at standard risk for clinical and subclinical disease and 74.4 Gy to the high-risk volume containing gross disease.

As indicated in Figure 21.4A and B, target coverage with the IMRT1 plan (which was optimized for OAR protection) is inferior to both proton plans; the doses of 95% of the PTV1, 95% of PTV2, 99% of the gross tumor volume (GTV) were only 44, 53, and 62 Gy with the IMRT1 plan compared to 53, 71, and 74 Gy (RBE) with the DS PT plan and 53, 70, and 75 Gy (RBE) with the IMPT plan. The IMRT2 plan, which was optimized for target coverage, produced excellent target coverage but was considered unacceptable because of OAR exposures and hot spots in the PTV. As apparent in Figure 21.4A, compared with both proton plans, the IMRT plan exposes a much larger volume of nontargeted tissue to low-dose radiation, which includes the right temporal lobe, posterior fossa, oral cavity, and supratentorial brain. For example, the volumes of left and right temporal lobes receiving 20 Gy are 54% and 31% with the IMRT2 plan, 46% and 26% with the IMRT1 plan, 17% and 5% with the DS PT plan, and 11% and 5% with the IMPT plan.

All four plans struggle with the difficulty of target coverage and sparing of the critical structures. With each of these plans, there is only a small risk of brainstem and optic chiasm injury. However, none were able to sufficiently spare the left optic nerve to avoid a high risk of loss of vision in the left eye. Despite the addition of apertures to the IMPT plan to increase the sharpness of the dose gradient between the optic nerve and target volume, the DS PT plan still offered the best chance of preserving the right optic nerve. Although the proton plans

both offer obvious advantages over the photon-based plan, neither avoids the necessity of prioritizing either tumor control or avoidance of injury to a critical organ.

Dagan et al.[134] from the University of Florida (Jacksonville, FL) have reported on 84 adult patients with a variety of sinonasal tumors treated with proton therapy, most with accelerated hyperfractionated regimens and chemotherapy. Local control, disease-free survival, and overall survival rates were 83%, 63%, and 68% at 3 years with a grade 3 or higher unilateral vision loss rate of 2%. Russo et al.[137] from the Massachusetts General Hospital (Boston, MA), reported on 54 patients with nasal cavity and paranasal sinus tumors treated with proton therapy with a median follow-up of 82 months; 2- and 5-year local control rates were 80% and 2- and 5-year survival rates were 67% and 47%.

Oropharyngeal Cancers

Oropharyngeal carcinoma is the most common head and neck cancer. There is a rising incidence of p16-positive oropharyngeal carcinomas related to human papillomavirus exposure. In contrast to tobacco-related carcinomas, this p16+ population is generally younger and healthier, has a better chance for disease control, and is thus more likely to experience the late effects of radiation than their tobacco-related p16-negative counterpart.

Figure 21.5A depicts IMRT, DS PT, and IMPT plans in a patient with oropharyngeal carcinoma. As apparent in Figure 21.5A, there is significant sparing of the oral cavity, posterior neck, and contralateral parotid with both proton plans compared with the IMRT plan, likely impacting the risks of acute mucositis, alopecia, and xerostomia and the need for a feeding tube. The mean OAR doses (Gy [RBE]) for the IMRT, DS PT, and IMPT plans were 39, 22, and 10 for the esophagus; 26, 26, and 5 for the right cochlea; 53, 27, and 18 for the left submandibular gland; 46, 18, and 11 for the larynx; 58, 45, and 38 for the pharyngeal constrictors; 39, 19, and 16 for the oral cavity; 40, 20, and 17 for the mandible; 22, 11, and 10 for the left parotid; and 51, 48, and 40 for the right parotid. Although there are some advantages to DS PT over IMRT, the benefits with IMPT are more striking and consistent and suggest the possibility of significant improvements in xerostomia and swallowing compared with IMRT.

An early report from Slater et al.[140] from the Loma Linda University suggested better tolerance of oropharyngeal radiation therapy with the use of protons for a portion of the treatment. Gunn et al.[141] from the MD Anderson

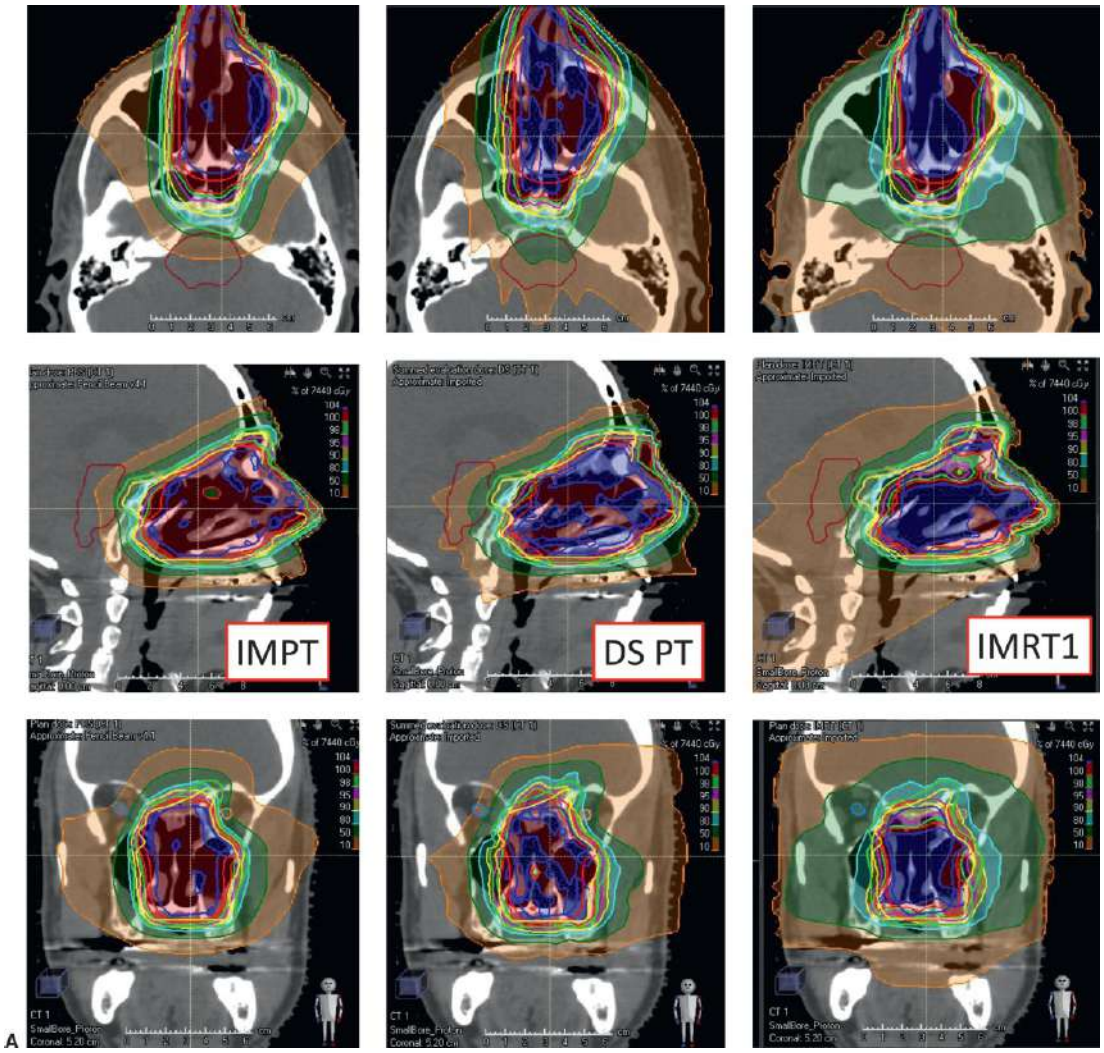
Cancer Center (Houston, TX) have reported 2-year overall and progression-free survival rates in advanced oropharyngeal cancer (98% stage III/IV) of 94.5% and 88.6% using IMPT. Blanchard et al.[142] reported a case-matched analysis of patients treated for oropharyngeal cancer at the MD Anderson Cancer Center with either IMRT or IMPT and showed equal disease control and survival rates but reduced rates of feeding tube dependency and severe weight loss among the patients treated with IMPT.

Pediatric Benign and Malignant Brain Tumors

Craniopharyngioma

Craniopharyngioma is usually diagnosed in children and adolescents. Its suprasellar location places the temporal lobes, hippocampi, hypothalamus, optic chiasm, and optic nerves at risk for radiation injury. Figure 21.6 shows IMRT, SRT, and DS PT plans in an adolescent patient. All three plans achieve target coverage goals of 54 Gy. Mean body and brain doses are 2.2 Gy and 9.2 Gy with IMRT, 2.2 Gy and 8.1 Gy with SRT, and 0.5 Gy (RBE) and 3.2 Gy (RBE) with DS PT. Some of the differences in relative mean organ doses with IMRT, SRT, and DS PT are as follows: in the right temporal lobe, 17%, 20%, and 8%; left temporal lobe, 18%, 22%, and 10%; left hippocampus, 50%, 61%, and 16%; right cochlea, 16%, 7%, and 0%; and left cochlea, 14%, 16%, and 1%, respectively. These reductions in dose to nontargeted brain tissues with proton therapy are likely to result in reduced loss in neurocognitive and auditory function.

A number of investigators have reported early outcomes in medulloblastoma, ependymoma, craniopharyngioma, and other tumors. Indelicato et al.[226] reported on a variety of pediatric brain tumors referred for treatment from overseas; within this cohort, the 3-year disease control rate for craniopharyngioma was 100%. Extensive work from Merchant et al.[219] at the St. Jude Children's Research Hospital in a variety of pediatric brain tumors has correlated the risk of radiation-related neurocognitive decline to radiation dose level and distribution; there is emerging evidence that proton therapy may cause less neurocognitive decline than conventional radiation consistent with dosimetric predictions; however, long-term data will be necessary to fully understand potential benefits.[215]



A

Targets	Goal Value	IMPT	DS PT	IMRT1	IMRT2*

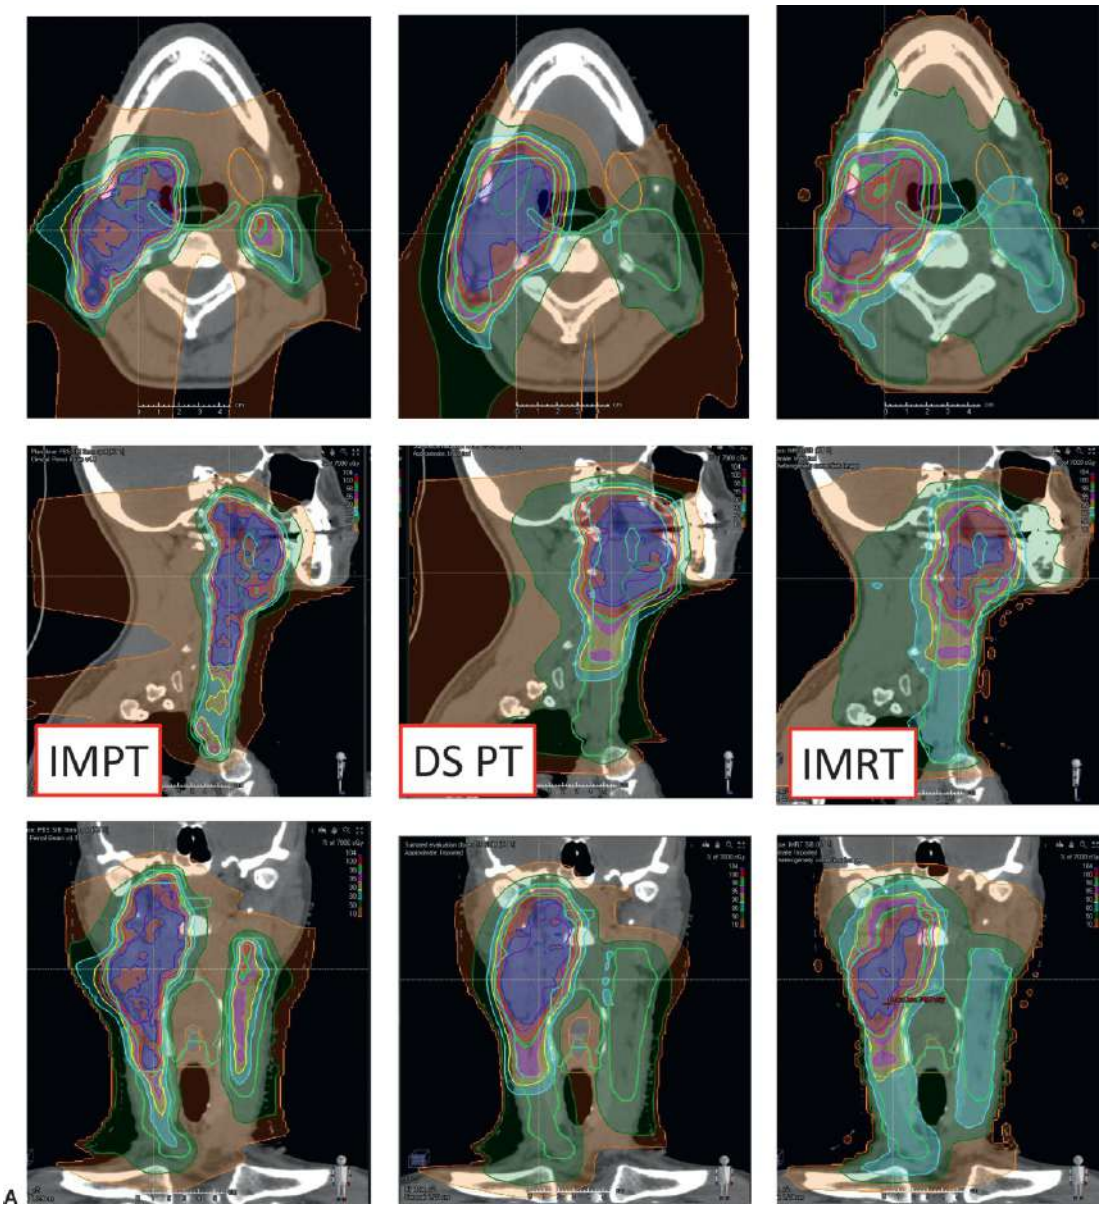
FIGURE 21.4. A: Axial, sagittal, and coronal displays of the dose distributions achieved with IMPT, DS PT, and IMRT for a **paranasal sinus tumor**. The *thick red line* indicates the GTV and the *thin red line* indicates the brainstem. The *color wash* indicates the radiation dose levels achieved with each treatment plan; the inner *bright blue wash* and *line* indicate the isodose volume receiving 104% of the prescribed radiation dose. The remaining colored regions indicate the following: *red*, isodose volume receiving the prescribed dose of 74.4 Gy (RBE); *bright green*, volume receiving 98% of the prescribed dose; *magenta*, volume receiving 95% of the prescribed dose; *yellow*, volume receiving 90% of the prescribed dose; *aqua*, volume receiving 80% of the prescribed dose; *dark green*, volume receiving 50% of the prescribed dose, and *orange*, volume receiving 10% of the prescribed dose. The goals of the plans were to deliver at least 50.4 Gy (RBE) to the PTV SR, at least 74.4 Gy (RBE) to the PTV HR, and a dose of 74.4 Gy (RBE) to 99% of the CTV HR while respecting dose constraint goals for organs at risk (OAR). The treatment plan delivered a total daily dose of 2.4 Gy (RBE) divided in 2 fractions of 1.2 Gy (RBE) delivered at least 6 hours apart. Two IMRT plans were created for comparison with the two proton plans, one prioritizing OAR protection (IMRT1) and one prioritizing target coverage (IMRT2), which is not shown. (IMPT, pencil beam scanning delivery of proton therapy using single-field uniform dose [SFUD] optimization and/or multifield uniform dose [MFUD] optimization treatment planning techniques; DS PT, double-scatter delivery of proton therapy; IMRT, photon-based intensity-modulated radiation therapy ; CTV SR, clinical target volume including both gross tumor and an area at “standard risk” for subclinical disease; CTV HR, clinical target volume at “high risk” for gross tumor and a high burden of subclinical disease; PTV, clinical target volume plus a margin or expansion for daily setup variations; OARs, organs at risk; PRV, planning risk volume, an OAR volume plus an expansion to account for daily setup variations.) **B:** A DVH analysis of IMPT, DS PT, and IMRT for the **paranasal sinus tumor** depicted in **(A)**. The goals of the plans were to deliver at least 50.4 Gy (RBE) to the

PTV SR, at least 74.4 Gy (RBE) to the PTV HR, and a dose of 74.4 Gy (RBE) to 99% of the CTV HR while respecting dose constraint goals for the OARs. Treatment was planned to deliver a total daily dose of 2.4 Gy (RBE) in 2 fractions of 1.2 Gy (RBE) per day as smaller doses per fraction have been associated with improved radiation tolerance in the optic structures, which, in this case, are partially contained within the PTV HR. Two IMRT plans were created for comparison with the two proton plans, one which prioritized OAR protection (IMRT1) and one which prioritized target coverage (IMRT2). Both proton plans and the IMRT2 plan were significantly better able than the IMRT1 plan to deliver the prescribed dose of 50.4 Gy (RBE) to the PTV SR with doses of 53 Gy (RBE), 53 Gy (RBE), 44 Gy (RBE), and 67 Gy (RBE) to 95% of the PTV SR with IMPT, DS PT, IMRT1, and IMRT2, respectively. Although the IMRT2 plan best achieved the goal of delivering at least 74.4 Gy (RBE) to at least 95% of the PTV HR, it did so with a “hot spot” of 98.85 Gy (RBE) to 2% of the PTV HR [not shown]. Although not achieving the PTV HR goal, the proton plans both provided acceptable coverage of the PTV HR, in contrast to the IMRT1 plan, with doses of 70 Gy (RBE), 71 Gy (RBE), 53 Gy (RBE), and 77 Gy (RBE) to 95% of the PTV HR with IMPT, DS PT, IMRT1, and IMRT2, respectively. With respect to OAR protection, all four plans would likely preserve optic chiasm function but result in left optic nerve injury and unilateral blindness. Therefore, preservation of the right optic nerve was a high priority. The IMRT2 plan would almost certainly result in right optic nerve injury and thus bilateral blindness; the DS PT plan provided the lowest dose to the right optic nerve and thus the best hope of preserving unilateral vision. The better sparing of the right optic nerve with DS PT compared with IMPT is related to the penumbra at a depth of even a 3-mm pencil beam scanning spot size and the sharper penumbra achievable with apertures with the DS PT. The best preservation of unilateral vision with DS PT would carry a small risk of brainstem injury. Most of the other OARs show significant dose reduction with both proton plans compared to both IMRT plans, generally with the best sparing achievable with IMPT. In this case, the IMRT2 plan would be rejected due to the risk of bilateral blindness and an unacceptable hot spot of 98.85 Gy (RBE). The IMRT1 plan would be rejected due to inferior target coverage. The choice between IMPT and DS PT would be difficult but probably favors DS PT for the best chance of unilateral vision preservation with only a very small risk of brainstem injury. (IMPT, pencil beam scanning delivery of proton therapy using single-field uniform dose [SFUD] optimization and/or multifield uniform dose [MFUD] optimization treatment planning techniques; DS PT, double-scatter delivery of proton therapy; IMRT, photon-based intensity-modulated radiation therapy; CTV SR, clinical target volume including both gross tumor and an area at “standard risk” for subclinical disease; CTV HR, clinical target volume at “high risk” for gross tumor and a high burden of subclinical disease; PTV, clinical target volume plus a margin or expansion for daily setup variations; N/A PT, not applicable to proton therapy; D95%, the minimum dose to 95% of the volume of a target or OAR ; D99%, the minimum dose to 99% of the volume of a target or OAR. OARs, organs at risk; PRV, planning risk volume, an OAR volume with an expansion to account for daily setup variations; Gy, gray; Gy [RBE], a dose prescribed for protons intended to be radiobiologically equivalent to the prescribed photon dose and to the physical photon dose divided by a factor of 1.1.)

Craniospinal Axis Irradiation

Craniospinal axis irradiation is required in most medulloblastomas and occasionally in other brain tumors, such as advanced or metastatic germ cell

tumors, primitive neuroectodermal tumors, and ependymomas. Most patients with these tumors are young and at risk for late effects of radiation. As shown in Figure 21.7, the exit dose from photon therapy exposes the thyroid, heart, lung, gut, and gonads to functional and neoplastic risks that can be avoided with proton therapy. The total-body V_{10} and total-body integral dose in this case are 37.2% and 0.223 Gy-m^3 with 3DCRT compared with 28.7% and 0.185 Gy-m with DS PT, a reduction likely to result in a lower risk of second malignancy.



Targets	Goal Value	PBS PT	DS PT	IMRT
PTV SR (N/A PT)	D95% ≥50 Gy	48.54	51.21	56.50
PTV IR (N/A PT)	D95% ≥63 Gy	61.31	66.48	64.07
PTV HR (N/A PT)	D95% ≥70 Gy	69.55	71.61	70.00
CTV SR	D99% ≥50 Gy	51.49	51.36	56.73
CTV IR	D99% ≥63 Gy	65.35	66.09	64.28
CTV HR	D99% ≥70 Gy	70.00	71.54	70.05

OARs	Goal Value	PBS PT	DS PT	IMRT

B

FIGURE 21.5. A: IMPT, DS PT, and IMRT plans for a patient with a node-positive right-sided **oropharyngeal cancer**. The CTV HR is indicated by the *thick red line*. The goals of the treatment plans were to deliver at least 50 Gy (RBE) to the PTV SR, 63 Gy (RBE) to the PTV IR, and 70 Gy (RBE) to the PTV HR. (IMPT, pencil beam scanning delivery of proton therapy using single-field uniform dose [SFUD] optimization and/or multifield uniform dose [MFUD] optimization treatment planning techniques; DS PT, double-scatter delivery of proton therapy; IMRT, photon-based intensity-modulated radiation therapy; CTV HR, clinical target volume at high risk for subclinical and gross clinical disease; CTV IR, clinical target volume at intermediate risk for subclinical and gross disease; CTV SR, clinical target volume at standard risk for subclinical disease plus gross disease; PTV, CTV plus a margin or expansion to account for daily setup variations; Gy [RBE], a dose prescribed for protons intended to be radiobiologically equivalent to the prescribed photon dose and to the physical photon dose divided by a factor of 1.1.) **B:** DVH comparison for the IMPT, DS PT, and IMRT plans shown in **A**. The goals of the treatment plans were to deliver at least 50 Gy [RBE] to the PTV SR, 63 Gy [RBE] to the PTV IR, and 70 Gy [RBE] to the PTV HR. All plans provided adequate and similar doses to the PTV SR, PTV IR, and PTV HR, with the IMPT plan slightly below goals. However, with the exception of the right (ipsilateral) submandibular gland, the doses to all OARs were significantly reduced with IMPT compared with the DS PT and IMRT plans. The DS PT plan provided reduced doses to the esophagus, left submandibular gland, mandible, pharyngeal muscle constrictors, and larynx compared to the IMRT plan. In this case, both proton plans appear to be superior to the IMRT plan, but the IMPT plan was also superior to the DS PT plan for OAR protection. (IMPT, pencil beam scanning delivery of proton therapy using single-field uniform dose [SFUD] optimization and/or multifield uniform dose [MFUD] optimization treatment planning techniques; DS PT, double-scatter delivery of proton therapy; IMRT, photon-based intensity-modulated radiation therapy; CTV HR, clinical target volume at high risk for subclinical and gross clinical disease;

CTV IR, clinical target volume at intermediate risk for subclinical and gross disease; CTV SR, clinical target volume at standard risk for subclinical disease plus gross disease; PTV, CTV plus a margin or expansion to account for daily setup variations. OAR, organ at risk; D95%, the minimum dose to 95% of a target volume or OAR; D99%, the minimum dose to 99% of a target volume or OAR; DVH, dose–volume histogram; Gy, gray; Gy [RBE], a dose prescribed for protons intended to be radiobiologically equivalent [RBE] to the prescribed photon dose and to the physical photon dose divided by a factor of 1.1.)

In a multi-institutional cohort study of 88 children treated with chemotherapy and either photon or proton radiation for standard-risk medulloblastoma, Eaton et al.[220] found no significant difference in disease control, survival, or patterns of failure between proton and photon radiation, suggesting equivalent efficacy. Barney et al.,[252] reporting on 50 patients treated with proton craniospinal irradiation at the MD Anderson Cancer Center between 2007 and 2011, documented extremely low median radiation doses to the thyroid of 0.003 Gy (RBE); the lung 1.1 Gy (RBE), heart 0.002 Gy (RBE), kidney 0.04 Gy (RBE), bowel 0.02 Gy (RBE), testicles 0.003 Gy (RBE), and ovaries 0.003 Gy (RBE). Treatment-related morbidity in this series included grade 3 leukopenia in 9%, thrombocytopenia in 2%, and median weight loss of 1.1 kg or 1.6% loss from baseline. Progression-free survival rates at 2 and 5 years were 82% and 68%, with 80% of treatment failures involving a local recurrence. These data suggest that craniospinal irradiation with proton therapy is effective but potentially much less toxic acutely and much less likely to result in late effects.

Lymphomas

Lymphomas frequently involve the mediastinum and often require a low-to-moderate dose of radiation therapy in conjunction with chemotherapy for maximum probability of disease control. Unfortunately, even low-to-moderate radiation doses place the patient at risk for late cardiac injury and second cancers, particularly breast cancers. Figure 21.8 shows a comparison of 3DCRT, IMRT, and DS PT plans in a young woman with Hodgkin lymphoma. The proton plan shows a significant reduction in the volume of the heart, lung, breast, spinal cord, and other soft tissues exposed to low-dose irradiation. Mean lung V_4 and lung V_{20} are 59% and 25% with 3DCRT, 62% and 10% with IMRT, and 31% and 16% with DS PT. Mean cardiac V_4 and cardiac V_{20} are 79% and 54% with 3DCRT, 76% and 26% with IMRT, and 40% and 26% with DS PT, respectively. These reductions are likely to result in lower risks of late cardiac injury and second malignancy.

In a variety of settings in a single institution as well in a multi-institutional registry study, Hoppe et al.[188–193,195,196,229] have reported minimal acute toxicity and excellent early disease control outcomes with proton therapy in lymphoma. Pinnix et al.[253] from the MD Anderson Cancer Center have reported that small doses to large volumes of lung had the greatest influence on the risk of radiation pneumonitis in patients receiving IMRT for lymphoma, so it is likely that the reductions in volumes of lung receiving low doses with PT, compared with IMRT, will result in lower rates of pulmonary injury.

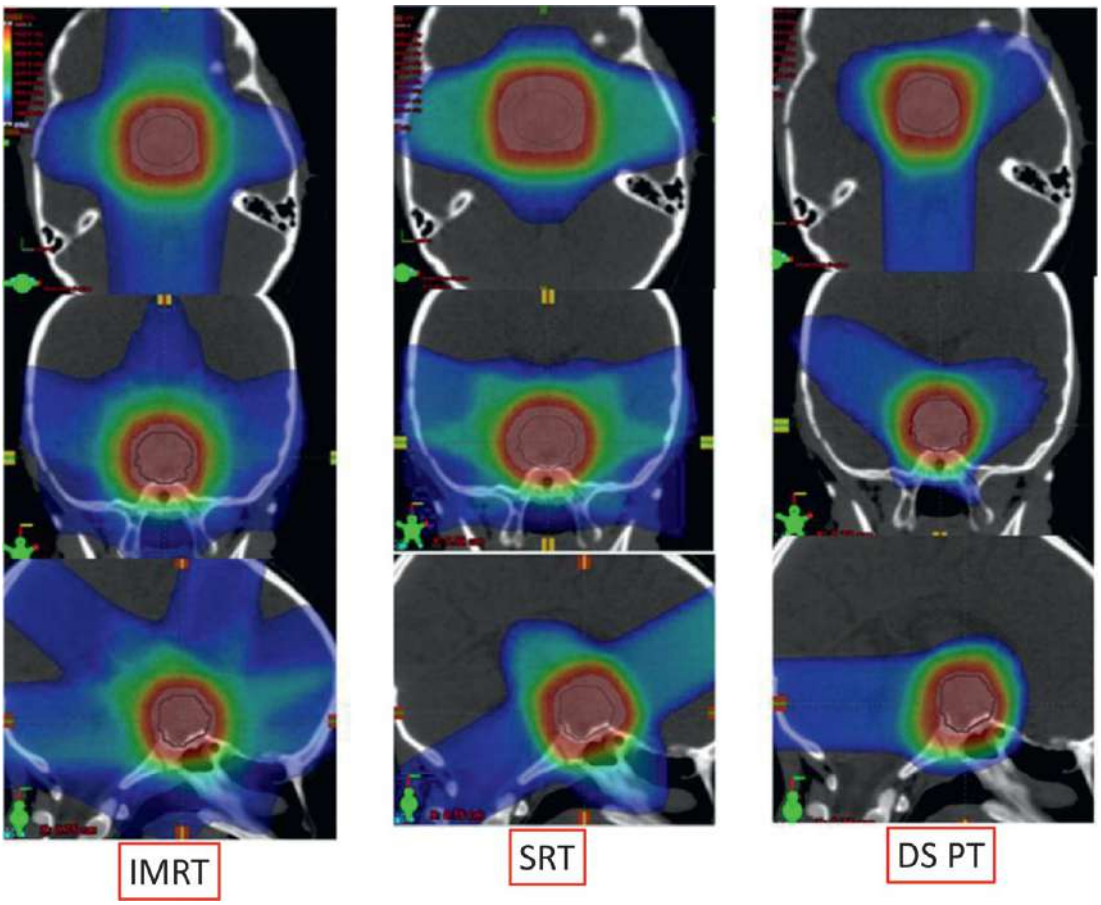

FIGURE 21.6. Axial, coronal, and sagittal displays of the dose distributions achieved with IMRT (*left*), SRT (*center*), and DS PT (*right*) plans for a small **craniopharyngioma**. The prescription dose was 54 Gy (RBE) to the PTV. All treatment techniques provided excellent conformal coverage of the target. As apparent, the volume of tissue exposed to low- and intermediate-dose irradiation is reduced with the DS PT plan. A DVH comparison of doses to OARs showed mean body and mean brain doses, excluding the PTV, of 233 cGy and 888 cGy with IMRT, 215 cGy and 810 cGy with SRT, and 63 cGy (RBE) and 358 cGy (RBE) with PT, respectively. The mean right temporal lobe doses are 904 cGy with IMRT, 1,090 cGy with SRT, and 297 cGy (RBE) with PT. The mean left temporal doses are 951 cGy with IMRT, 1200 cGy with SRT, and 370 cGy (RBE) with PT. The mean left hippocampal doses are 2,749 cGy with IMRT, 3,299 cGy with SRT, and 815 cGy

(RBE) with PT. The mean right cochlear doses are 807 cGy with IMRT, 388 cGy with SRT, and 7 cGy (RBE) with PT. The mean left cochlear doses are 792 cGy with IMRT, 887 cGy with SRT, and 5 cGy (RBE) with PT. (IMRT, photon-based intensity-modulated radiation therapy; SRT, photon-based stereotactic radiation therapy; DS PT, double-scatter delivery of proton therapy. GTV, gross residual tumor volume; CTV, GTV plus volume at risk for subclinical disease; PTV, CTV plus a margin or expansion to account for daily setup variations. OAR, organs at risk for radiation injury. Gy, gray; cGy, 1/100th of a Gy; Gy [RBE], a dose prescribed for protons intended to be radiobiologically equivalent [RBE] to the prescribed photon dose and to the physical photon dose divided by a factor of 1.1.)

Lung Cancers

Lung cancers typically are diagnosed at an advanced stage and often occur in patients with underlying lung damage. Consequently, concern for protection of unaffected lung tissue often mandates compromise in the tumor dose. Figure 21.9 shows IMRT and proton plans in a patient with stage III lung cancer. As apparent, a smaller volume of nontargeted lung tissue, spinal cord, esophagus, and heart is exposed to radiation with proton therapy. With 3DCRT, IMRT, and DS PT, the mean lung doses were 11.7 Gy, 14.2 Gy, and 8.2 Gy (RBE); lung V5s were 36%, 50%, and 21%; lung V20s were 23%, 22%, and 13%; mean heart doses were 11.6 Gy, 7.1 Gy, and 5.5 Gy (RBE); and mean esophageal doses were 34 Gy, 26.2 Gy, and 21.7 Gy (RBE).

Chun et al.[254] reporting secondary analyses from RTOG 0617, a randomized trial of 60 Gy versus 74 Gy with concurrent chemotherapy using carboplatin and paclitaxel with or without cetuximab, showed that lung V20 was associated with increased ≥3 pneumonitis risk ($P = .026$) and the cardiac V40 was associated with overall survival ($P < .05$). In a retrospective study, Wang et al.[255] found significant associations between mean heart doses and symptomatic cardiac events in an analysis that accounted for WHO/International Society of Hypertension scores and history of coronary artery disease; the 2-year competing risk-adjusted event rates for patients with heart mean doses of <10, 10 to 20 Gy, and ≥20 Gy were 4%, 7%, and 21%, respectively. In the case illustrated above, the proton plan produces a dose distribution that carries a lower risk of acute (potentially fatal) pneumonitis, likely impacting the delivery of chemotherapy; the proton therapy plan also lowers the cardiac exposure, possibly correlating with a greater chance of survival.

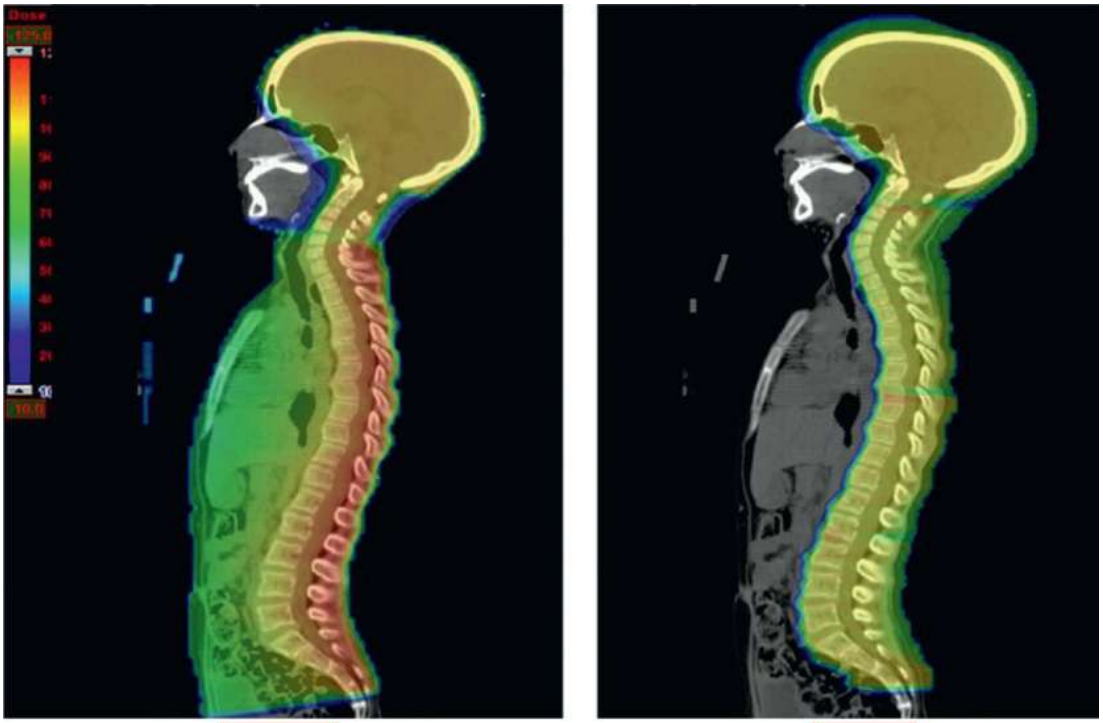

FIGURE 21.7. Sagittal planes from 3DCRT plans (*left*) and DS PT plans (*right*) for **craniospinal irradiation** necessary in a variety of brain tumors, most of which occur in young patients at risk for late effects. As apparent in the figure, the risks for functional and neoplastic effects in the thyroid, heart, lungs, breast, gut, and gonads from photon therapy can be avoided with proton therapy because of the lack of an exit dose. The total-body V10 and total-body integral doses are 37.2% and 0.223 Gy-m^3 with 3DCRT compared with 28.7% and 0.185 Gy-m^3 with proton therapy. (3DCRT, photon-based three-dimensional conformal radiation therapy; DS PT, double-scatter delivery of proton therapy. Total-body V10 = the relative percentage of total body receiving a dose of 10 Gy.)

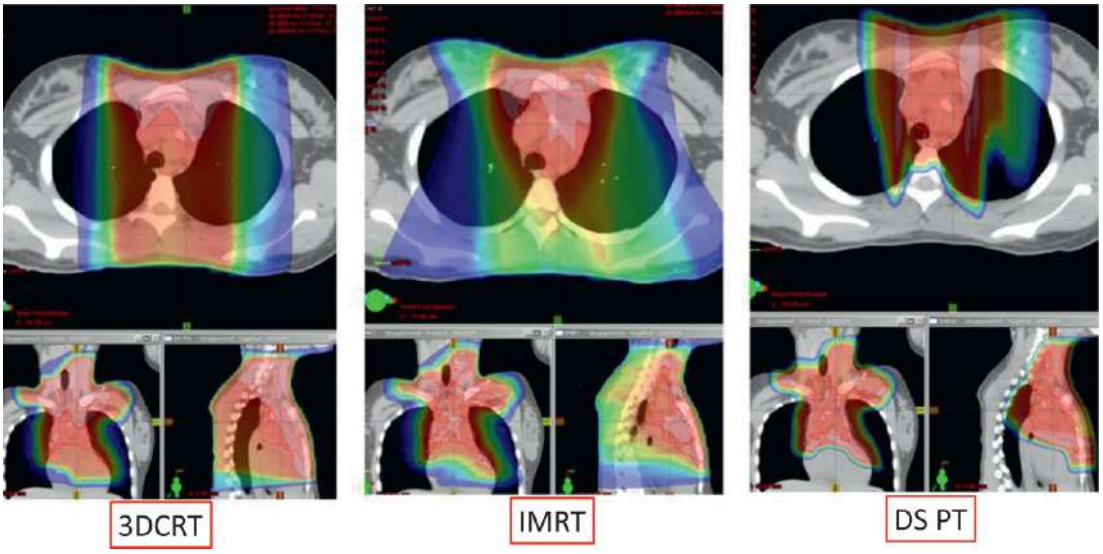

FIGURE 21.8. Axial, coronal, and sagittal planes are shown for 3DCRT (*left*), IMRT (*center*), and DS PT (*right*) for a female patient with neck and mediastinal involvement with Hodgkin lymphoma. As apparent, the proton therapy plans expose a smaller volume of nontargeted tissue (particularly the heart, lung, spinal cord, and breast) to radiation than either photon plan. Lung V4 and V20 are 59% and 25% with 3DCRT, 62% and 10% with IMRT, and 32% and 16% with proton therapy, respectively. Heart V4 and V20 are 79% and 54% with 3DCRT, 76% and 26% with IMRT, and 40% and 26% with proton therapy, respectively. (3DCRT, photon-based three-dimensional conformal radiation therapy; IMRT, photon-based intensity-modulated radiation therapy; DS PT, double-scatter delivery of proton therapy; V, volume; V4, the relative volume [%] of an organ receiving 4 Gy; V20, the relative volume [%] of an organ receiving 4 Gy.)

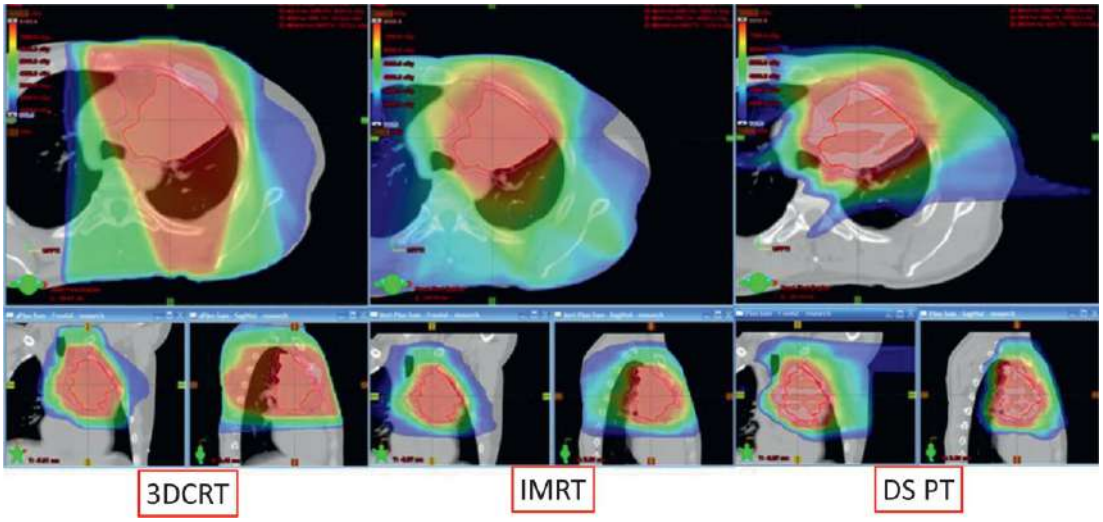

FIGURE 21.9. Axial, coronal, and sagittal planes are shown for 3DCRT (*left*), IMRT (*center*), and DS PT (*right*) for a patient with lung cancer. As apparent, both the IMRT and DS PT plans reduce the volume of nontargeted tissue receiving high-dose irradiation. The DS PT plan further reduces the volume of nontargeted tissue receiving low- and intermediate-dose irradiation compared to both the 3DCRT and IMRT plans. 3DCRT, IMRT, and DS PT plans, respectively, produced mean lung doses of 11.7 Gy, 14.2 Gy, and 8.2 Gy (RBE); lung V5 of 36%, 50%, and 21%; lung V10 of 27%, 37%, and 18%; lung V20 of 23%, 22%, and 13%; mean heart doses of 11.6 Gy, 7.1 Gy, and 5.5 Gy (RBE); and mean esophageal doses of 34 Gy, 26.2 Gy, and 21.7 Gy (RBE). (3DCRT, photon-based three-dimensional conformal radiation therapy; IMRT, photon-based intensity-modulated radiation therapy; DS PT, double-scatter delivery of proton therapy; V, volume; V5, the relative volume or percentage of an organ receiving 5 Gy; V10, the relative volume or percentage of an organ receiving 10 Gy; V20, the relative volume or percentage of an organ receiving 20 Gy; Gy [RBE], a dose prescribed for protons intended to be radiobiologically equivalent [RBE] to the prescribed photon dose and to the physical photon dose divided by a factor of 1.1.)

Pancreatic Cancers

Pancreatic cancers have an extremely low therapeutic ratio with radiation alone or combined with surgery and chemotherapy. The disease is frequently localized for a window of time before spreading, providing a potential opportunity to

improve the overall outcome by intensifying local therapy. Figure 21.10 shows IMRT and proton therapy plans for a patient with cancer in the pancreatic head. As apparent, there is much less low-to-intermediate dose to the bowel, kidney, and liver with the proton plan. Mean doses with IMRT and DS PT are 1,174 cGy and 760 cGy (RBE) to the liver and 1,705 cGy and 443 cGy (RBE) to the small bowel, respectively. Although mean right and left kidney doses are similar for the IMRT and DS PT plans, over 40% of the left kidney tissue is unirradiated with the proton therapy plan. This savings in normal-tissue exposure may be leveraged to permit either radiation or chemotherapy dose escalation or intensification, potentially increasing the opportunity for complete surgical resection, cure, or both. It is unclear whether motion management of upper abdominal organs is sufficient at this time to employ IMPT techniques, which may provide further sparing of critical organs.

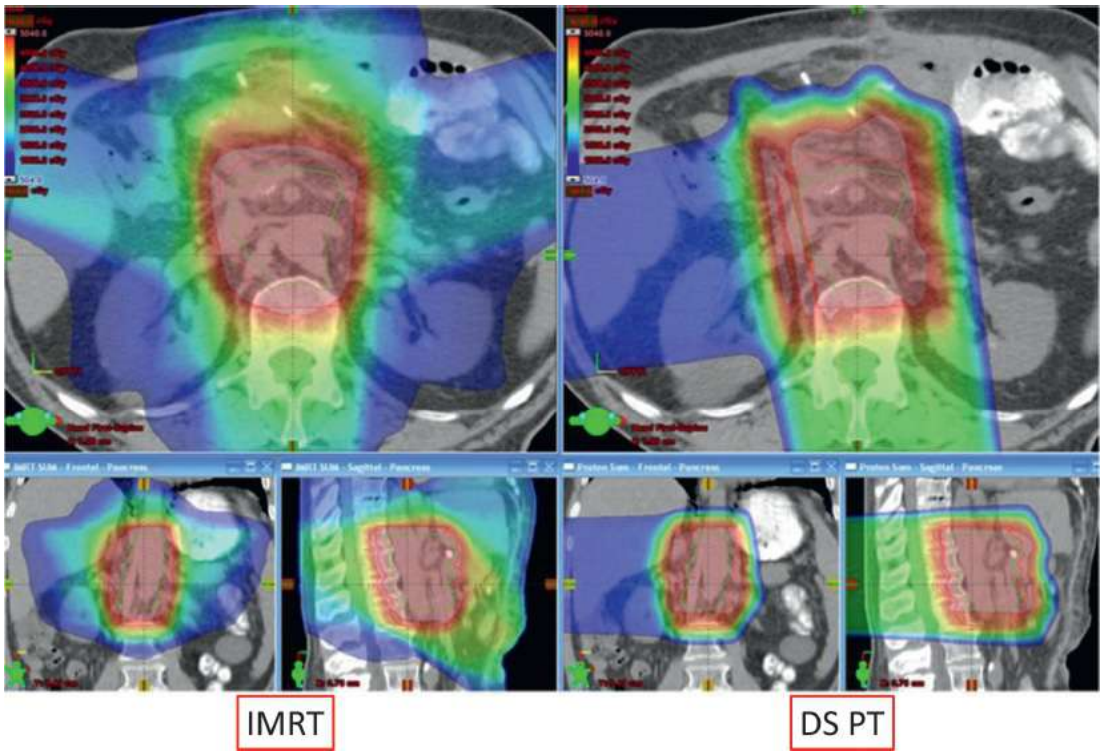

FIGURE 21.10. Axial, coronal, and sagittal planes of IMRT (*left*) and DS PT (*right*) plans for a **pancreatic head carcinoma**. As apparent, there is much less low-to-intermediate dose to the bowel, kidney, and liver with the proton plan. Mean doses with IMRT and proton therapy are 1,174 cGy and 760 cGy (RBE) to the liver and 1,705 cGy and 443 cGy (RBE) to the small bowel, respectively. Although mean right and left kidney doses are similar for the IMRT and proton therapy plans, over 40% of the left kidney tissue is unirradiated with the proton therapy plan. (IMRT, photon-based intensity-modulated radiation therapy; DS PT, double-scatter delivery of proton therapy; Gy, gray; Gy [RBE], a dose prescribed for protons intended to be radiobiologically equivalent to the prescribed photon dose and to the physical photon

dose divided by a factor of 1.1.)

Hong et al.[208] reported phase 1/2 trial from Massachusetts General Hospital of neoadjuvant short-course proton therapy with capecitabine followed by surgery and adjuvant gemcitabine. Proton therapy was delivered to the pancreas and draining lymphatics to 25 Gy (RBE) in 5 fractions. Surgery was performed in 37 of the 50 patients with the findings of positive nodes in 81%, positive margins in 16%, and no pathologic complete responses. The median progression-free and overall survival times in the 37 patients who had surgery were 14.5 months and 27 months with 16% experiencing locoregional recurrence. The rate of grade 3 or higher toxicity was 4.1%. The same institution performed a separate phase 1 trial of photon-based stereotactic body radiation therapy using the same treatment volumes and dose fractionation regimen; this study was terminated early because of intraoperative toxicity.[209] The investigators concluded that preoperative proton therapy was feasible and well tolerated and that it did not delay surgical resection. Nichols et al.[206] reported on the University of Florida experience with 22 patients treated with concomitant capecitabine and proton therapy for resected (n = 5), marginally resectable (n = 5), and inoperable (n = 12) pancreatic and ampullary carcinomas. Doses ranged from 50.4 to 59.4 Gy (RBE). No grade 3 or higher toxicity was observed. Median weight loss was 1.3 kg or 1.75% of the body weight, and 99% of the prescribed chemotherapy doses were given. Two of the twelve patients with inoperable disease achieved excellent radiographic responses, including one pathologically documented complete response. Despite the much higher radiation dose delivered in the University of Florida experience, the University of Florida experience confirmed the low rate of gastrointestinal toxicity with proton therapy observed by Hong et al.,[208] suggesting the potential for improvement in efficacy through dose escalation to accomplish complete pathologic responses. Neither proton experience delayed surgery or resulted in increased surgical complications, suggesting an additional potential value of proton therapy in facilitating both surgical resection and chemotherapy intensification.

Breast Cancer

Among breast cancer patients, there is level I evidence for treating all regional nodes, including internal mammary nodes and axillary nodes, in patients at risk for residual disease after surgery because of positive axillary nodes, tumor size,

and in some cases tumor location and grade.[256–264] There is also growing interest in minimizing dose to the heart and lung as increases in late cardiac and pulmonary morbidity and mortality continue to be documented.[256,257,265–268] The excess in cardiac disease has primarily been associated with left-sided breast cancer patients[256,266,268] presumably because a greater volume of the heart is exposed to radiation with left-sided breast cancers compared with right-sided breast cancers. More recently, evidence suggests that the risk of heart disease may be related to dose–volume histogram parameters,[265] which has led groups to recommend minimizing heart exposure to radiation as much as possible.[269,270]

Figure 21.11A shows comparative treatment plans for a breast cancer patient receiving left-sided breast and regional node irradiation using IMRT, DS PT, and IMPT plans. As indicated in Figure 21.11B, there is excellent coverage of the breast with all plans. Coverage of the axillary and supraclavicular nodes is similar among the plans, but coverage of the internal mammary nodes is inferior with IMRT (44 Gy) compared with both the DS PT and IMPT plans (50 Gy [RBE]). Striking differences are apparent among the IMRT, DS PT, and IMPT plans in heart V10s, 23%, 2%, and 3%; mean heart doses, 7, <1, and 1; mean LAD doses, 14, 2, and 2; and left lung V5s, 85%, 27%, and 38%.

MacDonald et al.[186] from the Massachusetts General Hospital reported the acute toxicity and feasibility of proton therapy in a prospective trial of 12 postmastectomy patients; at a median follow-up of 6 months, there were no cases of pneumonitis and maximum skin toxicity was grade 2. Bradley et al.[185] from the University of Florida have reported a pilot study of proton therapy for right- and left-sided cancers (stage IIA to IIIB) after either breast-conserving therapy or mastectomy. The study included a treatment plan comparison of PT DS and conventional radiation plans, with the best treatment plan recommended to the patient. The proton plans were consistently better for coverage of the internal mammary nodes ($P = .0005$), minimization of cardiac V5 ($P < .0001$), and minimization of ipsilateral lung V5 and V20 ($P < .0001$). The only grade 3 toxicity was radiation dermatitis observed in 22% of patients.

Prostate Cancer

The recent ProtecT trial has underscored (1) the importance of early definitive treatment for prostate cancer in men with a ≥10-year life expectancy to maximize freedom from distant metastases[271] and (2) documented increased toxicity with surgery compared to radiation therapy without an attendant increase in disease control.[272] These findings are likely to change patterns of

care by increasing the role of radiation therapy in prostate cancer. Prostate cancer results with radiation therapy are generally excellent, but dose escalation trials indicate that increasing the dose to the prostate is associated with improved disease control.[171,273–275] Dose escalation photon-based trials from the RTOG also show that increasing dose, dose per fraction, and the volume of the rectum exposed to a high-radiation dose are associated with an increased risk of rectal toxicity.[276] Analysis of outcome data with proton therapy indicates a similar correlation between increasing volume of rectal wall receiving high doses and the risk of gastrointestinal toxicity.[277] Hypofractionation of the treatment regimen is of great interest in prostate cancer, and studies have demonstrated similar outcomes[278,279] but often more toxicity[280] so that attention to radiation exposure of the OARs is critically important.[281] Most physician-reported gastrointestinal toxicity has been temporary rectal bleeding or ulceration.[277] However, rectal urgency, frequency, and incontinence have been identified as problems that may occur later, persist, and significantly impact long-term patient-reported quality of life.[282–285] This symptom complex has been found to be related to reduced rectal elasticity and sphincter tone,[282,286] and these symptoms have been associated with the volumes of anus and rectum receiving 5 to 40 Gy.[281,287,288] Comparative IMRT and proton dosimetry studies[84,289] have shown that with historical techniques for prostate stabilization, the volumes of the rectum and rectal wall receiving high-radiation doses associated with rectal bleeding and ulceration are similar; however, the volume of the rectum and rectal wall receiving low-to-moderate doses is significantly less with proton therapy compared to IMRT. It is likely that strategies to create distance between the anterior rectal wall and posterior prostate[290,291] will reduce the risk of rectal bleeding and/or ulceration in eligible patients receiving either photon- or proton-based radiation, so the main gastrointestinal issue will become rectal urgency and frequency. At this point, bladder and urethral toxicities with photon- and proton-based external beam radiation have not clearly been associated with dose–volume parameters; however, with dose escalation or hypofractionation of treatment, this may change.

The most controversial indication for proton therapy at this time is prostate cancer. More than 20,000 men with prostate cancer have been treated with proton therapy or a combination of proton therapy and photon therapy with excellent results; however, it is unclear whether outcomes with proton therapy in prostate cancer are superior to outcomes with photon-based therapy. Tables 21.1 and 21.2 show disease control and toxicity rates for early dose escalation trials

and contemporary proton and photon experiences with standard and hypofractionated radiation regimens.[170–173,182,273–275,278,279,298,299] Disease control and toxicity rates with proton experiences compare favorably with contemporaneous photon experiences. A comparison of prospectively collected patient-reported quality of life data from cohorts of men treated with IMRT and proton therapy has shown similar overall functional summary scores but significant differences in selected questions that potentially reflect radiation injuries associated with the volume of the rectum receiving low-to-moderate doses,[300] perhaps providing the first evidence of anticipated differences in functional outcomes related to proton and photon therapy reported directly by patients.

Figure 21.12 shows VMAT, DS PT, and IMPT plans for two patients with low-risk prostate cancer, the first with a large median lobe and the second with more typical prostate anatomy. As apparent, the rectal volumes receiving 25 Gy and 45 Gy are generally lower with both proton plans than with the VMAT plan and lowest with the IMPT plan. Treatment planning is rapidly evolving for both VMAT and IMPT, and the relative value of high-dose conformality versus minimization of integral dose in prostate cancer will require further investigation.

FIGURE 21.11. A: IMPT, DS PT, and IMRT plans for a woman with a left-sided node-positive breast cancer. Targets included the internal mammary; levels I, II, and III axillary; and supraclavicular nodal areas as well as the breast. The prescribed dose is 50 Gy to the breast PTV and nodal PTV. (IMPT, pencil beam scanning delivery of proton therapy using single-field uniform dose [SFUD] optimization and/or multifield uniform dose [MFUD] optimization treatment planning techniques; DS PT, double-scatter delivery of proton therapy; IMRT, photon-based intensity-modulated radiation therapy; PTV, the clinical target volume, which includes the volume at risk for clinical and subclinical disease, plus a margin or expansion to account for daily setup variations.) **B:** Comparison of treatment plans for left-sided node-positive breast cancer shown in Figure 21.10A. The prescribed dose is 50 Gy to the breast PTV and nodal PTV. The DVH goals were to deliver a dose of 47.5 Gy to at least 95% of the breast PTV and to deliver at least 45 Gy to 95% of the nodal target volumes. As apparent from the DVH comparison, all three plans met the target coverage goals for the breast and SCV and axillary nodal targets. The DS PT and IMRT plans had “hot spots” within the breast volume of 57 Gy (RBE) and 64 Gy, respectively. The IMRT plan provided inferior coverage of the IMN compared with either proton plan. With respect to the OARs, the heart V10, mean heart dose, and LAD mean dose were all substantially higher with the IMRT plan than either proton plan. The volume of lung receiving a dose of 20 Gy, 10 Gy, and 5 Gy and the volume of ventricles receiving a dose of 5 Gy were all substantially greater in the IMRT plan than in either proton plan. (DVH, dose–volume histogram; PTV, planning target volume; DS PT, double-scatter delivery of proton therapy; IMRT, photon-based intensity-modulated radiation therapy; SCV, supraclavicular; IMN, internal mammary nodes; LAD, left anterior descending

artery.)

FIGURE 21.12. A: Axial, sagittal, and coronal planes of treatment plans with VMAT, DS PT, and IMPT for a **prostate cancer** patient with a very large median lobe, which protruded into the bladder, making it difficult to meet dose constraints to the bladder wall. The target volume is shown in the heavy *magenta line*, the bladder is outlined in *aqua*, and the rectum in *yellow*. A rectal balloon was used to stabilize the prostate and reduce the dose to the posterior portion of the rectum. As apparent, the VMAT plan delivered a low dose to a larger volume of nontargeted pelvic tissue, including the rectum. (VMAT, photon-based intensity-modulated volumetric arc treatment planning; DS PT, double-scatter delivery of proton therapy; IMPT, pencil beam scanning delivery of proton therapy using single-field uniform dose [SFUD] optimization and/or multifield uniform dose [MFUD] optimization treatment planning techniques.) **B:** Comparison of IMRT, DS PT, and IMPT treatment plans for a prostate cancer patient with a large median lobe. The target coverage goals were to deliver 100% of the prescribed dose to 95% of the PTV and to deliver 95% of the prescribed dose to 100% of the PTV. As apparent, all plans met both target coverage goals with a high degree of dose homogeneity. The OAR protection goals for the volume of bladder wall receiving 30 and 80 Gy could not be met with the IMRT (VMAT) plan; the DS PT plan met the goal for the volume of bladder receiving 80 Gy, but not the volume receiving 30 Gy. The IMPT plan met all bladder protection goals. All plans met the relative rectal wall dose goals, but not the rectum absolute dose goals. A gel spacer may have helped in this case to meet the rectum dose constraint. (IMRT, photon-based intensity-modulated radiation therapy; DS PT, double-scatter delivery of proton therapy; IMPT, pencil beam scanning delivery of proton therapy using single-field uniform dose [SFUD] optimization and/or multifield uniform dose [MFUD] optimization treatment planning techniques; VMAT, photon-based intensity-modulated volumetric

arc treatment planning; PTV, planning target volume; OAR, organ at risk.) **C:** Comparative plans using pencil beam scanning delivery of proton therapy, double-scatter delivery of proton therapy, photon-based intensity-modulated volumetric arc treatment planning (VMAT) prioritizing rectal sparing, and VMAT prioritizing hip sparing for a patient with a normal-sized prostate and a rectal spacer. The major difference is the substantial low-to-moderate dose bath in both VMAT plans compared with both proton plans. **D:** Although all plans met all dose constraints, the IMPT plan provided the best sparing for low-to-moderate doses of both the bladder wall (27.5 Gy) and the rectal wall (25 to 45 Gy) as well as the lowest overall integral dose. The DS PT plan was better than the IMRT1 plan for hip sparing and better than the IMRT2 plan for sparing of the rectal wall for low-to-moderate doses as well as providing a lower integral dose. (IMRT, photon-based intensity-modulated radiation therapy; IMPT, pencil beam scanning delivery of proton therapy using single-field uniform dose [SFUD] optimization and/or multifield uniform dose [MFUD] optimization treatment planning techniques.)

Comparative Effectiveness of Proton and Photon Therapy

In medical interventions, level I evidence of comparative effectiveness is desirable but frequently difficult to generate. Currently in the United States, fewer than 5% of adults participate in clinical trials. Among the reasons cited for low clinical trial participation are restrictive eligibility criteria, insurance coverage, distrust of physicians or the medical system, patient preference for either the “tried and true” or the “new” approach, physician equipoise, and institutional disincentives. In radiation therapy, randomized trials were not conducted to compare orthovoltage and cobalt, cobalt and x-rays, or 3DCRT with either SRT or IMRT before the general adoption of each of these technologies; each technology was adopted based on improved radiation dose distribution and the expectation of consequent improved clinical outcomes. However, many entities have called for comparative effectiveness evidence before adoption of proton therapy.

With respect to the design of comparative effectiveness studies in proton therapy, the basic difference between protons and photons is the difference in beam entrance dose and exit dose that leads to significant differences in integral dose to nontargeted tissues. The essence of a randomized clinical trial of proton therapy and photon-based therapy thus would be to test whether changes in integral dose result in clinical outcomes that can be measured, that is, toxicity or functional loss from injury to nontargeted tissue. Altruism, therefore, would be the primary motivation for patient participation. It is unclear how willing patients would be to participate in such trials. Given the relatively few sites providing proton therapy at this point in time (~26 in the United States compared with ~4,000 photon facilities), there are also practical issues affecting

comparative effectiveness research in protons. For example, some patients would not be able to travel to receive proton therapy, and others who might travel to receive proton therapy might withdraw from a randomized study if assigned to receive conventional radiation therapy, which could be delivered more conveniently in their hometown. Insurance coverage with proton therapy has been unpredictable, often not verified in a time frame that would permit study participation. Finally, the numbers of patients and resources required for randomized controlled trials raise concerns regarding the best use of currently available proton therapy treatment slots. Some investigators believe that more questions could be answered in the same time frame as a randomized controlled trial with a series of well-designed sequential studies aimed at optimizing proton therapy through dose escalation and hypofractionation or comparative effectiveness cohort studies.

Despite these challenges, there are a few completed or ongoing randomized trials comparing photon and proton-based therapy in lung cancer,[298,299,301] prostate cancer,[302] oropharyngeal carcinoma,[303] glioblastoma,[304] and breast cancer[305] and a trial comparing proton and carbon-based therapy in skull base sarcomas.[306]

In pediatric cancer survivors, increased risks of second malignancies and cardiovascular disease have been associated with radiation doses as low as 4 to 15 Gy.[307] In addition, elegant dose modeling studies at St. Jude Children's Research Hospital (Memphis, TN) have suggested no threshold dose for radiation injury in the childhood brain.[221] Thousands of children and many years of follow-up would be required to assess the results of a hypothetical controlled trial of proton therapy and conventional radiation to determine whether the reduction in low-dose exposure to the brain and total body with proton therapy would indeed result in a lower incidence of second malignancies or late cardiac injury. In the process, many children would intentionally be exposed to low-dose radiation in nontargeted tissues in the brain, likely resulting in permanent decreased neurocognitive function. Therefore, comparative trials will likely not be done in pediatric patients. Similar arguments may follow for Hodgkin lymphoma, which also affects relatively young patients with a high cure rate, long life expectancy, and substantial risks for second malignancy and late cardiac injury.

Comparative Cost-Effectiveness

Many factors must be accounted for in comparing the costliness and cost-

effectiveness of different radiation technologies. Some of these include facility and equipment costs, operating and maintenance costs, patient throughput, clinical outcomes, and the global and individual impact of those clinical outcomes.

Current proton therapy equipment and facilities are up to 10-fold more expensive to construct than current conventional radiation therapy facilities capable of treating a similar patient volume. In addition, operating costs are higher by one- to threefold. There are substantial differences between patient throughput in conventional radiation and proton facilities, however, that may offset differences in initial costs. Typically, conventional radiation equipment is used for a single daily work shift and is replaced every 7 to 10 years. Most proton therapy facilities, however, operate two shifts a day and equipment is expected to last 20 or more years. The Harvard Cyclotron was in use for over 40 years and closed primarily because of the availability of a new gantry-based clinical facility. The Loma Linda University (Loma Linda, CA) synchrotron and most of its gantries have been in continuous operation for over 27 years. Proton therapy equipment appears to be substantially more durable than linear accelerators. Thus, the actual patient throughput (*for a given patient mix*) in a proton facility may be substantially higher than typical for a conventional radiation therapy facility, perhaps double the patients per day (because of double shifts) for 2 to 6 times as many years of operation, leading to a 4- to 12-fold increased throughput with proton facilities compared to photon facilities. Proton therapy throughput may be further enhanced if hypofractionation is more feasible with proton therapy than with x-rays. Although initial cost of the facilities and equipment is a known factor, ultimate throughput and clinical outcomes evolve over time, so that the true cost-effectiveness of proton therapy relative to conventional radiation will not be known until there are long-term facility performance and clinical outcome data.

The impact of a particular clinical outcome may affect stakeholders differently. For example, if there is no intervention (cost) associated with a radiation injury that affects a patient’s quality of life, that particular clinical outcome may be valued differently by a patient and that patient’s insurer. Currently, there is no objective way to resolve such valuation differences. Meaningful cost-effectiveness analyses must account for a number of variables that are ill-defined and difficult to reduce to financial units. Regardless of the outcomes of cost and cost-effectiveness analyses, a shift to proton therapy as a predominant radiation modality will likely require a paradigm shift in

philosophy about both profit and daily operations.

CHALLENGES

The multiple challenges facing proton therapy are complex and interrelated.

The first involves **technical developments** necessary to realize the full clinical outcome potential of proton therapy, including the following:

- *Improved treatment planning systems that better account for proton stopping power and biologic effects of variations in LET and RBE along the beam path.*
- *Online volumetric imaging and real-time range verification to assure accuracy.*
- *Real-time treatment plan adaptation to changes in tumor and/or normal tissue.*
- *Increased delivery speed to minimize motion mitigation and improve operational workflow.*

The second challenge is the generation of **reasonable evidence of improved clinical outcomes** that are anticipated with improved dose distributions. The development of reasonable evidence requires a critical mass of treatment facilities, a sufficient number of patients, sufficient technology maturation to reflect the modality's potential for outcome improvements, sufficient physician expertise to employ optimal techniques, and clinical trials that are scientifically credible, appealing to patients, nondisruptive to general clinical operations, and supported by funding agencies. The larger the anticipated clinical difference between treatment arms, the less likely a physician would have equipoise and a patient would consent to randomization, making accrual to a randomized study difficult. With smaller anticipated differences, accrual might be feasible, but larger numbers of subjects would be required to assess the difference. A full assessment of clinical outcome typically involves long follow-up to document differences in late effects, as well as early outcomes. Thus, comparative studies of proton and photon therapy will likely require large numbers of patients, possibly nonrandomized study designs, and long-term follow-up, making the funding of such studies challenging.

The third challenge is the development of **less expensive equipment** to lower the cost of participation in proton therapy by patients, providers, hospitals, and payors. Despite the paucity of comparative effectiveness data for proton therapy, the compelling dosimetric rationale is driving increased capacity, although not as rapidly as commonly perceived. Although proton therapy facilities have been described as increasing in number exponentially, studies by Miller et al.[308] and

Waddle et al.[309] have shown minimal diffusion. The primary barrier to more rapid diffusion has been the cost of facilities. Vendors' current solutions to lowering the cost of proton therapy have converged on developing one-room facilities. Instead of installing a single large cyclotron or synchrotron that provides a proton beam for three to five treatment rooms, a smaller cyclotron could service only a single room, permitting access to the technology for 30% to 40% of the cost of a full facility but at a commensurate reduction in capacity. It is likely that true cost reduction will require significant technology development, which may only be driven by a significant increase in market demands.

Finally, the fourth challenge to progress in proton therapy is attaining a **critical mass of facilities**. In 2005, there were just three proton facilities treating nonocular tumors in the United States. In 2015, just a decade later, there were 5 times as many facilities in operation in the United States treating approximately 5,000 patients per year.[310] Today, in 2017, despite an eightfold increase in the number of facilities over the past 12 years, there are currently only 26 centers in operation, compared with >4,000 conventional radiation facilities. A critical mass of facilities, physicians, and physicists is necessary to collaborate with industry on technologic developments, conduct sound clinical research, and drive significant market-driven cost reduction developments.

CONCLUSIONS

Proton therapy offers the promise of reduced toxicity to patients compared with photon therapy—by reducing the radiation dose to nontargeted tissues—and possibly enhanced disease control through differential tumor effects and normal tissue biologic responses. Reduced toxicity may be leveraged to increase disease control through dose escalation or intensification (hypofractionation). Hypofractionation may result in lower health care costs as well as increased disease control and reduced toxicity. Additional clinical research and technical development are needed to optimize treatment planning and delivery of proton therapy, to document and maximize its potential clinical benefits, and to understand its full impact on health care economics.

CHAPTER 22

Neutron Therapy and Boron Neutron Capture Therapy

George E. Laramore

INTRODUCTION

The neutron was discovered by Sir James Chadwick at the Cavendish Laboratory in 1932 as a neutral particle that was produced by naturally produced α-particles interacting with the nuclei of various elements. At approximately the same time, E. O. Lawrence invented the cyclotron at the Radiation Laboratory of the University of California thus paving the way for the generation of higher-energy particle beams. The first cyclotron was only 11 inches across and could accelerate protons to 80 keV. Lawrence built a series of larger cyclotrons, one of which was used by Robert Stone to treat 240 patients with "fast" neutrons at the Crocker Radiation Laboratory, the forerunner of the Lawrence Berkeley Laboratory.[1] In Stone's era, the radiobiology of fast neutrons was poorly understood and almost all of his patients suffered severe radiation sequelae. A subsequent review of the work by Brennan and Phillips[2] showed that the majority of Stone's patients had been significantly overdosed. Catterall et al.[3–5] at the Hammersmith Hospital in London resumed clinical trials with fast neutrons in the 1960s and, after treating several hundred patients, concluded that with appropriate fractionation schemes, neutron radiotherapy was well tolerated and many advanced tumors responded amazingly well. Following these initial reports, clinical trials using fast neutrons were instituted at many other facilities throughout the world, and to date, over 41 centers have been involved in fast neutron radiotherapy with over 35,000 patients treated. Although fast neutron radiotherapy has been shown to have significant clinical utility in many situations, it has not proven to be the panacea that was initially hoped for. In what follows, I will describe the important elements of the historical development and discuss the important areas of current clinical use.

An alternate way of using neutrons to treat cancer is via neutron capture therapy. Although several isotopes have a high cross-section for capturing low-energy neutrons leading to an energy-releasing reaction, the great majority of laboratory and clinical work involves boron-10 (^{10}B). The concept of using a low-energy thermal neutron to target cancer cells via a capture reaction involving ^{10}B nuclei was first proposed by Locher in 1936.[6] This is a binary process requiring a source of thermal or epithermal neutrons and a carrier compound both having adequate specificity for tumor cells and being able to deliver sufficient ^{10}B. The beam of low-energy neutrons is broad, and so, tumor selectivity comes almost entirely from the ^{10}B carrier. Because carrier agents are typically cleared from the body via the liver or the kidneys, there is an advantage to using an intrinsically nontoxic compound rather than tagging the carrier with a toxic moiety such as ricin. The first human clinical trials using boron neutron capture therapy (BNCT) took place in the 1950s at the Brookhaven National Laboratory using ^{10}B-enriched boric acid derivatives to treat patients with high-grade brain tumors.[7,8] This compound produced high levels of ^{10}B in the blood and low absolute levels of ^{10}B in the tumors resulting in substantial blood vessel damage and no therapeutic benefit. Several other trials were conducted in the 1960s, but interest in the technique waned until Hatanaka and others[9,10] in Japan began using a different compound, ^{10}B–sodium mercaptoundecahydrododecaborate (BSH), to treat brain tumors. This produced a better tumor-to-blood ratio than the boric acid derivatives and resulted in less damage to normal brain tissue. Favorable reports on patient outcomes have generated renewed worldwide interest in the technique. To date, all treatments have been carried out using beams from nuclear reactors, but there is active ongoing work to develop accelerator-based neutron sources suitable for a medical center environment. I will discuss the important elements in the historical development of this technique with emphasis on current areas of active investigation.

BASIC RADIOBIOLOGY

The rate of energy transferred by ionizing radiation along its path is referred to as *linear energy transfer* (LET). Conventional photon and electron beams used in therapy typically have LETs in the range of 0.2 to 2.0 keV/μ, whereas a high LET form of radiation such as a fast neutron typically has an LET in the range of 20 to 100 keV/μ. The biologic effect of radiation is highly dependent on its LET.

This is characterized by the relative biologic effectiveness (RBE) factor, which is the ratio of the dose of ^{60}Co radiation to the dose of particle radiation producing the same biologic end point. The RBE of a given type of radiation is, of course, dependent upon many factors such as the tissue type, chosen end point, dose fractionation schema, etc. However, for practical clinical work using common fractionation schedules, one can use a set of simple numbers in comparing the effective doses of the various types of particle radiation. Fast neutrons have RBEs in the range of 3.0 to 3.5 in terms of most normal tissue late effects, in the range of 4.0 to 4.5 in terms of damage to the central nervous system (CNS), and in the range of 8.0 for salivary gland malignancies.[11–13] In the BNCT reaction shown in Figure 22.7, the emitted α-particle and ^{7}Li nucleus are also high LET forms of radiation. It is the different radiobiology of high LET radiation that makes it interesting in the treatment of certain cancers.

Low LET radiation primarily kills cells via an indirect, free radical–mediated mechanism.[12] For this to be effective, a long free radical lifetime is required. Oxygen acts as an electron scavenger; hence, free radical lifetimes are longer in cells that are well oxygenated. Oxygen also acts to stabilize the free radical damage. In hypoxic cells, the free radical lifetimes are shorter; hence, these cells are “protected” from much of the damage. Thus, it takes a higher radiation dose in hypoxic cells to achieve the same biologic end point compared to the required dose in well-oxygenated cells. High LET radiation causes a higher proportion of direct damage to the critical cellular targets and therefore is not as dependent on a free radical intermediary. The oxygen enhancement ratio (OER) is the ratio of the radiation dose required to produce a specific biologic effect under anoxic conditions to the dose required to produce the same effect under well-oxygenated conditions. For most mammalian cells, the OER for conventional low LET radiation is in the range of 2.5 to 3.0, whereas for clinically used high LET radiation, the OER is in the range of 1.4 to 1.7. Although the lower OER was one of the primary motivating factors in using high LET radiation, its actual importance in most clinical settings may not be that great because of reoxygenation during a course of fractionated radiotherapy.

Another potential advantage to high LET radiation relates to the reduced ability of cells to repair the radiation damage it produces. The dense chain of ionization events produced by high LET radiation causes simultaneous damage to both strands of the cellular deoxyribonucleic acid (DNA) and also nonrepairable damage to other targets within the cell. Cell survival curves for low LET radiation characteristically exhibit a shoulder at low radiation doses,

indicating the ability of the cells to repair this “sublethal” damage. High LET radiation, however, exhibits a very reduced shoulder, resulting in a cell survival curve that is almost log-linear in shape over the range of radiation doses of clinical relevance.[12,14] One therefore would expect tumors having a large capacity for radiation damage repair to be among those better treated with high LET radiation. Another type of radiation damage is “potentially lethal” damage, which occurs in cells that are in a noncycling, plateau phase.[12,15] This has been demonstrated in the laboratory and may be important in tumors having a large fraction of cells in the G0 phase of the cell cycle. This type of repair is less important for high LET radiation than for low LET radiation.

A final point relates to the variation of radiosensitivity across the cell cycle. Mammalian cells are more radiosensitive in M and late G1/early S phase than in early G1 and G2. If radiation is given to an asynchronously dividing cell population, then cells in the sensitive portions of the cycle are killed preferentially. Over a course of fractionated radiotherapy, cells continue through the cycle, and when other fractions of radiation are delivered, many of the formerly resistant cells are in the more sensitive phases of the cycle. The variation in radiosensitivity across the cell cycle is about a factor of four less with high LET radiation.[12,16] Hence, tumors with long cell cycle times theoretically would be better treated with high LET radiation.

FAST NEUTRON RADIOTHERAPY

At one time or another, 41 different centers in North America, Europe, Asia, and Africa treated patients with fast neutrons. To date, over 35,000 patients have received neutron radiotherapy as all or part of their cancer therapy. Although neutron radiotherapy has demonstrated clinical utility in the treatment of certain tumors, it has not proven to be a panacea as was originally hoped, and current indications are limited. There are currently four operating neutron radiotherapy facilities, which are listed in Table 22.1 along with some of their more important characteristics. The more important conclusions from the neutron clinical trials are discussed later in this chapter. Because space does not permit us to be all inclusive, we will emphasize the areas where neutrons show therapeutic benefit compared to conventional radiotherapy.

TABLE 22.1 LOCATION OF OPERATING FAST NEUTRON RADIOTHERAPY CENTERS—2017

Location	Beam Reaction	Comments
United States		
University of Washington Medical Center—Seattle, WA	50 MeV p→Be	Isocentric gantry and multileaf collimator
Europe		
Tomsk Polytechnical University—Tomsk, Russia	Cyclotron	Mean neutron energy 6.3 MeV
Technisch Universtät Munich—Munich, Germany	Fission neutrons	FRMII reactor, horizontal beam with multileaf collimator, mean neutron energy 1.9 MeV
Institute of Physics and Power Engineering—Obninsk, Russia	Fission neutrons	Horizontal beam

Salivary Gland Tumors

Although fast neutron radiotherapy has been used in the treatment of many different types of tumors, its major therapeutic advantage has been demonstrated for salivary gland tumors. In retrospect, this could have been predicted from the early radiobiologic work of Battermann and associates,[11] in which the RBE for fractionated radiotherapy was found to be approximately 8, compared to values in the range of 3 to 3.5 expected for late damage in most normal tissues. With appropriate field shaping, one can deliver neutron radiation doses of approximately 20 Gy_{n_γ} (by convention the γ-rays produced by the neutron interactions are included in the physical dose measurement) to the head and neck region with blocking to reduce the dose to the spinal cord. This roughly corresponds to an equivalent photon dose of 60 to 70 Gy equivalent (Gy equivalent = physical dose × RBE) as far as normal tissues are concerned but approximately 160 Gy equivalent as far as the tumor is concerned. Thus, the therapeutic gain factor for salivary gland tumors is in the range of 2.3 to 2.6.

Early single-institution series seemed to confirm this therapeutic advantage, and the Radiation Therapy Oncology Group (RTOG) and the Medical Research Council of Great Britain conducted a prospective randomized trial for this disease site. A final report on this study showed improved locoregional control at 10 years (56% vs. 17%, P = .009) but no improvement in long-term survival because of distant metastases.[17] This study was stopped early for ethical reasons when 2-year survival data showed a strong trend in favor of the neutron patients. At the 10-year end point, there was a slight (but not statistically significant) benefit to median patient survival on the neutron arm of about 8 months, but with the patients living longer as a result of controlled locoregional disease, the

subsequent development of distant metastases became the dominant cause of death. The final locoregional control curve from this study is shown in Figure 22.1.

More recent single-institution data continue to support the efficacy of fast neutron radiotherapy in the treatment of salivary gland tumors. Douglas et al.[18] have analyzed their results for tumors of the major salivary gland (all histologies) and found that if the overall tumor size was <4 cm, the local control rate at 9 years was 78%. The control rate was about 40% for the larger tumors. Figure 22.2 shows actuarial local control probabilities as a function of tumor size as taken from this analysis. Tumor size and location (parotid vs. submandibular and sublingual) were also factors affecting locoregional control and survival. Another analysis of Douglas et al.[19] focused specifically on patients with adenoid cystic carcinomas. Control rates and cause-specific survival as a function of tumor location are given in Table 22.2. The lower locoregional control rates for tumors arising in the paranasal sinuses or nasopharynx are attributable to tumors invading the cavernous sinus or skull base where the proximity of critical CNS structures limited the neutron dose that could be given relative to tumors in other sites. On multivariate analysis, the presence of base of skull involvement was found to be a statistically significant adverse factor for locoregional control at the $P \leq .01$ level. The risk of developing distant metastases was approximately 50% at 2 years for node-positive patients. For node-negative patients, the metastatic risk also reached approximately 50% but took 10 years to do so. Clearly, better systemic therapy is needed for this tumor.

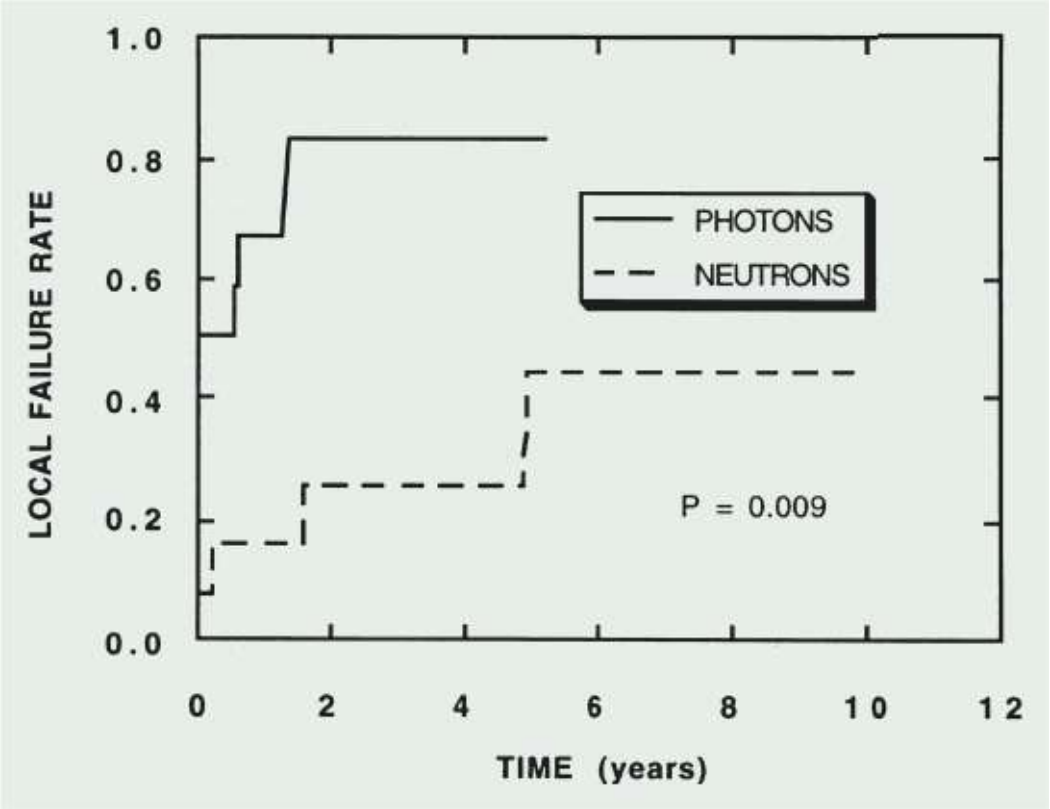

FIGURE 22.1. Actuarial locoregional control rates for patients with unresectable salivary gland tumors who were treated on the RTOG/MRC randomized trial (80–01). The neutron curve is shown as the dashed line and the photon curve is shown as the solid line. The difference between the two curves is statistically significant at the *P* = .009 level. (Reprinted from Laramore GE, Krall JM, Griffin TW, et al. Neutron versus photon irradiation for unresectable salivary gland tumors: final report of an RTOG-MRC randomized clinical trial. *Int J Radiat Oncol Biol Phys* 1993;27[2]:235–240. Copyright © 1993 Elsevier. With permission.)

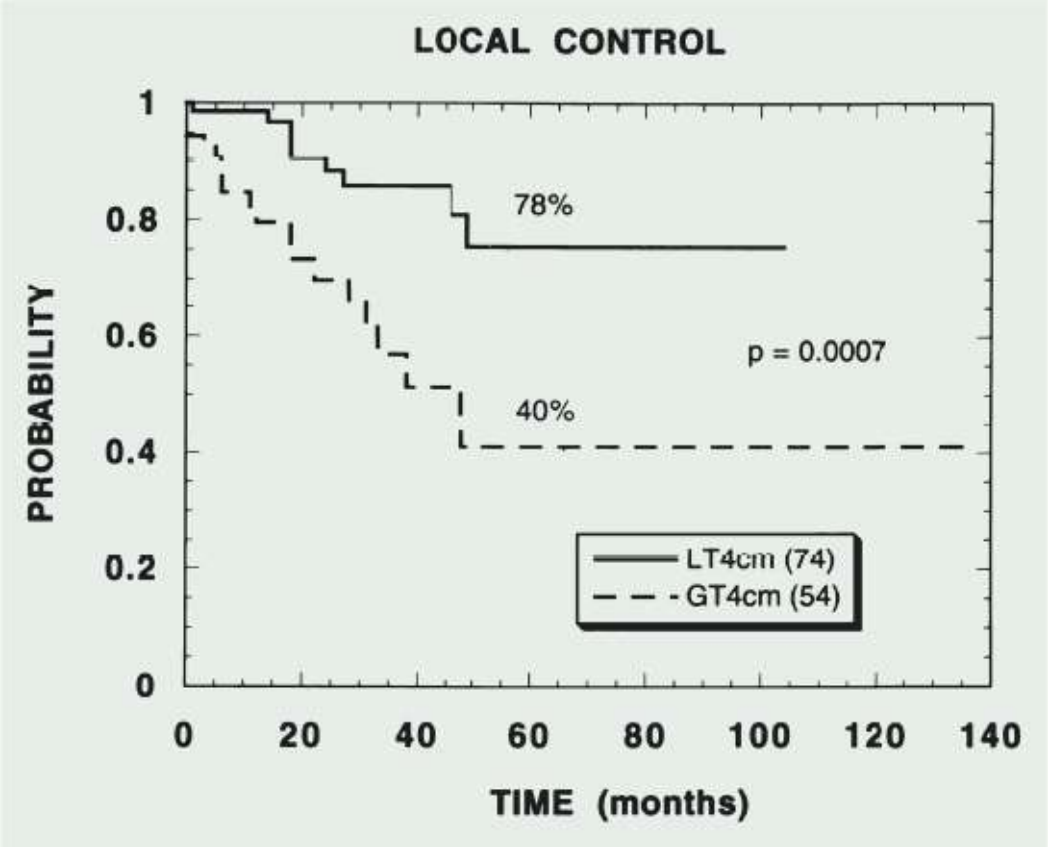

FIGURE 22.2. Actuarial locoregional control rates for patients with major salivary gland tumors who were treated at the University of Washington Fast Neutron Radiotherapy facility. On both univariate and multivariate analysis, tumor size was a predictive factor for locoregional control. The *solid line* depicts the results for patients with tumors <4 cm in extent, whereas the *dashed line* depicts the results for tumors >4 cm in extent. (From Douglas JD, Lee S, Laramore GE, et al. Neutron radiotherapy for the treatment of locally advanced major salivary gland tumors. *Head Neck* 1999;21[3]:255–263. Copyright © 1999 John Wiley & Sons, Inc. Reprinted by permission of John Wiley & Sons, Inc.)

The poorer outcomes associated with skull base invasion appears to be due to the necessity of reducing the neutron dose to the upper part of the tumor to avoid damage to the CNS, which has an RBE in the range of 4 to 4.5. In an attempt to compensate for this, a stereotactic boost to the superior aspect using a gamma knife has been instituted at the University of Washington. Figure 22.3 shows the dramatic improvement in local tumor control compared to an earlier cohort of patients with skull base tumors treated without the gamma knife boost.[20] The use of a proton boost in an attempt to obtain better coverage for large, irregular tumor volumes at the skull base is currently being explored.

TABLE 22.2 FIVE-YEAR ACTUARIAL LOCOREGIONAL CONTROL

RATES AND CAUSE-SPECIFIC SURVIVAL AS A FUNCTION OF PRIMARY SITE FOR PATIENTS WITH ADENOID CYSTIC CARCINOMAS TREATED WITH FAST NEUTRONS

Site	Patient Number	Locoregional Control (%)	Cause-Specific Survival (%)
Paranasal sinus	32	43	67
Parotid	27	67	82
Oral cavity	26	68	87
Oropharynx	19	75	92
Submandibular/sublingual	15	59	83
Nasopharynx	15	21	35
Lacrimal gland	7	80	100
Trachea	4	25	75
Other	6	100	100

gland neoplasms with base of skull invasion following neutron radiotherapy. *Head Neck* 2008;30[4]:492–496. Copyright © 2007 Wiley Periodicals, Inc. Reprinted by permission of John Wiley & Sons, Inc.)

Late effects associated with any high LET form of radiotherapy are always a concern. A study of the University of Washington patient population was conducted in collaboration with the Department of Dentistry, evaluating 140 patients with either minor salivary gland tumors of the oral cavity or tumors of the submandibular and sublingual glands where substantial amounts of the oral cavity were irradiated.[21] The study population was treated between 1997 and 2006, and so, there was a minimum of 10 years at risk at the time of analysis. Because of the wide geographic referral region and the intervening time, only 27 patients could be located for an updated quality of life assessment. Otherwise, the data in the existing medical records were utilized. In terms of acute effects, xerostomia and significant mucositis occurred, respectively, in 88% and 89% of patients, which is about the same as would be expected with patients treated with concurrent chemotherapy and photon radiotherapy using the same treatment fields. The actuarial locoregional control at 6 years was 72.2%, and the overall survival was 58%. In terms of late effects, 15 patients reported significant trismus, and 8 patients had osteoradionecrosis of the mandible.

To reduce the side effects associated with the poorly penetrating properties of the early beams, early neutron work often involved treating patients with a combination of neutrons and photons (known as a “mixed beam” regimen) rather than with neutrons alone. There is a concern that this approach also might reduce the tumor control probability in the case of adenoid cystic carcinomas where there is a high therapeutic gain factor. Huber and colleagues[22] reported on a series of patients with adenoid cystic carcinomas treated at the Heidelberg neutron facility and found a 5-year local control rate of 75% for patients treated with neutrons alone compared to 32% for groups of patients treated with a “mixed beam” regimen or with photons alone. In settings where treatment morbidity is not a major problem, it appears advantageous to use the more effective modality, for example neutrons, for the entire treatment. A high rate of distant metastases prevented improved locoregional control from being translated into improved survival.

Neutron radiotherapy has also been used to treat high-risk, multiply recurrent, pleomorphic adenomas of the major salivary glands.[23] For 16 patients with a median time of 96 months from completion of treatment until analysis, the 15-year locoregional control was 76% for patients with gross disease and 100% for

patients with microscopic disease at the time of treatment. The 15-year actuarial risk for grade >3 complications (RTOG/EORTC [European Organization of Radiation Treatment Centers]) was 21%. There were no facial nerve injuries as a result of the neutron treatment.

Squamous Cell Tumors of the Head and Neck

The results for the more common squamous cell tumors of the head and neck have not paralleled those of salivary gland tumors. Early reports by Duncan and associates[24,25] did not confirm the findings of Catterall and colleagues.[4,5] In an attempt to more rigorously evaluate the results of the Hammersmith group, the RTOG conducted a randomized trial comparing conventional photon irradiation with a mixed beam (neutron/photon) fractionation schedule for patients with inoperable tumors.[26,27] Although there was no improvement in terms of local control of the primary tumor or in survival, there was an apparent benefit in terms of improved regional control in the neck for patients presenting with clinically positive adenopathy. In contrast to the results of Catterall and colleagues,[4,5] many patients who had an initial apparent complete locoregional response with fast neutrons developed failures within the radiation fields with passage of time—just as occurred for those patients on the photon control arm. The results of this trial were criticized because its neutron arm did not correspond to the particular regimen used at Hammersmith Hospital. Instead, it was “diluted” with photon irradiation and also had a substantially longer overall treatment time of 7 weeks compared to the 4-week fractionation schema used at Hammersmith. The Neutron Therapy Cooperative Working Group (NTCWG) therefore repeated this study using the second-generation, hospital-based facilities located in the United States and Great Britain with the experimental neutron treatment regimen being identical to that used by Catterall. The results of this second randomized trial also showed no benefit in either locoregional control or survival for the neutron-treated patients.[28] There was a suggestion of improved regional control of clinically positive nodes with fast neutrons, but it did not achieve clinical significance. Late complications graded “severe or greater” according to the joint RTOG/EORTC scoring schema were 40% on the neutron arm compared to 17% on the photon arm (P = .008). Hence, it currently is felt that neutron radiotherapy is of limited utility in the treatment of head and neck squamous cell tumors with the possible exception of patients with massive cervical adenopathy.

Non–Small Cell Lung Cancer

The first reported experience using fast neutron radiotherapy for non–small cell lung cancer was by Eichhorn,[29] who utilized a very low–energy neutron beam. Autopsy rates showed higher rates of tumor sterilization as the percentage of the dose given with neutrons increased: photons alone produced a 33% sterilization rate in 149 patients, mixed beam (20% neutrons and 80% photons) produced a sterilization rate of 48% in 75 patients, and mixed beam (37% neutrons and 63% photons) produced a sterilization rate of 57% in 49 patients. There have been two reported series that showed exceptionally high local control rates for Pancoast or superior sulcus tumors: Komaki and associates[30] found a 91% local control rate, which translated into improved survival relative to a group of photon-treated patients, and Sawada and colleagues[31] found a mean survival of 11.5 months for 18 patients treated with neutrons compared to 4 months for five patients treated with conventional photon irradiation.

There have been two randomized, clinical trials for inoperable, non–small cell lung cancer. The first was a three-armed study comparing conventional photon radiation versus mixed (neutron/photon) radiation versus neutron radiation alone.[32] The complication rate was higher on the neutron-only arm (perhaps due in part to the relatively low-energy neutron beams in use at that time), and there was no difference in overall survival. A second randomized trial was conducted using the modern hospital-based facilities, which compared a neutron-only regimen with conventional photon irradiation.[33] For the entire cohort of patients, there was no difference in overall survival. However, there was a statistically significant survival advantage for the subset of patients having squamous cell histology. The survival curves for this subset of patients are shown in Figure 22.4. There was also a nonsignificant trend toward increased survival ($P = .15$) for patients of all histologies having favorable prognostic factors (no pleural effusion, not T4 or N3 in stage, weight loss <5% of normal body weight). Except for skin and subcutaneous changes, which were more severe on the neutron arm, acute and late toxicities were comparable.

The overall results are consistent with the conclusions of conventional photon therapy—namely, that a more aggressive form of radiation treatment delivering higher doses resulting in improved local control will only affect survival in a favorable subgroup of patients that are not prone to early distant metastases. There have been no reported studies in which chemotherapy was used along with neutron irradiation.

Prostate Cancer

There have been two important randomized clinical trials comparing neutron radiotherapy versus conventional photon radiotherapy for patients with locally advanced prostate cancer. In the late 1970s and early 1980s, the RTOG conducted a study (77–04) comparing mixed (neutron/photon) beam radiation with standard external beam radiotherapy for patients with stages C and D_1 tumors.[34] At the 10-year end point, there were both improved locoregional control (70% vs. 58%, $P = .03$) and survival (46% vs. 29%, $P = .04$) in favor of the mixed beam arm. The survival curves from this study are reproduced in Figure 22.5. There was no difference in the rate of significant complications between the two arms. This is one of the few published studies showing improved survival, as opposed to local control, with an experimental form of treatment for prostate cancer. This study was criticized because of its relatively small size (91 evaluable patients), its unbalanced randomization (3:2 in favor of the experimental arm), and the fact that the photon control group appeared to do somewhat worse than would have been expected for supposedly comparable patients based on historical results. Hence, although this study was maturing, a second randomized trial comparing fast neutron radiotherapy alone versus conventional photon radiotherapy was initiated by the NTCWG for patients with high-grade T_2 or any grade T_3–T_4, N_0–N_1, M_0 tumors. One hundred seventy-two evaluable patients were entered into the study, and 5-year data have been reported.[35] A routine, posttreatment biopsy was designed into the study to assay for local control in the pre-PSA (prostate-specific antigen) era, but unfortunately, all patients at risk for failure at the 2-year end point did not undergo this biopsy. Figure 22.6 shows local failure rates for the two arms of this study as well as the local failure rate for a comparable group of photon-treated patient on RTOG 75–06. The clinical local failure rate in the neutron arm of this study was 11%, compared to 32% for the photon control arm ($P < .01$). Thus, the control arm of this study had a comparable rate of local tumor control to that of other published literature as shown in the figure. However, there was no statistical difference in either actual survival or cause-specific survival between the two arms of NTCWG protocol 85–23. Posttreatment PSA levels in those patients at risk at 5+ years were elevated in 17% of patients on the neutron arm, compared to 45% of patients on the photon arm ($P < .001$). Although there was increased treatment morbidity on the neutron arm, it appeared to be confined to those neutron facilities not having a multileaf collimator to precisely shape the radiation fields.[35,36] Given the steepness of the neutron dose–response curves for both

tumor control and normal tissue damage, precise field shaping is a prerequisite for safe treatment delivery.

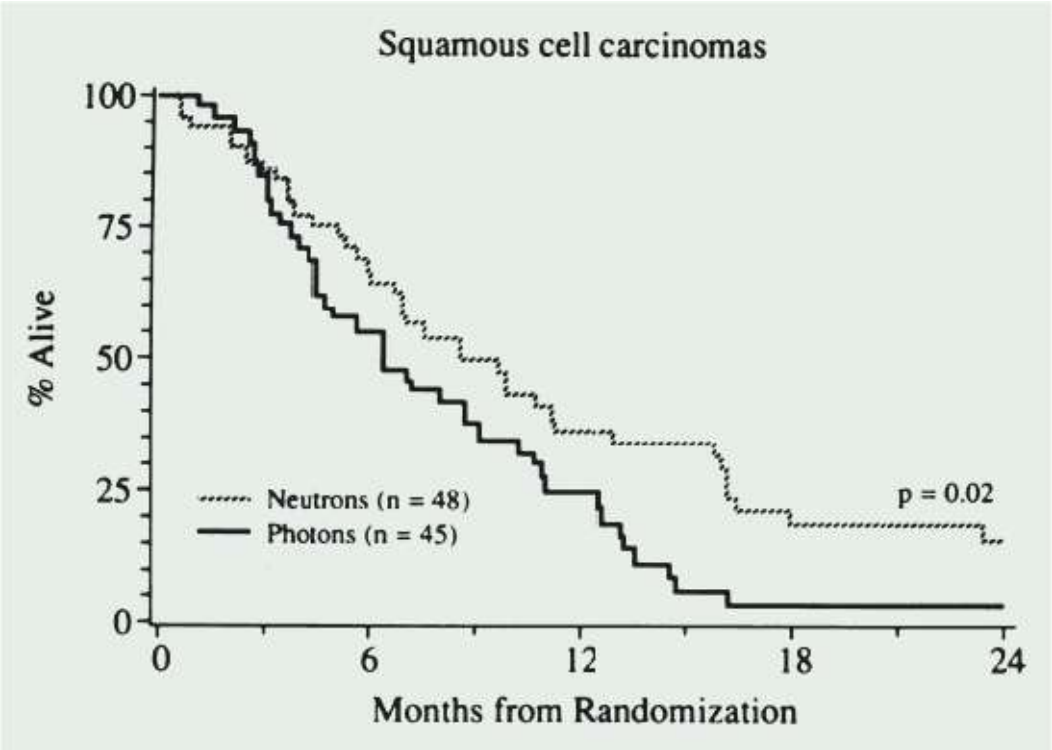

FIGURE 22.4. Actuarial survival curves in patients having squamous cell carcinomas of the lung treated on NTCWG study 85–24. The neutron-treated group is shown as the *dotted line*, and the photon-treated group is shown as the *solid line*. The difference between the two curves is statistically significant at the *P* = .02 level. (Reprinted from Koh WJ, Krall JM, Peters LJ, et al. Neutron vs. photon radiation therapy for inoperable regional non-small cell lung cancer: results of a multicenter randomized trial. *Int J Radiat Oncol Biol Phys* 1993;27[3]:499–505. Considerable work has been done by the Wayne State University group using a combination of neutrons and photons (mixed beam) to treat prostate cancer. This work was done using a multirod collimator for field shaping and achieved an acceptable level of morbidity with over 1,500 patients having been treated at the present time. Forman et al. have summarized this work and discussed the sequence of studies that were undertaken.[37,38] Following dose escalation studies to determine the maximum safe radiation doses, the Wayne State group compared two different treatment schemas: (a) giving the neutron portion of the treatment before the photon portion and (b) giving the photon portion prior to the neutron portion. Interestingly, they found a higher therapeutic advantage when the neutron radiotherapy was given prior to the photon radiotherapy with disease-free survival being 93% if the neutron radiation was given initially versus 73% if the photon radiation was given initially. Furthermore, they found that the overall complication rate was about the same as that expected using conventional photon irradiation delivered via a three-dimensional conformal

schema.

There also have been several reported single-institution studies from Europe[39,40] and Asia[41,42] that showed high local control rates with fast neutrons and support the results of the two randomized trials. Among these was a major review of prostate cancer patients treated at the Universite Catholique de Louvain reported by Scalliet et al.[39] Five hundred thirty-three patients were treated between 1978 and 1998 with a mixed beam combination of neutrons and photons with three neutron treatments of 0.7 Gy_{n_γ} and 2 photon treatments of 2 Gy given per week on a daily basis. The total dose was felt to be equivalent to 66 Gy photon based upon RBE estimates for their neutron beam. Prior to 1992, only simple field blocking was available; after 1992, a multileaf collimator was used for more precise field shaping. The review group consisted of 308 consecutive patients treated from 1990 to 1996 with either the mixed beam regimen or photon radiotherapy alone. Of these, 262 were presumed alive and QOL questionnaires mailed to them. There were 230 responses: 20 in the photon group and 210 in the mixed beam group. Bowel problems, nocturia, urinary incontinence, and loss of sexual potency were present in each group. There were more patient-reported side effects in the mixed beam group with the difference in bowel problems felt to be significant ($P = .003$). The authors acknowledge that this was likely due to unsophisticated rectal blocking utilized for the lateral fields.

Although there is certainly increased risk of rectal complications with the use of high LET neutron radiotherapy, the aggregate data showed improved locoregional control compared to contemporaneously treated photon patients. This is consistent with more recent radiobiologic models showing a low α/β ratio in the range of 1.5 to 3 for prostate cancer based upon fits to clinical data.[43,44] High values of β indicate tumor ability to repair sublethal damage from conventional photon irradiation, and it is exactly this situation where high LET radiotherapy would be of benefit. It should also be noted that the neutron studies were generally done in the absence of antiandrogen therapy, which has been shown to be advantageous in improving survival in photon-treated patients.

Sarcomas

Sarcomas generally are thought to be “radioresistant” and have many of the characteristics noted by Battermann and associates[11] as being favorable for neutron radiotherapy. A review of this historical data for neutron radiotherapy seems to show a probable benefit for high LET radiotherapy with comparative

local control rates (neutrons vs. photons) for patients treated for inoperable gross disease being 53% versus 38% for soft tissue sarcomas, 55% versus 21% for osteogenic sarcomas, and 49% versus 33% for chondrosarcomas.[45] Schwarz and colleagues[46] have summarized the results of 1,171 patients treated between 1972 and 1990 at 11 European neutron radiotherapy centers. For patients treated following primary resection with either clear or microscopically positive margins (categories R0–R1), the local control rate was about 90%—about the same as would be expected for conventional postoperative photon irradiation. For patients with unresectable tumors (category R2), the approximate control rate was 47%. Complication rates ranged between 7% and 29% and were correlated with field size and the limited degree of technical sophistication available at some of the treatment centers. Clearly, the results are inferior to those expected using a "clean" resection followed by conventional postoperative radiotherapy, but neutron radiotherapy appears to be more effective than photon radiation alone for those tumors where a surgical resection is not an option.

Other Cancers

Adenoid cystic carcinomas can arise in glandular elements located at nontraditional head and neck sites, and we would expect the radiobiology of such tumors to be similar to those arising in salivary glands. Examples are larynx, trachea, lacrimal glands, and breast. Small patient series treating tumors in these sites with fast neutrons report control rates similar to those expected for salivary gland tumors. Bittner et al. reported on 20 patients with adenoid cystic carcinomas of the trachea treated with neutron radiotherapy and found the 5-year actuarial survival to be 89.4%, although the 5-year local control rate was only 54.1%.[47] Six of the patients were given a brachytherapy boost following the neutron radiotherapy, but this did not statistically improve the local control rate. Gensheimer et al.[48] reported on 11 patients with lacrimal gland tumors who were treated with neutrons with gross residual disease present in 8 patients. With a median follow-up of 6.2 years, the Kaplan-Meier locoregional control rate at 5 years was 80%, and the median overall survival was 11.1 years. Anecdotal data from patients with adenoid cystic carcinomas of the breast treated at the University of Washington also show the efficacy of neutron radiotherapy.

Neutron radiotherapy may have a role to play in the treatment of other relatively radioresistant tumors in the head and neck region. Liao et al.[49] evaluated 14 patients with mucosal melanomas treated with fast neutrons. Local control was achieved in 79% of patients until death or last follow-up.

Unfortunately, 50% of patients developed distant metastases. Neutron radiotherapy has also been utilized to treat advanced thyroid malignancies in certain clinical situations.[50] Sixty-two consecutive patients with advanced thyroid cancers were treated with external beam radiotherapy between 1985 and 2015 with 23 receiving neutron radiotherapy and 39 receiving conventional photon irradiation. There was no overall survival difference between the groups, but interestingly, patients with low-grade subtypes (papillary and follicular) did better with standard photon radiation while there was a trend toward improved survival with fast neutrons for the more aggressive medullary and anaplastic histologies.

BORON NEUTRON CAPTURE THERAPY (BNCT)

The key to BNCT is the development of a boron compound that selectively localizes on or within the tumor cells in sufficient concentration to have a high probability of eradicating them when irradiated by a low-energy neutron beam. The boron neutron capture reaction is shown schematically in Figure 22.7. Currently, only three boron carrier compounds have been approved for human clinical trials: sodium mercaptoundecahydro-*closo*-dodecaborate (BSH), (L)-4-dihydroxy-borylphenylalanine (BPA), and sodium decaborane (GB10). Unfortunately, with the possible exception of BPA being concentrated in cells, which synthesizes melanin, these compounds do not exhibit tumor-specific uptake. ^{18}F can be incorporated into BPA thus allowing for positron emission tomography (PET) imaging to ascertain boron concentration. There is considerable work taking place on the development of more effective compounds, and for a synopsis, the reader is referred to the article by Barth et al.[51] The low-energy neutron beams used in BNCT are currently produced using nuclear reactors, and at one time or another, 14 centers have been involved in clinical BNCT work. There is increasing interest in developing accelerator-based sources suitable for hospital environments. Actual, as opposed to idealized, epithermal beams contain γ-ray and fast neutron components, which have markedly different radiobiologic properties. In addition, there are capture reactions via naturally occurring isotopes in biologic material—^{1}H, ^{16}O, ^{14}Ni, ^{12}C, ^{35}Cl, etc. The resulting radiation field is complicated, but for clinical work, the dose is expressed as a single, RBE-weighted dose, Gy_w, with the weighting factors based upon experiments in animal models. This is specific to the boron carrier used because the effectiveness of the BNCT reaction is dependent upon

the cellular location of the ^{10}B.[52,53] Monte Carlo calculations are required for the dose calculations because of the complex nature of neutron transport through matter. Boron levels are measured in the patient's blood and the boron concentration in tumor and surrounding tissue inferred based upon prior experimental studies. The depth-dose properties of epithermal neutron beams limit their effective treatment depth to around 10 cm with currently available boron compound, which restricts the classes of tumors that can be treated.[54] BNCT treatment plans give combined RBE-weighted doses for the entire region of interest using boron concentrations with different weighting factors being used for tumor and normal tissue under the assumption that microscopic tumor extension may occur well outside the image detectable tumor volume. An example of this calculation for tumor and normal brain is shown in Figure 22.8.

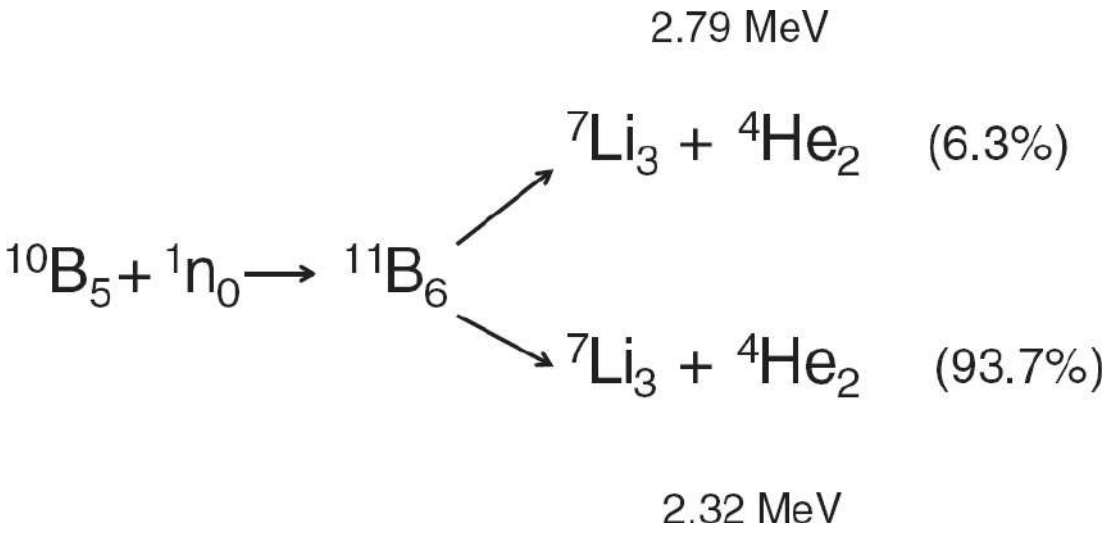

FIGURE 22.7. The boron neutron capture process. The atomic nucleus ^{10}B captures a thermal neutron, going into an excited state, which then decays into a ^{1}He nucleus and a ^{7}Li nucleus, which have respective ranges of approximately 10 μ and 6 μ, respectively. A 0.47 MeV γ-ray is also emitted on the higher probability branch of the decay.

High-Grade Gliomas

The second generation of BNCT trials for high-grade gliomas of the brain took place in Japan using BSH as the boron carrier.[9,10,55] These studies were not randomized and were not controlled for prognostic factors important in predicting outcomes.[56] An analysis of a subset of these patients who came from the United States was undertaken, and for this subset, there was no difference in outcomes compared to what would have been expected with the standard therapy of the time.[57] Many aspects of this early work were suboptimal, including the

use of a poorly penetrating thermal neutron beam requiring an open craniotomy procedure to expose the tumor bed. The relatively low neutron flux meant that treatment times in the range of 4 to 8 hours were required to deliver a surface fluence in the range of 10^{13} neutrons/cm^2, which was necessary for treatment given the tumor boron dose being in the range of 15 to 25 μg/g. After approximately a 30-year hiatus, a BNCT clinical program resumed in the United States using the Harvard-MIT reactor and the Brookhaven National Laboratory Medical Reactor using BPA as the boron delivery agent. Using a single BNCT treatment, medial survival times were comparable to those achieved with more prolonged, conventionally fractionated radiotherapy.[58,59]

Kawabata and Miyatake et al. have utilized a higher-energy epithermal beam along with either BPA alone or in combination with BSH to treat patients with either *de novo* or recurrent glioblastoma multiforme (GBM).[60–63] The patients with recurrent tumors had received on the order of 60 Gy previously, and so, radiation necrosis and/or symptomatic pseudoprogression were major issues. *De novo* tumors are a better test for BNCT efficacy, and Figure 22.9 shows survival curves for patients treated either with BNCT alone or in combination with standard photon radiotherapy. Compared with a historical control group from their institution, median survival was better for the BNCT-treated group. While interesting, it is important to note that this was not a randomized, controlled trial.

Recurrent Head and Neck Cancer

There is a small body of work using BNCT to retreat recurrent head and neck tumors using BPA as the B-carrier. Kankaanranta et al.[64] have reported on 29 patients with recurrent head and neck tumors treated at the FiR 1 TRIGA reactor in Helsinki, Finland, with a single radiation fraction. ^{18}F-L-BPA PET imaging was used to determine the tumor background normal tissue boron levels, and it was estimated that approximately 91% of the tumor dose came from the BNCT reaction. With a median follow-up of 31 months, the 2-year local control was 27%, the 2-year overall survival was 30%, and the 2-year progression-free survival was 27%. Acute side effects included mucositis and oral pain in 54% of patients and fatigue in 32% of patients. Late effects included grade 3 osteoradionecrosis in 3 patients and grade 4 soft tissue necrosis in 1 patient. A subsequent report by the Finnish group on 9 patients treated with BNCT for recurrent or persistent laryngeal cancer showed a median time to progression after BNCT of 6.6 months with a median overall survival of only 13.3 months.[65]

Wang et al.[66] treated 17 patients with recurrent head and neck tumors at the

THOR reactor facility in Taiwan using 2 radiation fractions spaced 28 days apart using BPA. With a median follow-up time of 19.7 months, there were 6 patients with partial tumor responses and 6 patients with complete tumor responses, and at 2 years, the Kaplan-Meier plots showed a local control rate of 28% and an overall survival rate of 47%. There was a 29% incidence of acute grade 3 mucositis, and 1 patient had grade 4 laryngeal edema and carotid hemorrhage. Late effects included 2 patients with grade 3 neuropathy, 1 patient with grade 3 soft tissue necrosis, and 1 patient with grade 3 local pain.

The overall results using BPA-based BNCT in the retreatment setting appear to be about the same as with other retreatment methods.

Other Cancers

BPA acts as a dopamine analogue in the melanin synthesis pathway, and Mishima et al. utilized it to treat malignant melanoma skin nodules and lymph node metastases.[67–70] Good regression was found in the 12 patients who were treated. A larger series of 104 extremity skin nodules in 7 patients has been treated at the Centro Atomico Bariloche in Argentina.[71] The authors found a high control rate of >80% when the tumor volume was <0.1 cm^3 when 20 Gy_w was given but <40% for larger tumors even when doses >40 Gy_w were given.

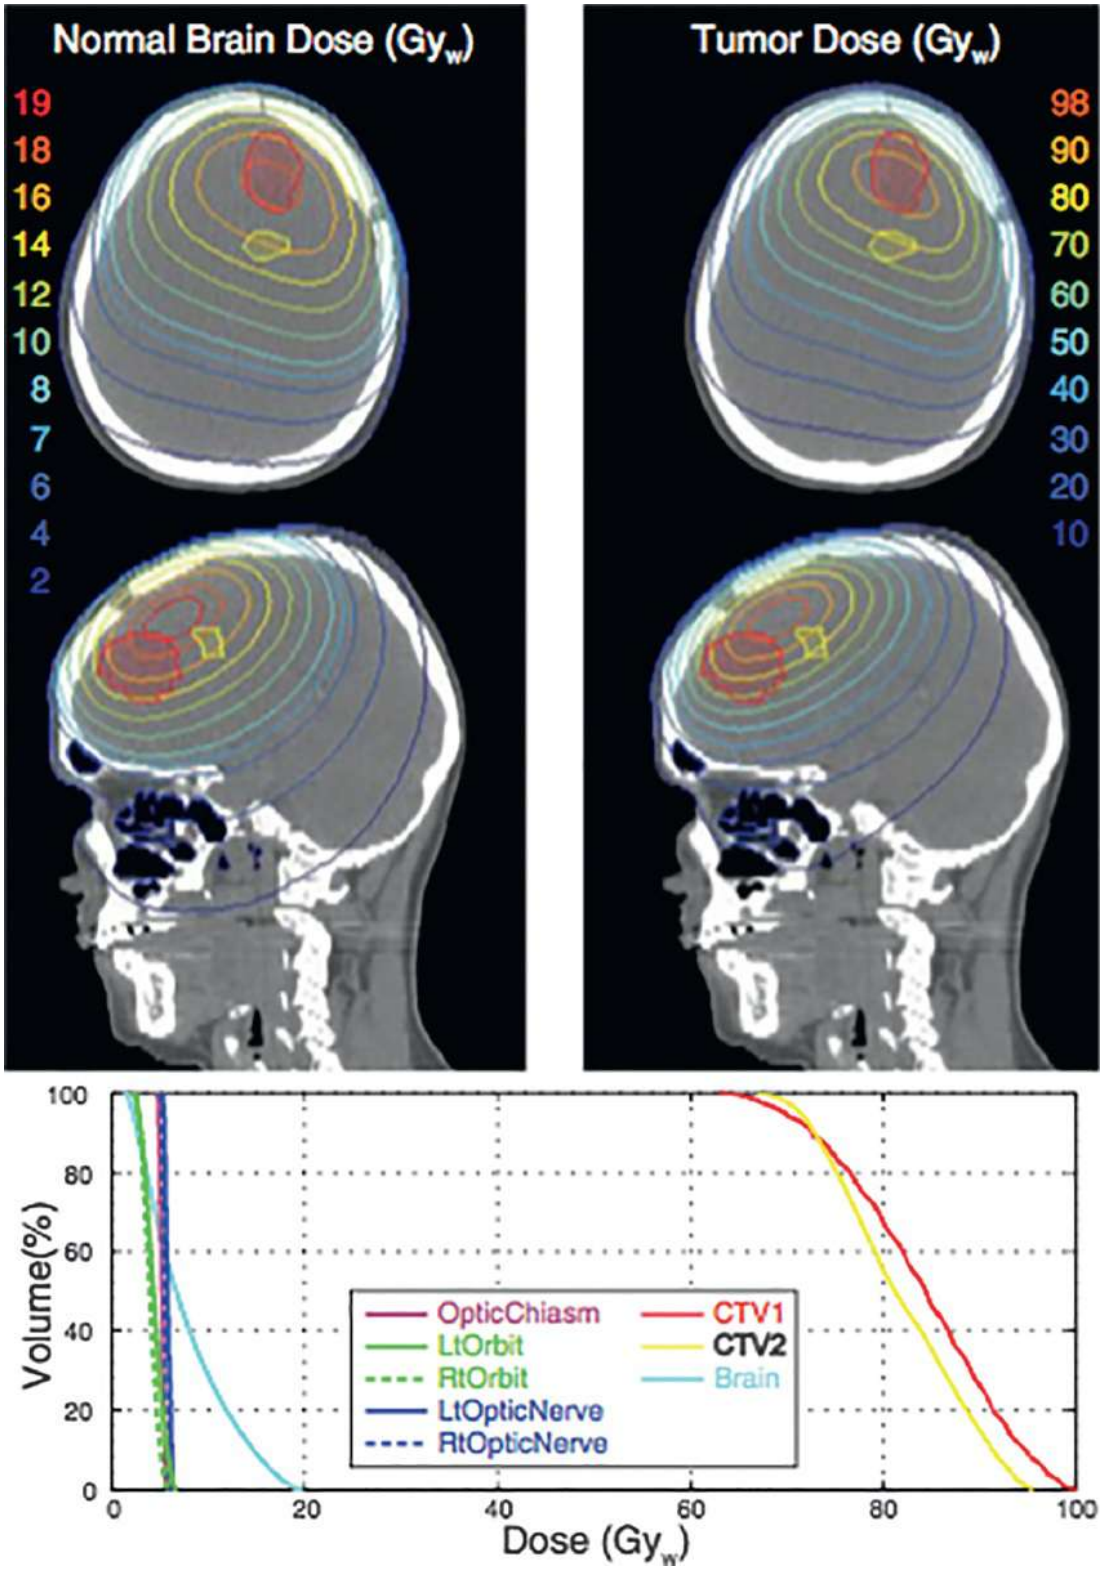

FIGURE 22.8. A treatment plan for a GBM patient using three treatment fields. The prescription is for a mean brain dose of 7.7 Gy_W with isodoses calculated for tumor (*right*) and normal brain (*left*) shown on axial and sagittal slices. (Reprinted from Barth RF, Vicente MGH, Harling OK, et al. Current status of boron neutron capture therapy

of high grade gliomas and recurrent head and neck cancer. *Radiat Oncol* 2012;7:146–166, with permission.)

BNCT has also been used to treat patients with malignant meningiomas that were either nonresponsive or recurrent to conventional treatment. Miyatake et al. reported on 32 consecutively treated cases with 20 cases at risk for more than 4 years.[72,73] For these 20 patients, the medial survival time was 14.1 months, but only 3 patients had infield failures.

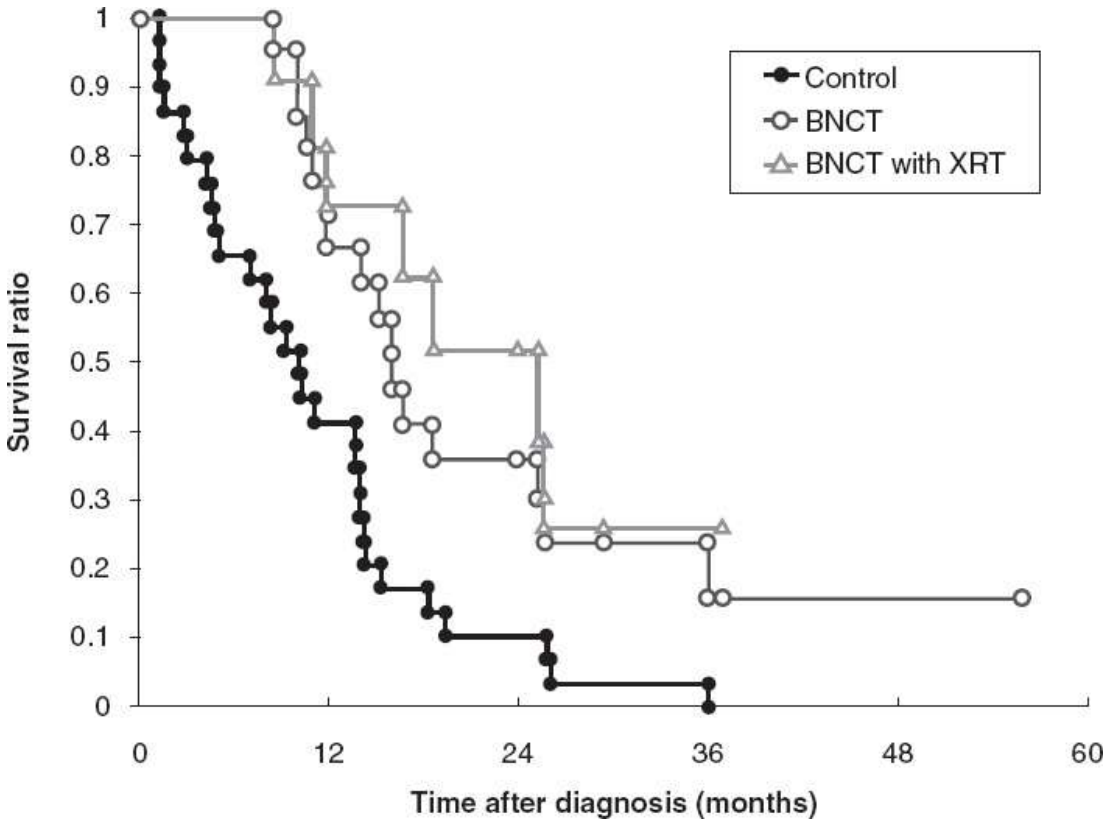

FIGURE 22.9. Kaplan-Meier survival curves for patients with *de novo* glioblastoma patients treated BNCT compared with a historical control group of 27 patients treated at the same institution with surgery, photon radiotherapy, and ACNU-based chemotherapy (medial survival 10.3 months). There are two groups of BNCT patients, those treated with BNCT alone (median survival 15.6 months) and those treated using a combination of BNCT and photon radiotherapy (median survival 23.5 months). (Reprinted from Miyatake S, Kawabata S, Hiramatsu R, et al. Boron Neutron Capture Therapy for Malignant Brain Tumors. *Neurol Med Chir* [*Tokyo*] 2016; 56[7]:361–371. Copyright © 2016 The Japan Neurosurgical Society. With permission.)

A very interesting approach to the treatment of liver metastases was begun at the University of Pavia in Italy.[74] The patient is infused with BPA, and the diseased liver is extirpated and irradiated in the reactor and then reimplanted into

the patient. Two patients have been treated in this manner, with one long-term survivor who eventually died of distant metastases 4 years from the time of the procedure.

SUMMARY

Both fast neutron radiotherapy and BNCT are forms of high LET radiotherapy. Fast neutron radiotherapy has been more extensively studied, including many randomized clinical trials comparing it to conventional radiotherapy. Only in limited clinical settings has it been shown to be more effective than standard radiotherapy. Work is in progress to develop a form of intensity-modulated neutron radiotherapy (IMNT), which may reduce treatment-related side effects and extend its applicability. BNCT has been much less well studied with no randomized clinical trials to date. It is a conceptually intriguing, binary treatment and currently is limited by the available boron compounds approved for clinical use. To date, the neutron beams used in clinical BNCT have been produced using nuclear reactors, which are certainly sufficient for proof-of-concept studies, but accelerator-based neutron sources will be necessary if this technology is to be placed in a hospital environment. Because of reactor safety concerns following the Fukushima incident, the Japanese BNCT program is switching to accelerator-based neutron sources. Currently, there are only three operating reactor-based programs, the THOR reactor in Taiwan, an in-hospital neutron irradiator at the Third Xiangya Hospital of Central South University in Beijing, and the Centro Atomico Bariloche reactor in Argentina, that are actually treating patients. Programs at other centers are in the planning stage.

CHAPTER 23

Carbon Ions

Pascal Pommier, Stephanie E. Combs, and Tadashi Kamada

INTRODUCTION: PRESENT STATUS AND PERSPECTIVE FOR CARBON IONS

Carbon ion therapy is an innovative radiotherapy modality mostly dedicated to cancers considered as unresectable and radioresistant to photons, thanks to its radiobiologic properties combining the advantages of the high dose distribution conformity of protons for deep tumors (superior to photons and neutrons) and of the higher biologic effectiveness (compared to photons and protons) of high linear energy transfer (LET) particles such as neutrons. Moreover, the combination of the biologic and ballistic properties of carbon ions also permits to greatly reduce the treatment period compared with photon or proton radiotherapy. Long-term clinical data based on phase I and II large studies are now available, allowing to consider carbon ions as an alternative (see a referent therapy in some specific situations), and phase III trials are ongoing to measure the expected benefit of the radiotherapy modality and favor its diffusion.

Lawrence Berkeley Laboratory

The use of charged particles (protons and ions) for clinical applications has been first proposed in 1946 by R.R. Wilson.[1] A decade after, the Lawrence Berkeley Laboratory (LBL) in California started patients' irradiation, first with protons (1954) and then with light ions, helium from 1957 to 1974 (more than 2,000 patients) and higher particles, mainly neon ions (433 patients from 1975 to 1992, date of the closure of the center). Few patients were treated with carbon ions at the LBL. Miscellaneous cancer types were treated with neon ions, mainly base of skull tumors with several pathologic types including chordoma, chondrosarcoma, meningioma, adenoid cystic carcinomas (ACCs) as well as osteosarcomas, sacral chordoma, glioblastoma, cholangiocarcinoma, head and neck squamous cell carcinoma, and prostate cancer. Despite severe limitations in

terms of beam application (fixed horizontal beam only), quality of imaging modalities available at that time, and limited periods for clinical applications (30% of the Bevalac running time), the LBL experience permitted first to report a high local tumor control in radioresistant tumors, especially with neon particle, and to demonstrate the feasibility and the safety of high-LET particle therapy.[2–6]

National Institute of Radiological Science

The heavy ion radiotherapy project in Japan started in 1984. A unique double-synchrotron ring heavy ion accelerator system dedicated to the project was designed and constructed. It consists of two ion sources, an RFQ (radiofrequency quadrupole) linear accelerator, an Alvarez linear accelerator, two synchrotron rings, a high-energy beam transport system, and an irradiation system. It was completed in October 1993 at the National Institute of Radiological Sciences (NIRS), Chiba, Japan, and named the Heavy Ion Medical Accelerator in Chiba (HIMAC). There are three treatment rooms with fixed vertical and horizontal beam lines. The accelerated energy of the vertical carbon ion beam is 290 or 350 MeV/u and that of the horizontal beam is 290 or 400 MeV/u. The range of the 290-MeV/u carbon ion beam is approximately 15 cm in water, that of the 350-MeV/u beam is 20 cm, and that of the 400-MeV/u carbon ion beam is 25 cm. Maximum field size is 15 cm by 15 cm.[7] To produce uniform irradiation fields, a passive beam delivery system was employed with a pair of wobbler magnets and a scatterer. The range shifter is applied for adjusting the residual range of carbon ions in the patient and the ridge filter to spread out the Bragg peak in the depth dose distribution of carbon ions. After commissioning of the system including preclinical biologic study, in June 1994, NIRS started heavy ion radiotherapy using carbon ion beams generated by HIMAC.[8]

Since then, clinical studies to develop safe and secure irradiation technologies such as respiration gating and optimized dose fractionation for various cancers have been conducted. All the carbon therapies have been performed as prospective phase I/II and II clinical trials in an attempt to identify tumor sites suitable for this treatment including radioresistant tumors and to determine optimal dose fractionation, especially for hypofractionation in common cancers. In the phase I/II studies to confirm the safety of carbon ion therapy and to obtain a clue to an antitumor effect, the number of fractions and treatment period were fixed for each disease, and the total dose was gradually increased by 5% to 10%. When the recommended dose was determined in the phase I/II studies, they were incorporated into the phase II studies. At NIRS, more than 10,000 patients have

been treated with carbon ion beams for the last 23 years, and the clinical efficacy of carbon ion therapy has been demonstrated for many malignant diseases.

A new medical facility at HIMAC, using the existing synchrotron, has been opened in 2011. It comprises three rooms, two with a robotic arm–controlled patient table for fixed horizontal and vertical scanning irradiation ports, and the third one is equipped with a lightweight rotating gantry with the superconducting magnets. NIRS completed installation of scanning equipment including compact rotating gantry and commissioning of the system and started the clinical trial using compact rotating gantry in May 2017.

Present Status and Perspective for Carbon Ions in Japan

At present, 10 carbon ion therapy facilities are operating around the world, 5 of them in Japan. In 1984, Japanese government decided to embark on a program of carbon ion therapy at Chiba. Clinical studies, started in 1994, have been showing the promising outcomes in general. They have lead to other carbon ion therapy facilities in Japan.

Hyogo Ion Beam Medical Center (HIBMC) was established in 2001 and was the world's first ion beam facility that provided both proton and carbon ion beams. Since then, a total of 2,367 patients were treated with carbon ion beam by the end of September 2010 at Hyogo (PTCOG data). Its lower energy (320 Mev/u) and smaller field size (10 cm by 10 cm) for carbon ion beam compared with other Japanese facilities (more than 400 Mev/u) restricted indications of carbon ion therapy for smaller and shallower tumors. HIBM increased the energy up to 375 Mev/u recently.

The third carbon ion therapy facility was completed in March 2010 at Gunma University Heavy Ion Medical Center. It is a concise carbon ion therapy accelerator, complex realized almost one-third of size and construction cost of HIMAC with same performance.

The fourth facility, named SAGA HIMAT (heavy ion medical accelerator in Tosu), a concise Gunma-type system, located southern part of Japan, was completed in August 2013 and started treatment. The fifth is in Kanagawa Prefecture near Tokyo and begun treatment using scanning beam with fixed beam lines in December 2015. Another two facilities are under construction in Osaka and Yamagata using scanning beam, and Yamagata will be equipped with more compact rotating gantry.

Data from Germany: Gesellschaft für Schwerionenforschung and

Heidelberg Ion Therapy Center

In Germany, the unique possibility to perform carbon ion research and treatment was possible at a basically preclinical research institution. At the GSI in Darmstadt, Germany, patients were treated with carbon ions from 1997 on by the Department of Radiation Oncology in Heidelberg, Germany. Within the research context of GSI, three beam time blocks per year were provided for patient treatment. As a collaborative effort consisting of clinicians, biologist, physicist, and engineers from the University Hospital of Heidelberg; the German Cancer Research Center (DKFZ) in Heidelberg, Germany; the Forschungszentrum Rossendorf in Dresden; and the Biophysics Group at GSI, patient treatment could be realized accompanied by extensive preclinical research.

For beam delivery provided by a synchrotron, the intensity-modulated raster scanning technique was developed, and biologic dose calculation was refined using the local effect model (LEM) developed by Scholz and coworkers.[9–11] Clinical efficacy of this approach was shown and validated in over 600 patients with special focus on radioresistant tumors such as chordomas and chondrosarcomas of the skull base, ACCs, and high-grade meningiomas.

In Europe, the first medical center treating patients with carbon ion radiotherapy was the Heidelberg Ion Therapy Center (HIT) in Heidelberg, Germany. The center is equipped with a synchrotron providing different particle species for three treatment rooms. Two rooms are equipped with a horizontal beam line, and in one room, the world's first carbon ion gantry has been realized. Since November of 2009, the center is in clinical operation offering particle treatment for about 1,300 patients per year. The center is directly connected to the existing department of radiation oncology to allow for streamlined work flow; patients can be treated as in- and outpatients.[12,13] The center delivers particle treatments via active raster scanning, which has been developed at the Gesellschaft für Schwerionenforschung (GSI), and treatment planning and biologic plan optimization have been adopted from the work performed also previously at GSI.[14]

Uptake of clinical routine was based on the indications treated at GSI, focusing on skull base chordomas, chondrosarcomas, as well as ACCs. Subsequently, a number of clinical studies on varying indications started recruiting with different treatment concept including randomized trial comparing carbon ions versus proton radiotherapy.[15–17]

On December 2015, more than 2,000 patients received carbon ion at the HIT (PTCOG data). Initial clinical experience included predominantly brain and skull

base tumors. Especially important are long-term data on skull base chordomas and chondrosarcomas including both patients treated at GSI and in Heidelberg. Most patients are treated within clinical trials, some of the comparing protons to carbon ions, and come providing evidence for dose escalation concepts.

Marburg Ion-Beam Therapy Centre

The Marburg Ion-Beam Therapy Centre (MIT), located in Marburg, Germany, is in clinical operation since October 2015 for protons and carbon ion therapy.

The accelerator facility consists of a LINAC and synchrotron provided by Siemens Healthcare/Danfysik and is equipped with the raster scanning technique.

National Centre of Oncology Hadrontherapy, Italy

The Italian National Center of Oncologic is operational since 2011 in Pavia.[18] National Centre of Oncology Hadrontherapy (CNAO) is provided with an accelerator (synchrotron P-C 400 MeV/u) working with the same technology of one of CERN and is able to produce protons and carbon ions.

The Center has three treatment rooms (equipped with horizontal, vertical, and oblique beams) with 6-DOF robotic couches and 3-D in room imaging.

The total number of patients treated is 1,365 (up to November 2015). The treatments with carbon ions are about three times those with protons. Treatment of moving targets with gating and rescanning technology, such as treatment of pancreatic adenocarcinomas and hepatocellular carcinomas, is ongoing.

China

In China, two facilities are in operation. Institute of modern physics in Lanzhou started their treatment in 2006, and 213 patients were treated with passive beam until December 2015. Shanghai Proton and Heavy Ion Center is affiliated to Fudan University also in operation using scanning beam since 2014 and treated 149 patients.

MedAustron (Austria)

In Austria, the carbon facility at Wiener Neustadt has completed the certification process and will offer proton and carbon ion treatments in 3 medical rooms (2 rooms for carbon ions with fixed beam lines, horizontal only and vertical + horizontal, respectively).

TECHNICAL ASPECTS: PRESENT STATUS AND PERSPECTIVE

Beam Delivery

The current passive beam delivery system used in Chiba is a quite reliable and robust system and had proven stable performance at HIMAC since 1994. A respiratory-gated irradiation technique was also put into practical use for the treatment of moving targets with the passive beam delivery system.[19] The similar systems are adopted at Hyogo and Gunma University.

A scanning irradiation method, which uses “narrow” pencil beams of carbon ions to cover a target volume by superimposing the spot beams of carbon ions slice by slice, has been developed and applied at GSI and then at HIT. The new facilities at HIMAC, Pavia, Shanghai, Kanagawa, Germany, and Austria are (will be) equipped with this system. Compared to passive methods, the scanning irradiation techniques permit a more conformal irradiation of the target volume especially with a better sparing of the normal tissue located in the beam channel entrance (i.e., skin) and are therefore more appropriate for the treatment of complex-shaped lesions that cannot be adequately irradiated by the passive beams. The scanning also permits to eliminate the need for constructing compensation filters as well as patient-specific collimators. The motion management is usually more complex and difficult in scanning treatment; however, respiratory gating, high-speed rescanning, and sophisticated target volume definition like field-specific target volume (FTV) were developed to realize the clinical application of scanning for the moving target.[20,21]

Gantry

The world’s first carbon ion gantry was designed and constructed at HIT (total weight of over 600 t of steel; about 420 t precisely turning around the patient; length 25 m with a diameter of 13 m). Clinical operation of the gantry started in 2012.

A lightweight rotating gantry using superconducting magnets has been designed and was installed in the new HIMAC facility in 2015. The compact gantry was put into clinical use in May 2017 at NIRS.

Gating and Tracking

To reduce the enlargement of irradiated volume with respiration, a respiratory-gated irradiation technique was developed for carbon ion therapy at HIMAC.[22] In this technique, the irradiation-gate signal is generated only when the target is

located at the designed position and the synchrotron can extract a beam. Thus, one of the key technologies for the respiratory-gated irradiation is the beam-extraction method from the synchrotron according to the gate signal. For this purpose, the RF-KO slow extraction method, which utilizes a transverse beam heating by an RF-field tuned with a wave number of a horizontal betatron oscillation, was developed[23] as well as the respiratory-gated irradiation system.[18] In this system, the respiration signal is generated by observation of movement of an LED set on the surface of the patient's body through a position-sensitive detector. The respiratory-gated irradiation system has been utilized for treatments mainly for liver and lung tumors since 1996 and very effective for reduction of fraction number in these tumors moving along with respiration.

Treatment of moving organs with ions applied with the raster scanning technique confronts the physicist and clinical with novel challenges. Because of the interplay effect of the scanning beam and the moving target substantial over- and underdosage within the target volume is generated, therefore, it cannot be precisely calculated and guaranteed that the planned dose will be applied homogeneously.[24] Therefore, effective compensation mechanisms are necessary for the treatment of moving targets.

Several approaches are currently under investigation: Monitoring breathing motion and using the information for gating strategies (irradiating during set gating windows) can significantly reduce interaction.[24] Another approach is the rescanning technique: The volume is not scanned one by the beam with the whole calculated dose, that is, particle number, but the volume is scanned several times, and the particles (or dose) are divided onto the scanning runs. With this concept, a more homogeneous spread of the particles and dose over the volume can be achieved, with increasing homogeneity with the number of scanning runs.[25] A sophisticated concept is monitoring organ motion and making the beam follow the movement of the target volume; this required fast communication between the beam scanning system and the monitoring setup, to provide real-time tracking of the volume.[24]

All three concepts are currently under evaluation; potentially, the technique used may be depending on the tumor type or anatomical region treated; additionally, target volume concepts might help compensate for some minor organ movement. However, using only compensatory target volumes, such as internal target volumes (ITVs) as used in photon radiotherapy, will not suffice.[24] Variation of spot scanning size and reduction of grid size can also help compensate organ motion. It is most likely that a combination of several

approaches, that is, specific target volume, modification of spot size, and perhaps gating, will provide optimal and clinically applicable dose distributions.

Beam Imaging (TEP)

As a by-product of particle radiotherapy, β^+ activity is generated and can be monitored using conventional PET scanners to *in vivo* monitoring of dose application. Several centers offering particle therapy have established this possibility.

At GSI, an online PET imager had been built into the treatment cave allowing for online monitoring of β^+ activity during each fraction, enabling later correlation with the planned and calculated treatment plan for passive beam delivery centers, such as Mass General in Boston or Centers in Japan.

Promising experience in PET imaging of proton and carbon ion therapy has been so far obtained for more than 50 patients monitored after passive proton treatments in the United States and Japan, as well as more than 400 patients monitored during scanned carbon ion beam irradiation at GSI Darmstadt, Germany. At the GSI pilot project, the value of PET for improving the accuracy of the semiempirical CT-range calibration curve employed by the treatment planning system as well as for detecting and quantifying deviations between planned and actual treatment delivery because of patient misalignments or anatomical changes over the course of fractionated therapy could be demonstrated.[26] At HIT, a commercial PET/CT scanner has been installed in a dedicated room adjacent to the treatment area and implemented in clinics.[27–29]

CARBON IONS' RADIOBIOLOGIC PROPERTIES: RATIONALE FOR PATIENTS' SELECTION

Carbon ions for clinical applications are characterized by two main properties: (a) a depth dose distribution with a sharp maximal energy deposition at a definite depth (the "Bragg peak") related to the beam incidence energy, with almost no dose deposited beyond this peak (Fig. 23.1), and (b) a biologic efficiency increasing at the end of the beam's range, within the Bragg peak.

Although not demonstrated by large prospective randomized clinical trials, the potential clinical gains achievable by these ballistic advantages led to the definition of several "standard" indications for protons and carbon ion therapy.[30,31]

Dose Distribution: Bragg Peak and Spread-Out Bragg Peak

Although similar, there are some notable differences between the dose-depth distribution of protons and carbon ions that may have clinical impacts, the presence of a "fragmentation tail" for carbon ions because of nuclear interactions, allowing high-quality PET imaging, and a very narrow penumbra for carbon ions compared to protons.[31]

Similarly to protons, carbon ion beams are spread out to conform to the target, resulting in the spread-out Bragg peak (SOBP) after a low dose "plateau" within the entrance channel beyond the target (Figs. 23.2 and 23.3). This can be achieved by several techniques, mainly with passive scattering, but also with more advanced techniques (pencil beam and wobbling or uniform scanning), achieving a lower dose deposit within the normal tissue in the entrance of the beam (proximally to the tumor volume) while optimizing the distal dose distribution and therefore a higher dose distribution conformation.

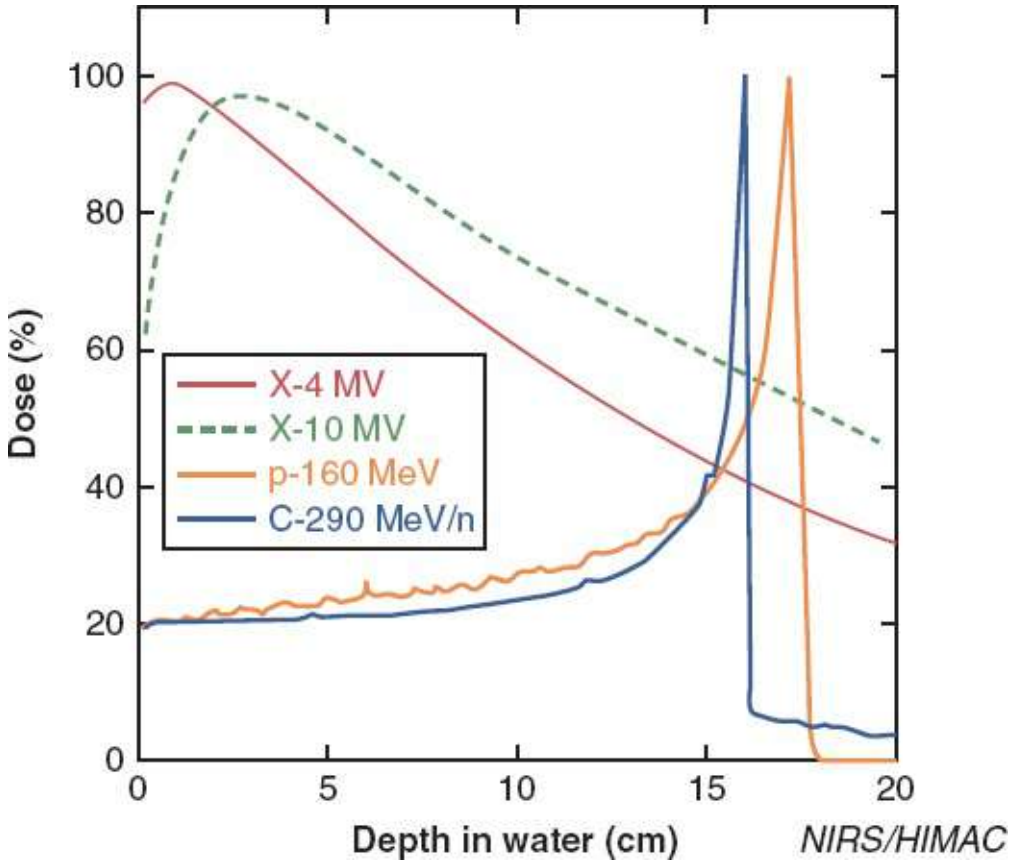

FIGURE 23.1. Bragg peak (protons vs. carbon ions vs. photons).

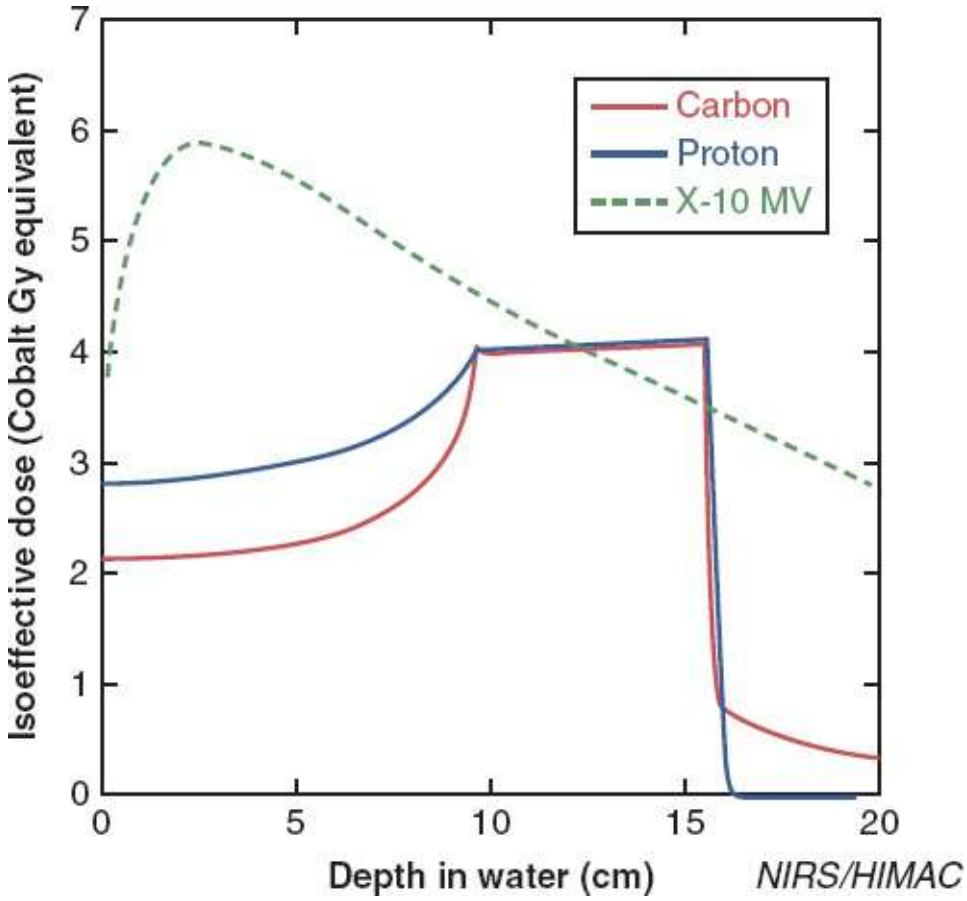

FIGURE 23.2. Spread-out Bragg peak (protons vs. carbon ions vs. photons).

Treatment Plan Intercomparisons

Several treatment planning comparative studies between carbon ions and protons or photons have been so far published.

For similar and strict constraints to critical organs at risk, carbon ions alone or a combination of carbon ions and photon intensity–modulated radiotherapy (IMXT) was superior to IMXT alone or proton therapy for spinal chordomas or sarcomas.[32,33]

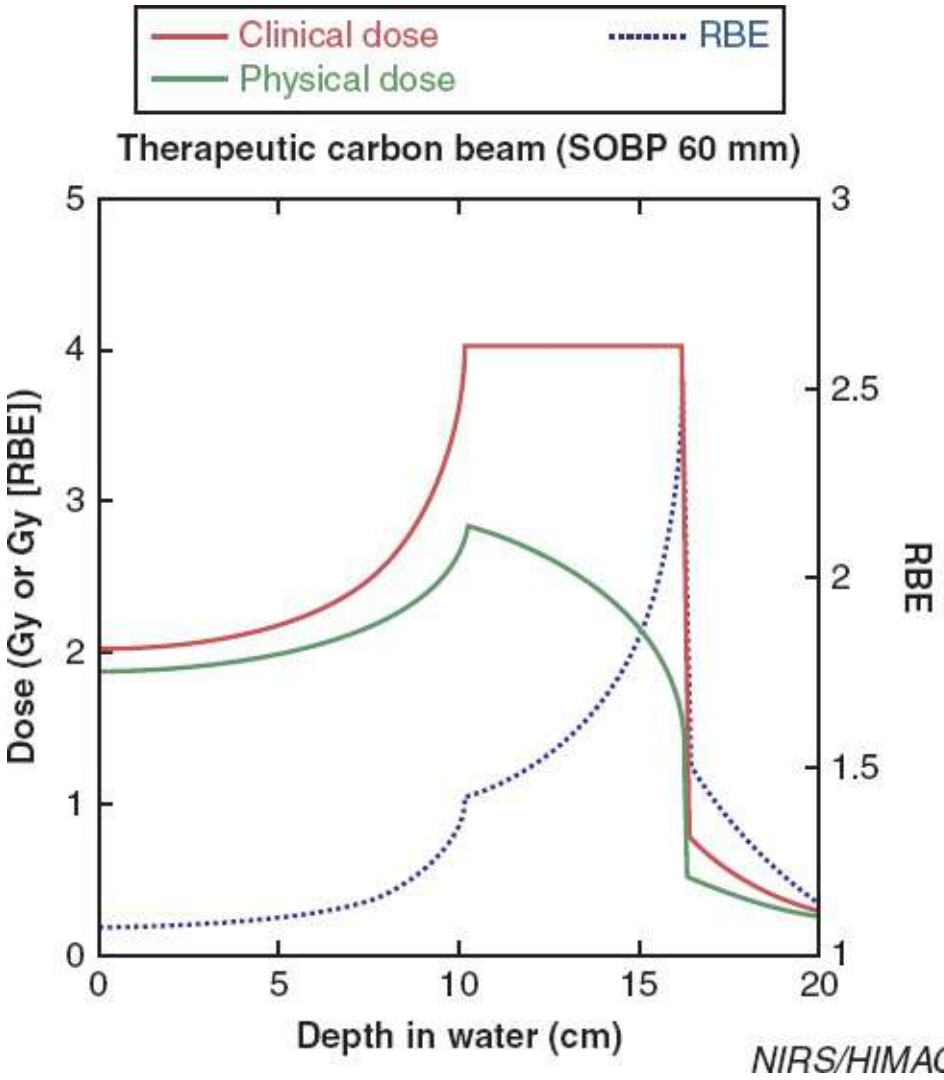

FIGURE 23.3. Design of a carbon ion spread-out Bragg peak (SOBP). The high-LET region of the carbon ion beam is located in the distal part of the Bragg peak, and the SOBP becomes a weighted function of several Bragg peaks at various energies, which results in a dilution of the dose-average LET in the target volume. Therefore, the physical dose (*gray*) has to be decreased as the relative biologic effectiveness (RBE) value rises so as to have a flat biologically effective dose across the SOBP.

Similar results have been reported for selected head and neck tumor and ACC with infiltration of the skull base[34,35] with carbon ion versus photons both for tumor coverage and OAR preservation. More recently, the ROCOCO multicentric in silico trial also demonstrated a benefit with carbon ions over photons but also over protons in reducing at-risk organs' mean dose in reirradiation.[36] However, as expected, particle therapy (protons or carbon ions) were less effective to protect the bladder and rectal wall compared to brachytherapy for prostate cancer.[37]

Based on meta-analysis, a tumor control probability (TCP) model has been developed and validated in prostate cancer treated by photons, protons, or carbon ions and should be of interest for future prospective clinical evaluation.[38]

Integral Dose

Another advantage of particle beams is that fewer fields are required to achieve an acceptable dose distribution for difficult cases, which lead to a dramatic decrease of the integral dose (and potentially a lower incidence of radio-induced cancer, especially in pediatric indications) compared to IMXT.[39]

Biologic Effectiveness and Equivalent Biologic Rate

Similarly to neutrons, carbon ion interactions are characterized by a high LET that provides for a given physical dose a higher biologic effect compared to low-LET irradiation modalities (photons and protons). Therefore, the dose delivered with high-LET particles is prescribed in gray equivalents (GyE) or cobalt gray equivalents (CGE) equal to the measured physical dose in gray multiplied by a relative biologic effectiveness (RBE) factor.

Interestingly for clinical applications, this higher biologic efficiency may lead to a higher TCP for "radioresistant tumors" but may also increase the normal tissue complication probability (NTCP), which is limited to the Bragg peak (though to the SOBP). Within the "entrance" channel where the main proportion of the organs at risk should be, there is no additional biologic effect.

The RBE of carbon ions is difficult to calculate, and for dose-reporting purposes, a value of 3 is often utilized based on neutron experience. However, several other parameters should be taken into account such as dose per fraction, fractionation, tissue type, target volume, and pO_2 value at each point in the irradiated volume and in addition the variation in RBE along the SOBP (higher at the distal part than at the proximal part)[31] (Fig. 23.3). In NIRS, the LET dependency is taken into account in the design of clinical dose distribution by choosing the 10% survival of the HSG tumor cells as end points, and it was evaluated through the TCP analysis for non–small cell lung cancer (NSCLC).[40,41] The LEM, a generic model allowing for RBE calculation in various tissue types and for various end points, has been developed and applied in GSI and is in use for biologic treatment planning in the HIT.

Dose Fractionation

The capacity for normal and cancer tissues to repair sublethal radiation injury is

sharply reduced with high-LET radiation both for normal tissues and cancer cells. This leads to question the need for dose fractionation (applying standard fractionation scheme with low dose per fraction) justified in low-LET therapy (photons and protons) by a higher kinetics of sublethal radiation injury repair for normal tissue versus “radiosensitive” tumors.

Experimental data with high-LET particles did not find any differences in RBE values between tumor and normal cell lines in standard culture condition.[42,43] However, experiments conducted with fast neutrons and carbon ions have demonstrated that increasing the dose per fraction tends to lower the RBE of both the tumor and normal tissues but with a more important decrease for the normal tissue given a higher therapeutic ratio for short-course hypofractionation schemes with carbon ion RT.[42,44] At the NIRS in Chiba, Japan, hypofractionated carbon ion RT has been investigated systematically for a variety of tumor entities, and it seems that a significant reduction of overall treatment time can be accomplished for many tumor entities without enhancing toxicity.[7]

Applications for Patients’ Selection and Radiotherapy Schemes

To summarize, the best indications for carbon ions based on its biologic advantages over low-LET radiation (photons and protons) and poor dose-depth distribution (photons and neutrons) are tumors that demonstrate low radiosensitivity when treated with photons, particularly if the tumor is surrounded by radiosensitive normal tissue.

Carbon ions’ biologic and physical properties also justify the use of a larger fraction dose than in conventional radiotherapy schemes with an impact on patients’ quality of life (shorter overall treatment time) and also a major economical impact (reduction of the cost for the health insurance).

CLINICAL DATA

Mainly based on the clinical experience of the NIRS and the GSI, several clinical data are available to assess the efficacy and tolerance of carbon ion radiotherapy in miscellaneous tumor locations and pathologies.

To date, medical data on carbon ion therapy rely on prospective phase I (dose escalation and hypofractionation assessments) and II trials conducted in more than 20,000 patients mostly at the NIRS, GSI and HIT[45] (*PTCOG data*). The main clinical data are summarized for each tumor sites in Tables 23.1 to 23.10.

Head and Neck Cancers (Table 23.1)

Carbon ion therapy has been applied in several tumor types for head and neck primary or recurrent cancers (unresectable or R1-R2 tumors) in phase I and II prospective studies and in some selected case as a second irradiation.[46]

Data from Japan (NIRS, Hyogo, and multicenter studies)[47–55] and from Germany (HIT)[56–60] have been recently updated and are summarized in Table 23.1.

The most impressive data with carbon ion only or with an mixed treatment beam (using carbon ions as a boost) have been obtained for ACC with high local control obtained at 5 years and even later, however, with the exception of very locally advanced tumor with brain involvement (T4b). Similar results have been obtained for non-ACC malignant tumors. Regarding mucosal melanoma, despite a high local control, the prognostic is still very poor because of the frequent occurrence of distant metastases. The benefit of adding an adjuvant and concomitant chemotherapy has been suggested in the Japan Carbon Ion Radiation Oncology Study Group (J-CROS).[53]

When compared to their historical data, a dose response was observed for head and neck sarcoma in the NIRS experience in terms of 3-year local control and 3-year overall survival.[61] These results have been confirmed in a large multicentric analysis (Sulaiman, 2018).

The feasibility of dose escalation with carbon ions used as a boost has been demonstrated, thanks to the prospective phase II trial COSMIC for malignant salivary gland tumors.[56] In addition, the comparison of the clinical outcome for locally advanced ACC treated within the same period by the Heidelberg radiotherapy team either with a combination of photon IMRT with a carbon ion boost (39 pts) (total median dose 72 GyE) or with photon IMRT alone (29 pts) (median dose 66 Gy) was in favor of the dose escalation carbon ion boost versus photons only.[57]

A prospective trial has been launched at the HIT to evaluate the association with cetuximab for these tumors.[62]

Another unresolved question would be to compare the two main strategies developed for these tumors: exclusive carbon ion irradiation (applied at NIRS and CNAO) versus carbon ions as a boost, associated with photon IMRT (standard protocol at HIT).

A large literature review performed in 2011 by the Maastricht group[63] on head and neck cancer comparing photons, protons, and carbon ions was also in favor of carbon ions. Based on these data, a prospective randomized study

(PHRC–ETOILE) has been launched in France in 2017 to compare carbon ions and low-LET radiotherapy (either by photons or protons) in terms of progression-free survival and also in terms of medicoeconomics benefit for unresectable or R2 head and neck ACC (and sarcoma).

Many data have been recently updated, with to date large retrospective and prospective phase I to II study, with a median follow-up of more than 5 years for the NIRS and the HIT experience.

Base-of-Skull Chordoma and Chondrosarcoma (Table 23.2)

A dose–response relationship has been observed by the NIRS and HIT with a 5-year local control of 60% and 100% for dose less or above than 60 GyE, respectively.[65,66]

Results from the HIT have been updated in 2014.[67,68] Five- and 10-year overall survival was similar for both histologies, whereas chondrosarcoma was associated with a higher long-term local control compared to chordoma (respectively, 88% and 54% at 10 years).

Two phase III randomized studies have been launched by the HIT to prospectively compare protons versus carbon ion radiotherapy in these indications.[15,16]

Interestingly, the HIT teams have shown that reirradiation with carbon ions via active raster scanning may be offered in some selected patients with skull base–relapsed chordoma and chondrosarcoma.[69,70]

Combs et al. published their experience in 17 young adults and children (median age 18)[5–21] treated with carbon ions for a primary (14 pts) or a recurrent (3 pts) chordoma (10 pts) or chondrosarcoma (10 pts).[71] With a median 49-month follow-up, no severe toxicity has been observed and only 1 patient

experienced a recurrence marginal to the treated volume.

Sacral Chordoma and Chondrosarcoma

CIRT appears effective and safe in the management of patients with sacral chordoma and offers a promising alternative to surgery with a high local control; similarly, see superior to surgical procedures alone[72–74] or with adjuvant proton therapy[75] and a higher functional outcome with few or no severe toxicity regarding urinary and anorectal function.[73,76–80] The occurrence of severe neuropathy was related to the dose level (more than 73.6 GyE).[77] In the series of the HIT, local control was significantly higher when carbon ions were delivered for primary tumors versus at the time of recurrence after a previous surgery.[79]

The application of particle radiotherapy for tumors adjacent to the gastrointestinal tract may be restricted because of the low tolerance of the intestine. In that situation, a surgical spacer may be placed before the particle radiotherapy.[81,82] To note, more than 10% of tumor volume increase at the end of the radiotherapy without further progression was described in 50% of cases.[83]

The HIBMC has recently published its results at 3 years for bone and soft tissue unresectable or R2 sarcomas of the pelvic (mainly chordoma and chondrosarcoma) using protons or carbon ions, with to date no significant differences between both modalities.[84] As expected, chordoma and tumor volume < 500 mL were associated with higher overall survival and progression-free survival.

A randomized phase II trial has been launched by the HIT to compare hypofractionated protons versus carbon ion radiotherapy in sacrococcygeal chordoma.[85]

Osteosarcoma

Several series with protons and photons have demonstrated that high dose irradiation may lead to a relatively high local control at 5 years (~70%) in unresected or incompletely resected osteosarcoma, with a 5-year overall survival of 40% to 67%.[76,86,87]

Similar results have been reported by the NIRS in a series of 78 patients treated with exclusive carbon ion therapy for an unresectable osteosarcoma of the trunk (median diameter of 9 cm), a location known as having the worst prognostic.[88,89] The authors reported a 5-year local control and overall survival of 62% to 33%, respectively.[90] Tumor volume was a major prognostic factor (5-year local control and overall survival of 87% and 31% for volume less or more

than 500 cc, respectively).

A prospective nonrandomized study has been launched at the HIT for nonresectable osteosarcoma.[91]

Other Locations and Histology for Sarcomas

Phase I and II studies have been reported by the NIRS with exclusive carbon ion therapy for unresectable (or refusal of surgery) retroperitoneal sarcoma[92] and extremity[93] and spinal[94] sarcomas, with a high local control (respectively, 69%, 76%, and 79% at 5 years) and a 5-year overall survival of 50% to 56%, with no or limited severe late toxicities.

The role of carbon ion is still debated in unresectable Ewing family of tumors. Results in 5 patients have been reported. With a 12- to 160-month follow-up, only 1 patient experienced a local failure 22 months after the radiotherapy completion, but 3 developed distant metastases.[95]

Meningioma

The Heidelberg team demonstrated the feasibility in terms of tolerance of a protocol with carbon ions used as a boost (18 GyE) after photon therapy (50.4 Gy) even when used as a second irradiation.[96–99] However, the data are still not mature to assess a potential benefit compared to their own experience with high standard fractionation photon and proton therapy or to stereotaxic photon therapy.[100] The long-term results of a prospective protocol in patients with atypical meningiomas after incomplete resection or biopsy are still awaiting.[101]

Astrocytoma and Glioblastoma (**Table 23.4**)

A dose effect has been observed in a phase I/II series of 48 patients treated at the NIRS with a combination of photons, boost with carbon ion (dose escalation), and concomitant chemotherapy for malignant gliomas.[102] The NIRS also reported their experience in 14 diffuse grade 2 astrocytoma patients treated with exclusive carbon ion therapy, also reporting a high local control for high carbon ion dose and no severe toxicities.[103]

Two prospective randomized protocols are ongoing at the HIT for glioblastoma: a randomized phase II trial evaluating a carbon ion boost applied after a combined radiochemotherapy with temozolomide versus a proton boost after radiochemotherapy with temozolomide in patients with primary glioblastoma[14] and a phase I/II trial reirradiation using carbon ions compared to fractionated stereotactic radiotherapy (FSRT) in patients with recurrent gliomas.[104]

Reirradiation (Brain, Skull Base, Head and Neck, and Sacral Region)

Thanks to its ballistic and biologic properties, carbon ion therapy has been performed for reirradiation after local recurrence following photon (or carbon ions) therapy.

The HIT reported their experience in patients with recurrent tumors of the brain, skull base, head and neck, and sacral region (mainly skull base chordoma).[46,69] Survival after reirradiation was 86% at 24 months and 43% at 60 months. For skull base tumors, local tumor control after reirradiation was 92% at 24 months and 64% at 36 months.[69]

Lung Cancer (Table 23.5)

Stage I NSCLC has been a model for the NIRS to assess the feasibility of dose escalation and hypofractionation with exclusive carbon ion therapy.[105]

From 1994 to 1999, phase I/II trials established two standard radiotherapy protocols leading to more than 95% local control with a low severe toxicity (grade 3 pneumonitis in 2.7%) established: 90 GyE in 18 fractions over 6 weeks and 72 GyE in 9 fractions over 3 weeks.[106,107] The results of the latter fractionation were confirmed in a phase II trial including 50 patients.[108] At the same time, another phase II trial permitted to validate another radiotherapy

schedule using only 4 fractions with two levels of dose according to the tumor size (52.8 and 60 GyE, respectively, for stages IA and IB).[109]

These results led to initiate a phase I/II single-fraction dose escalation protocol. The total dose was raised from 28 to 50 Gy RBE. In 20 patients irradiated with 48 to 50 Gy RBE, LC at 5 years was 95.0%, OS was 69.2%, and progression-free survival (PFS) was 60.0% (median follow-up was 58.6 months). As for adverse reactions of the lung and skin, there were no patients with grade 3 or higher, and grade 2 was <2%.[105]

On multivariate analysis, overall survival outcome obtained with carbon ions was significantly better when compared with conventional radiotherapy and similar to those obtained by stereotactic radiotherapy and protons.[110]

Liver (Table 23.6)

From 1995 to 2001, phase I dose escalation and hypofractionation studies (110 pts) have been conducted at the NIRS,[111] resulting to a phase II study (47 pts) with 52.8 GyE delivered in 4 sessions (1 week).[112,113] A high local control was obtained (96% at 3 and 5 years), without severe toxicity (≥2 increase of the Child-Pugh score in 10%), however, with a low overall survival related to the poor general status of these patients. Recently, these detailed results of stepwise dose escalation and hypofractionation in 2 combined prospective trials were published.[113]

DS, disease-free survival; LC, local control; LRFS, locoregional relapse-free survival; OS, overall survival.

An even more hypofractionated scheme with only 2 fractions within a phase I and then a phase II study was then developed, showing a dose effect and for the high dose group (>40.8 GyE) also a high local control rate (94.5% at 3 years), whatever the diameter of the tumor (100% for tumor > 5 cm), and a low rate of severe toxicity (≥2 increase of the Child-Pugh score in 5% to 7%),[112,114] which may be due to a compensatory enlargement in the nonirradiated liver after CIRT that contributes to the improvement of prognosis.[115]

Taking into account the alternative therapies, the optimal candidates for carbon ion therapy would be Child-Pugh A or B liver functions, tumor diameter more than 3 cm, and tumor adjacent to the porta hepatis (size and locations more difficult to treat with radiofrequency ablation or percutaneous ethanol injection).[114]

A phase I study is also planned at the HIT.[116]

Locally Recurrent Rectal Cancer (Table 23.7)

Phase I/II studies have been conducted at the NIRS since 2001 and a phase II study is still ongoing, delivering 73.6 Gy (RBE) in 16 fractions for postoperative locally recurrent rectal cancer (no previous radiotherapy). Although most of the patients had tumors considered as unresectable, results in 180 patients (186 lesions) including 151 patients treated with the highest dose were comparable

than the best published surgical results.[117] A dose effect has been observed for the 5-year local control, 35%, 77%, and 88%, respectively, for 67.2, 70.4, and 73.6 Gy (RBE).

In addition, the clinical outcomes of 34 patients treated with carbon ions (48 to 52.8 Gy [RBE]) for isolated paraaortic lymph node metastasis from colorectal cancer showed a high local control rate (2 y: 70.1%) and overall survival (2 y: 83.3%) without any grade 3 to 5 toxicity.[118]

Some data are also available for carbon ion therapy reirradiation for rectal carcinoma pelvic recurrence. The preliminary results in 62 patients treated at the NIRS demonstrated a high local control (87% at 3 and 5 years) and overall survival (5 y: 43%) for carbon ions (70.4 GyE in 16 fractions) used as a second irradiation after local rectal cancer recurrence, however, with a late grade 3 toxicity in 11 patients (skin toxicity and infection) and a grade 2 peripheral neuropathy in 9 patients.[119]

The HIT is conducting a prospective phase I/II prospective study with carbon ion therapy for recurrent rectal cancer and previously treated with photons,[120] and the first results in 19 patients most of them treated with relatively low doses (median 36 Gy RBE) have been published.[121] With a limited median follow-up of 8 months, 4 experienced a local progression and 3 developed distant metastases. No grade 3 late toxicities were observed.

Pancreatic Cancer (Table 23.8)

Carbon ion therapy has been assessed as a neoadjuvant therapy in radiographically resectable pancreatic cancer[122] within a phase I dose escalation study (30 to 36.8 GyE with 8 fractions in 2 weeks). With a median follow-up time of 33.8 months, there has been no local failure in postoperative patients (21/26 pts), however, with a high rate of metastases (65%). Two patients experienced a grade 3 to 4 toxicity unrelated to carbon ion radiotherapy.

The NIRS also demonstrated the feasibility of carbon ion RT combined with gemcitabine in locally advanced pancreatic cancers, resulting in a low toxicity rate and a high local control and survival for the highest radiotherapy dose compared to historical data.[123]

The carbon ion RT facilities in Japan conducted a retrospective observational study to confirm the treatment outcome for locally advanced pancreatic cancer, which was the first multi-institutional study of carbon ion RT for pancreatic cancer. In total, 72 patients from 3 institutions in Japan were enrolled in the analysis. The data revealed that clinical outcome was comparable to historical

data and toxicity was limited as well.[124]

Prostate Cancer (Table 23.9)

More than 2,700 patients have been treated with carbon ion beam for prostate cancer (mainly high and intermediate risk) at the NIRS, with three main fractionations (20, 16, and 12 fractions).[125–127] Results indicate a higher disease-free survival especially in high-risk patient and a lower incidence of radiation toxicity when compared with standard alternative therapies. A multi-institutional analysis of four Japanese institutes performing carbon ion therapy for prostate cancer was conducted, and similar results to those reported at the NIRS were obtained, with a 5-year biochemical relapse-free survival of high-risk group was more than 90% without any grade 3 or worse radiation toxicity.[128]

CIRT, carbon ion radiotherapy; DS, disease-free survival; LC, local control; LRFS, locoregional

relapse-free survival; OS, overall survival.

The HIT has conducted a prospective randomized phase II study comparing protons and carbon ions using hypofractionation (66 GyRBE with 20 fractions) in both arms in 92 patients.[129] With a 22-month median follow-up, no statistical differences in acute toxicity were reported.

Gynecologic Tumor (Table 23.10)

Carbon ion therapy has been applied in locally advanced squamous cell and adenocarcinoma advanced cervix carcinomas,[130–133] within phase I to II trials. As previous studies show, carbon ion therapy produces high local control without administration of brachytherapy for locally advanced bulky cervical squamous cell carcinoma. Recent phase I/II study, with dose escalation of carbon ion radiotherapy for cervical adenocarcinoma, was accomplished without severe toxicities except 1 case, and a 5-year local control rate (55%) was observed.[133] A new clinical trial of carbon ion radiotherapy with concurrent chemotherapy for locally advanced cervical adenocarcinoma is ongoing.

Carbon ion therapy has been also applied in gynecologic melanoma. Primary melanoma of the gynecologic organs is extremely rare; it has as yet not been possible to establish an optimum treatment modality. A total of 23 patients were treated with carbon ion radiotherapy; the 3-year local control and overall survival rates were 49.9% and 53.0%, respectively.[134] Thus, carbon ion radiotherapy may become a noninvasive treatment option for gynecologic melanoma.

Choroidal Melanoma

A hundred and sixteen choroidal melanoma patients were treated with carbon ions between 2001 and 2012, and the similar local control rate (92.8% at 5 years) and survival rate (80.4% at 5 years) to the proton therapy was obtained. Although most patients had locally advanced or unfavorably located tumor, eye retention rate (92.8% at 5 years) was quite high.[135,136]

Miscellaneous

Several other tumor sites and pathology have been treated with carbon ions within phase I/II trial, the skin and[137] esophagus,[138]which need continued investigation to confirm therapeutic efficacy.

CONCLUSIONS AND PERSPECTIVES

The accumulated clinical experience has indicated that certain types of tumors such as advanced radioresistant head and neck tumors (ACC, adenocarcinoma, and mucosal malignant melanoma), large skull base tumors, rectal cancer (postoperative pelvic recurrence), and sarcomas can only be appropriately controlled and cured by carbon ion therapy with high probability. It has also been made clear that this therapy is capable of suppressing several types of tumors such as peripheral type NSCLC, liver cancer, and prostate cancer safely in a relatively short period of time through these clinical trials. Patients with these types of tumors can be remarkably healed by this therapy within a few days or weeks with minimal discomfort.

relapse-free survival; OS, overall survival.

To date, no randomized clinical trial has shown the superiority of carbon ion beams to protons or photon radiotherapy. Therefore, in the future, not only evaluation of carbon ions alone in specific tumor types but also comparing to advanced photon and proton techniques are required to exploit the full advantage of high-LET particle therapy and to stratify patients for specific treatments.

CHAPTER 24

Patient Positioning Methods: Immobilization, Stabilization, and Monitoring

Josh Evans, Bruce Libby, Laura Padilla, and Stanley H. Benedict

OVERVIEW OF EXTERNAL BEAM IMMOBILIZATION AND STABILIZATION

Rationale for Patient Immobilization and Stabilization

The success or failure of a radiotherapy treatment hinges on the accuracy with which the radiation is delivered. There are many sources of uncertainty in the radiation therapy delivery process that can result in a geometric miss of the intended target volume. A geometric miss of the intended target volume will not only decrease the probability of tumor control but also increase the volume of normal tissue that is irradiated, which can increase the probability of a treatment-related complication. Geometric uncertainties may be broadly classified as mechanical inaccuracies, localization inaccuracies, and positioning inaccuracies. Mechanical inaccuracies include the coincidence of the light and radiation fields, mechanical stability of the couch, laser alignment, and correspondence of the simulation and treatment isocenters. Localization error relates to the difficult nature of defining the location and extent of the target volume during both planning and treatment delivery. The most undesirable result of patient positioning uncertainties, the focus of this chapter, is movement of the target volume out of the treatment field.

The goal of daily patient setup is to reproduce the position at the time of simulation as best as possible; however, setup variations will inevitably occur, which is generally appreciated as a tangible problem and has earned considerable attention in the literature. In an early example, Dunscombe et al.[1] assessed components of positioning accuracy in head and neck patients and

concluded that observed field placement errors were primarily attributable to patient motion. Patients may fidget from being uncomfortable or anxious during the treatment delivery. Furthermore, organs can move internally with respect to bony anatomy, skin marks, and other soft tissues because of normal and unavoidable physiologic processes such as breathing, swallowing, and peristalsis.

The focus of this chapter is to describe devices and methods for immobilization and stabilization of the radiotherapy patient, in which the goal is to reduce positioning uncertainties during each fraction (intrafraction error) and to increase the reproducibility of the patient setup for each fraction (interfraction error). In addition, immobilization devices can decrease the time needed for daily setup and target localization, thus increasing a clinic's throughput. Certain immobilization devices may also allow setup marks to be made directly on the device instead of the patient's skin, which can improve the patient's psychological well-being while under treatment, and some devices may even confer dosimetric advantages in treatment planning. The immobilization system should be lightweight for ease of setup and transport, yet strong and durable so that the device does not break during the patient's course of treatment. Furthermore, the device should be made of materials that minimally affect the megavoltage treatment beam and do not cause imaging artifacts that could impact three-dimensional (3D) visualization of the patient's anatomy for target identification or imaging used for patient alignment.

The devices and techniques for patient immobilization and stabilization described in this chapter have been shown to improve interfraction setup reproducibility as well as reduce intrafraction uncertainties. The overall accuracy of any immobilization system, however, is dependent on the skill and patience of the personnel forming the device at the time of simulation and setting the patient up on the treatment table for each fraction. Adequate training should be provided for each immobilization system employed in a given clinic, and adequate time should be scheduled for proper patient setup and immobilization. Furthermore, some patients will be more challenging to reproducibly align than others such as patients in pain and/or with mobility issues. A variety of devices and positions should be available for each treatment indication to help create a treatment position that maximizes both inter- and intrafraction reproducibility for each patient.

Surface imaging technologies for aiding in the initial setup and for real-time monitoring of the patient during treatment have begun to gain clinical adoption,

and a new section has been added to this chapter to introduce these systems in the context of reducing patient positioning uncertainties. Finally, it must be noted that in some cases, even the most robust techniques for patient immobilization and monitoring do not guarantee accurate daily localization of the tumor volume and should not be a substitute for image guidance when indicated. Tumors are well known to change position relative to other soft tissue anatomy, the external surface, and bony anatomy. Thus, strategies for daily target localization, described elsewhere in this textbook, are also important and are intimately tied to patient immobilization.

Simple Immobilization Devices

Simple methods to reduce intrafraction positioning uncertainty because of patient motion have been in use for decades to ensure that the patient is comfortable. Figure 24.1 illustrates a variety of simple devices currently available that can be used to enhance the patient's comfort. For patients treated in a supine position, a wedge or roll underneath the knees (Fig. 24.1A) can help to reduce stress on the lower back. For arm-down positioning, a ring for the patient to grip (Fig. 24.1D) can increase comfort. For lung and liver treatments, it may be preferable to position the patient with the arms above the head. In these cases, the arms may be supported under the shoulder by foam wedges (Fig. 24.1B) to help the patient attain a restful position. For some head and neck patients, the patient's shoulders may block the inferior portion of lateral treatment fields. In this case, a simple strap (Fig. 24.1C) can be used to pull the shoulders down and out of the treatment fields. A headrest is almost always used with supine positioning to elevate the head and reduce strain on the neck. Standard sets of "Timo" and "Silverman" headrests (Fig. 24.1E) come in a variety of shapes, sizes, and materials. For those not adequately accommodated by the standard set of headrests, several manufacturers offer customizable head cushions that can be molded to the patient's head contour. All of these devices are relatively inexpensive and are often reusable if they can be covered and/or cleaned between uses.

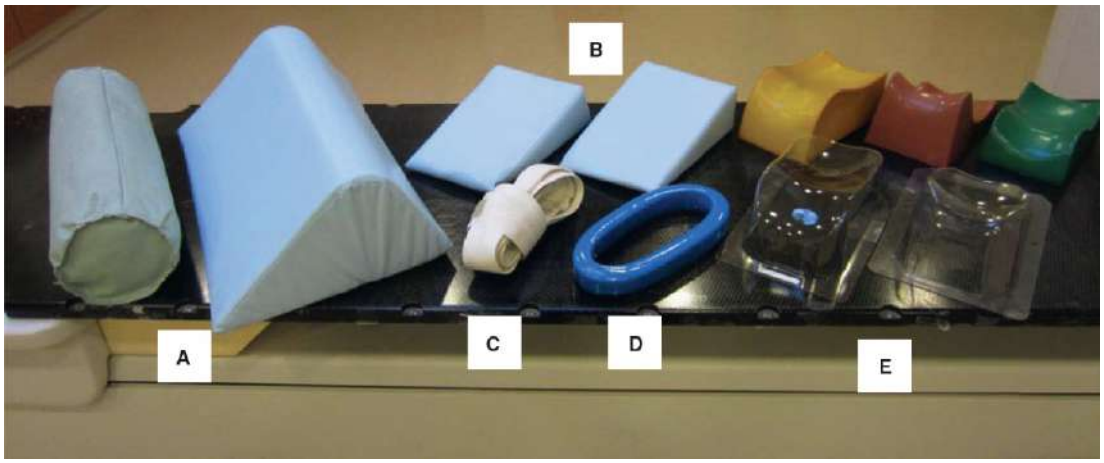

FIGURE 24.1. Simple devices to improve patient comfort. Simple devices are cost-effective and can reduce intrafraction positioning errors by increasing patient comfort. Shown here are (*A*) rolls and wedges that can be placed under the knees and (*B*) wedges to support the arms and shoulders. (*C*) A simple strap can be used to suppress the shoulders in head and neck patients and (*D*) grip rings can be used for the patient to hold on to. (*E*) Headrests are available in a wide range of shapes and sizes. (Image taken at UVA by the author—September 2011.)

Immobilization Features of a Dedicated Radiation Oncology Computed Tomography Simulator

Simple devices incorporated during initial simulation can improve patient comfort and reduce intrafraction motion because of patient movement. However, they may not address day-to-day variations of overall patient setup and positioning accuracy. A major objective of a robust immobilization system is to reproduce the patient's anatomical geometry at the time of simulation for all subsequent treatment fractions. An example of a robust immobilization system to treat a patient with breast cancer is shown in Figure 24.2 to illustrate some of the desired features of a dedicated radiation oncology computed tomography (CT) simulator. With this immobilization system, the patient lies supine with an ergonomic wedge (Fig. 24.2E) under the knees. The arms are positioned above the head and out of the tangential treatment fields. A custom-formed, reusable vacuum-lock bag (Fig. 24.2C), described in more detail in the following body conformal section, helps to support the patient's arms, and a T-bar (Fig. 24.2B) may be used for the patient to grip. The angled baseboard (Fig. 24.2C) on which the vacuum-lock bag rests utilizes gravity to help the breasts fall into a more reproducible position and can be adjusted to minimize skin folds. Many of these devices provide indexing systems for the therapists to record the geometry used for each patient at the time of simulation. This example of a breast setup, where one or both arms may be positioned above the head, highlights the advantage of

a wide bore (e.g., >85-cm diameter) CT scanner (Fig. 24.2B) for radiation oncology treatment simulation, as opposed to the more common 70-cm bore diameter, which may limit the options for positioning certain patients.

Flat couches are favored for radiation oncology treatments to accommodate a wide range of patient sizes, setup positions, and immobilization devices. Diagnostic CT scanners feature a curved couch for patient comfort; the geometry of a patient simulated on a curved diagnostic couch top will be challenging to reproduce on a flat treatment couch. Flat couch top inserts are offered by numerous vendors to reproduce the couch geometry of the treatment unit. An important feature of a couch top insert is the indexing system (Fig. 24.2D), which allows an assortment of immobilization devices to be rigidly affixed in concert to both the simulator and treatment tables with high accuracy. The indexing system improves the interfraction reproducibility of the patient setup and can also decrease the amount of time to set up a patient.

External marks placed on either the patient's skin or the immobilization devices are used for initial laser alignment on the treatment machine as a surrogate for the internal target anatomy. An in-room laser system in the CT simulator suite (Fig. 24.2A) is a necessary feature to provide external reference points that correlate to the internal reference point location. After the simulation CT scan is acquired, the isocenter(s) is(are) defined and the coordinates are transferred to the in-room laser system. The laser system and CT table are then moved to the defined setup point and external setup marks can be made, thus correlating the position of an internal setup point to the external markings.

HEAD AND NECK IMMOBILIZATION DEVICES

Thermoplastic Masks

Adequate immobilization is particularly critical in the treatment of head and neck (H&N) cancers as the target is frequently located in close proximity to critical structures. Thermoplastic masks have replaced traditional plaster-casting methods in most clinics. Thermoplastic masks are heated to approximately 70°C in a water bath or a dry heat oven. At this temperature, the thermoplastic material becomes malleable and can be stretched and shaped to conform to the patient's face, head, and neck. The patient's head and neck is supported by a simple preformed cushion, like those previously described and illustrated in Figure 24.1, or a custom-formed cushion may be made. The mask is connected to a base plate, which is attached to the couch via the indexing system. Setup

marks can be made directly onto the thermoplastic mask, eliminating the need for unsightly marks to be placed on the patient's face for the duration of the treatment.

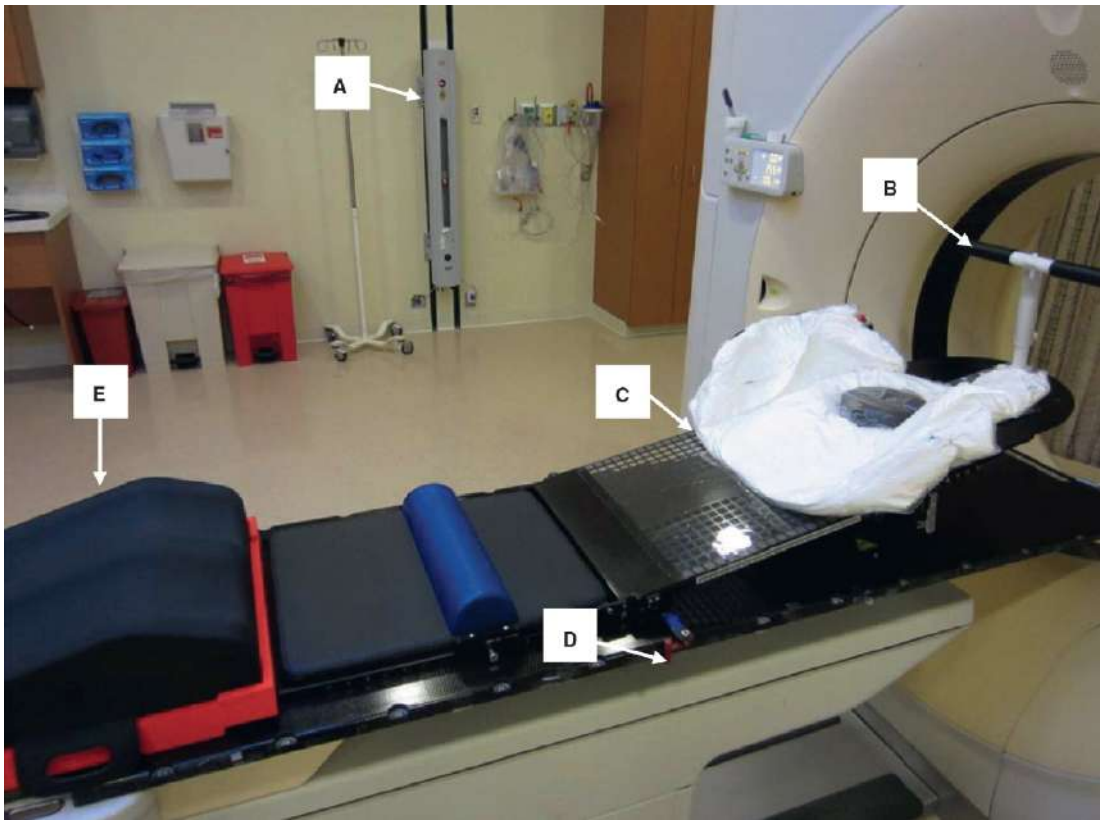

FIGURE 24.2. Dedicated radiation oncology CT simulator. Displayed here is an immobilization system for a breast cancer patient in the simulator suite at the University of Virginia. Some key features of a dedicated radiation oncology CT simulator are (*A*) an in-room laser system to mark the reference point position, (*B*) a wide patient bore (85 cm diameter) to allow more flexibility in patient positioning, and (*D*) an indexed flat couch-top overlay to reproduce the geometry of the treatment table. (*C*) An angled breast board can improve patient comfort and provide optimal positioning of the breast for radiotherapy. (*D*) An indexing bar is used to attach the breast board to the flat couch-top overlay. A vacuum-lock mattress and a T-bar (*B*) support the patient's arms above the head. An ergonomic knee support (*E*) can reduce stress on the lower back. (Image taken at UVA by the author—September 2011.)

Early work with thermoplastic mask immobilization for H&N cancer by Bentel showcased the efficacy of the thermoplastic mask in comparison to the traditional plaster three-strip immobilization technique.[2] In terms of the rate of physician-requested shifts from port films, the thermoplastic mask had a frequency of 6.2% compared to 16.1% for the plaster-casting method. However, this advantage was only observed when the mask was rigidly affixed to the

couch, highlighting the importance of the couch indexing system.[2] Since then, numerous studies quantifying the accuracy of patient setup for H&N cancer have appeared in the literature. The bulk of these studies utilized two-dimensional (2D) portal imaging to quantify setup displacements, though studies utilizing 3D cone-beam CT data have become more common as this technology has recently gained widespread clinical adoption. Generally, systematic and random errors have been reported to have standard deviations ranging from 1 to 4 mm.[3–5] Based on a review of studies assessing setup errors using portal imaging, Hurkmans et al. suggest that random and systematic errors of 2 mm or less should be a practically achievable goal for H&N patients given current immobilization technology and methods.[4]

Figure 24.3 illustrates the flexibility of patient positioning options with thermoplastic masks. Masks can encompass the head only or can extend inferiorly to cover the shoulders (Fig. 24.3A). Gilbeau et al.[3] compared the setup accuracy of the short and long thermoplastic masks in the treatment of head and neck cancer. Portal images were acquired for isocenters placed at the level of the head, neck, and shoulders. Their results show similar setup accuracy with the long and short mask for the isocenters in the head and neck. For isocenter placement at the shoulder level, the use of the long mask resulted in a random setup error of around 1.0 mm, which was significantly less (P = .01) than the 2.3 mm error of the short mask.[3] Thus, a long mask to immobilize the shoulders is recommended for patients receiving supraclavicular treatment in which the isocenter will be placed at the level of the shoulders.

FIGURE 24.3. Thermoplastic masks for H&N patients. For treatment of targets in the

head and neck, thermoplastic masks are routinely used for custom immobilization. **A:** Thermoplastic sheets are commercially available in short versions that cover only the head, as well as longer versions that extend over the patient's shoulders. **B:** They can also be used to treat patients in the prone and lateral positions. **C:** Additional space is needed to accommodate the water bath used to warm the thermoplastic sheets. (Images **A** and **B** courtesy of BionixRT. Image **C** taken at UVA by the author.)

Thermoplastic mask systems are available with a myriad of features including multilayer masks to increase rigidity and masks with cutouts for the patient's eyes to reduce anxiety and accommodate optically guided setup. They can also accommodate prone or lateral setups when these positions may be indicated (Fig. 24.3B). Some commercially available base plates can be angled to allow for the patient to be set up with the neck in an extended or flexed position, which may be used to avoid critical structures such as the eyes. Neck extension can be used with prone positioning for craniospinal irradiation. For prone setup, a donut-shaped cushion supports the patient's face in the base plate and the thermoplastic mask is formed around the posterior aspect of the head to hold the patient's face in the donut. A potential disadvantage of treatment with a flexed or extended neck position is the need for registration with different imaging modalities (e.g., PET-CT or MR-CT) in which the PET or MR were not performed in the patient treatment position.

Every clinic must consider space limitations when selecting particular immobilization and stabilization systems. Thermoplastic H&N systems necessitate more equipment and thus more space in the simulation suite. The water bath or dry heat oven used to heat the thermoplastic sheets for the long H&N masks can be large (Fig. 24.3C). For clinics with insufficient space to house a large heating device, smaller devices are commercially available that will fit the short head-only masks. Furthermore, some commercially available base plates (e.g., VersaBoard; Bionix Radiation Therapy, Toledo, OH) incorporate shoulder suppression systems, which consist of rigid plastic panels to push down on the shoulders. When a long thermoplastic mask is not indicated or not available, a base plate with shoulder suppression panels can help to keep the shoulders out of the beam path for lateral head and neck beams (Fig. 24.3A). In lieu of long thermoplastic masks or base plates with shoulder suppression panels, the patient can pull on a simple shoulder strap (Fig. 24.1C) to move the shoulders inferior and avoid unnecessary irradiation of the shoulders when opposed lateral beams are used to treat the neck.

Thermoplastic masks have been observed to shrink as they cool in the 24-hour period after formation, and this has been shown to lead to systematic setup

errors if not taken into consideration.[6] Furthermore, a mask that has shrunk after the simulation process may be uncomfortable for the patient and may require a full resimulation. BionixRT has attempted to address this problem with the Klarity Green line of thermoplastic material, which is designed to have reduced shrinkage coupled with increased rigidity. As with any immobilization system, the thermoplastic manufacturer's recommendations should be carefully followed, and adequate time should be allowed during simulation for the mask to harden properly while on the patient to minimize the effect of shrinkage.

Bite Blocks as an Alternative to Masks

Thermoplastic masks are widely used for H&N treatment indications; however, they are not well tolerated by all patients, particularly patients with claustrophobia. For these patients, bite block systems that do not incorporate a mask may be an acceptable alternative. Elekta offers a bite block system, the HeadFIX, which is illustrated in Figure 24.4. A custom dental mold is formed to the patient's maxillary teeth, and a vacuum system creates suction of the mold to the hard palate. A custom cushion is placed under the patient's head, neck, and shoulders. The mouthpiece is attached to a carbon fiber frame, which is fixed to the treatment table's indexing system. The head is thus rigidly immobilized via the connection of the mouthpiece to the head frame. The carbon fiber design of the HeadFIX product allows for the use of in-room kV image guidance systems for target localization. The mold can be quickly released from the frame if the patient feels claustrophobic. Setup accuracy has been shown to be similar to thermoplastic masks, on the order of 1 to 3 mm.[7] These stand-alone bite block systems, however, require a high level of patient compliance and may not be suitable for patients with poor dentition or with edentulism. Bite blocks formed with a patient's false teeth are highly discouraged and may result in inaccurate setups or breakage of the patient's dentures. Custom-formed dental molds can also be incorporated in the conventional thermoplastic mask systems described above to provide an additional point of support for the patient. A custom bite block may also be formed with primary goals other than immobilization, for example, to separate the tongue from the roof of the mouth. This can be useful in treatment of sinus/nasal cavity tumors to decrease dose to the tongue and vice versa. Table 24.1 includes a top level summary of the pros and cons of available intracranial immobilization devices.

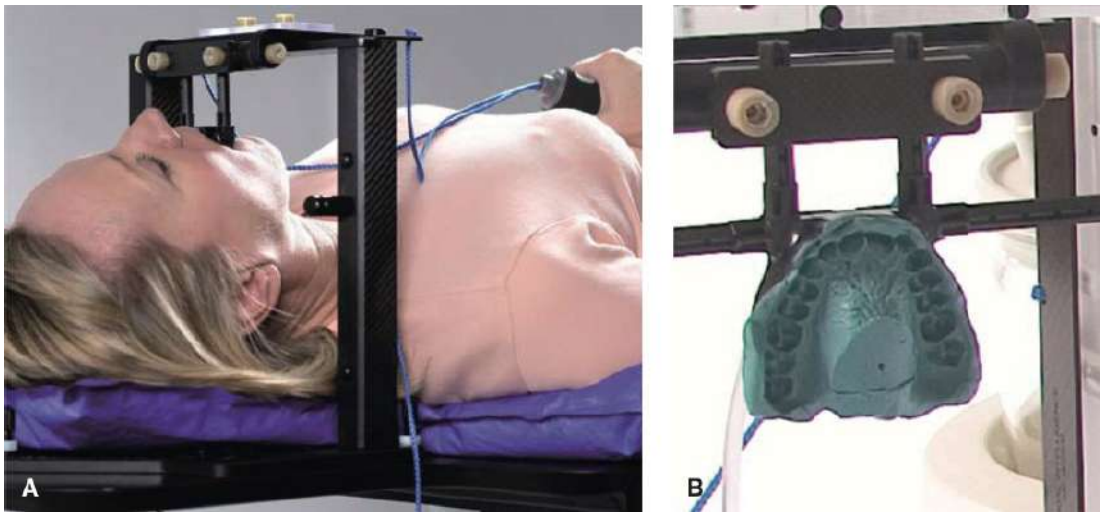

FIGURE 24.4. Bite block system. **A:** The Elekta HeadFIX® (Stockholm, Sweden) is an example of a bite block system that can provide an alternative method for immobilizing head and neck patients who are not able to tolerate a thermoplastic mask because of anxiety or claustrophobia. A custom dental mold **(B)** is formed for each patient and is suctioned to the patient's hard palate. The dental mold is attached to a carbon fiber frame featuring a quick-release handle. (Images courtesy of Elekta, Stockholm, Sweden.)

BODY CONFORMAL IMMOBILIZATION DEVICES

Numerous commercial body conformal immobilization devices are available for a variety of treatment indications. One type of body conformal system uses a two-part foaming agent to form a permanent mold of the patient's body. One such system, the Alpha Cradle, is illustrated in Figure 24.5A. Forms are available for treatment of patients with a variety of disease sites, including the head and neck, breast, thorax, abdomen, pelvis, and extremities. At the time of simulation, the appropriate body form is chosen and placed in a polyvinyl bag where the two-part chemical foaming agents are mixed together, initiating the chemical reaction that causes the foam to expand. The mixed foaming agent is distributed evenly throughout the body form and sealed inside the polyvinyl bag, and the patient is positioned inside the form as the foaming agent expands and conforms to the patient's body contour. The foam continues to expand for approximately 10 to 15 minutes during which the therapists will need to vigilantly guide the foam around the patient to prevent the foam from escaping the bag and moving into locations of least resistance that may contribute little to immobilizing the patient. As with any immobilization device, adequate training is needed to form a high-quality customized patient mold and the manufacturer's instructions should be carefully followed. Chemical foaming agent systems

generally require two therapists to form at the time of simulation, and the process can require approximately 30 minutes. Obviously, great care is needed to prevent any of the chemicals from having direct contact on the skin as this may cause irritation.

Another class of body conformal systems, commonly referred to as “vacuum-lock bags,” is comprised of a bag filled with plastic mini-spheres. These bags are available in a variety of sizes to accommodate different treatment sites and patient positioning techniques. At the time of simulation, the bag is first conformed to the patient’s body contour by pushing the mini-spheres to fill in around the patient. A vacuum pump is then connected to the bag and the air is evacuated from the bag, causing the plastic mini-spheres to lock together to rigidly retain the device’s shape. During the evacuation, the therapists will maneuver the mini-spheres within the immobilization device to provide optimal fit and stabilization of the patient’s body contour. These vacuum-lock bags are made of a durable nylon material to resist tears or punctures and can be expected to retain their shape for 6 weeks or more. They are reusable and may require less time to generate a customized mold than the expanding foam systems. Another advantage of the vacuum-lock bag is that if during the simulation process the device is found not to provide the intended level of immobilization or is found to be uncomfortable for the patient, it can be reinflated and remolded to achieve the desired shape as many times as necessary. The vacuum-lock systems, however, do require a time commitment to clean and remove any setup marks prior to use with subsequent patients. Also, if a tear or puncture occurs during the course of treatment, a new vacuum-lock bag would need to be formed and the simulation and treatment planning process may need to be repeated to deliver the remaining fractions. Each clinic should consider the benefits and drawbacks of each system and it is not uncommon to see both types of body conformal systems used within one institution.

As body conformal devices are used to treat a wide range of sites throughout the entire body, careful thought should be given to each specific case to ensure that the treatment site is properly immobilized, that the setup is reproducible from day to day, and that the patient is able to maintain the position for the duration of each fraction. An immobilization device that extends well beyond the treatment site to encompass adjacent anatomy can be more effective than a more local device that focuses only on the treatment region. For example, Bentel[8] has shown that for Hodgkin lymphoma, a cradle that extends below the pelvis is more effective than a cradle that only includes the upper torso. Devices that

extend around the patient also give the ability to make setup marks directly on the immobilization device for alignment. Aligning the beam to setup marks on the immobilization device can increase the daily setup reproducibility by reducing the reliance on skin marks, which can be especially troublesome for larger or older patients where the skin can be more mobile over the underlying anatomy. Marks can then be made on the patient to help align the patient within the immobilization device. Longer devices also allow for longer setup marks to be made in the superior–inferior direction, which can help detect rotational setup errors.

TABLE 24.1 INTRACRANIAL IMMOBILIZATION DEVICE SUMMARY

Device Name	Description	Pros	Cons	Typical Sites	Re
Timo and Silverman head rests	Foam and plastic head rests with various sizes for a range of body habitus	Inexpensive and reusable.	Not custom formed.	H&N, craniospinal, thoracic, abdominal, pretty much all supine patients	Ye
Custom-formed head rests	Vacuum-lock or water activated custom formed head rests	Custom- formed to patient. Some are re-usable	Added time to simulation process. Some are not reusable	H&N, craniospinal, thoracic, abdominal	Sc Sc
Thermoplastic masks	Thermoplastic mask material is warmed in a water bath until pliable and then is stretched over the patient's face to create a customized device.	Accurate, custom formed immobilization. Can cut-out treatment portals to reduce blousing.	Potential for mask shrinkage. Patient anxiety or claustrophobia. Bolusing effect.	H&N, craniospinal	Nc
Elekta HeadFIX	Bite block for image guided Tx. Advantageous for claustrophobic patients.	Non-invasive, relocatable. Does not require thermoplastic mask material to be tightly	Requires operator skill to create custom maxillary dentition molds. May not be best option	H&N	Fr

		molded to patient's face.	for patients with poor dentition.		
Elekta eXtend	Relocatable bite block system designed for fractionated stereotactic radiotherapy.	Non-invasive, relocatable. Does not require thermoplastic mask material to be tightly molded to patient's face. Allows for fractionated SRS. High degree of patient setup accuracy.	Requires operator skill to create custom maxillary dentition molds. May not be best option for patients with poor denitition.	Intracranial and some extracranial SRS targets in neck	Fr
Invasive, nonrelocatable stereotactic intracranial immobilization devices. E.g.: Leksell Stereotactic Coordinate Frame G, Radionics BRW Frame system	Frame is attached to the patient's skull with four screws. Used for single fraction radiosurgery.	Excellent accuracy in patient repositioning.	Typically requires sedation. Risk of infection and bleeding. Patient discomfort.	Intracranial	Fr
Non-invasive, relocatable intracranial mask based immobilization (e.g.: Brainlab non-invasive mask system)	3 thermoplastic shells custom molded to patient's head and face, which are attached to U shaped frame via two posts on either side of the patient's head.	Does not require placement of screws into the patient's skull. Allow for fractionated SRS. High degree of patient set up accuracy.	Thermoplastic mask may be undesirable in certain patients, such as those with claustrophobia or anxiety.	Intracranial	Ye No
Non-invasive, relocatable intracranial mask-less immobilization (e.g., Gill-Thomas-Cosman	Variety of frame based, non-invasive techniques for reproducible immobilization of the head. May be used	Do not require placement of screws in to the patient's skull. Allow for fractionated SRS. No thermoplastic	May require bite block in some systems. Some systems require additional time for setup verification	Intracranial	Ye No

Relocatable head ring, Stereoadapter 5000)	for single fraction and fractionated SRS.	mask required. High degree of set up accuracy.	(e.g.: Depth Helmet).

FIGURE 24.5. Body conformal systems. Body conformal systems are used for treatment indications throughout the body. **A:** Shown here are two patients in

treatment position with the Alpha Cradle, which uses a twopart foaming agent to create customized conformal body immobilization. (Images courtesy of Smithers Medical Products, Inc. Alpha Cradle is a registered trademark of Smithers Medical Products, Inc., South Canton, OH.) **B:** In the Elekta BodyFIX® system, a cover sheet (*i*) is placed over the patient after being positioning inside the vacuum-lock bag (*ii*) that was formed at the time of simulation. A separate vacuum system (*iii*) evacuates the air between the cover sheet and the patient. The pressure from the cover sheet can help reduce patient motion and improve setup reproducibility. (Image courtesy of Elekta, Stockholm, Sweden.) **C:** Shown here is a room used for storing vacuum-lock bags in the simulation suite at the University of Virginia. The simulation suite services multiple treatment machines at satellite locations. After simulation, the immobilization devices are transported to the satellite treatment sites (pictured on the *right*) via a courier service. (Image taken at UVA by the author, October 2011.)

The Elekta BodyFIX is a unique immobilization system that utilizes a dual vacuum system as illustrated in Figure 24.5B. For simulation, the patient is first placed in a vacuum-lock bag system. A thin plastic cover sheet is then placed over the patient, which is attached to the vacuum-lock bag via special adhesive strips. A vacuum pump is then used to evacuate the air under the cover sheet creating a continuous pressure of up to 600 mbar. The additional pressure created by the cover-sheet vacuum system helps the patient settle into the vacuum-lock bag, which is molded to the patient and then evacuated with a second vacuum system to create the body conformal device. For all subsequent treatment fractions, the pressure from the cover-sheet vacuum system helps the patient settle reproducibly in the vacuum-lock bag. The BodyFIX's vacuum sheet can also provide a degree of abdominal compression, which may help decrease the respiratory excursion of certain tumors. Internal target motion management is discussed further in the stereotactic immobilization section. Patients tolerate the BodyFIX dual vacuum system very well, with infrequent complaints of claustrophobia or discomfort. If the patient feels that the pressure from the cover sheet is uncomfortable, the vacuum pressure for the cover sheet can be turned down or the vacuum-lock bag can be used by itself.

As an early example of body conformal immobilization's efficacy, Bentel and colleagues at Duke University showed that immobilization with the Alpha Cradle expanding foam system reduced the frequency of physician-requested setup corrections based on portal images for a variety of treatment indications, including Hodgkin lymphoma and prostate, lung, and breast cancer.[8,9] It should be noted, however, that not all studies show a clear-cut advantage in setup accuracy with body conformal immobilization devices. For example, an early study by Song et al.[10] showed no statistical advantage of using immobilization in the treatment of prostate cancer in terms of the number of deviations > 5 mm as

quantified on portal images. They did show that obese patients tend to have larger setup errors[10] highlighting the fact that certain subpopulations of patients may be more difficult to set up than others.

Hurkmans' assessment of setup accuracy based on portal imaging provides a good review of the available data up to 2001.[4] This work concludes that with current patient setup, portal imaging, and immobilization techniques, systematic and random setup errors on the order of 2.5 to 3.5 mm should be achievable for treatments of the thorax, abdomen, and pelvis. The integration of cone-beam CT units with treatment machines is an excellent tool for assessing setup accuracy and is being used in an increasing number of studies comparing and evaluating various immobilization systems. CBCT has been especially helpful to study the setup accuracy of stereotactic immobilization devices, the subject of a later section in this chapter. It should again be emphasized that the degree of interfraction setup accuracy achievable by a particular institution will depend on the skill and knowledge of the personnel involved in forming patient immobilization devices, setting up patients for daily treatments, making adjustments based on verification imaging, and the understanding of the limitations of each step of the process. Table 24.2 provides a top level summary of the pros and cons of commonly available body conformal immobilization systems.

Prone Positioning for Pelvic and Breast Treatments

The body conformal devices described above can help provide reproducible patient setup from day to day for a wide range of disease sites. The patient is most often positioned supine in these devices. For certain treatment indications, a prone setup may provide a dosimetric advantage. In pelvic and abdominal irradiation, the small bowel is an important organ at risk, and acute toxicity is correlated with the amount of small bowel that receives a high dose. For patients receiving pelvic irradiation, a popular method is to use a bellyboard (Fig. 24.6A) on which the patient lies prone with their stomach positioned over the cutout region. With the aid of gravity, the small bowel will fall into the board's cutout and can reduce the amount of bowel in the treatment fields. The use of a prone bellyboard has been demonstrated to reduce the volume of small bowel at all dose levels.[11–13] Even with IMRT, the use of a belly-board technique has been shown to further reduce the small-bowel dose.[11]

TABLE 24.2 EXTRACRANIAL IMMOBILIZATION DEVICE

SUMMARY

Device Name	Description	Pros	Cons	Typical Sites	Reus ?
Alpha Cradle	Expanding foam device custom-molded to patient body contour.	Rigid immobilization for wide range of body sites.	One time use. One-shot to achieve adequate and comfortable immobilization.	Thorax, abdomen, pelvis, extremities	No
Vacuum-lock bags	Nylon bag filled with plastic minispheres. Upon evacuation mini-spheres lock together to form a custom mold of the patient body contour	Re-usable. Can quickly re-inflate and re-form during simulation if necessary.	Punctures, tears or loss of vacuum may necessitate re-simulation of the patient.	Thorax, abdomen, pelvis, extremities	Yes
Elekta BodyFix	Vacuum-lock bag with plastic cover sheet. Dual vacuum system for increased immobilization	Re-usable. Cover sheet may provide abdominal compression.	Some patients may find cover sheet uncomfortable.	Thorax, abdomen, pelvis	Vacu loc = y cov she no
Prone breast board	Prone breast board can improve dosimetry for patients with large, pendulous breasts.	Separates target tissue from chest wall to minimize skin folds and lung dose.	May not be tolerated by all patients. Poor visualization of treatment field alignment. Not suitable for regional nodal irradiation.	Breast	Yes
Prone belly board	Prone board to help the small bowel fall out of the treatment	Displacement of bowel out of treatment field can reduce toxicity.	May not be tolerated by all patients. Variability in bowel sparing.	Pelvis	Yes

	fields.				
Modular stereotactic body immobilization systems. E.g.: Elekta Stereotactic Body Frame, Civco Body-Pro Lok, Bionix Omni V	Indexed base board with a wide range of attachments for immobilization, localization and motion management	Flexibility to treat variety of disease sites with SBRT. Attachment of devices for abdominal compression	More room for storage. More time for setup and indexing of attachments.	Spine, lung, liver, abdomen, pelvis, neck	Yes

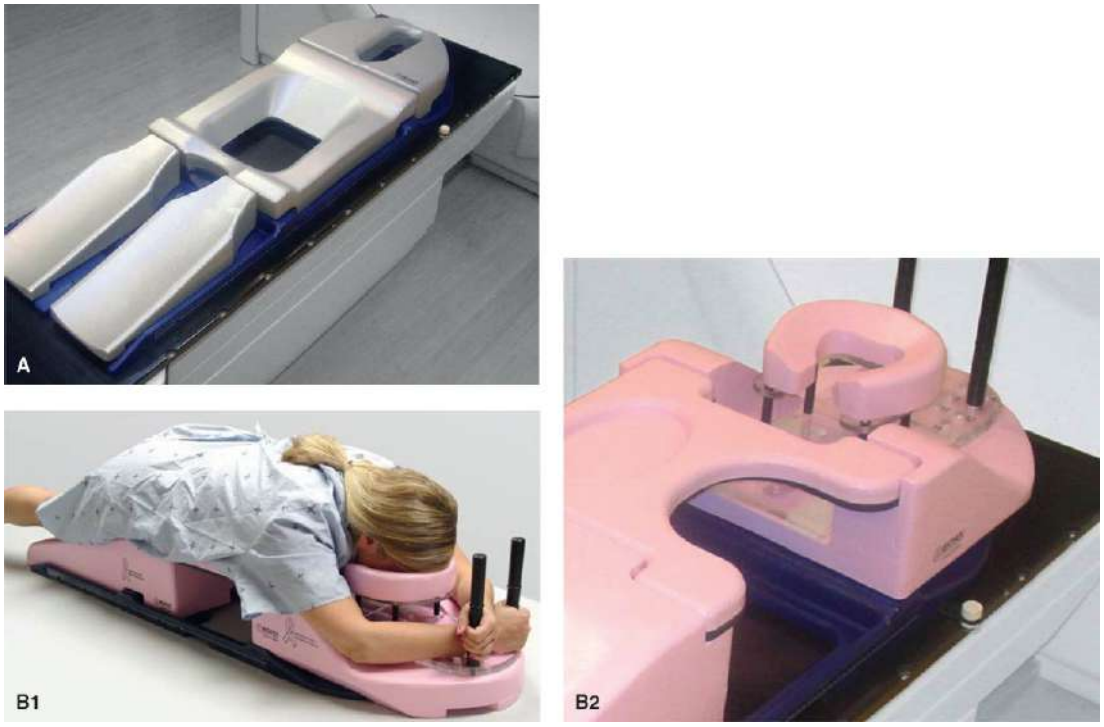

FIGURE 24.6. Specialized prone immobilization devices. Immobilization devices specifically designed for prone positioning. **A:** A prone bellyboard can be used in treating targets in the pelvis. Gravity assists small-bowel migration out of the treatment fields, which can reduce treatment-related toxicity. **B:** A prone breast board offered by BionixRT can be advantageous for patients with large, pendulous breasts. The board features a cutout that is easily reversible for treatment of either breast. (Images courtesy of BionixRT, Toledo, OH.)

The magnitude of the small-bowel reduction with prone bellyboard positioning can be highly patient dependent. Kim et al.[11] correlated the amount of small bowel at the 50% isodose level with a patient's age, weight, and gender. For example, this work showed a larger amount of small bowel (total volume in cc) at the 50% isodose level for the subgroups of patients over 56 years old,

female patients, and patients weighing <65 kg (143 pounds). It must also be noted that some investigators have reported that the use of a bellyboard worsened the reproducibility of patient setup. For example, Martin et al. reported having to reposition the patient based on portal imaging 68% of the time with a prone belly-board system, compared to 23% of the time with supine positioning.[12] In contrast, Acht et al.[13] reports similar setup reproducibility between prone positioning with a bellyboard and patients in the supine position. Each patient should be assessed at the time of simulation for the efficacy of the bellyboard method to displace small bowel as intended, as well as the patient's ability to tolerate lying on the bellyboard itself.

Another site where prone positioning has been used is in the treatment of breast cancer. Figure 24.6B illustrates a patient positioned on a prone breast board offered by BionixRT. The patient is positioned on the cushioned platform with her face resting in a donut-shaped cushion. The patient can hold the hand posts to help improve reproducibility and comfort. The prone positioning is most efficacious for patients with large, pendulous breasts, though it may also be an effective option for patients with severe arthritis that may be unable to hold their arms over their head.[14] Patients with large breasts tend to have larger tissue separation, larger treatment volumes, worse surface irregularity, and an accentuated inframammary fold, which can cause these patients to have higher reported rates of toxicities such as high-grade dermatitis and fibrosis.[15]

The goal of prone positioning for breast treatment is to minimize the lateral tissue separation and thus improve dose homogeneity. Improved dose homogeneity may decrease the rate of late toxicities such as fibrosis, an undesirable cosmetic outcome, and decreased tissue separation can reduce the entrance dose needed to provide target coverage at depth, which may decrease the overall hot spot for the treatment plan, particularly at the skin surface.[14] Improved dose homogeneity and decreased skin dose from prone positioning may also prove to be advantageous for hypofractionated breast regimens where larger doses per fraction are delivered. Five-year follow-up data from Stegman et al.[14] have shown that the prone position offers comparable local control to traditional supine positioning for whole-breast irradiation, with lower levels of toxicity. With the breast hanging in the prone setup, it may also be possible to reduce the dose to other nearby normal tissues. The increased separation of the breast tissue from the chest wall has been shown to decrease the amount of irradiated lung in whole-breast irradiation.[16] Dose to the heart is more variable; for left-breast patients, most heart doses (20 to 30 Gy levels) are decreased in the

prone position, though some patients did exhibit higher heart doses when prone.[16]

It can be difficult to set up patients with large or pendulous breasts in a supine position because the breast can lie in a different position each day. In the supine position, a ring or tube can be used to keep the pendulous breast from folding over. With the aid of gravity, daily setup can be more reproducible with the breast hanging in the prone position. There are, however, potential disadvantages to the prone setup for breast patients, for example, reduced visibility of the breast for alignment purposes. Furthermore, the prone positioning may not be tolerable for elderly or obese patients. And finally, the prone position may not be logistically suitable for patients requiring regional nodal irradiation as the prone position would severely limit visual alignment of an anterior supraclavicular field.

Space Considerations

Whole body expanding foam or vacuum-lock bag systems can provide excellent patient comfort and immobilization, but they are large devices making the issue of space very relevant. Adequate space is required to store each patient's custom-formed device for up to 6 weeks or more while a patient is under treatment. At the Emily Couric Clinical Cancer Center at the University of Virginia, a dedicated room next to the simulation suite and large closets in each treatment room are used for storing patient's body conformal immobilization devices (Fig. 24.5C). For clinics where one simulation suite is used to support multiple satellite clinics, the logistics of transporting the immobilization device must also be considered. At the University of Virginia and Virginia Commonwealth University, a courier service is used to transport the large body conformal devices from the simulation site to satellite treatment facilities. Each clinic must assess space availability when deciding which system to adopt in patient care.

DOSIMETRIC EFFECTS OF IMMOBILIZATION DEVICES

Any material placed between the patient and the radiation source can modify dosimetric characteristics of the treatment beam. Modern immobilization devices made of low-density materials have little impact on the depth-dose characteristics of megavoltage energy treatment beams; however, electrons liberated within the immobilization device can lead to a measurable increase in

the patient's surface dose, that is, a bolusing effect. Clinical experience supports this effect and has shown that skin reactions are more frequent and tend to occur earlier in the treatment course, when beams are delivered through an immobilization device. The magnitude of the bolus effect can vary greatly depending on the composition, density, and thickness of the immobilization device as well as beam energy, field size, and geometric arrangement.

AAPM Task Group 176 has published an excellent report regarding the dosimetric effects of couch tops and immobilization devices including the basic physics rationale, a well-rounded literature review of relevant studies, and techniques that can be utilized to reduce and better model the dosimetric effects of these devices.[17] Body conformal immobilization devices have been reported to exhibit dosimetric behavior similar to an additional 0.2 to 0.5 cm of water equivalent thickness for physical device thicknesses of 2 to 5 cm, respectively, a roughly 1:10 ratio for low-density vac-loc bags.[18] Thermoplastic masks show similar effects; for example, Hadley et al. reported increased surface dose using 6-MV photons from 16% without a mask to 61% with a mask.[19]

For thermoplastic head and neck masks, the bolus effect is reduced when the masks are stretched more as the thickness of material in the beam's path is subsequently reduced. The clinician may also cut out parts of the mask to remove material in the beam path to reduce skin reactions. Care must be taken, however, to ensure that the integrity of the mask and its ability to provide rigid immobilization is not compromised. With proper skill and attention, thermoplastic masks with cutouts to improve skin sparing have been shown to achieve similar setup accuracy as unmodified masks.[5] For custom-made foam body conformal systems, such as the Alpha Cradle, foam lying in the beam path can be shaved away to reduce the thickness along the beam path. Reusable vacuum-lock bags are commercially available with treatment beam portals for standard beam arrangements to avoid bolusing. Regardless of the immobilization device chosen for treatment and methods employed to reduce the bolusing effect, AAPM TG-176 recommended best practices are to include any patient-specific devices in the dose calculation to support more realistic clinical plan assessment. The TG-176 report also provides details for measuring skin dose and bolusing effect in order to verify the accuracy of the planning system's skin dose calculation.

STEREOTACTIC IMMOBILIZATION AND STABILIZATION

Introduction

Hypofractionated stereotactic techniques enable the radiation oncologist to deliver high-dose conformal radiation therapy with a sharp dose falloff to both intracranial and extracranial targets. Here, we describe radiation therapy delivered as a single high-dose fraction as stereotactic radiosurgery (SRS), and therapy delivered over a small number of high-dose fractions stereotactic radiotherapy (SRT). Delivering a high dose to the target volume in only a few fractions increases the requirements for precise delivery of the radiation. Advances in online image guidance have enabled the delivery of high-dose extracranial stereotactic treatments, and improvements in patient immobilization have accompanied to help decrease interfractional variation in patient setup and intrafractional patient and target motion. Intrafraction target motion occurs in lung and liver tumors because of normal physiologic processes such as respiration, and longer treatment times associated with high-dose SRT may further reduce intrafractional treatment accuracy.[20] Numerous immobilization-based strategies to minimize this motion are discussed later in this section. In general, intrafraction error from patient movement within the device during treatment can be reduced by improving the comfort and stability of the immobilization system. As with all immobilization methods and devices, patients with poorer performance status may have worse interfractional setup reproducibility and more intrafraction motion within the immobilization device,[21] so patient-specific immobilization options may need to be considered.

Intracranial Immobilization Devices

Intracranial immobilization devices can generally be classified into two categories: invasive and noninvasive, which are reviewed in the following sections. Other important characteristics include if the device is relocatable or not, and what system is used to align the patient for treatment.

Invasive Cranial Immobilization

Invasive cranial immobilization devices enabled intracranial SRS treatments prior to the widespread adoption of in-room image guidance and are exemplified by rigid metal frames attached to metal pins driven directly into the skull. Generally, two long posts are placed anterior and two shorts posts are placed posterior in the patient’s skull. The patient then undergoes imaging (either CT or MRI, depending on device compatibility) with a fiducial-based system attached to the frame to provide stereotactic localization of the tumor position within the

frame. A treatment plan is then developed, and at the time of treatment, the head frame is connected to either a floor-mounted stand or the treatment table to provide rigid cranial immobilization. The fiducial-based stereotactic localization system is then used to align the target to the machine isocenter and the treatment is delivered, usually in a single fraction. The primary advantage of the invasive, frame-based, nonrelocatable stereotactic head frame is the rigid immobilization it provides with accuracy generally reported on the order of <1 mm.[22,23]

The Leksell Stereotactic Coordinate Frame G (Elekta, Stockholm, Sweden) (Fig. 24.7) is an example of an invasive cranial immobilization frame that is compatible with gamma knife or linear accelerator platforms. A phantom study of the Leksell Frame G on the gamma knife system using GafChromic film found the overall accuracy (mean ± standard deviation) of an MR-defined target to be 0.21 ± 0.32 mm and 0.15 ± 0.26 mm in the *x* and *y* axes and 0.06 ± 0.09 mm and 0.04 ± 0.09 mm for a CT-based target.[22] The Brown-Roberts-Wells (BRW) frame by Integra is another invasive cranial device for linac-based SRS. The BRW localizer frame features a set of vertical and diagonal indicator rods to facilitate stereotactic localization and alignment. Ramakrishna et al.[24] used stereoscopic kV x-ray imaging to evaluate setup accuracy and intrafraction motion using the BRW system and reported a mean deviation between frame-based and image-guided positioning of 1.0 ± 0.5 mm and a mean intrafraction deviation of 0.4 ± 0.3 mm.

A disadvantage of these invasive, nonrelocatable devices is that they are for the most part limited to single-fraction SRS, requiring frame placement, imaging, planning, quality assurance, and delivery to occur in the same day before the frame can be removed. One invasive immobilization device designed to accommodate fractionated SRT is the TALON removable head frame system designed by Best Nomos. The TALON system is a relocatable invasive stereotactic head frame that utilizes two self-tapping titanium screws inserted into the patient's skull at the vertex. The detachable TALON assembly is then attached to the screws for patient positioning on imaging and treatment tables. After each fraction is delivered, the frame can be removed and the patient can leave with the two screws remaining in the skull. Salter et al. evaluated repositioning accuracy of the system with CT imaging and reported a mean isocenter deviation of 0.99 ± 0.28 mm in patients treated with SRS and a mean isocenter deviation of 1.38 ± 0.48 mm in patients treated over 6 weeks of treatment.[25]

Noninvasive Cranial Immobilization

Invasive cranial immobilization devices have been successfully used for many years to deliver intracranial SRS, but these systems require placing of screws into the patient's head, which carries the risk of bleeding and infection and requires premedication and dedicated nursing support.[24] The compressed treatment planning time required for nonrelocatable systems may also be less desirable in certain scenarios. Numerous relocatable and noninvasive systems have been developed that can provide accurate and reproducible immobilization of the head without the use of screws driven into the skull and provide the flexibility to deliver multifraction SRT. Some of these systems, as described below, utilize traditional fiducial-based localizer systems, and others have leveraged the widespread adoption of in-room image guidance systems for patient positioning.

The Stereoadapter 5000 is a noninvasive and relocatable immobilization device commercially available through Sandstrom Trade & Technology, Inc. The device is attached to the patient's head with two earplugs that are secured in place by tightening a screw on the nasal bridge support. Side arms connect to a vertex stabilizer and a band is fastened against the occiput to provide additional stabilization. Millimeter scales on the Stereoadapter components are used to reproduce the setup, and the device is compatible with both MRI and CT imaging. Kalapurakal et al.[26] evaluated setup reproducibility of this immobilization system using portal images coregistered with the CT scout image and reported mean isocenter shifts of 1.0 ± 0.7 mm, 0.8 ± 0.8 mm, and 1.7 ± 1.0 mm in the *x*, *y*, and *z* axes.

FIGURE 24.7. Stereotactic—invasive intracranial. The Leksell® Coordinate Frame G is **(A)** fixed to the patient's head via four self-tapping screws. At the time of treatment

delivery **(B)**, the frame is attached to the treatment table. (Images courtesy of Elekta, Stockholm, Sweden.)

The Gill-Thomas-Cosman (GTC) Relocatable Head Ring (Integra) is a noninvasive, relocatable cranial immobilization device that is compatible with the BRW stereotactic localizer system. A custom mold of the patient's upper dentition is formed and mounted to the head ring anteriorly, and a custom-formed headrest is mounted to the ring posteriorly. Setup accuracy is verified with the XKnife Depth Helmet, a clear plastic device that is placed over the head ring. A rod with millimeter scale is inserted into holes in the depth helmet and measurements obtained to ensure accurate placement. Das et al. measured the daily relocation error of the GTC frame using the Depth Helmet prior to each fraction and found a mean radial displacement of 1.03 ± 0.34 mm.[27] Kumar et al.[28] evaluated daily setup reproducibility with daily pretreatment portal imaging coregistered to the planning CT digitally reconstructed radiograph (DRR) and found a total 3D mean displacement of 1.8 ± 0.8 mm.

The Elekta (Stockholm, Sweden) eXtend frame system (Fig. 24.8) is a relocatable, noninvasive cranial immobilization device for fractionated SRT. Similar to the previously described HeadFIX system, a custom dental mold is formed and is attached to a carbon fiber frame that is connected to the treatment couch. Active suction to the hard palate aids in immobilizing the patient. Similar to the Depth Helmet described above, the repositioning check tool (RCT) is used to confirm that the patient is accurately relocated within the frame (Fig. 24.8B). Ruschin et al.[29] evaluated the setup accuracy of the eXtend frame using the RCT, reporting a mean 3D setup error of 0.8 mm and 1.3 mm in patients treated on a linear accelerator and a Gamma Knife Perfexion, respectively. The mean intrafraction motion was measured at 0.4 ± 0.3 mm, leading the authors to conclude that the RCT was adequate to confirm frame repositioning and that the system provided excellent intrafraction immobilization.

Systems like those above are able to provide accurate patient setup by defining the tumor's stereotactic location within the coordinate system of a rigid localizer frame. An alternative strategy is to align the patient using daily x-ray image guidance. One example is the Brainlab mask system (Fig. 24.9) that utilizes a U-shaped frame, two vertical posts, a three-piece thermoplastic mask, and an optional bite-block attachment for cranial immobilization. At the time of simulation, three thermoplastic shells are formed to the anterior and posterior aspects of the patient's head. The shells are fastened to the vertical posts, which are attached to the head ring that is mounted to the CT or treatment couch. A

stereotactic localizer device is available, though studies have shown it may not achieve the desired positioning accuracy. Ali et al.[30] evaluated the setup accuracy of the Brainlab mask system with the localizer device by acquiring verification onboard kV images and reported mean shifts of 0.7 ± 2.0 mm, 1.6 ± 2.6 mm, and 0.1 ± 2.2 mm in the *x*, *y*, and *z* dimensions. The random setup errors exhibited by standard deviations larger than 2 mm supports the argument for daily pretreatment image guidance as opposed to relying solely on the localizer device. Ramakrishna et al.[24] evaluated intrafraction motion with the Brainlab system using posttreatment kV imaging and reported a mean intrafraction shift of 0.7 ± 0.5 mm, highlighting the device's suitability for patient immobilization following image-guided alignment.

FIGURE 24.8. Intracranial stereotactic—relocatable Elekta Extend™ system. The Elekta Extend™ system is a relocatable immobilization device designed for fractionated stereotactic radiotherapy. A custom mold of the maxillary dentition **(A)** is fixated to the hard palate with suction and then attached to a carbon fiber frame to provide rigid immobilization to the couch. Setup accuracy is assessed with the RCT **(B)** prior to the delivery of each treatment. (Images courtesy of Elekta, Stockholm, Sweden.)

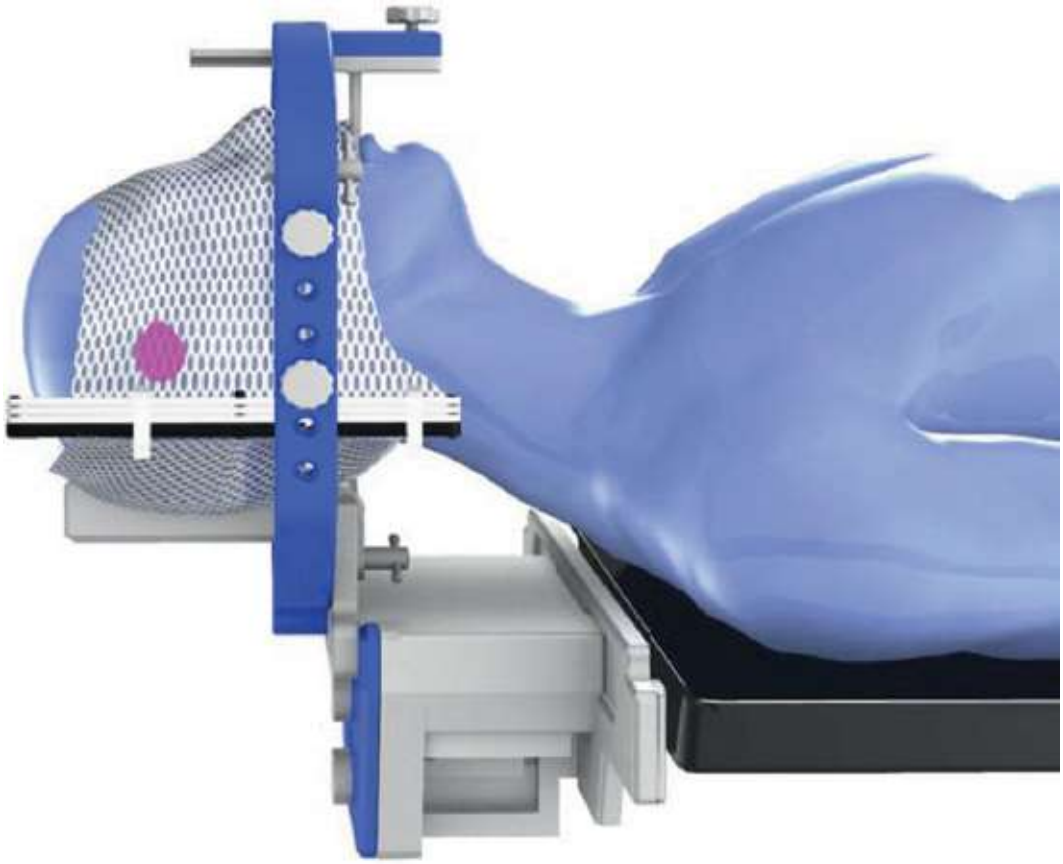

FIGURE 24.9. Intracranial stereotactic—relocatable Brainlab mask (Brainlab, Munich, Germany). The Brainlab noninvasive mask system utilizes three pieces of thermoplastic mask custom molded to the patient's head and attached to vertical posts on either side of the patient's head. These posts are then attached to a U-shaped frame, which is attached to the treatment couch, thus providing rigid immobilization of the head. A stereotactic localizer box may be used for target localization. (Image courtesy of Brainlab.)

Other thermoplastic mask systems have been evaluated for use in cranial SRS treatments. Tryggestad et al.[31] evaluated four thermoplastic mask systems using pre- and posttreatment CBCT. They reported a mean interfraction deviation of 2.1 to 2.7 mm, and mean intrafraction deviation of 0.7 to 1.1 mm for the four-mask systems, reaching a similar conclusion that certain thermoplastic mask systems can provide rigid immobilization to minimize intrafraction errors for intracranial SRS, when used in combination with image guidance to reduce interfractional setup errors.

Another option for intracranial SRS immobilization and positioning is to use a thermoplastic mask with optically guided fiducial markers for daily target localization and to monitor patient motion in real time. Bova et al.[32] reported in 1997 on an in-house, optically guided system that consisted of a posterior

headrest and an anterior thermoplastic mask extending from the forehead to the upper lip for immobilization and a physically separate custom bite plate with a set of six infrared light-emitting diodes attached for stereotactic localization with an infrared camera system. They reported the bite plate could be positioned and repositioned to within 0.5 ± 0.3 mm and the system allowed for real-time tracking of the infrared markers, and thus patient motion. In a similar fashion, Peng et al.[33] evaluated the accuracy of using the Varian SonArray system with optically guided fiducials for setup by acquiring a verification CBCT, reporting a mean setup error of 1.2 ± 0.7 mm.

Extracranial Immobilization Devices

In 1995, Hamilton and colleagues from the University of Arizona published their preliminary clinical experience with linear accelerator–based SRS of the spine in five patients.[34] For immobilization, clamps were secured transcutaneously to the spinous processes one to two vertebral levels above and below the target volume under local or general anesthesia, through a 2-cm incision. The spine was rigidly immobilized by attaching the clamps to a frame consisting of a rigid box with two semicircular metal arches. After CT simulation and treatment planning, the patient and frame were transferred to a modified linear accelerator and setup according to stereotactic coordinates derived from the planning CT. Although this invasive device was important in demonstrating the feasibility of extracranial stereotactic body radiation therapy (SBRT), the overwhelming majority of modern immobilization systems for extracranial SBRT utilize noninvasive customizable devices like the previously described body conformal vacuum-lock bags, with added features to allow for more precise positioning and the attachment of specialized devices such as compression plates.

Examples of modular immobilization systems for extracranial SBRT included the Body Pro-Lok from CIVCO Medical Solutions (Coralville, IA), the Bionix Omni V SBRT positioning system, and the Elekta Stereotactic Body Frame all depicted in Figure 24.10. SBRT-specific frames like these include indexing along the entire length of a lightweight carbon fiber platform allowing reproducible isocenter localization and for accessories to be attached. Attachment options typically include headrests, forehead restraints, upper arm supports, shoulder restraints, thigh and foot positioners, external fiducial arches, and abdominal compression devices.

Numerous investigators have assessed the reproducibility of these extracranial SBRT immobilization systems. Gutierrez et al. evaluated the

CIVCO Body Pro-Lok system using TomoTherapy with pretreatment megavoltage CT (MVCT) to determine the mean interfractional setup error of twenty liver and lung SBRT patients[35] and reported mean localization errors of 0.9 ± 3.1 mm, 1.2 ± 5.5 mm, and 6.5 ± 2.6 mm in the *x*, *y*, and *z* dimensions, and a mean composite displacement vector of 8.2 ± 2.0 mm. Purdie et al.[20] evaluated the intrafraction positioning reproducibility by comparing pretreatment localization CT to a mid- or posttreatment CBCT with the Elekta Stereotactic Body Frame in 28 lung SBRT patients. The mean 3D tumor position was within 2.2 ± 1.2 mm of planned when repeat imaging was performed within 34 minutes of target localization, and 5.3 ± 3 mm when performed more than 34 minutes after target localization ($P < .01$). While this particular device is no longer commercially available, this study highlights the important consideration that longer treatment times can increase the intrafractional positioning error.

FIGURE 24.10. Stereotactic body frames. **A:** The Body Pro-Lok is a modular immobilization system that can be used of stereotactic body radiotherapy (SBRT). Multiple attachments are available to build a device customized to the needs of each patient. This particular setup utilizes an abdominal compression plate. (Image courtesy of Civco Medical Solutions, Coralville, IA.) **B:** The Stereotactic Body Frame has a reference system that runs along the length of the device. (Image courtesy of Elekta, Stockholm, Sweden.) **C:** The Omni V is another modular system with a variety of options to provide customized patient immobilization. (Image courtesy of Bionix Radiation Therapy, Toledo, OH.)

The Elekta BodyFIX is another example of a body conformal system with

features specifically designed for SBRT. As described in the preceding section and illustrated in Figure 24.5B, the distinguishing characteristic of the BodyFIX system is the thin clear plastic cover sheet that uses an active vacuum pump to create negative pressure providing additional immobilization of the patient. A study of 126 lung SBRT patients used pre- and posttreatment cone-beam CT (CBCT) to determine intrafractional stability of the BodyFIX system and reported the intrafraction variation of mean tumor position to be 2.7 ± 2.6 mm.[36]

Immobilization and Internal Motion Management

In addition to intrafractional error because of patient movement within the immobilization device, internal target motion because of breathing must be accounted for in SBRT, particularly in treatment of lung and liver tumors. The report of AAPM Task Group 76[37] addressed the management of respiratory motion in radiation therapy and presented the results of a variety of studies evaluating the motion of lung and liver tumors under respiration. Lung and liver targets exhibit a wide variation in motion amplitude across patients and for targets in different regions of the lungs and liver. For lung tumors, mean tumor motion amplitudes from various studies ranged between 2.4 and 7.3 mm (left to right), 3.9 and 12.5 mm (sup to inf), and 2.4 and 9.4 mm (ant to post). For liver tumors, reports of superior–inferior mean motion amplitude ranged between 10 and 25 mm for shallow breathing and between 37 and 55 mm for deep breathing. Working from this wealth of available motion data, the report of AAPM Task Group 101 recommends that all thorax and abdomen SBRT patients undergo tumor motion assessment[38] and some immobilization devices have been designed to help mitigate or regularize respiratory motion.

Multiple strategies have been developed to account for or control internal target motion from respiration, including deep inspiration breath hold (DIBH), active breathing control, respiratory gating, real-time tumor tracking, and abdominal compression devices. Relevant to this chapter, some extracranial immobilization systems offer the ability to use abdominal compression devices to control respiratory excursion. This technique may also be referred to as forced shallow breathing. Abdominal compression devices typically consist of a plate attached to an arch that is indexed to a stereotactic body frame or the treatment couch. The plate is placed a few centimeters below the patient’s xiphoid process and a screw is tightened until the desired amount of internal motion control is achieved. The screw is marked so that it can be reproducibly tightened for multiple fractions. Abdominal compression devices are available from a variety

of companies, including CIVCO Medical Solutions for use on the Pro-Lok immobilization system, and from Bionix for use on the Omni V system.

Studies report varied results with the use of abdominal compression in reducing lung and liver tumor motion amplitude. Negoro et al.[39] studied lung tumor motion in 18 patients treated with SBRT and found the mean tumor motion in the superior–inferior dimension measured with fluoroscopy to decrease from 12.3 to 7.0 mm (range 2 to 11 mm) with the use of abdominal compression. The mean amplitude for liver motion measured with fluoroscopy was shown to decrease from 40 mm with free breathing to 11 mm with the use of abdominal compression.[40] Another study showed that while abdominal compression reduced the superior–inferior and anterior–posterior motion, an increased motion amplitude in the left–right dimension of 15% on average (maximum 1.6 mm) was observed,[41] indicating that compression may also be redistributing breathing motion. It should also be noted that the abdominal forces required to mitigate motion are often reported to be uncomfortable and may not be suitable for all patients.[42]

OPTICAL SURFACE IMAGING FOR MONITORING OF PATIENT POSITIONING

Introduction

Optical surface imaging (OSI) is a new technology used in radiation oncology for patient positioning and monitoring. As it has been established throughout this chapter, immobilization devices are a crucial tool for the appropriate delivery of radiation treatments. They promote consistent setups throughout the radiotherapy course and help patients hold their treatment position for the duration of each fraction. However, these systems have their limitations and it can sometimes be cumbersome to replicate the planned position just based on these devices and skin marks. Moreover, these tools oftentimes must balance patient comfort with motion restriction. Hence, although immobilization devices conform to the patient and limit their mobility, patients can still move during treatment increasing the delivery uncertainty. This becomes progressively worrisome as margins are reduced and fraction doses escalate. Under these conditions, patient monitoring during treatment to detect undesired motion becomes especially important. Surface imaging systems can help facilitate patient setup and allow for intrafraction monitoring without the use of additional ionizing radiation, in what is currently known as Surface-Guided Radiation

Therapy (SGRT) or Surface Image-Guided Radiation Therapy (SIGRT).

OSI can be useful for initial positioning of any site, but internal imaging must be performed when the target location might not properly correlate with the surface. Intrafraction monitoring with these systems can be used to detect external motion or even track breathing,[43] but this does not necessarily reflect the true target motion as not all internal involuntary movements will be revealed by the patient's surface. It is important to understand the technology and the information these systems provide in order to ensure they are utilized correctly and to their full potential. This section aims to give the reader a general overview of these systems, their characteristics, and some typical clinical uses.

Overview of Selected Commercial Systems

Surface imaging systems acquire the patient's surface in the treatment room and compare it to the patient's planned surface position, known as the reference surface. The reference surface is typically generated using the DICOM structure and plan file information from the treatment planning system. The external CT contours from the DICOM structure file are used to create the reference surface, and the location of the reference surface within the treatment room is determined based on the treatment isocenter coordinates from the DICOM plan information. The treatment isocenter coordinates are read, and the reference surface is translated to place that point at the machine isocenter. Surface imaging systems are calibrated so that their origin coincides with the machine isocenter. The approach to obtain the real-time patient surface and its registration with the reference surface varies depending on the specific surface imaging system.

There are two main manufacturers of surface imaging equipment for radiotherapy: Vision RT (London, UK) who manufactures the AlignRT system (also available through Varian as the Optical Surface Monitoring System, OSMS) and C-RAD (Uppsala, Sweden) who manufactures the Sentinel and Catalyst systems. Each system uses a different approach in both physically acquiring the current surface and registering the acquired and reference surfaces. Details of these two systems are presented in the following sections. This list is not meant to be a comprehensive description of all available options but merely an introduction to a few examples that illustrate the current state of technology in OSI.

FIGURE 24.11. C-RAD surface imaging system. **A:** The C-RAD Catalyst HD OSI system consists of three ceiling-mounted camera pods to acquire patient's surface in the treatment room with a vendor-quoted accuracy of 0.5 mm. **B:** The system projects a visible pattern of light on the patient's surface to guide the therapists in aligning the patient to the reference surface. (Images courtesy of C-RAD, Uppsala, Sweden.)

C-RAD Systems

This family of OSI systems includes Sentinel 4DCT, and a variety of Catalyst products. Sentinel is used at the CT simulator for respiratory tracking during 4DCTs and other gated scans, whereas the Catalyst family of systems is used for patient positioning and monitoring during treatment. Both the breathing trace and reference surface acquired by Sentinel at the simulator can be read by Catalyst systems for use during treatment. Sentinel is comprised of a sweeping visible red laser (635 to 690 nm wavelength) and a camera that captures the reflected light as the laser sweeps across the patient at discrete intervals to read his/her surface. It takes approximately 1 to 2 seconds to scan a length of 40 cm with a measurement reproducibility of 0.2 mm, and it detects respiratory signal with a frequency of 15 Hz. The maximal scan volume is 80 × 130 × 70 cm^3. Although this system is most commonly used at simulation, it can also be used for patient positioning and monitoring during treatment.[44,45]

The Catalyst system can be comprised of 1 or 3 pods, for the standard and HD versions respectively, mounted on the ceiling of the treatment room and facing the machine isocenter. In contrast with Sentinel, Catalyst uses light in the near-invisible violet range (405 nm). This allows the full patient surface to be read at once, instead of with discrete laser sweeps, which allows for a scan speed of up to 80 frames-per-second (fps) for the standard system and 200 fps for HD. Catalyst provides 6 degree-of-freedom (DOF) isocentric shift information by comparing the real-time surface of the patient to that from simulation using deformable registration. A visible pattern of red or green light is projected

directly on the patient's skin to indicate to the therapists how the patient's position needs to be adjusted (see Fig. 24.11). The position and motion detection accuracy is quoted as 1 mm for the standard system and 0.5 mm for the HD system. Both maximum scan volume and measurement reproducibility match that of the Sentinel system. Details of the performance of these systems can be found in the literature.[46–48]

Vision RT Systems/Varian Optical Surface Monitoring System

Vision RT provides a family of surface imaging systems that allow for patient positioning and monitoring during treatment (AlignRT), respiratory tracking at simulation for 4DCT acquisition (GateCT), and gating during treatment delivery (GateRT). AlignRT is typically a 3-pod system mounted on the ceiling of the treatment room facing the machine isocenter as shown in Figure 24.12A below. For surface acquisition, each pod contains two cameras and a projector that casts a red light speckle pattern on the patient. The stereoscopic cameras read the structured light projection pattern and reconstruct the patient's surface based on the deformation of the known pattern. The patient's current acquired surface is then rigidly registered to the reference surface. The reference surface is derived either from the external contours of the planning CT or from a reference capture acquired in the treatment room with the system, for example, after CBCT imaging and alignment. The reference surface for the first fraction is always based on the planning CT. The three rigid translations and three rotations needed to best align the two surfaces are then displayed on the system's screen (see Fig. 24.12B). The rigid registration is only performed in the area defined by the user as the region of interest (ROI). The frame rate for this system depends on the size of the ROI and is typically around 1 to 3 fps for thorax ROIs. There is literature on its use in radiation therapy for all treatment sites, but especially in left-sided breast DIBH treatments[49–51] and SRS.[52–54] This same equipment is commercially available through Varian Medical Systems (Palo Alto, CA) under the name of Optical Surface Monitoring System (OSMS).

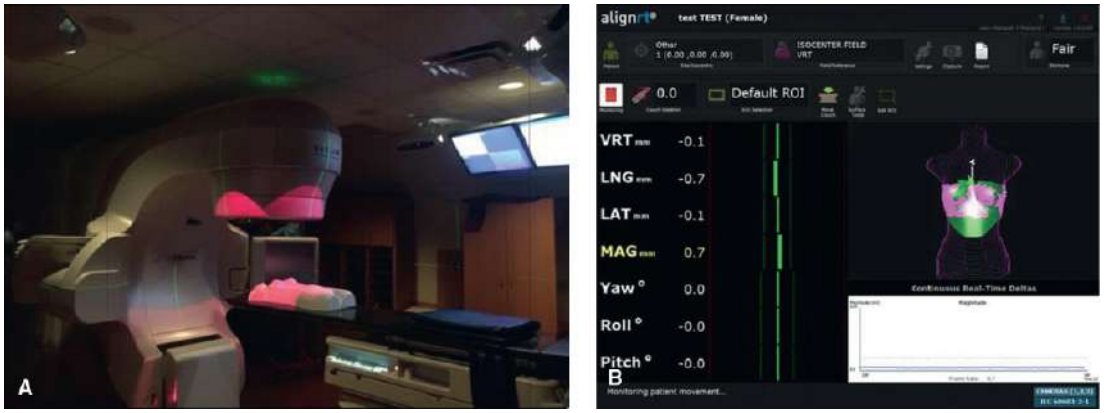

FIGURE 24.12. AlignRT surface imaging system. **A:** AlignRT's three ceiling-mounted camera pods acquire the patient's surface in the treatment room by projecting a structured light speckle pattern onto the patient. **B:** Monitors in the control and treatment rooms provide the therapists with real-time feedback about the current alignment of the patient's current and reference surfaces including rigid translations and rotations to help align the patient prior to treatment and track intrafraction surface motion during treatment. (Images taken at Virginia Commonwealth University by the author—May 2017.)

The GateRT system uses the same technology, but the software display presents information optimized for respiratory tracking and beam gating. The GateCT package typically includes a single pod installed in the CT simulation room for respiration and motion tracking of the patient during 4DCT scans to provide a reference trace for treatment gating.

Current Clinical Applications

Current commercially available systems use a reference surface of the patient to guide therapists during setup. The reference surface for daily alignment is generated from the CT planning data contours, acquired from an OSI system at the time of simulation, or acquired during an earlier treatment fraction, typically following x-ray image-guided alignment. As the patient's current surface is read and compared to the reference surface in real time, visual feedback is either projected on the patient's skin or shown on a screen, informing therapists what adjustments are needed to achieve the desired surface position. Six degree-of-freedom shift information is also displayed as three translations (vertical, longitudinal, lateral) and three rotations (yaw, roll, pitch). Once the desired external position has been achieved, anatomical alignment can be confirmed with internal image guidance techniques.

Surface imaging systems give users the option to acquire a new reference surface with the optical cameras. These surfaces tend to capture a larger extent of the patient's external anatomy when compared to the DICOM reference. The

purpose of updating the reference surface is twofold: (a) having a reference with extended external anatomy may facilitate setup for subsequent fractions, for example, of the elbows in arms-up positioning, and (b) rebaselining the reference position will allow for better intrafraction monitoring. Although ideally the patient's external surface should exactly match the planning position every time, this is often not the case. If the patient's current position is found to be acceptable as confirmed with internal imaging, acquiring a new reference surface will zero out any residual surface offsets between the patient's approved treatment position and the original patient surface from the time of simulation. Hence, any motion throughout the fraction will become more obvious in the displayed shift values. This is even more important if the surface imaging system interfaces with the treatment machine to gate the beam. Removing the inherent shifts between the current approved treatment surface and the original reference will allow for tighter monitoring thresholds for any given fraction and less beam interruptions from false large readings. It is important to note that for most commercial systems, the original reference surface based on the DICOM information remains available for selection throughout the course, giving the option to perform initial alignment with either reference surface at any time.

Although surface imaging may be used for the initial positioning and monitoring of patients treated to any anatomical site, it has shown special utility for DIBH breast treatments and SRS because of the close correlation between surface and target positions.

Deep Inspiration Breath Hold Treatments for Breast Radiotherapy

DIBH treatments for left-sided breast cancer patients can provide cardiac sparing because the heart moves further away from the chest wall, and hence from the treatment volume, as the lungs inflate.[49] Surface imaging has emerged as a useful tool for voluntary DIBH treatments. The use of this technology can achieve reproducible patient setups and reasonably consistent distances between the heart and the chest wall during breath holds, reliably minimizing cardiac side effects from radiotherapy.[49,50] When using OSI for this purpose, the external surfaces from both a free-breathing and a DIBH scan are sent to the system. The patient is initially setup to the free-breathing scan, and the breath hold reproducibility is checked with the DIBH surface. This is the surface used for treatment, and the radiation is only delivered when the patient's current surface is within a preset tolerance of the DIBH reference surface.

Intracranial Stereotactic Radiosurgery

Intracranial SRS patients can also benefit from OSI setup and monitoring. Conventional masks used for frameless SRS are not suitable for OSI because they cover the patient's entire face; OSI technology requires uncovered skin for proper tracking. Open masks, such as the one shown in Figure 24.13, allow for immobilization of the patient while maintaining part of the face exposed for surface monitoring. Open mask immobilization in this scenario has the advantage of both allowing continuous tracking the patient's surface directly, instead of monitoring infrared markers on an array or mask, and providing increased patient comfort. Several authors have published on the feasibility and accuracy of this technique for radiosurgery.[54–56] Whereas initial positioning is always confirmed with internal imaging to ensure the target alignment is satisfactory, the use of OSI for these treatments allow for real-time, uninterrupted monitoring of the patient without the delivery of any additional ionizing radiation dose.

Conclusions and Future Applications

OSI is an emerging technology that can improve setup efficiency of patients and provide intrafraction monitoring without the use of additional radiation dose. Patient monitoring has become increasingly popular in stereotactic treatment settings where the prescribed dose per fraction is increased and treatment margins are reduced. Although surface imaging provides the means to externally ensure the patient remains in position, it is important to remember that it does not directly relay information about internal motion. Movement from involuntary processes such as digestion will not be readily detected by this technology. Despite this limitation, these systems have benefits beyond what has already been described. They intrinsically offer the possibility of increased patient safety by reading a larger range of the patient's anatomy when compared to internal imaging. This can help avoid confusion during setup and consequently reduce mistreatment of lesions because of problems identifying the correct vertebral level or accidental couch movements between imaging and treatment. Additionally, surface imaging could be utilized in the future for automatic facial recognition of patients before treatment and identification and tracking of anatomical changes such as swelling or weight loss based on the changes of the patient's surface.

IMMOBILIZATION METHODS IN BRACHYTHERAPY

Introduction

Historically, the focus in brachytherapy has been on immobilization of the applicator, leaving the patient to move freely. For example, manufacturers such as Nucletron and Varian sell brachytherapy stands that clamp onto the applicator. Whereas advancement in design has made these stands CT and MR compatible, the patient can still move and possibly change the position of the applicator with respect to the organ that is to be treated. Additionally, patient flow issues can cause difficulties in brachytherapy treatments. An applicator typically is placed in the patient in an operating room. The patient is then moved to either the radiology or radiation oncology department for imaging and then to the brachytherapy treatment room. Each time the patient is moved, the applicator can become displaced from the optimal position. While the development of integrated brachytherapy suites has lessened this workflow in academic centers, it is still common in community practices. Thus, proper patient and applicator immobilization is still important in brachytherapy.

Immobilization for Genitourinary Treatment

Brachytherapy treatment is common for prostate cancer for men and various

gynecologic malignancies for women. Image-guided brachytherapy (IGBT) allows the imaging of the patient during applicator placement, analogous to image-guided radiotherapy for external beam patients. This imaging can be done by various means, including ultrasound, CT, or MR systems. The most common IGBT system is the use of ultrasound for the prostate brachytherapy. Shown in Figure 24.14 is a diagram of an ultrasound probe mounted in a stepper that is used to localize the prostate during low-dose rate (seed implant) or high-dose rate brachytherapy treatments.[57] It has been well established that insertion of needles into the prostate for brachytherapy treatment can cause both motion and deformation of the prostate.[58] The stabilizing needle (Fig. 24.14) is designed to reduce the amount of prostate movement from the insertion of the needles used to deposit seeds throughout the prostate. Stabilizing needles are commercially available from RPD, Inc., as well as the Mick Radio-Nuclear Morgenstern needle. Immobilization of the prostate is accomplished by deploying a side barb into the prostate tissue. The stabilizing needle is then secured with a “lock spring” to the proximal side of the implantation template. Two stabilizing needles are used in the periphery of the prostate to provide adequate stabilization.

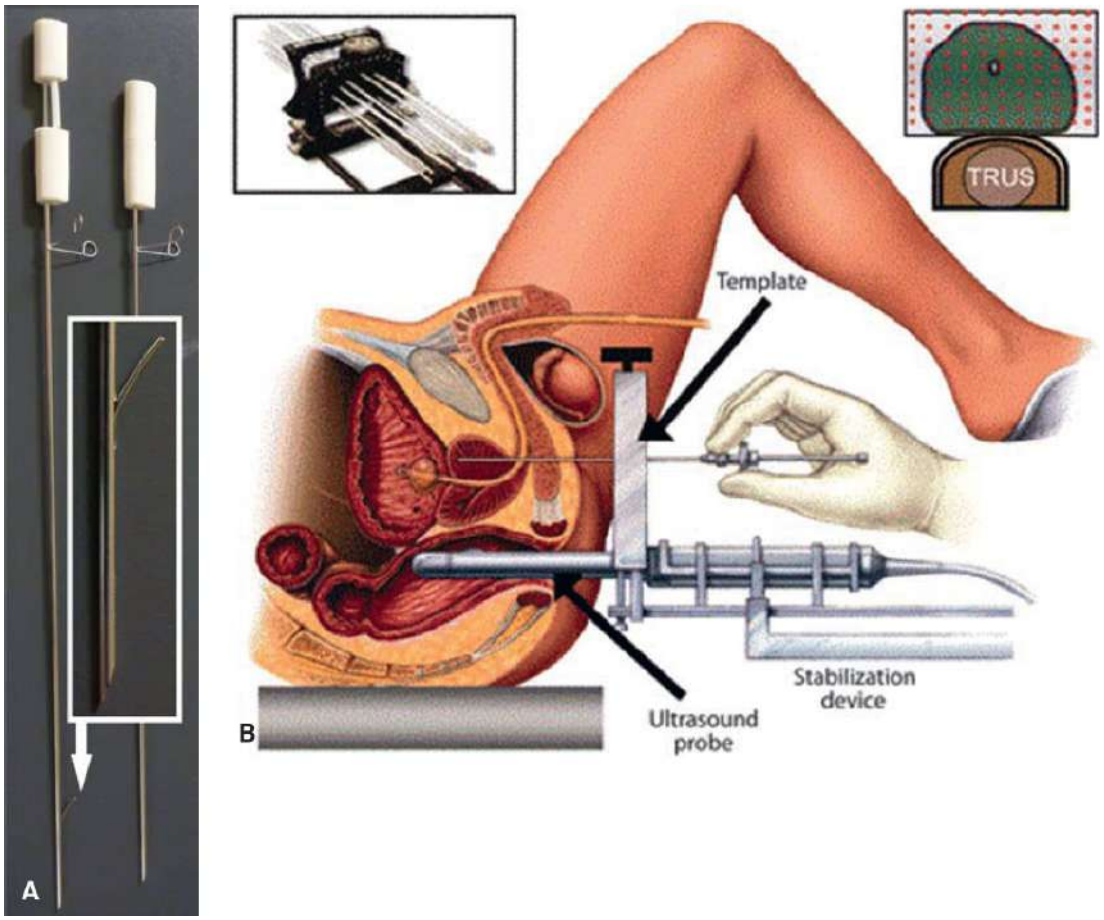

FIGURE 24.14. Prostate stabilizing needles. **A:** Stabilizing needles used in prostate brachytherapy. Note the barb (inset) that is deployed in the prostate. **B:** A diagram illustrating the prostate brachytherapy implantation procedure using transrectal ultrasound for prostate visualization and a template for guiding the needle-loading process. More advanced imaging for prostate cancer is the use of MR to image the placement of needles within the prostate as well as for treatment planning purposes. Rather than the dorsal lithotomy position most common for ultrasound imaging, MR imaging usually requires the patient to be immobilized in a lateral decubitus position as shown in Figure 24.15.[59] The use of Aquaplast material can be used to prevent the patient from moving during needle placement, planning, and treatment. In addition to immobilization of the patient, a rectal coil used for imaging is connected to the template used for needle placement. In this way, patient, coil, and template are connected together, as shown in Figure 24.15. The patient can be withdrawn from the MR for needle placement and then

reinserted for imaging.[59,60]

The issue of immobilization of applicators for brachytherapy of gynecologic malignancies has been known for many years. Maintenance of the relative position of the applicator to the target and normal tissue, such as bladder and rectum, can determine the quality of the outcome. Vaginal packing and waistbands have commonly been used to immobilize the applicator but are physician-dependent and may often be unsatisfactory.[61] An early study measured the displacement of tandem and ovoid applicators of up to 5 mm because of movement of the patient from simulation to the treatment room and then back to simulation.[62] This movement caused a change in dose of up to 10% to Point A, and 9% and 17% to the rectal and bladder points, respectively. More recently, a comparison of immobilization methods for vaginal cuff brachytherapy was undertaken, showing that even when the cylinder insertion was performed by the same physician with the same immobilization method and identical patient setup position, variations occurred in the cylinder geometry between simulation and subsequent insertions.[63] The magnitude of the deviation was smaller for stand-type applicator immobilization as opposed to a skirt-type system. It has been shown that the angle of the applicator in vaginal brachytherapy can have a large effect on the normal tissue (bowel) dose and that the applicator should be held in a horizontal position.[64] Additionally, as vaginal cuff brachytherapy has migrated from a single-applicator insertion for LDR brachytherapy to multiple-applicator insertions used in high–dose rate HDR treatments, the positional variation of the applicator geometry has been documented, along with variations in the dose to the normal tissue.[65] Furthermore, because of the steeper dose gradient around HDR sources, the variation of the applicator position magnifies the variation of the dose.

The ideal situation to mitigate motion in brachytherapy would be to scan, plan, and treat in a single room without having to move the patient from the treatment position. The development of integrated brachytherapy suites, such as the Nucletron Integrated Brachytherapy Unit (IBU) or the Varian Acuity Suite, allows for the placement of applicators, imaging, and treatment all in the same room. These suites utilize an in-room cone-beam CT system for image guidance. At the University of Virginia (UVA), the IGBT suite (Fig. 24.16) features CT on rails for in-room patient imaging and 3D treatment planning. Contrary to conventional CT in which the patient translates through the scanner, in this setup, the scanner itself translates over the patient while he or she is immobilized on the table. The image-guided suite at UVA is also designed to accommodate a

full anesthesia team. With in-room imaging capabilities, if the imaging study shows that the applicator is not optimally placed, it can be readily adjusted. Furthermore, in-room imaging allows for real-time treatment planning with the patient in the treatment position. Treatment can then be delivered with confidence that the planned treatment geometry is what is actually being delivered.

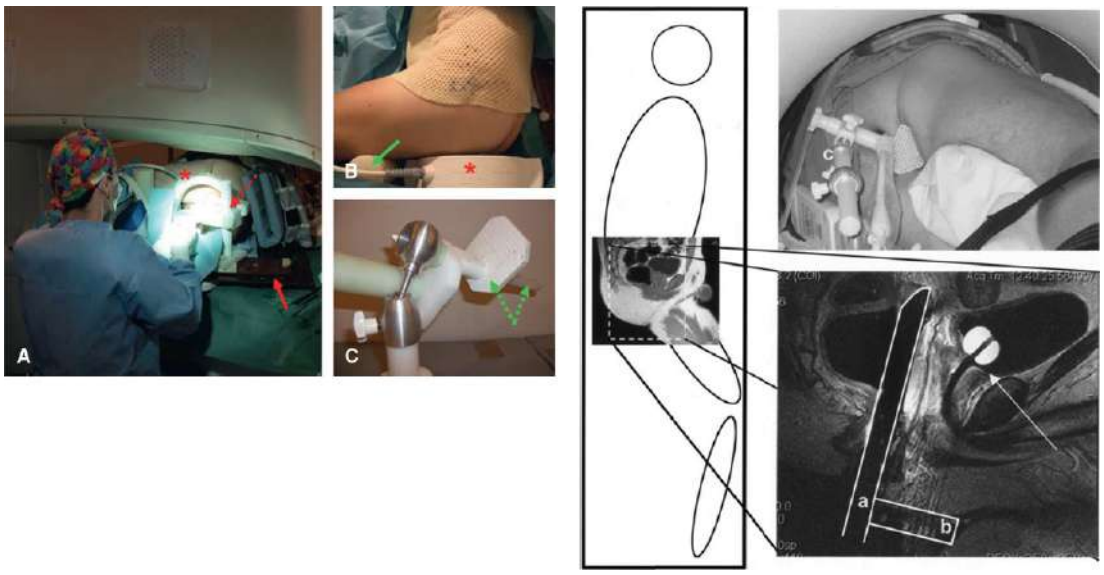

FIGURE 24.15. MR-guided prostate brachytherapy. Two MR-guided prostate HDR procedure examples from the literature. **Left:** As shown in this image from Lakosi et al.'s report, a large sheet of thermoplastic material can be formed around the pelvis to help stabilize the patient in the lateral decubitus position. The rigid connection between the rectal coil and the needle template is also well illustrated. FIGURE 24.16. Image-guided brachytherapy suite at University of Virginia. The brachytherapy suite at the Emily Couric Clinical Cancer Center features a CT on rails for image guidance. The rails are on either side of the table on the floor along which the CT scanner translates over the patient. The room is equipped with high-quality operating room lights and has full anesthesia capabilities. The operating room table allows for numerous attachments to be mounted; illustrated here are leg stirrups for placement of the legs in the dorsal lithotomy position and a transrectal ultrasound stepper. Note the HDR afterloader to the right side of the table. (Image taken at University of Virginia, December 2011.)

Because of better soft tissue contrast, MR imaging within a brachytherapy suite has been developed. An MR on rails system allows placement of the applicator followed by MR imaging, planning, and treatment.[66] A disadvantage of this system is the requirement of MR compatible applicators and ancillary equipment.

Unfortunately, most facilities lack the ability to perform volumetric CT imaging and HDR brachytherapy treatments within the same dedicated room. In lieu of a dedicated image-guided suite, one strategy to decrease displacement of the applicator is to minimize movement of the patient after applicator placement. The Zephyr patient transport system, shown in Figure 24.17, is designed to minimize applicator motion when the patient is moved between different rooms during the course of a brachytherapy treatment. The patient is kept in the same position on the transport system to allow for CT scanning and subsequent

treatment. The Zephyr system uses air-bearing technology to easily move patients from the transport bed to the CT or treatment couches. This system has the potential to minimize logistical and applicator movement issues of patient transport for departments without a dedicated IGBT suite.[67]

Immobilization for Breast Brachytherapy

The use of brachytherapy to treat breast cancer has become more common since the introduction of balloon-based catheter systems, such as the MammoSite or the Contura, along with the related SAVVI applicator. Traditionally, breast irradiation has been delivered to the whole breast over 6 to 7 weeks after the tumor has been removed. Implanted catheters or balloons have allowed the use of accelerated regimens decreasing this time to 5 treatment days.[68,69] These implanted devices are simpler to administer, compared to the more complicated interstitial implants, in which catheters were placed through the breast tissue to treat the lumpectomy cavity.[70,71] The implanted balloon or SAVVI applicators, along with the interstitial implants, are used to only treat the lumpectomy cavity, which is known as partial breast irradiation (PBI). Partial breast irradiation can also be accomplished with external beam radiation. The arrangement of beams to treat the lumpectomy cavity, however, is much more complicated than the normal tangential arrangement for whole-breast irradiation. Breast bridges, such as the one manufactured by Varian shown in Figure 24.18, made the interstitial placement of catheters more reproducible between patients, as opposed to freehand placement.[71]

A more recent development for noninvasive breast brachytherapy (NIBB), as opposed to the insertion of catheters or balloons, which can lead to infection, is the AccuBoost system, which immobilizes the breast for imaging and subsequent high–dose rate brachytherapy treatment.[72] NIBB using the AccuBoost system consists of a three-step process. In the first step, the breast is immobilized between two mammographic paddles, achieving a stable position for imaging and treatment. This immobilization of the breast aids in the delivery of the PBI without the uncertainties that can arise from delineating the target with a CT scan. Additionally, respiratory motion and daily setup errors can also affect the treatment if external beam radiation is used for the PBI. After the mammogram has been performed, the lumpectomy cavity is delineated, typically using radio-opaque clips placed at the time of surgery. The brachytherapy treatment is then delivered in a parallel-opposed technique from each orthogonal direction, creating dose distributions shown in Figure 24.19.[73]

TOTAL BODY IRRADIATION IMMOBILIZATION

Several devices are available for clinical programs that include total body irradiation (TBI) with photons, generally utilized in preparation for bone marrow transplantation. These devices can also be designed to rotate and may also support total skin irradiation (TSI) treatments for mycosis fungoides. Features of these systems generally include a beam spoiler, because a maximum dose at the skin entrance is preferred for TBI; systems for positioning partial lung blocks; and methods to keep the patient stable while standing for the treatments, which may take from 10 to 40 minutes, depending upon the treatment protocol. The major disadvantage for these systems is identifying storage in the treatment room; they are large and often take up vital space in the treatment area. It is important to note that these systems usually operate at a distance of about 5 m from the target, with the gantry at a horizontal angle (90 or 270 degrees). Figure 24.20 shows two representative TBI devices from Radiation Products Design, Inc. and Mick Radio-Nuclear Instruments, Inc. Features such as a bicycle seat, handgrips, and shoulder stabilizers are used to help support the patient. Some photon TBI stands offer a harness that will provide an additional measure of security to prevent the patient from falling over in case the patient succumbs to fatigue and faints.

IMMOBILIZATION STRATEGIES FOR INTRAOPERATIVE

RADIOTHERAPY

In intraoperative radiotherapy (IORT), a single high-dose fraction of radiation is delivered directly to the tumor bed immediately following surgical resection. The dose delivery occurs in the operating room while the patient is still under anesthesia. There is growing evidence that many low-risk breast cancer patients can achieve comparable local control with PBI as with traditional whole-breast radiotherapy.[68] Smaller volumes of irradiated tissue in PBI allows for treatment courses to be delivered on an accelerated schedule. The potential to deliver a therapeutic dose in a shorter period of time can increase patient convenience and expand access to treatment for those with transportation limitations. IORT, which delivers a highly localized dose, is well suited for PBI candidates; and hence, most of the clinical experience with IORT is in the treatment of low-risk breast cancer. The advantages of IORT are lower rates of toxicity, as less normal tissue is irradiated, and enhanced patient convenience, as a therapeutic dose can be delivered during the surgical procedure.[74] IORT is currently being used as both sole therapy[75,76] and also as an upfront boost with external beam whole-breast therapy to follow.[77] Reitsamer presents an excellent overview of the rationale and methodology of intraoperative RT.[74]

Both electrons and low-kVp photons are currently being utilized to deliver IORT. The TARGIT trial uses a 50-kVp x-ray source that is placed directly in the lumpectomy cavity following excision of the tumor.[75] The x-ray source is housed in a spherical applicator to provide separation between the source and the target tissue. An alternative delivery method utilizes a mobile linear accelerator (linac) to deliver the dose to the target tissue with electrons. The current commercially available accelerators designed for IORT are capable of producing electrons with energies up to 12 MeV, giving therapeutic ranges of up to roughly 3 cm in tissue. When using a linear accelerator–based delivery method for electron IORT, a collimator cone must be placed on the target tissue and then aligned with the electron beam exiting the linac.

FIGURE 24.20. Total body irradiation (TBI) stand. A stand is commonly used to help position patients for TBI with photons and electrons. Common features of TBI stands include **(A)** handgrips and a seat to help support the patient. Note **(B)** the harness used to prevent the patient from falling in the case of fatigue and/or fainting. (**A** taken at University of Virginia, December 2011. **B**, courtesy of Radiation Products Design, Inc.)

One mobile accelerator system, the Mobetron, has an interesting method to immobilize and stabilize the irradiation geometry, illustrated in Figure 24.21. Following excision of the tumor, the tissue surrounding the lumpectomy cavity that is to be irradiated is sewn together by the surgeon. A metal shield is placed downstream of the target tissue to protect the thoracic wall and underlying lung tissue. The appropriate diameter collimator cone is chosen and placed by the physician directly over the target tissue. The linac is then rolled into place to be connected to the collimator cone. For most mobile accelerator systems, the linac

must then be rigidly connected to the cone, a process termed “hard-docking,” which requires great care and skill to properly align the linac while maintaining the physician’s cone positioning. In this situation, the end result is that the cone is attached to the linac itself. For the Mobetron system, the cone is immobilized following physician placement via a rigid arm clamped to the surgical table. A unique feature of the Mobetron is the “soft-docking” system in which an internal laser-guided system uses a mirror on the top of the cone to precisely align the radiation beam; the linac never actually contacts the collimating cone. The entire procedure is performed while the patient is under anesthesia.

SUMMARY: THE EVOLUTION OF PATIENT IMMOBILIZATION

Strategies to immobilize patients for radiotherapy have been developed since it was introduced as a treatment modality over 100 years ago. In this chapter, we have presented a wide array of simple devices that have continued to be used for decades, albeit with new designs and materials that make their use more comfortable, convenient, and sanitary for the patient and the therapists. We have also presented highly specialized systems that may be used in the most sophisticated of radiation therapy treatment modalities that address specific needs of image guidance, highly conformal and high-dose stereotactic treatments, brachytherapy, and intraoperative therapy. Tables 24.1 and 24.2 have been included to provide a top level summary of the pros and cons of the wide array of commercially available immobilization systems. Common themes in modern radiation therapy immobilization include striking a balance between patient comfort and stability, supporting effective and safe approaches for target localization during treatment, and supporting systems to verify the patient position prior to treatment using x-ray or surface imaging. Image-guided radiation therapy (IGRT) and immobilization are interlinked, and IGRT is proving to play an increasing role with every type of treatment. It is therefore not surprising that the radiation therapy commercial industry will continue to focus on providing safe and effective immobilization that is compatible in both CT and MRI.

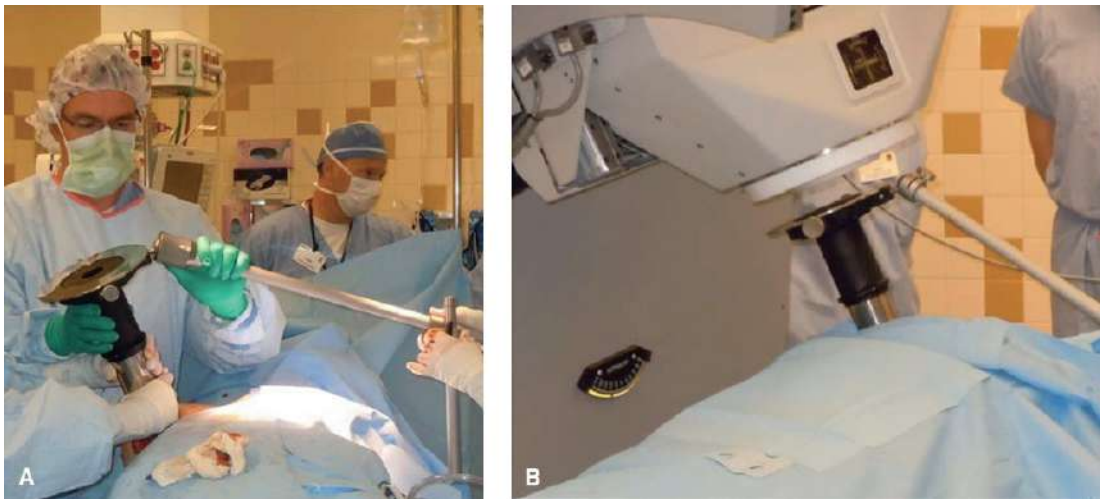

FIGURE 24.21. Intraoperative RT. For intraoperative radiotherapy with the Mobetron system **(A)**, the cone is placed by the physician directly over the target tissue following lumpectomy. The cone is fastened to the surgical table by a rigid arm. **B:** The linear accelerator is then positioned above the cone and automatically aligned using laser guidance with the mirror on the cone. (Images courtesy of IntraOp Medical Corporation, Sunnyvale, CA.)

The importance of patient and applicator immobilization has begun to be integrated into brachytherapy treatments, especially with the development of IGBT, analogous to IGRT, in which the applicator is placed, simulation is performed, and the patient is treated with minimal motion of the patient or applicator. The advances that have been made in immobilization devices for external beam radiation, such as CT and MR compatibility, are finding increased use in brachytherapy. Integrated brachytherapy suites, which can combine imaging and treatment modalities, are becoming increasingly common.

In conclusion, effective radiation treatment is dependent on both the proper localization of the tumor as well as proper immobilization of the patient. As radiation therapy has evolved, so too have the strategies for immobilization of the patient. IGRT, including hypofractionated SBRT, as well as IGBT, require that the patient be comfortably immobilized to ensure that the radiation is properly delivered to the tumor. This is especially necessary as the dose per fraction is increased, which could lead to serious complications should the normal tissue surrounding the tumor receive excessive dose because of poor localization and immobilization.

CHAPTER 25

Physics and Biology of Brachytherapy

Jeffrey F. Williamson and David J. Brenner

Brachytherapy (BT) (*brachy* is from the Greek for short distance) consists of placing sealed radioactive sources very close to or in contact with the target tissue. Because the absorbed dose falls off rapidly with increasing distance from the sources, high doses may be delivered safely to a localized target region over a short time. This chapter reviews the properties and applications of commonly used sealed radionuclides and sources, the basic biologic principles governing clinical response to BT, methods of dose calculation and source strength specification, and principles of implant design and dose specification for interstitial and intracavitary BT.

BASIC TERMINOLOGY

Implantation techniques may be classified in terms of surgical approach to the target volume (interstitial, intracavitary, transluminal, or mold techniques); the means of controlling the dose delivered (temporary or permanent implants); the source loading technology (preloaded, manually afterloaded, or remotely afterloaded); and the dose rate (low, medium, or high).

Intracavitary insertion consists of positioning applicators (bearing the radioactive sources) into a body cavity in close proximity to the target tissue. Intracavitary BT is used most widely for treatment of localized gynecologic malignancies and postoperative treatment in early-stage conservatively managed breast cancer. All intracavitary implants are *temporary implants*; they are left in the patient for a specified time to deliver the prescribed dose. With a few exceptions, during temporary implantation, the patient must be confined to a controlled, if not shielded, area in the hospital to manage the radiation safety hazard posed by the large ambient exposure rates around the implant.

Interstitial brachytherapy consists of surgically implanting small radioactive sources directly into the target tissues. A *permanent* interstitial implant remains

in place indefinitely and is not removable; the initial source strength is chosen so that the prescribed dose is fully delivered only when the implanted radioactivity has decayed to a negligible level.

Surface-dose applications (sometimes called plesiocurie therapy or mold therapy) uses an applicator containing an array of radioactive sources, usually designed to deliver a uniform dose distribution, that is placed on the skin or mucosal surface immediately adjacent to the target tissue.

Transluminal brachytherapy consists of inserting a single line source into a body lumen to treat its surface and adjacent tissues.

Until the early 1960s, radioactive sources (needles for interstitial therapy or preloaded applicators for intracavitary therapy) were implanted directly into the patient. Radiation exposure to the brachytherapist and operating room staff was reduced significantly with the advent of *afterloading* technology.[1,2] *Manual afterloading* consists of implanting nonradioactive tubes or intracavitary applicators into the patient. Following transport of the patient to his or her room, sources are manipulated into the applicators by means of forceps and other handheld tools. Exposure to staff responsible for source loading and the care of BT patients can be greatly reduced or eliminated by the use of a *remote afterloading system*, which consists of a pneumatically driven or motor-driven source transport system for robotically transferring radioactive material between a shielded safe and each treatment applicator.

According to Report No. 38 of the International Commission on Radiation Units and Measurements (ICRU),[3] *low–dose rate* (*LDR*) implants deliver doses at the rate of 40 to 200 cGy/h (0.4 to 2 Gy/h), requiring treatment times of 24 to 144 hours, during which the patient is confined to an inpatient treatment room. At the other extreme, *high–dose rate* (*HDR*) BT uses dose rates in excess of 0.2 Gy/min (12 Gy/h). In fact, modern iridium-192 (^{192}Ir) HDR remote afterloaders deliver instantaneous dose rates as high as 0.12 Gy/s (430 Gy/h) at a distance of 1 cm, resulting in treatment times of a few minutes. Such treatments must be delivered in heavily shielded vaults using remote afterloading devices, but allow fractionated BT to be delivered on an outpatient basis. Medium–dose rate delivery, defined as the 2 to 12 Gy/h range, rarely is used. Although not recognized by ICRU Report No. 38, the ultralow dose rate (ULDR) range (0.01 to 0.3 Gy/h) is of great importance; it is the dose-rate domain used in permanent implants with ^{125}I and ^{103}Pd seeds.

PROPERTIES OF BRACHYTHERAPY SOURCES AND RADIONUCLIDES

The clinical utility of any radionuclide depends on physical properties such as half-life, radiation output per unit activity, specific activity (Ci/g), and photon energy. In addition, the methods of producing the radionuclide and its physical or chemical form strongly influence cost-effectiveness, safety, and toxicity. Detailed properties of BT radionuclides are listed in Table 25.1.

Photon Spectrum and Dosimetric Characteristics of Brachytherapy Sources

The dose delivered by a BT procedure depends on the individual source strengths, source arrangement, and implant duration as well as the dosimetric characteristics of the implanted sources. These dosimetric characteristics are described by specifying the distribution of dose rates per unit strength about the source, often in terms of an "away-and-along" table[4] in cartesian coordinates or in terms of the Task Group 43 protocol[5] described later in this chapter. The single-source dose distribution is of central importance to treatment planning because commercial computer planning systems estimate dose distribution from the spatial coordinates of the implanted sources using the principle of superposition. The source superposition algorithm estimates the contribution of each source, given its tip-and-end coordinates and the single-source dose-rate array, to each point of interest. These contribution estimates are summed to estimate the total dose rate at each point. Often, total dose rates are calculated over a two-dimensional (2D) grid of points and are represented as isodose rate curves.

For conventional BT, for which the therapeutically relevant distance range is 3 to 20 mm, only photons (γ-rays or characteristic x-rays) with energies in excess of 15 keV (kiloelectron volts) contribute to the therapeutic effect. In general, four factors influence the single-source dose distribution for photon-emitting sources: (a) distance (inverse-square law), (b) absorption and scattering in the source core and encapsulation, (c) photon attenuation, and (d) scattering in the surrounding medium (Fig. 25.1). Encapsulation prevents radioactive material from leaking out of the source and absorbs nonpenetrating radiation (β-rays, α-rays, and low-energy photons), which would otherwise give rise to high surface doses while contributing nothing to the therapeutic effect.

TABLE 25.1 PHYSICAL PROPERTIES AND USES OF BRACHYTHERAPY RADIONUCLIDES

Element	Isotope	Energy (MeV)	Half-Life	HVL-Lead (mm)	Exposure Rate Constant[a] Γ_δ	Source Form	Clin App

[a]No filtration in units of $R \cdot cm^2 \cdot mCi^{-1} \cdot h^{-1}$.
[b]0.5-mm platinum filtration; units of $R \cdot cm^2 \cdot mg^{-1} \cdot h^{-1}$.
HDR, high-dose rate; HVL, half-value layer; LDR, low-dose rate; LET, linear energy transfer.

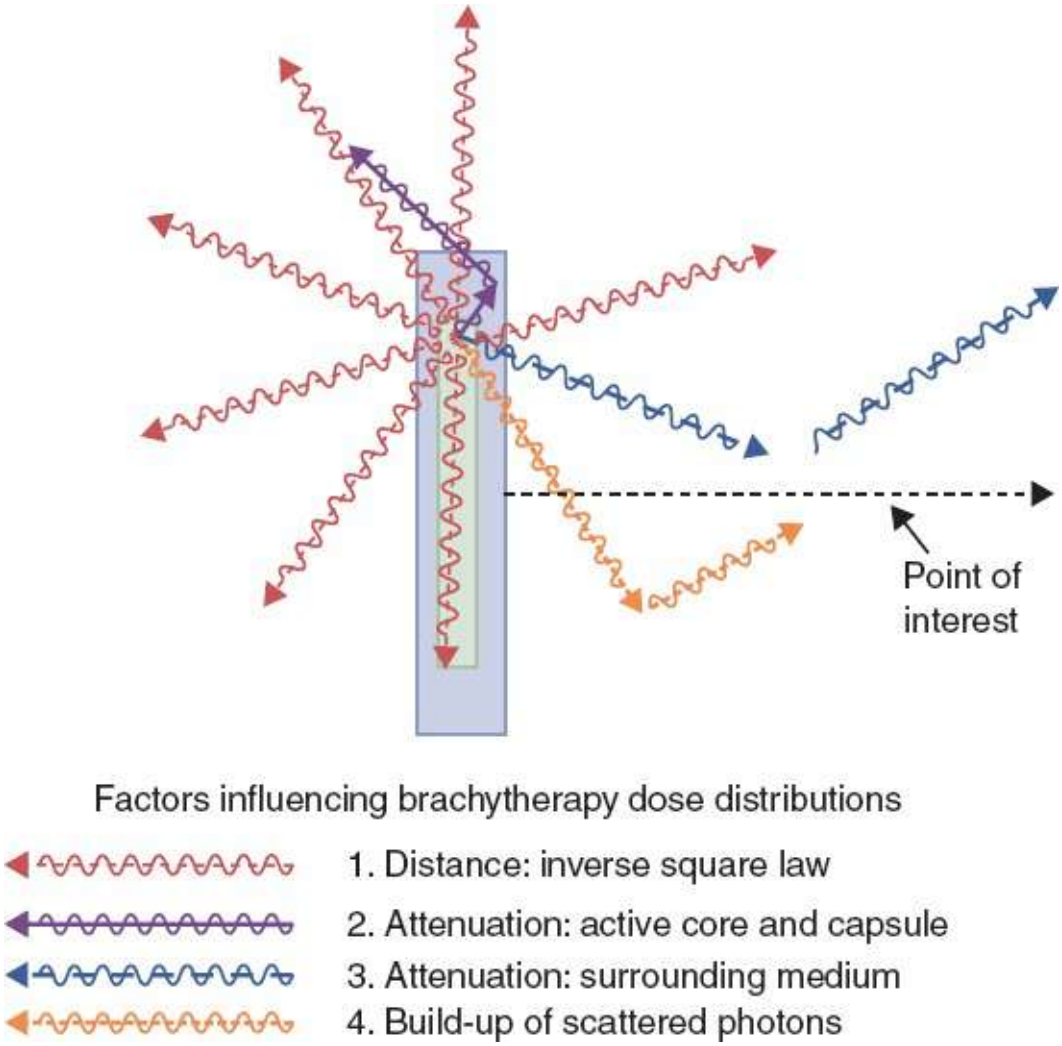

FIGURE 25.1. Typical cylindrical brachytherapy source, consisting of an active core (inner cylinder within which radioactivity is uniformly distributed) and the surrounding encapsulation (usually stainless steel or titanium for modern sources). The four principal factors influencing the relative dose distribution include (*1*) distance, (*2*) attenuation and scattering of photons by the source structure, and two competing

effects of the surrounding medium: attenuation of primary photons (*3*) and accumulation of scattered photons (*4*) originating throughout the medium.

Each voxel of radioactive core material shown in Figure 25.1 can be assumed to be an isotropic point source (Fig. 25.2). Because of the straight-line emission of photons with equal likelihood in all directions, photon intensity or fluence, $\Phi(r)$, at any point is proportional to the inverse square of its distance, r:

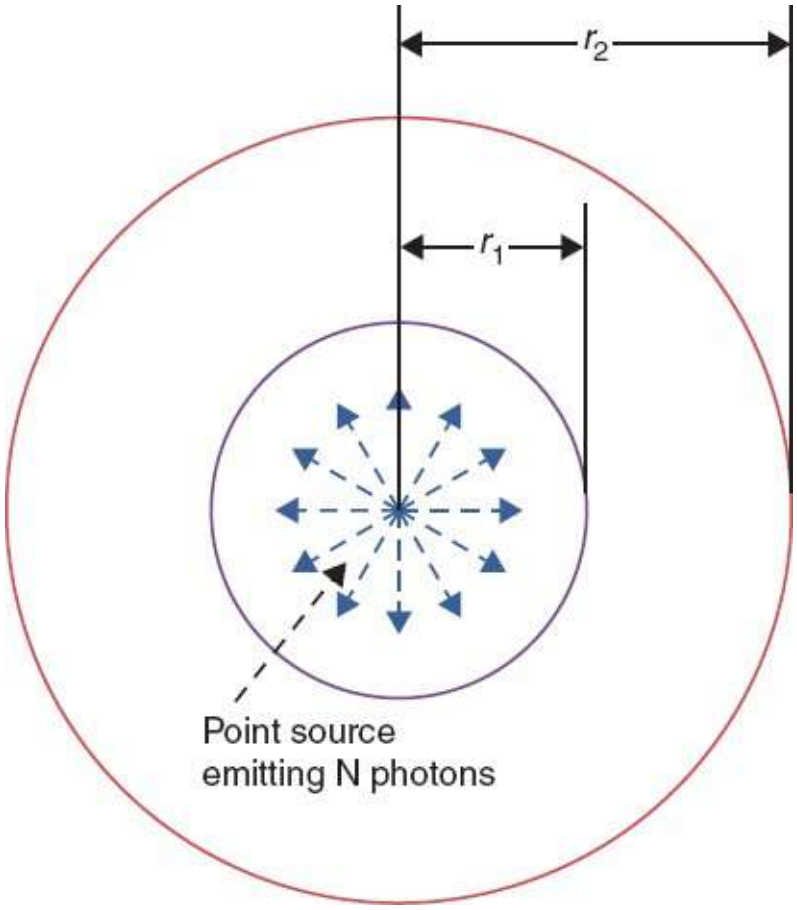

FIGURE 25.2. An *isotropic point source* of activity, A. To illustrate the derivation of inverse-square law, the source is surrounded by vacuum and placed at the center of two concentric spherical surfaces of radii r_1 and r_2. By definition, an *isotropic point source* has no extension and radiates photons with equal likelihood in all directions in straight-line paths.

$$\Phi(r) = \frac{\text{no. of incident photons}}{\text{unit area irradiated}} = \frac{\text{no. of photons emitted}}{4\pi r^2} \propto \text{dose}\,(r) \propto \text{exposure}\,(r) \tag{1}$$

assuming that attenuation and scattering can be neglected.

As a result of this purely geometric effect, the absorbed doses $D(r_1)$ and $D(r_2)$ at the two distances r_1 and r_2 (Fig. 25.2) are related by:

$$\frac{D(r_1)}{D(r_2)} = \frac{\Phi(r_1)}{\Phi(r_2)} = \left(\frac{r_2}{r_1}\right)^2 \qquad (2)$$

This fundamental law applies exactly to each point of the radioactive core of the source shown in Figure 25.1 assuming that there is no attenuation and scattering of photons by the surrounding medium. However, Eq. (2) will not accurately describe the "collective" dose falloff arising from the combined action of the point sources distributed throughout the core, unless both r_1 and r_2 are large relative to the active source dimensions. Of the four factors influencing the dose distribution (Fig. 25.1), inverse-square law is by far the most important. For a pure isotropic point source, dose will decrease by a factor of 100 between the distances of 0.5 and 5 cm. The influence of the remaining factors over the same distance range rarely exceeds a factor of 2 or 3. Consequently, the dosimetric characteristics of implants (e.g., the heterogeneous dose distribution within the target tissue and rapid falloff of dose outside the implanted volume) can be accounted for by applying inverse-square law to each pointlike element of radioactivity within the implant. Control of intersource spacing and positioning relative to the target and dose-limiting tissues is the most challenging issue in delivering BT.

Although inverse-square law dominates BT dose distributions, the surrounding medium and the source structure do significantly affect the dose distribution (Fig. 25.1). The source core and surrounding capsule reduce dose at the point of interest through absorption and scattering of primary photons. Primary photons contributing dose to points located near the longitudinal source axis (cylindrical axis of the source or axis of rotation) must traverse longer pathlengths of capsule and core material and therefore experience more attenuation than do photons contributing dose to equidistant points on the transverse source axis (plane perpendicular to the longitudinal source axis that bisects its active core). For any fixed distance from the source center, doses near the longitudinal axis are usually smaller than on the transverse axis. This phenomenon is known as *oblique filtration* and is the main cause of dose *anisotropy* (variation of dose as a function of polar angle at each fixed distance relative to the source center) characteristic of extended BT sources. Because BT sources are cylindrically symmetric, the dose distribution will be equatorially

isotropic (constancy of dose as a function of azimuthal angle for each fixed polar angle and distance).

The tissue-equivalent medium surrounding the source affects the dose distribution in two competing ways (factors 3 and 4 of Fig. 25.1). At each point of interest, the intervening medium reduces the dose distribution by attenuating primary photons (deflecting them from their straight-line trajectories). At the same time, photons are being emitted in all directions from the source and interacting with the medium by means of Compton scattering and photoelectric absorption. Thus, each volume element of tissue is effectively radiating scattered photons in all directions, many of which contribute to dose at the point of interest. This mechanism, known as scattered-photon buildup, enhances the dose. The overall influence of the surrounding medium is the combined effect of these two competing processes: photon attenuation and scattered-photon build-up. In contrast to external beam therapy, in which the scattering volume is limited to a narrow cone, scattered photons dominate BT dose distributions at distances >2 cm. Photon scattering is the main source of complexity in BT dose measurement and algorithm development.

Figure 25.3 demonstrates that the relative dose versus distance from the source is nearly independent of its photon energy so long as the average photon energy is >200 keV. In this energy range, dose deviates from inverse-square law by <5% over the 1- to 5-cm distance range. All of the “radium-equivalent” isotopes, including ^{137}Cs, ^{192}Ir, and ^{198}Au, fall into this energy range. This behavior, which greatly simplifies BT dosimetry, is the result of equilibrium between primary photon attenuation and buildup of scattered photons. Only for low-energy sources (e.g., ^{103}Pd and ^{125}I) does the depth–dose curve significantly deviate from inverse-square law. Because photon absorption rather than Compton scattering dominates energy deposition below 40 keV, scatter buildup is unable to compensate for loss of dose resulting from attenuation.

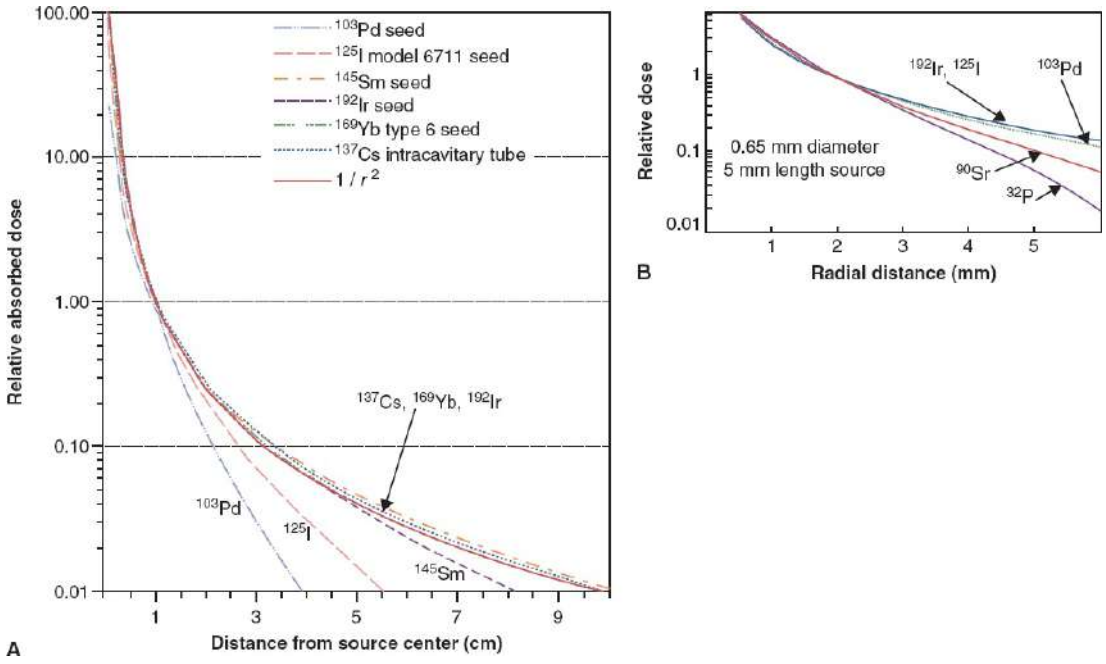

FIGURE 25.3. A: Variation of dose as a function of distance for point sources of ^{60}Co, ^{226}Ra, ^{137}Cs, ^{198}Au, ^{192}Ir, and ^{125}I. The results are normalized to 100% at 1-cm distance. The function ($1/r^2$) is plotted for comparison. **B:** Relative dose (normalized to 1.0 at 1 mm) versus distance for various cylindrical sources (0.65 mm diameter and 5 mm long) over the 1 to 5 mm distance range. (Reprinted from Amols HI, Zaider M, Weinberger J, et al. Dosimetric considerations for catheter-based beta and gamma emitters in the therapy of neointimal hyperplasia in human coronary arteries. *Int J Radiat Oncol Biol Phys* 1996;36[4]:913–921. Copyright © 1996 Elsevier. With permission.)

For radium-equivalent radionuclides, Figure 25.4A and B shows that both absolute dose rates (cGy/h to fat or water tissue per mgRaEq or unit air-kerma strength [S_K]) and relative dose distributions are nearly independent of energy and composition of the surrounding medium above 100 keV. Compton scattering, which dominates photon absorption and scattering above 100 keV, depends mainly on electron density (electrons/g) of the medium, which is nearly constant for all biologic materials. Below this energy range, absolute and relative dose distributions vary significantly with energy and composition (atomic number) of the surrounding medium. Implanting an ^{125}I seed in fat medium (effective atomic number of Z_{eff} = 6) will deliver about half the absorbed dose at 1 cm, compared to the expected dose in water (Z_{eff} = 7.5). This is because energy absorption per unit mass from photo-effect interactions is proportional to the cube of the atomic number (Z_{eff}^3) of the medium. Despite the significant impact of tissue composition heterogeneities on low-energy seed BT dose delivery, only recently have treatment planning and dose measurement practices began to

address tissue and applicator inhomogeneities.[6]

Figure 25.4B demonstrates that the inverse-square law actually underestimates relative dose at 5 cm by as much as a factor of 2 in the 60- to 100-keV energy range. In this narrow energy range, called the intermediate low-energy range, photoelectric effect is negligible, whereas Compton scattering transfers most of the colliding primary photon energy to the scattered photon rather than to the Compton electron. As a result of this imbalance between energy absorption and photon scattering, buildup of scattered photons overcompensates for loss of dose as a result of primary photon attenuation out to distances of 4 to 6 cm.

Above the 100-keV threshold, the photon energy spectrum is much less important to optimizing BT dose-rate distributions than in external beam therapy. Because artificial BT radionuclides in this energy range (^{60}Co, ^{137}Cs, ^{192}Ir, ^{198}Au) have dose-rate distributions nearly identical to those of ^{226}Ra in the 1- to 5-cm distance range, they are referred to as radium substitutes.

Figure 25.3C demonstrates that although photon energy is a relatively unimportant determinant of radium-equivalent tissue dosimetry, it significantly influences the cost, weight, and thickness of shielding required to protect critical anatomic structures in the patient and personnel involved in patient care. The half-value layer (HVL) in lead varies from 0.5 mm for a 100-keV source to 12 mm for ^{60}Co BT sources. Thus, for classical radium-equivalent BT, a radionuclide with a mean energy of about 100 to 200 keV is optimal. The major benefit of ^{125}I and ^{103}Pd as a BT source is the ability to provide complete protection by thin lead foils (0.1 to 0.2 mm), greatly reducing exposure to physicians during the implant procedure and allowing permanent-implant patients to be released from medical confinement without posing a radiation safety hazard to the general public. Recently, interest has been expressed in using radionuclides in the intermediate low-energy range (60 to 120 keV).[7–9] Tissue dose distributions are still approximately radium equivalent in this energy range, and thin layers of lead provide significant sparing of dose-limiting normal tissues near the implanted volume.

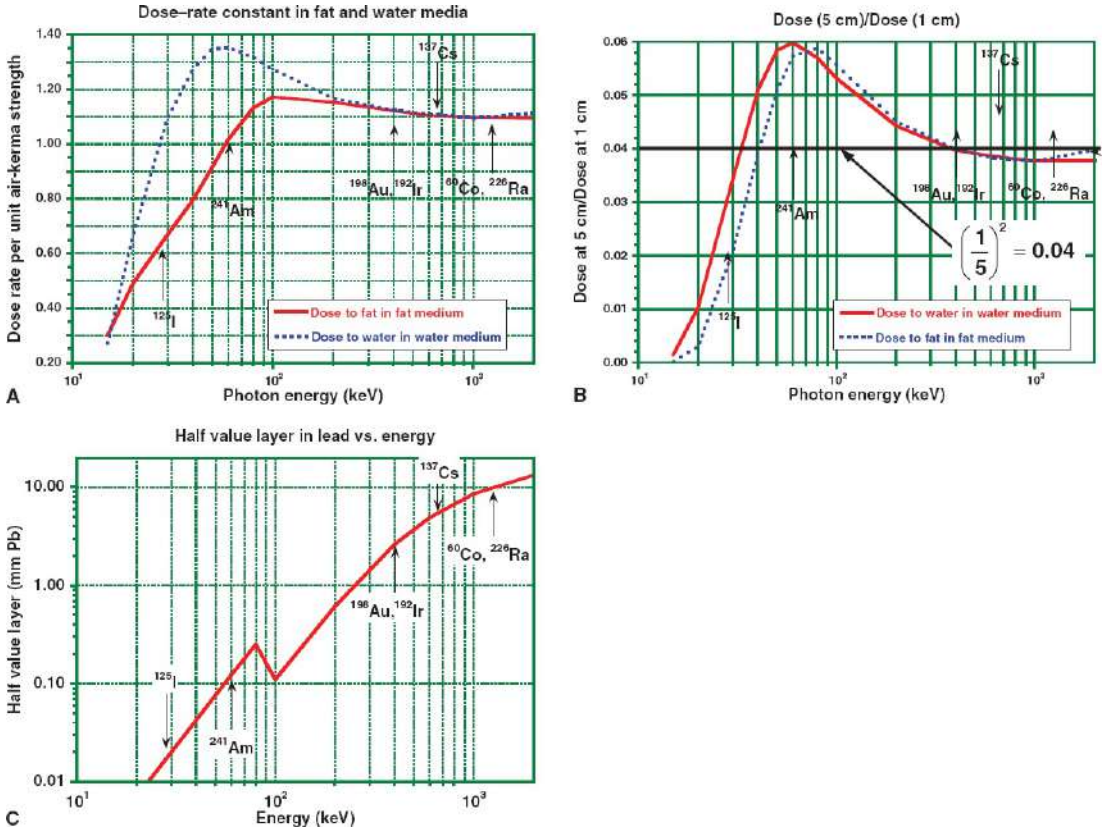

FIGURE 25.4. Variation of dosimetric properties of monoenergetic point sources as a function of photon energy. The location (in terms of average energy) of commonly used radionuclides is indicated by the labeled *vertical arrows*. **A:** Absolute dose rate per unit source strength in fat and water media at 1-cm distance. Source strength is specified in terms of output in air. **B:** Dose at 5 cm as a fraction of dose at 1 cm in fat and water media. The effect of inverse-square law, $(1/5)^2 = 0.04$, is shown for comparison as a *broken line*. **C:** Half-value layer in lead, the thickness (mm) in lead required to reduce primary dose by a factor of 2.

Intracavitary Sources for Low–Dose Rate Gynecologic Brachytherapy

Since the 1930s, sources for classical LDR intracavitary BT have taken the form of "tubes" having a physical length of 2 to 2.5 cm and an external diameter of about 3 mm. For treatment systems influenced by the Manchester[10] and M.D. Anderson[11] treatment techniques, active lengths of 1.3 to 1.5 cm are typical. Radionuclides for intracavitary applications should have a half-life long enough to support a 5- to 10-year working life without large variations in prescription dose rate so that the high cost of these reusable sources can be amortized over a large number of patient treatments. The average photon energy should be at least 60 to 100 keV, as the dose falloff for lower-energy sources (e.g., ^{125}I) is too rapid to adequately treat the target-volume periphery (2 to 5 cm from the applicator

center) without overtreating the mucosal tissues in contact with the applicator system.

Radium-226 Sources

Radium-226 (^{226}Ra), a naturally occurring radionuclide, was the first radionuclide isolated, intensively investigated, and used in clinical BT. The unit of activity, the curie (Ci), originally was defined as the rate of disintegration within 1 g of ^{226}Ra. Radium-226 has a complex decay scheme, consisting of a cascade of transformations from one daughter product to another, ending with a stable isotope of lead, $^{206}_{82}$Pb. Radium decays to gaseous ^{222}Rn with a half-life of 1,626 years. Approximately 75 γ-rays are emitted by radium and its decay products, ranging in energy from about 0.05 to 2.4 MeV, giving an average energy of about 0.8 MeV. The maximum β-ray energy is about 3.26 MeV. The exposure-weighted average energy of ^{226}Ra is 1.25 MeV when its photon spectrum is filtered by 0.5 mm of platinum. Nearly all ^{226}Ra BT sources are filtered by at least 0.5 mm Pt, which reduces the surface dose contributed by β particles to a negligible level.

Clinical ^{226}Ra sources consisted of discrete cells of radium salt (radium sulfate plus filler) placed in needles or tubes with platinum walls of thickness of 0.5 and 1.0 mm, respectively. Intracavitary radium tubes were usually 22 mm long, containing 5 to 30 mg of radium (S_K = 30 to 200 μGy·m^2·h^{-1}), with active lengths of 15 mm. For interstitial BT, the full-, half-, and quarter-intensity needles popularized by the Manchester LDR implant system typically contain 0.66, 0.33, or 0.165 mg of radium per centimeter of active length, respectively.

The clinical use of radium has disappeared and is now only of historic interest. The potential of damaged sources to leak radioactive salts or emit radon gas (^{222}Rn) is the major reason for its decline, and the exposure hazard to interstitial BT practitioners.[12] Further, the long half-life and disposal costs of spent ^{226}Ra sources present a significant financial liability. However, because of its many years of therapeutic use, several widely used quantities for source strength specification and prescription of intracavitary treatment are derived from the early experience with ^{226}Ra.

Cesium-137 Sources

Cesium-137, a fission by-product, was a popular radium substitute because of its 30-year half-life, dominating gynecologic intracavitary brachytherapy from 1970 to 2000. Its single γ-ray (0.66 MeV) is less penetrating (HVL_{Pb} = 0.65 cm) than

the γ-rays from radium (HVL_{Pb} = 1.4 cm) or ^{60}Co (HVL_{Pb} = 1.1 cm). Because ^{137}Cs decays to solid barium 137, ^{137}Cs sources have virtually replaced ^{226}Ra intracavitary tubes in LDR gynecologic applications.

Cesium-137 BT sources were introduced in the early 1960s.[13,14] Recently marketed sources, for example, the Amersham model CDCS-J tube and 3M model 6500 intracavitary tube, consist of radioactive cesium distributed within an insoluble glass or ceramic matrix,[4] which produces far less radiochemical hazard from ruptured sources than does the radon gas or cesium salts. These sources are encapsulated in stainless steel sheaths with wall thicknesses of 0.5 to 1.0 mm, active lengths of 13.5 to 15 mm, diameters of 2.6 to 3.1 mm, and total lengths of about 20 mm. Figure 25.5 shows that cesium and radium sources produce nearly identical transverse-axis dose–rate distributions when their active lengths and source strengths are the same. However, the ^{226}Ra tube isodose curves exhibit significant retraction along the longitudinal source axis as a result of oblique filtration of ^{226}Ra γ-rays through the dense (ρ = 21 g·cm^{-3}) 1-mm-thick platinum capsule. In contrast, lightly filtered ^{137}Cs tubes produce nearly elliptical isodose curves. Consequently, vaginal applicator systems containing modern ^{137}Cs sources with their axes positioned perpendicular to the coronal patient plane (e.g., the Fletcher colpostat) always will give rise to higher bladder and rectal doses than when loaded with ^{226}Ra tubes.[15] However, LDR brachytherapy has been largely abandoned in favor of HDR BT using high-intensity ^{192}Ir sources, with 85% of respondents in a recent survey reporting use of HDR or pulsed dose-rate (PDR) BT.[16] ^{137}Cs intracavitary tubes and other source configurations ceased to be commercially available in 2014. Recently manufactured but “orphaned” sources still in clinical use include intracavitary tubes produced by Isotope Product Laboratories[17] and Eckert & Ziegler BEBIG.[18]

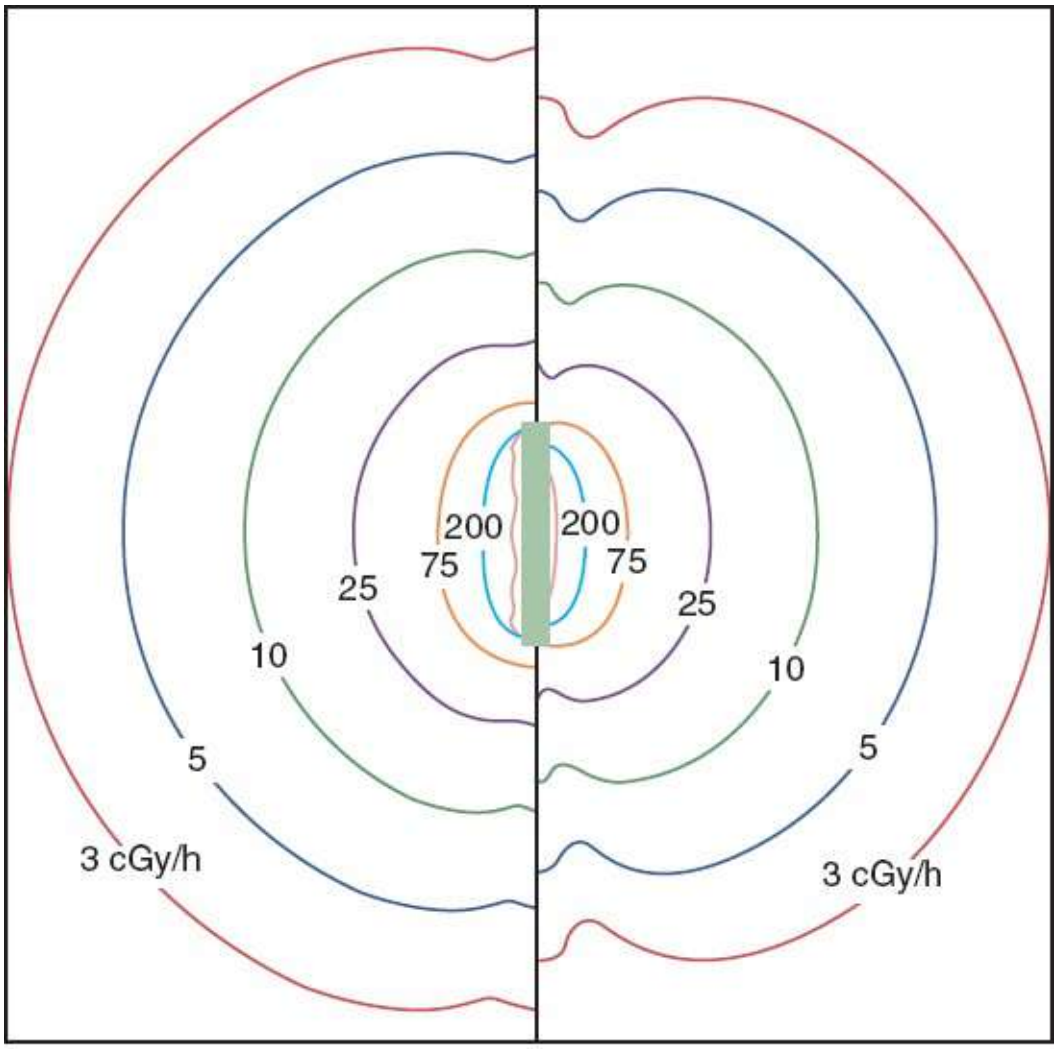

FIGURE 25.5. Comparison of isodose curves for a modern steel-clad ^{137}Cs source *(left)* containing radioactive ceramic pellets (From Williamson JF. Dose calculations about shielded gynecological colpostats. *Int J Radiat Oncol Biol Phys* 1990;19:167–178, with permission) and a ^{226}Ra tube *(right)* consisting of a $RaSO_4$ core encapsulated in 1-mm thick Pt. Both sources have an air-kerma strength of 72 $\mu Gy \cdot m^2 \cdot h^{-1}$ (10 mgRaEq).

Experimental Intracavitary Brachytherapy Radionuclides

Californium-252 is a unique radionuclide that decays by α-emission with a half-life of 2.65 years and emits neutrons by spontaneous fission with average energies of 2.1 to 2.3 MeV. Depending on the distance from the source, one-half to two-thirds of the total dose is the result of the neutron component. Assuming a relative biologic effectiveness (RBE) of 6 for the neutron component,

approximately 90% of the biologically effective dose derives from the neutron component. The radiobiologic rationale for using ^{252}Cf, especially in treating bulky gynecologic malignancies, is that the high linear energy transfer (LET) neutron component more effectively depopulates the tumor's radioresistant hypoxic core, thereby improving local control, while the rapid dose falloff maintains an acceptable level of late complications.[19] Californium-252 tube sources[20] require carefully designed radiation protection and source handling procedures to reduce radiation exposure hazards to an acceptable level, because of the high neutron quality factor of 10 to 20 that is assumed by radiation protection standards.[21] Oak Ridge National Laboratory ceased fabrication of ^{252}Cf sources for medical use in 1997. To date, ^{252}Cf medical sources are not being manufactured elsewhere in the world. However, ^{252}Cf brachytherapy continues to be of clinical interest. Two groups who are actively practicing brachytherapy have recently reported long-term clinical experiences[22,23] based on cohorts of locally advanced cervical cancer patients treated relatively recently with orphan ^{252}Cf intracavitary sources and remote afterloading systems.

Ytterbium-169 (^{169}Yb)[8] and americium-241 (^{241}Am)[7] are examples of so-called intermediate low-energy photon emitters, giving rise to 60- and 100-keV photons, respectively. The emitted photon energy is low enough that relatively thin lead foils can be used to shield personnel and dose-limiting tissues in the patient, but high enough that the resultant dose distributions in tissue remain approximately radium equivalent.[24] Because relatively thin lead sheets can be used to shield critical structures (e.g., 0.4-mm-thick lead for 50% dose reduction from ^{169}Yb), customized rectal and bladder shielding can be more easily fabricated. Ytterbium-169 seeds[8] (100-keV mean energy, 32-day half-life) have been investigated as a possible substitute for ^{192}Ir in interstitial implants[25] and for intracavitary treatment. In addition, ^{169}Yb has an extremely high specific activity. Despite recent efforts to design and fabricate ^{169}Yb sources and accessories for both LDR[26] and HDR remote afterloading[9] brachytherapy, none of these systems has been commercially realized. Other promising medium-energy photon–emitting radionuclides under investigation for brachytherapy applications include ^{57}Co,[27] ^{153}Gd,[28] and ^{101}Rh.[29]

Sources for Low–Dose Rate Temporary Interstitial Brachytherapy

The main additional requirement for radionuclides used in temporary interstitial BT is a specific activity sufficient to support fabrication of miniaturized sources (<2 mm external diameter) so as to minimize trauma to the implanted tissues.

Current interstitial implantation techniques favor disposable sources containing short-lived radionuclides that support afterloading and customization of active length.

Nonafterloading ("Preloaded") Sources: Radium and Cesium Needles

Radium-226 needles were the mainstay of interstitial BT until about 1970. These sources had external diameters of 1.5 to 2 mm, active lengths ranging from 3 mm to 4.5 cm, and Pt–Ir alloy encapsulation ranging from 0.5 to 0.65 mm in thickness. Because needle implantation can result in large exposures to the radiation oncologist's fingers, as well as whole-body exposure to operating room and implant imaging staff, neither interstitial implantation of ^{226}Ra nor ^{137}Cs needles is currently practiced.

Afterloading Interstitial Sources: ^{192}Ir Ribbons and Wires

Temporary interstitial BT experienced a renaissance in the 1960s because of the introduction of ^{192}Ir.[12] This useful radionuclide is produced by bombarding nonradioactive ^{191}Ir with thermal neutrons in a nuclear reactor, which is available in relatively pure form, has an extremely large neutron capture cross section, and produces no significant contaminant radioisotopes. Because of these properties, very high specific activities can be achieved. Miniaturized interstitial sources can be fabricated relatively cheaply. The use of ^{192}Ir in BT was pioneered by Ulrich Henschke,[30] who developed a family of widely used afterloading techniques, and to Pierquin and Dutreix,[31] who developed the ^{192}Ir-based Paris interstitial system in the early 1960s.

Iridium-192 has a 73.8-day half-life and a complex decay scheme, dominated by β decay to ^{192}Pt, but also including some electron capture and β+ decay. Its photon spectrum includes characteristic x-rays and γ-rays ranging from 63 keV to 1.4 MeV and has an exposure-weighted average energy of 397 keV. Compared with higher-energy ^{137}Cs, the thicknesses of lead and concrete shielding can be reduced by 33% and 20%, respectively.[32] More important advantages of ^{192}Ir sources are compatibility with afterloading techniques, technical flexibility, and patient comfort.

In the United States, ^{192}Ir is still available (but rarely used) in the form of seeds, 0.5 mm in diameter and 3 mm long, for LDR BT. The seeds are encapsulated in a 0.8-mm-diameter nylon ribbon and spaced at 1- or 0.5-cm center-to-center intervals and are available in strengths of 1 to 150 μGy·m^2·h^{-1}

(0.1 to 20 mgRaEq). In Europe, ^{192}Ir was used in the form of a wire (0.3- or 0.6-mm outer diameter) consisting of an iridium–platinum radioactive core encased in a 0.1-mm sheath of platinum. In addition to eliminating radiation exposure hazards in the operating room, ^{192}Ir ribbons and wires can be trimmed to the appropriate active length for each catheter. Manual and remotely afterloading LDR interstitial brachytherapy utilization has markedly declined in the developed world over the last two decades. A recent survey[33] indicates that in high-income European countries, only 11% of brachytherapy procedures performed in 2007 used LDR techniques compared to HDR (52%), PDR (10%), and permanent seed implants (21%).

Low-Energy Sources for Temporary Interstitial Brachytherapy

High-intensity ^{125}I sources[34] have been proposed for temporary interstitial implantation at classical dose rates. High-intensity ^{125}I seeds[35,36] now are used routinely as temporary interstitial sources for episcleral plaque treatment of intraocular choroidal melanoma.[37] By placing a 0.5-mm-thick gold shield over the episcleral plaque, tissues posterior to the eye are shielded, and radiation directed toward the tumor is partially collimated.[38] A disadvantage of high-intensity ^{125}I seed therapy is their high cost relative to ^{192}Ir seeds.

Sources for Permanent Interstitial Brachytherapy

There are two basic approaches to permanent implantation. Classical LDR permanent BT originally used ^{222}Rn seeds, and more recently ^{198}Au seeds, both of which have half-lives of a few days. To manage the radiation hazard as a result of the high-energy γ-rays emitted by these sources, the patient must be confined to the hospital until the source strength decays to a safe level (two to three half-lives or about 10 days). The contemporary approach to permanent implantation, ULDR BT, uses longer-lived but low-energy photon emitters (e.g., ^{103}Pd and ^{125}I). The patient's tissues or a thin lead foil is sufficient to limit ambient exposure rates to negligible levels, eliminating the need to hospitalize patients solely for radiation protection. During the implant procedure, low-energy photon sources markedly reduce radiation exposure to operating room personnel and to the radiation oncologist's hands.

Mathematics of Radioactive Decay

The phenomenon of exponential decay results in a reciprocal relationship between dose rate achieved and radionuclide half-life. The total activity, $A(t)$, present in the implant after an interval of time t has elapsed after source insertion

is given by Figure 25.6:

$$A(t) = A(0) \cdot e^{-\ln 2 \cdot t / T_{1/2}} \tag{3}$$

where $A(0)$ is the activity at the time of insertion, ln 2 is the natural logarithm of 2 (equal to 0.693), and $T_{1/2}$ is the half-life of the radionuclide. The quantity $\ln 2/T_{1/2}$, represented by the symbol λ, is called the decay constant. Equation (3) is applicable to any measure of source strength (S_K, equivalent mass of radium, etc.). Because dose rate, $\dot{D}(t)$, at time t is proportional to activity, that is, $\dot{D}(t) \propto A(t)$, we can write:

$$\dot{D}(t) = \dot{D}(0) \cdot e^{-t \cdot \ln 2 / T_{1/2}} \tag{4}$$

where $\dot{D}(0)$ is the dose rate at the time of source insertion. The total dose, $D(T)$, accumulated over time interval T after source insertion, is the shaded area under the curve of Figure 25.6 and can be obtained by integrating Eq. (4):

$$\begin{aligned} D(T) &= \dot{D}(0) \cdot \int_0^T e^{-t \cdot \ln 2 / T_{1/2}} \cdot dt \\ &= \dot{D}(0) \cdot T_{1/2} \cdot 1.443 \left[1 - e^{-T \cdot 0.693 / T_{1/2}} \right] \end{aligned} \tag{5}$$

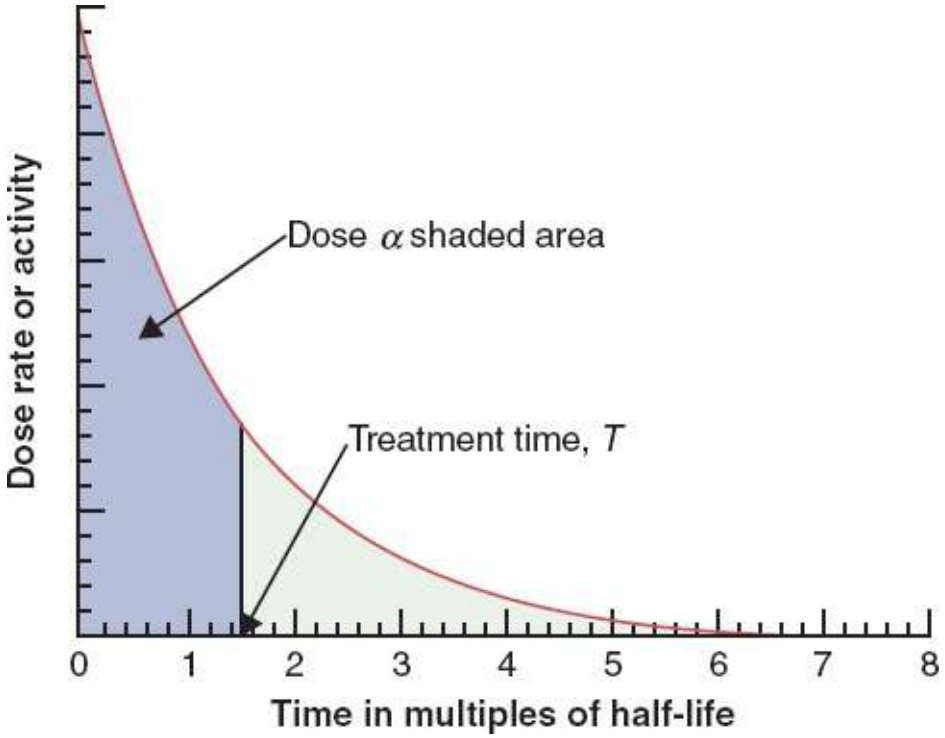

FIGURE 25.6. Illustration of exponential decay of source strength and dose rate. The area of the shaded region is the total dose administered to the patient over treatment

time, T.

The product $T_a = 1.443T_{1/2}$ is called the average life of the radionuclide and is the time required for all radioactive atoms to decay assuming the rate of decay remains fixed at its initial value, $A(0)$. Equation (5) should be used to calculate the total dose delivered by any implant when the treatment time, T, is more than 5% of the half-life. For shorter treatment times (<4 days for ^{192}Ir or <3 days for ^{125}I), the approximate expression:

$$D(T) = \dot{D}(0) \cdot T \tag{6}$$

is accurate within 2%.

For permanent implants, the total dose administered to the patient, D_{tot}, resulting from complete decay of the implant can be obtained from Eq. (5):

$$D_{tot} = \lim_{T \to \infty} D(T) = 1.443 \cdot T_{1/2} \cdot \dot{D}(0) = T_a \cdot \dot{D}(0) \tag{7}$$

This equation demonstrates that initial dose rate and radionuclide half-life are in reciprocal relationship with one another: the longer the half-life, the lower the dose rate will be. Typical total dose rates and total doses are given in Table 25.2 for commonly used permanent implant sources. These sources fall into two categories: short-lived radium-substitute sources with initial dose rates within the classical LDR range and longer-lived low-energy sources with dose rates below the classical range (ULDR).

Classical Low–Dose Rate Permanent Implant Sources: ^{198}Au

Seeds consisting of ^{222}R gas encapsulated in thin-walled gold tubes[39] were used for permanent implantation for many years. Institutions[40] that are still practicing classical LDR permanent interstitial BT use a reactor-produced radionuclide, ^{198}Au, which emits monoenergetic 412-keV γ-rays and has a half-life of 2.7 days. Its decay product is a nontoxic solid, thereby eliminating the contamination hazards associated with production and use of ^{222}Rn. ^{198}Au seed implantation is not widely practiced (although sources are commercially available) because of exposure hazards to operating room personnel (especially the brachytherapist), the need to confine the patient to the hospital for radiation protection reasons, and the logistic problems associated with maintaining an appropriate inventory of such short-lived sources.

Ultra Low–Dose Rate and Energy Permanent Implant Sources: ^{125}I

and ^{103}Pd

An important development was the introduction of interstitial seeds using electron-capture decay radionuclides, which have moderately long half-lives (10 to 60 days) and emit cascades of low-energy (20 to 40 keV) characteristic x-rays and γ-rays. The first practical K-capture source, the titanium-encapsulated ^{125}I seed (half-life, 59.6 days; mean energy, 28 keV), was developed by Donald C. Lawrence[41] in the early 1960s, and its clinical applications were developed in the late 1960s by Basil Hilaris and his colleagues[42–44] at Memorial Sloan Kettering Hospital. Iodine-125 is produced by neutron activation in a specially equipped reactor designed to minimize activation of the contaminant radioisotope, ^{126}I. It decays by electron capture, producing a single 35-keV γ-ray. The captured K-shell electron produces a cascade of 27- to 32-keV characteristic x-rays. In addition, 93% of the γ-rays are internally converted, producing a second characteristic x-ray cascade. Thus, ^{125}I is an "x-ray emitter" because 95% of the useful primary photons are characteristic x-rays of atomic rather than nuclear origin.

TABLE 25.2 TOTAL DOSE AND INITIAL DOSE RATES FOR PERMANENTLY IMPLANTED RADIONUCLIDES

Radionuclide	Mean Photon Energy	$T_{1/2}$	Typical Prescribed Dose (Gy)	Initial Dose Rate (cGy/h)
^{222}Rn	1.2 MeV	3.83 d	100	75
^{198}Au	412 keV	2.70 d	100	107
^{131}Cs	29 keV	9.7 d	115	34.2
^{125}I	28 keV	59.6 d	145	7.0
^{103}Pd	22 keV	17 d	125	21.2

Other important radionuclides are ^{103}Pd (^{103}palladium, 19.0-day half-life and mean energy: 22 keV), commercially realized in 1987, and ^{131}Cs (^{131}Cs, 9.6-day half-life and 29-keV mean energy), which was initially proposed by Lawrence and Henschke[45] but became available as commercial product in 2006.[46,47] The low-energy photons emitted by these radionuclides dramatically reduce external exposure hazards: an 8-cm thickness of tissue reduces exposure 10-fold. Thin (0.2 mm) lead foils also produce almost complete shielding. Thus, there is usually no need to confine patients to the hospital solely for radiation safety reasons. The rapid growth trajectory of transperineal ultrasound (TRUS)-guided permanent seed brachytherapy[48,49] in the 1990s for definitive treatment of low-

and intermediate-risk prostate cancer[50,51] resulted in the introduction of approximately 25 different models of ^{125}I and ^{103}Pd to the market from 1997 to 2005 (see the American Association of Physicists in Medicine [AAPM] revised TG-43 Report[5,52,53] for a review of many of the available sources). Although brachytherapy remains a widely elected treatment modality for localized prostate cancer, its utilization has fallen from 24% in 2002 to 12% in 2010.[54] As a result, there has been consolidation in the low-energy seed market. The Joint Imaging and Radiation Oncology Core (IROC)-Houston QA Center (IROC-Houston, formerly the Radiological Physics Center)/AAPM brachytherapy source registry[55,56] lists all commercially available and clinical used orphan sources that meet the AAPM dosimetric prerequisites for clinical use.[57] According to the IROC-Houston/AAPM Registry, six ^{125}I, four ^{103}Pd, and one ^{131}Cs seed models are commercially available.

Most of low-energy interstitial seeds are encapsulated in thin (0.05- to 0.10-mm-thick) titanium tubing (exception: polymer-encapsulated Civa ^{103}Pd source[58]) with external dimensions of approximately 0.8 × 4.5 mm. Most of the available ^{125}I seed products are variations on the Model 6711 seed[61] design. This source, the only ^{125}I source available from 1983 to 1998, contained a 3-mm-long silver rod on which radioactive iodine is absorbed and is available in strengths of 0.5 to 13 μGy·m^2·h^{-1} (0.5 to 9 mCi) (Fig. 25.7A, top). The radiopaque silver rod enables seeds to be visualized on orthogonal or stereo shift radiographs.

^{103}Pd decays by K-electron capture and emits characteristic x-rays of 21 keV. It has all of the radiation protection advantages of ^{125}I along with a significantly shorter half-life of 17 days. With this source, an implant can deliver 112 Gy (90% of prescribed dose) in approximately 8 weeks at an initial peripheral dose rate of 21 cGy/h. The Model 200 seed (Fig. 25.7A, middle) was the only commercially available ^{103}Pd seed from 1988 to 1999. The radioactive palladium is distributed within a thin Pd metal coating of the two graphite pellets, which are encapsulated in Ti tubing of the same dimensions as ^{125}I seeds. The biologic rationale for using shorter-lived ^{103}Pd and ^{131}Cs interstitial sources is discussed below in the Biology section of this chapter.

(Figures reproduced with permission from references Williamson [2005],[59] Monroe [2002],[60] and IROC-Houston.[55]) **B:** Isodose curves for a ^{198}Au seed (*left half*) and Model 6711 ^{125}I seed (*right half*) both with air-kerma strengths of 72 μGy·m^2·h^{-1} (equivalent to 35 mCi of ^{198}Au and 57 mCi of ^{125}I)

Low-energy seed implantation poses a number of challenges. Their dose distributions are not radium equivalent (Fig. 25.7B), falling off more rapidly with distance. Dose estimation is inherently more complex, depending significantly on photon energy and composition of the surrounding medium (Fig. 25.4),[62,63] and is more sensitive to the internal seed geometry.[59,60] Because of shifts in calibration standards, large uncertainties in dose measurement, and questionable applicability of classical dose calculation model, ^{125}I and ^{103}Pd dosimetry has been uncertain and variable over most of the clinical life of these products.[12] For example, between 1975 and 1999, the ^{125}I dose-rate constant was revised downward, in several steps, by nearly 50%.[12] Only with development and validation of more sophisticated experimental and computation dosimetry techniques in the past 10 to 15 years can we claim to know low-energy seed dose-rate distributions with an uncertainty of 3% to 7%.[64] Because of the low dose rates used, low-energy seed implantation is effectively a different therapeutic modality than classical LDR BT. In addition, 20- to 30-keV photons have a significantly higher LET spectrum, which results in an RBE for ^{125}I of 1.3 to 2.1 in *in vitro* systems compared with unity for radium-substitute photon spectra.[65–67] Thus, classical LDR clinical experience cannot be used to guide therapeutic decision-making for ^{125}I permanent implantation. Despite these limitations, low-energy source permanent implantation has been demonstrated to be a highly effective and convenient treatment for prostate cancer,[68,69] which produces tumor control rates comparable or superior to those of competing modalities.

Sources for High–Dose Rate Brachytherapy

Radionuclide Sources

In contrast to inpatient-based LDR BT, HDR BT uses high-intensity sources to deliver discrete fractions ranging from 3 to 10 Gy in an outpatient setting. As described in more detail in Chapter 21, a remote afterloading device must be used. Typically, a cable-mounted HDR source is sequentially inserted to each catheter (see Fig. 25.8A), mechanically driven to its distal end, and retracted, stopping at each programmed dwell position, remaining for the programmed

dwell time (typically 1 to 60 seconds). A radionuclide with high specific activity (activity per unit mass; Ci/g) is needed so that overall treatment dose rates of at least 12 Gy/h can be achieved without sacrificing the level of miniaturization needed to support intracavitary and interstitial BT. A source no larger than 1 mm diameter by 4 mm long with an exposure rate of at least 1 R/s at 1 cm is required. Figure 25.8A and C illustrates typical PDR and HDR sources, respectively.

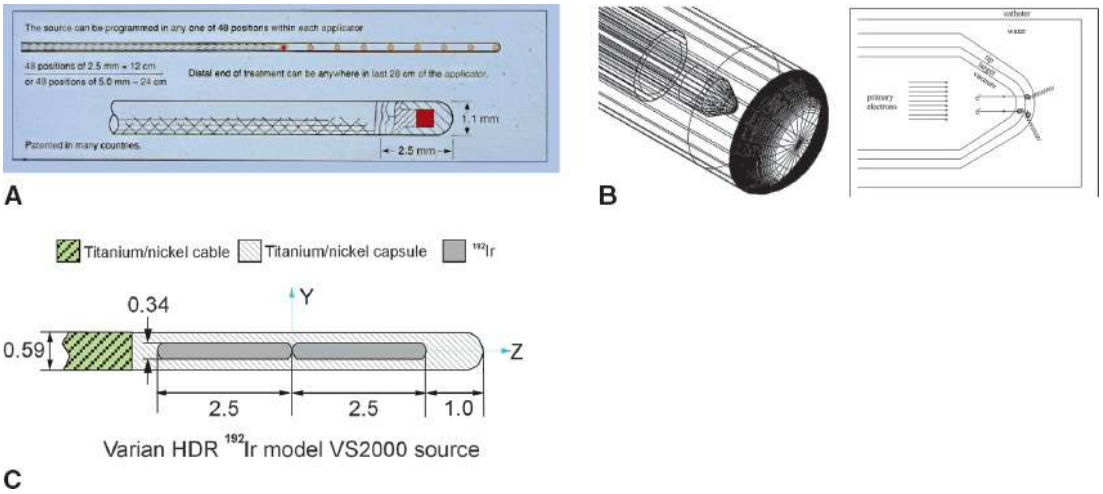

FIGURE 25.8. A: *Top*: A single stepping source being withdrawn along the catheter axis from right to left illustrating the concepts of discrete dwell positions. *Bottom*: geometry of the original pulsed dose rate (PDR) ^{192}Ir source introduced by Nucletron in 1993. **B:** Geometric model (*left*) of the Xoft electronic brachytherapy source consisting of an inner catheter terminated by a 0.07-μm-thick tungsten transmission target. Also illustrated is the oversize (5.3 mm OD) outer catheter is needed to water cool the approximately 2.25-mm-diameter by 15-mm-long x-ray tube (see *right* figure) which can support an air-kerma rate of 170,000 μGy·m^2·h^{-1} when operated at 50 kVp and 300 μA.[70,71] (From Liu D, Poon E, Bazalova M, et al. Spectroscopic characterization of a novel electronic brachytherapy system. *Phys Med Biol* 2008;53[1]:61–75. doi:10.1088/0031-9155/53/1/004. © Institute of Physics and Engineering in Medicine. The upper limit on specific activity of any substance, achieved when 100% of its atoms are radioactive, is a fundamental property that depends on its number of atoms per gram:

$$\text{atoms/g} = \left(\frac{\text{Avogadro's no. } (6.023 \times 10^{23} \text{ atoms/mole})}{\text{Atomic Weight}} \right) \quad (8)$$

For radionuclides produced by neutron activation, competition with radioactive decay precludes activating 100% of the target atoms. The theoretically achievable maximum Ci/g (Table 25.3) depends on the neutron capture cross section of the target and the neutron flux in the reactor.[73] The extent to which this limit can be reached in practice depends on isotopic purity of the target, limits on reactor activation time, and the time required for shorter-lived contaminant radioisotopes to decay to an acceptable level. Finally, the exposure rate achieved by a small source (e.g., a 1 × 4-mm cylinder as shown in Table 25.3) depends on the chemical form (i.e., relative mass of nonradioactive atoms) of the source, its density, exposure-rate constant of the radionuclide, and photon self-absorption.

Table 25.3 shows that ^{226}Ra cannot support HDR BT radionuclide and that ^{137}Cs is, at best, a marginal choice. Cobalt 60 (5.26-year half-life and γ-rays of 1.17 and 1.33 MeV) has been widely used as an intracavitary HDR source in the form of small spherical pellets. Based solely on specific activity considerations, ^{192}Ir is the optimal choice for HDR BT and is the most widely used radionuclide for this application. Sources with external diameters as small as 0.6 mm (see Fig. 25.8C) are now available for use in single-stepping source remote afterloading devices. In contrast to ^{60}Co, the lower-energy ^{192}Ir photons are shielded effectively by the scatter and leakage barriers present in most existing ^{60}Co teletherapy and linear accelerator vaults. Because of their short half-lives, ^{192}Ir HDR sources usually are replaced at quarterly intervals. Because of the relative ease with which its low-energy photons can be shielded, ^{169}Yb source has been proposed for HDR intraoperative and intravascular BT.[9]

Electronic Brachytherapy Sources

Currently, there are two brachytherapy delivery systems on the market that use miniaturized low kilovoltage x-ray tubes to eliminate radionuclide sources of radiation. The Zeiss INTRABEAM system uses magnetic focusing and steering to transport externally accelerated 50-keV electrons down a long 3.2-mm diameter drift tube, which collide with a thin gold transmission target at the end of the implanted catheter.[74,75] In contrast, the Xoft Axxent electronic brachytherapy (EBT) system[76] is based upon miniaturizing the entire x-ray tube (see Fig. 25.8B), which is placed in a somewhat larger diameter (5.4 mm)

intracavitary catheter to allow for water cooling of the system. Although the intrabeam system has used several tumor sites, including skin cancer,[77] the main application for both systems has been intraoperative accelerated partial breast irradiation (APBI). Although the use of EBT as an APBI modality is supported by a randomized, phase III prospective noninferiority trial,[78] its equivalence to ^{192}Ir-based APBI remains controversial.[79] However, because of the lower penetration and more rapid falloff of 50 kVp x-rays compared to ^{192}Ir, for a fixed level of APBI PTV coverage, EBT gives rise to larger $V_{150\%}$ and $V_{200\%}$ values.[80] A recently published debate[81] highlights many of the operational and physical differences between the two classes of HDR sources.

TABLE 25.3 SPECIFIC ACTIVITIES AND MAXIMUM EXPOSURE RATES ACHIEVABLE FOR DIFFERENT RADIONUCLIDES

Radionuclide	Maximum Ci/g Possible	Fraction Practicably Achievable (%)	Exposure Rate[a] (R/s) at 1 cm From 1 mm × 4 mm Seed
^{226}Ra	0.98	100	0.04 $R \cdot cm^2 \cdot s^{-1}$
^{137}Cs	87	23	0.22 $R \cdot cm^2 \cdot s^{-1}$
^{60}Co	1,020[b]	49	50 $R \cdot cm^2 \cdot s^{-1}$
^{192}Ir	7,760[b]	35	248 $R \cdot cm^2 \cdot s^{-1}$
^{169}Yb	33,700[b]	14	51 $R \cdot cm^2 \cdot s^{-1}$

[a]Neglecting self-absorption.
[b]Reactor produced by neutron activation: a flux $\phi = 10^{14}$ $n \cdot cm^{-2} \cdot s^{-1}$ and 100% target purity are assumed.

BRACHYTHERAPY DOSIMETRY AND SOURCE-STRENGTH SPECIFICATION

Two eras of BT dosimetry can be distinguished. The *classical era* (1940 to 1980) encompassed the maturation of the classical BT systems, the transition from ^{226}Ra to artificial radionuclide sources, and the rise of modern BT. It began with the successful application of Bragg-Gray cavity theory[82] to the calibration of ^{226}Ra and other high-energy sources in terms of exposure,[83] which allowed BT treatment intensity to be quantified using the same system of units and quantities as the external orthovoltage beam therapy of the day. Classical or semiempirical dose-computation models are based on the dose distribution about an idealized point source. Dose rates around needle and tube sources were calculated by integrating the basic point-source model over their extended radioactivity

distributions. Because of the technical difficulties in measuring absorbed dose in the presence of steep dose gradients, BT treatment planning relied largely on calculated rather than measured dose distributions.

The modern or *quantitative* era of BT dosimetry began in the 1980s and continues to the present. Quantitative dosimetry relies on measurement of source-specific dose distributions by means of small thermoluminescent dosimeters (TLDs) or silicon diode dosimeters.[84] Alternatively, radiation transport calculations in the form of three-dimensional (3D) Monte Carlo simulations are accepted as an accurate and reliable source of clinically useful dosimetry data.[84] These technical developments were motivated by concerns that semiempirical dose-calculation algorithms were not valid in the low-energy regimen of ^{125}I and ^{103}Pd sources. To clinically utilize dose measurements and Monte Carlo calculations, and empirical dose-calculation formalism, the TG-43 protocol[5] was developed. Both the classical and quantitative dosimetry methods are based on the principle that BT source strength should be specified in terms of radiation output in free air.

Source-Strength Specification Quantities and Units

Brachytherapy calibration is an unnecessarily confusing topic because of the multitude of quantities that have been used to specify source strength throughout its history. Many of the historically obsolete but still widely used quantities (e.g., apparent activity and equivalent mass of radium) were defined in terms of ^{226}Ra properties, the only BT radionuclide intensively studied until about 1940. Such quantities obscure the experimental origin of calibration measurements by describing output measurements in activity units. Finally, the BT literature has added to the lack of conceptual clarity by obscuring the important distinction between quantities and units. A *quantity* is a property of nature that is directly or indirectly measurable (e.g., kerma, equivalent mass of radium, length, time), whereas a *unit* is a selected sample of a quantity to which the magnitude unity (1.0) is assigned (e.g., gray, mgRaEq, meter, second). A quantity such as absorbed dose can have many units (e.g., rad, cGy, Gy, J/kg).

Regardless of the units and quantity chosen to describe a calibration, all photon-emitting sealed BT sources are calibrated in terms of output (kerma rate, dose rate, or exposure rate) in air at a specific reference point on the transverse bisector of the source. Much like superficial x-ray beam calibration, a calibrated ion chamber (Fig. 25.9) is used to measure the BT source output in a free-air geometry in which the source and chamber are suspended in air in a large room.

Air-Kerma Strength

In North America, photon-emitting source strength is specified in terms of air-kerma strength, denoted by S_K, a practice that was introduced by the AAPM in 1987.[85] The AAPM[5] currently defines S_K as the air-kerma rate, $\dot{K}_{\delta,\mathrm{air}}(d)$ at distance d, in vacuo and due to photons of energy greater than δ, multiplied by the square of this distance, d^2.

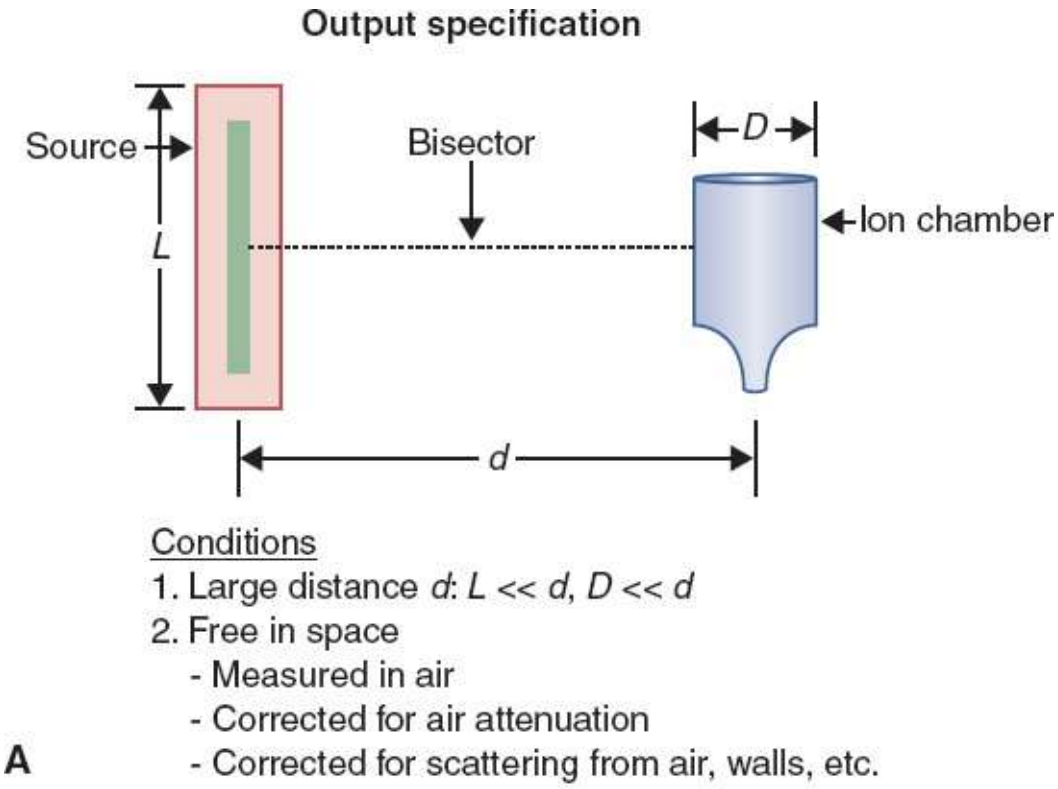

FIGURE 25.9. **A:** Illustration of a free-air geometry for measuring brachytherapy source strength in terms of a radiation output quantity such as air kerma. In practice, the source and cavity chamber are suspended in air in a large room and separated by 20-cm to 100-cm distance (which must be large in relation to the detector and source

dimensions). The measured air-kerma must be corrected for photon scattering from walls, floor, and ceiling and for photon scattering and attenuation by the intervening air. **B:** Definition of air-kerma strength. For an actual source, the air-kerma rate must be measured at a distance, *d*, which is large in relation to the source dimensions.

$$S_K = \dot{K}_{\delta,\mathrm{air}}(d) \cdot d^2 \qquad (9)$$

The distance *d* is the distance from the source center to the point of air-kerma rate specification (usually but not necessarily the point of measurement), which must be in the transverse plane of the source (the plane normal to the long axis of the source, which bisects its radioactivity distribution). S_K is independent of specification distance so long as *d* is large relative to the maximum linear dimension of the radioactivity distribution. $\dot{K}_{\delta,\mathrm{air}}(d)$is usually inferred from transverse-plane air-kerma rate measurements performed in a free-air geometry (see Fig. 25.9) at distances large in relation to the maximum linear dimensions of the detector and source, typically of the order of 1 m. The "*in vacuo*" qualifier (equivalent in meaning to "in free space") means that $\dot{K}_{\delta,\mathrm{air}}(d)$must be specified as if the source and small mass of air, producing ionization at distance *d*, were immersed in a vacuum. Air-kerma rate measurements must be corrected for photon attenuation and scattering by the surrounding air as well as for scattering from nearby objects. The energy cutoff, δ, is intended to exclude low-energy or contaminant photons (e.g., characteristic x-rays originating in the outer layers of steel or titanium source cladding[86]) that increase $\dot{K}_{\delta,\mathrm{air}}(d)$without contributing significantly to dose at distances >0.1 cm in tissue. The value of δ is typically 5 keV for low-energy photon–emitting BT source. The unit of air-kerma strength is μGy·m^2·h^{-1} and is often denoted in the literature by the symbol "U:" where 1 U = 1 cGy·cm^2·h^{-1} = 1 μGy·m^2·h^{-1}.

Air-kerma strength is numerically (but not dimensionally) equal to the quantity reference air-kerma rate, $\dot{K}_{\mathrm{ref}}$, a very similar quantity defined by the ICRU[3] and used outside North America. $\dot{K}_{\mathrm{ref}}$is defined as the air-kerma rate in free space at a reference distance, *l* (taken to be 1 m), on the transverse axis; it has units of μGy·h^{-1} at 1 m. Thus, $\dot{K}_{\mathrm{ref}} = S_K/l^2$. The procedures for standardizing and measuring $\dot{K}_{\mathrm{ref}}$and S_K are identical.

The U.S. National Institute of Standards and Technology (NIST) maintains primary S_K standards for commercially available ^{137}Cs sources,[87] LDR ^{192}Ir seeds,[88] and all ^{103}Pd, ^{131}Cs, and ^{125}I seeds.[89] A *primary standard* is an instrument against which all other S_K measurement devices, called secondary or

tertiary standards, must be intercompared. Such instruments are designed to permit inference of air-kerma values from the measured charge and instrument design using first principles. For ^{137}Cs and ^{192}Ir sources, the S_K standard is based on transverse-axis air-kerma measurements using spherical ion chambers with carbon walls[87,88]—the same instruments used to maintain the ^{60}Co teletherapy air-kerma standard. For low-energy interstitial seeds, a special free-air chamber,[89] called the wide-angle free-air chamber (WAFAC), is used. Brachytherapy sources calibrated directly by the NIST standard or one of the AAPM-Accredited Dosimetry and Calibration Laboratories (ADCL) are said to have *directly NIST-traceable calibrations*. Sources that are calibrated against sources or ion chambers, which themselves have directly traceable NIST calibrations, are said to have *indirectly NIST-traceable* calibrations. The Xoft EBT has its own air-kerma standard based on the Lamperti free-air chamber for low-energy x-ray beams.[90] Because accurate estimation of the air attenuation correction for 50-kVp x-rays is conceptually and technically challenging, NIST chose to specify EBT source strength in terms of $\dot{K}_{\text{air}}(50\ \text{cm})$, the air-kerma rate in air (rather than free space) at 50-cm source-to-surface distance, rather than S_K. For a more detailed description of air-kerma–based standards, measurement techniques, and traceability requirements, the reader is referred to a recent review by Sander.[91] The AAPM recommends[92] that individual clinics using BT sources maintain instrumentation able to make indirectly traceable calibration measurements for verification of vendor-supplied calibrations.

Kerma (kinetic energy released in the medium), K_x, is the ratio $\Delta E_{tr}/\Delta m$, where ΔE_{tr} is the total kinetic energy transferred to charged particles by photon interactions with atoms in small mass, Δm, of medium x.[93] For photons, ΔE_{tr} includes the initial kinetic energies of any secondary charged particles (e.g., Compton electrons, photoelectrons, and positrons) liberated by Compton, photoelectric, and pair production interactions. Kerma is defined only for indirectly ionizing radiations (e.g., photons and neutrons) and quantifies the transfer of energy from these radiation fields to matter. It takes the same units (cGy and Gy) as the related quantity absorbed dose. Although kerma can be specified in any medium x, usually air medium (x = air) is assumed for radiation metrology. K_{air} replaces the obsolete quantity exposure and is closely related to absorbed dose, D: the ratio, $\Delta E_{ab}/\Delta m$, where ΔE_{ab} is the energy imparted to Δm by the radiation field. Because the secondary electrons released by photon collisions may travel a significant distance before depositing their energy and

may convert some of their kinetic energy to bremsstrahlung radiation, D_{air} and K_{air} are not necessarily equal. When kerma remains relatively constant over the range of the secondary electrons, a special condition, secondary charged particle equilibrium (CPE), exists.[73,94] When the CPE is achieved, the rates of energy absorption and energy transfer are approximately equal, so that kerma closely approximates absorbed dose:

$$D_{air} = X \cdot \left(\frac{W}{e}\right) = K_{air} \cdot (1 - g) \qquad (10)$$

where X represents the quantity exposure. The quantity (W/e) is the average energy imparted to air per ion pair created and is a constant, independent of photon energy: (W/e) = 33.97 eV/ion pair = 33.97 J/C = 0.876 cGy/R.[95] The factor g is the fraction of kinetic energy transferred to the medium converted back to radiant energy (photons) by the bremsstrahlung process; g is <0.001 at BT energies and usually is ignored, further simplifying Eq. (10). Most BT dose-calculation algorithms and dosimetric analyses assume that CPE obtains and that dose, D_{med}, can be well approximated by kerma, K_{med}, everywhere. Although generally valid, CPE can be expected to break down in the presence of steep dose gradients near sources,[96] near metal–tissue interfaces,[97] and within the active elements of thin, bounded detectors.[98] The combination of CPE failure and beta ray transmission give rise to (D_{med}/K_{med}) ratios that deviate from unity by 10% to 50% 0.4 to 1.5 mm from the surface of lightly encapsulated HDR ^{192}Ir sources.[99]

Activity

To define the obsolete quantities for describing source output, the quantity activity, A, must be introduced. It is defined as the rate of nuclear disintegration or transformation within a radioactive source. The contemporary unit of activity is the Becquerel (1 Bq = 1 disintegration/s). We will freely use the more traditional but obsolete unit, the curie (1 Ci = 3.7×10^{10} disintegrations/s = 3.7×10^{10} Bq). A more convenient multiple of the curie, the millicurie, is defined as 1 mCi = 10^{-3} Ci = 3.7×10^{7} disintegrations/s. Each disintegration represents the spontaneous transformation of an atom from one nuclear state to another. For most BT radioisotopes, such transformations of nuclear state give rise to photons in the form of unconverted γ-rays, annihilation photons, characteristic x-rays, and bremsstrahlung photons. Activity is measured by counting the number of

photons, β particles, or other particles emitted by an unencapsulated point source of the radionuclide by means of scintillation or coincidence counters, from which its activity is inferred.[100] For sealed BT sources, A refers to activity contained inside the sealed source.

Activity, as defined in this strict sense, is no longer used in BT dosimetry. However, activity continues to serve as the basis for treatment specification and dosimetry of unsealed radiopharmaceuticals used for diagnosis and therapy and may play a future role in dosimetry of sealed beta-emitting sources for intravascular BT and other clinical applications. NIST maintains contained activity standards for a wide variety of radionuclides in aqueous solution.[101]

Relationship Between Activity and Exposure Rate

The activity, A, of a radioactive nuclide emitting photons and the air-kerma rate in free space, $\dot{K}_\delta(r)$ (in Gy/s) at distance r (in meters) because of photons of energy greater than δ, are related by a fundamental quantity, the air-kerma rate constant, $(\Gamma_\delta)_K$, defined as follows[93]:

$$(\Gamma_\delta)_K = \frac{\dot{K}_\delta(r)\cdot r^2}{A} \text{ air-kerma rate constant } (\mathrm{m^2\cdot Gy\cdot Bq^{-1}\cdot s^{-1}})$$
$$(\Gamma_\delta)_X = \frac{\dot{X}_\delta(r)\cdot r^2}{A} \text{ exposure-rate constant } (\mathrm{cm^2\cdot R\cdot mCi^{-1}\cdot h^{-1}}) \quad (11)$$

Even though it is obsolete, this chapter will freely use the closely related and familiar quantity exposure rate constant, $(\Gamma_\delta)_X$, with units of R $\mathrm{cm^2\cdot mCi^{-1}\cdot h^{-1}}$. $(\Gamma_\delta)_X$ is equal to the exposure rate in R/h at 1 cm from a 1-mCi point source. It describes the rate at which air is ionized as a result of the emission of photons resulting from radioactive decay. The energy cutoff δ eliminates low-energy bremsstrahlung and characteristic x-rays from consideration that are always absorbed within any practical source. The precise value of δ depends on the application; it usually is assumed to be about 10 keV. Because $(\Gamma_\delta)_X$ is defined in terms of an isotropic point source with exposure rates corrected for air attenuation and scattering, inverse-square law applies exactly. Thus, $(\Gamma_\delta)_X$ is independent of the distance *r* used in Eq. (11).

$(\Gamma_\delta)_X$ depends only on the number and energy of the photons emitted per disintegration. Suppose there are *N* different photons emitted per disintegration with energies E_1, E_2, …, E_N in units of MeV. We assume that each nuclear decay emits P*i* photons of energy E_i where $i = 1, \ldots, N$. The list $\{E_i, P_i\}_{i=1}^{N}$ is the photon

spectrum of the radionuclide. If the spectrum is known, then $(\Gamma_\delta)_X$ can be calculated by:

$$(\Gamma_\delta)_X = 193.7 \cdot \sum_{i=1}^{N} \mathrm{P}_i \cdot \mathrm{E}_i \cdot (\mu_{\mathrm{en}}/\rho)_i^{\mathrm{air}} \qquad (12)$$

where $(\mu_{\mathrm{en}}/\rho)_i^{\mathrm{air}}$ is the mass–energy absorption coefficient (in units of cm^2/g) for air at energy E*i*. A detailed derivation of this fundamental relationship is given elsewhere.[24,102] $(\Gamma_\delta)_X$ is the fundamental property of the radionuclide's unencapsulated photon spectrum; applies only to an ideal point source; and neglects many significant properties of real sources such as self-absorption, filtration, and extension.

^{226}Ra is an exception to this practice. First, radium source strength is specified by the quantity—mass of ^{226}Ra contained inside the source—denoted by M_{Ra}. M_{Ra} excludes the nonradioactive core components as well as radioactive decay products. Historically, M_{Ra} was introduced and widely used before the more general activity standards were available. Indeed, the unit curie originally was defined as the number of disintegrations produced by 1 g of ^{226}Ra. M_{Ra} standards were prepared by carefully weighing pure ^{226}Ra samples in an analytic balance. The first M_{Ra} standard was prepared by Marie Curie in 1913, and the currently used NIST standard was prepared by Hönigschmidt in 1934.[103] To calibrate a user's source in M_{Ra}, its radiation output is compared with that of the NIST radium standard by means of an ion chamber. NIST no longer offers an M_{Ra} calibration service. In contrast to the other radionuclides, exposure-rate constant of ^{226}Ra—denoted by the special symbol $(\Gamma_\delta)_{\mathrm{Ra},t}$ in this chapter—is tabulated as a function of its effective capsule thickness, *t*, in millimeters of platinum.[104] $(\Gamma_\delta)_{\mathrm{Ra},t}$ is normalized to the mass of radium contained in the source and has units of R $cm^2 \cdot mg^{-1} \cdot h^{-1}$.

Obsolete Quantities for Specifying Source Output

Because of the close association of early BT with ^{226}Ra, it is not surprising that the measured output of BT sources continues to be expressed as multiples of the output of a 1-mg radium needle. This quantity, equivalent mass of radium (M_{eq}), was introduced when artificial radioisotopes, such as ^{60}Co and ^{137}Cs, were developed as radium replacements. It allowed old implant and radium needle dosimetry tables, which gave dose per milligram-hour (mg-h) of ^{226}Ra, to be used without modification for these new sources. M_{eq} is that mass of ^{226}Ra

filtered by 0.5 mm Pt that has the same S_K as that of the given source. Because M_{eq} is simply a statement of S_K relative to that of a hypothetic radium needle, the given source being quantified need not contain ^{226}Ra, be encapsulated in Pt, nor have a wall thickness of 0.5 mm. Because $K_{air} = X \cdot$ (W/e) and $(\Gamma_\delta)_{Ra,0.5} = 8.25\ R \cdot cm^2 \cdot mg^{-1} \cdot h^{-1}$ for ^{226}Ra filtered by 0.5 mm Pt,[105] S_K and M_{eq} are related by:

$$S_K = M_{eq} \cdot (\Gamma_\delta)_{Ra,0.5} \cdot (W/e) = M_{eq} \cdot 7.223$$
$$M_{eq} = \frac{S_K}{(\Gamma_\delta)_{Ra,0.5} \cdot (W/e)} = \frac{S_K}{7.223} \quad (13)$$

where (W/e) = 33.97 eV/ion pair. Until relatively recently, M_{eq} was widely used to specify strength of intracavitary and interstitial BT radium-substitute sources such as ^{137}Cs and ^{192}Ir.

Similar to the philosophy of M_{eq}, apparent activity, A_{app}, is a statement of source output relative to that of a hypothetic unfiltered point source. A_{app} is the activity of a hypothetic unfiltered point source of the same radionuclide has the same S_K as that of the given source:

$$A_{app} = \frac{S_K}{(\Gamma_\delta)_X \cdot (W/e)} \quad (14)$$

Apparent activity in units of mCi continues to be widely used for specifying strength for permanent interstitial implants (e.g., ^{125}I and ^{103}Pd sources). In contrast to M_{eq}, which is based on the universally accepted $(\Gamma_\delta)_{Ra,0.5}$ value of 8.25 R·cm^2·mCi^{-1}·h^{-1}, no consensus as to $(\Gamma_\delta)_X$ values for the other radionuclides exists. Often, different vendors will assume different $(\Gamma_\delta)_X$ values for the same radionuclide. Thus, A_{app} is an inherently ambiguous means of describing source strength. In an effort to reduce low-energy dose-calculation errors associated with this ambiguity, the AAPM recommends[106] that the $(\Gamma_\delta)_X$ values of 1.476 and 1.45 R·cm^2·mCi^{-1}·h^{-1} for ^{103}Pd and ^{125}I sources, respectively, be used universally for specification of A_{app}. For many years, virtually all scientific societies involved in BT[3,92,107] have recommended that M_{eq} and A_{app} be abandoned in favor of S_K for source ordering, dose calculation, and implant prescription.

Milligram/Hours and Integrated Reference Air-Kerma

In gynecologic intracavitary therapy, the quantities M_{Ra} and M_{eq} were widely used to describe source loadings and to prescribe individual treatments. For prescribing therapy, these quantities, in units of milligrams of ^{226}Ra or mgRaEq, are integrated over treatment time yielding the so-called quantities mg-h and mgRaEq-h. As the product of total source strength and treatment time, mg-h and mgRaEq-h represent the total exposure or air-kerma accumulated at a distance of 1 m from the implant, under the assumptions that the implant is a point source and that tissue attenuation is negligible. The ICRU[108] recommends that mg-h be abandoned as a prescription or reporting quantity in favor of total reference air kerma (TRAK), which is defined in terms of air-kerma strength. TRAK, symbolized by K_{ref} is given by:

$$K_{ref} = \sum_{i=1}^{N} (S_{K,i}/l^2) \cdot t_i \qquad (15)$$

where $S_{K,i}$ and ti are the air-kerma strength and treatment time in hours, respectively, of the i-th source and l is the reference distance (taken to be 1 m or 1 cm). Thus, 1 U of TRAK = 1 cGy at 1 cm = 1 μGy at 1 m. TRAK is related to mg-h and mgRaEq-h:

$$K_{ref} = \begin{cases} \text{mg-h} \cdot 6.754 & \text{for filtration } t = 1 \text{ mm Pt} \\ \text{mgRaEq-h} \cdot 7.227 & \text{for filtration } t = 0.5 \text{ mm Pt} \end{cases} \qquad (16)$$

Intracavitary treatment systems[11] historically based on ^{226}Ra tubes (1 mm Pt encapsulation) typically use mg-h, whereas systems based on ^{137}Cs or other radium substitutes prescribe therapy in units of mgRaEq-h. Because of the difference in platinum filtration assumed by these two milligram-based quantities, numerically identical prescriptions can deliver quantities of TRAK that differ by 7%. The use of TRAK as an integrated output reporting quantity eliminates this 7% ambiguity that has confused comparison of different implant systems since the appearance of radium-substitute sources for BT.

Classical Dose-Calculation Formalism: Isotropic Point Source

Consider an unencapsulated point source with an air-kerma strength of S_K, illustrated in Figure 25.10. Because this source has no extension, there is no attenuation of the emitted radiation by the source itself. Isotropy (Fig. 25.2) implies that photons are emitted with equal likelihood in all directions and travel in straight lines. In reality, actual BT sources are encapsulated, have finite

dimensions, and usually are cylindrically rather than spherically symmetric. The dose rate, $\dot{D}(r)$(cGy/h), at distance r (cm) in the water-equivalent medium surrounding the source is given by:

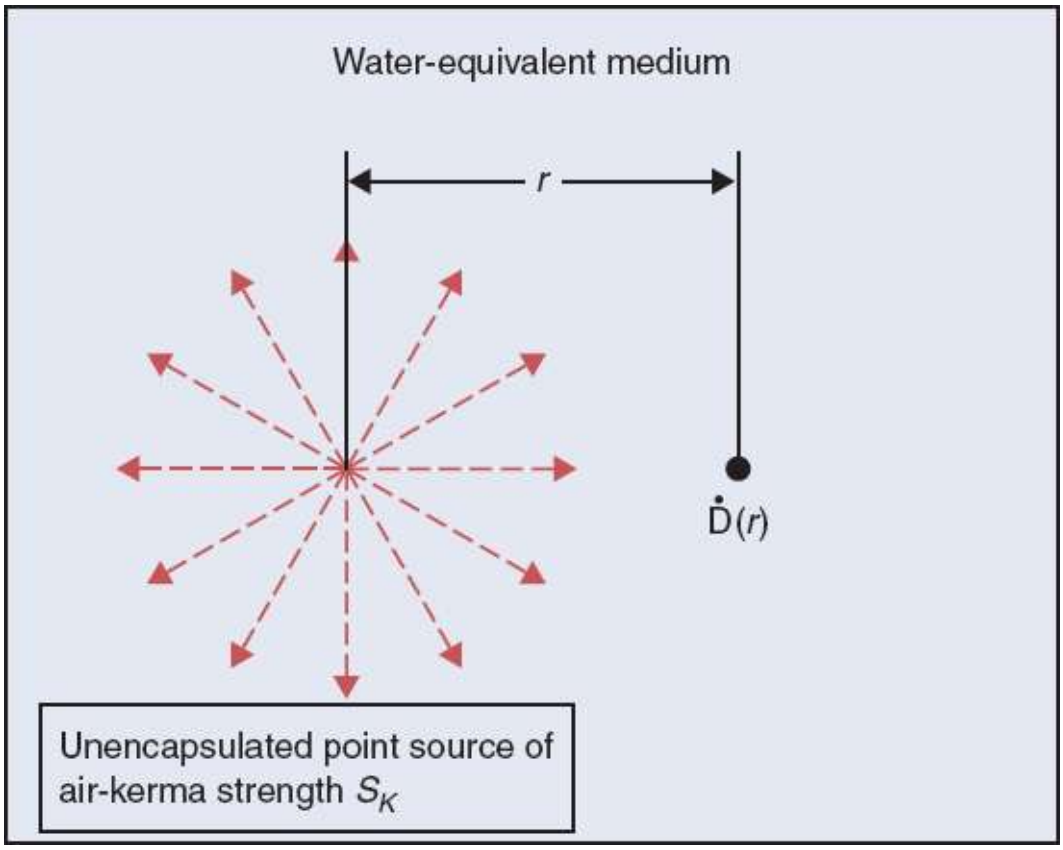

FIGURE 25.10. Unencapsulated point source of strength S_K immersed in an unbounded water-equivalent medium.

$$\dot{D}_{\text{med}}(r) = S_K \cdot \frac{\overline{(\mu_{\text{en}}/\rho)}^{\text{med}}_{\text{air}}}{r^2} \cdot T(r) \qquad (17)$$

The inverse-square law term corrects for the difference in dose-specification distance, r, and the 1-cm reference point assumed by the units of air-kerma strength. The quantity $\overline{(\mu_{\text{en}}/\rho)}^{\text{med}}_{\text{air}}$ is the ratio of mass–energy absorption coefficients in medium to that in air averaged over the photon spectrum in free space. This correction, equal to $\dot{K}_{\text{med}}/\dot{K}_{\text{air}}$ in free space, is a consequence of the fundamental relationship between particle fluence and dose.[24,102] It corrects for the efficiency with which the medium extracts energy from the emitted photons compared with air. For all radionuclides emitting photons with energies >200 keV, including all radium substitutes, $\overline{(\mu_{\text{en}}/\rho)}^{\text{med}}_{\text{air}}$ has the value 1.11 in water

medium.

The last term of Eq. (17)—the kerma-to-dose conversion factor, $T(r)$—describes the net influence of primary photon attenuation and buildup of scattered photons in the surrounding medium. Sometimes, this factor is termed the effective attenuation factor or the scatter buildup factor:

$$T(r) = \frac{\text{Dose in medium}}{\text{Medium} - \text{kerma in free space}} = \frac{\text{Exposure in medium}}{\text{Exposure in air}} \left\{ \begin{array}{l} \text{at distance } r \\ \text{from a point source} \end{array} \right. \tag{18}$$

Figure 25.11 shows $T(r)$ for several radium-substitute radionuclides as well as for a few low-energy radionuclides. For ^{226}Ra-equivalent radionuclides, $T(r)$ deviates <5% from unity (1.00) out to distances, r, of 5 cm. Numerous tabulations of $T(r)$ are available in the literature; those of Meisberger and colleagues,[109] Berger,[112] and Van Kleffens and Star[113] are among the best known. Most of these data are derived from theoretic photon transport calculations. The classical semiempirical model assumes that $T(r)$ is a function only of the radionuclide photon spectrum and that a single data set (e.g., for ^{192}Ir) can be used for all ^{192}Ir sources regardless of their construction.

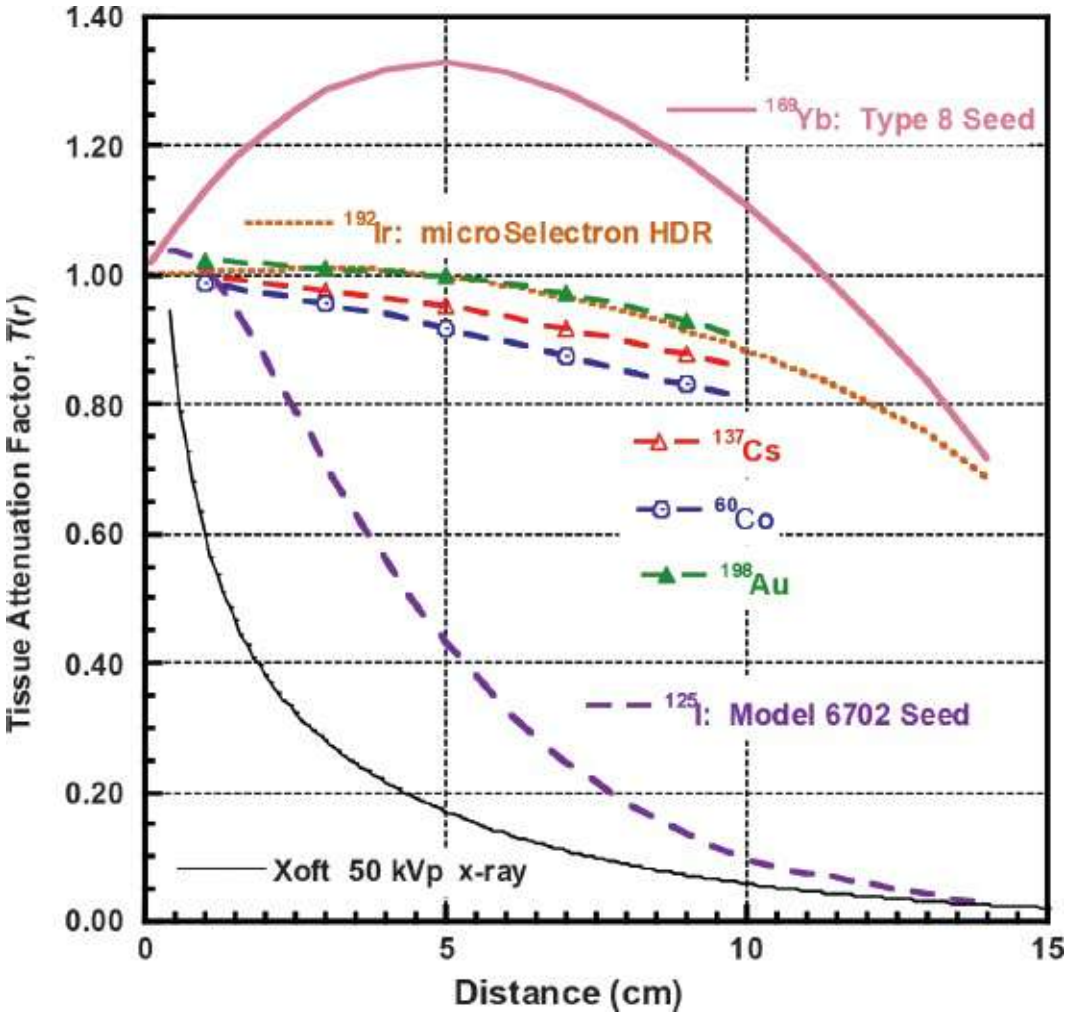

FIGURE 25.11. Photon attenuation and scatter factors, *T(r)*, for a number of brachytherapy radionuclides. The data for ^{137}Cs, ^{198}Au, and ^{60}Co are from the classic paper by Meisberger et al.[109] The HDR ^{192}Ir, Model 6702 ^{125}I, and Xoft 50 kVp x-ray T(r) are from Daskalov et al.,[110] Dolan et al.,[111] and Hiatt et al.[70]

By solving Eqs. (13) and (14) for *SK* and substituting the results into Eq. (18), one can derive equations relating the dose rate at distance *r* to equivalent mass of radium and apparent activity for the same unfiltered point source:

$$\dot{D}_{\text{med}}(r) = M_{\text{eq}} \cdot \frac{(\Gamma_\delta)_{Ra,0.5} \cdot f_{\text{med}}}{r^2} \cdot T(r) \quad \text{Equivalent Mass of } ^{226}\text{Ra} \quad (19a)$$

$$\dot{D}_{\text{med}}(r) = A_{\text{app}} \cdot \frac{(\Gamma_\delta)_X \cdot f_{\text{med}}}{r^2} \cdot T(r) \quad \text{Apparent Activity} \quad (19b)$$

where f_{med} is the dose-to-exposure conversion factor given by:

$$f_{med} = \frac{D_{med}}{X} = (W/e) \cdot \left[\frac{\overline{(\mu_{en}/\rho)^{med}}}{(\mu_{en}/\rho)^{air}} \right] = 0.876 \frac{cGy}{R} \cdot \overline{(\mu_{en}/\rho)_{air}^{med}} \Big\} \text{ in free space} \quad (20)$$

For radionuclides with photon energies of more than 200 keV, f_{med} has the value 0.974 cGy·R^{-1} for water and 0.966 cGy·R^{-1} for muscle medium.[73]

Equations (17) and (19) give the dose rate, $\dot{D}_{med}(r)$, for a point source surrounded by an arbitrary medium that has been specified in terms of equivalent mass of radium, apparent activity, and S_K. Assuming that the same exposure rate constants, $(\Gamma_\delta)_{Ra,0.5}$and $(\Gamma_\delta)_X$, were used to evaluate absorbed dose as were used to convert the measured air-kerma strength to M_{eq} and A_{app} via Eqs. (13) and (14), all three equations should give numerically identical dose rates. This demonstrates that Γ_δ is, in fact, a "dummy" constant that plays no physical role in the dosimetry of output-calibrated sealed sources because any arbitrary, but consistently used, value will yield identical dose-rate distributions. Because these unit conversions may be performed by different individuals at various stages of the calibration and clinical treatment planning processes, the potential for significant dose-calculation errors exists. The use of S_K for clinical source-strength specification eliminates these dummy constants, thereby eliminating errors resulting from inconsistent conventional choices.

Modeling of Source Anisotropy: The Anisotropy Factor

Despite its simplicity, the classical isotropic point-source model, Eq. (17), accurately predicts the transverse-axis dose-rate distributions of most actual radium-substitute sources. Simply by using an output quantity to calibrate the source, rather than contained activity, A, the influence of its internal structure (filtration and self-absorption) has been implicitly accounted for. Had true activity, A, instead of A_{app} been used in Eq. (19b), then the expression for $(\Gamma_\delta)_X$ (Eq. [12]) would require correction for attenuation and scattering in the radioactive core and surrounding encapsulation. Any uncertainties in $\{E_i, P_i\}_{i=1}^{N}$ (which are large for many radionuclides) and filtration corrections would directly degrade dose-calculation accuracy. In addition, fundamental activity measurements are technically difficult for the high-intensity sources used in BT. For these reasons, contained activity does not play a role in photon BT dosimetry. In contrast, Eq. (17) infers dose rate from a quantity measured outside

the source, which is not influenced significantly by knowledge of the unfiltered photon spectrum. The required quantities, $\overline{(\mu_{en}/\rho)}^{med}_{air}$ and $T(r)$, are ratios and are therefore insensitive to errors in the assumed spectrum.

Practically all BT sources are cylindrical, giving rise to anisotropic dose distributions. In addition, some sources, especially those used in intracavitary BT, have active lengths that are comparable to typical calculation distances. Thus, the dose rate, $\dot{D}(r,\theta)$, around a BT source depends both on distance r and polar angle, q (Fig. 25.8B). $\dot{D}(r,\theta)$ may deviate significantly from the transverse-axis dose rate, $\dot{D}(r,\pi/2)$, predicted by Eq. (17), especially near the long axis of the seed.

In the case of implants consisting of many randomly oriented seeds with active lengths less than the minimum distance of interest, Eq. (17) will accurately represent the multiple-seed dose distribution if an average correction for single-seed dose anisotropy is applied.[114] This correction factor, which the TG-43 protocol refers to as the "1D anisotropy function," $\phi_{an}(r)$, is defined by averaging the dose at each fixed distance r with respect to solid angle, Ω:

$$\phi_{an}(r) = \frac{\text{Average dose at } r}{\text{Transverse-axis dose at } r} = \frac{\int_{4\pi} \dot{D}(r,\theta)\cdot d\Omega}{4\pi\dot{D}(r,\pi/2)} = \frac{\int_0^{\pi} \dot{D}(r,\theta)\cdot\sin\theta\cdot d\theta}{2\cdot\dot{D}(r,\pi/2)} \tag{21}$$

Often, a distance-independent average value of $f_{an}(r)$, called the anisotropy constant, $\bar{\phi}_{an}$, is used. Incorporating this average correction into Eq. (17) leads to:

$$\dot{D}_{med}(r) = \frac{S_K\cdot\overline{(\mu_{en}/\rho)}^{med}_{air}}{r^2}\cdot T(r)\cdot\bar{\phi}_{an} \tag{22}$$

For early radium-substitute sources, $\bar{\phi}_{an}$ was often evaluated by measuring relative photon fluence in air at relatively large distances (30 to 100 cm) using a NaI or GeLi scintillation detector.[61,115]

Equation (22) implies that source strength should be increased by a constant fraction ranging from 2% (^{192}Ir seeds) to 10% (^{103}Pd seeds) to correct for polar anisotropy effects. Lindsay et al.[116] compared prostate implant 3D dose distributions derived from the isotropic point-source model, $\dot{D}(r)$, to those

derived from the full 2D single-source dose-calculation model, $\dot{D}(r,\theta)$. Based on voxel-by-voxel comparisons, they found that the isotropic point-source model introduced errors exceeding 10% of the D_{90} (see section on dose specification) in 8% and 33% of the target volume for the Model 6711 ^{125}I and Model 200 ^{103}Pd sources. Corbett and colleagues[117] found that despite local large local dose-distribution differences, including 2D anisotropy effects did not alter the dose/volume histogram (DVH): neither the V_{100} nor the margin between D_{100} and prostate boundary was altered significantly. For volume implants consisting of parallel arrays of ^{192}Ir seeds, a similar finding has been reported.[114]

Dose Calculation for Extended Sources: The Sievert Integral Model

Dose distributions around larger sources, such as intracavitary tubes and interstitial needles, are calculated by partitioning the extended source into a set of point sources to which corrections for distance, oblique filtration, attenuation, and scattering are applied separately. By summing these point-source contributions, the dose at point P can be estimated. This class of algorithms, first described by Rolf Sievert in 1921,[118] is known as the Sievert integral algorithm or, more generally, the 1D pathlength model.[24,119]

Assume that the source illustrated in Figure 25.12 has an air-kerma strength, *SK*, and contained activity, A. The classical Sievert model approximates the cylindrical active core by a line of radioactivity positioned along its axis. The axial length of the core is called the active length, L. Oblique filtration is modeled by assuming that the capsule reduces dose by exponential attenuation using an effective filtration coefficient, μ'. The dose rate $\Delta\dot{D}(x,y)$ at point (x,y) from the incremental source ΔL located at angle q is

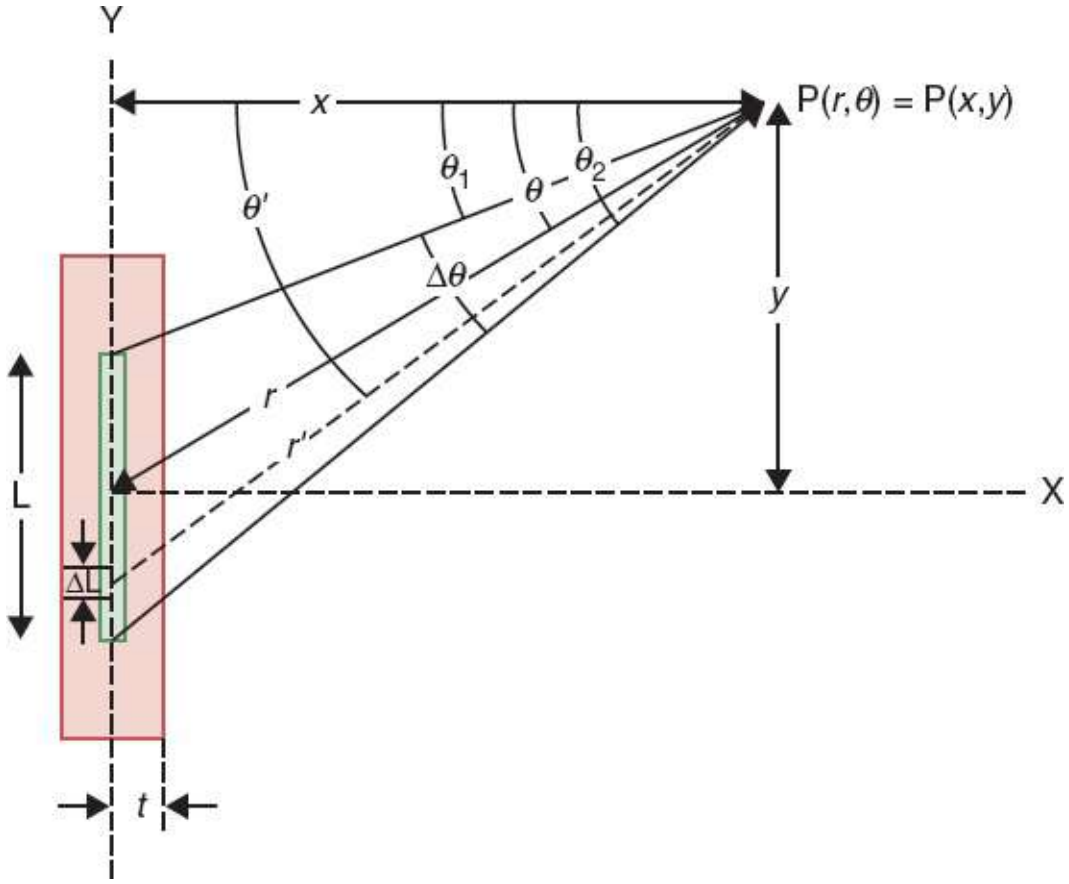

FIGURE 25.12. A typical encapsulated line source, illustrating calculation of dose rate at point P at (*x*,*y*) relative to the source center by the Sievert integral method. The active length and radial encapsulation thickness are denoted by L and t, respectively. The distances x and y are referred to as "distance away" and "distance along," respectively, in the literature.

$$\Delta\dot{D}(x,y) = A \cdot \frac{\Delta \mathrm{L}}{\mathrm{L}} \cdot \frac{(\Gamma_\delta)_X \cdot \mathrm{f}_{\mathrm{med}}}{(x/\cos\theta)^2} \cdot T(x/\cos\theta) \cdot \mathrm{e}^{-\mu' \cdot t/\cos\theta} \qquad (23)$$

where $(\Gamma_\delta)_X$ is the exposure rate constant of the unfiltered source material. Because $S_K = A \cdot (\mathrm{W/e}) \cdot (\Gamma_\delta)_X \cdot \mathrm{e}^{-\mu' t}$, Eq. (23) becomes:

$$\Delta\dot{D}(x,y) = S_K \cdot \frac{\Delta \mathrm{L}}{\mathrm{L}} \cdot \mathrm{e}^{\mu' \cdot t} \cdot \frac{\overline{(\mu_{\mathrm{en}}/\rho)}^{\mathrm{med}}_{\mathrm{air}}}{(x/\cos\theta)^2} \cdot T(x/\cos\theta) \cdot \mathrm{e}^{-\mu' \cdot t/\cos\theta} \qquad (24)$$

By summing over all these incremental sources (i.e., integrating with respect to q') and transforming to polar coordinates, we obtain the Sievert integral:

$$\dot{D}(r,\theta) = \frac{S_K \cdot \overline{(\mu_{\mathrm{en}}/\rho)}^{\mathrm{med}}_{\mathrm{air}} \cdot \mathrm{e}^{\mu' \cdot t}}{\mathrm{L} \cdot r \cdot \cos\theta} \cdot \int_{\theta_1}^{\theta_2} \mathrm{e}^{-\mu' t \cdot \sec\theta} \cdot T(\mathrm{x} \cdot \sec\theta) \cdot \mathrm{d}\theta \qquad (25)$$

The extra $e^{\mu' t}$ term outside the integral is needed to avoid global "double correction" for filtration.

Variants of Eq. (25) applicable to the regions near the source capsule ends are available. Numerous improvements to the basic model have been introduced over the years,[104,120] including modeling of photon absorption by the source core, extension to noncylindrical sources, generalization to radioactivity distributed over a volume,[4] extension to low-energy sources,[119] and treatment of applicator shielding and attenuation.[121,122]

The Sievert algorithm was widely used to model 2D dose distributions around ^{137}Cs tubes and needles for clinical treatment planning prior to acceptance of the Task Group 43 table lookup method. Both experimental[123,124] and Monte Carlo studies[4,125] have demonstrated that the Sievert model accurately predicts dose-rate distributions in this energy range. When the filtration coefficient μ' is approximated[126] by the linear energy absorption coefficient, μ_{en} (0.023 mm^{-1} for steel-clad ^{137}Cs sources), maximum errors are no larger than 5% to 8% and are much smaller (<3%) near the transverse axis. Published dose-rate distributions derived from the Sievert model, tabulated in terms of distances away and along, are available for several types of ^{137}Cs sources[4,125] and ^{226}Ra sources.[127] Williamson[119] showed that the classical Sievert integral gives rise to large errors (20% to 37% maximum error, 7% to 16% average error) when applied to lower-energy sources of ^{192}Ir, ^{169}Yb, and ^{125}I. Although accuracy can be improved by modifying the basic model,[119] classical semiempirical models should be used cautiously at photon energies below ^{137}Cs. Tabulated dose-rate distributions derived from direct measurement or Monte Carlo simulation are preferable for these sources.

If the encapsulation thickness is set to zero (t = 0) in Eq. (25), the Sievert integral reduces to a simple closed-form analytic expression:

$$\dot{D}(x,y) = S_K \cdot \overline{(\mu_{en}/\rho)}^{med}_{air} \cdot \frac{\Delta\theta}{L \cdot x} \qquad (26)$$

where $\Delta\theta$ is the angle, in radians, subtended by the active length, L, with respect to the point of interest (Fig. 25.12). When the interest point lies on the transverse axis (y = 0), then $\Delta\theta = 2 \cdot \tan^{-1}(L/2x)$, where $\tan^{-1}$ denotes the inverse tangent or arctan function. Angles must be specified in units of radians rather than degrees (180 degrees = π radians). This approximation is extremely useful as a manual calculation aid and is highly accurate near the transverse axis of lightly encapsulated ^{137}Cs sources.

Figure 25.13 shows that as the distance $r = \sqrt{(x^2 + y^2)}$ becomes large in relation to active length, L, Eq. (26) reduces to the point-source formula. For distances less than L (1.5 cm for intracavitary tubes), use of Eq. (17) will yield errors of at least 10%. For distances >1.5 L (2 to 2.5 cm for gynecologic tubes), the point-source approximation is accurate within 5%.

Modern Quantitative Dosimetry

In contrast to classical dose-calculation models, which assume that the parameters $T(r)$ and $\overline{(\mu_{en}/\rho)}_{air}^{wat}$ depend only on the radionuclide used, quantitative dosimetry methods assume that dosimetry parameters are source-geometry specific and should be measured or calculated specifically for each type of source. Classical approaches to BT dosimetry began to break down with the introduction of ^{125}I interstitial seeds in the early 1970s, as this 30-keV x-ray emitter clearly fell outside the scope of validated analytic models.[12] Although ^{125}I dose distributions derived from semiempirical models were published[128] and widely used, it was recognized[61] that internal seed structure could modulate the emitted photon spectrum and have significantly alter the absorbed dose distribution. The growing use of ^{125}I and the introduction of a primary exposure standard in 1985[129] motivated investigation of more quantitative dosimetry methods. For a more detailed discussion of early of ^{125}I dosimetry, the reader is referred to Appendix C of the original TG-43 report.[130] Currently, both experimental methods and sophisticated computational dosimetry approaches are routinely used to derive such source-specific parameters. Both the classical and quantitative dosimetry approaches are based on the NIST air-kerma strength standards.

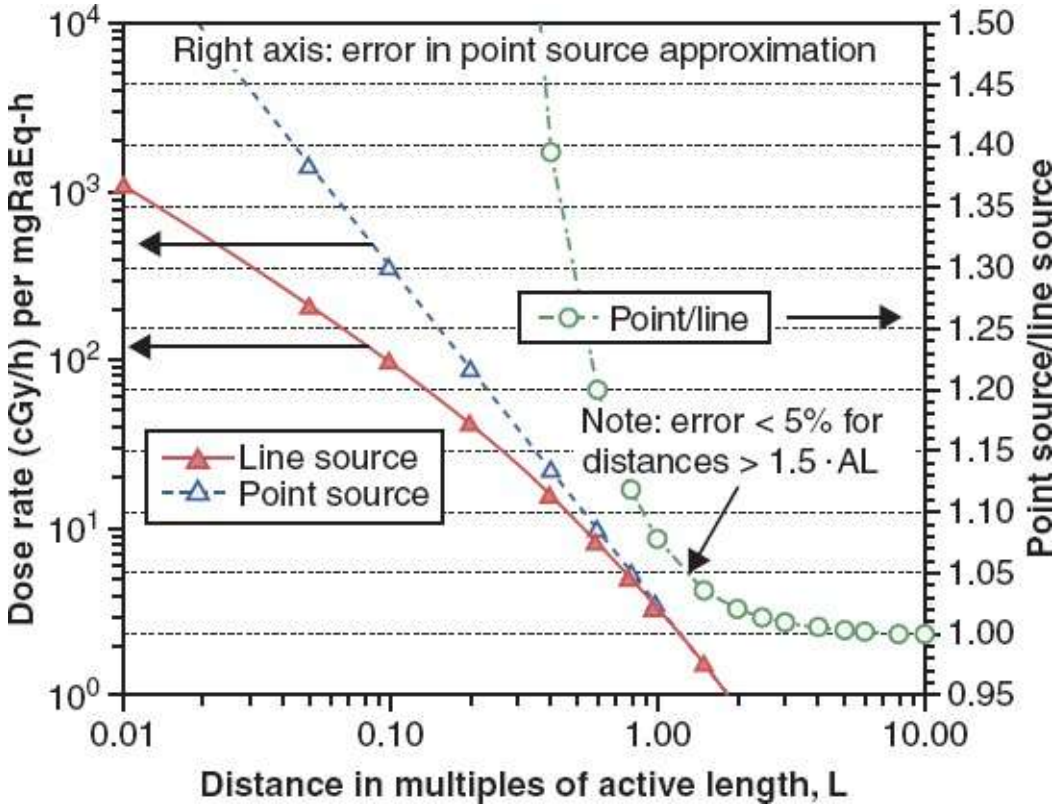

FIGURE 25.13. Error in the isotropic point source model relative to the line-source model Eq. (26) as a function of transverse-axis distance expressed in multiples of active length.

Experimental Brachytherapy Dosimetry

Clinical acceptance of measured dose rates in BT is a relatively recent phenomenon, beginning in the mid-1980s. Historically, this is due not only to the difficulties and labor-intensity attending such measurements, but to a consensus that dose measurement was so difficult and intrinsically inaccurate that even simplistic theoretic models were more reliable. Brachytherapy dose measurement does indeed place severe demands on detectors because the dose distributions are characterized by large dose gradients, a large range of dose rates, and relatively low photon energies. The most severe measurement artifact is the exquisite sensitivity of detector response to positioning errors; measurement of dose near a point source with 2% accuracy requires that the source-to-detector distance be specified with accuracy of 20, 50, 100, and 200 μm, respectively, at distances of 2, 5, 10, and 20 mm.

Commonly used dose detectors include thermoluminescent detectors (TLDs), small ion chambers, diode detectors, and silver-halide radiographic film. Radiochromic film[131–133] and plastic scintillator detectors[134,135] show promise as

planar dose measurement systems. Three-dimensional dose measurement technologies under investigation include liquid scintillation cocktails[136] and polymer gel dosimetry[137,138] using either magnetic resonance imaging (MRI) or reconstructed by optical transmission tomography to quantify the detector signal. One consideration in selecting a detector for BT dosimetry is minimizing energy response artifacts, which arise from compositional differences between water and the detector and can result in variation of detector reading/unit dose in medium as the photon spectrum changes with position. Silicon diodes are useful detectors for measuring relative dose distributions around ultra-low-energy sources (e.g., ^{103}Pd and ^{125}I) because diode sensitivity is nearly independent of measurement point location[139,140] but are not recommended for higher-energy BT sources, as variations in sensitivity with position in the phantom as large as 15% for ^{137}Cs and 75% for ^{192}Ir have been reported.[141]

Among the established dosimetric techniques, LiF TLD dosimetry is considered to offer the best compromise between sensitivity, small size, and freedom from energy-response artifacts[84,142] and is currently considered to be standard of practice.[5] The acceptance of TLD dosimetry owes much to a 3-year (1987 to 1989) multi-institutional contract to perform a definitive review of low-energy seed dosimetry that was funded by the National Cancer Institute. The three institutions, collectively called the Interstitial Collaborative Working Group (ICWG), consisted of Memorial Sloan Kettering, Yale, and UCSF.[142] Using TLD-100 thermoluminescent chips and powder capsules, embedded in machined solid-water phantoms, the ICWG developed the procedures used to this day, including TLD dose calibration and energy response correction, for making quantitative estimates of absolute dose rates in water. Each investigator groups independently measured transverse-axis dose distributions for the ^{125}I and ^{192}Ir sources than available to validate their TLD measurement methodology.[142] This was followed by more complete 2D dose distributions about ^{125}I, ^{192}Ir, and ^{103}Pd BT sources then available.[139,143,144] The results showed good agreement among the different measurements and overall, substantial differences between measured and classically computed dose rates for ^{125}I seeds (when normalized to the air-kerma strength standard,[129] $S_{K,\mathrm{N85}}$, then available), but good agreement between the classical and experimental approaches for ^{192}Ir. With careful correction for TLD linearity, perturbation of the photon field by the detectors, and relative energy response, absolute dose rate (cGy/h in tissue per unit S_K) can be measured with a total uncertainty of 6% to 9% in the 1- to 5-cm distance range.[5,84,111]

Measured dose-rate distributions using TLD detectors are available for many common BT sources, including nearly all commercially available ^{125}I and ^{103}Pd sources (see the revised TG-43 Report[5] and a recent review article[84] for more comprehensive discussions); many LDR ^{192}Ir sources for LDR, HDR, and PDR sources, as well as for many investigational sources. For radium-substitute sources, the measurements are in close agreement with the classical semiempirical models: isotropic point source and Sievert integral models.[4,24,119] For ^{125}I sources normalized to the 1984 Loftus[129] S_K standard, measured dose rates were found to be 10% to 20% lower than those predicted by Eq. (17).[5,145] Better agreement[84] was observed between classical models and measurements with calibrations traceable to the 1999 WAFAC standard ($S_{K,\mathrm{N99}}$).[89] However, classical models such as the Sievert integral are not recommended for the low-energy source regimen as they poorly predict low-energy source anisotropy and do not take into account modulation of the dose distribution by internal source geometry.[119]

Computational Dosimetry Methods: Monte Carlo Photon Transport Simulation

Concurrently with the development of TLD dosimetry in the 1990s, other investigators were investigating the use of Monte Carlo photon-transport techniques as tools for quantitative evaluation of single-source dose distributions. Based on an accurate and detailed mathematical model of the internal structure of the source, photon histories can be generated and then evaluated to assess absorbed dose. Monte Carlo techniques are now accepted as a reliable and probably the most accurate source of BT dosimetry data.[5,84] As illustrated in Figure 25.14, this theoretical method uses a digital computer to randomly select a small number (10^5 to 10^7) of photon trajectories or "histories." A geometric model defining the location of all media boundaries and photon sources must be available. By using probability distributions derived from total and differential cross sections, a photon history is randomly constructed by following each photon from birth through successive scattering events and, eventually, to absorption or escape from the system. At each decision point, random sampling is used to decide the fate of the photon. The process of randomly constructing photon trajectories is equivalent to selecting photon histories from the set of all those possible by random sampling. To statistically estimate the dose rate at a specified point, the dose contributed by each simulated collision is estimated and then averaged over all collisions. Monte

Carlo simulation techniques are reviewed in more detail elsewhere.[84] Because particle histories can be accurately and efficiently constructed even in the presence of complex 3D geometries, approximation-free but statistically inexact solutions, derived from first principles, are possible for a wide range of geometrically complex but clinically relevant BT problems.

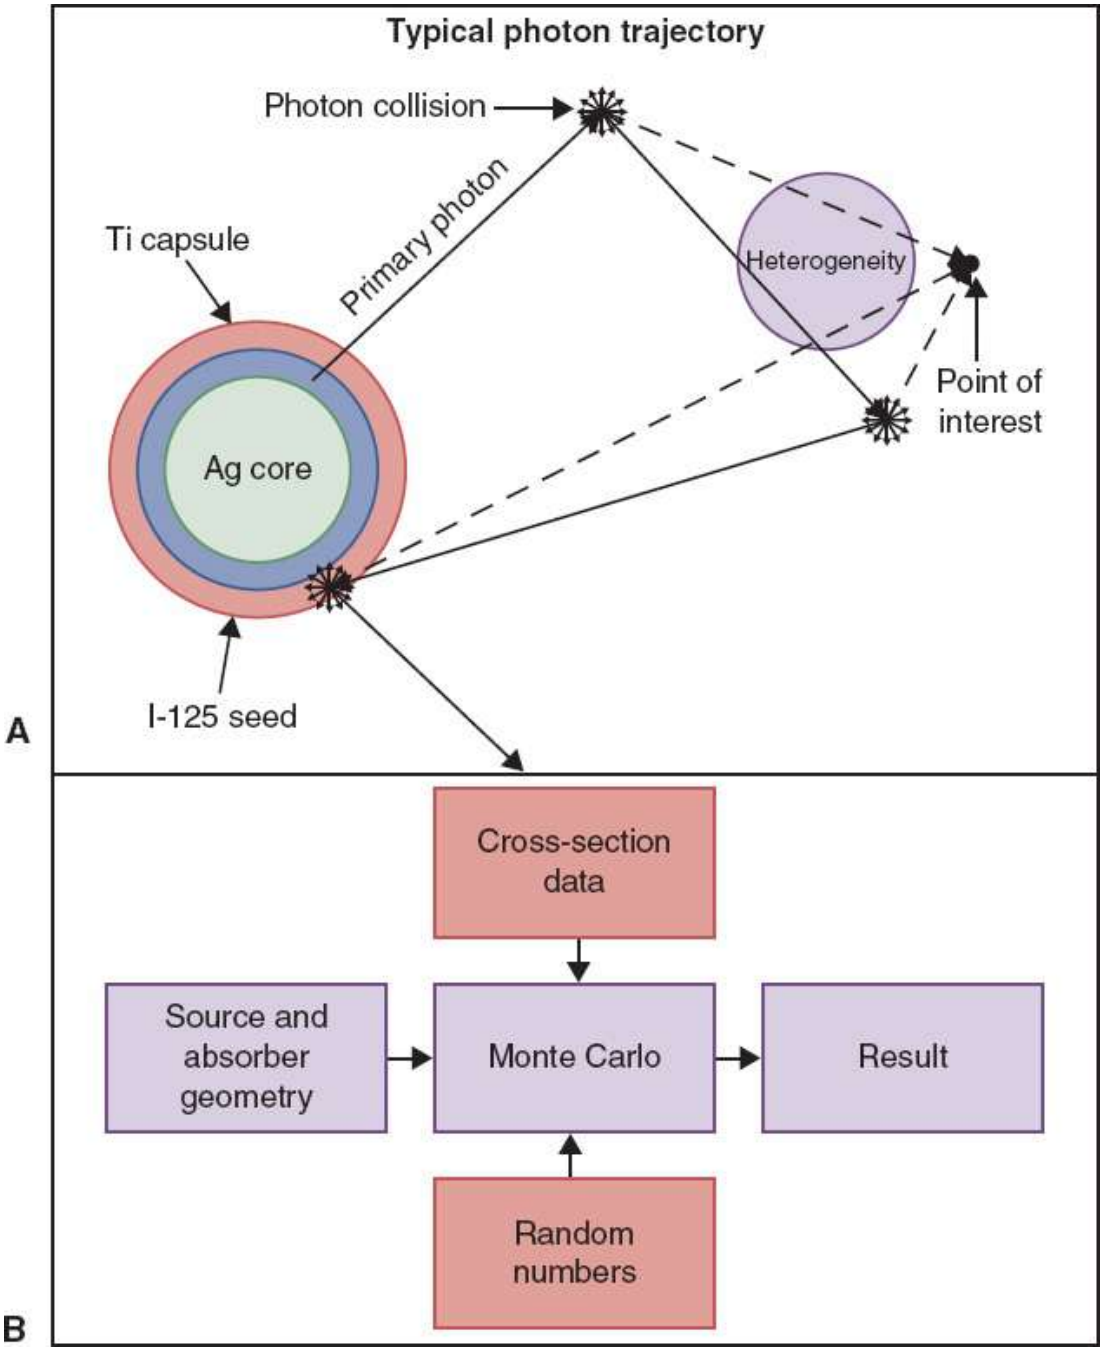

FIGURE 25.14. A: Two-dimensional representation of a typical photon history. The *heavy solid lines* illustrate the origin of the primary photon (randomly selected from the assumed distribution of radioactivity), and each successive collision, which is

randomly selected from the competing collision mechanisms (photo-effect, Compton scattering, and coherent scattering), is based on their relative probabilities. The *dashed lines* illustrate the problem of estimation (i.e., calculating the probable contribution of each simulated collision to the point of interest). **B:** Functional diagram of a Monte Carlo code illustrating the required input data. Cross-sectional data include total attenuation coefficients, total cross-sections for each collision process, and differential cross-sections, which are used to randomly sample the distance between successive collisions, the interaction mechanism at each collision, and the angle and energy of the scattered photon leaving each collision, respectively. Sequences of random numbers are obtained from a "random number generator," a computer program designed to generate a pseudorandom sequence of numbers uniformly distributed between 0 and 1.

The dosimetric accuracy of Monte Carlo simulation has been confirmed across the entire energy spectrum from ^{125}I to ^{137}Cs. Agreement between Monte Carlo and TLD measurement ranges from 2% to 6%, both in homogeneous medium and in the presence of tissue and applicator heterogeneities.[8,63,141,146,147] In contrast to experimental methods, Monte Carlo accuracy is not limited by dosimeter artifacts such as energy response and volume averaging. Because the geometric model can be specified exactly, detector positioning error is not an issue in Monte Carlo. Recent analyses[5,64,84] have shown that the uncertainty (including all known systematic and random error sources) of Monte Carlo absolute dose-rate estimates on the transverse axis of ^{125}I seeds is 2.5% to 5% over the 1- to 5-cm distance range. Unlike dose measurements, Monte Carlo dose calculations cannot account for unsuspected deviations from the design specifications of the problem (e.g., a contaminant radionuclide in the source or an error in measuring its source strength). A recent analysis,[148] which compared 25 sets of published TLD-100 low-energy seed measurements with parallel Monte Carlo calculations performed using a single EGSnrc-based Monte Carlo code,[149] found average differences between measurement and calculation 3.8% and 2.8% for ^{125}I and ^{103}Pd seeds, respectively, based upon treating TLD intrinsic energy corrections as best fit parameters.

Historically, the most important role of Monte Carlo simulation was calculation of reference-quality transverse-axis dose-rate distributions and anisotropy functions for low- and medium-energy BT sources. For low-energy interstitial seeds for routine clinical use, both experimental and Monte Carlo–based published dosimetry studies in peer-reviewed journal are required for developing AAPM-approved consensus datasets or posting the interstitial seed product on the Joint IROC-H/AAPM Source Registry.[55] Monte Carlo simulation is a useful alternative to dose measurement in many other applications such as

characterizing the effects of applicator shielding materials[8] and tissue heterogeneities[63] on BT dose distributions, validating heuristic dose calculation algorithms,[150] and optimizing new source and applicator designs.[151]

AAPM Task Group 43 Report: A Table-Based Dose-Calculation Formalism

An important milestone in modern BT dosimetry is the publication of the original AAPM Task Group 43 Report in 1995[130] and a substantially revised and expanded version in 2004,[5] including two recent supplements.[52,53] The TG-43 approach consists of using measured and Monte Carlo–generated dose-rate distributions directly for clinical dose calculation aided by a standard table-lookup formalism. The revised TG-43 report and its supplements include the following:

- A recommended table-based dose-calculation formalism for representing 2D and 1D dose distributions around interstitial sources specifically designed to use a sparse matrix of Monte Carlo or measured dose rates as its input.
- A critically reviewed set of 2D dose-distribution data for a total of 27 ^{125}I, ^{103}Pd, and ^{131}Cs seed models that satisfy the AAPM dosimetric prerequisites.[57] For each of these source types, a consensus dose-distribution in TG-43 formalism format is recommended based upon “merging” published TG-43–compliant Monte Carlo and experimental dosimetry datasets.
- A history of air-kerma strength primary standards,[89,129] which summarizes previous AAPM guidance,[152,153] including the impact of calibration shifts on the delivered-to-prescribed dose ratio.
- Methodologic recommendations for obtaining TG-43 dosimetry parameters from TLD measurements or Monte Carlo simulations, including uncertainty analyses.
- Guidance on clinical implementation of TG-43 report recommendations.

The TG-43 report recommends that all treatment-planning software systems utilize the TG-43 formalism as the basis of dose calculation or at least for data entry, allowing users to easily input the new data into their systems. With the introduction of the new WAFAC-based air-kerma strength standard by NIST and over 20 low-energy interstitial BT sources into the marketplace at various times, the radiotherapy community has embraced the TG-43 dose-calculation formalism as well as many AAPM recommendations associated with TG-43 implementation. Most important among these are the AAPM dosimetric prerequisites for routine non–IRB-approved BT procedures.[57] Only low-energy

sources with NIST-traceable *SK* calibrations supported by annual intercomparisons among NIST, the ADCLs, and the vendor[154] and two independent Monte Carlo and experimental dosimetry studies published in the peer-reviewed literature will be posted on the Joint IROC-Houston/AAPM Registry website[55] or included in future TG-43 supplements. In 2012, a similar dosimetry validation process was introduced for higher-energy sources.[72]

Because embracing new calibration standards and dosimetry parameters alters prescribed-to-delivered dose ratios, radiation oncologists must understand the implications for selection of prescribed dose, interpreting published outcome studies, and consistently reproducing their clinical experience through time. AAPM reports provide detailed discussions and recommendations on managing these changes. For example, in ^{125}I monotherapy for prostate cancer, the Pre-TG43 prescribed dose of 160 Gy is equivalent to 145 Gy using the TG-43 dosimetry parameters.[152,155] Managing the up to 10% variations in prescribed-to-administered dose ratios because of the complex dosimetric history of ^{103}Pd monotherapy is reviewed in a 2005 AAPM report.[155]

General Formalism for the Two-Dimensional Case

For a cylindrically symmetric source of strength S_K (Fig. 25.15), dose rate, $\dot{D}(r,\theta)$, at the point (r,q), is calculated in the TG-43 formalism as follows:

$$\dot{D}(r,\theta) = S_K \cdot \Lambda \cdot \frac{G_L(r,\theta)}{G_L(r_0,\theta_0)} \cdot g_L(r) \cdot F(r,\theta) \qquad (27)$$

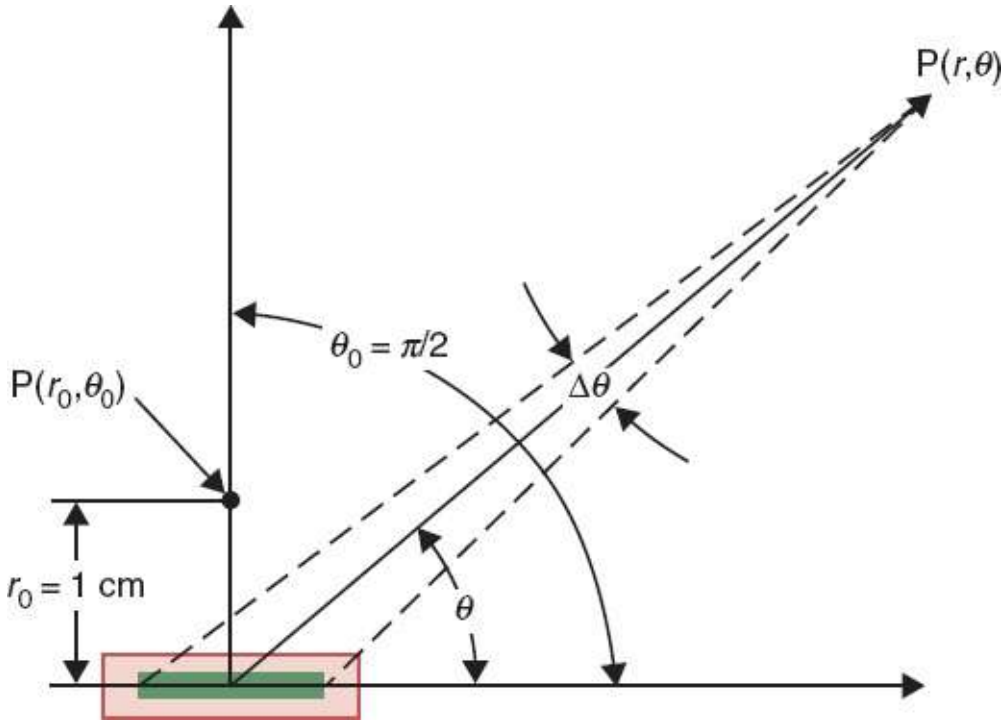

FIGURE 25.15. Illustration of TG-43 formalism for calculation of absorbed dose rate, D.(r,θ), at (r,θ), in a polar coordinate system centered about the source active core.

where r denotes the distance (in cm) from the center of the active source to the point of interest, q denotes the polar angle specifying the point of interest relative to the source longitudinal axis, r_0 denotes the reference distance (specified to be 1 cm), and q_0 is the reference angle (90° or π/2 radians) that defines the source transverse plane. For ^{125}I and ^{103}Pd sources, AAPM guidance[155] uses the symbols $S_{K,\mathrm{N99}}$ and $S_{K,\mathrm{N85}}$ to designate the 1999 WAFAC-based NIST standard[89] and the prior Loftus[129] free-air standard introduced in 1985. The other symbols in (27) denote the following quantities:

G_L (r,q) is the line-source geometry function in units of cm^{-2}.

Λ is the dose-rate constant of the source type in units of cGy·h^{-1}·U^{-1}.

F(r,q) is the dimensionless 2D anisotropy function that takes the value unity for q_0 at all r.

g(r) is the dimensionless radial dose function that takes the value unity at $r = r_0$.

The dose-rate constant in liquid-water medium is defined by:

$$\Lambda = \frac{\dot{D}(r_0, \theta_0)}{S_K} = \frac{\dot{D}(1\,\mathrm{cm}, 90^\circ)}{S_K} \qquad (28)$$

where $\dot{D}(r_0, \theta_0)$ is the measured dose rate at the reference point. Λ includes the effects of source geometry, spatial distribution of radioactivity, encapsulation, self-filtration in the source, and attenuation and scattering of photons in the surrounding medium. It also depends on the standardization measurements to which the *SK* calibration of the source is traceable. For radium-substitute point sources, $\Lambda \approx \overline{(\mu_{en}/\rho)}^{med}_{air} \cdot T(r) \cdot G_L(1\text{ cm}, \pi/2)$. Table 25.4 shows that during the $S_{K,N85}$ era (1984 to 1999), the classical point-source model overestimated absolute doses by as much as 15% for ^{125}I sources relative to TLD measurements and Monte Carlo calculations. In 1999, the WAFAC ($S_{K,N99}$) standard replaced $S_{K,N85}$, which required an upward adjustment of these Λ values, bringing the classical and quantitative values closer together. The old and new dose calculations are in close agreement for ^{192}Ir and other radium substitutes.

The purpose of the geometry function, $G_X(r,q)$ (where the subscript "X" denotes point (P) or line source (L)), is to improve the accuracy with which dose rates can be estimated by interpolation from data tabulated at discrete points. Physically, $G_X(r,q)$ neglects scattering and attenuation and provides an effective inverse-square law correction based upon an *approximate model* of the spatial radioactivity distribution within the source. Because the geometry function is used only to interpolate between tabulated dose-rate values at defined points, highly simplistic approximations yield sufficient accuracy for treatment planning.[5] To improve the accuracy of linear interpolation near the source, the AAPM protocol requires use of (r,q) for 2D calculations and prefers $G_L(r,q)$ over $G_P(r,q)$ for 1D calculations. For small cylindrical seeds, $G_X(r,q)$ is approximated by a line source:

$$G_P(r,\theta) = r^{-2} \qquad \text{point-source approximation}$$

$$G_L(r,\theta) = \begin{cases} \dfrac{\Delta\beta}{L r \sin\theta} & \text{if } \theta \neq 0^\circ \\ (r^2 - L^2/4)^{-1} & \text{if } \theta = 0^\circ \end{cases} \qquad \text{line-source approximation} \tag{29}$$

where $\Delta\beta = q_2 - q_1$ is the angle subtended by the active source with respect to the point (r,q). For sources where the radioactivity is distributed over or within a right cylindrical volume or annulus, L can be taken as the length of this cylinder. For sources containing uniformly spaced multiple radioactive components, L

should be taken as the effective length, L_{eff}, given by $L_{eff} = \Delta S \times (N)$, where N represents the number of discrete pellets contained in the source with a nominal pellet center-to-center spacing, ΔS.

The 2D anisotropy function $F(r,q)$ gives the angular variation of dose about the source at each distance as a result of self-filtration, oblique filtration of primary photons through the encapsulating material, and photon attenuation and scattering in the surrounding medium:

$$F(r,\theta) = \frac{\dot{D}(r,\theta)}{\dot{D}(r,\theta_0)} \frac{G_L(r,\theta_0)}{G_L(r,\theta)} \tag{30}$$

where the dose rates, $\dot{D}(r,\theta)$, are obtained by measurement or Monte Carlo simulation. The line-source geometry function is used to suppress the influence of inverse-square law on the angular dose distribution at short distances. Thus, $F(r,q)$ need be tabulated only at a few distances, r, to facilitate accurate interpolation at all distances. Examples of anisotropy functions for various interstitial sources are illustrated in Figure 25.16 and in Table 25.6.

The radial dose function, $g_X(r)$, accounts for the falloff of dose along the transverse axis as a result of attenuation and scattering in the medium, capsule filtration, and self-absorption:

$$g_X(r) = \frac{\dot{D}(r,\theta_0)}{\dot{D}(r_0,\theta_0)} \frac{G_X(r_0,\theta_0)}{G_X(r,\theta_0)} \tag{31}$$

$g_X(r)$ is normalized to unity at 1 cm distance and is illustrated by Table 25.5. For 2D dose calculations, TG-43 recommends that X = L.

One-Dimensional Isotropic Source Approximation

Most commercial treatment planning systems used for permanent implant dose computation support only 1D isotropic point-source calculations. Thus, the TG-43 formalism includes a 1D equation analogous to the classical isotropic point-source model, Eq. (22):

$$\dot{D}(r) = S_K \cdot \Lambda \cdot \frac{G_L(r,\theta_0)}{G_L(r_0,\theta_0)} \cdot g_L(r) \cdot \phi_{an}(r) \qquad (32)$$

INTERSTITIAL IMPLANTATION

The traditional implant systems (Manchester, Quimby, and Paris) that arose early in the 20th century were developed to guide the radiation oncologist in arranging and positioning radium needles within the surgically identified target volume. In contrast, the most frequently practiced implant procedure today, transperineal permanent implants of the prostate, uses image guidance to position the sources. In place of nomograms and classical system lookup tables, 3D computerized planning is used to prescribe dose and to optimize the implant geometry. However, even the most sophisticated commercially available dwell-weight

optimization software used with single-stepping source remote afterloaders (see Chapters 26, 27, and 28) requires the operator to specify the source and needle locations. To guide source positioning, we continue to rely on the classical systems of BT and their later variants.

Classical Systems for Interstitial Brachytherapy with Radium-Substitute Sources

The Manchester and Quimby systems were developed before the advent of computer-aided dosimetry in implant therapy, whereas the Paris system is based on multiplanar isodose distributions. All interstitial implant systems consist of the following components:

- *Distribution rules:* Given a target volume, the distribution rules determine how to distribute the radioactive sources and applicators in and around the target volume.
- *Dose-specification and implant-optimization criteria:* At the heart of each system is a dose-specification criterion (i.e., a definition of prescribed dose). In the Manchester system, for example, the prescribed dose is the modal dose in the volume bounded by the peripheral sources. The distribution rules and dose-specification criterion together often reflect a compromise between mutually exclusive goals such as dose homogeneity, normal tissue sparing, number of catheters implanted, dosimetric margins around the target, and presence of high-dose regions outside the target.
- *Dose calculation aids:* These devices are used to estimate the source strengths required to achieve the prescribed dose rate as defined by the system for source arrangements satisfying its distribution rules. Older systems (Manchester and Quimby) use tables that give dose delivered per mgRaEq-h as a function of treatment volume or area. The more recent Paris system makes extensive use of computerized treatment planning to relate absorbed dose to source strength and treatment time.

The Manchester System

The Manchester system was developed by Ralston Paterson (radiation oncologist) and Herbert Parker (physicist) in the 1930s[158–161] and often is called the Paterson-Parker (P-P) system. The P-P system remains relevant to today's practice patterns: Its distribution rules, anticipating the "peripheral loading technique," were designed to maximize dose homogeneity inside the implanted volume for volume implants and in the treatment plane (plane parallel to the needles at the treatment distance) for mold or planar implants (Fig. 25.17). Its

volume and area lookup tables remain useful as QA tools for optimized HDR volume implants.

The P-P system rules preferentially concentrate radioactivity in the rind or periphery of the implant, compensating for the dose falloff characteristic of a uniform density implant, thereby improving dose uniformity. After deriving the optimal fraction of radioactivity to be implanted in the rind and core (4:2 ratio) using a radioactive fluid model, Parker coalesced the continuous radioactivity distribution into several concentric cylindrical surfaces and then further discretized these surfaces into individual needles. A more detailed discussion of the mathematical derivation of the Manchester system is given by Anderson and Presser.[162] Table 25.7 lists the rules of the Manchester system, and Table 25.8 lists the stated dose per mgRaEq-h and unit TRAK as a function-treated area or volume.

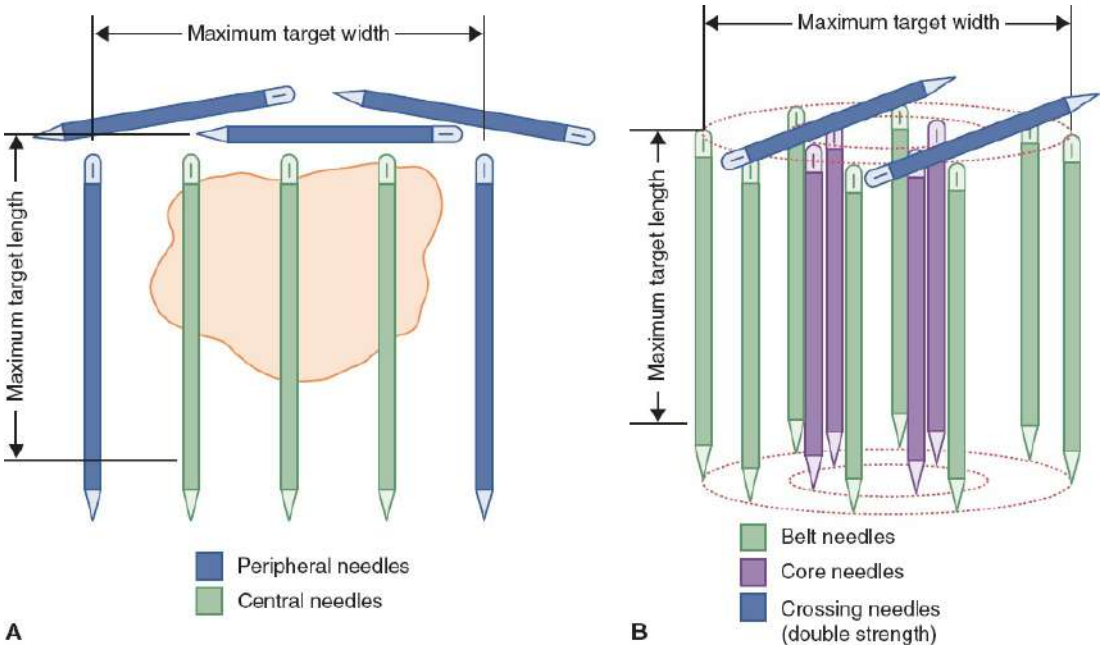

FIGURE 25.17. **A:** Relationship between target volume or area and peripheral needles (*solid color active regions*) and central needles (*green active regions*). Notice that peripheral needles always are placed on the boundary of the target region. **B:** For a cylindrical volume implant, the peripheral needles distributed on the cylindrical surface of the target are called *belt* needles, whereas those at right angles are called *end* or *crossing* needles. Because the inferior end of the implant is uncrossed, the target volume effectively treated is 7.5% shorter than the active length of the belt needles.

The P-P rules are designed to yield target area or volume dose distribution that deviates by no more than ±10% of the stated dose, excluding cold spots in

the corners and local hot spots at distances <5 mm from the source centers. For planar implants, the target or treatment surface (Fig. 25.17) is that area bounded by the peripheral needles, which is parallel to and 5 mm from the needle plane. For volume implants, the target volume is that region bounded by the peripheral sources. The distribution rules assume that both planar and volume implants will be crossed at both ends by needles placed orthogonal to the predominant direction of insertion and at the level of the belt needle active tips. Fixed 1-cm needle spacing is recommended, with full-intensity sources placed on the periphery of planar implants and partial-strength needles used as central needles. For volume implants, these two groups of sources are called “belt” and “core” sources, respectively. The stated or prescribed dose is the modal dose in the target region and is approximately 10% higher than the minimum peripheral dose (minimum dose to the implanted volume or area) and 10% below the effective maximum dose.

TABLE 25.7 MANCHESTER SYSTEM RULES

Feature	Paterson and Parker (Manchester System) Rules	
Dose and dose rate	6,000–8,000 R in 6–8 d (1,000 R/d; 40 R/h)	
Dose specification criterion	Effective minimum dose is 10% above the absolute minimum dose in treatment plane or volume.	
Dose gradient	Dose in treatment volume or plane varies by no more than ±10% from stated dose except for localized hot spots.	
	For double-plane implants with a separation >1 cm, dose is specified on interior plane 0.5 cm from implanted plane resulting in 10%–30% midplane cold spot. Single-plane mgRaEq-h is multiplied by a separation factor to obtain total double-plane mgRaEq-h.	
Linear activity	Variable: 0.66 and 0.33 mgRaEq/cm	
Source strength distribution: planar	Area < 25 cm^2:	2/3 periphery; 1/3 center
	25 < Area < 100 cm^2:	1/2 periphery; 1/2 center
	Area >100 cm^2:	1/3 periphery; 2/3 center
Source strength distribution: volume	Cylinder:	belt : core : end : end = 4:2:1:1
	Sphere:	belt : core = 6:2
	Cube:	1/8 of the activity in each face
		2/8 of the activity in the core
Source implant pattern and	Constant uniform spacing: 1-cm separation between sources recommended. Smaller spacings must be used to satisfy distribution	

spacing between sources	rules for small implants.					
Crossing needles	Perpendicular to and at the active ends of the parallel needles; if placed beyond the active ends of the needles, should be double strength. Crossing needles used when possible.					
	Planar implant: Target area effectively treated is reduced in length by 10% per uncrossed end.					
	Volume implant: Target volume effectively treated is reduced by 7.5% per uncrossed end.					
	1 uncrossed end : belt : core = 4:2:1					
	2 uncrossed end : belt : core = 4:2					
Elongation corrections	Long : Short Dimension:	1.5:1	2:1	2.5:1	3:1	4:1
	Correction factors (Applied to mgRaEq-h, not area or volume)					
	Planar	1.025	1.05	1.07	1.09	1.12
	Volume	1.03	1.06	1.10	1.15	1.23
Relation between implanted volume/area and treated (target) volume/area	Peripheral and crossing needles placed on the target-volume boundaries. Active length determines target length.

[a]Original Manchester values from Paterson R, Parker HM. A dosage system for interstitial radium therapy. *Br J Radiol* 1938;11:313–339.
[b]Modified from original values for Ir-192 assuming 860 cGy minimum peripheral dose per 1,000 “P-P” R and 7.227 μGy·m^2/mgRaEq-h.

In effect, single-plane interstitial implants with crossed ends treat a 1-cm-thick target volume with an area equal to that bounded by the peripheral sources. Target volumes thicker than 1 cm must be treated by using two parallel planes of needles placed on the target-volume boundaries (double-plane implant), with source strength arranged in each plane according to the single-plane rules. The mgRaEq-h is calculated from the 0.5-cm single-plane table, multiplied by the appropriate two-plane separation factor, and divided between the two planes. The dose actually is delivered to the inner plane 0.5 cm from each needle plane, resulting in midplane cold spots ranging from 10% to 30% for separations of 1.5 to 2.5 cm. Target volumes thicker than 2.5 cm must be treated by the volume implant system.

Volume implants can treat cylindrical, spherical, or cubic target volumes in which needles or seeds are arranged on concentric cylinders, concentric spheres, or parallel planes, using a 1-cm needle-to-needle spacing when possible. The target region is the volume encompassed by the peripheral sources. Regardless of implant size, 75% of the source strength should be placed in the rind and 25% in the core, with more specific rules for cylinder implants.

To apply the P-P system, the relationship between target volume, implanted volume (region enclosed by peripheral sources), and treated volume (region receiving 90% of the stated dose) must be appreciated for crossed and uncrossed end cases. The treated volume may be larger than the target volume but always should contain the latter. When both ends are crossed, the active length (AL) required and target length (TL) are identical. For volume implants, AL should be at least 7.5% longer than TL for each uncrossed end. For planar implants, the AL:

$$\begin{aligned}
&\text{Two crossed ends} && \text{AL} = \text{TL planar and volume} \\
&\text{One crossed end} && \text{AL} = \begin{cases} \text{TL}/0.90 & \text{planar} \\ \text{TL}/0.925 & \text{volume} \end{cases} \\
&\text{No crossed ends} && \text{AL} = \begin{cases} \text{TL}/0.81 & \text{planar} \\ \text{TL}/0.85 & \text{volume} \end{cases}
\end{aligned} \tag{33}$$

Conversely, given AL, the length of the treated volume always can be calculated by solving the appropriate Eq. (33) for TL. The area and volume used for looking up dose per mgRaEq-h from Table 25.8 should be calculated using the treated length. For example, for a single-plane implant with two uncrossed ends, width (W) and needles of active length (AL), the area, A, used for table lookup is given by $A = W \times AL \times 0.81$.

To apply P-P tables to modern implants using ^{192}Ir wires or ribbons, several corrections must be applied. The 1938 P-P tables assumed a Γ value of 8.4, ignored attenuation and scattering, neglected oblique filtration, and specified treatment in terms of exposure rather than absorbed dose. For ^{226}Ra needles, an average correction of 0.90[127] is needed to convert exposure in the original P-P tables to absorbed dose. Modifying these corrections for ^{137}Cs needles and ^{192}Ir seeds and adding an additional factor of 10% to convert from stated (modal target dose) to minimum target volume dose, we obtain the following equivalencies:

$$1'\text{P–P'R} = \left\{ \begin{array}{llll} 0.97 \cdot \dfrac{8.25}{8.4} & 0.98 & 0.98 & 0.90 \\ 0.97 \cdot \dfrac{8.25}{8.4} & 1.00 & 0.98 & 0.90 \\ 0.97 \cdot \dfrac{8.25}{8.4} & 1.00 & 1.00 & 0.90 \\ (\text{cGy/R}) \cdot \left(\dfrac{\Gamma_{\text{new}}}{\Gamma_{\text{old}}} \right) & (\text{filtration}) & (\text{attenuation/buildup}) & \left(\dfrac{\text{min}}{\text{stated}} \text{dose} \right) \end{array} \right\} \tag{34}$$

$$= \left\{ \begin{array}{l} 0.82 \text{ cGy radium needles} \\ 0.84 \text{ cGy cesium needles} \\ 0.86 \text{ cGy iridium ribbons} \end{array} \right. \left(\frac{\text{Modern cGy}}{\text{'P–P' R}} \right)$$

Using the 0.90 cGy/P-P R conversion factor, Stovall and Shalek[127] found excellent agreement between computer calculations and the P-P tables for a variety of planar and cylindrical implants following the Manchester distribution rules. For single-plane implants, 90% of the stated dose in cGy covers 94% to 99% of the target area. For cubic arrays of seeds using fixed 1-cm spacing, agreement between the tables and computer calculations is excellent for treatment volumes of more than 100 cm^3,[163,164] but results in errors ranging from 10% to 40% for smaller arrays. These discrepancies probably result from deviations from the 4:2 activity ratio and use of a dose-specification criterion incompatible with the Manchester system.

The classical implant systems are based on ^{192}Ir wires or interstitial needles, consisting of continuous distributions of radioactivity (i.e., line sources) with well-defined active lengths. To apply the classical systems to modern interstitial sources consisting of discrete equispaced seeds or single-stepping source dwell positions, the dosimetric equivalence between linear arrays of discrete seed sources and line sources must be appreciated (Fig. 25.18). An array consisting of N seeds with center-to-center separations, S, has a dose distribution that closely approximates that of a continuous line source of length, AL, and strength $(S_K)_{\text{line}}$[114,165]:

$$\left. \begin{array}{l} \text{AL} = \text{N} \cdot \text{S} \\ (S_K)_{\text{line}} = \text{N} \cdot (S_K)_{\text{seed}} \end{array} \right\} \tag{35}$$

This equivalence tends to break down at distances less than S/2: the cylindrical isodose curves break up into ellipsoidal shapes centered about each

seed. In addition, the ribbon isodose curves undulate significantly at distances comparable with or less than the gap, S, between adjacent seeds, although on average the equivalence remains accurate.

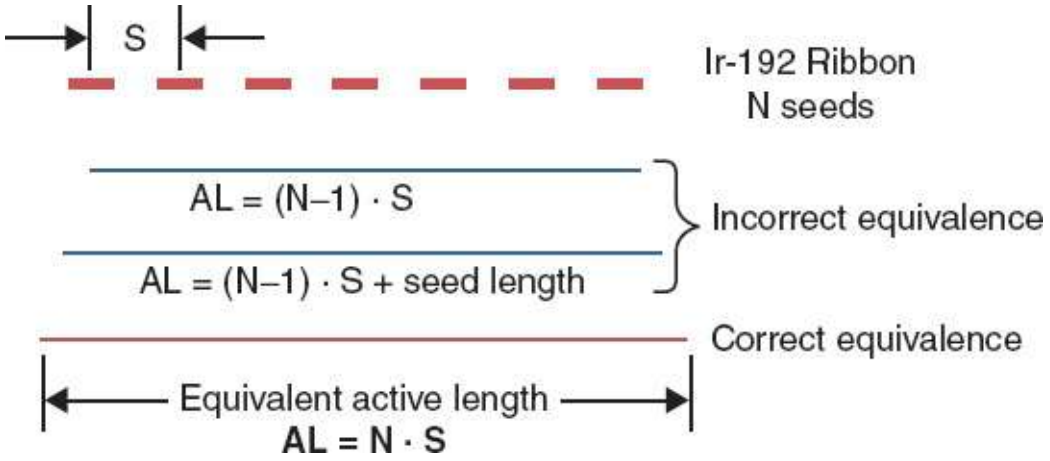

FIGURE 25.18. Relationship between a linear array of equally spaced discrete seeds and its dosimetrically equivalent line source. Both sources are assumed to have the same total strength. Common errors in defining this equivalence are illustrated.

Because the P-P system uses 1-cm interneedle spacing, the fraction of sources in the core (vs. periphery) increases as volume increases. Thus, using uniform-strength ^{192}Ir ribbons and fixed spacing results in underloading the core for very small implants and overloading the core for very large implants, relative to the P-P distribution rules. In the latter case, the gap between minimum peripheral dose and central maximum dose widens. An alternative to the differential loading method is to vary the ribbon spacing with implant size, using smaller (<1 cm) spacing for very small implants and larger spacing (up to a limit of 1.5 cm) for larger implants, so that the relative number of central ribbons complies approximately with the P-P rules, allowing uniform seed strengths to be used. Two examples of this strategy are given in the next section.

To use the Manchester tables for verification of computerized dose calculations requires a method for objectively identifying the computer-generated isodose surface that corresponds to the minimum peripheral dose rate predicted by the Manchester system. For volume implants, mean central dose (MCD), a quantity proposed by the ICRU Report 58 on dose specification in interstitial BT, is useful[166] (Fig. 25.19). In the authors' experience, the maximum dose (110% of stated dose) of the Manchester system is closely approximated by MCD. Minimum peripheral dose and stated dose are given by 80% and 89%, respectively, of MCD. For planar implants, the minimum dose/MCD ratio varies

from 55% to 70%, depending on catheter spacing and is of limited value.

Manchester Volume Implant Example

A 5-cm-high by 5-cm-diameter cylindrical target volume is to be treated using ^{192}Ir ribbons with seed-to-seed and intercatheter spacings of 1 and 1.3 cm, respectively (Fig. 25.20). Calculate the (a) minimum ribbon length needed, (b) the required ribbon arrangement, and (c) the strength/seed needed to deliver 45 cGy/h to the P-P minimum dose specification volume.

a. There are two approaches: treating the ribbons as needles with uncrossed ends or treating the proximal and distal seeds of each ribbon as crossing sources. In the uncrossed end approach, Eq. (33) implies that
AL = target length/0.925^2 = 5 cm/0.85 = 5.9 cm
Equation (35) implies that N = 6 seeds/ribbon are required.
In the crossed-end approach, the first and last seeds must be placed at the target volume surfaces, again requiring 6 seeds/ribbon.
b. To satisfy the 1.3-cm ribbon-spacing requirement, 12 ribbons must be placed on the cylindrical target boundary, 6 ribbons must be placed on an inner cylindrical surface, and there should be 1 central ribbon. Treating the ends as uncrossed and assuming that the ribbons have uniform strengths, the belt-to-core ratio is 0.63:0.37, which is close to the P-P 4:2 ratio. Again, assuming all seeds have the same strength, Figure 25.20 shows that the required crossed-end ratios are also closely approximated. This illustrates ribbon spacing can be manipulated to adhere to the P-P distribution rules with uniform strength sources.
c. Assuming the uncrossed end point of view:
TL = AL × 0.85 = (1 cm) × 0.85 = 5.1 cm
Treated (lookup) Volume = $\pi \times (2.5)^2 \times 5.1 = 100.1$ cm^3

Hence:

$$\frac{734\ \text{mg} - \text{h}}{1000'\text{P} - \text{P}'\text{R}} = \frac{734\ \text{mg} - \text{h}}{860\ \text{cGy minimum dose}} = \frac{1\ \mu\text{Gy} \cdot \text{m}^2}{0.162\ \text{cGy}}$$

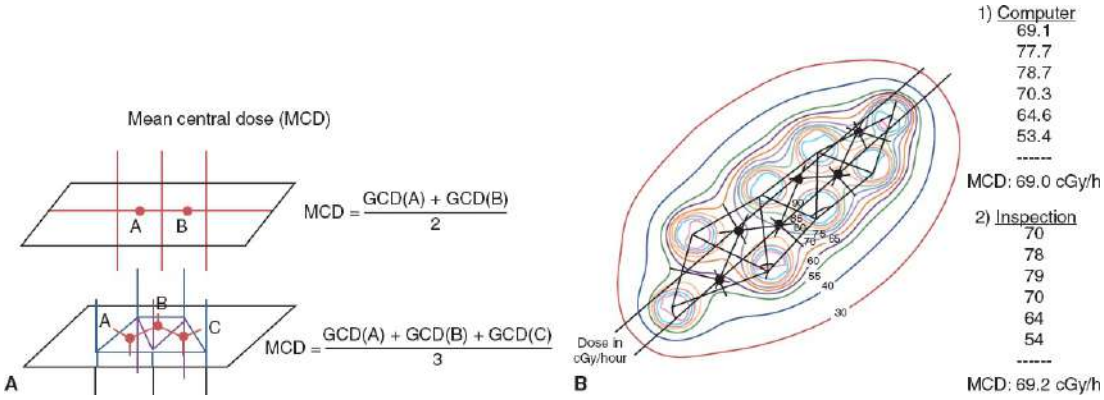

FIGURE 25.19. A: Calculation of mean central dose (MCD) as the arithmetic mean of the doses at mid-distance between each pair of adjacent sources for single-plane implants and the mean of the local minimum doses between each group of three adjacent sources in a multiple-plane implant. All local minimum doses are specified in the "central transverse" plane, which is normal to and bisects the source axes. Practical specification of MCD for a computer plan is illustrated in **(B)**.

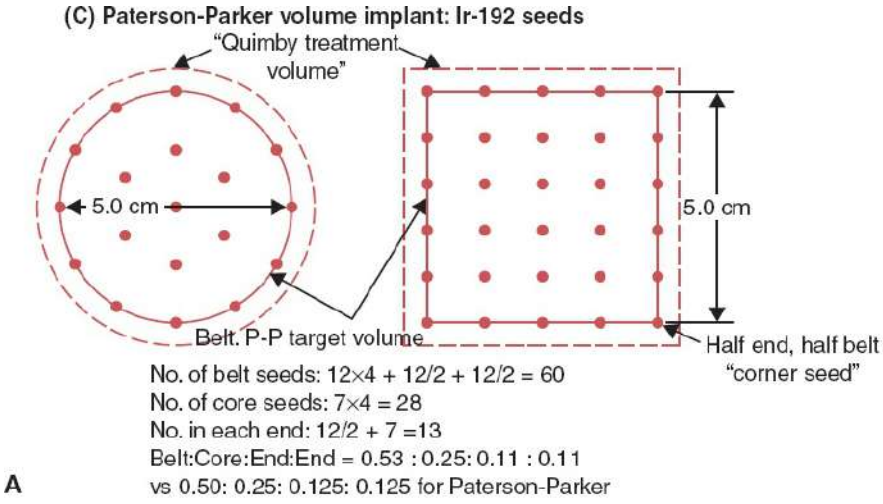

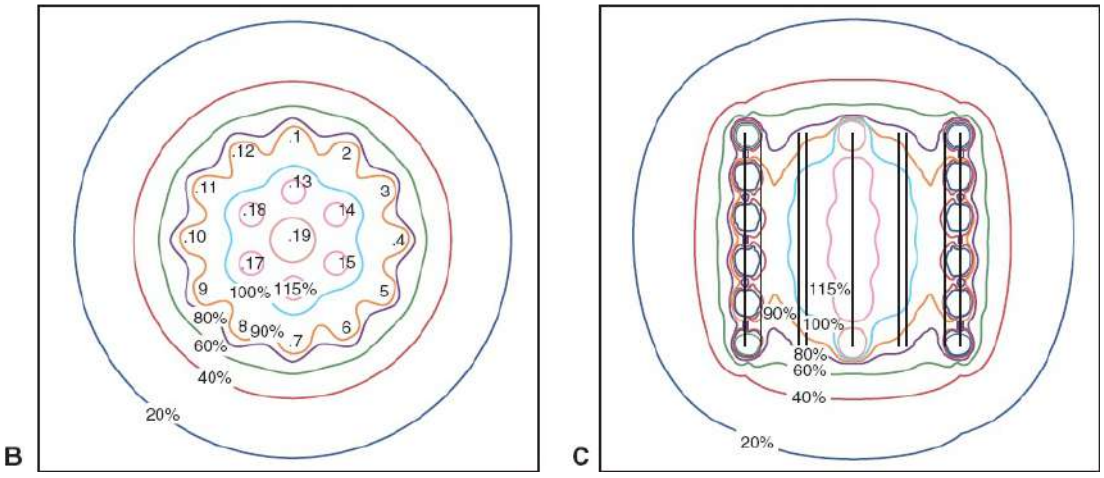

FIGURE 25.20. A: Cylindrical volume implant, example (*C*), using uniform-strength ^{192}Ir ribbons spaced at 1.3-cm intervals. Central transverse **(B)** and coronal **(C)**

isodose curves are plotted normalized to the mean central dose (MCD) = 58.9 cGy/h = 100%: 115% (68 cGy/h), 100% (59 cGy/h), 90% (53 cGy/h), 80% (47 cGy/h), 60% (35 cGy/h), 40% (24 cGy/h), 20% (12 cGy/h). Note that 80% of MCD, 47 cGy/h, agrees closely with the minimum peripheral dose rate of 45 cGy/h predicted by the Paterson-Parker tables.

Differential Loading:

$$S_{K/seed} = \frac{45\ cGy/h}{0.162\ cGy} \cdot \times \begin{cases} \frac{2}{3} \cdot \frac{1\mu\,Gy \cdot m^2}{12\,ribbons \times 6\,seeds/ribbon} = 2.6\,\mu\,Gy \cdot m^2 \cdot h^{-1}\ periphery \\ \frac{1}{3} \cdot \frac{1\mu\,Gy \cdot m^2}{7\,ribbons \times 6\,seeds/ribbon} = 2.2\,\mu\,Gy \cdot m^2 \cdot h^{-1}\ core \end{cases}$$

Uniform Loading:

$$S_{K/seed} = \frac{45\,cGy/h}{0.162\,cGy/h} \cdot \frac{1\,\mu Gy \cdot m^2}{19\,ribbons \times 6\,seeds/ribbon} = 2.4\,\mu Gy \cdot m^2 \cdot h^{-1}$$

The Quimby System

The Quimby system was developed by Edith Quimby and colleagues[167–169] at New York Memorial Hospital from 1920 to 1940. Unlike the Manchester system, equal linear intensity (mgRaEq/cm) needles are distributed uniformly (fixed spacing) in each implant. Like the Manchester system, the associated Quimby tables give the mgRaEq-h needed to deliver a stated exposure of 1,000 R as a function of target volume or area.

The so-called planar implant tables were intended for surface molds; none of the early Memorial publications suggest that it was used for single-plane interstitial implants. In part because Quimby's stated dose is the maximum dose in the treatment plane, Quimby planar implants deliver 30% to 40% less radiation (TRAK) per unit stated dose than an equivalent Manchester implant delivers. Rules for distributing radium needles (relationship to target-area boundaries, crossed ends, spacing, etc.) are not clearly described. Volume implant needle arrangements are similar to their Manchester counterparts; both systems recommend crossed ends and placing peripheral needles on or beyond the target-volume boundaries. However, Quimby allows the needle spacing to vary with implant size and specifies dose as the absolute minimum to the target

volume. The physical and mathematical origins of the widely cited Quimby volume implant table are obscure; the tables published in the 1951 edition of *Physical Foundations of Radiology*[168] deliver 25% to 90% more mgRaEq-h per unit dose than P-P volume implants of similar size. Because they are evenly spaced, uniform-strength sources approximate the Manchester distribution rules for medium-size volumes, and these differences are likely a result of differences in the definition of "minimum dose" used by the two systems. Although vague on the subject, Quimby appears to specify minimum dose at a point located 3 to 5 mm from the peripheral needles (and therefore outside the target volume) near their active tips.[169] This corresponds to a treatment volume (volume encompassed by prescription isodose surface) that is 6 to 10 mm larger than the implanted volume (used for table lookup) in each linear dimension. The Quimby planar and volume dose specification criteria are clearly inconsistent, and a detailed derivation of the associated tables is lacking. For these reasons, we do not recommend Quimby tables for clinical use.

The Paris System

The Paris system was developed in the early 1960s by Pierquin, Chassagne, Dutreix, and Marinello[170,171] and was motivated by the ^{192}Ir afterloading techniques developed by Henschke. Outside the United States, the Paris system is widely used for definitive BT of localized lesions in the head and neck, breast, and many other sites. An up-to-date summary of the system has been published by Gillin and coworkers.[172]

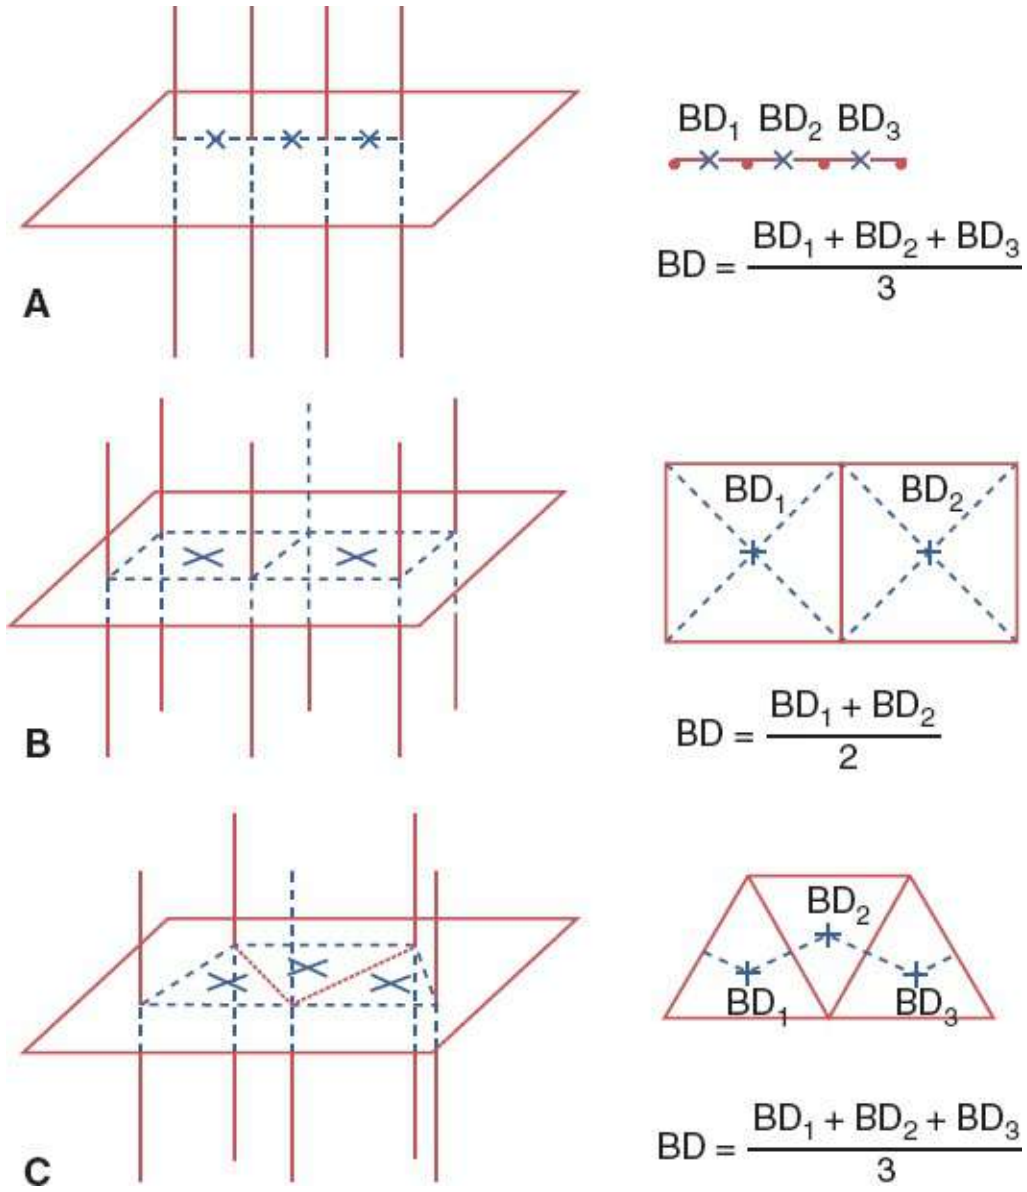

FIGURE 25.21. The three central plane configurations allowed by the Paris system: **(A)** single-plane implant, **(B)** double-plane implant using the pattern of squares; and **(C)** double-plane implant using the pattern of equilateral triangles. The calculation of basal dose rate at a point equidistant from each group of adjacent sources is illustrated for each configuration. (From Gillin MT, Albano KS, Erickson B. Classical systems II for planar and volume temporary interstitial implants: The Paris and other systems. In: Williamson JF, Thomadsen BR, Nath R, eds. *Brachytherapy physics*. Madison, WI: Medical Physics Publishing, 1995:232–343. Reprinted by permission of Medical Physics Publishing.)

The starting point of the Paris system is the definition of the target volume, which is described in terms of thickness (T), length (L), and width (W). The system provides rules for constructing implants, which, if followed, guarantee that the target volume is completely covered by the prescription isodose surface

(Table 25.10). The prescription dose level, called the "reference dose," is a fixed percentage (85%) of the basal dose (see Fig. 25.21), which closely resembles the more general concept of MCD in Figure 25.19. ^{192}Ir wire sources are arranged in parallel rectilinear arrays with their centers located in the central plane, which is perpendicular to the sources. Adjacent sources must be equidistant from one another, resulting in single-plane implants with equal spacing and double-plane implants with groups of adjacent sources arranged in equilateral triangles or squares in the central plane. The linear density (μGy·m^2·h^{-1}/cm) must be uniform and the same for all sources. Interneedle spacing scales with the thickness, T, of the target volume. The number of sources is determined largely by the relative shape of the target volume cross-sectional area, W × T. In contrast, the Manchester system uses fixed spacing and increases the number of sources as the cross-sectional area of the target volume increases.

Table 25.9 shows that the location of the peripheral sources relative to the treated volume (region encompassed by the reference isodose-rate surface, as shown in Fig. 25.22) differs from the Manchester system, which implants to the boundary of the treated tissue. In the transverse plane, the peripheral sources lie 2 to 4 mm (the lateral margin distance, M) inside the treatment surface, whereas longitudinally, the AL extends 15% to 20% beyond the distal and proximal margins of the target volume. In practice, the margin, M, is treated as a safety margin, and the peripheral needles are implanted along the margins of the clinical target volume (CTV). The maximum thickness, T, of a target volume treatable in the Paris system is about 2.5 cm. An example of a double-plane implant arranged in squares is shown in Figure 25.23.

TABLE 25.9 PARIS SYSTEM CHARACTERISTICS

Feature	Paris System Rules
Dose and dose rate	6,000–7,000 cGy in 3–11 d (25–90 cGy/h).
Dose specification criterion	Reference dose (prescribed dose) is 85% of the basal dose and encompasses the target volume when distribution rules are followed. Basal dose is the average of the minimum doses between pairs or groups of adjacent sources in the central transverse plane.
Dose gradient	Fixed 15% gradient between reference dose and basal dose. The "hyperdose sleeve" (region receiving at least twice the reference dose) diameter should be <8–10 mm.
Linear activity	Constant (4–14 μGy m^2·h^{-1}/cm) linear density Ir-192 wires used.
Source arrangement geometry for target volume of thickness,	Only single- and double-plane implants allowed. Spacing, S, and lateral margin (called "safety margin" for double-plane case), M, are fixed fractions of T and constant within a given implant. Active

width, and length of T × W × L	length, AL, is a fixed fraction of L, which varies with S. *Single plane:* T = 12 mm S = 2 × T (2 sources) S = 1.67 × T (3 sources) M = 0.37 × T AL = (1.3 − 1.49) × T *Double plane:* (square pattern) (triangle pattern) S = 0.62 × T S = 0.77 × T M = 0.27 × T M = 0.15 × T AL = (1.37 − 1.62) × L AL = (1.33 − 1.49) × L
Source spacing, S, limits	Short sources (1–4 cm): Long sources (≤10 cm): 15 mm ≤ S ≤ 22 mm
Crossing needles	Generally not used; AL ~1.45 × L to compensate for uncrossed ends. For oral cavity implants, hairpins are common, which approximate crossed ends.
Relation between target volume and implanted volume	W = distance between outermost sources + 2 × M L = (1.3 − 1.62) × L $T = \begin{cases} S/1.67 & \text{Single plane} \\ S + 2 \times M & \text{Double plane : squares} \\ S \times \cos 30° + 2 \times M & \text{Double plane : triangles} \end{cases}$

To apply the Paris system, the target thickness T must be known, which defines the spacing and determines whether single-plane or double-plane geometry is required. The number of sources and selection of a square or triangular arrangement are defined by the relative cross-sectional shape of the target volume in the central plane perpendicular to the sources. Finally, the active length is calculated. The source tip and end coordinates are reconstructed from orthogonal radiographs, and the dose distribution and basal dose are calculated by computer for the actual implant geometry realized in the patient, not the idealized implant of clinical intention. This approach differs from the classical Manchester method, which bases dose prescription on the P-P table and, in general, ignores deviations of the actual implant geometry from the ideal. The Paris system addresses only single- and double-plane implants; large-volume implants for treating pelvic masses and brain tumors were not part of the original system. Extensions of Paris system principles to large-volume implants are discussed by Leung[173] and Gillin and coworkers.[174]

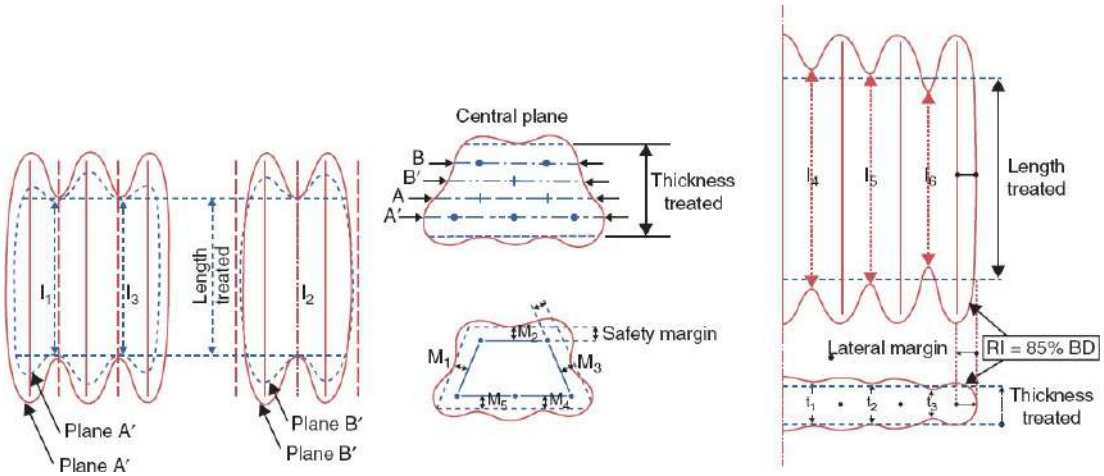

FIGURE 25.22. Relationship of the reference isodose, source locations, and target-volume dimensions for each of the basic implant configurations allowed by the Paris system. The concept of safety margin (lateral margin, M) is illustrated. (Adapted from Pierquin B, Wilson JF, Chassange D. Modern brachytherapy. New York: Masson, 1987.)

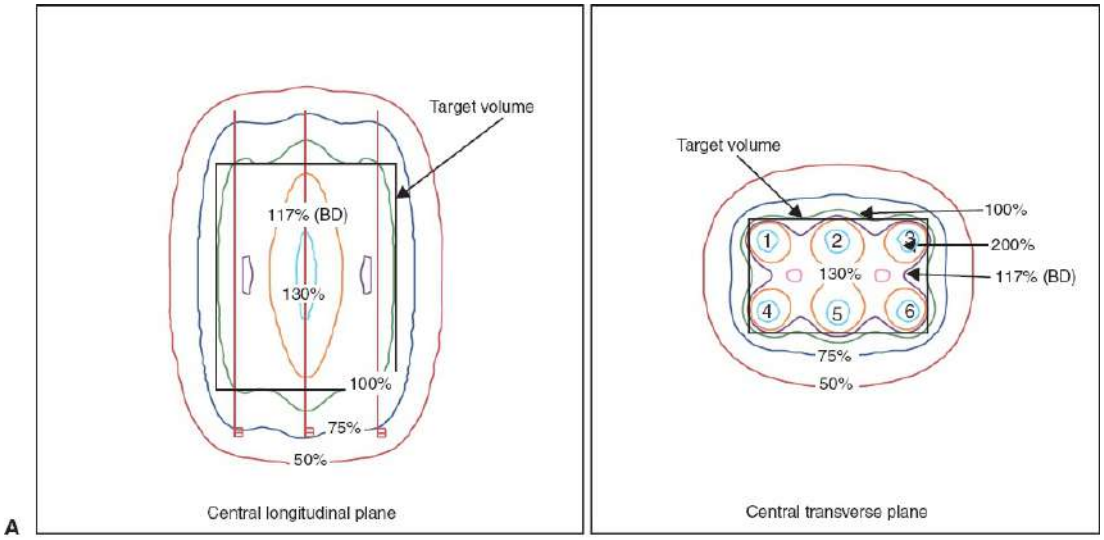
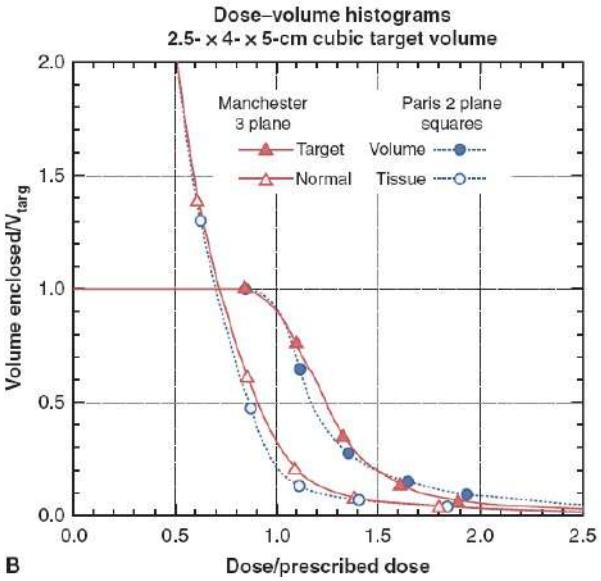


A



B

FIGURE 25.23. A: Isodose curves of a Paris system double-plane implant arranged "in squares" to treat a 2.5-cm × 4-cm × 5-cm target volume (*heavy lines*).The separation and active lengths of the ^{192}Ir wires are 1.6 and 7.3 cm, respectively. A linear strength of 6 μGy·m^2·h^{-1}/cm gives reference (100%) and basal (117%) dose rates of 60 and 70.6 cGy/h, respectively. **B:** Comparison of dose/volume histograms (DVHs) calculated separately for the 2.5-cm × 4-cm × 5-cm target volume and the tissue outside the target for the Paris implant shown and a Manchester implant consisting of 3 planes, 15 ^{192}Ir ribbons with 6 seeds each, and 1.25-cm spacing between planes and ribbons. Each graph shows volume of tissue (in multiples of volume of the target) receiving at least the specified dose (in multiples of prescribed dose). For the Paris and Manchester implants, respectively, the prescribed dose is calculated reference dose and minimum target dose predicted by the Paterson-Parker volume table. In both systems, the prescription isodose surface covers about 90% of the target. Surprisingly, both normal tissue sparing and dose homogeneity in the target are slightly better for the Paris implant.

Dose Specification in Interstitial Brachytherapy

Many of the differences between the Manchester, Paris, and Quimby systems can be attributed to fundamental differences in dose specification. Because of the high-dose gradients near the peripheral sources or the target volume boundary, reproducible specification of dose and evaluation of implant quality are difficult. Conversely, small differences in dose-specification criteria can lead to large differences in treatment time or in the geometric relationship between implanted and treated volume. The term “dose specification” means objective identification of a spatial volume or location for evaluating absorbed dose for the purposes of prescription (defining the dose that the radiation oncologist intends to deliver), for describing the quantity of radiation actually delivered to the patient, or for reporting. The “specified dose” sometimes is called “reference dose.” The dose that an implant actually delivers to the patient, based on postinsertion treatment planning, may differ significantly from the dose prescribed for a variety of reasons. For example, anatomic or technical constraints may preclude accurate positioning of sources at their intended locations, resulting in a partial geometric miss or underdose of the specified volume. Dose specification for reporting purposes usually refers to efforts to develop reproducible and system-independent specification schemes to promote comparison of different implantation systems so as to minimize patient-to-patient and operator-to-operator variability in level of treatment delivered. The ability to objectively compare different interstitial implant plans as to target volume coverage, normal-tissue sparing, and dose homogeneity depends on dose specification. Several divergent and rather abstract approaches to dose specification have been developed and promoted by various national and international advisory groups; no single approach to dose specification has been widely accepted within the BT community.

Minimum Dose to an Anatomically Defined Target Volume

The minimum dose to the anatomically defined target volume harboring malignant cells is conceptually attractive because it is based on the intuitively satisfying premise that local tumor control will be determined by the minimum dose received by tumor cells. The American Brachytherapy Society (ABS)[175] recommends that minimum dose should be identified as accurately as possible by the best means available and should be used for dose prescription, evaluation, and reporting. In practice, minimum target dose specification is difficult to implement clinically for many implants. In the prostate BT literature,[176]

minimum target dose usually is called “minimum peripheral dose,” or mPD, when used for implant preplanning prescription and D_{100} (see discussion on dose/volume histograms) when used for postimplant dose evaluation. When imaging data showing the target volume in relation to the sources is not available, the ABS recommends approximate target localization by means of intraoperatively placed surgical clips, orthogonal planar imaging, or measurements relative to peripheral sources. A clear disadvantage of minimum dose specification is that the target-volume surface lies within the zone of the largest dose gradient. This can result in large patient-to-patient fluctuations in the central-to-specified dose ratio because of small variations in the peripheral source locations relative to the apparent target boundary or uncertainties in delineating the target volume. As discussed in the “Permanent Implantation” section, reviews of CT-based prostate implant dose evaluations show that absolute minimum delivered doses (D_{100}) relative to the prescribed dose show large patient-to-patient variabilities and average 30% to 60%.[177,178] The minimum dose covering at least 99% (or 95%) of the target volume was found to be much less sensitive to small changes in the peripheral seed locations or uncertainties in the target volume surface location.

Minimum Implant Dose Relative to Sources

Traditional treatment planning uses planar radiographs for 3D reconstruction of radioactive source positions, yielding accurate dose estimates relative to the sources but not relative to an anatomic target volume.[24,179] Thus, it is natural to prescribe treatment to a point or surface that has a fixed relationship to the peripheral sources. The minimum implant dose, or MID, is the minimum dose received by the “target” volume defined relative to the implanted volume, the smallest regular geometric shape circumscribing the peripheral sources. Often, this specification volume is taken to be that volume that is 2 to 5 mm larger in each linear dimension relative to the implanted volume, as in the Paris and Quimby systems. Prior to acceptance image-guided BT, MID was perhaps the most widely used specification approach and is the basis of the classical systems and the US practice of selecting prescription isodose surfaces from 2D isodose curve plots. However, MID yields information about tumor coverage only to the extent that the radiation oncologist has implanted peripheral sources at known distances from the anatomic target volume boundaries. In addition, MID lies in the zone of maximum dose gradient and can be difficult to evaluate objectively for an implant of irregular shape, again leading to large patient-to-patient

variations and variations in the central-to-prescribed dose ratio. The Paris and Manchester systems eliminate the possibility of subjective isodose selection by rigidly specifying dose rate by means of basal dose rate and implant tables, respectively.

Mean Central Dose

The ICRU report on dose specification in interstitial BT[166] emphasizes reporting mean central dose (MCD; see Fig. 25.19), although it recommends reporting the prescribed dose, the peripheral dose (minimum target dose), and a description of dose uniformity as well. MCD specifies dose in the low-gradient regions located between adjacent source locations in the central plane of the implant. Thus, MCD is relatively free of the variability inherent in minimum peripheral or target dose specification. It is a generalization of the Paris system basal dose. As a reporting parameter, MCD can be reproducibly estimated from 2D central transverse-plane isodoses and should be very useful for comparing implants performed using different clinical systems. However, for systems other than the Paris and Manchester systems (which rigidly specify how sources are to be arranged relative to the target volume), MCD does not have a known relationship to minimum peripheral or target dose. Thus, its value as a prescription parameter is limited.

3D Dose/Volume Histogram Representations

Dose/volume histograms (DVHs) are 1D plots that describe the distribution of tissue volumes, V, irradiated by the implant with respect to dose, D. DVHs can be presented in either differential, $\Delta V(D)/\Delta D$, or cumulative, V(D), forms. DVH computation involves calculating dose over a fine 3D grid extending at least 2 cm beyond the peripheral seeds, dividing the dose axis into small bins of width ΔD, and then counting the number of voxels falling into each dose interval. The cumulative DVH gives the volume of tissue, V(D), receiving a dose of at least D.

DVHs can be evaluated for specific anatomic regions (e.g., target and normal tissue as illustrated by Fig. 25.23) or can be evaluated for tissue irradiated by the implant without regard to anatomic boundaries. For bounded volumes, V(D) is flat below the minimum dose received by the structure. When evaluated over unbounded space, V(D) steeply increases with decreasing dose and asymptotically approaches the central point-source DVH, $V_{\text{point}}(\dot{D}) = (4\pi/3) \cdot [S_K \cdot \Lambda / \dot{D}]^{3/2}$. The use of DVHs has enriched discussions of

dose specification by focusing attention on describing the 3D dose distribution rather than on single parameters. However, in the absence of target volume and normal-tissue geometry, DVHs in themselves do not solve the dose-specification problem.

Because 3D anatomic models were often lacking until recently, several figures of merit (FOMs) derived from DVHs have been proposed that do not require an anatomically defined target volume. Such FOMs may be useful for ranking the quality of competing implant geometries in terms of uniformity and normal-tissue sparing or for optimally selecting a specification dose rate for a given implant geometry. An important contribution is the "natural" DVH introduced by Anderson.[180,181] The natural DVH is a plot $\Delta V(u)/\Delta u$ where $u = D^{-3/2}$. The natural DVH plots as a horizontal line for a central point source. It suppresses r^{-2} effects, which dominate the conventional V(D) plot, making its detailed implant geometry–specific structure more evident. Low and Williamson[182] introduced an alternative modified DVH, $R_p(D) = V_{impl}(D)/V_{point}(D)$. Both of these modified DVHs show a sharply defined peak centered about MCD, the width and height of which quantify the volume of tissue receiving an approximately uniform dose. Other useful quality measures include the uniformity index[183] and the dose nonuniformity ratio (DNR).[184] The DNR, usually plotted as a function of reference dose, D_r, is defined as the ratio of volume receiving a specified multiple of D_r (usually 1.25 or 1.5) to that receiving at least D_r.

Target-volume–dependent DVH quality indices were introduced into brachytherapy by Saw and Suntharalingam.[185] For single- and double-plane implants designed to cover specified cubic target volumes, respectively, they defined three indices as a function of reference dose D_r. The coverage index, $CI(D_r)$, is that fraction of the target tissue receiving a dose greater than or equal to D_r. The homogeneity index, $HI(D_r)$, is the fraction of target volume receiving doses between D_r and 1.5 D_r. The external volume index, $EI(D_r)$, is the volume of tissue outside the target volume, expressed in multiples of the target volume, receiving dose rates greater than or equal to D_r. When these indices are plotted (Fig. 25.24), the trade-offs among these clinical end points are evident. If a prescription dose rate is selected to maximize dose homogeneity (i.e., maximize HI), then 85% to 95% coverage of the target must be accepted. To minimize irradiation of tissue outside the target, both target coverage and dose homogeneity must be compromised. Low and Williamson[182] suggested ranking

competing implant geometries by specifying the HI achieved for the maximum reference dose level that yields a CI of unity.

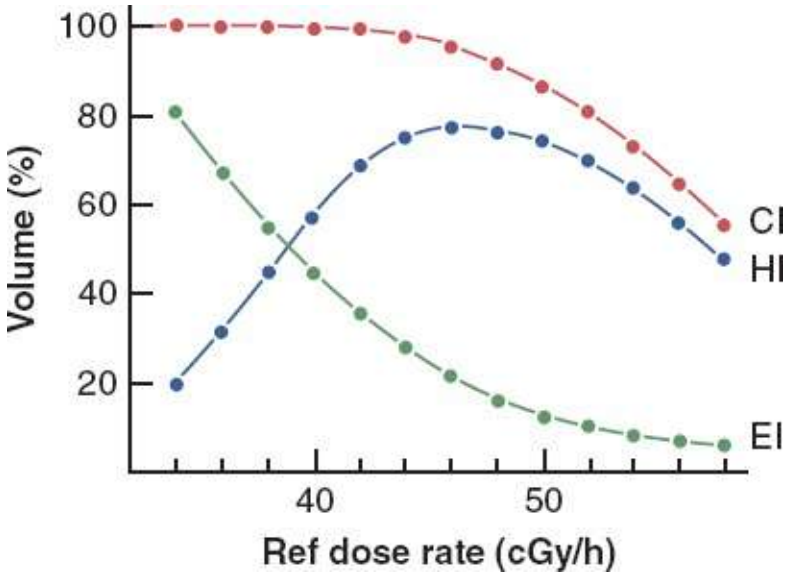


FIGURE 25.24. Plot of coverage index (CI), external index (EI), and homogeneity index (HI) as a function of reference dose rate for double-plane implant consisting of five ^{192}Ir ribbons with seven 1-mCi seeds in each plane and a 6-cm × 6-cm × 2.5-cm target volume. Ribbon and plane spacings of 1.5 cm were used. (From Saw CB, Suntharalingam N. Reference dose rates for single and double plane ^{192}Ir implants. *Med Phys* 1988;15[3]:391–396. Copyright © 1988 American Association of Physicists in Medicine. Reprinted by permission of John Wiley & Sons, Inc.)

For TRUS-guided prostate implantation, DVH metrics such as D_{100}, D_{99}, and D_{90}, denoting the minimum doses administered to the highest dose volumes covering 100%, 99%, and 90% of the contoured CTV or PTV (planned target volume), respectively, have become widely accepted as reporting parameters.[186,187] Volumetric indices, such as the V_{150}, V_{100}, and V_{90}, which denote the fraction of the CTV or PTV receiving at least 150%, 100%, and 90%, respectively, of the prescribed dose, are recommended to assess dose homogeneity and to assess adequacy with which the prescription has been fulfilled.

Permanent Implantation

In contrast to temporary implantation, in which treatment time is varied to control the total dose delivered, the dose delivered by a permanent implant is determined by the initial geometric arrangement of sources and *SK* per source: once the patient is implanted, neither the total dose delivered nor the relative

distribution can be modified easily. Up through the mid-1980s, manual planning and dose-calculation tools were used widely to estimate the number and density of sources needed to deliver the prescribed dose or to intraoperatively correct for deviations between the planned actual source locations. For radium-substitute sources (e.g., ^{198}Au), the Manchester, Laughlin,[163] or Shalek[164] tables and associated distribution rules have been used for this purpose. Although 3D treatment planning and dose calculation have replaced manual preplanning tools, manual aids are still widely used for verifying the correctness of patient treatment plans.

Manual planning aids for high-energy sources cannot be applied to low-energy seed (^{125}I and ^{103}Pd) implants because of the importance of tissue attenuation in this energy range. The influence of photon energy on the relationship between dose rate, $\dot{D}$, and implanted volume, V, is illustrated by Figure 25.25. Parker[158] recognized that this relationship can be described accurately by a power-law formula, of the form:

$$\dot{D} = \alpha \cdot S_K \cdot V^{-\beta} \qquad (36)$$

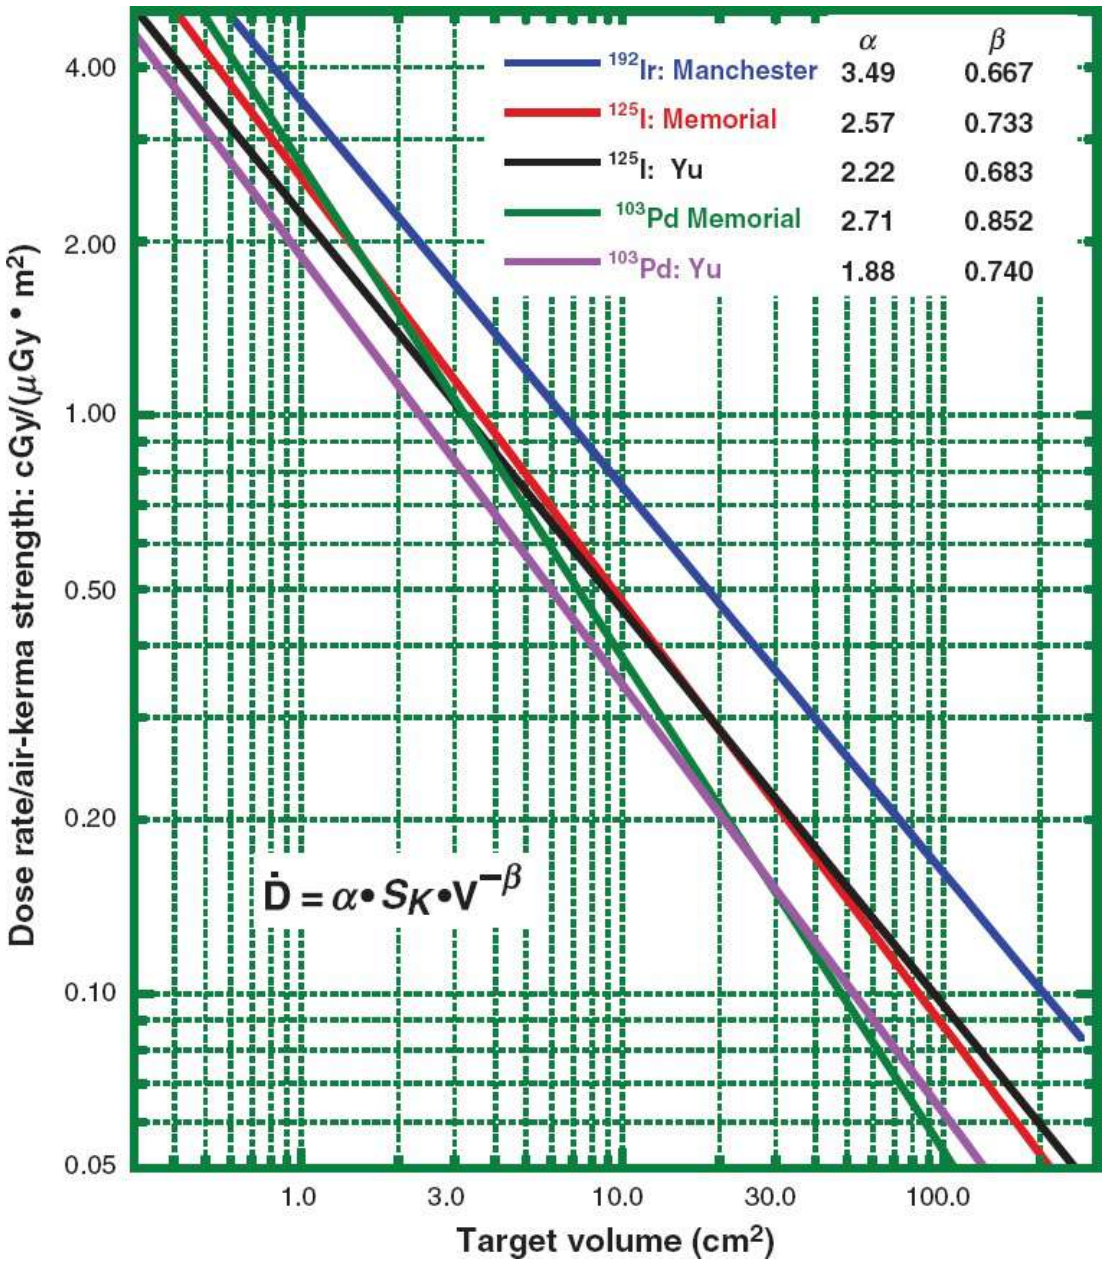

FIGURE 25.25. Comparison of reference dose rate per unit air-kerma strength versus volume of the target volume for Manchester volume implants and ^{103}Pd and ^{125}I permanent prostate implants. The inset gives the exponents and proportionality constants needed to describe these relationships in terms of a simple power law Eq. (36). The data in the figure are from the following references: Yu,[188] Memorial,[189] and Manchester.[158]

In fact, the original Manchester table (Table 25.8), converted to modern units and quantities, can be derived from Eq. (36) by setting α = 3.49 and β = 2/3. Although ^{103}Pd and ^{125}I volume implants also can be described by the power law formula, they have somewhat larger exponents, β, demonstrating that dose rate

falls off faster with increasing volume than for radium-substitute sources.[188,189] The proportionality constants, α, are substantially lower, indicating that low-energy seed implants require higher source strengths to achieve a stated dose rate. The author-to-author variations in α values for the same radionuclide are due, in part, to differences in dose specification and implant construction. Anderson's analysis,[189] based on the pre-TRUS era Memorial nomogram, assumes that dose is specified in terms of matched peripheral dose (MPD) and that all seeds are implanted 2 to 5 mm inside the target (prostate) boundary, whereas the Yu nomogram assumes[188] that peripheral seeds are implanted on or outside the boundary and that minimum target dose is specified. Before using a nomogram or lookup table for QA checks or preplanning, readers should assess carefully its consistency with dose calculation and planning methods used in their clinical practices.

The best-known manual planning tool for permanent ^{125}I implantation is the Memorial dimension averaging method.[189,190] The associated nomogram was used for manual intraoperative planning of implants delivered by directly implanting seeds into the surgically exposed prostate retropubic approach. After surgical exposure of the target volume (prostate), the three orthogonal dimensions of target volume are measured, and the arithmetic mean of these measurements, or average diameter, d_a, in units of centimeter, is calculated. Next, the total apparent activity, A_{app} (in mCi units), to be implanted is calculated as follows:

$$A_{app} = \begin{cases} 5 \cdot d_a & d_a < 3 \text{ cm} \\ 1.34 \cdot d_a^{2.2} & d_a \geq 3 \text{ cm} \end{cases} \tag{37}$$

By means of a nomogram consisting of several juxtaposed logarithmic scales, the total number of seeds needed is estimated graphically given the strength per seed. Other nomogram scales were used to estimate the spacing between needles given the seed spacing along each needle track. The seeds are to be implanted inside the target-volume boundary, such that peripheral needle-to-target boundary distance is <50% of the interneedle spacing.

The calculation method is designed to deliver an MPD of 160 Gy over the life of the implant when d_a is more than 3 cm.[189] MPD is defined as the dose level whose corresponding 3D isodose surface encompasses a volume, V_E, equal to that of an ellipsoid having the same orthogonal dimensions as the originally measured target volume ($V_E = \pi d_x d_y d_z/6$). For a given implant, MPD is derived

from the corresponding cumulative DVH, V(D), according to $V_E = V(MPD)$. By design, the Memorial nomogram delivers significantly higher MPDs to target volumes with average dimensions <3 cm. Prescribed doses of 160 Gy delivered in the 1985 to 1999 era correspond to doses of 144 Gy when corrected for implementation of the WAFAC primary standard and Task Group 43 dosimetry parameters.[155] The MPD overestimates minimum target dose (mPD) because the prostate gland is rarely ellipsoidal and has small protrusions that may extend outside the MPD isodose surface. Likewise, small deviations of the peripheral seeds from their planned locations can alter dramatically the shape of the MPD isodose surface. One study[191] found that, on average, MPD was twice the D_{99} level (the dose ensuring 99% target coverage on postoperative CT imaging) and that only 69% to 89% of the target volume received a dose equal to or greater than MPD.

Modern Developments in Interstitial Brachytherapy

Model-Based Dose Calculation

As noted earlier, the TG-43 source-superposition algorithm[5] assumes that patients consist of uniform liquid water, ignoring tissue-composition inhomogeneities, seed-to-seed attenuation, and applicator-shielding effects. The effects can be significant ranging from a few percent to a factor of 2. For ^{192}Ir brachytherapy, tissue composition heterogeneities introduce relatively small dose perturbations. However, both Monte Carlo and deterministic model-based dose calculations demonstrate skin contours (missing scatter volume) and can reduce skin and rib doses by 4% to 8% for breast brachytherapy,[192] whereas shielded vaginal applicators can reduce bladder and rectal doses by 8% to 25%.[193,194] In contrast, doses delivered by low-energy permanent seed BT and EBT are very sensitive to deviations of target tissues and organs at risk from water equivalence, since photoelectric dominates energy deposition in this energy range. Using standard ICRP[195] bulk tissue compositions for prostate tissue, Carrier et al.[196] found that TG-43 underestimated D_{90} from ^{125}I seed implants by 9% relative to Monte Carlo studies, with 18/28 prostate cancer patients showing a 10% effect or more. Calcifications as small as 1% to 2% of the prostate mass perturb DVH metrics by as much as 35%.[197] Even larger and highly variable (4% to 50%) deviations of Monte Carlo D_{90} estimates from corresponding TG-43 estimates[198,199] were found for low-energy seed breast implants, because the breast tissue consists of a mixture of adipose and glandular tissues which varies significantly from patient to patient.

To address the potentially large impact of tissue and applicator heterogeneities on brachytherapy dose evaluation, sophisticated model-based dose calculation algorithms have become available.[6] Monte Carlo simulation is the most widely investigated methodology. Because Monte Carlo simulation statistical uncertainty is proportional to the square root of computing time, the computing times (several hours or even days) associated with general purpose codes used for dosimetry have limited Monte Carlo–based treatment planning[200] to the experimental setting. However, with advances in hardware and sophisticated variance reduction techniques,[201] this logistic barrier has been effectively overcome. As early as 2005, single-processor calculation times of the order of a minute for clinical prostate seed implants were reported.[197] Even faster specialized BT codes have been introduced, including a fast correlated sampling code[199] and an efficient EGSnrc-based planning code.[202] Other groups have investigated deterministic transport solutions, mainly discrete ordinates codes[203] (also called "grid-based Boltzmann solvers" or GBBS by some investigators) or heuristic 3D algorithms based on superposition/convolution of scatter dose point kernels.[150,204] Interestingly, planning software vendors have gravitated toward deterministic rather than Monte Carlo solutions. Varian Medical Systems has integrated a discrete ordinates dose-calculation engine (ACUROS)[156,205] into its BrachyVision HDR planning system, the first commercially available BT dose-calculation engine based on a rigorous radiation transport solution. Elekta Brachytherapy (formerly Nucletron) has incorporated an Advanced Collapsed-Cone Engine (ACE) algorithm[150,206] into its planning system, which was adapted from the external beam collapsed-cone scatter-superposition/convolution algorithm.[207] To guide early clinical adopters of the rapidly emerging model-based dose-calculation technology, the AAPM has published a major guidance document, the Task Group 186 Report.[6]

Temporary Interstitial Implant Developments

A major development of the last two decades is a pronounced shift from LDR manual afterloading to HDR BT. Single-stepping HDR source remote afterloading (see Chapters 26 and 27 for a detailed treatment) allows the treatment time (dwell time) to be individually specified at each treatment (dwell) position in the catheter. This permits the use of dwell-weight optimization as a tool for improving dose uniformity and target coverage within implants. In contrast to the classical systems, which assume that ribbons and needs are of uniform linear density, dwell-weight optimization supports far more elaborate

nonuniform source-strength distributions than those envisioned by the Manchester system rules. The published experience, confined largely to Paris-like double-plane breast implants, demonstrates that geometric optimization[208] preferentially increases the dwell times at dwell positions near the catheter ends. The most striking finding is that optimization allows the active-to-target length (AL/TL) ratio to be reduced from 1.33–1.5 to 1.1–1.25.[209–211] In the transverse plane, target coverage remains unchanged, whereas dose homogeneity is improved modestly, depending on the figure of merit used to quantify this effect. When dose-point optimization (specifying dose constraints at dose calculation points throughout the treatment volume) is used, acceptable dose homogeneity results with even smaller AL/TL ratios, even when all peripheral dwell positions are placed inside the target volume (AL/TL = 1.0)[182,212] for idealized volume implants and clinical volume implants.[210] These early efforts did not address the practical problem of how to distribute dose constraint points in clinical volume implants with irregular catheter spacings and how to select dwell positions to be activated in each catheter. While dwell-weight optimization techniques have the potential to reduce AL/TL ratios to near unity with good CI and HI, it is influenced by the direction and location of the catheters relative to the target, and thus requires distribution rules drawn from the classical systems or one's own clinical experience.

The use of 3D imaging to preplan implants or intraoperatively guide catheter or seed insertion is growing rapidly. The most widely practiced form of image-guided BT is the use of intraoperative TRUS to guide transperineal insertion of needles used to implant the prostate gland with low-energy seeds.[48,49] However, image-guided implant methodologies have been developed for HDR multicatheter interstitial.[213] and balloon-applicator intracavitary[214] implants for APBI following lumpectomy and HDR interstitial implantation for prostate cancer.[215] All of these approaches require delineation of the target volume and critical structure surfaces from 3D imaging studies. Then, catheter or needle trajectories and, ultimately, seed or dwell position locations can be selected to improve target-volume coverage while minimizing unnecessary dose to critical structures. The issues involved in utilizing image-guided and image-based BT in HDR interstitial brachytherapy, including treatment planning, selection of imaging modality, and impact on clinical workflow, are covered in detail elsewhere.[179]

As practiced by most brachytherapists, image-guided, intraoperatively planned implants continue to rely on the planner's judgment for selecting source

locations. These decisions are guided by a “loading approach,” or set of guidelines that specify margins, seed locations relative to the target boundary, spacings, and approximate periphery-to-core loading ratios.[216,217] Dose calculations and DVH quality indices often are used to guide manual source position adjustments to improve target-volume coverage, improve dose homogeneity, and select source strengths (or dwell times) and the prescription isodose.

An important advance upon standard dose-point optimization is anatomy-based optimization in which constraints and treatment goals are defined in terms of doses to the CTV or normal tissues contoured from 3D imaging studies rather than surfaces defined relative to dwell positions. The simulated annealing HDR dwell-time optimization technique developed by Lessard and Pouliot[218] illustrates the general features of the various optimization approaches[219–222] that have been brought to bear on this problem (see Ezzell’s review[223] for a highly readable introduction to BT optimization techniques). An objective function, consisting of penalty factors summed over dose calculation points in the CTV, urethra, rectum, and other organs, is minimized. The penalty factors are functions that, by increasing in value, penalize candidate dose distributions deviate from constraints and planning goals specified by the planner. The inverse planning technique of Pouliot and colleagues[218] reduces CTV dose heterogeneity (V150 of 29% vs. 50%) and urethral doses in clinical prostate implants compared to geometric optimization[224] and solves the problem of selecting active dwell positions and locations for dose constraint points faced by the older dose-point optimization algorithms. Although anatomy-based inverse planning does not optimize catheter trajectories, its proponents argue[225] that it reduces the dependence of implant quality on the number and accurate positioning of the catheters relative to the CTV boundary. If true, inverse planning could reduce the dependence of implant quality on operator skill and reduce the need to follow system-based needle-insertion rules.

In summary, computerized dose calculation, dwell-weight optimization, and image-guided BT have made anatomy-based dose specification and meaningful implant optimization a reality in some clinical settings. However, as currently available, these innovations still require users to conceptually plan implants in terms of specified source and needle-distribution patterns, implant-target-volume margins, and loading ratios. Specific rules borrowed from the classical systems (e.g., AL/TL ratios) may require significant modification when adapted to these modern technologies.

Permanent Implant Developments

The most important advance in permanent implantation in the last two decades is the rise of image-based and image-guided techniques in prostate BT, currently its only widely practiced indication. The retropubic approach has been abandoned in favor of the transperineal approach using intraoperative TRUS,[48,226] which typically consists[179] of (a) preplanning using a TRUS examination, or "volume" study, obtained 2 to 3 weeks before the scheduled implant; (b) inserting the needles using interactive real-time TRUS imaging; and (c) followed by CT-based postprocedure planning 0 to 30 days after the procedure. During preplanning, the PTV often is defined as the contoured prostate gland plus a discretionary margin. Most brachytherapists practice some form of peripheral loading to improve uniformity and reduce dose to the urethra. For example, the modified uniform loading as defined by Butler[216] distributes about 75% of the source activity in the periphery and emphasizes insertion of peripheral needles on or near the PTV boundary. Typically, needle locations and seed strengths are manipulated to achieve a prescribed minimum target dose (mPD or $D_{100\%}$) of 145 Gy for ^{125}I monotherapy. For ^{103}Pd monotherapy, the ABS[227] recommends retaining the prescribed dose of 125 Gy (compared to 115 Gy used before 2000) following implementation of the NIST $S_{K,N99}$ standard and recently revised TG-43 parameters, based on the AAPM's most recent analysis[155] of ^{103}Pd prescribed-to-administered dose ratios because of changes in calibration standards and dosimetry practice.

Dose specification, for recording and reporting doses actually administered by a permanent implant, is based on postimplant dose evaluation.[176] Following the implant procedure, a CT exam is obtained; the prostate gland, rectum, and bladder are contoured; and the seed locations are identified from the transverse images. The choice of dose-specification parameter for this purpose has been the subject of intense investigation. Based on analysis of both idealized and actual implants, Yu and colleagues[188] found that the postinsertion D_{100} was very sensitive to small random displacements of the seeds from their intended positions, which resulted in underdoses of 15% or more to small volumes in the target periphery. However, they found that the mPD of the idealized implant (no seed displacement) covered at least 90% of the target (i.e., $D_{90} \geq$ mPD and $V_{100} \geq 90\%$), even in the face of 6-mm seed displacements. In a study of 60 consecutive implant patients, Merrick and associates[177] found mean V_{100} and D_{90} values of 94% of the CT prostate volume and 108% of the prescribed dose

(mPD of preplanned implant), respectively. Of the patients, 82% had a D_{90} exceeding the preplanned mPD and no patient had a D_{90} smaller than 90% of mPD. In contrast, D_{100} was only 68% of the prescribed mPD, on average. Two groups[228,229] have found a correlation between prostate-specific antigen (PSA) relapse-free survival at 4 years and D_{90}. In particular, Potters and colleagues[228] found a D_{90} dose–response cutoff of 90% of the prescribed dose but could find no statistically significant cutoffs for D_{100} and V_{100}.

An important contemporary development is "intraoperative planning"[179,230] in which TRUS-based planning (and postimplant dose evaluation as well, in some implementations) is performed during the procedure itself rather than on a volume study acquired weeks before. Intraoperative planning eliminates uncertainties due to differences in planning and treatment anatomy due to probe positioning errors, impact of hormone ablation, or external beam therapy. An extension of intraoperative planning is dose-guided implantation[179,231] or "dynamic dose planning,[232]" in which intraoperative planning is repeated one or more times during the implantation procedure, thereby allowing optimized insertion of needles yet to be implanted to overcome errors in previously inserted sources.

INTRACAVITARY BRACHYTHERAPY

In contrast to the comparatively uniform dose distributions of interstitial BT, the unidirectional source arrangements used in gynecologic intracavitary BT give rise to dose distributions that fall off rapidly with distance from the applicator surface, producing large dose gradients across the target volume. Such large dose gradients make target volume–based dose specification difficult and give this treatment modality a highly empirical character. Numerous parameters have been used to prescribe, constrain, or report intracavitary therapy applications, including mg-h, mgRaEq-h, reference point doses (points A and B), bladder and rectal reference point doses, vaginal surface dose, treatment time, and the ICRU Report No. 38[3] 60-Gy reference volume. This section will emphasize the physical relationships among these parameters and their dependence on applicator characteristics. Systems for treating carcinoma of the cervix, the most intensively studied form of intracavitary therapy, will be reviewed. Our focus will be further restricted to applicator geometries and treatment systems (e.g., Fletcher and Washington University/Mallinckrodt systems) derived from the Manchester system. This limited focus is justified by the fact that Manchester- or Fletcher-style applicators continue to be the dominant choice across the world for both HDR and LDR treatments.

The Manchester Family of Intracavitary Therapy Systems

The Manchester system, developed in 1938 by Tod and Meredith,[10] has heavily influenced intracavitary treatment practice patterns throughout the world, especially in North America. The widely used Fletcher-Suit applicator system, the Fletcher loadings, and the point A and B reference points are all derived from the Manchester system. This system was the first to use applicators and loadings designed to satisfy specific dosimetric constraints.[10,233] It was the first system to use a radiation field quantity, exposure at point A, rather than mg-h, to specify treatment.

The Classical Manchester System

The original Manchester applicator system consisted of a rubber intrauterine tandem and two vaginal “ovoids,” whose ellipsoidal shape was designed to conform to the isodose curves arising from ^{226}Ra tubes placed along their long axes. The applicators were designed for use with ^{226}Ra tubes 2.2 cm long with 1-mm platinum filtration and an active length between 1 and 1.5 cm. The small,

medium, and large ovoid minimum diameters were 2, 2.5, and 3 cm, respectively, and are the same as Fletcher's small, medium, and large colpostats.[234] The preloaded ovoids contained no shielding and relied on extensive anterior and posterior packing to spare bladder and rectal tissue.

The reference point A (Fig. 25.26) originally was defined as the point "2 cm lateral to the center of the uterine canal and 2 cm from the mucous membrane of the lateral fornix in the plane of the uterus."[10] This seemingly arbitrary definition reflected the system developers' view that "radiation necrosis is not the result of direct effects of radiation on the bladder and rectum, but high dose effects in the area in medial edge of the broad ligament where the uterine vessels cross the ureter."[235] They believed the radiation tolerance of this area, termed "the paracervical triangle," to be the limiting factor in the treatment of cervical cancer and used point A exposure to represent its average dose. In current practice, point A dose is used to approximate the average or minimum dose to the tumor. Point B, defined to be 5 cm from the patient's midline at the same level as point A, was intended to quantify the dose delivered to the obturator lymph nodes.

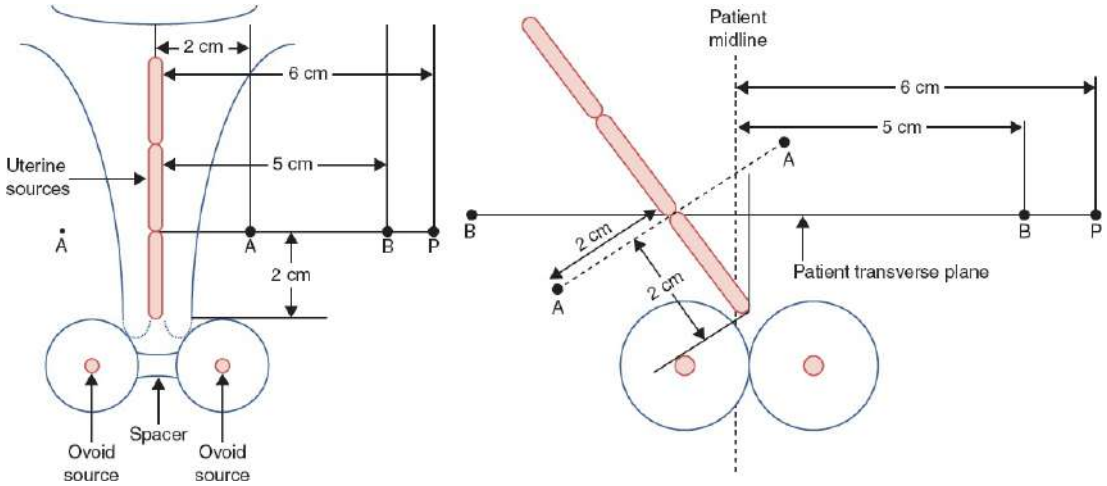

FIGURE 25.26. Definition of points A and B in an ideal application (*left*) and a distorted application (*right*), which is displaced to the left of the patient's midline, and a uterus, which is tilted toward the right. Note that point A is carried with the uterus, whereas points B and P are defined to be 5 and 6 cm, respectively, to the right and left of patient midline. Point P is used by the Mallinckrodt Institute of Radiology system to specify minimum dose to the pelvic lymph nodes. (Adapted from Meredith WJ. Dosage for cancer of cervix uteri. In: Meredith WJ, eds. Radium dosage: *The Manchester System*. 2nd ed. Edinburgh: E. & S, Livingston, Ltd, 1967;42–50.)

The Manchester ovoid dimensions and applicator loadings were designed to ensure that the point A dose rate, about 0.52 Gy/h in modern units, remained constant for all allowed applicator loadings and combinations. The design also

ensured that the vaginal contribution to point A was limited to 40% of the total dose. Small, medium, and large ovoids were loaded with 17.5, 20, and 22.5 mg of radium, respectively, to compensate for the greater source-to-point A treatment distances with the larger ovoids. Medium (4 cm long) and long (6 cm) tandems were loaded, os to fundus, with source trains consisting of 10- and 15-mg sources and 10-, 10-, and 15-mg sources, respectively, whereas the short tandem (used for cervical stump cancer) was loaded with a single 20-mg radium tube. With the exception of the short tandem, these loadings satisfied the dosimetric constraints within 2%. The point B dose, determined largely by inverse-square law, is approximately 9 Gy for every 4,000 mg-h administered.

Without external-beam treatment to the whole pelvis, a total point A exposure of 8,000 R (72.8 Gy) in 140 hours split between two applications was prescribed.[233] Because the point A dose rate is constant whether the application contains 60 mg of ^{226}Ra (small ovoids, medium tandem) or 80 mg (large ovoids, long tandem), delivery of a fixed point A dose amounts to using time, not milligram-hours, as the factor that terminates the treatment. In contrast to the Paris and Stockholm systems, which prescribed a fixed number of milligram-hours, equivalent Manchester treatment regimens could deliver from 8,400 to 11,200 mg-h—a variation of 33%.

As the size of an intracavitary application (i.e., colpostat diameter and tandem length) increases, the penetration or “lateral throw-off” of the dose distribution increases. As colpostat diameter increases from 2 to 3 cm, the vaginal surface dose decreases by 35% relative to the dose 2 cm from the applicator surface; this is simply a consequence of increasing the source-to-surface distance. Similarly, increasing the tandem length increases the point B contribution relative to the uterine cavity surface dose; the radioactivity near the ends of the long tandem contributes little to the surface dose (because of inverse-square law), whereas each tandem segment makes roughly equal contributions to points remote from the applicator. These physical principles underlie the practice of using the largest colpostats and longest tandem that the patient’s anatomy can accommodate.[11,233]

Modern Fletcher-Suit Applicator Systems

The Fletcher applicator system (Fig. 25.27A) adhered to the basic Manchester design while incorporating many improvements including internal shielding. These shields are located on the medial aspects of the anterior and posterior colpostat faces (Fig. 25.27B) and consist of 180-degree and 150-degree disk-shaped 3- to 5-mm-thick tungsten sectors to shield the rectum and bladder,

respectively.[234] The cylindrical colpostat body has a diameter of 2 cm that can be increased to 2.5 and 3 cm by the use of small and large slip-on plastic caps, thereby retaining the Manchester ovoid dimensions. Afterloading capability was added to the Fletcher applicator by Suit and coworkers.[2] The Fletcher loadings—15, 20, and 25 mg for small, medium, and large colpostats, respectively—are similar to those of the Manchester system, whereas tandem loadings are identical to their Manchester counterparts. Because of the similarity of Fletcher loadings (55 to 85 mg) to the Manchester loadings, point A dose rates are nearly independent of applicator dimensions.

The shielded Fletcher colpostat was designed to reduce dose to the bladder trigone and the anterior rectal wall without decreasing irradiation to the uterosacral and broad ligaments, thereby reducing the need for the extensive vaginal packing characteristic of Manchester insertions.[234] For a single colpostat (Fig. 25.27B–D), the maximum dose reduction varies from 40% to 50%.[15,236,237] When the effects of the intrauterine tandem and the contralateral colpostat are included, applicator shielding reduces midline rectal and bladder doses by 21% to 34% relative to conventional treatment planning calculations, which ignore shielding and include only the effects of source encapsulation.[194] CT-based dose evaluation studies reveal that colpostat shielding modestly reduces rectal doses, reducing the rectal $D_{2\%}$ by 2% to 11%[238] and D_{2cc} by 10%.[239] Modern versions of the shielded Fletcher colpostat for LDR BT include the LDR 3M Fletcher-Suit-Delclos (FSD)[15] and reproductions of the round-handled Fletcher-Suit[236] colpostats. For HDR BT, the Fletcher-Williamson[240] applicator duplicates the original Fletcher shielding configuration. Weeks and Montana[241] have designed a CT-compatible version with afterloadable shields and an aluminum body having the same dimensions as the FSD applicator.

Dose Specification in Intracavitary Brachytherapy

Point A Dose and Milligram/Hours

Two quantities are used widely to prescribe intracavitary BT: mg-h (or its modern equivalent, TRAK) is used in practices influenced by the M.D. Anderson Cancer Center system,[11,242,243] whereas some form of the Manchester point A dose specification is used by most other practitioners. Efforts to unify these two prescription practices by identifying a linear relationship between the two quantities are misguided[244] from the perspective of the Manchester system. The Manchester-like loadings specified by the Washington University (WU)/Mallinckrodt Institute of Radiology clearly show (Fig. 25.28) that despite

a twofold variation in source strength loaded into the smallest versus the largest applicator system, the point A dose rate varies by only 15%. To deliver a fixed point A dose of 65 Gy with WU loadings, a constant total treatment time of approximately 100 hours is needed, resulting in delivery of mgRaEq-h ranging from 5,200 to 10,000 in any sample of patients characterized by a range of applicator sizes. Conversely, for fixed mgRaEq-h, prescription would result in a nearly twofold variation in total treatment time and point A dose.

The proportionality of point A dose and treatment time applies only to the classical (Manchester) definition of point A. Many radiation oncologists use a revised definition of point A (Fig. 25.29) that references its location to the cervical os (tandem collar, proximal aspect of the most caudal tandem source, or a gold seed implanted in the cervix) rather than to the lateral fornix. This practice obscures the relationship between point A and milligram/hour prescription philosophies. Potish and Gerbi's[244] study of 90 Fletcher applications demonstrates that the revised point A dose rates vary widely from patient to patient and are, on average, significantly higher than the classical Manchester value. Because point A is fixed to the tandem and the vertical tandem-to-colpostat displacement varies with each patient, the vaginal contribution to point A is highly variable. In contrast, classically defined point A dose rates are tightly grouped, are independent of the loading, and are in close agreement with the Tod-Meredith value. The vaginal contribution to classical point A is fixed by definition, whereas the intrauterine contribution is insensitive to colpostat-to-tandem displacement because of the parallel tandem isodose curves. Thus, the revised point A definition does not have the physical significance of the classical quantity. The use of revised point A dose to prescribe therapy for "free-floating" tandem and colpostat insertions may introduce large patient-to-patient fluctuations in treatment times because of small, clinically insignificant variations in implant geometry. Significantly, the recent ICRU Report 90[108] on prescribing and reporting brachytherapy for cervical cancer has endorsed the classical point A definition.

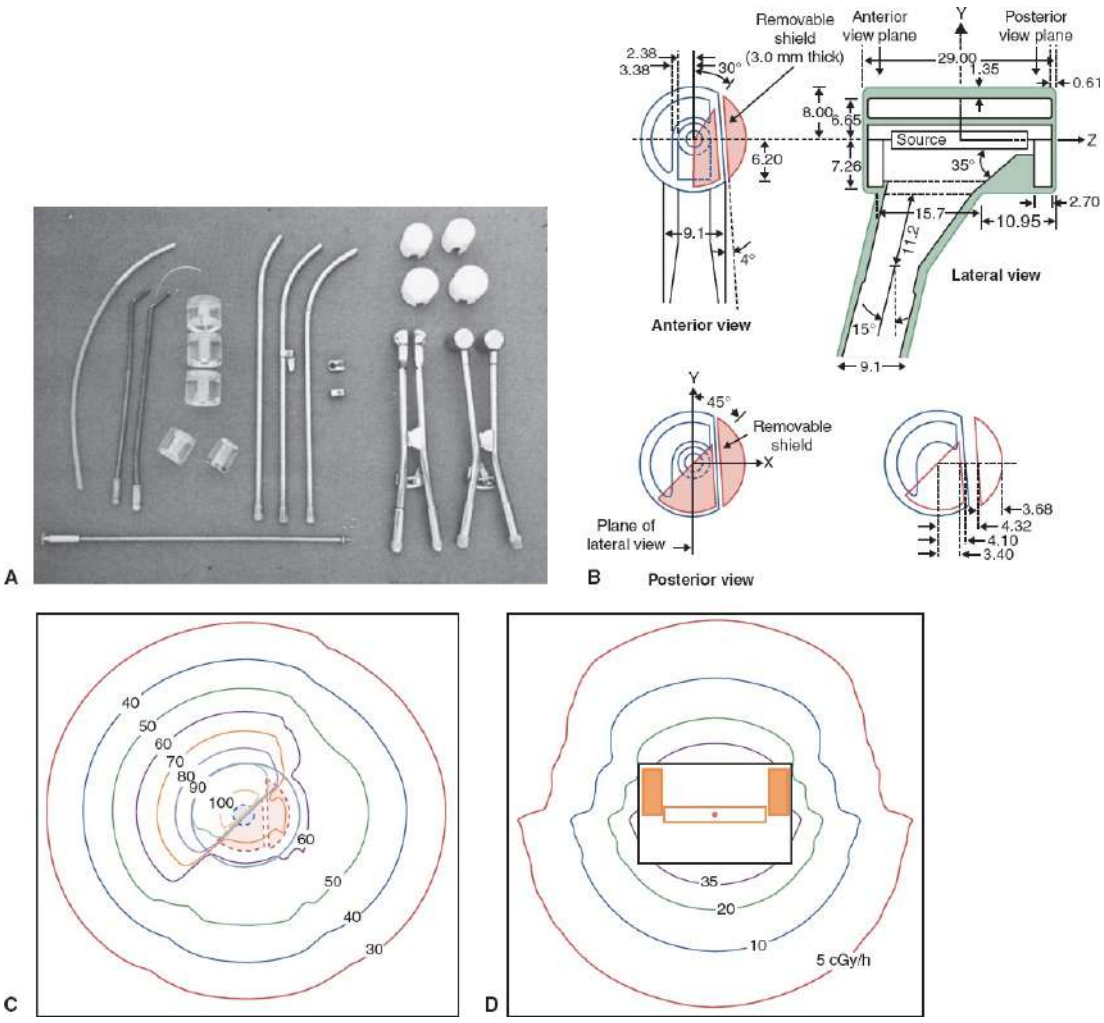

FIGURE 25.27. A: Fletcher-Suit applicator system. From *left* to *right* are tandem insert loaded with dummy sources, colpostat source holders, vaginal cylinder sleeves, three curvatures of intrauterine tandems, cervical collars, Delclos mini-colpostats, and round-handled Fletcher-Suit colpostats with small and medium caps. The tube-like instrument in the left foreground is a cervical localization seed implanter. (From Fletcher GH, Hamberger AD. Squamous cell carcinoma of the uterine cervix: Treatment techniques according to size of the cervical lesion and extension. In: Fletcher GD, ed. *Textbook of radiotherapy*. 3rd ed. Philadelphia: Lea & Febiger, 1980:732–772. With permission.) **B:** Three orthogonal views of the 3M Fletcher-Suit-Delclos colpostat, consisting of a stainless steel body. The removable parts of the tungsten alloy shield, which allow conversion of the applicator to a shielded Delclos mini-colpostat, are inserted into a nylon cap (not shown) with an outer diameter of 2 cm. Shown are isodose curves **(C)** in the coronal plane 10 mm from the posterior face of the applicator and **(D)** in the transverse plane of the colpostat for a 72 μGy·m ^{2}·h^{-1} ^{137}Cs tube. (Figures **B–D** reprinted from Williamson JF. Dose calculations about shielded gynecological colpostats. *Int J Radiat Oncol Biol Phys* 1990;19[1]:167–178. Copyright © 1990 Elsevier. With permission.)

The previous discussion is applicable only to the Fletcher applicator system with relative loadings approximating those of the Manchester system. As the

intrauterine-to-vaginal loading ratio (1:1 for the Manchester system) increases, and the maximum width of the pear-shaped reference isodoses falls and the rectal dose increases.[245] Appreciation of how loading influences isodose shape and normal-tissue doses is especially important in HDR BT as dwell-weight optimization invites deviation from classical loading rules. Using judiciously placed dose points to control the relative dimensions of the point A isodose surface, Mai[246] was able to increase tapering near the cephalad aspect of the tandem, to reduce the vaginal surface dose, and to modestly reduce the rectal dose with only slight loss of the maximum width of the pear-shaped isodose. These considerations suggest that dose-point driven optimization of the dwell-weight distribution should be accompanied by a geometric analysis of the point A isodose surface so that changes to target coverage can be assessed at least approximately.

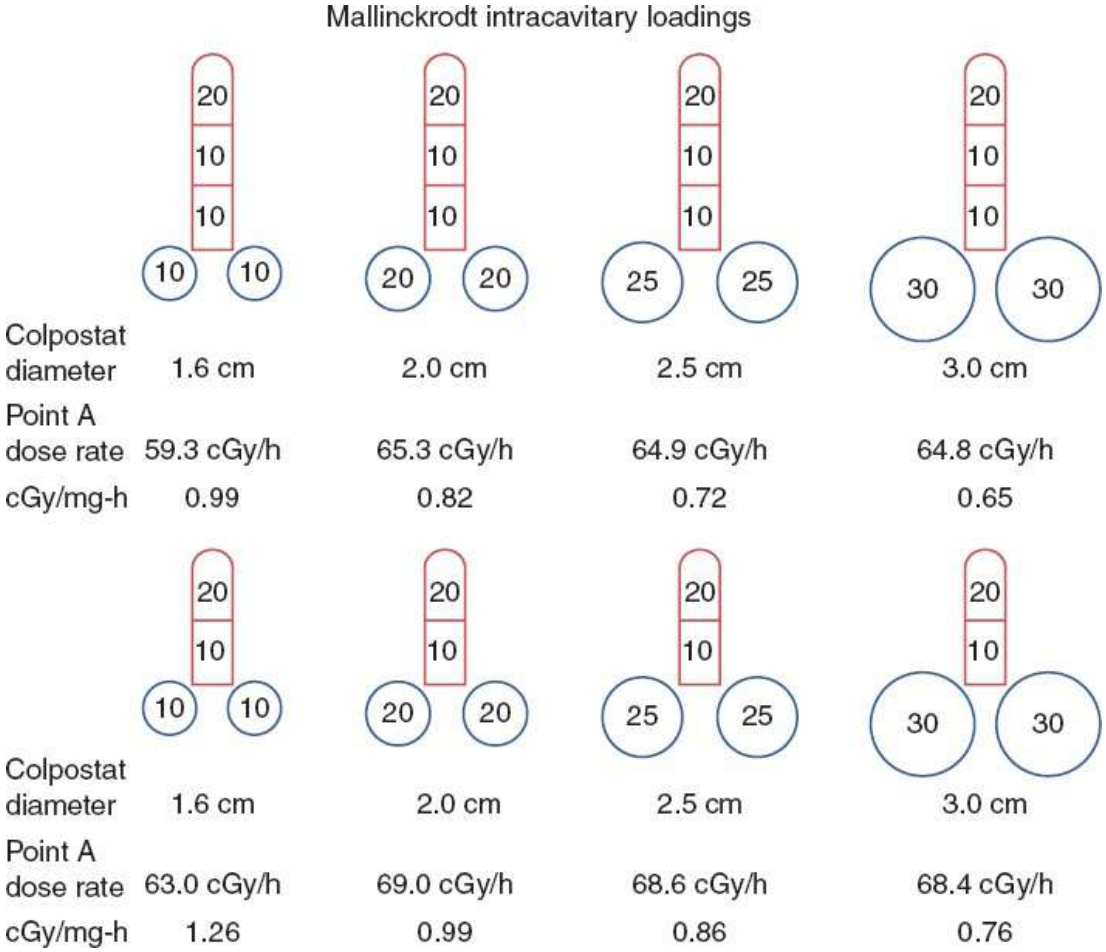

FIGURE 25.28. Mallinckrodt Institute of Radiology/Washington University (WU) applicator loadings used with Fletcher-Suit applicators for treatment of cervix carcinoma. Because the WU system uses Model 6500 3M ^{137}Cs tubes, equivalent

mass of radium is used to specify loadings and mgRaEq-h, rather than mg-h, to prescribe intracavitary therapy. The point A dose rates assume the classical Manchester definition and average colpostat separations and tandem colpostat alignments.

Other applicators in current use include the HDR tandem and ring applicator[247] and the LDR Henschke applicator.[1] The latter consists of hemispheric colpostats rigidly attached to the tandem with the vaginal source axes parallel to the intrauterine sources rather than transverse as in the Fletcher system. Henschke colpostats with internal shielding[248] are available. The vaginal ring applicator consists of a circular guide tube (usually 34 mm outer diameter) with its plane fixed rigidly normal to the tandem. It is placed up against the cervix and vaginal fornices with a donut-shaped cap attached, which increases the distance between the vaginal mucosa and the circular array of dwell positions (of which only the lateral dwell positions are activated) to 7 mm (compared to 10 to 15 mm for the Fletcher colpostat). Thus, the fraction of source strength loaded into the ring must be reduced to avoid overdosing the vaginal mucosa.[246,249] Although rectal and vaginal vault doses relative to the point A dose similar to that of the Fletcher system can be achieved through careful optimization, the lateral coverage (i.e., maximum coronal width of the point A isodose) is reduced.[246] Care must be taken in positioning the applicator system to avoid underdosing the gross tumor volume (GTV). Applicator geometry and loading practices should be changed only after extensive comparative evaluation of the old and new dose distributions to avoid dose distribution changes that would invalidate the evaluated clinical experience on which the brachytherapist’s knowledge of dose response rests. Finally, for applicator systems that deviate from the classical Manchester geometry or relative loading rules, one cannot assume that point A dose is proportional to treatment time over all allowed variations of applicator sizes and loadings.

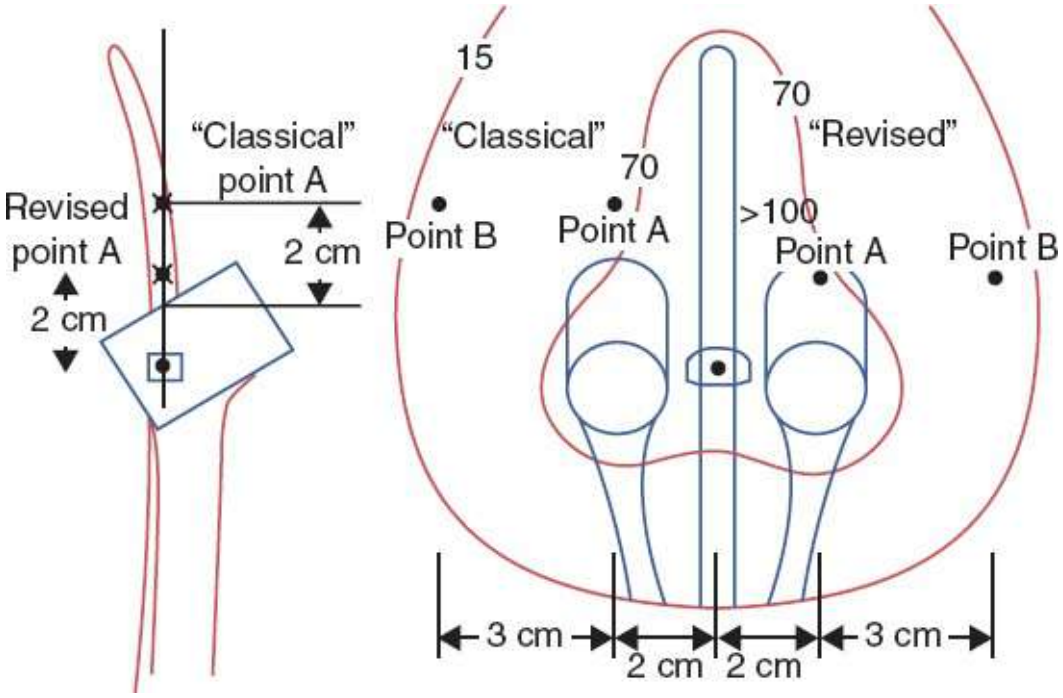

FIGURE 25.29. Radiographic definition of classical point A (2 cm above the cephalic-most aspect of the colpostat in the tilted coronal plane) and the revised point A (2 cm above the cervical collar top or center). Because the distance from caudal-most intrauterine source tip to colpostat center (tandem-to-colpostat displacement) varies from patient to patient, the vaginal contribution to revised point A is highly variable. (Reproduced with permission from Potish RA, Gerbi BJ. Role of point A in the era of computerized dosimetry. *Radiol* 1986;158:827–831.) The revised definition was suggested by Tod and Meredith in their 1953 paper.[233]

Volumetric Specification of Intracavitary Treatment: ICRU Report No. 38 Recommendations

The ICRU[3] introduced the concept of reference volume enclosed by the reference isodose surface for reporting and comparing intracavitary treatments performed in different centers regardless of the applicator system, insertion technique, and method of treatment prescription used. Specifically, ICRU Report No. 38 recommended that the reference volume be taken as the 60-Gy isodose surface, resulting from the addition of dose contributions from any external-beam whole-pelvis irradiation and all intracavitary insertions. The ICRU proposed that this pear-shaped reference volume (Fig. 25.30) be described in terms of its three orthogonal maximal dimensions, height (d_h), width (d_w), and thickness (d_t), measured in the oblique coronal and sagittal planes containing the intrauterine sources. Figure 25.31 illustrates the bladder and rectal reference points recommended by the ICRU.

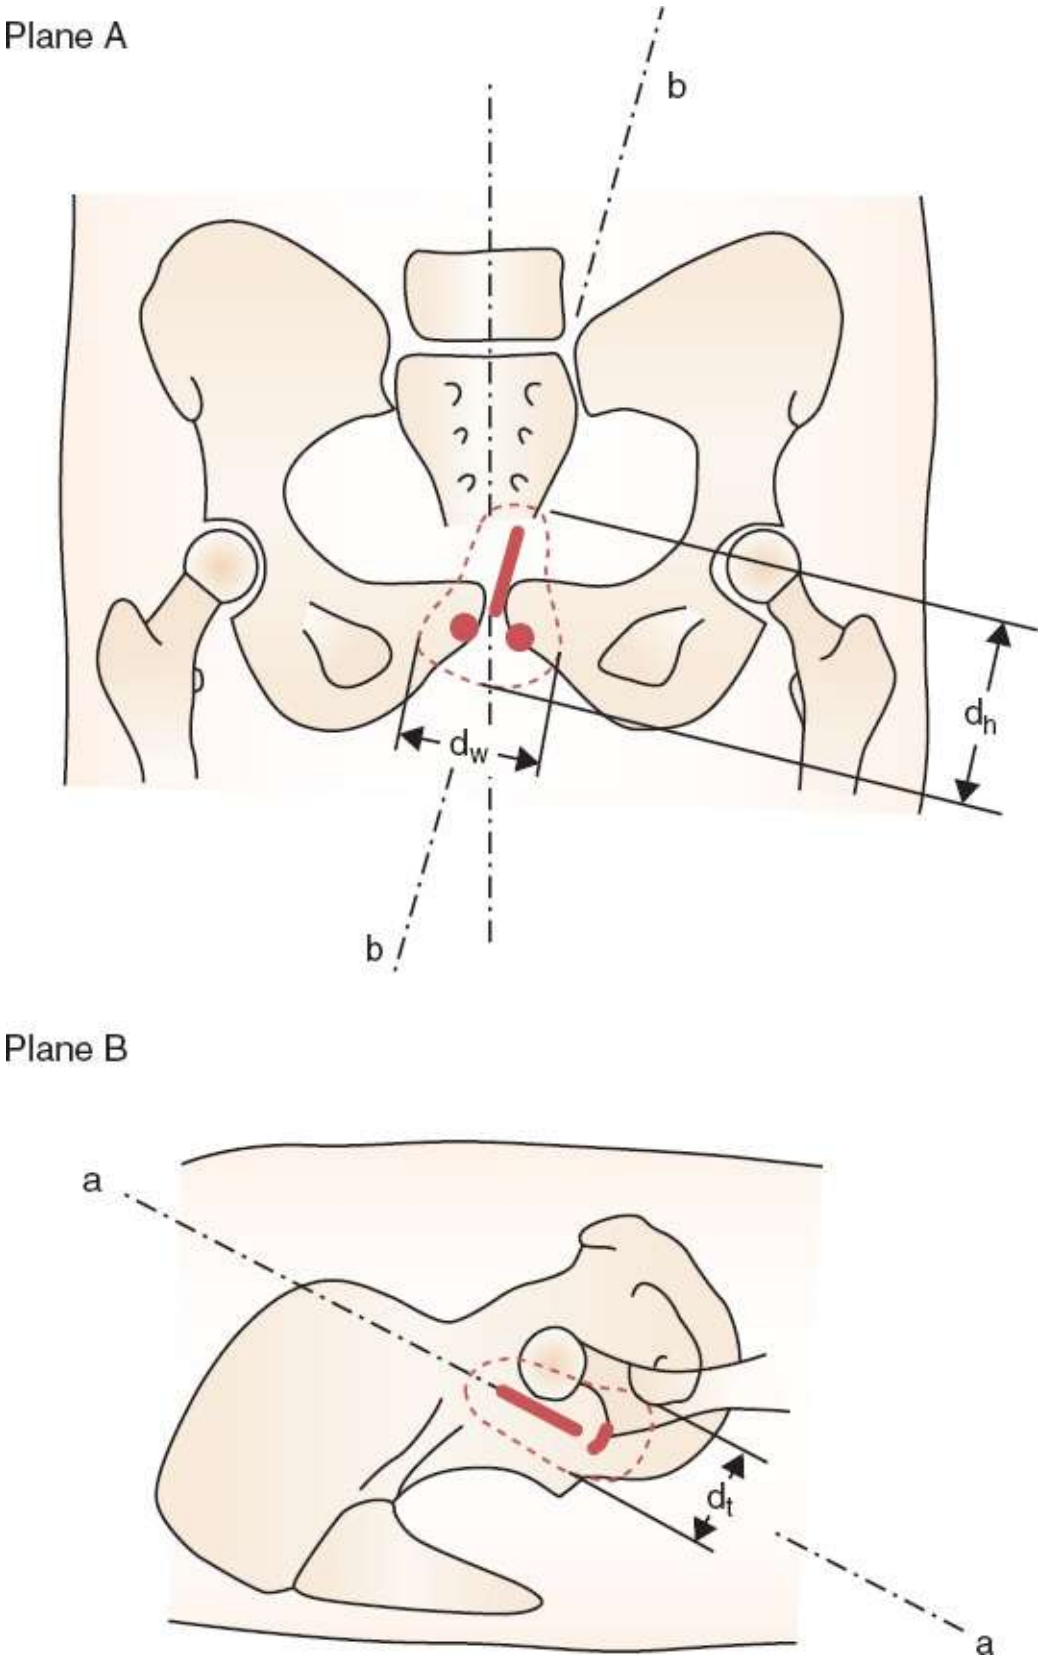

FIGURE 25.30. Geometry for measuring of the three orthogonal dimensions of the pear-shaped ICRU (International Commission on Radiation Units and Measurements)

reference isodose surface (*broken line*) in a typical treatment of cervix carcinoma using one rod-shaped uterine applicator and two vaginal applicators. *Plane A* is the "oblique" frontal plane that contains the intrauterine device. The oblique frontal plane is obtained by rotation of the frontal plane around a transverse axis. *Plane B* is the "oblique" sagittal plane that contains the intrauterine device. The oblique sagittal plane is obtained by rotation of the sagittal plane around the AP axis. The height (d_h) and the width (d_w) of the reference volume are measured in *plane A* as the maximal sizes parallel and perpendicular to the uterine applicator, respectively. The thickness (d_t) of the reference volume is measured in *plane B* as the maximal size perpendicular to the uterine applicator. (From Chassagne D, Dutreix A, Almond P, et al. *ICRU Report 38. Dose and volume specification for reporting intracavitary therapy in gynecology*. Bethesda, MD: International Commission of Radiation Units and Measurements, 1985. Reproduced by permission of International Commission on Radiation Units and Measurements.)

In contrast to point A dose and mgRaEq-h, the ICRU proposal is only a means of describing or reporting treatment. No guidance is given as to how to prescribe treatment, use these measurements to evaluate implant quality, or correlate reference volume dimensions with clinical outcome. The 60-Gy dose-level choice appears to have been motivated by the preoperative radiotherapy regimen popular within the French school of radiotherapy.[250] Descriptions of institution-specific treatment techniques for early-stage cervical cancer patients include rules for evaluating the 60-Gy reference volume dimensions and offsets relative to the applicator system for the allowed combinations of applicator dimensions and loadings.[250] Within North America, Potish et al.[251,252] and later Eisbruch et al.[253] found that the individual ICRU reference volume dimensions and various geometric characteristics of Fletcher implants, for example, colpostat separation and vertical and horizontal displacement of the tandem from the colpostat centers, were moderately well correlated. Other investigators[254–256] have proposed using the product of ICRU dimensions, $V_{ICRU} = d_t \times d_w \times d_h$, as a surrogate for relative volume contained within the reference isodose surface. Esche et al.[255] found that V_{ICRU} was directly proportional to mg-h, whereas Nath[256] pointed out that V_{ICRU} increased steeply with increasing whole-pelvis dose. In a retrospective clinical study,[254] grade 3 rectal complications were correlated with high $d_t \times d_w \times d_h$ product, whereas severe bladder complications were associated with the combination of high bladder doses and large V_{ICRU} on a 2D scattergram. The rationale for studying the product of ICRU reference volume dimensions is the well-established correlation between the volume of tissue irradiated by external irradiation and clinical outcome.[257] In agreement with these authors, the current ICRU Report 89[108] discards the concept of a

reference isodose surface for a single fixed-dose level, in favor of a more flexible system, for example, for 2D dosimetry specifying the volume enclosed by total dose isodose surfaces determined by prescribed doses (typically 85 and 60 Gy) to the high-risk and intermediate-risk CTVs (CTV-HR and CTV-IR, respectively). The ICRU no longer endorses measuring and reporting the three orthogonal dimensions of these reference isodose surfaces. The ICRU 38 and 89 reference volume concepts appropriately emphasize that the volume of tissue irradiated, as well as dose, is an important predictor of clinical response to intracavitary irradiation. Wilkinson and Ramachandran[258] and Eisbruch et al.[253] used DVHs to study the correlation between volume enclosed by intracavitary isodose surfaces and other prescription parameters. The latter analyzed the volumetric characteristics of 204 intracavitary insertions in 128 patients with carcinoma of the cervix s and demonstrated that intracavitary implants delivering the same mgRaEq-h have nearly identical DVHs over the dose range of clinical interest despite significant differences in geometry and loadings (Fig. 25.32). They also showed that the volume, V(D,M), enclosed by isodose surfaces can be estimated accurately from a modified power-law model requiring knowledge of only the intracavitary dose in cGy (D) and mgRaEq-h (M):

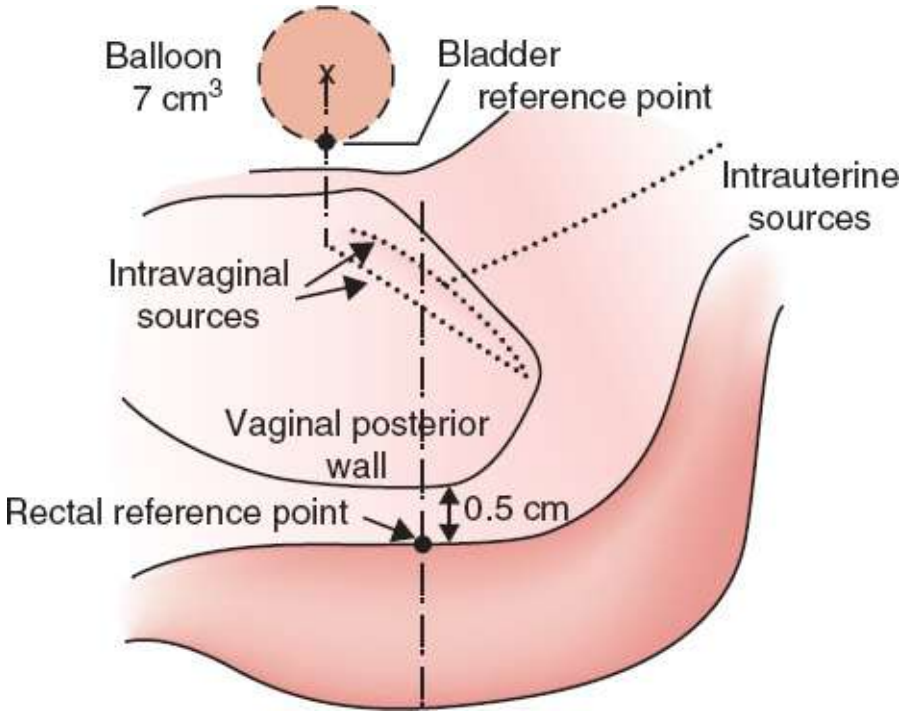

FIGURE 25.31. Reference points for bladder and rectal brachytherapy doses proposed by the International Commission on Radiation Units and Measurements Report 38.[3] (From Chassagne D, Dutreix A, Almond P, et al. ICRU Report 38. *Dose and volume specification for reporting intracavitary therapy in gynecology*. Bethesda,

MD: International Commission of Radiation Units and Measurements, 1985. Reproduced by permission of International Commission on Radiation Units and Measurements.)

$$V(D,M) = \left[104.8 - 8.103\left(\frac{M}{D}\right) + 0.437\left(\frac{M}{D}\right)^2\right] \cdot \left(\frac{M}{D}\right)^{1.635} \qquad (38)$$

The volume predicted by this simple model is accurate within ±10% in 95% of the implants when M/D is more than 0.8, which corresponds to an intracavitary dose of 100 Gy for 8,000 mgRaEq-h of intracavitary therapy. In addition, the ratio of ICRU dimension product to the true volume given by DVH analysis, $d_t \times d_w \times d_h/V(D, M)$, varied widely from patient to patient and differed systematically from one implant type to another.

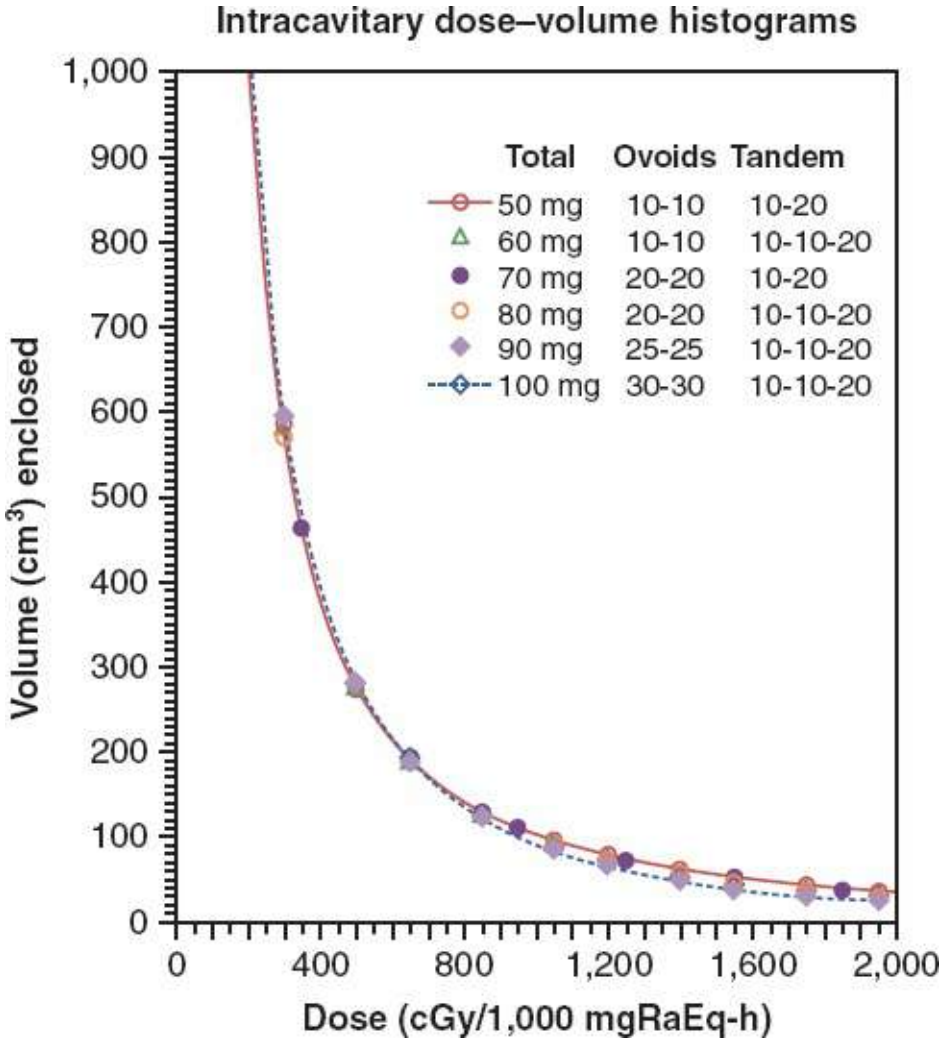

FIGURE 25.32. Dose/volume histograms for seven WU intracavitary insertions using 1.4-cm active length ^{137}Cs sources. The strength of each source was determined by

the loading rules for WU schema C (20 Gy, whole pelvis plus 8,000 mgRaEq-h) and then was scaled down to 1,000 mgRaEq-h. Note that as the size of the insertion increases, the volume of tissue encompassed by the high-dose isosurfaces decreases. Point A doses ranged from 8.28 to 11.35 Gy.

The consequences of Eq. (38) can be summarized as follows:

- Volumetrically, an intracavitary implant behaves like a central point source: $V(D, M) \propto (M/D)^{3/2}$
- Describing an implant in terms of volume contained within its isodose curves carries no more information content than a statement of mgRaEq-h or total reference air-kerma.
- The volume of tissue irradiated to a specified dose is closely related to total exposure given by the implant in terms of mgRaEq-h or TRAK.

Consequence (2) suggests that the correlation between clinical outcome, in terms of tumor control and complications and isodose surface volume, should be no better or worse than the correlation between clinical outcome and mgRaEq-h for a fixed external pelvis dose. Consequence (3) suggests a new and fundamental physical interpretation of mgRaEq-h or its derivative, TRAK. Prescribing intracavitary BT by mgRaEq-h is equivalent to treating until each specified isodose surface achieves a fixed volume independent of the underlying implant geometry. The use of mgRaEq-h to constrain intracavitary treatment therefore limits the volume of tissue irradiated to high doses. This observation may help explain the clinical utility of mgRaEq-h as a dose-specification parameter. Finally, the individual reference isodose dimensions, which are more strongly influenced by implant geometry than their product, clearly convey additional information about the spatial extension of the reference isodose surface in their respective planes and cannot be reduced to a statement of total exposure from the implant and may have additional prognostic significance.

Practical Systems for Intracavitary Prescription and Reporting

For Manchester-like loadings and applicators, if treatment were to be prescribed as a fixed number of mgRaEq-h or TRAK without regard to the diameter and length of the applicators, the treatment times and total point A doses would differ by the ratio of total source strengths in the applications. Small applications would have unacceptably high point A and vaginal vault surface doses and excessively long treatment times. In contrast, large applications treated to a fixed mgRaEq-h prescription would underdose these reference points. In contrast, the ICRU reference volume for fixed levels of whole-pelvis irradiation and

mgRaEq-h would be independent of the loading because the mgRaEq-h is constant. Conversely, when the point A dose is held constant, the mgRaEq-h needed to deliver these doses will vary significantly, introducing corresponding variations in the volume of the ICRU reference isodose.

Clearly, no TRAK-based system would endorse such a naive approach. Actual mgRaEq-h–based systems use a combination of parameters. Physically, mgRaEq-h or TRAK controls the volume of tissue treated to high doses, and parameters such as time, colpostat surface dose, and point A are used to control doses at points near the applicator to ensure that normal tissue tolerance is not exceeded and that the tumor is not undertreated. For each applicator combination and choice of external-beam dose, a compromise between volume of tissue treated and dose delivered near the applicator must be reached. For example, the Fletcher system[11,252] specifies both a maximum treatment time and maximum milligram/hour constraint for each combination of external-beam and intracavitary therapy (Table 25.10). Whichever constraint is reached first terminates the application. Small applications tend to be terminated by the maximum time constraint, which limits the milligram-hours and prevents tissues near the applicator from exceeding tolerance doses, whereas larger applications are terminated by the milligram-hour constraint, ensuring adequate dose to the tumor. Although the historical Fletcher system does not use point A dose either for prescription or reporting, the total point A dose is constant within 12% for allowed tandem and colpostat loadings within each treatment scheme (A–E) of Table 25.10. The reader should note that the Fletcher system is a complex, highly individualized treatment system that resists formulation in terms of a few rules. Table 25.10 is a highly condensed and simplified summary derived from the literature, not from observation of current M.D. Anderson Cancer Center practice patterns.

TABLE 25.10 Simplified Fletcher System Prescriptions[a]

Treatment Scheme	Indications	External Beam		Intracavitary Maximum		Range: Smallest to Largest Insertion		
		Whole Pelvis	Split Field	mg-h[b]	Time (h)	Point A	Point B[c]	mg-h[b]

The Washington University (WU)/Mallinckrodt Institute of Radiology system prescribing intracavitary therapy illustrates another empirical approach for ensuring adequate dose delivery to the tumor while limiting the volume of tissue treated to high doses. Like the Fletcher system, intracavitary BT prescriptions are stated in mgRaEq-h. Historically, the WU system used Manchester-like applicators and loadings preloaded with ^{226}Ra or ^{60}Co tubes, until the late 1950s when the Ter-Pogossian applicator was introduced. The system changed with the introduction of high-energy x-ray external-beam therapy in 1958, the adoption of the Fletcher-Suit applicator in 1965, and the acquisition of ^{137}Cs tubes in 1971.[243] Because of the long association of the WU system with artificial radionuclides, equivalent mass of radium rather than mass of radium is used to specify source strength; hence, 1 mgRaEq-h in the WU system is equivalent to 1.07 mg-h in the Fletcher system, which, in turn, is equivalent to a TRAK of 0.00723 mGy at 1 m.

Manchester-like applicator loadings (Fig. 25.28) currently are used for LDR applications, yielding an approximately constant point A dose rate of 65 cGy/h. For HDR applications, the dwell weights are selected to duplicate the relative Manchester loadings, and the TRAK per insertion is reduced to reflect the increased radiobiologic effectiveness of the HDR fractionation schedule relative to the LDR regimen. Classically defined point A doses are calculated for

reporting purposes for all patients, although this quantity plays no role in prescribing therapy. Dose to the pelvic lymph nodes is calculated at point P, located 2 cm superior to the lateral fornix and 6 cm lateral to the patient's midline. The 2013 ICRU Report 89[108] continues to recommend the ICRU Report No. 38[3] Bladder and rectal reference points (Fig. 25.31) for conventional 2D orthogonal film dosimetry. The prescribed doses for the external-beam and intracavitary (delivered in two LDR insertions) components of treatment are listed in Table 25.11 as a function of extent and stage of disease. The mgRaEq-h prescription is divided equally between the vaginal and uterine components and is delivered exactly as prescribed only in the case of the standard 80-mgRaEq application (2-cm diameter colpostats and long tandem, loaded 20-10-10). For nonstandard loadings using mini-colpostats, the vaginal and intrauterine TRAK prescriptions are modified independently. When Delclos mini-colpostats are used, vaginal TRAK is constrained by the vaginal vault surface dose limit, which for LDR is 150 Gy (including whole-pelvis dose and the dose from the ipsilateral colpostat but excluding dose from the tandem and contralateral colpostat). For medium and large colpostats, the vaginal mgRaEq-h is increased by 16% and 28%, respectively, to compensate for their larger source-to-surface distances. When medium and short tandem loadings are used, the target TRAK prescription is modified by the ratio of the actual loading to the standard loading (80 mgRaEq-h).

Table 25.12 illustrates the detailed application of the WU system to three applicator configurations for prescription schema C, listing total doses for point A, point P, and the vaginal mucosa along with the volumes of tissue enclosed by point A and 60-Gy total dose reference isodose surfaces. The mgRaEq-h actually delivered by equivalent implants varies by a factor of 1.62, leading to a reference volume variation of 2.08. However, compared to fixed point A prescription 65 Gy, which would allow administered mgRaEq-h to vary by a factor of 2.31, the variation of irradiated volume is somewhat limited. These rules represent an empirically developed compromise between limiting volume of tissue treated and maintaining a tumoricidal dose contribution to the colpostat surface and to point A.

Table 25.11 shows that as tumor size increases and therapeutic emphasis shifts from intracavitary insertions to external-beam therapy, the point A dose increases, from 58 Gy for small IB lesions (schema A) to 94 Gy for stage 4 lesions (schema E). The mgRaEq-h actually administered within a given treatment group may deviate from the target mgRaEq-h prescriptions by as much

as −30% to +40% for very small and large insertions, respectively. Despite reliance on the mgRaEq-h prescription philosophy, treatment times are approximately constant, and total point A doses are nearly independent of applicator size, the defining features of the Manchester system.

Summary Principles: Intracavitary Brachytherapy Dose Specification

The most widely used intracavitary BT systems in North America are based on Manchester-type loadings and applicators, in which the point A dose rate is approximately constant and independent of loading, leading to a linear relationship between point A dose and time, not mgRaEq-h. Practical mgRaEq-h systems use various dose-specification parameters to constrain and guide treatment and are far more Manchester-like than the "strict" milligram-hour philosophy would suggest. These parameters have the following roles: (a) TRAK limits the volume of tissue treated to a high dose; (b) point A dose ensures that tumor periphery receives adequate dose; (c) vaginal surface dose ensures that dose to mucosal surfaces in contact with applicator system remains within tolerance; and (d) treatment time ensures indirect control of point A dose.

Although the traditional treatment specification quantities have clear physical meanings and interrelationships, these concepts can be applied to patient treatment only within a clinical system supported by a base of evaluated clinical experience. In current practice, implant placement is guided by direct visualization and palpation, and treatment prescription is guided by the radiation oncologist's knowledge of treatment outcome averaged over groups of uniformly treated patients with similar tumor size and location and medical condition. This implies that the implant system must be applied as a whole: Mixing dose specification methods, insertion techniques, and normal-tissue dose–response

relationships from different clinical systems is a dangerous practice that can lead to suboptimal or indeterminate clinical outcomes. For example, use of the WU-recommended rectal tolerance dose (75 to 80 Gy) to guide prescription in a system using higher whole-pelvis doses will not guarantee an acceptable level of complications. Second, because classical dose-specification quantities incompletely describe the dose distribution, a radiation oncologist must be trained in all details of an intracavitary system to duplicate the results of its developers. Finally, for the clinical physicist, consistency of current dosimetric practice with past clinical experience maybe more important than absolute dose-computation accuracy or compliance with a practice standard external to the treatment system.

Image-Guided Intracavitary Brachytherapy

Classical intracavitary BT, with its empirically based rules, prescription practices, and feedback derived from patient follow-up to shape and position intracavitary dose distributions, demonstrates that even massive cervical cancers are potentially curable with concomitant chemoradiation therapy. In an effort to improve clinical outcomes in locally advanced cervical cancer and to reduce the significant incidence of local failure and late normal-tissue toxicity, anatomy-based dose specification using 3D x-ray CT or magnetic resonance (MR) imaging studies acquired with the applicator system in place has been intensively investigated. Early studies[259–261] consistently demonstrated that conventional orthogonal film-based reference points (2D planning) overestimate minimum doses to the cervix and underestimate maximum doses to critical structures by factors of 1.5 to 2.3 with large patient-to-patient variations. Because MR imaging has been shown to be far superior to CT for distinguishing tumor from normal cervical stroma[262] and for delineating surrounding critical structures, advisory groups[263,264] recommend using T2-weighted MR imaging studies acquired prior to initiating treatment and after each intracavitary insertion for BT planning and dose reconstruction. This has culminated in the publication of a revised ICRU report[108] that provides detailed guidance for planning, prescribing, and reporting intracavitary brachytherapy in the MRI-guided era. An important innovation is a widely accepted target-volume nomenclature (high-risk, intermediate-risk, and low-risk CTVs, denoted by CTV_{HR}, CTV_{IR}, and CTV_{LR}, respectively) and specific DVH parameters[265] for assessing the correlation between clinical outcome and the delivered dose distribution. The CTV_{HR} includes the entire cervix along with all palpable or presumed residual

gross tumor volume (GTV_{res}) at the time of each intracavitary insertion. ICRU Report 89 recommends a dynamic adaptive treatment philosophy: the goal of each insertion to deliver the prescribed D_{90} dose (roughly comparable to point A dose) to the "residual" CTV_{HR} for a total (external beam and brachytherapy) $D_{2Gy,90}$ dose (in 2 Gy fraction equivalents) of 85 to 90 Gy. The CTV_{IR} consists of the initial CTV_{HR} (based on the pretreatment GTV_{init} plus a margin for microscopic disease (typically 5 mm anterior–posteriorly and 10 mm elsewhere). It typically receives a total D_{90} dose (D_{2Gy}) of 65 to 70 Gy for locally advanced disease. In addition to recommending tracking the classical dose specification quantities (TRAK and point A, bladder, and rectal reference doses), ICRU Report 89[108] recommends tracking D_{90} and D_{98} for CTV_{HR} and CTV_{IR} coverage and D_{2cm^3} and $D_{0.1cm^3}$for assessing bladder and rectal doses. The report also provides a simplified linear-quadratic model for converting LDR, HDR, and external beam doses into equivalent 2-Gy fractionated doses.

Early reports of image-based conformal therapy in locally advanced cervical cancer are promising. For example, the use of intensity-modulated radiation therapy (IMRT) to replace traditional whole- and split-pelvis fields[266,267] suggests that grade 3/4 late toxicity is significantly reduced relative to historical controls without increasing local recurrence. The most extensively reported experience with MRI-based intracavitary BT planning (156 patients at Medical University of Vienna), achieved excellent 3-year local control rates of 86% to 100% (FIGO Ib-IIIb) with 3 grade 2/4 late toxicities of 4% or less, and[268] demonstrated a robust dose–response relationship between CTV_{HR} D_{90} and D_{100} for large tumors[269] and a good correlation between bladder and rectal DVH parameters, for example, D_{2cm^3}, and major late complications.[270] Challenges to image-guided intracavitary therapy include substantial soft-tissue displacement and deformation due to applicator insertion and removal, tumor regression, and bladder and rectal filling variations (all ignored by clinical experiences cited above), making it difficult to meaningfully evaluate cumulative dose distributions. An important area of research is application of deformable image registration to account explicitly for the temporal sequence of deforming 3D anatomies needed to accurately characterize a multiple insertion course of intracavitary and external beam therapy.[271] Using dose summation over weekly MR image sets that had been contoured and nonrigidly registered, Lim et al.[272] demonstrated that 5-mm PTV expansion of CTV_{IR} for the IMRT component of treatment was adequate for most patients, although large variations between

planned and cumulative normal-tissue doses were observed for some patients. As IMRT is used to create more conformal external-beam dose distributions and to address peripheral CTV_{HR} underdoses by the intracavitary treatment components, the need to accurately account for local tissue deformation will become more acute.[273]

THE RADIOBIOLOGY OF BRACHYTHERAPY

The development of high-strength remote-afterloading stepping sources and low-energy permanently implantable sources has resulted in clinical utilization of dose rates and dose-time-fractionation patterns that can differ radically from conventional LDR BT protocols, making it logistically easier to combine BT with external beam radiation therapy (EBRT). A clear understanding of the principles governing selection of dose-time-fractionation protocols in BT or combined EBRT–BT has become an essential clinical tool.

The highly conformal dose distribution characteristic of BT sources significantly reduces the exposed volume, and, often, the maximum dose in adjacent normal tissues, compared to EBRT.[273,274] As well as diminishing late-responding normal-tissue complications, such dose sparing keeps early-responding normal-tissue sequelae to acceptable levels, dose sparing also makes the short treatment times commonly used in temporary implant BT tolerable. This is in contrast to EBRT where the risk of early-responding tissue sequelae requires treatment times to be prolonged for up to 8 weeks, potentially reducing tumor control through repopulation. The short overall treatment times used in temporary implants are likely to contribute significantly to clinical efficacy and social–economic benefits for those tumor sites (e.g., cervix, head and neck, and lung) where long overall treatment time is associated with reduced local control.

Biophysical Modeling of Brachytherapy

Along with a clear understanding of the radiobiologic basis of BT, biophysical models for predicting responses to alternative temporal dose-delivery schemes have been developed. In the 1970s, before the differential response of early- and late-responding tissues was understood, the most widespread approach for designing alternative fractionation schemes was the nominal standard dose (NSD) equation,[275] which was based on data from early-responding tissues only. By contrast, the currently used linear-quadratic (LQ) model unequivocally distinguishes between early and late responses and is based on mechanistic

notions about how cells are killed by radiation. After several decades of investigation and use, the basic ideas and parameters in the LQ model have been well supported by clinical experience and outcome data.

The Linear-Quadratic Model and Its Mechanistic Basis

Central to the LQ approach is a biologic model of radiation action, which was spelled out in detail more than 50 years ago by Lea and Catcheside,[276,277] based on a mechanistic analysis of radiation-induced chromosome aberration induction. The application of the LQ formalism to radiation therapy has been reviewed by Thames and Hendry,[278] Dale,[279] Fowler,[280] and many others. The LQ model assumes that radiotherapeutic response is primarily related to cell survival (or survival of groups of cells). Although not the sole determinant of biologic response, there is now a wealth of evidence that cell killing, that is, loss of reproductive integrity, is the dominant determinant of radiotherapeutic response, both for early- and late-responding end points.[278]

In the most basic LQ approach, cellular survival, S, from dose D given in a single acute exposure or fraction, is written as

$$S(D) = \exp(-\alpha D - \beta D^2) \tag{39}$$

The mechanistic interpretation of Eq. (39) is that cell killing results from the interaction of two elementary damaged species, most often DNA double-strand breaks (DSB), to produce species that cause cell lethality, such as dicentric chromosomal aberrations. The first term in (39), which is linear in dose, describes production of two DSBs by the same ionizing radiation quantum (usually a charged particle), whereas the second term, quadratic in dose, describes production of multiple DSBs by two independent quanta. If the radiation is delivered over a protracted period rather than delivered acutely, the two DSBs may be formed at different times. Therefore, it is possible that the first may be repaired before it has a chance to interact with the second. This will not affect the first term in Eq. (39), because the two DSBs are formed simultaneously from a single particle track, but DSB repair during a prolonged exposure will result in a reduction of the second, quadratic term in Eq. (39) by a factor denoted by "G"[276,277]:

$$S(D) = \exp(-\alpha D - G \times \beta D^2), \tag{40}$$

where, for acute exposures, $G \rightarrow 1$, and for very long exposures, $G \rightarrow 0$. In this context, "acute" and "long" are defined relative to the half-time (T_r) for DSB

repair of sublethal damage. In general, G will depend on the detailed temporal distribution of dose delivery, as well as on T_r. For many simple cases, G can be calculated analytically. For example, for a permanent exponentially decaying implant, G can be approximated as $\lambda/(\mu+\lambda)$ where $\lambda = \ln 2/T_{1/2} = 0.693/T_{1/2}$ is the decay constant of the radionuclide and μ ($=0.693/T_r$) is the sublethal damage repair rate. In the case of our two DSB damage models, μ describes repair of single DSBs. Formulae for G for many other standard schemes also have been derived,[277,281] as has a general formalism for any possible protraction scheme.[282]

The LQ formalism, described by Eqs. (39) and (40), is not simply a convenient formula for fitting cellular survival curves, but can be derived from a variety of underlying mechanistic models via first-order time–dependent perturbation theory when the dose or dose rate is not too high, a constraint that includes most clinically and experimentally relevant doses and dose rates.[283] For example, the theory of dual radiation action[284] is only one of several different approaches to describing radiobiology damage mechanistically. The approach devised by Lea and his coworkers[276,277] deals instead with the kinetics of damage development. Typical kinetic models track the temporal evolution of lesions as a cell gradually repairs or misrepairs initial damage.[285–287] Many different molecular mechanisms have been studied kinetically, such as pairwise misrepair of DNA DSBs, direct one-hit induction of lethal lesions, and saturable repair pathways in which the repair enzyme system can be overloaded.

Practical Applications of the LQ Model

Equation (40) can be used either to design “equivalent” dose protraction protocols (i.e., design a regimen with the same tumor response, or the same late complications, as a “tried and tested” regimen) or to predict absolute radiotherapeutic responses. We will discuss both approaches here, although we will argue that designing equivalent protraction schemes is a considerably more robust procedure.

In order to design a new dose protraction protocol (labeled “2”), which will have the same effect as a current protocol (labeled “1”), based on Eq. (40), we need to ensure the quantity ($\alpha D + G\beta D^2$) is equal for the two protocols, that is

$$D_1(1 + G_1 D_1/(\alpha/\beta)) = D_2(1 + G_2 D_2/(\alpha/\beta)) \qquad (41)$$

The quantity on either side of (41) is often called the biologically effective dose (BED),[280] so generating a new “equivalent” regimen amounts to matching BEDs for the old and new regimens.

By contrast, to use the LQ model to calculate absolute tumor-control probabilities (TCP) or normal-tissue complication probabilities (NTCP), we need additional models relating cellular survival (*S*) with TCP or with NTCP. The simplest approach, originating with Munro and Gilbert,[288] equates TCP with the probability that after radiation treatment, there are no remaining tumor stem cells capable of initiating tumor regrowth. Let us suppose that a dose, D, delivered in a given protraction pattern produces a stem-cell survival probability, S. Let K be the initial number of potential stem cells in the tumor. Then, the probability that any given stem cell will be unable to initiate tumor regrowth is (1 − S). Thus, the TCP for the irradiated tumor is simply $(1 - S)^K$, which, for small values of S, can be approximated as:

$$\mathrm{TCP} = \exp(-S \cdot K) \tag{42}$$

Thus, if cell survival, S, is described by Eq. (40), then:

$$\begin{aligned} \mathrm{TCP(D)} &= \exp(-\mathrm{K} \cdot \exp[-\alpha \mathrm{D} - \mathrm{G} \cdot \beta \mathrm{D}^2]) \\ &= \exp(-\exp[\ln \mathrm{K} - \alpha \mathrm{D} - \mathrm{G} \cdot \beta \mathrm{D}^2]) \end{aligned} \tag{43}$$

Equation (43) may also be used to calculate NTCP, except that now, the parameter K does not refer to the number of tumor cells that need to be sterilized, but rather to the number of groups of cells in the normal tissue ("tissue-rescuing units"),[289] whose destruction would result in the late complication.

A problem with Eq. (43), or similar approaches to estimate clinical outcomes de novo, is that absolute values of TCP or NTCP are exquisitely sensitive to the parameter values, particularly the K parameter. In contrast, using the LQ model to compare competing protraction regimens (Eq. (41) and its extensions described below) makes no assumptions about the relationship between surviving fraction and clinical outcome, and, therefore, is much less sensitive to the LQ parameter values.[290]

To improve the clinical utility of TCP or NTCP models, extensive efforts have been made to fit these models to clinical data, yielding tumor-/tissue-specific model parameters, for example, for head-and-neck tumors,[291,292] breast tumors,[293,294] prostate cancer,[295,296] brain tumors,[297] rectal cancer,[298] and liver cancer.[299]

Use of the Linear-Quadratic Model in Brachytherapy

Quantifying the Rationale for Low–Dose Rate Brachytherapy

It has long been known that lowering the dose rate generally reduces biologic damage[300] because of increased opportunity to repair sublethal damage.[276,277] It also has been clear since the pioneering work of Coutard and colleagues[301] that fractionating or protracting a radiotherapeutic exposure improves the "therapeutic ratio" (ratio of tumor control to complications). However, the exact link between these observations was not clearly made until the 1980s by Withers and colleagues.[302,303]

To understand their insight, consider the isoeffect curves in Figure 25.33 representing "equivalent" schemes for either early- or late-responding end points as a function of treatment time. For higher-dose rates, the dose reduction needed to match late effects is larger than the dose reduction needed to match tumor control. For any selected dose, increasing the dose rate will increase late effects much more than it will increase tumor control. Conversely, decreasing the dose rate will decrease late effects much more than it will decrease tumor control. Thus, the therapeutic ratio increases as the dose rate decreases.

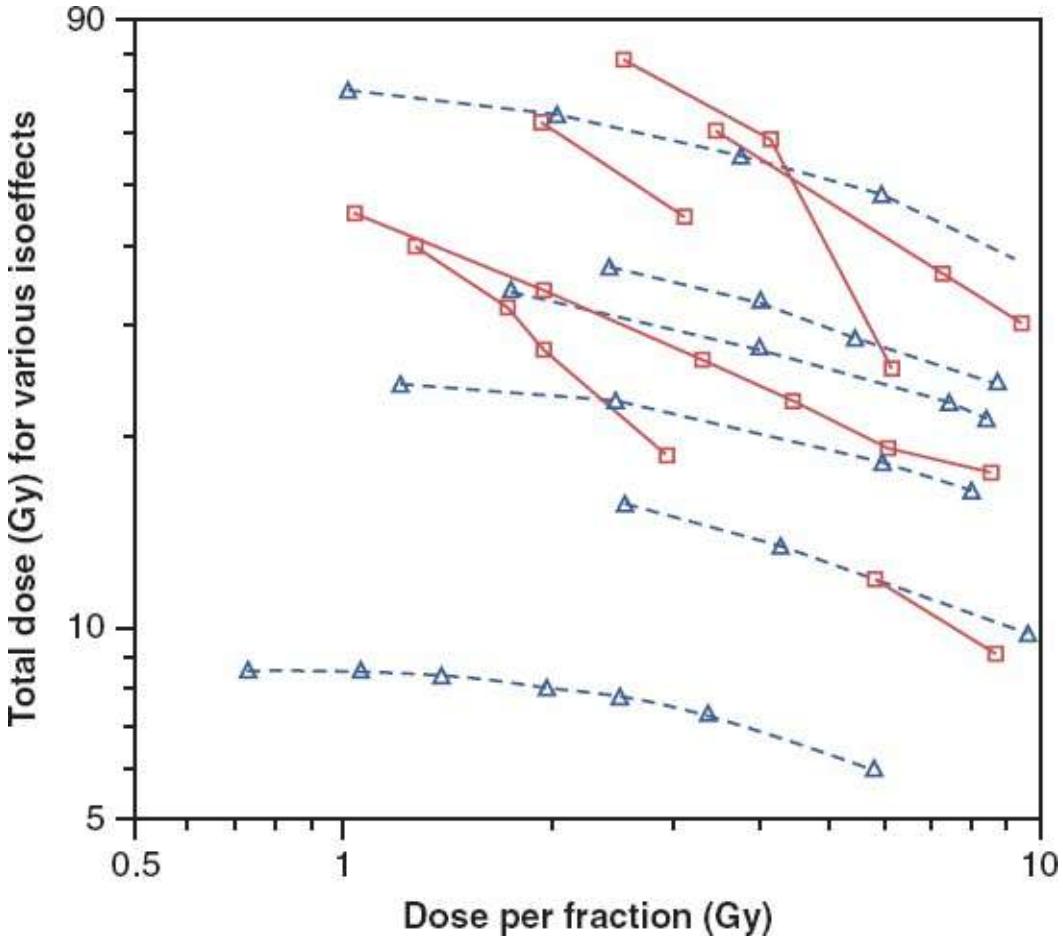

FIGURE 25.33. Isoeffect curves showing the total dose to produce a given end point, plotted against dose per fraction, a surrogate, in this context, for dose rate. The triangles, joined by *dashed lines*, refer to a variety of different early-responding end points (of which tumor control is an example), whereas the squares, joined by solid lines, refer to a variety of different late-responding sequelae. Note the generally steeper slopes of the solid lines, suggesting that late-responding tissues are more sensitive than early-responding tissues to changes in the protraction of a given radiation dose. (Adapted with permission from Withers HR, Taylor JMG, Maciejewski B. The hazard of accelerated tumor clonogen repopulation during radiotherapy. *Acta Radiol* 1988;27[2]:131–146. Copyright © 1988 SAGE Publications.)

These observations can be interpreted in terms of the α/β ratio[302] in the LQ Eq. (41). In terms of survival curves (Fig. 25.34), the α/β ratio essentially describes the degree of "curviness" of the acute survival curve. A small value of α/β means that the β (dose squared) term dominates cell killing at radiotherapeutic doses, resulting in a curvy survival curve (Fig. 25.34). A large value of α/β means that the linear-in-dose α term dominates, resulting in a straighter semilog survival curve. Now, as a first approximation, the dose–response relation for a fractionated (or LDR) regimen can be thought of as simply the result of multiple repeats of the initial part of the survival curve. It is clear that repeating the early part of a curvy survival curve many times will result in far more sparing than repeating the early part of a straighter survival curve.

Thus, late effects, which are very sensitive to changes in fractionation, are characterized by small values of α/β (a typical value is 3 Gy), and early effects (tumor control or early-responding normal sequelae) are characterized by large values of α/β, a typical value for most tumors being about 10 Gy. As clinical data from which α/β ratios can be derived have accumulated, the dichotomy between α/β ratios for early and late effects has held up remarkably well. Consequently, when using the LQ model, it is essential to be clear about whether the calculation is designed to refer to early- or late-responding tissue and to then use the appropriate α/β value. From Eq. (41), it is clear that the use of different values of α/β will result in different predictions for the isoeffect dose.

Modeling the Effect of Treatment Time

For temporary implants or HDR, the effect of tumor cell repopulation is generally small, but this is not necessarily the case with longer permanent implants. Equation (40) can be simply modified to take into account repopulation, that is, the effects of overall time. Following the original formulation by Travis and Tucker,[305] repopulation is taken into account by

increasing the surviving fraction by a factor exp(γT), where T is the overall treatment time. One can also take into account delay in the onset of accelerated repopulation, by replacing T with $(T-T_D)$, where T_D is the delay after the beginning of the treatment before tumor–cell proliferation begins[280]). Then, the surviving fraction is given by:

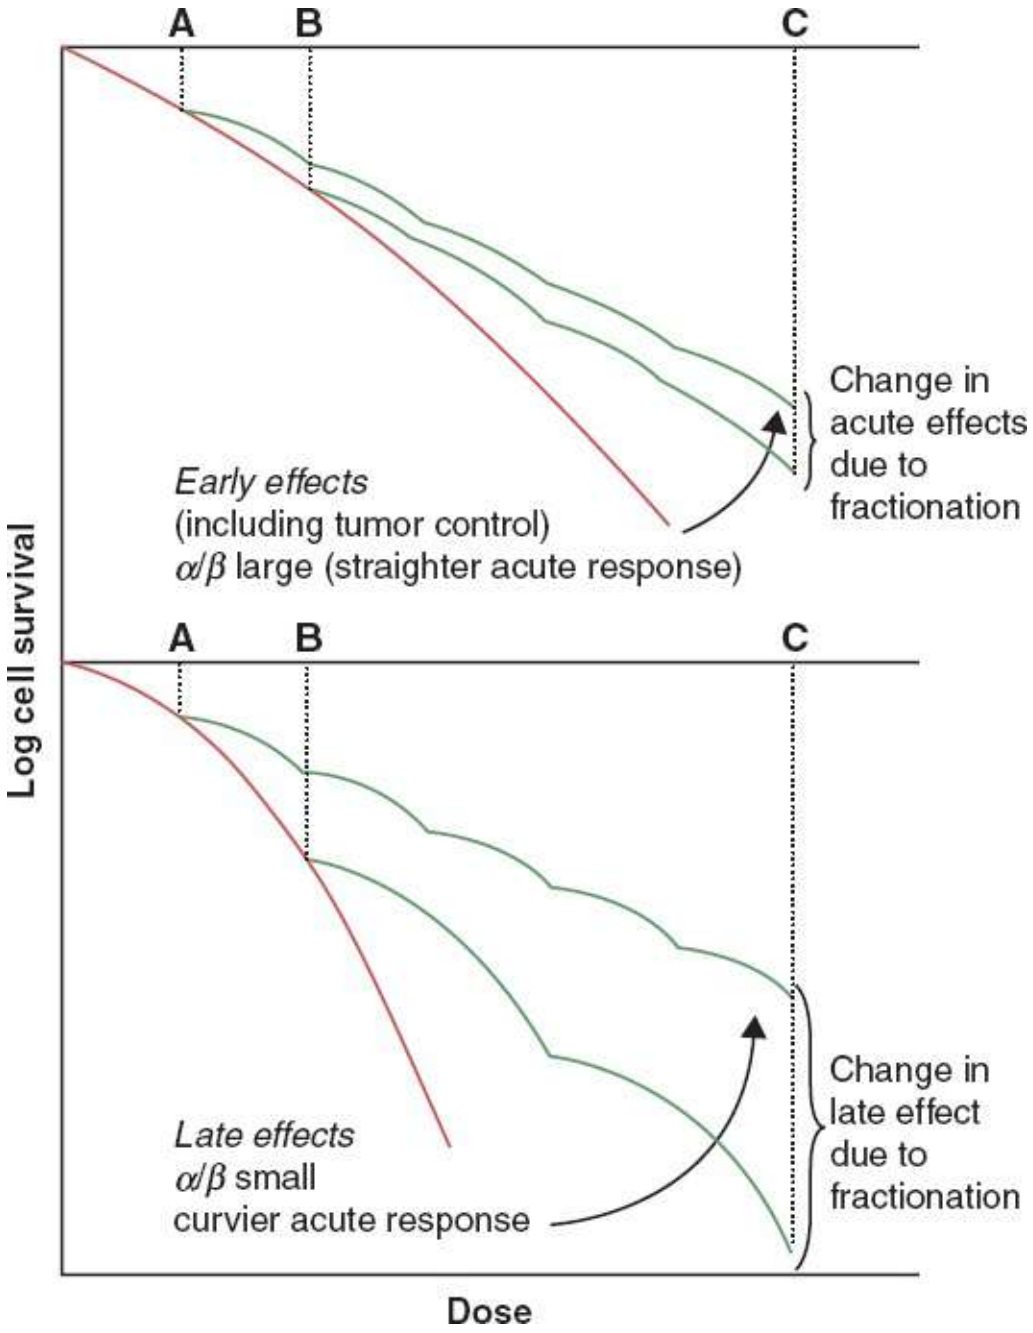

FIGURE 25.34. Illustrating the differing effects of protraction on early- and late-responding tissues, as elucidated by Thames and colleagues.[302] (Reprinted from Thames HD Jr, Withers HR, Peters LJ, et al. Changes in early and late radiation

responses with altered dose fractionation: implications for dose-survival relationships. *Int J Radiat Oncol Biol Phys* 1982;8[2]:219–226. Copyright © 1982 Elsevier. With permission.)

$$S = \exp\left(-\alpha D - G \cdot \beta D^2 + \gamma\left[T - T_D\right]\right) \qquad (44)$$

The parameter γ determines the speed of repopulation and is given by $\gamma = 0.693/T_P$, where T_P is the effective doubling time of cells in the tumor. If we can ignore cell loss, T_P is the same as T_{POT}, which is the measurable[306] *in vitro* doubling time of the tumor cells.

If tumor repopulation is relevant, then, in order to designed a new equivalent regimen, rather than match the quantity ($\alpha D + G \cdot \beta D^2$), we need to match the quantity ($\alpha D + G \cdot \beta D^2 - \gamma[T - T_D]$), and Eq. (41) or (43) can be modified correspondingly.

Redistribution and Reoxygenation

Radiobiologic response is dominated by the four "Rs": repair, repopulation, redistribution, and reoxygenation.[307] Equation (40) describes repair, which is extended using Eq. (44) to include repopulation. The LQ model can be further extended to include the remaining two "Rs"[308] by treating both redistribution cell cycle progression during irradiation and reoxygenation as aspects of a single phenomenon, termed resensitization, which occurs when a radiation exposure preferentially kills the more radiosensitive cells in a diverse population, leaving a cell population with decreased average radiosensitivity. Subsequent biologically driven changes then tend to gradually restore the original population average radiosensitivity. The resultant LQR model uses two additional adjustable parameters—an overall resensitization rate τ_S (analogous to sublethal damage repair rate) and overall resensitization amplitude $\frac{1}{2}\sigma^2$. The LQR model replaces the LQ Eq. (40) with:

$$S(D) = \exp(-\alpha D - G\beta D^2 + \tfrac{1}{2}\sigma^2 \hat{G} D^2 \qquad (45)$$

The new term, $\frac{1}{2}\sigma^2\hat{G}D^2$, is the product of $\frac{1}{2}\sigma^2$(representing the average of the dominant resensitization effects over the heterogeneous tumor), whereas the factor $\hat{G}$ models the influence of fractionation on resensitization. In fact, $\hat{G}$ has exactly the same form as the sublethal damage repair function, G, except that μ replaced by τ_S. In contrast to repair, resensitization tends to increase radiosensitivity as the overall time increases. For example, tumor cells in a

resistant part of the cell cycle at the beginning of the treatment, and thus were spared preferentially, may move to a more sensitive part of the cell cycle as the treatment progresses. Although mechanistically driven, LQR is sufficiently simple that it can be used for isoeffect calculations in radiation therapy and supporting reasonable fits to relevant experimental data.[308]

If reoxygenation or repopulation is relevant, then, in order to designed a new equivalent regimen, rather than match the quantity ($\alpha D+G\beta D^2$), we need to match the quantity $(\alpha D + G\beta D^2 - \frac{1}{2}\sigma^2 \hat{G} D^2)$, and Eqs. (41) or (43) can be modified correspondingly.

The Effects of Tumor Shrinkage

If the reference surface to which dose is prescribed diminishes in size as the tumor shrinks during the treatment, then the physical dose rate and total dose will increase as cells near the dose-specification surface are closer to the implanted sources. This phenomenon has been described using the LQ formalism by Dale and colleagues.[309,310] For permanent implants in tumors with long doubling times, tumor shrinkage may significantly enhance the clinical potential of longer-lived permanent implant radionuclides such as I-125, but would have much less effect for short-lived radionuclides such as Pd-103 or Cs-131, or for rapidly growing tumors. In fact, this is one argument against the use of long-lived nuclides for permanent-implant BT, in that the outcome may depend on shrinkage parameters that we are not able to predict.

Nonuniform Dose Distributions

Many implementations of the LQ and other radiobiologic models assume that an implant dose delivery can be approximated by a single uniformly administered prescribed dose, an assumption that ignores the highly nonuniform dose distributions produced by BT. A simple scalar metric for quantifying impact of such nonuniform dose is the equivalent uniform dose (EUD) concept proposed by Niemierko[311] or the corresponding equivalent uniform biologically effective dose (EUBED).[186,312–314] EUD is defined as the uniform dose, which, if delivered with the same dose protraction regimen as the nonuniform dose distribution of interest, yields the same radiobiologic effect. The related concept, EUBED,[186,312,314] addresses both spatially nonuniform dose distributions and spatially variable temporal dose distributions, by replacing physical dose with BED (biologically effective dose; see Eq. [41]). Suppose the dose distribution over an organ or tumor is described by a DVH, $\{D_i, v_i\}_{i=1}^{N}$ where v_i is the

fractional volume of dose bin D_i. Then, EUBED is given by:

$$\mathrm{EUBED} = -\frac{1}{\alpha}\ln\left(\sum_i \mathrm{v}_i e^{-\alpha\cdot \mathrm{BED}_i}\right) \tag{46}$$

where v_i is the fraction of the tumor target receiving the ith physical or biologically effective dose, D_i and BED_i.

Alternatively, dose inhomogeneity may be taken into account using other measures of cell survival, S, also weighted with the DVH[315–317]:

$$S = \sum_i v_i S(\mathrm{BED}_i). \tag{47}$$

This equation can also be used to estimate the overall TCP or to estimate equivalences between different treatments.[315–317]

To extend the concept of EUD to normal tissues, Niemierko (1999) proposed a phenomenologic formula referred to as the generalized EUD or gEUD:

$$\mathrm{gEUD} = \left(\sum_i v_i D_i^a\right)^{1/a} \tag{48}$$

where v_i is the fractional organ volume receiving a dose D_i and a is a tissue-specific parameter that describes the volume effect. For $a \rightarrow -\infty$, gEUD approaches the minimum dose; thus, negative values of a are used for tumors. For $a \rightarrow +\infty$, gEUD approaches the maximum dose (serial organs). For $a = 1$, gEUD is equal to the arithmetic mean dose. For $a = 0$, gEUD is equal to the geometric mean dose. The original EUD concept has a more mechanistic interpretation than the empirical gEUD (described below). However, the gEUD is often used in plan comparison and optimization metric for EBRT and may be used for comparing different protraction schemes in BT because the same functional form can be applied to both targets and OARs with a single parameter capturing (it is hoped) the dosimetric "essence" of the biologic response. By replacing the physical dose DVH $\{\mathrm{D}_i, v_i\}_{i=1}^N$ with biologically equivalent counterpart, $\{\mathrm{BED}_i, v_i\}_{i=1}^N$, the related metric, gEUBED,[274] is obtained.

The NTCP and TCP formalisms can also be generalized to accommodate nonuniform dose distributions. To compare different inhomogeneous dose distributions, TCP and NTCP can be computed by substituting Eq. (47) into the Poisson TCP model, Eq. (43), yielding:

$$\mathrm{TCP}(\{D_i, v_i\}) = \exp\left(-K \cdot \sum_i v_i S(\mathrm{BED}_i)\right) = \prod_i \left[\exp(-K \cdot S(\mathrm{BED}_i))\right]^{v_i} = \exp(-K \cdot e^{-\alpha \cdot \mathrm{EUBED}}) \quad (49)$$

The second equation shows that inhomogeneous dose TCP, TCP($\{D_i, v_i\}$), is the product of exponentially scaled (by volume fraction, v_i) TCPs, each describing uniform tumor irradiation by dose bin D_i. The third equation shows that substituting the EUBED value derived from the DVH $\{D_i, v_i\}_{i=1}^{N}$ into the uniform dose TCP also reproduces TCP($\{D_i, v_i\}$). Several authors[313,316,317] have extended this approach to spatial dose inhomogeneity to also include the possibility of inhomogeneous distributions of target cells within the tumor and radiosensitivities over the population of tumors.

Similar approaches for accounting for dose heterogeneity can also be applied to NTCP models[318] based on the survival of functional subunits (FSUs). Many organs are best modeled by FSUs organized with a parallel architecture such that a complication results only if or when sufficiently large number of FSUs are inactivated,[319] although serial architectures such as the spine can also be modeled.[316]

The literature suggests that dose nonuniformity can have a large impact on biophysical surrogates of clinical outcome. For example, for permanent seed prostate implants, Ling et al.[314] demonstrated that doses between 100% and 130% of the D_{99} prescribed dose enhanced EUBED by 20% to 70%, whereas Fatyga et al.[274] found that dose inhomogeneity enhanced EUBED by 22% for HDR prostate implants. In a population of 423 prostate cancer patients with minimum follow-up of 3 years and individual 3D dose distributions, Haworth et al.[320] were able to identify a TCP cutpoint (TCP > 0.62) that was significantly correlated with freedom from biochemical failure at 5 and 8 years. In contrast, conventional D_{90} doses were not significantly correlated with outcomes in this population. Lindsey et al.[321] found that α/β values derived by equating external beam and ^{125}I monotherapy TCPs ranged from 1.9 to 5.9 Gy when postimplant dose heterogeneity was accounted for compared to $\alpha/\beta \approx 1.5$ Gy for assumed uniform brachytherapy dose distributions. However, they cautioned that in their spatially uniform clonogen density model, α/β estimates for individual patients were highly sensitive to peripheral cold spots.

Although the above studies leave no doubt that brachytherapy dose

heterogeneity can profoundly impact the results of biophysical model predictions, a major source of uncertainty is the sensitivity of TCP, NTCP, and EUBED calculations to the ubiquitous focal hot and cold spots characteristic of brachytherapy. Most applications of TCP and EUBED to 3D brachytherapy dose distributions assume a spatially uniform clonogen density and employ a cutoff (typically 110 Gy[322] or D_{99}[314]) which excludes low-dose voxels from the calculation, thereby avoiding unrealistically low estimates for clinical implant geometries. In a study of 613 postprocedure ^{125}I prostate implant dose distributions, Miksys et al.[323] found that the mean EUBED ranged from 78 to 122 Gy for BED cutoffs ranging from 30 to 130 Gy (e.g., EUBED = 108 Gy for BED > 110 Gy). The corresponding range of mean TCP was 0.20 to 1.0 (e.g., TCP = 0.92 for BED > 110 Gy). In a study of 10 HDR prostate boost dose distributions, Fatyga et al.[274] found that gEUBED for bladder and rectal tissue was highly sensitive to focal hot spots, requiring the use of a high BED cutoff taken to be the prescribed BED_{98}. Including higher-dose focal hot spots for rectal complications was found to reverse the relative ranking of HDR and IMRT plans. This result is significant, because the gEUD formalism is equivalent to the DVH reduction scheme employed by the widely used Lyman-Kutcher-Burman (LKB) NTCP model.[324,325] In summary, straightforward application of EUBED and TCP to 3D dose calculations without arbitrary dose cutoffs requires patient-specific GTV and realistic spatially variant clonogen density models. Avoiding arbitrary high-dose cutoffs for normal-tissue response modeling requires a yet-to-be-advanced model for predicting local injury saturation.

The Relative Effectiveness of Different Radioisotopes Used in Brachytherapy

As discussed earlier in this chapter, the mean photon energies of currently used BT radionuclides range from 398 keV (^{192}Ir) down to 21 keV (^{103}Pd). It is well established that biologic effectiveness varies with photon energy, as a result of different patterns of energy deposition produced by the different photon spectra.[67,326] It is possible, however, to estimate the RBE of these different isotopes directly from the energy deposition patterns—the subject matter of microdosimetry.[327] In this approach, the response per unit dose at low-dose rates (or low doses), R_i, to a particular radiation, i, can be written as[328]:

$$R_i = \int w(y) \cdot d_i(y) \cdot dy \qquad (50)$$

where y is the stochastic quantity, lineal energy,[327] defined as the energy imparted to a cellular target arising from all ionizing radiation events caused by a single photon track and its secondary particles, divided by the target's mean chord length. The quantity $d_i(y)$ is the dose-weighted probability that a photon will deposit lineal energy y in the target volume of interest. The quantity $d_i(y)$ often is referred to as the microdosimetric single-event spectrum. It can be measured using a low-pressure proportional counter or calculated.[327] The quantity $w(y)$ describes the response of an individual cellular target to a lineal energy deposition, y. For sparsely ionizing radiations, for example, photons and electrons, it is reasonable to assume that $w(y)$ is proportional to y.[327] Thus, at low-dose rates:

$$\mathrm{RBE}_i \propto \int y \cdot d_i(y) \cdot dy \qquad (51)$$

where $d_i(y)$ is the dose-averaged lineal energy. Based on this approach, RBE values have been estimated from measured or calculated microdosimetric spectra.[67,329] For example, Wuu et al.[67] report low-dose rate RBE values relative to ^{60}Co of 1.3, 2.1, 2.1, and 2.3, respectively, for ^{192}Ir, ^{241}Am, ^{125}I, and ^{103}Pd, respectively. These values are comparable to those obtained experimentally. The approach outlined above is applicable only to LDR BT, but it can be generalized to HDR regimens.[328] Incorporating the low-dose–rate RBE into the LQ equations is surprisingly easy (Dale and Jones 1988), requiring a simple modification of Eq. (41):

$$\mathrm{BED} = D[\mathrm{RBE} + G \cdot D/(\alpha/\beta)] \qquad (52)$$

The LQ Model for Permanent Implants

To use the LQ model to predict the total dose that a permanent implant needs to deliver to a repopulating tumor with an effective doubling time of T_p, we need to match the quantity $(\alpha D + G \cdot \beta D^2 - \gamma[T - T_D])$ (see Eq. [44] to an appropriate reference regimen.). However, as shown by Dale,[330] the effective treatment time, T_{eff}, for a permanent implant is not infinite, but achieves a finite value when the dose rate becomes sufficiently low that the rate of cell kill equals the number tumor cells created per unit time by repopulation. At this point, the treatment is effectively over, and any subsequent dose is wasted. This can be expressed mathematically by $\alpha(\partial \mathrm{BED}(T_{eff})/\partial t) = \alpha \dot{D}_0 e^{-\lambda T_{eff}} \approx \gamma$ assuming that $G \approx 1$ at low-dose rates and $T_D \ll T_{eff}$. Thus:

$$T_{eff} = -\frac{1}{\lambda}\ln\left[\frac{0.693}{\alpha \dot{D}_0 T_p}\right] = -\frac{1}{\lambda}\ln\left[\frac{\gamma}{\alpha \dot{D}_0}\right] \quad (53)$$

where λ is the radioactive decay constant of the particular nuclide used and T_{pot} is the potential doubling time of the tumor. At time T_{eff}, the dose that has been delivered is not the total dose, D, but rather a smaller effective dose, given by:

$$D_{eff} = D(1 - e^{-\lambda T_{eff}}) \quad (54)$$

As an example, using reasonable parameters for prostate tumors, the effective dose for a 145 Gy I-125 permanent seed implant is actually 139 Gy, which is the value that would be used in LQ-based calculations.

The LQ model can be used to optimize the choice of radionuclide for a permanent implant.[157,331,332] The most common sources in current use are I-125 and Pd-103 (with half-lives of 59 and 17 days, respectively), although Cs-131 (half-life 10 days) is being increasingly considered.[333] The optimal radionuclide for a given tumor depends on, among other factors, its growth rate, α/β value, radiosensitivity (α), and DSB repair rate. Generally speaking, short-lived radionuclides are more advantageous for treating fast-growing tumors, whereas longer-lived radionuclides are more optimal for slow-growing tumors. However, short-lived radionuclides can effectively treat both fast- and slow-growing tumors[157,331] and, in addition, are less sensitive to the tumor properties and LQ parameter values assumed than is the case for long-lived radionuclides.

HDR Intracavitary Brachytherapy for Cervical Cancer

There has been a trend in the past few years toward the increased use of HDR BT in some tumor sites, driven largely by the economic and logistical benefits of outpatient-based fractionated HDR BT. While sometimes delivered in a single fraction, more often 3 to 12 HDR fractions are used. In some situations, such as palliative or intraoperative BT, the therapeutic ratio between tumor control and late sequelae is not a primary consideration; but, in general for curative intent treatments, increasing the dose rate is likely to *decrease* the therapeutic advantage between tumor control and late sequelae. However, there are two curative applications (intracavitary implants for cancer of the uterine cervix and implant therapy for prostate cancer) where, for differing reasons, HDR BT is as effective, or potentially even more effective, compared to LDR BT.

The radiobiologic principles involved in converting LDR to HDR intracavitary insertions are illustrated schematically in Figure 25.35, which

shows typical dose–response relationships for early- and late-responding tissues. As we have discussed, the dose–response relations for late effects are significantly “curvier” (smaller α/β ratio) than for early-responding tissues such as tumors, which have larger α/β ratios. Suppose that we want to replace a LDR treatment delivering dose D by an HDR treatment that gives identical tumor control. As illustrated in the left panel, we need to reduce the dose by a dose reduction factor (DRF) (see left panel). From the right panel, however, it can be seen that this adjusted dose, DRF × D, will result in increased late effects, i.e., lower late responding tissue cell survival, compared to LDR. But now, let us suppose that the LDR dose to organ at risk (OAR) giving rise to the late effects is not the treatment dose D, but some lower dose. This is the case for cervical BT because the bladder and rectum are generally some significant distance from the cervical implant. To be specific, let us suppose that this OAR dose is half the treatment dose, that is, D/2. From the right-hand panel in Figure 25.35, we see that if HDR preserves the LDR level of dose sparing, that is, delivers dose DRF × D/2 to the OAR, where DRF matches tumor control, we will *not* get more late effects for HDR compared to LDR, but actually a similar late-effect probability because we are further up the survival curve. Indeed, if the rectal dose were an even smaller fraction of the treatment dose (say D/3, in Fig. 25.35), HDR would have even *less* late effects than the equivalent LDR regimen. In fact, if the cervical BT results in a dose to the bladder/rectum which is less than about three-fourths of the treatment dose, then if the HDR dose is reduced to give equal tumor control compared with LDR, the HDR late effects should not be worse than the LDR late effects.[282,334]

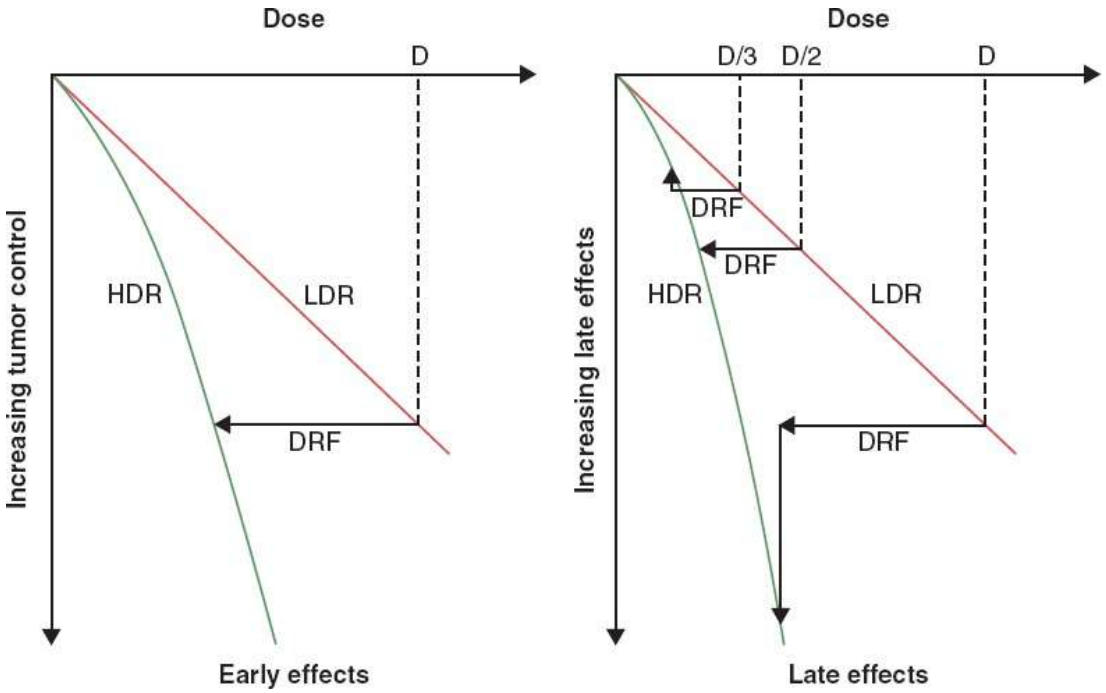

FIGURE 25.35. Illustration of the interplay between early and late effects for low–dose rate (LDR) and high–dose rate (HDR) brachytherapy for cervical cancer. DRF is the dose reduction factor that produces the same early effects (tumor control) for HDR as LDR. If D is the LDR dose giving rise to late effects, then reducing D by DRF for HDR will result in more late effects than at LDR. As the HDR dose to late-responding tissue is reduced by treatment planning, then reducing that dose by the factor DRF no longer produces worse late effects than at LDR.

Of course, there is another related factor to consider, which is that the short treatment time characteristic of HDR allows packing and retraction of the sensitive organs, which typically results in a 20% further decrease in the rectal/bladder dose compared to that achievable with LDR.[335] This gives an extra physically based advantage to HDR, in addition to the biologic factors discussed here.

The following recommendations can be made based on radiobiologic consideration about the appropriate usage of HDR versus LDR for cervical cancer BT: when the dose to the dose-limiting critical normal tissues (bladder/rectum) is less than about three-fourths of the prescribed dose, HDR (with at least about five fractions to ensure adequate tumor reoxygenation) results in comparable (or less) late effects than LDR—for the same level of tumor control. These considerations are supported by a number of clinical studies.[336–342] These reports generally show that HDR and LDR for cervical BT produce similar local control and late complications.

As BT is often combined with pelvic EBRT, different time-dose patterns of

EBRT and intracavitary BT should be taken into account to calculate the combined effects to tumor and OARs. For a given BED of BT, the equivalent EBRT dose expressed in conventional fractionation of 2 Gy/d (EQD2) can be calculated as EQD2 = BED/(1 + 2/(α/β)). Also, the dose from EBRT has to be recalculated if a fractionation schedule different from 2 Gy/d is used. EQD2 from EBRT and BT may be summed up assuming that the volumes and points of interest of BT receive the full EBRT dose. This estimate serves as a worst-case assumption for OARs and is reasonable for the target volume of BT which is often a boost volume of the PTV of EBRT. A more appropriate calculation should consider highly heterogeneous dose of BT, which will be demonstrated in the next section.

Brachytherapy for Prostate Cancer

Optimized Dose Protraction for Prostate Cancer Brachytherapy

As discussed above, one of the main reasons for protracting any radiotherapeutic exposure is that late sequelae are characterized by relatively low α/β ratios (3 Gy is typical) and, therefore, are spared more than tumor control, for which higher α/β ratios (10 Gy is typical), by lowering the dose rate, generally spares late-responding tissues more than the tumor. Such higher α/β ratios (10 Gy is typical) are thought to be due to the larger proportion of cycling cells in tumors compared with normal tissues. Because prostate tumors contain unusually small fractions of cycling cells,[306] it has been hypothesized that they may have α/β ratios and responses to protraction more typical of late-responding normal tissues.[343,344] If so, much of the rationale for low dose rate, or highly fractionated regimens, would disappear.

A first estimate of α/β for prostate cancer was made in 1999,[343] by comparing results from EBRT with those from permanent seed I-125 BT. Consistent with the theoretical hypotheses (see above), the estimated value of α/β was 1.5 Gy [95% CI, 0.8–2.2 Gy], indeed comparable to α/β values for late-responding normal tissues, and much smaller than those for most tumors.

The problem with this α/β estimate, and almost all subsequent ones,[296,345–350] is that they involved comparing or equating EBRT results with permanent implantation results. There are many pertinent differences between EBRT and BT (different dose distributions, different RBEs, different overall times, different institutions, different PSA distributions, hypoxia), any or all of which could bias the α/β estimate. Much debate has been centered on the significance of these biases and how to take them into account. For example, it has been reported that

the consideration of hypoxia can significantly impact the α/β estimate[351] Despite these problems, most of the analyses above support the hypothesis that the α/β value for prostate cancer is indeed quite low, probably in the 1 to 4 Gy range, which is similar to the values for most late-responding tissues.

One analysis,[352] which avoids many, though not all, of the potential biases involved in comparing EBRT and BT. Here, EBRT + two HDR boost fractions were compared with EBRT + three HDR boost fractions—all done with the same technique at the same institution. The resulting estimated α/β ratio for prostate cancer was 1.2 Gy [95% CI, 0.03–4.1 Gy], again comparable with α/β values for late-responding normal tissues. A meta-analysis of four reports summarizing 21 studies yielded an estimated α/β ratio of 1.3 Gy.[353] A recent analysis of pooled multi-institutional datasets[354] led to $\alpha/\beta = 1.4$. A critical review of α/β ratio estimation methodologies and clinical analyses has been published by Oliveira et al.[355]

If the α/β value for prostate cancer is indeed similar to that for the surrounding late-responding normal tissue, HDR or hypofractionated external beam therapy regimens could be employed to match conventional fractionated regimens with respect to tumor control and late sequelae while reducing early urinary sequelae[356] and improving cost-effectiveness and patient convenience.

The arguments presented here really relate to the α/β value for prostate cancer in relation to the α/β value for the relevant late-responding normal tissue. Brenner reported an α/β value for RTOG grade ≥2 late rectal toxicity of 5.4 ± 1.5 Gy based on an analysis of clinical data.[357] Another recent analysis of RTOG 94-06 data suggested that the α/β value for grade ≥2 late rectal toxicity was 4.8 Gy.[358] These α/β values, which are larger than that of most late-responding tissues, are higher than recent estimates of prostate tumor α/β ratio. This suggests that HDR prostate BT, as well as being logistically convenient, might actually improve the therapeutic outcome of prostate cancer BT.

HDR (or hypofractionation) in a curative setting, even when the dose is appropriately lowered, is a prima facie unsettling idea. However, there is now a significant body of clinical evidence suggesting that these approaches do not lead to increased early or late sequelae after prostate radiotherapy, either for EBRT or for BT, providing further evidence to support the underlying radiobiologic rationale. For EBRT, in those hypofractionation studies that have reported on potential late sequelae, there is to date little indication of any unexpected late sequelae after median follow-up periods of 21 months,[359] 31 months,[360] 48 months,[361] 59 months,[362] 66 months,[363] and 97 months.[364] HDR

has been used in prostate BT both as a monotherapy[365,366] and, more commonly, as a boost to external beam radiotherapy.[367–370] In both cases, the results are promising with no evidence for excessive normal-tissue complications.

Summary: Biophysical Outcome Models in Brachytherapy

This survey of biophysical models for predicting clinical outcomes from brachytherapy regimens shows that the basic LQ model is sufficiently supported by clinical experience to be used for developing equivalent fractionation regimens or to optimizing therapeutic ratios in many clinical settings. More sophisticated NTCP and TCP models, although not sufficiently robust for use in clinical planning, are able to semiquantitatively account for the LDR and HDR brachytherapy clinical outcomes in several sites in terms of underlying descriptive radiobiologic mechanisms.

CONCLUSIONS

This chapter has focused on several basic topics including physical source properties, single-source dosimetry, source-strength specification, classical interstitial and intracavitary brachytherapy systems and dose specification, and their impact on biologic effects and clinical utility. Many topics usually covered in an introductory survey have been omitted. For a review of radiographic imaging and localization of brachytherapy sources, the reader is referred to more specialized reviews.[371,372] For discussions on quality assurance of manual and remote afterloading brachytherapy and treatment planning, the reader is referred to Chapters 26, 27, and 28 of this text as well as a number of excellent reviews[92,373–377] including appropriate chapters from *Brachytherapy Physics, 2nd Edition*.[378] For useful reviews of the radiobiology of brachytherapy, the reader is referred to excellent reviews by Dale,[379] King,[380] and Carlson.[381] For a discussion of brachytherapy licensing and regulatory issues, the review by Glasgow[382] is suggested.

CHAPTER 26

Clinical Applications of Brachytherapy: Low Dose Rate and Pulsed Dose Rate

Sophie J. Otter, Caroline Holloway, Phillip M. Devlin, and Alexandra J. Stewart

Brachytherapy was the first form of conformal radiation therapy, utilizing placement of radioactive sources within or very close to a tumor, allowing high cancer to normal tissue dose ratios. From the time that Roentgen discovered radiography, the effects of ionizing radiation on the skin were noticed. Those exposed to the early cathode ray tubes, both patients and radiographers, developed radiation dermatitis and hair loss. After the isolation of radium, Henri Becquerel and Pierre Curie reported radium burns similar to those experienced by the early x-ray users. Radium was first used to treat skin lesions and superficial tumors using boxes and tubes as applicators. From there, radium in metal needles or radon gas in glass seeds was placed in direct contact with tumors using surface applicators and intracavitary and interstitial implants.[1] Source positioning within the tumor allowed high doses within the cancer with small volumes of normal tissue irradiated and a sufficient dose at the margin between cancer and normal tissue to eradicate microscopic tumor foci. Early results were promising and revolutionized cancer treatment.

In the 1950s, the use of brachytherapy was widespread; however, at that time brachytherapy had a number of disadvantages. Classic radium needles were rigid with a wide outer diameter ($\geq$1.5 mm^2). Brachytherapists had to have a high level of surgical skill to site the needles accurately and to achieve good dosimetry quickly to minimize their own and others' radiation exposure. Therefore, the emergence of teletherapy with the advantages of decreased staff radiation exposure and radiation accessibility to more areas of the body with no dependence on surgical techniques led to a decrease in the use of brachytherapy.

However, brachytherapy has experienced a revival as a result of the emergence of newer artificial high-activity isotopes, afterloading systems, and

improved radiologic imaging with more sophisticated dose planning techniques. Modern radiotherapy techniques have focused on dose escalation to the target and decreasing the dose to normal tissues. Brachytherapy can deliver both of these objectives in a highly conformal manner over a wide variety of disease sites. One advantage includes patient convenience. For example, prostate brachytherapy requires one or two hospital visits compared with 7 to 8 weeks with prostate external beam radiotherapy (EBRT). Reimbursement can have a marked impact on technique uptake with high reimbursement in nonnationalized health care systems playing a part in the resurgence of brachytherapy. However, it can also have a negative impact with a drop in uptake of prostate brachytherapy boost treatments corresponding to a fall in reimbursement rates using this approach.

Early texts describe the important principles of brachytherapy as uniformity in cross section, uniformity in depth, and uniformity in opportunity (time).[2] These principles remain the cornerstone of modern brachytherapy practice, though modern techniques allow better assessment of these. Computed tomography (CT), ultrasound, and magnetic resonance imaging (MRI) scanning have enabled enhanced imaging in brachytherapy, allowing more accurate target definition, superior determination of applicator position, and improved evaluation of the position of normal tissues. In combination with computerized dosimetry, this has allowed better determination of the dosimetric coverage of a brachytherapy implant and an estimation of the subsequent risk of normal tissue toxicity.

DOSE RATE DEFINITIONS

Three categories of brachytherapy were defined in Report 38 of the International Commission on Radiation Units and Measurements[3]:

- Low Dose Rate (LDR): a range of 0.4 to 2 Gy/hour. In clinical practice, the usual range is 0.4 to 1 Gy/hour.
- Medium Dose Rate (MDR): a range of 2 to 12 Gy/hour.
- High Dose Rate (HDR): over 12 Gy/hour.

Permanent seed implants deliver a high total dose at a very low dose rate (vLDR), usually at < 0.4 Gy/hour. Pulsed dose rate (PDR) brachytherapy was developed in an effort to simulate the radiobiologic advantages and dosimetric properties of LDR, but with the advantages of computer optimization of dose, a stepping source, and remote afterloading usually achieved by HDR. PDR is a

misnomer; in fact, the dose rate is often high but the pulse intervals are short so that the radiobiologic effect is similar to LDR. A source with activity in the realm of one-tenth of HDR activity is used. Generally, the same total dose and total time as LDR are prescribed but the radiation is administered in a large number of small fractions, usually a pulse every 1 to 4 hours. Published series in a variety of tumor sites indicate that the clinical efficacy and the toxicity of PDR are similar to those of LDR/HDR.[4] It also has the advantage of a single afterloaded source compared to an inventory of LDR sources of different strengths. This will become increasingly important as manufacture of traditional LDR sources ceases and disposal costs of existing LDR sources rise. Traditional LDR sources iridium-192 and cesium-137 are no longer available in Europe and are becoming scarce in the rest of the world. Table 26.1 demonstrates the advantages and disadvantages of LDR and PDR brachytherapy.

CLINICAL USES OF BRACHYTHERAPY ISOTOPES

Brachytherapy uses radioactive isotopes to deliver therapeutic doses of radiation. The ideal radioisotope for brachytherapy should have a relatively short half-life in order to deliver the radiation in as short a time as possible and a high specific activity so that the source is small and therefore more versatile to implant. The emissions produced should have an adequate penetration to deliver the dose to the depth desired with rapid falloff to prevent damage to the surrounding normal tissue. Particular source characteristics such as half-life or specific activity can be tailored to the tumor and the surrounding organs at risk (OAR).

Temporary Implants

Cobalt-60 (^{60}Co) was one of the first artificial radionuclides used, available in interstitial needles and wires, but its usefulness for brachytherapy was limited by its low activity and short half-life, though it is still used in afterloaders in the developing world with the advantage of decreased pressures on quality assurance and cost.[5,6] Cesium-137 (^{137}Cs) sealed into a ceramic or glass pellets was in use from the 1960s. From the 1970s, ^{137}Cs was the predominant isotope used worldwide for intracavitary gynecologic implants. However, production of this isotope ceased in 2002, and most departments wishing to continue using LDR-style dose and characteristics have switched to isotopes more suitable for remote afterloading, often using PDR techniques. Strontium-90 (^{90}Sr) is a pure beta emitter and therefore is suitable for very superficial applications; it is commonly

used for coronary brachytherapy and ophthalmic problems such as pterygium. It has a half-life of 28.1 years, so many departments are still using applicators purchased in the 1980s. Ruthenium-106 (^{106}Ru) is also a beta emitter but with a much shorter half-life (1 year), making disposal concerns less and treatment delivery faster.

TABLE 26.1 THE ADVANTAGES AND DISADVANTAGES OF LDR AND PDR BRACHYTHERAPY

Advantages		Disadvantages	
LDR	**PDR**	**LDR**	**PDR**
>100 years of data Standardized doses Standardized treatment plans Less source changes needed (depending on isotope used) Less shielding needed during treatment	Source easily available Standard source strength Minimal staff exposure Dose optimization of normal tissues Radiation-free periods aid nursing care No source inventory required With short pulse intervals uses long held doses with known safety and efficacy	Often inpatient treatment with prolonged bed rest Radiation exposure to staff Limited by available source strength Many LDR sources no longer being manufactured	One machine per patient used for 3–5 days More intense maintenance Requires more physician/physicist time in certain locations More expensive than LDR[279] Caution with conversion of dose from LDR to PDR especially as intervals increase May require prolonged bed rest depending on implant location

Iridium-192 (^{192}Ir) has been used since the 1960s in afterloading systems—both manual and remote. Its high specific activity makes it extremely suitable for remote afterloading because of the increased flexibility available with a smaller source. The small source size has enabled implants in areas where cesium sources would be too large, and the afterloading machine allows implants into much longer applicators, such as esophagus and bronchus, than was easily attainable with manually afterloaded ^{192}Ir wires.

Permanent Implants

The artificial isotopes iodine-125 (^{125}I), palladium-103 (^{103}Pd), and cesium-131 (^{131}Cs) are all used in modern permanent vLDR implants. The isotope used can be chosen according to individual characteristics that may be desirable in different implants; for example, slower dose delivery may decrease normal tissue toxicity or a tumor with a higher alpha/beta ratio may theoretically have more

cell kill using an isotope with a shorter half-life. All three isotopes are almost completely shielded with 0.2 cm of lead foil, making radiation protection easier.

Clinical Suitability for Brachytherapy

Cancers with clinically and radiologically well-defined margins with a low risk of regional and metastatic spread are the most suitable for brachytherapy as a single modality. However, brachytherapy is becoming increasingly important when integrated with EBRT to give a highly localized boost. EBRT is used to sterilize a larger area of possible microscopic or nodal spread, with brachytherapy used for areas of gross macroscopic or microscopic residual disease. This ensures that high doses are achieved within tumors whereas normal tissues are not taken beyond recognized organ tolerance levels. It also has the potential for highly conformal localized dose escalation to areas at high risk of tumor recurrence.

In EBRT, the dosimetric goal is a homogeneous dose distribution with doses ranging from 95% to 107% of the prescribed amount.[7] In contrast, brachytherapy has an extremely heterogeneous dose distribution with isolated areas receiving in excess of 200% of the dose. The steep gradients are a consequence of the proximity of the clinical target volume (CTV) to the sources and decreasing dose with distance secondary to the inverse square law. The very high doses in the center of the implant contribute to additional cell kill, and the normal tissues also benefit from the inherent heterogeneity of the brachytherapy dose. As the dose falls off with distance, the normal tissue experiences not only a reduced dose but also a reduced dose rate that results in enhanced cell sparing. The sharp dose falloff with brachytherapy contrasts with the more gradual dose falloff seen with photon-based EBRT.

Brachytherapy can be given over a short duration (e.g., using PDR, a radical head and neck treatment course can be administered over 5 to 6 days compared to 5 to 7 weeks for a conventional EBRT head and neck regimen). Brachytherapy can also be used as a method of retreatment when a patient has received irradiation to normal tissue tolerance using EBRT. Using the principles described previously of sharp dose falloff and highly conformal dosing, a clinically useful radiation dose can be administered while minimizing the risk of increased late toxicity resulting from reirradiation.

Brachytherapy can be used anywhere in the body that can be accessed for direct source placement. For many years, surface applicators and intracavitary gynecologic brachytherapy were the predominant modes of brachytherapy.

However, with the advent of modern surgical techniques and interventional radiology, many more areas of the body are now accessible to the brachytherapist.

Brachytherapy applicators can be placed within tubular organs in the body, either under direct vision (e.g., cervix or vagina) or with the use of radiologic or endoscopic guidance (e.g., bile ducts or esophagus). Interstitial implants can be placed with or without image guidance (e.g., prostate implants using rectal ultrasound guidance and a template or a freehand extremity sarcoma implant). Interstitial implants can take the form of free seeds, seeds within linked strands, or catheters that will be afterloaded with the radioactive source. Of course, surface applicator techniques are still used, with the added benefits of modern imaging and dosimetry techniques to ensure target coverage.

LDR sources can be placed directly into the body; however, with higher activity sources and large implants, this can result in a high radiation exposure to the brachytherapist and operating room staff. To overcome this problem, afterloading techniques were developed. Initial techniques required applicator placement in the operating room and manual afterloading of sources in a shielded room at a later time. This has mainly been supplanted by remote afterloading techniques, where the patient has the applicators placed in the operating room and is later connected to a remote afterloading machine in a shielded room. The sources will only enter the patient when all personnel are at a safe distance from the patient; this can be used for LDR and is essential for PDR.

When using afterloaded LDR or PDR, it is important that the patient can be safely left in a room without direct supervision, because during the period of source excursion, radiation dose to staff must be kept to a minimum. During an LDR implant, careful monitoring of the sources must be maintained to detect source displacement. During a PDR implant, the patient should be monitored for applicator displacement between pulses; this may be under direct vision or using radiologic confirmation. Devices aiding local protection of OAR may be used (e.g., leaded gum shield during lip brachytherapy). An analysis of 1,300 PDR treatments showed that patients received their dose as originally planned in 98% of treatments, with a deviation of 1.1% due to technical reasons and 0.9% due to coexisting medical illness. The error rate was very dependent on tumor site, with errors up to 14.9% for orbital tumors.[8] Errors due to malfunctioning catheters were often resolved during the treatment course by replanning the patient.

Target Definition

Many of the same definitions for delineation of treatment volumes in EBRT are used for brachytherapy.[7,9] There may be delineation of high-risk and low-risk areas if discrete areas of dose escalation are required within the CTV. The high-risk area has the highest risk of local recurrence, usually due to the presence of gross residual disease. An intermediate area may be defined that corresponds to areas where there was macroscopic tumor at the time of diagnosis that has regressed by the time of brachytherapy implant. The low-risk area includes potential microscopic spread, that is, the traditionally defined CTV. In EBRT, the planning target volume (PTV) traditionally consists of the CTV plus a margin that will allow for physiologic movement and setup uncertainty. Generally in brachytherapy these variations are minimized, and therefore the PTV is usually the same as the CTV.

In a brachytherapy implant there will be *high dose regions* around each source. Generally, the volume of the region receiving over 150% of dose is reported (V_{150}).[3] *Low dose regions* are those within the CTV receiving <90% of the prescribed dose. Because of the heterogeneity of dose in brachytherapy, the average dose within the prescribed volume is usually far higher than the prescribed dose at the reference isodose point on the periphery of the implant. This is tolerated because of the volume–effect relationship: very small normal tissue volumes (e.g., 1 to 2 cm^3) can tolerate very high radiation doses that larger volumes would not tolerate. The dose to OAR should be reported, either as a total dose or as a ratio of volume. Parameters such as the minimum dose received by the most irradiated 2 cm^3 (D2cc) of tissue or the volume receiving over 90% of the dose (V_{90}) or dose received by 90% of the CTV (D_{90}) are assessed.

RADIOBIOLOGIC CONSIDERATIONS

Radiobiologic principles are important in the daily clinical use of all forms of brachytherapy. Brachytherapy was initially developed empirically with doses being determined by clinical effect. These correspond to many of the LDR and PDR dose schedules in current use. In the modern era, radiobiologic modeling is used to predict the biologic effect of varying dose prescriptions. The importance of radiobiology and its use within brachytherapy was emphasized by the move from LDR treatment to PDR and fractionated HDR treatment. Of course, it must be remembered that applicator and source placement remains the single most important factor in brachytherapy, such that in an implant with poor geometry,

changing radiobiologic parameters, such as fractionation or dose rate, will not improve the outcome.

Factors contributing to the response of tissues to radiotherapy have been labeled the "4 Rs of radiotherapy."[10] These are repair, reassortment, repopulation, and reoxygenation. The way in which these radiobiologic characteristics relate clinically to the use of LDR and PDR either alone or in comparison to HDR is as follows:

Repair

Sublethally damaged cells are capable of repair if they are allowed sufficient time and if the cell contains all of the necessary DNA repair proteins and enzymes. If sublethally damaged cells are exposed to further irradiation before repair occurs, the damage may become lethal. Late-reacting normal tissues seem more capable of repair than tumor cells, so, at a given therapeutic dose, tumor is preferentially killed over normal tissue. This is probably a result of a loss of repair fidelity in addition to a lack of relevant repair proteins and enzymes in the tumor cell. The lower the dose rate of radiation that a cell is exposed to, the more likely it is that repair of normal tissues will occur within that cell before a second injury occurs.

The time course of LDR or PDR treatment over several days allows time for sublethal damage repair in normal tissues. In contrast, the short treatment time of HDR treatment prohibits this repair during the actual irradiation. Using PDR, generally the same total dose and total time as LDR are prescribed. If PDR is given at a pulse width of 10 minutes and a 1-hour pulse interval, the dose is equivalent to LDR 0.6 Gy/hour.[11,12] If the dose per pulse is small (≤0.5 Gy) and the normal tissue repair half-time is over 30 minutes, the differential effect to LDR is <10%. If the dose per pulse is over 2 Gy or the tissue repair half-time is under half an hour, this is not the case and the PDR effect becomes biologically closer to a highly fractionated HDR treatment, especially in close proximity to the source.[13] In this situation, a lower total PDR dose than LDR can be given in the same overall time to achieve equivalent clinical effect. Sometimes PDR is prescribed using an "extended office hours" schedule (i.e., 8 a.m. to 8 p.m.). This is commonly to overcome regulatory issues where a physicist and physician must be present for every source excursion. One general rule when transferring LDR to PDR dose is to not exceed the overall dose rate that would be delivered by LDR in a day (e.g., at a dose rate of 0.5 Gy/hour, LDR delivers a total dose of 12 Gy over 24 hours); thus, using a daytime-only PDR schedule providing a

similar biologic effect and normal tissue complication probability, the overall treatment time will commonly be slightly extended.[14]

Dose rate is a key factor in determining the biologic effects of brachytherapy. In general, the effects of radiotherapy increase as the dose rate increases, predominantly because of a decrease in repair. It has been suggested that the total dose of LDR prescribed should be corrected for overall time of the implant[15] though some investigators have found no difference in local control with the same total dose administered using a dose rate ranging from 0.05 to 0.167 Gy/minute.[16] A randomized study in cervix carcinoma showed no difference in overall survival or local control for an LDR dose rate of 0.4 versus 0.8 Gy/hour.[17,18] However, there was a significant increase in late complications in the higher dose rate group. A similar trend has also been seen in LDR brachytherapy for breast cancer and head and neck carcinoma.[19,20] Therefore, it is recommended that the LDR dose rate (and PDR equivalence) should be in the range of 0.3 to 1 Gy/hour because of the effects on late complications rather than local control. If the dose rate exceeds 1 Gy/hour, a reduction in the total dose can be calculated using the biologically equivalent dose (BED) equation.

Reassortment

In normal cells, proliferation occurs in a sequence of events termed the cell cycle.[21] There is a theoretical advantage of an improved effect on reassortment using LDR treatment because, during the overall treatment time, cells will pass out of the relatively radioresistant cell cycle phases of late S and early G_2 into the more radiosensitive phases of late G_2 and M. This has been shown *in vitro*,[22] but *in vivo*, the effect of reassortment has not been shown to give a true advantage, possibly because of a disruption of the mechanisms of the cell cycle in cancer cells.[21]

Repopulation

In squamous cell carcinoma, studies have shown improved tumor control and increased survival when a radiotherapy course is given in the shortest overall time.[23–26] This may be because shorter treatment times allow less time for tumor cell repopulation or for accelerated repopulation to occur. The continuous administration of LDR and PDR probably prevents repopulation during treatment.

Reoxygenation

The response of cells to radiation is strongly dependent on oxygen. Radiation results in free radical formation within a tumor, and oxygen reacts with these free radicals to make DNA damage irreparable. The effect of hypoxia on tumor control has been well documented, with decreased survival in certain patients with a low initial hemoglobin level.[27–29] There are two hypoxic cell populations within tumors, chronic and transient. As a tumor outgrows its blood supply, a proportion of cells will become necrotic. Viable cells near this necrotic zone will be chronically hypoxic. Transient hypoxia may occur over minutes to hours as small vessels within the tumor open and close or small tumor emboli intermittently block blood vessels. When using LDR and PDR, transient hypoxia may correct during the treatment time,[30] which is not possible during the short duration of HDR brachytherapy. If the brachytherapy is fractionated, tumor shrinkage and reoxygenation of areas of chronic hypoxia may occur between insertions.

MEASUREMENT OF BRACHYTHERAPY DOSE

Dosimetry systems aim to give the brachytherapist a set of guidelines to follow that result in a prescribed dose being delivered to a patient in a predictable fashion. Initial brachytherapy dosimetry systems were developed for LDR implants using an empirical approach toward source placement and dose calculation. More modern techniques use computer programs to generate isodose distributions that can then be analyzed in two dimensions, three dimensions, and volumetrically. To achieve the best ratio of cancer to normal tissue dose, the selection of an appropriate prescription point is essential. Again applicator positioning is of primary importance, as differential loading cannot compensate for a poorly sited implant.

The Manchester dosimetry system was one of the first published dosimetry systems, with origins dating from the 1930s.[31] Guidelines for the use of LDR wires and tubes are set out for surface molds, interstitial planar implants, and volume implants. However, it required a range of isotope activities to be available, and at that time, the available radium sources in the United States had a more limited range of activity. Therefore, the Quimby system modified the Manchester system to allow uniform source strengths to be used throughout the implant.[32] The Paris dosimetry system developed guidelines in the 1970s for modern LDR brachytherapy sources such as flexible ^{192}Ir wires.[33] It is difficult to achieve an implant that conforms exactly to the Paris rules without the use of

a template.

Whereas LDR uses fixed source positions and strengths to calculate the dose at the prescription point, afterloading machines and computerized dosimetry systems allow optimization of source dwell times to customize dose delivery to the patient's individual anatomy and tumor volume. PDR takes advantage of this dose optimization in a way that LDR cannot. Optimization results in nonuniform source loadings that give greater dose uniformity and CTV coverage that is often similar to an idealized Manchester dosimetry system implant.[34] Prior to the introduction of computerized dosimetry, the dosimetry of an implant was based on the intended source position rather than the actual source position. This could be highly dependent on the expertise of the individual brachytherapist. Improved radiologic imaging has allowed more accurate definition of the CTV and associated normal tissues, giving dose specification according to patient anatomy rather than applicator position. This is more likely to correlate with patient outcome than previous dosimetry systems. This may result in not only better tumor control but also decreased risk of late complications.

Now that computerized dosimetry is available, brachytherapists may be tempted to abandon knowledge of the previous dosimetric systems and place sources as they see fit, using the computer to calculate dose distribution. This approach risks overdosing part of the volume. There is a steep dose gradient around each wire/catheter, and widely spaced sources may form large high dose regions and increase the risk of necrosis. The maximum source separations and treatment thickness in the Paris system are useful rules to remember to decrease this risk. The principle of extending the sources beyond the target or crossing at the ends should also be remembered, to overcome the inherent dose falloff at the end of the source, though this can be achieved routinely with HDR and to some extent using optimization with PDR brachytherapy. The rules from individual systems should not be mixed, even if computerized dosimetry is used for dose calculation.

Brachytherapy dose delivery traditionally was thought not to be affected by alterations in the treatment position. Although this may be true for dose delivery to the target volume, the position of OAR in relation to the brachytherapy implant may be altered, thereby increasing the dose delivered; for example a patient undergoes simulation lying flat on a CT scanner with a breast implant that falls laterally with gravity. On sitting up, this applicator may then fall more medially potentially changing cardiac, lung, and skin doses. Therefore for temporary implants, treatment should take place in the planning position to allow

accurate OAR dose determination.

CLINICAL SITES

There are areas where LDR techniques continue to predominate (e.g., vLDR prostate brachytherapy) and areas where HDR techniques predominate (e.g., esophageal brachytherapy). In some disease sites, the use of HDR and LDR was generally equal (e.g., cervix cancer), but now HDR predominates with a small but significant proportion of centers worldwide using PDR treatment. Next is presented an overview of clinical uses for LDR and PDR with an emphasis on the brachytherapy dose rate rather than the treatment technique. Individual indications will be described in the site-specific chapters.

Cervix Cancer

The use of LDR for cervix cancer treatment was first described with intracavitary implants in 1903 and with interstitial implants in 1913.[35] Brachytherapy has withstood technologic innovations to remain an essential part of curative cervix cancer treatment[36,37] for all but the very earliest stages of the disease. The use of LDR has many years of safety and efficacy data, and physicians can be confident in their choice of brachytherapy dose. These doses have been shown to be biologically equivalent using PDR so long as the rules governing pulse length and pulse interval are carefully followed.[14,38] In contrast, a wide variety of HDR dose and fractionation schemes are used,[39] with shorter follow-up data for efficacy and toxicity. Randomized clinical trials have shown the equivalence of HDR brachytherapy and LDR brachytherapy,[40] and some of these studies suggested a lower morbidity with HDR brachytherapy, which could be postulated to be due to the ability to optimize the dose away from normal tissues.[41,42]

Several trials demonstrated the superiority for chemoradiotherapy over radiotherapy alone in cervix cancer treatment.[43] All of these trials used LDR brachytherapy, and there are no prospective randomized safety data on the use of HDR brachytherapy and chemoradiotherapy. PDR brachytherapy utilizes the dose and scheduling of LDR and thus should have a similar efficacy profile while allowing the dose optimization capability of HDR, which may improve normal tissue toxicity. Studies have shown this to be the case in clinical practice.[44–46]

With the use of CT and MRI-based target volume and organ at risk definition,

dose reporting in cervix cancer brachytherapy has changed from point-based to volume-based.[47–49] This means that tumor coverage is improved and the doses to normal tissues can be decreased. This method relies on the use of dose optimization and thus moves away from LDR and toward PDR as an equivalent treatment modality.[50,51] The longer time taken to deliver one overall fraction of PDR versus HDR is important when optimizing dose away from normal tissues, and it is important to recognize that the dose delivered to normal tissues over the whole treatment time may differ from that predicted, by up to 33% more.[52] Rectal volume has been shown to increase during the course of delivery of PDR, and therefore serial imaging and adaptive planning may be necessary as the cumulative rectal dose correlates with late rectal toxicity better than the planned dose.[53]

A recent randomized controlled trial has shown that there is no significant difference between late rectal, bladder, and vaginal toxicity and survival when comparing PDR with HDR brachytherapy.[54] American Brachytherapy Society (ABS) guidelines for the use of LDR and PDR in cervix cancer[55] incorporate the volume-based dosimetry and updated quality control recommendations.

The applicator is generally placed under operative conditions. Review of preoperative imaging is essential to determine which applicator is most appropriate. The patient may require a general anesthetic, but spinal anesthesia (see Fig. 26.1) has been shown to provide excellent analgesia, which can be maintained throughout the length of the implant using a spinal catheter.[56] Spinal anesthesia does not affect tumor oxygenation during an HDR implant[57] and thus is unlikely to do so during the whole duration of an LDR or PDR implant. A variety of commercial applicators are available for intracavitary brachytherapy (see Fig. 26.2) with the tandem and ring applicator becoming increasingly popular for tumors <5 cm. For tumors over this size, the addition of interstitial needles into specialized applicators is becoming more common because it has brought the ability to deliver interstitial brachytherapy to a wider group. Interstitial template applicators such as the Syed-Neblett[58] or the MUPIT[59] can be used to treat disease with lateral extension, though it is important to maintain a degree of central dose heterogeneity (in contrast to the heterogeneity preferred in interstitial implants in other areas of the body) to maintain the central cervix doses needed for cure[60] (see Figs. 26.3 and 26.4). Customized vaginal molds can be used and are particularly prevalent in France,[61] offering truly customized brachytherapy dosing.

FIGURE 26.1. Administration of a spinal anesthetic prior to a pelvic brachytherapy procedure.

An LDR applicator is typically manually afterloaded once the patient returns to the shielded isolated patient room. The patient will undergo CT scanning and computerized planning before dose delivery. When the patient is receiving the dose she will be nursed lying flat with prophylaxis against venous thromboembolism. Typically, agents are given to slow bowel motility, and it may be preferable to follow a low-irritant fiber diet before and during implantation. A urinary catheter is maintained throughout treatment. Prophylactic antibiotics are not routinely required but can be considered for interstitial implants. Pain and discomfort may be managed by epidural or intravenous patient-controlled analgesia. During LDR, care is taken to minimize exposure to the medical staff caring for the patient with the use of mobile shielding placed around the bed and by training of the staff in the time/distance radiation safety rules. The use of pregnant staff is not allowed so as to minimize risk of dose to fetus.

Endometrium

Endometrial carcinoma is the most common female pelvic malignancy in Western countries.[62,63] Brachytherapy for the management of endometrial carcinoma was first described by Heyman in 1935, prior to the routine use of hysterectomy for uterine cancer.[64] The majority of endometrial cancer patients now present at an early stage, and the use of radiation alone has evolved. The primary treatment for endometrial cancer is surgery (total abdominal hysterectomy and bilateral salpingo-oophorectomy) with or without adjuvant radiotherapy and chemotherapy, based on the histology of the tumor and stage of presentation. Pelvic lymph node sampling or lymphadenectomy is also used to give prognostic information and direct adjuvant treatment. As endometrial carcinoma is linked to obesity and hypertension, some patients have medical comorbidities that preclude surgery; for those, radiation therapy may be the definitive treatment of choice. In this group, treatment is delivered via intracavitary uterine brachytherapy, with or without EBRT.[65–67]

For definitive treatment, packing the uterus with capsules allows excellent coverage of the entire endometrial cavity that can be adapted to every patient's individual anatomy.[68,69] Standardized applicators may provide more

straightforward and reproducible dosimetry. Double-channel applicators such as the Rotte applicator (Elekta AB, Stockholm, Sweden)[70] can be used with CT planning, and computerized optimization with HDR delivers a very similar dose to the serosa[71]; this could be replicated with PDR (see Figs. 26.5 and 26.6). Various whole uterus prescription points have been described[72,73]; however, CT planning allows contouring of the outer contour of the uterus for volume-based dose prescription. A typical dose is 70 to 80 Gy prescribed to the outer contour of the uterus alone or 35 to 50 Gy in combination with 30 to 45 Gy EBRT.[74] The Groupe Européen de Curiethérapie and the European SocieTy for Radiotherapy & Oncology (GEC-ESTRO) have published guidelines on converting LDR schedules to PDR schedules for all gynecologic cancers.[75]

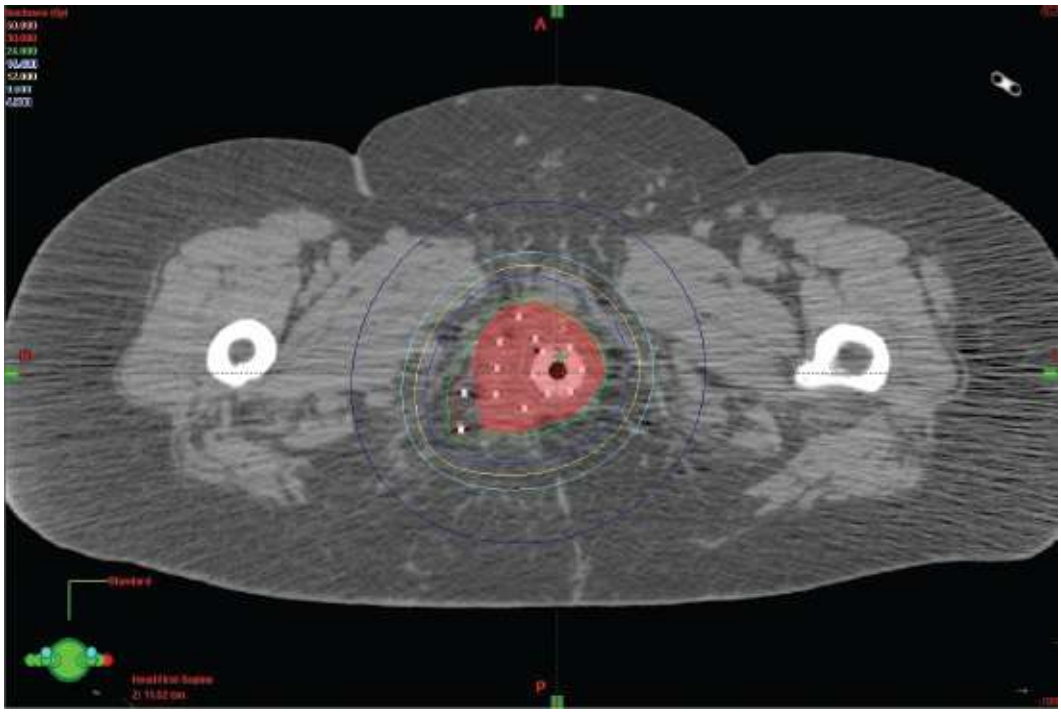

FIGURE 26.4. Axial computed tomography slice demonstrating the target volume and dosimetry of an LDR vaginal vault template interstitial implant.

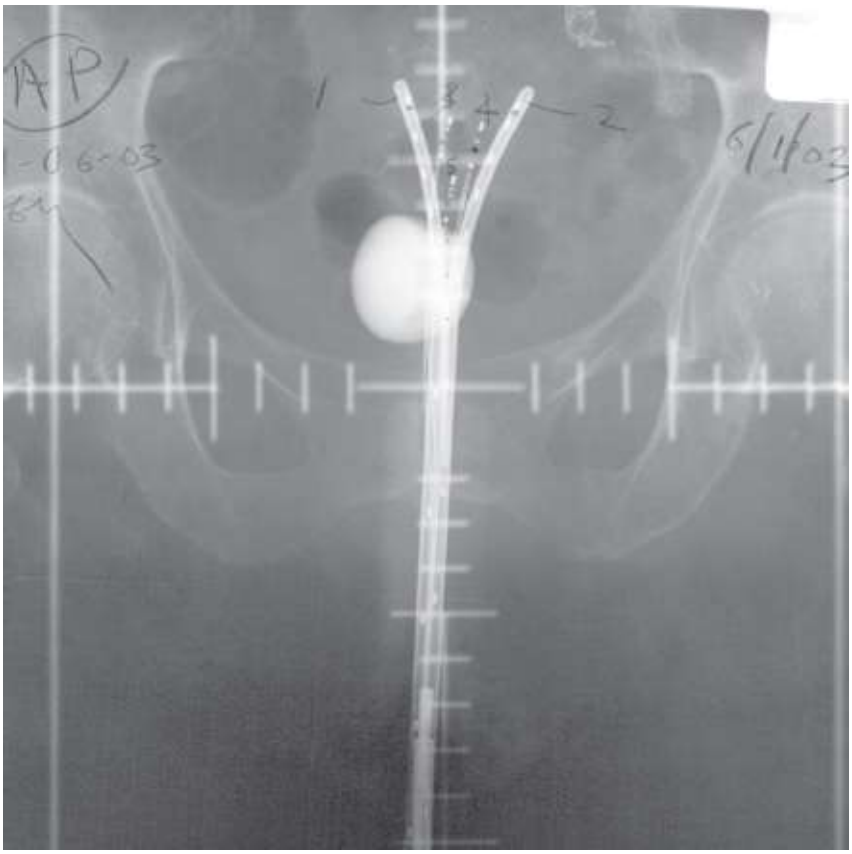

FIGURE 26.5. Double tandem Martinez applicator in place with three Heyman capsules placed within the uterus.

Vaginal vault brachytherapy can be used in the adjuvant treatment of endometrial cancer and vaginal vault recurrence of endometrial carcinoma and also in other gynecologic malignancies such postoperative early-stage cervical cancer or early stage vaginal cancer.[63,76–78] The target for adjuvant vaginal vault brachytherapy is the vaginal mucosa and the operative scar. Ninety percent of recurrences occur at the vaginal vault and 10% in the distal vagina[79]; therefore, in the majority of cases the upper third to half of the vagina is treated. This decreases the morbidity associated with treating the whole vagina, such as vaginal dryness or shortening.[74] However, for certain clinical situations such as clear cell or serous histology or lymphovascular invasion, some centers will treat the whole length of the vagina. A balance is made between late vaginal morbidity and the risk of distal vaginal relapse. Brachytherapy can be prescribed at the cylinder surface or at 5 mm into tissue, a depth that approximates the vaginal lymphatics.

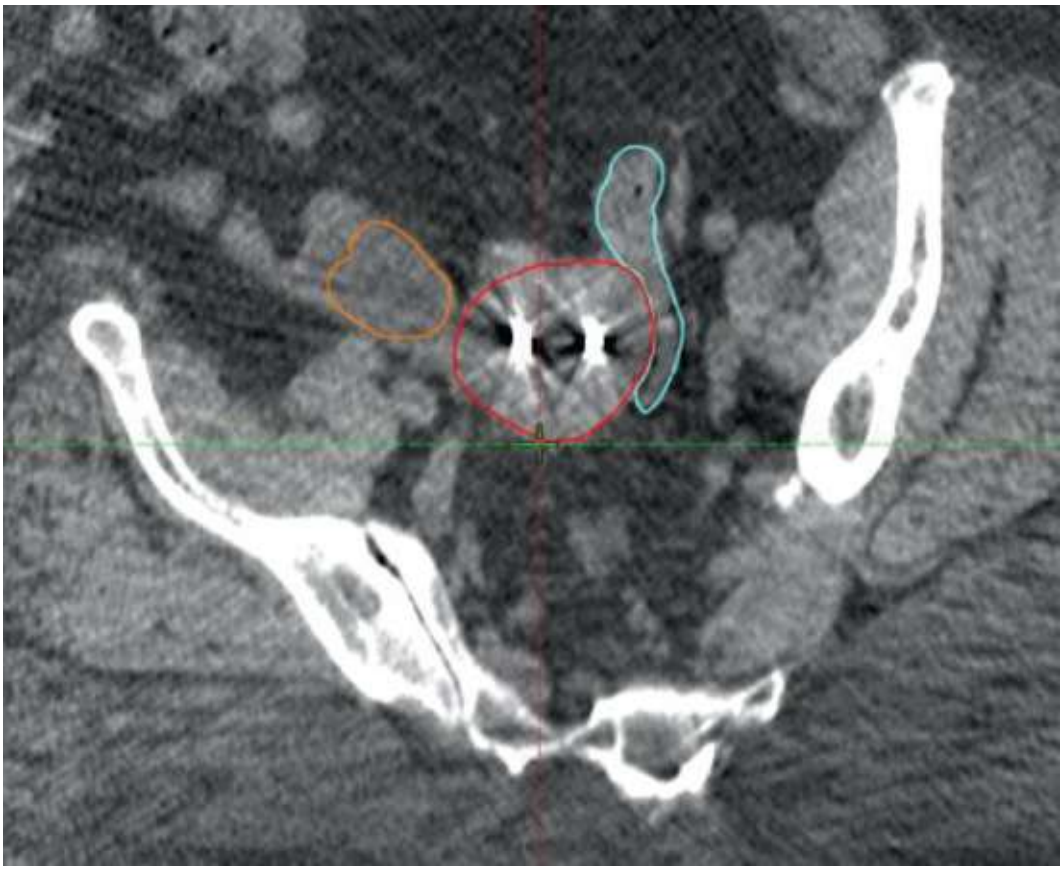

FIGURE 26.6. Axial CT slice demonstrating the Martinez applicator *in situ*. The high-risk CTV is outlined in *red*, sigmoid in *blue,* and bowel in *orange*.

Vaginal vault brachytherapy can be administered using a variety of different applicators. The commonly used single channel cylinder comes in a variety of widths chosen according to patient anatomy and comfort (see Fig. 26.7). This may be a less favorable choice when using LDR as the lack of optimization leads to effects from source anisotropy. The vaginal apex is located along the longitudinal axis of the source; therefore, the vaginal apex is exposed to the greatest effects of source anisotropy. It is important that planning systems contain modifications for source anisotropy. Li et al.[80] used Monte Carlo simulations to show that not accounting for anisotropy can result in underdosing by as much as 30% at the vaginal apex. The use of optimization with PDR to points off the cylinder apex can overcome this problem and may lead to decreased late toxicity.[81] Of course it must be considered that the doses we commonly prescribe for brachytherapy to the vaginal apex are those formulated using years of empirical dosing and the received dose at the vaginal apex may have actually been much higher than the prescribed dose. If the same prescribed dose is now used but with a lowering of the actual dose received by the vaginal

mucosa using methods such as optimization to the cylinder apex or anisotropy correction, it is possible that this could be detrimental to tumor control. A vaginal colpostat is an alternative applicator that delivers a dose more localized to the vaginal vault and less dose to the mid-lower vagina.

Adjuvant primary vaginal vault irradiation has been shown to decrease the incidence of vaginal apex recurrence in early-stage endometrial cancer from 12% to 15% to as low as 0% in selected patients although it has no impact on overall survival.[76,82] The dose for LDR vaginal vault alone is 50 Gy prescribed at 5 mm over 4 to 5 days or 0.5 Gy/hour and approximately 15 Gy when combined with 45 Gy EBRT.[74] The radiation dose received by the pelvic organs varies according to physiologic variations (e.g., the bladder dose may vary according to the extent of bladder filling, which may also affect the amount of small bowel in the field).[83,84]

Prostate

Prostate brachytherapy has become part of the treatment paradigm in prostate cancer for all stages of localized disease (see Table 26.2). It can be used as monotherapy or in combination with EBRT and/or hormone therapy for higher risk disease. A Surveillance, Epidemiology, and End Results (SEER) database analysis of men <60 years of age has shown that prostate cancer–specific mortality (PCSM) was reduced in those treated with brachytherapy (+/−EBRT)

compared to those treated with EBRT alone.[85]

The most common application for monotherapy is still LDR permanent seeds, although more recently single-dose HDR monotherapy has been shown to be effective.[86] When used as a boost, LDR,[87] HDR,[88] and PDR[89,90] techniques can be used. Prostate brachytherapy is also being investigated as salvage therapy after external beam radiation[91,92] and is currently under investigation through the Radiation Therapy Oncology Group (RTOG) study RTOG-0526, which is now closed to accrual.

A transrectal ultrasound-guided transperineal technique is the most popularized technique for implanting the prostate. Other modalities incorporating MRI[93] and MRI spectroscopy imaging have also been proposed.[94] The techniques for implanting ^{125}I and ^{103}Pd have been well described.[95–97] The patient criteria for selection include ability to undergo a general, spinal, or less commonly local anesthetic[98]; prostate volume <60 cm^3 [87]; favorable anatomy (minimal or no pubic arch interference, median lobe); and minimal obstructive uropathy. Significant transurethral resection of prostate defect is also a relative contraindication to a seed implant.[99]

Tumor criteria depend on whether monotherapy or boost therapy is planned. Typically, monotherapy is reserved for patients with so-called favorable risk disease (e.g., low- to intermediate-risk disease: T1 to T2b disease, Gleason < 7, PSA < 15 ng/mL). However, there is emerging evidence that intermediate-risk disease may also be treated effectively with monotherapy[100]; therefore, boost therapy may be reserved for patients with unfavorable intermediate-risk and high-risk disease.[99,101]

The role of EBRT and hormone therapy in combination with LDR brachytherapy is unclear and under investigation. Adjuvant androgen deprivation therapy (ADT) is used for prostatic cytoreduction in patients who do not have ideal prostatic geometry.[99,102] Cytoreduction may be achieved with use of luteinizing hormone–releasing hormone agonists and antiandrogens or antiandrogen in combination with 5α reductase inhibitors.[102] ADT is also considered in patients thought to be at higher risk of prostate cancer recurrence; however, the benefit of ADT in this setting is not well defined.[103–106] A systematic review has reported no benefit of ADT in low-risk and favorable intermediate-risk patients but up to 15% improvement in biochemical progression-free survival in patients with suboptimal dosimetry or unfavorable intermediate-risk or high-risk disease.[107] None of the studies included showed an improvement in overall survival, but three did show a reduction in overall

survival due to cardiovascular disease. There are several randomized controlled trials addressing this issue, and the results of RTOG 0815 are awaited.

TABLE 26.2 INCLUSION CRITERIA FOR PROSTATE BRACHYTHERAPY

Selection Criteria for Prostate Brachytherapy
Patient Factors
Life expectancy > 5 years
IPSS < 15
Prostate volume < 60 cc
No defect if previous TURP
Minimal pubic arch interference
Tumor Factors
Monotherapy: T1-T2b, Gleason ≤ 7, PSA ≤ 15[a]
Boost therapy: ≥T2c, Gleason ≥ 7, PSA ≥ 10

[a]Gleason 7 and PSA > 10 may be considered for either monotherapy or boost therapy.
IPSS, International Prostate Symptom Score; TURP, Transurethral resection of prostate.

In transperineal techniques, treatment planning can be done either as a preplan or intraoperatively. In the preplan technique, a volume study is acquired prior to the procedure, and the prostate volume and pubic arch interference are assessed. Axial images (5 mm) of the prostate from the base to the apex are taken and then used for brachytherapy planning (see Fig. 26.8A and B). Sagittal imaging can be used to help identify the base and apex. Reproducibility of the prostate position on the day of insertion must be ensured in this technique. Intraoperative techniques are defined as intraoperative preplanning, interactive planning, and dynamic dose calculation. Intraoperative preplanning avoids two separate ultrasound studies and involves the creation of a plan at the time of the implant procedure. It, like preplanned techniques, does not account for deviations of needle position or prostate geometry changes from the preplan.[108] The time required for the implant tends to be more prolonged using this technique compared to the preoperative technique. Interactive planning allows for refinement of the treatment plan based on needle-position feedback and estimation of seed placement. Modifications can then be made to needle

position, or additional seeds can be added to optimize the plan. Dynamic dose calculation allows constant updating of the dose distribution based on the actual seed positions and takes into account changes in the prostate volume.[109,110]

TABLE 26.3 PRESCRIPTION DOSE FOR PERMANENT LDR BRACHYTHERAPY WHEN USED AS MONOTHERAPY OR AS A BOOST COMBINED WITH 40 TO 50 Gy EXTERNAL BEAM RADIATION THERAPY

	Monotherapy (Gy)	Boost (Gy)
^{125}I	145	110
^{103}Pd	125	100
^{131}Cs	115	85

Current permanent LDR techniques involve implanting ^{125}I or ^{103}Pd seeds. ^{131}Cs is also approved for prostate brachytherapy and is used at some institutions. These isotopes have differing energies and half-lives and therefore differing initial dose rates (see Table 26.1). It had been postulated that ^{103}Pd compared with ^{125}I was more effective at treating dedifferentiated tumors as the dose rate is higher; however, studies evaluating clinical outcomes for patients with prostate cancer have shown no difference.[111–113] Studies evaluating the toxicity to OAR including rectum, bladder, and sexual function have shown no difference in acute or long-term toxicity or difference in sexual function.[114–116] There is a difference in the time for the International Prostate Symptom Score (IPSS) score to return to the preimplant baseline with ^{103}Pd returning to baseline faster.[117] ^{131}Cs has not been studied as extensively. Commercially ^{125}I and ^{103}Pd seeds are available either loose or stranded. Dosimetrically, the two are similar. The incidence of seed migration is decreased with stranded seeds as compared with that of loose seeds with the greatest difference being in migration to the lung and perineum.[118]

The prescription dose for permanent LDR brachytherapy is dependent on the isotope and the indication for the implant: either monotherapy or as a boost. Table 26.3 describes the recommended doses for ^{125}I, ^{103}Pd, and ^{131}Cs when used as monotherapy or when combined with 40- to 50-Gy external beam radiation.[119–121] The prescription dose covers the entire prostate (CTV) and typically includes a margin. The dose for ^{131}Cs is still investigational.

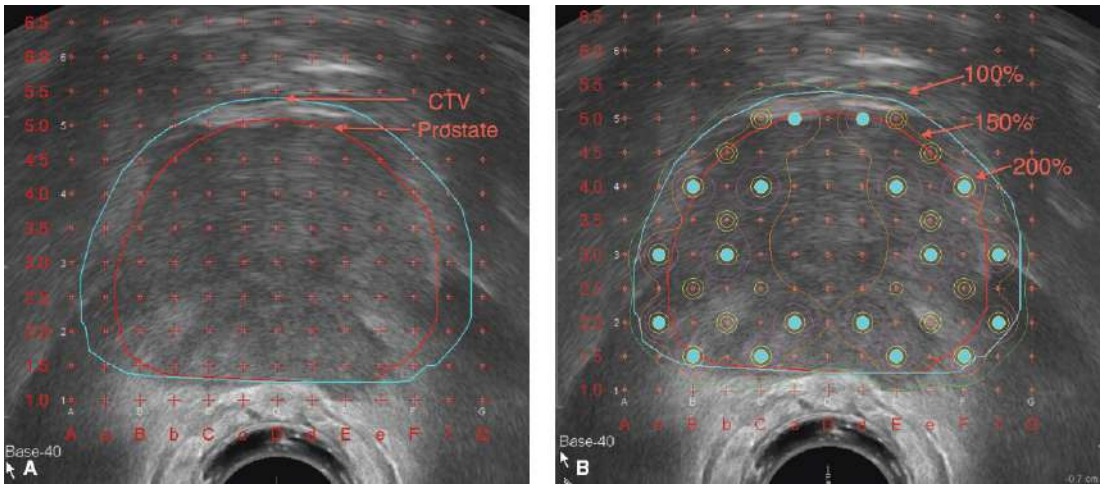

FIGURE 26.8. Prostate volume study with prostate and CTV defined **(A)**, preplan with peripheral loading technique **(B)**.

In the preoperative technique, the dose to the target volume as well as the OAR is evaluated. Different loading techniques are used to achieve these goals based on the needle placement, spacing of seeds, and seed energy.[122] A peripheral loading technique is common to avoid excess dose to the urethra with ^{125}I and a modified uniform loading with ^{103}Pd.[123] The source placement with ^{131}Cs has different guidelines to ^{125}I and ^{103}Pd with needles placed further from the urethra and rectum.[120] Good preimplantation dosimetry and toxicity levels correlate with a V_{100} > 95% of CTV, D_{90} > 100%, V_{150} ≤ 50% of CTV, rectum D2cc < reference prescription dose, D_{max} < 150% of reference prescription dose, prostatic urethra D_{10} < 150%, and D_{30} < 130%.[110] Dose limits to structures such as the penile bulb and neurovascular bundles are under investigation.

Postimplant dose reporting in a structured quality assurance program is highly recommended and should include dose parameters to both the target as well as the OAR.[121,124] Timing of the postimplant imaging varies at different centers but ideally should relate to the time at which edema is at a minimum. Evaluation at either day 0 or day 30 is most common. Seed localization is crucial as is the contouring of the prostate and normal structures. CT/MRI fusion if possible allows for both identification of the seeds and accurate definition of the prostate, particularly at the apex and base, which tend to be difficult to delineate on CT (see Fig. 26.9A and B). Primary parameters to report and evaluate include the intended dose, D_{90}, D_{100}, V_{100}, V_{150} to the prostate gland, and rectal volume and dose and urethral doses. For patients with unacceptably cold implants, consideration for reimplantation should be given. There are no parameters at present for penile bulb and neurovascular bundles.

Studies have shown that prostate brachytherapy is associated with a “learning curve” effect.[125–127] As with any brachytherapy technique, outcomes and toxicities are dependent on where the radiation has been delivered. With permanent seed brachytherapy, there can be no dose optimization once the seeds are placed. A quality assurance process that enables closing the feedback loop for optimizing subsequent implants therefore is crucial. Peer review; assessments of dosimetry, toxicity, and outcomes; as well continuing education should be part of any prostate brachytherapy program.[128–132]

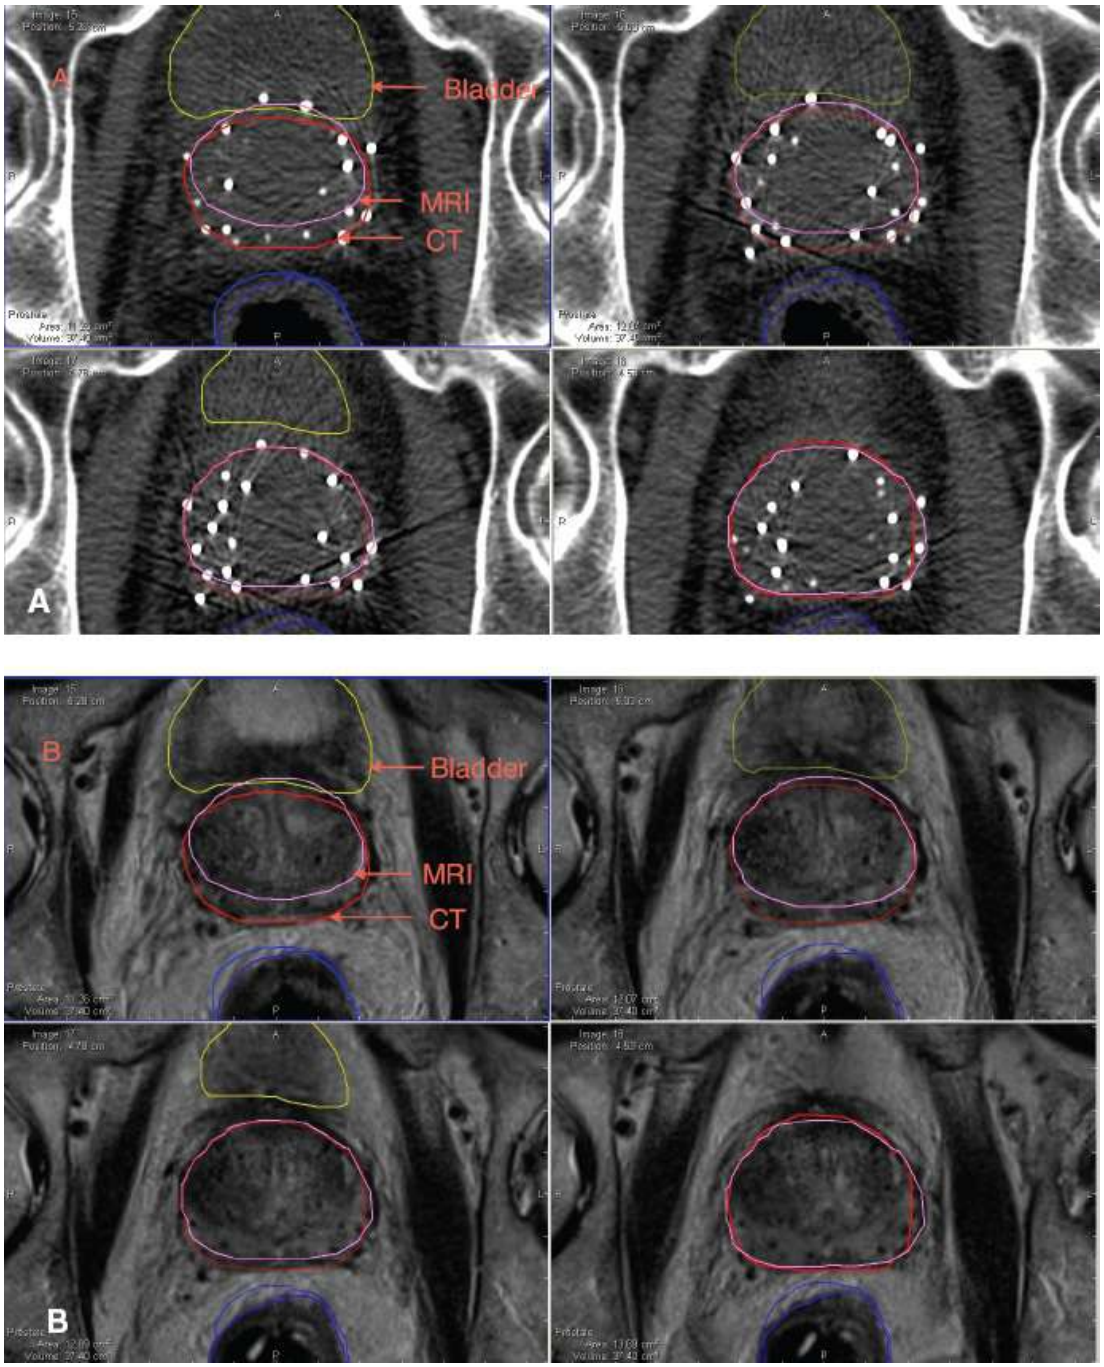

FIGURE 26.9. Prostate brachytherapy post plan with computed tomography and magnetic resonance (CT-MRI) fusion. The prostate volumes were drawn independently on the CT **(A)** and MRI **(B)** to show the difference in contours at the base of the prostate. The MRI images are better able to delineate the prostate, whereas the CT scan is better able to give information on the brachytherapy seed location.

Under spinal or general anesthetic the patient is positioned supine in the lithotomy position. If a preplan was used, the same couch angle and ultrasound

probe angle must be reproduced. Contrast agent is typically injected into the bladder for visualization under fluoroscopy. Visualization of the urethra is essential and can be accomplished by injecting foamed Mucogel into the urethra during the procedure. Alternatively, a urethral catheter can be inserted and left in place during the implant; however, some clinicians avoid the latter technique to avoid changing the shape of the prostate. The prostate, bladder, seminal vesicles, and pubic arch are identified on ultrasound. The base and apex of the prostate gland are also identified. Preloaded needles are kept within a shielded vault or sleeve until the physician is ready to insert the individual needles. Each hollow-bore needle has a beveled edge and central stylet. Ultrasound images in both the axial and sagittal views (if available) guide the placement of the needle. Once the first needle is in the correct position (in three-dimensional coordinates), the retraction plane is set for positioning of the remaining needles. To drop the seeds within the prostate, the central stylet is held securely in place and the outer needle is slowly pulled back along the stylet. On-demand fluoroscopy can be taken to check seed position relative to bony and organ anatomy. Additional seeds may be placed at the end of the procedure as required. Bladder irrigation and cystoscopy can be performed to evacuate migrated seeds in the bladder. Patients are conveniently discharged home the same day of the procedure; the majority of patients do not require a urinary catheter on discharge.

In intermediate- to high-risk prostate cancer, brachytherapy in combination with EBRT has been evaluated with both LDR permanent seeds and HDR brachytherapy.[133–136] The same techniques used in HDR boost brachytherapy can be applied to temporary implants with LDR ^{192}Ir strands or PDR brachytherapy with special attention to techniques that insure that the apparatus stays in place over the treatment time. PDR boost brachytherapy is not as extensively studied as HDR or permanent implants, but preliminary studies[90,137] show acceptable toxicity and tumor control with limited follow-up. In the Pieters et al. study, the patients were treated with ≤1.2 Gy/pulse at short time intervals ≤2.2 hours. The doses in their study are relatively low with an equivalent dose at 2 Gy per fraction (EQD_2) between 68.8 and 74.4 Gy. They note that the tumor control at 5 years is comparable to that in many HDR studies and that there are large areas of prostate receiving >20% of the prescription dose because of the heterogeneous nature of brachytherapy. They recorded low rectal and urinary toxicity and the IPSS returned to baseline by 12 weeks post brachytherapy. Further dose escalation with PDR was felt to be worth pursuing because of the low rectal and urinary toxicity. Studies evaluating ^{192}Ir LDR for boost have also

been done but are not commonly used.[138–140]

Penile Cancer

Penile Cancer is rare in Western countries, representing only 1% of male malignancies. Squamous cell carcinoma is the predominant histology. Brachytherapy is used as an organ-sparing technique in T1, T2, and select T3 lesions (<4 cm) that do not involve the shaft of the penis.[141–143] Both surface mold techniques (lesions < 5 mm)[144,145] and interstitial techniques (see Fig. 26.10)[146–150] have been described. The 5-year local control with interstitial brachytherapy is 70% to 86% with penile preservation of 72% to 88%. Typical doses range from 50 to 65 Gy delivered in 4 to 7 days. Typically, at least two planes of catheters are required as it is difficult to assess the depth of disease. Crook et al.[151] describe their implantation technique in detail for 75 cases implanted between 1989 and 2009 with both ^{192}Ir wire/seeds and PDR techniques. The implants are based on the Paris system using rigid templates with spacing between 12 and 18 mm. Computerized dosimetry mimics the Paris system and allows for visualization of dose to the target and OAR. They prescribed 60 Gy at a dose rate of 0.5 to 0.6 Gy/hour with manually afterloaded ^{192}Ir or 0.5 to 0.6 Gy in hourly fractions when using PDR. Treatment takes approximately 5 days.[143] Penile preservation was 88% at 5 years and 67% at 10 years with actuarial survival of 59% at 10 years and cause specific survival of 83.6%.[147] They reported a soft tissue necrosis rate of 12% and urethral stenosis rate of 9%. The soft tissue necrosis rate quoted in the literature ranges from 12% to 26% and increases with dose > 60 Gy, T3 disease, large volume implants (>30 cm^3), and >2 needle planes.[147–150,152] If conservative measures fail to manage soft tissue necrosis, hyperbaric oxygen therapy has shown success prior to resorting to surgical interventions such as debridement or amputation.[153] Urethral stenosis is reported in 10% to 45%[147–150,154] of cases and relates to the proximity of the needles to the urethra and the number of treatment planes. Using PDR brachytherapy allows manual optimization of dose around the urethra and may decrease the rate of stenosis. It is recommended that all men undergo circumcision prior to brachytherapy as this exposes the tumor, potentially removes disease allowing for a smaller implant, and decreases the risk of ulceration and necrosis to the foreskin.[149,151] Dose to the urethra and testes should be recorded. In men wishing to retain fertility, lead shielding around the testes can be placed.

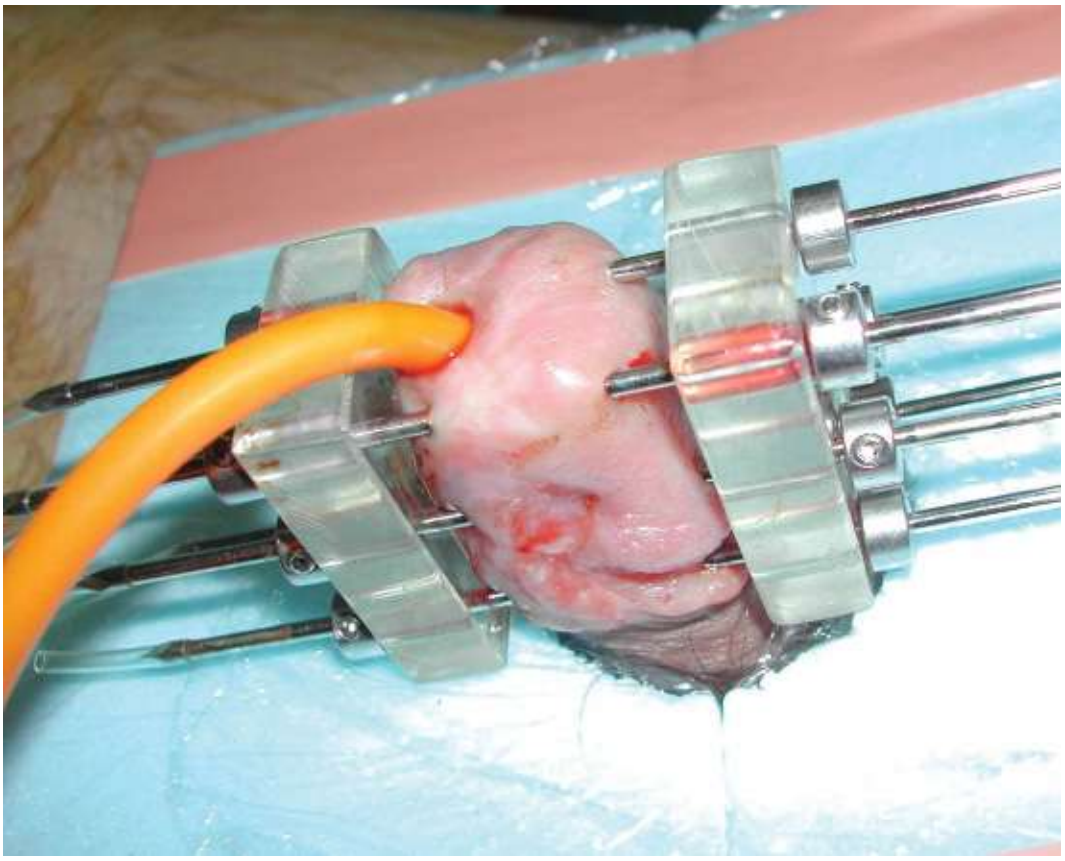

FIGURE 26.10. Low dose rate interstitial multiplane penile implant.

Urethra

Brachytherapy may be used in the treatment of both male and female urethral cancers. Intraluminal, intracavitary, and interstitial techniques have been described. Intraluminal brachytherapy is limited to superficial lesions and involves a single catheter into the urethra.[155] Interstitial implants for the penile urethra are similar to penile implants. In treatment of the female urethra, an interstitial implant may be used in combination with a molded vaginal applicator[155] or alone (see Fig. 26.11). The dose with LDR as a monotherapy is 60 to 70 Gy in 3 to 5 days (0.5 to 1 Gy/hour PDR) and 20 to 25 Gy if used as a boost. Milosevic et al.[156] published their experience of 34 patients who were treated with radiation. Twenty of these patients received brachytherapy (5 brachytherapy alone, 15 EBRT + brachytherapy). The tumors treated with brachytherapy tended to be ≤4 cm, involve the distal urethra, and did not invade adjacent organs. The majority of the patients underwent volume implants. Patients who had brachytherapy as part of their treatment had better local control with 7-year local relapse-free rates of 77% versus 32% with EBRT alone. There was no difference in cause-specific survival and 7-year actuarial overall survival

(41%). The risk of vesicovaginal fistulas was reported as 15%.

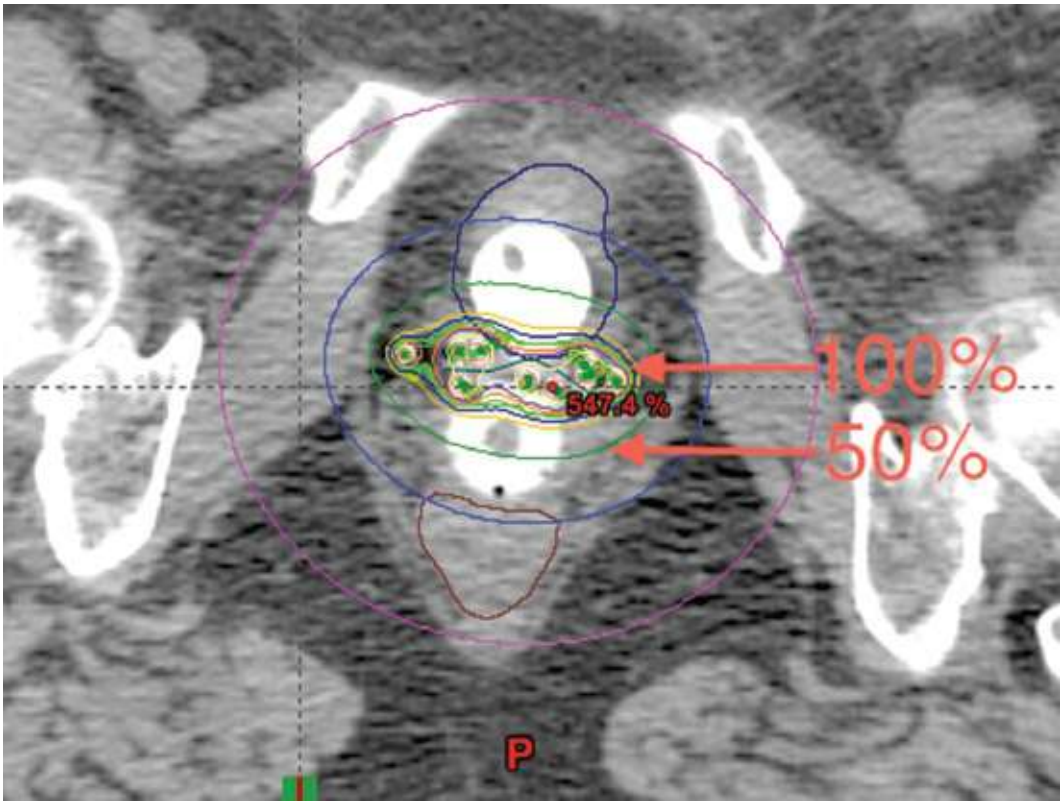

FIGURE 26.11. Low dose rate interstitial multiplanar urethral implant.

Bladder Cancer

Bladder cancer can be treated either with radical cystectomy or with chemoradiotherapy for an organ-preserving approach.[157,158] Several studies have shown good results with the addition of brachytherapy to EBRT.[159,160] Aluwini et al.[159] reported on 192 patients with muscle-invasive bladder cancer (MIBC) who were treated with EBRT followed by surgical exploration (with or without partial cystectomy) and interstitial brachytherapy (LDR or PDR). Salvage cystectomy-free survival at 5 and 10 years was 93% and 85%. The 5- and 10-year overall survival rates were 65% and 46%, whereas cancer-specific survival at 5 and 10 years was 75% and 67%. The distant metastases-free survival rate was 76% and 69% at 5 and 10 years. Multivariate analysis revealed no independent predictors of local recurrence-free survival. RTOG grade ≥3 late bladder and rectum toxicity were recorded in 11 patients (5.7%) and 2 patients (1%), respectively.

GEC-ESTRO guidelines have recently been published and recommend that EBRT and brachytherapy are reserved for patients with a solitary tumor <5 cm,

T2 to T3, no additional carcinoma in situ, and not located at the bladder neck or prostatic urethra.[161] Radiotherapy doses and schedules vary, but a typical schedule is 40 Gy in 20 fractions EBRT followed by 25- to 30-Gy brachytherapy (HDR or PDR). The implant can be sited by open surgery (retropubic approach) or endoscopically (simultaneous laparoscopy and cystoscopy). The catheters are passed through the abdominal wall into the detrusor muscle and out to the opposite side of the abdominal wall.

Head and Neck

Brachytherapy can be used to treat head and neck cancers either as definitive treatment or as a boost following EBRT. Use of brachytherapy may avoid disfiguring or mutilating surgery and allow organ conservation. Brachytherapy can also be used as a method of reirradiation for localized recurrence.[162] There are many years of safety and efficacy data for LDR brachytherapy, and PDR appears to replicate these results.[163–167] Intensity-modulated radiation therapy (IMRT) is becoming increasingly standard for head and neck cancer; however, there are indications that delivery of CT-planned optimized brachytherapy continues to deliver superior results over IMRT.[168,169] Aspects of plan quality that are important for local control and risk of toxicity are similar to interstitial implants elsewhere—quality index, volume gradient ratio, and tube distance.[170]

GEC-ESTRO have issued consensus recommendations for the use of head and neck brachytherapy[171,172] with a particular focus on dose, treatment selection, and quality assurance in the 2017 update. Data support the use of both hourly pulses and two-hourly pulses, with a dose of 0.4 Gy/pulse (24 pulses/day) or 0.8 Gy/pulse (12 pulses/day). The overall dose is decreased slightly when using 12 pulses/day—for example a monotherapy dose for a T1N0 cancer would be 70 Gy using 24 pulses/day and 60 Gy using 12 pulses/day. The ABS have recently updated guidelines for head and neck brachytherapy focusing on treatment selection in the era of advanced EBRT techniques.[173]

Patient selection is key for head and neck brachytherapy. Patients who are unfit for radical surgery may still be poor candidates for brachytherapy. PDR may allow the use of brachytherapy for patients with more complex nursing needs in whom LDR would have been contraindicated. It is important that the patient is fully assessed prior to brachytherapy. Dental assessment is essential, tooth extractions may be required, and for implants encompassing the oral cavity customized leaded mandibular shields decrease the risk of osteoradionecrosis. Feeding needs should be assessed and where necessary nasogastric or

percutaneous gastrostomy feeding tubes placed before the implant. For base of tongue implants, the patient should be prepared to have a tracheostomy, which can be reversed as soon as the postimplant edema subsides. The patient should be assessed regularly during the duration of the implant for displacement of the sources or applicators. Analgesia should be administered, and mouthwashes are often helpful.

The majority of head and neck implants are placed in an operative procedure by freehand technique in a multiplane implant (see Figs. 26.12 and 26.13). These can be sited using a variety of techniques with use of afterloading catheters being preferred in the modern era for radiation safety reasons.[174] Standard applicators such as the Rotterdam applicator that can be sited under local anesthetic without image guidance are also available (see Figs. 26.14 and 26.15). Similar to other sites described below, interstitial ^{125}I seed implants can be used in cases of unresectable disease with favorable rates of control and toxicity.[175–178]

Brachytherapy is indicated in the majority of lip cancers, either as sole modality in tumors 0.5 to 5 cm or as a boost following EBRT in tumors over 5 cm. For very superficial tumors, a surface applicator may be appropriate (see Fig. 26.16), thus preventing scars from puncture wounds. However, the majority of tumors require the placement of 2 to 3 interstitial catheters across the tumor (see Fig. 26.17); these can be placed freehand under local anesthetic. Typical doses are 45 to 75 Gy at the 85% reference isodose (higher doses for larger tumors, though at the risk of decreased cosmesis). Five-year local control rates with LDR are 90% to 95%[174,179] and 94% with PDR.[180,181]

FIGURE 26.12. Catheters placed to deliver a brachytherapy boost to the pharynx.

For oral tongue tumors, brachytherapy offers similar control rates to surgery with the benefit of organ and function preservation. Brachytherapy alone can be used for smaller lesions or as a boost for larger lesions. Interstitial implants are preferred, placed under general anesthetic using a metal trocar and threading the afterloading catheters through these. Looped catheters were popular when using ^{192}Ir ribbons, but with optimized PDR, it is difficult for the source to pass into the curved tube; therefore, individual button-ended catheters are preferred for source excursion (see Fig. 26.18). To prevent a cold spot on the tongue, an extra spacer can maintain the catheter above the tongue or dose optimization can be used, taking care not to cause a localized hot spot. Mandibular shielding is preferred. A dose of 65 Gy is typical as sole treatment and 20 to 25 Gy as a boost.[182] Local control compares well with surgery with small superficial tumors showing local control rates over 90%.[20] When combined with EBRT, a PDR boost for base of tongue tumors gives results at least equivalent to LDR with 5-year local control of 89%.[183]

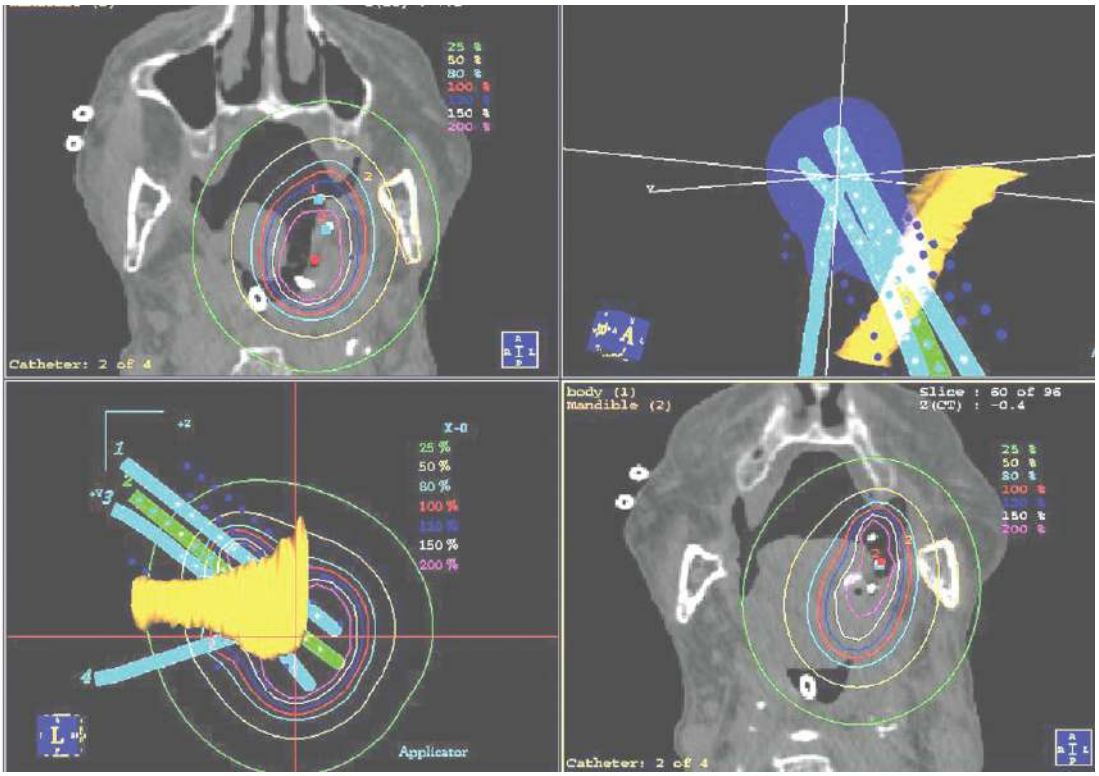

FIGURE 26.13. Three-dimensional computer-optimized dosimetry of the pharynx implant.

FIGURE 26.14. Patient with a Rotterdam applicator *in situ* within the nasopharynx.

Floor of mouth tumors are also best treated with interstitial implants with similar technique to tongue implants. Distance to the mandible is critical to prevent osteoradionecrosis. It may be preferable to perform surgery with reconstruction rather than risk late sequelae. Elective nodal dissection may be preferable to EBRT in advanced cases.[184] A dose of 65 Gy for sole treatment and 20 to 30 Gy boost is recommended, keeping overall treatment time as short as possible. Control rates range from 50% to 92% depending on tumor size, but bone necrosis is more common than other sites up to 30%.[174,184]

Oropharyngeal cancers traditionally present at an advanced stage because of their location in an area that is not visible with few pain fibers. Surgery can be very debilitating; therefore, EBRT and localized boost techniques are favored. A boost of 20 to 30 Gy is delivered using an interstitial implant. The implant is performed under general anesthetic with nasal intubation, and a covering tracheostomy is usually required. Hemorrhage may occur in implant removal, so it is important to remove the catheters under controlled conditions with wide-bore venous access, suction, and surgical support.

Most nasopharyngeal tumors are inoperable because of their position at the base of the skull. However, the nasopharynx is easily accessible to brachytherapy catheters. These can be placed under topical anesthetic—for example, the Rotterdam applicator—or under direct vision using a Le Fort osteotomy. The main role of brachytherapy is as a localized boost or as a sole reirradiation technique with typical doses of 12 to 20 Gy and 60 Gy, respectively. Local control is excellent even in reirradiation where control rates of at least 50% are reported.[174]

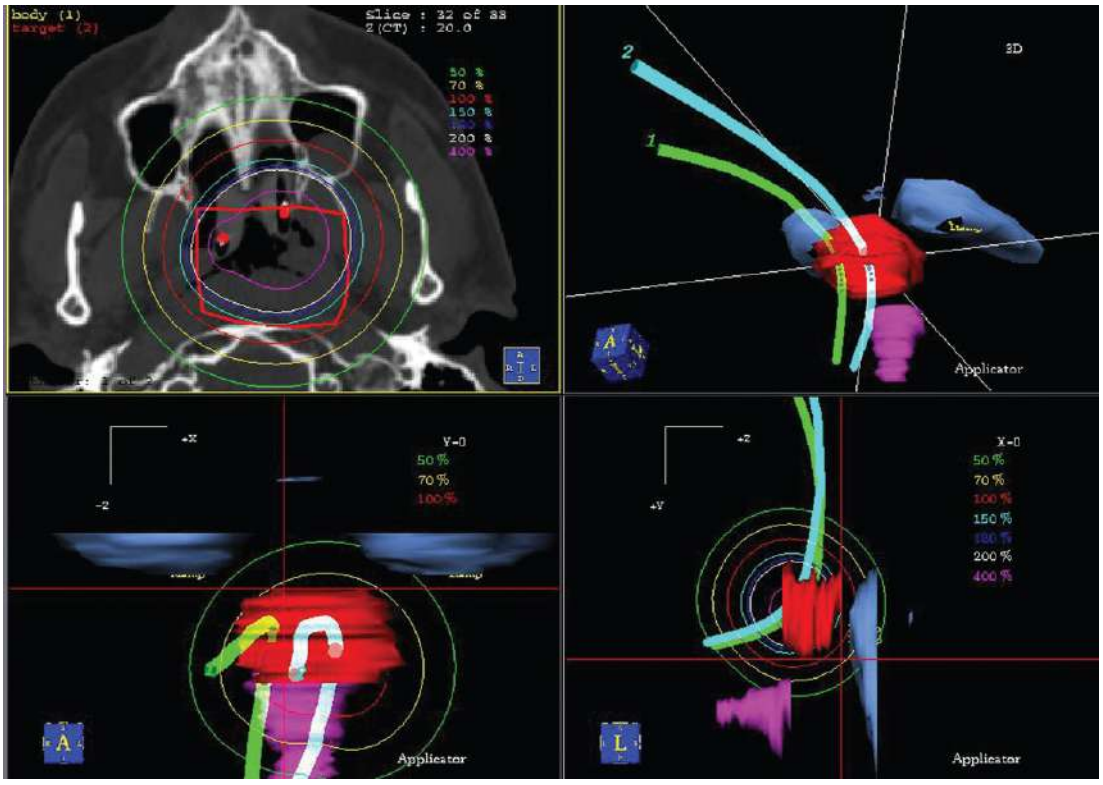

FIGURE 26.15. Three-dimensional dosimetry of the Rotterdam applicator, delivering computer-optimized brachytherapy.

Brachytherapy is particularly suitable for reirradiation of head and neck cancer, administered with curative intent. A series of 104 patients with recurrent head and neck cancer were treated with brachytherapy alone (81) or a brachytherapy boost (23), often with concomitant chemotherapy (56%) or hyperthermia (32%). At a median follow-up of 60 months, 5-year local control was 82% with acceptable rates of late toxicity, only requiring surgery for toxicity in 3% of cases.[185]

FIGURE 26.16. Surface applicator technique used to deliver a boost dose to a lower lip sarcoma following external beam radiation therapy. The wax mouth bite was used to displace the tongue and could be placed for every pulse of the pulsed dose rate.

FIGURE 26.17. Multicatheter single-plane cheek implant. The metal gum shield can be placed for every pulse of the pulsed dose rate.

Thoracic Seed Implants

Intraoperative permanent radioactive ^{125}I seed implantation can be used in the treatment of malignant thoracic tumors when resection margins are close or macroscopically or microscopically involved with tumor[186–201] or for palliation of inoperable disease.[202] The surgeon selects patients preoperatively when there is a concern of incomplete tumor resection or close or positive margins and refers to the brachytherapist. The patient is consented in advance for a permanent implant to be placed intraoperatively if required. Details of previous radiotherapy and chemotherapy treatment are carefully reviewed prior to surgery. The brachytherapy team is on call for the surgical procedure. Frozen section analysis of margins may be needed to assess whether an implant is needed. Seeds are placed directly into a tumor as a volume implant, or woven in a grid pattern in a planar implant. Volume implants require the use of an applicator or preloaded needles to deliver the seeds directly to the tumor. A planar implant can be ordered ready-made in advance (see Fig. 26.19) or custom-made intraoperatively[203] (see Fig. 26.20). ^{125}I seeds set into Vicryl suture with 1 cm spacing between seeds can be woven into a mesh or sutured directly to the area at risk. The Vicryl suture and accompanying mesh degrades naturally after approximately 60 days; at this point, much of the dose has been delivered and the seeds are often held in position by local fibrotic reactions. The mesh can be used in open surgery, thoracoscopically, or utilizing a robotic system.[204] Seeds can be placed at equally spaced intervals into a layer of foam,[193,205] but this implant may be more difficult to suture in place, as the seeds are not easily visible and are therefore at risk of being displaced or damaged by the suture needle. Alternative seed placement devices may aid seed placement such as the customized suture gun (see Fig. 26.21). Radiation exposure during the procedure to the implanting radiation oncologist and surgeon is very low[206] and well within occupational radiation exposure guidelines. When the implant has been sited, the operating room is surveyed for the presence of radiation. The patient is surveyed at the outer body surface over the implant, at 0.5 m and 1 m. In the immediate postoperative period no change in patient care is required, subject to standard post-vLDR implant precautions of preventing exposure to children or pregnant women.[207]

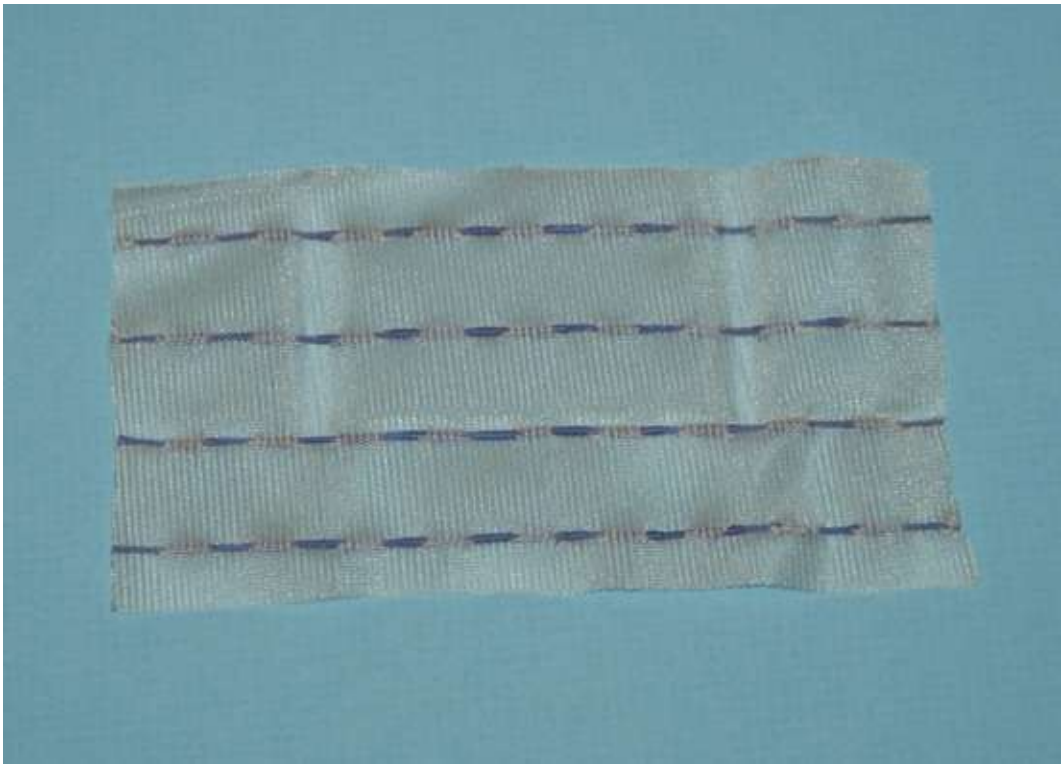

FIGURE 26.19. Premade seed mesh.

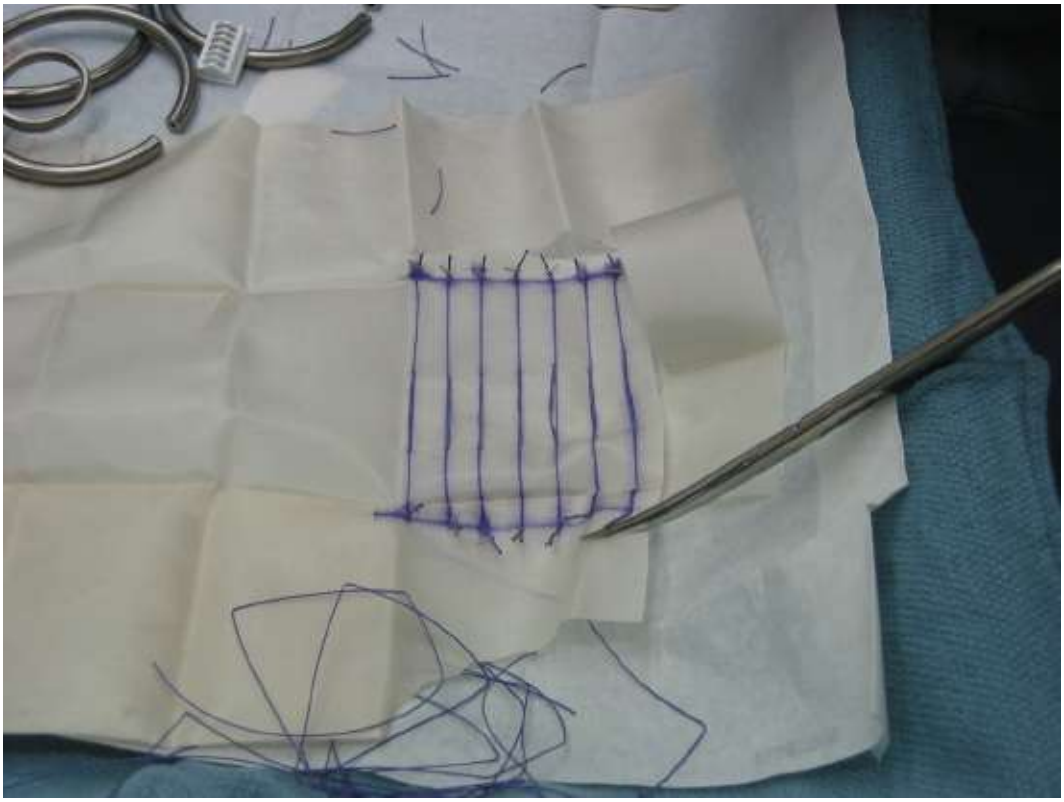

FIGURE 26.20. Custom-made 6-by-10-cm mesh implant using iodine-125 seeds in Vicryl carrier. The steel rings used to shield the isotope in transit can be seen at the

top left of the picture.

FIGURE 26.21. Seed staple gun.

For sublobar resection the dose recommended is 100 Gy, at 5 mm from the mesh or 7 mm from the central axis of the implant. For incomplete resection of tumor or positive margins, the dose chosen will depend on many factors such as adjacent structures or previous radiation; the type of surgery performed must also be considered in case there is an increased risk of late normal tissue toxicity.[208] The curvature of the implant should also be assessed because over a curved surface dose penetration is asymmetric compared to a linear implant.[209] Isodoses on the concave side of a curvature are further from the implant surface, potentially decreasing the dose delivered. The asymmetry increases with decreasing radii of curvature (see Fig. 26.22). Interestingly, *in vitro* studies have shown that selected human lung cancer cell lines show a greater sensitivity to ^{125}I seed brachytherapy than HDR irradiation, an effect that was further potentiated with the use of radiosensitizers.[210]

Lobectomy is the standard of care for patients with operable Stage I non-small cell lung cancer; however, intraoperative ^{125}I seed placement has been used in conjunction with sublobar resection in patients with lung cancer who are medically unfit for lobar resection.[191,194,195,197–201] Retrospective studies showed that patients undergoing sublobar resection had similar rates of disease-free and overall survival but that patterns of relapse differed with higher rates of local recurrence in the sublobar resection group.[211] Thus intraoperative permanent seed implant brachytherapy was been evaluated in a multi-institution randomized phase III prospective trial by the American College of Surgeons Oncology Group (ACOSOG) Z4032.[212,213] This demonstrated that there was no difference in 5-year local recurrence with the addition of brachytherapy (17% with brachytherapy vs. 14% without, $P = .59$). There was no difference in disease-free or overall survival. There was a trend toward favoring brachytherapy in patients with positive staple line cytology. Better than expected rates of negative margins were achieved, so the trial may have been underpowered to detect a small difference. Therefore, the ABS consensus

recommendations do not recommend this outside the confines of a clinical trial.[214]

For intrathoracic tumors with incomplete resection or microscopic close margins, retrospective and prospective series have shown that disease-free and overall survival rates with the addition of an intraoperative permanent seed implant are improved over those that would be expected with incomplete resection alone[186–189,192] (see Fig. 26.23).

Breast

Breast-conserving surgery is a proven alternative to mastectomy in patients with early-stage breast cancer, offering equivalent disease-free and overall survival.[215–217] Adjuvant radiotherapy is required because it results in a significant reduction in the risk of death from breast cancer, Unfortunately, this is offset by an increase in deaths due to other causes.[217] In the nonirradiated breast, recurrences tend to occur in the tumor bed with an elsewhere recurrence rate of up to 3.5%.[215,216,218,219] Accelerated partial breast irradiation (APBI) has similar ipsilateral breast recurrence and survival rates to whole breast IMRT but lower acute and late toxicities and better cosmetic outcome.[220] ABPI can be delivered with brachytherapy, localized radiotherapy, or intraoperatively with electrons[221] or photons.[222]

Postoperative APBI using brachytherapy was initially developed using interstitial implants. A number of needles or tubes are placed across the tumor bed usually under general anesthetic, either using a template or freehand (see Figs. 26.24 and 26.25). The treatment volume is generally the tumor cavity plus

a 1- to 2-cm margin. The dose is custom-shaped to this treatment volume. The dose can be delivered using LDR or PDR brachytherapy, typically over 4 to 5 days. The large number of catheters in an interstitial implant allows more control over skin and chest wall doses than do single catheter techniques, especially with PDR dose optimization. The dose within the tumor is more homogenous with lots of smaller hot spots, compared to one large hot spot with single catheter techniques.[223] Single-catheter technique for left-sided tumors has also been shown to have a higher mean heart dose than deep inspiration breath-hold whole breast radiotherapy,[224] whereas this is less likely to happen with multicatheter brachytherapy.

Interstitial implants have been in use for over 10 years. Phase 3 trials have shown that PDR or HDR APBI is noninferior to whole breast radiotherapy with respect to 5-year local control, disease-free survival, and overall survival in low-risk invasive or ductal carcinoma *in situ* (DCIS).[225] Early toxicity was dramatically reduced in the brachytherapy ABPI arm (86% vs. 21% for grades 1 and 2 early skin toxicity).[226] Five-year toxicity and cosmetic outcomes were similar between the groups although grade 2 and 3 late skin toxicity was significantly reduced in the brachytherapy arm.[227] APBI with LDR, PDR, or HDR brachytherapy after lumpectomy is also an option for patients with ipsilateral local recurrence with an overall survival rate equivalent to salvage mastectomy.[228]

Permanent interstitial seed implant has been described for APBI[229] (see Fig. 26.26). ^{103}Pd seeds were implanted using ultrasound guidance and a dose of 90 Gy prescribed to the tumor cavity plus a 1.5-cm margin. In a group of 134

patients from 3 clinical trials, the observed local recurrence rate was 1.2% at 63 months, which is similar to the estimate for whole breast irradiation. Toxicity rates were acceptable. A radiobiologic dosimetric modeling study predicts that for APBI using brachytherapy, toxicity will be lower for a seed implant than for a multicatheter interstitial technique.[230]

Sarcoma

In the modern era, sarcoma surgery has become more refined, moving away from disfiguring, disabling surgery and towards a multidisciplinary approach combining surgery and EBRT and, in certain tumors, chemotherapy.[231,232] The use of LDR brachytherapy for soft tissue sarcoma (STS) was first described in 1963[233] using a variety of isotopes including ^{226}Ra and ^{192}Ir. Brachytherapy offers several advantages over EBRT; the catheters can be placed at the time of initial resection and loaded 5 days postoperatively, enabling the whole STS treatment to be completed within 10 to 14 days. Placement under direct vision allows accurate coverage of the resection cavity. There may be less hypoxia immediately postoperatively, enabling the radiotherapy to be more effective. The heterogeneity of dose delivery allows high doses to the tumor bed whilst minimizing the dose to surrounding normal tissues, thus minimizing toxicity.

The ABS issued consensus recommendations for the use of brachytherapy in patients with STS.[234,235] Table 26.4 presents a summary of the general principles for STS brachytherapy. Catheters are placed at the time of surgery, using either a single-entry sealed-end catheter (see Fig. 26.27), or double-entry button-ended catheters. The catheter is secured with plastic buttons that do not produce artifact in CT or MRI scanning. The CTV is the tumor bed plus a margin of 2 cm craniocaudally and 1 to 2 cm laterally.[234] The catheters can then be used for afterloaded LDR ^{192}Ir strands or connected to an afterloading PDR machine. A mesh implant can also be used with similar technique to that described in the thoracic vLDR section.[186] The doses recommended in the updated ABS guidelines are LDR/PDR 45 to 50 Gy for monotherapy and 15 to 25 Gy for boost (PDR pulses 0.45 to 0.5 Gy/hour or equivalent).[236] The doses for a typical radical mesh implant are 100 to 150 Gy at 5 mm and 50 to 70 Gy for a boost dose, depending on previous EBRT dose administered.

Phase 2 trials showed the utility of LDR brachytherapy for postoperative STS treatment,[189,237] and therefore a randomized phase 3 trial was conducted.[238] One hundred and seventeen patients were randomized to brachytherapy or no brachytherapy following R0 or R1 resection; patients were stratified by various factors including size and grade. Five-year actuarial local control for all patients was 82% vs. 69% (P = .04) but on subgroup analysis no effect seen in the
