Cholangiocarcinoma is a rare tumor in developed countries; there are approximately 2,000 to 3,000 cases per year in the United States. However, it is one of the most common cancers in endemic areas of developing countries, with incidences as high as 87 per 100,000 people in northeast Thailand.[144] Cholangiocarcinoma accounts for about 15% of the primary liver cancer worldwide. But the proportion differs regionally: 20% in Western countries, <10% in Asian nations, and as high as 90% in northern Thailand.[67,145]

A number of risk factors have been identified as important in the development of cholangiocarcinoma, most of which share a history of long-standing inflammation and chronic injury of the biliary epithelium.[146] The major risk factor in Western countries is primary sclerosing cholangitis, which is closely associated with chronic inflammatory bowel disease, particularly ulcerative colitis.[147] The risk of developing cholangiocarcinoma is higher in patients with primary sclerosing cholangitis, ulcerative colitis with colonic neoplasm than in patients with primary sclerosing cholangitis, and ulcerative colitis without colonic neoplasm.[148] Studies in Japan and the United states also showed that chronic hepatitis C infection elevates the incidence of ICC with the odds ratio

between 4 and 17.[149,150] In Asia, chronic infections of the biliary tract related to the infestation by certain liver flukes, such as *Clonorchis sinensis* and *Opisthorchis viverrini*, are associated with cholangiocarcinoma and hepatolithiasis.[144] Hepatolithiasis itself is also a risk factor for cholangiocarcinoma. Five to ten percent of patients with intrahepatic stones develop this complication.[151,152] Moreover, the combination of liver fluke infestation and nitrosamine exposure may explain the very high incidence of cholangiocarcinoma in northeast Thailand.[153] Other risk factors, although rare, include congenital fibropolycystic disease of the biliary system such as choledochal cysts and Caroli disease (cystic dilatation of intrahepatic bile ducts).[154] The observed incidence and mortality of ICC has increased in the past three decades in Japan, the United States, and the United Kingdom.[14,155,156] However, the incidence of extrahepatic cholangiocarcinoma is almost the same.[157] In the United States, the age-adjusted mortality rate has increased from 0.07 per 100,000 in 1973 to 0.69 per 100,000 in 1997. The estimated annual percent increase of mortality rate was 9.44% during this period. Between 1973 and 2012, the incidence of ICC increased from 0.44 to 1.18 cases per 100,000, representing an annual percentage increase of 2.30%; this trend has accelerated during the past decades to an annual percent increase of 4.36%.[157] Better case ascertainment and diagnosis from improved imaging, use of image-guided biopsies, or increased use of endoscopic retrograde cholangiopancreatography (ERCP) cannot fully explain this observation.[156,158]

Diagnosis

The most common presenting symptoms of biliary tract cancer are caused by obstruction of the bile duct. Those include painless jaundice, clay-colored stools, tea-colored urine, and pruritus. Other signs and symptoms include abdominal pain, fever, general malaise, abdominal distention, fullness, anorexia, and weight loss. The spectrum of cholangiocarcinoma can be classified into three broad groups: (a) intrahepatic, (b) perihilar, and (c) distal tumors. The age of onset is similar among the three groups and ranges from 60 to 65 years.[159] Patients with extrahepatic tumor usually present with jaundice, acholic stools, and tea-colored urine. Patients with intrahepatic tumors are less likely to be jaundiced and more likely to present with abdominal symptoms and more advanced disease.

There are no reliable screening methods; early diagnosis is almost impossible even in patients with high-risk situations such as primary sclerosing cholangitis, parasitic infestation, and hepatolithiasis.[160] Some patients are diagnosed when

screening blood work demonstrates elevation of alkaline phosphatase and γ-glutamyl transferase. Ultrasonography and CT are the initial primary tools to evaluate biliary tract tumor (Table 64.6). Further tests include percutaneous transhepatic cholangiography, ERCP with brushing cytology, serum carbohydrate antigen 19-9 (CA 19-9) levels, radiologic imaging with dynamic CT scan, MRI, or both, and angiography.

A serum CA 19-9 value >100 U/mL has a sensitivity of approximately 75% and a specificity of approximately 80%.[161] The optimal cutoff value for serum CA 19-9 that best discriminates between benign or malignant biliary tract diseases is influenced by the presence of cholangitis. Thus, in patients with symptoms of acute cholangitis, serum CA 19-9 concentrations should ideally be reevaluated after recovery. The sensitivity of serum carcinoembryonic antigen (CEA) is low, helpful only in one-third of the patients.[162] Biliary CEA levels increase significantly in patients with cholangiocarcinoma and also in patients with intrahepatic cholelithiasis (average, 50.2 to 57.4 ng/mL) compared with patients with benign strictures (average, 10.1 ng/mL) and patients with sclerosing cholangitis and choledochal cysts (average, 20.0 to 21.6 ng/mL).[161] Serum AFP may increase in some cases of cholangiocarcinoma, and this would suggest a diagnosis of mixed HCC and cholangiocarcinoma.[163]

Pathology

Cholangiocarcinomas arise from the epithelium of the biliary tract. There are two main histologic subtypes: bile ductular type (mixed), arising from small intrahepatic bile ducts, and bile duct type (mucinous), arising from large intrahepatic and extrahepatic bile ducts. Pathologic classification of ICC is based on a new concept.[164] Histologic diversity in cholangiocellular carcinoma reflects the different cholangiocyte phenotypes.[165] The majority of these cancers are adenocarcinomas (more than 90%). Squamous cell carcinoma is the second most common histologic type. Rare histologies include mucoepidermoid carcinoma, cystadenocarcinoma, and carcinoid tumor.

TABLE 64.6 DIAGNOSTIC WORKUP FOR CARCINOMA OF THE BILE DUCT

General
History
Physical examination
Laboratory studies
Complete blood cell counts

Blood chemistry profile to include liver function studies
Tumor markers: CA 19–9, CEA
Radiographic studies
Standard
Computed tomography scan
Ultrasonography
Transhepatic cholangiography
Endoscopic retrograde cholangiopancreatography
Optional
Endoscopic ultrasound
Magnetic resonance cholangiopancreatography
Dynamic computed tomography scan
Arteriography

Adenocarcinomas are divided into three types: sclerosing, nodular, and papillary. Sclerosing tumors are characterized by an intense desmoplastic reaction. This type of tumor tends to invade the bile duct wall early and, as a result, is associated with low resectability and cure rates. Most cholangiocarcinomas are of this type.[159] The nodular cholangiocarcinomas are also highly invasive tumors. Most patients have advanced disease at diagnosis. The resection and cure rates are both very low. In contrast, papillary type tumors usually present as masses in the lumen of bile ducts causing biliary obstruction early in the course of disease. Therefore, these tumors have the more favorable prognosis.[166] Microscopically, cholangiocarcinoma is classically well differentiated to undifferentiated. Cells tend to be cuboidal or low columnar and resemble biliary epithelium; mucin is always demonstrable in the cytoplasm. Readers should be aware that bile duct obstruction can be associated with reactive hyperplasia of subepithelial mucous glands in the presence or absence of cholangiocarcinoma.[167] Cholangiocarcinomas frequently invade lymphatic, perineural, and periductal spaces, and portal tracts. Spreading along the lumen of large bile ducts can also be seen, especially in perihilar cholangiocarcinoma.[168]

The differential diagnosis of cholangiocarcinoma from HCC can be further affirmed by positive association with CEA, CA 19-9, and immunohistochemical stain with cytokeratin-19.[169] Mutations in p53 tumor suppressor gene and K-RAS proto-oncogene have been identified in cholangiocarcinoma.[92,170,171] p53 overexpression and K-RAS mutations are associated with a shortened survival.[170] Recent marker analysis of cholangiocarcinoma from the Cancer Genome Atlas revealed a distinct subtype enriched for isocitrate dehydrogenase

(IDH) mutants.[172] IDH mutations block normal cellular differentiation and promote tumorigenesis via the abnormal production of the oncometabolite D-2-hydroxyglutarate (2-HG). Mutant IDH could be the potential future target for developing inhibitors of tumor growth.[173]

Pathways of Tumor Spread

Bile duct cancers commonly spread by direct extension through the biliary tract and the abundant lymphatic network in the submucosa layer. These tumors also commonly involve the surrounding structures by direct invasion. Lymph node metastases in the porta hepatis and celiac axis are common. The lymph nodes in porta hepatis are more frequently involved with tumors in the intrahepatic duct and proximal extrahepatic bile duct, and the pancreaticoduodenal nodes are more often involved with tumors in the distal bile duct.[168,174]

The incidence of lymph node metastasis in ICC ranges from 50% to 60%.[175,176] ICCs, irrespective of their intrahepatic location, mainly spread to the nodes in the hepatoduodenal ligament, then to the paraaortic nodes, retropancreatic nodes, or common hepatic artery node group. In addition, the left peripheral type or hilar type of cholangiocarcinoma tends to spread along the left gastric nodes through the lesser curvature.[176] Lymph node metastasis in perihilar cholangiocarcinoma is common, which occurs in about half of the patients, with the frequency of 43% in pericholedochal nodes, 31% in the periportal nodes, 27% in the common hepatic nodes, and 15% in the posterior pancreaticoduodenal nodes. The celiac and superior mesenteric nodes are rarely involved.[168]

Lymph node metastasis in distal duct cancer is commonly observed near the duodenopancreatic regions. Yoshida et al.[174] examined 20 consecutive patients with distal bile duct cancer who underwent pancreaticoduodenectomy with extended lymph node dissection. Histologic evidence of lymph node metastasis was seen in 55% of the patients. The areas with frequent metastases were the posterior pancreaticoduodenal lymph nodes (35%), the nodes around the hepatoduodenal ligament (35%), and those around the common hepatic artery (30%). Paraaortic lymph node involvement occurred in 25% of patients and was significantly associated with pancreatic parenchymal invasion.

Staging for Cholangiocarcinoma

The American Joint Committee on Cancer TNM classifications (8th edition) for ICC are shown below:

T category:
T1: solitary tumor without vascular invasion
T1a: solitary tumor ≤ 5 cm
T1b: solitary tumor >5 cm
T2: solitary tumor with intrahepatic vascular invasion or multiple tumors, with or without vascular invasion
T3: tumor perforating the visceral peritoneum
T4: tumor involving local extrahepatic structures by direct invasion
N category:
N0: no regional lymph node metastasis
N1: regional lymph node metastasis present
M category:
M0: no distant metastasis
M1: distant metastasis present

The complete stage groups are listed in Table 64.7. The American Joint Committee on Cancer TNM staging for both perihilar and distal cholangiocarcinoma has been revised in 2017 (Table 64.7). The N category is classified based on the number of positive nodes (N1: one to three positive nodes; N2: four or more positive nodes). The T category of perihilar cholangiocarcinoma is as follows: T1 is tumor confined to the bile duct, T2 is tumor invaded beyond the bile duct wall, T3 is tumor invaded unilateral branches of portal vein or hepatic artery, and T4 is tumor invaded the main portal vein or its branches bilaterally. The T category in distal bile duct cancer is classified based on the depth of invasion (T1: <5 mm; T2: 5–12 mm; T3: >12 mm).

TABLE 64.7 AJCC STAGE GROUPS BY TNM CLASSIFICATION (8TH EDITION)

Intrahepatic Cholangiocarcinoma

Stage IA: T1aN0M0
Stage IB: T1bN0M0
Stage II: T2N0M0
Stage IIIA: T3N0M0
Stage IIIB: T4N0M0, or any T, N1M0
Stage IV: any T, any N, M1

Perihilar Cholangiocarcinoma

Stage I: T1N0M0
Stage II: T2a-bN0M0

Stage IIIA: T3N0M0
Stage IIIB: T4N0M0
Stage IIIC: any T, N1M0
Stage IVA: any T, N2M0
Stage IVB: any T, any N, M1

Distal Cholangiocarcinoma

Stage I: T1N0M0
Stage IIA: T2N0M0, T1N1M0
Stage IIB: T2-T3N1M0
Stage IIIA: T1-T3N2M0
Stage IIIB: T4, N1-N2, M0
Stage IV: any T, any N, M1

The most important prognostic factors for cholangiocarcinoma are resectability, regional lymph node metastasis, and distant metastasis. Multivariate analysis using Cox proportional hazards model demonstrated that multifocality, extrahepatic extension, grade, node positivity, and age >60 years (MEGNA) are independently associated with worse overall survival. This MEGNA prognostic score is an improvement of the discriminatory power of prognostication over AJCC 7th staging system.[177]

General Management

Surgical resection provides the only possibility of cure, but the resection rates for intrahepatic, perihilar, and distal lesions are 60%, 56%, and 91%, respectively, in one large series.[159] The 5-year survival rates after resection range from 10% to 40%, depending on the location of the primary tumor.[159] Patients with unresectable cholangiocarcinoma generally have a very poor prognosis; chemotherapy and radiotherapy have been used, but the results are disappointing.[178]

Intrahepatic Cholangiocarcinoma

ICC accounts for 5% to 10% of all biliary tract cancers and constitutes 10% to 20% of primary liver malignancies. The resectability rate in all patients is only 30% to 50%.[179,180] The outcomes after surgery for patients with lymph node metastasis are poor regardless of the site of nodal metastasis; the 5-year survival rate in patients with lymph node metastasis is lower than that in patients without lymph node metastasis (0% vs. 51%; $P < .0001$).[176]

Factors that affect tumor recurrence include lymph node metastasis, presence

of satellite nodules, positive resection margin, tumor size, and bilobar distribution.[176,181–183] The patterns of failure after resection of ICC are primarily in the liver (56%), regional lymph node (20%), and peritoneal seeding (24%).[184]

The role of postoperative adjuvant radiotherapy with or without chemotherapy in the management of ICC is controversial. The typical reports in the literature are retrospective with small numbers of patients and marked variations in radiation fields and doses.[185] A delineation of radiation fields based on patterns of failure analysis and lymph node spread of the disease will be necessary to rationally define the role of radiotherapy in any proposed phase III study. For unresectable cholangiocarcinoma, the purpose of treatment is palliative; however, some long-term survivals (a 4-year rate of 20%) have been observed in unresectable cholangiocarcinoma treated with conformal radiotherapy and intra-arterial infusion of fluorodeoxyuridine.[186] SBRT is another treatment option. With a median follow-up of 5.4 years of 26 patients, the median progression-free survival and overall survival were 6.7 and 10.6 months, respectively.[187] Others have reported similar results in perihilar cholangiocarcinoma (Klatskin tumors) treated with SBRT.[188]

Total hepatectomy with orthotopic liver transplantation also can be considered in cholangiocarcinoma. One systematic review combining all studies that included a minimum of 10 patients reported a median survival of 11.8 months, the 5-year overall survival of 22%, and the 5-year disease-free survival of 13%.[189] Because of the high rate of recurrence and lack of selection criteria for good prognostic patient, transplantation should seldom be used as a treatment for cholangiocarcinoma.[190]

Perihilar Cholangiocarcinoma

Perihilar cholangiocarcinoma is the most common biliary tract carcinoma and accounts for 65% to 70% of tumors of the biliary tract.[159] Perihilar tumor involving bifurcation of the hepatic duct is also called Klatskin tumors.[191] These tumors are further classified by Bismuth et al.[192] as tumors below the confluence of the left and right hepatic ducts (type I), tumors reaching the confluence (type II), tumors occluding the common hepatic duct and the right or the left hepatic duct (types IIIa and IIIb, respectively), and tumors that are multicentric or that involve the confluence and both the right and left hepatic ducts (type IV).

Only 25% to 79% of patients are amenable to surgical resection. Definitive surgery may involve combined bile duct and liver resection with caudate lobe lobectomy.[193] The 3-year survival rate was 55% for patients without nodal

involvement, 32% for patients with regional node metastasis, and 12% for patients with paraaortic node metastasis.[168] In multivariate prognostic analysis, only lymph node metastases and curative resection have proven to be of independent prognostic significance.[168]

The role of postoperative radiotherapy with or without chemotherapy in patients with completely resected cholangiocarcinoma remains unproven. A retrospective analysis from Johns Hopkins suggests that postoperative adjuvant radiation therapy does not improve survival.[194] However, postoperative radiotherapy or chemoradiotherapy reduces the rate of local recurrence in patients with incomplete resection.[195,196] In addition, many retrospective series and small phase II studies suggest superior outcomes for resected patients who receive external beam radiation therapy with or without concomitant chemotherapy.[68,197–199] For patients with microscopic residual disease after resection, a retrospective analysis from 63 patients with stage IV Klatskin tumor revealed that postoperative radiotherapy (with or without intraoperative radiotherapy) yielded significantly higher 5-year survival rates than in the resection-alone group (33.9% vs. 13.5%).[196]

An updated report from Mayo Clinic revealed that the 5-year survival in transplant patients of unresectable hilar cholangiocarcinoma after induction chemoradiotherapy was 80%, and in resection-only patients, it was 21%.[200] Others also have reported similar promising results in these unresectable cholangiocarcinoma treated with induction chemoradiotherapy followed by liver transplant.[201,202]

In general, patients with inoperable perihilar cholangiocarcinoma usually have obstructive jaundice and should be treated with endoscopic or percutaneous drainage and/or stent placement initially. External beam radiotherapy alone rarely controls advanced disease. Combinations of external beam radiotherapy, chemotherapy, and intraluminal brachytherapy may relieve pain and contribute to biliary decompression. Sometimes such approach achieves long-term survival. The most active chemotherapy agents include 5-FU, gemcitabine, docetaxel, and oxaliplatin.[203,204] The median survivals range from 17 to 21 months. In some cases, combined chemotherapy and radiotherapy could delay progression of cholangiocarcinomas while awaiting availability of liver transplant.[118,197]

Distal Bile Duct Carcinoma

Primary distal bile duct adenocarcinoma, which includes carcinoma of the ampulla of Vater, accounts for 25% to 30% of biliary tract carcinomas.[159]

Patients with distal duct carcinoma have the highest rate of curative resection as compared to proximal duct carcinomas. In an analysis of 171 patients who underwent surgical exploration at Mayo Clinic for extrahepatic cholangiocarcinoma from 1976 to 1985, the rate of curative resection (achieving negative margins) by site of the primary tumor was 15% for proximal, 33% for middle, and 56% for distal duct lesions.[93] The prognosis of patients with distal duct carcinoma is clearly better than those with proximal duct carcinoma.[148]

The role of postoperative radiotherapy is uncertain. Investigators at Thomas Jefferson University found that postoperative radiotherapy did not improve survival in distal duct carcinoma after complete resection.[205] However, studies of concurrent chemotherapy and radiotherapy show more promising results. Mehta et al.[206] from Stanford University treated 12 patients having unfavorable (mainly lymph node metastasis) ampullary carcinoma with concurrent radiotherapy and protracted venous infusion of 5-FU. Actuarial overall survival at 2 years was 89%, and median survival was 34 months. Another study conducted by the Eastern Cooperative Oncology Group revealed that unresectable pancreaticobiliary carcinoma treated with concomitant radiotherapy and protracted intravenous infusion of 5-FU achieved a 2-year survival of 19%.[199]

Systemic Chemotherapy

Although some retrospective reports showed benefit of postoperative chemotherapy,[207,208] a multi-institutional randomized trial from Japan showed only a trend toward better 5-year survival following a potential curative resection in patients who received postoperative chemotherapy.[195] But it was not a statistically significant difference. According to multiple retrospective studies, multivariate analysis, and expert consensus, adjuvant chemotherapy with fluoropyrimidine or gemcitabine-based chemotherapy is nonetheless recommended in margin-negative patients. Adjuvant chemoradiotherapy is also recommended for margin-positive patients.[195,209]

For treatment of advanced and metastatic cholangiocarcinoma, no single chemotherapy agent or combination regimen consistently leads to objective tumor shrinkage, although a small randomized trial showed a survival benefit with 5-FU–based chemotherapy comparing with best supportive care alone (median survival 6 vs. 2.5 months, respectively).[210] The most frequently used agents include 5-FU, gemcitabine, cisplatin, and oxaliplatin. Another phase III study enrolled 410 patients with locally advanced or metastatic

cholangiocarcinoma, gallbladder cancer, or ampullary cancer. As compared with gemcitabine alone, cisplatin plus gemcitabine was associated with a significant survival advantage (11.7 vs. 8.1 months) without substantial toxicity. Cisplatin plus gemcitabine is an option for the treatment of patients with advanced biliary tract cancer.[211] In summary, for unresectable or metastatic cholangiocarcinoma, gemcitabine combined with cisplatin or gemcitabine alone is first-line treatment of choice for this patient group. If gemcitabine and cisplatin fail, no established regimens in the second-line setting are currently available. Enrolling such patients into newer clinical trial is recommended.

Target Therapy

Existing data demonstrate no or only very modest survival benefits with the target agents tested. EGFR inhibitors (cetuximab, erlotinib, panitumumab), anti-VEGF (bevacizumab, cediranib, vandetanib), ERB2, MEK (selumetinib, trametinib), multi-tyrosine kinase inhibitors (such as dasatinib, imatinib, pazopanib, regorafenib, sorafenib, sunitinib), and c-MET–VEGF have been tested in ongoing or completed clinical trials. These agents can be used alone or in combination with chemotherapy.[212]

Radiation Therapy

The role of radiotherapy (with or without chemotherapy) in unresectable or recurrent cholangiocarcinoma is to relieve pain and biliary obstruction. At 1 year following conventional radiotherapy, 60% to 75% of patients have locoregional failure, and the median survival ranges only 7 to 12 months.[213,214] Local failure remains the first site of disease progression.[213] To enhance treatment effect, radiotherapy given with 5-FU–based chemotherapy is generally recommended.[198,206]

The development of novel technique in radiation in the past few years has made SBRT for biliary cancer more promising. Mahadevan et al.[215] reported a series of 34 patients with 42 lesions. With a median follow-up interval of 38 months, the 1-year local control rate with doses of 24 to 45 Gy in 3 to 5 fractions was 88% and the 4-year control rate was 79%. Another report included 27 patients with unresectable cholangiocarcinoma who underwent SBRT (45 Gy in 3 fractions). The local control was 84% in 1 year.[216] The major complications were severe duodenal/pyloric ulceration and bleeding, duodenal stenosis, and biliary stenosis. Radiotherapy technique for ICC is similar to the treatment for HCC. Tumor moves with respiratory excursion during radiation treatment. Oral

contrast to delineate the duodenum, 4D CT, breath-holding, and abdominal compression are the techniques used to reduce the movement of the organ and the tumor and to avoid unnecessary exposure of normal adjacent organs. The surrounding organs to be protected from SBRT include the liver, duodenum, stomach, and spinal cord.

Treatment Volumes

The extent of the tumor within the bile duct can be defined by percutaneous cholangiography, ERCP, and MRCP. However, the extraductal disease is difficult to define by any noninvasive procedure. Clip placement at the time of surgery is useful in delineating the extrahepatic portion of ductal lesions and helps define the primary tumor bed. With the incorporation of CT in radiation treatment planning, and to reduce errors to a minimum, we advocate placing patients in treatment position when performing pretreatment CT, using 1 to 3 mm per slice, and contrast medium to reconstruct the anatomy of bile ducts and gross tumor volume (GTV) (Fig. 64.3). The GTV is defined as any visible tumor by CT and/or MRI. Clinical target volume (CTV) is defined as 1.5-cm margin beyond the GTV, especially along the bile duct and potential lymphatic drainage areas, which include nodes along the porta hepatis, pancreaticoduodenal system, and celiac axis.[174,176,217,218] The planning target volume is defined by adding a margin of 0.5 to 1 cm to the CTV.[91]

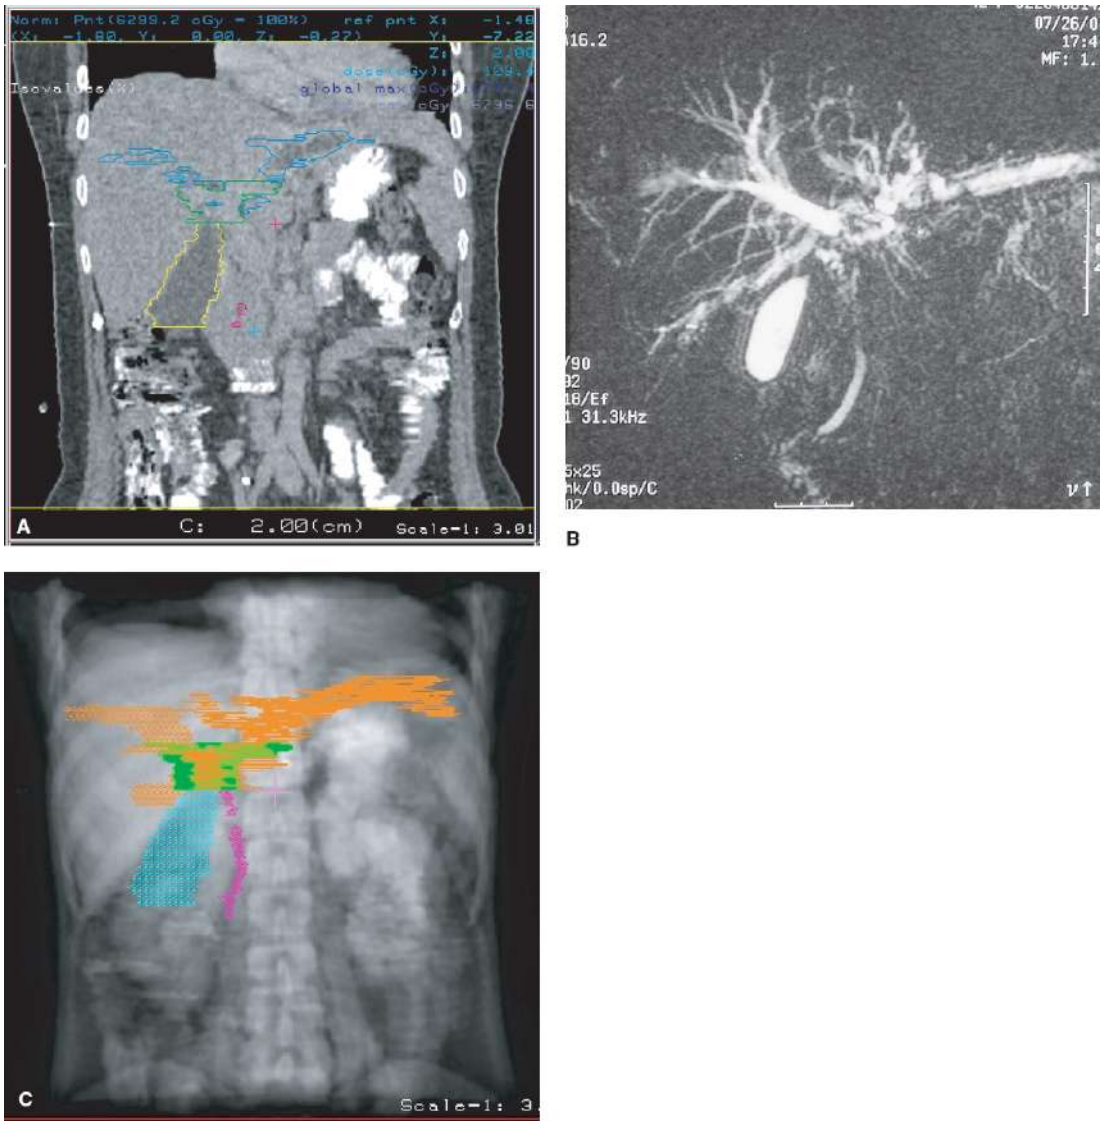

FIGURE 64.3. A: Computed tomography was performed in a 39-year-old woman who had cholangiocarcinoma of perihilar area. This image was reconstructed from a CT, at 2-mm slice interval. The tumor involved right and left hepatic ducts (*green line*). **B:** Magnetic resonance cholangiopancreatography affirmed the extent of tumor involvement. **C:** Digital reconstruction radiography revealed the gross tumor volume (*green*) and clinical target volume (*purple*).

Radiation Doses

Initial setup of radiation fields is to include GTV and CTV; the radiation fields can be coplanar or noncoplanar. The planning target volume is treated to 45 to 50 Gy in 1.8 to 2 Gy fractions given 5 days a week, using blocks to exclude the stomach, small intestine, kidney, and liver.[192,219] Higher radiation doses are used only to treat the GTV with the application of 3DCRT.[87] If boost-dose irradiation is feasible with brachytherapy techniques, the GTV is carried to 45 to 50 Gy

with external beam techniques or 20 to 30 Gy delivered via an intraluminal catheter.[82] The most commonly employed brachytherapy technique for the biliary tract begins with the placement, by an interventional diagnostic radiologist, of a percutaneous drainage catheter through the area of tumor. The radiation oncologist then threads a catheter inside the drainage system catheter. When a low-dose-rate system is employed, a wire with Ir-192 is then placed at the desired location inside the catheter.[220] If a remote high-dose-rate afterloading system is employed, then the appropriate dwell time and position are selected and programmed. It is a matter of some debate as to where the brachytherapy prescription point should be placed. Some physicians select the tumor's peripheral edge, away from the catheter, as determined by CT or MRI. Other practitioners prefer a point 0.5 or 1 cm away from the catheter. It is important to be familiar with the valves used to direct bile flow in the drainage system lest; during the administration of brachytherapy, bile leaks onto the patient's skin and dressings. If the drainage system remains in place for a long period of time (i.e., a month), enteric bacterial colonization and biliary tract infection are common. The combination of external beam irradiation and brachytherapy employed at Thomas Jefferson University resulted in 2 years and median survival rate to increase by twofold when doses were brought up to >55 Gy.[220] However, investigators at the University of Amsterdam reported no improved survival at doses >55 Gy.[221] The role of radiotherapy and its optimal dosage remains to be determined.

As for SBRT, the daily dose is similar to the treatment of HCC, and it ranges from 8 to 15 Gy per fraction with a total fraction number of 3 to 5. The daily dose to the duodenum and stomach should be limited to 400 cGy daily.

Acute and Late Complications

Acute complications of external beam and intraluminal radiotherapy include nausea, vomiting, and transient elevation of transaminases. These effects are usually mild and tolerable.[36]

Late complications are associated with radiation doses to surrounding organs. The most common complications are gastrointestinal bleeding, biliary bleeding, and duodenal stenosis.[36,220,221] With external beam doses of <55 Gy to the duodenum or stomach, the risk of severe gastrointestinal complications varies from 5% to 10%. At doses >55 Gy, one-third of the patients develop severe radiation-related complications.

Future Directions

There is a paucity of phase III studies for cholangiocarcinoma. We must rely on retrospective studies or prospective phase I–II trials. Further advances in treatment could potentially be made by: (a) defining when to use radiation and chemotherapy for high-risk patients after curative resection, (b) investigating the use of higher doses of conformal radiotherapy and chemotherapy in unresectable cholangiocarcinoma, and (c) identifying novel chemotherapeutic or novel pathway inhibitory agents. Patients with unresectable cholangiocarcinoma should be considered in the setting of investigative clinical trials.

ADENOCARCINOMA OF GALLBLADDER

Gallbladder carcinoma is the fifth most common cancer of the gastrointestinal tract. The incidence indicates a large geographic variation. The American Cancer Society's estimates for cancer of the gallbladder and nearby large bile ducts in the United States for 2017 are about 11,740 new cases diagnosed: 5,320 in men and 6,420 in women.[222] Cholelithiasis, anomalous junction of pancreaticobiliary ducts, and porcelain gallbladder are factors that predispose to gallbladder cancer.[223] Cigarette smoking, alcohol consumption, and obesity may also contribute to the risk. Patients with polyps >10 mm in diameter may be at increased risk for gallbladder cancer.[224,225] Chronic infection with *Salmonella typhi* and *Helicobacter bilis* is also associated with the risk of developing carcinoma of the gallbladder.[226,227]

The most common clinical presentation is pain, followed by anorexia, nausea, or vomiting. Patients with early invasive gallbladder carcinoma are most often asymptomatic, or they have nonspecific symptoms that mimic or are due to cholelithiasis or cholecystitis. In general, patients having gallbladder carcinoma manifest symptoms such as jaundice, anorexia, and weight loss and are associated with more advanced disease, which accounts for the poor prognosis.[154] A French study of 724 patients revealed that only 4% of the patients had Tis lesions, 11% had T1 to T2 lesions, and 85% had T3 to T4 lesions.[228] Five-year survival rates according to more than 10,000 patients reported in the U.S. National Cancer Data Base were stage 0, 80%; stage I, 50%; stage II, 28%; and stage III, 7% to 8%.[222] However, improved outcomes have been noted in the last decade and attributed to more aggressive surgery and the use of postoperative adjuvant therapy.[229] Studies from Japan report a 5-year survival rate in stage I patients of 100%, stage II at 50% to 78%, stage III at 0%

to 69%, and stage IV at 0% to 11%.[230,231]

Lymphatic metastasis initially is to cystic and pericholedochal nodes and then to the pancreaticoduodenal system, with later potential spread to the rest of the celiac axis or the superior mesenteric or aortic nodes.[230,232] The lymph node metastasis rate is associated with primary tumor stage: 0% to 2.5% in pT1a disease (involvement limited to the mucosa), 15% in T1b disease, 62% in pT2 disease, and 81% in pT3/pT4 disease.[230,233,234]

Surgery is the only potentially curative therapy, but only one-quarter of patients are eligible for resection.[235] The standard surgical procedure is removal of the gallbladder, resection of various amounts of liver surrounding the gallbladder bed, resection of the extrahepatic bile duct, and dissection of the regional lymph nodes. Patients with jaundice should be considered for preoperative percutaneous transhepatic biliary drainage for relief of biliary obstruction. Overall, the curative resection rates for gallbladder carcinoma range from 10% to 30% in Western countries.[236] The prognosis is related to the possibility of curative resection, primary tumor extension, and regional lymph node metastasis.

Patients with T1a disease often are cured after simple cholecystectomy and require no further adjuvant treatment.[234] However, for patients with ≥T2 disease, many reports support the benefit of radical resection.[229,233,237] In more advanced disease (≥T2), the benefit of adjuvant radiotherapy is uncertain. After “curative” resection, locoregional relapse in the tumor bed or regional nodes is common. Patients who received radiation postoperatively had a median survival of over 16 months. This was compared to <6 months for patients treated with surgery alone. Factors predicting recurrence are positive surgical margins, lymph node metastasis, and perineural invasion.[238] Several retrospective analyses demonstrate that postoperative radiotherapy improved local control and survival.[239–241] Benefits are also seen in patients who have microscopic residual tumors.[241] Combination radiotherapy and chemotherapy with 5-FU also reveal similar benefits.[242–244] However, there is a lack of phase III studies. Whether combination treatment is better than single modality is still unknown.

Patients with stage III and IV disease are at high risk for distant metastasis. The most frequent sites of involvement are the liver, peritoneum, and lung, with less frequent spread to ovaries, spleen, bones, and other organs.[91,243] In general, patients who are locally unresectable should be referred for chemoradiotherapy. Median survival is improved in several retrospective studies.[119,245] Systemic chemotherapy has limited success in the treatment of advanced gallbladder

carcinoma. Objective response rates range from 25% to 50%. Active agents include infusion of 5-FU in combination with agents such as leucovorin modulation, capecitabine, cisplatin, oxaliplatin, gemcitabine, and docetaxel, and 5-FU combined with recombinant IFN α-2b.[246–251] Currently, the standard of care for systemic chemotherapy is cisplatin and gemcitabine as mentioned in the section of Cholangiocarcinoma.[211]

OTHER RARE NEOPLASMS

Primary sarcomas of the liver are extremely rare in adults and represent only 1% to 2% of primary liver cancers.[252] Leiomyosarcoma is the most common histologic type, followed by malignant fibrous histiocytoma, epithelioid hemangioendothelioma, and angiosarcoma.[117] Some patients with angiosarcoma have a history of occupational exposure to vinyl chloride monomer.[253] Severity of histologic grade determines overall patient survival. Complete resection offers a chance of long-term survival.[117]

Hemangioma is a benign lesion and generally is asymptomatic. For symptomatic hemangioma, treatments include steroids, interferon-α, arterial embolization, and surgery.[254] If patients fail above treatments, radiotherapy may play a role. Long symptom-free duration has been obtained with doses as low as 13 to 30 Gy in 2.5 to 4 weeks to involved area.[255]

Hepatoblastoma is the most common malignant liver tumor of childhood. Children who have familial adenomatous polyposis of the colon and rectum are high risk for hepatoblastoma. The risk of hepatoblastoma in these children is 700 to 7,500 times higher than in the general population.[256,257] Surgery combined with chemotherapy has resulted in dramatic improvements in prognosis.[258] With the combination of chemotherapy and surgery, 75% to 80% of patients may be cured.[54] Preoperative chemotherapy often converts unresectable tumors to resectable and may reduce blood loss and technical complications.[259]

CHAPTER 65

Cancer of the Colon and Rectum

Manisha Palta, Brian G. Czito, and Christopher G. Willett

ANATOMY

The colorectum consists of the cecum, ascending colon, hepatic flexure, transverse colon, splenic flexure, descending colon, sigmoid colon, and rectum. Variability in the peritoneal investment, bowel mobility, and lymph node drainage of the colon and rectum presents unique therapeutic issues.[1]

The posterior and lateral surfaces of the ascending and descending colon are in direct contact with the retroperitoneum, whereas the anterior surface is draped with peritoneum.[1] These posterior attachments can prevent significant mobility, increasing the difficulty of surgical resection. In contrast, the transverse colon is completely surrounded with peritoneum and supported on a long mesentery. As the sigmoid colon evolves distally into the rectum, the peritoneal coverage recedes. The rectum, approximately 12 to 15 cm in length, extends from the rectosigmoid junction to the puborectalis ring. The upper one-third of the rectum is draped with peritoneum anteriorly and on both sides. As the middle one-third of the rectum moves deeper into the pelvis, only the anterior surface is covered with peritoneum, which forms the posterior border of the rectouterine pouch or rectovesical space. The lowest one-third of the rectum is devoid of peritoneal covering and in close proximity to adjacent structures, including the bony pelvis (Fig. 65.1). Distal rectal tumors have no serosal barrier to invasion of adjacent structures and are more difficult to resect, given the close confines of the deep pelvis.

Colonic nodal drainage consists of pericolic nodes and nodes in association with the vascular supply to the colon (i.e., mesenteric nodes). Because of the mobile and extensive nature of the colonic mesentery, complete regional lymph node coverage with external beam radiotherapy (EBRT) is challenging but is usually well treated surgically. In contrast, the major regional groups for rectal nodal drainage can be covered within a reasonable EBRT field and include the

perirectal, presacral, and internal iliac nodes.

EPIDEMIOLOGY AND RISK FACTORS

Colorectal cancer (CRC) remains a major worldwide health problem. In the United States alone, it was estimated that there would be 135,430 patients diagnosed with CRC and 50,260 deaths in 2017.[2] Worldwide, approximately 1.2 million new cases per year are diagnosed, with 600,000 deaths.[3] In the United States, incidence of CRC over the last two decades declined by 2% to 3% annually; this is largely attributed to improvements in cancer prevention, early detection, and treatment.[4]

Genetic and environmental factors can increase the likelihood of developing CRC. A number of hereditary CRC syndromes exist, including familial adenomatous polyposis (FAP), MUTYH-associated polyposis, and Lynch syndrome (hereditary nonpolyposis colorectal cancer [HNPCC]). Factors shown to increase the risk of developing CRC include the following: increasing age; male sex; family history of CRC; inflammatory bowel disease; increasing height; increasing body mass index; consumption of processed meat, refined grains, starches, and sugars; excessive alcohol intake and smoking; and low folate consumption.[5,6] Of these risk factors, only increasing age, male sex, and excessive alcohol use have been associated with rectal cancer.[7] Age is a major risk factor for the development of CRC, with median age of diagnosis in the seventh decade. Incidence rates increase dramatically between ages 40 and 50 years and each subsequent decade thereafter (data from Surveillance, Epidemiology, and End Results Program accessible online at www.seer.cancer.gov).

Although CRC may be linked to chemical carcinogens within the bowel lumen, it is not established whether these are ingested, the result of chemical activation of substances in the fecal stream, or a bacterial by-product.[8,9] The value of consumption of fruits and vegetables in the prevention of CRC remains controversial, although recent studies suggested that these associations might have been overstated.[10] Contemporary prospective and randomized data do not support a high-fiber diet in the prevention of CRC.[11] Other studies suggested that nonsteroidal anti-inflammatory drugs may serve in reducing recurrent adenomas and CRC, but long-term therapy must be weighed against potential side effects. The role of chemopreventive agents (carotenoids, aspirin, and other nonsteroidal anti-inflammatory drugs) in CRC remains an area of active

investigation. A detailed discussion of the biologic and genetic pathways of development of CRC is beyond the scope of this chapter. In brief, it has been established that the development of colon cancer is a multifactorial process, involving genomic instability, mutational inactivation of tumor suppressor genes, and activation of oncogene pathways. Microsatellites are mutated short-repeat DNA sequences, usually consisting of one to five nucleotides. The majority of patients with HNPCC, as well as a minority of sporadic CRCs, harbor microsatellite instability. It has been shown that this instability occurs in patients with mutations in genes encoding enzymes that repair DNA replication errors. These defects in mismatch repair lead to high-frequency microsatellite and hence genomic instability.[12] Studies suggested that patients with tumors possessing a high frequency of microsatellite instability have more favorable outcomes and lower likelihood of developing metastatic disease.[13] CRC appears to arise through inactivation of the tumor suppressor genes adenomatous polyposis coli (APC), P53, and TGF-β, as well as activation of the RAS, BRAF, and PI3 K proto-oncogenes.[12] Further elucidation of the genetic pathways in the development of CRC remains an active area of investigation and may ultimately affect therapy of this disease.

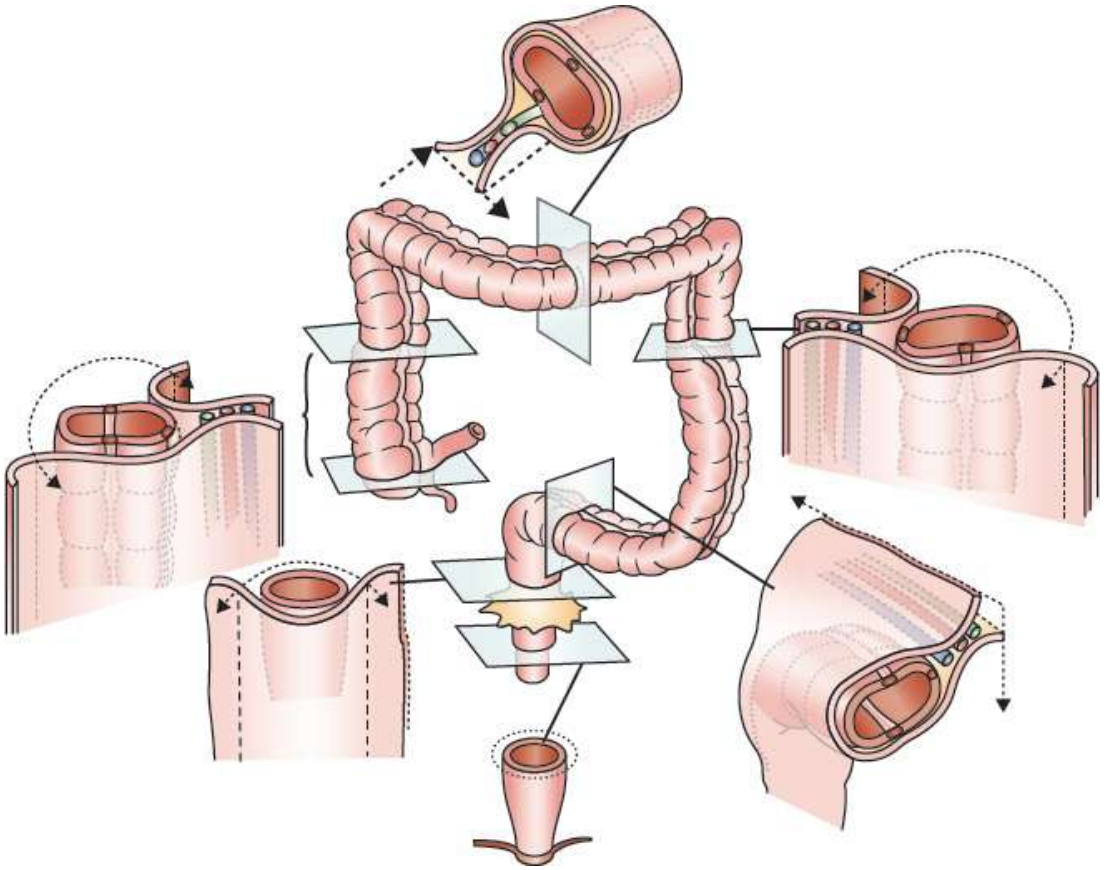

FIGURE 65.1. Idealized depiction of peritoneal relationships in the colon and rectum. The transverse and sigmoid colon are intraperitoneal, with a complete peritoneal covering (serosa) and mesentery. The ascending and descending colon are retroperitoneal, lack a true mesentery, and usually do not have a peritoneal covering posteriorly or laterally. The upper rectum begins above the peritoneal reflection and has peritoneum anteriorly and laterally. The lower one-half to two-thirds of the rectum is below the peritoneal reflection (infraperitoneal). (From Gunderson LL, O'Connell MJ. The postoperative chemotherapy/irradiation adjuvant strategy. CLINICAL PRESENTATION

CRC often produces minimal or no symptoms, emphasizing the need for screening programs in the general population. Patients with symptomatic CRC most commonly experience abdominal pain, change in bowel habits, hematochezia/melena, weakness, iron deficiency anemia, and weight loss.[14,15] Less commonly, patients present with nausea, vomiting, or abdominal distension, which may be signs of tumor-related obstruction.

The clinical presentation of CRC is determined largely by site of the tumor. Cancers of the right colon are often exophytic and commonly associated with

iron deficiency anemia due to occult blood loss, resulting in delayed diagnosis. During the last 20 years, the incidence of cancer of the right colon appears to have increased and accounts for one-third of large-bowel cancers.[16] Cancers of the left colon and sigmoid colon are often deeply invasive and annular ("apple core lesions") and accompanied by obstruction, rectal bleeding, and alteration in bowel habits.

SCREENING

Neoplastic polyps, including tubular adenomas, villous adenomas, and tubulovillous adenomas, are precursors of colon cancers.[8,17] Most CRC arise from preexisting polyps. As the cumulative lifetime risk of developing CRC in the United States is about 6%, screening programs for the general population have been initiated. The goal of screening is to detect preinvasive polyps or early invasive cancer. Mounting evidence supports that screening of asymptomatic, average-risk individuals can detect CRC at early, curable stage, thereby reducing CRC mortality.[18–20]

Given the data in favor of screening, health organizations such as the American Cancer Society (ACS), the United States Preventive Services Task Force, and the American College of Radiology recommend screening in average-risk individuals starting at age 50. The ACS advocates for tests that detect adenomatous polyps and cancer as follows:

- Flexible sigmoidoscopy every 5 years.
- Double-contrast barium enema every 5 years.
- Computed tomography (CT) colonography every 5 years.
- Colonoscopy every 10 years.[19]
- Guaiac-based fecal occult blood, fecal immunohistochemical, and stool DNA tests may be performed for CRC, but not polyp, detection.[21]

In high-risk patients (patients with adenomatous polyps, history of CRC, first-degree relative diagnosed with CRC or adenomas, inflammatory bowel disease, or high risk due to family history or genetic testing), more intensive surveillance is recommended. Individuals with FAP initiate annual sigmoidoscopy or colonoscopy beginning at age 10 to 12 years until age 35 to 40 years if negative. Patients with HNPCC initiate annual screening at age 20 to 25 years or 10 years prior to earliest familial CRC diagnosis.[22,23] Patients with inflammatory bowel disease should initiate screening with colonoscopy 8 to 10 years after initial diagnosis.[21] The American College of Gastroenterology recommends the

following for high-risk individuals based on family history[24]:

- Colonoscopy screening.
- If single, first-degree relative diagnosed with CRC, or advanced adenoma at age 60+ years, screening every 10 years beginning at age 50 years.
- If single, first-degree relative diagnosed with CRC, or advanced adenoma at age <60 years or two or more first-degree relatives with CRC or advanced adenoma at any age, screening beginning at age 40 years or 10 years before the youngest relative's diagnosis. Screening should be performed every 5 years.

Although screening methods can detect CRC at an early stage, <40% of patients are diagnosed with early disease, likely reflecting low rates of disease awareness, as well as the infrequency of screening in eligible candidates.[25] Approximately 50% to 60% of eligible adults aged 50 to 75 years underwent CRC screening in 2008.[26,27] Lower rates of screening are seen in younger patients, Hispanics, individuals of lower socioeconomic status, and individuals without health insurance.[27] Although all screening tests have potential drawbacks, patients should be educated regarding relative risks and benefits of screening modalities, including potential benefits in reducing risk of CRC.

PATHOLOGY AND PATHWAYS OF SPREAD

Tumors of the colorectum arise in the mucosa and virtually all (>90%) are adenocarcinomas.[8] Other histologic types include squamous cell carcinoma, melanoma, small cell carcinoma, carcinoid, sarcoma, and lymphoma. Most grading systems classify adenocarcinoma as well, moderately or poorly differentiated. Large-bowel tumors invade from mucosa through the bowel wall and beyond, with involvement of lymphatic channels and lymph nodes. Hematogenous spread can occur, primarily to the lung and liver. There is little propensity for colon cancer to spread longitudinally within the bowel wall, in contrast to esophageal or gastric cancers.

PATIENT EVALUATION/STAGING

Workup should include a complete history and physical exam, including digital rectal examination (DRE). On DRE, size, location, distance from the verge, mobile versus fixed, and sphincter function should be noted. Pelvic exam should be performed in women diagnosed with rectal cancer to assess for vaginal involvement where appropriate. Pretreatment evaluation should include

pathologic confirmation of adenocarcinoma, colonoscopy to evaluate extent of tumor and rule out synchronous primaries (occurring in 1% to 5%), and baseline lab tests, including blood counts, liver function tests, and carcinoembryonic antigen levels.[9] India ink may be used at the time of colonoscopy to mark the proximal and distal disease extent.

Patients with CRC should undergo abdominopelvic CT scan and chest x-ray or chest CT to evaluate extent of locoregional disease, as well as the presence or absence of distant metastases. Efforts to improve the clinical assessment of rectal cancers have been enhanced considerably with the evolution of new imaging modalities. CT appears to be more useful in identifying enlarged pelvic lymph nodes and metastasis outside the pelvis than the extent or stage of the primary tumor.[28] Standard CT does not permit the visualization of the layers of the rectal wall, and therefore its utility in the assessment of smaller primary cancers is limited.[29] The sensitivity of CT scan is reported as 50% to 80% accurate, with a 30% to 80% specificity (65% to 75% accurate for tumor staging and 55% to 65% accurate in mesorectal lymph node staging).[30] The ability of CT scans for detecting distant metastasis (DM), including pelvic and para-aortic lymph nodes, is higher than for detecting perirectal nodal involvement (75% to 87% vs. 45%).[31,32] Any lymphadenopathy near the rectum seen on a CT scan should be considered abnormal.

For rectal malignancies, endoscopic ultrasound (EUS) or pelvic magnetic resonance imaging (MRI) can assess primary disease and, with less sensitivity, evaluate nodal extent. Transrectal EUS techniques have been more helpful in efforts to clinically stage rectal cancers. EUS is 80% to 95% accurate in tumor staging and 70% to 75% accurate in mesorectal lymph node staging.[33,34] Transrectal ultrasound is able to visualize layers of the rectal wall, including the mucosa, muscularis mucosa, submucosa, and muscularis propria.[35,36] Its use is more limited in tumors of the upper rectum or for stenosing tumors. EUS can also identify enlarged perirectal lymph nodes but is not effective outside of the perirectum.[37] One situation in which EUS can be very useful is in determining extension of disease into the anal canal, which is an area that is poorly visualized on CT but of critical importance for planning sphincter-preserving surgical procedures.[38]

More recently, MRI techniques have been found to be of high accuracy in defining the extent of rectal cancer extension into the mesorectum and in determining the location and stage of tumor.[39,40] Different approaches to MRI have been explored, including the use of body coils, endorectal MRI, and

phased-array techniques. Although MRI appears to have high levels of accuracy, it requires a significant learning curve but is becoming a greater part of the standard presurgical workup for rectal cancer. Body-coil MRI, which first became available in the mid-1980s, has had an accuracy of 54% to 66% for T staging, but this has improved with the use of endorectal coil MRI, with reported accuracy rates of 80% to 95%.[16,41] A significant advantage of both endorectal and surface coil MRI is that it is less operator dependent and permits a larger field of view than does EUS. It also allows assessment for proximal tumors and stenotic lesions where EUS is not possible. Another advantage of MRI is that it can detect involved lymph nodes on the basis of characteristics other than size. MRI can also be helpful in determining the extent of lateral extension of disease, which is critical in predicting the adequacy of circumferential margins for surgical excision.[17] Several studies using phased-array MRI reported accuracy rates of 80% to 97% in predicting lateral disease extent and correlated the likelihood of tumor-free resection margin by visualizing tumor involvement of the mesorectal fascia.[42]

Positron emission tomography (PET) scan, although less accurate in assessment of primary disease, is useful in evaluating patients with oligometastatic disease who may be appropriate candidates for resection of metastatic sites with curative intent.[43] Liver MRI is considered the test of choice in assessment of hepatic metastases in patients with CRC.[44] All of these imaging techniques have advantages and limitations and should be considered complementary to physical examination. They are all less accurate in predicting response after neoadjuvant therapy, with high rates of false positivity, and should be interpreted with caution in this setting.[45,46] Prognostic factors influencing survival in CRC patients include the depth of tumor invasion into and beyond the bowel wall, the number of involved regional lymph nodes, and the presence or absence of distant metastases. The tumor, node, metastasis (TNM) system of the American Joint Committee on Cancer can be used as a clinical (preoperative) or postoperative staging system (Tables 65.1 and 65.2).

TABLE 65.1 AMERICAN JOINT COMMITTEE ON CANCER 2010 TNM STAGING OF COLORECTAL CANCER

Primary Tumor (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma *in situ:* intraepithelial or invasion of lamina propria

T1	Tumor invades submucosa
T2	Tumor invades muscularis propria
T3	Tumor invades through the muscularis propria into the subserosa or into pericolorectal tissues
T4a	Tumor penetrates to the surface of the visceral peritoneum[a]
T4b	Tumor directly invades or is adherent to other organs or structures[a,b]
Regional Lymph Nodes (N)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in one to three regional lymph nodes
N1a	Metastasis in one regional lymph node
N1b	Metastasis in two to three lymph nodes
N1c	Tumor deposit(s) in the subserosa, mesentery, or nonperitonealized pericolorectal tissues without regional nodal metastasis
N2	Metastasis in four or more regional lymph nodes
N2a	Metastasis in four to six regional lymph nodes
N2b	Metastasis in seven or more regional lymph nodes
Distant Metastasis (M)	
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis
M1a	Metastasis confined to one organ or site
M1b	Metastasis in more than one organ/site or peritoneum

[a]Direct invasion in T4 includes invasion of other organs or other segments of the colorectum as a result of direct extension through the serosa, as confirmed on microscopic examination (e.g., invasion of the sigmoid colon by a carcinoma of the cecum) or, for cancers in a retroperitoneal or subperitoneal location, direct invasion of other organs or structures by virtue of extension beyond the muscularis propria (i.e., respectively, a tumor on the posterior wall of the descending colon invading the left kidney or lateral abdominal wall or a mid or distal rectal cancer with invasion of prostate, seminal vesicles, cervix, or vagina).
[b]Tumor that is adherent to other organs or structures grossly is classified cT4b. However, if no tumor is present in the adhesion microscopically, the classification should be pT1-4a, depending on the anatomic depth of wall invasion. The V and L classifications should be used to identify the presence or absence of vascular or lymphatic invasion, whereas the PN site-specific factor should be used for perineural invasion.

TREATMENT OF COLON CANCER

Surgery

Surgery is the primary treatment modality for patients with colonic tumors. Resection with curative intent is possible in approximately 75% of patients.[9] Surgery of primary colon cancer is based on the anatomy and mechanisms by which this disease spreads. Adenocarcinomas of the colon may grow by direct extension into the lymphatics of the submucosa and bowel wall. To avoid cutting across tumor intramural lymphatics, sufficient lengths of bowel must be resected proximal and distal to the primary cancer. Colon cancer often extends through the serosa into mesenteric lymphatics that run along the blood vessels draining into the portal watershed at the root of the mesentery. Resection includes removal of the major lymphatic drainage system in the mesentery. Because anatomic resections are designed to include named blood vessels and draining lymphatics, the boundaries for resecting large-bowel cancer are relatively uniform. Right hemicolectomy, transverse colectomy, left hemicolectomy, and sigmoid resection are performed by adherence to surgical oncologic principles without major sacrifice of large-bowel function. Consensus guidelines recommend that a minimum of 12 lymph nodes should be excised for appropriate staging.[47–49] As with other gastrointestinal and pelvic malignancies,

the use of laparoscopic techniques has increased. Data suggest no difference in recurrence or survival outcomes with open versus laparoscopic resection.[50–53]

Resection results in excellent cure rates for lesions limited to the bowel wall with negative nodes (average 5-year survival, 97% for T1 N0; 85% to 90% for T2 N0). With a single high-risk feature of extension beyond the colonic wall (T3-4 N0) or involved nodes (T0-2 N+), 5-year survival with surgery falls to 65% to 75%, and adjuvant treatment is often indicated. When both high-risk features are present (T3-4 N+), 5-year survival with surgery alone drops to approximately 50% (T3 N+) and 35% (T4 N+), and adjuvant treatment is recommended.

Adjuvant Chemotherapy

The benefit of adjuvant chemotherapy has been clearly demonstrated in stage III patients, whereas benefit in stage II patients is more controversial. Prospective randomized trials have shown that the addition of 5-flourouracil (5-FU) and leucovorin (LV) improves survival for resected stage III patients.[54,55] More recently, newer agents have been investigated and have shown potential benefit. Capecitabine, an oral 5-FU prodrug, demonstrated similar overall survival (OS) and disease-free survival (DFS) rates to 5-FU/LV in patients with resected stage III colon cancer.[56,57] Oxaliplatin has also been investigated in the adjuvant treatment of resected colon cancer. A randomized study comparing 5-FU/LV with 5-FU/LV/oxaliplatin (FOLFOX) in resected stage II or III colon cancer patients showed improved DFS and OS in stage III patients treated with oxaliplatin-containing regimens.[58,59] These results were validated in the National Surgical Adjuvant Breast and Bowel Project (NSABP) C-07 trial, demonstrating an improvement in DFS with addition of oxaliplatin.[60,61] A Cancer and Leukemia Group B (CALGB) trial examined 5-FU/LV with and without the addition of irinotecan in resected stage III colon patients. No benefit was seen in DFS or OS.[45] These data helped to establish FOLFOX or capecitabine and oxaliplatin (XELOX) as new standard chemotherapeutic regimens in the adjuvant treatment of completely resected, high-risk colon cancer. The use of monoclonal antibodies, such as bevacizumab and cetuximab, although potentially efficacious in the metastatic setting, has not yielded similar results in the adjuvant setting.[62–65]

Adjuvant Irradiation with or without Concurrent Chemotherapy

Given the documented efficacy of adjuvant chemotherapy, as well as the

perception by many oncologists that colonic (as opposed to rectal) cancer is much more likely to relapse distantly than locally, there has been little evaluation of the efficacy of postoperative irradiation with chemotherapy. The potential indications for adjuvant radiation therapy in colon cancer are based on analyses of patterns of failure following resection (Table 65.3).[66,67] Advanced stage predicts for local failure in both colon and rectal cancers; however, local failure in colon cancer also depends on anatomic origin. The ascending and descending colon are considered "anatomically immobile," and their close proximity to the retroperitoneal tissues often limits wide surgical resection (Fig. 65.1). Limitations in achieving satisfactory circumferential margins increase the risk of residual disease and consequently local failure. In contrast, the midsigmoid and midtransverse colon are relatively "mobile," with a wide mesentery, permitting the surgeon to obtain wide margins regardless of extent of disease invasion into the mesentery. Unless there is adjacent organ adherence/invasion by tumor, local failure at these sites is uncommon. Local failure rates for cecal, hepatic/splenic flexure, and proximal/distal sigmoid tumors are variable, depending on the amount of mesentery present, tumor extension, and the adequacy of radial margins. When colon cancers adhere to or invade adjacent structures, local failure rates exceed 30% following surgery alone. In summary, local failure occurs in patients with colonic tumors where there are anatomic constraints on radial resection margins, including tumors adherent to or invading adjacent structures.

Data evaluating the use of adjuvant radiation therapy in high-risk colon cancer patients have largely been limited to single-institution retrospective analyses.[38,68–70] To summarize, these studies have suggested that operative bed failures in high-risk patients undergoing resection alone are at least 30% and that the risk of local failure is reduced by the administration of adjuvant radiation therapy. These are discussed in detail in what follows.

A report from the Massachusetts General Hospital (MGH) evaluated outcomes in high-risk patients undergoing resection followed by adjuvant radiation therapy and compared these to a similar cohort of patients treated over the same period undergoing surgery only.[70] Irradiated patients included those with T4 N0/N+, T3 N+ disease (excluding midsigmoid and midtransverse colon) and T3 N0 patients with margins of <1 cm. A total of 171 patients received postoperative radiation, with 63 patients receiving concurrent chemotherapy, usually with bolus 5-FU (500 mg/m^2/d) for 3 consecutive days during the first and last weeks of radiation therapy. Radiation treatment was administered

through parallel-opposed or other multifield techniques to treat the tumor bed with an approximate 3- to 5-cm margin to a total dose of 45 Gy, followed by reduced fields to a total dose of 50.4 to 54 Gy. Draining nodes were included if they were believed to be at high risk for involvement. This cohort was compared to 395 patients with T3-4 N0/N+ tumors undergoing surgery alone during the same time period. Table 65.3 shows 5-year actuarial local control (LC) and relapse-free survival (RFS) in the adjuvant group compared to patients undergoing surgery alone. LC rates in T4 N0 and T4 N+ patients treated with radiation therapy were 93% and 72%, respectively, versus 69% and 47%, respectively, in patients undergoing surgery alone. Similarly, RFS rates were 79% and 53%, respectively, in T4 N0/T4 N+ patients undergoing adjuvant radiation versus 63% and 38%, respectively, in those undergoing surgery alone. No significant outcome differences were observed in patients with T3 N0 and T3 N+ lesions; however, there may be an element of selection bias, given that most patients were referred out of concerns of adequacy of LC following surgery alone. A trend toward improved LC in patients receiving 5-FU was seen (Table 65.4). The rate of acute enteritis in patients receiving irradiation and 5-FU was 16% versus 4% in patients undergoing irradiation only. This rate of enteritis is similar to data from studies of concurrent 5-FU and radiation therapy in rectal cancer. Late bowel complication rates were not increased by concomitant 5-FU administration. The conclusion was that patients with T4 tumors, abscess/fistula formation, or margin-positive resection may benefit from postoperative radiation. In an updated analysis from MGH, 152 patients with T4 tumors received adjuvant irradiation.[70] On pathologic examination, 42 patients had tumors with positive margins. For patients with negative margins, the 10-year actuarial LC in T4 N0 and T4 N+ patients was 78% and 48%, respectively. In patients with node-negative tumors, the 10-year actuarial LC and RFS rates were 87% and 58%, respectively, compared to 65% and 33%, respectively, in patients with node-positive tumors. For patients with one involved lymph node, LC and RFS rates were similar to those without nodal involvement; however, with increasing numbers of nodes involved, survival steadily decreased.

TABLE 65.3 FIVE-YEAR ACTUARIAL LOCAL CONTROL AND RELAPSE-FREE SURVIVAL AFTER SURGERY PLUS POSTOPERATIVE RADIOTHERAPY VERSUS SURGERY ALONE, ACCORDING TO STAGE, FROM THE MASSACHUSETTS GENERAL HOSPITAL

	Surgery Alone			Surgery Plus Postoperative Radiation

[a]*P* < .05.
LC, local control; RFS, relapse-free survival; TNM, tumor, node, metastasis.

A report from the Mayo Clinic evaluated outcomes of 103 patients receiving radiation therapy following surgery for locally advanced colon cancer.[71] Microscopic and gross residual disease was present in 18 and 35 patients, respectively. Greater than 90% of patients had T4 N0/N+ disease. A median dose of 50.4 Gy was delivered through multifield techniques, and most patients received concurrent 5-FU–based chemotherapy. Eleven patients received an intraoperative radiotherapy (IORT) boost of 10 to 20 Gy. Five-year actuarial LC was 40%. Patients with margin-negative tumors had a 5-year local LC of 90%, compared to 46% for patients with microscopic residual tumor and 21% for those with gross residual tumor. In patients with residual disease, LC rates in patients undergoing intraoperative boost were 89%, compared to 18% in those undergoing external irradiation alone. Similarly, 5-year OS rates were improved in patients undergoing margin-negative resection (66%) compared to those with microscopic residual (47%) or gross residual (23%) disease. In addition, patients undergoing intraoperative boost demonstrated improved survival (76% vs. 26%).

TABLE 65.4 FIVE-YEAR ACTUARIAL LOCAL CONTROL AND RELAPSE-FREE SURVIVAL OF ADJUVANTLY IRRADIATED PATIENTS BASED ON 5-FLUOROURACIL ADMINISTRATION—MASSACHUSETTS GENERAL HOSPITAL

	Without 5-Fluorouracil			With 5-Fluorouracil		
TNM Stage	Number of Patients	LC (%)	RFS (%)	Number of Patients	LC (%)	RFS (%)
T3 N0	16	87	69	7	100	80
T4 N0	37	94	78	16	100	83
T3 N+	41	69	48	14	70	43

T4 N+	24	67	53	15	79	52	

LC, local control; RFS, relapse-free survival; TNM, tumor, node, metastasis.

A study from the University of Florida of patients with locally advanced but completely resected colon cancers receiving adjuvant radiation reported a LC rate of 88%, similar to the 90% reported from the Mayo Clinic series.[68] In addition, there appeared to be a dose–response relationship to LC. The 5-year rate of LC was 96% for patients receiving 50 to 55 Gy versus 76% for patients receiving <50 Gy ($P = .0095$).

These retrospective studies laid the foundation for further testing in a phase III trial. To assess whether the addition of radiation therapy to adjuvant chemotherapy would result in superior OS and LC rates in resected, high-risk colon cancer patients, the U.S. Intergroup initiated a randomized, prospective trial in 1992.[72] In this trial, patients with resected colon cancer were randomized to postoperative irradiation with 5-FU and levamisole or 5-FU and levamisole alone. Eligibility criteria included margin-negative tumors with adherence to or invasion of surrounding structures (i.e., T4 N0 or N+ disease, excluding peritoneal invasion) or tumors arising in the ascending or descending colon with metastatic regional nodes (T3 N+). Patients were randomized to receive (a) weekly 5-FU combined with levamisole for 12 months or (b) 5-FU and levamisole for 12 months with combined radiation therapy and chemotherapy beginning 1 month after the first 5-FU administration. The recommended total radiation dose was 45 Gy in 25 fractions over 5 weeks, with an optional 5.4-Gy boost.

The initial trial accrual goal was 700 patients; however, the study was closed in 1996 because of poor accrual (222 patients; 189 evaluable). Total accrual was less than one-third of the initial goal, and there was reduced statistical power to detect differences between the groups. No difference in OS or DFS was seen between the two groups. Five-year OS of patients receiving chemotherapy only was 62% versus 58% for patients randomized to chemoirradiation ($P > .50$). LR rates were identical in both arms (18 patients each). Grade III or IV hematologic toxicity was higher in patients receiving radiation therapy. Interpretation of study results was handicapped by decreased statistical power, high ineligibility rates, and lack of surgical clips or preoperative imaging to assist in the definition of appropriate radiotherapy fields in a high percentage of patients. Therefore, no definitive conclusions can be made regarding the efficacy of postoperative irradiation with 5-FU and levamisole based on this underpowered study with many flaws; however, this study provides no data supporting its routine use.

A recent study has examined the role of adjuvant radiation therapy in locally advanced colon cancer in the era of modern chemotherapy.[73] The investigators reported the outcome of 62 patients with T4 colonic cancer treated with surgery only, surgery followed by adjuvant chemotherapy only, or 13 patients adjuvant chemoradiation. A multivariate analysis demonstrated that treatment with adjuvant chemoradiation (vs. adjuvant chemotherapy alone) enhanced locoregional control and disease-free survival. The investigators concluded that adjuvant radiation therapy may be appropriate in select patients, specifically those with T4b lesions and/or residual disease following resection.

Neoadjuvant Treatment

Neoadjuvant chemotherapy or chemoradiation therapy can be considered for locally advanced or unresectable colon cancer. The FOxTROT pilot study showed that neoadjuvant chemotherapy for large T3 or T4 tumors was feasible with acceptable toxicity rates[74]; this study group has moved forward with a phase 3 trial. Although neoadjuvant chemoradiation has been shown in randomized trials to improve LC/DFS in rectal cancer patients,[75,76] there is no high-level evidence demonstrating its effectiveness in colon cancer patients. For locally advanced colon cancer patients receiving neoadjuvant chemoradiation, high rates of R0 resection and LC with low toxicity rates have been reported in retrospective studies.[77]

Locally Advanced Disease and Palliation

Patients with unresectable tumors or metastatic disease at presentation are usually treated with systemic therapy. An irinotecan-based (e.g., FOLFIRI: irinotecan–fluorouracil–leucovorin)[78] or oxaliplatin-based (e.g., FOLFOX: oxaliplatin–fluorouracil–leucovorin) regimen with the addition of bevacizumab[79] or an epidermal growth factor receptor (EGFR) inhibitor (e.g., panitumumab or cetuximab)[80] (KRAS/NRAS wild-type tumors) can prolong progression-free survival and potentially OS. Patients with refractory disease may be treated with EGFR inhibitors containing regimens (KRAS/NRAS wild-type tumors), PD-1 inhibitors like pembrolizumab[81] (MMR-deficient tumors), oral multikinase inhibitors like regorafenib, or tipiracil/trifluridine. Additional targeted and immunotherapy agents are under evaluation.

Patients with near colonic obstruction may benefit from a diverting ostomy or stenting. Nonsurgical candidates may benefit from palliative radiation to shrink a painful, near-obstructing or bleeding mass.

Techniques of Irradiation

Treatment field design in colon cancer is based on patterns of failure data. As is true in the treatment of rectal carcinoma, great care must be taken in the design of postoperative treatment of adenocarcinoma of the colon. Field arrangement will vary, depending on the site of the primary disease, as well as on areas judged to be at high risk for local recurrence (LR).[82] Patient positioning (supine, prone, decubitus) should be considered in planning. The small bowel is often a dose-limiting structure in this therapy, and it may be advantageous to position patients in the right or left decubitus position for at least a portion of their treatment, allowing displacement of the small bowel away from the treatment field. Immobilization devices may improve reproducibility. Small-bowel contrast aids in delineation of small-bowel volume within the treatment field. It may be useful to compare films in both the decubitus and supine positions to determine the actual amount of small-bowel displacement. CT-based planning may facilitate defining the tumor bed, determining beam orientation, and estimating the volume of small bowel included within the treatment fields. As in other abdominal malignancies, a portion of one kidney may be irradiated. Unilateral renal irradiation results in minimal long-term clinical sequelae, assuming that baseline function in the contralateral kidney is normal.[83]

The total radiation dose used in the adjuvant treatment of colon carcinoma depends on the amount of suspected residual disease and tolerance constraints of surrounding normal tissue. Generally, an initial dose of 45 Gy in 25 fractions at 1.8 Gy/fraction is delivered through larger fields to the primary tumor and at-risk tissues. Reduced fields may be treated to 50 Gy if only a small portion of small bowel is included. For patients with T4 tumors, the general goal is to treat the tumor bed to a total dose of up to 54 to 60 Gy. Surgical clips may aid in the identification of high-risk areas (i.e., positive margins) to assist in target delineation. Any treatment beyond 50 Gy generally mandates exclusion of all small bowel from the field to minimize late toxicity. Spinal cord dose should generally be limited to 45 Gy. In addition, at least two-thirds of one functional kidney should receive no more than 18 to 20 Gy, and at least two-thirds of the total liver volume should not receive >30 Gy. In a Mayo Clinic analysis, small-bowel obstruction rates were lower when more than two treatment fields were used, and attempts should be made to implement multifield techniques, which may be aided by CT-based planning.[84]

Generally, the primary tumor site should be covered with a 4- to 5-cm margin proximally and distally and with a 3- to 4-cm margin medially and laterally to

cover areas of potential residual disease. The nodal basins in the mesentery beyond surgical margins are usually not treated, as satisfactory margin clearance is often obtained in these sites. An exception to this may be right colon tumors, for which both small bowel and right colon are supplied by ileocolic vessels, limiting the extent of resection. In some instances, treatment of the para-aortic nodes may be indicated, particularly with extensive retroperitoneal involvement by tumor. Treatment of proximal mesenteric nodes may be appropriate if nodes adjacent to the surgical or resection margin are involved. Figures 65.2 and 65.3 show idealized radiation fields for varying colonic sites, including cecum, descending, and sigmoid cancer. In many situations, it may be appropriate to exclude treatment of para-aortic nodal basins, based on operative and pathologic findings.

Endorectal brachytherapy is an alternative or adjunct to EBRT where a high dose of radiation is delivered to the tumor. This technique of contact therapy was first described by Jean Papillon who pioneered this approach at the University of Lyon in the mid-1940s. In addition to contact therapy, radiotherapy may be delivered via high dose rate endoluminal brachytherapy or interstitial rectal brachytherapy implant.These techniques are primarily delivered as a boost in an effort to escalate dose and achieve higher rates of clinical complete response (cCR), which may allow for nonoperative management (NOM). The use of rectal brachytherapy is an area of ongoing investigation.

CONCLUSION

Subsets of patients with colon cancer have LR rates similar to patients with rectal cancer if surgery only is undertaken. Encouraging results from single-institution series utilizing postoperative irradiation with or without 5-FU for patients with resected high-risk colon cancers and the positive results of 5-FU and levamisole in high-risk adjuvant colon cancer prompted an Intergroup randomized trial. Patients with high risk of LR following surgery were randomized to 5-FU and levamisole or 5-FU and levamisole with tumor bed irradiation. There was no benefit in survival in patients receiving adjuvant radiation therapy; however, interpretation of these results is impaired by inadequate accrual and significant flaws, as previously discussed.

The value of adjuvant postoperative irradiation combined with systemic therapy for patients at high risk for LR is unlikely to ever be addressed in a definitive randomized trial. Treatment recommendations should be made on a

case-by-case basis with existing data in the setting of an informed consent. Adjuvant tumor bed irradiation with concurrent 5-FU–based chemotherapy should be considered for patients (a) with tumors invading adjoining structures, (b) with tumors complicated by perforation or fistula, and (c) with tumors where incomplete resection is performed.

The use of IORT as a supplement to EBRT in certain T4 tumors (i.e., those with uncertain margins) may also be appropriate. For patients with tumors adherent to or invading adjacent structures, one preferred treatment sequence would be preoperative EBRT plus 5-FU–based chemotherapy, followed by resection with or without IORT and postoperative systemic therapy, based on excellent results in preliminary IORT reports from both US and European institutions.[71,85,86] A similar approach would be reasonable for patients with locally recurrent cancers or with regional nodal relapse.[87,88]

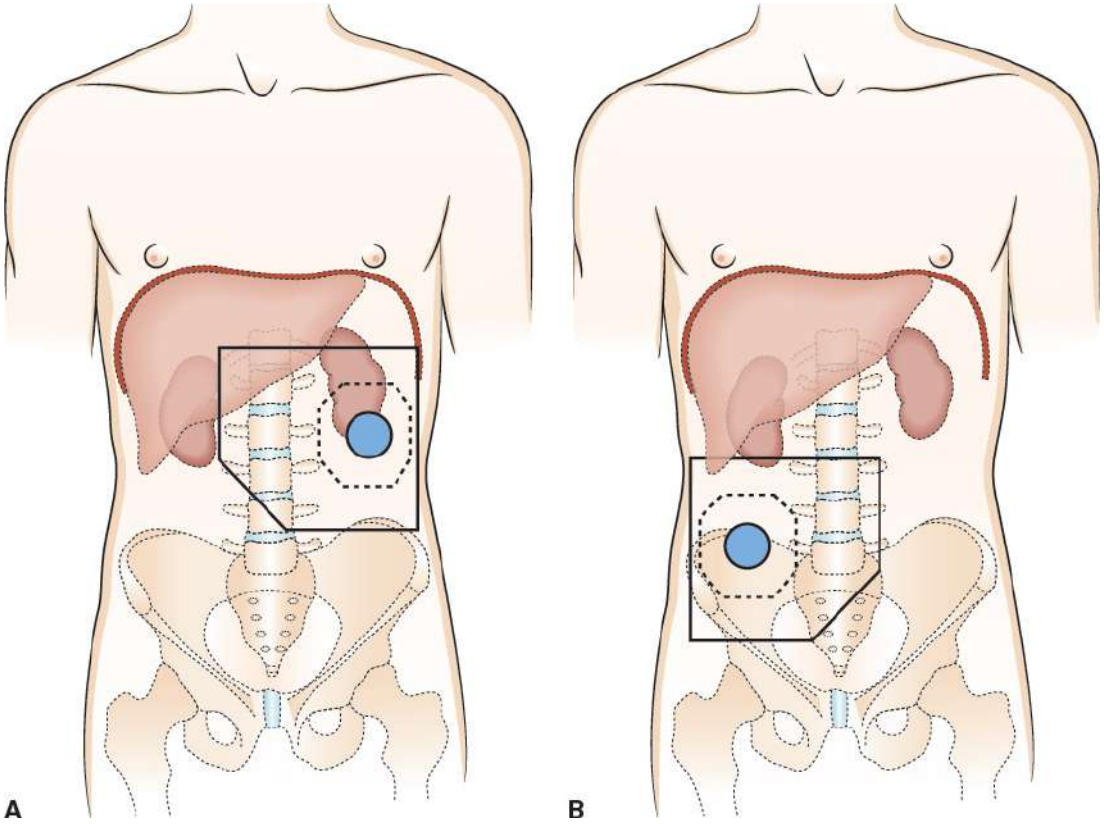

FIGURE 65.2. Idealized postoperative anteroposterior/posteroanterior irradiation fields of extrapelvic colon cancer (tumor bed and nodal regions). If treated preoperatively, lateral fields could be added based on imaging with computed tomography of the abdomen and colon radiograph. **A:** Para-aortic nodes may be at risk, in addition to tumor bed, because of tumor adherence to posterior abdominal wall with descending colon cancer. **B:** External and common iliac nodes may be at risk, in addition to tumor bed, from a proximal cecal/ascending colon cancer. THERAPY OF RECTAL CANCER

Management of cancer of the rectum has undergone dramatic changes in the last two decades. Surgery has been considered the primary treatment modality, but in spite of "curative" resections, historically, a significant proportion of patients developed LR of disease (20% to 50%).[89,90] Local tumor recurrence is highly correlated with both the depth of penetration of the tumor and the number of regional nodes.[43] Recent results of national cooperative group studies and several European randomized trials indicate that a multimodality treatment approach, particularly neoadjuvant treatment, results in a significantly better

outcome than does surgery alone.

Defining the True Rectum and Impact of Tumor Location

Rectal cancer represents a spectrum of disease stages that needs careful definition to optimize multimodality treatment strategies, and defining the true rectum is of critical importance. Traditionally, the rectum extends for 12 to 15 cm from the anal verge. The true surgical rectum begins at the anorectal ring, just proximal to the dentate line.[35] This represents the internal anal sphincteric muscle and is necessary for anal continence. It also represents the practical inferior limit for functional sphincter preservation surgery and defines the lymphatic watershed for rectal cancer spread. Tumors arising above the anorectal ring tend to metastasize along the distribution of the middle rectal vessels to the internal iliac lymph nodes, as compared to tumors that may extend into the anal canal, which may spread via nodes along the inferior rectal and external iliac pathways (Fig. 65.4).[91] Cancers that arise in the anal canal may metastasize to the lungs (caval drainage) rather than the liver (portal drainage), as is common with most true rectal cancers. The prognosis of patients worsens with more distal location of cancer, and these differences persist even with the addition of adjunctive therapy.[92–94] The proximal rectum has historically been defined by the level at which the peritoneum is reflected along the anterior surface of the rectum (usually at the level of S3).[95] This is a surgical observation and may be difficult to define in an intact patient. The middle valve of Houston is a useful landmark that can often be identified endoscopically (usually about 6 cm from the anorectal ring) and can be used to differentiate proximal tumors from more distal lesions. Most tumors that can be digitally palpated are generally considered distal cancers.

Prognostic Factors

Several prognostic factors, in addition to tumor location, have been shown to have a significant impact on tumor behavior.[92] Tumor stage, as defined by the American Joint Committee on Cancer staging, clearly remains the dominant determinant of survival.[96,97] In some reports, the presence of lymphovascular invasion has been shown to have a negative impact on survival.[98,99] Histopathologic grade is of borderline significance; however, signet cell cancers have been reported to portend a particularly poor outcome.[100] Circumferential tumors or those with total or near-total obstruction (lumen, <1 cm) may respond very poorly, and tumors with deep central ulceration are associated with a high

incidence of lymph node involvement.[98,101,102] Tumor mobility remains a key factor in both choice and outcome of treatment.[103,104] Mobile cancers have a much more favorable outcome as compared to tethered or fixed cancers. Some studies report that even among mobile cancers, only 75% to 80% are completely resected with negative surgical margins.[105] Surgery for fixed cancers has proven ineffective, and these tumors are often classified as unresectable. Tumor fixation, although harder to assess in the proximal rectum, is less often encountered without other adverse factors such as circumferential disease with obstruction or perforation.[106] Tumor fixation is much more problematic in the distal rectum because the confines of the bony pelvis inhibits the surgeon's ability to achieve adequate lateral/circumferential margins. Other patient factors, such as age, gender, and ethnicity, appear to have little association with outcome but may affect choice of therapy.[107–109] As neoadjuvant therapy has emerged as the standard of care, degree of tumor regression has become an important prognostic factor.[110,111] Pathologic assessment of tumors after neoadjuvant therapy receives a special designation of ypTNM classification.

Treatment

Surgery

Surgery remains the mainstay of curative treatment for carcinoma of the rectum. Surgical management depends on the stage and location of a tumor within the rectum. Early cancers can be managed with limited surgery (i.e., local excision) in selected situations; however, the majority of tumors tend to present as more advanced disease and require either a low anterior resection (LAR) or abdominoperineal resection (APR). The general principles of a surgical approach remain the removal of all gross and microscopic disease with negative proximal, distal, and circumferential margins. In the case of radical resection, this means removal of the adjacent mesorectal tissue (total mesorectal excision [TME]), containing the regional lymphatics and potential tumor deposits. Several studies have shown that the surgeon's experience with resection of CRC is an independent variable in the outcome of treatment.[112] The Intergroup 0114 trial found that for stage II and III rectal cancers, not only were APR rates higher in hospitals performing low-volume procedures (46% vs. 32%), but more patients had positive resection margins.[113]

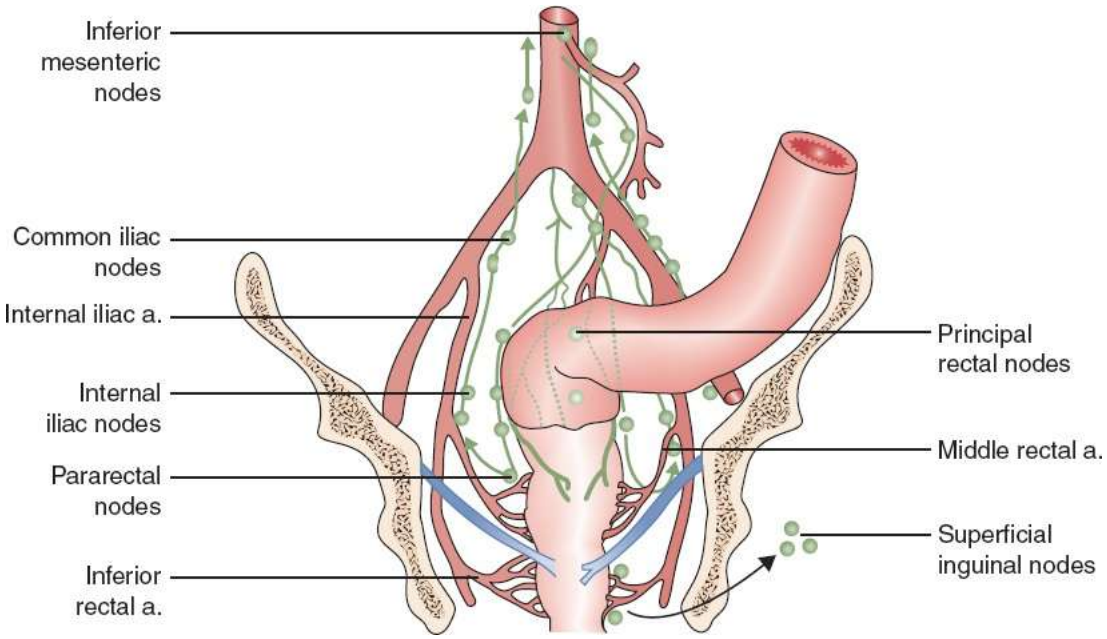

FIGURE 65.4. Lymphatics of the rectum.

Historically, the distal and proximal resection margins were considered important determinants in outcome, and a 5-cm distal margin of normal rectum was considered necessary for adequate surgical resection.[114–116] However, several retrospective studies have shown that distal intramural spread of tumor is rare beyond 1.5 cm, and, therefore, a 2-cm distal margin is generally considered acceptable, except in lesions that are poorly differentiated or widely metastatic.[117–119] The reduced requirement of 2-cm distal margin for adequate resection has led to a significant increase in the likelihood of sphincter preservation procedures in this disease.[120]

Laparoscopic surgery has emerged offering potential advantages of reduced blood loss/perioperative morbidity and shorter hospitalizations. In the hands of an experienced surgeon, outcomes from laparoscopic surgery appear no different than those from open resection in a number of randomized trials, although this remains a subject of ongoing investigation.[121–123]

Local Excision

Early rectal cancer may be resected with local excision techniques, avoiding major surgery and a colostomy, but patients should be carefully selected for these procedures. Transanal excision, transsphincteric excision (York-Mason), and a posterior parasacral approach (Kraske) permit removal of the tumor and adjoining rectum in one uninterrupted specimen. A transanal approach is usually associated with the least morbidity, but to be amenable for local excision, tumors

generally need to be located <8 cm from the anal verge. An anal sphincter–splitting approach can be used for tumors close to the anorectal junction, and occasionally a presacral Kraske approach can be used to access more proximal tumors, although this is now generally considered a historical procedure. An adequate resection requires full thickness (into the fat), with the tumor being removed in one uninterrupted specimen with at least a 1-cm margin so that careful pathologic assessment can be performed. A primary closure of the rectal defect may then be performed, although this is variable. The inability to sample perirectal and mesenteric lymph nodes can result in underestimation of cancer stage. Lymph node metastases have been observed in 5% to 10% of patients with T1 lesions and 20% to 35% of patients with T2 lesions.[124] Given the potential risk of lymph node spread, it is necessary to restrict local excision to patients with low-risk tumors where the risk of recurrence is <10% (i.e., very favorable T1 cancers). Properly selected T1 lesions have excellent results with local excision alone, with 5-year LC ranging from 82% to 97% and OS rates of 90% or better.[125,126] The risk of perirectal nodal metastasis and high incidence of reported LR rates for T2 cancers following local excision alone indicate the need for further adjuvant therapy.[127]

Radiation Therapy Oncology Group (RTOG) 89-02 examined the efficacy of local excision in a study of 65 patients with distal rectal cancers. Tumors had to be grade 1 or 2 and have margins ≥3 mm, no lymphovascular invasion (LVI), and no regional lymph node ≥2 cm by CT scan to be eligible for observation. T2 tumors with margins ≤3 mm received 59.4 to 65 Gy. Fourteen patients with T1 tumors were observed after surgery, whereas 13 patients with T1 tumors, 25 patients with T2 tumors, and 13 patients with T3 tumors received local excision with postoperative radiation of 50 to 65 Gy with 5-FU (1,000 mg/m^2 on days 1 to 3 and 29 to 31). None of the T1 tumors receiving postoperative treatment relapsed, compared to one DM and one LR in the T1 observation arm. Five patients in the T2 group relapsed (2 local, 1 distant, 2 both), and 4 patients in the T3 group had recurrence (1 distant, 3 both). Therefore, 20% of T2 and 23% of T3 tumors experienced LR after local excision plus chemoradiation (CRT).[128] Therefore, although it is possible that highly selected T2 and limited T3 tumors may be treated with local excision and postoperative adjuvant therapy, the high rate of LR makes this a potentially inferior approach.

The CALGB 8984 study provides some support for postoperative CRT after local excision for appropriately selected early stage rectal cancers.[129] Fifty-nine patients with T1 disease were treated with local excision alone, and 51 patients

with T2 disease received adjuvant therapy with 54 Gy and 5-FU (500 mg/m^2 on days 1 to 3 and 29 to 31). At 10 years, LR, DFS, and OS were 8%, 75%, and 84%, respectively, in T1 tumors. For T2 tumors LR, DFS, and OS were 18%, 64%, and 66%, respectively. Detailed information regarding salvage APR was not published in the updated study. In initial publication, one of two T1 local failures and four of five T2 local failures were salvaged by APR. Of note, 25% of the clinical T1 and T2 tumors were actually pathologic T3, highlighting the potential inaccuracy of preoperative staging.[130] The 20% recurrence rate and DFS of 64% for T2 cancers are considerably inferior to the results of radical surgery with TME alone or neoadjuvant therapy followed by surgery. This study supports the possibility of conservative sphincter-sparing surgery for well-selected T1 lesions, but for T2 tumors, the high rate of LR despite CRT warrants caution.

The American College of Surgeons Oncology Group conducted a multi-institutional, single-arm, open-label, nonrandomized, phase 2 trial of patients with clinically staged T2N0 distal rectal cancer treated with neoadjuvant chemoradiotherapy.[131] Patients with clinical T2N0 rectal adenocarcinoma staged by endorectal ultrasound or endorectal coil MRI, measuring <4 cm in greatest diameter, involving <40% of the circumference of the rectum, located within 8 cm of the anal verge, were treated with neoadjuvant chemoradiotherapy consisted of capecitabine (original dose 825 mg/m^2 twice daily on days 1 to 14 and 22 to 35), oxaliplatin (50 mg/m^2 on weeks 1, 2, 4, and 5), and radiation (5 days a week at 1·8 Gy/day for 5 weeks to a dose of 45 Gy, followed by a boost of 9 Gy, for a total dose of 54 Gy) followed by local excision. Because of adverse events during chemoradiotherapy, the dose of capecitabine was reduced to 725 mg/m^2 twice daily, 5 days/week, for 5 weeks, and the boost of radiation was reduced to 5.4 Gy, for a total dose of 50.4 Gy. Seventy-nine eligible patients were recruited to the trial and started neoadjuvant chemoradiotherapy. Two patients had no surgery and one had a TME. Four additional patients completed protocol treatment, but one had a positive margin, and three had ypT3 tumors. Thus, the per-protocol population consisted of 72 patients. Median follow-up was 56 months (IQR 46 to 63) for all patients. The estimated 3-year DFS for the intention-to-treat group was 88.2% (95% CI, 81.3 to 95.8) and for the per-protocol group was 86.9% (79.3 to 95.3). Of 79 eligible patients, 23 (29%) had grade 3 gastrointestinal adverse events, 12 (15%) had grade 3 to 4 pain, and 12 (15%) had grade 3 to 4 hematologic adverse events during chemoradiation. Of the 77 patients who had surgery, six (8%) had grade 3 pain, three (4%) had grade

3 to 4 hemorrhage, and three (4%) had gastrointestinal adverse events. Although the observed 3-year DFS was not as high as anticipated, the investigators suggested that neoadjuvant chemoradiotherapy followed by local excision might be considered as an organ-preserving alternative in carefully selected patients with clinically staged T2N0 tumors who refuse or are not candidates for transabdominal resection.

Based on the available data, local excision should generally be limited to tumors that are small (<4 cm), clinically T1 (or favorable T2 patients in selected situations), and well to moderately differentiated and involve <40% of the circumference of the rectum. These tumors are usually mobile, polypoid, and not ulcerated and have favorable pathology, including no LVI.[132–134]

Low Anterior Resection

The availability of circular stapling devices has expanded the role of sphincter preservation surgical options in rectal cancers, and LAR is now being performed not just for cancers of the upper one-third of the rectum, but also for middle and lower one-third cancers.[135] Preserving adequate anorectal function becomes increasingly difficult the more distal the level of anorectal anastomosis.[136] Patients should have good anal sphincter continence prior to considering sphincter-preserving options. Patient age, pelvic anatomy, gender, and body habitus can affect suitability for sphincter preservation. A 2-cm distal margin of preserved normal rectum is considered optimal for preservation of adequate bowel function. In carefully selected patients, a functional coloanal anastomosis can be achieved with significantly reduced margins for more distal cancers, particularly after neoadjuvant therapy. If LAR is planned following neoadjuvant radiation therapy, it is necessary to mobilize the splenic flexure to allow an unirradiated segment of the bowel to be used for the anastomosis. The latter can be performed with several techniques—an end-to-end, a side-to-end, or a colonic J-pouch technique to maximize preservation of sphincter function.[137,138] Several studies comparing results of LAR to APR generally reported similar outcomes for local and distant recurrence rates and survival as long as surgical margins are negative.[139,140] The absence of a colostomy, although offering a better quality of life with LAR, can be compromised with bowel urgency, frequency, or poor sphincter control.[141]

Abdominoperineal Resection

APR has been considered the gold standard for surgical resection of distal rectal

cancer and requires removal of the primary tumor along with a complete proctectomy, leading to a permanent colostomy. Recent data suggest a decline in the APR rate.[142] APR is associated with a slightly higher morbidity and mortality than LAR and a worse quality of life related to changes in body image and depression due to the presence of a colostomy.[140,142,143] There is also a higher risk of positive margins with APR because the mesorectum is thin in the distal segment of the rectum and margins are often restricted by the proximity of the prostate or vagina. The confines of the bony pelvis, particularly in males, can also restrict surgical access.[144]

Total Mesorectal Excision

The high LR of disease following standard APR or LAR (15% to 30% or more) has been believed by some to be due to blunt dissection that violates the planes of the mesorectal circumference.[145] Lateral spread of disease has been shown to occur not only at the level of the tumor but also distally within the mesorectum.[146] Heald et al.[147,148] recommended en bloc removal of the tumor within the envelope of the endopelvic fascia as necessary to obtain adequate lateral clearance of disease and reduced likelihood of LR. TME, as they described, has become the established standard for all radical rectal cancer resections and requires sharp dissection along the plane that separates the visceral from the parietal pelvic fascia with complete en bloc removal of the rectum so that all of the rectal mesentery remains within the envelope of the specimen.[149]

On gross pathology, an adequate TME specimen will have a bilobed, encapsulated appearance, with the surface looking smooth and unbroken, like a lipoma (Fig. 65.5). On pathologic review, an appropriate dissection should include a minimum of 12 to 15 perirectal and pelvic lymph nodes.[150–154] TME, although more difficult with APR than LAR, may be associated with a somewhat higher anastomotic leak rate, especially for low rectal lesions (15% to 17%).[105,149,155] Multiple series using TME surgery have reported low rates of LR (ranging from 5% to 10%) and an improvement in OS approaching 80% to 85% for stage II and 65% to 70% for stage III disease.[101,145,156–158]

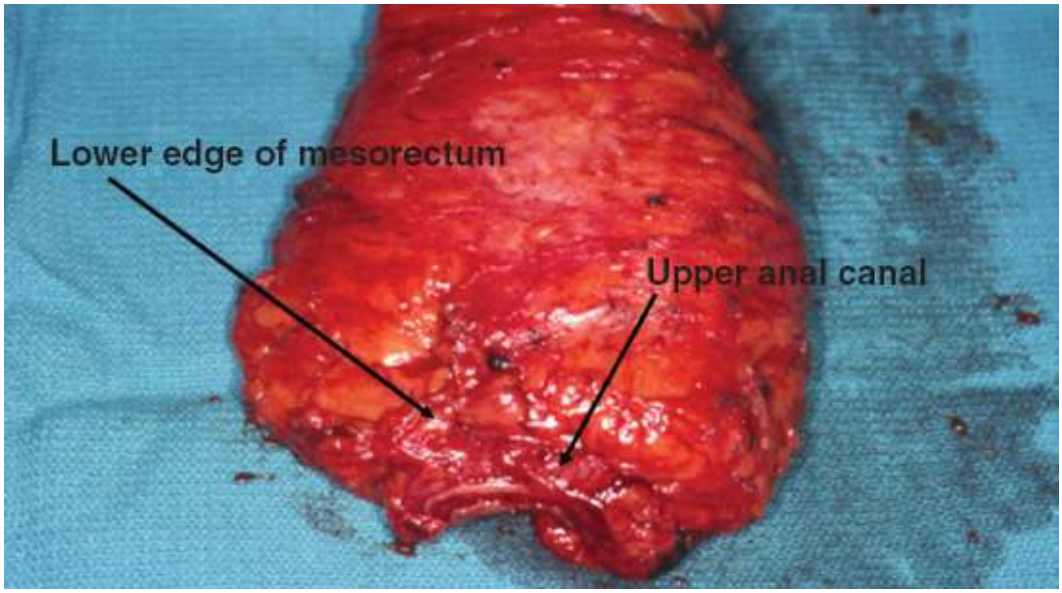

FIGURE 65.5. Total mesorectal excision specimen with designation of the lower mesorectum and upper anal canal.

Radial Margin

The National Institute of Health Consensus Conference on Rectal Cancer indicated that the principal reason for LR in resected rectal cancer appears to be related to the anatomic constraints in obtaining wide radial margins, despite adequate proximal and distal margins.[159] Using whole-mount specimens, Quirke et al. found that 27% (14 of 52) of patients showed spread to the lateral radial margin, even though the margins appeared negative with standard pathologic assessment. Eighty-six percent of those with positive radial margins developed LR of disease, as compared to only 3% without lateral resection margin involvement.[160] In addition, pathologic assessment in a large randomized trial found that the plane of surgery—mesorectal, intramesorectal, or muscularis propria plane—predicted for LR. Three-year LR was 4% in patients undergoing complete mesorectal excision, compared with 7% and 13% in the intramesorectal and muscularis propria groups, respectively.[101] A positive radial margin is a predictor not only of LR but also of inferior survival.[98] The mean surgical margin of resection has been shown to decrease with increasing stage of disease, ranging from 14 mm for T1 cancers to 3 mm for T4 cancers, with a corresponding increase in LR from 0% to 75%.[161]

Adjuvant Therapy

Postoperative

The problem of unacceptably high LR after surgery has led to many studies

exploring the potential benefit of postoperative adjuvant therapy. One of the advantages of postoperative radiation is the ability to selectively treat patients at high risk of LF on the basis of pathologic criteria. Disadvantages include a potentially hypoxic postsurgical bed, making radiation and chemotherapy less effective, and potentially higher complications due to increased small bowel in the radiation field. Postoperative treatments tend to require larger treatment volumes, particularly in patients undergoing an APR where the perineal scar may need to be covered. A number of trials assessed the role of adjuvant radiotherapy compared to surgery alone. These trials showed reduced LF with radiotherapy; however, no improvement in DFS, DM, or OS was seen.[162] Given this, the role of adjuvant CRT was evaluated in an effort to improve treatment outcomes. In general, surgery alone resulted in a 25% LF rate and 40% to 50% OS for T3 or T4 or node-positive patients, whereas CRT yielded a lower LF rate of 10% to 15% and higher OS of 50% to 60%.

The NSABP R-02 study enrolled 694 stage B and C patients and asked two questions in its study design: (a) Does the addition of radiation to chemotherapy improve outcome? (b) Are 5-FU, semustine, and vincristine superior to 5-FU/LV in men?[163] There were four treatment arms for male patients and two treatment arms for female patients. Five cycles of MOF were compared to six cycles of 5-FU/LV with or without radiation in male patients. For women, 5-FU/LV was compared against a similar regimen with radiation. The radiation dose was 50.4 Gy. At 5 years, the locoregional failure was 13% for the chemotherapy-only arm as compared to 8% with the addition of radiation to chemotherapy. 5-FU/LV demonstrated better RFS and DFS, but not OS, as compared to MOF chemotherapy. Although postoperative radiation treatment did not appear to improve OS, there was an improvement in LC.

Two trials of CRT demonstrating an improvement in OS were the Gastrointestinal Tumor Study Group (GITSG) and North Central Cancer Treatment Group (NCCTG) studies. The GITSG study was a four-arm trial of 227 patients with stage B2 and C rectal cancer who, after R0 resection, were randomized to (a) surgery alone, (b) postoperative chemotherapy of bolus 5-FU (500 mg/m^2 in weeks 1 and 5 and methyl-CCNU [semustine] given day 1), (c) postoperative radiation treatment of 40- to 48-Gy split course, or (d) postoperative CRT of 40 to 44 Gy plus bolus 5-FU.[34] The severe acute toxicity was 61% in the combined modality treatment arm, as compared to 31% with chemotherapy only and 18% with radiation only. This trial was terminated early, given the significant benefit seen with CRT. In a subsequent update,

postoperative CRT improved 10-year OS, 45% versus 27%, compared with observation after surgery.[164] There was a prolonged time to recurrence and a decreased recurrence rate of 33% versus 55% with CRT. LF rate was decreased to 10% versus 25% with surgery alone. Therefore, this trial concluded that there was a significant OS advantage (near doubling of survival) for patients who had CRT after surgical resection.

The Mayo–NCCTG study compared postoperative radiation therapy against postoperative CRT.[165] Two hundred four patients with T3/T4 or node-positive tumors received one cycle of 5-FU and semustine before randomization. The radiation dose was 45 to 50.4 Gy to tumor bed and adjacent lymph node regions. Bolus 5-FU (500 mg/m^2) was administered concurrently with radiotherapy. The 5-year locoregional failure was higher in the radiation-only arm, 25% versus 13%, and the 5-year OS was 40% versus 55% (in favor of CRT). Postoperative CRT reduced recurrence by 47%, LR by 46%, and DM by 37%. Cancer deaths were reduced by 36%, and overall deaths were reduced by 29%.

Given the potential benefits seen with CRT, subsequent trials attempted to refine the type and delivery of chemotherapy to maximize benefit with lower toxicity. The NCCTG 86-47-51 study compared chemotherapy regimens to be added to postoperative radiation therapy.[166] Six hundred sixty stage II or III patients were randomized 2 × 2 to systemic chemotherapy (5-FU vs. 5-FU + semustine) and the method of delivery (bolus vs. continuous infusion [CI] 5-FU). Nine weeks of chemotherapy were given, followed by the experimental chemotherapy concurrently with 50.4- to 54-Gy radiation therapy and additional chemotherapy thereafter. The bolus 5-FU dose was 500 mg/m^2 on day 1 to 5 during weeks 1 and 5, and the CI 5-FU was 225 mg/m^2/d. With a median follow-up of 46 months, there was a 27% improvement in RFS of 63% versus 53% in favor of CI 5-FU. The 4-year OS was 70% versus 60% in favor of CI. The time to relapse and the DM rate (31% vs. 40%) were also lower. There was no difference in LR. Bolus 5-FU had a higher rate of leukopenia, whereas CI had more acute severe diarrhea, which did not persist after conclusion of CRT. Semustine was of no additional benefit beyond 5-FU chemotherapy.[167]

The Intergroup 0114 study compared different chemotherapy regimens with radiation treatment in 1,695 patients.[168] Patients were randomized to one of four arms: (a) bolus 5-FU alone, (b) 5-FU and LV, (c) 5-FU plus levamisole, and (d) 5-FU, LV, and levamisole. Levamisole was not given during the radiation treatment. The radiation treatment dose was 45 Gy with a 5.4- to 9-Gy boost to a total of 50.4 to 54 Gy. With a median follow-up of 7.4 years, there was no

difference in OS or DFS among the four groups. Patients randomized to the three-drug regimen experienced greater toxicity. The addition of levamisole and/or LV did not appear to add any benefit to the 5-FU.

Favorable T3 N0

Several studies have shown that there may be a subset of tumors that might not need adjuvant therapy, given the low risk of recurrence with surgery alone. Memorial Sloan Kettering Cancer Center evaluated 95 patients with T3 N0 rectal cancer treated by surgery alone.[169] Seventy-nine patients underwent LAR and 16 patients underwent APR, both with sharp mesorectal excision. With 53.3-month follow-up, 6% had LR, 13% had DM, and 3% had both LR and DM. LVI was the only histologic factor that was important for LR. This study suggests that sharp mesorectal excision with LAR or APR for T3 N0 rectal cancers results in low LRs of <10% without the use of adjuvant therapy.

In a retrospective review of 117 patients with T3 N0 rectal cancer treated at MGH, perirectal tumor invasion ≥2 mm, LVI, and poorly differentiated histology were independent factors for increased risk of DM and worse RFS.[170] Only depth of invasion was significant for LC. Of the 25 patients with favorable histologic features (well differentiated/moderately differentiated, invading <2 mm into the perirectal fat, no LVI), the 10-year actuarial LC and RFS were 95% and 87%, respectively, as compared to 71% and 55% in the unfavorable group.

TA pooled analysis of five randomized, controlled trial assessed survival and relapse rates by T and N stage.[97] In patients with T3 N0 disease, 5-year survival of patients undergoing surgery and adjuvant chemotherapy alone was 84% and compared favorably to the 74% to 80% survival in patients undergoing surgery and adjuvant CRT. DFS in the T3 N0 subgroup was 69%. Since many of these trials, EUS and/or pelvic MRI has become standard in staging rectal cancers. One issue for the T3 N0 subset is the concern of understaging despite these technologies. A report from Memorial Sloan Kettering evaluated the pathologic complete response (pCR) and mesorectal lymph node involvement rate in 188 patients with either EUS or MRI staging undergoing radical resection after CRT.[171] Twenty-two percent of patients had mesorectal lymph node involvement. Although overstaging and overtreatment are possible with preoperative treatment, a larger number of patients would be understaged and require postoperative therapy. Thus, there is likely a limited subset of patients with T3 N0 rectal cancer who might have an excellent outcome with surgery alone, but there are no randomized data to support the omission of (neo)

adjuvant therapy for this group of patients at the present time.

Neoadjuvant

Neoadjuvant Radiotherapy

Although both preoperative and postoperative adjuvant therapies can be effective, neoadjuvant treatment has emerged as the standard of care. Neoadjuvant therapy is associated with tumor downstaging, improved resectability and tolerance (both acute and chronic), and potential for expanded sphincter preservation options in the distal rectum. Studies from Europe have demonstrated that appropriate neoadjuvant preoperative radiation results in improvement of both LC and OS, and these results have had a significant impact on the current management of this disease.[156,172]

The Swedish Rectal Cancer Trial included 1,168 patients accrued from 1987 to 1990 with resectable, Dukes A to C rectal cancer.[173] Patients were randomized to 25 Gy in five fractions in 1 week followed by surgery 1 week later versus surgery alone. The surgery was rated as curative if margins were negative. The 5-year LR (11% vs. 27%) and OS (58% vs. 48%) were superior with preoperative radiation treatment compared to surgery alone. The LR and OS benefit persisted with long-term follow-up. At a median of 13 years, LR was 9% versus 26% and OS was 38% versus 30%, both in favor of preoperative radiotherapy, with all stages benefiting.[172]

One caveat of this study is that the surgery-alone arm did not use TME, which may have resulted in an unacceptably high 5-year LF rate of 27%. Late effects suggested more bowel movement frequency, incontinence, urgency, and soiling in the preoperative radiation treatment arm, although overall quality of life was rated good.[174] A higher rate of small-bowel obstruction was also seen in the preoperative radiotherapy arm.[175] This trial set the standard of care in many European centers, but the dose of 5 Gy times five fractions may potentially contribute to late toxicity, and the short interval between radiation and surgery may not have allowed sufficient time for tumor regression (downstaging) for improved sphincter preservation.

Justification for a longer interval after preoperative radiation treatment before surgery was demonstrated in a French trial, Lyon 90-01, which delivered 39 Gy as 3 Gy/fraction (no preoperative chemotherapy).[176] Two hundred one patients were randomized to surgery within 2 weeks versus 6 to 8 weeks of radiotherapy. The LC and OS after a median follow-up of 33 months were the same in both arms of the study. However, the pCR was 7% versus 14% (*P* = NSS [not

statistically significant]), and the pathologic downstaging was 10% versus 26% (P = .007) in favor of the longer interval before surgery.

The TME experience by Heald et al.[147] suggested that TME alone may be sufficient for achieving low LR rates. A Dutch (CKVO 95-04) multicenter, phase III study of 1,861 patients was undertaken to evaluate the role of short-course preoperative radiation with TME. Patients were randomized to TME alone versus 25 Gy in five fractions followed by TME surgery. No fixed tumors were included in the study, and approximately half of the patients had T1 or T2 disease. The 2-year OS was 82% in both arms of the study; however, the 2-year LR was 8.2% in the TME-only arm as compared to 2.4% in the preoperative arm. This highlighted the value of radiation treatment, despite the use of TME. The sphincter preservation rate was the same in both arms, and there was no clear evidence of any downstaging effect. The perineal complication rate was slightly higher in the preoperative radiation arm of 26% versus 18% in the TME arm.[105,177] Ten-year follow-up indicates persistent benefit in LR of 5% (RT) versus 11% (TME alone).[156] Updated toxicity analysis indicates a higher incidence of sexual dysfunction and slower recovery of bowel function, more fecal incontinence, and generally poorer quality of life with short-course preoperative radiation.[178,179]

Two meta-analyses of approximately 6,000 patients each were carried out to explore the benefit of preoperative radiation treatment. One analysis included 14 randomized, controlled trials and reported that neoadjuvant radiation treatment was associated with significantly fewer LRs, improved specific survival, and an OS benefit.The second meta-analysis, provided by the Colorectal Cancer Collaborative Group, also reported on 14 randomized, controlled trials.[162] They noted a significant reduction in the risk of LR and death from rectal cancer with preoperative radiotherapy.

Neoadjuvant Chemoradiation

The improvement in outcomes with CRT in the postoperative setting led to adoption of this approach in the treatment of this disease. In the United States, neoadjuvant CRT has become widely accepted, but in other parts of the world, several groups have undertaken studies to examine the potential benefit from neoadjuvant CRT compared to radiation alone.

Preoperative radiation therapy was compared with combined preoperative CRT in a French study (Fédération Francophone de la Canérologie Digestive 9203).[180] Seven hundred thirty-three patients with resectable T3 and T4 tumors

accessible by DRE were randomized to 45 Gy of radiation alone versus radiation with concurrent bolus 5-FU (350 mg/m^2) plus LV on days 1 to 5 during weeks 1 and 5. After surgery, four cycles of adjuvant chemotherapy were given. The primary endpoint was OS. Although there was no difference in 5-year OS between the two arms, pCR rates (11.4% vs. 3.6%) were higher and LR rates (8.1% vs. 16.5%) were lower with CRT. Grade 3/4 acute toxicity was more frequent in patients receiving CRT, at 14.6% versus 2.7%.

A similar study undertaken by the European Organization for Research and Treatment of Cancer (EORTC 22921)[181] randomized >1,000 patients to four arms (2 × 2 design): 45 Gy alone versus 45 Gy plus 5-FU (350 mg/m^2) LV followed by surgery, with patients further randomized to adjuvant therapy with 5-FU/LV or no adjuvant therapy. Results of the study were similar to those of the French study, with increased tumor downstaging (14% vs. 5.3%; P = .0001) and lower rates of LR (9% vs. 17%) but no difference in 5-year OS (65% in both arms). This information suggests that although there are lower rates of recurrence, there is no conclusive evidence that combined treatment offers a survival benefit compared to radiation alone in the neoadjuvant setting. There is, however, a higher incidence of acute toxicity associated with combined CRT.

A subsequent meta-analysis pooled four trials and compared results of preoperative radiotherapy with preoperative CRT in patients with resectable stage II or III rectal cancer.[182] The addition of chemotherapy significantly increased rates of grade 3/4 acute toxicity (odds ratio [OR], 1.68 to 10) and higher rates of pCR (OR, 2.52 to 5.27) and lowered the incidence of LR (OR, 0.39 to 0.72). No difference was seen in 5-year DFS or OS. Although the aforementioned studies and meta-analysis do not show a DFS or OS benefit with the addition of chemotherapy to neoadjuvant RT, given higher pCR as well as improved LC, neoadjuvant CRT represents a reasonable standard of care.

Long-Course Neoadjuvant Chemoradiotherapy Versus Short-Course Neoadjuvant Radiotherapy

In parts of Europe where a hypofractionated preoperative radiotherapy regimen is preferred, a study to determine whether a short-course approach (5 Gy for five fractions) to neoadjuvant therapy is better than a protracted approach (50.4 Gy using 1.8- to 2-Gy fractions with concomitant bolus 5-FU/LV given during weeks 1 and 5) was undertaken by the Polish rectal cancer group.[183] Although a higher pCR rate was seen with CRT (16% vs. 1%) along with fewer positive radial margins (4% vs. 13%) and considerable size reduction of the

tumor (by ~1.9 cm), no difference in the rate of sphincter preservation, LC, or OS was seen. In a follow-up study from the Polish rectal cancer group, patients with fixed cT3 or cT4 cancer were randomized either to 5 × 5 Gy and three cycles of FOLFOX4 (group A) or to 50.4 Gy in 28 fractions combined with two 5-day cycles of bolus 5-FU 325 mg/m^2/d and LV 20 mg/m^2/d during the first and fifth week of irradiation along with five infusions of oxaliplatin 50 mg/m^2 once weekly (group B).[241] The protocol was amended in 2012 to allow oxaliplatin to be then foregone in both groups. Of 541 entered patients, 515 were eligible for analysis: 261 in group A and 254 in group B. Preoperative treatment acute toxicity was lower in group A than group B (P = .006), any toxicity being, respectively, 75% versus 83%, grade III to IV 23% versus 21%, and toxic deaths 1% versus 3%. R0 resection rates (primary endpoint) and pathologic complete response rates in groups A and B were, respectively, 77% versus 71% (P = .07) and 16% versus 12% (P = .17). The median follow-up was 35 months. At 3 years, the rates of OS and DFS in groups A and B were, respectively, 73% versus 65% (P = .046) and 53% versus 52% (P = .85) together with the cumulative incidence of local failure and distant metastases being, respectively, 22% versus 21% (P = .82) and 30% versus 27% (P = .26). Postoperative and late complication rates in groups A and group B were, respectively, 29% versus 25% (P = .18) and 20% versus 22% (P = .54). No differences were observed in local efficacy between 5 × 5 Gy with consolidation chemotherapy and long-course chemoradiation. The investigators concluded that an improved OS and lower acute toxicity favored the 5 × 5-Gy schedule with consolidation chemotherapy.[3]

In the Australian Intergroup Trial, three hundred twenty-six patients with cT3NxM0 rectal cancer within 12 cm of the anal verge were randomized to short-course RT (25 Gy in 5 fractions) with surgery within 1 week or long-course CRT (50.4 Gy in 28 fractions with continuous infusion 5-FU 225 mg/m^2) with surgery 4 to 6 weeks following completion of CRT.[184] Both regimens were followed by adjuvant 5-FU–based chemotherapy. The primary endpoint of this study was to compare LR rates at 3 years. Over 90% of patients were clinically staged with pelvic MRI or EUS. With a median follow-up of 5.9 years, there was no difference in 3-year LR (7.5% short course vs. 4.4% CRT), 5-year OS (74% short course vs. 70% CRT) or late toxicity. Despite tumor downstaging, there was no difference in rates of sphincter-sparing surgery. The optimal neoadjuvant approach for resectable rectal cancer remains far from clear. Both short-course RT (25 Gy in 5 fractions) and long-course CRT (50.4 Gy in 28 fractions) with concurrent 5-FU–based chemotherapy represent reasonable therapeutic options.

Many await long-term data from these randomized trials to assess for differences in late toxicities, which, as seen in the Swedish and Dutch experiences, can take many years to emerge.

The more recently published Stockholm III trial evaluated both fractionation and timing after radiation therapy to surgery. Patients with resectable rectal cancer were randomized to 1 of the following: (1) 5 Gy × 5 followed by surgery within 1 week, (2) 5 Gy × 5 followed by surgery after 4 to 8 weeks, and (3) 50 Gy in 25 fractions followed by surgery after 4 to 8 weeks. The primary endpoint was time to LR. Outcomes were similar between all three treatment arms. Although there was noted to be an increase in radiation-related toxicities in the short-course RT arm with delay to surgery, there was a significant decrease in postoperative complications in these patients. The authors suggest that short-course RT with delay may be an alternative to conventional short-course RT followed by immediate surgery.[185]

Alternative Chemotherapy Regimens with Neoadjuvant Radiotherapy

There is considerable variability in the administration of chemotherapy in many of the trials undertaken and those that are ongoing. 5-FU has been used concurrent with radiation because of its well-established potentiating effect with radiation. However, several studies have used bolus 5-FU, whereas others have administered LV-modulated 5-FU during the first and last weeks of radiation. The results of the Intergroup study demonstrating a superiority of low-dose continuous-infusion (CI)-FU were extrapolated to the neoadjuvant setting, and it appears to be a preferred approach to treatment.[167] New drugs, including oral fluoropyrimidines (capecitabine), oxaliplatin, and irinotecan, have been shown to be effective in the treatment of metastatic CRC. Oral fluoropyrimidines, as part of a CRT regimen, are commonly replacing infusional 5-FU. The incorporation of oxaliplatin and irinotecan into the neoadjuvant regimen has been less promising.

Capecitabine is an oral fluoropyrimidine prodrug that is readily absorbed in the gastrointestinal tract and mimics the efficacy of CI 5-FU while avoiding the risk of side effects and complications due to a central line for CI 5-FU.[186] Capecitabine requires the presence of thymidine phosphorylase (TP) for conversion to the active form of 5-FU within the cells. TP is present in higher concentration in tumor cells, particularly CRC, than in normal tissues, and this potentially creates a therapeutic advantage for capecitabine as compared to

intravenous 5-FU.[187] Capecitabine is generally given in two divided doses twice a day during the course of radiation treatment.

Two reports from randomized control trials indicate promising results for the use of capecitabine. A German trial compared capecitabine to infusional 5-FU, initially in the adjuvant setting and then later neoadjuvantly. Initially, patients in the capecitabine group were scheduled to receive two cycles of capecitabine (2,500 mg/m^2 days 1 to 14, repeated day 22), followed by chemoradiotherapy (50.4 Gy plus capecitabine 1,650 mg/m^2 days 1 to 38), and then three cycles of capecitabine. Patients in the fluorouracil group received two cycles of bolus fluorouracil (500 mg/m^2 days 1 to 5, repeated day 29), followed by chemoradiotherapy (50.4 Gy plus infusional fluorouracil 225 mg/m^2 daily), and then two cycles of bolus fluorouracil. The protocol was later amended to allow a neoadjuvant cohort in which patients in the capecitabine group received chemoradiotherapy (50.4 Gy plus capecitabine 1,650 mg/m^2 daily) followed by radical surgery and five cycles of capecitabine (2,500 mg/m^2/d for 14 days) and patients in the fluorouracil group received chemoradiotherapy (50·4 Gy plus infusional fluorouracil 1,000 mg/m^2 days 1 to 5 and 29 to 33) followed by radical surgery and four cycles of bolus fluorouracil. Five-year OS in the capecitabine group was noninferior to that in the fluorouracil group (76% [95% CI 67 to 2] vs. 67% [58 to 74]; P = .0004; post hoc test for superiority P = .05). Three-year DFS was 75% (95% CI 68 to 81) in the capecitabine group and 67% (59 to 73) in the fluorouracil group (P = .07). Similar numbers of patients had LRs in each group (6% in the capecitabine group vs. 7% in the fluorouracil group, P = .67), but fewer patients developed distant metastases in the capecitabine group (19% vs. 28%; P = .04). Diarrhea was the most common adverse event in both groups (any grade, 53% patients in the capecitabine group vs. 44% in the fluorouracil group; grade 3 to 4, 9% vs. 2%). Patients in the capecitabine group had more hand–foot skin reaction, fatigue, and proctitis than did those in the fluorouracil group, whereas leukopenia was more frequent with fluorouracil arm.[188]

A second study, the NSABP R-04, compared the efficacy of four chemotherapy regimens. More than 1,600 patients were randomized to 5-FU (225 mg/m^2, 5 days/week) or capecitabine (825 mg/m^2, twice a day, 5 days/week) with radiation therapy with subsequent randomization to ±oxaliplatin (50 mg/m^2/week ×5).[189] For patients who received 5-FU versus capecitabine, there were comparable rates of tumor downstaging, pCR, and sphincter preservation.

Several other options for neoadjuvant therapy that have been investigated include the addition of irinotecan or oxaliplatin to 5-FU–based CRT. Early data from phase I and II trials suggested that an oxaliplatin dose of 60 mg/m^2 can be combined safely with CI 5-FU and standard radiation approaches with acceptable grade 3 toxicity and promising rates of pathologic downstaging, with pCR rates of 20% to 30%.[190–193] These have not been confirmed in phase III testing, as reports from four randomized, control trials all demonstrate higher toxicity with oxaliplatin-containing regimens and no proven benefit. The STAR-01 trial randomized approximately 750 patients to CI 5-FU (225 mg/m^2/d) ± oxaliplatin (60 mg/m^2).[194] With the addition of oxaliplatin, there was no difference in pCR rate (16% in both arms), pN+ disease, or rates of positive circumferential radial margin, although higher rates of acute toxicity were seen. The ACCORD 12 study randomized approximately 600 patients with resectable T2 to T4 rectal cancer to CRT (45 Gy) with capecitabine (800 mg/m^2 twice daily) versus capecitabine and oxaliplatin (50 mg/m^2 weekly) delivered with 50-Gy radiation.[195] Similar to results of the STAR-01 trial, the addition of oxaliplatin increased grade 3+ acute toxicity (25% vs. 11%) and did not significantly improve pCR or sphincter preservation rates. A follow-up report showed that pCR (the primary endpoint) was achieved in 13.9% versus 19.2% of patients, respectively (P = .09).[196] Clinical results showed that at 3 years, there was no significant difference between the arms (cumulative incidence of LR, 6.1% vs. 4.4%; OS, 87.6% vs. 88.3%; DFS, 67.9% vs. 72.7%). Grade 3 to 4 toxicity was reported in four patients in the capecitabine-alone group and in two patients in the oxaliplatin-containing group. Bowel continence, erectile dysfunction, and social life disturbance were not different between groups. In multivariate analysis, the sterilization rate (Dworak score) of the operative specimen was the main significant prognostic factor (hazard ratio [HR], 0.32; 95% CI, 0.21 to 0.50). The authors concluded that no significant difference in clinical outcome was achieved with the intensified oxaliplatin regimen and that when compared with other recent randomized trials, these results indicate that concurrent administration of oxaliplatin and RT is not recommended.[196] The results of the NSABP R-04 trial also suggest higher rates of toxicity with minimal or no improvement in outcomes.[189] However, the German CAO/ARO/AIO-04 trial randomized patients with clinically staged T3-4 or any node-positive disease to a control group receiving standard fluorouracil-based combined modality treatment, consisting of preoperative radiotherapy of 50.4 Gy plus infusional fluorouracil (1,000 mg/m^2 days 1 to 5 and 29 to 33), followed

by surgery and four cycles of bolus fluorouracil (500 mg/m^2 days 1 to 5 and 29; fluorouracil group) versus an experimental group receiving preoperative radiotherapy of 50·4 Gy plus infusional fluorouracil (250 mg/m^2 days 1 to 14 and 22 to 35) and oxaliplatin (50 mg/m^2 days 1, 8, 22, and 29), followed by surgery and eight cycles of adjuvant chemotherapy with oxaliplatin (100 mg/m^2 days 1 and 15), LV (400 mg/m^2 days 1 and 15), and infusional fluorouracil (2,400 mg/m^2 days 1 to 2 and 15 to 16; fluorouracil plus oxaliplatin group). Of the 1,265 patients initially enrolled, 1,236 were assessable (613 in the investigational group and 623 in the control group). With a median follow-up of 50 months (IQR 38 to 61), DFS at 3 years was 75.9% (95% CI, 72.4 to 79.5) in the investigational group and 71.2% (95% CI 67.6 to 74.9) in the control group (HR, 0.79; 95% CI, 0.64 to 0.98; *P* = .03). Preoperative grade 3 to 4 toxic effects occurred in 144 (24%) of 607 patients who actually received fluorouracil and oxaliplatin during chemoradiotherapy and in 128 (20%) of 625 patients who actually received fluorouracil chemoradiotherapy. Of 445 patients who actually received adjuvant fluorouracil and LV and oxaliplatin, 158 (36%) had grade 3 to 4 toxic effects, as did 170 (36%) of 470 patients who actually received adjuvant fluorouracil. Late grade 3 to 4 adverse events in patients who received protocol-specified preoperative and postoperative treatment occurred in 112 (25%) of 445 patients in the investigational group and in 100 (21%) of 470 patients in the control group. The investigators concluded that adding oxaliplatin to fluorouracil-based neoadjuvant chemoradiotherapy and adjuvant chemotherapy (at the doses and intensities used in this trial) significantly improved DFS of patients with clinically staged cT3-4 or cN1-2 rectal cancer compared with our former fluorouracil-based combined modality regimen (based on CAO/ARO/AIO-94).[197]

The addition of irinotecan to 5-FU–based chemotherapy has also been investigated. Toxicity of irinotecan with a dose of 50 mg/m^2 weekly with CI 5-FU–based CRT is somewhat higher but appears to be tolerable and also has yielded high response rates, with pCR of 25% to 30%.[198] A number of retrospective studies suggest a benefit with the addition of irinotecan to neoadjuvant CRT.[199–201] The RTOG conducted a randomized, phase II study of neoadjuvant CRT for distal rectal cancer.[202] One hundred three patients with T3 or T4 distal rectal cancer (<9 cm from the dentate line) were randomized to CI 5-FU plus hyperfractionated radiation treatment of 55.2 to 60 Gy (1.2 Gy twice a day) versus CI 5-FU and irinotecan with conventional fractionation radiation of 50 to 54 Gy (1.8 Gy/fraction). The response rate between the two arms was

similar, with a pCR of 28%. Other groups attempted to incorporate biologic agents into the neoadjuvant regimen. Although reports of the addition of bevacizumab and cetuximab to conventional preoperative regimens appear tolerable, the benefit remains unclear, and no phase III evaluation of these agents has been performed.[203–209]

Preoperative Versus Postoperative Therapy

A number of phase III trials have compared preoperative versus postoperative CRT treatment strategies. The first trial was an RTOG 94-01/Intergroup 0417 trial that accrued 53 patients but closed early because of poor accrual. The NSABP R-03 study was scheduled to accrue 900 patients but also closed, after accruing 267 patients.[75] In this study, individuals with operable adenocarcinoma of the rectum were randomized (and stratified based on age and sex) to surgery followed by one cycle of 5-FU/LV and then concurrent bolus (weeks 1 and 5) 5-FU/LV with radiation treatment versus 5-FU/LV for one cycle and then concurrent CRT treatment followed by surgery. All patients received adjuvant 5-FU and LV for four cycles. Although the study was underpowered, 5-year DFS was superior in the preoperative therapy group: 64.7% versus 53.4%. There was a trend, although not statistically significant, of improved 5-year OS with preoperative therapy: 74.5% versus 65.6%. A pCR was seen in 15% of patients undergoing preoperative therapy.

A Korean trial randomized 240 patients with locally advanced (cT3/T4 or N+) rectal cancer to preoperative or postoperative CRT.[210] CRT consisted of 50 Gy in 25 fractions with concurrent capecitabine (1,650 mg/m^2/d). Standard surgical procedure was TME. Patients received four cycles of adjuvant chemotherapy with either capecitabine (2,500 mg/m^2/d for 14 days followed by a 1-week break) or bolus 5-FU (375 mg/m^2/d)/LV (for 5 days every 4 weeks). The 5-year DFS, OS, and LR rates were no different between the two arms. Patients with low-lying rectal tumors (<5 cm from the anal verge) had higher rates of sphincter preservation in the preoperative arm (68% vs. 42%).

The definitive phase III study in favor of preoperative radiation therapy was the CAO/ARO/AIO-94 study performed by the German Rectal Cancer Group.[211] Eight hundred twenty-three clinically staged T3/T4 or node-positive rectal cancers were randomized to preoperative CRT followed by TME 6 weeks later or TME followed by postoperative CRT. The radiation dose was 50.4 Gy in 28 fractions in all patients, with a 5.4-Gy small-volume boost in the postoperative arm. 5-FU (1 g/m^2/d) was administered during the weeks 1 and 5 of radiotherapy

as a 120-hour CI. Both arms received four additional cycles of 5-FU (500 mg/m^2/d for 5 days every 4 weeks). All surgeons were trained in the use of TME and were asked, prior to treatment, to evaluate the possibility of sphincter preservation. The 5-year results revealed a pelvic recurrence rate of 6% versus 13% (P = .02) in favor of the preoperative arm. The distant recurrence rate was 36% versus 38% (P = NSS), DFS was 68% versus 65% (P = NSS), and OS was 76% versus 74% (P = NSS) for preoperative radiation versus postoperative, respectively. There was significant tumor downstaging after preoperative CRT, with an 8% pCR. Nodal positivity was 25% in the preoperative versus 40% in the postoperative arm. The sphincter preservation rate in 188 patients with low-lying tumors (declared by the surgeon prior to randomization to require an APR) revealed that 39% versus 19% had a sphincter-preserving LAR (P = .004) in the preoperative versus the postoperative arm. There were fewer acute (27% vs. 40%) and late toxicities (14% vs. 24%) in preoperative treatment group. Thus, preoperative CRT resulted in half the LF and doubled the sphincter preservation rate compared to postoperative therapy. In addition, compliance rates were significantly improved in the preoperative arm. Of importance, there was no difference in OS or DFS between the two arms. An update, with a median follow-up of 11 years, continues to demonstrate an improvement in LC but no difference in DFS or OS with preoperative therapy.[76]

In the era of improved surgical technique, staging, and histologic assessment, the MRC CR07 trial reevaluated the role of radiotherapy.[212] A total of 1,350 patients were randomized to preoperative radiotherapy (25 Gy in five fractions) or up-front resection with selective postoperative chemoradiotherapy (45 Gy in 25 fractions with concurrent 5-FU) in patients with a ≤1-mm circumferential resection margin. At median follow-up of 4 years, the LR was significantly lower in the preoperative radiotherapy group (4.4% vs. 10.6%). Although 3-year DFS was improved in the preoperative therapy group (77.5% vs. 71.5%), there was no difference in OS. Attempts to identify patients at high risk of recurrence after resection (≤1-mm circumferential resection margin) and administration of selective CRT were inferior to up-front preoperative radiotherapy. Both the MRC CR07 and German rectal trial established preoperative therapy, either short-course (25 Gy in five fractions) or long-course chemoradiotherapy (50 Gy in 1.8-Gy fractions with concurrent 5-FU–based chemotherapy), as the current standard of care.

Locally Advanced Rectal Cancer

The definition of locally advanced rectal cancer is variable. One definition of locally advanced disease encompasses tumors that cannot be resected without high likelihood of residual gross or microscopic disease secondary to tumor fixation or adherence to adjacent structures. A preoperative therapy approach is recommended to potentially facilitate curative resections.

The superiority of preoperative CRT over radiotherapy alone was shown in a phase III, randomized control trial.[213] Two hundred seven patients with locally unresectable T4 primary rectal carcinoma or locally recurrent rectal cancer were randomized to CRT (50 Gy with 5-FU/LV) and further adjuvant systemic therapy for 16 weeks after surgery versus radiotherapy alone (50 Gy). Higher rates of R0 resections were seen in the CRT arm: 84% versus 68%. Results for LC (82% vs. 67%), time to treatment failure (63% vs. 44%), and cancer-specific survival (72% vs. 55%) all favored the CRT arm. Similarly, there was a nonsignificant trend to improved OS with CRT. As would be anticipated, patients receiving concurrent chemotherapy experienced higher grade 3/4 acute toxicity with no difference in late toxicity.

Despite preoperative CRT and complete surgical resection, LR rates in this subgroup remain high. In situations in which the margin of resection is compromised, IORT offers the possibility of improved LC. The IORT experience at MGH was reviewed by Nakfoor et al.[214] Preoperative CI 5-FU plus 50.4 to 54 Gy of radiation was given, followed by a 4- to 6-week break and surgery. No IORT was given if metastases were present at surgical exploration, if there were adequate margins >1 cm, or if there was less than T4 disease. 10 to 12.5 Gy was given for complete resection, 12.5 to 15 Gy for microscopic residual disease, and 17.5 to 20 Gy for gross residual disease. The 5-year LC was 90%, 65%, and 55%, and the disease-specific survival at 5 years was 65%, 45%, and 15%, for these three dose levels, respectively. However, the 5-year actuarial risk of complications was 15%. The risk of peripheral neuropathy was 20% for doses >15 Gy. IORT appeared to improve LC, especially with a gross total resection, but not OS for locally advanced rectal cancers.

A series from the Mayo Clinic evaluated outcomes in 146 patients with primary locally advanced CRC.[215] Patients received conventionally fractionated EBRT (45 to 50 Gy) with chemotherapy, surgery, and IORT (10 to 20 Gy). The rates of 5-year freedom from LR and DFS were 86% and 43%, respectively. Late complications occurred in 77 patients (53%) and included peripheral neuropathy (19%), bowel obstruction (14%), and ureteral obstruction (12%). In summary, IORT is a valuable tool in an effort to improve LC in situations in which the risk

of microscopic residual disease following resection remains high, albeit with potential risks for late toxicity.

Neoadjuvant Chemotherapy Only

The PROSPECT trial evaluates the efficacy of neoadjuvant chemotherapy utilizing contemporary chemotherapy regimens in hopes of permitting more selective use of RT. Patients with cT2N1, T3N0, or T3N1 disease located in the upper or middle thirds of the rectum, who are without evidence of mesorectal fascial involvement, are eligible.[216] In the experimental arm, patients receive six cycles of FOLFOX with subsequent assessment of treatment response. If the tumor has decreased in size by at least 20%, patients proceed directly to TME followed by six cycles of adjuvant FOLFOX. If the tumor has not decreased by at least 20%, patients receive neoadjuvant CRT (with 5-FU or capecitabine), TME, and then two cycles of adjuvant FOLFOX. This is being compared to standard long-course CRT (with 5-FU or capecitabine) followed by TME and eight cycles of adjuvant FOLFOX. Primary endpoints include rate of pelvic R0 resection and time to LR.

Neoadjuvant Chemotherapy and Radiation Therapy

The role of induction chemotherapy in patients with rectal cancer was examined in a phase II trial from Spain (GCR-3). Patients with clinical stage T3/4 tumors or node-positive disease with lesions in the distal or middle third of the rectum were randomized to neoadjuvant CRT followed by surgery and adjuvant CAPOX or four cycles of induction CAPOX followed by chemoradiation and then surgery. Clinical endpoints (LR, DM, DFS, and OS) were similar between the two groups at 5 years. There was improvement in compliance and lower rates of acute toxicity in patients undergoing induction chemotherapy. The authors advocated that this regimen deserves further evaluation in a phase III setting.[217]

A more recent prospective phase II trial has reported pCR rates following additional cycles of mFOLFOX6 after neoadjuvant chemoradiation and prior to surgery. All patients received CRT followed by TME 6 to 8 weeks later compared to 2, 4, or 6 cycles of mFOLFOX6 followed by TME. Increasing cycles of mFOLFOX6 improved the rate of pCR and this approach is currently being evaluated in a phase III setting.[218] However, extending the time after chemoradiation to surgery in this trial may also have contributed to improvement in pCR.

An ongoing phase II multicenter trial (NCI 13-213) evaluates 3-year DFS in

patients with locally advanced rectal cancer randomizing patients to either induction or consolidation chemotherapy (FOLFOX or CapeOX) in conjunction with neoadjuvant CRT (5-FU or capecitabine). Patients then undergo restaging with clinical exam, endoscopy, and MRI. Those with significant clinical response will be managed nonoperatively. Those with inadequate clinical response will undergo TME.[219]

Nonoperative Management

Despite the oncologic benefits of TME in patients with rectal cancer, there are potentially serious complications associated with this procedure including vascular injury, infection, wound complications, ureteral injury, and sexual dysfunction.[220–225] Long-term complications include chronic bowel dysfunction, urinary incontinence, and small-bowel obstruction.[4,5] Despite these risks, most patients with rectal cancer undergo surgery. However, there has been increasing interest in NOM, especially in patients with distal rectal cancers requiring APR, in elderly patients, or those with significant medical comorbidities. Additionally, many patients experience significant impact on their quality of life following either LAR or APR procedures. Another potential rationale for NOM management comes from the rate of pCR observed in patients undergoing neoadjuvant therapy, particularly those who undergo long-course CRT.

Investigators from the University of São Paulo School of Medicine evaluated NOM for patients with potentially resectable rectal cancer. The study included patients with T2-4 and N0-1 disease, who received neoadjuvant CRT to 50.4 Gy with concurrent 5-FU. Patients were reevaluated 8 weeks postoperatively. Response was assessed radiographically and pathologically via endoscopic biopsies. Patients with an incomplete response were sent immediately for resection. Those with cCR were followed closely with monthly physical exams, frequent proctoscopy with biopsies of any suspicious areas, serial CEA monitoring, and abdominopelvic CT scans every 6 months for the first year. Patients without evidence of disease for 1 year were considered to have a cCR.[226] Updated results have also been published with a larger cohort of patients.[227] The most recent report indicates that 31% of patients with an initial cCR went on to develop a LR, the majority of which occurred in the first 12 months. Only 7% of these patients were not amenable to salvage surgery. Five-year cause-specific OS and DFS were 91% and 68%, respectively, with 14% of patients failing distantly.[228]

In a retrospective analysis, Lim and colleagues reported on the outcomes of medically inoperable patients or patients refusing surgery treated with chemoradiation or radiation therapy only from six Australian centers. The majority of patients had distal T3 lesions and underwent CRT. Patients were followed clinically. Those patients who achieved a cCR had significantly longer PFS.[229]

Maas and colleagues attempted to build upon the results of the São Paulo group by employing modern MRI staging techniques. In this study, there was a noticeably lower rate of cCR, likely the result of the strict imaging criteria that was used.[230] Memorial Sloan Kettering investigators compared the outcomes of 32 patients who had a cCR with NOM to a comparable group who had achieved a pCR with surgical resection. The LR rate for patients undergoing NOM was 21% versus 0% in the pCR group after 28 months; however, all patients that failed locally were successfully salvaged with surgery. The clinical outcomes were otherwise similar between the groups.[231] This series has since been updated with OS and DFS remaining similar between the NOM and pCR groups.[232]

More recently, a prospective trial from Denmark evaluated patients with resectable T2-3 primaries and N0-1 disease who were treated with high-dose radiation to 60 Gy in 30 fractions with a 5-Gy endorectal brachytherapy[240] boost and oral tegafur–uracil. Response was assessed via endoscopy and MRI/CT. If patients achieved a cCR, they were followed closely with exams, endoscopy, and PET scans. Only 26% of patients had LR failure by 2 years and all patients were surgically salvaged.[233]

Radiotherapy Treatment Technique

External beam treatment fields for rectal carcinoma should encompass potential sites at greatest risk for harboring disease, including the presacral space, primary tumor site, and (for post-APR cases) the perineum. Other areas at risk include the internal iliac and distal common iliac nodes. Generally, the risk of disease involvement of the para-aortic region is sufficiently low, and the morbidity from treatment is sufficiently high, to exclude this region from radiation fields. The external iliac nodes may be covered for lesions involving the anterior structures, including the bladder, prostate, and vagina.

In general, patients with rectal carcinoma should be treated in the prone position to reduce the volume of small bowel within the pelvis. Maneuvers to reduce the volume of small bowel include treatment with a full bladder and the use of bowel displacement techniques such as a bellyboard (a device with a false

tabletop to allow the upper abdominal contents to fall anteriorly).[234] The use of shaped lateral fields reduces the dose to small bowel located in the anterior and superior aspects of the pelvis. A marker is generally placed at the anal verge, and intravenous, rectal, and small-bowel contrast is often administered at the time of simulation for accurate target and normal tissue delineation.

Generally, a four-field (anteroposterior/posteroanterior [AP/PA]/right/left [R/L] lateral) or three-field (PA/R/L lateral) technique is used. The superior field edge is placed at the L5/S1 interspace. The distal field edge depends on tumor location and should be roughly 3 to 5 cm below palpable tumor for patients receiving preoperative treatment. For postoperative cases, the distal field edge is about 5 cm below the best estimate of the preoperative tumor bed and (if an APR has been performed) below the perineum. AP/PA fields should have at least a 1.5-cm margin on the pelvic brim.

On lateral treatment fields, the superior and inferior borders remain the same as for AP/PA fields. Lateral fields should encompass the entire sacrum posteriorly to ensure adequate coverage of the presacral space. The anterior margin should be roughly 4 cm anterior to the rectum (ensuring adequate coverage of the mesorectum). If the tumor has considerable extrarectal extension, these guidelines should be modified to make certain that all disease is encompassed with appropriate margin.

The usual dose given to initial pelvic fields is 45 Gy in 25 fractions of 1.8 Gy each. An additional tumor boost may be administered, usually through opposed lateral fields, to an additional 5.4 to 9 Gy. Small bowel should be excluded from the boost volume after about 50 Gy in an effort to minimize acute and late toxicity (Fig. 65.6).

Management of Recurrent Rectal Cancer

Recurrent rectal cancer is often approached in the same way as T4 disease, often with an aggressive treatment plan of CRT, surgery, and adjuvant chemotherapy. At the time of surgery, IORT may be considered. Up to 10% of patients with T1 and T2 N0 disease will fail locally after surgery, usually because of an inadequate lymph node/mesorectal dissection. Recurrences may occur along the pelvic sidewall or in nonpelvic sidewall areas such as the uterus, prostate, or vagina. The 5-year OS is approximately 20% for all cases. LC is roughly 40% in patients with no prior radiation and 10% to 20% in patients with prior radiotherapy.[235] Given the difficulty of surgical resection of pelvic sidewall recurrences, these tend to fare worse.

In patients with no prior history of radiation, neoadjuvant CRT followed by surgical resection is a reasonable treatment approach. In one series, 123 patients with locally recurrent CRC received a course of EBRT (45 to 54 Gy) either before or after surgical resection and IORT.[87,88] Five-year OS in patients undergoing gross total resection was 24%, compared to 18% in patients with gross residual disease. A second series using a similar treatment approach of neoadjuvant therapy, surgical resection, and IORT achieved 5-year LC and OS rates of 54% and 32%, respectively. The 5-year LC and OS rates in patients undergoing radical resection were 69% and 42%, respectively. A series of 35 patients with recurrent rectal cancer not amenable to up-front surgical resection was treated with a course of preoperative CRT (50.4 to 59.4 Gy with 5-FU chemotherapy).[236] Eighty percent underwent curative resection, and 60% achieved negative surgical margins. Three-year OS rate in patients with complete resection was 82%.

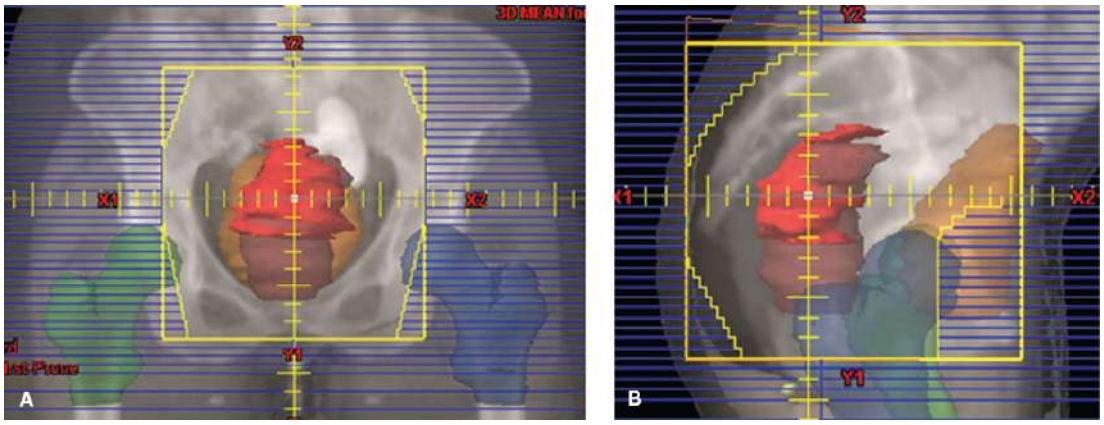

FIGURE 65.6. A: Posteroanterior treatment field of patient with T3 N1 rectal cancer. **B:** Lateral treatment field of a patient with T3 N1 rectal cancer. *Red*, gross tumor volume; *brown*, rectum; *orange*, bladder; *green/blue*, femoral heads.

One randomized control trial compared outcomes of preoperative CRT or radiotherapy alone prior to surgical resection in patients with locally advanced or recurrent rectal cancer who had not received prior radiotherapy.[213] This series included 25 patients with recurrent disease. Higher rates of R0 resection, LC, time to treatment failure, and cancer-specific survival were seen in the chemoradiation arm (see section Locally Advanced Rectal Cancer). Five-year OS rate in patients with recurrent rectal cancer was 37%.

In patients with prior history of radiation, reirradiation is possible in carefully selected situations. Forty-seven patients in an Italian retrospective study were treated with preoperative CRT.[237] Patients who did not have prior radiation

treatment received 45 Gy with CI 5-FU and mitomycin C, followed by surgery and IORT of 10 to 15 Gy. LV and 5-FU were given for six to nine cycles adjuvantly. If patients had prior radiation treatment, they received 23.4 Gy. The 5-year OS rate was 20% for all patients, 60% for resected tumors, 0% for unresected tumors, and 40% for patients treated by external beam, surgery, and IORT. The 5-year LC rate was 30% for all patients, 70% for completely resected tumors, 0% for unresectable tumors, and 80% for EBRT, surgery, and IORT. Eighty-five percent of patients had palliation of pain, with an average duration of 12 months.

Another retrospective series included 147 patients with locally recurrent rectal cancer, with the majority (127 patients) undergoing preoperative CRT.[86] Fifty-seven had received prior radiation and were reirradiated to a dose of 30.6 Gy. Preoperative treatment was followed by surgical resection and IORT. Five-year OS for the entire group was 32% and was 48% in patients with an R0 resection. Radical resection correlated significantly with improved OS, DFS, and LC rates. There was no difference in late toxicity in patients who received reirradiation.

Long-term results of reirradiation for patients with recurrent rectal carcinoma were also reported by Mohiuddin et al.[238] One hundred three patients who developed LR after surgery with preoperative or postoperative radiation treatment (median dose, 50.4 Gy) were reirradiated with concurrent CI 5-FU. Patients were treated with opposed laterals or three-field technique (PA/L lateral/R lateral) to the presacral area and gross tumor volume with 2- to 4-cm margin. Patients received 30 Gy (1.2 Gy twice a day) or 30.6 Gy (1.8 Gy every day), followed by a boost of 6 to 20 Gy to gross tumor volume (2-cm margin). Forty-one patients were surgically explored after treatment and 34 underwent resection, with 6 patients undergoing sphincter-sparing surgery. With a median follow-up of 2 years, the 5-year OS rate was 19%. Patients who underwent resection had a higher survival rate, with tolerable acute and late toxicity. Twenty-two patients experienced late toxicity, including severe, persistent diarrhea (18 patients), small-bowel obstruction (15 patients), fistula formation (4 patients), and stricture (2 patients). Palliation of bleeding was achieved in 100% of patients.

Hyperfractionated radiotherapy may be an alternative in an effort to reduce late toxicity. A retrospective series from MD Anderson Cancer Center evaluated reirradiation outcomes in 50 patients with prior history of pelvic radiotherapy.[239] Patients were treated in 1.5-Gy fractions twice daily to a total dose of 30 to 39

Gy (depending on the time interval between radiotherapy treatment courses). Concurrent chemotherapy was administered to the majority of patients. The 3-year freedom rate from local progression and OS rate in the entire cohort were 33% and 39%, respectively. Three-year OS rate was 66% in patients undergoing surgery, and the 3-year rate of grade 3/4 late toxicity was 35%.

Patients with recurrent rectal cancer and no prior history of EBRT are generally treated with a course of concurrent, preoperative CRT (50 to 54 Gy with 5-FU–based chemotherapy) followed by surgical resection (and consideration of IORT). Patients with prior history of radiotherapy may receive reirradiation to doses of 30 to 39 Gy but have the potential to experience significant late toxicity; therefore, efforts should be made to avoid small bowel within treatment fields (Fig. 65.7).

CHAPTER 66

Anal Cancer

James D. Murphy

INTRODUCTION

The standard treatment for primary squamous cell cancers of the anal canal is chemoradiation, using concurrent radiation therapy (RT), 5-fluorouracil (5-FU), and mitomycin C (MMC), with surgery reserved for residual cancer. This combination, developed empirically as preoperative adjuvant therapy in the 1970s,[1] has evolved to become the standard of care. Trials of other chemotherapy agents in combination with radiation have so far not improved results. Currently, about 65% of those with cancer confined to the pelvis will survive 5 years or more and about 75% will retain anorectal function.

In this chapter, the emphasis is on the management of squamous cell cancer of the anal canal. Note is also made of the role of RT in the treatment of squamous cell cancers of the perianal skin and of adenocarcinomas of the anal region.

ANATOMY

The anal canal is 3 to 4 cm in length, the posterior wall being longer than the anterior. The canal ends superiorly at the palpable upper border of the anal sphincter and puborectalis muscle of the anorectal ring. The distal end at the anal verge is the level at which the walls of the anal canal come in contact in their normal resting state; it approximates the palpable groove between the lower edge of the internal sphincter and the subcutaneous part of the external sphincter and the junction with true skin. The American Joint Committee on Cancer Clinical Staging (AJCC)[2] and the International Union Against Cancer (UICC)[3] recommend this definition rather than a convention used by some centers under which carcinomas that are above or exactly astride the dentate line are classified as anal canal tumors and those lying mainly or entirely below that line are called

anal margin tumors (Fig. 66.1). The terms *anal margin* and *perianal skin* are now generally used interchangeably. Perianal carcinomas are arbitrarily considered to be cancers arising from the skin within a 5-cm radius of the anal verge.

Four different types of epithelium are found within the anal region.[4] The perianal skin is similar to hair-bearing skin elsewhere. At the anal verge, the skin blends with a pale-colored zone, sometimes called the pecten, lined by modified squamous epithelium that lacks hair or glandular structures. This squamous zone merges just below the dentate or pectinate line, which marks the mucosal folds of the anal valves, with a transitional epithelium that incorporates features of rectal, urothelial, and squamous epithelium. The purplish red–colored transitional zone extends proximally for about 2 cm until the pinker glandular mucosa of the rectum becomes dominant.

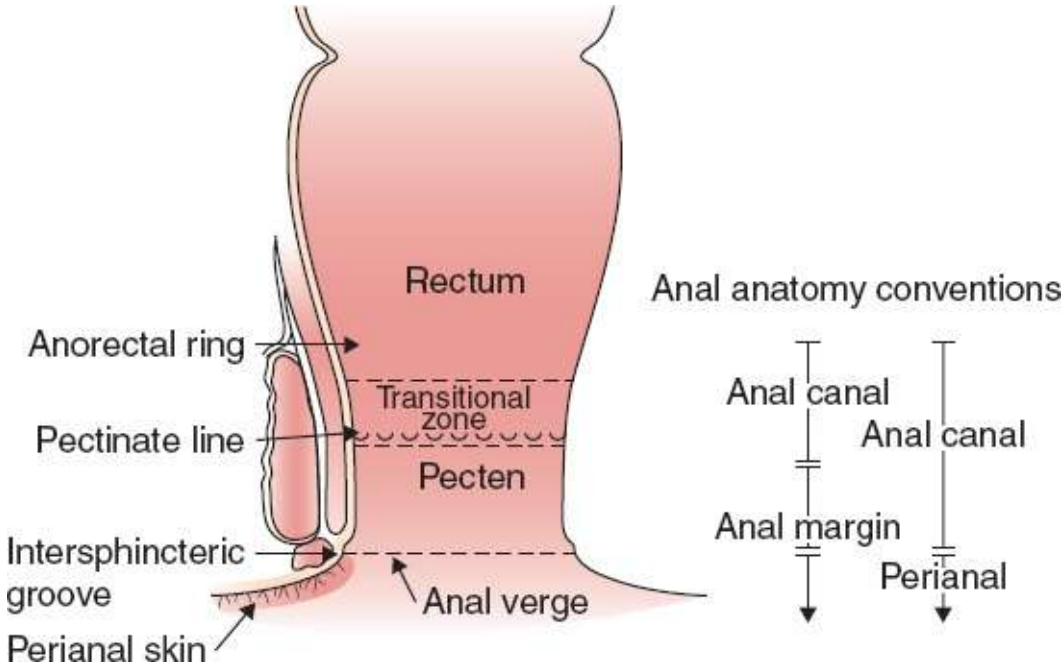

FIGURE 66.1. Anatomy of the anal region.

The major lymphatic pathways flow to three lymph node systems. The perianal skin, the anal verge, and the canal distal to the dentate line drain predominantly to the superficial inguinal nodes, with some communication to the femoral nodes and to the external iliac systems. Lymphatics from around and above the dentate line flow with those from the distal rectum to the internal pudendal, hypogastric, and obturator nodes of the internal iliac systems. The proximal canal drains to the perirectal and superior hemorrhoidal nodes of the

inferior mesenteric system. There are numerous lymphatic connections between the various levels of the anal canal, and an intramural system links the lymphatics of the canal with those of the rectum.[5]

The veins of the anal canal connect with both the systemic and the portal venous systems. Venous plexuses, which lie in and surround the mucosal and muscular structures of the anal wall, anastomose around the junction of the anal verge and distal canal. The veins draining the inferior parts of these plexuses communicate with the systemic venous system via the internal pudendal and internal iliac veins, and those from the superior canal flow predominately to the inferior mesenteric vein and then to the portal system.[5]

Anorectal continence is mediated by both cerebrospinal nerves and the autonomic system. The smooth muscle of the internal sphincter is supplied by parasympathetic fibers from the second, third, and fourth sacral segments as well as sympathetic fibers from the hypogastric plexus. The upper canal has selective sensitivity for intraluminal differences in pressure, and the autonomic nerves mediate both the inhibitor and facilitator reflexes of the internal sphincter. The striated muscle of the external sphincter is under voluntary control and innervated by the internal rectal nerve, a branch of the pudendal nerve arising from the second, third, and fourth sacral nerves. The internal rectal nerve also transmits pain, touch, and other sensations from the anal lining below the dentate line and from the perianal skin.[5]

PATHOLOGIC CLASSIFICATION

The most recent revision of the World Health Organization (WHO) classification of anal tumors, published in 2010, describes intraepithelial and invasive neoplasms.[6] The term *anal intraepithelial neoplasia* (AIN) is applied to precancerous changes in the epithelium of the anal canal and perianal skin.[7]

For invasive cancers, the term *squamous cell carcinoma* is applied to all the various subtypes: squamous; large-cell keratinizing and nonkeratinizing; and basaloid, cloacogenic, and transitional, all of which were considered separate entities in the previous classification.[6] Clinicians have for some years grouped these various subtypes as epidermoid cancers because of their similar natural history; the term epidermoid is not used in the WHO classification. About 85% to 90% of primary anal canal cancers are squamous cell type. The remaining 10% to 15% are predominantly adenocarcinomas, most of which arise from anal glands or within anal fistulae. Adenocarcinomas from the rectal-type mucosa in

the upper canal are classified as primary rectal cancers. The WHO system retains as separate entities rare variants such as squamous cell carcinoma with mucous microcysts, small cell, and undifferentiated cancers.

Primary cancers of the perianal skin are similar to cancers of the skin in other sites. Most are squamous cell cancers, with occasional basal cell cancers and skin adnexal adenocarcinomas.

EPIDEMIOLOGY

Anal cancers are about one-tenth as common as cancers of the rectum. Cancers arise in the canal with three to four times the frequency of perianal cancers. In North America and Europe, anal canal cancers are more common in women than in men, although this difference is decreasing[8]; perianal cancers occur with about equal frequency in both sexes. The annual age-adjusted rates per 100,000 for squamous cell cancers of the anus, anal canal, and anorectum in the U.S. Surveillance, Epidemiology, and End Results (SEER) registry for 2010 to 2014 were 1.5 for males and 2.1 for females.[8] The incidence varies widely in different parts of the world but has been increasing in North America and Europe over the past 40 years.[8] The annual incidence of invasive and intraepithelial neoplasia almost doubled in men and rose by about half in women between the periods 1973 to 1979 and 1994 to 2000.[9] The risk of anal cancer increases with age; the median age at diagnosis is 61 years.

RISK FACTORS

The most significant risk factors so far identified are sexually transmissible viruses, immunosuppression, and tobacco smoking. The role of sexual practices and sexually transmissible agents has been investigated intensively. Several mucosotropic types of human papillomavirus (HPV) are linked to cancer and precancerous lesions in the anogenital epithelium.[10–12] Subtypes of HPV with a high risk of association with cancer are type 16 in particular and, to a lesser extent, types 18, 31, 33, 35, and others.[10–12] These high-risk HPV types have been found in about 85% of anal squamous cancers in many series,[10,11] more commonly in cancer of the canal than of the perianal skin.[11,13] Some geographic variation was noted in the types of high-risk HPV identified.[11,14] Case–control studies suggest that a history of multiple sexual partners in homosexual or heterosexual relationships or of unprotected anal intercourse in males and in

females is predictive of an increased risk of AIN and invasive anal cancer.[15] Compared to the overall annual incidence of anal cancer in white males in the United States of approximately 0.7 per 100,000 in the early 1980s, the estimated incidence in the male homosexual population, prior to the human immunodeficiency virus (HIV) epidemic, ranged from about 12 to 37 per 100,000.[16] This rate increased to about 70 per 100,000 among HIV-positive male homosexuals.[17]

Compromise of cell-mediated immunity reduces the body's ability to prevent or eliminate infection by viruses such as HPV. An increased risk of anal cancer is associated with at least two situations in which cell-mediated immunity is significantly altered: infection with HIV and iatrogenic suppression of immunity in organ transplant patients. Interactions between HPV and HIV are complex. Although anal cancer has not been designated an acquired immunodeficiency syndrome (AIDS)-defining condition, data from the U.S. AIDS Cancer Registry linkage study showed that the rate of HPV-associated cancers and precursors was increased in HIV-infected persons for all anogenital sites compared with the general population. The relative risk for anal cancers was 6.8 in women and 37.9 in men.[18] A national cohort study in Sweden of 5,931 patients who had undergone organ transplantation showed a 10-fold excess risk of developing anal cancer.[19] Whatever the cause of suppression of cell-mediated immunity, those affected have increased rates of HPV infection, higher progression rates from normal epithelium to AIN and from lower- to higher-grade AIN, and lower rates of clearance of HPV and regression from abnormal to normal epithelium.[20,21]

The increasing effectiveness of antiretroviral therapy has led to longer survival of HIV-infected patients and an increased number with anal cancer.[22,23] There was a threefold increase in incidence in the HIV-positive population from the period prior to the introduction of highly active antiretroviral therapy (HAART) in about 1996 and the later HAART era.[23] Although there was a decrease in the incidence of Kaposi sarcoma and lymphoma by a few years after HAART became available, at the time of the review, there had been no significant reduction in the incidence of less common malignancies such as anogenital cancers.[24] Early success of prophylactic vaccines against HPV in both men and women suggests that the incidence of anal cancer can be reduced in the future.[25,26]

Tobacco smoking is associated with up to a fourfold increase in risk in several case–control studies. Current smokers are at greater risk than are past smokers.[15,27] Benign conditions such as fistulae, fissures, and hemorrhoids do

not appear to predispose to cancer.[28] Chronic anal inflammation due to inflammatory bowel disease has also been discounted as a risk factor.[29]

NATURAL HISTORY

Most squamous cell cancers of the anal region, especially the canal, are believed to be preceded by high-grade AIN.[7] However, it has been estimated that no more than 1% of cases with AIN develop invasive cancer per year,[30] a rate lower than that described for cervical intraepithelial neoplasia. Anal dysplasia recurs frequently despite excision, laser ablation, or topical therapies, presumably because of incomplete treatment or persistence of the HPV infection with which dysplasia is associated.[22] The natural history of AIN coexisting with anal cancers exposed to radiation, with or without chemotherapy, is unknown.

Squamous cancers of the anal canal spread most commonly by direct extension and lymphatic pathways. Hematogenous metastases are less common. Direct invasion from the anal mucosa into the sphincter muscles and perianal connective tissue spaces occurs early; in a series of 137 cases, cancers were confined to the mucosa and submucosa at diagnosis in only 12%, and to the sphincter muscles, without regional lymph node involvement, in only 34%.[31] In about half the cases, anal cancers extend into the rectum or perianal skin. Invasion of the vaginal septum and vaginal mucosa is more common than invasion of the prostate gland, but anovaginal fistulas occur in fewer than 5% of women. Extensive tumors may infiltrate the pelvic walls.

Lymphatic invasion occurs relatively early. The overall risk of regional nodal involvement at diagnosis is about 25%.[32,33] Pelvic lymph node metastases were found in as many as 30% of patients treated by abdominoperineal resection.[31,34,35] In an illustrative series, metastases were present in the superior hemorrhoidal nodes in 25% (15 of 61); in the external iliac, obturator, or hypogastric nodes in 30% (8 of 27); and in the inguinal nodes in 16% (12 of 74) of patients.[35] Inguinal metastases were detected clinically in up to approximately 20% of patients at initial diagnosis and were present subclinically in a further 10% to 20%.[31,35–37] Nodal metastases were associated with 30% of cancers confined to the sphincter muscles, and 60% of those that had extended through the sphincters or were more poorly differentiated.[34] Lymphatic metastases increase in frequency with progressive enlargement of the primary cancer.[34,38]

Extrapelvic metastases are identified at the time of first presentation in <10% of patients. They are found most frequently in the liver, lungs, and para-aortic

nodes. Relapse after initial treatment is more common in the area of the primary tumor and the pelvic lymph nodes than in extrapelvic organs. Locoregional relapse rates of up to about 30% are common. Failure outside the pelvis occurs in up to about 20%.[31,39–41]

Perianal cancers tend to grow locally and may extend into the anal canal. When the site of origin is in doubt, it is conventional to classify the cancer as arising in the anal canal. The ipsilateral inguinal nodes are the most common site of metastasis and are involved in from 5% to 20% of cases. Extrapelvic metastases are uncommon except in locally advanced cancer or those with nodal metastases.

CLINICAL PRESENTATION

The symptoms of anal cancer are nonspecific, contributing to delay in presentation by the patient and in diagnosis by the physician of more than 6 months in a third of patients.[42,43] Bleeding and anal discomfort are the most common symptoms and are reported by about half the patients.[44] Less common complaints include awareness of an anal mass, pruritus, and anal discharge. Pain is uncommon but may be severe. In patients with tumors in the proximal canal, there may be an alteration in bowel habits, but this is uncommon with distal cancers.[44] Occasionally, asymptomatic tumors are found during physical examination or in the course of investigation of an enlarged inguinal node. Unsuspected microinvasive carcinoma is sometimes found in mucosa removed at hemorrhoidectomy.[45]

Small carcinomas are often nodular or plaque-like, but larger tumors are more typically ulcerated and infiltrative. Coexisting benign conditions such as anogenital warts, hemorrhoids, and anal fissures may be present. Anal sphincter tone is usually preserved and may be increased by painful spasm. Gross fecal incontinence resulting from sphincter destruction occurs in <5% of patients, although some fecal soiling is often reported. Similarly, vaginal fistulas are uncommon. Rarely, extrapelvic metastases may be the only symptomatic feature or finding.

DIAGNOSTIC WORKUP

The history and physical examination should stress features that delineate the extent of the primary tumor, including anal sphincter competence and possible

invasion of adjacent organs. A biopsy of the primary tumor is necessary to establish the diagnosis and the histologic type. General anesthesia may be needed to permit detailed pelvic and anorectal examination, which should include proctoscopy. Sigmoidoscopy and colonoscopy, although often performed, infrequently disclose colonic pathology.[46] Physical examination should include detailed examination of the genital region, especially in patients who give a history of previous anogenital area dysplasia or cancer, genital warts, or anal-receptive intercourse or are HIV positive.

Only the inguinal and low perirectal lymph nodes are accessible to clinical examination. Because lymph node enlargement may be caused by reactive hyperplasia in as many as half of those with palpable inguinal nodes, clinically suspicious nodes should be assessed histologically by needle biopsy or simple excision.[44] Metastases in the internal iliac and superior hemorrhoidal node chains, about half of which are <0.5 cm in diameter,[47] cannot be identified reliably by current techniques of lymphangiography, pelvic lymphoscintigraphy, computed tomography (CT), magnetic resonance imaging (MRI), or transanorectal ultrasonography. MRI is considered the most accurate method for assessing the primary cancer and pelvic nodes.[48] Both fluorodeoxyglucose (FDG) positron emission tomography (PET) with CT and inguinal sentinel lymph node biopsy (ISLN) have been used to identify inguinal node metastases and to refine RT plans.[49–51] However, a comparison of FDG-PET-CT and ISLN biopsy in 27 patients found several false-positive PET studies (4 of 7).[52] Also, late inguinal node metastases have been reported after a previous negative ISLN biopsy.[53] A meta-analysis of twelve studies found that FDG-PET resulted in a change in nodal staging in 28% of anal cancer patients. Guidelines from the National Comprehensive Cancer Network recommend considering a PET-CT for radiation planning as part of the workup for anal cancer patients.

Thoracic, abdominal, and pelvic CT and pelvic MRI identify liver or lung metastases or enlarged nodes. If the diagnosis is uncertain, image-guided biopsy should be considered. Skeletal studies are not indicated in the absence of focal symptoms.

Examination of blood and serum should include full blood count, renal and liver function tests, and, if any risk factors are present, assessment of HIV antibody status.

STAGING

The staging systems for anal canal and perianal cancers most commonly used are those proposed by the UICC[3] and the AJCC[2] (Tables 66.1 and 66.2). Most authors continue to report results by T (tumor) category or N (node) category rather than by composite TNM (tumor, node, metastasis) stages. Under the UICC and AJCC systems, the regional lymph nodes for anal canal cancer are the perirectal, internal iliac, and inguinal nodes. Spread to all other pelvic node groups, including the external iliac, common iliac, and sigmoid nodes, is classified as metastasis (M1). For perianal cancers, the only regional nodes are the ipsilateral inguinal nodes. The 8th edition of the AJCC staging manual for anal cancer includes changes to nodal classification and stage groupings.

In a review of 19,199 patients with squamous cell carcinoma of the anal canal, diagnosed between 1985 and 2000 and recorded in the U.S. National Cancer Database (NCDB), the stage distribution per AJCC 7th edition was stage I, 25.3%; II, 51.8%; III, 17.1%; and IV, 5.7%. Tumors were >5 cm in size (T3) in at least 20.6% (tumor size in T4 category not available). Nodal involvement was present in 21.8% of those for whom information on nodal status was recorded.[33]

TABLE 66.1 ANAL CANAL TNM CLASSIFICATION—8TH EDITION

Primary Tumor (T)

Tis	High-grade squamous intraepithelial lesion
T1	Tumor 2 cm or less in greatest dimension
T2	Tumor more than 2 cm but not more than 5 cm in greatest dimension
T3	Tumor more than 5 cm in greatest dimension
T4	Tumor of any size invades adjacent organ(s) (e.g., vagina, urethra, bladder) (invasion of the rectal wall, perirectal skin, subcutaneous tissue, or sphincter muscle is not included as T4).

Regional Lymph Nodes (N)

N0	No regional lymph node metastases
N1a	Inguinal, mesorectal, or internal iliac lymph nodes
N1b	External iliac nodes
N1c	External iliac nodes *plus* any node in the N1a group

Distant Metastases (M)

M0	No distant metastasis
M1	Distant metastasis

Stage Grouping

Stage 0	Tis	N0	M0
Stage I	T1	N0	M0
Stage II	T2	N0	M0

	T3	N0	M0
Stage IIIA	T1	N1	M0
	T2	N1	M0
Stage IIIB	T4	N0	M0
Stage IIIC	T3	N1	M0
	T4	N1	M0
Stage IV	Any T	Any N	M1

PROGNOSTIC FACTORS

Tumor Factors

Features related to the anatomic extent of disease generally provide the most prognostic value.[54] The most adverse factor for survival is the presence of extrapelvic metastasis.[55–57] When anal cancer is confined to the pelvis, the size of the primary tumor is the most useful predictor for local control and preservation of anorectal function and survival.[39,58,59] Involvement of regional lymph nodes is an adverse factor for survival but, in most series, not for control of the primary tumor.[39,59]

Among the 19,199 patients recorded in the NCDB between 1985 and 2000, the overall 5-year survival was 58%.[33] Patients with distant metastases had a 5-year survival of 18.7% versus 59.4% for those without metastases. Patients with regional node metastases had a 5-year survival of 37.4% versus 62.9% in node-negative patients. Five-year survival rates by T category were T1, 68.5%; T2, 58.9%; T3, 43.1%; and T4, 34.3%. The survival rates by AJCC stage are shown in Figure 66.2.

From Ajani JA, Winter KA, Gunderson LL, et al. US Intergroup Anal Carcinoma Trial: tumor diameter predicts for colostomy. *J Clin Oncol* 2009;27:1116–1121; Ajani JA, Winter KA, Gunderson LL, et al. Prognostic factors derived from a prospective database dictate clinical biology of anal cancer. The Intergroup Trial (RTOG 98–11). *Cancer* 2010;116:4007–4013.

In detailed analyses of data collected prospectively for Radiation Therapy Oncology Group trial RTOG-9811,[59,60] tumor diameter >5 cm correlated with an increased likelihood of colostomy (hazard ratio [HR] 1.8; P = .008)[59] (Table 66.3). A tumor size >5 cm and clinically positive nodes were each associated with significantly poorer 5-year disease-free and overall survival.[60] These findings were combined into prognostic groups.[60] These groups are shown in Figure 66.3, with additional data drawn from the analyses by Ajani et al.[59,60] These groupings have not been verified prospectively.

Patient Factors

Patient-related factors are not consistent between series. Age, performance status, gender, baseline hemoglobin level, and race have all been considered prognostic in one or more series. Patients who continue to smoke tobacco may be at greater risk of local relapse.[61] In some series of HIV-positive patients, high viral load, low lymphocyte CD4-positive counts, and AIDS have been

prognostic of poor local tumor control and survival and, in some series, of impaired tolerance of RT and chemotherapy.[62–64]

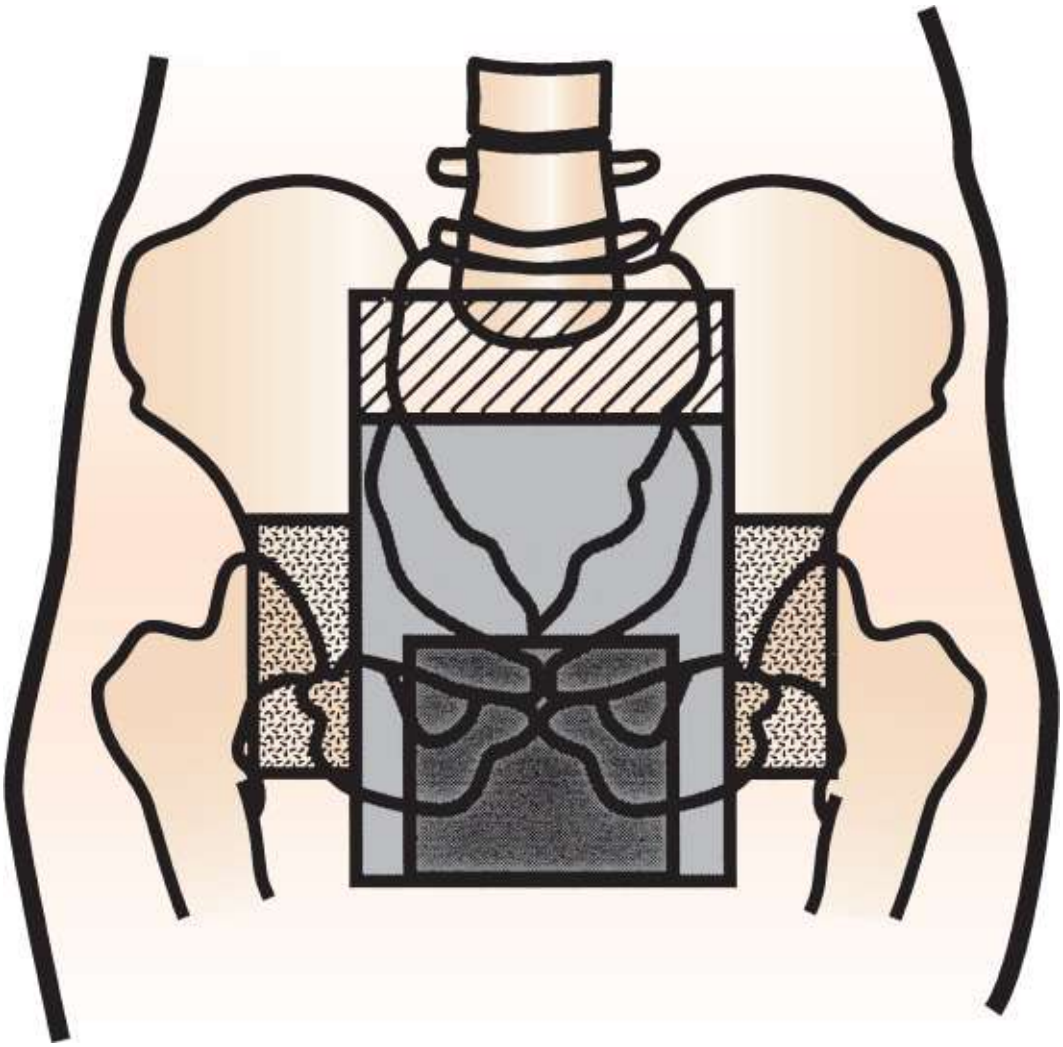

FIGURE 66.3. Example of radiation fields used to cover pelvic nodes and primary cancer. Upper border generally lowered from lumbosacral junction to lower border of sacroiliac joints part way through course. Fields are later reduced further to give higher dose to primary tumor. Separate anterior fields are applied to cover lateral inguinal nodes.

Biochemical and Molecular Factors

A survey of nearly 50 reports on cytogenetic, flow cytometric, immunohistochemical, and other factors considered that these studies offered some insights on pathogenesis but did not help with selection of treatment or provide guidance on prognosis.[65] Recent studies suggested that biomarkers such as p53,[66] Ki 67, nuclear factor kappa B, 5HH, and Gli-1[67] may be associated with locoregional control or disease-free survival. High levels of MCM7 protein

detected in gene expression analysis were associated with improved cancer survival in one series.[68] None of these suggested markers has yet been validated in prospective studies. Recent studies suggest that HPV-positive anal squamous cell carcinoma may confer an overall survival advantage over HPV-negative anal cancer patients.

Treatment Factors

Early response and the extent of response to chemoradiation were correlated with survival in several multivariate analyses.[54,69,70] An association with total radiation dose or with treatment duration, although expected, has not been demonstrated consistently for either locoregional control or survival. A daily fraction size of 2.5 Gy appeared to be associated with increased acute and late toxicity, compared with 2-Gy fractions.[39]

TREATMENT OF ANAL CANCER

Although squamous cell cancer of the anal canal is a relatively uncommon malignancy, several multicenter randomized trials have been completed successfully. These have established RT, 5-FU, and MMC, with surgery reserved for failure, as the standard against which other treatments should be compared. These trials are outlined here and in Table 66.4.[41,71–78] The original references should be consulted for full details of patient eligibility, treatment regimens, outcomes, and statistical analyses. There have also been more than 100 nonrandomized studies, many of which provided hypotheses subsequently tested in the randomized studies, or information that guided the development of technical aspects of radiation treatment.[79]

It is of note that the combination of RT and chemotherapy has supplanted surgery as the preferred treatment for anal canal squamous cell cancer without formal comparison in a randomized trial. Nonrandomized comparisons of radical resection with this combination of RT, 5-FU, and MMC[32] or with RT alone[80] have shown the ability of radiation-based regimens to produce survival rates at least equal to those of surgical series while allowing preservation of anorectal function in the majority of patients.

COMBINED RADIATION AND CHEMOTHERAPY

Radiation, 5-Fluorouracil, and Mitomycin C Versus Radiation Alone

In both the United Kingdom and Europe in the 1970s, more so than in North America, there was already some acceptance of RT as the primary treatment for anal cancer[81]; this facilitated the development of the first multi-institutional randomized trials in which RT alone was compared with RT plus chemotherapy. The randomized trials conducted by the U.K. Coordination Committee for Cancer Research (UKCCCR)[41] and the European Organisation for Research and Treatment of Cancer (EORTC)[72] both demonstrated significant improvement in control of the primary cancer and regional nodes and in colostomy rate or

colostomy-free survival in patients who received RT, 5-FU, and MMC. Overall survival rates were not improved significantly in the initial reports. However, in a later report of the UKCCCR trial after a median of 13 years' follow-up, locoregional control, colostomy-free survival, disease-free survival, and deaths due to anal cancer all significantly favored chemoradiation.[71] The absolute difference in risk of dying from all causes was 5.1% lower in the chemoradiation group at 5 years and 5.6% lower at 12 years from randomization. This difference approached statistical significance (HR 0.86; 95% confidence interval [CI], 0.70 to 1.04; $P = .12$).[71]

The UKCCCR trial included 577 patients with all stages (UICC staging system, 1987 edition) of squamous cell cancer of the anal canal (75% of patients) or anal margin (23%).[41] The radiation dose was 45 Gy in 20 to 25 fractions in 4 to 5 weeks. Those randomized to chemotherapy received 5-FU (1,000 mg/m^2/d for 4 days or 750 mg/m^2/d for 5 days) by continuous peripheral intravenous infusion in the first and final weeks of radiation treatment, plus MMC (12 mg/m^2) by bolus intravenous injection on day 1 of the first course of chemotherapy. If the primary tumor had not regressed by at least 50% by 6 weeks after treatment (as occurred in 10% in each group), surgery was recommended; otherwise, the patients received an additional 15 Gy in 6 fractions by a perineal field or 25 Gy over 2 to 3 days by iridium-192 implant. The locoregional recurrence rates at 3 years were 61% after RT and 39% after RT, 5-FU, and MMC ($P < .0001$). The overall survival rates at 3 years were 58% and 65% ($P = .25$), respectively. There were six (2%) deaths due to treatment in the combined-modality arm and two (0.7%) in the irradiation-alone arm. Acute toxicity, other than hematologic, was considered comparable in each group. In the first few years after treatment, surgery that included colostomy was necessary for management of toxicity in 10 patients (3.5%) in each group.[41] Late toxicity events (severity was not graded) after a median of 13 years' follow-up were similar in each treatment group.[71]

In the EORTC study, 103 patients with advanced cancers of the anal canal were randomized in a trial of similar design.[72] The radiation dose was 45 Gy in 25 fractions over 5 weeks. Chemotherapy included 5-FU (750 mg/m^2/d for 5 days) in weeks 1 and 5 of radiation, and a single dose of MMC (15 mg/m^2) by bolus intravenous injection on day 1 of the first course of 5-FU only. After 6 weeks, boost irradiation of 15 Gy (if complete clinical response to previous treatment had occurred) or 20 Gy (after partial response) was given by external-beam or interstitial irradiation. The 5-year locoregional recurrence rate was 48%

after RT and 32% after RT, 5-FU, and MMC (P = .02). The difference between overall survival rates (53% and 58%, respectively) was not significant. One of 51 patients who received combined modality treatment died of toxicity. Otherwise, acute and late toxicity rates did not differ markedly. These two trials established RT, 5-FU, and MMC as the standard first-line treatment.

Radiation, 5-Fluorouracil, and Mitomycin C Versus Radiation and 5-Fluorouracil

The RTOG and Eastern Cooperative Oncology Group (ECOG) established in a randomized trial that the combination of MMC with 5-FU and RT is more effective than is 5-FU alone with RT.[73] This study was undertaken to determine whether MMC was a necessary component of the protocol and whether the hematologic toxicity of that drug could be avoided. Two hundred and ninety-one patients with cancers of the anal canal of any T and N category (RTOG staging system) who did not have evidence of extrapelvic metastases received 45 Gy to 50.4 Gy in 25 to 28 fractions over 5 weeks, plus 2 courses of 5-FU (1,000 mg/m^2/d by continuous peripheral intravenous infusion) over 4 days, with or without MMC (10 mg/m^2 by bolus intravenous injection) on the first day of each course of chemotherapy. Chemotherapy was administered in weeks 1 and 5 of RT. All patients underwent biopsy of the primary tumor site 6 weeks after treatment. Biopsies were positive in 15% of those who received 5-FU only and in 8% of those who received both MMC and 5-FU (P = .14). Patients with positive biopsies had the option of receiving an additional 9 Gy in 5 treatments concurrently with a 4-day infusion of 5-FU (1,000 mg/m^2/d) and a single injection of cisplatin (CDDP) (100 mg/m^2) if it was thought that anal function might still be salvaged. At 4 years, the rates of local failure (16% vs. 34%; P = .0008) and of colostomy (9% vs. 22%; P = .002), significantly favored treatment with radiation, 5-FU, and MMC. There was no significant difference in overall survival rates (76% with RT, 5-FU, and MMC vs. 67%); however, the disease-free survival rate (73% vs. 51%; P = .0003) was improved by the three-agent combination. Acute hematologic toxicity was more common in the patients who received MMC, but the rates of other acute and late toxic effects were similar in each treatment group. Four of 146 (2.7%) patients who received both 5-FU and MMC suffered fatal toxicity as did 1 of 145 treated with RT and 5-FU alone. On the evidence from this trial, MMC was retained in combination with RT and 5-FU.

Radiation, 5-Fluorouracil, and Mitomycin C Versus Radiation, 5-Fluorouracil, and Cisplatin

Several pilot studies suggested high tumor response rates to concurrent, induction, or induction plus concurrent 5-FU and CDDP with RT.[82–88] Cisplatin was known to be effective against squamous cell cancers in several other sites and to be associated with stronger laboratory evidence as a radiosensitizer than MMC.

The RTOG elected to evaluate a strategy of CDDP-based induction chemotherapy intended to downsize the primary tumor and nodal metastases prior to concurrent chemoradiation. This trial included a higher total radiation dose than the earlier RTOG randomized trial,[73] based on analysis of nonrandomized studies that suggested a radiation dose–control relationship[89,90] and on pilot studies, which had demonstrated that a proportion of patients could tolerate uninterrupted radiation schedules of up to 59.4 Gy over 6.5 weeks with either concurrent MMC with 5-FU[91,92] or CDDP with 5-FU.[83]

In RTOG-9811,[74] one patient group received 59 Gy in 6.5 weeks (45 Gy in 1.8-Gy fractions, followed without interruption by 14 Gy in 2-Gy fractions), together with concurrent 5-FU (1,000 mg/m^2/d) by continuous infusion on days 1 to 4 and 29 to 32 plus MMC 10 mg/m^2 intravenous bolus on days 1 and 29; the other group received 5-FU (1,000 mg/m^2/d) days 1 to 4, 29 to 32, 57 to 60, and 85 to 88 plus CDDP (75 mg/m^2 bolus injection on days 1, 29, 57, and 85) with the same 59-Gy radiation schedule (start day 57). Acute grade 3 or 4 nonhematologic toxicity rates were 75% in each arm, but hematologic toxicity was higher in the MMC group (67% vs. 47%). No treatment-related deaths were reported. The rate of severe long-term toxicity was similar in each group (11% MMC vs. 10% CDDP). The first report of this trial (after median patient follow-up of 2.5 years) described a significantly higher rate of colostomy at 3 years in those who received CDDP rather than MMC plus 5-FU and RT. There were no significant differences in disease-free or overall survival rates.

After longer follow-up, the 5-year colostomy rates and locoregional failure rates showed trends in favor of 5-FU, MMC- and RT but were not significant. However, the 5-year disease-free (68% vs. 58%; $P = .004$) and overall survival rates (78% vs. 71%; $P = .021$) significantly favored RT, 5-FU, and MMC.[75] The investigators concluded that RT, 5-FU, and MMC should remain the standard approach.

The second U.K. Anal Cancer Trial (ACT II) also has not identified a role for CDDP in addition to or in place of MMC. This trial has so far been reported in

abstract only.[76] The trial incorporates a double randomization, either to 5-FU and MMC or to 5-FU and CDDP concurrently with RT and to 2 courses of adjuvant (or maintenance) 5-FU and CDDP or to no additional chemotherapy following concurrent chemoradiation. The primary endpoints were improvements in complete tumor response rates and disease-free survival rates. Complete tumor response rates at 6 months were similar: 94% (MMC arm) and 95% (CDDP arm). Three-year disease-free and overall survival rates were not improved in those who received adjuvant 5-FU and CDDP. MMC-treated patients had more severe hematologic toxicity, but rates of neutropenic sepsis were similar (about 3%).

A French intergroup conducted a factorial-designed four-arm trial (ACCORD 03) that evaluated the addition of induction 5-FU and CDDP and of a higher dose of boost RT (20 Gy to 25 Gy vs. standard 15 Gy). The baseline standard RT schedule was 45 Gy in 25 fractions in 5 weeks. The outcome has been reported in abstract only.[77,78] The actuarial 3-year colostomy-free survival rate (the primary study endpoint) ranged from 80% to 85% in the four arms, with no significant advantages for either experimental treatment. Local control, event-free survival, and overall survival rates were similar in each arm.

Other Drug–Radiation Combinations

In an effort to develop a simplified schedule, the U.K. National Cancer Research Institute Anal Subgroup conducted a phase II trial of RT (50.4 Gy in 28 fractions in 5.5 weeks), a single intravenous injection of MMC (12 mg/m^2 on day 1) and oral capecitabine (825 mg/m^2 twice daily on each RT treatment day).[93] The schedule was described as well tolerated with acceptable compliance (although only 58% received the full planned doses). The overall tumor response rate after treatment was 90% (complete in 24 of 31 and partial in 4 of 31). Although this use of oral capecitabine is promising and removes the need for continuous intravenous infusions of 5-FU, at this time, delivery of both 5-FU and MMC intravenously remains standard.

The EORTC conducted a randomized phase II trial in which RT (36 Gy + 2-week gap + 23.4 Gy) was combined with either MMC and 5-FU or MMC and CDDP. The overall response rates at 8 weeks were 92% (34 of 37) to RT, MMC, and CDDP versus 80% (31 of 39) to RT, 5-FU, and MMC, although greater compliance to the full regimen was seen with RT, 5-FU, and MMC.[94] It is not known whether this group has proceeded with a planned phase III trial.[95]

Because epidermal growth factor receptor (EGFR) is known to be

overexpressed in many epithelial cancers, including squamous cell cancer of the anal canal,[96] EGFR blockers are being evaluated. The ECOG is conducting a phase II study of RT, 5-FU, CDDP, and cetuximab in HIV-negative patients.[95] The AIDS Malignancy Clinical Trials Consortium is performing a similar study in HIV-positive patients.[95] Other anti-EGFR agents under study include nimotuzumab and panitumumab.[95] Initial laboratory studies suggest that EGFR and *K-RAS* mutation analysis are not likely to be useful as a screening test for sensitivity to anti-EGFR therapy in anal canal cancer.[96]

In Sweden, bleomycin was given concurrently with RT in nonrandomized studies, but no benefit was apparent.[97–99] A pilot study in the United Kingdom in which all three of the major drugs investigated, 5FU, MMC, and CDDP, were combined with RT was not pursued further because of excessive toxicity.[100]

CONCLUSION

Much remains to be learned about the mechanisms of interaction between radiation and chemotherapy in the treatment of cancer. The synergistic interactions of various combinations of RT, 5-FU, MMC, and CDDP observed in some laboratory studies are difficult to evaluate clinically, and no trials designed to study such interactions have been performed. Also, there have not been formal comparisons of more prolonged, but less daily dose-intense, infusions of 5-FU with the 96-hour to 120-hour infusions generally favored, nor of bolus injections with continuous infusions of 5-FU or CDDP. In most series, the timing of delivery of chemotherapy each day relative to irradiation was not tightly controlled, and the importance of scheduling is not known.

The current standard chemoradiation combination is RT with two concurrent 96-hour or 120-hour continuous intravenous infusions of 5-FU and one or two bolus injections of MMC. The most effective doses have not been established. When patients are to be managed outside a clinical trial, it is suggested that a schedule used in one of the prospective randomized trials, for which there are data on efficacy and toxicity, be adopted.

RADIATION THERAPY

The use of RT alone, either brachytherapy or external beam, has been greatly reduced since the confirmation of improved outcome of combined modality therapy. Radiation alone is now recommended mainly to patients who are unable

to undergo RT plus chemotherapy or for the treatment of smaller cancers up to about 3 to 4 cm in size where the physician does not wish to add chemotherapy. As with combined RT and chemotherapy, primary tumor control is better with small tumors. Selected results, mainly from the period prior to the adoption of chemoradiation, are shown in Table 66.5.

TABLE 66.5 SELECTED STUDIES OF THREE-DIMENSIONAL CONFORMAL RADIATION AND INTENSITY-MODULATED RADIATION THERAPY

Study (Reference)	RTOG 9811 MMC arm (74)	Boston (159)	RTOG 0529 (158)	Toronto (139)

SURGERY

For Residual and Recurrent Cancer

Random biopsies from the site of the primary tumor, or abnormal nodes, shortly after chemoradiation have been advocated by some but are not necessary. Elective biopsies at predetermined times do not appear to lead to better results than can be achieved by biopsies directed only to areas suspected clinically of harboring residual or recurrent cancer. A negative biopsy does not exclude the

possibility of cancer regrowth.[101,102] Residual masses at the site of the original anal cancer may take several months to resolve fully after chemoradiation or RT alone.[39,102] A post hoc analysis of the ACT II study evaluated the optimal timepoint to assess clinical complete response. Patients in the ACT II study had assessments after chemoradiotherapy at 11 weeks, 18 weeks, and 26 weeks. The investigators found that among patients who did not have a clinical complete response by 11 weeks, 151 of 209 (72%) would ultimately achieve a clinical complete response by 26 weeks. Together, these findings highlight the potentially slow primary anal tumor response to chemoradiotherapy, and most authors now recommend biopsy only when persistent cancer is suspected clinically.

Suspected residual or recurrent cancer at the primary site or in regional nodes should be confirmed histologically if possible. Full restaging imaging is recommended. FDG-PET scans may disclose otherwise unidentified cancer.[103] Abdominoperineal resection or multivisceral pelvic resection is usually required. Survival rates are poor when R0 resection cannot be achieved.[104,105] Locoregional recurrence is common, despite apparent R0 resection.[104,106] Five-year survival rates following salvage surgery range from 30% to 50%, reflecting the varying criteria applied when selecting patients for surgery.[104–107]

Salvage for inguinal node metastases is usually by radical or selective inguinofemoral lymphadenectomy. Pelvic sidewall node metastases may not be resectable because of invasion of muscle or bone or neurovascular structures.

For Primary Cancer

Surgery is the principal treatment for AIN[108] but retains only a limited place in the initial management of primary invasive anal cancer. A few patients (<5% in most series) are incontinent for solid stool at presentation. This is usually due to extensive tumors that have destroyed the competence of the anal sphincters or fistulized into the vagina. Eradication of cancer by RT, with or without chemotherapy, does not restore continence in such patients, likely because the cancer is replaced by fibrous tissue rather than the specialized muscle of the anal sphincters. One approach is to perform colostomy before preoperative RT and chemotherapy using doses of 45 to 50 Gy over 5 weeks, followed by immediate or delayed resection. An alternative is initial abdominoperineal resection with postoperative RT and chemotherapy. There are insufficient data to compare the outcomes of these approaches.

Local excision, preserving anorectal function, is possible in some patients,

although this is now usually restricted to small well-differentiated squamous cell cancers that have not invaded the sphincter muscles and are located distal to the dentate line.[109–111] This approach is based on the finding in surgical series that pararectal or superior hemorrhoidal system lymph node metastases were associated with <5% of well-differentiated squamous cell cancers <2 cm in size.[31,34] Local excision of small cancers of the distal canal or perianal skin is generally more expedient and associated with less morbidity than radiation-based treatments. However, if resection margins are positive or considered inadequate, and further local excision is not possible, the patient should receive chemoradiation or RT alone. There is no evidence that elective management by limited tumor excision and postoperative radiation-based protocols improves local control.[112]

The role of surgery in the management of inguinal node metastases detected at initial diagnosis has not been well defined. Although nodal metastases are generally treated successfully by the same doses of RT and chemotherapy effective against the primary cancer, there is no consensus on whether control of the nodal region involved is improved by limited node dissection prior to RT and chemotherapy and on how such an approach affects morbidity such as late limb edema.[36,38–40] After local excision of gross node metastases, the dose to the groin can usually be limited to 50 to 54 Gy over 5 to 6 weeks, provided imaging does not show residual metastases. The combination of local surgery and RT and chemotherapy has resulted in regional control rates in the groin of 80% or better.[38,39] However, 5-year survival rates are usually −20% less than in those who do not present with inguinal node metastases.

Extrapelvic Metastases

Deaths from extrapelvic metastases alone are relatively infrequent. Extrapelvic metastases are identified in about 10% to 20% of patients. Among 77 patients in the UKCCCR ACT I trial who died of anal cancer after treatment with RT, 5-FU, and MMC, 38 of 77 (49% of the cancer deaths) had cancer in the pelvis only and 21 of 77 (27%) had extrapelvic metastases only. In that trial, the overall crude rate of metastasis in those who received RT and chemotherapy was 10%, compared with 17% in those treated by RT alone.[41] In the EORTC trial, 17% of those treated by RT and chemotherapy developed metastases, as did 21% of those treated by RT only.[72] In RTOG-9811, the rates of distant metastases at 5 years were 13% in those who received RT, 5-FU, and MMC and 18% after RT, 5-FU, and CDDP.[75] In the U.K. ACT II trial, there was no suggestion in the 3-

year disease-free and overall survival rates of benefit from the addition of 2 courses of adjuvant 5-FU and CDDP.[76] The rates of metastases in patients treated by chemoradiation are similar to those reported following management of the primary cancer and regional nodes by surgery or RT only. There is still considerable uncertainty regarding the effects on subclinical metastases outside the pelvis from the chemotherapy given concurrently with RT and as short-term induction or adjuvant treatment.

The median survival time after diagnosis of extrapelvic metastases ranges from 8 to about 24 months.[55,56,113] These metastases have been relatively resistant so far to all chemotherapy, RT, or combined modality protocols.[113] The most active combination is 5-FU and CDDP, although complete or durable responses are uncommon.

Many recently developed drugs and molecular targeted agents have not yet been evaluated, but the possibility of new approaches is illustrated by preliminary reports of responses to cetuximab and irinotecan.[114] A recently reported phase II trial evaluated the anti–PD-1 antibody nivolumab in patients with treatment of refractory metastatic anal squamous cell carcinoma. Among the 37 patients treated with nivolumab, two had complete responses and seven had partial responses for an overall response rate of 24%. Radiation alone may provide useful palliation, especially for painful metastases. Stereotactic body RT or metastasectomy may be offered to selected patients, but metastases are commonly multiple.

TREATMENT OF PERIANAL CANCER

The most common histologic type of invasive cancer of the perianal skin is squamous cell carcinoma, usually keratinizing. Basal cell cancers and adenocarcinomas can also occur.

Wide local excision with a 1-cm margin is recommended for all histologic types, provided anal continence can be preserved.[111] Radiation alone or in combination with chemotherapy is also effective against squamous cell cancers.[40,69,115–119] Radiation-based protocols identical to those for anal canal cancer are preferred when anal continence would be impaired by surgery. In the UKCCCR ACT I trial, one of four patients had a cancer that arose in the perianal skin (anal margin). Results by site of cancer origin were not reported, but local control and cause-specific survival rates favored combined modality therapy.[41,71] The UK investigators also included perianal cancers in their subsequent trial.[76]

In institution-based series, locoregional control rates ranged from 60% to 90%, sphincter preservation rates from 65% to 85%, and 5-year overall survival from 55% to 80%.[40,69,115–119] Local necrosis was seen as a complication more frequently when brachytherapy was used, although in general, the rates of serious complications were <5%.

The regional nodes for the perianal skin are the ipsilateral inguinal nodes. Perirectal and pelvic node metastases are uncommon unless the cancer involves the anal canal extensively. The risk of inguinal node metastases is about 10%, principally with category T3 or T4 tumors or poorly differentiated cancers. Elective bilateral inguinal nodal irradiation may be considered when these larger tumors are treated, although some advocate elective inguinal RT for all perianal cancers.[119] The lower pelvic nodes should be included if the anal canal is invaded. The management of abnormal inguinal nodes is similar to that for anal canal cancer.

The principles of management for the uncommon basal cell and adenocarcinomas of the perianal skin are similar to those for these histologic types elsewhere on the skin.

PATIENTS WITH HUMAN IMMUNODEFICIENCY VIRUS/ACQUIRED IMMUNODEFICIENCY SYNDROME

The numbers of HIV-infected patients with anal squamous cell cancer are increasing.[23] The median age at diagnosis is in the fourth decade, about 20 years earlier than in non–HIV-infected patients. There is a marked preponderance of male patients.[23] HIV-infected patients were not eligible for any of the randomized trials described earlier. Anal cancers in HIV-infected patients have been treated by combined modality therapy or RT alone.[62–64,120–124] HIV-infected patients are at increased risk of toxicity, particularly in the perineal skin, anorectal mucosa, and hematologic system when treated with RT with or without chemotherapy. The mechanisms for this increased toxicity are not known.[125] Most recent reports indicate that it is not necessary to electively modify standard protocols of RT (with respect to dose, fractionation, or volume) and chemotherapy (either 5-FU and MMC or 5-FU and CDDP), but modifications should be based on the severity of side effects in each individual patient.[62,120] Two factors may predict for heightened acute normal tissue toxicity or poor cancer control: a CD4 count <200/μL at the start of treatment or the presence of AIDS.[63,126] But these findings are not inevitably associated with poor tolerance.

Concurrent antiretroviral therapy does not reliably reduce the severity or incidence of toxicity of RT and chemotherapy.[30]

Locoregional control rates of about 65% or better were described in some series, similar to those in HIV-negative patients. However, some investigators reported lower rates of local control and sphincter preservation in HIV-positive patients, despite earlier-stage disease and good initial tumor response.[64,124] In a study of 40 HIV-positive patients, the 5-year overall survival rate was similar to that in 81 HIV-negative patients, but the major cause of death in HIV-positive patients was anal cancer, in contradistinction to the HIV-negative patients in whom causes other than cancer predominated.[64]

ADENOCARCINOMAS

Most adenocarcinomas involving the anal canal arise from rectal-type mucosa that extends below the upper muscular boundary of the canal. They are generally treated similarly to those that arise in the rectum. The uncommon adenocarcinomas that develop from anal glands or in fistulae are more aggressive than squamous cancers and often metastasize early.[127] They have usually been managed by abdominoperineal resection. Five-year survival rates following surgery alone are commonly below 50%, with local recurrence rates of about 25%.[32,111,127–130] Any advantage from adjuvant radiation and chemotherapy is unknown, although, by analogy, protocols used for primary rectal cancers are sometimes applied. A few centers have treated some anal adenocarcinomas by chemoradiation protocols developed for squamous cell cancers or rectal adenocarcinomas and have deferred surgery. Experience is limited, but anorectal function has been retained, and apparent cures have been reported, particularly in patients with smaller cancers, following treatment with RT alone or with RT and chemotherapy.[127–133]

SMALL CELL CARCINOMAS

Small cell carcinomas are rare cancers characterized by early metastases and have a poor prognosis.[31] The primary tumor may be managed by surgery or radiation. Systemic chemotherapy similar to that used for small cell cancers that arise elsewhere may be combined with radiation for the primary tumor and used to treat metastases, but responses are generally limited.

RADIATION THERAPY: TECHNIQUES AND DOSES

Anal Canal Cancer

Current radiation treatment strategies have been developed through better understanding of the natural history of anal cancer and correlation of sites of treatment failure with the treatment plan.[134–136] Most failures were at the site of the primary tumor, followed by the regional and other pelvic node groups.

The treatment volumes of interest are also influenced by the philosophy adopted with regard to which lymph node groups should be treated electively. Only well-differentiated squamous cell cancers ≤2 cm in size situated in the distal canal appear to have a risk of nodal metastases <5%.[31,34] The finding in surgical series of histopathologically verified metastases in the pararectal and internal iliac nodes in up to 30%, and in the inguinal nodes in up to 20%, has encouraged most radiation oncologists to irradiate these node groups electively. Retrospective and prospective studies have shown the advantages of elective nodal irradiation (ENI).[38,39] Following ENI to a total dose of 40 to 50 Gy (1.8 to 2 Gy fractions), investigators from France reported 5-year cumulative rates of inguinal recurrence of 2% in those who received ENI (n = 75) versus 16% in those who did not (n = 106). In the no-ENI group, recurrence rates were 12% from T1 to T2 and 30% from T3 to T4 tumors.[38] In a prospective study in Australasia in which patients with T1 or T2 tumors up to 4 cm in diameter did not receive inguinal ENI, inguinal node failure occurred in 9 of 40 (23%), in 5 as first site of failure.[137] Treatment of larger cancers by interstitial brachytherapy alone resulted in failure in pelvic nodes above the treated volume in 16% (14 of 88).[138] Control of most subclinical pelvic node metastases by pelvic ENI and chemotherapy can be inferred from the low failure rates reported in pelvic node sites.[134–136] The minimum effective dose for ENI is not known. Doses as low as 24 Gy in 12 fractions in 2.5 weeks appeared effective in one series,[39] but most centers give from 30.6 Gy in 17 fractions in 3.5 weeks to 50 Gy in 25 fractions in 5 weeks.[38,73,74]

The randomized trials described earlier all used radiation plans generated by two- or three-dimensional (2-D or 3-D) planning techniques and, for the most part, employed predominantly anteroposterior opposed field techniques for a substantial part of the schedule. Most radiation oncologists prefer to treat the primary tumor, the regional internal iliac, and perirectal nodes and inguinal nodes and other pelvic node groups such as the external iliac and presacral nodes in continuity. If the patient is prone, the anus can be visualized readily and bolus

placed selectively over any perianal tumor extension. However, it is difficult to boost the inguinal area when the patient is prone if a 2-D or 3-D treatment technique is used. Alternatively, the patient may be treated supine. This facilitates boosts to the inguinal areas and reduces some of the inhomogeneities produced by the natural curvatures of the pelvic soft tissues. In that position, it is difficult to ensure that bolus placed over the anal area remains in place.

In the discussion that follows, the radiation doses described are typical of those prescribed when RT is combined with 5-FU and MMC. When an anteroposterior opposed pair of fields is used, the upper border of the fields is placed at the lumbosacral junction if the intent is to include the common iliac, upper presacral, and lower rectosigmoid nodes, in addition to the regional nodes. This border is commonly moved down during treatment to the lower end of the sacroiliac joints (typically after 30.6 Gy in 17 fractions to 36 Gy in 20 fractions), thus encompassing in the reduced volume only the perirectal, lower presacral, and internal iliac nodes (and, if the fields are sufficiently wide, the lower external iliac nodes), in order to reduce the risk of radiation enteritis (Fig. 66.3). A further field reduction is made at 45 Gy, following which a final phase of treatment of 9 Gy in 5 fractions or 14.4 Gy in 8 fractions is delivered to the primary tumor. It is advisable to add a CTV margin of 2 to 3 cm around the primary tumor for this boost phase. If the primary tumor cannot be identified on the planning CT, the anal sphincter complex is often used as a surrogate target, adjusted for any known tumor extension beyond the anal canal. The overall total dose to the primary tumor is 54 Gy in 30 fractions in 6 weeks to 59.4 Gy in 33 fractions in 6.5 weeks when all RT is delivered by external-beam radiation. If there are metastatic nodes, these are treated by appropriate fields to the same total dose as the primary tumor. It may not be possible to deliver more than about 45 to 50.4 Gy to abnormal nodes in the pelvis if these lie adjacent to small bowel; in many cases, these doses are enough to achieve control. In the absence of abnormal nodes in the lower pelvis, some consider elective treatment of radiologically normal nodes above the lower border of the sacroiliac joints unnecessary.[39,139,140]

The inferior field border is placed 3 cm distal to the lower most extension of the primary tumor, which should be indicated by a radio-opaque marker during simulation.

The position of the lateral borders depends on the philosophy adopted with respect to the desirability of treating a continuous homogeneous volume, without multiple fields and field junctions, and minimizing irradiation of the femoral

head and neck. Options include anterior and posterior fields of equal size encompassing the inguinal nodes; anterior and posterior fields of equal size, but restricted to include the medial borders of the pelvis only, the inguinal nodes being treated by anterior electron beams matched to the photon fields; asymmetric photon fields, with a larger anterior field to cover the primary tumor and pelvic and inguinal nodes in continuity; and a posterior beam restricted to the primary tumor and pelvic nodes. In this latter arrangement, an anterior electron beam may be used to supplement the dose to the inguinal nodes to the desired level. The location and depth of the inguinal nodes should be obtained by axial imaging.[141] Another popular alternative, if 30.6 to 36 Gy in 3.5 to 4 weeks is felt to be sufficient dose for ENI for radiologically normal nodes, is to treat the primary and pelvic and inguinal nodes with the AP:PA fields and then to use a three-field arrangement (posterior and two lateral fields) to encompass the primary tumor to 45 to 59.4 Gy total dose, according to the size of the primary cancer and local practice. Other field arrangements, such as oblique fields[142] and a direct perineal field coupled with a posterior partial arc beam,[138] have been described. When asymmetric or matched fields are used, there is potential for both over- and underdosage.[143]

The final phase of treatment, beyond which includes both lymph nodes and primary cancer, typically delivers from 9 to 20 Gy to a reduced volume encompassing the primary tumor only. This phase may be delivered by brachytherapy. Brachytherapy is used more commonly in Europe than in North America, where external-beam treatment is favored. There are a number of reports of effective brachytherapy, including low–dose rate (LDR),[69,144,145] pulsed dose rate (PDR),[146–148] and high–dose rate (HDR) techniques.[149,150] Brachytherapy has usually been given 2 to 8 weeks after external beam therapy, although one schedule introduced HDR in the interval during split-course external beam therapy.[149] There is no agreement on whether the treatment volume should include the full extent of the initial primary cancer[69,138,147,149] or only the tumor remaining at the time of implant.[151] The brachytherapy dose depends on the composite dose of the total radiation prescription. Occasionally, significant toxicity has been encountered.

The introduction of intensity-modulated radiation therapy (IMRT) offers the possibility of further reducing the dose to normal tissues beyond that achievable with 3-D conformal techniques. Several initial studies of IMRT and similar highly conformal techniques described improvements in radiation dose distributions.[135,152–157] However, it is apparent from the selected results in Table

66.6 that a wide range of severe acute toxicities was seen and that about half the patients treated by IMRT had breaks in treatment. Comparisons of the different case series and interpretation are difficult because most studies used differing RT techniques and doses and practices for recording toxicities. There are no high-quality data as yet on long-term toxicity following IMRT for anal cancer.

TABLE 66.6 SELECTED RESULTS OF RADIATION THERAPY ALONE

Author (Reference)	Radiation	Primary Tumor Control			Serious Complications—Colostomy	5-Year Survival
		T1	T2	T3 T4		
Newman et al. (178)	50 Gy/20/4 wk	8/9 (≤2 cm)	42/52 (81%) (≤5 cm)	13/20 (65%) (>5 cm or T4)	2	66%
Cummings et al. (139)	50 Gy/20/4 wk (some EB-I/I)	6/6 (≤2 cm)	19/29 (66%) (≤5 cm)	13/28 (46%) (>5 cm or T4)	6	61%
Martenson and Gunderson (179)	45–50 Gy/25–28/5–6 wk Plus boost to 55–67 Gy	9/9(≤2 cm)	17/17 (100%) (≤5 cm)	—	2 temp	94%, actuarial
Otim-Oyet et al. (180)	60–65 Gy/30–33/6–7 wk (Some with boost)	2/2 (≤2 cm)	16/22 (73%) (≤4 cm)	8/17 (47%) (>4 cm)	1	56% Cause-specific

EB, external beam; I, interstitial brachytherapy; NS, not stated; temp, temporary.

Highly conformal IMRT and related techniques require considerable attention to identifying gross target volumes (GTV) and relevant elective clinical target volumes (CTV). In a trial conducted by RTOG to test the reproducibility of IMRT in multiple centers, 79% of 51 cases were found on pretreatment review to not comply with the protocol treatment volumes, particularly those for nodal regions to be irradiated electively.[156] The RTOG study found that IMRT had similar rates of grade 2+ acute gastrointestinal/genitourinary toxicity (primary study endpoint) compared to historic RTOG controls treated with conformal

radiation, though the IMRT patients had decreased rates of grade 2+ hematologic toxicity (73% vs. 85%), grade 3+ gastrointestinal toxicity (21% vs. 36%), and grade 3+ skin toxicity (23% vs. 49%) compared to historic controls. The RTOG subsequently published an atlas of elective CTV templates developed by a consensus panel for use in planning IMRT for anal and rectal cancers.[158] When IMRT techniques are to be used, particular attention to patient positioning and immobilization is necessary. If possible, the accuracy of setup should be verified frequently, for example, by image-guided radiation treatment.

The results of IMRT appear similar to those achieved with 3-D conformal RT, though we lack long-term clinical outcomes with IMRT. Despite this lack of data, current guidelines endorse IMRT as the preferred option over 3-D conformal RT.

There has been increasing attention to radiation dose–time factors. Recent protocols have sought to improve local control rates, particularly for larger tumors, by intensifying RT or chemotherapy or both. Primary tumor control rates (excluding salvage treatment) in most studies of RT, 5-FU, and MMC are about 90% to 100% for tumors up to 2 cm (T1), 65% to 75% for tumors from 2 to 5 cm (T2), and 40% to 55% for those >5 cm and for most deeply invasive cancers (T3 or T4); the primary tumor control rate is about 60% overall.[39,57,102,145,159–162]

Increases in total radiation doses have been advocated. When combined with 5-FU and MMC, radiation doses of as little as 30 Gy in 15 fractions over 3 weeks have been shown to eradicate up to about 90% of cancers ≤3 cm in size. Higher doses, from 45 Gy in 25 fractions in 5 weeks to 54 Gy in 30 fractions in 6 weeks, sometimes supplemented with additional radiation after an interval of 6 to 8 weeks to a total of 60 to 65 Gy over a total time of about 12 weeks, have controlled from 65% to 75% of primary tumors >4 cm.[39,57,102,159–162] Recent trials in North America used up to 59 Gy in 32 fractions over 6.5 weeks for large or node-positive cancers[74,83,91,92]; the effectiveness and long-term tolerability of these increased doses have not yet been reported in detail. Analysis of the UKCCCR ACT I trial suggested that delivery of boost radiation of 15 to 25 Gy 6 weeks after the initial 45 Gy in 4 to 5 weeks did not improve local control but was associated with an increased risk of necrosis (8% vs. 0% if no boost was given).[163] Many centers are developing graduated dose schedules according to the size of the primary tumor and lymph node metastases.[74,134,153,157]

A potential advantage frequently proposed for IMRT is the ability to selectively increase the radiation dose to the cancer. It is not known whether this will be possible as a strategy to increase control rates for larger anal tumors

because of the limited tolerances of the distal rectum, anal canal, and perianal skin.[164,165] The introduction of single-phase IMRT plans has led to the use of nonstandard dose fractionation, particularly for lymph node regions treated electively. For example, if all target volumes are to be treated to 30 fractions and the primary tumor is to receive 54 Gy at 1.8 Gy/fraction, elective treatment of uninvolved nodes to 36 Gy would be delivered at 1.2 Gy/fraction and to 45 Gy at 1.5 Gy/fraction. Some authors have also introduced biologically effective dose corrections to allow for different fractional doses or alterations in time over which the lower doses are delivered.[153,157] The long-term effectiveness of these nonstandard doses has not been determined.

In the era of 2-D treatment planning, and later with 3-D conformal planning, interruptions in external-beam treatment, generally of no more than 2 weeks but of up to 4 weeks in some series, were introduced into many combined modality protocols, either as elective breaks after about 3 weeks' treatment or as required by individual patients, to reduce the severity of acute anoproctitis and perineal dermatitis. Longer intervals of 6 to 8 weeks were part of some schedules to allow time for tumor regression, particularly where further RT was to be prescribed based on the extent of the clinical or histopathologic response to the first phase of treatment.[41,72,73,138] The possible adverse effects of split-course irradiation on the control of anal cancer have not been studied formally, but the limited data available on the potential tumor doubling time of anal cancer suggest that it is relatively rapid and of the order of 4 days (range 1 to 30 days; $n = 26$),[166] so some adverse effect may be expected from unnecessarily prolonged treatment. Recent analyses of treatment duration indicate that the overall treatment time (OTT), including time for induction chemotherapy if given and for prolonged intervals prior to boost RT, may have more influence on outcome than the duration of radiation (RTT). Review of the UKCCCR ACT I trial did not identify an association between OTT and locoregional failure.[163] Analysis of two RTOG trials[73,74] showed a trend toward an association between longer OTT and colostomy failure and a statistically significant association with local failure. RTT and OTT were not correlated with overall or colostomy-free survival rates.[167] There are many potentially confounding factors in these retrospective comparisons, and the optimum duration of overall treatment or RT is not known. The introduction of IMRT techniques does not appear to have led to a consistent reduction in interruptions in RT. The general principle recommended is to avoid, or minimize the length of, all interruptions in the delivery of radiation.

Radiation Alone

If external-beam irradiation is given without concurrent chemotherapy, it is usual, as in other cancers, to prescribe doses close to the tolerance of the normal tissues. There have been no studies to establish the optimum dose–time factors. A dose to the primary tumor of 60 to 65 Gy over 6 to 7 weeks, in 1.8- to 2-Gy fractions, is commonly prescribed, with doses to lymph nodes to be treated electively in the range of 36 Gy in 4 weeks to 50.4 Gy in 5.5 weeks. Brachytherapy may be used for part of the treatment. As with chemoradiation, interruptions in treatment should be minimized.

Perianal Cancer

If small (<4 cm) perianal cancers with low risk of regional node metastases are treated by radiation, a dose of 60 to 66 Gy in 2-Gy fractions over 6 weeks may be used. A direct perineal field is preferred as this minimizes the area of skin irradiated. Orthovoltage equipment may suffice, although electrons or low-energy megavoltage photons (with bolus) are used more commonly. Care should be taken to flatten the perineum as much as possible to avoid areas of over- or underdosage. Larger perianal cancers, or cancers invading the anal canal, are usually treated by the techniques and schedules of radiation and chemotherapy used for anal canal cancers, based on the results of the UKCCCR ACT I trial.[41] Elective nodal irradiation is given to the inguinal and lower external iliac nodes and to the lower perirectal and internal iliac nodes if the tumor extends into the anal canal. The upper border of the fields is usually placed at the lower end of the sacroiliac joints. The final phase of radiation may be given by direct perineal photon or electron therapy. Although brachytherapy may be used for the final phase, full treatment of perianal cancers by brachytherapy was associated with high rates of necrosis in some series.

SEQUELAE OF THERAPY

Surveys of published studies suggest that the delivery of chemotherapy concurrently with RT is associated more with increases in acute rather than late normal tissue toxicity, beyond that expected with RT alone. Some nonrandomized series have described higher acute and late toxicity rates from combined modality therapy than those reported in the multicenter randomized trials. This probably results from use of different criteria for recording and reporting toxicity.

In programs that combined RT, 96-hour to 120-hour infusions of 5-FU (750 to 1,000 mg/m^2/24 h) and bolus injections of MMC (10 to 15 mg/m^2), moderate leukopenia, thrombocytopenia, anoproctitis, and perineal dermatitis were recorded in about 30% of patients after doses of 25 to 30 Gy in 2.5 to 3 weeks.[39,168] More profound proctitis and dermatitis occurred in up to 55% of those who received from 50 Gy in 4 to 5 weeks[39,102] to 59.4 Gy in 6.5 weeks.[91] When CDDP was substituted for MMC, marrow toxicity was less, but at radiation doses of 59.4 Gy in 6.5 weeks, acute soft tissue toxicity rates were similar.[74,83] Most large studies of RT, 5-FU, and MMC or CDDP reported some mortality (<2% overall) associated with acute toxicity, usually as a result of neutropenia with sepsis. This risk can be reduced with prophylactic antibiotics[41] and aggressive supportive care.

Serious late toxicity has not been reported after doses of 30 Gy in 3 weeks with 5-FU and MMC, but significant complications, often requiring surgery, were recorded in about 5% to 10% of those receiving higher radiation doses. A review of anal cancer management in Denmark from 1995 to 2003 found 5-year cumulative incidences of tumor-related and treatment-related colostomy of 26% (95% CI, 21% to 32%) and 8% (95% CI, 5% to 12%), respectively.[169] In the randomized RTOG-9811 trial, in those who received RT, 5-FU, and MMC, only 10 of the 30 colostomy procedures performed by about 3 years were for treatment-related problems, a crude rate of about 3%.[59] It is probable that some reports, many of which were retrospective, also overlooked some treatment-related toxicity. For example, a large cohort study of 556 women aged ≥65 who developed anal cancer showed a higher risk of pelvic fracture, principally of the hip, in those who received radiation (n = 399) compared to those not irradiated (n = 157). The cumulative 5-year fracture rate was 14% versus 7.5% (P < .01).[170] One of the objectives of current 3-D conformal and IMRT techniques is to reduce RT dose to the proximal femurs.

There are two additional areas of possible toxicity that need further study. Pelvic RT increases the risk of secondary malignancies,[171] and some of the chemotherapy agents used to treat anal cancer also are associated with a raised risk; these risks have not been quantified in detail for patients treated for anal cancer. Second, in the only report so far of long-term follow-up of patients in a randomized trial, it was found that there were more deaths due to causes other than cancer, particularly cardiovascular related, in the first 10 years following treatment with RT, 5-FU, and MMC.[71] This difference reached +9% at 5 years, but the effect almost disappeared by 10 years. The magnitude of this difference

was less than the reduction in deaths from anal cancer. Information from other randomized trials is needed to determine whether this observation was a chance phenomenon or a risk that should be addressed by further research.

Although preservation of anorectal anatomy is an advantage of treatment by chemoradiation, late anorectal function is often abnormal. Side effects of treatment are very common and may cause patients considerable discomfort and social disability, although they are often graded as only level 1 or 2 toxicity.[172–175] These effects include changes in anorectal function such as urgency and frequency of defecation, bleeding from anorectal telangiectasia, perineal dermatitis, pelvic fibrosis, dyspareunia, and impotence. They are usually managed medically with varying success. Systematic and prospective evaluations of the function of the anorectum and of other organs potentially affected by treatment are now being reported, as are formal quality-of-life studies.[135,176] There is often dissociation between a patient's and his or her physician's assessment of anal and rectal function and continence and physiologic measurements of anorectal function. The few studies in this area have been inconclusive.[174,177] Prospective studies of pelvic organ function can be expected to assist the development of radiation treatment protocols by facilitating correlation of function with radiation–chemotherapy interactions, radiation techniques and dose distributions, and time–dose factors.

PART G

Urinary Tract

CHAPTER 67

Cancer of the Kidney, Renal Pelvis, and Ureter

Hiram A. Gay and Jeff M. Michalski

ANATOMY

The kidneys are retroperitoneal structures located at the level between the 11th rib and the transverse process of the 3rd lumbar vertebral body. Usually, the right kidney is inferior to the right hepatic lobe and slightly more inferior than the left kidney. The renal axis runs parallel to the lateral margin of the psoas muscle. Each kidney is approximately 11 to 12 cm in length. The kidney is encased by a fibrous capsule and surrounded by perinephric fat, which is enveloped by Gerota fascia. At the renal hilus are the pelvis, ureter, renal artery, and vein. The organs adjacent to the right kidney include the liver superiorly, the duodenum and the vertebral bodies medially, and the transverse colon and small bowel anteriorly. On the left, the kidney abuts the spleen laterally; the stomach, pancreas, and vertebral bodies medially; and the small bowel and colon anteriorly.

The kidney consists of the cortex (glomeruli, convoluted tubules) and the medulla (Henle loops, collecting ducts, and pyramids of converging tubules). Each papilla opens in the minor calices, which unite in the major calices and drain into the renal pelvis. The caliceal collecting systems lie on the anteromedial surface of each kidney. The ureteropelvic junction is variable in position but serves as the landmark to separate the renal pelvis and the ureter. The ureters course posteriorly and inferiorly, paralleling the lateral border of the psoas muscle until they curve anteriorly to join the bladder at the trigone. The mucosal surfaces of the renal collecting tubules, calyces, renal pelvis, ureter, bladder, and urethra all have the same embryologic origin. The renal pelvis and ureter have the following layers: epithelium, subepithelial connective tissue, and muscularis, which is continuous with a connective tissue adventitial layer.

The lymphatics of the kidney and renal pelvis drain along the renal vessels.

The right kidney drains predominantly into the paracaval and interaortocaval lymph nodes, and the left kidney drains exclusively to the para-aortic lymph nodes.[1] The lymphatic drainage of the ureter is segmented and diffuse and may involve any of the renal hilar, abdominal para-aortic, paracaval, common iliac, internal iliac, or external iliac lymph nodes.

EPIDEMIOLOGY AND RISK FACTORS

The lesions discussed in this chapter are limited to adult renal cell carcinoma (RCC) and urothelial carcinoma of the renal pelvis and ureter. Lymphomas, Wilms tumor, neuroblastoma, and primary retroperitoneal sarcomas, including rhabdomyosarcoma, are discussed in Chapters 79, 81, 82, 89, 90, and 91, respectively. Approximately 88% of solid renal masses are malignant, and the probability of malignancy is proportional to the size of the lesion.[2] RCCs comprise 80% to 85% of primary kidney tumors, whereas urothelial (transitional cell) carcinomas of the renal pelvis account for 7% of kidney tumors.

Renal Cell Carcinoma

Globally in 2012, the male kidney cancer incidence and mortality age-standardized rate per 100,000 (ASR) was 12.6 and 4.2 in more developed areas and 3.4 and 1.7 in less developed areas, respectively. The estimated new kidney cancer cases in males in developed countries were 125,400, with 47,900 deaths. In contrast, the female kidney cancer incidence and mortality ASR was 6.2 and 1.7 in more developed areas and 1.8 and 0.9 in less developed areas, respectively. The estimated new kidney cancer cases in females in developed countries were 47,900.[3]

In the United States in 2017, the estimated number of new cases of kidney and renal pelvis cancer was 64,990, with 14,400 deaths. Men are twice as likely as women to be diagnosed with kidney cancer. These figures represent approximately 4% of all new cancers and 2% of cancer-related deaths. Incidence rates of kidney cancers increased over the past decades from incidental diagnoses during abdominal imaging, but appear to have stabilized in recent years. Since 2002, kidney cancer death rates have decreased approximately 1% per year.[4]

The median age of RCC diagnosis is 65 years. Few large epidemiologic studies have demonstrated a significant link between occupational exposure and RCC. Danish workers exposed to trichloroethylene, an industrial solvent used as

a metal degreaser, had an 8-fold higher incidence of kidney cancer.[5] Occupations associated with a higher risk of RCC are employment in the blast-furnace, coke-oven, or the iron and steel industry and exposure to asbestos, cadmium, dry-cleaning solvents, gasoline, and other petroleum products.[6] A number of other environmental (e.g., exposure to thorium dioxide), hormonal (e.g., diethylstilbestrol), dietary (e.g., high total energy intake and fried meats increase the risk, whereas vegetables, fruits, and alcohol are protective), cellular, and genetic factors have been associated with the development of RCC.[7–9]

Long-term cigarette smoking is associated with an increased risk of developing RCC. Obesity, diabetes, hepatitis C, and hypertension are also associated with a higher relative risk for development of these tumors.[10–12] Cytotoxic chemotherapy may predispose childhood cancer survivors to translocation RCC, bearing TFE3 or TFEB gene fusions.[13]

Acquired cystic kidney disease (ACKD), which occurs in up to 50% of patients on dialysis for more than 3 years, increases 50-fold the risk of developing RCC.[14,15] The ACKD-associated RCC is seen mostly in males, occurs approximately 20 years earlier than in the general population, and is frequently bilateral (9%) and multicentric (50%).[15]

Several inherited cancer syndromes affect the kidney: von Hippel-Lindau (VHL) disease, hereditary papillary renal cancer (HPRC), hereditary leiomyomatosis renal cell carcinoma (HLRCC), Birt-Hogg-Dubé (BHD) syndrome, and constitutional chromosome 3 translocation. VHL is autosomal dominant and is caused by germ-line mutations of the VHL tumor suppressor gene, located on chromosome 3p25–26. The VHL protein is involved in cell cycle regulation and angiogenesis. In patients with VHL disease, loss of the sole functioning VHL allele in somatic tissues causes a situation similar to hypoxia, with elevated levels of HIF-1-α, despite the presence of normal oxygen tension.[16] The renal manifestations of VHL are kidney cysts and clear cell RCC. The mean age onset for VHL-associated clear cell RCC is 37 years, and periodic screening with MRI should start after the age of 10 years.[17]

HPRC is autosomal dominant with high penetrance and is characterized by multiple, bilateral, late-onset papillary RCCs. HLRCC is autosomal dominant with a predisposition to papillary type 2 RCC. BHD is autosomal dominant with incomplete penetrance and is associated with multiple chromophobe and clear cell RCCs, papillary RCCs, and oncocytomas. Constitutional chromosome 3 translocation is associated with multiple, bilateral clear cell RCCs.[18] Autosomal dominant polycystic kidney disease does not appear to increase the incidence of

RCC, but the tumors are more often multicentric (28% vs. 6%), bilateral (12% vs. 1% to 5%), and sarcomatoid in type (33% vs. 1% to 5%) than in the general population.[19]

Renal Pelvis and Ureter Carcinoma

Urothelial carcinoma of the upper urinary tract accounts for 7% of all kidney tumors and 5% of all urothelial malignancies.[20] The incidence of bilateral upper urinary tract tumors is 1.5% to 2% for synchronous and 6 to 8% for asynchronous presentations.[21] Renal pelvis tumors are found two to three times more commonly in men than in women, and the peak incidence is in the fifth and sixth decades of life. Because the mucosal surfaces of the renal pelvis, ureter, and bladder have the same embryologic origin, many of the etiologic factors in renal pelvis and ureter tumors also apply to tumors of the urinary bladder. Urothelial carcinomas of the upper urinary tract tend to be multifocal because of "field cancerization," which may be caused by exposure of the urothelium to potential carcinogens. Urothelial tumors can also spread to urothelial structures that are either distal or proximal to the primary tumor and are referred to as "drop metastases." About 40% to 50% of patients with upper urinary tract tumors will have a synchronous or metachronous bladder cancer.[22,23]

Cigarette smoking is the most important factor contributing to the overall incidence of urothelial cancer in Western countries. Patients with Lynch syndrome, an autosomal dominant genetic condition because of inherited mutations that impair DNA mismatch repair, have an increased risk of developing urinary tract cancer.[24]

Exposure to aristolochic acid has been associated with acute, near–end-stage renal disease. Aristolochic acid is commonly found in the Aristolochiaceae family of plants commonly used in Chinese herbal medicine. A high incidence of cellular atypia and urothelial carcinoma of the renal pelvis, ureter, and bladder has been associated with aristolochic acid nephropathy.[25] Arsenic-contaminated water has been associated with a high incidence of upper urinary tract urothelial carcinoma in Taiwan.[26] Prolonged heavy phenacetin-containing analgesic use can lead to urothelial carcinomas of the renal pelvis, ureter, and bladder (which may be multiple and bilateral).[27]

Balkan endemic nephropathy (BEN) is a chronic tubulointerstitial disease of unknown etiology most commonly reported in southeastern Europe. A high frequency of urothelial atypia, occasionally progressing to tumors of the renal pelvis and urethra, but also involving the bladder, is associated with BEN.[27]

NATURAL HISTORY

Renal Cell Carcinoma

Primary renal cell tumors may spread by local infiltration through the renal capsule to involve the perinephric fat and Gerota fascia. The tumor may grow directly along the venous channels to the renal vein or vena cava. Lymph node metastases occur with an incidence of 9% to 27%, and most often involve the renal hilar, para-aortic, and paracaval lymph nodes.[28,29] The renal vein is invaded by tumor in 21% of cases, and the inferior vena cava is invaded in as many as 4% of cases.[30]

Approximately 45% of patients with RCC have localized disease, 25% have regional disease, and about 30% have evidence of distant metastases at the time of diagnosis.[29,31] Of patients with metastases, about 1% to 3% have solitary lesions.[32] About half of the patients with RCC eventually develop metastatic disease.[33]

Among patients presenting with metastatic RCC, the sites of distribution include the lung, bone, brain, liver, adrenal gland, and distant lymph nodes. RCC can metastasize to unusual sites like nasal sinuses, skin, penis, etc. Patients with metastatic disease at diagnosis have an extremely poor prognosis, with an expected survival of <5 years regardless of the site of metastasis.[29,31]

Renal Pelvis and Ureter Carcinoma

Upper urinary tract carcinoma is frequently a multifocal process. Patients with cancer at one site in the upper urinary tract are at significant risk for development of tumors elsewhere along the urothelium. The probability of multifocal occurrence is greatest in patients with large tumors and those with carcinoma *in situ*. Ureteral tumors tend to occur in the distal third of the ureter.

Urothelial carcinoma of the upper urothelial tract may spread both by direct extension and by hematogenous and lymphatic metastases. Implantation of tumor cells in the bladder has been demonstrated, especially in previously traumatized areas. The incidence of lymph node metastasis is highly dependent on the grade of the primary tumor. Low-grade tumors have a very low metastatic propensity. In a series of 94 patients, none of 43 low-grade tumors had lymph node metastasis, compared with 3 of 22 grade 3 or 4 tumors.[34] Lymph node metastases were reported in 9 of 26 patients selected to receive adjuvant radiotherapy.[35]

CLINICAL PRESENTATION

Renal Cell Carcinoma

Patients with RCC may present with an occult primary tumor or with signs and symptoms attributable to a local mass or systemic paraneoplastic syndromes. Gross hematuria, palpable flank mass, and pain describe a classic triad that occurs only in 5% to 10% of patients.[36,37] Indeed, a finding of the classic triad often suggests advanced disease with a poor prognosis. The most frequent symptom associated with RCC is hematuria, either gross or microscopic, when there is invasion of the collecting system.[38] Scrotal varicoceles, mostly left-sided, are observed in as many as 11% of men with RCC.[39] Other symptoms include anemia, hepatic dysfunction in the absence of liver metastases (called Stauffer syndrome and because of a paraneoplastic elevation in alkaline phosphatase), secondary (AA) amyloidosis, fever, hypercalcemia, cachexia, erythrocytosis, thrombocytosis, and a syndrome resembling polymyalgia rheumatica.[39–45] RCC presenting as an incidental mass on a diagnostic imaging study ordered for other purposes accounts for 61% of all diagnoses.[46]

A wide range of paraneoplastic syndromes has been associated with RCC. Parathyroid-like hormones, erythropoietin, renin, gonadotropins, placental lactogen, prolactin, enteroglucagon, insulin-like hormones, adrenocorticotropic hormone, and prostaglandins have been identified in patients with RCC.[47,48]

Renal Pelvis and Ureter Carcinoma

Gross or microscopic hematuria occurs in 70% to 95% of patients with renal pelvis or ureter tumors.[20] The other less common symptoms include pain (8% to 40%), bladder irritation (5% to 10%), or other constitutional symptoms (5%). About 10% to 20% of patients may present with a flank mass secondary to tumor or hydronephrosis.

DIAGNOSTIC WORKUP

Renal Cell Carcinoma

Renal masses are not uncommon, and most of them are benign. A central renal mass may suggest the presence of urothelial carcinoma; if so, urine cytology, ureteroscopy, and biopsy should be considered. Renal masses are frequently diagnosed as an incidental finding during abdominal imaging for metastatic evaluation for an unrelated malignancy or other disease. An algorithm for the workup of renal masses has been proposed.[49] Most contrast-enhancing masses

tend to be malignant, and the odds ratio of malignancy increases with increasing size.[50] If computed tomography (CT) or ultrasound clearly identifies the mass as a cyst, no further workup is necessary. If a solid lesion is identified, then tumor removal by nephrectomy should be considered. In the case of small lesions, a follow-up CT scan to evaluate potential growth of the mass may raise the suspicion of malignancy. The diagnostic and staging workup for RCC is given in Table 67.1. The diagnosis of RCC is established clinically and radiographically in most cases. Pathologic confirmation often is made at the time of nephrectomy.

Once a radiographic diagnosis is made, a staging evaluation should be undertaken, which should include a complete history and physical examination, complete blood count, and liver and kidney function tests. A metastatic workup should include a chest CT and an abdominal–pelvic CT or abdominal magnetic resonance imaging (MRI) scan of the abdomen. Patients with symptoms suggestive of bone metastases and those with an elevated alkaline phosphatase level should undergo a bone scan. If metastatic lesions are detected, histologic confirmation should be made by biopsy of either the metastatic focus or the primary tumor. MRI can be valuable when evaluating the extent of involvement of the collecting system or inferior vena cava, or radiographic contrast cannot be administered. Renal arteriography is sometimes helpful in planning surgery.

TABLE 67.1 DIAGNOSTIC WORKUP FOR RENAL CELL CARCINOMA

General
History and physical examination
If ≤46 years, refer to a hereditary cancer clinic for further evaluation[159]
Avoid biopsy if resection is being considered. Consider needle biopsy, if clinically indicated, for small lesions to confirm diagnosis or guide surveillance, cryosurgery, or radio-frequency ablation strategies
Radiographic Studies
Abdominal ± pelvic CT (preferred because it shows calcification and better visualization of other body parts) or abdominal MRI with or without contrast depending on renal function. MRI is superior to CT when evaluating the inferior vena cava and right atrium for tumor involvement
Consider CT urography, which allows imaging of both the renal parenchyma and the collecting system
As clinically indicated to rule out metastases:
Chest CT or chest x-ray
Bone scan, if patient has bone pain or has an elevated alkaline phosphatase

Brain MRI with or without contrast depending on renal function, if clinical signs, presentation, and symptoms are suggestive of brain metastases
Laboratory Studies
Urinalysis
Complete blood cell count (CBC)
Comprehensive metabolic panel (including LDH, serum corrected calcium, liver function tests, blood urea nitrogen, and serum creatinine)

CT, computed tomography; MRI, magnetic resonance imaging.

TABLE 67.2 DIAGNOSTIC WORKUP FOR RENAL PELVIS AND URETER CARCINOMA

General
History and physical examination
Radiographic Studies
CT of the abdomen and pelvis or MRI urogram
Multidetector CT urography (CTU)
Chest CT or chest radiograph
Bone scan, if patient has bone pain or has an elevated alkaline phosphatase
Brain MRI, if suspecting brain metastases
Special Tests
Cystoscopy, the entire urinary tract has to be evaluated due to the high incidence of multiple tumors
Ureteroscopic visualization of the tumor is desirable, and tissue biopsy through a ureteroscope may be performed if feasible
Urine cytology may help determine tumor grade if tissue is not available. False-negative rate can be high in upper tract and low-grade tumors
Laboratory Studies
Complete blood cell count
Comprehensive metabolic panel (including liver function tests, blood urea nitrogen, and serum creatinine)
Urinalysis

CT, computed tomography.

Renal Pelvis and Ureter Carcinoma

The diagnostic workup for renal pelvis and ureter carcinoma is listed in Table 67.2. Staging includes a complete history and physical examination, complete blood count, and liver and kidney function tests. CT urography is now used to evaluate patients with renal pelvis carcinoma. CT or MRI of the abdomen and pelvis before and after contrast administration gives useful information

regarding the possible extension of tumor outside the collecting system. Ureteroscopic visualization of the tumor is desirable, and tissue biopsy through a ureteroscope should be performed if feasible. Cystoscopy is very important because of the high incidence of multiple tumors. Urine cytology may help determine tumor grade if tissue is not available, but false-negative rates can be high for upper tract and low-grade tumors.

STAGING

Renal Cell Carcinoma

The American Joint Committee on Cancer (AJCC) system is currently being utilized to stage patients with RCC (Table 67.3).[50] T1 and T2 cancers are limited to the kidney. T3 tumors extend into major veins or perinephric tissues, but not into the ipsilateral adrenal gland and not beyond Gerota fascia. T4 tumors invade beyond Gerota fascia (including contiguous extension into the ipsilateral adrenal gland). Regional lymph node metastases may involve spread to the renal hilar, caval, and aortic drainage sites. Metastasis in regional lymph node(s) is classified as N1. This staging system underwent some modifications for the 8th edition: For T3a disease, the word “grossly” was eliminated from the description of renal vein involvement, “muscle containing” was eliminated, and “invasion of the pelvicalyceal system” was added.[50]

Renal Pelvis and Ureter Carcinoma

Tumors of the renal pelvis and ureter have a natural history that is not too dissimilar from that of other urothelial malignancies originating in the bladder. Their prognoses are dependent on tumor invasiveness and pathologic grade. The 2017 AJCC 8th edition staging classification for renal pelvis and ureter carcinoma is shown in Table 67.4.[51] This staging system underwent one modification for the 8th edition: The N3 category of a metastasis in a single lymph node larger than 5 cm in greatest dimension was collapsed into the N2 category.

TABLE 67.3 2017 KIDNEY CANCER TNM STAGING AJCC UICC

Primary tumor (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Tumor ≤7 cm in greatest dimension, limited to the kidney

T1a	Tumor ≤4 cm in greatest dimension, limited to the kidney
T1b	Tumor >4 cm but ≤7 cm in greatest dimension limited to the kidney
T2	Tumor >7 cm in greatest dimension, limited to the kidney
T2a	Tumor >7 cm but ≤10 cm in greatest dimension, limited to the kidney
T2b	Tumor >10 cm, limited to the kidney
T3	Tumor extends into major veins or perinephric tissues, but not into the ipsilateral adrenal gland and not beyond Gerota fascia
T3a	Tumor extends into the renal vein or its segmental branches, or tumor invades the **pelvicalyceal system** or invades perirenal and/or renal sinus fat but not beyond Gerota fascia
T3b	Tumor extends into the vena cava below the diaphragm
T3c	Tumor extends into the vena cava above the diaphragm or invades the wall of the vena cava
T4	Tumor invades beyond Gerota fascia (including contiguous extension into the ipsilateral adrenal gland)

Regional lymph Nodes (N)[a]

NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in regional lymph node(s)

Distant metastasis (M)

M0	No distant metastasis
M1	Distant metastasis

Stage grouping

Stage I	T1	N0	M0
Stage II	T2	N0	M0
Stage III	T1 or T2	N1	M0
	T3	N0, N1	M0
Stage IV	T4	Any N	M0
	Any T	Any N	M1

Histopathologic grade

GX	Grade cannot be assessed
G1	Nucleoli absent or inconspicuous and basophilic at 400× magnification
G2	Nucleoli conspicuous and eosinophilic at 400× magnification, visible but not prominent at 100× magnification
G3	Nucleoli conspicuous and eosinophilic at 100× magnification
G4	Marked nuclear pleomorphism and/or multinucleate giant cells and/or rhabdoid and/or sarcomatoid differentiation

[a]The regional lymph nodes are as follows: renal hilar, caval (precaval, interaortocaval, paracaval, and retrocaval), and aortic (preaortic, para-aortic, and retroaortic).

PATHOLOGIC CLASSIFICATION

Renal Cell Carcinoma

RCC is a group of malignancies arising from the epithelium of the renal tubules and comprises 90% of all malignancies in the kidney.[18] The World Health Organization (WHO) classifies renal cell tumors as clear cell RCC, multilocular cystic renal neoplasm of low malignant potential, papillary RCC, HLRCC-associated RCC, chromophobe RCC, collecting duct RCC, renal medullary carcinoma, MiT family translocation RCC, succinate dehydrogenase (SDH)-deficient RCC, mucinous tubular and spindle cell carcinoma, tubulocystic RCC, acquired cystic disease–associated RCC, clear cell papillary RCC, and unclassified RCC.[52]

Clear cell RCC is the most common (80% to 90% of tumors), followed papillary RCC (10% to 15%) and chromophobe RCC (4% to 5%). Papillary RCC can be subdivided into type 1, which tends to be low-grade and have a better prognosis, and type 2, which is the opposite, each biologically distinct. Renal medullary carcinoma is very aggressive malignancy mostly associated with young black patients with sickle cell trait and, less commonly, sickle cell disease.[53]

Renal Pelvis and Ureter Carcinoma

More than 90% of malignant tumors arising from the renal pelvis and ureter are urothelial (also called transitional cell) carcinomas. The WHO classifies urothelial tumors as infiltrating urothelial carcinoma or infiltrating urothelial carcinoma with the following variants: with squamous differentiation, with glandular differentiation, and with trophoblastic differentiation, nested, microcystic, micropapillary, lymphoepithelioma-like, plasmacytoid, sarcomatoid, giant cell, and undifferentiated.[52]

TABLE 67.4 2017 TUMORS OF THE RENAL PELVIS AND URETER TNM STAGING AJCC UICC

Primary tumor (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Ta	Papillary noninvasive carcinoma

Tis	Carcinoma *in situ*
T1	Tumor invades subepithelial connective tissue
T2	Tumor invades muscularis
T3	For renal pelvis only: Tumor invades beyond the muscularis into peripelvic fat or into the renal parenchyma For ureter only: Tumor invades beyond the muscularis into the periureteric fat
T4	Tumor invades adjacent organs, or through the kidney into the perinephric fat

Regional lymph Nodes (N)[a]

NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single lymph node, ≤2 cm in greatest dimension
N2	Metastasis in a single lymph node, >2 cm; or multiple lymph nodes

Distant metastasis (M)

M0	No distant metastasis
M1	Distant metastasis

Stage grouping

Stage 0a	Ta	N0	M0
Stage 0is	Tis	N0	M0
Stage I	T1	N0	M0
Stage II	T2	N0	M0
Stage III	T3	N0	M0
Stage IV	T4	N0	M0
	Any T	N1 or N2	M0
	Any T	Any N	M1

Histopathologic grade

WHO/ISUP recommended grading for urothelial histologies:

LG	Low grade
HG	High grade

For squamous cell carcinoma and adenocarcinoma:

GX	Grade cannot be assessed
G1	Well differentiated
G2	Moderately differentiated
G3	Poorly differentiated
G4	Undifferentiated

[a]The regional lymph nodes for the renal pelvis are renal, hilar, paracaval, aortic, and retroperitoneal, NOS. The regional lymph nodes for the ureter are as follows: renal hilar, iliac (common, internal [hypogastric], external), paracaval, periureteral, and pelvic, NOS.

PROGNOSTIC FACTORS

Renal Cell Carcinoma

The 5-year survival rate of patients with kidney cancer has doubled over the last 50 years, from 34% in 1954 to 70.9% in 2007.[54,55] The stage at initial presentation remains the most important prognostic factor for RCC survival. Prognostic features for RCC are tumor, patient, and laboratory related. Tumor-related prognostic factors include stage, tumor size, tumor grade, histologic type, tumor necrosis, sarcomatoid transformation, and ≥2 sites of organ metastases. Patient-related factors include asymptomatic versus local symptoms versus systemic symptoms, weight loss, paraneoplastic syndromes, and an interval of less than a year from original diagnosis to start of systemic therapy. Laboratory prognostic factors include thrombocytosis, and elevated ESR or CRP.[50,56]

For patients with metastatic RCC, the following factors were predictive of survival in a retrospective study of 670 patients: low Karnofsky performance status (<80), high LDH (>1.5 times upper limit of normal), low hemoglobin (less than lower limit of normal), high “corrected” serum calcium (>10 mg/dL or 2.5 mmol/L), and absence of prior nephrectomy.[57]

Lymph node metastases are associated with increased rates of local recurrence and distant metastasis.[36,58–60] Nuclear grade, sarcomatoid component, tumor size, stage, and the presence of tumor necrosis increase the likelihood of lymph node involvement.[61] The overall risk of lymph node metastases is 20%.[62,63] Patients with lymph node metastases in radical nephrectomy specimens have a local failure rate of 21%, compared with only 4% in patients without lymph node metastases (P = .0002).[60] A select group of patients with solitary metastases may have a 5-year survival rate of 25% to 35%.[64,65]

Nuclear grade, after stage, is the most important prognostic feature of clear cell carcinoma. Fuhrman developed a four-tier grading system that is based upon nuclear and nucleolar size, shape, and content.[66] Fuhrman grade is the most widely used grading system. Grade is also an independent prognostic factor for papillary RCC and chromophobe RCC especially when using standardized criteria.[67] Worsening pathologic grade is associated with a poor 5-year disease-free survival.[31,36]

Papillary RCC has a 5-year survival rate that approaches 90% and metastasizes less frequently than clear cell RCC. The spindle cell or sarcomatoid

variants of RCC are associated with statistically significant inferior 5-year survival rates, compared with pure clear or clear and granular histologic variants.[31,36]

Nuclear morphology is a strong predictor of tumor stage and prognosis.[66] High nuclear grade is associated with an increased incidence of advanced tumor stage, lymph node involvement, distant metastases, renal vein involvement, tumor size, and perirenal fat involvement. In a series of 190 patients reported by Bretheau and colleagues,[68] the 5-year actuarial survival rates of patients with grade I, II, III, and IV tumors were 76%, 72%, 51%, and 35%, respectively. Sarcomatoid differentiation carries a significantly poorer prognosis than the clear cell or granular cell subtypes. Almost half of patients with sarcomatoid RCC have bone metastases at presentation. The median survival time of patients with sarcomatoid renal cell cancer is only 6.6 months, compared with 19 months for other histologic types.[69]

Nomograms and algorithms have been described to facilitate the determination of cancer-free survival in patients with RCC. Based on 601 patients treated at Memorial Sloan Kettering Cancer Center with radical nephrectomy, Kattan used variables including patient symptoms (incidental, local, or systemic), histology (chromophobe, papillary, or conventional), tumor size, and pathologic stage to predict risk of recurrence after surgery (note: uses older 1997 staging and is available at the Memorial Sloan Kettering Cancer Center website https://www.mskcc.org/nomograms/renal/post-op).[70] Frank et al.[71] from the Mayo Clinic developed a predictive algorithm based upon 1,801 patients treated with radical nephrectomy. This system combines stage, size, grade, and necrosis (SSIGN) to predict patient survival. Finally, Zisman et al.[72] from UCLA have developed an algorithm that utilizes AJCC TNM stage, Fuhrman grade, and Eastern Cooperative Oncology Group (ECOG) performance status to divide patients into low-risk, intermediate-risk, and high-risk groups. This model is also known as the UISS or the UCLA integrated staging system.

A number of molecular markers are being explored for their prognostic significance including lack of B7H1 expression,[73] immunohistochemical detection of carbonic anhydrase IX (CAIX),[74] the proliferative marker Ki67,[74] immunohistochemical expression of IMP3,[75] and others.

Renal Pelvis and Ureter Carcinoma

The major prognostic factors in patients with renal pelvis or ureter carcinoma are initial stage and grade of the tumor. There is no significant difference in

prognosis between urothelial carcinomas originating in the ureter compared to those arising in the renal pelvis.[76]

High-grade tumors are associated with a higher incidence of metastases and worse survival. Corrado et al.[77] reported 5-year survival rates of 83%, 75%, 52%, and 0% for grades 1 through 4, respectively. These results are comparable to those described by Heney and colleagues,[78] who reported 100% survival for grade 1, 81% for grade 2, and 0% for grade 3. Local recurrence was identified in three of 24 patients with grade 3 tumors. No survival differences were seen for patients with papillary versus solid tumors. In the series of Charbit et al.,[23] lymph node metastases were seen exclusively in patients with high-grade tumors. Of tumor-related deaths, 90% were in patients with high-grade tumors. Hall et al.[79] reported a retrospective series of 252 patients treated surgically for upper urinary tract urothelial cancers. Significant factors for recurrence included high tumor grade and advanced clinical stage. Older patients and patients treated with parenchymal-sparing surgical procedures had higher rates of recurrence. In their series of 77 patients, Akdogan et al.[80] reported from a multivariate analysis that higher recurrence rates were associated with tumor location, higher grade, and advanced T-stage. Tumors in the ureters were more likely to recur than tumors involving the renal pelvis. In a series of 86 patients, Park et al. also reported a higher rate of recurrence in ureteral tumors, compared to those arising in the renal pelvis.[81]

A prior history of bladder cancer has been reported to worsen the prognosis of patients with second urothelial cancers involving the upper tracts.[80,82] From the Memorial Sloan Kettering Cancer Center series of 129 patients, a multivariate analysis demonstrated that patients with advanced primary tumors and a prior history of bladder cancer were associated with worse disease-free survival.[82]

Flow cytometry may aid in estimating long-term prognosis. In a multivariate analysis, Corrado et al.[77] demonstrated that, although stage and grade were the most important prognostic indices, DNA pattern (diploid vs. nondiploid) and the number of lesions (unifocal vs. multifocal) identified at initial diagnosis also determined prognosis. Patients with diploid tumors had a 79% survival rate, compared with only 46% in patients with nondiploid tumors ($P = .0003$). Recent data suggest that hypermethylation of the promoter region of patients with urothelial cancers of the urothelium is associated with a worse prognosis. Tumors of the renal pelvis and ureters demonstrate hypermethylation in 94% of cases compared to 76% of similar appearing tumors in the bladder, $P < .0001$. Hypermethylation was also associated with higher tumor stage, tumor

progression, and mortality.[83]

GENERAL MANAGEMENT

Renal Cell Carcinoma

Surgery is the therapeutic foundation for the management of kidney cancer. Radiotherapy has an important and growing role in the palliative management of RCC. Although RCC is traditionally considered to be radioresistant, it has a clear dose response to radiation.[84,85] As long as sufficient radiation dose is delivered to the tumor while respecting normal tissue dose constraints, RCC "radioresistance" can be overcome with modern techniques. The kidney cancer NCCN guidelines (version 2.2017) offer the following surgical options depending on the stage[86]:

- Stage I (pT1a): partial (preferred) or radical nephrectomy (if partial not feasible or central location), active surveillance, or ablative techniques in selected patients
- Stage I (pT1b): partial or radical nephrectomy
- Stage II and III: radical nephrectomy or partial nephrectomy if clinically indicated
- Stage IV: nephrectomy and surgical metastasectomy if potentially resectable primary with solitary metastatic site, followed by systemic first-line therapy; cytoreductive nephrectomy if potentially resectable primary with solitary metastatic site, followed by systemic first-line therapy; or systemic first-line therapy if surgically unresectable

Elderly patients and those with small renal masses and other comorbidities often have a low RCC-specific mortality.[87]

Surgery

A radical nephrectomy includes a perifascial resection of the kidney, perirenal fat, regional lymph nodes, and ipsilateral adrenal gland. It is the preferred treatment if the tumor extends into the inferior vena cava and usually requires the assistance of a cardiovascular surgeon if there is a caval or atrial thrombus. Adrenalectomy is not indicated when imaging shows a normal adrenal gland or if the tumor is not high-risk.[88] An experienced team should be involved in the context of thrombus, as treatment-related mortality can reach 10%.[86] Open, robotic, and laparoscopic techniques may be used to perform a radical nephrectomy. Improved preoperative assessment with CT can identify patients

who have no significant risk of adrenal gland involvement.[89] In 76% of cases, the adrenal gland can be spared at the time of surgery. The EORTC conducted a randomized trial of radical nephrectomy with or without an elective lymph node dissection, and there was no survival advantage between the two study groups. The incidence of unsuspected lymph node metastases was low (4%).[90] Nevertheless, the lymph node dissection does provide valuable prognostic information.

Radical nephrectomies should be avoided if nephron-sparing surgery is feasible for T1a and T1b renal tumors. In this setting, nephron-sparing surgery has shown equivalent outcomes to radical nephrectomy.[91,92] Radical nephrectomy–induced chronic renal insufficiency is associated with an increased risk of cardiovascular death and death from any cause.[93] For this reason, nephron-sparing surgery is preferred in T1a and T1b tumors. Nephron-sparing surgery is also preferred in patients with hereditary RCC to preserve renal function and decrease the risk of cardiovascular events.[94] In a matched-pair analysis of 164 patients undergoing nephron-sparing surgery at the Mayo Clinic, the disease-free survival was 79%, which compared favorably to 77% in patients undergoing radical nephrectomy.[95] In 117 patients with renal tumors 4 cm or less undergoing partial nephrectomy at the Memorial Sloan Kettering Cancer Center, the 5-year freedom from recurrence was 98.6% compared to 96.4% in a similar group of 173 patients undergoing radical nephrectomy. Compared to patients undergoing partial nephrectomy, those undergoing radical nephrectomy were at a higher risk of chronic renal insufficiency.[96] There is some risk that sparing of the renal parenchyma may leave microscopic residual tumor or inadequately treat multifocal cancers.[97–99] Bilateral RCC occurs in 2% to 3% of patients. In these patients, nephron-sparing surgery is an attractive option because bilateral radical nephrectomy sentences the patient to a lifetime of renal dialysis or the need for a renal transplant.

Following surgery, 20% to 30% of patients with localized tumors relapse, with a median time to relapse of 1 to 2 years, and most occurring within 3 years.[86] Although at present there is no role for adjuvant therapy after surgery, a number of recent trials are exploring the role of targeted therapy.

Patients who have local symptoms, such as hematuria, pain, hypertension, or other paraneoplastic syndromes, may benefit from a palliative nephrectomy. Spontaneous regression of metastatic renal cell cancer after nephrectomy has been reported. In an extensive literature review, the incidence of regression of metastatic foci induced by nephrectomy was 0.8% (4 of 474 patients).[33]

Cytoreductive surgery performed to prolong or increase the response of metastatic disease in response to systemic therapy may be beneficial.[100–102]

Thermal Ablation

Recently, the minimally invasive ablative technologies of cryoablation and radio-frequency ablation (RFA) have emerged as potential treatment options for clinically localized RCC, especially in the elderly, or patients with a solitary kidney or comorbidities impeding surgery. Long-term oncologic efficacy for these modalities remains to be established. The most favorable lesions for this approach are <4 cm and in the periphery of the kidney. Relative contraindications for RFA and cryoablation include distant metastases, tumors > 5 cm, tumors in the hilum or central collecting system, and life expectancy less than a year. A meta-analysis comparing cryoablation and RFA suggested that cryoablation results in fewer retreatments and improved local tumor control and that cryoablation may be associated with a lower risk of metastatic progression compared with RFA.[103]

Systemic Therapy in the Treatment for Relapsed, Metastatic, or Unresectable Renal Cell Carcinoma

Until 2005, systemic treatment for RCC was mostly limited to cytokine therapy. The NCCN guidelines list the following first-line systemic therapies for clear cell histology: pazopanib (Category 1, preferred), sunitinib (Category 1, preferred), bevacizumab + interferon (Category 1), temsirolimus (Category 1 for poor-prognosis patients and Category 2B for selected patients of other groups), axitinib, high-dose IL-2 for selected patients, and sorafenib for selected patients. Subsequent therapy includes cabozantinib (Category 1, preferred), nivolumab (Category 1, preferred), axitinib (Category 1), everolimus, pazopanib, sorafenib, sunitinib, bevacizumab (Category 2B), high-dose IL-2 for selected patients, or temsirolimus (Category 2B).[86]

For non–clear cell histology, the NCCN guidelines list the following first-line systemic therapies: sunitinib, axitinib, bevacizumab, cabozantinib, erlotinib, everolimus, lenvatinib + everolimus, nivolumab, pazopanib, sorafenib, and temsirolimus (Category 1 for poor-prognosis patients and Category 2A for other risk groups).[86]

Pazopanib is a multikinase inhibitor targeting c-KIT, FGFR, PDGFR, and VEGFR. Sunitinib is a multikinase inhibitor targeting c-KIT, FGFR, FLT-3, CSF-1R, PDGFR, VEGFR, and RET. Bevacizumab is a recombinant

monoclonal antibody that binds VEGF-A. Temsirolimus and everolimus are mTOR inhibitors. Axitinib is a small molecule tyrosine kinase inhibitor targeting VEGF, c-KIT, and PDGFR. Sorafenib is a small inhibitor of several tyrosine protein kinases, such as VEGFR, PDGFR, and Raf family kinases. Cabozantinib is a small molecule inhibitor of the tyrosine kinases c-Met and VEGFR2. Nivolumab is an antibody that selectively blocks the interaction between PD-1 and its ligands. Erlotinib is a receptor tyrosine kinase inhibitor of EGFR. Lenvatinib is a multikinase inhibitor targeting VEGFR, FGFR, PDGFR, c-KIT, and RET.

Chemotherapy has limited use in RCC because it is one of the most chemotherapy-resistant solid tumors. Gemcitabine in combination with doxorubicin or sunitinib has shown some benefit in patients with sarcomatoid features (Category 2B).

Metastasectomy

Patients with a solitary metastatic lesion have a 5-year survival rate of 24% (compared with 4% for those with more than one metastatic focus), and they may benefit from aggressive therapy.[104] The resection of one or a limited number of metastases in combination with nephrectomy or at relapse has been associated with a 13% to 50% 5-year survival in small series of selected patients.[105–107] Selected lung, bone, brain, liver, and even pancreatic metastases, among other sites, have been treated using this approach.

Radiation Therapy (RT) Trends

A study of the National Cancer Database in the United States observed a decrease in the use of RT for patients with RCC from 1998 to 2010. Patients with more aggressive disease characteristics were more likely to receive RT. Of 233,572 patients diagnosed with nonmetastatic RCC between 1998 and 2010, 0.9% were treated using radiotherapy. Overall, there was a decreasing trend in the utilization of RT (1.5% in 1998 to 0.6% in 2010; $P < .001$). Of 45,855 patients diagnosed with metastatic RCC, 30% received radiotherapy. Overall, there was a decreasing trend in the utilization of RT from 1998 to 2010 (33.3% to 28.5%; $P < .001$).[108] Nevertheless, there is an increased interest in dose escalation using single fractions and other hypofractionated regimens for the primary treatment of kidney lesions and palliation of cranial and extracranial metastases.

Neoadjuvant (Preoperative) Radiation Therapy

Neoadjuvant radiotherapy is not recommended in patients with resectable RCC. Two European studies were undertaken to test the efficacy of neoadjuvant/preoperative RT in RCC (Table 67.5). A prospective randomized study of neoadjuvant RT and nephrectomy versus nephrectomy alone was conducted in Rotterdam. No advantage was demonstrated in patients receiving 30 Gy RT in 2 Gy fractions with respect to overall survival or survival free of distant metastasis. Neoadjuvant radiotherapy did appear to increase the rate of complete resectability in patients with locally advanced tumors.[109] Subsequent patients received 40 Gy in 2 Gy fractions. No benefit was demonstrated at the higher radiation dose.[110] In Sweden, a second prospective randomized clinical trial was also unable to demonstrate an advantage for neoadjuvant radiotherapy. In this trial, patients were randomly assigned to receive neoadjuvant RT to 33 Gy in 15 fractions administered to the flank with a betatron unit followed by nephrectomy or nephrectomy alone. Patients receiving neoadjuvant RT had a 5-year survival rate of 47%, compared with 63% for patients undergoing surgery alone.[111]

Adjuvant (Postoperative) Radiotherapy

Adjuvant radiation therapy is not recommended in RCC after complete resection. Two prospective randomized studies testing the value of adjuvant radiation therapy did not demonstrate an advantage to patients receiving RT after surgery (Table 67.6). The first study from New Castle, United Kingdom, demonstrated an inferior survival for patients receiving adjuvant RT compared with those treated by surgery alone.[112] Local tumor recurrence rates were not affected by adjuvant RT. Four patients died of fatal hepatotoxicity after RT to a right-sided nephrectomy bed. Patients in this study received 55 Gy in 2.04-Gy daily fractions.[7] A second randomized study conducted by the Copenhagen Renal Cancer Study Group compared patients with stage II or III renal cell cancer treated with nephrectomy alone with patients who received nephrectomy and adjuvant RT to 50 Gy in 20 fractions to the kidney bed and regional ipsilateral and contralateral lymph nodes. No difference in the relapse rate was found between the two study groups. There were significant complications involving the stomach, duodenum, and liver in 44% of patients receiving adjuvant RT. Specifically, 19% of deaths in the RT group were attributed to RT-induced complications.[113]

Aref et al. analyzed the patterns of failure in 116 patients undergoing nephrectomy for RCC. They observed that locoregional failure is rare following

nephrectomy and that distant metastases is the main pattern of failure. Consequently, their data did not support the role of adjuvant radiation in RCC.[114] Moreover, a retrospective study of 1,344 patients who underwent 1,390 partial nephrectomies for kidney cancer found that positive surgical margins were not associated with an increased risk of local tumor recurrence or metastatic disease.[115] A SEER-based study of adjuvant RT in sarcomatoid RCC did not show an overall survival benefit.[116]

In contrast, a meta-analysis including the two prospective randomized trials previously mentioned and five retrospective trials with a total of 735 patients observed a significant reduction in locoregional failure with adjuvant RT ($P < .0001$). The patient accrual for all the studies combined spanned from 1968 to 1999. There was no difference in overall survival or disease-free survival. The authors proposed a prospective randomized trial using modern RT techniques for high-risk patients with tumor size > 5 cm, positive margins or gross residual disease, perinephric fat invasion, capsule invasion, renal vein/inferior vena cava invasion, positive lymph nodes, or high-grade histology.[117]

Stereotactic Body Radiation Therapy (SBRT) for Primary Treatment

A number of small phase I and II trials are exploring the role of SBRT in the primary treatment of renal tumors. The largest of these studies included 40 patients, 11 with transitional cell cancer and 29 with RCC. All tumors were treated with a single 25-Gy fraction to the 70% isodose. The local tumor control rate 9 months after SBRT was 98% (95% CI 89 to 99). There was a measurable size reduction in 38 lesions, including complete remission in 19.[118]

Whole-Brain Radiation Therapy for Brain Metastases

A retrospective study of 60 patients receiving whole-brain radiotherapy (WBRT) for RCC brain metastases showed that local control (LC) at 6 months was 21% after 3 Gy × 10 and 57% after higher doses of 2 Gy × 20 or 3 Gy × 15 ($P = .013$). The LC at 12 months was 7% and 35%, respectively. The overall survival (OS) at 6 months was 29% after 3 Gy × 10 and 52% after higher doses ($P = .003$). The OS at 12 months was 13% and 47%, respectively. The authors concluded that escalating the WBRT dose beyond 3 Gy × 10 could improve the outcomes in RCC patients with brain metastases.[119]

TABLE 67.5 SURVIVAL AFTER NEPHRECTOMY OR NEOADJUVANT RADIOTHERAPY AND NEPHRECTOMY FOR

RENAL CELL CARCINOMA, PROSPECTIVE RANDOMIZED TRIALS

Study	No. of Patients	Radiation Dose/Fraction Size (Gy)	Treatment	5-Yr Survival Rate (%)	Comments

Stereotactic Radiosurgery (SRS) for Brain Metastases

A retrospective study of 280 consecutive patients with metastatic brain tumors (of which 80 were RCC) treated with gamma knife radiosurgery (GKS) observed that to control symptomatic peritumoral edema, a higher marginal dose of 25 Gy or more was necessary. The authors developed an algorithm for the management of RCC metastases where lesions ≥ 3 cm undergo resection; lesions > 2 cm with symptomatic peritumoral edema undergo resection (because a 25 Gy was not considered safe for tumors > 2 cm) and those without it GKS; and lesions ≤ 2 cm receive GKS.[120] Another retrospective study of 46 patients and 99 RCC brain lesions treated with radiosurgery observed that the good-response group (as assessed by MRI) survived significantly longer than the poor-response group

(median survival times of 18.0 and 9.0 months, respectively; $P = .025$).[121]

Kano et al. reported 158 consecutive RCC patients (531 lesions) who underwent stereotactic radiosurgery. The overall survival after SRS was 60%, 38%, and 19% at 6, 12, and 24 months, respectively, with a median survival of 8.2 months. Median survival for patients with <2 brain metastases, higher KPS (>90), and no prior WBRT was 12 months after SRS. Sustained local tumor control was achieved in 92% of patients. Symptomatic adverse radiation effects occurred in 7%. Overall, 70% of patients improved or remained neurologically stable.[122]

A retrospective study of 61 patients with RCC treated with GKS, median dose 20 Gy, showed that the use of targeted agents (tyrosine kinase inhibitors, mammalian target rapamycin inhibitors, and bevacizumab) was the only factor that predicted for improved survival. The median survival for patients receiving targeted agents ($n = 24$) was 16.6 months compared with 7.2 months ($n = 37$) for those not receiving targeted therapy ($P = .04$).[123]

A systematic review including 16 publications of cranial RCC showed that the weighted local control was 92%, overall survival ranged from 6.7 to 25.6 months, grade 3 to 4 toxicity ranged from 0% to 6%, and the weighted rate of treatment-related mortality was 0.6% secondary to intratumoral hemorrhage.[124]

Conventional Radiation Therapy for Extracranial Metastases

Palliative radiotherapy is effective at relieving symptoms from metastatic renal cell cancer.[125–128] A patient with a solitary bone metastasis may have a long survival time, and a sufficient radiation dose should be administered to allow durable pain relief. If surgery is used to remove a metastatic lesion, postoperative radiotherapy is indicated to prevent its recurrence. In a prospective phase II study using validated quality of life questionnaires, Lee and colleagues from the Princess Margaret Hospital demonstrated that 83% of patients treated for pain had experienced significant pain relief with 30-Gy radiation delivered in 10 fractions.[127] DiBiase et al. observed a dose response in the palliative treatment of 107 patients with RCC. A biologically effective dose (BED) > 50 Gy_{10} (α/β ratio of 10) was associated with a statistically significant increased rate of response: 59% versus 39% ($P = .001$).[84]

Figure 67.1 illustrates a painful RCC cutaneous metastasis that had a complete response after 375 cGy × 13 fractions (BED = 67 Gy_{10}) over 5 weeks. The lesion was treated with electrons, a custom bolus, and 2-cm peripheral margin.[129]

FIGURE 67.1. Patient with RCC who received 375 cGy × 13 fractions over 5 weeks to a painful, fixed, and pulsatile cutaneous RCC metastasis. Appearance after **(A)** 3 fractions and **(B)** complete response 6 months after the completion of treatment. The patient had durable pain palliation without local recurrence until death. (From Gay HA, Cavalieri R, Allison RR, et al. Complete response in a cutaneous facial metastatic nodule from renal cell carcinoma after hypofractionated radiotherapy. *Dermatol Online J* 2007;13[4]:6; © 2007 Dermatology Online Journal. Reprinted with permission of Dr. Hiram A. Gay.)

Stereotactic Body Radiation Therapy for Extracranial Metastases

A systematic review including 10 publications of extracranial RCC showed that the weighted local tumor control was 89%, overall survival ranged from 11.7 to 22 months, grade 3 to 4 toxicity ranged from 0% to 4%, and the weighted rate of treatment-related mortality was 0.5%.[124]

Zelefsky et al. reported 105 RCC lesions treated with either single-dose, image-guided, intensity-modulated radiotherapy (IMRT) to a prescription dose of 18 to 24 Gy (median, 24) or hypofractionation (3 or 5 fractions) with a prescription dose of 20 to 30 Gy. The 3-year local progression-free survival for those who received a high single-dose (24 Gy; $n = 45$), a low single-dose (<24 Gy; $n = 14$), or hypofractionation regimens ($n = 46$) was 88%, 21%, and 17%, respectively. Multivariate analysis showed that significant predictors of improved local progression-free survival were 24 Gy versus a lower dose ($P = .009$) and a single dose versus hypofractionation ($P = .008$).[130]

In a series of 50 patients with metastatic RCC, Wersäll et al. reported that stereotactically delivered radiation to sites including the lung, liver, and adrenal resulted in complete regression in 30% of cases and either partial regression or stabilization of the lesions in 60%.[131] Of 162 treated tumors, only 3 recurred. Dose and fractionation ranged from 8 Gy × 4, 10 Gy × 4, and 15 Gy × 3 all

delivered in 1 week.

Spine

In a study of 48 patients (55 lesions) with metastatic RCC to the spine, patients received 24 Gy × 1, 9 Gy × 3, or 6 Gy × 5 fractions. The actuarial 1-year spine tumor progression-free survival was 82.1%. At pretreatment baseline, 23% patients were pain-free; at 1 and 12 months post-SBRT, 44% and 52% patients were pain-free, respectively. No grade 3 to 4 neurologic toxicity was observed.[132] A prospectively collected study of 71 spinal segments treated with SBRT showed that the 1-year overall survival and LC rates were 64% and 83%, respectively. The 1-year vertebral compression fracture (VCF)-free probability rate was 82%. Multivariate analysis identified single-fraction SBRT (18 to 24 Gy) and baseline VCF as significant predictors of SBRT-induced VCF (P = .028 and P = .012, respectively).[133] A retrospective study of 57 patients with RCC metastases to the spine who received single-fraction SBRT to 88 treatment sites showed that the median time to radiographic failure and unadjusted pain progression were 26.5 and 26.0 months, respectively. The median time to pain relief from simulation and duration of pain relief from treatment were 0.9 months (range 0.1 to 4.4 months) and 5.4 months (range 0.1 to 37.4 months), respectively. Multivariate analyses demonstrated that multilevel disease and neural foramen involvement were correlated with radiographic failure; multilevel disease and vertebral fracture were correlated with unadjusted pain progression. Twelve treatment sites (14%) were complicated by subsequent vertebral fractures.[134]

Bone

A study was conducted on 46 consecutive RCC patients with 95 lesions who were treated as follows: 50 SBRT and 45 conventional fractionation (CF) RT. A biologically effective dose ≥ 80 Gy (α/β = 7) was predictive of clinical local control. Median time to symptom control between SBRT and CFRT was 2 (range, 0 to 6 weeks) and 4 weeks (range, 0 to 7 weeks), respectively. Toxicity rates were low and equivalent in both groups, with no grade 4 or 5 toxicity reported.[135]

A potential added benefit of extracranial stereotactic radiotherapy is what is called the abscopal effect, in which there is tumor response at a distance from the irradiated volume. Wersäll and colleagues observed an abscopal effect in 4 out of 28 RCC patients with treated and untreated metastatic lesions. In these 4

patients, nonirradiated metastases regressed either temporarily or seemingly permanently after treatment with SBRT of either the primary tumor or other metastatic lesions. The authors' findings argued for a more active and liberal use of SBRT in metastatic RCC. They suggested that further studies were necessary to define the underlying mechanisms behind such responses or to combine SBRT with immunomodulating agents.[136]

Intraoperative Radiation Therapy for Advanced or Recurrent RCC

A retrospective study of 98 patients who received intraoperative radiation therapy (IORT) for advanced or locally recurrent RCC at 9 institutions showed a 5-year overall survival of 37% for advanced disease and 55% for locally recurrent disease. The respective 5-year disease-free survival was 39% and 52%. IORT was delivered during nephrectomy for advanced disease (28%) or during resection of locally recurrent RCC in the renal fossa (72%). Preoperative or postoperative external beam radiation therapy was administered to 27% and 35% of patients, respectively. Initial nodal involvement, presence of sarcomatoid features, and higher IORT dose were statistically significantly associated with decreased survival. The outcomes for patients receiving IORT in the setting of local recurrence compared favorably to similar cohorts treated by local resection alone.[137]

Ongoing Phase III Clinical Trials

There are numerous clinical trials taking place in advanced RCC. Many of these trials are employing antiangiogenesis agents, thymidine kinase inhibitors, tyrosine kinase inhibitors, mTOR inhibitors, anti–PD-1 monoclonal antibodies, and other immunologic therapies alone or in combination.

Renal Pelvis and Ureter Carcinoma

Surgery is the therapeutic foundation for the management of renal pelvis and ureter carcinoma. The bladder cancer NCCN guidelines (version 2.2017) recommend the following treatment options for renal pelvis low-grade tumors: nephroureterectomy with a cuff of bladder or endoscopic resection ± postsurgical intrapelvic chemotherapy or BCG.[138] High-grade renal pelvis tumors, large tumors, or tumors that invade the renal parenchyma have the following management options: nephroureterectomy with a cuff of bladder and regional lymphadenectomy, with consideration of neoadjuvant chemotherapy in selected patients.

The management of ureter tumors depends on the location of the tumor,

upper, mid, or distal location, and on disease extent. Neoadjuvant chemotherapy may be considered in selected patients.[139]

For both renal pelvis and ureter tumors, once the pathologic staging is obtained, patients with pathologic stage pT2, pT3, pT4, or N+ should be considered for adjuvant chemotherapy with or without radiotherapy.

Surgery

Radical nephroureterectomy is the only potentially curative treatment for most patients with urothelial carcinoma of the renal pelvis or ureter. This operation includes removal of the contents of Gerota fascia, including the ipsilateral ureter with a cuff of bladder at its distal extent. Less radical surgeries have been plagued by high local or regional recurrence rates, sometimes approaching 30%.[140] Hall et al.[79] reported an increase rate of recurrence when parenchymal-sparing procedures were performed. Conservative surgical excision should be considered only in patients with low-grade, low-stage, solitary tumors in whom radical nephrectomy is not indicated because of poor kidney function or an absent contralateral kidney. Conservative surgical options in selected cases include laparoscopic nephroureterectomy, nephrectomy and partial ureterectomy, endoscopic resection, and fulguration. The role of lymph node dissection in this disease is unclear. Patients who have the highest risk of lymph node metastases also have a high risk of systemic disease.

Adjuvant Radiation Therapy

There are no randomized trials on the role of postoperative RT in patients who have had a complete resection of an upper urinary tract cancer. Tumors of the renal pelvis and ureter have a significantly high local recurrence rate after nephroureterectomy, particularly in patients with high-grade tumors or deep invasion.[141] Retrospective studies suggest that adjuvant RT may diminish the likelihood of local tumor recurrence, but it does not appear to have an impact on overall survival or reducing future distant metastases.[34,142]

Cozad et al. reported a retrospective study of 94 patients with urothelial carcinoma of the renal pelvis, of which 77 had resections without residual. On multivariate analysis, adjuvant RT had a significant effect on local control (P = .02). In terms of survival, the use of adjuvant radiation therapy was of borderline significance (P = .07). Of the 27 patients that were excluded from local failure and survival analysis, 19 had unresectable local disease and of these 11 received radiation therapy. Two long-term disease-free survivors in this group received 45

and 50.4 Gy. The authors recommended consideration of adjuvant radiotherapy in patients with high grade or stage, close surgical margins, or positive lymph nodes to improve local control.[34]

In another retrospective study of 133 patients with urothelial carcinoma of the renal pelvis, 67 patients received external beam RT following surgery (RT group) and 66 patients received intravesical chemotherapy (non-RT group). The clinical target volume included the renal fossa, the course of the ureter to the entire bladder, and the paracaval and para-aortic lymph nodes (Fig. 67.2). The tumor bed or residual tumor was targeted in 14 patients. The median radiation dose administered was 50 Gy. There was a significant difference between the survival rates for these groups based on patients with T3/T4 stage cancer. A significant difference was observed in the bladder tumor relapse rate between the irradiated and nonirradiated bladder groups (P = .004). The authors concluded that radiation therapy may improve the overall survival for patients with T3/T4 cancer of the renal pelvis or ureter and delay bladder tumor recurrences.[143]

The patterns of failure were described in 252 patients undergoing surgery at the University of Texas Southwest Medical Center for urothelial carcinoma of the upper urinary tract.[79] Local recurrence occurred only 9% of the time, whereas new invasive urothelial tumors or distant metastases occurred in 69% and 22% of cases, respectively. Isolated local recurrences were rare. Another series from the Princess Margaret Hospital confirms the high rate of distant metastases. Although local failure occurred in 35% of patients with locally advanced disease, most patients also experienced distant metastases as well.[144]

Systemic Chemotherapy

The pathologic similarity of urothelial carcinoma of the renal pelvis and ureter to bladder cancer has encouraged medical oncologists to use similar chemotherapeutic regimens in the management of upper tract urothelial carcinomas. Dose-dense methotrexate, vinblastine, doxorubicin, and cisplatin (ddMVAC) for 3 or 4 cycles and gemcitabine and cisplatin for 4 cycles are considered standard neoadjuvant or adjuvant regimens. Standard MVAC is no longer used because it is less efficacious and more toxic ddMVAC.[145] Radiosensitizing chemotherapeutic agents include cisplatin, taxanes (docetaxel or paclitaxel) (Category 2B), 5-FU (Category 2B), 5-FU and mitomycin (Category 2B), capecitabine (Category 3), and low-dose gemcitabine (Category 2B).[138]

Ongoing Phase III Clinical Trials

There are various clinical trials enrolling patients with renal pelvis and ureter carcinoma. Some of these trials are employing tyrosine kinase inhibitors, ATR kinase inhibitors, anti–PD-1 monoclonal antibodies, and other immunologic therapies alone or in combination with chemotherapy.

RADIATION THERAPY TECHNIQUES

Normal Tissue Dose Constraints

A number of organs at risk have to be taken into consideration when palliating an unresected kidney tumor or a kidney tumor bed recurrence. These organs include the spinal cord, liver, spleen, stomach, duodenum, small bowel, any normal contralateral or ipsilateral kidney, and normal adrenal gland(s).

There are no established dose constraints for sparing the remaining kidney after nephrectomy or in the palliative setting when both kidneys are present. In the context of two normal kidneys, the QUANTEC kidney panel recommended a mean bilateral kidney dose of <15 to 18 Gy and a bilateral kidney DVH with a $V_{12} < 55\%$, $V_{20} < 32\%$, $V_{23} < 30\%$, and $V_{28} < 20\%$.[146] The dose to the stomach should be kept below 45 Gy and the small bowel $V_{45} < 195$ cc when it is contoured as a bowel bag (Fig. 67.3).[147] The male and female RTOG normal pelvis atlases illustrate how to contour the bowel bag and are accessible at http://www.rtog.org/CoreLab/ContouringAtlases.aspx. The mean liver dose should be kept below 30 to 32 Gy, excluding patients with pre-existing liver disease or hepatocellular carcinoma who have a lower tolerance. Sparing at least 700 cc of the liver from radiation is another potential strategy to avoid complications.[148] There are no recognized splenic or adrenal dose constraints. Nevertheless, based on the spleen's exquisite radiosensitivity and experience with palliative radiotherapy for myeloproliferative disorders,[149] it seems prudent to limit the spleen to a total of 5 to 10 Gy. The spinal dose should be limited to an absolute maximum of 45 Gy.

Renal Cell Carcinoma

Neoadjuvant or adjuvant radiotherapy is not routinely recommended for patients with RCC. However, there may be special cases where the clinician may consider neoadjuvant radiotherapy to improve respectability or adjuvant radiotherapy if there are clinical tumor features suggestive of a high risk of local recurrence. Careful planning is paramount because ignoring any of the critical

structures surrounding the kidney or nephrectomy bed could result in serious, even fatal, patient toxicity.

Patients receiving radiation therapy to the kidney may be simulated supine, arms up, using a wing board or alpha cradle, a wire on the surgical scar, and a planning CT scan. The kidneys are mobile organs and move vertically within the retroperitoneum an average of 0.9 to 1.3 cm and as much as 4 cm during normal respiration.[150–152] In going from the supine to upright position, the kidneys can shift inferiorly between 0.5 and 7.5 cm with an average of 3.6 cm.[153] This finding, although critical for total-body irradiation treatments, further highlights the mobility of the kidneys.

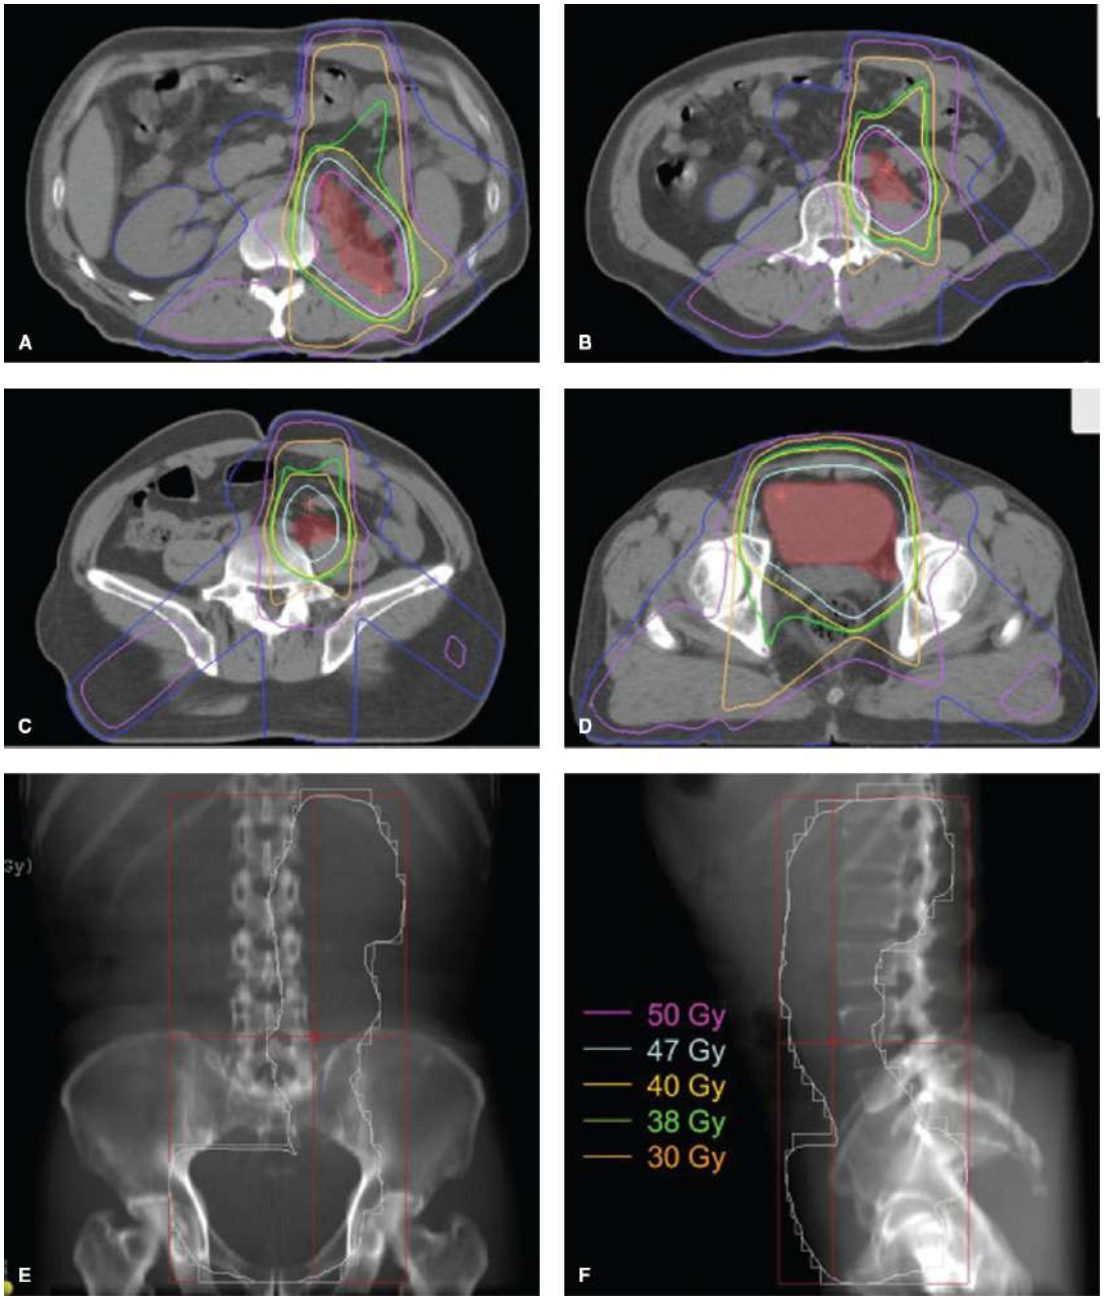

FIGURE 67.2. Dose distribution of a patient with renal pelvis cancer and beam arrangements of 0°, 129°, and 229° gantry: **(A)** renal fossa; **(B, C)** course of ureter; and **(D)** bladder. Digitally reconstructed radiograph for views of **(E)** 0° gantry and **(F)** 90° gantry. Internal *pink* and *yellow* lines represent the CTV_{50} and CTV_{40}, respectively. (From Chen B, Zeng ZC, Wang GM, et al. Radiotherapy may improve overall survival of patients with T3/T4 transitional cell carcinoma of the renal pelvis or ureter and delay bladder tumour relapse. *BMC Cancer* 2011;11:297; © 2011 Chen et al; licensee BioMed Central Ltd.)

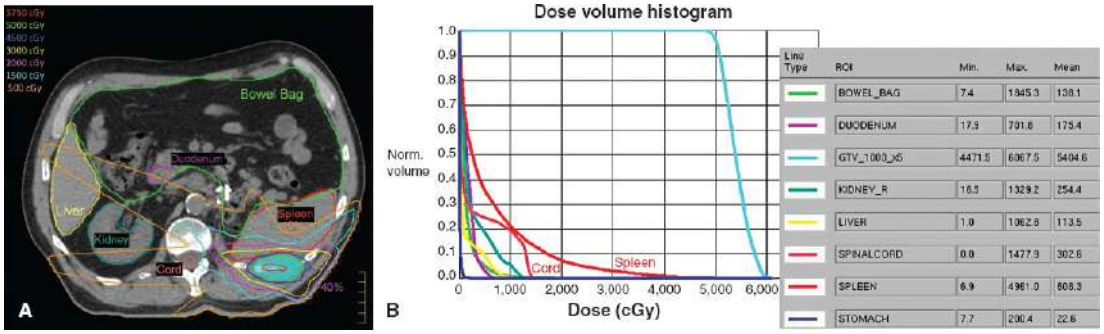

FIGURE 67.3. Patient with metastatic clear cell RCC who developed a painful, destructive, 55-cc metastasis in the left 12th rib. Treatment plan **(A)** and dose–volume histogram **(B)** showing the normalized volume versus dose (cGy). The metastasis was treated with 10 Gy × 5 using a six-field step-and-shoot, 6-MV IMRT technique. The isodose-based methodology was used to evaluate the plan.[155] The skin was limited to the 40% isodose (400 cGy × 5), the spinal cord to the 30% isodose (300 cGy × 5), and the spleen to the 10% isodose (100 cGy × 5) or less as feasible. The cyan-filled contour is the GTV. Doses to the bowel, liver, remaining kidney, and duodenum were well below tolerance.

The high complication rates reported in the prospective trials of postoperative RT have taught radiation oncologists an important lesson regarding radiation therapy planning, patient selection, and the tolerance of the upper abdominal viscera. IMRT may be a reasonable consideration because of the sensitivity of adjacent surrounding structures. If IMRT is considered, a plan to manage the uncertainties in target localization such as 4-DCT treatment planning, IGRT, abdominal immobilization devices, gating, or breathing control needs to be considered. Renal function scans may assist in the treatment planning or patient selection process, but this has not been formally studied.

In unresectable lesions, 40 to 50 Gy neoadjuvant radiation therapy (1.8 to 2 Gy/fraction) directed to the kidney tumor and regional lymphatics may improve resectability.[110] Multiple-field techniques, similar to those described for adjuvant radiation therapy, should be considered in patients receiving preoperative treatment.

CT-based treatment planning contributes to good local control with minimal morbidity. Careful definition of the target volume to encompass the nephrectomy bed, lymph node drainage sites, and surgical clips on the planning CT scan is important. Exclusive use of anterior- and posterior-field arrangements, particularly on the right side, is likely to result in irradiation of large volumes of bowel and liver beyond tolerance. The use of multiple beams is paramount for protecting the surrounding normal structures. Total radiation doses of 45 to 50 Gy (1.8 to 2 Gy/fraction) to the nephrectomy bed and regional lymph nodes with

a boost to small volumes of microscopic or gross residual disease of 10 to 15 Gy (total dose 50 to 60 Gy) are appropriate. Stein and coworkers[154] reported two scar recurrences and recommended that the incision site be included in the target volume. If the scar cannot be covered without increasing the amount of normal tissue irradiated, an additional electron-beam field to treat the scar may be considered.

Figure 67.3 illustrates a patient with metastatic clear cell RCC, with sarcomatoid and rhabdoid differentiation, status post left radical nephrectomy, pT3aN1M1. The kidney tumor was Fuhrman nuclear grade IV and 15.5 cm in diameter. The patient was treated with temsirolimus, pazopanib, bevacizumab, and finally adriamycin plus gemcitabine with some objective response. The patient developed a painful, destructive, 55-cc metastasis in the left 12th rib. The metastasis was treated with 10 Gy × 5 using a six-field (RPO 210, LAO 60, LT LAT 90, LPO 120, LPO 150, PA) step-and-shoot, 6-MV IMRT technique. The isodose-based methodology was used to evaluate the plan and is explained in detail in the reference.[155] The skin was limited to the 40% isodose (400 cGy × 5), the spinal cord to the 30% isodose (300 cGy × 5), and the spleen to the 10% isodose (100 cGy × 5) or less as feasible. Doses to the bowel, liver, remaining kidney, and duodenum were well below tolerance (Fig. 67.3A). Daily imaging with 2D:2D match and cone-beam CT was used prior to the delivery of the 5 fractions over 3 weeks.

Because of the possibility of long survival even in the presence of distant metastases, aggressive treatment for palliation should be considered in patients who have limited metastatic disease with good performance status. Treatment fields should encompass metastatic foci with adequate (2 to 3 cm) margins. See previous sections on *Stereotactic Body Radiosurgery (SBRS) for Primary Treatment*, *Whole-Brain Radiation therapy for Brain Metastases*, *Stereotactic Radiosurgery (SRS) for Brain Metastases*, *Conventional Radiotherapy for Extracranial Metastases*, *and Stereotactic Body Radiation Therapy for Extracranial Metastases*.

Renal Pelvis and Ureter Carcinoma

Adjuvant radiation therapy has been used in the management of renal pelvis and ureter cancers. For elective radiotherapy, the clinical target volume should include the renal fossa, the course of the ureter to the bladder, the entire bladder, and the paracaval and para-aortic lymph nodes (Fig. 67.3).[143] As in RCC, CT-based planning may facilitate dosimetric coverage of the regions at risk while

minimizing dose to normal tissues. Radiation doses of 45 to 50 Gy at 1.8 to 2 Gy per day are appropriate to treat subclinical and microscopic disease. For more extensive disease (e.g., multiple positive nodes), R1 (microscopic positive margins) or R2 (macroscopic residual margins) resections, a boost of 5 to 10 Gy should be considered. For unresectable or gross residual disease, higher doses may be necessary. In this event, multiple-field arrangements including oblique and lateral fields with field reductions are important to minimize toxicity to surrounding normal structures (Fig. 67.2). CT-based simulation, three-dimensional treatment planning, and contrast-enhanced radiographs are helpful in defining the radiation therapy target volume. IMRT may be considered if organ motion is managed to avoid underdosing the planning target volume. Chemotherapy may allow a lower radiation dose for gross disease.

FOLLOW-UP

Renal Cell Carcinoma

The NCCN Kidney Cancer Panel recommends patients be seen every 6 months for the first 2 years after surgery and then annually up to 5 years after diagnosis. Each visit should include a history and physical examination and comprehensive metabolic panel.[86] The NCCN recommends a baseline abdominal CT, MRI or ultrasound within 3 to 12 months of surgery, and chest imaging with its frequency depending on the initial stage. The UCLA UISS (described in *Prognostic Factors* section) uses the older 1997 TNM staging and also provides surveillance recommendations according to risk category.[156] The greatest risk of recurrence following surgery for RCC is in the first 1 to 2 years, with most relapses occurring within 3 years, but recurrences can occur more than a decade later. Early diagnosis of metastatic disease could identify patients who may be candidates for metastasectomy and potentially result in long-term survival.

Renal Pelvis and Ureter Carcinoma

Because patients with urothelial carcinoma of the upper urinary tract are at a high risk of urothelial tumors of the bladder, monitoring with cystoscopy at periodic intervals is necessary. For patients who underwent a renal-sparing procedure, imaging with CT or MRI and/or ureteroscopy may be necessary. The NCCN Bladder Cancer Panel recommends a cystoscopy every 3 months for 1 year and then at increasing intervals. For endoscopic procedures, imaging (IVP, CT urography, retrograde pyelogram, ureteroscopy, or MRI urogram) of the

upper tract collecting system at 3- to 12-month intervals is recommended. Imaging to exclude metastatic disease such as a chest radiograph or chest CT or abdominal/pelvic CT or MRI should be considered.

SEQUELAE OF RADIATION THERAPY

The side effects and complications from radiation therapy for cancer of the kidney, renal pelvis, and ureters are similar to those expected from irradiation of the upper abdomen and pelvis. These side effects include nausea, vomiting, diarrhea, and abdominal cramping. Patients with right-sided tumors may have significant portions of the liver irradiated, and radiation-induced liver damage is possible. The Copenhagen Renal Cancer Study Group reported that 12 (44%) of 27 patients developed significant complications: Three had biochemical changes indicating radiation hepatitis, three had duodenum and small-bowel stenosis, and six had duodenum and small-bowel bleeding.[113] Surgery was performed on four of nine patients with bowel-related radiation therapy complications, and five patients died of treatment-related complications. The total radiation dose in this study was 50 Gy given in 2.5-Gy fractions per day—a fractionation schedule that may account for the high rate of complications. Fugitt also reported four cases of "liver" failure among 52 patients who received postoperative irradiation.[112]

The complication rate after radiation therapy for tumors of the kidney and upper urinary tract is related to the irradiated volume, total dose, fraction size, and technique of irradiation. CT-based simulation and 3-D treatment planning may decrease the risk of complications after elective radiotherapy in patients with upper urinary tract malignancies. In a prospective clinical trial, patients received single-fraction renal stereotactic ablative body RT (SABRT) (26 Gy) for tumors < 5 cm or fractionated SABR (3 × 14 Gy) for tumors ⩾5 cm. For every 10 Gy of physical dose delivered, an exponential decline in affected kidney GFR was observed at 39% for 26 Gy in 1 fraction and 25% for 42 Gy in 3 fractions. When normalized to BED_{3Gy}, the dose–response relationship for each treatment prescription was similar with a plateau beyond 100 Gy. The authors concluded that sparing the functional kidney from high-dose regions (>50% isodoses) may help reduce risk of functional loss.[157] Another study of 14 patients receiving SBRT for RCC (50, 60, or 70 Gy in 10 fractions) showed significant renal atrophic change. The dose distribution of SBRT at 20 to 30 Gy had a strong correlation with renal atrophy when using these 10 fraction

regimens.[158]

ACKNOWLEDGMENTS

Thanks to Michael Watts, M.S., CMD, for masterfully planning the case in Figure 67.3 and obtaining the screen captures of the plan.

CHAPTER 68

Bladder Cancer

Carlos A. Perez

INTRODUCTION

This is an update of a chapter published by James et al.[1] in Principles and Practice of Radiation Oncology 6th edition.

Every aspect of the perceptions and management of bladder cancer requires change; departing from the use of the term “superficial” bladder cancer is the first step,[2] because the term is both inaccurate and implies an inappropriate lack of importance. In particular, given the very high costs to health care systems from long-term surveillance and treatment of the disease,[3] it is particularly surprising that there has not been more emphasis on the disease from health policy makers and pharmaceutical companies.

In addition, a rethinking of the view that cystectomy is the gold standard for invasive bladder cancer is long overdue. Comparisons of large surgical[4] and radiation therapy[5] series document similar long-term survival rates, and population-based studies do not appear to show any survival differences linked to the mode of treatment.[6] Furthermore, most large surgical series have median ages in the mid-60s,[4,7] well below the (rising) disease population median, suggesting the results may not be applicable to many or even most patients with invasive bladder cancer. Use of bladder preservation varies worldwide from around 10% in the United States[8] to 25% in Scandinavia[9] to around 50% in the United Kingdom.[10] Moreover, there is good evidence that older or less fit patients in low-volume centers are less likely to be referred for surgery, despite the likelihood of them being fit for radiation therapy.[8,9]

In contrast, recent large randomized radiation therapy series from the United Kingdom suggest that definitive radiation therapy with chemosensitization, either with low-dose chemotherapy[11] or with hypoxia-targeting agents,[12] is effective and well tolerated by elderly patients (median age in both studies was 72 to 73 years). Long-term functional outcomes with radiation therapy are

excellent,[11–13] making it particularly suitable for less fit patients who may struggle with major surgery or a urinary diversion.

This chapter outlines the evidence base for the current therapeutic approaches to bladder cancer and in particular will examine the proposition that bladder preservation for muscle-invasive disease is an approach that merits continuous emphasis and re-evaluation.

ANATOMY OF THE BLADDER

The bladder is a hollow, muscular organ situated in the pelvis when empty but able to extend up into the abdomen when full, particularly in situations where bladder emptying is impeded. At birth, the pelvis is relatively small in comparison to the abdomen, and thus, the bladder has a larger abdominal component at birth and becomes more “pelvic” as growth and maturity proceed. By puberty, the bladder has migrated to the confines of the deepened true pelvis.

The bladder is described as having an apex, a superior surface, two inferolateral surfaces, a base or posterior surface, a trigone, and a neck. The apex reaches a short distance cephalad above the pubic bone and ends as a fibrous cord, the remnant of the fetal urachus, which connects the bladder to the allantois. The urachus lies anterior to the peritoneal cavity and is important as tumors can arise in the urachal remnant. The superior surface is covered by the peritoneum, again an important anatomical feature as it means that there is bowel lying superiorly to the bladder, which is potentially a critical site to consider when planning radiotherapy, particularly in men. In women, it is associated with the uterus and ileum. The base of the bladder is posterior and is separated from the rectum by the vas deferens, seminal vesicles, and ureters in the male and by the uterus and vagina in the female. The seminal vesicles form a V-shaped structure at the base of the bladder, with the vas deferens entering the middle of the “V.” The ureters enter into the bladder slightly superior and lateral to the seminal vesicles, with the vas deferens coursing above and in a caudal direction to the ureters. Again, these relations are critical as enlarging tumors either at the base or in the prostate can involve the ureters with consequent hydronephrosis. Inferiorly and laterally to the bladder lie the various pelvic bones and muscles: pubis, the levator ani, and obturator internus muscles. Within the pelvis, the lateral parts of the bladder are surrounded by loose connective tissue. Anteriorly, the bladder is separated from the pubic bone by the retropubic space. The inferior part of the bladder is described as the neck and is in

continuity with the urethra and, very importantly, the prostate gland in males. The neck of the bladder is anchored in the pelvis, and the superior portions distend and expand upward as the bladder fills.

The mucosal lining of the bladder comprises a transitional epithelium that extends from the renal pelvis to the urethra. The most common tumors arising in the urinary system are transition cell (or urothelial) carcinomas (TCC or UC). These tumors can arise from anywhere within the urothelium, so diagnosis, treatment, and surveillance protocols must take account of this important biologic feature. As a distensible organ, the macroscopic appearance of the urothelium varies with distension from smooth and flat to folded when empty. A ridge called the interureteral fold lies between the ureteric orifices.

EPIDEMIOLOGY

Bladder cancer, with over 385,000 new cases reported worldwide in 2008[14] is a major cause of cancer morbidity and mortality. Median age at diagnosis is above 70 years, and as the tumor is often smoking related, many patients have significant comorbidity, posing risks for radical surgical approaches. Survival rates are poor, with around 45% of muscle-invasive cancer patients surviving 5 years irrespective of treatment modality.[4,5,7] Demographically, the industrializing nations will contribute to a significant rise in the global incidence of bladder UC,[15] with particularly large numbers likely in China given the rapid improvement in standards of living and the high prevalence of smoking. However, despite the decreasing incidence in developed nations, there remain specific challenges, mainly because of the aging population and increased life expectancy. Within two large cohorts separated by 15 years (1991 to 1992 and 2005 to 2010), researchers have recently demonstrated an increase in the median age at presentation of 4 years, with an increase from 13% to 24% in the proportion of patients over 80 years old.[16] Overall, around 75% to 80% of patients with bladder cancer are male, mostly reflecting historic trends in cigarette smoking.

There are well-known associations of squamous cell bladder carcinomas with bilharzia caused by *Schistosoma haematobium* infection in Africa, particularly in Egypt.[17] Aromatic amines, polycyclic aromatic and chlorinated hydrocarbons, arsenic-laced drinking water, aristolochic acid, cyclophosphamide exposure, and a range of industrial chemicals have been implicated in urothelial carcinogenesis. Importantly, as with most carcinogens, there are variations in

individual susceptibility, and the basis of some of these polymorphisms regulating varied detoxification mechanisms has been identified.[18] With increasing awareness of these industrial associations, regulation of these processes means that these cases are becoming increasingly rare in the developed world. Their principal importance now is that those with industrially linked tumors may be entitled to compensation payments. In Egypt, there have been successful public health approaches to the control of *S. haematobium* infections, leading to a substantial decline in incidence and mortality from squamous carcinomas of the bladder.[19]

Within the developed world, the overwhelming majority of bladder tumors are now TCCs, and the main known causative factor is tobacco (particularly cigarette) smoking,[20–25] explaining approximately half of the cases in men and one-third of the cases in women in Europe (discussed in detail below). The relation between smoking and other prognostic factors is interesting, as it could give insight into biologic mechanisms of disease and, perhaps more importantly, have clinical implications by increasing our ability to identify patients at risk of more malignant disease.

NATURAL HISTORY

Non–Muscle-Invasive Bladder Cancer

Most cases (70% to 80%) present with non–muscle-invasive bladder cancer (NMIBC, stage Ta, T1, and carcinoma *in situ* [Tis]), which is rarely lethal, but shows a high recurrence rate of 50% to 70% after treatment by transurethral resection of the bladder tumor (TURBT).[26] In about 10% to 20% of patients with NMIBC, the disease progresses to muscle invasion (≥T2 lesions), which can lead to metastasis and death.[26] However, the majority of patients with NMIBC will die of other causes, given the typically advanced age at presentation and the strong association with cigarette smoking,[20–25] although it is worth noting that up to 21% of patients with Ta tumors and 49% of patients with T1 tumors will die from bladder cancer.[27] For patients with NMIBC, it has been observed that tumor grade and stage, and also tumor number, size, presence of carcinoma *in situ* (CIS), recurrence rate, and age at diagnosis are risk factors of progression.[28–30] The risk of both recurrence and progression necessitates lifelong follow-up for patients with bladder tumors. However, there are factors that predict a higher risk of progression (to invasion) as opposed to recurrence in lower-risk tumors, and the European Organisation for Research and Treatment of

Cancer (EORTC) “bladder cancer calculator” quantifies the risk depending on the tumor characteristics imputed.[30]

Invasive Disease

Muscle-invasive bladder cancer has a poor prognosis because of a very high rate of occult metastatic disease at the time of diagnosis. Evidence for this comes from the high rate of death from metastasis after apparently successful surgery. Furthermore, reported 5-year survival rates with radiotherapy or surgery are remarkably similar at around 45% to 50%,[4,5] despite a higher rate of pelvic recurrence after radiation therapy versus surgery, suggesting that prognosis is driven by the presence, or otherwise, of metastases at the time of diagnosis, driven by tumor-related factors such as stage and grade.[6]

Metastatic Disease

A minority of patients (probably <10%) present with metastatic disease, carrying a poor prognosis; most patients with metastatic disease have had prior treatment for apparently localized disease. Overall survival from diagnosis of metastasis is difficult to ascertain as many patients receive only palliative treatment. A minority of patients are fit for systemic chemotherapy, and there are good data on outcomes with chemotherapy. In essence, extensive randomized studies, mostly carried out in the 1980s and 1990s, have demonstrated the superiority of cisplatinum-based combinations over those containing other drugs or cisplatinum alone.[31] Of the platinum-based combinations, methotrexate/vinblastine/doxorubicin (Adriamycin)/cisplatinum (MVAC)[32] and gemcitabine/cisplatinum (GC)[33] have proven to be superior to other combinations and broadly similar in efficacy to each other[34,35] (as reviewed by Hussain and James).[36] Median survival is 12 to 18 months, depending on the extent of disease and fitness of the patient. Intriguingly, however, a small minority of patients do appear to survive long term after chemotherapy for metastatic disease, but this percentage has sadly proved very hard to increase from that originally observed in the MVAC trials.

ETIOLOGY

The link between occupational exposure and an increased risk of urothelial cancer of the bladder was established more than a century ago when Rehn[37] reported on three cases of bladder cancer in a German chemical dye works in 1895.[38] During the following 40 years, similar reports appeared from around the

world.[39] In 1938, Hueper et al.[39] demonstrated that when naphthylamine, an industrial arylamine used in the synthetic dye industry, was fed to dogs, it caused bladder carcinomas identical to the human disease. The link between industrial arylamines and bladder cancer was thus established and later confirmed by Case et al.[40] in 1954. These authors also identified an excess of bladder cancer in the tire industry, attributable to the use of 2-naphthylamine in the manufacture of rubber.[38,40] Around this time the "o-aminophenol hypothesis" of arylamine-induced human bladder cancer was proposed, suggesting that conjugation of aromatic amines by the liver and excretion in the urine with subsequent urinary reactions would liberate the carcinogen o-aminophenol.[41] Other workers later added to this hypothesis: arylamines are hydroxylated in the liver and conjugated with glucuronic acid, followed by excretion into urine and reliberalization of the active carcinogenic metabolite into the bladder lumen by urinary glucuronidases.[38,42,43] Slow acetylation by *N*-acetyltransferase, an enzyme involved in the metabolism of arylamines, has been shown to be a contributory risk factor for bladder carcinogenesis.[20,44,45]

Because of the widespread use of arylamines in textile dyes, hair dyes, and paint pigments, a number of high-risk occupations have been identified, including chemical, dye, textile, and rubber workers and painters and hairstylists.[21,46–48] In addition, the presence of various arylamines in tobacco smoke means that a significant proportion of bladder cancer cases can be attributed to cigarette smoking.[20–23] In fact, abandonment of the manufacture of many of these arylamines in the latter half of the 20th century means that smoking is currently the single most important cause of urothelial cancer.[24,49–51] Tobacco (particularly cigarette) smoking now explains approximately half of bladder cancer cases in men and one-third of cases in women in Europe. It has been demonstrated that an increased smoking frequency and duration and a lower age at initiation are associated with an increased risk of bladder cancer, whereas cessation seems to reduce the risk.[49] The relation between smoking and other prognostic factors is interesting, as it could give insight into biologic mechanisms of disease and, perhaps more importantly, have clinical implications by increasing the ability to identify patients at risk of more malignant disease. Cigarette smoking also appears to be a risk factor for disease recurrence following a diagnosis of bladder UC,[49,52] although because of a lack of conclusive evidence, there is currently a low rate of physicians providing smoking cessation assistance.[49]

Studies also demonstrate a relation between *N*-acetyltransferase-2 slow

acetylators and cigarette smoking, resulting in a further increase in the risk of bladder cancer, especially in those individuals with a high smoking intensity.[53–55] A similar relation has also been demonstrated with arylamine exposure.[56,57] A number of other susceptibility loci have also been identified, although such markers do not yet have sufficient discriminatory ability to be utilized for risk prediction in the general population or for prediction or prognostication in patients diagnosed with bladder cancer.[54,58,59]

CHRONIC INFLAMMATION AND BLADDER CANCER

Squamous metaplasia is considered a precursor of squamous cell carcinoma of the bladder and is a relatively common occurrence, especially on the trigone of the female bladder where a prevalence of up to 50% is reported.[60,61] Experimental evidence suggests that this does not occur by direct transformation of the superficial apical umbrella cells of the urothelium or by their dedifferentiation and redifferentiation; it is postulated that basal cells (probable stem cells) are selectively activated.[60] The normal urothelium is slowly proliferating, but urothelium undergoing squamous metaplasia becomes hyperplastic, and it may be that the hyperplasia component of urothelial squamous metaplasia is a major contributor to an enhanced risk of cancer formation.[60,61]

Squamous cell carcinoma and adenocarcinoma of the bladder often occur in the presence of chronic inflammation. In Africa and the Middle East, where these tumors are much more prevalent, the chronic inflammation occurs as a result of infestation with the parasite *S. haematobium* (bilharziasis), with a bladder carcinoma incidence of 2 to 4 per 100,000 in *S. haematobium* endemic areas.[62–64] This infestation can lead to malignancy through local tissue damage, mechanical irritation, bilharzial toxins, secondary bacterial infection, and the production of nitrosamines.[62,65] With liver involvement and subsequent liver dysfunction, tryptophan metabolism may be disturbed, resulting in excretion of carcinogenic metabolites.[62] In *S. haematobium*–infected individuals, the prevalence of squamous metaplasia rises significantly during the first 10 to 15 years of life, with a plateau at roughly constant levels thereafter (30% to 40% in males and 40% to 50% in females) when the active infection may have subsided.[61] It is suggested that proliferative changes in the bladder urothelium may become independent of ongoing infection after long periods of chronic *S. haematobium*–induced inflammation.[65,66] Severe metaplasia of the bladder may

represent a precancerous transformation in some individuals, but in others, it may only represent a marker for the prolonged inflammation that is associated with a high cancer risk.[65] This sort of proliferative growth combined with the increased excretion or local formation of mutagens in the *S. haematobium*–inflamed bladder may significantly contribute to the onset of cancer formation, possibly involving mutations of the *p53* and *CDKN2* tumor suppressor genes.[65]

In Europe and North America, the stimulus of chronic bladder inflammation is usually chronic bacterial infection, bladder calculi, or long-term indwelling catheters.[67–70] A number of metaplastic conditions (squamous metaplasia, von Brunn nests, cystitis cystica, and cystitis glandularis) may occur prior to frank malignant change, although the premalignant nature of some of these lesions is still unclear.[67–76]

Field Cancerization and Clonality

A fundamental characteristic of neoplasia is monoclonality, in which one transformed cell gives rise to daughter cells that all exhibit the same genetic changes that provided the initial growth advantages to the originally transformed parent cell.[77] Further genetic changes accumulate in subsequent daughter cells and provide additional growth advantages.[77] However, TCC behaves as a multifocal disease, often with multiple primary tumors and frequent recurrences that can occur anywhere in the urinary tract from the renal pelvis to the urethra. These observations gave rise to the idea of a "field defect" or "field cancerization," suggesting that the whole urothelium is exposed to the same urinary carcinogens, leading to the transformation of many independent separate urothelial cells and resulting in multiple tumors developing independently in multiple sites. Such tumors are thus genetically unrelated. An alternative explanation is that the multifocality of TCC arises as a result of a single carcinogenic insult to a single cell or group of cells. The progeny or clones of these cells spread throughout the bladder, either through intraepithelial migration or through cell shedding and reimplantation, leading to multiple synchronous and metachronous tumors.[77] These tumors are thus topographically distinct but are genetically related. This is the hypothesis of clonality.

Utilizing the relatively rudimentary technique of X-inactivation,[77–79] the early studies in this field appeared to show that the urothelium is derived from a small number of cells (200 to 300), which subsequently develop into larger patches; each patch is clonally related and possesses different predispositions to tumorigenesis.[80] Such stem cell–derived clonal units actively replenish the

urothelium during aging.[81] Multiple synchronous and metachronous TCCs in the same patient appear to be clonally related when studied by X-inactivation.[77,79,82–85] However, these studies only provide a 50% probability that one particular TCC is related to the primary TCC, although that probability improves when multiple TCCs are analyzed. Clonal patch size also needs to be taken into consideration, and because of the large patch size of the urothelium (120 mm^2), X-inactivation studies are heavily biased toward demonstrating monoclonality.[78] Ideally, these studies should have taken into account the relation of the tumors to patch boundaries.[78] In addition, DNA methylation patterns change as a natural consequence of aging.[86] Therefore, although X-inactivation studies provided an early insight into the relative importance of the processes of clonality and field cancerization, they cannot be considered as entirely accurate and reliable. Similarly, using immunohistochemistry to study specific *p53* and *pRb* mutations cannot be considered to be wholly reliable for demonstrating monoclonality.

The accuracy of these investigations has been improved by utilizing newer and more sensitive techniques such as comparative genomic hybridization, fluorescence *in situ* hybridization, and loss of heterozygosity studies. These experiments revealed both monoclonality and oligoclonality in synchronous and metachronous TCCs. More recently, research has suggested that a genetic expression profile is established early in bladder tumor development and that this profile is stable and maintained in recurring tumors.[87–89] Majewski et al.[82] matched the clonal allelic losses in distinct chromosomal regions to specific phases of bladder neoplasia: these genetic changes mapped to six regions or “forerunner genes” involved in the early phases of bladder cancer development, representing critical hits driving bladder carcinogenesis. It is suggested that the clonal expansion, over vast expanses of the bladder mucosa, of urothelial cell populations containing losses of forerunner genes may represent the earliest molecular change in bladder carcinogenesis. A further wave of genetic “hits” within subregions of these clonally expanded cells leads to the first microscopically recognizable features of dysplasia, and a third and final wave is associated with the fully transformed phenotype of severe dysplasia or CIS.[88,90] The genetic changes map to six chromosomal regions that are suggested to represent the critical hits driving the development of bladder cancer.[88,90] In addition, Knowles et al.[85] have demonstrated that deletions of chromosome 9 occur in over half of bladder tumors of all grades and stages (9p, 51%; 9q, 57%). Loss of heterozygosity also occurs on 17p (32%), 11p (32%), 8p (23%), 4p

(22%), and 13q (15%), and loss of heterozygosity of 5p, 8p, and 21q is significantly associated with worse grade and stage.[85] Genomic copy number alterations are also frequent in bladder TCC, with the most frequent changes involving complete or partial loss of 4q (83%) and gain of 20q (78%).[91] Other frequent losses are of 18q (65%), 8p (65%), 2q (61%), 6q (61%), 3p (56%), 13q (56%), 4p (52%), 6p (52%), 10p (52%), 10q (52%), and 5p (43%).[92]

Taken together, the studies described above show that multifocal TCCs are frequently monoclonal, whereas others show oligoclonality. The evidence for both theories is compelling (as reviewed by Duggan et al.[87]), with evidence supporting both the clonality and field cancerization theories. In reality, these theories are equally valid, with both processes seemingly often occurring simultaneously in the same patient.[83,84] In addition, many of these studies have demonstrated that deletions on chromosome 9p occur most frequently and early in transitional cell carcinogenesis with 17p13 losses (*p53* gene mutations) occurring in more advanced TCCs, shedding some light on the molecular pathology of bladder TCC.

Pathways to Muscle-Invasive and Non–Muscle-Invasive Bladder Cancer

A number of different approaches can be taken to describe the molecular alterations involved in bladder tumorigenesis (TCC). Some authors[93,94] have previously described such pathways in detail based on the six original "hallmarks of cancer" described by Hanahan and Weinberg[90] in 2000. In 2011, Hanahan and Weinberg[92] updated their original landmark review, describing genome instability and inflammation as underlying these hallmark changes and proposed "reprogramming of energy metabolism" and "evading immune destruction" as two emerging hallmarks with potential for generality. In addition, they reported that tumors exhibit another dimension of complexity by containing a repertoire of recruited, ostensibly normal cells that contribute to the acquisition of hallmark traits by creating the "tumor microenvironment." The particular timing and sequence of hallmark events can vary widely between tumors of the same type and within the same tumor, but ultimately, these hallmark capabilities of cancer will be reached.[95] In their 2011 update, Hanahan and Weinberg[92] also introduce the concept of "cancer stem cells," a concept that has existed for quite some time for hematopoietic malignancies.[96,97] Cancer stem cells are a subset of tumor cells that have the ability to self-renew and to generate all of the heterogeneous cells that comprise a tumor (properties that are analogous to a

stem cell, the original cell of an organ, and responsible for organogenesis and organ maintenance).[96,98–101] It is proposed that these cells are responsible for tumorigenesis, tumor differentiation, tumor maintenance, tumor spread, and tumor relapse.[96,98–101] In the setting of bladder cancer, cancer stem cells appear to play a role in a subset of tumors, but their true significance has yet to be clarified.[99]

A number of other authors have also reviewed this field in detail,[102–107] and there is general consensus on a divergent pathway for the development of Ta/T1 disease and Tcis/T2+ disease, as illustrated in Figure 68.1[108–114] (Leeds, UK); in their 2010 review, Goebell and Knowles[102] propose a third hypothetical pathway for the development of high-grade papillary tumors. Significant contributions to work in this field have been made by Knowles et al.[103]

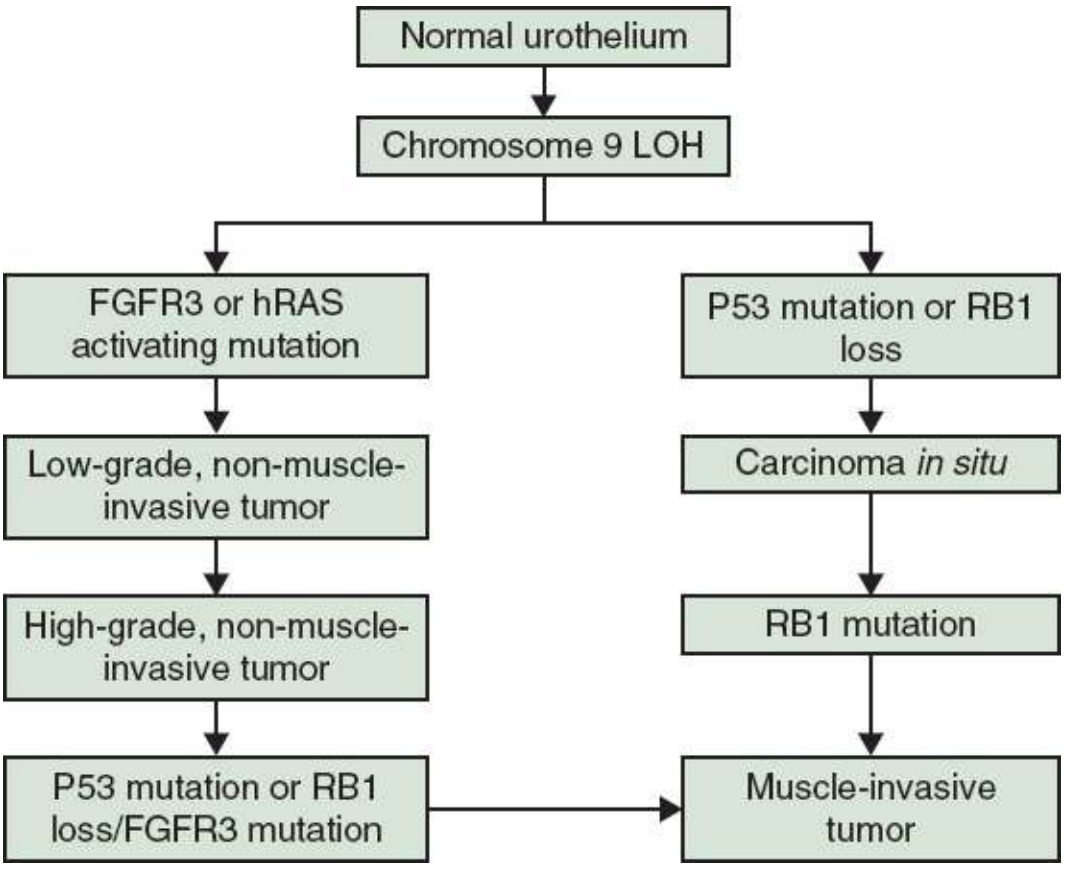

FIGURE 68.1. Pathways to development of bladder cancer. (Data from Pollard C, Smith SC, Theodorescu D. Molecular genesis of non-muscle-invasive urothelial carcinoma [NMIUC]. *Expert Rev Mol Med* 2010;12:e10.)

A detailed examination of these pathways and related biomarkers is beyond the scope of this chapter. In addition, this is a rapidly changing field, and new

developments appear frequently with the advent of high-throughput experimental platforms, including "deep sequencing,"[115] proteomics,[116,117] and metabolomics,[118] so readers are directed to the reviews cited above or to the latest work in this field.

SYMPTOMS AND SIGNS

The typical presenting symptoms of bladder cancer include painless, visible hematuria, infection, and storage symptoms. As the first of these is typically transient and the latter two are also attributable to prostate problems, patients often go undiagnosed for considerable periods.[27] Given the intermittent nature of the hematuria associated with bladder cancer, patients presenting with a convincing episode of hematuria require urgent assessment. Similar considerations apply to male patients with a urinary tract infection. Female patients present a more difficult problem because of the higher incidence of urinary infection and the lower risk of bladder cancer. Hematuria is also more likely to be misinterpreted in women of child-bearing age.

INVESTIGATION OF PATIENTS WITH BLADDER CANCER

This section is divided into the investigation of patients with suspected bladder cancer and the subsequent staging of those with an established diagnosis.

Suspected Bladder Cancer

In developed countries, most patients will be referred for evaluation because of hematuria or suspected bladder cancer. A minority may present via other routes (e.g., gynecologic clinics) or with metastatic symptoms (<10%). Hematuria clinics will generally include a clinical assessment, full blood count and biochemical profile, prostate-specific antigen (if indicated), urine cytologic examination, flexible cystoscopy, and some sort of imaging of the urothelium (e.g., ultrasound, intravenous urogram, or computed tomography [CT] urogram), which will vary with local practice and facilities.[119,120] Patients identified as having a bladder tumor on flexible cystoscopy will then require further investigations to stage the disease.

Staging Bladder Cancer

The next stage for most patients will be an examination under anesthetic coupled with TURBT. The presence or absence of a mass after TURBT is also an

important prognostic factor as it potentially indicates either unsuccessful clearance of tumor, extravesical extension, or both. This serves as both definitive staging of the bladder lesion as well as a substantial proportion of the initial treatment. Pathologic review of the resected specimen will ascertain whether muscle invasion is present or not and whether there is CIS; these are the key determinants of further investigation and treatment. Patients with NMIBC, including CIS, do not usually require detailed further imaging, and treatment and surveillance are primarily by intravesical means. The main exception to this is patients with either extensive CIS or grade 3 lesions for whom additional cross-sectional imaging may be warranted. Patients with muscle-invasive bladder cancer (MIBC) will require detailed cross-sectional staging with CT or magnetic resonance imaging (MRI) of the chest, abdomen, and pelvis. If there are any features suggestive of bone metastasis (e.g., raised alkaline phosphatase, bone pain), an isotope bone scan will be indicated in addition.

A major confounding factor with imaging in bladder cancer is the effect of TURBT on the interpretation of the extent of the primary bladder tumor. Recent TURBT will cause perivesical changes that may be interpreted as extravesical spread. For similar reasons, enlarged pelvic nodes may be related to reactive rather than metastatic effects. On the other hand, changes such as infiltration of adjacent organs or hydronephrosis are likely to be reliable indicators of tumor stage and poor prognosis.

STAGING SYSTEM

The 2010 version of the UICC International Union Against Cancer's TNM system is the current, internationally used staging system,[120] and it is based on the size and extent of the primary tumor (T-stage), presence or absence of nodal (N), and metastatic (M) spread (Table 68.1). The TNM stage must be used in conjunction with the pathologic assessment of tumor removed at TURBT to decide on optimal therapy. Disappointingly, despite a substantial volume of research, no biomarkers have yet established themselves in clinical practice as either prognostic or predictive markers as has happened, for example, with estrogen receptor or *HER2* status in breast cancer. It is hoped that the wider availability of high-throughput systems such as proteomics, in-depth sequencing, and others to be developed will allow the development of such markers in the future.

The American Joint Committee on Cancer Staging Manual 8th edition

published in 2017 basically uses the same TNM definitions, except for minor terminology variations.[121]

PATHOLOGY

In excess of 90% of bladder cancers are transitional cell carcinomas. Of the remainder, around 5% are squamous, although it should be noted that squamous differentiation is often present in poorly differentiated TCCs, so the extent to which these are genuinely distinct is open to question. As already noted, infestation with *S. haematobium* can lead to squamous cell carcinoma, but this is rapidly decreasing due to eradication programs. Small cell carcinoma is rare but important as it is generally very chemosensitive and treatment tends to follow schedules adapted from treating small cell lung cancer. Other tumor types include melanoma, carcinosarcoma, and adenocarcinoma (particularly in the urachal remnant). Typically, bladder TCCs will be graded using the standard TNM system of Gx (cannot be assessed) and then G1 through to G3 (well through to poorly differentiated).[120] CIS will frequently be found in addition to a tumor mass and critically affects treatment choices.

TABLE 68.1 TNM CLASSIFICATION OF TUMORS (2009)

Tx	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Ta	No invasive papillary carcinoma
Tis	Carcinoma *in situ*: “flat tumor”
T1	Tumor invades subepithelial connective tissue
T2	Tumor invades muscle T2a superficial muscle (inner half) T2b deep muscle (outer half)
T3	Tumor invades perivesical tissue: T3a microscopically T3b macroscopically (extravesical mass)
T4	Tumor invades any of the following: prostate stroma, seminal vesicles, uterus, vagina, pelvic wall, abdominal wall T4a tumor invades prostate, stroma, seminal vesicles, uterus, or vagina T4b tumor invades pelvis or abdominal wall
N0 regional lymph nodes	Defined as nodes of the true pelvis below the bifurcation of the common iliac arteries. Laterality does not affect the N classification
Nx	Nodes cannot be assessed
N0	No lymph node metastasis
N1	Metastasis in a single lymph node in the true pelvis (hypogastric, obturator,

	external iliac, or presacral)		
N2	Metastasis in multiple lymph nodes in the true pelvis (hypogastric, obturator, external iliac, or presacral)		
N3	Metastasis in a common iliac lymph node(s)		
M—distant metastasis			
Mx	Cannot be assessed		
M0	No distant metastasis		
M1	Distant metastasis present		
Stage grouping			
Stage 0a	Ta	N0	M0
Stage 0is	Tis	N0	M0
Stage I	T1	N0	M0
Stage II	T2a,b	N0	M0
Stage III	T3a,b	N0	M0
	T4a	N0	M0
Stage IV	T4b	N0	M0
	Any T	N1, 2, 3	M0
	Any T	Any N	M1

TREATMENT OF BLADDER CANCER

Non–Muscle-Invasive Bladder Cancer

Around 80% of patients with bladder cancer present with non–muscle-invasive disease. These are classified as Tis, Ta, and T1 by the TNM classification system. The gold standard for diagnosis is the resection of the lesion with adequate sampling of the detrusor muscle deep to the lesion (TURBT). This will give tissue for accurate staging of the bladder lesion as well as definitive treatment for the lesion. Recurrences after TURBT are found in up to 70% of patients undergoing surveillance, and more importantly, up to 15% of patients on surveillance will progress to muscle-invasive bladder cancer. At the time of diagnosis, the upper urinary tract also needs assessment. This can be done with intravenous urography, CT urography, or ultrasound. The incidence of upper tract tumors at the time of presentation with hematuria is only 1.8%, calling into question the use of contrast imaging for the group as a whole.[122] Ultrasound is

now being used more frequently, with contrast imaging modalities being used for the higher-risk disease.

Prognostication and management strategy are based on accurate initial staging and grading of the disease. There can be variation in the interpretation of pathologic specimens, so review of pathology is recommended (European Association of Urology [EAU] guidelines).[123] If there is uncertainty over the pathology, a further early re-resection is indicated. The risk of residual tumor can be as high as 53% in T1 tumors.[124] If the disease is defined as NMIBC, it can be characterized as low, intermediate, or high risk, and this will dictate how the disease is managed (see below). The EORTC bladder cancer calculator provides a valuable online tool for doing this and determining follow-up frequency.[125]

Following resection of the tumor, there is good evidence that a single dose of mitomycin C administrated into the bladder for 1 hour within 24 hours of surgery will reduce the relative risk of recurrence by 24.2% but will not impact disease progression and disease survival.[125] Recurrences after TURBT are found in up to 70% of patients undergoing surveillance, and up to 15% of patients on surveillance will progress to muscle-invasive bladder cancer. Emerging endoscopic techniques employing photodynamic therapy aimed at improving diagnostic yield and thereby ultimately reducing the rates of recurrence and progression have demonstrated promising results.[126]

Low-risk tumors are single tumors that are <3 cm in diameter and are graded as G1 disease and staged as Ta with no evidence of CIS. These tumors have a 15% probability of recurrence and a 0.2% risk of progression at 1 year.[30] These patients should undergo a flexible cystoscopy 3 months after the initial resection, and if this is negative, a flexible cystoscopy should be undertaken 9 months later and then annually thereafter.

Intermediate- and high-risk tumors are defined using a scoring system based on a number of clinical and pathologic factors:

a. Number of tumors
b. Tumor size
c. Prior recurrence rate
d. T category
e. Presence of concurrent CIS
f. Tumor grade[127]

The high-risk tumors should be followed up with 3 monthly flexible cystoscopy for 2 years and 6 monthly for a further 5 years and then annually

thereafter. Intermediate-risk tumors should be followed up using a surveillance regimen somewhere between that used for low- and high-risk diseases, which is adapted according to personal and subjective factors. The intermediate-risk tumors have up to a 38% probability of recurrence and a 5% risk of progression at 1 year. The high-risk tumors have a 61% probability of recurrence and a 17% risk of progression at 1 year.[30]

The use of flexible cystoscopy with urine cytology is the standard of bladder surveillance, with ongoing research into improving the sensitivity and specificity of flexible cystoscopy. There are a wide number of urinary biomarkers available such as NMP22, UroVysion (Abbott Laboratories, Abbott Park, Illinois), and ImmunoCyt (Scimedx, Denville, New Jersey). These agents suffer from high false-positive rates and variable sensitivity and are costly (as reviewed by Vrooman and Witjes[123]).

The presence of CIS in the bladder carries a 54% risk of disease progression without treatment.[128] Patients with high-risk tumors or CIS should be offered intravesical immunotherapy using bacille Calmette-Guérin (BCG) (EAU and American Urology Association guidelines).[124,129] There are a variety of treatment schedules in the literature, but the authors recommend an intravesical treatment once a week for 6 weeks followed by a subsequent 3 weeks as an induction treatment. If there is no cystoscopic evidence of recurrence, the patient should then be offered ongoing maintenance BCG with 6-week courses of BCG every 3 to 6 months with regular cystoscopic surveillance. In a recent meta-analysis of trials with BCG maintenance, a 32% reduction in the risk of recurrence was seen for BCG compared with mitomycin C ($P < .0001$), whereas there was a 28% increase in the risk of recurrence ($P = .006$) for patients treated with BCG in the trials without BCG maintenance.[127] BCG is a very effective treatment, but not all patients with NMIBC should be treated with BCG because of the risk of toxicity. In a phase III study for NMIBC tumors using maintenance BCG therapy, 20.3% patients stopped BCG because of side effects, mostly local side effects; 68% who stopped because of side effects did so during the first 6 months. The choice of treatment depends on the patients' risk of recurrence and progression based on EORTC subgroups. The use of BCG does not alter the natural course of tumors in the low risk of recurrence subgroup and is therefore considered to be overtreatment. In patients with tumors at high risk of progression, for whom cystectomy is not carried out, BCG, including at least 1-year maintenance, is indicated. In patients at intermediate or high risk of recurrence and intermediate risk of progression, BCG with 1-year maintenance

is more effective than chemotherapy for prevention of recurrence; however, it has more side effects than chemotherapy. For this reason, both BCG with maintenance and intravesical chemotherapy remain options. The final choice should reflect the individual patient's risk of recurrence and progression and the efficacy and side effects of each treatment modality (EAU guidelines). In treatment refractory disease, the patient should be offered radical treatment for the bladder.

Muscle-Invasive, Nonmetastatic Disease

For a review of recent guidelines and recommendations for broad therapeutic options in the multidisciplinary integrated management of invasive non–metastatic muscle-invasive bladder cancer by the American Urological Association (AUA), American Society of Clinical Oncology (ASCO), the American Society for Radiation Oncology (ASTRO) Society of Urologic oncology, and the European Association of Urology, the reader is referred to the original publications in the Journal of Clinical Oncology and the Journal of Oncology Practice.[126,130]

Relative Roles of Cystectomy and Bladder Preservation

Radiation therapy has been used as the primary treatment for muscle-invasive bladder cancer for many years, but utilization rates vary around the world from around 10% in the United States[8] to 25% in Scandinavia[128] to in excess of 50% in the United Kingdom.[10] There are no prospective randomized trials comparing surgery with radiation therapy, so the data on comparative efficacy can only be inferred indirectly. US authors in particular tend to refer to surgery as the gold standard of care, with bladder preservation with radiation therapy (with or without chemotherapy) being viewed as experimental. However, this opinion seems to be based on custom and practice and not on any hard comparative data. It is thus worth examining in some detail the data that exist on this topic. There is a solitary attempt using modern techniques to compare surgery with bladder preservation combining chemotherapy and radiotherapy. The UK SPARE trial (randomized trial of Selective Bladder Preservation against Radical Excision [cystectomy] in muscle-invasive T2/T3 transitional cell carcinoma of the bladder) was a feasibility study that has now closed due to poor accrual. These phase II and III trials attempted to investigate the potential of using the response to neoadjuvant chemotherapy as a predictive tool for selecting patients for radiation therapy compared with the surgical standard. In the authors'

experience, one of the problems with the trials was that the study used response to neoadjuvant chemotherapy to decide on suitability for bladder preservation. However, once this was explained to the patients in the information sheet, there were patients who had a good response but were reluctant to undergo surgery, particularly if the bladder was free of tumor at the interim cystoscopy.

Large population-based studies suggest that the main determinants of survival after diagnosis of bladder cancer are stage, grade, age, and to some extent social class. For example, Hayter et al.[6] studied patterns of care and outcomes in over 20,000 patients with bladder cancer in Ontario. They found significant variations in the use of cystectomy and radiation therapy between different districts but no evidence that these variations led to any differences in long-term outcomes. They concluded that bladder-sparing approaches were equivalent to surgery for invasive bladder cancer.

Another way to compare outcomes between surgery and radiation therapy is to look at large published series. In the United Kingdom, where both of these approaches are routinely employed, it is possible to compare the outcomes in Cancer Registry data. A recent paper from Munro et al.[10] examined outcomes in 458 patients with invasive bladder cancer treated in Yorkshire between 1993 and 1996. The ratio of cystectomy to radiation therapy was 1 to 3, reflecting UK practice at the time. Overall 10-year survival was similar between those who underwent radiation therapy (22%) and radical cystectomy (24%). Prognostic factors for inferior outcome at 10 years were female versus male, poor performance status, hydronephrosis, and increasing T-stage; treatment modality was not a factor in the prognosis.

One of the most widely quoted surgical series comes from the University of Southern California and reports the results of 1,054 patients undergoing cystectomy with overall 5- and 10-year survival rates of 60% and 43%, respectively. This series is discussed in detail below. However, this series included patients undergoing surgery for noninvasive tumors and excluded from the denominator 112 patients referred but deemed incurable at operation. If we look at the 5-year survival of those with invasive tumors, the rate drops to around 47% from the quoted 60%. A contemporary series of radiation therapy cases from Rödel et al.[5] reports 5- and 10-year survivals of 51% and 31% but included patients deemed inoperable.

Furthermore, if we analyze the outcomes in the surgical control arm in the U.S. Intergroup Neoadjuvant MVAC trial, the median survival was 38 months and the 5-year survival was 42%. Other relatively contemporary series quote

similar 5-year survivals: for example, Dalbagni et al.[131] cite 45% overall and 65% disease-specific survival rates in a series of 300 patients. Furthermore, the only significant prognostic factors in this series were age, T-stage, and use or nonuse of neoadjuvant chemotherapy (see the Role of Systemic Therapy section). Data also exist from single-institution series with widespread use of both modalities. Kotwal et al.[132] report results on 169 patients treated between March 1996 and December 2000 in Leeds, United Kingdom. There were no differences in overall, cause-specific, and distant recurrence-free survival at 5 years between the two groups, despite the radiotherapy group being older (median age, 75.3 vs. 68.2 years). There were 31 local bladder recurrences in the radiation therapy group (24 of which were solitary and hence potentially suitable for salvage surgery), but no significant difference in distant recurrence-free survival. In another more recent (2002 to 2006) cohort, the median age of radiation therapy patients but not the cystectomy patients had increased to 78.4 from 75.3 years, respectively, whereas the age of those undergoing surgery remained similar at 67.9 and 68.2 years for surgery, consistent with the aging trend in new bladder cancer cases. These authors concluded that although the patients undergoing radical cystectomy were significantly younger than the radiation therapy patients, treatment modality did not influence survival. They went on to state that radical radiotherapy is a viable treatment option for these patients, with equivalent long-term survival to surgery and the advantage of organ preservation.

Giacalone et al.[133] conducted an analysis of 465 patients with cT2e-T4a bladder cancer treated at a single institution with maximal transurethral resection of bladder tumor (TURBT) followed by concurrent cisplatin-based chemotherapy and RT. A subset of patients also received neoadjuvant chemotherapy. Repeat cystoscopy with biopsies was performed after 40 Gy. Patients with a complete response (CR) received consolidation chemoradiation to 64 to 65 Gy, and those with less than a CR or invasive recurrence were recommended to undergo salvage RC.

Median follow-up was 4.8 years for all patients and 7.5 years for surviving patients. Seventy-six percent of patients had a CR to induction chemoradiation, 84% after a visibly complete TURBT achieved a CR versus 59% with an incomplete TURBT ($P < .001$). When evaluated in 4-year intervals, the CR rate has improved from 64% in years 1986 to 1990 to 96% in years 2010 to 2012. One hundred twenty-five patients (27%) underwent salvage RC, 55 for less than CR and 70 for superficial or invasive recurrences. For those patients who

achieved a CR, the 10-year actuarial rates for noninvasive, invasive, pelvic, and distant failures were 32%, 16%, 14%, and 29%, respectively. Five-, 10-, 15-, and 20-year DSS rates were 66%, 59%, 56%, and 50% (T2 Z 75%, 66%, 61%, and 58%; T3eT4a Z 50%, 45%, 45%, 36%), respectively.

Median OS was 6.4 years. Five-, 10-, 15-, and 20-year OS rates were 57%, 39%, 25%, and 18% (T2 Z 66%, 46%, 29%, 23%; T3eT4a Z 41%, 26%, 17%, 10%), respectively.

Neoadjuvant chemotherapy did not improve DSS or OS.

The authors noted this series represented one of the largest cohorts of MIBC treated with CMT and the data supported the high rates of CR and bladder preservation in patients receiving CMT and demonstrated long-term DSS similar to modern cystectomy series.

Using the National Cancer Database (NCDB), patients with AJCC clinical T2-T3, N0, and M0 urothelial carcinoma (MIBC) diagnosed between 2004 and 2013, Zhong et al.[134] carried out an analysis of patients treated with definitive intent with either radical cystectomy (with or without chemotherapy) or concurrent chemotherapy and radiation (bladder preservation) (BPCRT). Only patients documented to undergo a transurethral tumor resection followed by a definitive course of radiation with chemotherapy were included in this BPCRT cohort.

Among 8,454 MIBC patients, 7,276 (86%) underwent radical cystectomy with or without chemotherapy, and 1,178 (14%) underwent BPCRT. Patients undergoing BPCRT were significantly older (median age 77 vs. 68 years, $P <$ .001) and had higher comorbidity scores (P Z 0.002). The median follow-up time was 4.5 years. The unadjusted 5-year OS rates were 45.0% and 31.8% for surgery and BPCRT cohorts, respectively ($P <$ .001). Using matched propensity score analysis, there were 1,002 patients remaining in each cohort, and there was no significant difference in 5-year OS between the two groups (39.7% surgery vs. 32.4% BPCRT, P Z 0.10). BPCRT demonstrated similar survival outcomes compared to those treated with radical cystectomy with or without chemotherapy. In the absence of prospective randomized studies, these results may help guide decision-making for MIBC patients considering nonsurgical management options.

Vashista et al.[135] searched seven databases (PubMed, Scopus, EMBASE, Proquest, CINAHL, and ClinicalTrials.gov) for randomized, controlled trials and prospective and retrospective studies directly comparing RC with CMT from database inception to March 2016. They conducted a meta-analyses evaluating

OS, DSS, and PFS with hazard ratios (HRs). Nineteen studies evaluating 12,380 subjects were selected. For the 8 studies encompassing 9,554 subjects eligible for meta-analyses, we found no difference in OS at 5 years (HR 0.96, favoring CMT) or 10 years (HR 1.02, favoring cystectomy). No difference was observed in DSS at 5 years (HR 0.83, favoring radiation) or 10 years (HR 1.17, favoring cystectomy), or PFS at 10 years (HR 0.85, favoring CMT). The cystectomy arms had higher rates of early major complications, whereas rates of minor complications were similar between the two treatments. In summary, this meta-analysis showed no differences in OS, DSS, or PFS between RC and CMT. Further randomized, controlled trials are necessary to identify the optimal treatment for specific patients.

The Surveillance, Epidemiology, and End Results (SEER) program was used by Wilhite et al.[136] to identify patients diagnosed from 1992 to 2013 with localized, muscle-invasive bladder (stages II to III) urothelial carcinoma, squamous cell carcinoma, or adenocarcinoma histology. Cystectomy was defined as partial or radical. Those who did not receive either cystectomy or RT were excluded. Treatment utilization patterns over time were assessed using Cochran-Armitage tests. Among 16,175 patients eligible for analysis, 11,917 (74%) and 4258 (26%) received cystectomy and RT, respectively. Patients who received RT were older (median age 79 vs. 68, $P < .01$), Over time, there was a statistically significant increase in the proportion of patients receiving RT relative to cystectomy (24% in 1992 to 2003 vs. 28% in 2004 to 2013, $P < .01$), despite median patient age throughout the study period remaining unchanged (71 for both 1992 to 2003 and 2004 to 2013). For RT, compared with patients diagnosed from 1992 to 2009, those diagnosed from 2010 to 2013 showed improved CSS (71% vs. 67% at 1 year, P Z 0.01; 51% vs. 40% at 3 years, $P < .01$) and OS (64% vs. 60% at 1 year, $P < .01$; 38% vs. 29% at 3 years, $P < .01$). In these SEER data, utilization of RT for localized, muscle-invasive bladder cancer increased relative to cystectomy from 1992 to 2013, despite the median age of treated patients over that period remaining unchanged. There was significant improvement in CSS and OS for patients receiving RT who were diagnosed from 2010 to 2013 compared with earlier years, support continued use of bladder preservation strategies utilizing RT.

Solanki et al.[137] conducted an electronic survey of US radiation oncologists regarding the management of patients with cT2-3N0M0 transitional cell muscle-invasive bladder cancer; 277 physicians completed the survey. Most respondents (58%) stated that they only treated 1 to 3 patients with bladder cancer in the

prior year. Seventy-four percent of respondents primarily treated patients deemed unfit for cystectomy, whereas only 28% saw patients prior to cystectomy for consultation to discuss bladder preservation therapy. The majority of radiation oncologists (91%) used conventional fractionation instead of hypofractionation (7.6%), but more variability existed for radiation therapy targets. Sixty percent used a small-pelvis field, 29% used a whole-pelvis field, and 12% treated the bladder only. There was increased use of hypofractionation (29%) and bladder-only radiation therapy (34%) in patients who were not candidates for cystectomy or chemotherapy ($P < .001$). Cisplatin-based concurrent chemotherapy was most commonly preferred (89%). In noncisplatin candidates, most respondents preferred 5-fluorouracil plus mitomycin C (32%) or carboplatin (32%). IMRT use and midtreatment cystoscopic reevaluation were variable, whereas hyperfractionation use was low. Although there are areas of consistency, variability exists in many technical and practical aspects of treatment delivery. Further research and education are needed to determine the optimal radiation therapy target, dose/fractionation, and concurrent chemotherapy regimen.

Mitin et al.[138] performed a pooled analysis of 119 patients with muscle-invasive bladder cancer enrolled on NRG Oncology Radiation Therapy Oncology Group trials 9906 and 0233, who were classified as having a complete (T0) or near-complete (Ta or Tis) response after induction chemo-RT and completed consolidation with a total RT dose of at least 60 Gy.

One hundred one patients (85%) achieved T0, and 18 (15%) achieved Ta or Tis after induction chemo-RT and proceeded to consolidation. After a median follow-up of 5.9 years, 36 of 101 T0 patients (36%) versus 5 of 18 Ta or Tis patients (28%) experienced bladder recurrence (P Z .52). Thirteen patients among complete responders eventually required late salvage cystectomy for tumor recurrence, compared with 1 patient among near-complete responders. Disease-specific, bladder-intact, and overall survivals were not significantly different between T0 and Ta/Tis cases. Therefore, it is reasonable to recommend that patients with Ta or Tis after induction chemo-RT continue with bladder-sparing therapy with consolidation chemo-RT to full dose (60 to 64 Gy). Neoadjuvant chemotherapy randomized trials had been previously reported by the International Collaboration of Trialists.[139]

Walker et al.[140] reported on a Canadian survey of 64 urologists, 29 radiation oncologists (RO), and 26 medical oncologists (MO) on treatment of muscle-invasive bladder cancer. Participants reported comparable survival at 5 years

with cystectomy (51%) and RT with concurrent chemotherapy (50%). Despite this, participants reported low RT referral/treatment rates: Urologists referred a median of 2/10 patients to RO; ROs treated a median of 5/10 patients referred; and MOs referred a median of 2/8 patients not referred to RO by urology.

A proportion of patients undergoing radiation therapy will relapse within the bladder and go on to salvage cystectomy. An important consideration, therefore, is whether cystectomy after radiation therapy can be carried out safely and whether the delay compromises survival. Again, there are no randomized data on this topic. However, UK surgeons in particular have good practical experience on this topic and have commented that neither prior chemotherapy nor radiation therapy compromises surgical salvage and that long-term results appear similar to primary cystectomy series.

Particularly intriguing in this regard is a comparison of survival rates following primary surgery or salvage surgery following failed radiation therapy from the Christie Hospital in Manchester, United Kingdom. The group examined the outcomes in 552 patients who underwent radical cystectomy between 1970 and 2005. Of these, 313 patients underwent primary radical cystectomy and 239 underwent salvage radical cystectomy following radiation failure. The median age was 62.5 years (range, 32.2 to 87.2) for the primary surgical group compared with 65.5 years for the salvage group. Overall 5-year survivals reported were 45.5% for the primary group and 42% for the salvage group, with cause-specific survivals of 51% and 50%, respectively. These differences persisted after stratification for stage, and the authors concluded that a policy of primary radiation therapy with surgical salvage did not compromise the long-term survival chances of patients.[139]

Clearly, there are surgical series with much higher survival rates than this in the literature. However, there are two factors accounting for this. One is case selection, the other is that these series are, to a degree, personal, so to publish results that appear inferior to other major centers is potentially a threat to a center’s (or surgeon’s) reputation and will tend to have a “ratchet” effect on published results. These data also suggest that the predominant prognosis driver in bladder cancer is the presence or absence of distant micrometastasis at diagnosis of invasive disease. The (relatively modest) effect of neoadjuvant chemotherapy tends to bear this out, particularly as the biggest effect in the Medical Research Council (MRC)/EORTC trial was on metastasis-free survival rather than pelvic tumor control rates.[139]

There is little in the way of randomized data on the efficacy of radiation

therapy in either non–muscle-invasive disease or CIS. The only randomized trial on this topic comes from the United Kingdom and compared radiation therapy with surveillance for patients with a new diagnosis of pT1G3 NXM0 transitional cell carcinoma with unifocal disease and no CIS. Patients with multifocal disease or CIS were randomized between intravesical therapy and radiation therapy. There was no evidence of benefit from radiation therapy in terms of progression-free interval (hazard ratio [HR] 1.07; 95% confidence interval [CI], 0.65 to 1.74; *P* = .785), progression-free survival (HR 1.35; 95% CI, 0.92 to 1.98; *P* = .133), or overall survival (HR 1.32; 95% CI, 0.86 to 2.04; *P* = .193).[141] There is thus no indication for radiation therapy in these groups of patients.

In truth, surgery and radiation therapy do not compete but are complementary approaches of treatment of invasive bladder cancer. There are particular groups who appear to do poorly with primary radiation therapy, for example, those with poorly functioning bladders or extensive CIS in addition to their invasive disease. In the former case, radiation therapy is unlikely to improve bladder function; in the latter, the lack of effect of radiation therapy on CIS means that the patient remains at risk of further bladder intervention and ultimately cystectomy.[139] Similar considerations apply to patients with pT1G3 disease.[141] North American authors will also cite features such as hydronephrosis as a contraindication to radiation therapy.[142] However, hydronephrosis is also a poor prognostic factor for surgery and does not help in selecting patients one way or another.[6] On the other hand, there are many patients who may benefit from radical therapy but are poor surgical candidates, such as older patients, the obese, diabetics, poor anesthetic-risk patients, or those who may struggle with whatever form of neobladder is fashioned. Although large surgical series will include patients over age 80, these will typically comprise only a few percentage of the total, whereas, with a median age at diagnosis of bladder cancer in the middle to late 70s, there are probably many more who do not make it to surgery.

Surgery

Management of Invasive Bladder Cancer

Although the majority of patients present with NMIBC, 20% to 40% will either present with or ultimately develop muscle-invasive disease. Invasive bladder cancer is potentially lethal; if untreated, over 85% of patients will die of the disease within 2 years of diagnosis.[141] Furthermore, a certain percentage of patients with high-grade bladder tumors without involvement of the lamina propria will recur or progress or fail intravesical management, and they may be

best treated with an earlier cystectomy when survival outcomes are optimal.[142] In these groups of patients, the 5-year survival rates after cystectomy exceed 80%.[143]

The rationale for an aggressive treatment approach employing radical cystectomy for high-grade, invasive bladder cancer is based on several important observations. First, the good long-term survival rates, coupled with the lowest local recurrences, are seen following a definitive surgical approach removing the primary bladder tumor and regional lymph nodes.[4,144,145] Although there are no randomized trials comparing radical cystectomy with bladder-preserving approaches, surgery remains the preferred treatment option for many clinicians for advanced, localized invasive bladder cancer.[144,145] Second, the morbidity and mortality of radical cystectomy has substantially improved over the past several decades.[144,146] Third, advocates say that radical cystectomy provides accurate pathologic staging of the primary bladder tumor (p stage) and regional lymph nodes, thus, selectively determining the need for adjuvant therapy based on precise pathologic evaluation. However, it should be noted that the evidence base for adjuvant (as opposed to neoadjuvant) therapy is rather weak (see on the Role of Systemic Therapy section). For the abovementioned reasons, radical cystectomy has become a standard form of therapy for high-grade, invasive bladder cancer. Nonetheless, many articles on cystectomy emphasize the need for careful patient selection to achieve optimal results. Although this is undoubtedly true, it begs the question of what should be done with patients who do not meet these stringent selection standards but still need to be treated. This issue is rarely, if ever, addressed in cystectomy series publications.

The evolution and improvements in lower urinary tract reconstruction, particularly orthotopic diversion, have been major components in enhancing the quality of life of patients requiring cystectomy. Currently, most men and women can safely undergo orthotopic lower urinary tract reconstruction to the native, intact urethra following cystectomy,[147] although availability varies worldwide. Orthotopic reconstruction aims to mimic the native bladder in location and function, provides a continent means to store urine, and allows volitional voiding per urethra, although patients need to do this by coordinating opening the sphincter with a Valsalva maneuver, which does require training. The orthotopic neobladder eliminates the need for a cutaneous stoma, urostomy appliance, and the need for intermittent catheterization in most cases. These efforts have improved the quality of life of patients who require removal of their bladders and have also stimulated patients and physicians to consider radical cystectomy

at an earlier more curable stage for high-grade, invasive bladder cancer.[148,149] A dedicated effort has been made to improve the surgical technique of radical cystectomy and to provide an acceptable form of urinary diversion, without compromise of a sound cancer operation.

Timing of cystectomy after the TURBT is important, and it has been demonstrated that a delay of more than 3 months undermines patient survival. This evidence forms the basis to negotiating resource needs with health care providers[150]. Certain technical issues regarding radical cystectomy and an appropriate lymph node dissection are critical to minimize local recurrence and positive surgical margins and to maximize cancer-specific survival.[151] Attention to surgical detail is important in optimizing the successful functional outcomes of orthotopic diversion by preserving the urinary sphincter mechanism and therefore continence. Finally, the observed associations between hospital volume and operative mortality are largely mediated by surgeon volume. Patients can often improve their chances of survival substantially, even at high-volume hospitals, by selecting surgeons who perform the operations frequently, as those centers that have adopted this strategy have demonstrated declining mortality in the past decade.[152,153]

Radical cystectomy by definition implies the *en bloc* removal of the pelvic–iliac lymph nodes along with the pelvic organs anterior to the rectum: the bladder, urachus, prostate, seminal vesicles, and visceral peritoneum in men and the bladder, urachus, ovaries, fallopian tubes, uterus, cervix, vaginal cuff, and the anterior pelvic peritoneum in women. An appropriate lymphadenectomy is an important component of radical cystectomy and is related to the clinical outcomes of patients with high-grade, invasive bladder cancer. Evidence suggests that a more extended lymphadenectomy is beneficial in both lymph node–positive and lymph node–negative patients with bladder cancer,[154–156] although this could be a surrogate for either case selection or surgical skill. Although the exact limits of the lymphadenectomy for patients with bladder cancer undergoing cystectomy are currently debated, the boundaries include initiation at the level of the inferior mesenteric artery (superior limits of dissection), extending laterally over the inferior vena cava or aorta to the genitofemoral nerve (lateral limits of dissection), and distally to the lymph node of Cloquet medially (on Cooper ligament) and the circumflex iliac vein laterally. This dissection includes bilaterally all obturator, hypogastric, presciatic, and presacral lymph nodes.[157,158] Removal of more than 15 lymph nodes has been postulated to be both sufficient for the evaluation of the lymph node status as

well as beneficial for overall survival in retrospective studies.[158,159] However, potential interindividual differences in the number of pelvic and retroperitoneal lymph nodes and difficulties in processing of the removed tissue by pathologists are issues. Furthermore, the reality is that even in today's practice, the number of lymph nodes retrieved are low (<10) in a majority of patients (75%) and the chances are even lower if the patients are older, Hispanic (in the United States), and managed at low-volume, nonurban centers.[158] The true curative value of lymph node dissection and the optimal extent of dissection are both still unknown.

Technical variations from the standard cystectomy have been performed to improve patients' quality of life, including prostate-sparing cystectomy in order to preserve continence and potency. However, it carries a higher risk of missing unsuspected adenocarcinoma of the prostate. Coexistent prostate cancer and prostatic urothelial cancer are reported in 23% to 54% cases, of which 29% were clinically significant, leading to local recurrence and even metastasis.[160,161]

Radical cystectomy is an appropriate standard treatment for patients with high-grade, invasive bladder cancer. The clinical outcomes are presented in Table 68.2. These results should provide a benchmark for outcomes to which other therapies can be compared.

Both laparoscopic and robot-assisted cystectomy have been shown to be feasible and safe, but with a relatively shorter follow-up.[162–164] Despite an increased materials cost for a robotic-assisted cystectomy, it has been demonstrated to be cost-effective in a subgroup of patients undergoing ileal conduit when the impact of complications are considered in a single-institution series.[164,165]

Morbidity and Mortality of Radical Cystectomy and Lymphadenectomy

The early clinical results and outcomes with regard to the morbidity and mortality of radical cystectomy were disappointing. Lack of universal acceptance of this procedure was attributed to the considerable complication rate and the need for improvements in urinary diversion. Prior to 1970, perioperative complication rates of radical cystectomy were approximately 35%, with a mortality rate of nearly 20%. However, with contemporary medical, surgical, and anesthetic techniques, along with better patient selection, the mortality and morbidity from radical cystectomy have dramatically decreased (Table 68.2). Importantly, in high-volume centers, the administration of preoperative therapy

(radiation or chemotherapy) and the form of urinary diversion performed (continent or incontinent) did not obviously increase the mortality rate of patients undergoing radical cystectomy.[142] The issue of the need to select patients for surgery complicates the comparison of bladder-sparing techniques, because frequently those not suitable for surgery will be the ones who appear in the radiotherapy-based series.

The early complication rate following radical cystectomy should not be underestimated in this elderly group of patients. The median age of patients undergoing cystectomy in a University of Southern California series was 66 years.[4] Of the 1,054 patients treated, 28% developed an early complication within the first 3 months of surgery. Early complications included all events related to the cystectomy, perioperative care, and urinary diversion. The administration of preoperative therapy (radiation or chemotherapy) and the form of urinary diversion did not significantly increase the early complication rate in these cystectomy patients. Most early complications following radical cystectomy are unrelated to the urinary diversion (85% diversion unrelated) and can be managed conservatively without the need for reoperation in approximately 90% of cases.[166] The most common early diversion-unrelated complication is dehydration, whereas the most common early diversion-related complication following radical cystectomy is prolonged urinary leakage. Overall, the most surgical complications after cystectomy are associated with urinary diversion in relation to the intestinal segments.[144,167]

Neoadjuvant chemotherapy is discussed in a later section, but it does not seem to increase the perioperative morbidity or mortality.[7,168] Preoperative radiation therapy is discussed below.

Radical cystectomy may appropriately be performed in carefully selected elderly patients[169]; however, this emphasis in the surgical literature on “careful selection” highlights as much the deficiencies as the efficacy of cystectomy as it emphasizes that the published results are not applicable to the entire population. It is emphasized that physiologic age may be more important than chronologic age when determining appropriate candidacy for radical cystectomy. Proper patient selection, strict attention to perioperative details, along with a dedicated and meticulous team-oriented surgical approach are critical components to minimize the morbidity and mortality of surgery and to ensure the best clinical outcomes in all patients following radical cystectomy.[166,170,171] A recommended approach from the authors’ center previously pioneered by the Danish is adoption of an enhanced recovery pathway protocol (Fig. 68.2).[172]

Pathologic Stage and Subgroups

The pathologic stage of the primary bladder tumor and the presence of regional lymph node metastases are the most important survival determinants in patients undergoing cystectomy for bladder cancer.[4,145,147] These pathologic determinants may also be categorized into pathologic subgroups that provide risk stratification and direct the need for adjuvant therapy in the appropriately selected individual. Pathologic subgroups are defined as organ-confined, lymph node–negative tumors (P0, Pa, Pis, P1, P2a, P2b), nonorgan confined (extravesical) lymph node–negative tumors (P3, P4), and lymph node–positive disease (N+), representing 56%, 20%, and 24% of patients, respectively.[147] The 5- and 10-year recurrence-free survival rates for the entire group of 1,054 patients in the University of Southern California series were 68% and 66%, respectively (Table 68.2). Most deaths occurred within the first 3 years following radical cystectomy and were attributed to cancer recurrence. However, with longer follow-up (>3 years), most deaths in this elderly group of patients were primarily related to comorbid diseases unrelated to bladder cancer. This underscores the effective and durable outcomes of radical cystectomy.

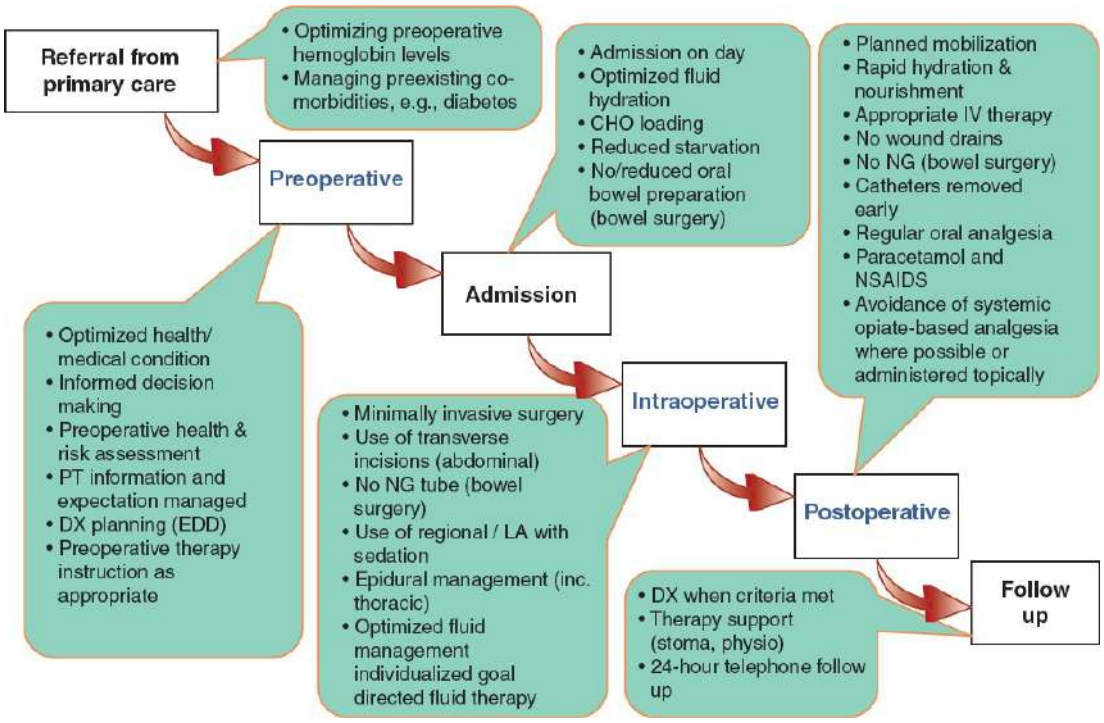

FIGURE 68.2. Schematic representation of the enhanced recovery program in patients undergoing a radical cystectomy.

Molecular Biomarkers

It has been reported that patients who expressed high levels of meiotic recombination homolog (MRE11) on transurethral resection of the bladder tumor biopsy had a better response to radical RT (*P* Z .005). Also, studying other protein expression within the biopsy material, it was found that p16 was associated with poor prognosis after either RT or cystectomy. Tat-interactive protein (TIP60) was associated with disease-specific survival after cystectomy (*P* Z .001).

Further, telomeres protect the ends of chromosomes from degradation and fusion but are shortened during the DNA replication process. Shortening of telomeres is associated with chromosomal instability and may be related to an increased risk of bladder cancer, especially as bladder cancer is associated with lifestyle and occupational risk factors. In a study that analyzed the telomere length in leukocytes of 463 bladder cancer patients with both MIBC and non-MIBC (NMIBC), the main finding was that shortened telomere length was independently associated with overall and bladder cancer–specific survival. This association was maintained whether the bladder cancer was of high or low grade and whether or not it was muscle invasive.[173]

Bladder cancer therapy is rapidly evolving. There is accumulating evidence

for the activity of programmed death 1 (PD-1) and programmed death ligand 1 (PD-L1) inhibitors, immunotherapeutic agents that reduce T-cell anergy. Gene expression profiles of bladder tumors suggest that there are several prognostic gene signatures present, which may predict benefit from systemic chemotherapy[12] and may also predict response to immunotherapy[9]. Furthermore, the fundamental biology represented by gene expression may provide a context for mutationally driven tumors. One example is the enhanced peroxisome proliferator–activated receptor-γ expression observed in the luminal subtype, which is also enriched for fibroblast growth factor receptor 3 (FGFR3) mutations. Several datasets also support the activity of specific targeted agents in a mutation-dependent context. There is mounting substantial evidence for PD-1– and PD-L1–directed therapies, and a vigorous debate surrounds the use of PD-L1 immunohistochemical assessment to identify appropriate patients for therapy. Data from the phase II assessment of atezolizumab suggest the potential use of mutational load as a predictor of response. These preliminary findings support the recent recommendation by the NCCN Bladder Cancer Guidelines panel, which recommends molecular profiling of advanced bladder cancer.[174]

Organ-Confined, Lymph Node–Negative Tumors

In the University of Southern California series, 56% of patients demonstrated pathologically organ-confined, lymph node–negative tumor.[4] The outcomes in this pathologic subgroup were excellent (Table 68.3), with a 5- and 10-year recurrence-free survival of 85% and 82%, respectively. No significant survival differences were observed when comparing superficially noninvasive (Pis, Pa), lamina propria invasive (P1), and muscle-invasive (P2a, P2b) tumors as long as the tumor was confined to the bladder without evidence of lymph node involvement. Similar outcomes for patients with pathologic non–muscle-invasive bladder tumors following cystectomy have been previously reported.[4,146,175] Collectively, these data support the treatment of patients with surgery when a tumor is confined to the bladder, without evidence of extravesical extension or lymph node metastasis. Treatment delays in patients with invasive bladder cancer should be avoided. Evidence suggests that prolonged delays may lead to more advanced pathologic stage and decreased survival in patients with muscle-invasive bladder cancer.[150] Furthermore, caution should be taken in delaying definitive therapy in patients with high-risk, non–muscle-invasive bladder tumors or those with non–muscle-invasive tumors that have not appropriately responded to conservative forms of therapy.[1]

Extravesical, Lymph Node–Negative Tumors

Non–organ-confined (extravesical), lymph node–negative tumors were found in 20% of University of Southern California series patients undergoing cystectomy (Table 68.3). No obvious survival differences between extravesical P3 and P4 (node-negative) tumors were observed. The 5- and 10-year recurrence-free survival rates for this pathologic subgroup were 58% and 55%, respectively. Similar outcomes were reported by Madersbacher et al.[144] and Dhar et al.,[159] who demonstrated a 56% 5-year recurrence-free survival for the same pathologic subgroup. Patients with locally advanced tumors have higher recurrence rates and decreased survival compared with those with organ-confined, lymph node–negative tumors.[176] The 1997 AJCC TNM staging system used for these studies stratified extravesical tumor involvement (previously defined as pT3b) into microscopic (pT3a) and gross (pT3b) extravesical tumor extension. No significant difference was observed in the recurrence-free and overall survival in patients when evaluating for pT3a and pT3b extravesical extension.[176] The incidence of lymph node involvement was similar (~45%); however, the presence of lymph node involvement was associated with a higher risk of recurrence and worse survival compared with node-negative patients.

Lymph Node–Positive Disease

Perhaps one-fourth of patients in large cystectomy series will have positive lymph nodes (Tables 68.2 and 68.4). Although patients with lymph node tumor involvement are a high-risk group of patients, nearly one-third of these patients were alive at 5 years in the series by Stein et al..[4] It is possible that the surgical approach employing an extended lymph node dissection provides some survival advantage in selected individuals with node-positive disease.[159] The role of adjuvant therapy in these patients is difficult to assess due to the absence of adequately powered trial data (see on the Role of Systemic Therapy section). In an analysis of lymph node–positive patients carried out by the University of Southern California group, the administration of adjuvant chemotherapy was a significant and independent predictor for recurrence and overall survival in this group[183]; however, case-mix effects will be prominent in this type of retrospective analysis as patients need to survive long enough and be fit enough to even start chemotherapy to figure in the analysis. Inevitably, this will bias results in favor of adjuvant chemotherapy by excluding those who died early or who never became fit enough postoperatively to receive chemotherapy. The authors own experience with attempting to recruit to adjuvant chemotherapy trials suggests that only the most fit patients are able to recover quickly enough postoperatively to undergo systemic chemotherapy, so these data are highly likely to be biased by underlying patient fitness. A further interesting feature of the BC2001 trial,[175] discussed in detail below, was that although no attempt was made to include pelvic nodes in the treatment field, the rate of nodal relapse was low at around 6% with radiotherapy alone, falling to 4% with chemoradiation. One possible interpretation of these data is that successful treatment of the primary, with either surgery or radiotherapy, may affect the subsequent behavior of low-volume nodal disease.

The prognosis in patients with lymph node–positive disease can be stratified by the number of lymph nodes involved (tumor burden), the stage of the primary tumor, and the presence of lymph node capsule perforation.[4] Patients with fewer than five positive lymph nodes among those with lymph node–positive organ-confined bladder tumors had a significantly improved recurrence-free survival rate.[4,156,157]

The number of lymph nodes involved with tumor and the extent of the lymph node dissection are both important variables for patients undergoing cystectomy for bladder cancer. Stein et al.[156] examined 246 patients with lymph node tumor involvement following radical cystectomy to evaluate other prognostic factors in

this high-risk group. They used lymph node density to account for the extent of the lymph node dissection (number of lymph nodes removed) and the tumor burden (number of positive lymph nodes) following cystectomy for patients with lymph node–positive disease. Lymph node density as defined in this study was a significant and independent prognostic variable in patients with lymph node metastases. Future staging systems and the application of adjuvant therapy in clinical trials may consider applying these concepts to better stratify this high-risk group of patients.

Recurrence Following Radical Cystectomy

Recurrence following radical cystectomy for bladder cancer correlates well with the pathologic stage and subgroup.[4,144] With long-term follow-up (median, >10 years), recurrences in the University of Southern California series were classified as local (pelvic), distant, and urethral. Local recurrences were defined as those occurring within the soft tissue field of exenteration. Distant recurrences were defined as those occurring outside the pelvis, whereas urethral tumors were classified as a new primary tumor occurring in the retained urethra. Overall, 30% of all patients in the University of Southern California series experienced tumor recurrence.[4] The median time to any recurrence was 12 months, with 86% of all patients developing their recurrences within the first 3 years of cystectomy. Of the 311 patients who developed a recurrence, the median time to distant recurrence was 12 months, whereas the median time to local recurrence was 18 months. Late tumor recurrences, defined as 5 years or more after surgery, do occur and underscore the need for lifelong follow-up.

Pelvic (Locoregional) Recurrence

Pelvic recurrence rates of 6% to 9% are reported in large series,[144,146,175] with higher rates in tumors with extravesical spread or node-positive disease at cystectomy.[4]

In patients with muscle-invasive bladder cancer, locoregional failure (LRF) has been reported to occur in up to 20% of patients following radical cystectomy.

Reddy et al.[184] examined records in an institutional radical cystectomy database of 334 patients with pathologic T3-4 N0-1 bladder cancer after radical cystectomy and bilateral pelvic lymph node dissection. Of these, 46% received perioperative chemotherapy. The median follow-up was 11 months. On univariate analysis, margin status, pT stage, and pN stage were all associated with LRF ($P < .05$); however, on multivariate analysis, only pT and pN stages were significantly associated with LRF ($P < .05$). Three strata of risk were defined, including low-risk patients with pT3N0 disease, intermediate-risk patients with pT3N1 or pT4N0 disease, and high-risk patients with pT4N1 disease, who had a 2-year incidence of LRF of 12%, 33%, and 72%, respectively. The most common sites of pelvic relapse included the external and internal iliac lymph nodes (LNs) and obturator LN regions. Notably, 34% of patients with LRF had locoregional-only disease at the time of recurrence.

Metastatic (Distant) Recurrence

Recurrences following radical cystectomy are most commonly found at distant

sites. This is consistent with the benefits observed in the neoadjuvant chemotherapy trials, where the maximum effect would be expected on low-volume, occult metastases rather than large-volume primary disease (discussed below). Distant recurrence rates of 20% to 35% are reported in large series (Table 68.5). However, overall death rates from bladder cancer are higher than this, so there would appear to be either underreporting of deaths in these series or the cases selected were not representative of wider experience.

Urethral Recurrence

Urethral tumor recurrence in patients with a history of bladder cancer following radical cystectomy represents a second manifestation of the multicentric defect of the primary transitional cell mucosa that led to the original bladder tumor. The term urethral recurrence is therefore somewhat misleading, suggesting a failure of definitive treatment of the bladder cancer. Most urethral tumors probably represent simply another occurrence of the transitional cell carcinoma in the remaining urothelium. Because radical cystectomy with orthotopic diversion has increasingly been performed, the fate of the retained urethra has become an increasingly important oncologic issue.

TABLE 68.5 RECURRENCE-FREE SURVIVAL AND THE INCIDENCE OF RECURRENCE IN SELECTED STUDIES OF RADICAL CYSTECTOMY

Study (Reference)	Number of Patients	Median Follow-Up (Month)	Recurrence-Free Survival (%)		Recurrence (%)	
			5 Year	10 Year	Local	Distant
Stein et al./USC[4]	1,054	122	68	66	7.3	22.2

Yafi et al./Canada[175]	2,287	29	48	—	6.0	27.0

The advent of orthotopic lower urinary tract reconstruction has provided a more natural voiding pattern in patients following radical cystectomy. Approximately 85% of all patients undergoing cystectomy for TCC of the bladder at the University of Southern California research center receive an

orthotopic neobladder substitute. From an oncologic perspective, only those with a positive surgical margin at the proximal urethra (distal to the apex of the prostate in men and just distal to the bladder neck in women) on intraoperative frozen section are absolutely excluded from orthotopic reconstruction. This enthusiasm to preserve the native urethra following radical cystectomy and allow for orthotopic reconstruction has rightfully increased concerns for a urethral recurrence in these patients.

Prior to the orthotopic era in women, urethral tumor recurrence was not an important oncologic issue because the entire urethra was removed at the time of cystectomy. With a better understanding of female pelvic anatomy and the innervation of the urinary sphincter and continence mechanism in women,[185] along with the identification of various pathologic risk factors for urethral tumor involvement in these patients, orthotopic diversion has now become a commonly performed form of urinary diversion in women following cystectomy.[183] Tumor involving the bladder neck is the most important risk factor for urethral tumor involvement in women.[186,187] Although bladder neck involvement is a significant risk factor for urethral tumors, not all women with tumor involving the bladder neck will have urethral tumors. Approximately 50% of female patients with tumor at the bladder neck will have an uninvolved urethra free of tumor. In this situation, the patient may potentially be considered an appropriate candidate for orthotopic diversion. Furthermore, intraoperative frozen-section analysis of the distal surgical margin is an accurate and reliable means to pathologically evaluate the proximal urethra.[187]

A growing population of male patients reconstructed to the urethra following cystectomy exists today. With longer follow-up, could this expose them to a greater risk for a urethral recurrence? The historical incidence of urethral recurrence in the retained urethra following cystectomy for bladder cancer ranges from 6% to 10%.[1] Specific clinical and pathologic risk factors that have been identified to provided risk assessment for urethral recurrence include multifocal tumors, CIS, tumor involvement of the prostate (particularly invasion of the prostatic stroma), and the form of urinary diversion (orthotopic or cutaneous) performed.[188–192]

Stein et al.[188] evaluated urethral recurrence in a large group of male patients undergoing radical cystectomy and urinary diversion for TCC of the bladder. In this study, the clinical and pathologic results of 768 consecutive male patients undergoing radical cystectomy with a median follow-up of 13 years were analyzed. Of these 768 patients, 397 men (51%) underwent an orthotopic

diversion (median follow-up 10 years) and 371 men (49%) underwent a cutaneous diversion (median follow-up 19 years). Overall, 45 patients (7%) developed a urethral recurrence. The median time to a urethral recurrence was 2 years (range, 0.2 to 13.6 years). Of these 45 patients, 16 men (5%) had an orthotopic and 29 (9%) had a cutaneous form of urinary diversion. In this cohort of male patients, multiple risk factors were analyzed with regard to urethral recurrence. In a multivariate analysis, two important variables were identified that significantly increased the risk of a urethral tumor recurrence following cystectomy, including any prostate involvement and the form of urinary diversion. The estimated 5-year probability of a urethral recurrence was 5% without prostate involvement, which increased to 12% and 18% with superficial (prostatic urethra and ducts) and invasive (stroma) prostate involvement, respectively. Patients undergoing an orthotopic diversion demonstrated a statistically significantly lower risk of urethral recurrence compared with those undergoing a cutaneous form of urinary diversion.

The follow-up and management of the urethra in male patients treated for high-grade invasive bladder cancer is of importance. The indications and timing of a prophylactic urethrectomy in those undergoing cystectomy and a cutaneous diversion is debatable. It may include urethrectomy at the time of cystectomy based on preoperative clinical parameters or based on the intraoperative frozen-section analysis of the urethral margin or a delayed urethrectomy based on final pathologic evaluation of the cystectomy specimen. These issues are best detailed with the patient preoperatively ensuring proper informed consent.

Management of the Retained Urethra Following Cystectomy

Intraoperative frozen-section analysis of the proximal urethra by an experienced pathologist is a reliable and accurate means to determine indications for orthotopic diversion in all patients. It is good practice to proceed with an orthotopic neobladder in men and women whose intraoperative frozen section of the proximal urethra is free of tumor. This approach does not appear to increase the risk of a urethral recurrence in these patients.[1,193] Male patients with known prostatic tumor involvement should not necessarily be excluded from an orthotopic substitute if the intraoperative biopsy is normal. Similarly, female patients with bladder neck involvement should not necessarily be excluded from an orthotopic neobladder if the intraoperative biopsy is also normal. All patients should be carefully counseled regarding the need for follow-up, the long-term risks of a urethral recurrence, and the possible need for urethrectomy following

cystectomy.

Salvage Cystectomy

Salvage cystectomy after prior radiation therapy was discussed above in the section comparing surgical with bladder-sparing approaches.

Summary of Surgical Therapy

Surgery is an important mode of therapy for invasive bladder cancer and undoubtedly can provide durable disease control for many patients with the disease. In addition, an integrated approach with other treatment modalities such as neoadjuvant chemotherapy and radiation therapy is essential if the best results are to be achieved in the entire patient population, especially those who are borderline fit for major surgery. Radical cystectomy probably provides the best local pelvic control of the disease and provides accurate evaluation of the primary bladder tumor along with the regional lymph nodes yielding important prognostic information. This, coupled with the evolution and successful application of orthotopic lower urinary tract reconstruction in both men and women, has provided patients a more physiologic and acceptable means to store and eliminate urine. However, most deaths from bladder cancer still occur due to distant metastases, presumably present at the time of original surgery, so further improvements in outcome will depend on the development of both better systemic therapies and also predictive (as opposed to prognostic) markers that will allow better selection of therapies.

Radiation Therapy

External Beam Radiation Therapy

Whatever the merits or otherwise of radiation therapy as a treatment for bladder cancer, its use in the United States has declined since the 1980s, and the treatment is now used mainly in certain centers such as Boston in carefully selected patients rather than as a mainstream alternative to surgery. As discussed above, patterns vary worldwide with the US pattern of care predominating. Potential indications for radiation therapy are summarized in Table 68.6. Patients with radiologic node-positive or metastatic disease should be managed predominantly with either chemotherapy or palliative approaches such as local radiotherapy to bulk disease (see below). Patients with radiologic node-negative, muscle-invasive disease may be considered for radical radiotherapy. In North America, radiation therapy is administered as part of a package of care comprising maximal TURBT, chemotherapy, and radiation therapy, the so-called

trimodality therapy (Fig. 68.3).[194,195]

The schedules used are complex but can be summarized as initial maximal TURBT followed by initial radiation therapy combined with synchronous chemotherapy, usually with cisplatinum followed by interim check cystoscopy. Patients experiencing a good response to treatment continue to consolidate chemoradiotherapy and then adjuvant polychemotherapy, usually with a cisplatinum base. Patients remain on long-term cystoscopic surveillance. Noninvasive recurrence can be managed by further TURBT and intravesical therapy. Those with isolated muscle-invasive recurrence or failure to respond (but with no systemic relapse) can undergo salvage cystectomy with or without further chemotherapy.

The optimal radiation therapy schedule has yet to be established. In North America, split schedules often used are 39 or 40 Gy in 1.8- or 2-Gy fractions with an interval cystoscopy; patients with responding disease proceed to a total dose of 64 to 68 Gy. Generally, these schedules achieve long-term survival comparable to surgical series. A significant risk of cystectomy remains, however, with 22% undergoing immediate cystectomy, 13% delayed cystectomy for local recurrence, and 65% retaining a functioning bladder.[195]

In some countries, particularly the United Kingdom and Australia, an alternative schema is used (Fig. 68.4). As in the trimodality approach, patients will undergo maximal TURBT for diagnostic and staging purposes. They can then be treated either with primary surgery (as elsewhere) or alternatively with either neoadjuvant chemotherapy or primary radiation therapy. The role of cystectomy was discussed above, and the evidence and use of neoadjuvant therapy is discussed in the section Role of Systemic Therapy. In the United Kingdom, the radiation therapy itself is given as a single definitive course, usually to the whole bladder, only with no attempt to treat the nodes (as discussed below). Typical dose schedules would be 64 Gy in 32 fractions or hypofractionated schedules such as 55 Gy in 20 fractions. Following radiation therapy, patients undergo cystoscopic surveillance as in the US model, with salvage cystectomy for isolated local failure.

TABLE 68.6 INDICATIONS FOR RADIATION THERAPY IN BLADDER CANCER

Stage	Recommendation
CIS, Ta, T1	No role for radiation therapy

T2-T4aN0M0	Potential role for radiation therapy, combined with synchronous chemotherapy if patient sufficiently fit (bladder preservation)
T any N1-3M0 or T any N any M1	No role for radical radiation therapy as sole treatment for stage IV disease. It may be worth considering, as part of "radical" palliation in combination with systemic chemotherapy. No randomized data on the use of radiation therapy in this setting beyond studies of fractionation

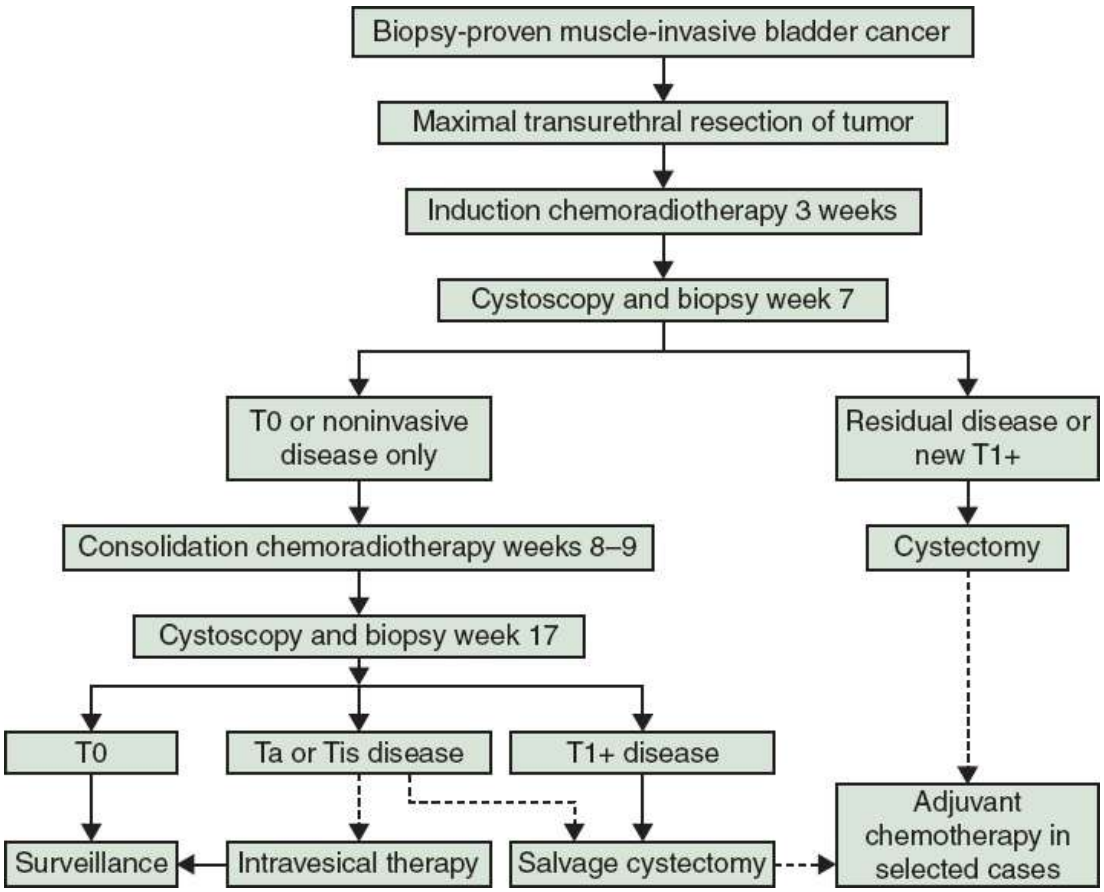

FIGURE 68.3. Trimodality therapy.

There are key differences between these two approaches. The first and most obvious is that in most disease sites, definitive radiation therapy is not given as a split course but as a single continuously fractionated treatment as in the United Kingdom. To understand how this approach has arisen, it has to be understood that trimodality therapy is offered as an alternative to cystectomy in countries where the prevailing opinion is that surgery is the treatment of choice. Patients undergoing this treatment are offered what is termed selective bladder preservation, with the multiple checkpoints allowing early exit to surgery aimed at providing reassurance to surgeons in particular that the opportunity for cure is not being lost. The median ages (mid-60s) reported in studies using this

approach reflect this patient selection and are similar to large surgical series.[4,134] The UK approach is completely different in this respect as there is a long tradition of using radical radiation therapy after TURBT, and the much older patient groups compared with surgical series reflect a different decision-making process in which younger, more fit patients are more likely to get surgery and older or less fit patients radiation therapy.[10,12,135,136,196] Interestingly, the long-term bladder preservation rates in older series seem similar to the rates for salvage cystectomy postradiotherapy occurring in approximately one-fourth of patients managed with radiation therapy alone at 10 years median follow-up,[197] with around two-thirds of surviving patients retaining their bladders. The authors' own more recent chemoradiotherapy series suggests a higher rate of bladder preservation with the use of synchronous chemotherapy combined with full-dose radical radiation therapy.[11]

In summary, there are limited data exploring the effect of radiation therapy (RT) dose on outcomes in muscle-invasive bladder cancer (MIBC). As noted, most radiation oncologists use 60 to 70 Gy; many studies have used 64 to 66 Gy, but the optimal RT dose is not definitely known.

Korpics et al.[198] conducted a retrospective cohort study of 843 patients with cT2-4 N0-3 M0 transitional cell MIBC treated with RT using the National Cancer Database. Patients were divided into dose groups: <50, 50 to 59, 60 to 66, and >66 Gy. A subgroup analysis was performed for patients treated with 60 to 66 Gy by dividing them into 3 groups (60 to 62, 63 to 64, and 65 to 66 Gy).

Median follow-up was 16.3 months; 267 patients (32%) received <50 Gy, 169 (20%) received 50 to 59 Gy, 376 (45%) patients received 60 to 66 Gy, and 31 (4%) patients received >66 Gy. Patients receiving concurrent chemoradiotherapy were more likely to receive an RT dose of 60 Gy ($P < .001$), and patients with higher T-stage were more likely to receive a lower RT dose (P Z 0.003).

Two-year OS rates, when divided by RT dose, were 26%, 31%, 56%, and 55%, respectively, for <50, 50 to 59, 60 to 66, and >66 Gy. Univariate analysis demonstrating increasing RT dose ($P < 0.001$) was associated with improved OS. On multivariate analysis (MVA), when compared to a dose of 60 to 66 Gy, <50 Gy (hazard ratio [HR] 2.36, $P < .001$), and 50 to 59 Gy (HR 1.72, $P < .001$) were associated with worse OS. Escalation of dose to higher than 66 Gy was not associated with OS (HR 1.01, P Z .977). In the subgroup of patients treated with 60 to 66 Gy, MVA revealed that compared to 65 to 66 Gy, there was worse OS with a dose of 60 to 62 Gy (HR 1.66, P Z .020), but no difference in OS with a dose of 63 to 64 Gy (HR 1.12, P Z .549).

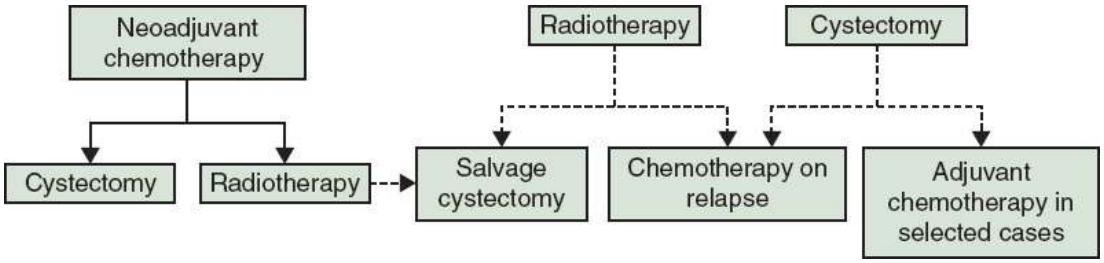

FIGURE 68.4. Integration of neoadjuvant chemotherapy, radiotherapy, and surgery in the United Kingdom.

The authors concluded that RT doses of <60 Gy are associated with worse OS in patients undergoing bladder RT and thus should be avoided in definitive treatment. Additionally, there is no survival advantage to increasing dose beyond 66 Gy. They felt that 63 to 66 Gy is the optimal RT dose when treating patients with bladder-preserving radiation therapy.

With regard to target volumes the usual practice is to treat the pelvis, including the iliac lymph nodes to the aortic bifurcation (L4-5 in most patients to doses, as noted above in the range of 50 Gy, with a volumes reduction encompassing the whole bladder to 60 Gy and an additional volume reduction targeted to residual gross tumor to complete 66 to 68 Gy.

Huddart et al.,[197] in a multicenter study, evaluated whether reducing radiation dose to uninvolved bladder while maintaining dose to the tumor would reduce side effects without impairing local control in the treatment of muscle-invasive bladder cancer. In this phase III multicenter trial, 219 patients were randomized to standard whole-bladder radiation therapy (sRT) or reduced high-dose volume radiation therapy (RHDVRT) that aimed to deliver full radiation dose to the tumor and 80% of maximum dose to the uninvolved bladder. Participants were also randomly assigned to receive radiation therapy alone or radiation therapy plus chemotherapy in a partial 2 x 2 factorial design (with a noninferiority margin of 10% at 2 years).

Overall incidence of late toxicity was less than predicted, with a cumulative 2-year Radiation Therapy Oncology Group grade 3/4 toxicity rate of 13% and no statistically significant differences between groups. The difference in 2-year locoregional recurrence-free rate (RHDVRT vs. sRT) was 6.4% under an intention to treat analysis and 2.6% in the “per protocol.”

The authors concluded that RHDVRT did not result in a statistically significant reduction in late side effects compared with sRT, and noninferiority of locoregional control could not be concluded formally. However, overall low rates of clinically significant toxicity combined with low rates of invasive

bladder cancer relapse confirmed that (chemo)radiation therapy is a valid option for the treatment of muscle-invasive bladder cancer.

Inter- and intrafraction anatomy changes in patients undergoing radiation therapy (RT) for bladder cancer (BC) are common and have been studied with implanted fiducial markers, 2D orthogonal films, and computed tomography (CT).

Fischer-Valuck et al.[199] assessed the soft tissue imaging capabilities of an integrated magnetic resonance image-guided RT (MR-IGRT) system to analyze daily positioning in a preliminary study of 14 patients with BC treated on a MR-IGRT system (ViewRay Corp, Sunnyvale, CA, USA). Patient setup was performed via volumetric MR imaging with a resolution of 0.15 × 0.15 cm. Alignment was performed according to skin marks and shifts assessed by comparing the treatment volume from the planning CT to the daily MR image. Two hundred forty pretreatment MR images were analyzed, and 3 shifts were recorded for each image.

The daily volumetric MR imaging allowed for accurate alignment and daily monitoring of bladder volume and normal tissue anatomy. Recorded shifts of the treated volume were 0.9 x 0.5 cm in the right/left direction, 0.7 x 0.3 cm in the anterior/posterior direction, and 0.7 x 0.4 cm in the craniocaudal direction. In 66 (28%) of cases, the vector shift was initially greater than the PTV margin. For 2 patients, pretreatment MR imaging showed the tumor reduced in size and dose to the bowel would have exceeded constraints, and treatment adaptation was performed to reduce normal tissue toxicity. Using CTCAE criteria, no grade 3 or higher toxicities have been reported.

Adaptive radiation therapy is sparingly used in selected centers. Foroudi et al.[179] described a multicenter feasibility study at 12 departments of online adaptive radiotherapy, using a choice of three “plan of the day” for patients with muscle-invasive bladder cancer. Departments were activated if they were part of the pilot study or after a site-credentialing visit and real-time review of the first two cases from each department. Fifty-four patients (mean age 78 years, 43 males and 7 females) were recruited, with 50 proceeding to radiation therapy. The tumor stages included T1,[1] T2,[35] T3,[10] and T4.[4] One patient died of an unrelated cause during radiation therapy. The three adaptive plans were created before the 10th fraction in all cases. In 8 (16%) of the patients, a conventional plan using a “standard” CTV to PTV margin of 1.5 cm was used for one or more fractions where the pretreatment bladder CTV was larger than any of the three adaptive plans. The bladder CTV extended beyond the PTV on posttreatment

imaging in 9 (18%) of the 49 patients. However, without further bladder filling control or imaging, a CTV to PTV margin of 7 mm is insufficient.

Treatment Results

It is difficult to compare results of older series to more contemporary ones for a number of reasons. First, staging systems have changed over the years, as have imaging techniques. Patients who may have been staged as organ confined in the early or pre-CT era may now be more accurately staged as more advanced with contemporary imaging. In contrast, surgical series will report accurate pathologic stage. It is well documented that more accurate staging will bring about a paradoxical improvement in reported results by stage because of upstaging of apparently early disease cases, the so-called Will Rogers phenomenon.[199] Treatment techniques in the past were obviously less refined, with little or no ability for conformal beam shaping, and hence, toxicity would have been higher. Nonetheless, it is clear from large series that tumor control could be attained in significant numbers of patients. For example, a study from Western General Hospital, Edinburgh, conducted between 1971 and 1982, reported treatment results from 963 patients. The reported stage mix was T1, 20%; T2, 32%; T3, 40%; and T4, 8%, with the administered dose of 55 Gy in 20 fractions—a widely used UK schedule. The overall 5- and 10-year survival rates were 30% and 18%, respectively.[179] This study reports tumor control at cystoscopy in 46% of patients, and this seems to be a pretty typical response rate with radiation therapy alone.

Similar control rates were reported in the radiation therapy–alone arm of the National Cancer Institute of Canada (NCIC) trial comparing radiation therapy with chemoradiotherapy with cisplatinum[198] and also in the radiation therapy–only arms at 2 years of the UK trials BCON[12] and BC2001[200] at 2 years. The latter two trials give an accurate reflection of the results of modern radiation therapy. They ran contemporaneously between 2000 and 2009 and between them recruited more than 800 patients from around 70 UK sites, including all major UK radiation therapy centers. Both trials had similar designs, including near identical entry criteria (essentially T2-4aN0M0, with a small number of T1G3 patients entered the BCON trial), the same control arms (definitive radiation therapy to bladder only to either 55 Gy in 20 fractions or 64 Gy in 32 fractions), and the same outcome measures (locoregional disease-free and overall survival). Both trials assessed both acute and late toxicities (Figs. 68.5 and 68.6). In addition, the BC2001 trial included an optional second randomization comparing

whole-bladder radiation therapy with a reduced dose to uninvolved bladder of 80% of the isocenter dose. The BC2001 permitted neoadjuvant chemotherapy, which was a stratification factor. Around one-third of the chemoradiotherapy patients also received neoadjuvant chemotherapy.

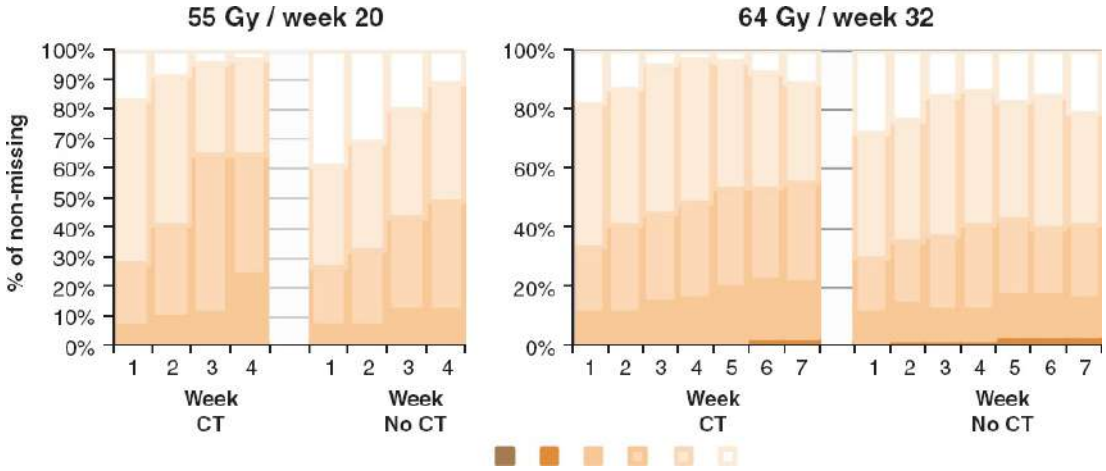

FIGURE 68.5. Acute toxicity of radiotherapy with and without synchronous chemotherapy. Graphs show worst grade of on-treatment toxicity by radiotherapy dose and week. *Darkest bars* indicate National Cancer Institute common terminology class grade 4; *white* indicates grade 0. Proportions with a grade 3 or 4 at any time on treatment: 64/178 (36.0%) chemotherapy (CT) versus 50/182 (27.5%). No CT-stratified chi-square test (P = .07).

The trials give a comprehensive insight into UK radiation therapy practice and great detail on outcomes. Median age in both trials was 73 to 74 years, with age range up to 90 years. Overall, around 40% of patients received 55 Gy in 20 fractions and 60% 64 Gy in 32 fractions. In both trials, over 95% of patients received at least 90% of the target dose in both arms, with no reduction associated with the two radiosensitizing treatments. Although the protocol recommended complete debulking at TURBT, this was only achieved in one-third to one-half of the cases, probably reflecting technical factors at surgery rather than deliberate intent.

The overall 5-year survival rate was 50% for radiation therapy plus carbogen and nicotinamide compared with 39% for radiation therapy alone (48% and 35%, respectively, if T1 tumors are excluded), with the greatest effect seen in T2 tumors. For BC2001, the estimated 5-year survival with radiation therapy alone was very similar at 34% (95% CI, 25% to 43%).

Toxicity

The toxicity of definitive radiation therapy varies with the dose and schedule

used. Within BC2001 and BCON, there were two schedules: 55 Gy in 20 fractions and 64 Gy in 32 fractions. Acute toxicity is shown in Figure 68.5 for both schedules, with and without chemotherapy with 5-fluorouacil/mitomycin C.

The majority of patients experienced only grade 1 or 2 toxicity with very low rates of grade 4 events. Synchronous chemotherapy increased toxicity but was predominantly grade 1 or 2, with a nonstatistically significant effect on grade 3 or 4 events (27.5 vs. 36%; P = .07; boundary for significance set at 0.01 to reflect multiplicity of testing). The reduced-volume randomization failed to demonstrate a reduction in overall toxicity. However, when the volume of bowel irradiated was calculated, this did show a significant reduction; in an exploratory analysis, volume of bowel irradiated did correlate with the risk of grade 3 or 4 toxicity. There was no increase in acute toxicity observed in BC2001 if patients had received prior neoadjuvant chemotherapy.[200]

Treatment completion rates in both trials were very high, with an excess of 95% of patients receiving the prescribed dose. The majority of patients failing to complete did so for tumor-related reasons rather than toxicity. Late toxicity was of great interest in both trials and was analyzed somewhat differently. In BCON, the cumulative rates of grade 3 or 4 events were reported, which gives the worst-case scenario but does not reflect the overall toxicity at any given time point post treatment. BC2001 reports the toxicity rates at prespecified times.

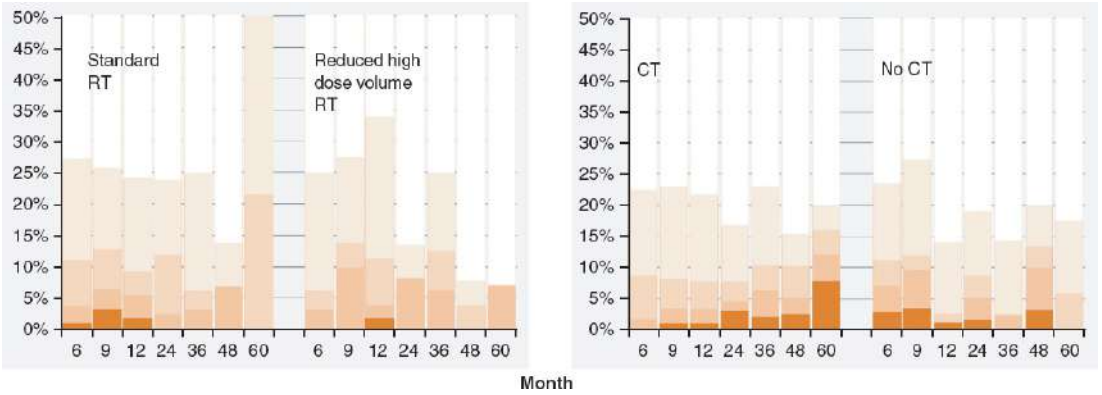

FIGURE 68.6. Late toxicity in the BC2001 trial. *Darkest bars* indicate Radiation Therapy Oncology Group (RTOG) grade 4; *white* indicates grade 0. Proportion of patients with grade 3 or 4 RTOG toxicity at any month during follow-up (6 months onward), up to 3 months before a recurrence: RT, 12.9% sRT versus 17.9% RHDV; odds ratio (95% confidence interval) 1.34 (0.55, 3.24); P = .52; CT, 8.3% CT versus 15.7% no CT; odds ratio 0.48 (0.21, 1.10); P = .07. Patients with no available assessment were excluded from analysis. CT, chemotherapy with radiotherapy; RT, radiotherapy; sRT, standard volume radiotherapy; RHDV, reduced high-dose volume radiotherapy.

There are a number of points of note here. First, late toxicity was the same with both randomizations in BC2001 (i.e., reduced-volume radiation therapy did not impact late toxicity). More significantly, the addition of synchronous chemotherapy also had no effect on reported late side effects. In addition, at any given point, 75% to 80% of patients report no late toxicity at all. This is supported by bladder capacity measurements in BC2001, which show a mean change in bladder volume at 1 and 2 years of <5 mL. Of those reported side effects, fewer than 5% report grade 4 events and fewer than 10% overall grade 3. Very similar findings pertain to the BCON trial.[12] In 2009, Efstathiou et al.[201] reported late toxicity results in 285 patients who had participated in four Radiation Therapy Oncology Group trimodality therapy trials. Overall 5.7% reported persistent late genitourinary and 1.9% gastrointestinal toxicity of grade 3 or above, consistent with the BCON and BC2001 results. The good toxicity and functional results associated with radiotherapy are borne out by surveys of quality of life and symptoms in cystectomy and radiotherapy patients carried out by Henningsohn et al. and others.[13,179,186,187,194,195,197–199,202–204] Furthermore, radiotherapy and cystectomy patients report different patterns of symptoms, with sexual dysfunction being more prominent in surgical patients and bowel symptoms more prominent in radiotherapy patients. The preservation of sexual function by radiotherapy is particularly striking given that the patients were an average of around 10 years older.

Lin et al.[205] analyzed 125,879 patients with stage II to IV, M0 bladder cancer diagnosed between 2004 and 2014 without a second primary malignancy identified from the National Cancer Database. Patients who received no treatment, cystectomy only, chemotherapy only, radiation only, radiation and cystectomy, or trimodality therapy were excluded from the analysis. There were 9,834 patients treated with cystectomy/chemo, and 4399 patients treated with chemo-RT (60 Gy to the bladder). Age ($P < .001$), sex ($P < .001$), race ($P < .001$), Charlson/Deyo Comorbidity Score (CDCS; $P < 0.001$), insurance status ($P < .001$), type of facility ($P < .001$), income (P Z .05), and stage (P Z .005) were significantly correlated with overall survival on univariate analyses. Prior to a matched pair analysis, patients treated with cystectomy/chemo were younger (mean: cystectomy/chemo 63.6 vs. chemo-RT 73.7, $P < .001$), had better performance status (CDCS 0: cystectomy/chemo 74.2% vs. chemo-RT 68.5%, $P < .001$), were privately insured (cystectomy/chemo 42.8% vs. chemo-RT 19.9%, $P < .001$), and were more likely female (cystectomy/chemo 32.7% vs. chemo-RT 28.4%, $P < .001$). Before a matched pair analysis, overall survival (OS) was

significantly better for patients treated with cystectomy/chemo (3 years 50.9% and 5 years 41.4%) compared to chemo-RT (3 years 40.6% and 5 years 28.4%) ($P < .001$). A matched pair analysis matching age, sex, race, CDCS, insurance status, income, and stage produced 722 pairs ($N = 1,444$). After the matched pair analysis, OS was no longer significantly different between cystectomy/chemotherapy (3 years 47.3% and 5 years 37.8%) and chemo-RT (3 years 45.7% and 5 years 32%).

Effect of Synchronous Chemotherapy

There are a large number of phase I or II trials from North America,[20,194,195,198,202,203,206–209] mainland Europe,[5,210–212] and the United Kingdom that have examined various chemotherapy agents in combination with radiation therapy.[1] There are, however, only a few trials reported in which radiotherapy alone is compared with radiotherapy with synchronous chemotherapy. The only randomized study using the trimodality therapy approach was carried out by the NCIC and reported in 1996.[192] This study compared radiation therapy to 40 Gy in 20 fractions with the same schedule combined with cisplatinum 100 mg/m^2 twice weekly ×3. Patients then underwent interim cystoscopy and either consolidation radiotherapy to 20 Gy in 10 fractions or cystectomy depending on response and fitness for surgery. Synchronous cisplatinum had no effect on the rate of distant metastasis, consistent with a lack of effect in neoadjuvant trials. The study, however, was relatively small and could only have detected very large effects. Concurrent cisplatinum had a highly significant effect on pelvic recurrence, with 25 of 48 control patients having a pelvic recurrence, compared with 15 of 51 cisplatinum-treated patients ($P = .036$; HR 0.50; 90% CI, 0.29 to 0.86). It should be noted that a similar platinum schedule given prior to radiation therapy had no effect whatsoever on recurrences, either local or distant.[1]

There are two randomized trials of radiosensitization using UK schedules: the BC2001 and BCON studies, as already discussed. These two large phase III randomized control trials reported results in 2009 to 2010. These trials used radiosensitization with either concurrent chemotherapy (BC2001) or carbogen and nicotinamide (BCON). BC2001 has shown a significant improvement in locoregional disease-free survival with concurrent 5-fluorouracil and mitomycin C of 34% (HR 0.66; 95% CI, 0.46 to 0.95) driven by a reduction of 47% in invasive locoregional recurrences (HR 0.53; $P = .007$), which is very similar to that observed in the NCIC trial with cisplatinum using the trimodality

approach.[192] Figure 68.7 shows the Kaplan-Meier curves for invasive locoregional disease-free survival. Survival data show a trend toward an improvement in overall survival (HR 0.81; *P* = .16), although the data are immature. The BCON trial[12] with synchronous carbogen and nicotinamide narrowly failed to meet its primary endpoint of an improvement in local relapse-free survival (HR 0.87; 63% vs. 74%; *P* = .1) but did report an improvement in overall survival at 3 years (46% vs. 59%; HR 0.86; 95% CI, 0.745 to 0.996; *P* = .04).

Taken together, the trial data with chemoradiotherapy suggest good tolerability even in relatively elderly patients with excellent late toxicity profiles in the majority of patients whether treated with the North American trimodality approach or the UK single-treatment block.[1] The similar hazard ratios observed with cisplatinum and 5-fluorouacil/mitomycin C suggest that a range of chemotherapy approaches can probably be used with the selection based on toxicity. It is noteworthy that comparisons of platinum and 5-fluorouacil–based chemoradiotherapy combinations have been carried out in anal cancer, with the two approaches being similarly effective. The high rates of locoregional control seen make radical chemoradiotherapy a viable treatment option for many patients presenting with muscle-invasive bladder cancer.

Pattern of Failure

As already discussed above, a significant proportion of patients will experience locoregional failure and undergo salvage surgery. The BC2001 study gives a good indication of patterns of failure using the single-block approach to radical radiotherapy. A summary of relapse patterns in the chemoradiotherapy arm of the trial is shown in Figure 68.8.

There are a number of features of note here. First, the majority of locoregional failures are in the bladder, and there are more noninvasive than invasive recurrences. This underlines the need for regular surveillance postradiation therapy and the requirement for good integration of radiation therapy and surgical services if patients are to be managed by bladder conservation. In the authors' experience, the majority of noninvasive recurrences can be successfully managed conservatively without the need for cystectomy. For those with invasive recurrence, cystectomy remains an option if the patients are sufficiently fit. The low rate of nodal relapse in BC2001 is also of interest, as no attempt was made to include pelvic nodes in the field, although lower pelvic nodes would have been included in the treated volume. For improvement in the

metastatic relapse rate, better systemic therapies must be found. However, the rate of second cancer is also notable and probably relates to the age of the patients and the historic high rate of tobacco consumption in the bladder cancer population.

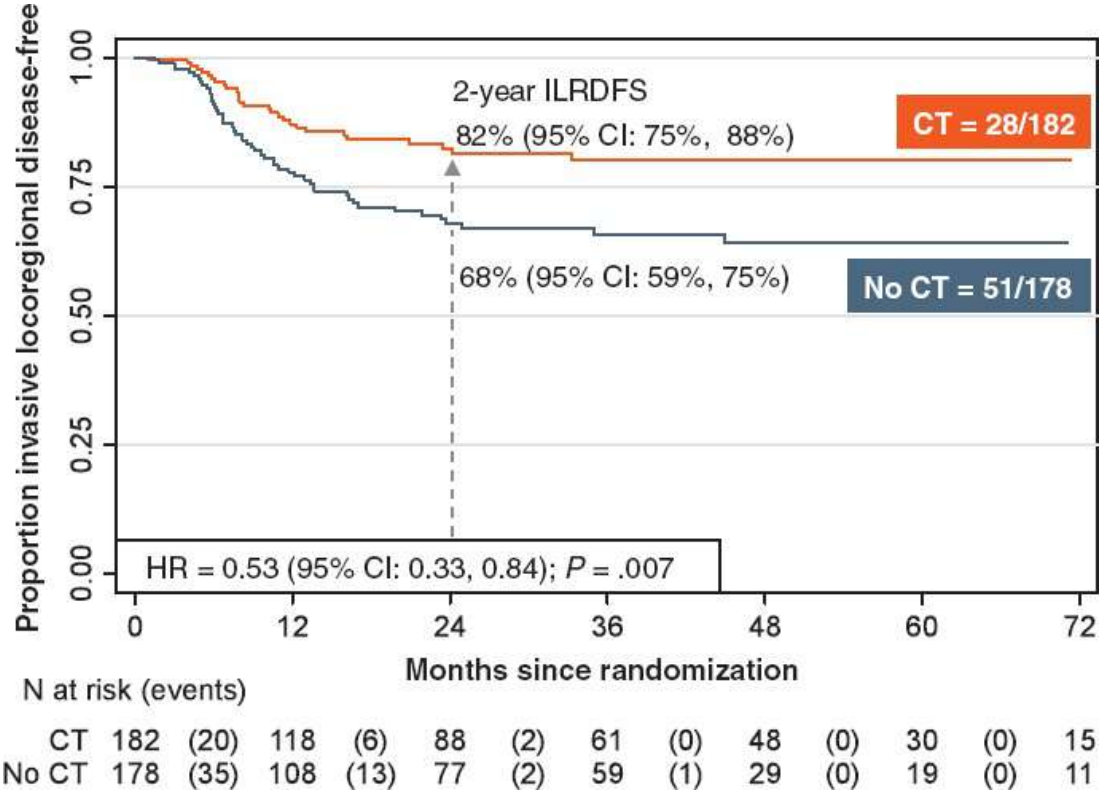

FIGURE 68.7. Invasive locoregional disease-free survival with or without chemotherapy.

Altered Fractionation Schedules

There are old data examining hyperfractionation in comparison to conventional treatment to 64 Gy in 32 fractions, both given as a split course. The data suggest an improvement with the hyperfractionated regimen; however, given the suboptimal nature of the control arm, it is hard to draw firm conclusions[1]. A study from the Royal Marsden Hospital compared 64 Gy in 32 fractions to 60.8 Gy in 32 fractions over 26 days in 228 patients.[213] Hypofractionated schedules are widely used in the United Kingdom and elsewhere for radical treatment and for palliation (as discussed below).

In Canada, Turgeon et al.[214] carried out a retrospective review of 24 patients 70 years or older treated with maximally feasible TURBT followed by concomitant chemoradiation using hypofractionated IMRT, treated between

January 2008 and August 2012.

The patients had histologically proven muscle-invasive transitional cell carcinoma of the bladder stage T2-T3N0M0 and were planned for a course of hypofractionated IMRT (50 Gy in 20 fractions). IMRT was delivered to the bladder volume only in 7 patients (29%). The remaining 17 patients received 50 Gy/20 fxs to the bladder and 40 Gy/20 fxs to the pelvic lymph nodes. All patients received concomitant chemotherapy either with gemcitabine 100 mg/m^2 weekly (21 patients) or cisplatin 40 mg/m^2 weekly.

Twenty-four patients with a median age of 79 years were eligible for our study. Nine patients refused cystectomy, and the remaining 15 were not considered medically fit for cystectomy. TURBT was not possible or judged incomplete by the urologist in five patients. Median follow-up was 16 months (range, 6 to 55 months). A cystoscopically and/or biopsy-proven complete response in the bladder was confirmed in 83% of the patients. Of the remaining patients, one of them underwent salvage cystectomy, and no disease was found in the bladder on histopathologic assessment. Seven patients recurred, four locoregionally and three with distant metastasis. Cancer-specific and the overall survival rates at 2 years were 74% and 63%, respectively. Grade 2 acute genitourinary (GU) and/or gastrointestinal (GI) toxicities occurred in 42% of the patients. A single patient had febrile neutropenia with combined grade 3 GU and GI acute toxicities. Grade 3 hematologic toxicity was seen in 13% of the patients. There was no grade 4 to 5 toxicity.

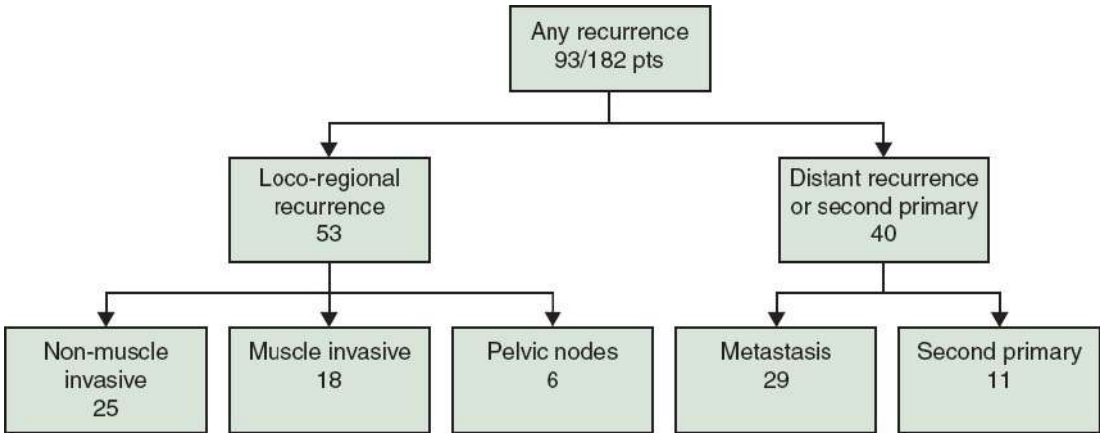

FIGURE 68.8. Patterns of failure after chemoradiotherapy in BC2001.

Hafeez et al.[215] reported on 55 patients with T2-T4aNx-2M0-1 bladder cancer not suitable for cystectomy or daily radiation therapy treatment. A plan of radiation therapy was used, treating the whole (empty) bladder to 36 Gy in 6

weekly fractions. Acute toxicity was assessed weekly during radiation therapy, at 6 and 12 weeks, and late toxicity was assessed at 6 and 12 months. Cystoscopy was used to assess local tumor control at 3 months.

Median age of the patients was 86 years. Eighty-seven percent of patients completed their prescribed course of radiation therapy. Genitourinary and gastrointestinal grade 3 acute toxicity was seen in 18% (10/55) and 4% (2/55) of patients, respectively. No grade 4 genitourinary or gastrointestinal toxicity was seen. Grade 3 late toxicity (any) at 6 and 12 months was seen in 6.5% (2/31) and 4.3% (1/23) of patients, respectively. Local tumor control after radiation therapy was 92% of assessed patients (60% total population). Cumulative incidence of local tumor progression at 1 year and 2 years for all patients was 7% and 17%, respectively. Overall survival at 1 year was 63%.

There are no modern trials comparing these schedules to 64 Gy in 32 fractions.

Harland et al[215a] conducted a multicenter randomized trial in the United Kingdom to determine the efficacy of radical radiation therapy in reducing the incidence of progression of pT1G3 transitional cell carcinoma of the bladder to muscle invasive disease and disease mortality.

Patients with a diagnosis of pT1G3 NXM0 transitional cell carcinoma with unifocal disease and no carcinoma in situ (group 1), or with multifocal disease and/or carcinoma in situ (group 2) were eligible for the trial. Patients in group 1 were randomized between observation and radiation therapy to the bladder, and in group 2 between intravesical therapy and radiation therapy.

A total of 210 patients from 37 centers in the United Kingdom were in the study (77 patients in group 1 and 133 patients in group 2); 6 patients were excluded because they were found to have pT2 disease by the reference pathologist. No evidence of an advantage with radiation therapy was found in terms of progression-free interval progression-free survival (hazard ratio 1.35) or overall survival (hazard ratio 1.32)There is no evidence that radiation therapy was better than conservative treatment.

Palliative Radiation Therapy

A prospective randomized trial was conducted in 500 patients to compare the outcome in two treatment groups. Group 1 received 35 Gy in 10 fractions and group 2 received 21 Gy in 3 fractions. Five hundred patients were recruited, but data on symptomatic improvement at 3 months were only available on 272 patients. Of these, 68% achieved symptomatic improvement (71% for 35 Gy,

64% for 21 Gy), with no evidence of a difference in efficacy or toxicity between the two arms. On the basis of these results, 21 Gy in 3 fractions is widely used in the United Kingdom as a palliative schedule. The data are congruent with other data on hypofractionation for palliation[1] as well as the growing trend for hypofractionation in other pelvic sites, in particular the prostate.

Preoperative Irradiation

Preoperative radiation therapy has been investigated in the past, but interest in the technique has waned, largely because none of the trials carried out showed any evidence of worthwhile benefit. In addition, the observed chemosensitivity of bladder cancer lead to a wave of neoadjuvant chemotherapy trials carried out in the 1980s and 1990s, effectively ending interest in the technique. Given the subsequent improvements in both radiotherapy and surgical technique, it may be appropriate to revisit the possibility of combining surgery with radiotherapy, particularly given the apparent plateau in progress with systemic therapy since the licensing of gemcitabine more than 10 years ago. Most of the studies in the literature are old, retrospective, nonrandomized comparisons, and little can be concluded from them.

There are few randomized trials in the literature, and those that are available are also old, for the reasons outlined above. A study from the Royal Marsden Hospital randomized patients to preoperative radiation therapy to 40 Gy in 4 weeks followed by cystectomy, against definitive radiation therapy to 60 Gy in 6 weeks. The 5-year survival in patients receiving the combined therapy was 38% versus 29% for those treated with radiation therapy alone, the difference not reaching statistical significance. This trial of course did not compare radiotherapy plus surgery versus surgery alone and thus does not address the primary question in this section. However, it is noteworthy that no tumor was found in 31% of the cystectomy specimens, a similar complete response rate to that observed in the intergroup neoadjuvant MVAC study.[7] Similar response rates have been reported in other series.[1]

A second randomized study was carried out by the Memorial Sloan-Kettering Cancer Center in New York comparing radiation therapy to 40 Gy in 4 weeks followed by cystectomy 4 weeks later with a shorter 20 Gy in a 5-day course with immediate cystectomy modeled on the Swedish preoperative rectal cancer trials. Again, this study is not informative on the primary issue of the utility of adding irradiation to surgery but does demonstrate the feasibility and safety of such an approach. A retrospective review from the MD Anderson Cancer Center

assessed the use of preoperative irradiation (50 Gy in 5 weeks) in patients with T3b bladder tumors. The 5-year local tumor control was 91% in the preoperative group (n = 92) compared with 72% for those treated with radical cystectomy alone (n = 43; P = .003).[1]

Parsons and Million[216] reviewed the results of retrospective studies and six prospective randomized trials on the use of preoperative irradiation. They concluded that the use of the technique may improve outcomes by up to 15% to 20% at 5 years. In particular, they noted that many preoperative radiotherapy series report pathologic complete response rates of around one-third, similar to that seen with neoadjuvant chemotherapy. There are no modern trials of preoperative radiation therapy, and the topic seems to be ripe for revisiting with modern techniques, particularly given the low long-term toxicity associated with chemoradiotherapy schedules, as summarized above.

Postoperative Radiation Therapy

As with many areas of bladder cancer practice, there are little in the way of randomized data on the use of adjuvant radiation therapy following surgery. When used, it is mostly based on the grounds of positive surgical margins or tumor spillage at surgery, where a high local recurrence rate can be anticipated.

Using the National Cancer Database (NCDB), Venigalla et al.[209] identified 46,380 patients diagnosed with nonmetastatic urothelial cell or squamous cell bladder cancer from 2004 to 2014 treated with radical cystectomy. Only 488 (1.1%) received adjuvant RT. In the overall cohort, administration of adjuvant RT was significantly associated with squamous cell carcinoma histology (P < .001), higher pathologic T-stage (P = .01), and positive surgical margins (P < .001). Other variables significantly associated with receipt of adjuvant RT included treatment at nonacademic facilities, receipt of chemotherapy, and earlier year of diagnosis. There were 2,766 patients in the positive surgical margin subgroup of which only 120 (4.3%) patients received adjuvant RT. Thus, in this pattern of care study, <5% of patients with positive surgical margins following radical cystectomy received adjuvant radiation therapy from 2004 to 2014 in the United States. A few studies combining pre- and postoperative irradiation have been published.[217]

With regard to radiation therapy technique in this cohort of patients, Baumann et al.[218] published a set of guidelines for postcystectomy irradiation, with emphasis on contouring of target volumes, which is challenging. The group proposed that patients at elevated risk for locoregional failure with negative

margins should be treated to the pelvic nodes alone (internal/external iliac, distal common iliac, obturator, and presacral), whereas patients with positive margins should be treated to the pelvic nodes and cystectomy bed. Proposed OARs included the rectum, bowel space, bone marrow, and urinary diversion. Consensus language describing the CTVs and OARs was developed and externally validated.

With the use of neoadjuvant chemotherapy worldwide being at low levels, chemo-naive patients at high risk of recurrence can be offered adjuvant chemotherapy, although the evidence base for this approach is also somewhat lacking. What few data there are on radiation therapy suggests that limited doses are well tolerated. Given the more solid evidence base for neoadjuvant chemotherapy and the failure of adjuvant chemotherapy trials to accrue, the use of postoperative radiation therapy would also seem to be a topic well-worth revisiting with modern treatment techniques. An approach combining neoadjuvant chemotherapy, surgery, and adjuvant radiation therapy for patients at high risk of local recurrence would combine all three of the major bladder cancer treatment modalities in a novel fashion.

Electron Beam

Electron beams are only of interest in the context of intraoperative radiation therapy. The role of this modality for carcinoma of the bladder needs to be assessed in a prospective trial and cannot at present be recommended outside of a suitable study.

Neutron Beam

There are a small number of studies examining the use of neutrons beams for bladder cancer therapy. A single randomized trial failed to show a survival advantage but did show increased morbidity. There are currently no reasons to recommend neutron therapy for bladder cancer.[1]

Protons

There is scanty published information on the use of protons in the treatment of patients with muscle-invasive bladder cancer. The purpose of the present study is to retrospectively analyze the clinical outcomes of bladder preservation therapy using proton boost for muscle-invasive bladder cancer. Between August 1990 and February 2014, Kanuma et al.[180] treated 72 patients with stage T2-3N0M0 bladder cancer with concurrent chemoradiation therapy (CRT) as a bladder preservation therapy. Transurethral resection of the bladder tumor was

performed, and pathologic examination for tumor invasion performed before CRT. Three cycles of intra-arterial chemotherapy consisting of MTX 30 mg/m^2 and CDDP 50 mg/m^2 were administered every 3 weeks during small-pelvis irradiation by x-ray (41.4 Gy/23 fractions). Upon completion of CRT, patients were evaluated by transurethral biopsy to confirm disappearance of cancer cells, and patients without residual tumor received boost irradiation (36.3 Gy equivalent/11 fractions) using proton beams. Median follow-up time was 36 months (range, 2 to 237 months).

Recurrences developed in 18 patients (25.0%); initial recurrence sites were bladder alone in 9, both bladder and distant organs in 2, lymph nodes in 4, distant organs alone in 2, and renal pelvis in 1. Recurrences at the bladder were observed in 11 cases (15.3%): seven tumors were noninvasive, and bladder function was preserved in 5 of them. Until the last follow-up, 9 patients died of disease recurrences, but 6 patients died of intercurrent diseases without any signs of recurrence. The 5-year rates of overall survival, local tumor control, and bladder preservation were 71.4%, 83.4%, and 86.3%, respectively. Treatment-related late toxicities grade 3 to 4 were observed in 3 patients: urinary hemorrhage, urethral stricture, and ureter stricture in each. There were no grade 3 gastrointestinal toxicities. Statistical analyses revealed that multiple tumors (*P* Z .04), T3 (*P* Z .014), and existence of hydronephrosis before treatment (*P* Z .021) were prognostic factors for overall survival, and multiple tumors (*P* < .001) and tumor size (*P* Z .02) had an impact on the local control rates.

Radiation Therapy Planning and Treatment Techniques

Patient Position and Immobilization

- The patient should be planned and treated in the same position; supine with arms on their chest. Knee and ankle immobilization should be used to ensure patient positioning is reproducible.
- The rectum should be empty of flatus and feces. The use of daily microenemas may be considered.
- Patients should be asked to empty the bladder 10 to 15 minutes prior to scanning.
- While breathing normally, the patient should have a CT scan performed with 3- to 5-mm slices. Patients are scanned from bottom of ischial tuberosities to 3 cm above the dome of the bladder or bottom of L5 (whichever is higher). A flattop CT scanner should be used.
- Neither intravenous nor oral contrast is thought to be of benefit in this

instance.

- Reference tattoos should be made at the base of the abdomen and over each hip. The location of the tattoos should be marked on the planning scan by the use of radio-opaque markers to allow cross-referencing of planning scan and setup instructions.

Target Volumes or Field Localization

- The gross tumor volume can be difficult to define and should integrate information from the staging CT or MRI as well as the TURBT. MRI–CT fusion may be helpful, where available.
- The use of fiducial markers or contrast medium at the time of TURBT has been explored and may help identify tumor for image-guided adaptive radiation therapy.
- There are few data on the optimal radiation therapy volume. A standard approach is to define the planning target volume as the whole bladder, identified by its noninvolved outer bladder wall with a 1.5-cm margin plus extravesical extent of tumor with a 2-cm margin.
- All planning and treatment should be carried out with the bladder empty to minimize the risk of geographic miss and to keep the treated volumes as small as possible. Patients with significant residual volumes post voiding should be considered for planning and treatment with a catheter *in situ*, although this is likely to increase urinary toxicity.
- There are no data to support the routine irradiation of radiologically negative lymph nodes. The nodal relapse rate in the BC2001 trial, with planning target volume and clinical target volume defined as above, was only 3% in the chemoradiotherapy arm and 6% with radiation therapy only.

Brachytherapy

There is considerable historic literature on the use of brachytherapy, particularly from the Netherlands. Reported results seem to be very good, for example, van der Werf-Messing et al.[219] report the outcomes in 328 patients treated with 3 × 3.5 Gy external irradiation followed by a radium implant. Overall 5- and 10-year survival rates were 56% for T2 tumors and 39% and 13%, respectively, for T3 disease. Similar results have been obtained in more recent series with iridium-192 implants and manual afterloading.[220–222] There are also descriptions in the literature of the use of high dose rate afterloading, although one paper suggests that this may be less effective and more toxic than low dose rate treatment.[177] The striking feature of most of these series is the very low patient numbers and

long time spans reported, suggesting that these techniques are only rarely used, even in centers with relevant expertise.

Recently, van der Steen-Banasik[223] reported on 57 patients with a T2 solitary bladder tumor treated with transurethral bladder resection followed by external beam irradiation to the bladder and regional iliac lymph nodes (40 Gy in 20 fractions, 5 fractions per week), and within 1 week interstitial HDR brachytherapy (BT), in selected cases combined with partial cystectomy and lymph node dissection. The BT catheters were placed via a transabdominal approach with robotic assistance from a Da Vinci robot. The fraction schedule for HDR was 10 fractions of 2.5 Gy, 3 fractions per day, which was calculated to be equivalent to a reference low dose rate schedule of 30 Gy in 60 hours.

Average postoperative hospitalization was 6 days, with minimal blood loss and no wound healing problems. Two patients had severe acute toxicity: 1 pulmonary embolism grade 4 and 1 cardiac death. Late toxicity was mild (2 urogenital grade 3 toxicity). The median follow-up was 2 years; the 2-year overall, disease-free, and disease-specific survival and local tumor control rates were 59%, 71%, 87%, and 82%, respectively.

As previously stated, the standard treatment for muscle-invasive bladder cancer (MIBC) is a radical cystectomy with pelvic lymph node dissection with or without neoadjuvant chemotherapy. In selected cases, a bladder-sparing approach is possible, with a limited surgical excision combined with external beam radiation therapy and brachytherapy. To perform brachytherapy, flexible catheters are implanted in the target volume of the bladder wall, which is done either by an open retropubic approach or by endoscopic surgical approach.

The largest experience for brachytherapy is with low dose rate and pulsed dose rate, although some short-term experience with high dose rate is also reported.

The main advantage for this technique is the conservation of bladder function, with comparable local tumor control as cystectomy series in selected cases.[221,222]

The GEC-ESTRO/ACROP (Groupe Européen de Curiethérapie-European Society for Radiotherapy and Oncology/Advisory Committee on Radiation Oncology Practice) published recommendations to perform bladder implants and brachytherapy as a treatment option for MIBC and techniques were described.[224]

Treatment of Patients with Uncommon Bladder Tumors

Squamous cell carcinoma is uncommon in the developed world, and many

reported cases may in addition reflect sampling of squamous elements within a transitional cell carcinoma. As these tumors are often excluded from systemic therapy trials, there are few data on outcomes with treatment as most papers are retrospective collections of unconnected observations.[225,226] It appears that local failure may be more prevalent than distant relapse, but even that observation is based on very few cases. Urachal adenocarcinomas are extremely rare. Surgical resection with a partial cystectomy and *en bloc* resection of the urachal ligament with umbilicus are the treatment choices in the setting of localized disease. There is currently no definitive role for neoadjuvant or adjuvant chemotherapy in this tumor. Unfortunately, there are many patients who present with metastatic disease, which currently is not likely to be curable. There is no standard chemotherapy regimen for these patients.

Although squamous cell carcinoma (SCC) is represented in many of the studies on bladder preservation, some physicians may be reluctant to offer this approach to MIBC patients with this rare histology because of its perceived poor response to therapy and adverse outcomes in comparison to more common histologies of MIBC. Stokes et al.[227] queried the National Cancer Database (NCDB) for patients with T2-T4 or TX, N0M0 SCC of the urinary bladder diagnosed from 2004 to 2012 receiving both chemotherapy and high-dose radiation therapy (>55 Gy) without up-front cystectomy. Patients with urothelial cell carcinoma (UCC) were queried separately to serve as a comparison group.

Fifty-four SCC and 2,054 UCC patients were identified. SCC patients were more likely to be younger, female, or nonwhite and were more likely to have more advanced disease at presentation. Age >70, comorbidity score >0, and stage _T3 were associated with worse OS, whereas gender, race, insurance status, household income, facility type, chemotherapy (single vs. multiagent), and histology showed no association with OS. OS estimates were not significantly worse for SCC compared to UCC (5-year OS 25.4% vs. 33.3%; adjusted hazard ratio 1.34, *P* Z 0.12). Their conclusion was that OS did not significantly differ between SCC and UCC patients undergoing organ preservation for MIBC, whereas other prognostic factors were relevant in both groups.

Li et al.[228] evaluated the Surveillance, Epidemiology, and End Results (SEER) database (1998 to 2007) for patients with muscle-invasive (stage II to IV) SCC of the urinary bladder who underwent complete cystectomy. A total of 331 patients were included in the analysis; Majority were received cystectomy alone (*n* Z 297), whereas 10% (*n* Z 34) received postoperative RT. Factors

associated with postoperative RT were younger age (pZ 0.03) and more advanced stage at diagnosis (*P* < 0.001). The addition of RT was not associated with an OS benefit (*P* Z 0.55). Median survival was 21 months for patients treated with cystectomy alone and 18 months for postoperative RT. Cox regression analysis confirmed the lack of improvement in OS among patients who received postoperative RT (*P* Z 0.47).

The lack of a survival benefit associated with postoperative RT suggests that RT for muscle-invasive SCC of the urinary bladder might be used with caution.

Carcinosarcoma is even more rare and appears to have a poor prognosis.[1] Similar considerations apply to small cell carcinoma (SCCB), although the consensus seems to be that metastasis is more likely and initial response to chemotherapy is usually good. These patients generally get treated along the same lines as small cell lung carcinoma, but the benefit of prophylactic cranial irradiation is unclear.[1,229–232]

Pasquier et al.[233] reported on a retrospective study at 15 Rare Cancer Network medical centers that contributed 107 cases of pure or mixed small cell carcinoma of the bladder, local, locoregional, and metastatic stages and age >18 years. Mean follow-up time was 4.4 years with 66% of these patients having pure SCCB. Seventy-two percent and 12% of the patients presented with T2-4N0M0 and T2-4N1-3M0 stages, respectively, and 16% presented with synchronous metastases. The most frequent curative treatments were radical surgery and chemotherapy, sequential chemotherapy and radiation therapy, and radical surgery alone. The median (interquartile range, IQR) OS and DFS times were 12.9 months (IQR, 7 to 32 months) and 9 months (IQR, 5 to 23 months), respectively. The metastatic, T2-4N0M0, and T2-4N1-3M0 groups differed significantly (*P* Z .001) in terms of median OS and DFS. In a multivariate analysis, impaired creatinine clearance (OS and DFS), clinical stage (OS and DFS), Karnofsky Performance Status <80 (OS), and pure SCC histology (OS) were independent and significant adverse prognostic factors. In the patients with nonmetastatic disease, the type of treatment (i.e., radical surgery with or without adjuvant chemotherapy vs. conservative treatment) did not significantly influence OS or DFS, suggesting that conservative treatment is appropriate in these patients.

ROLE OF SYSTEMIC THERAPY

Up to 50% of patients will develop metastatic disease. Bladder cancer is a

chemosensitive disease, with responses reported to a range of agents. Systemic combination chemotherapy can be effective and result in tumor responses and symptom control. Overall response rates may be as high as 70%, with a median survival of approximately 12 to 14 months.[1,35] These agents were initially evaluated in the metastatic setting and subsequently in the neoadjuvant and adjuvant settings. However, despite over 30 years of research in the field, there remain many unanswered questions, including the role of adjuvant therapy and optimal second-line chemotherapy.

Neoadjuvant Chemotherapy

There are two principal rationales for neoadjuvant chemotherapy: first, to improve survival in patients with micrometastatic disease and, second, to preserve the bladder by shrinking the primary tumor to facilitate radiation therapy as an alternative definitive therapy to surgery.[1] The potential disadvantage of neoadjuvant chemotherapy, and a frequent reason cited for its nonuse, is the delay in definitive treatment (cystectomy or chemoradiotherapy), because this may lead to disease progression in a proportion of nonresponding patients who may conceivably become inoperable or unsuitable for radical organ preservation treatment. However, it is equally plausible that by undergoing neoadjuvant chemotherapy, these patients can be identified as those with biologically aggressive disease and therefore spared the morbidity of futile radical therapy. It should also be noted that a significant proportion, possibly up to two-thirds, of bladder cancer patients are elderly with multiple comorbidities and poor renal function and, therefore, unsuitable for neoadjuvant chemotherapy.[234] In the authors' experience, a patient who is considered fit for a radical cystectomy is likely to be fit for chemotherapy as well.

Chudhury et al.[234a] reported on 50 patients with transitional cell carcinoma, stage T2-3, N0, M0 after transurethral resection and magnetic resonance imaging treated with Gemcitabine IV (100 mg/m2 on days 1, 8, 15, and 22 of a 28-day RT schedule that delivered 52.5 Gy in 20 fractions). All patients completed RT; 46 tolerated all four cycles of gemcitabine. Two patients stopped after two cycles, and two stopped after three cycles, because of bowel toxicity. Forty-seven patients had a post-treatment cystoscopy; 44 (88%) achieved a complete endoscopic response. At a median follow-up of 36 months (range, 15 to 62 months), 36 patients were alive, and 32 of these had a functional and intact bladder. Fourteen patients died; seven died as a result of metastatic MIBC, five died as a result of intercurrent disease, and two died as a result of treatment-

associated deaths. Four patients underwent cystectomy; three because of recurrent disease and one because of toxicity. One patient required a bowel resection for late toxicity. Using Kaplan-Meier analyses the3-year cancer-specific survival was 82%, and overall survival was 75%.

There are two particularly key studies in the area of neoadjuvant chemotherapy. The South Western Oncology Group (SWOG) neoadjuvant study comparing surgery alone with 3 cycles of MVAC followed by surgery reported an estimated median survival of 6.2 versus 3.8 years in favor of patients having neoadjuvant chemotherapy (P = .027).[7,235] Updated results from the UK MRC/EORTC neoadjuvant chemotherapy trial, which used 3 cycles of cisplatinum, methotrexate, and vinblastine (CMV) prior to surgery or radiation therapy, show a statistically significant 16% reduction in the risk of death (HR 0.84; 95% CI, 0.72 to 0.99; P = .037), corresponding to an increase in 10-year survival from 30% to 36% after neoadjuvant chemotherapy.[236] In total, 976 patients with high-grade T2 to T4a urothelial bladder cancer accrued over 5.5 years from 106 institutions were randomly assigned to 3 cycles of neoadjuvant CMV chemotherapy (n = 491) or no chemotherapy (n = 485), followed by the institution's choice of definitive therapy with either radical cystectomy or radiation therapy. Of patients in the chemotherapy and no chemotherapy groups, 42% and 43%, respectively, received radiation therapy alone as definitive therapy. Pathologic complete response with neoadjuvant chemotherapy was 33%. Overall survival at 3 years in the two groups was 55.5% versus 50%, respectively. The recent update, after 8 years of follow-up, showed an increase in 3-year survival from 50% to 56%, an increase in 10-year survival from 30% to 36%, and an increase in median survival time of 7 months (from 37 to 44 months) in CMV-treated patients compared with those treated with local therapy only. The SWOG study showed that of the 82% patients who underwent cystectomy, 38% had no evidence of disease pathologically. Patients who achieved pT0 status had a better prognosis than those who did not, although this difference may be accounted for by better disease biology rather than treatment effect. By definition, the SWOG study did not address organ preservation, because the mandated treatment plan was for surgery following neoadjuvant chemotherapy.

Meta-analyses show a 5% overall survival benefit at 5 years with cisplatin-containing regimens.[31] Thus, there have been two large randomized neoadjuvant studies in muscle-invasive bladder cancer, both showing significant survival advantage. Although many disciplines in cancer care would consider these data

sufficient to change the standard of care, this does not seem to have taken place for the management of invasive bladder cancer.[235] The lack of widespread adoption of neoadjuvant chemotherapy may relate to the selected patients in clinical trials, not reflecting typical muscle-invasive bladder cancer patients who may be older or have impaired renal functions, which may limit the applicability of some chemotherapy regimens. GC,[33] standard,[7] or accelerated MVAC are widely used with definitive radical treatment (either surgery or radiotherapy/synchronous chemoradiotherapy) 4 to 6 weeks later. It is worth noting that these trials have been restricted to patients with well-preserved renal function (typically glomerular filtration rate >60 mL/min), thus excluding a significant proportion of bladder cancer patients who are elderly or have ureteric obstruction and therefore deemed unsuitable for neoadjuvant chemotherapy. This regimen requires in-patient or prolonged hydration and therefore has a significant impact on patient quality of life and health service resources. Level 1 evidence supports the use of cisplatin-based chemotherapy regimens in the neoadjuvant setting and for frontline therapy of patients with metastatic disease. In the second-line setting and beyond, there are no U.S. Food and Drug Administration–approved treatment options. The National Comprehensive Cancer Network (NCCN) guidelines list a variety of cytotoxic regimens, such as pemetrexed, paclitaxel, and docetaxel, all of which are supported by phase II trials[6]. These trials showed minimal benefit, with progression-free survival and overall survival generally ranging from 3 to 6 months and 6 to 9 months, respectively.[7]

Clinical trials investigating chemotherapy regimens that may broaden the spectrum of patients receiving cisplatin-based treatment have been conducted in palliative settings, for example, a split-dose regimen of cisplatin in combination with gemcitabine on days 1 and 8 of a 21-day schedule allowed safe treatment of patients with calculated glomerular filtration rate as low as 40 mL/min in the day case setting.[237] This regimen could be tested within a randomized clinical trial in the neoadjuvant setting and may go far in increasing the uptake of neoadjuvant chemotherapy. It is the responsibility of urology and oncology colleagues to work together to provide state-of-art care for our patients with muscle-invasive bladder cancer, which should include neoadjuvant chemotherapy prior to surgery or organ preservation therapy in fit patients.

Adjuvant Chemotherapy

Adjuvant chemotherapy has the potential advantage of enabling better patient

selection based on the findings at surgical and pathologic staging. The major disadvantages, although, are the delay in systemic therapy and the inability to assess the response to chemotherapy in the absence of measurable disease. Randomized adjuvant chemotherapy studies (Table 68.7) have been conducted with the methodologic flaws of inadequate sample size, early closure, and suboptimal choice of chemotherapy, preventing a clear interpretation of the results. A systematic review and meta-analysis of updated individual patient data from all available randomized controlled trials in the adjuvant setting have been performed.[243] Updated data were collected, validated, and reanalyzed for 491 patients from 6 randomized controlled trials, representing 90% of all patients randomized in cisplatin-based combination chemotherapy trials and 66% of patients from all eligible trials. In view of this, the power of this meta-analysis was limited. The overall hazard ratio for survival of 0.75 (95% CI, 0.60 to 0.96; P = .019) suggests a 25% relative reduction in the risk of death favoring adjuvant chemotherapy. However, the impact of trials that stopped early of patients not receiving allocated treatments or not receiving salvage chemotherapy is less clear.[243] An Italian multicenter randomized phase III trial enrolled 194 patients (one-third of its target) with muscle-invasive TCC and assigned them to 4 cycles of GC or observation after cystectomy. The trial was stopped early because of poor accrual. After a median follow-up of 32.5 months, relapses were similar in both groups (43% vs. 45%) with no difference in disease-free survival. The 3-year overall survival was 67% for the chemotherapy arm and 48% for the observation arm and the 3-year disease-free survival was 47% and 35%, respectively, suggesting no statistically significant improvement in either survival rate with adjuvant GC in these patients.[1] A large phase III trial by EORTC (protocol 30994) evaluating observation versus adjuvant chemotherapy with one of the three chemotherapy regimens (GC, MVAC, or high-dose MVAC) in high-risk bladder cancer (pT3-4 and/or node-positive disease) was also prematurely closed due to poor accrual after enrollment of 278 of a planned 1,344 patients. This appropriately designed and sized study thus failed to conclusively address the issue of adjuvant chemotherapy following cystectomy. A possible reason for the failure of this trial was the tight window postsurgery for commencing chemotherapy. In the authors' experience, relatively few patients were able to enter the trial sufficiently soon because of slow postoperative recovery. This suggests that adjuvant chemotherapy may be less suitable than neoadjuvant chemotherapy in this patient population. The adjuvant chemotherapy question still requires international collaboration with an

appropriately sized pragmatic study for a conclusive answer. In various disease sites, neoadjuvant chemotherapy followed by adjuvant chemotherapy is an acceptable norm with level I evidence. With an anticipated rise in uptake of neoadjuvant chemotherapy, patients with bladder cancer should not be precluded from this strategy where neoadjuvant chemotherapy is followed by radical treatment followed by a trial of adjuvant chemotherapy versus no chemotherapy in an appropriately sized phase III trial that meets its recruitment target, thus providing a definite answer for or against this strategy. Previous failures in meeting recruitment targets can be overcome by using better-tolerated regimens in common use now and by extending the recruitment window from 12 to 16 weeks to allow full recovery post surgery and to allow more dose-intense adjuvant chemotherapy treatment.[1]

TABLE 68.7 RANDOMIZED TRIALS OF ADJUVANT CHEMOTHERAPY

Author (Reference)	N	Standard Arm	Adjuvant Arm	Results
Skinner et al.[238]	91	Cystectomy	Cystectomy + CAP	Benefit, but few patients received planned therapy
Stockle et al.[239]	49	Cystectomy	Cystectomy + MVAC	Benefit, but limited trial size, premature closure, and no therapy upon relapse
Studer et al.[240]	77	Cystectomy	Cystectomy + cisplatinum	No benefit
Freiha et al.[241]	55	Cystectomy	Cystectomy + CMV	Benefit limited to relapse-free survival
Bono et al.[242]	83	Cystectomy	Cystectomy + CM	No benefit

CAP, cyclophosphamide/Adriamycin (doxorubicin)/cisplatin; CM, cisplatinum/methotrexate; CMV, cisplatinum/methotrexate/vinblastine; MVAC, methotrexate/vinblastine/doxorubicin (Adriamycin)/cisplatinum.

Chemotherapy Regimens in Metastatic Disease

Currently, systemic combination chemotherapy is the only treatment that may prolong survival in patients with metastatic disease. The chemosensitivity of bladder cancer is demonstrated by objective response rates of 12% to 73% and complete response rates of 0% to 35%. Although antitumor activity has been demonstrated with several single agents, the median survival associated with single-agent therapy is short (4 to 6 months).[1] Prior to the development of gemcitabine, a range of trials were done with doublet regimens, which typically

showed median survival times of approximately 8 months.[244] The development of the four drug combination for MVAC chemotherapy extended this to over 12 months and became the established standard of care. The triplet combination CMV is also widely used but has not been compared with MVAC directly.[1]

The addition of paclitaxel to gemcitabine was evaluated in a phase III clinical trial by EORTC (protocol 30987), which enrolled 627 patients with advanced urothelial carcinoma. The regimens were well tolerated. Results showed that the GCP arm resulted in a higher rate of overall response rate (57% vs. 46%), CR (15% vs. 10%), and survival (15.7 vs. 12.8 months) compared with GC arm, but these differences were not statistically significant.[244]

Combination of docetaxel and cisplatin (DC) has been compared with MVAC in a multicenter phase III clinical trial by the Hellenic Cooperative Oncology Group.[245] Patients (n = 220) were randomly assigned to MVAC every 4 weeks versus docetaxel plus cisplatin every 3 weeks. Treatment with MVAC resulted in significantly superior response rate (54.2% vs. 37.4%), median time to progression (9.4 vs. 6.1 months), and median survival (14.2 vs. 9.3 months), suggesting that MVAC was superior to DC. Toxicity of MVAC was considerably lower than that previously reported for MVAC administered without granulocyte colony–stimulating factor. Currently, GC, MVAC, and high-dose MVAC with granulocyte colony–stimulating factor support are the acceptable standard of care as first-line chemotherapy in advanced or metastatic bladder cancer setting.

Second-Line Chemotherapy Treatment

The role of salvage chemotherapy after relapse following first-line chemotherapy remains an important subject of recent clinical trials. The enrollment in such trials is challenging in view of patients' poor performance status and deranged renal functions. Although various phase I or II studies have been reported, to date, there is only one completed phase III trial comparing vinflunine with best supportive care (BSC) alone. Patients (n = 370) were randomly assigned in a 2-to-1 ratio to receive vinflunine plus BSC (n = 253) or BSC alone (n = 117). Both arms were well balanced. Grade ≥3 toxicities for the vinflunine arm were neutropenia (50%), febrile neutropenia (6%), anemia (19%), fatigue (19%), and constipation (16%). A median survival advantage of 2.3 months (6.9 months for vinflunine plus BSC vs. 4.6 months for BSC) was achieved but was not statistically significant (P = .287). Cox multivariate analysis adjusting for prognostic factors showed a statistically significant effect of vinflunine on overall survival (P = .036), reducing the death risk by 23%.

Objective response rate (8.6% vs. 0%), disease control (41.4% vs. 24.8%), and progression-free survival (3.0 vs. 1.5 months) were all statistically significant, favoring vinflunine. Because vinflunine was well tolerated, it is a reasonable second-line therapy option for patients with bladder cancer who have relapsed following cisplatin-based therapy.[246] Future second-line chemotherapy studies should incorporate vinflunine as the standard of care arm when testing any experimental treatment in a randomized trial.

Cost of Chemotherapy

In a retrospective study[247] using the SEER-Medicare dataset, first-line (1 L) and second-line (2 L) chemotherapy treatment patterns, health care visits, costs of health care in 2016 US dollars, and survival patterns were calculated from the index therapy date. Of 1215 patients diagnosed with advanced bladder cancer, 411 (33.8%) received 1 L chemotherapy and 189 (15.6%) subsequently received 2 L chemotherapy. During the 1 L and 2 L treatment courses, totals of 28.5 and 22.7 visits per patient were recorded, respectively. The total costs of cancer care during the 1 L and 2 L treatment courses were $36,790 and $26,730, respectively, of which more than $10,000 in costs were paid directly by the patient. Systemic therapy for bladder cancer is costly and should be weighed against the clinical outcomes likely to be achieved. Neither 1 L nor 2 L patients in this study experienced a median survival beyond 1 year following treatment initiation.

PART H

Male Genitourinary

CHAPTER 69

Low-Risk Prostate Cancer*

Carlos A. Perez, Jeff M. Michalski, and Michael J. Zelefsky

ANATOMY

Gross Anatomy and External Architecture

The prostate gland is an ovoid-shaped structure composed of fibrous, glandular, and muscular elements. It is located in the pelvis, adjacent to the rectum, bladder, dorsal and periprostatic venous complexes, pelvic sidewall musculature, the pelvic plexus, and cavernous nerves. Because of its shape, the prostate and the rectum curve away from each other as two convex surfaces. The prostate surrounds segments of the urethra before it passes through the genitourinary diaphragm (GUD; Fig. 69.1). Two of the five segments of the male urethra are the preprostatic urethra adjacent to the preprostatic sphincter and the prostatic urethra, which is placed from the verumontanum to the GUD. The paired seminal vesicles are situated posterosuperiorly to the prostate gland and secrete seminal fluid into the bilateral ductus deferens as they become the ejaculatory ducts. These ducts transverse the prostate to join the urethra at the verumontanum (Fig. 69.1, right). At this point, the urethra changes its angulation by bending 30 to 40 degrees anteriorly.

The prostate is contained within a thin, fibrous adherent capsule that is structurally continuous with the stroma of the gland. The apex of the gland rests above the GUD. The GUD surrounds the membranous sphincter and may vary in length and thickness. The puboprostatic ligaments extend anteriorly from the surface of the gland to the pubic symphysis. The prostate is separated from the rectum posteriorly by Denonvilliers fascia (rectovesical septum), which attaches above to the peritoneum and below to the GUD. It is this portion of the prostatic fascia that restricts posterior extension of prostatic carcinoma into the rectum. The lateral margins of the prostate are usually delineated against the levator ani muscles, forming the lateral prostatic sulci.

The anterior aspect of the prostate and the lateral pelvic floor are covered

with the periprostatic fascia (Fig. 69.2). The endopelvic fascia lateral to the prostate gland contains neurovascular structures, including the venous plexus of Santorini, which is the primary drainage for the penis. This venous network, also referred to as the *dorsal vein complex*, covers the anterolateral surfaces of the prostate. The primary arterial blood supply to the prostate is via branches of the internal pudendal, inferior vesical, and middle hemorrhoidal arteries. The internal pudendal arteries also provide the blood flow to the penis. The nerves originate from the pelvic plexus, containing both sympathetic and parasympathetic fibers, and are distributed to the prostate, seminal vesicles, and the corpora cavernosa of the penis and urethra.

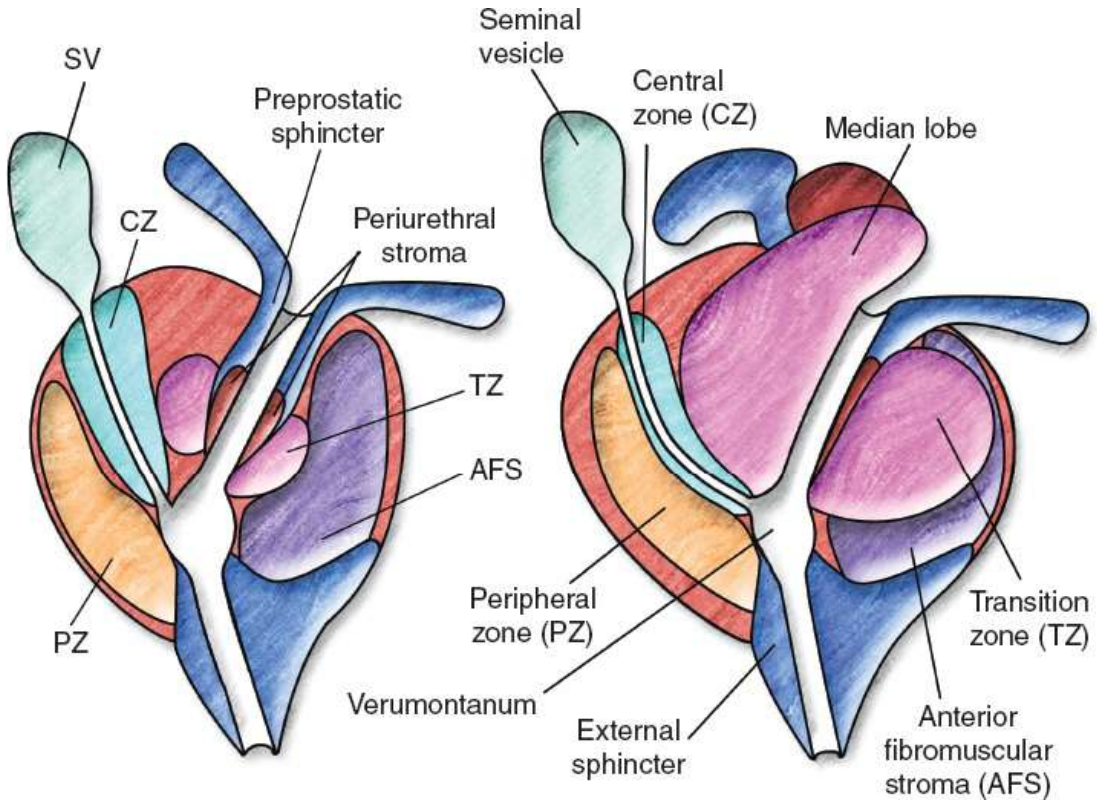

FIGURE 69.1. Zonal anatomy of the prostate. On the left, a young man with minimal transition zone (TZ) hypertrophy. Note that the preprostatic sphincter and periejaculatory duct zone (central zone of McLean) are clearly defined. On the right, an older man with TZ hypertrophy, which effaces the preprostatic sphincter and compresses the periejaculatory duct zone. AFS, anterior fibromuscular stroma; CZ, central zone; PZ, peripheral zone; SV, seminal vesicle. (Reprinted from McLaughlin PW, Troyer S, Berri S, et al. Functional anatomy of the prostate: implications for treatment planning. *Int J Radiat Oncol Biol Phys* 2005;63[2]:479–491. Copyright © 2005 Elsevier. With permission.)

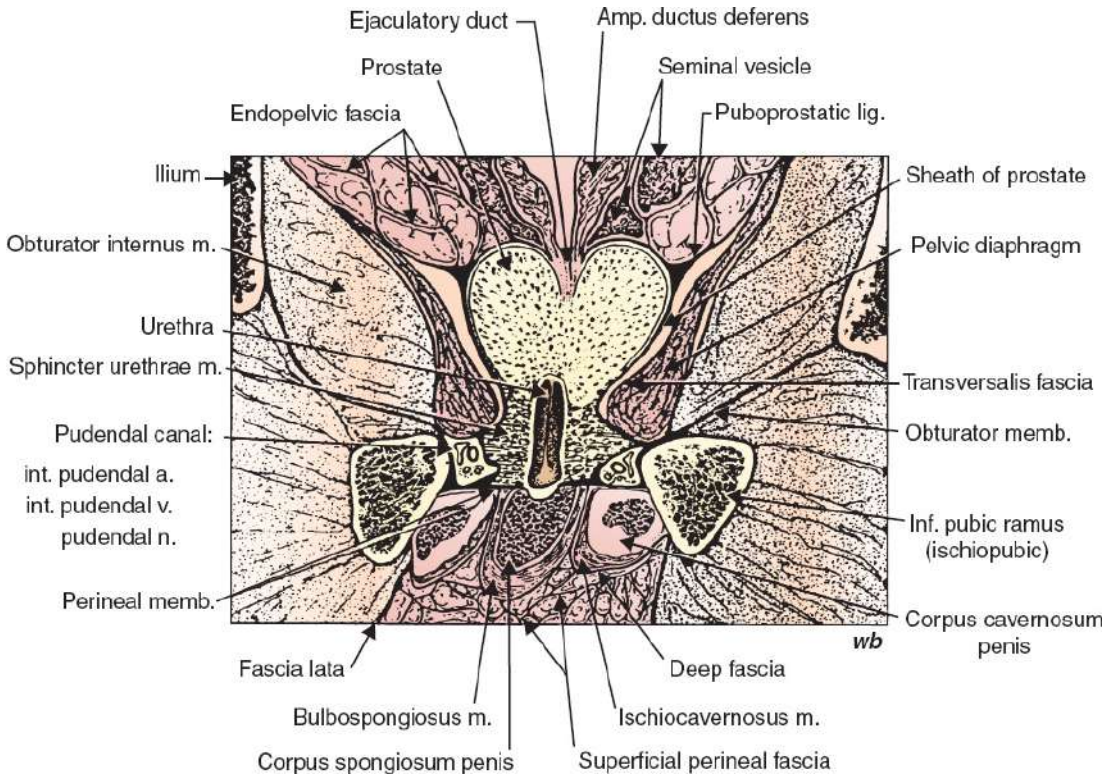

FIGURE 69.2. Frontal section of male pelvis at right angles to perineal membrane. (From Oelrich TM. The urethral sphincter muscle in the male. *Am J Anat* 1980;158[2]:229–246. Copyright © 1980 Wiley-Liss, Inc. Reprinted by permission of John Wiley & Sons, Inc.)

The prostatic apex is definable on diagnostic imaging and is very important anatomically for radiation therapy treatment planning. Although the apex and the GUD, which surrounds the membranous sphincter, are easily visualized on coronal magnetic resonance imaging (MRI), it is important to recognize that the level of the GUD from the apex to the penile bulb may vary because the absence of an apical capsule contributes to the difficulty in discrimination of the gland from the GUD during computed tomography (CT)-based treatment planning. Delineation of the neurovascular bundle is also limited on CT imaging.

Prostatic Zonal Anatomy

Zonal anatomy has essentially replaced lobar anatomy of the prostate. There are four zones of the prostate (Fig. 69.1): the peripheral zone (PZ), transition zone (TZ), central zone, and anterior fibromuscular stroma zone. The central zone that surrounds the ejaculatory ducts has marked histologic differences from the PZ. It is the PZ, extending across the entire posterior surface of the gland, that is palpated on rectal examination and is the location of most prostate cancers. The TZ is the location of benign prostatic hypertrophy. The anterior fibromuscular

zone consists of an anterior band of fibromuscular tissue contiguous with bladder muscle and external sphincter. In young men, the PZ is the prominent zone, whereas the TZ becomes the dominant zone with age. It is important to note that there is no “median lobe” zone in this nomenclature, although such a “lobe” may be present in some prostate cancer patients and may have important implications for treatment planning and treatment selection. Histologically, the median lobe arises from the TZ or periurethral stroma, with varying proportions of fibrous, glandular, and muscle tissue.

Prostate Physiology

Histologically, the prostate consists of compound tubuloalveolar glands lined by two layers of cells. The glands are embedded in connective tissue comprising collagen and abundant smooth muscle that constitutes the prostatic stroma. This fibromuscular stroma functions both to control micturition by acting as a sphincter of the urethra and to express acidic prostatic secretions into the urethra by contracting during ejaculation.

The major function of the prostate is the production of seminal fluid that protects and nourishes the sperm after ejaculation. The prostate contributes approximately 30% to the seminal fluid, and the seminal vesicles, testicles, and bulbourethral glands provide the remaining 70%. Enzymes, including acid phosphatase and prostate-specific antigen (PSA), are secreted into the seminal fluid. PSA is a serine protease that is involved in the liquefaction of the seminal coagulum. Because PSA is produced primarily by benign and malignant prostatic epithelial cells and normally found at low concentrations in the serum, it is useful for prostate cancer screening and posttreatment monitoring of disease status.

The synthetic activity and growth of the prostate gland is regulated by androgens. The primary circulating androgen is testosterone. In the prostatic stroma, testosterone is converted to its active and more potent form, α-dihydrotestosterone, by 5-α-reductase. Secretory epithelial cells and stromal cells have intracellular androgen receptors. Dihydrotestosterone forms a complex with the dihydrotestosterone-binding domain of the androgen receptor, altering the structure of the DNA-binding domain such that it can reversibly bind DNA sequences known as *androgen response elements* in promoter or enhancer regions of androgen-regulated genes. The response includes stimulation of cell division, inhibition of apoptosis (programmed cell death), or cellular differentiation. In secretory epithelial cells, testosterone stimulation may result in

the production and secretion of prostatic fluid. These mechanisms are tightly regulated at many levels, from the hypothalamus secreting luteinizing hormone–releasing hormone to maintain testosterone levels in the blood, to the local regulation of 5-α-reductase in the prostate stroma.

EPIDEMIOLOGY AND RISK FACTORS

Clinical Incidence

Adenocarcinoma of the prostate is the most frequently diagnosed visceral cancer of men in the United States, accounting for 33% of nonskin cancers. The lifetime risk for American White and African American men is 18% and 21%, respectively. This corresponds to a respective lifetime risk of prostate-specific mortality of 3% and 5%.[1,2] After large annual increases from 1988 to 1992, coinciding with the introduction of the PSA screening test, prostate cancer incidence in the United States leveled off and then showed modest decreases of approximately 1.9% per year between 2000 and 2008. Incidence rates between 1975 and 2015 were approximately 114 per 100,000 men, 107 for White, 186.8 for Black, 97 for Hispanic, and 54.8 for Asian[2]

Perhaps because of widespread use of PSA screening and effective early treatment for localized disease, the age-adjusted death rates have begun to decrease. It was estimated that 241,740 new cases of prostate cancer would be diagnosed in 2012, but only approximately 28,170 patients would die of the disease. This compares with 164,690 new cases and 29,430 estimated deaths in 2018.[2] Despite this encouraging incidence trend, carcinoma of the prostate remains the second greatest cause of male cancer mortality behind cancer of the lung and bronchus.[2]

Of the known or suspected risk factors for prostate cancer, the most important is age (Table 69.1).[3] The median age at diagnosis is 68 years, and the disease incidence escalates sharply with increasing age. The incidence among men aged 50 to 59 years is 1 in 58, increasing to 1 in 21 among men aged 60 to 69 years, and 1 in 12 among those aged 70 years and older.[2] According to autopsy data, 70% of men older than 80 years of age and 40% of men older than 50 years of age have pathologic evidence of cancer in the prostate.[4]

Although the risk for development of histologic evidence of cancer in the prostate is fairly constant across countries and races, there is considerable variability in the incidence of clinically evident disease and mortality among different populations worldwide and in the United States.[5]

The highest rates of prostate cancer are in Scandinavia, where it is the leading cause of male cancer death. The lowest recorded rates are in Asia. In the United States, incidence and mortality are higher among African Americans. The mortality rates of prostate cancer in Japan dramatically increased from 1960 to 2000 in all age groups before showing modest but sustained decreases from 2000 onward.[6]

TABLE 69.1 KNOWN OR SUSPECTED RISK FACTORS FOR PROSTATE CANCER

Factor	Effect on Prostate Cancer Risk
Age	Increase
African American race	Increase
Geography	Scandinavia, high; Asia, low
Family history	Increase
Dietary fat	Increase
Agent Orange	May increase
Vasectomy	No effect
Benign prostatic conditions	No effect
Sexually transmitted diseases	No effect
Tobacco	Inconclusive data
Androgens	Inconclusive data

Risk Factors

Hormonal Influences

It is relatively well established that androgenic influences over time affect prostate carcinogenesis and disease progression.[7] Generally, androgens are required for the development of prostate cancer, and it has been noted that men deficient in 2,5α-reductase are rarely diagnosed with benign prostatic hypertrophy or prostate cancer. In a study of 1,008 men, there was a positive correlation with plasma androstenedione levels and the development of prostate cancer.[8] However, Gann et al.[9] found no clear association between individual hormone levels, including dihydrotestosterone, and the incidence of prostatic cancer. Yet, these investigators noted that high levels of testosterone in combination with low levels of the serum protein that binds testosterone, sex hormone–binding globulin, correlated with a higher risk of prostate cancer. Meikle et al.[10] observed a higher sex hormone–binding globulin level and a higher rate of testosterone synthesis in men with prostate cancer compared with

control subjects.

The most conclusive evidence supporting the hormonal influence in the development of prostate cancer comes from two large, randomized trials evaluating the use of 5α-reductase inhibitors in chemoprevention. The Prostate Cancer Prevention Trial was the first large-scale, population-based trial testing the hypothesis that treatment with finasteride, which lowers intraprostatic dihydrotestosterone levels, prevents prostate cancer.[11] In this trial, a total of 18,882 men ≥55 years old and with normal digital rectal examination (DRE) and PSA level ≤3.0 ng/mL were randomized to 7 years of finasteride (5 mg/d) or placebo. This study found that the prevalence of prostate cancer was reduced by 25% in men taking finasteride compared to placebo, with the prevalence of Gleason sum 7 to 10 tumors higher in the former group. The Reduction by Dutasteride of Prostate Cancer Events (REDUCE) trial randomized 8,231 men at high risk for prostate cancer (aged 50 to 60 years with a PSA of 2.5 to 10.0 or age ≥ 60 years with a PSA of 2.5 to 10.0 and a negative prostate biopsy within 6 months of enrollment) to dutasteride (0.5 mg daily) or placebo.[12] At 4 years, a relative risk reduction in the diagnosis or a subsequent prostate cancer of 22.8% was noted in men taking dutasteride, with a trend toward increased Gleason 8 to 10 tumors. For both trials, it remains controversial whether this increased risk of high Gleason tumors is real or artifactual. However, the U.S. Food and Drug Administration has declined to add chemoprevention of prostate cancer as an indication for finasteride and dutasteride.[13]

Dietary Influences

The development of prostate cancer may be attributed to both familial and environmental factors. Epidemiologic studies strongly suggest that a diet deficient in certain micronutrients is an important environmental risk factor. This has been supported through migration studies that indicate higher rates of prostate cancer in Asian men living in the United States compared with their counterparts in Japan or China.[14,15] It has been postulated that nutritional factors play a role in stimulating the progression of microscopic disease. Salient features of the “Western diet” that differ from the traditional Asian diet are high fat intake and low soy consumption. A Western diet has been associated with increased production of both androgens and estrogens and a vegetarian diet with lower levels.[16] Diets high in fat content may increase the relative risk of prostate cancer by a factor of 1.6 to 1.9.[17,18] In addition, several studies showed that men with diets high in fiber and presumably lower in fat have a decreased risk of

prostate cancer.[19,20]

One prospective study found that the type of fat intake was directly related to risk of prostate cancer.[21] Red meat represented the food group with the strongest positive association with advanced cancer, with a relative risk of 2.64. Fat from dairy products (with the exception of butter) or fish was unrelated to risk. When analyzed by fatty acid type, only *α*-linolenic acid (an omega-3 fatty acid found in red meats and butter), and not linoleic acid (omega-6 fatty acid found in fish oil), was implicated, with an increase in risk for prostate cancer of more than threefold. Conversely, a subsequent Canadian case-controlled study suggested that saturated fat consumption, not *α*-linolenic acid consumption, may play a role in prostate cancer progression.[22] Finally, a Swedish study of 406 men with prostate cancer and 1,208 without it (control subjects) demonstrated that body mass index and total amount of food consumed were independent risk factors.[23]

Plant-based foods and their products, such as soy, tomatoes, cruciferous vegetables, and certain nutrients, are favorably associated with prostate cancer. It is believed that these dietary factors contribute to antioxidant effects against DNA and cell damage.

Several vitamins and trace nutrients, including selenium, vitamin E, and vitamin C, have garnered attention as potential protective agents. Early experimental and epidemiologic data supported the anticarcinogenic effects of selenium through apoptotic, angiogenic, or antioxidative pathways.[24] The Nutrition Prevention Trial identified a 50% reduction in prostate cancer risk in men blindly and randomly assigned selenium supplements compared with placebo.[25] Promising data for vitamin E as a protective agent were reported in the Finnish Alpha-Tocopherol, Beta-Carotene Cancer (ATBC) Prevention Study, which evaluated supplementation with vitamin E and beta-carotene in male smokers for chemoprevention of lung cancer.[26] Secondary analysis suggested a 32% reduction in prostate cancer risk among men randomized to receive vitamin E. However, a large, prospective, randomized trial failed to confirm these findings for selenium or vitamin E. The Selenium and Vitamin E Cancer Prevention (SELECT) Trial randomized 35,533 men to four arms: selenium (200 µg/d), vitamin E (400 IU/d rac-*α*-tocopheryl acetate), both selenium and vitamin E, or placebo only.[27] With a minimum follow-up of 7 years, the study identified no reduction in risk of prostate cancer with either vitamin E or selenium supplementation but identified an increased hazard ratio (1.17) for development of prostate cancer among men randomized to vitamin E alone. Vitamin E was contemporaneously evaluated in the randomized Physicians'

Health Study II, which failed to demonstrate a reduction in prostate cancer incidence by supplementation with vitamin E or C.[28]

The beneficial effects of soy are attributed to isoflavones, one of several plant pigments found in soybeans. Isoflavones are a type of phytoestrogen compounds that have weak estrogenic, antiestrogenic, and antioxidant effects that may all be protective against progression of prostate cancer in humans. These isoflavones, most significantly genistein and daidzein, have been shown to inhibit the growth of prostate cancer cell lines in nude mice.[29] In particular, genistein has been shown to be a potent inhibitor of several steroid-metabolizing enzymes, such as aromatase, 5α-reductase, and 17β-hydroxysteroid dehydrogenase, as well as enzymes that are crucial to cellular proliferation, such as tyrosine kinase and topoisomerases I and II. Genistein is also an inhibitor of angiogenesis. It is estimated that Japanese men consume approximately 20 mg of isoflavones per day, whereas for Western men, the daily consumption is <1 mg/d. This is reflected in a mean plasma concentration of genistein of 180 ng/mL in Japanese men, compared with a level of <10 ng/mL for Western men.[30]

Another protective nutrient is lycopene present in tomatoes, processed tomato products, and other fruits, which is one of the most potent antioxidants among dietary carotenoids. Although the antioxidant properties of lycopene are believed to be primarily responsible for its beneficial effects, other mechanisms may also be involved. In a review of 72 epidemiologic studies that investigated a link between cancer risk and consumption of tomato products, 57 linked tomato intake with a reduced risk; in 35 of those studies, the association was considered statistically significant.[31] Two large, prospective studies reported a decrease in prostate cancer risk with higher tomato product consumption.[32,33] Tomatoes were one of only four specific food items associated with significantly reduced prostate cancer risk in a prospective study of 14,000 Seventh-Day Adventist men.[33] A prospective study examined the relationship between the plasma concentration of several antioxidants and the risk for prostate cancer, using plasma samples obtained in the Physicians' Health Study. Higher serum and tissue lycopene levels were found to be inversely related to the incidence of prostate cancer development.[34] In a recent meta-analysis of 21 studies, high intake of tomatoes was associated with a 10% to 20% risk reduction in prostate cancer, with lower risk because of cooked versus raw tomatoes.[35] A summary of various epidemiologic studies indicating associations of various dietary factors to prostate cancer development and morality is shown in Table 69.2.

Familial Associations

A large cohort study of the Utah Mormon population demonstrated a positive family history of prostate cancer in 6.6% of families of probands with prostate cancer and only 2.2% of families of probands without prostate cancer.[36] A subsequent study using data from the Utah State Cancer Registry reported a familial relative risk of prostate cancer of 2.2.[37] Multiple studies have confirmed these findings, including a large case–control study from Johns Hopkins.[38] Extensive cancer pedigrees were obtained from 691 prostate cancer cases and 640 spouse control subjects showing a twofold increased risk in men with a family history of prostate cancer in a single first-degree relative. There was a fivefold risk if there were two affected relatives, and the relative risk rose to 11 for three first-degree relatives with prostate cancer.

In a Canadian study, the frequency of prostate cancer detected in men who had a first-degree relative with a history of prostate cancer was 2.6 times greater than for men without such a history.[39] Aprikian et al.,[40] in a study of 2,968 patients, noted that prostate cancer was detected in 40% (1,300 patients) of men with a family history of prostate cancer, compared with 29% of 769 men without a family history ($P < .0001$). In a review of the epidemiology of prostate cancer, Giovannucci[32] reported that approximately 9% of cases may be attributed directly to a family history, although this may be as high as 43% among men younger than 55 years of age.

TABLE 69.2 NUTRITIONAL RISK FACTORS FOR PROSTATE CANCER INCIDENCE, RECURRENCE, AND MORTALITY

Food or Nutrient	Direction of Association with Prostate Cancer Risk	Direction of Association with Prostate Cancer Recurrence or Mortality	Overall Quality of Evidence
Selenium	Inverse		Strong
Tomato and lycopenes	Inverse	Inverse[a]	Good
Other carotenoids	Inverse	Inverse[a]	Good[a]
Vitamin E	Inverse (seen in smokers)	Inverse[a]	Good
Vitamin D	Inverse		Good
Calcium and dairy	Null to positive		Good
Red meat	Positive		Good
Fish/omega-3	Inverse	Inverse[a]	

Soy/isoflavones	Null to inverse	Null for PSA recurrence	Fair[a]
Tea/polyphenols	Null to inverse		Fair[a]
Zinc	Positive		Fair[a]
Heterocyclic amines	Positive		Fair[a]

[a]Limited data available.

TABLE 69.3 PARTIAL LIST OF PROSTATE CANCER SUSCEPTIBILITY GENES AND CANDIDATE GENES

Gene	Location	Alterations	Proposed Phenotypic Consequences
RNASEL/HPC1	1q24-25	Base substitutionsFour-base deletion leading to premature truncation	Encodes endoribonuclease Early age at diagnosis
ELAC2/HPC2	17p11	Base insertion leading to premature terminationBase substitutions	Unknown
MSR1	8p22-23	Base substitutions	Encodes subunit of class A macrophage-scavenger receptor
AR	Xq11-12	Polymorphic polyglutamine (CAG) and polyglycine (GGC) repeats	Encodes androgen receptor, and androgen dependent transcription factor
CYP17	10q24.3	Base substitutions in transcriptional promoter (T → C transition leading to a new Sp1 recognition site)	Encodes cytochrome P-450c17*α*, and enzymes that catalyzes key reactions in sex-steroid biosynthesis
SRD5A2	2p23	Base substitutions	Encodes the predominant 5-*α*-reductase in the prostate, converts testosterone to dihydrotestosterone
AMACR	5p13.2	Missense mutations	Unknown
BRCA2	13q12-13	Various	Possible link to higher Gleason score and stage at diagnosis
CHEK2	22q12.1	Frameshift/missense mutations	Unknown
HOXB13	17q21	Missense mutations in highly conserved functional domain	Early age at diagnosis
KFL6	10p15	DNA polymorphism	Leads to alternative splicing in encoded tumor suppressor gene
MMR genes (MLH1,	Various	Various	Various

MSH2, HSH6, PMS2)			
NBS1	8q21	Loss of heterozygosity in carriers	Role in DNA repair
HPCX	Xq27-28	Unknown	Unknown
CAPB	1p36	Unknown	Early age at diagnosis; association with CNS malignancies

Despite the familial clustering of prostate cancer observed in these epidemiologic studies, causation cannot be inferred, given the shared environmental factors among family members. Segregation analyses of cancer in multiple family members have been used to examine the role of genetic factors and inheritance patterns in prostate cancer. Segregation analysis is a statistical method used to determine the best-fitting model of inheritance for a particular disease in a study population. The largest segregation analysis of prostate cancer families suggested that the familial pattern was best explained by Mendelian inheritance of a rare, autosomal dominant gene in a subset of men with early-onset prostate cancer.[41] The allele is highly penetrant, accounting for cancer by age 85 years in 88% of carriers compared with only 5% of noncarriers. Although this gene appears to be responsible for many of the early-onset cases, only 9% of all prostate cancer cases are in patients with this genetic predisposition, a percentage similar to that seen in both hereditary breast and colon cancers. Twin studies have also been used in the analysis of prostate cancer inheritance and have shown four to five times higher concordance rates for monozygotic twins.[42]

Genetic and Molecular Influences

Progress in cytogenetic studies using polymerase chain reaction (PCR)-based polymorphism analysis has facilitated the identification of regions of the genome associated with various types of cancer. There is ongoing investigation into the role of chromosomal deletions, oncogenes, and tumor suppressor genes in the initiation and progression of prostate cancer. Emerging data from analysis of DNA from high-risk families suggest that specific high-risk alleles exist for prostate cancer, as they do for other tumors. A major susceptibility locus for prostate cancer on the long arm of chromosome 1 (1q24-25) was identified

through a genome-wide scan.[43] The gene, *HPC1* (hereditary prostate cancer 1), has been linked to families with multiple members affected with an early average age at diagnosis.[44] However, this association has not been identified in all studies. Subsequent studies have sought to identify additional susceptibility loci and germ-line mutations implicated in familial prostate cancer. A recent study by Ewing et al.[45] identified a recurrent mutation in HOXB13, a homeobox transcription factor gene involved in prostate development on the long arm of chromosome 17 (17q21-22) implicated in early-onset, familial prostate cancer. A number of other candidate susceptibility genes have been studied,[46] several of which are summarized in Table 69.3.

Research delving into the molecular physiology of the prostate gland has also uncovered specific DNA sequences that may be related to the occurrence and progression of prostate cancer. It is well known that prostate cancer cells, like their normal counterparts, are usually sensitive to androgens, and their growth depends on androgen-stimulated cell division. The androgen receptor gene contains a polymorphic CAG repeat sequence that encodes the portion of the receptor involved in DNA transcription. The length of the CAG repeat sequence was found to be inversely proportional to the activity of the androgen receptor; therefore, shorter CAG repeat sequences may be related to prostate cancer growth.[47] Giovannucci et al.,[48] in an analysis of the activity of the androgen receptor in men with prostate cancer, found that a shorter CAG repeat sequence in the androgen receptor gene predicts higher grade and more advanced stage of prostate cancer at diagnosis, as well as metastasis and mortality from the disease. Other studies found that the prevalence of short CAG repeats is higher among African Americans than Whites[49] and that these sequences are longest among Chinese men.[7]

In addition to these genetic alterations identified in prostate cancer, epigenetic changes such as abnormal DNA methylation have also been observed and may play a role in up-regulation or loss of expression of genes.[50] Millar et al.[51] observed that abnormal methylation of specific sites throughout the genome of prostate cancer cells leads to loss of glutathione *S*-transferase P1 (GSTP1) gene expression. The GSTP1 gene product is an enzyme that provides protection to mammalian cells against electrophilic metabolites of carcinogens and reactive oxygen species. Loss of GSTP1 may lead to a transition between proliferative inflammatory atrophy and prostatic intraepithelial neoplasia or prostate cancer.[52]

Other Risk Factors

Chronic or recurrent inflammation may have a role in the development of prostate cancer, as has been recognized in many other human cancers. In one large population-based study, prostate cancer risk was increased in men with a history of gonorrhea or syphilis (odds ratio [OR] 1.6; 95% confidence interval [CI] = 1.2 to 2.1).[53] A criticism of such epidemiologic studies is the bias that men with symptomatic prostatitis compared with men without it are more likely to seek out care with urologists, have an increased serum PSA test, and have prostate biopsies.[52]

Several commonly used medications have gained attention as potential chemopreventive agents, with particular interest in 5-hydroxy-3-methylglutaryl-coenzyme. Data for the effects of statin (a reductase inhibitor) use on subsequent risk of prostate cancer are conflicting, with some observational cohort studies and retrospective analyses suggesting a reduced risk of advanced prostate cancer,[54] reduced risk of death from prostate cancer,[55] and lower rates of relapse following radiotherapy[56] or radical prostatectomy (RP).[57] However, several large meta-analyses failed to identify a relationship between statin use and prostate cancer risk,[58,59] and no prospective, randomized studies have confirmed these observations.

Other risk factors for prostate cancer have been implicated but not corroborated. Several reports suggested an association between vasectomy and prostate cancer. In a prospective study of 10,055 vasectomized men and 37,800 nonvasectomized men, Giovannucci et al.[60] found an increased risk of 1.85 in the vasectomized men. In a retrospective study of 14,607 vasectomized or nonvasectomized men, the increased risk was 1.56.[61] In contrast, a population-based case–control study of 923 new cases of prostate cancer among men aged 40 to 74 years from the New Zealand Cancer Registry showed no association between prostate cancer and vasectomy.[62] Although there appears to be no definite etiologic relationship, it is possible that men undergoing vasectomy are more conscious of health care and more likely to be screened for prostate cancer.[63] Circumcision has not been correlated with development of prostate cancer.[64]

Armenian et al.,[65] in a study of 296 patients with benign prostatic hyperplasia diagnosed either histologically or clinically and 299 age-matched control subjects observed from 7 to 27 years, found the incidence of prostatic cancer to be 3.7 times higher in the hyperplasia group than in the control group. This association was not observed by others.[66]

Some studies correlated smoking with increased risk of prostate cancer,[67]

whereas another study did not find a significant correlation.[68] In one analysis of 359 patients,[69] a greater tumor-specific mortality rate among smokers than nonsmokers with stage A and D tumors was observed. No occupational factors have been confirmed as risks, but some evidence suggests that occupational exposure to cadmium and some aspects of farming may increase risks moderately, although these factors would account for only a small proportion of the total cases. Japanese men exposed to atomic bomb explosions in Hiroshima and Nagasaki have not had a significantly higher incidence of prostatic cancer.[70]

NATURAL HISTORY

Local Growth Patterns

The studies of prostate morphology conducted by McNeal[71] showed that almost all prostatic carcinomas (>70%) develop in the PZ of the prostate, whereas benign prostatic hyperplasia (>90%) arises from the transition zone (TZ). In addition, examination of prostatectomy specimens revealed that small tumors tend to occur in the anteromedial gland, adjacent to the fibromuscular stroma, whereas larger, more advanced T-stage tumors are often located in the posterior gland near the prostatic capsule.[72,73]

Multifocality is characteristic of prostate cancer. On DRE, there may be one nodule or many, located unilaterally or bilaterally. Histologic and molecular studies of prostatectomy specimens of patients with prostate cancer have revealed that most contain a dominant or index tumor and one or more spatially separate, often heterogeneous, tumors.[74–77] Jewett[78] reported that multiple foci of disease were found throughout the prostate in 77% of prostatectomy specimens. Wise et al.[79] noted that only 17% of 486 patients treated by radical retropubic prostatectomy had one carcinoma detected by 3-mm step-section histologic examination. Of the 83% with multifocal disease, secondary cancers were mostly small; 58% were <0.5 cm^3 in volume. Qian et al.,[80] using fluorescence *in situ* hybridization to detect chromosomal abnormalities, found that an increasing incidence of chromosomal anomalies among specimens was positively correlated with progression from high-grade prostatic intraepithelial neoplasia to prostatic carcinoma. When lymph node involvement was present, there was usually evidence of one or more foci of the primary tumor sharing chromosomal anomalies with associated lymph node metastases, suggesting that just a single focus of carcinoma may give rise to metastases. This heterogeneity and multicentricity may account for the discrepancy between needle biopsy

Gleason score and the grade determined from the dominant tumor in the prostatectomy specimen.

Tumors arising from the TZ tend to demonstrate a lower frequency of extracapsular extension and may harbor large volumes of disease with relatively high PSA levels but remain confined to the prostate. Despite a high PSA value (≥10 ng/mL), these tumors should be considered to have a favorable prognosis and be managed accordingly. Noguchi et al.[81] described the histologic characteristics of 148 cases of TZ prostate cancer from RP specimens. Seventy percent were clinical stage T1c, with a preoperative serum PSA of 10 ng/mL or greater in almost two-thirds of cases. Only 63% had a positive initial prostatic biopsy. On pathologic review, 80% had organ-confined disease, and more than one-third of cases had a cancer volume >6 mL. When compared with 79 PZ cancers matched by volume, there were no differences in percentage Gleason grade 4/5, serum PSA, or prostate weight, although differences in clinical stage T1c to T2c and organ-confined cancer were highly significant. The actuarial 5-year PSA relapse–free survival rate was 71.5% among men with TZ cancer, compared with 49.2% for those with PZ cancer.

PZ cancers tend to spread along the capsular surface of the gland and may extend through the capsule of the gland, invade seminal vesicles and periprostatic tissues, and involve the bladder neck or the rectum. Clinical stage closely correlated with risk of extracapsular extension and disease progression.[82–84] The incidence of microscopic tumor extension beyond the capsule of the gland (at the time of RP) in patients with clinically organ-confined disease ranges from 8% to 57%.[85,86] Oesterling et al.,[87] in an analysis of patients with stage T1c disease treated with RP, noted that 53% had pathologically organ-confined tumors, 35% had extracapsular extension, and 9% had seminal vesicle invasion. Of the last group, 66% had positive surgical margins, an incidence comparable with that for clinical stage T2 tumors. In a similar group of patients with T1c tumors, Epstein et al.[88] found that 34% had established extracapsular extension, 6% had seminal vesicle invasion, and 17% had positive surgical margins.

Pretreatment serum PSA is also predictive of extraprostatic extension and seminal vesicle invasion. The rate of organ-confined prostate cancer ranges from 53% to 67% for men with a PSA level between 4 and 10 ng/mL and from 31% to 56% for men with a PSA level between 10 and 20 ng/mL.[89–91] D'Amico et al.,[92] in a pathologic evaluation of 347 RP specimens, reported that none of 38 patients with PSA of ≤4 ng/mL had seminal vesicle involvement, in contrast to 6% of

144 patients with PSA of 4 to 10 ng/mL, 11% of 101 with PSA of 10 to 20 ng/mL, 36% of 45 with PSA of 20 to 40 ng/mL, and 42% of 19 with PSA of >40 ng/mL. The incidence of positive surgical margins for these PSA subgroups was 11%, 20%, 33%, 56%, and 63%, respectively. The incidence of seminal vesicle involvement also is associated with the level of PSA, the Gleason score, and the clinical stage.[93,94] Seminal vesicle involvement has been observed in from 10% of patients with A2 tumors to 30% of the patients with B2 lesions.[95,96]

Roach[97] proposed formulas based on analysis of RP specimens to estimate the probability of extracapsular extension (ECE+) and seminal vesicle involvement (SV+):

Regional Lymph Node Involvement

Tumor size and degree of differentiation affect the tendency of prostatic carcinoma to metastasize to regional lymphatics.[98,99] With an increasing number of patients being diagnosed in earlier stages (as a result of screening PSA), there has been a decreased incidence of lymph node metastases in patients with clinical stage T1c and T2 tumors.[100] In the low-risk prostate cancer patients, the risk of lymph node involvement is generally considered <10%.

Several groups[89,101–106] have developed models based on clinical or pathologic data that predict the risk of lymph node metastases. This information is important to decide whether a prostate cancer patient should be subjected to a staging lymphadenectomy (including laparoscopic technique) or considered for irradiation of the pelvic lymph nodes. Partin et al.[107] analyzed data from 703 patients and generated a nomogram for predicting nodal metastases based on three factors: clinical stage, preoperative PSA, and tumor biopsy grade. This model was validated in a larger multicenter study of 7,014 men and accurately predicted nodal metastases in 78% of patients.[108] The negative predictive value was 99%. Bluestein et al.[103] tested a model based on multivariate logistic regression analysis on 1,632 patients who underwent pelvic lymphadenectomy at the Mayo Clinic for staging of prostate cancer. Using this method, they determined that 29% of the patients with clinical stage T1a to T2c disease would have been spared pelvic lymphadenectomy with only a 3% rate of missed nodal metastases. Bishoff et al.[102] reported similar results demonstrating that 20% to 63% of patients with prostate cancer could be spared pelvic lymphadenectomy when accepting a 2% to 10% risk for missed nodal metastasis. These results suggest that many patients can be spared pelvic lymphadenectomy solely by analyzing preoperative PSA, Gleason grade, and clinical stage, without incurring

an unacceptable risk for failing to identify regional metastasis.[109]

Stock et al.,[94] in a study of 99 patients who underwent laparoscopic lymph node dissection, correlated incidence of positive nodes with PSA, Gleason score, stage, and involvement of seminal vesicles. None of the patients with a Gleason score of 4 or lower, even those with PSA of >20 ng/mL, had positive pelvic lymph nodes, and 8% in the group with Gleason scores of 5 or 6 and PSA levels of 4 to 10 ng/mL had positive nodes. However, the incidence of positive lymph nodes increased significantly (to 24%) in patients with PSA of >20 ng/mL. These results are similar to those reported in patients treated with RP.[103,107]

In an analysis of 2,144 patients treated at two institutions, Rees et al.[110] noted that only 30 (2.2%) of 1,390 patients with a negative DRE and either PSA of 5 ng/mL or less, Gleason score of 5 or less, or a combination of PSA of <25 ng/mL and Gleason score of ≤7 had pelvic lymph node metastases.

Roach[97] suggested a formula based on pathologic findings in prostatectomy specimens to estimate the incidence of metastatic pelvic lymph nodes (nodes+)

Prognosis is closely related to the presence of regional lymph node metastases; patients with positive pelvic lymph nodes have a significantly greater probability (>85% at 10 years) for development of distant metastasis than those with negative nodes (<20%).[111] However, a single nodal metastasis is not an unfavorable prognostic sign. In a study by Cheng et al.,[112] 322 patients with positive lymph nodes after RP and bilateral pelvic lymphadenectomy were followed for a median of 6 years. Patients with prostate carcinoma who had multiple regional lymph node metastases had increased risk of death from disease, whereas patients with a single positive lymph node appeared to have a more favorable prognosis after RP and immediate adjuvant hormonal therapy. Prout et al.,[113] in 92 patients with various stages of prostatic carcinoma, noted solitary lymph node metastasis in 11 (34%) of 32 patients with positive nodes. Bilateral pelvic lymph node involvement was present in 14 (58%) of 24 patients who had more than one metastatic lymph node. Only 2 (18%) of 11 patients with a single metastasis showed tumor progression, compared with 15 (76%) of 21 with multiple lymph node involvement. Golimbu et al.[114] noted a 10-year survival rate of 50% in patients with a single positive lymph node, compared with 20% for those with multiple lymph node involvement.

The prognostic significance of multiple involved lymph nodes should be considered with the extent of lymphadenectomy. Several studies have evaluated the anatomic extent of pelvic lymph node dissection on outcome.[115,116] At Johns Hopkins University Hospital, two surgeons performed 4,000 RP with or without

an extended lymph node dissection. The extended dissection removed more lymph nodes (mean 12 vs. 9; $P < .0001$) and detected more lymph node–positive prostate cancer (3.2% vs. 1.1%; $P < .0001$) than more limited procedure. If disease was found involving <15% of the extracted lymph nodes, extended lymph node dissection resulted in a more favorable 5-year PSA progression-free survival (PFS). Thus, in certain subgroups, an extended dissection may be beneficial. In another study, the number and percentage of involved lymph nodes correlated with recurrence-free and overall survival.[116] These results need additional validation in prospectively controlled studies.

CLINICAL PRESENTATION AND DIAGNOSTIC WORKUP

Screening Methods and Markers

Although DRE is still an essential element in screening and assigning clinical stage, only 25% to 50% of men with an abnormal DRE have prostate cancer on biopsy. Moreover, because carcinoma of the prostate can be asymptomatic until attaining a significant size, if a patient presents with a palpable tumor, there is a significant risk that there already may be locally advanced or metastatic disease. With the advent of PSA screening, the diagnosis of prostate cancer may precede palpable disease on DRE and the symptoms of urinary obstruction or metastatic disease by many years. DRE is associated with 70% sensitivity and 50% specificity.[117] In fact, 70% of cancers detected by PSA screening are confined to the prostate, and 40% of cancers detected by PSA are not palpable.[86]

PSA, initially identified and purified from prostatic tissue by Wang et al.[118] in 1979, is a protein with a molecular weight of 33,000. PSA is detected not only in prostatic tissue (normal tissue, benign hyperplasia, and malignant tumors) and in seminal fluid but also in the sera of patients with prostatic cancer. It is localized in the cytoplasm of ductal epithelial cells and in secretory materials in ductal lamina.[119] PSA has been detected with immunohistochemical techniques in pancreas and salivary glands and in women; therefore, it is not absolutely specific for prostatic epithelium.[120]

Widespread use of PSA screening has come into question following publication of two landmark screening trials. The European Randomized Study of Screening for Prostate Cancer (ERSPC) randomized 162,387 men aged 50 to 74 years to PSA screening an average of once every 4 years or to no such screening.[121] At a median follow-up of 9 years, PSA screening showed a modest reduction in death from prostate cancer that would require screening of 1,410

men and treatment of 48 men to prevent one death from prostate cancer. The reduction in death from prostate cancer was apparent only in men aged 55 to 69 years. The contemporaneous U.S.-based Prostate, Lung, Colorectal, and Ovarian (PLCO) Cancer screening trial randomized 76,693 men aged 55 to 74 years to annual PSA testing for 6 years and annual DRE for 4 years versus no such screening.[122] At a median follow-up of 7 years, no difference in mortality was noted between the arms. As of August 2008, the U.S. Preventive Services Task Force recommended against PSA screening in men aged 75 years or older and concluded that current evidence is inadequate to make a PSA screening recommendation for men younger than the age of 75 years.[123] The American Urological Association continues to recommend annual DRE and PSA screening tests for men older than 40 years of age if their life expectancy is >10 years.[124]

Radioimmunoassays for prostatic acid phosphatase (PAP) have a sensitivity of approximately 10% and a specificity of about 90% for malignant tumors[117] and to a large extent have been superseded by PSA testing. Stamey et al.[125] reported PSA and PAP measurements by radioimmunoassay in 2,200 serum samples from 699 patients, 378 of whom were known to have prostatic carcinoma. PSA was elevated in 122 of 127 patients with newly diagnosed prostatic carcinoma, whereas PAP was elevated in only 57 patients with cancer and correlated less closely with tumor volume than did PSA. PSA was increased in 86% and PAP in 14% of the patients with benign prostatic hyperplasia.

After RP for cancer, PSA routinely declines to undetectable levels, with an associated half-life of 2.2 days. PAP, if initially elevated, normalizes within 24 hours after surgery. Several authors concluded that PSA is more sensitive than PAP and DRE in the detection of prostatic carcinoma and that PSA would be more useful in monitoring response and recurrence after therapy.[125–127] A caveat is that both PSA and PAP may be elevated in benign prostatic hyperplasia. Hudson et al.[126] reported that only 3% of 168 men with benign prostatic hyperplasia had PSA levels of >10 ng/mL, compared with 44% of 231 patients with prostatic carcinoma.

Several investigators[128–130] reported no significant impact of DRE on the plasma levels of PSA or PAP in patients with various prostatic abnormalities in whom blood samples were collected before, immediately after, and 30 minutes after rectal examination of the prostate. Others[131–133] detected a significant increase in PSA after DRE. Ornstein et al.[133] noted an increase in both total and free PSA in 31% and 48% of men, respectively, at 1 hour after DRE. Matzkin et al.[134] found no significant change in PSA levels after inserting a urethral catheter

and maintaining it for several days. Yet, significant PSA elevation has been demonstrated after prostatic massage, transrectal ultrasonography (TRUS), prostate biopsy, and transurethral resection of the prostate (TURP).[130,131,135,136] The kinetics of serum PSA elevation after DRE and needle biopsy were investigated in a Dutch study with few participants.[137] Blood samples were taken at 1 and 30 minutes and 1, 3, 6, and 12 hours and then every 24 hours until 5 days had elapsed. The peak levels were between 30 and 60 minutes after DRE and returned to baseline 24 to 72 hours after the examination. There was a threefold increase in PSA after needle biopsy, and only two of seven patients had returned to their baseline PSA at 5 days. Studies reporting the effect of ejaculation on PSA also have contradictory results. Some authors found no effect at all,[138,139] whereas others demonstrated that ejaculation increased PSA levels in 87% of 64 men evaluated with serial determinations (at 1, 6, 24, and 48 hours).[140] A return to baseline was observed in 92% of subjects by 24 hours and in 97% by 48 hours.

Nadler et al.[141] quantified causes of elevated PSA in 148 men with PSA of >4 ng/mL (a finding suspect for cancer) and multiple negative biopsies. They were compared with 64 men who had a suspect DRE, multiple negative biopsies, and PSA of ≤4 ng/mL. Acute or chronic inflammation of the prostate was more prevalent in the high PSA group (63% vs. 27%; P = .0001). Patients with elevated PSA had significantly larger prostate volumes (median, 68 cm^3) than those without PSA elevation (median, 32.5 cm^3). Simultaneous regression analysis demonstrated that prostatic size accounted for 23%, inflammation for 7%, prostatic calculi for 3%, and nonisoechoic ultrasonographic lesions for 1% of the PSA serum variances.

TABLE 69.4 LIKELIHOOD OF DETECTING PROSTATE CANCER ON TRANSRECTAL BIOPSY FOR 2,054 MEN AGED 40 TO 80 YEARS AS A FUNCTION OF SERUM PSA LEVEL, INDEPENDENT OF DRE RESULT

	Likelihood at Given Age[a]			
PSA (ng/mL)	<50 Year	51–60 Years	61–70 Years	>71 Year
<2.5	10	14	17	23
2.6–4.0	11	15	19	24
4.1–6.0	12	16	21	26
6.1–10.0	14	18	23	29

10.1–20.0	17	23	31	37
>20.0	40	49	60	69

The positive predictive value for PSA of >4 ng/mL ranges from 31% to 54%. A greater yield is observed when elevated PSA is coupled with positive ultrasonographic and rectal examinations (Tables 69.4 and 69.5).[142] The estimated rate of cancer detection by PSA screening ranges from 1.8% to 3.3%. The percentage of clinically localized tumors detected by PSA ranges from 81% to 97%. The percentage of pathologically localized tumors ranges from 36% to 91% and is significantly higher when serial PSA screening is done.

An important issue is the clinical significance of small tumors detected by PSA testing. Epstein et al.[88,143] identified a subset of patients with potentially biologically insignificant tumors among men with clinical stage T1c disease who underwent RP. On multivariate analysis, the best model predicting insignificant tumor was PSA density of <0.1 ng/mL per gram and no adverse pathologic findings on needle biopsy, or PSA density of 0.1 to 0.15 ng/mL per gram, with a low- to intermediate-grade cancer <3 mm found in only one needle biopsy core specimen. The positive predictive value of the model was 95%, with a negative predictive value of 66%.[88] Dugan et al.[144] offered a definition of clinically insignificant cancer as a tumor that gives rise to no more than 20 cm^3 of cancerous tissue in the prostate by the time of expected death and a Gleason score of <4 in 40-year-old patients, 5 in 50- to 59-year-old patients, 6 in 60- to 69-year-old patients, and 7 in 70- to 79-year-old patients. Using these definitions, a review of 337 prostatectomy specimens showed that, for cancer volume doubling times of 2, 3, 4, and 6 years, clinically insignificant cancer was identified in 1 (0.3%), 13 (3.9%), 25 (7.4%), and 49 (14.5%) of specimens, respectively. Humphrey et al.[145] determined that in 11% to 30% of PSA-detected prostate cancers, the tumor volumes were <0.5 mL. Therefore, by these definitions, most men treated with RP or radiation therapy have clinically significant cancer.

TABLE 69.5 LIKELIHOOD OF DETECTING PROSTATE CANCER ON TRANSRECTAL BIOPSY FOR 2,054 MEN AGED 40 TO 80

YEARS AS A FUNCTION OF PATIENT AGE, SERUM PSA LEVEL, AND DRE FINDINGS

PSA (ng/mL)	Likelihood at Given Age[a]							
	<50 Year		51–60 Years		61–70 Years		71–80 Years	
	DRE−	DRE+	DRE−	DRE+	DRE−	DRE+	DRE−	DRE+
<2.5	9	37	12	39	15	42	20	44

The incidence of clinically unimportant cancers has been reported to be between 4% and 16%.[88,100,146,147] Researchers at the Fred Hutchinson Cancer Research Center developed a computer model to estimate the rates of prostate cancer overdiagnosis because of PSA testing. Using the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) registry data as a comparison for their computer-generated incidence rates, they calculated overdiagnosis rates of 15% in whites and 37% in blacks. These men were predicted to have prostate cancer that would be detected only at autopsy.[148] Conversely, an epidemiologic study randomizing men from Göteborg, Sweden, to PSA screening or a control group demonstrated that screening did not lead to overdiagnosis of prostate cancer; rather, most cancers detected at PSA-guided screening would eventually develop into clinical, frequently fatal, disease.[149]

Although PSA screening–detected cancers may be smaller, they may harbor aggressive disease. Investigators from the Netherlands studied 121 RP specimens from screened patients and found that screening-detected specimens were more likely to be pathologically organ-confined tumors and to have Gleason scores of <8.[150] However, 60% of screening-detected tumors contained areas with high-grade cancer (Gleason pattern 4 or 5), and 50% had a Gleason score of 7, suggesting that most of these tumors are clinically important. Updated results from a study of expectant management of patients with nonpalpable prostate

cancer believed to have small-volume disease showed a 6.5-year median survival free of intervention and a 33% intervention rate at a median of 2.2 years, with a median follow-up among the entire cohort of 2.7 years.[151] Increased PSA density and decreased percentage free PSA correlated with progression of disease. Ninety-two percent of patients had curable disease at the time of their diagnosis of progression. These investigators concluded that observation with close follow-up may be a reasonable alternative for older men with a high likelihood of harboring small-volume prostate cancer.

Refinements of the PSA screening test have been introduced to increase the sensitivity and specificity of the test. It was anticipated that such approaches would be able to more readily find curable cancers in younger men and to avoid unnecessary biopsies of benign hypertrophic disease in older men. Unfortunately, none of these modifications listed in the following sections has proven reliable enough alone on which to base a treatment decision for the individual patient.

Prostate-Specific Antigen Density

PSA density relies on the fact that cancers produce less PSA per cell than nonmalignant prostatic tissues. It is calculated by dividing the serum PSA concentration by the volume of the prostate gland measured by TRUS. A higher PSA density is associated with malignancy.

Prostate-Specific Antigen Velocity

Another method is to obtain serial PSA measurements and calculate the rate of rise in PSA, or PSA velocity. A rate of rise of >0.75 ng/mL per year has been associated with a higher frequency of cancer. Two large retrospective analyses suggested that a >2.0 ng/mL increase in PSA in the year prior to diagnosis is correlated with greater prostate cancer–specific mortality following radiotherapy[152] and RP[153] for localized prostate cancer, respectively.

Free Prostate-Specific Antigen

Serum tests for the molecular forms of PSA (free vs. complexed vs. total) have been developed to discriminate between elevated PSA levels from benign prostatic hyperplasia versus cancer. This is based on the concept that PSA exists in serum in a complexed form bound to either α_1-antichymotrypsin or α_2-macroglobulin, two extracellular protease inhibitors. Bound to α_1-antichymotrypsin or α_2-macroglobulin, the enzyme is inactive but still detectable

using conventional immunoassays. In a study of free PSA, complexed PSA, and total PSA (free + complexed), the complexed-to-total ratio was higher and free PSA lower in patients with prostate cancer relative to those with benign prostatic hyperplasia.[154] Catalona et al.[155] reported on 113 patients with PSA levels between 4.1 and 10 ng/mL (63 with histologically confirmed benign prostatic hyperplasia, 30 with prostate cancer and enlarged gland, and 20 with cancer and a normal-sized gland). The median percentage of free PSA was 9.2% for men with cancer and a normal-sized gland, 15.9% for those with cancer and an enlarged gland, and 18.8% for those with benign prostatic hyperplasia ($P < .001$). Men with prostate cancer and either a normal or an enlarged gland had a significantly lower percentage of free PSA than men with benign prostatic hyperplasia only. At Washington University, a ratio of free to total PSA of ≤0.2 was most likely associated with prostate cancer and with higher percentages with benign prostatic hypertrophy. A ratio of ≤0.15 was associated with a higher Gleason score and poorer prognosis.[156]

Oesterling et al.[157] analyzed free, complexed, and total PSA in 422 healthy men aged 40 to 79 years. The respective recommended age-specific reference ranges (95th percentile) for the three forms were 0.5, 1, and 1 ng/mL for men aged 40 to 49 years; 0.7, 1.5, and 3 ng/mL for men aged 50 to 59 years; 1, 2, and 4 ng/mL for men aged 60 to 69 years; and 1.2, 3, and 5.5 ng/mL for men aged 70 to 79 years. Similar observations were made by investigators at Johns Hopkins.[158]

Reverse Transcriptase–Polymerase Chain Reaction Assay

Recent developments include using molecular biologic methods, particularly reverse transcriptase–PCR (RT-PCR), to measure markers by detecting low levels of messenger RNA (mRNA) for PSA and prostate-specific membrane antigen (PSMA) expressed by circulating metastatic prostate cancer cells.[159–163] The assay is highly specific because the only cells expressing PSA in the peripheral blood are circulating prostate cancer cells. However, there is a wide range of sensitivities of detection of PSA-expressing cells in the peripheral blood reported in the literature.[164]

Katz et al.,[165] in 94 patients on whom RT-PCR assay for PSA mRNA was performed, reported an enhanced reaction in 26 (72%) of 36 patients who had extraprostatic tumor at the time of surgery. The test was negative in 51 (88%) of 58 patients with organ-confined disease. Six months after surgery, an increased PSA level was noted in 19% and 2% of the two groups, respectively. This

bioassay may have significant staging value in patients who are candidates for RP. Cama et al.[159] noted that, in contrast to the RT-PCR assay for PSA, the assay for PSMA did not correlate with pathologic stage of prostate cancer.

Oefelein et al.,[166] using RT-PCR for PSA, identified positive cells in 20 (91%) of 22 operative field samples, and 4 (25%) of 16 had evidence of intraoperative hematogenous dissemination ($P = .046$). Their results suggest that tumor cell spillage and, less frequently, hematogenous dissemination may be associated with operative manipulation of the prostate during RP and may potentially represent the mechanism of failure after this treatment.

Israeli et al.,[167] using the PCR assay, also reported circulating prostatic tumor cells in 2 (6.7%) of 30 men. However, prostate-specific membrane primer assay demonstrated tumor cells in 19 (63%) of 30 patients. All 16 negative control subjects had negative PSA and PSMA PCR results. Using PSA mRNA as a marker for prostatic epithelial cells, Seiden et al.[168] noted that 5 of 65 patients with clinically localized carcinoma of the prostate had PSA mRNA–detectable cells by transcription and PCR. On the other hand, 10 of 20 patients with hormone-refractory and progressive prostate cancer also demonstrated the same increased frequency of PSA mRNA–detectable cells.

Overall, most studies report a 0% PSA rate by RT-PCR in negative control cases, whereas the positive rate in the metastatic group ranges between 31% and 88%.[163] However, 25% of men with localized prostate cancer who underwent RP and had specimen-confined disease had a positive PCR PSA assay.[165] These men would be denied surgery if it was concluded that circulating prostate cancer cells are synonymous with incurable disease. A new approach is to use a combination of primers to improve the overall staging accuracy of RT-PCR. Preliminary work from the Cleveland Clinic suggests that combining RT-PCR for PSA and PSMA may improve the staging accuracy.[169] Until the significance of a positive PCR assay is determined with long-term follow-up, RT-PCR remains experimental and should not change treatment recommendations.

Staging Workup

Patients with localized prostatic carcinoma are frequently asymptomatic; the diagnosis is often made with a screening PSA test. In the pre-PSA era, asymptomatic patients were diagnosed on the basis of palpating a firm prostate nodule on DRE. Patients with locally advanced tumors have presented with bladder outlet obstructive symptoms such as urinary hesitancy, decreased force of the urinary stream, and postvoid dribbling as the tumor impinges on the

membranous urethra. Chronic obstruction and bladder distension can lead to decreased compliance of the detrusor muscle that is manifested by symptoms of urinary frequency, urgency, and nocturia. Very early-stage disease (T1a or T1b) may occasionally be diagnosed at TURP for symptoms of bladder outlet obstruction caused by benign prostatic hyperplasia. With local invasion into the urethra or ejaculatory ducts, patients may experience hematuria or hematospermia. As the disease penetrates the capsule of the prostate, there may be invasion into the neurovascular bundles that course along the lateral aspects of the prostate, leading to erectile dysfunction. Disseminated disease frequently manifests as bone pain from distant osseous metastases.

A complete clinical history and a general physical examination including DRE are mandatory. The DRE is best performed with a well-lubricated glove; the patient may be standing and bent over at the waist with his elbows resting comfortably on a firm surface or in the lateral decubitus position on the examining table. The examiner should note the size of the prostate gland, its overall consistency, the presence of any firm areas, and, currently, rarely, extraprostatic tumor extension. A typical neoplastic nodule of prostatic carcinoma is extremely firm, often not elevated above the surface of the gland, but surrounded by compressible prostatic tissue. The examiner should determine whether the lateral sulci are involved by tumor and also the degree of spread superiorly. In most patients, the seminal vesicles cannot be palpated as discrete structures, and the finding of a firm area extending above the prostate suggests that the seminal vesicles are involved by malignancy. Only approximately 50% of prostatic nodules found on DRE are confirmed to be malignant on biopsy.[78]

An abnormal DRE result, a consistently elevated PSA, or a combination of the two warrants a biopsy to establish a pathologic diagnosis. A TRUS-guided needle biopsy is the most common method for obtaining representative samples of the prostatic tissue. Ten to eighteen cores are taken, including cores from the base, mid, and apex bilaterally and additional cores from the midline and lateral PZ. If clinically indicated by obstructive symptoms, a separate biopsy of the TZ is taken. The pathology report frequently includes the length of each core and the length of each core that contains tumor.

Once the tissue diagnosis of prostate cancer is ascertained, the patient should undergo a staging workup including laboratory data such as a baseline PSA, complete blood count, and testosterone level. The standard tests required in the evaluation of patients with prostatic carcinoma are listed in Table 69.6. Although a chest radiograph is recommended, a study of 236 patients undergoing RP

showed abnormal findings in only 28 (11.9%), mostly related to cardiac or pulmonary problems or arterial hypertension; one primary lung cancer was found.[170] According to the American College of Radiology appropriateness criteria, a chest radiograph should be performed as part of the initial staging only with suspected metastatic disease.[171]

Imaging Studies

Some diagnostic imaging studies have become an essential aspect of pretreatment evaluation and treatment selection. New techniques have allowed for more precise assessments of tumor location, volume, and extent, as well as biologic activity. As a result, clinical staging can be used more accurately as a prognostic factor for defining treatment options.

Transrectal Ultrasonography

The normal adult prostate imaged by TRUS appears as a symmetric, triangular, relatively homogeneous structure with an echogenic capsule. TRUS is used routinely for guidance during the transrectal biopsy and during prostate brachytherapy. However, only prostate cancers located in the PZ can be reliably detected by ultrasonography. Attempts to characterize adenocarcinoma by pattern on TRUS have indicated that prostate cancers can have variable echogenicities. Rifkin et al.,[172] in 443 men undergoing TRUS of the prostate, found 130 pathologically proven cancers and 313 cases of benign prostatic disease. Cancers were hyperechoic in 69% of the cases and had poorly defined margins, whereas benign lesions were hyperechoic in only 46% of the cases.

Chodak et al.,[173] in a prospective, randomized study of TRUS in 216 men, reported a sensitivity of 86% but a specificity of only 41%; tumors <1 cm were the most difficult to detect. For staging purposes, Rifkin et al.[172] found a sensitivity of only 60% using TRUS to distinguish between T2 and T3 lesions.

TABLE 69.6 DIAGNOSTIC WORKUP FOR CARCINOMA OF THE PROSTATE

Routine
Clinical history and clinical examination
Rectal examination
Laboratory
Complete blood cell count, blood chemistry
Serum prostate-specific antigen (total, free, percentage free)
Plasma acid phosphatases (prostatic/total)
Radiographic imaging

Magnetic resonance imaging with endorectal coil
Radioisotope bone scan (prostate-specific antigen, >20)
Computed tomography of the pelvis
Chest radiograph (high risk for metastatic disease)
Transrectal ultrasonography (for biopsy guidance)
Needle biopsy of the prostate (transrectal, transperineal)
Staging lymph node dissection (high risk for lymph node metastases)

Computed Tomography

The primary role of CT in prostate cancer is for size determination of the prostate gland, radiation therapy treatment planning, and assessment of pelvic nodal metastases. Roach et al.[174] compared prostate volumes defined by MRI and CT and found a 32% increase in prostate volume when defined by noncontrast CT scan. Using image fusion, they identified four areas, including the posterior aspect, the posteroinferior apical aspect of the gland, the prostatic apex, and the neurovascular bundles, which tended to be areas of discrepancy between the two imaging modalities. Kagawa et al.,[175] using CT-MRI fusion software for planning three-dimensional conformal radiation therapy (3DCRT), demonstrated that MRI was clearly superior to CT in defining the prostate apex, neurovascular bundles, and anterior rectal wall. The discrepancy in prostate location between the two imaging studies was also greatest at the apex and base of the gland.

CT lacks the soft tissue resolution needed to detect intraprostatic disease, capsular extension, or seminal vesicle involvement. Moreover, for most patients with newly diagnosed prostate cancer, the incidence of positive lymph nodes is <5%; thus, there is little role for CT as a routine staging procedure.[176,177] CT identification of pelvic adenopathy depends on lymph node enlargement, and the correlation between nodal size and metastatic involvement is poor.[176,178,179]

Albertsen et al.[180] performed a population-based analysis to determine the positive yield of imaging studies performed on men with newly diagnosed prostate cancer. The positive yield of a CT scan was <12% for men with PSA of 4 to 20 ng/mL. More than 10% of men with PSA of >20 ng/mL and Gleason score of 6 or greater were likely to have CT scans positive for extracapsular or metastatic disease. For combinations of high Gleason scores and PSA of >50 ng/mL, the positive yield on CT scan was as high as 62%. Flanigan et al.[176] retrospectively studied 173 men who underwent preoperative CT scanning and

found that none of the patients with a PSA of <25 ng/mL had an abnormality by CT scan. Of 33 patients with PSA levels of >25 ng/mL, 9 had nodal metastases, but only 3 (9%) of these 33 patients were correctly diagnosed by CT scanning. These authors concluded that routine preoperative CT scanning could not be justified in patients with a PSA of <25 ng/mL. Although the histologic incidence of positive pelvic lymph nodes is substantial when PSA levels exceed 25 ng/mL, the sensitivity of CT for detecting positive nodes is only approximately 30% to 35% even at these levels.[177]

Bone Scan

A close correlation exists between pretreatment PSA level and incidence of abnormal bone scan results.[181,182] Given the low risk of osseous metastasis in patients with early-stage prostate cancer, the yield of a bone scan is low unless the PSA is >20 ng/mL or the patient complains of bone pain. In a retrospective analysis of 589 patients with untreated carcinoma of the prostate and PSA levels of ≤20 ng/mL, Rees et al.[177] reported that only 3 (1%) of 274 patients evaluated by bone scan and 3 (1%) of 262 patients evaluated by CT scan had evidence of metastatic disease. Only 1 of 108 patients with a PSA of ≤10 ng/mL had metastatic disease, and no patient with a Gleason score of ≤5 had an abnormal bone scan or CT scan result or positive lymph nodes.

Huncharek and Muscat,[183] in an analysis of 265 patients with localized carcinoma of the prostate, noted that no patients with PSA of <4 ng/mL had a positive bone scan. In patients with PSA of 4.1 to 10 ng/mL and PSA of 10.1 to 20 ng/mL, 2.2% and 3.6%, respectively, had positive bone scans. In patients with PSA of >20 ng/mL, 6.7% had a positive bone scan.

Albertsen et al.[180] analyzed prospective data from the Prostate Cancer Outcomes Study from 1995 and found that physicians ordered bone scans for approximately two-thirds and CT for one-third of all new patients. Less than 5% of the imaging studies yielded positive results. Only 1% of bone scans were positive for metastatic disease for men with PSA of <10 ng/mL and Gleason score of ≤6. Only men with PSA of >50 ng/mL and Gleason scores of 8 to 10 had positive yields on bone scan of >10%. The guidelines established by the American College of Radiology appropriateness criteria for pretreatment staging of clinically localized prostate cancer recommend that a radionuclide bone scan be considered only for patients with PSA of ≥20 ng/mL, T3-T4 disease, or Gleason score of ≥8 or for patients with skeletal symptoms.[171]

Falchook et al.[184] evaluated about 57,000 patients in the SEER–Medicare

database diagnosed with prostate cancer from 2004 to 2007. They reported use of bone scans from the date of diagnosis to the earlier of treatment or 6 months. In patients who underwent bone scans, they noted use of bone-specific x-ray, CT, and MRI scans and bone biopsy within 3 months after bone scan. In all, 31% and 48% of patients with apparent low- and intermediate-risk prostate cancer underwent a bone scan; of these patients, 21% underwent subsequent x-rays, 7% CT, and 3% MRI scans. Bone biopsies were uncommonly performed. Overall, <1% of low- and intermediate-risk patients were found to have metastatic disease. The annual estimated Medicare cost for bone scans and downstream procedures was $11,300,000 for low- and intermediate-risk patients. For patients with apparent high-risk disease, only 62% received a bone scan, of whom 14% were found to have metastasis.

Thus, in this study, there was overuse of bone scans in patients with low- and intermediate-risk prostate cancers, which is unlikely to yield clinically actionable information and results in a potential Medicare waste. However, there was underuse of bone scans in high-risk patients for whom metastasis is more likely.

From a clinical standpoint, a baseline bone scan may be helpful before treatment with radiation therapy, especially in elderly patients or those with a history of arthritis, to document degenerative changes that may later be interpreted as metastatic osseous disease. Bone scintigraphy in routine follow-up has no value because PSA is more sensitive in detecting recurrence, and treatment of asymptomatic bone metastases (except in cases of impending pathologic fracture) cannot be justified. Periodic PSA assessment is adequate for follow-up of these patients, and bone scan should be limited to patients with rising PSA levels when clinically warranted.[184]

Magnetic Resonance Imaging

With the maturation of MRI technology, there have been significant improvements in MR technique and performance for imaging the prostate. Some of the recent advances include the use of multiparametric MRI (MP-MRI) that improve spatial resolution, analytic image correction software to eliminate artifacts, fast spin-echo imaging to reduce image acquisition time and provide higher signal-to-noise ratio, and magnetic resonance spectroscopy imaging (MRSI) to detect metabolic activity in the prostate.[185] Moreover, increasing reader experience has greatly improved the accuracy of MRI staging for prostate cancer. Strict MRI criteria for the diagnosis of extracapsular extension have been elucidated. Nevertheless, there is still interobserver variability, depending on the

experience of the radiologist. One study demonstrated that the specificity for diagnosis of extracapsular extension was 93% for senior readers and 94% for junior readers, whereas sensitivity was only 50% for senior readers and 14% for junior readers.[186]

The appearance of the prostate and the information that can be gleaned for staging purposes depend on the MR technique used. On axial T1-weighted images, the prostate gland appears homogeneous and the zonal anatomy is not well appreciated.[187] However, there is a larger field of view, allowing for detection of locoregional adenopathy and suspected bony lesions (Fig. 69.3A). Postbiopsy hemorrhage is evident on T1-weighted images as high T1 signal intensity (Fig. 69.3B), which may be in the prostate, seminal vesicles, or both. This is an important observation because hemorrhage may mimic tumor on T2-weighted images and because hemorrhage greatly limits the accuracy in the assessment of extracapsular extension.[188]

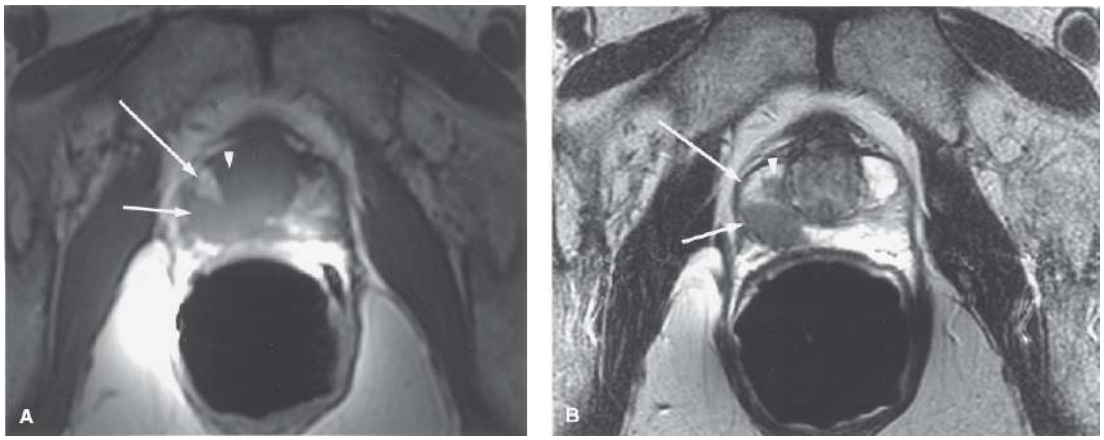

FIGURE 69.3. A: Normal T1-weighted axial magnetic resonance image. Age-related benign prostatic hyperplasia in the transition zone is evident (*long arrow*). The neurovascular bundles lie adjacent to the peripheral zone (*short arrow*). **B:** The T2-weighted axial image of the same level of the gland demonstrates areas of low signal intensity adjacent to the postbiopsy hemorrhage that are suspect for tumor (*short arrow* and *arrowhead*). This is an example of the hemorrhagic exclusion sign. (Courtesy of Steven Eberhardt, MD.)

The zonal anatomy of the prostate is clearly depicted on axial and coronal T2-weighted images. The vas deferens and seminal vesicles are also discernible on T2-weighted axial and coronal images, whereas the neurovascular bundles can be seen best on axial images (Fig. 69.4).[187] The penile bulb is better imaged on T2-weighted coronal sections and is seen much more accurately than with CT. The PZ is normally of high signal intensity, whereas tumor appears as low signal intensity. There are many other causes of low T2 signal intensity, including

hemorrhage, prostatitis, hormone treatment, and radiation therapy. An area of low signal intensity can be attributed to hemorrhage if it causes high T1 signal intensity in the corresponding region. Low T2 signal intensity due to treatment (radiation or hormonal therapy) may be suspected when the signal change is diffuse and associated with a small, featureless prostate gland. Signs of extracapsular extension are a focal, irregular capsular bulge, asymmetry or invasion of the neurovascular bundles, and obliteration of the rectoprostatic angle.[186]

FIGURE 69.4. Normal T1-weighted axial magnetic resonance image. Age-related benign prostatic hyperplasia in the transition zone is evident (*long arrow*). The neurovascular bundles lie adjacent to the peripheral zone (*short arrow*). (Courtesy of Steven Eberhardt, MD.)

Magnetic Resonance Spectroscopy Imaging

Spectroscopy is based on the principle that the electron cloud surrounding different chemical compounds shields the resonant atoms of interest to varying degrees, depending on the specific atomic structure of the compound.[189] Because MRSI uses the same clinical MRI scanner, gradients, and radiofrequency coils as MRI, it can be added to an MRI examination, and the metabolic data can be overlaid directly on the corresponding anatomic images.[185] This modality is particularly useful in the prostate because there are metabolic compounds that localize to regions of the prostate and can be used to distinguish between normal prostate cells and malignant cells. Human prostatic glandular cells produce large amounts of citrate during cellular metabolism that are secreted into the prostatic fluid, yielding concentrations 240 to 1,300 times greater than blood plasma concentrations. High levels of citrate are found in the glandular regions of the prostate such as the PZ and lower levels in the transition and central zones. Choline is another metabolite found at intermediate levels in the normal prostate and seminal vesicles. On MRSI, regions of prostate cancer can be identified by differences in these two metabolite levels. A significant reduction in prostate citrate and a significant increase in prostate choline levels relative to the normal PZ have been observed.[185] The elevated levels of choline in prostate cancer may be attributed to the increased rate of cell proliferation, an increase in cell density in regions of cancer, and a change in the composition of the cell membrane leading to higher concentrations of choline-containing phospholipids.[185] The result of MRSI is a metabolic map of the prostate corresponding to normal and abnormal metabolic activity that can be used to pinpoint the location of prostatic tumors. This is exceptionally useful for accurate localization of prostate tumors and, in particular, when distinguishing between tumor and postbiopsy hemorrhage, which obscures MRI interpretations of prostate cancer. Moreover, there is great potential for the use of this technique for follow-up after treatment and in the development of more focused therapy.

The contribution of metabolic information gleaned from MRSI to MR anatomic imaging has improved the diagnostic accuracy of MRI both in localizing and staging prostate cancer.[189] Investigators at the University of California, San Francisco,[190] assessed the accuracy of combined MRSI and MRI for tumor detection and localization in 62 patients by comparing preoperative imaging results with histopathologic step-section examination after prostatectomy. MRI tended to have a higher sensitivity and MRSI a higher specificity for detecting definite sites of cancer. The addition of MRSI significantly improved specificity over MRI alone. Compared with step-section

pathology results, the specificity for tumor location with combined MRI and MRSI reached 91%. Combined MRI/MRSI allowed localization of cancer to a sextant of the prostate with a sensitivity of up to 95% compared with MRI alone when either MRI or MRSI was positive. Moreover, a study from the University of California, San Francisco,[191] found MRI and MRSI are comparable with biopsy in accurately localizing intraprostatic cancer and are more accurate than biopsy in the prostate apex.

In addition to improving prostate cancer localization, MRSI is complementary to MRI in staging and risk-stratifying patients with prostate cancer. Combined MRI/MRSI enhances the assessment of both extracapsular extension and seminal vesical invasion.[186] Furthermore, the addition of MRSI to MRI improves the accuracy of less experienced MRI readers and reduces interobserver variability in the diagnosis of extracapsular extension.[189] Emerging data suggest that metabolic information from MRSI may also be predictive of tumor aggressiveness. Preliminary MRI/MRSI studies have shown that citrate levels are lower in poorly differentiated prostate cancers, and choline levels may be elevated in more aggressive tumors with greater membrane phospholipid synthesis.[192]

RISK STRATIFICATION SYSTEMS AND STAGING CLASSIFICATION

Based on tumor stage, pretreatment PSA, and biopsy Gleason score, PZ prostate cancer is generally grouped according to one of several risk stratification models. These systems are useful to stratify disease-free survival, compare treatment results, and provide a means to appropriately recommend treatment options.[93] The most commonly used system is the prognostic risk grouping from the National Comprehensive Cancer Network (www.nccn.org), which defines low risk as PSA of ≤10 ng/mL, T1c-T2, and Gleason score of ≤6; intermediate risk as PSA of 10 to 20 or Gleason score of 7; and high risk as PSA of >20 ng/mL, Gleason score of 8 to 10, or any T3 disease.

Traditionally, clinical and pathologic staging systems were used alone to categorize outcome, but now they are primarily used as components in risk stratification systems. Nevertheless, it is critical to be familiar with the different updated staging systems in order to appropriately manage men with newly diagnosed prostate cancer. In 2010, the American Joint Committee on Cancer (AJCC) and International Union Against Cancer (UICC) updated the 2003 TNM

classification system.[3] The TNM staging system is based on separate designations for the primary tumor, regional nodes, and distant metastases. All information that is available before first definitive treatment may be used for clinical staging, including imaging studies. The 2010 staging system maintains many of the features of the 2003 systems but reclassifies microscopic invasion of the bladder neck (previously T4) as T3a and includes new Anatomic Stage/Prognostic Groups that incorporate both Gleason score and preoperative PSA. The 2017 AJCC/UICC staging system and the new anatomic stage/prognostic groups are outlined in Tables 69.7 and 69.9. The updated AJCC 2017 staging system has issued a new classification for histologic grading, as illustrated in Table 69.8.

TABLE 69.7 AMERICAN JOINT COMMITTEE ON CANCER 2010 TNM STAGING SYSTEM FOR PROSTATE CANCER

Primary Tumor (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Clinically inapparent tumor neither palpable
T1a	Tumor incidental histologic finding in 5% or less of tissue resected
T1b	Tumor incidental histologic finding in more than 5% of tissue resected
T1c	Tumor identified by needle biopsy found in one or both sides but not palpable
T2	Tumor is palpable and confined within the prostate
T2a	Tumor involves one-half of one side or less
T2b	Tumor involves more than one-half of one side but not both sides
T2c	Tumor involves both sides
T3	Extraprostatic tumor that is not fixed or does not invade adjacent structures
T3a	Extraprostatic extension (unilateral or bilateral)
T3b	Tumor invades seminal vesicle(s)
T4	Tumor is fixed or invades adjacent structures other than seminal vesicles, such as the external sphincter, rectum, bladder, levator muscles, and/or pelvic wall
Regional Lymph Nodes (N)	
NX	Regional lymph nodes were not assessed
N0	No positive regional nodes
N1	Metastasis in regional nodes
Distant Metastasis (M)	
M0	No distant metastasis
M1	Distant metastasis
M1a	Nonregional lymph node(s)
M1b	Metastasis in bone(s)

M1c	Metastasis in other site(s) or without bone disease

PATHOLOGY

Adenocarcinoma, arising from peripheral acinar glands, is the most common tumor in the prostate. It is graded as well, moderately, or poorly differentiated according to cellular characteristics such as nuclear content, number of nuclei, pleomorphism, gland formation, and invasion of the stroma.[93]

Gleason[193,194] and Gleason and Mellinger[195] initially proposed a prognostic classification system based on the clinical stage and the degree of differentiation of primary and secondary morphologic patterns of the tumor, each graded from 1 to 5. Subsequently, only pathologic features were scored, resulting in the Gleason score that sums grades to yield nine discrete scores (range, 2 to 10). The Gleason score is one of the strongest predictors of biologic behavior in prostate cancer, including invasiveness and metastatic potential; however, it is limited by its subjectivity. There is significant interobserver and intraobserver variability reported using the Gleason grading system.[196] In addition, the treatment with hormonal therapy agents can affect the pathologist's ability to accurately identify a Gleason score.[197]

TABLE 69.8 DEFINITION OF HISTOLOGIC GRADE

Grade Group	Gleason Score	Gleason Pattern
1	≤6	≤3 + 3
2	7	3 + 4
3	7	4 + 3
4	8	4 + 4
5	9 or 10	4 + 5, 5 + 4 or 5 + 5

Note: Recently, the Gleason system has been compressed into so-called Grade Groups.

Moreover, grading errors may reflect sampling error because the needle biopsy samples a small fraction of the prostate gland, and the grade of cancer obtained on needle biopsy may not always be representative of the actual histologic subtype or degree of differentiation of the tumor. Most studies demonstrate a tendency of pathologists to undergrade biopsy specimens. Johnstone et al.[198] noted that, compared with subsequent RP specimens, the incidence of correct grading of prostatic carcinoma from needle biopsies was 71%, with 23% undergrading and 6% overgrading. In a study from Memorial Sloan Kettering Cancer Center (MSKCC), Gleason scores from 18-gauge needle biopsies were compared with radical retropubic prostatectomy specimens in 226 consecutive patients. The biopsy score was identical to the specimen score in 31% of cases, whereas 26% were discrepant by ≥2 Gleason scores. Overall, 54% of biopsies were undergraded and 15% were overgraded.[199] The University of Minnesota researchers found similar results from 466 patients.[200] The biopsy grade was the same as that of the prostatectomy specimen in 54% of the patients, with upgrading of the most common discordance in 75% of the well-differentiated tumors. When the biopsy grade was compared with the surgical pathologic stage, 49% of low-grade lesions and 82% of high-grade lesions in the biopsy had capsular penetration or locally advanced disease. A large, retrospective analysis[201] of the correlation between Gleason scores from biopsy

and prostatectomy specimens and prediction of disease-free survival was carried out among 1,031 patients. Overall accuracy was 58.3%. When categorized by Gleason scores of <7, 7, and >7, patients with tumors of Gleason score <7 on prostatectomy specimens had a significant survival advantage over those with Gleason scores of <7 by biopsy, whereas disease-free survival was superior for patients with Gleason scores of >7 by biopsy than those with Gleason scores of >7 on prostatectomy specimens. The overall disease-free survival was similar among all patients with Gleason scores of 7. These data should be kept in mind when results of RP and irradiation are compared.

Predicting tumor extent and location using biopsy results was investigated by Humphrey et al.[145] in a correlative study of multiple parameters with pathologic features in 50 RP specimens. They noted that it was very difficult to predict tumor extent in the gland quadrants based on extent of tumor in the needle biopsy. There were 53 negative quadrant biopsies with carcinoma present in that quadrant in the RP specimen. Gregori et al.[202] evaluated the accuracy of sextant biopsies in predicting tumor location among 289 patients with clinically localized prostate cancer who underwent radical perineal prostatectomy. These investigators found that 33% of patients with a unilateral positive biopsy had cancer confined to one side of the gland, whereas 66% showed bilateral disease in the prostatectomy specimen.

The primary grade in the Gleason score provides additional prognostic information, particularly in Gleason score 7 prostate cancer. D'Amico et al.[203] studied pretreatment clinical and pathologic variables to predict time to postoperative PSA failure for patients with a PSA of <10 ng/mL and T1c or T2a disease. They noted that 5-year PSA failure-free survival rates were not statistically different for patients with a biopsy Gleason score of 2 to 6 versus 3 + 4 but were significantly different for patients with a biopsy Gleason score of 2 to 6 versus 4 + 3 or 2 to 6 versus 8 to 10. Five-year biochemical control rates were 79%, 81%, 62%, and 18% for patients with biopsy Gleason scores of 2 to 6 (no grade 4 or 5), 3 + 4, 4 + 3, and 8 to 10, respectively. Makarov et al.[204] at Johns Hopkins evaluated 537 patients with Gleason score 7 tumors on biopsy to determine whether Gleason score 3 + 4 = 7 and 4 + 3 = 7 cancers behave differently regardless of the number of positive cores. Five variables (3 + 4 versus 4 + 3, number of positive cores, PSA, age, and DRE) were analyzed with respect to pathologic findings after RP. Postoperative Gleason score and pathologic stage significantly correlated with preoperative PSA and preoperative Gleason scores of 4 + 3 versus 3 + 4 on biopsy.

Stamey[205] and Stamey et al.[206,207] emphasized that, with regard to natural history of prostate cancer and prognosis, it is not just the Gleason score that is important, but also how much of the tumor is present. In a study of histologic prognostic variables for PSA relapse among 372 men with prostate cancer followed for 3 years after retropubic prostatectomy, the most important variables predicting biochemical disease-free status for PZ cancers were percentage Gleason grade 4/5, cancer volume, serum PSA, and prostate weight.[207] Percentage Gleason grade 4/5, cancer location in the PZ, cancer volume, and lymph node involvement had prognostic value in large-volume prostate cancer. These investigators also noted that TZ cancers have a better prognosis than PZ tumors because they are separated from the neurovascular bundles and the ejaculatory ducts by the compressed surgical capsule caused by expanding benign hyperplastic nodules.[72] From the Stanford experience,[208] cancer location in the PZ and percentage Gleason grade 4/5 were the most powerful predictors of biochemical failure in men whose cancer was ≥6 cm^3 and contained in the prostatic capsule. Preoperative serum PSA was not helpful in distinguishing biochemical failure rates in large-volume cancers regardless of whether they were organ confined.

D'Amico et al.[209,210] showed that the percentage of positive prostate biopsies added clinically significant information regarding time to PSA failure among 960 men with PSA-detected or clinically palpable prostate cancer treated with RP. Investigators at the University of Michigan,[211] in an analysis of preoperative factors, including clinical stage, PSA, biopsy Gleason score, greatest percentage of a biopsy core involved by cancer, number of biopsy cores containing cancer, and perineural invasion, found that only PSA, Gleason score, and greatest percentage of a biopsy core involved by cancer were highly predictive of PSA relapse-free survival on multivariate analysis. This additional prognostic information may identify patients who are candidates for adjuvant therapy after RP. In addition, with the use of radiation therapy, histologic features from prostatectomy specimens are not available to incorporate into prognostic models, and pretreatment risk stratification is important owing to the increasing use of nonsurgical treatment options.

Prostate core biopsy histologic features have been investigated for predicting extraprostatic extension and lymph node involvement. Researchers at the Mayo Clinic[212] compared biopsy specimen Gleason scores, percentage positive cores, and percentage surface area involved in all cores with pathologic stage determined from RP specimens. Multivariate analysis using these pathologic

variables, in addition to patient age, clinical disease stage, and PSA, showed that the percentage of positive cores, initial serum PSA, and Gleason score of cancer in the needle biopsy were the only parameters that jointly predicted pathologic stage (T2 vs. T3 disease). Narayan et al.[105] used the combination of preoperative PSA plus biopsy Gleason score in 932 patients who had undergone pelvic lymphadenectomy to predict risk of positive pelvic lymph nodes. Patients with biopsy Gleason scores of ≤6 and preoperative PSA concentrations of ≤10 ng/mL had a <1% false-negative rate for pelvic lymph node metastases, suggesting that a staging pelvic lymphadenectomy is unnecessary.

Finally, the tumor histologic characteristics change with time and progression of disease. Cheng et al.[213] reported a trend toward histologic dedifferentiation when prostate carcinoma metastasized to regional lymph nodes. Among 242 patients treated with RP and pelvic lymphadenectomy at the Mayo Clinic, Gleason score in the lymph node metastases was higher than in the primary tumor in 45% of patients, lower in 12% of patients, and matched exactly in 43% of patients. The 5-year PFS rate was significantly different between patients with histologic dedifferentiation and those without dedifferentiation.

Other Histologic Subtypes

Periurethral duct carcinoma is a separate clinicopathologic entity, usually consisting of a transitional cell type of carcinoma, although a mixture of glandular and transitional cells is also observed.[214–216] Large anaplastic tumor cells cluster in the periurethral ducts and spread into the stroma. Frequent mitoses are seen.[217] This tumor does not invade the perineural spaces as commonly as does adenocarcinoma of the prostate.

Reese et al.[218] reviewed 49 patients with *transitional cell carcinoma* of the prostate; 29 patients had stromal invasion and 20 had transitional cell carcinoma in the prostatic ducts only. Lymph node metastases were found in 14 (54%) of 26 patients with stromal invasion, compared with 4 (24%) of 17 with duct/acinar involvement. The 5-year survival rates were 80% for stromal node–negative, 45% for ductal node–negative, 55% for ductal node–positive, and 30% for stromal node–positive patients.

Ductal adenocarcinoma arises rarely from the major ducts. These tumors are usually papillary and on microscopic sections are composed of tall columnar cells with eosinophilic cytoplasm that may resemble endometrial carcinoma.[51,219–221] Originally, this lesion was believed to originate in the prostatic utricle, a mullerian remnant[222]; however, most ductal adenocarcinomas

are not derived from mullerian remnants and behave as acinar adenocarcinomas.[76]

Most reports point to aggressive behavior, with invasion of the prostatic stroma and the bladder neck and metastases to the lymph nodes, bone, and lung. In most series, the majority of patients die of the tumors within 4 years.[223,224] This tumor is moderately hormonally responsive and is sensitive to radiation therapy.[223] The treatment of choice is RP.[223,225] Kopelson et al.[215] reported a good prognosis in early stages; however, in stage C the 5-year survival rate was only 34.5%. They noted a 76% local tumor-control rate and a 58% 5-year survival rate in patients treated with irradiation, in contrast to 14% local tumor control and 24% 5-year survival rates in patients not receiving this treatment. Brinker et al.[226] also observed a shortened average time to progression relative to a previous study group of men with acinar carcinoma among 58 patients treated with RP at Johns Hopkins.

Neuroendocrine tumors are a rare variant of a malignant tumor composed of small or carcinoid-like cells. Neuroendocrine cell substances found in these tumors include serotonin, neuron-specific enolase, chromogranin, calcitonin, and others. PAP and PSA are valuable to determine the prostatic origin of the tumor. Of 22 patients with stage T2 lesions, 4 died of the disease, and 3 of them had positive neuroendocrine cell findings.[227] Of 20 patients with stage T3, 5 died of the disease, and all 5 had positive neuroendocrine cell features

Mucinous carcinoma, not arising in major ducts or in the urethra, with positive histochemical stains for PAP, has been reported.[228]

Sarcomatoid carcinoma is a rare tumor and is difficult to distinguish from a true sarcoma. There is coexistence of prostatic adenocarcinoma with sarcomatoid components that have spindle cells with large pleomorphic hyperchromatic nuclei. The pattern is that of a high-grade sarcoma in most patients, similar to the malignant fibrous histiocytoma of soft tissues. Mitotic figures range from 6 to 36 per 10 high-power fields. In 12 patients reported by Shannon et al.,[229] tumor presentation was stage A or B in 4, C or D in 5, and unknown in 3 patients. Metastases data were available for 10 patients; the most common metastatic sites were the bone (7 patients), lymph nodes (2 patients), lung (2 patients), liver (1 patient), and skin (1 patient). Immunostaining or electron microscopy demonstrated epithelial differentiation in the sarcomatoid areas in 6 of 11 patients on whom these studies were performed. All 9 patients for whom follow-up data were available died of disease within 3 to 48 months after diagnosis. In 3 patients, sarcomatoid elements were part of the tumor at

initial diagnosis; in the other 9, the sarcomatoid component was confirmed in subsequent evaluations after initial diagnosis (2 to 89 months). Four patients were treated with radiation therapy without beneficial result. These tumors are considered a very aggressive variant of prostatic adenocarcinoma.

Endometrioid tumors occasionally arise from the verumontanum. Endometrial glands and cells with numerous mitotic figures may be seen. These tumors may have an exophytic configuration in the prostatic urethra or infiltrate the adjacent tissues.

Adenoid cystic carcinoma is a rare tumor in the prostate (representing <0.1% of all tumors of this gland). The histologic appearance is similar to that of its salivary gland counterpart.

Other epithelial tumors, such as carcinoid or small cell carcinoma, have been reported in the prostate.[230,231] The experience with these lesions is very limited and, in most patients behavior, is highly aggressive and fatal.[232] A review of the literature showed that in 130 patients reported with small cell carcinoma of the prostate, the 2-year survival rate was 3.6%, the 3-year rate was 1.8%, and the 5-year rate was <1%.[233] A subsequent SEER database analysis of 241 cases of small cell carcinoma of the prostate identified 1- and 5-year overall survival of 47.9% and 14.3%, respectively.[234] Squamous cell carcinoma originating primarily in the prostate is rare.[235] Metastatic malignant tumors from other locations to the prostate are occasionally reported.[235,236]

Sarcomas (leiomyosarcoma, rhabdomyosarcoma, or fibrosarcoma) constitute approximately 0.1% of all primary neoplasms of the prostate.[217] Leiomyosarcoma is more common in middle-aged or older men, whereas rhabdomyosarcoma is found more frequently in younger patients. Several cases of malignant schwannoma have been described.[237] These tumors tend to invade lymphatics and blood vessels, causing widespread regional lymphatic and distant metastases.

Carcinosarcoma of the prostate constitutes 0.1% of prostatic neoplasms. A mixture of adenocarcinoma invading the stroma and sarcomatous elements is seen histologically; smooth or striated muscle, fibroblasts, or other mesenchymal malignant cells may be identified.

Primary lymphoma of the prostate is rare, with <100 cases having been reported. It accounted for only 0.1% of newly diagnosed lymphomas and only 0.09% of all prostatic neoplasias at MD Anderson Cancer Center.[238]

GENERAL MANAGEMENT IN THE UNITED STATES

The optimal management of clinically localized prostate cancer remains controversial and is often a source of confusion, frustration, and anxiety for many patients who are compelled to make a decision regarding a treatment intervention for their disease. The practitioner must be aware that the natural history of this tumor is variable and influenced by multiple prognostic factors. All of the various forms of therapy for prostate cancer can affect quality of life and sexual function in varying degrees. In the process of counseling and discussing therapeutic options, it is important for the radiation oncologist to present all available data regarding the natural history of this disease, prognostic significance of the diagnosis, potential therapeutic benefit of the various modalities, and immediate as well as late treatment-related sequelae. Life expectancy and quality of life considerations should be carefully discussed with the patient and spouse or significant other.

Based on the available data, when comparing patients with similar prognostic features, there are no significant differences in the biochemical and disease-free survival outcomes for patients with early-stage prostate cancer treated with active surveillance (AS), RP, high-dose external beam or stereotactic radiation therapy (EBRT or SBRT), or interstitial brachytherapy.[239–243] In the absence of randomized trials demonstrating superiority of one treatment over another, there are wide geographic variations in the preferred therapeutic intervention for early-stage prostate cancer practiced by urologists and radiation oncologists.

Observations from the Cancer of the Prostate Strategic Urologic Research Endeavor (CaPSURE) database—a registry of 11,000 men accrued from 36 community-based urologic practices across the United States—shed further light on practice patterns. Cooperberg et al.[244] reported that, in this cohort of patients, 50% elected to be treated with RP, 12% were treated with EBRT, 13% received brachytherapy, 4% received cryotherapy, and 14% were treated with primary ADT. In these patients, it was noted that among those with higher prognostic risk features, there was an increased use of primary ADT. Younger patients and especially those with low-risk disease were more often selected for prostatectomy. In addition to age playing a role in treatment selection, the presence of medical comorbidities, the socioeconomic status of the patient, and the personal practice trends of individual clinic treatment sites (irrespective of the patient’s stage of disease) played important roles in treatment selection as well. There was an increasing trend observed for patients presenting at diagnosis with more favorable-risk disease in 2001 to 2002 (47%) compared to 1989 to

1990 (31%). A lower percentage of high-risk patients (defined as PSA of >20 ng/mL, Gleason 8 to 10 disease, or T3-T4 disease) was noted on initial presentation (15% compared with 41%) for 2000 to 2001 and 1989 to 1990, respectively.

A recent report[245] based on the SEER–Medicare linked database included 85,088 men with the diagnosis of prostate cancer at age 65 years and older. In this cohort of patients, 42% were treated with radiation therapy (RT), 21% were treated with RP, 17% were treated with primary ADT, and 20% were followed expectantly. The authors also noted a strong association between the type of specialist seen (urologist vs. radiation oncologist vs. medical oncologist) and the primary therapy the patient had received. For patients who were 65 to 69 years old and evaluated by a urologist, 70% underwent a prostatectomy, whereas among patients who were 70 to 74 years old, surgery was selected in 45% of patients. In addition, among men who were seen by both a urologist and a radiation oncologist, RT radiation therapy was the most commonly used treatment modality (83% of this cohort). These data are consistent with prior studies showing that specialists more often made treatment recommendations favoring their particular specialty.

Within the practice of radiation oncology, there have been new trends in management and treatment delivery. Higher radiation doses and the use of adjunctive ADT with RT for various prognostic risk groups are more common than in the past. There has been a significant increase in the use of intensity-modulated radiation therapy (IMRT) for the treatment of localized prostate cancer and increasing use of image-guided radiation therapy (IGRT) with fiducial makers inserted into the prostate prior to therapy for daily target localization (cone-beam imaging), as well as the use of TomoTherapy prior to the administration of the daily fraction. In some institutions, there is increasing use of stereotactic external beam radiation therapy with regimens employing dose per fraction of 6.5 to 8 Gy for five treatments.

Zelefsky et al.[246] reported the results of the Quality of Research Radiation Oncology (QRRO) group, which surveyed 414 patients with clinically localized prostate cancer treated with EBRT or brachytherapy that were selected from 45 institutions in the United States. Indicators used as specific measurable clinical performance measures to represent surrogates for quality of radiotherapy delivery included established measures, such as the use of prescription doses of ≥75 Gy for intermediate- and high-risk EBRT patients and androgen deprivation therapy (ADT) in conjunction with EBRT for patients with high-risk disease.

Among favorable-risk patients, 72% were treated to ≥75 Gy. For high-risk EBRT patients, 60 (87%) were treated with ADT in conjunction with EBRT and 13% (*n* = 9) with radiotherapy alone. Among low- and intermediate-risk patients, 10% and 42%, respectively, were treated with ADT plus EBRT. For patients treated with EBRT, weekly electronic portal imaging was obtained as verification films without daily target localization in 35%, and the remaining 64% were treated with daily localization of the target, such as fiducial markers, cone-beam imaging, TomoTherapy, or intrafraction localization with a ferromagnetic marker device.

Active Surveillance

For selected patients with low-risk prostate cancer, expectant management (active surveillance) is an increasingly acceptable approach to avoid overtreatment and the potential morbidity associated with any therapy. Candidates for expectant management include those patients with low PSA values with relatively slow doubling times who have low-volume disease (5% core involvement) and Gleason score 6 disease based on biopsy findings. The long-term results of a phase III, randomized trial from the Scandinavian Prostate Cancer Group demonstrated a reduction in the cause-specific mortality with local therapy compared to an expectant management approach.[247] In this study, 695 men were included with early-stage T1 or T2 prostate cancer. The median follow-up was 12.8 years, the primary endpoint was death attributed to prostate cancer, and the secondary endpoint was overall survival. In the watchful-waiting group, 58% died, compared with 48% in the RP group (P = .007). The cumulative incidence of death directly related to prostate cancer was 14.6% in the surgery group versus 20.7% for the expectant management cohort. The survival benefit was noted among low-risk patients, and this benefit was limited to patients who were younger than 65 years of age.

As noted by Choudhury in an editorial,[248] a United Kingdom landmark Prostate Testing for Cancer and Treatment (ProtecT) study was published in September 2016 in the NEJM.[249] The trial used a cohort of over 82,000 male patients who had undergone PSA screening, of whom 2,664 received a diagnosis of prostate cancer and of whom 1,643 agreed to be randomized to either active surveillance, RP, or radical external beam radiation therapy (EBRT). From this cohort, 545 men were randomized to active surveillance, 545 to EBRT, and 553 to surgery. Analysis was on an intention-to-treat basis. The median age was 62 years (range, 50 to 69 years), the median PSA level was 4.6 mg/L (range, 3 to

19.9 mg/L), 77% of patients had a Gleason score of 6, and 76% of patients had T1c disease.

The active surveillance protocol was based on PSA levels alone with no routine imaging or repeat biopsies. A >50% increase in PSA level triggered review. EBRT was delivered as 74 Gy in 37 fractions using 3DCRT with ADT for 3 to 6 months. Failure was defined according to nadir plus 2 mg/L.

The primary outcome was prostate cancer mortality at 10 years. Secondary outcomes were all-cause mortality, rate of metastatic disease, clinical progression, primary treatment failure, and treatment complications.

The trial showed no difference in prostate cancer mortality (P = .48) or all-cause mortality (P = .87) among all three groups. However, disease progression as defined by metastatic disease, clinical T3 or T4 disease, or initiation of lifelong ADT was higher in the active surveillance group (P < .001).

As pointed out by Choudhury[248] although many investigators might say that this trial confirmed what is known, it did raise a number of interesting points. First, given that these patients form a younger age group than those men often seen in the clinic, not only are the death rates from prostate cancer very low at 10 years, with only 17 deaths overall (~1%), but all-cause mortality is also very low across all three groups (~10%).

Second, over half of the men assigned to active surveillance have undergone active treatment by 10 years, but 44% of men had undergone no treatment at all (Fig. 69.5) and had thus been spared any overtreatment. This is despite the fact that active surveillance protocols have evolved since the conception of this trial with the regular use of MP-MRI and repeat, often targeted biopsies.

A companion article describing patient-reported outcomes is of particular interest as a comparison of toxicity across the three groups.[250] Sexual and urinary outcomes are significantly worse with surgery, whereas the rate of bowel side effects is higher with EBRT. However, the long-term side effects after surgery are far from inconsequential, with approximately 1 in 5 men using urinary incontinence pads and a similar number unable to maintain an erection at 6 years. This does beg the question: If men are to be treated for their low-risk prostate cancer, is EBRT the treatment of choice? Surgeons will say that there has been an evolution in prostatectomy with robotic laparoscopic surgery and nerve-sparing techniques; however, there is little evidence that in the multicenter setting, late effects are significantly different in the modern era.[251] Conversely, there is significant evidence that with the advent of image-guided IMRT and brachytherapy, radiation therapy toxicity has decreased further since the

conception of ProtecT.

The results of the Conventional or Hypofractionated High-Dose IMRT for Prostate cancer (CHHiP) trial have confirmed that hypofractionated radiation therapy is as effective as conventional radiation therapy, leading to a change of practice in the United Kingdom,[252] with EBRT being delivered in 4 weeks with minimal side effects and favorable long-term quality of life compared with prostatectomy; advocates of surgery for low-risk prostate cancer should be wary.

Taken alongside the results of other large treatment comparison studies, the Scandinavian Prostate Cancer Group Trial Number 4 (SPCG-4) and Prostate Cancer Intervention Versus Observation (PIVOT)[253] trials, the differences between the results and the advancement of prostate cancer care make drawing firm conclusions a challenge. However, all three studies suggest that active surveillance and active treatment both have roles in the management of low-risk prostate cancer. This trial, funded by the National Institute for Health Research, part of the National Health Service, has provided important data to inform decisions about the role of a prostate cancer screening program within the United Kingdom. Even now, there is still controversy as to whether routine screening using PSA levels should be introduced to improve outcomes from prostate cancer. Parallels are drawn with the NHS breast cancer and cervical cancer screening programs. Results from the Cluster Randomised Trial of PSA Testing for Prostate Cancer (CAP) study (ISRCTN9218725), which directly addresses screening, and the Prostate MRI Imaging Study (PROMIS) (ISRCTN16082556), which is due to report on diagnostic strategies, will be put together to recommend a suitable national strategy to manage the burden of prostate cancer in the United Kingdom. Current national guidance published by the UK National Institute for Health and Care Excellence in 2014 recommends active surveillance or radical treatment for men with localized low- or intermediate-risk prostate cancer, involving a MP-MRI scan with PSA tests every 3 to 4 months for the first year and a repeat biopsy, followed by PSA tests every 3 to 6 months for the next 2 years and then every 6 months, with further imaging and biopsies if indicated. Definitive treatment is recommended for men with localized prostate cancer at high risk of tumor progression. RP, EBRT with hormone therapy in selected patients, and brachytherapy are all acceptable options. High-intensity ultrasound or cryotherapy was not recommended unless the patient is part of a clinical trial

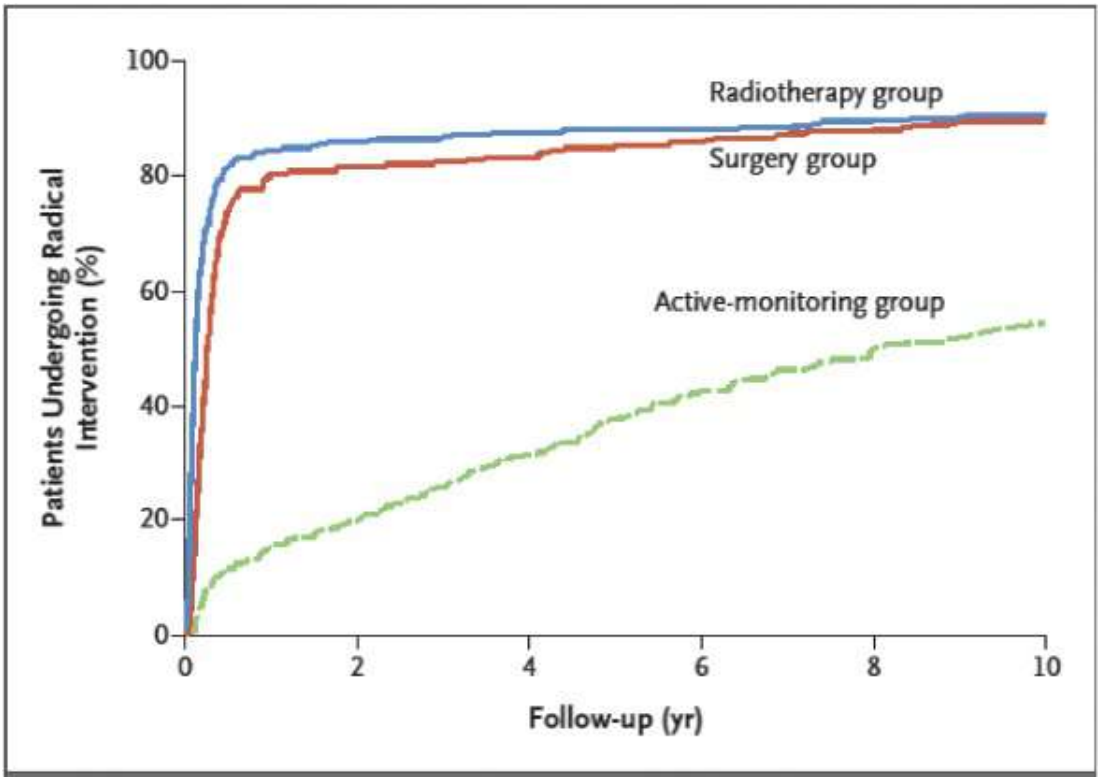

FIGURE 69.5. Cumulative probability of men undergoing definitive treatment intervention during the follow-up period, according to treatment group. (From Hamdy FC, Donovan JL, Lane JA, et al. 10-Year Outcomes after Monitoring, Surgery, or Radiotherapy for Localized Prostate Cancer. *N Engl J Med* 2016;375[15]:1415–1424. Copyright © 2016 Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society.)

Keeping men well informed of their options and considering individual preferences are key tenets of these guidelines. It is clear that patient information and careful selection are key. There are a number of studies seeking to address the role of genomic markers of both radiation therapy responses to tumor and normal tissues. Recent suggestions that molecular subgroups outside of the traditional prognostic factors can stratify patients more accurately need to be explored further. No definitive data on genetic or molecular markers in primary prostate cancer are available.[249]

The Prostate Cancer Intervention versus Observation Trial (PIVOT)[253] enrolled 761 US patients diagnosed by PSA screening. At 12-year follow-up, prostatectomy did not significantly reduce all-cause or prostate cancer–specific mortality compared with observation for localized prostate cancer in selected patients (T1-T2NxM0 with PSA <50 ng/mL, life expectancy of at least 10 years, negative bone scan for metastatic disease, and age no >75 years). Unlike the Scandinavian Prostate Cancer Group Study, the PIVOT study stratified overall

survival and prostate cancer–specific survival by patient race; nearly one-third of study patients (233 of 761) were African American. The generalizability of PIVOT trial[253] conclusions to the contemporary US population has been questioned by a recent National Cancer Database analysis of PIVOT-eligible patients, which found that US men were younger, healthier, and more likely to have RP for higher-risk disease than men in the PIVOT trial.

Unfortunately, subsequent SEER-based work has indicated that the encouragement of deferring definitive intervention (RP or definitive radiation therapy) in favor of active surveillance may be deleterious for African American patients with low-risk prostate cancer. One study involving more than 51,000 men with low-risk prostate cancer (T1-T2a, Gleason score =6, and PSA = 10 ng/mL) found African American race to be an independently predictive risk factor for prostate cancer–specific mortality (43,792 Caucasian vs. 7,523 African American patients). Another analysis found that definitive intervention for screening detected, low-risk prostate cancer (T1c, Gleason score = 6, and PSA = 10 ng/mL) was more likely to occur in men who were Caucasian, married, and/or with high socioeconomic status.

As noted by McClelland et al.,[254] the absence of race-based results from two of these RCTs and questions about generalizability of PIVOT results to the general population (even more so to African American men), combined with findings from SEER, which examined more than 7,500 African Americans with low-risk prostate cancer, indicate that the results of active surveillance versus definitive intervention for clinically localized prostate cancer may not be as robust for African Americans as the RCTs indicate.

This situation sheds light on the dangers of interpreting RCT results independent of patient race or sociodemographic factors such as insurance status, when these factors have clearly influenced access to optimal care for cancers of the prostate and other organ systems. Recent work utilizing genomic sequencing samples from within The Cancer Genome Atlas has found Caucasians overrepresented in comparison with the US population, with samples from racial minorities being comparatively insufficient to detect moderately common mutational frequencies. The relatively low enrollment of racial minorities in cancer sequencing studies hinders the ability to detect race-specific targetable mutations, which could prove particularly pertinent for African Americans with prostate cancer.

The authors concluded that the findings from a low-risk prostate cancer population more than 30 times larger than the ProtecT study and 75 times larger

than the Scandinavian Prostate Cancer Group and PIVOT studies should at minimum raise questions toward endorsing a blanket recommendation of delaying intervention for the sake of active surveillance for African Americans or other underrepresented ethnic groups (Hispanics, Native Americans) with low-risk prostate cancer.

Musunuru et al.[255] reported on 522 patients with low-risk prostate cancer (T1-T2a, Gleason score = 6, and PSA = 10 ng/mL) between 2006 and 2008 who were recruited to AS, low-dose rate brachytherapy (LDR BT), SABR, or standard EBRT. Out of the 522 patients, 178 opted for AS program, 76 for standard EBRT (76 Gy/38 fractions), and 83 for SABR (35 Gy/5 fractions) as part of a phase 2 trial, and 185 patients had LDR BT (I-125 implant-median dose of 145 Gy). Median follow-up was 51 months for the entire cohort; 10.1%, 16.85%, 6.02%, and 21.05% of the patients in AS, LDR, SABR, and EBRT groups had clinical T2 disease; median pretreatment PSAs for the four groups were 4.65, 5.66, 5.90, and 6.57 ng/mL ($P < .0001$). In the AS cohort, 38 patients (21.3%) underwent active treatment. Median time to treatment was 18.25 months (8 to 72 months). Among the 522 patients, 17 had biochemical failure. The 6-year bDFS was 96.1%. There was no difference in bDFS when stratified by clinical stage or pretreatment PSA. The results for 6-year bDFS were 97.7%, 93.2%, 97.4%, and 96.8% for the AS, LDR, SABR, and EBRT groups ($P = .28$). Hematochezia was observed in 2.24%, 3.13%, 7.14%, and 9.88% of the AS, LDR, SABR, and EBRT groups, respectively. Higher incidence of hematuria was noticed in the LDR BT cohort (11.98%), when compared to the other groups. Thus, AS, LDR, EBRT, and SABR were effective management options for low-risk prostate cancer patients.

The National Comprehensive Cancer Network (NCCN) recommends active surveillance (AS) for men with low-risk prostate cancer and life expectancy 10 years. Lester-Coll et al.[256] investigated trends and predictors of AS in a large national cohort of men with low-risk prostate cancer (nonmetastatic cT1eT2a, Gleason 6, and PSA < 10), in the National Cancer Database (NCDB) from 2010 to 2012. Management strategy and facility type (academic vs. nonacademic) were compared using univariable logistic regression. Additional covariates tested against management strategy included T-stage (T1c vs. T2a), age (<age 65 vs. 65 or older) Charlson/Deyo comorbidity score, location, insurance, rurality, race, education, and income.

Eighty-one thousand six hundred ninety men were identified, among whom 34,612 (42%) were evaluated at an academic center and 47,078 (58%) at a

nonacademic center. Median age was 63.

Initial management was AS in 8,228 (10%), definitive treatment (DT) in 70,064 men (86%), and no treatment (NT) in 3,398 (4%). Patients evaluated at academic centers were significantly more likely than those at nonacademic centers to receive AS than DT or NT (15% vs. 7% AS, 81% vs. 89% DT, 4% vs. 4% NT, $P < .001$). After adjusting for age, T stage, insurance, and location, evaluation at an academic versus nonacademic facility was independently associated with increased odds of AS utilization (adjusted OR 1.91; 95% CI = 1.83 to 1.99, $P < .001$).

Treatment Techniques

Radical Prostatectomy

RP, initially described by Young[257] in 1905 and popularized by Jewett,[78] is a therapeutic option in selected patients, when the tumor is confined to the prostate. In the past, according to most urologists, it had a limited role in the management of gross extracapsular disease or seminal vesicle involvement or in the presence of lymph node metastases; however, more recently, there has been an increased use of surgery for locally advanced disease. Two approaches for the classic RP are used: retropubic and perineal. The procedure consists in complete removal of the prostate and its surrounding capsule together with the seminal vesicles, the ampulla, and the vas deferens. The prostate is removed completely by excision of the urethra at the prostatomembranous junction, leaving no residual prostatic tissue at the apex. The retropubic approach is preferred by many urologic surgeons as this procedure also facilitates access for performing a bilateral pelvic lymph node dissection.

In the last 5 to 10 years, there has been an increasing interest and practice of laparoscopic and robotic RP approaches in both the United States and Europe. Advantages cited for the use of the laparoscopic procedure versus the open approach include improved visualization of the anatomy optical magnification, less blood loss, less postoperative pain, and more rapid resumption of normal activities. Preliminary functional and oncologic outcomes with this approach compare favorably to those achieved with open RP approaches. The da Vinci robotic surgical system (Intuitive Surgical, Sunnyvale, CA) uses three multijoint robotic arms, with one arm controlling the binocular endoscope and the other arms controlling small-wristed instruments. This system is controlled by the surgeon, who can be in a remote location from the patient, seated at an operative console. The stereoscopic view of the operative field provides the surgeon three-

dimensional visualization with a 10-fold magnification. In a comparison of open versus laparoscopic and robot-assisted RP (RARP) approaches, there were no significant differences in perioperative complication rates and tumor-control outcomes among the various surgical approaches. Among 239 patients evaluated with a median follow-up of 50 months, the 5-year biochemical control outcomes were 88% for open prostatectomy and 88% and 90% for laparoscopic and robotic-assisted prostatectomy, respectively. The incidence of positive margins also was similar among the different approaches. Long-term results of 184 patients treated with robot-assisted laparoscopic prostatectomy were reported by Suardi et al.[258] With a median follow-up of 67 months, the 7-year biochemical control rates for pathologic T2 and T3a and pathologic T3b disease were 85%, 84%, and 43% disease, respectively.

Radiation Therapy Techniques

Conformal and Intensity-Modulated Radiation Therapy Techniques

In the late 1980s, three-dimensional (also known as conformal) treatment techniques became increasingly available. CT-based images referenced to a reproducible patient position are used to localize the prostate and normal organs and to generate high-resolution 3D reconstructions of the patient anatomy. Treatment field directions are selected using beam's–eye view techniques, and the fields are shaped to conform to the patient's CT-defined target volume, thereby minimizing the volume of normal tissue irradiated. Conformal radiation therapy simulation, treatment planning, and delivery incorporate various additional maneuvers to reduce treatment uncertainties and enhance set-up reproducibility required during a protracted course of therapy.

IMRT is a refinement of 3D conformal techniques that uses treatment fields with highly irregular radiation intensity patterns to deliver exquisitely conformal radiation dose distributions.[259]

IMRT delivery is significantly more complex than 3D conformal delivery, requiring a computer-controlled beam-shaping multileaf collimator (MLC).

Simulation, Treatment Planning, Target, and Normal-Tissue Contouring

The techniques for simulation and treatment planning have been described in details in earlier chapters. Anatomical details and target volumes are defined in CT scan sections of 1 to 3 mm thickness. Although in the past prostate cancer patients were treated in the prone position at Memorial Sloan Kettering Cancer Center based on comparative studies[260] that demonstrated improved geometry of

the normal anatomy juxtaposed to the prostate target, currently patients are routinely treated in the supine position. These changes were made based on the observation of less prostate motion observed in the supine compared to the prone position.[261] All patients undergo fiducial marker placement via transrectal ultrasound guidance 1 week prior to simulation. For immobilization, a thermoplastic mold is fabricated for simulation, CT scanning, and treatment to ensure that the patient is in the same treatment position during all procedures. The thermoplastic sheet is heated in warm water and molded to the patient's shape from the knees to midabdomen. Small sections of the mold are cut away to provide ports for marking and tattooing. The patient is scanned through an approximately 20- to 30-cm region around the prostate with a slice spacing and thickness of 3 mm. Before start of the CT planning study, several transverse images through the prostate and bladder are obtained to ensure that the rectal lumen is clearly visible, the bladder and rectum are not excessively filled, and the patient is properly positioned within the scan circle. With the use of the CT dataset, a "virtual simulation" is performed, using digitally reconstructed radiographs to localize the treatment area rather than conventional simulation films. The treatment isocenter is placed according to anatomic landmarks near the center of the prostate gland: midline, at the caudad aspect, and approximately 5 cm posterior to the symphysis pubis. The triangulation points for the isocenter are then tattooed, along with an additional alignment tattoo, along the sagittal line, approximately 10 cm superior to the isocenter. To ensure reproducible leg position, tattoos are placed on the back of the legs at the midshaft level, and the distance between the tattoos is recorded for future reference.

The clinical target volume (CTV) is defined as the prostate and seminal vesicles. The planning target volume (PTV) is defined as the CTV with a margin to account for physical uncertainties including set-up reproducibility and interfractional and intrafractional organ motion.

A 0.5- to 1-cm margin is added to the CTV to form the PTV in all directions except posteriorly at the interface with the rectum, where the margin is reduced to 0.5 cm. Clinically, these margins were found to provide adequate target coverage based on a serial CT scan study evaluating organ motion during a course of 3DCRT.[260] When using image-guided approaches with daily target localization, margins are reduced to 5 to 6 mm circumferentially around the CTV. Normal tissues identified on each CT slice include the inner and outer walls of the rectum and bladder, the femoral heads, and the outer skin surface. Portions of the small bowel or sigmoid colon within 1 cm of the PTV are also

contoured and taken into consideration, if necessary, during planning. In addition, the central 1-cm diameter portion of the prostate encompassing the prostatic urethra is defined for dosimetric consideration and evaluation during high-dose IMRT planning.

Accurate anatomic delineation of the prostate and, in particular, the prostatic apex has been a topic of some controversy. Some have advocated urethrography at the time of simulation as a method to accurately localize the apex.[261] Mah et al.[262] performed sagittal MR scans immediately before and after urethrogram in 13 patients. No significant systematic motion of the prostate itself or the apex was observed, leading the authors to conclude that urethrography during simulation does not introduce localization error.

The contribution of MRI to improved accuracy and reproducibility of target localization in prostate cancer has also been well studied.[263] Roach et al.[174] evaluated 10 patients with both MR and CT images of the prostate and noted that the prostate volume was 32% larger when defined by noncontrast CT than when determined by MRI. Areas of disagreement tended to occur in the posterior and posteroinferior–apical portions of the prostate, the apex (because of disagreement between urethrography and MRI), and the regions corresponding to the neurovascular bundle. Rasch et al.[264] also observed differences in CT- and MR-defined volumes. On average, the prostate and seminal vesicle volume defined on CT was 40% larger than that defined on MR. The CT-defined prostate was 8 mm larger at the base of the seminal vesicles and 6 mm larger at the prostatic apex. This difference was found to be significantly larger than interobserver variation.

Contouring Techniques

There have been several reports documenting the variability of prostate-contouring techniques among practitioners.[1] McLaughlin et al.[265] provided an excellent demonstration of common contouring errors such as overestimation of the prostatic apex and underestimation of the prostatic base. The apex and the base in particular represent regions of the target volume that can be challenging to identify on CT images and better defined with MRI imaging. Two methods recommended include the inspection of lateral view projections of the contours to detect regions of the irregularities of the target geometry and improved recognition of the GUD elements. These elements are shown in the MRI representation of the GUD in Figure 69.6 and in the CT representation in Figure 69.7.

The beam weights are adjusted to obtain a uniform dose within the PTV and to place the hot spots away from the rectum. The plan was normalized so that the prescription isodose (95% to 100%) covers the PTV with a hot spot of 6% to 9% within the PTV. Although a small volume of the rectal wall close to the PTV is expected to receive the prescription dose or slightly higher, the rectal wall volume receiving 75.6 Gy or more should not exceed 20%. Other normal-tissue dose limits for these 3DCRT plans included limiting the maximum dose to the femurs to ≤48 Gy (90%), the maximum dose to large bowel to ≤60 Gy, and the maximum dose to small bowel to ≤50 Gy.

Most institutions performing IMRT planning set up templates that specify both the clinical goals of the dose distribution and initial target and normal-tissue constraints for optimization. The MSKCC template for prostate IMRT planning to 81 Gy is shown in Table 69.10. Dose and dose–volume constraints for the PTV, PTV overlap with the rectum, and rectal and bladder walls are listed. It should be noted that constraint templates vary significantly among treatment planning systems; therefore, these constraints should be used only after a thorough evaluation on the user's system.

A variety of beam arrangements have been proposed for prostate IMRT treatment, including multifield axial or noncoplanar arrangements, in addition to intensity-modulated arc therapy.[266–268] Primarily because of concern about increased risk of secondary cancers from higher neutron doses associated with IMRT treatment at high energies,[269,270] 6-MV IMRT techniques are preferred for the treatment of prostate cancer. As shown by Pirzkall et al.,[271] however, a larger number of treatment fields may be necessary to achieve a dose distribution similar to that observed with 15-MV x-rays.

The MSKCC clinical goals used to evaluate the IMRT dose distributions and dose–volume histograms for prostate patients are outlined in Table 69.10. These dosimetric guidelines defining acceptable target coverage, dose uniformity, and normal-tissue doses have grown out of our 3DCRT and IMRT planning experience during the last 20 years and include several refinements resulting from retrospective outcome and toxicity analyses from our institution. Most notably, studies by Skwarchuk et al.[272] and Jackson et al.[273] retrospectively evaluating the rectal wall dose–volume histograms for patients treated to 70.2 and 75.6 Gy using 3DCRT techniques found that, on average, patients with late rectal bleeding had significantly higher rectal dose–volume histograms than patients who did not bleed. Both high- and intermediate-dose levels were found to be independently correlated with rectal bleeding. As a result of these studies,

two rectal wall dose–volume histogram limits were implemented and are routinely enforced at MSKCC when treating prostate cancer: No more than 30% of the rectal wall may receive more than 75.6 Gy, and no more than 53% of the rectal wall can receive more than 47 Gy.

TABLE 69.10 OPTIMIZATION CONSTRAINT TEMPLATE AND PLANNING GOALS FOR MEMORIAL SLOAN KETTERING CANCER CENTER 81-GY AND INTENSITY-MODULATED RADIATION THERAPY PROSTATE TREATMENT

Structure	Optimization Constraints[a]			Treatment Plan Goals[b]	
	Maximum Dose (Gy)/Penalty	Minimum Dose (Gy)/Penalty	Volume (%)	Dose (Gy)	Volume (%)
Planning target volume (excluding rectal overlap)	82.6/50	79.4/50	—	111% max	V_{95} >90
Planning target volume and rectum					
Overlap region	77.8/20	75.3/10	—	—	—
Rectal wall	77/20	—	—	75.6	30
Rectal wall	32.4/20	—	30	47	53
Bladder wall	79.4/35	—	—	—	—
Bladder wall	32.4/20	—	30	40	60

[a]Optimization constraints = initial target and normal-tissue constraints entered into the IMRT optimization planning system.
[b]Treatment plan goals = dosimetric criteria used for evaluation and acceptance of an IMRT dose distribution.

Typical dose distributions and dose–volume histograms for an 86.4-Gy IMRT plan are shown in Figure 69.8. The physician should carefully review the treatment plan and dose–volume histograms of the target and normal-tissue structures to select the optimal treatment plan for the patient. Target coverage should be carefully assessed, as well as the dose inhomogeneity and location of hot spots. In addition, careful attention should be given to determining whether the treatment plan adequately meets acceptable dose constraints for the rectum, bladder, and bowel.

Standard Prescription Doses for 3DCRT and IMRT

In general, 78 Gy with conventional fractionation is frequently used, although at

MSKCC, 81 to 86 Gy has been delivered to favorable-risk patients using IMRT. Daily fractions of 1.8 to 2 Gy, five fractions per week, are routinely used. However, others have reported encouraging results with a hypofractionated scheme delivering 70 Gy with fractions of 2.5 Gy.[274,275] The dose is prescribed to an isodose line that encompasses as much of the PTV as possible while still respecting the target and normal-tissue goals listed in Table 69.10. Typically, at least 90% to 95% of the PTV receives the prescription dose.

Treatment Delivery and Organ Motion Control

Movement of the prostate during treatment or between treatment fractions has long been a concern for prostate radiation therapy. Many studies investigating interfractional and intrafractional motion of the prostate and seminal vesicles have been reported.[276–279] Most groups have measured prostate motion relative to bony landmarks through repeated imaging of implanted radiopaque markers or serial CT studies. Although the reported magnitude of motion has varied, relatively little motion in the lateral direction and potentially significant movement in the anterior–posterior and superior–inferior directions has been consistently reported. Many studies have also observed a correlation between prostate and seminal vesicle motion and rectal or bladder filling.

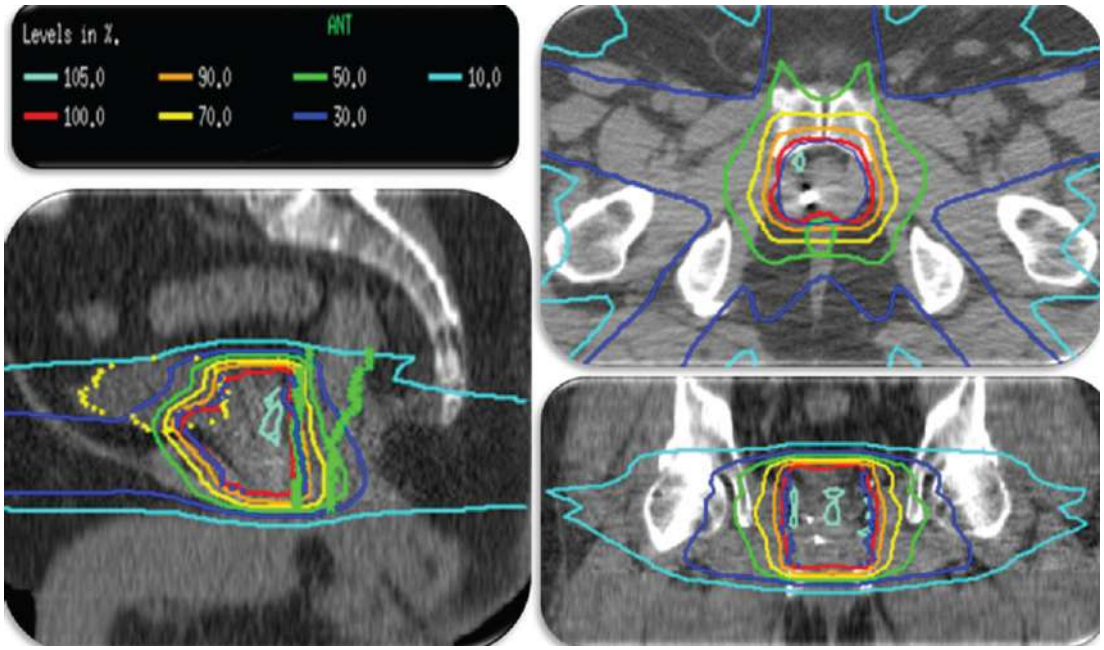

FIGURE 69.8. Dose distribution and dose–volume histogram display for a typical five-field intensity-modulated radiotherapy treatment plan whose prescription to the prostate target is 86.4 Gy. (Courtesy of Daniel Spratt MD.)

Interfractional prostate motion was studied in approximately 50 patients by Crook et al.[278] Gold seeds implanted in the prostate were visualized on kilovolt radiographs taken at the simulation and approximately midway through treatment. Minimal prostate motion was observed in the lateral directions (0.1 to 0.5 cm), but inferior displacements of 0.5 and 1.0 cm or more were observed in 43% and 11% of their patients. Average displacement in the posterior direction was 0.72, 0.62, and 0.46 cm for seeds placed at the seminal vesicles, posterior aspect of the prostate, or apex of the gland, respectively; 60% of patients showed >0.5-cm posterior displacement of the prostate base, and 30% showed >1 cm.

Zelefsky et al.[278a] obtained four serial CT studies for 50 patients (planning scan and three additional scans during the course of therapy). Prostate displacements in the anteroposterior and superior–inferior directions were most frequently observed. The mean prostate motion in the anterroposterior, superoinferior, and left–right directions was 1.2, 0.5, and 0.6 mm, respectively. Anterior–posterior movements were correlated with changes in rectal volume. Patients with large rectal volumes (>60 cm^3) and large bladder volumes (>40 cm^3) on the planning scan experienced a higher likelihood of having >3-mm systematic displacement of the prostate and seminal vesicles, leading the authors to conclude that these patients may require more generous PTV margins to ensure adequate CTV coverage. However, among patients without larger bladder and rectal volumes, a 1-cm margin around the CTV with a 6-mm margin at the prostate–rectal interface enclosed the posterior, anterior, superoinferior, and left–right aspects of the CTV within the prescription dose level with a probability of 90%, 100%, 99%, and 100%, respectively, indicating that the MSKCC margins provided adequate CTV coverage for most patients.

Intrafractional prostate motion was studied in 20 patients by Huang et al.[279] using pretreatment and posttreatment B-mode rectal ultrasound evaluations. Although the intrafractional motion was relatively insignificant in all directions, the predominant directions of motion were in the anterior and superior directions. Standard deviations of 0.4, 1.3, and 1.0 mm were observed in the lateral, anterior, and superior directions, respectively. Several methods have been developed to reduce uncertainty because of interfractional organ motion and thereby improve treatment delivery using computer-assisted transabdominal ultrasonography, radiopaque marker tracking, or CT/cone-beam image guidance. Recent technologic advances have opened up the possibility of acquiring pretreatment or posttreatment megavoltage or kilovoltage CT images directly on the linear accelerator (LINAC) with the patient in the treatment position, such as

TomoTherapy. Langen et al.[280] compared three methods of registering megavoltage CT images from a TomoTherapy unit with the kilovoltage planning CT images and found that manual registration performed using implanted fiducial markers exhibited the least interobserver variability and agreed best with automatic registration computed from the center of mass of the three implanted fiducial markers. LINAC-based kilovoltage image guidance systems are routinely used now for image-guided therapy approaches. They possess capabilities for kilovoltage two-dimensional projection imaging (radiographs), fluoroscopy, and 3D cone-beam CT and are ideally suited for monitoring of interfractional and intrafractional motion.

Using intensity-modulated radiation therapy (IMRT, VMAT), 10-year biochemical control has been in the range of 85% to 88%, with acceptable morbidity. These recent technologic advances have allowed dose escalation, with improvement in the results of treatment. A study from MD Anderson Cancer Center showed that patients with favorable (low risk) prostate cancer treated with 78 Gy had a 10-year biochemical control of 88% compared to 63% in patients treated with 70 Gy. Grade 3 toxicity was 7% versus 1% respectively. A French multicenter trial compared 8,000 to 7,000 cGy in patients with various risk prognostic groupings. The 5-year BCFFR was 76.5% versus 67.9%, respectively. There was a trend toward more toxicity in the 8,000 cGy group (grade 3 rectal toxicity 6.5% and 1.5%, respectively).

In a study comparing 8-year outcomes of RP or EBRT, Kupelian et al. (Cleveland Clinic) reported on 1,054 patients who were treated with surgery and 628 with EBRT. With a median follow-up of 51 months, the PSA relapse-free survival was 72% and 70%, respectively.

Brachytherapy for Early-Stage Disease: Treatment Techniques

Preplanned Transperineal Implantation Techniques

The preplanning technique essentially attempts to map the seed-loading patterns prior to the implantation procedure, and during the procedure, the brachytherapist will try to simulate the preplanned needle positions with the operative conditions and settings. The technique can be summarized as follows: TRUS imaging is obtained before the planned procedure to assess the prostate volume. A computerized plan is generated from the transverse ultrasound images, producing isodose distributions and the ideal location of seeds within the gland to deliver the prescription dose to the prostate. Several days to weeks later, the implantation procedure is performed. Needles are then placed under

ultrasonographic guidance through a perineal template according to the coordinates determined by the preplan. Radioactive seeds are individually deposited in the needle with the aid of an applicator or with preloaded seeds on a semirigid strand containing the preplanned number of seeds. In the latter case, this is accomplished by stabilizing the needle obturator that holds the seed column in a fixed position while the needle is withdrawn slowly, depositing a row or series of seeds within the gland. One of the inherent advantages of a stranded-seed approach is the reduction of seed migration and embolization to the lung compared with the use of free seeds. Among patients implanted with loose seeds, usually <2% of the implanted seeds are likely to migrate. There is no evidence of any adverse effect caused by seed embolization.[281]

Careful evaluation of the preplan with attention to dose–volume histogram analyses of both the target and normal tissues is essential to ensure that the dose to the urethra and rectum is within tolerance ranges and the prescription dose is being delivered to the prostate target. In a multi-institutional analysis, there remains a great deal of variability within preplans as to acceptable target volume, seed strength, dose homogeneity, treatment margins, and extracapsular seed placement, although prostate brachytherapy prescription doses are uniform.[282]

Intraoperative Planning Techniques for Prostate Brachytherapy

With the current availability of sophisticated treatment planning programs that can rapidly generate highly conformal dose distributions in the operating room, intraoperative planning for prostate brachytherapy is an attractive method. Intraoperative planning takes advantage of the opportunity of using real-time measurements of the prostate during the procedure, whereas preplanning is often performed several weeks before implantation, frequently under different conditions than the actual operative procedure. Subtle changes in the position of the ultrasound probe, as well as the distortion of the prostate associated with needle placement and subsequent edema, may result in profound changes in the shape of the gland compared with the preplanned prostatic contour. Consequently, intraoperative adjustments of seed and needle placements are frequently required using a preplanned technique, and the postplan CT-based dosimetry does not always correspond to the idealized preplan.

At MSKCC, intraoperative conformal optimization and planning for ultrasound-based transperineal implantation have been routinely used for well more than 10 years.[283] This technique involves a sophisticated optimization system that incorporates acceptable dose ranges allowed within the target, as

well as dose constraints for the rectal wall and urethra. An ultrasound probe is positioned in the rectum, and the prostate and normal anatomies are identified. Needles are inserted through the perineal template at the periphery of the prostate. The prostate is subsequently scanned from apex to base, and these 0.5-cm images are transferred to the treatment planning system using a PC-based video capture system. On the computer monitor, the prostate contours and the urethra are digitized on each axial image. Needle positions are identified on each image, and their coordinates are incorporated into a genetic algorithm optimization program. After the optimization program identifies the optimal seed-loading pattern and the dose calculations are completed, isodose displays are superimposed on each transverse ultrasound image and carefully evaluated. Dose–volume histograms for the target volume, rectum, and urethra are also carefully assessed. For the intraoperative plan, the V_{100} for the prostate is set at 95% or higher, and the maximum urethral and rectal dose thresholds are set at <130% and 1 cm^3 <100% of the prescription doses, respectively. The entire planning process from the contouring of images to the generation of the seed-loading pattern requires approximately 10 minutes. Seeds are then loaded with a standard applicator. A cone-beam CT scan from a mobile unit is routinely used to obtain postimplantation dosimetric analysis while the patient is under anesthesia before the conclusion of the procedure to ensure optimal coverage of the target volume with the prescription dose. Figure 69.9 shows a postimplantation CT image used for dosimetric evaluation.

Dose, Isotope, and Activity Considerations for Prostate Brachytherapy

At present, the commonly used dose for LDR interstitial implantation when using ^{125}I is 144 Gy, prescribed to the isodose surface that completely encompasses the prostate as contoured from imaging studies. For ^{103}Pd, 125 Gy is the recommended prescription dose when the isotope is used as monotherapy,[284] There are clear physical differences between these two isotopes. The half-life of ^{125}I is 60 days, with mean photon energy of 27 keV and an initial dose rate of 7 cGy/h. In contrast, the half-life of ^{103}Pd is 17 days, with mean photon energy of 21 keV and an initial dose rate of 19 cGy/h. Dosimetric analyses of treatment plans performed with either isotope have not revealed significant differences between them.[285] Most retrospective reports[286,287] failed to demonstrate any benefit in terms of local tumor control or long-term complications for either isotope. A randomized trial has been conducted

comparing ^{125}I with ^{103}Pd for the treatment of early-stage prostate cancer. No differences in tumor-control outcomes have been noted between the two arms of the study. Preliminary findings from this study noted that patients treated with ^{103}Pd had more intense radiation prostatitis in the first month after implantation but recovered from their radiation-related symptoms sooner than ^{125}I patients, consistent with palladium's shorter half-life.[288] In a retrospective analysis, Kollmeier et al.[289] reported the outcome of patients treated with ^{125}I or ^{103}Pd in conjunction with supplemental EBRT. There were no differences in toxicity or PSA relapse–free survival outcomes between patients who received the ^{103}Pd or ^{125}I boost.

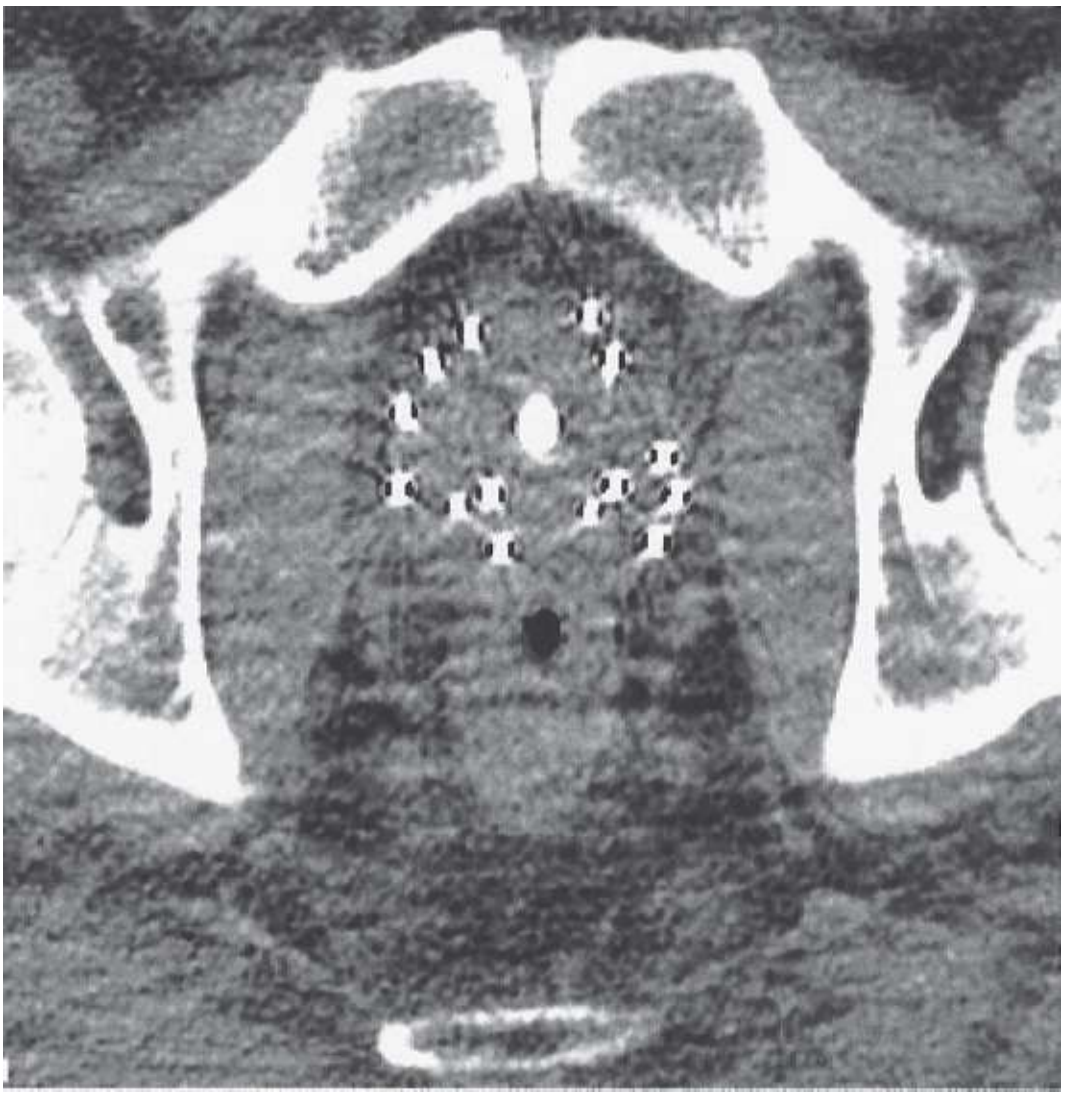

FIGURE 69.9. Postimplantation computed tomography scan after permanent transperineal ultrasound-guided seed implantation with urethral sparing.

Postimplantation Dosimetric Evaluation

Postimplantation dosimetric evaluation after prostate brachytherapy is recommended as the standard assessment of the quality of permanent interstitial implantation used for the treatment of prostate cancer.[290] The adequacy of the target coverage with the intended prescription doses is evaluated with surrogate parameters such as volume of the prostate treated to 100% of the prescription dose (V_{100}) and the dose delivered to 90% of the prostate target (D_{90}). These parameters have been shown by several investigators to be associated with biochemical relapse and posttreatment biopsy outcomes.[291–294] Equally important, other parameters of implant quality measure the dose exposure to the urethra and rectum. These measurements have been correlated with postimplantation urinary and rectal-related toxicities.[295–298] Commercial software is routinely available to determine the coverage of the prostate and dose to critical normal-tissue structures. Isodose curves and dose–volume histograms produce a detailed analysis of the radiation dose distribution relative to the prostate and surrounding normal tissues. Postimplantation evaluation is performed on the day of the procedure or 30 days after the procedure. Although the latter time point takes advantage of assessments when prostate edema is less significant after the implant, with potential decreased underestimate of the prostate coverage with the prescription dose, assessments made on the day of the procedure provide more rapid feedback regarding the adequacy of the dose delivered to the prostate.

A summary of published dosimetric outcomes after LDR BT based on postimplantation CT-based dosimetric outcomes is shown in Table 69.11.

Postimplantation evaluation is a critical quality assurance procedure for prostate brachytherapy and provides important feedback to the brachytherapist concerning the quality of the implant, dose delivered to the prostate, and what corrections need to be made to optimize target coverage to reduce normal-tissue dosing. Stock et al.[299] reported that, among patients with low-risk disease who had an optimal dose based on retrospective postimplantation dosimetry evaluation from the day-30 CT scan (D_{90} > 140 Gy; n = 49), the PSA relapse–free survival at 8 years was 94%, compared to 75% for those who received lower-dose levels (P = .02). Investigators from Memorial Sloan Kettering Cancer Center recently demonstrated that higher D_{90} values based on the postimplantation dosimetric analysis from the CT taken on day 0 (the day of the procedure) also were associated with improved long-term biochemical control outcomes.[300] In that report, the 7-year PSA relapse–free survival was 99%

compared to 89% for patients with D_{90} > 140 and <140 Gy, respectively (*P* = .005).

Safdieh et al.[301] noted that several studies have suggested that brachytherapy utilization has markedly decreased, coinciding with the recent increased utilization of IMRT, as well as an increase in urologist-owned centers. They investigated brachytherapy or EBRT utilization in patients with prostate cancer at a large, hospital-based registry (2004 to 2012) and were abstracted from the National Cancer Database (NCDB). To be included, men had to be clinically staged as T1c-T2aNx-0Mx-0, Gleason 6, PSA = 10.0 ng/mL.

There were 89,413 men included in this study, of which 37,054 (41.6%) received only EBRT and 52,089 received prostate brachytherapy. Of those who received brachytherapy, 47,710 (91.6%) received monotherapy and the remaining received brachytherapy as a boost to EBRT. The use of brachytherapy declined over time from 62.9% in 2004 to 51.3% in 2012 (*P* < .001).

This decline was noted in both academic facilities (from 60.8% in 2004 to 47.0% in 2012, *P* < .001) as well as nonacademic facilities (from 63.7% in 2004 to 53.0% in 2012, *P* < .001). The use of IMRT increased during this same time period from 18.4% in 2004 to 38.2% in 2012 (*P* < .001). On multivariate analysis, treatment at an academic center (OR 0.89; 95% CI = 0.87 to 0.92, *P* < .001), increasing age, and years of diagnosis from 2006 to 2012 were significantly associated with reduced brachytherapy usage.

High dose rate (HDR) brachytherapy (iridium-192 sources) has been used in some institutions to treat patients with localized prostate cancer, including monotherapy. For techniques' description and dose schedules, the reader is referred to Chapters 27 and 28.

Results of Standard Treatment Interventions for Clinically Localized Prostate Cancer

Outcome with Radical Prostatectomy

Bianco et al.[302] reported the long-term outcomes of 1,963 patients who underwent RP, all performed by one surgeon. The positive margin rate was 12%. The overall 5- and 10-year biochemical tumor-control outcomes were 82% and 77%, respectively. Among patients with pretreatment PSA levels of 4 to 10, 10 to 20, and >20 ng/mL, the 10-year PSA relapse-free survival outcomes were 83%, 64%, and 47%, respectively. The overall cause-specific survival was 99% and 95%. At 24 months after surgery, 60% were potent, continent, and free of disease. Roehl et al.[302a] recently reported the outcome of 3,478 men who

underwent RP for clinically localized prostate cancer at Washington University. In that report, the mean follow-up was 65 months. The overall biochemical recurrence (BCR) rate at 10 years was 32%, with a median time to failure of 28 months. The 10-year PSA relapse-free survival rates for patients with preoperative PSA levels of <2.6, 2.6 to 4, 4.1 to 10, and >10 ng/mL were 91%, 78%, 74%, and 49%, respectively. Multivariate analysis revealed that predictors for PSA relapse-free survival outcomes included the preoperative PSA level, clinical tumor stage, Gleason sum, pathologic stage, and treatment era. The 10-year cancer-specific and overall survival rates were 97% and 83%, respectively. The cancer-specific survival outcome was influenced by the pathologic stage ($P < .004$), Gleason sum ($P = .004$), and treatment era ($P = .04$).

NS, Not stated.

Han et al.[304] reported the long-term outcome of RP from the Johns Hopkins Hospital. In that report, 2,091 men underwent RP. In this series, 79% of patients had PSA levels of <10 ng/mL, and 62% of the patients had Gleason scores of ≤6. The mean follow-up was 6.3 years. The overall 10- and 15-year PSA relapse-free

survival outcomes were 85% and 79%, respectively. The 10-year PSA control rates for patients with preoperative PSA values of 0 to 4, 4 to 10, 10.1 to 20, and >20 ng/mL were 91%, 79%, 57%, and 48%, respectively.

Outcome with Conventional External Beam Radiation Therapy for Low-Risk Disease

Kuban et al.[305] reported the results of a large multi-institutional analysis comprising 4,839 patients with T1-T2 prostate cancer treated with EBRT between 1986 and 1995; no patient received neoadjuvant hormone therapy . The median follow-up was 6.3 years. Most of the patients included (70%) were treated with conventional EBRT, and 30% were treated with 3DCRT planning techniques. Prescription doses ranged from 60 to 78 Gy. For the cohort of patients treated to dose levels of <70 Gy, the median dose was 67 Gy; among those patients who received 70 Gy or more, the median dose in this cohort was 72 Gy. PSA failure as defined according to ASTRO definition was three consecutive rising PSA values above the nadir value. The overall 8-year PSA control rates for patients with pretreatment PSA values of 0 to 4, 4 to 9.9, 10 to 20, and >20 to 30 ng/mL were 80%, 60%, 46%, and 34%, respectively. The overall 8-year PSA control rates for patients with posttreatment nadir PSA values of 0 to 0.49, 0.5 to 0.99, 1 to 1.99, and ≥2.0 ng/mL were 93%, 88%, 86%, and 72%, respectively. Higher prescription dose levels of ≥72 Gy were associated with a significant decrease in PSA relapse rates, and these differences were most noted among patients with intermediate- and higher-risk disease. Although there was no apparent dose response for low-risk patients, the number of patients who received higher doses in this study was small.

Dose Escalation for Low-Risk Prostate Cancer

Phase III randomized trials and several single-institution trials have confirmed the advantage of high-dose CRT for patients with localized prostate cancer. These trials have shown long-term biochemical control advantages especially among patients with intermediate- and high-risk disease. More recently, however, updates of some these studies have indicated a benefit for the application of higher radiation dose levels even for patients with favorable-risk disease. The phase III trial from MD Anderson Hospital accrued 301 patients with T1-T3 prostate cancer, of whom 150 were treated to 70 Gy (conventional EBRT) and 151 were treated to 78 Gy (conventional EBRT followed by a 3D boost). The PSA relapse-free survival rates for the 78- and 70-Gy arms were

70% and 64%, respectively (P = .03). In a recent update of this trial,[306] a significant improvement in 8-year biochemical control was noted among low-risk patients who received 78 Gy compared to 70 Gy (88% vs. 63%; P = .042; Fig. 69.10).

Zietman et al.[307] reported the result of a randomized trial of 393 patients with T1-T2 prostate cancer with pretreatment PSA levels of <15 ng/mL. Patients were randomized to receive conventional EBRT to a dose level of 70.2 or 79.2 Gy. In both treatment arms, radiotherapy was delivered using a combination of photon and proton beams. The median follow-up in this study was 5.5 years. The 5-year PSA relapse-free survival rates for the low- and high-dose arms were 61% and 80%, respectively, which represented a 49% risk reduction in biochemical failure. What was most noteworthy in this trial was that a clear advantage for higher dose was observed among the subset of patients with low-risk disease, which represented the majority of patients accrued to the trial (PSA of <10 ng/mL, stage ≤ T2a, or Gleason score of <6). In this subgroup of patients, a significant advantage for higher doses was observed, with an associated 51% risk reduction in biochemical relapse (80% vs. 60% for higher vs. lower doses; P < .001).

The experience from MSKCC was reported by Zelefsky et al.[308] in 2,551 patients with T1-T3 prostate cancer treated with follow-up that extended beyond 20 years. The radiation dose was systematically increased from 64.8 to 86.4 Gy by increments of 5.4 Gy in consecutive groups of patients. This study also demonstrated an advantage for dose escalation in low-risk patients. The 10-year PSA relapse-free survival among patients with low-risk disease who received dose levels of 75.6 Gy and higher was 84%, compared to 70% for patients who received lower-dose levels (P = .04; Fig. 69.11). In this report, there were no apparent differences in long-term outcomes among patients who received 81 versus 75.5 Gy for low-risk disease. Others did not demonstrate dose escalation advantages for low-risk disease,[309,310] but the follow-up was relatively limited in these studies. The 10-year biochemical outcomes from MSKCC patients for IMRT-treated patients have been reported.[311] The 10-year actuarial PSA relapse-free survival rates for favorable-, intermediate-, and unfavorable-risk group patients were 81%, 78%, and 62%, respectively. The 10-year actuarial distant metastases–free survival outcomes for favorable-, intermediate-, and unfavorable-risk group were 0%, 6%, and 10%, respectively. The 10-year actuarial risk of a prostate cancer–related death for favorable-, intermediate-, and unfavorable-risk group was 0%, 3%, and 14%.

Michalski et al.[312] reported the outcome of RTOG 94-06, which evaluated dose escalation using 3D conformal radiotherapy for patients with localized prostate cancer. Patients were accrued on five sequential dose levels: 68.4, 73.8, 79.2, 74, and 78 Gy. For patients with low-risk disease (n = 403), the 5-year PSA relapse-free survival outcomes for these respective dose levels were 68%, 73%, 67%, 84%, and 80%.

Comparison of EBRT Outcomes with Surgery for Early-Stage Prostate Cancer

Kupelian et al.[311] compared the 8-year outcomes of surgery and EBRT from the Cleveland Clinic. In this report, 1,054 patients were treated with surgery and 628 were treated with EBRT. Treatments (surgery or radiotherapy) were given between 1990 and 1998, and the median follow-up was 51 months. There were significant differences in the patient groups because, in general, those treated with surgery were younger and had lower clinical stages, pretreatment PSA levels, and Gleason scores. The 8-year PSA relapse-free survival outcome for patients who underwent RP and EBRT was 72% and 70%, respectively ($P = .01$). Multivariate analysis demonstrated that the clinical stage, pretreatment PSA, biopsy Gleason score, use of neoadjuvant therapy, and year of treatment were all independent predictors of disease relapse, whereas the treatment modality (RT vs. surgery) did not influence likelihood of failure. These authors also noted a benefit for higher radiation doses in the favorable-risk subset of patients. Among favorable-risk patients who received 72 Gy or more, the 8-year PSA relapse-free survival outcome was similar ($P = .08$) to that of patients treated with RP and significantly better, in turn, than that of patients treated with RT to dose levels of <72 Gy ($P < .001$). Similarly, Zelefsky et al.[242] found similar distant metastases–free survival outcomes between high-dose IMRT and surgery for low-risk patients.

In the absence of randomized trials comparing surgery to RT, it is difficult to definitively make claims of the superiority of one treatment over another. It has been stated frequently that, whereas the results of radiation and radical surgery are comparable up to 10 years, there is a rapid decrement in the probabilities of both disease-free and overall survival after that time point among irradiated patients. However, such conclusions are likely erroneous owing to selection bias factors favoring a younger cohort with more favorable prognostic features who are more often chosen for surgery compared with radiation therapy. In addition, because of the lack of information in most radiation therapy series of the pathologic status of the lymph nodes, patients with microscopic nodal disease will likely be included in radiation therapy reports yet routinely excluded from surgical series. An additional argument posed for surgery is that if such an approach fails, salvage radiotherapy remains a viable option, whereas for those who fail radiotherapy, salvage surgery can be associated with an increased of risk of postoperative complications. Nevertheless, patients need to be informed that there are risks associated with salvage radiation therapy after a failed prostatectomy, and the likelihood of a successful outcome after well-delivered primary radiotherapy is high and comparable to surgery outcomes.

Outcome with Brachytherapy

Similar to the predictors of biochemical outcome after EBRT for prostate cancer, PSA relapse-free survival after permanent seed implantation depends on several prognostic variables, including the pretreatment PSA, biopsy Gleason score, clinical stage, and the implant dose delivered to the target volume. In general, among patients with pretreatment PSA of ≤10 ng/mL, permanent seed implantation alone is associated with excellent biochemical outcome and appears comparable with other local interventions. Fifteen-year outcomes were reported by Sylvester et al.[313] from 215 patients treated between 1988 and 1992. The PSA relapse-free survival outcomes were 86%, 80%, and 62% for favorable-, intermediate-, and high-risk patients, respectively. Similarly, Taira et al.[314] reported on 1,656 patients. For low-risk patients, the 7-year biochemical tumor control, cause-specific survival, and overall survival outcomes were noted to be 98.6%, 99%, and 77.5%, respectively.

Eleven institutions combined data on 2,693 patients treated with permanent interstitial brachytherapy monotherapy for T1-T2 prostate cancer.[294] Of these patients, 1,831 (68%) were treated with ^{125}I (median dose, 144 Gy) and 862 (32%) were treated with ^{103}Pd (median dose, 108 Gy). The median follow-up was 63 months. The 8-year PSA relapse-free survival outcomes for favorable-, intermediate-, and unfavorable-risk patients were 82%, 70%, and 48%, respectively ($P < .001$) according to the ASTRO consensus definition. Among patients in whom the dose to 90% of the prostate (D_{90}) was >130 Gy, the 8-year PSA relapse-free survival outcome was 90% compared with 73% for those with D_{90} dose levels of ≤130 Gy ($P < .001$). The PSA nadir value at 3 years after implantation was associated with the long-term biochemical outcome. The 8-year PSA relapse-free survival outcomes were 92%, 86%, 79%, and 67%, respectively, for patients who achieved PSA nadir values of 0 to 0.49, 0.5 to 0.99, 1.0 to 1.99, and >2.0 ng/mL ($P < .001$). Among patients who were free of biochemical relapse at 8 years, the median nadir level was 0.1 ng/mL, and 90% of these patients achieved a nadir PSA level of <0.6 ng/mL.

Stone et al.[315] reported on 2,111 patients who underwent brachytherapy followed for a median of 6 years. In this group, 56% of the patients were treated with ^{125}I, 10% were treated with ^{103}Pd, and 34% were treated with combined external beam radiotherapy and ^{103}Pd implant. Among low-risk patients, the PSA relapse-free survival outcome at 12 years was 88%. Significant predictors of long-term biochemical tumor control included the use of ADT ($P = .03$), pretreatment PSA level ($P = .026$), and a higher biologically effective dose ($P =$

.003). Among patients who had a posttreatment biopsy 2 years after treatment, higher biologically effective dose levels were associated with improved local tumor-control outcomes.

In an update of the outcomes of real-time intraoperative planning at MSKCC reported by Zelefsky et al.,[300] 1,466 patients with prostate cancer were treated with permanent interstitial implantation using a transrectal ultrasound-guided approach. Real-time intraoperative treatment planning, which incorporated inverse planning optimization, was used. The 5-year PSA relapse-free survival outcomes for favorable- and intermediate-risk patients were 98% and 95%, respectively. In these patients, no dosimetric parameter was identified that influenced the biochemical outcome. For this cohort of patients, the use of androgen deprivation did not affect the long-term PSA relapse-free survival outcomes. Among patients treated with ^{125}I, improved biochemical control outcomes were observed for patients who had D_{90} values of >140 Gy compared to lower doses. It should be noted that this improved biochemical control outcome based on this dosimetric parameter was observed for postimplantation, CT-based assessments made on the day of the procedure (and not 30 days later).

TABLE 69.12 FIVE-YEAR BIOCHEMICAL CONTROL AFTER BRACHYTHERAPY ALONE FOR CLINICALLY LOCALIZED PROSTATE CANCER ACCORDING TO PROGNOSTIC RISK GROUP CLASSIFICATIONS

Study	Patients	Projected Results (Year)	Favorable Risk (%)
Taira et al.[314]	1,656	7	98
Sylvester et al.[313]	215	15	86
Multi-institutional[294]	2,693	8	82
Stone et al.[315]	2,111	12	88
Potters et al.[292]	1,449	12	89
Zelefsky et al.[300]	1,466	7	98

Table 69.12 summarizes the published biochemical outcomes after low dose rate interstitial seed implantation according to prognostic risk groups.

Brachytherapy with iodine-125 or palladium-103, in prostate cancer, has yielded comparable or better results than prostatectomy or EBRT. In a report of 2,693 patients from 11 institutions with T1-T2 tumors, for those with low-risk tumors, the 8 year PSA relapse-free outcome was 82%. Stone et al.[315] reported on 2,111 patients treated with brachytherapy. With a median follow-up of 6

years, the PSA relapse-free survival in the low-risk group was 88% at 12 years. Zelefsky et al. reported on 1,466 patients treated with interstitial brachytherapy with a 5-year PSA relapse-free survival in the group with favorable tumors of 98%. Equal results have been reported with HDR brachytherapy, usually combined with external beam irradiation.[300]

ACUTE AND LATE TREATMENT-RELATED SEQUELAE OF STANDARD TREATMENT INTERVENTIONS

Sequelae of Radical Prostatectomy

Complication rates after prostatectomy vary in the literature and recently have been shown to depend on the experience of the surgeon. Begg et al.[316] used the Medicare claim records from 11,522 patients who underwent prostatectomy between 1992 and 1996. Postoperative morbidity was found to be significantly reduced in hospitals that were considered to have high volume compared with lower-volume ones (27% vs. 32%; $P = .03$) and among surgeons with a high-volume practice compared to those with lower volumes (26% vs. 32%; $P < .001$).

Immediate intraoperative/postoperative complications include pelvic pain and transient incontinence. Although intraoperative blood loss can range from 300 to 4,000 mL, meticulous surgical technique should reduce blood loss. The operative mortality rate has been reported to be 1% to 2%, but in experienced hands, the incidence is a fraction of 1%. The incidence of postoperative stress incontinence ranges from 5% to 57%.

Catalona et al.[317] reported on the complication rates in 1,870 patients who underwent RP. They reported a 2% incidence of a thromboembolic event and a 4% incidence of an anastomotic stricture. Recovery of urinary continence depended on the age of the patient. Among patients in their 50s, 60s, and 70s, the likelihood of persistent urinary incontinence was 3%, 8%, and 13%, respectively. The incidence of impotence after bilateral and unilateral nerve-sparing surgery procedures was 53% and 32%, respectively. Bilateral nerve-sparing procedure was associated with improved potency preservation among patients who were younger than 70 years of age (71% vs. 48%; $P < .001$), whereas these differences were not significant in the older age group.

Bianco et al.[302] reported continence and potency outcomes in 1,472 patients who underwent surgery since 1991 and were operated on by a single surgeon. Among 1,288 patients who were continent prior to surgery, the actuarial

likelihood of maintained continence was 91% at 12 months and 95% at 24 months. Of 785 patients with potency information available, the median time to erectile function recovery was 12 months, and the 2-year likelihood of potency preservation was 70%.

A large review from the Nationwide Inpatient Sample extracted from this dataset 11,889 patients who underwent RARP and compared the perioperative complication rates to 7,389 patients who underwent an open RP.[318] This analysis found that, among patients undergoing a RARP, significantly lower likelihoods for blood transfusions and intraoperative and postoperative complications were observed compared to the open prostatectomy procedure. In addition, a shorter duration of hospital stay was noted for the patients who underwent a RARP. However, one of the limitations of this retrospective study was the fact that these findings were not adjusted by the clinical stage of the patients and the surgeon's experience or volume, which play important roles in the frequency of surgical-related complications.

Sequelae of Conventional External Beam Radiation Therapy

EBRT delivered with conventional techniques is fairly well tolerated, although grade 2 or higher acute rectal morbidity (discomfort, tenesmus, diarrhea) or urinary symptoms (frequency, nocturia, urgency, dysuria) requiring medication occur in approximately 60% of patients. Symptoms usually appear during the 3rd week of treatment and resolve within days to weeks after treatment is completed. The incidence of late complications that develop ≥6 months after completion of treatment is significantly lower, whereas serious complications that require corrective surgical intervention are rare. In general, the incidence of chronic urinary sequelae (i.e., cystitis, hematuria, urethral stricture, or bladder contracture) using conformal treatment delivery techniques is <5%, and the incidence of grade 3 and 4 urinary-related complications requiring major surgical interventions or hospitalization is <1%. The incidence of chronic intestinal or rectal sequelae (chronic diarrhea, proctitis, or rectal bleeding) that requires medical management ranges from 3% to 10%, and <1% of grade 3 to 4 complications are observed after more targeted treatment delivery techniques such as IMRT and image-guided radiotherapy. Fecal urgency and incontinence are documented side effects after treatment and have been reported to occur in <2% of patients, occur less than once per week, and are often associated with incontinence for flatulence.[319] Most complications attributed to radiation therapy are observed within the first 3 to 4 years after treatment, and the likelihood of

complications developing after 5 years is low. The risk of complications is increased when radiation doses exceed 72 Gy. Several factors have been associated with increased bowel or rectal toxicity after EBRT,[272,319–325] and these include the volume of the rectum exposed to higher doses of radiation, increasing age of the patient, concomitant use of ADT, and the presence of diabetes and inflammatory bowel disease. Even patients with a prior history of inflammatory bowel disease currently in remission may have significant increases of rectal toxicity, and alternative treatments should be considered for these patients. Among patients who undergo radiotherapy and experience acute rectal side effects, a higher incidence of late rectal toxicity has been observed.[323,325]

Michalski et al.[326] published a report on the toxicity outcomes of various risk groups enrolled in RTOG 9406, a phase I dose escalation study. The dose levels evaluated in this report included patients treated to the initial two dose levels of the study, 68.4 and 73.8 Gy. The median follow-up times in these subgroups ranged from 2.2 to 3.4 years. The acute grade 2 bowel/rectal toxicity rates ranged from 16% to 25%. The crude incidence of late bowel/rectal toxicities ranged from 2% to 8%. With a median follow-up of 2.5 years, the crude late grade 2 and 3 gastrointestinal (GI) toxicities for those patients treated to 78 Gy (2-Gy fractions) were 22% and 2%, respectively.

Storey et al.[327] reported late rectal toxicity among patients treated on the phase III trial form the MD Anderson Hospital. The 5-year actuarial risks of late grade 2 rectal toxicity for the 70- and 78-Gy dose level arms were 14% and 21%, respectively. In that report, the dose–volume histogram analyses of the patients treated to 78 Gy were analyzed to ascertain whether there were any predictive patterns for late rectal toxicity. These investigators reported a significant correlation for the percentage of the rectum treated to 70 Gy or higher and the likelihood of late rectal toxicity. Patients with >25% of the rectal wall treated to 70 Gy or higher had a 37% risk of grade 2 rectal toxicity, compared with 13% among patients who had <25% of the rectal wall exposed to these doses (P = .05). In an update of that experience, Kuban et al.[306] noted that the volume of rectum exposed to higher radiation doses was associated with the risk of rectal toxicity after external beam radiotherapy. The incidence of grade 2 rectal toxicity was 46% when >26% of the rectal volume was exposed to >70 Gy of the prescription dose. In contrast, among patients who had lower volume of rectum exposed to these dose levels, the incidence of grade 2 toxicity was significantly lower (14%).

Zelefsky et al.[328] reported the long-term tolerance of high-dose CRT at MSKCC. The 10-year actuarial rate of grade 2 or higher rectal toxicity was 9%. The use of IMRT significantly lowered the risk of grade 2 and higher toxicities from 13% to 5% ($P < .001$). This decline in rectal toxicity was observed despite the application of higher-dose levels of 81 Gy with IMRT compared to generally lower doses used with 3DCRT of 75.6 Gy (Fig. 69.12). In addition, patients who experienced acute GI side effects during treatment were six times more likely to experience late GI toxicities than were patients who did not experience such acute side effects (42% vs. 9%; $P < .001$). The 10-year incidence of grade 2 or higher late urinary toxicities was 15%, and the predictors for late toxicity included higher radiation doses and the presence of acute urinary symptoms during the course of EBRT. The 10-year toxicity outcomes of 81-Gy IMRT were recently updated by investigators from MSKCC.[329] The incidence of grade 2 and 3 GI toxicities was 2% and 1%, respectively. The 10-year actuarial incidence of grade 2 and higher urinary-related toxicities was 17%.

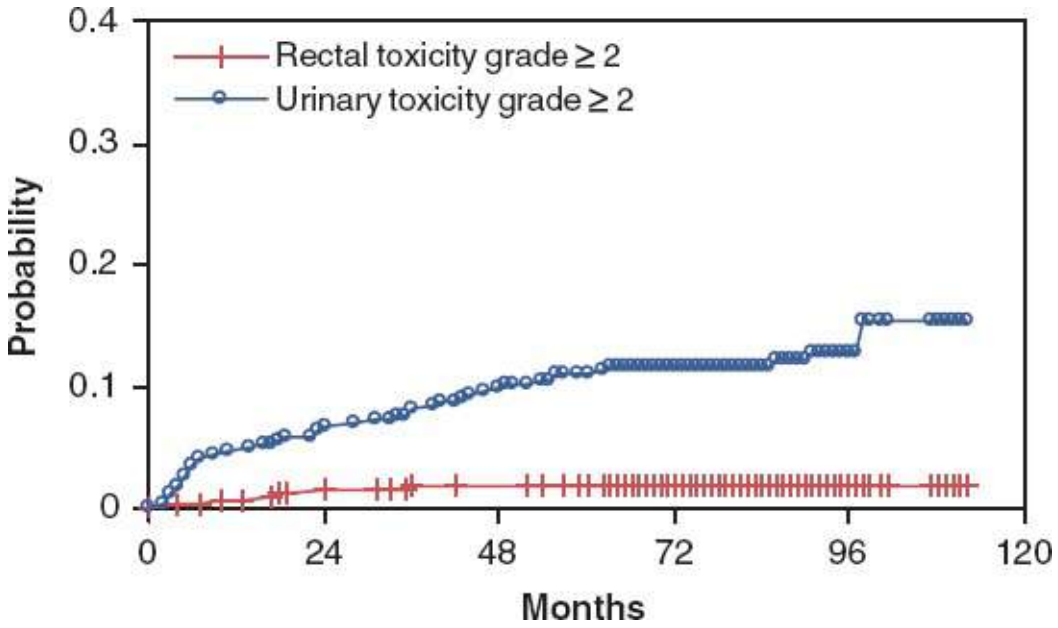

FIGURE 69.12. Actuarial likelihood of late grade 2 or greater rectal toxicities or late grade 2 or greater rectal toxicities. (Reprinted from Zelefsky MJ, Chan H, Hunt M, et al. Long-term outcome of high dose intensity modulated radiation therapy for patients with clinically localized prostate cancer. *J Urol* 2006;176[4]:1415–1419. Copyright © 2006 American Urological Association. With permission.)

Peeters et al.[330] described the incidence of acute and late complications in a multicenter randomized trial comparing 68- to 78-Gy 3DCRT. The median follow-up was 31 months. The 3-year incidence of grade 2 and higher GI and

genitourinary (GU) toxicities for the 68-Gy dose arm was 23% and 28.5%, respectively. The 3-year incidence of grade 2 and higher GI and GU toxicities for the 78-Gy dose arm was 26.5% and 30%, respectively. The differences were not significant. However, the authors did note a significant increase in grade 3 rectal toxicity requiring laser cauterization for the higher-dose arm. For patients treated to 78 Gy, the incidence of grade 3 rectal bleeding at 3 years was 10%, compared to 2% for those treated to 68 Gy. The following variables were found to be predictive of late GI toxicity: a history of abdominal surgery ($P < .001$) and the presence of pretreatment GI symptoms ($P = .001$). The following variables were predictive of late GU toxicity: pretreatment urinary symptoms ($P < .001$), the use of neoadjuvant ADT ($P < .001$), and prior transurethral resection of the prostate ($P = .006$).

Urethral strictures have been observed in 1.5% of 1,100 patients treated with 3DCRT. Grade 3 hematuria requiring fulguration was observed in <0.5% of the patients. Among patients who previously underwent a TURP, a 4% incidence of stricture development after 3DCRT was observed.[331] Other late urinary toxicities were not observed among patients with a prior history of a TURP. Lee et al.[332] observed a 2% incontinence rate among patients with a prior history of TURP who were treated with EBRT, compared with a 0.2% rate in patients without a prior TURP. At present, it does not appear that the use of IMRT has significantly reduced long-term urinary symptoms compared to conventional 3DCRT.

Potency Preservation with External Beam Radiation Therapy

The rates of erectile dysfunction after EBRT ranged from 6% to 84%.[333] The wide range of outcomes is a reflection of the varying assessment tools used and disparity in patient population, with heterogeneity of comorbidities, ages, and baseline functional status. Most studies show a progressive decline in erectile function with longer follow-ups, consistent with what is observed in an aging population with coexisting comorbidities such as hypertension, atherosclerotic heart disease, and diabetes. Investigators from the University of Chicago reported potency rates after EBRT.[334] With a median follow-up of 34 months, actuarial potency rates at 1, 20, 40, and 60 months were 96%, 75%, 59%, and 53%, respectively. In one report[335] comparing erectile function between patients who received 68 versus 78 Gy, no differences were observed between the different dose levels. Overall, in the studied cohort, the incidence of erectile dysfunction at 1 and 2 years after therapy was 27% and 36%, respectively. Aside from erectile dysfunction, other aspects of sexual dysfunction after radiotherapy

include decreased volume of ejaculate, absence of ejaculate, decreased intensity of orgasm, and decreased libido. A summary of reported potency rates after treatment is shown in Table 69.13.

Significant limitations exist with the aforementioned reported potency preservation rates because the data are derived from retrospective analyses and information was often obtained without the use of validated questionnaires. Prospective studies suggest that when patients are assessed with validated tools, erectile dysfunction—defined as inability to achieve adequate erection sufficient for sexual intercourse—reaches 60% to 70%. What also complicates the interpretation of published incidence rates is the multifactorial nature of erectile dysfunction. The factors that impact erectile function include age, presence of medical comorbidities such as cardiac disease and diabetes, antihypertensive medications, baseline erectile function, and the use of neoadjuvant and concurrent hormonal therapy. Pinkawa et al.[336] observed that the presence of spontaneous erection in evening or morning before treatment was a strong predictor for maintained erectile function after radiation therapy.

BRT, brachytherapy; EBRT, external beam radiation therapy.
Modified from Incrocci L, Slob AK, Levendag PC. Sexual (dys)function after radiotherapy for prostate cancer: a review. *Int J Radiat Oncol Biol Phys* 2002;52(3):681–693. Copyright © 2002 Elsevier. With permission.

Radiation-mediated impotence is likely multifactorial. However, it has been observed that 63% of patients evaluated for impotence after radiation therapy were diagnosed as having arteriogenic dysfunction, whereas 31% had cavernosal dysfunction. Only 3% were believed to have neurogenic impotence.[336] Sildenafil administration results in significant improvement in erectile function.[337,338] In one report, sildenafil improved erectile function in 74% of patients who underwent 3DCRT (median dose, 75.6 Gy), whereas 22% of patients had no response.[338]

Low Dose Rate Brachytherapy: Acute and Late Toxicity

Urinary Toxicity

Acute urinary retention (AUR) is a known risk that can occur immediately after prostate brachytherapy, and the incidence varies in the literature. Roeloffzen et al.[339] recently reported the incidence and predictors of AUR in a cohort of 714 patients who were treated with ^{125}I brachytherapy. In 8% of patients, retention developed at a median of 30 days from the implantation procedure. In that report, multivariate analysis revealed that patients with prostate volume >35 cm^3 experienced a higher incidence of AUR compared to patients with smaller volumes (10.4% vs. 5.4%). In addition, those with higher International Prostate Symptom Scores (IPSS) had a higher likelihood of developing urinary retention, consistent with other reports. Other reports for AUR after low dose rate brachytherapy range from 5% to 15%.[340–342] There does not seem to be any relationship between dosimetric outcomes, such as urethral dose and V_{150}, and the incidence of AUR after brachytherapy because this condition seems to be more related to acute trauma and intraprostatic inflammation and edema. Consistent with this notion is the fact that some reports demonstrated that greater number of needles placed or seeds deposited is associated with higher rates of AUR.[340–342] In general, almost all patients after prostate brachytherapy develop acute urinary symptoms such as urinary frequency, urgency, and occasional urge incontinence. Depending on the isotope used, these symptoms often peak at 1 to 3 months after the procedure and subsequently gradually decline over the ensuing 3 to 6 months. Most patients significantly benefit with the use of an α-blocker, which ameliorates such symptoms in 60% to 70% of patients.

Keyes et al.[343] reported on the acute and long-term urinary outcomes in 712 patients who were treated with ^{125}I permanent interstitial implantation who were followed for a median of 5 years. At 6 and 12 months after the procedure, approximately 37% and 23% experienced grade 2 acute urinary toxicities, and

4% and 2% experienced acute grade 3 urinary toxicities. Most urinary symptoms resolved within 12 months after the procedure, and significant residual toxicity was unusual. Multivariate analysis demonstrated that the use of ADT before implantation, higher baseline IPSS, and use of higher number of needles was associated with increased rates of grade 2 acute toxicity. The 5-year likelihood of developing late grade 2 and 3 urinary toxicities was 24% and 6%, respectively. Fewer than 1% of patients experienced a grade 4 urinary toxicity. In this report, predictors for increased risk of grade 2 or higher late urinary toxicity included the following variables: higher baseline IPSS, maximal postimplantation IPSS, presence of acute toxicity, and higher prostate V_{150}. The demonstration in this report that the V_{150} was an independent predictor of late urinary toxicity after brachytherapy highlights the importance of maintaining tight urethral dose constraints during the planning for brachytherapy. Urinary incontinence requiring pads was reported in <1% of treated patients. In a more recent report from MSKCC,[243] the 7-year incidence of grade 2 and 3 urinary toxicities after ^{125}I brachytherapy for low-risk patients was 15% and 2.2, respectively.

Rectal Tolerance

Zelefsky et al.[243] reported 5.1% and 1.1.% grade 2 and 3 late rectal toxicity, respectively, after prostate brachytherapy among 448 low-risk patients treated with ^{125}I implantation. Phan et al.[344] reported a 4% incidence of grade 2 rectal toxicity after permanent interstitial implantation and <1% incidence of grade 3 toxicity. In general, the incidence of grade 2 rectal toxicity after prostate brachytherapy ranges from 4% to 12%. Grade 3 or 4 rectal toxicity is unusual (<2%). Grade 2 symptoms manifest as rectal bleeding or increased mucous discharge. The onset of symptoms often peaks at 8 to 12 months and is self-limited in nature. Several reports noted that rectal bleeding is associated with the rectal dose and its volume exposed to a particular dose. Snyder et al.[297] noted that the rectal volume in cubic centimeters exposed to the prescription dose of 160 Gy correlated with the incidence of grade 2 proctitis. For patients with 0.8 cm^3 or less of rectal volume exposed to the prescription dose, no patient developed proctitis; from 0.8 to 1.8 cm^3, approximately 8% of patients developed rectal bleeding. However, among patients with >1.8 cm^3 of the rectal volume exposed to 160 Gy, 25% of patients developed rectal toxicity. The American Brachytherapy Society recommends that rectal dose constraints should be maintained to restrict the dose to 1 cm of the rectum to the prescription dose or less to reduce the risk of rectal toxicity after brachytherapy.[345]

Erectile Function

Erectile dysfunction after brachytherapy has been reported to occur in from 20% to 80% of patients. The age of the patients, baseline function, and the presence of medical comorbidities play an important role in the likelihood of maintaining durable erectile function after therapy, as described earlier after EBRT. Stone et al.[346] noted a 62% potency preservation based on a patient questionnaire among patients who underwent brachytherapy and were potent prior to treatment. The median follow-up in that cohort was 7 years. Investigators from the Princess Margaret Hospital in Toronto reported a 93% of patients with good erectile function whose baseline function was considered potential prior to therapy.[347] In that cohort, 45% of patients who were potent after therapy required a phosphodiesterase inhibitor to maintain adequate posttreatment function.

The impact of short-course ADT in conjunction with brachytherapy on long-term erectile function is unclear. Some reports suggested that ADT produces only temporary deterioration in sexual function and with testosterone recovery the function returns.[348] Data from MSKCC suggest that the use of short-course ADT for the purpose of volume reduction among patients treated with brachytherapy was not associated with a higher incidence of ED compared to patients treated with brachytherapy alone.[243]

Taira et al.[349] evaluated posttreatment erectile function after brachytherapy in 226 men with adequate preimplantation erectile function. Adequate baseline function in this report was defined as an International Index of Erectile Function (IIEF-6) of >13 without pharmacologic support. The 7-year incidence of maintained erectile function was 56%. Posttreatment function depended on baseline pretreatment sexual function. Among patients with baseline IIEF scores of ≥24 and 18 to 23, the incidence of long-term erectile function preservation was 75% and 52%, respectively. Although not significant in a multivariate analysis, these investigators noted that higher doses delivered to 25% of the penile bulb created an added detrimental effect on long-term erectile function, especially among those baseline potent patients with lower IIEF scores or those who were of older age at the time of treatment. Excellent responses were observed with sildenafil citrate in the treatment of posttreatment impotence after brachytherapy, with response rates up to 85%.[350,351]

POSTIRRADIATION PROSTATE-SPECIFIC ANTIGEN

A transient increase of PSA during radiation therapy, even as soon as the first fraction, has been reported in some patients.[352,353] Because there is no prognostic significance to the PSA response during a course of radiation therapy, obtaining PSA levels during treatment is not necessary or recommended. PSA fluctuations are common in the follow-up period and have been termed *PSA bounce*. In one report,[354] 35% of patients after combined permanent interstitial implantation and EBRT experienced a transient rise in their PSA value after treatment. The median time from treatment to this bounce effect was 18 months, and 92% of the fluctuating levels were observed during the first 26 months after radiation therapy. These investigators reported fluctuations ranging from 0.11 to 15.8 ng/mL. Similar results have been reported by Cavanagh et al.[355] for patients treated with implantation alone or when combined with EBRT. Hanlon et al.[356] observed a PSA bounce effect in approximately one-third of patients treated with EBRT alone. In that series, the 5-year biochemical control rate for patients who experienced a PSA fluctuation was inferior to that in those patients who did not have a PSA bounce in their follow-up period (69% vs. 52%; $P = .02$). On the other hand, investigators from the MD Anderson Hospital[357] noted that, of 964 patients treated with EBRT, only 12% experienced a PSA bounce, and the 5-year PSA outcome was superior for those patients who experienced this PSA fluctuation compared with those who did not (82% vs. 58%; $P = .0001$).

Ciezki et al.[358] defined PSA bounce as an increased PSA level of at least 0.2 ng/mL greater than the nadir PSA with a subsequent PSA value declining back to the nadir level or lower. One hundred sixty-two patients were treated with a permanent ^{125}I implantation and followed for a minimum of 5 years. With this as the definition of a PSA bounce, almost half of the patients (46%) experienced this phenomenon. The authors observed that the patients who experienced this fluctuation were more likely to be younger and less likely to develop a biochemical relapse. The authors also noted that PSA bounces generally occurred much sooner after treatment than did a true PSA relapse. The median time to the first rise in PSA from the nadir was 15 months, compared with 30 months for an ASTRO-defined biochemical relapse or 22 months for a nadir +2-defined relapse. Other reports define PSA bounce in various ways, and for this reason, the literature needs to be interpreted with caution.[359]

Although a low absolute PSA level or nadir value after radiation therapy has

prognostic significance for improved disease-free survival, it is difficult to assign a specific PSA cut-point or nadir level as a definition of biochemical relapse. Currently, the nadir + 2 definition (a rise by ≥2 ng/mL above the nadir PSA) is considered the standard definition for biochemical failure after EBRT with or without hormonal therapy. A consensus panel[360] also recommended that the date of failure be determined "at call" (not backdated). Several studies examined the significance of posttreatment PSA doubling time (PSADT). Following prostatectomy, in a single-institution experience, Pound et al.[361] noted that, for patients treated with RP, PSADT of <10 months predicted the development of metastatic disease. Zelefsky et al.[362] reported on the impact of PSADT in a cohort of patients who developed biochemical relapse after EBRT. The PSADT for favorable-, intermediate-, and unfavorable-risk patients who developed a biochemical failure was 20.0, 13.2, and 8.2 months, respectively ($P < .001$). The 3-year incidence of DM for patients with PSADT of 0 to 3, 3 to 6, 6 to 12, and >12 months was 49%, 41%, 20%, and 7%, respectively ($P < .001$). Patients with PSADT of 0 to 3 and 3 to 6 months demonstrated a 7.0 and 6.6 increased hazard of developing distant metastases or death, respectively, compared with patients with a doubling time of >12 months. Freedland et al.[363] noted that PSADT of <9 months correlated with prostate cancer–specific mortality but did not evaluate postprostatectomy PSADT as a surrogate for cause-specific survival. Using larger, multi-institutional databases, Albertsen et al.[180] and D'Amico et al.[364] noted that short PSADT correlated with an adverse effect on survival in patients treated with either prostatectomy or radiation therapy for prostate cancer.

Emerging data strongly correlate a rising PSA level with positive postirradiation prostate biopsies. Crook et al.[365] reported on 226 patients treated with conventional EBRT who underwent serial biopsies after treatment. At 13 months after radiation therapy, the incidence of a positive biopsy was 51%, but it decreased to 30% for biopsies obtained at 30 months. Posttreatment biopsies require an experienced pathologist to interpret because of the significant radiation effect that takes place in the prostate, which can easily be mistaken at times for residual disease. Immunohistochemical staining for high molecular weight keratin can often distinguish radiation atypia in benign glands from residual tumor.

Other Innovative Treatment Modalities

Recent developments in staging, predictive genomic testing, MP-MRI, and treatment techniques succinctly discussed on subsequent sections of this chapter,

are influencing the management of patients with localized prostate cancer, including those in the low-risk group that opt for definitive treatment at diagnosis or who initially, in an active surveillance program, eventually require intervention because of tumor progression.

Genomic Testing and Molecular Biomarkers

The Genomic Prostate Score (GPS), based on the OncotypeDX Prostate Cancer assay, ranges from 0 to 100, with increasing scores indicating more biologically aggressive disease. Previous studies have validated it as a predictor of adverse pathology and BCR after RP. Van Den Eeden and colleagues[366] retrospectively assessed how the GPS predicted distant metastases and prostate cancer–specific death in 259 men with localized prostate cancer treated with RP between 1995 and 2010. During a median follow-up of 9.8 years, 64 prostate cancer–specific deaths, 79 metastatic events, and 117 BCRs occurred, according to an European Urology online report (Oct 6, 2017). Each 20-point increase in GPS was associated with a 2.34-fold increased risk of distant metastases, a 2.69-fold increased risk of prostate cancer–specific death, and a 2.11-fold increased risk of BCR, after adjustment for other variables. Among the four biologic pathways represented in the GPS, down-regulation of androgen signaling and up-regulation of stromal response gene groups were most strongly associated with each outcome, although all four gene groups contributed to the prediction. The score predicted all three outcomes within clinically relevant subsets of patients by NCCN risk groups, age, race, and central biopsy Gleason score. One of the authors noted that “it was unclear which subset of patients might benefit most from this test, because men with low-risk prostate cancer have very high 10-year survival, and those with high-risk cancer are usually recommended for treatment. Furthermore, our study was limited to patients who had undergone RP, and it is unknown how the test may perform for those treated with radiation therapy or who undergo active surveillance.” The authors commented that “several other genomic assays exist and have been validated to predict the risk of death from prostate cancer. In addition, other refined risk prediction tools include advanced imaging, such as multi-parametric MRI, that allows for more accurate clinical staging. Comparative studies are currently lacking, and may be increasingly important as we seek to understand how best to evaluate patients with newly diagnosed prostate cancer.”

Prolaris is a panel of RNA cell cycle progression (CCP) genes measuring cancer proliferation. The primary endpoint of this test is the 10-year risk of

prostate cancer death with conservative management. Cuzick et al.[367] examined the biopsy specimens from 761 men diagnosed with prostate cancer who were managed conservatively. After adjusting with PSA and Gleason score, CCP score was a significant predictor of prostate cancer death [hazard ratio (HR 1.65).

The Prolaris test measured on biopsy has also been shown to predict outcomes after radical treatment. Freedland et al.[368] reported on 141 men diagnosed with prostate cancer who received external beam radiation. CCP score was a significant predictor of BCR (HR 2.11, $P = .034$) after adjusting for PSA, Gleason score, positive cores, and use of hormonal therapy. There was also a statistically significant relationship with prostate cancer death on univariate analysis, but the number of events was small. Similarly, Bishoff et al.[369] showed that biopsy CCP scores were a significant predictor of BCR after RP (HR 1.47) in a multi-institutional cohort. It was also a significant predictor of metastatic disease on univariate analysis. Another recent study by Oderda et al.[370] in 52 Italian men treated by RP showed that mean Prolaris scores were −1.2, −0.444, and 0.208 in low-, intermediate-, and high-risk patients. Prolaris was a significant predictor of high-risk disease (odds ratio [OR], 5.73). Prolaris was also significantly associated with BCR on univariate but not multivariate analysis, although there were only 15 events.

Clinical utility studies have been performed using surveys, such as shown by Shore et al.[371] who surveyed 15 urologists about the influence of Prolaris results in 294 different cases, and they reported that approximately one-third of the results would potentially lead to changes in practice. Another study by Crawford et al.[372] reported changes from interventional to noninterventional management, and vice versa due to Prolaris results. Less is known about the long-term impact of changing initial management decisions on the basis of genomic test results or how these tests fit in a context with widespread MP-MRI use.

The Ontario (Canada) Technology Assessment[373] conducted a systematic review of the clinical and economic evidence of the CCP test in low- and intermediate-risk, localized prostate cancer in a medical and health economic databases search from 2010 to June or July 2016. For the review of clinical effectiveness, 3,021 citations were screened, and two before–after studies met their inclusion criteria. In one study, the results of the CCP test appeared to change the treatment plan (from initial to final plan) in 64.9% of cases overall (GRADE rating of the quality of evidence: very low). In the other study, the CCP test changed the treatment received in nearly half of cases overall, compared with the initial plan (GRADE: very low). No evidence was available on clinical

outcomes of patients whose treatment was informed by CCP results. For the review of cost-effectiveness, 100 citations were identified and screened and no studies met the inclusion criteria. Patients viewed the test as potentially helpful but, because of the complexity of treatment decision-making, were unsure the test would ultimately change their treatment choices. The study found no evidence to demonstrate the impact of the Prolaris CCP test on patient-important clinical outcomes. The limited evidence available showed that the test appeared to provide information that, when considered in addition to clinical risk stratification, may change the treatment plan or actual treatment for some low- and intermediate-risk prostate cancer patients, but there are insufficient data to assess the cost-effectiveness of the CCP test.

The *OncotypeDx* prostate biopsy test calculates a GPS based on genes from four different pathways involved in prostate cancer: stromal response, androgen signaling, proliferation, and cellular organization. The primary endpoint of this test is to predict the risk of adverse disease at RP. Unlike Prolaris and Decipher (in postprostatectomy patients), OncotypeDx was designed for use with biopsy tissue and does not have a commercially available test for postprostatectomy risk stratification.

Klein et al.[374] defined the 17-gene panel for use in the OncotypeDx GPS and tested it in the biopsies of 395 men with low- to intermediate-risk prostate cancer. A 20-unit increase in GPS was associated with a significantly increased risk of high-grade and/or high-stage disease (OR 2.1; 95% CI = 1.4 to 3.2), after adjusting for the CAPRA score. Adding in a GPS measurement improved the discrimination of adverse disease compared with that of the CAPRA risk classification alone (area under the curve (AUC) 0.67 vs. 0.63). Cullen et al.[375] subsequently validated the OncotypeDx biopsy test in independent populations of men from military hospitals. On multivariable analysis adjusting for National Comprehensive Cancer Network (NCCN) risk group, a 20-unit increase in OncotypeDX GPS associated with 3.3× increased risk of adverse disease at RP and 2.7× increased risk of BCR. Badani et al.[376] reported that the GPS was discordant to the NCCN risk category in 39% of patients and that 18% of recommendations between active surveillance and treatment changed as a result of OncotypeDx. Clinicians also reported that the results increased their confidence in decisions.

Ehro et al.[377] using a transcriptome-wide assay developed a biomarker signature for patients assessed as low risk at diagnosis who are upgraded or upstaged following RP. Gene expression data of 56 RP samples from the

Memorial Sloan Kettering Oncogenome Project (GSE21034) that met the low-risk criteria (i.e., biopsy Gleason score (GS) ≤ 6, clinical stage T1 or T2A, and preoperative PSA (preop PSA) ≤ 10 ng/mL) were used. Of these tumors, 31 underwent upgrading or upstaging (defined by pathologic GS ≥ 7 or a pathologic tumor stage > T3A). In the training set (n = 29), a median fold difference filter (MFD > 1.4) was applied to select features. The top 16 t-test ranked features were modeled with a K-nearest neighbor (KNN) classifier (k = 3), which predicted upgrading/upstaging events. The KNN was applied to the test set (n = 27) and achieved an area under the receiver operating characteristic curve (AUC) of 0.93, significantly better discrimination than preop PSA (AUC = 0.52) or tumor stage (AUC = 0.63). Compared to the null model's accuracy of 56%, the KNN correctly predicted 81% (P < .005) of the upgrading/upstaging events. In multivariable analysis with preop PSA, tumor stage, and age at diagnosis, the KNN remained the only significant (P < .05) factor with an odds ratio of 2.7. Validation studies of this signature in prospectively designed cohorts of active surveillance candidates have been underway to determine if the molecular signature can improve treatment and management decisions for low-risk PCa patients.

Multiparametric Magnetic Resonance Imaging (MP-MRI)

MP-MRI can visualize prostate tumor characteristics (extraprostatic extension (ECE), tumor volume, etc.) that can be predictive of final pathologic findings such as lymph node (LN) involvement, pathologic ECE (pECEs), and BCR, all pivotal factors in the decision-making process regarding treatment. Tumor contact length (TCL) is defined as the length of cancer in contact with the prostatic capsule. Kongnuyun et al.[378] evaluated the ability of 3T MP-MRI–determined TCL in predicting pECE, BCR, and LN in patients undergoing RP. All 1,260 patients who underwent a 3T MP-MRI at the NCI from 2007 to 2015 were retrospectively classed into no ECE, suspicious ECE (sECE), and frank ECE (fECE) based on MP-MRI findings. sECE was defined as tumor with capsular bulge on MRI, whereas fECE was clear capsular obliteration and tumor extension beyond the prostatic capsule. Demographic data were obtained on patients with fECE and sECE on MP-MRI with the presence of pECE, LN, and BCR status following RP from a single surgeon (PP) experience. The authors focused on 146 patients who had sECE (68) or fECE (78) on MP-MRI. Median PSA was 11.7 ng/mL. Logistic regression analysis showed that MP-MRI–determined TCL was predictive of ECE (P = .01), LN status (P = .0001) on final

pathology, and BCR (P = .05) during follow-up. Patients with pECE had a longer median MP-MRI TCL (2.8 cm) compared to those without pECE (2.4 cm), P = .04. When analyzed individually, fECE correlated with pECE (P = .05), whereas s ECE did not correlate with pECE (P = .11). Although not statistically significant, the median MP-MRI TCL for sECE with pECE was still longer than in sECE with no pECE in the subgroup analysis.

Stereotactic Body Radiation Therapy

There has been increasing interest in the use of stereotactic body radiation therapy (SBRT) for the treatment of low- and intermediate-risk prostate cancer. SBRT has been used primarily in patients with low- (favorable) and intermediate-risk tumors. The main advantage is that the treatment, based on image-guided approaches with narrow margins, is delivered in 5 fractions (750 to 800 cGy per fraction), with lower doses to adjacent organs at risk, more convenient for the patient. Biochemical control has been comparable to standard IMRT and treatment morbidity has been low.

Freeman and King[379] reported the outcomes of 41 patients who were treated with SBRT to doses of 35 to 36.25 Gy in five fractions and followed for a median of 5 years. The 5-year PSA relapse–free survival outcome was 93%. The incidence of grade 2 late rectal and urinary toxicity was 2.5% and 7%, respectively. The incidence of grade 3 rectal and urinary toxicity was 0% and 2.5%, respectively. Katz et al.[380] reported on 304 patients with a limited follow-up of 2.5 years who were treated with 35 to 36.25 Gy. Among 206 patients with a minimum follow-up of 12 months, the incidence of grade 2 urinary and rectal toxicity was 5.8% and 2.9%, respectively. One late grade 3 urinary toxicity has been observed. No information was available regarding biochemical tumor control because of the limited follow-up observations in this report.

Boike et al.[381] recently reported the preliminary outcomes of a phase I dose escalation study for low- and intermediate-risk prostate cancer using SBRT. Cohorts of 15 patients were prospectively dose escalated from 45 to 50 Gy in 9-, 9.5-, and 10-Gy fractions. In these patients, a rectal balloon was routinely used to separate the posterior and lateral walls of the rectum and reduce the volume of rectal tissue exposed to the high doses of therapy. Patients were treated every other day to further reduce toxicity, as has been demonstrated in the Stanford experience with SBRT. The overall grade 2 and 3 rectal toxicities observed were 18% and 2%, respectively. The overall grade 2 and 3 urinary toxicities observed were 31% and 4%, respectively. In the 50-Gy dose cohort, two patients

developed grade 3 cystitis, which developed approximately 1 year after therapy, and one patient developed a grade 4 rectal injury. At MSKCC, a phase I dose escalation study has been underway in which patients with low- and intermediate-risk prostate cancer are being treated with SBRT using image-guided IMRT with margins of 5 mm around the prostate except at the prostate–rectal interface, where a 3-mm margin is used. Intrafraction tracking with a ferromagnetic marker is used for all patients, and the beam is interrupted upon organ motion exceeding 2 mm from the start position. The initial dose arm included 20 patients treated to 32.5 Gy in five fractions and subsequently to 35 Gy in five fractions. Patients are being treated to 37.5 Gy in five fractions with a final dose arm of 45 Gy in five fractions. Toxicity outcome is the primary endpoint, with a secondary endpoint of tumor control based on posttreatment biopsies performed at 2 years.

Katz and Kang[382] reported on 515 patients with organ-confined prostate cancer (471 T1c and 44 T2a, all N0M0) who received robotic radiosurgery SBRT. Mean PSA was 6.48 ng/mL; 343 were low-risk, 134 intermediate-risk and 38 high-risk. ADT was administered to 70 patients. One hundred fifty-eight patients received 3,500 cGy delivered in 5 daily fractions. The remaining patients, from all risk groups, received a total dose of 3,625 cGy in 5 daily fractions. At a median follow-up of 54 months (range, 9 to 79 months), 40 patients died of other unrelated causes and 33 were lost to follow-up. The median PSA at 60 months was 0.11 ng/mL. Biochemical failures occurred for 8 low-risk patients (none locally), 9 intermediate-risk patients (one locally), and 9 high-risk patients (2 proven local failures). The actuarial 6-year freedom from biochemical failure was 97.4%, 92%, and 70.4%, for the low-, intermediate-, and high-risk groups ($P < .001$). Late RTOG toxicity was mild with 4% grade 2 rectal, 7.8% grade 2 urinary, and 1.4% grade 3 urinary (all with 36.25 Gy). Late grade 2 urinary toxicity for 35 Gy was 5.1% versus 9.9% for 36.25 Gy. Sexual QOL declined by 23% at 6 to 12 months where it remains. Seventy-four percent and at 8 years 62% of the patients potent at baseline remain potent.

Meier et al.[383] described results in 309 patients with biopsy-proven adenocarcinoma of the prostate 172 low-risk (CS T1-T2a, Gleason 6, PSA < 10 ng/mL) and 137 intermediate-risk (CS T1c-T2b with either Gleason score 7 and PSA < 10 ng/mL or Gleason 6 and PSA between 10 and 20 ng/mL) treated with a nonisocentric robotic SBRT using real-time tracking of implanted fiducials, at 21 community, regional, and academic hospitals. The prostate dose was 40 Gy in 5 fractions of 8 Gy and seminal vesicles received 36.25 Gy. Normal tissues were

rigidly constrained (rectal V_{36Gy} <1 cc; bladder V_{37Gy} <5 to 10 cc). No patient had concomitant or adjuvant androgen ablation therapy. Median follow-up was 61 months. Five grade 3+ toxicities (1.6%) were reported, far below the 10% rate deemed excessive. There were no grade 4 or 5 toxicities. All reported grade 3 GU toxicities occurred between 11 and 51 months after treatment. Five patients (1.6%) developed urinary retention, which required a temporary catheter placement. Seven patients were diagnosed with bladder cancers between 21 and 50 months after treatment. For the entire population, actuarial 5-year overall survival was 95.6%. Actuarial 5-year nadir +2 RFS was 97.1% for all patients and was 97.3% and 97.1% for the low- and intermediate-risk groups, respectively. Actuarial 5-year ASTRO RFS was 92.3% and 91.3% for these respective risk groups.

Dess et al.[384] evaluated sexual potency preservation in 830 men treated with SBRT in a prospective trial at a single institution. Prospective Health-Related Quality of Life (HRQOL) data were collected via the EPIC-26, including five major domains of urinary irritative, urinary incontinence, bowel, sexual, and hormonal.

The median age was 69 years old, 25% were low risk, 57% were intermediate risk, and 18% were high risk. Twenty percent received ADT and 16% received supplemental standard fractionation radiation in addition to SBRT for higher-risk features. With a best possible score of 100, the mean baseline urinary irritative, urinary incontinence, bowel, sexual, and hormonal scores were 91, 87, 95, 53, and 92, respectively. Depending on the time point post-SBRT, between 10% and 15% of patients had 1× MID multidomain decline, and 1% to 5% of patients had 2× MID multidomain declines. On multivariable analysis, early toxicity in urinary incontinence, bowel, and hormonal domains predicted 3- and 12-month multidomain declines, with no consistent predictors at 2-, 3-, and 5-year time points.

Johnson et al.[385] evaluated bowel, urinary, and sexual patient-reported quality of life following treatment for prostate cancer with either moderately hypofractionated radiation therapy (<5 Gy/fraction) or SBRT (5 to 10 Gy/fraction). Three hundred and seventy-eight men who underwent moderate hypofractionation were compared to 534 men treated with SBRT.

After 1 year, patients receiving moderate hypofractionation were more likely to experience worsening in bowel symptoms (39.5%) when compared to SBRT (32.5%; P = .06), with a more substantive difference at 2 years (37.4% vs. 25.3%, respectively, P = .002).

Similarly, patients receiving moderate fractionation had worsening urinary symptom score compared to patients who underwent SBRT at 1 and 2 years (34.7% vs. 23.1%, $P < .001$; and 32.8% vs. 14.0%, $P < .001$, respectively). Patients receiving moderate hypofractionation had more frequent worsening in sexual symptom score, although the difference was nonsignificant at either 1 or 2 years (32.7% vs. 29.1%, $P = .30$; and 38.5% vs. 33%, $P = .18$, respectively). After adjusting for age, and cancer characteristics, patients receiving moderate hypofractionation were more likely to experience worse urinary symptoms scores than patients receiving SBRT at 2 years (OR 0.24; 95% CI = 0.07 to 0.79); there was no difference in likelihood of worsening bowel or sexual symptoms scores between groups at 1 or 2 years in the adjusted analysis.

Greco et al.[386] evaluated 86 hormone-naïve patients with low- and intermediate-risk PCa and an IPSS score <15 who were recruited to a phase I/II study of extreme hypofractionated IGRT to assess feasibility of urethral and rectal sparing. Minimum follow-up was 12 months. CT/MR fusion was used to delineate the CTV and organs-at-risk. Beacon transponders were placed inside the urethra via a preloaded Foley catheter at the time of simulation. Mean CTV was 49 cc (range 31 to 95) and CTV to PTV margin was 2 mm in all directions. The prescription dose was 9 Gy in five fractions delivered over 5 consecutive days. With a 2-mm expansion around the catheter, dose optimization was implemented to fulfill $D_{1cc} < 36$ Gy. Patients were treated with 10 MV FFF VMAT and an endorectal balloon (air filling of 150 cc) was used to mitigate prostate motion. Accurate patient setup was assisted by beacon transponders and confirmed by CBCT before treatment. Online tracking was used to monitor intrafractional motion, with a tolerance threshold of 2 mm in all directions. Quality of life was assessed using the Expanded Prostate Cancer Index Composite (EPIC-26) at baseline, 1 week, 1 month, every 3 months for the first year, and every 6 months thereafter. Patient compliance to treatment was excellent with all treatments completed in five consecutive sessions. Beacon transponders-detected target motion was compatible with the prescribed 2-mm CTV-PTV expansion. Median follow-up was 20 months (range, 12 to 31). Mean PSA at baseline was 9.2 ng/mL, reduced to 1.5, and 0.4 ng/mL at 12 and 24 months, respectively. There was 2.4% acute G2 urinary toxicity and no instances of acute G2 bowel toxicity.

Blacksburg et al.[387] reported on 773 patients with prostate cancer treated with robotic SBRT (35 Gy in 5 daily fractions) without the use of ADT. Mean age was 67 years; 43.2%, 47.7%, and 9.1% of patients had low-, intermediate-, and

high-risk disease by NCCN risk stratification. The Gleason score was 6 in 50.5%, 7 in 42.0%, and 8 to 10 in 7.5%. The median pretreatment PSA was 5.73 ng/mL (range 1.2 to 68.18): At 30 months, the median PSA was 0.36, 0.41, and 0.40 ng/mL in low-, intermediate-, and high-risk patients. Despite a convergence in absolute PSA values at this time point, the shape of posttreatment PSA curves prior differs considerably based on Gleason score and initial PSA. At 12 months, 42.2%, 50.0%, and 70.8% of patients with low-, intermediate-, and high-risk disease have a PSA that has declined by at least 80% ($P < .0001$). 44.3%, 50.3%, and 66.7% of patients with Gleason scores 6, 7, and 8 to 10 experience this decline at the same time point ($P = .007$). 44.5% of patients with an initial PSA <10 ng/mL experience this decline as compared to 70.9% of those with an initial PSA >10 ng/mL ($P < .0001$).

Proton/Heavy Ion Particle Therapy

Proton or heavy ion therapy in localized prostate cancer is controversial. The main advantage of these modalities is that, because of their physical characteristics, the dose to the target in depth is optimized, with less radiation dose delivered to the normal structures in front and behind the target (bladder and rectum) and potential for dose escalation. Lee et al.[388] conducted a comparison of treatment plans in 27 prostate cancer patients treated at their proton center. Each patient had a photon IMRT backup plan independently designed. For comparison, opposed lateral proton beams were used to account for proton beam range uncertainties. All plans were designed to give 75.6 Gy or Cobalt Gray Equivalent (CGE) in 42 fractions to the entire CTV. Of these 27 pairs of clinically accepted plans, the mean doses to the prostate were 78.5 Gy for IMRT and 77.9 CGE for protons. On dose–volume histograms (DVH), the rectal wall dose was essentially identical for both plans between 45 to 73 Gy, but the proton plans were lower at doses lower than 45 Gy. The integral body dose was almost identical for doses higher than 50 Gy, but proton plans spared body dose below 30 Gy, which may be significant when considering the large absolute volume of tissue irradiated. The bladder wall DVHs were similar over 35 Gy (curves not shown for space). The proton plans gave a slightly higher dose between 40 and 75 Gy (maximum difference was at 60 Gy: 13.7% for IMRT and 16.2% for proton), but bladder wall dose <35 Gy was lower for proton plans. The proton treatment plans were almost identical to IMRT plans for target coverage and for normal tissues in higher-dose regions (i.e., >45 Gy); however, tissue sparing at lower doses was seen in all proton plans.

In a report by Choi et al.[389] comparing intensity-modulated proton therapy (IMPT) with scanning beam protons (PSPT) for the treatment of prostate cancer, the authors noted that IMPT significantly decreased the dose given to the rectum and the anterior rectal wall without sacrificing target coverage. This improvement was seen at all dose levels analyzed. The study showed that IMPT with scanning beam proton therapy offers an improved method of treating patients who need treatment to their prostate and seminal vesicles (i.e., patients with intermediate- and high-risk prostate cancers) over conventional passively scattered proton beam radiation therapy.

Biochemical and tumor control with protons or heavy ions is comparable to the results of dose escalation with IMRT/VMAT. The main benefit is in a lower rectal or urinary toxicity with protons, which has been reported as 1% to 2%.

In the absence of randomized trials comparing efficacy and toxicity to high-dose photon therapy, there is no cogent evidence supporting its superiority over other forms of EBRT. Investigators from Loma Linda reported the initial tumor-control outcomes and toxicity in 1,277 patients treated with early-stage disease with 74 CGE.[390] The authors noted excellent PSA relapse–free survival outcomes and low risks of late toxicity, although these findings appeared to be comparable to outcomes currently achieved with high-dose IMRT photon therapy. It should be noted that the Proton Radiation Oncology Group 95-09 randomized trial, which randomized patients to receive 79.2 CGE of proton therapy compared to 70.2 CGE, was testing the advantage of dose escalation. This study did not attempt to compare proton to photon therapy. Such a randomized trial is essential to elucidate the role of protons in the management of localized prostate cancer.

In a study of men treated with proton beam therapy (PBT) +/− ADT for localized prostate cancer enrolled on a prospective registry trial, patients received 75.6 Gy (RBE) in conventional fractionation; 344 men received proton scattered therapy(PSPT) and 79 IMPT. Both PSPT and IMPT confer favorable rates of grade 2 GI or GU toxicity with preservation of clinically meaningful sexual, urinary, and hormonal QOL at 48 months.

Takagi et al.[391] reported on 1,375 patients treated in Japan with protons for prostate cancer. The median follow-up period was 70 months (range, 4 to 145 months). For all patients, the 10-year overall survival (OS) and bRFS were 89.2% and 77.0%, respectively. The 10-year bRFS rates were 94.5%, 82.6%, 63.3%, and 45.5% for the low-, intermediate-, high-, and very high-risk groups, respectively. The cumulative grade 2 or greater late GI and GU toxicity rates

were 4.1% and 5.4%, respectively.

Mendenhall et al.[392] reported on 211 prostate cancer patients treated with proton therapy (PT), 89 low-risk patients received 78 CGE in 39 fractions to the prostate, 82 intermediate-risk patients received 78 to 82 CGE on a dose escalation trial to the prostate and proximal seminal vesicles, and 40 high-risk patients received 78 CGE in 39 fractions with weekly concomitant docetaxel and 6 months of ADT. Twenty (22%) of the low-risk patients were “very low” risk according to recent National Comprehensive Cancer Network (NCCN) guidelines, and 28 (34%) of the intermediate-risk patients were unfavorable with PSA > 15, clinical stage T2C, or Gleason score 4 + 3. The median time of follow-up is 5.2 years (range, 0.1 to 6.0). Sixty-five patients required pre-PT urologic symptom management. Clinical and biochemical-free survival rates at 5 years for low-, intermediate-, and high-risk patients are 99%, 99%, and 76%, respectively, whereas overall survival rates are 93%, 88%, and 90%. Using Common Terminology Criteria for Adverse Events version 3.0 toxicity criteria, grade 3 GI toxicity has occurred in 1.4% of all patients and grade 3 GU toxicity in 5.3%. Patient-reported outcomes, including International Prostate Symptom Score (IPSS) and Expanded Prostate Index Composite-26 bowel, urinary continence, and urinary irritability, and sexual summary scores, have been excellent. Median pretreatment and 5-year posttreatment IPSS scores are 8 and 7. Median pretreatment and posttreatment 5-year scores are 95.8 and 93.8 for bowel summary, 100.0 and 100.0 for urinary continence, 93.8 and 93.8 for urinary irritability, and 61.0 and 40.2 for sexual summary.

Choi et al.[393] published a study of the combination of two prospective single-institution cohorts of prostate cancer patients treated with proton therapy. Outcomes were presented according to NCCN risk group. From 2006 to 2015, 1,869 prostate cancer patients were treated using proton therapy in these two cohorts, out of which 1,628 (87%) had sufficient follow-up for inclusion in the present analysis (low-risk [LR] 516, 31.7%, intermediate-risk [IR] 978, 60%, high-risk [HR] 134, 8.2%). Proton therapy delivered a median dose of 76 (range 75.6 to 78) Cobalt Gray Equivalent (CGE) in 2 CGE fractions according to risk group. Pelvic lymph nodes were not treated. Hormonal therapy was mostly used for IR (56.7%) and HR (96.3%) patients. The median follow-up was 4.1 years for the entire cohort and 4.4, 4.1 and 3.1 years for LR, IR, and HR patients, respectively. Two-/five-year overall survival rates were 100%/98.0% for LR, 99.2%/95.9% for IR and 99.2%/87.0% for HR (P = .004 for the differences between groups). Forty-four patients had died, of which twenty (45%) died

because of prostate cancer (5-year prostate cancer–specific survival of 98% with no difference between groups, *P* = .1).

Five-year bPFS rates were 95.7%, 92.3%, and 80.7% for LR, IR, and HR, respectively (*P* = .0001) Five-year cPFS rates were 95.9%, 92.7%, and 78.0% for LR, IR, and HR, respectively (*P* = .0001).

Acute grade 2+ GU and GI toxicity occurred in 39.4% (*n* = 641) and 5.2% (*n* = 85) of the entire cohort, with only two grade 3 GU and no grade 3 GI toxicity. Five-year cumulative incidence of late grade 2+ GU and GI toxicity, defined as occurring 90 days or more after treatment, was 15.9% and /10.6%, respectively.

Late grade 3 and 4 GU toxicity occurred in 0.6% (*n* = 9) and 0.1% (*n* = 1) of patients, respectively, and late grade 3 and 4 GI toxicity occurred in 0.6% (*n* = 10) and 0.1% (*n* = 1) of patients, respectively.

Vargas et al.[394] reported on 82 patients with low-risk prostate cancer randomized to 38 Gy RBE in 5 treatments (*n* = 49) versus 79.2 Gy RBE in 44 treatments (*n* = 33). Randomization patient allocation scheme was 2:1 favoring the 38-Gy RBE arm. Proton therapy was administered using fiducial markers and daily image guidance. MRI registration for target delineation was mandatory for all cases. Adverse events (AE), Expanded Prostate Index Composite (EPIC) domains, and AUA were evaluated at various times. Median follow-up for both groups was 18 months, with 33 patients reaching follow-up of 2 years or more. Patient characteristics for both groups were similar, with most patients being T1c (84%) and all having a Gleason score of 6 and a PSA level of <10 (median, 5.6). Baseline median AUA was 5 for the 38-Gy RBE arm (range, 0 to 15) and for the 79.2-Gy RBE arm (range, 0 to 14). There was no difference between the 2 groups with regard to Expanded Prostate Index Composite (EPIC) urinary, bowel, or sexual function scores at 3, 6, 9, 12, 18, or 24 months.

The only significant difference was the International Prostate Symptom Score at 12 months, 8 for the 38-Gy RBE arm versus 5 for the 79.2-Gy RBE arm (*P* = .039), but there was no difference in the AUA scores at the other time points. No grade 3 or higher AEs were seen in either arm.

Ho et al.[395] at the same institution described quality of life in 255 men 60 years old and younger (143 low-risk, 106 intermediate-risk, and 6 high-risk patients) treated with definitive proton therapy for prostate cancer without ADT. Follow-up included serum PSA levels performed every 3 to 6 months with annual examinations by physicians.

Median follow-up was 5 years and 58% of men had 5-year Expanded Prostate Index Composite (EPIC) follow-up. The 5-year biochemical-free survival and

overall survival rates were 98.6% and 99.2%, respectively. All three patients with biochemical progression (one high-risk and two intermediate-risk) were alive at 5 years without clinical progression, and none of the deaths were prostate cancer related.

Within the EPIC subscales, the urinary irritative/obstructive mean score initially declined from a baseline of 90 to 88 at 2 years that maintained for subsequent years. For the urinary incontinence mean score, a similar decline was noted from a baseline of 96 to 93 at 2 years that remained stable for subsequent years; additionally, only 1.4% of men required a pad at 2 years, which is unchanged at 5 years after treatment. The bowel habits mean score initially declined from a baseline of 96 to 88 at 1 year, which subsequently improved to 93 by the 5-year follow-up. The sexual mean score declined from a baseline of 84 to 69 after 2 years, which then stabilized for the subsequent years. Further, the potency rate declined rapidly from 90% to 71% over the first 2 years and then leveled off at 66% in the following 3 years. On multivariate analysis, only EPIC sexual summary score was a significant factor associated with potency (P = .0002). Five-year potency rates were 88%, 61%, and 40% for baseline sexual summary scores of 100, 99 to 68, and <68 (representing 75th, 50th, and 25th percentile, respectively).

Coen et al.[396] reported a case-matched analysis comparing high-dose EBRT for prostate cancer delivered on Proton Radiation Oncology Group (PROG) 95-09, a randomized trial, with permanent prostate brachytherapy over the same era (1996 to 1999); 196 patients were accrued to the high-dose arm (79.2-Gray equivalent [GyE] using photons and protons) of PROG 95-09 at the Massachusetts General Hospital and Loma Linda University Medical Center. Entry criteria specified T1-T2 and PSA ≤ = 15 ng/mL. When Gleason score >7 was excluded, 177 men were left for case matching. At Massachusetts General Hospital, 203 similar patients were treated by a single brachytherapist from 1997 to 2002. Minimum follow-up was 3 years. Case matching, based on T-stage, Gleason score, PSA, and age resulted in 141 matches (282 patients). Median follow-up was 8.6 and 7.4 years for EBRT and brachytherapy, respectively.

Using the Phoenix definition, the 8-year BF rates were 7.7% and 16.1% for EBRT and brachytherapy, respectively (P = .42). A stratified analysis was performed by risk group. In the EBRT group, 113 and 28 patients were low- or intermediate-risk, respectively. In the brachytherapy group, 118 and 23 were in low- or intermediate-risk groups. When stratified by risk group, the BF rates were similar by either technique.

Habl et al.[397] reported a trial in Heidelberg, Germany, of 92 patients with localized prostate cancer randomized to receive either proton therapy (arm A) or carbon ion therapy (arm B) and were treated with a total dose of 66 Gy (relative biologic effectiveness [RBE]) administered in 20 fractions (single dose of 3.3 Gy [RBE]). Patients were stratified by the use of antihormone therapy. Primary endpoint was the combined assessment of safety and feasibility. Secondary endpoints were specific toxicities, PSA progression–free survival (PFS), overall survival (OS), and quality of life (QoL).

Ninety-one patients completed therapy and have had a median follow-up of 22.3 months. Among acute GU toxicities, grade 1 cystitis rates were 34.1% (39.1% in A; 28.9% in B) and 17.6% grade 2 (21.7% in A; 13.3% in B). Seven patients (8%) required urinary catheterization during treatment because of urinary retention, five of whom were in arm A. Regarding acute GI toxicities, two patients treated with protons developed grade 3 rectal fistulas. Grade 1 radiation proctitis occurred in 12.1% (13.0% in A; 11.1% in B) and grade 2 in 5.5% (8.7% in A; 2.2% in B). No statistically significant differences in toxicity profiles between arms were found. Reduced QoL was evident mainly in fatigue, pain, and urinary symptoms during therapy and 6 weeks thereafter. In conclusion, hypofractionated irradiation using either carbon ions or protons results in comparable acute toxicities and QoL parameters.

Because of the occurrence of gel in the rectal wall and the consecutive occurrence of two rectal fistulas, the authors stopped using the insertion of spacer gel.

Takagi et al.[398] reported on 1,375 consecutive patients treated at their institution between April 2003 and October 2012 with definitive proton therapy; 99% of the patients received 74.0 GyE in 37 fractions, 56% received neoadjuvant hormonal therapy, and 4% received adjuvant hormonal therapy. Patients were stratified by prognostic risk groups based on National Comprehensive Cancer Network (NCCN) criteria. The numbers of patients (%) were 249 (18.1%), 602 (43.8%), 499 (32.7%), and 75 (5.5%) in the low-, intermediate-, high-, and very high-risk groups, respectively. Biochemical failure was defined using the Phoenix consensus definition of the nadir PSA concentration plus 2 ng/mL.

The median follow-up period for the entire cohort was 70 months (range, 4 to 145 months). For all patients, the 5-/10-year OS and bRFS were 96.0%/82.3% and 89.2%/77.0%, respectively. The 5-/10-year bRFS rates were 98.7%/94.5%, 90.8%/82.6%, 85.6%/63.3%, and 65.6/45.5% for the low-, intermediate-, high-,

and very high-risk groups, respectively. The cumulative grade 2 or greater late GI and GU toxicity rates were 4.1% and 5.4%, respectively. In the univariate analysis, anticoagulant drugs (P = .04) and diabetes mellitus (P = .05) were predictive factors for grade 2 late GI and GU toxicities.

Iwata et al.[399] published a retrospective analysis of prostate cancer patients treated with proton therapy at seven centers in Japan between January 2008 and December 2011. The inclusion criteria for this analysis were (a) histologically confirmed prostate cancer, (b) no lymph node or distant metastasis, (c) Japanese men, (d) no prior radiation therapy, (e) no castration-resistant prostate cancer, (f) minimum follow-up of 6 months for surviving patients, and (g) written informed consent.

A total of 2,091 patients were evaluated, 215 in the low-risk, 520 in the intermediate-risk, and 556 in the high-risk groups. The median follow-up period of surviving patients was 69 months (range: 7 to 107). In total, 98.8% of patients were treated using conventional fractionation (1.8 to 2.0 GyE) schedule (70 to 82 GyE/35 to 41 Fr), and 1.2% of patients were treated by hypofractionation schedule (63 to 66 GyE/21 to 22 Fr); 58.5% and 21.5% of patients received neoadjuvant and adjuvant ADT, respectively. The 5-year rates of bRFS and OS in the low-risk, intermediate-risk, and high risk patients were 97.0%, 91.1%, and 83.1% for bRFS and 98.4%, 96.8%, and 95.2% for OS, respectively. The incidence of grade 2 late GI and GU toxicities was 3.6% and 2.6%, retrospectively, but grade 3 toxicities were observed in only 6 and 4 patients, respectively.

Amini et al.[400] queried the National Cancer Database (NCDB) for men with localized (N0, M0) prostate cancer diagnosed between 2004 and 2013, treated with EBRT, with available data on EBRT modality (photon vs. protons-PBT). In total, 143,702 patients were evaluated with relatively few men receiving PBT (5,709 [4.0%]). Patients treated with PBT were generally younger, NCCN low-risk compared to intermediate- or high-risk, and white versus black race (0.66), with less comorbidity, lived in higher-income counties, and were more likely to travel >100 miles to the treatment. Annual PBT utilization during the study time period significantly increased in both total number and percentage of EBRT over time. PBT utilization increased most in men classified as NCCN low-risk (4% to 10.2%). The southern US region showed the largest PBT utilization increase over time (0% to 44% of all PBT).

With regard to use of protons in the treatment of patients with prostate cancer, Mehta et al.[401] reported on an analysis of patients treated by the Proton

Collaborative Group in the United States. As of December 2014, the registry had been enrolling patients since July 2009 at an average of 66 per month. Patients with prostate cancer accounted for 91% of enrolled patients at the end of year 1; this dropped to 67%, 64%, 58%, 53%, and 48% by years 2 to 6, reflecting the increased use of protons for other conditions than prostate cancer (head and neck, lung, and pediatric patients). Mishra et al.[402] published a review of active PBT clinical trials from ClinicalTrials.gov and the World Health Organization International Clinical Trials Platform Registry.

A total of 122 active PBT clinical trials were identified, with target enrollment of >42,000 patients worldwide. Ninety-six trials (79%), with a median planned sample size of 68, were classified as interventional studies. Observational studies accounted for 21% of trials but 71% (n = 29,852) of planned patient enrollment. The most common PBT clinical trials focus on GI tract tumors (21%, n = 26), tumors of the central nervous system (15%, n = 18), and prostate cancer (12%, n = 15). Five active studies (lung, esophagus, head and neck, prostate, breast) will randomize patients between protons and photons, and three will randomize patients between protons and carbon ion therapy.

Focal Ultrasound Therapy

Focal ultrasound therapy is an emerging approach to the treatment of localized prostate cancer. Ghai et al.[403] reported the 6-month follow-up of a phase 1 trial of four patients treated with focal transrectal MRI-guided focused ultrasound in North America. The patients had PSA level of 10 ng/mL or less, tumor stage cT2a or less, and a Gleason score of 6 (3 + 3). Under MRI guidance and real-time monitoring with MR thermography, focused high-frequency ultrasound energy was delivered to ablate the target tissue. MRI and repeat transrectal ultrasound-guided biopsy were performed 6 months after treatment. All four patients had normal MRI findings in the treated regions (100%); biopsy showed that three patients (75%) were clear of disease in the treated regions, representing complete ablation of five target lesions (83%). It was concluded that MRI-guided focused ultrasound is a feasible method of noninvasively ablating low-risk prostate cancers with low morbidity.

Bolton et al.[404] created a centralized database—accessible only by nonurologist researchers—within a cancer epidemiology center, and a single researcher prospectively entered baseline, treatment, and clinical/biochemical follow-up data from all patients treated with HIFU in the state of Victoria over the study period. The study accrued 108 patients, of whom 103 had been staged

as having clinically localized disease. Ninety-three patients (86.1%) had low- or intermediate-risk prostate cancer. Forty-four patients (40.5%) had persistent mild urinary incontinence at 3 months after treatment, and three of these ultimately underwent further surgical procedures to correct incontinence. Twenty-seven patients (25%) additionally experienced occasions of urinary retention in the first 3 months after treatment because of passage of tissue. Twenty-nine patients achieved a PSA level of <0.2 ng/mL at 3 months after HIFU. Fifty-six patients underwent post-HIFU prostate biopsy, and this was positive for residual cancer in 51 cases. Forty-five of the patients who had a positive post-HIFU biopsy underwent secondary treatment for prostate cancer. Oncologic control and complication outcomes in this cohort were inferior to those previously reported for HIFU in single-user series. Given the population-based multiuser nature of our series, the authors believed their observations are more likely to reflect the community outcomes that might be expected from widespread adoption of HIFU than generalizing from single-operator series. Ultrasound focal therapy for primary localized prostate cancer should remain investigational pending further study, according to a 2018 European Association of Urology (EAU) position paper (Eur Urol 2018, http://bit.ly/2E8q605).

CHAPTER 70

Management of Intermediate- and High-Risk Prostate Cancer: What Do We Know?

Mack Roach III and Hans T. Chung

"It's not what you don't know that gets you into troubles,
it's what you know for sure that ain't so"

Attributed to Mark Twain

INTRODUCTION

The management of clinically localized prostate cancer has changed considerably over the past 10 years. Fewer men are being treated for low-risk disease (e.g., prostate-specific antigen [PSA] < 10 ng/mL, Gleason score [GS] < 7, and T-stage < T2b), and more frequently, such men are being managed by active surveillance (AS).[1] Consequently, a higher percentage of men diagnosed with prostate cancer are now being treated with what is categorized as "intermediate-" to "high"-risk disease.[2] Concurrent with these developments, there has been a resurgence in enthusiasm among urologist for recommending radical prostatectomy (RP) as the treatment of choice for men with high-risk and locally advanced disease.[3,4] This trend appears to be in part fueled by plethora of post hoc retrospective studies.[5–7] This practice is not supported however by other recent studies that attempt to account for the "quality of care delivered" (defined as treatment delivered in compliance with National Comprehensive Cancer Network [NCCN] Guidelines) nor is it supported by the findings from contemporary phase III randomized trials.[2,8–13] This chapter was written in an attempt to bring clarity to the controversies surrounding the management of patients currently considered to have "intermediate-" and "high"-risk disease. We focus on the radiation-based therapeutic options and the evidence behind our recommendations. Since the last edition, a number of advances have been made

in the technical delivery of radiation for prostate cancer, and some have now been established as “standard of care.” Details on the management of low-risk prostate cancer can be found in Chapter 69.

CLINICAL PRESENTATION

Patients with intermediate- or high-risk prostate cancer may present with locoregional symptoms, but this is not common (although it appears to be increasingly common since PSA screening has become less popular). Lower urinary tract symptoms (LUTs) when seen may include nocturia, urinary frequency, urgency, decreased flow, incomplete voiding, intermittent flow, or hesitancy and occasionally erectile dysfunction (ED). Rarely, patients with bulky primary disease may present with urinary tract obstruction or difficulty in passing stool or even bloody stool. With increasing PSA and Gleason score, the risk of metastases increases. Metastatic spread is generally sequential, proceeding from the prostate to the periprostatic pelvic lymph nodes, but some appear to spread directly to the common iliac nodes and then to bone. Rarely, patients may present with renal failure, lymphedema of the lower extremities, and bone pain.

DEFINITIONS OF INTERMEDIATE- AND HIGH-RISK DISEASE

National Comprehensive Cancer Network–Defined Groups

Three prognostic factors have generally been used to define intermediate- and high-risk patients: (a) clinical T-stage (generally based on palpation [although imaging when compelling is included]), (b) the pretreatment PSA, and (c) the biopsy Gleason score (GS). To simplify treatment recommendations and prognostication, several risk classification schemes have been proposed by grouping patients who are thought to have similar biochemical and/or clinical outcomes.[14–17] The most widely recognized definitions for intermediate- to high-risk prostate cancers are that put forth by the NCCN.[2] This system represents a modification of the system proposed by D’Amico et al. However, the NCCN has modified subgroups to account for some of the heterogeneity in risk, by specifying that patients with multiple adverse factors “may be shifted into the next highest risk group.”[18] Given the widespread acceptance of this system, for practical purposes, the readers should assume we are referring to this

classification system throughout this chapter. Low risk is defined as meeting all the criteria: T1c to T2a, PSA <10 ng/mL, and Gleason score ≤6. Intermediate risk is defined as T2b to T2c, PSA 10 to 20 ng/mL, or GS = 7. High-risk (HR) prostate cancer is any of the following: ≥T3a, PSA >20 ng/mL, or GS 8 to 10.

Limitations of Risk Group Classifications and Other Risk Factors to Be Considered

Perhaps the greatest misunderstanding in using the risk groups based on PSA, GS, and stage is the implied assumption that each of these factors is roughly equally important. For example, a patient can be considered intermediate risk if either the clinical stage is T2b, PSA = 10 to 20, or the GS = 7. However, clinical T-stage is relatively subjective with a high degree or interobserver variability. Pretreatment PSA appears to be a strong predictor of biochemical (PSA) recurrence but a relatively weak predictor of cause-specific survival (CSS) and GS is the most powerful predictor of CSS, followed in importance by T-stage.[19] This has major implications for post hoc comparisons of the results of treatment wherein the distribution of these factors cannot be adequately controlled for.

Another major limitation of the risk groups most commonly used is their dependence on biochemical recurrence or PSA relapse after radiation therapy. In 1996, the American Society for Therapeutic Radiology and Oncology (ASTRO) developed a consensus definition of PSA relapse based on datasets of patients treated with external beam radiation therapy (EBRT) alone (i.e., no hormones).[20] After considerable scrutiny, it was determined that the first ASTRO definition was sensitive to follow-up bias, censoring artifact from backdating, and correlated poorly with clinical progression.[21] To address these issues, the RTOG-ASTRO cosponsored a conference in 2005 in Phoenix, Arizona, to develop a new definition, henceforth known as the Phoenix definition.[21] PSA relapse is defined as a rise of 2 ng/mL or more above the absolute PSA nadir. This definition was considered applicable only to patients treated with EBRT with or without short-term androgen deprivation therapy (ADT). The date of failure is taken at the time of meeting the definition and not backdated. Any salvage therapy initiated prior to meeting the criteria should also be declared as failure. With the Phoenix definition, sensitivity and specificity are 64% and 78%, respectively. This definition to date continues to be considered the standard definition for biochemical failure but should not be used to determine cure rates (e.g., compared to RP) nor should PSA that are consistently rising be ignored in men who could potentially benefit from salvage therapies.[21–23]

In addition to the T-stage, GS, and PSA, a number of other factors are known to impact outcomes. More than 10 years ago, a number of studies showed that the number and/or percentage of biopsy cores positive for prostate cancer (PPC) impacted the outcomes of patients treated definitively by RP or EBRT.[24,25] For example, status post RP, those patients with <34% PPC had similar outcomes as low-risk patients (5-year PSA control 85% vs. 91%, respectively), whereas patients with more than 50% PPC had similar outcomes as high-risk patients (5-year PSA control 30% vs. 43%, respectively). The prognostic significance of PPC has also been reported to extend to prostate cancer–specific mortality (PCSM) in intermediate-risk patients such that when stratified by ≤50% and >50% PPC, 7-year prostate cancer–specific survival was 100% versus 57% (P = .004), respectively.

The readers should be aware that there are a number of other limitations associated with attempting to use the risk groups described above to manage patients using the evidence from phase III randomized trials. Most importantly, essentially none of the mature trials on which our level I evidence is based were designed using the grouping systems described above. In fact, these trials generally included a heterogeneous mixture of relatively low- to very high-risk patients. To get around this problem, some investigators have attempted to leverage this mix of patients to create prognostics groupings directly from the patients included in the trials. For example, the Radiation Therapy Oncology Group (RTOG) conducted a meta-analysis based on multiple phase III trials.[14,26] In addition to the large sample size (>1,500 patients), long-term follow-up (out to 15 years), and study endpoints (PCSM and overall survival [OS]), it also incorporated central pathologic review.[14,26] Lessons learned from this meta-analysis (which were subsequently validated by the findings of multiple phase III trials) include the following: (a) the observation that low-risk patients (however defined) do not benefit from the addition of ADT; (b) patients with intermediate-risk disease benefitted from short-term ADT (e.g., 4 months), with no need for longer-term ADT; and (c) patients with high-risk (HR) disease benefitted most from long-term ADT. The RTOG also subsequently demonstrated that older age (>70) patients were associated with a reduced risk of PCSM and metastases, even after adjusting for the expected increased risk of non–prostate cancer–specific mortality in this subgroup.[27]

There have been a number of very recent (and not so recent) attempts to incorporate biomarkers as prognostic and/or predictors of response to radiation therapy +/− ADT–based treatments.[28–32] Unfortunately, to date, none have been

validated so as to provide actionable-based guidance. The critical need for validation is highlighted by the contradictory results noted following early impressive results associated with Bcl-2 and bax expression.[33,34] There is little doubt that one day not only will predictors of therapeutic outcomes be identified but radiation-induced complications as well.[28,35–39] In addition to cautionary notes surrounding the use of predictive markers for patients with intermediate- and high-risk disease, there are a few major cautionary notes related to patients treated on high-profile prospective randomized trials that are summarized in the next section below.

Cautionary Notes on Selected Phase III Randomized Prostate Cancer Trials

Much of the confusion concerning the optimum management of men with intermediate- to high-risk prostate cancer comes from the misinterpretation of high-profile phase III trials. There are several features that these trials have in common: (a) They tend to be underpowered for making evidenced-based conclusions concerning the management of high-risk disease; (b) the problems arising from the underpowered nature of these trials are exacerbated by patient heterogeneity; and (c) the findings appear to justify assertions (i.e., biases) that the investigators are seeking to prove. The underlying principle for these studies is that "if one wants to prove something does not work, make the study too small." Three examples of such high-profile trials suffering from these flaws are shown in Table 70.1.

#1 Beware of Randomized Trials that Are Too Small and Heterogeneous Patient Selection!

The conclusions of the PIVOT (Prostate Intervention Versus Observation Trial) suggest treatment is of limited value with the authors stating, "… After nearly 20 years of follow-up, among men with localized prostate cancer, surgery was not associated with significantly lower all-cause or prostate-cancer mortality than observation …."[40] Although this trial does not explicitly address the issue of treatment of intermediate- and high-risk disease, it is relevant because the data actually strongly suggest a benefit, thus contradicting the conclusions in their abstract. Although it was grossly underpowered, the hazard ratios ranged from 0.54 to 0.69, and the differences reached borderline statistical sensitivity (0.08) for survival from death of any cause favoring treatment of patients with intermediate- and high-risk disease. Our assertion that this trial was

underpowered is supported by the authors initial study design and comparisons to adequately powered phase III trials. In 1994, Wilt and Brawer described the launching of PIVOT and committed to recruiting 2,000 men. Given the low event rate expected with low-risk patients (42% of total cohort) and inclusion of men >65 years (68% of cohort recruited), even a trial of 2,000 men would be hard pressed to demonstrate a survival benefit. It is well known that active surveillance (AS) is the preferred approach for men with low-risk disease because the risk of death from prostate cancer is very low particularly in men older than 65 years of age. In addition, it is well known that the benefits of RP are most obvious in men <65 years of age. These investigators only recruited 1/3 of the planned accrual goal and still nearly had a positive trial. Thus, with the trends of the benefit favoring treatment for the most relevant subgroups, I consider this a positive trial supporting treatment and the authors' conclusions statistically invalid.

TABLE 70.1 SUMMARY OF CAUTIONARY NOTES ON RANDOMIZED TRIALS INCLUDING INTERMEDIATE-/HIGH-RISK PROSTATE CANCER

First Au. (Ref.) (yr Published) Study	No. Pts	Author's Conclusions	Why the Study Is Underpowered
Wilt[40] 2017, PIVOT	731 (457)[a]		Underpowered based on their own plan to recruit 2,000 men but only recruited roughly 1/3 of this number
Nabid[41,42]	630	18 mo of ADT as effective as 36 mo	Criteria for high risk less evidence based (PSA >20 ng/mL) OS at 5 y 92% vs. 87% (*P* = .052) favoring 36 mo over 18 mo Because of the underpowered nature of the trial, known factors such as GS and T-stage were not significant either
Pommier[43] 2016, GETUG-01	446 (203)[b]	Pelvic node radiation did not improve outcomes	RTOG-9408 required 2,000 pts to show that 4 mo of ADT improved survival
James[44] STAMPEDE	1,917 (369)[c]	"Among men with locally advanced … ADT plus abiraterone … was associated with significantly higher rates of overall and failure-free survival	No overall survival advantage for nonmetastatic patients, and no trend for benefits for men >70 y of age (median age for men treated on phase III trials involving RT). Thus, it remains unclear of the role of abiraterone in the setting of typical high-risk prostate

than ADT alone …”	cancer

[a]Intermediate and high risk (D’Amico).
[b]Number >15% risk of lymph node involvement.
[c]Node positive, non-metastatic.

Another major underpowered trial reported by Nabid et al. argues for a shorter duration of long-term ADT suggesting that 18 months of ADT is as effective as 36 months in 630 men managed with EBRT.[41,42] Based on these data, some physicians have concluded that it has established a new standard of care for high-risk patients. However, the earlier trial that established that 36 months was superior to 6 months (Bolla et al.) recruited 50% more patients (*n* = 970). Should not a study lengthening ADT by 12 months require at least as many patients, particularly if they were lower risk (e.g., fewer T3 patients), to redefine the standard of care? Criteria for high risk in this study were less evidence based (PSA >20 ng/mL). Evidence that this study was underpowered is supported by the observation that known prognostic factors such as GS and T-stage were also not significant predictors of outcome. The desire to shorten the duration of ADT is admirable, and many patients would love to be spared the unnecessary use of ADT, but for most, a loss of life may be deemed an excessive price.

A third trial suffering from being underpowered and an unfortunate study design is GETUG-01 (Groupe d’Etude des Tumeurs Uro-Génitales). This French multicenter phase III reported by Pommier et al. concluded that there was no value to the use of prophylactic lymph nodal irradiation.[43] The fact is, not only was this trial grossly underpowered with only 203 men with a risk of lymph node involvement >15% (e.g., RTOG-9413 enrolled 1,200+ patients: RTOG-0924 targets 2,580), but *none* of the patients actually received “whole-pelvic” EBRT (see the discussion below) but instead were treated using a “mini-pelvic” technique.[45]

At the other end of the spectrum are studies suggesting a role for more aggressive drug therapy.[46] For example, although STAMPEDE (Systemic Therapy in Advancing or Metastatic Prostate Cancer: Evaluation of Drug Efficacy) was a rather large randomized trial (*n* = 1,917), its analysis is complicated by its very heterogeneous design. STAMPEDE included patients with metastatic and nonmetastatic disease (the latter including node + patients with high-risk localized prostate cancer), making it difficult to parse out who benefitted the most. Per protocol, EBRT was mandated for patients with node-negative, nonmetastatic disease and “encouraged” for those with positive nodes. The primary outcome measure was overall survival, with failure-free survival (treatment failure was defined as radiologic, clinical, or PSA progression or

death from prostate cancer), defined as an “intermediate primary outcome.” The authors concluded that “Among men with locally advanced … prostate cancer, ADT plus abiraterone … was associated with significantly higher rates of overall and failure-free survival than ADT alone ….” However, in fact, there is no overall survival advantage for “nonmetastatic” patients, and no trend for benefits for men >70 years of age (the median age for men treated on previous phase III RTOG trials involving RT and ADT). Thus, although encouraging it remains unclear of the role of abiraterone in the setting of typical high-risk prostate cancer managed with ADT and EBRT.

#2 Beware of Large Post Hoc Population-Based and Biased Retrospective Studies!

In addition to the problem of underpowered randomized trials, there are a large number of problematic post hoc studies comparing the outcomes following RP versus EBRT. Key characteristics of these have been the sizes of the databases used and efforts to use statistical methods to convince the readers that all meaningful biases have been accounted for so as to imply that the findings are likely to be accurate.

If a 700-patient, prospective randomized trial (PIVOT) can be published in the *New England Journal of Medicine* (twice) to show RP does not prolong survival compared to observation, why analyze 118,000 nonrandomized men with missing information and make clinically relevant conclusions? These studies tend to ignore or inadequately adjust for fundamental differences in patient selection (e.g., patient selection, existing baseline morbidity, a lack of modern radiation-based treatment techniques, and the use of ADT) and tend to be based on very large sample sizes (e.g., >50,000 to 100,000 or more), with no relevance to clinical medicine. These large sample sizes use hazard ratios (HR) that result in statistically significance but relatively small clinical differences. The potential for erroneous conclusions to be reached is quite high, given the absence in detailed patient level information (e.g., percent positive cores, bulkiness of disease). The practical reality is that the largest trials comparing survival outcomes after definitive treatment in men with localized disease conducted to date have included approximately 700 to 3,000 patients (e.g., PIVOT, PROTECT, RTOG-9408, RTOG-0924, CHHIP), so great caution must be taken in attempting to use post hoc analysis of cohorts of 7,500 to 118,000.[5,6,47] Small errors in the rate in attribution of cause of death and selection bias can easily explain biased conclusions.[10]

#3 Beware of Confusion Concerning the Evidence for the Importance of Radiation Dose and Volume!

We (radiation oncologist) have been a bit illogical, concerning our interpretation of the data from trials involving the three major "tweakable" interventions, namely, (a) radiation dose, (b) radiation volume, and (c) the use of ADT. Despite a plethora of trials involving dose-escalated radiation, all failing to prove that higher doses improve overall survival, high doses have become standard of care (see JNCI and NCCN guidelines). These studies have generally demonstrated improved biochemical control based on PSA but at increased cost and in some cases with increased toxicity. In contrast, the improvement in PSA associated with whole-pelvic radiation therapy (WPRT) demonstrated by the only adequately powered phase III trial, using an adequately sized pelvic field, has not convinced roughly 1/2 radiation oncologists to adopt this as standard for high-risk patients (personal communication, based on an informal audience survey). Even less logical is the willingness of radiation oncologists to look for reasons to shorten the duration or completely abandon ADT based on post hoc retrospective data, despite their lack of reliability. For example, numerous post hoc studies fail to show the value of ADT and tout the advantages of surgery compared to radiation but have not been borne out by randomized trials. Omitting ADT because "maybe, it would not be needed if higher doses of radiation were used" is potentially dangerous and should require a randomized trial to justify.

Novel Imaging Techniques: Implications of Nodal Imaging for Radiation Therapy

Until very recently, imaging contributed relatively little to the management of patients with clinically localized prostate cancer, such that the patient eligibility for RTOG trials has generally been based on palpation T-stage.[26] This philosophy is largely based on the fact that neither CT nor magnetic resonance imaging (MRI) has been shown to be sensitive or specific enough to be routinely used to rule out lymph node involvement.[48] In the absence of definitive evidence of the presence and location of lymph node involvement, a class solution is used to design radiation fields when WPRT is intended.[49,50] However, there are at least three major imaging approaches that may compliment the use of class solutions including (a) positron emission tomography (PET) imaging, (b) the use of lymphotropic nanoparticles, and (c) sentinel lymph node imaging.

PET imaging agents have recently grown in popularity with studies showing

superior results compared to conventional imaging such as CT scans.[51] It also appears that prostate specific membrane antigen (PSMA)-based PET imaging may be as good or better than other available agents.[52] Higher detection rates have been observed with (68)Ga-PSMA PET/CT compared to choline PET/CT. Although PET (68)Ga-PSMA-11 appears to have a higher detection rate than (11)C-choline for nodes and bones lesions, this comparison is complicated by the fact that there was a lack of concordance when applying both tracers.[53] However, there appear to be size limitations associated with this approach that hampers the sensitivity of PET imaging.[54] In one study, using a lymph nodal region-based analysis, the sensitivity of 68Ga-PSMA PET/CT was 56%, the specificity was 98%, and the positive predictive value (PPV) was 90%. Of note, the mean size of the false-negative nodes was 2.7 mm; thus, smaller nodes are likely to be missed.

Sentinel lymph node dissections are standard in a variety of cancer sites (e.g., breast cancer), but its application in prostate cancer has been very limited. Intraoperative gamma probe and dynamic lymphoscintigraphy appear to be a very sensitive approach for defining disease intraoperatively. For example, Wawroschek et al. reported that about a third of sentinel lymph nodes were in areas outside of a limited node dissection, such as the presacral, hypogastric, and pararectal regions.[55] Holl et al. also demonstrated that sentinel lymph node dissections guided by using radiolabeled nanocolloid were reliable in detecting positive nodes in over 2,000 patients.[56] Using a 2-day protocol, involving injection of a radioisotope injected into the prostate, combined with intraoperative scanning, they concluded that the detection rate was 97.6% and false-negative rate only 6%. Krengli et al. reported on the application of sentinel lymph node imaging (single-photon emission computed tomography [SPECT]) to pelvic radiation therapy for prostate cancer and reported that at least 25% of patients had nodes outside the standard nodal pelvic clinical target volume (CTV).[57] More recently, Chen et al. reported on a feasibility study performed at University of California San Francisco (UCSF) using sentinel lymph node image-guided intensity-modulated radiation therapy (IMRT) for prostate cancer and compared it to RTOG-based IMRT plans.[58] Patients were injected with ^{99m}Tc-sulfur colloid into six prostate locations and then imaged with SPECT to generate a lymphatic drainage map. Although all patients had sentinel nodes identified in the internal or external iliac nodal basins, 50% had sentinel nodes in the para-aortics. We concluded that RTOG consensus guidelines on pelvic lymph coverage would have included all relevant lymph nodes in only 30% of cases.

Guided by this sentinel nodal study we reported in comparative radiation therapy plans, there would have been no significant increase in the doses received by organs at risk.

Perhaps the most sensitive (but least available) diagnostic imaging test involves the use of lymphotropic superparamagnetic nanoparticles, which, combined with MRI, has been reported to be a very sensitive and specific test for detecting lymph node involvement.[59,60] It not only appears to be more specific than the "Roach equation" in assessing nodal involvement, but it can identify the location of disease. These nanoparticles are transported by lymphatic vessels, and filtered by lymph nodes. Lymph nodes that have been infiltrated by metastases will have distorted lymphatic flow and accumulate the nanoparticles. Of particular note, documented by histologic confirmation, 71% would not have met the MRI size criteria for malignancy. This imaging approach was associated with sensitivity in excess of 90% versus 35% with MRI alone ($P < .001$). When only nodes that were between 5 and 10 mm in diameter on the short axis were considered, the sensitivity increased from 28.5% to 96.4% ($P < .001$). Shih et al. proposed margins around major vessels as an alternative based on their studies because of the lack of availability of this imaging agent.[61] Dinniwell et al. proposed a pelvic nodal model based on nanoparticles and recommended CTV margins to the distal para-aortic (12 mm), common iliac (10 mm), external iliac (9 mm), and internal iliac (10 mm), drawn in continuity with a 12-mm expansion anterior to the sacrum and 22-mm expansion medial to the pelvic sidewall.[62] Unfortunately, despite great promise, this agent is currently only available in the Netherlands.[63]

MANAGEMENT OF PELVIC LYMPH NODAL DISEASE: THE RATIONALE AND EVIDENCE

The Rationale

Despite the improvements in the detection rate of lymph node involvement (LNI) provided by PET imaging agents, the ability of current imaging techniques to detect involved nodes is hampered by their sole reliance on size criteria.[54] The true incidence of clinically occult disease is generally much higher when sophisticated assays, imaging agents that have increased affinity to lymph nodes, and more extensive node dissections are performed. For example, Shariat et al. studied reverse-transcriptase polymerase chain reaction (RT-PCR) assay for human glandular kallikrein 2 (hK2) mRNA expression in *histopathologically*

normal pelvic nodes in patients with pT3N0 prostate cancer.[64] Of the 199 evaluable men, 20% and 40% had positive and equivocal results, respectively. In multivariate analysis, a positive RT-PCR/hK2 result was associated with PSA progression, development of distant metastases, and PCSM.

When an extended pelvic lymph node dissection (including the nodes surrounding obturator vessels and internal iliac veins) is performed rather than the traditional limited dissection (or sampling), wherein the posterior extent is carried to the obturator nerve, more diseases are found. For example, Bader et al. conducted a prospective study of the anatomic extent of pelvic nodal involvement in a cohort of 365 men who underwent an extended lymph node dissection and radical prostatectomy.[65] The median number of nodes retrieved was 21. They used hematoxylin and eosin (H&E) stains to evaluate the extracted nodes, 24% of patients had node-positive disease, of which 49% of them had a PSA >20 ng/mL. The internal iliac nodes, which are not usually dissected in a limited dissection, were involved in 58% of men with node-positive disease. Of note, 19% of node-positive men had involved nodes that were exclusively found in the internal iliac region, suggesting that the lymphatic drainage of prostate cancer is variable. The rate of problematic lymphocele was 2%.

Another important consideration, when reviewing surgical studies, is whether H&E staining was performed or more sensitive analyses were included, such as immunohistochemistry (IHC) or RT-PCR. Heidenreich et al. reported on the incidence of lymph node involvement between standard and extended pelvic lymphadenectomies in 203 patients.[66] IHC staining was performed if the H&E findings were negative. There were more dissected nodes in the extended dissection group (28 vs. 11; $P < .01$), at the expense of longer operative time (179 vs. 125 minutes; $P < .03$). There were more than twice the number of patients with positive nodes (26% and 12%; $P < .03$) in the extended dissection group, with 42% of all metastases lying outside the planes of a limited dissection. In patients deemed as high risk (Gleason score 7 to 10 and PSA ≥10.6 ng/mL) for lymph node metastasis, 60.9% of patients had histologically positive nodes. There was no difference in pelvic lymphocele or postoperative complications between the two groups. Data reported by Briganti et al. also attempted to address the question concerning the optimal number of lymph nodes to be removed during a nodal dissection.[67] In a cohort of 858 men who were treated predominantly with an extended lymph node dissection and who had a median PSA of 5.8 ng/mL and 62% with GS ≤ 6 and approximately 25% GS = 7, based on a receiver operator curve (ROC) analysis, they concluded that

the removal of 28 nodes yielded a 90% ability to detect LNI. They also concluded that assessment of 10 or fewer nodes was associated with a very high false-negative rate. This data highlight the shortcomings of studies postulating much lower rates of LNI involvement than suggested by the so-called Roach equation.[68–71]

Relevant to the rationale of recognizing the true incidence of LNI are circumstantial data to suggest that there may be a benefit of removing more involved lymph nodes even if they are occult. For example, retrospective study from Johns Hopkins, the pathologic findings and biochemical outcomes were compared between two high-volume surgeons, each of whom exclusively performed either limited (n = 1,865) or extended (n = 2,135) node dissections during radical prostatectomy.[72] As expected, the extended dissection group had more lymph nodes retrieved than the limited group (11.6 vs. 8.9 nodes; P < .0001). Yet the proportion of patients with involved nodes was also significantly higher in the extended dissection group (3.3% vs. 1.2%; P < .0001). When only patients with Gleason score 7 or 8 to 10 were considered, the difference was even more striking (8.2% vs. 2.4% and 23.2% vs. 8.9%, respectively). The relative risks of detecting a patient with involved nodes were remarkably similar, varying between 2.5 and 3 when adjusted by Gleason score, organ-confined status, seminal vesicle invasion (SVI), and surgical margin status. There was a trend in favor of the extended dissection group for 5-year biochemical recurrence-free survival (34.4% vs. 16.5%; P = .07). Among patients with <15% positive lymph nodes, the difference was more remarkable (42.9% vs. 10%; P = .01), suggesting a therapeutic benefit of an extended dissection in low-volume disease. Clinically significant lymphoceles occurred in only 0.3% in the extended dissection group. However, more recent studies have questioned the therapeutic value of more extensive dissection.[73]

On the basis of these studies, the NCCN guidelines recommend an extended lymph node dissection for all patients who have a predicted probability of lymph node metastases of >2% for both diagnostic and potentially therapeutic reasons.[2] Although there have been numerous nomograms to predict nodal involvement, most are derived from surgical data where only limited node dissections were performed.[74,75] Nomograms also have been developed using surgical data from patients who had an extended lymph node dissection to predict pelvic nodal involvement.[76] Despite these advances from a practical standpoint, because of its simplicity, it appears that the so-called Roach equation is still held relevant and has been validated with a cohort of over 3,000 patients treated with RP and

extended lymph node dissections.[71,77] Overall, the accuracy of this equation was found to be 80% in this cohort; however, Abdollah et al.[71] found that applying the recommended cutoff of ≥15% (to decide on whether to treat the pelvic nodes) might lead to missing about a third of patients with lymph node involvement, and thus, they recommended that the threshold be lowered to 6%.

Whole-Pelvic Radiation Therapy

Collectively, these studies argue that an extended node dissection may or may not yield a therapeutic benefit in the subgroup of patients with minimal nodal disease.[73] In the application of radiation with curative intent, this issue may have great relevance to prophylactic WPRT. Unfortunately, only one relevant large phase III trial has been completed to date, and although most retrospective studies have been supportive, some post hoc population-based studies have yielded conflicting results.[78–80] Much of this confusion concerning this issue stems from a misunderstanding of the data available from RTOG-9413.[81] Table 70.2 summarizes a body of selected literature addressing WPRT in patients with intermediate- to high-risk disease managed in the definitive and the postoperative setting.

RTOG-9413 was a landmark trial that featured a two-by-two factorial randomization scheme to either prostate-only radiation therapy (PORT) or WPRT followed by a prostate boost and either 4 months of neoadjuvant and concurrent hormones or 4 months of adjuvant ADT (AHT) at the completion of EBRT.[78] Patients with an estimated nodal risk of >15% or T2c to T4 with a Gleason score of ≥6 were eligible for the study. The 4-year progression-free survival was 54.2% and 47% in the combined WPRT arms and PORT arms (P = .02), respectively. When the four arms were analyzed separately, the neoadjuvant hormone and WPRT arm (59.6%) had a significantly better 4-year progression-free survival than the other three arms (44.3% to 49.8%; P = .008). Although there was no difference in acute (3% vs. 4%; P = .39) and late (2% vs. 2%; P = .85) grade 3 to 5 genitourinary (GU) morbidities, a trend toward increased acute (2% vs. 1%; P = .06) and late (1.7% vs. 0.6%; P = .09) grade 3 to 5 gastrointestinal (GI) morbidities was seen in the combined WPRT and prostate-only arms, respectively.

Although RTOG-9413 affirmed the role of WPRT and neoadjuvant hormonal therapy (NHT) in HR prostate cancer, there has been some lingering reluctance among some radiation oncologists, with many instead opting for “mini-pelvic” fields or omitting the pelvic field entirely.[101] To reinforce this notion of the

volume dependence on control of microscopic nodal disease, we conducted a secondary post hoc secondary subset analysis of patients treated on RTOG-9413.[45] Because of the disparity in the time point at which the neoadjuvant and adjuvant ADT arms became susceptible to relapse (i.e., end of both radiation therapy and ADT), only patients (n = 649) who received NHT were included in this analysis. After stratifying by volume irradiated, the 7-year progression-free survival was 40%, 31%, and 27% in the groups that received whole-pelvic, mini-pelvic, and prostate-only radiation therapy, respectively (P = .02; Fig. 70.1). There was no difference in acute grade ≥3 genitourinary or gastrointestinal toxicities among the three volumes. No difference was seen in the incidence of late grade ≥3 genitourinary toxicities between the whole-pelvic, mini-pelvic, and prostate-only radiation therapy groups at 48 months (3.0%, 2.4%, and 0%, respectively; P = .24). There was a small but significant increase in the incidence of late grade ≥3 gastrointestinal toxicities with larger fields at 48 months (4.3%, 1.2%, and 0%, respectively; P = .006). Of note, 3D conformal radiation therapy (3DCRT), let alone IMRT, was not routinely performed in this study. It is conceivable that with either modality, late toxicities may be further decreased (Fig. 70.2).

TABLE 70.2 Selected Studies Assessing the Value of WPRT in the Definitive and Postoperative Settings[a]

Authors (Chronologic)	Source	Study Design	Key Findings
Seaward[82,83]	UCSF	Retrospective single institutional analysis of patients undergoing prostate only or WPRT with and without hormonal therapy	WPRT (superior border L5-S1) associated with improved PSA control rate. Greatest benefit seen for those with risk between 15% and 30%
Pan[84]	U of Mich.	Compared men undergoing EBRT treated divided into three categories based on the estimated risk (Partin table) of LN involvement: 0–5%, >5–15%, and >15%	Benefit for WPRT in men with risk of lymph node involvement of 5–15% with an improved 2-year PSA control rate, 90.1% vs. 80.6% (P = .02)
Roach[78,85]	RTOG	Randomized trial (n ~ 1,200) compared sequence of ADT and WPRT vs. PO. Primary	WPRT associated with improvement in PFS when preceded by combined hormonal blockade (CAB) but

		endpoint: PFS (PSA, clinical failure, death)	not when administered before CAB
Jacob[86]	Fox Chase	Retrospective study of patients with risk + LN >15% treated with “whole-” vs. “partial”-pelvic EBRT vs. PO fields (*n* = 420). Concluded no benefit to WPRT or ADT	None received WPRT (defined as defined by RTOG-9413). “Whole”-pelvic field use would have been included in PO arm of RTOG-9413
Pommier[43,87]	France	444 pts with T1b-T3N0M0 randomized to prostate +/− WPRT 46 Gy with superior border at S1-S2. Only 55% had LN risk <15%	None of the patients received WPRT (defined as top L5-S1); most low risk for lymph node involvement
Spiotto[88]	Stanford	Retrospective analysis of postop patients undergoing prostate only or WPRT with and without hormonal therapy	Use of WPRT associated with better PSA control with greatest benefit seen in patients with adverse features
Da Pozzo[89]	Italy	Retrospectively compared pts with + nodes with 129 treated with WPRT + ADT vs. 121 with ADT alone	Use of WPRT was a major predictor of PSA control (*P* = .002) and CSS (*P* = .009)
Aizer[90]	Yale	Retrospective review of 277 consecutive patients with estimated risk of lymph node involvement ≥15%	WPRT associated improved 4 y biochemical control rate (69.4% vs. 86.3%)
Milecki[91]	Poland	Retrospective analysis of HR prostate ca. with and without WPRT	Improved CSS with WPRT
Bittner[92]	USA	Compares PSA control CSS and OS among HR pts treated with brachytherapy and a mini-pelvic (MP) radiation therapy or WPRT	Trend toward improved PSA control, CSS, and OS with WPRT, most apparent among the ADT naive, who had improved OS
Mantini[93]	Italy	WPRT vs. PO in pts with HR prostate cancer treated with RT and long-term (>1 yr) ADT	Patients with >30% risk of + nodes had an improvement with WPRT (*P* = .03)
Moghanaki[94]	Virginia	WPRT vs. PBRT in the postoperative setting (pts excluded if they had + nodes or ADT)	In pts with PSA >/= 0.4 ng/mL, WPRT associated with a 53% reduction in PSA failure (*P* = .031).

Tward[95]	Utah	Evaluated EBRT on CSS and OS in cT1-T4, cN1, M0 prostate ca. using SEER data	Better 10-year CSS but not OS with EBRT with TNT 8 to prevent one death at 10 y
Amini[80]	Colorado	Compared WPRT vs. PORT for HR pts, using the NCDB in treated from 2004 to 2006, with propensity matching was performed	Authors concluded WPRT had no OS benefit vs. PORT. We conclude pts with WPRT had: higher T-stage, GS, PSA, ># adverse factors, and criteria for WPRT unknown
Braunstein[96]	Harvard	WPRT vs. PORT +/− ADT using a multi-institution cohort of 3,709 pts assessed all-cause mortality (ACM)	Authors concluded that WPRT and ADT were associated with a decrease in ACM, but the combination yielded no greater benefit, suggesting a shared mechanism treatment of micrometastatic nodal disease
Song[97]	Korea	Compared postop WPRT vs. PBRT in the salvage setting and propensity score matched	WPRT group had better PSA control vs. PBRT group (63.1% vs. 43.4%, *P* = .034)
Mason[98]	UK, Canada, USA	Reported prespecified final analysis of a randomized trial ADT vs. ADT + EBRT (*n* = 1,205)	Pts planned for WPRT showed a trend toward improved OS vs. PORT (HR = 0.70; *P* = .12) and DSS (HR = 0.53; *P* = .098)
James[99,100]	UK	Exploratory analysis using data from the STAMPEDE trial to assess the impact of RT on failure-free survival by nodal status	Failure-free survival outcomes favored planned use of RT for HR pts with N0M0 *and* N+M0 disease
	USA, multi-institutional	Explored WPRT +/− ADT vs. PORT PSA control using a data from 10 academic institutions	MVA showed both WPRT and ADT improved PSA control

[a]Studies in *blue* tend to argue against WPRT, whereas those in *black* tend to support it.
ADT, androgen depression therapy; CSS, cause-specific survival; EBRT, external beam radiation; HR, high risk; NCDB, National Cancer Database; OS, overall survival; PBRT, prostate bed radiation therapy; PFS, progression-free survival; PO, prostate only; pts, patients; SEER, surveillance, epidemiology and end results; TNT, the number needed to treat.

The only other modern randomized trial is GETUG-01 (Groupe d'Etude des Tumeurs Uro-Génitales), which is a French multicenter phase III trial and was recently updated.[43] It randomized 444 patients with T1b-T3N0M0 prostate cancer to "WPRT" or PORT. Four to 8 months of neoadjuvant and concurrent hormones was not part of the protocol treatment for all patients. Patients were stratified based on estimated node involvement, and only those deemed to be

high risk, defined as ≥T3, Gleason score ≥7, or PSA ≥3 times normal, for nodal involvement received hormones. The total prostate dose in the study was 66 to 70 Gy. With a median follow-up of 11 years, no significant difference was seen in progression-free survival between the WPRT and PORT arms. Although the results of GETUG-01 seem to contradict that of RTOG-9413, there are significant differences in the methodology of the two studies that warrant mention. First, more than half of the patients (~54%) had an estimated nodal risk of <15% ("Roach formula"), meaning that these patients had more favorable disease than those in RTOG-9413 and therefore would likely not benefit from WPRT. Thus, this study was vastly underpowered, as is made a bit clearer, by considering this example. Suppose you designed a trial wherein the minimum eligibility was a risk of lymph node involvement >15%, such that the average risk for this cohort was 1/3rd. If you enrolled 1,200 patients, then 400 would really be the basis for the study outcome because only this number could potentially benefit. If the local recurrence rate was 50% (e.g., as might be expected after 66 Gy), then only 200 patients would be left to assess the merits of WPRT. This means that really only 100 patients would remain on the WPRT arm that could potentially benefit. If competing causes of death eliminated 50% of the patients, the remaining assessable patients would then be down to 50 per arm. Thus, even starting off with 1,200 patients, it would be challenging to assess the potential impact of WPRT. Clearly, GETUG-01, which only started out with 200 patients with a risk >15%, was not adequately powered to either disprove or prove the value of WPRT. Equally important, the protocol-defined pelvic fields were much smaller than those used in RTOG-9413. Specifically, the superior border was taken at the level of S1-S2 interspace, rather than L5-S1 interspace, which meant that a significant portion of the presacral and common iliac nodes were not treated. Thus, *none* of the patients included in this trial received WPRT in accordance with RTOG-9413, and *all* of the patients assigned to the "pelvic nodal" radiation arm would have been included in the PORT arm of RTOG-9413.

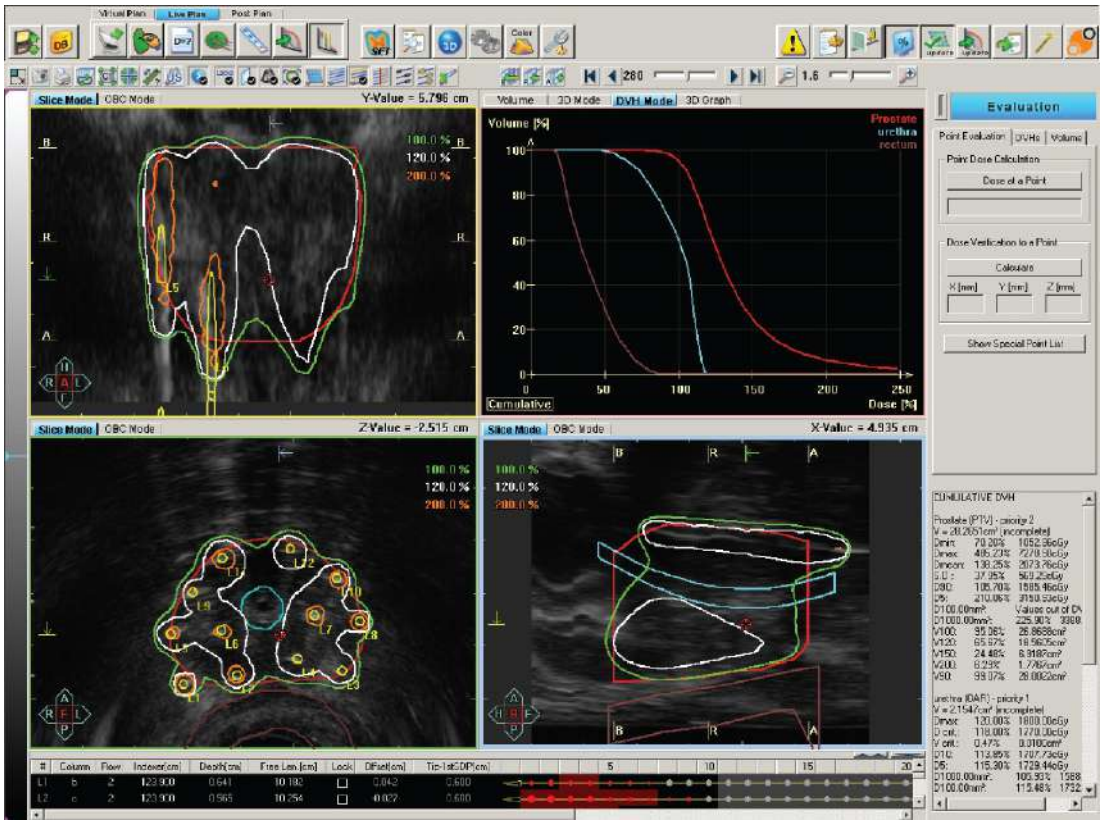

FIGURE 70.2. Isodose lines and dose–volume histogram from a representative patient treated with single-fraction 15 Gy high dose rate prostate brachytherapy with ultrasound-based planning. Twelve catheters were implanted. On dose–volume histogram, the prostate (*red line*), urethra (*blue line*), and rectum (*brown line*) are represented. (Courtesy of Gerard Morton, MD, Sunnybrook Odette Cancer Centre, University of Toronto, Toronto, Canada.)

One of the most common questions regarding RTOG-9413 is whether the beneficial finding of NHT and WPRT still holds true in the dose escalation era where doses of more than 80 Gy to the prostate is given. For example, retrospective data from Fox Chase Cancer Center were used to investigate the effects of dose escalation, WPRT, and short-term hormones in the subgroup of patients who would otherwise be eligible for RTOG-9413 based on the inclusion criteria.[86] Multivariate results suggest that radiation dose (70 to 72.9 vs. 73 to 76.9 vs. ≥77 Gy), PSA, clinical T-stage, and Gleason score were significant predictors of biochemical failure, whereas short-term hormones and radiation field size were not. Despite being provocative, there are some shortcomings of this study, as pointed out by the authors, which merit closer attention. Although the inclusion criteria were identical to RTOG-9413, 42.4% and 31.4% of patients had a PSA <10 and 10 to 20 ng/mL (median PSA 10.95 ng/mL), respectively, whereas the median PSA in RTOG-9413 was 22.6 ng/mL. In addition, only 67

patients received neoadjuvant hormones. Radiation fields were prostate only, partial pelvis, and whole pelvis in 11.4%, 17.6%, and 71%, respectively. In the latter group, the whole-pelvic field extended superiorly to the inferior sacroiliac joints, which would not be considered adequate pelvic irradiation according to RTOG-9413, where a minimum unblocked field size of 16-by-16 cm was used. Because only 16% patients received NHT and none received WPRT (per RTOG-9413), there is a great potential for selection bias (patients treated with NHT may have had worse disease than those not receiving NHT). Thus, these data do not make a compelling argument against WPRT and NHT acquired from a large phase III trial.

When we designed NRG/RTOG-0924, we first identified a subset of patients from our original report of RTOG-9413 who appeared to have benefited the most from WPRT.[78,79] We also incorporated the percentage of positive biopsy cores into the eligibility criteria. Patients eligible for this study should have an estimated nodal risk of at least 15% and have either the following:

- Gleason score 7 to 10 and T1c-T2b and PSA < 50 ng/mL
- Gleason score 6 and (T2c-T4 or >50% biopsies) and PSA < 50 ng/mL
- Gleason score 6 and T1c-T2b and PSA >20 ng/mL

For NRG/RTOG-0924, we made the WPRT slightly larger and the PORT fields slightly smaller, and the phase I dose was 45 Gy in both arms and can be delivered with 3DCRT or IMRT. The phase II prostate boost can be achieved by IMRT (34.2 Gy; total dose 79.2 Gy), low dose rate (LDR) brachytherapy (110 Gy for iodine-125 [^{125}I] and 100 Gy for palladium-103 [^{103}Pd]), or high dose rate (HDR) brachytherapy (15 Gy in one fraction with iridium-192 [^{192}Ir]). Patients will be stratified into 4 to 6 or 32 months of androgen suppression therapy.

The bottom-line concerning WPRT as summarized in Table 70.3 is as follows:

- Most retrospective studies involving EBRT support the value of WPRT. Thus, there is no strong evidence to withhold WPRT based on retrospective data.
- Every major RTOG and EORTC trial including high-risk patients with ADT included WPRT. Thus, there is no evidence that the results of these trials would be the same if WPRT was withheld.
- The only large contemporary phase III randomized trial completed to date (RTOG-9413) continues with support an improved PSA control when NHT is added to WPRT compared to PORT. A larger confirmatory study with a

survival endpoint is pending with >2,000 patients already enrolled.

RADIATION THERAPY TECHNIQUES: REGIONAL AND LOCAL

Boost Techniques: Options and Considerations

Over the past 20 years, the therapeutic options for definitive radiation in men with clinically localized disease have evolved immensely. At UCSF, favorable intermediate-risk patients are usually managed with monotherapy, a permanent prostate implant (PPI), a HDR implant, stereotactic body radiation therapy [SBRT] directed only at the prostate +/− the proximal SVs without ADT, or image-guided EBRT (IGRT). For patients with more unfavorable intermediate-risk disease, IGRT directed at periprostatic tissues (+/− the pelvic lymph nodes) is combined with an IGRT, a PPI, an HDR, or an SBRT boost +/− short-term ADT (e.g., 4 months), whereas for high-risk (HR) patients, long-term ADT (e.g., 2 to 3 years) with WPRT is usually recommended. Off study, the authors recommend prophylactic WPRT using IMRT to patients with an estimated nodal involvement of >15% and unfavorable intermediate- and high-risk prostate cancer. The authors recommend either adherence to the RTOG GU Radiation Oncology consensus statement on pelvic nodal volumes or use of a higher superior border.[49,102,103] If positive pelvic nodes are suggested by imaging (e.g., CT or PET), prophylactic para-aortic nodal treatment is usually added to WPRT. The prostate boost is delivered with either an IMRT, a PPI, or an HDR brachytherapy, or an SBRT boost. Brachytherapy or SBRT are generally preferred by the authors because of their ability to deliver a higher biologic dose to the prostate. Brachytherapy or SBRT can be performed either before or performed 1 to 3 weeks following pelvic radiation therapy. For T3 disease, the authors use an SBRT, HDR, or IMRT boost, which allows better coverage of extranodal disease than PPI boost. Table 70.3 summarizes some of the consideration when selecting the type of boost preferred for a given patient. Figures 70.3 and 70.4 provide a summary of some of the data supporting SBRT +/− ADT.[104] Based on the results of patients treated on RTOG-0232 comparing PPI to PPI + EBRT, the former is preferred in favorable intermediate-risk patients.[105]

TABLE 70.3 RADIATION THERAPY "PREFERRED" OPTIONS AND RELATIVE CONTRAINDICATIONS FOR PROSTATE CANCER AT

UCSF (2017)

Type of Radiation Therapy	Year[a]	Primary Indications	Relative Contraindications
IGRT (intensity-modulated image-guided external beam radiation)[b]	Pre 1996	1. Combination therapy pre-/postboost treatment 2. Postop adjuvant treatment 3. Postop salvage treatment 4. Large TURP defects 5. Other options not covered by insurance 6. Patient preference	1. Previous full-dose radiation 2. Patient preference (e.g., logistically problematic) 3. Focal recurrence (favor focal treatments) 4. Technical issues (e.g., too large for CT scan but BT suitable) 5. Inflammatory bowel disease or connective tissue disorder 6. Noncompliant for many visits
PPI (permanent prostate implant) BT (brachytherapy)	1996	1. Monotherapy for low or favorable int. risk pts 2. Boost in clinically T1-T2 with IMRT 3. Focal salvage postrecurrence after IMRT 4. Focal salvage postrecurrence after PPI 5. Patient preference	1. Not a candidate for anesthesia 2. Discontinuation of anti-coagulation is unadvisable 3. Excessive pubic arch interference (PAI) 4. Excessively large TURP defect 5. Severe baseline urinary symptoms (e.g., urinary retention)
HDR (high dose rate) BT	1999	1. Monotherapy for low or favorable int. risk pts 2. Boost in clinically T1-T3 with IMRT 3. Focal salvage postrecurrence after IMRT 4. Pubic arch interference prohibiting PPI 5. Median lobe too large for SBRT 6. Insurance prohibits SBRT 7. Patient preference	1. Not a candidate for anesthesia 2. Discontinuation of anticoagulation is unadvisable 3. Excessive pubic arch interference 4. Excessively large TURP defect 5. Severe baseline urinary symptoms (e.g., urinary retention)
SBRT (stereo tactic body radiation therapy)	2005	1. Monotherapy for low- or favorable-risk pts 2. Boost for clinically T1-T4 with IMRT 3. Focal salvage in selected pts postrecurrences after IMRT when not a candidate for BT salvage 4. Patients presenting with	1. Very large median lobe 2. Unable to lie still and flat for 45 min (e.g., tremor) 3. Poor localization because of metal artifacts (e.g., hip replacement, presence of PPI seeds) 4. Poor seed positioning (“too close”)

	obstruction because of locally advanced disease (e.g., “reverse” boost) 5. Patient preference (e.g., convenience)	5. Not covered by insurance 6. Protocol requires other treatments

[a]Approximate year program started at UCSF.
[b]Delivered with either conventional fractionation or hypofractionation.
“Primary”: this term reflects the clinical nuances that go into the decisions concerning the use of various radiation options considered while practicing the “Art” of radiation therapy. There may be exceptions to what physicians decide to recommend to specific patients, but these “Primary” options as listed in this table reflect our typical considerations and our practice habits. It is recognized that for purposes of continuity of care and presumed clinical equivalence, patients who could be managed appropriately by more than one boost modality are more likely to be managed via the modality favor by the “clinical lead” radiation oncologist as listed above.

FIGURE 70.3. Biochemical disease-free survival (bDFS) (Phoenix) of high-risk (HR) patients treated with stereotactic body radiation therapy (SBRT) boost, high dose rate (HDR) boost, external beam radiation therapy plus long-term androgen deprivation therapy (EBRT + LTADT), dose-escalated external beam radiation therapy (DE-EBRT), and low dose rate brachytherapy (LDR-BT) arm of the ASCENDE-RT trial. Data from the ASCENDE-RT trial were estimated from the Kaplan-Meier curve of bDFS for HR patients. Data for RTOG-9202 (EBRT + LTADT) were estimated from biochemical rate reported. *RTOG-9202 used the ASTRO definition for biochemical failure. **DE-EBRT arm of the ASCENDE-RT trial received 8 mo of neoadjuvant androgen deprivation therapy. (Modified from Gonzalez-Motta A, Roach M. Stereotactic body radiotherapy (SBRT) for high-risk prostate cancer: where are we now? *Pract Radiat Oncol* 2018;8[3]:185–202. Copyright © 2017 American Society for Radiation Oncology. With permission.[104])

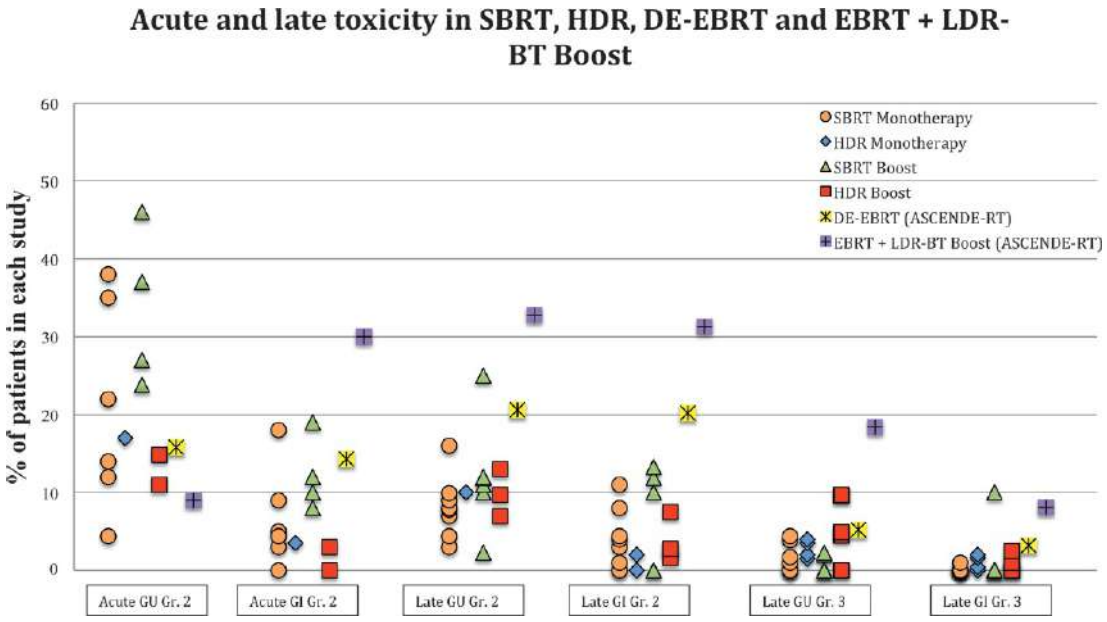

FIGURE 70.4. Acute and late toxicity reported in stereotactic body radiation therapy (SBRT), high dose rate (HDR) monotherapy, dose-escalated external beam radiation therapy (DE-EBRT), and low dose rate brachytherapy (LDR-BT) studies. Not all SBRT and HDR studies reported toxicity data. Three scales were used in the studies: the common terminology criteria for adverse events (CTCAE), the Radiation Therapy Oncology Group (RTOG) scale, and the LENT/SOMA (late effects normal tissue task force/subjective, objective, management, and analytic) scale. However, they were plotted together in the figure. (Modified from Gonzalez-Motta A, Roach M. Stereotactic body radiotherapy (SBRT) for high-risk prostate cancer: where are we now? *Pract Radiat Oncol* 2018;8[3]:185–202. Copyright © 2017 American Society for Radiation Oncology. Brachytherapy and Stereotactic Body Radiation Therapy Boost

Brachytherapy Boost

Notwithstanding the downsides that brachytherapy is an invasive procedure that requires anesthesia, additional resources, and expertise, the advantages of incorporating prostate brachytherapy as a means of boosting the dose to the prostate gland are compelling. First, the achievable biologically effective dose (BED) to the prostate far exceeds what can be achieved by IMRT, which appears to translate into a higher rate of local control and possibly cure. In addition to the recently reported ASCENDE-RT trial involving PPI boost there are a number of other comparative studies supportive of HDR brachytherapy boost as well.[106] For example, Hoskin et al. reported the results of their phase III trial comparing EBRT alone (55 Gy in 20 fractions) with combined EBRT (35.75 Gy in 13 fractions) followed by HDR prostate brachytherapy (17 Gy in 2 fractions over 24 hours) among 218 patients with clinically localized prostate cancer.[107] Biochemical control was significantly higher in patients treated with EBRT +

HDR (P = .04). In multivariate analysis, risk category and ADT were significant covariates for risk of relapse. Of note perhaps because of the study size, there were no differences in OS. Fortunately, the incidence of severe late urinary and bowel morbidity was similar. In addition to apparently rendering improved PSA results, with a brachytherapy boost, the overall treatment time is usually less than the usual 8 weeks of conventionally fractionated x-ray therapy (XRT) and therefore more convenient for patients.

As compared to LDR brachytherapy, HDR brachytherapy yields the following advantages: greater flexibility in source positioning, adaption of dose to target and healthy organs, target volume–dose optimization, high-quality planning and dose distribution, lower risk of radiation exposition to health care personnel or public, and reduced cost. The potential disadvantage of HDR is that it is often fractionated and takes more time and therefore may require more workload and careful coordination from the health care personnel. The indications of combined EBRT and brachytherapy boost are those with intermediate- or high-risk prostate cancer, particularly in patients who are relatively young and have high-volume disease. Relative contraindications to the use of a brachytherapy boost includes those with a large prostate (>60 cc), prior transurethral resection of the prostate with a large residual urethral defect, anticoagulation use, and significant urinary symptoms (i.e., International Prostate Symptom Score (IPSS) >20).

As noted previously, HDR brachytherapy may be performed before, during, or after the EBRT. The optimal HDR dose fractionation is currently unknown, and there is significant variability across centers. Nonetheless, there is a shift toward fewer implants, fewer fractions, and higher dose per fraction because of the radiobiologic advantage of high dose per fraction in prostate cancer. Reflecting this lack of consensus, RTOG-0815 and RTOG-0924 stipulate different HDR prescription doses. In RTOG-0815, the HDR brachytherapy boost may be performed during EBRT or within 1 week prior to its initiation or following its completion. The prescription is 21 Gy delivered in 2 equal fractions of 10.5 Gy, separated by at least 6 hours and given within 24 hours. In RTOG-0924, the implant may be done during EBRT or within 2 weeks prior to its initiation or following its completion. The prescription is 15 Gy in a single fraction. In both protocols, the dose constraints to the bladder is V75 <1 cc, rectum is V75 <1 cc, and urethra is V125 <1 cc and V150 is 0%.

SBRT Boost

More recently, there has been an increased interest in the use of SBRT as an alternative to the use of brachytherapy.[104] Gonzalez-Motta and Roach recently reviewed outcomes reported for patients with high-risk disease treated with SBRT as monotherapy or as a boost following EBRT.[104] Their systematic literature review was conducted to review the current evidence of biochemical disease-free survival (bDFS) and toxicity associated with the use of SBRT in high-risk prostate cancer either as monotherapy or as a boost. In addition, they compared their outcomes to selected series including patients treated with HDR, PPI, and EBRT (Fig. 70.3). A total of 20 SBRT studies (median follow-up 1.6 to 7 years) were included in their review with 5-year bDFS of 81% to 91% in monotherapy and 90% to 98% in boost studies compared to, 19 studies reporting bDFS of 85% to 93% and 72% to 93%, respectively, with HDR monotherapy or boost in selected high-risk patients, respectively. They also reported that the incidence of late grade 3 genitourinary toxicity was 0% to 4.4% and 0% to 2.3% in SBRT monotherapy and SBRT boost studies, respectively, not dissimilar to those seen with other forms of radiation (Fig. 70.4). Based on this analysis, outcomes appear to be similar with SBRT as with HDR, although ideally this should be validated in clinical trials. Table 70.3 summarizes the generally preferred options and the associated indications for how various types of boost techniques are chosen in patients undergoing definitive radiation therapy for clinically localized prostate cancer at UCSF.

TECHNICAL CONSIDERATIONS FOR EXTERNAL BEAM RADIATION

External Beam Radiation Therapy

EBRT using IMRT is recommended for optimal conformal target coverage and avoidance of rectum and bladder. At a minimum, the prostate, seminal vesicles, and periprostatic tissue should be irradiated. Inclusion of the first echelon lymph nodes (i.e., mini-pelvis) or the entire pelvic nodal contents (i.e., whole pelvis) may be considered, based on the estimated risk of involvement. The recommended EBRT dose is 45 to 50.4 Gy in 1.8 to 2.0 Gy per fraction. Generally speaking, the role of hypofractionated regimens has been less well defined in patients with unfavorable to higher-risk disease.[108–110] LDR brachytherapy boost may be performed either prior to starting the EBRT or 2 to 4 weeks after completing EBRT. The technique is identical to that of LDR brachytherapy as monotherapy (see Chapter 65). The American Brachytherapy

Society recommends (^{125})I and (^{103})Pd doses of 100 to 110 Gy and 80 to 90 Gy, respectively.[111]

Prostate Motion and the Use of IGRT (Image-Guided IMRT)

The use of fiducial gold seed markers and daily electronic portal imaging (EPI) with online correction and/or the use of cone-beam computed tomography (CBCT) or endorectal balloons may be considered.[112,113] Well-placed marker migration was found to be minimal, with 79% within 1 mm and 96% within 1.5 mm. The latter results have been corroborated by Kupelian et al., who demonstrated that the average absolute variation in intermarker distance was 1.01 ± 1.03 mm.[114–116] Only 1% of the markers exhibited frequent movement, and it was found to be due to prostate deformation secondary to rectal filling. CBCT for online correction is gaining popularity as it allows for soft tissue matching and does not require an invasive procedure to implant fiducial markers. Moseley et al. compared kilovoltage CBCT with fiducial markers and EPI and found no significant difference as a means for image guidance.[113] Langen et al. described broadly two different types of intrafraction motions.[117,118] One is by a slow, small drift, usually posteriorly and inferiorly, that is thought to be associated with pelvic muscle relaxation or the gradual movement of rectal contents away from the prostate. Second is a sudden and transient motion, usually anteriorly and superiorly, that can be significant in extent and is thought to be due to peristalsis. In the cohort of 17 patients (550 fractions), the average proportion of the total treatment time that the prostate was displaced by >3 and >5 mm was 13.6% and 3.3%, respectively. However, when analyzed by patient-to-patient basis, the prostate was displaced by 36.2% and 10.9%, respectively. An analysis of patients treated at UCSF, Chen et al. demonstrated that an isocenter shift of 5 or 10 mm in the superior direction could reduce nodal target coverage by 11% and 26%, respectively, with whole-pelvic IMRT. Xia et al. compared multiple adaptive plans, isoshifting, and multileaf collimator (MLC) shifting and concluded that MLC shifting was the most effective in addressing the independent movement of the prostate and pelvic nodes during radiation therapy.[119–121] In a study by Chung et al., patients treated with image-guided IMRT to pelvic nodes had significantly lower dose to the rectum and bladder and fewer toxicities than those who received IMRT only.[122] Rectal spacers are not generally recommended because of the potential concern for areas of extracapsular extension (ECE) and the observed marginal impact on grade 1 toxicity.[123,124]

Volumes and Setup Variation

We routinely place three fiducial gold seed markers into the prostate under transrectal ultrasound guidance—two in the base and one in the apex. Each marker is approximately 1.1 mm in diameter and 3 mm in length. We use an amorphous silicon flat panel detector to make any necessary adjustments prior to each treatment. As such, the authors apply a 3-mm margin around the prostate gland and seminal vesicles in defining the PTV. For patients with hip replacements, the authors use cone-beam CT for image guidance. At institutions without daily EPI to control for intra- and interfraction prostate motion, larger margins such as 0.5 to 1 cm should be considered. Patients are instructed to empty their rectum with an enema prior to simulation. Patients are told to maintain a full bladder during simulation and treatment. A retrograde urethrogram is no longer performed at UCSF to assist in identifying the apex of the gland, except in patients undergoing SBRT for whom an MRI is not possible or contraindicated. Three-millimeter slice thickness is used for the CT simulation. The critical organs that are contoured include the penile bulb, small bowel, rectum, bladder, and femoral heads. The entire rectum is contoured from the anus to the rectosigmoid junction. Rectal spacers are not recommended for patients with intermediate-risk and/or high-risk disease.

Intensity-Modulated Radiation Therapy Treatment Planning

For patients opting for definitive IMRT to the pelvis and prostate, the authors use a two- or three-phase plan. The first phase delivers 25 to 30 fractions of 1.8 Gy (total 45 to 60 Gy [the latter PET positive sites], superior border L4–L5 with node negative by imaging). Concurrently 2 Gy per fraction (total 54 to 56 Gy) to the seminal vesicles and prostate PTV. PET + nodes are boosted to 60 Gy and para-aortic nodes added if pelvic nodes are positive. The second phase is a cone-down boost to the prostate PTV alone with 12 fractions of 2.0 Gy per fraction. Therefore, the minimum total dose to the prostate (prescribed to the PTV) is 78 Gy. In postoperative patients opting for pelvic radiation therapy, the authors prescribe 25 fractions of 1.8 Gy to the nodes (total dose 45 Gy) and 2 Gy per fraction to the tumor bed PTV (total dose 50 Gy) and then 9 fractions of 2.0 Gy per fraction to the prostate bed (total minimal PTV dose 68 Gy).

Toxicity of Pelvic Intensity-Modulated Radiation Therapy

Since the previous edition, IMRT has been adopted as standard of care for pelvic nodal irradiation. For historical purposes, with conventional technique, pelvic

irradiation is usually treated with a four-field box. The target volume usually includes the prostate, seminal vesicles, obturator, and proximal internal and external iliac nodal regions. Occasionally, common iliac, para-aortic, and even perirectal nodes are included in the initial target. The traditional field borders of the anteroposterior portals previously were as follows: superior at the L5-S1 interspace, inferior at 2 cm distal to the membranous urethra (defined by the apex of the urethrogram peak), and 1.5 to 2 cm lateral of the pelvic brim. More recently based on work involving sentinel lymph nodal imaging, we now recommend extending the superior border to L3-L4 or L4-L5 instead of L5-S1. Corner blocks are usually placed at all four corners to limit dose to the small bowel and femoral heads. In the lateral portals, the superior and inferior borders are placed at the same point as the anteroposterior portals; the anterior border is placed at the anterior most aspect of the pubic symphysis, and the posterior border is placed at the S2-S3 interspace. With CT planning, the prostate, seminal vesicles, rectum, small bowel, bladder, pelvic vessels, and penile bulb may be contoured to facilitate shielding of the rectum and small bowel.

Compared to conventional technique, IMRT allows unprecedented sparing of nearby critical structures like the rectum, small bowel, bladder, and femoral heads. In a study from UCSF, Wang-Chesebro et al. compared the nodal target coverage by conventional field borders with IMRT (Fig. 70.5).[125] The nodes that were contoured included the obturator, internal or external iliac, common iliac, and presacral regions. In the conventional four-field plan, only 70.3% of the nodal target volume received the prescription dose of 45 Gy, whereas 96.2% was covered in the IMRT plan (P = .002). Even worse, conventional field placement led to 20.2% of the nodal target volume to receive <80% of the prescription dose. The rectal and bladder volume receiving 95% of the prescribed dose was significantly reduced with IMRT, with an absolute reduction of 23% and 80%, respectively.

Whereas conventional technique involved simply placing field borders based on bony anatomy, IMRT requires the delineation of a nodal target volume based on vasculature. Investigators have used lymphotropic nanoparticle-enhanced MRI and ultra-small superparamagnetic iron oxide lymph node contrast agent, ferumoxtran-10, to develop nodal CTV models.[48] These MRI studies have formed the foundation for the RTOG Genitourinary Radiation Oncology Consensus on pelvic nodal CTV delineation, as shown in Figure 70.6.[49,103] However, the RTOG guidelines did not use sentinel lymph node imaging, which in a study by Chen et al. demonstrated that the RTOG pelvic nodal CTV

included all identified sentinel lymph nodes in only 30% of patients.[58] In the same consensus, Lawton et al. recommended dose constraints to the rectum (V50 Gy ≤50%, V70 Gy ≤20%), bladder (V55 Gy ≤50%, V70 Gy ≤30%), femoral heads (V50 Gy <5%), and small bowel (maximum dose <52 Gy). Based on an extensive literature search, Chan et al. proposed guidelines on rectal dose constraints for patients receiving pelvic radiation therapy.[126]

ANDROGEN DEPRIVATION THERAPY AND RT: EVIDENCE AND INDICATIONS

EBRT Versus EBRT + ADT and ADT Versus ADT + EBRT

The optimal dose of radiation required to obtain a high level of local control while maintaining an acceptably low level of complications is not known. Several phase III randomized trials have compared conventional-dose with high-dose (76 to 82 Gy) EBRT, and although essentially all have demonstrated an improvement in PSA control, no survival advantage attributable to radiation dose were observed.[8,127,128] As expected, grade 3 GI toxicities appear to be worse with dose escalation. Of note, the Medical Research Council (MRC) RT01, Dutch CKVO96–10, and the Spanish trial permitted ADT.[127–129] The MRC and Spanish trials mandated ADT on both arms, yet dose escalation still appeared to be beneficial. This suggests that dose escalation alone cannot replace hormonal therapy as a strategy to improve cure and that both may be necessary in patients with intermediate- and high-risk disease. Recently, the RTOG (now NRG [NSAB, RTOG, and GoG]) completed accrual to RTOG-0815, a phase III multicenter trial evaluating the addition of 6 months of androgen blockade with dose-escalated radiation therapy, achieved by either 3DCRT or IMRT (79.2 Gy), combined low dose rate (110 Gy with ^{125}I or 100 Gy with ^{103}Pd) brachytherapy boost with 3DCRT or IMRT (45 Gy to the prostate and seminal vesicles), or combined HDR (2 fractions of 10.5 Gy per fractions); hopefully, this trial will finally fully address the question of the need for ADT when dose-escalated radiation is used. At UCSF, we have long favored brachytherapy boost (BT) for suitable patients treated with curative intent, based on the lower PSA nadir, degree of metabolic atrophy noted, and PSA control rates compared to any form of dose-escalated EBRT (including proton beam radiation therapy).[130–132] This philosophy seems to have been vindicated by the recent findings from the ASCENDE-RT trial, which confirmed a substantially higher PSA control rate with a LDR brachytherapy boost after ADT and EBRT compared to ADT and

dose-escalated EBRT alone (see the discussion of brachytherapy below).[106]

Multiple phase III randomized controlled trials and several meta-analyses have been published in the peer reviewed literature that compared radiation therapy alone with radiation therapy and ADT.[8] At UCSF, the authors' practices regarding integrating pelvic radiation therapy and hormonal therapy are summarized in Table 70.4. Whether the benefit of ADT remains in the current era of dose escalation is currently unclear and is the basis of the recently completed RTOG-0815. Previously, RTOG-9408 was designed to evaluate whether similar duration and timing of ADT (2 months neoadjuvant [NHT] and 2 months concurrent) could improve outcomes in patients with more favorable disease.[133] Among the 1,979 eligible patients, 54% had intermediate-risk disease and 11% had high-risk disease. All patients had prostate-only radiation therapy to 68.4 Gy, except for those with a PSA <10 ng/mL, Gleason score of 2 to 6, or negative lymph node dissection. The latter group received pelvic radiation therapy to 46.8 Gy and a total prostate dose of 66.6 Gy. With a median follow-up of 9.1 years, 10-year overall survival (57% vs. 62%; $P = .03$), PCSM (8% vs. 4%; $P = .001$), PSA failure (41% vs. 26%; $P < .001$), and distant metastases (8% vs. 6%; $P = .04$) were significantly in favor of the ADT arm. In *post hoc* analyses, the benefit in overall survival and PCSM appeared to be primarily among intermediate-risk patients. Two-year positive prostate biopsy rates (39% vs. 20%; $P < .001$) were significantly improved with ADT. The authors give 2 months of NHT using a luteinizing hormone–releasing hormone (LHRH) agonist and an antiandrogen.

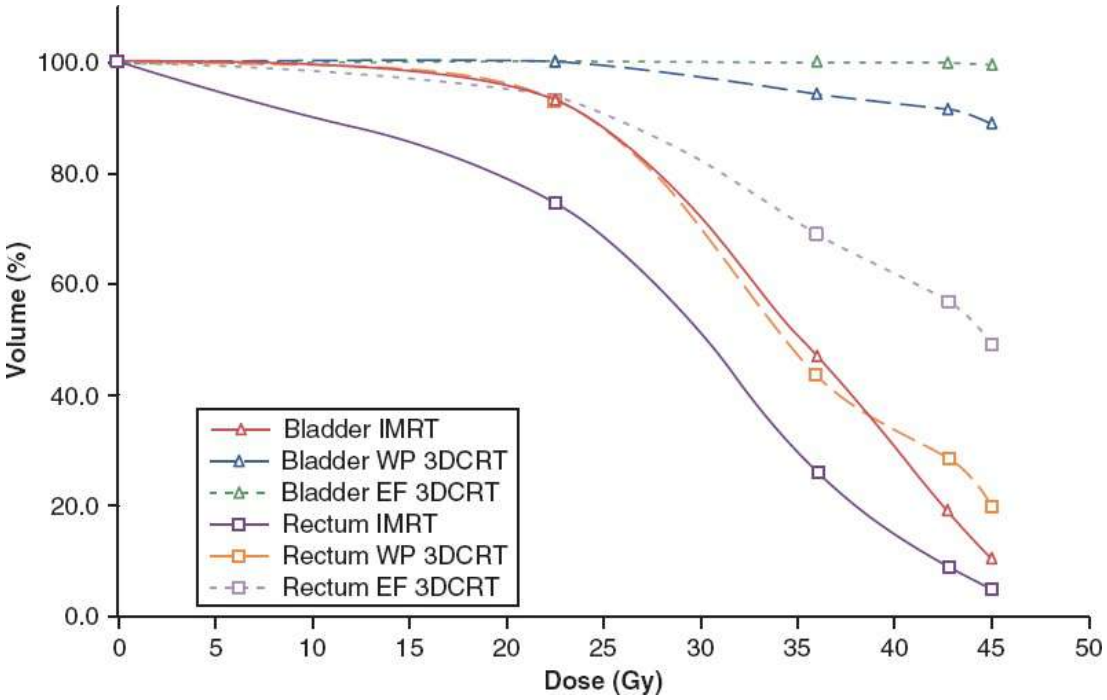

FIGURE 70.5. Comparison of dose–volume histograms for the rectum and bladder for whole-pelvic only phase using intensity-modulated radiotherapy (IMRT), whole-pelvic (WP) three-dimensional conformal radiotherapy (3DCRT), and extended-field (EF) 3DCRT plans. For both the bladder and rectum, IMRT significantly reduced V45, V42.75, V36, and V22.5 ($P < .01$ for all comparisons) compared to both WP and EF 3DCRT plans. TABLE 70.4 GENERAL RECOMMENDATIONS FOR RADIATION THERAPY AND ADT

	Low Risk	Favorable Intermediate Risk	Unfavorable Intermediate Risk	High Risk
Active surveillance	Preferred	In highly selected patients	Only appropriate in those with a short life expectancy	Only appropriate in those with a very short life expectancy
Radiation therapy	PORT	PORT + ADT (4 mo)	WPRT + NHT (4 mo or longer in selected patients)	WPRT
ADT	Not indicated	Neoadjuvant and concurrent with EBRT (4 mo)	Neoadjuvant (2 mo)	Neoadjuvant (2 mo)
		Adjuvant (4 mo)	Concurrent +/− adjuvant	Concurrent + adjuvant (24–36 mo)
Other				+/− Second-generation ADT in selected patients[a]

[a]Age < 70, node +?
ADT, androgen deprivation therapy; PORT, prostate-only radiation therapy; WPRT, whole-pelvic radiation therapy.

In addition to NHT, 2 to 3 years of adjuvant ADT (e.g., LHRH agonist) is recommended for high-risk disease, but on occasion, lifelong androgen deprivation is used in patients with very high-risk disease (Table 70.4). Early trials demonstrated that for men with locally advanced disease, initial management with hormonal therapy resulted in a survival advantage when compared to deferred ADT.[8,134] Subsequently, numerous trials showed that the addition of ADT to EBRT improved survival for men with intermediate- and high-risk disease.[8] There is also clear level I evidence that EBRT + ADT renders a better survival than ADT alone for men with locally advanced disease.[135–137]

SEQUENCING, OPTIMAL TIMING, AND DURATION OF ADT AND RADIATION THERAPY

Sequence-Dependent Interactions Between ADT and EBRT

NHT by definition implies delivery of the hormone prior to definitive radiation, whereas adjuvant ADT (AHT) implies the initiation of hormonal therapy after

the completion of radiation. Few studies have assessed the optimal sequence or precise duration of ADT. RTOG-9413 randomized 1,323 men to either receive 4 months of NHT (commenced 2 months prior to starting EBRT) compared to 4 months of AHT.[78] The authors noted sequence-dependent beneficial interactions, such that when NHT is used, PSA control favored the use of WPRT over PORT. However, NHT + WPRT was also associated with higher rates of late grade 3 GI toxicity at 10 years occurring in 5.1%, compared to 1.6 and 0.6% in both AHT groups and pts treated with NHT + PORT, respectively (P = .0009). Of note, when PORT is used, AHT appears to be at least as effective as NHT. The mechanism by which these sequence-dependent interactions occurs is unknown.

Optimal Duration of Short-Term ADT

To date, there are at least eight randomized trials (two Canadian, one Irish, one Australian, two conducted in the United States [RTOG-9202, 9910], and two conducted by the EORTC) evaluating the optimal duration of ADT with a survival endpoint and an additional three randomized trials (two Canadian and one EORTC) with a PSA control endpoint.[8] The Canadian Urologic Oncology Group (CUOG) study randomized 378 patients to either 3 or 8 months of NHT plus EBRT, whereas the Irish Clinical Oncology Research Group designed a randomized study comparing 4 and 8 months of NHT with EBRT.[138,139] TROG compared 0 versus 3 versus 6 months ADT with EBRT, whereas RTOG-9910 compared 8 versus 28 weeks of NHT (total 4 vs. 9 months).[140,141] Taken together, these studies suggest that for patients with intermediate-risk disease, there is no reason to extend short-term ADT beyond 4 months when combined with EBRT.[8,26]

Optimal Duration of Long-Term ADT

A meta-analysis of RTOG trials suggested that long-term ADT was superior to short-term ADT for patients with high-risk disease.[26] This assertion has been subsequently confirmed by EORTC-22961 that compared 6 months with 36 months of adjuvant ADT in 1,113 patients with locally advanced prostate cancer and demonstrated the superiority of the latter.[142] RTOG-9202, another phase III trial, also demonstrated that the addition of 24 months of adjuvant ADT could improve outcome in high-risk patients, compared to short term (4 months).[143] Aside from overall survival, all other endpoints were significantly in favor of the long-term ADT arm: PCSM (83.9% vs. 88.7%; P < .0001), disease-free survival (13.2% vs. 22.5%; P < .0001), and biochemical control (31.9% vs. 48.1%; P <

.0001). In subgroup analysis, again, patients with a Gleason score of 8 to 10 had a significant improvement in overall survival with long-term AST but not with a Gleason score of 2 to 7. The authors speculate that the absence in overall survival difference may be due to insufficient follow-up among patients with a Gleason score of 2 to 7. These data, as previously noted, are completely consistent with the meta-analysis of five consecutive RTOG randomized controlled prostate cancer trials (including RTOG-8531 and RTOG-8610), where 2,742 men were stratified into four previously identified risk groups based on Gleason score, clinical T-stage, and pelvic nodal involvement.[26]

Toxicities Associated with Androgen Deprivation Therapy

Having established that ADT improves survival when combined with radiation therapy, enthusiasm has been somewhat tempered by the increasing recognition of the potentially serious complications of ADT.[144] Some of these complications have been exaggerated.[145] What is clear is that the risk of fractures, fatigue, weight gain, osteoporosis, depression, decreased cognitive function, erectile dysfunction, loss of libido, gynecomastia, anemia, decreased high-density lipoprotein, insulin resistance, and hot flashes are increased with ADT. For example, in a study of 50,613 men with prostate cancer compiled from a linked database of Surveillance, Epidemiology, and End Results (SEER) and Medicare, the addition of ADT significantly increased the risk of any fracture from 12.6% to 19.4%; fractures requiring hospitalization similarly increased from 2.37% to 5.19%.[146]

More controversial is the issue of the impact of ADT on cardiovascular disease.[147–151] Some studies have raised the question of whether ADT, by way of increasing body fat and cholesterol levels, increases the risk of cardiovascular disease.[145] In an observational study of a population-based cohort of 73,196 patients with clinically localized prostate cancer, ADT was associated with an increased risk of incident diabetes (HR 1.44; $P < .001$), cardiovascular disease (HR 1.16; $P < .001$), myocardial infarction (HR 1.11; $P = .03$), and sudden cardiac death (HR 1.16; $P = .004$). However, data from randomized controlled trials of radiation therapy with or without ADT have not shown any increased cardiovascular disease, although these studies were not powered adequately.[152] The bottom-line is that *if* ADT increases the risk of cardiovascular disease, the risk is quite low and the subset of patients who are at risk are those with severe underlying cardiovascular disease.[148]

In addition to cardiovascular risk, another area to which much attention has

been paid is the risk of the potential impact of ADT on the brain. For example, Nead et al. published a series of methodologically flawed studies that essentially ignore the tendency for men with declining mental status to be at greater risk for receiving ADT.[153,154] The best data suggest that the risk of damage to both the central nervous system and cardiovascular systems is low, such that with rare exceptions the benefits justify the risk.[152,155]

POSTOPERATIVE (AFTER A RADICAL PROSTATECTOMY) RADIATION THERAPY

Local Versus Distant Recurrence

A substantial number of men undergoing a radical prostatectomy will experience a recurrence with the only curative treatment afterward being postoperative radiation.[156] Positive surgical margins (PSM) and ECE are associated with increased risk of PSA and local recurrences. Rates of PSM have been reported to be 5% to 53%, with variations because of surgeon experience, surgical technique, preoperative PSA, clinical stage, and ECE.[157,158] In a multicenter study of 5,831 men treated with radical prostatectomy from eight international institutions, the 5-year biochemical control rates were 83.8% and 53.1% for men with negative and PSM, respectively ($P = .0001$).[159] In an analysis of patterns of treatment failure in the study by the South West Oncology Group, SWOG-8794, a randomized trial evaluating adjuvant radiation therapy (ART) in patients with adverse pathologic features (pT3a-b or PSM), the predominant site of failure was local rather than metastatic.[160] Overall, local failure was observed in 22% and 8% of patients in the observation and ART arms, respectively. In contrast, distant metastasis was observed in 16% and 7% of patients, respectively.

Many investigators have reported on the merits of Gleason score, time to PSA relapse, postradiation PSA nadir, and PSA doubling time (PSA-DT) after PSA failure as a predictor of distant metastases versus local recurrence and PCSM. Pound et al.[161] reported that time to PSA recurrence ≤2 years after surgery, Gleason score of 8 to 10, and PSA-DT ≤10 months predicted for metastatic disease. Lee et al.[162] reported similar findings, with a PSA-DT of <12 months and an interval of <12 months from end of radiation therapy to PSA rise as significant independent predictors of distant failure. In a multi-institutional analysis of 4,839 patients treated with radiation therapy alone, PSA nadir and time to PSA nadir were significant independent predictors of biochemical and distant failure-free survival.[163] Eight-year biochemical control was 75%, 52%,

41%, and 18% and distant failure-free survival was 97%, 96%, 91%, and 73% with a PSA nadir of 0 to 0.49, 0.5 to 0.99, 1 to 1.99, and ≥2 ng/mL, respectively ($P < .0001$). A nomogram incorporating PSA-DT has been created to predict risk of distant metastases.[164]

Prostate Cancer–Specific Mortality

Sandler et al.[165] observed that a PSA-DT of <12 months had significantly greater PCSM than when it was >12 months. A study from Johns Hopkins found similar results with PSA-DT, Gleason score (≤7 vs. 8 to 10), and disease-free interval (≤3 vs. >3 years) independently associated with PCSM.[166] Compiled from two multi-institutional databases with a cumulative cohort of 8,669 men treated with surgery or radiation therapy, CaPSURE and CPDR, Zhou et al.[167] showed that a PSA-DT of <3 months ($P < .0001$) and Gleason score of 8 to 10 ($P < .0001$) were significantly associated with PCSM. Zelefsky et al.[168] reported that the postradiation therapy 2-year PSA nadir of ≤1.5 ng/mL was associated with a reduced risk of developing distant metastases and PCSM.

Adjuvant Radiation Therapy

The argument for ART is that patients with PSM or ECE after radical prostatectomy are at an increased risk of local recurrence. Yet it is also known that having either ECE or PSM does not necessarily mean that local recurrence is inevitable. Epstein et al.[159] reported on 617 men with clinically confined disease treated with radical prostatectomy and found that despite ECE, the 10-year progression-free survival was 58.4% to 67.7% depending on the extent. By the same token, 10-year progression-free survival was 54.9% in men with PSM. Progression was independently predicted by Gleason score, PSM, and ECE.

How common are PSM and ECE seen? In a large series from Memorial Sloan-Kettering Cancer Center and Baylor College of Medicine, the outcomes of 4,629 men with T1 to T3 prostate cancer were analyzed.[157] Overall, PSM were seen in 20% of cases (range 0% to 48%). ECE was observed in 30.1% of cases. When only surgeons who had contributed more than 10 cases were considered, the rate of PSM ranged from 10% to 48%. Independent predictors of PSM were PSA, Gleason score, ECE, the surgeon, and surgical volume.

Three large phase III trials, evaluating the merits of adjuvant versus expectant management in postoperative patients with PSM or pT3 disease, were reported.[169–171] EORTC-22911 consisted of 1,005 men with pT2-3N0 and at least one of the following risk factors: ECE, PSM, or SVI.[169] In the ART arm,

radiation was commenced at a median of 90 days postoperative. ART consisted of 50 Gy in 25 fractions to a large volume that encompassed the surgical limits and subclinical disease, followed by 10 Gy boost given over 5 fractions to a reduced margin around the prostatic bed. The protocol salvage radiation therapy (SRT) dose fractionation was 70 Gy in 35 fractions. Toxicity was surprisingly mild. Radiation therapy was interrupted due to toxicities in only 3.1%, with diarrhea responsible in 8 of the 14 patients. In the ART arm, grade 3 diarrhea (5.3%) and urinary frequency (3.3%) were relatively low; the only grade 4 toxicity was urinary frequency (0.4%). There was no added risk of urinary incontinence with ART. Five-year biochemical progression-free survival was significantly improved from 52.6% to 74.0% ($P < .0001$) with ART, representing a 52% reduction in PSA relapse. The treatment benefit was significant for all postoperative prognostic factors, including negative surgical margins or absence of SVI and ECE. Long-term results, with a median follow-up of 10.6 years, were recently published and continued to support the use of ART.[172] The ART arm continued to have significantly improved biochemical progression-free survival (60.6% vs. 41.1%; HR 0.49, $P < .0001$). Similarly, 10-year cumulative rate of locoregional relapse was lower in the ART arm (7.3% vs. 16.6%; HR 0.45, $P < .001$). No difference in metastases-free or overall survival was observed, though it was not powered to detect a difference. However, the 10-year cumulative incidence of severe (grade 3) late toxicities (5.3% vs. 2.5%, $P = .052$) and late grade 2 or higher genitourinary toxicities (21.3% vs. 13.5%; $P = .003$) were higher in the ART arm. There was no significant difference in cumulative incidence of distant metastases ($P = .94$), prostate cancer mortality ($P = .34$), or overall survival ($P = .20$). In the wait-and-see arm, 275 patients had clinical or biochemical progression, of which 231 (84%) went on to receive active treatment and 155 (56%) received SRT at a median PSA of 1.7 ng/mL.

SWOG-8794 randomly assigned 425 node-negative patients initially treated with radical prostatectomy but found to have either PSM or pT3 (ECE and/or SVI) disease to ART or observation.[170] Central pathology review was performed in 73% of patients, and there was a 95% concordance with the community pathologist. Ninety percent of patients had ECE or PSM. Two-thirds of patients had a postoperative PSA <0.2 ng/mL. ART consisted of 60 to 64 Gy. Median PSA relapse-free survival was significantly longer with ART (10.3 vs. 3.1 years; HR 0.43; $P < .001$). Updated results have been published with a median follow-up of 12.6 years.[173] The 10-year distant metastasis-free survival (71% vs. 61%; HR 0.71; $P = .016$) and overall survival (74% vs. 66%; HR 0.72; $P = .023$) were

significantly improved with ART. The median distant metastasis-free survival was prolonged from 12.9 to 14.7 years with ART, and overall survival from 13.3 to 15.2 years. On subgroup analyses, there was no interaction between the adverse pathologic features and treatment effect, and therefore, the benefit in distant metastasis-free survival was seen in all subsets. Among patients in the ART arm, those with an undetectable postoperative PSA had a significantly better 10-year distant metastasis-free survival (73% vs. 65%; $P = .03$) than those with a PSA >0.2 ng/mL. In the observation arm, only one-third of patients eventually received SRT, of which the median preradiation therapy PSA was 1.0 ng/mL. Hormonal therapy was initiated later (median 12.4 vs. 9.9 years) and less frequently (39% vs. 50%) in the ART arm. Complications observed in the ART arm included proctitis (3.3% vs. 0%), urethral stricture (17.8% vs. 9.5%), and total urinary incontinence (6.5% vs. 2.8%).

From the German Cancer Society, ARO-96–02/AUO-09/95 accrued 388 patients from 22 centers with pT3 or PSM to either ART (60 Gy in 2 Gy fractions) or observation.[171] In contrast to SWOG-8794 and EORTC-22911, only patients who achieved an undetectable postop PSA were included, 3DCRT planning was mandated, and central pathology review was required. In the initial report with a median follow-up of 54 months, using intention-to-treat analysis of only patients who achieved an undetectable postoperative PSA, ART significantly improved progression-free survival ($P < .0001$). When analyzed according to the received treatment, 5-year progression-free survival was 72% versus 54% in favor of ART ($P = .0015$; HR 0.53). ART was very well tolerated, with only 3% reporting acute grade 3 bladder toxicity and none with grade 3 rectal toxicity (12% had grade 2 rectal toxicity). Of note, the compliance in the ART arm was surprisingly poor—19% did not proceed with radiation therapy. Updated results with 10-year follow-up have since been published.[174] The 10-year progression-free survival was significantly better in the ART arm (56% vs. 35%; HR 0.51, $P < .0001$). However, despite longer follow-up, no difference in the development of distant metastases ($P = .53$) or overall survival ($P = .59$) was seen. The cumulative incidence of late grade 3 toxicities was 5.3% with ART and 2.5% with observation ($P = .052$). There was only one event of late grade 3 toxicity, which involved the bladder, and no late grade 4 GI or GU toxicities were observed.

A significant limitation of these three clinical trials was that they were conducted prior to the current era of ultrasensitive PSA assays, which can detect PSA levels as low as 0.01 ng/mL. For instance, the ARO trial defined

undetectable PSA as those <0.1 ng/mL, of which 59% had a PSA of >0.03 to 0.1 ng/mL. In the EORTC-22911 and SWOG-8794 studies, 11% and 34% of patients, respectively, had a postoperative PSA >0.2 ng/mL. In effect, a significant proportion of patients enrolled in these trials had "measurable disease" and thus received SRT.[175] Although there was an initial surge in enthusiasm in embracing ART, it has given way to increasing skepticism. In an observational study of postop patients identified by the National Cancer Data Base, which tracks outcomes on 71% of newly diagnosed cancer cases in the United State, 130,681 patients with at least one high-risk pathologic factor and diagnosed between 2004 and 2011 were analyzed.[176] The overall rate of ART was surprisingly low (9.9%) and did not change during the study period despite three randomized controlled trials demonstrating improved outcomes with ART. Similarly, SEER data of 35,361 postop patients diagnosed between 2004 and 2011 revealed that ART utilization remained low, 15.8% after March 2009 versus 13.5% before.[177]

Given the prevalence of ultrasensitive PSA assays, it is unclear whether a strategy of active surveillance with PSA tests and the early initiation of radiation therapy only when PSA has shown an upward trend can yield equivalent or better results. The advantage of such an approach is that perhaps the 50% of patients who do not relapse after surgery will be spared from radiation therapy. The disadvantage is that biochemical control and distant metastasis-free survival (SWOG-8794) may be compromised by waiting too long to intervene with definitive treatment, which could serve as a nidus for metastatic spread. In an editorial, King[175] showed that for every 0.1 ng/mL increment in postoperative PSA, there is an estimated 4% reduction in biochemical control. Nonetheless, the EORTC-22911, SWOG-8794, and ARO-96–02 provide consistent level I evidence that ART is better than expectant management in terms of biochemical control, at an acceptable toxicity. It remains to be seen whether with longer follow-up this translates into an improvement in survival. Accordingly, in 2013, the ASTRO/AUA published guidelines based on a systematic review on adjuvant and SRT.[178] The panel recommended that for those with adverse pathologic features (SVI, EPE, and PSM) should be counseled and that there is level I evidence that ART reduces the risk of biochemical recurrence, local recurrence, and clinical cancer progression.

Currently accruing are three key randomized phase III trials, RADICALS, RAVES, and GETUG-17, which are investigating ART versus early SRT. RADICALS, an MRC-led phase III trial, randomizes postoperative patients to

immediate postoperative radiation therapy or early SRT.[179] RADICALS also has a hormone duration randomization substudy in which patients are randomized to radiation therapy alone or 6 months or 2 years of adjuvant hormones. Accrual was recently completed for RADICALS. RAVES is another phase III multicenter study being run in Australia and New Zealand that is randomizing patients to ART versus early SRT that is administered within 4 months following the first PSA ≥0.2 ng/mL.[180] GETUG-17 is a French study that is randomizing patients to ART and ADT versus early SRT with ADT.[181]

Salvage Radiation Therapy

As discussed earlier, the findings from EORTC-22911, SWOG-8794, and ARO-96–02/AUO-09/95 strongly advocate for the use of ART.[169–171] Accordingly, the ASTRO and AUA jointly recommended that SRT be offered to patients with biochemical recurrence, defined as a rising postop PSA ≥0.2 ng/mL with a second confirmatory level ≥ 0.2 ng/mL, or local recurrence after radical prostatectomy in the absence of distant metastases.[156] Yet none of these trials address the concept of early SRT given when the PSA is still low. The attraction of this strategy is that only half of the patients with adverse pathologic features will relapse and thus sparing them from unnecessary radiation. Furthermore, the observed benefit from ART as compared to SRT may have been augmented by some patients in the adjuvant arms who would have been cured with surgery alone.

An update of the often cited Stephenson predictive nomogram to estimate biochemical recurrence following SRT was recently published.[182,183] This was based on multi-institutional data of 2,460 patients. Unlike the initial nomogram, patients with pre-SRT PSA <0.2 ng/mL were included in the updated nomogram. The median pre-SRT PSA was 0.5 ng/mL, with 18% of patients <0.2 ng/mL. Higher pre-SRT PSA was associated with worse outcomes. The 5-year freedom from biochemical failure was 71%, 63%, 54%, 43%, and 37% for those with a pre-SRT PSA of 0.01 to 0.2, 0.21 to 0.50, 0.51 to 1.0, 1.01 to 2.0, and >2.0 ng/mL, respectively ($P < .001$). Similarly, the 10-year cumulative incidence of distant metastasis was 9%, 15%, 19%, 20%, and 37%, respectively ($P < .001$). Independent predictors of biochemical recurrence included higher pre-SRT PSA, higher Gleason score, presence of extraprostatic extension, SVI, negative surgical margins, lack of ADT, and SRT dose <66 Gy.

In the largest single-institution cohort of 1,106 patients treated with SRT, the 5- and 10-year cumulative incidence of biochemical recurrence was 50% and

64%, respectively.[184] On multivariate analysis, increasing tumor stage, Gleason score, pre-SRT PSA levels, SRT dose <68 Gy, and use of ADT were independent predictors of biochemical recurrence. Furthermore, patients with pre-SRT PSA >0.5 ng/mL had significantly higher 5-year rates of biochemical recurrence (56% vs. 42%, $P < .001$), distant metastases (14% vs. 7%, $P < .001$), and cause-specific mortality (4% vs. 1%, $P < .001$) as compared to those with pre-SRT PSA ≤0.5 ng/mL. Each doubling of pre-SRT PSA was associated with a 32% increase in the relative risk of distant metastases.

Using a multi-institutional cohort of 472 patients, Briganti et al. developed a nomogram to predict biochemical recurrence following early SRT, defined as PSA ≤0.5 ng/mL (median 0.24 ng/mL), for biochemical recurrence after previous radical prostatectomy.[185] All patients had an undetectable PSA after radical prostatectomy, but subsequently failed biochemically. With a median follow-up of 48 months, the 5-year biochemical recurrence-free survival after early SRT was 73.4%. On multivariate analysis, predictors of biochemical recurrence after early SRT included higher pathologic tumor stage, PSM, higher pathologic Gleason score, and higher pre-SRT PSA.

More recently, genomic classifiers are being developed to try to identify postop patients with adverse pathologic features who would benefit from ART. In a study by Dalela et al., they evaluated a risk stratification tool that included the Decipher multigene expression array score (GenomeDx Biosciences, Vancouver, British Columbia, Canada) with routine clinicopathologic features.[186] Their cohort included 512 postop patients with at least one pathologic adverse feature (≥ pT3a disease, PSM, or pathologic lymph node involvement) and received either ART or initial observation (with 42% subsequently receiving SRT). In multivariate analysis, in addition to Gleason score, pathologic pT3b-4 disease, and lymph node involvement, a high Decipher score was an independent predictor of higher risk of clinical recurrence. Based on these factors, a novel nomogram was created to identify those at higher risk of clinical recurrence and thus would benefit from ART, with a predictive accuracy of 85%. In another study of Decipher, Freedland et al. investigated whether it could predict for the subsequent development of metastatic disease in 170 postop patients treated with SRT for recurrence.[187] On multivariate analysis, the Decipher score was significantly predictive of metastases (HR 1.56, $P = .003$). By identifying patients at high risk of developing metastases, treatment intensification with hormonal therapy and/or systemic therapy can be explored. Likewise, patients with low risk of developing clinical recurrence or metastases

could be observed. While encouraging, external validation in larger prospective cohorts is needed.

As it stands, we have only retrospective data, though very large patient cohorts, that suggest that early SRT is more effective than later SRT, and this is likely due to reduced tumor burden.[182] Whether *early* SRT is as good as ART is unknown. As discussed earlier, RADICALS, RAVES, and GETUG-17 are three studies that will provide further insight into ART and early SRT.[179,180,188]

Androgen Suppression Therapy and Postoperative Radiation Therapy

Extrapolating from the benefits of shown in multiple phase III trials in the definitive setting, it is not surprising that ADT would be investigated in the postoperative setting. Recently, the results of RTOG-9601, a placebo-controlled phase III study to evaluate the addition of 2-years of antiandrogen therapy with SRT, were published.[189] Eligible patients included those with pathologic stage T2 with a PSM or T3 without nodal involvement. Patients were also required to have a detectable PSA of 0.2 to 4.0 ng/mL were eligible. Bicalutamide 150 mg daily for 24 months was used in the antiandrogen arm. The median follow-up among surviving patients was 13 years. The addition of antiandrogen significantly improved 12-year overall survival (76.3% vs. 71.3%; HR 0.77, P = .04), incidence of death from prostate cancer (5.8% vs. 13.4%, P < .001), cumulative incidence of metastatic prostate cancer (14.5% vs. 23.0%, P = .005), and biochemical recurrence (44.0% vs. 67.9%, P < .001). Post hoc subgroup analyses suggested that those with a PSA >1.5 ng/mL or a Gleason score of 7 had the greatest overall survival benefit. There was no difference in radiation-related acute or late toxicities. As expected, gynecomastia was more common in the antiandrogen arm and occurred in 69.7% of patients. Of note, antiandrogens alone are rarely used currently, replaced by gonadotropin-releasing hormone agonist and antagonist, and are no longer approved by the U.S. Food and Drug Administration.

GETUG-AFU16 was a phase III trial that randomized 743 postoperative patients undergoing SRT for biochemical recurrence to with or without 6 months of goserelin.[181] All patients had to have an undetectable postop PSA before biochemical recurrence. The PSA at time of randomization was <0.5 ng/mL in 80% of patients, with the upper limit of acceptance being 2 ng/mL. After a median follow-up of 63 months, the 5-year progression-free survival was significantly better in the hormone arm (80% vs. 62%, P < .0001). Independent

predictors of disease progression were pre-SRT PSA >0.5 ng/mL, seminal vesicle involvement, negative surgical margins, and pre-SRT PSA doubling time <6 months. There was no significant difference in acute or late genitourinary and gastrointestinal adverse events between the two arms.

In postop patients with *very high-risk* clinicopathologic features, investigators are evaluating the addition of docetaxel to radiation therapy and ADT based on docetaxel improving survival in men with metastatic prostate cancer.[190] RTOG-0621 is a phase II study of 74 patients who had either a postop PSA nadir >0.2 ng/mL and a Gleason score ≥ 7 or a PSA nadir ≤0.2 ng/mL, Gleason score ≥8, and ≥pT3. Patients received 6 months of ADT, radiation therapy, and six cycles of docetaxel postradiation therapy. The 3-year freedom from progression was 73%. Although grade 3 to 4 hematologic toxicities were common, only 4.1% of patients developed febrile neutropenia. Currently accruing, the follow-up phase II/III trial is NRG-GU002, which is randomizing patients with a Gleason score ≥7 and postop PSA nadir ≥0.2 ng/mL to ART and ADT with or without adjuvant docetaxel.

In summary, the evidence to date suggests that the inclusion of hormonal therapy to postoperative radiation therapy may be beneficial, although the optimal type of hormones, duration, and timing remains unknown. The results of two important phase III studies, RTOG-0534 and RADICALS, will provide more clarity on the role and duration of ADT and postoperative radiation therapy. RTOG-0534 is a three-arm trial evaluating the role of short-term hormones (4 to 6 months) and pelvic radiation therapy in the salvage setting. RADICALS is a two-part study, with the hormone component randomizing patients to no hormones (i.e., radiation therapy alone), 6 months or 2 years of gonadotrophin-releasing hormone analogue.

Postoperative Radiation Therapy Dose

Currently, ART doses of 60 to 64 Gy and SRT doses of 66 to 70 Gy appear to be the most commonly used. The ASTRO/AUA guidelines recommend at least 64 to 65 Gy in the postop setting, with no distinction between adjuvant and salvage doses.[156] In a retrospective study by Cozzarini et al., 334 patients with adverse pathologic features and an undetectable postoperative PSA who received ART were analyzed for a dose response.[191] From 1993 to 2003, the radiation therapy dose gradually increased from 55.8 to 72 Gy. When stratified by dose (<70.2 Gy [median 66.6 Gy] vs. ≥ 70.2 Gy [median 70.2 Gy]), the high-dose group had significantly better 5-year biochemical relapse-free survival (83% vs. 71%; *P* =

.001) and disease-free survival (94% vs. 88%; $P = .005$). In a systematic review, 71 studies (10,034 patients) of patients treated with SRT were identified.[192] The median radiation dose prescribed was 65.8 (range 60 to 76 Gy). A sigmoidal dose–response relationship was identified between SRT dose and relapse-free survival, with a TCD_{50} of 65.8 Gy and a 2.0% improvement with each additional Gy within a dose range of 60 to 70 Gy. Based on the sigmoidal dose–response curve, the relapse-free survival was 58.4% and 38.5% for 70 and 60 Gy, respectively. The initial results of the only randomized controlled dose escalation trial for SRT were recently published.[193] Patients with biochemical recurrence with a preradiation therapy PSA ≤ 2.0 ng/mL following radical prostatectomy were randomized to 64 or 70 Gy. There was no significant difference in acute grade 2 and 3 genitourinary or gastrointestinal toxicities between the two arms. No acute grade 4 to 5 toxicities were observed. However, on QOL questionnaires, a small but clinically relevant worsening in urinary symptoms was observed in the 70 Gy arm. Clinical outcomes are eagerly awaited. Open to accrual, NRG-GU003 is a randomized phase III trial of hypofractionated versus conventionally fractionated radiation therapy in postprostatectomy patients.

Postoperative Radiation Therapy Volume

Several consensus guidelines on delineation of the CTV in postop patients have been published, including RTOG and EORTC.[194–197] According to the RTOG contouring consensus guidelines, the limits of the prostatic fossa CTV are superior at the level of the caudal vas deferens remnant and inferior to >8 to 12 mm caudal to the vesicourethral anastomosis.[194] Above the pubic symphysis, the anterior border should include 1 to 2 cm of the posterior bladder wall, posterior border is the mesorectal fascia, and lateral border is the bounded by the sacrorectogenitopubic fascia. Below the superior border of the pubic symphysis, the anterior border is at the posterior aspect of the pubis, posterior border to the rectum, and lateral border extending to the levator ani.

Another area of research is the utility of elective nodal irradiation (ENI) in the postop setting, especially for those with higher-risk disease.[88,94,97,198] In a large multi-institutional retrospective study of 1,861 patients, ENI with SRT was associated with a significantly better 5-year freedom from biochemical failure of 62% versus 49% ($P < .001$).[100] The use of ADT with SRT was also associated with improved 5-year freedom from biochemical failure (55% vs. 50%, $P = .012$). Closed to accrual, RTOG-0534 is evaluating ENI and ADT in a three-arm study whereby patients would be randomized to prostate bed radiation therapy,

prostate bed radiation therapy with 6 months of LHRH agonist, or ENI with 6 months of LHRH agonist.

University of California, San Francisco, Recommendations of Postoperative Radiation Therapy

We endorse the ASTRO/AUA guidelines whereby patients with adverse pathologic features should be jointly counseled by their urologist and radiation oncologist on the pros and cons of ART.[156] In those with an undetectable postop PSA of <0.02 ng/mL, we recommend observation with a PSA every 3 months. We would offer early SRT in those with two postop PSA readings above 0.2 ng/mL. The authors recommend adherence to the RTOG consensus guidelines on the definitions of CTV in the postoperative setting.[194] For adjuvant patients, the authors prescribe 68 Gy, whereas for salvage patients, the authors use 70.2 Gy, both of which are in 1.8-Gy fractions. WPRT, as defined by the RTOG contouring guidelines, to a dose of 45 Gy, is considered depending on the extent of pelvic lymph node dissection, presence of SVI, and the estimated nodal involvement. For both the prostate bed and ENI, we recommend IMRT technique with image guidance. There are now two phase III trials that support the addition of ADT with postop radiation therapy.[181,189] We recommend that those at higher risk of developing metastatic disease, including a detectable postop PSA, pre-SRT PSA >0.5 ng/mL, SVI, PSA doubling time <6 months, or node-positive disease, be considered for 4 to 6 months of LHRH. In addition, we favor image-guided radiation (IGRT) in the postoperative setting guided by the place of gold marker seeds at the anastomosis.[199]

CONCLUSIONS AND RECOMMENDATIONS

In conclusion, because of patient convenience, cost, and PSA control, we favor PPI, HDR, or SBRT monotherapy for patients with favorable intermediate-risk disease. For unfavorable risk disease, we favor short-term ADT (4 months) combined with IMRT and a boost with either PPI, HDR, or SBRT, with WPRT in selected patients. For high-risk patients, we favor long-term ADT (e.g., ≥28 months) combined with WPRT and an HDR, an SBRT, or a PPI boost. Image-guided techniques without rectal spacer are preferred at UCSF. In selected patients (age <70 years with node positive), additional systemic agents (e.g., abiraterone) are strongly considered. It remains to be determined if and when biomarkers or molecular assays or advances in imaging will help us refine what

we mean by the categories that range from favorable intermediate- to very high-risk disease.[2] In the postoperative setting, we favor adjuvant or early salvage IMRT guided by ultrasensitive PSA monitoring combined with ADT.

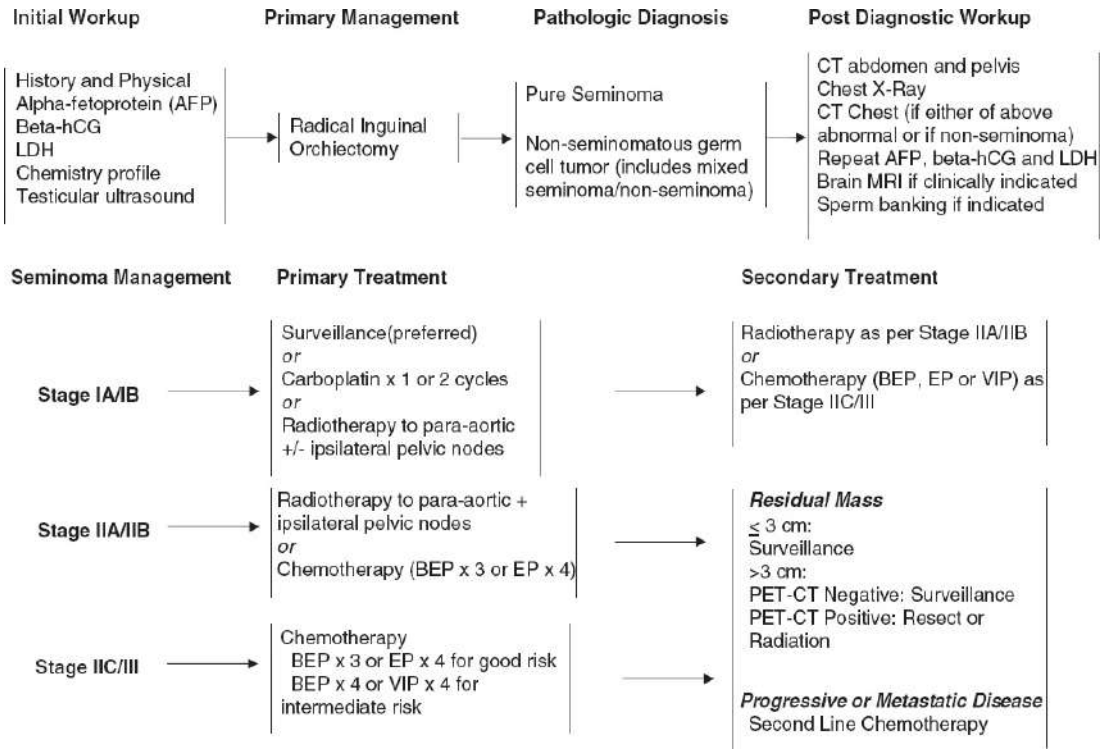
CHAPTER 71

Testicular Cancer

Lucas C. Mendez and Gerard C. Morton



Algorithm 71.1

EPIDEMIOLOGY

Testicular cancer is the most common malignancy among young men in North America and most Western European Countries, although accounts for only 1% of all male tumors.[1] More than 95% of testicular cancers are germ cell tumors, with almost equal division between seminomas and nonseminomas. Seminomas are most commonly diagnosed between the ages of 30 and 34 years, whereas nonseminomas are usually diagnosed 5 to 10 years earlier. Other histologies such as sex cord–stromal tumors and lymphomas are less frequent, although the latter is the most common testicular malignancy in men older than 60 years.[2] It is

estimated that just under 9,000 new cases of testicular cancer are diagnosed annually in the United States, with approximately 400 deaths.[1]

There is marked variation in incidence worldwide. The highest incidence occurs in Northern and Western European countries (up to 9 per 100,000) and the lowest in Asian and African populations (<1 per 100,000).[3,4] In North America, incidence rates are highest among Caucasians and lowest among African Americans, with an overall increase in age-adjusted incidence rate in the United States of 72% between 1975 and 2004.[5,6] A similar increased incidence has been reported in Europe and Australasia.[7–9] Over the past 30 years, the global incidence of testicular cancer has doubled with the highest annual increase seen in developed countries.[10] Despite the increased incidence of both seminoma and nonseminoma, there has been a significant reduction of mortality and improvement in survival. The most dramatic reduction in mortality occurred in the 1970s with the introduction of cisplatin-based chemotherapy.[11,12] The 10-year survival for seminoma increased from 81% in 1970 to 1979 to 95% in 2000 to 2002; that for nonseminoma increased from 54% to 92%.[13]

A history of undescended testicle has long been recognized as a risk factor for the development of testicular cancer. There is also an increased risk of malignancy in the normally descended contralateral testicle. The relative risk is estimated to be 6 in the undescended testicle and 2 in the contralateral testicle.[14] The mechanism of the increased risk is unclear. It is hypothesized that a common etiologic agent predisposes both to testicular maldescent and subsequent malignancy (uterine theory). Nevertheless, it is also possible that the maldescended testicle is subject to a hostile and malignancy-inducing environment (position theory). If that were the case, orchidopexy during the prepubertal phase would be expected to reduce the risk of testicular cancer. However, the relative risk of developing testicular cancer remains higher than in the general population even after early orchidopexy.

The temporal and geographic variation in incidence rates strongly suggests environmental etiologic factors. Male infertility is associated with an increased risk of testicular cancer, and infertile men with abnormal semen analyses have a 20-fold greater risk of testicular cancer than the general population.[15] The increasing incidence has paralleled decline in semen quality over the past several decades.[16,17] This has led to the hypothesis that poor semen quality, testicular cancer, cryptorchidism, and hypospadias represent a testicular dysgenesis syndrome as a result of disruption of gonadal development during embryonal development.[18] Various exogenous hormonal disruptors (e.g., exogenous

estrogens) have been proposed, although with no conclusive evidence implicating one particular agent.

A few modifiable environmental exposures have been identified as possible risk factors for testicular cancer. Men who have used muscle-building supplements were found to have an increased incidence of testicular cancer. The association was greatest in men who started supplement use at a younger age were exposed to different supplement types or used supplements for a longer duration.[19] Likewise, cannabis exposure was found to be associated with risk of testicular germ cell tumors, especially nonseminomas.[20] These associations need further validation, but the magnitude of the association and the positive correlation between dose and incidence supports a causal relationship.

Approximately 2% of patients report a positive family history. Sons of cases have a 4- to 6-fold increase in risk and brothers an 8- to 10-fold increase.[21] Migration studies in the Nordic countries have strengthened the hypothesis of shared genes rather than shared environmental exposure, and several candidate genes have been proposed to explain familial testicular cancer; however, it is likely that no single genetic change explains most familial cases.

In summary, germ cell tumors are thought to arise in testes predisposed to the development of malignancy owing to a combination of familial predisposition and intrauterine hormonal imbalance, later compounded by environmental factors and manifested by impaired spermatogenesis.

PATHOLOGY

More than 95% of testicular neoplasms are germ cell tumors. The most recent WHO classification of testicular tumors[22] divides germ cell tumors into two groups: those derived from germ cell neoplasia *in situ* (GCNIS) and those unrelated to GCNIS. The former group includes seminomas and nonseminomas that share recognizable morphologic and genetic similarities such as impaired spermatogenesis, microlithiasis, and amplification of chromosome 12. Nonseminomas include embryonal carcinoma, yolk sac (postpubertal type), teratoma (postpubertal type), choriocarcinoma, and mixed germ cell tumors. The group not derived from GCNIS is heterogeneous and includes spermatocytic tumor, prepubertal teratoma, and yolk sac tumors. Sex cord–stromal tumors make up the remaining 3% to 4% of testicular neoplasms, and most are benign (Table 71.1).

TABLE 71.1 CLASSIFICATION OF TUMORS OF THE TESTIS

Germ Cell Tumors Derived from Germ Cell Neoplasia *In Situ*
Germ cell neoplasia *in situ*
Seminoma
Seminoma with syncytiotrophoblast cells
Nonseminomatous germ cell tumors
Embryonal carcinoma
Yolk sac tumor, postpubertal type
Teratoma, postpubertal type
Teratoma with somatic-type malignancy
Trophoblastic tumors
Mixed germ cell tumors
Regressed germ cell tumor
Germ Cell Tumors Unrelated to Germ Cell Neoplasia *In Situ*
Spermatocytic tumor
Yolk sac tumor, prepubertal type
Teratoma, prepubertal type
Mixed teratoma and yolk sac tumor, prepubertal type
Sex Cord–Stromal Tumors
Leydig cell tumor
Sertoli cell tumor
Granulosa cell tumor
Tumors in the fibroma–thecoma group
Mixed sex cord–stromal tumor
Unclassified sex cord–stromal group
Gonadoblastoma

CLASSIFICATION OF TESTICULAR TUMORS

Germ Cell Tumors

Tumors Derived from Germ Cell Neoplasia In Situ

Germ Cell Neoplasia *In Situ*

GCNIS, previously called intratubular germ cell neoplasia or testicular carcinoma *in situ*, is currently the World Health Organization recommended term for this precursor lesion. This entity is found adjacent to invasive germ cell tumors in >95% of cases and also in all clinical groups known to be at high risk for testicular cancer development: cryptorchidism (2% to 4%), infertility (1%), ambiguous genitalia (25%), and contralateral testes of patients with testicular cancer (5%).[23] GCNIS is characterized by seminiferous tubules showing

decreased spermatogenesis in which the normal constituents of the tubules are replaced by abnormal germ cells with the appearance of seminoma cells. These cells stain strongly for placental-like alkaline phosphatase (PLAP), whereas normal germ cells are negative. GCNIS is a precursor to testicular germ cell cancer and has a 50% risk of developing into an invasive tumor within 5 years. It is hypothesized that the cells originate from primordial germ cells early during embryogenesis, possibly owing to an excess of estrogens. They likely remain within the seminiferous tubules in a dormant stage until puberty when replication begins, possibly as a consequence of raised sex hormone levels. Transition to an invasive germ cell tumor then occurs.

SEMINOMA

Seminoma accounts for >50% of all germ cell neoplasms. Serum level of human chorionic gonadotropin (HCG) is elevated in 15% to 30% of men at presentation, related to the presence of syncytiotrophoblastic cells. These may be identified in 7% of tumors on routine hematoxylin and eosin sections or by immunoperoxidase stains in 24%. The presence of syncytiotrophoblastic cells does not alter prognosis. Serum alpha-fetoprotein (AFP) is not elevated in pure seminoma. Grossly, seminoma is a soft tan-colored diffuse multinodular mass. Focal necrosis is sometimes present. A prominent lymphocytic infiltrate is commonly seen within the fibrous stroma. More than 90% of seminomas will stain positive for PLAP.

NONSEMINOMATOUS GERM CELL TUMORS

Nonseminomatous germ cell tumors (NSGCTs) usually contain a mixture of germ cell types (embryonal, yolk sac, teratoma, and choriocarcinoma), although tumors comprised of just one component may also be found. Commonly, NSGCTs are heterogeneous and present with considerable amount of necrosis and hemorrhage on gross examination.

Embryonal carcinoma is the most common component in mixed tumors, and AFP- and HCG-positive cells are present in 33% and 20%, respectively. Postpubertal yolk sac tumors rarely occur in a pure form and have a complex histology. High levels of AFP are usually present. Postpubertal teratoma has marked morphologic differences from the prepubertal type with a predominantly solid appearance, disordered tissue arrangement, and frequent mitotic figures.[24]

This tumor is not associated with elevated AFP or HCG and presents with distant metastasis in approximately 20% of the cases. Trophoblastic tumors have choriocarcinoma as the main component. This is the least common type of pure NSGCT and is present in about 4% of mixed tumors. It is particularly aggressive, almost always metastatic at diagnosis, often to brain, and is associated with high levels of HCG. Seminomatous components are also common in mixed tumors, and serum markers (AFP and HCG) are elevated depending on the relative germ cell elements present.

Tumors Unrelated to Germ Cell Neoplasia *In Situ*

This heterogeneous group of tumors lacks association with GCNIS and abnormalities on chromosome 12. These include spermatocytic tumor, prepubertal-type yolk sac tumor, and prepubertal-type teratoma.

Spermatocytic Tumor

Previously known as spermatocytic seminoma, the spermatocytic tumor accounts for 2% of testicular tumors. It tends to occur in an older age group at a mean age of 54 years. The new nomenclature better differentiates this from seminoma, which reflects its different origin and natural history. Spermatocytic tumor is confined to the testes, is not associated with elevated HCG levels,[25] and is almost always cured by orchiectomy alone. Bilaterality occurs in 10%, and metastasis is rare. The cell of origin of the spermatocytic tumor is probably the postpubertal mature spermatogonia that acquires abnormal proliferative capacity. Spermatocytic tumor does not contain glycogen, stains negative for PLAP and is not associated with GCNIS. It has a unique amplification on chromosome 9 and is not associated with other germ cell tumors.[26,27]

Yolk Sac Tumor and Teratoma, Prepubertal Type

Prepubertal-type yolk sac tumor is the commonest type of germ cell testicular cancer in infants and children and is associated with high levels of AFP. This malignancy arises from a distinct pathway to the postpubertal-type yolk sac tumors although has no significant morphologic difference. The prepubertal teratoma is composed of somatic elements from ectoderm, mesoderm, and endoderm. These tumors lack cytologic atypia and arise from a germ cell line that has not undergone malignant transformation. Both prepubertal yolk sac tumor and teratoma are less aggressive and have a better prognosis than the postpubertal versions.

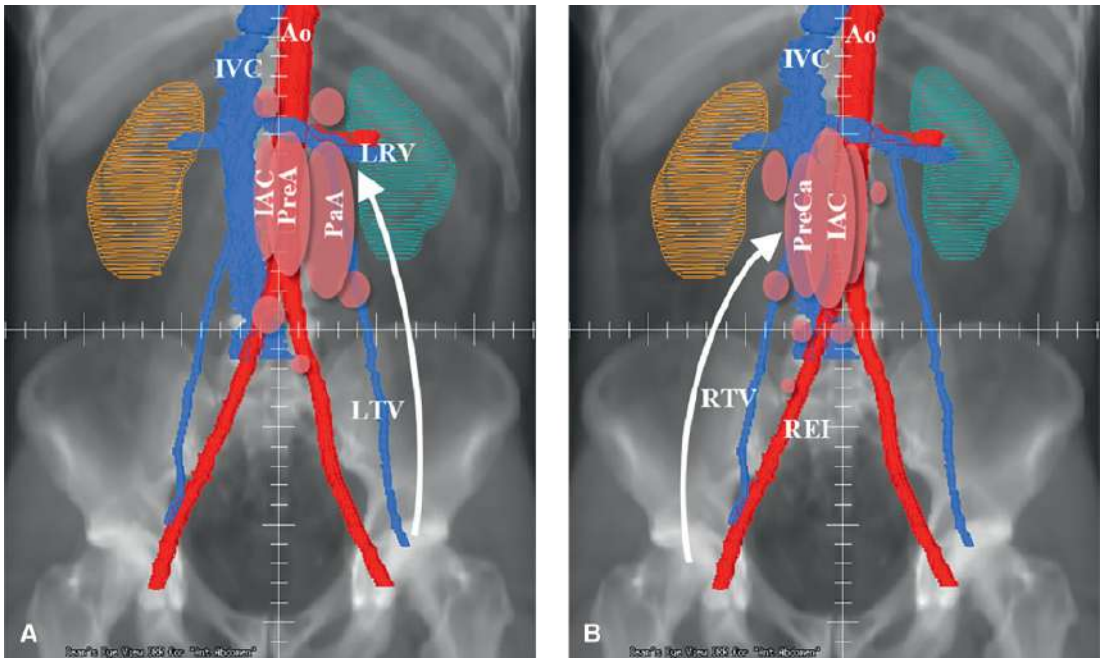


FIGURE 71.1. A: The left testis drains primarily by lymphatics along the left testicular vein (*LTV*) to lymph nodes inferior to the left renal vessels (*LRV*). Left paraaortic (*PaA*), preaortic (*PreA*), and interaortocaval (*IAC*) nodes are most commonly involved. Less commonly, nodal involvement may be found inferior to bifurcation of the aorta (*Ao*) or inferior vena cava (*IVC*), or superior to the renal vessels. **B:** Primary lymphatic drainage from the right testis (*arrow*) is along the right testicular vein (*RTV*) to precaval (*PreCa*) and then to interaortocaval and preaortic nodes. Less commonly, preaortic, right common iliac, or right external iliac (*REI*) nodes are involved.

ANATOMY AND NATURAL HISTORY

In the developing embryo, the testes originate from the genital ridge located near the second lumbar vertebra. Accompanied by their blood supply and lymphatics, they descend into the scrotum via the inguinal canal. As a result, the primary lymphatic drainage from the testis is to the retroperitoneal lymph nodes. The lymphatic vessels first drain into the collecting trunks at the hilum of the testicle. These lymphatic trunks accompany the testicular artery, vein, and spermatic cord through the internal inguinal ring and then continue proximally to the retroperitoneal lymph nodes. The retroperitoneal lymph nodes are situated anterior to the T11 to L4 vertebral bodies, concentrated at the L1-3 level. On the left, the lymphatics drain primarily into the preaortic and paraaortic lymph nodes around the left renal hilum and from there to the interaortocaval nodes (Fig. 71.1A). On the right, the first nodes involved are usually in the precaval or interaortocaval region, followed by the preaortic lymph nodes (Fig. 71.1B). Contralateral spread is mainly seen with right-sided tumors and rarely with left-

sided tumors. Exclusive metastasis in the contralateral nodes (without ipsilateral involvement) is rare.

From the retroperitoneal nodes, the lymph drains into the cisterna chyli, thoracic duct, posterior mediastinum, and left supraclavicular fossa. The thoracic duct drains into the left subclavian vein in the left supraclavicular region. In 5% to 10% of patients, drainage into the right supraclavicular area can occur.

Aberrant lymphatic drainage may occur in the event of previous scrotal or inguinal surgery. Hernia repair alters the drainage of the testicle. The testicular lymphatic vessels anastomose with the regional lymph vessels, resulting in drainage into the ipsilateral inguinal and iliac lymph nodes. In addition, the testicular trunks may abandon the spermatic vessels at the internal inguinal ring and pass posteriorly and superiorly into the external iliac lymph nodes. The scrotum drains directly into the inguinal and external iliac lymph nodes. Therefore, direct invasion of the tunica vaginalis or scrotum could result in spread to pelvic and inguinal nodes.

Seminoma has an orderly and predictable pattern of spread. Locoregional lymphatics are the first site of metastatic disease. From the retroperitoneal lymph nodes, seminoma spreads proximally to involve the next echelon—the mediastinal lymph nodes—and then the supraclavicular lymph nodes. Very occasionally, metastases from retroperitoneal lymph nodes can drain directly via the thoracic duct to the supraclavicular fossa, resulting in supraclavicular metastases in the absence of mediastinal disease. Hematogenous metastases are rare in pure seminoma, being much more common with NSGCT. Lung is the most common site of distant disease, although bone, liver, and brain may also be involved.

CLINICAL PRESENTATION AND DIAGNOSTIC WORKUP

A testicular tumor usually presents as a painless swelling in the scrotum, however, pain, heaviness, and tenderness at presentation are not uncommon. Disease in the lymph nodes of the retroperitoneum may produce back pain or abdominal swelling. Widely disseminated parenchymal disease in lungs, liver, bone, or brain is rare but, if present, may produce systemic symptoms. Gynecomastia is a rare presentation of embryonal carcinoma that may be seen in association with the very uncommon sex cord–stromal tumors. Gynecomastia and hyperthyroidism may rarely result from high levels of HCG produced by the tumor. Occasionally, patients present with metastatic germ cell malignancies

diagnosed by biopsy or elevated levels of serum tumor markers without evidence of a palpable mass in the testis. Occult primary disease in the testis is often detected by testicular ultrasound. If there is no evidence of a primary tumor in the testis, a diagnosis of an extratesticular germ cell tumor—usually mediastinal, retroperitoneal, or pineal—may be made.

DIAGNOSTIC WORKUP (TABLE 71.2)

A complete history should be taken, including information about previous inguinal or scrotal surgery, cryptorchidism, retractile testes, and orchidopexy. The physical examination should pay special attention to possible sites of lymph node metastases. The presence or absence of gynecomastia is an important observation. If testicular tumor is suspected, testicular ultrasound should be performed. This helps define the origin of the scrotal mass as the vast majority of extratesticular lesions are benign.[28] Testicular tumor usually appears as a solid mass within the testis, often with associated testicular microlithiasis. The contralateral testis should be examined clinically and by ultrasound. Inguinal biopsy of the contralateral testis may sometimes be considered during surgery if atrophy, cryptorchidism, or suspicious abnormalities on ultrasound are found. Radical orchiectomy through an inguinal incision is diagnostic and removes the primary tumor.

TABLE 71.2 DIAGNOSTIC WORKUP FOR TUMORS OF THE TESTIS

General

History (document cryptorchidism and previous inguinal or scrotal surgery)
Physical examination

Laboratory Studies

Complete blood count

Diagnostic Radiology

Chest x-ray films, posterior/anterior and lateral views

Computed tomography (CT) scan of the abdomen and pelvis
CT scan of the chest for nonseminomas and stage II seminomas
Bilateral testicular ultrasound

Special Study
Semen analysis

Laboratory Studies

A routine complete blood count and chemistry screen, including renal function tests, should be performed. Pulmonary or renal function tests should be performed for patients who may receive bleomycin or combination chemotherapy. NSGCTs of the testes are uniquely associated with reliable serum tumor markers: the β-subunit of human chorionic gonadotropin (β-HCG) and AFP. One or both of these serum markers are elevated in 80% to 85% of patients with disseminated nonseminomatous disease. These markers are important prognostic factors and contribute to cancer staging.

The metabolic half-life of AFP is approximately 5 days and for β-HCG is approximately 18 to 24 hours. Although β-HCG may be modestly elevated in 15% to 30% of patients with pure seminomas, usually any elevation of AFP connotes nonseminomatous disease. In the setting of elevated AFP with pure seminoma seen in the pathology specimen, an undetected nonseminomatous focus may be assumed, and the clinical management should follow accordingly. Serum tumor markers may be elevated in other circumstances or conditions, such as laboratory error, cross-reactivity with luteinizing hormone, marijuana use, hepatitis, or development of antibodies to the glycoproteins. Serum lactate dehydrogenase (LDH), although nonspecific, is elevated in 80% of patients with advanced testicular cancer and has prognostic value.

If a testicular cancer is suspected, serum tumor markers should be assayed before and after orchiectomy, and interpretation of the levels of markers should take into account their metabolic half-lives. Serum tumor markers can document persistent or recurrent cancer after surgery or chemotherapy and may predict the responsiveness of nonseminomas to treatment. The level of β-HCG should decrease by $\geq$90% every 21 days with each successful treatment cycle of chemotherapy. A slow decline in β-HCG after treatment may imply suboptimal response to chemotherapy, permitting early implementation of salvage therapy before the development of overt resistance to chemotherapy. The decline of AFP is less predictable.

Semen analysis and banking of sperm should be considered for patients in

whom treatment is likely to compromise fertility. With newer technologies, it is possible to retrieve and bank sperm even with poorer-quality sperm.

Radiographic Studies

Investigations should routinely include chest x-ray films for all patients and computed tomography (CT) of the thorax for any patient with NSGCTs of the testis. CT scans of the abdomen and pelvis should be performed to evaluate the retroperitoneal nodal areas and assess the liver. A thoracic CT scan should also be performed in seminoma patients with an abnormal abdominal CT scan or chest x-ray. Magnetic resonance imaging (MRI) of the brain and bone scan are indicated if symptoms are present. Brain MRI is also indicated for choriocarcinoma.

CT of abdomen and pelvis relies on nodal size to assess the retroperitoneal nodes, with a sensitivity of 40% and a specificity of 95% using a 1-cm threshold.[29] A higher accuracy level can be achieved if a 7- to 8-mm threshold is used[30]; however, there is considerable overlap between the size of normal and abnormal lymph nodes using either size limit. CT therefore has limited ability to exclude the presence of disease, although enlarged lymph nodes in the appropriate clinical context (location, laterality, disease parameters) are very likely to be truly positive. Likewise, lymph nodes with certain morphologic features, such as central necrosis and rounded shape, are considered more suspicious.[31] MRI appears equivalent to CT in determining the size and location of retroperitoneal adenopathy and generally is performed in patients in whom iodinated contrast is contraindicated. Fluorodeoxyglucose–positron emission tomography (FDG-PET) scan has a slightly higher sensitivity (66%) than CT with a comparable specificity (98%). It has little role in initial disease staging but may have a role where CT is questionable.[29] It is unable to detect lesions <5 mm in size or teratomas of any size owing to their very low metabolic activity. It also has an important role in evaluating residual retroperitoneal disease following chemotherapy.

In ultrasound imaging, a solid intratesticular mass associated with internal vasculature suggests tumor. Testicular Doppler ultrasonography has a high accuracy in detecting malignancy, with both sensitivity and specificity over 90%.[32] Ultrasonography is not reliable in predicting tumor histology, but in general, seminomas are commonly hypoechoic and homogeneous, whereas calcifications and heterogeneity in echotexture are more often seen in NSGCTs. Baseline ultrasonography of the remaining testis should also be performed. If the

contralateral testis is atrophic and the patient is <30 years of age, then there is a 30% risk of GCNIS. Biopsy of the contralateral testis is suggested by some authorities in this setting.

STAGING AND PROGNOSTIC FACTORS

Patients are staged according to the American Joint Committee on Cancer (AJCC) criteria as indicated in Table 71.3, which incorporates features of the primary tumor (T), node (N), metastasis (M), and level of serum tumor markers (S).[33] Approximately 80% of seminoma patients and 50% to 60% of nonseminoma patients have stage I disease at presentation. For stage I seminoma, tumor size (>4 cm) and rete testis invasion are the most commonly reported predictors of recurrence. For nonseminomas, T stage, extensive embryonal component, and lymphovascular invasion are prognostic. Increased age is an adverse prognostic factor for patients diagnosed with all stages of testicular cancer.[34]

TABLE 71.3 AMERICAN JOINT COMMITTEE ON CANCER 2010 STAGING FOR TESTICULAR CANCER

Primary Tumor (T) (Pathologic Classification)

*p*Tx	Primary tumor cannot be assessed
*p*T0	No evidence of primary tumor (scar, etc.)
*p*Tis	Intratubular, noninvasive
*p*T1	Tumor limited to testis and epididymis, no vascular/lymphatic invasion
*p*T2	Tumor limited to testis and epididymis, with vascular/lymphatic invasion or involvement of the tunica vaginalis
*p*T3	Tumor invades spermatic cord
*p*T4	Tumor invades scrotum

Lymph Node (N)

N0	No regional node metastasis
N1	Metastasis in single or multiple nodes ≤2 cm in greatest dimension
N2	Metastasis in single or multiple nodes 2–5 cm greatest dimension
N3	Metastasis in lymph nodes >5 cm in maximum diameter

Distant Metastasis (M)

M0	No distant metastasis
M1a	Nonregional lymph node or pulmonary metastasis
M1b	Nonpulmonary visceral metastasis

Serum Tumor Markers (S)

Sx	Serum tumor markers not performed
S0	Serum tumor markers within normal limits
S1	LDH <1.5 × N and HCG <5,000 and AFP <1,000
S2	LDH 1.5–10 × N or HCG 5,000–50,000 or AFP 1,000–10,000
S3	LDH >10 × N or HCG >50,000 or AFP >10,000

TABLE 71.4 International Germ Cell Cancer Collaborative Group Consensus Classification of Metastatic Germ Cell Cancer[a]

Nonseminoma	Seminoma
Good prognosis group with all of the following:	
Testis/retroperitoneal primary	Any primary site
No nonpulmonary visceral metastases	No nonpulmonary visceral metastases
AFP < 1,000 ng/mL	Normal AFP
HCG < 5,000 IU/L	Any HCG
LDH < 1.5 × normal	Any LDH
Intermediate prognosis group with all of the following:	
Testis/retroperitoneal primary	Any primary site
No nonpulmonary visceral metastases	Nonpulmonary visceral metastases
Intermediate markers:	
AFP > 1,000 and <10,000 ng/mL *or*	Normal AFP
HCG > 5,000 and <50,000 IU/L *or*	Any HCG
LDH > 1.5× and <10× normal	Any LDH
Poor prognosis group with any of the following:	
Mediastinal primary *or*	
Nonpulmonary visceral metastases *or*	

AFP > 10,000 ng/mL
HCG > 50,000 IU/L *or*
LDH > 10× normal

[a]Survival at 5 years is approximately 91%, 80%, and 50% for good, intermediate, and poor prognostic groups, respectively.
AFP, alpha-fetoprotein; HCG, human chorionic gonadotropin; LDH, lactate dehydrogenase.

The International Germ Cell Cancer Collaborative Group (IGCCCG) developed a widely accepted classification system for patients with metastatic germ cell malignancies,[35] which has been incorporated into the TNM system (Table 71.4). The prognostic classification is based on data collected on approximately 6,000 patients with metastatic germ cell tumor from 10 countries during the platinum era. The classification was internally and prospectively validated on a subsequent cohort of patients. The factors most strongly associated with a poor prognosis were mediastinal primary, nonpulmonary visceral metastases, or grossly elevated tumor markers (AFP >10,000 ng/mL, HCG >50,000 IU/L, or LDH >10 times normal). Patients with NSGCT were divided into three prognostic groups (good, intermediate, and poor prognosis) and seminomas into either good or intermediate prognostic groups (Table 71.3). The good prognosis group comprised >50% of all patients with metastatic NSGCTs and 90% of seminomas and was associated with a 5-year survival >90%. The intermediate prognosis group comprised 25% to 30% of patients and had a 5-year survival of 80%. The poor prognosis group comprised 15% to 20% of patients with NSGCT and had a 5-year survival of approximately 50%.

GENERAL MANAGEMENT

The initial management of a suspected malignant germ cell tumor of the testis consists of obtaining serum AFP and β-HCG measurements and then performing a radical (inguinal) orchiectomy with division of the spermatic cord at the internal inguinal ring. In this procedure, the involved testis is removed en bloc with the spermatic cord, enclosed by the tunica layers through an inguinal incision, minimizing the chance of tumor spillage. Historically, it had been thought that scrotal violation (transscrotal orchiectomy, open testicular biopsy, or fine needle aspiration) compromised prognosis. Scrotal violation is associated with a slight increase in local recurrence rate compared with inguinal

orchiectomy (2.9% vs. 0.4%, respectively) but is not associated with any difference in distant recurrence rates or overall survival.[36] Orchiectomy is both diagnostic and therapeutic. Further management depends on pathologic diagnosis and the stage and extent of disease. Radiation treatment plays a significant role in the management of seminomas. Nonseminomatous tumors are generally managed by cisplatin-based combination chemotherapy and/or surgical resection.[37] A detailed discussion of the management of nonseminomatous tumors is beyond the scope of this chapter.

SEMINOMA

Stage I

Most patients with stage I seminoma are cured by orchiectomy alone, and approximately 20% will relapse if no adjuvant therapy is offered. Either adjuvant radiation therapy or adjuvant chemotherapy with single-agent carboplatin is associated with a disease-free survival >95% and disease-specific survival approaching 100%.[38] Surveillance, with treatment at time of relapse, is associated with a similar survival outcome and allows 80% of patients to avoid morbidity of treatment.[39]

Surveillance

Surveillance has become the management strategy of choice for most men with stage I seminoma. A survey of Canadian radiation oncologists in 2006 revealed that 56% felt surveillance was the preferred management.[40] Kollmansberger et al. document the increasing use of surveillance for managing patients with stage I seminoma in a population-based cohort from British Columbia, Canada, and Oregon.[41] Between 1999 and 2008, the proportion of patients receiving adjuvant radiation therapy decreased from 50% to 9%, and the proportion being managed by surveillance increased from 47% to 87%. A similar trend was seen in the United States by Matulewicz et al. through analysis of the National Cancer Data Base.[42] The authors reported that the use of surveillance for stage I seminoma increased from 24.7% in 1998 to 2000 to 61.2% in 2010 to 2012.

The reported series (Table 71.5) include >2,400 patients, and all report similar rates, timing, and patterns of recurrence.[41,43–51] When managed by surveillance, up to 20% of patients will relapse at a median time of around 14 months. Over 90% of relapses occur in the first 3 years. Given the small event rate in the individual reports, Warde et al.[52] performed a pooled analysis from four series

(PMH, Royal Marsden Hospital [RMH], Royal London Hospital, and the Danish Testicular Cancer Study Group). Individual patient data on 638 stage I seminoma patients managed by surveillance were obtained. With a median follow-up time of 7 years, the 5- and 10-year relapse-free rates were 82.3% and 78.7%, respectively. Most relapses (69%) occurred within the first 2 years of surgery, whereas 7% relapsed beyond 6 years. The 5-year cause-specific survival was 99.3%. A more recent pooled analysis[53] of databases from Sweden and Norway, the Princess Margaret Cancer Centre, British Columbia and Oregon, Bart's Cancer Institute, and the University of Oxford reported similar findings. With a median follow-up time of 52 months, relapse occurred in 13% of 1,344 stage 1 seminoma patients at a median of 14 months. No patient died from seminoma, although one patient died from complications of treatment.

Almost all patients (99%) who relapse after surveillance are classified by IGCCCG in the good risk category, and the predominant site of relapse is in the retroperitoneum (76% to 94%). Approximately 5% to 15% of patients relapse in the mediastinum or lungs, with inguinal relapse described in 3% to 11%, usually only after previous scrotal interference. Some variability is reported in management at the time of relapse. Traditionally, most (74% to 82% of patients in the older series) were initially managed by radiation therapy, with a second relapse occurring in about 10% (6% to 16%). Second relapse almost always occurred at distant sites with a 90% to 95% rate of successfully salvage with chemotherapy. More recent series describe a greater use of chemotherapy as initial salvage treatment. In the population-based study from the Swedish Norwegian Testicular Cancer Study Group (SWENOTECA), cisplatin-based combination chemotherapy as salvage treatment was given to 89% of relapsing patients,[51] with further relapse in only 1 of 58 patients. Kollmansberger et al.[41] report the use of salvage chemotherapy in 68% of relapsing patients in the British Columbia and Oregon Testis Cancer Program database. No further relapse occurred in the 32 patients managed by chemotherapy, whereas relapse occurred in 3 of 15 patients who received salvage radiotherapy. Although salvage chemotherapy is effective, it is associated with greater toxicity than salvage radiotherapy.

In the pooled analysis,[52] tumor size, rete testis invasion, and lymphovascular invasion were predictive of relapse on univariate analysis. On multivariate analysis, tumor size (hazard ratio [HR] 2.0) and rete testis invasion (HR 1.7) remained significant. The relapse-free rate decreased from 87.8% for tumors <4 cm without rete testis invasion to 68.5% for tumors >4 cm with rete testis

invasion. Tyldesley et al.[54] also noted the importance of size >4 cm and rete testis invasion, reporting a 5-year relapse-free rate of 86%, 71%, and 50% in patients with no risk factor, one risk factor, or both risk factors, respectively. Choo et al.[47] reported a reduction in 10-year relapse-free rate from 86% to 52% with rete testis invasion. These risk factors were recently validated by the SWENOTECAVII study.[55] In this prospective and population-based protocol, a significant difference in relapse was seen between patients with no risk factor (4%) and patients with these 1 to 2 factors (15.5%) managed by surveillance.

Based on pattern and timing of relapse, a reasonable surveillance policy involves assessments every 4 to 6 months in the first 2 years, six monthly assessments in years 3 to 5, and annual assessments until year 10. Assessment should include physical examination and abdominopelvic CT. Serum markers may be included for the first 2 years if initially elevated.

Although chest x-ray was routinely used in most surveillance series, no relapse was detected on chest x-ray alone. Therefore, some authors suggest omitting routine chest imaging from the follow-up schedule.[56] The use of low dose CT,[57] less intensive imaging protocol,[58] and MRI are being investigated to further reduce long-term radiation exposure.

Surveillance is a more costly approach to management than adjuvant nodal

irradiation owing largely to the increased number of radiologic investigations,[59] although leading to less overall treatment burden to patients than upfront treatment.[60] Surveillance should be conducted only with a compliant patient and with an understanding that because of the risk of late relapse, the patient should be monitored for at least 10 years. Although there is no randomized trial comparing surveillance and adjuvant treatment, the survival rate of 99.5% from the large surveillance series indicates that this therapeutic option produces a result equivalent to that achieved with immediate adjuvant treatment and is a safe and effective alternative management, provided that guidelines are followed. Moreover, a recent analysis with a median follow-up time over 14 years has shown that patients with stage I seminoma managed by surveillance have comparable survival to that of the general population.[61]

Adjuvant Radiation Therapy

In the past, the standard postoperative management of patients with stage I seminoma has been adjuvant radiation therapy to the paraaortic and ipsilateral pelvic lymph nodes (the “dog-leg” or “hockey stick” radiation field). This is a highly effective treatment, with a reported relapse rate between 1% and 5% and a disease-specific survival of 100% in many mature series[51,62–72] (Table 71.6) without the need for ongoing abdominal imaging.[73] With the realization that most of the relapses on surveillance occur in the paraaortic region, many have adopted smaller radiation target volumes to reduce treatment toxicity. Series that treat just the paraaortics report a higher rate of failure in the pelvic nodes; however, the disease-free survival is minimally compromised. A multicenter single-arm trial of paraaortic radiotherapy was reported by the German Testicular Cancer Study Group, which included 721 patients with stage I seminoma.[68] Disease-free survival at 8 years was 95%. Of 26 recurrences, 21 were within infradiaphragmatic lymph nodes beyond the treatment volume (mostly ipsilateral pelvic), with no in-field recurrences. The Medical Research Council (MRC) performed a randomized controlled trial comparing classic dog-leg irradiation to paraaortic irradiation in stage I seminoma.[72] Those with previous ipsilateral inguinal or scrotal surgery were excluded. Radiation therapy was better tolerated in the paraaortic alone arm with a reduction in the severity and frequency of acute gastrointestinal and hematologic toxicity. At a median follow-up of 4.5 years, there was no difference in the 3-year relapse-free survival or overall survival. For those in the paraaortic radiation therapy arm, the pelvis was the most frequent site of recurrence, whereas the pelvis was a rare site of

recurrence in those in the paraaortic and ipsilateral pelvic radiotherapy arm. A retrospective review showed that the median size of pelvic nodal recurrence was 7.3 cm (range, 2.8 to 13 cm) if CT scans were not included in the follow-up schedule of patients treated with paraaortic radiation therapy.[74]

DL, dog leg; PA, paraaortic.

Given that nearly all recurrences following paraaortic radiation therapy are in the lower common iliac or upper external iliac nodes, a common approach is to use a modified dog leg wherein the inferior border is placed at the midpelvic level. This encompasses the nodal areas at risk while further reducing volume of

normal tissue irradiated.[75]

Adjuvant Chemotherapy

Adjuvant chemotherapy using single-agent carboplatin was proposed as a less toxic approach than radiotherapy for stage I seminoma. For men with advanced seminoma, carboplatin has long been known to have significant efficacy with relatively low toxicity.[76] It was logical to investigate the use of one or two cycles of carboplatin as adjuvant treatment following orchiectomy.[77–79] With a median follow-up of 75 months, Steiner et al.[80] reported a 5-year relapse-free survival of 98.1% in a population of 276 men with stage I seminoma treated with two cycles of carboplatin. Aparicio et al.[49] described a risk-adaptive strategy wherein patients with stage I seminoma deemed at low risk of recurrence were managed with surveillance, and those considered at higher risk based on large tumor size or rete testis invasion received two cycles of carboplatin. With a median follow-up of 34 months, the 5-year disease-free survival following carboplatin was 96.2%. In light of the higher (9.3%) relapse rate reported with one course of carboplatin in patients with 1 to 2 risk factors from the SWENOTECA VII study, two cycles of carboplatin seem more appropriate for higher-risk patients.[55]

Recurrence following adjuvant carboplatin tends to be in the retroperitoneum and can be salvaged with cisplatin-based chemotherapy in approximately 85% of the cases[81] resulting in an overall disease-specific survival approaching 100%. Between 2001 and 2006, the use of single-course carboplatin following orchiectomy for stage I seminoma increased from 0% to 70% in Sweden and Norway.[51] Over the same time period, the use of adjuvant radiotherapy decreased from 40% to 5%. The relapse risk with chemotherapy was higher than that following radiotherapy (3.9% vs. 0.8%); however, overall survival was the same. In the British Columbia/Oregon database,[41] 73 patients received either one or two cycles of carboplatin, with only one relapse, yielding a relapse-free survival probability of 98% and a cause-specific survival of 100%.

The MRC performed a randomized comparison of single-agent carboplatin and nodal irradiation in stage I seminoma.[71] Almost 1,500 patients from 14 European countries were randomized to receive either adjuvant radiation therapy or one injection of carboplatin. Radiation was limited to paraaortic fields in 87%, and the remainder also had inclusion of the ipsilateral pelvic nodes. Information on tumor size and rete testis invasion was not detailed. With a median follow-up time of 6.5 years, the 5-year relapse-free survival rates were similar at 96.0% and 94.7% in the radiation therapy and carboplatin arms, respectively. In the

adjuvant radiation therapy arm, the most common site of recurrence was either distant (57%) or in the pelvic nodes (31%). In the carboplatin arm, most of the relapses (74%) were in paraaortic nodes. Only one death from testicular cancer occurred in the radiation therapy group, with no cancer-related deaths in the chemotherapy group. An 80% reduction in the rate of contralateral testicular cancer was seen in the carboplatin arm (2 vs. 15 cases). Long-term toxicity (e.g., risk of leukemia) is unknown; however, the regimen is well tolerated acutely with only mild myelotoxicity. Powles et al.[82] found no increased risk of death from circulatory disease or risk of second malignancy in a cohort of 199 patients who received adjuvant carboplatin and were followed for a median of 9 years.

Mead et al.[38] analyzed mature results of three randomized noninferiority MRC clinical trials for stage I seminoma, which included nearly 2,500 patients. They concluded that either radiation therapy or carboplatin was a reasonable adjuvant therapy. It is clear that the survival of patients with stage I seminoma approaches 100%, no matter what treatment strategy is employed. The goal of management is to limit treatment morbidity without compromising chance of cure. For the compliant patient, surveillance is probably the option of choice. For patients not suitable for surveillance, adjuvant radiation therapy or adjuvant chemotherapy significantly reduces the risk of relapse. There are, however, limited data on the long-term efficacy or toxicity of adjuvant carboplatin. Furthermore, ongoing surveillance of the retroperitoneal nodes will still be required.

Stage II

For patients with stage II seminoma, the recommended treatment depends on the bulk of retroperitoneal nodal disease. Radiation therapy, 25 to 35 Gy, is the treatment of choice for patients with stage IIA or IIB seminoma. Irradiation of the paraaortic and ipsilateral pelvic nodes is a highly effective treatment strategy with a recurrence rate <10% (Table 71.7) and a disease-specific survival rate of 97% to 100%.[63,83–91] The most common site of relapse following infradiaphragmatic radiation therapy is in the supraclavicular fossa or mediastinum. In the past, some authors[85] recommended prophylactic supraclavicular irradiation. However, the proportion of patients destined to relapse exclusively in the supraclavicular fossa is <5%, and results with infradiaphragmatic irradiation alone with chemotherapy as salvage are excellent.[92]

No clinical trial has prospectively compared radiation therapy with cisplatin-

based chemotherapy in stage II disease. Recently, a study using the U.S. National Cancer Database[93] compared these treatment strategies in stage II patients and suggested a lower overall survival for multiagent chemotherapy in stage IIA disease, with no differences found in stage IIB patients. Better local control and less toxicity associated with radiation therapy are possible explanations. Other series have reported conflicting results and indicated equivalence between both treatment strategies in patients with stage IIA disease.[94,95] Although it is clear that most patients with stage IIA/B seminoma can be cured with cisplatin-based chemotherapy, greater levels of toxicity are expected with this treatment than that associated with radiotherapy alone.[96] Radiation therapy is therefore considered the preferred treatment for nonbulky stage II seminomas.

Disease control rates for stage IIA/B seminoma with single-agent carboplatin appear inferior to that with radiation therapy. A phase II study by the German Testicular Cancer Study Group[78] delivered three or four cycles of carboplatin to patients with stage IIA or stage IIB seminoma, respectively. The overall failure rate was 18%, with all relapses occurring in the retroperitoneum. A few authors have retrospectively assessed the benefit of a combined approach using neoadjuvant carboplatin followed by radiation therapy in patients with stage

IIA/B seminomas.[86,97] Although these results are not definitive, this strategy appears to reduce the rate of relapses and may be a promising approach, especially for bulkier disease.

Factors other than stage may be considered in selection of treatment strategy after orchiectomy in stage II seminoma. A greater number of retroperitoneal nodal metastases may suggest an overall greater bulk of disease, indicating a higher likelihood for distant metastasis. Furthermore, Domont et al.[98] have reported that nodal diameter ≥ 3 cm on CT is associated with higher risk of distant failure following local therapy and suggested that these patients would be better managed with systemic treatment. The risk of distant metastasis is likely proportional to the extent of disease seen in the retroperitoneal nodes, and this should be taken into account when deciding which strategy to follow.

Patients with stage IIC retroperitoneal disease (nodes > 5 cm) are usually managed with systemic chemotherapy. Radiation therapy remains a treatment option; however, the relapse rate of >30% is considered by many to be excessive. Chung et al.[83] reported recurrence in 10 of 16 patients with stage IIC disease managed with radiation therapy compared to only one relapse in a similar group of 23 patients managed by chemotherapy. The choice of modality is also influenced by the size and location of the retroperitoneal nodal mass. If the mass is centrally located and does not overlie most of one kidney or significantly overlap the liver, primary radiation therapy remains an option. If the location of the mass is such that the irradiation volume covers most of one kidney or significant volumes of the liver, then the potential morbidity of radiation therapy can be avoided by the use of primary cisplatin-containing combination chemotherapy (usually etoposide/cisplatin [EP] or bleomycin/etoposide/cisplatin [BEP]). For nodal disease >10 cm in diameter, the relapse rate is >40% with radiotherapy and such patients should be managed with systemic chemotherapy.

For the rare patient with stage III disease (i.e., supradiaphragmatic nodal disease or dissemination to parenchymal organs), or those with relapse following radiation therapy, the current standard therapy is three courses of BEP or four courses of EP chemotherapy. These patients are classified into either a good prognosis or intermediate prognosis group by the International Germ Cell Cancer Collaborative Group Consensus Classification, depending on the absence or presence of nonpulmonary visceral metastases, respectively. The 5-year survival is around 91% for good prognosis patients and 80% for intermediate prognosis patients. Despite initial favorable reports, single-agent carboplatin is

not as effective as cisplatin-based combination treatment. In a pooled analysis of two randomized trials of 361 patients with metastatic seminoma, Bokemeyer et al.[99] reported an inferior progression-free (72% vs. 92%) and overall (89% vs. 94%) survival with carboplatin.

Residual Mass

For patients with stage II or III disease treated with primary chemotherapy, residual masses are present at 1 month in up to 80% of patients. Most of these then gradually regress over a period of several months. Flechon et al.[100] reported that 50% of residual masses disappeared on follow-up, and viable cancer cells were found only in masses >3 cm in size. Management strategies involve the use of consolidative radiotherapy, surgical resection, or observation. In an effort to define the role of postchemotherapy radiation therapy, the MRC Testicular Tumour Working Party conducted a retrospective review of patients with advanced seminoma managed by chemotherapy from 10 European centers.[101] Of 302 patients identified, 174 (58%) had residual masses on completion of chemotherapy, with a subsequent 3-year progression-free survival of 85%. Approximately half of these patients underwent postchemotherapy radiation therapy, with selection based predominantly on institutional preference. Radiation therapy did not significantly influence risk of progression, contributing an absolute increase in progression-free survival of only 2.3%. Instead, the most important prognostic factors for progression were the presence of prechemotherapy visceral metastases or raised LDH, or persistent visceral metastases postchemotherapy. At St. Bartholomew's Hospital, 43 of 107 patients (40%) with advanced seminoma had a residual mass postchemotherapy.[102] Positive histology was found in 3 of 19 patients (15%) who underwent surgical exploration, whereas relapse at the site of the mass occurred in 3 other patients observed. Residual disease was only found in masses >3 cm in size. Of the 107 patients, 98 patients (92%) remained alive and free from recurrence. The largest report of surgical resection following chemotherapy comes from the Memorial Sloan-Kettering Cancer Center.[103] A total of 55 patients with advanced seminoma underwent resection or biopsy of residual mass within 4 weeks of chemotherapy. Of 27 patients with a mass >3 cm, 8 patients (30%) had residual tumor. No viable tumor was found in any of the 28 patients with a residual mass <3 cm in maximal diameter.

From the reports discussed, it is clear that observation alone is adequate for a residual mass <3 cm in size. Two patterns of response to chemotherapy are

evident on CT: the residual mass may be well defined with discrete borders or the mass may have indistinct borders merging into surrounding structures and resembling a fibrous plaque. The former are more amenable to surgical resection. Furthermore, if the tumor is well defined on CT and measures >3 cm in greatest dimension, positive histology can be found in 50%. It is reasonable to resect these masses. If the mass is poorly defined, even if >3 cm, the chance of finding positive histology is <10%. Resecting such a mass is hazardous, with risk of great vessel, ureteric, and small bowel injury. These should be observed.

FDG-PET scans have been shown to reliably predict the presence of viable disease in retroperitoneal masses postchemotherapy in seminomas. This diagnostic examination has a high accuracy in identifying persistent disease, which is greater than CT.[104] De Santis et al.[105] evaluated the efficacy of FDG-PET by analyzing 51 patients with 56 postchemotherapy lesions. The FDG-PET correctly identified 54 lesions with two false-negative results, both in nodes <3 cm. For the whole cohort, this test sensitivity was 80%, but FDG-PET accuracy for residual masses >3 cm was 100%. Based on this result, authors estimated that 45% to 73% of patients with >3 cm residual mass would be overtreated with surgery if FDG-PET information is not taken into account, as a negative scan may be reliably used as a tool for avoiding surgical resection. FDG-PET should be performed 6 weeks after day 21 of the last chemotherapy cycle, as earlier imaging has a higher risk of false-positive results.

Bilateral Testicular Cancer

Testicular cancer is bilateral in up to 5% of cases, with one-third being synchronous and two-thirds being metachronous.[106] Although bilateral orchiectomy is an effective management strategy in synchronous disease, the option of testis-sparing surgery and postoperative radiation therapy has emerged as an alternative.[107] Partial orchiectomy may be considered for selected patients with bilateral disease or a solitary testicle. Ideally, tumors should be <2 cm in size and have negative surgical margins for invasive disease. Postoperative radiotherapy to a dose of 18 to 20 Gy is usually administered to the residual testicle to eradicate GCNIS, which is found in >80% of cases.[108,109] Observation alone has also been reported.[110] In either case, some degree of hormonal dysfunction is common, and many patients may still require lifelong testosterone replacement. Patients with testicular cancer are at a higher risk of developing contralateral malignant disease. In consequence, some authors advocate performing a biopsy of the contralateral testis during the radical orchiectomy

procedure for early diagnosis of GCNIS or invasive disease. However, routine biopsy of the contralateral testicle has not been shown to significantly reduce the incidence of metachronous germ cell malignancy.[111] In the setting of GCNIS identified by the biopsy, a course of radiation therapy may be considered to the contralateral testis for treatment of the *in situ* component of the neoplasia, as patients with GCNIS almost invariably progress to invasive cancer. In this setting, a low dose of radiation is able to preserve some function of the Leydig cells and avoid progression of disease.

RADIATION THERAPY TECHNIQUE

Target Volume and Field Borders

For stage I disease, the clinical target volume (CTV) encompasses the interaortocaval, preaortic, and paraaortic nodes (Fig. 71.1). The left renal hilar nodes are included for left-sided tumors. The ipsilateral external iliac and common iliac nodes may also be included, particularly if there is concern about aberrant drainage. Inclusion of the inguinal scar, inguinal lymph nodes, or hemiscrotum is not routinely warranted. For stage II disease, a gross tumor volume is identified from diagnostic imaging, and the CTV also usually includes the ipsilateral pelvic nodes.

The planning target volume (PTV) includes the CTV plus a margin to account for positional and setup uncertainties. To cover the known location of the retroperitoneal and iliac lymph nodes with an appropriate margin, standard anatomic field borders have been used. This is commonly referred to as the dog-leg or hockey stick field. Classically, the superior border is placed between the T9 and T10 vertebral bodies, with the inferior border at the top of the obturator foramen. A modified approach is now commonly used wherein the superior border is placed between T10 and T11, and the inferior border is placed at the superior aspect of the acetabulum (Fig. 71.2). The field is approximately 9 cm wide in the paraaortic region and usually covers the transverse processes. On the left, the lateral border is extended to include the left renal hilum, and customized shielding is positioned to reduce the amount of kidney irradiated. Field width here is typically 11 to 12 cm. At the mid-L4 level, the field is extended laterally to cover the ipsilateral external iliac nodes. Multileaf collimators are used to define the field shape. If retroperitoneal nodes alone are to be treated, the superior and lateral borders are as described previously, and the inferior border is placed at the L5/S1 disc space. Some report using a lower superior border, T10-

11, and a higher inferior border, the bottom of L4.[69]

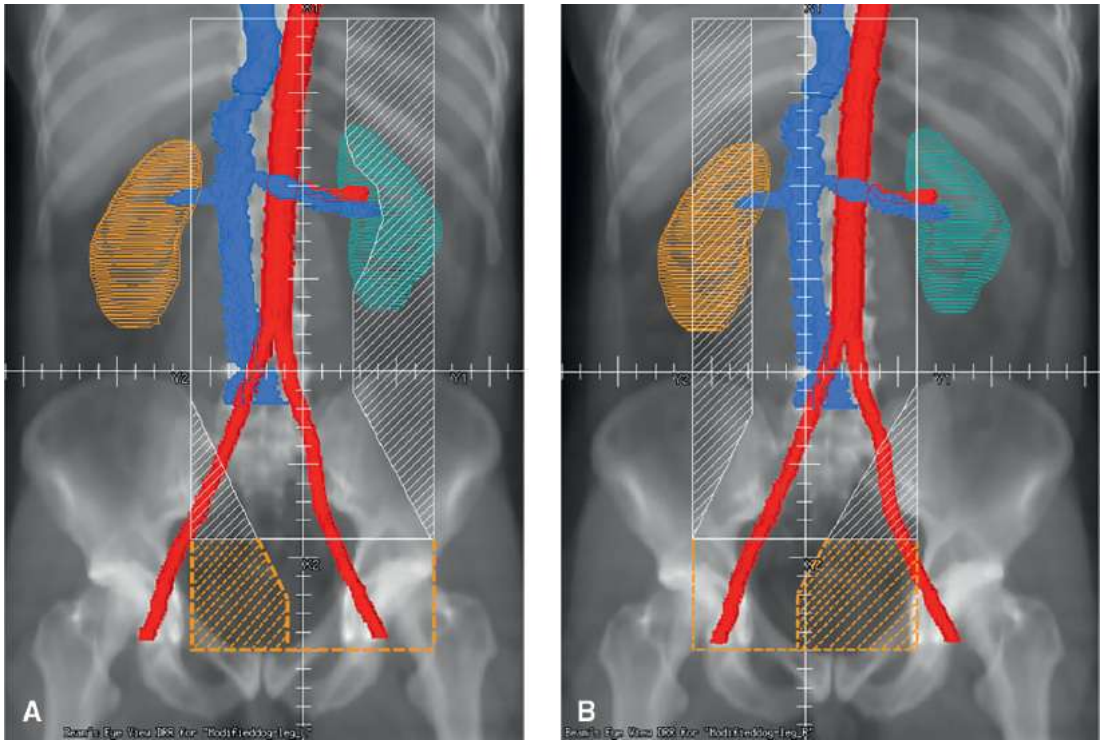

FIGURE 71.2. For stage I seminoma, a modified "dog-leg" field is used to encompass nodal regions at risk. The superior border is placed at the upper border of T10 or T11 and the inferior border at the superior aspect of the acetabulum. Traditionally, the inferior border was placed at the superior obturator foramen (indicated in *orange*) to include all external iliac nodes. These nodes are rarely involved, and using a higher border as indicated will reduce toxicity. If paraaortic fields are to be used, the inferior border is placed at the bottom of L5. The left renal hilum is included for left-sided tumors **(A)** but not for tumors on the right **(B)**.

Once these borders are placed, the planning CT can be used to ensure adequate coverage of the target volume. Distance from the PTV to the field border is 8 to 15 mm depending on field size, energy, separation, and shielding. It should be noted that there is often a distance of several centimeters between the cranial and caudal field edges and the 95% isodose, which is related to the large field size and variability in separation.

In stage II disease, the PTV includes the same CTV as for stage I disease with an appropriate margin. Care must be taken to include the gross nodal disease in the CTV (Fig. 71.3). If the lymphadenopathy is >4 cm in size, a boost to gross disease is commonly used. This may be delivered either concurrently or sequentially. The advantage of a sequential approach is that it allows for reduction in disease volume and less irradiation of normal tissues. This is

particularly appropriate where the initial disease is large and overlies the kidney.

A study has analyzed the location of metastatic lymph nodes relative to vascular structures in stage II or stage I patients presenting with nodal relapse after surveillance. Authors found, after analyzing 90 patients, that almost all detected nodes were contained within a 2.5-cm posterior and lateral margin and a 2.1-cm anterior margin from the arterial vasculature. No positive nodes were identified above the L1 level.[75] Although requiring further validation, this suggests that the classic field borders based on bony anatomy treats a larger volume than required and modification, for example, by lowering the superior border, may be considered in the future.

Simulation and Treatment Planning

A volumetric planning CT scan is acquired with the patient supine and arms at the sides. Testicular shielding (often in the form of a clamshell device) is used. Utilization of a CT-based planning technique enables visualization of the location of the lymph node regions, adjacent tissues, and critical normal structures including the kidneys and liver. In addition, the beam's eye view (BEV) allows evaluation of the coverage of the PTV, and shielding can be appropriately placed. Treatment is delivered with a linear accelerator using anterior and posterior parallel-opposed fields. Depending on the separation, 6- to 18-MV photons are utilized. More elegant treatment techniques using intensity-modulated radiotherapy (IMRT) to cover the target volume with greater sparing of organs at risk are described.[112] Although IMRT enables reduction of dose to organs at risk (stomach, bowel, bone marrow), it may increase low radiation doses to surrounding normal tissues, and it is not clear how this is reflected in reduction of early or late side effects of treatment, including risk of second malignancy.

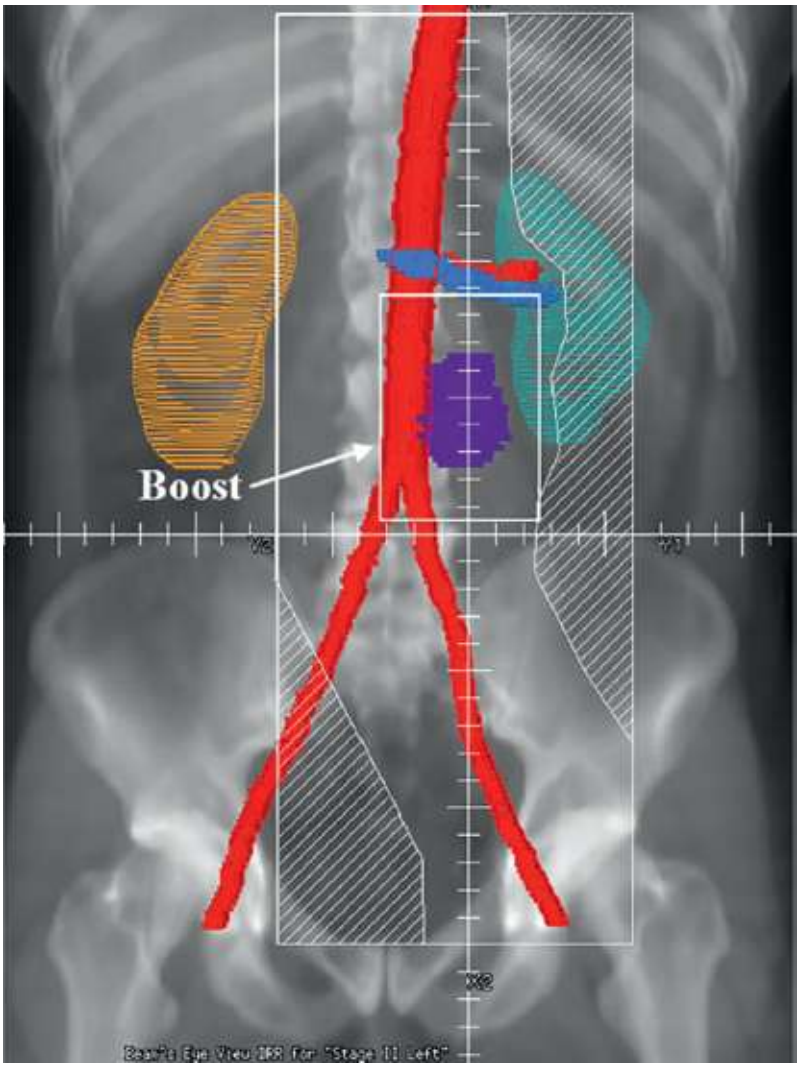

FIGURE 71.3. Stage IIA and stage IIB seminomas may be treated with a traditional or modified dog leg to a dose of 25 Gy in 20 fractions, with a boost of 10 Gy in 5 fractions to nodes >3 cm in diameter.

Dose and Fractionation

Stage I Seminoma

Radiation doses between 20 and 40 Gy at 1.25 to 2 Gy per fraction have been reported. A dose of 25 Gy in 20 fractions has been the most commonly used dose/fractionation at North American institutions,[113] with close to 100% control of retroperitoneal disease. The United Kingdom's MRC (MRC TE18) completed a randomized controlled trial of 30 Gy in 15 fractions over 3 weeks or 20 Gy in 10 fractions over 2 weeks.[70] Relapse-free survival was similar in both groups. Acutely, there was significantly more moderate or severe lethargy and inability to carry out normal work in the group that received 30 Gy. However, by 12 weeks, there were no differences between the two groups.

Stage II Seminoma

In general, patients with stage II seminoma should have the ipsilateral pelvic nodes treated. The optimal radiation dose is yet to be determined, and several regimens are used. One regimen of 25 Gy in 20 fractions is frequently used with a boost (10 Gy in 5 to 8 fractions) to the residual mass for lymphadenopathy >2 to 3 cm.[83] Alternatively, 30 Gy in 15 fractions for stage IIA and 36 Gy in 18 fractions for stage IIB seminoma have been shown to provide excellent local control.[84]

Testicular Shielding

During a fractionated course of radiotherapy to the retroperitoneal and ipsilateral iliac lymph nodes, the dose to the remaining testis ranges between 0.3 and 1.5 Gy. Dose received strongly depends on distance from the testicle to field edge. Several effective shielding devices have been described to reduce dose received by the testicle to <1% of the midplane dose.[114–116] Most departments use simple forms of gonadal shielding, such as the clamshell device, which consists of a cup that is 1 cm thick. This shields the testicle from low-energy scattered photons and effectively reduces the testicular dose by a factor of 4.

RESULTS OF THERAPY

Seminoma

The outcome of treatment depends on the stage and extent of disease at presentation. Age >40 years at diagnosis is also an adverse prognostic factor.[34] For stage I disease, routine irradiation of the paraaortic and ipsilateral pelvic nodes results in 10-year relapse-free survival rates of 96% to 98%. Approximately 1% to 4% of patients relapse after infradiaphragmatic irradiation, usually within the first 3 years. The sites of relapse are usually evenly distributed between the mediastinum and distant sites. Occasional relapses occur as nonseminomatous germ cell malignancies, even after careful review of the initial tumor has shown a pure seminoma. Deaths from stage I seminoma are extremely rare. Most relapsing patients are salvaged with subsequent treatment, usually chemotherapy. Cause-specific survival rates in the large series are 99% to 100%.

The outcome for patients with stage II disease treated with infradiaphragmatic irradiation is shown in Table 71.7. Disease-free survival is approximately 92% and 86% for patients with stage IIA and IIB disease, respectively. Relapse most commonly occurs in the mediastinum, supraclavicular nodes, and lungs.

Cisplatin-based chemotherapy is able to salvage in excess of 80% of the relapses, leading to a 5-year cause-specific survival of 96% to 100%. The relapse rate for patients with stage IIC disease managed by primary radiotherapy is >30%, and these patients are best managed with initial chemotherapy. Because of the ability to salvage patients who relapse following radiotherapy with cisplatin-based combination chemotherapy, the survival results following primary radiotherapy or chemotherapy as initial therapy even in patients with bulkier nodal disease are comparable. The potential toxicities of each approach must be evaluated for each patient, along with other factors influencing the choice of therapy.

Cisplatin-based chemotherapy (BEP × 3 fractions or EP × 4 fractions) is the standard treatment for patients with stage III seminoma, as well as for those with retroperitoneal masses >5 cm. Mencel et al.[117] reported that 93% of 142 patients with advanced seminoma achieved a favorable response to platinum-based chemotherapy, with an overall progression-free survival of 86%.

SEQUELAE OF TREATMENT

Radiation Therapy

The long-term sequelae of standard infradiaphragmatic irradiation for stages I and IIA disease are related to the dose of radiation used. There appears to be no curative advantage for doses >25 Gy; however, there is an increase in toxicity. In the MRC randomized trial comparing 30 Gy in 15 fractions delivered to either dog-leg or paraaortic fields, 33 of 478 patients (7%) were diagnosed with a peptic ulcer during follow-up. The occurrence rate was similar in both treatment arms. Very few patients report diarrhea as a long-term consequence, and most patients report a satisfactory quality of life, with a maintained body image and few side effects.[70]

Approximately 50% of patients with testicular seminoma have some degree of impairment in spermatogenesis at the time of presentation. Exposure of the remaining testis to therapeutic irradiation may further impair fertility, and the degree of impairment is dose dependent. Available data suggest that hormonal function and spermatogenesis may be compromised at dose levels as low as 0.5 Gy and those cumulative doses >2 Gy probably lead to permanent injury.[118] Hahn et al.[119] reported the induction of aspermia in 10 of 14 patients who received >65 cGy to the remaining testis. Aspermia was not detected at doses <50 cGy. Recovery of sperm in the semen occurred in most within 30 to 80

weeks of radiation therapy. A detailed assessment of fertility and sexual function was performed in the Southwest Oncology Group Study 8711 in a series of men following orchidectomy and radiation therapy for seminoma.[120] Fourteen of 26 patients (54%) were subfertile at baseline, with a sperm count <20,000/mL. The average prescribed dose was 26 Gy in 1.6-Gy fractions, delivering a median dose of 79 cGy to the remaining testis. With a testicular dose below the median, the sperm count tended to drop to a nadir value around 6 months, with recovery of fertility by 12 months. With higher testicular dose, recovery of sperm count was further delayed. Jacobsen et al.[121] reported a 50% reduction in sperm count at 1 year in 21 men following dog-leg radiation therapy (median testis dose, 32 cGy). No change in sperm count was noted in 24 men treated with paraaortic fields (median testis dose 9 cGy). Dog-leg radiation therapy also results in an elevation of serum follicle-stimulating hormone (FSH) levels, with no change in serum testosterone. FSH levels are highest within 6 months of radiation therapy and return to normal within 3 years. With current radiation techniques, most men will have return to baseline sperm concentrations and hormone levels with minimal impact on fertility.

Patients are at the increased risk of developing a second primary malignancy following treatment for testicular cancer.[122–124] Travis et al.[125] investigated the occurrence of second malignancies among >40,000 men who had undergone treatment for a testicular cancer between 1943 and 2001 from 14 population-based cancer registries in North America and Europe. The risk of developing a second solid tumor among 10-year survivors was almost twice that of the general population, with a relative risk (RR) of 1.9. The risk remained elevated for 35 years, with the highest risk for cancers of the stomach (RR 4.0), pancreas (RR 3.6), and bladder (RR 2.7). There was also an increased risk of developing cancers of the lung, esophagus, colon, and pleura. An increased risk was found for both seminomas and nonseminomas and in patients treated with radiation therapy alone (RR 2.0), chemotherapy alone (RR 1.8), and both modalities (RR 2.9). A case–control study of leukemia risk in a cohort of 18,567 patients treated for testicular cancer between 1970 and 1993 has also been reported.[126] Radiation therapy (mean dose 12.6 Gy to bone marrow) without chemotherapy was associated with a threefold elevated risk of leukemia. Risk increased with increasing dose of radiation to bone marrow largely associated with the use of mediastinal irradiation. The cumulative dose of cisplatin was also predictive of excess leukemia risk, being 3.2 with the commonly administered dose. In absolute terms, it is estimated that 25 Gy to the retroperitoneum would result in

9 excess cases of leukemia in 10,000 patients followed for 15 years. Commonly used doses of cisplatin might result in 16 excess cases. Although treatment factors are strongly implicated in the development of second primary malignancies following treatment, an excess risk of second cancers is seen even among testicular cancer patients who have just been observed. An increased rate of spontaneous chromosomal translocations is seen in lymphocytes of patients with early-stage seminoma compared to healthy controls.[127] Following adjuvant radiation therapy, the translocation rate increases before returning to preradiotherapy levels at around 30 months.[128] It is hypothesized that this genomic instability may be a predisposing factor toward malignancy development.

Long-term survivors following radiation therapy for seminoma are also at increased risk of death related to cardiac disease, even without mediastinal irradiation,[129] with a cardiac standardized mortality ratio of 1.85 in patients followed out beyond 15 years. One suggested explanation for the increased risk of cardiovascular deaths relates to the higher prevalence of diabetes in patients previously treated with radiation therapy to the paraaortic site.[130]

Chemotherapy

Cisplatin-based chemotherapy is associated with alopecia and the potential for substantial nausea and vomiting. Modern antiemetics have improved gastrointestinal reactions. Serious short-term problems are myelosuppression, bleomycin-induced pulmonary fibrosis, and rarely cisplatin nephrotoxicity. Myelosuppression and pulmonary fibrosis are fatal in 0.5% to 4% of treated patients. A recently recognized effect of chemotherapy used in the treatment of germ cell tumors is the risk of secondary malignancy. As discussed previously, the cumulative dose of cisplatin strongly correlates with the risk of subsequent malignancy.[126] Etoposide exposure increases the risk of leukemia. Morphologically, these leukemias are usually monocytic or myelomonocytic. Characteristic chromosomal translocations are frequently but not invariably present. The onset of leukemia is ordinarily closer to chemotherapy exposure than is the typical leukemia induced by alkylating agents.

Other late toxicities reported include high-tone hearing loss, neurotoxicity, Raynaud phenomenon, ischemic heart disease, hypertension, renal dysfunction, and pulmonary toxicity. In an observational study of 1,800 men treated with cisplatin-based chemotherapy for testicular cancer, Brydoy et al.[131] noted long-term Raynaud-like phenomena in 39%, paraesthesia in 29%, hearing impairment

in 22%, and troubling tinnitus in 22%. Long-term fertility seems little impaired following chemotherapy.[132] BEP causes immediate azoospermia; however, with time, more than half of patients may recover normal or near-normal spermatogenesis.[133] The paternity rate following two to four cycles of BEP is 70% to 85%.[134,135] Symptomatic hormone dysfunction only occurs with high cumulative doses of cisplatin,[136] although subclinical endocrine abnormalities are more common.[137]

CHAPTER 72

Cancer of the Penis and Male Urethra

Hiram A. Gay and David B. Mansur

ANATOMY

The basic structural components of the penis include two corpora cavernosa and the corpus spongiosum. These are encased in a dense fascia (Buck fascia), which is separated from the skin by a layer of loose connective tissue. Distally, the corpus spongiosum expands into the glans penis, which is covered by a skin fold known as the prepuce. The skin extends over and is firmly attached to the glans.

The male urethra is composed of a mucous membrane and the submucosa. It extends from the bladder neck to the external urethral meatus. The posterior urethra is subdivided into the membranous urethra, the portion passing through the urogenital diaphragm, and the prostatic urethra, which passes through the prostate. The anterior urethra passes through the corpus spongiosum and is subdivided into fossa navicularis (a widening within the glans); the penile urethra, which passes through the pendulous part of the penis; and the bulbous urethra, the dilated proximal portion of the anterior urethra. The prostatic urethra is covered by transitional epithelium only. The distal portion of the anterior urethra is covered by stratified squamous epithelium, which changes proximally to pseudostratified columnar epithelium. The columnar epithelium gradually changes into transitional epithelium in the membranous urethra.

The lymphatic channels of the prepuce and the skin of the shaft drain into the superficial inguinal nodes located above the fascia lata. The rich anastomotic network of the lymphatics within the penis and at the base of the penis means that for practical purposes, lymphatic drainage may be considered bilateral. There is some disagreement as to whether the glans and the deep penile structures drain into the superficial or deep inguinal lymph nodes (those under the fascia lata). The so-called sentinel nodes located above and medial to the junction of the epigastric and saphenous veins have been identified as the primary drainage sites in carcinoma of the penis.[1] Selective biopsy of this group

of nodes is of obvious importance in assessment of tumor extent, because, if they are not involved by tumor, a complete nodal dissection may not be necessary. The reliability of this procedure has not been supported by some.[2,3] Catalona[4] found that biopsy of the sentinel nodes showed false-negative results in 10% of Cabanas's[5] cases who died of carcinoma.

The lymphatics of the fossa navicularis and the penile urethra follow the lymphatics of the penis to the superficial and deep inguinal lymph nodes. The lymphatics of the bulbomembranous and prostatic urethra may follow three routes. Some pass under the pubic symphysis to the external iliac nodes, some go to the obturator and internal iliac nodes, and others end in the presacral lymph nodes. The pelvic (iliac) lymph nodes are rarely involved in the absence of inguinal lymph node involvement.[6]

EPIDEMIOLOGY AND RISK FACTORS

Penile Cancer

In the United States, in 2017, the estimated number of new cases of penis and other genital cancers was 2,120, with 360 deaths. This accounts for <1% of cancer in males in the United States.[7] In the European Union, the annual number of males that develop penile cancer is estimated at 3,100, which is equivalent to an age-standardized rate (ASR) of 12 per million males. The 5-year relative survival rate is 69%. Squamous cell carcinoma is the predominant morphologic entity.[8]

A systematic review and meta-analysis showed that men circumcised in childhood/adolescence are at substantially reduced risk of invasive penile cancer, and this effect could be mediated partly through an effect on phimosis. In contrast, there was some evidence that circumcision in adulthood was associated with an increased risk of invasive penile cancer.[9] A trade-off analysis of routine newborn circumcision was performed on the Comprehensive Hospital Abstract Reporting System for Washington State. Routine newborn circumcisions performed over 9 years (1987 to 1996) were retrospectively examined. Of 354,297 male infants born during the study period, 37% were circumcised during their newborn stay. Overall, 0.2% of circumcised children and 0.01% of uncircumcised children had complications potentially associated with circumcision. The authors estimated that almost two complications can be expected for every case of penile cancer prevented.[10]

A study of 1,010 penile invasive cancers diagnosed between 1983 and 2011

from 25 countries showed that between one-quarter and one-third of penile cancers are related to human papillomavirus (HPV). HPV16 was the most frequent HPV type detected in HPV-positive cancers.[11] A Brazilian study of 110 asymptomatic men and 30 patients who underwent circumcision because of phimosis showed that HPV was present in 46% of patients with phimosis, of whom 50% were high-risk phenotypes. They detected a significantly high rate of HPV genital infection in patients presenting with phimosis compared with asymptomatic men. The prevalence of high-risk HPV genotypes in patients with phimosis was also statistically significant.[12]

The quadrivalent vaccine against HPV serotypes 6, 11, 16, and 18 has been approved for females aged 9 to 26 years to prevent cervical cancer. Based on the demonstrated ability to significantly decrease the incidence of penile lesions (primarily HPV-6– and HPV-11–associated genital warts) in young men, the U.S. Food and Drug Administration also approved the use of the vaccine in males aged 9 to 26 years. Because the incidence of penile cancer in the United States is much lower than that of genital warts, the reduction in penile cancer incidence is expected to be low. Perhaps the greatest benefit of vaccination of young men in the United States would be the reduced HPV infection rate in the overall population and subsequent reduced transmission to females at risk for cervical cancer.[13] Other potential strategies for the prevention of penile cancer could include smoking cessation and hygienic measures.[14]

Urethral Cancer

Carcinoma of the male urethra is also rare. Each year, around 650 individuals in the European Union develop cancer of the urethra. The ASR for cancer of the urethra is 1.1 (males 1.6; females 0.6) per million inhabitants, respectively. The 5-year relative survival rate for cancer of the urethra is 54%. Transitional cell carcinoma (TCC) is the predominant morphologic entity of cancer of the urethra.[8]

There are no recognized racial or geographic predisposing factors. Although the etiology remains unknown, there seems to be some correlation between the incidence of carcinoma of the urethra and chronic irritation (infection, venereal diseases, strictures). Some evidence suggests that some cases of female urethral carcinoma may originate from Skene glands.[15] Significant past medical history of male urethra cancer patients includes venereal disease (24% to 37%), urethral stricture (35% to 54%), urethral trauma (7%), and urethral polyps (2%).[16,17] The part of the urethra covered by the transitional epithelium (prostatic and

membranous urethra) may be susceptible to the same carcinogenic factors that affect the bladder and the upper urinary tract. Average age at presentation of these tumors is 58 to 60 years, although 10% occur in men younger than 40 years.[5,17]

NATURAL HISTORY

Penile Cancer

Most carcinomas of the penis start within the preputial area, arising in the glans, coronal sulcus, or the prepuce itself. Lesions arising in the skin of the shaft are rare. In most patients, carcinoma of the penis is characterized by slow locoregional progression. The penis is handled and observed daily, yet there is often significant debate as to when patient recognition and medical diagnosis should have occurred. The patient experiences fear and embarrassment, which probably contributes to delayed diagnosis. Therefore, expeditious diagnosis of all penile lesions should be the rule. Extensive primary lesions may involve the corpora cavernosa or even the abdominal wall. The inguinal lymph nodes are the most common site of metastatic spread. Pathologic evidence of nodal metastases is reported in about 35% of all patients and in approximately 50% of those with palpable lymph nodes.[5,18–20]

Distant metastases are uncommon (about 10%), even in patients with advanced locoregional disease, and usually occur in patients with inguinal lymph node involvement. These patients often die of septic complications, erosion of large vessels in the groin, or a combination of the two.

Tumors can also metastasize to the penis. Most common primary sites are the genitourinary tract (mostly bladder urothelial carcinoma and prostatic adenocarcinoma) and the lower gastrointestinal tract (rectal and sigmoid colon adenocarcinomas). Secondary tumors tend to be localized in the penile shaft and to invade the vascular spaces of erectile tissues, with corpora cavernosa involvement in most of the cases. For patients with penile metastasis, cancer-related death rate is high and the prognosis is dismal.[21]

Urethral Cancer

The natural history of carcinoma of the anterior urethra in the male is similar to that of carcinoma of the penis. Approximately 40% of tumors originate in the anterior urethra.[16] Many tumors are low grade and progress slowly at primary and regional sites rather than spread to distal areas. Tumors of the penile urethra

spread to the inguinal lymph nodes first, whereas those of the bulbomembranous and prostatic urethra metastasize first to the pelvic lymph nodes. Approximately one-third of men will present with either clinically or pathologically involved lymph nodes.[16]

Urethral cancers tend to spread by direct extension to adjacent structures. Invasion into the vascular space of the corpus spongiosum in the periurethral tissues is common. Malignancies beginning in the bulbomembranous urethra often invade the deep structures of the perineum, including the urogenital diaphragm, prostate, and adjacent skin. In the majority of prostatic urethral tumors, the bulk of the prostate gland is invaded at the time of diagnosis. Hematogenous spread is uncommon except in advanced regional disease. Kaplan et al.[17] reported distant metastases in about 15% of patients, and most had corpora cavernosa invasion at diagnosis.

CLINICAL PRESENTATION

Penile Cancer

Carcinoma of the penis may present as either an infiltrative–ulcerative or an exophytic papillary lesion. Figure 72.1 demonstrates the localization of penile tumors in 259 patients from 14 cancer institutes in France. The glans and the prepuce were the predominant sites of the primary lesion, whereas tumors of the shaft were rare.[22] Assessment of the primary lesion may be obscured by the presence of phimosis. Secondary infection and associated foul smell are quite common. Urethral obstruction is an unusual symptom of carcinoma of the penis. The most common presenting symptom is a mass, which occurs in over two-thirds of patients. Ulceration is also common, occurring in approximately half of patients.[20,23] In a collective series of 552 patients with penile carcinoma, the presenting symptoms were mass lesions (78%), pain or itching (12%), bleeding (7%), groin mass (7%), and urinary symptoms (4%).[24–26] Inguinal lymph nodes are palpable on presentation in 30% to 45% of patients[5,18,19,25,27,28]; however, only half contain tumor.[19,20] Enlargement of the lymph nodes is often related to inflammatory (infectious) processes. Administration of antibiotics over several weeks results in regression of inguinal lymph nodes in a substantial proportion of cases, and many have advocated this practice before the status of the regional lymph nodes is definitively assessed. Conversely, between 20% and 40% of patients with clinically negative inguinal lymph nodes have occult metastases.[3,29–32]

Urethral Cancer

Patients with urethral carcinoma most commonly present with obstructive symptoms (43%). Other presenting signs and symptoms include mass (28%), bleeding (20%), abscess (20%), and irritative symptoms (20%).[16] These symptoms are often attributed to urethritis or urethral stricture, which may precede the development of urethral carcinoma and may also result in delay in diagnosis. The majority of urethral carcinomas occur in the bulbomembranous (posterior) region (61%), and tumors in this location have a worse prognosis compared with those arising in the anterior urethra.[16]

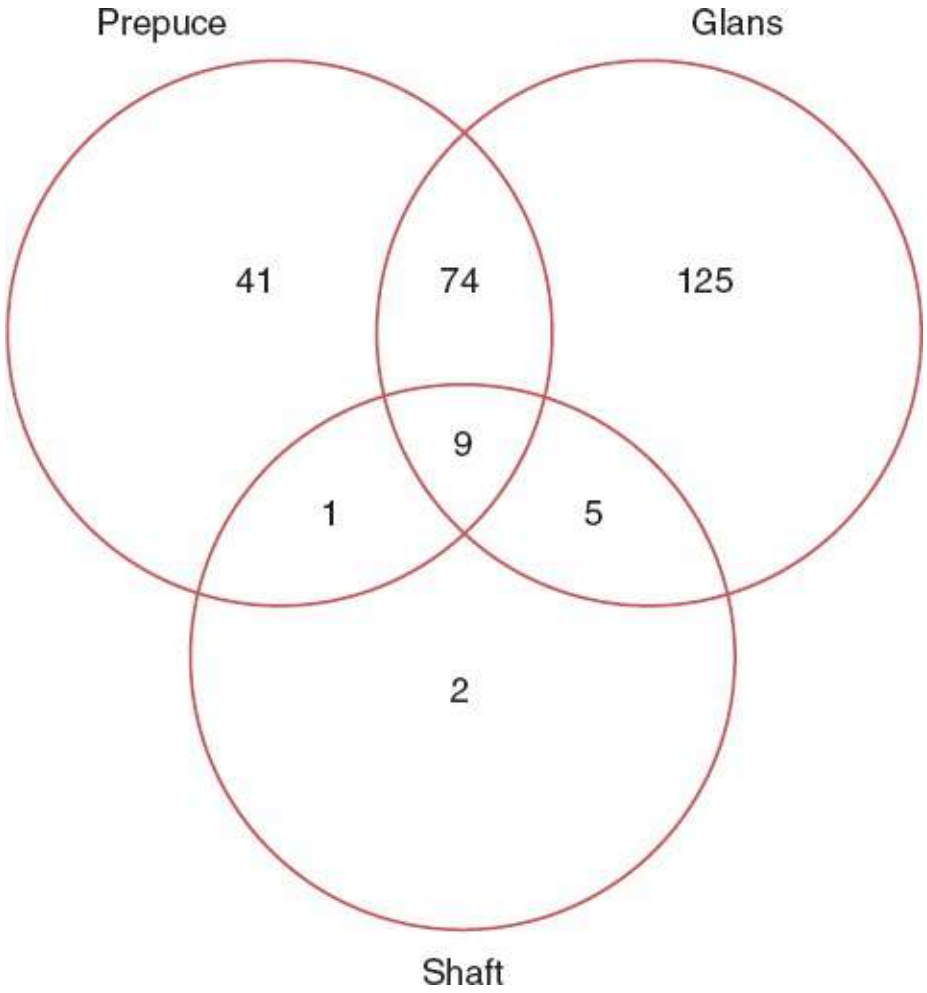

FIGURE 72.1. Localization of the primary tumor in 259 patients; each circle represents one anatomic compartment. Intersections indicate involvement of two or three compartments. Unknown: two. DIAGNOSTIC WORKUP

In penile and urethral cancers, imaging plays a crucial role in enhancing the precision of clinical staging and facilitating optimal surgical planning. High-resolution magnetic resonance imaging (MRI) now represents the gold standard for evaluating the primary tumor and its local extension. Lymphotropic nanoparticle–enhanced MRI and dynamic sentinel lymph node biopsy (DSNB) combined with FNA seem to be superior for imaging regional lymph nodes. Positron emission tomography/computed tomography (PET/CT) has shown great promise for the detection of distant metastases.[33]

Penile Cancer

See Table 72.1 for the diagnostic workup of penile cancer based on the Penile Cancer National Comprehensive Cancer Network (NCCN) Guidelines.

On MRI, penile tumors are best evaluated on T2-weighted images because of the superior contrast resolution between the hypointense fascial layers and the adjacent hyperintense corporal bodies. Squamous cell carcinomas typically appear as hypointense lesions when compared to the adjacent corpora. On MRI, nonsquamous variants of penile cancer can appear different from squamous carcinomas. Although penile cancers enhance with gadolinium, the normal corporal bodies enhance even more, which makes contrast enhancement less useful.[33]

The presence of central nodal necrosis and/or an irregular nodal border of the regional lymph nodes on preoperative CT images are accurate and reproducible (sensitivity of 95% [21 of 22] and a specificity of 82% [31 of 38]) criteria to identify high-risk pathologic node-positive penile cancer.[34]

Sentinel lymph node biopsy with a radiotracer (Tc-99m nanocolloid) is a reliable method with low morbidity that is associated with a low-radiation burden for clinical staff. The false-negative rate and morbidity were <5%.[35]

Limited prospective data regarding the use of PET with CT are available, but preliminary results show encouraging sensitivity (88%) and specificity (98%) in evaluating inguinal lymph nodes[36] and a diagnostic accuracy of 96% in evaluating pelvic lymph nodes in patients with known inguinal metastases.[37]

Urethral Cancer

See Table 72.2 for the diagnostic workup of urethral cancer based on the Bladder Cancer NCCN guidelines.[38]

A cystourethroscopy is essential for urethral primaries. Inguinal lymph nodes

should be thoroughly evaluated. CT is useful in the identification of enlarged pelvic and periaortic lymph nodes in patients with involved inguinal lymph nodes.[33]

TABLE 72.1 DIAGNOSTIC WORKUP FOR PENILE CANCER

General

History and physical examination

- Risk factors: balanitis, chronic inflammation, penile trauma, tobacco use, lichen sclerosus, poor hygiene, sexually transmitted disease
- Primary characteristics: diameter, location, number of lesions, morphology (papillary, nodular, ulcerous, or flat), relationship to other structures (submucosal, corpus spongiosum and/or corpora cavernosa, urethra)
- Lymph node characteristics: diameter, unilateral or bilateral, number, relationship to other structures, mobility or fixation, skin involvement

Punch, excisional, or incisional biopsy

Palpable lymph nodes: abdominal and pelvic MRI or CT with contrast unless contraindicated and chest imaging (CT or x-ray). Percutaneous lymph node biopsy, ultrasound or CT guided.

CT, computed tomography; MRI, magnetic resonance imaging.

TABLE 72.2 DIAGNOSTIC WORKUP FOR URETHRAL CANCER

General

History and physical examination

Cystourethroscopy, examination under anesthesia, transurethral resection, or transvaginal biopsy

Radiographic Studies

MRI of pelvis with and without contrast

Palpable lymph nodes: chest, abdominal, and pelvic CT with contrast. Lymph node biopsy.

CT, computed tomography; MRI, magnetic resonance imaging.

On MRI, urethral tumors tend to show a decreased signal intensity relative to that of the surrounding normal corporal tissue on T1- and T2-weighted images. Malignant lesions usually enhance with gadolinium.[33]

STAGING

Penile Cancer

The American Joint Committee on Cancer (AJCC) staging systems for carcinoma of the penis and urethra are shown in Tables 72.3 and 72.4, respectively.[39]

PATHOLOGIC CLASSIFICATION

Penile Cancer

The World Health Organization (WHO) classifies malignant epithelial tumors of the penis as squamous cell carcinoma (basaloid, warty [condylomatous], verrucous, papillary NOS, sarcomatous, mixed, and adenosquamous carcinoma), Merkel cell carcinoma, small cell carcinoma of neuroendocrine type, sebaceous carcinoma, clear cell carcinoma, and basal cell carcinoma.[40] Basaloid carcinoma has a poor prognosis and frequently early inguinal nodal metastases. Warty carcinoma has a good prognosis with rare metastases. Verrucous carcinoma has a good prognosis with no metastases. Papillary carcinoma has a good prognosis with rare metastases. Sarcomatous carcinoma has a very poor prognosis with early vascular metastases. Mixed carcinoma has a heterogeneous prognosis. Adenosquamous carcinoma occurs in the central and perimeatal glans, is high grade with a high metastatic potential but low mortality.[41]

Most malignant penile tumors are well-differentiated squamous cell carcinomas.[42] Although an apparent adverse prognostic effect of anaplasia has been reported in some series,[18] others found no significant correlation between histologic grade and survival.[25,43]

Bowen disease is squamous cell carcinoma *in situ* that may involve the shaft of the penis as well as the hairy skin of the inguinal and suprapubic area. Clinically, the lesion is a solitary, dull-red plaque with areas of crusting and oozing. Approximately 25% to 50% of patients with this disease have a concomitant visceral malignancy.[6]

Erythroplasia of Queyrat is an epidermoid carcinoma *in situ* that involves the mucosal or mucocutaneous areas of the prepuce or glans.[42] It appears as a reddened, elevated, or ulcerated lesion. Graham and Helwig[44] reported that 10 of 100 patients presenting with erythroplasia of Queyrat had invasive squamous cell carcinoma at diagnosis. Mikhail[45] reported on 5 of 15 patients with the same presentation. Erythroplasia of Queyrat is not as frequently associated with internal malignancies as Bowen disease.[40]

Basal cell carcinoma is infrequently reported, accounting for 1% to 2% of all cases of penile cancers.[41,42]

Extramammary Paget disease is a rare intraepithelial apocrine carcinoma. The most common sites are the scrotum, inguinal folds, and perineal region.[45] The lesion has a propensity to metastasize, necessitating frequent assessment of regional nodes. Radiation therapy has been recommended as palliative

treatment.[45]

TABLE 72.3 2017 PENIS CANCER TNM STAGING AJCC UICC

Penis

T category	T Criteria
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma *in situ* (penile intraepithelial neoplasia [PeIN])
Ta	Noninvasive localized squamous cell carcinoma
T1	Glans: Tumor invades the lamina propria Foreskin: Tumor invades dermis, lamina propria, or dartos fascia Shaft: Tumor invades connective tissue between epidermis and corpora regardless of location All sites with or without lymphovascular invasion or perineural invasion and is or is not high grade
T1a	Tumor is without lymphovascular invasion or perineural invasion and is not high grade (i.e., grade 3 or sarcomatoid)
T1b	Tumor exhibits lymphovascular invasion and/or perineural invasion or is high grade (i.e., grade 3 or sarcomatoid)
T2	Tumor invades into corpus spongiosum (either glans or ventral shaft) with or without urethral invasion
T3	Tumor invades into corpora cavernosum (including tunica albuginea) with or without urethral invasion.
T4	Tumor invades other adjacent structures (i.e., scrotum, prostate, pubic bone)

Regional Lymph Nodes (N)[a]

Clinical N (cN)

cN Category	cN Criteria
cNX	Regional lymph nodes cannot be assessed
cN0	No palpable or visibly enlarged inguinal lymph nodes
cN1	Palpable mobile unilateral inguinal lymph node
cN2	Palpable mobile ≥2 unilateral inguinal nodes or bilateral inguinal lymph nodes
cN3	Palpable fixed inguinal nodal mass or pelvic lymphadenopathy unilateral or bilateral

Clinical N (pN)

pN Category	pN Criteria
pNX	Lymph node metastases cannot be established
pN0	No lymph node metastasis
pN1	≤2 unilateral inguinal metastases; no ENE
pN2	≥3 unilateral inguinal metastases or bilateral inguinal metastases
pN3	ENE of lymph node metastases or pelvic lymph node metastases

Primary lymphoma of the penis was reported in one patient with Peyronie disease, without other evidence of lymphomatous involvement. Five cases of secondary involvement of the penis by lymphoma were reported in the literature.[48]

Cancers metastatic to the penis are rare and usually represent late, advanced carcinomatosis. The most common neoplasms metastasizing to the penis are from the genitourinary organs, followed by the gastrointestinal and respiratory systems (Table 72.5). The predominant cell type is carcinoma, occurring in 202 of 219 cases.[49] Sarcomas and tumors of unknown histologic type are rare. A palpable mass, swelling, nodule, or skin change frequently occurs. Priapism as an initial presenting feature or subsequent development occurs in 40% of patients.[49]

Urethral Cancer

The histologic subtypes in the Memorial Sloan Kettering Cancer Center series of urethral cancers included squamous cell carcinoma (52%), TCC (33%), epidermoid carcinoma (11%), adenocarcinoma (2%), and anaplastic carcinoma (2%).[16] Primary malignant melanoma arising from the urethra has been reported.[50,51] The frequency of histologic type varies with site. Over 90% of carcinomas of the prostatic urethra are of transitional cell type. Adenocarcinomas occur only in the bulbomembranous urethra.

PROGNOSTIC FACTORS

Penile Cancer

The principal prognostic factors in carcinoma of the penis are extent of the primary lesion and status of the lymph nodes.[23,52] The incidence of nodal involvement is related to the size, location, and grade of the primary lesion. Invasion of deep-seated structures (corpora cavernosa) carries a high risk of deep inguinal node involvement.

A study of 212 penile cancer cases in the Netherlands showed a statistically significant difference in the 5-year disease-specific survival between the high-risk HPV-negative group (82%) and the high-risk HPV-positive group (96%).[53] In addition, p16 positivity, a surrogate for HPV infection, confers an improved prognosis and has excellent interobserver reproducibility.[54]

Tumor-free regional nodes imply an excellent (80% to 90%) long-term

survival or cure.[19,28,52] Patients with involvement of the inguinal nodes fare considerably worse, and only 40% to 50% survive long term.[19,28,52,55] Pelvic lymph node involvement implies a still worse prognosis; <20% of these patients survive.[5,19,25] Gerbaulet and Lambin[56] reported the results of 109 patients with carcinoma of penis at Institut Gustave Roussy. The actuarial survival rates of patients with negative nodes were 82% at 5 years and 59% at 10 years. For patients with positive nodes, the survival rates were 36% and 18%, respectively. The number of positive lymph nodes has also been reported to have prognostic significance. Brkovic et al.[57] reported a 5-year survival rate of 71% in patients with solitary inguinal lymph node metastasis compared with 33% in patients with multiple positive inguinal nodes.

Tumor differentiation was shown to be an important prognostic factor by Fraley et al.[58] None of 9 patients with carcinoma *in situ*, 1 of 20 with well differentiated, 5 of 13 with moderately differentiated, and 3 of 4 with poorly differentiated lesions died of their tumors. Other investigators have confirmed the prognostic significance of tumor grade.[23,52,59,60]

Carcinoma of the penis has been reported to have greater propensity to metastasize and poorer prognosis in patients younger than 50 years of age[58] and patients older than 65 years of age.[59] Soria et al.[23] reported younger age at presentation adversely affected disease-free survival, but not overall survival. Conversely, Marcial et al.[61] observed no difference in survival in relation to age.

An epithelial–mesenchymal transition (EMT) phenotype at the invasion front of squamous cell carcinoma of the penis confers a worse prognosis. EMT is a process that allows polarized epithelial cells to undergo biochemical, molecular, and morphologic changes that affect the acquisition of a mesenchymal cell phenotype with increased migration, tissue invasion, and resistance to apoptosis. A retrospective study of 149 penile cancers showed that the 10-year overall survival and cancer-specific survival (CSS) rates in patients with presence or absence of complete EMT status were 38.0% and 55.6% and 48.0% and 91.9%, respectively.[62] Activation of mTOR signaling may contribute to penile squamous cell carcinoma progression and aggressive behavior.[63] CD44 levels and patterns of expression can be considered as markers for penile squamous cell carcinoma aggressiveness and may serve as predictive markers for lymph node metastases.[64]

Predictors of cancer-specific mortality after disease recurrence in patients with squamous cell carcinoma of the penis include shorter time to disease recurrence, lymph node metastasis at the time of initial treatment, and regional

recurrence.[65]

Urethral Cancer

A SEER database study of 2,065 men from 1988 to 2006 showed that advanced age, higher grade, higher T stage, systemic metastases, other histology versus TCC, and no surgery versus radical resection were predictors of death and death from disease. Adenocarcinoma was associated with a lower likelihood of death and death from disease as compared with TCC. Nodal metastasis was a predictor of death. Surgery had a better outcome than radiation for stage T2 to T4 nonmetastatic disease.[66]

Another SEER database study of 722 women from 1983 to 2008 showed that advanced age, T stage, node-positive disease, nonsquamous histologic features, and black race were associated with reduced CSS. Surgical resection was associated with a longer CSS. Black women presented with more advanced tumors and had a shorter CSS than white women.[67]

Overall prognosis in males with carcinoma of the urethra varies considerably with location of the primary lesion.[16,68–73] Distal lesions generally have a prognosis similar to that of carcinoma of the penis. Lesions of the bulbomembranous urethra are usually quite extensive and are associated with a dismal prognosis. Dalbagni et al.[16] reported a 5-year overall survival of 69% in patients with anterior tumors compared with 26% in patients with posterior tumors. Other prognostic factors included lymph node status and histology (superficial vs. invasive). A study of an international cohort of 154 patients with primary urethral cancer showed that clinical nodal stage is a critical parameter for outcomes.[74] Tumors of the prostatic urethra show prognostic features similar to those in bladder carcinoma. Superficial lesions have a good prognosis and may be managed with transurethral resection.[71] Deeply invasive tumors have a greater tendency to develop inguinal or pelvic lymph node and distant metastases.

GENERAL MANAGEMENT

Penile Cancer

General Treatment Approach

According to the NCCN Guidelines for Penile Cancer, clinical Tis, Ta, and T1 penile cancer lesions may be amenable to organ-sparing approaches like topical therapy (5-FU or imiquimod), laser therapy, glansectomy, wide local excision,

and Mohs micrographic surgery. For T1 G1 to G2 tumors, interstitial brachytherapy (preferred) or external beam radiation therapy (EBRT) can be considered (category 2B). Circumcision should always precede RT to prevent radiation-related complications. For T1 G3 to G4 or T2 tumors smaller than 4 cm with negative nodes, interstitial brachytherapy and EBRT ± inguinal lymph node RT are options after circumcision. Tumors 4 cm or larger or node-positive disease that is unresectable, circumcision followed by chemoradiotherapy, and carefully selected patients may be amenable to brachytherapy. Postsurgical RT to the primary tumor site may be considered for positive margins.[75]

If the patient is unable or unwilling to undergo surgical management, prophylactic EBRT to the lymph nodes should be considered. Patients with pN2 to N3 disease, a pelvic lymph node dissection (PLND) with or without adjuvant chemotherapy or chemoradiotherapy should be considered. Definitive chemoradiotherapy is also an option. Postoperative RT or chemoRT may be considered after PLND, particularly in the setting of a positive surgical margin, viable cancer in multiple inguinal or pelvic lymph nodes, and/or extranodal extension on pathology.[75]

The International Penile Advanced Cancer Trial (InPACT; NCT02305654) sponsored by the Institute of Cancer Research (United Kingdom) will consist of two randomizations. The first randomization relates to the inguinal management has three arms: therapeutic inguinal node dissection (arm A), neoadjuvant chemotherapy followed by therapeutic inguinal node dissection (arm B), and neoadjuvant chemoradiotherapy followed by therapeutic inguinal node dissection (arm C). Patients who have a pathologic high risk defined as ≥3 nodes or extranodal spread undergo a second randomization: arm A and arm B are randomized between adjuvant chemoradiotherapy and prophylactic PLND followed by adjuvant chemoradiotherapy, and arm C is randomized between surveillance and prophylactic PLND. Neoadjuvant chemotherapy consists of up to four cycles of paclitaxel, ifosfamide, and cisplatin (TIP), and concurrent chemoradiotherapy uses cisplatin.[76]

Conservative Therapies

Treatment for carcinoma *in situ* and very small penile carcinomas includes topical imiquimod and 5-fluorouracil (5-FU).[77] For larger lesions, conservative laser surgery[78] or Mohs micrographic surgery is used.[79]

Surgery

Treatment of patients with carcinoma of the penis is generally performed in two phases: initial management of the primary tumor and later treatment of the regional lymphatics. According to the NCCN Guidelines, organ-sparing surgical interventions at the primary site may range from laser therapy, wide local excision, glansectomy, and Mohs micrographic surgery. Partial or total penectomy should be considered for high-grade primary penile tumors or tumors invading the corpora cavernosum.[75]

In very advanced proximal tumors, more aggressive resections such as total emasculation (penectomy, scrotectomy, orchiectomy) or cystoprostatectomy may be indicated. Although surgical resection is a highly effective and an expedient treatment modality in most cases, it may not be acceptable to sexually active patients. Radical surgery, especially total penectomy, may be psychologically devastating to the patient. The ideal surgical procedure removes the disease with adequate margins while preserving sexual and urinary function, although this is not always possible because of the extent of disease. The high local recurrence rates described in some reports with limited surgery[80,81] illustrate the need for careful patient selection in choosing a surgical approach.

Lesions confined to the prepuce may be treated with wide circumcision. Microsurgical techniques have shown local excision to be an acceptable and desirable option with small superficial lesions. A local control rate of 92% was achieved in 29 patients with a 5-year survival rate of 81% for stage I and 57% for stage II lesions.[82] It is possible for some patients to remain sexually active after partial penectomy. Jensen[83] reported 45% of patients with 4 to 6 cm and 25% of patients with 2 to 4 cm of penile stump could perform sexual intercourse. D'Ancona et al.[84] evaluated the quality of life in 14 patients treated with partial penectomy. Sexual function was reported to be normal or only slightly decreased in 64% of patients. Complete loss of sexual function was reported in 14% of patients.

Surgical Treatment of Inguinal Lymph Nodes

According to the NCCN Guidelines, standard or modified inguinal lymph node dissection (ILND) or DSNB is indicated in patients with high-risk features for nodal metastases: lymphovascular invasion, ≥pT1G3 or ≥T2, or >50% poorly differentiated. If DSNB is positive, then ILND is recommended. PLND should be considered at the time or following ILND in patients with ≥2 positive inguinal nodes on the ipsilateral ILND site or extranodal extension on pathology. A bilateral PLND should be considered at the time or following ILND in patients

with ≥4 positive inguinal nodes total.[75]

The clinical evaluation of inguinal lymph nodes in men with cancer of the penis is unreliable. Several series have shown the sensitivity of clinical staging of the nodes to be 40% to 60% and false-negative rates to be 10% to 20%.[3,4] McDougal et al.[85] reported the correlation between clinical findings and pathologic positivity of inguinal nodes in patients with penile carcinoma. For tumors with no invasion or superficial invasion, moderately or well differentiated, only 12% of clinically enlarged inguinal nodes were pathologically positive. However, 78% to 88% of invasive or poorly differentiated tumors metastasized to inguinal nodes regardless of clinical findings. In a prospective study involving 37 patients with clinically negative groins, Solsona et al.[32] have demonstrated the predictive value of histologic grade and T stage in predicting the likelihood of occult-positive lymph nodes. Three groups were identified: low, intermediate, and high risk with an incidence of occult-positive nodes of 0%, 33%, and 83%, respectively (Table 72.6).

Radiation Therapy

The primary advantage of radiation therapy is organ preservation. According to the NCCN Guidelines for Penile Cancer, T1 to T2 tumors <4 cm can be managed with circumcision followed by brachytherapy alone (category 2B), EBRT (category 2B), or EBRT with concurrent chemotherapy (category 3) to a total dose of 65 to 70 Gy with conventional fractionation. Prophylactic EBRT to the inguinal lymph nodes may be considered for nonsurgical candidates or those who decline surgery.[75]

TABLE 72.6 T STAGE AND GRADE PREDICT THE RISK OF OCCULT-POSITIVE LYMPH NODES

Risk Group		Occult-Positive Lymph Nodes (%)
Low	Tis, T1 grade 1	0/13 (0)
Intermediate	T1 grade 2–3 T2 grade 1	4/12 (33.3)
High	T2 grade 2 T2–T3 grade 3	10/12 (83.3)

Reprinted from Solsona E, Iborra I, Rubio J, et al. Prospective validation of the association of local tumor stage and grade as a predictive factor for occult lymph node micrometastasis in patients with penile carcinoma and clinically negative inguinal lymph nodes. *J Urol* 2001;165(5):1506–1509. Copyright © 2001 American Urological Association, Inc. With permission.

T1 to T2 tumors ≥4 cm can be managed with circumcision followed by EBRT with concurrent chemotherapy (category 3) to 45 to 50.4 Gy to a portion of or the whole penile shaft depending on the extent of the lesion plus pelvic lymph nodes, followed by a boost to the primary lesion to 60 to 70 Gy with conventional fractionation. Brachytherapy alone may be considered in select cases.[75]

T3 to T4 or N-positive tumors (surgically unresectable) can be managed with circumcision followed by 45 to 50.4 Gy to the whole penile shaft, pelvic lymph nodes, and bilateral inguinal lymph nodes followed by a boost to the primary lesion to 60 to 70 Gy with conventional fractionation.[75]

If the margins are positive following penectomy, postsurgical EBRT to 60 to 70 Gy to the primary tumor site and surgical scar is recommended. Bilateral inguinal lymph nodes and pelvic lymph nodes may be treated if no or inadequate lymph node dissection. Brachytherapy may be considered in select cases.[75]

Palliative courses of 20 Gy in 5 fractions or 30 Gy in 10 fractions are acceptable for painful metastases. A short course is unlikely effectively palliate advanced locoregional disease. If the patient's general condition permits, a more prolonged fractionation, especially with the addition of chemotherapy, such as low-dose weekly cisplatin, may produce longer-lasting benefit.[86]

Chemotherapy

The use of systemic chemotherapy as either an adjuvant or concomitantly with radiation therapy has not been fully investigated in patients with penile cancer. Modern multiagent chemotherapy regimens have overall response rates ranging from 15% to 55% in patients with advanced disease (Table 72.7). Additional clinical trials are needed to adequately define the role of chemotherapy in the management of cancer of the penis.

Preoperative paclitaxel/ifosfamide/cisplatin (TIP) can yield clinically significant responses among patients with regionally advanced penile cancer. About 50% of such patients with an objective response to chemotherapy who undergo consolidative lymphadenectomy will remain alive at 5 years.[93] Cetuximab has antitumor activity in metastatic penile cancer and may enhance the effect of cisplatin-based chemotherapy.[94]

According to the NCCN Guidelines, the preferred chemotherapy regimens are TIP and 5-FU + cisplatin (not recommended neoadjuvantly). For chemoradiotherapy, cisplatin ± 5-FU is preferred with mitomycin C + 5-FU or capecitabine (palliation) as alternatives.[75]

Urethral Cancer

The primary mode of therapy for carcinoma of the male urethra is surgical excision. According to the NCCN Guidelines, patients with clinical Tis, Ta, or T1 tumors should be managed with a transurethral resection followed by intraurethral chemotherapy or BCG in selected cases.[38]

Clinical T2 tumors of the male pendulous urethra can be managed with a distal urethrectomy or partial penectomy. Positive margins are managed with further surgery, radiotherapy, or chemoradiotherapy (preferred). Clinical T2 tumors of the male bulbar urethra are managed with urethrectomy with or without cystoprostatectomy. Subsequently, pathologic T3 to T4 or N1 to N2 tumors can be considered for adjuvant chemoradiotherapy or chemotherapy. Clinical T2 tumors of the female urethra can be treated with chemoradiotherapy or urethrectomy plus cystectomy.[38]

Clinical T3 and T4 tumors that are cN0 can receive neoadjuvant chemotherapy and consolidation with surgery or radiotherapy, chemoradiotherapy, or radiotherapy. Clinical T3 and T4 tumors that are cN1 or cN2 can be treated with radiotherapy preferably with chemotherapy (especially for squamous cell carcinoma), chemotherapy, or chemoradiotherapy followed by consideration of consolidative surgery.

Because of the rarity of this disease, comparison of the cure rates with radiation therapy or surgery is difficult. The principal advantage of radiotherapy is organ preservation. Noninvasive carcinoma of the proximal urethra can be treated with transurethral resection. In lesions of the distal urethra, results with either penectomy or radiation therapy are similar to those for carcinoma of the penis, and the 5-year survival rates are comparable (50% to 60%).[95] Involved regional lymph nodes are treated with lymphadenectomy.

Most patients, however, present with advanced invasive lesions, which are difficult to manage with either radical surgery or radiation therapy. The major problem is the high rate of local recurrence. In an attempt to improve the locoregional control rate, extended resections encompassing the inferior pubic rami, prostate, bladder, and perineum have been performed after preoperative radiation therapy.

Chemotherapy

Gheiler et al.[50] reported their experience with multimodality treatment of 21 patients (10 women, 11 men) with urethral carcinoma. Treatment consisted of cisplatin- and 5-FU–based chemotherapy for squamous cell carcinoma and concomitant external beam irradiations. Patients with TCC were treated with concomitant methotrexate, vinblastine, Adriamycin (doxorubicin), and cisplatin. Some patients underwent surgical resection following chemoradiation. With a median follow-up of 42 months, the overall disease-free survival rate was 62%. Of significance is the pathologic complete response rate of 87.5% in eight women undergoing resection following chemoradiation. Another retrospective study of 29 males with urethral cancer treated with 2 cycles of 5-fluorouracil and mitomycin C with concurrent EBRT to the genitalia, perineum, and inguinal and external iliac lymph nodes showed that 79% had a complete response to treatment, whereas the rest did not respond and died of their disease. Of the complete responders, 42% had disease recurrence at a median of 12.5 months. The 5-year overall, disease-specific, and disease-free survival rates were 52%, 68%, and 43%, respectively.[96]

A series of 124 patients with primary urethral cancer treated between 1993 and 2012 from 10 referral centers showed that those who received neoadjuvant chemotherapy or neoadjuvant chemoradiotherapy with adjuvant chemotherapy for cT3 and/or cN+ tumors appeared to demonstrate improved survival compared with those who underwent upfront surgery with or without adjuvant chemotherapy. Proximal tumor location correlated with an inferior 3-year

relapse-free survival and overall survival.[97]

RADIATION THERAPY TECHNIQUES

Penile Cancer

If indicated, circumcision must be performed before radiation therapy is initiated. The purpose of this procedure is to minimize radiation therapy–associated morbidity: swelling, irritation of the skin, moist desquamation, and secondary infection.

Although external beam therapy has become prevalent in the treatment of the primary lesion in carcinoma of the penis, plastic molds or interstitial implants are still used.

External Beam Radiation Therapy

External beam therapy requires specially designed accessories (including bolus) necessary to achieve homogeneous dose distribution to the entire penis. Frequently, a plastic box with a central circular opening that can be fitted over the penis is used. The space between the skin and the box must be filled with tissue-equivalent material (Fig. 72.2). This box can then be treated with parallel-opposed megavoltage beams. An alternative to the box technique is the use of a water-filled container to envelop the penis while the patient is in a prone position.[98]

Another more complex device consists of a Perspex tube attached to a baseplate resting on the skin.[99] This is placed as close as possible to the base of the penis, and a flexible tube is connected to a vacuum pump. The suction effect keeps the penis in a fixed position during treatment. Appropriate bolus is placed outside the tube. The patient can also be treated in the prone position, with the penis hanging through a small hole placed in the Perspex's cylinder.

Regional lymphatics may be treated with external beam radiotherapy. Both groins should be irradiated. The fields should include inguinal *and* pelvic (external iliac and hypogastric) lymph nodes (Fig. 72.3). The posterior pelvis may be partially spared by anterior loading of the beams. Depending on the extent of the nodal disease and the proximity of the detectable tumor to the skin surface or the presence of skin invasion, application of a bolus to the inguinal area should be considered. Techniques such as intensity-modulated radiation therapy (IMRT) may allow for the treatment of the inguinal lymph nodes and/or pelvic lymph nodes while sparing the bladder, small and large bowel, and

rectum. Primary lesions should be boosted with 2-cm margins. Treatment doses are discussed in the previous “Radiation Therapy” section.

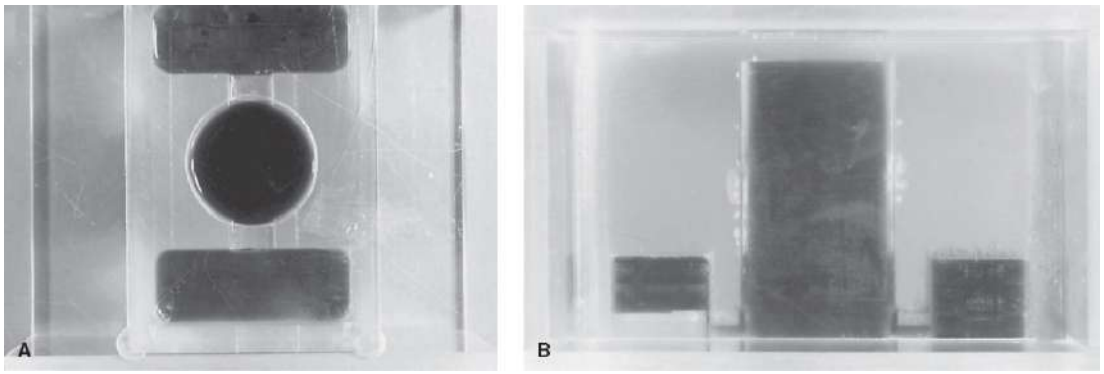

FIGURE 72.2. A: View from above of plastic box with central cylinder for external irradiation of the penis. Patient is treated in the prone position. The penis is placed in the central cylinder, and water is used to fill the surrounding volume in the box. Depth dose is calculated at the central point of box. **B:** Lateral view.

Brachytherapy

For detailed coverage of this topic, we refer the reader to the American Brachytherapy Society-Groupe Européen de Curiethérapie-European Society of Therapeutic Radiation Oncology (ABS-GEC-ESTRO) consensus statement for penile brachytherapy. Tumors that are of clinical stage T1b or T2 and <4 cm in maximum diameter are most suitable for primary brachytherapy. Lesions confined to the glans are ideal, but those with minor extension across the coronal sulcus are also suitable provided the extension can be covered with no more than one additional plane of needles.[100]

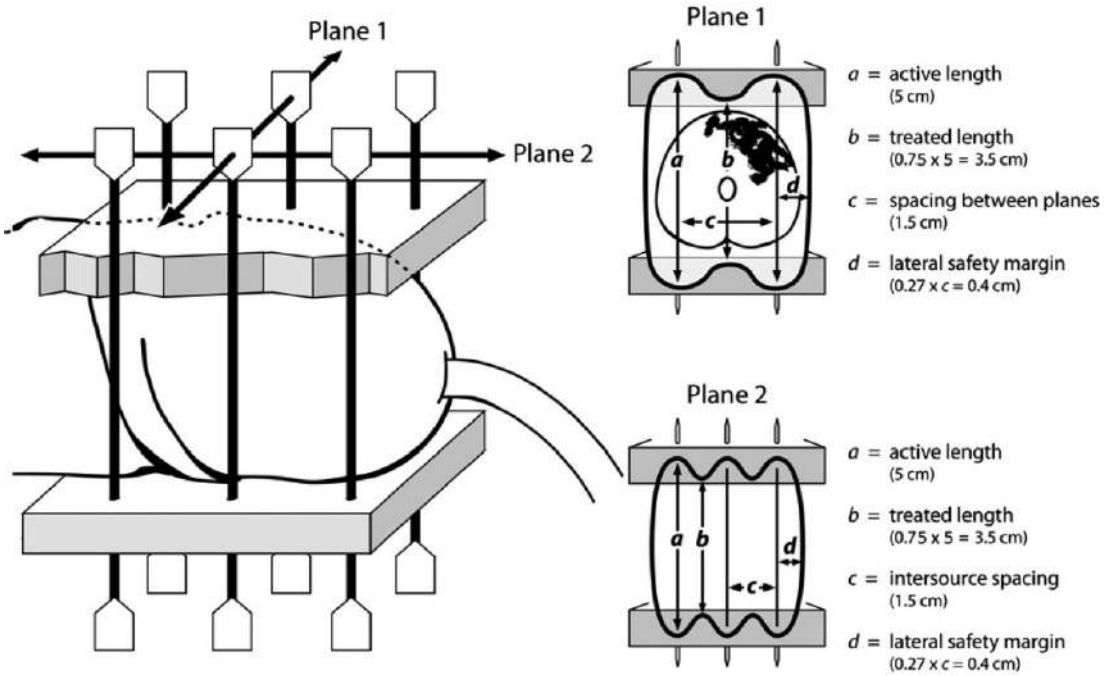

FIGURE 72.4. Schematic of a 2-plane, 6-needle implant showing the prescription isodose coverage according to the Paris System rules. (Reprinted from Crook JM, Haie-Meder C, Demanes DJ, et al. American Brachytherapy Society-Groupe Européen de Curiethérapie-European Society of Therapeutic Radiation Oncology (ABS-GEC-ESTRO) consensus statement for penile brachytherapy. *Brachytherapy* 2013;12[3]:191–198. Copyright © 2013 American Brachytherapy Society. With permission.)

The low-dose rate (LDR) prescribed dose is generally 60 Gy at 0.5 to 0.6 Gy/h with the treatment completed in about 5 days. For pulsed dose rate (PDR) treatments, pulses equivalent to the hourly dose rate of an LDR implant are delivered every hour. According to the Paris System, prescription for LDR and PDR is to 85% of the dose rate minima between the planes (Fig. 72.4).[100]

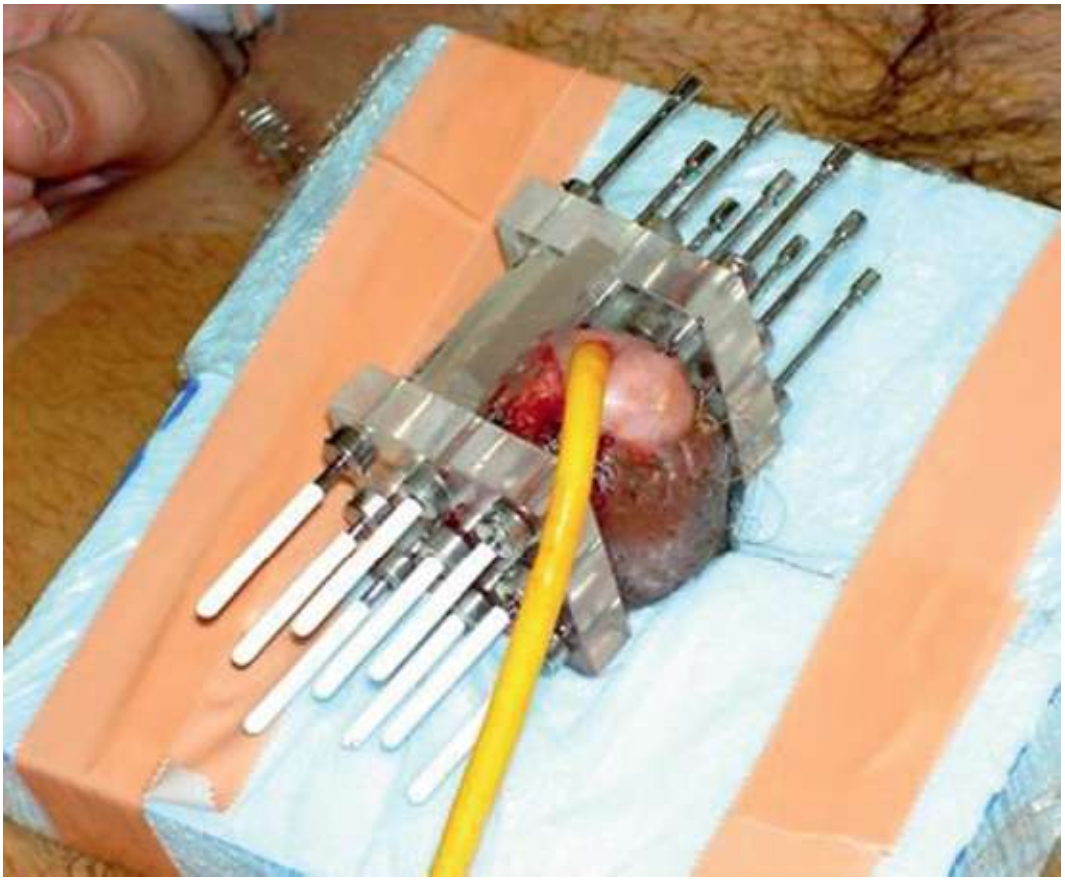

FIGURE 72.5. Interstitial implant showing the templates and needles in place. A layer of tissue-equivalent bolus material is seen on the left side of the photograph (patient's right) with an overlying plane of needles, to ensure that full dose is delivered to the skin surface. (Reprinted from Crook J. The role of radiotherapy in the management of penile cancer. *Curr Probl Cancer*. 2015;39[3]:158–165. Copyright © 2015 Elsevier. With permission.)

ABS-GEC-ESTRO experts concluded that high-dose rate (HDR) fractionation volume implants of 3.2 Gy twice daily for a total of 38.4 Gy in 6 days is well tolerated (Figs. 72.5 and 72.6). The interval between fractions should be at least 6 hours. Penile necrosis has been observed after doses of 3.5 to 3.75 Gy × 12 Gy in 6 days, but this risk may be reduced if attention is paid to dose homogeneity and the V125 (percentage of the planning target volume receiving 125% of the prescribed dose) is <40% and the V150 is <20%. To decrease the incidence of urethral strictures, the urethra V115 should be <10% and the V90 <95% of the volume. Confluent areas of the skin receiving >125% of the prescription will reduce the risk of skin necrosis. CT-based planning is mandatory for HDR 192Ir penile brachytherapy, with three-dimensional delineation of the gross tumor volume, clinical target volume, skin, and urethra.[100]

FIGURE 72.6. 3D printing can be used to make a custom mold fitted with catheters for delivery of the high-dose rate (HDR) source. This device would be applied twice per day for 5 days and is used to treat superficial cancers where no more than 5-mm depth of treatment is required. 3D, 3-dimensional. Urethral Cancer

Radiation therapy for carcinoma of the anterior (distal) urethra is quite similar to that for carcinoma of the penis; lesions of the bulbomembranous urethra can be treated with a set of parallel-opposed fields covering the groins and the pelvis, followed by perineal and inguinal boost. Lesions of the prostatic urethra can be treated with techniques and doses similar to those used for carcinoma of the prostate.

RESULTS

Penile Cancer

At many institutions, patients with carcinoma of the penis are treated surgically. A summary of selected modern surgical series is presented in Table 72.8. Ornellas et al.[31] reported the results of 350 patients treated with surgery alone. Five-year disease-free survival was 62% for patients treated with immediate lymphadenectomy versus 8% for those treated with delayed lymphadenectomy. For all node-negative patients, 5-year disease-free survival was 87% compared

with 29% for node-positive patients. Boon et al.[104] reported tumor control in 13 of 16 patients (81%) with carcinoma *in situ* or T1 and T2 tumors treated with wide local excision and lasers.

Tables 72.9 to 72.11 summarize tumor control rates achieved with external beam irradiation alone, LDR and PDR brachytherapy, and HDR brachytherapy, respectively.

The 20-year experience of the Institut Gustave Roussy was reported by Soria et al.[23] 102 patients with tumors <4 cm in diameter with <1 cm corpora cavernosa invasion were treated with a conservative approach consisting of limited surgery (biopsy, local excision, or therapeutic circumcision) and interstitial brachytherapy (65 to 70 Gy delivered over 5 to 7 days). Regional lymph nodes were not treated electively but were dissected in patients with clinically enlarged nodes. With a median follow-up of 111 months, local tumor recurrence rate was 25%. A regional nodal recurrence developed in 21% of patients. Disease-free survival at 5 and 10 years was 56% and 42%, respectively. Overall survival at 5 and 10 years was 63% and 50%, respectively.

Irradiation of the involved regional lymph nodes in patients with carcinoma of the penis results in permanent control and cure in a substantial proportion of patients. In the classic series of Staubitz et al.,[43] 13 patients with proven involvement of regional lymph nodes received radiation therapy to these nodes. Five of 13 (38%) survived 5 years. Mazeron et al.[111] described tumor control in 8 of 9 patients with stage T1, 21 of 27 with T2, and 10 of 14 with T3 tumors treated with ^{192}Ir, using the Paris dosimetry system, to deliver doses of 60 to 70 Gy to the 85% minimal tumor isodose. The tumor-free 5-year actuarial survival rate was 63%. The penis was preserved in 75% of patients with a follow-up of 8

years. Thirty-seven patients received no prophylactic treatment to the inguinal nodes, and only two (one with a T2 and another with a T3 lesion) later developed inguinal lymph node metastases treated by inguinal node dissection and postoperative irradiation. One patient was alive with no evidence of disease at 10 years. Five patients with metastases to the lymph nodes at the time of diagnosis were treated with therapeutic nodal dissection and postoperative irradiation. Four patients had uncontrolled lymph node metastases, and all 5 died with distant disease.

Urethral Cancer

Historically, men with urethral carcinoma have been treated surgically. Dalbagni et al.[16] have reported the outcome of 46 patients with carcinoma of the anterior and bulbar urethra treated at the Memorial Sloan Kettering Cancer Center. The majority of patients were treated with definitive surgery. With a median follow-up of 125 months, the local control rate was 51%. The 5-year overall survival was 42%. Improved survival was seen in patients with anterior lesions (69%) compared with those with posterior lesions (26%).

Bracken et al.[114] described results in 11 patients with tumors at or anterior to the penoscrotal junction, 8 of which were epidermoid carcinoma, 2 TCC, and 1 melanoma. Three of four patients treated with total penectomy and perineal urethrostomy had tumor control. Partial penectomy controlled the local tumor in two patients. The patient with melanoma had a local recurrence after operation. Two patients were treated with radiation therapy and a third with a combination of preoperative irradiation (45 Gy) and total penectomy. In all of these patients, tumor recurred locally. In four patients with inguinal lymph node metastases, the regional disease was controlled by bilateral lymphadenectomy. All six patients in whom local and regional tumor was controlled remain alive and disease free at 1 to 20 years. In 16 patients, the urethral tumors arose posterior to the penoscrotal junction: 13 lesions were squamous cell carcinoma, 2 transitional cell, and 1 adenocarcinoma. Penectomy was performed in five patients, all of whom had tumor control and no evidence of recurrence 5 to 29 months after therapy. Two patients treated with local excision died of disease 14 and 18 months after surgery. Irradiation was used in three patients unsuccessfully, and all died of cancer 13 to 31 months after therapy.

Kaplan et al.[17] reported on 29 patients treated at Northwestern University and reviewed the literature. In their analysis, lesions of the distal urethra carried the best prognosis and those in the bulbomembranous urethra the worst. Five-year survival rates were 22% (16 of 71 patients) with tumors in the distal urethra, 10% (10 of 99 patients) with bulbomembranous urethra lesions, and 25% (4 of 16 patients) with prostatic urethra tumors. Radiation therapy was infrequently used for these patients. Table 72.12 demonstrates equivalent local tumor control with either definitive radiation therapy or *en bloc* resection.

TABLE 72.11 RESULTS OF HDR BRACHYTHERAPY FOR PENILE CANCER

The combination of radiation therapy and chemotherapy using 5-FU and mitomycin C has been reported for urethral carcinoma for organ preservation in locally advanced tumors. Reports by Baskin and Turzan,[117] Johnson et al.,[118] Licht et al.,[119] and Shah et al.[120] support the efficacy of this combination for squamous cell carcinoma of the male and female urethra. Cleveland Clinic[119] reported results of patients with locally advanced squamous cell carcinoma of the urethra treated with concomitant chemoirradiation including 5-FU (1 g/m^2 intravenous infusion on days 1 to 4 and days 29 to 32) and mitomycin C (50 mg/m^2 bolus intravenous injection on day 1). External beam irradiation (30 Gy in 15 fractions) to the pelvis and inguinal lymph nodes began on day 1. An additional 20-Gy tumor boost was given. Complete response was obtained in three patients, who remained disease free after 43 months of follow-up. A patient with a T2N2M0 lesion treated with 30 Gy died of myocardial infarction several months after radiation therapy. Chemotherapy was well tolerated and required no dose reduction or delay in treatment. One grade 3 acute toxicity (skin reaction) occurred that did not compromise the therapeutic plan. One patient developed urethral stricture that was managed successfully with urethral dilatation.

As previously described in this chapter, the largest chemoradiation experience for urethral carcinoma is the Wayne State experience.[50] Concomitant 5-FU and cisplatin were used for squamous cell carcinoma, whereas concomitant methotrexate, vinblastine, doxorubicin, and cisplatin (MVAC) were used for TCC. A pathologic complete response was reported in 87.5% of women undergoing resection following chemoradiation. With a median follow-up of 42 months, the overall disease-free survival rate was 62%.

SEQUELAE OF TREATMENT

Irradiation of the penis produces a brisk erythema, dry or moist desquamation, and swelling of the subcutaneous tissue of the shaft in virtually all patients. Although quite uncomfortable, these are reversible reactions that subside with conservative treatment within a few weeks. Telangiectasia is a common late consequence of radiation therapy and is usually asymptomatic (Figs. 72.7 and 72.8).

In the reported LDR and PDR brachytherapy series, stenosis occurs in 9% to 45% of patients and necrosis in 0% to 26% of patients (see Table 72.10).[22,23,106–111] This incidence compares favorably with the incidence of urethral stricture following penectomy.[20] Most strictures following radiation therapy are at the meatus.

Lymphedema of the legs has been reported following inguinal and pelvic radiation therapy, but the role of irradiation in the development of this complication remains controversial. Many patients with this symptom have active disease in the lymphatics that may be responsible for lymphatic blockage.

FIGURE 72.7. Telangiectasia and area of hypopigmentation 6 years after pulsed dose rate brachytherapy. (Reprinted from Crook JM, Haie-Meder C, Demanes DJ, et al. American Brachytherapy Society-Groupe Européen de Curiethérapie-European Society of Therapeutic Radiation Oncology (ABS-GEC-ESTRO) consensus statement for penile brachytherapy. *Brachytherapy* 2013;12[3]:191–198. Copyright © 2013 American Brachytherapy Society. With permission.)

Routine use of a meatal dilator in the healing phase and for a few months beyond can decrease the rate of meatal stenosis. Soft tissue ulceration is more frequent in larger and more deeply invasive cancers but will usually heal with conservative measures such as attention to hygiene, topical antibiotics, or steroid creams.[86] More severe cases may respond to a course of hyperbaric oxygen.[121]

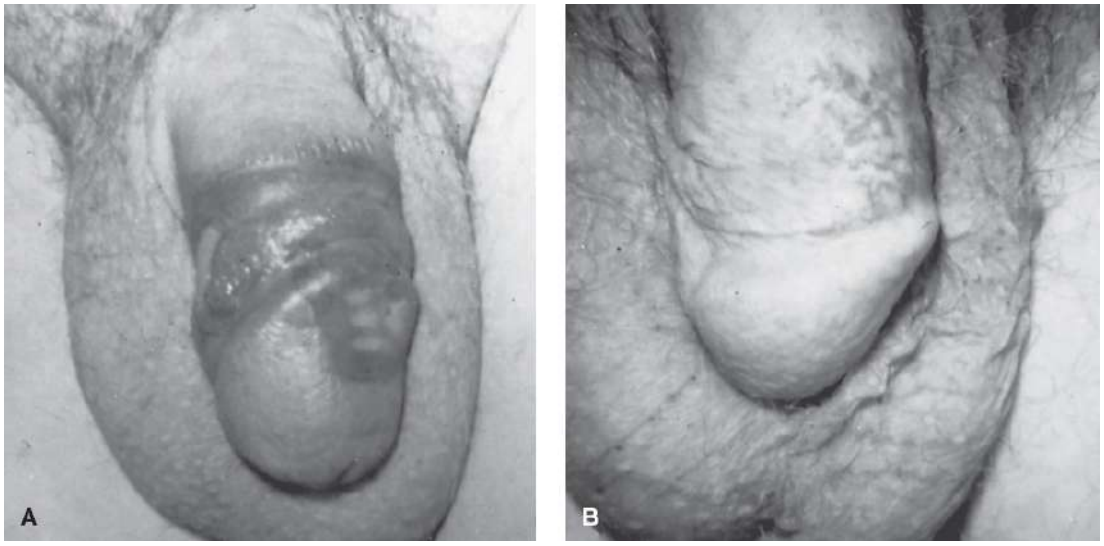

FIGURE 72.8. A: Squamous cell carcinoma of the balanopreputial region with extension into the glands (stage I). Patient was treated with 120-kVp x-rays, 0.3-mm Cu half-value layer, receiving 60-Gy skin dose in 5 weeks. **B:** Same patient 4 years later with no evidence of disease. Telangiectasia is present.

Of all male genitourinary cancers, penile cancer poses the greatest threat to sexual function and carries the most devastating psychological impact of penectomy. Despite recent advances in treatment, sexual function is not likely to be adequately preserved in some patients. These patients and their partners need information about the physical impairments after surgical intervention and should be taught adjustment skills prior to undertaking treatment. Referral to a trained sexual consultant or therapist for help is indicated.

PART I

Gynecologic

CHAPTER 73

Uterine Cervix

Akila N. Viswanathan

ANATOMY

The uterus is a hollow, thick-walled, pear-shaped, muscular organ located in the pelvis above the vagina, behind the bladder, and in front of the rectum (Fig. 73.1). On average, it is approximately 7 to 8 cm long, 5 to 7 cm wide, and 2 to 3 cm thick. The uterus is divided into the uterine corpus superiorly and the uterine cervix inferiorly, with the most superior part of the corpus also known as the fundus and the middle portion of the corpus known as the body. The fundus is located superior to the line joining the entrance of the fallopian tubes. The body of the uterus is enclosed between layers of the broad ligament and is freely mobile. The regions of the body where the fallopian tubes enter are called the cornua. The most inferior, slightly constricted, portion of the uterus is called the isthmus or lower uterine segment (LUS). The cervix rests inferior to the LUS.

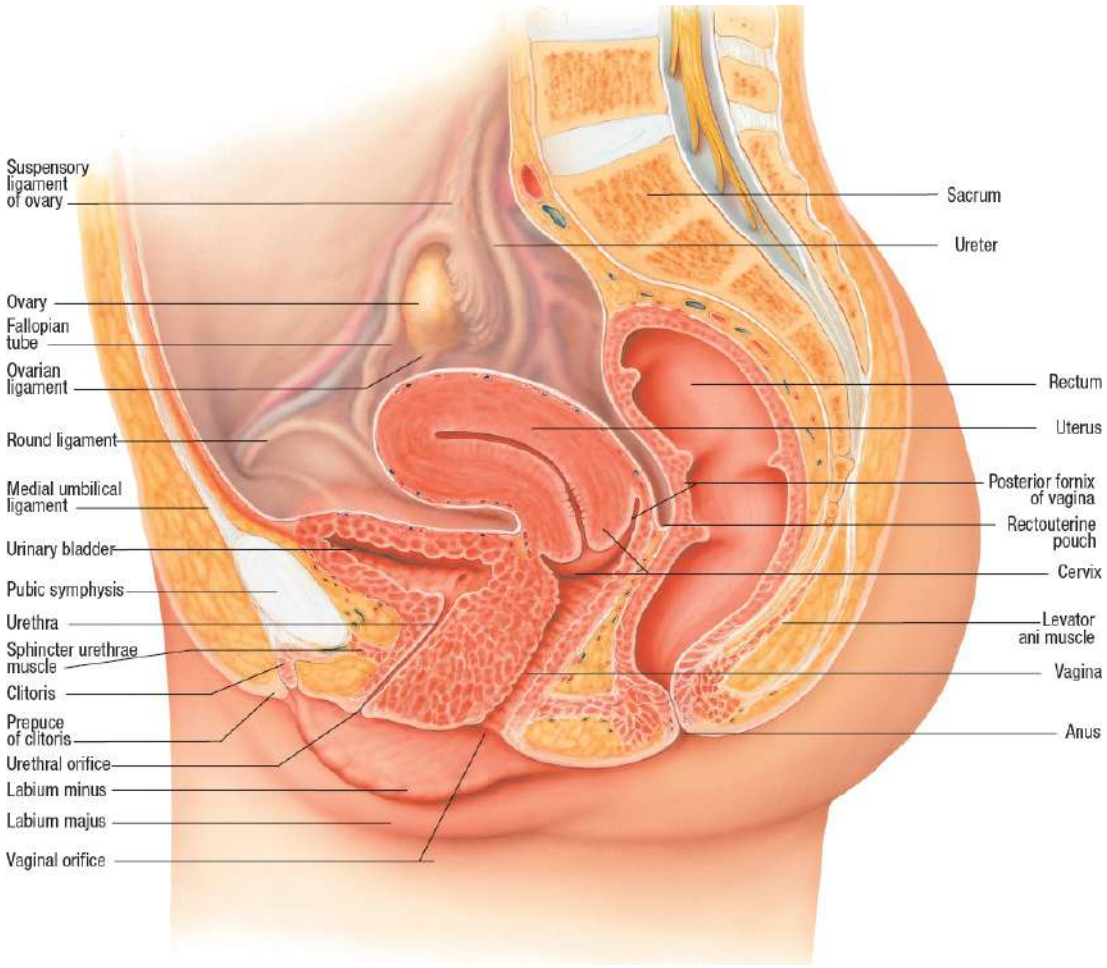

FIGURE 73.1. Anatomy of the pelvis. (Anatomical Chart Company, Lexington, SC.)

The uterus is usually bent anteriorly (anteflexed) between the cervix and the uterine body. The entire uterine cervix structure is normally bent anteriorly (anteverted) in the pelvis. The uterus may be posteriorly retroverted, especially in older women who have a small uterus. The wall of the uterus has three layers: the outer serosal layer; the middle myometrium, which is approximately 12 to 15 mm of muscle through which the main blood vessels and nerves flow; and the inner coat called the endometrium.

The cervix measures approximately 3 by 3 cm and is predominantly a fibrous organ. The cervix is divided into an upper or supravaginal portion, above the ring containing the endocervical canal, and the vaginal portion, projecting in the vaginal vault. Central in the rounded vaginal region is the external os, bounded by the anterior and posterior lips of the cervix, extending inward to the internal os, the endocervical canal, and endometrial canal.

The uterus is partially covered by peritoneum in its fundal and posterior

portions; its anterior and lateral surfaces are related to the bladder and the broad ligaments, respectively. It is attached to the surrounding structures in the pelvis by two pairs of ligaments—the broad and the round ligaments. The broad ligament is a double layer of peritoneum extending from the lateral margin of the uterus to the lateral wall of the pelvis. It contains the fallopian tubes. The two layers of peritoneum forming the broad ligament enclose the parametrium as it reaches the uterus. Inferiorly, the broad ligament follows the plane of the pelvic floor and ends medially in the upper portion of the vagina.[1]

The round ligament, a band of smooth muscle and connective tissue that contains small vessels and nerves, extends forward horizontally from its attachment in the anterolateral portion of the uterus to the lateral pelvic wall. The cord ascending from the lateral wall of the true pelvis crosses the pelvic brim and extends laterally to reach the abdominoinguinal ring, through which it leaves the abdomen to traverse the inguinal canal and terminates in the superficial fascia.

The uterosacral ligaments are paired supports for the lower uterus, extending from the uterus to the sacrum and running along the rectouterine peritoneal fields.[1] The cardinal ligaments, also called transverse cervical ligaments (Mackenrodt), are thickened connective tissue and fascia arising at the upper lateral margins of the cervix and inserting into the fascial covering of the pelvic diaphragm.

The uterus including the uterine cervix has a rich lymphatic network (Fig. 73.2) that drains principally into the paracervical lymph nodes; from there, it goes to the external iliac (of which the obturator nodes are the innermost component) and the hypogastric lymph nodes. The major lymphatic drainage of the cervix runs in the cardinal ligament superior to the ureter, and in the utero-sacral ligaments to the rectal area. No lymphatic vessels run in the vesicouterine space, rather those from the upper vagina fuse with those from the bladder and extend laterally into the parametrium.[1a] The pelvic lymphatics drain into the common iliac and the para-aortic lymph nodes (PALNs). Lymphatics from the fundus pass laterally across the broad ligament continuous with those of the ovary, ascending along the ovarian vessels into the PALNs. Some of the fundal lymphatics also drain into the common iliac lymph nodes. The main artery supplying the uterus is the uterine artery, which originates from the anterior division of the hypogastric artery.

EPIDEMIOLOGY

Over the last 80 years, the relative morbidity and mortality of locally advanced invasive cervical cancer has declined in the United States and Europe because of effective screening and treatment of preinvasive lesions.[2] In the United States, 50% of women who develop cervical cancer have never been screened, and another 10% have not been screened within the previous 5 years. However, in the last decade, incidence rates of invasive carcinoma have remained relatively constant due to population growth and aging. The American Cancer Society estimates in 2018 that approximately 13,240 new cases of invasive carcinoma of the cervix arise in the United States and about 4,170 deaths will occur per year, in addition to >60,000 cases of carcinoma *in situ*.[3]

Worldwide, cervical cancer remains the most common gynecologic cancer and the fourth most common malignancy in women, with over 526,000 women globally developing this tumor as reported in 2015 and 239,000 dying of the disease every year.[4] Adjusting for population growth and aging, the global incidence rate for cervical cancer declined by 1.2% from 2005–2015.[4a] The majority of cases are in Africa, because of the paucity of screening measures and the prevalence of immunodeficiency because of human immunodeficiency virus (HIV). Unfortunately, it often affects young women, resulting in loss of the ability to bear future children. An economic analysis from India demonstrates the economic benefit to treating women with cervical cancer with MR-based advances.[5]

Cervical cancer is more common in areas where women have less access to screening, including parts of Asia, Africa, and Central and South America. Whether regional differences in predisposition to developing cervical cancer exist is debated because it is impossible to adequately correct for unknown and known confounders, such as socioeconomic status, access to health care, parity, smoking, presence of other infections, immune status, and other factors affecting host immunity such as nutritional status.[6]

Human Papillomavirus

Estimates indicate that >90% of cervical cancers are related to the presence of human papillomavirus (HPV) and are contracted via sexual intercourse.[7] HPV is a small, double-stranded deoxyribonucleic acid (DNA) virus; HPV-16 and HPV-18, as well as a long list of other, less frequent subtypes, including but not limited to HPV types 31, 33, 35, 39, 45, 51, 52, 56, and 58, have been well characterized as causative agents for cervical cancer, with some geographic

variation.[8] The HPV genome integrates into the host cell chromosomes in cervical epithelial cells and codes for six early and two late open reading frame proteins, of which three (E5, E6, and E7) alter cellular proliferation. Two viral genes, E6 and E7, are typically expressed in HPV-positive cervical cancer cells. The E6 protein inactivates the major tumor suppressor p53; this causes chromosomal instability, inhibits apoptosis, and activates telomerase. The E7 protein affects the retinoblastoma protein (Rb), resulting in a loss of regulation of the cell's proliferation and immortalization.[9] The Cancer Genome Atlas (TCGA) identified three main subtypes: keratin-low, keratin-high, and adenoma-rich. HPV integration was observed in all HPV-18 and 76% of HPV-16 related cases. Endometrial-like cervical cancer was HPV-negative, occurred in 5% of cases, and had high frequencies of KRAS, ARID1A, and PTEN mutations.[9a]

Although a high prevalence of HPV exists worldwide, peaking at ages 25 to 35 years, <15% of exposed women develop persistent infection that results in dysplasia,[10] whereas the majority of women clear the infection within 2 years.[11] Cervical cancer may develop 10 to 20 years after initial exposure to HPV. Social factors related to cervical cancer include those associated with HPV transmission, such as early age of first intercourse; a history of multiple sexual partners; a male partner with a history of multiple sexual partners; a large number of pregnancies[12,13]; and a history of sexually transmitted disease, including gonorrhea, chlamydia,[14] herpes simplex virus II, and/or HIV.[15] A higher incidence of cervical cancer exists among women whose spouses are known or suspected to have had higher exposure to HPV[16] or whose partners have a history of penile carcinoma.[17,18] Whether circumcision may be protective to women is controversial[19] because circumcision may be a surrogate for unknown factors related to HPV transmission.[20] The integration pattern of HPV as episomal (best), single-copy or multiple-copy tandem repetition, or undetectable (worst) is a strong prognostic factor for disease-free survival (DFS) after radiation therapy in cervical cancer.[21]

Treatment portal is shown. **C:** The incidence of cervical cancer increased slightly in the United States from 2007 to 2017.

Chemical,[22] hormonal, or other carcinogens[23] may be implicated in cervical cancer. An association between cervical carcinoma and oral contraceptive use has been reported but is considered controversial.[24] Prenatal exposure to diethylstilbestrol (DES) is linked to the development of clear cell adenocarcinoma, although the overall incidence is small (0.14 to 1.4 per 1,000 DES-exposed women).[25–27] Cigarette smoking may increase the risk of cervical cancer.[28] However, passive smoking may not be an independent factor in the absence of active smoking.[29] A review of >50 studies considers smoking a cofactor for HPV infection and carcinogenesis,[30] although one study does not confirm this.[16] Current smoking (relative risk [RR] = 1.55) and younger age at HPV exposure (RR = 1.75) are considered risk factors among HIV-positive women.[31] Intrauterine device use may decrease cervical cancer risk, potentially through an increase in cellular immunity triggered by the device.[32]

HPV Vaccination

The quadrivalent human papillomavirus recombinant vaccine for HPV types 6,

11, 16, and 18, first approved in the United States in 2006 for girls and women ages 9 to 26 years, is now available for boys ages 9 to 26 years, with the goal of eradicating HPV-related gynecologic, penile, anal, and oropharyngeal cancers. A second vaccine with strong immunogenicity to HPV types 16 and 18, approved for girls 9 to 25 years old, is more frequently administered in Europe. In 2015, results of a 9-valent HPV vaccine were reported, showing significant activity against HPV types 31, 33, 45, 52, and 58 in addition to 6, 11, 16, and 18.[33] Although its development is a major advance in the prevention of cancer, vaccine implementation has been hindered worldwide by cost and access. To date, 64 countries have implemented national HPV vaccination programs. A total of 59 million women have received at least one dose, (1·7% of the population). In more developed regions, 33·6% of females aged 10–20 years received the full course of vaccine, compared with only 2·7% (of females in less developed regions.[33a] With an increase in understanding and availability, the hope is that all children will be given a vaccine covering all subtypes in the future.

NATURAL HISTORY AND PATTERNS OF SPREAD

Squamous cell carcinoma of the uterine cervix usually originates at the squamous columnar junction (transformation zone) of the endocervical canal and portion of the cervix.

Cellular transformation follows a stepwise progression from normal to higher levels of dysplasia. Of patients diagnosed with cervical intraepithelial neoplasia (CIN) type 1, 60% have regression of the lesion, and of those with CIN2, 40% regress. Higher levels of dysplasia are more likely to progress to cancer, particularly in the presence of cofactors such as smoking or impaired immunity. Although progression typically takes 10 to 20 years,[34] in some instances, a rapid development of carcinoma may be associated with aggressive disease.

The development of a malignant phenotype results from cells that break through the basement membrane of the epithelium and invade the cervical stroma. Invasion may result in spread to pelvic lymph nodes or other, more distant sites.[35] If the cells are detected at this stage by a Papanicolaou (Pap) or thin preparation test, appropriate minimally invasive therapy may suffice. However, if the lesion progresses, it may present as a superficial ulceration or exophytic tumor in the ectocervix or with extensive infiltration of the endocervix. If untreated, the tumor may spread to the adjacent vaginal fornices, paracervical or parametrial tissues,[36] or adjacent organs, including the bladder,

the rectum, or both. Landoni et al.[37] studied 230 patients with clinical stage IB and IIA tumors treated with radical hysterectomy with pelvic lymphadenectomy and noted that the tumor spread endocervically equally in all directions. Tumor extension into the vesicocervical ligament (anterior parametrium) was noted in 23% of cases, into the uterosacral ligaments (posterior parametrium) and the rectovaginal septum in approximately 15%, and into the parametria in 28% to 34% of cases. Paracervical extension was related to the depth of stromal invasion, tumor size, lymphatic invasion, and presence of lymph node metastasis.

Approximately 10% to 30% of patients with carcinoma of the uterine cervix have extension into the LUS and the endometrial cavity.[38] Decreased survival rates and a greater incidence of distant metastases were reported by Perez et al.[38] and Chao et al.[39] in patients with stromal endometrial invasion (EI) or replacement of normal endometrium by cervical carcinoma. Regional lymphatic or hematogenous spread may occur and increases with stage, although dissemination does not always follow an orderly sequence, and occasionally, a small primary tumor may be seen infiltrating the pelvic lymph nodes, invading the bladder or rectum, or metastasizing distantly.

Both adjacent parametrial and pelvic lymph nodes may be involved. Girardi et al.[40] analyzed 359 radical hysterectomy specimens and found positive parametrial nodes in 280 patients (78%); the incidence of positive nodes was 11.4% in stage IB and 21.5% in stage IIB disease. With negative parametrial nodes, only 26% of patients had positive iliac lymph nodes, whereas 81% of patients with positive parametrial lymph nodes also had pelvic node metastases. These data underscore the need to irradiate the parametrial tissues or carry out a complete bilateral pelvic lymphadenectomy with a radical hysterectomy in patients with invasive cervical carcinoma.

Spread of carcinoma of the cervix may progress to the obturator lymph nodes, considered a medial group of the external iliac chain, to other external iliac nodes, and to the hypogastric lymph nodes. From these, there may be tumor metastases to the common iliac or PALNs.[41] The incidence of metastasis to pelvic or PALNs for various stages of the disease is listed in Tables 73.1 and 73.2. In one study, pelvic lymph nodes were dissected in 225 patients with cervical carcinoma treated with radical hysterectomy; positive pelvic nodes were identified in 13 of 91 women (14.2%) with stage IB and IIA, 16 of 81 (19.8%) with stage IIB, and 11 of 40 (28%) with stage IIIB diseases.[56] The most commonly involved groups were the parametrial, obturator, external iliac, and

common iliac nodes (Fig. 73.3). PALNs were involved in 3 of 91 patients (3.3%) with stage IB or IIA tumors 4 cm or less and in 5 of 38 patients (13.1%) with stage IIB or III disease.

Spread through the venous plexus and the paracervical veins resulting in hematogenous dissemination, though infrequent, is relatively common with more advanced stages. In an analysis of 322 patients in whom distant metastases developed, the most frequently observed metastatic sites were the lung (21%), PALNs (11%), abdominal cavity (8%), and supraclavicular lymph nodes (7%).[57] Bone metastases occurred in 16% of patients, most commonly to the lumbar and thoracic spine (Table 73.3). Spinal epidural compression from metastatic tumor, often involving lumbar segments, can occur rarely,[58] and metastases to the brain and the heart have been reported, although it is unusual to have spread to the brain without evidence of pulmonary metastases already present,[59] even for small cell carcinoma of the cervix.[60]

PAP SMEAR SCREENING

The American College of Obstetrics and Gynecology guidelines published in 2009[61] state that Pap smear screening should begin at age 21 years regardless of sexual activity status and continue every 2 years until age 30 years; then, if there are three normal consecutive Pap smears and no history of CIN2, CIN3, DES exposure, or HIV infection and the woman is not otherwise immunocompromised, screening should be every 3 years. The US Preventive Services Task Force and American College of Obstetricians and Gynecologists (ACOG) updated recommendations in 2012.[62] Instead of every 2 years, the recommendation is now to repeat the exam every 3 years until age 30. HPV testing is not recommended for women younger than age 30. After age 30, women have the option of having Pap smears every 3 years, of having Pap with HPV testing every 5 years. At age 65, women can stop having Pap smears as long as their routine screening was within the past 10 years, with normal results. Women who have had a hysterectomy for benign reasons and have no history of high-grade squamous intraepithelial lesion may discontinue testing. Women who have been treated for CIN2 or CIN3 need annual screening for at least 20 years. Those who have had a hysterectomy and a history of CIN2/CIN3 should continue to undergo screening with annual pelvic exams.

When obtaining the Pap smear, special attention should be directed to not using a lubricating agent (warm water on the speculum will suffice), to obtaining

good “scrapings” from the cervix and vaginal posterior fornix (without blood), and to using a small brush to obtain an endocervical sample. The patient should be instructed not to cleanse with a douche before the examination, and if indicated, specimens should be obtained to check for trichomonas. If the cytologic smear shows atypia or mild dysplasia (class II), it should be repeated no sooner than 2 weeks after the initial test to allow representative cellular exfoliation to occur. Guidelines for reporting results of cervical and vaginal cytology were promulgated in 1988. The Bethesda system eliminated the classes of Pap cytology. The correlation between the cytologic diagnosis and subsequent histologic examination is >90%.[63] This system was modified in 1991 and in 2001.[64]

CLINICAL PRESENTATION

Cervical cancer in the United States is most frequently identified during routine gynecologic examination. Intraepithelial or early invasive carcinoma of the cervix may be detected by cytologic smears before symptoms appear; Pap smear, colposcopy and biopsies, and HPV testing have high specificity and sensitivity. Visible lesions present with an exophytic mass or a barrel-shaped cervix because of an endocervical lesion. Patients may present complaining of metrorrhagia (intermenstrual bleeding), menorrhagia (heavier menstrual flow), or postcoital bleeding. If chronic bleeding occurs, the patient may complain of fatigue or other symptoms related to anemia.

In cases with more advanced disease, bowel obstruction, renal failure, foul-smelling serosanguinous or yellowish vaginal discharge, pelvic pain, flank and/or leg pain, rectal bleeding, obstipation, dysuria, hematuria, or persistent

edema of lower extremities because of lymphatic/venous blockade by pelvic sidewall disease may occur. Pain in the pelvis or hypogastrium may be caused by tumor necrosis or associated pelvic inflammatory disease. In patients with pain in the lumbosacral area, the possibility of PALN involvement with extension into the lumbosacral roots or hydronephrosis should be considered.

DIAGNOSTIC WORKUP

When a patient presents with an abnormal smear or if abnormal squamous cells of undetermined significance (ASCUS) are detected but HPV status is negative, follow-up in 1 year is recommended. If the second smear reveals ASCUS, regardless of HPV status, colposcopy is recommended. When both ASCUS and HPV are present or adenocarcinoma *in situ* or a squamous intraepithelial lesion is identified, directed biopsies at the time of colposcopy should be carried out. Endocervical curettage may be performed except in pregnant women. If the biopsy results are negative, the procedure should be repeated in 6 months, and if they are positive, a conization should be performed.

Patients presenting with low-grade squamous intraepithelial lesions (LSIL) on cytology are further triaged based on age and HPV status. Women age 30 and older with LSIL and positive HPV are evaluated with colposcopy; those with LSIL and negative HPV testing are recommended to follow up in 1 year with

repeat cervical and HPV cotesting rather than colposcopy. Women younger than age 30 with LSIL are managed based on cytology alone. Guidelines for management of abnormal cervical cytology in women age 21 to 24 have been revised recently, based on the higher prevalence of HPV infection and low risk of cervical cancer in this population. For younger women, ASCUS or LSIL on cervical cytology is managed with repeat cytology at 12 months.[65]

Results from a large-scale cervical cancer screening trial, conducted over a span of 15 years from Mumbai, India, were reported. Over 75,000 women were screened every 2 years using visual inspection and acetic acid vinegar. There was a significant 31% reduction in cervical cancer mortality in the screening group, compared with the control group. The 7% reduction in all-cause mortality in the screening group did not reach significance. These results suggest acetic acid screening can be utilized in places that lack standard Pap smear screening and treatment resources.[66]

Patients who present with a clinically visible lesion should be jointly evaluated by the radiation and gynecologic oncologists. After obtaining a careful clinical history and performing a general physical examination, with attention to the inguinal and supraclavicular (nodal) areas, abdomen, and liver, a careful pelvic examination should be carried out with as little discomfort to the patient as possible without compromising the thoroughness of the evaluation.[67] Pelvic examination should include inspection of the external genitalia, vagina, and uterine cervix, a rectal examination, and bimanual palpation of the pelvis. Pelvic examination under anesthesia (EUA) is a universally accepted component in the evaluation and clinical staging of patients in order to provide a pain-free examination that allows a clearer estimation of parametrial or sidewall tumor extension. In countries in which magnetic resonance imaging (MRI) is available, this may be used to assist with assessing tumor extension beyond the lower cervix, and in many institutions, it has replaced the EUA. Cystoscopy or rectosigmoidoscopy should be performed in all patients with symptoms consistent with presence of a fistula of the urinary or lower gastrointestinal tract, patients with clinical stage IIB, III, or IVA disease who cannot undergo an MRI, or patients with an MRI suspicious for bladder or bowel invasion. The diagnostic procedures for carcinoma of the cervix are presented in Table 73.4.

Conization/Loop Excision

Conization involves a conical removal of a large portion of the ectocervix and endocervix. Cold knife cone biopsy specimens should always be obtained with a

scalpel or other appropriate instrument. At least 50% of the endocervical canal should be removed without compromising the internal sphincter. Curettage of the remaining endocervical canal should be carried out.

Conization must be performed in the following situations: no gross lesion of the cervix is noted and an endocervical tumor is suspected; the entire lesion cannot be seen with the colposcope; diagnosis of microinvasive carcinoma is made on biopsy; discrepancies are found between the cytologic and the histologic appearances of the lesion; or the patient is not reliable for all necessary follow-up. With careful selection of patients who have a negative positron emission tomography (PET) scan and an MRI with a central lesion <2 cm in width, knife conization with lymphadenectomy may be considered for fertility preservation. Laser conization and loop diathermy excision are frequently done in an office setting as an alternative to conization; loop excision is less expensive and more reliable than laser conization.

Biopsy

Multiple punch biopsies of a grossly visible lesion should be adequate to confirm the diagnosis of invasive carcinoma. Specimens should be obtained from any suspect area and from all four quadrants of the cervix and from any suspect areas in the vagina. It is important to obtain tissue from the periphery of the lesion with some adjoining normal tissue; biopsy specimens from central ulcerated or necrotic areas may not be adequate for diagnosis. Dilation and curettage is not required if the biopsy confirms a diagnosis of invasive disease.

TABLE 73.4 DIAGNOSTIC WORKUP FOR CARCINOMA OF THE UTERINE CERVIX

General

History

Physical examination, including bimanual pelvic and rectal examinations

Diagnostic Procedures

Cytologic smears (Papanicolaou) if not bleeding

Colposcopy

Conization (subclinical tumor)

Punch biopsies (edge of gross tumor, four quadrants)

Dilation and curettage

Cystoscopy, rectosigmoidoscopy (stages IIB, III, and IVA)

Radiographic Studies

Standard
Chest radiography
Intravenous pyelography
Barium enema
Computed tomography
Magnetic resonance imaging
Positron emission tomography scan

Laboratory Studies

Complete blood count
Blood chemistry
Urinalysis

Laboratory Studies

For invasive carcinoma, patients should have the following laboratory studies: complete peripheral blood evaluation, including hemogram, white blood cell count, and differential and platelet count; blood chemistry profile, with particular attention to blood urea nitrogen and creatinine; liver function values; and urinalysis.

Imaging Studies

In countries where three-dimensional (3D) imaging is not routinely available, FIGO recommended evaluation for patients with cervical cancer includes a chest radiograph to assess for lung metastases and an intravenous pyelogram (IVP) to determine whether hydronephrosis is present. The IVP in many countries has been replaced by computed tomography (CT) scan of the pelvis and abdomen with intravenous (IV) contrast material or by PET–CT scan. In places where CT is not available, patients with stage IIB, III, and IVA diseases who have symptoms in the colon and rectum may benefit from a barium enema. A skeletal survey may be performed to determine whether bone metastases are present. Historically, pedal lymphangiography was used to assess lymph node involvement in the pelvic or para-aortic nodes with mixed results.[68,69] The number of physicians trained to perform lymphangiography has declined in the United States, and instead, PET scan is preferred.

Since the 1990s, the use of CT scanning has rapidly increased worldwide. A CT provides diagnostic information about the presence of metastases, enlarged lymph nodes, and the primary tumor. On a CT scan, the cervical tumor may be seen as an enlarged, irregular, hypoechoic cervix or as a mass with ill-defined margins. Parametrial regions appear dense when involved, and uterosacral

involvement may be seen. Lymph nodes appear enlarged, with most >1 cm on axial dimension considered pathologic. The overall accuracy of CT scanning in staging cervical cancer ranges from 63% to 88%.[68,70] In the detection of lymph node abnormalities, the overall accuracy of conventional CT scanning is 77% to 85%, with sensitivity of 44% and specificity of 93%.[71]

In order to correlate radiographic and surgical findings, Camilien et al.[72] reported on 61 patients with carcinoma of the cervix who had both preoperative CT scans and exploratory laparotomy; results showed that 75% of the enlarged pelvic lymph nodes on CT contained metastases, and 97% of patients with negative nodes on CT scan had pathologically negative findings (specificity of 97%). However, histologically positive pelvic nodes were often missed on CT scan (sensitivity of 25%). The CT scan is more valuable in evaluation of the PALNs (specificity of 100% and sensitivity of 67%).

Several studies evaluated the role of CT or PET–CT with regard to para-aortic nodal detection (Table 73.5). The ACRIN6671/GOG0233 trial enrolled 109 patients with PET and pathology available; sensitivity of PET was 0.5 and for diagnostic CT was 0.42 (P = .052).[75] Heller et al.[76] conducted a prospective evaluation of 320 patients with stage IIB to IVA carcinomas of the cervix entered into a Gynecologic Oncology Group (GOG) protocol in which preoperative CT scan, lymphangiography, and ultrasonography of the aortic area were performed. Para-aortic node dissection was done in patients with negative staging studies. Lymphangiography, CT scan, and ultrasonography had false-negative frequencies for pelvic lymph node evaluation of 14.2%, 25%, and 30%, respectively. The sensitivity was 79% for lymphangiography, 34% for CT scan, and 19% for ultrasonography, and the specificity ratings were 73%, 96%, and 99%, respectively. Ultrasonography, therefore, is not reliable in preoperative detection of lymph node metastases, but it has limited value in evaluating extrauterine tumor involvement. Ultrasound (US) has a primary role in assisting with intracavitary brachytherapy applicator insertion and may detect uterine perforation, allowing for proper positioning, which is critical for adequate dosing and affects survival.[77,78] PET has a higher sensitivity than CT and higher specificity than MR in detecting bone metastases.[79]

Magnetic Resonance Imaging

MRI is frequently used for the initial assessment of the cervical tumor and of extracervical tumor extension,[80] often in lieu of an EUA. MRI is contraindicated in patients with pacemakers/ICDs, cochlear implants, metallic prostheses, metallic fragments from prior accidents, or large vascular clips. On T2-weighted images, a cervical cancer may be seen as a mass of intermediate to high signal intensity, usually of greater intensity than the fibrocervical stroma. On T1-weighted images, tumors are usually isointense with the normal cervix and may not be seen[81] but can increase in intensity with the administration of IV contrast. Abnormal, irregular cervical margins, prominent parametrial strands, exocentric parametrial enlargement, and loss of parametrial fat planes on T1-weighted images or high signal in the parametria or cardinal/uterosacral ligaments on T2-weighted images are indicative of more extensive tumors.[70,80,82] Parametrial tumor may be identified as brighter regions on T2-weighted images when compared to the low signal intensity of the cervix and uterine ligaments.

Pretreatment tumor staging and volume were assessed by EUA, transrectal ultrasonography (TRUS), and MRI in 60 patients with invasive carcinoma of the cervix.[83] TRUS and MRI assigned the same tumor stage in only 30% of patients, and EUA and MRI agreed on tumor stage in an additional 27%. In cases of disagreement, the MRI staging correlated better with outcome than TRUS or EUA. Sixty-two percent of patients with enlarged lymph nodes on pretreatment MRI either died or had tumor recurrence or metastases. MRI was superior to both TRUS and EUA in assessing the full extent of bulky tumors and lymph node enlargement.

Postema et al.[84] compared MRI with pelvic examination (including under

general anesthesia in selected patients) and surgicopathologic findings in 103 patients with invasive cervical carcinoma. MRI was better at identifying extracervical tumor spread, but it had more false-positive results. The pelvic examination led to correct treatment decisions in 89% of patients. In a study by Hansen et al.,[85] clinical assessment (done according to International Federation of Gynecology and Obstetrics [FIGO] recommendations) was superior to low-field MRI with contrast enhancement in staging cervical cancer in 95 women who had both within 2 weeks after clinical diagnosis; the clinical staging correctly classified 57 patients (accuracy, 92%) compared with 52 for MRI (accuracy, 84%).

A prospective study by the American College of Radiology Imaging Network compared clinical examination, CT, and MRI.[71] MRI was significantly better than clinical examination or CT for detecting uterine body involvement or measuring tumor size,[86] but no method was accurate at evaluating the cervical stroma. MRI was significantly better[87] at detecting the tumor and parametrial involvement. MRI also somewhat increased detection of involved lymph nodes.[71]

The tumor is less likely to be as visible on MRI for adenocarcinoma cases, compared to squamous cell cancer. Haider et al.[88] evaluated 56 patients with adenocarcinoma involving the cervix using MRI and noted that 42 (75%) had a visible mass. Kodaira et al.[89] reviewed records of 84 patients with stage II cancer evaluated by MRI. The 5-year DFS rate of patients with maximal tumor size (D_{max}) of ≥50 mm was significantly lower than that for patients with D_{max} < 50 mm (46% vs. 88%; P < .0001).

Ebner et al.[90] reviewed MRI findings in 12 women with recurrent pelvic tumors and 10 with a fibrotic mass (confirmed by laparotomy or biopsy in 21 patients). They were able to differentiate between the two processes accurately in most instances. However, it is highly desirable to confirm abnormal or suspect lymph node radiographic findings with CT-guided fine-needle aspiration biopsies.

Corn et al.[91] evaluated endorectal coil MRI in 18 patients with stage IB to IIIB cervical carcinoma; in 7 patients, tumors were a higher stage by endorectal coil MRI because of proximal vaginal involvement or the combination of proximal vaginal involvement and parametrial extension. Compared with those who had a dark or intermediate signal, patients with bright signal characteristics tended to present with earlier stages, were less likely to have anemia, and were more likely to have complete response to external beam radiation.

Radiation-induced changes detected over the course of radiation may predict local recurrence and survival. Mayr et al.[92] studied 34 patients with cervical cancer of various FIGO stages who underwent 1.5-T MRI before and after radiation therapy. Tumor volumetry (3D measurements) based on T2-weighted images quantified the tumor regression rate. Sequential tumor volumetry using MR imaging may be a very effective measure of the responsiveness of cervical cancer to irradiation. MRI dynamic contrast enhancement (DCE) during the first 2 weeks of radiation therapy may provide early prediction of tumor regression rate. In seven patients, tumor regression rates ranged from 2% to 15.2% per day and correlated positively with changes in both peak and mean tumor enhancement ($P < .01$). Hatano et al.[93] evaluated MRI in 42 patients with advanced cervical cancer treated with external beam irradiation and high–dose rate (HDR) brachytherapy. In biopsies performed immediately after radiation therapy (RT), no residual cancer was found in 36 patients (86%). The simultaneous MRI study demonstrated no high signal intensity on T2-weighted images in 28 patients (75%). A high signal intensity area was observed in 14 patients, and this disappeared 3 months after RT in 8 patients with a negative biopsy. The sensitivity, specificity, and accuracy of MRI tumor response studies at 3 months after radiation therapy were 100%. MRI studies performed after 30 Gy of external beam irradiation and 3 months after all radiation therapy predicted local tumor control. Similar studies were published by Gong et al.[94] and van de Bunt et al.[95] Furthermore, MRI is useful in providing accurate target volume definition in brachytherapy treatment planning (Fig. 73.4).[96]

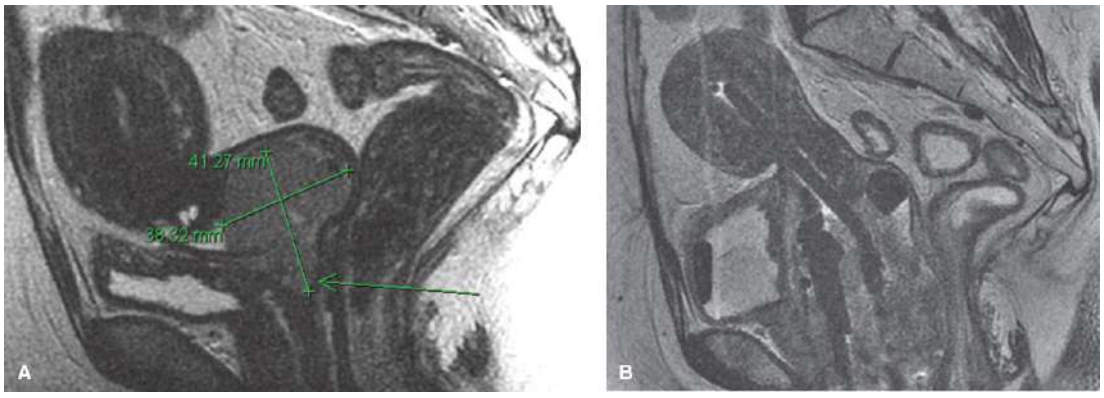

FIGURE 73.4. A: Magnetic resonance imaging (MRI) at diagnosis showing an enlarged cervical tumor. **B:** MRI with tandem and ring brachytherapy applicator in place showing dramatic shrinkage of the tumor after concurrent chemotherapy with external beam radiation.

Positron Emission Tomography

PET scanning is increasingly used in the evaluation of patients with malignant neoplasia, including invasive cervical cancer, using 2-[^{18}F]-fluoro-2-deoxy-D-glucose (FDG). Rose et al.[97] observed uptake in 91% of the primary tumors in 32 patients with locally advanced carcinoma of the cervix. Squamous cell carcinoma is more often FDG avid than is adenocarcinoma. Compared with surgical staging, PET scanning had a sensitivity of 75% and a specificity of 92% in detecting para-aortic metastasis.[98] PET–CT provides highly accurate localization of focal radiotracer uptake, which significantly improves the diagnostic accuracy compared with PET or CT alone. Diagnostic PET images may be fused with simulation CT images to ensure accurate radiation dose coverage of the target and any PET-avid lymph nodes (Fig. 73.5). Care must be taken in interpretation because physiologic FDG excretion into the urinary bladder may result in false-positive assessment of the primary tumor, and ureters may be contoured as lymph nodes; therefore, tracing the ureters and complete bladder voiding prior to imaging are recommended.

Grigsby et al.[98] compared CT and FDG-PET scanning for lymph node staging in 101 patients with carcinoma of the cervix. CT demonstrated abnormally enlarged pelvic lymph nodes in 20 patients and PALNs in 7, whereas PET demonstrated abnormal FDG uptake in pelvic lymph nodes in 67, in PALNs in 21, and in supraclavicular lymph nodes in 8. The 2-year progression-free survival (PFS) rate, based solely on para-aortic lymph node status, was 64% in CT-negative and PET-negative patients, 18% in CT-negative and PET-positive patients, and 14% in CT-positive and PET-positive patients ($P < .0001$). The most significant prognostic factor for PFS was the presence of positive PALNs on PET imaging ($P = .025$). Among 76 patients with no abnormal FDG uptake, the 2-year survival rate was 86%, with persistent abnormal uptake in 40%; there were no survivors among patients who developed new sites of abnormal uptake.[99] In a follow-up study of 152 patients, the authors reported a 5-year cause-specific survival (CSS) rate of 80% in 114 patients without abnormalities on posttherapy FDG-PET versus 32% in 20 patients with persistent uptake and no survivors among 18 patients with new sites of abnormal uptake.[100] In another study, Grigsby et al.[101] noted in 208 patients a close correlation between radiation doses, number and size of positive lymph nodes, and outcome (treatment failures and survival; Fig. 73.6). Hope et al.[102] performed FDG-PET scans in 58 patients with cervical carcinoma who had an endometrial biopsy or dilation and curettage; 36 (64%) had pathologic EI. Pelvic lymph node metastasis was more commonly detected in this group than in patients without EI

(70% vs. 23%; *P* < .001), as were para-aortic and supraclavicular nodal metastasis (30% vs. 0%; *P* = .006). Furthermore, 2-year survival rates were 78% versus 58%, and overall survival rates were 92% versus 65%, respectively (*P* = .047). Lin et al.,[103] using FDG-PET in 32 patients with cervical carcinoma, observed a reduction in physiologic tumor volume of 50% occurring within 20 days from the initiation of radiation therapy.

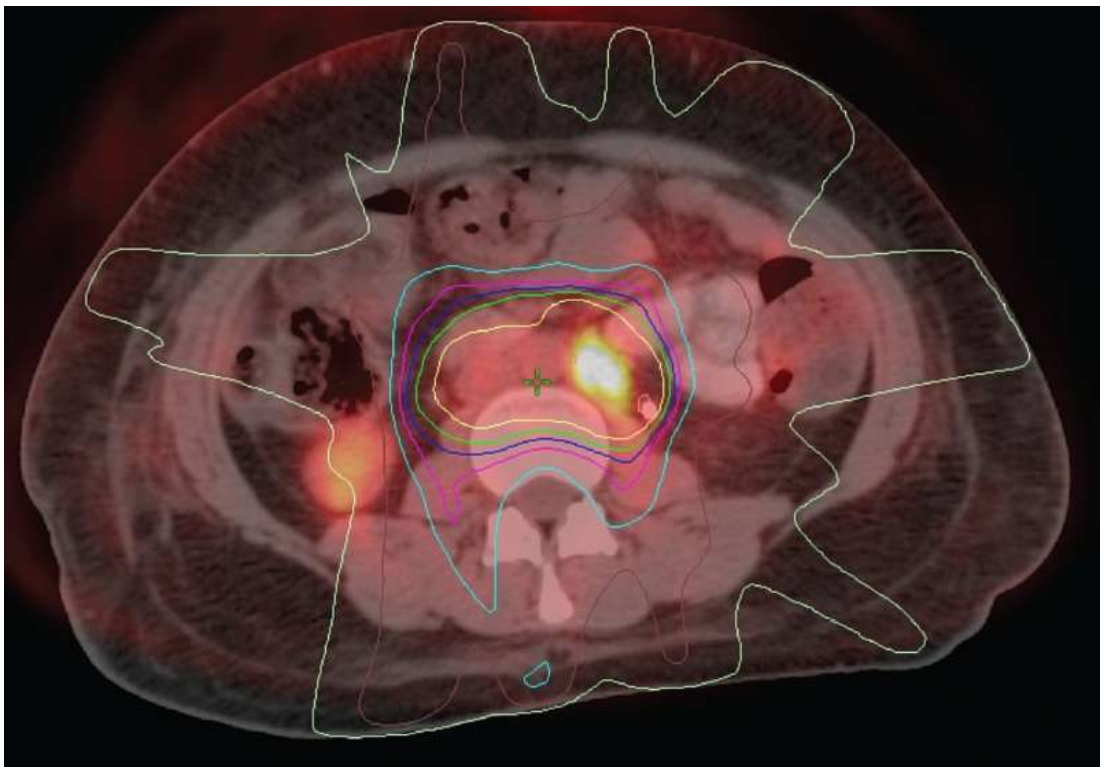

FIGURE 73.5. A fusion of a diagnostic positron emission tomography (PET) scan with simulation CT delineates the hypermetabolic lymph nodes, allowing for radiation dose escalation. In this case, the entire para-aortic chain received 45 Gy, followed by a sequential boost to the PET-avid node with a 7-mm margin to approximately 65 Gy. Caution is necessary to protect small bowel and kidneys when escalating dose to an enlarget para-aortic node.

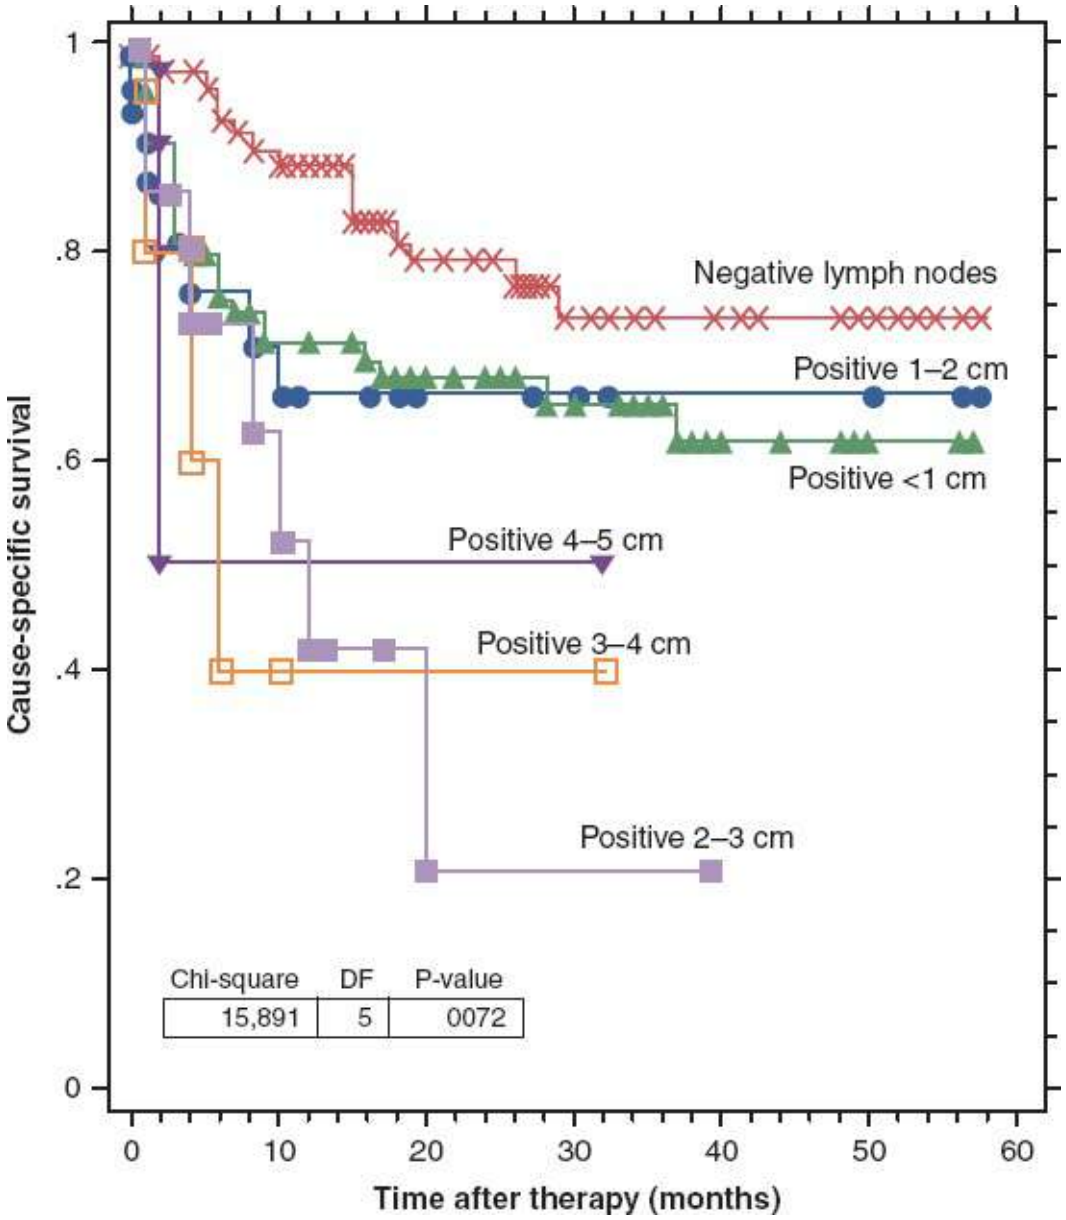

FIGURE 73.6. Cause-specific survival in patients with carcinoma of the cervix correlated with pelvic lymph node status on posttreatment 2-[^{924}F]fluoro-2-deoxy-D-glucose/positron emission tomography. (Reprinted from Grigsby PW, Singh AK, Siegel BA, et al., Lymph node control in cervical cancer. *Int J Radiat Oncol Biol Phys* 2004;59[3]:706–712. Copyright © 2004 Elsevier. With permission.)

Kidd et al.[104–108] demonstrated that maximum standardized uptake value (SUV max) is an independent predictor of death from cervical cancer and is associated with persistent disease. Similarly, the SUV of the pelvic node predicts pelvic disease recurrence. Survival rates are worse with supraclavicular nodal PET positivity; PALN metastases portend a survival rate between those of pelvic node and supraclavicular positivity. The detection of supraclavicular metastases

on FDG-PET at diagnosis and its relationship to clinical outcome for 186 cervical cancer patients was reported by Tran et al.[109] Fourteen patients (8%) had abnormal FDG uptake in left supraclavicular lymph nodes without palpable disease, confirmed on biopsy; six were treated with palliative intent, and seven received definitive irradiation and concurrent chemotherapy. The median overall survival was 7.5 months; all patients developed distant metastases. After external beam radiation is finished, an FDG-PET scan provides important information about posttreatment uptake and is prognostic with regard to outcome.[110–113]

STAGING

The FIGO staging system is based on clinical evaluation (inspection, palpation, colposcopy); roentgenographic examination of the chest, kidneys, and skeleton; and endocervical curettage and biopsies. Lymphangiograms, arteriograms, imaging findings, and laparoscopy or laparotomy findings should not be used for clinical staging. The 2009 FIGO staging system for cervical cancer has one modification from the previous version: Stage IIA has been divided into stage IIA1, with tumors invading into the upper vagina but ≤4 cm in size, and stage IIA2, with tumors >4 cm in size.[114]

Patients with hydronephrosis or a nonfunctioning kidney ascribed to extension of the tumor are classified as stage IIIB regardless of the pelvic findings. Other prognostic factors, such as endometrial extension of cervical carcinoma, stromal invasion, lymphatic/vascular permeation, and involvement of the lateral parametrium (as opposed to the medial parametrium) in stage IIB, are not included in the staging system. Suspected invasion of the bladder or rectum should be confirmed by biopsy. Bullous edema of the bladder and swelling of the mucosa of the rectum are not accepted as definitive criteria for staging. For a lesion to be classified as stage IIIB based on tumor extension without hydronephrosis, the tumor should extend to the lateral pelvic wall, although fixation is not required.

A parallel tumor-node-metastasis (TNM) staging system is published by the American Joint Committee on Cancer[115]; however, this system requires nodal staging, which is not feasible in many settings, and radiologic nodal information is not available to most patients with cervical cancer worldwide. The FIGO system remains the standard staging system, given the lack of 3D imaging to determine nodal status in countries with the highest incidence of cervical cancer. All histologic types should be included. When there is a disagreement regarding

the staging, the earlier stage should be recorded (Table 73.6 and Fig. 73.7).

TABLE 73.6 FIGO STAGING OF CARCINOMA OF THE UTERINE CERVIX

Primary Tumor (T)	
I	Cervical carcinoma confined to the uterus (extension to the corpus should be disregarded)
IA	Preclinical invasive carcinoma, diagnosed by microscopy only
IA1	Minimal microscopic stromal invasion
IA2	Tumor with an invasive component ≤5 mm in depth taken from the base of the epithelium and ≤7 mm in horizontal spread
IB	Clinical lesions confined to the cervix or preclinical lesions greater than IA
IB1	Clinical lesions ≤4 cm in size
IB2	Clinical lesions ≤4 cm in size
II	Cervical carcinoma invades beyond the uterus but not to the pelvic wall or to the lower one-third of the vagina
IIA	Tumor in the upper two-thirds of the vagina without parametrial invasion
IIA1	Tumor in the upper two-thirds of the vagina without parametrial invasion, ≤4 cm in greatest dimension
IIA2	Tumor in the upper two-thirds of the vagina without parametrial invasion, >4 cm in greatest dimension
IIB	Tumor with parametrial invasion
III	Cervical carcinoma extends to the pelvic wall and/or involves lower one-third of the vagina and/or causes hydronephrosis or nonfunctioning kidney
IIIA	Tumor involves lower one-third of the vagina, with no extension to the pelvic wall
IIIB	Tumor extends to the pelvic wall and/or causes hydronephrosis or nonfunctioning kidney
IVA[a]	Tumor invades mucosa of the bladder or rectum and/or extends beyond the true pelvis
IVB	Distant metastasis

[a]Presence of bullous edema is not sufficient evidence to classify a tumor as T4.
FIGO, International Federation of Gynecology and Obstetrics.

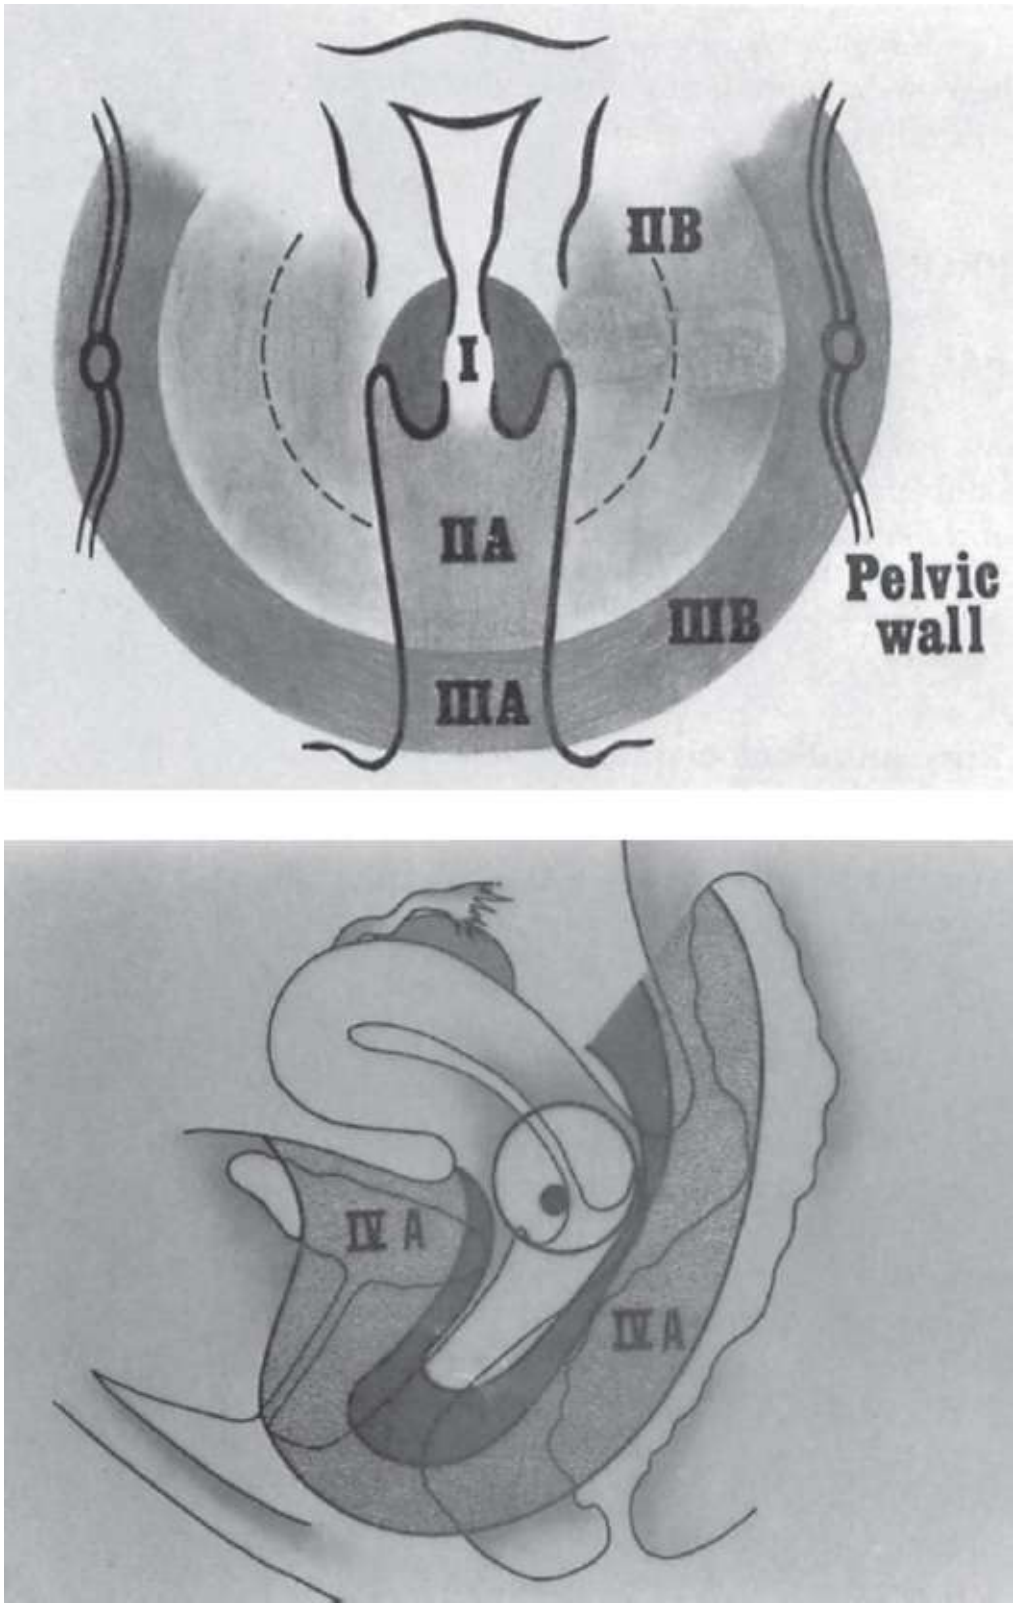

FIGURE 73.7. Diagrammatic representation of various anatomic stages of carcinoma of the uterine cervix, according to the FIGO classification. Stage IIA has been divided into stage IIA1, with tumors invading into the upper vagina but ≤4 cm in size, and

stage IIA2, with tumors >4 cm in size.

PATHOLOGIC CLASSIFICATION

More than 90% of tumors are squamous cell carcinoma. Approximately 7% to 10% are classified as adenocarcinoma, and 1% to 2% are the clear cell mesonephric type. Squamous cell (or epidermoid) carcinoma is composed of cores and nests of epithelial cells arranged randomly; cells show central keratinization with pearls and sometimes necrosis. Nonkeratinizing tumors may be seen. Electron microscopy may show desmosomes and tonofilaments. Squamous cell carcinomas are divided into three types: large-cell keratinizing, nonkeratinizing, and small cell carcinomas. They are subdivided according to the degree of differentiation into well, moderately, or poorly differentiated.

Verrucous carcinoma is a variant of a very well-differentiated squamous cell carcinoma that characteristically has a tendency to recur locally but not to metastasize.[116] Mitotic activity is very low. It may be difficult to discriminate verrucous carcinoma from a giant condyloma with cytologic atypia or from a well- differentiated invasive squamous carcinoma. Microscopically, verrucous carcinoma is exophytic, with an undulating, hyperkeratotic surface; the deep margin is composed of large, bulbous masses that invade along a wide front in a “pushing” fashion.

Adenocarcinoma arises from the cylindrical mucosa of the endocervix or the mucus-secreting endocervical glands. Mucinous is the most common subtype of adenocarcinoma. This endocervical adenocarcinoma may form mucosal glands lined by high columnar cells and produce tubular folds oriented in many directions. In another subtype, cells resemble those of the intestines; the epithelium tends to be pseudostratified and may contain goblet cells. The third variant is the signet-ring cell adenocarcinoma, which is rare and usually mixed with the endocervical or intestinal patterns.

Endometrioid carcinoma is the most common cell type of endocervical adenocarcinoma; the cells resemble those of the endometrium, and the presence of intracytoplasmic mucin in some cells may be seen in a substantial proportion of tumors. The World Health Organization recommends that endometrioid or endocervical types of adenocarcinoma be graded according to their architecture, based on the degree of gland formation.[117]

Sometimes, it is difficult to differentiate a primary endocervical adenocarcinoma from an endometrial tumor. In the future, genomic analyses

may provide information to guide classification. Drescher et al.[118] described a higher incidence of involvement of the uterine corpus and the regional lymph nodes in 21 patients with adenocarcinoma compared with a similar number of patients with squamous cell carcinoma. Chao et al.[119] and Contag et al.[120] described the use of microarray analysis for gene profiling (cDNA/RNA) to understand the molecular features of these tumors, which could aid in their classification. HPV has been identified in some subtypes of adenocarcinoma of the cervix.[121]

Adenoma malignum is a rare form of cervical cancer that is difficult to diagnose and often highly malignant and refractory to treatment.[122] Adenoma malignum is associated with Peutz-Jeghers syndrome and has an ominous natural history, with few reported cures.[123] Adenosquamous carcinoma is also relatively rare (2% to 5%) and consists of intermingled epithelial cell cores with squamous features and glandular structures. The squamous component is frequently nonkeratinizing. If the squamous component is benign metaplasia, the tumor is called adenoacanthoma.

Glassy-cell carcinoma (1% to 2%) is considered a poorly differentiated adenosquamous tumor; it is rare and highly malignant. Survival is poor after surgery or irradiation. Ulbright and Gersell,[124] in five cases of glassy-cell carcinoma evaluated by light and electron microscopy, described both glandular and squamous differentiation. Littman et al.[125] reported only 4 of 13 patients, the majority with stage II disease, surviving 5 years (6 had extrapelvic failures). Piura et al.[126] reported on five patients with cervical glassy-cell carcinoma, three with stage IB1 disease. All three patients were alive without disease 4, 12, and 18 months after diagnosis.

Adenoid cystic carcinoma is a rare variant of adenocarcinoma of the cervix (<1%), with an appearance similar to its counterparts in the salivary gland or the bronchial tree.[127] The tumor is composed of nests and nodules of small carcinoma cells with a few characteristic cribriform patterns. Immunohistochemical findings for type IV collagen and laminin reveal intercellular cylinders composed of basement membrane material in the solid area without a cribriform pattern. They are locally aggressive and prone to metastasize.[128]

Clear cell carcinoma (mesonephric), not related to DES exposure, comprises approximately 2% primary cervical adenocarcinomas and is believed to arise in mesonephric remnants.[26] These tumors are submucosal, composed of clear and “hobnail” cells, and may grow in a tubular, glandular, papillary, or solid pattern.

They appear at any age, with one-third occurring in women younger than 30 years of age. The clear cell is characterized by a voluminous cytoplasm filled with glycogen and the hobnail cell by single-cell apical projections into the neoplastic lumina. These tumors tend to be deeply positioned, with the bulk of the lesion on the stroma forming tubular structures, diffusely infiltrating the cervical stroma.

Cervical malignant mixed Müllerian tumors, compared with their counterparts in the corpus, are more commonly confined at presentation and may have a better prognosis. Clement et al.[129] described the clinicopathologic features with mixed Müllerian tumors of the cervix in nine patients. Gross examination revealed polypoid or pedunculated masses that invaded the cervical wall in 50% of the hysterectomy specimens. On microscopic examination, five tumors contained basaloid carcinoma or squamous cell carcinoma and four contained adenocarcinoma. In seven tumors, the sarcomatous component was homologous, usually resembling fibrosarcoma or endometrial stromal sarcoma, and two tumors contained heterologous sarcomatous elements.

Small cell carcinoma of the cervix, according to some authors, arises from endocervical argyrophilic cells or their precursors, multipotential neuroendocrine cells; however, some small cell tumors do not contain morphologic evidence of neuroendocrine origin. Nuclear molding, absence of nucleoli, cell necrosis, and high mitotic activity are common. One-third to one-half stain positively for neuroendocrine markers such as chromogranin, serotonin, synaptophysin, or somatostatin.[60] In the majority of patients, the cervical stroma is extensively infiltrated by single small, round cells.[130] Lymphatic and vascular invasion are significantly more common in small cell carcinomas (noted in 58% of patients with stage IB disease; 40% of these patients had lymph node metastases at the time of radical surgery).[131] HPV-18 has been detected in the majority of these tumors.[132]

Van Nagell et al.,[133] in an analysis of 25 patients, noted a 5-year survival rate of 54% for all stages of small cell carcinoma, compared with 68% for matched large-cell nonkeratinizing squamous cell and 74% for keratinizing squamous cell carcinomas. Viswanathan et al.[60] studied 21 patients. All were confirmed after central pathology review to stain positively for chromogranin, synaptophysin, or CD56. The median time to first relapse from the initiation of treatment was 8.4 months. No patient had brain metastases as the sole site of first recurrence. However, two patients developed brain metastases concurrently with lung metastases. The overall survival rate was 29% at 5 years; none of the patients

who had disease more extensive than stage IB1 or clinical evidence of lymph node metastases survived their disease. Similar 5 year overall survival of 29% was reported in 487 patients in the SEER registry.[133a]

Basaloid carcinoma or adenoid basal carcinoma, an extremely uncommon tumor, is characterized by nests or cords of small basaloid cells, prominent peripheral palisading of cells in the tumor nests, no significant stromal reaction or capillary space invasion, and an infiltrating growth pattern. Some authors have suggested a slow growth pattern with limited local invasiveness and low probability of lymph node metastases.[134] Prognosis is excellent.[135]

Primary sarcomas of the cervix have been occasionally described (e.g., leiomyosarcoma, rhabdomyosarcoma, stromal sarcoma, carcinosarcoma).[136] Malignant lymphomas, primary or secondary in the cervix, have been sporadically reported. They should be treated like other lymphomas.[137] Melanoma of the cervix is similarly extremely rare and difficult to cure despite attempts at radical surgery. Metastasis of distant tumors to the uterine cervix is rare (about 4% of all tumors) and should be considered in the differential diagnosis. Metastases to the cervix from the breast, ovary, and kidney have been reported.[138–140]

PROGNOSTIC AND PREDICTIVE FACTORS

The NRG/GOG combined data from randomized trials of chemoradiotherapy and created nomograms predicting progression-free survival, overall survival, and pelvic recurrence in locally advanced cervical cancer. Multivariable analysis of 2,042 patients identified histology, race/ethnicity, performance status, tumor size, stage, grade, pelvic node status, and treatment with cisplatin-based chemotherapy concurrently as significant measures for outcomes.[141]

Patient-Related Factors

Age

According to some reports, age is not a prognostic factor in carcinoma of the cervix.[142] Other authors noted decreased survival in women younger than 35 or 40 years,[143] who have a greater frequency of poorly differentiated tumors. In contrast, two European studies showed improved outcome for younger patients.[144] This apparent contradiction may be explained by an analysis by Rutledge et al.,[145] who showed an interaction between age and stage in the relative hazard plots for 250 patients younger than 35 years of age and matched

control subjects. Mitchell et al.[146] evaluated 398 patients with stage I to III cervical carcinoma treated with radiation therapy. Patients were divided into non-elderly (35 to 69 years of age; n = 338) and elderly (≥70 years of age; n = 60) groups. Comorbid conditions in the elderly resulted in diminished ability to undergo intracavitary brachytherapy. Although the 5-year actuarial disease-free survival and CSS rates were comparable in the two groups, tumor recurrence and death from cervical cancer were more common beyond 5 years in the elderly group.

Race/Socioeconomic Status

Several authors noted a correlation between racial or socioeconomic characteristics of patients and outcome of therapy. Mundt et al.[147] examined factors affecting outcome in 316 African American and 94 white patients undergoing RT for cervical cancer. With a median follow-up of 72.4 months, African Americans had a trend toward poorer 8-year CSS rates (47.9% vs. 60.6%; P = .10) compared with white patients. Factors correlating with poor outcome, including lower hemoglobin (Hb) levels during RT (P = .001), lower median income (P = .001), and less frequent intracavitary brachytherapy (P = .09), were more likely to be present in the African American group. Multivariate analysis demonstrated that race was not an independent prognostic factor after controlling for differences in patient, tumor, and treatment factors. In a report on 452 white and 124 African American women with stage II or III cancer of the cervix treated with RT alone, Grigsby et al.[148] observed 5-year CSS rates of 66% and 61% (P = .56) for those with stage II and of 38% and 47% (P = 0.34) for those with stage III disease, respectively. Overall survival rates for stage II for the two racial groups were different (60% and 51%, respectively; P = .02) and may be related to non–cancer-related comorbidity factors.

Brooks et al.[149] evaluated 1,009 patients with invasive carcinoma of the cervix: 606 white, 354 African American, and 5% “other” races. African Americans were more likely to have Medicaid or to be uninsured (44% vs. 23%; P = .001) and were more likely to be admitted for an emergency or for a cancer-related complication (P = .036), to have comorbid illness (P = .001), to be admitted for a transfusion (P = .01), or to be treated with radiation rather than surgery (P = .001). Racial differences existed in patterns of admission, type of therapy, and severity of illness.

Moreover, in an analysis of the 1994 Patterns of Care study of 471 cases of squamous cell carcinoma treated in the United States and a randomly selected

215 additional cases from 17 institutions that admitted >40% minority patients, women who lived in low-income neighborhoods, who had only Medicaid coverage, or who were treated at large academic or minority-rich institutions tended to have a poorer initial performance status, higher-stage or bulky central tumor, and a lower pretreatment hemoglobin level.[150]

General Medical Factors

Anemia and Tumor Hypoxia

Although stage, tumor volume, histologic type of the lesion, and vascular or lymphatic invasion are known to affect the prognosis of patients with cervical carcinoma, whether hemoglobin levels contribute to patient prognosis is controversial. Many radiation oncologists routinely administer red blood cell transfusions (RBCTs) to correct anemia before treatment with radiation therapy. This may have a generally favorable effect on the patient's sense of well-being and energy level and an impact on tumor radiosensitivity. Typically, patients receive transfusion to maintain hemoglobin levels >12 to 12.5 g/dL.

Hirst[151] emphasized that in animal tumor models, the opportunity to affect radiosensitivity by blood transfusion is transient. Blood transfusion is in general beneficial to the anemic patient with cancer, but it must be given as soon as possible before the first radiation dose to maximize its effects. Accounting for both the normal pulmonary and peripheral circulation and parallel flow through tumor tissue, Kavanagh et al.[152] calculated that decreasing hemoglobin–oxygen affinity should render a quantitatively greater decrease in radiobiologically hypoxic regions than what has been measured after the use of transfusions alone.[153]

Investigators have reported worse outcomes for patients whose tumors have either a median partial pressure of oxygen (Po_2) level, measured using polarographic needle electrodes for direct tumor tissue oxygen measurements, of <10 mm Hg[154] or a high percentage of Po_2 measurements <5 mm Hg.[155,156] Comparisons of intratumoral oxygen measurements before and after external beam radiation therapy have usually indicated a trend toward improved oxygenation after radiation therapy,[157,158] but the significance of posttreatment measurements is unclear.[159] Hypoxic tumors are more likely to recur locoregionally than well-oxygenated tumors regardless of whether surgery or radiation therapy is the primary local treatment.[154]

Haensgen et al.[160] analyzed 70 patients with stage IIB to IVA cervical cancer treated with external beam radiotherapy (EBRT) and brachytherapy. *In vivo*

oxygenation was measured with an Eppendorf probe, and patient hemoglobin levels were recorded. Patients with a hemoglobin level of <11 g/dL had a 3-year survival rate of 27%, compared with 62% for those with a hemoglobin level of ≥11 g/dL (P = .006). Combining hypoxia and tp53 allowed stratification of subgroups with differing 3-year survival rates: 79% for tp53 (n = 10) and 47% for tp53 without hypoxia (n = 44).

A randomized trial reported by Bush[161] on 132 patients with stage IIB to III cervical cancer required the control arm to receive transfusions only if the hemoglobin level dropped to <10 g/dL, whereas the experimental arm had to maintain the hemoglobin level ≥12.5 g/dL. The results suggested an improved outcome for patients in the experimental arm who received transfusion; however, there was not a statistically significant difference in outcome between treatment arms when compared using an intent-to-treat analysis.[162] Second, the randomization was not stratified according to the potentially confounding influence of tumor size. Finally, the thresholds for transfusion were based on anemia during therapy, not the initial hemoglobin. Thomas[163] reviewed the Canadian experience and found that in 605 eligible patients with cervical cancer, 25% received blood transfusions, most frequently when Hb was <100 g/L. On multivariate analysis, baseline Hb was not a significant prognostic factor, but average weekly nadir during radiation therapy was significant, those with values >120 g/L having lower incidences of local relapse and distant metastasis and a better 5-year survival rate.

Dunst et al.[164] showed that pretreatment anemia had a significant impact on 3-year relapse rates (6% in 20 patients with Hb of >13 g/dL, 15% in 47 with Hb between 11 and 13 g/dL, and 67% in 20 with Hb of <11 g/dL). The 3-year survival rate was 38% in patients with poorly oxygenated tumors, compared to 68% in patients with higher P_{O_2} (P = .02). Munstedt et al.,[165] in a study of 183 patients who received adjuvant RT after radical surgery, noted that those with Hb of <11 g/dL had lower recurrence-free and overall survival rates, primarily in a subgroup of women who had inadequate surgery.

In a retrospective review of >600 patients treated at seven different cancer centers in Canada, Grogan et al.[166] observed that the patients who maintained an average weekly hemoglobin level of >12 g/dL with or without transfusions had a significantly higher 5-year survival rate than patients with lower average weekly hemoglobin levels, regardless of the hemoglobin at presentation.

Kapp et al.[167] reported on 204 patients who received RBCT during RT when Hb level was <11 g/dL. Patients whose Hb was corrected (18.5%) had outcomes

similar to those of nontransfused patients. However, nonresponders to RBCT had decreased tumor control and survival rates. Vaupel et al.,[168] in a review of published data, concluded that maximum oxygenation of tumors is expected with Hb in the range of 12 to 14 g/dL for women and that higher Hb levels may not be better.

A large retrospective review of 2,454 patients with cervical cancer showed on univariate analysis that low hemoglobin levels were significantly associated with central recurrence, distant metastases, and disease-specific survival. On multivariate analysis, a hemoglobin level of <10 g/dL during RT was found to be significant for lower DSS (HR 1.28) and freedom from distant metastases (HR 1.33), but not freedom from central recurrence. In a subset analysis of patients receiving chemoradiation, transfusion did not provide a benefit.[169]

Recombinant human erythropoietin is not routinely recommended as an alternative means of sustaining or raising hemoglobin levels during radiation therapy. Thrombotic complications[170] and the lack of any survival benefit[171] mitigate the utility of this as a therapeutic intervention.

Other Medical Factors

Jenkin and Stryker[172] observed a higher incidence of pelvic recurrences and complications in patients with arterial hypertension (diastolic pressure of >110 mm Hg). Kapp and Lawrence[173] reported on 398 patients. Patients with temperatures of >101°F had a higher incidence of distant metastases and a lower survival rate. In patients with cervical cancer screened for HIV and treated with RT, Campbell et al.[174] observed a 4.2% positive HIV rate. These patients had more-advanced tumors. The duration of remission was shorter than in the HIV-negative group. RT had no effect on the HIV titers. Women who are HIV positive or have acquired immunodeficiency syndrome associated with *in situ* or invasive carcinoma of the cervix are at a higher risk for tumor recurrence after treatment and death as a consequence of the malignant process.[175,176]

Evidence continues to mount that increasing levels of plasma micronutrients are associated with a decreasing risk of cervical cancer. Increasing serum lycopene and α- and γ-tocopherol levels and higher intake of dark green and deep yellow vegetables and fruit were significantly inversely associated with cancer.[177–179] Women should be counseled to eat a well-balanced diet, particularly those at high risk for developing cervical cancer.

The neutrophil-to-lymphocyte ratio has been shown to be prognostic, with an NLR > 2.95 associated with a worse OS (HR 1.65, $P < .001$) and EFS (HR 1.57,

$P < .001$).[180]

Tumor Factors

HPV Subtype

HPV-16 and HPV-18 are the most frequent HPV subtypes worldwide. Studies have reported a higher risk of lymph node and other distant metastases with HPV-18 compared to HPV-16.[181,182] Wang et al.[183] studied 1,010 patients with cervical cancer after radiotherapy between 1993 and 2000. The HPV genotypes were determined by a gene chip that can detect 38 types of HPV. A total of 25 genotypes of HPV were detected in 992 specimens, of which 8 types that predominated were HPV types 16, 58, 18, 33, 52, 39, 31, and 45. Two high-risk HPV species were identified: α-7 (HPV types 18, 39, 45) and α-9 (HPV types 16, 31, 33, 52, 58). Risk groups determined included the high-risk group, which consisted of patients without HPV infection or those infected with the α-7 species only. The medium-risk group included patients coinfected with the α-7 and α-9 species.

Tumor Volume

There is a close correlation between depth of stromal invasion, tumor size, and incidence of parametrial and pelvic node metastases and survival in patients with cervical cancer.[42,43] In a study of women treated with radical hysterectomy, the 5-year DFS rate was 90% in 181 patients with stage IB1 (≤4 cm) and 72.8% in 48 patients with stage IB2 disease ($P = .02$).[184]

Toita et al.,[185] in a review of 70 patients with stage IIB and IIIB carcinoma of the uterine cervix treated with RT alone, reported no significant correlation of 5-year DFS with size of the cervical tumor <60 mm (70% to 85%); however, in patients with tumor ≥60 mm, the 5-year DFS was 28.6%. Piver and Chung[44] showed a greater incidence of lymphatic and distant metastasis and lower survival rates in patients with bulky and barrel-shaped stage IB and IIA tumors treated by radical hysterectomy. In addition, a higher incidence of pelvic recurrences and distant metastases and a decreased survival rate were reported by Fletcher,[186] Eifel et al.,[187] and Perez et al.[188] in patients with larger tumors treated with irradiation. In stages IB and IIA, higher radiation doses improved local tumor control.[189,190]

Furthermore, Leveque et al.,[191] in patients with stage I to II adenocarcinoma of the cervix treated with RT alone or combined with radical surgery, noted that FIGO stage and pelvic node involvement were the most important parameters

influencing overall survival. Silver et al.,[192] in 93 patients with stage I adenocarcinoma of the cervix, described patient age and tumor grade as significant prognostic variables for survival ($P < .01$ and .01, respectively); tumor size was significant ($P < .01$) for survival and PFS.

In contrast, Grigsby et al.,[193] in patients with stage IB and IIA carcinoma of the cervix treated with preoperative irradiation and radical or conservative hysterectomy, observed no correlation of tumor volume with outcome. The 5-year pelvic failure rates for stage IB were 16% for tumors <3 cm and 9% for larger tumors ($P = .90$) and for stage IIA were 22% for tumors <3 or >3 cm ($P = .75$).

Several retrospective studies demonstrated decreased survival and a greater incidence of distant metastases in patients with endometrial extension of a primary cervical carcinoma (endometrial stromal invasion or replacement of the endometrium by tumor only).[38] Grimard et al.[194] on the other hand, confirmed these findings only in patients with stage IB tumors but not in more advanced stages. Similar findings were noted by Noguchi et al.[195] Patients without uterine body invasion had a 5-year survival rate of 92.4%, compared with 53.8% in patients with invasion.

Perez et al.[190] in an update of a previous report[188] reviewed 1,499 patients (stages IA to IVA) treated with definitive irradiation (combination of external beam irradiation plus two intracavitary insertions to deliver doses of 70 to 90 Gy to point A). There was a close correlation between tumor size and extent and pelvic tumor control, incidence of distant metastasis, and DFS in all stages.

Impact of Histology on Outcomes

Several series have questioned whether adenocarcinoma has a worse prognosis than squamous cell carcinoma. A Surveillance, Epidemiology, and End Results (SEER) analysis of women with stage IB to IVB cervical cancer treated between 1988 and 2005 stratified 24,562 women by squamous cell carcinoma (77%), adenocarcinoma, or adenosquamous histology. Patients with adenocarcinoma were younger and presented with early-stage disease ($P < .0001$). For both early and advanced stage diseases, women with adenocarcinoma had an increased likelihood of dying from disease compared to those with squamous neoplasms (HR 1.39 and HR 1.21, respectively).[196]

In a retrospective analysis of 1,671 patients accrued on prior prospective GOG trials with locally advanced cervical carcinoma treated with either radiation alone or chemoradiation, a total of 70 adenocarcinoma patients treated

with radiation alone had a borderline poorer survival difference (P = .0499) compared to 647 patients with squamous cell carcinoma. In patients treated with concurrent chemoradiation, 112 adenocarcinoma patients had no difference in overall survival (P = .47) compared to 842 patients with squamous cell carcinoma. The authors conclude that in the era of chemoradiation, no difference in outcome exists between squamous cell and adenocarcinoma in this large retrospective analysis.[197]

Margin Status After Radical Hysterectomy

In addition to the known high-risk factors of positive margins, positive parametrial spread, and/or positive lymph nodes and the intermediate-risk factors of depth of stromal invasion, lymphovascular invasion, and tumor size, small series have indicated the significance of close margin status.[198,199] Viswanathan et al.[200] studied 284 patients after radical hysterectomy (RH) and central pathology review. The crude rates for any recurrence were 11%, 20%, and 38% for patients with negative (≥1 cm), close (>0 and <1 cm), and positive margins, respectively. Postoperative RT decreased the rate of local recurrence (LR) from 10% to 0% for negative, 17% to 0% for close, and 50% to 25% for positive margins. The significant predictors of decreased relapse-free survival on univariate analysis were the depth of tumor invasion (hazard ratio [HR] = 2.14/cm increase, P = .007), positive margins (HR = 3.92, P = .02), tumor size (HR = 1.3/cm increase, P = .02), lymphovascular invasion (HR = 2.19, P = .03), and margin status (HR = 0.002/increasing millimeter from cancer for those with close margins, P = .03).

Histologic Grade

Most reports have shown no significant correlation of survival or tumor behavior with the degree of differentiation of squamous cell carcinoma or adenocarcinoma of the cervix.[201–203] Alfsen et al.[201] analyzed 417 adenocarcinomas and 88 other nonsquamous cell carcinomas of the cervix; on multivariate analysis, small cell histology, corpus infiltration, vascular invasion, and positive lymph nodes were significant prognostic variables. Although Reagan and Fu[204] demonstrated prognostic value of histologic differentiation in patients treated with irradiation, Crissman et al.[205] failed to observe a correlation between histologic parameters and patient survival. In the era of chemoradiation, Monk et al.[206] showed no significant impact of histology or grade on survival in postoperative cervical cancer patients with other high-risk features.

Lymph Node Ratio

In a review of 95 patients with stage I to II cervical cancer treated with a radical hysterectomy and pelvic and/or para-aortic lymphadenectomy, the ratio of involved lymph nodes was associated on multivariate analysis with worse survival. A ratio of positive to negative of >7.6% had an HR of 3.96 (P = .01).[197]

Treatment Duration

In patients treated with radiation therapy, overall treatment time (OTT) should be as short as possible, and any planned or unplanned interruptions or delays should be avoided. Timely integration of external beam and intracavitary irradiation in patients with carcinoma of the uterine cervix is an important factor in improving pelvic tumor control (Fig. 73.8).[207] Several studies described lower pelvic tumor control and survival rates in invasive carcinoma of the uterine cervix when the overall time in a course of irradiation is prolonged.[142,208–210] Chatani et al.,[211] in 216 patients with stage IIB to III cervical carcinoma treated with a combination of external beam and HDR brachytherapy, noted that OTT was the most highly significant factor for local tumor control in multivariate analysis (P = .0005). For relapse-free survival, stage classification (P = .0001), OTT (P = .0035), and hemoglobin level (P = .0174) were the three most important prognostic factors; there was no relationship between treatment time and late complications.

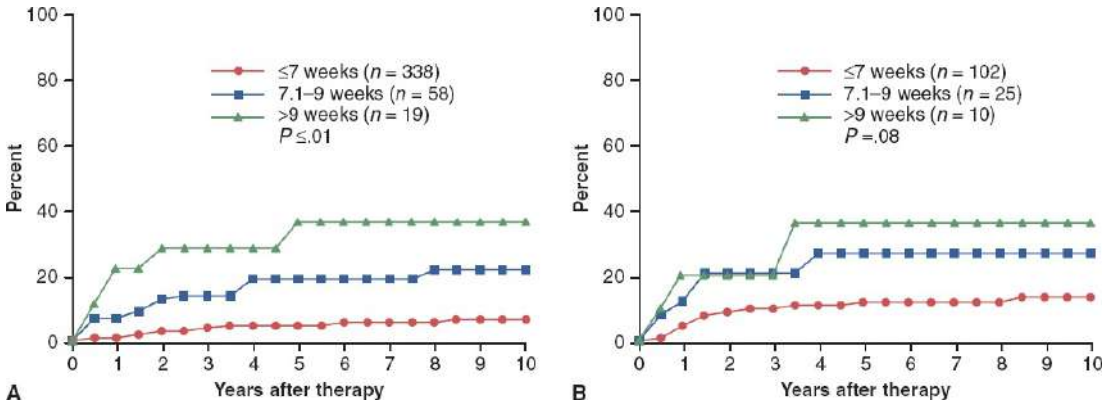

FIGURE 73.8. Pelvic failure rate correlated with length of treatment in stage IB **(A)** and IIA **(B)** carcinomas of the uterine cervix. (Reprinted from Perez CA, Grigsby PW, Castro-Vita H, et al. Carcinoma of the uterine cervix: I. Impact of prolongation of treatment time and timing of brachytherapy on outcome of radiation therapy. *Int J Radiat Oncol Biol Phys* 1995;32[5]:1275–1288. Copyright © 1995 Elsevier. With permission.)

Whether treatment duration has an impact in the era of chemoradiation has been assessed. Shaverdian et al. analyzed 480 cervical cancer patients treated

either with RT alone or with chemoradiation (CRT). In patients treated with RT, a treatment duration of 62 days or greater was not associated with a decreased DFS (HR 1.42, P = .086) nor was CRT.[212] In a retrospective review of 488 patients all treated with CT or MR image-based brachytherapy in the retroEmbrace study, D_{90} dose, clinical target volume (CTV) volume, and longer OTT were associated with local control.[213]

Fyles et al.[208] reported approximately 1% loss of tumor control per day of prolongation of treatment time beyond 30 days in 830 patients with cervical carcinoma treated with irradiation alone. Lanciano et al.,[210] in an analysis of 837 patients with squamous cell carcinoma of the cervix from the Patterns of Care Study who were treated with irradiation and received doses of 66 Gy or greater, described a 4-year actuarial in-field recurrence increase from 6% to 20% when total treatment time increased from 6 weeks or fewer to 10 weeks (P = .0001); this translated into significantly decreased survival. Girinsky et al.,[209] in 386 patients with stage IIB or III carcinoma of the cervix, also observed that the 10-year local recurrence–free survival rate decreased when OTT exceeded 52 days. A 1.1% loss of pelvic tumor control per day was also observed in their regression analysis.

Perez et al.,[214] in 1,330 patients treated with definitive irradiation, noted a major impact of prolongation of treatment time on pelvic tumor control in stages IB, IIA, and IIB. In stage III, although the rate of pelvic failure was higher with prolongation of treatment time, the difference was not statistically significant. There was also a strong correlation between OTT and survival. Regression analysis confirmed previous reports that prolongation of OTT resulted in an increased failure rate of 0.59% per day in stage IB and IIA and 0.86% per day in stage IIB disease. Performance of all intracavitary insertions within 4.5 weeks from initiation of irradiation yielded lower pelvic failure rates (8.8% vs. 18% in stage IIB tumors; $P \leq .01$).

Biomarkers

Several studies assessed various biologic markers to determine whether they are prognostic; however, the majority suffered from not having multivariate analyses to determine whether these may be valid independent factors. Noordhuis et al.,[215] in a systematic review of 42 studies with 82 cell biologic markers, reported that on univariate analysis, 34 biologic markers showed a relation with survival, 27 of which were independently associated with survival.

Angiogenesis and Hypoxia

Angiogenesis—the formation of new blood vessels—relies on the presence of proangiogenic growth factors, such as vascular endothelial growth factor (VEGF). As new blood vessels form, they deliver nutrients and oxygen to the cancerous cells. As tumors expand, the newly formed blood vessels may no longer reach the central portions of the tumor, and a hypoxic core develops. Hypoxia-inducible factor (HIF-1α) and HIF-2α regulate the response to hypoxic stress; HIF-1α but not HIF-2α has been associated with poor DFS.[216–219] The HIF-2α/CD68 ratio was correlated with poor DFS.[219] One study found that VEGF decreased overall survival.[220,221] Loncaster et al.,[220] in a retrospective study of 100 patients, found that VEGF expression in tumor biopsies in advanced carcinoma of the cervix was associated with a poor prognosis. Level of thymidine phosphorylase,[221] which increases hypoxic conditions, similarly was associated with poor outcomes. Nitric oxide synthase[222] and carbonic anhydrase (CA) may be prognostic for a poor outcome. In particular, CA9 is related to poor DFS.[223,224] CA12, in contrast, was related to metastasis-free survival.[225]

Microvessel count is higher in patients with cervical neoplasia than in control patients and higher in patients who experience posttreatment recurrences. Obermair et al.,[226] in 166 patients with stage IB cervical cancer, observed a 5-year survival rate of 89.7% in 102 patients whose tumors had a microvessel density of 20 per field or less and 63% in 64 patients whose tumors had a microvessel density of >20 per field (log rank $P < .0001$). In a multivariate Cox model, microvessel density, lymph node involvement, tumor size, and the application of radiation therapy were independent prognostic factors for survival. Similar findings were reported by Cooper et al.[227]

Flow Cytometry Studies on DNA and Growth Fraction

Some authors noted no significant difference in recurrence rates between patients with diploid or aneuploid tumors. Kristensen et al.,[228] in a study of 465 patients with invasive carcinoma of the uterine cervix on whom DNA index and S-phase fraction studies were performed, observed that neither ploidy level nor S-phase fraction had prognostic significance. Others[229] noted more relapses in tumors with an S-phase rate of 20% or greater.

Apoptosis

Whether apoptotic markers might be of importance in cervical cancer is unclear, given heterogeneity in the data. Morphologic studies have been negative, but

some studies evaluating apoptotic protein expression such as that of Bcl-2 and p63 show association with poor DFS.[230,231]

Ohno et al.[232] studied 20 patients before and after administration of 9 Gy and found an increase in apoptotic cell index and Bax protein. Wootipoom et al.,[230] in 174 patients with cervical cancer, noted Bax, Bcl-2, and p53 expression in 68.4%, 25.9%, and 77.6% of the cases, respectively. Bax expression was associated with better survival, whereas Bcl-2 expression was associated with poor survival. Jain et al.[233] also found that neither Bcl-2 nor p53 expression was an independent predictor of outcome in locally advanced cervical cancer.

The p53 gene controls entry into the S-phase of the cell cycle. Mukherjee et al.[234] analyzed radioresistant cervical cancer cases and found that 15% had positivity for Bcl-2 and p21 proteins and 34% showed mutant p53 protein. None of the radiosensitive tumors were positive for these proteins. Seventy-five percent of the radiosensitive tumors were positive for the Bax antibody, whereas 81% of the radioresistant tumors were negative for Bax ($P < .01$). Kainz et al.,[235] in a study of 109 surgically treated patients, and Ebara et al.,[236] in 46 patients with stage IIIB squamous cell carcinoma of the cervix treated with RT alone, noted no significant difference in outcome when correlated with p53 protein expression.

Cell Cycle and Cellular Oncogenes

Cerciello et al.,[237] in 40 patients with stage IIA to IIIB cervix cancer treated with RT without chemotherapy, obtained biopsies before and after five fractions of RT. They observed significant changes in the cell cycle of cervical cancer, indicating intact G2/M checkpoint function, leading to the expectation that targeting compounds interfering with G2/M transition may enhance the effect of irradiation on cervix cancer.

In patients with carcinoma of the uterine cervix treated with irradiation, Tsang et al.,[238] observed that the most significant factors for DFS were large tumor size ($P = .01$), low hemoglobin ($P = .01$), labeling index (LI) flow cytometry (DFS, 67% for LI < 7%; 33% for LI ≥ 7%; $P = .03$), and potential doubling time (T_{pot}; 66% for $T_{pot} > 5$ days, 35% for $T_{pot} \leq 5$ days; $P = .04$). For small tumors (<6 cm in diameter), either a high LI (>7%) or a high apoptotic index (>1%) was associated with poorer DFS. West et al.[239] evaluated the intrinsic radiosensitivity of 145 tumor biopsies from patients with cervical carcinoma (*in vitro* survival fraction at 2 Gy using a clonogenic assay). Diploid tumors tended to be more radioresistant than aneuploid tumors ($P = .07$).

The p27/Kip1 gene inhibits a variety of cyclin-dependent kinase complexes and regulates cell growth. Oka et al.[240] studied 202 biopsy specimens obtained from 77 patients with squamous cell carcinoma of the cervix before and during RT for expression of p27 and p53 proteins. A high p27 LI before radiation therapy was associated significantly with good disease-free and metastasis-free survival rates. A high p53 LI before irradiation was associated with poor overall survival.

Both specific point mutations and amplification of *ras* genes have been noted. Overexpression of the ras gene p21 product is associated with a poor prognosis and increased frequency of lymph node involvement.[241] Although loss of heterozygosity of the c-Ha-ras gene in squamous cell carcinomas was not associated with advanced-stage disease, mutations were associated with a poor prognosis. In contrast, mutations of the Ki-ras gene have been detected in a small percentage of cervical adenocarcinomas but have not been significantly associated with stage, grade, or survival.[242,243]

The c-*myc* oncogene is amplified from 3 to 30 times in approximately 20% of squamous cell carcinomas and is more frequent in high-stage compared with low-stage tumors. Overexpression of c-myc has been associated with a worse clinical outcome.[244,245]

Gadd45 belongs to the class II family of DNA damage-inducible genes, and its role in DNA repair has been proven in many experimental models. Santucci et al.,[246] in 14 patients with cervical cancer, found a correlation between the lack of gadd45 induction and a clinical response to irradiation (both local tumor control and DFS) when a dose ranging from 18 to 25 Gy was delivered to the pelvis.

CD34 is an antigen present in hemopoietic progenitor cells and is a sensitive marker for endothelial cells. In 62 patients with cervical cancer evaluated by Vieira et al.,[247] CD34 reactivity and higher microvessel density were associated with squamous cell carcinoma. CD109 is a cell surface protein that was found to be expressed in cervical cancer more than in endometrial adenocarcinoma.[248]

Cytokeratin Markers and the Epidermal Growth Factor Receptor Pathway

Altered expression of c-ercB-2 (HER2) protein was shown to have prognostic significance in adenocarcinoma but not in squamous cell carcinoma of the cervix.[249] HER1, as well as coexpression of epidermal growth factor receptor and HER2, has been associated with poor DFS.[250] PTEN mutations have also been associated with poor prognosis.[251]

In 80 patients with carcinoma of the cervix, expression of cytokeratin 10 and 13 and involucrin was found in 24%, 64%, and 53%, respectively.[252] There was no difference in the expression of cytokeratin or involucrin between patients with positive or negative lymph nodes, although in the lymph node–positive group, survival was higher in patients lacking cytokeratin 13 expression (P = .02).

Squamous Cell Carcinoma Antigen and Carcinoembryonic Antigen

Tsai et al.,[253] in 117 patients with adenocarcinoma of the cervix, 28 of whom had preoperative carcinoembryonic antigen (CEA) levels of >5 ng/mL, noted a correlation with larger tumor size, deeper cervical invasion, and lymphovascular invasion (P < .001). A Spanish study of 96 patients with invasive carcinoma of the cervix and 7 with intraepithelial neoplasia showed elevated CEA levels in 33%, CA 19.9 in 32%, and CA 125 in 21.5% of patients.[254] Specificity for each tumor marker was 98%. Increased CEA and CA 19.9 levels were found with more advanced stages of the disease and in patients with adenocarcinoma compared with squamous cell carcinoma. At follow-up, all cases of progressive tumor or recurrence were detected by elevation of one of the three antigens. Specificity during follow-up was 92% for CEA and CA 125 and 92.6% for CA 19.9.

In a study of 272 patients with invasive carcinoma of the cervix with 1,053 samples, Bolli et al.[255] noted an elevation of squamous cell carcinoma antigen (SCC-Ag) before treatment in 53% of 103 patients, increasing with advancing tumor stage at diagnosis. In 70 patients with recurrent tumor, 81% had elevated SCC-Ag. Ngan et al.[256] also identified elevation of serum SCC-Ag in 62% of 308 women with carcinoma of the cervix. Posttreatment SCC-Ag levels were raised in 69 patients (22.4%), and this was associated with a <5% 5-year survival rate, in contrast to 87% in women with normal SCC-Ag levels.

Hong et al.,[257] in 401 patients with stage I to IV squamous cell carcinoma of the cervix treated with RT, noted that the preirradiation SCC-Ag level strongly correlated with disease stage. A persistently elevated SCC-Ag level 3 months after RT was a stronger predictor for treatment failure than residual induration by pelvic examination, and it was associated with a higher incidence of distant metastasis.

Similarly, Micke et al.,[258] in 141 patients with cervical cancer treated with RT, noted that the pretherapy serum level of SCC-Ag was elevated in 72% (>2 ng/mL). Patients with an SCC-Ag of <7.2 U/mL had better tumor response than

those with higher levels. After RT, 98% of patients in complete remission and 87% of those in partial remission had a serum level below the cutoff. In recurrent tumors, 82% of patients had a significant increase in serum levels before clinical manifestation of relapse (≤0.001). Hong et al.,[259] in 1,031 patients with squamous cell cervical cancer treated with RT with or without chemotherapy, noted that independent risk factors for local relapse were advanced stage and age <45 years; 5-year local relapse–free survival was higher (90%) if squamous cell carcinoma antigen was <2. This antigen may be a useful marker in the prognosis of patients with carcinoma of the uterine cervix. Huang et al.[260,261] noted that SCC-Ag and CEA were predictive of para-aortic node failure. Markovina et al. note that SCC-Ag is a significant independent predictor of positive post-therapy FDG-PET/CT, recurrence and death.[261a]

Epstein-Barr Virus, Transforming Growth Factor, β-Integrin, and Other Markers

Activity of Epstein-Barr virus antigen–specific killer T cells and shedding of Epstein-Barr virus were evaluated in 55 patients with carcinoma of the cervix.[262] Activity was decreased in patients with cervical carcinoma compared with control patients; it became increasingly lower as the clinical stage of the disease advanced, and activity after treatment was clearly related to patient survival. These data may indicate an imbalance in local immunity against viral infection and impairment of T-cell immunity in patients with advanced cervical carcinoma.

In 79 patients undergoing radiation therapy for carcinoma of the cervix, pretreatment transforming growth factor-β_1 (TGF-β_1) levels were a significant prognostic factor for survival and local tumor control. There were weak significant correlations of TGF-β_1 levels with disease stage and the levels of circulating tumor markers (CA 125).[263] Hazelbag et al.[264] also assessed TGF-β_1 and plasminogen activator inhibitor (PAI-1) expression in 108 specimens of cervical carcinoma and noted that TGF was not associated with worse prognosis, whereas PAI-1 was.

Gruber et al.,[265] in biopsies of 82 patients with cervical cancer, found that β_3-integrin was expressed in 50 (61%) and correlated it with higher incidence of locoregional recurrences and decreased survival.

Cyclooxygenase-2

Gaffney et al.,[266] in 24 patients with carcinoma of the cervix treated with RT,

observed that 5-year overall survival rates for tumors with low versus high COX-2 values were 75% and 35%, respectively (P = .021). COX-2 staining intensity was found to correlate positively with tumor size (P = .022).

Kim et al.[267] screened 84 patients with stage IIB squamous cell and 21 with adenocarcinoma cervical cancer and found COX-2 expression more frequently in the adenocarcinoma group (57% vs. 24%; P = .007). The 5-year survival rate was 83% for COX-2–negative and 57% for COX-2–positive patients, regardless of histologic subtype (P = .001). Pyo et al.[268] also showed that expression of COX-2 and coexpression of COX-2 and thymidine phosphorylase were correlated with high locoregional recurrence and lower survival. Moreover, Kang et al.,[269] in 84 patients with cervix adenocarcinoma, observed a higher incidence of lymph node metastasis and decreased survival with elevated expression of COX-2.

Hormonal Receptors

Suzuki et al.[270] investigated the expression of estrogen receptors and progesterone receptors (PgRs) in biopsy specimens from cervical tumors before RT in 44 patients with cervical adenocarcinoma and 22 with adenosquamous cell carcinomas. Staining for estrogen receptors or PgR was positive in 12 patients (19%). The estrogen receptor status did not correlate with the local tumor control, disease-free survival, or CSS. The DFS rate of PgR-positive patients was significantly higher than that of PgR-negative patients (P = .044), but PgR status was not statistically significant in relation to 5-year CSS or local tumor control.

Cancer Genome Atlas

Using RNA sequencing and whole exome DNA sequencing, several mutations have been reported in cervical cancer.[271] Notable APOBEC mutagenesis patterns and novel significantly mutated genes in SHKBP1, ERBB3, CASP8, HLA-A, and TGFBR2 were identified. Amplifications in PD-L1 and PD-L2 and BCAR4 were also noted. Categories of cervical cancer were defined as endometrial like (predominantly HPV-negative), keratin-low squamous, keratin-high squamous, and adenocarcinoma-rich subgroups.[272]

TECHNIQUES USED FOR TREATMENT

Preinvasive Disease

Patients with CIN may be candidates for observation or treatment. CIN1-2 has a spontaneous regression rate in 1 to 3 years of >50%,[273] and therefore, observation may be an appropriate course. For patients with persistent dysplasia, cryotherapy has a very low complication rate and is highly successful but may be less effective than laser ablation for high-grade dysplasia.[274] Patients with no visible lesion undergo frequent serial exams. Cold knife conization (CKC) may be used for diagnostic and therapeutic intent, with side effects of bleeding, cellulitis, cervical stenosis, or loss of cervical competence. Loop electrosurgical excision procedure (LEEP) has become popular, although bleeding and stenosis may occur; pregnancy outcomes may be better with LEEP than with CKC.[275–277]

Invasive Disease

Surgical Techniques

Simple Conization

In patients with minimal invasion, no parametrial involvement, and small tumor size, simple conization with lymphadenectomy has been reported. Although only 36 patients were studied, after a median follow-up of 66 months, only 1 pelvic nodal relapse was observed.[278]

Radical Trachelectomy

Described in the 1960s,[279] trachelectomy entails removal of the cervix entirely. Radical trachelectomy also removes the parametrial tissue. As a means of fertility preservation in early-stage cervical cancer patients,[280] trachelectomy should be combined with preoperative PET imaging to confirm no nodal involvement and with MRI to confirm no endocervical canal extension of tumor into the uterus.[281] A laparoscopic lymphadenectomy should accompany the trachelectomy to confirm no nodal involvement. A non-absorbable cerclage is placed around the uterine isthmus. Radical abdominal trachelectomy also may result in successful fertility preservation.[282] Selection criteria for a trachelectomy include those patients requesting fertility-sparing surgery; age <40 years; stage IA1, IA2, or IB1 with no nodal involvement detected on MRI or PET scan; squamous cell or adenocarcinoma with a lesion <2 cm; no lymphovascular invasion on initial biopsy; and no upper endocervical involvement. The main site for recurrence is the central pelvis (average 5% risk), at the cervicouterine junction, or in the adjacent parametrial tissue. In a retrospective review of 29 patients with stage IB1 disease with tumor size 2 cm or greater treated with radical trachelectomy, patients with high-risk features were taken to immediate

hysterectomy, and 21% required chemoradiation. A total of nine patients (31%) were able to undergo a fertility-sparing procedure, with one recurrence at a median follow-up of 44 months.[283] If high- or intermediate-risk features are present (i.e., presence of positive lymph nodes or positive margins) after a trachelectomy, radiation should be performed without requiring a completion hysterectomy. Leaving the uterus intact results in less small-bowel dose; radiation or chemoradiation followed by image-based brachytherapy with an attenuated dose based on amount of residual disease in the uterus is feasible in order to minimize bladder and rectal dose.[283a]

Types of Hysterectomy

Several types of hysterectomy are used in the management of carcinoma of the uterine cervix (Table 73.7).[284]

Total (extrafascial) abdominal hysterectomy (class I) consists of removal of the cervix and adjacent tissues, as well as a small cuff of the upper vagina in a plane outside the pubocervical fascia. There is minimal disturbance of the ureters and the trigone of the bladder. This may be the surgical treatment of choice for stage IA1 cervical cancer.

The use of a radical hysterectomy for cervical cancer was first described by Wertheim in 1912.[285] In a modified radical extended hysterectomy (class II), the cervix and upper vagina are removed, including paracervical tissues, and the ureters are dissected in the paracervical tunnel to their point of entry into the bladder. Because the ureters are unsheathed and retracted laterally, parametrial and paracervical tissue can be safely removed medial to the ureter. This operation is performed with a lymphadenectomy. This is the most common surgical approach selected for stage IA2 cervical cancer.

Radical abdominal hysterectomy (class III) with bilateral pelvic lymphadenectomy consists of a wider resection of the parametrial tissues to the pelvic wall, with dissection of the ureters and mobilization of the bladder, as well as of the rectum to allow for more extensive removal of tissues. This approach was described by Meigs in 1944.[286] In addition, a vaginal cuff of at least 2 to 3 cm is always included in the procedure, as well as the uterosacral ligaments.[284] A bilateral pelvic lymphadenectomy is usually carried out. This operation is often referred to as the Wertheim or Meigs procedure. The extended radical hysterectomy (class IV) includes complete dissection of the ureter from the vesicouterine ligament, sacrifice of the superior vesicle artery, and removal of the upper three-fourths of the vagina. Because of the high rate of fistula and

significant morbidity, it is rarely used.[284] In 2007, after a consensus conference in Japan, a new classification system was released based only on the lateral extent of the resection.[287] Four levels of hysterectomy are described (A to D) and four levels of lymphadenectomy (1 to 4). The levels of lymph node dissection include the internal and external iliac (level 1), common iliac and presacral (level 2), aortic intramesenteric (level 3), and aortic infrarenal (level 4). The levels of primary tumor resection include the following:

Type A: Extrafascial hysterectomy, with minimum resection of the paracervix medial to the ureter and minimal vaginal resection <1 cm, without removal of the paracolpos.

Type B: Modified radical hysterectomy with partial resection of the vesicouterine and uterosacral ligaments, unroofing of the ureter, transection of the parametrial tissue at the ureter, and removal of at least 1 cm of the vagina. This type is divided into B1, without removal of paracervical lymph nodes, and B2, with removal of lateral paracervical nodes.

Type C: Classic radical hysterectomy, variant in which the entire uterosacral and vesicouterine ligaments are removed, 1.5 to 2 cm of the vagina with paracolpos is excised, and neuronal preservation is critical.

Type D: Includes the complete radical hysterectomy and resects tissues to the pelvis sidewall, including the hypogastric (internal iliac) vessels, and exposes the sciatic nerve (type D1). Type D2 also removes the fascial and lateral muscles, called the laterally extended endopelvic resection.

Pelvic Exenteration

Pelvic exenteration has been used for en masse removal of the pelvic viscera for recurrent carcinoma of the cervix. Modern radiation therapy with concurrent chemotherapy results in high complete response rates and has made residual extensive disease a rare indication for exenteration. Patients with adjacent organ invasion are given a course of radical concurrent chemoradiation, followed by interstitial brachytherapy, with exenteration reserved for salvage.[288–290]

This operation, which is not done as a palliative procedure, consists of a radical hysterectomy, pelvic lymph node dissection, and removal of the bladder (anterior exenteration), removal of the rectosigmoid colon (posterior exenteration), or both (total exenteration). The ileum or sigmoid has been the usual means of achieving urinary diversion. Because some patients have a pelvic recurrence after radiation therapy, the bowel is used for the urinary conduit.

Proof that there is no fixation to the pelvic wall and no extension of disease beyond the pelvis is mandatory. Metastases outside the pelvis, including those in PALNs or any viscera, are absolute contraindications to the procedure. Bilateral ureteral obstruction secondary to tumor is also a relative contraindication.[291] Patients with sacroiliac or hip pain or leg edema rarely benefit from this procedure and should be excluded on a clinical basis.

TABLE 73.7 TYPES OF ABDOMINAL HYSTERECTOMY

	Intrafascial	Extrafascial Type I	Modified Radical Type II	Radical Type III–IV[a]
Cervical fascia	Partially removed	Completely removed	_____	_____
Vaginal cuff removal	None	Small rim removed	Proximal 1–2 cm removed	Upper one-third to one-half removed
Bladder	Partially mobilized	_____	_____	Mobilized
Rectum	Not mobilized	Rectovaginal septum partially mobilized	_____	Mobilized
Ureters	Not mobilized	_____	Unroofed in the ureteral tunnel	Completely dissected to the bladder entry
Cardinal ligaments	Resected medial to the ureters	_____	Resected at level of the ureter	Resected at pelvic the sidewall
Uterosacral ligaments	Resected at level of the cervix	_____	Partially resected	Resected at postpelvic insertion
Uterus	Removed	_____	_____	_____
Cervix	Partially removed	Completely removed	_____	_____

[a]Type IV, extended radical hysterectomy (partial removal of the bladder and/or ureter), in addition to type III.

Pretreatment Surgical Nodal Assessment

Exploratory laparotomy and nodal staging to evaluate the presence of metastases to the pelvic or para-aortic nodes may provide diagnostic information but has not had a demonstrated impact on survival (Table 73.8). In a prospective evaluation of 290 patients with carcinoma of the cervix[52] para-aortic node metastases were found in 19 of 58 patients (32.8%) with clinical stage IIB and 19 of 61 (31.1%) with stage IIIB disease. A number of studies compared the significance of para-aortic nodal metastases with other clinical and surgical findings with regard to PFS and overall survival.[292] In 626 patients treated on GOG randomized studies, the RR associated with positive para-aortic nodes was 11.0 for time to recurrence and 6.2 for survival time. In addition to the significant increase in risk of regional relapses, patients with para-aortic nodal metastasis are more likely to have extrapelvic failure.[293]

Cosin et al.[294] reviewed 266 patients with locally advanced cervical carcinoma who underwent extraperitoneal pelvic and para-aortic lymphadenectomy before RT. Patients were divided into four groups: group A had negative lymph nodes; B, resected, microscopic lymph node metastases; C, macroscopically positive lymph nodes that were resectable at the time of surgery; and D, unresectable lymph nodes. Lymph node metastases were detected in 50% of patients. All patients received pelvic EBRT (pre–intensity-modulated radiation therapy [IMRT] era) and brachytherapy; patients with lymph node metastases received extended-field irradiation. Five- and 10-year DFS rates were similar for all patients in groups B and C. All patients in group D recurred. There was a 10.5% incidence of severe radiation-related morbidity and a 1.1% incidence of treatment-related deaths.

The potential benefit of surgical nodal debulking followed by irradiation has been studied.[295] Potish et al.[296] noted that more than half of the patients with advanced cervical cancer with grossly positive pelvic nodes that were debulked survived, compared with none with unresectable lymph nodes, findings closely paralleling those of Inoue and Morita[297]; however, these studies predated the ability to implement dose escalation with IMRT to the involved nodes. Nonetheless, surgical debulking of nodes decreases the dose of radiation

required to these regions. The use of high-energy photon beams and limitation of the tumor dose to extended volumes in the para-aortic region for those with completely resected but positive nodes to 45 to 50 Gy decrease the probability of complications. IMRT also enhances the sparing of adjacent abdominal normal tissues.[298,299] However, if node dissection is not feasible or would result in a treatment delay, patients may successfully be managed with IMRT with dose escalation to approximately 60 to 65 Gy to the grossly enlarged lymph nodes.[101,300–302]

TABLE 73.9 COMPLICATION RATE FOR PRETHERAPY SURGICAL STAGING

	Transperitoneal (122/189; 64.6%)		Retroperitoneal (67/189; 35.4%)	
	Prior Laparotomy (*n* = 52), Group 1	No Prior Laparotomy (*n* = 70), Group 2	Prior Laparotomy (*n* = 27), Group 3	No Prior Laparotomy (*n* = 40), Group 4
Complications per group	32 (61.5%)	25 (37.9%)	8 (29.6%)	1 (2.5%)
Percentage of total complications (*n* = 66)	48.5	37.9	12.1	1.5

Complication risk may be high (Table 73.9), particularly when patients are treated with postresection RT. One study showed an 11.5% incidence of major primarily small-bowel complications with transperitoneal compared with 3.9% in the extraperitoneal lymphadenectomy group (P = .03).[303] Transperitoneal lymphadenectomy should be avoided.[45,304]

Because of a high rate of complications, preirradiation laparotomy was discontinued at the MD Anderson Cancer Center. The status of the lymph nodes is investigated with lymphangiography and verified when possible with percutaneous transabdominal needle biopsy. Wharton et al.[46] reported on 120 patients who had preirradiation celiotomy; 16 had fatal complications, and 32 had major intestinal complications. Most patients with positive lymph nodes died with distant metastasis. More recently, PET–CT followed by biopsy may be a useful approach. In one series of 60 patients without evidence of PALN involvement on preoperative CT or MRI, patients underwent a preoperative

PET–CT followed by surgery. Twenty-six patients had a negative PET–CT, of whom 3 (12%) had positive nodes pathologically. Of the 27 with positive pelvic but negative para-aortic nodes on PET–CT, 6 (22%) had pathologically positive para-aortic nodes, indicating a sensitivity of 36% and a specificity of 96%. In another study, 125 patients had a PET–CT followed by para-aortic lymphadenectomy.[50] Seventeen percent had positive para-aortic metastases, 66% of whom had a negative PET–CT. The sensitivity and specificity of PET–CT were 33% and 94%, respectively. Morbidity of the surgery was 7%, and there was no delay in initiating chemoradiotherapy. A Cochrane overview of pretreatment surgical para-aortic lymph node assessment in stage IB2 to IVA cervical cancer identified one randomized trial of 61 women that favored CT or MRI over surgical staging.[305,306] Alternatively, para-aortic node sampling may be performed through a laparoscopic approach; the procedure is well tolerated, recovery is prompt, and yield is adequate.[307,308]

Aside from para-aortic nodes, supraclavicular metastases may rarely be involved. Perez-Mesa and Spratt[309] found no supraclavicular node metastasis in 73 consecutive patients with various stages of cervical carcinoma. Manetta et al.[310] also did not detect scalene node metastasis in 24 patients with recurrent carcinoma of the cervix evaluated for exploration and possible pelvic exenteration. There is no indication for removal of the supraclavicular nodes.

Sentinel Lymph Node Biopsy

Sentinel lymph node (SLN) studies show mixed results, with a 20% false-negative rate and a 50% incidence of other pelvic metastases.[311] However, the method allows for aborting surgery and pursuing RT instead. Sentinel node biopsy in patients with cervical cancer is used in several institutions; a seven-center prospective study analyzed 139 patients and detected 454 SLNs. Intraoperative examination did not detect micrometastasis or isolated tumor cells. Other techniques, such as molecular assays, may improve SLN assessment in the future.[312,313] The SENTICOL study[314] injected 145 stage IA1 to IB1 cervical cancer patients with combined technetium-99 and patent blue. The sensitivity (92%) and lack of false-negative results were favorable, but SLN biopsy was reliable only when SLNs were detected bilaterally.

Ovarian Transposition

In premenopausal women, surgery and radiation may directly impact gonadal function. For women with early-stage cervical cancer who undergo a radical

hysterectomy, ovarian function may be preserved. In patients who require postoperative radiation, transposition of ovarian tissue outside of the radiation field may help to preserve ovarian function, although even low doses to the ovaries may cause acute ovarian failure (Fig. 73.9). In women who require radical radiation to the uterus and ovarian tissue, counseling before treatment begins with a fertility expert in reproductive endocrinology may be of benefit if an intervention such as egg retrieval is desired. Care must be taken to ensure that any potential intervention does not delay the initiation of curative treatment. In addition, women with early-stage cervical cancer have an approximately 1% risk of ovarian metastasis with squamous cell carcinoma and 5% risk with adenocarcinoma. Therefore, women should be counseled on the potential risks of recurrence with ovarian preservation.[315]

In a survey of 124 patients who had undergone radical hysterectomy and lymphadenectomy with ovarian transposition, 68 responders were premenopausal at the time of surgery. Six of 30 women (20%) with ovarian preservation experienced early hormonal failure (5 had one ovary, and 1 patient had both preserved).[316] Combined modality therapy affects ovarian function more than operation alone.[317] Anderson et al.[318] noted that only 4 of 24 patients (17%) with ovarian transposition who received postoperative pelvic irradiation had continued ovarian function. Feeney et al.[319] reported on 132 patients on whom lateral ovarian transposition was performed at the time of radical hysterectomy; 28 patients received postoperative pelvic irradiation. Fourteen of 28 patients (50%) who received pelvic irradiation had evidence of ovarian failure, in contrast to 3 of 104 patients (2.9%) on whom ovarian transposition was performed, without postoperative irradiation. Buekers et al.[320] also evaluated ovarian function in 102 patients with cervical cancer, 83 of whom underwent radical hysterectomy and 19 of whom had a staging laparotomy, all with ovarian preservation (80 included ovarian transposition); 26 patients received postoperative radiation therapy. After ovarian transposition without RT, 98% of patients retained ovarian function for a mean of 126 months, with menopause at a mean age of 45.8 years. When ovarian transposition and RT were added, 41% retained ovarian function for a mean of 43 months and experienced menopause at a mean age of 36.6 years.

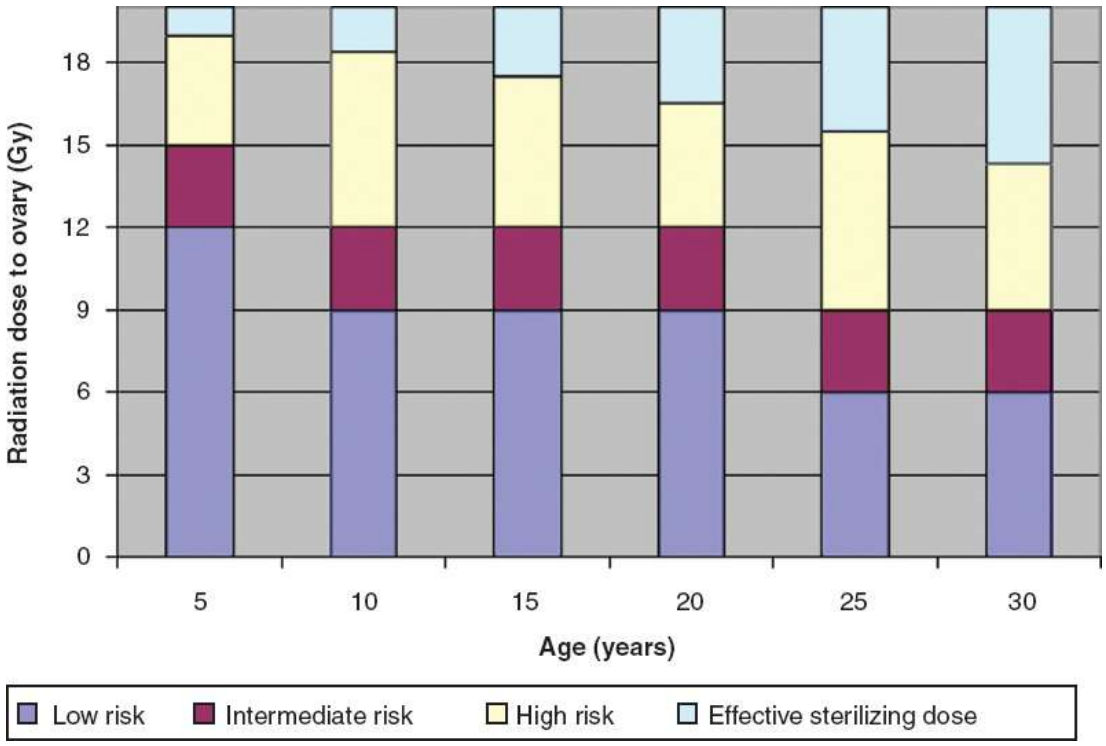

FIGURE 73.9. Risk of developing acute ovarian failure, defined as ovarian failure within 5 years, stratified by age and radiation dose to the ovary. (Reprinted from Wo JY, Viswanathan AN. Impact of radiotherapy on fertility, pregnancy, and neonatal outcomes in female cancer patients. *Int J Radiat Oncol Biol Phys* 2009;73[5]:1304–1312. Copyright © 2009 Elsevier. With permission.)

Morice et al.[321] reported on 107 patients treated for cervical cancer with radical hysterectomy and lymphadenectomy, 104 of whom (98%) had ovarian transposition to the paracolic gutters performed. Preservation of ovarian function was achieved in 100% for patients treated exclusively by surgery, 90% for those treated by postoperative vaginal brachytherapy, and 60% for patients treated by postoperative EBRT and vaginal brachytherapy.

Ovarian transposition or oophoropexy has been performed using laparoscopy, achieving continued hormonal function in 68% (8 of 11) and 50% (3 of 6) of the patients.[322] Mean follow-up was 8.5 years, and mean radiation absorbed dose to the displaced ovaries was 26 Gy. Stockle et al.[323] performed laparoscopic lateral ovarian transposition during staging lymphadenectomy in 11 patients with carcinoma of the cervix treated with brachytherapy (11 cases), EBRT (9 cases), and chemotherapy (2 cases). Ovarian preservation was achieved in 30% of the cases. Age was the most predictive factor for ovarian function preservation. Pahisa et al.[324] performed laparoscopic ovarian transposition on 29 FIGO stage IB1 cervical cancer patients. After a mean follow-up of 44 months, ovarian

function was preserved in 93% of the nonirradiated and 64% of the irradiated patients.

Radiation Therapy Techniques

Since the early 1900s, radiation has been used in the curative management of cervical cancer, with a combination of external beam and brachytherapy resulting in the highest survival rates. Over the ensuing 100 years, treatment planning techniques have evolved, as has the equipment used for treatment. Several methods have been developed to aid with conformality and normal-tissue sparing. External irradiation is used to treat the whole pelvis. Structures treated include the uterus and cervix or, in the postoperative cases, the tumor bed, the vagina, the parametrial tissue, and the pelvic lymph nodes, including the internal, external, and common iliac nodes. In selected cases, the PALNs may be treated. In patients with locally advanced disease, in addition to external beam radiation, treatment of central disease (cervix, vagina, and medial parametria) relies heavily on dose given with intracavitary sources through brachytherapy. The techniques described apply, with some individualization, to most patients with locally advanced cervical carcinoma.

External Beam Irradiation

External beam treatments may be routinely administered to cervical cancer patients with stages IB2 to IVA in a curative fashion. Patients with stages IA to IB1 may be considered for external beam treatment if they are deemed inoperable or prefer to avoid surgery. Patients with stage IVB disease may receive palliative radiation to the pelvis for selected indications such as to stop vaginal bleeding, relieve pain, or alleviate urethral obstruction from extrinsic compression. External beam radiation covers the primary cervical tumor; treats any adjacent parametrial or uterosacral, uterine, or vaginal extension; and, most important, addresses microscopic disease present in pelvic lymph nodes. In treatment of invasive carcinoma of the uterine cervix, it is important to deliver adequate doses of irradiation not only to the primary tumor but also to the pelvic lymph nodes to maximize tumor control.

The initiation of external beam radiation typically precedes brachytherapy. Although brachytherapy may be interdigitated with external beam treatment, based on the desire to minimize the duration of treatment, the brachytherapy dose to the normal tissues may be better optimized after maximal tumor shrinkage; therefore, many institutions prefer to wait until the completion of 45-

Gy treatment before initiating brachytherapy, particularly for patients with large tumors.

Patient Positioning

Patients may be positioned in either the supine position for stability or the prone position on a belly board. The prone position aids in shifting the small bowel out of the pelvis. In patients who have had a hysterectomy, the small bowel may drop into the pelvic area. For those patients treated for cervical cancer with an intact cervix, the small bowel often lies superior to the uterus and above the pelvic brim, creating less need to shift the bowel out of the pelvis. For patients receiving IMRT, because of stability of the pelvis, the supine position is typically preferred with immobilization devices surrounding the pelvis to ensure minimal motion during treatment. IV contrast may be helpful to localize the pelvic vessels for contouring but is not routinely used in most centers. Oral contrast delineates the small bowel. Rectal contrast and placement of a Foley catheter for bladder contrast are not considered necessary in the majority of cases that use CT simulation because the outer wall of these normal-tissue structures can be contoured without contrast on CT.

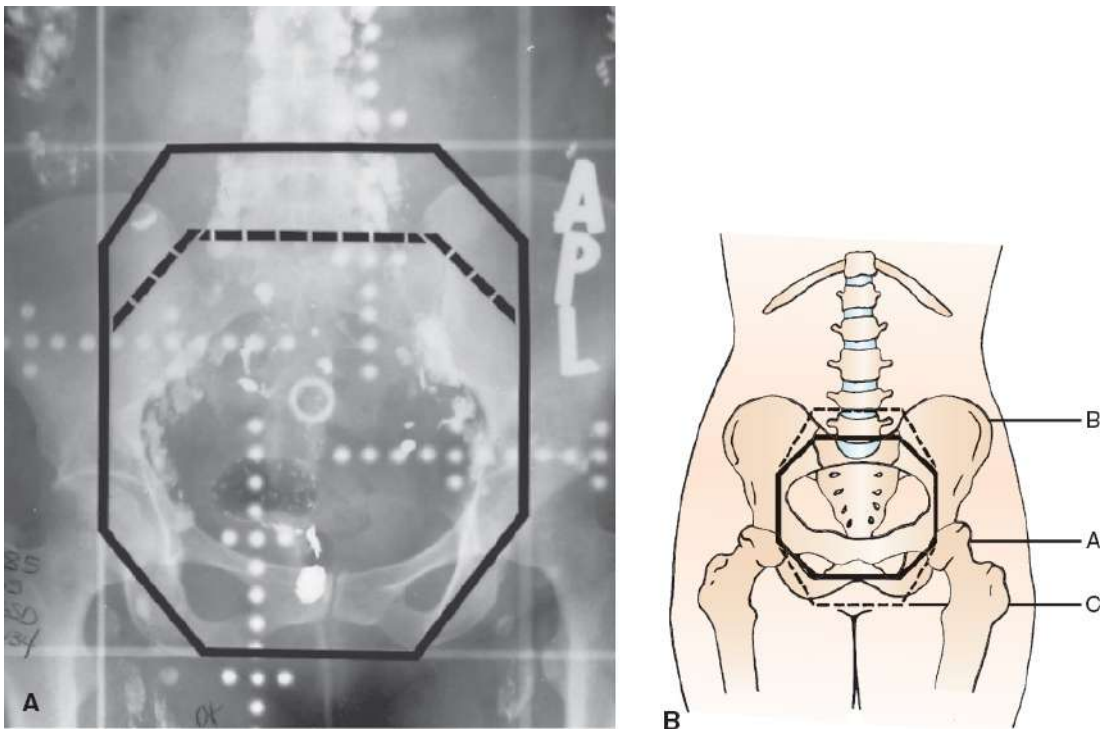

FIGURE 73.10. A: Anteroposterior simulation film of the pelvis illustrating portals used for external irradiation. The 15 by 15 cm portals at source-to-skin distance are used for stage IB (*broken line*), and 18 by 15 cm portals are used for more advanced

disease (*solid line*). This allows better coverage of the common iliac lymph nodes. The distal margin is usually placed at the bottom of the obturator foramina. **B:** Diagram of pelvic portals used in external irradiation of carcinoma of uterine cervix. Standard portal for stage IB tumors is outlined (*solid line indicated as A*). When the common iliac nodes are to be covered, the upper margin is extended to the L4-L5 space (*indicated in section B*). If there is vaginal tumor extension, the lower margin of the field is drawn at the introitus (*indicated in section C*).

Plain X-Ray Simulation

If CT is not available, simple plain film simulation may be performed. The standard plain radiographic simulation to the pelvis with x-rays, typically using opposed anterior–posterior/posterior–anterior (AP-PA) fields, results in comprehensive coverage of all pelvic regions. Because of the lack of visible soft tissue detail, contrast may be placed using barium in the rectum, a vaginal tube in the vagina, and/or a wire marker over surgical scars. The superior border is set at the L4-L5 interspace in order to cover the common iliac lymph nodes and the lateral borders 1.5 to 2 cm from the pelvic brim, and the inferior border covers at least the obturator foramen (Fig. 73.10). More commonly in patients with large tumors, the inferior border extends to the ischial tuberosities. When there is vaginal involvement, the entire length of this organ should be treated down to the introitus. It is very important to identify the distal extension of the tumor at the time of simulation by placing a radiopaque clip or bead on the vaginal wall or inserting a small fiducial marker in the vagina. When the tumor involves the distal half of the vagina, the portals should be modified to cover the inguinal lymph nodes because of the increased probability of metastases (see Fig. 73.2).

For the lateral field borders, in both postoperative and intact cervix settings, the posterior border must be set in such a way that the entire sacrum is covered because the uterosacral ligaments are at high risk for harboring microscopic extension. The uterosacral ligaments insert onto the sacrum, and therefore, the posterior block should ensure coverage of the entire sacrum. The anterior border on the lateral field should be set at a vertical line anterior to the pubic symphysis, because the external iliac lymph nodes must be covered.

For patients with para-aortic nodal involvement, simple plain film simulation followed by AP-PA treatments to the para-aortic nodal chain may overdose the kidneys, spinal cord, and small bowel. Dose escalation to para-aortic nodes to approximately >45 Gy is not feasible with AP-PA fields, given potential bowel complications. The use of four fields, including AP-PA and two lateral fields, is implemented as an alternative to AP-PA alone as a way to reduce some of the dose to the anterior small bowel. Patients receive oral barium approximately 30

minutes before the simulation to ensure blockage of as much small bowel as feasible superiorly. The superior border covers the renal hilum, often at the T12-L1 interspace, and the inferior borders cover the obturator foramen, unless there is distal vaginal or inguinal node involvement. For the para-aortic portion of the field, the anterior border rests 2 cm in front of the vertebral body or enlarged nodes as contoured, and posteriorly, the border bisects the midvertebral body. The pelvic portion mimics that described for the four-field pelvic setup. The use of lateral fields allows a decrease in dose to the small bowel, but care must be taken to include all structures of interest.[325–327]

Three-Dimensional Conformal Treatment Planning

CT simulation allows direct assessment of the pelvic vessels and by adjacent location the para-aortic and pelvic nodes. Oral contrast is beneficial to identify the small bowel. Cerrobend customized blocks or multileaf collimator blocking is used on each field to block the radiation to selected areas, including the skin, muscle, soft tissue, anterior small bowel, and portions of the anus and lower rectum (Fig. 73.11).

The superior border is set based on the CT-visualized bifurcation of the common iliac nodes into the external and internal iliac nodes, which may lie as high as the L3-L4 interspace. If patients have positive pelvic nodes based on PET imaging, the superior border may be shifted to either the superior border of the common iliac nodes or the superior aspect of the renal hilum to treat the para-aortic nodes. In postoperative cases in which the patient has had an extensive surgical staging, the superior border may be reduced to the L5-S1 interspace. Similar to plain x-ray simulation, in patients with vaginal involvement, the inferior border is extended to cover 2 cm below the lowest extent of disease, which may lie in the vulvar tissue, and in such cases, the inguinal lymph nodes are treated, resulting in a wider AP field.

On the lateral fields, the anterior border covers the front of the pubic symphysis. Bonin et al.,[328] in a review of 22 patients on whom detailed anatomic mapping of the anatomy of the pelvic lymph nodes was carried out by lymphangiography, concluded that if the criteria for adequacy of standard pelvic fields as defined in prior clinical trials were applied (anteroposterior: 1.5-cm margin on the pelvic rim; lateral field anterior edge is a vertical line anterior to the pubic symphysis and posterior border), 10 patients (45%) would have had inadequate nodal coverage in the irradiation fields. The incompletely irradiated lymph nodes were in the lowest lateral external iliac group. However, CT

simulation with contouring may prevent omission of these nodes.

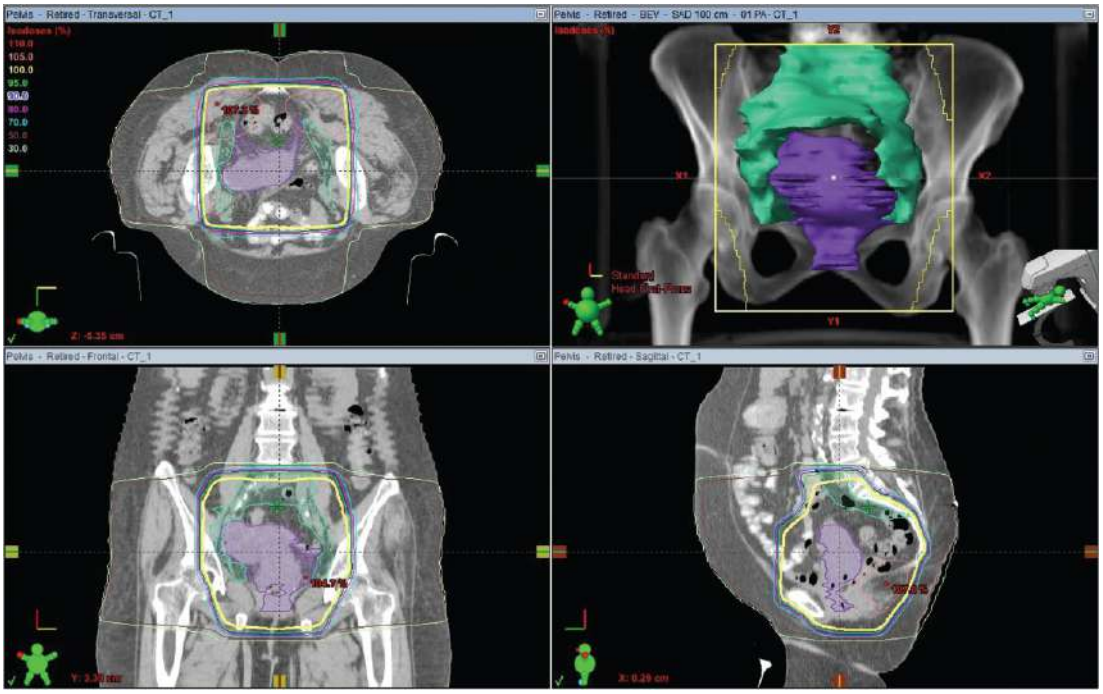

FIGURE 73.11. Anterior–posterior and lateral digitally reconstructed radiograph simulation film of the pelvis, illustrating portals used for external irradiation with the patient in the prone position on a belly board to minimize small-bowel dose. Pelvic lymph nodes are indicated in their approximate position. The uterus, cervix, and vagina are contoured to ensure adequate coverage.

For the lateral borders in postoperative and intact cervix cases, posterior coverage of the entire sacral hollow is imperative. Zunino et al.[329] reviewed the appropriateness of radiation therapy box technique for cancer of the cervix in 35 sagittal MRIs and 10 lymphangiograms. If the posterior border were to be placed at the S2-S3 interspace, for 50% of the patients with FIGO IB and in 67% with stage IIA disease, the posterior border of the lateral field would not adequately encompass the planning target volume (PTV). In stage IIB, the posterior border was inadequate in eight patients (42%). In patients with stage IIB and IVA disease, the PTV was not encompassed. Furthermore, Knocke et al.[330] used standard simulator planning guided by bony landmarks for pelvic irradiation in 20 patients with primary cervical carcinoma, stages I to III, using a four-field box technique. After defining the PTV with a 3D planning system, they compared the field configuration of the simulator planning with a second one based on the defined PTV. They evaluated the ability of the PTV to encompass the treatment volume (International Commission on Radiation Units and

Measurements [ICRU]). Planning by simulation resulted in 1 geographic miss, and in 10 more cases, the coverage of the PTV by the treatment volume was inadequate.

Finlay et al.[331] contoured pelvic blood vessels on CT scans as surrogates for lymph nodes in 43 patients and found this to be more accurate than bony landmarks for field delineation. In total, 95% of patients planned with conventional fields had inadequate coverage of some portion of lymph node coverage, whereas 56% additional normal tissue was treated that did not require radiation. Therefore, most centers implement 3D simulation when feasible. Taylor et al.[332] used MRI to outline the pelvic lymph nodes in 20 patients and noted that with margins of 10 mm, nodal coverage was 94% and with 15 mm, 99%; with a modified 7-mm margin, they ensured 99% nodal coverage with less volume of small bowel at risk.

In the postoperative setting, van den Berg et al.,[333] using 47 lymphangiograms and 15 CT scans, asked radiation oncologists (n = 17) to define the CTV and PTV and to delineate on simulation films the RT treatment portals to be used after a radical hysterectomy with lymph node dissection for stage IB or IIA cervical carcinoma with positive iliac lymph nodes. Large variations were observed in the portals used and in treatment techniques. From the digitized films, it appeared that in 50% of the cases, the defined PTV was not covered adequately. Furthermore, 71% of the treatment plans would not cover the lateral borders of the reference PTV sufficiently. Thus, there is a need for careful adherence to standardized guidelines.

Treatment techniques may have an effect on outcome. Yamazaki et al.[334] compared 34 patients with cervical cancer treated with irregularly shaped four-field whole-pelvis radiation therapy using CT simulation and 40 patients receiving whole-pelvis EBRT with parallel-opposed fields in a nonrandomized study of postoperative radiation therapy consisting of 50 Gy in 25 fractions in 6 weeks. With a mean follow-up of 60 months, the actuarial 5-year pelvic tumor control was 94% with the two-field technique and 100% for the irregularly shaped four-field technique. The incidence of grade 2 or 3 bowel complications in the irregularly shaped technique group (2.9%, 1 of 34) was significantly lower than that in the two-field technique group (17.5%, 7 of 40; $P < .05$).

Burnett et al.[335] described a prosthetic silicone plastic device that is filled with saline and Renografin for x-ray visualization (capacity between 750 and 1,500 mL) to conform to the pelvis and exclude the small bowel from the irradiated volume. The device remains in place throughout the radiation therapy

course and is removed through a small incision after draining the contents of the prosthesis. Seven devices had been placed to date of the report. In the postoperative period, there was one pulmonary embolism. All seven patients completed planned radiation therapy. The devices have been removed with no adhesions to the prosthesis.

Intensity-Modulated Radiation

IMRT was developed using the techniques required for inverse planning. That is, one starts with the necessary dose around the target and then works backward to develop the requisite beam intensities. IMRT spatially modulates the intensity of the beam using the motion of multileaf collimators. Because of the increasing use of intensity-modulated or image-guided radiation therapy (IMRT/IGRT) including volumetric arc therapy (VMAT) in the treatment of patients with gynecologic malignancies, there is growing emphasis on imaging the pelvic anatomic structures, including lymph nodes, for treatment planning.[336] IMRT may reduce the amount of small bowel and bone marrow that receives the full dose of radiation.

The use of IMRT has been standardized in the postoperative setting and is more frequently used for intact cervix cases though caution must be exercised to cover the full uterosacral ligaments and to provide a large enough anterior margin to account for shifts in uterine anatomy. What constitutes adequate margins in the intact cervix setting continues to be a matter of concern, given significant organ motion during treatment. Uncertainties in the definition of target volumes arise using 3D techniques. Bladder filling and rectal filling changes require accurate definition of margins for the PTV.[337] Beadle et al.[338] found that mean maximum changes in the center of the cervix were 2.1, 1.6, and 0.82 cm in the superior–inferior, anterior–posterior, and right–left lateral dimensions, respectively. Mean maximum changes in the perimeter of the cervix were 2.3 and 1.3 cm in the superior and inferior, 1.7 and 1.8 cm in the anterior and posterior, and 0.76 and 0.94 cm in the right and left lateral directions, respectively. Haripotepornkul et al.[339] found in 10 women with locally advanced cervical cancer that within and between radiation treatments, cervical motion averages approximately 3 mm but may be up to 18 mm in any given direction. The mean intrafractional movements in cervical seed positions in the lateral, vertical, and AP directions were 1.6 mm (standard deviation [SD] ± 2.0), 2.6 mm (SD ± 2.4), and 2.9 mm (SD ± 2.7), respectively, with a range from 0 to 15 mm for each direction. The mean interfractional movements in the lateral, vertical,

and AP directions were 1.9 mm (SD ± 1.9), 4.1 mm (SD ± 3.2), and 4.2 mm (SD ± 3.5), respectively, with a range from 0 to 18 mm for each direction. Tyagi et al.[340] show that a uniform CTV planning treatment volume margin of 15 mm would not encompass the cervical CTV in 32% of fractions. with IMRT, there is a need for continual replanning (at least every other week), given rapid tumor regression and internal-organ motion.[341–343] The dosimetric effect of organ motion during intact IMRT for cervical cancer was studied in 10 patients. With 10- to 15-mm PTV margins, significant CTV underdosing was identified during treatment, primarily because of changes in bladder volume. Larger margins of up to 2–3 cm in the AP direction and bladder volumes at 150 to 300 cc are recommended.[344]

After a CT and/or MRI scan for simulation, the images are brought into a treatment planning workstation. Contouring the gross tumor volume (GTV) on MRI may include the uterus, cervix, and/or vagina. Lim et al.[345] had 19 experts in gynecologic radiation oncology contour a case of locally advanced cervical cancer on axial MRI of the pelvis. Substantial Simultaneous Truth and Performance Level Estimation (STAPLE) agreement sensitivity and specificity values were seen for GTV delineation (0.84 and 0.96, respectively) with a kappa statistic of 0.68 ($P < .0001$). Agreement for delineation of cervix, uterus, vagina, and parametria was moderate. The greatest variability in physician contouring was in the parametrial tissue.[345]

The CTV for the pelvic lymph nodes was based on the Radiation Therapy Oncology Group (RTOG) atlas for the female postoperative pelvis.[346] An example of dose distribution achieved with supine IMRT pelvic irradiation is illustrated in Figure 73.12. Fiducial markers may be placed in the apex of the vagina for identification on CT scan and show up to 3.5 cm of vaginal cuff motion during treatment.[347] Therefore, for postoperative patients, the vagina is contoured using a full-bladder CT scan fused to an empty-bladder CT scan to account for vaginal mobility because of differences in bladder filling.[348] This vaginal target volume has been referred to as an integrated target volume (ITV). The expansion of the CTV and/or ITV to the PTV is necessary, although given the movement of the uterus, the exact amount of margin is a matter of debate. Generous margins of approximately 2 to 3 cm are considered, particularly in the regions of the uterus and cervix or in the postoperative case around the ITV vagina. In order to cover the uterosacral ligaments, the rectum cannot be spared. Rectal filling with gas may change the position of the anterior rectal wall over 5 cm during treatment. Dose constraints required for an optimal IMRT plan have

not been standardized. In the RTOG postoperative clinical trial 0921 using IMRT,[349] a PTV of 7 mm around the nodal contours is recommended, and the dose is prescribed to cover 97% of the vaginal PTV and nodal PTV. A volume of 0.03 cc within any PTV should not receive >110% of the prescribed dose. No more than 0.03 cc of any PTV will receive <93% of its prescribed dose. Any contiguous volume of 0.03 cc or larger of the tissue outside the vaginal/nodal PTVs must not receive >110% of the dose prescribed to the vaginal/nodal PTV; for normal tissues, the small/large bowel (30% of the entire bowel volume must not receive >40 Gy), rectum/sigmoid (60% of the rectosigmoid volume must receive ≤40 Gy), bladder (35% of the bladder volume must receive ≤45 Gy), and femoral head (15% of the femoral head volume must receive <35 Gy) constraints are being tested in RTOG 0921. Careful attention must be paid to all normal-tissue organ motion because the bladder and rectum may have 3- to 5-cm shifts because of filling changes in a short time frame.

For patients that have had a diagnostic PET or MRI before the simulation, these images may be registered to create a fused dataset for contouring, particularly when a nodal boost is required. This allows the physician to visualize areas of PET enhancement or tumor volume, as seen on the MRI, onto the simulation films. Grigsby et al.[350] use a PET-defined target volume contoured with a metabolically active tumor specified at the 40% threshold. Normal-tissue structures, including the rectum, sigmoid, bladder, and small bowel, are routinely contoured for patients treated with IMRT who will be undergoing a nodal boost in order to limit the dose received primarily to the small bowel. Based on an overview of published data, the absolute volume of small bowel receiving ≥15 Gy should be held to <120 cc when possible to minimize severe acute toxicity if delineating the contours of bowel loops themselves. Alternatively, if the entire volume of peritoneal space in which the small bowel can move is delineated, the volume receiving >45 Gy should be <195 cc when possible.[351] For the rectum, dose–volume constraints selected as a conservative starting point that have not yet been validated for 3D treatment planning include V_{50} < 50%, V_{60} < 35%, V_{65} < 25%, V_{70} < 20%, and V_{75} < 15%.[352] No dose constraint for external beam planning for the bladder could be identified, although the limits for prostate cancer may be adopted for gynecologic IMRT, including a dose constraint of no more than 15% of the volume to receive a dose >80 Gy, no more than 25% of the volume to receive a dose >75 Gy, no more than 35% of the volume to receive a dose >70 Gy, or no more than 50% of the volume to receive a dose >65 Gy.[353]

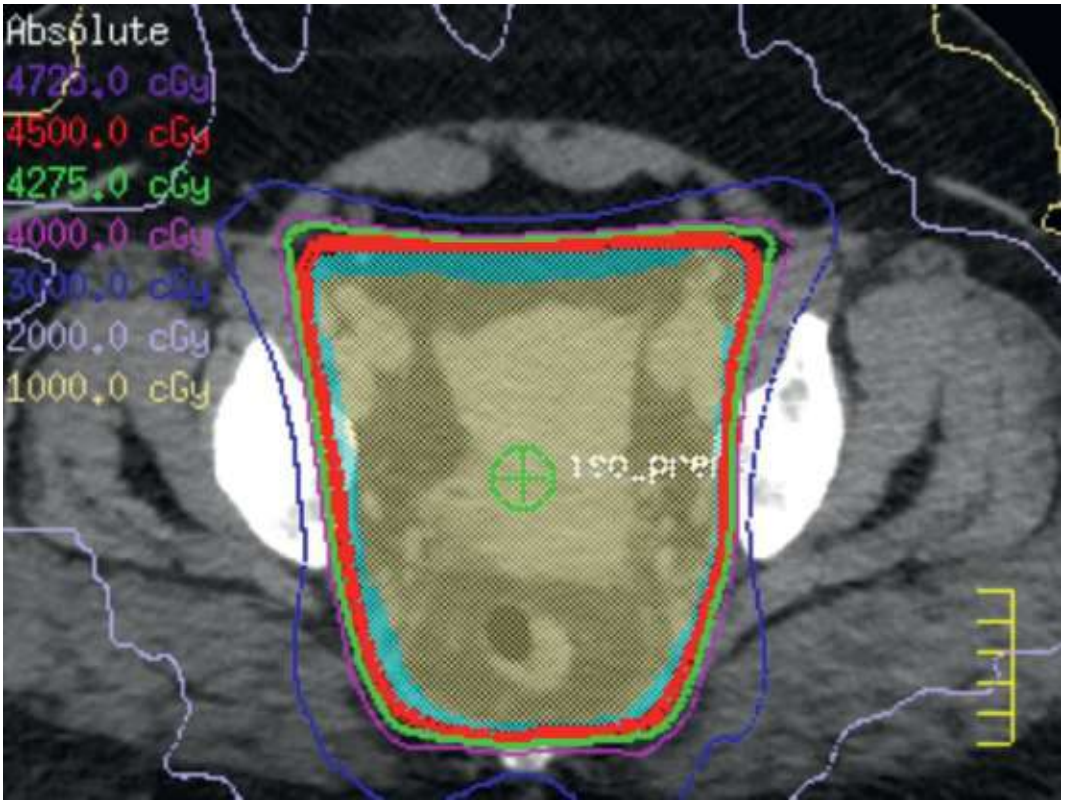

FIGURE 73.12. Intensity-modulated radiation therapy treatment plan for external irradiation of pelvic lymph nodes while sparing organs at risk. Note margins required to cover uterosacral ligaments posteriorly while accounting for organ motion with daily cone beam imaging.

Imaging may guide more accurate definition of lymph nodes.[332] Portelance et al.[299] carried out IMRT as well as conventional planning with two- and four-field techniques in 10 patients. Prescription was 45 Gy in 25 fractions to the uterus and the pelvic and PALNs. All IMRT plans were normalized to obtain a full coverage of the cervix with the 95% isodose curve (Fig. 73.13A). The volumes of the small bowel receiving the prescribed dose (45 Gy) with IMRT para-aortic–only technique were, with four fields, 11%; with seven fields, 15%; and with nine fields, 13.5% (Fig. 73.13B). These dose distributions were all significantly better than with two-field or four-field conventional techniques ($P < .05$). Ahmed et al.[354] arrived at similar conclusions in five patients with para-aortic node metastasis, and they demonstrated the feasibility of escalating the dose to 60 Gy while sparing the kidneys, spinal cord, small bowel, and bone marrow. Heron et al.,[355] in a study of 10 patients, showed that with IMRT there was a reduction of 52% in the small-bowel volume receiving >30 Gy and a decrease of 66% for the rectum and 36% for the bladder compared with 3D radiation therapy. D'Souza et al.,[356] in 10 patients, also noted a reduction of

small-bowel volume (33%) with IMRT compared with four-field pelvic RT; however, small volumes of bowel received 55 to 60 Gy with the IMRT plans. Positioning the patient prone on a belly board was shown to reduce the volume of small-bowel irradiated. However, patients on a belly board may have large daily anatomic shifts that make prone IMRT unreproducible.[357]

Brixey et al.[358] and Lujan et al.[359] also used IMRT planning to spare the bone marrow of patients with gynecologic tumors. Brixey et al.,[358] in 36 patients, noted no significant difference in hematologic toxicity with IMRT or conventional RT alone; however, in patients receiving chemotherapy, less grade 2 white blood cell toxicity was observed with IMRT (31.2% vs. 60%, respectively. PET-detected bone marrow was spared using an atlas).[360] In a single-arm phase II study of 83 patients, with median follow-up of 26.0 months, the incidence of grade ≥3 neutropenia and clinically significant GI toxicity was 19.3% (95% confidence interval [CI], 12.2% to 29.0%) and 12.0% (95% CI, 6.7% to 20.8%), respectively. Compared with patients treated without IG-IMRT (n = 48), those treated with IG-IMRT (n = 35) had a significantly lower incidence of grade ≥3 neutropenia (8.6% vs. 27.1%; 2-sided χ^2 P = .035) and nonsignificantly lower incidence of grade ≥3 leukopenia (25.7% vs. 41.7%; P = .13) and any grade ≥3 hematologic toxicity (31.4% vs. 43.8%; P = .25).[361]

Hasselle et al.[362] report on 111 patients treated with multiple different approaches, including 22 treated with postoperative IMRT, 8 with IMRT followed by intracavitary brachytherapy and adjuvant hysterectomy, and 81 with IMRT followed by planned intracavitary brachytherapy. Median follow-up time was 27 months. Acute and late grade 3 toxicity or higher was 2% (95% CI, 0% to 7%) and 7% (95% CI, 2% to 13%), respectively. Guerrero et al.[363] proposed using an IMRT simultaneous integrated boost (SIB) as an alternative to conventional whole-pelvis irradiation and used the linear quadratic equation to calculate equivalent uniform dose in multiple plans. However, a report by Kavanagh et al.[364] found that accelerated fractionation caused an unacceptably high rate of complications. A combination of an SIB to approximately 50 Gy followed by a sequential boost to 60 to 65 Gy has been shown to be feasible to both pelvic and para-aortic nodes. Caution in the pelvis when also administering brachytherapy is required to ensure bowel dose is limited, and in the para-aortic region, rapid shrinkage of the tumor may result in movement of bowel into the boost field, and replanning immediately prior to beginning the sequential portion of the boost is recommended.[365,366]

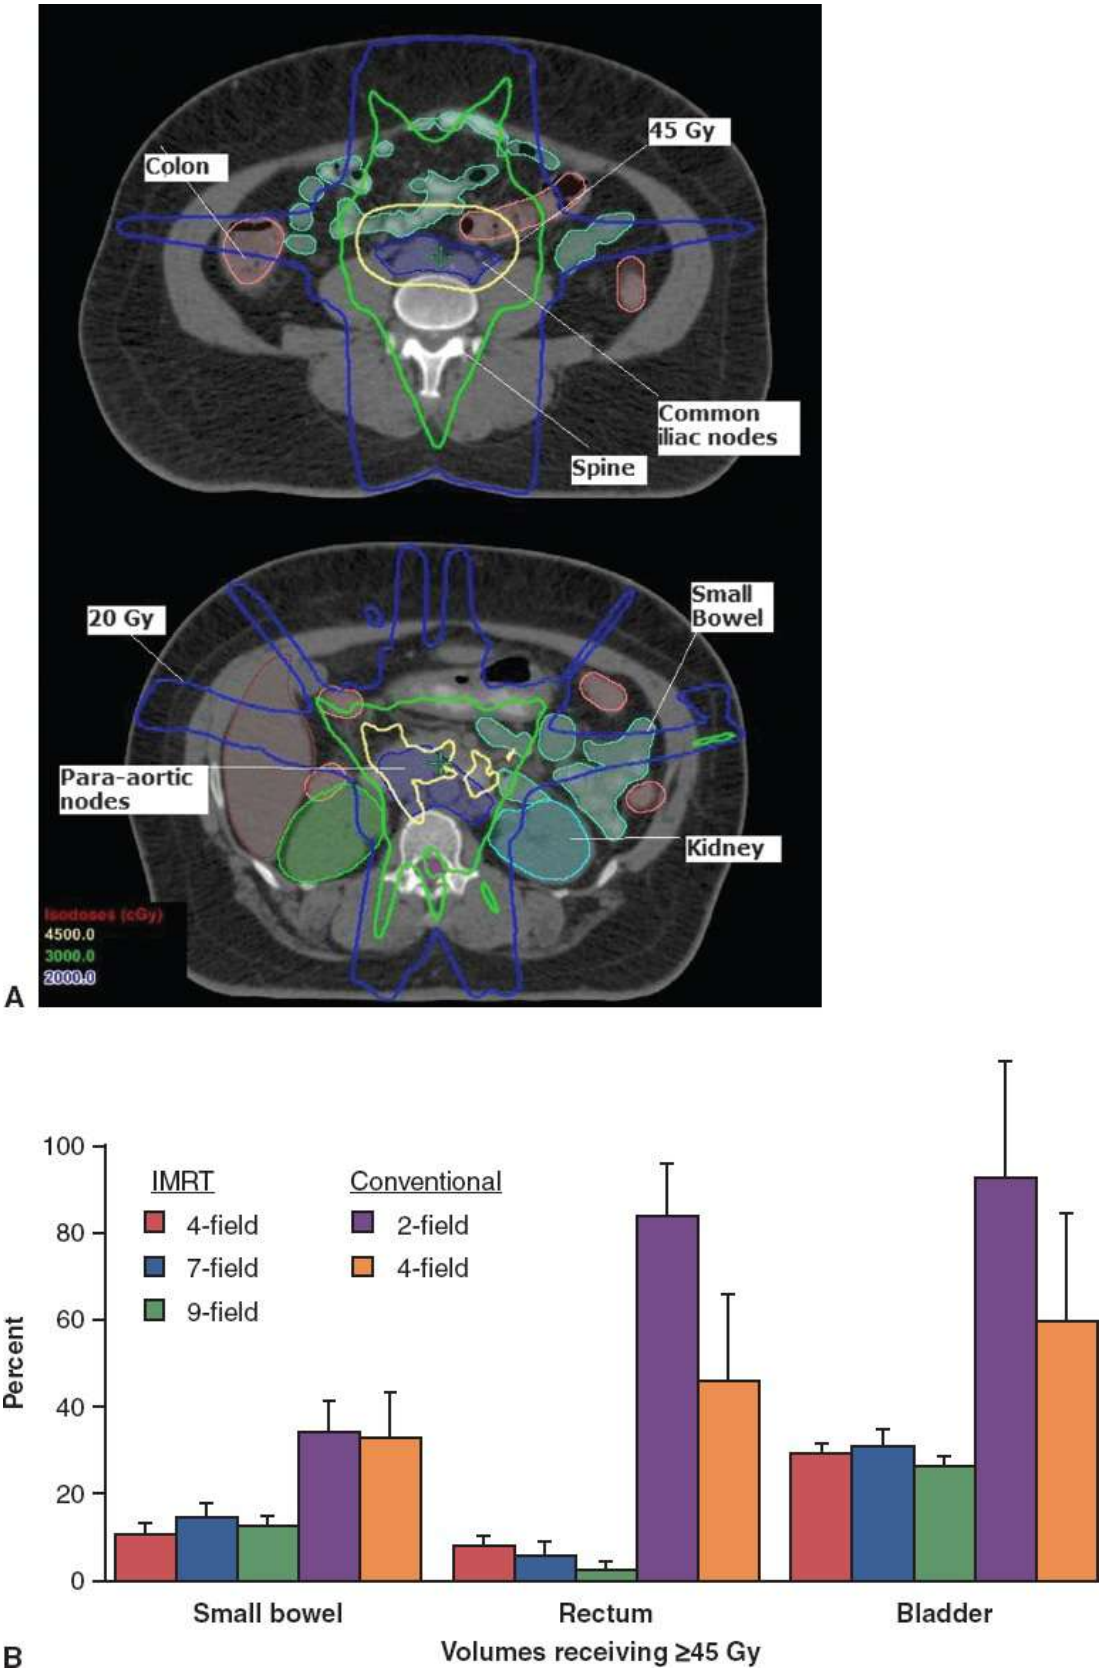

FIGURE 73.13. **A:** Axial views of IMRT dose distribution. **B:** The functional volume of

the small bowel, rectum, and bladder receiving ≥45 Gy with IMRT or conventional techniques when 100% of the target volume (uterus) receives ≥95% of the prescription dose (45 Gy). (Reprinted from Portelance L, Chao KSC, Grigsby PW, et al. Intensity-modulated radiation therapy [(IMRT)] reduces small bowel and bladder doses in patients with cervical cancer receiving pelvic and para-aortic irradiation. *Int J Radiat Oncol Biol Phys* 2001;51[1]:261–266. Copyright © 2001 Elsevier. With permission.)

Postoperative IMRT with cisplatin was reported in 34 patients with stage IA2 to IIA cervical cancer; 5 year disease-free and overall survival was 91%. One patient (2.9%) had a grade 3 side effect (proctitis).[367]

Although IMRT has dosimetric advantages over conventional RT, IMRT exposes a greater amount of normal tissues to lower irradiation levels, which has the potential to increase the incidence of radiation-induced second cancers,[368] a phenomenon already described with conventional RT techniques.[369]

Image-Guided Radiation Therapy

Although not always available, daily cone-beam CT imaging for in-room image-guided RT (IGRT) permits visualization of bladder and rectum.[370] Particularly in cases with a large, mobile uterus, such as is seen in young women, if an extended field is used and there is concern that the uterus may be out of the field, this may be instituted helpful to confirm full coverage of the CTV daily. When IMRT is used for locally advanced cervical cancer, the priority should be to treat with wide margins, so that the field mimics that of a 3D conformal (four-field) plan in order to ensure no increase in the risk of local recurrence.[340] IGRT daily may demonstrate organ motion, but criteria for replanning have not been defined.

Stereotactic body radiotherapy (SBRT) uses highly conformal treatments with large fraction sizes and in selected cases has been considered for a nodal boost of an isolated para-aortic node, although care must be taken to treat the entire para-aortic chain to 45 Gy with IMRT or 4 Field (4F) prior to considering an SBRT boost in order to ensure eradication of adjacent micrometastatic disease.[371] SBRT should not be used instead of brachytherapy, given the significant increase in normal-tissue doses with SBRT compared to brachytherapy.[372]

Midline Shielding in AP-PA Portals and Use of a Parametrial Boost

Depending on the institution and brachytherapy dose administered, midline shielding with rectangular or specially designed blocks has been traditionally used for a portion of the external beam dose delivered with the AP-PA ports.[326]

Midline blocks may be individualized, based on the point A isodose line or a rectangular block of approximately 4-cm width. In one series, overall survival and incidence of chronic complications were not related to the type of shielding.[373] However, in the era of 3D brachytherapy planning, the use of a midline block has been questioned because it may result in tumor underdosing while still contributing significant dose to the bladder, sigmoid, and rectum.[374]

Several institutions reported placing a midline block after a full course of external beam treatment to the pelvis in order to boost the parametria or nodes for patients with persistent disease after approximately 45 to 50 Gy. When parametrial tumor persists, 50 to 60 Gy may be delivered to the parametria, with reduced anteroposterior/posteroanterior portals (8 by 12 cm for unilateral and 12 by 12 cm for bilateral parametrial coverage). However, careful estimation of dose to the small bowel, sigmoid, and rectum is needed. In the modern era, the use of highly conformal boosts with 3D planning allows an increase in normal-tissue sparing. Contours on CT of the parametrial and nodal region allow more precise tailoring of dose. For patients with enlarged nodes, when available, IMRT techniques may be best at providing conformal dose escalation to 54 to 65 Gy.

Similarly, with 3D brachytherapy and computerized optimization as available with high HDR or pulsed dose rate (PDR) brachytherapy, the physician may cover the adjacent parametria using large enough fraction sizes that an additional external beam boost is not needed. When one prescribes HDR brachytherapy, the per fraction nodal dose is approximately 25% of prescription. In one study, the per fraction dose to the pelvic lymph nodes by HDR brachytherapy, when the high-risk clinical target volume (HR-CTV) received 5.5 Gy per fraction, was 1.4 Gy per fraction. Therefore, HDR brachytherapy may obviate the need for a parametrial boost, given the high per fraction dose to the parametria and pelvic sidewall.[374]

In a comparison of three different approaches, Fenkell et al.[375] reported on parametrial boost with midline shielding in six patients with locally advanced cervical cancer (IIB to IIIB) treated with definitive chemoradiotherapy and MRI-guided brachytherapy. A three-phase plan was modeled: 45-Gy (1.8 Gy per fraction) four-field box, 9-Gy (1.8 Gy per fraction) midline-shielded anteroposterior/posteroanterior fields (MBB), and intracavitary MRI-guided brachytherapy boost of 28 Gy (7 Gy per fraction). Midline shields 3, 4, and 5 cm wide were simulated for each patient. Brachytherapy and MBB plans were volumetrically summed. After a 4-cm MBB, HR-CTV D_{90} remained <85 Gy in

all cases (mean, 74 Gy; range, 64 to 82 Gy). Bladder, rectum, or sigmoid D_{2cc} increased by >50% of the boost dose in four of six patients. The authors concluded that a midline block may not be beneficial in patients receiving 3D image-planned brachytherapy with adequate optimization of dose to the tumor and away from the normal tissues.

Para-aortic Lymph Node Irradiation

If para-aortic node metastases are enlarged or suspected to harbor disease, patients are treated with 45 to 50 Gy to the para-aortic area plus a sequential 5- to 10-Gy boost to enlarged lymph nodes through reduced lateral or rotational portals.[302] If feasible, 3D planning with IMRT treatment is preferred to spare normal tissues, superiorly covering above the level of the renal hilum or the highest extent of disease and inferiorly covering 2 cm below the lowest extent of disease (Fig. 73.14).

The use of IMRT has allowed dose escalation to para-aortic nodes, particularly unresectable nodes. Clinical reports show excellent control of disease with dose escalation, with one report demonstrating an 85% 2-year nodal control rate after IMRT with a median dose of 63 Gy.[376] Esthappan et al.[298] described a technique using CT and FDG-PET to treat the PALNs (50.4 and 59.4 Gy) with IMRT (Fig. 73.15). Acceptable dose distribution of the target volumes and sparing of the stomach, liver, and colon were achieved. Sparing of the spinal cord was dependent on the number and arrangements of the beams, as it was for the small bowel, sparing of which was limited because of overlap with the target volume. Adjusting the number of beams and prescription parameters minimally improved kidney sparing.

When only conventional techniques are available, the PALNs are irradiated either with an extended field, often using a four-field approach, that includes both the para-aortic nodes and the pelvis or through a separate portal (Fig. 73.16).[326,377] This may be done as one long field, or in cases requiring extended distance, one may instead choose to separate the pelvic and para-aortic fields. This requires a “gap calculation” between the pelvic and para-aortic portals to avoid overlap and excessive dose to the small intestines. The upper margin of the field is at the T12-L1 interspace to reach the infrarenal hilum and the lower margin at L5-S1. The width of the para-aortic portals (in general, 8 to 10 cm) can be determined by CT scans, MRI, lymphangiography, FDG-PET scans, or IV pyelography outlining the ureters with the goal to treat all tissue between the right and left psoas muscle. The spinal cord dose (T12 to L2-L3) should be kept

to <45 Gy by interposing a 2-cm-wide 5–half-value-layer shield on the posterior portal (usually after 40-Gy tumor dose) or using lateral ports and limiting the kidney dose to <18 Gy. A technique using four isocentric fields weighted 2:1 anteroposterior/posteroanterior over lateral portals and 1.8-Gy fractions was described by Russell et al.[378] to deliver high-dose therapy (56 to 61 Gy). Kodaira et al.[379] evaluated a four-field para-aortic irradiation technique with 10-MV photons (mean, 50.4 Gy) in 97 patients with cervical cancer. The 5-year CSS rate was 32.2%. Grade 1 or 2 stomach and duodenum sequelae developed in 26.8%, grade 2 sequelae of small bowel in 3.1%, and grade 2 sequelae of bone in 3.1%. Rates of toxicity with IMRT are lower though dose escalation with a simulataneous integrated boost to large nodes next to the duodenum must be done with caution given the risk of duodenal perforation.[302]

Beam Energies

For IMRT, 6-MV energy is used to provide the most homogeneous dose. However, in conventional irradiation, because of the thickness of the pelvis, high-energy photon beams (10 MV or higher) are especially suited for this treatment. They decrease the dose of radiation delivered to the peripheral normal tissues (particularly bladder and rectum) and provide a more homogeneous dose distribution in the central pelvis. With lower-energy photons (^{65}Co or 4- to 6-MV x-rays), higher maximum doses must be given, and more complicated field arrangements should be used to achieve the same midplane tumor dose (three-field or four-field pelvic box or rotational techniques) while minimizing the dose to the bladder and rectum and to avoid subcutaneous fibrosis (Fig. 73.17).[380] Biggs and Russell[381] noted that the presence of a metallic prosthesis when using lateral fields or a box pelvic irradiation technique may result in a dose decrease of approximately 2% for 25-MV x-rays and average increases of 2% for 10-MV x-rays and 5% for ^{65}Co. Allt[382] and Johns,[383] in an update of a randomized study, reported better pelvic tumor control and survival and fewer complications in 65 patients with stage IIB and III cervical carcinomas treated with 23-MV photons compared with 61 treated with external irradiation with ^{65}Co in addition to brachytherapy in both groups. In contrast, Holcomb et al.[380] compared outcome of 195 patients with stage IIB and IVA cervical carcinomas treated with ^{65}Co radiation therapy (group 1) and 53 treated with linear accelerators (group 2). There was no significant difference in overall survival, although there was a trend toward increasing pelvic recurrence in the ^{65}Co group (50.8%) compared with group 2 (35.8%; P = .08). Mixed beam external radiation with neutrons and

photons resulted in unacceptably high toxicity rates and is not recommended.[384] Similarly, carbon ion therapy was reported but resulted in major intestinal complications.[385]

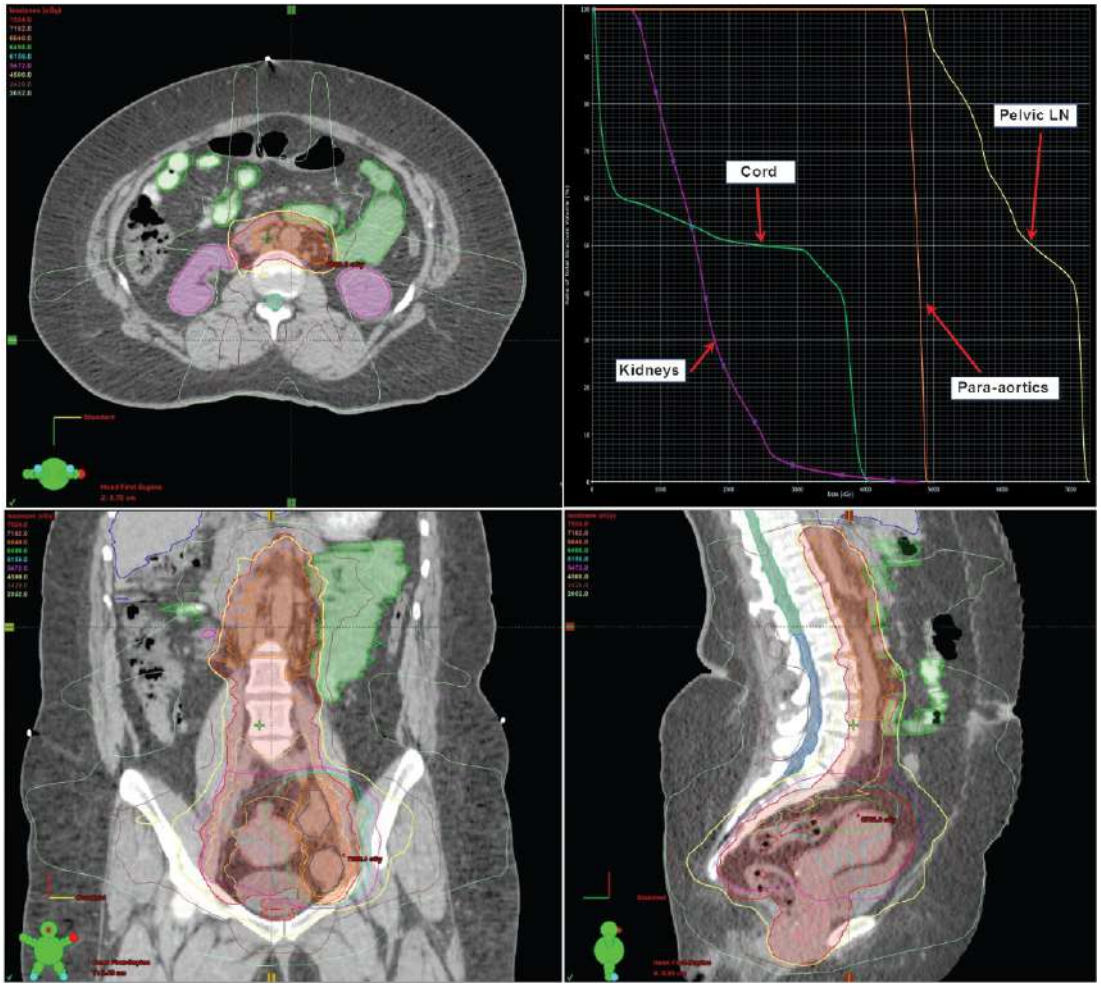

FIGURE 73.14. Extended-field IMRT for external irradiation of uterine cervix and pelvic and para-aortic lymph nodes. Dose–volume histogram values for the spinal cord, kidneys, para-aortic nodes, and pelvic node boost are shown for a patient who had an unresectable 4-cm pelvic lymph node.

Hyperfractionated or Accelerated Hyperfractionated Radiation Therapy

MacLeod et al.[386] reported on a phase II trial of 61 patients with locally advanced cervical cancer treated with accelerated hyperfractionated radiation therapy (1.25 Gy administered twice daily at least 6 hours apart to a total pelvic dose of 57.5 Gy). A boost dose was administered with either low–dose rate (LDR) brachytherapy or EBRT to a smaller volume. Thirty patients had acute toxicity that required regular medication. One patient died of acute treatment-

related toxicity. The overall 5-year survival was 27%, relapse-free survival was 36%, and actuarial local tumor control was 66%. There were eight severe late complications observed in seven patients, who required surgical intervention (actuarial rate of 27%). Five patients also required total hip replacement.

A: Example of treatment plan with IMRT for irradiation of para-aortic lymph nodes. **B:** Dose–volume histogram illustrating sparing of kidney and small intestine and dose escalation with nodal boost. (Reprinted from Mutic S, Malyapa RS, Grigsby PW, et al. PET-guided IMRT for cervical carcinoma with positive para-aortic

lymph nodes—a dose-escalation treatment planning study. *Int J Radiat Oncol Biol Phys* 2003;55[1]:28–35. Copyright © 2003 Elsevier. With permission.)

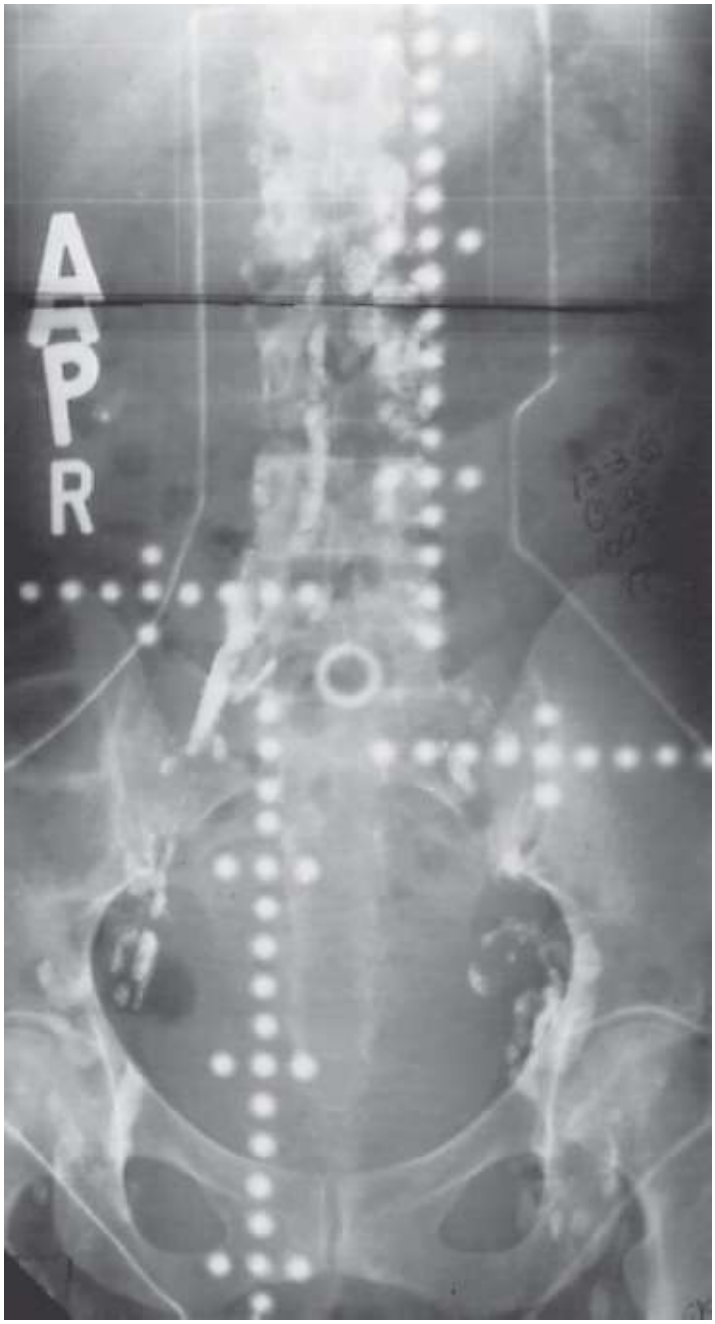

FIGURE 73.16. Extended field simulated with conventional plain films for external irradiation of pelvic and para-aortic lymph nodes.

Another study reported on 30 patients with stage II or III cervical cancer randomized to receive either hyperfractionation (15 patients) or conventional fractionation (15 patients).[387] At 5 years, two patients in the hyperfractionation

group and eight patients in the conventional treatment group had recurrent tumor (P = .04). Delayed bowel complications (grade 2 and 3) occurred in nine women in the hyperfractionation group and two patients in the conventional group (P = 0.0006).

RTOG 88-05 conducted a phase II trial of hyperfractionation (1.2 Gy to the whole pelvis twice daily at 4- to 6-hour intervals, 5 days/week) with brachytherapy in 81 patients with locally advanced carcinoma of the cervix. Total dose to the whole pelvis was 24 to 48 Gy, followed by one or two LDR intracavitary applications to deliver 85 Gy at point A and 65 Gy to the lateral pelvic nodes. Grigsby et al.[388] updated the results and noted that external irradiation was completed in 71 cases (88%). The 5-year cumulative rate of grade 3 and 4 late effects for patients with stage IB2 or IIB tumors was 7% and at 8 years was 10%, and with stage III or IVA disease, it was 12% at 5 years. The absolute survival was 48% at 8 years, and DFS was 33%. Comparison with historical control patients treated on other RTOG studies showed equivalent rates of pelvic tumor control, survival, and grade 3 and 4 toxicities at 3, 5, and 8 years, respectively.

Calkins et al.[389] assessed the toxicities of multiple daily fractionated (twice-daily, 1.2-Gy fractions) whole-pelvis radiation plus concurrent chemotherapy for locally advanced carcinoma of the cervix. In the first study (GOG 8801), for 38 patients, hydroxyurea was given orally (80 mg/kg to a maximum of 6 g) at least 2 hours before irradiation, twice every week. In the second study (GOG 8901), for 30 patients, cisplatin and fluorouracil (5-FU) were used concomitantly with RT. Acute toxicity was primarily enteric and appeared to be dose related. The maximum tolerated dose of whole-pelvis radiation that could be delivered in a hyperfractionated setting with concomitant chemotherapy was 57.6 Gy in 48 fractions, followed by brachytherapy.

Thomas et al.[390] conducted a four-arm study in which 234 women with bulky stage IB to IVA cervical cancer were randomized to receive either standard RT (EBRT and brachytherapy to deliver 90 Gy to point A) with or without a 4-day infusion of 5-FU (1 g/m^2) on days 1 to 5 and 22 to 25 or partially hyperfractionated RT with or without the same chemotherapy regimen. The partially hyperfractionated regimen delivered two fractions, 6 hours apart, on the first 4 days of treatment, coinciding with the infusion of 5-FU. The addition of 5-FU did not improve pelvic tumor control (37% to 75% at 5 years) or overall survival. However, this study closed without reaching target patient accrual. A concomitant boost technique was reported by Kavanagh et al.[364] but had an

unacceptably high rate (8 of 20 patients) of late complications.

GENERAL MANAGEMENT

Carcinoma *In Situ*

Patients with persistent high-grade carcinoma *in situ* are usually treated with a total abdominal hysterectomy with or without a small portion of the upper vagina removed. The decision to remove the ovaries depends on the age of the patient and status of the ovaries. Occasionally, when the patient wishes to have more children, carcinoma *in situ* may be treated conservatively with a therapeutic conization,[391] laser therapy, or cryotherapy.[392] This approach should be judiciously selected when the extent of tumor allows it and the patient is reliable for continued follow-up.[393] Conization microscopic margins are critical in decision-making regarding a conservative approach or proceeding with a hysterectomy. A therapeutic hysterectomy can be performed 6 weeks after the conization.

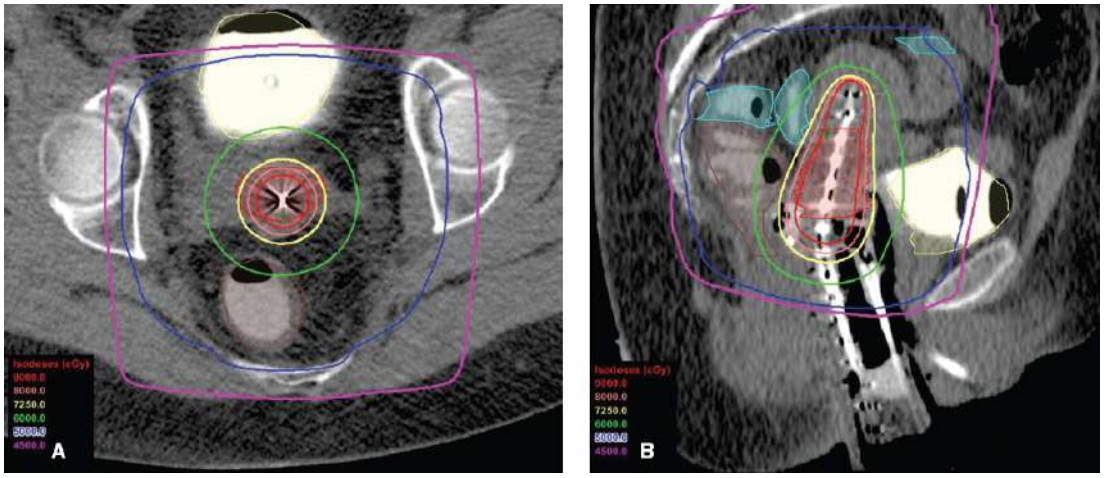

FIGURE 73.17. Example of isodose curves of 4F box irradiation of the pelvis with high-energy photons and CT-based high–dose rate brachytherapy optimized to cover the tumor and minimize dose to the bladder and rectum. **A:** Axial. **B:** Coronal view.

Irradiation may be useful for the treatment of carcinoma *in situ*, particularly in patients with strong medical contraindications to surgery or when there is extension of the lesion to the vaginal wall or multifocal carcinoma *in situ* in both the cervix and the vagina.[326,394] In a group of 26 patients with carcinoma *in situ* treated at Washington University with intracavitary brachytherapy alone (~5,000 milligram-hours [mgh], 45 Gy to point A with LDR) with tandem and ovoids, no recurrences were recorded[395] Ogino et al.[396] used HDR brachytherapy in 14

patients with grade 3 cervical and 6 with grade 3 vaginal intraepithelial neoplasia (3 with microinvasion) and 6 with recurrent CIN after hysterectomy. Seventeen patients were treated with HDR brachytherapy alone and three in combination with EBRT without surgery. The mean dose of HDR brachytherapy was 26.1 Gy (range, 20 to 30 Gy) prescribed at point A for intact uterus, at 1 cm superior to the vaginal apex, or 1 cm beyond the vaginal mucosa for lesions of the vaginal stump. At mean follow-up of 90 months, 14 patients were alive and 6 had died from intercurrent disease; none had recurrent disease. Rectal bleeding occurred in three patients and subsided spontaneously. Moderate and severe vaginal reactions were noted in two patients in whom the treatment included the entire vagina.

Invasive Disease

Based on available resources globally and the stage of disease, a debate continues among those who advocate radical surgery,[326,397,398] those who favor radiation, and those who favor chemoRT for the treatment of carcinoma of the uterine cervix. Patients should be treated with close collaboration between the gynecologic oncologist and the radiation oncologist, and an integrated team approach should be vigorously pursued. In countries with access to RT facilities and financial resources to supply chemotherapy, the use of concurrent chemoRT represents the accepted standard for patients with stage IB2 to IVA cervical cancer. For earlier-stage patients, the use of either surgery or chemoRT is recommended. The most recent survey of patterns of radiotherapy practice again documented a rise in the use of cisplatin-based concurrent chemoRT in patients with advanced stages, from 63% in 1999 to 74% in 2007.[177,399,400] Moreover, Barbera et al.[401] also reported a significant increase in the use of chemoRT in Canada after the *U.S. National Cancer Institute Bulletin* on the subject.[402]

Carcinoma of the Cervix Inadvertently Treated with a Simple Hysterectomy

Occasionally, a simple or total abdominal hysterectomy is performed and invasive carcinoma of the cervix is incidentally found in the surgical specimen. In general, extrafascial abdominal hysterectomy is not curative because the paravaginal or paracervical soft tissues and vaginal cuff are not removed. Furthermore, it may be technically difficult to perform an adequate radical operation after previous simple hysterectomy. If only microinvasive carcinoma is found when a total or extrafascial hysterectomy with a wide cuff is performed,

no additional therapy is necessary for lesions with deeper stromal invasion; at most, one or two vaginal intracavitary insertions to deliver a 65-Gy LDR mucosal dose (or 7 Gy × six fractions prescribed at the vaginal surface or 5 Gy at 0.5 cm × six fractions with HDR brachytherapy) to the vault are sufficient. If a less comprehensive resection was carried out, it is critical that these patients receive radiation therapy immediately with or without concurrent chemotherapy, depending on the risk factors present pathologically when their postoperative status allows it because the prognosis is worse if postoperative irradiation is not administered.

TABLE 73.10 Results of Postoperative External Beam Irradiation After Conservative Hysterectomy in Early-Stage Carcinoma of the Cervix[a]

Author (Reference)	Number of Patients	Local Control (%)	Survival		Severe Complications (%)[b]
			Percentage	Months	
Andras et al.[403]	80[c]	89	89	60	4
Ampil et al.[58]	27[c]	89	70	60	4
Saibishkumar et al.[384]	105	72	55	60	12
Sharma et al.[404]	83	70	62	60	6

[a]Patients with postsurgery gross residual or recurrent disease before irradiation were excluded from the total number of cited cases.
[b]Remedial surgery was performed because of bowel or bladder damage in some patients in some series.
[c]All or some of the patients had additional vaginal cuff irradiation.
Modified from Ampil F, Datta R, Datta S. Elective postoperative external radiotherapy after hysterectomy in early-stage carcinoma of the cervix: is additional vaginal cuff irradiation necessary? *Cancer* 1987;60(3):280–288. In patients with fully invasive tumor, therapy consists of approximately 40 to 45 Gy to the whole pelvis with cylinder brachytherapy to the vaginal vault for an approximately 60-Gy mucosal dose. If there is gross tumor present in the vaginal vault or parametrium, the dose to the whole pelvis should be 45 Gy with concurrent weekly cisplatin chemotherapy, followed by an additional parametrial dose of 10 to 20 Gy. An intracavitary insertion should be performed. If there is gross residual tumor, an interstitial implant should be carried out to selectively increase the dose to this volume.

Several studies have reported results of postoperative external beam

irradiation after conservative surgery (Table 73.10). Andras et al.[403] reported on 148 patients, 90 of whom were available for 10-year evaluation, who were divided into five groups, depending on tumor extent when therapy was instituted. The majority of patients were treated with 50-Gy total-pelvis irradiation (with 10-Gy parametrial boost through reduced fields), at times combined with vaginal vault intracavitary irradiation. Eight major complications were noted in 148 patients.

Ampil et al.[405] described results in 44 patients receiving postoperative irradiation after hysterectomy for stage IB and IIA carcinoma of the uterine cervix (15 patients treated with radical hysterectomy). Their 5-year results were 80% local tumor control and 63% overall survival. In three patients treated with intracavitary vaginal cuff irradiation only, two had tumor control.

Green and Morse[406] reported 9 of 30 patients (30%) surviving 5 years after definitive radiation therapy for treatment of invasive cervical carcinoma after simple hysterectomy. The same authors noted that 14 of 32 patients retreated with another surgical procedure, usually a Wertheim hysterectomy, died within 5 years. They pointed out that the 5-year cure rate was 30% in patients treated within 1 year after the hysterectomy but was only 16% in those treated after 1 year. Thus, the time at which the patient is treated and the volume of tumor are important prognostic factors.

Crane and Schneider[407] described results in 18 patients treated with RT (with or without brachytherapy) for invasive carcinoma of the cervix discovered after simple hysterectomy. The 10-year actuarial local tumor control was 88%, and the overall survival rate was 93%. Huerta Bahena et al.,[408] in 59 patients with carcinoma of the cervix incidentally found in simple hysterectomy specimens (27 with gross residual tumor) who were treated with postoperative RT, reported a 3-year survival of 59%; factors affecting prognosis included gross residual tumor, time between hysterectomy and irradiation >6 months, RT doses <50 Gy, and histologic tumor type.

Münstedt et al.[409] reported on 119 patients who received postoperative RT after radical hysterectomy and 80 who received it after simple hysterectomy. There was a trend toward better survival in the radical hysterectomy group, but the authors concluded that postoperative RT is a good treatment in patients with invasive cervical cancer who undergo a simple hysterectomy. In another report of 105 patients with invasive cervical carcinoma found in inadequate surgery specimens treated with postoperative RT, 5-year pelvic tumor control was 72% and the survival rate was 55%. Late rectal toxicity was 19%, bladder toxicity

was 4.8%, and small-bowel toxicity was 14.3%.[410]

In a series of 147 patients treated at Asan Medical Center in Korea, 48 patients with stage IA1 lesions did not receive further treatment. Another 99 patients had stage IA2 to IIA lesions incidentally identified. Of these, 26 received no further therapy, 44 had either radiation or chemoradiation, and 29 had a radical parametrectomy. For patients with stage IA1 disease who were observed, 0% relapsed, whereas 35% of patients with stage IA2 to IIA disease who were observed suffered from a recurrence.[411] Either radical parametrectomy or radiation is required for patients with stage IA2 or higher cancer after a simple hysterectomy. However, these treatments increase the risk of side effects[412] including for those patients receiving robotic parametrectomy.[413]

Stage IA

The definition of microinvasive (stage IA) carcinoma of the cervix includes invasive carcinoma diagnosed only by microscopy. Conization is mandatory for a more accurate diagnosis. According to Kolstad,[414] lesions <1 mm in depth can be treated with conization, provided all margins are tumor-free and continued careful follow-up is instituted. Raspagliesi et al.[415] used margins of 8 to 10 mm as guidelines for clearance in conization. Smaller margins and lymphovascular invasion in addition to depth of invasion were prognostic factors for recurrence.

Tumor volume in the stroma may be a more reliable criterion than depth of invasion to arrive at a definition of stage IA. Vascular space involvement does not impact stage. Depth of invasion and tumor confluence have been identified as prognostic factors that should be taken into consideration in the planning of therapy.[416]

Early invasive carcinoma of the cervix (stage IA2) is usually treated with a total abdominal or modified radical hysterectomy or in some cases with simple conization[278] or radical trachelectomy.[417] Inoperable patients may be treated with intracavitary radioactive sources alone with 6,500 to 8,000 mgh, 60 to 75 Gy to point A, in two LDR insertions, respectively, or with the equivalent dose using HDR brachytherapy, approximately 10 fractions of 5 Gy per fraction. In 47 patients with microinvasive carcinoma treated at Washington University—20 with intracavitary therapy only and 27 patients with combined external irradiation and intracavitary brachytherapy—only 1 patient had a pelvic recurrence and distant metastases 10 years later; the 5-year DFS rate was 96%.[397]

When the depth of penetration of the stroma by tumor is <3 mm, the

incidence of lymph node metastasis is 1% or less, and a lymph node dissection or pelvic external irradiation is not warranted.[326,397] With more extensive lesions, a Wertheim radical hysterectomy with pelvic lymphadenectomy is the preferred treatment. Tumor control with all treatment methods is >95%, with patients eventually dying of intercurrent disease. Gadducci et al.[418] treated 30 patients with conization and 82 with total and 54 with radical hysterectomy; the recurrence rates were 10%, 4.9%, and 9.3%, respectively. None of 67 patients subjected to lymphadenectomy had positive pelvic nodes. In 98 patients with adenocarcinoma of the cervix, none of 48 with depth of invasion (DOI) of ≤5 mm had involved parametria or positive nodes, in contrast to 6 of 36 (16%) with DOI of >5 mm.[419]

Vaginal trachelectomy (removal of the cervix) and laparoscopic lymphadenectomy have been used to treat young patients with microinvasive carcinoma to preserve fertility. The overall incidence of central recurrence is approximately 5%.[395] Webb et al.[420] analyzed lymph node status and survival rates of women with microinvasive cervical adenocarcinoma (FIGO stages IA1 and IA2) from the SEER database between 1988 and 1997. Among reported cases, 131 had stage IA1 and 170 had stage IA2 disease. Simple hysterectomy was done in 54 women with IA1 and in 64 women with IA2 disease and radical hysterectomy in 50 and 83 women, respectively. Only 1 of 140 women who had lymphadenectomy had a single positive lymph node. There were 4 tumor-related deaths (1 with IA1 and 3 with IA2 disease). The survival rate was 98.7%.

Stages IB to IIA

The choice of definitive irradiation or radical surgery for stage IB and IIA carcinoma of the cervix remains controversial, and the preference for one procedure over another depends primarily on the impact on the patient's fertility and on the institution, the gynecologic oncologist or radiation oncologist involved, the general condition of the patient, and characteristics of the lesion. An operation has been preferred by some in young women to preserve the ovaries, attempting to prevent premature menopause. However, in some reports,[318] ovarian function preservation has been observed in only 50% to 60% of surgically treated patients not receiving irradiation. Postmenopausal patients may have a survival benefit with chemoradiation and avoid the operative risks. When therapeutic results in invasive carcinoma of the cervix are evaluated, a direct comparison of surgically treated or irradiated patients is fraught with many uncertainties, including patient selection, reporting of surgical cases using

staging determined by laparotomy findings, and different treatment techniques.[421] In particular, in the modern era when concurrent chemoradiation is known to be superior to radiation alone, a direct comparison of chemoradiation versus surgery in early-stage cervical cancer is needed.

Surgery provides an opportunity for a thorough pelvic and abdominal evaluation. However, surgical staging has not been shown to improve overall patient survival.[46,53] Kupets et al.[422] assessed the value of debulking large nodes and concluded that the incremental overall benefit by stage was small. Delgado et al.[43] described a GOG study in which 1,125 patients were registered before surgery; 80 were ineligible after strict pathology review, and an additional 129 patients were explored, but the hysterectomy was abandoned because of intraoperative complications in 49 patients or extent of disease beyond the uterus in 80 patients. In the era of MRI, surgeons may rely on imaging findings to screen for operability. The impact of patient selection in results of surgical series was illustrated by Whitney and Stehman[423] who evaluated the frequency with which intended radical hysterectomy for cervical cancer is abandoned and the outcomes for those selected patients. In 1,127 patients with stage IB carcinoma of the cervix entered on GOG Protocol 49, 98 women (8.7%) were found at surgery to have extrauterine disease, and the proposed radical operation was abandoned. Subgroups of patients with extrapelvic disease[34] and pelvic extension[419] including grossly positive pelvic nodes,[42] other pelvic implants,[424] and gross serosal extension[130] were identified. Sixty-three (93%) patients subsequently underwent pelvic radiation therapy and brachytherapy. Para-aortic fields were added for eight patients who were found to have positive para-aortic nodes. The DFS was shorter for patients whose radical procedure was abandoned than for those patients who underwent radical hysterectomy.

The important contribution of external beam irradiation to improve pelvic tumor control in larger lesions has been documented. Hamberger et al.,[425] in 151 patients with stage IA or IB lesions <1 cm in diameter treated with intracavitary therapy alone to high doses (8,640, 9,340, and 13,680 mgh), noted no failures in 41 patients with stage IA disease and only 4 of 93 patients (4%) with stage IB, small-volume disease. However, 3 of 17 patients (18%) with more extensive stage IB lesions, treated with intracavitary therapy only, had regional failures. Only 3 of 151 patients (0.2%) had grade 3 complications.

Volterrani and Lombardi[426] reported 5-year survival of 82.6% in 23 patients with occult stage IB carcinoma of the cervix treated with intracavitary[251] Ra only (7,500 mgh), in contrast to only 64.8% with larger stage IB tumors and 50%

with stage II. Unfortunately, the authors did not report the exact location of the failures. It is obvious that intracavitary therapy alone is grossly inadequate to irradiate larger primary tumors, including stage IB1.

With EBRT and brachytherapy without chemotherapy, the usual 5-year survival rate for stage IB is 86% to 92% and for stage IIA is approximately 75%.[410] Late toxicity was observed in 1% to 2% of patients. Concurrent chemotherapy significantly improves survival, including in stage IB to IIA disease. In RTOG 90-01, for the subset of 272 stage IB to IIA patients, the 8-year overall survival was 55% with RT alone versus 78% with concurrent chemoradiation ($P < .001$).[427]

Randomized Studies: Surgery Versus Radiation

Few randomized trials have compared the results of radical hysterectomy with definitive RT, and none have compared surgery to chemoradiation. Outcome between radiation alone versus surgery is comparable. Newton[428] and Roddick and Greenlaw[429] reported, in prospectively randomized studies, equivalent survival and pelvic recurrence rates in patients with stage IB and IIA carcinoma of the uterine cervix treated with a radical hysterectomy or irradiation alone. Landoni et al.[37] published results of a prospective, randomized trial of radiation therapy versus surgery; 469 women with stage IB and IIA cervical carcinoma were referred for treatment and 343 were randomized (172 to surgery and 171 to radiation therapy). Postoperative irradiation was delivered after surgery for women with surgical stage pT2b or greater, <3 mm of cervical stromal invasion and cut-through margins, or positive pelvic nodes. Scheduled treatment was delivered to 169 and 158 women, respectively; 62 of 114 women with cervical diameters of <4 cm and 46 of 55 women with >4 cm received radiation therapy. After a median follow-up of 87 months (range, 57 to 120 months), 5-year overall survival and DFS rates were nearly identical in the surgery and radiation therapy groups (83% and 74%, respectively); recurrent disease developed in 86 women: 42 (25%) in the surgery group and 44 (26%) in the radiation therapy group (Fig. 73.18). Forty-eight patients (28%) in the surgery group had severe morbidity, compared with 19 (12%) in the radiation therapy group ($P = .0004$; Table 73.11). The combination of surgery and radiation therapy had the worst morbidity, especially urologic complications.

Of note, no randomized study has compared chemoRT to radical hysterectomy, although chemoRT has a significant survival advantage over RT alone for patients with stage IB to IIA cervical cancer.[430] In a meta-analysis

looking at the value of adjuvant cisplatin-based chemotherapy after radical hysterectomy, radiation therapy, or both for patients with stage IA2, IB1, or IIA cervical cancer, three randomized clinical trials were evaluated.[430] Two of the three trials showed a significant benefit compared to adjuvant chemotherapy concurrent with radiation, with a reduced risk of death (HR = 0.56, 95% CI = 0.36 to 0.87). No benefit was seen when chemotherapy was given prior to radiotherapy.

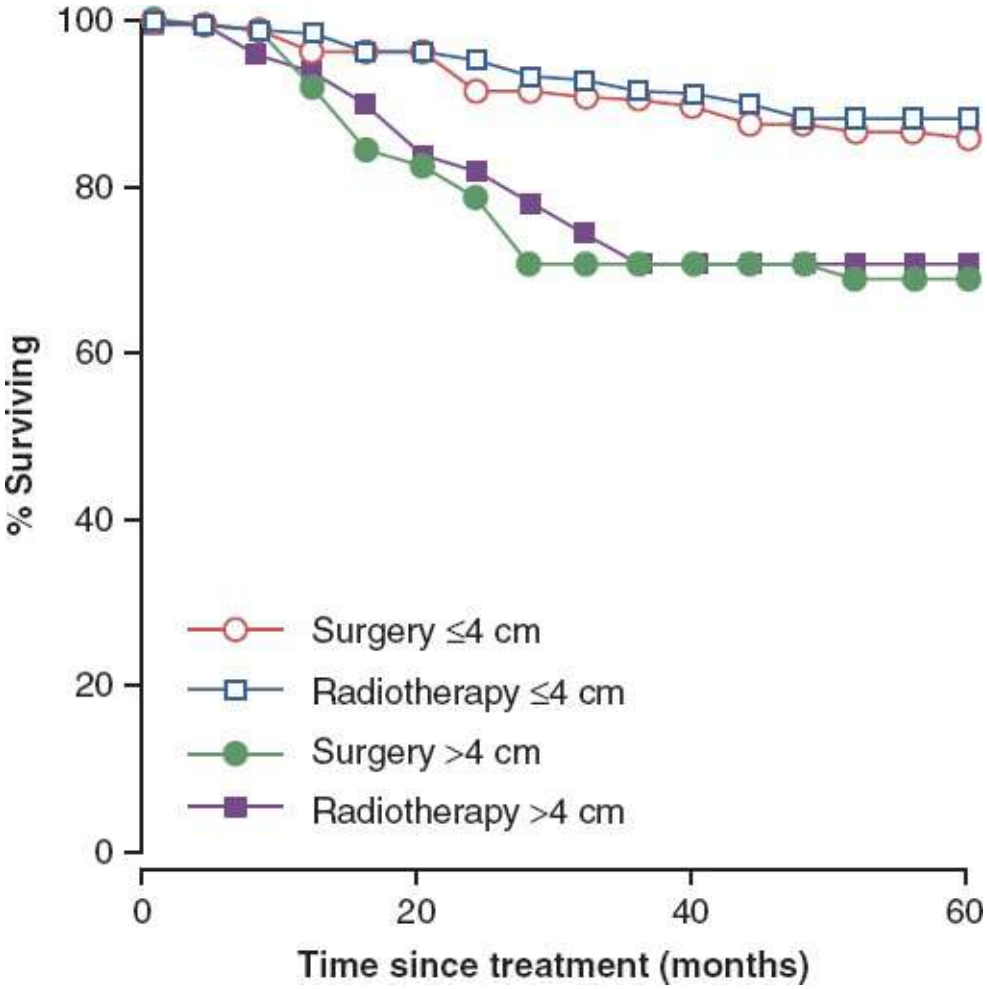

FIGURE 73.18. Overall actuarial survival of patients with carcinoma of the cervix randomized to treatment with radical surgery or radiation therapy according to treatment group and cervical diameter. (Reprinted from Landoni F, Maneo A, Colombo A, et al. Randomised study of radical surgery versus radiotherapy for stage IB-IIA cervical cancer. *Lancet* 1997;350[9077]:535–540. Copyright © 1997 Elsevier. With permission.)

Neoadjuvant chemotherapy plus surgery does not improve survival over surgery alone.[431] In a meta-analysis of six trials, although there was an

improvement in PFS with neoadjuvant chemotherapy (HR = 0.76, 95% CI = 0.62 to 0.94, *P* = .01), this did not translate into an overall survival benefit. Another meta-analysis reviewed 18 trials with locally advanced cervical cancer patients treated with neoadjuvant chemotherapy before radiation or surgery or both and excluded concurrent chemoradiation trials; it showed significant heterogeneity and no conclusive results.[432]

Nonrandomized Studies Comparing Surgery to Radiation

Keilbinska et al.,[433] in a long-term study of 792 women treated with irradiation and 789 women treated with hysterectomy and/or irradiation for stage I cervical carcinoma, found no difference in survival, general health, incidence of recurrent carcinoma, or appearance of second primary malignancies. Piver et al.[434] treated 103 women with stage IB cervical carcinoma with either radical hysterectomy and pelvic lymphadenectomy (if tumor was <3 cm in greatest diameter) or irradiation (tumor of >3 cm or medically inoperable). The 5-year DFS rate was 92.3% for the surgical group and 91.1% for the radiation therapy group. Equivalent overall 5-year survival rates were noted. Einhorn et al.,[435] in a nonrandomized study, observed a 100% 5-year survival rate in 49 patients with stage IB disease receiving combined therapy in comparison with 81% in 64 patients treated with irradiation alone. No difference was observed in 25 patients with stage IIA tumor treated with combined therapy and 40 patients treated with irradiation alone (5-year survival rate, 75%).

TABLE 73.11 RANDOMIZED TRIAL OF RADICAL SURGERY OR IRRADIATION IN STAGE I TO II CERVICAL CANCERS: RELAPSES AND MORBIDITY

	Surgery							
	Surgery Only		Surgery Plus Radiation Therapy		Total		Radiation Therapy Alone	
	≤4 cm	>4 cm	≤4 cm	>4 cm	≤4 cm	>4 cm	≤4 cm	>4 cm

Perez et al.[51] reported on a prospectively randomized study of 118 patients with stage IB or IIA carcinoma of the uterine cervix in which patients were treated with RT alone or irradiation and surgery (20 Gy to the whole pelvis, one intracavitary insertion for 5,000 to 6,000 mgh, followed by a radical hysterectomy with pelvic lymphadenectomy 2 to 6 weeks later). In stage IB, the 5-year tumor-free survival was 80% and 82% (P = .23), respectively, and in stage IIA, it was 56% and 79%, respectively (P = .13). The incidence of grade 2 or 3 complications for radiation alone was 13.8% and with preoperative irradiation and surgery was 11%. Subsequently, Perez et al.[436] described results in 415 patients with stage IB or limited stage IIB treated with preoperative or postoperative irradiation and surgery. The 10-year CSS rate for patients with stage IB nonbulky tumors treated with irradiation alone or irradiation combined with surgery was 84% with either modality. With bulky tumors (>5 cm), the 10-year rates were 61% and 68%, respectively (P = .5). For patients with stage IIA nonbulky tumors, the 10-year CSS rates were 66% and 71%, respectively, and with bulky tumors, 69% and 44%, respectively (P = .05). In patients with stage IIB nonbulky tumors treated with irradiation alone or combined with surgery, the 10-year CSS rates were 72% and 65%, respectively. In stage IB and IIA disease after a hysterectomy and lymphadenectomy (even combined with irradiation), patients with metastatic lymph nodes have survival rates that are approximately 50% of those of patients with negative nodes.[437]

Randomized Trials of Postoperative Radiation Therapy or Chemoradiation After Radical Hysterectomy

Patients who have undergone radical hysterectomy with no preoperative radiation therapy are considered for postoperative chemoradiation therapy if they

have high-risk prognostic factors, which include positive pelvic lymph nodes, as are patients with negative nodes who have microscopic positive margins of resection or parametrial involvement.[438]

Patients with any two of deep stromal invasion, vascular/lymphatic permeation, and large tumor size are candidates for postoperative radiation.[439] These patients have an intermediate risk of failure.[43] Whether to add concurrent chemotherapy to postoperative radiation in the intermediate-risk group is being tested in an accruing randomized trial; many institutions routinely implement chemoRT for intermediate-risk patients. Song et al.[440] reported a 20-year experience in stage IB to IIA cervical cancer patients with intermediate-risk factors (two or more of deep stromal invasion, lymphovascular invasion, and large tumor size) who received postoperative RT or chemoradiation. Chemoradiation significantly decreased pelvic recurrence and distant metastases; there was no difference in acute or chronic grade 3 and 4 gastrointestinal side effects.

One randomized study showed improved recurrence-free survival with postoperative pelvic irradiation (46 to 50.4 Gy in 23 to 28 fractions) after radical surgery in the presence of positive pelvic nodes or node-negative high-risk factors in women with stage IB cervical cancer treated by radical hysterectomy and pelvic lymphadenectomy. There were 277 eligible patients with at least two of the following risk factors: greater than one-third stromal invasion, capillary lymphatic space involvement, and large clinical tumor diameter; 137 patients were randomized to pelvic radiation therapy and 140 to no further treatment. The results were updated by Rotman et al.[441]; 24 (17%) patients in the irradiation group and 43 (30.7%) in the no-further-treatment group had cancer recurrences. In the radiation therapy group, 27 patients died of cancer, and in the no-further-treatment group 40 died from cancer. There was a statistically significant reduction in risk of recurrence in the irradiation group, with recurrence-free rates at 2 years of 88% versus 79% for the irradiation and no-further-treatment groups, respectively. Overall survival difference did not reach statistical difference (P = .074; Fig. 73.19). Severe or life-threatening (GOG grade 3 or 4) adverse effects occurred in 9 patients (6.6%) in the radiation therapy group and 3 (2.1%) in the observation group. A meta-analysis of trials including stage IB1 to IIA cervical cancer found that women who received postoperative radiation had a significantly lower risk of disease progression at 5 years (RR = 0.6, 95% CI = 0.4 to 0.9). The risk of serious adverse events was not significantly higher if women received radiotherapy rather than no further treatment, possibly because

the rate of adverse events was low.[442]

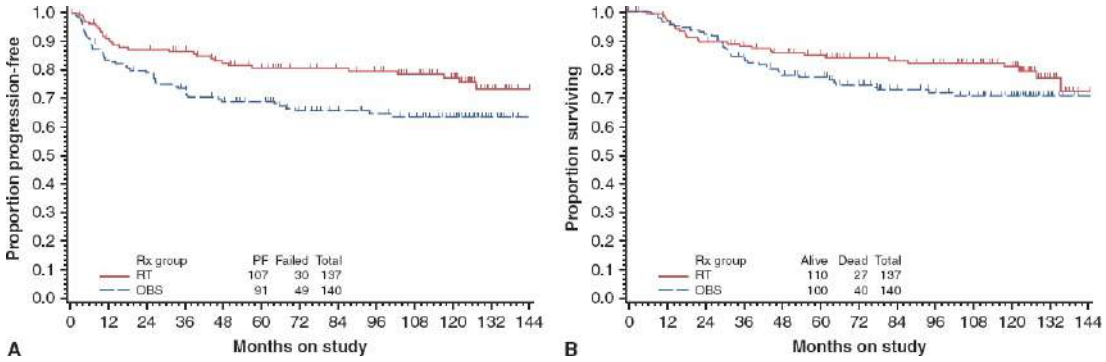

FIGURE 73.19. Recurrence-free survival **(A)** and overall survival **(B)** of patients with stage IB carcinoma of the cervix, correlated with treatment method. (Reprinted from Rotman M, Sedlis A, Piedmonte MR. A phase III randomized trial of postoperative pelvic irradiation in patients with stage IB cervical carcinoma with poor prognostic features: follow up of a Gynecologic Oncology Group study. *Int J Radiat Oncol Biol Phys* 2006;65[1]:169–176. Copyright © 2006 Elsevier. With permission.)

Sundfør et al.[443] conducted a randomized study in which 122 patients with stage IIA and 20 patients with stage IIB cervix cancer were treated with intracavitary radium followed by either radical pelvic surgery including lymphadenectomy (group A, 72 patients) or EBRT (40 Gy) to the pelvis (group B, 70 patients). Postoperative RT (40 to 50 Gy) was given to patients in group A found to have node metastasis at operation. Fourteen patients in group A and 23 in group B died of recurrent cancer. The 10-year survival was 84% and 69%, respectively.

Nonrandomized Trials of Postoperative Radiation Therapy or Chemoradiation After Radical Hysterectomy

Snijders-Keilholz et al.[444] described results in 233 women who underwent radical hysterectomy for stage I or IIA cervical carcinoma; 156 were treated with surgery alone, and 77 received adjuvant radiation therapy for tumor-related high-risk prognostic factors. The most important prognostic factor for survival and DFS was pelvic lymph node positivity; additional factors were depth of invasion and positive surgical margins. Twelve patients recurred after surgery alone, all in the pelvis (100%). Of the 23 recurrences after surgery and adjuvant radiation therapy, 13 were in the pelvis (56%; $P = .003$). Ten patients with poor prognostic factors and negative nodes received adjuvant radiation therapy, and none of these patients recurred. The incidence of severe gastrointestinal radiation-related side effects was 2%. The incidence of lymphedema of the leg was 11%, which was

similar to that in the surgery-alone group.

Garipagaoglu et al.[445] investigated prognostic factors in 100 patients with stage IB or IIA cervical carcinoma treated with radical hysterectomy and postoperative irradiation. The 5-year overall survival, DFS, and pelvic tumor control rates were 83.6%, 82.8%, and 91.8%, respectively. Pelvic lymph node metastasis (P = .008), interval between surgery and irradiation (P = .001), overall radiation therapy time (P = .007), and tumor size (P = .028) were significant factors for pelvic tumor control, as well as for overall survival.

Lahousen et al.[446] reported on a GOG prospectively randomized, multicenter trial in which patients with stage IB or IIB cervical cancer treated with radical hysterectomy who had pelvic lymph node metastases or vascular invasion randomly received adjuvant chemotherapy (400 mg/m^2 carboplatin and 30 mg bleomycin), external pelvic radiation therapy, or no further treatment. After a median follow-up of 4.1 years (range, 2 to 7 years), there were no statistically significant differences (P = .9539) in DFS rates among the three treatment arms, suggesting that adjuvant chemotherapy or radiation does not improve survival or recurrence rates in high-risk patients with cervical cancer after radical hysterectomy.

González González et al.[447] reported that in 89 patients with stage IB or IIA cervical cancer with positive lymph nodes receiving postoperative irradiation, the 5- and 10-year survival rates were 60% and 51%, respectively. By comparison, 43 patients with negative lymph nodes had a survival rate of 85%. In the surviving patients, there were four gastrointestinal and seven genitourinary severe complications requiring surgical correction. In four patients, asymptomatic stenosis of the ureters was detected by IV pyelography performed routinely every year.

Bianchi et al.,[448] in 60 patients receiving external irradiation for pelvic node metastasis after radical hysterectomy, observed a 65% 5-year survival rate. In contrast, in 15 patients who refused postoperative irradiation, only 3 (20%) survived 5 years.

Chatani et al.[449] reported on 128 patients with stage IB to IIB carcinoma of the cervix who underwent radical hysterectomy with bilateral pelvic lymphadenectomy and postoperative EBRT. The 5-year local and distant failure rates were, respectively, 2% and 12% for negative nodes, 23% and 25% for one positive node, and 32% and 57%, for two or more positive nodes (P = .0029 and .0051, respectively). The 5-year CSS rates were 90%, 59%, and 42%, respectively (P = .0001). The most common complication was lymphedema of

the lower extremity, experienced by half of the patients (42% at 5 years and 49% at 10 years).

Uno et al.[450] evaluated results of postradical hysterectomy irradiation in 98 patients with stage IB to IIB cervical cancer; all of the patients had at least one pathologic risk factor for pelvic recurrence. The 5-year overall survival was 82%. There were pelvic recurrences in 5 cases and distant metastases in 15 cases. The 5-year overall survival rates for patients with or without pelvic lymph node metastasis were 76% and 89%, respectively ($P = .018$).

Kinney et al.[451] compared results of therapy in 82 patients with stage IB or IIA carcinoma of the cervix found to have pelvic lymph node metastases at Wertheim hysterectomy and bilateral lymphadenectomy without additional adjuvant therapy with 103 similar patients who received 50 Gy to the pelvis after surgery. The 5-year survival rate was 72% for the surgery-only patients and 64% for the group receiving adjuvant irradiation. The incidences of pelvic recurrence were 67% and 27%, respectively. The lack of impact on overall survival in the irradiated patients is most likely related to a higher incidence of distant metastases, which may be a reflection of shorter survival time and more high-risk patients. In 117 patients treated with radical hysterectomy and pelvic lymphadenectomy, histologically proven nodal metastatic disease was detected in 51 patients (44%; squamous cell in 35 and nonsquamous in 16). Nodal involvement was bilateral in 24 patients (47%).[452] PALN dissection was performed in 14 patients, and 5 had tumor involvement. Postoperative pelvic irradiation was administered to 29 of 51 patients (51.2 Gy, two fractions). Extended fields to the para-aortic area were used in six patients. The 5-year survival rates were 33% for the group receiving irradiation and 50% for the nonirradiated group. Only one patient treated with postoperative irradiation had a pelvic failure, in contrast to seven patients not irradiated.

Inoue and Morita[297] described results in 72 patients treated with extended-field irradiation after radical surgery for nodal metastases with stage IB (37 patients), IIA (6 patients), and IIB (29 patients) cervical cancers. The median dose to PALNs was 43.5 Gy and to the pelvis was 45 Gy. The 5-year DFS rates were 72% in 61 patients with squamous cell carcinoma and 27% in 11 patients with nonsquamous cell carcinoma. The 10-year DFS rates were 88% for 22 patients with one positive node, 67% for 15 patients with two or three positive nodes, 64% for 16 patients with four to 17 positive nodes, and 20% for 10 patients with unresectable lymph nodes. Nineteen severe complications occurred in 17 patients; 5 were attributed to surgery, 5 to irradiation, and 9 to both

modalities. Four patients (5%) died of severe complications. Another six patients (8%) underwent major abdominal surgery for rectovaginal and ureterovaginal fistulas.

Mitsuhashi et al.[453] described an analysis of 108 patients with carcinoma of the cervix treated with postoperative EBRT to the pelvis followed by intravaginal cone boost with electron beam to the vaginal cuff. The 5-year CSS rates were 89% for 89 patients undergoing elective radiation therapy and 56% for 19 patients undergoing salvage irradiation ($P < .001$). Recurrent tumors at the vaginal cuff were observed in only two patients in the elective irradiation group. Vesicovaginal fistula developed in four patients; only one patient had grade 2 rectal complications.

A Japanese group treated 189 stage IIB cervical cancer patients; 95 had a radical hysterectomy followed by adjuvant RT, and the other 94 patients had RT alone.[454] There was a significant increase in grade 3 to 4 late toxicities in the surgery group, 24% versus 10%, $P = .048$. Therefore, RT is preferable, and in the modern era, chemoRT provides a superior outcome and should be administered to all stage IIB patients. The same group reported on 55 stage IA2 to IIB patients with multiple positive pelvic lymph nodes treated either with pelvic RT and concurrent chemotherapy or extended-field RT. Overall survival significantly improved with concurrent chemotherapy ($P = .03$).[455]

Okazawa et al. reported on 129 patients with stage IB1-IIB cervical cancer and showed significant improvement in PFS and OS with chemoradiation compared to RT. Patients with deep stromal invasion also had an improved PFS compared to observation.[456] A meta-analysis of 397 women with early-stage cervical cancer showed that postoperative RT reduced disease progression (RR 0.58, 95% CI 0.37 to 0.91).[457]

Lee et al.[458] retrospectively compared 201 stage IB1 to IIB cervical cancer patients who had a radical hysterectomy with pelvic lymph node dissection followed by adjuvant concurrent weekly cisplatin to triweekly combination chemotherapy. With a median follow-up of 52 months, the weekly cisplatin group had the same therapeutic effect with less toxicity. The 5-year disease-free and overall survival were 82% and 81%, respectively, for patients treated with weekly cisplatin chemotherapy versus 74% and 79% for those treated with triweekly combination chemotherapy (P = NS). Leukopenia, neutropenia, thrombocytopenia, anemia, and hepatopathy were significantly more common in the triweekly combination chemotherapy group.

Postoperative External Beam Radiation Dose

When metastatic pelvic lymph nodes are present, treatment has consisted of 45 Gy to the whole pelvis delivered with a four-field technique with concurrent weekly cisplatin. If gross residual disease is present, dose escalation to 54 to 65 Gy, depending on small-bowel dose limits (e.g., $D_{5cc} < 55$ Gy), may be considered with a sequential IMRT nodal boost.[101] Patients with positive common iliac or para-aortic node metastases should receive 45 Gy to the entire para-aortic region with the superior border covering the renal hilum, with consideration of a boost to the tumor bed. If gross residual nodal disease is left, a nodal boost up to 65 Gy with IMRT is particularly suited to treat these patients.[301,302]

In patients for whom postoperative irradiation is indicated for deep stromal invasion in the cervix or close or positive surgical margins, an alternative is to deliver 45-Gy pelvic external irradiation in combination with an intracavitary insertion (LDR, PDR, or HDR) and LDR equivalent dose of 65 Gy to the vaginal mucosa, using colpostats or a cylinder.[459] At some institutions, external irradiation alone (50 Gy to the midplane of the pelvis) with a four-field box technique has been used. Hong et al.[199] recommended, for node-negative patients with high-risk factors, to irradiate only the low pelvis (median dose, 50 Gy), which resulted in a reduction of grade 3 small-bowel morbidity (3 of 149 = 2%) in comparison with patients treated to the whole pelvis (6 of 79 = 8%). Five-year disease-specific survival was 84% and 86%, respectively.

Postoperative Intracavitary High–Dose Rate Brachytherapy

Depending on the extent of surgical resection of the vagina, the vaginal cuff may be at risk for recurrence. There is no clear agreement on the indications for vaginal brachytherapy after radical hysterectomy, although adjuvant vaginal brachytherapy for cervical cancer is most commonly used as a boost after EBRT, particularly in patients with positive margins.[460] Based on the American Brachytherapy Society guidelines, vaginal cuff boost should be considered in patients with a less-than-radical hysterectomy, close or positive margins, large or deeply invasive tumors, parametrial or vaginal involvement, or extensive lymphovascular invasion.[459] Consideration of postoperative vaginal intracavitary brachytherapy after external beam therapy is recommended for patients with carcinoma at the vaginal margin of resection.[326] If parametrial margins were close or positive, defined by either surgical clips or in the region of the surgical tumor bed, an external beam dose of at least 54 Gy for close margins and higher

for positive margins is recommended.

In patients receiving postoperative irradiation, extreme care should be exercised in designing treatment techniques, including intracavitary insertions; because of the surgical extirpation of the uterus, the bladder and rectosigmoid may be closer to the radioactive sources than in the patient with an intact uterus. Furthermore, vascular supply may be affected by the surgical procedure, and adhesions can prevent mobilization of the small-bowel loops that may be fixed in the pelvis. HDR brachytherapy after surgery is particularly suited for patients with cervical cancer because it prevents the prolonged immobilization required for LDR brachytherapy. In some patients at higher risk for parametrial tumor or lymph node metastases, HDR brachytherapy is combined with external beam pelvic irradiation.

Hart et al.[461] described results in 83 patients who received postoperative RT for early-stage cervical cancer with positive surgical margins, positive pelvic or PALNs, lymphovascular space invasion, or deep stromal invasion or for disease discovered incidentally at simple hysterectomy. Twenty-eight patients were treated with LDR brachytherapy with or without EBRT and 55 with EBRT to the pelvis and HDR intracavitary. Of these 83 patients, 66 were evaluable (20 LDR and 46 HDR patients). Mean follow-up time was 101 months for the LDR group and 42 for the HDR group. The 5-year DFS rates were 89% and 72%, and local tumor control rates were 90% (18 of 20) and 89% (41 of 46), respectively. Three of 20 patients (15%) receiving LDR and 4 of 46 (9%) receiving HDR experienced grade 2 or 3 late treatment-related complications. No patient in either group had grade 4 or 5 complications.

Busch et al.[462] studied the outcome of 68 patients with cervical carcinoma; 48 were treated with radical hysterectomy and, because of risk factors, with postoperative RT (group 1), and 20 patients (group 2) were pretreated with standard hysterectomy and then admitted to the hospital for postoperative radiation therapy of the whole pelvis. Postoperative pelvic RT consisted of 39.6 Gy (box technique) and 6-Gy external beam therapy to the pelvic lymph nodes, sparing the midline, plus two HDR applications (7.5 Gy each). Survival, locoregional tumor control, and metastatic disease rates were nearly identical in both groups. Patients with positive lymph nodes had a worse prognosis (75% 3-year survival rate).

Atkovar et al.[463] described results in 126 patients treated with postoperative irradiation (median of 50 Gy in 5 weeks); 37 received vaginal cuff HDR brachytherapy (three fractions of 8 to 10 Gy at 5 mm, weekly). Overall survival

and DFS and locoregional tumor control rates were 71%, 69.9%, and 78.1%, respectively. Grade 2 and 3 complications developed in 5.5% of patients. Survival was the same in 67 patients treated with total abdominal hysterectomy and bilateral salpingo-oophorectomy and in 59 patients treated with radical hysterectomy and pelvic lymphadenectomy.

Stages IB2 to IVA: Chemoradiation

Patients with stage IB2 to IVA tumors are treated with irradiation including external beam and brachytherapy combined with concurrent chemotherapy. Numerous reports have been published on the concomitant use of irradiation and cytotoxic agents (hydroxyurea, cisplatin, and 5-FU, in some trials combined with mitomycin C) administered to obtain a radiosensitizing effect.[464–466] Cisplatin is one of the most active cytotoxic agents in squamous cell carcinoma of the uterine cervix.[467] When cisplatin and irradiation are used concomitantly, substantial enhancement of cell killing is observed. Coughlin and Richmond[465] and Douple[468] suggested two mechanisms for radiation enhancement by cisplatin: (a) in hypoxic or oxygenated cells, free radicals with altered binding of cisplatin to DNA are formed at the time of irradiation, and (b) interaction inhibits repair of sublethal damage.

It is important, however, that patients complete the full course of 45 Gy with, ideally, five to six weekly doses of cisplatin or two doses of cisplatin and 5-FU every 3 weeks. In a study of 41 patients who had weekly biopsies while receiving RT and chemotherapy for cervix cancer, increased tumor cell proliferation and accelerated repopulation was observed within 2 weeks from the initiation of therapy. Patients with a sustained yield and high S-phase fraction for 2 or more weeks were at increased risk for tumor progression.[469]

Green et al.,[470] in a search of medical databases for randomized trials of cervical cancer that compared RT with or without concurrent chemotherapy, identified 19 trials comprising 4,580 randomized patients, and they were the subjects of the meta-analysis. Concomitant chemotherapy and radiation improved tumor control and overall survival (RR = 0.71; $P < .0001$) and PFS (RR = 0.61; $P < .0001$). The benefit was maximal in early-stage (I and II) disease. The absolute survival benefit was 12%. Patients receiving chemoirradiation had a higher incidence of grade 3 or 4 hematologic and gastrointestinal toxicities.

Patients with stage IVA disease (bladder and/or rectal invasion) can be treated either with higher doses of external radiation to the whole pelvis with concurrent

chemotherapy followed by intracavitary or interstitial insertions (total dose to point A with LDR brachytherapy about 90 Gy) and additional parametrial irradiation or with pelvic exenteration.[471] Niibe et al.,[472] in an analysis of 179 patients with stage IIIB adenocarcinoma, suggested that an optimal dose for large tumors was a total biologic effective dose of >100 Gy.

A prospective single-arm trial, RTOG 0116, treated patients with positive para-aortic or high common iliac lymph nodes with extended-field radiation combined with cisplatin chemotherapy followed by brachytherapy.[473] IMRT was not allowed. The trial showed that this regimen is feasible, but the late grade 3 and 4 toxicity rate was 40%. There was no reduction in acute toxicity with the addition of amifostine.[474] The use of extended-field IMRT has been shown to reduce the risk of gastrointestinal toxicity in two retrospective series reports[302,475] and may be of benefit to patients with positive common or PALNs requiring extended-field radiation with concurrent chemotherapy.

In countries or circumstances where a wait time exists and patients cannot immediately start on concurrent chemoradiation, induction chemotherapy may be considered. An alternative to cisplatin in this situation may be concurrent nedaplatin, which did not cause any nephrotoxicity in an analysis of 104 patients.[476]

Randomized Trials of Chemoradiation

Results from several cooperative oncology groups demonstrated that cisplatin-based chemotherapy, when given concurrently with RT, prolongs survival in women with locally advanced cervical cancers (Table 73.12), as well as in women with stage I to IIA disease who have metastatic disease in the pelvic lymph nodes, positive parametrial disease, or positive surgical margins at the time of primary surgery.[480]

The GOG conducted randomized Protocol 85, in which patients with carcinoma of the cervix, a clinical stage of IIB to IVA, and negative para-aortic nodes were treated with external pelvic irradiation (51 Gy) combined with 30 Gy to point A with LDR brachytherapy.[478] One hundred twenty- seven patients received 5-FU (IV infusion, 1 g/m^2 for 4 days) and cisplatin (50 mg/m^2 IV) on days 1, 29, and 30 to 33, and 191 patients received hydroxyurea (80 mg/kg orally twice weekly). With a median follow-up for survivors of 8.7 years, the 5-year survival rate in the cisplatin/5-FU arm was 60%, compared with 47% for women in the hydroxyurea arm.

After completion of GOG 85, the group opened GOG 120[479,481] for the same

patient population, which was a three-arm randomized trial comparing irradiation plus hydroxyurea versus irradiation plus weekly cisplatin versus irradiation plus hydroxyurea, cisplatin, and 5-FU. In 526 evaluable patients with a median follow-up for survivors of 106 months, the 5- and 10-year survival rates for women in both the weekly cisplatin and irradiation arm and the irradiation, 5-FU, and cisplatin arm were 60% and 53%, respectively, compared with 40% and 34% in the hydroxyurea and irradiation arm ($P \leq .01$). Overall survival was also significantly better in the two patient groups receiving cisplatin. Hematologic toxicity was greater in the group treated with the three drugs compared with cisplatin or hydroxyurea alone.

The RTOG conducted a randomized study of 389 patients with stage IB to IIA of >5 cm, proven positive pelvic lymph nodes, or stage IIB to IVA carcinoma of the cervix in which patients were treated with either pelvic and para-aortic irradiation (best arm of RTOG Protocol 79-20) or pelvic irradiation and three cycles of concomitant chemotherapy with cisplatin (75 mg/m^2) and 4-day infusion of 5-FU (1,000 mg/m^2 per day).[482] Results were updated by Eifel et al.[427] with a median follow-up of 6.6 years for 228 survivors, the 8-year overall survival rate for women on the irradiation and cisplatin/5-FU arm was 67% versus 41% in the irradiation-only arm ($P < .0001$). DFS rates were 66% and 36%, respectively. There were no significant differences in late complications in the treatment groups.

Southwest Oncology Group 8797 was a study for women with FIGO stage IA2, IB, or IIA carcinoma of the cervix with metastatic disease in the pelvic lymph nodes, positive parametrial involvement, or positive surgical margins at the time of primary radical hysterectomy with total pelvic lymphadenectomy. Patients had confirmed negative PALNs; if the PALNs were not sampled, the patients had confirmed negative common iliac lymph nodes. One hundred twenty-seven patients were randomized to treatment with pelvic EBRT with 5-FU infusion and cisplatin, and 116 were treated with irradiation alone. The 3-year survival for women on the adjuvant cisplatin/5-FU and RT arm was 87%, compared with 77% for women on the pelvic irradiation arm.[438] The difference was statistically significant. An updated analysis with 5.2-year median follow-up reported 5-year overall survival of 80% versus 66%, favoring postoperative chemoradiation in high-risk patients.[206]

TABLE 73.12 DETAILS OF THE TREATMENT PROTOCOLS OF THE FIVE RANDOMIZED TRIALS THAT FORMED THE BASIS OF THE

NATIONAL CANCER INSTITUTE ANNOUNCEMENT

Author (Reference)	Number of Patients	Tumor Stage	Surgical Staging	Control Arm	Investigational Arm
Keys et al.[477] (GOG 123)	369	Bulky IB (≥4 cm)	Completion hysterectomy	XRT	XRT + cisplatin (40 mg/m^2 IV weekly × 6 wk)
Whitney et al.[478] (GOG 85)	368	IIB, III, IVA	Yes	XRT + hydroxyurea (80 mg/kg PO 2×/wk)	XRT + cisplatin (50 mg/m^2 IV days 1, 28) + 5-FU infusion (1 g/m^2 per day, days 2–5, 30–33)

In GOG 123, 369 women were enrolled. One hundred eighty-three women with bulky (≥4 cm) stage IB carcinoma of the cervix with negative pelvic and para-aortic nodes radiographically or surgically determined were randomized to be treated with pelvic EBRT and brachytherapy, followed by extrafascial hysterectomy, and 186 received EBRT and brachytherapy with weekly cisplatin (40 mg/m^2; total dose not to exceed 70 mg/week) followed by extrafascial hysterectomy.[477] In an updated analysis with median follow-up of 101 months[483] the 6-year PFS rate for women treated with irradiation and cisplatin was 71%, compared with 60% for those treated with RT alone, after adjusting for age and tumor size ($P < .004$). The unadjusted 6-year overall survival rates were 78% and 64%, respectively ($P < .015$).

The results of randomized trials using concurrent chemoradiation are summarized in Table 73.13.[486] Curtin et al.[487] completed a small phase III trial in which 89 patients with high-risk stage IB or IIA undergoing radical hysterectomy and pelvic node dissection were randomized to be treated with postoperative cisplatin/bleomycin alone (44 patients) or combined with pelvic RT (45 patients). There were 9 and 10 recurrences, respectively, and survival was equivalent.

On the other hand, Pearcey et al.[484] reported on a Canadian randomized study in which 127 patients with stage IB to IIA of >5 cm or IIB carcinoma of the cervix were randomized to be treated with cisplatin (40 mg/m^2 weekly) and RT, and 126 patients were treated with RT alone (50.4 Gy to the pelvis combined with brachytherapy). With a median follow-up of 65 months, the 5-year survival rates were 59% and 56%, respectively ($P = .43$). There was a somewhat greater incidence of significant late morbidity in the RT-alone group (12% vs. 6%; $P = .08$). Possible explanations for the discrepancy in results between the five US trials[402] and the Canadian study were analyzed by Lehman and Thomas.[480] Some theories include that a higher percentage of early-stage patients were accrued, who therefore had less of a difference in survival, given that the baseline survival rate for both arms was quite high; and that treatment time was short for both arms, again minimizing the difference in improving survival in the chemotherapy arm. This was the smallest of the randomized chemoradiation trials, and although the HR was reduced, given the factors equalizing the two arms, a larger number of patients would have possibly shown a significant

difference.

A 2005 update of a meta-analysis of concomitant chemotherapy and radiation therapy found 24 trials and concluded that chemoradiation improves overall survival and PFS, whether or not cisplatin was used, with absolute benefits of 10% and 13%, respectively.[488] Similarly, a 2008 meta-analysis of the 13 trials that compared chemoradiotherapy to radiation found that there was a 6% improvement in 5-year survival with concurrent chemoradiation (HR 0.81, $P < .001$). The effect was attributed to a reduction in both local and distant recurrence. Chemoradiation increased acute hematologic and gastrointestinal toxicity, but no confirmation was made about a difference in late toxicity.[489]

In the United States, weekly cisplatin has become the preferred approach, with less toxicity than an every 3-week regimen and increased likelihood of completing the treatment on schedule. The number of completed cycles of weekly treatment was shown by Nugent et al.[490] to be predictive of survival. One hundred eighteen patients with locally advanced cervical cancer (stages IB2 to IVA) were treated with combination weekly cisplatin (40 mg/m^2) and radiation between 2003 and 2007. Thirty percent of patients completed fewer than six cycles of chemotherapy. In multivariate analyses, the number of chemotherapy cycles was independently predictive of progression-free survival (PFS) and overall survival (OS). Patients who received fewer than six cycles of cisplatin had a worse PFS (HR = 2.65; 95% CI = 1.35 to 5.17; $P = .0045$) and OS (HR = 4.47; 95% CI = 1.83 to 10.9; $P = .001$). Advanced stage, longer time to RT completion, and absence of brachytherapy were also associated with decreased OS and PFS ($P < .05$). Similar results were found when analysis was conducted using a breakpoint of at least but not less than five chemotherapy cycles. The authors concluded that aggressive supportive care to minimize missed chemotherapy treatments may improve survival after chemoradiation. A retrospective review[491] questioned whether cervical cancer patients should receive cisplatin 20 mg/m^2 × 5 days every 21 days concomitant with RT or weekly 40 mg/m^2 weekly concomitant with RT, given that an advantage with regard to both acute toxicity and PFS was seen in the 5-day regimen.

High-risk patients may benefit from adjuvant chemotherapy after chemoRT. A randomized trial of 515 cases of stage IIB to IVA cervical carcinomas treated with concurrent gemcitabine plus cisplatin followed by adjuvant gemcitabine and cisplatin compared to standard concurrent cisplatin with radiation showed a significant 3-year PFS benefit of 74% versus 65% (P = .03), as well as one in overall survival (HR = 0.68, 95% CI = 0.49 to 0.65).[492] Grade 3 and 4 toxicities were higher in the extended-chemotherapy arm, including two deaths. A trial comparing “outback” Carboplatin/Taxol chemotherapy completed accrual.

Alternatives to Concurrent Cisplatin-Based Chemoradiation

In GOG Protocol 165, patients with stage IIB to IVA cervical cancers received either radiation therapy and concurrent weekly cisplatin (40 mg/m^2) or radiation

therapy and a protracted venous infusion (PVI) of 5-FU. Lanciano et al.[485] reported that the study was prematurely closed after an interim analysis showed a failure rate 35% higher and would not result in improved DFS with PVI 5-FU/RT compared with weekly cisplatin.

Lorvidhaya et al.[493] reported on 673 patients with predominant stage IIB and IIIB disease randomized to receive either irradiation alone or combined with chemotherapy administered in an adjuvant, concurrent, or adjuvant and concurrent schedule. Concomitant chemotherapy consisted of mitomycin C (10 mg/m^2) given on days 1 and 30 and oral 5-FU (300 mg/m^2 per day) given on days 1 to 14 and 42 to 56. Adjuvant chemotherapy consisted of three cycles of oral 5-FU (200 mg/day) given for 4 weeks, with a 2-week rest every 6 weeks. With a median follow-up of 25 months, there was a statistically significant improvement in DFS for all patients who received chemotherapy/RT, regardless of the timing of administration of the chemotherapy. However, the authors did not state the radiation dose delivered with brachytherapy, the total dose prescribed to point A, or the OTT. In the absence of this information, the adequacy of the radiation therapy cannot be evaluated, and we cannot assume that the results of this study apply to all patients treated with irradiation.

In a randomized trial comparing monthly fluorouracil and cisplatin versus weekly cisplatin concurrent with pelvic radiation, Kim et al.[494] enrolled 158 stage IIB and IVA patients. With a median follow-up of 39 months, the acute grade 3 and 4 hematologic toxicities were significantly worse in the fluorouracil/cisplatin arm, 43% versus 26% (P = .04). The trial was not powered to detect a survival difference, and no difference in the overall survival or PFS was noted.

Tseng et al.[495] published results of a study in which patients with advanced carcinoma of the cervix were randomly assigned to either RT alone or concurrent chemotherapy (cisplatin, vincristine, and bleomycin every 3 weeks for a total of four courses) and RT. After a median follow-up of 46.8 months, the DFS and actuarial survival rates were 51.7% and 61.7% in the concurrent group and 53.2% and 64.5% in the RT group, respectively (P = .27). Treatment-related toxicity was higher with the combination therapy compared with irradiation alone (36.7% vs. 17.7%; P = .02).

Several small phase II studies have been performed showing no advantage to weekly paclitaxel over weekly cisplatin[496] and too high toxicity with concomitant cisplatin–paclitaxel.[497] Concurrent weekly carboplatin alone has been shown in many studies to be feasible[498] including in the elderly; it is also

an alternative in patients that have an elevated creatinine. Docetaxel and carboplatin concurrent with radiation was also found to be a feasible regimen.[499]

The GOG carried out a trial of irradiation with either concomitant hydroxyurea (HOU) or a placebo in patients with stage IIIB or IVA cervix cancer.[500] The study was criticized because patients were not surgically staged, half of the 190 patients were not evaluable, and radiation doses were low.[326] Piver et al.[501] published an update of a study of 130 patients (13 with PALN metastasis), 75 of whom were surgically staged. Of 66 patients who underwent surgical staging, 33 received hydroxyurea and 33 a placebo in combination with irradiation. Of the patients who did not have surgical staging, 27 received hydroxyurea and 37 received placebo. The 2-year survival was higher in the HOU group. Symonds et al.,[502] in a review of seven randomized trials, found no evidence to support the use of hydroxyurea with RT in cervix cancer.

In larger randomized trial by the GOG reported by Stehman et al.,[503] 296 surgically staged patients with stage IIB to IVA disease and negative para-aortic nodes were randomized to irradiation plus either hydroxyurea (139 patients) or misonidazole (157 patients). Survival was not statistically different between the regimens, with 33.8% deaths in the hydroxyurea group and 38.9% deaths in the misonidazole group (P = .25). Failure limited to the pelvis occurred in 18% of patients in the hydroxyurea group and 23.6% in the misonidazole group. Of note, in a randomized RTOG trial of patients with stage III disease, Leibel et al.[504] and Overgaard et al.[505] reported lower survival in patients receiving misonidazole than in the patients treated with irradiation alone.

Grigsby et al.[506] published results of an RTOG study in which 120 patients with carcinoma of the cervix were randomized to receive irradiation alone or combined with misonidazole. The 5-year PFS was 22% and 29%, respectively. These findings are similar to those reported by Overgaard et al.[505] who, in a randomized study of 331 patients with carcinoma of the cervix treated with either misonidazole or a placebo and irradiation, found no significant difference in local tumor control (50% vs. 54%), DFS (47% vs. 46%), or crude survival (39% vs. 45%). Immunotherapy studies are ongoing.

Nonrandomized Studies of Chemotherapy and Irradiation

Numerous preliminary reports have been published on results of neoadjuvant/concomitant use of cisplatin and 5-FU, with or without mitomycin C, combined with irradiation to treat patients with locally advanced or recurrent carcinoma of the cervix.[507]

Trials with Cisplatin, 5-Fluorouracil, or Both

Perez and Grigsby[508] reported on 58 patients with locally advanced carcinoma of the cervix treated with concurrent 5-FU/cisplatin and irradiation and compared the results with 257 patients with similar stages treated with irradiation alone during the same period. Pelvic tumor control and disease-free survival and CSS were comparable. The incidence of rectal and bladder fistula was 7% in the chemoirradiation group and 4% with irradiation alone ($P = .61$).

Park et al.[466] described results in 113 patients with high-risk invasive cervical carcinoma treated with cisplatin and 5-FU. For adenocarcinoma, doxorubicin (45 mg/m^2 IV) was added. The patients subsequently received radiation therapy (not described in the publication). For patients with stage I or II tumors >4 cm, the 5-year survival rate was 78.3% with chemoirradiation and was 48% for 77 patients treated with RT alone ($P < .01$). For stages III and IV, the rates were 69.1% and 57.4%, respectively. Toxicity with combined chemoirradiation was not significantly enhanced compared with irradiation alone.

Sardi et al.[509] reported results of three courses of cisplatin, vincristine, and bleomycin (days 1 to 3) at 10-day intervals combined with RT in 205 unselected patients with stage IB cervix cancer (tumors >2 cm) who were divided at random into two groups treated with surgery and RT or neoadjuvant chemotherapy, surgery, and irradiation. After 67 months, no difference in survival was seen in patients with tumors 2 to 4 cm in both groups (77% for control patients vs. 82% with neoadjuvant chemotherapy), but statistically significant differences were seen in bulky tumors (>4 cm): 61% versus 80% in favor of neoadjuvant chemotherapy.

Souhami et al.[510] treated 50 patients with bulky, locally advanced carcinoma of the cervix with a combination of weekly cisplatin (30 mg/m^2) concurrent with RT. At 44 months, the actuarial survival rate was 65%, the total pelvic failure rate was 26%, and the distant metastasis rate was 24%. The incidence of late gastrointestinal toxicity was high, with 10 rectal ulcers (4 colostomies required for severe bleeding), 2 rectovaginal fistulas, and 2 small-bowel obstructions.

Park et al.[511] treated patients with stage I and II carcinomas of the cervix >4 cm with RT alone or concurrent or sequential chemoradiation with cisplatin and 5-FU. The 30-month survival rates were 100% with concurrent chemoirradiation, 89.5% with sequential treatment, and 79.5% with irradiation alone ($P < .05$).

Lee et al.[512] treated 40 women with cervix cancer using 50-Gy EBRT and brachytherapy; in 25 cases, three concurrent cycles of cisplatin/5-FU were given,

and in 15 cases, six cycles of consolidation chemotherapy were given. There was no difference in 2-year survival between the two groups (98% to 100%). Grade 2 or greater hematologic toxicity was more frequent in the consolidation patients.

Grigsby et al.,[513] in a prospective study of 65 patients with cervical cancer and node negative on FDG-PET treated with RT alone (15 patients) or combined with concurrent weekly cisplatin (50 patients), noted a 5-year CSS of 78% and 74%, respectively. Severe complications included 1 rectovaginal fistula and 1 rectal stricture in the concurrent chemotherapy/RT group and 1 chemotherapy-related death.

Trials with Carboplatin

Katanyoo et al.[498] reported 148 patients with stage IIB to IVA cervical cancers treated with concurrent weekly carboplatin (100 mg/m^2 or area under the curve 2) for a median of six cycles and radiation. Among the 142 responders, 36 experienced recurrences: pelvic recurrences in 7 (4.7%), distant failure in 25 (16.9%), and both pelvic and distant in 4 (2.7%). The 2- and 5-year PFS rates were 75.1% and 63.0%, respectively, with the corresponding 2- and 5-year overall survival rates of 81.9% and 63.5%. No grade 3 or 4 hematologic and nonhematologic toxicities were observed during treatment in any patients. Late grade 3 to 4 gastrointestinal or genitourinary toxicities were 10.1% and 0.7%, respectively.

Cetina et al.[514] looked at the use of weekly carboplatin in 59 elderly, diabetic, and/or hypertensive stage IB2 to IIIB cervical cancer patients. All patients completed radiation and 80% received five of six planned cycles, with 83% reaching a complete response. With a median follow-up of 20 months, 33% relapsed, and the 3-year overall survival rate was 63%. Although the regimen is safe and tolerable, it may have reduced efficacy compared to weekly cisplatin.

Trials with Mitomycin C or Tirapazamine

Mitomycin C acts as an alkylating agent and inhibits DNA and RNA synthesis. Activation of mitomycin C is increased in hypoxic conditions, and thus, it acts as a hypoxic radiosensitizer. Interstitial pneumonitis and pulmonary fibrosis are usually related to the dose of drug. Use of IV dexamethasone before administration of the drug may prevent pulmonary toxicity.

Christie et al.[464] described results in three groups of patients with stage IIB and III carcinomas of the cervix treated with pelvic irradiation and an intracavitary insertion combined with chemotherapy. Group A (64 patients)

received 5-FU infusion during the first and last weeks of irradiation combined with mitomycin C (10 mg/m^2 IV). Group B (29 patients) received 5-FU without mitomycin C, and group C (84 patients) received irradiation alone. With median follow-up of 7.2 years, the 5-year survival rates were 56%, 32%, and 36%, and the local tumor control was 73%, 53%, and 50%, respectively. Toxicity was greater in group A (36% grades 3 and 4) compared with the 5-FU and irradiation group (14%) and the irradiation-alone group (20%).

Roberts et al.[515] reported on a trial in which 160 patients with locally advanced cervical cancer were randomized to receive RT alone (82 patients) or RT with concomitant mitomycin C (78 patients). The 4-year actuarial survival was 72% and 56%, respectively (P = .13), and the local recurrence–free survival rate was 78% and 63%, respectively (P = .11). There were no treatment-related deaths. No excess in nonhematologic toxicity has been observed with combined mitomycin C and irradiation.

Tirapazamine, a radiation sensitizer with selective cytotoxic effect on hypoxic cells, was combined with cisplatin in 56 patients with recurrent or metastatic cancer. After six cycles given every 21 days, 4 complete and 13 partial responses were noted. Overall 6-month survival was 56%. Better response was seen in patients who had not received radiosensitizing chemotherapy previously.[516]

Besides the usual hematologic and pelvic toxicity described in many of these studies with chemoradiation, Wun et al.,[517] in a retrospective analysis of 75 patients with gynecologic cancer who received erythropoietin and chemotherapy/RT, noted that 17 had upper- or lower-extremity thrombosis, in contrast to 2 of 72 who did not receive erythropoietin. Of note, Anders et al.,[518] in a review of the literature, reported that 6 of 128 patients (4.7%) treated with chemotherapy/RT without erythropoietin developed grade 4 or 5 thrombosis toxicity.

Trial with Bevacizumab Concurrent with RT

RTOG 0417 treated patients with once-weekly cisplatin (40 mg/m^2) chemotherapy and standard pelvic radiotherapy and brachytherapy. Bevacizumab was administered at 10 mg/kg intravenously every 2 weeks for three cycles. A total of 49 patients were evaluable. The median follow-up was 12.4 months (range, 4.6 to 31.4 months). There were no treatment-related serious adverse events. There were 15 (31%) protocol-specified, treatment-related adverse events within 90 days of treatment start; the most common were hematologic (12 of 15; 80%). Eighteen (37%) occurred during treatment or

follow-up at any time.[519] An update with 3.8 years follow-up (range 0.8 to 6 years) showed a 3-year OS 81.3%, DFS 68.7%, and LRF 23.2%, with 26.5% grade 3 adverse events (mainly hematologic) and 10.2% grade 4 events.[520]

Trial with Epidermal Growth Factor Receptor Inhibition Concurrent with RT

Nogueira-Rodrigues et al.[521] reported a phase I study administering escalating doses of erlotinib (50/100/150 mg) combined with cisplatin (40 mg/m^2, weekly, five cycles) and radiotherapy (external beam, 4,500 cGy in 25 fractions, followed by four fractions/600 cGy weekly of brachytherapy) in squamous cell cervical carcinoma patients, stages IIB to IIIB. Fifteen patients were enrolled, 3 at dose level (DL) 50 mg, 4 at DL 100 mg, and 8 at DL 150 mg. Three patients did not complete the planned schedule. One patient at DL 100 mg withdrew informed consent because of grade 2 rash; at DL 150 mg, 1 patient presented with Raynaud syndrome and had cisplatin interrupted, and another patient presented with grade 4 hepatotoxicity. The latter was interpreted as dose-limiting toxicity, and a new cohort of 150 mg was started. No further grade 4 toxicity occurred. Grade 3 toxicity occurred in six cases: diarrhea in three patients, rash in two patients, and leukopenia in one patient. Treatment did not lead to limiting infield toxicity.

Intra-arterial Chemotherapy

Intra-arterial infusion of chemotherapeutic agents in cervical carcinoma was used for some years based on the distinct arterial supply to the tumor-bearing area. Unfortunately, the responses have been uncommon and short, and the toxicity and complication rates have been significant.[522]

Onishi et al.[523] evaluated intra-arterial cisplatin through catheters inserted into both internal iliac arteries in cervix carcinoma. Patients were randomized into a concurrent intra-arterial infusion of cisplatin with RT (18 patients) or RT alone (15 patients). Five-year overall survival rates were 44.4% and 50%, respectively. In the group receiving intra-arterial infusion, grade 3 or 4 late bowel complications were seen in 44% and grade 3 or 4 myelosuppression in 33%, significantly more than in the RT group.

Neoadjuvant Chemotherapy

Thomas[524] summarized the rationale and potential limitations of neoadjuvant chemotherapy in carcinoma of the cervix. Although response rates to the chemotherapy are between 30% and 85%, none of the studies showed an advantage for pelvic tumor control or survival.[525–532] Colombo et al.,[533] in a review of the literature, concluded that the role of neoadjuvant chemotherapy followed by radiation and by concomitant chemotherapy or by surgery is controversial because no significant advantages in survival or local control have been shown, and receiving upfront chemotherapy may compromise immune status and the patient's ability to receive definitive treatment with radiation or surgery.

Souhami et al.[534] randomized 107 patients with stage IIIB carcinoma of the cervix to treatment with irradiation alone or combined with bleomycin, vincristine, mitomycin, and cisplatin. The overall 5-year survival rate for the neoadjuvant-treated patients was 23%, in contrast to 39% for those treated with irradiation alone ($P = .02$). Locoregional and distant failure rates were similar in both groups.

Kumar et al.[535] reported a randomized trial in which 94 patients with carcinoma of the cervix were treated with chemotherapy (two cycles of bleomycin, ifosfamide–mesna, and cisplatin) followed by RT, and 90 patients were treated with irradiation alone. In the chemotherapy/RT group, 32-month survival was 63% for stage IIB and 50% for stage III, and in the RT group, the rate was 59% for stage IIB and 27% for stage IIIB tumors (differences not

statistically significant). There was no difference in radiation-induced toxicity between the two groups.

In a Swedish study,[531] 47 patients with carcinoma of the cervix were randomized to be treated with irradiation alone (64.8 Gy, 1.8-Gy fractions) and 47 with a combination of three cycles of cisplatin and 5 days of 5-FU administered every third week, followed by the same pelvic irradiation. The 5-year DFS rates were 70% with chemoirradiation and 57% with irradiation alone (P = .07). The incidences of pelvic recurrence were 60% and 47%, respectively, and for distant metastasis, they were 19% and 35%, respectively. Two patients in the chemoirradiation and 1 in the irradiation-alone group died as a consequence of therapy.

Response to Chemotherapy Alone for Patients with Metastatic or Recurrent Disease

Cisplatin has been combined with other cytotoxic agents. Long et al.[536] conducted a randomized study comparing methotrexate, vinblastine, doxorubicin, and cisplatin (MVAC), cisplatin/topotecan, or cisplatin alone in patients with advanced cervical cancer. The MVAC arm was closed after 4 deaths in 63 patients. In 294 patients assigned to the other arms, response rate was 27% for cisplatin/topotecan and 13% for cisplatin alone, with median survival of 9.4 and 6.5 months, respectively.

Paclitaxel, a natural product found initially in the bark of the western yew tree, produces depolymerization and irreversible bundling of tubulin in the cell. It has been shown to have a radiosensitizing effect and may also be considered for patients with metastatic disease. Rose et al.[537] reported on a phase II study of 44 patients in which the starting dose was paclitaxel (135 mg/m^2, maximum 170 mg/m^2) infused over 24 hours, followed by cisplatin (75 mg/m^2) every 21 days. Forty patients (90.9%) had received prior radiation therapy. A median of six courses of chemotherapy was given. Of the 41 assessable patients, 5 (12.2%) had a complete response and 14 (34.1%) had a partial response. Vinorelbine is a semisynthetic derivative of vinblastine. In a phase II trial in patients with prior irradiation, a 28% response rate was observed.[538] Other trials used the drug as neoadjuvant chemotherapy; in 42 patients, 2 complete and 17 partial responses (45%) were observed.[539,540]

Irinotecan and topotecan are camptothecin derivatives whose cytotoxic mechanism is believed to target topoisomerase I.[541] An international phase II trial reported a similar 21% response rate in patients predominantly with prior

irradiation (1 complete and 8 partial responses among 42 patients).[542]

Gemcitabine, a nucleoside analogue, showed a 4.5% partial response and 36% stable disease in 22 patients.[543] In combination with cisplatin, it was evaluated in 32 women with previously treated cervix cancer (initial dose 800 mg/m^2 on days 1 and 8, then every 28 days); there were 7 (22%) partial responses and 12 stable disease responses.[544]

A phase II trial of docetaxel and gemcitabine showed an overall response rate of 21%. With a median survival of 7 months, 39% were alive at 1 year. Docetaxel combined with carboplatin has been shown to have a 25% response rate.[499]

A four-arm comparison of cisplatin/paclitaxel versus cisplatin/vinorelbine, cisplatin/gemcitabine, or cisplatin/topotecan found that the standard arm of cisplatin/paclitaxel remained the best option for patients with stage IVB, recurrent or persistent cervical carcinoma.[545]

In a phase II GOG study of cetuximab 400 mg/m^2 initial dose followed by 250 mg/m^2 weekly until disease progression or prohibitive toxicity, 38 patients (15%) had no progression for at least 6 months. The median OS was 7 months. When cetuximab was combined with cisplatin, no additional benefit beyond cisplatin was identified.[546]

Ifosfamide, paclitaxel, and carboplatin as a triple regimen showed a 33% objective complete or partial response, with an overall median survival of 10 months.[547] Antiangiogenic tyrosine kinase inhibitors pazopanib and lapatinib were tested in 230 patients with stage IVB persistent/recurrent cervical carcinoma. An improvement in progression-free and overall survival was seen with pazopanib.[548] A trial of PD-1 positive cervical cancer treated with immunotherapy is ongoing.

Studies with Radiation Alone

For patients unable to tolerate concurrent chemotherapy or in countries where chemotherapy is not readily available, radiation alone may be used as an alternative to chemoradiation. Mendenhall et al.[549] analyzed 1,211 patients treated with radiation alone with a minimum follow-up of 3 years. In patients with stage IB and IIA disease, there was no significant correlation between doses to these points and pelvic tumor control. In stage IIB, doses of <6,000 cGy to point A correlated with a high pelvic failure rate (8 of 12, 66.7%) in contrast to doses of 6,000 to 9,000 cGy (61 of 261, 23.4%) or higher than 9,000 cGy (10 of 74, 13.5%) (P = 0.01). In stage III, the pelvic failure rate with doses below 6,000

cGy to point A was 72% (18 of 25) compared to 39% (71 of 180) for 6,000 to 9,000 cGy or 35% (27 of 77) with doses above 9,000 cGy ($P \leq .01$).

Thoms et al.[550] reported on 363 patients with bulky endocervical carcinoma treated with curative intent (246 with irradiation alone and 117 with irradiation and surgery); 10-year survival was 45% and 64%, respectively. In a subset of 48 patients with similar tumors treated with irradiation alone and 45 treated with irradiation and surgery, the 10-year survival rates were comparable, and the pelvic tumor control rates were 90% and 87%, respectively.

Eifel et al.[189] evaluated 1,526 patients, of whom 371 had tumors 6 cm or greater. There were biases in treatment selection, but a statistically significantly higher 10-year survival rate was noted in patients treated with irradiation and surgery (64% vs. 45%). Tumor diameter was highly significant as a prognostic factor, and the authors concluded that only patients with lesions >8 cm in diameter benefited from adjuvant hysterectomy. In the same study, 98 patients with stage IB and IIB bulky endocervical carcinomas (≥6 cm in diameter) were treated with RT alone. Twenty-four patients received <6,000 mgh of intracavitary treatment, and 73 received higher doses. Despite having somewhat more favorably treated tumors, patients who received <6,000 mgh had a higher rate of pelvic recurrence at 5 years (33%) than those who received higher doses (16%; $P = .03$). Actuarial 5-year survival rates were 44% and 60% for low- and high-dose groups, respectively ($P = .14$).

Kim et al.[551] assessed the prognostic factors for pelvic tumor control in 40 patients with FIGO stage IB or IIA carcinoma and 25 patients with stage IIB carcinoma classified as barrel shaped (i.e., at least 5 cm in diameter) treated with curative intent. Seventy-two percent were treated with RT alone and 28% with RT and extrafascial hysterectomy. The extent of tumor regression after external beam radiation therapy correlated with the likelihood of local tumor control ($P = .02$). For patients treated with radiation therapy alone, increased brachytherapy dose was associated with better local tumor control. The 10-year overall and CSS rates were 53% and 68%, respectively, and did not differ significantly between treatment groups.

Paley et al.[552] reported on 57 patients with barrel-shaped (mean diameter, 5 to 9 cm) cervical carcinoma treated with preoperative EBRT and BT (mean dose to point A, 79.6 Gy) followed by extrafascial hysterectomy 6 to 8 weeks later. Residual disease was present in 35 (61%) of the hysterectomy specimens; tumor sterilization correlated significantly with the mean dose to point A ($P = .016$). Ninety-five percent of the patients with negative specimens remained clinically

free of disease at their last follow-up versus 31% of those with residual disease ($P < .001$).

The GOG and RTOG conducted a randomized phase III clinical trial in which 282 patients with carcinoma of the cervix measuring 4 cm or greater (exophytic or barrel shaped) were treated with either external beam and intracavitary irradiation or a slightly lower dose of intracavitary irradiation and the same pelvic EBRT followed by an extrafascial hysterectomy.[553] The survival rates were 61.4% for irradiation alone and 64.4% for the combined irradiation and surgery group. The incidence of recurrences was 43.3% in the irradiation group compared to 34.5% with combined therapy ($P = .081$). The incidence of local recurrences was 25.8% and 14.4%, respectively. The incidence of grade 3 and 4 sequelae of therapy was 10.5% and 9.8%, respectively. Thus, the addition of hysterectomy to standard irradiation did not significantly affect survival, although there was a small reduction in the local recurrence rate. When combined therapy is used, the dose of irradiation delivered to the lymph nodes, the time of the operation, and the pathologic examination of the specimens are critical in determining the presence of postirradiation residual tumor.

Perez et al.[38] noted that in patients with primary carcinoma of the uterine cervix who had endometrial stromal invasion or tumor only in the curettings, the addition of a hysterectomy did not improve the survival rate because most of the patients failed at distant sites.

For stage IIB tumors treated with irradiation alone, the 5-year survival rate is 60% to 65%. The pelvic failure rate ranges from 18% to 39%. In an analysis of the Patterns of Care Study in 157 patients who had stage IIB disease, Coia et al.[554] reported a better 4-year survival rate (67% and 54%) and infield tumor control rate (78% and 68%) in patients with unilateral versus bilateral parametrial involvement, respectively. Similarly, in a review of 1,178 patients with stage IIB disease, the 5-year survival rates were 70% with medial parametrial and 58% with lateral parametrial involvement ($P = .004$).[555] Kim et al.,[556] in patients with stage IIB disease, found a correlation of point A dose and incidence of pelvic failures.

In stage IIIB carcinoma, the 5-year survival rates range from 25% to 48%, and pelvic failure rates range from 38% to 50%.[186,557] Hanks et al.,[558] reporting on the Patterns of Care Study, noted a 28% probability of 5-year survival in patients with stage III carcinoma of the cervix treated in a large number of facilities in the United States versus 60% survival in selected large centers (extended survey). Later, Komaki et al.[559] reported a significant increase in local

pelvic tumor control (69%) in patients with stage III carcinoma of the cervix treated in 1983, compared with 37% and 49% in earlier periods (P = .03). The 5-year survival rate increased from 25% to 47% (P = .02). The improvement in pelvic tumor control may be associated with higher external beam doses but more likely is related to the substantial increase in the percentage of patients receiving brachytherapy (96%) and more careful dosimetry and dose calculations for intracavitary therapy. They noted a decrease in major complications from 15% in the 1973 and 13% in the 1978. Patterns of Care Surveys to 7% in 1983. Montana et al.[560] reported that calculation of doses to the bladder and rectum were performed in 80% and 76% of patients, respectively, in the 1983 survey, which may also have resulted in decreased toxicity.

Arthur et al.,[561] in 89 patients with stage IIIB carcinoma of the cervix treated with external irradiation and brachytherapy, observed a locoregional tumor control rate of 22.5% and a DFS rate of 15% in 16 patients treated with 78 Gy or lower doses to point A, in comparison with 53% and 47%, respectively, in 24 patients receiving higher doses.

Horiot et al.[562] reported the results of a French cooperative study of 1,383 patients with invasive carcinoma of the uterus treated with irradiation alone following the MD Anderson Hospital treatment guidelines. Survival and locoregional tumor control were similar in both groups, except in stage III, in which the pelvic and central failure rates were lower in the French patients, may be because of different tumor volumes or socioeconomic factors. Major urinary complications were noted in 2% of the patients. Grade 3 bowel complications occurred in 3% of the patients with stage I and IIA diseases and in 7% of patients with stage IIB and III diseases. Barillot et al.[563] updated the results in 642 patients; the analysis was divided into three periods: 1970 to 1978 (use of standard prescriptions), 1979 to 1984 (implementation of individual adjustments), and 1985 to 1994 (systematic individual adjustments). There was a significant reduction of the external radiation dose (>40 Gy in 47% of patients before 1979 vs. 36% after 1984), use of parametrial boost (55% vs. 39%), use of vaginal cylinder (28% vs. 11.5%), and combined intracavitary and external irradiation volume (842 vs. 503 cm^3 on average). The 5-year actuarial toxicity rates were as follows: grade 2, 23.5%; grade 3, 10%; and grade 4, 3%. The three main predictive factors for rectal and bladder sequelae were increased external radiation dose, higher dose rate at reference points, and whole-vagina brachytherapy.

Marcial et al.[564] described results of a randomized trial in 301 patients with

stage IIB, III, and IVA carcinomas of the uterine cervix treated with split-course irradiation (10 fractions of 2.5 Gy, five weekly doses up to 25 Gy, followed by a rest period of 2 weeks, and an additional 25 Gy delivered in the same manner) or continuous irradiation (30 fractions of 1.7 Gy daily, five times per week, total dose 51 Gy) combined with LDR brachytherapy for 30 Gy to point A. There was no significant difference in tumor control, acute or late complications, or survival in the two groups.

In patients with stage IVA disease, the 5-year survival rates range from 18% to 34%, and pelvic failures from 60% to 80% after definitive irradiation.[288] Million et al.[289] reported 18 of 53 patients (34%) with bladder involvement surviving without disease after definitive irradiation, results comparable with those obtained with exenteration. Kramer et al.[288] reported on 48 patients with stage IVA carcinoma of the cervix treated with definitive RT. Patients with minimal parametrial involvement had a 5-year survival rate of 46%, compared with only 5% for those with extensive parametrial tumor. The major complication rate was 22%, consisting mostly of vesicovaginal fistula in five patients.

Crozier et al.[565] described equivalent 5-year survival rates after salvage pelvic exenteration (37% in 35 patients with adenocarcinoma and 39% in 70 patients with squamous cell carcinoma). In the adenocarcinoma group, 14 of 22 patients and, in the squamous cell carcinoma group, 14 of 30 patients had distant metastases after pelvic exenteration.

Combination of Irradiation and Surgery

Preoperative Chemoirradiation

Bulky endocervical tumors and the so-called barrel-shaped cervix have a higher incidence of central recurrence, pelvic and PALN metastases, and distant dissemination.[566] When using plain x-ray point-based planning for brachytherapy, because of the inability of intracavitary sources to encompass the entire tumor in a high-dose volume, larger doses of external radiation to the whole pelvis, extrafascial hysterectomy, or both have been advocated to improve therapeutic results.[4] Alternatively, the use of 3D planning for the brachytherapy component significantly improves survival,[567] and the ability to dose escalate because of a more precise dose delivery improves local control.[568] In rare cases with large residual after 45 Gy external beam, an Extrafascial hysterectomy may be considered 6 to 12 weeks after completion of preoperative irradiation (45 Gy to the whole pelvis and one intracavitary LDR insertion for 5,500 mgh,

delivering approximately 50 Gy to point A, with a total dose to point A of 70 Gy, or the equivalent dose in HDR, approximately three fractions of 6 Gy per fraction). Higher doses of irradiation alone yield equivalent pelvic tumor control and survival rates.[189]

Keys et al.[477] reported on 183 women with bulky (≥4 cm) stage IB carcinoma of the cervix with negative pelvic and para-aortic nodes radiographically treated with pelvic EBRT and brachytherapy, followed by extrafascial hysterectomy, or EBRT and brachytherapy (to 70 Gy) with weekly cisplatin followed by extrafascial hysterectomy. A significant survival advantage was seen with the combination of concurrent chemoradiation. However, in comparison to other trials, the survival was not significantly improved with the addition of a hysterectomy. The use of PET scanning to determine residual disease allows selection of patients who may be appropriate candidates for a hysterectomy after completion of external beam treatment.[111] Therefore, patients should receive definitive doses of chemoradiation, with hysterectomy reserved for salvage in patients with either gross residual disease or PET-positive disease that is biopsy proven at 3 months after completion of radiation. A subsequent reanalysis including GOG 123 and GOG 71 analyzed 464 patients allocated to pelvic radiation (75 Gy, n = 291) plus hysterectomy or to pelvic radiation (75 Gy) and cisplatin (40 mg/m^2, n = 176) plus hysterectomy. A benefit to chemoradiation was seen for patients who had a poor response.[569]

Morice et al.[570] reported a randomized trial of 61 patients treated with adjuvant hysterectomy versus none after EBRT with concurrent weekly cisplatin and vaginal brachytherapy (15 Gy to intermediate-risk CTV) for stage IB2 or II cervical cancer. Hysterectomy increased the number of deaths, with an 11% nonsignificant survival advantage in the no-hysterectomy arm (86% vs. 97%). As a result of this trial, routine adjuvant hysterectomy is no longer practiced for patients who have no residual disease at 6 weeks after chemoradiation.

Motton et al.[571] retrospectively reviewed 171 patients treated with chemoradiation followed by simple extrafascial hysterectomy or extended hysterectomy. There was no difference in survival or complication rate based on type of surgery. Lèguevaque et al.[572] reported on 111 patients treated with or without adjuvant hysterectomy after chemoradiation; there was no advantage to overall survival, but there was a significant difference in recurrence rates.

Touboul et al.[573] reported on toxicities for 150 patients with stage IB2 to IVA cervical cancers treated at Institut Gustave Roussy (IGR) with extrafascial versus modified radical hysterectomy after chemoradiation. After a median follow-up

of 3.6 years, 15% had grade 2 or greater side effects, including lymphedema, ureteral fistula, bowel fistula, and iliac and vessel rupture. There were two postoperative deaths. Modified radical versus extrafascial hysterectomy had a higher odds ratio (OR) for complications of 2.4 (P = .04), as did the presence of residual disease.

Elective Para-Aortic Lymph Node Irradiation

Rotman et al.[441] updated results of an RTOG randomized study of 337 patients with stage IIB carcinoma of the uterine cervix with no clinical or radiographic evidence of para-aortic lymphadenopathy who, in addition to standard pelvic irradiation, were randomized to electively receive or not 45 Gy to the para-aortic region (1.6- to 1.8-Gy fractions). The 10-year survival rate was 55% for patients receiving elective para-aortic irradiation and 44% for those treated to the pelvis only (P = .02). The locoregional tumor control rate was similar (69% in the para-aortic node–irradiated group and 65% for the pelvis-irradiated group). The 10-year grade 4 or 5 (major) complication rate was 8% in the group receiving para-aortic irradiation, compared with 4% in patients treated with pelvic irradiation alone (P = .06).

A similar randomized study was reported by Haie et al.[574] and the European Organization for Research and Treatment of Cancer (EORTC) on 441 patients with cervical carcinoma, including stage III, who had no evidence of PALN involvement. In the study group, the para-aortic area either received or did not receive 45 Gy with external beam irradiation. No statistically significant difference was found between the two treatment arms with regard to local tumor control, distant metastases, or survival. However, the incidence of para-aortic and distant metastases without pelvic failure was significantly higher in patients receiving pelvic irradiation alone. The incidence of small-bowel injury was 0.9% in the pelvic irradiation group and 2.3% in the pelvic plus para-aortic irradiation group. A severe complication rate of 9% was observed in patients receiving para-aortic irradiation, compared with 4.8% in those treated to the pelvis only.

Sood et al.[575] treated 54 patients with cervix cancer using extended fields (45 Gy) and HDR brachytherapy; 44 received concurrent cisplatin (20 mg/m^2 per day for 5 days during weeks 1 and 4 and once after the second HDR insertion). During a median follow-up of 28 months, six patients had died. The 3-year local tumor control was 100% and 85%, respectively. Late toxicity was 10% and 6%, respectively.

Huang et al.[260] assessed 758 patients and found that 38 (5%) and 42 (6%) had

isolated and nonisolated PALN recurrences after a median follow-up of 50 months (range, 2 to 159 months), respectively. The 3- and 5-year overall survival rate after PALN recurrence was 35% and 28%, respectively, with those with isolated recurrences faring better than those with a nonisolated recurrence ($P < .001$). An SCC-Ag level of >40 ng/mL ($P < .001$), advanced parametrial involvement (score 4 to 6; $P = .002$), and the presence of pelvic lymphadenopathy ($P = .007$) were independent factors associated with PALN relapse on multivariate analysis. This group subsequently identified pretreatment CEA of ≥10 ng/mL as an additional risk factor of PALN relapse after definitive concurrent chemoradiation therapy (CCRT) for SCC of the uterine cervix in patients with pretreatment SCC-Ag levels of <10 ng/mL.[261] The role of prophylactic para-aortic radiation, particularly in patients with large tumor size, parametrial involvement, or involved pelvic lymph nodes, must be carefully weighed against the potential toxicities of para-aortic radiation.

METASTASES TO PARA-AORTIC LYMPH NODES

PALN metastases are frequently combined with distant dissemination but are clinically apparent in only 10% to 20% of patients who have recurrences.

Varia et al.[576] reported on GOG Protocol 125, in which 87 patients with biopsy-confirmed PALNs from cervical cancer were treated with extended-field irradiation (45 Gy in 1.5-Gy fractions) and higher doses to the pelvis (~80 Gy to point A) in combination with 5-FU and cisplatin. The 3-year PFS rate was 33%, and the overall survival rate was 39%. Grade 3 and 4 hematologic toxicities were noted in 13 patients (15%) and chronic proctitis in 3 (3.5%), and 4 patients (4.6%) required surgery for rectal complications.

Nelson et al.[53] reported on 104 patients with stage II and III cervical carcinomas who had exploratory laparotomy and PALN biopsies; 12.5% of patients had stage IIA disease, 14.9% had stage IIB disease, and 38.4% had stage III disease and had PALN metastases. They were treated with 60 Gy to the para-aortic region. Within 4 years, 50% of these patients had distant metastases, and only 1 out of 13 was alive. There was no significant increase in complications in the patients receiving para-aortic irradiation (39% and 32%). The authors concluded that the main goal of exploratory laparotomy and PALN biopsy is to define the extent of disease.

Lovecchio et al.[577] noted a 50% 5-year survival rate in 36 patients with stage IB and IIA cervical carcinomas who had histologically confirmed PALN

metastases treated with RT (including 45 Gy to the PALNs). Fourteen of 31 evaluable patients had pelvic recurrences (12 combined with distant metastases). Unfortunately, the authors did not specify how many patients had para-aortic recurrences, although they reported four abdominal failures.

Stryker and Mortel[578] determined survival after extended-field treatment of PALN metastasis plus brachytherapy or pelvic boost in 35 patients; 5-year survival was 41.7% for 12 patients with microscopic PALN metastasis and 26.1% for 23 patients with grossly enlarged lymph nodes. Three patients (8.6%) had grade 4 morbidity.

Grigsby et al.[579] reviewed 43 patients with cervical cancer and biopsy-proven positive PALN treated with external irradiation to the pelvis and para-aortic regions (45 to 50 Gy) combined with brachytherapy. The 5-year overall survival rate was 32%, and the CSS rate was 49%. Tumor recurrence occurred in 20 patients (3 in the pelvis, 9 in pelvis and distant metastasis, and 8 in distant metastasis only). Severe grade 3 complications occurred in 2 patients (1 had an enterovaginal fistula and the other had radiation myelitis).

Hacker et al.,[580] in 437 patients with invasive cervical carcinoma, 222 of whom were treated with radical hysterectomy and lymphadenectomy, identified 34 in whom resection of bulky pelvic or PALNs was carried out without a complete lymphadenectomy. Thirty-three patients received pelvic external irradiation, and 28 combined pelvic and para-aortic extended-field irradiation (50.4 Gy in 1.8-Gy fractions using a four-field technique). Four cycles of cisplatin were administered to 23 patients. The 5-year survival was 80% in patients with pelvic and common iliac nodes and 48% in those with positive PALNs. Serious long-term morbidity occurred in 6 patients (18%). Radiation enteritis was observed in 5 patients, leading to small-bowel obstruction necessitating resection.

Grigsby et al.[581] evaluated twice-daily external irradiation to the pelvis and para-aortic nodes (1.2 Gy at 4- to 6-hour intervals, 5 days/week) combined with brachytherapy and concurrent chemotherapy in 29 patients with carcinoma of the cervix and positive PALNs. EBRT doses were 24 to 48 Gy to the whole pelvis, 12 to 36 Gy parametrial boost, and 48 Gy to the para-aortics, with additional boost to a total dose of 54 to 58 Gy to known metastatic para-aortic sites. One or two LDR brachytherapy applications were performed to deliver a total dose of 85 Gy to point A. Cisplatin (75 mg/m^2, days 1 and 22) and 5-FU (1,000 mg/m^2 per 24 hours for 4 days, days 1 and 22) were given for two or three cycles. Hyperfractionated external radiation therapy was completed in 86% (25 of 29).

Radiation therapy toxicity was grade 2 in 34%, grade 3 in 21%, and grade 4 in 28%. An unacceptably high rate (31%, 9 of 29) of grade 4 nonhematologic toxicity was recorded. With a median follow-up of 18.9 months, at 2 years, the overall survival rate was 47%, and the probability of locoregional failure was 49%.

Malfetano et al.[582] treated 67 patients with carcinoma of the cervix (44 with stage IIB and 23 with stage III disease) with cisplatin (1 mg/kg up to 60 mg weekly) and extended-field radiation therapy, including the para-aortic nodes, and brachytherapy; 75% were alive without evidence of disease with a mean follow-up of 47.5 months.

Chou et al.[583] treated 19 patients with isolated PALN metastasis from cervix cancer, 14 of them with chemoradiation, 4 with chemotherapy, and 1 with irradiation alone. Seven of the 14 patients receiving chemoradiation survived.

Goodman et al.[584] compiled survival statistics on patients with PALN metastasis and found an average 5-year survival rate of approximately 40%.

Toxicity to the small bowel and duodenum is important to consider when treating para-aortic nodes. In a retrospective study of 14 cervical cancer and 39 endometrial cancer patients treated to the para-aortic nodes with extended-field (EF) IMRT, 6.5% developed acute and 6.5% developed late ≥ grade 3 GI toxicity. Planning constraints were set as small bowel (contrast-enhanced loops) at ideal 5 cc < 55 Gy and maximum at 30 cc < 55Gy. No patients experience duodenal toxicity.[302] In 105 patients with enlarged para-aortic nodes (PAN), 36% had cervical cancer; the 3-year rate of duodenal toxicity was 11.7%, with fatal events in two patients because of perforation. The recommended V_{55} < 15 cc resulted in 7% toxicity, whereas V_{55} > 15 cc resulted in 48% toxicity.[589] A retrospective analysis of 103 patients with cervical cancer and PAN metastases, demonstrated factors associated with improved DSS included concurrent chemoradiation (P = .001), baseline PET imaging (P = .01), and treatment of PANs with IMRT (P = .02). The crude rate of grade 3 or higher late treatment-related adverse effects was 17%.[590] Simultaneous integrate boost to 50-54 Gy followed by a sequential boost to 60-65 Gy has been demonstrated, with adherence to small bowel dose constraints.[590a,590b]

CARCINOMA OF THE CERVICAL STUMP

A supracervical hysterectomy, which removes the uterus and leaves the cervix behind, may be performed for benign conditions of the uterus. The use of

subtotal hysterectomy has declined, given the persistent risk of cervical cancer arising in the remnant tissue and the difficulty of managing cancer of the cervical stump.

It is important to divide carcinoma of the cervical stump into true, when the first symptom occurs 3 or more years after subtotal hysterectomy, or coincidental, when the symptoms are noticed before the third postoperative year. This separation is important because the prognosis for true carcinoma of the stump is significantly better than for coincidental lesions, in which carcinoma was probably present when the hysterectomy was performed.[326]

The natural history and patterns of spread of carcinoma of the cervical stump are similar to those of the cervix in the intact uterus. The diagnostic workup, clinical staging, and basic principles of therapy are the same. Treatment also follows similar paradigms. When surgery is indicated for early stage I tumors, it may be more difficult because of the previous surgical procedures and the presence of adhesions in the pelvis. With radiation therapy, external beam treatments are identical, although small bowel may be adherent to the superior portion of the cervix because of scar tissue, and using the prone position, as well as having the patient maintain a full bladder for treatment, may aid in attempting to move the small bowel out of the radiated field. Whole-pelvic radiation is recommended, with the superior border set at the level of the bifurcation of the common iliac nodes as determined by a CT simulation, or at the L4-L5 interspace for those planned with plain film radiographs. A dose of 45 Gy in 1.8-Gy fractions over 5 weeks is the most commonly recommended dose, with concurrent weekly cisplatin at 40 mg/m^2 given for five doses. For brachytherapy, if >2 cm of the endocervical canal remain, it is best to insert a short tandem surrounded by ovoids, a ring, or, if indicated because of vaginal extension or lateral extension, interstitial catheters. For LDR insertions, as many sources as technically feasible should be inserted in the remaining cervical canal. For HDR brachytherapy, the tandem should extend from the cervical os superiorly to the full extent of the canal. When there is no opportunity to insert any sources in the cervical canal, an interstitial implant to bring the tumor dose to approximately 80 to 90 Gy for brachytherapy after completing a standard dose of 45 Gy to the whole pelvis is recommended while monitoring the radiation dose to the organs at risk (OAR). The use of external beam radiation alone is not recommended due to the significant mobility of the cervix because of bladder motion, the low dose tolerance of the surrounding small bowel, and the high dose of radiation necessary for cure in patients with bulky disease. Total dose (external and LDR

intracavitary brachytherapy) to the upper vaginal mucosa should not exceed 150 Gy, and tolerance doses to small volumes (D_{2cc}) of the bladder (90 to 100 Gy) or rectum and sigmoid (70 to 75 Gy) should be carefully monitored.

The 5-year survival rate for carcinoma of the cervical stump treated with irradiation is similar to that reported for patients with carcinoma of the intact uterus.[591,592] The anatomic sites of failure and the incidence of recurrences are similar to those of patients in whom the uterus is intact. Distant metastases also follow the same distribution. In 253 patients with carcinoma of the cervical stump treated at MD Anderson Cancer Center, median survival was 203, 140, and 32 months for stages I, II, and III, respectively.[593] Kovalic et al.[591] reported on 70 patients with carcinoma of the surgical stump treated with irradiation; 16 also underwent a surgical procedure. The 10-year DFS was 79% for stage IB, 66% for stage IIB, and 39% for stage IIIB disease. The pelvic failure rates were 10%, 9%, and 50%, respectively. Major gastrointestinal complications were noted in 9% of patients and urinary complications in 3.8%. The results are comparable with those seen in patients treated for invasive carcinoma of the cervix with an intact uterus.

Hannoun-Levi et al.[594] published results in 77 patients treated for carcinoma of the cervical stump. Treatment consisted of a combination of EBRT and brachytherapy, and in a few cases, patients underwent surgery or interstitial brachytherapy. Three-year pelvic tumor control was achieved in 59 of 77 patients (76.6%); tumor control probabilities were 77%, 73.7%, and 56% in patients with stage I, II, and III tumors, respectively. Late complications were grade 2 in 5 patients (6.5%); grade 3 in 1 patient (1.3%), and grade 4 in 2 patients (2.6%).

Hellstrom et al.[595] published a retrospective study of 145 patients treated for carcinoma of the cervical stump, representing 2.2% of all cervical cancers. Three control cases to each case were matched from the cohort of cases with cervical carcinoma with intact uterus. The dose of irradiation from the intracavitary application given to the stump cancers was lower than for comparable cases with intact uterus. Long-term prognosis for squamous cell carcinoma of the uterine stump was comparable to that of the ordinary cervical carcinomas. Stump adenocarcinomas had a worse prognosis compared with adenocarcinoma of the intact uterus ($P < .07$) and with squamous cell carcinoma stump ($P = .05$). The complication rate was higher for stump cancer cases compared with that for cervical cancers with an intact uterus.

Because of the close proximity of the bladder, rectum, and small intestine to

the intracavitary sources and to the often higher doses of external beam irradiation given to the whole pelvis, complications are somewhat more frequent than in carcinoma of the cervix with an intact uterus. Care in brachytherapy treatment planning, including the use of 3D-based treatment planning to minimize dose to the normal tissues, should be considered.

SMALL CELL CARCINOMA OF THE CERVIX

Small cell carcinoma of the cervix, like its counterparts in the lung and other anatomic locations, has a high proliferation rate and marked propensity for regional lymph node and distant metastases. Miller et al.[596] demonstrated that all small cell carcinomas of the cervix are aneuploid, compared with only 30% of large-cell nonkeratinizing squamous carcinomas. The incidence of lymphatic vascular space invasion is 80% to 90%, and that of lymph node metastases has been reported to be 40% to 67%.[597] These patients must be evaluated in conjunction with a medical oncologist; the workup should include bone marrow aspiration biopsy of the iliac crest and other tests to rule out metastatic spread. Furthermore, the basic therapy should include a combination of cytotoxic agents with pelvic EBRT and intracavitary brachytherapy to doses similar to those used in squamous cell carcinoma, although some patients have been treated with radical surgery. If bleeding is present, prompt institution of radiation therapy with concurrent chemotherapy is necessary. Patients have extremely poor outcomes, with the only reported survivors having had triple-modality therapy of small tumors treated by radical hysterectomy, concurrent chemoRT, and adjuvant chemotherapy. Prophylactic cranial irradiation is not indicated because cervix cancer will most commonly spread first to lung and then to brain.

Patients with small cell carcinoma of the cervix are treated with the same irradiation techniques as outlined for other histologic varieties of cervical carcinoma in combination with multiagent chemotherapy, including external beam radiation to 45 Gy, followed by nodal boost if PET-positive nodes are identified, followed by brachytherapy. The most frequently prescribed drugs are cisplatin and etoposide (VP-16) every 3 weeks.[598] Hoskins et al.[599] used a multimodality regimen of four cycles of cisplatin and etoposide with concurrent locoregional RT in 11 women with small cell carcinoma of the cervix. The 3-year overall and failure-free survival rates were 28%. Four patients were alive in first remission; the remaining seven died (two from toxicity, five from cancer). Toxicity of therapy was significant, with 70% experiencing severe neutropenia;

40% were admitted to the hospital for emesis control.

Twelve patients with small cell carcinoma of the cervix were treated with radical hysterectomy (five received postoperative RT for lymph node metastases and two for close margins). With a mean follow-up of 73 months, the DFS rate was 36.4%, compared with 71.6% for patients with non–small cell carcinoma.[597] Four of five patients who received postoperative irradiation died with pelvic recurrence, and three also had disseminated metastases. However, only those with small lesions or those who received adjuvant irradiation were cured.

Delaloge et al.[600] reported only 2 of 10 patients with neuroendocrine small cell carcinoma of the cervix surviving at 13 and 53 months after treatment, which included surgery, irradiation, and cisplatin/etoposide combination chemotherapy.

Boruta et al.[601] reviewed results in 11 of their and 23 other patients with early-stage[601] neuroendocrine cervical carcinoma identified by a Medline search. Lymphovascular space invasion was present in 21 of 27 patients (78%) (7 unknown), and 15 of 29 (52%) had lymph node metastases. Fifteen patients were treated with cisplatin/etoposide (PE), 7 with vincristine/doxorubicin/cyclophosphamide (VAC), 2 with alternating cycles of VAC and PE, and 10 with other chemotherapy regimens. Twenty women were treated with radiation therapy. The presence of lymph node metastases was a poor prognostic factor ($P < .001$). PE and VAC chemotherapy were associated with increased survival ($P < .01$).

ADENOCARCINOMA OF THE CERVIX

Squamous cell carcinoma accounts for 80% of cervical cancers, adenocarcinoma for 15%, and adenosquamous carcinoma for 3% to 5%. SEER data from 1972 to 2002 suggest that the incidence of cervical adenocarcinoma is rising, but based on SEER data, cause-specific mortality is not significantly different than that for SCC.[602] Adenocarcinoma has been linked to HPV-18, which has a higher rate of nodal and distant metastases than HPV-16.[183] Despite a slower regression after irradiation, reflecting cellular kinetics and slow growth, no difference in tumor control or survival has been observed in adenocarcinomas compared with squamous cell carcinomas[603,604] although prognosis is related to clinical stage, volume of disease, and dose of irradiation.[605] Because of the predilection for endocervical involvement in adenocarcinoma, a combination of irradiation and conservative hysterectomy has been advocated by some authors[606] although

results are comparable with those obtained with irradiation alone.[603] Given a lower toxicity profile with chemoRT, this is preferable to a planned course of RT alone followed by hysterectomy upfront. Patients who have residual disease after chemoRT may be candidates for adjuvant hysterectomy.

Grigsby et al.[603] found no difference in 5-year DFS in patients with adenocarcinoma of the cervix (AC) compared with SCC treated with RT alone or combined with surgery. In contrast, Eifel et al.[607] reported that overall 5-year survival rates for patients with SCC and AC were 81% and 72%, respectively ($P < .01$). Patients with AC had a maximum cervical diameter of <4 cm more often than did those with SCC (53% vs. 47%). For 903 patients with tumors of ≥4 cm, 73% of those with SCC survived ≥5 years, compared with only 59% of those with AC ($P < .01$). Although there was no significant difference in the rate of pelvic disease recurrence for patients with AC or SCC tumors of ≥4 cm (17% vs. 13%; $P = .16$), the rate of distant metastases was greater for patients with AC (37% vs. 21%; $P < .01$). For patients with tumors of ≥4 cm, prognosis was strongly correlated with tumor size ($P < .01$) and lymphangiogram findings ($P < .01$) but not with age ($P = .58$) or tumor morphology (exophytic vs. endocervical; $P = .33$); a trend toward better survival in 165 patients who underwent adjuvant hysterectomy (78% vs. 71%) was not significant ($P = .09$). Multivariate analysis confirmed a highly significant independent association between histology and survival; patients with tumors ≥4 cm in diameter that were AC had an estimated risk of death 1.9 times that of patients with SCC ($P < .01$).

Nakano et al.[608] studied 58 patients with adenocarcinoma of the cervix treated with LDR or HDR brachytherapy and external pelvic irradiation. The 10-year survival rates for stages I, II, III, and IV were 85.7%, 60%, 27.6%, and 9.1%, respectively. The local tumor control rate with HDR treatment was 45.5%, significantly lower than with LDR (85.7%) or mixed–dose rate treatments (72.7%). Kilgore et al.,[604] in a study of 162 patients with adenocarcinoma compared with matched patients with squamous cell carcinoma, found that clinical stage and lesion size were the most important prognostic factors. In patients with stage I tumors, no significant difference in survival was found when they were treated with radical surgery, irradiation alone, or irradiation combined with hysterectomy. In contrast, Kjorstad et al.[609] reported a worse 5-year survival rate in 102 patients with adenocarcinoma (51%) compared with that of 1,900 patients with squamous cell or other differentiated carcinomas (68%).

A Cochrane database review[610] found only one randomized trial, the Landoni study, in which a small subgroup analysis that was not powered to detect a difference showed an apparent improvement with surgery, although the majority of patients required adjuvant RT, rather than chemoradiation, which increases the rates of toxicity. Adenocarcinoma predicts worse OS on multivariate analysis (HR = 2.68, 95% CI = 1.9 to 3.8). Primary chemoradiation is considered the standard regimen for patients with locally advanced cervical adenocarcinoma.

Huang et al.[611] reported on 318 stage IB to IIB postoperative cervical cancer patients, 202 (63.5%) with SCC and 116 (36.5%) with AC/atypical squamous cells (ASC), treated by radical hysterectomy and adjuvant RT/concurrent chemoRT (CCRT). The 5-year relapse-free survival rates for SCC and AC/ASC patients were 83.4% and 66.5%, respectively ($P < .001$). Distant metastasis was the major failure pattern in both groups. After multivariate analysis, prognostic factors for local recurrence included younger age, parametrial invasion, AC/ASC histology, and positive resection margin; for distant recurrence, they included parametrial invasion, lymph node metastasis, and AC/ASC histology. Compared with SCC patients, those with AC/ASC had higher local relapse rates for the intermediate-risk group but a higher distant metastasis rate for the high-risk group. Postoperative CCRT tended to improve survival for intermediate-risk but not for high-risk AC/ASC patients.

A SEER analysis showed that patients with adenocarcinoma had an increased risk of dying compared to squamous cell carcinoma patients.[196] A review of GOG prospective trial patients showed that there was no difference between adenocarcinoma and squamous cell carcinoma if patients received chemoradiation.[197]

TREATMENT OF ELDERLY PATIENTS

Oguchi et al.[612] reported on 23 patients 90 years of age or older treated for cervix carcinoma. Definitive radiation therapy was completed in 13 of the patients, and local tumor control at 6 months was attained in 9 patients. Palliative RT was completed in 7 of 11, and palliation was observed in 9 patients (81%). Seven patients were alive for 15 to 67 months. Fourteen patients died because of intercurrent disease or senility associated with active cancer and 2 because of senility without evidence of cancer. The 2-year overall and relapse-free survival rates were 30% and 21%, respectively.

CARCINOMA OF THE CERVIX AND PREGNANCY

The concurrent presence of carcinoma *in situ* or invasive carcinoma of the uterine cervix and pregnancy, although rare, poses a therapeutic dilemma to gynecologic and radiation oncologists. Reported incidence is approximately 1 to 10 per 10,000 pregnancies.[613] In the United States, the incidence has decreased. Norstrom et al.,[614] in Sweden, found that cervical cancer was diagnosed in 33 women in association with pregnancy (incidence, 11.1 cases per 100,000 deliveries and 7.5 per 100,000 pregnancies). Abnormal bleeding was the symptom that led to diagnosis in 54.5% of the women; 45.5% were asymptomatic but had an abnormal cervicovaginal cytologic test result (39.4%) or abnormal vaginal examination (6.1%) in association with pregnancy. During the follow-up, 1 of 12 women with cervix cancer in the first trimester, 4 of 12 in the third trimester, and 2 of 9 postpartum died of the disease. Primary surgery was used more frequently than radiation therapy.

For carcinoma *in situ*, if the pregnancy is allowed to reach full term, confirmation of the diagnosis by colposcopy and conservative management with monthly Pap smears constitutes the best approach. Conization has frequently been performed. Punch biopsies can be obtained, but the diagnostic accuracy is less reliable. As many as 50% of the patients have residual carcinoma *in situ* after delivery.

In patients with invasive carcinoma, the lesion is usually clinically apparent. Multiple punch biopsies are adequate to confirm the diagnosis. Management is individualized based on tumor size and stage, patient age, and desires of the patient (or couple) regarding the pregnancy. The majority of patients with cervical cancer diagnosed during pregnancy (~75%) have stage I tumors.[613,615,616]

Women with tumors diagnosed early in pregnancy are often recommended to abort the fetus. Because there is a greater need to institute therapy as soon as possible, the accepted method of treatment in patients in the first 6 months of pregnancy is to carry out definitive surgery or radiation therapy, as indicated by the stage of the disease, with resultant loss of the fetus. An abortifacient may be administered before initiating radiation to ensure fetal demise and delivery of the placenta prior to initiation of treatment. The whole pelvis is irradiated (40 to 45 Gy in 4 to 5 weeks). However, in one series of 45 patients, 27% did not abort spontaneously and surgical evacuation was required[617]; misoprostol may be administered as an alternative to surgical evacuation after failed spontaneous abortion.[618] After this dose of radiation, careful evacuation of the uterus and

LDR (or equivalent-dose HDR) brachytherapy may be performed under general anesthesia. If a radical hysterectomy is performed and positive pelvic lymph nodes are found, the usual postoperative irradiation, including external beam with or without intracavitary insertion, should be carried out.

If the woman refuses abortion, serial MRI scans at 2- to 3-month intervals to ensure no growth or spread to lymph nodes is recommended. Neoadjuvant chemotherapy may be considered in selected patients.[619] Sorosky et al. reported on eight pregnant women with stage I carcinoma of the cervix who had declined immediate therapy and followed until the late third trimester; a cesarean section–radical hysterectomy was performed, with delay in therapy ranging from 3 to 40 weeks during the pregnancies. There was no clinical progression of the disease with follow-up of 33 months.

When patients are diagnosed in midpregnancy (second trimester), consideration to keeping the pregnancy and treating with chemotherapy is given. A French series reported five cases between 2002 and 2009.[620] Three patients received neoadjuvant chemotherapy; one patient died of cancer. A Chinese report described treatment of two patients with neoadjuvant paclitaxel and cisplatin as feasible.[621]

Occasionally in late pregnancy (final trimester), if tumors are small and an MRI confirms no lymph node involvement, definitive therapy is postponed until after imminent delivery. In a review of the literature, intentional treatment delay was associated with a recurrence rate of 4%.[392] Greer et al.[325] noted that in 600 infants without congenital abnormalities, when stage IB cervical carcinoma was diagnosed during pregnancy and fetal survival was chosen, the neonatal mortality rate decreased from 30% when the fetus was delivered at 26 to 27 weeks to 2.7% when the fetus was allowed to mature to 34 to 35 weeks. In the third trimester of pregnancy, some gynecologic oncologists prefer a postpartum cesarean section, combined with a radical hysterectomy and lymphadenectomy followed by radiation for high-risk features when present. However, some authors report that vaginal delivery has no detrimental effect on the prognosis.[622]

Patients who require high doses of pelvic irradiation should be counseled regarding the permanent loss of reproductive capability, not only because of ovarian ablation (which happens with doses of 8 Gy or higher) but also as a consequence of radiation effects in the uterus.[623,624]

Survival is the same regardless of the trimester of the pregnancy in which definitive treatment is instituted. Creasman et al.[622] reported on 48 patients treated by irradiation, 45 by irradiation followed by surgery, and 5 with radical

hysterectomy alone. The survival was comparable with that of nonpregnant patients for similar stages. The survival rate for patients with stage I disease was comparable whether vaginal delivery was allowed or a cesarean section was performed (~85% in stage I and 50% to 64% in stage II). In addition, the percentage of infants surviving (>80%) was the same in both groups.

Sood et al.[624] performed a retrospective analysis of 26 women with cervical carcinoma diagnosed during pregnancy and treated primarily with radiation therapy (mean dose, 46.7 Gy) and LDR intracavitary radiation (mean dose, 56.5 Gy to point A). These cases were matched with 26 nonpregnant control patients based on age, histology, stage, treatment, and year of treatment. There were no statistically significant differences in recurrence rates or survival between the pregnant group and the control patients. Short-term toxicity was comparable in pregnant and nonpregnant patients. Long-term complication rates were 12% in pregnant patients and 27% in control patients, but this difference was not statistically significant. Most complications were likely related to radiation techniques (particularly the predominance of ^{65}Co).

Sood et al.[625] compared the prognosis of 56 women who had cervical cancer diagnosed during pregnancy and 27 who were diagnosed within 6 months after delivery. Control patients (cervical cancer diagnosed at least 5 years since last delivery) were matched one to one with cases based on age, histology, stage, treatment, and time of treatment. Among the postpartum women, 11 were treated with radical hysterectomies and 14 with radiation therapy, and 2 with stage IA1 disease were treated with vaginal hysterectomies. One of seven patients who had cesarean sections had a local and distant recurrence. In contrast, 10 of 17 (59%) patients who delivered vaginally had recurrences (P = .04). In multivariate analysis, vaginal delivery was the most significant predictor of recurrence, followed by high tumor stage. Survival for patients diagnosed in the postpartum period was significantly worse than for control patients and for those diagnosed during pregnancy. The authors concluded that pregnant women with cervical cancer should be delivered by cesarean section.

Jones et al.[626] published a survey by the American College of Surgeons that evaluated management of invasive cervical carcinoma in 161 pregnant patients; 86 were treated with surgery alone, 30 with radiation therapy alone, and 45 with a combination of the 2 modalities. Approximately one-third of patients were diagnosed in each trimester. The 5-year survival was 94.6% for patients diagnosed in the first trimester, 76.9% for the second, and 68.9% for the third. The prognosis of patients with invasive carcinoma of the cervix associated with

pregnancy was similar to that of nonpregnant patients. There was no significant difference in 5-year survival between the patients delivered by cesarean section and by normal vaginal delivery.

Senekjian et al.[627] reported no difference in survival or patterns of failure in 24 women who were pregnant at the time of diagnosis of clear cell adenocarcinoma of the cervix and vagina compared with 408 who had never been pregnant. The 5- and 10-year actuarial survival rates were 86% and 68% for the pregnant patients and 87% and 79% for the patients who had not been pregnant, respectively.

The practice popularized 30 years ago of administering a "restraining dose of radium" and deferring definitive radiation therapy until delivery is carried out should be strongly rejected. Strauss[628] reported 2 of 11 infants being born with microcephaly in addition to other complications such as alopecia, facial deformity, eye damage, and chromosomal abnormalities after this procedure.

BRACHYTHERAPY

After the discovery of radium in 1898 by the Curies, publications followed describing use of the first glass radium capsule in 1904 and a metal brachytherapy applicator for cervical cancer in 1905.[629] The incorporation of brachytherapy after external beam treatment arose from the recognition that tumor control probability correlated with radiation dose and cancer volume.[630] Evidence confirms that brachytherapy as used for dose escalation after external beam treatment for cervical cancer significantly improves survival.[558,631–634] Therefore, brachytherapy is a standard part of the treatment of locally advanced (stages IB2 to IVA) cervical cancer after external beam radiation; brachytherapy alone may be used as primary treatment for selected cases with early-stage (stages IA to IB1) cervical cancer.[635] The increasing complexity of brachytherapy administration, including the use of complex imaging, mandates implementation of careful quality assurance measures and a culture of open communication to ensure safe practices in the clinic.[635]

Dose Rate

The ICRU in its Report 38[636] defines brachytherapy dose rate as follows: LDR, 0.4 to 2 Gy/hour; medium dose rate (MDR) or PDR, 2 to 12 Gy/hour; and HDR, >12 Gy/hour. For LDR, the most commonly used isotope is ^{144}Cs, and for PDR and HDR, it is ^{206}Ir. The use of HDR has significantly increased in the United

States, from 13% in the 1996–1999 Quality Research in Radiation Oncology (formerly known as the Patterns of Care) survey to 62% in the 2007–2009 survey.[400,637] In other US, European, and Japanese surveys of gynecologic brachytherapy practitioners, approximately 85% state that they use HDR brachytherapy,[638–640] whereas in Canada, the reported use is 68% HDR, 10% PDR, and 23% LDR.[641] The dose delivered per fraction for HDR and proportion of dose delivered with external beam versus brachytherapy vary substantially in different centers around the world.[639]

Most institutions in the United States have either LDR or HDR brachytherapy available. Larger centers may have LDR, PDR, and/or HDR. Overall, outcomes are similar regardless of dose rate, with the caveat that for HDR, 3D imaging should be incorporated to ensure coverage of the tumor, particularly for large-volume disease.[642] Several studies demonstrate worse survival for stage IIIB cervical cancer treated with HDR because of initiating the treatment early in the course of external beam therapy[643] when the tumor mass was >4 cm and therefore a prescription to point A did not cover the tumor volume or by not using 3D planning to cover large residual disease.[644]

Biology of High–Dose Rate Brachytherapy for Cervical Carcinoma: Equivalent Dose in 2 Gy and Biologically Effective Dose

To achieve tumor control using HDR equivalent to that with LDR brachytherapy, attention to the dose/fractionation schedule and to normal tissue doses is mandatory.[645–647] The linear-quadratic (LQ) model provides calculation estimates of biologically equivalent dose taking into account dose rate, dose per fraction, and OTT.[648,649] For comparison of LDR to HDR, the LQ model doses are normalized to an equivalent dose in 2 Gy (EQD2).[650,651] The α/β ratio is a critical component of the LQ model.[651] For cervix cancer, an α/β ratio of 10 Gy is used for tumor and an α/β of 3 Gy is used for normal tissues,[652] which may have inherent inaccuracies in generalizability[653] although an α/β ratio of 3 Gy for the rectum has been correlated with late rectal complications.[654–656]

Spreadsheets to assist with HDR EQD2 dose conversions are available from the American Brachytherapy Society (www.americanbrachytherapy.org/guidelines). The values derived are not actual doses but biologically effective ones that take into consideration dose rate and effect of fraction size.[657]

Although use of a detailed EQD2 conversion is preferred, an approximation of these values was proposed by Orton et al.[647] with an LDR-to-HDR reduction

factor of 0.54 to 0.6 (Table 73.14) and by Patel et al.[644] with a similar correction factor of 0.58. These conversion factors are valid when three to five HDR fractions are used, but with a higher number of fractions (six to eight), the conversion factor is closer to 0.75. Therefore, use of the EQD2 worksheet is recommended for consistency.

The importance of adopting biologically based equivalent doses when switching from LDR to HDR brachytherapy is exemplified in a report by Newman[658] on 115 patients treated with external irradiation (40 to 50 Gy) and manual afterloading cesium sources delivering 60 Gy to point A with a dose rate of 0.75 Gy/hour, or a Selectron device with 40-mCi sources, which delivered from 0.75 to 1 Gy/hour to point A. Because of the increased dose rate, the total intracavitary dose was reduced by 20%. Grade 3 genitourinary and gastrointestinal complications were observed in 3 of 87 patients (3.4%) treated with LDR, in contrast to 30 of 132 patients (22.7%) treated with the Selectron HDR sources. No significant differences in local tumor control and survival were found.

TABLE 73.14 MEAN VALUES OF THE NUMBER OF FRACTIONS, DOSE/FRACTION TO POINT A (FOR HIGH DOSE RATE) AND TREATMENT TIME, DOSE RATE FOR LOW DOSE RATE (WITH STANDARD ERRORS), AND THE RATIO OF TOTAL DOSES

	HDR		LDR		
Stage	Fractions	Dose Per Fraction (Gy)	Treatment Time (Hour)	Dose Rate (Gy/Hour)	Ratio of Total Doses (HDR/LDR)
I	5.3 ± 0.40	7.6 ± 0.40	75.4 ± 7.3	0.87 ± 0.14	0.60 ± 0.13
II	4.7 ± 0.30	7.4 ± 0.30	80.2 ± 7.0	0.80 ± 0.11	0.54 ± 0.10
III	4.6 ± 0.40	7.4 ± 0.40	77.3 ± 8.9	0.87 ± 0.14	0.50 ± 0.11
IV	4.7 ± 0.70	7.5 ± 0.60	79.6 ± 18.5	0.89 ± 0.27	0.50 ± 0.21
All	4.82 ± 0.21	7.45 ± 0.20	78.1 ± 4.4	0.85 ± 0.07	0.54 ± 0.06

HDR, high dose rate; LDR, low dose rate.

Figure 73.20 illustrates the late normal-tissue effect, which is proportional to log cell kill, and the relationship to the number of HDR treatment fractions.[659] Each solid curve is calculated assuming the same log cell kill. Late damage rises

sharply as the number of HDR fractions is decreased. When these curves are above the dashed lines that represent the maximum late effect of 70 Gy of LDR brachytherapy given at 0.5 Gy/hour, the risk of late complications increases. Displacing the bladder and rectum away from the HDR sources for the short duration of therapy may offset the radiobiologic disadvantage of using a few brachytherapy fractions.[647]

Brachytherapy Process: Preparation and Timing

Standard procedures for pretreatment evaluation, imaging, anesthesia use, and treatment duration should follow accepted general principles in the guidelines published by the American Brachytherapy Society in 2012.[635,660,661] Planning the course of brachytherapy should begin at the time of initial presentation. An examination at diagnosis assessing disease extension and tumor size should be recorded. Periodic examinations during external beam treatment should be performed to monitor response. For patients receiving concurrent chemoradiation, rapid shrinkage should be expected because treatment may regress the tumor to 70% to 80% of the pretherapeutic volume. Therefore, a clinical gynecologic examination at the time of brachytherapy is also important.[662,663] Inserting radiopaque marker seeds (“fiducials”) at the time of diagnosis that mark the inferior, lateral, and superior extension of a vaginal tumor may aid in identifying regions requiring dose escalation with brachytherapy even after complete regression during external beam treatment.

Treatment schedules integrating external beam irradiation and brachytherapy were initially designed with regard to the disease stage and volume.[664] For LDR, insertion of the applicator may be done after all external beam finishes, with the caveat that one or two insertions may be required, approximately 1 week apart. All treatments, including external beam treatment and brachytherapy, should finish 8 weeks from the initiation of radiation.[207]

The optimal time–dose–fractionation scheme and the technique for remote control afterloading intracavitary brachytherapy for cervical cancer have yet to be established through systematic clinical trials. For HDR or PDR brachytherapy, the applicator insertion and treatment may commence after external beam treatment finishes, to ensure optimal geometry with normal tissues far from the applicator. Alternatively, the physician may choose to insert the applicator for treatment as early as during the second week of external radiation if the tumor is small enough, to minimize total treatment time. However, brachytherapy and external beam treatments are not given on the same

day.

Applicator Selection

The tandem and ovoid applicator provides radiation dose covering the cervix, uterus, inner parametria, and approximately 1 to 2 cm of the upper vagina. The tandem and ring applicator has a slightly narrower dose distribution, but with HDR, the dose distribution may be optimized and mimics that obtained with the tandem and ovoid applicator. For patients with a very narrow vagina because of stricturing, a tandem and cylinder applicator may be the only option available. However, this applicator provides insufficient dosing to the parametrial tissue and should be used with caution. For patients with large tumors with residual bulky disease after external beam radiation or those with vaginal extension, fistulae, or pelvic sidewall invasion, a combination of tandem/ring or ovoid with interstitial applicator or tandem/interstitial applicator alone may be inserted.

Applicator Insertion

General guidelines from the American Brachytherapy Society should be followed.[635] The patient receives appropriate anesthesia for pain management. In the lithotomy position, the perineum is sterilely prepped and draped. The Foley catheter is inserted into the bladder. The catheter is clamped and the bladder filled with 150 to 200 cc of saline if US is used. US with a transabdominal probe can significantly speed up the insertion process and assist with accurate placement because the uterine canal is often clearly visible after instilling fluid in the bladder (Fig. 73.21). Transabdominal US can measure uterine width and height in patients who do not have large fibroids or tumor volumes that greatly distort uterine configuration.[665] US does not define the target volume as clearly as MRI but may be used to assist with 3D-based planning when CT or MRI is unavailable.[666] Transrectal US may assist with interstitial brachytherapy when other imaging modalities are not available. For interstitial insertions, CT or MRI may be used during the insertion process iteratively using real-time guidance to ensure proper tumor coverage and no inadvertent insertions into the rectum or bladder.[667] After tandem and ovoid or tandem and ring applicator placement, vaginal packing covered with lubricant gel is placed in the vagina to separate the bladder and rectum, which also helps to maintain applicator position.

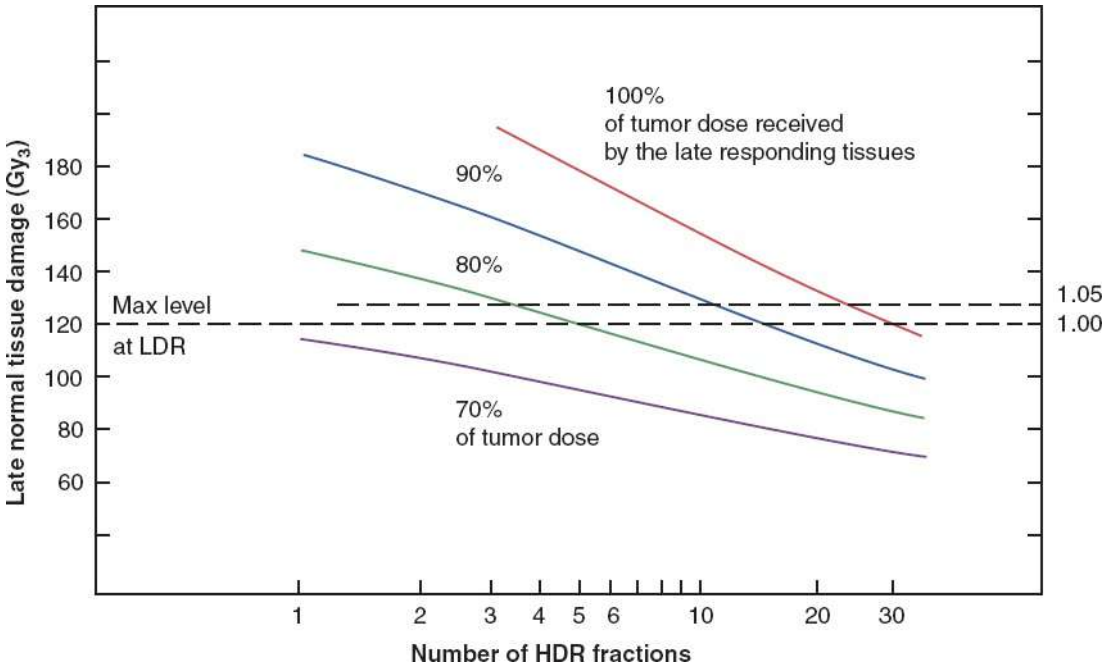

FIGURE 73.20. Relationship between number of high–dose rate (HDR) fractions and late normal tissue effects. *Solid lines* show the increase in normal-tissue late effects as the number of HDR fractions used to treat cervical cancer decreases. *Dotted lines* indicate the maximum level of late damage calculated for conventional low–dose rate brachytherapy of 70 Gy at 0.5 Gy/hour for 140 hours and an arbitrary level 5% above this. The intersection of the *solid lines* with the *dotted lines* indicates the number of HDR fractions needed to give equal late normal-tissue effects. In this model, the dose to late-responding tissues should be kept at 83% of the tumor dose when treating with four to six HDR fractions. (Modified from Fowler JF. The radiobiology of brachytherapy. FIGURE 73.21. Ultrasound used during intrauterine tandem insertion can ensure proper placement into the intrauterine canal and shorten overall procedure time. **A:** Ultrasound depicts that the tandem is placed in the posterior myometrium. **B:** Ultrasound directs the tandem into the intrauterine canal.

Applicator Position

An experienced brachytherapist has greater familiarity with applicator insertion

and evaluation.[399] Applicator position is a critical determinant of dose specification[637,668] and pelvic control.[78,669] As Fletcher[566] emphasized, conditions for an adequate intracavitary insertion include the following:

- The geometry of the insertion must prevent underdosing around the cervix.
- Sufficient dose must be delivered to the paracervical areas.
- Vaginal mucosal, bladder, and rectal tolerance doses must be respected.

For LDR Fletcher-Suit applicators, Potish et al.[670] used linear least-squares regression to show that although there was a moderately good correlation between the milligram-hours and dose to point A, it was markedly affected by the position of the colpostats and the tandem. A review of plain films of 808 LDR intracavitary applications in 396 cervical cancer patients treated at MD Anderson[671] quantified acceptable implant geometry. The median distance from the tandem to the sacrum was 4 cm, or one-third the distance from the pubis to the sacrum. The distance between the vaginal ovoids and cervical marker seeds was 7 mm, and the median distance between the tandem and the posterior edge of the ovoids was 50% of the ovoid length. In 92% of insertions, vaginal packing was posterior to or within 5 mm of a line that passed through the posterior edge of the ovoids, parallel to the tandem. The median doses to point A and rectal, bladder, and vaginal surface reference points were 87, 68, 70, and 125 Gy, respectively. Analysis of the LDR and HDR brachytherapy positions for 103 patients enrolled on RTOG trials 0116 and 0128 found that patients with unacceptable symmetry of ovoids to the tandem had a significantly higher risk of LR than patients in the acceptable group (HR = 2.67; 95% CI = 1.11 to 6.45; *P* = .03).[78] Patients with displacement of ovoids in relation to the cervical os had a significantly increased risk of LR (HR = 2.50; 95% CI = 1.05 to 5.93; *P* = .04) and a lower DFS rate (HR = 2.28; 95% CI = 1.18 to 4.41; *P* = .01). Inappropriate placement of packing resulted in a lower DFS rate (HR = 2.06; 95% CI = 1.08Y3.92; *P* = .03).

Imaging After Insertion

For LDR brachytherapy, active sources may be inserted after the films have been reviewed and the position of the applicators judged to be satisfactory.[78,671] Placing a small amount of contrast into the bladder and rectum before CT or plain film may clarify the location of these structures.

When a CT scan is obtained after applicator insertion, it also verifies proper placement (no perforation) and analyzes cervix and normal-tissue location in

relationship to brachytherapy dose distribution.[638] CT provides a reasonable estimate of the location of the uterus and cervix. The CT contours of the cervix overestimate the tumor contours compared to an MRI, although the additional width contoured on a CT may not be of detriment to the patient because cervical cancer tends to spread laterally along the parametrial tissues.[672] CT depicts changes in the OAR related to tumor shrinkage, organ motion, and the location of the brachytherapy applicator in relation to the uterus. However, separating the OAR, such as the sigmoid or the small bowel from portions of the uterus or cervix, may be difficult on CT, given the lack of contrast. OAR dosimetry based on CT is similar to that based on MRI when optimized similarly.[673] CT may not provide sufficient detail of the tumor if selected dose escalation is required, such as in cases with large residual tumors. In the vast majority of cases, however, it should suffice.[674–676] The uterus and cervix cannot be distinguished as separate structures on a CT, whereas they can on an MRI. Therefore, CT-based contouring guidelines recommend delineating the entire cervix and uterus.[672]

In a multicenter study, MR imaging was significantly better than CT for tumor visualization and detection of parametrial involvement.[87] Other advantages of MR include multiplanar capability and excellent soft tissue contrast resolution. The strength of a magnet in an MR scanner is expressed by a unit of measurement referred to as a tesla (T). Higher field strength produces a better overall signal-to-noise ratio and more accurate imaging.

Regardless of whether a plain film radiograph, CT, or MR is obtained after insertion to aid treatment planning, in order to properly visualize the apparatus, radiopaque markers should be inserted to identify source position to aid with dosimetric planning. Identifying the applicator using either a radiopaque marker inserted into it or for interstitial cases undergoing MR, a special 3-T MR sequence may be used to create artifact that allows the tip of the needle to appear as a balloon on the sagittal image and as a cross on the axial images.[677]

Dose Specification

Point A

Several methods for specifying dose in brachytherapy evolved over the 20th century.

Because of the limited availability of 3D imaging worldwide and a 100-year history of plain film radiography, the majority of institutions internationally use point-based dosimetry based on the ICRU 38 nomenclature[636] defining point A rather than prescribing dose to a tumor volume.[638] Other institutions use a

system of milligram-hours, whereas others consider the volume of the region of interest. Based on the general principles guidelines for cervical cancer brachytherapy published by the American Brachytherapy Society and the ICRU report, the point A definition was updated in 2012.[635] To determine point A, connect a line through the center of each ovoid or the lateral most dwell position in the ring; extend this line superiorly along the radius of the ovoids (or ring), and then move an additional 2 cm superior along the tandem. From this point, extend out 2 cm on each side laterally on a line perpendicular to the tandem (Fig. 73.22). For tandem and cylinders, begin at the flange or cervical marking seed and move 2 cm superiorly along the tandem and then 2 cm laterally.

Three-dimensional image-based brachytherapy treatment planning precisely defines the tumor and aids with the precision of radiation dose delivery, which may reduce the dose to the normal tissues and reduce toxicity.[678] In the era of increasing use of HDR brachytherapy, proper applicator placement and precise estimation of the location of the normal tissue is critical. When 3D imaging is available, point-based radiographic dosimetry has limited utility for the dose adaptation required for HDR brachytherapy because point A may overestimate or underestimate the tumor dose based on 3D imaging.[679,679] Kim et al.[680] found that dose to point A was significantly lower than the D_{90} for HR-CTV calculated using 3D image-based optimization. With imaging, one may visualize the tumor volume and conform dose to the volume, which may result in the dose to point A being lower than the prescription 100% isodose line (covering a smaller tumor volume) or a higher-than-prescription dose to point A because of a large tumor volume extending beyond the boundaries of point A. The tumor coverage relies on tumor volume at the time of brachytherapy, with larger tumors requiring greater optimization to be adequately covered by the prescribed isodose line.[679,681,682] The dose to point A should be reported to ensure consistency in terminology between centers.[683]

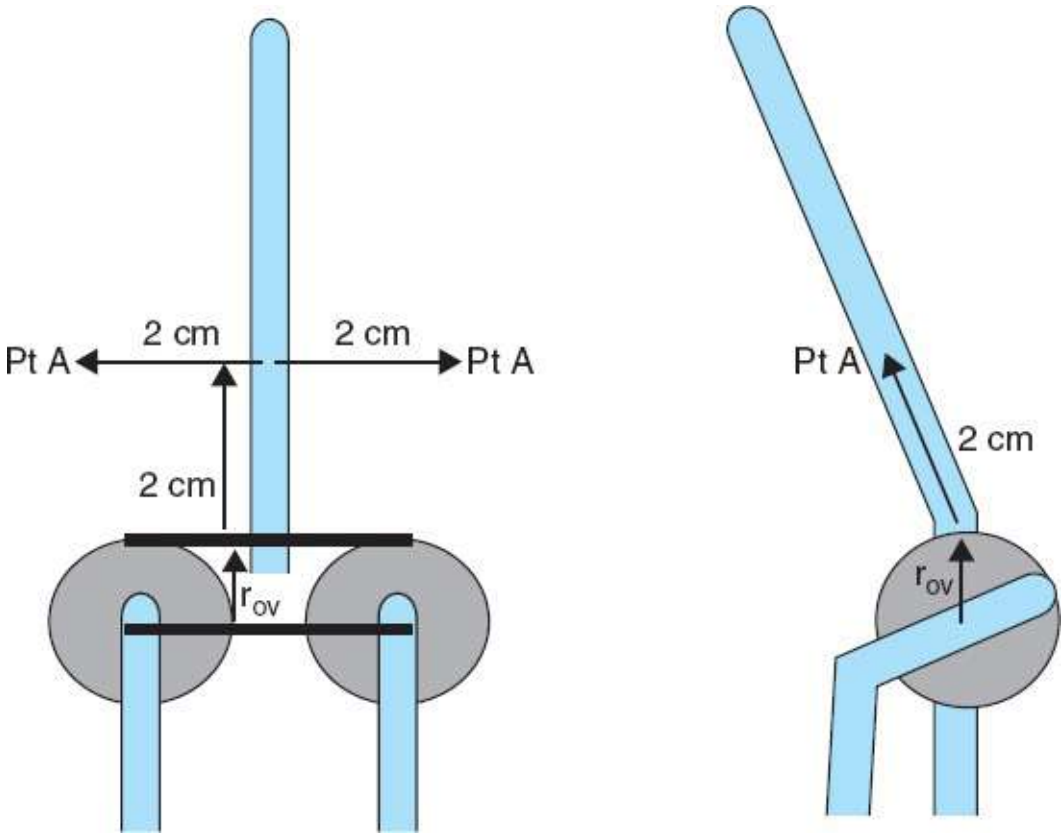

FIGURE 73.22. Definition of point A shown on a tandem and ovoid applicator based on the American Brachytherapy Society 2012 Guidelines for Cervical Cancer.

Accurate delineation of the tumor and OAR is critical for precise treatment planning (Fig. 73.23). Because of the rapid falloff of dose, imprecise contouring can dramatically change dosing to normal-tissue structures. Formal contouring education programs reduce the variability of interobserver contours.[684]

Computed Tomography Imaging for Brachytherapy Contouring

A CT scan can define a CTV with the lateral borders of the cervix and any parametrial extension defined based on suspicious regions seen on the scan. CT-contouring guidelines should be followed.[672] Uterosacral ligaments may be visualized on CT, and if detected, they should be included in the CTV contours. No GTV may be identified on CT. The superior border of the cervix is not defined, but instead, the entire tandem length is planned and the top dwell is optimized off the sigmoid to reduce bowel dose.

Magnetic Resonance Imaging for Brachytherapy Contouring

For MR-based contouring, the Groupe Europeen Curietherapy-European Society for Therapeutic Radiation Oncology (GEC-ESTRO) guidelines[662,663] delineate

volumes for MR. The recommended volumes include the GTV, including all T2-bright areas of enhancement; the HR-CTV, which is the entire cervix, any regions of high to intermediate signal intensity in the parametria, uterus, or vagina, and any residual disease detected on clinical examination at the time of brachytherapy; and the intermediate-risk clinical target volume (IR-CTV), which subtracts out the OARs but includes the tumor extension at the time of diagnosis, adding 1 cm to the HR-CTV volume. The IR-CTV defines regions with potential microscopic seeding of tumor cells (Fig. 73.24).[652] Lang et al.,[650] in a multicenter study, confirmed the feasibility of these recommendations, with total doses to point A from both BT and EBRT ranging from 85 to 91 Gy and to CTV from 69 to 73 cGy. Doses to OAR were comparable to those obtained with standard dosimetric methods, although they were more accurately determined with dose–volume histograms (DVHs).

The American Brachytherapy Society conducted a survey on the use of image-based brachytherapy in 2007[638] and updated this in 2014. Of 219 respondents in 2014, 13% obtain an MR after the first fraction of brachytherapy, and 7% with subsequent fractions, whereas 6% use MR for every fraction. The majority (52%) specify dose to a contoured volume rather than to point A.[685]

A panel of gynecologic radiation oncologists generated a 95% consensus volume contouring atlas to delineate the CTV in locally advanced cervical cancer. Patients with parametrial extension benefitted most from MR at the time of brachytherapy, particularly those with an apparent complete response.[686] The atlas is available online at https://www.nrgoncology.org/Scientific-Program/Center-for-Innovation-in-Radiation-Oncology/GYN-Cervical-Brachytherapy.

Dose–Volume Histogram Reporting

With MR-planned brachytherapy, the most common dose–volume parameters reported for target structures of the entire cervix and any residual disease at the time of brachytherapy, the HR-CTV, are D_{90}, defined as the dose received by at least 90% of the target volume, D_{100}, and V_{100}, based on the GEC-ESTRO recommendations.[687,688] The cumulative D_{90} equals the sum of D_{90} values from the individual fractions plus the dose from a homogeneous 3D conformal external beam treatment. D_{100}, the minimum target dose, may be more sensitive to inaccuracies in contouring and dose calculation. V_{100} assesses dose coverage of the whole target volume and is 100% when the entire target is covered by the

prescribed dose. V_{150} and V_{200} are often reported in interstitial brachytherapy. One may report these for CT, although the dimensions of the target will differ significantly from the absolute dimensions on MR, and the CT contour of the HR-CTV will include the cervix, residual areas in the parametria or uterosacral ligaments, and part of the uterus because the superior border of the cervix is not visible.[672] CT contours are more accurate if an MRI can be performed immediately before or with the first fraction of brachytherapy.[689] In both CT and MRI, prescribed dose is based on the physician's directive of the dose intended for the target volume, that is, the volume covered by the 100% isodose line, and point A should be recorded. Several institutions have validated the use of these guidelines with HDR, LDR, or PDR brachytherapy.[682,689–693]

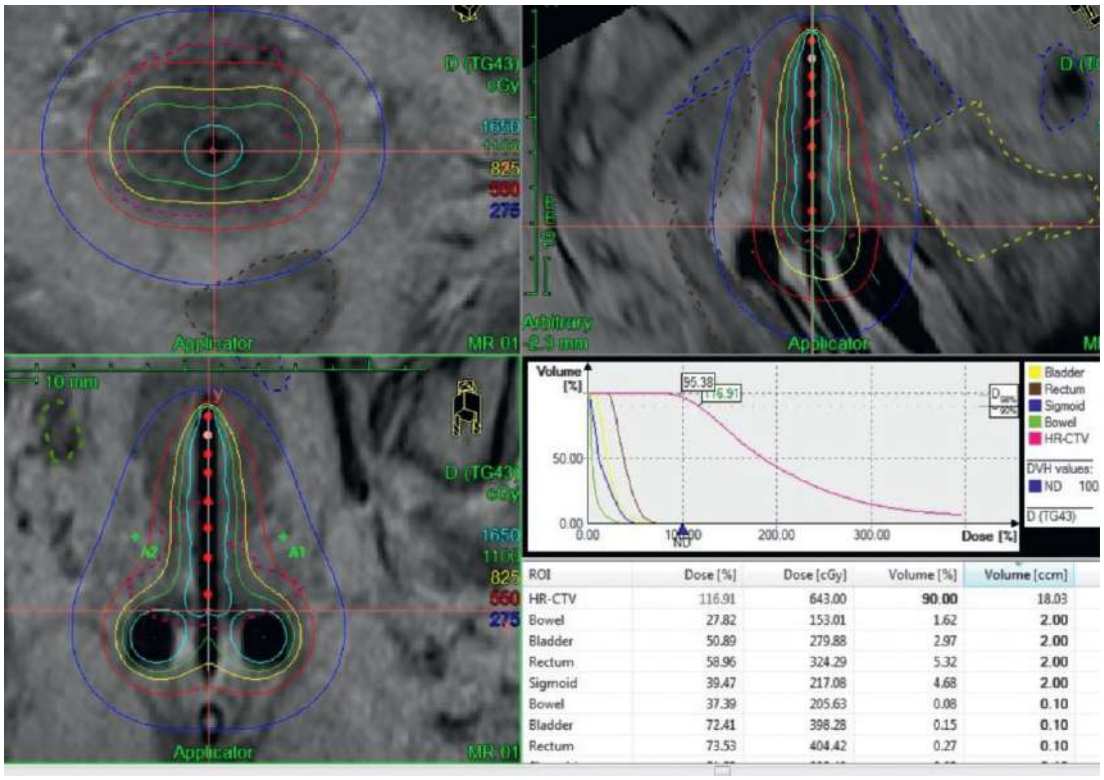

FIGURE 73.23. Tandem and ring implant showing the use of three-dimensional (magnetic resonance or computed tomography) imaging to adequately cover the high-risk clinical target volume (HR-CTV) while minimizing dose to the organs at risk (OAR)—the rectum, sigmoid, and bladder. Dose–volume histograms record the D_{2cc} limits to the OAR. The dose at point A is recorded but varies between patients based on optimization of the HR-CTV and OAR.

With 3D imaging, one may define the surrounding normal tissue structures as the OAR, including the rectum, sigmoid, and bladder. With 2D imaging, the ICRU 38 report requires only reporting point estimates for the rectum and

bladder because the sigmoid cannot easily be visualized.[636] However, the ICRU bladder point may underestimate maximum doses to the OAR, in particular for the bladder[694,695]; it is less likely that rectal doses will be incorrectly estimated. Numerous publications correlate the ICRU point dose and the probability of late complications for bladder and rectum.[696,697] Nevertheless, DVH metrics may provide a more reliable predictor of long-term complications.[698] In a review of 50 patients treated with LDR or HDR brachytherapy who then had a CT for treatment planning, the closest point of the sigmoid was related to sigmoid dose but varied in proximity to the tandem up to 40% between fractions, with a median distance of 1.7 cm. No sigmoid toxicity was noted after a median follow-up of 31 months.

Kapp et al.[699] analyzed 720 ^{206}Ir HDR applications in 331 patients with gynecologic tumors to evaluate the dose to normal tissues. CT-based dosimetry showed that the maximum doses to bladder and rectum were generally higher than those obtained from orthogonal films, with an average ratio of 1.44 for the bladder neck, 2.42 for the bladder base, and 1.37 for the rectum. The ratio of bladder–base dose to bladder–neck dose was 1.5 for intracervical and 1.46 for intravaginal applications. If conventional methods are used for dosimetry, the authors recommended that doses to the bladder base should be routinely calculated because single-point measurements at the bladder neck seriously underestimate the dose to the bladder. In addition, the rectal dose should be determined at several points over the length of the implant because of the wide range of anatomic variations.

Eich et al.,[700] in 11 applications of HDR brachytherapy for cervical carcinoma, calculated doses to ICRU points on orthogonal radiographs, and the doses at rectum reference points were compared with *in vivo* measurements. The *in vivo* measurements were 1.5 Gy below the doses determined for the ICRU rectum reference point (4.05 ± 0.68 vs. 6.11 ± 1.63 Gy). The advantage of *in vivo* dosimetry is the possibility to determine rectal dose during radiation. The advantages of computer-aided planning at ICRU reference points are that calculations are available before radiation and they can be taken into account for treatment planning.

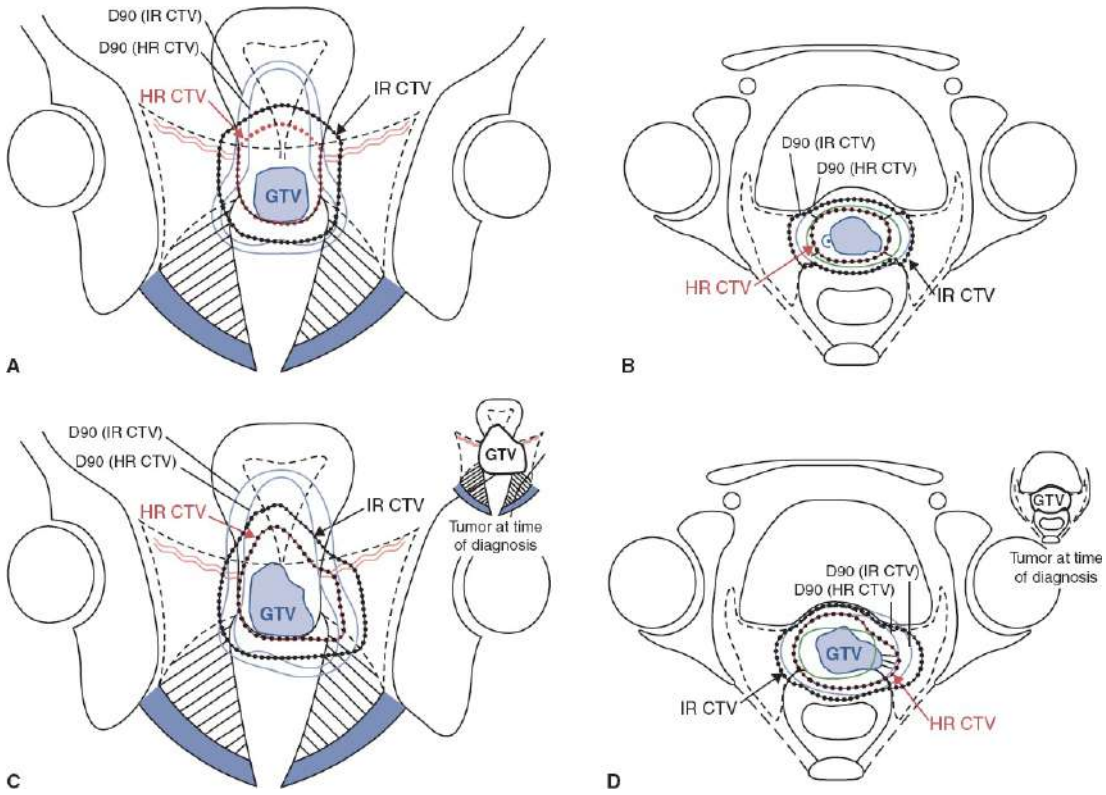

FIGURE 73.24. Diagrammatic representation of gross tumor volume (GTV) and clinical target volume (CTV) for three-dimensional treatment planning in carcinoma of the uterine cervix. Coronal **(A** and **C)** and transverse **(B** and **D)** sections for limited (**A** and **B**) and advanced (**C** and **D**) disease (*gray zones in left parametrium*). (Reprinted from Potter R, Haie-Meder C, Limbergen EV, et al. Recommendations from gynaecological (GYN) GEC ESTRO working group (II): Concepts and terms in 3D image-based treatment planning in cervix brachytherapy-3D dose volume parameters and aspects of 3D image-based anatomy, radiation physics, radiobiology. *Radiother Oncol* 2006;78[1]:67–77. Pelloski et al.[701] compared CT-based volumetric calculations and ICRU reference point radiation doses in 60 patients with cervix cancer treated with LDR brachytherapy. Of 118 insertions performed, 93 were evaluated, and the minimal doses delivered to the 2 or 3 cm of bladder or rectum (DBV2 and DRV2, respectively) were determined on a DVH. They concluded that the ICRU dose was a reasonable surrogate for the DRV2 but not for the DBV2. Furthermore, these calculations may not be applicable to other treatment guidelines or intracavitary applicators.

Patil et al.[702] found significant correlations between ICRU point doses to the bladder and rectum and volumetric doses, particularly the D_{2cc}. However, there was significant variability, and they concluded that 3D imaging is essential to properly assess doses to the OAR.

Both CT- and MR-based OAR dosimetry report similar cumulative DVH parameters, including D_{2cc} and $D_{0.1cc}$. The D_{2cc} is the minimum dose received by the most exposed 2-cm^3 volume of the analyzed organ. For CT-based brachytherapy, contrast placed in the OAR may cause some artifact, resulting in some variation in contouring the wall of the organ. MR-based brachytherapy relies less on contrast because the organ wall may be more clearly visualized. Wachter-Gerstner et al.[703] analyzed the correlation between DVHs for the bladder and rectum and found that D_{2cc} served as a good estimate for doses to the organ wall, whereas D_{5cc} was less reliable as it changes more based on filling status. Rectal wall thickness did not significantly affect D_{2cc}.[704]

Based on CT dosimetry, Koom et al.[705] showed that more severe rectal side effects (endoscopy score >2) occurred in patients with a higher D_{2cc}. Seventy-one patients with FIGO stage IB to IIIB uterine cervical cancers had CT-based HDR intracavitary brachytherapy. The mean values of the DVH parameters and ICRU rectal point (α/β = 3) were significantly greater in patients with a score of >2 than in those with a score of <2 at 12 months after brachytherapy (ICRU, 71 Gy vs. 66 Gy [P = .02]; $D_{0.1cc}$, 93 vs. 85 Gy [P = .04]; D_{1cc}, 80 vs. 73 Gy [P = .02]; D_{2cc}, 75 vs. 69 Gy [P = .02]). The probability of a score of >2 was significantly correlated with the DVH parameters and ICRU rectal point (ICRU, P = .03; $D_{0.1cc}$, P = .05; D_{1cc}, P = .02; D_{2cc}, P = .02).

For MR-based dosimetry, Georg et al.[698] tested the predictive value of dose–volume parameters for late effects of the rectum, sigmoid colon, and bladder using the D_{2cc}, D_{1cc}, and $D_{0.1cc}$ of these three OARs for 141 cervical cancer patients treated with tandem and ring HDR brachytherapy after EBRT. The mean D_{2cc} values for bladder, rectum, and sigmoid were 95 ± 22, 65 ± 12, and 62 ± 12 Gy, respectively. This study confirmed that D_{2cc} was a predictor of late toxicity for the rectum and bladder. A rectoscopy study[706] was done in 35 patients in which EQD2 (α/β = 3 Gy) of the $D_{0.1cc}$, D_{1cc}, and D_{2cc} of the rectum was recorded. After a mean follow-up time of 18 months, telangiectasia was found in 26 patients (74%), and 5 had ulceration that corresponded to the $D_{0.1cc}$ of the anterior rectal wall. The D_{2cc} was higher in patients with rectoscopy score of >3 compared to <3 (72 ± 6 vs. 62 ± 7 Gy; P < .001) and in symptomatic versus asymptomatic patients (72 ± 6 vs. 63 ± 8 Gy; P < .001).

Mazeron et al. described late rectal morbidity in 960 patients treated with MR-based brachytherapy in the EMBRACE study. With a median follow-up of 2

years, rectal events peaked at 2 years post treatment. The total crude rate of events was 28%, including 18% proctitis, 16% bleeding, 1% stenosis, and 1% fistula. Rectal dose morbidity was 6% 60 Gy, 8% 65 Gy, 10% 70 Gy, and 13% 75 Gy. The authors conclude that a D_{2cc} < 65 Gy results in a <10% risk of rectal toxicity.[707]

For interstitial brachytherapy, in which a much longer portion of the anterior rectal wall is treated as part of the target volume, D_{2cc} > 62 Gy predicted for late toxicity.[708] The development of mucosal and clinical changes in the rectum seems to follow a clear dose effect and volume effect. For patients receiving interstitial brachytherapy who require treatment to the entire vaginal length, the dose to the rectum should be reduced as much as possible without compromising target coverage.

The dose given to the vagina is also associated with vaginal toxicity,[709] with a threshold of 108 Gy analyzed in one study.[710]

3D Treatment Planning for Pulsed and High Dose Rate Brachytherapy

Treatment planning for PDR and HDR brachytherapy can be accomplished by a variety of techniques. Treatment planning for LDR is covered in a separate chapter. For cervical cancer, customized optimization of source loading for each HDR insertion is recommended (Fig. 73.25), given significant changes in tumor and OAR dosimetry between fractions.[664,711] Himmelmann et al.[712] described individualized computer treatment optimization of source position and the dwell time for each position. Customized planning does increase the time needed for planning and requires experience on the part of the physics and dosimetry staff.[713]

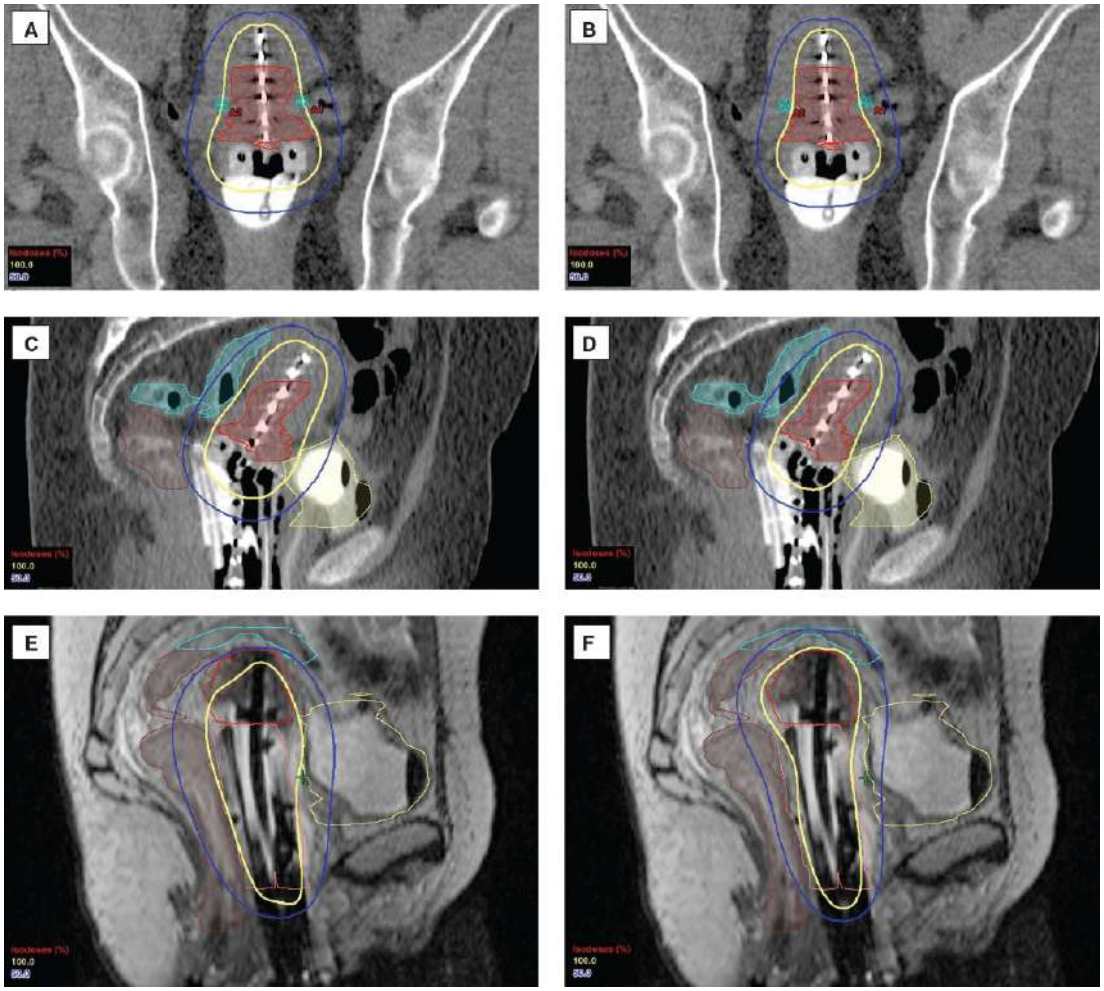

FIGURE 73.25. **A:** Coronal view of a CT-planned tandem and ring applicator with standard HDR loading (to point A). **B:** Tandem and ring treatment plan optimized to maximize tumor coverage and minimize the dose to the organs at risk (OAR) including the rectum (*brown*), sigmoid (*blue*), and bladder (*yellow*). **C:** Sagittal CT of the standard plan at point A. **D:** Sagittal CT image of the optimized plan showing the reduction in OAR dose. **E:** Cervical stump cancer showing an MR-planned tandem and interstitial brachytherapy implant without HDR optimization. **F:** Optimized tandem and interstitial plan cover the posterior border of the cervical stump while minimizing dose to the bladder and rectum.

CT-Based Treatment Planning

Fellner et al.[714] compared treatment planning for cervical carcinoma based on CT sections and 3D dose computations or, when these techniques were not available, dose evaluation based on orthogonal radiographs. The CT-based planning provides information on target and organ volumes and DVHs. The radiography-based planning provides dimensions and doses only at selected points. For the study, 28 patients with 35 applications receiving HDR treatment with ^{206}Ir were investigated. For a dose prescription of 7 Gy at point A, 83% (44

cm^3) of the CTV received at least 7 Gy.

Gebara et al.[715] estimated the external, internal, and common iliac dose rates using 3D CT-based dose calculations in tandem and ovoid brachytherapy in 30 patients with carcinoma of the uterine cervix treated with LDR brachytherapy using a CT-compatible Fletcher-Suit-Delclos device. Thirty-six implants were performed, and the authors concluded that the point B dose is similar to the maximum common iliac nodal dose. With HDR brachytherapy, the dose to the pelvic lymph nodes is approximately 25% of the per fraction dose.[374]

Dewitt et al.,[716] in 15 patients with cervical cancer, defined target and OAR for planning of HDR brachytherapy and established guidelines for volume and dose constraint parameters using image-guided inverse treatment planning.

Careful assessment of the quality of brachytherapy and dose distributions is critical. Suyama et al.[717] analyzed the minimal radiation dose to the peripheral area of the cervix in relation to local tumor failure using CT images taken at the time of intracavitary brachytherapy in 80 patients with carcinoma of the cervix. After CT scanning, isodose curves were superimposed on the CT images. Histograms of both the minimum percentage peripheral dose and the dose to the cervical area showed significant correlation in the local tumor control and local failure groups ($P < .001$).

With HDR intracavitary applicators, the use of a rectal retractor has been shown to substantially reduce the rectal dose.[647] Lee et al.,[718] in a study of 15 patients, found that this reduction was significant only in the subgroup who received >70% of the prescription dose ($P < .05$).

Wanderas et al.[719] reviewed data from 19 patients (72 fractions) retrospectively. Standard library plans were compared to individually optimized plans using a Fletcher HDR applicator. For standard treatment planning, the tolerance dose limits were exceeded in the bladder, rectum, and sigmoid in 26%, 4%, and 15% of the plans, respectively. This was observed most often for the smallest target volumes. The individualized planning of the delivered treatment gave the possibility of controlling the dose to critical organs to below certain limits. The dose was still prescribed to point A. An increase in target dose coverage was achieved when additional individual optimization was performed while keeping the dose to the OARs below predefined limits. Relatively low average target coverage was seen, however, especially for the largest volumes.

MR-Based Treatment Planning

Basic principles of MR imaging during brachytherapy have been described.[720]

Several institutions have reported the dosimetric advantages of MR-based brachytherapy, with reduction in OAR doses with optimization.[682,691,721–723] Tanderup et al.[721] showed that point A dose was a poor surrogate of HR-CTV dose, and MR-based planning improved target coverage and reduced OAR dose. Starting with a standard plan is important for consistency because relative uniformity of the dose distribution should be maintained.[724]

A comparison of MR to US was reported by Van Dyk et al.[666] for 71 patients, showing comparability between the two modalities in terms of target volume and rectal point dose. Mahantshetty et al.[725] similarly confirmed the feasibility of US for institutions that do not have easy access to MR or CT. One study hypothesizes that US may be more similar to MR than CT.[726]

Recommended Doses

Stage IA (microinvasive) tumors are treated with intracavitary therapy only. LDR dose is approximately 60 Gy in one insertion or 75 to 80 Gy in two insertions to point A, or with HDR an equivalent dose, with one or two fractions per week. This may be given in approximately 5 Gy per fraction for 10 fractions or other regimens based on normal-tissue exposure.

For stage IB to IVA cervical cancers in the United States, the most common EBRT dose treats the elective pelvic nodes to 45 to 50 Gy given in 1.8 Gy per fraction.[635] Some institutions instead use lower doses of whole-pelvis external irradiation (20 to 40 Gy) in addition to parametrial doses to complete 50 to 60 Gy to the involved parametrial tissues or nodal regions for more advanced stages. Brachytherapy follows, with a goal EQD2 dose of 80 to 90 Gy to point A or to the HR-CTV. For LDR, intracavitary treatment for approximately 4,000 to 5,000 mgh (36 to 50 Gy to point A at 60 cGy/hour) is given, depending on the tumor volume and stage and age of the patient. Fyles et al.[159] identified FIGO stage as the most significant prognostic factor in 965 patients with invasive carcinoma of the cervix, followed by dose of irradiation to point A and overall time of radiation therapy. The 10-year survival rate was 62% in 743 patients receiving doses to point A of 85 Gy or higher, in contrast to 53% for 222 patients receiving lower doses.

For HDR, one study found that a dose to the HR-CTV of >87 Gy resulted in a local recurrence rate of 4% compared to 20% for D_{90} < 87 Gy when the tumor was >5 cm and using an HDR tandem/ring or tandem/ring/interstitial approach. They concluded that local control rates of >95% can be achieved for patients with a poor response after EBRT if D_{90} for the HR-CTV is 87 Gy or higher.[727]

The IR-CTV intended dose should be approximately 60 Gy EQD2. In the United States, the most common regimen uses five fractions (5 to 6 Gy per fraction), with two fractions per week, 24 to 48 hours between fractions.

DVH constraints for both PDR and HDR are 90 Gy (EQD2) for bladder and 70 to 75 Gy (EQD2) for both rectum and sigmoid as minimal doses to the most exposed D_{2cc} of the OAR. There are no generally accepted constraints for the 0.1-cm^3 level. Given the rapid regression of the tumor and the dramatic change in the location and size of the normal tissues, it is recommended to replan and determine the doses to the OAR with each fraction if the patient is treated on an outpatient basis.[711]

Dose Fractionation in High Dose Rate Brachytherapy

The relationship between dose and fractionation for HDR and LDR intracavitary irradiation of stage I and II carcinoma of the cervix was examined by Arai et al.[681] The dose rate at point A was 2 to 3 Gy/minute (120 to 180 Gy/hour) for HDR and 0.6 to 0.9 Gy/hour for LDR irradiation. Concurrent EBRT was given to the whole pelvis (23 to 30 Gy), followed by 25 to 30 Gy with central shielding, along with brachytherapy. The authors concluded that the optimal dose fractionation schedules for HDR brachytherapy were 28 ± 3 Gy in 4 to 5 fractions, 34 ± 4 Gy in 8 to 10 fractions, or 40 ± 5 Gy in 12 to 14 fractions at point A. Petereit and Pearcey,[656] based on their preliminary results and published reports in the literature, recommend doses of 45 to 50.5 Gy in a 1.8-Gy per fraction external beam followed by HDR with either 5.5 or 6 Gy per fraction in the era before the standardization of chemoradiation. Since the implementation of concurrent chemoradiation, several institutions in the United States have standardized the use of 5.5 Gy for five fractions, given some concerns about rectal toxicity with 6 Gy per fraction.[728]

Chatani et al.[729] described a study in which 165 patients with carcinoma of the cervix were randomized to an HDR brachytherapy point A dose of 6 Gy (group A) or 7.5 Gy (group B) per fraction, both combined with external irradiation. The 5-year local failure rate was 16% in both groups, and distant failure rates were 23% and 29%, respectively (P = .2955). Moderate to severe complications requiring treatment were comparable (six patients, 7%) in the two groups.

Hama et al.[730] compared the effectiveness and safety of once- versus twice-weekly HDR brachytherapy for cervical cancer in 124 patients treated with EBRT (50 Gy); 74 patients (group A) were treated with one HDR brachytherapy

insertion weekly (three fractions of 7 Gy each to point A), and 50 patients (group B) were treated twice weekly (six fractions of 4.5 Gy each to point A). Overall survival rates were 65.2% and 65.3%, respectively ($P = .96$). Local recurrence–free survival rates were 69% for group A and 90% for group B ($P < .001$). The rate of grade 2 (moderate) and grade 3 (severe) complications was significantly lower for group B (6%) versus 32% in group A ($P < .001$).

Mayer et al.[731] compared HDR BT in two schedules used to treat 210 patients with cervix cancer—one sequential (SRT), consisting of four fractions of 8 Gy followed by EBRT, and the other continuous (CRT), consisting of five fractions of 6 Gy one session per week integrated with EBRT (four fractions per week). Total dose to point A was 68 to 70 Gy. PFS was 71% with CRT versus 56% with SRT ($P > 0.05$). Late bladder and rectal morbidity were 13% in the CRT group and 25% in the SRT group ($P = .037$), related to the higher dose per fraction (8 Gy).

Nam and Ahn[732] compared, in a randomized study of 46 patients, two schedules of HDR BT (10 fractions of 3 Gy or five fractions of 5 Gy) followed by a small BT boost to residual tumor in combination with EBRT (30.6 Gy to whole pelvis and 14.4 Gy to parametria with midline block). Three-year pelvic tumor control was 90% in both groups, and disease-specific survival was 90.5% and 84.9% ($P = .64$), respectively. Late grade 2 and greater bladder or rectal morbidity was 23.8% and 9.1%, respectively ($P = .24$).

Liu et al.[733] based on the LQ model, developed isoeffect tables to convert traditional LDR doses and number of fractions to point A to HDR brachytherapy; depending on dose rate, different dose values can be calculated for various fractionation schedules. They predicted that, using therapeutic gain ratio, similar results would be obtained with either brachytherapy modality with two to four fractions of LDR and four to seven fractions of HDR.

The optimal time–dose–fractionation scheme for HDR brachytherapy for cervical cancer has yet to be established. In an international survey from the Gynecologic Cancer Intergroup, 28 different fractionation regimens were used by international cooperative group members (Table 73.15); the most common was 6 Gy for five fractions after 45 Gy.[639] The American Brachytherapy Society published recommendations for HDR brachytherapy for carcinoma of the cervix.[660] Each institution should follow a consistent treatment policy, including complete documentation of treatment parameters and correlation with clinical outcome (pelvic tumor control, survival, and complications). The goals are to treat point A to at least a total LDR equivalent of 80 to 85 Gy for early-stage

disease and 85 to 90 Gy for advanced-stage disease. The pelvic sidewall dose recommendations are 50 to 55 Gy for early lesions and 55 to 65 Gy for advanced ones. As with LDR BT, every attempt should be made to keep the bladder and rectal doses to <100 Gy and 75 Gy LDR-equivalent doses, respectively. Interstitial brachytherapy should be considered when the tumor cannot be optimally encompassed by intracavitary brachytherapy. Some suggested dose and fractionation schemes for combining the external beam radiation therapy with HDR brachytherapy for each stage of disease have been presented by the American Brachytherapy Society, although they have not been thoroughly tested. The responsibility for the medical decisions ultimately rests with the treating radiation oncologist. Petereit and Pearcey,[656] in a review of 24 HDR dose fractionation schedules published in the last three decades, found no dose relationship for either tumor control or late morbidity. Viswanathan et al.,[639] for the Gynecologic Cancer Intergroup, found significant international variation in the HDR dose/fractionation regimens reported, but aside from Japan, where the ratio of HDR brachytherapy dose to external beam is higher, there was consistency in converted EQD2 doses administered.

TABLE 73.15 HIGH DOSE RATE BRACHYTHERAPY DOSE AND FRACTIONATION REGIMENS WORLDWIDE

Percentage Respondents (Number)	Dose/Fraction	Number of Fractions	EQD2
Standard Fractionation for Stage IB to IIA Cervical Cancers

5% (3)	6	3	24

5% (3)	8	3	36

Gynecologic Cancer Intergroup physicians worldwide who use high–dose rate (HDR) brachytherapy for cervical cancer were queried regarding the specific fractionation regimen that they routinely implement for stage IB to IIA and stage IIB to IVA cervical cancer patients. Results are shown for regimens reported by three or more respondents. The most common external beam dose was 45 Gy in 1.8 Gy per fraction, followed by five fractions of 5 to 6 Gy per fraction. The EQD2 formula was used to convert the HDR dose and number of fractionations and does not include the external beam dose contribution.

Clinical Outcomes of Brachytherapy

Randomized Studies Comparing HDR to LDR Using Plain X-Ray Dosimetry

Four randomized trials (Table 73.16) and a meta-analysis summarizing the results of these have been published comparing HDR and LDR brachytherapy for carcinoma of the cervix.[737,738] Teshima et al.[734] reported on a prospective, randomized study of 430 patients with carcinoma of the uterine cervix treated with either LDR (171 patients) or HDR (259 patients) brachytherapy combined with external irradiation. Cause-specific and overall survival rates were comparable for each clinical stage with either modality, except for stage I overall survival. The conversion factor of total intracavitary dose from LDR to HDR was 0.5 to 0.53. With HDR, four fractions usually were delivered, and with LDR, two fractions. The incidence of pelvic failures was comparable in both groups. The incidence of grade 2 and 3 morbidity was somewhat higher in the HDR group (~10%) than in the LDR group (4%; $P = .002$).

Patel et al.[644] published a randomized trial of 482 patients with invasive squamous cell carcinoma of the cervix. The overall local tumor control rate with LDR brachytherapy was 79.7%, compared with 75.8% with HDR. The 5-year survival rates were 73% with LDR and 78% with HDR in stage I, 62% and 64%, respectively, in stage II, and 50% and 43% in stage III. The only statistically significant difference was the incidence of overall rectal complications, which was 19.9% for LDR, compared with 6.4% for HDR. However, the incidences of more severe grade 3 and 4 complications were not significantly different (2.5% and 0.4%, respectively). Bladder morbidity was similar in both groups.

Hareyama et al.[735] conducted a randomized study in 132 patients with stage II or IIIB cervical carcinoma treated with LDR or HDR BT and identical pelvic EBRT. The conversion factor from LDR to HDR was 0.588. The 5-year DSS with HDR for stages II and IIIB was 69% and 51%, respectively, and with LDR it was 87% and 60%, respectively. Pelvic tumor control for stage II and III was 89% and 73% with HDR and 100% and 70% with LDR, respectively, and grade 3 or greater morbidity was 10% and 13%, respectively (differences were not statistically significant).

Lertsanguansinchai et al.[736] randomized 237 patients with cervical cancer to be treated with LDR (109 patients) or HDR (112 patients) brachytherapy and EBRT. Median follow-up was 40 and 37 months, respectively. Three-year pelvic tumor control was 89% and 86.4%, respectively, and relapse-free survival was

69% in both groups. Grade 3 or 4 morbidity was noted in 2.8% of LDR and 7.1% of HDR patients (P = .23).

A meta-analysis[738] including these four trials reported a pooled RR for HDR versus LDR of 0.95 (95% CI = 0.79 to 1.15), 0.93 (95% CI = 0.84 to 1.04), and 0.79 (95% CI = 0.52 to 1.20) for 3-, 5-, and 10-year overall survival rates and 0.95 (95% CI = 0.84 to 1.07) and 1.02 (CI = 0.88 to 1.19) for 5- and 10-year DSS rates. For local control rates, the RR was 0.95 (95% CI = 0.86 to 1.05) and 0.95 (95% CI = 0.87 to 1.05) at 3 and 5 years, respectively. For bladder, rectosigmoid, and small-bowel complications, the RR was 1.33 (95% CI = 0.53 to 3.34), 1.00 (95% CI = 0.52 to 1.91), and 3.37 (95% CI = 1.06 to 10.72), respectively, indicating no significant differences except for increased small-bowel complications with HDR (P = .04). Of note, none of the randomized studies used 3D imaging to optimize away from normal tissues.

The use of 3D imaging to guide brachytherapy treatment planning has allowed optimization of HDR and PDR brachytherapy, thereby reducing the high per fraction doses to the normal tissues that might potentially cause significant side effects. A retrospective comparison of LDR and HDR with pretreatment MRI used for tumor volume determination showed a significant reduction in complications with HDR when image-based planning was implemented.[739] Similarly, the use of 3D imaging optimizes tumor coverage, which is critical with fractionated HDR therapy.

Prospective Data Using Point A Dosimetry

Haie-Meder et al.,[740] in 204 patients with cervical cancer randomized to receive one of two preoperative LDR brachytherapy procedures (0.4 or 0.8 Gy/hour), noted similar local tumor control (93%) and overall survival (85%) rates at 2 years with either dose rate. Grade 3 late complications were observed in 7% of patients treated with 0.4 Gy/hour and in 13% of patients treated with 0.8 Gy/hour. There was 1 small-bowel obstruction in the 0.4-Gy/hour group (1%), in contrast with 5 (5%) in the 0.8-Gy/hour group. Vesicovaginal fistulas were observed in 2% and 4%, respectively.

A prospective study in Japan of stage I and II cervical cancer with tumors <4 cm (by T2 MRI) and no lymphadenopathy treated 60 patients with whole-pelvis EBRT 20 Gy/10 fractions with midline block followed by 30 Gy/15 fractions and HDR 24 Gy/4 fractions (at point A).[741] The cumulative BED was 62 Gy (α/β = 10) at point A, lower than that reported by any other institution worldwide. Median tumor diameter was 28 mm (range, 6 to 39 mm). Median OTT was 43

days. Median follow-up was 49 months (range, 7 to 72 months). Seven patients developed recurrences: three patients had pelvic recurrences (two central, one nodal), and four patients had distant metastases. The 2-year disease-free and overall survival rates were 90% (95% CI = 82% to 98%) and 95% (95% CI = 89% to 100%), respectively. The 2-year late complication rates (according to RTOG/EORTC grade ≥ 1) were 18% (95% CI = 8% to 28%) for large intestine/rectum, 4% (95% CI = 0% to 8%) for small intestine, and 0% for bladder. No cases grade ≥3 were observed for genitourinary/gastrointestinal late complications.

The prospective French STIC trial[742] reported patients treated with x-ray simulation compared to 3D-based planning. A total of 705 patients with stage IB to IIIB cervical cancers were enrolled. Toxicity and survival were significantly improved with 3D-based treatment planning. Plain film–based 2-year local control was 74% for patients treated with chemoradiation and LDR or PDR brachytherapy. Detailed results are shown in Table 73.17.

Retrospective Data Using Point A Dosimetry for Low Dose Rate Brachytherapy

Fowler[748] analyzed results in 270 patients with carcinoma of the cervix treated with either 75 cGy/hour from manually loaded cesium or 150 cGy/hour by remote afterloading. There was an increase in grade 3 late complications from 4% to 22%, in spite of a reduction of 20% in dose, implying a rather large difference in biologic effect between the two systems. The effect of the increased dose rate was also described by Leborgne et al.[749] LQ modeling was used to calculate biologically effective doses in the clinical protocols used. When the LDR was doubled, it was called MDR. The maximum ratios calculated for the biologic effective doses of 16 Gy at MDR to 20 Gy at LDR were 1.06 to 1.15,

assuming α/β = 4 to 2 Gy, the latter being an unlikely extreme for rectal or urinary complications. The theoretically ideal dose reduction factors, calculated using the $t_{1/2}$ values derived from the clinical data, are in the range of 24% to 29% instead of 20%.

Rodrigus et al.[750] analyzed late complications in 143 patients with cervical cancer treated with two different brachytherapy schedules and external radiation. Seventy-seven patients had two intracavitary applications with a dose rate of 0.54 Gy/hour and 66 patients with that of 1.07 Gy/hour. Because of the expected increase in complications with the higher dose rate, the latter dose per application was reduced from 25 to 20 Gy. Late intestinal and urinary complications were scored in 49 of 77 and 46 of 68 patients, respectively. Actuarial estimates at 5 years showed 42% and 54.1% late intestinal complications and 16.9% and 24.1% late urinary complications, respectively. Thus, despite the dose reduction, there was a clear dose rate effect on late morbidity. These studies emphasize the importance of the dose rate of brachytherapy in carcinoma of the cervix.

Rotmensch et al.[751] compared the outcome in 140 patients with early-stage cervical cancer undergoing whole-pelvis radiation therapy with one versus two LDR intracavitary brachytherapy applications. The two groups had similar 5-year local tumor control (P = .83), disease-free (P = .23), and cause-specific (P = .29) survival. Late complications were similar in the two groups. These results support the use of a single LDR application in patients with early-stage disease undergoing definitive radiation therapy after 45-Gy external beam pelvic irradiation.

In a retrospective analysis, Perez et al.[190] noted that in patients with cervical cancer treated with radiation therapy alone for stage IB tumors <2 cm in diameter, the pelvic failure rate <10% with LDR doses of 70 to 80 Gy to point A, whereas for larger lesions, even doses of 85 to 90 Gy resulted in 25% to 37% pelvic failure rates. In stage IIB with LDR doses of 70 Gy to point A, the pelvic failure rate was approximately 50%, compared with 20% in nonbulky and 30% in bulky tumors with doses >80 Gy. In stage III unilateral lesions, the pelvic failure rate was approximately 50% with 70 Gy or less to point A versus 35% with higher doses, and in bilateral or bulky tumors, it was 60% with doses <70 Gy and 50% with higher doses.

A study from France reported on preoperative LDR followed by radical surgery with lymph node dissection for 257 patients with stage IB1, IIA, and IIB cervical cancers of <4 cm.[752]

Residual tumor was identified in 44% of patients, whereas 4.3% of patients had parametrial invasion and 17.9% of patients had lymph node involvement. Late complications of grade 2 occurred in 7.4% and of grade 3 in 2.7% of patients. Five-year actuarial overall survival and DFS were 83% (CI = 78.3 to 87.5) and 80.9% (CI = 76.3 to 85.7), respectively. In multivariate analysis, lymph node involvement, parametrial involvement, and smoking factors significantly affected overall survival and DFS rates.

Retrospective Results Using Point A with Pulsed Dose Rate Brachytherapy

Rogers et al.[753] treated 52 patients with cervical carcinoma, 31 of whom had staging laparotomy before radiation therapy. Brachytherapy was interstitial in 18 patients and intracavitary in 28. The median EBRT pelvis dose was 45 Gy in 25 fractions. Median total doses were 75.8 Gy to the implant volume with interstitial and 84.1 Gy to the A points with intracavitary at a median dose rate of 0.55 Gy per pulse per hour. Six patients had laparotomy-documented para-aortic node involvement and received EBRT to this site (45 Gy in 25 fractions). Thirty patients received concomitant weekly cisplatin chemotherapy (40 mg/m^2). With a median follow-up of 25 months, the actuarial 4-year DFS rates were 66% for the entire group (100% for stage IB, 69% for stage II, 68% for stage III/IVA, and 43% in patients treated for recurrences after surgery). Grade 4 complications occurred in 2 patients (4.3%). One patient (2.2%) had a grade 3 complication (frequent hematuria), and 5 (10.9%) had grade 2 complications.

Kaneyasu et al.[754] treated 419 patients with squamous cell carcinoma of the cervix from 1969 to 1999 with LDR or MDR. LDR required overnight admission, whereas MDR was given over approximately 5 hours on an outpatient basis. The 5-year overall survival rates for stages I, II, III, and IVA in the LDR group were, respectively, 78%, 72%, 55%, and 34% versus 100%, 68%, 52%, and 42% in the MDR group (not statistically different). The actuarial rates of late complications of grade 2 or greater at 5 years for the rectum, bladder, and small intestine in the LDR group were 11.1%, 5.8%, and 2.0%, respectively, whereas for the MDR group, they were 11.7%, 4.2%, and 2.6%, respectively (not significantly different).

El-Baradie et al.[755] published a prospective study in which 45 patients with carcinoma of the uterine cervix were randomly allocated to either HDR or MDR. The external beam radiation dose was the same in the two groups. The point A dose rate correction factor from LDR to HDR was 0.53, and that from LDR to

MDR 0.6. The 3-year survival and locoregional tumor control rates for both modalities were equivalent (respectively 62% and 67% for HDR and 68% and 74% for MDR). The rectal and bladder complication rates were the same in both groups (29% at 3 years). Tanaka et al.[756] also compared HDR and MDR brachytherapy in 150 and 56 patients, respectively. The survival was equivalent in the two groups; grade 2 or greater late toxicity tended to be higher in the HDR group (14% vs. 6%, respectively).

Bachtiary et al.[757] reported on 109 patients treated with LDR BT and 57 who received PDR BT. The 3-year overall survival and DFS rates were 70% and 57% for the LDR group and 82% and 70% for the PDR group, respectively (P = .25 and .19). The 3-year probability rate for late grade 3 or worse toxicity was 7.4% for LDR BT patients and 7.6% for PDR BT patients (P = .69) and was 6.9% and 7.6%, respectively, for concurrent chemotherapy versus none (P = .69).

Rath et al.[758] reported on 48 patients treated with PDR brachytherapy (ICRT) and pelvic irradiation. A single session delivered a dose of 27 Gy to point A by PDR (hourly pulse, 70 cGy). Ten patients had disease recurrence (five each in stage IIB and stage IIIB). Eight patients had pelvic failure, one had bone metastases, and one had supraclavicular node metastases. Overall, the grade III to IV late toxicity rate at 50 months was 6%. For the median follow-up period of 15 months, the actuarial recurrence-free survival in stages I to II was 82% and in stages III to IV was 78%.

Retrospective Results with Point A Using High Dose Rate Brachytherapy

Many nonrandomized studies compared the results of HDR with those of historic or concurrent control patients receiving LDR at the same institution.[645,664,712,759–761] HDR in patients with stage IIIB disease or large tumors must be used cautiously because the brachytherapy prescription dose should cover the tumor volume and avoid the normal tissues as much as possible (Table 73.18). Although it is generally recommended not to give concurrent chemotherapy on the day of HDR brachytherapy[635] several studies indicate that HDR does not increase toxicity in patients treated with chemoradiation (Table 73.19). Most studies used point A as a reference point, although the definition of point A may have differed from center to center.

A retrospective population-based cohort study of all uterine cervix cancer cases in Saskatchewan diagnosed between 1985 and 2001 had 107 LDR and 37 HDR cases with similar stage distribution. The 5-year CSS rate was 56% for

HDR and 67% for LDR (P = .72). Acute toxicities were diarrhea (60%) and abdominal cramps (12.5%), and chronic toxicities were vaginal stenosis (5.5%) and small-bowel obstruction (4%).[778]

Petereit et al.[643] reported on 191 patients receiving LDR brachytherapy and 173 receiving HDR brachytherapy with equivalent external beam radiation therapy techniques. Pelvic tumor control and survival rates were comparable with the two techniques, except in stage III; in this subgroup, outcome was better with LDR brachytherapy, but this may have been related to a lower HDR equivalent dose administered. In an analysis of 198 patients treated with LDR brachytherapy, the 3-year survival rate was 66% versus 77% for 40 patients treated with HDR brachytherapy.[768] Pelvic tumor control rates were 80% and 77%, respectively. The incidences of complications requiring hospitalization or surgery were 10% (20 of 198) and 2.5% (1 of 40), respectively.

Kapp et al.,[779] in a study of 181 patients with FIGO stage IB to IV carcinomas of the cervix, documented that prognostic factors for patients treated with HDR are similar to those in previous series with LDR brachytherapy. In multivariate analysis, tumor size was the most powerful factor for pelvic tumor control and incidence of distant metastasis.

Ferrigno et al.[763] carried out a retrospective study of 190 patients treated with LDR and 118 with HDR brachytherapy in combination with pelvic EBRT for cervical cancer. For stage I or II patients, there was no difference in outcome; however, in the stage III group, local tumor control was 58% with LDR and 50% with HDR (P = .19), and DFS was 49% versus 37% (P = .03). At 5 years, rectal sequelae were 16% versus 8% (P =.03), bladder sequelae were 6% and 3% (P = .13), and small-bowel sequelae were 4.6% and 8.9% (P = .17).

Falkenberg et al.[762] reviewed 160 patients, 103 treated with LDR and 57 treated with HDR from 1990 to 2000. Locoregional control was 78% for LDR and 76% for HDR (P = .96); overall survival was 60% for LDR versus 55% for HDR (P = .48) at 3 years. Late complications were reported in 2 HDR patients (3.5%) and 5 LDR patients (4.8%).

Orton et al.[647] noted that dose per fraction of HDR brachytherapy significantly influenced toxicity. Morbidity rates were significantly lower for point A doses/fractions of 7 Gy or less for both severe (1.28% vs. 3.44%; P <.0001) and moderate plus severe injuries (7.58% vs. 19.51%; P <.001). The effect of dose/fractionation on cure rates was equivocal.

Kuske et al.[780] described a method to improve target coverage and locoregional tumor control with HDR tandem and ovoid applications by which HDR endocavitary and interstitial brachytherapy are applied in the same session for tumors with a lateral expansion of 25 mm or more from the axis of the cervical canal. Seventy-six combined applications were given to 41 patients. With a follow-up average of 23 months, in stage IIB tumors, 3-year DFS was 75%. No severe early or persistent late complications were observed. Combined applicators with the tandem and ring with interstitial[781] and tandem and ovoid with interstitial[693,782] are now available for HDR brachytherapy.

Forrest et al.[728] presented the results of 122 patients treated with EBRT

followed by 6 Gy per fraction for five fractions of HDR. They reported a 2-year DFS rate of 70% and grade 3/4 toxicity rate of 14% (13 patients). The median time to recurrence was 8 months (range, 2 to 22 months) and to toxicity was 10 months (range, 4 to 27 months). They concluded that the high toxicity of this regimen should prompt consideration of dose reduction in BT dose or use of 3D imaging to shape the dose. Several institutions in the United States now report 5.5 Gy × five fractions instead of 6 Gy per fraction for patients treated with chemoradiation.[638,639]

Anker et al.[783] treated 65 patients with HDR with 6 Gy × fractions, and 45 patients had the top dwells retracted as the tumor regressed. With a median follow-up of 24.5 months, the 3-year overall, disease-free distant metastases–free survival, and local control rates were 67%, 76%, 79%, and 97%, respectively. Acute and actuarial 3-year late grade 3 toxicity or greater occurred in 24.6% and 17% of patients, respectively.

Le Pechoux et al.[784] treated 130 patients with cervical cancer with HDR brachytherapy (for stage I, 30 Gy in 6 weekly sessions) in combination with EBRT (50-Gy mean dose with midline shielding). Patients with more advanced disease received four sessions of biweekly brachytherapy for a total dose of 18 to 24 Gy and external irradiation (20 to 30 Gy to the whole pelvis, 50 to 66 Gy to parametria with midline shielding). The 5-year survival rates were 82% for patients with stage IIB and 47% with stage IIIB disease. There were 4 rectovaginal or vesicovaginal fistulas and 1 case of proctitis requiring colostomy. Survival, local tumor control, and morbidity were equivalent in 76 patients treated with 6 Gy once a week and in 54 patients receiving twice-weekly brachytherapy of 5 Gy per session.

Hsu et al.[764] dosed 92 patients with cancer of the cervix with HDR brachytherapy, six fractions of 7 Gy per fraction (42 Gy) at point A (HDR-6); 57 received four fractions of 8 Gy per fraction (32 Gy) at point A (HDR-4). A twice-daily program was used for all patients receiving HDR in two split courses. A historic control group of 259 patients was treated with LDR brachytherapy (40 Gy in two split courses). All patients received whole-pelvis external irradiation of 36 to 45 Gy (mostly 40 Gy) before brachytherapy. Five-year local tumor control rates were equivalent in the three groups (82%, 85.5% for HDR, and 89.5% for LDR). Five-year survival rates were also comparable (67.7%, 77.9%, and 74.1%, respectively). However, late complications were lower in the HDR-4 group, which received treatment more biologically equivalent to the LDR regimen, than in patients in the HDR-6 group (11% vs.

25.6%).

Selke et al.[785] published results in 187 patients with primary carcinoma of the cervix treated with whole-pelvis irradiation (46 Gy) and HDR brachytherapy with a dose rate to point A of 1.6 Gy/minute, decreasing to approximately 0.8 Gy/minute at the end of the 5-year study. Three HDR fractions (8 to 10 Gy to point A per fraction) were concurrently administered with the last 2 to 3 weeks of external irradiation. The 5-year actuarial survival rates were 72% for stage IB, 65% for IIA, 66% for IIB, 66% for IIIA, and 45% for stage IIIB. With a median follow-up of 54 months, 23 patients had 25 complications; 13 (7.6%) were grade 3 or 4. Rectal complications were significantly higher in patients who received a total rectal dose of >54 Gy (P = .045).

Choi et al.[786] treated 136 patients with carcinoma of the cervix with external beam whole-pelvis irradiation (46 Gy in 23 fractions) and three weekly applications of HDR brachytherapy of 7 or 8 Gy per fraction to point A. The actuarial 5-year survival was 85% in stage IB, 64% in stage IIA, 70% in stage IIB, and 53% in stage IIIB. Grade 3 or higher complications occurred in 3% to 7% of the patients. The most significant determinants of severe rectal complications were the addition of a lower vaginal tandem (P < .01), uterine tandem length >5 cm, a total biologically effective dose to the rectum of >120 Gy, and stage III disease.

Kagei et al.[787] reported on 217 patients with carcinoma of the cervix (71 patients with stage II and 146 with stage III disease) who received whole-pelvis EBRT (40 Gy in 20 fractions or 39.6 Gy in 22 fractions) and an additional 10 Gy in five fractions to the parametria followed by HDR brachytherapy. Cause-specific 5-year survival rates were 77% for stage II and 50% for stage III. Pelvic failure rates were 13% and 36%, respectively. The rates of severe (grade 4) late complications were 2% for the rectum, 1% for the small intestine or sigmoid colon, and 1% for the bladder.

Takeshi et al.[788] treated 265 patients with stage III cervical carcinoma with external beam radiation therapy (50.3 Gy) and intracavitary HDR brachytherapy (19.8 Gy). The 5-year overall survival, relapse-free survival, and locoregional event–free rates were 50.7%, 57.1%, and 71.2%, respectively. The 5-year incidence of major complications was 2.6% for bladder and 8.3% for rectum. The radiation dose in the subgroup with rectal complications was significantly greater than that in the subgroup without complications.

Wang et al.[789] reported treatment results in 173 patients with cervical carcinoma treated with HDR brachytherapy and whole-pelvis irradiation (40 to

44 Gy in 20 to 22 fractions) followed by pelvic wall boost (6 to 14 Gy in three to seven fractions with central shielding). HDR brachytherapy delivered 7.2 Gy to point A in each of three applications 1 to 2 weeks apart. Five-year pelvic tumor control rates were 94%, 87%, and 72% for stages IIA, IIB to IIIA, and IIIB to IVA, respectively. Five-year actuarial survival rates were 79%, 59%, and 41%, respectively. Sixty-six patients (38%) had rectal complications, and 19 (11%) had bladder complications. The 5-year actuarial rectal complication rates were 15%, 4%, and 3% for grades 2, 3, and 4, respectively.

Lorvidhaya et al.[769] reported the results in 1,992 patients with carcinoma of the cervix treated by external irradiation and HDR brachytherapy. There were 211 patients with stage IB, 225 with stage IIA, 902 with stage IIB, 14 with stage IIIA, 675 with stage IIIB, 16 with stage IVA, and 16 (0.8%) patients with stage IVB. With a median follow-up of 96 months, the actuarial 5-year DFS rates were 70%, 59.4%, 46.1%, 32.3%, 7.8%, and 23,1%, respectively. The late complication rates (RTOG) for bowel and bladder combined were 7% for grade 3 and 1.9% for grade 4 complications.

Leborgne et al.[790] described a 4-year pelvic control rate of 93% and a DFS rate of 88% for 59 patients with stage IB to IIA disease. All were treated with 18 Gy to the whole pelvis and 22 Gy to the parametria combined with six HDR fractions (14 Gy/hour to point A) of 7 Gy to point A, two in each treatment day, with 6-hour interfraction intervals. The corresponding parameters for 29 patients with stage IIB disease were 79%, 75%, and 75%. The actuarial 4-year late grade 2 and 3 complication rate was 4.7%.

In 1,148 patients with squamous cell cervical cancer treated with external RT and HDR brachytherapy with 22 years median of follow-up, the 10-year pelvic tumor control was 93% for stage IB, 82% for stage II, and 75% for stage III.[791] CSS was 89%, 74%, and 59%, respectively. Major sequelae were 4.4% in the rectosigmoid, 0.9% in the bladder, and 3.3% in the small intestine. Nakano et al.[792] subsequently presented a study of 210 patients with stage IIIB cervical cancer from eight Asian countries treated from 1996 to 1998 with radiation and brachytherapy. Though follow-up was difficult to obtain, the reported 5-year major complication rates were 6% in the HDR group and 10% in the LDR group. The 5-year overall survival rates were 51.1% in the HDR group and 57.5% in the LDR group.

Novetsky et al.[793] presented data on 77 patients treated with external beam with concomitant cisplatin followed by two HDR brachytherapy fractions of 9 Gy each. Median follow-up was 3.5 years. The local control rate was 88% for

stages IB2/II and 68% for stages III/IV. Grade 3/4 gastrointestinal acute symptoms occurred in 47%. Grade 3/4 late toxicities occurred in 5 (6%) patients. Patel et al.[794] describe 104 cervical cancer patients treated with external beam and HDR, either 9 Gy for two fractions or 6.8 Gy for three fractions, each fraction 1 week apart. Median follow-up was 31 months. The 3-year actuarial local control was 81.35% with 9 Gy versus 65.18% with 6.8 Gy (P = .04). The 3-year actuarial risk of developing any grade 3 or worse late toxicity was 7.47% with 9 Gy and 3.57% with 6 Gy (P = 0.3).

Prospective Trial with CT or MR Compared to X-Ray

The clinical outcome results from institutions using CT- or MR-based treatment planning for cervical cancer brachytherapy are listed in Table 73.17. The French STIC trial[793] collected data from 20 centers prospectively and stratified to 2D versus 3D (mainly with CT) brachytherapy. A total of 705 patients were treated with one of three arms: (a) brachytherapy followed by surgery (stage IB1, 165 patients); (b) EBRT plus chemotherapy, BT, then surgery (305 patients); or (c) EBRT plus chemotherapy and then BT (235 patients). For the 235 patients treated with concurrent chemoradiation and then brachytherapy, 2-year overall survival was 74% for 3D versus 65% for 2D (P = .27); DFS was 60% versus 55% (P = .09); local regional relapse–free survival was 70% versus 61% (P = .001), and local-only relapse–free survival was 79% versus 74% (P = .003). Toxicity was reduced overall from 23% with 2D to 2.6% with 3D (P = .002); urinary from 9% in 2D to 1% with 3D (P = .02), gastrointestinal from 9% to 0% (P = 0.17), and gynecologic from 15% to 1% (P = .01).

Retrospective Comparison of CT to MR-Planned Brachytherapy

Three studies compared CT to MRI contouring for HDR tandem and ring brachytherapy. Wachter-Gerstner et al.[795] compared MR-based plans in 15 patients to those derived with either CT or orthogonal films. CT and MR enabled higher dose to the target volume with similar OAR dosing. Viswanathan et al.[672] compared CT contours to MR contours based on a standard set of guidelines; the CT contours were larger in width, but no other significant differences in DVHs were identified. A report by Eskander et al.[673] of 10 patients treated with an MR for the first fraction only, showed that CT volumes had a greater length on the coronal plane, whereas MR images had a greater height on the sagittal plane. No differences were found in DVH parameters after optimization.[673] Similar to the Eskander et al.[673] study, using an MR for the first fraction and CT for subsequent

fractions, Beriwal et al.[689] treated 44 patients with 5- to 6-Gy per fraction HDR after EBRT. Ninety-three percent had a complete response by PET at 3 months. Of those with a CR, 2 had a local recurrence at 6 and 8 months. With a median follow-up of 8 months (range, 2.5 to 38 months), 2-year local control, disease-specific, and overall survival rates were 88%, 85%, and 86%, respectively.

One study compared CT to MR interstitial based brachytherapy for cervical cancer and showed 2-year LC rates for MR-based and CT-based treatments as 96% and 87%, respectively (log-rank $P = .65$). At 2 years, OS was significantly better in the MR-guided cohort (84% vs. 56%, $P = .036$). On multivariate analysis, squamous histology was associated with longer OS (HR 0.23, 95% CI 0.07 to 0.72) in a model with MR BT (HR 0.35,95% CI 0.08 to 1.18). There was no difference in toxicities between CT and MR BT.[796]

Retrospective Results with CT-Planned Brachytherapy

Potter et al.[743] reported results in 189 patients treated with HDR brachytherapy and EBRT (48.6 to 50 Gy). Small tumors were treated with five to six fractions of 7 Gy at point A (25 Gy in the brachytherapy volume), which is isoeffective to 76 to 86 Gy at point A. Large tumors received three to four fractions of 7 Gy after 50 Gy of EBRT, which is isoeffective to 82 to 92 Gy at point A. Three-dimensional treatment planning for brachytherapy was based on conventional x-rays and in 181 of 189 patients on CT scan. The mean brachytherapy dose was 16.2 Gy at the ICRU rectum reference point and 14.4 Gy at the ICRU bladder point. Taking into account the dose for EBRT, the mean isoeffective dose at the ICRU rectum reference point was 69.9 Gy. After a mean follow-up of 34 months, the actuarial pelvic control rate was 78% and the late complication rate for grades 3 and 4 was 2.9% for bladder, 4% for bowel, 6.1% for rectum, and 30.6% for the vagina (shortening and obliteration).

CT-based clinical outcomes were reported by the Addenbrooke's Hospital. Twenty-eight patients had HDR, 8 Gy × 3, CT-planned brachytherapy.[745] The 3-year actuarial cancer-specific survival rate in this group was 81%, with a pelvic control rate of 96%. Five of the 28 patients died of para-aortic or other distant disease, 1 of them being the only one with local recurrence presenting as a malignant vesicovaginal fistula. In 24 patients, $D_{90} \geq 74$ Gy was achieved. The only patient with local recurrence had $D_{90} = 63.8$ Gy, which was a 20% improvement over historical non–image-guided controls.

At Brigham and Women's Hospital, 115 stage IB to IVA cervical cancer patients had CT-planned brachytherapy and were treated with 595 fractions of

5.5- to 6-Gy per fraction HDR brachytherapy.[747] The 2-year local relapse rate was 6.9%. The 2-year disease-specific survival was 83%, and overall survival rate was 78%.

Cho et al. reported on 128 patients treated with CT-based brachytherapy. The 2-year LC rate was 96%, PFS was 88%, and OS was 88%. No patients had LR only. Point A was 85% of prescription for tumors <4 cm and decreased approximately 3% over 5 fractions compared to 90% of prescription for tumors >4 cm that decreased approximately 4%.[747]

Retrospective Results with MR-Planned LDR Brachytherapy

An initial report of MRI during intracavitary gynecologic brachytherapy was published in 1992 from the University of Michigan by Schoeppel et al.[797] Three patients had CT and MRI with their first of two intracavitary implants. A CT- and MR-compatible Fletcher applicator was used. CT could not distinguish the tumor with as much clarity as MR. Tardivon et al.[798] at IGR treated 10 patients with MR evaluation of the tumor during intracavitary brachytherapy for cervical and vaginal cancer and found that in 7 cases MR findings were concordant with clinical examination. MR was useful to determine the tumor/applicator relationship and distinguish the adjacent OAR.

A review was published of 39 patients treated at IGR with MRI-guided LDR brachytherapy in the preoperative setting.[746] A total dose of 60 Gy to the IR-CTV was followed 6 weeks later by extrafascial hysterectomy and bilateral salpingo-oophorectomy with pelvic node dissection. Adjuvant chemoradiation was delivered to patients with pelvic lymph node involvement. After a median follow-up of 4.4 years (range, 2.6 to 6.6 years), there were no central recurrences; 1 local recurrence occurred in the lateral pelvis (2.6%). The 4-year actuarial overall and DFS rates were 94% and 86%, respectively. The 2- and 4-year actuarial local relapse–free survival rates were 94% and 91%, respectively. Haie-Meder et al.[692] subsequently published a series of 84 patients treated with LDR MR-planned brachytherapy after chemoradiation. With a median follow-up of 53 months (range, 31 to 79 months), the 4-year overall survival and DFS rates were 57 (95% CI = 43 to 69) and 52% (95% CI = 40 to 64), respectively. Thirty-nine late complications occurred in 28 patients (33.3%): 13 bladder, 7 rectal, 5 small bowel, 4 urethral, 3 colic, 2 vaginal, 1 pelvic fibrosis, and 4 others. Four grade 3 delayed complications were observed, and no grade 4 complication occurred.

Retrospective Results with MR-Planned PDR or HDR Brachytherapy

With a 0.2-T MRI at the Medical University of Vienna, 145 patients with stage IB to IVA cervical cancer were treated with four fractions of 7-Gy HDR from 1998 to 2003.[744] Complete remission was achieved in 138 patients (95%), with 7 patients having locally persistent or progressive disease in the central (n = 5) or noncentral (n = 2) pelvis. With a median follow-up of 40 months, the 4-year local control rate was 83%, compared to 63% for historical controls. A subsequent analysis of 156 patients treated from 2001 to 2008 with MR-based brachytherapy was reviewed.[690] Local control was 98% for tumors 2 to 5 cm and 92% for tumors >5 cm. Overall survival, however, was 72% for tumors 2 to 5 cm and 65% for tumors >5 cm, indicating that despite the increase in local control with MR-based brachytherapy, death from distant metastases remains a problem in patients with large-volume cancer.

Investigators at the IGR reported on 45 patients treated between 2004 and 2006 with a tandem and mold technique using PDR brachytherapy and MR-based contouring.[688] Until recently at IGR, surgery was often performed after brachytherapy if disease was suspected on clinical examination. A dose of ≥15 Gy (after EBRT) was prescribed to the IR-CTV. The dose to the HR-CTV was approximately 250% of the dose to the IR-CTV (i.e., 80 Gy to the HR-CTV). With a median follow-up of 26 months, the 2-year overall and DFS rates were 78% and 73%, respectively. At Tata Memorial Hospital in India, 24 patients with squamous cell carcinoma were treated with MRI-based HDR. With a median follow-up of 12 months,[799] two patients had local failures.[653] Other European centers[682,691,693] and one Canadian center[800] reported feasibility data for MR-based cervical cancer brachytherapy, showing a reduction in the normal-tissue toxicity rate. When implementing 0.5- to 1.5-T MR-based tandem/ring or tandem/ovoid brachytherapy with MRI, specific guidelines for MR use should be followed.[720]

Toxicities

Table 73.17 lists general toxicities in series using CT- or MR-planned brachytherapy. In the Medical University of Vienna series reporting patients treated from 2001 to 2008, 73% received concurrent cisplatin chemotherapy.[690] A total of 11 grade 3 and 4 late events were recorded in 143 patients. With a median follow-up of 3.5 years, the actuarial grade 3 and 4 late morbidity at 3 and 5 years was, respectively, as follows: gastrointestinal, 4% and 4%; urinary, 2% and 3%; and vaginal, 1% and 3%. Two patients developed massive rectal

bleeding requiring transfusions. Three patients required stoma (grade 4) for rectal wall ulceration, resulting in a fistula, a rectal perforation, and a rectovaginal fistula. Three patients developed grade 3 urinary frequency or urgency. Three patients experienced grade 3 or 4 coaptation of the vagina.

At IGR, of the 45 patients studied,[688] 23 and 2 developed acute grade 1 or 2 and grade 3 complications, respectively; 21 patients presented with delayed grade 1 or 2 complications. One other patient presented with a grade 3 vesicovaginal fistula. No grade 4 or greater complications, whether acute or delayed, were observed. In the IGR experience with LDR brachytherapy from 2000 to 2004, 39 late complications were reported; 13 bladder, 7 rectal, 5 small bowel, 4 urethral, 3 colic, 2 vaginal, 1 pelvic fibrosis, and 4 others. Grade 3 complications were 1 rectal, 2 bladder, and 1 urethral. Tan et al.[745] reported on 28 patients treated with CT-guided brachytherapy for stage IB to IIIB cervix cancer. Their overall actuarial 3-year grade 3 and 4 morbidity rate was 14%. Two patients had grade 3 abdominal pain and 1 had a colovaginal fistula. Overall, the data indicate that a potential reduction in morbidity appears to be a benefit of image-guided brachytherapy. Advocating for contouring bowel as a separate organ at risk during image-based brachytherapy, a report of 32 patients showed that when bowel was present around the brachytherapy applicator, contouring the bowel reduced the D_{2cc} optimized dose.

Template-Based Interstitial Brachytherapy

Interstitial implants with ^{240}Ra, ^{144}Cs needles, or ^{206}Ir afterloading plastic catheters to limited tumor volumes are helpful in specific clinical situations. Indications include large residual bulky cervical tumors after external beam treatment, residual tumor with sidewall invasion, vaginal extension, presence of a fistula and/or adjacent organ invasion, or a prior supracervical hysterectomy (Fig. 73.26). Syed-Neblett[801] and Martinez et al.[802] perineal applicators are the most commonly selected. Methods for insertion have been described.[635] A tandem should be inserted when a uterus is present.[803] If the os is not visible, US guidance to determine the proper placement of the tandem is advised.[804] A ring applicator modified to allow simultaneous insertion of interstitial needles[687] and ovoid application with interstitial needles have been described.[693]

Traditionally, plain x-ray films are used for brachytherapy treatment planning. Determination of normal tissue doses and optimization is not feasible, and the risk of complications is high. In these cases, consideration of laparoscopic approaches is recommended.[635] Syed et al.[801] reported on 185 locally advanced

cervical cancer patients treated with LDR interstitial brachytherapy from 1977 to 1997. Patients received external beam treatment to 50.4 Gy, followed by interstitial brachytherapy to 40 to 50 Gy. Local control was 82%; 5-year DFS rates were 65%, 67%, 49%, and 17% for patients with stage IB, II, III, and IV disease, respectively. Eighteen (10%) of the 185 patients developed RTOG grade 3 or 4 late complications.

Clinical outcomes using traditional techniques have been reported by several institutions. Thirty patients with stage IIB and 37 patients with stage III carcinoma received interstitial irradiation in the parametrium to supplement the dose delivered by external beam treatment and intracavitary brachytherapy. Despite the fact that the patients treated with interstitial implant were in a high-risk group, local tumor control was comparable to that of patients treated with standard techniques.[190] Pierquin et al.[805] described locoregional recurrences in 6% of 53 patients with T1, 11% in 47 patients with T2, and 42% of 19 patients with T3 primary tumors of the uterine cervix treated with a combination of external beam irradiation and the Creteil method for interstitial implantation of ^{206}Ir sources in a plastic cervical–vaginal moulage and a uterine tandem. Prempree[806] reported a 96% local tumor control rate and 61% 5-year DFS rate in 23 patients with stage IIIB carcinoma of the cervix treated with a combination of external irradiation and intracavitary and interstitial implants to the parametrium. Overall, major complications were noted in 8% of the patients. Martinez et al.,[802] using the Martinez Universal Perineal Interstitial applicator, treated 37 patients with advanced or recurrent carcinoma of the cervix and 26 with vaginal–urethral tumors. Doses of approximately 35 Gy were given, in addition to external irradiation (36 Gy to the whole pelvis and 14 Gy to the pelvic sidewall). They reported 6 local failures in the patients with cervical lesions and 5 in the group with vaginal–urethral tumors. The overall complication rate was 5.1%. Nag et al.[807] reported on 31 patients with carcinoma of the cervix treated with external beam radiation therapy and fluoroscopically guided interstitial brachytherapy. With a median follow-up of 36 months, 16 patients (51%) with cervical had no local recurrence. The 5-year actuarial survival rate was 34%. Only 1 patient experienced grade 3 complications (2.5%).

Fallon et al. reported on 315 patients treated from 1992 to 2009 with interstitial brachytherapy. The 10-year local control was 87% and late grade GU and GI toxicities were 4.8% G3 and 5.4% G4.[808]

Recio et al.[809] used laparoscopy at the time of interstitial brachytherapy in six patients with FIGO stage IIB to IVA cervical carcinomas after completion of

whole-pelvis radiation; a total of 98 needles were inserted to deliver a median interstitial brachytherapy dose of 20 Gy. Eleven perforations in the pelvic peritoneum or bladder were identified during surgery in five of the six patients, leading to immediate repositioning of needles. No acute or short-term morbidity related to the procedure was noted.

Sharma et al.[810] presented results on 42 patients treated from 2005 to 2007 in a prospective study of two weekly sessions of 10 Gy, 1 week after finishing external beam radiation. Median follow-up was 23 months. Delayed toxicity was 9%. The 3-year overall survival for all stages was 47%, and the 3-year recurrence-free survival for stages IIB, IIIB, and IVA was 67%, 34%, and 20%, respectively. Sharma et al.[811] also reported on the use of transrectal US to assist with insertion of the interstitial needles.

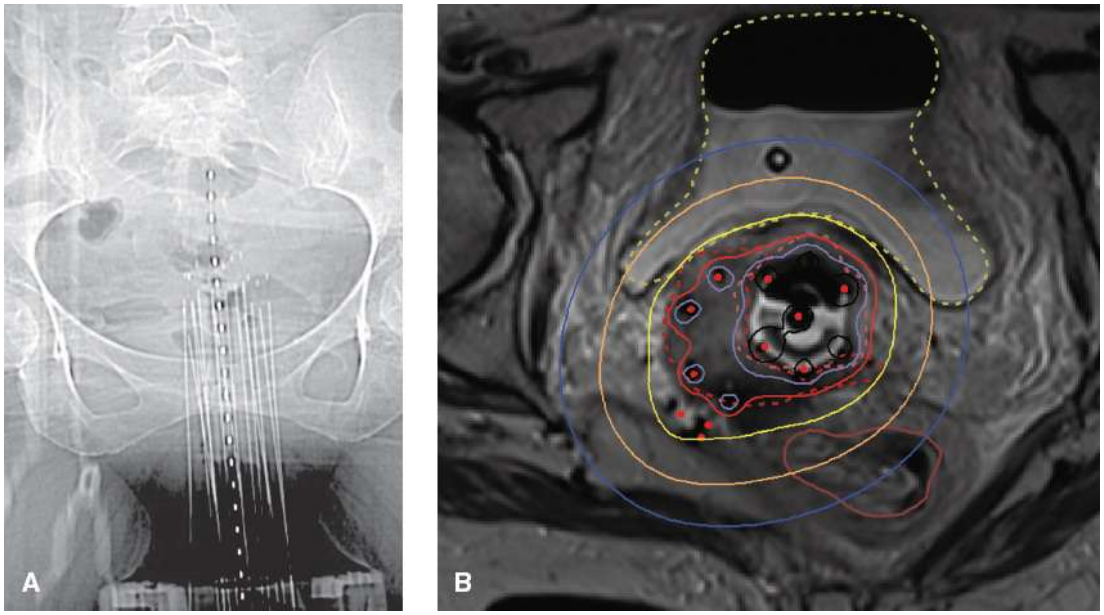

FIGURE 73.26. A: Picture of anterior scout CT showing a template-based interstitial brachytherapy application. **B:** Magnetic resonance imaging during interstitial needle insertion in a patient with stage IIIB cervical cancer ensures proper placement of the catheters adjacent to the tandem. The 100% isodose line is in *yellow*.

With image-based planning including either a CT[674,675] or an MRI,[667] the physician evaluates the placement of the needles and may choose either to not treat specific catheters or to lower the dose given through catheters close to normal-tissue structures. An approximate 11% rate of bowel insertion and a long-term fistula rate of 4% to 10% have been reported in studies using CT for planning after insertion.[674,675] When a physician has the facility to insert the applicator in a CT or MR suite while the patient is under anesthesia, an iterative

process of image-guided needle insertion ensures proper placement of the catheters and prevents an inadvertent insertion into a surrounding normal-tissue structure, such as the rectum, sigmoid, or bladder.[667]

Dose optimization with either PDR or HDR may improve the normal-tissue doses for interstitial therapy for some patients. The University of Pittsburgh reported on 11 cervical cancer patients treated with CT-guided HDR interstitial brachytherapy (5 fractions of 3.5 Gy per fraction).[812] From 1998 to 2004, interstitial brachytherapy was chosen for cases with distorted anatomy or extensive vaginal disease. The 5-year actuarial local control rate was 63%. No patient had acute grade 3 or 4 toxicity. Grade 3 or 4 late toxicity occurred in 1 patient, with a 5-year actuarial rate of 7%. Three patients had late grade 2 rectal toxicity, and 1 patient had grade 2 small-bowel toxicity.

Dimopoulos et al.[781] reported on the use of tandem/ring with short interstitial needles and MR-planned HDR brachytherapy for 22 cervical cancer patients followed for a median of 20 months; no grade 3 or 4 toxicities were noted, and 1 patient had a local recurrence. Nomden et al.[782] described the use of tandem/ovoid application with short interstitial needles for the second insertion with MR-planned PDR brachytherapy for 20 cervical cancer patients. They compared the first insertion with just a tandem and ovoid applicator to the second insertion, which included the addition of interstitial needles. There was an average increase in dose of 4.4 Gy (SD 2.3), with better coverage of the HR-CTV with the second insertion.

A prospective cohort of MR-guided interstitial brachytherapy showed a local control rate of 96%. In a comparison of CT- to MR-based brachytherapy, no difference in toxicities were noted, whereas MR had superior outcomes.[796] A systematic review of 672 patients described a local control rate of 79% with image-based planning.[813]

Mikami et al.[814] analyzed needle applicator displacement in 10 patients treated with 30 Gy HDR in five fractions and found on daily CT scans an average of 1 to 2 mm of caudal displacement. Shifts of >3 mm were replanned. Shukla et al.[815] presented data on 20 patients with cervical cancer treated with interstitial brachytherapy who underwent every-other-fraction CT imaging. The mean needle displacement was 2.5 (range, 0 to 7.4), 17.4 (range, 0 to 27.9), 1.7 (range, 0 to 6.7), 2.1 (range, 0 to 9.5), 1.7 (range, 0 to 9.3), and 0.6 mm (range, 0 to 7.8 mm) in cranial, caudal, anterior, posterior, right, and left directions, respectively. The mean displacement in the caudal direction was higher between days 1 and 2 than that between days 2 and 3 (13.4 vs. 3.8 mm; $P = .01$). Damato

et al.,[816] in a study of 10 patients treated with interstitial brachytherapy, found on average that <1-cm displacements and deformations of the implant occurred over the course of treatment. The most significant dosimetric consequences were due to changes in organ filling rather than catheter shifts. Proper quality assurance methodologies should be in place to detect shifts that can potentially result in inadvertent insertion into normal tissue.

Brachytherapy in the Elderly

Magné et al.[817] reported on 113 patients with median age of 76 years (range, 70.7 to 94.4 years) treated by conventional LDR BT as a part of their treatment. For rectal complications, grade 1/2, 3/4, and 5 (fatal) crude incidences were 19.4% (22 of 113), 1.8% (2 of 113) and 0.9% (1 of 113), respectively. Acute toxicity death occurred in 1 patient with major diarrhea associated with a hemodynamic shock. For small-bowel complications, grade 1/2 and 3/4 crude incidences were 3.5% (4 of 113) and 0.9% (1 of 113), respectively. For urinary tract complications, grade 1/2 and 3/4 crude incidences were 11.5% (13/113) and 2.7% (3/113), respectively. With a median follow-up of 3.1 years, 10 patients developed distant metastases, and 10 others had local relapses. The 3-year specific overall survival rate was 88.6% (95% CI = 77 to 92), and the corresponding DFS rate was 81% (95% CI = 72 to 88). Age did not influence the effectiveness of BT in elderly patients, and BT should be considered whenever possible, even in elderly patients presenting with a cervix cancer.

Image-Guided Brachytherapy Versus External Beam Boost

Studies of external beam treatment as an alternative boost instead of brachytherapy demonstrate significantly inferior survival rates compared to those that use brachytherapy. In a SEER analysis, 63% of 7,359 women received brachytherapy in combination with EBRT, and 37% received EBRT alone. The brachytherapy utilization rate decreased from 83% in 1988 to 58% in 2009 (P < .001). In a propensity score-matched cohort, brachytherapy treatment was associated with higher 4-year CSS (64.3% vs. 51.5%, P < .001) and overall survival (OS; 58.2% vs. 46.2%, P < .001). Brachytherapy treatment was independently associated with better CSS (HR, 0.64; 95% CI, 0.57 to 0.71) and OS (HR 0.66; 95% CI, 0.60 to 0.74).[818,819] In the study of the NCDB, only 44% of patients received standard of care therapy; black patients were less likely to receive no boost or brachytherapy.[820] The use of US enables tandem placement in most cases, even when the os cannot be identified, and should be attempted

for difficult cases. Barraclough et al.[821] reported on 44 patients with cervical cancer who did not receive brachytherapy and were treated with EBRT to 54 to 70 Gy via a 3D conformal boost. After a median follow-up of 2.3 years, 48% relapsed, with 16 of 21 developing a central recurrence. The 5-year overall survival rate was 49%, which is much lower than for brachytherapy-treated patients.

The dosimetry of brachytherapy cannot be adequately mimicked by external beam techniques. A treatment planning report compared inversely planned EBRT with photons (IMRT/SBRT) and protons (IMPT) to 3D MRI-guided brachytherapy.[822] EBRT was planned to deliver the highest possible doses to the PTV while respecting D_{2cc} limits from brachytherapy, assuming the same fractionation. Volumes receiving 60 Gy (in equivalent dose in 2-Gy fractions) were approximately twice as large for IMRT compared with brachytherapy, and the high central tumor dose was lower than that seen with brachytherapy. Both IMRT and protons were inferior to 3D image-based brachytherapy.

With IMRT, there is a need for replanning because of rapid tumor regression[341–343] and an increase in integral dose, with normal tissues throughout the pelvis receiving more radiation than with brachytherapy. Given the large movement and the increased dose to the normal tissues resulting in an increase in normal-tissue toxicity, highly conformal (IMRT, IGRT, SBRT) methods for boosting the cervix are not routinely recommended. Every effort should be made to use image guidance to insert a tandem into the uterus in order to provide adequate brachytherapy doses for all cervical cancer cases receiving radiation.

External Beam Irradiation Alone

Occasionally, brachytherapy procedures cannot be performed because of medical reasons or unusual anatomic configuration of the pelvis or the tumor (i.e., extensive lesion, inability to identify the cervical canal). These patients may be treated with higher doses of external beam irradiation alone, although survival is significantly worse than when brachytherapy is implemented, and normal-tissue toxicity is higher due to the excessive dose to the rectum and bowel. Therefore, every attempt to treat with brachytherapy should be made because brachytherapy moves with the patient and provides high regions of dose in the central regions of the tumor. With IMRT, a significantly higher normal-tissue dose is administered, and the desired high central regions of radiation cannot safely be administered.

Coia et al.,[554] in an analysis of 565 patients with various stages of cervical

carcinoma treated in the Patterns of Care Study, reported better survival (67%) and pelvic tumor control (78%) for patients treated with external irradiation and brachytherapy than for patients who had no intracavitary brachytherapy applications (36% 4-year survival rate and 47% infield failure rate). Patients treated with two intracavitary applications had a higher 4-year survival rate (73%) and infield tumor control rate (83%) than those receiving only one application (60% 4-year survival rate and 71% infield tumor control rate).

Hanks et al.[558] and Montana et al.[557] reported a higher incidence of central pelvic recurrences in patients with stage III cervical carcinoma treated with external beam therapy alone than in patients receiving brachytherapy in addition to external beam irradiation (Table 73.20). The incidence of major complications was similar in both groups of patients.

Akine et al.[824] treated 104 patients with carcinoma of the uterine cervix with external irradiation alone (anteroposterior–posteroanterior or four-field box techniques) because of inability to perform intracavitary brachytherapy. Average doses delivered were 50 Gy to the whole pelvis, followed by additional doses with reduced portals to deliver a total of 60.8 Gy in 6 weeks, 72.3 Gy in 7.5 weeks, or 80.5 Gy in 8 weeks, with a daily dose of 1.9 or 2 Gy. The local tumor control rate was 27% for stage II, 19% for stage III, and 15% for stage IVA disease. The 5-year survival rates were 36%, 17%, and 5%, respectively. Four patients had major complications (usually proctitis) that required surgical treatment, and one patient died of rectal bleeding. Eight of 23 patients treated with conformal therapy had control of the tumor and survived 5 years without major complications. Saibishkumar et al.[825] treated 146 patients with cervix cancer with EBRT alone (60 to 66 Gy) because of unsuitability for brachytherapy; 5-year pelvic tumor control was 21.9% and DFS was 11.6%.

Cost-Effectiveness of LDR Versus HDR Brachytherapy

Wright et al.[826] developed a questionnaire to elicit patient preference for two brachytherapy methods (one LDR or three HDR fractions and two HDR or five HDR fractions, assuming both methods to be isoeffective). The questionnaire was completed by 90 female staff members at their center, 18 previously treated patients, and 20 newly diagnosed patients. When both methods were assumed to be isoeffective, only 34% of the 38 patients preferred three HDR fractions to one LDR fraction. However, when HDR was assumed to be 2% more curative or 6% less toxic, 50% said they would prefer the HDR therapy. Both preference and strength of preference for LDR were significantly associated with a greater

traveling distance for treatments. More studies on resource utilization[827] are needed.

TABLE 73.20 CARCINOMA OF THE UTERINE CERVIX: INCIDENCE OF CENTRAL/PELVIC RECURRENCES CORRELATED WITH METHOD OF THERAPY

		Incidence of Pelvic Failures		
Author (Reference)	Stage	External Beam Only	External Beam and Intracavitary	*P*
Hanks et al.[558]	III	33/38 (86%)	55/109 (50%)	.0002
Montana et al.[557]	III	14/35 (40%)	12/37 (32%)	.6725
Coia et al.[554]	I, II, III	(53%)	(22%)	<.0100
Longsdon and Eifel[823a]	IIIB	641 (45%)	266 (24%)	<.0001

[a]Five-year disease-free survival.
Modified from Stehman FR, Perez CA, Kurman RJ, et al. Uterine cervix. In: Hoskins WJ, Perez CA, Young RC, eds. *Principles and practice of gynecologic oncology*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2000:841–918. With permission.

Alternative Isotopes

Californium has been proposed as an alternative to iridium as the radioactive isotope. Maruyama and Muir[828] reported on 41 patients with stage IB cervix cancer treated with 40 to 50 Gy to the whole pelvis followed by a 5- to 15-Gy boost to the lateral pelvic wall and a single ^{268}Cf-neutron brachytherapy insertion in approximately 8 hours. Nearly total tumor clearance was achieved in >90% of the patients; tumor regression was more rapid in the ^{268}Cf group than in similar patients treated with ^{144}Cs and the same external beam irradiation dose.

FOLLOW-UP

After treatment, patients should be regularly followed by both the radiation and the gynecologic oncologist. Careful history taking and a complete physical and pelvic/rectal examination usually are performed every month for the first 3 months after completion of irradiation, every 3 months for the remainder of the first year, every 4 months the second year, every 6 months during the third through the fifth year, and yearly thereafter. The use of Pap smears for cervical and vaginal cytology as a follow-up study is controversial because of postirradiation cellular morphology that renders it difficult to distinguish

postirradiation changes from residual or recurrent malignant cells.[829,830] DNA analysis of postirradiation cytologic smears demonstrating atypia or dysplasia may provide ancillary information.[831]

Rintala et al.[832] evaluated the reliability of cytologic analysis and atypia after radiation therapy in 89 patients treated for cervical carcinoma. A total of 697 Pap smears were taken; during the follow-up, 44 patients had recurrent disease, which was local in 17 (39%) cases. The rate of false-positive samples was only 3%. Radiation-induced atypia was detected in 28% of the Pap smears taken during the first 4 months after radiation therapy, and its incidence decreased thereafter. In 1,000 patients treated with either surgery or radiation therapy at the MD Anderson Cancer Center for stage IB cervical cancer posttreatment, Pap smears did not detect a single asymptomatic recurrence among 133 patients with recurrent disease.[833]

The presence of apparently viable tumor cells in the cytologic smear 3 months after irradiation should be evaluated with cervical biopsies, dilation and curettage, and careful EUA, as indicated.

Complete blood counts and chemistry profile tests are obtained as clinically indicated. Chest radiography is commonly obtained on a yearly basis, usually for the first 5 years posttreatment, although its value to detect curable lung metastasis is not proven. If radiographs are consistently negative, obtaining them every other year thereafter may be sufficient.

Other imaging studies, such as CT, MRI, PET scanning, or bone scans, are obtained when clinically warranted. When persistent or recurrent tumor is suspected, biopsies should be obtained for histologic confirmation. If a biopsy is positive, immediate treatment should be instituted, as is discussed later.

Usually, hematometra after radiation therapy for cervical carcinoma is related to recurrent disease but occasionally may be related to estrogen replacement therapy, endometrial activity, or fibrosis and obliteration of the endocervix.[834]

TREATMENT OF RECURRENT CARCINOMA OF THE CERVIX

After Previous Surgery

Radiation may salvage approximately 50% of patients with localized pelvic recurrences after surgery alone. A combination of whole-pelvis external irradiation (45 to 50 Gy) with concurrent chemotherapy followed by interstitial brachytherapy is recommended. If the tumor lies outside of an accessible region

for brachytherapy, dose escalation with conformal or IMRT techniques may be attempted, depending on the location of the tumor and the need to protect the bowel, with at least 65 to 70 Gy necessary for adequate control. In the setting of recurrent disease, the total mucosal dose from the external and brachytherapy can approach 140 Gy to the upper vagina and 95 Gy to the distal vagina without a high risk.[835] With interstitial brachytherapy, doses of 20 to 35 Gy are administered with single, double-plane, or volume implants, for a total tumor dose of approximately 80 Gy, depending on the extent of the tumor.

Larson et al.[836] observed 27 recurrences (11%) in 249 patients treated with radical hysterectomy and pelvic lymphadenectomy for stage IB carcinoma of the cervix; 17 (63%) had tumor recurrence in the pelvis or vulva; the other 10 patients had recurrences outside the pelvis. Eight of 15 patients (53%) treated with irradiation for an isolated recurrence in the pelvis or vulvar region were tumor-free between 10 and 126 months after treatment of the recurrence (median, 48 months).

Ijaz et al.[837] reported on 50 patients treated with RT for an isolated pelvic recurrence of cervical carcinoma after radical hysterectomy; 7 patients were treated with palliative intent using hypofractionated RT. The remaining 43 patients were treated with curative intent, 33 with RT only and 10 with cisplatin-based chemoirradiation. The overall 5-year survival rate was 33% for all 50 patients, 39% for the 43 patients treated with curative intent, and 25% for patients with isolated sidewall recurrences treated with curative intent. Three patients experienced late treatment complications.

Hille et al.[838] described results in 17 patients with recurrent cervix cancer (9 had a complete microscopically incomplete resection) treated with EBRT and brachytherapy to 50 to 65 Gy. The 5-year pelvic tumor control was 48%, and relapse-free survival was 24%.

After Definitive Irradiation

Reirradiation of previously irradiated patients must be undertaken with extreme caution. It is very important to analyze the techniques used in the initial treatment (beam energy, volume, doses delivered with external or intracavitary irradiation). In addition, the period of time between the two treatments must be taken into consideration because it is postulated that some repair of the initial damage may take place in the interval. In general, external irradiation for recurrent tumor is given to limited volumes (40 to 45 Gy, 1.8-Gy tumor dose per fraction, preferentially using lateral portals). Occasionally, intracavitary or

interstitial irradiation can be used to treat relatively circumscribed recurrences.

Sommers et al.[839] described the results of retreatment in 376 patients with recurrent carcinoma of the uterine cervix. Ninety-one patients received irradiation, mostly external (86.8%), occasionally combined with brachytherapy (7.7%) to control bleeding of central recurrences; brachytherapy alone was administered in 5.5% of patients. The usual dose for recurrent pelvic masses was 40 to 45 Gy, and for PALN metastases, it was 45 to 50 Gy in 5 weeks. Other metastatic sites were treated with 35 to 40 Gy in 3 to 4 weeks. Pelvic exenteration was attempted in 23 patients, only 10 of whom were deemed to be operable (43.5%), but it was completed in only 7. The probability of 5-year survival after treatment for recurrence was 30% with combined surgery and external irradiation, 12% with surgery alone, and 4% with external irradiation alone. The 5-year survival rate for 10 patients who underwent pelvic exenteration was 16%. Only 1% of the untreated patients survived 5 years. Six of 140 patients (4.3%) experienced grade 2 or 3 complications.

Selected patients with limited pelvic recurrences not fixed to the pelvic wall and without evidence of extrapelvic metastases can be potentially salvaged by radical hysterectomy or pelvic exenteration. Coleman et al.[840] described results in 50 patients who underwent radical hysterectomy for persistent (18 patients) or recurrent (32 patients) cervical cancer after primary radiation therapy. Lymph node metastases were identified in 5 of 39 patients (13%) in whom the lymph nodes were evaluated. The 5- and 10-year survival rates were 72% and 60%, respectively.

In 65 patients on whom pelvic exenteration was carried out at Memorial Sloan-Kettering Cancer Center, the 5-year survival rate was 23%.[841] The operative mortality rate was 9.2%. The authors pointed out that the significant mortality and morbidity associated with this procedure preclude its use as palliative therapy.

Urinary diversion, either by nephrostomy or ileal bladder, may be of palliative value in patients with either recurrent carcinoma in the pelvis or complications. It must be kept in mind that diversion may prolong life but runs the risk of denying a terminally ill patient with cancer the oblivion and insensibility of uremia.

Kastritis et al.[842] treated 200 patients with stage IV or recurrent cervix cancer with cisplatin-based chemotherapy; response rate was 43.5% in 142 patients with squamous cell and 53.5% in 58 patients with nonsquamous tumors (P = .79). Median survival was 11.57 and 19 months, respectively. Tinker et al.[843]

treated 25 women for recurrent cervical cancer with carboplatin–paclitaxel and noted a 20% cure rate and 20% progression rate, with median survival of 21 months. Brewer et al.,[544] in 32 women, all of whom had previous chemotherapy and 29 of whom had previous RT, used cisplatin and gemcitabine, with a progression rate of 22% and median time to progression of 3.5 months.

GOG 240 was a four-arm randomized trial of 452 women with recurrent or metastatic cervical cancer randomized to cisplatin and paclitaxel, or topotecan and paclitaxel, either alone or in combination with 15 mg/kg of bevacizumab. There was a significant improvement of median survival with the addition of bevacizumab, from 13.3 to 17 months (P = .0035), but with higher toxicities (grade 3 to 4 bleeding 5%, thromboembolism 9%, and GI fistula 3%).[844]

Para-aortic Lymph Node Recurrences

Isolated recurrences in the para-aortic nodes after pelvic irradiation have been described in about 3% of patients, and some may be salvaged with aggressive therapy. The advent of IMRT makes treatment easier, with less morbidity.

Kim et al.[585] treated 12 patients with isolated PALN metastasis with hyperfractionated RT (60 Gy in 1.2-Gy fractions twice a day) and concurrent cisplatin–paclitaxel. Fields extended from the superior plate of T12 to the lower plate of L5. Three-year survival was 19%. Grade 3 or 4 hematologic toxicity developed in two patients. Singh et al.[586] detected 14 isolated PALN metastases in 816 patients previously treated with RT; these women were subsequently treated with RT to the PALNs combined with concurrent chemotherapy. Seven patients survived 5 years.

In a review of 1,955 patients treated with RT for cervix cancer, Jhingran et al.[845] identified 120 patients with recurrent tumor above the pelvic fields. Initially, 10 had common iliac and 5 had para-aortic node involvement. In 104 patients, recurrences were immediately adjacent to the upper borders of the RT fields. In 15 patients treated with curative intent for the PALN recurrence, 5-year survival was 25%.

Intraoperative Irradiation

Intraoperative radiation therapy (IORT) has been used for treatment of locally advanced and recurrent carcinoma of the cervix, with 3-year survival rates of 8% to 21% as reported by Mahé et al.[846] and Garton et al.,[847] and a 5-year survival rate of 33% in 14 patients described by Kinney et al.[452] Patient selection may have had an impact on the different results. Abe and Shibamoto[848] noted that

central recurrences, particularly in nonirradiated patients, and resection of the gross recurrent tumor in irradiated patients improve the benefit from IORT. Significant toxicity included peripheral nerve injury and ureteral stenosis (with doses >15 to 20 Gy).

IORT was used in 70 patients with pelvic recurrences in a European cooperative study.[846] Complete tumor resection was carried out in 30 patients, partial in 37, and unspecified in 3. Sixty-five patients had electron beam therapy (12 to 25 MeV), with mean doses of 18 Gy (10 to 25 Gy) after gross complete resection and 19 Gy (10 to 30 Gy) after partial resection. The 3-year overall survival rate was 8%. Grade 2 or 3 toxicity was observed in 19/70 patients (27%), with 10 complications being related to IORT.

Martinez Monge et al.[849] reported a study of IORT in 26 patients with recurrent gynecologic tumors, some relapsing after full-dose radiation therapy (group 1) or after surgery (group 2). Cervical carcinoma was the initial tumor site of involvement in 18 patients. Treatment consisted of maximal surgical resection and IORT (10 to 25 Gy) to high-risk areas. Patients not previously irradiated also received external beam irradiation (with or without chemotherapy) before or after surgery. There was 1 IORT-related incidence of motor neuropathy. The local tumor control rates were 33% and 77%; the 4-year actuarial survival for group 1 was 7%, and the 6-year actuarial survival rate for group 2 was 33%.

In another study, 42 patients with stage IIA to IVA cervical cancers initially received 50.4 Gy of pelvic external beam radiation with concurrent cisplatin and 5-fluorouracil.[850] Patients then underwent radical surgery 6 to 8 weeks later with IORT. The 5-year DFS and OS were 46% and 49%, respectively, which are inferior to reported results with standard concurrent chemoradiation followed by brachytherapy without surgery or IORT. Therefore, this regimen remains of questionable value in potentially curable patients.

URGENT BLEEDING AND PALLIATIVE IRRADIATION

Frequently, the radiation oncologist is faced with the challenge of treating a patient with stage IVB or recurrent carcinoma requiring palliation of pelvic pain or bleeding. Tumors respond rapidly to radiation, and bleeding usually resolves within a few days of treatment. If vaginal bleeding is the main concern, several possibilities may be effective. In a descriptive review of eight papers that presented palliative treatment data,[851] five papers were found to report using 10

Gy per fraction, with the best resolution of bleeding and/or pain when each 10-Gy fraction was given at 3- to 4-week intervals for a total of three fractions. Alternatively, common palliative regimens used in other sites of the body, such as 4 Gy for five or six fractions or 3 Gy for 10 fractions, or a Quad shot regimen may be implemented. Patients who present with a new diagnosis may be treated with 3 to 4 Gy for two or three fractions, followed by standard 1.8 Gy to approximately 39.6 Gy and then brachytherapy. Alternatively, patients may receive 1 to 2 days of 1.8 Gy twice a day, switching to once-a-day treatment with 1.8 Gy per fraction after bleeding has stopped on day 2 or 3, completing treatment after 45 Gy and then commencing routine brachytherapy.

A single LDR intracavitary insertion with tandem and colpostats for approximately 6,000 mgh (55 Gy to point A) may be used for palliation. If irradiation was delivered previously, lower intracavitary doses should be prescribed (4,000 to 5,000 mgh). Grigsby et al.[852] used two fractions of HDR brachytherapy with a ring applicator (once weekly) with control of bleeding in 14 of 15 patients.

Several high-dose fractionation schedules with external beam radiation have been used. Spanos et al.[853] reported on a phase II study of daily multifractionated split-course irradiation in 142 patients with recurrent or metastatic disease in the pelvis. Irradiation consisted of 3.7 Gy per fraction given twice daily for 2 consecutive days, repeated at 3- to 6-week intervals for a total of three courses, aiming at a total tumor dose of 44.4 Gy. Occasionally, this regimen was combined with an LDR intracavitary insertion (4,500 mgh), blocking the midline for the last 14.4-Gy external dose. Twenty-seven patients survived >1 year. There were only two recorded cases of grade 3 toxicity (lower gastrointestinal tract). This study was expanded to a phase III protocol randomizing 136 patients between a short (2 weeks) or a longer (4 weeks) rest period between the split courses of irradiation.[854] There was a trend toward increased acute toxicity in patients with shorter rest periods (5 of 58 vs. 0 of 68; $P = .07$). Late toxicity was not significantly different in the two groups. Pelvic tumor response was comparable in both groups (34% vs. 26%). Spanos et al.[853] reported a 6% complication rate in 290 patients treated in RTOG Protocol 85-02. No patient receiving <30 Gy experienced late toxicity. There was no significant difference in the incidence of complications for patients with a 2- or 4-week rest ($P = .47$).

IRRADIATION AND HYPERTHERMIA

Because of technical limitations in the delivery of adequate heat to large parts of the body such as the pelvis, the use of hyperthermia in the treatment of carcinoma of the uterine cervix has been rare. Hornback et al.[855] described a nonrandomized study in which the combination of microwave hyperthermia (433 MHz) and irradiation resulted in improved pelvic tumor control (72%) in a group of 79 patients with stage IIIB carcinoma compared with previously irradiated historic control patients (53%). However, 5-year survival rates were comparable in both groups (22% to 30%).

Sharma et al.[856] reported a 70% DFS rate at 18 months in 20 patients with stage IIB or III carcinoma of the uterine cervix treated with a combination of irradiation and hyperthermia (13.5 MHz, 42°C to 43°C, 30 minutes before irradiation) in comparison with a 50% DFS rate in 22 patients treated with irradiation alone. The grade 3 complication rate (8%) was similar in both groups.

Dinges et al.[857] treated 18 patients with advanced carcinoma of the cervix with RT plus hyperthermia (in the first and fourth weeks, two regional hyperthermia treatments were applied). The acute toxicity was low and similar to that with RT alone. The local tumor control was 48% at 2 years.

Harima et al.[858] evaluated radiation therapy or thermoirradiation (three sessions of hyperthermia) for stage IIIB cervical carcinoma; two groups of 20 patients each were randomly divided. A complete response was achieved in 50% (10 of 20) in the RT group versus 80% (16 of 20) in the thermoirradiation group (P = .048). The 3-year overall survival and DFS rates for the patients who were treated with thermoirradiation (58.2% and 63.6%) were better than with RT (48.1% and 45%), but differences were not statistically significant. The 3-year local relapse–free survival rate of the patients who were treated with thermoirradiation (79.7%) was significantly better than that of the patients treated with irradiation alone (48.5%; P = .048). Thermoirradiation was well tolerated and did not add to either acute or long-term toxicity over radiation alone.

Vasanthan et al.[859] reported on 110 patients with locally advanced cervix cancer randomized to treatment with RT alone or combined with hyperthermia (minimum five sessions, 60 minutes each, once weekly). Overall 3-year pelvic tumor control was 68.5% and survival was 73.2%, with no difference in either group, although survival was lower in the patients with stage IIB treated with hyperthermia. Acute toxicity was 18% (10 of 55) in the hyperthermia patients and 4% (2 of 55) with RT alone. Late toxicity was not different in the two arms.

A Cochrane database review identified six randomized, controlled trials published between 1987 and 2009 comparing RT versus combined hyperthermia and RT. The results show 74% of patients had stage IIIB cervical cancer. A significantly higher complete response rate (RR = 0.56, 95% CI = 0.39 to 0.79) and lower local recurrence rate (HR = 0.48, 95% CI = 0.37 to 0.63) and improved overall survival (HR = 0.67, 95% CI = 0.45 to 0.99) with no difference in acute or late grade 3 to 4 toxicity were seen for patients treated with combined therapy.[860] Catheter-based US devices provide a method to deliver heat with HDR brachytherapy, but clinical results are not yet available.[861]

SIDE EFFECTS: SURGERY AND RADIATION

Descriptions of sequelae vary among institutions because toxicity-grading scales are not uniform and the scoring system for complications is not clearly stated in all reports. Surgical side effects alone depend on the extent of surgery and the amount of disease. Radical hysterectomy alone may cause long-term side effects such as urinary retention requiring chronic suprapubic catheter placement, sciatic nerve injury, postoperative seroma or hematoma formation, pelvic pain, or, when lymphadenectomy is performed, lifelong edema. Oophorectomy also may induce menopause; hysterectomy removes the ability to carry a pregnancy, and removal of a portion of the vagina may significantly change sexual function if vaginal shortening is severe.

With improved anesthesia, surgical techniques, and antibiotic therapy, the mortality rate for radical hysterectomy with pelvic lymphadenectomy has decreased to 1% or less. The most frequent sequela after radical hysterectomy is urinary dysfunction as a result of partial denervation of the detrusor muscle. Patients may have various degrees of loss of bladder sensation, inability to initiate voiding, residual urine retention, and incontinence.

In 375 patients treated with a modified radical hysterectomy for various gynecologic disorders, Magrina et al.[862] observed some form of postoperative (within 42 days of surgery) complications in 89 patients (24%). Patients who had a pelvic lymphadenectomy experienced a greater incidence of lower extremity lymphedema than those who did not undergo this procedure. Preoperative or postoperative pelvic irradiation was a significant predisposing factor for urinary tract infection, lymphedema, and bowel obstruction in these patients compared with those who did not receive pelvic irradiation.

Some loss of defecatory urge associated with chronic rectal dysfunction was

observed by Barnes et al.[863] after radical hysterectomy. Manometric studies suggest a disruption of the spinal arcs controlling defecation.

Other complications include ureterovaginal fistula (the incidence of which has decreased to <3%), hemorrhage, infection, bowel obstruction, stricture and fibrosis of the intestine or rectosigmoid colon, and bladder and rectovaginal fistulas. Postsurgical complications are usually more amenable to correction than are late complications after irradiation.

When postoperative radiation therapy is given to selected patients, further complications of the additional therapy are expected. The main areas of side effects because of radiation are bowel, bladder, skin, and sexual function.[864] Because of intestinal adhesions to denuded surfaces in the pelvis, enteric complications, such as obstruction, fistula, or dysfunction, were observed in 24% of patients reported by Fiorica et al.[865] Other investigators, however, have reported no increase in the incidence of severe complications in patients treated with postoperative irradiation.[419,866]

Lower body mass index (BMI) is correlated with an increase in toxicity. A total of 404 patients with stage IB1 cervical cancer with positive lymph nodes or stage IB2 or higher were treated from 1998 to 2008. A BMI of <18.5 was associated with a decreased overall survival (HR = 2.37, $P < .01$). Grade 3 and 4 complications appeared to trend higher; overall, 17% versus 14%; specifically, for fistula, 11% versus 9% ($P = .05$), for bowel obstruction, 33% versus 4% ($P < .01$), and for lymphedema, 5.6% versus 1.2% ($P = .02$).[867]

Montz et al.[868] evaluated bowel obstruction in 98 patients undergoing radical hysterectomy for a nonadnexal gynecologic malignancy. The incidence of small-bowel obstruction was significantly higher ($P < .05$) in patients who received concomitant radiation therapy (20%). None of these patients had recurrent disease at the time of small-bowel obstruction. Findings at surgery consisted of minimal incisional adhesions but extensive matted small-bowel loops adherent to the pelvic operative sites.

When irradiation is combined with surgery, the complication rate tends to be somewhat higher, particularly because of injury to the ureter or the bladder (ureteral stricture or ureterovaginal or vesicovaginal fistula).[869] The dose of irradiation, technique, and type of surgical procedure performed are important in determining the morbidity of combined therapy. Jacobs et al.,[870] in 102 patients with invasive cervical carcinoma treated with low-dose preoperative irradiation and radical hysterectomy with lymphadenectomy or high-dose preoperative irradiation and conservative extrafascial hysterectomy, noted a major

complication rate of 5%. After combined treatment, some degree of lymphedema may be observed (30% to 40%).

A significant number of complications are associated with pretherapy staging laparotomy, particularly if irradiation (>55 Gy) is given to metastatic PALNs. The incidence of complications is between 5% and 20%, depending on the extent of the PALN dissection, use of transperitoneal or retroperitoneal approach for the operation, and dose of irradiation given.[46]

Late Sequelae: Overall

The incidence of major late sequelae of radiation therapy for stage I and IIA carcinomas of the cervix ranges from 3% to 5% and for stages IIB and III between 10% and 15%. The most frequent major sequelae for the various stages are listed in Tables 73.21 and 73.22. Injury to the gastrointestinal tract usually appears within the first 2 years after radiation therapy, whereas complications of the urinary tract are seen more frequently 3 to 5 years after treatment.[609,871] Pedersen et al.,[872] in a review of morbidity of radiation therapy in 442 patients with cervical cancer stages IIB, III, and IVA, recommended that actuarial estimates rather than frequency of sequelae be reported to avoid underestimation of risks of late morbidity after radiation therapy in long-term survivors. In fact, Eifel et al.,[869] in 1,784 patients with stage IB carcinoma of the cervix, noted that the greatest risk of sequelae is in the first 3 years after therapy. The risk of rectal complications declined after the first 2 years of follow-up to 0.6%/year, whereas the risk of major urinary tract complications for survivors continued at 0.3%/year, with a 20-year actuarial risk of major complications of 14.4%.

Montana et al.[557], Perez et al.,[873] and Pourquier et al.[874] noted a greater incidence of complications with higher doses of irradiation. Perez et al.[871] and Pourquier et al.[874] reported that with doses <75 to 80 Gy delivered to limited volumes, grade 2 and 3 complications in the urinary tract and rectosigmoid were approximately 5%. However, the incidence increased to >10% with higher doses of irradiation to these organs (Fig. 73.27). Doses >60 Gy were also correlated with a greater incidence of small-bowel injury (Fig. 73.28). The same analysis showed that patients who experienced sequelae of therapy had slightly better survival rates than patients without any complications. This was related to improved tumor control with higher doses of irradiation.[871]

Perez et al.[873] quantitated the effect of total doses of irradiation, dose rate, and ratio of doses to bladder or rectum and point A on sequelae in 1,456 patients treated for cervical cancer with external beam irradiation plus two LDR intracavitary insertions to deliver 70 to 90 Gy to point A. Median follow-up was 11 years. In stage IB, the frequency of grade 2 morbidity was 9%, and in grade 3, it was 5%; in stages IIA, IIB, III, and IVA, the frequency of grade 2 morbidity was 10% to 12% and that of grade 3 was 10%. The most frequent grade 2 urinary/rectal sequelae were cystitis and proctitis (0.7% to 3%). The most

common grade 3 sequelae were vesicovaginal fistula (0.6% to 2% in patients with stage I to III tumors), rectovaginal fistula (0.8% to 3%), and intestinal obstruction (0.8% to 4%). In the bladder, doses <80 Gy correlated with a <3% incidence of morbidity, which was 5% with higher doses (P = .31). In the rectosigmoid, the incidence of significant morbidity was <4% with doses <75 Gy and increased to 9% with higher doses. For the small intestine, the incidence of morbidity was <1% with 50 Gy or less, 2% with 50 to 60 Gy, and 5% with higher doses to the lateral pelvic wall (P = .04). Multivariate analysis showed that dose to the rectal point was the only factor influencing rectosigmoid sequelae and dose to the bladder point affected bladder morbidity.

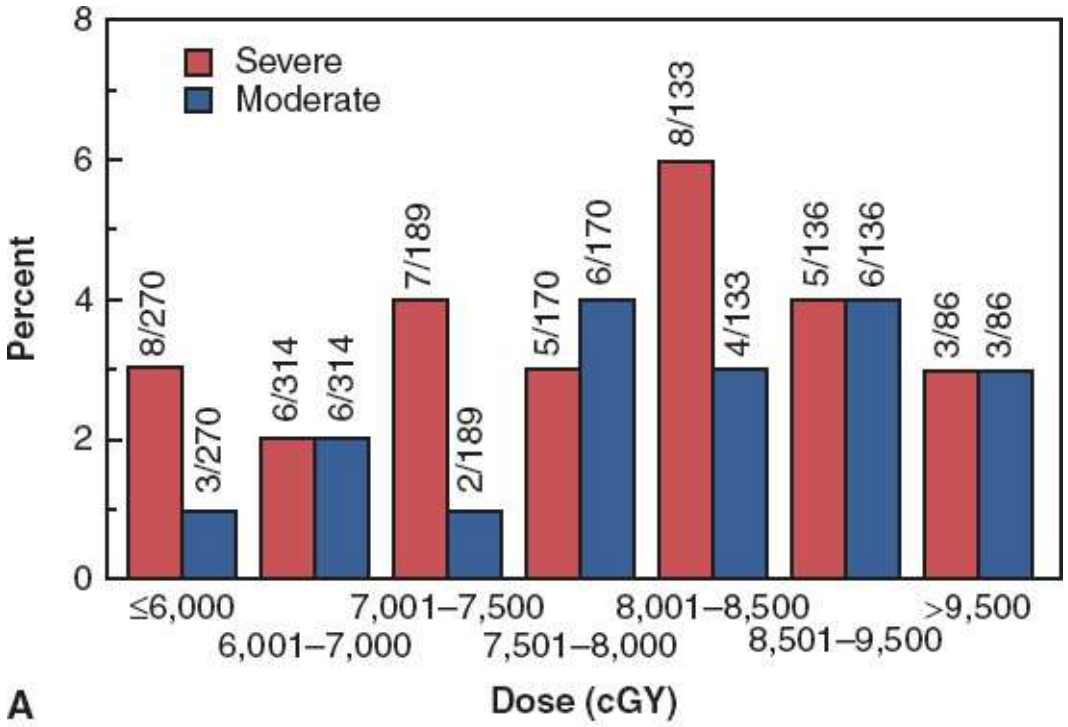
In a review of the Patterns of Care Study, Lanciano et al.[875] observed a 5-year actuarial rate of 14% for major late complications in 1,558 patients treated with irradiation for invasive carcinoma of the cervix. Women <40 years of age or with a history of prior surgery or laparotomy for staging had a greater incidence of significant morbidity (15% to 18% vs. 8% to 9%). In addition, EBRT dose per fraction of >2 Gy, paracentral doses of 85 Gy or greater, and lateral parametrial doses >60 Gy were independently associated with a higher complication rate.

Lee et al.,[876] using 3-Gy fractions with EBRT, calculated the rectal point dose in the anterior wall at the level of the cervical os and noted that total higher BED (142.7 Gy) was associated with more frequent rectal sequelae compared with BED of <131 Gy.

Mitchell et al.[146] evaluated 398 patients with stage I to III cervical carcinomas treated with radiation therapy. Patients were divided into nonelderly (35 to 69 years of age; n = 338) and elderly (≥70 years of age; n = 60) groups. The frequency and severity of acute and chronic sequelae were equivalent in both groups.

Gastrointestinal Toxicity

When late radiation proctitis occurs, initial treatment is the same as for acute proctitis. If the symptoms and rectal bleeding persist, laser treatment of rectal telangiectasis or ulcers is frequently beneficial. Roche et al.[877] treated six patients with hemorrhagic radiation-induced proctitis using outpatient intrarectal application of formaldehyde 4%. In four cases, the bleeding ceased after the first formaldehyde application; two patients continued to bleed, but another application 3 weeks later definitively controlled the hemorrhage. There were no complications, such as burns or late stenosis of the deep layers of the rectum, and this technique was well tolerated. Rubinstein et al.[878] and Seow-Choen et al.[866] also reported treatment of radiation proctitis with a similar technique. Patients are sedated, a local anesthetic block is administered, and a sponge moistened with 4% formalin is applied for 4 minutes to each bleeding area of the rectum. Care is taken to protect the perianal skin from any caustic effects of the formalin.



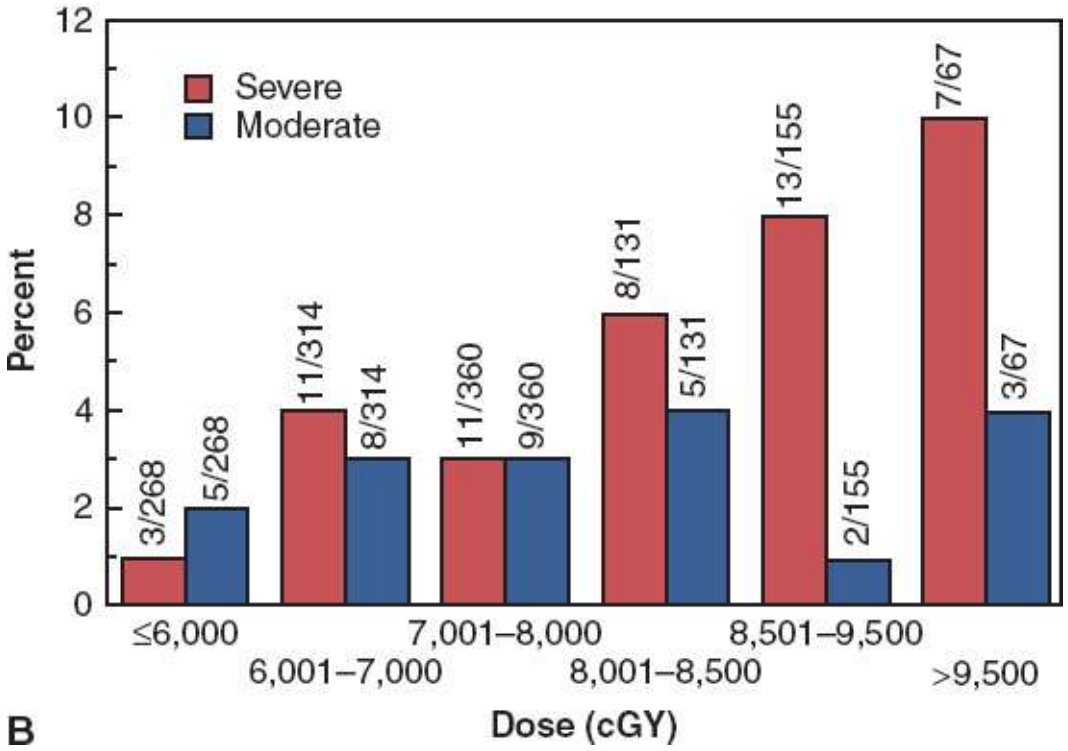


FIGURE 73.27. Incidence of moderate or severe genitourinary **(A)** or rectosigmoid **(B)** complications in patients with carcinoma of the uterine cervix (all stages) treated with irradiation alone (external and brachytherapy). A greater frequency of complications is noted with maximum doses of >75 to 80 Gy to the bladder or rectum.

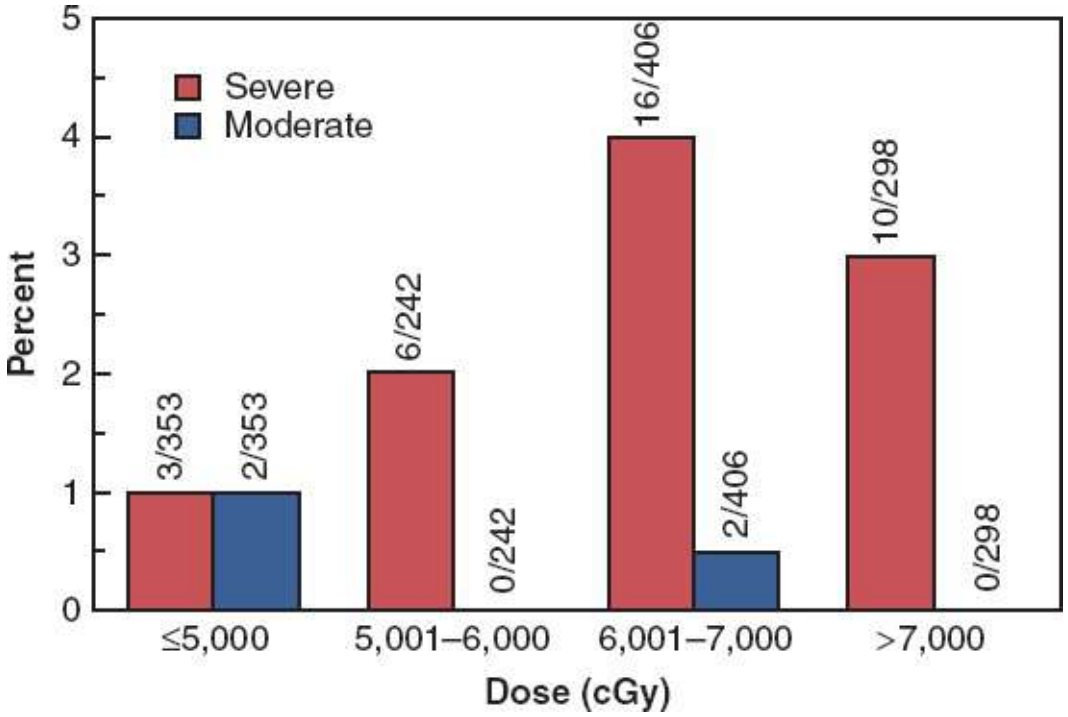

FIGURE 73.28. Incidence of moderate or severe complications in small intestine correlated with doses of irradiation.

Occasionally, a colostomy is necessary if conservation management fails. The importance of performing colonoscopy in patients with rectal bleeding to exclude other lesions in the colon, including polyps or cancer, is emphasized. If routine screening colonoscopy is not urgent, unless there is a medical reason, the colonoscopy may be postponed until 1 year after pelvic radiation to ensure no issues with poor wound healing, bleeding, or ulceration secondary to biopsy performed at the time of colonoscopy.

Anal incontinence is occasionally observed. This sequela must be assessed in light of a report by Nelson et al.,[879] who in a survey of 6,959 nonirradiated patients, identified 153 (2.2%) who reported anal incontinence, without specific etiology. Thirty percent of incontinent subjects were >65 years of age, and 63% were women. Of those with anal incontinence, 36% were incontinent to solid feces, 54% to liquid feces, and 60% to gas.

Kim et al.[880] investigated the effects of radiation on anorectal function using manometry in 24 patients with carcinoma of the uterine cervix who had late radiation proctitis. These data were compared with those from 24 age-matched nonirradiated female volunteers. Regardless of the severity of proctitis symptoms, 75% of irradiated patients exhibited abnormal manometric parameters for sensory or motor functions. Radiation damage to nerves and to

the external sphincter muscle was considered to be an important cause of motor dysfunction.

Quilty[881] noted a greater incidence of pelvic complications in patients treated with higher doses to the whole pelvis (40 to 50 Gy). The author commented that the intracavitary radium dose was not correlated with severe complications. Similar observations were made by Stryker et al.[882] who recorded a 9% incidence of fistulas and a 14% incidence of grade 2 and 3 complications in 132 patients after delivery of 50 Gy or higher to the whole pelvis (1.8-Gy daily dose) combined with intracavitary insertion. They recommended that the whole-pelvis dose should not exceed 40 to 45 Gy when doses of approximately 40 Gy are delivered to point A with LDR intracavitary insertions.

Kuske et al.[780] reported results of therapy in 99 patients with carcinoma of the cervix on whom minicolpostats were used and noted a 15% incidence of grade 2 and 3 complications, which was higher than the 8% incidence noted in a similar group of patients treated with regular colpostats during the same period (P = .08).

Perez et al.[871] reported that the incidence and type of complications with interstitial therapy were approximately the same as in patients treated with intracavitary technique only. In contrast, Kasibhatla et al.[883] noted 6% small-bowel obstruction in 36 women with gynecologic cancer treated with EBRT and interstitial brachytherapy, which was aggravated by previous abdominopelvic surgery. The 3-year risk of rectovaginal fistula was 18%, and it was significantly higher in patients who received total doses of >76 Gy (100% vs. 7%; P = .009).

Irradiation of the PALNs has been reported to cause increased morbidity, particularly if it is done after transperitoneal staging para-aortic lymphadenectomy. In a randomized study reported by Rotman et al.,[884] a somewhat higher incidence of grade 2 and 3 complications was reported in 170 patients (10 complications) given 45 Gy to the para-aortic area in addition to standard pelvic irradiation, compared with 5 complications in 167 patients treated by pelvic irradiation only. The incidence of fatal (grade 5) complications was 4 and 1, respectively. In a similar randomized study by Haie et al.[574] for the EORTC, the incidence of grade 3 small-bowel injury was 2.3% in the para-aortic irradiation group and 0.9% in the pelvic irradiation–only group. The overall incidences of severe complications were 9% and 4.8%, respectively.

Willett et al.[885] reported on 28 patients with inflammatory bowel disease (10 with Crohn disease, 18 with ulcerative colitis) who underwent external beam abdominal or pelvic irradiation. Patients were treated either by specialized

techniques (16 patients) to minimize small- and large-bowel irradiation or by conventional approaches (12 patients). The overall incidence of severe toxicity was 46% (13 of 28 patients), and 6 patients (21%) experienced severe acute toxicity necessitating cessation of radiation therapy. Late toxicity requiring hospitalization or surgical intervention was observed in 8 of 28 patients (29%). For patients treated with conventional approaches, the 5-year actuarial rate of late toxicity was 73% versus 23% for patients treated by specialized techniques (P = .02). In patients with inflammatory bowel disease, abdominal or pelvic irradiation must be used judiciously.

In contrast, Song et al.,[440] in a review of 24 patients with a history of inflammatory bowel disease who received RT (median dose of 45 Gy in 1.8- to 3-Gy fractions) to fields encompassing some portion of the gastrointestinal tract, noted that 5 patients (21%) experienced acute intestinal toxicity of grade 3 or greater and 2 (8%) had grade 3 or greater late intestinal toxicity. Fifteen patients also received concurrent chemotherapy. The authors believed that the gastrointestinal toxicity in these patients was more modest than generally perceived. Tiersten and Saltz[886] noted that five patients with inflammatory bowel disease and gastrointestinal malignancy completed planned radiation therapy (30 to 54 Gy), usually with concurrent 5-FU, without difficulty.

Salama et al.[475] reported preliminary observations on acute toxicity with extended-field IMRT in 13 patients with gynecologic cancer. With median follow-up of 11 months, 2 patients treated with chemoradiation experienced grade 3 or higher morbidity, and 1 (with a history of previous surgeries) developed small-bowel obstruction.

Levenback et al.[887] identified 116 of 1,784 patients (6.5%) with stage IB carcinoma of the cervix treated with irradiation in whom hemorrhagic cystitis developed, 23% grade 2 (repeated minor bleeding) and 18% grade 3 (hospitalization required for medical management). The median interval to onset of hematuria was 35.5 months. The risk of severe hematuria requiring surgical intervention was 1.4% at 10 years and 2.3% at 20 years. Minor episodes of hematuria are managed by antibiotic therapy. Cystoscopic, laser, or cautery treatment of bleeding points is indicated. Clot evacuation and continuous bladder irrigation are important elements in the acute management of patients with heavy bleeding. Occasionally, a urinary diversion is required for intractable severe hematuria.

Genitourinary Toxicity

Ureteral stricture at 20 years was observed in 2.5% of 1,784 patients with stage IB carcinoma of the cervix treated with irradiation (274 followed for up to 20 years or longer).[888] The most common presenting symptoms were flank pain and urinary tract infection. In 5 patients, ureteral stricture was complicated by a vesicovaginal fistula. Seven of 43 patients who had no evidence of cancer and had hydroureter or hydronephrosis died of radiation complications. Treatment of ureteral stenosis may consist of stenting or resection of the fibrotic segment and reimplantation of the ureter with either ureteroneocystostomy or ureteroileocystostomy. In approximately half of the patients, diversion of urinary stream and ileal conduits are necessary. Occasionally, a nephrectomy is performed for removal of a nonfunctional kidney. Buglione et al.[889] reported a 10% incidence of late urinary morbidity and 1% ureteral fibrosis, grade III or IV, in 191 patients. They postulated the role of TGF-β_1 in the activation of fibroblasts and remodeling of extracellular matrix, which may be important in the induction of these sequelae.

Patients with gynecologic malignancies, including those receiving radiation therapy, are prone to development of urinary tract infections. Prasad et al.[890] collected 216 urine samples from 36 patients receiving pelvic irradiation, 12 of whom had urinary tract infection. The most common organism isolated was *Escherichia coli*, followed by *Enterococcus* species. Appropriate urine bacterial studies and cultures are indicated in patients suspected of having superimposed urinary tract infection during the course of radiation therapy.

Parkin et al.[891] reported a 26% incidence of severe urinary symptoms (urgency, incontinence, and frequency) in patients treated with irradiation alone for cervical carcinoma. They carried out urodynamic studies in 42 women and compared them with 28 women having urodynamic evaluations before and after treatment. There was no difference in the mean maximum flow rate or mean *residual* volume in the two groups. However, mean volume of full bladder sensation was significantly lower in the postirradiation group than in the pretreatment group, as was the mean maximum cystometric capacity. This same dysfunction may be noted in approximately 10% of the general female population, and the incidence increases in older women.[326]

Ureteroarterial fistula is a rare occurrence, and it is associated with a high mortality rate. When profuse urinary tract bleeding occurs in patients previously diagnosed with a gynecologic malignancy and treated with radiation therapy and extensive surgery, ureteroarterial fistula should be considered in the differential diagnoses.[892]

Neurologic Toxicity

Although extremely rare, lumbosacral plexopathy has been occasionally reported in patients treated for pelvic tumors with doses of 60 to 67.5 Gy. This syndrome was observed in 4 of 2,410 patients with cervical or endometrial carcinoma receiving 45 Gy to the PALNs (without spinal cord shielding) or external pelvic irradiation (60 Gy to the parametria) and brachytherapy, with the lumbosacral plexus receiving total doses of 70 to 79 Gy.[893] Lower extremity paralysis secondary to lumbosacral plexopathy was reported in one patient after standard radiation therapy for cervical cancer.[894]

Patients previously reported as having radiation myelopathy to the lumbar spine may have suffered a lumbar and sacral nerve plexopathy instead of or in addition to the spinal cord injury. The differential diagnosis of plexopathy with recurrent tumors is sometimes difficult. In a comparison of 20 patients with lumbosacral plexopathy after irradiation and 30 patients with plexus damage from pelvic malignancy, Thomas et al.[895] noted that indolent leg weakness occurred early in radiation-induced plexopathy (pain occurred initially in 10% of patients, although ultimately it was present in 50%), whereas pain was most frequently associated with tumor plexopathy. Muscular weakness, numbness, and paresthesia are common in both groups. Electromyography showed abnormal myokymic discharges in 57% of patients, whereas this finding was very unusual in tumor-induced plexopathy. CT is extremely helpful in the detection of pelvic masses or bone destruction caused by tumor. The authors also reported extensive retroperitoneal fibrosis of the lumbosacral plexus in two patients and femoral nerve fibrosis with plexopathy in one patient. Although cystometrograms have demonstrated bladder atonicity in some cases, several authors have failed to observe bladder or rectal sphincter disturbances. Unfortunately, as in radiation myelopathy, the neurologic deficit is irreversible, and no effective therapy other than supportive care has been found.

Sexual Function

Other types of clinically significant sequelae have been described. Bruner et al.,[896] in 90 patients treated with intracavitary irradiation for either carcinoma of the cervix (42 patients) or endometrial carcinoma (48 patients), 78 of whom also received external pelvic irradiation (44.5-Gy mean dose), noted that vaginal length decreased in most patients (at 24 months, in endometrial carcinoma from 8.8 to 7.8 cm, and in cervical carcinoma from 7.6 to 6.2 cm). Pretreatment sexual activity was reported by 31% of women in comparison with 43% after treatment.

However, 22% of women reported a decrease in sexual frequency and 37% a decrease in sexual satisfaction. This was correlated with increased dyspareunia, which was noted in 31% of women treated for carcinoma of the cervix and 44% of those treated for endometrial carcinoma. Grigsby et al.[897] described complex problems with sexual adjustment in women with gynecologic tumors treated with radiation therapy, with decreased frequency of sexual intercourse, desire, orgasm, and enjoyment of intercourse in 16% to 47% of patients.

Lammerink et al. published a systemic review of 20 studies on sexual functioning of cervical cancer survivors. Survivors had a higher rate of dyspareunia compared to controls, with pain during intercourse reported more frequently and for a longer duration of time in patients treated with radiotherapy.[898]

Regular vaginal dilation is widely recommended to maintain vaginal health and sexual functioning; however, the compliance rate with this recommendation is not consistent. In a study to test the effectiveness of an "information–motivation–behavior skills" model, the intervention improved the use of vaginal dilation after radiotherapy and decreased fear about sex after treatment.[899] There was no evidence that the experimental intervention improved global sexual health. Jensen et al.[900] described persistent sexual dysfunction throughout 2 years after RT in 118 women; 85% had low or no sexual interest, 35% had lack of vaginal lubrication, and 55% had mild to severe dyspareunia. However, 63% of the sexually active patients before RT remained active, although with decreased frequency.

Radiation causes ovarian failure with a cessation of menses over a 6-month to 1-year period after treatment. Radiation also causes uterine fibrosis in a dose-dependent fashion. The dose required for radical cervical cancer treatment causes sufficient uterine fibrosis that even if a woman were to become pregnant through embryo donation, the pregnancy terminates as a stillbirth because of insufficient uterine distensibility.[623,775]

Bone Toxicity

Grigsby et al.,[901] in 1,313 patients with gynecologic tumors treated with radiation therapy, identified 207 who received pelvic irradiation to the inguinal areas, including the hips. Femoral neck fractures developed in 10 patients (4.8%); 4 were bilateral. The cumulative actuarial incidence of fracture was 11% at 5 years and 15% at 10 years. Most of the fractures occurred in patients receiving 45 to 63 Gy, and although radiation dose could not be correlated with

the occurrence of fracture, no fractures were noted in patients receiving <42 Gy. Cigarette smoking and osteoporosis were significant prognostic factors for increased risk of fracture.

A retrospective cohort study using SEER cancer registry data linked to Medicare claims data analyzed 6,428 women of age 65 years and older diagnosed with pelvic malignancies from 1986 through 1999, and compared results for women who did (*n* = 2,855) with those who did not (*n* = 3,573) undergo radiation therapy. Results demonstrated that women who underwent radiation therapy were more likely to have a pelvic fracture than women who did not undergo radiation therapy. The cumulative 5-year fracture rate was 8.2% versus 5.9% in women with cervical cancer; the difference was statistically significant, and most fractures (90%) were hip fractures.[902] Concurrent chemoradiation may result in a higher risk than for patients treated with RT alone because the highest fracture rates were seen in patients with anal carcinoma treated with concurrent chemoradiation.

Blomlie et al.[903] reported radiation-induced insufficiency fractures of the pelvis on MRI (characterized by edema on T1-weighted images) in 16 of 18 women (9 premenopausal and 9 postmenopausal) with advanced cervical carcinoma. During the study, the fractures associated with edema subsided without treatment in 41 of 52 (79%) lesions in 15 of 16 (94%) patients. Moreno et al.[904] described eight patients with pelvic cancer who developed insufficiency fractures after pelvic irradiation, with an average onset of 13.7 months after treatment. The bone and CT scan showed abnormalities in the sacroiliac joint in all cases and in the pubis in three cases. In five patients, the initial diagnosis was incorrectly labeled as bone metastases. In patients over 50 years old, a sacrum D50% reduced from 40Gy to 35 Gy EQD2 reduced fracture risk from 45% to 22%.[905]

Huh et al.[906] reported on 463 patients treated for cervical cancer with RT alone, 1.7% of whom developed insufficiency fractures between 7 and 19 months (median, 12 months) after treatment. All had resolution of symptoms within <1 year with conservative therapy, including nonsteroidal anti-inflammatory medication and rest.

The most common complaint is persistent low back pain. Insufficiency fractures may be falsely diagnosed as metastases on PET–CT. The most common form of treatment is conservative management, followed by sacroplasty with polymethylmethacrylate. Bye et al.[907] assessed health-related quality of life (HRQOL) at 3 to 4 years after pelvic radiation therapy for carcinoma of the

endometrium and cervix in 94 survivors, 79 (84%) of whom answered a survey. The treated women scored lower than the general population on role functioning (81.5 vs. 90.6; $P < .01$) and higher on diarrhea (23.8 vs. 9.5; $P < .01$). Compared with pretreatment conditions, an increase in cases with pain in the lower back, hips, and thighs was seen and was associated with deterioration in HRQOL.

Toxicities Related to Brachytherapy

Descriptions of sequelae vary among institutions because toxicity-grading scales are not uniform and the scoring system for complications is not clearly stated in all reports. It is helpful to institute preventive measures when initiating radiation; for example, Dusenbery et al.[908] reported 21 (6.4%) life-threatening complications in 327 of 462 patient implants. Lanciano et al.,[909] in 95 tandem and ovoid insertions for cervical cancer in 91 patients and for endometrial cancer in 4, observed 2 uterine perforations and a vaginal laceration in 2 patients. Twenty-four percent of implants in 16 patients were associated with temperatures >100.5°F. Five implants (5%) were removed because of presumed sepsis, pulmonary disease, arterial hypotension, change in mental status, and myocardial infarction.

Jhingran and Eifel,[910] in 4,043 patients with carcinoma of the cervix who had undergone 7,662 intracavitary procedures, observed 11 (0.3%) documented or suspected thromboembolisms, resulting in 4 deaths; the incidence of postimplant thromboembolism did not decrease significantly with the routine use of minidose heparin prophylaxis. Other life-threatening perioperative complications included myocardial infarction (1 death in 5 patients), cerebrovascular accident (2 patients), congestive heart failure (3 patients), and halothane liver toxicity (2 deaths). Intraoperative complications included uterine perforation (2.8%) and vaginal laceration (0.3%), which occurred more frequently in patients 60 years of age or older ($P < .01$).

Wollschlaeger et al.[911] reported morbidity during hospitalization in 128 patients with cervical carcinoma undergoing 110 LDR intracavitary brachytherapy insertions. Forty-two implants (24.7%) were associated with acute problems; the most common were fever/infection (14.1%) or gastrointestinal problems (5.9%).

Acute gastrointestinal side effects of pelvic irradiation include diarrhea, abdominal cramping, rectal discomfort, and occasionally rectal bleeding, which may be caused by transient enteroproctitis. Patients with hemorrhoids may experience discomfort earlier than other patients. Diarrhea and abdominal cramping can be controlled with the oral administration of diphenoxylate hydrochloride, with loperamide, atropine sulfate, or opium preparations or emollients such as kaolin and pectin. Proctitis and rectal discomfort can be alleviated by small enemas with hydrocortisone and anti-inflammatory suppositories containing bismuth, benzyl benzoate, zinc oxide, or Peruvian

balsam. Some suppositories contain cortisone. Small enemas with cod liver oil are also effective. A low-residue diet with no grease or spices and increased fiber in the stool (psyllium, polycarbophil) usually helps to decrease gastrointestinal symptoms.

Genitourinary symptoms secondary to cystourethritis are dysuria, frequency, and nocturia. The urine is usually clear, although there may be microscopic or even gross hematuria. Methenamine mandelate and antispasmodics such as phenazopyridine hydrochloride or a smooth muscle antispasmodic such as flavoxate hydrochloride, hyoscyamine sulfate, oxybutynin chloride, or tolterodine tartrate can relieve symptoms. Fluid intake should be at least 2,000 to 2,500 mL daily. Urinary tract infections may occur; diagnosis should be established with appropriate urine culture studies, including sensitivity to sulfonamides and antibiotics. Therapy should be promptly instituted.

Erythema and dry or moist desquamation may develop in the perineum or intergluteal fold. Proper skin hygiene and topical application of petroleum jelly, petrolatum, or lanolin should relieve these symptoms. U.S.P. zinc oxide ointment and intensive skin care may be needed for severe cases.

Management of acute radiation vaginitis includes douching every day or at least three times weekly with a 1:5 mixture of hydrogen peroxide and water. Douching should be continued on a weekly basis until the mucositis has resolved or for 2 or 3 months as necessary. Superficial ulceration of the vagina responds to topical (intravaginal) estrogen creams, which stimulate epithelial regeneration within 3 months after irradiation. Use of vaginal dilators several times daily, started during the course of treatment, prevents vaginal stenosis. Psychoeducational intervention and motivation improve the compliance in use of dilators.[912] More severe necrosis may require debridement on a weekly basis until healing takes place. Judicious use of biopsies is recommended to rule out persistent or recurrent cancer.

Petereit et al.[913] reported 16 acute events (9.5%) in 169 patients treated with HDR brachytherapy (128 with cervical cancer also receiving external irradiation and 41 medically inoperable endometrial carcinomas). The overall 30-day morbidity rate for the patients with cervical cancer was 5.5%, and the 30-day mortality rate was 1.6% (2 patients; 1 died of pulmonary edema 12 days after first HDR insertion and the other had enteritis and died in a nursing home).

The complication rates for HDR and LDR techniques are usually equivalent.[645,647] Petereit et al.[643] observed a 12% 3-year actuarial overall toxicity (2.6% genitourinary and 5.6% rectum) with LDR, compared to 15%

overall (3% genitourinary and 4.6% rectum) with HDR brachytherapy. However, in the series by Cikaric,[759] the rectal complication rate was significantly higher in the LDR group. Bladder complication rates reported, in general, are lower than rectal complication rates; again, except for the series by Cikaric[759] showing a higher complication rate with the LDR technique, there were no significant differences with the two techniques.

Ogino et al.,[914] in 253 patients with invasive carcinoma of the cervix treated with HDR brachytherapy, noted that grade 4 rectal complications were not observed in patients with a time–dose factor of <130 or biologic equivalent dose of <147, assuming an α/β ratio of 3 Gy for late reactions.

Spontaneous intraperitoneal rupture of the urinary bladder, an extremely rare event, was reported by Fujikawa et al.[915] after radiation therapy for cervical cancer in 6 of 148 patients treated with HDR intracavitary brachytherapy combined with EBRT. All 6 patients underwent laparotomy and repair of the perforation; however, rerupture of the bladder occurred in 3 of these patients.

Clark et al.[916] reported on 43 patients treated with pelvic EBRT (46 Gy) and three HDR intracavitary treatments given weekly combined with concomitant chemotherapy (cisplatin, 30 mg/m^2 weekly) for advanced carcinoma of the cervix. At 40 months after treatment, 9 of 13 patients who received a dose to the rectal reference point greater than the prescribed point A dose had a 46% actuarial rate of serious (grade 3 and 4) rectal complications, compared with 14% in the remainder. A strong dose response was observed, with a threshold for complications at a brachytherapy dose of 8 Gy per fraction.

Hyperbaric Oxygen

In 13 patients with hemorrhagic cystitis treated with hyperbaric oxygen, all but 1 experienced durable cessation of hematuria.[917] Lee et al.[918] also noted that, in 16 of 20 patients (80%) with hemorrhagic radiation cystitis, significant improvement was observed after treatment with hyperbaric oxygen at 2.5 atm (44 sessions).

Several reports evaluated the efficacy of hyperbaric oxygen combined with irradiation in the treatment of a variety of human tumors, including carcinoma of the uterine cervix. Watson et al.,[919] in a randomized clinical trial of 320 patients (stages III to IVA), reported a 5-year survival rate of 33% in the oxygen-treated group in contrast to 27% in the control group treated in normal air ($P = .08$). The local recurrence rate was 33% in the 161 patients treated with oxygen and 53% in 159 patients treated in normal air ($P < .001$). Morbidity in the patients treated

with oxygen was greater (20 severe and 13 moderate complications) than in those treated in normal air (6 severe and 8 moderate complications, respectively). The difference was particularly striking in the bowel (13 and 2 severe complications, respectively).

Dische et al.[920] reviewed the data in a randomized study of patients with advanced carcinoma of the cervix treated with radiation therapy and hyperbaric oxygen or air and noted that the patients treated with oxygen had improved survival at Mount Vernon and Glasgow but not at Cape Town. Data from the three centers were merged, and analysis showed that local tumor control was significantly worse in patients treated in normal air who had a prior blood transfusion, but in the oxygen group, this effect was reversed. The same interaction was noted in the survival results ($P = .042$).

A trial reported by Fletcher[186] in which 233 patients with stage IIB, III, and IV carcinomas of the cervix were randomized to be treated with irradiation in normal air or with hyperbaric oxygen demonstrated no significant benefit in survival or tumor control (20 of 109 patients treated with oxygen failed in the pelvis, in contrast to 29 of 124 treated in normal air). Furthermore, morbidity was greater (26 complications) in patients treated with hyperbaric oxygen compared with the control group (15 complications).

Dische et al.[920] published results of a four-arm randomized trial of hyperbaric oxygen and radiation therapy of stage IIB and III carcinomas of the cervix in which 335 patients were randomized to treatment in 10 or 28 fractions in hyperbaric oxygen or in normal air. Data from 327 cases were analyzed. There was no advantage in tumor control with the use of hyperbaric oxygen. There was an increase in late radiation morbidity when treatment was given in hyperbaric oxygen rather than in normal air, and when using 10 fractions, a total dose of 45 Gy rather than 40 Gy was administered.

No definite conclusions can be drawn concerning the use of hyperbaric oxygen in carcinoma of the cervix. It is possible that hyperbaric oxygen administered with fewer high-dose fractions may be more efficacious than when combined with conventional dose and fractionation schemes. The trials reported have not shown an increased incidence of distant metastasis, which has been observed in a clinical study and in some animal experiments.[921]

Hormonal Replacement After Treatment of Cervical Cancer

After pelvic irradiation or bilateral salpingo-oophorectomy, usually carried out with a radical hysterectomy in patients treated for carcinoma of the uterine

cervix, symptoms of menopause may occur. They can be treated with replacement hormones, although some gynecologists have expressed reservations. During the past 25 years, hormonal replacement therapy has been shown to reduce the risk of cardiovascular diseases, osteoporotic fractures, and colon carcinoma. On the other hand, there is a significant increase of the risk in breast cancer with prolonged use of estrogen plus progesterone for >5 years. Consideration may be given to progesterone alone, which does not increase the risk of endometrial cancer but has potential thromboembolic risks.[922]

Burger et al.[923] concluded that squamous cell cancers of the cervix, vulva, and vagina are unlikely to be influenced by hormonal replacement therapy. In a study of women 50 years of age or younger with ovarian cancer, estrogen replacement therapy did not have a negative influence on DFS. Long-term hormonal replacement therapy in women treated for a gynecologic cancer must be based on the medical history of and discussion of risk with the individual patient (and her family when warranted). Usually, 0.625 to 1.25 mg of coagulated estrogen daily is sufficient.[924]

Second Malignancy

The risk for induction of secondary primary cancers by pelvic irradiation is low, and many potential confounders either are unknown or may not be fully accounted for, given the available information.[925] Using the population-based cancer registries of Denmark, Finland, Norway, Sweden, and the United States, Chaturvedi et al.[926] found a significantly increased cancer risk in both SCC and AC survivors, with standardized incidence ratio of 1.31 (95% CI = 1.29 to 1.34) and 1.29 (95% CI = 1.22 to 1.38), respectively. The risk of smoking-related lung cancer was higher in the SCC than in the AC population, whereas second malignancies of the colon, soft tissue, melanoma, and non-Hodgkin lymphoma were higher in the AC population. Similarly, 1-year survivors of cervical cancer had an increased risk of HPV-related cancers, including pharynx, genital, and anal cancers. Higher HRs for second cancer of the rectum, anus, bladder, and genital sites was seen for younger patients, with a 40-year cumulative risk of any second cancer of 22% for women diagnosed with cervical cancer before age 50 years versus 16% for those diagnosed at age >50 years.[927] In contrast, Lee et al.[928] observed no significant increase in the incidence of second malignancies in patients irradiated for carcinoma of the cervix in comparison with the Connecticut Tumor Registry prevailing rates.

Boice et al.,[369] in a review of 68,730 women with carcinoma of the cervix

treated with radiation therapy, observed a second malignant tumor in 3,324, compared with 3,063 expected (4.8% increase; $P < .001$). The excess was concentrated in the lung, other genital organs, the bladder, and the rectum. In addition, in 10,817 women with invasive cervical cancer not treated with irradiation, 479 secondary malignant tumors were observed versus 435 expected (4.4%; $P = .02$). Thus, the incidence of secondary tumors in women treated for carcinoma of the cervix with or without irradiation is only slightly greater than in the general population. Pelvic organs receiving a high dose of irradiation appear to have a somewhat greater incidence of a second primary.

Storm,[929] in a comprehensive analysis of the Danish Cancer Registry data of 24,970 women with invasive cervical cancer and 19,470 with carcinoma *in situ* of the cervix treated between 1943 and 1982, noted a small overall excess of secondary primary cancers in the lung, stomach, pancreas, rectum, and bladder and connective tissue sarcomas, although there was a decreased incidence of breast cancer in the irradiated patients compared with nonirradiated patients (attributable to ovarian ablation by radiation therapy). In the patients irradiated for invasive carcinoma, there was an excess of 64 cases per 10,000 women per year of tumors in organs close to or at an intermediate distance from the cervix, reaching a maximum after 30 years or longer of follow-up. A high risk for development of acute nonlymphatic leukemia was observed in irradiated patients with carcinoma *in situ* but not in those with invasive lesions. This could be explained by the lower doses of irradiation delivered to the bone marrow in the *in situ* tumors treated with brachytherapy alone, with greater induction of mutations and less cell killing, which may be responsible for the leukemogenic effect. Decreased risk was noted for tumors of the brain, myeloma of the skin, and tumors of the colon other than rectal.

In a study of 117,830 women diagnosed with cervical carcinoma *in situ* and 17,556 with invasive cervical carcinoma in Sweden, treatment not specified and *in situ* lesions traditionally treated with surgery alone, there was an increased incidence (RR = 2.3 to 3) of second primary tumors in the anus, rectum, urinary bladder, pancreas, esophagus, and lung compared with the standardized incidence rate for all women.[930] The data showed consistent increases in suggested targets for HPV at tobacco-related sites. A contributing role for a depressed immune response was considered.

Werner-Wasik et al.,[931] in an analysis of 125 women with stage I and II carcinomas of the cervix treated with radiation therapy, observed 11 secondary primary tumors in 10 patients (4 breast, 2 lung, and 1 each of myeloma, non-

Hodgkin lymphoma, bladder, thyroid, and vulva). All secondary primary tumors were located outside the irradiation fields. The increased RR of breast cancer in these patients was 2.64, higher than reported by Boice et al.[369]

In an analysis of 199,268 individuals by Wright et al.,[932] the risk of secondary leukemia increased 72% in patients who received pelvic radiotherapy, with a peak at 5 to 10 years after treatment; there was no increased risk of multiple myeloma. Mark et al.[933] identified 13 of 114 patients diagnosed with uterine sarcoma who had a prior history of pelvic irradiation (doses of 40 to 80 Gy). Criteria for radiation-induced sarcomas included a prior history of pelvic irradiation, a latent period of several years, development of sarcoma within previously irradiated field, and histologic confirmation of malignancy. Histologic types of tumor were mixed Müllerian in 6, leiomyosarcoma in 4 patients, endometrial stroma sarcoma in 1, fibrosarcoma in 1, and angiosarcoma in 1. Sarcoma developed in the uterus in 12 patients and at the vaginal cuff in 1 patient. Ten patients were treated with surgery and 2 with radiation therapy. The 5-year DFS rate after salvage therapy was 17%.

In a theoretical analysis of IMRT risk in postoperative cases relative to 3D conformal radiotherapy, the estimated increase in second cancer risk was 6% for 6-MV IMRT and 26% for 18 MV IMRT, with large increases in organs away from the primary beam and skin because with IMRT a much larger volume of skin was exposed.[934]

Seidman et al.[935] reviewed 15 cases of second malignancies after pelvic radiation; 5 were HPV-related vaginal primary tumors. The average latency period for development was approximately 20 years.

Kleinerman et al. reviewed 53,547 5-year survivors of cervical cancer from 5 population-based cancer registries. Over 90% were treated with radiation; there was a significant, linear dose–response relationship for the risk of stomach cancer (OR 4.2 for dose of 5Gy or higher).[936]
