CHAPTER 74

Endometrial Cancer

Kaled M. Alektiar

ANATOMY

The uterus is a hollow, muscular organ located in the true pelvis between the bladder and the rectum. The average adult uterus is about 8 cm long, 5 cm wide, and 2.5 cm thick. It is divided into the fundus, body (corpus), and cervix. The junction between the body and cervix is called the isthmus. The fundus is pierced at each cornu by the fallopian tubes. The uterine surface is partially covered by peritoneum. The uterine cavity is lined by endometrium, made up of columnar cells forming many tubular glands. The thickness of the endometrium varies during the menstrual cycle, but by the end of menstruation, it should be 2 to 3 mm in thickness. The wall of the uterus is composed of myometrium, consisting of smooth muscle fibers. The major supports of the uterus are the broad, round, uterosacral and cardinal ligaments. The major blood supply to the uterus is the uterine artery, which enters the uterus at the isthmus after it crosses over the ureter. The lymphatic drainage for the body of the uterus is mainly to the obturator and internal and external iliac lymph nodes. The lymphatics from the fundus accompany the ovarian artery and drain into the para-aortic lymph nodes.

EPIDEMIOLOGY AND RISK FACTORS

Endometrial cancer is the most common gynecologic cancer and the fourth most frequently diagnosed cancer in women in the United States. According to 2018 cancer statistics, the estimated number of newly diagnosed cases is 63,230, with a probability of 1 in every 35 women (2.8%) developing it during her lifetime.[1] Although it is a cancer that affects predominantly postmenopausal women, 14% are diagnosed in premenopausal women, with 5% being younger than 40 years.[2] The expected number of deaths from endometrial cancer in 2018 is 11,350,

making it the sixth leading cause of death from cancer in women. Recent estimates on the death rate from endometrial cancer seemed to indicate that the rate is on the rise, by about 2% per year.[1]

The incidence of endometrial cancer is higher in more developed areas of the world (5.5%) compared to less developed countries (4.2%), indicating a possible influence of environmental factors on the incidence of this disease.[3] The exact etiology of endometrial cancer remains unknown, but several risk factors have been associated with it, chiefly unopposed estrogen. It is well established that endometrial cancer risk is increased among women who have high circulating levels of bioavailable estrogens and low levels of progesterone, so that the mitogenic effect of estrogens is insufficiently counterbalanced by the opposing effect of progesterone.[4] The source of unopposed estrogen could be endogenous or exogenous. Regarding endogenous estrogen,[5] in a nested case–control study of 93,676 postmenopausal women, parent estrogens (estrone and estradiol) were positively related to endometrial cancer risk, with the highest risk observed for unconjugated estradiol (OR 5th vs. 1st quintile = 6.19; 95% confidence interval [CI], 2.95 to 13.03, Ptrend = 0.0001). The association with unconjugated estradiol was stronger for type I than type II tumors (Phet = 0.01). Lifetime cumulative number of menstrual cycles, that is, menstruation span, is associated with increased risk of developing endometrial cancer. This is due to the fact that endometrial cell proliferation increases during the follicular phase, which is the longest in the menstrual cycle. Thus, *early age at menarche* (estimated relative risk [RR], 1.5 to 2) and *late age at menopause* (RR, 2 to 3), examples of increased menstruation span, are risk factors for endometrial cancer.[6] *Nulliparity* (RR, 3) is also associated with increased risk of endometrial cancer[6] due in part to anovulatory menstrual cycles. O*besity* is a significant risk factor for endometrial cancer, with estimation that 38.4% of endometrial cancer worldwide could be attributed to high body mass index (BMI).[7] The increase in endometrial cancer risk is mainly through changes in endogenous hormone metabolism. After menopause, when ovarian production of both estrogen and progesterone ceases, the major source of estrogen is via peripheral conversion, mostly within adipose tissue, of androgens that continue being produced by the adrenal glands and ovaries. Thus, with obesity, there is an increase in the amount of bioavailable estrogens in the circulation and the endometrial tissue.[4] Obesity may also influence endometrial cancer risk via chronic hyperinsulinemia, which appears to be a key factor for the development of ovarian hyperandrogenism, associated with anovulation and progesterone deficiency, especially for

premenopausal women.[8] *Non–insulin-dependent diabetes mellitus* and *hypertension* (RR, 1 to 3) also increases the risk of endometrial cancer. This is often believed to be secondary to obesity, but there are data showing that these risk factors could be independent of obesity.[9] With regard to exogenous estrogen, it is well established that the use of *estrogen-only hormone replacement therapy* and *sequential oral contraceptives* greatly increases endometrial cancer risk, whereas combined preparations, that is, those that contain a progestogen as well as estrogen throughout the treatment period, have a protective effect (RR, 0.3 to 0.5).[10,11] The use of *tamoxifen* in patients with breast cancer has been associated with increased risk of endometrial cancer. The mechanism of action of tamoxifen is in competition with that of endogenous estrogen for estrogen receptors. In premenopausal women, tamoxifen has an antiestrogenic effect, but in postmenopausal women, it has a weak estrogenic effect because of the up-regulation of estrogen receptors. In a meta-analysis on adjuvant tamoxifen and endometrial cancer, for patients who were <55 years of age, there was little absolute risk compared to patients of 55 to 69 years of age, for whom the 15-year incidence was 3.8% in the tamoxifen group versus 1.1% in the control group (absolute increase 2.6% [standard error 0.6], 95% CI = 1.4 to 3.8), highlighting the influence of age and the length of its use on the risk of endometrial cancer from tamoxifen use.[12,13] Initial data seemed to indicate that the majority of endometrial cancers associated with tamoxifen use were of early stage with favorable features.[14] More recent data, however, show a change in the profile of these endometrial cancers, with a rise in the rate of serous, clear cell, carcinosarcoma, and sarcoma types.[15] Inherited genetic predisposition, especially in the setting of hereditary nonpolyposis colorectal cancer (HNPCC), probably accounts for <5% of all endometrial cancer cases. Mutations in one of the four mismatch repair (MMR) genes *hMLH1, hMSH2, hMSH6,* or *hPMS2* have been identified in patients with Lynch syndrome. Although HNPCC is thought of primarily in terms of risk of developing colorectal cancer, it is important to note that lifetime cumulative risk of endometrial cancer for women with HNPCC is 40% to 60%, which equals or exceeds their risk of colorectal cancer.[16] There seems to be a high rate of lower uterine segment involvement (LUSI) in patients with HNPCC-associated endometrial cancer.[17]

CLINICAL PRESENTATION AND NATURAL HISTORY

The most common presentation for endometrial cancer is postmenopausal

vaginal bleeding, which is reported by 80% to 90% of patients. The incidence of endometrial cancer in women presenting with postmenopausal bleeding is only 10% to 15%. This incidence, however, could range from 1% up to 25%, depending on patient age and the presence of other risk factors. In a report of a total of 3,548 women presenting with postmenopausal vaginal bleeding, 201 (6%) had a diagnosis of endometrial carcinoma. Use of a multiple logistic regression model showed that recurrent episodes of bleeding (odds ratio [OR], 3.64), a history of diabetes (OR, 1.48), older age (1.06), and high body mass index (OR, 1.07) increased the risk of endometrial malignancy when corrected for other characteristics.[18] Other patterns of presentations include vaginal discharge, abnormal Papanicolaou smear, or thickened endometrium on routine transvaginal ultrasound. For patients with advanced disease, they may present with urinary or rectal bleeding, constipation, pain, lower extremity lymphedema, abdominal distension due to ascites, and cough and/or hemoptysis.

The International Federation of Gynecology and Obstetrics (FIGO) annual report[19] showed that the 5-year survival rate for 8,110 patients with endometrial cancer treated between 1999 and 2001 was 80%. Such excellent outcome is a reflection of the fact that the majority of patients are diagnosed with early-stage disease. The tumor was limited to the corpus uteri in 71% of cases, involved the cervix in 12%, and extended beyond the uterus, but short of distant spread in 13%. For patients with disease limited to the endometrium or with <50% myometrial invasion, the 5-year survival rate was 91%. However, the rate dropped to 66% when disease extended to adnexa/serosa/positive peritoneal cytology, to 57% with regional lymph node involvement, to 25.5% with bladder or rectal involvement, and to 20% with distant spread. For clinically staged patients, the 5-year survival rate ranged from 67% for early-stage disease down to 15% for advanced disease. Mass screening for endometrial cancer in women at average risk or increased risk due to a history of unopposed estrogen therapy, tamoxifen therapy, late menopause, nulliparity, infertility or failure to ovulate, obesity, diabetes, or hypertension is not recommended. American Cancer Society (ACS) recommends that women at average and increased risk should be informed about risks and symptoms (in particular, unexpected bleeding and spotting) of endometrial cancer at the onset of menopause and should be strongly encouraged to immediately report these symptoms to their physician. However, screening has been recommended by the ACS for women who carry, or are related to carriers of, the HNPCC mutation, starting at age 35 years, including annual transvaginal ultrasound and endometrial biopsy.[20] Prophylactic

hysterectomy and bilateral salpingo-oophorectomy (BSO) once childbearing is completed have been shown to effectively reduce the risk of endometrial cancer in patients with HNPCC and should be strongly considered.[21]

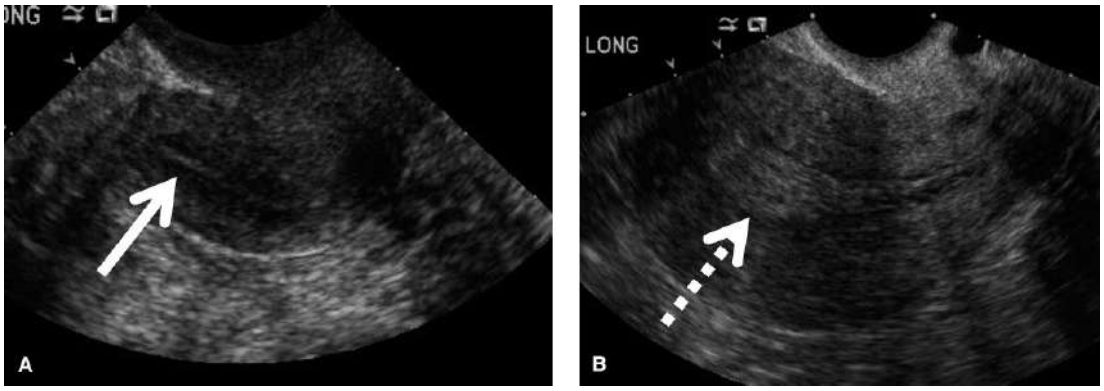

FIGURE 74.1. Sagittal view of the uterus on transvaginal ultrasound. **A:** Normal thin endometrium (*arrow*). **B:** Thickened endometrium (*arrow*).

DIAGNOSTIC WORKUP

Endometrial tissue sampling remains the gold standard by which the diagnosis of endometrial cancer is established. This is achieved via biopsy or dilation and curettage (D&C). *Endometrial biopsy*, which can be easily performed in the office with a Pipelle or similar device, is the preferred approach. Its sensitivity in detecting endometrial cancer in postmenopausal women is 99.6% compared to 91% in premenopausal women. Its specificity is >98% for both groups.[22] If the patient is undergoing hysterectomy, routine D&C is not necessary after an office Pipelle sampling has documented malignancy. However, if symptoms persist, the office sampling is inadequate, or the patient is being considered for conservative fertility-sparing approaches, a D&C should be performed. In addition, D&C provides more reliable assessments of final pathologic findings in hysterectomy specimens, mainly with regard to tumor grade.[23] Given that the incidence of endometrial cancer in women with postmenopausal bleeding is only 10% to 15%, it is unclear how feasible it is to perform endometrial sampling on every patient. *Transvaginal ultrasonography* (TVU) may be considered as a useful tool to assess patient's vaginal bleeding. Normal endometrium looks thin and homogeneously hyperechoic, but it is thickened and heterogeneous, with hyperplasia, polyps, and cancer[24] as shown in Figure 74.1. The consensus statement from the Society of Radiologists in Ultrasound defines an endometrial thickness of 5 mm or greater as being abnormal.[25] If the thickness of the

endometrium is <5 mm, the risk of endometrial cancer is minimal; the false-negative rate is about 4%. If the TVU is abnormal but the biopsy is negative/nondiagnostic or the uterine cavity is inaccessible, then *saline infusion sonography* or *hysteroscopy*[26,27] should be considered to help exclude intracavitary lesions, especially polyps that might contain cancer. In addition, these methods are also helpful in premenopausal women, for whom the accuracy of TVU is limited because the endometrial thickness fluctuates, depending on the level of female hormones. The potential downside to saline infusion or hysteroscopy is that there have been reports that the insufflation of the distending medium into the canal has been associated with an increase in positive peritoneal cytology, although the prognostic implications are unclear of such positive cytology "induced" by sampling.[28] Several imaging studies are available to define the extent of disease preoperatively.[29] Good-quality pelvic *computed tomography* (CT) scans obtained with oral and intravenous contrast can demonstrate the extent of the endometrial tumor. The endometrial carcinoma is a hypodense mass relative to the normal myometrium and may be seen as a diffuse, circumscribed vegetative or polypoidal mass within the uterine cavity. CT is helpful in assessing regional and distant metastasis. *Magnetic resonance imaging* (MRI) is considered the most accurate imaging study to assess tumor extension in endometrial cancer, especially myometrial invasion.[30,31] Dynamic contrast-enhanced (DCE) and diffusion-weighted (DW) MRI are equivalent in detecting deep myometrial invasion.[32] A clear junctional zone or preservation of a sharp delineation between the tumor and the myometrium implies disease limited to the endometrium. Disease characterized by disruption of the junctional zone, increased–signal-intensity tumor in the inner half of the myometrium with preservation of the outer myometrium, or both correlates with superficial myometrial invasion. If there is extension of the high–signal-intensity tumor into the outer myometrium with preservation of a peripheral rim of normal, intact myometrium, then that is considered deep myometrial invasion (Fig. 74.2). MRI also helps to delineate tumor extension into the cervix. The normal cervical stroma is hypointense on T2-weighted images and is replaced by intermediate–signal-intensity tumor in cases of invasion.[33] The reported sensitivity of MRI in detecting lymph node metastasis is on average 43.5% and the specificity is 95.9%.[31] *Positron emission tomography (PET)/CT* is also being used in endometrial cancer.[34] There seems to be little benefit in assessing the primary tumor extension. With regard to regional lymph node metastasis, the reported sensitivity is 72% and the specificity is 94%. The main advantage of PET-CT

over other imaging modalities is its accuracy in detecting distant metastasis.[33] The FIGO staging for endometrial cancer is a surgical staging, and thus, preoperative imaging studies (except chest x-rays) are not part of the staging. *Cancer antigen 125* (CA-125) serum levels could be elevated in patients with endometrial cancer. Kim et al.[35] in a review of 413 patients found that 23.9% of patients had >35 U/mL serum CA-125 levels. Hsieh et al.[36] found that preoperative levels of >40 U/mL correlated significantly with regional lymph node metastasis and suggested that such levels could be used as an indication for full-pelvic and para-aortic lymphadenectomy at the time of surgical staging in the absence of metastatic disease.

Pathologic Classification

Endometrial Hyperplasia

The diagnostic criterion for hyperplasia is an increase in the number and size of proliferating glands. The International Society of Gynecologic Pathologists standardized the subclassification of endometrial hyperplasia. In simple hyperplasia, there is only glandular proliferation and enlargement with increased stromal cellularity. This rarely progresses to carcinoma (<1%). Complex hyperplasia is characterized by back-to-back proliferation of glands with intraluminal papillae, epithelial pseudostratification, and few mitotic figures. If there is no cytologic atypia, the risk of malignant degeneration is again quite low, on the order of 3%. Any proliferation demonstrating cytologic

abnormalities (in cellular or nuclear morphology) is classified as atypical hyperplasia. Atypical hyperplasia has a much higher risk of progression to an invasive carcinoma—8% for simple atypical hyperplasia, increasing to 29% for complex hyperplasia associated with atypia.[37] The Gynecologic Oncology Group (GOG) conducted a prospective trial in which all patients with atypical hyperplasia of the uterus underwent an immediate hysterectomy. The rate of underlying concurrent carcinoma in the uterus was 42.6% in these patients.[38] The standard recommended treatment for atypical hyperplasia of the uterus is hysterectomy if childbearing is complete and the patient has no other contraindications to surgery. In patients who desire future fertility or have an absolute contraindication to surgery, progestational therapies may be used with caution.[39]

TABLE 74.1 PATHOLOGIC CLASSIFICATON OF ENDOMETRIAL CANCERS

Endometrioid adenocarcinoma
Not otherwise specified
Villoglandular
Secretory adenocarcinoma
Ciliated carcinoma
Adenocarcinoma with squamous differentiation
Uterine papillary serous
Clear cell carcinoma
Mucinous carcinoma
Squamous cell carcinoma
Transitional cell carcinoma
Mixed cell type
Undifferentiated carcinoma
Metastatic carcinoma to the endometrium

Carcinoma of the Endometrium

Endometrioid Carcinoma

Endometrioid adenocarcinoma is the most common endometrial carcinoma, constituting 75% to 80% of all cases (Table 74.1). The classic histologic appearance is that of marked glandular proliferation with back-to-back proliferation of glands and little intervening stroma (Fig. 74.3A). The name endometrioid is derived from resemblance to proliferative-phase endometrium. Architectural grading is determined by the amount of solid mass of tumor cells compared to well-defined glands. Grade 1 is an endometrioid cancer in which <5% of the tumor growth is in solid sheets. Grade 2 is an adenocarcinoma in

which 6% to 50% of the tumor is composed of solid sheets of cells. Grade 3 occurs when >50% of the tumor is made up of solid sheets. Nuclear grading is determined by the nuclear shape, size, chromatin distribution, and size of the nucleoli. The grading is primarily driven by the architectural grading, but if there is marked nuclear atypia in an otherwise grade 2 architectural grading, it should be increased to grade 3. Within endometrioid adenocarcinoma, the subtypes are endometrioid carcinoma not otherwise specified (NOS), endometrioid carcinoma with squamous differentiation, villoglandular endometrioid carcinoma, secretory carcinoma, and a ciliated cell variant.[40] Most of the endometrioid adenocarcinomas are designated NOS. Foci of squamous differentiation are often found with endometrioid adenocarcinoma. The squamous component could be benign, with the designation of adenoacanthoma, or malignant, in which case it is called adenosquamous carcinoma. Such designations have not been very useful, however, because the degree of differentiation of the squamous component parallels that of the glandular architectural grading. Therefore, most gynecologic pathologists use the term *adenocarcinoma with squamous differentiation.* Other subtypes of endometrioid adenocarcinoma include the relatively common *villoglandular carcinoma,* which grows in a papillary fashion. The prognosis of this subtype is similar to that of low-grade endometrioid cancer, and it must not be confused with serous carcinoma because of its papillary features. *Secretory carcinoma,* which represents <2% of all endometrial carcinomas, is characterized by a very well-differentiated glandular pattern with much intracellular glycogen, thus resembling early secretory endometrium. Although the cells have clear cytoplasm, their histologic and cytologic features are different from those of clear cell carcinoma. C*iliated carcinoma* is a very rare subtype, characterized by the presence of ciliated cells comprising >75% of the tumor specimen. It is usually associated with a history of prior estrogen use, and the prognosis is quite good, because most are well differentiated.

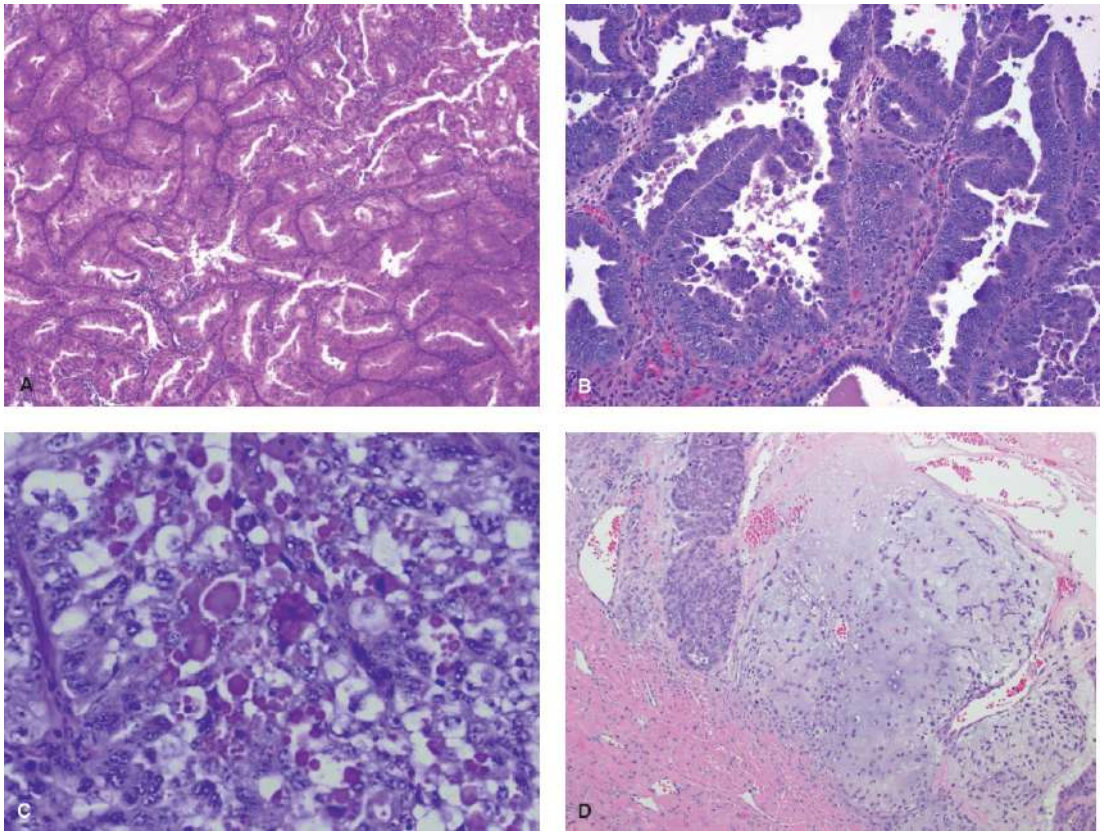

FIGURE 74.3. Different histologic types of endometrial cancer. **A:** Endometrioid. **B:** Papillary serous. **C:** Clear cell. **D:** Carcinosarcoma (heterologous; chondrosarcoma).

Mucinous Carcinoma

This designation requires >50% of the tumor cells to be mucinous. These cells are carcinoembryonic antigen positive and are laden with mucin, which stains positively with mucicarmine and periodic acid–Schiff stains but is diastase resistant. Because of the resemblance to endocervical adenocarcinoma, it is essential to exclude it by endocervical curettage. Mucinous carcinomas are usually well differentiated and have the same prognosis as ordinary endometrioid carcinomas.

Serous Carcinoma

Serous carcinomas, also known as papillary serous cancers, resemble ovary cancer in terms of histology and to some extent in terms of behavior. The mere presence of papillary structure is not diagnostic because other histologic types may have papilla as well. However, the presence of marked cellular atypia in addition to papilla distinguishes serous carcinoma from others (Fig. 74.3B). Psammoma bodies are found in up to 33% of cases. The incidence of serous endometrial cancer is about 11.4% that of endometrial carcinomas.[41] This is an

aggressive subtype, with a high propensity for early lymphatic and intraperitoneal dissemination, often despite little myometrial penetration. In the FIGO annual report, the 5-year survival rate was 52.6% compared to 83.2% for endometrioid carcinoma.[19]

Clear Cell Carcinoma

Clear cell carcinoma of the endometrium resembles renal carcinoma, but its origin from mullerian structures is now well established. Unlike vaginal and cervical clear cell carcinoma, it is not related to intrauterine diethylstilbestrol exposure. The microscopic structure may vary from solid patterns to glandular differentiation (Fig. 74.3C). In the latter pattern, small cells resembling "hobnail" cells line spaces and glands. These are cells that extruded their cytoplasm, leaving bare nuclei that protrude into the glandular lumens. The rate of clear cell carcinoma is about 3.5% of endometrial carcinomas.[41] The prognosis of this cancer is in between that of endometrioid and serous cancer.[42] In the FIGO annual report, the 5-year survival rate was 62.5% compared to 83.2% for endometrioid carcinoma and 52.6% for serous carcinoma.[19]

Squamous Carcinoma

This type of cancer is extremely rare, and the diagnosis has to be made after the exclusion of cervical origin. The 5-year survival rate based on the FOGO report is 68.9% overall, but the prognosis is poor for patients with extrauterine disease or distant spread.[19]

Undifferentiated Carcinoma

The World Health Organization classification describes endometrial undifferentiated carcinomas as "malignant poorly differentiated endometrial carcinomas, lacking any evidence of differentiation" without any further characterization.[43] Undifferentiated carcinomas can also be associated with an endometrioid carcinoma component, and such tumors have been referred to as "dedifferentiated carcinomas," which is being recognized with increased frequency. Some of these tumors may belong to the spectrum of gynecologic neoplasms seen in the setting of microsatellite instability and possibly Lynch syndrome.[44]

Mixed Histology

Mixed cell–type endometrial cancer composed of two or more pure types was observed in 4.5% of patients in GOG 210 study.[41] By convention, in order to be

designated as mixed, the other cell-type component has to comprise at least 10% of the tumor. Except for mixed endometrioid and serous or clear cell carcinoma, the clinical significance of mixed cell type is questionable.

Simultaneous Tumors

Occasionally identical tumor type, mainly endometrioid histology, can be discovered in the ovary and endometrium. Usually, the site of the largest tumor is assigned the primary origin, but at times, true primary endometrial and ovarian malignancies may coexist.[45] If the endometrial tumor is <5 cm in diameter, well differentiated, with no vascular invasion, limited to less than the middle one-third of the myometrium, and the ovarian lesions are bilateral, it is more likely that there are two concomitant primary tumors. Genetic profiling may represent a powerful tool in clinical practice for distinguishing between metastatic and dual primaries in patients with simultaneous ovarian/endometrial cancer and for predicting disease outcome.[46]

Molecular Biology

Several investigators pointed out that there are two distinct types of endometrial cancer.[47,48] In type I endometrial cancer, there is strong correlation with prior estrogen stimulation. The cancers in this category are often indolent in nature, with minimal myometrial invasion and low-grade histology. They affect premenopausal and perimenopausal women. Type II endometrial cancer often affects postmenopausal women with no prior history of estrogen stimulation. The histology of the tumors is often high grade, such as serous or clear cell cancers with deep invasion, and at a more advanced stage at the time of presentation.[2] What is intriguing is the fact that at the molecular level, the existence of two distinct types of endometrial cancer seems to be validated.[49] The most frequently altered molecular pathway in type I endometrial carcinomas is the PI3 K/PTEN/AKT pathway, which is dysregulated by oncogenic mutations, PTEN loss of function, and/or overexpression of upstream tyrosine kinase growth factor receptors, leading to uncontrolled cell proliferation and survival. On the other hand, the main pathway alterations in type II endometrial cancers involve the tumor suppressors p53. However, the findings from the Cancer Genome Atlas (TCGA) have revolutionized our understanding of endometrial cancer.[50] In that study, the genomic landscape of endometrioid and serous carcinoma histologies were evaluated (Fig. 74.4). Most endometrioid tumors had frequent mutations in PTEN, CTNNB1, PIK3CA, ARID1A, and

KRAS, novel mutations in the SWI/SNF chromatin remodeling complex gene ARID5B, and few copy number alterations or TP53 mutations. Uterine serous tumors and about 25% of high-grade endometrioid tumors (serous-like) had frequent TP53 mutations and extensive copy number alterations, but few deoxyribonucleic acid (DNA) methylation changes, and low estrogen receptor/progesterone receptor levels. A subset of endometrioid tumors (about 10%) that was identified had a markedly increased mutation frequency and newly identified hotspot mutations in the exonuclease domain of *POLE*. Based on these results, endometrial cancers can be classified into four categories: POLE ultramutated, microsatellite instability hypermutated, copy number low, and copy number high. The somatic copy number alterations (SCNAs) analysis showed that most endometrioid tumors have few SCNAs, whereas most serous and serous-like tumors (endometrioid) exhibit extensive SCNAs.

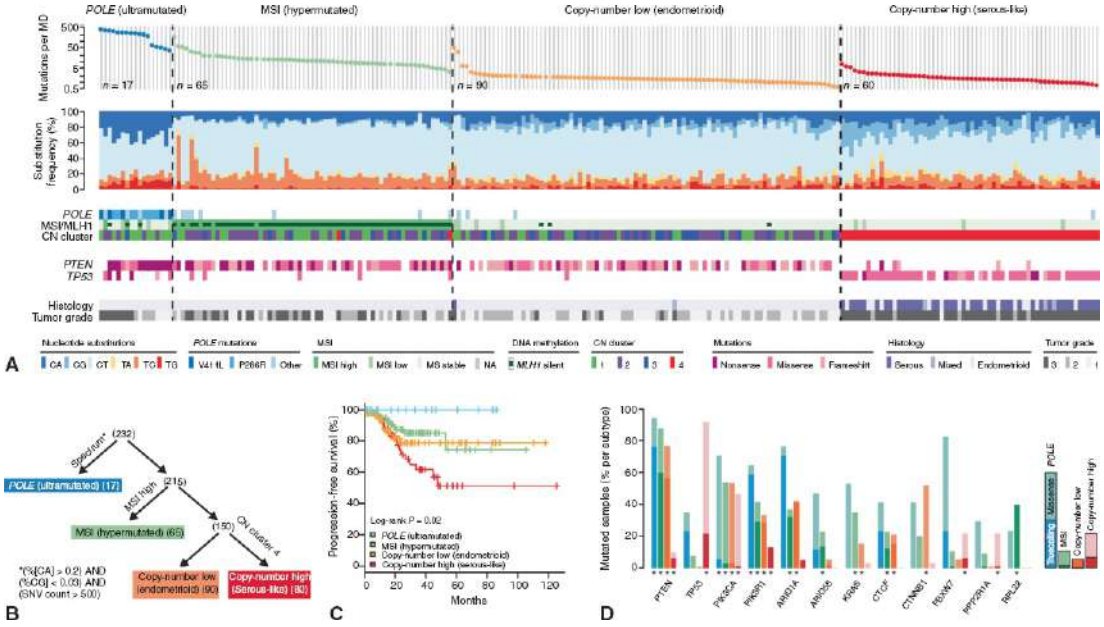

FIGURE 74.4. Genomic landscape of endometrial cancer.

Genomic analysis of clear cell carcinoma of the uterus demonstrated that, akin to endometrioid carcinomas, there are four gnomically distinct groups: POLE, MMR-deficient tumors, copy number low, and copy number high.[51]

STAGING

Before 1988, the staging system for endometrial cancer was clinical. Stage I was tumor limited to the uterus, with IA designation if the length was ≤8 cm and IB

if it was >8 cm. Stage II was for when cervix was involved, stage III when disease extension beyond uterus/cervix was limited to the true pelvis, and stage IV when it extended beyond the true pelvis or involved bladder or rectum (IVA) or distant spread (IVB). This system is applicable to the few patients who cannot have surgery and are treated with definitive radiation. Using the FOGO 1988 staging system, Creasman et al. reported a GOG 210 study on 5,855 patients with endometrial cancer who underwent hysterectomy/BSO and peritoneal cytology.[41] During the initial phase of the study of 3,715 patients, enrollment was unrestricted, but in the later phase, enrollment was restricted to patients (*n* = 2,151) with adverse features, such as nonendometrioid histologies, non-Caucasian race, and preoperative imaging suggestive of deep myometrial invasion, and such histologies were as follows: endometrioid (grade 1 was 37.8%, grade 2 was 26.3%, and grade 3 was 9.7%), serous 11.4%, clear cell 3.5%, and mixed 4.5%. The rate of positive peritoneal cytology was 8.9% and that of adnexal involvement was 8.6%. The breakdown by stage (FIGO 1988) was as follows: IA 24.8%, IB 38.4%, IC 11.2%, IIA 2.3%, IIB 4.4%, IIIA 4.6%, IIIB 0.2%, IIIC 9.8%, and IV 4.4% (Table 74.2).

In 2009, the FIGO staging system was modified.[52] Patients who formerly were staged as IB, that is, <50% myometrial invasion, are now considered IA. Patients with >50% myometrial invasion are designated as stage IB. Endocervical glandular involvement no longer affects staging; only patients with cervical stromal invasion are considered stage II. Having positive peritoneal cytology no longer affects staging. Parametrial extension is now considered IIIB. Patients with stage IIIC are now subdivided into IIIC1 if pelvic nodes are involved and IIIC2 if para-aortic nodes are involved (Table 74.3). The discriminating power of the new FIGO staging system is being debated. Page et al.[53] evaluated 10,839 cases from 1998 to 2006 using the Surveillance, Epidemiology, and End Results (SEER) Program. The analysis demonstrated the usefulness of two divisions rather than three for stage I in the new FIGO staging system. In contrast, a study from Memorial Sloan Kettering Cancer Center (MSKCC) of 1,307 patients with FIGO 1988 stage I disease showed that the revised system for stage I did not improve its predictive ability over the 1988 system.[54]

Prognostic Factors

Several clinicopathologic factors have been identified in patients with endometrial carcinoma to help predict the prognosis and individualize the

treatment plan. At MSKCC, a nomogram was developed for predicting overall survival of women with endometrial cancer (n = 1,735) after primary therapy.[55] Use of five prognostic factors—age, grade, histologic type, number of lymph nodes removed, and FIGO 1988 surgical stage—predicted OS with high concordance probability. Postoperative Radiation Therapy in Endometrial Cancer (PORTEC) group also developed nomogram for predicting recurrence in FIGO stage I disease.[56]

Age

The influence of older age on worse outcome has been well established. The adverse impact of older age is often explained by pointing out that older patients tend to present with aggressive histology and more advanced disease and are generally treated less aggressively. What is intriguing, however, is that the strongest correlation between older age and poor outcome is seen in patients with otherwise favorable characteristics. Furthermore, the adverse impact of advanced age on outcome persists even when elderly patients are treated as aggressively as their younger counterparts.[57,58]

TABLE 74.2 SURGICAL–PATHOLOGIC FINDINGS FROM GOG 120 STUDY

Characteristics	n	%
Age (years)		
<40	92	2.5
40–49	293	7.9
50–59	1,165	31.4
60–69	1,212	32.6

Other Extrauterine Metastasis	396	10.7
Lymphovascular Involvement	842	22.7

Race

The incidence of endometrial cancer is lower in African American than white women, yet the rate of high-risk features in this group is higher. In a GOG study, 24.3% of African Americans presented with stage III as opposed to 17.6% for white and the histology was serous in 24.4% as opposed to 11.2%, respectively. The higher recurrence rate could not be accounted for based on treatment received, indicating the need for better understanding of the biology of this

disease.[59]

TABLE 74.3 REVISED ENDOMETRIAL CANCER SURGICAL STAGING SYSTEM: INTERNATIONAL FEDERATION OF GYNECOLOGY AND OBSTETRICS 2009

Stage I	
IA grades 1–3	Tumor limited to the endometrium or invasion to <50% of the myometrium (includes endocervical glandular involvement)
IB grades 1–3	Invasion to ≥50% of the myometrium (includes endocervical glandular involvement)
Stage II	
II grades 1–3	Cervical stromal invasion
Stage III	
IIIA grades 1–3	Tumor invades uterine serosa or adnexa (positive cytology has to be reported separately without changing the stage)
IIIB grades 1–3	Tumor involving the vagina and/or parametria
IIIC grades 1–3	Pelvic or para-aortic lymph nodal involvement
IIIC1 grades 1–3	Pelvic nodal involvement only
IIIC2 grades 1–3	Para-aortic nodal involvement with or without pelvic nodal involvement
Stage IV	
IVA grades 1–3	Invasion of bladder, bowel mucosa, or both
IVB	Distant metastases, including intra-abdominal spread or inguinal lymph nodes

Histologic Subtype

According to the FIGO annual report, the 5-year survival rate was 83.2% for endometrioid adenocarcinoma, compared to 52.6% for serous cancer and 62.5% for clear cell cancer in 8,033 surgically staged patients. Patients with endometrioid histology have surgical stage III to IV disease only in 13.8% of patients, compared to 41.7% with serous and 33% with clear cell carcinoma,

which could explain the worse outcome. However, the influence of histology was seen even in patients with surgical stage I disease (*n* = 5,285), for whom 5-year survival dropped from 90% for endometrioid histology to 79.9% with serous and 85.1% with clear cell carcinoma.[19]

Grade

Tumor grade is one of the most sensitive indicators of prognosis. Grade directly affects the depth of myometrial penetration and the frequency of lymph node involvement. In GOG 210 report by Cresman et al.,[41] the rate of deep myometrial invasion was 15% for grade 1, 25% for grade 2, and 38% for grade 3. The rate of positive pelvic and para-aortic node based on depth of invasion and histology is shown in Table 74.4. In the FIGO annual report,[19] grade 3 was an independent predictor of poor survival on multivariate analysis within each stage—stages I (HR, 2.45), II (HR, 2.14), III (HR, 2.44), and IV (HR, 2.55). The recognition that about 25% of grade 3 endometrioid histology has copy number high mutations, that is, serous-like, further highlight the impact of genomic stratification on prognosis.[50]

TABLE 74.4 RATE OF PELVIC AND PARAORTIC METASTASIS BASED ON HISTOLOGY AND DEPTH OF INVASION

Depth of Invasion	EG1	EG2	EG3	Serous	Clear Cell
	Pel/PA%	Pel/PA%	Pel/PA%	Pel/PA%	Pel/PA%
Endometrium only	0.8/0	1.6/1.1	1.7/0	7.9/4.2	1.3/0
Inner half	2.0/1.3	3.9/1.7	3.9/0.8	18.3/11.3	15.5/6.4
Outer half	15.4/6.9	16.8/8.4	29.1/14.5	44.3/32.4	40.5/28.4
Serosa	42.9/28.6	50/33.3	67.6/43.2	66.7/61.5	70/60

E, endometrioid; G, grade; PA, para-aortic; Pel, pelvic.

Myometrial Invasion

Regardless of grade, only 1.7% of tumors limited to the endometrium had lymph nodal involvement, as compared with 29% pelvic and 14.5% para-aortic involvement with deep penetration.[41] Before the 1988 FIGO staging system, the depth of invasion had been reported as none or inner, middle, or outer one-third of the myometrium. The 1988 FIGO staging system subdivided myometrial invasion into none or inner or outer half. Under that staging system, for patients with <50% myometrial invasion, it seems that invasion to less than versus

greater than one-third is not a significant predictor of outcome.[60] In the current 2009 FIGO staging system, depth of invasion in stage I is divided into two categories: A (no or <50% myometrial invasion) and B (>50% invasion).

Lymphovascular Invasion

In GOG 210 study,[41] the rate of lymphovascular invasion (LVI) was 22.7%. The presence of LVI increased the rate of positive pelvic node from 4.1% to 37.5%, and para-aortic node from 2.3% to 23.8%. LVI is also associated with higher rate of relapse in the vagina[61] and a poorer outcome especially if it was substantial.[62] The presence of LVI needs to be viewed in the context of other risk factors so that its mere presence does not trigger excessive therapy.[63]

Lower Uterine Segment Involvement

The presence of LUSI is associated with worse outcome. In a study of 481 surgically staged endometrioid endometrial cancers (FIGO stage I to II), LUSI was present in 223 cases (46.4%) and was associated with both decreased disease-free survival (P = .02) and overall survival (P = .01) in univariate analysis.[64] There seems to be a high rate of LUSI in patients with HNPCC-associated endometrial cancer.[65]

Cervical Involvement

In the 1988 FIGO staging system, cervical involvement was divided into IIA when limited to endocervical glandular involvement and IIB when it involves the cervical stroma. According to the FIGO report, the 5-year survival for stage IIA was very good (89.9% for grade 1 and 83.7% for grade 2). In contrast, the corresponding figures for stage IIB were 81.2% and 76.9%, respectively.[19] This led to a change in the 2009 FIGO staging system, in which only cervical stromal invasion is considered stage II. Although the prognosis of the old stage IIA grades 1 and 2 approximated stage I rather than stage IIB, it is important to note that in the same FIGO annual report, patients with stage IIA grade 3 did not fare as well; their 5-year survival was 68.3%, which was worse than that for IC grade 3 (74.9%) and similar to that for IIB grade 3 (64.9%).

Peritoneal Cytology

In the 2009 FIGO staging, having positive peritoneal cytology is no longer considered stage IIIA. The reason for the change is due to lack of clear correlation between positive cytology and outcome for early-stage endometrial cancer. However, the true prognostic significance of positive peritoneal cytology

on outcome cannot be devoid of the influence of surgical techniques or other prognostic factors. There is some suggestion of a higher rate of positive cytology for patients undergoing laparoscopic hysterectomy, because of manipulation of the uterine cavity. In a randomized trial[66] trying to address this issue, the rate of positive cytology was 7.2% when manipulator was used compared to 1.8% when it was not, but that difference was not statistically significant (P = .147). In GOG 210 study, positive peritoneal cytology was found in 11.3% of patients undergoing surgical staging. This was associated with 31.8% pelvic lymph node involvement and 22.7% para-aortic node involvement.[41] Histology also impacts the rate of positive cytology: 7.7% for endometrioid histology compared to 20.2% for nonendometrioid histologies.[42] In patients with early-stage disease (low-grade endometrioid histology, minimal invasion), the influence of positive peritoneal cytology on outcome is not evident.[67] In contrast, for patients with stage III disease, having positive cytology affects prognosis significantly and needs to be taken into account.[68]

Adnexal/Serosal Involvement

In GOG 210 study,[41] the rate of positive adnexal involvement was 8.6%. The rate of positive pelvic node with such involvement is 41%, and for para-aortic is 31.4%. Jobsen et al.[69] reported on 46 patients with isolated adnexal involvement and 21 with isolated serosal involvement. There was no statistically significant difference in outcome between adnexal and serosal involvement. The 5-year disease-free survival was 76.4% versus 59.6% (P = ns), and the disease-specific survival (DSS) was 76.3% and 75.4%, respectively.

Pelvic and Para-aortic Lymph Node Involvement

The pattern of lymphatic spread in endometrial cancer is different than that in cervical cancer. In endometrial cancer, a simultaneous spread to both pelvic and para-aortic nodes could occur, whereas in cervical cancer, the spread to para-aortic nodes is almost always secondary to pelvic lymph node involvement. Overall, about 12.6% of patients with stage I and occult stage II endometrial cancer have pelvic nodal involvement. This increases to 27.7%, 41%, and 45.7% with deep myometrial invasion, adnexal involvement, and extrauterine spread, respectively.[41] Lymph node involvement is a major predictor of outcome; the 5-year disease-free survival rates drop to 65% to 70% in patients with pelvic lymph node involvement as their only risk factor.[70] In GOG 210 study, the rate of para-aortic nodal metastases is about 7.2%.[41] The biggest risk factor for para-

aortic node involvement is the presence of pelvic nodal metastases. The 5-year disease-free survival rates drop to about 30% in this subpopulation.[70]

Molecular Prognostic Factors

In the TCGA report on endometrial cancer,[50] there was a correlation between prognosis and genomic group (Fig. 74.4). In the PORTEC trials, patients with *POLE* mutations had excellent prognosis, with very low risk of recurrence, which could be attributed to its high mutational burden.[71] On the other end of the spectrum, patients with copy number high had the worst prognosis in the TCGA report.[50] The recognition that about 25% of grade 3 endometrioid adenocarcinoma (serous-like) do belong to the copy number high group (mainly serous) further highlight the prognostic importance of genomic classifications of endometrial cancer.[72] Patients with CTNNB1 (*β* catenin) mutations do significantly worse even in patients with early-stage endometrioid histology.[73] Analysis of GOG 210 showed that in endometrioid adenocarcinoma of the uterus, the presence of MMR defects was associated with higher rate of LVI and higher-grade cancers. But interestingly, MMR defects were not associated with significantly worse prognosis.[74]

SURGICAL MANAGEMENT

Surgery is the main treatment for endometrial cancer. It consists of simple hysterectomy, BSO, and inspection of the pelvic and abdominal cavities, with biopsy of any suspicious extrauterine lesions, accompanied by peritoneal washings. The FIGO staging system did not say that obtaining peritoneal washings is no longer required but only that the finding does not alter the stage. Surgical assessment of lymph nodes ranges from palpation, biopsy of suspicious nodes, to pelvic and para-aortic lymphadenectomy.

Hysterectomy

There are several approaches to simple hysterectomy, also known as extrafascial hysterectomy, but in the main, it consists of removal of the entire uterine corpus and cervix without contiguous parametrial tissue. The pubocervical fascia is entered, and the ureters are not unroofed. *Total abdominal hysterectomy/BSO* (TAH/BSO) is the most prevalent and time-tested form of simple hysterectomy in endometrial cancer. It is an abdominal approach, usually via a vertical midline incision that allows thorough exploration of intra-abdominal and pelvic cavities. The main drawback of TAH/BSO is that it is a laparotomy-based approach, in a

group of patients with pre-existing comorbidities such as obesity, hypertension, and diabetes. Therefore, it is not surprising that minimally invasive surgery, whether laparoscopically or robotically, has gained a great deal of acceptance in the surgical management of endometrial cancer. In *laparoscopic vaginal hysterectomy/BSO* (LAVH/BSO), the uterus is removed vaginally rather than abdominally. The benefit of using the laparoscope is to enable the surgeon to have a thorough intra-abdominal exploration and to perform BSO, which is difficult to accomplish with just a vaginal hysterectomy. The GOG completed a trial in which patients with clinical stage I to occult IIA uterine cancer were randomly assigned to laparoscopy (n = 1,696) or open laparotomy (n = 920), including hysterectomy, salpingo-oophorectomy, pelvic cytology, and pelvic and para-aortic lymphadenectomy. The main study endpoints were 6-week morbidity and mortality, hospital length of stay, conversion from laparoscopy to laparotomy, recurrence-free survival, site of recurrence, and patient-reported quality of life outcomes.[75] Laparoscopy had fewer moderate to severe postoperative adverse events than laparotomy (14% vs. 21%, respectively; P < .0001). Hospitalization of >2 days was significantly lower in laparoscopy than in laparotomy patients (52% vs. 94%, respectively; P < .0001). The conversion rate to laparotomy was 25.8%. With a median follow-up time of 59 months for 2,181 patients still alive, there were 309 recurrences (laparoscopy 210, laparotomy 99) and 350 deaths (laparoscopy 229, laparotomy 121). The estimated 5-year recurrence rate was 11.61% in the laparotomy arm and 13.68% for laparoscopy. The estimated 5-year overall survival rate was 89.8% for laparoscopy and 89.8% for laparotomy. The study demonstrated that surgical treatment of endometrial cancer can be performed laparoscopically with relatively small differences in recurrence rates (estimated difference at 3 years, 1.14%). These results, combined with improved quality of life and decreased complications associated with laparoscopy, are reassuring to patients and allow surgeons to reasonably suggest this method as a means to surgically treat and stage patients with presumed early-stage uterine cancers.[76] In recent years, *robotic-assisted hysterectomy*/BSO has emerged as an alternative minimally invasive surgery in endometrial cancer. It affords many advantages, including three-dimensional visualization, increased freedom of instrument movement, and enhanced ergonomics and surgeon comfort. The question of difference in cost is under debate debatable.[77] *Radical hysterectomy* is not routinely performed in endometrial cancer because of low incidence of parametrial involvement. There is no evidence to show that the cure rates are any better with such radical

operations. The possible exception to this might be in patients with gross cervical involvement.[78]

Surgical Assessment of Lymph Nodes

The question of which patients need routine surgical lymph nodal staging and, if so, to what extent is a matter of great debate. The uncertainty about lymphadenectomy relates to whether the benefit from it is prognostic rather than therapeutic. Those who advocate for *no lymphadenectomy* and limit nodal assessment to inspection and removal of any enlarged/suspicious pelvic or para-aortic nodes cite the lack of documented survival advantages to lymphadenectomy. Furthermore, patients who have adverse pathologic features that increase the risk of microscopic lymph node metastasis are generally offered adjuvant pelvic radiation. Advocates for *full-pelvic and para-aortic lymph node sampling* on the other end of the spectrum reason that surgical staging is the most accurate method to assess the extent of disease and that the sensitivity and specificity of palpation of lymph nodes are only 72% and 81%, respectively.[79] Lymphadenectomy in endometrial cancer includes removal of the fat pads surrounding the major vessels in the abdomen and pelvis without skeletonizing them. According to the GOG surgical guidelines, pelvic lymph nodes are to be removed from the distal one-half of the common iliac artery down to the circumflex iliac vein, and nodal tissue is to be removed anterior to the obturator nerve and surrounding the iliac arteries and vein. The para-aortic nodes include those overlying the vena cava, between the vena cava and aorta, and to the left of the aorta. The cephalad boundary of the para-aortic specimen is generally, but not limited to, the inferior mesenteric artery, and the distal boundary is the midpoint of the common iliac artery. For the sampling to be adequate, five lymphatic stations from each side need to be removed—para-aortic, common iliac, internal iliac, external iliac, and obturator—or a total of 10 nodes.[41]

Two trials addressed the role of lymphadenectomy. The first was an Italian study[80] in which 514 eligible patients with preoperative FIGO stage I endometrial carcinoma were randomly assigned to undergo pelvic lymphadenectomy (n = 264) or no lymphadenectomy (n = 250). The median number of lymph nodes removed was 30 in the pelvic lymphadenectomy arm. Both early and late postoperative complications occurred more frequently in patients who had received pelvic systematic lymphadenectomy (81 patients in the lymphadenectomy arm and 34 patients in the no-lymphadenectomy arm; P = .001). Lymphadenectomy improved surgical staging, as statistically significantly

more patients with lymph node metastases were found in the lymphadenectomy arm than in the no-lymphadenectomy arm (13.3% vs. 3.2%; $P < .001$). At a median follow-up of 49 months, the 5-year disease-free and overall survival rates in an intention-to-treat analysis were similar between arms (81.0% and 85.9% in the lymphadenectomy arm and 81.7% and 90.0% in the no-lymphadenectomy arm, respectively). In the second trial (Medical Research Council [MRC]/A Study in the Treatment of Endometrial Cancer [ASTEC]), patients with endometrial cancer believed preoperatively to be confined to the uterine corpus were first randomized to standard surgery consisting of hysterectomy/BSO, pelvic washing, and palpation of para-aortic nodes ($n = 704$) or to lymphadenectomy ($n = 704$). In the lymphadenectomy group, patients underwent standard surgery plus systematic dissection of iliac and obturator nodes.[81] If the nodes could not be dissected, sampling of suspect nodes was recommended. Whether to dissect the para-aortic nodes was left to the discretion of the surgeon. After a median follow-up of 37 months, 191 women (88 standard surgery group, 103 lymphadenectomy group) had died, with an absolute difference in 5-year overall survival of 1% (95% CI = 4 to 6) and an absolute difference in 5-year recurrence-free survival of 6%. The conclusion from both trials was that pelvic lymphadenectomy significantly improved surgical staging, that is, it is a good prognosticator, but it did not improve disease-free or overall survival. *Optional lymphadenectomy* is another approach, in which preoperative tumor grading with intraoperative assessment of depth of myometrial invasion, as well as histologic subtype, is frequently used to decide whether lymph node dissection is necessary at the time of hysterectomy. With such a policy, patients with grade 3 disease or serous or clear cell histology and those with deep myometrial invasion on frozen section will undergo lymphadenectomy. Opponents of this selective lymphadenectomy approach point out that depth of invasion on frozen section correlated with final pathology in only 67% of cases.[82] With regard to grade, preoperative FIGO grade 1 diagnosis correlates with final grade diagnosis in only 85% of cases of endometrial cancer.[23]

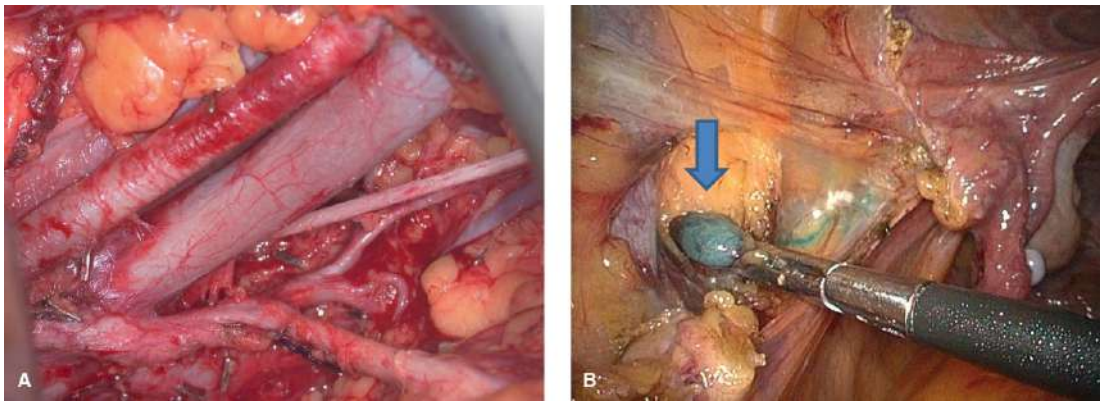

FIGURE 74.5. Comparison of nodal dissection **(A)** to sentinel node biopsy **(B)**. Solid *arrow* points to the blue dye in the sentinel node.

As a trade-off between lymphadenectomy and no surgical assessment at all in patients with endometrial cancer, there has growing interest in adopting a *sentinel lymph node (SLN) mapping* approach similar to that in breast cancer (Fig. 74.5). In a report from MSKCC, 266 patients with endometrial cancer underwent SLN mapping. At least one sentinel node was identified in 84% of cases. Location of SLN was in the pelvis in 94% of cases, in the pelvis and para-aortic in 5%, and in the para-aortic in 1%. Positive nodes were diagnosed in 12% of patients.[83] In a recent report of a prospective study[84] of 385 patients, 86% had successful mapping of at least one SLN. Positive node rate was 12%, with nodal metastases being identified in the SLNs in 97% of these 36 patients, yielding a sensitivity to detect node-positive disease of 97.2% (95% CI 85·0 to 100) and a negative predictive value of 99.6% (97.9 to 100). It is important to note that if a patient did not have bilateral mapping, a side-specific lymphadenectomy needs to be performed on the site that failed to map, because one reason for failed mapping might be due to the presence of nodal metastasis. In addition, any suspicious node on inspection needs to be removed even if it did not map. With such encouraging results, SLN mapping is gaining more acceptance in the staging of endometrioid adenocarcinoma for sure. This approach is gaining acceptance not only in the gynecologic oncology community[85,86] but also in other histologies. In a prospective study of 123 patients with grade 3 endometrioid histology, serous, clear cell, and carcinosarcoma, all underwent sentinel node mapping followed by lymphadenectomy. Overall, sentinel node detection rate was 89%, with an overall sensitivity of 95% and false-negative rate of 5% (1/20). The rate of positive node was 23% with only 1 patient having negative sentinel nodes but positive nonsentinel node.[87]

ROLE OF RADIATION

Radiation therapy plays a significant role in the management of endometrial cancer. It is often used as an adjuvant treatment after surgery (which will be discussed here) or as definitive treatment for patients who are medically inoperable or with local recurrence (which will be discussed later). In the past, most patients were treated with preoperative intracavitary brachytherapy with or without external beam radiotherapy, followed by hysterectomy. This approach is not without its merit, especially in patients with gross cervical involvement. However, most patients nowadays undergo surgery first; then, depending on the prognostic features obtained from the pathology review, the need for radiotherapy is determined. In recent years, there has been a plethora of data from prospective, randomized trials addressing several aspects of the management of endometrial cancer. However, unlike in cervical cancer, for which the data from the majority of the randomized trials pointed in the same direction, that is, chemoradiation is better than radiotherapy (RT) alone, the data in endometrial cancer are less conclusive. Therefore, it is important for radiation oncologists to be familiar with the methodology of these studies so that objections to the use of any form of adjuvant RT can be addressed with facts.

Role of RT in Stages I and II

Treatment options for patients with early-stage endometrial cancer after hysterectomy include observation, intravaginal RT, or pelvic RT. At MSKCC, intravaginal RT is the preferred approach for most patients because it provides the best therapeutic ratio. As the discussion will demonstrate, observation may have the best morbidity profile, but it does not provide the best therapeutic ratio because of the increased risk of local recurrence. Pelvic RT, on the other hand, although very effective in reducing recurrence, has a higher morbidity profile than intravaginal RT. The results of prospective, randomized trials will be discussed first, and then, treatment recommendations based on risk factors will follow.

Results of RT Randomized Trials

There are six randomized trials regarding the role of adjuvant RT in early-stage endometrial cancer, mainly pertaining to endometrioid histology and conducted in the “modern” era.

Observation Versus Pelvic RT

Three randomized trials compared pelvic RT to observation in early-stage endometrial cancer. The first trial was the PORTEC trial, which randomized 715 patients after TAH and BSO to observation or pelvic RT.[88] Patients included were those with stage (FIGO 1988) IB grades 2 and 3 and those with IC grades 1 and 2. Those with IB grade 1 and those with IC grade 3 were excluded because it was felt that adjuvant RT was not indicated for the former and most physicians would not omit it for the latter. No lymph node sampling was done, and the dose of pelvic RT was 46 Gy at 2 Gy per fraction. At 5 years, there was a statistically significant difference in the rates of vaginal/pelvic recurrence in favor of adjuvant pelvic RT (14% vs. 4%; $P < .001$). Overall survival, however, was not different between the two groups (81% RT vs. 85% surgery; $P = .31$), and the complications with pelvic RT were significantly higher (25% vs. 6%; $P < .0001$). In addition, many of the patients who relapsed locally after surgery alone were successfully salvaged with subsequent definitive RT. The second randomized trial was GOG 99. There were 190 patients with stage (FIGO 1988) IB to IIB (grades 1 to 3), who all underwent TAH/BSO, pelvic washing, and pelvic/para-aortic lymph node sampling and then were randomized to observation versus pelvic RT to a dose of 50.4 Gy at 1.8 Gy per fraction.[89] At 2 years, there was a statistically significant difference in the rates of relapse in favor of the adjuvant pelvic RT arm (3% vs. 12%; $P = .007$). The 2-year estimated incidence of isolated vaginal/pelvic recurrence was 1.6% in the RT group and 7.4% in the surgery-alone group. There was, however, no significant difference in 4-year overall survival (92% RT vs. 86% with surgery alone; $P = .557$), but there were more complications with pelvic RT. The third trial consisted of two trials with separate randomizations consolidated into one intergroup trial. One trial was conducted by the MRC and the other by the National Cancer Institute of Canada (NCIC). Furthermore, the MRC ASTEC trial in itself consisted of two trials with separate randomizations designed to answer a surgical as well as a radiation question.[90] The surgical question was discussed earlier and regarded the need for lymphadenectomy in clinical localized endometrial cancer. The radiation question was whether pelvic RT is needed. Intermediate- or high-risk early-stage patients were then randomized to observation or pelvic RT. Intermediate risk included stage (FIGO 1988) IA grade 3, IB grade 3, IC grades 1 and 2, and IIA grades 1 and 2. High risk included IC grade 3, IIA grade 3, and IA to IIA serous and clear cell tumors. Patients who had positive pelvic nodes (stage IIIC) were allowed but not those with cervical stromal invasion (IIB). The pelvic RT was given to a total dose of 40 to 46 Gy in 20 to 25 fractions over 4 to 5 weeks.

Intravaginal RT was permitted regardless of the pelvic RT randomization as long as it was the stated policy for the treating center to do so. The recommended dose was 4 Gy in two fractions prescribed to a depth of 0.5 cm treating the upper one-third of the vagina when using high dose rate (HDR) and 15 Gy when using low dose rate. The NCIC had a similar design but with a few exceptions. Patients with stage IIA serous or clear cell carcinoma were excluded, as were those with positive nodes. The dose of pelvic RT was 45 Gy in 25 fractions, and intravaginal brachytherapy was permitted in accordance with local practice.

Of the 905 patients (789 MRC and 116 NCIC) in the trial, 453 were randomized to observation and 452 to pelvic RT. The two arms were balanced except for more high-risk patients (113; 25%) in the observation arm than in the pelvic RT arm (89; 20%). There were 137 (32%) patients in the observation arm in whom nodes were removed, and 5 (4%) had positive nodes. In the pelvic RT arm, 159 (38%) had nodes removed, and 6 (4%) were positive. In the observation arm, 228 (51%) patients received intravaginal RT, 7 (2%) received pelvic and intravaginal RT, 3 (1%) received pelvic RT, and 3 (1%) were unknown. Only 212 (47%) received no form of adjuvant RT. Conversely, in the pelvic RT arm, 24 (5%) did not receive any adjuvant RT, 10 (2%) received intravaginal RT, and 2 (0.4%) were unknown. Combined intravaginal and pelvic RT was given to 232 (52%) patients, and only 184 (41%) received pelvic RT alone. The primary endpoint of this study was overall survival. With a median follow-up of 58 months, the 5-year overall survival was 84% in both arms (P = .77). The 5-year cumulative incidence for isolated vaginal or pelvic recurrence was 6.1% in the observation group and 3.2% in the pelvic RT group. This difference was statistically significant (P = .2) with a HR of 0.46 (95% CI = 0.24 to 0.89). The rate of any acute toxicity was 27% in the observation arm compared to 57% for pelvic RT. Similarly, late toxicity was more prevalent in the pelvic RT compared to observation (61% vs. 45%, respectively).

The triad of lack of overall survival advantage, increased toxicity, and high salvage rate of local recurrence for patients who are observed has led some to conclude that all forms of adjuvant RT, not simply pelvic RT, should be abandoned. The morbidity of pelvic RT and the validity of omitting adjuvant RT in favor of RT for salvage policy will be discussed later in the chapter. With regard to overall survival, it is considered the gold standard for primary endpoint in many randomized trials in oncology, but for early-stage endometrial cancer, it is perhaps unattainable with adjuvant RT for two reasons. First, many of the patients have other, competing causes of death such as hypertension, diabetes,

and obesity. In the PORTEC trial, the 8-year actuarial rates of intercurrent death were 19.7% in the RT arm and 15.6% in the surgery-alone arm.[91] Endometrial cancer–related deaths in comparison were only 9.6% and 7.5%, respectively. Similarly, in the GOG 99 trial,[89] approximately half of the deaths were due to causes other than endometrial cancer or treatment (surgery alone, 19 of 36; RT, 15 of 30). This led the authors of GOG 99 to write, "With this number of intercurrent deaths in both arms, even if RT reduces the risk of endometrial cancer-related deaths, the size of this trial is not adequate to reliably detect an overall survival difference." That is why overall survival was not the primary endpoint in GOG99 but rather the disease-free interval, which was significantly different in favor of adjuvant pelvic RT over surgery alone.[89] Therefore, it is not unreasonable to conclude that neither PORTEC nor GOG 99 was large enough to conclusively show whether adjuvant pelvic RT affected overall survival. The second difficult hurdle for adjuvant RT to overcome when discussing overall survival has to do with its localized nature. In the MRC/NCIC trial, the rate of first vaginal/pelvic recurrence was reduced from 11.4% (n = 37 of 453) in the observation arm to 2.8% (n = 13 of 452) with pelvic RT. Adjuvant pelvic RT, however, did not affect distant spread; the rate of first distant spread was 8.1% (n = 37 of 453) in the observation compared to 9% (n = 41 of 452) in the pelvic RT arm.[90] One would expect adjuvant RT to make a difference in overall survival only when systemic therapy has an effect on the rate of distant spread. This is exactly the story learned from postoperative chest wall irradiation in breast cancer. Because pelvic RT significantly improved local control, albeit with increased toxicity, why not replace it with intravaginal RT rather than advocating observation for all early-stage endometrial cancer?

Observation Versus Intravaginal RT

In a trial reported by Sorbe et al.,[92] 645 patients with stage (FIGO 1988) IA to IB grades 1 and 2 endometrioid adenocarcinoma were randomized after surgery to observation (n = 326) or intravaginal RT (n = 319). Surgery consisted of TAH/BSO (laparoscopic surgery was allowed), pelvic washing, and removal of enlarged nodes. The dose and type of intravaginal RT varied among the six centers participating in this trial, but 347 of 645 patients were treated with HDR to 18 Gy in six fractions. The proximal upper two-thirds of the vagina was treated with the dose prescribed to 0.5 cm from the surface of the cylinder. The rate of vaginal recurrence was 3.1% in the observation arm compared to 1.2% for the intravaginal RT arm (P = .114). The rate of pelvic recurrence was 0.9% in

the observation arm and 0.3% in the treatment arm (P = .326). No significance difference was seen between the two arms in terms of overall survival. There was significantly more grade 1 vaginal toxicity with intravaginal RT (8.8% vs. 1.5%; P = .00004). There was no significant difference in gastrointestinal (GI) or genitourinary toxicity.

Pelvic RT Versus Intravaginal RT

In the PORTEC-2 trial, 427 patients were randomized to pelvic RT (n = 214) or intravaginal RT (n = 213). Patients enrolled were those with stage (FIGO 1988) IB grade 3 and >60 years old, IC grades 1 and 2 and >60 years old, and IIA grades 1 and 2 of all ages but with <50% myometrial invasion. During surgery, patients underwent TAH/BSO, pelvic washing, and removal of suspicious pelvic or para-aortic lymph nodes. Routine lymphadenectomy was not performed. The dose of pelvic RT was 46 Gy given in 23 fractions. Intravaginal RT was delivered using a cylinder to treat the upper half of the vagina. The dose was prescribed to 0.5 cm from the surface of the cylinder. Three types of brachytherapy were used: HDR to 21 Gy in three fractions, low dose rate to 30 Gy at 0.5 to 0.7 Gy/h, and medium dose rate to 28 Gy at 1 Gy/h. With a median follow-up of 36 months, the 3-year vaginal recurrence rates were 0.9% in the intravaginal RT arm and 1.9% in the pelvic RT arm (P = .97). The pelvic recurrence was significantly different; the 3-year rate was 3.5% in the intravaginal RT arm compared to 0.6% in the pelvic RT arm (P = .03). The corresponding rates of isolated pelvic recurrence, however, were not significant: 0.6% versus 1.2%, respectively (P = .54). There was no significant difference in disease-free or overall survival between the two arms. The rate of grades 1 and 2 acute GI toxicity was 53% versus 12% in favor of intravaginal RT (P < .001). This trial showed that intravaginal RT alone is sufficient to control vaginal recurrence even in patients with intermediate- to high-risk features.[93]

In the Swedish trial reported by Sorbe et al.,[94] patients with stage (FIGO 1988) I endometrioid adenocarcinoma with at least one of the risk factors grade 3, ≥50% myometrial invasion, or DNA aneuploidy were randomized to adjuvant intravaginal RT (IVRT; n = 263) or pelvic and IVRT (n = 264). Lymphadenectomy was required. There was no difference in vaginal recurrence, which was 2.7% (7 of 263) in the IVRT-alone arm compared to 1.9% (5 of 264) in the combined arm (P = .555). Pelvic recurrence rate, however, was different: 5.3% in the IVRT arm compared to 0.4% in the pelvic plus IVRT arm (P = .0006). There was no significant difference in overall survival between the two

arms (90% vs. 89%, respectively). The toxicity was significantly higher in the combined arm compared to IVRT alone.

Radiation Treatment Recommendations for Early-Stage Disease Based on Risk Factors

Based on the results of these trials in early-stage endometrial cancer, it is clear that pelvic RT is an excessive treatment for most of those patients. Therefore, the treatment recommendations should be individualized based on risk factors. When deciding on whether to recommend observation, intravaginal RT, or pelvic RT, the risk of vaginal recurrence and pelvic recurrence should be assessed separately. With respect to vaginal recurrence, the data from randomized trials indicate that adjuvant intravaginal RT alone is sufficient to control potential microscopic disease in the vagina. The PORTEC-2 trial showed that intravaginal RT is as good as pelvic RT in controlling vaginal recurrence (0.9% vs. 1.9%, respectively; $P = .97$) despite the fact that patients included in this trial were at high risk for vaginal recurrence based on age ≥60 years old, deep myometrial invasion, or endocervical gland involvement.[93] The data from the Swedish randomized trial further confirmed that when it comes to vaginal control, IVRT alone is sufficient.[94] The vaginal recurrence was 2.9% in the IVRT arm compared to 1.9% ($P = .555$) in the pelvic plus intravaginal RT arm. How best to reduce pelvic recurrence is more controversial. For patients at low risk of having pelvic lymph node involvement, that is, endometrioid grade 1 or 2 with no or minimal myometrial invasion, neither lymphadenectomy nor pelvic RT is likely to be of significant benefit because of low rate of pelvic node involvement.[41] Those who are at higher risk of having lymph node involvement may need to have their lymph nodes surgically assessed to ensure that they are pathologically negative or receive pelvic RT to control potential microscopic disease. However, the two PORTEC trials, as well as the Swedish trial, showed that the risk of pelvic recurrence was only 2% to 6% even in the absence of lymphadenectomy.[88,93,94] This low rate of pelvic recurrence, coupled with the lack of survival advantage to lymphadenectomy and pelvic RT, raises the question of whether either approach is needed for the majority of patients with early-stage endometrial cancer. In the eyes of many, having LVI is almost indicative of nodal involvement. Cohn et al.[95] correlated LVI and the risk of positive pelvic nodes in 366 surgically staged patients. The rate of LVI was 25%, and the rate of positive pelvic nodes was 13%. Patients with LVI were significantly more likely to have nodal metastasis (35 of 92 vs. 11 of 274; $P <$

.001). However, the influence of LVI on pelvic nodal metastasis was the strongest in patients with deep myometrial invasion and high grade. Data from MSKCC on 126 patients with endometrioid FIGO (1988) stages IB to IIB and LVI also showed that the mere presence of LVI should not be a trigger for giving pelvic RT, especially when patients had lymphadenectomy. Patients were divided into two groups: those from the old era, when treatment was often pelvic RT, and those from the modern era, when patients were more often treated with lymphadenectomy and intravaginal RT.[63] The rate of pelvic relapse for patients with LVI was 7% in the old era compared to 3% (P = .3) in the modern era.

No Myometrial Invasion, Grades 1 and 2

The risk of vaginal recurrence is almost negligible. Straughn et al.[96] reported no vaginal recurrence in 103 such patients treated with surgery alone. Pelvic lymph nodal positivity was ≤3%. The 5-year progression-free survival (PFS) rate in this group was on the order of 95% to 98%. It is unlikely that postoperative pelvic or intravaginal RT would add anything to the final outcome, and therefore, radiation is not routinely recommended to this group of patients.

No Myometrial Invasion, Grade 3

In GOG study 210, there were only 69 patients out of 5,866 (1.1%) with disease limited to endometrium and had grade endometrioid histology, making it difficult to draw any meaningful conclusion.[41] Straughn et al.[96] reported on eight patients with stage IA grade 3 disease treated with surgery alone, with two of patients developing isolated vaginal recurrence. The risk of lymph node metastasis in this group of patients is about (1.7%) in GOG 210 study.[41] At MSKCC, these patients are offered either intravaginal RT alone or observation.

Less than 50% Myometrial Invasion, Grades 1 and 2

This group of patients constitutes the most common stage subgroup of all endometrial cancers. Straughn et al.[96] reported a 3% (9 of 296) risk of vaginal recurrence when surgery alone was done. In the surgery-alone arm of the PORTEC-1 trial,[88] the 5-year vaginal recurrence rate for patients with <50% myometrial invasion grade 2 was 5%. In a randomized trial reported by Sorbe et al.,[92] the vaginal recurrence rate was 3.1% for those in the observation arm compared to 1.2% for those in the intravaginal RT arm (P = .114). The trial was designed to detect a difference of 1% versus 5% in the vaginal recurrence rate in the two groups. The data were not reported separately based on whether myometrial invasion was present or not, making it difficult to determine the true

impact of intravaginal RT on the rate of vaginal recurrence in patients with myometrial invasion. Data from MSKCC on 233 patients with <50% myometrial invasion grade 1 or 2 showed a vaginal recurrence rate of only 1% using intravaginal RT alone.[97,98] In addition, Sorbe et al.[99] reported on 110 patients with IB grade 1 or 2 who were part of a prospective, randomized trial evaluating two different intravaginal RT doses; the rate of vaginal recurrence was 0.9%. The risk of pelvic recurrence was only 1.8%, even though lymphadenectomy was not required. This low rate of pelvic recurrence is similar to those reported by Straughn et al.[96] of 0.3% (1 of 296) and by Horowitz et al.[100] of 0% (0 of 62) in the setting of lymphadenectomy. This indicates that pelvic RT is of limited use, and therefore, it seems reasonable to suggest that either observation or intravaginal RT is a reasonable option for patients with grade 1 or 2 and <50% myometrial invasion.

However, when deciding on whether adjuvant RT is needed, it is important to address two issues. First, older patients tend to have higher rates of relapse. In the study by Straughn et al.,[96] 8 of the 10 vaginal/pelvic recurrences were in patients ≥60 years old. In the randomized trial by Sorbe et al.[92] comparing adjuvant intravaginal RT to observation, patients with vaginal recurrences were significantly (P = .018) older (mean age, 68.6 years) than patients without vaginal recurrences (mean, 62.6 years). Second, patients with LVI have a higher chance of vaginal recurrence, as demonstrated by Mariani et al.[61] who reported on 508 patients with endometrial cancer limited to the corpus treated with surgery alone. The presence of LVI significantly increased the vaginal relapse rate from 3% to 7% (P = .02). The rate of vaginal relapse would have been even higher if patients without myometrial invasion (152 of 508) had been excluded because LVI is exceedingly rare in patients without myometrial invasion. At MSKCC, patients who are ≥60 years old or have LVI are recommended to have intravaginal RT.

Greater Than 50% Myometrial Invasion, Grade 3

Some advocate observation for patients with <50% myometrial invasion grade 3, yet the 5-year vaginal recurrence rate in PORTEC-1 was 14% for such patients treated with surgery alone compared to none for those treated with pelvic RT.[88] Perhaps a better choice for those patients is intravaginal RT. The incidence of positive pelvic lymph nodes at time of surgery in this subset of patients is about 3.9%. In the PORTEC-1 trial, none of the 37 patients with grade 3 disease and <50% myometrial invasion who were treated with TAH/BSO alone relapsed in

the pelvis.[88] At MSKCC, intravaginal RT is recommended for this subset of patients irrespective of whether lymphadenectomy was performed.

Fifty Percent or Greater Myometrial Invasion, Grades 1 and 2

The risk of vaginal recurrence with surgery alone in this group of patients is not minimal. In the PORTEC-1 trial,[88] the 5-year vaginal recurrence for patients with ≥50% myometrial invasion treated with surgery alone was 10% for those with grade 1 and 13% for grade 2. The corresponding 5-year vaginal recurrence rates for patients treated with pelvic RT were 1% and 2%, respectively. With regard to pelvic control, the 5-year pelvic recurrence for patients with ≥50% myometrial invasion treated with surgery alone was 2% for grade 1 and 6% for grade 2. The data from the PORTEC-2 trial[93] and the Swedish trial[94] in which patients with ≥50% myometrial invasion grade 1 or 2 were included indicate that the omission of pelvic RT increased the risk of pelvic recurrence. In PORTEC-2 trial,[93] the 3-year rate was 3.5% in the intravaginal RT arm compared to 0.6% in the pelvic RT arm (P = .03). In the Swedish trial,[94] the pelvic recurrence rate was 5.3% in the IVRT arm compared to 0.4% in the pelvic plus intravaginal RT arm (P = .0006). At MSKCC, most of these patients undergo SLN mapping, and if the nodes are pathologically negative, they undergo intravaginal RT alone.

Fifty Percent or Greater Myometrial Invasion and Grade 3

In GOG 210, the risk of finding positive lymph nodes in this group of patients was 29.1.[41] Such patients were not enrolled in the PORTEC trials because it was felt that omitting pelvic RT when lymphadenectomy was not performed could not be justified. In the registry study reported by Creutzberg et al.,[101] 99 patients with ≥50% myometrial invasion grade 3 were treated with postoperative pelvic RT. The 5-year rate of vaginal recurrence was 5%, that of pelvic recurrence was 8%, and that of distant relapse was 31%. Very few investigators would recommend surgery alone for these patients. In fact, an argument could be made that pelvic RT might be needed even after a negative lymphadenectomy, especially for older patients and those with LVI. In GOG 99 trial, factors associated with an increased recurrence rate (25% at 5 years) were identified using proportional hazards regression modeling of historical data from GOG 33.[89] These factors were (a) increasing age, (b) moderate to poorly differentiated tumor grade, (c) presence of LVI, and (d) outer one-third myometrial invasion. From the results of that analysis, a subgroup of patients with high intermediate risk (HIR) was defined as follows: (a) at least 70 years of age with only one of

the other risk factors, (b) at least 50 years of age with any two of the other risk factors, or (c) any age with all three of the other risk factors. Those on the RT arm demonstrated a somewhat lower overall death rate when compared to those on the observation arm (relative hazard [RH] = 0.73, 90% CI = 0.43 to 1.26) in the HIR subgroup. AT MSKCC, patients with deep myometrial invasion grade 3 who are HIR per GOG 99 are offered postoperative pelvic RT. If they are not HIR, which is not that common in this subset of patients, they could be considered for intravaginal RT, but only in the setting of adequate surgical lymph node assessment.

Cervical Involvement

Gross cervical involvement increases the risk of parametrial extension as well as spread to pelvic lymph nodes in a fashion similar to primary cervical cancer. Such patients could undergo radical hysterectomy and pelvic lymph node dissection or preoperative radiation including pelvic radiation and intracavitary brachytherapy followed by simple hysterectomy. The FOGO 2009 staging system only recognizes cervical stromal invasion, and not endocervical gland involvement, as being stage II. But it is important to note that patients with endocervical gland involvement were included in POTEC 2 trial comparing pelvic RT to intravaginal RT.

There are also emerging data on the role of intravaginal RT alone in highly selected patients with cervical stromal invasion. Elsheaikh et al. reported on 27 patients treated with intravaginal RT. There were no vaginal recurrence and only 1 pelvic recurrence.[102,103] At MSKCC, patients with endocervical glandular involvement are often treated with IVRT. For patients with cervical stromal invasion grade 1 and 2 and the depth of cervical stromal invasion <50%, intravaginal RT could be offered if they underwent adequate surgical lymph node assessment. For those with grade 3 or deep cervical stromal invasion, pelvic RT is recommended irrespective of lymphadenectomy. Table 74.5 shows overall treatment recommendations for early-stage endometrioid adenocarcinoma at MSKCC.

ROLE OF SYSTEMIC THERAPY

Hormonal therapy has been used in the treatment of recurrent/advanced endometrial cancer for many years. Agents used include megestrol acetate (Megace), medroxyprogesterone acetate (Provera), and, to a lesser extent,

tamoxifen.[104–106] The response rate ranges from 9% to 33%, with an overall survival of 6 to 14 months. In GOG 107, doxorubicin was compared to doxorubicin and cisplatin.[107] The response rate was 42% versus 25% (P = .004), and the progression-free interval was 5.7 versus 3.8 months (P = .014) in favor of combination chemotherapy. However, this did not translate into overall survival advantage (9 vs. 9.2 months). In GOG 177 trial,[108] doxorubicin/cisplatin was compared to doxorubicin/cisplatin/paclitaxel. The three-drug regimen was superior in terms of response rate (57% vs. 34%, P < .01), progression-free interval (8.3 vs. 5.3 months, P < .01), and survival (15.3 vs. 12.3 months, P = .037).

TABLE 74.5 TREATMENT RECOMMENDATIONS AT MEMORIAL SLOAN KETTERING CANCER CENTER FOR STAGE I AND II PATIENTS WITH ENDOMETRIOID ADENOCARCINOMA

Extent/Grade	1	2	3
No MI invasion	Observation	Observation	IVRT or observation[a]
<50% MI	IVRT or observation[a]	IVRT or observation[a]	IVRT
≥50% MI	IVRT	IVRT	IVRT or IMRT[b]
Endocervical gland	IVRT	IVRT	IVRT or IMRT[b]
CSI <50%	IVRT	IVRT	IVRT or IMRT[b]
CSI >50%	IMRT	IMRT	IMRT

[a]Observation is offered to patients <60 years old and without lymph node invasion.
[b]IMRT if high to intermediate risk.
CSI, cervical stromal invasion; IMRT, intensity-modulated radiotherapy; IVRT, intravaginal radiotherapy; MI, myometrial invasion.

With the widespread use of chemotherapy in the recurrent/advanced setting, its use in the adjuvant setting has also started to increase and to challenge the role of adjuvant RT. There are several randomized trials addressing the role of adjuvant chemotherapy in advanced endometrial cancer.

Chemotherapy Versus RT Trials

There are three randomized trials comparing adjuvant chemotherapy to radiation. The Japanese Gynecology Oncology Group (JGOG) trial randomized 385 patients with stage (FIGO 1988) IC to III (25% with stage III) endometrial cancer to pelvic radiation (193 patients) or to chemotherapy (192 patients).[109] The surgery was hysterectomy with optional lymphadenectomy. The dose of pelvic RT was 45 to 50 Gy using open anteroposterior/posteroanterior (AP/PA)

fields. Chemotherapy consisted of cyclophosphamide (333 mg/m^2), cisplatin (50 mg/m^2), and doxorubicin (40 mg/m^2) every 4 weeks for three cycles or more. There was no significant difference in progression-free (P = .726) or overall survival rate (P = .462) between the two groups. A trial from Italy had a similar design, in which 340 patients with stage (FIGO 1988) IC grade 3, stage II grade 3, and stage III (two-thirds of patients) were randomized to radiation or to chemotherapy.[110] With a median follow-up of 95.5 months, the 5-year disease-free survival rate was 63% in both arms (P = .44) and the 5-year overall survival rate was 69% in the radiation arm and 66% in the chemotherapy arm (P = .77). Again, there was no significant difference in outcome despite using five cycles of Cytoxan, cisplatin, and doxorubicin. In GOG 122, 396 patients with stage (FIGO 1988) III to IV disease were randomized to whole-abdomen radiation (n = 202) versus doxorubicin/cisplatin (n = 194) for eight cycles. Progression-free survival was the primary endpoint of this study. With a median follow-up of 74 months, there was significant improvement in both progression-free (50% vs. 38%; P = .007) and overall survival rate (55% vs. 42%; P = .004), respectively, in favor of chemotherapy.[111] However, before concluding that chemotherapy alone is the answer, a closer examination of the data is warranted. The overall absolute rate of relapse was 54% in the radiation arm compared to 50% in the chemotherapy arm, a small difference, if any, and yet the corresponding 5-year PFS rates were 38% and 50% (P = .007), respectively. The reason for the discrepancy is that in this study, there was stage imbalance, in which there were more stage IIIA patients in the RT arm (28.2%) than in the chemotherapy arm (18%). Conversely, there were more patients with stage IIIC disease in the chemotherapy arm (51.5%) than in the RT arm (44.6%). Therefore, the 5-year disease-free survival rate for the chemotherapy arm was increased from 42% to 50%, which became significantly different than the RT arm (50% vs. 38%, P = .007) rather than 42% versus 38%, which is not likely to be significant. The 5-year overall survival rate in the chemotherapy arm was 55% compared to 42% for the RT arm (P = .004). What are we to make of the significant difference in overall survival? There were 15 deaths unrelated to endometrial cancer or protocol treatment in the radiation arm compared to only six in the chemotherapy arm, raising a question about whether the two arms of the study were truly balanced, especially because no stratification was performed in that trial.[111] The results of GOG 122 have led to the adoption of adjuvant chemotherapy as the preferred treatment for stage III endometrial cancer. It is important to note, however, that GOG 122, JGOG, and the Italian study all

showed no significant difference in the patterns of relapse between RT and chemotherapy. If one were to use the unadjusted PFS from GOG 122, then all three randomized trials failed to show that adjuvant chemotherapy is superior to adjuvant RT.

Chemoradiation Versus RT Trials

There are four randomized trials comparing adjuvant chemoradiation to radiation (Table 74.6). In the first trial from Finland,[112] 156 patients with stage (FIGO 1988) IA or IB grade 3 (n = 28) or stage IC to IIIA grade 1 to 3 (n = 128) were postoperatively randomized to receive radiotherapy (56 Gy) only (n = 72) or radiotherapy combined with three cycles of cisplatin (50 mg/m^2), epirubicin (60 mg/m^2), and cyclophosphamide (500 mg/m^2) chemotherapy (n = 84). The disease-specific overall 5-year survival was 84.7% in the RT arm versus 82.1% in the chemoradiation arm (P = .148). The second trial reported by Hogberg et al.[113] is two trials (Mario Negri Gynecologic Oncology Group [MaNGO] and Nordic Society of Gynecological Oncology [NSGO]/European Organisation for Research and Treatment of Cancer [EORTC]) combined in one report. In the MaNGO trial, there were 157 patients (two-thirds were stage III); 76 were randomized to postoperative pelvic RT (45 Gy) and 80 to chemotherapy followed by pelvic RT. The chemotherapy consisted of three cycles of doxorubicin (60 mg/m^2) and cisplatin (50 mg/m^2). The 5-year PFS was 61% in the RT group compared to 74% for the chemoradiation group, but that difference was not significant (P = .1). The 5-year overall survival (OS) was also not significant (73% vs. 78%, respectively; P = .41). In the NSGO/EORTC trial, 383 patients were randomized to RT (n = 191) versus RT and chemotherapy (n = 187). The type of chemotherapy varied, and only a handful of patients were stage III. The 5-year PFS was better for the chemoradiation arm (79% vs. 72% for RT; P = .04), but OS was not significantly better (83% vs. 76%, respectively; P = .1).

TABLE 74.6 EFFECT OF CHEMORADIATION COMPARED TO RADIATION ON OUTCOME IN HIGH-RISK ENDOMETRIAL CANCER

	Finland	NSGO	MaNGO	GOG 249	PORTEC-3
PFS	↔	↑	↔	↔	↔ stage I–II ↑ stage III
OS	↔	↔	↔	↔	↔

Gynecologic Oncology Group (GOG) 249 compared chemotherapy plus intravaginal RT to pelvic RT, whereas the Finland trial, Nordic Society of Gynecological Oncology (NSGO), Mario Negri Gynecologic Oncology Group (MaNGO), and PORTEC-3 compared chemotherapy plus pelvic RT to pelvic RT.
OS, overall survival; PFS, progression-free survival.
↔, chemoradiation equivalent to pelvic RT; ↑, chemoradiation better than pelvic RT.

The third trial is GOG 249 trial, where 601 patients with stage I to II high- to intermediate-risk endometrioid adenocarcinoma and all stage I to II serous or clear cell carcinoma were randomized to either pelvic RT (45 Gy) or intravaginal RT plus 3 cycles of carboplatin/paclitaxel. With median follow-up of 53 months, the 3-year recurrence-free survival was 82% in both arms. The overall survival rate was 91% in the pelvic RT arm compared to 88% for the chemotherapy and intravaginal RT arm. There was no significant difference in rate of vaginal relapse or distant metastasis. There was a higher rate of pelvic recurrence in the chemotherapy arm compared to pelvic RT (25 vs. 6 patients). Toxicity was also higher in the chemotherapy arm.[114] The fourth trial is PORTEC-3, which included stage III patients as well as high-risk early-stage disease. There were 660 patients who were randomized to either pelvic RT (46.8 Gy) or pelvic RT with concurrent cisplatin (50 mg/m^2) on weeks 1 and 4 followed by 4 cycles of carboplatin/paclitaxel.[115] With a median follow-up time of 60.2 months, the 5-year OS was 81.8% for chemoradiation arm versus 76.7% for RT arm; HR 0.79 (95% CI = 0.57 to 1.12, *P* = .183). The corresponding 5-year failure-free survival rates were 75.5% versus 68.9%, respectively, with an HR of 0.77 (0.58 to 1.03, *P* = .078).

Chemoradiation Versus Chemotherapy Trial

In GOG 258 trial, 736 patients with stage III and IVA endometrial cancer or stage I to II (but with positive cytology) were randomized to 6 cycles of carboplatin/paclitaxel versus postoperative external beam RT with concurrent cisplatin (50 mg/m^2) on weeks 1 and 4 followed by 4 cycles of carboplatin/paclitaxel.[116] With a median follow-up of 47 months, the 5-year recurrence-free survival was about 58% in both arms. The 5-year overall survival was 73% in the chemotherapy-alone arm compared to 70% for the chemoradiation arm. When comparing the chemoradiation arm to chemotherapy-alone arm, there were some differences in the rates of relapse: vaginal recurrence (3% vs. 7%), pelvic/para-aortic (10% vs. 19%), and distant (27% vs. 21%), respectively.

Systemic Therapy Recommendations Based on Risk Factors

When considering the use of adjuvant chemotherapy in endometrial cancer based on risk factors, one need to pay attention to whether we are dealing with an isolated as opposed to multiple risk factors. This is particularly important when dealing with FIGO 2009 stage III disease.

Early-Stage High-Risk Endometrioid Adenocarcinoma

In GOG 249 randomized trial[114] limited to high-risk stage I to II disease, 71% of patients had endometrioid histology. In PORTEC-3, patients with stage I (grade 3 with deep myometrial invasion and/or LVI) as well as stage II were included (55%); endometrioid histology was seen in 71% of patients.[115] In both trials, the addition of chemotherapy did not impact outcome of particularly distant metastasis, which was equivalent in GOG 249 and only slightly less in PORTEC-3 (23.1% for chemoradiation vs. 29.7% for pelvic RT; P = .077). Therefore, routine use of adjuvant chemotherapy in addition to radiation could not be recommended for all high-risk early-stage endometrioid adenocarcinoma.

Early-Stage Serous and Clear Cell Cancer

Serous cancer and to a lesser extent clear cell cancer tend to spread in a fashion similar to ovarian cancer, with a high propensity for upper abdominal relapse. Therefore, it is important to perform comprehensive surgical staging because of the high rate of surgical upstaging. For serous endometrial cancer, the preferred approach is intravaginal RT plus carboplatin/paclitaxel.[98,117,118] In a report from MSKCC on 41 patients with stage I to II (all had negative peritoneal cytology) treated as such, with a median follow-up time of 58 months, the 5-year disease-free and overall survival rates were 85% and 90%, respectively.[118] The 5-year actuarial recurrence rates were 9% in the pelvis, 5% in the para-aortic nodes, and 10% at distant sites. None of the patients developed vaginal recurrence. In a subsequent report, the presence of deep myometrial invasion and/or cervical stromal invasion was associated with higher rate of pelvic recurrence.[98] This issue raises the question of whether pelvic RT alone or in combination with chemotherapy should be considered for such a subset of early-stage serous cancers. More mature data from PORTEC-3 and GOG 249 may shed more light on the role of pelvic RT in this histology. At MSKCC, most patients with early-stage serous endometrial cancer disease who are surgically staged are treated with intravaginal RT interdigitated with 6 cycles of concurrent carboplatin/paclitaxel. Treatment recommendations for clear cell carcinoma

often mirror those for serous, but it is debatable if that is always warranted. When outcome of early-stage serous was compared to that with clear cell, the 5-year relapse-free and overall survival were identical despite the fact that only 38% of patients received adjuvant chemotherapy in the clear cell group compared to 67% with serous, $P = .02$.[119] At MSKCC, patient with early-stage clear cell carcinoma are treated with intravaginal RT and concurrent carboplatin/paclitaxel being reserved for those with deep invasion or cervical involvement.

Stage IIIA

The results of postoperative external beam RT in patients with *isolated* adnexal or serosal involvement are generally good. However, the rate of distant relapse is still 26% to 33%, indicating the need for adjuvant systemic therapy.[69] Furthermore, patients with more than one site of involvement, that is, *multiple risk factors*, do worse. Jobson et al.[120] reported on 141 patients with IIIA endometrioid adenocarcinoma (patients with isolated positive peritoneal cytology were excluded) treated with postoperative RT. The risk of abdominal relapse was 12.4% (11 of 89) for patients with one site of involvement compared to 36.5% (19 of 52) for more than one site ($P < .001$). Distant metastasis rate was 23.9% (21 of 89) compared to 34.6% (18 of 52), respectively. The 5-year DSS was 70.4% for one involved site compared to 43.3% for more than one ($P = .001$). On multivariate analysis, grade 3 (HR, 2.5; $P = .045$) and more than one site involvement (HR, 2.2; $P = .012$) were independent predictors of poor DSS. In the ongoing debate on whether chemotherapy alone is better than chemoradiation in patients with stage III, it is in this group of patients with multiple sites of involvement especially with positive peritoneal cytology and/or aggressive histologies[68,121] in which chemotherapy plus intravaginal RT might be a better choice than combining with pelvic RT.

Stage IIIC

The outcome of patients with *isolated* lymph node involvement (especially pelvic nodes), treated with postoperative pelvic RT is relatively good.[70] At MSKCC, we recommend external beam radiation with concurrent cisplatin followed by carboplatin/paclitaxel to try to reduce the risk of recurrence even further. Milgrom et al.[122] reported on 40 patients with stage III (82% were IIIC) treated with such an approach. With a median follow-up time of 49 months, the 5-year freedom from relapse was 79% and overall survival 85%. The rate of

vaginal recurrence was 3%, pelvic recurrence 3%, para-aortic 11%, peritoneal 5%, and other distant 11%.

Because stage IIIC is the most common subset in stage III disease (73% of patients in GOG 258), a discussion here about how to reconcile the data from GOG 258 and those from PORTEC-3 (stage III subset 45%) is in order. In PORTEC-3, the 5-year failure-free survival was 58% for RT alone compared to 69% for chemoradiation (P = .032) in stage III patients. The corresponding rates for OS were 70% and 79% respectively.[115] In GOG 258, the 5-year relapse-free survival was about 58% in both arms and overall survival was 70% in the chemoradiation arm and 73% in the chemotherapy-alone arm.[116] The question then becomes: Why was the rate of overall survival and relapse-free survival of the radiation-alone arm in PORTEC-3 for patients with stage III similar to both arms of in GOG 258? The answer might be found in the different inclusion criteria: GOG 258 allowed for patients with <2 cm gross residual disease (17 patients with 11/17 developing recurrence), whereas POTEC 3 excluded patients with gross residual disease.

As mentioned above in stage IIIA, the presence of *multiple risk factors* in stage IIIC has been shown to be a predictor of poor outcome.[123] In a recent SEER review, Garg et al.[124] showed that for patients with stage IIIC disease (n = 2,559), the 5-year DSS was 67%, which dropped to 43% when extranodal involvement (i.e., positive washing, adnexa/serosal, and vaginal/parametrial involvement) was present (P < .001). At MSKCC, such patients are treated with full systemic chemotherapy plus intravaginal RT rather than external beam and concurrent chemotherapy.

RADIATION THERAPY TECHNIQUES

Intravaginal Radiation

The purpose of this treatment modality is to deliver the highest dose of radiation to the vaginal mucosa while limiting the dose to the surrounding normal structures such as the bladder, rectum, and small intestines. HDR brachytherapy using ^{192}Ir sources is the preferred method of delivering intravaginal RT. The type of applicator used is generally a cylinder. The treatment is given on an outpatient basis without the need for anesthesia and without the radiation exposure to medical personnel. At MSKCC, patients start their treatment 4 to 6 weeks postoperatively, depending on the vaginal cuff healing. It takes longer for the vaginal cuff to heal [125] after LAVH/BSO and robotic hysterectomy than after

TAH/BSO. The treatment is given in three fractions of 7 Gy to a total dose of 21 Gy. The interval between each fraction is 1 to 2 weeks. When intravaginal RT is given with chemotherapy, it is given concurrently but not during the week when the patient is receiving their chemotherapy. The dose is prescribed to a 0.5-cm depth from the mucosal surface (Fig. 74.6). The treatment is usually delivered using a 3-cm-diameter cylinder to treat a 4- to 7-cm length of the vagina, depending on depth of invasion and tumor grade. For patients with grade 3, serous or clear cell carcinoma, the length of vagina treated is generally 7 cm (assuming an average length of vagina after simple hysterectomy of about 10 cm). This is done to account for potential submucosal extension that may lead to relapse in the distal periurethral region with these aggressive histologies. For patients with grade 1 or 2 endometrioid adenocarcinoma, the treated vaginal length increases from 4 cm if myometrial invasion is <50%, to 5 cm for >50% myometrial invasion, and to 6 cm for cervical involvement. Occasionally, the dose per fraction is lowered to 6 Gy instead of 7 Gy if the diameter of the cylinder is <3 cm. This is usually done to avoid a very high dose of radiation to the vaginal mucosa. The dose per fraction is also lowered to 4 to 5 Gy when pelvic radiation is added.

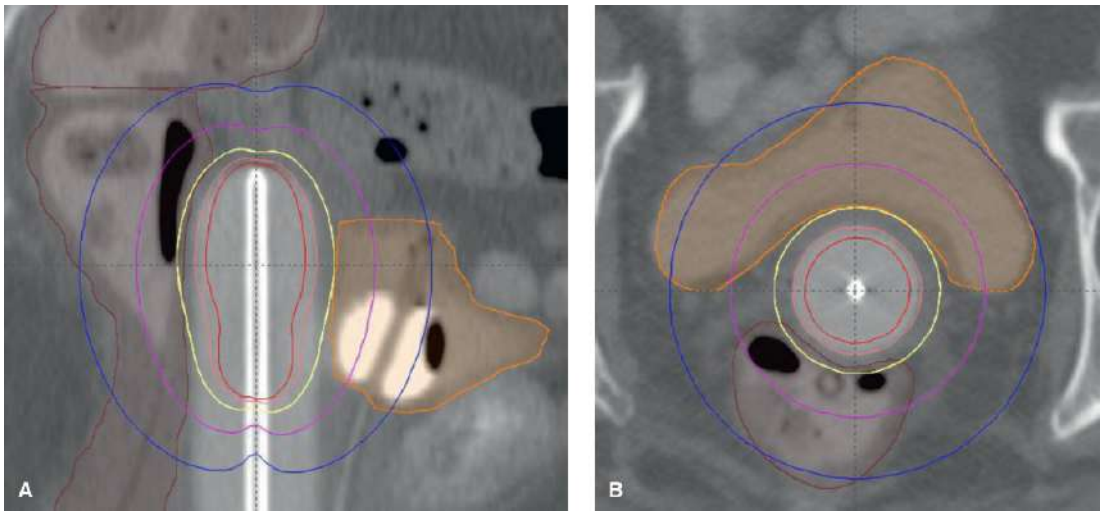

FIGURE 74.6. Dose distribution with intravaginal radiation therapy (prescription dose 7 Gy in *solid yellow*). **A:** Sagittal view. **B:** Axial view.

External Beam Radiation

Conventional RT

At the time of simulation for *pelvic* RT, the small bowel is opacified using oral contrast, a vaginal marker is used to define the vaginal cuff, and the rectum is

opacified with barium or CT-compatible contrasts. Patients are usually placed in the prone position to displace the small intestines from the radiation field. The target volume consists of the pelvic lymph nodes, including obturator, external, internal, and lower common iliac groups and the proximal two-thirds of the vagina. The presacral nodes are not included unless patients have gross cervical involvement. High-energy linear accelerators (15 MV) are preferred because of their sparing of the skin and subcutaneous tissue. The ideal beam arrangement with conventional radiation is the four-field pelvic-box technique to reduce the dose to the small intestines and to some extent the bladder and rectum. For AP/PA fields, the superior border is L5-S1, the inferior border is the bottom of the obturator foramina, and the lateral border is 2 cm beyond the widest point of the inlet of the true bony pelvis. For lateral fields, the anterior border is in front of the pubis symphysis and the posterior border at least at S2-S3. The superior and inferior borders are the same for the AP/PA fields. All fields are treated daily to a dose of 1.8 Gy. A total dose of 50.4 Gy is generally given when pelvic radiation is used alone, or 45 Gy when combined with intravaginal RT.

When para-aortic nodes are involved, *extended field* RT is used, and CT simulation is crucial for accurate delineation of the kidneys, small bowel, and liver in addition to nodal target. The latter should include, in addition to the pelvic nodes, the pericaval, interaortocaval, and para-aortic areas, defined by contrast-enhanced blood vessels. The preferred approach is the four-field box technique rather than AP/PA in order to lower the dose to the small intestines. However, attention should be paid to the dose that the kidneys might receive with the four-field arrangement. The lower border is the same as in pelvic radiation, but the upper border is extended usually to the T12-L1 interspace. The typical dose is 45.0 Gy at 1.8 Gy or 1.5 Gy if patients develop acute GI toxicity.

Intensity-Modulated RT

At MSKCC, postoperative intensity-modulated RT (IMRT) is used for most patients with endometrial cancer who need pelvic or extended field radiation (Fig. 74.7). At the time of simulation, patients are placed in the prone (pelvic) or supine (extended) position and immobilized using Aquaplast. Oral and rectal contrasts are used to better visualize the small and large intestines. In addition, contrast is inserted in the vaginal cuff to better visualize the upper vagina. Because pelvic lymph nodes are poorly visualized by CT when normal, they should be defined by encompassing the contrast-enhanced blood vessels. Taylor et al.[126] found that a modified 7-mm margin around contrast-enhanced vessels

offers a good surrogate target for pelvic lymph nodes. Small et al.[127] reported on consensus guidelines for delineation of clinical target volume (CTV) for intensity-modulated pelvic radiotherapy in postoperative treatment of endometrial and cervical cancer. A modified 7-mm margin (excluding bowel and muscles) is recommended around the iliac vessels to create nodal CTV. To create nodal planning target volume (PTV), an additional expansion of 7 mm all around nodal CTV is generally recommended. At MSKCC, vaginal PTV is created by outlining the contrast-enhanced vaginal cuff and adding a 3-cm margin axially and 2 cm superior and inferior to account for the impact of bladder and rectal filling, as well as of vaginal motion.[128] An alternative approach would be to simulate patient with bladder full and bladder empty and create an ITV. The Radiation Oncology Cooperative Group (RTOGO) established dose constrains for using postoperative IMRT in endometrial cancer.[129] For bladder, <35% receives ≥45 Gy; rectum, <60% receives ≥45 Gy; small bowel, <30% receives ≥40 Gy; femoral heads, <15% receives ≥30 Gy; and any ≤1% or ≤1 mL receives >110% prescribed dose normal tissue.

Data on outcome with postoperative IMRT in endometrial cancer are encouraging. He et al. reported on 129 patients (77% stage I to II). With median follow-up of 57 months, the 5-year DFS in the subset of patients with stage I to II (n = 98) was 85.7% for those with low intermediate risk and 71.6 for high intermediate risk. The corresponding rates for overall survival were 91.7% and 76.2%, respectively.[130] Shih et al. reported on 46 patients with high-risk endometrial cancer patients treated with postoperative IMRT. With a median follow-up of 52 months, the 5-year disease-free and overall survival rate in stage III (n = 36) were 84% and 95%, respectively.[131]

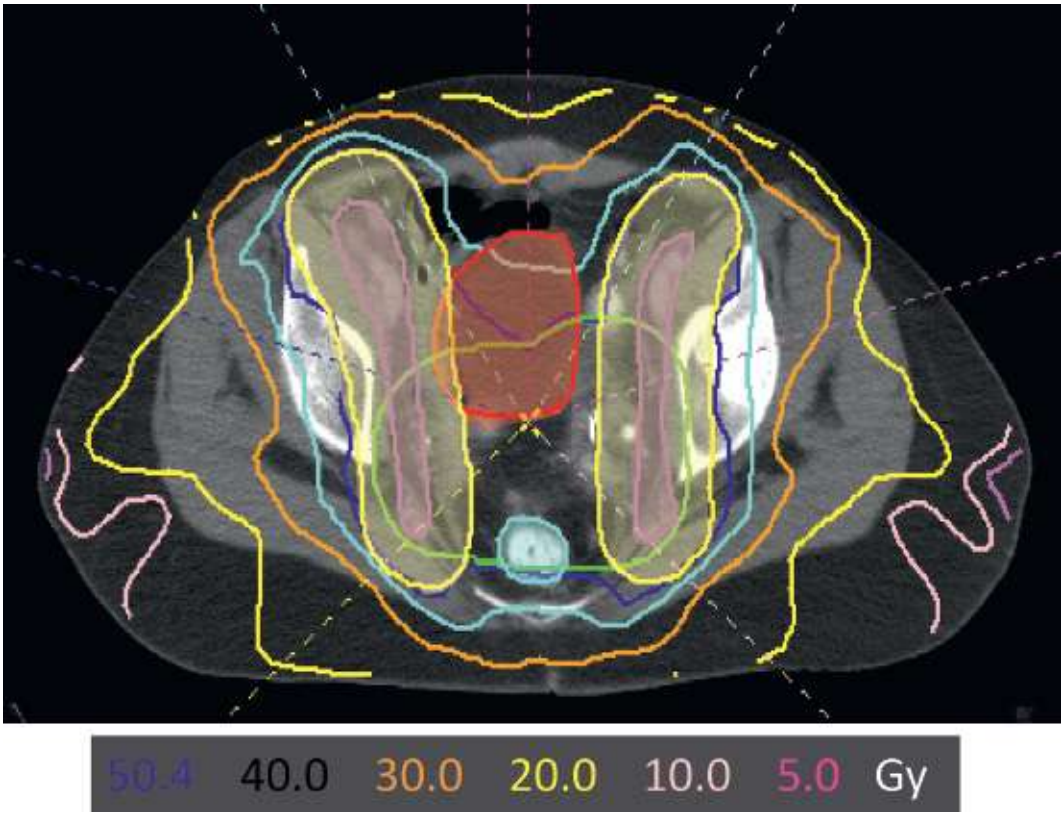

FIGURE 74.7. Pelvic intensity-modulated radiation therapy dose distribution. Outlined iliac vessels are shown in *pink* and nodal planning target volume in *yellow*.

COMPLICATIONS OF TREATMENT

Surgery

In PORTEC-1 trial,[88] the rate of complications in the surgery-alone arm was very low (6%). Surgical toxicity data are generally collected within 30 days of surgery, that is, before patients were enrolled in the trial. Therefore, it is important to assess surgical toxicity from trials addressing a surgical question. In the GOG LAP2 trial comparing laparotomy to laproscopy,[75] the rate of intraoperative complications was 8% versus 10%, respectively (P = .106). More importantly, the rate of postoperative (within 6 weeks of surgery) grade 2 or greater complications was 21% for laparotomy versus 14% for laparoscopy (P < .001). In the Italian randomized trial comparing hysterectomy to hysterectomy and lymphadenectomy, both early and late postoperative complications occurred significantly more frequently in the lymphadenectomy patients (81 of 264; 30.6%) than for hysterectomy alone (34 of 250, 13.6%; P = .001). Most of the difference in morbidity was due to lymphoceles and lymphedema, which occurred in 35 patients in the lymphadenectomy arm and 4 patients in the no-

lymphadenectomy arm.[79]

Radiation

Intravaginal RT

The main advantage of intravaginal brachytherapy is its ability to deliver a relatively high dose of radiation to the vagina while limiting the dose to the surrounding normal structures, such as the bowels and bladder. In PORTEC-2 trial, the long-term health-related quality of life (HRQL) analysis showed at 7 years, clinically relevant fecal leakage was reported by 10.6% in the pelvic RT group versus 1.8% for IVRT (P = .03), diarrhea by 8.4% versus 0.9% (P = .04), limitations due to bowel symptoms by 10.5% versus 1.8% (P = .001), and bowel urgency by 23.3% versus 6.6% (P < .001). Urinary urgency was reported by 39.3% of pelvic RT patients, 25.5% for IVRT, P = .05. No difference in sexual activity was seen between treatment arms.[132] However, such a low rate of severe complications cannot be taken for granted because special attention needs to be paid to the depth of prescription, the dose per fraction, the length of vagina treated, and the diameter of the cylinder used. Sorbe and Smeds[133] reported a 15% late complication rate and a very high incidence of vaginal stenosis after postoperative high dose rate intravaginal irradiation. This was attributed to the high dose per fraction of 6 to 9 Gy; moreover, this dose was prescribed at a depth of 10 mm from the surface of the cylinder, resulting in very high vaginal mucosal, bladder, and rectal doses. Adherence to vaginal dilator use[134] after IVRT as well as routine use of vaginal lubricants and moisturizers may further reduce the rate of vaginal stenosis.

In a cohort of 104 patients with early-stage endometrial cancer treated with surgery and IVRT, Female Sexual Function Index (FSFI) questionnaires were used to quantify levels of sexual functioning.[107] Sexual dysfunction defined as an FSFI score of <26 was reported by 81% of respondents. Multivariate analysis isolated factors associated with lower FSFI scores, including having laparotomy as opposed to minimally invasive surgery (effect size, −7.1 points; P < .001), lack of vaginal lubricant use (effect size, −4.4 points; P = .040), and short time interval (<6 months) from hysterectomy to questionnaire completion (effect size, −4.6 points; P = .059).

In a subsequent report[135] from MSKCC, 205 early-stage endometrial cancer survivors (>1 year from surgery) completed questionnaires containing the EuroQol (EQ5D) and the FSFI. A total of 136 (66.3%) underwent surgery alone, and 69 (33.7%) received additional IVRT. A majority of patients (80%) met

criteria for sexual dysfunction by FSFI <26.5. The two groups were well balanced with respect to demographics, comorbidities, and baseline sexual activity. Controlling for age and surgery type (open vs. minimally invasive), IVRT was not associated with poorer health state or sexual function. Receipt of laparotomy was associated with both poorer health state and sexual function (*P* = .0156 and *P* = .0247, respectively). These studies highlight the fact endometrial cancer patients whether treated with surgery alone or with additional IVRT, when compared to the index population (healthy women ages 18 to 74), all scores were low.

Pelvic Radiation

In the PORTEC-1 randomized trial,[136] the overall (grades 1 to 4) rate of late complications was 26% in the RT group compared to 4% in the observation group (*P* < .0001). Most of the late complications in the RT group, however, were grades 1 and 2 (22%), and only 3% were grades 3 and 4. It is also important to note that many patients in this trial were treated with AP/PA fields, for which the overall rate of complications was 30%, compared to 21% for those treated with the four-field box (*P* = .06). In GOG 99 when lymphadenectomy was performed, chronic lymphedema was seen in 2.5% of the patients randomized to surgery alone compared to 5% with postoperative pelvic RT.[89] There is an increased awareness of sacral insufficiency fractures (SIFs) as a potential complication of pelvic RT in gynecologic cancers. In a report from MSKCC, 222 patients were treated with postoperative pelvic RT.[137] In the subset of endometrial cancer (*n* = 144), the 5-year rate of SIF was 5.7%. Risk of secondary malignancies is often cited as one of the main reasons to avoid pelvic RT in endometrial cancer patients; however, when PORTEC-1 and PORTEC-2 trials were combined, there was no clear evidence of increased risk.[138]

The use of IMRT seems to be associated with less risk of obstruction (BO). In a report from MSKCC on 224 patients (152 with endometrial cancer) treated with postoperative radiation,[139] the 5-year rate of BO in the IMRT group was 0.9% compared to 9.3% for 3-D RT (*P* = .006). Patients with BMI ≥30kg/m^2 were less likely to develop BO (2.6% vs. 8.3; *P* = .03). On multivariate analysis, only IMRT retained its significance as an independent predictor of less BO (*P* = .022).

In PORTEC-3 trial, the addition of chemotherapy to radiation showed increased physician and patient-reported toxicities. However, by 24 months, results equalized, with the exception of persistence of patient-reported sensory

neurologic symptoms in 25% of patients in the chemoradiation arm.[140]

Definitive Radiation for Inoperable Disease

In medically inoperable patients with endometrial cancer, radiation is an effective alternative to surgery. These patients are usually treated in a fashion similar to those with cervical cancer by using intracavitary applicators with or without pelvic radiation. In a systematic review of twenty-five reports of patients treated with RT as single treatment, the 5-year DSS was 78.5%. External beam radiation therapy (EBRT) combined with brachytherapy (BT) was used in 1,278 patients (47.4%), BT alone in 1383 patients (51.3%), and EBRT alone in 33 patients (1.2%). The average rate of grade 3 or worse late toxicity was 3.7% for EBRT + BT, 2.8% for BT alone, and 1.2% for EBRT alone.[141] The American Brachytherapy Society established general guideline recommendations regarding HDR alone or in combination with external beam RT in terms of prescription point (2 cm from the central axis at the midpoint along the intrauterine sources), number of fractions, dose per fraction, combination with EBRT, and optimization. Patients with stage IIIB disease (vaginal involvement), an uncommon presentation, are usually not surgical candidates and are also treated with definitive radiation, including a combination of external beam and intracavitary/interstitial radiotherapy tailored to the extent of their disease.[142]

For patients with clinical stage I grade 1 or 2 and no evidence of myometrial invasion or lymph node metastasis on MRI, intracavitary brachytherapy alone is sufficient. Gephardt et al. reported on 45 patients with grade 1 to 2, clinical stage I endometrial adenocarcinoma, <50% myometrial invasion, and tumor ≤2 cm treated with 5 to 6 fractions HDR intracavitary brachytherapy to a median total dose of 37.5Gy. Median follow-up among living patients was 18.6 months. The 2-year local control, cancer-specific survival, and overall survival rates were 90%, 86%, and 97%, respectively. No grade 3+ acute or late toxicity was observed.[143] In another report, 43 consecutive patients with endometrial cancer FIGO stages I to III were treated definitively with HDR brachytherapy with or without EBRT.[144] Mean follow-up was 29.7 months. Median BMI was 50.2 kg/m^2. The 2-year overall survival was 65.2%. The 2-year cumulative incidence of pelvic and distant failures was 8.3% and 13.5%, respectively. Grade 3 disease was associated with a higher risk of all failures (hazard ratio [HR], 4.67; P = .044). The incidence of acute grade 3 GI/GU toxicities was 4.6%.

Radiation Therapy for Local Recurrence

Radiation therapy can be curative in a select group of patients with small vaginal recurrences who have not received prior radiation. Creutzberg et al. reported on survival after relapse based on the PORTEC-1 randomized trial.[91] In patients who were initially randomized to surgery alone (n = 46 of 360), the 5-year survival after vaginal relapse was 65%. However, before adopting salvage radiation as a treatment policy for all early-stage endometrial cancer, a few aspects of this trial need to be addressed. First, the 5-year survival rate from the PORTEC trial is much higher than what is reported in the literature.[145–148] Most likely, the vaginal recurrences in this trial were detected very early, unlike the situation for patients in the community. The extent and size of local recurrence in endometrial cancer are very significant predictors of outcome.[148] Second, this high rate of salvage pertains only to isolated vaginal recurrence. The rate of survival at 3 years for pelvic recurrence in the PORTEC-1 trial[91] was 0%. Third, although the trial does not mention any data on complications, it is not unrealistic to expect a higher complication rate than what is normally seen with adjuvant radiation. With salvage radiation, external beam RT and brachytherapy are often combined, and the doses of radiation required are much higher than those used with adjuvant radiation. The study from MD Anderson Cancer Center by Jhingran et al.[145] clearly highlights these issues. They reported on 91 patients who were treated with definitive radiation for isolated vaginal recurrence. The 5-year local control and overall survival rates were 75% and 43%, respectively. The median dose of radiation was 75 Gy, which often included external radiation and brachytherapy. The rate of grade 4 complications (requiring surgery) was 9%. Thus, when talking with a patient about adjuvant radiation versus radiation reserved for salvage, these issues need to be addressed and compared to the excellent local control and low morbidity obtained with adjuvant intravaginal brachytherapy. In a recent report from the University of Pittsburgh,[149] 41 patients were treated with HDR brachytherapy using image-based planning with contouring/optimization with each fraction to a median dose of 23.75 Gy in 5 fractions. Brachytherapy was combined with pelvic IMRT in 90% of patients to a dose of 45 Gy. At a median follow-up of 18 months, the 3-year local control, distant control, recurrence-free survival, and overall survival were 95%, 61%, 68%, and 67%. The 3-year rate of grade 3 or higher late toxicity was 8%. This indicates that even with more modern techniques, the morbidity of salvage RT cannot be ignored.

With the increased use of IMRT, salvage rate of nodal recurrence in endometrial cancer is better. In a report by Ho et al., 38 patients with

endometrial cancer who had no prior external beam radiation were treated definitively using IMRT for regionally confined pelvic or para-aortic nodal recurrences. Chemotherapy was given to 33 out of 38. The total dose of IMRT was 64.7Gy (range 59 to 73 Gy). The 2-year survival was 71%. Three patients (8%) experienced grade 3 to 4 late GI toxicity.[150]

UTERINE CARCINOSARCOMA

Uterine carcinosarcoma (UCS) is no longer considered a uterine sarcoma. In GOG 210, UCS represented about 4.1 of endometrial cancinomas.[41] Molecular evaluation of UCS revealed that frequent mutations were found in TP53, PTEN, PIK3CA, PPP2R1A, FBXW7, and KRAS, similar to endometrioid and serous uterine carcinomas. The range of epithelial-to-mesenchymal transition EMT scores in UCS was the largest among all tumor types studied via TCGA. UCSs shared proteomic features with gynecologic carcinomas and sarcomas with intermediate EMT features.[151]

The etiology of UCS is not well established but seems to share some similarity with endometrial adenocarcinoma. History of prior pelvic radiation has been reported in some patients with carcinosarcoma.[152] These neoplasms are often bulky, necrotic, and deeply invasive. The epithelial component is generally serous carcinoma. Homologous tumors have stroma that contains cell types normally seen in the uterus, in contrast to heterologous tumors, which may contain striated muscle cells (rhabdomyosarcoma), cartilage (chondrosarcoma), and bone (osteogenic sarcoma) (Figure 74.3D).

The main treatment is surgery, and these patients should undergo comprehensive surgical staging similar to that with serous cancer. Pelvic nodal metastasis is seen in 21.1%, and in para-aortic node in 15.2% of patients.[41] For carcinosarcomas, the 2009 staging system for carcinomas of the endometrium is used, recognizing the similarity in patterns of spread.

With regard to the role of *adjuvant radiation*, the EORTC performed a prospective, randomized trial addressing the role of postoperative pelvic RT in stages I to II uterine sarcomas. There were a total of 224 patients in the trial who underwent TAH/BSO, and 166 who had peritoneal washings. Lymphadenectomy was optional. There were 91 carcinosarcomas included in that study; the rate of pelvic recurrence only was 4% in the pelvic RT arm compared to 24% for the surgery-alone arm. The corresponding rates for any local recurrence were 24% and 47%, respectively, for this subset of patients.[153]

Adjuvant chemotherapy has been evaluated mainly in carcinosarcoma. Sutton et al.[154] reported on 65 patients with completely resected stage I or II carcinosarcoma of the uterus treated with adjuvant ifosfamide and cisplatin. None of the patients received adjuvant RT. Overall 5-year survival was 62%. Initial site of relapse was vaginal apex in 6 of 65 and pelvis in 4 of 64, suggesting that a combined chemoradiation approach might be ideal. GOG-150 is a phase III randomized study of whole abdominal RT versus three cycles of cisplatin, ifosfamide, and mesna (CIM). Eligible patients (n = 206) included those with stages I to IV UCS, no >1-cm postsurgical residuum, and/or no extra-abdominal spread. Stage distribution was as follows: I, 64 (31%); II, 26 (13%); III, 92 (45%); and IV, 24 (12%). The estimated crude probability of recurring within 5 years was 58% for chemotherapy and 52% for RT. Adjusting for stage and age, the recurrence rate was 21% lower for chemotherapy patients than for RT patients (RH, 0.789; 95% CI = 0.530 to 1.176; P = .245, two-tailed test). The estimated death rate was 29% lower in the chemotherapy group (RH, 0.712; 95% CI = 0.484 to 1.048; P = .085, two-tailed test). The conclusion was that there was not a statistically significant advantage in recurrence rate or survival for adjuvant chemotherapy over RT in patients with UCS. However, the observed differences favor the use of combination chemotherapy in future trials. The rate of vaginal recurrence was 4 of 105 (3.8%) in the WAI compared to 10 of 101 (9.9%). The corresponding abdominal relapse rates were 27.6% (29 of 105) and 18.8% (19 of 101). There was no difference in pelvic recurrence between the two arms. The rates of lung metastasis (14 of 105 vs. 14 of 101, respectively) or other distant sites (13 of 101 vs. 10 of 101, respectively) were similar. Analysis of the patterns of relapse from this trial also indicates the need for chemoradiation in patients with stage I to III carcinosarcoma.[155]

The use of intravaginal RT and chemotherapy is appealing in stage I to II carcinosarcoma. Desai et al. reported on 60 patients with stage I to II UCS and compared them to 112 stage I to II serous endometrial cancers.[156] Adjuvant therapy was to 90% of patients. With a median follow-up of 48 months, outcomes were better for serous versus UCS: 5-year actuarial rates of recurrence (17% vs. 45%; P < .001), disease-specific mortality (11% vs. 30%; P = .016), and all-cause mortality (12% vs. 34%; P = .007). However, in a subgroup analysis of 111 patients (77 serous, 34 UCS) who receive IVRT and chemotherapy, UCS no longer was associated significantly with increased recurrence (29% vs. 15%, P = .18), disease-specific mortality (22% vs. 10%, P = .39), or all-cause mortality (22% vs. 10%, P = .45). This indicates that when

early-stage UCS were treated aggressively, their outcome were not significantly different than serous endometrial cancer.

At MSKCC, patients with surgical stage I or II carcinosarcoma are treated with intravaginal RT and chemotherapy. Most stage III patients are treated in a similar fashion with few exceptions when extrauterine disease is limited to nodal disease. Then, consideration is given to concurrent pelvic RT/cisplatin followed by carboplatin/paclitaxel.

UTERINE SARCOMA

Uterine sarcomas are uncommon, representing about 3% to 7% of all uterine cancers.[157] The most common histology is leiomyosarcoma, followed by endometrial stromal sarcoma (resemble proliferative-phase endometrial stroma), undifferentiated uterine sarcoma, and adenosarcoma (benign epithelial component and low-grade sarcoma). Age-related incidences vary among the histologic types. The mean age at diagnosis for endometrial stromal sarcoma is 41 years, for leiomyosarcoma 53.5 years, and for adenosarcoma 57.4 years. Little is known about the risk factors for uterine sarcomas. Most uterine sarcomas present with vaginal bleeding, but leiomyosarcomas are more commonly discovered incidentally after simple hysterectomy for presumed uterine leiomyomata.

Pathology and Staging

Endometrial stromal sarcomas are generally divided into endometrial stromal sarcomas, which are low grade by definition, and undifferentiated endometrial sarcoma, which are high grade. Tumor cells in endometrial stromal sarcoma resemble those found in the stroma of proliferative endometrial lining. In contrast, tumor cells in undifferentiated endometrial stromal sarcoma do not resemble endometrial stroma. *Leiomyosarcomas* of the uterus have a fleshy appearance, often with areas of necrosis. They display nuclear atypia, high mitotic rates, and areas of coagulative tumor necrosis. *Adenosarcomas* have two components—a benign epithelial tumor and a malignant mesenchymal component (generally low-grade sarcoma that resembles endometrial stroma). Sarcomatous overgrowth, defined as the presence of pure sarcoma, usually of high grade and without a glandular component, occupying at least 25% of the tumor, has been reported in 33% of uterine adenosarcomas.[157] The 2009 FIGO staging recognizes the uniqueness of each uterine sarcoma. For leiomyosarcomas

and endometrial stromal sarcomas, the staging system recognizes the importance of tumor size on outcome. For adenosarcomas, the new staging system recognizes the importance of depth of myometrial invasion.

Management

The main treatment for uterine sarcoma is *surgery* in a similar fashion to endometrial adenocarcinoma. The extent of surgical staging varies, depending on the risk of lymph node involvement. Nodal metastases are seen in <5% of leiomyosarcoma unless there is obvious extrauterine disease.[158] For stromal sarcomas, dos Santos et al.[159] reported a 19% (7 of 36) rate of nodal metastasis. The rate of occult metastasis was only 10%. The corresponding rates from the literature review were 10.1% and 8.1%, respectively. Thus, patients with endometrial stromal sarcomas and adenosarcomas might benefit from lymph node sampling. On the other hand, for patients with leiomyosarcomas, the rate of nodal involvement is too low to justify routine lymphadenectomy.

With regard to the role of *adjuvant radiation*, the EORTC performed a prospective, randomized trial addressing the role of postoperative pelvic RT in stage I to II uterine sarcomas.[153] There were a total of 224 patients in the trial who underwent TAH/BSO, and 166 who had peritoneal washings. Lymphadenectomy was optional. There were 103 leiomyosarcomas (LMSs) and 28 endometrial stromal sarcomas. The 5-year cumulative incidence of locoregional recurrence was 18.8% in the pelvic RT arm compared to 35.9% in the surgery-alone arm. That difference was statistically significant (P = .0013). The 5-year cumulative incidence of distant relapse was 45.3% for the pelvic RT and 33.6% for surgery alone, but the difference was not statistically significant (P = .2569). There was no significant difference in progression-free (P = .3254) or overall survival (P = .923) between the two arms. For LMS patients, the rate of pelvic recurrence only was 2% in the pelvic RT compared to 14% in patients treated with surgery alone, and for any local recurrence, it was 20% versus 24%. It is important to note that the primary endpoint of this trial was pelvic control, which it met (P = .0013). The study was not powered to detect a significant difference in PFS or OS. Sampath et al.[160] performed a retrospective review of uterine sarcoma patients using the National Oncology Database. The impact of adjuvant radiation was assessed in patients who presented with nonmetastatic disease and underwent definitive surgery (n = 2,206). For endometrial stromal sarcoma, the rate was 97% with RT (109) versus 93% for surgery alone (n = 252; P < .05). For LMS, it was 98% for RT (n = 131) compared to 84% with surgery

alone (n = 398; P < .01).

For patients with leiomyosarcomas, the main treatment is surgery, and the role of adjuvant treatment, whether RT or chemotherapy, is not well defined. The high rate of distant relapse in these patients overshadows any local control benefit attained with adjuvant RT. These patients should be encouraged to participate in trials assessing the role of chemotherapy and/or targeted therapy. For patients with low-grade endometrial stromal sarcomas, observation is feasible, because most are hormonally sensitive and generally behave in an indolent manner, with long disease-free intervals. For those with undifferentiated endometrial sarcomas, adjuvant pelvic RT is reasonable. For patients with adenosarcomas, especially with sarcomatous overgrowth, adjuvant pelvic RT is also reasonable.

CHAPTER 75

Ovarian and Fallopian Tube Cancer

Larissa Lee, Ross Stuart Berkowitz, and Ursula A. Matulonis

INTRODUCTION

Ovarian neoplasms encompass a wide array of benign and malignant tumors with diverse histologic cell types, clinical features, and survival outcomes. Primary malignant tumors of the ovary include the epithelial ovarian cancers, germ cell tumors, and sex cord tumors. Low malignant potential (LMP) tumors of the ovary are noninvasive epithelial tumors often confined to the ovary, although extraovarian tumor implants may be detected. Metastases to the ovary occur from other primary malignancies including uterine, gastrointestinal (Krukenberg tumors), and breast cancers. Primary lymphoma, sarcoma, and melanoma of the ovary are rare. Relative to its incidence, epithelial ovarian cancers have substantially high mortality because effective screening tools are lacking; only 25% are detected as stage I at diagnosis, and current therapies for advanced cancer, although improving, have approached a therapeutic plateau. Surgery is the mainstay for diagnosis, staging, and the initial treatment for ovarian cancer. Platinum-based chemotherapy is indicated for patients with high-risk or advanced disease. Novel agents, such as antiangiogenics and poly (ADP-ribose) polymerase (PARP) inhibitors, are under active investigation in the adjuvant and/or recurrent setting. The use of whole-abdomen irradiation (WAI) or intraperitoneal (IP) radioisotopes is primarily historical, and radiation therapy now has a limited role in the management of ovarian cancer. Nonetheless, palliative radiotherapy may be of significant benefit for symptomatic disease relapse or select patients with localized recurrence.

ANATOMY

In premenopausal women, the ovaries are almond-shaped, gray–pink solid organs that measure approximately 4 × 2.5 × 1 cm, with an average weight of 4

to 5 g. After menopause, the ovaries atrophy and become nonfunctional and smaller in size. When normally positioned, the ovary is attached by the mesovarium to the broad ligament that covers the uterus and fallopian tubes. The infundibular pelvic, or suspensory, ligament extends from the surface of the ovary to the lateral pelvic wall, forming the superior and lateral aspect of the broad ligament (Fig. 75.1). The blood supply of the ovary is derived from the ovarian arteries, which arise from the aorta immediately below the level of the renal arteries and course through the retroperitoneum and infundibular pelvic ligaments. The venous return of the ovary empties to the renal vein on the left and directly to the vena cava on the right. The primary lymphatic drainage of the ovary parallels the course of the ovarian veins, with secondary lymphatic flow passing through the inguinal canal and to the iliac nodal system.[1] Histologically, the outer cortex of the ovary is covered by a layer of pseudocolumnar or cuboidal epithelium, termed the germinal epithelium of Waldeyer or ovarian surface epithelium (OSE). The inner medulla consists of a superficial tunica albuginea and dense stromal tissue filled with blood vessels and spindled, "muscle-like" connective tissue. Within the medulla, maturing follicles are present throughout the various layers.

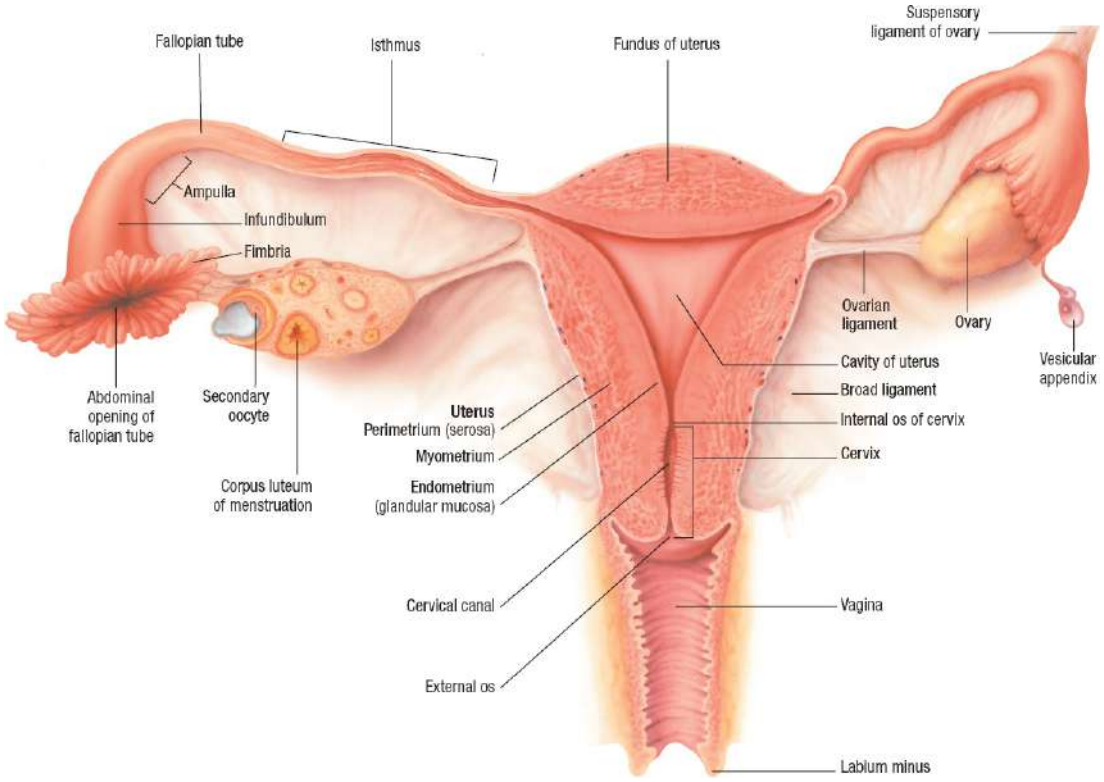

FIGURE 75.1. Anatomy of the ovary and female reproductive tract. (Asset provided by the Anatomical Chart Company.)

The fallopian tubes are positioned horizontally within the superior part of the broad ligament and extend from the superior–posterior portion of the uterine fundus to the ovaries. The fallopian tubes are hollow, muscular viscera that are in direct communication with the peritoneal cavity. The ovarian artery anastomoses with the uterine artery to supply the fallopian tube, and venous drainage is through the pampiniform plexus to the ovarian vein and uterine plexus. The mucosa of the fallopian tube contains a rich network of intercommunicating lymphatic sinusoids that anastomose with adjacent organs and drain into the ovarian lymphatics and para-aortic and iliac lymph nodes.[2] The fallopian tubes consist of four separate histologic layers: the mucosa, submucosa, muscularis (external longitudinal and inner circular layers), and outer serosal layer, which is continuous with the visceral peritoneum of the uterus. The mucosa is intricately folded, with the number of folds increasing from the interstitial portion to the ampulla. The epithelium is composed mainly of ciliated cells and secretory cells. Cyclic changes are evident in the tubal epithelium, similar to those of the endometrium, in response to estrogen and progesterone.

EPIDEMIOLOGY

Ovarian cancer is the second most common gynecologic malignancy in the United States after endometrial cancer. Approximately 22,440 women in the United States received a diagnosis of epithelial ovarian cancer in 2017, and 14,080 died of the disease[3,4] (Fig. 75.2). Ovarian cancer represents the fifth leading cause of cancer-related death in US women, following lung, breast, colorectal, and pancreatic cancers. The lifetime risk of ovarian cancer is approximately 1 in 77 women with a median age at diagnosis of 63 years; >80% of women are diagnosed after the age of 40 years.[5] The incidence of ovarian cancer rises with increasing age and peaks in the eighth decade of life. Differences in race and ethnicity are apparent in the age-adjusted annual incidence per 100,000 women, which in 2010 to 2014 was highest for White women (12.2), followed by Hispanic (10.6), American Indian/Alaska Native (9.5), Black (9.4), and Asian/Pacific Islanders (9.5).[5] The incidence of ovarian cancer also varies significantly by geography, with the highest rates in North America and northern Europe, which are three to seven times higher than that observed in Japan.[6] Survival rates for ovarian cancer have been increasing in the United States since 1975, when the 5-year survival rate reported by the Surveillance, Epidemiology, and End Results (SEER) program was 34%, which

has increased to 47% in 2009.[5]

Primary cancer of the fallopian tube was once considered a rare disease, accounting for 0.2% to 0.5% of female gynecologic malignancies. However, the true incidence has likely been underestimated considering a large proportion of extrauterine high-grade serous carcinomas may actually originate in the fimbriated end of the fallopian tube.[7,8] Precursor lesions, known as serous tubal intraepithelial carcinomas (STICs), have been detected in the fallopian tubes of prophylactic salpingo-oophorectomy specimens from high-risk patients. The model of the fallopian tube as the primary site of origin for extrauterine high-grade serous carcinoma is supported by epidemiologic, morphologic, and genetic data, as discussed later.

PATHOGENESIS

The female reproductive tract originates from the müllerian ducts, which are paired embryologic structures of mesodermal origin that give rise to the fallopian tubes, uterus, cervix, and upper vagina. Ovarian tissue is composed of embryonic yolk sac cells that give rise to the ova or germ cells, stromal cells that produce the steroid hormones, and mesothelium that provides the epithelial covering for the follicle cysts. These cell types give rise to germ cell tumors, sex cord–stromal tumors, and the epithelial tumors of the ovary, respectively. The traditional view of ovarian cancer pathogenesis is that all tumor subtypes arise from the OSE. In the “incessant ovulation hypothesis,” ovarian cancer develops from an aberrant repair process as a result of repeated rupture of the surface epithelium during each ovulatory cycle, thought to produce inflammation and scarring that serves as a nidus for carcinogenesis.[9–11] A second proposed mechanism is related to hormonal and reproductive factors such as persistent exposure to gonadotropins and elevated estradiol levels that stimulate malignant transformation.[12,13] Strong evidence exists that many borderline tumors and low-grade carcinomas of the ovary arise from cortical inclusion cysts (CICs) within the ovarian parenchyma. These benign cysts are composed of müllerian epithelium that closely resembles the fallopian tube. CICs are thought to result from invaginations of the OSE into the ovarian stroma through repeated ovulation and aging, acquiring a müllerian phenotype through metaplasia.[8] An alternate explanation is that remnants of müllerian-derived epithelia from the fallopian tube may adhere to the ovarian surface and become incorporated into CICs in a process known as endosalpingiosis. Nonetheless, as a result of

hormone exposure, damage repair processes, and inflammation within the ovary, neoplastic transformation gives rise to a variety of müllerian cell type differentiations, including serous carcinomas that resemble the fallopian tube, mucinous tumors as seen in the endocervix, endometrioid tumors from the endometrium, and glycogen-rich clear cell cancers similar to secretory-phase endometrial glands.

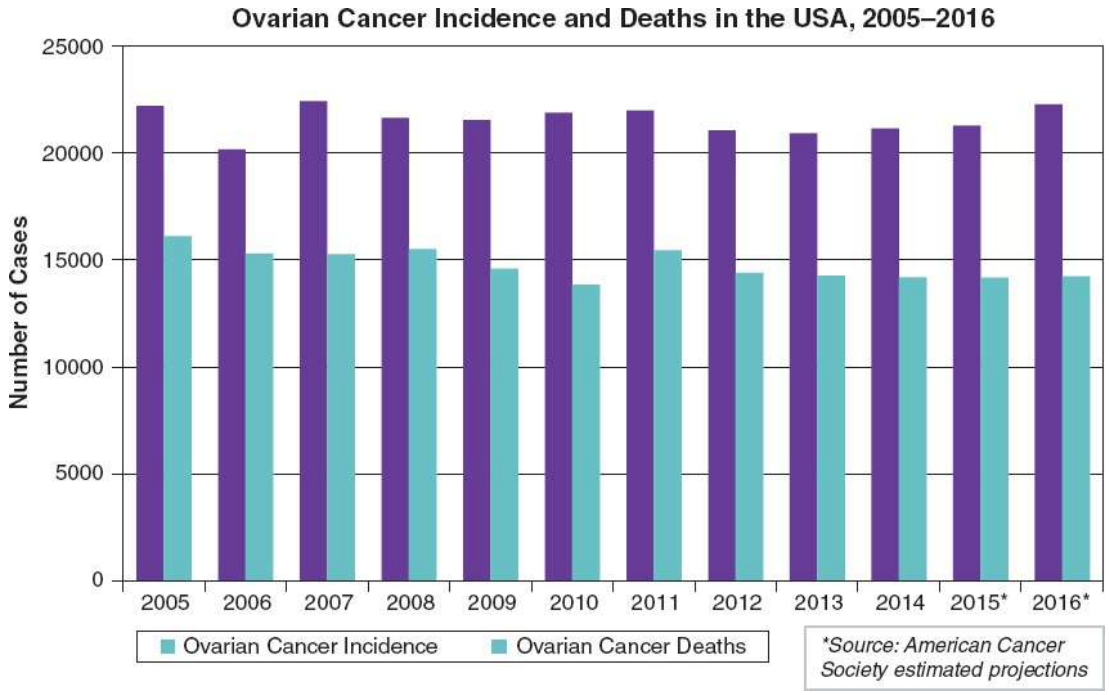

FIGURE 75.2. Ovarian cancer incidence and deaths in the United States from 2005 to 2016. (Courtesy of the American Cancer Society.)

High-grade serous ovarian carcinomas are infrequently associated with benign or borderline precursor lesions within the ovary, a contradiction of the OSE–CIC model. Furthermore, high-grade serous carcinomas of the ovary share distinct morphologic and genetic characteristics with high-grade serous carcinomas of other extrauterine sites, including serous fallopian tube carcinoma and primary peritoneal serous carcinoma. In this context, a second model of ovarian carcinogenesis has emerged with the recognition of the distal fallopian tube as the primary site of origin for many high-grade serous carcinomas. With rigorous pathologic processing, occult fallopian tube cancer has been detected in the fimbria of prophylactic salpingo-oophorectomy specimens from high-risk patients.[14,15] Furthermore, STICs have been found in a large proportion of high-grade serous carcinomas initially designated as primary ovarian cancers.[16] An adenoma–carcinoma sequence has since been described that involves a

dysplastic tubal precursor lesion with loss of p53 detectable by immunohistochemical staining ("p53 signature") with progression to a STIC characterized by increased proliferation, followed by the development of frank invasive serous carcinoma.[7,17] The concept of the fallopian tube as the primary site of high-grade serous carcinoma suggests that previously undetected serous STICs may spread to the adjacent ovary or peritoneal cavity early in the disease process of serous carcinogenesis.

In the two-pathway model of ovarian carcinogenesis, type I tumors include all major histologic subtypes (serous, endometrioid, mucinous, clear cell, and transitional) with low nuclear and architectural grade that may be linked to well-defined benign precursor lesions, and type II tumors account for the bulk of high-grade serous carcinomas (Table 75.1). The type I tumors are associated with distinct molecular alterations, such as mutations in *KRAS*, *BRAF*, and *PTEN*, which are rarely found in type II serous tumors.[18] Mutually exclusive *KRAS* and *BRAF* mutations, both of which activate the oncogenic *MAPK* signaling pathway, are observed in 65% of serous borderline tumors but are rarely seen in high-grade serous carcinomas.[19] *KRAS* mutations also occur in müllerian histologic subtypes, including 60% of mucinous, 5% to 16% of clear cell, and 4% to 5% of endometrioid carcinomas.[18] Mutations in *PTEN*, which lead to constitutive activation of the related PI3 kinase signaling pathway, have been detected in 20% of endometrioid carcinomas,[20] whereas activating mutations in *PIK3CA* have been identified in 30% of clear cell cancers.[21] Somatic mutations in *ARID1A*, a novel tumor suppressor gene, have been identified in 46% of ovarian clear cell cancers and 30% of endometrioid cancers. *ARID1A* mutation and corresponding loss of BAF250a expression, a key component in chromatin remodeling, were also seen in preneoplastic lesions and may represent an early event in the transformation of endometriosis.[22] In contrast, type II tumors exhibit a high frequency of p53 mutation and widespread DNA copy number change. Inactivation of the BRCA pathway, a critical component of DNA repair by homologous recombination, is also a hallmark of high-grade serous carcinomas.[23] Disruption of the BRCA pathway by germline or somatic mutation, epigenetic silencing, or microRNA regulation has been observed in >50% of serous cancers,[24] and functional assays show defective formation of homologous recombination repair foci following DNA damage.[25]

TABLE 75.1 TWO-PATHWAY MODEL OF EPITHELIAL OVARIAN CARCINOGENESIS

Type 1	Type 2
All müllerian subtypes (serous, endometrioid, mucinous, clear cell, transitional)	High-grade serous carcinoma
Usually low grade	High grade
Linked to benign or borderline precursor lesions	Associated with serous tubal intraepithelial carcinomas (STICs)
KRAS or *BRAF* mutation (MAPK pathway) *PTEN* or *PIK3CA* mutation (PI3K pathway) *ARID1A* mutation, loss of BAF250a expression	Inactivation of *BRCA* pathway
Wild-type p53 status	High frequency of p53 mutation
Chromosomally stable	Widespread DNA copy number change
Frequently platinum insensitive	Usually platinum sensitive

Angiogenesis plays an important role in normal ovarian function, as heavy vascularization occurs at the beginning of each ovulatory cycle with predictable variation in the serum levels of vascular endothelial growth factor (VEGF). Epithelial ovarian cancers frequently overexpress VEGF, fibroblast growth factor, platelet-derived growth factor (PDGF), and angiopoietin.[26] In preclinical models, expression of VEGF provides a survival advantage to transformed cells of the ovary. Other studies have found an association between preoperative serum VEGF level and clinical outcome.[27] Targeting the tumor microenvironment in ovarian cancer is an attractive treatment strategy given the inherent genomic instability of high-grade serous cancers.

RISK FACTORS

Epidemiologic studies have identified hormonal, genetic, and environmental factors that may play an important role in ovarian carcinogenesis (Table 75.2). The OSE–CIC model is consistent with well-established epidemiologic data indicating that suppression of ovulation results in substantial reduction of ovarian cancer risk. New insights into the pathogenesis of high-grade serous carcinomas have emerged through the study of high-risk populations with a genetic predisposition for the development of ovarian cancer. Nevertheless, the pathogenic mechanisms are not well understood and likely multifactorial, associated with both patient-related and environmental factors.

Patient-Related Factors

Risk factors associated with a higher frequency of ovulatory events, such as

advancing age, low parity, infertility, early menarche, and late menopause, support the proposed mechanism of incessant ovulation.[28–31] Although infertility is associated with ovarian cancer, the use of fertility drugs has not been conclusively linked.[32–34] Suppression of ovulatory events from pregnancy, breast feeding, and oral contraceptive use may explain the observed protective benefit.[30,31,35] With oral contraceptive use for 4, 8, or 12 years, the risk of ovarian cancer is reduced by 40%, 53%, and 60%, respectively.[36] In a collaborative meta-analysis of 45 epidemiologic studies from 21 countries, the use of oral contraceptives was significantly associated with a decreased risk of ovarian cancer in ever users (hazard ratio [HR] 0.73, $P < .0001$), with larger reductions observed for longer duration of use.[37] The authors conclude that 200,000 ovarian cancers and 100,000 deaths have been prevented since the introduction of oral contraceptives 50 years ago.

TABLE 75.2 FACTORS INFLUENCING THE RISK OF OVARIAN CANCER

Factor	Estimated Risk (%)	Estimated Relative Risk
Baseline lifetime risk	1.4	1
Race		
White	12.2 per 100,000	—
Hispanic or American Indian	10.6 per 100,000	—
African American	9.4 per 100,000	—
Risk factors		
Family history	9.4	5–7
BRCA1 mutation	35–46	18–29
BRCA2 mutation	13–23	16–19
Lynch II/HPNCC	3–14	6–7
Infertility	—	2–5
Obesity	—	1.1–4
Nulliparity	—	2–3
Late menopause	—	1.5–2
Early menarche	—	1–1.5
Unopposed estrogen use	—	1.2–2
Protective factors		
Multiparity	—	0.4–0.6
Oral contraceptive use	—	0.7
Hysterectomy or tubal ligation	—	0.6–0.7

Other patient-related risk factors such as polycystic ovarian disease and endometriosis may act through hormonal mechanisms attributable to elevated gonadotropins or by chronic inflammation. In a meta-analysis of eight case–control studies, women with polycystic ovarian disease had a 2.5-fold increase in ovarian cancer risk.[38] Endometriosis has been shown to be an independent risk factor for ovarian cancer with an estimated rate of malignant transformation of 2.5%.[39] Ovarian cancers that arise from endometriosis are most often low-grade tumors with endometrioid or clear cell histology and are associated with a better prognosis.[40] Altered hormonal levels such as elevated androgens may also increase risk, whereas progestins have been shown to be protective.[41] Large prospective cohort studies have demonstrated an increase in ovarian cancer risk and mortality with the use of exogenous estrogen and hormone replacement therapy.[42–44] Surgical procedures, including hysterectomy and tubal ligation, are independently associated with a 34% reduction each in ovarian cancer risk, although the protective mechanism is unknown.[29,45–47] Chronic inflammatory conditions such as pelvic inflammatory disease and tuberculous salpingitis were once believed to be causative factors in the development of fallopian tube malignancies, although this theory remains unproven.

Genetic Factors

Heredity tumors account for 10% to 15% of all ovarian cancers, and family history is the strongest risk factor after increasing age.[48,49] The risk of developing ovarian cancer in the general population is approximately 1.4%, whereas the lifetime risk for a woman with one first-degree family member with ovarian cancer is 5% and climbs to 7% with two first-degree relatives. If a hereditary syndrome is present, the lifetime risk is on the order of 25% to 50% with an age of diagnosis approximately 10 years younger than women with sporadic disease.[50]

Three distinct familial ovarian cancer syndromes have been identified by pedigree analysis with autosomal dominant patterns of inheritance.[51,52] *BRCA1* and *BRCA2* mutations are the most common genetic alterations, with up to 90% of all hereditary cases associated with a deleterious mutation of the *BRCA1* gene, located on chromosome 17q21, or the *BRCA2* gene, located on chromosome 13q22. The lifetime risk of ovarian cancer is approximately 40% in *BRCA1* mutation carriers and 18% in *BRCA2* mutation carriers.[53] BRCA-associated

ovarian cancers are most frequently invasive serous adenocarcinomas and less likely borderline or mucinous tumors.[54] Mutation carriers are also more likely to present with advanced-stage disease and have poorly differentiated tumors.[55] Nonetheless, *BRCA1* or *BRCA2* mutation carriers have a more favorable clinical course with a significantly longer recurrence-free and overall survival compared to noncarriers. The improved outcome appears related to a higher sensitivity to platinum chemotherapy across first and subsequent lines of treatment.[56–60]

The importance of the fallopian tube in the pathogenesis of extrauterine serous carcinoma was initially recognized in *BRCA1* and *BRCA2* mutation carriers. In a prospective study of 483 *BRCA1* mutation carriers, the incidence of fallopian tube cancer was reported as 120 times that of the general population.[61] High-grade serous primary peritoneal carcinomas are also frequently observed in mutation carriers.[62] Further attention was focused on the fallopian tube as the primary site of origin following reports of epithelial dysplasia and occult serous carcinomas in prophylactic salpingo-oophorectomy specimens from mutation carriers.[63–66] In contrast to the standard pathologic sampling of the ampullary region of the fallopian tube in ovarian cancer cases, more extensive complete sectioning of the tube revealed an abundance of lesions in the fimbria of the distal tube.[14–16] The detection of early serous carcinomas, or STICs, lent further support to the emerging concept of the fallopian tube as the primary site for extrauterine serous carcinoma. In this context, the National Comprehensive Cancer Network (NCCN) guidelines recommend that any woman with a diagnosis of ovarian, fallopian tube, or primary peritoneal carcinoma be referred to a cancer genetics professional for consideration of BRCA mutation testing.[67] BRCA screening in a population of women with non-mucinous ovarian cancer detected germline mutations in 14% of women, including 22% with high-grade serous cancer, reinforcing the importance of offering testing to all patients.[68]

Hereditary nonpolyposis colorectal syndrome, or Lynch type II cancer syndrome, is responsible for the remaining 10% of hereditary ovarian cancers.[69] In this syndrome, germline mutations of DNA mismatch repair genes lead to an increased risk of colorectal, stomach, endometrial, and ovarian cancer owing to underlying microsatellite instability. A total of seven mismatch repair genes have been identified with mutations in *MLH1* and *MSH2* accounting for 90% of the observed mutations in Lynch syndrome families.[70,71] Mutations in *MSH6* and *PMS2* have been reported in the remaining 10% of families, whereas alterations in the remaining three identified genes are uncommonly observed. Inactivating mutations in specific genes may modify the underlying cancer predisposition.

Women with *MSH6* mutations are twice as likely to develop endometrial cancer compared to carriers of *MSH2* or *MLH1* gene mutations, which are the most common alterations underlying colorectal cancer risk.[72] Women with *MSH2* gene mutations have been shown to have a risk of epithelial ovarian cancer twice that of *MLH1* carriers. In contrast to *BRCA1* and *BRCA2* mutation carriers, women with Lynch syndrome may present with a variety of non-serous epithelial tumor types, including endometrioid and clear cell histologies. Ovarian cancer associated with Lynch syndrome is more often diagnosed at an earlier stage with well- to moderately differentiated tumor grade. The lifetime risk of ovarian cancer in women with Lynch syndrome is estimated at 3% to 14% and is most commonly diagnosed in the fifth decade of life.[73] In women with a family or personal history suggestive of Lynch syndrome, tumor testing may be performed by microsatellite instability analysis or immunohistochemical staining for mismatch repair genes. Direct sequencing of the mismatch repair genes is used for detection of germline mutations. Other less common germline mutations have been identified by genomic sequencing and involve the following genes: *PALB2, BARD1, BRIP1, RAD51C, RAD51D, MSH2, MLH1, PMS2, and MSH6*.[74]

Other genetic disorders linked with nonepithelial ovarian cancers include Peutz-Jeghers syndrome, which is associated with an increased risk of sex cord–stromal tumors, and gonadal dysgenesis, associated with dysgerminomas and gonadoblastomas.

Environmental Factors

Environmental or physical causes of ovarian cancer have been investigated through numerous case–control studies. Women in developing countries have a lower incidence of ovarian cancer than those living in industrialized nations,[75] although, to date, no specific chemical carcinogens have been identified. Chronic exposure to asbestos-related products, including talc products, has long been implicated in the development of ovarian cancer.[76] The Nurses' Health Study reported a modestly elevated risk of invasive serous cancers with talc use (relative risk [RR] 1.4), although no association was detected with overall ovarian cancer risk.[77] The development of mucinous ovarian cancer has been found to be associated with cigarette smoking (RR 2 to 2.2) but not other epithelial subtypes.[78,79]

Dietary and metabolic factors have also been explored in large population-based studies as possible contributors to ovarian cancer risk. To date, there have

been no consistent associations of coffee or alcohol consumption with increased risk. Large epidemiologic studies also showed no relationship between consumption of animal fat and the development of ovarian cancer.[80,81] In a Swedish population–based cohort study of the effect of body mass index on cancer risk in >35,000 women, a 36% higher risk of cancer was observed in obese women (body mass index ≥ 30) relative to women with body mass index in the normal range (18.5 to 25); cancer sites most strongly related to obesity were endometrium, ovary (risk for top quartile 2.09; 95% confidence interval [CI], 1.13 to 4.13), and colon.[82] Obesity has also been associated with increased ovarian cancer mortality in a large prospective study of adults in the United States.[83] There is no clear relationship between exercise and ovarian cancer risk.

SCREENING

In the absence of a reliable screening test, most women with ovarian cancer are diagnosed with advanced-stage disease. In contrast to women with localized disease (stage I/II) who have estimated 5-year survival rates of 70% to 90%, overall survival for women with advanced disease (stage III/IV) is poor, ranging from 20% to 45% (Table 75.3). The low sensitivity and specificity of the available screening modalities and the low prevalence of the disease in the general population have hindered the development of a robust screening test. Recent screening approaches have been associated with a low positive predictive value and unacceptable false-positive rates without impacting disease mortality in the general population or high-risk groups.

Several screening strategies have been investigated, including pelvic exam, the serum tumor marker CA-125, and transvaginal ultrasound (TVUS), either alone or in combination.[84] CA-125 values >35 U/mL are observed in 80% of patients with epithelial ovarian cancer, including 90% of women with advanced-stage disease, but only in 50% of early-stage patients.[85] CA-125 is nonspecific for ovarian cancer, as it can be elevated in benign gynecologic and non-gynecologic conditions, including endometriosis, uterine leiomyoma, cirrhosis, pelvic inflammatory disease, the presence of pleural or peritoneal fluid, as well as endometrial carcinoma and non-gynecologic cancers of the breast, lung, and pancreas. Screening with CA-125 alone has been found to lack specificity in an average-risk population of postmenopausal women. Ultrasound alone is able to detect early-stage disease in an average-risk population,[86–88] although the significant false-positive rate remains a concern. In a United Kingdom multimodality screening study, diagnostic surgeries were performed nine times more frequently to detect one cancer in the group screened by TVUS alone compared to multimodality screening (CA-125 and TVUS).[89]

Several large screening trials currently in progress in the United States, United Kingdom, and Japan have been designed to assess reduction in mortality with early detection of ovarian cancer. The Prostate, Lung, Colorectal, and Ovarian Cancer (PLCO) screening trial in the United States randomized 78,216 women aged 55 to 74 to annual screening with CA-125 and TVUS versus usual medical care. Following baseline screening, 570 surgical procedures, including 325 laparotomies, were performed; 29 tumors were detected, 9 of which were of LMP.[90] The positive predictive value for the detection of invasive ovarian cancer was 3.7% for an abnormal CA-125, 1.0% for an abnormal TVUS, and 23.5% for both. Publication of the mortality data with 12-year follow-up showed no difference in the stage of cancer detected by screening (90% stage III or IV) and no reduction in cause-specific or overall mortality for women who underwent screening.[91] Furthermore, diagnostic evaluation for women with false-positive screening resulted in a serious complication rate of 15%.

A second trial, the United Kingdom Collaborative Trial of Ovarian Cancer Screening (UKCTOCS), has accrued >200,000 postmenopausal women to

evaluate multimodality screening with TVUS and serum CA-125. In the prevalence screen, the sensitivity, specificity, and positive predictive values of multimodality screening for invasive epithelial ovarian and tubal cancers were 89.5%, 99.8%, and 35.1%, respectively.[89] The initial results of baseline screening were more promising than the US study, with 43% of invasive cancers detected as stage I or II, which may reflect differences in study design and the diagnostic algorithm. However, after a median follow-up of 11 years, a significant mortality reduction with multimodality screening was not observed.[92] The multicenter, randomized Japanese study utilizes a similar screening strategy with TVUS and CA-125 and has accrued >80,000 women. Unlike the US and UK trials, there was a nonsignificant trend for the detection of more stage I cancers in the screened population (63% vs. 38%), although mortality rates have not yet been reported.[93]

The present data do not support routine screening for ovarian cancer in the general population. All of the North American expert groups, including the U.S. Preventive Services Task Force, the American College of Obstetricians and Gynecologists (ACOG), the Society of Gynecologic Oncologists (SGO), and the Canadian Task Force on the Periodic Health Examination, recommend against routine screening in asymptomatic women. The incidence of ovarian cancer is relatively low in the general population; thus, the concerns for false-positive screening and the associated risks of exploratory surgery are significant.[94] However, women at high risk for ovarian cancer with *BRCA1* or *BRCA2* mutations or hereditary nonpolyposis colorectal syndrome could potentially benefit from chemoprevention; screening with pelvic examinations, TVUS, and CA-125 on a biannual or annual basis; or prophylactic surgery.[95] Although the efficacy of screening has been disappointing in the high-risk population,[96] some physicians will follow women with high risk factors, such as *BRCA* mutation or family history, with pelvic exam, CA-125, and TVUS. The U.S. National Institutes of Health Consensus Development Panel recommends that prophylactic salpingo-oophorectomy be considered in women with ovarian cancer syndromes at age 35 years or after childbearing is complete, as the risk reduction with salpingo-oophorectomy is 80%.[98,99] Removal of the ovaries also reduces the risk of breast cancer in BRCA mutation carriers.[100]

HISTOLOGIC CLASSIFICATION

The World Health Organization and International Federation of Gynecology and

Obstetrics (FIGO) have adopted a unified classification of the common epithelial, germ cell, sex cord, and stromal tumors[101,102] (Table 75.4). Most ovarian malignancies (60% to 65%) are epithelial, with germ cell tumors (20%), sex cord–stromal tumors (5%), and metastases to the ovary (5% to 10%) accounting for the remainder.[103] Serous tumors are most common, comprising 50% to 60% of epithelial tumors. Other subtypes include mucinous carcinoma in 10%; endometrioid carcinoma, 8%; clear cell carcinoma, 3% to 5%; transitional, 3% to 5%; and undifferentiated carcinoma, 1%. Bilateral presentation occurs frequently in epithelial tumors, most commonly in serous tumors followed by endometrioid (15%) and mucinous tumors (5% to 10%).

High-grade serous carcinomas are often widely disseminated at diagnosis and account for most deaths from ovarian, tubal, and peritoneal cancers. In contrast, 5-year survival for low-grade serous carcinoma is 85%. Most serous tumors present as large ovarian masses and grossly appear nodular with multiple papillary projections and cysts filled with clear serous fluid. A two-tiered grading system separates high-grade serous carcinomas from low-grade tumors,[104,105] which have a similar prolonged natural history to noninvasive borderline tumors, or tumors of LMP.[106] As discussed previously, there is increasing evidence that high-grade serous carcinomas originate in the fimbria of the fallopian tube and may spread rapidly to the adjacent ovary and peritoneal sites. Low-grade tumors appear to follow a stepwise progression from borderline tumor to invasive carcinoma and involve molecular pathways distinct from their high-grade counterparts.[107–109] Although treatment is similar for all serous tumors, low-grade tumors have been shown to be less responsive to chemotherapy.[106,110,111]

TABLE 75.4 WORLD HEALTH ORGANIZATION CLASSIFICATION OF OVARIAN TUMORS

Serous low-grade carcinoma
Serous high-grade carcinoma
Mucinous carcinoma
Endometrioid carcinoma
Clear cell carcinoma
Malignant Brenner tumor
Seromucinous carcinoma
Undifferentiated carcinoma
Germ cell tumors
Dysgerminoma
Yolk sac tumor

- Carcinoid
- Neuroectodermal-type tumors
- Sebaceous tumors
- Carcinomas

Mixed epithelial and mesenchymal tumors
- Carcinosarcoma
- Adenosarcoma

LMP or borderline tumors have nuclear abnormalities and mitotic activity intermediate between benign and malignant tumors of similar cell type but lack stromal invasion (Fig. 75.3). Borderline tumors are a subcategory of ovarian malignancies that account for 10% to 20% of all epithelial neoplasms.[112,113] The prognosis, surgical approach, and postoperative treatment recommendations are vastly different as compared with those of their invasive counterparts. The majority of LMPs (75%) present with stage I disease, which directly contrasts with the 75% advanced stages in the invasive epithelial tumors. The 5- and 10-year survival rates for women with LMP tumors are >95%. Significant heterogeneity exists in the biologic behavior of borderline tumors. Women with

nonlocalized LMP tumors of the ovary have decreased survival compared to those with localized LMP tumors but is similar to that of women with localized, well-differentiated epithelial ovarian carcinoma.[114] Other pathologic features that affect prognosis include the cell type, tumor stage, implant type (invasive vs. noninvasive), the presence of micropapillary architecture, and microinvasion. Extensive sampling of all pathologic specimens is required to firmly establish the diagnosis.

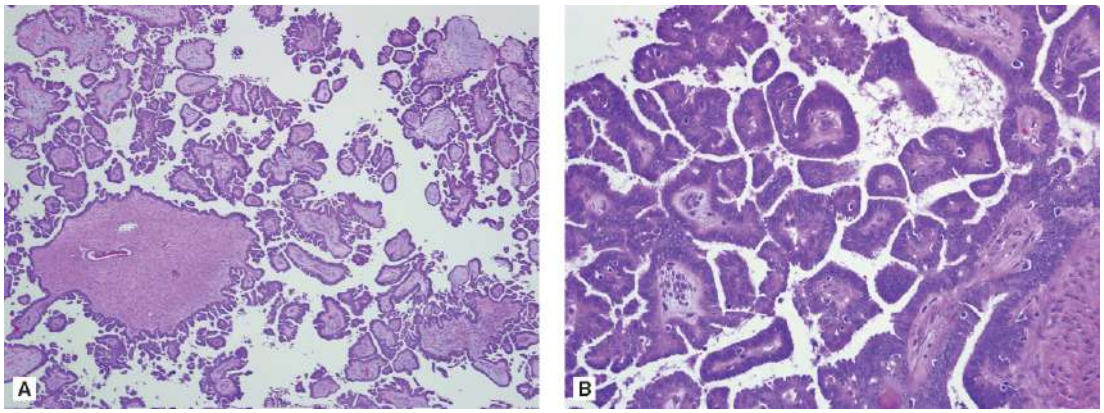

FIGURE 75.3. Serous tumor of low malignant potential of the ovary at low power **(A)** and high power **(B)**. At low power, note the progressively branching papillary fronds with fibrovascular support and detached papillary clusters; at high power, note the serous epithelium with nuclear hyperchromasia and cytologic atypia. By definition, there is no destructive stromal invasion.

Most endometrioid and clear cell carcinomas arise in foci of endometriosis and follow an adenoma to borderline tumor to carcinoma sequence. Endometrioid carcinoma of the ovary resembles its endometrial counterpart (Fig. 75.4), and synchronous primary cancers are detected in 10% of women with ovarian cancer and 5% of women with endometrial cancer.[115] Bilateral ovarian involvement, small multinodular ovaries, and surface and hilar spread suggest metastatic involvement from an endometrial primary, particularly if the endometrial tumor is high grade, deeply invasive, and associated with lymphovascular invasion. A large, cystic, unilateral tumor of low grade arising in a focus of endometriosis likely represents a primary ovarian tumor. Endometrioid tumors appear to have a better prognosis than serous cancers regardless of tumor stage.[116] Multiple synchronous primary tumors may represent a field defect related to endometriosis, which is associated with improved survival.[117]

Mucinous tumors follow a similar progression from cystadenoma to borderline tumor prior to invasion. All subtypes are more likely to be diagnosed

when confined to the ovary. Mucinous cancers may grow to a very large size, often measuring up to 20 cm in diameter and filled with large pockets of thick, necrotic, mucinous debris.[118,119] Ovarian mucinous tumors closely resemble mucin-secreting tumors originating from other sites—most commonly the gastrointestinal tract. The pathologic distinction between primary and metastatic mucinous carcinoma may be challenging, despite the use of immunohistochemical analysis. Further clinical evaluation is often required to exclude a clinically occult non-ovarian primary source. Secondary involvement of the ovary may also occur in association with pseudomyxoma peritonei arising from a low-grade tumor often of appendiceal origin.[120]

Clear cell carcinoma is characterized by clear and hobnail cells with a similar histologic appearance to clear cell carcinoma of the kidney, endometrium, and vagina. Ovarian clear cell carcinoma is often seen in association with venous thromboembolism and hypercalcemia. Although more likely to be stage I than serous carcinoma, clear cell histology is associated with a lower response rate to platinum-based chemotherapy, higher recurrence rate, and worse survival.[121] The transitional cell tumors, including Brenner tumors, are benign in most cases (98%) and carry a favorable prognosis.

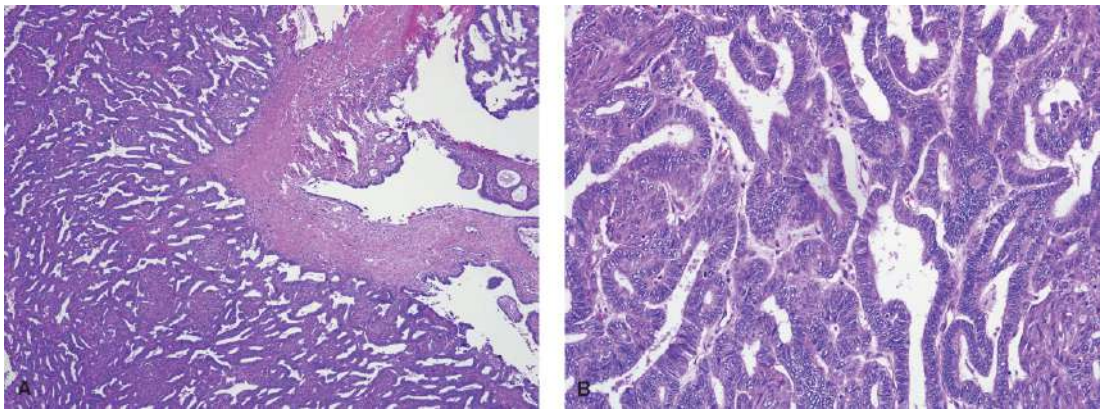

FIGURE 75.4. Endometrioid adenocarcinoma of the ovary. **A:** At low power, note the tumor composed of back-to-back endometrioid glands. **B:** At high power, note the squamous metaplasia, commonly seen in this epithelial variant. Assignment of tumor grade is based on similar criteria as for carcinomas arising in the endometrium. This tumor would qualify as well differentiated or grade 1.

Ovarian germ cell tumors comprise <5% of ovarian malignancies and are classified by the World Health Organization (Table 75.4). Dysgerminomas are the most common of the germ cell tumors and occur bilaterally in 10% to 20% of cases. The other germ cell tumor types are typically unilateral. Endodermal sinus tumors, also known as yolk sac tumors, are characterized by Schiller-Duval

bodies. Embryonal carcinomas are rare and tend to occur in younger populations; they may be seen with nongestational choriocarcinomas as part of mixed germ cell tumors (10% of all germ cell tumors). Immature teratomas are characterized by immature elements from the germ layers. The grade, treatment recommendations, and outcome are directed by the amount of immature neural elements.

Sex cord–stromal tumors are also classified by the World Health Organization (Table 75.4), with granulosa cell tumors being the most common (70%). Histologically, the granulosa cell tumors are composed of granulosa cells that have a pale, grooved, “coffee bean” nucleus or a rosette of cells surrounding eosinophilic material, a Call-Exner body. Thecomas (hormonally active) and fibromas (hormonally inactive) are both clinically benign tumors and are most common in middle-age women.

The most common histopathology of primary fallopian tube malignancies is papillary serous adenocarcinoma. Other less common müllerian subtypes include endometrioid, clear cell, and malignant mixed müllerian tumors.[122,123] Rare reports of squamous cell carcinoma, immature teratoma, glassy cell tumor, and sarcoma have also been described. Benign tumors are found even less frequently than malignant neoplasms. Metastatic involvement of the fallopian tube is reported in up to 12% of women with uterine cancer and 4% with cervical cancer.[124,125]

PATTERNS OF SPREAD

The primary mode of spread for epithelial ovarian and fallopian tube cancers is transperitoneal, as malignant cells exfoliate into the peritoneal cavity. Intraperitoneal spread is favored by intestinal peristalsis and negative hydrostatic pressure below the diaphragm. The exfoliated tumor cells follow the intra-abdominal fluid stream passing along the paracolic gutters toward the diaphragm, predominately on the right side, before implantation on any peritoneal surface.[126,127] Metastatic deposits are frequently seen in the posterior cul-de-sac, paracolic gutters, diaphragmatic surfaces, liver capsule, intestinal surfaces, and omentum. Metastases may also be found in the uterus or contralateral ovary from peritoneal spread or flow through the fallopian tubes. Dense tumor “caking” can cause infiltration into the abdominal organs creating a mass effect on the omentum, ureter, bowel, liver, pancreas, spleen, or adrenals, resulting in advanced disease stage at presentation with associated ascites.

Lymphatic drainage constitutes the second most common pattern of spread. The lymphatic capillaries of the ovary converge on the hilus and follow the ovarian blood vessels in the infundibular ligament to drain to the para-aortic nodes at the level of the renal hilum. Lymphatics also drain along the broad ligament to the hypogastric and external iliac nodes in the pelvis. Less frequently, spread can occur to the inguinal nodes via the round ligament.[128] Approximately 10% to 15% of women with disease that appears confined to the ovary have para-aortic lymph node involvement,[129] which becomes increasingly common in advanced-stage disease. Because of the rich lymphatic supply of the fallopian tubes, lymph node involvement is common even in the absence of tubal musculature involvement.[130] Pelvic and para-aortic lymph node involvement has been reported in 10% to 30% of women with fallopian tube cancer at diagnosis.[131]

Transdiaphragmatic spread occurs to the pleural cavity and is the most common finding in stage IV disease. Hematogenous spread is infrequent at the time of presentation, with only 2% to 3% of patients with parenchymal liver or lung disease. Brain metastasis is also rare. However, >50% of recurrences occur both within and outside the peritoneal cavity at the time of treatment failure.

CLINICAL PRESENTATION

As ovarian cancer has insidious growth and is asymptomatic in early-stage disease, most women do not present until symptoms arise from advanced disease progression. Vague gastrointestinal complaints of dyspepsia, nausea, early satiety, bloating, constipation, or obstipation are common presenting symptoms, as are genitourinary symptoms including frequency, urgency, or incontinence. Other ill-defined symptoms include fatigue, back pain, pain with intercourse, and menstrual irregularities. These nonspecific symptoms can be present for several months but may not trigger diagnostic evaluation until after the symptoms fail to clear with other medical therapy.[132] Detection of early-stage disease may occur by palpation of an asymptomatic adnexal mass on routine examination, although most adnexal masses require moderate size for palpation. In premenopausal women, most of these masses are benign, as ovarian cancer represents <5% of adnexal neoplasms. An adnexal mass in a postmenopausal woman has a higher likelihood of malignancy, and surgical exploration is often indicated. Physical examination findings such as a fixed pelvic mass, palpable upper abdominal mass, and ascites are highly suggestive of an ovarian

malignancy. According to a consensus statement on the symptoms of ovarian cancer published by the Gynecologic Cancer Foundation, SGO, and American Cancer Society, new and persistent symptoms of bloating, pelvic or abdominal pain, difficulty eating, early satiety, or urinary urgency or frequency should prompt women to seek medical evaluation.

A portion of women with fallopian tube carcinoma may present with early clinical signs and symptoms. Two triads have been described as pathognomonic for fallopian tube malignancy: (a) pelvic pain, pelvic mass, and leukorrhea and (b) vaginal bleeding, vaginal discharge, and lower abdominal pain. However, the percentage of patients presenting with either triad of symptoms has been reported as low as 11%.[133] Another classic sign—hydrops tubae profluens—is a sudden emptying of accumulated fluid in the distended fallopian tube that causes profuse, watery, serosanguineous vaginal discharge. The discharge is often accompanied by a decrease in pelvic mass size on physical examination. In a meta-analysis of 122 patients with primary fallopian tube cancer, hydrops tubae profluens was a presenting sign in only 9%.[124] In other series,[127,130] it has been specifically reported that neither a triad nor hydrops tubae profluens was present in any of the patients reviewed. When clinically apparent, the fallopian tube may be dilated and mimic more benign pathologic processes such as hydrosalpinx, pyosalpinx, or hematosalpinx.[134] In more advanced disease with tubal wall invasion, extension of a necrotic mass to involve the ovary may give the initial impression of a tuboovarian abscess.

Germ cell and stromal cell malignancies present at an earlier stage than epithelial ovarian or fallopian tube cancers, often related to abdominal discomfort or symptoms of excessive estrogen or androgen production. Granulosa cell tumors may lead to precocious puberty in young girls, and Sertoli-Leydig cell tumors may cause virilization.

DIAGNOSTIC WORKUP

Evaluation of a pelvic mass will be influenced by the patient's age, clinical presentation, and imaging features. An ovarian mass is more likely to be a malignant neoplasm in the pediatric, perimenopausal, and postmenopausal age groups and benign during the reproductive years. Ultrasound is often the first, noninvasive step for the evaluation of a pelvic mass. Sonographic characteristics suggestive of malignancy include irregular borders, a solid component that is not hyperechoic and often nodular or papillary, Doppler demonstration of flow in the

solid component, dense multiple irregular septa (>2 to 3 mm), and the presence of ascites, peritoneal masses, enlarged nodes, or matted bowel. Computed tomography (CT) or magnetic resonance imaging (MRI) of the abdomen and pelvis (performed with contrast) may be useful preoperatively to assess disease extent for surgical planning.[135–137] FDG-PET-CT may also be used to characterize indeterminate lesions and has increased sensitivity for the detection of occult metastatic disease when compared with CT alone or MRI, although further study is warranted.[97,138,139] Although limited as a screening tool,[140] an elevated CA-125 level may suggest more advanced or greater bulk of disease and high-grade serous histology but in general is a weak predictor of surgical resection.[141,142] Human chorionic gonadotropin (β-hCG), α-fetoprotein (AFP), total inhibin, and lactate dehydrogenase levels may aid in the diagnosis of and treatment for nonepithelial germ cell ovarian tumors, particularly in women younger than age 35 years with a pelvic mass.[143,144]

Other conditions may mimic ovarian cancer in their presentation, including colon, gastric, and appendiceal carcinomas as well as metastatic breast cancer and primary lymphoma.[145] Although ideally the primary site of disease is determined in the preoperative setting, the diagnosis often cannot be made accurately until the time of surgery, and frozen section pathologic evaluation may guide surgical approach. Among gynecologic malignancies, primary endometrial and cervical cancer may also present with an adnexal mass, and synchronous tumors of the ovary and endometrium have been reported in up to 10% of women, often in the setting of Lynch syndrome or an estrogen-secreting tumor.[115,146] Primary malignancies of the fallopian tube have been difficult to diagnose prior to surgical exploration, as the clinical presentation may be similar to that of salpingitis, ovarian abscess, pelvic inflammatory disease, or even ectopic pregnancy. Occult tubal primaries may be detected only by careful pathologic processing of the fimbriated tubal end.[147]

Referral to a gynecologic oncologist should be considered for any woman with a suspicious pelvic mass, family history of ovarian or fallopian tube cancer, or elevated CA 125.[148] Initial evaluation should include a thorough history and full physical and pelvic examination, laboratory studies (complete blood count, chemistries), and imaging (abdominal and pelvic CT/MRI, directed ultrasound, chest x-ray, or CT). The NCCN guidelines do not recommend the use of biomarkers such as CA-125 or HE4 for determining the status of an undiagnosed pelvic mass.[140] However, a baseline CA-125 drawn prior to surgery may be useful in follow-up to evaluate treatment response and monitor for recurrence.

Further evaluation with mammography, upper gastrointestinal endoscopy, or colonoscopy may be indicated in some scenarios to exclude an extraovarian primary cancer.[149] If possible, fine needle aspirate (FNA) for diagnostic purposes should be avoided in patients with presumed early-stage disease to prevent cyst rupture and tumor spillage, although it is often necessary in patients with bulky, nonoperable disease. Comorbid conditions may prompt additional evaluations, including cardiac risk assessment, pulmonary function testing, and nutritional evaluation.

SURGICAL STAGING

Surgical advances in staging and the therapeutic benefit of a maximal safe tumor resection have improved the progression-free and overall survival of women with ovarian cancer over the past two decades. Surgical staging for ovarian cancer is based on the FIGO staging system as shown in Table 75.5,[150] which was updated in 2014 and approved by the American Joint Committee on Cancer. In 2018, the FIGO/AJCC staging guidelines will combine staging for ovarian and fallopian tube carcinoma.

TABLE 75.5 FIGO STAGING FOR OVARIAN, FALLOPIAN TUBAL, AND PERITONEAL CARCINOMA

Stage I Tumor limited to the ovaries or fallopian tube(s)
IA Tumor limited to 1 ovary; ascites and peritoneal washings negative for malignant cells. No tumor on the external surface of ovary or fallopian tube; ovarian capsule intact
IB Tumor limited to both ovaries or fallopian tubes; ascites and peritoneal washings negative for malignant cells. No tumor on the external surfaces of ovaries or fallopian tubes; ovarian capsules intact
IC Tumor stage IA or IB, and including any of the following:
IC1: Surgical spill of ovarian or fallopian tube contents
IC2: Ovarian capsule ruptured before surgery, or tumor on surface of the ovaries or fallopian tube(s)
IC3: Ascites or peritoneal washings positive for malignant cells
Stage II Tumor involving 1 or both ovaries with pelvic extension or primary peritoneal cancer
IIA Extension and/or implants on the uterus and/or fallopian tubes and/or ovaries
IIB Extension to other intraperitoneal pelvic tissues (below pelvic brim)
Stage III Tumor involving 1 or both ovaries or fallopian tubes, or primary peritoneal cancer, with pathologically confirmed peritoneal implants outside the pelvis and/or positive retroperitoneal lymph nodes
IIIA Tumor grossly limited to the true pelvis, but with pathologically confirmed retroperitoneal lymph nodes or microscopic seeding of extrapelvic peritoneal surfaces (above the pelvic brim)
IIIA1: Positive retroperitoneal lymph nodes only
IIIA2: Microscopic seeding of extrapelvic peritoneal sites, with or without retroperitoneal nodal

involvement
IIIB Macroscopic peritoneal metastases involving extrapelvic peritoneal surfaces up to 2 cm in greatest dimension, with or without retroperitoneal nodal involvement
IIIC Macroscopic peritoneal metastases involving extrapelvic surfaces more than 2 cm in greatest dimension, with or without retroperitoneal nodal involvement. Tumor may extend to the capsule of the liver or spleen without parenchymal involvement.
Stage IV Presence of distant metastasis outside the peritoneal cavity.
IVA: Pleural effusion with positive cytology
IVB: Parenchymal metastasis (including the liver and spleen) and metastases to extra-abdominal organs, including the inguinal lymph nodes and nodal basins outside the abdomen and pelvis

Comprehensive surgical staging is the mainstay of diagnosis and initial treatment for ovarian, fallopian tube, and peritoneal cancers.[140] Based on improved outcomes, surgical staging and cytoreduction should be performed by a gynecologic oncologist.[151,152] In apparent early-stage cancers, surgical evaluation is required for accurate pathologic staging to guide adjuvant treatment recommendations. In patients with advanced disease, surgery represents the initial treatment by providing optimal cytoreduction. Comprehensive surgical staging begins with an exploratory laparotomy via a vertical midline incision followed by collection of peritoneal washings or any ascitic fluid for cytology. Select patients with early-stage disease may be candidates for minimally invasive procedures if performed by an experienced gynecologic oncologist.[153–155] The surgeon performs a thorough inspection of all visceral and peritoneal surfaces within the abdomen and pelvis, with particular attention to the intestinal serosal surfaces, mesentery, paracolic gutters, hemidiaphragms, gallbladder, and liver. Any peritoneal surface or adhesion that is suspicious for metastasis should be excised of biopsied. In the absence of suspicious areas, random peritoneal biopsies should be taken from the pelvis, paracolic gutters, and/or undersurfaces of the hemidiaphragms.[140] Total hysterectomy, bilateral salpingo-oophorectomy, and omentectomy should be performed with intact removal of the adnexal mass when possible. NCCN guidelines state that pelvic and para-aortic nodal dissection should be performed in patients with pelvic-confined disease or extrapelvic implants measuring 2 cm or less (presumed stage IIIB disease), although recent level 1 data suggest that there is not a therapeutic benefit for lymphadenectomy in clinically node-negative patients with advanced disease.[156] Every effort should be made to achieve maximal cytoreduction of all

gross disease in the pelvis, abdomen, and retroperitoneum.[157] In patients with advanced disease, bowel resection and/or appendectomy, diaphragm stripping, splenectomy, partial cystectomy and/or ureteroneocystostomy, partial hepatectomy, partial gastrectomy, cholecystectomy, and/or distal pancreatectomy may be considered. In the operative report, the surgeon should describe the following: (1) the extent of initial disease prior to cytoreduction; (2) the amount of residual disease following cytoreduction; and (3) whether a complete or incomplete resection was performed (including a description of the size and number of residual lesions).[140,158] In select cases, preservation of the contralateral unaffected ovary and the uterus can be achieved in young women wishing to retain fertility who have stage I (stage 1A or 1C, but not 1B) and/or low-risk tumors (early-stage, low-grade invasive tumors, LMP/borderline lesions, or malignant stromal or germ cell tumors).[140,159,160] In the setting of unilateral salpingo-oophorectomy, comprehensive surgical staging should be performed to exclude occult disease. Exceptions to upfront surgical management include patients with significant medical comorbidities who are poor operative candidates and patients with a complex ovarian cyst where extraovarian disease has not been excluded. Neoadjuvant chemotherapy followed by interval cytoreduction may be considered in patients with bulky stage III or IV disease. Before initiation of neoadjuvant chemotherapy, the pathologic diagnosis should be confirmed by biopsy, FNA, or paracentesis. The NCCN guidelines recommend that patients who are evaluated for neoadjuvant chemotherapy be seen by a fellowship-trained gynecologic oncologist before being deemed a nonsurgical candidate.[140]

PROGNOSTIC FACTORS

Tumor stage, grade, histology, and optimal cytoreduction by a trained gynecologic oncologist are the most important determinants of survival for ovarian and fallopian tube cancer. Patients with FIGO stage 1A disease who have negative staging laparotomy have 5-year survival rates of 80% to 90%. If extrapelvic disease is detected at the time of surgical staging, the patient is upstaged to stage III disease with corresponding 5-year survival rates of 30% to 50%. Primary or interval cytoreductive surgery should be performed by a gynecologic oncologist based on published evidence of a 6- to 9-month median survival benefit.[151,152,161]

The volume of residual disease after primary surgery is also an important

determinant of outcome.[162–167] The extent of cytoreduction may be defined as complete, no gross visible disease; optimal, residual disease that is 1 cm or less in maximal tumor diameter (GOG definition); or suboptimal, residual tumor nodules greater than 1 cm. Patients who have optimal cytoreduction of tumor have a 22-month improvement in median survival compared to those with suboptimal resection. In a meta-analysis of 18 studies, which included over 13,000 women with stage IIB or higher ovarian, tubal, or peritoneal carcinoma, each 10% increase in the proportion of patients undergoing complete cytoreduction showed a 2.3-month increase in median survival when compared to a 1.8-month increase for those with optimal cytoreduction.[167] Complete cytoreduction has also been associated with improved response to chemotherapy and less platinum resistance.[166,168] Preoperative CA-125 measurement is not independently prognostic, as it likely reflects disease burden. In contrast, the half-life and nadir of CA-125 during induction chemotherapy are associated with improved outcome in ovarian and fallopian tube cancers.[123,169–173]

Although a strong correlation exists between histologic grade and stage, grade has independent prognostic significance, particularly in early-stage disease. Survival rates for stage I disease with grade 1, 2, or 3 tumors are 96%, 78%, and 62%, respectively.[174] The impact of histologic subtype on survival is less robust owing to other more important clinical variables, including stage, grade, and volume of disease. Patients with mucinous and endometrioid subtypes have improved survival rates compared to serous adenocarcinoma, predominately related to the earlier stage at presentation. Clear cell carcinomas appear to be more aggressive than other epithelial malignancies. The 5-year survival rate for stage I clear cell carcinoma is 60% and for other stages is <15%.[121] Younger patients also have a more favorable prognosis, as they are more likely to have tumors of lower grade and less aggressive histology, as well as better baseline performance status.[175]

MANAGEMENT OF EPITHELIAL TUMORS

Treatment for ovarian and fallopian tube cancer depends largely on the stage and grade of disease at presentation. Table 75.6 presents a general schematic for treatment recommendations for women with epithelial ovarian, fallopian tube, and primary peritoneal cancer.

Early-Stage Disease

Surgical Therapy

Comprehensive surgical staging should be performed in all women with apparent early-stage disease to confirm that the cancer is confined to the adnexa. Fertility-sparing surgery with unilateral salpingo-oophorectomy may be considered in a small subset of women with stage IA disease if the contralateral ovary is normal in appearance.[176] In addition to abdominal exploration and full surgical staging, endometrial biopsy should be considered to sample the endometrium.

Postoperative Management

Early studies by the Gynecologic Oncology Group (GOG) and others have identified a small subgroup of patients with well- to moderately differentiated (grade 1 or 2) stage IA and IB tumors who have a low risk of relapse and may not require adjuvant therapy.[177,178] The NCCN guidelines state that women with early-stage (FIGO IA or IB) grade 1 endometrioid carcinoma of the ovary may be treated with surgical resection and observation with expected 5-year survival rates on the order of 90%.[140,179] If observation is considered for women with early-stage grade 2 disease, full surgical staging should be performed.

TABLE 75.6 SCHEMATIC OF THE PRIMARY TREATMENT FOR EPITHELIAL OVARIAN CANCER

Low risk, early stage	
Stage IA/B, grade 1	Observation
Stage IA/B, grade 2	Observation or IV taxane/carboplatin for 3–6 cycles
High risk, early stage	
Stage IC, all grades	IV taxane/carboplatin for 3–6 cycles
Stage IA/B, grade 3	IV taxane/carboplatin for 3–6 cycles
Stage II	IV taxane/carboplatin for 6 cycles IP chemotherapy in optimally cytoreduced patients
Advanced stage	
Optimal cytoreduced stage III	IP chemotherapy IV taxane/carboplatin for 6 cycles Clinical trial
Suboptimal cytoreduced stage III/IV	IV taxane/carboplatin for 6 cycles Clinical trial Interval cytoreduction if indicated by tumor response and resectability

IP, intraperitoneal; IV, intravenous.

Adjuvant Chemotherapy

Women with early-stage disease and a less favorable prognosis include patients with grade 3 tumors, clear cell histology, or disease extension beyond the ovarian capsule, positive peritoneal cytology, or pelvic extension or implants (stage IC or II). Various adjuvant treatment approaches have been investigated to improve clinical outcomes, although the optimal management remains controversial. Few randomized trials have been conducted in this population, and they have been limited by small sample size and lack of power to demonstrate a survival advantage.

Nonetheless, two large multi-institutional trials conducted in Europe randomized women with early-stage ovarian cancer to platinum-based chemotherapy or observation following surgery (Table 75.7). The International Collaborative Ovarian Neoplasm 1 (ICON1) trial enrolled 477 women with FIGO IA-C ovarian cancer inclusive of all tumor grades and histologic subtypes.[180] Adjuvant chemotherapy consisted of six cycles of a platinum-based regimen per institutional preference. With a median follow-up of 9.2 years, 10-year recurrence-free survival was 67% for the chemotherapy arm and 57% for observation (HR 0.7, $P = .02$).[181] Overall survival also favored the chemotherapy group (72% vs. 64%, $P = .06$). When stratified by histology and grade, the largest benefit for adjuvant chemotherapy was seen in patients with high-risk disease, defined as FIGO stage IA grade 3, stages IB or IC grades 2 and 3, or any clear cell histology. HRs for recurrence and death for the high-risk subset were 0.52 and 0.48, respectively (both $P < .01$). The second trial, Adjuvant Chemotherapy in Ovarian Neoplasm (ACTION), assigned 448 women with early-stage ovarian cancer to four to six cycles of platinum-based adjuvant chemotherapy or observation following surgery. Women with FIGO IA grade 2 and 3 diseases, all stages IC-IIA, or any clear cell histology were eligible for the trial. Recurrence-free survival, but not overall survival, was significantly improved in the chemotherapy group (70% vs. 62% at 10 years).[182,183] The greatest benefit was seen in the subset of women with nonoptimal surgical staging. In a combined analysis of the ICON1 and ACTION trials, adjuvant chemotherapy was associated with significantly improved overall survival at 5 years (82% vs. 74%) compared to observation.[184]

The GOG conducted a randomized trial to determine the optimal duration of adjuvant chemotherapy in women with high-risk, surgical stage I disease by comparing three versus six cycles of carboplatin and Taxol chemotherapy.[185] Rates of recurrence (25% vs. 20%) and overall survival (81% vs. 83%) were similar at 5 years for three and six cycles of chemotherapy, although six cycles

were associated with significantly more toxicity, including neuropathy, granulocytopenia, and anemia. However, subset analysis revealed a significantly lower risk of recurrence for women with serous tumors.[186] At 5 years, recurrence-free survival for women with serous tumors was 83% for six cycles of chemotherapy versus 60% for three cycles (HR 0.33, P = .04). Overall survival was also improved at 5 years (86% vs. 73%), although not statistically significant.

Adjuvant Whole-Abdomen Irradiation

WAI was an accepted standard modality in the adjuvant postoperative treatment for completely resected ovarian cancer; however, its use declined significantly after 1975. The practical advantage of WAI was the ability to treat all of the peritoneal surfaces within the abdomen and pelvis, although the delivered dose was limited by the relatively low tolerance of the liver and kidneys. Interest in WAI was established following the publication from Princess Margaret Hospital of a randomized comparison of 147 patients with FIGO IB, II, or III debulked ovarian cancer who received WAI with a pelvic boost or pelvic radiotherapy followed by chlorambucil.[187] WAI significantly improved 10-year survival rates over limited pelvic radiotherapy and chemotherapy (64% vs. 40%, respectively). The greatest magnitude of the survival benefit was observed in patients with <2 cm of residual disease (10-year survival 78% vs. 51%, respectively). No significant benefit was observed in patients with extensive residual tumor.

Subsequent randomized studies did not find a benefit for WAI compared to combined adjuvant treatment modalities. A multi-institutional trial by the National Cancer Institute of Canada (NCIC) randomized 257 high-risk stage I or optimally debulked stage II or III patients to receive melphalan, WAI, or IP phosphorus 32 (^{32}P).[188] All patients had previously received 22.5 Gy to the pelvis prior to study entry. The WAI arm delivered 22.5 Gy to the abdomen in 2.25-Gy fractions. Actuarial 10-year survival rates failed to demonstrate a statistically significant difference among all groups.[189] A second study from the Danish Ovarian Cancer Group (DACOVA) reported similar outcomes for women who received adjuvant WAI versus pelvic radiotherapy with cyclophosphamide or melphalan (4-year survival, 63% vs. 55%, respectively).[190]

WAI has also been shown to be comparable to single agent or combination chemotherapy in the adjuvant setting. A prospective study from the MD Anderson Cancer Center randomized 149 women with stage I through III ovarian cancer and <2 cm of residual disease to WAI or melphalan.[191] WAI was

delivered by a moving strip technique with a pelvic boost. Overall survival at 5 years was 71% for WAI and 72% for the melphalan arm. Severe late gastrointestinal toxicity requiring surgical intervention was reported in 14% of patients who received WAI, attributed to the moving strip technique that delivered excessive pelvic dose. A second prospective trial from the Northwest Oncologic Cooperative Group of Italy randomized 70 women with early-stage high-risk disease to adjuvant WAI or six cycles of cisplatin plus cyclophosphamide. Despite protocol violations in the assigned treatment groups, there was no difference in relapse-free or overall survival when analyzed by treatment received.[192] From these studies, WAI appears equivalent to chemotherapy when delivered in patients with optimally debulked disease but is no longer used. Further escalation of WAI to 27.5 Gy does not appear to provide additional survival benefit.[193]

TABLE 75.7 RANDOMIZED STUDIES OF ADJUVANT CHEMOTHERAPY IN EARLY-STAGE OVARIAN CANCER

Trial	Stage	Study Design	Number of Patients	5-Year DFS%	5-Year OS%	Notes
Observation vs. Chemotherapy						
GOG (1990)	IA, IB grades 1–2	Observation	44	91	94	No survival difference; optimal staging
		Melphalan	48	98	98	
ICON1 (2003, 2007)	I/II	Observation	236	62	70	Largest benefit for high-risk group; no surgical staging
		Platinum-based	241	73[a]	79[a]	
ACTION (2003, 2010)	IA, IB grades 2–3	Observation	224	68	78	Optimal staging in 1/3
	IC–IIA all grades	Platinum-based	224	76[a]	85	
	Clear cell					
Duration of Chemotherapy						
GOG (2006, 2010)	IA, IB grade 3	3 cycles CT	232	75	81	No survival difference; greatest benefit for serous tumors
	IC–II all grades	6 cycles CT	225	80	83

[a]Statistically significant.

The role of consolidative radiotherapy in patients with stage I or II disease and clear cell, endometrioid or mucinous histology has recently been raised by population-based studies. In a multicenter retrospective study of 241 patients with stage I and II ovarian clear cell carcinoma, consolidative radiation was associated with a 20% benefit in disease-free survival at 5 years for patients with stage IC or II disease.[194] Following surgical staging, patients were treated with either three cycles of carboplatin and paclitaxel followed by WAI (45 Gy to pelvis and 22.5 Gy to whole abdomen) or six cycles of chemotherapy alone. The survival benefit was most pronounced among patients with negative or unknown peritoneal cytology. Similar results were also seen for patients with stage I or II ovarian cancer of endometrioid, clear cell, and mucinous subtypes in a larger analysis of this population-based study, which reported a 40% reduction in disease-specific mortality and 43% reduction in overall mortality with the addition of consolidative radiotherapy. A survival benefit with the addition of consolidative radiotherapy was not observed in patients with stage II disease or serous tumors.[195] However, at this time, there is no level 1 evidence to support the role of adjuvant or consolidative radiation for patients with early-stage disease and non-serous histology.

Adjuvant Intraperitoneal Phosphorus 32

IP instillation of ^{32}P was extensively studied as an alternative to external beam radiotherapy but is no longer in clinical use. In high-risk, early-stage ovarian cancer patients, randomized trials of adjuvant IP ^{32}P versus chemotherapy from the GOG and Norwegian Radium Hospital found no significant differences in disease-free or overall survival in a population with high-risk early-stage disease.[178,196,197] Given a higher incidence of bowel toxicity and limitations of delivery, ^{32}P has largely been replaced by platinum and taxane combination chemotherapy as the adjuvant treatment for early-stage and advanced disease.

Advanced-Stage Disease

Surgical Considerations

Optimal or complete cytoreduction is one of the most important prognostic

factors for survival in patients with advanced-stage ovarian cancer. Cytoreductive surgery in advanced-stage disease may improve the patient's disease-related symptoms such as abdominal pain and early satiety and allow for the ability to maintain nutritional status. Optimal cytoreduction may also enhance chemotherapy delivery and response by removal of large hypoxic tumor masses. Bowel resection may be required to remove metastatic implants involving the bowel mesentery or serosa. Extensive upper abdominal surgery, including splenectomy, partial hepatectomy, partial gastrectomy, partial cystectomy and/or ureteroneocystostomy, cholecystectomy, distal pancreatectomy, and/or diaphragmatic resection, also results in prolonged palliation and improved survival.[157,198,199] Select patients may be potential candidates for intraperitoneal chemotherapy, as discussed below, and consideration should be given to placement of an IP catheter at the time of surgery. Laparoscopy may be utilized to identify which patients with advanced ovarian cancer have the greatest likelihood of attaining complete cytoreduction with primary surgery.[200,201] However, based upon the evaluation of 2,655 patients in GOG182, patients with larger tumor burden still have worse survival despite aggressive surgery attaining no residual disease.[202]

Second-look laparotomy (SLL) was introduced to assess the extent of residual disease following cytoreductive surgery and adjuvant chemotherapy. Up to 20% to 50% of patients may have residual disease after adjuvant therapy that was not detected on physical examination or by CA-125 levels or imaging. Although SLL demonstrated the prognostic importance of a pathologic remission, it was not found to have a therapeutic benefit in a GOG trial of 800 patients.[203] Therefore, second-look evaluations for the purposes of determining therapy, and not for interval cytoreduction, should be reserved for women enrolled in clinical trials.

Several studies have evaluated the importance of interval cytoreduction following an initial attempt at surgical debulking. In a randomized trial by the European Organisation for Research and Treatment of Cancer (EORTC), 319 women with suboptimally debulked disease (>1 cm residual) were assigned to six cycles of cisplatin/cyclophosphamide chemotherapy or interval cytoreduction after three cycles of chemotherapy, followed by additional three cycles.[204] Progression-free and overall survival were significantly improved with interval cytoreduction (median overall survival 26 vs. 20 months, $P = .04$) without increased surgical morbidity. However, a subsequent GOG trial of 550 women failed to reproduce these results.[205] Following a suboptimal resection in the

GOG trial, patients were randomized to three cycles of cisplatin and paclitaxel followed by interval debulking or chemotherapy alone for a maximum of six cycles in both arms. The absence of a survival benefit may be attributable to differences in the chemotherapy used or more aggressive initial surgical management by gynecologic oncologists in the GOG trial. The NCCN guidelines state that patients should be evaluated for potential interval cytoreduction before the fourth cycle of neoadjuvant chemotherapy.[140]

The role of neoadjuvant chemotherapy has been explored in a randomized EORTC/NCIC trial of 670 women with stage IIIC and IV ovarian, fallopian tube, or primary peritoneal cancer randomized to initial surgical debulking followed by six cycles of cisplatin-based chemotherapy or interval debulking after three cycles, followed by three additional cycles.[206] The cohort had extensive bulky disease, with >60% of patients with metastases >10 cm. Although progression-free and overall survival were similar between the two groups, interval surgery achieved optimal cytoreduction more often (81% vs. 42%) and with fewer surgical complications. A major criticism of the trial is that the median survival was significantly lower than that of recently reported US trials (approximately 30 months compared to overall survival averages of 50 months),[207,208] which may be related to selection of higher-risk patients. In a retrospective analysis of the EORTC/NCIC trial, patients with stage IVB disease and bulky tumors had better 5-year survival rates with neoadjuvant therapy, whereas those with stage IIIC and less bulky tumors had a greater survival benefit with upfront surgery.[209] NCCN guidelines state that neoadjuvant chemotherapy may be considered for patients with bulky stage III to IV disease who are not surgical candidates following assessment by a gynecologic oncologist.[140] However, more data will be necessary prior to recommending neoadjuvant chemotherapy in patients with potentially resectable ovarian cancer, as upfront debulking surgery remains the treatment of choice in the United States. In a single US institutional series of 586 patients with advanced ovarian cancer, upfront debulking surgery was associated with an improved median overall survival of 72 months compared to 43 months for those selected for treatment with neoadjuvant chemotherapy.[210]

Chemotherapy for Advanced-Stage Disease

Platinum agents are the most active class of compounds in the adjuvant treatment for ovarian cancer. Before 1980, alkylating-based regimens such as cyclophosphamide and doxorubicin were used with clinical response rates of

15% to 20%. GOG 47 demonstrated an improvement in clinical complete response rates (51% vs. 26%) and progression-free survival (13 vs. 8 months) with the addition of cisplatin to cyclophosphamide and doxorubicin. Cisplatin has since been used extensively in both single-agent and multidrug studies. A meta-analysis of 49 trials from the Advanced Ovarian Cancer Trialists' Group found that platinum combination chemotherapy improved survival rates over the same nonplatinum regimen (HR 0.88, 95% CI 0.79 to 0.98) and nonplatinum monotherapy (HR 0.93, 95% CI 0.83 to 1.05).[211] The women in the nonplatinum groups routinely received platinum chemotherapy at the time of relapse, likely obscuring the magnitude of the benefit. This meta-analysis also incorporated data from 11 trials that directly compared carboplatin and cisplatin, either as single agents or in combination with other drugs, which suggested no difference in efficacy between the two agents. Carboplatin clearly has fewer treatment-related side effects, including less nephrotoxicity, neurotoxicity, and emetogenic potential, and is considered standard of care. However, carboplatin does have more associated myelosuppression, primarily thrombocytopenia, which is cumulative and may be dose limiting.

In addition to platinum compounds, taxanes have become a cornerstone of the treatment schemas for women with epithelial ovarian cancer. GOG 111 was a randomized study comparing cisplatin and paclitaxel with cisplatin and cyclophosphamide in women with suboptimally debulked, large-volume ovarian cancer. The paclitaxel-containing arm demonstrated improved clinical response rates (73% vs. 60%), progression-free survival (18 vs. 13 months), and overall survival (38 vs. 24 months).[212] A second GOG study of 614 women with advanced disease and suboptimal resection compared single-agent cisplatin to 24-hour infusion of paclitaxel and to the combination of paclitaxel and cisplatin.[213] Cisplatin alone or in combination with paclitaxel resulted in improved clinical response rates and progression-free survival, although overall survival was similar in the three arms. Combination chemotherapy also had lower cumulative toxicity. As several trials have demonstrated the comparable efficacy of cisplatin and carboplatin, combination of carboplatin and paclitaxel has become the preferred first-line chemotherapy regimen. Although the standard dosing of intravenous carboplatin and paclitaxel is every 21 days, a phase III trial from Japan demonstrated significant gains in progression-free and overall survival with a dose-dense regimen of weekly paclitaxel in combination with carboplatin given every 3 weeks[214,215] (Table 75.8). Grade 3 or 4 anemia was more common in the dose-dense arm, although other toxicities were similar.

In the GOG-262 trial, weekly paclitaxel was associated with an increase in progression-free survival that was 3.9 months longer than that observed with paclitaxel administered every 3 weeks among patients who did not receive bevacizumab.[216] Carboplatin and docetaxel are also an acceptable first-line alternative and may be considered for patients at high risk for neuropathy.[217] In elderly patients or those with poor performance status, weekly paclitaxel and carboplatin may be considered.[218] Phase III trials have failed to show a benefit for the addition of a third cytotoxic agent to the carboplatin and paclitaxel regimen. GOG 182-ICON5 was a five-arm randomized trial of 4,312 women that compared the addition of gemcitabine, liposomal doxorubicin, or topotecan to carboplatin and paclitaxel. There were no improvements in progression-free or overall survival with any experimental regimen.[219] The recommended intravenous regimens accepted by a consensus of the NCCN panel include (1) paclitaxel and carboplatin given every 3 weeks for six cycles, (2) dose-dense weekly paclitaxel plus carboplatin every 3 weeks for six cycles, (3) weekly paclitaxel and carboplatin for 18 weeks, and (4) docetaxel and carboplatin every 3 weeks for six cycles.[140]

The role of novel biologics in the first-line treatment for ovarian, fallopian tube, and primary peritoneal cancers is under active investigation. Antiangiogenics have demonstrated activity in the recurrent treatment setting, and the addition of bevacizumab to conventional first-line chemotherapy has been tested in two randomized trials. Bevacizumab is a humanized monoclonal antibody directed against the VEGF receptor that may inhibit tumor angiogenesis and improve chemotherapy delivery. GOG 218 reported that the addition of concurrent and maintenance bevacizumab for 15 months significantly improved progression-free survival compared to six cycles of carboplatin and paclitaxel alone (14.1 vs. 10.3 months).[220] The benefit was not seen in the group who received concurrent bevacizumab without maintenance therapy. Rates of hypertension, gastrointestinal perforation, and fistula formation were higher with the use of bevacizumab. With a median follow-up of 17.4 months, overall survival was similar between the treatment arms, as was quality of life. In a subsequent analysis, women with ascites who received bevacizumab maintenance regimen had significantly improved progression-free and overall survival.[221] The ICON7 trial also reported a progression-free but not overall survival benefit with concurrent bevacizumab and carboplatin/paclitaxel chemotherapy when compared to chemotherapy alone although the absolute benefit was modest (2.4 months).[222] The greatest benefit was observed in

patients at high risk for progression, defined as FIGO stage IV or >1 cm of residual disease and FIGO stage III (median progression-free survival of 16 vs. 10.5 months). In an updated analysis, the addition of bevacizumab did not increase overall survival in the whole study population, although patients with a poor prognosis had a significantly longer survival time with bevacizumab (39.3 months) compared to those who received chemotherapy alone (34.5 months).[223] Concerns about cost and lack of an overall survival and/or quality of life benefit have tempered the widespread adoption of bevacizumab to the first-line chemotherapy backbone. The NCCN Ovarian Cancer Panel has included the addition of bevacizumab to upfront therapy with carboplatin/paclitaxel and maintenance therapy with a Category 2B recommendation.[140]

TABLE 75.8 RANDOMIZED STUDIES OF ADJUVANT CHEMOTHERAPY IN ADVANCED-STAGE OVARIAN CANCER

Trial	Stage	Study Design	Number of Patients	Median PFS (Months)	Median OS (Months)	Notes
GOG 172 (2006)	III	IP/IV cisplatin/paclitaxel	415	23.6	65.6	Greater toxic in IP/IV arr
	≤1 cm residual	IV cisplatin/paclitaxel		18.3[a]	49.7[a]	
Japanese GOG (2009, update 2013)	II–IV	Dose-dense CT	631	28.2	100.5	More anemia with dose-dense schedule
		CT (every 21 d)		17.5[a]	62.2[a]	
GOG 218 (2010)	III–IV	CT	1,873	10.3	39.3	Higher rates hypertensi GI perforation and fistula
		+ c. bevacizumab		11.2	38.7	
		+ c./m. bevacizumab		14.1[a]	39.7	
ICON7 (2010)	High risk I–II	CT	1,528	17.4	—	Greatest benefit in high-risk subset
	III–IV	+ c./m. bevacizumab		19.8[a]		

c., concurrent; CT, carboplatin and paclitaxel; GI, gastrointestinal; ICON7, International

Collaborative Ovarian Neoplasm 7; IP, intraperitoneal; IV, intravenous; m., maintenance; OS, overall survival; PFS, progression-free survival.
[a]Statistically significant.

Several VEGFR tyrosine kinase inhibitors (TKIs) have been evaluated in the concurrent and/or maintenance setting in the upfront treatment of ovarian cancer. A phase III trial of the oral antiangiogenic nintedanib (BIBF 1120) in combination with carboplatin and paclitaxel reported a significant benefit in progression-free survival (17.2 vs. 16.6 months), although a higher rate of serious adverse gastrointestinal events were observed when compared to chemotherapy alone.[224] Pazopanib, a potent multitargeted TKI against VEGF receptor, PDGF receptor, and c-Kit, was evaluated as maintenance therapy following surgical debulking and first-line chemotherapy in a randomized phase III trial of 940 patients (AGOOVAR 16 trial).[225] The addition of maintenance pazopanib resulted in a median progression-free survival benefit of 5.6 months at the expense of increased toxicity, and no overall survival difference was observed.

Intraperitoneal Chemotherapy

Because of the unique peritoneal dissemination of epithelial ovarian and fallopian tube cancer, there has been a significant interest in evaluating IP administration of chemotherapy, which allows for a severalfold increase in drug concentration compared to systemic delivery. However, penetration into tumor tissue may be limited such that therapy is best suited for patients with minimal residual disease after surgical cytoreduction. The National Cancer Institute published a consensus statement in 2006 stating that IP chemotherapy should be offered to every woman with optimally debulked advanced-stage ovarian cancer based on the findings of GOG 172 (Table 75.8), which showed a progression-free and overall survival benefit to IP chemotherapy when compared with intravenous therapy alone (23.6 vs. 18.3 months and 65.6 vs. 49.7 months, respectively).[207] In women with stage III disease, survival was significantly increased by 16 months after IP therapy using cisplatin/paclitaxel when compared to standard intravenous therapy (65.6 vs. 49.7 months). Only 42% of patients completed all six cycles of IP chemotherapy owing to treatment-related toxicity and catheter-related complications, which included gastrointestinal events, abdominal pain, metabolic abnormalities, neuropathy, catheter infection, and blockage. Despite the higher incidence of toxicity, additional support for IP chemotherapy is derived from a meta-analysis of eight trials comparing IP to intravenous administration of platinum-based chemotherapy. IP delivery resulted

in a 22% decrease in the risk of death, which translated into a 12-month median survival benefit.[226] NCCN guidelines recommend that all patients with stage III cancer with optimal cytoreduction (<1 cm residual disease) received intravenous/IP chemotherapy. Women with stage II disease may also receive IP chemotherapy, although randomized evidence has not yet been published.[140] Despite the clinical advisory, IP chemotherapy has not been consistently adopted for treatment in women with optimally cytoreduced ovarian cancer given the technical demands and increased toxicity. Patients with poor performance status, medical comorbidities, stage IV disease, or advanced age may not tolerate the IP regimen. The feasibility and effectiveness of IP carboplatin have been evaluated in the phase III GOG 252 study comparing a modified GOG 172 intravenous/IP cisplatin/paclitaxel regimen with a lowered cisplatin dose to IP carboplatin/weekly paclitaxel as well as intravenous carboplatin/weekly paclitaxel (dose-dense regimen). All three arms receive concurrent and maintenance bevacizumab for 1 year. Preliminary results have not shown a significant difference in progression-free survival for the IP chemotherapy compared to intravenous alone, which was 33.8 months for patients with complete cytoreduction and stage III disease, when compared to 60.4 months in GOG 172.[227]

CONSOLIDATIVE THERAPY FOR EPITHELIAL OVARIAN CANCER

Consolidative radiotherapy was introduced in hopes of eradicating subclinical residual disease in women who remain at high risk for relapse following surgical cytoreduction and adjuvant chemotherapy. Despite a negative SLL, 30% to 50% of women with confirmed clinical remission ultimately relapse, most commonly in the pelvis or upper abdomen. Consolidative WAI as well as IP radiocolloid have been evaluated in several studies, although randomized data are currently lacking. Radiotherapy is not currently used as consolidative treatment for ovarian or fallopian tube carcinomas, although it may have a role in the salvage or palliative treatment of select cases.

Consolidative Whole-Abdomen Irradiation

The efficacy of WAI has been demonstrated in early-stage patients with minimal residual disease (<2 cm) after cytoreductive surgery. A few early, prospective randomized trials have evaluated the role of consolidative WAI compared to

extended chemotherapy in patients with advanced-stage disease (stage III/IV) after initial surgical cytoreduction, adjuvant chemotherapy, and SLL. In all of these trials, disease-free and overall survival rates were not found to be significantly different between WAI and chemotherapy.[228–230] A possible limitation of these trials was that women with macroscopic residual disease after SLL were eligible for enrollment.

Two trials have evaluated consolidative WAI in patients with complete clinical or pathologic remission following cytoreductive surgery and adjuvant chemotherapy. A randomized study from Austria demonstrated improved disease-free and overall survival for consolidative WAI, with the greatest benefit seen in stage III patients.[231] The Swedish-Norwegian Ovarian Cancer Study Group recently reported their long-term results from a randomized trial of stage III patients.[232] Following primary cytoreductive surgery and four cycles of cisplatin-based chemotherapy, women with complete remission at second-look surgery were randomized to WAI, six additional cycles of chemotherapy, or observation (if pathologic remission confirmed). In the subgroup with pathologic remission, WAI improved progression-free survival compared to chemotherapy or no further therapy (56%, 36%, and 35%, respectively). Overall survival was not statistically different, although statistical power was limited because only 172 (23%) of 742 enrolled patients were randomized to consolidative treatment.

WAI does not appear to compromise the ability for patients to receive and tolerate salvage chemotherapy following relapse, as recently reported in a phase II study from Princess Margaret Hospital.[233] However, the long-term complication rate using conventional radiotherapy techniques is significant. In a multicenter retrospective study from France with a median follow-up of 14 years, late symptomatic enteritis occurred in 20% of patients, of which 8% required surgical intervention for bowel obstruction, and death related to bowel complications occurred in 4%.[234] At this time, WAI is not included in the NCCN guidelines as a treatment recommendation for initial or consolidative treatment in ovarian cancer.[140]

Consolidative Intraperitoneal Phosphorus 32

Randomized data evaluating IP ^{32}P as consolidative treatment following SLL are limited. The Norwegian Radium Hospital randomized 50 patients with stage IA high grade and IB through III disease and negative SLL to ^{32}P versus observation and found no significant difference between the arms.[196] The GOG also conducted a prospective randomized trial of 202 stage III patients with

complete clinical remission and microscopically negative disease at SLL.[235] Compared with patients who received no further therapy, those who received ^{32}P (15 mCi) within 10 days of SLL did not have improved 5-year disease-free survival (36% vs. 42%, respectively) or overall survival (63% vs. 67%, respectively).

Recurrent Ovarian Cancer

Women in clinical remission following initial adjuvant treatment for ovarian cancer may be followed with a combination of physical examination, serial CA-125 levels, and/or abdominal and pelvic CT. Detection of early relapse by a rising CA-125 is fairly specific, although the lead time between biochemical and clinical progression may be up to 6 months. Patients should also be educated about the signs and symptoms of recurrence, such as pelvic pain, bloating, early satiety, obstruction, weight loss, and fatigue.[140] Second-line chemotherapy is not curative; thus, the timing of salvage therapy is controversial. The EORTC conducted a randomized trial of early versus delayed treatment for relapsed ovarian cancer that showed no difference in overall survival between the arms and a decrement in quality of life.[236] These findings have not been widely adopted in the United States owing to criticisms regarding the study design, including lack of stratification by known prognostic factors and nonstandard second-line therapies. The NCCN panel encourages physicians to discuss the pros and cons of CA-125 monitoring with their patients and the implications regarding early treatment and quality of life.

Chemotherapy

The selection of second-line chemotherapy for recurrent ovarian cancer is based on the interval to disease relapse and determination of platinum sensitivity or resistance. The intent of recurrence therapy is to decrease tumor burden, control symptoms, improve progression-free survival, and/or increase length or quality of life. Patients who experience an early recurrence within 6 months of the completion of initial chemotherapy, have stable disease, or progress during initial induction chemotherapy are considered platinum-resistant with low likelihood of cure. Women who suffer an early recurrence do have treatment options, including second-line chemotherapy agents (topotecan, weekly paclitaxel, pegylated liposomal doxorubicin, gemcitabine, oral etoposide, docetaxel), hormonal therapies, targeted therapeutics, and the opportunity to participate in clinical trials. For women with a late recurrence, retreatment with a

platinum-based combination is a reasonable option, and the longer the disease-free interval, the higher the response rate to the agents. Preferred platinum-based combinations include carboplatin/paclitaxel, carboplatin/liposomal doxorubicin, carboplatin/weekly paclitaxel, carboplatin/docetaxel, carboplatin/gemcitabine, or cisplatin/gemcitabine.[140] With the exception of those women who have a prolonged disease-free interval, the opportunity for a meaningful second remission is low, and one needs to carefully balance quality of life, chemotherapy-related toxicity, cost, and the patient's goals of care. Several randomized phase III studies are testing the role of antiangiogenics in the recurrent setting with combination chemotherapy. The AURELIA trial evaluated bevacizumab in combination with liposomal doxorubicin, weekly paclitaxel, or topotecan compared to chemotherapy alone in patients with platinum-resistant ovarian cancer. The addition of bevacizumab resulted in a statistically significant progression-free survival benefit (6.7 vs. 3.4 months) and nonsignificant overall survival benefit (16.6 vs. 13.3 months) when compared to chemotherapy alone.[237] As the gastrointestinal perforation rate in the bevacizumab arm was 2.2%, these combination regimens are contraindicated in patients at increased risk. In the OCEANS trial, the addition of bevacizumab to carboplatin/gemcitabine chemotherapy resulted in improved response rates (79% vs. 57%) and progression-free survival (median 12.4 vs. 8.4 months) in women with platinum-sensitive recurrent disease.[238] In the final survival analysis, there was not a significant increase in overall survival with the addition of bevacizumab when compared to chemotherapy alone (33.6 vs. 32.9 months).[239] A third large multi-institutional trial of 674 women evaluated the role of secondary surgical cytoreduction and bevacizumab in women with recurrent platinum-sensitive ovarian cancer and found that the addition of bevacizumab followed by maintenance therapy until progression improved median overall survival by sensitivity analysis.[240] Phase II studies of bevacizumab have demonstrated single-agent activity in patients with platinum-resistant recurrent ovarian cancer with response rates of 15% to 20%.[241,242] However, one of these studies reported a gastrointestinal perforation rate of 11% in a heavily pretreated population. Based on the phase III trials discussed above, the NCCN panel recommends combination regimens with bevacizumab for patients with platinum-resistant recurrent ovarian cancer, although there is less consensus for those with platinum-sensitive disease.

Emerging data are confirming the activity of PARP inhibitors in select patients with recurrent ovarian cancer. This new class of targeted therapy inhibits

key enzymes involved in DNA repair and has been shown to be particularly active in treating cancers in BRCA mutation carriers. In the setting of BRCA deficiency, PARP inhibition results in accumulation of double-strand DNA breaks that are lethal to tumor cells through a mechanism known as synthetic lethality. A substantial number of patients with ovarian cancer have been found to have BRCA-deficient tumors related to germline or somatic mutation, epigenetic silencing, or alteration in microRNA levels. Olaparib has shown single-agent response rates ranging from 28% to 41% depending on dose and BRCA mutation status. In a phase II of 298 patients with germline BRCA1/2 mutation and advanced cancer, olaparib resulted in an overall response rate of 31% for those with platinum-resistant ovarian cancer.[243] In the platinum-sensitive setting, olaparib maintenance therapy resulted in progression-free survival benefit of 8.4 months compared to 4.8 months with placebo for women with relapsed ovarian cancer, although an overall survival benefit was not observed.[244] Single-agent olaparib is now recommended as recurrence therapy for patients with advanced ovarian cancer who have a germline BRCA mutation and received three or more lines of chemotherapy.[140] Olaparib maintenance therapy was recently granted FDA approval based on the results of the SOLO-2 trial, which showed a significant improvement in progression-free survival in patients with germline BRCA-mutated, platinum-sensitive recurrent ovarian cancer when compared to placebo.[245] Two other PARP inhibitors have also been recently granted FDA approval. In the NOVA trial, patients with recurrent epithelial, fallopian tube, or primary peritoneal cancer were stratified by germline BRCA mutation status and randomized to either niraparib or placebo following complete or partial response to platinum-based chemotherapy. Maintenance niraparib resulted in a significant improvement in progression-free survival, with the greatest benefit among patients with germline BRCA mutations.[246] Rucaparib was granted accelerated approval for patients with germline or somatic BRCA mutation who have been treated with two or more chemotherapy regimens. BRCA mutation status was determined by a next-generation sequencing diagnostic test. The overall response rate in a single-arm open-label clinical trial was 54% and ranged from 66% for patients with platinum-sensitive disease to 25% for those platinum-resistant.[247]

In summary, there are three PARP inhibitors that are FDA-approved for recurrent ovarian cancer that clinicians may select from: (1) olaparib for patients with recurrent germline BRCA-mutated ovarian cancer who have received three or more prior lines of chemotherapy or as maintenance therapy following

response to platinum therapy for those with platinum-sensitive recurrence, (2) rucaparib for patients with BRCA-mutated ovarian cancer (either deleterious tumor or germline mutation) who have received at least two prior lines of chemotherapy, and (3) niraparib for platinum-sensitive recurrent ovarian cancer patients as maintenance therapy following response to platinum-based chemotherapy, regardless of BRCA or tumor homologous recombination status. Further studies of PARP inhibitor agents as single agents and in combination therapy are under way in patients with platinum-sensitive and platinum-resistant disease.

A number of TKIs have been tested in the recurrent setting as single agents with demonstrated response rates of 3% to 29%.[27,248] These agents include cediranib (targets VEGF receptor and c-Kit), sunitinib (targets VEGF receptor, c-Kit, PDGF receptor, RET, and FLT-3), sorafenib (targets VEGF receptor, c-Kit, RAF, and PDGF receptor-b), ENMD2076 (targets VEGF receptor and aurora A), pazopanib (targets VEGF receptor, PDGF receptor, and c-Kit), trebananib (inhibits binding of angiopoietins 1 and 2 to the Tie2 receptor), and cabozantinib (targets VEGF receptor and c-MET). In the phase III ICON 6 trial, patients with platinum-sensitive recurrent ovarian cancer were randomized to platinum-based chemotherapy with or without cediranib as concurrent and/or maintenance therapy. The addition of maintenance cediranib showed a significant progression-free survival benefit, although at the expense of increased toxicity.[249] Trebananib has also been tested in the phase 3 setting with weekly single-agent paclitaxel and, similar to other agents in its class, resulted in prolonged progression-free survival, but with higher rates of serious adverse events, treatment discontinuation, and chronic edema.[250] Combinatorial therapy with PARP and VEGF inhibition has also been explored with promising results in a phase II study,[251] and large phase III evaluations are underway.

Palliative Surgery

Secondary cytoreductive surgery with the intent of prolonging survival may benefit a select subset of patients with a long disease-free interval, good performance status, and single or few sites of recurrence.[252,253] A recently reported phase III trial randomized 407 women with platinum-sensitive disease at the time of first relapse to cytoreduction followed by second-line chemotherapy versus chemotherapy alone. Eligible patients had an excellent performance status, volume of ascites of 500 cc or less, and complete cytoreduction at diagnosis. The median progression-free survival was 21 versus

13.9 months in favor of surgery. The primary endpoint of overall survival will be reported in subsequent analysis.[254] Palliative surgery may also be considered in women who present with symptomatic tumor masses or intestinal obstruction. However, the risk of perioperative mortality and reobstruction is significant, and the patient's medical condition, performance status, and anticipated life expectancy should be carefully considered before operative intervention. For patients who are not surgical candidates, percutaneous decompression and intravenous hydration with consideration of palliative chemotherapy and/or hospice referral may be appropriate.

Palliative Radiation Treatment

Radiation therapy may be an effective palliative treatment modality in settings where localized recurrences are causing significant symptoms that are unresponsive to systemic therapy. Symptoms such as bleeding, pain, or obstruction in the pelvis, groin, abdomen, or chest may be palliated with an abbreviated course of radiation treatment. Clinical response rates have been reported in the range of 70% to 100%, with complete clinical response rates of 30% to 70% and a median duration of 5 to 11 months.[255–259] Palliative radiotherapy is effective even in patients heavily pretreated with systemic or IP chemotherapy. Pain relief and cessation of bleeding are achieved in >80% of patients and symptoms from bowel or ureteral obstruction in 60% to 75%.[260] A recent report found that response rates to palliative radiation did not vary among patients with platinum-resistant versus platinum-sensitive disease either at the time of diagnosis or time of radiation treatment. However, patients with clear cell ovarian cancer had lower clinical response rates when compared to those with serous or endometrioid cell types, although these patients may still experience symptomatic relief with radiation.[261] When delivered locally to symptomatic sites, radiation therapy appears to be of significant and durable benefit and should be considered for palliative purposes in select patients with symptomatic relapses, particularly in those who are refractory to chemotherapy.

The role of salvage radiotherapy in select patients with isolated pelvic recurrences has been suggested by several reports. In a series by Firat and Erickson,[262] 28 patients with recurrent or persistent disease involving the vagina and/or rectum received palliative radiotherapy delivered by external beam radiotherapy, brachytherapy, or a combination of both. Bleeding was controlled in all cases, and 79% achieved a complete symptomatic response. Of the 21 patients with no evidence of liver or extra-abdominal disease, 2-year survival

was 57% compared to 0% for the 7 patients with liver and extra-abdominal metastases at the time of radiotherapy. In the group of 14 patients with pelvic-confined disease, 5 patients had recurrences in the upper abdomen and 4 patients were long-term survivors >5 years after radiotherapy administration. A second study by Albuquerque et al.[263] evaluated the outcomes of 20 women treated with salvage radiotherapy for isolated extraperitoneal recurrence. Most recurrences were in the pelvis, although 3 patients had regional nodal recurrences and 1 patient had an abdominal wall recurrence. The median delivered dose to a tumor-directed volume was 50.4 Gy, and a brachytherapy boost was delivered in select cases. Local recurrence–free survival at 2 years was 89% for patients with optimal debulking prior to radiotherapy compared to 42% for patients with suboptimal debulking or gross residual disease. The corresponding disease-free survival rates at 3 years were 72% and 22%, and overall survival rates at 5 years were 50% and 19%, respectively. In a large single institutional series of 102 patients with epithelial ovarian cancer who received salvage involved–field radiotherapy, 5-year rates of progression-free and overall survival were 40% and 24%, respectively, with an infield control rate of 71%. Of note, the time interval to relapse and subsequent chemotherapy was prolonged following radiation treatment compared to the time interval to relapse before radiation. Furthermore, 25 patients did not experience relapse for a median of 61 months, and patients with clear cell histology had the highest rates of progression-free and overall survival after salvage radiation therapy.[264] Given the exceptional local control rates, minimal toxicity, and long-term survival, select patients with isolated extraperitoneal recurrences may be appropriate candidates for salvage involved–field radiation treatment.

Ovarian cancer metastatic to the brain is a rare occurrence reported in <1% of patients in autopsy cases and in 2% of clinical series.[265,266] More recent series have suggested an increased incidence as chemotherapy regimens have become more effective.[266] Nonetheless, long-term prognosis is poor, as brain metastases are often a late manifestation of advanced disease, with a median survival time <12 months. In a series of 24 patients with metastatic brain disease treated with whole-brain radiotherapy, stereotactic radiosurgery (SRS), or a combination of whole-brain radiotherapy and SRS, median survival was 8.5 months. Patients with solitary metastatic lesions had significantly improved survival compared to those with multiple metastases, 17 versus 6 months, respectively.[267] Platinum sensitivity was also recently identified as an important prognostic factor in women with metastatic brain involvement from ovarian cancer. In an analysis of

4,277 women treated at six German hospitals, 74 patients (1.7%) had clinical documentation of brain metastases, of which 61 patients received radiotherapy alone or in combination with surgical resection and chemotherapy.[268] On multivariate analysis, platinum sensitivity (HR 0.23) and good performance status (HR 0.45) were associated with improved survival, whereas multiple lesions (HR 4.4) and low tumor grade (HR 3.1) were associated with adverse outcome. Although the extent of extracranial disease was not associated with outcome in this study, it is unclear whether the prognostic importance of platinum sensitivity was related to control of intracranial or systemic disease. In a retrospective analysis from the MITO (Multicenter Italian Trials in Ovarian cancer) group that included 174 women with epithelial ovarian cancer, most of which had platinum-sensitive disease, the presence of extracranial disease (HR 1.8), older age (1.7), monotherapy (HR 2.6), and multiple brain metastasis (HR 1.9) were associated with worse overall survival following a diagnosis of brain metastases.[269]

SPECIALIZED RADIATION THERAPY TECHNIQUES

Whole-Abdominal Radiation Therapy

The clinical target volume for WAI includes the entire peritoneum from the diaphragm to the pelvic floor, encompassing both the visceral and parietal surfaces as well as the pelvic and para-aortic nodes. Conventionally, large anterior and posterior fields have been used. The simulation technique requires attention to the excursion of the diaphragm at the superior margin during respiration to ensure appropriate coverage. The field should encompass the pouch of Douglas inferiorly as well as the lateral extent of the peritoneal margins, which may be located outside the pelvic brim in obese patients. Fluoroscopy may be used to assess the range of quiet respiratory motion. Alternatively, image fusion of CT scans obtained at inspiration and expiration or throughout the respiratory cycle (four-dimensional [4D] CT) may be used to design the treatment fields. Extended source to skin distance may be required in some patients to ensure adequate coverage. Organs at risk that are dose limiting include the kidneys, liver, small and large bowel, and bone marrow. Kidney doses are limited to 15 Gy with customized blocking, and whole-liver tolerance is 30 Gy. The standard whole-abdomen dose is 30 Gy delivered in 1.2- to 1.5-Gy fractions. An additional boost may be delivered to the pelvis and para-aortic lymph nodes to 45 to 50 Gy, depending on the clinical requirements. Patients

will need to be monitored for acute gastrointestinal and hematologic toxicity as well as nutritional support.

The use of intensity-modulated radiation therapy (IMRT) to deliver WAI has been proposed as a means to reduce the radiation dose to the bone marrow and kidneys to decrease the incidence of myelotoxicity and renal damage. Dosimetric analysis has demonstrated improved planning target volume (PTV) coverage and significant dose reductions to bones with equivalent kidney sparing using dynamic multileaf collimator IMRT when compared with conventional fields.[270] The PTV receiving 95% of the prescribed dose improved from 72% to 84%, and the volume of pelvic bones receiving >21 Gy was reduced by a relative 60% from 86% to 35%. Dose inhomogeneity, however, increased slightly, with small regions of underdosing near the kidneys. Similar improvements in PTV dose coverage were reported in a study using IMRT arc therapy.[271] It remains to be seen whether the dosimetric advantages gained from WAI–IMRT will translate to a significant and clinically relevant benefit. Furthermore, technical considerations must be considered with great care given the complex anatomy and delineation of the peritoneal cavity boundaries. Patient breathing motion and setup uncertainties will also need to be addressed. Early-phase clinical trials assessing the feasibility and toxicity of WAI–IMRT as consolidation following optimal cytoreduction and platinum-based chemotherapy are ongoing.[272]

Intraoperative Radiation for Ovarian Cancer

Several studies have suggested that intraoperative radiation therapy (IORT) as part of salvage surgery for locally recurrent gynecologic cancers, including ovarian cancer, may improve local–regional control and overall survival.[273–277] The largest IORT retrospective study to date that reported results of 22 ovarian cancer patients treated with IORT (median dose, 12 Gy; range, 9 to 14 Gy) suggests that the addition of IORT to cytoreductive surgery may potentially improve local–regional control and achieve palliation in highly selected patients with locally recurrent ovarian cancer.[273] Various sites were treated, most commonly the pelvic sidewall. Most patients received additional treatment after IORT, including WAI, pelvic and/or inguinal radiation, and chemotherapy. Local–regional control was achieved in 68% of patients, with a median time to recurrence of 14 months and 5-year disease-free survival of 18% and overall survival of 22%. Overall treatment-related grade 3 toxicities occurred in 41%. Bowel obstruction occurred in seven patients, all of whom received

postoperative WAI and two of whom also had a component of local–regional relapse. No long-term neurologic sequelae were reported.

SEQUELAE OF TREATMENT

Acute Toxicity

Acute toxicity from WAI is common but rarely severe. The use of large radiation fields that encompass multiple abdominal organs, including the liver, kidneys, gastrointestinal tract, bladder, spleen, lungs, and pancreas, contributes to the development of predictable side effects. Gastrointestinal side effects are the most common acute and subacute toxicities encountered with WAI given the large volume of bowel within the treatment field. Up to 75% of patients treated with WAI experience mild to moderate diarrhea; severe diarrhea requiring hospitalization and intravenous hydration is seen in 10% of patients. Limiting bowel exposure through the use of shielding or appropriately timed field reductions can minimize or prevent this toxicity. Approximately 60% to 70% may also experience nausea, particularly early during treatment, although emesis occurs infrequently. Premedication with antiemetic therapy 30 to 60 minutes prior to treatment may help to mitigate this side effect. Routine intravenous hydration to prevent dehydration is also recommended. Appetite loss accompanied by weight loss is a frequent concern. It is thus essential to closely monitor and ensure proper nutrition to avoid malnourishment and dehydration that may result in hospitalization and treatment interruption.

Clinically significant liver damage is extremely rare with appropriate shielding.[278] Approximately 50% of patients will develop transiently elevated alkaline phosphatase levels; however, symptomatic hepatitis occurs in <1%.[279] Hematologic toxicity including leukopenia and thrombocytopenia occurs in 10% to 20% of patients, although significant drops in blood counts causing treatment interruption are rare. Splenic damage may occur even at low radiation doses because of the exquisite radiosensitivity of the spleen, resulting in transient reduction in platelet counts.

Urethritis and bladder spasm from pelvic irradiation may occur and should be treated symptomatically. Adequate and careful shielding of the kidneys to limit the delivered dose to <15 Gy is critical to minimize renal damage and failure. Stricture of the ureters or urethra is rare, occurring in <1% of cases and is usually not seen until 3 to 6 months postradiation. Because treatment to the entire peritoneal cavity with adequate margins requires extension of fields above

the diaphragm, inclusion of the lung bases bilaterally is required. Chest radiographs may show fibrosis or bibasilar pneumonitis in 5% to 20% of patients but is generally self-limited and rarely symptomatic.

Late Toxicity

Late toxicities following WAI were more common with the moving strip technique than with the open-field technique, primarily because of the higher doses and hot spots that were generated. High radiation doses can exceed normal organ tolerances, leading to permanent organ damage and failure. Chronic gastrointestinal damage (i.e., bloating, intermittent diarrhea) occurs in <5% of treated patients. The overall incidence of bowel obstruction has been reported to be 5% to 10% at 5 years in cases in which IP ^{32}P or WAI is used independently. Approximately 50% of these patients who develop bowel obstructions will require surgical intervention (incidence, 3% to 5%); however, recent data suggest that this incidence may be higher and closer to 10% in long-term survivors at 10 years.[234] Bowel obstructions occur more frequently with doses >45 Gy and in patients with gapped or abutted split fields. In addition, adhesions in the peritoneal cavity and the combination of additional pelvic radiation to ^{32}P or WAI may double the risk of significant bowel complications up to 20% to 25%.[188,196] As with most anatomic sites, escalating doses of radiation come with an increase in rate and degree of toxicity. Major bowel complications from 10 pooled series of 1,098 patients reported an incidence of 1.4% with abdominal dose of 22.5 Gy compared with 14% with 30 Gy.[279]

MANAGEMENT OF GERM CELL TUMORS

In general, the presentation and management of nonepithelial tumors are similar to those of their epithelial counterparts, as patients usually experience vaginal bleeding, abdominal bloating, or pain and typically require surgical intervention and chemotherapy. On presentation, routine workup is identical to that for other ovarian cancers as outlined previously. Pretreatment AFP and β-hCG levels are of particular importance in diagnosis and treatment. An elevated β-hCG with a normal AFP is strongly suggestive of dysgerminoma. Lactate dehydrogenase and CA-125 levels should also be drawn, as the germ cell tumors may have several tumor markers that can be followed (Table 75.9). Variations in surgical management and adjuvant chemotherapy and radiation do exist among the nonepithelial tumors, and treatments should consider the patient's desire to

maintain fertility while offering the greatest chance for cure.

TABLE 75.9 SERUM MARKERS FOR OVARIAN GERM CELL TUMORS

Tumor Type	AFP	hCG	LDH
Dysgerminoma	—	+/−	+
Choriocarcinoma	—	+	—
Endodermal sinus tumor	+	—	—
Immature teratoma	+/−	—	—
Mixed germ cell tumor	+/−	+/−	+/−
Embryonal carcinoma	+/−	+	—
Polyembryoma	+/−	+	—

AFP, *α*-fetoprotein; hCG, human chorionic gonadotropin; LDH, lactate dehydrogenase.

Most ovarian neoplasms diagnosed in children and adolescents are germ cell tumors, with approximately two-thirds of these tumors being malignant at the time of diagnosis. Germ cell tumors comprise 20% of all ovarian neoplasms and 2% to 5% of all ovarian malignancies. The most common germ cell tumor is the mature cystic teratoma (also the most common ovarian neoplasm); however, fortunately, only the minority contain a malignancy or immature elements.

Dysgerminoma

Dysgerminoma is the most common of the malignant germ cell tumors and also has the highest bilaterality rate (20%), with 10% of the ovaries being grossly involved and 10% being microscopically involved. As shown in Table 75.9, dysgerminomas may secrete lactate dehydrogenase and have elevated *β*-hCG levels. Most women with dysgerminomas receive a diagnosis of early-stage disease, and 80% present before the age of 30 years. In many instances, young women affected by this disease wish to maintain fertility after therapy. The high rate of contralateral disease confers a greater risk with conservative surgical therapy. Comprehensive staging is recommended as initial surgery for patients who do not desire fertility preservation, although may be omitted in children or adolescents.[140]

Postoperative therapy for patients with dysgerminoma can be separated into those women with stage I disease and those with disease of a more advanced stage. Women with stage I dysgerminoma may be monitored closely without compromising cure. Approximately 15% to 25% of these women will experience

a recurrence, although successful salvage treatment with chemotherapy results in survival rates close to 100%. For women with more advanced-stage disease, chemotherapy with three to four cycles of BEP (bleomycin, etoposide, and cisplatin) is recommended.[280] In a report from MD Anderson Cancer Center, >95% of the patients with ovarian dysgerminoma were free from relapse at a median of 7 years follow-up.[281] Of the 16 women treated with fertility-sparing surgery, 10 patients maintained menstrual function during chemotherapy and 13 patients returned to their prechemotherapy baseline. Five pregnancies were reported, and two of the women had difficulty conceiving.

Dysgerminomas are unique in that they are exquisitely radiosensitive tumors. Radiotherapy may be considered for patients who are not candidates for platinum-based chemotherapy. The appropriate radiation dose for dysgerminoma is 25 Gy in 12 to 14 fractions with a boost of 10 Gy for gross residual disease. However, radiotherapy will affect ovarian function and fertility, which must be taken into consideration when recommending adjuvant radiation therapy in a young patient.

Other Germ Cell Tumors

Nondysgerminomas are almost always unilateral. For apparent early-stage disease, unilateral salpingo-oophorectomy appears to be as effective as more extensive surgery. Patients with stage I grade 1 immature teratomas usually require no further therapy after unilateral salpingo-oophorectomy. All others, including stage I grade 2 and 3 immature teratoma, should be treated with three or four cycles of BEP chemotherapy.[140] Because of the low number of diagnosed cases, large-scale studies comparing adjuvant therapy are uncommon.

Extrapolation of data regarding the efficacy of chemotherapeutic regimens in treatment for nonseminomatous testicular germ cell tumors has had a great impact on treatment in patients with nondysgerminoma ovarian germ cell tumors. Patients with less well-differentiated tumors and all those with endodermal sinus tumor, embryonal carcinoma, choriocarcinoma, or mixed germ cell tumors should receive adjuvant postoperative chemotherapy. Various regimens have been used, including VAC (vincristine, dactinomycin, and cyclophosphamide), PVC (cisplatin, vincristine, and cyclophosphamide), and CVB (cyclophosphamide, vincristine, and bleomycin). The BEP regimen was prospectively evaluated by the GOG in patients with completely resected, surgically staged I, II, and III disease and resulted in a 96% disease-free survival rate.[282] NCCN guidelines recommend three to four courses of BEP as the

standard treatment for well-staged patients with resected ovarian germ cell tumors. Six cycles of chemotherapy may be considered for patients with gross residual or stage IV disease.

Management of Sex Cord–Stromal Tumors

Sex cord–stromal tumors derive from the intraovarian matrix of mesenchymal and connective tissue elements that supports the germ cells. The most common sex cord–stromal tumors are the granulosa cell tumors, derived from the sex cord cells along with Sertoli cell tumors. The mesenchymal derivatives include fibromas, thecal cell tumors, and Leydig cell tumors. These tumors are responsible for <5% of all ovarian malignancies but account for 90% of all functioning ovarian neoplasms. One-third of the tumors will produce estrogen, progesterone, testosterone, or other androgens. This hormonal expression may lead to presenting signs and symptoms such as precocious puberty, postmenopausal bleeding, hirsutism, or virilization. Sex cord–stromal tumors can develop in women of any age (with the granulosa cell tumors having a bimodal age distribution) with a peak incidence in postmenopausal women around 50 years of age. These tumors typically behave in a benign fashion with LMP. Surgery remains the mainstay of treatment; however, occasionally, postoperative therapy is required, although these tumors are considered relatively insensitive.

Adult granulosa cell tumors account for 95% of all granulosa cell tumors. Most women are diagnosed after 30 years of age, with a median age of 52 years. Abdominal pain, distension, and vaginal bleeding are the most common signs and symptoms. Because of the relative state of estrogen excess produced by these tumors, 25% of women will also have concomitant endometrial pathology, such as hyperplasia or adenocarcinoma.[283] These tumors tend to be large with an average diameter of 12 cm. If a granulosa cell tumor is suspected preoperatively, inhibin A and B levels may be elevated and useful in narrowing the differential diagnosis. Ninety percent of patients present with stage I disease, and the tumors are typically unilateral in 90% of cases. Stage is the most important prognostic factor for granulosa cell tumors; other factors include tumor rupture, stage IC disease, poorly differentiated tumor, and tumor size >10 to 15 cm. The 10-year survival for women with stage I disease is approximately 90%, with 15% to 25% of stage I patients ultimately suffering a disease recurrence. The 10-year survival for women with advanced-stage disease is 26% to 49%.

Juvenile granulosa cell tumors are rare, although they account for 90% of the

granulosa cell tumors that occur in prepubertal girls and women <30 years of age.[284] Similar to the adult form, the juvenile tumors may also secrete estrogen; therefore, the prepubertal girls may present with isosexual precocious puberty. This may be the most dramatic presentation; however, the most common presentation is that of an abdominal mass. As with the adult variant, the juvenile variant is rarely bilateral, with bilaterality occurring in only 5% of cases. More than 90% of cases will be stage I at the time of diagnosis, and other prognostic factors apply as with the adult variant. The 5-year survival rate is 95%, and the prognosis remains poor with advanced-stage or recurrent disease.

Most granulosa cell tumors are unilateral and can be treated with fertility-preserving therapy consisting of unilateral salpingo-oophorectomy and appropriate surgical staging. Given the rarity of pelvic and para-aortic nodal involvement, lymphadenectomy may be omitted for patients with stage IA or IC disease.[140] Endometrial sampling should be performed in all women retaining their uterus, as these tumors may be associated with concomitant hyperplasia or adenocarcinoma. In women not wishing to preserve fertility or those who are postmenopausal, complete hysterectomy with bilateral salpingo-oophorectomy is the procedure of choice. Surgery alone is typically curative. However, risk factors for relapse that should be considered in adjuvant treatment for stage I disease include tumor rupture, stage IC disease, poorly differentiated tumor, and tumor size >10 to 15 cm. Adjuvant treatment options for high-risk stage I and advanced-stage disease include observation or consideration of platinum-based chemotherapy.[140] Radiation therapy may also be considered for patients with stage II to IV tumors and localized disease. Inhibin levels, if initially elevated, may be a useful tumor marker for surveillance of patients under observation.[285]

FUTURE DIRECTIONS

Ovarian cancer represents a spectrum of distinct disease processes, ranging from noninvasive borderline tumors to disseminated high-grade serous carcinomas. The cell of origin may be extraovarian in a large proportion of cases, as many high-grade serous carcinomas appear to originate in the distal fallopian tube. Clear cell, endometrioid, and mucinous cancers may arise from metaplastic transformation of the OSE, although an extraovarian origin has been proposed. Recent insights from molecular and genomic studies also support the concept of distinct biologic subtypes of ovarian cancer. Gene expression profiling has revealed greater similarity between ovarian clear cell carcinoma and renal clear

cell carcinoma than other ovarian subtypes.[286] High-grade serous carcinoma shares genomic and transcriptional features with the basal subtype of breast cancer, characterized by a BRCA-deficient phenotype.[23] Driver mutations that activate the PI3 kinase signaling pathway and mutations in the tumor suppressor *ARID1A* have been identified in endometrioid and clear cell ovarian cancers, which share a strong epidemiologic link with endometriosis.

The recognition of distinct ovarian cancer subtypes has implications for prevention, early detection, clinical trial design, and the identification of new therapeutic targets, particularly for advanced-stage and recurrent disease. Results from the large screening trials of postmenopausal women in the United States, United Kingdom, and Japan using CA-125 and TVUS do not at present support routine screening for ovarian and fallopian tube cancer in the general population. Future screening strategies may focus on women at greatest genetic risk by high-throughput sequencing and mutation testing. Genome-wide association studies have recently identified new ovarian cancer risk loci.[287,288] Novel screening strategies will also be needed to detect precursor lesions within the fallopian tube, particularly for high-grade serous carcinomas. It is not yet known whether prophylactic salpingectomy without removal of the ovaries is an acceptable prevention strategy for premenopausal women with familial ovarian cancer syndromes. Clinical trials will soon incorporate targeted therapies with blood and imaging biomarkers to assess pathway inhibition and accurately measure disease response. Trial endpoints should also include robust quality-of-life tools to assess the effect of palliative chemotherapy on symptom control as well as evaluation of its toxicity. Although no longer used in the initial management of ovarian cancer, the role of radiation therapy in palliation remains of significant importance for symptomatic recurrence, particularly for women with chemotherapy–refractory disease.

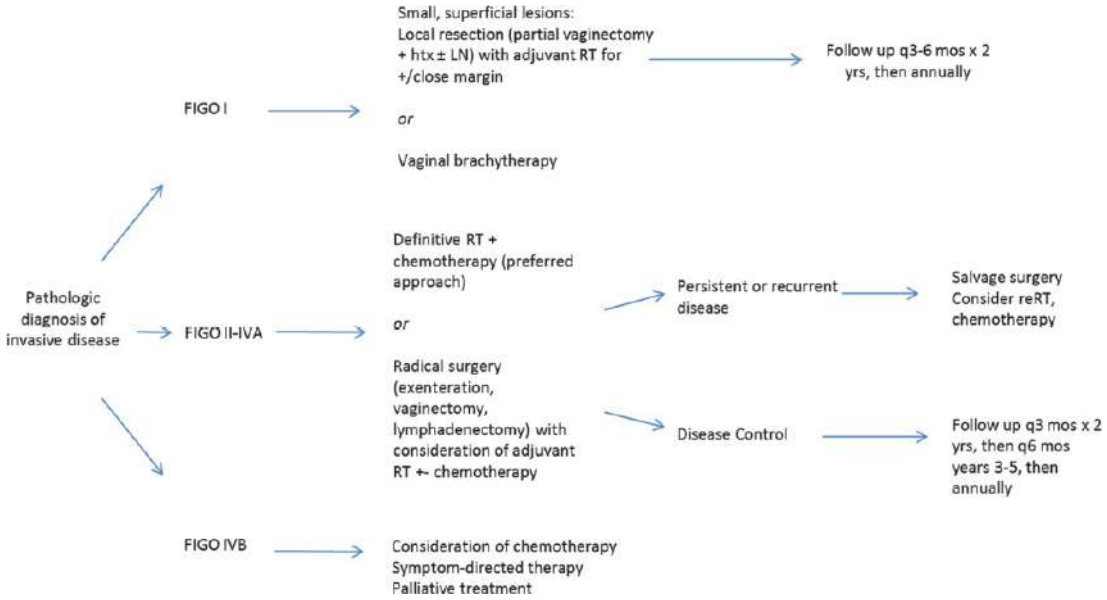
CHAPTER 76

Vaginal Cancer

Josephine Kang, Stephanie L. Wethington, and Akila N. Viswanathan

TREATMENT SCHEMATIC



ANATOMY

The vagina is a fibromuscular tube that extends from the cervix down to the vestibule, or cleft, between the labia minora. The average length of the vagina is 3 to 4 inches or 7.5 cm. It lies dorsal to the urethra and bladder base and ventral to the rectum. Invaginations between the vaginal mucosa and cervix form the anterior, posterior, and lateral fornices. Embryologically, the vagina is believed to be of dual origin, with the upper third derived from the uterine canal, whereas the lower two-thirds are derived from the urogenital sinus.[1]

Proximally, the vagina joins the uterine cervix at an angle, and, as a result, the posterior vaginal wall is longer than the anterior wall (Fig. 76.1). The proximal

posterior vaginal wall is separated from the rectum by the rectovaginal septum or fascia. The overlying peritoneal reflection forms the posterior cul de sac, also known as the pouch of Douglas. Invaginations between the vaginal mucosa and cervix form the anterior, posterior, and lateral fornices. Laterally, the vagina is adjacent to the pelvic fascia and levator ani muscles. Inferiorly, the vagina extends through the urogenital diaphragm to lie dorsal to the urethra and ventral to the rectum. The fibromuscular perineal body separates the vagina from the anal canal. At the introitus, the vagina has a perforated fold of thin connective tissue and mucous membrane known as the hymen.

The vaginal wall is comprised of the mucosa, muscularis, and adventitia. The innermost lining of the vagina is formed by a nonkeratinizing, stratified squamous epithelium overlying a basement membrane. This epithelial mucosa lacks glandular structures and instead receives lubrication from mucous secretions originating in the cervix. Underneath the mucosa is the connective tissue composed of elastin and a thick muscularis layer composed of two layers of smooth muscle. The inner layer is arranged circularly, whereas the outer layer is arranged longitudinally. This muscular layer is covered by the third layer, a thin adventitia that merges with neighboring organs.

The vagina has a complex, extensive network of lymphatic drainage, with vessels that course through the submucosal and muscularis layer (Fig. 76.2). The proximal portion drains primarily via cervical lymphatics. The proximal anterior vagina drains along cervical channels to the internal iliac and parametrial nodes and the proximal posterior vagina drains into the inferior gluteal, presacral, and anorectal nodes. The distal aspect of the vagina drains into the superficial inguinal nodes, and ultimately to the pelvic nodes, following drainage patterns of the vulva. Lesions in the midvagina have been shown to drain either way.[2] Lesions infiltrating the rectovaginal septum may spread to the pararectal and presacral nodes because there are multiple interconnections between the lymphatic channels, and pattern of drainage cannot be reliably predicted based on location of the primary tumor.

The vagina is supplied by the vaginal artery, which arises from the cervical branch of the uterine artery and runs lateral to the vagina until it anastomoses distally with the inferior vesical and middle rectal arteries. The venous plexus runs parallel to the arteries, draining into the internal iliac vein. The vaginal vault is innervated by the lumbar plexus and pudendal nerve, with branches from sacral roots 2 to 4.[3]

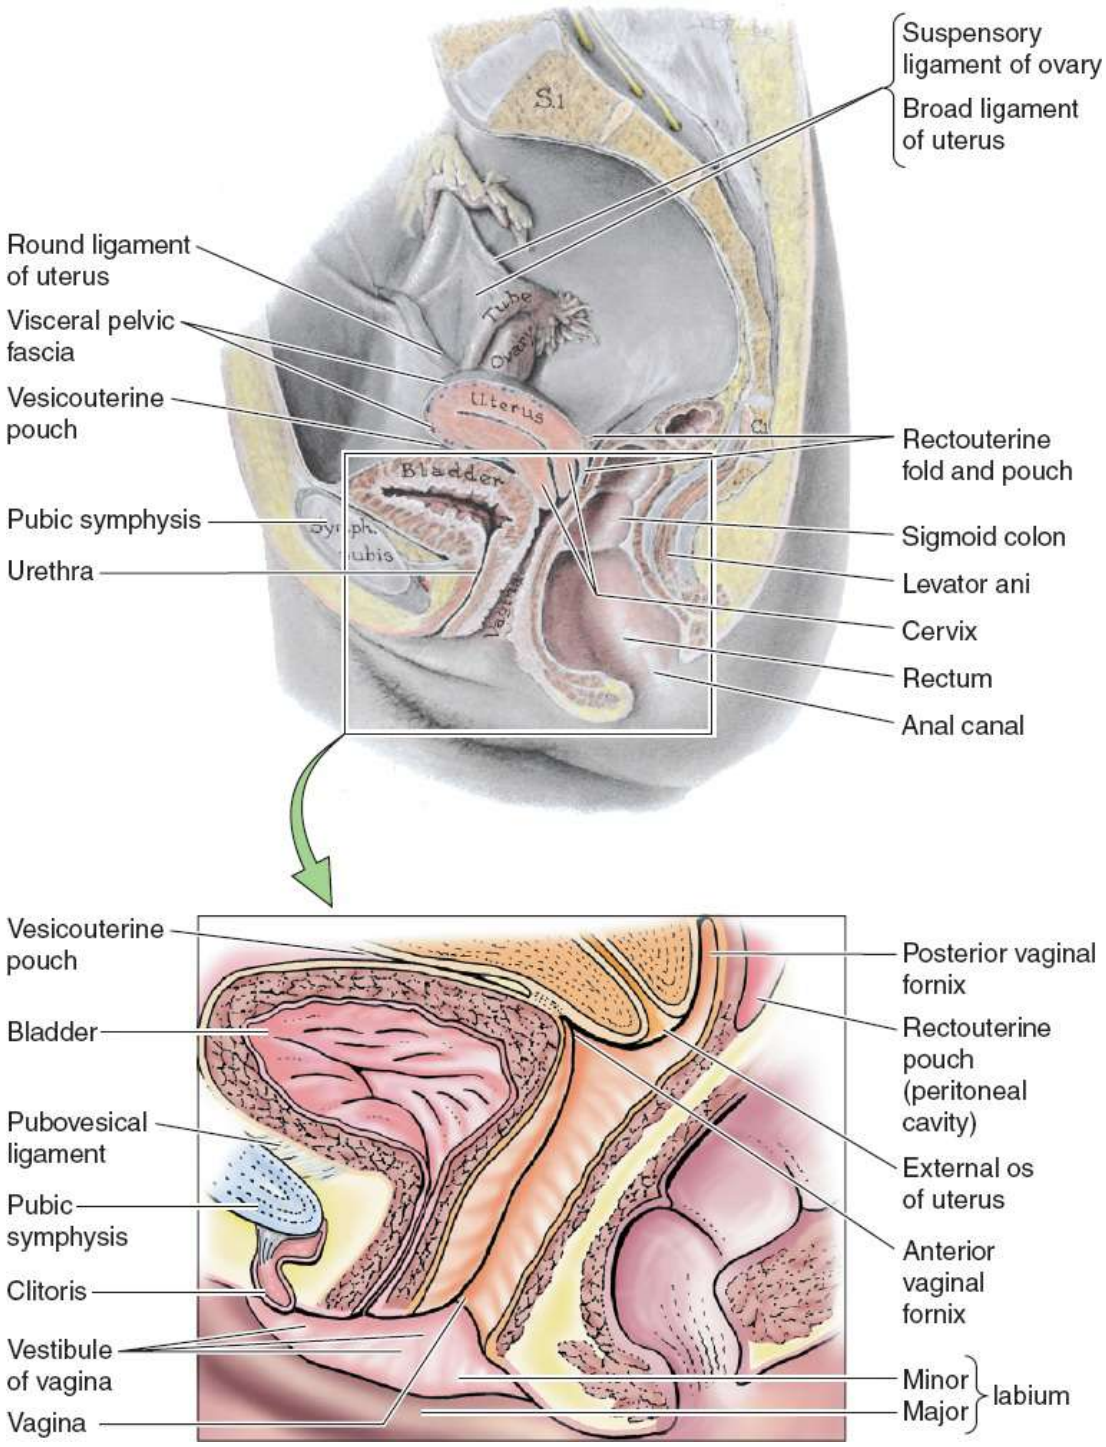


FIGURE 76.1. Anatomy of female pelvis.

EPIDEMIOLOGY, PRESENTATION AND MANAGEMENT

Primary vaginal cancer is a rare malignancy, constituting 1% to 2% of all gynecologic malignancies. There are approximately 4,600 new cases and 950

deaths from primary vaginal cancer in the United States every year.[4]

The majority of malignant lesions in the vagina are attributable to direct spread or metastases from other gynecologic malignancies. According to the staging system set by the International Federation of Obstetrics and Gynecology (FIGO), any tumor involving both the vagina and cervix should be classified as a cervical carcinoma. Similarly, any tumor involving both the vagina and vulva is to be classified as a vulvar carcinoma.[5] A malignant vaginal lesion in a patient with prior history of invasive cervical carcinoma within the past 5 years also excludes diagnosis as a primary vaginal cancer.[6] As a result, only a minority of vaginal carcinoma cases meet the criteria of being a primary vaginal cancer.

The peak incidence of primary vaginal cancer is in the sixth and seventh decade of life. According to data from the Surveillance, Epidemiology, and End Results (SEER) program,[7] 2,149 women in the United States were diagnosed with primary vaginal cancer from 1990 to 2004. The mean age at diagnosis was 65 +/− 14 years and incidence rates increased with age. There has been an overall decrease in the incidence of primary vaginal tumors, possibly secondary to earlier detection and to implementation of strict exclusion criteria in the FIGO staging system.

According to the SEER study by Shah et al.,[7] most women diagnosed with primary vaginal cancer are non-Hispanic whites (66%), followed by African Americans (14%), Hispanic whites (12%), Asian/Pacific Islanders (7%), and others (1%). Incidence rates were highest for African American women (1.24/100,000 person-years) and lowest for Asian/Pacific Islanders (0.64/100,000 person-years).

A review of five series, encompassing a total of 1,375 cases of vaginal cancer, reported a FIGO stage distribution as follows: 26% stage I, 37% stage II, 24% stage III, and 13% stage IV.[8] Consistent with this, the National Cancer Database (NCDB) review by Creasman et al.,[9] for the period of 1985 to 1994, revealed 3,244 cases of invasive primary vaginal carcinoma, with 24% of patients presenting with American Joint Committee on Cancer (AJCC) stage I disease, 20% AJCC stage II, 24% AJCC stages III-IV, and 32% unknown. Most tumors were moderately (28%) or poorly (28%) differentiated at presentation.

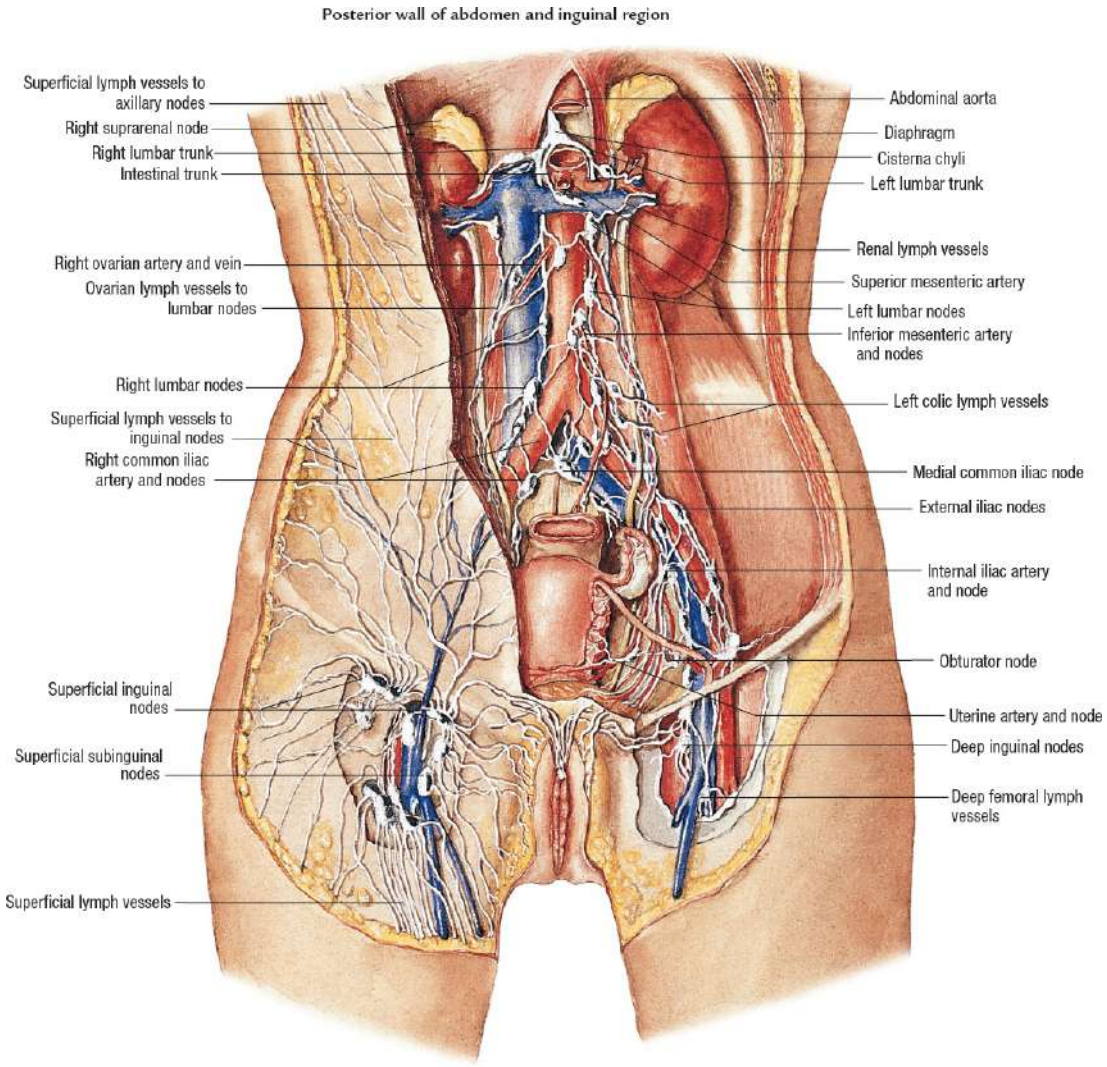

FIGURE 76.2. Lymphatic drainage of the vagina.

Because of the low incidence, treatment recommendations are based on results from relatively small retrospective series comprised of heterogeneous patient populations and treatments, and it remains unlikely that randomized clinical trials will be feasible.

Vaginal Intraepithelial Neoplasia

It is hypothesized that vaginal intraepithelial neoplasia (VAIN) is a precursor lesion to squamous cell carcinoma of the vagina.[10] There has been a steady increase in the diagnosis of VAIN over the past several decades, perhaps because of a combination of increased cytologic screening, awareness, and incidence of human papillomavirus (HPV). VAIN is defined as atypical of squamous cells without evidence of stromal invasion and was first reported by Hummer and

colleagues in 1933.[10]

VAIN is further classified into low grade (VAIN 1) and high grade (VAIN 2 to 3). VAIN 1 is characterized by cytomorphologic changes limited to the upper one-third of the epithelium. Such changes include nuclear enlargement, nuclear hyperchromasia, cytoplasmic halos, and occasional binucleation. VAIN 2 to 3 is characterized by cytomorphologic changes in the basal keratinocytes, including nuclear pleomorphism, nuclear hyperchromasia and crowding, and mitotic figures (including atypical forms). VAIN 2 and 3 are distinguished by depth of cytologic change. Cytologic changes confined to the lower two-thirds of the epithelium are designated VAIN 2, whereas changes involving the full thickness of the epithelium are VAIN 3. Carcinoma *in situ* encompasses the full epithelial thickness and is included under VAIN 3.

The overall incidence of VAIN is estimated to be 0.2 to 0.3 cases per 100,000, with peak incidence found in women who are 40 and 60 years of age.[10] The incidence of VAIN 3, or *in situ* vaginal cancer, is estimated to be 0.1 per 100,000 women with peak incidence between ages 70 and 79, according to data from the US Centers for Disease Control and Prevention's National Program of Cancer Registries and the National Cancer Institute's SEER Program.[11]

VAIN is typically asymptomatic.[12] As a result, many cases are detected after cytologic evaluation as part of surveillance in patients with a history of CIN or invasive cervical carcinoma.

Although the likelihood of VAIN progressing to invasive disease is difficult to predict for individual cases, multiple clinical series have demonstrated a significant overall increase in risk of invasive vaginal cancer after a diagnosis of VAIN. Several retrospective studies have demonstrated a range of 2% to 20% of patients with VAIN progressing to invasive vaginal cancer.[12,13] The rate of occult invasive disease in patients with VAIN 3 has been reported to be as high as 28%.[14] The risk of malignant transformation in VAIN 1 and 2 is less clearly elucidated.

Risk Factors

HPV is implicated in development of VAIN, though the relationship between HPV and development of intraepithelial neoplasia has been best demonstrated for cervical lesions. HPV 16 and 18 are the most prevalent subtypes associated with VAIN. It is estimated that HPV 16/18 is identified in 40% of VAIN 1 and 60% of high-grade VAIN 2/3 cases.[15] With widespread implementation of HPV vaccination, it is anticipated that the incidence of VAIN will start to decline. It is

predicted that HPV vaccination will ultimately prevent up to 70% of VAIN cases.[16]

The diagnosis of VAIN is often associated with prior or concurrent neoplasia elsewhere in the lower genital tract. Multiple series suggest approximately 50% to 90% of patients with VAIN have concurrent or prior history of intraepithelial neoplasia or carcinoma of the cervix or vulva.[13,17,18]

Treatment Options for VAIN

In general, women with low-grade VAIN can be offered close surveillance, as lesions often regress spontaneously. In a study by Aho et al.,[13] 78% of patients with VAIN 1 or VAIN 2 had spontaneous regression of disease without treatment. Over time, however, VAIN 1 can recur; in one series, up to 54% of patients with VAIN 1 who were observed ultimately developed recurrent, persistent or progressive disease,[10] at a median time of 17 months. High-grade VAIN has a higher likelihood of occult invasive disease and progression to invasive disease [14,19] and is typically treated aggressively. There is currently no consensus on optimal treatment modality for patients with high-grade VAIN. Treatment approaches include local excision, partial or total vaginectomy, laser vaporization, electrocoagulation, topical 5% fluorouracil administration, topical 5% imiquimod, and radiation.[18–26] Reported success rates for different approaches range from 48% to 100% for laser vaporization,[27,28] 52% to 100% for colpectomy,[14,19,29] 75% to 100% for topical 5-FU,[20,30–34] 57% to 86% for topical 5% imiquimod,[26] and 83% to 100% for radiation[22,35–38] (Table 76.1). Given the breadth of available therapies, an individualized approach to patient management is advised, with consideration given to the patient's overall health, desire to preserve sexual function, candidacy for surgery, disease multifocality, and prior treatment failures.

Surgical and Ablative Therapies

Surgical excision for VAIN is an option in select cases, particularly for vaginal vault lesions or lesions close to the introitus. Approaches include wide local excision, partial vaginectomy and, in rare cases, total vaginectomy for highly extensive disease, which provides the advantage of obtaining a complete pathologic diagnosis. Most resections can be performed through a transvaginal approach. Smaller lesions can be excised or ablated using a cold-knife approach, electrosurgical loop excision, laser, or via ultrasonic surgical aspiration.[55–57]

Location of VAIN in the vaginal vault or posthysterectomy suture recesses

may require partial vaginectomy for complete resection, as redundancy of the vaginal mucosa makes it difficult to rule out occult disease with biopsy alone. Multifocal or extensive lesions may require a more extensive approach, such as total vaginectomy with or without skin grafting.[19]

Overall, series looking specifically at upper vaginectomy report control rates of 68% to 88%.[14,19,29,58]

Potential complications depend on the extent and method of surgical resection and range from vaginal shortening and stenosis to standard postoperative morbidity associated with abdominal procedures such as injury to bowel or bladder. Complication rates of upper vaginectomy have been variably reported; in the series by Indermaur, there was a 9% complication rate. It should be noted that patients with a history of radiation treatment are at higher risk of postoperative complications, with a higher rate of fistula formation reported in one study.[17]

Topical Treatments

Topical treatments include topical 5-fluorouracil (5-FU) and 5% imiquimod cream, with response rates of 41% to 88% for 5-FU and 50% to 86% for imiquimod.[22,30–32,34,53,54,59] Imiquimod increases levels of interferon alpha, interleukin 12, and tumor necrosis factor[53] thought to result in immunomodulation of the vaginal mucosa. Long-term efficacy is unknown as well as response rates in immunocompromised patients.

Topical therapies have been utilized in patients with early-stage lesions, multifocal disease, or multiple comorbidities rendering them nonideal surgical candidates. Topical creams are favored in management of young, HPV-positive women presenting with multifocal lesions. Topical applications have also been utilized prior to surgery, to reduce lesion size and improve stripping of neoplastic epithelial cells from underlying stroma.[18] Side effects of topical treatments include local irritation, burning, and ulceration.[31,32]

Radiation Therapy

In general, radiation is reserved for patients who relapse after more conservative treatments, and/or have VAIN 3, particularly if there is an *in situ* disease component. Numerous small series over the past 20 to 30 years have reported control rates ranging from 80% to 100%.[12,22–24,35–37,60] Drawbacks to radiation include potential undertreatment of occult invasive disease, the risk of secondary malignancy, and long-term morbidity, although there are no prospective data

available regarding the impact of treatment on sexual function and quality of life. High–dose rate (HDR), medium–dose rate (MDR), and low–dose rate (LDR) techniques have been reported with acceptable results, although it is difficult to compare regimens because of small patient numbers, generally short follow-up times and overall nonuniformity among series.

Overall, excellent local control and low toxicity have been reported for LDR brachytherapy. LDR treatment is delivered with an intracavitary vaginal cylinder using cesium-137. Typically, a dose of 60 Gy is prescribed to the vaginal mucosa, but a wide range of doses, depending on depth of dose prescription, as well as a variety of techniques, have been reported.[22,35,36,41] Chyle et al.[40] prescribed 70 to 80 Gy to the vaginal surface and reported a 17% recurrence rate at 10 years in their series of 37 patients. Perez et al.[41] treated patients to the vaginal surface with a dose of 60 to 70 Gy and reported 1 recurrence out of 20 patients. The recurrence occurred in the distal vagina and was noted to be a marginal recurrence. Blanchard et al.[35] published a series on 28 patients with VAIN 3 treated at Institut Gustave Roussy from 1985 to 2008. Patients were treated with LDR brachytherapy, using a vaginal mold technique, to dose of 60 Gy prescribed 5 mm below the vaginal surface; 18 patients received treatment to the upper half of the vagina, 6 were treated to the upper two-thirds, and 4 were treated to the whole vaginal length. With a median follow-up time of 41 months, the authors report only 1 in-field recurrence, with a 10-year local control rate of 93%. Treatment with LDR brachytherapy is overall well tolerated; in the Perez series, there was only 1 grade 3 urinary complication among 40 patients with VAIN 3 or stage 1 vaginal cancer treated with LDR.[41]

TABLE 76.1 VAGINAL INTRAEPITHELIAL NEOPLASIA OUTCOMES BY TREATMENT MODALITY

Series	Follow-Up	No. of Pts	% Recurrence	Comments
Radiation				
Prempree[39]		7	0%	ICB 70–80 Gy
Chyle[40]		37	17%	ICB or orthovoltage radiation

HDR, high-dose rate; ICB, intracavitary brachytherapy; LDR, low-dose rate; MDR, medium-dose rate; PV, partial vaginectomy; TV, total vaginectomy; WLE, wide local excision.

There are limited data on use of MDR brachytherapy treatment for VAIN. Graham et al.[24] reviewed their experience using MDR intracavitary brachytherapy for VAIN 3 at the Beatson Oncology Centre in Glasgow, UK. Using a MDR Selectron, 48 Gy was prescribed 0.5 cm lateral to the ovoid surface (point Z) over two insertions, spaced 1 week apart. Ovoids were chosen over vaginal cylinder placement in order to adequately cover epithelium sutured into the superolateral vagina at hysterectomy. With a median follow-up duration of 77 months, recurrent/residual VAIN 3 was documented in 3 patients, and 2 of these patients subsequently developed invasive or microinvasive vaginal carcinoma. One other patient developed late progression 14 years after treatment.

Several series have reported promising results for HDR brachytherapy, with disease-free survival rates of 90% or greater. Ogino et al.[37] reported their experience treating 6 patients with VAIN 3 at Kanagawa Cancer Center from 1983 to 1993, with a mean dose of 23.3 Gy (range, 15 to 30 Gy); most treatments were delivered in 5 fractions using two ovoids, with dose calculated to a point 1 cm superior to the vaginal apex. Lesions distal to the vaginal vault had doses calculated 1 cm beyond the plane of the vaginal cylinder in order to deliver adequate dose to the entire vagina. Median follow-up was 90.5 months, with no evidence of disease recurrence in the treated patients. MacLeod et al.[38] reviewed their experience treating 14 patients with VAIN 3 from 1985 to 1995. Total dose was 34 to 45 Gy to the vaginal surface, in 8.5-Gy fractions delivered twice a week, or 4.5-Gy fractions delivered four times a week. One patient developed invasive cancer, and 1 patient had persistent VAIN 3. There were no major acute toxicities, and 2 patients developed late grade 3 vaginal atrophy and stenosis. According to one study that evaluated toxicity after use of HDR brachytherapy for VAIN in 20 patients, with utilization of the CTCAE scale, a

biologically equivalent dose of 70 Gy or greater results in significantly greater toxicity. The most commonly seen toxicities were decreased libido, vaginal discharge, dryness, mucositis, stenosis, and vaginitis.[43]

Malignant Tumors of the Vagina: Squamous Cell Carcinoma

Clinical Presentation

Symptoms

Up to 20% of women are asymptomatic at the time of diagnosis,[61] with lesions detected via cytologic screening or by speculum examination. Squamous cell carcinoma accounts for 65% to 85% of vaginal cancer cases,[7] and the greatest proportion of women present with stage I disease (36%). Up to 65% of patients with vaginal cancer present with irregular vaginal bleeding as their primary symptom.[61,62] Vaginal discharge is the second most common symptom, occurring in 10% to 15% of patients. Less frequent symptoms, associated with locally advanced disease, include the presence of a mass; pain; urinary symptoms including frequency, dysuria, or hematuria; or gastrointestinal complaints such as tenesmus, constipation, or melena. Because of the proximity of anterior wall lesions to the urethra and bladder, urinary symptoms can be seen more commonly in vaginal cancer than in cervical cancer.

Location

Vaginal cancer most frequently involves the superior one-third of the vaginal canal, with series reporting 50% to 83% of cases occurring in this region.[58,63–66] There is approximately equal involvement of the middle and inferior thirds,[58] although some studies suggest that involvement of the lower third is more common than involvement of the middle third.[61,63] The lateral walls are less frequently involved. Tumors may exhibit an exophytic or ulcerative, infiltrating growth pattern.

A high proportion of patients have a history of prior hysterectomy. Involvement of the cervix (if present) or vulva at the time of diagnosis excludes classification as a primary vaginal cancer. Lesions can extend radially, either into the lumen to form exophytic masses or through the vaginal wall to invade surrounding musculature and organs. Anterior wall lesions can infiltrate the vesicovaginal septum and/or urethra. Posterior wall lesions can infiltrate the rectovaginal septum and involve the rectal mucosa. Advanced disease can extend laterally toward the parametrium and paracolpal tissues or into the urogenital diaphragm, levator ani muscles, or pelvic fascia and eventually to the

pelvic side wall.

Advanced or recurrent disease can present with distant metastases. The most frequent site of hematogenous metastasis is the lung, with less commonly noted sites being liver and bone.[40] In a series by Perez et al.,[67] the incidence of distant metastasis was 16% for stage I, 31% for stage II, 46% for stage IIB, 62% for stage III, and 50% for stage IV. Some histologies may have a higher likelihood of distant metastases than others. Chyle et al.[40] noted a higher incidence of distant metastases in patients with adenocarcinoma (48%) than in those with SCC (10%), with correspondingly lower 10-year survival rates (20% vs. 50%).

Histopathology

Grossly, SCC of the vagina can present as nodular, ulcerated, indurated, exophytic, or endophytic lesions. Histologically, tumors are graded as well, moderate or poorly differentiated and have been described as keratinizing, nonkeratinizing, basaloid, warty, or verrucous. The majority of these lesions are nonkeratinizing and moderately differentiated.[68] It is not possible to histologically distinguish a primary vaginal SCC from recurrent cervical or vulvar carcinoma.

Verrucous carcinoma is a distinct histologic variant of vaginal SCC[69] that typically presents as a well-circumscribed, soft, cauliflower-like mass that is microscopically well differentiated, with a papillary growth pattern and acanthotic epithelium. There is surface maturation with parakeratosis or hyperkeratosis without koilocytosis. This variant of SCC exhibits less aggressive behavior and rarely metastasizes.[69] It is also resistant to radiation and often transforms to a more aggressive histology if treated with radiation. Therefore, it should be considered as a distinct entity separate from other vaginal SCC.

Sarcomatoid squamous cell carcinoma is a rare subset of vaginal SCC, comprising 2% of all cases. It is characterized by spindle-shaped neoplastic cells that can initially be mistaken for sarcoma. However, positive stains for cytokeratin help distinguish sarcomatoid SCC as a poorly differentiated variant of vaginal SCC.[70]

Patterns of Lymphatic Drainage

The vagina has a complex pattern of lymphatic drainage, with multiple interconnections. The upper vagina drains to the obturator and hypogastric nodes, similar to the cervix. The lower vagina drains to the inguinal, femoral, and external iliac nodes, and posteriorly situated lesions can drain to the inferior

gluteal, presacral, or perirectal nodes. Lymphatic channels in the mucosa run parallel to networks of channels in the submucosa and muscular layer, ultimately converging to form trunks at the vaginal wall periphery, which subsequently drain to major pelvic nodal groups.

Because of considerable crossover drainage, the location of the primary tumor is not a reliable indicator of drainage site. Frumovitz et al. utilized lymphoscintigraphy to determine patterns of lymphatic drainage in 14 women diagnosed with primary vaginal cancers[71] and found a substantial degree of anomalous drainage, resulting in a change in radiation treatment for 33% of patients. For example, among 4 women with lesions located in the upper third of the vagina, which is predicted to drain along the cervical lymphatic chains to the pelvis, 2 (50%) were found to have a sentinel node in the inguinal region. Among 5 women with lesions located at the vaginal introitus, a location predicted to drain along the vulvar lymphatic chains to the inguinal triangle, 3 (60%) were found to have a sentinel node in the pelvis.

The risk of nodal involvement increases significantly with stage. At diagnosis, up to 20% of patients have clinically positive inguinal nodes, with reported ranges of 5.3% to 20%.[41,67] Sparse data on nodal metastases are derived from series in which exploratory laparotomies and lymphadenectomies were performed.[72] However, the true incidence of positive lymph nodes is difficult to determine because most patients receive treatment with radiation therapy and do not undergo surgical lymphadenectomy. The incidence of lymph node involvement has been reported to be 0% to 14% in stage I and 21% to 32% in stage II disease.[72–74] The incidence of nodal involvement in stages III and IV has been reported to be as high as 78% and 83%, respectively.[63]

The risk of nodal failure increases significantly if there is local recurrence. Chyle et al.[40] reported 10-year inguinal and pelvic failure rates of 16% and 28%, respectively, in patients with local recurrence, in contrast to 2% and 4%, respectively, in patients without local recurrence.

Staging

The AJCC[75] and FIGO[5] systems are used to stage vaginal cancer (Tables 76.2 and 76.3). Primary vaginal melanomas and lymphomas are staged according to the AJCC staging systems for melanomas and lymphomas, respectively.[75]

For patients with a prior gynecologic malignancy, a 5-year period free of disease is generally considered adequate to allow for distinction between recurrent disease and a new primary vaginal cancer. FIGO no longer recognizes

carcinoma *in situ* as stage 0.

TABLE 76.2 INTERNATIONAL FEDERATION OF GYNECOLOGY AND OBSTETRICS STAGING SYSTEM FOR CARCINOMA OF THE VAGINA

Stage	Description
Stage I	Carcinoma is limited to vaginal wall.
Stage II	Carcinoma has involved the subvaginal tissue but has not extended to the pelvic wall.
Stage III	Carcinoma has extended to the pelvic wall.[a]
Stage IV	Carcinoma has extended beyond the true pelvic or has involved the mucosa of the bladder or rectum; bullous edema as such does not permit a case to be allotted to stage IV.
Stage IVA	Tumor invades the bladder and/or rectal mucosa and/or direct extension beyond the true pelvis.

[a]Pelvic wall is defined as muscle, fascia, neurovascular structures, or skeletal portions of the bony pelvis.

TABLE 76.3 AMERICAN JOINT COMMISSION ON CANCER STAGING OF VAGINAL CANCER 7TH EDITION

Primary Tumor (T)	
Tx	Primary tumor cannot be assessed.
T0	No evidence of primary tumor
Tis/0	Carcinoma *in situ*
T1/I	Tumor confined to the vagina
T2/II	Tumor invades paravaginal tissues but not to the pelvic wall.
T3/III	Tumor extends to the pelvic wall*.
T4/IVA	Tumor invades the mucosa of the bladder or rectum and/or extends beyond the pelvis (bullous edema is not sufficient to classify a tumor as T4).
Regional Lymph Nodes (N)	
Nx	Regional lymph nodes cannot be assessed.
N0	No regional lymph nodes
N1/IVB	Pelvic or inguinal lymph node metastasis
Distant Metastasis (M)	

Mx	Distant metastasis cannot be assessed.
M0	No distant metastasis
M1/IVB	Distant metastasis
Stage Groupings	
Stage 0	Tis N0 M0
Stage I	T1 N0 M0
Stage II	T2 N0 M0
Stage III	T1–3 N1 M0, T3 N0 M0
Stage IVA	T4, any N, M0
Stage IVB	Any T, any N, M1

*Pelvic wall is defined as muscle, fascia, neurovascular structures, or skeletal portions of the bony pelvis.

Stage I disease is defined as limited to the vaginal wall, and stage II disease involves subvaginal tissue without extension to the pelvic wall. Discriminating between stages I and II can be subjective; thin tumors <0.5 cm are generally classified as stage I, with thicker infiltrating tumors or those with paravaginal nodularity classified as stage II. Perez et al. proposed a modification to the FIGO system in 1973, distinguishing tumors with paravaginal submucosal extension only (stage IIA) from tumors with parametrial infiltration (stage IIB).[41] The study reported a 20% 5-year survival difference (55% vs. 35%) between stages IIA and IIB. This modification has not been adopted into FIGO staging. However, some investigators consider the distinction to be prognostically relevant.[39,67] Stage III disease extends to the pelvic sidewall or involves lymph nodes, whereas stage IV disease reflects spread to the bladder, bowel, or distant sites.

Diagnostic Workup

The diagnostic workup should start with a thorough history and physical examination. During speculum examination, the speculum blades can obscure the anterior and posterior walls, so it is essential to rotate the speculum for visualization of all four walls from the introitus to the apex. Bimanual examination, with careful digital palpation, should be performed, assessing for parametrial and pelvic side wall involvement and invasion of tumor to the rectal mucosa. Complete assessment of tumor extent and assessment of vaginal walls are facilitated by examination under anesthesia.

Inguinal nodes should be palpated for disease involvement, particularly if the primary lesion is situated in the lower portion of the vagina, as 5% to 20% of patients have been reported to have involved inguinal nodes at presentation.[41,67] Suspicious nodes warrant a biopsy. Laboratory tests include a complete blood count with differential and assessment of renal and hepatic function.

A definitive diagnosis is achieved with biopsy of suspected lesions, which can present as an exophytic mass, plaque, or ulcer. If a lesion is not visible in the setting of abnormal cytology, colposcopy with acetic acid, followed by Lugol iodine stain, is conducted. Biopsies of white epithelium or atypical vascularity should be obtained after application of acetic acid. Iodine will identify Schiller-positive regions, which are nonstaining and should correspond with areas identified following application of acetic acid. Adequate biopsies should include the cervix, if present, to rule out a cervical primary. Patients can present with multiple regions of abnormality.

FIGO staging of vaginal cancer is clinical and allows chest x-ray, intravenous pyelography (IVP), barium enema, cystoscopy, and proctosigmoidoscopy. FIGO encourages the utilization of more advanced imaging modalities, such as computed tomographic (CT) imaging, magnetic resonance imaging (MRI), and positron emission tomography (PET), as guidance for treatment, though imaging findings cannot be used to reassign stage.[76] Cystoscopy or proctosigmoidoscopy may be necessary in patients with symptoms suggestive of bladder or rectal infiltration. CT of the pelvis is obtained in place of IVP to assess the renal parenchyma and also to obtain information on the extent of local disease and lymph node status. MRI can provide salient treatment planning information by characterizing extent of invasion and differentiating malignant tumor, which is isointense to muscle on T1, and hyperintense on T2, from normal structures and/or fibrosis.[77] Advantages of MRI over other imaging modalities include superior soft tissue contrast resolution, allowing accurate assessment of tumor volume and extent of local invasion and accurate assessment of pelvic nodal involvement. In general, MRI is regarded as superior to CT for staging of gynecologic malignancies and should be obtained when available.

Positron emission tomography (PET) has shown efficacy in detecting the extent of primary tumor and abnormal lymph nodes in vaginal cancer with higher sensitivity than CT (Fig. 76.3), as is the case with cervical carcinoma.[78,79] Primary vaginal carcinoma and metastatic lesions demonstrate avid uptake of 2-[fluorine 18] fluoro-2-deoxy-D-glucose (FDG). In one study, 23 patients with primary vaginal carcinoma received both PET and CT during staging. CT

identified the primary tumor in only 43% of patients, whereas PET identified the tumor in 100%. PET identified suspicious uptake in groin and pelvic nodes in 8 of 23 patients, compared to 4/23 with CT. Treatment planning was modified in 14% of patients because of findings from PET, and the authors concluded that PET detects primary tumor and abnormal lymph nodes more often than CT.[78] Another series compared detection of suspicious lymph nodes using PET/CT versus MRI and CT; PET/CT outperformed both MRI and CT, resulting in a change in management in 36% of cases.[79] It is important that the patient have an empty bladder prior to imaging, as physiologic FDG activity in a filled bladder can potentially interfere with accurate estimation of vaginal involvement. In practice, most patients undergo planning for radiation treatment with multiple imaging modalities.

Risk Factors

Risk factors for primary vaginal SCC are similar to VAIN and cervical neoplasia. Commonly cited factors include HPV infection and/or history of cervical or vulvar intraepithelial neoplasia, immunosuppression, multiple sexual partners, smoking, and early age at first intercourse.

It is believed that majority of cases of vaginal cancer can be attributed to HPV infection. According to a meta-analyses comprised of 14 studies, the overall HPV prevalence was 70% for vaginal carcinomas, with the most common subtypes as follows: HPV 16 (53.7%), HPV 18 (7.6%), and HPV 31 (5.6%). Multiple subtypes of HPV were identified in 3.4% of vaginal carcinoma cases.[80] In a population-based case control study of 156 women with VAIN or invasive cancer, HPV DNA was detectable in 80% of patients with *in situ* disease and 60% of those with invasive disease, and 30% of patients reported a history of treatment for invasive malignancy, most commonly cervix, or *in situ* anogenital neoplasia.[81]

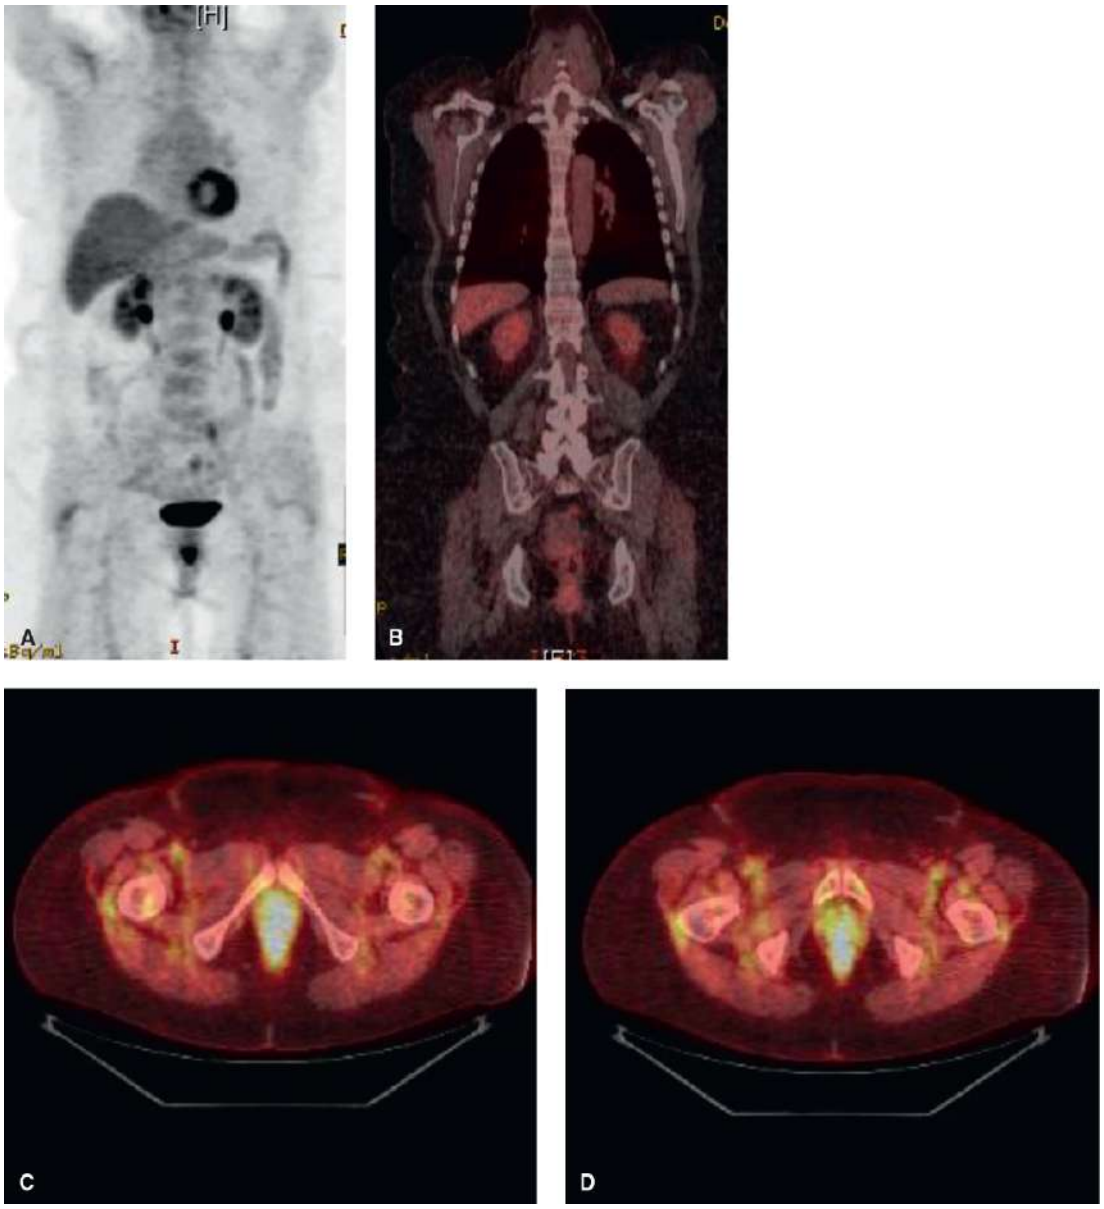

FIGURE 76.3. CT/PET fusion images of vaginal carcinoma. Coronal **(A, B)** and axial **(C, D)** images of a localized invasive vaginal carcinoma, extending into the central and lower 1/3 portion of the vagina above the introitus.

Patients with a history of cervical cancer have a significantly higher risk of developing *in situ* as well as invasive carcinoma of the vagina. Studies suggest that 10% to 50% of patients with a history of VAIN or invasive carcinoma of the vagina have undergone treatment for *in situ* or invasive cervical carcinoma,[12,40,61,67,82–86] with the interval from treatment of cervical disease to development of vaginal carcinoma averaging approximately 14 years.[61,72] Early hysterectomy appears to be a risk factor in some studies, if performed for malignant or premalignant disease.[81,87]

The role of ionizing radiation to the pelvis in the development of vaginal carcinoma is unclear, with conflicting reports. According to one study which analyzed 1,200 patients treated over a 20-year period for carcinoma of the cervix, prior RT was not shown to result in increased secondary pelvic neoplasms.[88] A second study by Boice et al.,[89] however, reported a 14-fold increased risk of vaginal cancer in women with a history of pelvic irradiation before the age of 45, with a significant dose–response relationship.

Another potential risk factor is chronic irritation of the vaginal mucosa, resulting in chronic inflammation, hyperkeratosis, thickening, and acanthosis,[90] with subsequent metaplastic and dysplastic changes; however, this is not proven. Although older studies showed that more vaginal cancers arise from the posterior vaginal wall, other studies report approximately equal distribution of invasive carcinomas on the anterior and posterior walls,[58,61,63,64,91] arguing against the theory that pooling of irritating substances in the posterior fornix contributes to development of vaginal cancers, particularly on the posterior wall. Chronic irritation from use of vaginal pessaries has also been implicated as a contributor in vaginal cancer development.[92]

Other, lesser reported risk factors include low socioeconomic status, history of genital warts, and vaginal trauma.[93] A larger case–control study of 36,856 women found an increased risk of vaginal cancer in alcoholic women, likely associated with a higher incidence of lifestyle factors, such as promiscuity and smoking, which are also associated with a higher incidence of HPV infection. HIV-infected and other immunocompromised women are at higher risk of developing vaginal carcinoma, which tends to behave more aggressively than in the immunocompetent patients.[90]

Prognostic Factors

Stage at time of presentation is the most significant prognostic factor.[7,41,84,94] According to an NCDB study by Creasman et al.,[9] 5-year survival rates are as follows: 96% for stage 0, 73% for stage I, 58% for stage II, and 36% for stage III/IV disease.

The series by Shah et al.,[7] based on SEER data for women diagnosed between 1990 and 2004, also reveals the correlation between stage and outcome, with 5-year disease-specific survival rates of 84% for stage I, 75% for stage II, and 57% for stage III/IV; the adjusted hazard ratio for mortality, on multivariate analysis, was 4.67. In the Perez et al. series,[67] 165 patients with primary vaginal cancer were treated with definitive radiation therapy, and had 10-year actuarial disease-

free survival rates of 94% for stage 0, 75% for stage I, 55% for stage IIA, 43% for stage IIB, 32% for stage III, and 0% for stage IV.[95]

Size of the initial lesion is a prognostic factor that has shown significance in several series. The SEER database study,[7] which included 2,149 women with primary vaginal cancer, noted a significantly lower 5-year survival rate in women with tumors 4 cm or larger than in women with tumors smaller than 4 cm (65% vs. 84%); however, size information was missing for 52% of women. After multivariate analysis, the women with the larger tumors had an adjusted hazard ratio of 1.71 for mortality. Chyle et al.[40] in their review of 301 patients treated at M.D. Anderson Cancer Center (MDACC) from 1953 to 1991 found that women with lesions larger than 5 cm in maximum diameter had a significantly higher 10-year local recurrence rate than those with smaller lesions (40% vs. 20%). The series by Hellman et al.,[94] with 314 patients treated at the Karolinska University Hospital from 1956 to 1996, found only three factors to independently predict for poor survival on multivariate analysis: advanced age, tumor size greater than or equal to 4 cm, and advanced stage. Tumors comprising two-thirds or more of the vagina and tumors growing circumferentially were associated with an extremely poor prognosis. The series by Tran et al.,[96] which reviewed records of 78 patients with SCC treated at Stanford University Medical Center from 1959 to 2005, also found size to be a prognostic factor for disease-free survival on multivariate analysis, along with stage, prior hysterectomy, and pretreatment hemoglobin level. Smaller series by Tjalma et al.[97] and Kirkbride et al.[84] also describe adverse outcomes with larger tumor size. Other series have failed to show significance, but likely are hindered by small numbers, difficulties in accurate assessment of size, and treatment heterogeneity.

Extent of vaginal canal involvement has also been examined and found to be significant, perhaps because it is a surrogate for tumor size. In a series by Stock et al.,[64] which examined 100 cases of primary vaginal carcinoma treated at Magee-Women's Hospital from 1962 to 1992, patients with involvement of one-third of the vaginal canal or less had a significantly higher 5-year disease-free survival rate (61%) than patients with more extensive involvement (25%).

Several studies suggest HPV status is an indicator of favorable prognosis. Fuste et al. found a trend toward longer survival in women with HPV-positive tumors in their series of 32 patients, with median survival times of 113.9 months versus 19.7 months for women with HPV-positive and HPV-negative tumors, respectively (P = .15).[98] Alonso et al.[99] evaluated 57 total patients, of whom 70.2% had evidence of high-risk HPV. On multivariate analysis, HPV-positive

status was a favorable prognostic variable for OS (HR 0.35, *P* = .038). Brunner et al.[100] evaluated 35 patients with primary invasive SCC of the vagina. Using *in situ* hybridization, HPV was detected in 51.4% of cases. There was no significant influence on clinical stage, grade or tumor size, nor did prognosis differ between HPV-positive and HPV-negative tumors. However, in a subset of patients with FIGO stage III or higher disease, HPV positivity was found to correlate with improved disease-free and overall survival, with *P* values of .004 and .023, respectively.

There is conflicting evidence on the impact of lesion location on prognosis; it has been noted in some[40,65,101] but not all[66,67] reports. In an analysis of 110 patients by Kucera et al.,[102] 5-year survival rates were 60% for lesions of the upper third of the vagina, 37.5% for lesions of the middle third and 37% for the lower third. Chyle et al.[40] noted a 17% rate of pelvic relapse in patients with tumors in the upper third of the vagina, 36% for patients with tumors in the middle or lower third, and 42% for patients with whole-vaginal involvement. Lesions in the posterior wall were also noted to be associated with a worse prognosis than lesions involving the anterior vaginal wall,[40] with 10-year recurrence rates of 32% versus 19% on univariate analysis (*P* < .007). The Hellman series,[94] however, found no difference in prognosis between the anterior and posterior tumors. Similarly, histologic grade has been found to be an independent significant predictor of survival in several series[65,84,101] but not others.[94] Hellman et al. evaluated the impact of tumor grade and other histopathologic variables (mitotic activity, koilocytosis, growth in vessels, lymphocytic reactions) and found no correlation with survival.

Several series suggest there is a correlation between older age and decreased survival.[10,94,101] For example, age was also noted to be a significant prognostic factor in the Urbanski et al. series,[101] with 5-year survival rates of 83% for patients younger than 60 compared to 25% for those 60 years of age or older (*P* < .0001). Age >60 years was negatively associated with survival in the series by Gunderson et al., which examined a total of 110 patients (HR 2.16; *P* = .0339). Other series have failed to demonstrate the statistical significance of age.[41,103]

For patients treated with radiation, treatment time may be a significant factor impacting tumor control.[104,105] Lee et al.[105] found overall treatment time of 9 weeks or less to be associated with a pelvic tumor control rate of 97% as compared to 57% for treatment time > 9 weeks (*P* < .01). Pingley et al. also noted a correlation between treatment time and outcome; patients receiving brachytherapy within 4 weeks of external beam radiation therapy (EBRT) had a

5-year disease-free survival rate of 60%, compared to a 30% rate in patients who had an interval >4 weeks.[104]

Other possible prognostic factors include hemoglobin levels, prior hysterectomy, and smoking status. Tran et al. reviewed records of 78 patients with primary SCC of the vagina treated at Stanford University Hospital, and found a hemoglobin level <12.5 g/dL prior to definitive treatment to be prognostic for worse pelvic control and disease-specific survival[73]; 5-year disease-specific survival rates were 55% for women with Hg levels <12.5 g/dL and 76% for those with levels greater than or equal to 12.5 g/dL. This remained significant after multivariate analysis, along with prior hysterectomy, stage, and tumor size. The study by Tran et al.[96] is the first to identify prior hysterectomy as a favorable prognostic factor on multivariate analysis. This may reflect more rigorous surveillance in posthysterectomy patients, resulting in tumors discovered at an earlier stage, or may be a reflection of less overall vaginal tissue as a substrate for tumorigenesis. Two subsequent studies have identified hysterectomy as a significant prognostic factor but only in univariate analysis.[40,94]

Treatment: Surgery

For most patients with invasive vaginal cancer, surgery has a limited role and radiation is the treatment of choice. Because of the rarity of these lesions, and required individualization of treatment, it is recommended that patients are referred to a tertiary center with experienced practitioners. In general, surgery is considered beneficial only in carefully selected patients. Typically, amenable lesions are small, superficially invasive and well-demarcated, and localized to the upper vagina. For patients who have previously undergone hysterectomy, a radical upper vaginectomy and pelvic lymphadenectomy can be considered. If the uterus is present, a radical hysterectomy (which include upper vaginectomy and radical parametrectomy) with lymph node assessment could be considered, particularly for patients with a lesion in the posterior proximal vagina.[6] Regardless of surgical procedure, wide negative margins are necessary.

Older surgical series often required pelvic exenteration in 40% to 50% of cases to obtain negative margins.[63,72] Invasive anterior wall lesions may require anterior exenteration, which removes the vagina, urethra, and bladder. Posterior exenteration requires resection of the vagina and rectum. Deeply invasive, circumferential lesions may require a total exenteration in order to achieve clear margins. If positive margins, adjuvant radiation should be offered. Lesions that

extend to the inferior vagina require a total vaginectomy with radical hysterectomy, pelvic lymphadenectomy, and possibly vulvovaginectomy and inguinofemoral lymphadenectomy.[61,63,64,83] It is not uncommon for relatively small lesions to invade the rectum or urethra early in the disease course, given the close proximity of the vagina to these structures. Given the potentially devastating functional results associated with radical surgery, definitive radiation is the treatment of choice for most patients with invasive vaginal cancer and has largely replaced surgery as the primary therapeutic modality.

Exenterative surgical procedures can be a considered for previously irradiated patients with a pelvic confined tumor who cannot receive further radiation.

Patients with advanced disease are typically not candidates for curative intent surgery because of difficulty achieving negative margins, morbidity of resection, and metastatic disease.

Reported 5-year overall survival rates for stage I vaginal cancer treated with surgery range from 75% to 100% (Table 76.4).[9,64,72,83,97,107] The distinction between stage I and II disease is made clinically, based on physical examination, and can be subject to variability. The NCDB review for cancers of the vagina noted superior survival rates in patients treated with surgery,[9] though this likely reflects selection of healthier patients with good performance status for radical surgery. A more recent analysis utilizing the SEER database[7] found women with stage I disease treated with surgery only to have a lower risk of mortality than those treated with radiation only, combined modalities or no treatment; however, this difference did not reach statistical significance. For stage II vaginal cancer patients, there was a similar trend toward increased mortality in women who did not have surgery alone as their primary treatment modality, but values once again did not reach statistical significance in their multivariate adjusted model.

TABLE 76.4 OUTCOMES AFTER PRIMARY SURGERY IN EARLY-STAGE VAGINAL CANCER

Series	Stage	No. of Pts	Outcomes	Comments
Jain (2010–2015)[106]	I	10	1 y DFS 89%	6 pts received adjuvant treatment for + margins/nodes
	II	1	1 y OS 100%	2 RV; 5 TV; 4 PV
Tjalma (1974–1999)[97]	I	26	5 y OS 91%	4 pts received adjuvant RT 5 LE, 19 HTX, 2 EXT
Creasman (1985–	I	76	5 y OS	

1994)[9]			90%	
	II	34	5 y OS 70%	
Otton (1982–1998)[107]	I	8	5 y OS 100%	6 PV; 2 HTX + removal of vaginal cuff
Stock (1962–1992)[64]	I	17	5 y DFS 56%	6 LE, 7 PV, 4 RV
	II	33	5 y DFS 68%	6 EXT, 17 RV, 8 PV, 2 LE
Davis (1960–1987)[72]	I/II	52	5 y OS 85%	21 EXT
Rubin (1957–1980)[63]	I/II	9	5 y OS 75%	
Ball (1947–1978)[83]	I	19	5 y OS 84%	4 EXT
	II	8	5 y OS 63%	1 EXT

DFS, disease-free survival; EXT, exenteration; HTX, hysterectomy; LE, local excision; OS, overall survival; pts, patients; PV, partial vaginectomy; RV, radical vaginectomy; TV, total vaginectomy.

Ling et al., in a small series consisting of 4 patients with stage I disease, report their experience using laparoscopic radical hysterectomy with vaginectomy and reconstruction of the vagina.[108] With follow-up times ranging from 40 to 54 months, they report all patients to be free of disease, with satisfactory sexual function. The authors suggest that laparoscopic surgery can be an option for select patients with early-stage disease, with good outcomes.

Other series also report excellent results with primary surgical therapy, though authors acknowledge bias resulting from selection of healthier patients with less extensive disease for primary surgery over radiation. In a review of 100 cases by Stock et al.,[64] with 85 SCC cases, surgical treatment was noted to be a significantly favorable prognostic factor for disease-free survival (63%), compared to treatment with radiation alone (26%). This benefit appears to skew from the advanced stage patients and potentially therefore with a selection bias. For stage I patients, disease-free survival rates were 56% and 80% for patients treated with surgery versus radiation, respectively. For stage II patients, survival rates were 68% and 31% after surgery and radiation, respectively, though this likely reflects selection bias, with patients with more extensive involvement offered radiation. Overall 5-year survival was 47%. Stock et al. concluded that surgery consisting of radical hysterectomy, pelvic lymphadenectomy, and upper vaginectomy could be reasonable for stage I lesions and select stage II lesions, with radiation being the preferred primary modality for patients with stage IIB

disease. It should be noted, however, that 23 of 33 stage II patients (70%) treated with surgery required a total vaginectomy or exenterative procedure, which carries significant morbidity and functional impairment.

Smaller series also support use of surgery in select patients with early-stage disease. Tjalma et al.[97] reported on 55 cases of primary vaginal SCC. Of 27 patients with stage I disease, 26 received surgery, with 4 subsequently receiving some form of adjuvant radiation. With a median follow-up time of 45 months, 5-year survival was reported to be 91%. Otton et al.,[107] in their retrospective review of 70 patients with stage I to II vaginal carcinoma, treated at Queensland Centre for Gynaecological Cancer between 1982 and 1998, report that patients treated with surgery alone, or a combination of surgery and radiation, had significantly longer survival times than patients treated with radiation alone. The authors suggest that surgery may be effective in a select subset of patients with small, localized tumors that permit clear surgical margins. Peters et al.[66] reviewed records of 86 patients with vaginal carcinoma, including 68 SCC cases, treated at the University of Michigan Medical Center. Twelve selected patients had surgery as primary therapy, with a 75% survival rate. Similarly, Rubin et al.[63] reported on 8 patients with stage I or II disease who received surgery as primary treatment; 5-year survival was 75%, and the overall local control rate for the stage I patients was 80%, suggesting that highly selected patients can achieve excellent outcomes with surgery. Davis et al.[72] reported on 89 patients with vaginal carcinoma, treated primarily at the Mayo Clinic from 1960 to 1987. A total of 52 patients were treated with surgery as primary therapy, with 5-year survival of 85%, compared to 65% for patients who received radiation alone. In the stage II patients, the 5-year survival rates were 49%, 50%, and 69% for surgery, radiation, and combined treatment with surgery and radiation, respectively. However, treatment modalities cannot be effectively compared using retrospective series, given selection biases.

A case report documented the use of neoadjuvant chemotherapy consisting of bleomycin and cisplatin, followed by radical surgery, for 1 patient with stage II SCC of the vagina. The patient was free of disease, with satisfactory sexual function, at 30 months.[109] However, larger series of patients treated with this approach, with longer follow-up, are necessary to further evaluate the feasibility of this treatment.

Another approach that has been proposed involves neoadjuvant chemotherapy followed by radical surgery.[109,110] Benedetti et al. reported results on 11 patients with stage II SCC of the vagina,[110] treated with using three cycles of

neoadjuvant paclitaxel and cisplatin followed by surgical resection. Ninety-one percent of patients obtained a partial or complete response to neoadjuvant chemotherapy; 27% achieved a complete response. All patients had disease-free resection margins after surgery, and only 1 patient had positive lymph nodes. At a median follow-up time of 75 months, 10 of 11 patients (91%) were alive, and of those, 8 (73%) were free of disease. Postoperative complications were mild.

TABLE 76.5 OUTCOMES BY STAGE FOR VAGINAL CANCER TREATED WITH PRIMARY RADIATION, +/− CHEMOTHERAPY

Series	Outcome	Stage I	Stage II	Stage III	Stage IV	Treatment	Notes
Kanayama (1993–2012)[111]	3 y OS	81%	86%	83% (St III = IV combined)		EBRT + BT (*n* = 9), EBRT (*n* = 8), BT (*n* = 7); 12% CRT

Rubin (1958–1980)[63]	5 y OS	75%	48%	54%	15%	RT and/or S

BT, brachytherapy of any form; CRT, chemoradiation; CSS, cause-specific survival; DFS, disease-free survival; DSS, disease-specific survival; EBRT, external beam radiation therapy; HDR, high-dose rate; LC, local control; OS, overall survival; PC, pelvic control; RT, radiotherapy (any form); S, surgery.

[a]Outcomes for stages IVA, IVB, respectively.

[b]Outcomes for stages IIA, IIB, respectively.

Advanced vaginal cancers are generally treated with definitive radiation in combination with chemotherapy. The use of combined modality treatment is imputed from the cervical cancer literature. Several series report their experience using surgery for advanced stage III or IV patients, with most cases requiring radical excision, typically pelvic exenteration.[61,63,64,83] Control rates, at best, are around 50%, even with highly selected patients.

Treatment: Radiation

For most patients, radiation is the treatment of choice given the desire for organ preservation and the significant morbidity that may be incurred by exenterative surgery. It is important to individualize radiation therapy techniques based on size, depth, and location of the lesion. The outcomes of retrospective series on use of radiation for vaginal cancer are summarized in Table 76.5 and in detail below.

Stage I

For very small, superficial tumors, brachytherapy alone can be considered, but appropriate patient selection is critical. Reported local control rates range from 62% to 100%.[62,65,67,85,91,101,111,121] Perez et al.[41] reported pelvic tumor control of 88% in patients with stage I disease who received brachytherapy alone, using a dose of 60 to 70 Gy, prescribed 5 mm beyond the plane of the implant or vaginal mucosa, with a vaginal surface dose of 80 to 120 Gy. Notably, tumor control in stage I vaginal carcinoma was similar to brachytherapy alone, versus brachytherapy plus EBRT. This observation is consistent with reports from some groups,[41,102,122] but not others.[62,111] Other series suggest high locoregional failure rates with brachytherapy alone. Kanayama et al. report 3 out of 8 (38%) patients with stage I vaginal cancer, treated with brachytherapy alone, developed lymph node recurrence. Frank et al.[62] reported on 21 patients with stage I disease who were treated with local radiation only, without regional node coverage. Nine received brachytherapy alone, 11 received EBRT with or without brachytherapy, and 1 received local EBRT using a transvaginal orthovoltage cone. Three of 9 patients treated with brachytherapy alone developed recurrent disease in the pelvis, resulting in a 10-year pelvic disease control rate of 67%. Patients who received EBRT with or without brachytherapy did not have pelvic recurrences. A pelvic relapse rate of 18% at 10 years was noted by Frank et al.,[62] with all pelvic failures occurring in patients treated with brachytherapy alone. Overall, results suggest caution should be taken when brachytherapy alone is used without

prophylactic lymph node irradiation, given fairly high rates of lymph node recurrence. Appropriate patient selection is critical when utilizing brachytherapy alone as primary treatment, particularly since the distinction between stage I and II is based on clinical exam and can vary between providers.

With LDR, treatment can be delivered in two applications, with the first designed to treat the entire vaginal wall and a second application to cover the tumor volume. When HDR brachytherapy is the primary treatment, the entire length of the vagina is typically treated to a mucosal dose of 60 to 65 Gy, with an additional mucosal dose of 20 to 30 Gy delivered to the area of tumor involvement.[123] Treatment can be delivered with a shielded vaginal cylinder or with a multichannel HDR cylinder to treat the tumor with a 2-cm margin and block uninvolved mucosal surfaces.[124] HDR can also be used to treat superficial lesions.

Use of a multichannel HDR cylinder is an alternative technique with favorable local control and low toxicity. The standard multichannel HDR cylinder is comprised of a central channel with 6 to 12 peripheral channels, allowing preferential dosing to the target while decreasing dose to normal structures. Vargo et al.[125] reported their outcomes for 41 patients with vaginal cancer treated with this technique to median EQD2 (equivalent dose in 2 Gy fractions) of 77.1 Gy. Definitive treatment consisted of EBRT followed by brachytherapy. The majority (71%) of patients had FIGO 1 disease. At 2 years, there was 93% local control, and 4% overall late grade 3 or higher toxicity, demonstrating comparable results to historical treatments. A tumor thickness cutoff of 5 mm for the apex and posterior vagina, and 7 mm for other locations was utilized.

Guidelines from the American Brachytherapy Society recommend a cumulative D90 (dose to 90% of volume) EQD2 of 70 to 85 Gy prescribed to the vaginal tumor.[126] Various regimens can be utilized to achieve this dose, with commonly utilized schedules of 45 Gy in 25 fractions EBRT followed by HDR brachytherapy in 5 fractions of 4.5 to 5.5 Gy (EQD2 = 71.4 to 79.8 Gy) or 9 to 10 fractions of 3 Gy (EQD2 = 73.5 to 76.8 Gy).

Poorly differentiated or extensively infiltrating stage I lesions should be treated with a combination of EBRT and brachytherapy. Given possible underestimation of submucosal disease and/or nodal disease, resulting in a potentially high likelihood of recurrence with brachytherapy alone, some groups recommend incorporating EBRT into treatment of all stage I patients, except for those with very small, superficial lesions.[62,111] Damast et al. reported outcomes

for early-stage vaginal cancer treated with a combination of EBRT and MRI-based intracavitary brachytherapy between 1998 and 2008.[114] With mean EBRT dose of 45, followed by intracavitary HDR brachytherapy, 5-year overall survival, disease-specific survival, and local failure-free survival were 67%, 80%, and 90%, respectively. Notably, 60% of patients had a complete response after EBRT; of this group, there were no recurrences. Concurrent cisplatin was used as a radiosensitizer in 40% of patients.

Actuarial 5-year survival rates for stage I disease range from 60% to 85%.[7,62,67,96] Disease-specific survival rates for stage I disease, treated with definitive radiation, range from 75% to 95%.[40,41,86] The 10-year pelvic relapse rate, comprised of local, pelvic nodal, and inguinal nodal failures, was noted to be 16% by Frank et al. for stage I patients.[62] Most failures are locoregional. Distant metastases are uncommon and occur in about 5% of patients.[41,72,121]

Stage II

Stage II vaginal carcinoma involves the subvaginal tissue but does not extend to the pelvic side wall. The primary treatment for stage II disease is radiation, most commonly as a combination of EBRT followed by vaginal brachytherapy; chemotherapy is typically considered. Outcomes with brachytherapy alone have been poor; thus, this approach is not recommended. With brachytherapy alone, Perez et al.[41] noted a 36% pelvic tumor control rate in stage II patients, compared to 67% in patients treated with a combination of EBRT and brachytherapy. The benefit of combining EBRT and brachytherapy, as opposed to using either alone, has been shown in other series as well.[40,64]

During EBRT, the pelvis generally receives 45 to 50.4 Gy in 1.8 Gy fractions, with consideration of a parametrial boost if there is extensive primary infiltration or high suspicion of nodal disease. Inguinal lymph nodes are included in a modified whole pelvic field for lesions involving the distal one-third of the vaginal canal.

Subsequent brachytherapy should be carefully delivered to ensure adequate coverage of tumor volume. An interstitial technique, ideally with three-dimensional (3D) imaging for treatment planning, is required for tumors >5 mm in depth.[85] Extensive tumors, or deeply infiltrating tumors with nondistinct margins, may be poor candidates for brachytherapy. In such cases, boosting tumors with conformal techniques or intensity-modulated radiation therapy (IMRT) can be considered and may yield better outcomes than suboptimal brachytherapy.[62] The tumor volume should receive a minimum of 75 to 80 Gy

using combined EBRT and brachytherapy. Fleming et al.[127] and Puthawala et al.[128] both report improved outcomes with higher doses of 80 to 100 Gy.

The 5-year survival rate for patients with stage II disease treated with RT alone ranges from 35% to 70% for stage IIA and 35% to 60% for stage IIB.[29,129,130] Pelvic relapse at 10 years has been reported to be 25% by Frank et al., consistent with recent series reporting 5-year pelvic control rates ranging from 76% to 84%.[62,96] The likelihood of distant metastasis is higher for stage IIB lesions compared to stage IIA,[67,122] with overall reported rates ranging from 22% to 46%.[67,72]

Stages III and IVA

Locally advanced vaginal cancer is treated with a combined modality approach of radiation and chemotherapy, extrapolating from favorable outcomes with use of CRT in cervical cancer patients.[131,132] Radiation is delivered as pelvic EBRT, followed by additional parametrial boost when warranted. If adequate tumor coverage can be achieved without undue toxicity, interstitial brachytherapy is employed to deliver a minimum tumor dose of 75 to 80 Gy. If brachytherapy is not feasible because of extensive tumor infiltration of the rectovaginal septum or bladder, a shrinking field technique or IMRT have been used to deliver additional dose to the primary lesion.[133,134] The overall cure rate for patients with stage III disease ranges from 30% to 50%. Stage IVA carries a worse prognosis. In highly selected patients with small volume stage IV disease, pelvic exenteration can yield good long-term control; however, in practice, EBRT remains the primary treatment.[7,9,41,62–64,101]

Five-year actuarial survival rates for women with stage III disease range from 25% to 58%,[7,9] with local failure rates of 30% to 75%.[62,67,96] Outcomes for stage IV disease are worse, with survival rates of 0% to 40%.[40,64,119] Despite treatment with EBRT and brachytherapy, only 20% to 30% of patients with stage III to IV disease achieve local control. Pelvic recurrences occur more often than distant recurrences.[62]

Role of Combined Chemotherapy and Radiation

Chemotherapy has been incorporated with radiation for treatment of vaginal cancer, extrapolating from studies in cervical cancer showing improved progression-free and overall survival when cisplatin is added to RT.[41,131,132,135,136] Given rarity of vaginal cancer, there are no randomized trials comparing radiation alone to radiation plus chemotherapy.

Retrospective series are limited by small numbers or inclusion of other cancers, such as cervical and vulvar carcinomas. Nonetheless, the majority of retrospective studies suggest that a combined modality approach is feasible and may yield improved outcomes. These studies are summarized as follows (Table 76.6).

An NCDB study identified 13,689 women with primary vaginal cancer treated between 1998 and 2011 and explored the impact of concurrent chemoradiation on survival.[141] Median survival with chemotherapy and radiation was significantly longer, compared to radiation alone (56.2 months vs. 41.2 months, $P < .0005$). It was noted that only 48.6% of all patients received chemotherapy, but there was a consistent trend toward increased use of concurrent chemoradiation from 20% to 59.1% between 1998 and 2011.

Ghia et al.[142] published a retrospective patterns of care analysis using the SEER database, analyzing data from women with primary vaginal cancer treated with EBRT and/or brachytherapy between 1991 and 2005. Of the 326 women in the study cohort, 80.4% had SCC. It was noted that CRT was used in 7.5% of patients treated before 1999 compared to 36.1% of those treated afterward ($P < .001$). Cisplatin was the most frequently utilized agent, accounting for 59% of CRT treatments. Chemotherapy was significantly less likely to be used in conjunction with radiation for women older than 80 years of age; otherwise, there was no difference for race, stage, grade, histologic diagnosis, comorbidities, or brachytherapy use. On multivariate analysis, CRT was not found to correlate with improved cause-specific or overall survival.

TABLE 76.6 OUTCOMES AFTER COMBINED CHEMORADIATION IN VAGINAL CANCER

Series	Stage	Outcomes	Notes
Miyamoto (1972–2009)[136]	St I, *n* = 18; St II, *n* = 19; St III, *n* = 8, St IVA, *n* = 6	3 y OS 79%	RT + cis, 5FU or carboplatin
Dalrymple (1986–1996)[137]	St I, *n* = 1; St II, *n* = 10; St III, *n* = 1	NED *n* = 9 (FU 74–168 mo); DOD *n* = 1 (12 mo); DID *n* = 4 (46–109 mo)	RT + 5-FU, cis/5FU or MMC
Gunderson (1990–2004)[138]	St I, *n* = 31; St II, *n* = 30; St III/IV, *n* = 69	4 y OS 64% (stage I), 40% (stage II) 12% (stage III/IV)	CRT, *n* = 87; S + CRT, *n* = 43

Samant (1999–2004)[139]	St II, *n* = 6; St III, *n* = 4; St IVA, *n* = 2	5 y OS 66%	RT + cis
Nashiro (2002–2005)[140]	St II, *n* = 2; St III, *n* = 1; St IVA, *n* = 3	DOD *n* = 1 (25 mo); NED *n* = 4 (FU 19–54 mo); AWD *n* = 1 (FU 19 mo)	RT + cis or cis/5FU

AC, adenocarcinoma; AWD, alive with disease; B, brachytherapy; cis, cisplatin; CRT, chemoradiation; DID, died of intercurrent disease; DOD, died of disease; EBRT, external beam radiation therapy; FU, fluorouracil; 5-FU, 5-fluorouracil; LR PFS, locoregional progression-free survival; MMC, mitomycin; NED, no evidence of disease; OS, overall survival; SCC, squamous cell carcinoma.

In a retrospective analysis of 71 patients with primary vaginal cancer treated at Dana-Farber Cancer Institute/Brigham and Women's Hospital from 1972 to 2009, 51 patients were treated with radiation alone and 20 were treated with CRT and RT.[136] Of patients treated with chemosensitization during radiation, 85% of patients received weekly cisplatin chemotherapy, whereas the remainder received either carboplatin or 5-FU. Three-year actuarial overall survival and disease-free survival was 56% for the RT alone group, compared to 79% for the CRT group (P = .01). Three-year disease-free survival was 43% for the RT alone group, compared to 73% for the CRT group (P = .01). At a median follow up of 3 years, tumor relapse was seen in 15% of patients treated with CRT compared to 45% of patients treated with radiation alone (P = .03). On multivariate analysis, the addition of chemotherapy was a significant predictor of DFS (HR 0.31).

Evans et al.[143] reported the use of radiation with 5-fluorouracil (5-FU) and mitomycin C (MMC) in 7 patients with vaginal cancer. Four out of 7 patients were free of disease with follow-up times ranging from 19 to 39 months. Roberts et al.[144] reported results for 7 patients with vaginal cancer treated with concurrent 5-FU, cisplatin, and radiation. Three patients received interstitial brachytherapy after EBRT, and 2 patients received intracavitary brachytherapy after EBRT. Eighty-five percent of patients achieved a complete response initially. Ultimately, 61% recurred, with a median time to recurrence of 6 months. There were 3 local recurrences and 1 distant metastasis and the 5-year overall survival rate was 22%. Kirkbride et al.[84] reported on the use of concurrent 5-FU, with or without MMC, in 26 of 153 patients with vaginal carcinoma treated at Princess Margaret Hospital. Seventy-seven percent of the patients had stage III/IV disease. Radiation was EBRT followed by interstitial or

intracavitary brachytherapy to a total dose of 62 to 74 Gy. The 5-year survival rate was 50%. Dalrymple et al.[137] reported results using 5-FU–based chemotherapy in combination with radiation for treatment of primary SCC of the vagina. Thirteen of 14 patients (93%) had stage I or II disease. The median dose of radiation was 63 Gy, achieved using EBRT alone or EBRT with intracavitary brachytherapy. The 5-year survival rate was 86% for all patients, and 9 patients were free of disease with a median follow-up time of 100 months, suggesting that good local control can be achieved despite the use of lower radiation doses. There was a 31% rate of severe bowel complications reported, with 2 deaths as a result of bowel obstruction.

A retrospective series from MDACC by Frank et al.[62] included 9 patients with stage II to IVA SCC of the vagina treated with radiation therapy and concurrent cisplatin-based CRT. With a mean follow-up time of 129 months, improved local control with the use of chemotherapy was noted; with 44% of patients treated with concurrent CRT remaining free of disease. Samant et al. published a review of 12 vaginal cancer patients, Stage II to IVA, treated with concurrent weekly cisplatin at a dose of 40 mg/m^2 for 5 weeks.[139] Patients received concurrent EBRT to a median dose of 45 Gy, with LDR interstitial or an HDR intracavitary brachytherapy boost of median dose 30 Gy. Six patients had stage II disease, 4 had stage III disease, and 2 had stage IVA. Ten of 12 patients (83%) had SCC; the other 2 had adenocarcinoma. Overall, treatment was well tolerated, with 92% of patients completing therapy as prescribed. Two of 10 patients who received interstitial brachytherapy required surgery for fistula repair. The 5-year overall survival, progression-free survival, and locoregional progression-free survival rates were 66%, 75%, and 92%, respectively, supporting use of concurrent weekly cisplatin therapy. A small series of 6 patients treated with CRT at the University of the Ryukyus was reported by Nashiro et al. All patients received EBRT to 50 Gy, followed by either a boost with shrinking fields (n = 4) or intracavitary brachytherapy (n = 2). Radiation was delivered with two to three cycles of cisplatin. Two patients had stage II, 1 had stage III, and 3 had stage IVA disease. All 6 achieved a complete response, and 4 of 6 patients remained free of disease at follow-up times of 18 to 55 months.

Outcomes

In general, the rate of locoregional recurrence ranges from 10% to 20% for stage I and 30% to 40% for stage II. Patients with advanced disease often have

persistent disease despite treatment. In a series by Dixit et al.,[103] 68% of failures in stage III patients were due to persistent disease. Most treatment failures occur within 5 years, with a median time to recurrence of 6 to 12 months,[62,145] and local recurrence is the most common pattern of treatment failure in the majority of published series. Extravaginal recurrences in the pelvic lymph nodes are less common. The reported rates of distant metastasis vary, ranging from 7% to 33% and usually occur later in the course of disease, with approximately half of all distant metastases presenting at the time of local recurrence.[67,85,103,146]

According to SEER-based data, outcomes for vaginal cancer may be improving. A recent study by Shah et al.[7] analyzed records from the SEER database of 2,149 women diagnosed with primary vaginal cancer between 1990 and 2004. The risk of mortality is noted to have decreased over time, with a 17% decrease in the risk of death for women diagnosed after 2,000 relative to those diagnosed between 1990 and 1994. The authors reported 5-year disease-specific survival rates of 84% for stage I, 75% for stage II, and 57% for stage III to IV. An older study by Creasman et al.[9] focused on 4,885 women diagnosed with vaginal cancer between 1985 and 1994 and reported 5-year survival rates of 96% for stage 0, 73% for stage I, 58% for stage II, and 36% for stages III–IV, with 85% of invasive cases being SCC.

Melanoma

Vaginal melanomas comprise approximately 4% of all primary vaginal cancers,[9] with just over 100 new cases of vaginal melanoma reported each year in the United States. Melanomas arising from the vaginal mucosa are thought to originate from mucosal melanocytes in regions of melanosis or from atypical melanocytic hyperplasia.

The incidence of vaginal melanoma has remained stable and is reported to be approximately 0.26 per million.[147] The majority of reported cases are in Caucasian women; one study of 37 women with primary melanoma of the vagina reported 84% of patients to be Caucasian, and only 3% African American.[148] According to a report by Hu et al.[149] analyzing SEER data from 1992 to 2005 on 125 cases of vaginal melanoma with known race/ethnicity, there is no significant difference in incidence rate of vaginal melanoma between Caucasian and African American women, with a white/black ratio of 1.02 after age adjustment. In the report by Creasman et al.,[9] most patients were of advanced age at presentation, with only 23% of patients diagnosed before the age of 60; 28% were diagnosed between the ages of 60 and 69, 28% were

diagnosed between the ages of 70 and 79, and 22% were diagnosed at age 80 or older.

Grossly, melanoma of the vagina tends to be pigmented and may present as a dark mass, plaque, or ulceration; multifocal presentation is also common. In a case series of 37 women with primary vaginal melanoma reported by Frumovitz et al.,[148] median tumor size at presentation was 3 cm (range, 0.4 to 5 cm), with median depth of invasion of 7 mm (range, 1 to 21 mm). Twenty-one percent of patients presented with multifocal disease. Twenty-four patients (65%) presented with lesions in the distal third of the vagina or introitus. The most common appearance is polypoid nodular.[150] The most common location at presentation is the anterior vaginal wall and lower one-third of the vagina.[148]

Microscopically, tumors may be composed of epithelioid, spindle, or nevus-like cells, with variable morphology, and stain frequently positive for S-100 protein, HMB-45, and melan A. When S-100 is negative or only focally positive, tyrosinase and MART-1 are useful markers. Poorly differentiated tumors may be difficult to distinguish from carcinomas or sarcomas. Tumor thickness correlates with prognosis and is measured by the methods of Breslow.[151]

Vaginal melanoma is a high malignant disease with a propensity for early hematogenous spread. The most common presenting symptoms reported have been slight vaginal bleeding and vaginal discharge which is usually blood-tinged, foul smelling, or purulent.[152] Reid et al. reviewed 115 patients with primary melanoma of the vagina, found depth of invasion and lesion size >3 cm to be negative prognostic factors.[153] Stage was not found to be prognostic for outcome, but only 42 of the 115 patients had this information available. Compared to women with SCC, patients with vaginal melanoma have a significant 1.5-fold increased risk of mortality.[7]

Treatment Options

Primary vaginal melanoma is uncommon and treatment outcomes for only a small number of patients have been reported.[148,152,154–157] As a result, it is difficult to make definitive treatment recommendations. Treatments used in published series include wide local excision, radical surgery, radiation and chemotherapy, or a combination of modalities.

Some authors advocate incorporation of radical surgical resection into the treatment paradigm, when feasible.[158,159] The rationale for favoring surgery over radiation is based upon the observation that melanoma tends to be radioresistant. Geisler et al.[158] recommend primary pelvic exenteration for vaginal melanomas

with >3 mm invasion, reporting a 5-year survival rate of 50% if pelvic nodes are free of disease. Morrow and DiSaia,[160] in their review of gynecologic melanoma, recommend radical surgery based on a review of the literature revealing 3 out of 19 long-term survivors after exenteration with wide local excision. Chung et al.[154] reviewed 19 cases of primary vaginal melanoma treated between 1934 and 1976. All patients who received wide local excision developed recurrence. Five-year survival was only 21%. Miner et al.[161] reported on 35 patients treated at Memorial Sloan-Kettering Cancer Center from 1977 to 2001. Sixty-nine percent underwent surgery, which was either *en bloc* removal of the involved pelvic organs, wide excision, or total vaginectomy, with elective pelvic lymph node dissection in 74% of cases. Thirty-one percent of patients received definitive radiation. Primary surgical therapy was significantly associated with a longer overall survival time (25 months vs. 13 months). Recurrence-free survival was not found to correlate with surgical extent. A study by Huang et al. found 5-year overall survival to be 32% but as high as 47% in patients who underwent surgical treatment.[162]

The goal of surgical excision should be complete resection with a negative margin. Drawing on the general melanoma guidelines this would be between 0.5 and 2 cm depending on the Breslow thickness of the primary tumor. Given the close proximity of the bladder and rectum, a wide local excision can rarely achieve this. Because of the risk of metastatic disease and the aggressive nature of the tumor, however, several series comparing radical surgery and local excision find equivalent outcomes.[152,155,163,164]

The role of surgical lymphadenectomy, lymph node sampling or sentinel lymph node mapping is not established in vaginal cancer given the vast variability in lymphatic drainage and substantial morbidity in the form of lymphedema that could result from sampling of both the inguinal and pelvic nodal basins. Lymphadenectomy could be considered in patients with nodal disease with the goal of locoregional control.

The use of wide local excision followed by postoperative EBRT and brachytherapy has been proposed. Bonner et al.[165] reported on nine cases of vaginal melanoma. Three patients were treated with wide local excision and 6 underwent radical surgery. All 9 patients developed locoregional recurrence. As a result, the authors suggest adding pelvic radiation therapy to improve local control. A more recent review by Frumovitz et al.[148] reported that radiation after wide local excision can reduce local recurrences. However, most patients develop distant metastases, most commonly in the lungs and liver. New

advanced in immunotherapy hold promise for changing the outcomes of patients and evolving the management of patients with melanoma. There is no general recommendation for the treatment of primary vaginal melanoma. When radiation is administered, vaginal melanoma is treated similarly to vaginal carcinoma, with volumes and doses ranging from 50 Gy for subclinical disease to 75 Gy for gross tumor.

Retrospective data suggest that radiation may improve local control for vaginal melanoma.[152,166] Among the few long-term survivors reported in the literature are a handful of patients who were treated with radiation. Harwood and Cummings[167] described a complete response in 4 patients with vaginal melanoma treated with radiation, although two subsequently relapsed. Rogo et al.,[168] in their series of 22 cases of vulvovaginal melanoma, reported comparable results for surgery and radiation, with 8 patients (36%) alive 5 years after treatment. Petru et al.,[166] in their series documenting 14 patients treated for primary malignant melanoma of the vagina, noted that 3 of 9 patients treated with radiation, either as primary treatment (n = 2) or in the postoperative setting (n = 1), survived longer than 5 years. Median overall survival for all patients was 10 months, with a 5-year disease-free survival rate of 14% and an overall survival rate of 21%.

Frumovitz et al., in their review of 37 women with stage I melanoma of the vagina treated at MDACC between 1980 and 2009, report very poor prognosis even in this group of patients with localized disease, with a 5-year overall survival rate of 20%. In that study, 10% of patients received nonsurgical treatment with radiation, chemotherapy, or both. Patients treated surgically had significantly longer survival times compared to those treated nonsurgically. Radiation delivered after wide local excision reduced local recurrence and demonstrated a trend toward longer survival times, from 16.1 to 29.4 months.[169] A study by Xia et al. evaluated 44 women, diagnosed and treated for vaginal melanoma between 2002 and 2011.[157] There was no difference in overall survival between local excision and radical surgery. However, the authors note increased progression-free survival with the addition of adjuvant chemotherapy and radiation (8.6 months vs. 16.0 months, P = .038). Given the high rates of distant metastases, chemotherapy has been used, either alone or in conjunction with radiation.[148,170] Other reports have described the use of immunotherapy after surgery.[162]

Recommendations for the use of adjuvant chemotherapy for vaginal melanoma derive from the general melanoma literature where multiple agents

have been the focus of investigation. One of the first drugs used was interferon alpha, which was been found to bring an improvement in recurrence-free survival with no overall survival benefit. More recently in a phase II study, patients treated with surgery followed by adjuvant temozolomide in combination with cisplatin were noted to have a 48.7-month overall survival, superior to IFN-α (40.4 months) or observation (21.2 months) ($P < .01$). Further studies are ongoing.[171]

Effectiveness of targeted molecular therapies and immunotherapy in cutaneous melanoma has significantly expanded the options for patients with advanced melanoma. Approved therapies for advanced, unresectable melanomas include ipilimumab (antibody against cytotoxic T-lymphocyte–associated protein 4 [CTLA-4]), nivolumab (inhibitor of programmed cell death 1 [PD-1] protein), pembrolizumab (PD-1 inhibitor), vemurafenib (B-raf proto-oncogene serine/threonine kinase [BRAF] inhibitor), dabrafenib (BRAF inhibitor) and trametinib (mitogen-activated protein kinase kinase [MEK] inhibitor). However, it is difficult to extrapolate the effectiveness of these therapies for cutaneous melanoma to vaginal melanoma, and there are no specific trials that have validated efficacy of these regimens in vaginal melanoma. Testing of tumors for BRAF, NRAS, and c-KIT can be used to guide therapy. There appears to be high levels of PD-1 and PDL-1 expression in both vaginal and vulvar melanomas, suggesting utilization of immunotherapy may have efficacy for this disease.[129]

Regardless of primary treatment, outcomes have been disappointing. Overall prognosis is poor, with historic 5-year survival rates ranging from 5% to 30% regardless of treatment modality or extent of surgical resection.[153,154,156] There is a high rate of distant metastases, ranging from 66% to 100%.[154,172]

Sarcoma

Sarcomas represent 3% of all primary vaginal cancers.[9] In a report based on data from the NCDB between 1985 and 1994,[9] there were 135 cases of primary vaginal sarcoma of heterogeneous histologies and varying age. Twenty-two percent of patients were under 14 years of age, with a median age at presentation of approximately 50 years. Consistent with this, a recent analysis of the Surveillance, Epidemiology, and End Results (SEER) database identified 221 patients with primary vaginal sarcoma, diagnosed between 1988 and 2010, with mean age of 54.9.[173] Compared to other vaginal cancers, sarcomas tended to be larger, with decreased likelihood of lymph node involvement, and more likely to be treated with primary surgery without radiation. It was estimated that, after

adjusting for other variables, vaginal sarcomas had a 69% greater risk of cancer-related mortality when compared to squamous cell carcinoma.

Vaginal sarcoma most frequently presents as an asymptomatic vaginal mass.[174] In one series, this was the most frequent symptom, found in 35% of patients, followed by vaginal, rectal or bladder pain (26%), bleeding, or serosanguinous discharge from the vagina or rectum (18%), leucorrhea (9%), dyspareunia (7%), or difficulty in micturition (7%).

Leiomyosarcoma is the most common histology in adults, representing up to 65% of all vaginal sarcoma cases; however, overall numbers are very small, with <150 published reports in the literature.[174] Vaginal leiomyosarcomas originate from the smooth muscle of the vaginal wall but may also develop from smooth muscle cells in tissues adjacent to the vagina. Leiomyosarcomas have a predilection for the posterior vaginal wall, with published reports suggesting approximately 43% to 45% in the posterior vagina, 17% to 21% anteriorly, and 34% to 39% laterally.[174,175]

Grossly, patients present with a palpable submucosal nodule, although advanced tumors may demonstrate palpable necrosis or exophytic polypoid tissue.[176] Criteria to distinguish between benign leiomyoma and leiomyosarcoma include the mitotic index, cytologic atypia, and coagulative tumor necrosis.[176a] Because of considerable variation in smooth muscle tumors from area to area, adequate sampling is recommended to achieve an accurate diagnosis. Microscopically, leiomyosarcomas demonstrate interlacing bundles of spindle-shaped cells, with blunt-ended nuclei and fibrillar cytoplasm.[152,177] Leiomyosarcomas are also aggressive; they undergo early hematogenous dissemination, recur locally[9,174] and demonstrate pulmonary metastases.[178]

Other less common histologies include endometrial stromal sarcoma and angiosarcoma.[179,180] Fewer than ten cases of angiosarcoma of the vagina have been reported in the literature.[181,182] A history of pelvic radiation is a risk factor for pelvic sarcomas, particularly angiosarcoma.[180] In the pediatric population, embryonal rhabdomyosarcoma/sarcoma botryoides is the most common histology,[183] with 90% of cases occurring in children younger than 5 years of age.[184]

Prognostic Factors

Review of the literature indicates that vaginal sarcomas undergo early hematogenous dissemination as well as frequent local recurrence. Pulmonary metastases are common.[174,175] Adverse prognostic factors for vaginal sarcoma

include high histologic grade, stage, size >3 cm, infiltrative borders, and cytologic atypia.[178]

Treatment Options

Despite surgery and the use of adjuvant RT in select cases, sarcoma patients sustain poor outcomes because of a high incidence of local recurrence and distant metastasis. Locoregional control is especially important for vaginal leiomyosarcoma. The addition of systemic treatment, typically with doxorubicin, is standard for leiomyosarcoma.[185] Postoperative radiation therapy has been used to manage soft tissue sarcomas in other sites, to reduce locoregional recurrence rates.[186] Results from adjuvant radiation for high-grade sarcoma in other regions of the body have been extrapolated to vaginal cancer. In patients with involved margins, high doses above 62.5 Gy are generally required to achieve local control.[187]

A series by Peters et al.[188] reported on 17 cases, comprised of 10 patients with leiomyosarcoma, 4 with MMT, and 3 with other types of sarcomas. There were only 3 patients alive and free of disease with follow-up times of 84 to 161 months. All 3 patients had undergone pelvic exenteration. Patients who received other forms of primary therapy all died of recurrence, with the pelvis as the first site of recurrence in all cases. In 50% of cases, the pelvis was the only site of failure, stressing the importance of local treatment. Overall survival of 8 and 10 years following wide local excision has been reported.[175]

Outcomes

In the SEER analysis, 5-year survival was 89% for stage I and under 50% for stage II vaginal sarcomas of all types.[173] Other series describe similarly poor outcomes. Five-year survival was 36% for patients with leiomyosarcoma in the Peters et al. series.[188]

Malignant Mixed Müllerian Tumors

Mixed müllerian tumors (MMT), also called carcinosarcomas, are highly aggressive, biphasic neoplasms composed of an epithelial component as well as a sarcomatous component. The epithelial component in vaginal MMT is most often SCC.[179] The sarcomatous component can be composed of fibroblasts and smooth muscle or includes cartilage, striated muscle, bone, and other heterologous tissues. The metaplastic carcinoma theory suggests that there is a common cell of origin for MMT, with carcinoma giving rise to the sarcomatous component via metaplasia.[189] The most common differential diagnosis is

sarcomatoid carcinoma. The spindle and carcinomatous components are positive for cytokeratin in sarcomatous carcinoma, whereas MMT demonstrates a sarcomatous component that is positive for vimentin, with the carcinomatous component positive for cytokeratin.[179] The first case of vaginal MMT was described in 1975 by Davis et al.[190]; since then, only 11 cases have been reported in the literature, with age ranging from 57 to 74 years.[179,191–194] At least one case report of MMT of the vagina detected high-risk HPV in both the carcinomatous and sarcomatous component, suggesting that some vaginal MMTs may be related to HPV.[191]

The survival rate for patients with MMT was even lower, at 17%. There are only a few case reports and small series detailing treatment of primary vaginal MMT. Neesham et al.[193] published a case report of a 74-year-old patient treated with wide local excision and radiation for a 5.5-cm stage I MMT. She developed distant metastases within 6 months of local therapy. Analysis of patterns of failure suggests that local therapy does not have a significant impact on survival because of early distant spread. For that reason, chemotherapy is typically administered after surgery for MMT in other sites and should be considered for primary vaginal lesions, along with adjuvant radiation as warranted. Platinum-based chemotherapy has been used for MMT occurring elsewhere in the pelvis. It has not yet been determined whether platinum agents are best administered alone or in combination with other agents. Combination regimens include a paclitaxel with either ifosfamide or a platinum agent.[195–197]

Clear Cell Adenocarcinoma

Epidemiology

Clear cell adenocarcinoma of the vagina was first reported in 1971 by Herbst and Scully,[198] who documented six cases of primary vaginal clear cell carcinoma in patients 15 to 22 years of age: five of the six had been exposed to the synthetic estrogen DES *in utero* during the first trimester. This was the first report suggesting that *in utero* exposure to DES, prescribed during the mid-1940s to 1960s for high-risk pregnancies, could result in an increased risk of clear cell adenocarcinoma. DES-related clear cell adenocarcinoma presents at a young age, with studies documenting median age at presentation to be within the second or third decade of life.[198]

Studies suggest that there is a bimodal distribution for clear cell adenocarcinoma of the vagina, with the first peak containing young women with a mean age of 26, most of whom were exposed to DES *in utero*, and a second

peak containing women with a mean age of 71 years, not exposed to DES.[198] The majority of patients present with stage I to II disease.[198,199] DES-related clear cell adenocarcinoma is rarely seen today, as DES is no longer administered to pregnant women.

Risk Factors

In 45% to 95% of cases, clear cell adenocarcinoma of the vagina is associated with vaginal adenosis, defined as the abnormal presence of glandular epithelium in the vagina.[200,201] Vaginal adenosis has three patterns: endocervical, tuboendometrial, and embryonic.[169,201,202] Grossly, vaginal adenosis appears as red, velvety, grapelike clusters in the vagina. Glandular columnar epithelium of müllerian type either appears beneath the squamous epithelium or replaces it, undergoing progressive squamous metaplasia.[203] Vaginal adenosis is believed to be a precursor lesion to clear cell adenocarcinoma of the vagina. It is a common histologic abnormality in women who have been exposed to DES *in utero*, presenting in up to 95% of such women.[200,201]

The risk of developing clear cell adenocarcinoma in DES-exposed women is estimated to be 1 in 1,000,[199] suggesting that there are multiple factors contributing to pathogenesis. However, it is not strictly confined to this population; there are rare, sporadic cases of primary adenocarcinoma of the vagina that is not associated with DES exposure.[204]

Histopathology

Clear cell adenocarcinoma of the vagina is most often located in the upper third of the anterior vagina and can vary greatly in size. Grossly, they exhibit exophytic growth and are superficially invasive.[205] Microscopically, they are composed of vacuolated, glycogen-rich cells, hence the term clear cell carcinoma. The most common histologic pattern is tubulocystic, although solid, papillary, and mixed cell patterns have also been described.[74,206] Cells are cuboidal or columnar in shape, with large, atypical protruding nuclei, rimmed by a small amount of vacuolated cytoplasm.

Clinical Presentation

Patients with clear cell adenocarcinoma most often present with abnormal vaginal bleeding,[198] which is found in 50% to 75% of cases. Cytology is not reliable, revealing abnormality in only 33% of cases; therefore, careful assessment of the entire vaginal vault to assess for submucosal irregularity is recommended, in addition to four-quadrant cytologic assessment.[207] The cervix

should be carefully inspected, as clear cell adenocarcinoma can arise from this region as well. Abnormal discharge, urinary symptoms, and lower gastrointestinal complaints can also be noted, particularly in advanced cases. The differential diagnosis of vaginal adenocarcinoma is often challenging, because it must be distinguished from metastases from distant sites.

Prognostic Factors

Prognostic variables associated with worse survival include advanced stage, nontubulocystic pattern of histology, size >3 cm, and depth of invasion >3 mm.[205] A study of 21 women with clear cell carcinoma of the vagina and cervix reported overexpression of wild-type p53 to be associated with a more favorable prognosis.[208] Primary adenocarcinoma of the vagina not associated with DES exposure is extremely rare, with poor outcomes. In a review of 26 such cases by Frank et al., 5-year overall survival was 34%, worse than in patients with SCC.[209] A recent series described 5 cases of clear cell adenocarcinoma in patients without prior DES exposure, treated between 1990 and 2013.[210] Patients were all older than 40 years of age. There was high incidence of distant spread, especially to the lungs. Overall survival at 5 years was 55%.

Treatment Options

The optimal management of clear cell adenocarcinoma is unclear. There are several published series on DES-related clear cell adenocarcinomas[74,130,205,211,212] using conventional treatments similar to those used for squamous cell carcinoma of the vagina for stage I and II disease, including surgery with radical hysterectomy, vaginectomy, and lymphadenectomy with construction of a neovagina or definitive radiation with consideration of radiosensitizing concurrent chemotherapy.[113,213] In these series, there has been an emphasis on preservation of ovarian and vaginal function, because of the earlier age at diagnosis in DES-exposed patients. According to data from the United States Registry for Research on Hormonal Transplacental Carcinogenesis, approximately one-half of all vaginal clear cell adenocarcinoma cases were treated with radical surgery alone as primary therapy.[214]

Wharton et al. report the use of intracavitary or transvaginal irradiation for early-stage disease, with excellent tumor control and preservation of ovarian function.[215] Herbst et al.[216] reported on 142 cases of stage I clear cell adenocarcinoma. For the 117 patients treated with radical surgery, there was an 8% risk of recurrence and 87% overall survival. For patients treated with

radiation, there was a 36% risk of recurrence. The authors acknowledge that it is difficult to compare surgery to radiation, as radiation was most likely used in patients with larger lesions less amenable to resection.

A series by Senekjian et al.[212] reported on 219 cases of stage I clear cell vaginal adenocarcinoma. Forty-three patients received local therapy alone, consisting of vaginectomy, local excision, or local irradiation with or without excision, and the rest had conventional radical surgery. At 10 years, the actuarial survival rates were equivalent (88% vs. 90%) for patients who received local therapy only and those treated conventionally, respectively. However, the actuarial recurrence rate was significantly higher (40% vs. 13%) with local excision alone. Patients who received local irradiation, with or without local excision, had decreased local recurrence compared to those treated with excision alone ($P < .03$).

A subsequent series by Senekjian et al. reviewed 76 cases of stage II clear cell adenocarcinoma.[74] The 10-year overall survival rate was 65%. The 5-year survival rates were 80% for patients treated with surgery, 87% for patients treated with radiation, and 85% for patients treated with both. The authors advocate treatment with combination EBRT and brachytherapy for stage II disease, with surgery reserved for smaller, more easily resectable lesions in the upper vagina. The use of pelvic exenteration for primary and recurrent lesions has been reported by Senekjian et al.[130] Survival outcomes were comparable to those of patients treated with other modalities. Thus, to minimize morbidity and preserve quality of life, exenterative approaches are advocated only for patients with disease recurrence after radiation. The 5-year survival rate after pelvic relapse is reported to be 40% by Herbst et al.[211]

Most recurrences occur within 3 years of therapy, although recurrences occurring 10 to 20 years after treatment have been reported.[217] Most recurrences are local or locoregional, with approximately one-third detected at distant sites, most commonly in the lungs or extrapelvic lymph nodes, although there have been rare cases of CNS metastases manifesting years after treatment.[218] The 10-year actuarial survival rate for clear cell adenocarcinoma of the vagina is 79%. For stage I and II disease, survival rates are 90% and 80%, respectively.

Other Adenocarcinomas

The majority of adenocarcinomas that present in the vagina are attributed to metastatic spread from other sites. Vaginal metastases from adenocarcinoma of the breast, kidneys, or other gynecologic primary sites have been

described.[219–221] Primary non–clear cell adenocarcinoma of the vagina is extremely rare and occurs predominantly in postmenopausal women. Histologic variants include endometrioid, mucinous, mesonephric, and papillary serous adenocarcinoma. Vaginal endometrioid adenocarcinoma is the most common non–clear cell subtype and presents most often in women with a history of endometriosis. Only a handful of case reports or series have been published in detail about endometrioid adenocarcinoma of the vagina.[222–226] In one series of 18 cases of primary vaginal endometrioid adenocarcinoma,[222] 10 cases arose from the apex. Fourteen out of 18 cases had vaginal endometriosis, important in indicating a primary vaginal tumor rather than secondary spread from the endothelium. Median age at presentation was 57, with a range from 45 to 81 years. There have been case reports of mucinous adenocarcinoma of the vagina,[227–229] with at least one arising from a focus of endocervicosis.[230]

On gross exam, endometrioid adenocarcinomas can be polypoid, papillary, rough, granular, fungating, exophytic, or flat, and most arise from the superior aspect of the vagina. Microscopically, tumors display a predominant component of typical endometrioid carcinoma, with tubular glands lined by columnar cells with moderate amounts of eosinophilic cytoplasm and large elongated nuclei. Only a handful of cases of mucinous adenocarcinoma have been described,[220,227–229] including rare cases arising in neovaginas[231] or arising from endocervicosis.[230] Mesonephric adenocarcinoma arises from mesonephric duct remnants situated in the lateral vaginal wall.[232,233] Primary papillary serous adenocarcinoma of the vagina has rarely been reported.[234]

Lymphoma

Lymphomas of the female genital tract are rare, accounting for only 1% of all primary extranodal lymphomas.[235] Lymphomas of the vagina are exceedingly uncommon, with fewer than 30 cases reported in the literature thus far.[236–249] In one review from the Armed Forces Institute of Pathology, only 4 of 9,500 cases of lymphoma were determined to originate from the vagina.[250] Diffuse large B-cell lymphoma is the most common histology, though there have also been reports of lymphoplasmacytic, Burkitt, and mucosa-associated lymphoid tissue (MALT) lymphomas.[241]

On exam, tumor is typically palpable, with infiltrative thickening and/or ulceration of the vaginal wall.[248] Immunohistochemical analyses are valuable techniques for confirming diagnosis, with tumors typically expressing CD20.[242,249] The most common symptom at presentation is vaginal bleeding.

Leukemic infiltrates may be difficult to distinguish from lymphoma; therefore chloroacetate esterase or myeloperoxidase staining may be useful. Though there is no established treatment protocol for primary lymphoma of the vagina, it seems reasonable to extrapolate from results for extranodal lymphomas elsewhere in the body and to use similar chemotherapeutic and response-based radiation regimens. For patients wishing to retain fertility, chemotherapy alone may be an option in select cases.

If diagnosed at an early stage, the prognosis for vaginal lymphoma is excellent, with 5-year survival rates ranging up to 90%. Of 10 cases reported in the literature between 1994 and 2007, all patients except 1 were cured of disease after treatment with chemotherapy or a combination of radiation and chemotherapy.[240,242,246,247,251–254] Follow-up periods for these 10 case reports ranged from 6 to 120 months and 1 patient died from other causes. Eight patients had Ann Arbor stage IEA disease, 1 had IIEA, and 1 did not have stage reported. The most common chemotherapy regimen was cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP). Complete remission was also achieved using methotrexate, doxorubicin, cyclophosphamide, vincristine, prednisone, and bleomycin (MACOP-B) in 1 patient. Half of the patients did not receive radiation because of an excellent response with chemotherapy alone.

Small Cell Carcinoma of the Vagina and Other Rare Histologies

Primary small cell carcinoma of the vagina is an exceedingly rare entity, with fewer than 25 cases reported in the literature.[255] Mean age at diagnosis is 59 years, with poor outcome because of early widespread dissemination. Eighty-five percent of patients die within 1 year of diagnosis.[256,257] Neuroendocrine differentiation is often manifested by secretory granules, argyrophilia, and expression of neuroendocrine markers,[258,259] staining positive for cytokeratin, neuron-specific enolase, chromogranin A, and serotonin. Thyroid transcription factor 1 can also be positive, and should not be used to differentiate primary from metastatic disease.[260] Microscopically, it is indistinguishable from that of the lung. These tumors can occur in pure form or be associated with squamous or glandular elements.[256,258] Ectopic Cushing's syndrome has been documented to occur in primary small cell carcinoma of the vagina.[259] Treatment typically follows general principles for small cell carcinomas of the cervix, with aggressive therapy, including combination cisplatin-based chemotherapy, radiation therapy, brachytherapy, and surgery if feasible indicated.

Vaginal paraganglioma is a rare neuroendocrine tumor, with <10 cases

reported in the literature in younger women, with median age at presentation of 31 years.[261–263] It is thought to be an indolent tumor, managed surgically. The tumor can manifest with catecholamine secretion, similar to paragangliomas elsewhere in the body.[261]

Adenosquamous carcinoma of the vagina is also uncommon. Microscopically, tumor cells are composed of glandular and squamous elements. One case report described adenosquamous carcinoma associated with small cell carcinoma of the endometrium in a 64-year-old female.[264] Treatment similarly follows general approaches for squamous cell carcinoma of the vagina, including consideration of combination chemoradiation for patients with gross disease.

RADIOTHERAPY TECHNIQUES

Definitive treatment of primary vaginal cancer with radiation typically involves a combination of EBRT and brachytherapy. The use of 3D-based imaging to guide brachytherapy treatment planning is evolving, and recent results for vaginal cancer show excellent outcomes.[265,266] Because of advances in conformal radiation therapy, tumor dose can be escalated, whereas the dose to surrounding normal structures, such as small bowel, rectum, bladder, urethra, and the femoral heads, can be minimized. Brachytherapy can be delivered via intracavitary or interstitial approaches, using LDR or HDR techniques.

External Beam Radiotherapy

In general, when radiation is delivered as primary therapy, EBRT is prescribed prior to or, in rare select cases, without brachytherapy for a subset of patients with stage I and all patients with stages II to IVA disease. The treatment technique, dose prescription, and selection of the appropriate energy level must be individualized for each patient.

At time of simulation, it may be helpful to identify the distal tumor margin with a radio-opaque marker. Unless contraindicated, the use of oral and intravenous contrast can be helpful, allowing delineation of vascular structures and facilitating the contouring of the bladder, small bowel, and rectum. CT simulation allows contouring of vessels as a surrogate for lymph node localization, allowing more precise and individualized field delineation relative to pelvic bony anatomy.[267] When available, fusion of diagnostic pelvic MRI or PET-CT to the treatment planning CT can assist in defining the tumor (Fig. 76.3). If inguinal nodes are to be treated, a “frog leg” position to expose the

groin region can be considered.

Three-Dimensional Conformal Treatment

The use of 3-D imaging for treatment planning has increased dramatically over the past two decades and is currently used at almost all centers for simulation and treatment planning. This allows treatment fields to be tailored to a patient's specific anatomy.

The target volume for EBRT is influenced by diagnostic imaging results and stage of disease. Treatment fields are designed to ensure coverage of the vagina and common iliac, external iliac, hypogastric, and obturator lymph nodes. A standard field has the L5-S1 interspace as the superior border, which ensures coverage of retroperitoneal nodes that lie caudal to the common iliac bifurcation.[268] However, because many initial failures occur predominantly in the vagina, paracolpos, and parametria, some authors suggest setting the superior border 1 to 2 cm superior to the inferior margin of the sacroiliac joints in patients with negative imaging of regional nodes, in order to minimize treatment toxicity.[269] If there are positive pelvic lymph nodes, the superior border should be raised to the L4-L5 interspace or higher in order to cover the common iliac nodes. The inferior border lies at the introitus to ensure coverage of the entire vagina or 4 cm distal to the most caudal aspect of the vaginal tumor. Lateral borders are 1.5 to 2.0 cm lateral to the pelvic brim. Lateral fields, when utilized, should extend anteriorly to the pubic symphysis and posteriorly to the junction of the S2-S3 interspace. The border should be extended accordingly to include the inguinal nodes, if warranted. The dose to the inguinal nodes should be calculated during treatment planning, to ensure appropriate coverage. When designing treatment fields, the interconnectivity of vaginal lymph node drainage should be kept in mind. Unexpected nodal drainage is possible and should be considered. In a study of 14 women with vaginal cancer who received pretreatment lymphatic mapping with sentinel lymph node identification, 2 out of 4 women with a lesion in the upper one-third of the vagina were found to have a sentinel lymph node in the inguinal region.[71]

Several techniques can be considered when treating the inguinal region, to minimize dose to the femoral heads. An electron boost can be used to raise the inguinal dose to appropriate levels. Alternately, unequally weighted beams (2:1, AP:PA) or a combination of low- and high-energy photons (4 to 6 MV AP; 15 to 18 MV PA) can be used. Another method uses a wide AP and a narrow PA field, with a daily photon boost to the inguinal nodes delivered with asymmetric

collimator jaws.[270]

The gross tumor volume (GTV) is defined as the extent of gross disease found on clinical examination, as well as palpable lymph nodes and suspicious lymph nodes and regions seen on CT, MRI, and/or PET. The GTV is expanded by 1 to 2 cm to form the clinical target volume (CTV), which also includes the entire length of the vagina, paravaginal tissue up to the pelvic sidewall, and bilateral pelvic lymph nodes. Visualization of vessels allows approximation of lymph node locations. The pelvic nodal CTV can be defined as a 1- to 2-cm margin around blood vessels and should include the common iliac, external iliac, internal iliac, obturator, perirectal, and presacral lymph node regions. For distal vaginal involvement, inguinal lymph nodes are commonly included, with the inferior border set at the lowest aspect of the ischial tuberosity or lesser trochanter. The CTV is expanded by 1 cm to form the planning target volume (PTV). The small bowel, bladder, and rectum are contoured and doses to normal structures calculated.

Standard dose to the pelvis is 45 to 50.4 Gy in 1.8-Gy fractions, followed in select cases by a parametrial boost ranging from 50 to 65 Gy. Elective nodal irradiation of the inguinal nodes may be delivered to 45 to 50 Gy. Gross nodal disease should receive 60 to 65 Gy, if feasible, using conformal therapy. For clinically palpable inguinal nodes, this can be achieved with reduced portals, using low-energy photons or electrons.

The location of the tumor, size, and extent of disease and treatment response are factors to be taken into consideration when individualizing treatment for each patient. After EBRT to the pelvis, tumors of the vaginal apex >0.5 cm in depth should be considered for interstitial brachytherapy or external beam boost; tumors <0.5 cm should be treated with intracavitary brachytherapy. Depending on location, tumors of the midvagina can be treated with external beam boost or considered for freehand interstitial brachytherapy, particularly if they are located anteriorly or laterally. Tumors of the distal vagina are also amenable to treatment with interstitial brachytherapy, especially if the tumor is relatively confined. In general, brachytherapy is delivered upon completion of EBRT and allows dose escalation to the vaginal tumor to 70 to 80 Gy.

Intensity-Modulated Radiation Therapy

Intensity-modulated radiation therapy (IMRT) may allow dose escalation to gross disease in areas such as inguinal or pelvic lymph nodes, diffusely infiltrative disease, or sidewall tumors inaccessible to brachytherapy. Shrinking

field techniques, or IMRT, can be used for dose escalation if brachytherapy is not feasible.[271,272] In such circumstances, a total dose of 70 to 75 Gy minimum should be delivered to gross disease. Higher doses are difficult to achieve without substantially increasing the risk of toxicity to adjacent normal tissues such as urethra, bladder, and rectum. Typical IMRT input parameters based on those used for postoperative endometrial cancer for the Radiation Therapy Oncology Group (RTOG) trial 0921 include ≤30% of small bowel to receive ≤40 Gy, with a dose to 2 cm^3 of the small bowel (D2cc) maximum of 55 Gy; ≤35% of bladder to receive ≤40 Gy with a D2cc maximum of 90 Gy; ≤60% of the rectum and sigmoid to receive ≤40 Gy with a D2cc maximum of 70 to 75 Gy; and the femoral heads 15% to receive ≤35 Gy. The IMRT plans are optimized to minimize the volume of PTV that receives more than 110% of the prescribed dose.[273]

When utilizing IMRT technique, it is important to take into account the possibility of significant shifts in tumor position because of constant normal tissue changes and rapid tumor regression. As a result, we recommend contouring an integrated vaginal volume (IVV), which reflects the CTV volume, paying close attention to rectal and bladder filling, and contouring the position of the vagina with both bladder full and bladder empty (Fig. 76.4).[274] A PTV margin of 1 to 1.5 cm is recommended given the degree of motion and uncertainties in target definition.

Brachytherapy

The utilization of brachytherapy should be considered for all patients with vaginal cancer who are undergoing radiation, unless they are unable to tolerate the procedure. According to a SEER database analysis spanning the years 1974 to 2011, the use of brachytherapy as a boost or definitive treatment provided a disease-specific and overall survival benefit across all FIGO stages of primary vaginal cancer.[275] An NCDB study spanning 2004 to 2011 found the use of brachytherapy as a boost in vaginal cancer has been declining, however, from 87.7% in 2004 to 68.4% in 2011 ($P < .001$), with increase in use of IMRT boost from 4.5% to 23.5%.[276] Treatment at a high-volume facility predicted for greater likelihood of brachytherapy as a boost.

Intracavitary brachytherapy as monotherapy can be considered for patients with VAIN and highly selected patients with minimally invasive stage I disease. In most cases, brachytherapy is offered after EBRT to boost the cumulative dose to a minimum of 70 to 80 Gy. Tumor response to EBRT is used to assess

suitability for intracavitary or interstitial brachytherapy. In general, patients with superficial disease that is 5 mm in thickness or less can receive intracavitary treatment, whereas thicker lesions require interstitial brachytherapy in order to achieve adequate dose coverage. Image-based interstitial brachytherapy technique should be utilized to optimize target dose delivery and minimize dose to organs at risk; this has been shown to maximize disease control compared to non–image-based techniques.[277]

Intracavitary Brachytherapy: Low Dose Rate

Intracavitary brachytherapy can be delivered with low dose rate or high dose rate technique. Low dose rate intracavitary brachytherapy (LDR-ICB) is most commonly performed using a vaginal cylinder loaded with cesium-137 radioactive sources. Use of LDR remote control afterloading can be utilized to minimize radiation exposure to hospital personnel.

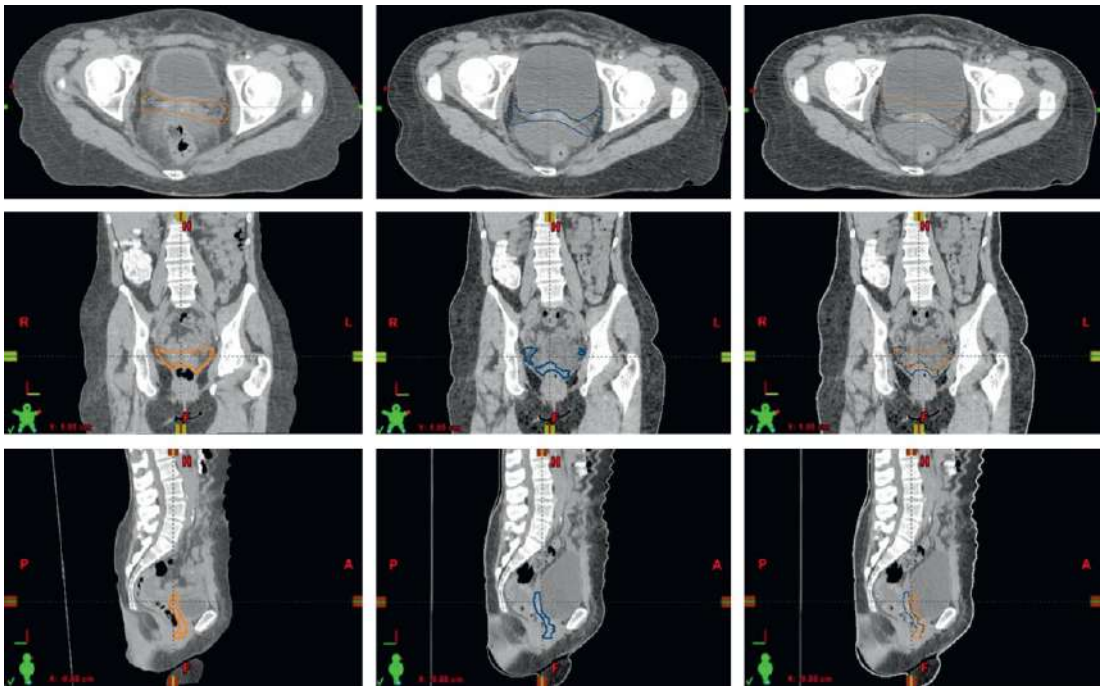

FIGURE 76.4. Displacement of the vagina with bladder filling. Axial, coronal, and sagittal images are shown for the same patient. The *left panel* shows a relatively empty bladder, with vaginal cuff contoured in *yellow*. *Middle panel* shows a full bladder, with vaginal cuff contoured in *blue*. *Right panel* shows a full bladder with the two vaginal contours superimposed, demonstrating the posterior deviation of the vaginal cuff that occurs with bladder filling.

A variety of vaginal applicators are available, such as Burnett, Bloedorn, Delclos[278] or MIRALVA.[279,280] Some cylinders have lead shielding to protect

regions of the vagina, bladder, and rectum. Most applicators come in different diameters, and the largest diameter cylinder that can be comfortably accommodated by the patient should be used to improve the ratio of mucosa to tumor dose.

Typically, two to three cesium sources are placed along the central tandem of the cylinder, and labia are sutured closed to secure the implant during the treatment. To minimize skin toxicity, it is important to avoid placing a source over the vulva. With appropriate selection of dose specification points, a uniform dose distribution can be achieved over the entire length of the vagina. In cases where disease is localized to the upper vagina or vaginal fornices, an intrauterine tandem can be used to anchor the vaginal cylinder or be used with vaginal colpostats. Vaginal colpostats alone can be used to treat the upper vagina. Some institutions report good results using custom vaginal molds.[281]

A retrospective series by Pingley et al.[104] reported their experience treating 134 women with primary vaginal cancer ranging from stage I to IV; intracavitary brachytherapy was delivered using LDR technique. Only the 75 patients who completed treatment were analyzed. Most patients received EBRT to 50 Gy, and 59 of 75 patients received subsequent brachytherapy (30 with LDR-ICB, 29 interstitial). The 5-year disease-free survival rate in patients treated with LDR-ICB was 53% and was 30% for patients who did not receive brachytherapy. Patients who received brachytherapy within 4 weeks of EBRT had a disease-free survival rate of 60%, compared to 30% in those who did not, suggesting that a shorter interval between EBRT and brachytherapy is preferable.

Intracavitary Brachytherapy: High Dose Rate

High dose rate intracavitary brachytherapy (HDR-ICB) is typically performed using iridium-192, with applicators that are similar to those described for LDR. HDR-ICB delivers treatment over a span of several minutes and has the potential advantages of limiting exposure to caregivers, as well as the ability to optimize dose distribution through varying dwell times.[282,283] The largest cylinder that a patient can comfortably tolerate should be selected.

Compared to LDR radiation, there is theoretically less potential sublethal damage repair and thus an increased likelihood of normal tissue toxicity. However, this has not been demonstrated in vaginal cancer, nor in cervical cancer, where multiple prospective and retrospective studies have failed to note any significant difference in local control, survival, or toxicity outcomes between HDR and LDR brachytherapy.[284]

Several single-institution studies with small numbers of patients have reported their outcomes for HDR brachytherapy and are summarized below.

The largest series of HDR brachytherapy for vaginal cancer is from Vienna by Mock et al.[60] and reported on 86 patients. Patients with stage 0 to stage II disease received treatment with intracavitary HDR brachytherapy alone (n = 26). Prescribed dose per fraction ranged from 5 to 8 Gy, with a mean dose of 7 Gy, and the number of insertions ranged from 2 to 6, with a median of 5. In that series, the 5-year recurrence-free survival rates were 100%, 77%, and 50% for stages 0, I, and II, respectively. The authors noted similar local failure rates for HDR brachytherapy administered with or without EBRT, for both stage I and II disease. Treatment was well tolerated.

Kucera et al.[285] described their experience with 80 patients who received treatment with HDR-ICB, with or without EBRT. Compared to a historical group of patients treated with LDR-ICB, with or without EBRT, no significant differences were noted for local and distant recurrences or rate of complications. Three-year actuarial overall and disease-specific survival rates were 51% and 61%, respectively. Three-year disease-specific survival rates for stage I and stage II patients were 83% and 66%, respectively.

Stock et al.[91] reported results for 49 patients treated with primary carcinoma of the vagina. Of this group, 15 patients were treated with EBRT and HDR brachytherapy for vaginal carcinoma, with dose per treatment ranging from 3 to 8 Gy. The total median dose delivered via HDR was 21 Gy, and the total median tumor dose overall was 63 Gy. No significant difference in outcome was noted between patients treated with LDR versus HDR. Five-year actuarial survival was reported to be 50% in the HDR brachytherapy group. In comparison, the 5-year survival rate for patients who received EBRT alone (n-11) was 9% (P < .001), with a higher rate of stage IV disease in the EBRT-alone group (36%) compared to the brachytherapy group (5%).

Nanavati et al.[286] published their experience treating 13 patients with primary vaginal cancer with EBRT to 45 Gy followed by HDR-ICB of 20 to 28 Gy, delivered in 3 to 4 fractions, and calculated 0.5 cm from the surface of the applicator. All 13 patients achieved a complete response; with a median follow-up time of 2.6 years, the local control rate was 92%. No grade 3 or 4 acute or chronic intestinal or bladder toxicity was noted during this short follow-up period, but 46% of patients developed moderate to severe vaginal stenosis. All patients had stage I or stage II disease, and the authors concluded that EBRT plus HDR-ICB is an acceptable treatment with a high response rate, good local

control and survival, and minimal toxicity.

Damast et al.[114] reported outcomes for 10 patients with small-volume, stage I to II primary vaginal cancer, treated with pelvic EBRT (mean dose 45 Gy), followed by MRI-based HDR- or LDR-ICB. For HDR, the total dose ranged from 18 to 21 Gy in 3 to 5 fractions, prescribed to 5 to 10 mm depth. In general, the entire vagina was treated to minimum EQD2 dose of 60 Gy, with additional boost to higher risk areas to at least 75 Gy. If warranted, partially shielded cylinders were utilized to reduce dose to uninvolved vaginal tissue. Concurrent cisplatin was considered for stage II patients; 40% received CRT. At median follow up of 60 months, the authors document 5-year local failure-free survival of 90% and disease-specific survival of 80%. One patient with approximately 5-mm-thick residual tumor after EBRT developed local recurrence; no patients with a complete response after EBRT developed local recurrence following ICB.

Beriwal et al.[115] described their experience using intracavitary HDR brachytherapy in 5 patients with either primary or recurrent vaginal cancer treated between 2000 and 2006. The median dose for intracavitary brachytherapy was 20 Gy in 3 to 5 fractions, prescribed 0.5 cm from the surface of the applicator. One patient received intracavitary brachytherapy only, because of prior radiation therapy with EBRT and HDR brachytherapy. Interpretation is limited because of short follow-up, and the results are combined with interstitial brachytherapy patients but suggest that EBRT followed by HDR brachytherapy is efficacious and safe.

The use of image-based HDR-ICB was reported by Vargo et al.,[125] in a series of 41 patients with vaginal cancer treated with chemotherapy and definitive radiation with image-based multichannel vaginal cylinder HDR brachytherapy. CT (41%) or MRI (59%) was used for each fraction, and high-risk clinical target volume drawn. The median dose to 90% of the high-risk clinical target volume was 77.1 Gy (equivalent dose of 2 Gy per fraction), and outcomes were favorable, with 2-year local, regional, and distant control of 93%, 100%, and 81%, respectively. There was 4% grade 3 or higher toxicity at 2 years.

Interstitial Brachytherapy

According to the American Brachytherapy Society Consensus Guidelines for interstitial brachytherapy for vaginal cancer, any lesions >5 mm in thickness after EBRT should be considered for interstitial BT, and image guidance is recommended to minimize dose to normal organs and optimize dose to the target volume.[126] Any paravaginal extension at the time of diagnosis, regardless of

treatment response, merits consideration of interstitial brachytherapy, as a vaginal cylinder is unable to deliver sufficient coverage to this region. Other candidates for interstitial brachytherapy include patients with lesions thicker than 5 mm, distal vaginal extension, or those with a vagina that is unable to accommodate standard intracavitary applicators. When possible, image-based interstitial brachytherapy should be utilized, as outcomes are superior to non–image-based techniques.[277] Further details of the procedure and planning are below.

Preoperative Assessment

When determining tumor thickness, MRI is superior to other imaging modalities. T1- with gadolinium and T2-weighted MRI should be obtained if possible after EBRT to assess residual disease.[124] Contrast, such as ultrasound gel placed to distend the vagina, may also aid in visualization of the tumor. Clinical examination provides an imprecise estimate of tumor thickness. An exam under anesthesia can be performed after EBRT; placement of gold fiducial markers can be considered to mark the proximal and distal end of residual disease. Use of a radio-opaque marker in the vagina placed at the time of diagnosis and after external beam will facilitate assessment of the lesion on CT imaging.

The patient should be assessed for general, epidural or spinal anesthesia. When feasible, a combination of general anesthesia during the insertion followed by an epidural patient-controlled anesthesia approach that continues during the entire inpatient hospitalization maximizes pain relief. Epidural anesthesia allows the patient to control the degree of pelvic anesthesia while avoiding the systemic effects, somnolence, and potential mental status changes that may occur with a peripheral patient-controlled anesthesia device. Patients with a history of laminectomy, significant degenerative disease, or labile blood pressure are suboptimal candidates for epidural anesthesia.

Patients on anticoagulation with medications such as warfarin should switch to low molecular weight (LMR) heparin approximately 1 week prior to the procedure, and LMR heparin may be discontinued 24 hours prior to insertion time and be withheld during the duration of the implant, though subcutaneous heparin for thrombosis prophylaxis may be initiated after the procedure is completed. Patients may have a gentle bowel preparation orally or an enema before the procedure.

Applicator Selection

Template systems are available to secure the position of the needles in the target volumes and include the Syed-Neblett template, the modified Syed-Neblett, and the MUPIT (Martinez Universal Perineal Interstitial Template).[287] These systems consist of a perineal template, a vaginal cylindrical obturator, and hollow guides for loading radionuclide sources. The perineal template requires suturing to perineal skin. The vaginal obturator allows for placement of a tandem, making it possible to combine interstitial with intracavitary treatment if desired. Lower vaginal tumors may be suitable for freehand technique, if the mass can be readily visualized and palpated.

Procedure

The insertion procedure is performed with the patient in a dorsal lithotomy position. A sterile setup is used at the time of insertion. A Foley catheter is placed for bladder drainage.

A digital and speculum examination allows assessment of vaginal width, tumor size and location, amount and thickness of residual parametrial or paravaginal disease, and presence of any fistulas. For patients with an intact uterus, a central tandem may be inserted to anchor the applicator. A vaginal central plastic cylindrical is placed over the tandem and secured. The template, which contains multiple openings through which needles can be inserted, is placed onto the perineum. The tumor volume is implanted by inserting the needles through the holes of the template, with the goal of covering the GTV with a 1- to 2-cm margin, utilizing 3-D imaging afterward to confirm proper needle location and uniform dose distribution around the tumor volume. Generally speaking, needles should extend approximately 5 to 10 mm past the disease, with 10 mm between each needle.[124] The physician should be mindful that slight needle displacement can occur when legs are lowered back to the supine position.

When possible, utilizing image guidance to perform implants is ideal in order to improve target localization and guide needle placement. Available modalities include laparoscopic guidance, ultrasound, CT, and MRI. Results with these various techniques are summarized below.

Several investigators have used laparoscopic guidance or laparotomy[288–290] to improve the accuracy and safety of interstitial implant placement. With open laparotomy, the bladder and urethra can be visualized during needle placement. The bladder and rectum can be protected either by using slings or tissue expanders or by lysis of adhesions. Disaia and Creasman[291] described the

creation of an “omental carpet,” where a section of omentum is placed along the descending colon into the pelvis in order to separate the bladder and rectum from the implant and prevent small bowel adhesions. If laparotomy is performed in a two-application course of treatment, it is typically done for the first application only. As expected, there is higher associated morbidity with the use of laparotomy compared to other techniques, as a result of increased operative time, longer postoperative recovery, risk of bleeding, and ileus.

Laparascopic visualization is an alternative to open laparotomy that has also been reported. Though laparoscopy is less invasive, both laparoscopic approaches and open laparotomy are limited by an inability to visualize extraperitoneal structures, such as parts of the bladder, uterus, and cervix, as well as the vagina and paravaginal tissues. However, these techniques can be considered when CT or MRI are not available during brachytherapy, to avoid needle insertion through the small bowel and sigmoid.

Stock et al. reported results using real-time transrectal ultrasound as visualization.[288] The ultrasound probe was brought into close proximity to the vagina, parametria, and cervix, and the longitudinal mode of the ultrasound probe was useful in determining the optimum depth of needle insertion. Transverse imaging was utilized during the procedure to ensure coverage of the target area and avoid entry into bladder, rectum, or small bowel. Using this technique, invasive laparotomy or laparoscopy was able to be avoided.

In general, temporary implants are preferred over permanent implants because of their relative safety/simplicity, cost-effectiveness, easy applicability, readily controlled distribution of sources, and easier modification of dose distribution. HDR interstitial brachytherapy has the advantage of limiting exposure to caregivers and visitors and offers the ability to optimize dose distribution using 3-D image-based treatment planning.[265,283] Use of permanent radioactive implants using gold-198 or iodine-125 have also been reported for smaller volume disease,[292] and can be considered for select patients; reports suggest long-lasting control can be achieved with appropriate selection of patients..

Image-Guided Brachytherapy

The use of 3-D imaging during HDR brachytherapy has increased with the rise of CT and MR availability and has been a favored approach when available because of lower morbidity and invasiveness compared to historic approaches.[293] Only a few institutions have access to real-time image guidance

during brachytherapy[294]; most scan patients after insertion is complete, with subsequent readjustment as needed. It is not feasible at many institutions to obtain an MRI at the time of brachytherapy. A diagnostic MRI obtained after EBRT prior to brachytherapy can be used instead to assist with treatment planning. MRI provides superior tumor delineation, whereas CT images can cause overestimation of tumor extension.[295]

The integration of 3D imaging during the brachytherapy procedure allows determination of depth and location of insertion and enables repositioning if perforation into the bladder or rectum is detected. Treatment planning based on 3D imaging allows high dose to be delivered to the tumor volume, while sparing critical adjacent organs. The use of 3D image-based HDR brachytherapy has been shown to improve local control and decrease treatment-related toxicities.[277,296] There are fewer published reports on 3D HDR brachytherapy for primary vaginal cancer, but results suggest similar outcomes.[266,277]

Dosimetry

Given close proximity of the rectum and bladder, it is important to minimize treatment toxicity by avoiding overdose of critical normal structures. However, underdosing the target volume is also a serious risk; thus, it is critical to optimize target localization and needle placement.[297]

Vaginal cancer with gross residual disease at the time of brachytherapy is prescribed a cumulative EQD2 dose of 70 to 90 Gy, with 60 Gy prescribed to the entire vaginal surface. Special care should be taken to minimize the dose to the bowel, which often lies in close proximity to gross disease. Image-based planning software, when available, allows the dose to conform to the target areas while avoiding organs at risk. As a result, optimal dose distribution can be achieved. Image-guided technique should be utilized when possible to reduce toxicity and improve local control.

Proposed dose schedules for HDR interstitial brachytherapy, depending on dose of initial EBRT, have been released by the American Brachytherapy Society[126] (Table 76.7). The number of fractions range from 3 to 10 with goal of delivering total EQD2 of over 70 Gy to the CTV. Given the difficulty of insertion, physicians may insert the applicator once and treat patients over a several day inpatient hospitalization. Twice-a-day regimens range from 9 to 10 fractions of 200 to 300 cGy per fraction, BID, or 3 to 6 fractions, ranging from 450 to 650 cGy, BID, with at least 6 hours between fractions. It is also feasible to perform two separate insertions with two hospitalizations required.

TABLE 76.7 DOSE SCHEDULES FOR HDR INTERSTITIAL BRACHYTHERAPY IN COMBINATION WITH EBRT, AS PROPOSED BY THE AMERICAN BRACHYTHERAPY SOCIETY CONSENSUS GUIDELINES FOR INTERSTITIAL BRACHYTHERAPY FOR VAGINAL CANCER

EBRT		HDR		EQD2
Total Dose	**# Fx**	**Dose per Fx**	**# Fx**	**CTV**
36 Gy[a]	18	5.0 Gy	6	72.9
		5.5 Gy	6	87
39.6 Gy[a]	22	5.0 Gy	6	76.4
		5.5 Gy	6	81.5
45 Gy	25	3.0 Gy	9	73.6
		3.0 Gy	10	76.8
		4.5 Gy	5	71.5
		5.0 Gy	5	75.5
		5.5 Gy	5	79.8
		7.0 Gy	3	74.1
50.4 Gy	28	4.0 Gy	5	72.9
		4.5 Gy	5	76.8
		5.0 Gy	5	80.9
		7.0 Gy	3	79.4

[a]Assumes midline block after 36–39.6 Gy, with total pelvic dose to 50.4 Gy.
EBRT, external beam radiation therapy; EQD2, equivalent dose in 2 Gy fractions; Fx, fractions; HDR, high-dose rate.
Modified from Beriwal S, Demanes DJ, Erickson B, et al. American Brachytherapy Society consensus guidelines for interstitial brachytherapy for vaginal cancer. *Brachytherapy* 2012;11(1):68–75. Copyright © 2012 American Brachytherapy Society. With permission.

For CT- or MRI-based 3D treatment planning, the D90, D100, V100, V150, and V200 are parameters used to describe tumor volumes and the doses to those volumes. D90 and D100 are defined as the minimum dose delivered to 90% and 100% of the volume, respectively. V100, V150, and V200 are defined as the volumes receiving 100%, 150%, and 200% of the prescribed physical dose, respectively.[298] Figure 76.5 depicts a representative isodose distribution.

When MRI-guided adaptive brachytherapy is utilized, the high-risk CTV (HRCTV) is defined as clinically palpable disease, plus any residual disease seen on MRI, and the entire circumference of the adjacent vagina at the level of the residual tumor. The intermediate-risk CTV (IRCTV) includes the region of initial tumor extension and the remaining vagina, in order to encompass potential

submucosal tumor spread. The low-risk CTV (LRCTV) is the remaining vagina.

The bladder, rectum, sigmoid, urethra, and small bowel are contoured as volumes at risk, and the D2cc and D0.1cc calculated.[299] The recommended maximum equivalent dose in 2-Gy fractions (EQD2) D2cc to the rectum and sigmoid is 70 to 75 Gy and should be <70 Gy when feasible.[126] Maximum EQD2 D2cc for the bladder should be 90 Gy. There are no DVH parameters specific to the female urethra, but in general, the D2cc should be comparable to parameters for the bladder and rectum. The small bowel dose can be limited with use of a full bladder; some institutions limit the EQD2 maximum point dose to 60 to 65 Gy.[124] A study from Brigham and Women's Hospital reported the incidence of grade 3 or higher complication rates in 51 women undergoing HDR 3D-planned interstitial brachytherapy.[120] Median D2cc for the bladder, rectum, and sigmoid were 64.6, 61.0, and 51.9 Gy, respectively. The actuarial rates of grade 3 to 4 complications at 2 years were 20% gastrointestinal, 9% vaginal, 6% skin, 3% musculoskeletal, and 2% lymphatic. The D2cc for the rectum was significantly higher in patients with grade 2 or more gastrointestinal toxicity. On univariate analysis, D2cc and D0.1cc for the rectum and sigmoid, tumor size, and tumor volume at the time of brachytherapy were associated with gastrointestinal complications. This analysis validated the recommended D0.1 cc and D2cc for the rectum and sigmoid.

Precautions for Interstitial Patients

Appropriate measures should be taken to reduce likelihood of needle displacement during hospitalization. Patients should be instructed to remain in bed, with head of the bed raised no more than 15 degrees. To ensure there has been no needle displacement between fractions, the needle length protruding the template can be measured and validated prior to every treatment.

Skin care is also critical. Given risk of decubitus ulcer, it is advisable to utilize an air mattress, when available. To minimize skin abrasion, gauze or Duoderm can be placed between the template and perineal skin.

To prevent development of a deep vein thrombosis, patients should receive subcutaneous heparin and pneumoboots.

Patients should be seen in follow-up 2 to 4 weeks after implant removal for a skin check, then at 3-month intervals up to a year, and then every 6 months. Dilute hydrogen peroxide douching is advised for patients with tissue necrosis development. Antibiotics with anaerobic coverage are recommended if a malodorous discharge accompanies the necrosis. Hyperbaric oxygen should be

considered for those that have been proven on biopsy not to have recurrent disease.

Outcomes with Interstitial Technique

There are only a handful of series describing outcomes for vaginal cancer treated with interstitial brachytherapy. They are summarized below.

The use of MRI-guided adaptive brachytherapy in locally advanced vaginal cancer was reported by Dimopoulos et al.[300] with excellent outcomes, supporting the use of the following parameters for image-guided adaptive brachytherapy: for HRCTV, D90 of ≥85 Gy; for IRCTV, D90 approximately 60 Gy; and for LRCTV, D90 of approximately 50 Gy. Thirteen patients with stage II to IV disease were treated. Mean D2cc doses to the bladder, urethra, rectum, and sigmoid colon were 80, 76, 70, and 60 Gy, respectively. Toxicity was acceptable, with two fistulas reported and one case of periurethral necrosis. The 3-year local control and overall survival rates were 92% and 85%, respectively, with a mean D90 to the HRCTV of 86 (±13) Gy. Consistent with these promising outcomes, image-guided interstitial brachytherapy results were reported by Manuel et al.,[277] with 2-year local control, disease-free interval, and overall survival of 93%, 86%, and 82%, respectively, in their cohort of 72 patients. Patients were treated with image-guided (n = 50) or non–image-guided (n = 25) technique treated during the time period of 1973 to 2014.[266] With the use of image-guided technique, there was a trend toward improved disease-free survival (2-year DFS 77% vs. 42%, respectively; P = .072), improved overall survival (84% vs. 47%; P = .26), and decreased gastrointestinal and genitourinary toxicity, supporting incorporation of CT and/or MRI as image guidance when available.

Kushner et al.[301] reported outcomes of HDR brachytherapy in 19 patients with primary vaginal cancer. Two-dimensional (2D) treatment planning was performed, with interstitial brachytherapy delivered to 8 patients at a median dose of 23 Gy in 4 fractions. The 2-year overall survival rate for patients for all patients was 66.1%. Three patients (15.8%) had serious late effects, including ureteral stenosis, vaginal necrosis, and small-bowel obstruction; 2 of these patients were treated with interstitial brachytherapy.

A series by Tewari et al.[302] reviewed long-term results using interstitial brachytherapy, with or without EBRT, in 71 patients with primary vaginal cancer. A Syed-Neblett template was used with an interstitial iridium-192 afterloading technique. Patients received a minimum of 20 Gy via implant, with a total tumor dose of approximately 80 Gy. With a median follow-up time of 66

months, 5-year disease-free survival rates were reported to be 100%, 60%, 61%, 30%, and 0% for stages I, IIA, IIB, III, and IV patients, respectively. Significant complications were noted in 13% of patients and included necrosis, fistula, and small-bowel obstruction. Overall, 75% of patients achieved local control.

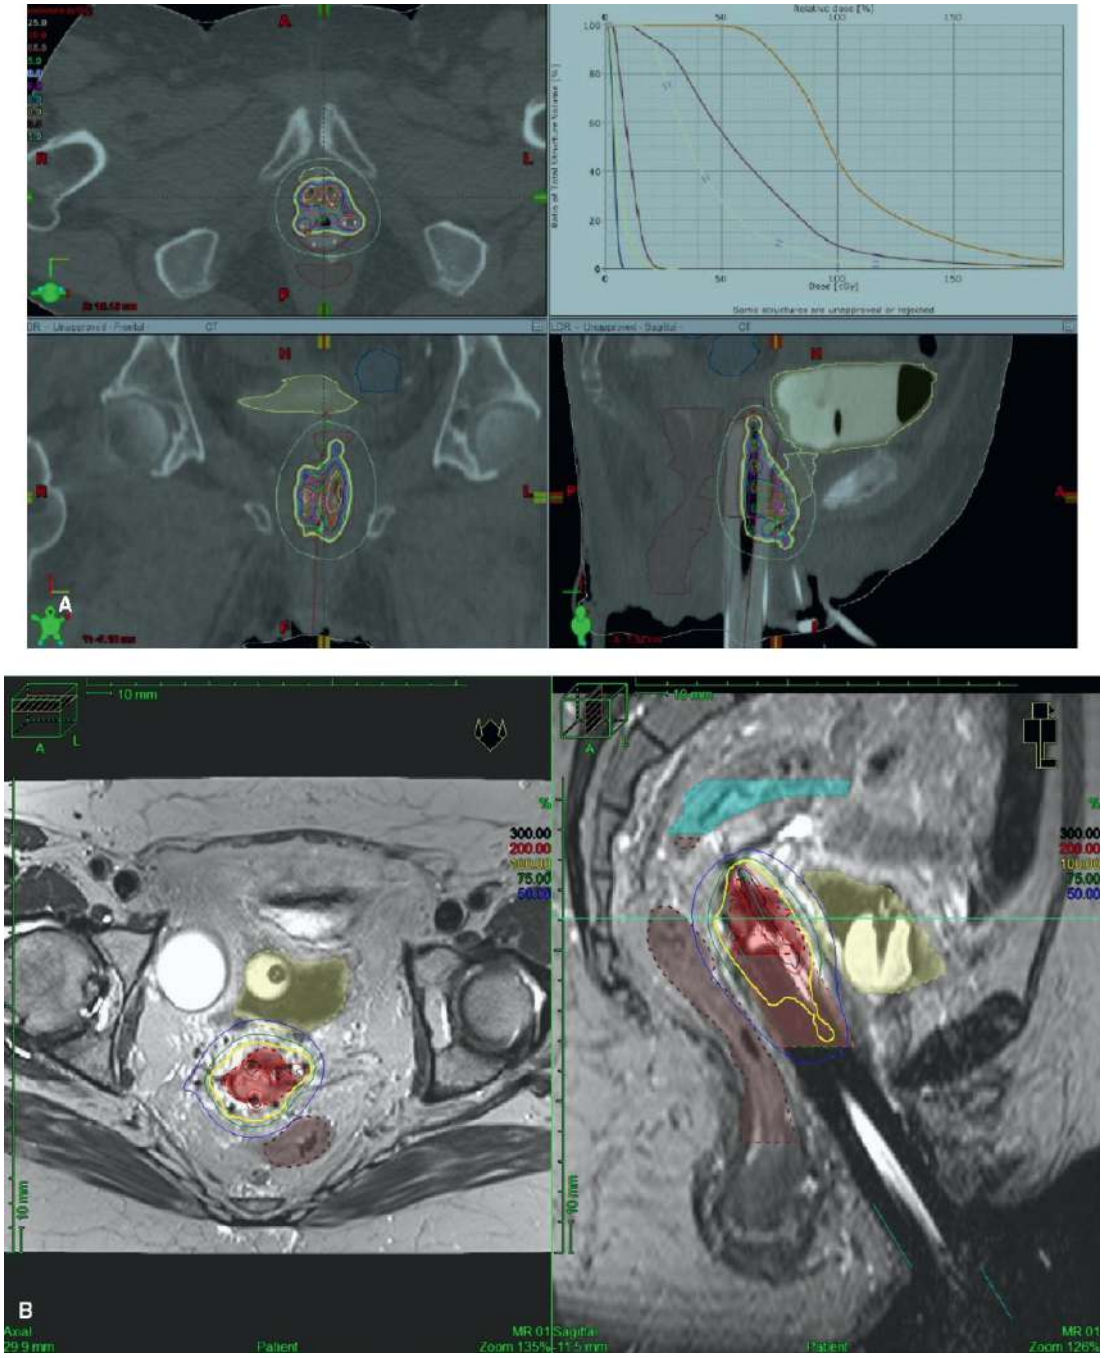

FIGURE 76.5. Interstitial implantation of a vaginal tumor. **A:** Axial, coronal, and sagittal isodose distributions are depicted with dose–volume histogram. **B:** Isodose distributions for a vaginal tumor on axial and sagittal MRI.

Beriwal et al. describe results using 3-D image–based HDR interstitial brachytherapy[265] at the University of Pittsburgh Cancer Institute. A total of 30 patients with primary vaginal cancer (*n* = 17) or recurrent gynecologic cancer to the vagina (*n* = 13) were treated using the Syed-Neblett template, with CT scan done after placement of needles for confirmation and treatment planning. Of the subset of 17 patients with primary vaginal cancer, the numbers of patients with stage I, II, III, and IVA disease were 2, 9, 5, and 1, respectively. Fifty-three percent of patients received concurrent chemotherapy with weekly cisplatin at 40 mg/m^2 and apical lesions had laparoscopic guidance during needle placement. The CTV and organs at risk were contoured on CT scan for treatment planning after placement of needles. Most patients (93.3%) received EBRT to a median dose of 45 Gy, followed by HDR interstitial brachytherapy at 3.75 to 5 Gy per fraction in 5 fractions to a median dose of 21.3 Gy. Overall median D90 to the high-risk CTV was 74.3 Gy, and median D2cc to the bladder, rectum, and sigmoid were 58.5, 57.2, and 50 Gy, respectively, showing excellent sparing of critical organs. At a median follow-up time of 16.7 months, the 2-year locoregional control and overall survival rates were 78.8% and 70.2%, respectively, suggesting good local control. Overall, the treatment was fairly well tolerated. There were no grade 3 or higher gastrointestinal complications. One patient developed late grade 3 vaginal ulceration and another had grade 4 vaginal necrosis.

Brachytherapy Versus External Beam Boost

In select circumstances when patients are not appropriate candidates for brachytherapy, IMRT can be considered as an alternative for boost to residual gross disease. A retrospective dosimetric analysis from Princess Margaret Hospital[303] reported data comparing IMRT boost treatment plans with conventional and 4-field radiation boost plans for 12 patients with cervical (*n* = 8), endometrial (*n* = 2), or vaginal (*n* = 2) cancer. IMRT conferred a significant improvement in dose conformity, with overall improvement in rectal and bladder dose-volume distributions, relative to conformal radiation, though inferior to brachytherapy. However, when comparing an ideal photon or proton external beam boost to brachytherapy, brachytherapy provided the best coverage and normal tissue sparing.[304]

Barraclough et al.[305] used an EBRT boost in 21 patients with cervical cancer who could not undergo intracavitary brachytherapy. A 3-D conformal boost was used to deliver a total dose of 54 to 70 Gy. With a median follow-up time of 2.3

years, 48% of patients had recurrent disease, with central recurrence in 16 of 21 patients, significantly higher than 3% to 4% local recurrence rates reported with MR-planned brachytherapy. These results are dramatically inferior to those reported with brachytherapy, suggesting that external beam boosts should only be considered as an alternative when brachytherapy is not feasible.

Stereotactic body radiotherapy (SBRT) is a relatively newer treatment modality with very little data to support its use. A review by Higginson et al.[306] reported on 2 vaginal cancer patients treated with a SBRT boost instead of brachytherapy. Fiducials were placed into the paravaginal, parametrial, or cervical tissues during outpatient clinical examination. The 2 patients with vaginal cancer received 40 to 45 Gy EBRT followed by 25 Gy in 5 fractions of SBRT; 1 patient had a local recurrence at 5 months, and another developed distant disease 17 months posttreatment. Toxicity included one acute grade 2 cystitis and one late grade 3 rectal bleeding.

Treatment Toxicity and Management

Acute Toxicity

The bladder and rectum are located in close proximity to the vagina and it is common for patients to develop acute bowel and urinary toxicity during treatment.[307] Increased urinary frequency, urgency, and dysuria can be managed with phenazopyridine, a urinary tract analgesic, as well as oral anticholinergic and antispasmodic medications. Antidiarrheal medications such as loperamide, or in more severe cases, tincture of opium, should be prescribed for symptom management early in the development of symptoms. Irritation of the anal mucosa can cause exacerbation of hemorrhoids and occasional hemorrhagic spotting and discomfort with defecation; topical hemorrhoidal ointments or suppositories can be used.

Acute irritation of the vaginal mucosa can be managed symptomatically through hygiene, recognition and treatment of infection, and pain control. Sitz baths and topical ointments may be useful for radiation dermatitis, and both topical and oral analgesics can be prescribed for mucositis and general discomfort during radiation and immediately thereafter. As *Candida* can exacerbate vaginitis, there should be a low threshold for starting antifungal medications.

Late Toxicity

Late toxicity after radiation can manifest as rectovaginal or vesicovaginal

fistulas, strictures in the rectum or vagina, premature menopause from radiation exposure to the ovaries, or cystitis, proctitis, or necrosis of the soft tissue or bone.

Clinically, vaginal stenosis and shortening can manifest several months after radiation, although presentation as late as 15 years posttreatment has been documented.[308] Pathologic changes in the vaginal mucosa after radiation treatment include marked mucosal atrophy with epithelial thinning and loss of the overlying stratified squamous layer. There can be hyalinization and collagenization of submucosal connective tissues, with fibrosis of the muscular layer and vasculature. Such changes result in compromised oxygenation of injured tissues, promoting ulceration and fistula formation. It is common to find cytologic abnormalities within the first 6 months after radiation, and it is important to distinguish postradiation atypia from new or recurrent malignancy during posttreatment follow-up.[309]

Regular use of a vaginal dilator to decrease stenosis and shortening should be recommended shortly after completion of radiation treatment, as it is difficult to reverse stenosis and shortening once fibrosis has ensued. Topical estrogen, applied three times a week for 6 to 9 months after radiation, was shown in a randomized controlled trial published in 1975 to reduce the incidence of stenosis, dyspareunia, and cytologic changes in vaginal epithelium.[310] However, because of a small potential for systemic absorption with untoward effects on endometrial proliferation, the use of topical estrogens is not favored for patients.

Radiation necrosis can be conservatively managed with local debridement, peroxide douches, antimicrobials, and estrogen. There is some evidence that hyperbaric oxygen can facilitate healing, with a >50% reduction in vaginal ulceration noted in one series.[311] Fistulas present more of a treatment challenge. Despite the use of interventions such as urinary or fecal diversions, additional surgical correction is often required for effective management, particularly in the case of rectovaginal fistulas.[312]

PATTERNS OF FAILURE

Most treatment failures occur within 5 years, with a median time to recurrence of 6 to 12 months,[62,145] and local recurrence is the most common pattern of treatment failure in the majority of published series. Extravaginal recurrences in the pelvic lymph nodes are less common.

Overall outcomes, by stage, are shown in Table 76.5. In general, the rate of

locoregional recurrence ranges from 10% to 20% for stage I and 30% to 40% for stage II. Patients with advanced disease often have persistent disease despite treatment, up to 68% according to one series.[103] The reported rates of distant metastasis vary, ranging from 7% to 33% and usually occur later in the course of disease, with approximately half of all distant metastases presenting at the time of local recurrence.[67,85,103,146]

GENERAL MANAGEMENT, TREATMENT OPTIONS, AND OUTCOME—SPECIAL SCENARIOS

The Posthysterectomy Patient

Approximately 60% of patients with primary vaginal cancer have had a prior hysterectomy. This likely reflects patients with a history of cervical neoplasia and carcinoma requiring surgical management.[313,314] Finding methods to improve target positioning during EBRT becomes especially important as treatment delivery becomes increasingly more conformal.

After hysterectomy, the small bowel tends to fall lower into the pelvis, increasing the likelihood of it being irradiated during treatment. There is also daily variation in vaginal vault position. A study by Jhingran et al.[274] evaluated the variations in vaginal vault position and bladder and rectal volumes in posthysterectomy patients undergoing IMRT and found significant variations in the position of the vaginal vault depending on bladder and rectal filling. Patients were instructed to have a full bladder prior to radiation treatment; however, the study showed a median difference of 247 cc despite this. It is likely that bladder movement impacts vaginal position. For patients with fiducial markers placed in the vagina, the median movement during treatment was 0.59 cm in the right-left direction, 1.46 cm in the anterior–posterior direction, and 1.2 cm in the superior–inferior direction. Thus, it is important to be mindful of target movement when delineating the treatment volume.

To minimize uncertainly, the treating physician can fuse planning CT scans taken with full and empty bladder in order to estimate the potential range of target volume positions during treatment. Another approach, though less practical, is to fill the bladder with a fixed volume of saline using a Foley catheter immediately prior to treatment or to utilize fiducial markers for daily localization.

History of Prior Pelvic Radiation

Up to 10% to 50% of patients with VAIN or invasive carcinoma of the vagina have a previous diagnosis of cervical carcinoma,[12,40,61,67,82–86] with average time interval of 14 years between diagnosis of cervical disease to development of vaginal carcinoma.[61,72] As a result, a proportion of patients with vaginal cancer have history of prior pelvic radiation. Reirradiation can be considered in this setting, but there is an increased risk of toxicity, particularly radionecrosis and fistula formation. Xiang-E et al.[315] published a series on 73 patients with a history of radiation treatment for cervical carcinoma who received a second diagnosis of vaginal malignancy 5 to 30 years later. All patients received EBRT and brachytherapy for treatment of their initial cancer. Reirradiation for the vaginal malignancy was planned according to site and volume of the vaginal tumor and location and dose of the prior radiation. Patients received brachytherapy, using either radium delivered to the tumor base (30 to 40 Gy in 3 to 5 fractions) or HDR with cobalt-60 to the tumor base (20 to 35 Gy in 3 to 5 fractions), followed by a dose to 0.5 cm below the vaginal mucosa at 20 to 30 Gy in 4 to 6 fractions delivered using a vaginal mold. For involvement of the vulva or groin, patients additionally received EBRT to a dose of 30 to 40 Gy. Most patients received radiation alone; 11 also received chemotherapy, most typically cisplatin based. The 5-year survival rate was 40.3% and 3 patients survived more than 15 years. There were significant side effects with reirradiation: 18 of 73 patients developed radionecrosis. Other side effects included 1 (1.4%) vesicovaginal fistula and 8 (11%) rectovaginal fistulas, hematuria (12.3%), and moderate to severe rectal sequelae (13.6%).

Beriwal et al. reported on the use of HDR interstitial and intracavitary brachytherapy for 5 patients with recurrent vaginal cancer with history of prior pelvic radiation.[115] Significant grade 3 or higher toxicities were noted in patients who received total EQD2 dose above 140 Gy. Median time from prior radiation to recurrence was 4 years (range, 6 months to 18 years). The recurrence was within 2 cm of the prior field in 2 patients and within the previous field for 4 patients. All patients received EBRT to a median dose of 45 Gy, followed by brachytherapy. For the 4 patients with prior overlapping fields, the cumulative EQD2 to the vaginal mucosa ranged from 120.7 to 154.54 Gy. Of these patients, one developed a rectovaginal fistula 2 years after treatment, and another developed chronic vaginal ulceration with vaginal shortening to 2 cm; the EQD2 values were 142.98 and 154 Gy, respectively.

Carcinoma of the Neovagina

The neovagina is a surgically constructed vaginal canal, typically described in patients with congenitally deformed or absent genitalia or patients desiring reconstruction of a functional vaginal after surgery for gynecologic malignancy. Various methods have been utilized for neovaginal construction, including split skin grafts, myocutaneous flaps, and formation of an artificial canal between the rectum and vagina.[316] Given its overall rarity, there are very few reports of *in situ* or invasive carcinoma arising in the neovagina.

A review of published literature reveals six published reports of carcinoma *in situ*.[317–322] The period of development of carcinoma *in situ* ranged from 6 months to 20 years after constructive surgery. Invasive carcinoma of the neovagina tends to be poorly differentiated, and majority of reported cases have been SCC. All reported patients have presented with large tumor masses and evidence of rapid progression, with poor overall outcomes.[231,323,324]

Treatment options include radiation, with or without an attempt at radical resection, and, in select cases, lymph node dissection. Of 16 reported cases from a review by Steiner et al.,[316] 9 received primary radiation alone, 1 received radiation followed by exenteration and intraoperative radiation, and 4 underwent exenteration. Recurrence status was not documented for all patients. Three were found to have rapid disease recurrence within several months. Two patients were free of disease at 10 and 18 months, respectively. One patient had a recurrence-free interval of 3 years but died a year later from disease.

Though there is no optimal treatment, resection followed by consideration of adjuvant radiation is preferable to definitive radiation alone, as surgery can offer full pathologic diagnosis. The extent of disease, patient characteristics, and treatment goals should be used to guide the choice of treatment.

Salvage Therapy for Recurrent or Persistent Disease

For patients with recurrent or persistent disease, it is important to determine whether there is a reasonable chance of cure with salvage treatment or whether the primary goal is palliation. Thus, multiple factors, including histology, sites and extent of recurrence, disease-free interval, patient age, comorbidities, and overall performance status, must be considered.

Early-stage lesions that recur after radiation therapy can be surgically salvaged. A retrospective review of pelvic exenteration for recurrent gynecologic malignancies at University of California Los Angeles Medical Center from 1956 to 2001 reported survival rates for patients with recurrent cervical and vaginal cancer to be 73% at 1 year and 54% at 5 years.[325]

Patients with tumor persistence or recurrence after limited surgical procedures can be considered for more extensive surgery. If not, systemic chemotherapy and/or radiation can be administered.

Recurrent disease in advanced stage patients is more challenging to treat. Most patients have received prior EBRT and thus have options limited to radical surgery or, in patients with localized disease, reirradiation. For patients with small pelvic recurrences, reirradiation with intracavitary or interstitial brachytherapy has been reported, with control rates between 50% and 75% and grade 3 or higher complication rates between 7% and 15%.[115,315,326–329] Beriwal et al. evaluated HDR brachytherapy for primary and recurrent vaginal malignancy. In the subset of patients with a previous malignancy, crude local control rates were 100% for patients without prior radiation and 67% for patients with a history of radiation.

Palliative Therapy

Local treatment can provide symptomatic benefit for patients with advanced disease, who have no curative options. Advanced disease can result in vaginal bleeding, pelvic pain, lymphedema, and visceral obstruction. Vaginal bleeding is a common symptom, which can become brisk if tumor erodes into a larger vessel. Large fractions of radiation delivered initially during the treatment course may be useful in achieving hemostasis for such cases. Other options include embolization, infusion of vasopressin, and balloon catheterization for severe hemodynamic losses.

FOLLOW-UP

Recommendations for posttreatment surveillance are based on Society of Gynecologic Oncologist (SGO) guidelines for gynecologic malignancies.[330] Patients with early-stage lesions, treated with surgery alone, can be followed every 6 months for 2 years, then annually thereafter. Patients with more advanced lesions are at higher risk of recurrence and are recommended follow up every 3 months for the first 2 years, then 6 months for the next 3 years, and annually thereafter.

There is insufficient evidence to support the use of regular cervical or vaginal cytology to detect cancer recurrence. However, the SGO recommends annual cytology as surveillance to detect lower genital tract dysplasia. The routine use of CT or PET as surveillance is not recommended.

SUMMARY

Vaginal cancer is a rare disease, accounting for 1% to 2% of all gynecologic malignancies. Treatment options depend on stage. For early-stage disease, definitive surgery and radiation are efficacious; more advanced disease is generally managed with a combination of chemotherapy and radiation.

CHAPTER 77

Female Urethra

Tony Y. Eng

INTRODUCTION

Primary urethral carcinoma is a rare tumor, accounting for <1% of all malignancies. Although previous data suggested that urethral cancer was more common in women than men, a recent Surveillance, Epidemiology, and End Results (SEER) study reports that primary urethral cancer is more common in men.[1] The ratio of female to male predominance is approximately 1:3. Because of its rarity and lack of prospective data, optimal management of female urethral cancer is based on retrospective data and depends on the clinical stage, tumor location, extent of nodal involvement, patient's health status, and treatment preference.

ANATOMY

The female urethra is approximately 3 to 4 cm long and 0.6 cm in resting diameter. It is embedded in the anterior vaginal wall behind the pubis symphysis, extending inferiorly and anteriorly from the urinary bladder through the urogenital diaphragm to the vestibule, where it forms the urethral meatus. Because of the proximity of the pubis symphysis, a small curve is formed with an anterior concavity. The lower distal half of the urethra is considered the anterior urethra, and the upper proximal half is considered the posterior urethra. Figure 77.1 illustrates the urethra and adjacent organs in the female pelvis.

The wall of the urethra consists of three layers. The muscular layer is continuous with that of the bladder. At the vesicular end of the urethra, this muscular wall forms the internal sphincter. The voluntary urethral sphincter is at the plane of the urogenital diaphragm. A thin layer of erectile tissue consisting of a plexus of veins and muscle fibers forms the middle layer of the wall. The inner layer is the mucous membrane, which is continuous with the bladder proximally

and with the vulva distally. This membrane consists of transitional epithelium near the bladder but distally changes to nonkeratinizing stratified squamous epithelium and pseudostratified columnar epithelium. The distal urethra also contains small mucous recesses and periurethral or Skene glands, most of which are in the region of the meatus.

FIGURE 77.1. MR T1-weighted sagittal image of the female pelvis.

The lymphatic drainage of the distal urethra and urethral meatus parallels that of the vulva to the superficial and deep inguinal and external iliac lymph nodes. The primary drainage of the posterior or entire urethra is mainly to the obturator and internal and external iliac nodes.

EPIDEMIOLOGY AND ETIOLOGY

The SEER database for 1973 to 2002 identified a total of 1,615 cases of primary urethral carcinoma, of which 540 were women.[1] The overall annual incidence was 1.5 per million for women (4.3 per million for men). Although previous

observation suggests that this cancer is more common in white women than in black women,[2,3] the SEER data show the incidence to be higher for African Americans and increase steadily with age. As carcinoma of the urethra is rare in women, only a few cases are seen annually at major cancer centers.[4–6] Carcinoma of the female urethra makes up 0.02% of all cancers in women and accounts for approximately 0.1% of all gynecologic cancers.[7,8] The average patient age at the time of diagnosis is 60 years, with most patients between 50 and 80 years of age.[1,2,9–11]

Although chronic infection and local irritation have been proposed, the etiology of female urethral cancer remains obscure. Unlike other transitional cell carcinoma of the urinary tract, there is no reported correlation between cigarette smoking and urethral carcinoma. Wiener and Walther[12] analyzed archival surgical specimens of women with urethral carcinoma. Human papillomavirus (HPV) was detected in 10 of 17 patients with invasive disease. HPV type 16 was found in eight patients. Eight women with squamous cell carcinoma and two with transitional cell carcinoma had HPV. Female urethral cancer may also be associated with urethral diverticula.[13–15] Figure 77.2 illustrates a carcinoma arising within a urethral diverticulum. Patients with transitional cell carcinoma of the bladder, especially the bladder neck, may have a higher risk of developing urethral cancer either synchronously or metachronously.[16,17]

NATURAL HISTORY

Most urethral cancers are clinically aggressive and historically carry a poor prognosis. During the later stages, cancers of the middle or posterior urethra tend to extend upward into the urinary bladder, downward to invade the remainder of the urethra, and posteriorly into the vaginal mucosa. Lesions involving the anterior urethra account for approximately 30% of all cases.[9,18]

Regional lymph node involvement is uncommon in early tumors (stage 0) of the urethral meatus. Advanced tumors (stages II and III) of the urethra have been associated with a 35% to 50% incidence of inguinal or pelvic lymph node involvement.[6,10,19–21] Bilateral nodal involvement occurs in approximately one-third of patients with positive nodes. Grabstald[9] confirmed nodal involvement in 24 of 25 patients with clinically palpable nodes. In his series of patients with advanced disease, 26 underwent pelvic lymph node sampling and 13 (50%) had nodal involvement.

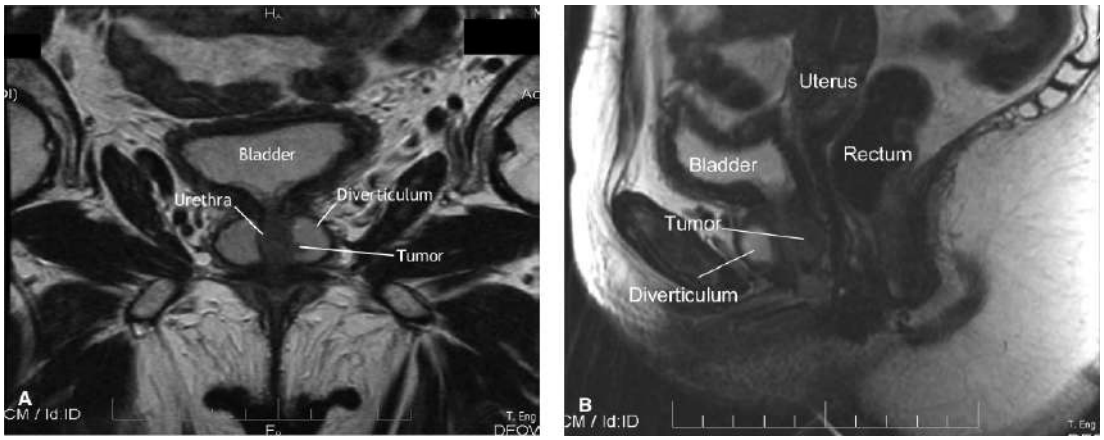

FIGURE 77.2. Coronal **(A)** and sagittal **(B)** T2-weighted MR images demonstrate a large diverticulum surrounding the urethra with a tumor mass arising within the confines of the diverticulum posteriorly that results in an impression at the vagina.

Distant metastases are found in approximately 10% of patients at presentation, and approximately 30% to 50% ultimately die of distant disease. The most common sites of metastasis are lung, liver, bone, and brain.[9,22]

CLINICAL PRESENTATION

A majority of patients with urethral cancer present with some degree of irritative or obstructive urethral symptoms.[23] Bleeding (hematuria) or spotting is the prevailing presenting sign in 50% to 60% of patients.[2,24,25] Approximately 30% to 50% of patients experience pain or irritative symptoms, difficulty urinating, and frequent micturition. Urinary retention and overflow incontinence may occur in advanced cases. Less frequently cited signs and symptoms are a mass in the introitus (10% to 20% of patients), dyspareunia, perineal pain, and inguinal lymphadenopathy.[20,22] Urethrovaginal and vesicovaginal fistulas may develop in advanced, neglected cases.

Small tumors involving the urethral meatus are often mistakenly diagnosed as urethral caruncle; a benign, inflammatory lesion; or a prolapse of the mucosa through the urethral orifice. As the lesion progresses, it enlarges and eventually ulcerates.[22] Tumors may arise in a urethral diverticulum.[15,26,27] Larger lesions of the distal urethra are readily identified on inspection (Fig. 77.3). Tumors occupying the proximal urethra may produce a fusiform enlargement that can be palpated during pelvic examination.

DIAGNOSTIC WORKUP

An outline for the diagnostic workup for carcinoma of the female urethra is presented in Table 77.1. A routine history and general physical examination should be performed for all patients. A detailed pelvic examination under anesthesia is necessary to fully evaluate the clinical extent of the disease. This examination can be performed at the time of urethroscopy and cystoscopy. Urine cytologic analyses have a high false-negative rate.[28] The definitive diagnosis is made by punch or incisional biopsy.

Routine radiographic evaluation should include chest radiographs, an intravenous urogram, and a computed tomography (CT) scan of the abdomen and pelvis[29,30] (Fig. 77.4). Barium enema can be cost-effective for patients with symptoms of advanced disease. Magnetic resonance imaging (MRI) of the pelvis helps delineate the tumor extent, especially when an endourethral coil is used (Fig. 77.2). It provides a discrete view of the muscular layers of the urethra.[31,32] Additional complementary studies include interactive virtual urethrography and ultrasonography that can help detect a urethral diverticulum without contrast agent filling.[33] Multidetector CT voiding urethrography yields real-time urethral images during micturition.

Currently, there are no studies addressing the role of PET-FDG (positron emission tomography with fluorodeoxyglucose) scan in urethral cancer. Perhaps, some genitourinary tumors do not accumulate sufficient FDG, which may not be a useful tracer for the detection of primary genitourinary tumors because of its physiologic excretion in the urine.[34] However, PET scans may potentially be useful for identifying nodal and distant sites of disease, especially in patients with equivocal findings on conventional imaging.[35–37]

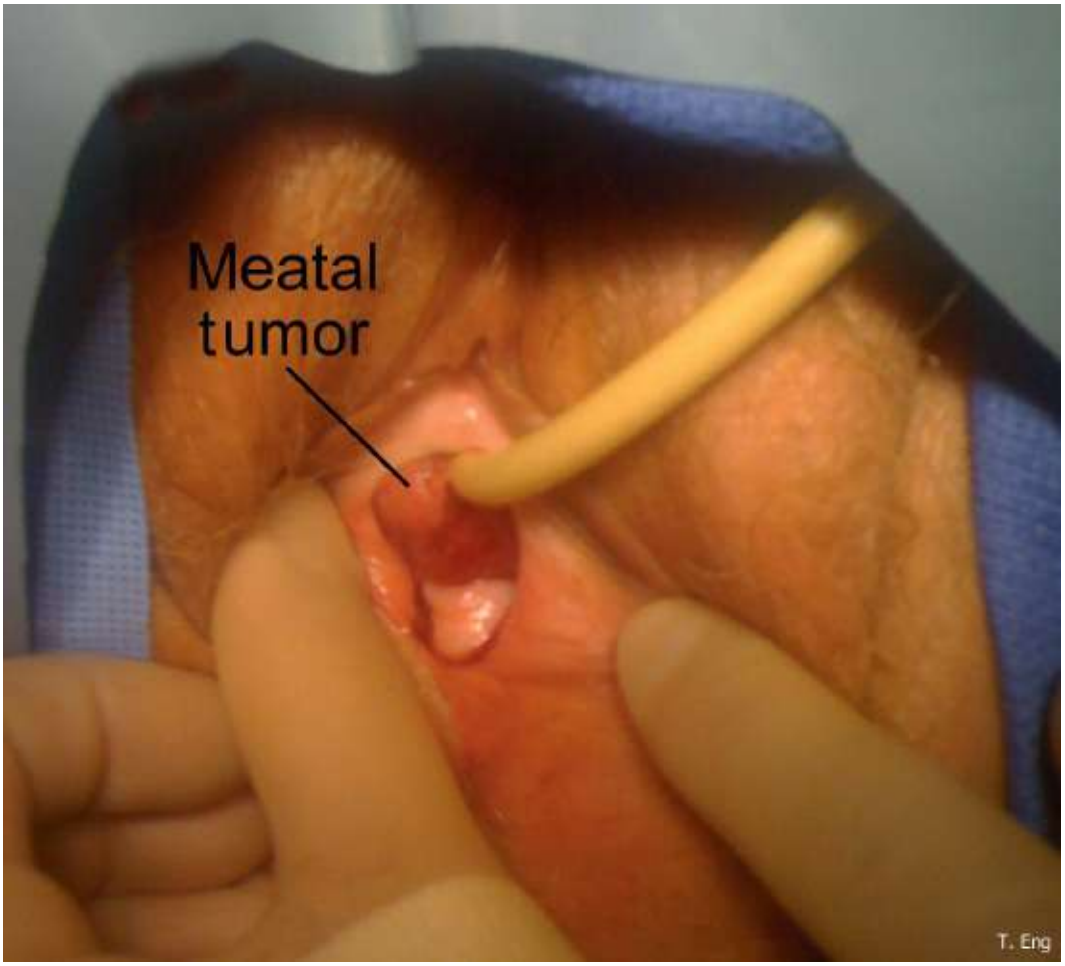

FIGURE 77.3. A meatal carcinoma of the urethra in a 68-year-old white woman presenting with hematuria.

TABLE 77.1 DIAGNOSTIC WORKUP FOR CARCINOMA OF THE FEMALE URETHRA

General
History
Physical examination, including detailed pelvic examination under anesthesia
Special procedures
- Punch biopsy
- Urethroscopy
- Cystoscopy
- Rectosigmoidoscopy (advanced stages or if symptomatic)

Radiographic evaluation
- Standard
- Chest radiographs
- Intravenous urography
- CT scan (abdomen and pelvis)
- Magnetic resonance imaging
- Complementary

- Bone scan (if symptomatic or elevated alkaline phosphatase)
- Barium enema (if symptomatic or advanced stages)
- Ultrasound
- Urethrography

Laboratory evaluation

- Complete blood count
- Chemistry profile
- Urinalysis

STAGING SYSTEMS

Clinical staging is based on findings on physical examination, chest x-ray, and CT scan of the abdomen and pelvis. Many attempts have been made to formulate a staging system for carcinoma of the urethra. Urethral tumors can be classified in two groups: those involving the distal half of the urethra and those located in the proximal or entire urethra. Most authors have found that this classification correctly depicts the feasibility of treatment and the prognosis. A staging system based on location has been proposed by Prempree et al.[38] (Table 77.2). The current TNM staging system of the American Joint Committee on Cancer[39] is shown in Table 77.3.

PATHOLOGIC CLASSIFICATION

As the urethra is lined by transitional cells proximally and stratified squamous cells distally, transitional cell carcinoma occurs typically in the proximal urethra, whereas squamous cell carcinoma occurs frequently in the distal urethra. The SEER data report the most common histologic type is transitional cell carcinoma followed by squamous cell and adenocarcinoma.[1] However, most published series suggest that squamous cell carcinoma is the most common histologic type in cancer of the female urethra, representing more than 50% of all cases whereas transitional cell carcinoma and adenocarcinoma represent approximately 15% to 20% and 10% to 15%, respectively.[14,40,41] The remainder of the histologic types include adenoid cystic carcinoma, melanoma, clear cell adenocarcinoma, anaplastic tumors, Kaposi sarcoma, lymphomas, and metastatic lesions.[5,35,42–45]

FIGURE 77.4. Transaxial CT image of a patient with urethral cancer illustrating the periurethral and anterior vaginal wall expansion and deviation of the urethra (*arrow*).

TABLE 77.2 PROPOSED CLINICAL STAGING SYSTEM FOR CARCINOMA OF THE FEMALE URETHRA

Tumor Stage	Characteristics
I	Disease limited to distal one-half of urethra
II	Disease involving entire urethra, with extension to periurethral tissues, but not involving vulva or bladder neck
III	
A	Disease involving urethra and vulva
B	Disease invading vaginal mucosa
C	Disease involving urethra and bladder neck
IV	
A	Disease invading parametrium or paracolpium
B	Metastasis
B1	Inguinal lymph nodes
B2	Pelvic lymph nodes
B3	Para-aortic nodes
B4	Distant metastasis

PROGNOSTIC FACTORS

Conventional prognostic factors such as grade and histology have not been consistently predictive for recurrence or survival for female urethral cancer. In the literature, some of the most important factors in determining prognosis and survival are stage, depth of invasion, tumor size, and anatomic location.[2,14,20,28,46,47] The 1983 to 2008 SEER database shows that advance age, T stage, node positivity, nonsquamous histology, and black race were associated with reduced cause-specific survival.[48] Dalbagni et al.[2] showed that primary stage was one of the major independent predictors of survival in 72 female patients with a 5-year survival of 83% for low-stage tumors and 33% for high-stage tumors.

TABLE 77.3 TNM CLASSIFICATION OF CARCINOMA OF THE URETHRA (MALE OR FEMALE)

Primary Tumor (T)

TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Ta	Noninvasive papillary carcinoma
Tis	Carcinoma *in situ*
T1	Tumor invades subepithelial connective tissue
T2	Tumor invades any of the following: corpus spongiosum, periurethral muscle
T3	Tumor invades any of the following: corpus cavernosum, anterior vagina
T4	Tumor invades other adjacent organs (e.g., invasion of the bladder wall)

Regional Lymph Nodes (N)

NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Single lymph node metastasis in the inguinal region or true pelvis [perivesical, obturator, internal (hypogastric) and external iliac], or presacral lymph node
N2	Multiple regional lymph node metastasis in the inguinal region or true pelvis [perivesical, obturator, internal (hypogastric) and external iliac], or presacral lymph node

Distant Metastasis (M)

M0	No distant metastasis
M1	Distant metastasis

From Amin MB, Edge SB, Greene FL, et al., eds. *AJCC cancer staging manual*. 8th ed. New York: Springer, 2017. Reproduced with permission of Springer International Publishing in the format Book via Copyright Clearance Center.

Lesions located in the meatus or distal urethra tend to be superficial, with a better prognosis; lesions in the posterior urethra are often deeply invasive and tend to have a worse prognosis.[8] Most investigators found that patients with advanced-stage disease do poorly, often irrespective of their treatment.[2,23,47,49]

Grigsby and associates[24,50] demonstrated a worsening prognosis with increased tumor size. The 5-year progression-free survival was 81% for patients with lesions <2 cm, compared with 37% for those with lesions 2 to 4 cm and 7% for patients with lesions >4 cm (P = .0001). For lesions confined to the proximal urethra, local control was observed in all four patients. However, patients with tumors involving the distal urethra had a 5-year progression–survival rate of 69%, and there was a 12% survival rate for those with involvement of the entire free urethra (P = .0001). Patients with meatal tumors, if diagnosed early and treated appropriately, can achieve an 80% to 90% survival rate (Figs. 77.5 and 77.6).[24] Bladder neck involvement, parametrial extension, and inguinal lymph node involvement have been identified as poor prognostic factors.

Several investigators found that the use of brachytherapy improves local control. Milosevic et al.[51] reported that patients who were treated with external beam therapy only were 4.2 times more likely to recur locally independent of other prognostic factors, compared with those who received brachytherapy as a component of management. Similarly, in a study of six patients with locally advanced urethral carcinoma, Dalbagni et al.[52] noted that high-dose intraoperative brachytherapy followed by external beam radiation appeared to improve local control.

The histology of the primary lesion appears to be less important as a prognostic factor in determining response to therapy and survival. Patients with adenocarcinoma have been reported to have a good prognosis, but most studies have shown no difference in survival among patients with adenocarcinoma, squamous cell carcinoma, and transitional cell carcinoma.[9,13,38,46] Grigsby[24] found a worse prognosis in patients with adenocarcinoma. Primary melanoma of the urethra, although rare, has a very poor prognosis.[53–55]

GENERAL MANAGEMENT

Although various therapeutic approaches have been advocated for the management of carcinoma of the female urethra, there are no established therapeutic guidelines. The variety of treatments reflects the dimensions and locations of disease and the approaches of the treating physicians.[3] In general,

surgical resection is a primary mode of treatment.[56] Radical urethral resection with urinary diversion and pelvic lymphadenectomy is commonly performed for lesions not involving the bladder neck. However, early-stage lesions of limited extent may be amenable to organ-sparing radiation therapy or conservative surgical management with or without adjuvant radiation therapy to minimize the morbidity associated with surgical intervention. Surgical approaches include neodymium:yttrium–aluminum–garnet (Nd:YAG) laser coagulation,[57] Mohs micrographic surgery, and partial or total urethrectomy.[41] Radiation therapy may include external-beam radiation, interstitial brachytherapy, or a combination of these treatments.[58] For patients who are medically nonsurgical candidates because of potential risks of anesthesia, outpatient high–dose rate (HDR) intracavitary and intraluminal brachytherapy may be an option.[52,59]

Multimodality Therapy

For patients with locally invasive urethral carcinoma, anterior exenteration may be required. Although most available data are insufficient, in patients with more advanced disease, some authors have advocated adjuvant radiation therapy and/or combined irradiation and chemotherapy including 5-fluorouracil, cisplatin, vinblastine, epirubicin, carboplatin, bleomycin, methotrexate, or mitomycin C after surgical extirpation.[56,60–63] A subgroup of patients with positive nodes may also benefit from preoperative cisplatin-based chemotherapy.[64]

Multimodality therapy appears to achieve similar or better overall results, even though those patients who receive combined modality tend to have more advanced disease. Although most studies included a small number of patients, those patients who received combined therapy seem to have better disease-free survival.[14,47,49] Combination therapy often consists of either chemotherapy with radiotherapy or radiotherapy with surgery. Combined chemotherapy and radiation therapy for locally advanced urethral cancer has shown a reasonable response in several reports.[47,49,60,62,65]

Anterior (Distal) Urethral Cancer

For stage 0 and I (Ta, Tis, or small T1) lesions, open excision, electroexcision, fulguration, and laser (Nd:YAG or CO_2) coagulation are possible for tumors at the meatus or with *in situ* involvement of the distal urethra (stage 0). For larger and more invasive lesions (stage T1 and T2), surgical resection of the distal third of the urethra is often adequate. Alternately, interstitial irradiation or a combination of interstitial and external-beam irradiation can be considered. For T3 to T4 or recurrent anterior urethral lesions previously treated by local excision or radiation therapy, anterior exenteration and urinary diversion may be curative. Adjuvant radiation therapy may be required, depending on surgical findings.

If a limited number of inguinal nodes are involved, ipsilateral node dissection or irradiation is indicated because cure is still achievable. If no inguinal adenopathy exists, node dissection is not recommended, but prophylactic groin irradiation is recommended for patients with invasive lesions.[5,46]

Posterior (Proximal) Urethral Cancer

Cancers of the posterior or entire urethra are usually associated with invasion of the bladder, a high incidence of inguinal and pelvic lymph node metastases, and a worse prognosis. For lesions <2 cm, radical resection, definitive radiation therapy, or combined treatment may provide adequate control.[50] However, for larger lesions or locally advanced disease, the best results have been achieved with preoperative irradiation, exenterative surgery, and urinary diversion. Pelvic lymphadenectomy is performed and inguinal node dissection may be indicated if the inguinal nodes are involved. In selected patients, it is possible to remove part of the pubis symphysis and the inferior pubic rami to maximize the surgical margin. A transpubic approach has been advocated by Golimbu et al.[66] Perineal closure and vaginal reconstruction can be accomplished with the use of myocutaneous flaps. Hedden et al.[67] have advocated the use of bladder-sparing surgery with or without irradiation.

Recurrent Urethral Cancer

In most cases, locally recurrent urethral cancer after surgery alone should be considered for combination radiation therapy and wider surgical resection. Locally recurrent urethral cancer after radiation therapy should be treated by surgical excision. For those who are not surgical candidates, local reirradiation (i.e., hyperfractionated intensity-modulated radiation therapy or brachytherapy) may be considered if radiation tolerance has not been exceeded. Patients with

metastatic urethral cancer should be considered for investigational chemotherapy protocols. Palliative radiation therapy may provide good symptomatic relief.

RADIATION THERAPY TECHNIQUES

Small meatal and distal urethral lesions are curable with limited therapy. Interstitial implants have been the usual method for treating meatal carcinomas. Radioactive needles, forming a double-plane or a volume implant, have been used (Fig. 77.7). Both low–dose rate (LDR) and HDR afterloading implants using ^{192}Ir have replaced radium.[7,52,59] For early localized disease without involvement of adjacent organs, a volume implant composed of 8 to 12 needles arranged in an arc around the urethral orifice is used (Fig. 77.8). Radiographs may be used to verify needle placement (Fig. 77.9). Computer planning with CT-based simulation and 3-D treatment planning should be the standard of care to spare the adjacent normal organs. A dose of 60 to 70 Gy (LDR) should be given in 6 to 7 days (0.4 to 0.5 Gy/h to the target volume) when an implant alone is used.

Alternatively, in patients with small localized disease receiving radiation therapy alone, noninvasive intracavitary or intraluminal HDR brachytherapy without sedation or anesthesia after pelvic external beam radiation has been used.[47,59] Figure 77.10 illustrates an intraluminal HDR brachytherapy using a Foley catheter. The resultant conformal radiation dose covers the periurethral tissue well while sparing the surrounding normal structures. At the University of Texas Health Science Center in San Antonio, we deliver 500 to 600 cGy at twice a week, 3 days apart, to a total dose of 2,400 to 2,500 cGy with good response.

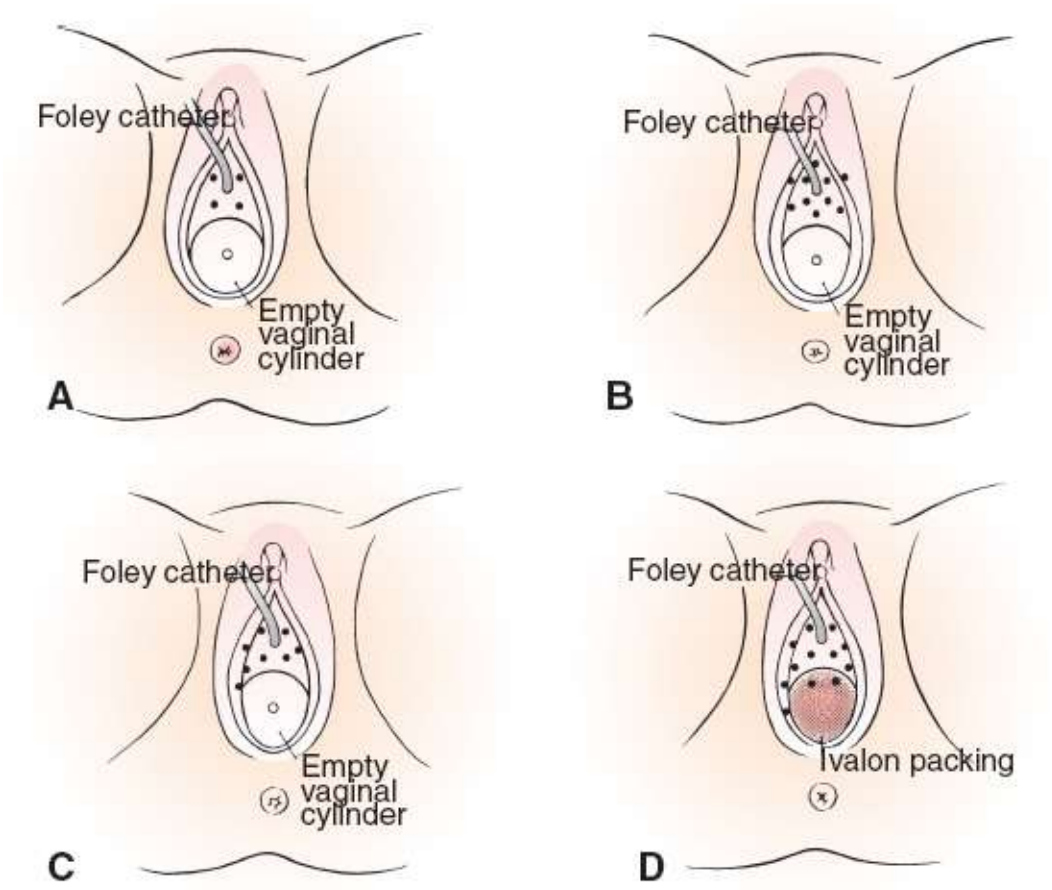

FIGURE 77.7. Diagrams of implants. **A:** Tumor limited to the urethra. **B:** Tumor extending to the periurethral tissues or originating in the periurethral glands. **C:** Tumor extending into the vagina or labia minora. **D:** Tumor involving the suburethral area. (Reprinted from Delclos L. Carcinoma of the female urethra. In: Johnson DE, Boileau MA, eds. *Genitourinary tumors: fundamental principles and surgical techniques*. New York: Grune & Stratton, 1982:275–286. Copyright © 1982 Elsevier. With permission.)

Large tumors or advanced disease extending into the labia, vagina, entire urethra, or base of the bladder should not be treated with an implant alone. For these patients, a combination of external-beam irradiation and implant is recommended.[51,59,68] The external-beam portal should flash the perineum to cover the entire urethra. The conventional portal should be wide enough to cover the inguinal nodes and should extend cephalad to the L5-S1 interspace to include the pelvic nodes (Fig. 77.11).[69] A bolus, appropriate for the photon energy used, should be added to the groin when inguinal nodes are positive. This technique minimizes the hazard of groin failure due to underdosing of gross tumor. Hahn et al.[70] have demonstrated the importance of treating the inguinal lymph nodes in all patients. The whole pelvis is treated to a dose of 45 to 50 Gy. A boost of 10 to 15 Gy is delivered to positive groin nodes through reduced anteroposterior

fields.

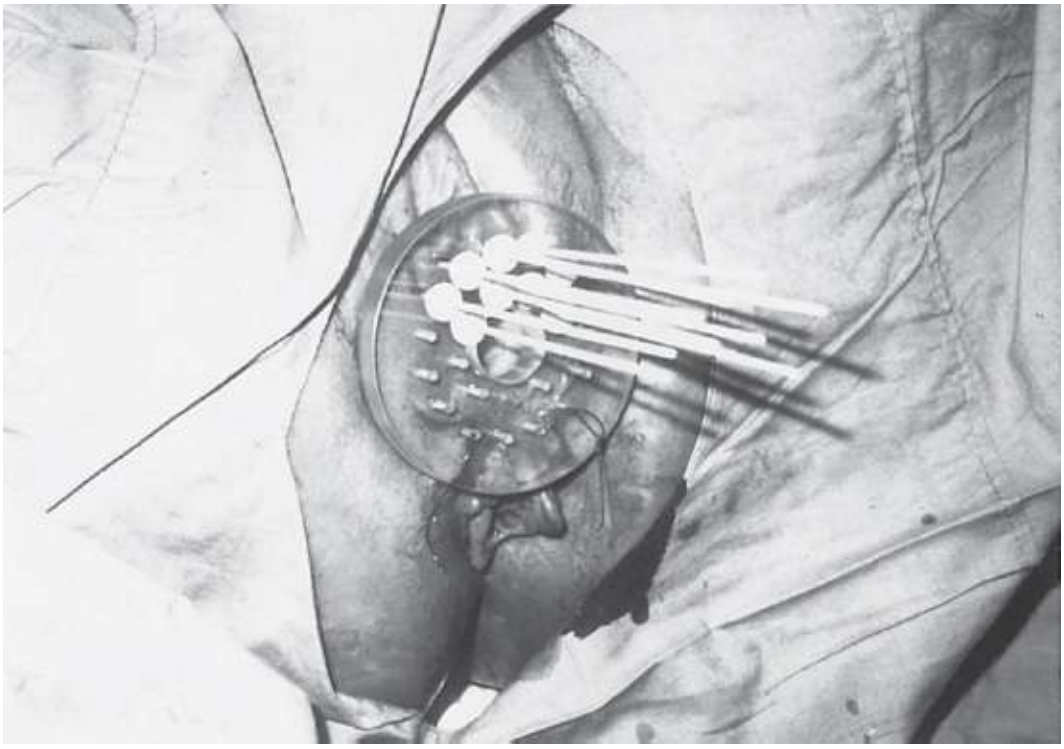

FIGURE 77.8. A template used for a curved, double-plane implant that surrounds the urethra. The closed-end flexible catheters inserted in the periurethral or vaginal tissues are glued to the template, which is sutured to the skin. The catheters are afterloaded with ^{192}Ir.

After pelvic radiation therapy, the primary tumor can be treated with a vaginal cylinder to bring the dose to the entire urethra to approximately 60 Gy. An interstitial implant is administered to raise the total tumor dose to 70 to 80 Gy. For patients undergoing postoperative therapy, the tumor bed is treated after pelvic radiation therapy with an additional 10 to 15 Gy using interstitial brachytherapy.[52] Intracavitary irradiation with the vaginal cylinder and an interstitial implant are almost never used simultaneously because of the resultant high dose rate at the vaginal mucosa interface of the intracavitary and interstitial implant fields. A vaginal cylinder with partial shielding posteriorly can be used in select patients. Gerbaulet et al.[71] have demonstrated the use of a catheter or a vaginal mold applicator for intraluminal/intracavitary brachytherapy and needles or guide gutters for interstitial brachytherapy.

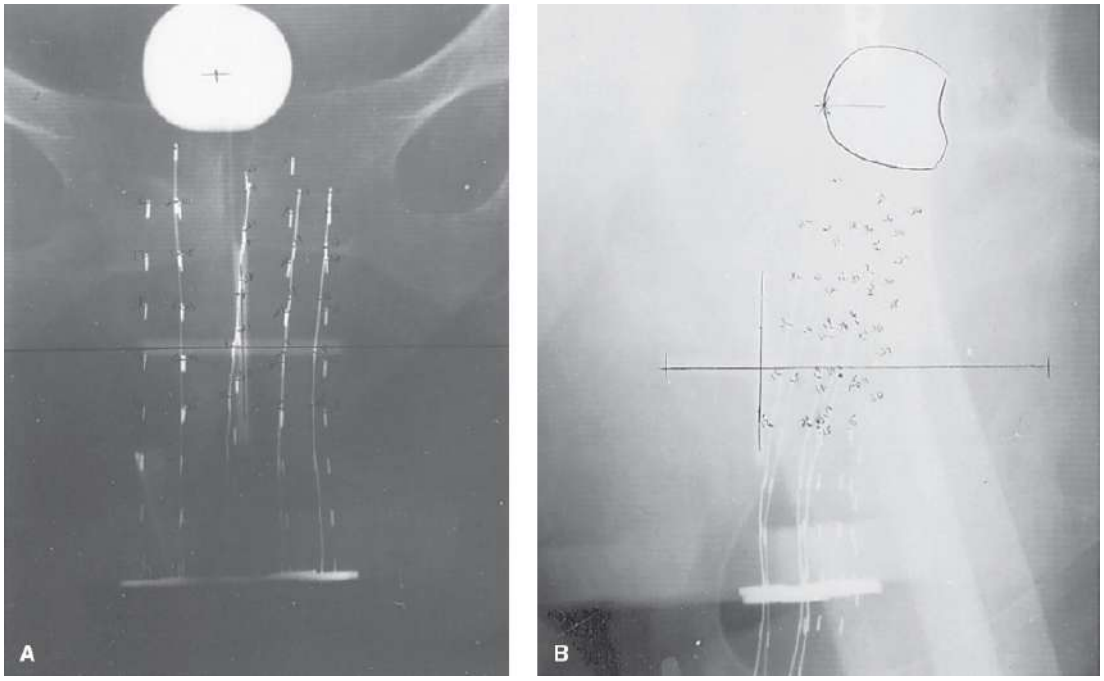

FIGURE 77.9. Anteroposterior **(A)** and lateral **(B)** simulation radiographs with dummy seeds in place. Contrast material is used to inflate the balloon of the urinary catheter, which is used to localize the bladder.

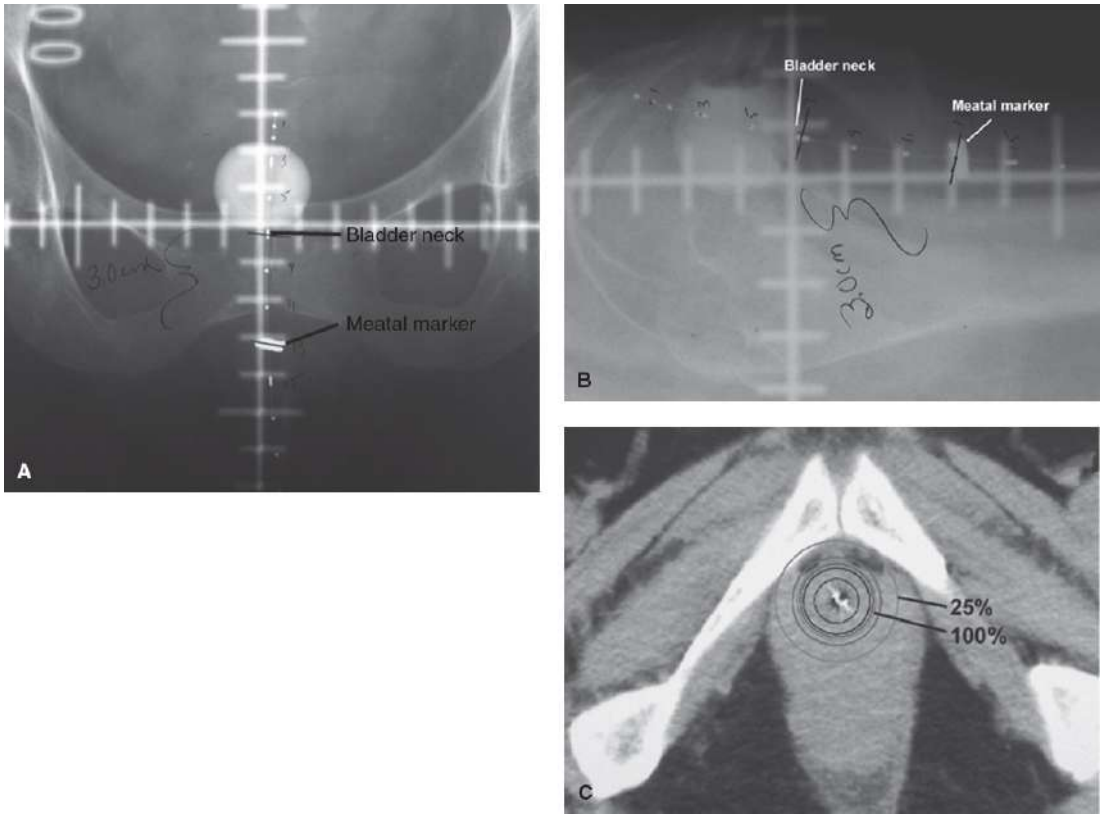

FIGURE 77.10. HDR brachytherapy with a Foley catheter. Anteroposterior **(A)** and lateral simulation films **(B)**, and transaxial CT image with isodose plan **(C)**. The

resultant uniformed, steep isodose lines cover the periurethral tissue well.

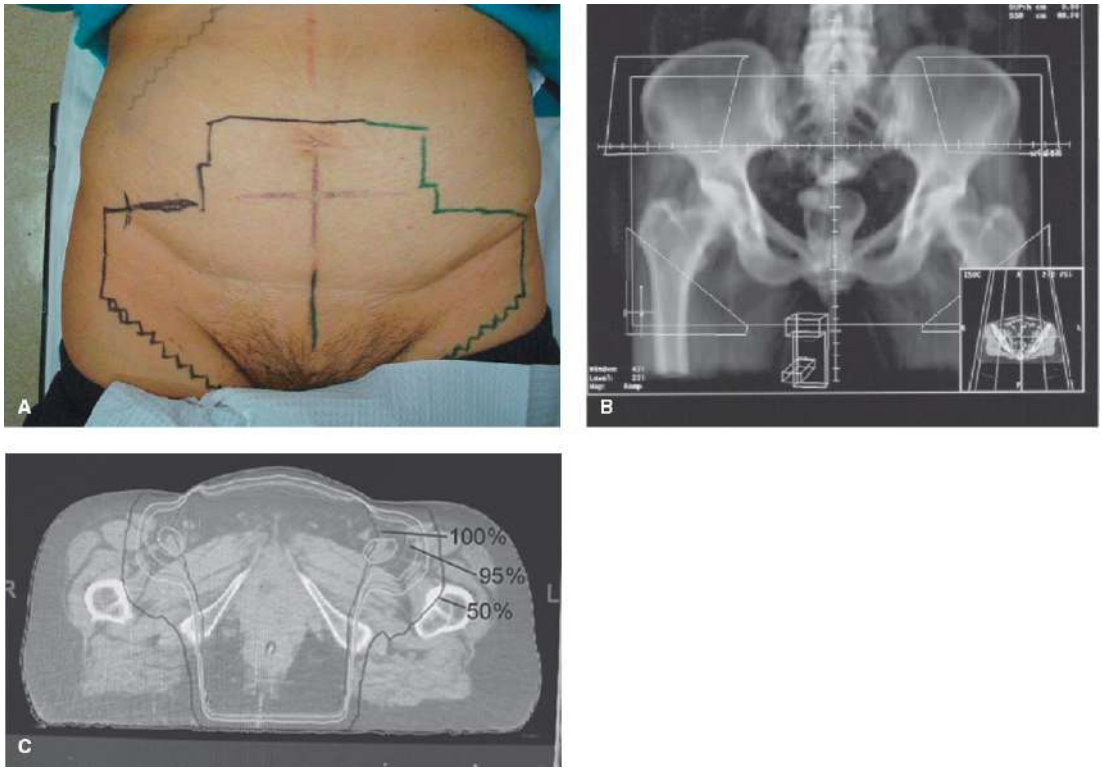

FIGURE 77.11. Whole pelvis and inguinal field. External skin marking **(A)** and anteroposterior simulation film **(B)** of a pelvic portal showing the lateral extension to cover the inguinal lymph nodes, and the isodose plan **(C)**.

At the University of Texas Health Science Center in San Antonio, we commonly deliver external beam therapy, 4,500 to 5,040 cGy, to the primary tumor and pelvic lymphatics using intensity-modulated radiation therapy technique (IMRT) with CT image guidance (Fig. 77.12). This is followed by interstitial HDR brachytherapy, 500 to 600 cGy twice a day, 6 hours apart. A vaginal cylinder is always employed to provide spatial protection of the posterior vagina and rectum. The HDR brachytherapy is repeated in one week to achieve a total dose of 2,000 to 2,400 cGy (Fig. 77.13). The major advantage of interstitial HDR brachytherapy is geometric or volume optimization by changing the dwell time and dwell position of the radioactive source along the afterloading catheter so that the target volume is well covered with good conformity while the doses to the vaginal mucosa and surround structures are kept below their tolerances. Modification of dose and fractionation may be made depending on the tumor size and response to external beam therapy. The HDR brachytherapy is performed as an outpatient treatment.

One of the limiting factors in the use of external-beam irradiation is the tolerance of the perineal and vulva skin (i.e., confluent moist desquamation). Extensive disease combined with advanced age can be a formidable obstacle to completing the irradiation course. Proper radiation therapy techniques and diligent personal hygiene and individualized skin care during and after treatment are necessary if patients are to complete the course of treatment.

RESULTS OF THERAPY

The SEER 1983 to 2008 database identified 722 women with urethral cancer.[48] The median overall survival was 42 months, and the 5- and 10- year overall survival was 43% and 32% respectively. The median cause-specific survival was 78 months, and the 5- and 10-year cause-specific survival was 53% and 46%, respectively. Table 77.4 summarizes the recent treatment results from various institutions. Depending on the various prognostic and treatment factors, the 5-year overall survival and cause-specific survival rates range from 32% to 59% and 40% to 61%, respectively. The recurrence rates range from 58% to 64%.

Surgery

There is a paucity of long-term outcome data. In general, female urethral cancers are clinically aggressive with high recurrence and poor survival rates.[2,9,14,21,49] DiMarco et al.[23] reviewed 53 female patients with primary urethral carcinoma undergoing partial urethrectomy or radical extirpation. The estimated 10-year cancer-specific survival was 60%. In a study of 72 patients treated at Memorial Sloan Kettering Cancer Center between 1925 and 1994, the 5-year disease-specific survival was 89% for low-stage tumors and 33% for high-stage tumors.[2] The overall survival was 78% and 22%, respectively, as shown in Table 77.4.

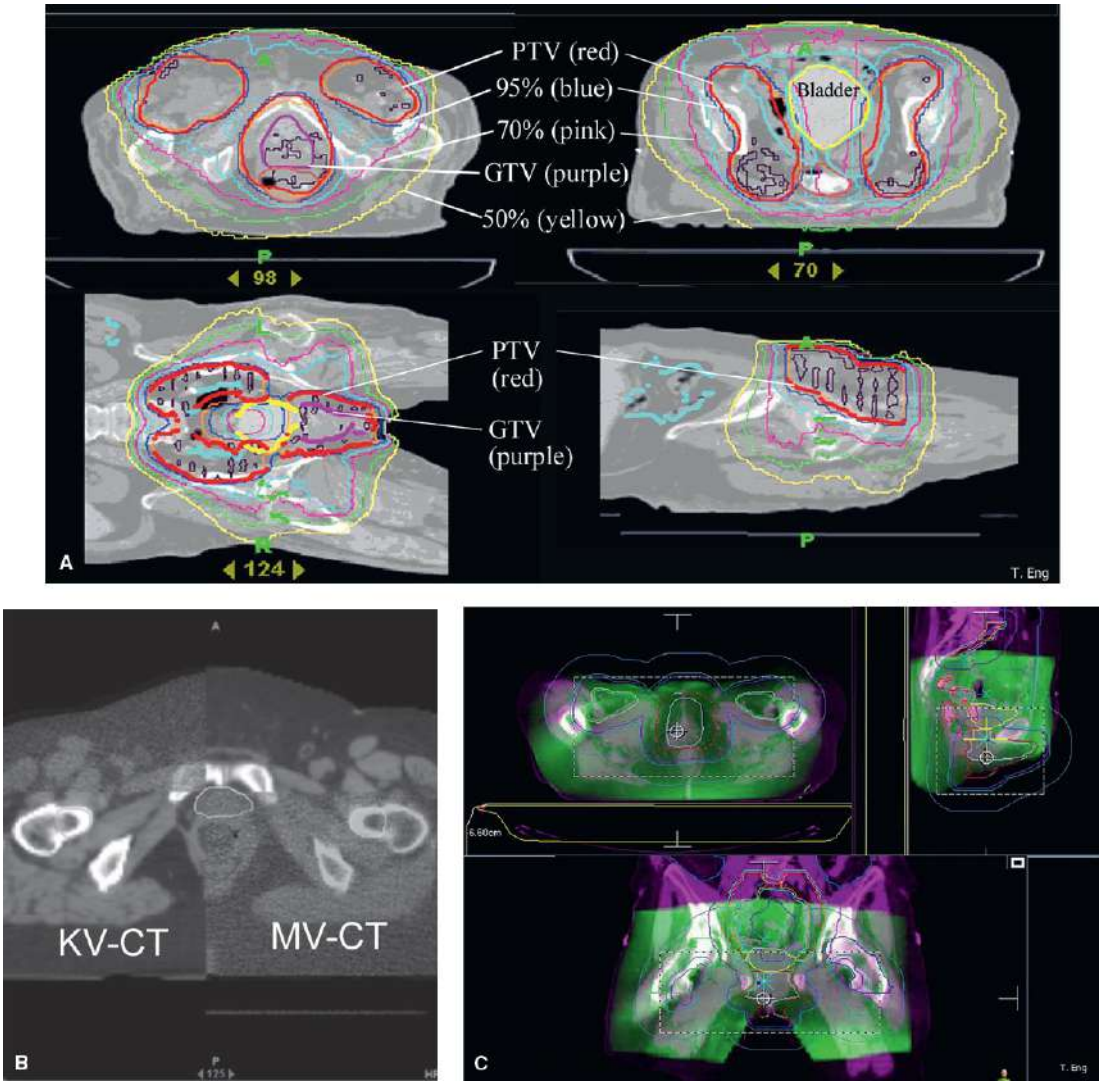

FIGURE 77.12. Pelvic IMRT plan. It shows a conformal dose distribution covering the lymphatics and primary target volume or the planning target volume (PTV) and gross tumor volume (GTV) **(A)**. Daily matching of MV-CT with the reference planning CT (KV-CT) **(B)** or CBCT **(C)** images is done prior to each treatment.

Five of seven patients with early meatal tumors were cured of disease in the series reported by Grabstald[9] after partial urethrectomy. In the remaining two patients, both local recurrences and distant metastases developed. Bracken et al.[46] reported local control in just one of four patients treated with local excision only for distal urethral lesions. Peterson et al.[22] reported on two patients in whom squamous cell carcinomas were excised successfully. In the same series, a patient with adenocarcinoma treated with local excision had a local recurrence and left inguinal adenopathy 4 years later.

Grabstald et al.[20] performed radical surgery on 15 patients with advanced disease; there were only 3 survivors at 5 years. Peterson et al.[22] performed

radical surgery on seven patients, three of whom were still alive at 5 years. Primary radical cystectomy with anterior vaginectomy and total urethrectomy was performed on eight patients by Mayer et al.[74] Three of these patients were free of disease at 1, 4, and 11 years.

Radiation Therapy

Although DiMarco et al.[23] found that adjuvant radiation did not improve local control or survival in the study of 53 female patients with urethral carcinoma, treatment selection bias may have played a role as the higher-stage tumors tended to receive adjuvant radiation therapy. Eng et al.[47] reported only one of six patients with low-stage disease was referred for adjuvant radiation therapy, whereas four of five patients with advanced disease received radiation therapy. The one who did not receive radiation died 10 months after surgery. Case review of early-stage urethral cancer treated with external beam radiotherapy, brachytherapy, or a combination of both seems to have equivalent results as surgery alone.[52,58,65,69]

Control of tumors of the urethral meatus or the distal urethra with irradiation alone is often satisfactory. Early meatal tumors have cure rates of 70% to 90%.[38] Chu[19] reported a 5-year progression-free survival rate of 64% for 11 patients with tumor involvement of the anterior urethra treated with irradiation alone. Prempree et al.[38] treated three patients with stage I disease with interstitial irradiation alone (50 to 65 Gy) and achieved local control in all three. In the same series, two of four patients with stage II disease achieved local control and were alive 5 years after treatment. Weghaupt et al.[8] reported a 5-year survival rate of 71% for 42 patients with cancer of the anterior urethra. Their doses ranged from 55 to 70 Gy from intracavitary and external irradiation. Princess Margaret Hospital reported an 87% relapse-free survival rate in patients with stage I or II disease.[51] The majority of patients with small primary tumors received brachytherapy as a component of their treatment. Patients receiving brachytherapy and external-beam radiation therapy had a median total dose of 65 Gy.

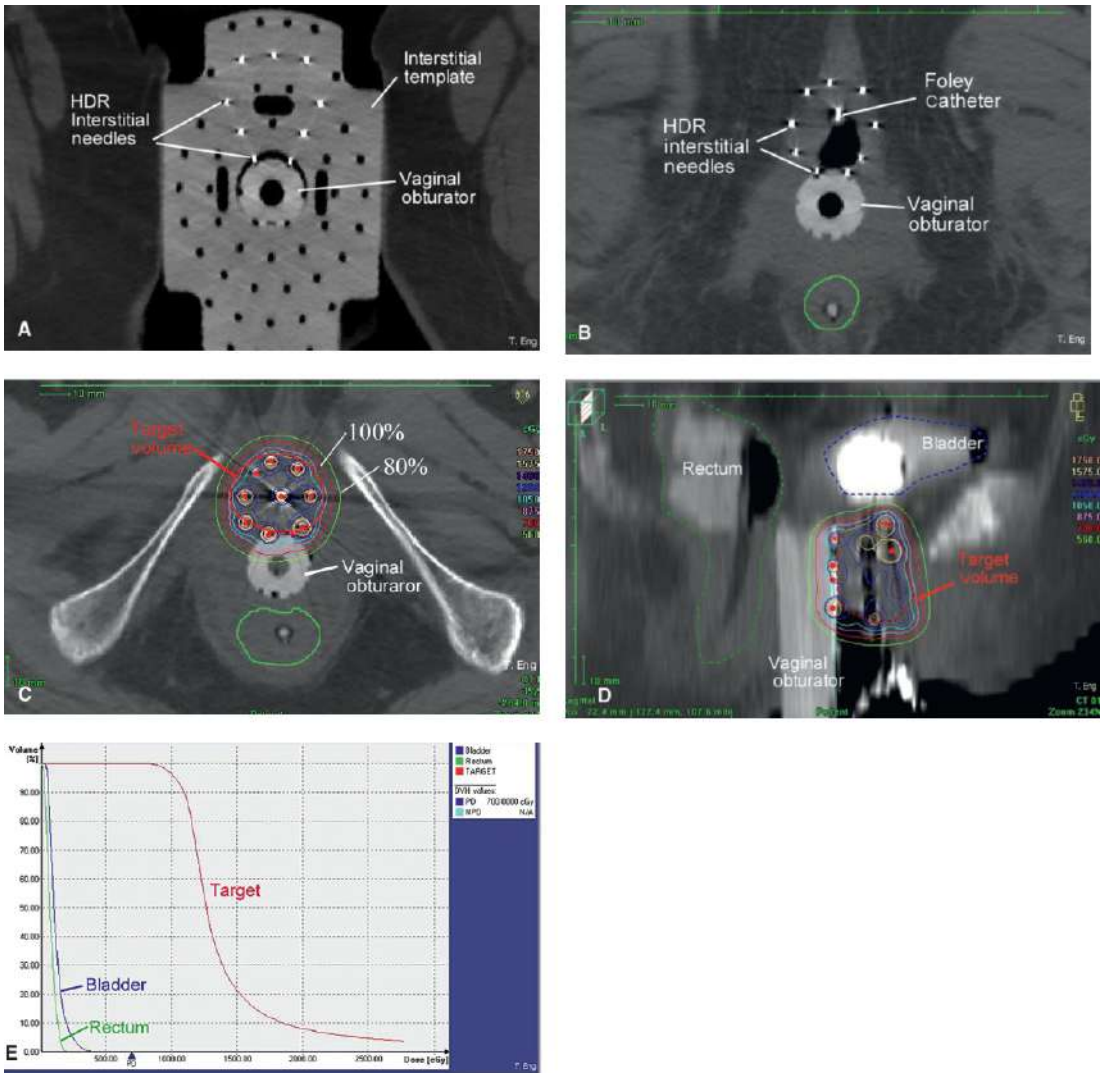

FIGURE 77.13. HDR interstitial brachytherapy. An interstitial template with a vaginal obturator is used to guide the needle placement **(A)**. The needles surround the urethra at approximately 1 cm distance **(B)**. With proper optimization, the resultant dose distribution conforms to the target volume while sparing all the surrounding organs **(C** and **D)**. Dose–volume histogram (DVH) shows a large dose separation of the target from the bladder and rectum **(E)**.

Tumors of the proximal urethra or the entire urethra are more difficult to treat. The overall local control rate is 20% to 30%. Bracken et al.[46] treated 81 patients, and the 5-year survival rate was approximately 25% for patients with stage III and 20% for those with stage IV disease. Princess Margaret Hospital reported stage III and IV tumors to have cause-specific survival rates of 26% and 16%, respectively.[40] Weghaupt et al.[8] reported a 5-year survival rate of 50% among 20 patients with tumor involvement of the posterior urethra who received irradiation alone or preoperative irradiation and surgery. Garden et al.[3] treated 86 patients

with irradiation only after excision or biopsy of the primary lesion. Radiation doses ranged from 40 to 106 Gy (median, 65 Gy). The 5-year disease-specific survival rate was 49%, and the 5-year local control rate was 64%. Preoperative irradiation combined with radical surgery is an approach used by Klein et al.[21] They treated five women in this manner and achieved a 5-year survival rate of 40%. Dalbagni et al.[52] used anterior pelvic exenteration with intraoperative tumor bed interstitial brachytherapy using ^{192}Ir, followed several weeks later by pelvic external beam radiation therapy. A variety of chemosensitizing agents were used. The median brachytherapy dose was 15 Gy, and pelvic radiation therapy given was 45 Gy. Local control was achieved in four of six women with T2 and T4 disease.

Chemotherapy and Multimodality

Dayyani et al.[64] reported the response rate of 72% in 36 patients with locally advanced urethral cancer who had received definitive or preoperative platinum-based chemotherapy. The median overall survival was 25.6 months. Gheiler et al.[49] reported a disease-free survival rate of 60% in selected patients with advanced T3 or higher disease treated with a multimodality regimen consisting of neoadjuvant chemotherapy and radiation therapy. A phase 2 study has shown the combination of ifosfamide, paclitaxel, and cisplatin used in 45 patients with advanced transitional carcinoma of the urothelial tract is well tolerated and

results in a median survival of 20 months.[75] Similar encouraging results have been reported in patients with advanced urethral cancer receiving concomitant fluorouracil, mitomycin C, and radiation therapy.[60,61,76]

SEQUELAE OF THERAPY

Complications as a result of surgery, irradiation, or combined-modality therapy vary greatly, from 0% to 42%, because of different tumor stages, the extent of surgery, and various irradiation doses.[10,19,24,67,77] In general, more aggressive treatment is expected to result in a higher complication rate. Garden et al.[3] reported that 27 of 55 patients (49%) achieving local control had complications, including urethral stenosis, fistula, necrosis, cystitis, and hemorrhage. Urethral strictures develop in some patients, necessitating dilation or urinary diversion. Others may experience incontinence, cystitis, and vaginal stenosis. Severe complications include fistula formation, bowel obstruction, and, occasionally, operative death. In the case of advanced neoplasms, fistula formation may be unavoidable because of tumor erosion of adjacent organs and subsequent tumor necrosis. Unlike the male counterpart, the physical loss of the female urethra is not uniformly associated with sexual impotence; nevertheless, the associated treatment side effects and negative self-image may affect sexual function and quality of life.

FUTURE DIRECTION

Early detection and intervention provide the best chance of organ preservation and cure. Although most clinical information comes from retrospective case series accumulated over a long span of time using various treatment modalities, multimodality shows encouraging results and should always be considered, especially in patients with locally advanced or metastatic disease. Clinical trials are clearly needed to obtain prospective data. Improved knowledge of tumor and normal tissue radiobiology along with continued technologic advances in external-beam radiation therapy and brachytherapy delivery will maximize organ preservation and minimize some of the treatment-related complications.

CHAPTER 78

Carcinoma of the Vulva

Junzo P. Chino, Brittany A. Davidson, and Gustavo S. Montana

ANATOMY

Vulva

The vulva is composed of the mons pubis, clitoris, labia majora and minora, vaginal vestibule, and their supporting subcutaneous tissues. The vulva blends with the urinary meatus anteriorly and with the perineum and anus posteriorly. The mons pubis consists of prominent tissue located anteriorly to the pubic symphysis. The labia majora are two elongated skin folds that course posteriorly from the mons pubis and blend into the perineal body. The skin of the labia majora is pigmented and contains hair follicles and sebaceous glands. The labia minora are a smaller pair of skin folds located between the labia majora. Anteriorly, the labia minora separates into two components that course above and below the clitoris, fusing with those of the opposite side to form the prepuce and frenulum, respectively. The skin of the labia minora contains numerous sebaceous glands but no hair follicles and has no underlying adipose tissue. The clitoris is 2 to 3 cm anterior to the urethral meatus and is supported externally by the fusion of the labia minora.

The vaginal introitus is demarcated laterally by the labia minora and posteriorly by the perineal body. Anteriorly, numerous small vestibular glands are located beneath the mucosa and open onto its surface adjacent to the urethral meatus. The Bartholin glands (or greater vestibular glands) are two small mucus-secreting glands situated within the subcutaneous tissue in the posterior aspect of the labia majora. The ducts of the Bartholin glands open onto the posterolateral portion of the introitus. The Skene glands (or paraurethral glands) open in the anterior aspect of the introitus but can be variable in location. The perineal body is a 3- to 4-cm band of skin that separates the vaginal introitus from the anus and forms the posterior margin of the vulva with the fusion of the labia minora, the fourchette.

Lymphatic Drainage

The inguinofemoral nodes are located within the triangle formed by the inguinal ligament superiorly, the border of the sartorius muscle laterally, and the border of the adductor longus muscle medially. There are superficial inguinal lymph nodes that lie along the saphenous vein and its branches between Camper fascia and the cribriform fascia overlying the femoral vessels. There are usually three to five deep nodes, the most superior of which, Cloquet node, is located under the inguinal ligament. Lymph drains from these nodes into the external and common iliac pelvic lymph nodes.

Lymphatic drainage is specific to the location of a vulvar lesion. Labial lesions drain into the superficial inguinal and femoral lymph nodes, and then penetrate the cribriform fascia and reach the deep femoral nodes. Lesions of the fourchette and perineum follow the lymphatics of the labia. Lymphatic drainage from the glans clitoris or perineal body enters either unilateral or bilateral superficial femoral nodes or the deep femoral and pelvic lymph nodes. Some lymphatics originating in the clitoris enter the pelvis directly, bypassing the femoral nodes to connect with the obturator and external iliac lymph nodes, though, in practice, the pelvic lymph nodes are rarely involved without synchronous involvement of the inguinal nodes (Fig. 78.1).

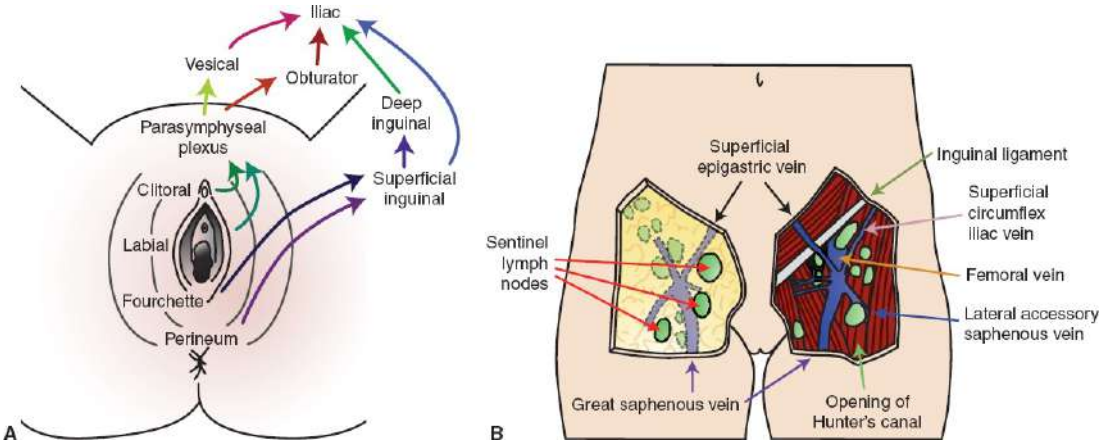

FIGURE 78.1. A: The lymphatic drainage of the vulva initially flows to the superficial inguinal nodes and then to the deep femoral and iliac group. Drainage from midline structures may flow directly beneath the symphysis to the pelvic nodes. (Modified from Plentl AA, Friedman EA, eds. *Lymphatic system of the female genitalia*. Philadelphia: WB Saunders, 1971. Copyright © 1971 Elsevier. With permission.) **B:** The superficial inguinal lymph nodes comprise 8 to 10 subcutaneous nodes located between the Camper fascia and the cribriform fascia. These nodes are immediately adjacent to the saphenous vein and its branches. (Modified from DiSaia PJ, Creasman WT, Rich WM. An alternative approach to early cancer of the vulva. *Am J Obstet Gynecol* 1979;133[7]:825–832. Copyright © 1979 Elsevier. With permission.)

EPIDEMIOLOGY

Vulvar cancer is a rare malignancy that represents <1% of all the cancers diagnosed in women and <5% of all gynecologic neoplasms. In the United States, it is estimated that there were 6,020 new cases in 2017, with 1,150 deaths due to the disease.[1] The incidence is 2.5 cases per 100,000 women; however, this incidence increases to 15.5 per 100,000 in women of age >75 years.[2] The incidence is slightly lower in black women (2.1 per 100,000) compared with whites (2.8 per 100,000).

There are two primary mechanisms believed to be involved in the carcinogenesis of this disease: human papillomavirus (HPV) and vulvar dystrophy, including lichen sclerosus (LS) and squamous hyperplasia. HPV DNA can be identified in between 30% and 40% of invasive vulvar cancers, with 16, 18, and 33 being the predominant subtypes.[3] This is in contrast to vulvar intraepithelial neoplasia (VIN), from which HPV can be isolated in 70% to 90% of lesions. Because HPV infection is related to numerous other cancers of the anogenital region (e.g., cervical cancer and anal canal cancer), the risk factors are similar: previous diagnosis of genital warts, multiple sexual partners, smoking history, previous abnormal Papanicolaou test, and immune suppression.[4] LS is often associated with the remaining HPV-negative cancers, although there is no histopathologic evidence of direct transformation.[5] Women with existing LS have a 5% to 7% risk of developing invasive disease, with risk increasing with older age and concurrent VIN (up to 19% risk of invasive cancer at 10 years).[6,7] The evidence for VIN as an obligate precursor to invasive vulvar disease, however, is less compelling than that established between cervical intraepithelial neoplasia and cervical cancer. Only one-third of vulvar cancers have an associated VIN-3 lesion, and only 5% to 7% of women with an existing VIN lesion will subsequently be diagnosed with invasive disease.[8]

VIN may in fact be divisible into two general types, depending on the lesion dependence (or independence) from HPV.[9] Usual-type VIN (uVIN) is often HPV driven and occurs in younger women with HPV risk factors. Differentiated-type VIN (dVIN) arises in the setting of LS and other chronic inflammatory processes and is associated with older age. These differing precursor lesions may then transform into two distinct classifications of squamous carcinoma: keratinizing squamous carcinomas (KSCs) arising from dVIN and basaloid squamous carcinomas (BSCs) arising from uVIN.[10] KSC is more common (80% of cases), and p53 mutations may play a role in pathogenesis in a subset of these neoplasms, whereas p16 is rarely positive indicating a lack of association with

HPV.[11,12] BSC, in contrast, is less common (20% of cases), and staining for p53 is often negative, whereas p16 is often positive because of its association with HPV. Similar to findings related to HPV-related cancers in other sites, HPV-driven lesions (uVIN and BSC) portend a better prognosis.[13] Overexpression of p16 may also be associated with an improved prognosis, even when high-risk HPV DNA is not detected.[14]

FIGURE 78.2. Squamous cell carcinoma of the vulva. **A:** Squamous cell carcinoma with ulceration, arising from the right labia minora. This elderly woman had no apparent predisposing disease. **B:** Photomicrograph of invasive keratinizing squamous cell carcinoma of the vulva. Note the keratin pearls. PATHOLOGY

Squamous Carcinoma

Eighty to ninety percent of invasive disease of the vulva is squamous cell carcinoma (Fig. 78.2),[15] arising within squamous epithelium, within or adjacent to areas of epithelial abnormalities or of premalignant conditions such as LS, erythroplasia of Queyrat, and Bowen disease.[16] The depth of invasion, critical for appropriate staging and management, is defined as the distance from the epithelial stromal junction of the most superficial adjacent dermal papillae to the deepest point of invasion. Tumor thickness is measured from the overlying surface epithelium, or the bottom of the granular layer if the surface is keratinized, to the deepest point of invasion as specified by the International Society of Gynecological Pathologists.[17]

There are three recognizable types of growth pattern of squamous carcinoma: confluent, compact, and spray or finger-like growth. Confluent growth is defined as a tumor mass composed of interconnected tumor >1 mm in dimension. This type of growth is characteristic for being deeply invasive with associated stromal

desmoplasia. Compact growth is associated with well-differentiated tumors, which maintain continuity with the overlying epithelium, infiltrating as a well-defined and circumscribed tumor mass, which rarely invades the vascular space. Histologically, the tumor cells resemble squamous cells of adjacent and overlaying epithelium. The spray or finger-like growth pattern is characterized by a trabecular appearance with small islands of poorly differentiated tumor cells found within the dermis or submucosa, deeper than the main tumor mass. This growth pattern is often associated with desmoplastic stromal response and a lymphocytic inflammatory infiltrate. Vascular space involvement is seen more commonly with this growth pattern than with tumors with a compact pattern.[18]

UNCOMMON HISTOLOGIC TYPES AND MANAGEMENT

Melanoma

Malignant melanoma of the vulva accounts for approximately 10% of all primary tumors of the vulva, with a peak incidence in the sixth and seventh decades (Fig. 78.3).[19,20] Sometimes, the tumor arises in a preexisting pigmented lesion, and in these cases, the differential diagnosis includes benign vulvar melanosis and pigmented VIN. Vulvar melanomas can be subclassified into three specific categories: superficial spreading malignant melanoma, nodular melanoma, and acral lentiginous melanoma. As is the case for melanomas arising in other mucosal sites, the level of invasion, tumor thickness, and nodal evaluations dictate the therapy and determine the prognosis.[21] Compared to nongynecologic melanomas, BRAF and KIT mutations are more frequently detected in vulvar and vaginal melanomas, and PD-L1 and PD-1 may be more frequently expressed, having implications for targeted therapies and immunmodulation.[22]

The prognosis is poor, with a 5-year overall survival of approximately 35%, and is worse in patients who have one or more of the following features: deep invasion, ulceration, nodular growth pattern, epithelioid cell type, and high mitotic rate.[23–25] The prognosis is also worse in older patients. Primary surgical excision with nodal evaluation is preferred if possible, with adjuvant radiotherapy for nodal disease or close margins at the primary site. In a study of 32 patients treated at the Royal Marsden Hospital in London, there was no difference in the outcome between patients treated with wide local excision and those treated with more radical surgical procedures.[26] Radiation may be considered for patients with positive margins or positive lymph nodes or for

palliation of symptoms. As with melanomas of other sites, the prognosis is guarded because of a propensity for distant metastasis.

Adenocarcinoma

Adenocarcinomas of the vulva arise predominantly in the Bartholin glands, although apocrine, eccrine, and Skene glands can also be the site of origin. In the rare instances when adenocarcinomas arise in the absence of glandular tissue, they may be of cloacogenic origin. Carcinoma of the Bartholin gland is seen more frequently in older women and is often solid and deeply infiltrative. The overlying epidermis or mucosa may remain intact, leading to misinterpretation as a benign process. Other histopathologic types are mucinous, papillary, mucoepidermoid, adenosquamous, and transitional. The transition from normal to malignant glandular tissue can be recognized in some cases. Adenocarcinomas often present with more locally advanced disease and metastases to the inguinofemoral lymph nodes.

The general approach to treatment, however, follows squamous cell carcinomas, with initial surgery with tailored adjuvant radiation therapy for resectable disease, and multimodality therapies for advanced stages. Survival after treatment is comparable to stage-matched squamous cell cancers.[27] The role of radiation for Bartholin gland carcinoma has been studied by Copeland et al. and Leuchter et al.[28,29] These two studies suggest that adjuvant radiation to the vulva and regional nodes after conservative surgery may decrease local recurrence, with 7% recurrence with radiation and 27% recurrence without it in the Copeland et al. study. Five-year survival of 67% was reported by Cardosi et al. in patients who were found to have close margins and were treated with primary surgery and adjuvant radiation.[30]

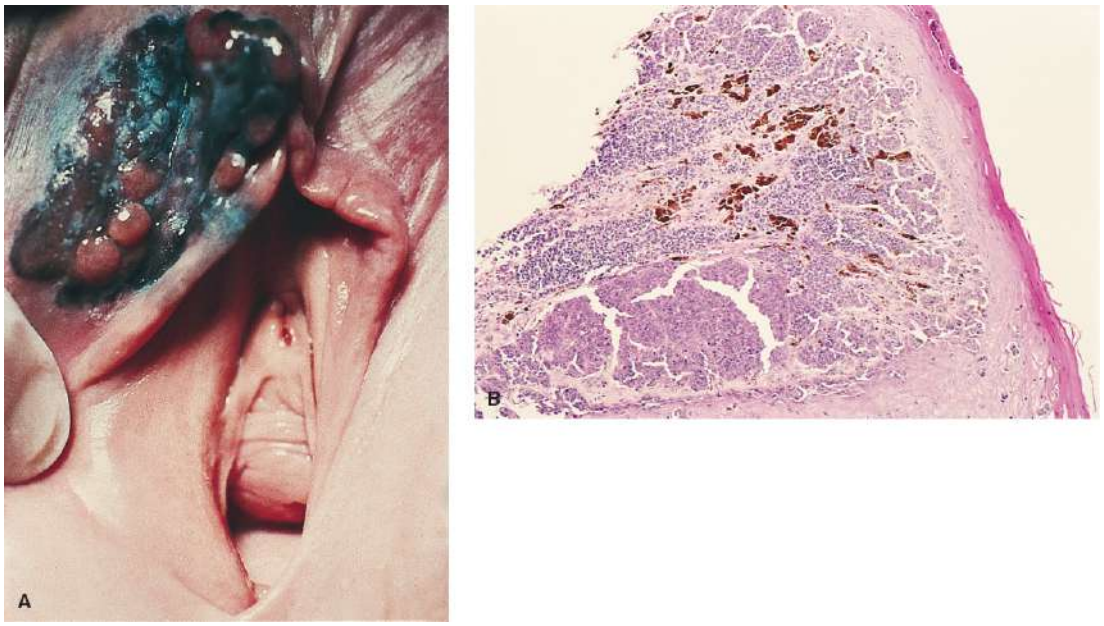

FIGURE 78.3. Melanoma of the vulva. **A:** A nodular, elevated, and darkly pigmented lesion arising from the right labia majora. **B:** Photomicrograph of invasive melanoma, with melanin apparent in portions of the tumor. (Courtesy of Dr. Stanley Robboy, Duke University Medical Center, Durham, NC.)

Paget Disease of the Vulva

Paget disease of the vulva (intraepithelial adenocarcinoma) is seen most often in postmenopausal, older white women. The disease varies in appearance, but most often, it presents as an eczematoid, red can, or weeping lesion, and it can be mistakenly diagnosed as eczema or contact dermatitis (Fig. 78.4). The lesion may be flat, raised, or ulcerated and may appear whitish (leukoplakia), red (erythroplastic), or hyperpigmented. This condition has a typical histologic pattern and often stains positive for carcinoembryonic antigen. Vulvar Paget disease is associated with invasive carcinoma in 10% to 20% of the cases.[31,32] The invasive disease may be an underlying adenocarcinoma of the apocrine or Bartholin glands, or it may be an adenocarcinoma arising elsewhere in the anogenital region. Management is generally focused on maximal safe resection, though radiotherapy is an effective therapy for recurrent or unresectable disease.[33] Topical imiquimod also shows promise as an effective nonoperative therapy.[34]

Verrucous Carcinoma

Verrucous carcinomas of the vulva are uncommon, usually diagnosed in the fifth or sixth decade of life. They are locally invasive tumors that present as fungating, ulcerative masses. Histologically, these tumors are often well differentiated and have a low incidence of metastasis to lymph nodes. In instances when the lesion is in early stage, excellent results are obtained with radical wide excision.[35] Inguinofemoral dissections are not recommended routinely because of the rarity of nodal metastases.

The literature regarding vulvar verrucous carcinomas consists largely of case reports, with the exception of the series by Japaze et al.[36] This study was based on 24 patients, 17 of whom were treated with surgery only and 7 of whom were treated with surgery and radiation. In the surgery group, only 1 patient developed recurrence and died as a result of it. In the radiation group, 4 patients developed recurrence, and all died from the disease. Although it is difficult to draw conclusions from this small series, there are no convincing data to recommend the routine use of radiotherapy for this disease. In addition, there is no sufficient evidence to support the notion that radiation induces anaplastic transformation.[37]

Other Histologies

Other vulvar malignancies arising from epidermal cell types are rare. Merkel cell tumors (neuroendocrine carcinomas) are aggressive locally, have a high incidence of distant metastasis, and carry a poor prognosis. Basal cell

carcinomas, on the other hand, seldom spread to lymph nodes and are appropriately treated with wide excision alone.[38] Transitional cell carcinomas may arise from the Bartholin glands or may also represent metastasis from the bladder and/or lower urinary tract.

Leiomyosarcomas are the most common subtypes of vulvar sarcoma followed by malignant fibrous histiocytomas, epithelioid sarcomas, and rhabdomyosarcomas. Rhabdomyosarcomas of the vulva require combination therapy, chemotherapy, and radiation, as per rhabdomyosarcoma protocols of other sites. Results of treatment with other sarcomas of the vulva are unpredictable, and wide resection and/or radical radiotherapy should be considered, given the relative inactivity of chemotherapy.

CLINICAL PRESENTATION

Vulvar pruritus is the most common presenting symptom, often associated with bleeding, pain, or discharge. If there is a visible lesion on physical examination, a biopsy is required to distinguish it from other vulvar lesions such as dystrophia, benign condylomata, and VIN. Unfortunately, many women have a long delay in diagnosis due to denial or minimization of symptoms and may present with a locally advanced tumor by the time of initial evaluation. These lesions may also present with symptoms related to the invasion of regional structures, including difficulty with urination or defecation. Metastatic disease is an uncommon presenting symptom because the primary lesion is usually much more problematic, although consequences of groin and distant disease may also be seen at presentation.

PATTERNS OF DISEASE AND SPREAD

Primary Site

Approximately 70% of vulvar malignancies arise in the labia majora and minora, 15% in the clitoris, 5% in the perineum and fourchette, 5% in the prepuce Bartholin glands and urethra, and 5% are too extensive at presentation to classify.[39]

Lymphatic Spread

High-grade tumors with “spray” growth pattern and lymphatic space invasion have a proclivity to spread to the regional lymphatic nodes. The superficial

inguinofemoral lymph nodes are the first echelon, followed by the deep inguinofemoral nodes. For well-lateralized lesions, metastasis to the contralateral inguinal or pelvic lymph nodes is unusual in the absence of ipsilateral inguinofemoral node involvement. Lesions of the clitoris or urethra can spread directly to pelvic lymph nodes, although this is rare without inguinal node involvement.[40,41]

The frequency of inguinal lymph node metastasis in surgically staged patients ranges from 6% to 50%, depending on tumor invasion and extent of disease (Table 78.1).[42–46] Physical examination alone is inaccurate to assess lymph node involvement: Plentl and Friedman reported a 62% incidence of lymph node metastases in patients with clinically palpable adenopathy and 35% involvement in patients without clinically palpable adenopathy.[39] In the Gynecologic Oncology Group (GOG) protocol 36, Homesley reported that 24% of the patients with clinically negative inguinal nodes were found to have nodal metastasis on final pathology. When the lymph nodes were clinically suspicious, 76% of the patients had histologically positive nodes.

Multiple clinical and histologic features of the primary tumor are associated with nodal metastasis, including tumor thickness, histologic grade, capillary-like space involvement, depth of invasion, location of the tumor, and tumor size.[47,48] Rutledge et al.[48] also described the adverse effect on local control and survival of tumor size, clinical stage, positive inguinal or pelvic nodes, and positive margins at the primary site. When the tumor thickness is ≤1 mm, the probability of nodal metastasis is ≤3%, but with a tumor thickness ≥5 mm, the probability increases to 33.3%. Depth of invasion of 1, 2, and 3 mm corresponds to a 4.3%, 7.8%, and 17% incidence of nodal involvement, respectively. It should be noted that thickness of the epithelium in the vulva varies significantly from one area to another, in some areas being >0.8 mm thick, which can influence the relative value given to tumor thickness and depth of invasion. Measuring tumor thickness in superficially ulcerated tumors can be misleading and may lead to underestimating the depth of invasion. Perineural invasion correlates strongly with lymph node metastasis.[49]

TABLE 78.1 INCIDENCE OF LYMPH NODE INVOLVEMENT CORRELATED WITH PRIMARY TUMOR SIZE AND EXTENT

Primary Tumor Size and Depth of Invasion	Number of Patients	Number of Patients with Positive Lymph Nodes (%)

Depth		
<1 mm	120	0 (0)
1.1–2 mm	121	8 (6.6)
2.1–3 mm	97	8 (8.2)
3.1–4 mm	50	11 (22)
4.1–5 mm	40	10 (25)
Size		
>5 mm	32	12 (37.5)
>2 cm	168	77 (45.8)
Any size of primary tumor extending beyond the vulva	70	38 (54.2)

Adapted from Perez CA, Grigsby PW, Chao C. Vulva. In: Perez CA, Brady LW, eds. *Principles and practice of radiation oncology*. 3rd ed. Philadelphia: Lippincott-Raven, 1997.

In analysis of the GOG database on carcinoma of the vulva, several clinical and histologic tumor characteristics were identified as predictors of nodal involvement. In order of importance, these are clinical node status (palpable vs. nonpalpable), grade, capillary lymphatic space involvement, tumor thickness, and patient's age.[47,50,51] There is also a correlation between the size of the primary tumor and involvement of the lymph nodes. In Donaldson et al.'s series of 66 patients, the probability of having positive inguinal nodes rose from 18.9% for patients with lesions <3 cm to 72.4% for patients with primary tumors ≥3 cm.[43] In a GOG study of 267 patients with superficial vulvar cancer reported by Sedlis et al.[47], the frequency of positive inguinal nodes was 18.1% for patients with lesions up to 3 cm in size and 29.3% for patients with lesions ≥3 cm. Extension of the primary tumor to the urethra, vagina, and anal area is associated with an increased incidence of nodal involvement and worse prognosis.

Inguinal nodal involvement is a strong predictor for pelvic nodal disease. In the GOG study reported by Homesley et al. of patients with positive inguinal nodes, the incidence of pelvic node involvement was 28%.[52] Because of the rarity of isolated pelvic nodal metastasis, the status of the inguinal nodes determines the management of the pelvic nodes. Although deep pelvic node involvement is an ominous sign, and is currently staged as metastatic disease, one-fourth to one-third of the patients are still potentially curable, and aggressive local therapy is indicated. In a series from MD Anderson, 5-year overall survival for women with involved pelvic nodes was 43% when treated with aggressive local therapy.[53]

Distant Metastases

Hematogenous dissemination generally occurs late in the natural history of the disease, with the most common sites being the lungs, liver, and bones. The overall survival is limited in these cases to a median of approximately 6 months.[54]

PROGNOSTIC FACTORS

Lymph node metastasis is the most important prognostic factor in patients with vulvar cancer. The presence of inguinal node metastases is accompanied by a 50% reduction in long-term survival.[55] Lymph node extracapsular tumor extension has been noted in several series, and it is known to have a negative effect on prognosis. Origoni et al.[56] evaluated the significance of the size of the metastases in the lymph nodes, the number of positive lymph nodes, and the extracapsular extension (ECE) of the disease and found that the presence of any one of these factors worsened the prognosis. Extracapsular tumor extension as an independent adverse prognostic factor on survival was also described by van der Velden et al.[57]

Pelvic nodal metastasis has an even more profound negative effect on survival.[58] Although deep pelvic node involvement is an ominous sign, and is currently staged as metastatic disease, one-fourth to one-third of the patients are still potentially curable, and aggressive local therapy is indicated. In a series from MD Anderson, 5-year overall survival for women with involved pelvic nodes was 43% when treated with aggressive local therapy.[53]

In an analysis of formalin-fixed tissue specimens, Heaps et al.[59] demonstrated a sharp rise in the incidence of local recurrence for tumors with microscopic, surgical margins <8 mm. This corresponds to a margin of 1 cm in fresh, unfixed tissue. Although the frequency of local recurrences correlates with the adequacy of the margins of the surgical resection, when dealing with larger or thicker tumors or when they involve midline structures, adequate surgical margins may be difficult to obtain.

Kurzl and Masserer[60] analyzed 124 patients with various stages of vulvar carcinoma treated with simple vulvectomy alone and local/inguinal irradiation. They found that age, disassociated growth, lymphatic spread, thickness, and ulceration of the primary tumor were important prognostic factors. In a detailed analysis of a GOG clinicopathologic study of 558 women with vulvar cancer, two significant risk factors were identified that predispose for recurrence in the

vulva: tumor size >4 cm and capillary lymphatic space involvement.[50] If either of these factors was present, the risk of local recurrence after radical vulvectomy was 21%, but if neither factor was present, the risk of local recurrence was only 9%. In this study, the depth of invasion did not predict for vulvar failure.

HPV-positive or p16-positive cancers may have a better prognosis, as described above in the epidemiology section.

INITIAL EVALUATION

A thorough examination of the genitourinary system is warranted in all women with vulvar cancer because the disease may be multifocal. Examination of the vagina, cervix, perianal skin, and anal canal is of particular importance in order to delineate the extent of disease and to identify synchronous lesions. Special attention as well is paid to the inguinofemoral basins for clinical detection of lymphatic spread.

Imaging studies may not be necessary in early lesions that may be approached with surgery as the first treatment modality. However, imaging in women with locally advanced disease or with clinically suspicious lymph nodes helps the clinician select the most appropriate treatment. Computed tomography (CT) scans can identify suspicious lymphadenopathy in the inguinofemoral chains, pelvis, or para-aortic regions.[61] Contrast-enhanced magnetic resonance imaging (MRI) is also helpful to delineate the primary lesion and contributes to the evaluation of inguinal lymph nodes, with a sensitivity of 80% and a specificity of 88%.[62] Clinically or radiographically detected inguinal nodes may be evaluated with ultrasound-guided fine needle aspiration, though a negative result does not rule out involvement.[63] Fluorodeoxyglucose (FDG) positron emission tomography (PET) has been used to evaluate the groin prior to surgical evaluation, with a sensitivity of 67% and a specificity of 95%.[64] FDG-PET at diagnosis may change the prior clinical impression in up to 50% of cases.[65] It should be noted that the sensitivities of all imaging modalities available are insufficient to omit surgical evaluation in women with a high risk of nodal involvement.

STAGING

The staging system first adopted in 1983 was based entirely on clinical findings. The system was modified in 1988 to give the clinical status of the nodes more

importance. In 1997, the staging was revised again to create a separate category for minimally invasive lesions, stage IA, emphasizing the need for histologic assessment of the inguinal nodes in all patients presenting with primary tumors with >1 mm depth of invasion.

The most recent Federation of Gynecology and Obstetrics (FIGO) staging revision was performed in 2009 and contains significant changes from the 1988 framework (Table 78.2).[17,66] Stage IB now includes primary lesions >2 cm in size (previously stage II), and stage II includes lesions with involvement of adjacent perineal structures (previously stage III). Stage III is now divided into three substages, reflecting the importance of the number and size of inguinal nodes involved and the prognostic significance of ECE. Presence of pelvic nodal metastases remains stage IVB disease.

TABLE 78.2 VULVAR CANCER: 2009 AMERICAN JOINT COMMITTEE ON CANCER (AJCC) STAGING AND CORRESPONDING INTERNATIONAL FIGO STAGING

2009 AJCC			FIGO
Tis	Carcinoma *in situ*		—
T1a	Confined to the vulva/perineum, size ≤2 cm, stromal invasion ≤1 mm	N0	IA
T1b	Confined to the vulva/perineum, size >2 cm or stromal invasion >1 mm	N0	IB
T2	Adjacent spread to distal one-third urethra and/or vagina or anus	N0	II
T3	Extension to proximal two-thirds urethra and/or vagina, bladder/rectal mucosa, or fixation to pubic bones		IVA
N1a	1–2 lymph nodes involved, all <5 mm		IIIA
N1b	1 lymph node involved, ≥5 mm		IIIA
N2a	3 or more lymph nodes involved, all <5 mm		IIIB
N2b	2 or more lymph nodes involved, ≥5 mm		IIIB
N2c	Any lymph nodes involved with ECE		IIIC
N3	Fixed or ulcerated lymph nodes		IVA
M1	Distant metastasis (including pelvic lymph node metastasis).		IVB

According to the AJCC, femoral and inguinal nodes are considered regional spread, whereas iliac nodes are considered distant metastasis.

MANAGEMENT OVERVIEW

Many factors make the treatment of carcinoma of the vulva challenging. Many women with this disease are older and have comorbidities. The tumor, by virtue of its location, can easily involve adjacent organs such as the bladder and the rectum, and the frequency of nodal involvement is high. Because of its relatively low incidence, most published reports consist of small and heterogeneous groups of patients. Management of carcinoma of the vulva is further complicated by the major psychosexual impact that the disease itself and its treatment can have on patients. For the aforementioned reasons, it has been difficult to study this disease and to develop general treatment guidelines.

The management of vulvar carcinoma has undergone very significant changes in the last few decades. En bloc resection of the primary tumor and a full inguinal node dissection used to be the standard of care, but this is no longer the case. Extensive surgery has been replaced by multimodality therapy, with the surgery being more tailored to the extent of the disease. This change is in large measure due to the recognition of the morbidity associated with radical surgery, the improved results achieved with multimodality therapy, and the recognition of the negative impact that radical surgery can have on sexual function and body image.[67–69] Although radical surgery retains a very important place in the management of vulvar cancer, it is no longer the initial and mainstay of treatment. The likelihood of controlling the primary tumor with surgery largely depends on the adequacy of the margins of resection, and it is not necessary to remove the entire vulva. A clear margin of ≥8 mm in all directions is sufficient to achieve a high rate of local control of the primary tumor.[59]

There have been refinements in the surgical technique that have made the procedures more tolerable. Examples of such improvements include primary closure of the perineal wound, the use of myocutaneous flaps to close the surgical defect in the inguinal area, and the use of separate incisions for the resection of the primary tumor and the inguinal nodes. These developments have resulted in a decrease in operative mortality and morbidity.

In recent decades, there have been also significant advances in all aspects of radiation therapy that apply to the treatment of carcinoma of the vulva. The technical resources available now make it possible to deliver effective doses of radiation to the vulvovaginal and inguinal regions with less acute and late morbidity. With high-photon energy units, well-collimated fields, multileaf collimators, electron beams of different energies, and intensity-modulated radiation therapy (IMRT), radiation is now delivered to the primary disease and lymph nodes with precise account of the differences in contour, tissue thickness,

and extent of the disease. It is possible to tailor the treatment to the specified treatment volume while keeping the dose to the normal tissues within acceptable limits of tolerance. Brachytherapy may also be used as primary treatment in very selected cases or in combination with external beam to bring the dose higher to limited volumes.

Perhaps the most significant advance of recent decades in the management of cancer patients is the use of more than one treatment modality concurrently or sequentially. Chemotherapy, radiation, and surgery in sequence and/or in combination lessen the impact of any one modality and can lead to functional organ preservation with comparable or improved local tumor control and survival (Fig. 78.5).

SURGERY

Wide Local Excision, Radical Vulvectomy, and Exenteration

In the past, even patients with early-stage IB disease were considered to have diffuse disease, and a radical vulvectomy was considered the standard of care, yielding 90% survival rates but with considerable physical and emotional sequelae. Although there is a lack of prospective data comparing radical local excisions versus more extensive radical vulvectomies, several retrospective studies reveal no difference in recurrence or survival outcomes.[70] For T1 and smaller T2 lesions (<4 cm) with ≤ 1 -mm invasion, a wide local excision is recommended without inguinofemoral node evaluation given the risk of nodal involvement in these cases is <1%.[71] For tumors with >1-mm invasion, a more radical excision with an inguinofemoral groin node evaluation is recommended. If these tumors are well lateralized (>2 cm from the midline), only an ipsilateral groin evaluation is necessary; however, for midline lesions, bilateral groin node evaluation is recommended.[72]

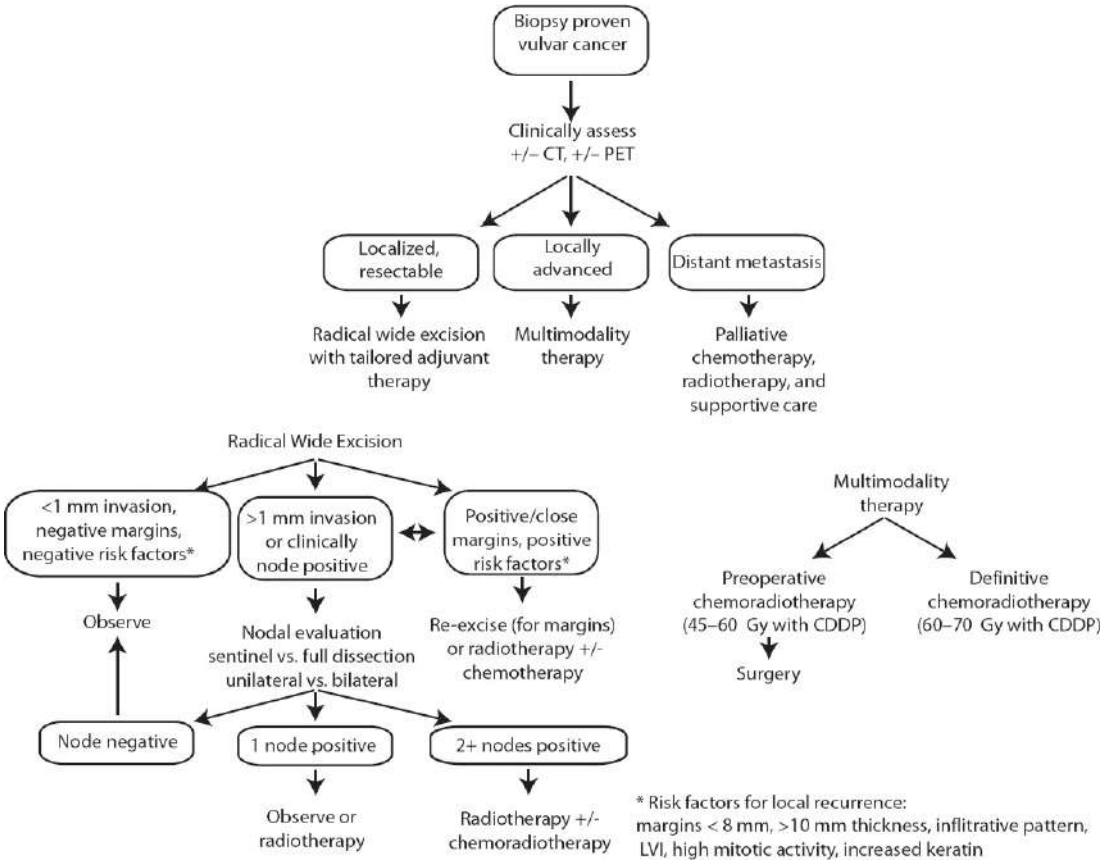

FIGURE 78.5. Treatment algorithm.

At surgical resection, the depth of the excision should be to the deep perineal fascia or periosteum of the pubis for more anterior lesions. Excision of 2-cm margins of grossly normal-appearing tissue is recommended when possible, with a goal of obtaining at least 1-cm microscopic margins in fresh tissue, and ≥8 mm following tissue processing. If the tumor involves or abuts the clitoris, preservation of this structure may not be possible.

Radical vulvectomy is reserved for patients with large or multifocal lesions in whom preservation of normal vulvar tissue is not possible or would not serve a functional or reconstructive benefit. When the anus, vagina, or urethra is involved by malignancy, extended radical vulvectomy or pelvic exenteration is required to clear the disease surgically.[73,74] Surgery alone for patients with advanced disease yielded disappointing results, stimulating interest in multimodality treatment in the mid to late 1980s.[75,76]

Surgical Evaluation of Inguinofemoral Lymph Nodes

Attention to risk factors for nodal involvement is critical as inguinal recurrences are very difficult to treat and a full inguinofemoral node dissection can be quite

morbid. The main complications of groin surgery are wound breakdown, infection, and lower extremity lymphedema. Although wound breakdown will often heal successfully by secondary intention, chronic lower extremity edema is very difficult to deal with and can lead to significant long-term disability. To reduce the frequency and the severity of these complications, an effort is made to identify patients in whom the extent of the node dissection can be decreased or eliminated altogether without compromising the likelihood of control of the disease.

As mentioned previously, patients with small (<2-cm diameter) superficial squamous cell carcinomas with a depth of invasion 1 mm or less and no lymph vascular invasion have a very low risk of nodal involvement, and the groin dissection may be omitted.[77] For lesions with >1-mm invasion, groin node assessment should be performed in the form of superficial inguinal lymphadenectomy or sentinel node procedure. Small (<4 cm), lateralized lesions (>2 cm from the midline) may be treated by unilateral groin evaluation, whereas for midline and clitoral lesions, both groins should be assessed. For patients undergoing primary surgery, palpable inguinal nodes should be removed if present.

The need to perform bilateral inguinal node dissection in patients with unilateral vulvar lesions, as well as the need to dissect the deep nodes whenever a superficial node dissection is carried out, has been re-examined in light of the additive morbidity of each procedure. When bilateral superficial and deep inguinal node dissections are performed, the potential for wound breakdown and lower extremity lymphedema increases. When a unilateral dissection is indicated and nodes are found to be negative, a contralateral node dissection is not required because of the low likelihood of contralateral metastasis.[78,79] The deep inguinal node dissection is usually omitted, based on the fact that if the superficial nodes are free of tumor, the deep nodes are rarely involved.[80] However, control of the disease in the lymph nodes is of utmost importance because many women who develop groin recurrences will die as a result of the recurrence.[81]

Women with fixed or ulcerated inguinal nodes are rarely curable with surgery alone. These patients should have a biopsy to document the nodal involvement and should be treated with combined radiation and chemotherapy, either primarily or in a preoperative fashion as discussed below.

Sentinel Lymph Node Dissection

Assessment of the groin nodes may be accomplished via full superficial inguinal dissection or alternatively via a sentinel lymph node procedure alone if performed by groups experienced with this technique. In the multicenter Groningen International Study on Sentinel Nodes in Vulvar Cancer (GROINSS-V), a sentinel node procedure using radioactive tracer and blue dye was performed in 623 groins and resulted in a 2.3% groin recurrence rate following a negative sentinel node.[82] This compares favorably to the 5% ipsilateral groin recurrence rate following negative full superficial inguinal dissection in a prospective GOG study of low-risk vulvar cancer.[81] Patients who underwent a sentinel but not a full node dissection had significantly lower groin wound breakdown (12% vs. 34%) compared to those who went on to a full inguinofemoral dissection following the sentinel procedure. Long-term follow-up of the GROINSS-V trial demonstrated 5- and 10-year recurrence rates of 24.6% and 36.4% for sentinel node–negative patients versus 33.2% and 46.4% in patients who had positive sentinel nodes with subsequent completion inguinofemoral node dissection.[83] Optimal lesions for sentinel node procedures are those with small (<4 cm), unifocal lesions with surgeons who have performed at least 10 prior sentinel procedures under supervision. If a sentinel node approach is undertaken, it is recommended that the sentinel nodes be evaluated prior to vulvar resection to avoid disruption of lymphatic channels emanating from the tumor. If no sentinel node is found, a full inguinofemoral lymphadenectomy is recommended.

The GOG 88 protocol tested whether radiation therapy alone could supplant nodal dissections after vulvectomy.[84] Women with clinically negative nodes after radical vulvectomy were randomized between 50 Gy to the bilateral inguinal regions or a lymph node dissection with selective radiation delivered to those with positive nodes. The radiation-alone arm had increased recurrences within the inguinal regions (at 2 years: 32% RT alone vs. 6% nodal dissection, $P = .033$), with an associated decrement in overall survival as well (59% RT alone vs. 90% nodal dissection, $P = .035$). Although the depth of the inguinal nodes to which the radiation dose was prescribed may account for the difference in local control and survival, surgical management of the lymph nodes remains the standard of care.[85]

Intraoperative diagnosis of inguinal node metastasis necessitates further diagnostic or therapeutic procedures. Because there is no established sentinel node metastasis size cutoff below which withholding further treatment of the groin can be considered safe, all women in whom a sentinel node is found to be

positive a full ipsilateral groin dissection and/or radiotherapy to the groin should be considered.[86] The GROINSS-VII/GOG 270 study is ongoing and evaluates groin radiotherapy versus completion inguinofemoral lymphadenectomy in this population.[87] In an interim analysis of this study, excessive recurrences were found in sentinel nodes with macrometastases (>2 mm) or ECE (20%), compared to those without either factor (2%), causing these subjects to be excluded from radiation alone. Particular care should be taken therefore with these risk factors, and completion dissection should be considered.

In the case of a non–sentinel node metastasis that is diagnosed intraoperatively, the options are to dissect the deep nodes as well as the opposite groin or to cover both groins with adjuvant radiotherapy. Standard adjuvant treatment for inguinal node metastasis consists of both inguinal and pelvic radiotherapies.[52] In the situation where an ipsilateral inguinal node is found to be positive for metastatic disease, nodal assessment of the contralateral groin versus radiation should be considered.

Pelvic Lymph Nodes

Patients with clinically or pathologically positive groin nodes are at risk for having contralateral groin and pelvic nodal involvement. Thus, the status of the groin nodes is to be taken into consideration when determining the management of the pelvic nodes. The randomized GOG trial of pelvic node dissection versus pelvic node radiation showed that control of the disease in the pelvis could be achieved with either form of therapy.[52] Radiation to the pelvic nodes is generally preferred over surgery as women in need of treatment to the pelvis often also require radiation to the primary and/or inguinal nodes.

ADJUVANT RADIATION THERAPY

In the setting of early invasive disease treated with wide local excision, radiation to the tumor bed may be advised to prevent local recurrence. As noted previously, pathologic features associated with higher risk of local recurrence at the primary site include lymphatic–vascular invasion (LVI), depth of invasion >5 mm, margins <8 mm, and microscopically positive margins.[59] Faul et al.[88] reported a retrospective study of 62 patients with close (≤8 mm) or positive surgical margins that found that local recurrence was significantly reduced from 58% with observation to 16% with postoperative radiation. Although postoperative radiation reduces the incidence of local recurrence, some may be

salvaged with surgery, resulting in equivalent survival and long-term control. However, in the absence of randomized trials, women with positive margins, margins <8 mm, deep invasion, and/or LVI should also be considered for adjuvant radiation.

The role of radiation in the management of inguinal and pelvic nodes was evaluated in the GOG 37 trial reported in 1986.[52] In this trial, women underwent bilateral inguinal lymphadenectomy, and those with positive groin nodes were randomized to either pelvic lymphadenectomy or radiation to the pelvis and bilateral groins. The radiation group had significantly lower groin recurrence rate, 5%, compared to 24% for the group that did not receive radiation. This translated into a 2-year significant survival benefit of 68% versus 54% (P = .03) in favor of the group that received postoperative radiation. Subgroup analysis of this study showed that the benefit was seen primarily in patients with more than one pathologically positive node. An update of this trial, suggested that if the ratio of involved nodes to submitted nodes was >20%, may be a better selection of this higher-risk cohort, which benefits most from radiation.[89] An analysis of the Surveillance, Epidemiology, and End Results databases in patients with one node positive revealed a significant survival difference in patients with <12 nodes submitted, supporting the hypothesis that the benefit of radiation may be greater in patients with an insufficient nodal dissection.[90] However, based on the entry criteria for the GOG 37 study, adjuvant radiation to the pelvis and both groins should be considered for all patients with nodal involvement.

All women with ECE of tumor in the nodes or with residual disease in the inguinal areas should receive postoperative radiation to the pelvis and inguinal areas, because of the increased risk recurrence at the primary and the lymph nodes.[57] When the surgical margins are clear and there is no pathologic indication to treat the vulva, a midline block can be used to avoid the reaction and the sequelae of the treatment to the vulvar area, though consideration should be paid to local risk factors. A series from Dusenbery et al. found the probability of vulvar recurrence to be 48% when midline blocks were used; however, the vulvar recurrence rates in GOG 37 and GOG 88 were only 4% to 9%.[52,84,91]

Adjuvant radiation therapy to the primary site may be delivered with either photons or en face electrons with bolus. When treating a large area of the vulva and groins, AP/PA photon fields may be used; however, increasing data suggest that use of IMRT may be equally effective with much less morbidity. Further details in regard to treatment planning may be found later in the chapter. The elective volume (grossly uninvolved nodal basins) can be treated to 45 to

50.4 Gy. When microscopic disease in the primary tumor area is suspected, a dose of 55 Gy is recommended. When there is ECE of tumor in the lymph nodes, the dose to the groins can be carried up to 60 Gy. If there is gross residual disease postsurgery, the dose to the area should be brought to a minimum of 65 to 70 Gy, a dose used for definitive therapy.

The GOG 37 study required treatment to both groins; however, in the dissection arm of GOG 88, only the ipsilateral groin and hemipelvis were treated suggesting that with well-lateralized lesions, ipsilateral-only treatment may be effective. In a small series of 20 women undergoing ipsilateral radiation alone (44 Gy in 2 Gy fractions), no contralateral recurrences were observed.[92] In fact, the *ipsilateral* recurrence rate was quite high (45% crude rate), suggesting that 44 Gy is an insufficient dose.

The use of adjuvant chemotherapy with radiation therapy, either sequentially or concurrent, has not be tested prospectively. A National Cancer Database (NCDB) study found that adjuvant chemotherapy has been used more frequently since 1999 (11% in 1998 to 41% in 2006) and that the use of chemotherapy is associated with improved overall survival (HR 0.62, 95% CI 0.48 to 0.79).[93] Unfortunately, no details are available in regard to the nature and timing of chemotherapy; however, concurrent cisplatin at 40 mg/m^2 weekly may be a reasonable extrapolation from the cervical cancer literature for women with higher risk of recurrence (≥2 nodes positive).

PREOPERATIVE RADIATION THERAPY WITH CONCURRENT CHEMOTHERAPY

As the treatment for vulvar cancer has evolved with the goals of decreasing the sequelae of radical surgery and to maximize functional outcome, multimodality therapies have become the standard of care, particularly for patients with advanced stages of disease.[94] After initial concurrent chemoradiation and healing of the reaction, the response to the therapy at the primary site and the lymph nodes is assessed. If there is complete clinical regression of the disease at the site of the primary, one option is to perform biopsies of the primary site, foregoing resection if there is a pathologic complete response.[95] In general, it is recommended to carry out an inguinal dissection as well, as residual disease may be found in lymph nodes.[94] It also should be noted that whereas recurrences at the primary site are potentially salvageable, nodal recurrences, particularly after any prior irradiation, are often fatal.

Preoperative chemoradiation was tested in the phase II GOG 101 trial for patients with advanced primary and/or nodal disease.[94,95] Radiation treatment consisted of 170 cGy twice daily on days 1 to 4 and 170 cGy once a day on day 5 and days 8 to 12, for a dose of 2,380 cGy. Cisplatin, 50 mg/m^2, was given on day 1, and 5-FU, 1,000 mg/m^2 by a 24-h infusion, daily on days 1 to 4. The combined cycle of chemotherapy and radiation was repeated after about a 2-week break, thus delivering a total radiation dose of 4,760 cGy. In the locally advanced cohort, the pCR rate was 34% and R0 resections were possible in 77% of subjects. 55% were alive and without disease at last follow-up. In the group of women with advanced nodal disease, the nodes became resectable in 83%, with a pCR rate of 40% in those who underwent surgery, with 43% of the patients being alive and disease free at last follow-up.

The follow-up phase II GOG 205 study enrolled women with T3 or T4 tumors, treated with a total dose of 5,760 cGy (180 cGy/fraction) and weekly cisplatin (40 mg/m^2), with no planned treatment breaks.[96] Sixty-nine percent of women were able to complete the protocol per plan, 64% achieved a complete response, and 50% had a pCR on surgical biopsy. Overall survival at 2 years (estimated from curves provided in the manuscript) was 40% for those with no or partial clinical response, 62% for those with a complete clinical response, and 81% for those with a complete pathologic response. As this regimen compares favorably with the prior 101 protocol, it is currently the preferred approach for preoperative therapy.

The next GOG/NRG study (GOG 279) to examine vulvar cancer utilizes a dose of 45 to 50 Gy to the elective nodal volume and 64 Gy to the vulva and gross nodal disease, with a combination of weekly cisplatin and gemcitabine.[97] Dissection is performed upfront for patients with initially resectable nodal disease, and further surgery is reserved for any residual disease after 6 to 8 weeks post treatment.

DEFINITIVE RADIATION THERAPY

The standard of care for early lesions is surgical resection; however, selected patients with small central lesions may be considered for definitive radiation, particularly when the lesions are in close proximity to the urethra, clitoris, or anus. There are few published series of radiation alone used as definitive therapy for vulvar cancer.[98–100] The reported series include patients with recurrent disease postsurgery and patients who are not medically suitable for surgery or

have declined it. In Ellis's series of 65 patients treated with brachytherapy and or external beam, the crude 5-year survival rate was 23%, with crude local control in 40%.[98] Slevin and Pointon[100] reported on the results of 58 patients treated also with brachytherapy and/or external beam, depending on the extent of the disease. The crude 5-year survival rate was 26% with a similar local tumor control rate of 40%. These series reflect the difficulty of achieving appropriate curative doses for gross disease with radiation alone.

Selected patients with a low risk of having nodal involvement (<1-mm invasion, or negative lymph node dissection, or sentinel node biopsy) may be treated to the vulvar area alone. The treatment may be delivered using electrons, low-energy photons, or IMRT. When the treatment is given with electrons only, a generous margin around the primary tumor should be used because the dose decreases toward the periphery of the field. Bolus material should be used also to avoid underdosing the surface of the tumor.

Brachytherapy has been used for inoperable vulvar cancer and as a boost to the primary tumor and/or to the lymph nodes. The efficacy of this treatment is difficult to evaluate because of the variability of the clinical situation in which this type of treatment may be employed. Vulvar necrosis was reported in up to one-third of the patients.[98] A series from the Centre Alexis Vautrin Institute in France describes 34 patients, 21 with primary and 13 with recurrent disease, treated with brachytherapy only.[99] The median brachytherapy dose was 60 Gy, with a range of 53 to 88 Gy. In the group of 21 patients who underwent brachytherapy as primary treatment, 3 patients developed locoregional recurrence, for a 5-year local control rate of 80% and a disease-specific survival of 70%. In the group of 13 patients who were treated for recurrence, 8 developed local recurrence, with or without disease at other sites, for a local control rate of 19%. Of the entire group of 34 patients, 5 developed necrosis. This relatively low complication rate most likely reflects that extensive experience and high quality of the brachytherapy carried out in this institution. The authors of this study advocate brachytherapy for primary vulvar cancer if the patient refuses surgery or if surgery is contraindicated. Nonetheless, because of the significant risk of necrosis, the use of brachytherapy should be limited to very selected cases and performed by experienced practitioners.

DEFINITIVE CHEMORADIATION THERAPY

Definitive chemoradiation is used for patients with advanced tumors considered unresectable at presentation or for patients who are medically inoperable (Table 78.3). This may be used when the tumor does not become resectable in the midst of preoperative intent chemoradiation or as an upfront alternative to surgically based treatment. In these patients, chemotherapy should be continued throughout the entire course of radiation for the purpose of radiosensitization of the tumor in the treatment volume and possible eradication of subclinical disease outside of the radiation field. With appropriate field reductions, the radiation dose should be brought up to 60 to 70 Gy. The total dose to certain areas is dependent upon the location and extent or bulk of the disease, the response to the therapy, and the estimated tolerance of the area requiring the high radiation dose. Often, it is the tolerance of normal tissue that limits the dose to ≤65 Gy.

There is little in the way of comparative prospective trials for chemotherapy selection with concurrent treatment; however, a retrospective series from Dana-Farber/Brigham and Women's Cancer Center and Massachusetts General Hospital does shed some light.[101] In this series of 44 women, 24 of whom were treated definitively without surgery, 16 received weekly platinum-based regimens, and 28 received a 5-FU–based regimen every 3 to 4 weeks. The 2-year overall survival (74% platinum, 70% 5-FU), disease-free survival (62% platinum, 56% 5-FU), and locoregional recurrence (31% platinum, 33% 5-FU) were no different. The grade 3 or higher skin toxicity was higher with weekly platinum (62% platinum, 32% 5-FU), but the nonskin toxicity was higher with 5-FU (13% platinum, 46% 5-FU). Given these data and the results of GOG 101 of weekly platinum in preoperative treatment (discussed above), weekly platinum at 40 mg/m^2 is a reasonable option for concurrent treatment.[96]

There are no prospective data comparing chemoradiotherapy alone and combined with surgery; however, an NCDB study has examined survival after both strategies have been reported.[111] In the overall cohort, women undergoing primary radiation had overall survival at 3 years of 42% compared to 57% with radiation plus surgery. However, when limiting the definitive cohort to those who received concurrent chemotherapy and radiation to doses ≥55 Gy, the survival improved to 57%, comparable to preoperative approaches. Although there are multiple possible confounders not captured in the NCDB, these data suggest that initial chemotherapy and radiation may be used initially with surgery reserved for salvage.

TREATMENT VOLUME AND TECHNIQUE

Simulation and Target Delineation

Appropriate identification of the targets of treatment is a challenging but critical process in vulvar cancer. CT- or MR-based 3-D planning is essential to establish the location, extent, and depth of the inguinal and pelvic nodal basins, as well as the primary. Specific components of each individual's treatment volume depend on the clinical scenario and are discussed above.

At the time of simulation, markers should be placed on the primary, the lymph nodes, and scars from previous surgery to document the extent of the disease. "Frog-leg" positioning may be used to reduce skin folds in the inguinal regions, though this may be less important if IMRT is used. Advanced immobilization devices such as a cradle can be considered, though, for some, the cradle itself may become uncomfortable during treatment because of the expected skin reaction. Bubble wrap or bariatric slings may also be used to reduce skin folds, particularly in patients with a pronounced panniculus. Bolus is often critical over the vulva and groins, which may be applied at the time of simulation or applied "virtually" at the time of treatment planning—however, obtaining good contact against the skin at all points to eliminate significant air gap is challenging. Use of wet gauze, towels, or impregnated gauze may be necessary. Placement of bolus should be confirmed at the time of treatment, either through direct inspection of setup or the use of onboard imaging such as a cone beam, if available.

The primary vulvar lesion (pGTV) may be hard to identify on CT imaging alone, making the use of radiopaque markers critical. MRI and PET imaging if available may also aid in the identification of the primary lesion. When defining a primary PTV, ample margins (1.5 to 2 cm) should be placed to account for microscopic spread of disease and the potential variations in daily setup. Additional clinical tumor volume (CTV) coverage of the vagina should be added for lesions that involve the introitus. The uterus, if present, is not usually target.

The nodal targets include the inguinal basins, which should be defined based on anatomic compartment; symmetric margins around the vessels are inadequate, leading to undertreatment medially and overtreatment to deep structures.[112] This compartment is defined by:

Lateral: The medial border of the iliopsoas
Medial: The lateral border of adductor longus or medial end of pectineus
Posterior: The iliopsoas muscle laterally and anterior aspect of the pectineus

muscle medially

Anterior: The anterior edge of sartorius muscle (Fig. 78.6).

The pelvic nodes are often also targets of treatment and include the obturator and external and internal iliac chains, defined in a manner similar to uterine or cervical disease. Common iliac nodes or para-aortic basins may be added if there are nodes positive in the more distal echelons. Presacral basins are usually not target, unless there is involvement of the anal canal or rectum.

Consensus contours are now available to guide treatment and may be very helpful particularly when more conformal techniques such as IMRT are used.[113]

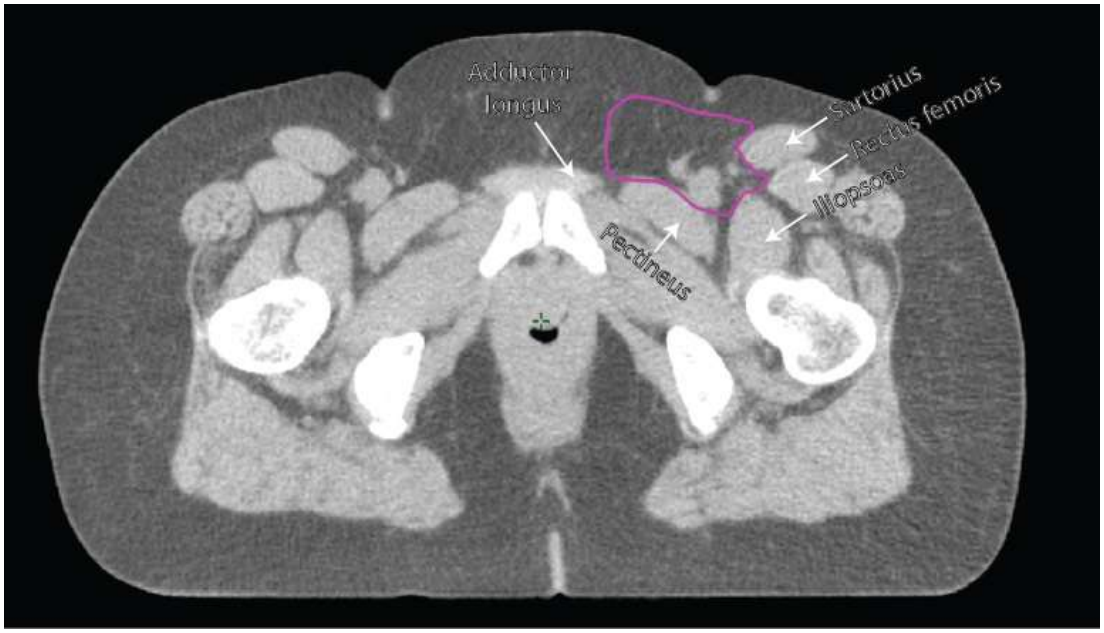

FIGURE 78.6. Example of a CTV for inguinal treatment (*purple contour*). The lateral border is the medial edge of the iliopsoas. The medial border is the lateral extent of the adductor longus or medial end of pectineus. The posterior border is bounded by the iliopsoas muscle laterally and anterior aspect of the pectineus muscle medially. The anterior border is carried over from the anterior edge of sartorius muscle. All benign nodes also should be included, and the inferior extent should extend 1 to 2 cm below the vulva and perineum.

2-D and 3-D Conformal Treatment

Medium- or high-energy photon beams with anteroposterior/posteroanterior (AP/PA) fields with the patient in the supine position are recommended for the 3-D delivery of external beam. The superior border of the pelvic field should extend to the middle of the sacroiliac joints to cover the external and internal iliac nodes. If a patient has internal or external iliac node involvement, the superior border should be extended to the L3/L4 interspace to cover the common

iliac nodes. The inferior border should cover the entire vulva and the most superficial, inferior inguinal nodes. Laterally, the pelvic field extends 2 cm laterally to the widest point of the pelvic inlet. Although there are no data regarding scar recurrences, it is common practice to include the inguinal node dissection scars in the radiation field.

Depending on whether the inguinofemoral lymph nodes and/or pelvic lymph nodes are to be included in the radiation volume, different field configurations may be used. To reduce the dose to the femoral heads while delivering an adequate dose to the inguinal nodes, various techniques are available.

One approach is to use a wide AP field that includes the pelvic and inguinal areas, with a narrow PA field covering only the pelvis and sparing the femoral heads. The photon fields are weighted equally, and the inguinal dose is supplemented by separate anterior electron fields matched to the pelvic field (Fig. 78.7). Bolus material should be used to ensure adequate dose to the superficial portions of the groin.

An alternative method consists of using a wide AP field and narrow PA field, with a partial transmission block placed in the central portion of the AP field. The desired dose at a specified depth is delivered to the inguinal nodes through the AP field.[114] The degree of central anterior beam attenuation is calculated so that the midpoint of the pelvis receives equal doses from the AP and PA beams. This technique eliminates the dosimetric problems of photon/electron field matching, as well as the potential for daily setup variation, but the design of a precise partial transmission block is difficult.

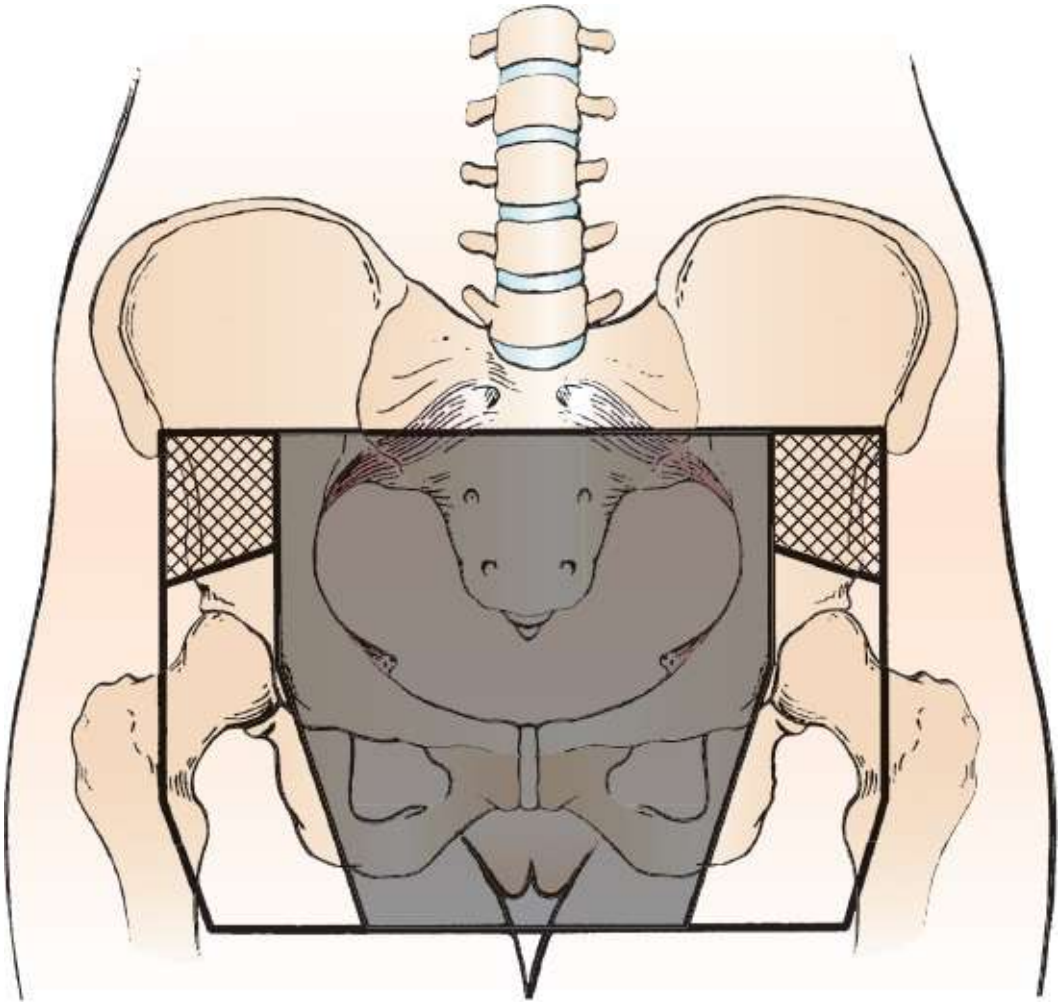

FIGURE 78.7. Treatment borders demonstrating the wide anterior field (*outer border*) and the narrow posterior field (*shaded region*).

Another method consists in using matched AP/PA fields to include the primary and the pelvic nodes and treating the groins through separate anterior electron fields. This approach has the advantage of relatively easy setup, but the main drawback is ensuring an adequate dose at the match line, particularly when the match line is over gross disease. An example of an AP radiation field encompassing the inguinal/femoral and pelvic lymph nodes is shown in Figure 78.8.

Moran et al.[115] described a modified segmental boost technique using multileaf collimators with a single-isocenter technique and a wide AP field to cover the vulva, pelvis, and groins and a narrow PA field to cover the vulva and pelvis. The supplemental anterior photon groin fields are angled such that the central axis is coplanar with the divergence from the PA field. The medial blocking of the groin fields is designed to match the divergence from the PA

field. This technique provides a more homogeneous dose distribution and is easier to reproduce on a daily basis.

Intensity-Modulated Radiotherapy

Intensity-modulated radiotherapy (IMRT) is now often used to treat the pelvis and inguinal nodes.[103,116,117] Beriwal et al.[116] reported 15 patients treated with IMRT using a median of 7 fields. The CTV was defined as a 1- to 2-cm margin around bilateral external iliac, internal iliac, and inguinofemoral nodes, as well as a 1-cm margin around the entire vulvar region. Gross tumor was also expanded by 1 cm for the CTV. The planning treatment volume was defined as 1-cm margin beyond the CTV, and the prescription dose was 43 to 48 Gy for preoperative treatment and 50 Gy for postoperative treatment, delivered partly on a twice-daily schedule. This early experience yielded reasonable clinical response, with 13 of 15 patients having no evidence of disease at last follow-up. This technique also resulted in improved dose conformality and lower doses to normal structures, including the rectum, bladder, small bowel, and femoral heads. The most recent update of this series found a pCR rate of 48%, 3-year overall survival of 61%, and 3-year local recurrence–free survival of 66%.[103] These results are comparable to the GOG 101 results and cause less acute skin toxicity than 2D or 3D techniques.

It must be noted that careful quality assurance is required when using IMRT. In particular, care should be placed to ensure that the surface of the vulvar tumor receives adequate dose. This may be accomplished by creating a “virtual flash” during treatment planning, where the PTV is expanded out of the skin by 1 to 2 cm, with additional placement of virtual tissue equivalent to allow for dose buildup. This protects against underdosing the tumor surface if there is superior displacement of the patient during treatment. Placement of thermoluminescent dosimetry chips or similar in the inguinal and perineum areas is recommended to document the dose given to the skin and target areas (Fig. 78.9).

CHEMOTHERAPY

The use of chemotherapy alone is usually reserved for patients having advanced, inoperable, or recurrent disease. Limited data exist given the rarity of this tumor type and the diversity of treatment regimens used in small, single-institution studies.

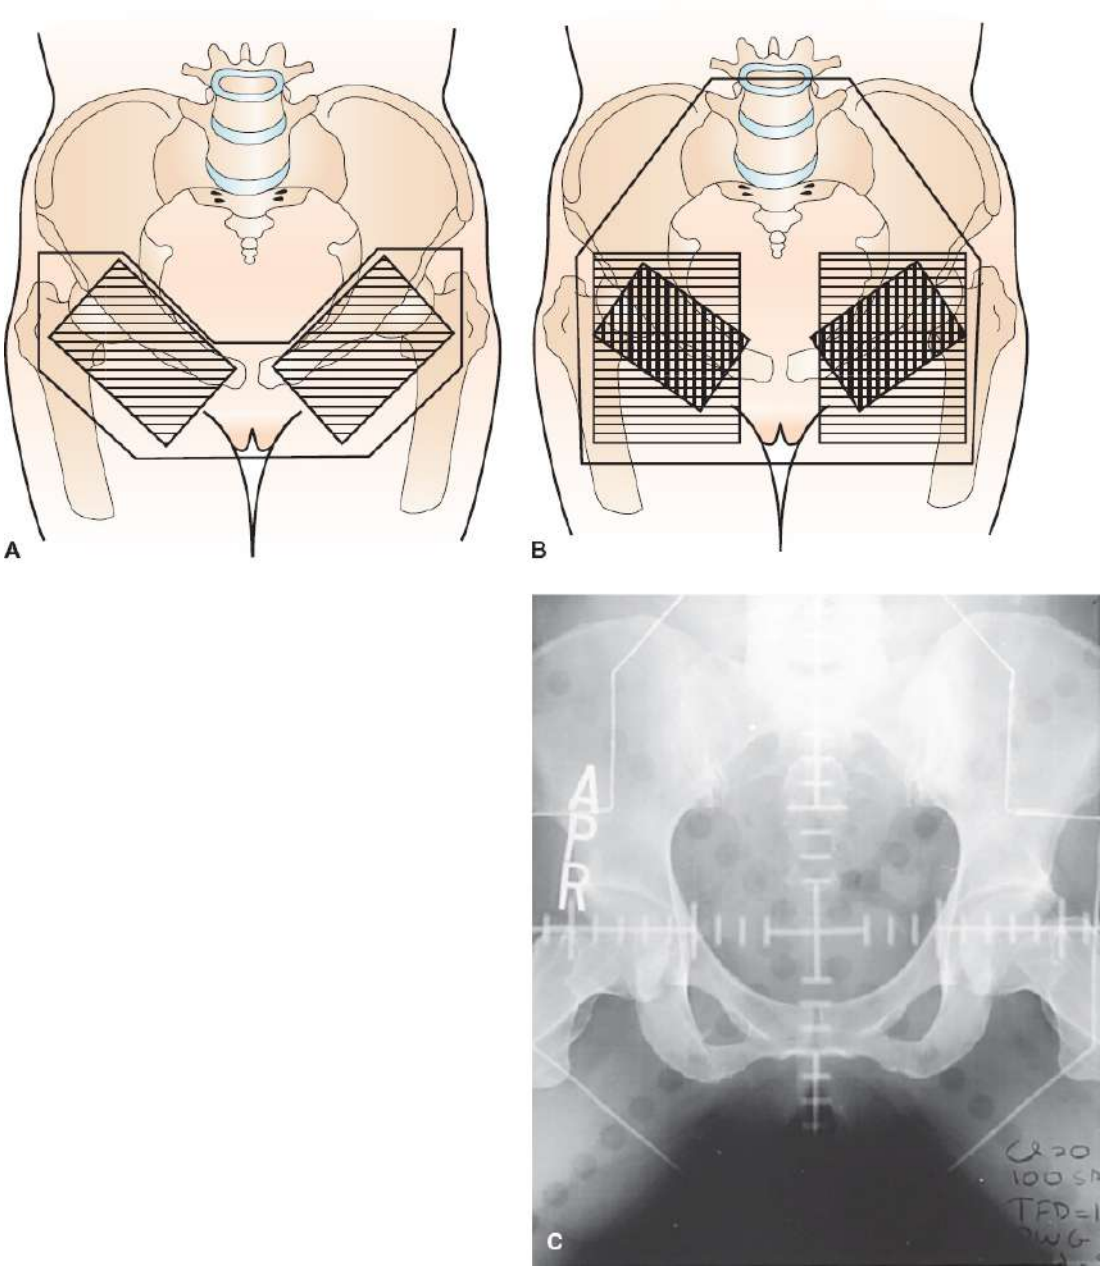

FIGURE 78.8. A: Portal for elective irradiation of regional lymphatics in patients with no clinical evidence of inguinal lymph node involvement. **B:** Portal for irradiation of pelvic and inguinofemoral lymph nodes and vulvar area. A final boost to the positive inguinal lymph nodes may be given with a reduced field. **C:** Simulation film of portal covering pelvic and inguinofemoral lymph nodes and vulva.

Single-Agent Chemotherapy

There is limited experience with single-agent chemotherapy for the treatment of vulvar cancer (Table 78.4). The single agents cisplatin, piperazinedione, mitoxantrone, and etoposide have all been evaluated prospectively by the GOG with disappointing results.[123–125] Paclitaxel has moderate activity, with a 14%

response rate described in a phase II trial of the European Organization for Radiation Therapy and Chemotherapy (EORTC).[54] Bleomycin has been tested in older studies as a single agent in both the neoadjuvant and recurrent settings with a high initial response rate.[126,127] Limited objective responses have also been reported in a small number of patients with doxorubicin.[128]

Multiagent Regimens

Combination chemotherapy regimens have included bleomycin, which is associated with considerable pulmonary toxicity.[129] The Gynecological Cancer Cooperative Group of the EORTC conducted two phase II studies using a regimen of bleomycin, 5 mg intramuscularly, given on days 1 to 5, methotrexate 15 mg orally on days 1 and 4, and lomustine, 40 mg orally on days 5 to 7 in the 1st week, followed by bleomycin 5 mg intramuscularly and methotrexate 15 mg orally on days 1 and 4 (modified to day 1 only in the second study) for 5 additional weeks.[119,120] The overall response rate was between 55% and 65%, with a complete response rate of 8% to 11%. Unfortunately, the toxicity was high. Severe mucositis was noted in up to 21% of patients, 13% had severe infections, and up to 7% developed severe pulmonary toxicity, with one death in each of the two studies possibly due to pulmonary toxicity. Other severe toxicities included nausea/vomiting and hematologic, renal, and mucocutaneous reactions. A group of prospective studies evaluated cisplatin, bleomycin, and methotrexate in the neoadjuvant setting and reported a 10% response rate of the primary tumor but a 67% response rate of nodal disease after two cycles of treatment.[121]

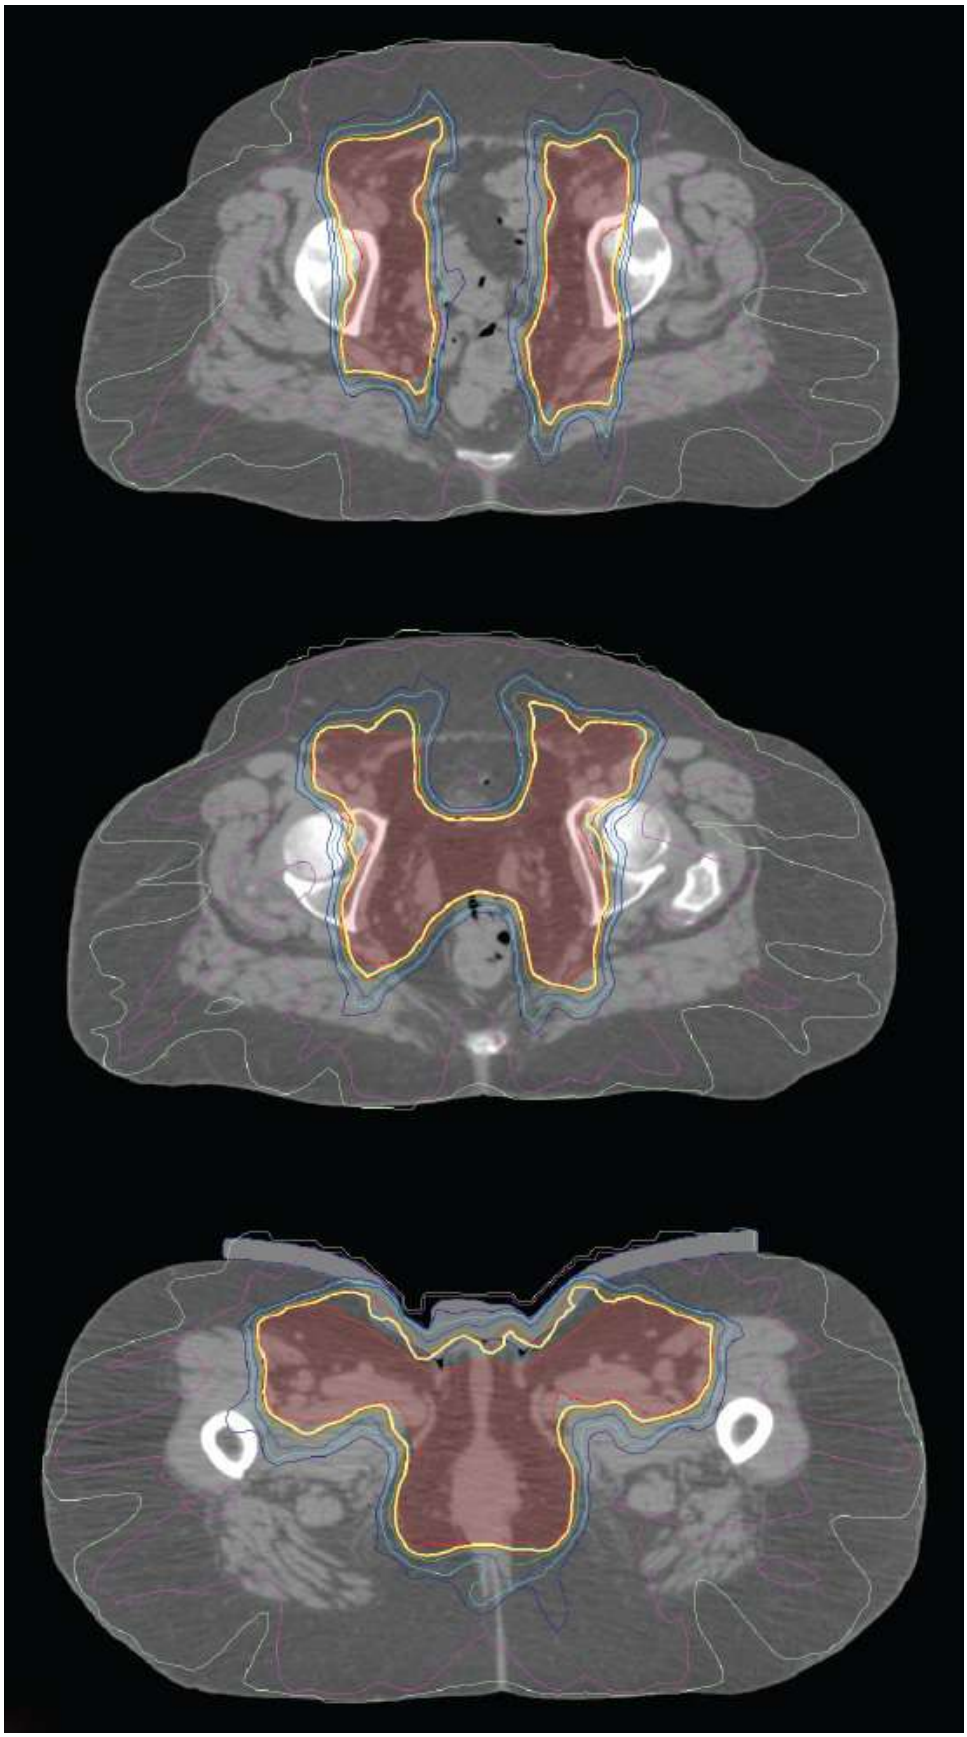

FIGURE 78.9. IMRT for vulvar cancer. This patient had a lesion of the posterior portion of the labia minora, involving the fourchette and the distal vagina. Three axial views are shown of the conformality of the 100% isodose line (*yellow*) and the planning treatment volume contour (*shaded red volume*). The central dose in the middle axial level is the superior margin for the vagina, added in this case because of the distal vaginal involvement.

TABLE 78.4 CHEMOTHERAPY FOR VULVAR CANCER

Authors	Number of Patients	Regimen	Partial Response (Number of Patients)	Complete Response (Number of Patients)
Geisler et al.[118]	9	FP	5	4
Geisler et al.[118]	3	P	0	0
Wagenaar et al.[119]	25	BMC	12	2
Durrant et al.[120]	31	BMC	15	3
Benedetti-Panici et al.[121]	21	PBM	Tumor, 2 Node, 3	Tumor, 0 Node, 11
Belinson et al.[122]	3	BOMP	0	0

BMC, bleomycin, methotrexate, CCNU; BOMP, bleomycin, vincristine, mitomycin C, cisplatin; FP, 5-fluorouracil, cisplatin; P, cisplatin; PBM, cisplatin, bleomycin, methotrexate.

In other small series, combinations of cisplatin with a second agent such as vinorelbine or 5-fluorouracil showed significant activity.[118,130] In a recent small report of neoadjuvant chemotherapy with cisplatin and 5-fluorouracil, at least a partial response was observed in all 10 patients. Of interest, three patients were treated with cisplatin alone in the same series with no responses.[118]

Biologic Agents

The epidermal growth factor receptor (EGFR) is a tyrosine kinase overexpressed in many squamous cell carcinomas of the vulva.[131] Erlotinib, an EGFR inhibitor, was reported to have significant activity in a case report, leading to the development of a phase II trial of this agent for women with lesions amenable to surgery or chemoradiation (cohort 1) or metastatic measurable disease.[132] The overall clinical benefit rate was 67.5% with 27.5% experiencing partial responses and 40% with stable disease. Responses, however, were of short duration. Rare but significant grade 3-4 toxicities included diarrhea/electrolyte

abnormalities, ischemic colitis, and renal failure.[133] In one other case report, the EGFR inhibitor cetuximab elicited a partial response when administered in combination with cisplatin.[134] Further studies may elucidate the role of EGRF-targeted agents and other biologics in the treatment of this disease.

In conclusion, paclitaxel and erlotinib are single agents showing activity against advanced vulvar cancer in phase II studies. Combination chemotherapy regimens, particularly those including cisplatin and 5-fluorouracil, yield improved response rates, but they are associated with significant toxicity. Bleomycin as single agent and in combination also appears to have activity but with risk of significant pulmonary toxicity. In the recurrent or metastatic setting, the choice of regimen requires consideration of single agents having modest activity but low toxicity versus combination regimens that carry both higher response and toxicity rates.

TREATMENT SEQUELAE

The adverse effects of treatment can be classified as acute or chronic and depend on the treatment modality or modalities used, as well as the intensity of the treatment. With early-stage disease and appropriately limited surgery to the primary site, the acute surgical complications are relatively minor and essentially consist of wound infection and hematomas. With more extensive surgery, the frequency and degree of the complications can be far more significant. With single “longhorn” or “butterfly” incisions for bilateral inguinal lymphadenectomies and for resection of the primary, wound infection, necrosis, and breakdown occurred in as many as 50% to 85% of the cases. Since the use of separate incisions was adopted, the incidence of groin wound infection, necrosis, and breakdown has decreased dramatically to a low as 15%.[44,135] Other potential complications of surgery include wound infections, seromas, hemorrhage, deep vein thrombosis, pulmonary embolism, osteitis pubis, and loss of sensory perception in the anterior aspect of the thigh secondary to femoral nerve injury.

The most significant chronic surgical complication is edema of the lower extremities. Lymphedema is related to the extent of the lymphadenectomy, and it is therefore more likely to occur with a deep inguinal node dissection. The incidence of lymphedema may be as high as 69%.[135,136] Lymphedema can be progressive and very difficult to manage. Early referral for physical therapy is indicated to prevent progression and stimulate regression of symptoms. Other

chronic complications reported are chronic cellulitis of the inguinal areas, stenosis of the introitus, femoral hernias, and rectovaginal or rectoperineal fistulas.

The most significant acute morbidity of radiation, alone or in combination with chemotherapy, is the mucocutaneous reaction in the vulva, perineum, and inguinal folds that may develop early during the course of the treatment. The severity of the reaction depends upon the radiation fractionation schema used and the type of chemotherapy employed. The degree of reaction may be such that a treatment interruption is unavoidable. Topical agents, such as zinc oxide preparations, may be helpful; however, this preparation must be off the skin during radiation treatments because it can exacerbate the skin reaction. Sitz baths with sodium bicarbonate may also aid in the cleansing and soothing of the affected skin. Treatment of candidal infections with appropriate antifungal agents should be provided as required. Narcotic pain medications may also be required in the final weeks of treatment.

Acute hematologic toxicity is common and depends upon the type and intensity of the chemotherapy used. Decreased leukocytes may be managed well with colony-stimulating factors, and blood transfusions may be necessary for anemia. Chemotherapy dose adjustments or interruptions are sometimes required. Severe hematologic toxicity can lead to septicemia, with fatal consequences in some instances.[94,109]

The late complications of chemotherapy/radiation and surgery combined include telangiectasis and atrophy of the skin and mucosa of the vulva, dryness of the mucosa of the vagina and vulva, and narrowing of the vaginal introitus. Avascular necrosis of the femoral head is rare, even when AP/PA photon fields that include the inguinal nodes are used. In the GOG combined-modality study for patients with advanced disease, only one patient developed avascular necrosis of the femoral head.[94] In this study, there were two instances of injury to the femoral artery. In one patient, necrosis of the femoral artery occurred immediately following surgery and was fatal. The second patient required femoral artery angioplasty.

Besides the generally recognized complications seen with surgery, radiation, and/or chemotherapy, the treatment of carcinoma of the vulva has significant psychosexual consequences. In some instances, these consequences can be far greater than expected when considering the type and extent of the therapy given. The psychosexual impact of the treatment has been studied by some investigators, but it has not received the attention that it merits, possibly because

of the difficulty in its nature and impact.[87] In a study by Andersen et al.[137] of 42 patients, most of whom were treated with conservative surgery, with wide local excision in 32 patients and simple vulvectomy in 10, there was a two- to threefold increase in the frequency of sexual dysfunction from the pretreatment level. In this study, 30% of the patients were sexually inactive at follow-up. Andersen and Hacker[138] also reported that vulvar surgery has a significant impact on sexual functioning and body image even when intercourse remains possible. As might be expected, after pelvic exenteration, patients also experience significant sexual dysfunction, even when a neovagina is created. Ostomies necessitated by exenteration have a significant detrimental impact on quality of life.[139] The concern for the significant impact of radical surgery on patients with carcinoma of the vulva has been the principal reason for the development of multimodality therapy. Organ preservation, maintenance of function, and improved body image with reasonable control of the disease can be achieved in women with this disease, particularly when the disease is in an early stage.

PART J

Adrenal and Retroperitoneal Tumors

CHAPTER 79

Retroperitoneum

Meng Xu-Welliver, Eric D. Miller, Joel L. Mayerson, Brian A. Van Tine, and Jeffrey C. Buchsbaum

Primary tumors of the retroperitoneum are rare and account for 0.1% to 0.2% of all malignancies[1–3] with up to 80% of lesions being malignant.[4] A retroperitoneal lesion was first reported by Morgagni in 1761 following an autopsy[5] with additional work by Pack and Tabah demonstrating the variety of histologies that can originate from the retroperitoneum.[3] This chapter focuses on lesions that primarily arise from tissues in the retroperitoneum.

ANATOMY

The anatomy of the retroperitoneum has been described in detail by Burkill et al.[6] and reviewed by Osman et al.[7] and shown in Figure 79.1. In summary, the anterior border of the retroperitoneal compartment is the posterior parietal peritoneum and the posterior border is the transversalis fascia. Superiorly, it extends to the diaphragm and inferiorly to the superior aspect of the pelvic diaphragm formed by the levator ani and coccygeus muscles. The retroperitoneum can be divided into three compartments: the anterior pararenal, the perirenal, and the posterior pararenal spaces. The anterior pararenal compartment is bordered anteriorly by the posterior parietal peritoneum, posteriorly by the anterior renal fascia, and laterally by the lateroconal fascia and contains the ascending and descending colon, the pancreas, and second portion of the duodenum. The perirenal compartment is located between the anterior and posterior renal fascia and contains the kidneys and adrenal glands. It is shaped like an inverted cone and superiorly abuts the bare liver on the right and the subdiaphragmatic space on the left. The posterior pararenal compartment is located between the posterior renal fascia and the transversalis fascia and contains fat without any visceral organs. Below the level of the kidneys, the anterior and posterior pararenal compartments combine to form the infrarenal

retroperitoneal space, which communicates with the pelvis inferiorly.[4] The aorta and inferior vena cava are contained within the great vessel space that is a primarily fat-containing region immediately anterior to the vertebral bodies and psoas muscles.[4]

EPIDEMIOLOGY

The population incidence of retroperitoneal tumors is based on two population studies and is estimated to be 3 per million persons.[1,2] The age range of patients varied between 3 and 83 years with half of the patients diagnosed between the ages of 60 and 80. There was no significant difference in frequency observed between males and females.[2]

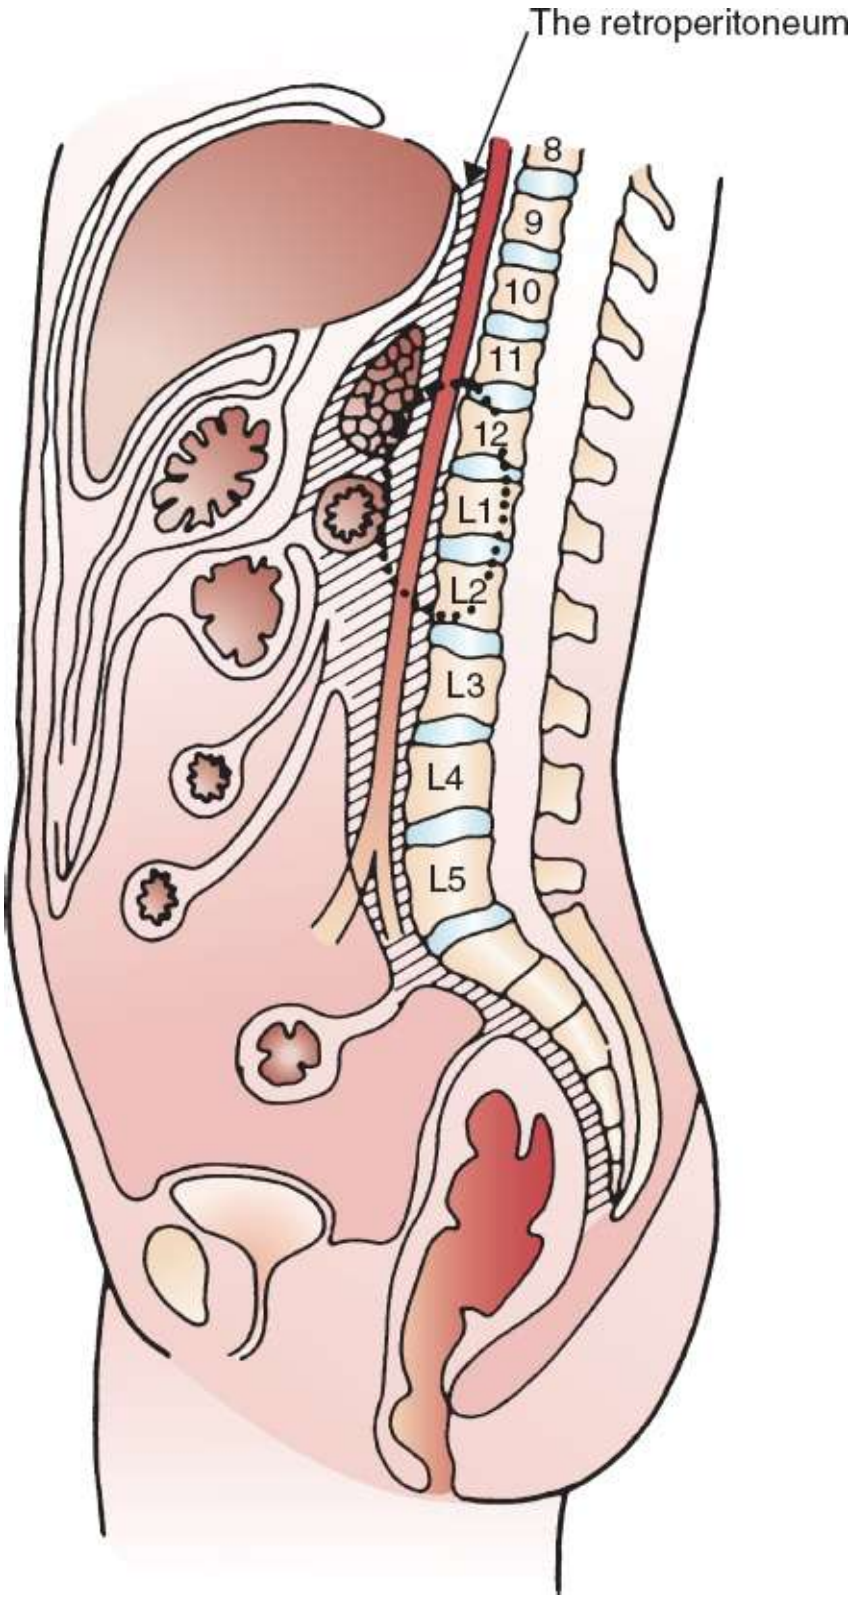

FIGURE 79.1. Sagittal view of trunk, showing the retroperitoneal space (*shaded area*). The kidney is outlined by *dots*. (From Wasserman TH, Tepper JE. Retroperitoneum. In: Perez CA, Brady LW, eds. *Principles and practice of radiation oncology*. 3rd ed. Philadelphia: Lippincott-Raven, 1997:1943–1956.)

The age at diagnosis of several large series of patients with primary retroperitoneal tumors is shown in Figure 79.2.[1–3,8,9] Two peak age periods are seen with the first peak occurring during the first decade of life generally caused by neuroblastoma or germ cell tumors, and a second peak occurring during the sixth decade generally caused by mesenchymal lesions. These histologies are outlined in Figure 79.3. Lawenda and Johnstone performed a comprehensive review of the Surveillance Epidemiology and End Results (SEER) public use registry focusing on retroperitoneal tumors.[10] As seen in the results of this review in Table 79.1, soft tissue sarcomas constitute a major portion of retroperitoneal tumors. However, in general, retroperitoneal sarcomas are uncommon representing approximately 15% of all soft tissue sarcomas[11] with an average estimated annual incidence of 2.7 cases per million persons.[12] The majority of this chapter will be focused on the diagnosis and management of retroperitoneal sarcomas.

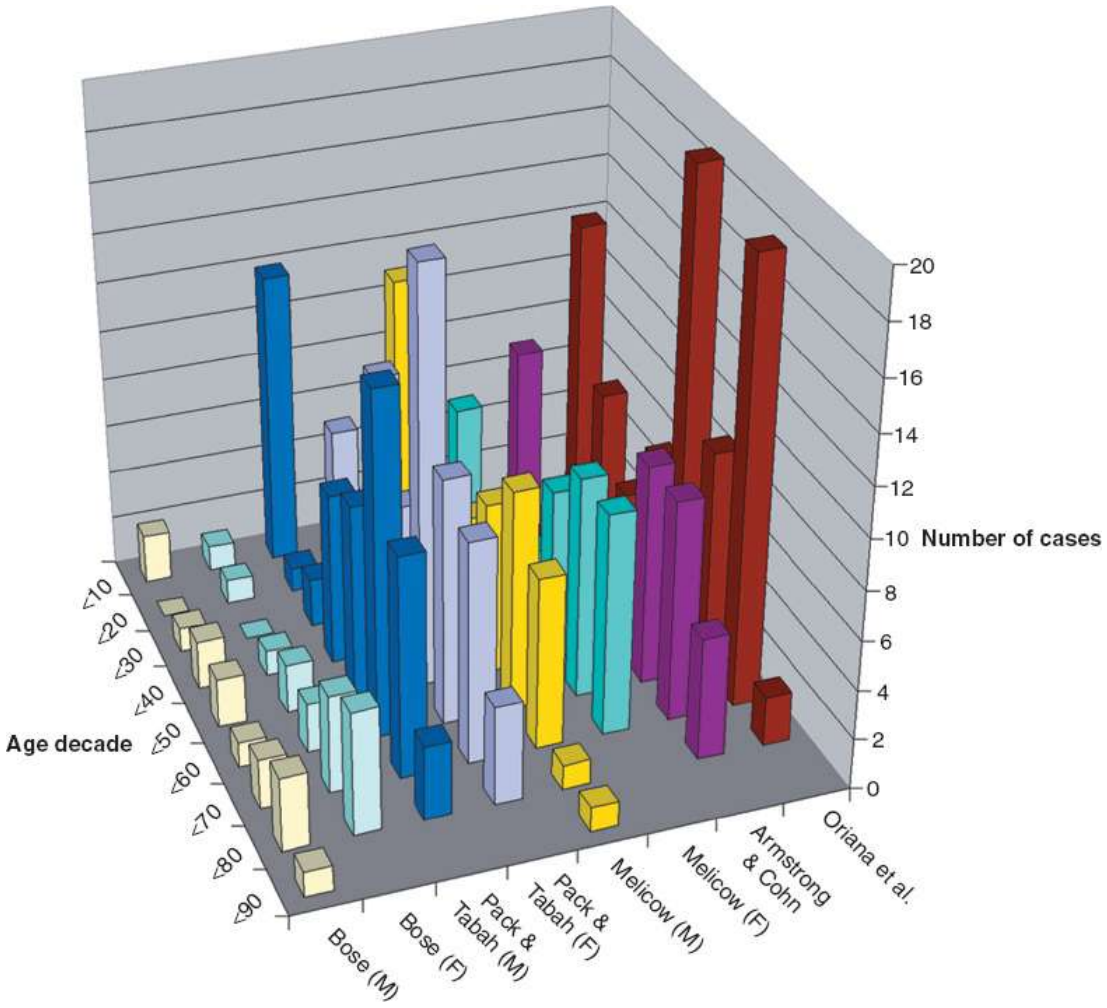

FIGURE 79.2. Age at diagnosis of malignant retroperitoneal tumors (pooled data from multiple series).

NATURAL HISTORY

With such varied neoplasms occurring in the retroperitoneum, the natural history is primarily dependent on histology. As the retroperitoneum is a potential space, neoplasms in this region can become quite large, weigh over 50 kg, and cause displacement or compression of adjacent organs prior to diagnosis.

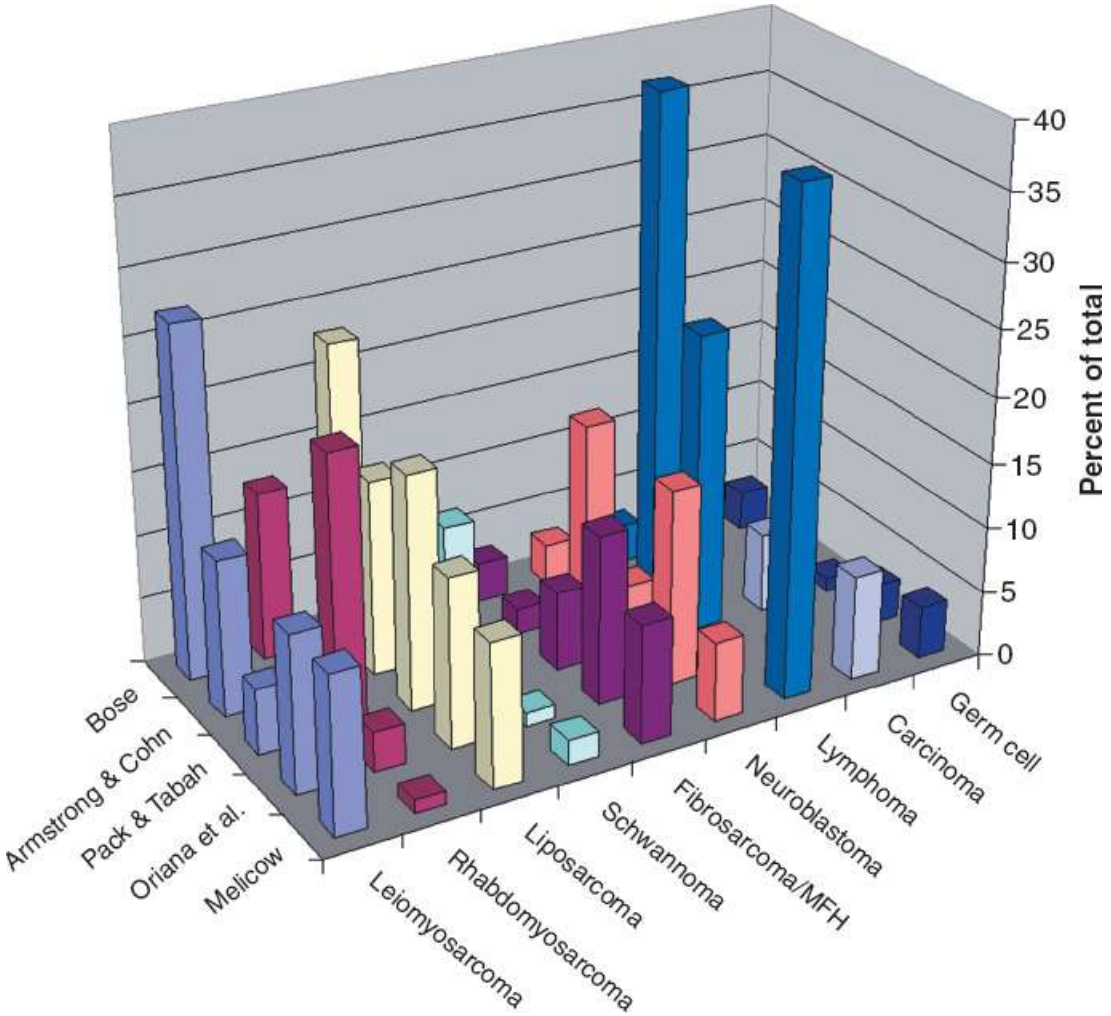

FIGURE 79.3. Percentage of retroperitoneal lesions by histology (pooled data from multiple published series).

TABLE 79.1 SURVEILLANCE, EPIDEMIOLOGY, AND END RESULTS DATA: RETROPERITONEAL MALIGNANCIES, 2002

Patient Data (*n* = 162)	Number	Percent

CLINICAL PRESENTATION

Table 79.2 outlines pooled data regarding signs and symptoms at presentation of retroperitoneal tumors. In general, presentation involves a mass or abdominal pain in the majority of cases.

DIAGNOSTIC WORKUP

Retroperitoneal tumors include a diverse group of both benign and malignant neoplasms that may be primary or secondary in origin.[7] Imaging serves an important role in differentiating retroperitoneal masses with computed tomography (CT) and magnetic resonance imaging (MRI) serving as the primary imaging modalities. Although the differential diagnosis is broad, certain imaging characteristics such as fat content, necrotic changes, contrast enhancement, presence of calcifications and/or cysts, and appearance on T1- and T2-weighted images all provide clues to narrow the differential diagnosis.[4] For example, in retroperitoneal liposarcoma, the most common subtype,[13] tumors appear as a hypoattenuating lesion on CT because of the fat content and are indistinguishable from a benign lipoma.[4,7] On MRI, a well-differentiated liposarcoma demonstrates high signal intensity on T1, intermediate signal on T2, and loss of fat signal intensity on fat-suppressed images and may be contrast enhancing.[4,7] However, in a dedifferentiated liposarcoma, both fat and solid

components are observed with occasional associated calcifications.[4] Leiomyosarcomas, the second most common subtype,[13] appear on CT as either homogeneously solid, but larger tumors may develop areas of necrosis and hemorrhage.[4] On MRI, these tumors demonstrate low T1 signal intensity and intermediate to high T2 signal intensity depending on the presence of necrosis with peripheral and heterogeneous contrast enhancement.[4,14] In general, retroperitoneal neoplasms can be divided into either solid or cystic tumors based on their imaging appearance.[7] Solid tumors fall into three main categories including mesodermal, neurogenic, or extragonadal germ cell origin, whereas cystic tumors include cystic changes in solid neoplasms as well as cystic lymphangioma, cystic teratoma, cystadenoma, cystadenocarcinoma, and cystic mesothelioma.[7]

TABLE 79.2 PRESENTING COMPLAINTS (%) OF PATIENTS WITH RETROPERITONEAL LESIONS (POOLED FROM LITERATURE SOURCES)

Sign/Symptom	Bose[2] (*n* = 30)	Pack and Tabah[3] (*n* = 120)	Oriana et al.[9] (*n* = 56)

Anorexia	20	NS	9
Nausea/vomiting	20	20	8
Lower extremity edema	17	7	9

[a]Indicates all patients with pain as presenting sign.
NS, data not stated.

As part of the primary workup, in addition to imaging the primary tumor with a CT of the abdomen/pelvis with intravenous (IV) contrast, a CT chest should also be obtained to evaluate for metastatic disease. MRI of the abdomen/pelvis with IV contrast can also be considered to further classify the lesion and evaluate extent of disease. Imaging with 18-fluorine–labeled 2-deoxy-2-fluoro-D-glucose ([18]F-FDG-PET) is not routinely performed for retroperitoneal sarcomas but may be useful for evaluating the extent of distant metastasis during initial staging if the primary lesion is PET avid in the first place.[15]

A definitive diagnosis is obtained with a biopsy and should be performed unless preoperative treatment is not planned. Image-guided core needle biopsy is

recommended with multiple cores obtained for histologic and molecular subtyping.[16] Both fine needle aspiration and laparotomy with open biopsy should be avoided. Ideally, biopsy of a solid, well-perfused portion of the tumor should be performed rather than an area of necrosis.[16]

RETROPERITONEAL SARCOMA GENERAL MANAGEMENT

Because of the rarity of retroperitoneal sarcoma, patients should be evaluated at high-volume centers with expertise in sarcoma by a multidisciplinary team including surgical oncology, radiation oncology, and medical oncology.[17] Based on guidelines presented by the National Comprehensive Cancer Network (NCCN, Version 2.2017), the first decision point is assessing if the patient is resectable or unresectable.[18] Surgical resection is the primary treatment for retroperitoneal sarcoma and is the only potentially curative option for localized and resectable disease. Criteria for unresectable tumors may include extensive major vessel involvement including the root of the mesentery, spinal cord involvement, peritoneal implants, and distant metastasis.[19] Achieving an R0 resection of a retroperitoneal sarcoma is often challenging due to the size and anatomic location of the tumor. Based on a review by Mendenhall et al.,[13] which includes data from 4 large institutional series, the rate of complete resection, which includes R0 and R1 resections, was 50% to 67%. Patients who have an R1 resection are at increased risk of local recurrence[20] with recent data from the National Cancer Database (NCDB) suggesting inferior survival as well.[21] Surgical resection often involves resection of adjacent organs to achieve complete extirpation of the tumor. Liberal visceral en bloc resections may increase morbidity but also have been associated with higher rates of local control and potentially an improvement in overall survival based on retrospective data although this practice has not yet been widely adopted.[22,23]

Although a number of retrospective studies have shown a local control benefit with adjuvant external beam radiotherapy (EBRT) following resection,[24–26] there are no randomized trials comparing surgery with and without adjuvant EBRT. Similarly, several nonrandomized prospective studies[27,28] have demonstrated acceptable local control and toxicity in patients with retroperitoneal sarcomas treated with preoperative radiation therapy although no prospective randomized trials have been performed. Currently, the European Organisation for Research and Treatment of Cancer (EORTC 62092-22092) is conducting a prospective, randomized phase III study in patients with retroperitoneal sarcoma comparing

patients treated with surgery alone to patients treated with preoperative radiation therapy (either 3-D conformal or intensity-modulated radiation therapy [IMRT]) followed by surgery, known as the STRASS trial.[29] A prior similar study conducted by the American College of Surgeons Oncology Group (ACOSOG Z9031) closed prematurely due to poor accrual.[30] Preoperative radiation therapy has several advantages over postoperative treatment. In the preoperative setting, the tumor is more clearly defined and the target volume is smaller because the entire operative bed must be included in the postoperative setting, which may reduce normal tissue toxicity. The tumor typically displaces adjacent normal tissues including bowel, kidney, and liver out of the target volume. In the postoperative setting, these organs may fall into the resection cavity making it difficult to deliver therapeutic postoperative radiation therapy doses. Finally, there is a theoretical radiobiologic advantage in treating a tumor with an intact vascular supply as it renders the tumor more sensitive to radiation therapy.

For patients with a resectable intermediate- or high-grade retroperitoneal sarcomas, preoperative radiation therapy should be considered prior to resection. If available, intraoperative radiation therapy (IORT) can also be considered to deliver a boost to the resection site to help improve local control. Based on the NCCN guidelines, for patients with unresectable or borderline resectable tumors, downstaging can be attempted using preoperative radiation therapy, combination chemotherapy with doxorubicin/ifosfamide/mesna (AIM), or chemoradiation.[18] Repeat imaging with CT chest/abdomen/pelvis with or without MRI abdomen/pelvis should then be performed to evaluate the treatment response and to verify that the patient has not developed metastasis. If the tumor progresses or the patient develops metastatic disease, palliative care can be considered, which may involve any combination of chemotherapy, radiation therapy, surgery to help control symptoms,[31] or other supportive care.[18] In patients with unresectable tumors, particle therapy may provide durable local control.[32]

Following preoperative radiation therapy in the definitive setting, surgical resection is typically delayed 3 to 8 weeks with radiographic restaging performed to assess for metastases and treatment response. In the setting of a positive microscopic margin (R1 resection) following preoperative radiation therapy, a postoperative external beam radiation therapy boost can be considered but is discouraged.[18] In general, postoperative radiation therapy is discouraged in the NCCN guidelines with the recommendation for observation following surgical resection with consideration of preoperative EBRT in the event of a local recurrence.[18] However, postoperative EBRT should be considered in the

situation where a local recurrence would cause significant morbidity because of a critical anatomic location. For patients who undergo a resection where gross residual disease is present (R2 resection), re-resection should be discussed, if possible.

Unlike extremity sarcomas where the majority of first recurrences are distant, retroperitoneal sarcomas tend to fail locally with a 5-year local control of approximately 50%.[13] In the setting of recurrent disease, patients who did not receive prior radiation therapy should be considered for preoperative radiation. Repeat resection should be offered, if possible, as patients who completed resection for recurrent disease had improved survival based on a large retrospective study from the Trans-Atlantic Retroperitoneal Sarcoma Working Group.[33] IORT can also be considered in an attempt to improve the chances of local control in the recurrent setting.[34–36]

Patients who present with or develop metastatic disease should be managed on a case-by-case basis. Any combination of chemotherapy, radiation therapy, surgery to palliate symptoms, and other supportive care is appropriate.[18]

Following definitive treatment, patients should undergo physical exam with imaging every 3 to 6 months for the first 2 to 3 years.[18] For the next 2 years, the patient should undergo physical exam and imaging every 6 months, and then annually after that. Imaging should include CT or MRI of the abdomen/pelvis with chest x-ray or CT of the chest also included.

A histology-based retroperitoneal sarcoma prognostic system identifies retroperitoneal sarcoma into three prognostic groups, and it can be used in both primary and recurrent retroperitoneal sarcoma. Distinct risk stratification is necessary for specific assessment of prognosis and decision regarding individualized adjuvant therapy.[37] Some authors recommend the formulation of a liposarcoma-specific postoperative nomogram based on histologic subtypes, which provides more accurate survival predictions for patients with primary retroperitoneal sarcoma.[38] Well-differentiated and dedifferentiated liposarcoma differ significantly in their biologic behavior and are treated by different surgical approaches at MD Anderson.[39] Researchers at the center recommend that the American Joint Committee on Cancer soft tissue sarcoma staging system needs to incorporate the primary site, histologic subtype, margin status, and recurrence to further shed light on prognosis.[40]

CHEMOTHERAPY

Adjuvant chemotherapy is controversial in the management of adult patients with macroscopically completely resected retroperitoneal soft tissue sarcomas. Retrospective analysis of both preoperative[41] or postoperative[19,42–44] chemotherapy has yet to demonstrate overall survival benefit. In a National Cancer Institute trial, patients with STSs were randomized to chemotherapy or observation following resection; some patients had postoperative irradiation.[45] Among patients who were assigned to chemotherapy, survival was favorably affected in those with extremity tumors. However, patients with head and neck and truncal lesions (including retroperitoneal sarcomas) did not benefit; the 5-year survival rate was approximately 40% in both arms. Similar findings were reported in a large meta-analysis of patients with STS.[46]

The use of neoadjuvant or adjuvant chemotherapy is not standard in the management of nonmetastatic adult retroperitoneal STSs. Neoadjuvant chemotherapy has been primarily studied in the setting of high-grade, extremity STSs. Pisters et al.[47] demonstrated feasibility of using preoperative concurrent doxorubicin and EBRT (18 to 50.4 Gy), followed by resection and IORT (15 Gy) in patients with RPS. An R0 or R1 resection was possible in 90% of the patients who went to surgery (83%). Newer studies have shown that doxorubicin-based adjuvant chemotherapy significantly improves local and distant recurrence in localized resectable soft tissue sarcoma.[48] Newer agents, such as olaratumab,[49] are currently being tested in the neoadjuvant setting to see if overall survival can be improved. Overall, treatment with chemotherapy is not recommended outside clinical protocols.

RADIATION THERAPY TECHNIQUES

External Beam Radiation Therapy

In patients where radiation therapy is recommended, preoperative radiation therapy is the preferred approach. Treatment guidelines based on the consensus of an international expert panel for preoperative radiation therapy of retroperitoneal sarcoma have been published by Baldini et al.[17] Suitable candidates for preoperative radiation therapy include patients with unifocal or localized tumors that are amenable to an R0 resection and where delivery of 50 to 50.4 Gy to the tumor while meeting the dose objectives for the adjacent normal structures is feasible. Patients with symptoms requiring urgent surgical intervention should not be considered for preoperative radiation therapy. Prior to any therapy, the surgical and radiation oncologist should work together to

develop a consensus plan. In the setting of kidney or liver involvement where surgical resection may involve either a nephrectomy or partial hepatectomy, or where radiation therapy may result in impaired function of one kidney, preliminary studies need to be performed to ensure adequate function in the remaining kidney or liver. Further, in the setting of a nephrectomy or partial hepatectomy, care should be taken to minimize the radiation dose to the remaining kidney and/or liver. Kidney function can be evaluated using a renal perfusion study, whereas the liver can be evaluated using serum liver chemistries.

CT simulation should be performed with the patient in the supine position with arms up using an Alpha Cradle with/without a wing board or equivalent custom immobilization device to allow reproducible setup during treatment. Both oral and intravenous contrast should be considered for the simulation scan to better delineate the tumor and adjacent normal structures including bowel. A four-dimensional CT should be performed to evaluate tumor motion during the respiratory cycle with more motion anticipated in superiorly located tumors in the abdomen.[50] For patients with more than 1 cm of motion, motion management techniques should be considered such as active breathing control, respiratory gating, or end-expiration breath hold. To aid with target and organ at risk of delineation, registration of the free-breathing planning CT with diagnostic studies should be performed. Useful diagnostic studies may include a diagnostic CT and/or T1-weighted postcontrast MRI. Data on the use of [18]F-FDG-PET in the staging of retroperitoneal sarcoma and for use in radiation therapy treatment planning are currently limited with more data likely to emerge in the coming years.

Target Delineation/Organs at Risk

Target volumes for retroperitoneal sarcomas are included in the international expert panel consensus guidelines from Baldini et al.[17] For upper abdominal tumors where a four-dimensional (4-D) computed tomography (CT) simulation is performed, the gross tumor volume (GTV) is delineated, and an internal gross tumor volume (iGTV) is made based on the motion of the GTV throughout the respiratory cycle. The internal target volume (ITV) is made using a 1.5-cm uniform expansion of the iGTV edited off of uninvolved bone, kidney, and liver. The ITV volume should expand 5 mm into the bowel and any air cavities and should be cropped away from uninvolved skin per institutional guidelines. If the tumor extends into the inguinal canal, the inferior expansion of the iGTV to

make the ITV should be 3 cm. For an upper abdominal tumor where a 4-D CT simulation is not performed, the GTV should be expanded by 2 to 2.5 cm in the superior–inferior direction and 1.5 to 2 cm radially. The CTV should be edited off of the interfaces in the same manner as the ITV in the upper abdomen case where a 4-D scan is obtained. For tumors below the level of the iliac crest, the GTV can be expanded 1.5 cm uniformly and edited off of the interfaces as mentioned above to create the CTV. In all cases, the planning target volume (PTV), which accounts for setup error and patient movement, should be based off of imaging frequency and institutional guidelines. The standard preoperative dose is 50.4 Gy in 1.8 Gy fractions or 50 Gy in 25 fractions. The delivery of a boost dose to the areas considered to be at high risk for a positive margin has been reported.[51] However, this approach remains experimental and is the subject of a currently accruing phase I/II trial at Massachusetts General Hospital.[52] In the setting of a positive surgical margin following preoperative EBRT, a postoperative EBRT boost may be considered. In this situation, a boost of 16 to 18 Gy for microscopic disease and 20 to 26 Gy for gross residual disease should be considered being certain to observe the limits of adjacent normal tissues.[18]

In the postoperative setting, the treatment volumes are generally larger with a larger volume of normal tissue in the treatment field as the bowel and other organs initially displaced by the tumor fall into the resection cavity. Temporary tissue expanders have been used in a limited number of studies to displace bowel and other organs at risk out of the treatment volume.[34,53] Target delineation in the postoperative setting is challenging and no consensus guidelines exist. Ideally, preoperative imaging is available and can be registered with the CT simulation scan. Postoperative diagnostic studies should also be considered to evaluate for residual disease. In the event where an R1 or R2 resection is expected, clips placed in the areas at highest risk for positive margins/residual disease aid greatly in target delineation. In general, the preoperative GTV and any surgical clips should be included in the posttreatment volume. CTV expansion volumes should be limited to exclude fascial and peritoneal boundaries not violated by tumor. Again, the PTV is based on the method of immobilization and institutional guidelines. The larger treatment field is generally treated to a dose of 50.4 Gy in 1.8 Gy fractions or 50 Gy in 25 fractions with a limited boost field based on the presence of residual disease and proximity to organs at risk. Based on the NCCN guidelines, a 10 to 16 Gy boost is recommended in the setting of negative margins, 16 to 18 Gy for microscopically positive margins, and 20 to 26 Gy for gross residual disease.[18]

The total dose is generally limited by the tolerance of adjacent normal tissues. Particle therapy such as protons may be advantageous in the postoperative setting by permitting delivery of a therapeutic radiation dose to the PTV while sparing abutting organs and tissues. This remains the subject of active investigation.

Adjacent organs at risk include liver, stomach, bowel including duodenum, small and large bowel, kidneys, spinal cord, testicles, ovaries, bladder, rectum, and femoral heads. To aid in normal organ contouring, consensus guidelines and an atlas are available from the Radiation Therapy Oncology Group.[54] Again, the consensus guidelines for preoperative radiation therapy for retroperitoneal sarcoma includes a summary of constraints for organs at risk primarily derived from Quantitative Analysis of Normal Tissue Effects in the Clinic (QUANTEC) data.[17,55] In brief, no more than 100% of the stomach should receive ≥45 Gy, the mean bilateral kidney dose is 15 to 18 Gy, and no more than 15% of the remaining kidney should receive >18 Gy if one kidney is removed. For the small/large bowel contoured as the peritoneal cavity, no more than 195 cm^3 should receive >45 Gy. The mean residual liver dose should be limited to <26 Gy and the spinal cord dose should be <50 Gy.

Treatment Planning and Delivery

For radiation therapy planning using photons, intensity-modulated radiation therapy (IMRT) is preferred over 3-D conformal radiation because of increased conformality with decreased dose to adjacent organs at risk.[56] Swanson et al.[56] determined the optimal radiation therapy technique for the treatment of retroperitoneal sarcomas by comparing plans prepared using 3-D conformal proton radiation therapy, IMRT, and 3-D conformal photon radiation therapy. The IMRT and conformal proton plans were more conformal than the 3-D photon plans. Furthermore, the IMRT and proton plans provided a lower bowel and kidney dose than the 3-D photon plans.

Based on the results of Wong et al., which demonstrated volumetric changes and significant interfraction displacement during preoperative radiation therapy for retroperitoneal sarcoma, daily image-guided radiation therapy should be considered where soft tissue is clearly visible such as cone-beam CT.[17,50] Prophylactic antiemetics should be considered for the patient depending on the location of the tumor.

Additional Radiation Techniques

IORT refers to the delivery of either brachytherapy or external beam irradiation to a target area, whereas the area is exposed during surgery. IORT is typically used to deliver a focal boost to areas of concern such as close or positive margins. The advantages of IORT include the ability to directly visualize the area of concern and manually remove normal tissues from the field or shield them prior to treatment delivery. When electron beams are used (IOERT), typical doses range from 10 Gy for completely resected tumors with negative margins, 12.5 to 15 Gy for positive microscopic margins, and 15 to 20 Gy for gross residual disease.[57] Typical electron energies range from 9 to 15 MeV based on the desired depth of penetration.

IORT can also be delivered using high dose rate intraoperative irradiation (HDR-IORT) as previously described in detail by Harrison et al.[58,59] For HDR-IORT, following displacement of normal tissue from the field of interest, a Harrison-Anderson-Mick (HAM) applicator (an array of catheters spaced 1 cm apart in a silicone rubber pad) is secured in the target region and a dose of 10 to 20 Gy at a tissue depth of 5 to 10 mm is typically delivered.[57] Following delivery of IORT, the applicators are removed from the target region, and the surgeon continues with the case. The advantages and disadvantages of each IORT technique have been previously summarized.[57] HDR-IORT allows for delivery of more conformal treatments along curved surfaces secondary to the flexible nature of the HAM applicator, the ability to treat large fields without field matching, and the ability to deliver radiation therapy to areas that may not necessarily be accessible with IOERT. HDR-IORT is limited to treating target areas ≤0.5 cm thick. IOERT can treat both superficial and deeper targets by varying the electron energy employed for treatment. Treatment with IOERT is also generally shorter than HDR-IORT, thus decreasing the overall procedure time.

RESULTS OF THERAPY

Surgical resection remains the only curative treatment for patients with retroperitoneal sarcomas, although local control rates with resection alone remain poor. Because of both the size and proximity of retroperitoneal sarcomas to critical organs, margin negative resections are difficult to achieve. Locoregional failure is the predominant pattern of failure,[13,60] and failure to achieve local control is the major cause of death in patients with retroperitoneal sarcoma.[61] A large retrospective series from Memorial Sloan Kettering reported

on 231 patients with primary retroperitoneal sarcoma that was resectable.[62] Of the 231 patients, 185 (80%) were able to undergo a gross total resection. Patients with a gross total resection were found to have a statistically significant increase in survival compared to those who underwent incomplete resection, 103 versus 18 months. No difference in survival was observed between patients with unresectable disease and patients who underwent incomplete resection. For patients with localized, completely excised retroperitoneal sarcoma, 5-year overall survival is 49% to 70% with selected studies summarized in Table 79.3.

LRF, locoregional failure.

Patients with positive microscopic margins are at increased risk of local recurrence[20] based on retrospective data with a recent study from the NCDB demonstrating a survival advantage in patients able to achieve an R0 resection versus R1 resection, 92 and 70 months, respectively.[21] As part of the analysis, preoperative radiation therapy was associated with an increased probability of R0 resection. A number of retrospective studies demonstrate an improvement in local control with postoperative radiation therapy with select studies summarized in Table 79.4. In the report by Stoeckle et al.,[24] patients with complete excision had a significant reduction in local recurrence risk when treated with received postoperative radiation therapy (median dose = 50 Gy) compared to those not treated with adjuvant radiation therapy (relative risk, 3.36; $P = .0021$). However, no improvement in overall survival on multivariate analysis was observed. Catton et al.[60] found that adjuvant radiation therapy for patients who had a complete resection increased the time to locoregional relapse, from 30 months (no radiation) to 103 months ($P = .06$). Again, radiation did not have an impact on survival.

Preoperative radiation therapy is preferred over postoperative radiation therapy because of improved target delineation, a smaller treatment volume, and the potential for displacement of normal tissues by the tumor. Preoperative radiation therapy has been evaluated in the prospective setting with small nonrandomized studies.[27,28] Pawlik et al.[28] reported the results of two prospective studies performed at MD Anderson. Patients with intermediate- or high-grade retroperitoneal sarcoma were treated with preoperative radiation therapy with a median dose of 45 Gy followed by surgical resection. Nearly 90% of the patients completed the planned radiation course with a complete resection achieved in 95% of patients. For the patients who had a complete resection, the 5-year local recurrence-free and overall survival rates were 60% and 61%, respectively. A separate NCDB study was performed comparing patients with retroperitoneal sarcoma treated with surgery alone versus pre- or postoperative radiation therapy. An improvement in overall survival was observed in the patients treated with either preoperative (HR 0.70; 95% CI 0.59 to 0.82; $P < .0001$) or postoperative (HR 0.78; 95% CI 0.70 to 0.85; $P < .0001$) radiation therapy compared to patients treated with surgery alone.[65] Hopefully, there will

be a definitive answer regarding the role of preoperative radiation therapy in the retroperitoneal sarcoma by completion of EORTC 62092, the STRASS trial.

IORT is used by some centers to deliver a boost to the resection cavity to improve local control. A prospective randomized trial was performed by the National Cancer Institute to evaluate the benefit of gross total resection with IORT followed by postoperative EBRT compared to gross total resection and postoperative EBRT alone.[66] IORT was delivered with electrons with an energy of 11 to 15 MeV delivered in a single dose of 20 Gy. For patients treated with IORT, the postoperative EBRT dose was 35 to 40 Gy delivered in 1.5 to 1.8 Gy fractions. For patients treated with postoperative EBRT alone, the dose was 50 to 55 Gy delivered in 1.5 to 1.8 Gy fractions. For patients treated in the IORT arm, significantly fewer locoregional recurrences were observed compared to the postoperative EBRT alone arm. No difference in survival was observed between the two arms. Additional nonrandomized studies summarized in Table 79.5 have demonstrated excellent local control with the use of IORT and EBRT with acceptable toxicity.

Patients with unresectable disease have a poor prognosis. Surgery may be considered to palliate symptoms. A retrospective study from Memorial Sloan Kettering was performed to evaluate patients with retroperitoneal sarcoma who underwent palliative procedures.[68] Patients most frequently underwent a procedure because of gastrointestinal (GI) symptoms (44% of patients). Overall, about 50% of patients were symptom-free at 100 days postprocedure, but only 23% of patients with GI obstructive symptoms were symptom-free at 100 days. The postoperative morbidity was 29%, and the postoperative mortality was 12%. Particle therapy can also be considered for patients with unresectable disease. Serizawa reported on a small series of patients with unresectable retroperitoneal sarcoma treated with carbon ion radiotherapy.[32] The patient cohort included both primary and recurrent disease with doses ranging from 52.8 to 73.6 GyE in 16 fractions. The local control rates at 2 and 5 years were 77% and 69%, respectively, with a 2- and 5-year overall survival of 75% and 50%, respectively. No grade ≥3 toxicities were observed.

Recurrence is common, and there are minimal data to guide management in the recurrent setting.[33] A large retrospective series from the Trans-Atlantic Retroperitoneal Sarcoma Working Group evaluated postrelapse outcomes in 408 patients.[33] For patients with a local recurrence only, the median time from initial resection to recurrence was 23 months. Repeat resection was performed in 48% of patients with chemotherapy and radiation therapy given to 31% and 18% of

patients, respectively. Following local recurrence, the median overall survival was 33 months and the 5-year overall survival was 29% with repeat resection and longer time interval to recurrence found to be significant predictors for survival. Treatment with radiation therapy trended for significance. The 5-year overall survival for patients who underwent repeat resection was 43% versus 11% for those not able to undergo repeat resection. The 5-year overall survival for patients with distant metastasis and those with local recurrence and distant metastasis was 20% and 14%, respectively. For patients with distant metastasis only, resection of the distant metastasis was found to be a significant predictor of improved disease-specific survival. For patients with both a local recurrence and distant metastasis, patients who completed resection of the recurrent disease had longer survival than those who did not.

TREATMENT SEQUELAE

Acute symptoms from EBRT of the retroperitoneum include fatigue, radiation dermatitis, nausea, vomiting, and diarrhea. For large radiation fields where the adjacent spine is included, a significant portion of bone marrow may also be included and anemia, neutropenia, and thrombocytopenia may occur. At minimum, weekly monitoring of vital signs should be performed and monitoring of blood counts should be considered. Reported postoperative complications include bleeding, impaired wound healing or dehiscence, infection, myocardial infarction, and death.[27,67]

Late toxicities of surgery and radiation include small bowel enteritis, stricture, perforation, fistula, and obstruction. Development of nephritis is possible after radiation doses >30 Gy with resultant hypertension. Late complications are associated with the number of laparotomies to which the patient has been subjected and to the radiation dose and volume.[69] A lower incidence of enteritis has been reported with the use of EBRT and an IORT boost compared with EBRT alone, as the bowel is able to be moved from the field resulting in a lower radiation dose[66] (Table 79.5). Overlap of adjacent IORT fields can increase the risk of neuropathy and ureteral injury.[27,36,67] As discussed previously, preoperative radiation therapy is the preferred approach over postoperative radiation therapy because of a more favorable toxicity profile and ease of target delineation.[17] Proton therapy may also allow decreased dose to the bowel resulting in a decrease in acute and late toxicity.[70]

Callegaro et al.[71] performed a cross-sectional study to assess the long-term morbidity of patients treated for retroperitoneal sarcoma. Patients were evaluated for lower limb function using the Lower Extremity Functional Scale (LEFS) and pain was assessed using the Brief Pain Inventory–Short Form, both self-report questionnaires. Radiation therapy and chemotherapy were used in 28.8% and 51.4% of patients, respectively. Overall, sensory impairment of the limbs was reported in 76% of patients with a median LEFS score of 60 out of a maximum 80 (high function) indicating overall good motor function. Mean pain scores varied from 1.23 to 2.68 out of a maximum of 10 (bad pain) indicating mild pain overall. No difference in median creatinine levels on multivariate analysis was observed in patients requiring nephrectomy compared to those who did not.

LYMPHOMAS

Lymphomas frequently involve the retroperitoneum with the predominant histologic variant being non-Hodgkin lymphoma. Workup generally includes CT and/or MRI and 18F-FDG-PET. On CT, lymphomas appear as a homogeneous mass that generally spreads between normal structures occasionally causing displacement, but generally not resulting in compression.[4] On MRI, lymphomas are isointense on T1 and iso- to hyperintense on T2-weighted images with patchy contrast enhancement.[4] PET imaging is also generally used with FDG avidity dependent on histologic subtype.[72] A definitive diagnosis requires a tissue biopsy that can be difficult in the retroperitoneum. An image-guided needle biopsy is to be used over fine needle aspiration for diagnostic purposes if

no other superficial lymph nodes are accessible and also because sarcoma is in the differential.[73] Flow cytometry and immunohistochemical stains are used to confirm the diagnosis of lymphoma. The diagnosis, staging, and management of retroperitoneal lymphoma are similar to that of other lymphoma sites and are discussed elsewhere in this text. As with all retroperitoneal tumors, radiation doses and treatment volumes may be limited by adjacent normal tissues.

OTHER LESIONS

Neuroblastoma is the most common solid extracranial tumor in children and the most common cancer in infants younger than 12 months, though this can occur rarely in adults.[74] In the United States, approximately 650 new cases are diagnosed per year[75] with a prevalence of 1 case per 7,000 live births and an incidence of 10.54 cases per 1 million per year in children younger than 15 years.[74] Ninety percent of cases are diagnosed in children <5 years of age with about 37% diagnosed as infants.[74] Neuroblastoma accounts for approximately 15% of all pediatric cancer fatalities. This tumor is extraordinarily uncommon in adults with an estimated incidence of 0.2 per million population in those aged 30 to 39.[76] The paradigm for treatment of neuroblastoma includes combination therapy with chemotherapy, surgery, and radiotherapy in advanced-stage disease, which is most commonly found in adults.[77]

Wilms tumor (WT) or nephroblastoma is the most common intra-abdominal malignancy of childhood with an incidence of 7.1 cases per 1 million children younger than age 15 years with approximately 650 cases diagnosed in the United States each year.[74] It is the second most common extracranial solid neoplasm of childhood and the most common renal malignancy in children.[78] In contrast, it is an uncommon malignancy in patients ≥16 years of age with an estimated incidence of 0.2 per million population.[79,80] Adults frequently present with flank pain and painless hematuria,[81] whereas children are more likely to present with painless hematuria and/or a palpable abdominal mass.[74] The treatment and outcomes of patients with adult Wilms tumor (AWT) remain controversial with no standard therapy yet developed.[82] Kalapurakal et al.[83] reported the outcomes of 23 adults (>16 years of age) treated on Children Oncology Group (COG) protocols (National Wilms Tumor Study Group; NWTS 4 and 5) and found no difference between the adults and their pediatric counterparts. Similarly, the International Society of Pediatric Oncology (SIOP) published results from an SIOP retrospective review of 30 AWT patients >16 years of age with comparable

results between adults and children.[81] Conversely, Izawa et al.[84] reported on 128 AWT patients from SIOP as well as individual institutional reports and concluded that the outcomes in adults were inferior to that of children. A SEER study by Ali et al.[85] concluded that the outcome in 152 AWT patients was worse than in children. Overall survival at 5 years was 69% in AWT versus 88% in children ($P < .001$). On multivariate analysis, adult status (≥16 years), SEER stage, treatment era (before 1990), and lack of surgical staging of lymph nodes were significant prognostic factors in this cohort. A consensus statement by an international group of childhood renal experts was published that recommends adoption of the pediatric paradigm for treatment of AWT patients including surgical resection, chemotherapy agents depending on stage and histologic subtype, and local therapy with irradiation depending on the stage of disease.[82] Furthermore, patients <30 years old are included on the current COG WT studies. The toxicities of treatment (severe acute neuropathy, grade 4 hematologic toxicity) in AWT patients may be somewhat higher than in the pediatric population but are thought to be reasonable in view of the high response rates.[81]

Retroperitoneal schwannomas are a rare tumor, accounting for approximately 4% of retroperitoneal tumors, but are the most common benign tumor found in this location.[86,87] They belong in the family of peripheral nerve sheath tumors, which in addition to schwannomas includes neurofibromas, solitary circumscribed neuromas, and perineuriomas.[88] Schwannomas may occur in any nerve trunk in the body with the exception of cranial nerves 1 and 2 (which are not covered by Schwann cells) and are most commonly found at peripheral nerve sites of the upper extremities and cranial nerves with only 0.3% to 3.2% of all schwannomas occurring in the retroperitoneum.[88] Benign schwannomas are associated neurofibromatosis 2 (NF2) in approximately 5% to 18% of NF2 patients, presenting most commonly between 20 and 50 years of age.[89] They are slow-growing nonaggressive tumors that displace rather than invade normal tissues and often form large, well-circumscribed masses.[87,88] They may display cystic degeneration, calcification, hemorrhage, and hyalinization on imaging studies. In several moderate to large series, there appears to be a slight female patient propensity and the tumors are often diagnosed incidentally during radiologic examinations for unrelated symptoms.[90,91] Bone changes may occur in tumors adjacent to the spine with invasion into nerve roots or the spinal canal, which may lead to neurologic symptoms including paresthesias, weakness, and pain. MRI examinations are the preferred method of imaging these soft tissue

neoplasms although CT scanning may be necessary to better visualize potential bone abnormalities particularly in the spine. Because these tumors are frequently quite vascular, some investigators do not recommend the use of CT-guided biopsies because of the risk of hemorrhage.[92] Whenever feasible, complete surgical resection with negative margins is the treatment of choice although adjuvant radiation therapy may be necessary for incompletely excised sacral schwannomas.[93] NF1 patients have a particularly high risk of developing STS, particularly and malignant peripheral nerve sheath tumors (MPNST), often with an aggressive clinical presentation and poor outcome.[94]

Aggressive fibromatosis, also referred to as desmoid tumors, is a rare fibroblastic neoplasm that arises from deep musculoaponeurotic connective tissue and has an incidence of 2 to 4 cases per million population,[95] occurring either sporadically or associated with familial adenomatous polyposis (FAP).[96–99] Ten to 30% of patients with FAP eventually develop desmoid tumors with the majority occurring in either the extremities or abdomen/retroperitoneum.[100–102] They occur slightly more frequently in women than in men.[103] Although benign in nature, they are locally aggressive and may infiltrate critical structures. Complete surgical resection is the mainstay of treatment, but because the local recurrence rate and morbidity from resection can be high, some patients are now managed with observation and close clinical radiologic follow-up per NCCN guidelines. Local recurrence is common even in the setting of a wide local resection in up to 40% of patients depending on the series.[104–107] Postoperative radiotherapy and/or chemotherapy may be indicated when a complete surgical resection is not achieved or is not feasible or in multiple recurrent disease, though some institutions have been adopting a watch-and-wait approach to the treatment of desmoids as they are an indolent disease. The data are variable regarding the dose and treatment volumes for this disease; however, most reported series suggest that a dose of 50 to 60 Gy with margins of 5 to 7 cm is appropriate.[107,108] Doses >56 Gy may not be necessary to control gross disease.[108] A meta-analysis by Nuyttens et al., which included data from 22 studies, suggested that local control was improved with adjuvant radiation therapy compared to surgery alone; local control after surgery alone was 72% (R0) and 41% (R1 and R2) compared to 94% (R0) and 75% (R1 and R2) after surgery and adjuvant radiation.[107] In patients with unresectable disease, radiation therapy alone is effective in providing long-term local control in up to 80% of patients.[107,109] Systemic therapy may also play a role in unresectable, incompletely resected, or recurrent disease. Systemic therapy options include

both cytotoxic and noncytotoxic agents including anthracyclines, hormonal therapy, nonsteroidal anti-inflammatory drugs, imatinib, and clinical trials with agents like sorafinib.[110]

Extragonadal germ cell tumors (EGCTs) account for approximately 1% to 5% of all germ cell tumors and occur in the retroperitoneum as the second most common extra gonadal site in adults after the mediastinum.[111] Primary retroperitoneal germ cell tumors account for approximately 5% of all primary malignant retroperitoneal tumors in adults.[112] It is believed that these tumors arise from primordial germ cells, which are displaced during their migration along the urogenital ridge to the gonads.[111] When they occur in the retroperitoneum, they are considered to be metastases from an occult or "burned out" gonadal primary until proven otherwise. EGCTs are most typically found in children or young adults and mostly arise in midline locations. The majority of these tumors occur in young men, and the majority are nonseminomatous germ cell tumors (NSGCTs) rather than seminomatous germ cell tumors (SGCTs).[111] In young women, the histologic varieties are dysgerminomas and nondysgerminomas. NSGCTs include the following histologies: teratoma, embryonal carcinoma, endodermal sinus tumor (yolk sac tumor), choriocarcinoma, and mixed histologies. Any proportion of nonseminomatous component is enough to classify a tumor as an NSGCT. NSGCTs generally have a much more aggressive course than do SGCTs. Serum markers, although nonspecific, may help to categorize the histology and can be useful for following both response to therapy and the presence of recurrence. Beta human chorionic gonadotropin (β-HCG) is elevated in choriocarcinoma and embryonal carcinoma and in approximately 10% to 15% of SGCTs.[113] Serum α-fetoprotein is elevated in endodermal sinus tumors and embryonal carcinomas. These tumors often present as large masses in the retroperitoneum and frequently displace, compress, or encase abdominal vessels. There are no distinguishing features by imaging to differentiate germ cell tumors from other retroperitoneal masses; thus, image-guided biopsy is necessary. Gonadal primaries must be ruled out using high-resolution ultrasound.[114] A biopsy of the gonads appears to be unnecessary in the presence of a negative ultrasound. Common sites of metastases are liver, bone, brain, and lungs. The prognosis of retroperitoneal SGCTs and their mediastinal counterparts are similar; however, retroperitoneal NSGCTs actually have a better prognosis than those occurring in the mediastinum.[111]

TABLE 79.6 The International Germ Cell Cancer Collaborative Group Classification System for Assessing Prognosis in NSGCT and SGCT[115]

Tumor	Good Prognosis	Intermediate Prognosis	Poor Prognosis
NSGCT	• Testis/retroperitoneal primary, no nonpulmonary visceral metastases, AFP <1,000 ng/mL, *β*-hCG <1,000 IU/L, and LDH <1.5 × upper limit of normal • 5-y PFS, 89% • 5-y survival rate, 92%	• Testis/retroperitoneal primary, no nonpulmonary visceral metastases, AFP >1,000 ng/mL and <10,000 ng/mL and/or *β*-hCG 5,000–50,000 IU/L and/or LDH >1.5 × normal to 10 × normal • 5-y PFS, 75% • 5-y survival rate, 92%	• Indicated by any of the following: mediastinal primary, nonpulmonary visceral metastases or AFP >10,000 ng/mL, *β*-hCG >50,000 IU/L, or LDH >10 × normal • 5-y PFS, 41% • 5-y survival rate, 48%
Seminoma	• Any primary site, no nonpulmonary visceral metastases, normal AFP, any *β*-hCG, any LDH • 5-y PFS, 92% • 5-y survival rate, 88%	• Any primary site, nonpulmonary visceral metastases, normal AFP, any *β*-hCG, any LDH • 5-y PFS, 67% • 5-y survival rate, 72%	• No patients classified as having poor prognosis

The treatment for EGCTs has evolved over past 10 to 15 years from the use of primary radiotherapy for SGCTs to the more commonly recommended treatment of platinum-based chemotherapy regimens.[111] Treatment paradigms for early-stage SGCT and NSGCT are covered elsewhere in this book. The International Germ Cell Cancer Collaborative Group established a classification system for assessing prognosis in NSGCT and SGCT[115] (Table 79.6), which is used to guide treatment decisions. For patients with a retroperitoneal SGCT, the preferred treatment approach is systemic chemotherapy using a cisplatin-based regimen similar to a patient with advanced testicular SGCT. In an international retrospective review of EGCTs, patients with retroperitoneal SGCTs had an overall survival of approximately 90% with the majority of patients treated with chemotherapy alone.[111] Patients treated with primary radiation therapy had an inferior progression-free survival compared to patients treated with either chemotherapy alone or chemotherapy plus radiation therapy.[111] For retroperitoneal NSGCTs, the preferred treatment is also cisplatin-based

chemotherapy as in a testicular NSGCT with the number of cycles dependent on if the patient is in the good or intermediate/poor prognosis group (Table 79.6). Residual masses should then be resected. In the international retrospective review of EGCTs, patients with retroperitoneal NSGCTs were primarily treated with primary chemotherapy with 45% of patients undergoing a secondary surgery for residual disease.[111] The 5-year overall survival for patients with retroperitoneal NSGCTs was 62%.[111]

CONCLUSIONS

The retroperitoneum is a challenging space for clinicians with a wide variety of possible histologies and adjacent normal tissues limiting therapeutic options. Advances in imaging have improved the ability to characterize these lesions, although ultimately, a histologic diagnosis is necessary. In general, treatment is driven by histology. For the majority of neoplasms in the retroperitoneum, evaluation by a multidisciplinary team is necessary. Radiation therapy technology advances, including the use of intensity-modulated radiation therapy and particle therapy, have improved the ability to deliver a therapeutic radiation dose to the tumor in this challenging space while sparing abutting organs at risk. Although much progress has been made with advances in surgery, systemic therapy, and radiation therapy, patient outcomes remain poor, thus, additional advancements need to be made including more prospective multi-institutional studies.

CHAPTER 80

Adrenal Cancer

Filip T. Troicki and John J. Coen

ANATOMY

The paired suprarenal (adrenal) glands are located between the superomedial aspects of the kidney and the diaphragmatic crura. They are surrounded by connective tissue containing perinephric fat. The glands are enclosed by renal fascia but separated from the kidneys by fibrous tissue. The triangular right gland relates to the diaphragm posteriorly and the inferior vena cava and liver anteriorly. The semilunar left adrenal gland is positioned in the middle of the left crux of the diaphragm. The omental bursa separates it from the stomach. It is also related to the spleen and pancreas.[1]

The endocrine function of the adrenal glands necessitates an abundant blood supply. The superior suprarenal arteries are derived from the inferior phrenic artery, the middle suprarenal arteries from the abdominal aorta near the origin of the superior mesenteric artery, and the inferior suprarenal arteries from the renal artery. A large central vein leaves the anterior surface of the gland at the hilum. The shorter right suprarenal vein drains into the inferior vena cava, and the longer left suprarenal vein drains into the left renal vein.[1]

The lymphatic drainage follows the arterial supply and is predominantly to lumbar lymph nodes. The superior lymphatic trunks end in aortocaval lymph nodes located near the origin of the celiac plexus. The inferior lymphatic trunks end in lateroaortic nodes above the renal pedicle. Some trunks may pass through the diaphragm, following the splanchnic nerves, ending in retroaortic nodes in the posterior mediastinum. On the right, some lymphatic trunks may penetrate the liver.[2]

The adrenal gland is composed of a central catecholamine-producing medulla enveloped by the steroid-secreting cortex. Although they are in intimate contact, they represent two functionally separate organs with different embryologic origins.

EPIDEMIOLOGY

Adrenal Cortical Tumors

Adrenocortical tumors are rare. Benign tumors are more common, occurring in 1% to 8% of the general population, and the incidence of carcinoma is approximately 1 per million population in the United States.[3,4] There are approximately 75 to 115 new cases per year.[5] Adrenal cortex carcinoma deaths account for 0.2% of all yearly cancer deaths. There is a bimodal age distribution with disease peaks before the age of 5 years and in the fourth to fifth decades of life.

Overall, adrenocortical carcinoma (ACC) is slightly more common in women than in men. Nonfunctional carcinomas occur in an older age population (>30 years old) and are more common in men (3:2 male-to-female ratio), although functional tumors are more common in women (7:3 female-to-male ratio) and younger patients. As they frequently present with symptoms related to hormone production, functional tumors are usually detected at an early stage.

Although most cases of ACC are sporadic, it has been described as a component of several hereditary cancer syndromes, including Li-Fraumeni syndrome (breast cancer, soft tissue and bone sarcoma, brain tumors, and ACC), Beckwith-Wiedemann syndrome (Wilms tumor, neuroblastoma, hepatoblastoma, and ACC), multiple endocrine neoplasia type I (MEN-I) (parathyroid, pituitary and pancreatic neuroendocrine tumors, and adrenal adenomas and carcinomas), and SBLA syndrome (sarcoma, breast, lung, ACC, and other tumors).[6–9] A role for p53 mutations in sporadic ACC is suspected.

Adrenal Medulla Tumors

Ganglioneuromas are rare, benign tumors of the adrenal medulla seen in children and young adults.[10,11] Neuroblastoma is the most common malignant tumor of the adrenal gland in children, accounting for 90% of all cases.[3,12]

Pheochromocytomas and functional ganglioneuromas (or extra-adrenal pheochromocytomas) are rare tumors that rise from chromaffin cells in the adrenal medulla and elsewhere. They secrete catecholamines and cause intermittent, episodic, or sustained hypertension. Pheochromocytomas have an estimated prevalence of 0.1% in hypertensive patients.[13] In autopsy series, there is a 0.01% to 0.1% prevalence of unsuspected pheochromocytomas. Extra-adrenal tumors are more commonly malignant.[14] Estimates of the incidence of malignancy in pheochromocytoma range from 5% to 46% in different series.[15,16]

Approximately 400 new cases of malignant pheochromocytomas are expected each year in the United States.[17,18]

Pheochromocytomas may be associated with a variety of endocrine and nonendocrine inherited disorders. Bilateral pheochromocytomas are a component of multiple endocrine neoplasia type IIa (MEN-IIA) syndrome (pheochromocytoma, medullary thyroid carcinoma, and parathyroid hyperplasia) or MEN-IIB syndrome in which they are associated with marfanoid habitus, mucosal neuromas, and medullary thyroid carcinoma. Pheochromocytomas occur in 25% of patients with von Hippel-Lindau syndrome and <1% of patients with neurofibromatosis and von Recklinghausen disease.[19,20]

NATURAL HISTORY

Fifty-nine percent of adrenal cortex tumors are functional, the left-to-right ratio is approximately 1:1, and 2.4% are bilateral.[21] Diagnosis is frequently delayed because of the rarity of disease and the deep retroperitoneal location of the adrenal glands.[22]

Nonfunctioning ACCs are typically larger tumors, >6 cm, whereas functioning tumors tend to be discovered at an earlier stage (for TNM staging, see Table 80.1). Incidentally discovered adrenal masses <3 cm are rarely malignant. ACC is an aggressive malignancy that frequently violates the tumor capsule and invades surrounding tissues. It metastasizes to lungs, liver, brain, and regional lymph nodes. Many patients present with widespread metastasis; most of these patients die within 6 months of diagnosis. This situation is especially common in the pediatric population. For all stages, the 5-year overall survival is only 20% to 25%.[22]

Malignant pheochromocytomas exhibit a similar pattern of spread but also metastasize to bone. They are equally common in men and women. The average age of presentation is 40 to 50 years old, but these carcinomas may also occur in children.

CLINICAL PRESENTATION

Functional adrenocortical tumors most frequently secrete cortisol and androgens, resulting in Cushing syndrome, virilization, and hypertension. Estrogen or aldosterone production is less common. Approximately 60% of ACCs are functional. In a child, virilization is the most common symptom of ACC, and Cushing syndrome is relatively uncommon. By contrast, adults usually present with either Cushing syndrome alone or mixed with virilization. Patients with nonfunctioning tumors present with nonspecific symptoms related to tumor burden, including abdominal fullness, early satiety, pain, weight loss, weakness, fever, or an abdominal mass. Nonfunctioning ACCs are more common in older patients and tend to progress more rapidly. An increasing number of adrenal tumors are incidentally discovered during abdominal imaging in the absence of any symptoms.

Pheochromocytomas arising in the setting of an inherited disorder occur in the adrenal medulla in 90% of cases, as compared with 75% of sporadic pheochromocytomas. When associated with MEN-II syndromes, 80% are bilateral. A tumor >5 cm more commonly has a malignant course than a smaller lesion. Serum catecholamines and urinary metanephrine and vanillylmandelic acid levels are elevated in 90% of pheochromocytomas. These patients present with a range of symptoms from mild labile hypertension to sudden cardiac death secondary to hypertensive crisis, myocardial infarction, or cerebrovascular accident. The classic triad of symptoms consists of episodic headaches, diaphoresis, and tachycardia.[8,23] About half of patients have paroxysmal hypertension, and others have sustained hypertension. Pheochromocytomas may also present with normal blood pressure in 5% to 15%. Other symptoms may

include pallor, palpitations, panic attack symptoms, or generalized weakness. Orthostatic hypertension may occur in association with hypovolemia.

DIAGNOSTIC WORKUP AND STAGING

Patients with adrenal gland tumors should be evaluated for other primary tumors, because metastasis to the adrenal gland is common. In metastatic tumors that are not adrenal in origin, a biopsy is recommended. Prior to obtaining a biopsy, however, pheochromocytomas must be ruled out by measuring the fractionated plasma-free metanephrine, as well as the 24-hour urine fractionated metanephrines and catecholamines. Low suspicion for pheochromocytoma either clinically or biochemically should steer providers toward obtaining an adrenal biopsy. Furthermore, any patient with a suspected adrenal tumor should be screened for hormonal hypersecretion, including cortisol, aldosterone, and catecholamine secretion (Table 80.2). As hypercortisolism is the most frequent abnormality, serum cortisol, a 24-hour urinary cortisol, and an overnight dexamethasone suppression test should be obtained.

TABLE 80.2 DIAGNOSTIC WORKUP FOR ADRENAL TUMORS

Complete blood count, blood chemistry, urinalysis
Serum and urine cortisol (adrenal cortical tumors)
Serum and urine catecholamines (pheochromocytoma)

CT, computed tomography; MRI, magnetic resonance imaging.

Morphologic evaluation of the adrenal glands with computed tomography (CT) of the abdomen should be performed as per adrenal protocol. CT of the abdomen with thin cuts through the adrenal gland is the imaging test of choice for the evaluation of adrenal tumors. Carcinomas can mimic adenomas but are

characterized by larger size, irregular margins, and heterogeneous enhancement. They may also demonstrate tumor necrosis and cystic degeneration. Local invasion, tumor extension into the vena cava, as well as lymph node or other metastases are often seen in advanced ACC. Magnetic resonance imaging (MRI) is useful in the evaluation of adrenal tumors (Fig. 80.1). ACC and pheochromocytomas are hyperintense on T2-weighted images, and venous invasion is better imaged on MRI. If there is still question of vascular invasion, an angiographic study can be performed preoperatively, either selective arteriography or vena cavography. Fluorodeoxyglucose positron emission tomography may be useful in differentiating benign from malignant lesions. It may also serve as an additional staging study for patients with known ACC. A chest CT should also be performed.

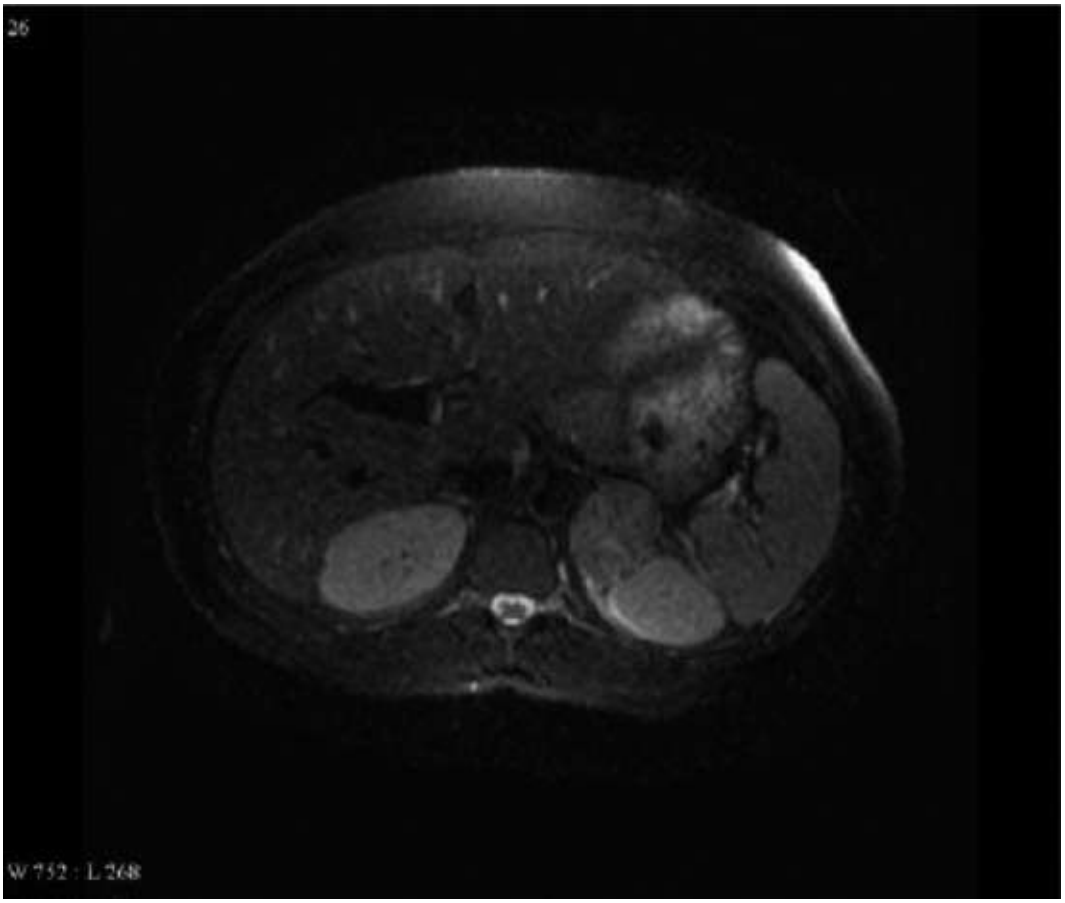

FIGURE 80.1. T2-weighted magnetic resonance image of a 35-year-old woman with a left adrenal carcinoma.

Evaluation of the patient's adrenal function is indicated if there is no suspicion of adrenal metastasis. Workup for hyperaldosteronism, Cushing

syndrome, and pheochromocytoma should be performed when clinically indicated. The diagnosis of pheochromocytoma is confirmed by measurements of urinary and plasma fractionated metanephrines and catecholamines. Medication-induced elevation of metanephrine levels is common and should be evaluated prior to initiating further costly workup. Levels of metanephrine four times the normal limit are diagnostic of pheochromocytoma, and biochemical confirmation of disease is followed by imaging to locate the tumor. Other scans, including the OctreoScan (Mallinckrodt Inc., St. Louis, MO) and a bone scan, may be indicated if metastatic disease is suspected.

Levels of plasma aldosterone (high) and renin (low) activity should be assessed when suspecting primary aldosteronism (hyperaldosteronism). The ratio of aldosterone to renin above 30 is suggestive of hyperaldosteronism and should be confirmed with saline suppression or salt loading tests, and electrolytes should be measured. Although malignant hyperaldosteronism is rare, these patients require an open adrenalectomy to prevent tumor rupture. In benign cases of hyperaldosteronism, adrenal vein sampling for aldosterone is considered standard of care.

Patients with Cushing syndrome require an evaluation of serum levels of corticotropin, cortisol, as well as the sex steroid dehydroepiandrosterone sulfate (DHEA-S). If cortisol levels are elevated, a confirmatory test with dexamethasone suppression is recommended. It is important to remember that elevated corticotropin levels do not indicate adrenal origin, and further workup is necessary to look for primary causes of increased corticotropin. Benign adrenal tumors can be removed laparoscopically. Patients who present with Cushing syndrome in the presence of large (>4 cm), inhomogeneous, or invasive masses should be suspected to have malignant tumors, and imaging of the chest, abdomen, and pelvis is warranted to look for metastasis.

Pathologic Classification

Tumors <6 cm are more likely adenomas, although some smaller tumors may be malignant (Table 80.3). In order to establish stability of an adrenal mass, imaging should be repeated in 6 to 12 months for benign-appearing adenomas measuring <4 cm, and 3 to 6 months for larger lesions up to 6 cm. Hemorrhage and necrosis may be observed macroscopically in carcinomas. Numerous mitotic figures and cellular undifferentiation are common microscopic findings. Larger size, vascular invasion, or invasion of surrounding tissues and numerous mitotic figures are poor prognostic features.[24]

Pheochromocytomas have malignant features in <10% of cases. Macroscopically, they tend to be encapsulated with areas of cystic change, hemorrhage, and necrosis. The capsule is frequently invaded, but that does not constitute malignant change. Benign and malignant pheochromocytomas may appear identical histologically. The only absolute criterion for malignancy is metastasis.[9] Histologically, cell size, nuclear size, and arrangement of cells are variable. A twisted cell cord pattern, basophilic or cytophilic staining with fine intracytoplasmic pigment granules, and periodic acid–Schiff staining of secretory droplets aid in the diagnosis.

GENERAL MANAGEMENT

Benign tumors are nonfunctioning and are most often found incidentally. After the benign nature of these tumors is confirmed, small tumors can be left untreated and can be followed up by repeat imaging 6 to 12 months after diagnosis to confirm their stability. Larger tumors (>4 cm) should be followed up with imaging in 3 to 6 months after diagnosis. A small benign mass that grows at the rate of >1 cm/year can be removed electively, but any significant growth of a larger mass should alert the clinician to a potentially malignant nature of the tumor and adrenalectomy is recommended in that case.

Nonfunctioning adrenal tumors that are >4 cm, are heterogeneous, or have irregular margins are suspicious for adrenal carcinomas. Surgery with removal of

adjacent lymph nodes is the primary treatment for ACC. Complete resection, such as an open adrenalectomy, is the only treatment that offers long-term disease-free survival, but it is not always feasible.[25] For patients with a macroscopically complete resection, a margin-free resection is a strong predictor for survival. Efforts to avoid tumor spillage are warranted, and the tumor capsule should remain intact. Invasion or adherence of adjacent structures often necessitates *en bloc* resection of the kidney or spleen, partial hepatectomy, or pancreatectomy. The presence of tumor thrombus in the renal vein or vena cava does not preclude resection. A lymphadenectomy is often included. An extensive regional lymph node dissection has not been shown to have any impact on overall survival (OS) or disease specific survival (DSS).[26] For patients with localized disease who have high-risk features, such as positive margins, rupture of capsule, high grade, or large size, postoperative radiation should be considered. The role of tumor debulking in the presence of metastatic disease is not clear. Incomplete resection of the primary tumor or metastatic disease not amenable to surgery is associated with a poor prognosis. Still, tumor debulking may help control hormonal oversecretion or relieve local symptoms in certain cases. Even with a complete resection, local recurrence and metastatic disease are common. For isolated distant metastases and locally unresectable disease, cytoreductive resection with or without radiation is recommended.

The role of radiation in the management of ACC is not well defined. It has been proposed as adjuvant therapy in high-grade adrenal carcinoma as well as after complete resection or as management of microscopic residual disease. One series reports a 10-year crude survival rate of 33% for surgical resection followed by adjuvant radiation.[27] External radiation results in good response rates and effective palliation in patients with residual macroscopic disease or bone or nodal metastasis.[18,28]

Mitotane, a chemical congener of the insecticide DDT (dichlorodiphenyltrichloroethane), is an adrenolytic compound with specific activity on the adrenal cortex. It is the chemotherapeutic agent most commonly used in the management of ACC. In patients with measurable disease, overall response rates of 14% to 36% have been reported, but most studies have reported no significant survival benefit.[29] The largest retrospective study from Italy and Germany that included 177 patients with resected ACC (stages I to III) showed improvements in disease-free survival and overall survival.[30] Unfortunately, responses are usually partial and transient, with only an occasional complete remission.[21] The role of mitotane as adjuvant therapy after complete surgical

resection is questionable. Despite limited supporting data, it is frequently employed in this setting, given the high rates of locoregional and distant recurrence. Serum levels of mitotane are monitored in order to optimize therapy because objective response in the metastatic setting was associated with higher serum levels (>14 mg/L). Unfortunately, increased toxicity is also associated with higher serum levels. Side effects are predominantly gastrointestinal, particularly nausea, but anorexia and diarrhea also occur. Although less common, central nervous system toxicity can include lethargy, somnolence, ataxia, dizziness, or confusion.

Single-agent chemotherapy has proven disappointing in the management of ACC. Doxorubicin and cisplatin have both been evaluated as single-agent therapy and in combination with mitotane. Neither drug was efficacious.[31] Multiagent chemotherapy has shown more promise. A multicenter phase II study by the Italian Group for the Study of Adrenal Cancer demonstrated 49% overall response rate using a regimen of etoposide, doxorubicin, and cisplatin in combination with mitotane. The regimen was well tolerated. The most common side effects were gastrointestinal. The time to progression in responding patients was 2 years.[6] Inclusion of mitotane in a multidrug regimen is rational as ACCs are prone to multidrug resistance mediated by the multidrug resistance-1/P glycoprotein drug pump, whose mechanism is inhibited by mitotane. This multidrug regimen is worthy of further study.

Surgical resection is the definitive management of pheochromocytoma, but it is a high-risk procedure. Cardiovascular and hemodynamic parameters must be monitored closely. Preoperative medical therapy is aimed at controlling hypertension and expanding intravascular volume. Preoperative pharmacologic preparation typically includes combined α- and β-adrenergic blockade.

In patients with undiagnosed pheochromocytomas who undergo surgery for other reasons, surgical mortality rates are high because of lethal hypertensive crisis and multiorgan failure.[32] In the largest series of 147 patients undergoing surgery for pheochromocytoma, perioperative mortality and morbidity rates were 2.4% and 24%, respectively.[33] Although it results in rapid symptomatic control, surgical removal of a pheochromocytoma does not always lead to a longtime cure. In a large series of 176 patients, pheochromocytoma recurred in 16% of patients. Half of these recurrences were malignant.[34] In patients with bilateral pheochromocytomas, usually in the setting of an inherited syndrome, bilateral adrenalectomy is recommended. Hormone replacement is required in this setting. Although not curative, debulking surgery for control of symptoms is the

primary therapy for malignant pheochromocytoma.

The radioisotope iodine-131 metaiodobenzylguanidine (^{131}I-MIBG) has been used as a therapeutic agent in malignant pheochromocytomas that demonstrate avid uptake of the agent. Investigators have reported partial responses, based on biochemical response as well as decreased tumor volume, ranging from 18% to 82%.[35–37] Symptomatic improvement was observed in responding patients with regard to both painful metastases and manifestations of increased catecholamine levels. Partial remissions are usually temporary, with some patients relapsing between doses of MIBG. In other patients, sustained partial remissions have been noted with durable palliation extending 2 to 3 years.[36,38] Prolonged survival has been associated with measurable responses and higher administered doses of MIBG (>500 mCi).[39] Toxicity includes bone marrow toxicity (particularly thrombocytopenia), nausea, and vomiting.

Combination chemotherapy with cyclophosphamide, vincristine, and dacarbazine has shown efficacy in a small study. In 14 treated patients, the clinical and biochemical response rates were 57% and 79%, respectively. Response was associated with objective improvement in performance status and blood pressure, and treatment was well tolerated.[40]

RADIATION THERAPY TECHNIQUES

The role of radiation in the management of ACC is controversial. Locoregional disease control remains a major problem in this disease, and some reports suggest that external radiation may reduce recurrence rates.

In the primary management of ACC, external radiation may play a role preoperatively for unresectable tumors, postoperatively for patients with residual disease or high risk of local failure, or as definitive therapy for patients who are medically unfit for surgery. Radiation is also effective in the palliative setting for bone and nodal metastases.

For patients with macroscopic or unresectable disease, doses of 50 to 60 Gy delivered during 5 to 6 weeks should be considered. Initial fields should encompass the gross tumor with adequate margins as well as the regional lymph nodes, which should include the contralateral para-aortic lymph nodes. Dose to regional nodes can be limited to 45 Gy when they are not macroscopically involved. Care should be taken to limit dose to the spinal cord, kidneys, liver, and small bowel. For macroscopic disease for which high dose is desired, conformal techniques and intensity-modulated radiation should be considered.

For patients receiving postoperative treatment for high-risk or microscopic disease, doses of 45 to 54 Gy are appropriate. The role of stereotactic body radiotherapy (SBRT) for primary adrenal tumors has not been established, although it's gaining popularity for metastatic disease to the adrenal gland. A handful of case series have shown potential efficacy of SBRT for primary adrenal tumors that are unresectable because of comorbidities or patient preference. SBRT utilization for oligometastatic disease to the adrenal gland is increasing across institutions. The popularity of SBRT is mainly based on results of case series and retrospective reviews, which show good local control rates ranging from 60% to 70% at year 1 and between 40% and 50% at year 2.[41] No prospective randomized trials are available to compare the efficacy of SBRT against a surgical resection.

In the palliative setting, doses of 30 to 40 Gy given during the course of 2 to 3 weeks are reasonable. In patients with painful bone metastases, hypofractionated regimens should be considered for patients with poor performance status or otherwise limited life expectancy.

External beam radiation is limited to a palliative role in the management of pheochromocytomas.

FOLLOW-UP

Patients with pheochromocytomas should have frequent follow-up that includes a thorough history and physical examination with an evaluation of vital signs and plasma markers. This should be done every 6 months for the first 3 years starting around 3 months postsurgery and annually thereafter. Advanced or persistent disease may require more frequent follow-up and symptom management.

Lymphoma and Hematologic Tumors

CHAPTER 81

Hodgkin Lymphoma

Richard T. Hoppe and Bradford S. Hoppe

INTRODUCTION

The management of Hodgkin lymphoma (HL) continues to evolve. Since the last edition of this text, functional imaging has become standard for initial staging and end-of-treatment response evaluation as well as to assess early response to therapy and define adaptive approaches to therapy intensification and deintensification. Recent clinical trials in adaptive therapy have established a role for chemotherapy alone in early-stage disease following a favorable response on interim positron emission tomography (PET). New, more precise techniques for radiation therapy delivery have been devised and adopted, and guidelines for radiation field design have been endorsed by professional societies. New systemic agents have been approved by the U.S. Food and Drug Administration. Large prospective, randomized clinical trials have allowed us to refine treatments, and data regarding late effects continue to influence the development of management approaches.

ANATOMY

HL almost always begins in the lymph nodes. Over 80% of patients present with cervical lymph node involvement and over 50% have mediastinal disease. Disease can extend into extralymphatic sites, such as lung, pericardium, and soft tissue, but solitary extralymphatic involvement without nodal disease is rare.

EPIDEMIOLOGY AND RISK FACTORS

The reported incidence of HL is just below 3 per 100,000 with a slight male predominance (1.2:1). It accounts for 0.56% of all cancers diagnosed, but only 0.23% of all cancer deaths in the United States each year, a death rate that decreased by more than one-third between 1990 and 2006 (0.85 per 100,000 to

0.56 per 100,000).[1] Although HL is rare in children <10 years of age, it is the most common diagnosed malignancy among 15- to 19-year-olds.[2] The median age of patients at the time of diagnosis is 26 years. Its incidence shows a bimodal peak as a function of age.[3] The early peak, from ages 25 to 30 years, shows an incidence of approximately 5.5 per 100,000 per year. A second peak, from age 75 to 80 years, shows a similar incidence.

Geographic clusters of patients with HL have been reported, but these are likely coincidental.[4] Inherited risk has also been reported among first-degree relatives.[5,6] A relation between HL and previous infection with Epstein-Barr virus (EBV) has been proposed,[7] and Weiss et al.[8] identified components of the EBV genome in the cellular DNA of Reed-Sternberg (R-S) cells in lymph nodes involved by HL. The risk for development of HL is 2.55 times higher among individuals with a history of infectious mononucleosis than among noninfected control subjects.[9] Several series have demonstrated an association between EBV infection and mixed cellularity HL (MCHL), especially among children in developing countries.[10] However, the precise relationship between EBV infection and development of HL remains undefined. Recently, data have emerged suggesting that people with human immunodeficiency virus and AIDS are at a higher risk of developing HL.[11] Studies attempting to link occupational exposures or other etiologic factors with the development of HL have been inconclusive or contradictory.[4]

NATURAL HISTORY AND CLINICAL PRESENTATION

Patients with HL usually present with painless lymphadenopathy. Some note systemic symptoms such as unexplained fevers, drenching night sweats, weight loss, generalized pruritus, fatigue, and alcohol-induced pain in tissues involved by HL. Still other patients are diagnosed after detection of a mediastinal mass on a routine chest radiograph.

Sites of involvement are typically contiguous, although occasional skip areas occur.[12,13] The theory of contiguity of spread and the development of treatment programs with radiation that included treatment of uninvolved sites were important conceptual advances in the treatment of HL in the latter half of the 20th century.

HL can extend from the lymph nodes to adjacent organs, as when it spreads from enlarged mediastinal or bronchopulmonary (pulmonary hilar) nodes directly into the pulmonary parenchyma. It can also be hematogenous, as with

nodular disease in the liver or multiple bony sites. Involved bones can undergo blastic changes, especially those in the vertebrae (creating the classic "ivory vertebra" on plain radiographs), pelvis, sternum, or ribs.

The likelihood of disseminated disease, including bone marrow and liver involvement, increases with increased splenic involvement.[14,15] HL rarely involves the Waldeyer lymphoid region or the gut-associated lymphoid tissues such as Peyer patches. It also rarely involves the upper aerodigestive tract, central nervous system, and skin.[12]

The rapidity of HL's growth and spread varies. Disease can evolve over several years, as demonstrated on serial radiographs or suspected by clinical history, and it is uncommon to document progression during evaluation and staging.

Three "B symptoms" are included as part of the staging system for HL (see later discussion). They are fever, drenching night sweats, and significant weight loss (10% of baseline weight). One-third of patients present with 1 of these symptoms. Fevers may present in the classic waxing-and-waning Pel-Ebstein pattern. Drenching night sweats may require a change of bedclothes. The B symptoms can occur even in patients with relatively limited disease (stage II), but they are uncommon in stage I disease.

Historically, children fare better with treatment than adults, so different treatment strategies have been developed for children (see Chapter 93).[16,17] More recently, results from adult treatment programs have been as successful as those in children. Older adults (>60 years) have a worse prognosis, often secondary to intercurrent illness or an inability to tolerate standard therapies, especially bleomycin, anthracyclines, and extended-field irradiation.[18,19] In fact, a recent report of older adults demonstrated a 5% treatment-related mortality rate following four cycles of ABVD (doxorubicin, bleomycin, vinblastine, dacarbazine).[19]

If HL is diagnosed during pregnancy, special treatment considerations are warranted; however, no evidence exists that pregnancy affects the natural course of the disease.[20–22] Many women become pregnant after successful treatment. Among patients infected with human immunodeficiency virus type 1, HL tends to behave differently, with a poorer prognosis.[23,24]

DIAGNOSTIC WORKUP

Diagnostic and staging procedures commonly used for HL are listed in Table

81.1. Patient age and intercurrent disease may influence the selection of staging studies.[25–27]

Hematologic evaluation may reveal anemia, leukocytosis, lymphopenia, or thrombocytosis, common paraneoplastic effects stimulated by cytokines. Anemia, lymphopenia, leukocytosis, and hypoalbuminemia are adverse prognostic factors, especially in patients with advanced disease (stages III to IV).[28] The serum alkaline phosphatase level can serve as a nonspecific marker of tumor activity or hepatic, bone marrow, or bone disease. The erythrocyte sedimentation rate (ESR) is a prognostic factor for patients with limited disease (stages I to II).[29] Other useful markers include lactate dehydrogenase and β_2-microglobulin levels.

Radiographic evaluation should include posterior–anterior (PA) and lateral chest radiographs. Mediastinal adenopathy can be measured by dividing the maximum width of the mediastinal mass by the maximum intrathoracic diameter (near the level of the diaphragm) on a standing PA chest radiograph, as shown in Figure 81.1. When this ratio exceeds 1:3, the disease is defined as bulky, which affects assignment to many clinical trials. Other definitions of bulky mediastinal adenopathy include a mass >10 cm and a ratio of mediastinal mass to the chest diameter at T5-T6 exceeding 0.35 (employed in European Organization for the Treatment of Cancer [EORTC] clinical trials). Contrast-enhanced (diagnostic) computed tomography (CT) scans of the chest, abdomen, and pelvis may reveal adenopathy or organ involvement. If irradiation to the cervical nodes is being considered, a CT scan of the neck can help identify their precise location for treatment planning. Lymph nodes larger than 1.5 cm on CT scan are considered enlarged.[27] Although splenomegaly or hepatomegaly alone do not suggest involvement of HL (in the absence of confirmatory findings on a contrast-enhanced CT scan or 2-fluoro-2-deoxy-D-glucose (FDG)-PET scan), a spleen over 13-cm long is considered likely involved per the current staging system.[27]

TABLE 81.1 DIAGNOSTIC AND STAGING PROCEDURES FOR HL

History

Systemic B symptoms: unexplained fever, drenching night sweats, weight loss >10% of body weight in the last 6 mo.

Other symptoms: alcohol intolerance, pruritus, respiratory problems, fatigue

Physical Examination

Palpable nodes (note number, size, location, shape, consistency, mobility)

Palpable viscera

Laboratory Studies

Complete blood count, differential, platelets
ESR
Serum albumin, lactate dehydrogenase, liver function studies
Blood urea nitrogen, creatinine
If indicated:
- Pregnancy test in women of child-bearing age
- Pulmonary function studies
- Cardiac ejection fraction
- HIV testing

Imaging

Chest radiograph: posterior–anterior and lateral
Contrast-enhanced CT scan of thorax, abdomen, and pelvis
Contrast-enhanced CT scan of the neck (if neck irradiation is indicated)
Integrated PET-CT scan (skull base to midthigh)

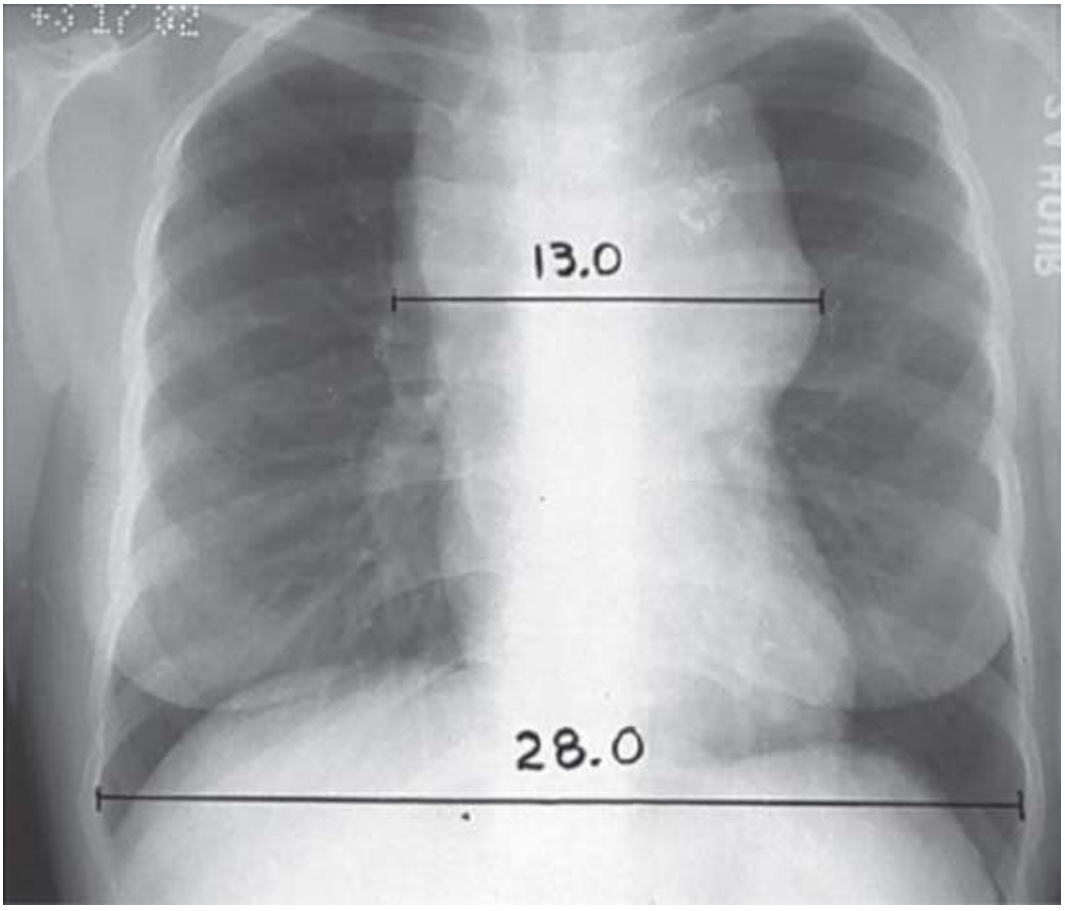

FIGURE 81.1. The mediastinal mass ratio (MMR). This ratio is defined as the maximum single horizontal mediastinal mass measurement divided by the maximum intrathoracic diameter, which is usually near the diaphragm. In this example, MMR = 13.0/28.0 = 0.46.

PET using FDG with fused CT images (PET-CT scan) has become essential

to staging HL. Omitting PET-CT as part of staging can negatively influence outcomes, especially as they pertain to designing radiation treatment fields.[30] Tissues affected by HL are intensely FDG-avid, and FDG-PET is more sensitive than CT for detecting disease.[31] FDG's uptake pattern in bone defines whether bone or bone marrow is involved, obviating the need for a bone marrow biopsy.[32,33] The overall incidence of bone marrow involvement in HL is only approximately 5%.

PET-CT is an essential study for response assessment, is particularly useful for evaluating residual masses detected by CT scanning, and can be a useful prognostic indicator when repeated after some chemotherapy has been administered (*vide infra* interim PET-CT).[26,27] The 5-point Deauville score is used to evaluate the degree of response to therapy, based on the comparison of active disease to levels in the liver and mediastinal blood pool (Table 81.2).

TABLE 81.2 DEAUVILLE FIVE-POINT SCALE FOR ASSESSING TREATMENT RESPONSE ON PET-CT

Score	PET-CT Scan Result
1	No uptake
2	Uptake ≤ mediastinum
3	Uptake > mediastinum but ≤ liver
4	Uptake moderately higher than liver
5	Uptake markedly higher than liver and/or new lesions
X	New areas of uptake unlikely to be related to lymphoma

PET-CT, positron emission tomography–computed tomography.

TABLE 81.3 THE ANN ARBOR STAGING CLASSIFICATION FOR HODGKIN DISEASE

Stage I	Involvement of a single lymph node region
Stage II	Involvement of two or more lymph node regions on the same side of the diaphragm (II) or localized involvement of an extralymphatic organ or site and one or more lymph node regions on the same side of the diaphragm (IIE)
Stage III	Involvement of lymph node regions on both sides of the diaphragm (III), which can be accompanied by involvement of the spleen (IIIS) or by localized involvement of an extralymphatic organ or site (IIIE) or by both (IIISE)
Stage IV	Diffuse or disseminated involvement of one or more extralymphatic organs or tissues, with or without associated lymph node involvement

Note: The absence or presence of fever, night sweats, and/or unexplained loss of 10% or more body weight in the 6 mo before diagnosis is denoted by the suffix letter A or B, respectively.

The Cotswolds system used X to designate bulky disease, variably defined, but including a mediastinal mass width exceeding 1/3 of the thoracic ratio at the T5-T6 interspace and any disease >10 cm.[35] The Lugano system recommended deleting X and instead noting the size of the largest node.[27]

Although not widely used, magnetic resonance imaging (MRI) is an alternative to chest or abdominal–pelvic CT scanning for initial staging. Its main value is in the staging evaluation of pregnant women (without contrast) and children. Furthermore, it can be incorporated with FDG-PET to generate fused PET-MRI scans.[21,34]

STAGING

The Ann Arbor staging system for HL, used since 1971, was modified in the Cotswolds, England, in 1989[35] and in Lugano, Switzerland, in 2014[27] (see Table 81.3).[36] The lymphoid regions as defined in the Ann Arbor staging system are shown in Figure 81.2. Although somewhat arbitrary in their borders, these definitions reliably describe the extent of disease and help define clinical risk groups for clinical trial assignment. Defining the “E” lesion has always been a challenge. The Cotswolds system attempts to clarify it as direct disease extension from any nodal site that can be encompassed by a radiation field; however, some scenarios are more complex.[37] The final stage reflects the distribution of disease as observed on physical examination and imaging studies, with or without B symptoms.

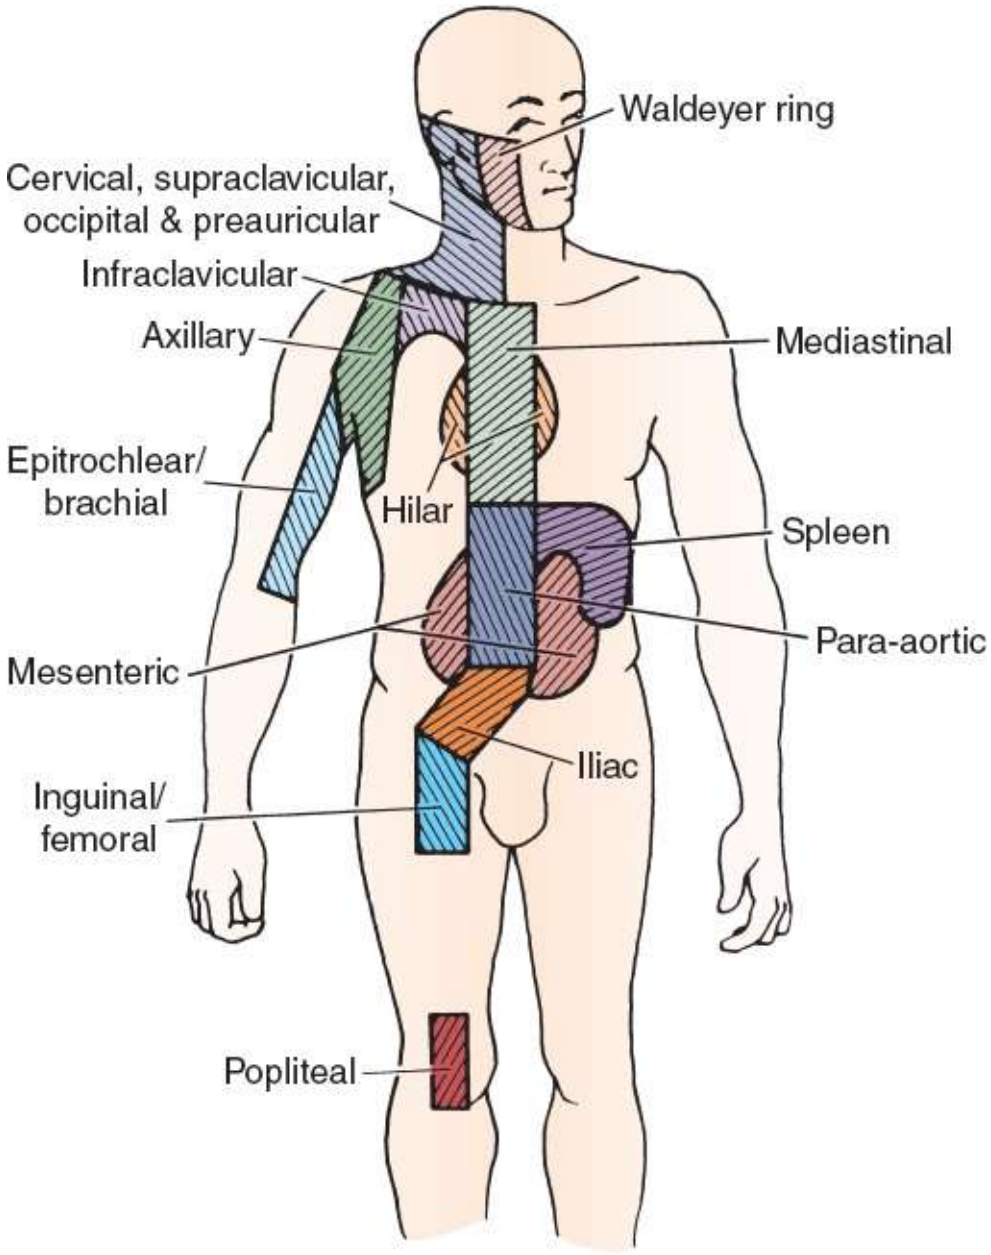

FIGURE 81.2. The lymph node regions as defined in the Ann Arbor staging system. Note that the ipsilateral supraclavicular, cervical, preauricular, and occipital nodes are defined as a single region. The mediastinum and pulmonary hila are defined as separate regions. The infraclavicular region corresponds to the subpectoral nodes. The GHSG and EORTC define the lymph node regions slightly differently. Both combine the hilar and mediastinal regions. The GHSG also combines subpectoral with cervical, whereas the EORTC combines subpectoral with axilla. (Reprinted from Hoppe RT. The non-Hodgkin lymphomas: pathology, staging, treatment. *Curr Probl Cancer* 1987;11[6]:364–434. Copyright © 1987 Elsevier. With permission.)

PATHOLOGIC CLASSIFICATION

The World Health Organization (WHO) defines two major categories of HL:

classic HL and nodular lymphocyte–predominant HL (NLPHL).[38]

Classic HL is characterized by its signature neoplastic cell, the R-S cell. Morphologically, the R-S cell is binucleate with a prominent, centrally located nucleolus in each nucleus, a well-demarcated nuclear membrane, and eosinophilic cytoplasm with a perinuclear halo. R-S cells usually account for <1% of the cells in a lymph node involved by HL. The components of the microenvironment include lymphoid cells, eosinophils, plasma cells, and other normal inflammatory cells.[39]

R-S cells probably originate from B-lineage cells at various stages of development, including pre–B-cell and germinal center B-cell origin. Interactions of these cells with the cells of the microenvironment are complex.[40] In most instances, the R-S cells stain positively with the lymphocyte activation marker CD30, with PAX5 (dimly), and with variable expression of the antigranulocyte monoclonal antibody CD15. CD20, a marker of mature B cells, is expressed on some tumor cells with variable intensity in as many as 40% of cases. They stain negatively with CD45, ALK, and J chain.[41] Nearly all R-S cells express the PD-1 ligand.[41] The expression of CD30 and PDL-1 open opportunities for targeted therapy of classic HL.

Classic HL is divided into four histologic subtypes. *Nodular sclerosis HL* (NSHL) is the most common histologic subtype diagnosed in developed countries. Involved nodes often have a thickened capsule and are traversed by broad bands of birefringent collagen that surround nodules of cells consisting of lymphocytes, eosinophils, plasma cells, and tissue histiocytes intermixed with a variable proportion of atypical mononuclear cells, inflammatory cells, and R-S cells. The syncytial variant of NSHL refers to cases of prominent cellular aggregates of atypical cells and histiocytes. Patients with NSHL typically present in the clinic with mediastinal involvement, and one-third have B symptoms. It is more common among women, especially young ones. The natural history of NSHL is favorable.

Mixed cellularity Hodgkin lymphoma (MCHL) is characterized by lymph nodes that are diffusely effaced by lymphocytes, eosinophils, plasma cells, inflammatory cells, and relatively abundant atypical mononuclear and R-S cells. Patients with MCHL usually present with advanced disease and tend to be slightly older than those with NSHL. The natural history of MCHL is less favorable than that of NSHL.

Lymphocyte-rich Hodgkin lymphoma (LRHL)[42,43] typically has a nodular growth pattern but may be diffuse. In the past, many cases of LRHL were

confused with lymphocyte-predominant HL (LPHL); however, the staining characteristics of the malignant cells in LRHL are consistent with those of classic HL. The clinical characteristics of patients affected by LRHL resemble those of NLPHL: early stage, absence of B symptoms, and excellent prognosis.

Lymphocyte-depleted Hodgkin lymphoma (LDHL) varies in its microscopic appearance but reveals a paucity of normal-appearing cells and an abundance of abnormal mononuclear cells, R-S cells, and R-S variants. Differentiating LDHL from anaplastic large cell lymphoma is challenging, especially because both are CD30 positive.[44] It is an exceedingly uncommon subtype of HL. It tends to occur in older patients and is more likely to be associated with advanced disease and B symptoms. It has the worst prognosis of all histologic subtypes of HL.[45]

TABLE 81.4 MAJOR HISTOLOGIC SUBTYPES CORRELATED WITH CLINICAL CHARACTERISTICS OF 615 ADULT PATIENTS TREATED FOR HL AT STANFORD UNIVERSITY (1989 TO 2011)

	NLPHL	NSHL	MCHL
Number of patients (%)	40 (7)	468 (76)	49 (8)
Age (y)			
Range	15–85	15–83	17–81
Median	45	30	35
Male to female ratio	23:17	228:241	32:17
Stage			
I (%)	14 (36)	30 (6)	10 (21)
II (%)	14 (36)	272 (58)	14 (29)
III (%)	11 (28)	89 (19)	12 (25)
IV (%)	0	78 (17)	12 (25)
B symptoms (%)	4 (10)	147 (31)	16 (33)

MCHL, mixed cellularity Hodgkin lymphoma; NLPHL, nodular lymphocyte–predominant Hodgkin lymphoma; NSHL, nodular sclerosis Hodgkin lymphoma.

Nodular lymphocyte–predominant Hodgkin lymphoma (NLPHL) has recently been subdivided into six entities based on morphology and immunohistochemistry characteristics termed typical and variant histologies.[46,47] It is characterized by having many more normal-appearing lymphocytes than abnormal cells. Unlike the other subtypes of HL, the abnormal cells (“L and H cells” or “popcorn cells”) are strongly reactive for CD20, CD45, CD79a, and PAX5 and negative for CD15 and CD30.[39,41] NLPHL is often diagnosed in young people who present with early-stage disease, usually in a solitary

peripheral nodal site. Systemic symptoms are uncommon (<10%). The natural history is the most favorable of the histologic subtypes. Some patients demonstrate a pattern of late relapse but good survival, resembling that observed in the follicular (B-cell) lymphomas. For up to 14% of patients, NLPHL will transform into an aggressive B-cell lymphoma as part of its natural history.[48,49] Patients with a variant histology, versus those with typical NLPHL, are at greater risk for transformation[47] and are also more likely to present with advanced disease and experience disease relapse. A reactive process termed *progressive transformation of germinal centers* may be observed either before, with, or after the diagnosis of NLPHL.[50,51]

Table 81.4 summarizes the characteristics of patients treated at Stanford University (California) from 1989 to 2010 stratified by the major histologic subtypes and represents most large centers in the United States and Western Europe. Histologic subtype distribution and clinical behavior will differ for patients in South America, Asia, Africa, Eastern Europe, and even some parts of the United States, with a higher ratio of unfavorable histologic subtypes and more aggressive clinical behavior in economically developing regions.[52,53]

TABLE 81.5 INTERNATIONAL PROGNOSTIC SCORE FOR ADVANCED HL

Factor	Unfavorable Covariate
Serum albumin	<4 g/dL
Hemoglobin	<10.5 g/dL
Sex	Male
Age	≥45 y
Stage	IV (Ann Arbor)
Leukocyte count	≥15,000/mm^3
Lymphocyte count	<600/mm^3 or <8% of white count

PROGNOSTIC FACTORS AND THERAPEUTIC IMPLICATIONS

In HL, prognostic factors are important for defining therapy and predicting outcome. Histologic subtypes have little impact on therapy, except when identifying NLPHL for which different treatment algorithms apply.[25] Although large series report a slightly worse outcome for men than women,[1] gender influences treatment choice more because of potential reproductive

complications than outcome (see “Sequelae of Treatment”).

Although it is probably safe to argue that Ann Arbor stage is the greatest determinant of therapy, and that early data show that stage has a marked impact on prognosis, current management programs blur its influence. For many patients, disease bulk influences treatment selection, especially bulky mediastinal disease. In general, the risk of relapse after treatment with single-modality therapy is high and, therefore, combined modality therapy has been standard for patients with bulky disease.[25,54]

An important international study evaluated a series of prognostic factors among 5,141 patients with advanced-stage HL (Table 81.5).[28] Seven factors were identified, each of which had an independent yet similar relationship with prognosis. Unfavorable factors included male gender, age >45 years, Ann Arbor stage IV, hemoglobin level <10.5 g/dL, white cell count >15,000/mL, lymphocyte count <8% or absolute lymphocyte count <600, and albumin <4 g/dL. This International Prognostic Score is now used to assign patients to clinical trials. Patients with three or more adverse risk factors are often considered to be in an unfavorable prognostic group for advanced HL.

Patients with stage I or II disease often have only one or two adverse factors based on this index. Other factors, such as number of sites of disease, age, ESR, bulky disease, and presence of B symptoms, can help stratify these patients with early-stage disease by prognosis. Unfortunately, the criteria for defining “unfavorable” presentations of stage I to II disease vary among clinical trial groups (Table 81.6).

TABLE 81.6 DEFINITION OF “UNFAVORABLE” STAGE I TO II HL

	EORTC	GHSG[a]	NCIC	NCCN
Age (y)	≥50	—	≥40	—
Histology	—	—	MC/LD	—
ESR/B symptoms	≥30 mm with any B sx.	≥30 mm with any B sx.	≥50 mm or any B sx.	Any B sx
	≥50 mm without B sx.	≥50 mm without B sx.		>50 mm
Mediastinal mass	MTR ≥ 0.35	MMR > 0.33	MMR > 0.33	10 cm or MMR > 0.33
Number of nodal regions	>3[b]	>2[c]	>3	>3
E lesion	—	Any	—	—

E, extralymphatic; EORTC, European Organization for Research and Treatment of Cancer; ESR,

erythrocyte sedimentation rate; GHSG, German Hodgkin Study Group; LD, lymphocyte depleted; MC, mixed cellularity; MMR, maximum mediastinal width/maximum chest width on chest x-ray; MTR, maximum mediastinal width/chest width at T5-T6 on chest x-ray; NCCN, National Cancer Center Network; NCIC, National Cancer Institute, Canada; sx, symptoms.
Patients with one or more of these factors were considered to have “unfavorable” stage I to II disease.
[a]Patients with B symptoms and either E lesion or large mediastinal mass treated in advanced disease clinical trials.
[b]Mediastinum and both hila considered as a single region; subpectoral and ipsilateral axilla considered a single region.
[c]Mediastinum and both hila considered as a single region; subpectoral and ipsilateral cervical/supraclavicular considered a single region.

GENERAL MANAGEMENT

Radiation Therapy

Radiation therapy is the most effective therapeutic agent for treating HL and has been used in its management for over a century.[55] The optimal irradiation technique includes meticulous pretreatment evaluation of disease sites, precise simulation and immobilization, individually contoured treatment volumes according to the location of a patient’s tumor configuration, radiation exposure to all adjacent organs at risk (ORAs) that is as low as reasonably achievable (ALARA), an adequate target dose, a multifield fractionated regimen, and image guidance during therapy. Outcomes are best maximized and risks minimized through scrupulous attention to every detail of therapy.[56]

Chemotherapy

The standard drug combinations in use worldwide for the primary treatment of HL are ABVD[57,58] and bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone (BEACOPP), which includes baseline, escalated, and 14-day schedules.[59] Another combination, specifically devised to minimize toxicity and that is used with radiation, is nitrogen mustard, bleomycin, doxorubicin, vinblastine, vincristine, etoposide, prednisone (Stanford V).[60]

Table 81.7 summarizes the doses and scheduling of these drug combinations.[61]

Targeted Therapy

New systemic agents have been approved by the Food and Drug Administration for the treatment of HL. These include brentuximab vedotin (BV) and the checkpoint inhibitors nivolumab[62] and pembrolizumab.[63] BV is an anti-CD30

monoclonal antibody linked to an antitubulin agent. BV has demonstrated efficacy in CD30+ lymphomas, including HL and anaplastic large-cell lymphoma. It is approved for patients whose disease recurs after stem cell transplantation and is being introduced in clinical trials to define its potential in other settings.[64] Because of overlapping pulmonary toxicity, however, bleomycin is removed from any drug combination that includes BV, so trials of primary therapy with an ABVD backbone typically incorporate BV-AVD. Owing to the ETHERA trial, BV has been approved as a maintenance therapy following autologous hematopoietic cell transplant.[65] Pembrolizumab is approved for patients with disease that is chemoresistant or has relapsed after three or more lines of therapy, and nivolumab is approved for patients whose disease has relapsed or progressed after autologous hematopoietic cell transplant and posttransplant brentuximab.

TABLE 81.7 COMMON DRUG COMBINATIONS USED IN THE TREATMENT OF HL

Drug Combination and Cycle Duration	Agents	Dose (mg/m^2)	Route	Treatment Day(s)
ABVD, 28 d	Doxorubicin[a]	25	IV	1, 15
	Bleomycin	10	IV	1, 15
	Vinblastine	6	IV	1, 15
	Dacarbazine	375	IV	1, 15
Stanford V, 28 d	Doxorubicin[a]	25	IV	1, 15
	Vinblastine	6	IV	1, 15
	Nitrogen mustard	6	IV	1
	Vincristine[b]	1.4	IV	8, 22
	Bleomycin	5	IV	8, 22
	Etoposide	60	IV	15, 16
	Prednisone	40	PO	Every other day
BEACOPP, 21 d	Bleomycin	10	IV	8
	Etoposide	100 (200)[c]	IV	1–3
	Doxorubicin[a]	25 (35)[c]	IV	1
	Cyclophosphamide	650 (1250)[c]	IV	1
	Vincristine[b]	1.4	IV	8
	Procarbazine	100	PO	1–7
	Prednisone	40	PO	1–14
	G-CSF		SC	8–14

IV, intravenous; PO, oral; SC, subcutaneous.
[a]Adriamycin.
[b]Maximum, 2 mg.
[c]Higher dose is for escalated BEACOPP.

Combined Modality Therapy

Combined modality therapy has become the most common form of general management for patients with HL. Modern treatment protocols can include irradiation of all initially involved sites, bulky sites only, slowly responding sites, or sites of incomplete response to chemotherapy. In general, irradiation of all initially involved sites is indicated when combined with abbreviated chemotherapy in early-stage HL. Treatment of just high-risk areas, such as bulky disease, slowly responding disease, or incompletely responding disease, is reserved for more advanced-stage disease treated with definitive chemotherapy (i.e., six cycles of ABVD, 12 weeks of Stanford V, or six cycles of escalated BEACOPP).

RADIATION THERAPY TECHNIQUES

The principal objective of radiation therapy in HL is to treat regions at high risk for containing disease to a dose associated with a high likelihood of tumor eradication, meanwhile keeping the dose to adjacent tissues and organs ALARA. Thoughtful evaluation of all imaging studies, especially diagnostic CT and integrated PET-CT scans; precise simulation with appropriate immobilization and consideration of organ motion; detailed treatment planning; and effective and conformal treatment delivery, including image guidance, treatment verification, and appropriate quality assurance measures are requisite to achieving the best outcomes.[56]

Simulation

Patient positioning for simulation must allow for patient comfort, daily reproducibility, displacement of ORAs (such as breasts) beyond the treatment field, impact of positioning on target delineation, and feasibility of treatment delivery. For patients with low neck and mediastinal involvement, a headrest with a face mask that extends the head can help pull the chin superiorly and beyond the radiation field. However, a headrest and face mask can also introduce uncertainties when fusing with the prechemotherapy PET-CT scan, which often is done with the head flexed on a pillow for comfort. Arm position, in general, is more comfortable at the patient’s side or slightly akimbo and affects whether

breast tissue falls inferior/laterally or beyond the field, especially when combined with an inclined board and immobilization bag. Conversely, patients with axillary, infraclavicular, or subpectoral involvement may have smaller target volumes with less uncertainty when their arm position resembles that in the prechemotherapy PET-CT scan because defining the target is challenging after chemotherapy. In these circumstances, the best position in which to treat the patient may be with arms above the head in an immobilization bag, which helps with reproducibility and with reducing the dose to the lungs. Occasionally, the prechemotherapy CT imaging is performed with arms up, whereas the PET-CT scan is performed with arms down, providing both options to optimize treatment.

With proton therapy, some immobilization devices can hinder the path of the particle beam and compromise beam selection, a concern that should be evaluated with physics and dosimetry before simulation.

Simulation should be done with intravenous contrast to help define the interface between normal soft tissues and residual disease. Furthermore, it can be helpful in identifying the cardiac substructures.

Motion Management

Patients with mediastinal involvement must undergo motion management strategies with the use of a 4-dimensional (4D) CT scan or deep-inspiration breath hold (DIBH) technique. For sites below the diaphragm, respiration management may be necessary. For example, when splenic irradiation is required, a 4D treatment planning scan can help define the phase in the respiratory cycle that allows for the most sparing of the heart, left lung, or left kidney. Retroperitoneal and pelvic nodes, in contrast, tend to not require motion management.

4D CT scans acquire imaging throughout the full 10 phases of the respiratory cycle, allowing us to assess the margin to add to the clinical target volume (CTV) that will account for normal respiratory motion. This internal treatment volume (ITV) margin can be an expansion of the CTV on the average scan of the 4D CT scan or independently drawn as the ITV, ensuring coverage of all 10 phases of the scan. In some cases, respiratory gating can be used to minimize the ITV margin.

Alternatively, DIBH is a technique that results in reduced doses to the lungs and heart for patients with mediastinal involvement.[66] DIBH can spare additional volume of the lungs when treating superior mediastinal disease.

Additionally, DIBH pulls the heart medially and down, away from mediastinal disease located above the heart. Figure 81.3 demonstrates this effect. In most cases, DIBH is likely to reduce the lung and heart doses, but in cases with extensive lower mediastinal involvement including cardiophrenic nodes, the relative benefit of DIBH may diminish.[67]

Various techniques of DIBH have been described.[66,68,69] Important concepts to consider with DIBH include breath hold reproducibility, the patient's ability to maintain the breath hold or multiple breath holds during treatment, and the breath hold's impact on contouring.

Involved-Node and Involved-Site Radiotherapy

The classic field configurations for HL treatment with radiotherapy alone have included the mantle and inverted Y. However, clinical trials have shown the equivalence of "involved field" treatment (IFRT) with "extended-field" or "subtotal lymphoid" irradiation as part of combined modality therapy programs; thus, IFRT was adopted as the standard for combined modality therapy in clinical trials.[70–72] Field reductions and three-dimensional (3-D) target-volume definitions comprise the loosely described techniques for "intelligent-field radiation therapy" and "modified IFRT." The more clearly defined "involved-node radiotherapy" (INRT)[73] and "involved-site" irradiation (ISRT)[56] have become the standard of care in clinical practice and more recent clinical trials. INRT, as defined by Girinsky et al. for the EORTC-GELA Lymphoma Group, requires prechemotherapy diagnostic CT and PET-CT imaging with the patient in the treatment position, postchemotherapy contrast-enhanced CT simulation, and fusion of the prechemotherapy and postchemotherapy images.[73–75] The fields are designed to treat only the initially involved nodes with some modifications to avoid OARs. This gross tumor volume (GTV) then becomes the CTV, and a 1-cm expansion of the CTV defines the planning target volume (PTV).

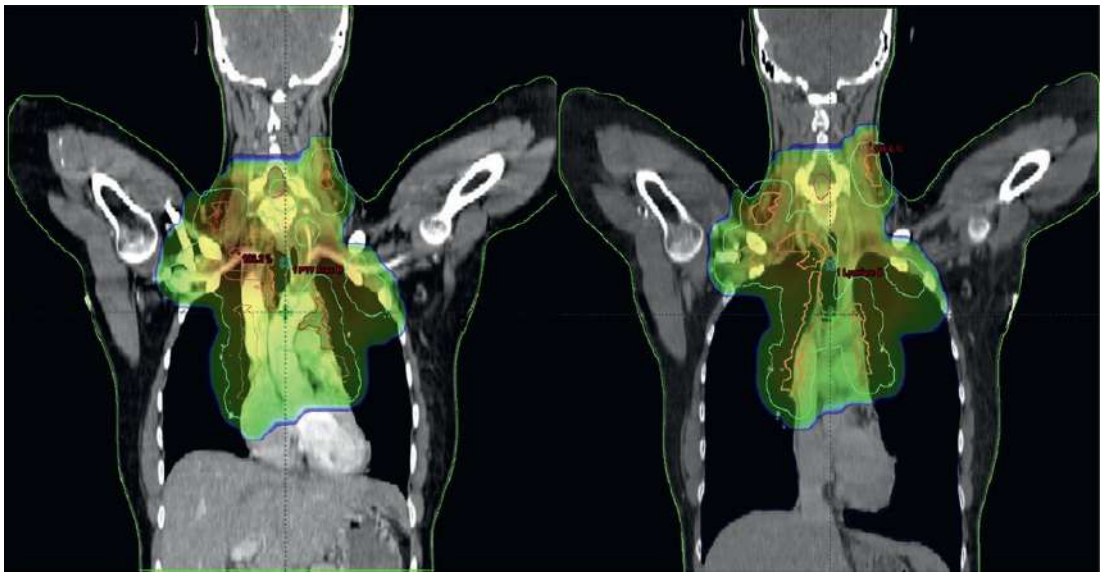

FIGURE 81.3. ISRT treatment plans for a patient with extensive mediastinal HL during free breathing *(left)* and inspiration breath hold *(right)*. The mean radiotherapy lung dose with free breathing was 15.7 Gy; with inspiration breath hold, it was 11.2 Gy. (Reprinted from Specht L, Yahalom J, Illidge T, et al. Modern radiation therapy for Hodgkin lymphoma: field and dose guidelines from the international lymphoma radiation oncology group (ILROG). *Int J Radiat Oncol Biol Phys* 2014;89[4]:854–862. Copyright © 2014 Elsevier. With permission.)

When components of this planning process are missing—perhaps the pretreatment PET-CT scan was not done in the treatment position, there is poor registration between scans, or the CT simulation scan was done without intravenous contrast—it may be impossible to treat such strictly defined INRT fields. However, field reduction is still possible to what has been termed ISRT.[56]

ISRT volumes will vary depending on the clinical situation and treatment protocol. In general, because of the use of abbreviated chemotherapy (i.e., two to four cycles of ABVD or 8 weeks Stanford V), patients with favorable early-stage HL receive ISRT to all initial sites of disease after completing chemotherapy.

For patients treated with radiotherapy alone (i.e., NLPHL), the ISRT CTV should be increased to include sites of potential subclinical disease. In practice, this would mean an additional 2- to 5-cm margin within the lymphatic stations superior and inferior to the initially involved disease on PET-CT imaging, taking into account the OARs

Among patients with unfavorable early-stage HL, ISRT to all sites of disease should be used when abbreviated chemotherapy has been delivered; however, for those who receive more intensive chemotherapy, certain complete responding areas that could result in an unacceptable dose to an OAR if included could be omitted (i.e., cardiophrenic nodes or axillary lymph nodes in a young woman

could be omitted if she has had a complete response [CR] by CT scan). Patients with stage III/IV disease are more likely to receive ISRT to sites of initially bulky disease or sites of slow or incomplete response to chemotherapy.

FIGURE 81.4. ISRT treatment plan for a 50-year-old man with stage IIA NLPHL involving the right axillary and subpectoral nodes. Note the extension of the field into the right supraclavicular fossa to treat possible subclinical disease in that location. Thick orange lines outline the PET-positive nodes (GTV); the thin orange line represents the PTV.

Design of ISRT Fields

The GTV (or prechemotherapy GTV) is based on localizing the initially positive lymph nodes (and extranodal sites) on the staging PET-CT scan fused to the treatment planning CT. When radiation therapy is the sole treatment modality, it is simple to identify the GTV, especially after PET-CT simulation. This may be the case for treating patients with primary radiotherapy for nodular LPHL (Figs. 81.4 and 81.5).[56]

For the more common situation of combined modality treatment, the CTV includes the entire initial disease volume but is modified (reduced) to exclude uninvolved normal organs (e.g., lungs, bones, muscles, great vessels) and to accommodate shrinking lymph node masses following chemotherapy, especially in the chest. The CTV can be expanded based on the quality of the initial imaging or owing to concerns of subclinical disease (Fig. 81.6). For initially large mediastinal masses, the postchemotherapy treatment fields should conform to the width of only the residual disease (absent any pulmonary parenchymal

extension), and the superior and inferior field margins should encompass the initial extent of disease with the margin previously noted (Fig. 81.7).[56] Adjacent organ dose constraints may also mean reducing the CTV. The PTV is an expansion of the CTV based on day-to-day set-up uncertainties.

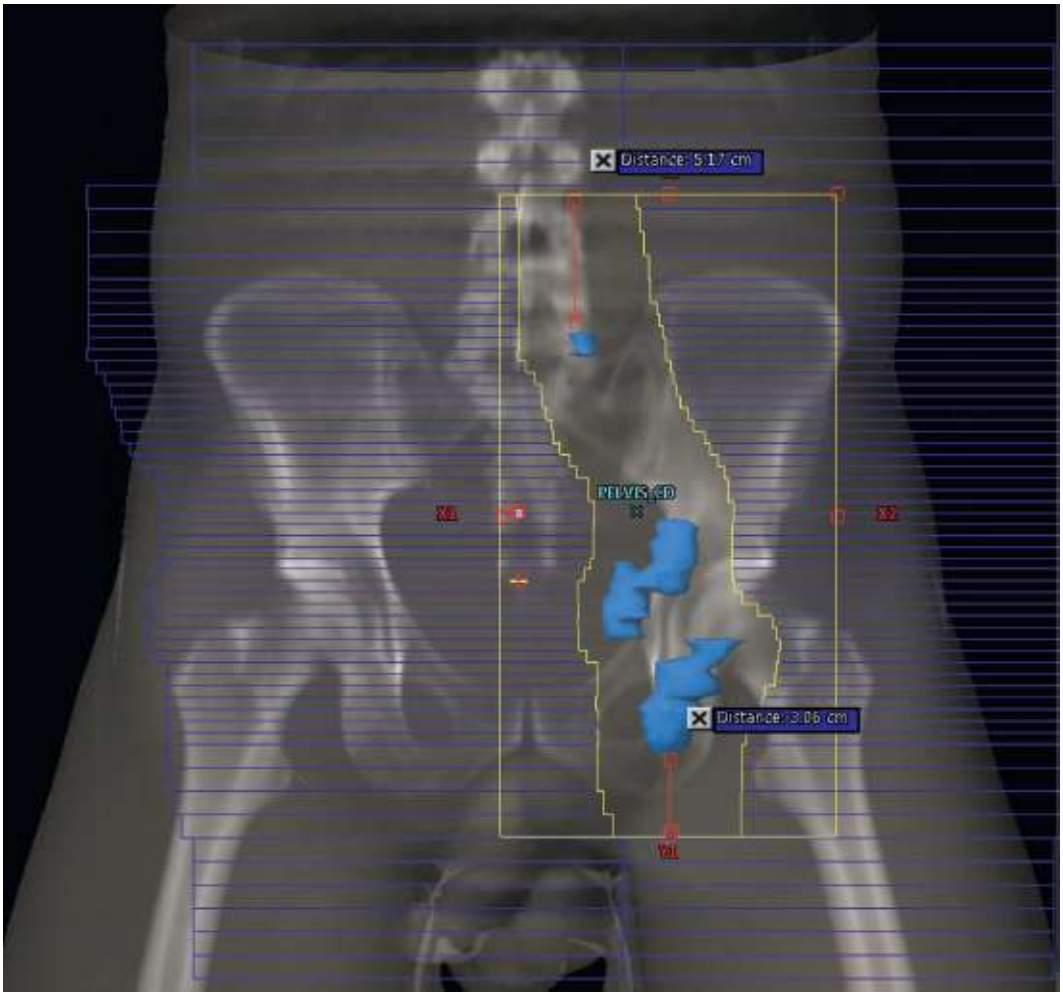

FIGURE 81.5. ISRT field for treating unilateral pelvic nodes, in this case for a 34-year-old man with stage IIA lymphocyte predominance HL. The initial PET-positive nodes (GTV) are shown in blue. The treatment field includes margins superiorly and inferiorly to include potential areas of microscopic spread, in this case approximately 5 cm cephalad and approximately 3 cm caudad.

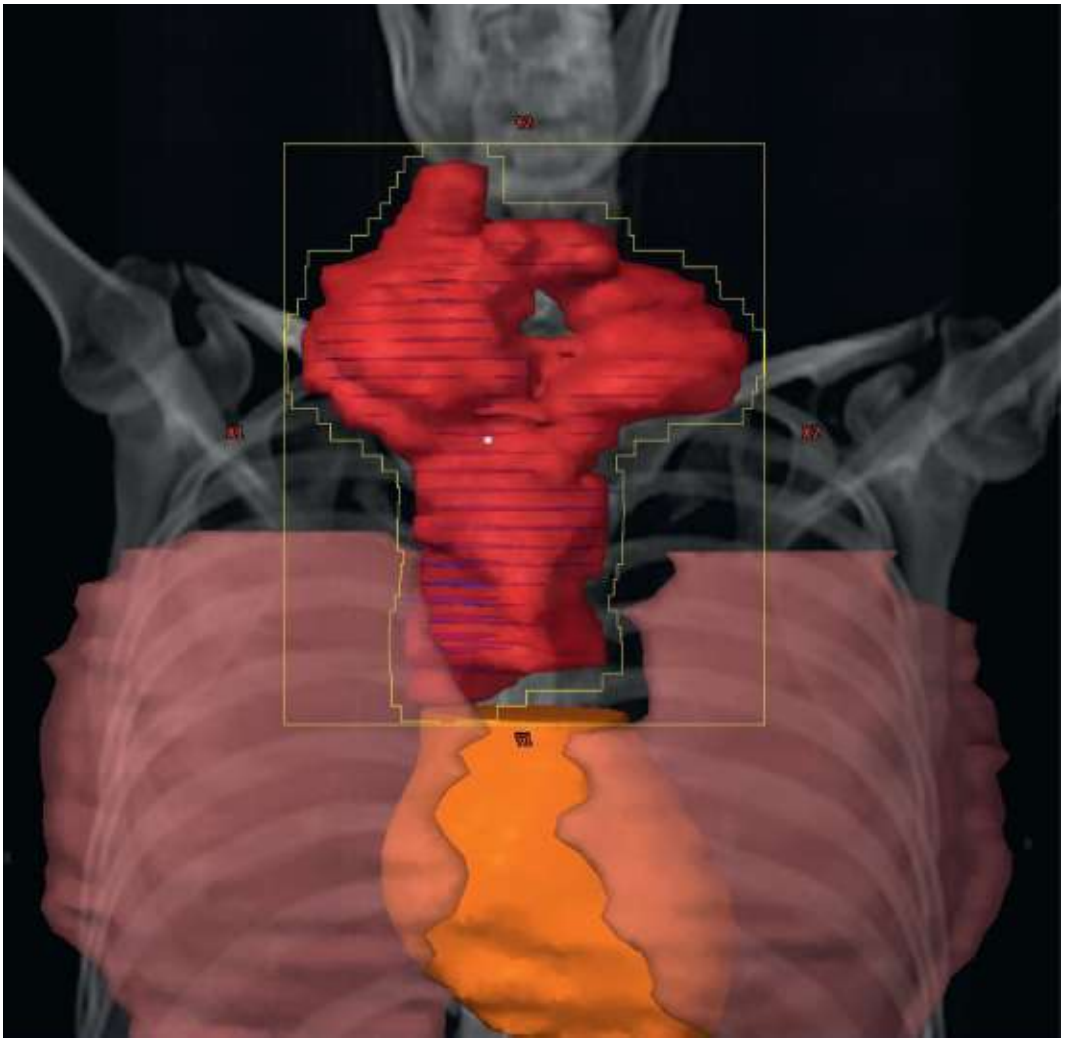

FIGURE 81.6. Involved-site 3-D radiotherapy AP/PA field design and treatment plan for a 28-year-old woman with stage II NSHL involving the right neck, bilateral supraclavicular, and superior mediastinum. *Faint blue horizontal lines*, GTV; *red,* PTV; *orange*, heart; *pink*, breasts.

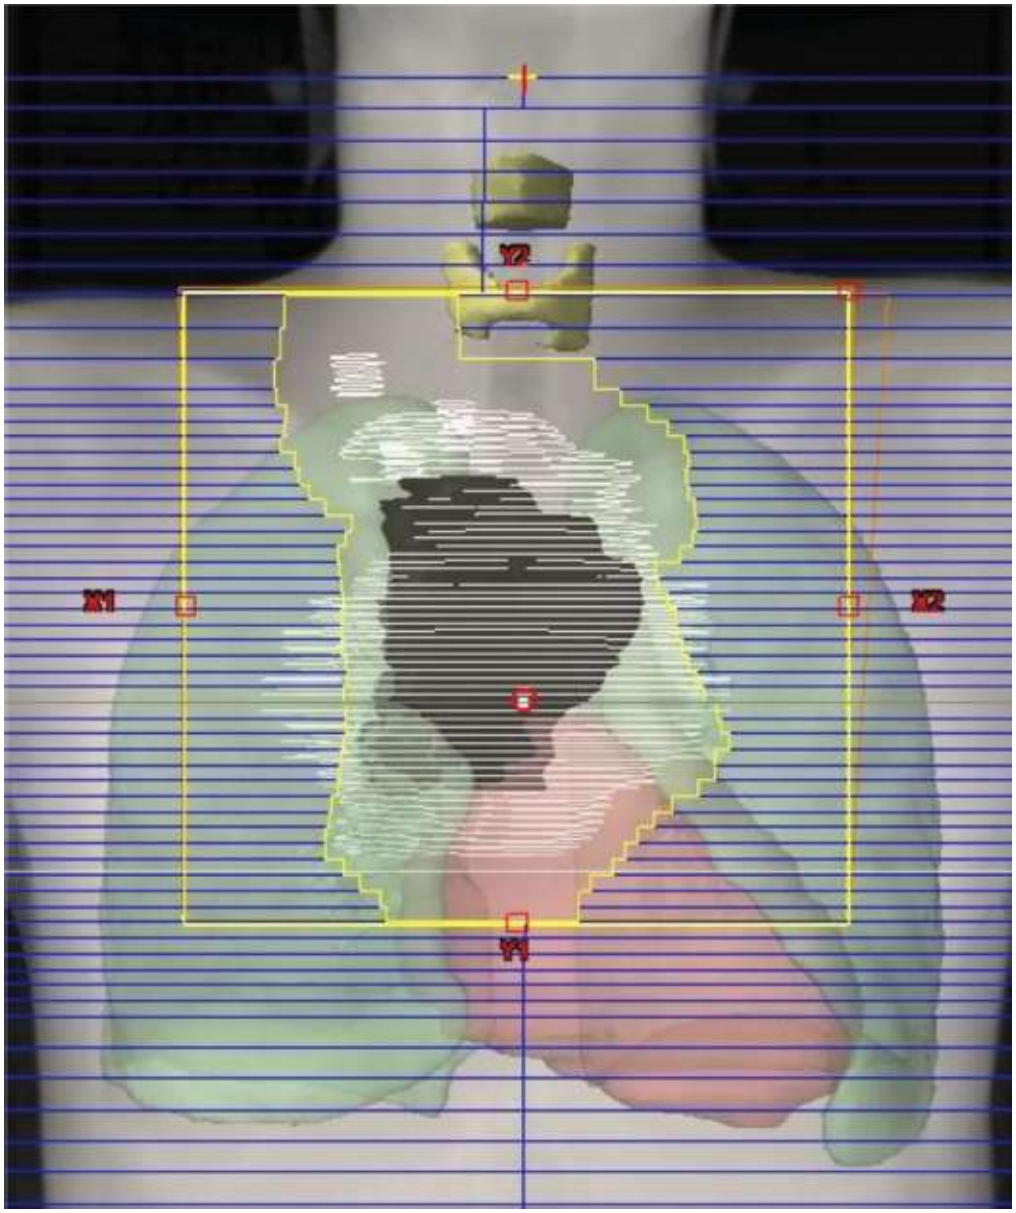

FIGURE 81.7. A 28-year-old man with massive mediastinal NSHL and right supraclavicular disease, following completion of chemotherapy, with a negative PET scan. *White*, pretreatment PET-positive disease; *black*, postchemotherapy residual abnormality on CT. Multileaf collimators define the ISRT field.

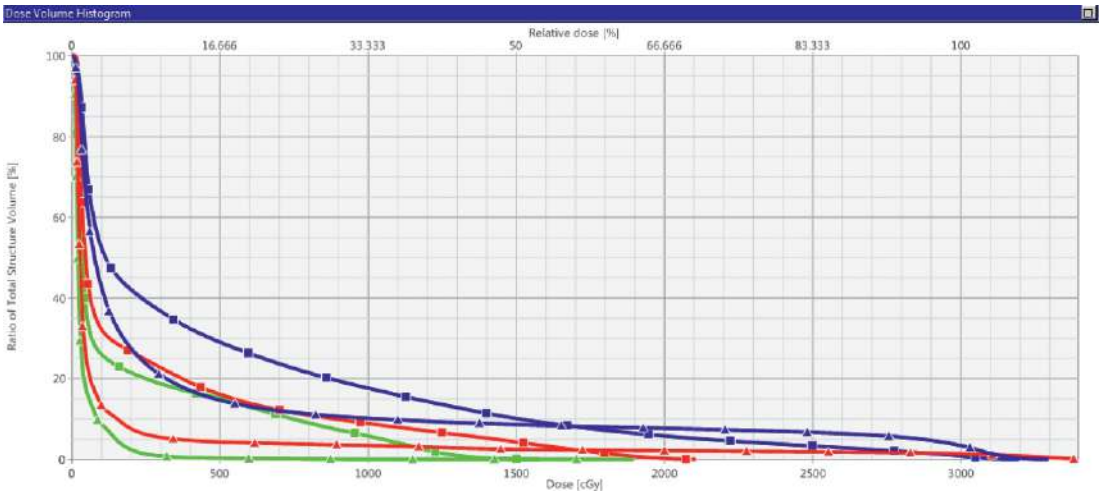

FIGURE 81.8. For the patient displayed in Figure 81.6, DVHs for a 3-D AP/PA treatment plan (*triangles*) and an intensity-modulated radiotherapy plan (*squares*). *Blue*, combined lungs; *red*, right breast; *green*, left breast. The 3-D plan was chosen for this patient because the mean dose and V_4 to the breasts were less than in the IMRT plan, whereas the V_{20} and V_{30} for the lungs were similar. (See also Table 81.8.)

Radiation Dose

In the uncommon scenario that radiation therapy alone is used for the treatment of HL (most commonly for NLPHL), the National Cancer Center Network (NCCN) Guidelines recommend a dose of 30 to 36 Gy to involved sites and 25 to 30 Gy to sites of potential subclinical involvement, delivered in 1.5- to 2-Gy fractions.[25] More commonly, however, radiation therapy is as a component of a combined modality approach, with chemotherapy expected to eradicate subclinical disease, and radiation playing a role in eradicating disease in involved sites. Doses vary considerably among trials, depending on the prognostic category of patients, disease bulk, and chemotherapy regimen. The dose ranges considered acceptable per the NCCN are 20 to 30 Gy for nonbulky and 30 to 36 Gy for bulky sites, delivered 1.5 to 2 Gy per fraction.[25] Patients with incomplete metabolic response (Deauville 4, 5) following chemotherapy can receive higher doses (36 to 45 Gy).

Radiation Delivery

Historically, irradiation was delivered after 2-D or 3-D treatment planning, typically with opposed anterior–posterior (AP)/PA treatment fields. Over the last 15 years, however, with more refined radiation fields and 3-D target delineation, modern radiation delivery systems have helped with reducing the radiation dose to the OARs. Such techniques require photon-based systems (intensity-modulated radiation therapy [IMRT], volumetric modulated arc therapy

[VMAT], and tomo therapy) and proton-based systems (3-D and intensity-modulated proton therapy [IMPT]) with passive scatter, uniform scanning, and pencil beam scanning. The benefit of each treatment type depends on various factors, including disease distribution relative to the OARs, patient age and comorbidities, and type of prior chemotherapy. An example of the dose distributions achieved with 3-D conformal radiotherapy (CRT) versus IMRT for the patient depicted in Figure 81.6 is shown in Figure 81.8 and Table 81.8. An example of the dose distributions achieved with IMRT and proton plans for a patient with mediastinal HL is shown in Figure 81.9.

In general, when comparing IMRT with 3-D CRT plans, IMRT delivers a more conformal dose distribution in the high-dose region, but less conformality in the low-dose region and the creation of a "low-dose bath." Conversely, when comparing proton therapy techniques with 3-D CRT, protons deliver a more conformal dose distribution in both the high- and low-dose ranges.

Among patients with high cervical disease, IMRT or protons can be useful in reducing the radiation dose to the parotid glands and oral cavity. But the radiation dose to the thyroid warrants consideration because the low-dose bath of IMRT can increase its exposure to radiation compared with conventional 3-D CRT.

For most patients with involvement of the mediastinum and/or axilla, IMRT can improve dose–volume histogram (DVH) criteria for the heart, coronary arteries, esophagus, and lungs, compared with 3-D CRT. The dose-sparing effects for these normal tissues may be dramatic when using IMRT and will lead to adopting an IMRT plan (Fig. 81.9). The low-dose bath that puts larger volumes of normal tissue at risk for the development of secondary cancer[76,77] or pneumonitis[78] is often overshadowed by the significant sparing of the heart and coronary arteries with the IMRT plan. Proton therapy allows for a reduced dose to the heart, lungs, breast, and body compared with either IMRT or 3-D CRT techniques[77,79] without generating a low-dose bath (Fig. 81.10).

Infradiaphragmatic radiation may also benefit from the use of IMRT or proton therapy, especially when the spleen is irradiated, to help minimize the radiation dose to the heart, stomach, pancreas, and left kidney.[80,81]

IMRT and proton therapy are also useful in patients reirradiated for relapsed disease close to or within a previously treated area.[82]

TABLE 81.8 DOSE TO KEY ORAS FOR THE PATIENT SHOWN IN FIGURE 81.6 AND DVHS DISPLAYED IN FIGURE 81.8

Organ at Risk	IMRT Plan	3-D AP/PA Plan
Right breast V_4	19%	5%
Right breast mean dose	2.5 Gy	1.3 Gy
Left breast V_4	17%	0.5%
Left breast mean dose	1.9 Gy	0.04 Gy
Combined lung V_5	29%	15%
Combined lung mean dose	4.8 Gy	3.8 Gy

3-D, 3-dimensional; AP, anterior–posterior; IMRT, intensity-modulated radiation therapy; PA, posterior–anterior.

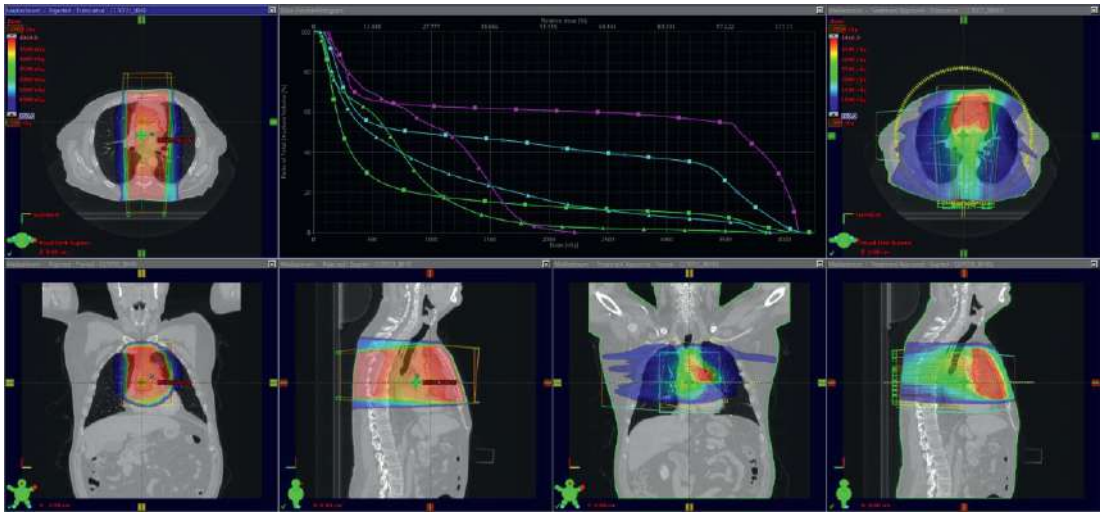

FIGURE 81.9. Comparison plans for 3-D conformal AP/PA fields and IMRT for a 45-year-old man with bulky mediastinal disease. In the DVH panel, *squares* show the 3-D plan and *triangles* indicate the IMRT plan. The *green lines* show a larger low dose–volume to the lungs for the IMRT plan, but there is a much lower dose to the heart (*light blue*) and LAD artery (*pink*). The IMRT plan was selected.

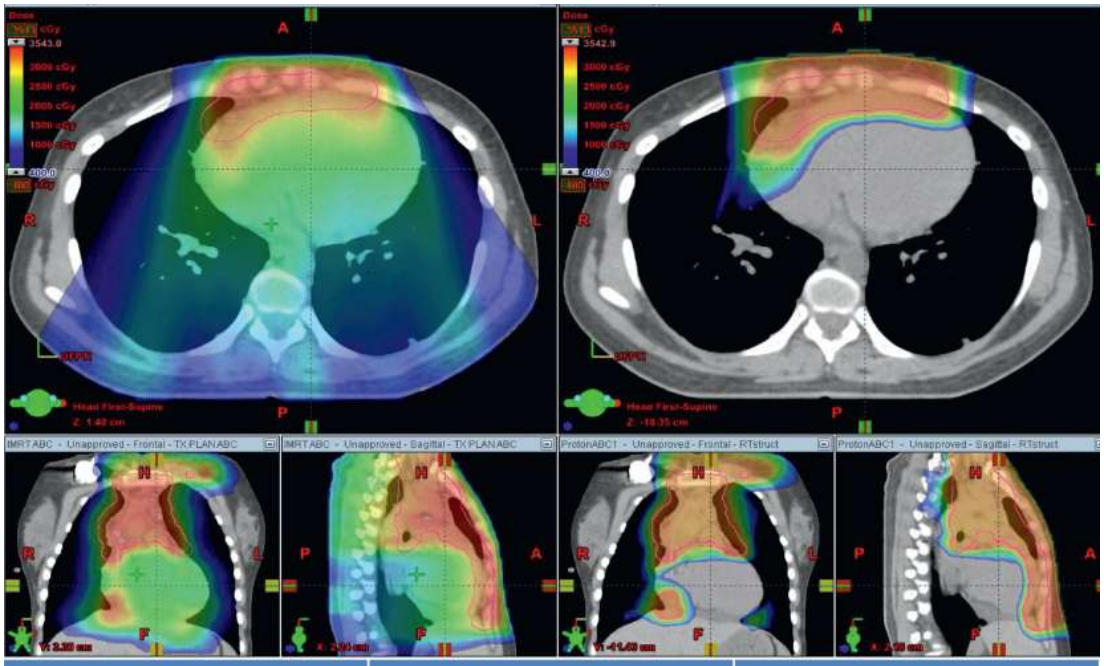

IMRT	Organ dose	Proton
24.9 Gy	Heart (mean)	15 CGE
20.6 Gy	Left Ventricle(mean)	2.9 CGE
30.2 Gy	LAD (mean)	32.7 CGE
13 Gy	Lung (mean)	7.3 CGE
6.6 Gy	Breast (mean)	7.1 CGE
148.2 Joules	Body (integral)	75.2 Joules

FIGURE 81.10. Color-wash dose distribution comparisons for two different plans for treating bulky mediastinal HL in a 30-year-old woman. **Left:** IMRT; **Right:** proton therapy. Both plans were done in breath hold.

Clinical results using these modern radiation technologies are beginning to emerge, but, thus far, they only demonstrate clinical effectiveness in regard to disease control and acceptable rates of acute toxicities. Investigators at three centers have reported their experiences using IMRT for HL (N = 40 to 60 patients), observing excellent relapse-free survival (~95%).[75,83,84] Similar results have been found by investigators at proton therapy institutes, some of whom conducted a small prospective clinical trial. In a combined analysis of academic and community proton centers where patients received consolidative proton therapy, the 3-year event-free survival rate was approximately 95% for patients with a CR before radiation.[85,86] The true benefit of these technologies won't be

realized for at least two decades, when late toxicities become apparent. Until then, radiation oncologists should utilize all tools available to them to minimize the dose to the OARs and, therefore, minimize acute and late toxicities.

IMRT, VMAT, and Tomotherapy for Mediastinal Disease

Various techniques exist for delivering IMRT, VMAT, and tomotherapy.[83] Cella et al. reported comparison planning using forward-planned IMRT wherein the treatment fields were chosen to mimic an AP/PA field arrangement and then compared with a 7-field IMRT plan or tomotherapy. The forward-planned IMRT was better at reducing the radiation dose to the lungs and breast, but the 7-field IMRT plan and the tomotherapy plan were better at sparing the heart. Accordingly, the optimal treatment approach should be individually tailored to address potential toxicities.

Proton Therapy

Several techniques exist for delivering proton therapy, including passive scatter, uniform scanning, and pencil beam scanning with single-field optimization or multifield optimization. Several important factors should be considered when proton therapy is employed.[77] Guidelines are currently under development. When disease extends low and anterior to the heart, one should utilize anterior beams and avoid using posterior beams that traverse the heart unnecessarily. Similarly, for disease extending low and posterior to the heart, one should utilize posterior beams and avoid using anterior beams that traverse the heart unnecessarily.[87]

Organs at Risk

The dose range used for HL (20 to 36 Gy) is below the threshold tolerance for most organs; however, intrathoracic structures can be affected by these doses, and careful review of DVHs is warranted to minimize both acute and late effects. Table 81.9 provides a summary of published data on radiation doses to various OARs and their impact on the risk of acute and late toxicity.

The risk for pneumonitis is related to the volume of lung irradiated, total dose, and fraction size. The relationship between mean lung dose or V_x and pneumonitis is complex, can vary for different diseases, and will depend on patient age, smoking history, presence of intercurrent disease, prior chemotherapy, prior surgery, and possibly other factors.[102] Some investigators identified a higher risk for Radiation Therapy Oncology Group grade 2

pneumonitis in patients with HL when the mean lung dose exceeded 14 Gy or the V_{20} exceeded 35%.[103] In another study using IMRT that included RTOG grade 1 to 3 pneumonitis, the mean lung dose threshold was set at 13.5 Gy, the V_{20} to <30%, and the V_5 to <55%.[78] Conversely, a recent report using proton therapy demonstrated no significant risk of pneumonitis.[104] The likelihood of radiation-related pulmonary complications increases with the use of bleomycin,[105] although the impact of total bleomycin dose, which varies significantly with different drug combinations, has not been well defined. For example, the bleomycin dose after six cycles of ABVD is 120 u/m^2, whereas with 12 weeks of Stanford V, it is only 30 u/m^2. Bleomycin dose may influence lung DVH parameters following chemotherapy. Following Stanford V chemotherapy, an acceptable threshold to minimize the risk of radiation pneumonitis is a mean lung dose of 17 Gy. When used alongside high-dose therapies and autologous hematopoietic cell transplants, the risk of pneumonitis with radiotherapy increases and lower-dose constraints are warranted. New targeted agents, such as BV, nivolumab, and pembrolizumab, also may be associated with a higher risk of pneumonitis and should be used cautiously with mediastinal radiotherapy until further data are generated. BV should not be used in conjunction with bleomycin because of the high pneumonitis risk.[64]

With respect to carcinogenesis, because data indicate that lung cancer risk increases after doses as low as 5 Gy, it is reasonable to define and minimize the lung V_5 if multiple plans are reviewed, taking into account potential toxicity to other organs.[90] The lung cancer risk is also increased by the use of alkylating agent chemotherapy or procarbazine.[106,107]

The criteria for cardiac dose tolerance are less well defined. Tolerances are influenced by lifestyle; comorbidities such as diabetes mellitus, hyperlipidemia, and hypertension; family history; and prior treatment with cardiotoxic drugs like doxorubicin. In a large analysis of Dutch patients treated before 1996 (with lymphoma radiation fields and doses that are no longer employed), patients who received mediastinal irradiation had a 4- to 6-fold increased standardized incidence ratio of cardiovascular disease.[95] In a more detailed comparison of coronary heart disease and mean heart dose (MHD), the excess relative risk (ERR) was 7.4% per Gy of MHD.[96] The ERR was negligible with an MHD <5 Gy and was approximately 2 for an MHD of 12 Gy, a dose which should be achievable in most patients with contemporary treatment techniques. Although the MHD has been used as a surrogate for the likelihood of developing secondary cardiac effects, the dose to individual subunits of the heart is more

likely to define the true cardiac risks. Therefore, effort should be made to contour all of the cardiac subunits using one of the standard cardiac atlases as a guide.[108] It is likely the dose to the left anterior descending (LAD) coronary artery and left ventricle is the most important; however, it is only recently that the dose to these structures has been contoured and measured, so limited retrospective data are available regarding acceptable threshold doses. The best approach is to keep the dose ALARA. With respect to valvular disease, the ERR is increased only minimally for valve doses up to approximately 20 Gy, but with a steep increase in risk thereafter.[97] Congestive heart failure risk is demonstrable when the left ventricular mean dose exceeds 15 Gy, or V_{30} is ≥50%, but the greatest increase in risk for congestive heart failure is associated with the use of anthracycline-based chemotherapy.[98] Acute pericarditis, an occasional risk following treatment with classical mantle-field irradiation that includes large parts of the pericardium treated to doses >30 Gy, has essentially disappeared with current standard radiation treatment techniques.

In women, given the excess risk of secondary breast cancer for doses as low as 4 Gy, it is reasonable to track the breast V_4 and keep the volume as small as possible, especially for women <30 years of age.[89] A less rigorous constraint is to keep the mean breast dose <4 Gy. When calculating the V_4 and mean breast dose, only the glandular tissue of the breasts should be contoured, not the anatomical structures.

Treatment techniques such as IMRT may help reduce the cardiac dose but increase the V_5 to the lungs or V_4 to the breasts, potentially resulting in a higher risk for secondary cancer in those organs (Figs. 81.6 and 81.7). This is not a problem when using proton therapy.[77]

TABLE 81.9 SUMMARY OF STUDIES DESCRIBING THE RISK OF SECONDARY CANCERS, CARDIOVASCULAR DISEASE, PULMONARY TOXICITY, AND ENDOCRINOPATHIES AMONG PATIENTS TREATED WITH RADIATION THERAPY FOR HL

	Outcome	Referent Group	Risk (95% Confidence Interval)
Second Cancers			
Castellino et al., 2011[88]	Fatal second malignant neoplasms	No RT	<30 Gy[a]: HR 1.9 (0.4–8.7) ≥30 Gy[a]: HR 7.4 (1.8–30.3)

In treating retroperitoneal nodes or the spleen, the organ at greatest risk is the left kidney. QUANTEC data recommend that the mean kidney dose (bilateral) should be <18 Gy, which should always be achievable in the context of treating HL.[109] In women who require pelvic nodal irradiation, the dose to the ovaries must be considered, as they are near the iliac nodes. Occasionally, an oophoropexy is necessary to provide sufficient ovarian protection. If an oophoropexy is performed, the surgeon should clip the superior and inferior poles of the ovary for precise localization on simulation scans. The menopausal effect of irradiation on the ovaries is dependent upon a woman's age. At age 20, the mean sterilizing dose is 15 Gy, but it drops to 12 Gy at age 30 and 8 Gy at age 40.[110] Alkylator agent chemotherapy, such as is in BEACOPP, will induce menopause in >50% of women, also correlating with age.[111] Among men, the possibility of inadvertent testicular irradiation is most likely to occur when the inguinal–femoral nodes are treated. This dose can be readily reduced 3- to 10-

fold by use of a “clamshell” testicular shield.

Hypothyroidism is a common complication following cervical/supraclavicular node irradiation, as the thyroid cannot be spared completely because of involvement of those nodes. Data regarding dose–volume risks are limited. One analysis showed that the risk of developing hypothyroidism is only 11.5% if the V_{30} is ≤62.5 and 70.8% if the V_{30} is >62.5.[101]

A summary of the OAR dose constraints is displayed in Table 81.9.

RESULTS OF THERAPY

HL is responsive to both irradiation and chemotherapy, and a variety of regimens can achieve similar survival rates. However, significant differences in freedom from relapse rates and potential complications of therapy can occur. The results described in the following sections emphasize treatment programs that adhere to the NCCN Guidelines.[25] Clinical trial results that have helped define the current standards are shown in Tables 81.10 to 81.12.

Interim PET-CT

The utility of PET-CT imaging as a prognostic indicator after two cycles of chemotherapy was first demonstrated in patients with stage III to IV HL.[127] Patients with a positive interim PET study had a significantly higher risk for relapse than patients with a negative study, regardless of their initial international prognostic score. The impact on patients with stage I to II disease is less clear, and most patients with stage I to II disease will do well regardless of interim PET studies.[128,129] Nevertheless, interim PET is employed in current clinical trials for all stages of HL and has also become standard in clinical practice and treatment guidelines.[25]

Favorable Prognosis Stage I to IIA Classic HL

Favorable presentation of stage I to II disease usually excludes patients with systemic (B) symptoms or large mediastinal adenopathy. Some clinical trial groups also exclude patients with an elevated ESR (≥50), extralymphatic extension (E lesion), multiple sites of disease (>2 or 3), older age (≥50 years), or unfavorable histology (mixed cellularity or lymphocyte depleted) and treat them according to algorithms for intermediate prognosis disease (Table 81.10).

In favorable prognostic groups, patients are treated with either chemotherapy alone or combined modality therapy. According to trials by the German Hodgkin Study Group (GHSG), patients with just one or two disease sites, an ESR < 50, and no extranodal disease can be treated with just two cycles of ABVD followed by 20 Gy ISRT.[114,130] For patients who do not fit these criteria, standard combined modality therapy programs can include four cycles of ABVD followed by 30 Gy ISRT[120] or, if the interim PET is negative (Deauville 1 or 2), three cycles of ABVD followed by 30 Gy ISRT.[116,131] Another option for these patients is 8 weeks of Stanford V followed by 30 Gy ISRT.[113]

After a positive interim PET following two cycles of ABVD, and absent progressive disease, additional treatment can include two additional cycles of ABVD (total four) plus 30 Gy ISRT[131] or treatment escalation to two cycles of escalated BEACOPP followed by 30 Gy ISRT.[116] Outcomes for any of these approaches are excellent (Table 81.10).

Owing to concerns for late radiation-related toxicity, clinical trials have

evaluated the role of ABVD alone as treatment for patients with favorable disease presentations. The NCIC-CTG HD.6 trial was the first large trial to compare ABVD alone to combined modality therapy.[132] This trial has been criticized for including subtotal lymphoid radiation rather than IFRT or ISRT in the combined modality arm. However, the outcome of treatment with ABVD alone at 12 years yielded a 94% survival rate, 87% progression-free survival (PFS) rate, and 85% event-free survival rate. These findings set the stage for other trials of ABVD alone (three or four cycles total after a negative interim PET) versus combined modality therapy (Table 81.10).[116,131] The details related to the outcomes of these studies can influence their interpretation. Ultimately, the difference in PFS or event-free survival is approximately 6% to 12%, favoring management with combined modality therapy. The median follow-up of these trials has been too short to know whether differences in survival truly exist, owing to either the late effects of radiation or salvage therapy required for relapse. Nevertheless, the smaller radiation fields and lower doses now used compared to previous trials should result in a lower risk of radiation-related late effects. Selecting the right treatment for these patients depends on many variables, and patient education and engagement are encouraged. For example, a young woman with mediastinal and axillary node involvement might choose the risk of relapse with ABVD alone over the risk of breast cancer from combined modality therapy. The opposite may be true for a patient with neck and superior mediastinal involvement, for which the heart and breasts would receive little radiation exposure.

Subdiaphragmatic involvement is seen in fewer than 10% of patients with stage I or II HL. For patients in whom disease is nonbulky and limited to pelvic lymph nodes with or without extension into the lower para-aortic nodes, the same general treatment principles apply as for supradiaphragmatic disease. In general, the outcome of treatment for these patients resembles that of patients with supradiaphragmatic disease.[133,134]

Patients with bulky abdominal presentations or those with involvement of the spleen are typically treated according to guidelines for "unfavorable" stage I or II disease or for stage III or IV disease.

Stage I to IIA Nodular Lymphocyte–Predominant HL

Contrary to the experience with classic HL, patients with limited presentation of NLPHL can achieve long-term disease-free survival after treatment with limited irradiation (IFRT) alone.[135–138] In contemporary terms, we use ISRT, but ISRT is defined somewhat differently than in the classic HL sense, which is treatment with combined modality therapy. The CTV expansion must account for possible microscopic spread beyond the lymph nodes clinically observed on PET-CT imaging (Fig. 81.5). For a patient who presents with unilateral level I or IIA disease, the CTV should be expanded to include ipsilateral levels IIB, III, and even IV. For a femoral node presentation, the CTV should include at least a 5-cm extension along the lymphatic chains superiorly and a 2-cm extension inferiorly.[139] The usual dose for NLPHL is 30 to 36 Gy. Doses below 30 Gy have been evaluated, but responses have not been as durable as with conventional doses.[140] Retrospective data from the GHSG show a 4-year PFS rate of 93.2% and an 8-year overall survival (OS) rate of 99% for patients with stage I NLPHL treated with IFRT.[137] There was no benefit from extending the radiation fields or adding chemotherapy. Single-institution results for treatment of stage I to II disease with radiation therapy alone include a 10- to 15-year PFS rate of 75% to 82% and 10-year OS rate of 83% to 100%.[135,136,141,142] In general, the results for PFS are a bit inferior for stage II versus stage I disease, but long-term survival rates are similar.

At some treatment centers, management resembling that for classic HL is preferred, utilizing combined modality therapy.[142] With combined modality

therapy, the chemotherapy delivered can be ABVD (with or without rituximab), but evidence exists that alkylator-based chemotherapy may be superior for this histologic subtype.[143]

Based on these data, ESMO and NCCN guidelines reflect a preference for ISRT alone in stage I disease and, per NCCN, limited stage II disease.[25,54] For stage II disease, combined modality therapy is preferred, unless it is nonbulky and with no more than two contiguous sites involved.

Unfavorable Prognosis Stage I to II Classic HL

This category includes a diverse patient group. Unfavorable factors in different series nearly always include patients with B symptoms or bulky mediastinal disease (variably defined). Additional factors include more than two or three involved nodal regions, ESR above 50, age over 40 years, unfavorable histology (mixed cellularity or lymphocyte depleted), and extranodal disease (Table 81.11).

Based on consensus data, the most commonly used treatment for stage I or II HL with large mediastinal adenopathy is combined modality therapy with four to six cycles of ABVD plus 30 Gy ISRT. The expected FFP is 80% to 90%.[70,120,130] The EORTC H9U study showed no significant benefit to six cycles compared with four cycles of ABVD[144] when given with RT. An essential concern with this treatment program is the potential for overlapping toxicities with doxorubicin, bleomycin, and irradiation (i.e., cardiac and pulmonary effects).

Although ABVD remains the standard chemotherapy for this clinical presentation, both Stanford V and BEACOPP regimens have been evaluated in clinical trials. The GHSG HD11 trial for patients with intermediate prognosis—which included patients with large mediastinal adenopathy, elevated ESR, extranodal disease, or more than two sites of involvement—randomized the chemotherapy to baseline BEACOPP versus ABVD and the IFRT dose to 20 versus 30 Gy.[118] Twenty percent of patients had bulky mediastinal disease. This trial demonstrated that 20 Gy was sufficient if BEACOPP chemotherapy was used but inadequate following ABVD. Nevertheless, owing to the greater toxicity of BEACOPP, ABVD × 4 plus 30 Gy IFRT became the standard arm of the next trial, the GHSG HD14.[120]

The Stanford V regimen has been used for patients with large mediastinal adenopathy. The 12-week chemotherapy program is followed by irradiation (30 to 36 Gy) to all sites >5 cm. In the setting of large mediastinal adenopathy, this program included irradiation of the mediastinum, bilateral hilar, and

supraclavicular areas.[145] The Eastern Cooperative Oncology Group (ECOG) compared treatment with ABVD × 6 to 8 versus Stanford V × 12 weeks, in both cases followed by 36-Gy irradiation to the mediastinum and bilateral hilar and supraclavicular areas (the E2496 trial). Of the patients, 100% had bulky mediastinal involvement. There were no significant differences in 5-year OS (95% and 92%) or failure-free survival (FFS; 85% and 77%) for the two treatment arms.[119]

Clinical trials groups have investigated the use of chemotherapy alone in patients with stage I to II disease and unfavorable characteristics. The RAPID trial, cited above, excluded patients with large mediastinal adenopathy or B symptoms, but 32% of its patients were judged unfavorable by GHSG criteria and 38% by EORTC criteria.[131] Results were not reported separately for those different cohorts, however. The EORTC H10U trial evaluated the use of interim PET-CT to define a group of patients who might be treated effectively with ABVD chemotherapy alone.[116] In this trial, 40% of patients had bulky mediastinal disease (mediastinal–thoracic ratio ≥0.35 at the T5-T6 interspace). Patients with a negative interim PET were randomized to 4 additional ABVD or 2 ABVD + INRT. Among the patients randomized to treatment with ABVD alone, the 5-year PFS rate was 89.6% versus 92.1% with combined modality therapy. No subset analysis was performed to analyze the impact of specific unfavorable characteristics.

In the same trial, there was a benefit to escalated BEACOPP following an interim positive PET scan. All patients then received INRT. Patients whose treatment was escalated had a significantly improved 5-year PFS compared to those who continued ABVD + INRT (90.6% vs. 77.4%). The OS difference (96% vs. 89.3%) was not statistically significant ($p = .062$)

Approximately 15% to 20% of patients with stage I or II disease exhibit B symptoms. In general, these patients are managed analogous to those with stage III to IV disease. However, given the limited anatomic extent of disease with stage I to II, there is a strong argument for the inclusion of consolidative ISRT for these patients, as is recommended by the ESMO and NCCN.[25,54]

Stage III to IV Classic HL

Chemotherapy is the mainstay of treatment for patients with stage III to IV HL. The landmark study informing chemotherapy programs was the prospective, randomized clinical trial conducted by the Cancer and Leukemia Group B. Patients with stage III_2A, IIIB, or IV HL were randomly assigned to treatment

with MOPP (six to eight cycles), MOPP/ABVD (12 months), or ABVD (six to eight cycles). Treatment results with MOPP/ABVD and ABVD were equivalent, and both were superior to MOPP alone. Among the 115 patients treated with ABVD chemotherapy, the CR rate was 82%, the 5-year FFS rate was 61%, and the OS rate was 73%.[58] More recently, the "gold standard" of ABVD has been challenged by the GHSG, which developed the BEACOPP regimen and has demonstrated in a series of trials that results using escalated BEACOPP (often including irradiation) are superior to those achieved with ABVD. The GHSG HD9 trial compared escalated BEACOPP, baseline BEACOPP, and COPP/ABVD.[146] Outcomes were best in the escalated BEACOPP arm, with a 5-year freedom from treatment failure (FFTF) rate of 87% and an OS rate of 91%. However, in an Italian multi-institutional study that compared an initial treatment strategy of ABVD (four to eight cycles) with BEACOPP (four escalated plus four baseline cycles), which took into account the possibility of autologous stem cell transplant as salvage therapy, there was no significant difference in 7-year freedom from second progression or OS (89% vs. 84%), and severe adverse events were more likely in the BEACOPP group.[147] In general, comparisons of escalated BEACOPP and ABVD chemotherapy show an advantage to escalated BEACOPP with respect to PFS, but no difference in OS (Table 81.12).

The value of treatment adaption based on interim PET results has been evaluated in advanced disease. Both the RATHL study[125] and the SWOG S0816[126] trial used escalated BEACOPP for PET-positive patients. Although escalated BEACOPP improved patient outcomes, neither trial had a comparison arm for continued treatment with ABVD. An important conclusion of the RATHL study was that patients with a negative interim PET scan could have bleomycin removed from cycles three to six of ABVD without compromising outcomes.

Because 70% of patients who receive chemotherapy alone relapse exclusively in sites of initial disease, combined modality therapy may be recommended for those with stage III to IV disease.[148] In addition to their low accrual, early trials evaluating the use of radiation in this setting were poorly designed and relied on chemotherapy programs that are no longer thought optimal. Nevertheless, trials of systemic therapy for advanced disease continue to include the selective use of consolidative irradiation.[146,147,149]

The EORTC–Groupe Pierre-et-Marie Curie H34 (20884) trial evaluated the role of radiation in advanced disease by treating patients with six to eight cycles

of nitrogen mustard, vincristine, procarbazine, prednisone, Adriamycin, bleomycin, and vinblastine chemotherapy (MOPP-ABV).[150] Those who achieved a CR (57%) were randomized to no further therapy versus 25 Gy IFRT. No differences in FFTF or OS were identified. A detailed evaluation of causes of death revealed an unusually high rate of secondary myelodysplasia in the group randomized to combined modality therapy, but a similar risk was not observed in the nonrandomized patients, all of whom received irradiation to a higher dose! Most importantly, this trial demonstrated the important contribution radiation therapy made to the outcomes of the 43% of patients who did not exhibit a CR on CT. These patients received 30 Gy IFRT. The subsequent FFTF and OS rates for this group closely paralleled those for patients who had achieved a CR, suggesting value to adding IFRT when only a partial response has been achieved.[121]

Although the value of consolidative irradiation after CR to conventional chemotherapy (ABVD or BEACOPP) has not been proven, programs of attenuated chemotherapy in which radiation therapy is an essential component exist. The Stanford V program includes only 12 weeks of chemotherapy, with highly attenuated total doses for some drugs (see Table 81.7). Compared to six cycles of ABVD, it includes only 50% of the cumulative dose of doxorubicin (Adriamycin) and 25% of the cumulative dose of bleomycin. Radiation therapy (30 to 36 Gy) is routinely added to initially bulky (>5 cm) sites of disease as well as to macroscopic splenic involvement and commences 2 to 3 weeks after completing chemotherapy. The results of this approach have been excellent.[122,145,151] A similar study that did not employ the same guidelines for radiotherapy, however, showed much worse outcome, proving the importance of radiotherapy.[152] The ECOG E2496 trial compared management with ABVD versus Stanford V for patients with advanced-stage or locally advanced disease. There was no difference in 5-year FFS (73% for ABVD, 71% for Stanford V) or OS (88% for ABVD, 87% for Stanford V).[122] The United Kingdom National Cancer Research Institute Lymphoma Group Study ISRCTN 64141244 also showed no difference between ABVD and Stanford V.[153]

The use of PET to identify patients with advanced disease who might benefit from RT was incorporated into the GHSG HD15 trial.[124] In this trial, patients with residual abnormalities on CT scan ≥2.5 cm underwent PET imaging. Only if the PET scan was positive did they receive local RT to that site. This strategy proved effective as the patients who were PET positive enjoyed a 5-year PFS rate of 86.2%. Although this outcome was statistically inferior to that in the PET-

negative population (5-year PFS, 92.6%), these patients might otherwise be considered “chemotherapy resistant” and go on to autologous hematopoietic cell transplant. Clearly, that does not seem necessary in this setting.

A general conclusion regarding the role of combined modality therapy compared with chemotherapy alone for patients with stage III to IV disease is that patients who achieve a CR to a full course of conventional chemotherapy experience no proven benefit from adding radiotherapy. However, irradiation is often selectively added to such programs, especially for patients with bulky disease or sites of suspected residual disease. Furthermore, attenuated chemotherapy programs may confer a benefit by adding radiotherapy, and outcomes of patients who achieve only a partial response to chemotherapy may benefit from added radiotherapy. Ultimately, improvements in imaging and evaluations of early response to chemotherapy with FDG-PET or other diagnostic tests may help identify a subset of patients who would benefit reliably from consolidative radiotherapy (see section on “Current Clinical Trials”).

Pediatric Patients

Most contemporary programs for managing pediatric HL rely on clinical staging. They employ chemotherapy alone or combined modality therapy with low-dose irradiation because higher doses are associated with an unacceptably high risk of growth impairment and late effects.[16] Radiotherapy doses in children should not exceed 15 to 30 Gy. Regardless of stage, children treated with these programs experience 5-year OS rates of approximately 90% and relapse-free survival rates exceeding 80%.[154–158] The management of children with HL is dealt with more comprehensively in Chapter 93.

Older Adult Patients

Treating HL in older patients (>60 years) is challenging because they often have less favorable histologies and a worse performance status.[159–161] They are also more likely to have intercurrent disease that compromises the aggressive management programs used for younger patients. Overall outcomes for patients ≥60 years old are comparably poor.[159] Chemotherapy programs must often be modified to minimize cardiac or pulmonary toxicity, and the hematologic reserve in elderly patients requires dose reductions or premature discontinuation.[162] Bleomycin should be avoided, and BEACOPP should not be used in patients over 60 years old.[163] Drug combinations better tolerated by older adults include ChlVPP,[164] procarbazine, Alkeran, and vinblastine,[165] and vinblastine,

bleomycin, and methotrexate (used primarily for stages I to II).[166] Patients receiving radiotherapy may require slower fractionation programs and must be observed carefully for signs of weight loss or general decline in performance status. Extended fields are more difficult to tolerate than limited ones.[167]

Treatment for Relapse

Treatment for relapse must be individualized. Initial disease characteristics, initial treatment and response duration, relapse sites, and general patient status must be considered in developing an effective secondary treatment program. The conventional salvage therapy for most patients who were treated initially with chemotherapy alone or combined modality therapy is high-dose chemotherapy followed by autologous hematopoietic cell transplantation, which is effective in approximately 50% of patients.[168,169] Allotransplantation is not used often for relapsed HL but can be considered after an unsuccessful autotransplant or when disease is refractory to both conventional chemotherapy and biologic agents. Reduced-intensity conditioning regimens appear to be safer than myeloablative regimens.[170]

An increasing dilemma is the management of patients who present with stage I to II disease and are treated with abbreviated chemotherapy only, such as three cycles of ABVD. In these patients, relapse may be restricted to initial sites of disease.[171] In the RAPID trial, for example, only 7 of 22 patients whose disease relapsed after 3 cycles of ABVD went on to an autologous transplant. Five were treated with radiotherapy alone, four with chemotherapy alone, and six with combined modality therapy. Although more evidence is needed to define the best "salvage" regimens for these patients, it has become apparent that autologous transplant can be avoided in many situations.

The Role of Radiation Therapy in Hematopoietic Cell Transplantation

Radiation therapy can be incorporated into high-dose therapy/hematopoietic cell transplantation programs for relapsed or refractory HL. Fractionated TBI is sometimes used, but its value is debatable. Often, relapse is locoregional rather than systemic. Data suggest that radiotherapy doses resembling those used for total-body irradiation (12 to 15 Gy) are likely to eradicate disease in only approximately 20% of treated sites.[12] Thus, radiation should be limited to sites of failure or sites at high risk for disease, such as initially bulky ones.

Other considerations relevant to the issue of radiation therapy are its timing

(pretransplant or posttransplant), field design, and dose. The advantages of using radiation therapy as cytoreductive treatment before high-dose therapy are that it can effectively reduce the tumor burden before high-dose treatment and the risk of interruption or delay of the locoregional radiation therapy is minimal. The primary disadvantages include potential delay of the high-dose therapy and the potential overlapping toxicities of the locoregional irradiation and high-dose therapy, including mucositis and pneumonitis.[172]

Many published series of high-dose therapy for HL have included locoregional irradiation in selected patients, usually after transplant.[173] The range of intervals from transplant to irradiation varies from 1 to 4 months. Often, the fields treated include sites of bulky disease (variably defined) at the time of relapse or sites that remain positive on PET imaging before the transplant. Some fields included all sites involved at the time of relapse.

In these studies, radiation doses ranged from 18 to 40 Gy. In general, lower doses were employed when initially nonbulky disease was included in the treatment or when there was a CR to high-dose therapy.

The use of locoregional irradiation in high-dose therapy programs can alter disease patterns and reduce the failure risk. At Stanford University, 49 patients with relapsed stage I to III disease underwent high-dose therapy and received IFRT as a component of their salvage treatment.[174] Investigators observed 3-year freedom from relapse, OS, and event-free survival rates of 100%, 85%, and 85%, respectively, compared with only 67%, 60%, and 54%, respectively, for patients who received high-dose chemotherapy alone. The difference in freedom from relapse was statistically significant (p = .04). The same was observed in a cohort of patients who received transplants at several centers.[175,176] The International Lymphoma Radiation Oncology Group has developed radiation treatment guidelines for patients undergoing hematopoietic cell transplantation.[176a]

FOLLOW-UP

All studies that initially yielded abnormal results (e.g., blood work and imaging) should be repeated upon completing therapy to document the patient's response to treatment. The Lugano response criteria mandate PET-CT imaging immediately following therapy for this purpose.[26,27] Earlier challenges with interpreting residual mediastinal abnormality after therapy have been obviated by the adoption of FDG-PET imaging as a posttreatment assessment tool, so

concern can be limited to those patients with residual PET activity.[177]

The follow-up interval is typically every 3 to 6 months during the first 2 years and every 6 to 12 months thereafter.[25] The most important component of follow-up is an interim history and physical examination, which help to identify two-thirds of relapses.[178] Relapses can be detected by enlarged nodes or when the initial symptoms return, such as night sweats, pruritus, or alcohol intolerance. If ESR, serum albumin, and other serum marker studies were abnormal at presentation, they can be repeated, although they rarely suggest disease recurrence without clinical symptoms or physical findings.[179] Given the effectiveness of primary therapy for HL, the low rate of relapse, the risk for "false-positive" imaging studies, and the expense to the health care enterprise, the value of routine imaging has become debatable and guidelines remain nonspecific.[178,180,181] The NCCN Guidelines endorse up to 3 CT scans in the first 2 years after therapy.[182,183] Surveillance PET imaging is not indicated because of the high likelihood of false-positive findings, radiation exposure, and economic costs.[184–186]

In virtually every case, the first episode of relapse should be documented by biopsy. Inflammatory disease, progressive transformation of germinal centers, or the rebound growth of the thymus in young patients are other reactive processes that can be confused with recurrent HL. All of these processes can be FDG-avid on PET imaging.

Long-term follow-up helps detect late effects and ensures health maintenance. Serum thyroxine (T_4) and sensitive thyroid-stimulating hormone (TSH) levels should be obtained at least annually in patients who received radiation to the neck to detect subclinical hypothyroidism.

Cardiovascular risk factors should be managed aggressively, especially for patients exposed to thoracic radiation or Adriamycin chemotherapy. The NCCN Guidelines[25] recommend annual fasting blood sugar and biannual lipid panels and a stress echocardiogram, and carotid ultrasound should be done 10 years after treatment. Women exposed to thoracic radiation should initiate routine mammographic screenings 8 years after therapy or at age 40, whichever occurs first. Also, women treated before 30 years old should undergo both routine mammography and magnetic resonance mammography annually. Surveillance for other malignancies should conform to the American Cancer Society guidelines. Annual immunization against influenza is recommended.

SEQUELAE OF TREATMENT

Depending on the fields treated, the acute side effects of radiotherapy can include mild skin reactions, sore throat, an altered sense of taste, dysphagia, reflux symptoms, dry cough, nausea, occasional vomiting, diarrhea, and blood count suppression. Most of these sequelae can be managed symptomatically. Complications that arise in the early phase of the follow-up program can include mild radiation pneumonitis, radiation pericarditis, hypothyroidism, herpes zoster, Lhermitte sign, and xerostomia.

Radiation pneumonitis can develop within 6 to 12 weeks after completing mantle irradiation. After classic mantle therapy, <5% of patients experience symptomatic pneumonitis, manifested by cough, fever, pleuritic chest pain, and an infiltrate on chest radiography that usually conforms to the radiotherapy fields; this rate has been reported as higher following IMRT[78] and lower following proton therapy.[104] Symptomatic management is usually sufficient; however, some patients require treatment with corticosteroids, usually beginning with a daily dose of 40 to 60 mg of prednisone (or other corticosteroid equivalent). Corticosteroid therapy is a 4- to 6-week commitment at minimum, with slow, careful tapering to avoid exacerbation of symptoms.

Subclinical hypothyroidism develops in as many as half of patients who receive doses above 30 Gy to the neck.[187] It can be detected by elevated TSH levels even in the presence of a normal T_4 level. Thyroid replacement therapy with L-thyroxine is recommended, with an initial dose of up to 0.1 mg/d. The T_4 and TSH values are monitored regularly to adjust dose. Evidence suggests that thyroid replacement therapy in this setting reduces the risk of developing benign thyroid nodules.[188] It is likely that newer treatment techniques with lower doses and better shielding of the thyroid gland will result in decreased risk.

Herpes zoster can occur either during or within the first few years of HL treatment in 10% to 15% of patients.[189] The outbreak is usually limited to one or two contiguous dermatomes. Cutaneous dissemination is uncommon, and visceral involvement is extremely rare. If the cutaneous eruption is identified within 72 hours of onset, treatment with acyclovir (800 mg five times per day for 7 to 10 days or another antiviral equivalent) can be initiated. Acyclovir can limit the duration and intensity of the infection and decrease the likelihood of cutaneous or visceral dissemination. Currently, zoster vaccine immunization is not recommended for patients treated for lymphoma (www.cdc.gov/vaccines).

Lhermitte sign develops in approximately 10% to 15% of patients after

radiation therapy to a significant length of the spinal cord via AP/PA fields. It is more likely to occur among patients who have been treated with vinca alkaloids (vincristine and vinblastine). It is marked by paresthesias that extends into the arms and legs on neck flexion and can be related to transient demyelinization of the spinal cord. Its onset is usually 1 to 2 months after completing mantle therapy and typically resolves spontaneously after 2 to 6 months. This sequela is not related to the more serious problem of transverse myelitis and is much less common among patients treated with IMRT or proton therapy, for whom the spinal cord doses are much lower.

Significant xerostomia can follow irradiation of the Waldeyer lymphoid region or the bilateral submandibular regions, which is rarely necessary, and permanent attention to dental care is required for these patients. Frequent dental prophylaxis and use of fluoride supplements are recommended.

An uncommon but potentially serious complication is overwhelming sepsis after splenectomy or splenic irradiation.[190,191] The most serious infections occur with gram-positive organisms, including *Streptococcus pneumoniae*, meningococci, and *Haemophilus* strains. Immunizing against these organisms minimizes risk. Patients can be immunized upon diagnosing the HL. Recommendations vary for the immunization of patients who have been previously treated but not immunized. Recent data suggest that patients can develop adequate antibody titers to *H. influenzae* type b-conjugate, 4-valent meningococcal polysaccharide vaccine, and 23-valent pneumococcal polysaccharide vaccine 2 after treatment.[192] Reimmunization is recommended for every 5 to 7 years. Fortunately, sepsis has become even more rare with the declining use of staging laparotomy and splenic irradiation.

An important concern of many patients with HL is the possible effect of treatment on reproductive potential. In men, pelvic irradiation can be followed by azoospermia if no special precautions are taken to shield the testes. With the appropriate testicular shielding, however, azoospermia is typically transient, and sperm counts will recover to fertile levels.[193] Chemotherapy programs such as MOPP, MOPP-like combinations that include alkylating agents and procarbazine, or BEACOPP will cause sterility in most men. However, the ABVD and Stanford V regimens seem to preserve male fertility.[145,194] Among women, the risk for infertility is influenced by patient age. When undergoing radiotherapy, despite proper oophoropexy and well-planned pelvic treatment fields, the scattered dose may be sufficient to affect ovarian function and cause menopausal symptoms in women >30 years old.[195] In younger women,

radiotherapy may not have an immediate effect on reproductivity but can eventually cause premature menopause. Similarly, chemotherapy with alkylating agents will not typically affect menstruation in women younger than 25 years old, but women above 30 years may see changes; also, premature menopause may occur.[111,196] In contrast to MOPP and BEACOPP, the ABVD and Stanford V combinations appear to preserve female fertility.[145,194]

An uncommon but significant treatment complication is the "dropped-head syndrome" secondary to cervical muscle atrophy that occurs in just some patients treated with high-dose irradiation (>36 Gy) to the neck.[197] This is a late risk, not usually apparent until >10 years after therapy. Management of this problem is challenging, with varying responses to physical therapy and use of a "soft collar." Surgical intervention has been attempted in some patients.[198] The use of contemporary therapies should obviate this risk.

Long-term follow-up is essential to identifying significant adverse late treatment complications in all patients.[199–202] The most important long-term concerns are secondary malignancies[107] and cardiovascular disease.[96]

Secondary malignancies include leukemia, lymphoma, and solid tumors. In a large series by Schaapveld et al., the standardized incidence ratio for developing a second malignancy after treatment for HL was 4.6, with 121.8 excess cancer cases per 10,000 patients per year.[107] Breast cancer was the greatest contributor to excess risk, followed by lung cancer, gastrointestinal tract cancers, and non-HLs. The highest (relative) risks were for thyroid cancer, soft tissue sarcoma, mesothelioma, and non-HL. Patients were also at an elevated risk of developing esophageal, gastric, pancreatic, and lung cancers as well as leukemia. These data were gathered in an earlier era of larger radiation fields, higher doses, and alkylating agent chemotherapy; therefore, risks are likely much lower now with the current management programs.[76,203–205] Secondary solid tumors, which have a latency of at least 7 to 10 years, are largely attributable to radiation therapy, although chemotherapy plays a part, especially with secondary lung cancers and gastrointestinal tract cancers.[93,106,107]

Myelodysplastic syndrome or acute myelogenous leukemia can develop after treatment that includes alkylating agents, procarbazine, or etoposide (e.g., MOPP or BEACOPP) after a latency of 3 to 7 years. During the era when alkylating agent chemotherapy was commonly used, the relative and absolute risks for this complication were 9.5 and 6.1, respectively.[107] Leukemia after treatment with irradiation alone is unusual.

Secondary lymphomas are usually of the diffuse large-cell B-cell type. The

latent interval is typically over 5 years. The relative risk is 13.4, and the absolute excess risk is 16.0.[107] The development of secondary lymphomas does not seem to be related to any specific component of therapy but can be related to underlying immunosuppression.

A recent study of >1,000 women below age 51 years when treated for HL reported a 5.6-fold increased risk for developing invasive breast cancer compared with the general population of women (absolute excess risk, 57 cases per 10,000 persons per year).[204] The increased risk was primarily among women younger than 40 years at the time they were treated, and the risk was greater for women treated to a full mantle field compared with mediastinal irradiation only. The risk can also be related to radiation dose. Travis et al.[89] reported that doses exceeding 4 Gy were associated with an increased risk for developing a secondary cancer.

The lung cancer risk after irradiation exposure is also dose related, with an increased risk for lung cancer following doses as low as 5 Gy.[90] In addition, it has been clearly demonstrated that the lung cancer risk is extraordinarily high among irradiated patients who continue to smoke after treatment.[206] Because of this inordinately high risk for lung cancer, patients who continue to smoke after treatment should be urged to stop and encouraged to enter smoking cessation programs.

Potential cardiac complications following treatment for HL include pericarditis (which can occur during therapy), valvular dysfunction, conduction abnormalities, coronary artery disease, and ventricular dysfunction.[96] Radiation pericarditis is a potential risk if a large portion of the pericardium is treated, which is uncommon in the current management programs; it presents as an acute febrile syndrome associated with chest pain and friction rub, an asymptomatic pericardial effusion diagnosed by chest radiograph or echocardiogram, or constrictive pericarditis or tamponade. Mild manifestations can be managed with conservative medical treatment including analgesics and nonsteroidal anti-inflammatory agents; it usually clears within a few weeks. Although rare, tamponade or constrictive pericarditis is the most serious and can require surgical intervention.

Long-term cardiovascular sequelae result in increased morbidity and mortality.[96] Coronary heart disease for patients increases 2.5-fold for those who receive an MHD of 20 Gy. The use of Adriamycin did not increase this risk, although it did increase the risk for congestive heart failure nearly 3-fold.[98] Compared with the general population, the risk for cardiac morbidity requiring

hospitalization is 2.77-fold for patients treated with both mediastinal irradiation and Adriamycin and 1.82-fold following mediastinal irradiation alone.[207] Screening studies have shown a significant risk of asymptomatic coronary artery disease, although optimal screening guidelines for patients after mediastinal irradiation have not been clearly defined.[208] Aggressive management of hypertension, diabetes, and serum lipid abnormalities is recommended for all patients.[25,209]

Another group of sequelae involves psychosocial problems, fatigue, marital difficulties, and employment issues.[210–212] Identifying these problems can promote the development of rehabilitation programs to anticipate and deal with these issues early in the course of treatment.

CURRENT CLINICAL TRIALS

Two clinical trials are evaluating reduced therapy for patients with negative PET scans after two cycles of ABVD. In the GHSG HD16 trial, patients without risk factors receive two cycles of ABVD chemotherapy followed by an interim PET. In the standard treatment arm, all patients receive 20 Gy IFRT, independent of the PET result. In the experimental arm, PET-positive patients are irradiated with 20 Gy IFRT and those with a negative FDG-PET receive no further treatment (two cycles of ABVD total). In the CALGB/Alliance 50604 trial, following a negative interim PET, all patients receive just two additional cycles of ABVD (no randomization).

Most current clinical trials emphasize the use of novel systemic therapies, including BV and the checkpoint inhibitors. The LCCC 1115 trial includes patients with stage I to II nonbulky disease. Following two cycles of ABVD and an interim PET, patients receive up to four additional cycles of ABVD, based on initial risk factors. This is followed by six doses of brentuximab and another PET scan. Only patients with a positive scan (Deauville ≥3) receive local irradiation. All other patients are observed.

The Memorial Sloan Kettering Cancer Center (New York, NY) 13-034 trial[213] includes patients with stage I to II disease and unfavorable characteristics. All patients receive two cycles of BV and AVD (no bleomycin, BV-AVD), followed by an interim PET and two more cycles of the same systemic therapy and another PET. Those who are PET-negative proceed to ISRT.

The GHSG proposed a phase II trial as a follow-up study to the HD16 trial for

patients with early-stage favorable HL without risk factors. All patients will be treated with a checkpoint inhibitor (anti-PD1 antibody) combined with 20 Gy of ISRT. They will be randomized to either concurrent or sequential (anti-PD1 followed by ISRT) treatment. No patient will receive conventional chemotherapy. For patients with stage I to II disease with risk factors, the proposed randomized arms will be four cycles of nivolumab plus AVD followed by 30 Gy ISRT versus nivolumab monotherapy followed by two cycles of nivolumab–AVD, two cycles of AVD, and then consolidation with 30 Gy ISRT.

In patients with advanced disease, the ECHELON-1 industry-sponsored international study randomized patients to primary therapy with ABVD or BV-AVD. Recently reported, this trial showed an improved 2-year modified progression-free survival for BV-AVD, but no difference in survival.[214] Another, nonrandomized trial tests the effectiveness of nivolumab + AVD as induction therapy for patients with stage IIB or III to IV disease.

For patients with relapsed disease who are otherwise candidates for treatment with high-dose chemotherapy followed by autologous hematopoietic cell transplantation, combined BV and nivolumab is being evaluated as an alternative to high-dose chemotherapy for cytoreduction before transplant.

CHAPTER 82

Non-Hodgkin Lymphomas

Chris R. Kelsey, Jeremy M. Brownstein, Grace J. Kim, and Leonard R. Prosnitz

Non-Hodgkin lymphomas (NHLs) are a heterogeneous group of malignancies of the lymphoid system characterized by an abnormal clonal proliferation of B cells, T cells, or NK (natural killer) cells. Scientific knowledge regarding NHL has increased dramatically in the last several decades, resulting in significant advances in the spheres of molecular biology and immunobiology leading to new histopathologic classifications and therapies. Chemotherapy, immunotherapy, and radiation therapy (RT) all play important roles in the management of NHL.

There are currently approximately 70 distinct NHL entities within the 2016 WHO classification. A description of all the varieties of NHL is not practical and beyond the scope of this chapter. We focus on the most common entities including diffuse large B-cell lymphoma (DLBCL), follicular lymphoma (FL), marginal zone lymphoma (MZL), mantle cell lymphoma (MCL), primary central nervous system lymphoma (PCNSL), and peripheral T-cell lymphomas (PTCLs) including extranodal NK/T-cell lymphoma, nasal type. Other entities less frequently encountered by radiation oncologists are also briefly discussed.

EPIDEMIOLOGY

The US age-adjusted incidence rate for NHL was 19.5 per 100,000 between 2009 and 2013, according to the Surveillance, Epidemiology, and End Results (SEER) Program of the National Cancer Institute. In 2017, the projected number of new NHL cases in the United States is 72,240 comprising 4.3% of new cancer diagnoses; deaths from NHL are projected at 20,140. NHL is primarily a disease of older populations with a median age of 65 at diagnosis.[1] In 2012, worldwide estimated incidence was 386,000 new cases and 200,000 deaths.[2] International NHL incidence rates vary, with the highest incidence rates in North America,

Europe, and Australia/New Zealand. The lowest rates have been reported in Asia, Central America, the Caribbean, and West Africa.[3]

Between 1975 and 2000, there was a striking increase in new cases of NHL with incidence rates nearly doubling. New cases peaked at 21.3/100,000 in 2010 and have since subtly decreased to 20/100,000 in 2014.[1] The US mortality rate rose from 5.6/100,000 to 8.2/100,000 between 1975 and 2000. Since a peak of 8.9/100,000 in 1997, the mortality rate has steadily declined with most recent SEER data reporting 5.7/100,000 deaths in 2014.[1]

The increased incidence of NHL in the late 20th century has been attributed to several factors including advances in molecular diagnostic techniques, aging of the population, immunosuppression from human immunodeficiency virus (HIV), infectious agents, and occupational/environmental exposures.[4] There are likely other contributing factors, which remain unknown at present.

ETIOLOGY

Several genetic diseases, environmental exposures, and infectious agents have been associated with the development of lymphoma. Additionally, a family history of hematologic malignancy appears to be an important risk factor for lymphoma. Specifically, a family history of leukemia is associated with development of PTCL, chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL), and MCL. A family history of NHL is associated with an increased risk of all forms of NHL.

Immune Disorders

The frequency of NHL is greatly increased in immunocompromised patients. The two most common clinical circumstances are among HIV-infected patients and solid organ transplant recipients, both associated with prolonged immunosuppression.[5,6] Between 1996 and 2009, the cumulative incidence of NHL among those infected with HIV was 4.5%—the highest of any malignancy.[7] Among those who died from NHL between 2005 and 2012, 4.2% were infected with HIV. Burkitt lymphoma (BL), DLBCL, and PCNSL are the most frequent lymphomas among those infected with HIV and are considered AIDS-defining illnesses.[8] The introduction of highly active antiretroviral therapy (HAART) has resulted in the decline in NHL incidence and mortality among those infected with HIV. This trend is seen in most HIV-associated NHL subtypes apart from BL whose incidence has subtly increased since the advent of

HAART. This may be explained by BL's unique pathogenesis, which is dependent on an intact immune system capable of producing germinal centers.[9]

Immunosuppression caused by organ transplantation and end-stage renal disease is also associated with increased risk of NHL. A large registry study in Sweden found that solid organ transplant recipients and dialysis patients had an incidence of NHL 7.9 and 5.1 times that of the general population, respectively.[10] Additionally, those with rare inherited immunodeficiency disorders such as X-linked lymphoproliferative syndrome, common variable immunodeficiency, Wiskott-Aldrich syndrome, and ataxia telangiectasia experience up to a 7% lifetime risk for development of NHL.[11]

NHL is more common among those with certain autoimmune diseases. Sjögren disease is strongly associated with increased incidence of MZL.[12] Sjögren disease is also associated with DLBCL, as are other B-cell–activating autoimmune diseases such as autoimmune hemolytic anemia, systemic lupus erythematosus, and rheumatoid arthritis.[13–15] Unsurprisingly, T-cell–activating autoimmune disorders such as celiac disease are associated with T-cell lymphomas, as are chronic skin diseases such as psoriasis, bullous pemphigoid, and atopic dermatitis.[14,16]

Infectious Agents

Epstein-Barr virus (EBV), a member of the herpes family, has been implicated in the pathogenesis of several lymphomas. The EBV viral genome can be found within tumor cells of nearly every endemic BL case, 40% of HIV-associated BL and 10% to 15% of sporadic BL.[17,18] Given that the distribution of BL in equatorial Africa closely overlaps that of holoendemic malaria, many have suspected that *Plasmodium falciparum* infection may also play a role in the development of BL.[19,20] The molecular basis for this link remained elusive until evidence recently emerged suggesting *P. falciparum* may work synergistically with EBV to increase the likelihood of malignant transformation within germinal centers.[21–23] EBV infection is also implicated in the development of DLBCL, PCNSL, plasmablastic lymphoma, primary effusion lymphoma, and NK/T-cell lymphoma, nasal type.[24]

The human T-cell lymphotropic virus type 1 (HTLV-1) is an RNA virus that is endemic in Japan, the Caribbean, intertropical Africa, South America, and Papua New Guinea.[25] Infection with HTLV-1 conveys a 5% lifetime risk of developing adult T-cell leukemia/lymphoma, though the risk is substantially lower for those infected after adolescence.[26] Human herpes virus 8 (HHV-8), the causative agent

of Kaposi sarcoma, is associated with several rare lymphoproliferative diseases, including primary effusion lymphoma, which can occur in immunosuppressed individuals with or without HIV infection.[27]

Hepatitis C virus (HCV) is the leading cause of both chronic hepatitis and hepatocellular carcinoma worldwide.[28] A large analysis of seven case–control studies through the InterLymph Consortium indicates that HCV infection is associated with a two- to threefold increased incidence of DLBCL, lymphoplasmacytic lymphoma, and MZL.[29]

MZL is peculiar among the NHLs in its association with localized bacterial infections. Specifically, there is a strong causal link between infection with *Helicobacter pylori* (*H. pylori*) and the development of gastric MALT lymphoma (mucosa-associated lymphoma tissue). Infection with this organism is found in over 90% of patients with gastric MALT.[30] Moreover, successful eradication of *H. pylori* with antibiotic therapy in localized gastric MALT results in complete remission in 62% of patients.[31]

The role of other bacterial infections in nongastric MALT is controversial.[32] Several studies document a strong association between *Chlamydia psittaci* (*C. psittaci*) and ocular adnexal MALT. In a series of 40 patients from Northern Italy, *C. psittaci* DNA was found in 80% of cases, compared with 0% found in nonneoplastic orbital biopsies.[33] However, another series including 142 patients from Europe, Asia, and North America found *C. psittaci* in only 22% of cases. Although this differed significantly from the prevalence of *C. psittaci* in nonneoplastic biopsies and non-MALT lymphoma biopsies (10% and 9%, respectively), there was marked geographic heterogeneity, suggesting that the association may be variable and dependent on other factors such as the prevalence of infection within the region's population.[34] *Borrelia burgdorferi* and *Campylobacter jejuni* have been linked to cutaneous MZL and immunoproliferative small intestine disease/MZL of the small bowel, respectively. However, the data supporting these associations are based on anecdotal reports and small case series.[35] *There remains no clear role for the use of antibiotics in the treatment of nongastric MZL.*

Environmental and Occupational Exposures

Many occupations have been associated with a higher risk of developing NHL. A recent pooled analysis from the InterLymph Consortium demonstrated an increased incidence of NHL in farmworkers (OR 1.19; 95% CI [1.01 to 1.36]), women's hairdressers (OR 1.34; [1.02 to 1.75]), charworkers/cleaners (OR 1.17;

[1.01 to 1.36]), spray painters (OR 2.07; [1.30 to 3.29]), electrical wiremen (OR 1.24; [1.00 to 1.54]), and carpenters (OR 1.42; [1.04 to 1.93]).[36] Several other studies have documented an increased incidence of NHL among teachers,[37–39] though this association was not borne out in the aforementioned InterLymph Consortium analyses.[16,36] Exposure to solvents such as benzene, toluene, xylene, and styrene are linked to development of FL.[40] Exposure to individual pesticides has been extensively studied with conflicting results.[41]

The connection between cigarette smoking and lymphoma is controversial. A large meta-analysis found a subtle association between cigarette smoking and development of NHL (OR 1.05; [1.00 to 1.09]).[42] A second large meta-analysis found an association only among female smokers (OR 1.40; [1.14 to 1.73]),[43] although several large studies detected no association.[16,44,45]

The data concerning UV radiation are conflicting as well with some studies suggesting a positive association between increased sun exposure with NHL,[46–48] whereas other studies suggest that sunlight may be protective.[49] Ionizing radiation exposure is associated with development of leukemia and many solid tumors. However, the link to the development of NHL is tenuous. Large analyses of atomic bomb survivors, radiologic technologist, and those who have received therapeutic radiation have not detected any association with NHL.[50–52] Conversely, a large Dutch study evaluating 3,905 survivors of Hodgkin lymphoma (HL) treated between 1965 and 2000 found a significantly increased risk of developing NHL among those who underwent mantle field/supradiaphragmatic RT compared to those who received no radiation treatment, though the absolute excess risk was small.[53]

PATHOLOGY

NHL comprises numerous disease entities, often difficult to diagnosis, with a correspondingly complex histopathologic classification that has changed relatively frequently over the years. The predecessor to the currently utilized World Health Organization (WHO) classification was the Working Formulation.[54] It subdivided NHL into low-grade, intermediate-grade, high-grade, and miscellaneous entities. Such groupings were convenient and appeared clinically useful, but represented an oversimplification and did not account for several distinct clinical–pathologic entities.

The WHO 2008 classification divided NHL into B-cell, T-cell, and NK cell neoplasms.[55] Substantive revisions were published in 2016 (Table 82.1).[56] These

specific entities are distinguished on the basis of reproducibly identifiable morphologic, immunologic, and genetic characteristics. Combining pathologic findings with clinical presentation is required to distinguish some entities (e.g., CD30+ lymphoproliferative disorders). The specific diseases described may be either indolent or aggressive in behavior. Within a given disease, there may be a range of behaviors (e.g., anaplastic large-cell lymphoma [ALCL]). Similarly, the histologic grade and the biologic behavior may vary within a specific disease entity (e.g., FL). The WHO classification describes new disease categories not clearly recognized in the Working Formulation, notably MZL, MCL, PTCLs, ALCL, and primary mediastinal large B-cell lymphoma.

TABLE 82.1 2016 WHO Classification of Mature Lymphoid Neoplasms[a]

Mature B-cell Neoplasms

- Chronic lymphocytic leukemia/small lymphocytic lymphoma
- Monoclonal B-cell lymphocytosis
- B-cell prolymphocytic leukemia
- Splenic marginal zone lymphoma
- Hairy cell leukemia
- Splenic B-cell lymphoma/leukemia, unclassifiable
  - Splenic diffuse red pulp small B-cell lymphoma
  - Hairy cell leukemia variant
- Lymphoplasmacytic lymphoma
  - Waldenstrom macroglobulinemia
- Monoclonal gammopathy of undetermined significance (MGUS), IgM
- *μ* Heavy chain disease
- *γ* Heavy chain disease
- *α* Heavy chain disease
- Monoclonal gammopathy of undetermined significance (MGUS), IgG/A
- Plasma cell myeloma
- Solitary plasmacytoma of bone
- Extraosseous plasmacytoma
- Monoclonal immunoglobulin deposition diseases
- Extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue (MALT lymphoma)
- Nodal marginal zone lymphoma
  - Pediatric nodal marginal zone lymphoma
- Follicular lymphoma
  - *In situ* follicular neoplasia
  - Duodenal-type follicular lymphoma
- Large B-cell lymphoma with IRF4 rearrangement
- Primary cutaneous follicle center lymphoma
- Mantle cell lymphoma
  - *In situ* mantle cell neoplasia

- Diffuse large B-cell lymphoma (DLBCL), NOS
  - Germinal center B-cell type
  - Activated B-cell type
- T-cell/histiocyte-rich large B-cell lymphoma
- Primary DLBCL of the central nervous system (CNS)
- Primary cutaneous DLBCL, leg type
- EBV+ DLBCL, NOS
- EBV+ mucocutaneous ulcer
- DLBCL associated with chronic inflammation
- Lymphomatoid granulomatosis
- Primary mediastinal (thymic) large B-cell lymphoma
- Intravascular large B-cell lymphoma
- ALK+ large B-cell lymphoma
- Plasmablastic lymphoma
- Primary effusion lymphoma
- HHV8+ DLBCL, NOS
- Burkitt lymphoma
- Burkitt-like lymphoma with 11q aberration
- High-grade B-cell lymphoma, with *MYC* and *BCL2* and/or *BCL6* rearrangements
- High-grade B-cell lymphoma, NOS
- B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and classical Hodgkin lymphoma

Mature T and NK Neoplasms

- T-cell prolymphocytic leukemia
- T-cell large granular lymphocytic leukemia
- Chronic lymphoproliferative disorder of NK cells
- Aggressive NK-cell leukemia
- Systemic EBV+ T-cell lymphoma of childhood
- Hydroa vaccineformelike lymphoproliferative disorder
- Adult T-cell lymphoma/leukemia
- Extranodal NK/T-cell lymphoma, nasal type
- Enteropathy-associated T-cell lymphoma
- Monomorphic epitheliotropic intestinal T-cell lymphoma
- Indolent T-cell lymphoproliferative disorder of the GI tract
- Hepatosplenic T-cell lymphoma
- Subcutaneous panniculitislike T-cell lymphoma
- Mycosis fungoides
- Sezary syndrome
- Primary cutaneous CD30+ T-cell lymphoproliferative disorders
  - Lymphomatoid papulosis
  - Primary cutaneous anaplastic large-cell lymphoma
- Primary cutaneous *γδ* T-cell lymphoma
- Primary cutaneous CD8+ aggressive epidermotropic cytotoxic T-cell lymphoma
- Primary cutaneous acral CD8+ T-cell lymphoma
- Primary cutaneous CD4-positive small/medium T-cell lymphoproliferative disorder
- Peripheral T-cell lymphoma, NOS
- Angioimmunoblastic T-cell lymphoma
- Follicular T-cell lymphoma
- Nodal peripheral T-cell lymphoma with TFH phenotype

Anaplastic large-cell lymphoma, ALK+
Anaplastic large-cell lymphoma, ALK−
Breast implant–associated anaplastic large-cell lymphoma

[a]Excludes Hodgkin lymphoma, posttransplant lymphoproliferative disorders, and histiocytic/dendritic cell neoplasms.
Republished with permission of American Society of Hematology from Swerdlow SH, Campo E, Pileri SA, et al. The 2016 revision of the World Health Organization classification of lymphoid neoplasms. *Blood* 2016;127(20):2375–2390; permission conveyed through Copyright Clearance Center, Inc.[56]

It must be emphasized that lymphoma pathology is complex with a long history of interobserver disagreement. The National Comprehensive Cancer Network (NCCN) guidelines describe as "essential" specialized hematopathology review of all slides and adequate immunophenotyping to establish the diagnosis.[57] Fine needle aspiration alone is rarely acceptable for the initial diagnosis of lymphoma because of lack of nodal architecture.[58] Specific pathologic features for each lymphoma subtype will be discussed under the relevant disease sections.

CLINICAL FEATURES AND EVALUATION

Clinical Presentation

NHL is predominantly a disease of older adults, in contrast to HL, with a median age at presentation of approximately 65 years.[1] There is a slight male preponderance (55% to 60% male). NHL may involve lymph nodes in almost any area of the body but may also present at extranodal sites, in contrast to HL in which extranodal presentation is rare.

The clinical features differ somewhat depending on the histology. For patients with primarily nodal disease, presentation is typically an asymptomatic lump in the neck or inguinal–femoral regions. Axillary involvement is somewhat less common. Patients with FL frequently give a history of waxing and waning of lymph nodes, sometimes over several years. Although patients with nodal presentations may initially appear to have localized disease, subsequent staging evaluation usually results in assignment to a more advanced stage, particularly in patients with FL. Most nodal presentations of NHL are asymptomatic. B symptoms including unexplained fevers, drenching night sweats, and >10% weight loss are much less frequently encountered than in HL, are not prognostic, and usually do not influence choice of treatment.

Patients with extranodal presentations are likely to have symptoms related to

the organ in question (e.g., the stomach or head and neck sites). Extranodal involvement is common in DLBCL, occurring in approximately 50% of patients with early-stage disease[59] and approximately 70% of all patients.[60] With the exception of bone marrow involvement, extranodal disease is relatively rare with FL. Extranodal presentation is the rule for MZL. Considering patients with DLBCL, primary extranodal disease, stage for stage, is managed in the same fashion as primary nodal disease and has a virtually identical outcome. There are a few notable exceptions such as primary CNS lymphoma and testicular DLBCL; the latter has a special tendency to spread to the contralateral testis and CNS.[61]

Initial diagnosis of lymphoma is made on appropriate histologic tissue preferably by an experienced hematopathologist and is dependent on morphology, immunohistochemistry, flow cytometry, and, in some instances, appropriate molecular studies. As stated, a fine needle aspirate rarely provides sufficient tissue for diagnosis of a new lymphoma.[58] An incisional or excisional biopsy is ideal; sometimes, a core needle biopsy is sufficient.

Evaluation and Staging

It is important to define the extent of disease at presentation to allow for appropriate therapeutic decisions (Table 82.2). One begins with a careful history and physical examination, a truism but often neglected in the age of extensive and readily available imaging. The history should record the presence or absence of B symptoms, performance status, growth history of any lymph node enlargement, and any specific symptoms suggestive of extranodal disease. All peripheral nodal areas including the epitrochlear nodes and Waldeyer ring should be examined clinically and enlarged nodes measured with readily available inexpensive calipers and the largest diameter of any enlarged nodes recorded.

TABLE 82.2 Clinical, Laboratory, and Radiologic Evaluation of Patients with NHL[a]

History and physical examination including performance status
Incisional/excisional biopsy with appropriate hematopathology review
Blood studies
Complete blood count
Comprehensive metabolic panel
Lactate dehydrogenase
Pregnancy test in women of child-bearing age
Hepatitis serologies and HIV testing (as indicated)
Imaging evaluation

	Positron emission tomography/computed tomography with contrast (preferred) Computed tomography scan of the chest, abdomen, pelvis with contrast (head and neck as indicated)
Bone marrow aspirate and biopsy (as indicated)	

HIV, human immunodeficiency virus.
[a]Additional tests may be necessary based on underlying histology and presentation.

Laboratory procedures include complete blood count, metabolic panel, LDH, β2 microglobulin, and hepatitis B and HIV antibodies in selected patients.

In the United States and much of the developed world, PET-CT is now the imaging procedure of choice for FDG-avid lymphomas, which comprise the great majority of NHLs. The CT aspect of the PET-CT examination should be performed with contrast in a similar fashion to a regular diagnostic CT scan. If PET-CT is not available, routine CT examination will suffice. A regular chest x-ray is no longer recommended because of the greater accuracy and sensitivity of CT.[62]

Routine bone marrow biopsy has been standard in lymphoma evaluation for many years, but the high sensitivity of PET-CT for bone marrow involvement in DLBCL is calling this practice into question for that entity.[62] If a PET-CT indicates marrow involvement in DLBCL, a confirmatory bone marrow biopsy is not recommended. There are considerably less data, however, for other histologies, particularly FL where bone marrow biopsy remains standard of practice and is particularly important in patients with ostensible stage I or II disease who are candidates for curative radiotherapy.

In the past, staging systems for lymphoma were primarily the Ann Arbor system and the Cotswolds modification, but they have been superseded by the Lugano classification (Table 82.3). For NHL, A and B subtypes have been dropped because of the infrequency of systemic symptomatology, the unclear influence on prognosis, and the usual lack of relevance for management decisions. Tumor bulk is no longer a part of the staging system because of the lack of consensus as to what constitutes bulky disease as well as the uncertain influence of bulk on prognosis in the current therapeutic era. The Lugano recommendation is simply to record the largest diameter of a given nodal site.[62]

Response Assessment

Response assessment should include clinical evaluation with repeat history and physical examination and appropriate imaging studies. If available, PET-CT is the most accurate imaging modality for response assessment as well as the initial

evaluation. Use of PET-CT eliminates the need for the category CRu (complete response uncertain), a situation observed with static CT imaging in which tumor masses were observed to have decreased in size but had not completely disappeared, raising the question of whether viable tumor remained. End-of-treatment assessment is probably most accurate and most meaningful.

TABLE 82.3 REVISED STAGING SYSTEM—THE LUGANO CLASSIFICATION

Stage	Involvement	Extranodal (E) Status[a]
Limited		
I	One node or a group of adjacent nodes	Single extranodal lesion without nodal involvement
II	Two or more nodal groups on the same side of the diaphragm	Stage I/II by nodal extent with limited contiguous extranodal involvement
II bulky	II as above with "bulky" disease[b]	N/A
Advanced		
III	Nodes on both sides of the diaphragm; nodes above the diaphragm with spleen involvement	N/A
IV	Additional noncontiguous extralymphatic involvement	N/A

[a]Tonsils, Waldeyer ring, and spleen are considered nodal tissue.
[b]Definition of bulky disease in DLBCL not validated but 6 to 10 cm generally accepted.

TABLE 82.4 DEAUVILLE CRITERIA (PET-CT 5-POINT SCALE)

Score	Definition
Deauville 1	No uptake above background
Deauville 2	Uptake ≤ mediastinal blood pool
Deauville 3	Uptake > mediastinal blood pool but ≤ liver
Deauville 4	Uptake moderately increased compared to the liver
Deauville 5	Uptake markedly increased compared to the liver or new sites of disease

Adapted by permission from Springer: Barrington SF, Qian W, Somer EJ, et al. Concordance between four European centres of PET reporting criteria designed for use in multicentre trials in Hodgkin lymphoma. *Eur J Nucl Med Mol Imaging* 2010;37(10):1824–1833. Copyright © 2010 Springer-Verlag.

Responses may be divided into complete, partial, no response or stable disease, and progressive disease. Detailed descriptions of response criteria were described at the Lugano meeting.[62] A complete metabolic response is defined as absence of all palpable disease, and a PET score of 1, 2, or 3 utilizing the 5-point scale or Deauville criteria, with or without a residual mass on static CT imaging (Table 82.4). A partial metabolic response is defined as a score of 4 or 5 but with reduced uptake compared with original scans. Similarly, on CT imaging, a partial remission indicates >50% decrease in measurable disease. No response or stable disease suggests no change in lesion size on static imaging and no significant change in FDG uptake. Progressive disease is a worsening of these findings.

The term partial response can be somewhat misleading. A Deauville score of 4 or 5 at the completion of therapy strongly suggests treatment failure even if uptake has been reduced from baseline. It is often advisable, however, to confirm the presence of active disease histologically with biopsy in patients with a partial metabolic response if major therapeutic changes are contemplated (e.g., stem cell transplantation). The use of radiotherapy in the circumstance of partial metabolic response is discussed in the individual disease sections.

Imaging response assessment is also frequently carried out midway through the course of therapy, so-called interim PET imaging. Many studies of interim PET-CT have been carried out, particularly in DLBCL, suggesting that an interim positive PET-CT (Deauville 4 or 5) predicts for a worse outcome. Thus far, however, there is no conclusive evidence that changing treatment according to the interim PET findings improves outcome. This question is currently under active investigation.

For the less aggressive histologies such as FL, data regarding the role of interim PET are sparse but do not suggest any particular benefit. Considering the generally incurable nature of advanced FL, if the patient is doing clinically well at the completion of therapy, the value of extensive imaging can be questioned.

Follow-Up and Routine Surveillance

Follow-up procedures and routine surveillance studies have been infrequently addressed in the literature. NCCN guidelines suggest a history and physical and routine laboratory assessment every 3 to 6 months for 5 years and then annually as indicated.[57] Routine surveillance PET scanning is not recommended. CT imaging can be considered depending on underlying histology and clinical presentation but is of unclear benefit.

Detection of relapse is most relevant for DLBCL where curative therapy is available, most notably a stem cell transplant. The NCCN does point out, however, that even for DLBCL, there is no evidence demonstrating improved survival outcome with early detection of relapse. Further, the great majority of relapses are associated with clinical symptoms or abnormal physical findings. It is rare to discover recurrent disease on a routine imaging study in a patient who is clinically well with a normal exam.

Curative potential also exists for recurrent MZL. Relapses often occur at sites prone to development of MZL such as the orbit, skin, or head and neck area, are often localized, and respond well to a second course of radiotherapy. Such patients may well be long-term survivors—whether they are truly cured is controversial.

For most other histologic varieties of NHL, particularly FL, the detection of recurrence is less relevant. Generalized FL is still regarded as incurable (in contrast to localized FL). Relapse after treatment of localized FL is almost always generalized. An ostensibly localized nodal recurrence on the opposite side of the diaphragm, for example, would be considered generalized disease. Of course, if the disease was generalized at onset, it remains so at relapse, even if the recurrence is ostensibly localized to a nodal area. Because generalized FL is often observed without treatment until specific criteria for initiating therapy are met, there is little rationale for aggressive attempts at early detection of relapse in an asymptomatic patient with a normal exam.

DIFFUSE LARGE B-CELL LYMPHOMA

DLBCL, the most common type of NHL (30% of all cases in North America and Western Europe),[64] comprises a heterogeneous group of neoplasms with multiple morphologic variants and subtypes described in the current WHO classification.[55] Distinct subtypes include PCNSL, primary cutaneous DLBCL, leg type, T-cell/histiocyte-rich large B-cell lymphoma, and EBV-positive DLBCL of the elderly. Further, numerous other NHL entities arise from large B cells including primary mediastinal (thymic) large B-cell lymphoma (PMBCL).

Pathology

DLBCL is a neoplasm of large, transformed B cells with a diffuse growth pattern that totally or partially effaces the nodal architecture. The proposed normal counterparts are peripheral B cells of either germinal center or postgerminal

center (activated B cell) origin. Indeed, DNA microarray analyses using fresh frozen tissue show that unique molecular subgroups exist, which include a germinal center B-cell (GCB) subgroup and an activated B-cell (ABC) subgroup.[65,66] PMBCL also has a unique molecular signature that closely resembles classical HL.[67] Assays utilizing immunohistochemistry to identify molecular subgroups, using formalin-fixed, paraffin-embedded tissue, have also been developed.[68–73] No single algorithm using immunohistochemistry is perfect in regard to predicting gene expression profiling results, though each divides patients into groups with different survival outcomes. Treatment tailored to molecular subclassification of this disease is currently being evaluated in prospective studies and is not routinely practiced.

DLBCL express one or more pan B-cell markers (CD19, CD20, CD22, and CD79a) and often surface and/or cytoplasmic immunoglobulin.[74] *MYC*, *BCL2*, and/or *BCL6* gene rearrangements are present in a minority of patients with DLBCL. However, DLBCL with gene rearrangements of *MYC* (a potent oncogene) together with a translocation of *BCL2* (an antiapoptotic gene), or less frequently *BCL6*, is now referred to as a double-hit lymphoma. If all three genes are rearranged, it is referred to as a triple-hit lymphoma. Approximately 5% to 10% of patients with DLBCL have double-hit or triple-hit genetics, which carries a particularly poor prognosis, despite the fact that the molecular subgroup is typically the GCB-like.[75,76] Similarly, other patients, typically with an ABC-like subtype, have overexpression by immunohistochemistry of MYC and BCL2 and/or BCL6, without the accompanying gene rearrangements. Such DLBCLs are referred to as double or triple expressors. Such patients also have a worse prognosis, though more favorable than double-hit lymphomas.[77]

Clinical Presentation

DLBCL is primarily a disease of older adults, with a median age of 64 years and a slight preponderance of men (55%). B symptoms are present in approximately one-third of patients but are not prognostic, and current guidelines do not recommend including an “A” or “B” staging designation, as is done for HL.[62] Just over half the patients (55%) have localized disease (stages I or II). As is opposed to localized FL, where nodal presentations are predominant, about half of patients with stage I to II DLBCL present with extranodal disease. Patients most often present with an enlarging peripheral nodal mass or with symptoms related to a primary extranodal site of involvement.

Prognostic Factors

The International Non-Hodgkin's Lymphoma Prognostic Factors project examined data on 2,031 patients, all with aggressive histology NHL.[60,78] Two indices were developed, the International Prognostic Index (IPI) and the age-adjusted IPI, because age was found to be a highly significant prognostic variable (>60 vs. ≤60 years). For the IPI, five prognostic variables were found to be significant: age, performance status, stage, number of extranodal sites, and LDH (Table 82.5). The relative risks of these factors were low, ranging from 1.47 for stage to 1.96 for age. Five-year survival was 73%, 51%, 43%, and 26% when 0 to 1, 2, 3, and 4 to 5 risk factors were present. When patients were divided by age, three factors remained independently significant: performance status, stage, and LDH.

The IPI was designed in the prerituximab era. In the last 10 to 15 years, multiple randomized studies have shown that rituximab significantly improves survival when combined with standard combination chemotherapy.[81–83] Using data from three prospective trials, the German High-Grade Non-Hodgkin's Lymphoma Study Group found the IPI to retain prognostic significance in the rituximab era.[84] Adding approximately 10% survival to each IPI subgroup approximates outcomes when rituximab is added to combination chemotherapy.

TABLE 82.5 PROGNOSTIC INDICES—DIFFUSE LARGE B-CELL LYMPHOMA AND FOLLICULAR LYMPHOMA

Prognostic Index	Risk Factors	Score (Number of Factors)	Outcome
Diffuse Large B-Cell Lymphoma			
IPI[60]	Age > 60 y Performance status ≥ 2 Stage III-IV Elevated LDH >1 extranodal site	Low (0–1) Low Intermediate (2) High Intermediate (3) High (4–5)	73% (5-year survival) 51% 43% 26%
Follicular Lymphoma			
FLIPI[79]	Age ≥ 60 y >4 nodal sites Elevated LDH Stage III–IV Hemoglobin <12 g/dL	Low (0–1) Intermediate (2) High (≥3)	71% (10-year survival) 51% 36%
FLIPI-2[80]	Age > 60 y B2M elevated Hemoglobin <12 g/dL	Low (0) Intermediate (1–2) High (≥3)	80% (5-year PFS) 51% 19%

	BM involvement
	Nodal diameter >6 cm

*β*2M, beta-2 microglobulin; BM, bone marrow; FLIPI, Follicular Lymphoma International Prognostic Index; IPI, International Prognostic Index; LDH, lactate dehydrogenase; PFS, progressionfree survival.

As mentioned previously, several pathologic factors carry prognostic implications. Distinct subgroups of DLBCL, based on different cells of origin, can be identified using either gene expression profiling[85] or immunohistochemistry.[68–73] The GCB subtype has a more favorable prognosis compared with the ABC subtype (defined using gene expression profiling) or non–GCB-like subtype (defined using immunohistochemistry).[65,86] Additional molecular signatures that appear to influence tumor behavior have also been proposed.[66] Also, double-expressor, and particularly double-hit, lymphomas carry a worse prognosis.[75,76]

Both interim and postchemotherapy PET-CT assessments also carry prognostic importance. Although PET-CT interpretation was not standardized in most of these studies, in current practice, the 5-point scale (Deauville criteria) should be utilized.[62] In numerous studies, residual PET-positive disease after the completion of chemotherapy alone in aggressive NHLs (mostly DLBCL) is associated with a high risk of disease progression.[87–90] For example, in the setting of advanced DLBCL with PET-positive disease after chemotherapy without rituximab, the risk of progression was 100% in a series by Mikhaeel et al. (n = 9)[88] and Spaepen et al. (n = 26).[87] Similarly, poor outcomes have been noted when a posttreatment PET-CT is still positive after R-CHOP (rituximab, cyclophosphamide, doxorubicin, vincristine, prednisone).[91] Outcomes appear to be much better when RT is administered in this clinical setting.[92,93]

Achievement of a negative PET-CT early in the course of therapy (after 2 to 3 cycles) is associated with improved progression-free survival (PFS), but not always overall survival (OS),[91] compared with a positive interim PET-CT.[89,91,94–97] For example, in a study by Safar et al., 3-year progression-free and OS were 84% and 88%, respectively, in patients achieving a negative PET-CT after 2 cycles of chemotherapy plus rituximab.[97] This compared with 47% and 62%, respectively, in patients who were still PET positive. Interim PET-CT response appears to have prognostic significance in both the low- and high-risk IPI groups[89,96] but may be less prognostic in the ABC subtype compared with the germinal center-like subtype.[98]. Although the negative predictive value of interim PET-CT is high, the positive predictive value is relatively low. When

compared with interim response assessment, postchemotherapy PET-CT response appears to be more prognostic, particularly in terms of the positive predictive value.[91,95,99]

Clinical Management

Chemoimmunotherapy, with or without consolidation RT, is standard in all stages of DLBCL. Perhaps, the most promising innovation in the last several decades in the treatment of B-cell NHLs, including DLBCL, has been the development of effective immunotherapy. DLBCL expresses the B-cell antigen CD20, which led to the genetic engineering of the human chimeric anti-CD20 antibody rituximab. In contrast to prior murine-derived monoclonal antibodies, rituximab is quite well tolerated in humans. Rituximab was the first antibody of any type FDA approved (1997) for the treatment of any human malignancy. Multiple phase III trials have now demonstrated the value of adding rituximab to standard CHOP.

The GELA study compared CHOP alone with rituximab and CHOP in 399 patients over age 60.[81] PFS improved from 30% to 54% and 5-year OS from 45% to 58%. Similarly, a European cooperative trial compared R-CHOP and CHOP in 824 patients aged 18 to 60 with stages II to IV DLBCL.[82] Three-year PFS was 79% in the R-CHOP group compared with 59% in the CHOP group. Three-year OS was 93% and 84%, respectively. In this trial, unlike the GELA trial, RT was given to select patients with bulky disease and/or extranodal disease. These studies have led to the rapid adaptation of R-CHOP as standard initial therapy of DLBCL for all stages of disease. The effect of the addition of rituximab is so substantial as to force a re-evaluation of prognostic factors as well as other adjuvant therapies (such as stem cell transplantation or RT) in the rituximab era.

The most widely used chemotherapy combination is CHOP. An older randomized study by the Southwest Oncology Group (SWOG) demonstrated that CHOP was just as effective, less costly, and with fewer side effects than more aggressive regimens that demonstrated promise in phase II studies.[100] A more recent randomized trial demonstrated that R-CHOP was just as effective as the more aggressive regimen DA-EPOCH-R (dose adjusted, etoposide, prednisolone, vincristine, cyclophosphamide, doxorubicin, rituximab).[101] Thus, R-CHOP remains the standard regimen for DLBCL.

Stage I to II DLBCL

In the prechemotherapy era, early-stage DLBCL was treated with RT alone.[102–108] The doses of RT varied widely from 30 to 60 Gy. Field sizes and arrangements also varied widely, but, in general, involved field RT was used. The complete response rate was high, usually >80% with 10-year PFS and OS ranging from 30% to 60%, depending on the mix of patients and prognostic variables. The pattern of failure in these series was primarily distal, either organ involvement or nodal sites remote from the primary site. Patients with both nodal and extranodal diseases were included in these series and appeared to have equivalent prognoses. Stage II patients did worse than stage I with a long-term PFS in the range of 25%, in contrast to patients with stage I disease where PFS was higher (50% to 60%).

In the late 1970s and early 1980s, efforts to improve upon these results by the addition of chemotherapy were begun. With combination chemotherapy plus RT, complete response rates of approximately 90% were reported with PFS and OS in the range of 70% to 85%.[109–112] The chemotherapy regimen as well as the number of cycles varied, as did the doses of RT. None of the trials used rituximab as part of the therapy (now standard) nor was functional imaging employed for assessment of response.

After improved outcomes were seen with the addition of chemotherapy, the question was raised whether RT was still necessary. Multiple randomized studies in early-stage DLBCL have been conducted comparing chemotherapy with a combined modality program (Table 82.6).[59,113,115–117,119] Interpretation of the trials can be challenging, given their individual peculiarities. Only one, unpublished to date, included rituximab or functional imaging. A brief summary of each of the trials follows.

The SWOG S8736 study compared brief CHOP chemotherapy (3 cycles) plus RT (40 to 55 Gy) to a more extended CHOP regimen (8 cycles) without RT.[113] Both PFS (77% vs. 64%) and OS (82% vs. 72%) at 5 years were improved in the combined modality arm with less toxicity. However, after median follow-up of almost 18 years, no significant differences were apparent, because of late systemic relapses in the arm with only 3 cycles of CHOP. Interestingly, a continual pattern of relapse was noted in both arms throughout the follow-up period.[114] Long-term data from the phase II SWOG S0014 trial evaluating 3 cycles of R-CHOP + RT also demonstrated a continuous risk of relapse over time.[114] Thus, brief chemotherapy may provide insufficient systemic treatment for most patients with DLBCL.

The Eastern Cooperative Oncology Group (ECOG) 1484 study evaluated

whether consolidation RT (30 Gy) would reduce the risk of relapse in the setting of extended chemotherapy (8 cycles of CHOP in this case).[59] The primary outcome was PFS which was significantly improved with the addition of RT (73% with consolidation RT vs. 56% with observation at 6 years) (P = .05). No difference in OS was noted, though the study was not powered to evaluate this. This study suggests that consolidation RT provides benefit even after an extended course of chemotherapy.

TABLE 82.6 RANDOMIZED TRIALS OF CHEMOTHERAPY OR COMBINED MODALITY THERAPY FOR EARLY-STAGE DLBCL

Study	*n*	Disease Characteristics	Randomization	Progression-Free Survival[a]	Comments
SWOG[113,114]	401	I II (nonbulky)	CHOP × 8 CHOP × 3 + RT	64% 77% (P = .03)	No difference with long f/u
ECOG[59]	172	I (high-risk) II	CHOP × 8 CHOP × 8 + RT	56% 73%[b] (P = .05)	Only patients in CR by CT randomized
GELA 93-4[115]	576	I–II without risk factors	CHOP × 4 CHOP × 4 + RT	61% 64% (P = .6)	Only patients ≥ 60 years old
GELA 93-1[116]	647	I–II without risk factors	ACVBP × 3[c] CHOP × 3 + RT	82% 74% (P < .01)	Only patients ≤ 61 years old
IELSG[117]	44	I–II gastric DLBCL	CHOP[d] CHOP[d] + RT	82% 100% (P = .04)	Closed early because of poor accrual
LYSA/GOELAMS[118]	301	I–II nonbulky	R-CHOP × 4–6 R-CHOP × 4–6 + RT	87% 88% (P = .13)	PET-CT imaging utilized

ACVBP, doxorubicin, cyclophosphamide, vindesine, bleomycin, and prednisone; CHOP, cyclophosphamide, adriamycin, vincristine, prednisone; DLBCL, diffuse large B-cell lymphoma; ECOG, Eastern Cooperative Oncology Group; GELA, Groupe d'Étude des Lymphomes de l'Adulte; IELSG, International Extranodal Lymphoma Study Group; The Lymphoma Study Association/The French Acute Leukemia and Blood Diseases West–East Group; RT, radiation therapy; SWOG, Southwest Oncology Group.

[a] 5 y unless otherwise noted.

[b] 6 years.

[c] Plus consolidation chemotherapy with methotrexate, etoposide, ifosfamide, and cytarabine.

[d] CHOP or CHOP-like chemotherapy.

The Groupe d'Etudes des Lymphomes de l'Adulte (GELA) 93-4 enrolled older patients (>60 years) with early-stage disease without adverse risk factors.[115] Crude rates of local failure were less with RT (18% vs. 7%). However, neither PFS nor OS was improved with consolidation RT (40 Gy) after 4 cycles of chemotherapy. This study has been criticized by protocol violations (12% of patients did not receive RT) and delays in starting RT (median of 35 days after last cycle of chemotherapy). This study also suggests that older patients, especially those with favorable prognostic factors and/or medical comorbidities, may derive less benefit from consolidation RT.

GELA 93-1 demonstrated that an aggressive chemotherapy regimen (induction ACVBP [doxorubicin, cyclophosphamide, vindesine, bleomycin, prednisone] followed by consolidation methotrexate, etoposide, ifosfamide, and cytarabine) was superior to CHOP plus RT but at the expense of significantly increased toxicity.[116] Despite the apparent advantage of the aggressive chemotherapy program, it has not been generally adopted due to its toxicity profile.

Finally, the International Extranodal Lymphoma Study Group (IELSG) enrolled a small number of patients with gastric DLBCL to CHOP versus CHOP plus RT. PFS was improved with the combined approach.[117]

A randomized study from the LYSA/GOELAMS group compared 4 to 6 cycles of R-CHOP with and without RT (40 Gy) in stage I to II nonbulky DLBCL who achieved a complete response by PET-CT.[118] Event-free survival at 5 years was 87% with R-CHOP versus 91% with R-CHOP plus RT (P = .13). There were no local failures in the arm receiving RT, whereas approximately 50% of failures in the no-RT arm failed at original sites of disease involvement. Most patients in this study had low-risk disease by the IPI. To date, this study has only been presented in abstract form.

In summary, the results from the randomized studies are mixed. The majority of the randomized studies (excepting the LYSA/GOELAMS trial) did not employ rituximab or PET-CT imaging, which is a significant limitation. However, using data from the modern era, the advantage of combined modality therapy has been observed using large databases including SEER,[120] NCCN,[121] and NCDB (National Cancer Database),[122,123] in addition to a large single institutional experience.[124] Given the modest doses employed (~30 Gy), high rates of local control after RT (~95%),[59,92,115] and predominance of data showing a benefit for consolidation RT, we favor a combined modality approach.

Stage III to IV DLBCL

The mainstay of treatment of advanced DLBCL is clearly systemic chemoimmunotherapy, typically R-CHOP, with 5-year survival of approximately 60%.[81] Many strategies have been explored to improve upon CHOP and R-CHOP including more chemotherapy cycles,[125] dose dense chemotherapy,[126,127] more intensive chemotherapy regimens,[100,101] maintenance rituximab,[83] and high-dose chemotherapy (HDC) and autologous stem cell transplant (ASCT).[128] None have consistently improved survival compared with standard R-CHOP. A comparatively unexplored approach is the use of consolidation RT in combination with chemotherapy for advanced DLBCL. One rational for the use of consolidation RT is the tendency of patients with advanced lymphoma to relapse at sites of original involvement and, in particular, sites of original bulk.[129–131] In view of the efficacy of combined modality therapy in localized disease, exploration of its value in more advanced disease appears worthwhile.

Several institutional series have evaluated the role of consolidation RT in advanced DLBCL. In the prerituximab era, series from M.D. Anderson[129] and Milan[130] both demonstrated improved local control and PFS with the additional of RT. Although OS was improved in the Milan series, which only included patients with disease >6 cm, survival was not improved in the M.D. Anderson series. In the rituximab era, series from M.D. Anderson,[132] Duke,[133] and Emory[134] have demonstrated improvements in local control[133,134] and survival[132,134] with consolidation RT, even when patients are in complete response by PET-CT. The Duke series suggests such benefits can be accomplished with low doses of radiation that are well tolerated with a low risk of long-term complications (~20 Gy).

Results from prospective studies have demonstrated the benefit of consolidation RT in the presence of bulky disease. The RICOVER-60 trial was a four-arm randomized study comparing different chemotherapy regimens. Consolidation RT was delivered to sites of initial bulk (≥7.5 cm) or extranodal disease. At the conclusion of the trial, an additional cohort was accrued and treated with the most effective regimen from the randomized trial (R-CHOP-14 × 6 cycles) but without consolidation RT (referred to as the RICOVER-noRTh trial). When comparing the two arms receiving the same chemotherapy regimen, the addition of consolidation RT improved both PFS (75% vs. 61%, $P < .001$) and OS (90% vs. 65%, $P = .001$).[135] Similarly, the German UNFOLDER trial (NCT00278408) prematurely closed the R-CHOP arms not receiving consolidation RT because of excess relapses in those with bulky disease (≥7.5

cm). Results from this trial have not yet been published. Other circumstances that may warrant consideration of consolidation RT include limited skeletal disease,[136] partial response to chemotherapy,[92,93,137] and limited presentations (e.g., mediastinal and upper retroperitoneal disease).

Relapsed and Refractory DLBCL

There has been a great interest in the application of HDC with ASCT in the treatment of malignant lymphomas, primarily in the setting of relapsed or refractory disease. Alternatively, an allogeneic transplant may be carried out in individuals with a suitable matched donor. In this procedure, it is hoped that the infused donor stem cells will additionally mount an immunologic attack on the tumor. Allogeneic transplantation may be preceded by full-dose (myeloablative) chemotherapy designed to have not only an antitumor effect but also to condition the patient for the infusion of the donor cells, or it may be preceded by a nonmyeloablative or reduced intensity conditioning (RIC) program designed primarily to enable the recipient to accept the donor stem cells. In this latter situation, the major antitumor effect is postulated to derive from the infused donor stem cells. Nonmyeloablative allogeneic transplants are associated with a much lower treatment-related mortality (10% to 20%) compared with myeloablative allogeneic transplants (40% to 50%).[138,139] Total-body irradiation is often a component of the conditioning program with doses varying quite widely from 2 to 4 Gy in nonmyeloablative regimens to 12 to 13.5 Gy in ablative regimens. An expert committee of the American Society for Blood and Marrow Transplantation has recently issued guidelines surrounding autologous and allogeneic transplantation.[140]

In general, ASCT has been investigated in three types of situations: (1) patients who have been treated with conventional chemotherapy and then relapsed, (2) patients who fail conventional chemotherapy from the onset (so-called primary refractory disease), and (3) patients who have responded well to primary chemotherapy but are considered at high risk for relapse. The most widely accepted use is for the treatment of patients with DLBCL who have relapsed following initial CHOP or R-CHOP chemotherapy.

In a phase III trial from the Parma group, patients with DLBCL who had relapsed following initial CHOP chemotherapy and who were responsive to a salvage program (dexamethasone, cisplatin, cytarabine) were then randomly assigned to receive either four additional cycles of DHAP or a HDC program with ASCT.[141] Those receiving ASCT had a markedly improved PFS (46% vs.

12%) and OS (53% vs. 32%), compared with those getting conventional chemotherapy. Note that in both arms of this trial, RT to original bulky sites of disease (≥5 cm) was utilized, dose of 35 Gy in 20 fractions in the conventional chemotherapy arm and 26 Gy in 1.3 Gy fractions bid in the ASCT arm. All patients in the Parma trial were younger than 60 years of age. Those with a short remission after initial chemotherapy had a worse outcome.[142]

The Parma trial has led to the adaptation of ASCT as standard of care for patients <60 years of age with DLBCL relapsing after initial chemotherapy. Note that the Parma trial is the only phase III investigation of relapsed DLBCL patients ever done. It is also important to recognize that in this as well as almost all other transplant trials, patients who do not respond to the initial salvage program do poorly with subsequent HDC and are not considered good candidates. More recently, PET-CT imaging is the preferred method to define response; those with a persistently positive PET-CT after a salvage program (Deauville 4) do poorly with HDC.[143,144]

Patients with primary refractory disease (i.e., those who are chemotherapy induction failures) should be managed similar to relapsed disease and proceed with salvage chemotherapy, typically R-ICE (rituximab, ifosfamide, carboplatin, etoposide) or R-DHAP (rituximab, dexamethasone, cytarabine, cisplatin). If a good response is achieved to salvage chemotherapy, ideally a complete response by PET-CT, then outcomes with subsequent stem cell transplantation are relatively good.[145] Those with primary progressive disease generally have a poor prognosis, however.

The role of RT in patients undergoing stem cell transplant, either autologous or allogeneic, is undefined.[146] The rationale for RT lies in the observation that most treatment failures after transplant occur at sites of initial involvement. As mentioned above, consolidation RT was employed in the landmark Parma trial. It is also commonly used at a number of institutions, usually directed at bulk disease sites present before the start of salvage chemotherapy but with considerable interinstitutional variation and without a clear definition of what constitutes bulk disease. We recommend doses of 20 to 30 Gy for those patients who have not received prior RT, depending on clinical circumstances and also dependent on whether or not TBI is planned as part of the conditioning regimen.

Palliation

For patients with relapsed/refractory disease, RT is an effective modality to achieve palliation of symptomatic disease. Although doses of 24 to 30 Gy are

most commonly utilized, low-dose RT (2 Gy × 2) may be reasonable in select circumstances. Response rates of 50% to 80% have been reported with 2 Gy × 2 with a median time to progression of about 1 year.[147,148] Larger and more durable responses are likely achieved with more traditional dosing schemes.

RT Dose and Field Design

The dose of RT in a combined modality treatment program depends principally on the stage of disease and response to chemotherapy. For patients with stage I to II disease, the standard dose is 30 Gy when a complete response (Deauville 1 to 3) has been achieved by PET-CT after chemoimmunotherapy, typically R-CHOP. A British National Lymphoma Investigation randomized study showed no difference in freedom from local progression, PFS, or OS between 30 Gy and 40 to 45 Gy.[149] Numerous other studies have shown high (~95%) rates of local control when approximately 30 Gy of RT is given after a complete response by CT or PET-CT to systemic therapy Gy.[59,92,93,112,132,150]

Even smaller doses may suffice with more effective systemic therapy, including rituximab-based regimens. A phase II study from Duke University recently completed accrual evaluating 20 Gy in the setting of a complete response by PET-CT after R-CHOP. The primary endpoint was local control. Preliminary results, with a median follow-up of 34 months, demonstrated no local failures with PFS at 3 and 5 years of 92% and 78%, respectively.[151]

For patients who have persistent PET-positive disease (Deauville 4), higher doses of consolidation RT may be required to achieve optimal local control (≥40 Gy)[92,93] (Fig. 82.1). In the unusual circumstance when RT alone is pursued for patients with localized disease, a dose of 40 Gy is recommended. There is little evidence for doses above 40 Gy.

In regard to field design, detailed guidelines from the International Lymphoma Radiation Oncology Group are available.[152,153] These guidelines recommend treatment using “involved-site” principles. Involved-site radiation therapy (ISRT) involves creating a clinical target volume that consists of the prechemotherapy extent of disease, adjusted to exclude uninvolved normal tissues after chemotherapy, and expanded to account for uncertainties in recreating the prechemotherapy extent of disease (anatomical changes, patient positioning differences between diagnostic PET-CT and planning CT scan, imaging uncertainties, etc.). A planning target volume is then created to account for setup variation and potential organ motion. Such recommendations are supported by prior studies demonstrating that the dominant pattern of failure

after combined modality therapy is usually disseminated disease, with a small percentage with local failure.[113] On the other hand, after chemotherapy alone, more local failure occurs.[113,154] Failure in nodal areas adjacent to the original disease is uncommon.

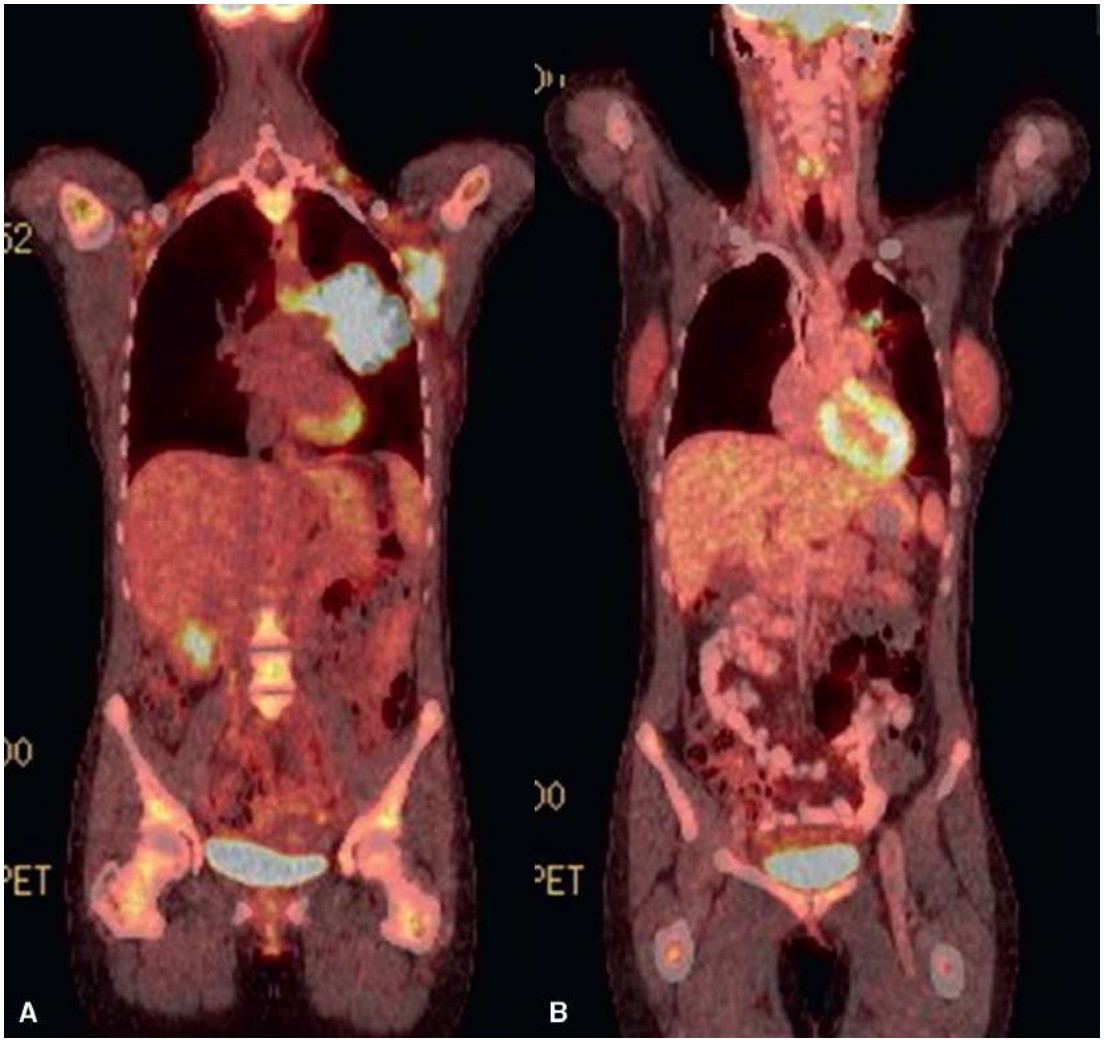

FIGURE 82.1. Fused coronal positron emission tomography/computed tomography (PET-CT) images of a patient with diffuse large B-cell lymphoma before **(A)** and after **(B)** chemoimmunotherapy. The postchemotherapy PET-CT was scored as a Deauville 4 (uptake above the liver) in the left hilum. Biopsy confirmed persistent disease.

For patients with localized disease (stage I to II), all sites of original involvement should be treated. For patients with advanced disease (stage III to IV), treatment fields should be customized. In those with reasonably limited presentations, consolidation of all sites of original involvement is favored. When this is not practical, treatment of select sites may be more prudent. This may include original sites of bulk, limited skeletal involvement, or a site that failed to

achieve a complete response to chemotherapy.

FOLLICULAR LYMPHOMA

FL is the second most common NHL in the United States and Western Europe, comprising approximately 20% of cases. It is the most common “indolent” lymphoma.

Pathology

FL is a tumor of follicle center B cells (centrocytes and centroblasts) with a follicular (nodular) pattern that morphologically is similar to normal germinal centers. The neoplastic follicles may be present in the entire tumor, or the lymphoma may contain a diffuse component as well. FL is graded based on morphology. There is a predominance of small cleaved cells (centrocytes), grade 1; a mixture of small cleaved and large cells, grade 2; or predominantly large cells (centroblasts), grade 3. In the WHO classification, the number of large cells per high-powered field is used to assign grades (0 to 5, 5 to 15, >15 for grades 1 to 3, respectively). Grade 3 is further subdivided into 3A and 3B with the latter characterized by an absence of centrocytes. Grade 1, 2, and 3A FLs are all closely related with similar biologic behavior and response to therapy. FL grade 3B, however, has a clinical course very similar to DLBCL and is usually managed as such.[155]

The tumor cells of FL are usually surface immunoglobulin positive and express pan B-cell–associated antigens (CD19, CD20), CD21, and CD10 (60% of the time), but lack CD5. Most cases are BCL-2 positive; nuclear BCL-6 is expressed by at least some of the neoplastic cells. The (14;18) translocation is characteristic for FL and together with the BCL-2 rearrangement is present in approximately 85% of cases. It is frequently absent, however, in FL grade 3B, further supporting the biologic distinctiveness of this category.

Recently, inactivating mutations of MLL-2 have been found in over 80% of FL patients, interfering with the ability of MLL-2 to activate gene transcription through H3K4 methylation.[156]

Clinical Presentation

FL primarily affects older adults (median age 65 years). There is a slight female preponderance. Most patients present with painless peripheral lymphadenopathy involving cervical, axillary, or inguinal–femoral regions. There may often be a history of spontaneous waxing and waning of lymph node size. Constitutional B

symptoms of fever, sweats, or weight loss are uncommon. In contrast to DLBCL, approximately 80% of patients present with generalized disease, most often with stage IV disease. The bone marrow is the principle extranodal organ involved. The presence of minimal bone marrow involvement as determined by BCL-2/IgH rearrangement detected by polymerase chain reaction (PCR) is much more common, found probably in the majority of stage I to II patients. The significance of this finding is uncertain and is not presently used to change the staging of such patients.

In contrast to DLBCL, localized extranodal presentation of FL is uncommon, reported in only 6% of the ILSG series.[157] A unique but uncommon variant of FL is extranodal presentation in the intestinal tract, usually the duodenum, usually stage I.[158] The WHO has classified duodenal FL as a separate entity, but the biologic behavior is very similar to localized FL at other sites.

The principle indicated imaging study is the PET-CT scan. Although FL is typically less FDG-avid than DLBCL, increased uptake is still seen in about 90% to 95% of cases.[159] Bone marrow biopsy should be performed in all patients thought to have early-stage disease given the high incidence of involvement. PET-CT is less accurate in detecting bone marrow involvement than in DLBCL. For patients with advanced disease, a bone marrow can be pursued if the results will change clinical management.

Large-cell transformation to DLBCL occurs in approximately 30% of patients with FL at a rate of approximately 2% per year.[160] This should be suspected if LDH levels are rising, B symptoms develop, extranodal sites become involved, disproportionate growth occurs, or high SUVmax is observed (>10).[161] The prognosis after transformation is generally not good but better in the rituximab era, with a median survival of 50 months following transformation. The outlook is better with an increasing interval between FL diagnosis and the occurrence of transformation.

Prognostic Factors

Subsequent to the development of the widely used IPI for DLBCL, attempts were made to apply it to FL, but here, it was less useful because most patients fell into a favorable prognostic category. Additional efforts to address this problem led to the development of the FLIPI, the follicular lymphoma IPI[79] (Table 82.5). The initial database included 4,167 patients with FL diagnosed between the years 1985 and 1992 (the prerituximab era). Five adverse prognostic factors were identified on multivariate analysis, age (>60 vs. <60 years), stage

(I/II vs. III/IV), hemoglobin level (<12 g/dL vs. ≥12 g/dL), number of nodal areas (>4 vs. ≤4), and finally serum LDH. Low-risk patients had 0 to 1 adverse factors, intermediate risk 2 factors, and poor risk 3 or more. Patients were divided approximately equally between the three groups with good separation in terms of OS (Table 82.5).

The FLIPI was subsequently modified to take into account the advent of rituximab leading to the FLIPI-2 categorization.[80] That index identified age, elevated β2 microglobulin (B2M), hemoglobin, bone marrow involvement, and lymph node diameter >6 cm as independent risk factors for PFS (OS data not as yet available) (Table 82.5).

TABLE 82.7 RADIOTHERAPY FOR STAGE I/II FOLLICULAR LYMPHOMA

Study	Year	Number of Patients	Radiation Fields	Radiation Dose (Gy)	Failure-Free Survival % (10 Years)	Overall Survival % (10 Years)
Vaughan Hudson[107]	1996	208	NS	35	47	71–84[a]
MacManus[166]	1996	177	IF, EF, TNI	34–55	44	64
Stuschke[167]	1997	117	ER, TNI	36	59	86
Wilder[168]	2001	80	IF, EF	26–50	57	65
Petersen[169]	2004	460	IF	16–47	41	62
Guadagnolo[170]	2006	106	IF, EF	30–42	46	75
Pugh[171]	2010	2,222	NS	NS	NS	62–79[a]
Campbell[172]	2010	237	IN, EF	20–40	49	66–82[a]
Vargo[173]	2015	10,613	NS	NS	NS	68

EF, extended field; IF, involved field; IN, involved nodal; NS, not specified; TNI, total nodal irradiation.
[a]Overall survival and cause-specific survival.

Recently, a third prognostic index is under development utilizing genetic risk factors as well and known as the M7-FLIPI.[162] This model integrates the mutational status of seven genes known to be important in FL.

As with DLBCL, interim and posttreatment PET-CT response appears to have prognostic significance, particularly posttreatment PET response.[163,164] Limited studies on interim PET scanning have suggested no benefit from this.[164,165]

Clinical Management

The majority of patients with FL present with advanced stage disease. Advanced FL is still considered incurable despite advances in chemoimmunotherapy in the last several years with resulting prolongation of both PFS and OS. For the minority of patients who present with localized disease, a subset varyingly reported to range from 20% to 32%, local radiotherapy has curative potential.

Stage I to II FL

A large number of retrospective studies have shown a high rate of local disease control with approximately 50% of patients achieving long-term survival without relapse in early-stage FL. Selected series are shown in Table 82.7. The great majority of patients in these series have been staged and treated in an era prior to widespread use of modern imaging technology, particularly PET-CT scanning. With modern staging including PET-CT, its likely results would be even better. Unfortunately, there are no prospective phase III studies demonstrating the value of definitive radiotherapy, most likely because of the relative infrequency of localized FL at presentation and the necessity for a study with very long follow-up.

Several comments about the series listed in Table 82.7 are in order:

- Most of the studies shown are older, which gives them the advantage of long follow-up but the disadvantage of lack of modern staging (PET-CT). Further, most of the series included some patients with other low-grade lymphoma histologies other than FL, although the great majority were FL.
- The radiation doses used varied widely from 16 to 50 Gy, although most patients received in the neighborhood of 30 Gy. None of the series report detailed dose response data. In general, there appeared to be no dose response demonstrated, with >90% local control with doses in the 30 Gy range.
- The field sizes also varied considerably with somewhat different definitions than are now used. In brief, involved field radiation, in which the nodal area in question was treated with a generous margin, appeared to be as effective as larger fields.
- Ten-year PFS is remarkably close to 50% in all of the series. There was more variation in the OS, which generally ranged from about 60% to 80% depending on whether lymphoma-only deaths were counted or all deaths because of any cause. In general, the risk of a patient with stage I/II FL treated with radiation alone *dying of lymphoma* at 10 years was approximately 20%.
- As can be inferred by the high local control rate of approximately 90%, the great majority of relapses were at distant sites from the original disease, not adjacent nodal areas. This has led directly to the practice of irradiating only the

involved nodal site with a generous margin. Importantly, few relapses were observed after 10 years with a general flattening of the PFS curve.

The largest series in the literature is the report from Pugh et al.[171] The SEER database forms the basis of this study. 6558 patients were identified from 1973 to 2004 with localized FL. 2,222 (34%) of these patients were treated with initial radiotherapy. No details as to radiation fields or dose are available. Compared with patients from the SEER database who received no radiotherapy, cause-specific survival was improved in the radiation group at 10 years from 65% to 79%. Survival at 10 years was 60% in the radiated patients and 50% in those not receiving radiotherapy.

On the basis of these studies, radiotherapy remains the treatment of choice for early-stage FL. Most of the patients in these series had stage I disease or contiguous stage II disease. For noncontiguous stage II disease, the data are sparse. Many centers individualize the treatment of such patients rather than automatically treating with radiotherapy.

Small series of patients with localized disease have been observed without treatment with apparently favorable results.[174] Experience with this approach, however, is quite limited. NCCN guidelines recommend radiotherapy as the standard approach for localized disease with observation reserved for selected patients in whom there might be a concern for the ability to tolerate radiotherapy.[57]

Despite the above data and NCCN and ESMO guidelines[175] endorsing radiotherapy as the preferred initial management, the use of radiation in patients with early-stage FL continues to decline. In the Pugh study, only 24% of patients with localized disease received radiotherapy as initial treatment.[171] In the National LymphoCare study, 23% of patients with stage I FL received radiotherapy alone.[176] The remainder of the patients were treated in a variety of ways including rituximab plus chemotherapy (30%), rituximab alone (13%), and observation (29%). OS at 5 years was approximately 90% in all treatment groups.

Adjuvant systemic therapy after definitive RT in early-stage FL has been infrequently studied. In the prerituximab era, there were four randomized trials.[109,110,177,178] Three of the trials had only small numbers of patients as part of a larger trial including patients with DLBCL. In brief, no benefit was seen in FL for the use of systemic therapy along with radiation. A larger British National Lymphoma Investigation of adjuvant chlorambucil was similarly negative.[177]

In the rituximab era, two retrospective trials have looked at this question, both

of which were relatively small.[179] They suggested benefit for adjuvant systemic therapy, but the numbers are small and the follow-up short. A recent multicenter prospective phase III trial randomized 150 patients with limited-stage FL to radiotherapy alone or with addition of systemic therapy (CVP).[180] Of the 75 patients randomized to the latter, only 31 received rituximab-containing chemotherapy with a benefit in PFS seen in the latter. No OS benefits were seen. Thus, outside of a clinical trial, this approach cannot be recommended.

Stage III and IV FL

Advanced FL is still considered an incurable disease with survival curves that never become parallel to that of the corresponding normal population. The clinical course, however, is often prolonged with multiple effective therapeutic agents available. Because of the relatively indolent nature of advanced FL, a strategy of initial observation without therapy was introduced first at Stanford University.[181] It was later confirmed with randomized trials that this approach did not adversely affect long-term survival.[182] It should be cautioned that these trials were performed in the prerituximab era. Nonetheless, the strategy of "watchful waiting" has gained widespread acceptance. NCCN guidelines consider observation the "standard practice for patients with advanced stage low tumor burden FL."[57] Tumor burden has generally been assessed with the GELF criteria in which any one of the following signifies a high tumor burden: (1) three distinct nodal sites each ≥ 3 cm, (2) a single nodal site ≥ 7 cm, (3) symptomatic splenomegaly, (4) organ compression or compromise, (5) pleural effusions or ascites, (6) B symptoms, and (7) elevated LDH or beta-2 microglobulin.[183]

One nonrandomized study in the rituximab era, the FL2 registry study of the International Follicular Lymphoma Prognostic Factor Project, compared outcomes in 107 patients with a low tumor burden initially observed with 242 patients of similar tumor burden who were treated with a rituximab-containing regimen. Five-year OS and freedom from relapse were not statistically different in the two groups.[184]

One randomized trial has compared single-agent rituximab to the watch and wait policy. At 3 years, the proportion of patients without progression was 33% in the watch and wait group, approximately 70% in the rituximab-treated patients. OS did not differ, however.

Another algorithm divides patients with advanced stage disease into four categories: asymptomatic or symptomatic with a low tumor burden or high

tumor burden, the tumor burden defined as above under the GELF criteria. For asymptomatic patients with a low tumor burden, the proposed therapeutic strategies are either observation or treatment with single-agent rituximab. For asymptomatic patients with a high tumor burden, proposed therapeutic choices are observation or chemotherapy along with rituximab. For symptomatic patients with low tumor burden, treatment choices include single-agent rituximab or in combination with chemotherapy. For high tumor burden symptomatic patients, the preferred strategy is rituximab-containing chemotherapy with maintenance rituximab. In this decision-making process, there is room for considerable individualization with consideration for the patient's age, comorbidities, predicted life expectancy, and general patient preference.[185]

The majority of patients for whom systemic therapy is desirable will receive rituximab in combination with chemotherapy. In the last two decades, the addition of rituximab to chemotherapy constitutes a major therapeutic advance. Its use has been associated with increased response rates, duration of response, and improvement in PFS at a minimum. One recent meta-analysis suggests a benefit in OS as well, although longer follow-up is needed.[186]

Multiple chemotherapy combinations have been studied in combination with rituximab. These include CHOP, CVP, and fludarabine. In brief, no one drug program when combined with rituximab has demonstrated superiority over another. Recently, however, the alkylating agent bendamustine has been introduced for therapy of FL in combination with rituximab. A phase III trial from the Study Group Indolent Lymphoma (SCIL) compared bendamustine–rituximab (BR) to R-CHOP and demonstrated increased efficacy and reduced toxicity with the BR combination.[187] This improved efficacy was manifested by prolongation of PFS and improved response rates, but, as is so often the case with FL, no differences in survival were found. A second study, a randomized phase III noninferiority trial (BRIGHT study), indicated the equivalence of BR to R-CHOP or R-CVP with, however, somewhat different toxicity profiles.[188] Because the BR combination appears to be generally significantly less toxic, this has led to the rapid adaptation in the United States of BR as first-line systemic therapy for advanced stage FL patients who require treatment.

Another novel strategy for first-line treatment has involved combining rituximab with the immunomodulatory agent lenalidomide. An overall response rate of 98% was reported by M.D. Anderson investigators with a 3-year PFS of 78% with acceptable toxicity.[189] This particular approach is now being compared in phase III trials to more standard chemotherapy with rituximab.

The use of maintenance rituximab after chemoimmunotherapy has gained widespread acceptance following a large phase III intergroup trial (PRIMA study).[190] In this trial, patients with previously untreated FL who had responded to chemoimmunotherapy were randomly assigned 2 years of maintenance with rituximab or placebo. With short follow-up, the 2-year PFS in the rituximab maintenance arm was 75% compared with 58% in the observation arm. There was a slight increase in adverse events in the maintenance arm. There was no difference in OS. Thus, the benefit of rituximab maintenance is unclear but is being increasingly employed.

Given the radiosensitivity of FL and the effectiveness of rituximab, therapy with a radiolabeled monoclonal anti-CD20 antibody is an attractive option. High response rates, PFS, and OS have been reported, both in localized and advanced stage FLs.[191,192] Toxicity has generally been minimal and limited to reversible myelosuppression, although late development of myelodysplastic syndrome (MDS) is a concern.[193]

Initially, there were two such products investigated and on the market, but in the United States, only one is still available, ^{90}y-ibritumomab tiuxetan. This drug is a combination of the beta-emitting isotope ^{90}y, linked to rituximab. Its use has been recently extensively reviewed.[193a] A recent international trial of ^{90}y-ibritumomab as first-line therapy for advanced disease revealed an overall response rate of 94% with a CR of 58%.[194] The 3-year PFS was 58% and OS 95%. Toxicity was minimal and limited to hematologic effects.

In addition to its use as initial therapy, radioimmunotherapy (RIT) has been studied as maintenance or consolidation treatment after initial chemotherapy. In a phase III multicenter European trial, a tripling of the median PFS was observed from 13 to 36 months.[195] However, when R-CHOP was directly compared to CHOP followed by RIT, no difference was found.[196]

Thus, the role of RIT remains uncertain. It is an attractive option for patients needing systemic treatment who might not tolerate conventional R-chemotherapy. It has not been explored as consolidation treatment after R-CHOP. Finally, RIT has never been studied as consolidation treatment after curative radiotherapy for localized disease.

Treatment of Relapsed, Refractory, or Transformed FL

Patients who relapse after initial therapy of localized FL almost always have generalized disease, even if the area of relapse is ostensibly localized. For example, patients who initially present with localized disease above the

diaphragm and who sustain a relapse inferior to the diaphragm are considered to have generalized disease, even if there is no evidence of supradiaphragmatic disease at the time of the infradiaphragmatic relapse. These patients should be re-evaluated in a similar fashion to those who present with advanced disease, as has been already discussed. Similarly, patients who presented with advanced disease and relapse after initial therapy should be re-evaluated in a similar fashion as they were at the time of diagnosis. Are they symptomatic, what is the extent of the tumor burden, do they meet the GELF criteria for treatment, what is the goal of therapy, what are the patient preferences, and finally what is the patient's overall medical condition. Answers to these questions will guide the therapeutic choices.

At the time of relapse, biopsy of a new disease site is appropriate to rule out transformation to a more aggressive histology. Restaging is usually appropriate as well with the procedures mentioned above including routine blood studies, LDH, β2 microglobulin, and PET-CT scan. A bone marrow examination is less important in the presence of known generalized disease.

For patients relapsing with limited extent of disease, low-dose palliative radiotherapy, to 4 Gy total, should be strongly considered. Such low doses have been found to be remarkably effective (see below). Side effects are minimal—1% grade 3 to 4 toxicity. Unfortunately, low-dose palliative radiotherapy is often overlooked in the management of generalized disease.

For patients with generalized disease who do require systemic therapy, the choice of agents is greatly influenced by what prior therapy the patient has received. For example, if the initial systemic therapy was BR, it would be logic to proceed with R-CHOP or vice versa. If the patient has not received RIT, that may have a significant role to play. A new anti-CD20 antibody, obinutuzumab, may be employed.[197] A new class of drugs, phosphatidylinositol 3-kinase (P13K) inhibitors, has been developed. Idelalisib, a selective oral inhibitor of P13K, has been studied in relapsing disease with an overall response rate of 57%.[198]

Finally, stem cell transplantation has been extensively studied in FL, both autologous (ASCT) and allogeneic. In the only phase III trial to compare ASCT to conventional chemotherapy in relapsed FL, patients appeared to demonstrate a higher PFS and OS when treated with ASCT.[199] However, the procedure is not believed to be curative for relapsed disease, in contrast to the situation with DLBCL. Allogeneic transplantation may have curative potential, but its use has been hindered by the high treatment-related mortality of approximately 40% at 3

years for a full myeloablative transplant and a treatment-related mortality of up to 20% even for the reduced intensity conditioning transplant, as well as the logistical difficulties of finding a matched donor. In a recent NCCN database retrospective analysis, however, 3-year OS for allogeneic SCT versus autologous SCT was 87% versus 61%.[200] It should be noted that neither ASCT nor allogeneic SCT has any proven role in the initial treatment of generalized FL, such as consolidation therapy for patients in first remission.

Histologic transformation to DLBCL occurs in approximately 2% to 3% of patients per year and historically has been associated with a poor clinical outcome. The prognosis directly relates to the number of prior therapies the patient has received with a much poorer outlook in those with multiple prior therapies. Aggressive chemotherapy has most often been employed in this situation. In selected patients in a Canadian trial, treated after transformation by induction chemotherapy followed by HDC and ASCT, a 5-year survival of 65% has been reported.[201]

Radiation Dose and Field Size

As can be seen from Table 82.7, the dose of radiotherapy employed in older retrospective studies varied widely from approximately 20 to 44 Gy with local control being achieved in over 90% of patients irrespective of dose. Retrospective dose analyses reported from the Princess Margaret Hospital and the University of Florida suggested local control rates over 90% with doses in the range of 25 to 35 Gy at the Princess Margaret[202] and 30 Gy at the University of Florida.[203]

These discrepancies led to the performance of a large prospective trial by the British National Lymphoma Investigation comparing 24 Gy to 40 to 45 Gy.[149] This is one of the few prospective phase III trials of different radiotherapy doses in any disease. In brief, no differences were observed in any measured outcome, either local control, PFS, or OS between the two different doses employed. This study made no mention of bulk of disease. Such patients appeared to have been included. There is no information as to whether their outcome was any different from those with small-volume disease.

This study has led to the widespread adoption of 24 to 30 Gy as the appropriate dose for curative treatment of FL and other so-called indolent lymphomas. Most centers stay within this dose range irrespective of the bulk of disease but would probably give 30 Gy for bulk disease (variably defined) and only exceed this dose if the clinical response was not satisfactory. Doses around

24 Gy are typically employed when there is concern for normal tissue toxicity, such as when irradiating the eye. One could argue for only treating to 24 Gy in all cases of localized FL irrespective of site, but 30 Gy remains a popular option, given the long experience with this dose and its excellent safety profile.

Even lower doses (2 to 4 Gy) have been found to be quite effective in the palliation of advanced FL. Response rates of 80% to 90% have been reported with a median duration of response ranging from 22 to 45 months.[204–206] These data have led some to propose the use of very low doses of 2 to 4 Gy as appropriate for curative treatment of limited-stage FL, leading to a randomized trial involving 548 patients who were prospectively allocated to receive either 4 or 24 Gy.[205] In 40% of these patients, the treatment was curative in intent and 60% palliative. PFS at 2 years was superior in both the curative and palliative cases for the 24 Gy dose. Thus, 24 to 30 Gy remains the standard dose for curative therapy of localized FL with 2 to 4 Gy reserved for palliation of advanced disease.

The choice of an appropriate radiation field size for localized FL is more complex. Prospective randomized trials addressing this issue do not exist. The field sizes used in the studies in the table were highly variable with no suggestion of a different outcome related to field size. Almost none of the studies employed modern imaging techniques in either the initial diagnosis or subsequent therapy. CT-based three-dimensional treatment planning was carried out in almost none of these studies, yet alone IMRT. The only trial that looked at involved nodal radiotherapy or involved-site radiotherapy and compared it with larger fields was the Campbell trial from British Columbia.[172] This trial had a relatively large number of patients. No difference was observed in the treatment outcome depending on field size. Additional evidence for small fields derives from the patterns of failure in limited-stage FL patients treated with radiotherapy alone. Most recurrence is at distant sites, either nodal, extranodal, or both, very seldom at adjacent nodal areas or within the radiation field.

Extensive guidelines for both radiation field size and target definition and radiation doses have been developed by the International Lymphoma Radiation Oncology Group[153] (Fig. 82.2). Most patients with FL will not have received preradiation systemic therapy, but for those who may have, the target volume is the initial extent of disease prior to any therapeutic intervention. Modern imaging techniques should be used to define the extent of disease, preferably a PET-CT scan. The involved area should be treated with a generous margin, not well defined in the literature and highly dependent on the clinical situation. For

example, the margin may be greater when the disease is not close to important normal organs or tissues. It may be prudent to increase the margin to account for respiratory motion if the latter is not compensated for in some other fashion, such as 4-D planning. For localized FL, the margins should probably be a little larger than customary for localized DLBCL in which the patient is receiving systemic therapy in almost all instances. Patients with localized FL may receive systemic therapy as well, but the lack of proven effectiveness for systemic therapy in this disease would suggest more generous margins to account for subclinical microscopic disease than might be the case for a more aggressive histology such as DLBCL.

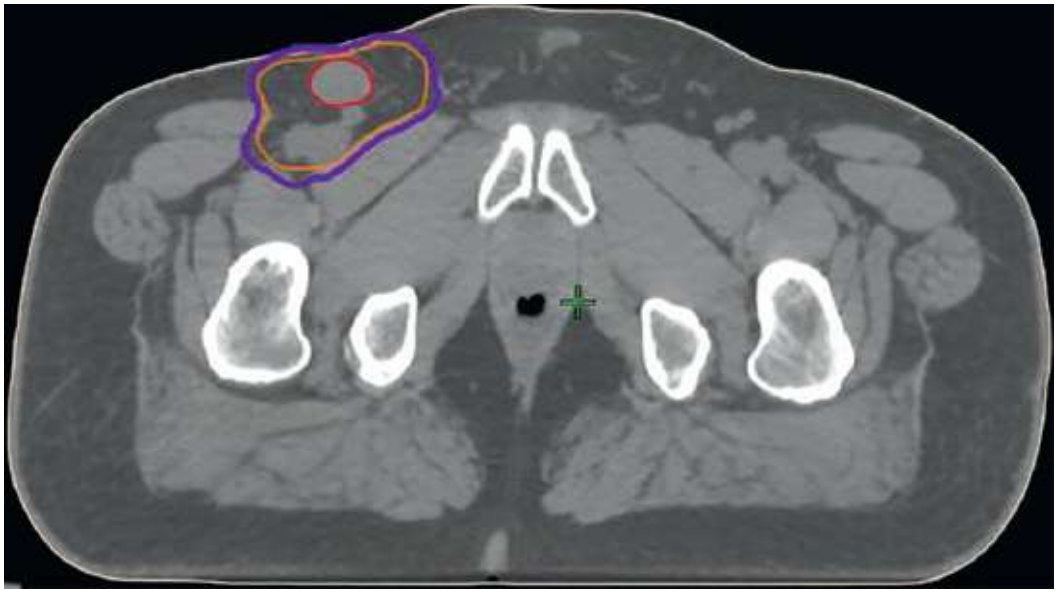

FIGURE 82.2. Stage I follicular lymphoma of a right inguinal lymph node treated with radiation therapy alone using involved-site principles. The gross tumor volume is contoured in *red*. The clinical target volume (*orange*) includes the immediate area at risk of harboring microscopic disease. The planning target volume (*purple*) includes a small margin to account for daily set-up error.

Most patients with localized FL have peripheral nodal areas involved such as the neck or inguinal–femoral regions. Usually, relatively simple field arrangements such as AP-PA will suffice, but 3-D planning or IMRT should be considered depending on individual circumstances.

MARGINAL ZONE LYMPHOMAS

MZL accounts for approximately 10% of all cases of NHL. MZL entities include nodal MZL, splenic MZL, and extranodal MZL of mucosa-associated lymphoid

tissue (MALT). MALT as a distinct clinical pathologic type of lymphoma was first described in 1983,[207] is the most frequent MZL entity encountered in clinical practice, and will be the focus of the following section. A brief synopsis of nodal and splenic MZL is also included.

Pathology

MALT lymphoma is characterized by a polymorphous infiltrate of marginal zone (centrocyte-like) B cells, small lymphocytes, monocytoid B cells, and plasma cells, as well as rare large basophilic blast cells (centroblast- or immunoblast-like).[208] In epithelial tissues, the marginal zone B cells typically infiltrate the epithelium forming lymphoepithelial lesions defined by invasion and partial obstruction of mucosal glands by tumor cells.[209] Although transformed large cells are typically present, they are in the minority. If present in large numbers, a diagnosis of DLBCL is warranted.

The tumor cells express pan B-cell–associated antigens including CD19, CD20, CD22, and CD79a, but there is no specific marker for MALT at present. However, lack of CD5 (positive in CLL/SLL and MCL), CD10 (positive in FL), and cyclin D1 (positive in MCL) expression helps distinguish MALT from other small B-cell lymphomas.[210]

Clinical Presentation

Two-thirds to three-fourths of patients have stage I or II disease, usually stage I. The most common locations for MALT lymphoma are the stomach, orbit, and skin.[211] Other less common anatomic sites include the parotid, breast, thyroid, and lung. Involvement of paired organs simultaneously, or less commonly two distinct extranodal sites, is occasionally encountered. With such scenarios, it is best to stage each site separately as opposed to making a stage IV designation. Such patients may be treated with local RT to both paired sites with long-term disease control.[212]

The most common site of MALT is the stomach. A unique feature of gastric MALT is the association with *H. pylori* infection, initially reported by Isaacson's group.[30,213] *H. pylori* can be identified in up to 92% of patients.[30] Lymphoid tissue is not normally present in the stomach, but in response to an antigenic stimulus brought about by *H. pylori*, normally, present T cells in the gastric mucosa attract a B-cell population, giving rise to lymphoid follicles and, after prolonged antigenic stimulation, lymphomas.[214]

Recently, an association with bacterial infection for MALT at sites other than

the stomach has been described.[215] *Chlamydia psittaci* has been found in many cases of ocular adnexal lymphoma. Additionally, *B. burgdorferi* and *C. jejuni* have been associated with MZL arising in the skin and small intestine, respectively.[215,216] This association is somewhat controversial, however, and unlike gastric MALT, the standard initial treatment for these conditions remains local radiotherapy, as opposed to antibiotics, with very high rates of complete response and local control in excess of 90%, similar to what has been reported for gastric MALT.[217,218]

Patients with orbital MALT typically present with mass lesions in the bulbar or palpebral conjunctivae, described in the literature as “salmon pink” in color. Tumors of the retrobulbar region may present with swelling, proptosis, double vision, and/or other associated disturbances in function of the extraocular muscles. Bilaterality is not unusual, occurring in 10% to 15% of cases. Similar to salivary gland and skin tumors, this does not adversely affect prognosis.

Prognostic Factors

The primary prognostic factor is disease site. MALT arising in paired organs (e.g., orbit or salivary gland) appears to have a higher risk of relapse compared with that arising in a single organ (e.g., stomach or thyroid).[211,217,219] Relapse after RT for cutaneous MZL is also rather frequent.[220]

Treatment of gastric MALT with antibiotics is a special consideration. Predictive factors associated with a lower chance of achieving and maintaining a complete response after antibiotic therapy include deep gastric wall invasion,[221–223] nodal involvement,[223,224] and the translocation t(11;18).[225,226]

Clinical Management

First-line treatment for localized MALT lymphoma should be RT, with the exception of *H. pylori*–positive gastric MALT lymphoma. Complete response rates approach 100% with doses approximately 24 to 30 Gy.[219] Local failure is rare.[211] The overall prognosis of patients with localized MALT lymphoma treated with RT is generally excellent with >90% 5-year survival, although relapses occur in approximately 25% of patients.[211,219,227] Relapses rarely develop within nodal areas but rather sites prone to MALT development. Many such relapses are localized, often in the contralateral paired organ, and after appropriate treatment, often further RT alone, long-term survival is excellent.

For patients with gastric MALT lymphoma, antibiotic treatment is indicated in the presence of *H. pylori* infection. Eradication of *H. pylori* is near universal

after antibiotics. A frequently recommended combination is omeprazole, metronidazole, and clarithromycin.[228] A complete response is achieved in approximately 80% of patients, though this may take up to 2 years or longer to achieve.[225] As long as the lymphoma is regressing on serial endoscopy, a watch and wait policy is appropriate.

Of patients achieving a complete response to antibiotics, approximately 30% will relapse. Many such relapses are subclinical and only apparent on histologic examination of random biopsies performed during upper endoscopy. Continued observation and monitoring is preferred for these patients as many will subsequently revert to a histologic complete response.[31,225]

For patients who are *H. pylori* negative, do not respond to or relapse clinically after antibiotics, the treatment of choice is RT. Long-term progression-free and OS exceeds 90%.[219] Interestingly, the original B-cell clone is also detected frequently after RT for gastric MALT lymphoma but without an associated risk of relapse.[229]

Orbital MZL has been associated with the bacterium *C. psittaci*.[33] A trial of antibiotic therapy has been suggested for patients in whom this organism is identified,[230] but a meta-analysis has shown highly variable results of antibiotic therapy with an overall incidence of *C. psittaci* of 23%.[231] It has also been suggested that observation only is a reasonable strategy. In a Japanese series of 36 patients, 70% did not require treatment with a median follow-up of 7 years.[232] However, for stage I orbital MALT, RT remains the standard of care.

Radiation Dose and Field Design

Detailed radiation field and dose guidelines for extranodal lymphomas, including MALT, have recently been published.[152] For MALT lymphoma, particularly gastric MALT, local control rates of 95% to 100% are achieved with doses of approximately 30 Gy.[219,233] Similar results, although in smaller numbers, are available for MZL at sites other than the stomach.[217,234] A small number of patients with MALT were included in the randomized British National Lymphoma Investigation demonstrating similar clinical outcomes with 24 Gy compared to 40 to 45 Gy.[149] Thus, in general, a dose of 24 to 30 Gy is recommended for localized MALT lymphoma with lower doses (24 Gy) preferred for orbital and parotid presentations.

For stage IE gastric MALT lymphoma, the entire stomach should be included in the clinical target volume. Both 3-D and intensity-modulated RT can be utilized to minimize dose to the heart, liver, and kidneys. Clinicians must be

mindful of several characteristics of the stomach that can make IMRT problematic. First, the shape and position of the stomach in the upper abdomen often change from day to day. The patient should fast for 3 to 4 hours before simulation and treatment. Daily cone-beam CTs with soft tissue matching can be helpful in some situations, but in others, the clinical target volume from the planning CT scan simply cannot be matched to the stomach as visualized on the cone-beam CT because of these variations. Second, the stomach typically moves significantly during the respiratory cycle necessitating some form of active respiratory management, especially if IMRT is utilized.

Often, simple AP/PA fields will exclude most of the liver and left kidney depending on the patient's anatomy. When this is unsatisfactory, one helpful 3-D approach is to use a single isocenter, half-beam block technique with the isocenter position at the top of the kidneys. AP/PA (or slightly obliqued) fields are utilized superiorly to treat the upper stomach (while avoiding almost all of the liver) with more obliqued fields (sometimes very close to laterals) utilized inferiorly to avoid the posteriorly positioned kidneys. When treating the entire stomach, 1.5-Gy daily fractions with prophylactic antiemetics are helpful to minimize nausea.

For conjunctival MALT, a single en face electron field provides appropriate coverage of the conjunctiva while minimizing dose to the lacrimal gland and posterior globe. It is usually appropriate to treat the entire conjunctiva. A lens shield is occasionally used to prevent cataracts but may increase marginal misses. We generally do not use one. Well-circumscribed orbital lesions elsewhere can be managed with either a 3-D or IMRT approach. Target volumes are somewhat controversial. Some authors suggest the entire orbit be treated to avoid marginal misses.[235,236] Depending on the size and location, partial orbit coverage may also be reasonable. With doses of approximately 24 Gy, cataract formation is the principle risk, occurring in 20% to 30% of patients,[236] which, however, can be easily corrected surgically. Some dryness may result from inclusion in the field of a portion of the lacrimal gland and meibomian glands.

As mentioned, orbital MZL may involve both eyes at presentation. Under these circumstances, RT alone remains the treatment of choice, with careful attention to treatment planning and prescribed dose to minimize eye complications. For MALT lymphomas of the thyroid and parotid, treatment of the entire gland is generally advisable, given the multifocality of the disease.

In the unusual circumstance of disseminated MALT lymphoma, treatment generally follows the guidelines for advanced FL. Chemotherapy is palliative

and reserved for patients with generalized disease who are symptomatic. MALT lymphomas also respond well to rituximab.[237] Asymptomatic individuals with generalized disease should be considered for observation, similar to patients with generalized FL because the course is so often indolent. Patients with generalized disease with symptoms because of a localized tumor mass may be easily palliated with modest doses of RT (e.g., 2 Gy × 2) to the mass in question. That approach is often superior to systemic chemotherapy. There is no role for chemotherapy or rituximab in localized disease.

Splenic and Nodal Marginal Zone Lymphoma

Splenic MZL patients usually present with splenomegaly.[238–240] Almost all have stage IV disease, principally because of bone marrow or blood involvement. The disease is relatively indolent with three-quarters of patients alive at 5 years, but a more aggressive subset does exist. Observation is typically pursued for asymptomatic patients. When symptomatic, splenectomy, rituximab, or chemoimmunotherapy are all options. Nodal MZL generally presents like FL, with widespread nodal disease. For the rare patient with localized disease, definitive RT (24 to 30 Gy) is recommended.

MANTLE CELL LYMPHOMA

MCL was first distinguished in the 1980s by Weisenburger et al.,[241] who described a type of FL in which there were wide mantles of malignant cells around apparently benign germinal centers. It was thought to represent a variant of FL and was classified under the Working Formulation as a low-grade lymphoma. Its behavior, however, is more characteristic of aggressive disease. MCL represents about 7% of all NHL.[64]

Pathology

Additional features of this disease have been recognized since Weisenburger and colleagues' original description. It is a neoplasm of small- to medium-sized B cells with irregular nuclei that resemble the cleaved cells (centrocytes) of germinal centers. The morphologic pattern may be diffuse, nodular, a mantle zone, or some combination thereof.[242]

Tumor cells are typically CD5 positive, CD23 negative, CD20 positive, and CD10 negative. A characteristic cytogenetic abnormality is t(11;14) involving the *BCL-1* gene and resulting in the overexpression of cyclin D1. The product of the cyclin D1 gene can be detected in paraffin-embedded tissue sections with the

immunoperoxidase technique and is useful in distinguishing MCL from other lymphoma variants.[243,244]

Immunophenotyping studies are useful in confirming malignancy (light-chain restriction) and in excluding other B-cell histologies such as chronic lymphocytic leukemia (CD5+) and FLs (CD10+).[210]

Clinical Presentation

MCL has a 74% male preponderance and a median age of 63 years.[157,245] Eighty percent of patients have stage III or IV disease at onset. IPI scores are high, with 23% of patients with a score of 4 or 5, 54% 2 or 3, and only 23% 0 or 1. In common with FL, the organ most likely to be involved is the bone marrow, which is positive in two-thirds of patients at the time of diagnosis. Gastrointestinal tract involvement is frequent as well.[246] CNS is occasionally encountered, particularly those with blastoid histology or elevated LDH.[247]

Prognostic Factors

Although originally classified among the low-grade/indolent lymphomas, the clinical course for MCL is unfavorable in the great majority of patients. The 5-year survival rate in the ILSG project was only 27%, with a PFS rate of 11%.[157] This PFS rate is, in fact, among the worst for virtually any type of lymphoma. The survival pattern of MCL resembles advanced FL in its response to therapy and PFS (i.e., no plateauing of the PFS curve and thus no indication of cure), but DLBCL in its OS (i.e., much shorter than FL).[248–251] A proportion of MCL patients have a more indolent course, but identifying these patients prospectively can be challenging.

A simple prognostic scoring has continued utility: the MIPI or MCL IPI.[252] This index uses four parameters: age, performance status, LDH, and leukocyte count. The MIPI score allows discrimination into three prognostic subgroups: median survival was not reached in the low-risk group with a 5-year OS of 60%, but was 51 and 29 months in the intermediate- and high-risk groups, respectively. Multiple reports have shown consistent reliability of the MIPI prognostic scoring that has had independent significance over pathologic, molecular-based, and clinical/therapeutic predictors.[253]

Clinical Management

Chemoimmunotherapy is the standard initial treatment for all stages of MCL. Rituximab is generally combined with chemotherapy regimens as it is CD20+.[254,255] There is no standard treatment regimen for MCL. The choice of

chemotherapy regimen is often guided by age and performance status. Both aggressive (e.g., R-hyperCVAD [rituximab, cyclophosphamide, vincristine, doxorubicin, dexamethasone, cytarabine, and methotrexate]) and less aggressive (R-CHOP, BR [bendamustine and rituximab]),[187] regimens are available. HDC and ASCT are often pursued in patients who achieve a complete response to first-time therapy. For patients not eligible for transplant, maintenance rituximab should be considered.[256]

Patients with localized MCL (stage I or II) are seldom encountered. One small series from British Columbia has been reported.[257] Of 26 patients reviewed, 17 received RT with or without chemotherapy and 9 patients received chemotherapy or were observed. RT was associated with improved PFS (68% vs. 11%, P = .002). This finding was corroborated by a large NCDB database analysis.[258] Thus, for early-stage disease, we recommend a combined modality approach. RT is also very effective palliation for patients with advanced disease.[259] Modest doses (4 to 10 Gy) are typically sufficient in the palliative setting.

Radiation Dose and Field Design

For the minority of patients presenting with localized (stage I to II) disease, we recommend consolidation RT after chemoimmunotherapy. In the setting of a complete response by PET-CT, a dose of 30 Gy is appropriate. Treatment of the original site of disease with a margin, following involved-site principles, is recommended.

PRIMARY CNS LYMPHOMA

PCNSL comprises all primary intracerebral or intraocular lymphomas. The incidence of PCNSL has been increasing for several decades.[260] This increase is only partially attributable to HIV-associated cases, with a significant rise in immunocompetent patients.

Pathology

The majority of PCNSL are of B-cell lineage, typically DLBCL though T-cell histology,[261] lymphoblastic, and Burkitt lymphomas are occasionally encountered.[262] In immunocompromised patients, the lymphoma is virtually always associated with EBV[263] but is rare in immunocompetent patients.

Clinical Presentation

The median age at presentation is 55 years for immunocompetent patients and 31 years for patients with HIV-associated disease. Neurologic symptoms are usually of brief duration, 3 months or less. Specific neurologic deficits depend on tumor location. Generalized symptomatology such as altered mental status, seizures, and symptoms of increased intracranial pressure such as headache, nausea, and vomiting may occur. Immunocompetent patients are more likely to have localized neurologic deficits, in contrast to patients with HIV infection who more often have diffuse disease with generalized symptomatology.[264,265]

Radiologic imaging often suggests the diagnosis. PCNSL is usually isodense or hyperdense on nonenhanced CT scans, in contradistinction to other primary brain tumors or metastatic lesions. The preferred imaging modality for PCNSL is MRI, which can detect up to 10% of lesions missed by CT. Lesions appear isointense to hypointense on T1-weighted images, and approximately 50% are hyperintense on T2-weighted imaging. Homogeneous contrast enhancement is commonly seen in immunocompetent patients.[266] Despite the appearance of a focal mass on CT or MRI imaging, diffuse parenchymal infiltration is often present, underestimated by imaging. The majority of PCNSL occur in a periventricular distribution, involving the corpus callosum, thalamus, or basal ganglia. In patients with HIV infection, disease is often multifocal in the brain and may be difficult to distinguish from CNS infections.[264]

At diagnosis, although most patients with PCNSL have a solitary brain lesion, the presence of leptomeningeal and ocular involvement is seen in approximately 33% and 20% of cases, respectively. Evaluation of these areas is indicated, including lumbar puncture (if the intracranial pressure is not increased and it can be done safely) and full ophthalmologic evaluation. Staging to evaluate for extracranial disease is appropriate.[264,267]

Prognostic Factors

Almost all studies reveal age and performance status to be important independent prognostic factors. A prognostic model developed at Memorial Sloan-Kettering from 338 patients with PCNSL incorporates age and Karnofsky performance status dividing patients into three prognostic classes with distinct survivals. Class 1 includes patients < 50 years with a median survival of 8.5 years. Class 2 patients are ≥50 years with good performance status (KPS ≥ 70) with median survival of 3.2 years. Class 3 includes patients ≥ 50 years with poor performance status (KPS < 70) with median survival of 1 year.[268] The International Extranodal Lymphoma Study Group (IELSG) has also reported

elevated LDH, increased CSF protein, and tumor location within the deep regions of the brain as significant prognostic variables.[268–270]

Clinical Management

The role of surgery in the management of PCNSL is limited to establishing the diagnosis, preferably by stereotactic biopsy. PCNSL is usually not amenable to surgical resection because of deep location, involvement of critical structures, and its microscopically widespread infiltrative nature. Occasionally, surgical decompression and shunt placement are necessary for relief of increased intracranial pressure. CSF analysis, including immunoglobulin gene rearrangement studies, can identify clonal populations to confirm the diagnosis of PCNSL.[271] Corticosteroids, commonly used to alleviate symptoms including intracranial pressure, have a direct antitumor effect.[267] Tumor regression may lead to difficulties in establishing diagnosis. Accordingly, steroids should be withheld if possible until after biopsy if the diagnosis of lymphoma is suspected.

The management of PCNSL has evolved over recent years. Historically, the treatment was whole-brain radiation therapy (WBRT) alone to address the disease's multifocal nature. Results were poor, however, despite the known radiosensitivity of DLBCL outside the CNS. Two representative series from Radiation Therapy Oncology Group (RTOG) and Princess Margaret Hospital report median survivals of 12.2 and 17 months, respectively, with 5-year survival rates of 10% to 20%.[272,273] Although the tumor initially responds to RT, regrowth is inevitable and uncontrolled disease in the brain is the primary cause of death. Attempts at dose escalation beyond 50 Gy resulted in high toxicity rates without improvements in survival.[273]

Given the poor results achieved with RT alone and the chemo-responsiveness of lymphomas generally, evaluation of systemic chemotherapy for PCNSL was soon undertaken. Initial programs consisted of CHOP and variations on that combination. Despite the efficacy of this combination in NHL outside the CNS, the results in PCNSL have been disappointing.[274] Other studies have come to similar conclusions. This lack of efficacy may be due to the failure of many drugs to penetrate the blood–brain barrier (BBB).

Methotrexate (MTX), particularly in high doses, is known to penetrate the BBB. It was first used for treatment of PCNSL in 1980 with subsequent use becoming widespread.[264] There has been much variability in dosage, scheduling, and combinations with intrathecal methotrexate and other cytotoxics such as cytarabine, vincristine, thiotepa, temozolomide, and rituximab. The phase II

RTOG 9310 study treated patients with combination chemotherapy, including high-dose MTX and WBRT. The 5-year OS was 32% with PFS of 25%, results better than historically obtained with RT alone.[275]

The primary concern with the combination of high-dose MTX and full-dose WBRT is neurotoxicity.[276,277] Neurologic complications can arise as early as 3 months post treatment with symptoms of attention deficit, ataxia, urinary incontinence, and memory impairment, which may ultimately lead to dementia.[278] Patients older than age 60 seem to be at highest risk. A multiinstitutional retrospective series reported a 30% actuarial rate of neurotoxicity overall, with patients >60 years having a 58% risk at 7 years.[279] Given higher neurologic toxicity rates in the elderly, many institutions treat this subset of patients with chemotherapy alone.[280,281]

An alternative approach is reduced-dose WBRT. The Memorial Sloan-Kettering group has reduced the dose to 23.4 Gy for patients achieving complete response to rituximab and MTX-based chemotherapy with promising results.[282] Median PFS and OS for all patients enrolled on the study were 3.3 and 6.6 years, respectively. For those patients who achieved a complete response and received reduced-dose WBRT, the 5-year OS was 80%. Significant post-WBRT neurotoxicity was not observed.

The largest phase III study in this disease was conducted in Germany and sought to evaluate the role of WBRT after high-dose MTX-based regimens. The dose of WBRT was 45 Gy. The study was hampered by poor protocol compliance and a complicated trial design. Although PFS was improved with WBRT, there was no difference in OS.[283]

Future areas of research include additional chemotherapeutic drugs in combination with high-dose MTX. Regimens including cytarabine and rituximab have been reported in the literature.[284,285] A recent randomized phase II trial with the International Extranodal Lymphoma Study Group-32 demonstrated that the MATRix regimen, methotrexate, cytarabine, thiotepa, and rituximab, had superior complete response rate versus methotrexate and cytarabine alone, 49% versus 23%.[284]

HDC with ASCT has also been evaluated. Soussain et al. reported 96% CR after HDC and ASCT. Two-year OS was 45% among the entire cohort and 69% among the 27 patients undergoing HDC and ASCT.[286] Additional studies have evaluated the use of HDC and ASCT, many in combination with WBRT, in newly diagnosed PCNSL.[287–292] A randomized trial for patients <60 years old comparing WBRT or HDC–ASCT as consolidation after high-dose MTX is

ongoing.[278]

To conclude, the role of WBRT after high-dose MTX is controversial, particularly in patients achieving a complete response to chemotherapy and in those >60 years old. It seems clear that 45-Gy WBRT results in unacceptable toxicity in older patients and perhaps in younger ones as well. Given the overall unsatisfactory results with chemotherapy alone, the addition of low-dose RT (23.4 Gy) to chemotherapy for patients achieving a complete response remains a promising approach. Several trials are ongoing that may help delineate the role of WBRT in PCNSL–RTOG 1114, PRECIS, and IELSG 32.

Radiation Dose and Field Design

Radiation field design is a standard whole-brain field with a couple of adjustments. Because the CSF surrounds optic apparatus and is contiguous with the intracranial cavity, with the vitreous space frequently involved, the posterior globes should be encompassed in the RT field. In addition, the inferior border of the field should be at the C1/C2 vertebral body to cover the obex, where the fourth ventricle narrows to become the central canal of the spinal cord (Fig. 82.3). Prophylactic RT to the spine is not recommended.

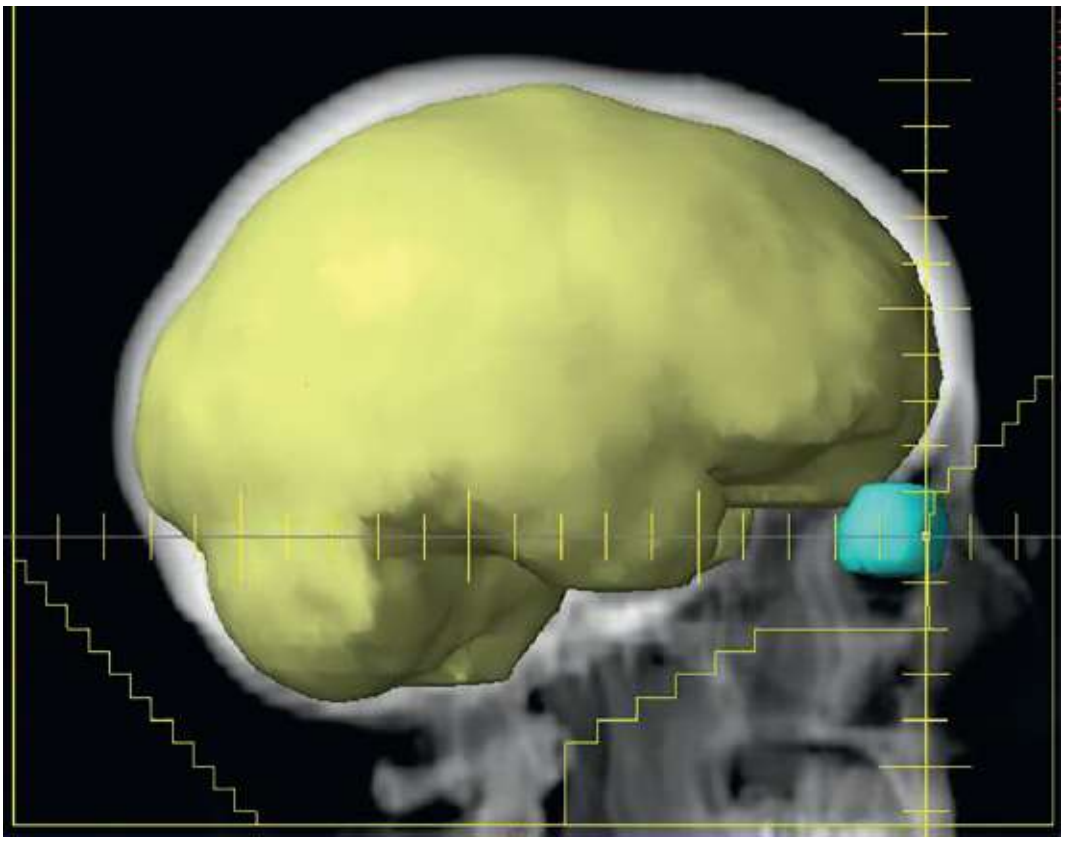

FIGURE 82.3. Whole-brain radiation fields to treat primary CNS lymphoma. Note the isocenter is placed at the lens and the posterior globe is included in the field.

PERIPHERAL T-CELL LYMPHOMAS

The PTCLs are the group most confusing to clinicians. The term PTCL is often misinterpreted. It refers not to the anatomic distribution of the lymphomas but to their origin, from so-called peripheral or mature T cells outside the thymus, as opposed to thymic (precursor) T lymphocytes. The T-cell and NK lymphomas collectively make up approximately 10% of all NHL.[293] Their frequency is quite different, however, by geographic locale with a roughly 5% to 10% incidence of PTCL in North America compared with 15% to 20% in Asia.[294] They are a diverse group that includes nearly 30 distinct entities (Table 82.1).

Pathology

PTCL, not otherwise specified (NOS), typically contains a mixture of medium and/or large cells with many mitotic figures. The architectural pattern is diffuse. T-cell–associated antigens (CD2, CD3, CD4) are variably expressed, and oftentimes, the T-cell antigens CD5 and CD7 are lost. A CD4+/CD8− phenotype is typical in nodal cases.[55] B-cell–associated antigens are lacking. The T-cell receptor genes (*TCR*) are usually but not always rearranged. T-cell receptor beta-chain is typically expressed distinguishing PTCL from NK and *γδ* T-cell lymphomas.

A special variant of PTCL is anaplastic large-cell lymphoma (ALCL).[295,296] In the ILSG project, this comprised 2% of all NHL.[64] The tumor is usually composed of large cells with round, pleomorphic, or horseshoe-shaped nuclei with single or multiple prominent nucleoli and abundant cytoplasm, giving the cells an epithelial or histiocyte-like appearance. The cells express CD30 (Ki-1) and usually express CD25 and either T-cell or null lineage–specific antigens.[296] CD30 was originally recognized on HL cells. In some cases, there may be confusion between ALCL and HL, but distinction between the two on the basis of immunophenotyping and morphology is usually possible. The WHO recognizes two distinct entities—ALK-positive ALCL and ALK-negative ALCL, with the former characterized by overexpression of anaplastic lymphoma kinase (ALK-1) protein, typically from a chromosomal translocation [t(2:5)].[297] Approximately 60% of cases overexpress the ALK protein; such cases have a better prognosis than ALK-negative cases (except primary cutaneous ALCL which is invariably ALK negative but has an excellent prognosis).

Extranodal NK/T-cell lymphomas are characterized by a diffuse lymphomatous infiltrate with an angiocentric pattern. Necrosis is common and attributed to vascular obstruction by lymphoma cells, though chemokines and cytokines may also be contributory. CD56, though not specific for NK cells, is generally expressed with extranodal NK/T-cell lymphoma. Cytotoxic molecules including granzyme B and perforin are also positive. Epstein-Barr virus analyses, preferably *in situ* hybridization, are mandatory and should be positive. No specific translocations have been observed for this disease.

Clinical Presentation

The most common T-cell lymphoma in North America is PTCL NOS, accounting for about one-third of cases (vs. ~20% in Asia).[298,299] This is a disease of older adults with a median age of 60 years with a slight male predominance. Both nodal and extranodal disease is common in a similar fashion to B-cell lymphoma. In contrast to DLBCL, however, the great majority of patients (70%) have stage III or IV disease at diagnosis, and overall the outlook is considerably worse. The International T-Cell Lymphoma Project reported 10-year survivals in the range of 20%.[300]

ALCL consists of both a systemic malignancy, typically presenting with widespread involvement of lymph nodes and extranodal sites, and a type limited to the skin (primary cutaneous ALCL).[296,301–305] The systemic type may in turn be separated into those patients who are ALK positive and those who do not overexpress this protein. The clinical features and prognosis differ widely among these two categories. Patients with ALK-positive ALCL are predominantly young men and, despite advanced stage disease, respond well to combination chemotherapy with 10-year survival rates of approximately 70%.[297,306] ALCL in children/young adults is usually ALK positive.[296] ALK-negative patients, in contrast, tend to be older with a more nearly equal male to female ratio, with a long-term OS of approximately 20%.

Cutaneous ALCL constitutes a special situation.[301] It is almost invariably ALK-negative but carries an excellent prognosis. It is often difficult to distinguish from benign lymphomatoid papulosis (LyP). The latter may spontaneously remit and tends to run a benign clinical course over many years. ALCL of the skin is quite responsive and highly curable with localized radiotherapy[307] (see Chapter 83). Chemotherapy generally has no role.

Extranodal NK/T-cell lymphoma is a T-cell lymphoma of special interest. This lymphoma has a variety of names in the older literature, including

angiocentric lymphoma, midline malignant reticulosis, polymorphic reticulosis, and lethal midline granuloma. It is much more frequent in Asia (about 22% of T-cell lymphomas) than in the United States and associated with EBV.[308] In contrast to most lymphomas, tissue destruction of the nasal/facial area is common. The response to chemotherapy and radiotherapy is variable and slow, in contrast to the usual rapid response observed in most other lymphomas.[309] The disease appears to progress primarily locally with only a small predilection for regional or systemic failure.[310]

A provisional entity in the current WHO classification is breast implant–associated ALCL.[56] Initially described in 1997, it often presents as an accumulation of fluid between the implant and the fibrous capsule. Given the rarity of this presentation, the optimal management remains largely unknown though capsulectomy, and removal of the implant appears to be essential.[311] Outcomes for those with disease confined within the fibrous capsule are excellent with surgery alone.

Prognostic Factors

Two prognostic scores are commonly utilized for PTCL NOS including the IPI and the Prognostic Index for PTCL-U (PIT). The IPI, primarily utilized for DLBCL, has also been shown to be prognostic in PTCL.[298] The PIT identified four factors on multivariate analysis including three that are also contained in the IPI—age ≥ 60 years, elevated LDH, and ECOG performance ≥ 2. The novel factor was bone marrow involvement.[312] Five-year survival was 33% with 0 to 2 risk factors and 18% for 3 or 4 risk factors. Patients with stage I to II disease, although quite uncommon, also appear to have a more favorable prognosis.[313]

Several studies have shown that survival is significantly better with ALK-positive ALCL compared with ALK-negative ALCL.[297,306,314,315] The International Peripheral T-cell Lymphoma Project demonstrated that ALK-positive ALCL has the most favorable prognosis among all T and NK histologies, followed by ALK-negative ALCL.[299] The heterogeneity and complexity of ALCL well illustrate past difficulties of attempting to group lymphomas in categories of low, intermediate, and high grade, indolent or aggressive, and favorable or unfavorable, on the basis of histologic appearance alone, because all ALCL appears aggressive histologically. There remains some uncertainty whether ALK expression is independently prognostic or simply correlates with other favorable factors (e.g., young age). A recent report from the Groupe d'Etude des Lymphomes de l'Adulte demonstrated elevated β2

microglobulin and older age as independent prognostic factors, but not ALK status.[314] ALK was also not independently prognostic in the study by Suzuki et al.[316] However, other reports have demonstrated independent prognostic significance of ALK.[297,306]

For extranodal NK/T-cell lymphomas, age ≥ 60 years, stage III to IV disease, distant lymph node involvement, and nonnasal type disease are unfavorable prognostic factors. A validated prognostic index stratifies patients into low-, intermediate-, and high-risk cohorts with 0, 1, or ≥ 2 risk factors.[317] In a study of 527 patients, 3-year OS was 81%, 62%, and 25%, respectively. Detectable EBV DNA in the circulating blood at diagnosis also appeared to be a negative prognostic factor.

Clinical Management

For PTCL NOS and ALCL, CHOP is probably the most commonly employed regimen in the United States. For younger patients, the addition of etoposide (CHOEP) can be considered.[318] Because this is a T-cell lymphoma, there is no role for rituximab. For the minority of patients who present with stage I to II PTCL[298,319] or ALCL,[320] consolidation RT after chemotherapy is recommended. Three-year PFS and OS were 50% and 33% in early-stage PTCL NOS with combined modality therapy versus 23% and 15% with chemotherapy alone, in one small series.[319]

The optimal treatment of localized NK/T-cell lymphoma, nasal type is not established. Treatment approaches have consisted of RT alone, chemotherapy alone, and the two combined. With RT alone, approximately two-thirds of patients achieved CR,[310,321,322] but half of those relapsed. The prognosis appears somewhat worse for stage II than stage I.[322]

The contribution of chemotherapy to the management of NK/T-cell lymphoma is unclear. When treated initially with CHOP-like regimens, CR occurs in only a minority of patients,[309,322–324] in contrast to the results seen with most other lymphomas. Japanese and Korean investigators have reported the use of concurrent chemotherapy and radiation with encouraging results.[325,326] The Japanese series used concurrent dexamethasone, etoposide, carboplatin, and ifosfamide with a dose of 50 Gy. The CR rate was 77% and the 2-year survival 78% compared with historical controls of 45%.[325] The Korean series employed concurrent cisplatin and radiation (40 to 50 Gy), followed by 3 cycles of cisplatin, dexamethasone, ifosfamide, and etoposide. The CR rate was 83%, the 3-year survival 86%.[326] In both series, the number of patients was

small (33 and 30 patients, respectively), but the results are quite promising and worthy of further study. Sequential chemoradiation regimens using pegaspargase (e.g., SMILE, GELOX) can also be considered. There are no data, particularly from the United States, to recommend one regimen over another at this point.

RT Dose and Field Design

Doses and field sizes of RT for PTCL NOS and ALCL should approximate those for DLBCL. For extranodal NK/T-cell lymphomas, nasal type, higher doses of RT are generally employed. With RT alone, the recommended tumor dose is 50 to 56 Gy. When RT is given with concurrent or sequential chemotherapy, doses of 45 to 56 Gy can be considered. In general, adhering to published protocols, in relation to both dose and field, is prudent, given the rarity of this disease. IMRT is often, but not always, required given the proximity of the tumor to critical structures such as the optic apparatus, parotid glands, and brain and brainstem (Fig. 82.4). More detailed recommendations have been published by the International Lymphoma Radiation Oncology Group.[152]

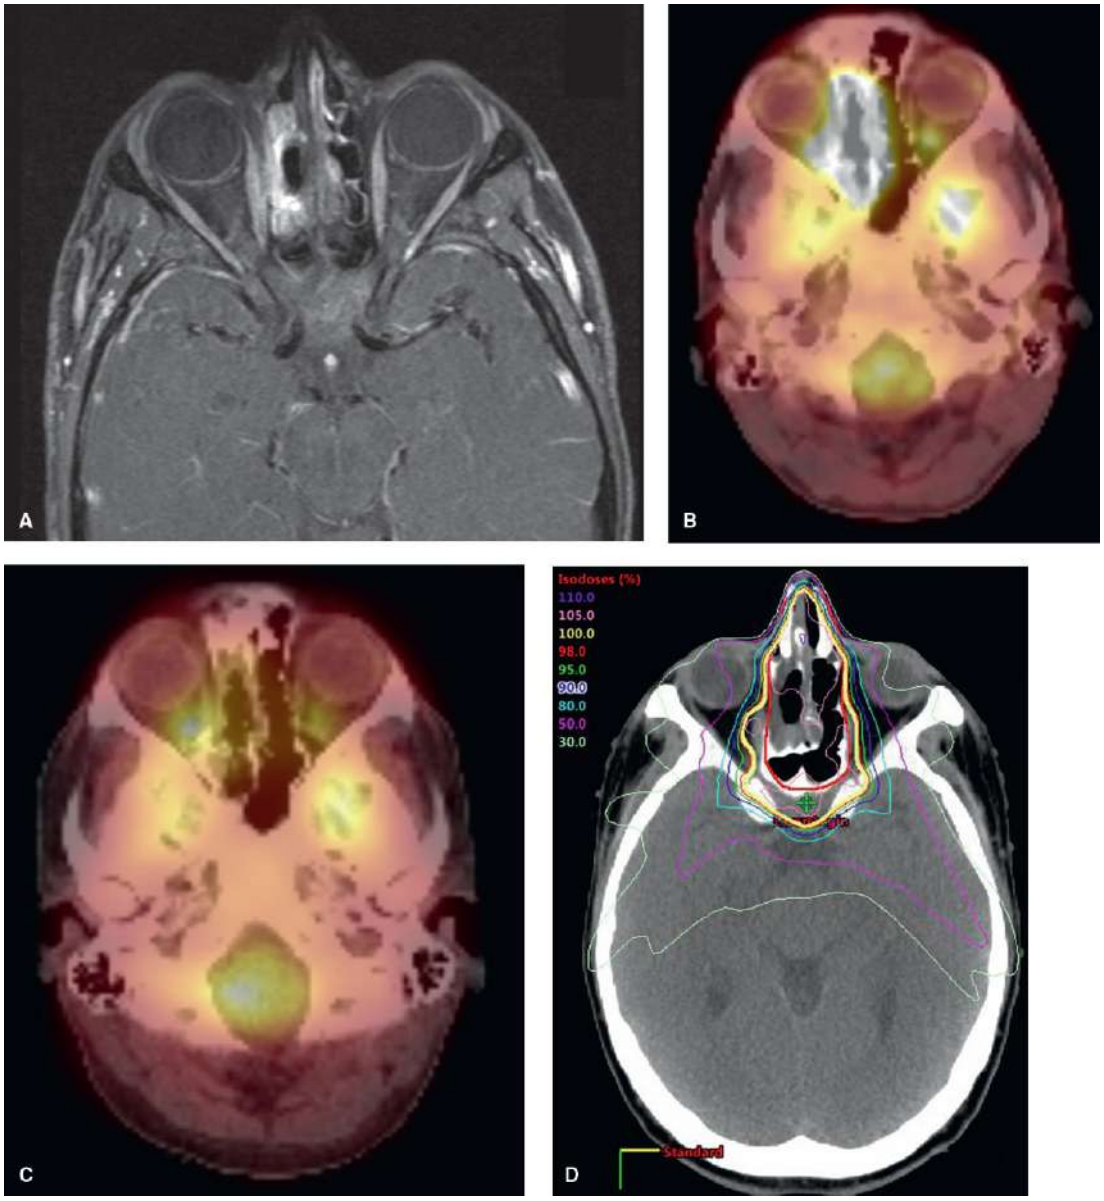

FIGURE 82.4. IE NK/T-cell lymphoma of the left nasal cavity and ethmoid sinuses on MRI **(A)** and PET-CT **(B)**. The patient achieved a complete response **(C)** by PET-CT (Deauville 2) after SMILE chemotherapy (dexamethasone, methotrexate, ifosfamide, pegaspargase, etoposide). He then received consolidation RT **(D)** to 50 Gy. The clinical target volume (*red contour*) included bilateral nasal cavities and ethmoid sinuses.

PRIMARY MEDIASTINAL (THYMIC) LARGE B-CELL LYMPHOMA

Primary mediastinal (thymic) large B-cell lymphoma (PMBCL) comprises about 2% of all NHL and is believed to arise from thymic medullary B cells. Although the histologic appearance can vary, compartmentalizing alveolar fibrosis is a

common feature. PMBCL expresses pan B-cell antigens, including CD20, but are negative for surface immunoglobulin. CD30 is present in a majority of patients but stains weaker than classical HL.[55] Microarray studies have revealed a unique molecular signature for PMBCL with a resemblance to nodular sclerosis HL.[327] The disease affects primarily young women (median age 37) and is generally confined to the anterior mediastinum, sometimes with supraclavicular or cervical adenopathy. When grouped according to the IPI, the prognosis is similar to that of DLBCL generally, perhaps a bit more favorable[327,328] with a plateau observed in the PFS curve after 18 to 24 months.[328]

PMBCL is typically managed with standard chemotherapy (R-CHOP) plus consolidation RT (30 Gy) or more intensive chemotherapy (DA-EPOCH-R) without RT.[329,330] Omission of RT with DA-EPOCH-R is primarily based on phase II[331] and retrospective data,[330] and more studies are needed. The failure of DA-EPOCH-R to improve outcomes compared with R-CHOP in DLBCL NOS should temper enthusiasm of this regimen in PMBCL until more data are available.[101] An ongoing randomized trial (IELSG-37, NCT01599559) is evaluating the role of RT when a complete metabolic response is achieved to R-CHOP-like regimens. As this disease presents in a similar fashion to nodular sclerosis HL, with a gene expression profile more closely aligned with HL then DLBCL, a combined modality approach is still reasonable with R-CHOP, perhaps utilizing a lower dose of consolidation RT (20 Gy) if a complete response is achieved by PET-CT.

T-CELL/HISTIOCYTE-RICH LARGE B-CELL LYMPHOMA

T-cell/histiocyte-rich B-cell lymphoma consists of large malignant B cells with a florid background of inflammatory T cells, with or without histiocytes. Clinically, it occurs in a younger population compared with DLBCL, generally with a male predominance.[332,333] This entity is also more likely to present with B symptoms and involve the spleen, liver, and bone marrow. Treatment recommendations are similar to DLBCL, not otherwise specified.

CHRONIC LYMPHOCYTIC LEUKEMIA/SMALL LYMPHOCYTIC LYMPHOMA

CLL/SLL represents a spectrum of hematopoietic neoplasia involving an

overproliferation of mature B cells, typically afflicting the elderly. A diagnosis of CLL requires the presence of > 5.0 × 10^9/L monoclonal CLL cells in the peripheral blood with or without lymph node/splenic involvement, whereas a diagnosis of SLL includes CLL involvement of the lymph nodes and/or spleen in the absence of a lymphocytosis >5.0 × 10^9/L.[334] Monoclonal B lymphocytosis is a third entity seen in healthy asymptomatic adults who have a monoclonal B-cell lymphocytosis <5.0 × 10^9/L with no evidence of cytopenias, splenic, or nodal involvement. Histologically, CLL cells have a similar appearance to mature lymphocytes with scant cytoplasm, a dense nuclei, and no discernible nucleoli.[335] During the tissue preparation process, CLL cells are more prone to rupture than healthy lymphocytes forming “smudge cells” (Gumprecht phenomenon). There is some evidence to suggest that an increased percentage of these cells present on peripheral smear conveys a poor prognosis.[336]

CLL/SLL is most commonly diagnosed following an elevated WBC discovered during a routine office visit. In symptomatic patients, 80% present with lymphadenopathy and 60% with splenomegaly. Less common symptoms include weight loss, bleeding, infections, and anemia, which are usually indicative of advanced disease.[337]

Diagnosis of CLL is made by flow cytometry of peripheral blood, which should confirm a monoclonal B-cell population. A typical immunophenotype of CLL is CD5+, CD10-, CD20 dim, and CD23+. FISH analysis for t(11:14) is helpful to distinguish it from MCL, which is included in the differential diagnosis of CD5+ B-cell neoplasms.[338] If analysis of peripheral blood confirms CLL, a bone marrow biopsy is not required. A diagnosis of SLL can similarly be made with flow cytometry of a biopsied lymph node or with immunohistochemistry for the above cell surface makers. Workup for CLL/SLL should include history (with specific inquiry into the presence of B symptoms) and physical exam (with focus on node-bearing areas, liver and spleen). Imaging with a CT chest/abdomen/pelvis may be helpful to characterize the extent of disease, but PET-CT is typically not recommended in CLL unless Richter transformation is suspected.[339]

The modified Rai staging system stratifies CLL patients into risk categories as follows: low-risk disease is confined to marrow and blood; intermediate risk includes presence of lymphadenopathy, splenomegaly, or hepatomegaly; and high risk includes thrombocytopenia or anemia. Approximately 30% present with low-risk disease and 10% present with high-risk disease.[337] The Binet system separates patients by the number of sites involved: Stage A includes two

or fewer sites; stage B includes three or more sites; and stage C includes those with cytopenias.[335] Additionally, the Ann Arbor staging may be applied for lymph node–only disease.

In the 1990s, the mutational status of the variable region of the immunoglobulin heavy chain (IgH) was identified as a prognostic marker. Somatic mutation of the IgH naturally occurs as part of B-cell maturation in the germinal centers. In CLL, those with an unmutated IgH (i.e., >98% homology with the germ line) have a worse prognosis than mutated IgH independent of stage.[340] Elevated expression of cell surface proteins Zap70 (>20%), CD38 (>30%), and CD49d (>30%), as well as elevated serum levels of β2 microglobulin (>3.5 mg/L), and thymidine kinase (>10 U/L) have all been associated with a worse prognosis.[341] The advent of interphase FISH and next-generation genetic sequencing has led to a better understanding of the cytogenetic and mutational underpinnings of CLL and has improved prognostic stratification. An integrated mutational and cytogenetic analysis by Rossi et al. yielded four prognostic groups: very low risk (del13q14) with 10-year survival of 69.3%—similar to general population, low risk (normal genetics or trisomy 12) with 10-year survival of 57%; intermediate risk (NOTCH1 mut, SF3B1 mut, and/or del11q22-23) with 10-year survival 37%, and high risk (TP53 or BIRC3 abnormalities) with 10-year survival 29%.[342,343]

For asymptomatic CLL/SLL patients with low- or intermediate-risk disease, observation is usually advised until the development of symptoms, anemia or thrombocytopenia. In progressive or high-risk disease, first-line chemotherapy with fludarabine, cyclophosphamide, and rituximab is recommended for young and fit patients, whereas bendamustine and rituximab are recommended for those >65 or with significant comorbidities.[344,345] Response to chemotherapy is poor in patients with p53 mutations or del17p. Ibrutinib monotherapy may have activity in this population.[346]

Definitive RT is preferred in the treatment of localized SLL (stage I), which is seldom encountered. Radiation technique is similar to that of other indolent NHLs. The recommended total dose is 24 to 30 Gy, and treatment volumes should follow involved-site principles similar to FL. Like FL, RT can be used to palliate symptomatic lymphadenopathy in CLL/SLL. A small series of 14 patients with symptomatic SLL was treated with 2 Gy × 2 with involved field radiation, resulting in an overall response rate of 85% with a median time to local progression of 14 months.[204] The regimen can be safely repeated if symptoms recur.

POSTTRANSPLANT LYMPHOPROLIFERATIVE DISORDERS

The number and the success of solid organ and hematopoietic stem cell transplants have increased with corresponding improvements in OS. Unfortunately, with long-term immunosuppression, posttransplant lymphoproliferative disorders (PTLD) are being increasingly diagnosed. EBV is implicated in the majority of cases (50% to 80%), especially if PTLD occurs within 2 years of transplantation. All other non-EBV cases of PTLD are of unknown etiology.[347]

During the diagnostic workup, infection with lymphoplasmacytic infiltrations, graft rejection, graft-versus-host disease, and/or recurrence from a previous lymphoma should be ruled out. Pathology presents on a spectrum and is divided into four main categories: (1) early lesions, (2) polymorphic PTLD, (3) monomorphic PTLD, and (4) classic HL-like PTLD. The most common subtypes are posttransplant DLBCL, BL, and plasmablastic lymphoma.

The prognosis of PTLD is poor compared to immunocompetent counterparts with similar histologies. Five-year OS ranges from 40% to 60%. The IPI can be used in patients with PTLD to predict outcomes. Other various prognostic indices have been developed as well but ultimately are fraught with validation inconsistencies. Still, older age, advanced disease, poor KPS, elevated LDH, and CNS involvement are consistently associated with inferior outcomes.[348]

In solid organ PTLD, reduction of immunosuppression should be considered, which can lead to responses in about 10% of people within a matter of weeks. Caution should be taken to prevent graft rejection or graft-versus-host disease. If no response is achieved with immunosuppression reduction, rituximab can be considered for CD20+ PTLDs. Overall response rates are approximately 40%, and complete response rates can be almost 30% with little risk of treatment-related mortality.[349] Chemotherapy can also provide good responses but are associated with increased toxicity. A phase II study demonstrated that the combination of rituximab and CHOP is an effective combination with up to a 90% response rate and a 68% complete response rate.[350] Mortality from chemotherapy remains a significant risk in PTLD.[350,351]

Radiation is reserved for localized disease (consolidation after chemotherapy or as a definitive modality) or in palliative situations. Involved site radiation principles with appropriate doses depending on the underlying histology are recommended.

CHAPTER 83

Primary Cutaneous Lymphomas

James E. Hansen, Youn H. Kim, Richard T. Hoppe, and Lynn D. Wilson

INTRODUCTION

Primary cutaneous lymphoma is defined by an accumulation of malignant lymphoid cells in the skin without evidence of extracutaneous disease at the time of diagnosis. The distinction between a primary cutaneous lymphoma and a nodal lymphoma with secondary cutaneous involvement is important and markedly impacts evaluation, staging, prognosis, and therapeutic management. The term *primary cutaneous lymphoma* encompasses a heterogeneous group of extranodal non-Hodgkin lymphomas, and in 2005, the World Health Organization (WHO) and European Organisation for Research and Treatment of Cancer (EORTC) endorsed a consensus classification system that defines three categories of primary cutaneous lymphomas: cutaneous T-cell and NK-cell lymphomas, cutaneous B-cell lymphomas, and precursor hematologic neoplasms/immature hematologic malignancies (Table 83.1).[1] This chapter will review the primary cutaneous lymphomas in the context of this consensus system. A slightly modified classification system was released by the WHO in 2008.[2]

CUTANEOUS T-CELL AND NK-CELL LYMPHOMAS

Cutaneous T-cell lymphoma (CTCL) is the most common primary cutaneous lymphoma. In the United States, 71% of the 3,884 cases of primary cutaneous lymphoma diagnosed during 2001 to 2005 were CTCL.[3] Similarly, 78% of primary cutaneous lymphoma diagnoses recorded in the Dutch and Austrian Cutaneous Lymphoma Group registry over 1986 to 2002[1] and 85% of diagnoses in the Central Cutaneous Lymphoma Registry of the German Society of Dermatology over 1999 to 2004 were CTCL.[4]

CTCL subtypes include mycosis fungoides (MF); CD30+ lymphoproliferative disorders; extranodal NK-/T-cell lymphoma, nasal type; subcutaneous panniculitis-like T-cell lymphoma; adult T-cell leukemia/lymphoma; and primary cutaneous peripheral T-cell lymphomas. MF is the most common CTCL, responsible for 54% of CTCL diagnoses in the United States over 2001 to 2005.[3] CD30+ T-cell lymphoproliferative disorders and cutaneous peripheral T-cell lymphomas represent the majority of the remaining cases of CTCL. The remaining CTCL subtypes are extremely rare and represent <1% of primary cutaneous lymphomas.

Mycosis Fungoides

MF is the archetype cutaneous lymphoma. The first case of MF was reported in 1806 by the French dermatologist Jean-Louis-Marc Alibert in his atlas of dermatoses, *Descriptions des maladies de la peau* (Fig. 83.1). After Alibert released his depiction of MF, approximately 300 similar cases were reported over the next decade, and in modern times, approximately 1,500 new cases of MF were diagnosed during 2001 to 2005.[3] MF is a disease of skin-homing CD4+ T-helper cells[5] and is most commonly diagnosed in men (male:female ratio of 1.6 to 2.0:1) with a median age at diagnosis of 55 to 60.[1] Significant advances in MF therapy have been made over the past 200 years, but the precise etiology responsible for the development of MF remains elusive.

Cutaneous Disease

Pruritus, either diffuse or localized to areas of involved skin, is the most common symptom associated with MF. Ulcerated lesions may also cause patients significant pain. Cutaneous lesions in classic (or Alibert-Bazin) MF follow a predictable evolutionary course, and a consensus statement from the International Society for Cutaneous Lymphomas (ISCL), U.S. Cutaneous Lymphoma Consortium (USCLC), and EORTC defines the lesions found in distinct phases of MF.[6] In the *premycotic phase*, a small number of red, scaled, macular or patchlike lesions develop in sun-shielded areas of the skin such as the trunk, pelvis, and extremities. These early lesions are unstable and usually regress, followed by development of new lesions. Biopsies of premycotic lesions are rarely diagnostic because of a paucity of malignant lymphocytes in the lesion. With increased deposition of malignant T cells in the skin, the lesions become increasingly durable, and persistent cutaneous patches are characteristic of the *patch phase*. The ISCL/USCLC/EORTC consensus definition of an MF

patch is “any size lesion without induration or significant elevation above the surrounding uninvolved skin: poikiloderma may be present.”[6] As the lesions become more densely infiltrated by both malignant and reactive lymphocytes, they evolve into plaques with thickened and raised borders in the *plaque phase* of classic MF. Plaques are defined by the ISCL/USCLC/EORTC as “any size lesion that is elevated or indurated: crusting or poikiloderma may be present.”[6] Plaques may evolve into cutaneous tumors, which the ISCL/USCLC/EORTC defines as “any solid or nodular lesion ≥1 cm in diameter with evidence of deep infiltration in the skin and/or vertical growth.”[6] The presence of cutaneous tumors designates the tumor phase of MF. MF may also progress to or present with erythroderma, in which a diffuse erythema involves >80% of the skin surface area.[6] Representative images of patches, plaques, tumors, and erythroderma are shown in Figure 83.2.

Leukemic CTCL and the Sézary Syndrome

In rare CTCL cases, circulating malignant T cells are identified in the peripheral blood. This phenomenon, sometimes referred to as leukemic CTCL or the Sézary syndrome (SS), most commonly occurs in association with erythroderma but may occur in patients with minimal cutaneous disease.[1] The circulating malignant T cells (also called Sézary cells) are atypical T cells with hyperconvoluted nuclei seen at analysis of peripheral buffy coat smear. The circulating cells most commonly possess a CD4+/CD7− or CD4+/CD26− immunophenotype, and flow cytometry allows for quantification of the proportion of circulating malignant T cells. In addition, presence of a dominant circulating malignant clone may be demonstrated by evaluation of the T-cell receptor (TCR) by polymerase chain reaction (PCR) or Southern blotting. The degree of tumor burden in the peripheral blood is denoted as B0 (≤5% atypical or Sézary cells seen on examination of buffy coat smear), B1 (>5% of cells on buffy coat analysis are atypical, but further criteria meeting B2 disease are not met), or B2 (combination of presence of a dominant T-cell clone in the peripheral blood identified by PCR or Southern blot and ≥1,000 Sézary cells/mm,[3] an increased amount of CD3+ or CD4+ T cells with CD4:CD8 ratios >10, or increased quantities of abnormal T cells defined as loss of CD7 in >40% of cells or CD26 in >30% of cells).[6] If peripheral blood is evaluated for a circulating clone by PCR or Southern blot, B0 or B1 disease may be stratified into B0a or B1a (absence of circulating clone) or B0b or B1b (presence of circulating clone). The mechanism responsible for the development of leukemic

disease in MF is unknown and in some cases may simply reflect disease progression. In other cases, erythroderma and circulating cell disease develop simultaneously, which has historically been referred to as SS. The distinction between SS and erythrodermic MF with leukemic involvement (or SS syndrome preceded by MF) has been a point of controversy, and it remains unclear whether the two diseases are distinct or merely variants of one another. At present, SS is specifically defined as the combination of erythroderma with B2 disease.[6]

TABLE 83.1 Who/Eortc Classification[1]

Cutaneous T-Cell and NK-/T-Cell Lymphomas

Mycosis fungoides and variants (folliculotropic mycosis fungoides, pagetoid reticulosis, and granulomatous slack skin)
Sézary syndrome
CD30+ lymphoproliferative disorders (primary cutaneous anaplastic large-cell lymphoma and lymphomatoid papulosis)
Extranodal NK-/T-cell lymphoma, nasal type
Subcutaneous panniculitis-like T-cell lymphoma
Primary cutaneous peripheral T-cell lymphoma, unspecified
Primary cutaneous aggressive epidermotropic CD8+ T-cell lymphoma (provisional)
Primary cutaneous *g/d* T-cell lymphoma (provisional)
Primary cutaneous CD4+ small-/medium-sized pleomorphic T-cell lymphoma (provisional)

Cutaneous B-Cell Lymphomas

Primary cutaneous marginal zone lymphoma
Primary cutaneous follicle center lymphoma
Primary cutaneous diffuse large B-cell lymphoma, leg type
Primary cutaneous diffuse large B-cell lymphoma, other

Precursor Hematologic Neoplasm

CD4+/CD56+ hematodermic neoplasm (blastic NK-cell lymphoma)

FIGURE 83.1. Pian fungoide, from Jean-Louis-Marc Alibert's atlas of dermatoses, *Descriptions des Maladies de la Peau.*

Extracutaneous Disease

In advanced stages of disease, MF may progress to involve regional or distant lymph nodes or extracutaneous organ systems (most commonly the lungs, oral cavity, pharynx, or central nervous system), and these sites may cause patients significant pain or functional impairment.[7] Of note, in advanced cases of MF, the extent of cutaneous or extracutaneous disease may vary significantly in patients of the same clinical stage. Clinical trials that report results by stage alone may therefore be difficult to interpret. The ISCL/USCLC/EORTC consensus statement on clinical endpoints and response criteria should facilitate improved communication of the degree of disease and response to treatment in future clinical trials.[6]

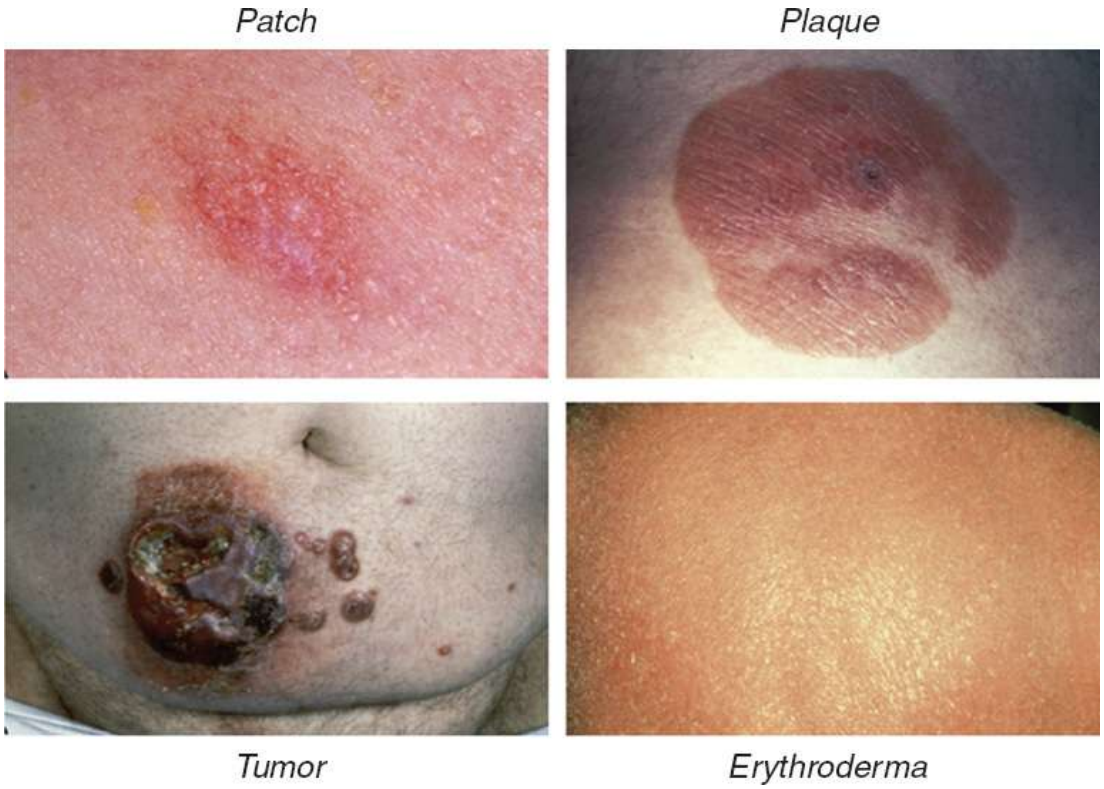

FIGURE 83.2. Representative images of cutaneous lesions in mycosis fungoides. (From Smith BD, Wilson LD. Management of mycosis fungoides. Part 1. Diagnosis, staging, and prognosis. *Oncology* 2003;17[9]:1281–1288. Reprinted by permission of Benjamin D. Smith.)

Molecular and Cellular Pathophysiology

Examination of early-phase MF lesions by hematoxylin and eosin staining commonly reveals epidermotropism, a profound infiltration of lymphocytes into the epidermis. As the lesions progress and become thickened, epidermotropism is gradually lost as the lymphocytes begin to localize more diffusely in the skin. Only a fraction of the skin-homing lymphocytes in MF are malignant, and the malignant T cells may be identified by visualization of their small to medium-sized hyperconvoluted (or cerebriform) nuclei and surrounding lacunae, which give them the impression of being surrounded by a halo. A Pautrier microabscess (Langerhans cell surrounded by atypical T cells in the epidermis) is a less common but pathognomonic histologic finding associated with MF.[1,5] The malignant cells in MF are CD4+ T-helper cells, which most commonly express a CD3+, CD4+, CD45RO+, CLA+, and CCR4+ immunophenotype. Evaluation of the TCR profile of malignant T cells in MF reveals a predominant TCR rearrangement indicative of clonal dominance in a majority of cases.

The specific stimuli and molecular events responsible for activation and

development of clonal dominance of a specific T cell are unknown. Genetic profiling studies have identified a number of chromosomal deletions and duplications associated with MF/SS, and microRNA profiling may reveal distinct molecular profiles associated with different phases of MF. More recently, whole exome/genome sequencing of leukemic CTCL cells revealed mutations of interest involving 17 genes associated with a range of cellular functions including TCR and NF-kB signaling pathways, chromatin remodeling, and DNA repair. In addition to any molecular aberrations intrinsic to the malignant T cells, the cutaneous microenvironment is also likely to play a key role in the development and maintenance of disease.[5,8–12]

Diagnosis and Evaluation

Evaluation of a patient with suspected or recently diagnosed MF should include a comprehensive history/physical examination, biopsy of cutaneous lesion(s) and suspicious lymph nodes, and appropriate laboratory and imaging studies. The ISCL has designed a diagnostic algorithm for early-stage MF (not applicable to MF variants) (Table 83.2),[13] and specific recommendations for patient evaluation have been released by the ISCL/EORTC.[14,15]

History and Physical Examination

The duration of symptoms, evolutionary course of cutaneous disease, and presence or absence of B symptoms should be determined. The percentage of body surface area involved by disease and presence or absence of cutaneous tumors should be documented, and a thorough evaluation of the lymphatic system should be performed. Appropriate images of cutaneous lesions should be recorded so that disease progression or response to therapy may be monitored.

TABLE 83.2 Diagnostic Criteria for Early-Stage Mycosis Fungoides[a][13]

Clinical	Immunopathologic
Persistent and/or progressive patches and plaques plus:	
1. Non–sun-exposed location 2. Size/shape variation 3. Poikiloderma *Scoring:* Two points if two or more criteria met. One point if only one criterion met.	1. CD2, 3, 5 <50% of T cells 2. CD7 <10% of T cells 3. Epidermal discordance from expression of CD2, 3, 5, or 7 on dermal T cells *Scoring:* One point if any criterion met.
Molecular/Biologic	**Histopathologic**

1. Clonal TCR gene rearrangement *Scoring:* One point if present.	1. Epidermotropism without spongiosis 2. Lymphoid atypia *Scoring:* One point for each.

[a]Not applicable to mycosis fungoides variants. Diagnosis made with 4 points or more.
Reprinted from Pimpinelli N, Olsen EA, Santucci M, et al. Defining early mycosis fungoides. *J Am Acad Dermatol* 2005;53(6):1053–1063. Copyright © 2005 American Academy of Dermatology, Inc. With permission.

Skin Biopsy

Biopsies should be taken from a minimum of two distinct sites of disease. Lesions of the greatest induration will be most likely to yield a diagnosis because of greater numbers of malignant cells. However, scaled lesions are more likely to show epidermotropism. Tissue should be evaluated with hematoxylin and eosin staining, immunostaining for surface marker expression profiles (including CD2, CD3, CD4, CD5, CD7, CD8, CD20, CD30, CD26, CD56, TIA1, granzyme B, βF1), and PCR for clonal TCR rearrangement. Slides should be reviewed by a dermatopathologist.

Excisional biopsies of enlarged or otherwise suspicious lymph nodes (fixed or matted lymph nodes, or lymph nodes ≥1.5 cm or ≥1 cm in the head and neck) should be evaluated as described previously. When multiple suspicious lymph nodes are encountered, the choice of lymph node to be excised should be based on size, fluorodeoxyglucose (FDG) avidity, and location, with priority given to the largest lymph node draining an affected area of skin or the lymph node with the highest standardized uptake value (SUV) on positron emission tomography (PET) scan. If all other factors are equal, priority should be given first to cervical nodes, followed by axillary and then inguinal nodes.[14,15]

Laboratory and Imaging Studies

Laboratory studies should include a complete blood count, chemistry panel, liver function tests, and lactate dehydrogenase (LDH). Examination of the peripheral blood for circulating disease by PCR and flow cytometry should also be considered, particularly for patients with erythroderma and nodal or extracutaneous disease. Bone marrow biopsy should be considered if peripheral blood or extracutaneous organs are found to harbor disease.[14,15] Computed tomography (CT) of the chest, abdomen, and pelvis is recommended in the evaluation of all patients with MF with the exception of patients with patch/plaque disease limited to 10% or less of the body surface area. In these cases, a chest x-ray or nodal ultrasound may suffice. PET scanning was shown to be more sensitive than CT in identifying involved lymph nodes, and the role of

PET in MF continues to evolve.[16]

Staging and Prognosis

MF is presently staged using the modified TNMB system proposed by the ISCL/EORTC (Table 83.3).[14] Based on a review of 525 patients with MF (staged using the previous 1979 TNMB system), the majority of patients present with early-stage disease (30% IA, 25% IB, 11% IIA, 16% IIB, 3% IIIA, 8% IIIB, 6% IVA, and 1% IVB). Only 7% of patients presented with peripheral blood involvement. The correlation of clinical stage to overall and disease-specific survival is presented in Figure 83.3.[7] Similar results were obtained in a validation study of the current staging system.[17] Of note, stage IA MF is not associated with any increase in mortality risk in comparison to an age- and ethnicity-matched control population and is associated with only a 16% rate of disease progression at 20 years of follow-up.[7] Benton et al. proposed a cutaneous lymphoma international prognostic index (CLIPi) for both early- and late-stage MF/SS that is based on presence of certain adverse features identified in a multivariate analysis including "male gender, age >60, plaques, folliculotropic disease and stage N1/Nx for early stage, and male gender, age >60, stages B1/B2, N2/3 and visceral involvement for late stage disease."[18] The CLIPi then stratifies patients into low (0 to 1 risk factors), intermediate (2 risk factors), and high (3 to 5 risk factors) risk groups.[18] A report from Emory University indicates that the CLIPi successfully stratified their early-stage but not late-stage MF/SS patients.[19] The Cutaneous Lymphoma International Consortium conducted a multi-institutional and international study of potential prognostic factors in advanced-stage (IIB to IV) MF/SS and have proposed an alternative prognostic index based on presence of four risk factors (stage IV disease, age >60, elevated LDH, and large-cell transformation in the skin). Based on these factors, patients are stratified into low (0 to 1 risk factor; 67.8% 5-year survival), intermediate (2 risk factors; 43.5% 5-year survival), or high (3 to 4 risk factors; 27.6% 5-year survival) risk groups.[20] Overall, these studies underscore the complexities and difficulties inherent to developing accurate prognostic indices for such rare disease entities. A prospective international effort (PROCLIPI) has been initiated to define better the prognostic factors for patients with advanced disease (stage IIB or greater).

TABLE 83.3 ISCL/EORTC Revisions to Mycosis Fungoides Staging[14]

T Stage	N Stage
T1: Limited patches, papules, and/or plaques covering <10% of the skin surface. May further stratify into T1a (patch only) vs. T1b (plaque/patch) T2: Patches, papules, or plaques covering ≥10% of the skin surface. May further stratify into T2a (patch only) vs. T2b (plaque/patch). T3: One or more tumors (≥1-cm diameter) T4: Confluence of erythema covering >80% body surface area	N0: No clinically abnormal peripheral lymph nodes; biopsy not required N1: Clinically abnormal peripheral lymph nodes; histopathology Dutch grade 1 or NCI LN0–2 (N1a, clone negative; N1b, clone positive) N2: Clinically abnormal peripheral lymph nodes; histopathology Dutch grade 2 or NCI LN3 N3: Clinically abnormal peripheral lymph nodes; histopathology Dutch grades 3 or 4 or NCI LN4; clone positive or negative NX: Clinically abnormal peripheral lymph nodes; no histologic confirmation
B Stage	**M Stage**
B0: Absence of significant blood involvement: <5% of peripheral blood lymphocytes are atypical (Sézary) cells B1: Low blood tumor burden: >5% of peripheral blood lymphocytes are atypical (Sézary) cells, but does not meet B2 criteria B2: High blood tumor burden: ≥1,000/mL Sézary cells with positive clone	M0: No visceral organ involvement M1: Visceral involvement (must have pathology confirmation and organ involved should be specified)

Skin-Directed Therapy

MF is not generally considered to be curable, although extended periods of disease-free survival after treatment have been reported. Efforts to treat MF are primarily focused on preventing progression and ameliorating symptoms. In

early-stage disease, a number of skin-directed treatments are effective and should be considered as first-line therapy. Topical therapies include corticosteroids (complete response [CR] rates of 63% for T1 and 25% for T2 disease),[21] nitrogen mustard (CR rates of 76% to 80% for stage IA and 35% to 68% for stage IB),[22] carmustine (CR rates of 86% for T1 and 47% for T2 disease),[23] and bexarotene gel (CR rate of 21% in early-stage MF).[24] Phototherapy with narrow-band ultraviolet B (NB-UVB) (54% CR in stages IA or IB)[25] or psoralen + UVA (PUVA) (CR rate of 65%)[26] is also frequently used. However, the most effective skin-directed therapy for MF is ionizing radiation.

Ionizing radiation is well suited to the treatment of cutaneous lymphoma. Lymphocytes are highly radiosensitive, and radiation doses may be effectively limited to the epidermis and dermis by appropriate selection of photon or electron energies. Options for irradiation include local superficial irradiation or irradiation of the entirety of the skin via total skin electron beam therapy (TSEBT). The International Lymphoma Radiation Oncology Group recently reported their suggested guidelines for field and dose selection.[27]

Local Superficial Irradiation

A small portion (5%) of patients with stage IA MF present with “minimal” disease, defined as a solitary lesion or two to three MF lesions clustered sufficiently close to one another that they are amenable to treatment with a single or abutting radiation fields.[28] For these patients, treatment with local superficial irradiation may be considered. Treatment fields should be designed to encompass the entirety of the lesion (determined by visual inspection, palpation, and/or appropriate imaging) with a 1- to 2-cm margin, with use of a lead or Cerrobend cutout to conform field borders to the anatomy of the cutaneous lesion. Skin collimation can also be incorporated. Treatment is most commonly provided with electrons, with energies (usually 6 to 16 MeV) carefully selected to optimize dose penetration. Bolus is usually required with the lower-energy electrons (6 to 9 MeV) in order to maximize the dose at the skin surface. The EORTC recommends that the 80% isodose line is set at the deep border of the dermis,[29] which is commonly at a depth of approximately 4.5 mm.

TABLE 83.4 EORTC Technical Recommendations for TSEBT[29]

The primary target in TSEBT is the epidermis, adnexal structures, and dermis.
The goal of treatment (either by primary or supplemental treatments) is to deliver a dose of 26–28 Gy to a depth of 4 mm below the skin surface, which usually translates to a truncal dose of 31–36 Gy.

Treatment should be provided in 30–36 fractions (1–1.2 Gy/fraction) over 6–10 wk. Fraction sizes should not exceed 2–2.5 Gy because of increased acute and late side effects.
The 80% isodose line should extend to 4 mm below the skin surface, the dose 20 mm deep to the skin must be <20% of the maximum dose at skin, and the dose at curved skin sites must not exceed 120% of the prescribed skin dose.
Patient positioning is critical, and patients must be positioned in a manner to maximize unfolding of the skin. A minimum of six treatment positions is recommended.
The optimal source-to-patient distance is 3–8 m, and dose should be homogenous to within 10% across the entire vertical and lateral dimensions of the beam at the patient's surface.
The globe of the eye must be limited to <15% of the maximum skin dose, and photon contamination at the bone marrow must be limited to <0.7 Gy.

Local superficial radiation is very effective in generating a CR for patients with "minimal" stage IA MF. In a review of 21 patients with "minimal" stage IA MF treated with local superficial radiation (superficial or orthovoltage x-rays or megavoltage electrons) to doses ranging from 20 to 40 Gy in four to five or 10 to 15 fractions, Wilson et al.[28] found a CR rate of 97%. Importantly, review of the recurrence rates associated with different total doses of local superficial radiation revealed a 25% local recurrence rate (two of eight fields) with treatment to 20 Gy and an 8% local recurrence rate (two of 25 fields) with treatment to 20 to 40 Gy. Similarly, Cotter et al.[30] reported a local recurrence rate of 42% for fields treated to 10 Gy or less, but 0% for fields treated to >30 Gy. More recently, treatment to 8 Gy in one or two fractions has been shown to yield a CR rate of 92 to 94%.[31,32] Based on these studies, it is recommended that "minimal" stage IA (i.e., unilesional or up to three closely approximated sites) MF lesions are treated to a dose of 30 to 36 Gy, and treatment as low as 8 Gy in one or two fractions may be considered as a palliative treatment. Side effects of local superficial radiation are usually limited to mild dermatitis, local alopecia, and pigmentation changes.

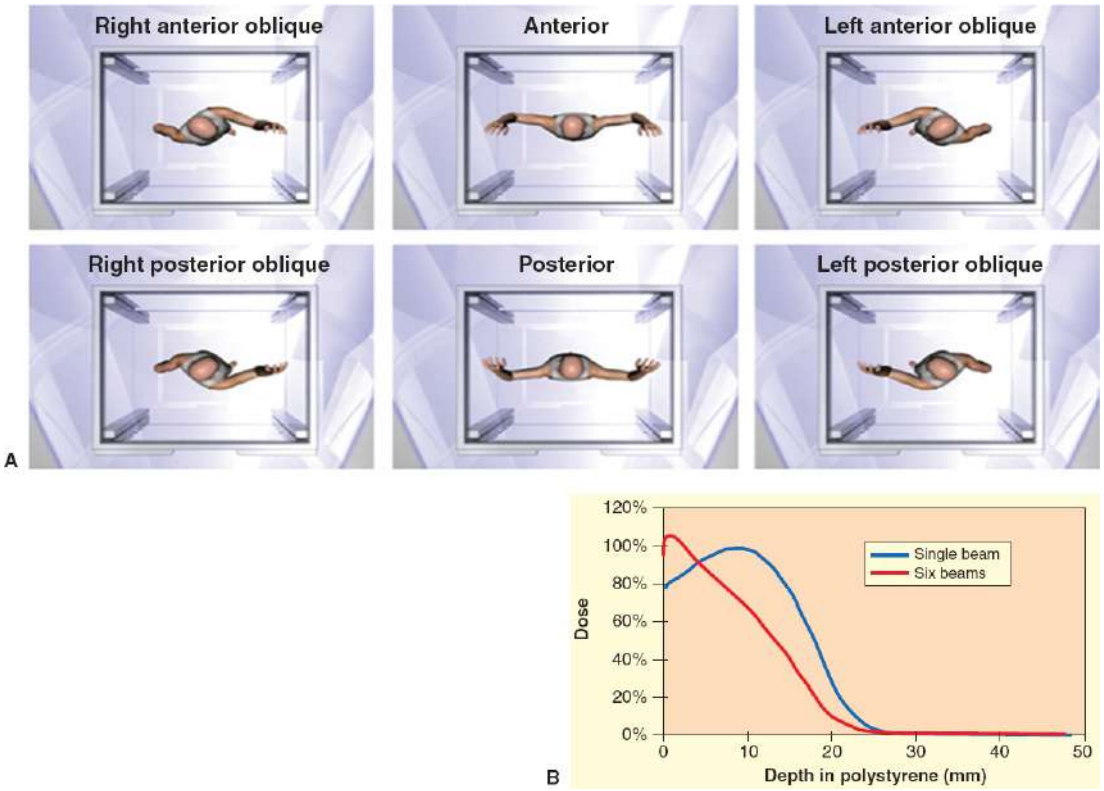

FIGURE 83.4. A: The six total skin electron beam therapy (TSEBT) treatment positions as viewed from above. Images not to scale. **B:** Comparison of depth dose profiles associated with a single treatment position (*blue curve*) versus six treatment positions (*red curve*). Treatment. *Oncology* 2003;17[10]:1419–1428. Reprinted by permission of Benjamin D. Smith.)

Total Skin Electron Beam Therapy

Technique

TSEBT is technically challenging and should only be attempted in centers with special expertise in its provision, including skilled physics support. EORTC recommendations regarding the technical aspects of TSEBT are presented in Table 83.4. Modern TSEBT is usually accomplished with 6- to 9-MeV electrons generated by a medical linear accelerator directed at a patient standing behind a polycarbonate screen, 3.8 m from the linear accelerator head. The polycarbonate screen scatters the incident electron beam and contributes to an improved surface dose. Treatment is provided in "cycles," with one cycle composed of treatment of the patient in six different positions (Fig. 83.4A) over 2 days (three positions each day). Typically, a dose of 2 Gy is provided to the entirety of the skin during one cycle, and two cycles are usually administered per week. Treatment in six positions optimizes dose distribution at the skin surface (Fig. 83.4B). At Yale

and Stanford, the anterior, right posterior oblique, and left posterior oblique positions are treated on cycle day 1, and the posterior, right anterior oblique, and left anterior oblique positions on cycle day 2.[33,34] When the patient stands in a treatment position, a dual-field technique is used to deliver treatment to a superior and inferior field by angling the gantry 16 to 17.5 degrees above and below horizontal, respectively, the specific angle dependent upon individual machine characteristics (Fig. 83.5). Treatment to the six positions using the dual-field technique, which is in use at Yale and Stanford, delivers maximum dose to a depth of 1 mm, 80% dose to 6 to 7 mm, and 20% dose to 12.5 mm.[33,34]

Dose and Fractionation

Sublethal damage repair does not appear to be a major factor in determining the response of MF to ionizing radiation,[35] and modern TSEBT is provided with a relatively protracted course of two cycles per week for 9 weeks, which provides a total dose of 36 Gy to the skin surface. The total radiation dose appears to be directly associated with CR rates, with 18% CR with treatment to <10 Gy, 55% CR with treatment to 10 to 20 Gy, 66% CR with treatment to 20 to 25 Gy, 75% CR with treatment to 25 to 30 Gy, and 94% CR with treatment to 30 to 36 Gy.[36] However, lower doses yield impressive rates of overall response (defined as a >50% reduction in cutaneous disease), overall survival, progression-free survival, and relapse-free survival rates. Relapse rates are relatively high even in patients in which a CR is obtained, and the absolute benefit of a CR relative to the increased side effects at higher doses of TSEBT is unclear. The application of reduced-dose TSEBT (10 to 20 Gy) in combination with additional therapies may be a viable alternative to the current standard of 36 Gy.[37,38]

Two prospective trials of low-dose (10 to 12 Gy) TSEBT have been reported.[38,39] In the Stanford/MD Anderson trial, 33 patients with stage IB to IIIA disease were treated with 12 Gy TSEBT over 3 weeks. The CR rate was only 27%, but the overall response rate was 88%. The duration of clinical benefit (time to which another total skin therapy or systemic therapy was required for management) was 70.7 weeks.[38] This approach of management with TSEBT allows more frequent use of this very effective modality for the duration of a patient’s illness, which is often many years. In addition, the toxicity is significantly less than with conventional dose treatment.

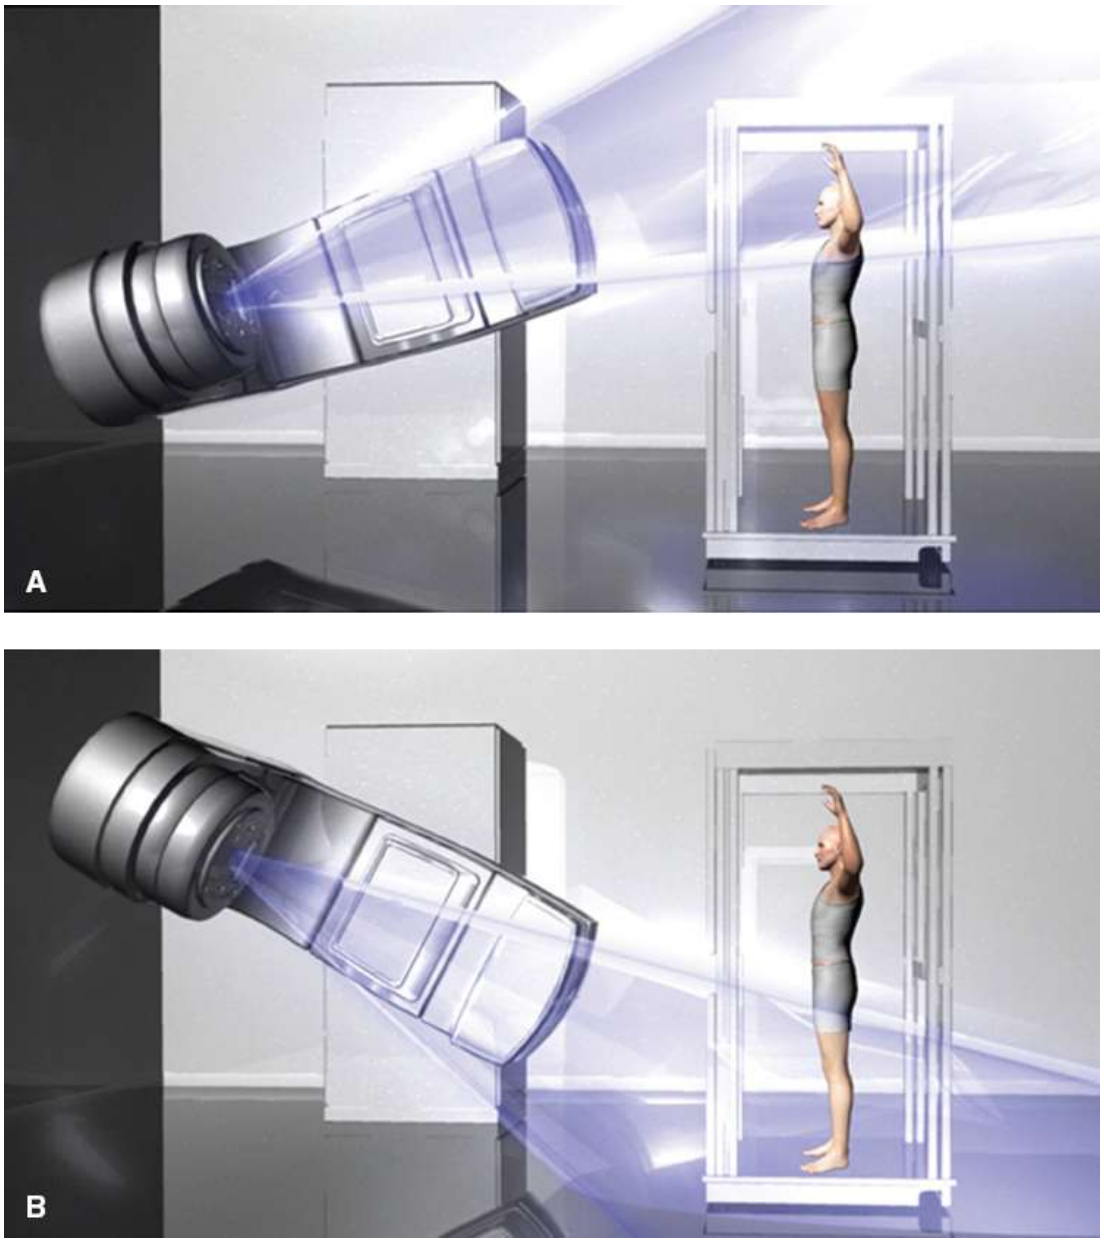

FIGURE 83.5. Dual-field technique for total skin electron beam therapy (TSEBT). **A:** Treatment of superior field. **B:** Treatment of inferior field. Images not to scale. (Courtesy of Christian Chang, www.christianchang.com, printed with permission from the artist.)

Supplemental Treatments

The six treatment positions in TSEBT maximize unfolding of the skin and exposure of the skin surface to the incident electron beam, but areas such as the soles of the feet, perineum, and scalp remain obscured and require supplemental doses to ensure that a minimum of 20 to 28 Gy is administered to a depth of approximately 4 mm. Supplemental treatment to these areas may be

accomplished by the use of 120-kV superficial photons with half-value layer (HVL) 4.2-mm Al or low-energy (6 MeV) electrons with 1-cm bolus to treat the soles of the feet (1 Gy/fraction) and the perineum (1 Gy/fraction). In some setups, the scalp is treated by placing an angled electron reflector above the patient,[33] but supplemental boosting is an alternative approach that is incorporated in some centers. Additional areas that may need supplemental dose include thick cutaneous tumors and skin folds secondary to body habitus, and the need for supplemental dose to such areas is based on the judgment of the radiation oncologist.[33,34]

Side Effects

In a review of perceptions of MF therapy, patients overall considered TSEBT to be a more difficult treatment to endure as compared to other treatments,[40] and it is important that patients are advised that symptoms such as pruritus and cutaneous erythema may be exacerbated during therapy. Additional acute side effects that commonly occur include xerosis, dry desquamation, extremity edema, blister/bullae formation over the lower extremities, alopecia (including hair of the scalp, eyebrows, eyelashes, and body), and nail changes (nails may ultimately be lost but usually regrow). Hypohydrosis secondary to damage to sweat glands may occur. Similarly, dryness and irritation of the nasal mucosa may result in nose bleeds. Gynecomastia is a rare occurrence. Late/chronic side effects are minimal and include cataract formation, chronic xerosis, persistent alopecia, dystrophic nails, telangiectasia, and secondary skin cancers including squamous and basal cell carcinomas and melanomas. Clinicians should be vigilant for the possibility of active cutaneous infection during the course of therapy.[29,41–45]

In an effort to minimize side effects, areas that are most susceptible to TSEBT such as the eyes, lips, hands, fingernails, feet, and testes are blocked during certain cycles of treatment. Shielding of the eye and lens may be accomplished by a combination of internal/external shields, selected based upon the proximity of clinical disease. Usually, if internal eyeshields are used, they are used for only a portion of the therapy (7 to 20 Gy). The lips, hands, and fingernails may be blocked by lead mitts or fingernail shields as clinical circumstances warrant. The feet may be blocked by footboards for a portion of the treatment. A testicular shield may be used during perineal boost treatments.[33]

Clinical Efficacy

TSEBT is very effective, particularly for early-stage disease. TSEBT yields a CR rate of >90% with a 15-year relapse-free survival of 40% in patients with T1 disease, although it is no longer recommended for such limited disease.[36] Of note, patients with recurrent disease after a course of TSEBT most commonly have disease restricted to <5% of the skin surface area, and these recurrences are therefore amenable to local salvage therapy with topical therapy or limited superficial radiation. When successful salvage of such limited recurrences is taken into account, relapse-free survival improves to 70% at 15 years.[46–48]

In T2 disease, TSEBT is similarly effective, with a CR rate of 76% to 90% and a 50% relapse-free survival rate at 5 years and 10% at 10 years. Relapse-free survival is significantly improved by addition of adjuvant PUVA or nitrogen mustard. Specifically, adjuvant PUVA improves 5-year relapse-free survival to 85%, and nitrogen mustard improves 10-year relapse-free survival to 40%.[29,48–50]

When cutaneous tumors are present (T3 disease), TSEBT is less effective but still yields an impressive CR rate of 44% to 54% of patients, much greater than any other single modality. Adjuvant treatment should be considered, and retrospective studies suggest that nitrogen mustard may increase the durability of response. Alternatively, a combination of nitrogen mustard and local superficial radiation may be considered for tumors localized to a small percentage of the skin surface.[48,50,51] Supplemental boosts should be considered for patients with tumors, and such boost treatment should be provided concomitantly with the initiation of TSEBT or prior to its initiation. The purpose of the boost is to diminish the thickness of the lesion so that electrons from TSEBT can effectively penetrate the entire lesion.

In erythrodermic MF (T4 disease), TSEBT yields a 70% to 100% response rate (for patients with T4N0 disease) and 5-year progression-free survival of 25% to 69%. When disease involves the peripheral circulation or extracutaneous sites, TSEBT is less effective and response and progression-free survival rates decrease to 74% and 36%, respectively. TSEBT appears to be synergistic with extracorporeal photopheresis (ECP), and the combination of TSEBT and ECP is associated with improved disease-specific survival and decreased levels of circulating malignant cells.[51–55]

Palliative Radiotherapy

Symptomatic nodal or visceral disease may be effectively palliated by a brief course of localized radiotherapy, usually to a total dose of 12 to 30 Gy. If this

treatment is given in conjunction with a course of TSEBT, a similar dose may be used. In the subset of patients that develop extensive recurrence of cutaneous disease after a previous course of TSEBT, additional courses of TSEBT to lower total doses can be considered and have proven effective in studies at Yale and Stanford.[56,57]

Systemic Therapy

Skin-directed therapy should be attempted first for patients with early-stage disease, but in patients with advanced or refractory disease, systemic therapy may be considered. Options for systemic therapy include oral bexarotene (response rate up to 54% in refractory CTCL at a dose of 300 mg/m^2, and bexarotene may be used in combination with other therapies),[58,59] denileukin diftitox (a fusion protein consisting of interleukin-2 and a portion of the diphtheria toxin that yields an overall response rate of 30% in refractory CTCL),[60] histone deacetylase inhibitors (such as vorinostat and romidepsin, 30% response rate in refractory CTCL),[61,62] alemtuzumab (a monoclonal antibody targeted against the CD52 surface marker with a 38% overall response rate in relapsed or refractory CTCL and 86% response rate in SS),[63,64] interferon-α2a (IFN-α) (a biologic modifier with a response rate of 40% to 80% in CTCL as a single agent and with synergistic activity with other MF therapies),[65–71] ECP (associated with improvement in peripheral blood and skin involvement, especially in those with T4 disease),[72] brentuximab vedotin,[73] and cytotoxic chemotherapy (single-agent chemotherapy with agents such as purine or nucleoside analogs, liposomal doxorubicin, and antifolate agents, including methotrexate and pralatrexate, is preferred because no distinct advantages have been identified with the use of multiagent regimens).[74–80]

Autologous or Allogeneic Stem Cell Transplant

Patients with MF/SS refractory to other therapies may be considered for stem cell transplant. Although autologous stem cell transplants have not proven to be overly effective, greater success has been achieved with allogeneic stem cell transplants. Additional studies are necessary to fully define the role of stem cell transplant in MF. This approach may prove to be a valuable option for patients with refractory disease.[81–85]

Treatment Recommendations by Stage

Treatment recommendations for MF/SS are presented by stage in Table 83.5.[82] The National Comprehensive Cancer Network (NCCN) has also published

treatment guidelines for MF/SS.[86]

Transformed Disease

In some cases, large-cell transformation of MF may occur, which is identified on biopsy by >25% large cells in the sample. Large-cell transformation may be associated with decreased survival rates and occurs in 8% to 39% of cases. Patients with advanced stage or high levels of β_2-microglobulin or LDH are at the greatest risk of large-cell transformation. Treatment options include systemic chemotherapy, stem cell transplant, and consolidative or local radiation for localized disease.[82]

Variants of Mycosis Fungoides

Variant forms of MF that share histologic and clinical features with classic MF but exhibit distinct clinical behavior have been recognized and include folliculotropic MF, Woringer-Kolopp disease, granulomatous slack skin, and hypopigmented MF.

Folliculotropic MF is characterized by a folliculotropic pattern of cutaneous infiltration of malignant T cells. Folliculotropic MF lesions present as patches, plaques, or tumors or may manifest in an acneiform pattern. Lesions primarily develop over the head and neck and are rarely found over the trunk. Localized alopecia secondary to the folliculotropic pattern is common. Folliculotropic MF is associated with a 15-year survival of 41% for early-stage disease. Early-stage disease may be treated with PUVA combined with bexarotene or IFN-α. Local radiation therapy may be advantageous because it can effectively treat to deeper depths of involvement seen in this variant. Advanced-stage disease is minimally responsive to cytotoxic chemotherapy, and alternate options such as irradiation or allogeneic stem cell transplant should be considered.[1,87,88]

TABLE 83.5 RECOMMENDATIONS FOR TREATMENT OF MF BY STAGE

Stage	First-Line Therapies	Options for Refractory or Relapsed Disease
"Minimal" IA	Local superficial irradiation	Consider standard-stage IA first-line therapies
IA, IB, IIA	Expectant observation (for stage IA) Topical therapies (corticosteroids, nitrogen mustard, BCNU, bexarotene) Phototherapy (PUVA, NB-UVB)	Second course TSEBT Oral bexarotene IFN-α Low-dose MTX

	TSEBT (consider adjuvant PUVA or nitrogen mustard)	Vorinostat Denileukin diftitox Clinical trials NOTE: Chemotherapy is not recommended
IIB	TSEBT (consider boosts to cutaneous tumors and adjuvant PUVA or nitrogen mustard) IFN-*α* PUVA	Second course TSEBT Oral bexarotene Vorinostat Denileukin diftitox Clinical trials Chemotherapy
IIIA, IIIB, leukemic CTCL or SS	TSEBT + ECP ECP alone IFN-*α* PUVA + IFN-*α* MTX	Second course TSEBT Oral bexarotene Vorinostat Denileukin diftitox Alemtuzumab Clinical trials Chemotherapy Allogeneic stem cell transplant
IVA(1–2), IVB	Chemotherapy TSEBT for palliation Oral bexarotene Denileukin diftitox IFN-*α* Vorinostat Romidepsin Low-dose MTX Clinical trials	Allogeneic stem cell transplant

BCNU, bis-chloroethylnitrosourea; CTCL, cutaneous T-cell lymphoma; ECP, extracorporeal photopheresis; IFN-*α*, interferon-alpha; MTX, methotrexate; NB-UVB, narrowband ultraviolet B; PUVA, psoralen plus ultraviolet A; SS, Sézary syndrome; TSEBT, total skin electron beam therapy.

Woringer-Kolopp disease (pagetoid reticulosis) is characterized by a solitary erythematous and scaling cutaneous patch on an extremity. Biopsy results are similar to classic MF, and the malignant T cells commonly carry a CD3+/CD4+/CD8− or CD3+/CD4−/CD8+ immunophenotype. If CD8+ disease is identified, it is important to consider the alternative diagnosis of CD8+ aggressive peripheral CTCL, and the distinction between these diagnoses is made by the aggressiveness of disease. Specifically, as compared to CD8+ aggressive peripheral CTCL, Woringer-Kolopp disease is very slowly progressive and carries an excellent prognosis. Treatment options include skin-directed therapies such as corticosteroids, nitrogen mustard, resection, or local irradiation. Local radiation may be very successful in achieving long-term local control even in locally very advanced disease. In rare cases of diffuse or

refractory disease, irradiation is also recommended.[1,89]

TABLE 83.6 ISCL/EORTC TNM Classification of Cutaneous Lymphoma Other than MF/SS[93]

T Stage	N Stage	M Stage
T1: Solitary skin involvement T1a: A solitary lesion <5 cm in diameter T1b: A solitary lesion >5 cm in diameter T2: Regional skin involvement: multiple lesions limited to 1 body region or 2 contiguous body regions T2a: All-disease-encompassing in a <15-cm-diameter circular area T2b: All-disease-encompassing in a >15- and <30-cm-diameter circular area T2c: All-disease-encompassing in a >30-cm-diameter circular area T3: Generalized skin involvement T3a: Multiple lesions involving 2 noncontiguous body regions T3b: Multiple lesions involving ≥3 body regions	N0: No clinical or pathologic lymph node involvement N1: Involvement of 1 peripheral lymph node region that drains an area of current or prior skin involvement N2: Involvement of 2 or more peripheral lymph node regions or involvement of any lymph node region that does not drain an area of current or prior skin involvement N3: Involvement of central lymph nodes	M0: No evidence of extracutaneous non–lymph node disease M1: Extracutaneous non–lymph node disease present

TNM classification system for primary cutaneous lymphomas other than mycosis fungoides and Sezary syndrome: a proposal of the International Society for Cutaneous Lymphomas (ISCL) and the Cutaneous Lymphoma Task Force of the European Organization of Research and Treatment of Cancer (EORTC). *Blood* 2007;110(2):479–484; permission conveyed through Copyright Clearance Center, Inc.

Granulomatous slack skin (GSS) is an extremely rare variant of MF, with <100 cases reported in the literature. It is characterized by cutaneous infiltration of a clonal population of malignant T cells coupled with a granulomatous

infiltration. The granulomatous infiltrate ultimately causes destruction of local elastin fibers and impairs the structural integrity and elasticity of the skin, which results in loose or "slack" skin. This loosening of the skin is most commonly observed in the axilla, groin, neck, and breast. Although GSS is itself an indolent disease, it is associated with an increased incidence of secondary lymphomas, most commonly Hodgkin lymphoma or MF. Given the rarity of this disease, it is difficult to make definitive recommendations regarding therapy, but surgical resection or local superficial radiation may be effective.[1,90]

Hypopigmented MF presents at an earlier age (childhood or adolescence) than classic MF and is characterized by development of hypopigmented patches frequently over the trunk or extremities. In contrast to classic MF, the malignant T cells are often CD8+. Treatment and disease course are otherwise similar to classic MF.[91,92]

Non–Mycosis Fungoides Cutaneous T-Cell Lymphoma

Staging

In 2007, the ISCL and EORTC presented a new TNM staging system for non-MF/SS cutaneous lymphomas (Table 83.6).[93]

CD30+ Lymphoproliferative Disorders

A review of the SEER registry identified 268 cases of primary cutaneous CD30+ lymphoproliferative disorders recorded between 1974 and 2004 (58% male and 42% female patients). The median age of diagnosis was 61, and population-matched 3-year relative survival was 87%, with 5-year disease-specific survival 92%. Localization of disease in the head and neck appears to be a negative prognostic factor.[94] The primary cutaneous CD30+ lymphoproliferative disorders recognized by the WHO/EORTC are primary cutaneous anaplastic large-cell lymphoma and lymphomatoid papulosis.[1] These cannot be differentiated histologically. It is essential to take a careful clinical history to document the distribution of lesions and their clinical course (e.g., history of spontaneous regression). The diagnosis is a clinicopathologic one. The EORTC, ISCL, and USCLC have provided consensus recommendations regarding the evaluation and treatment of primary cutaneous CD30+ lymphoproliferative disorders.[95]

Primary cutaneous anaplastic large-cell lymphoma (C-ALCL) is characterized by development of cutaneous plaques, nodules, or tumors that are usually solitary or clustered into a localized area. Multifocal disease is

uncommon (occurring in only 20% of patients), and lymph nodes are involved in only 10% of cases. Extracutaneous disease is rarely found. C-ALCL is most commonly diagnosed in males, with a male:female ratio of 2–3:1. When disease is localized to the skin and regional lymph nodes, prognoses are excellent, with anticipated 5-year overall survival and 10-year disease-specific survival rates of 90%. Progression to extracutaneous disease is associated with overall survival, and extensive limb disease (defined as “initial presentation or progression to multiple skin tumors in 1 limb or contiguous body regions”)[96] is associated with disease-specific survival. Biopsies of C-ALCL lesions reveal a diffuse infiltration of large anaplastic CD4+ T cells, and at least 75% of these anaplastic T cells express CD30. Similar to MF, clonal dominance is frequently detected by PCR evaluation for TCR rearrangement.[1]

Limited resection or local superficial irradiation is very effective in controlling localized cutaneous disease, and low-dose methotrexate may be considered when widespread cutaneous disease precludes simple resection or irradiation. Local superficial radiation to a dose of 34 to 44 Gy was associated with a 100% CR rate,[97] but more recent data suggest that lower doses such as 20 Gy may be adequate.[98] In rare cases in which extracutaneous disease is found, doxorubicin-based chemotherapy should be considered.

Of note, prior to initiating therapy, it is critically important to verify that C-ALCL has been correctly distinguished from the more common systemic ALCL. Molecular studies to evaluate the presence of the (2:5)(p23;q35) chromosomal translocation and expression of anaplastic lymphoma kinase (ALK) or epithelial membrane antigen (EMA) are useful in making this distinction, because the (2:5) translocation and expression of ALK and EMA are found in systemic ALCL but rarely found in C-ALCL.[1,99]

Lymphomatoid papulosis (LyP) carries an excellent prognosis, with a 5-year overall survival rate of 100%. However, 15% to 20% of patients with LyP will develop MF, C-ALCL, or a Hodgkin lymphoma. LyP is characterized by development of violaceous papular or papulonodular lesions over the trunk or extremities, which typically regress after 3 to 12 weeks, often leaving a residual scar. Biopsy of LyP cutaneous lesions reveals epidermotropic atypical CD3+/CD4+/CD8− lymphocytes, and clonal TCR rearrangement is identified in 60% to 70% of cases. Three distinct histologic subtypes are recognized: LyP A, B, and C. LyP A (characterized by large multinucleated CD30+ cells intermixed with an inflammatory infiltrate) and C (characterized by large CD30+ cells with minimal inflammatory infiltrate) represent 90% of cases. In contrast to types A

and C, atypical lymphocytes in LyP B are CD3+/CD4+/CD30−, reminiscent of MF.[1]

Aggressive therapies such as chemotherapy or radiation should be avoided in LyP. In the rare patient with a large cutaneous burden of disease, skin-directed therapy with PUVA or a topical chemotherapy agent may be considered. In addition, low-dose oral methotrexate may be effective in suppressing the development of new lesions and should be considered if previous LyP lesions caused significant scarring.[1]

Extranodal NK-/T-Cell Lymphoma, Nasal Type

Extranodal NK-/T-cell lymphoma, nasal type most commonly arises in the nasal cavity and nasopharynx but in select cases may present with cutaneous plaques or tumors over the extremities and trunk and is therefore included in the WHO/EORTC classification of cutaneous lymphomas. Biopsy of a cutaneous lesion reveals a dense lymphoid infiltrate, which may exhibit an epidermotropic component. The malignant cells are most commonly NK in origin with a CD3−/CD2+/CD56+ immunophenotype, but on occasion, the malignant cells are derived from cytotoxic T cells. Epstein-Barr virus (EBV) is directly associated with disease development, and cutaneous lesions are nearly always EBV+. Consistent with an EBV-mediated pathophysiology, the disease occurs more commonly in geographic distributions in which EBV is endemic (Central America, South America, South Asia). The TCR usually remains in germline configuration when the malignant cells are of NK-cell origin, but clonal TCR rearrangement may be observed in cases in which the malignant cells are derived from cytotoxic T cells. Optimal treatment regimens for cutaneous extranodal NK-/T-cell lymphoma, nasal type have not yet been determined. Treatment with extended field radiotherapy to a median dose of 50 Gy yields a CR rate of 95.4% in early-stage disease, but local or distant recurrences are common and adjuvant therapy with L-asparaginase and other regimens should be considered. Advanced-stage disease is treated primarily with chemotherapy.[1,100–102]

Subcutaneous Panniculitis-like T-Cell Lymphoma

Subcutaneous panniculitis-like T-cell lymphoma presents with subcutaneous nodules and/or plaques, which are commonly localized over the legs or trunk. Biopsy reveals a lymphoid infiltrate composed primarily of malignant cytotoxic CD8+ T cells. Prior to the establishment of the WHO/EORTC classification system, α/β and γ/δ T-cell forms of disease were each recognized as

subcutaneous panniculitis-like T-cell lymphoma. However, γ/δ T-cell lymphoma is now recognized as a distinct, more aggressive disease and is categorized as a primary cutaneous peripheral T-cell lymphoma. The 5-year survival of the less aggressive α/β disease approaches 80%, and treatment involves combinations of corticosteroids and radiation, and potentially chemotherapy for refractory disease.[1] Notably, presence of the hemophagocytic syndrome predicts a worse prognosis.

Adult T-Cell Leukemia/Lymphoma

Infection with the human T-lymphotropic virus 1 (HTLV-1) may result in adult T-cell leukemia/lymphoma in approximately 1% to 5% individuals, and patients may develop associated cutaneous disease characterized by papules, plaques, and tumors. In smoldering disease, cutaneous lesions may be the only sign of pathology. Chemotherapy is the primary therapy for acute adult T-cell leukemia/lymphoma, while smoldering cases may be treated with skin-directed therapies.[1]

Primary Cutaneous Peripheral T-Cell Lymphoma

Additional CTCLs that do not fit into the previously discussed categories are grouped as “primary cutaneous peripheral T-cell lymphomas,” and provisional subsets of this category described by the WHO/EORTC include primary cutaneous aggressive epidermotropic CD8+ cytotoxic T-cell lymphoma (characterized by cutaneous papules/plaques, nodules, and tumors with ulceration and a propensity for extracutaneous spread of disease; of note, it has recently been proposed that CD8+ should be removed from the naming of this disease entity in order to allow inclusion of diseases of similar behavior that is CD8- or has variability in TCR expression status),[103] cutaneous γ/δ T-cell lymphoma (most commonly characterized by subcutaneous plaques or tumors in the extremities), primary cutaneous CD4+ small/medium-sized pleomorphic T-cell lymphoma (usually presents as a single cutaneous plaque or tumor on the head and neck or upper trunk and has an indolent clinical behavior), and primary cutaneous peripheral T-cell lymphoma, unspecified (most commonly presents as solitary or generalized nodules). The primary cutaneous peripheral T-cell lymphomas are primarily treated with chemotherapy or allogeneic stem cell transplantation, with the exception of primary cutaneous CD4+ small/medium-sized pleomorphic T-cell lymphoma, which may be treated with local resection or radiation.[1]

CUTANEOUS B-CELL LYMPHOMAS

Primary cutaneous B-cell lymphoma (PCBCL) was first recognized as a distinct clinical entity in 1981 and accounts for only 29% of the 3,884 cases of primary cutaneous lymphoma diagnosed in the United States during 2001 to 2005.[3] The WHO/EORTC classification system recognizes three primary categories of CBCL: primary cutaneous marginal zone B-cell lymphoma (PCMZL), primary cutaneous follicle center B-cell lymphoma (PCFCL), and primary cutaneous diffuse large B-cell lymphoma, leg type (PCLBCL-LT).[1] Of the CBCL cases diagnosed in the United States in 2001 to 2005, the most common subtype was primary cutaneous DLBCL (40%, of which only 23% were of leg type), followed closely by cutaneous follicle center lymphoma (30%) and cutaneous marginal zone B-cell lymphoma (25%).[3] However, it should be noted that the histopathologic criteria for PLCBCL changed upon adoption of the WHO/EORTC consensus system, and it is likely that most of the PLCBCL cases diagnosed during 2001 to 2005 would now be reclassified as PCFCL. In a recent review, 65% of CBCL cases classified as DLBCL using the older WHO criteria were found to be PCFCL under the current WHO/EORTC classification.[104]

Primary Cutaneous Marginal Zone B-Cell Lymphoma

PCMZL commonly presents with isolated or multifocal red or violaceous papules, plaques, and/or nodules on the trunk or extremities. The malignant cells are marginal zone B cells with a CD20+/CD79a+/CD5−/CD10− immunophenotype. Biopsies reveal an infiltrate composed of numerous lymphoid cells including marginal zone B cells, lymphoplasmacytoid cells, plasma cells, centroblast-like and immunoblast-like cells, reactive T cells, and reactive germinal centers. The prognosis for patients with PCMZL is excellent, and extracutaneous disease is rarely seen. Five-year overall survival rates of approximately 99% are expected, and cutaneous disease is very responsive to therapy. Cutaneous relapses are common but do not predict decreased survival.[1]

Primary Cutaneous Follicle Center Lymphoma

In contrast to PCMZL, PCFCL frequently presents with solitary or clustered plaques and tumors on the scalp, forehead, and trunk. Biopsy reveals a nodular or diffuse lymphoid infiltrate containing varying proportions of centrocytes, centroblasts, and reactive T cells growing in patterns ranging from follicular to diffuse. Similar to PCMZL, the malignant cells in PCFCL are of a CD20+/CD79a+ immunophenotype. Clonal rearrangement of immunoglobulin

genes is usually observed. Importantly, the chromosomal translocation t(14:18) is infrequently seen in PCFCL, and therefore, detection of this translocation should prompt consideration of a nodal or systemic follicular lymphoma. Similar to PCMZL, cutaneous lesions respond well to treatment, but rates of cutaneous relapse are relatively high at 20% overall. Extracutaneous disease is detected in 5% to 10% of patients, and bone marrow biopsy is an important component of evaluation. The 5-year overall survival rate for PCFCL is estimated at 95%.[1]

Primary Cutaneous Diffuse Large B-Cell Lymphoma, Leg Type

PCLBCL, leg type, most commonly presents with violaceous cutaneous tumors over the lower extremities. Despite the nomenclature, anatomic restriction to the legs is not a requirement, and in rare cases, PCLBCL, leg type, may be found in other cutaneous sites than the leg. The disease is characterized by diffuse lymphoid infiltrates with a predominance of centroblasts and immunoblasts, with absence of any significant numbers of centrocytes being a key distinguishing feature from PCFCL. A CD20+, CD79a+, Bcl-6+/−, CD10−, Bcl-2+, MUM-1+, and FOXP1+ immunophenotype is usually observed. In contrast to PCMZL and PCFCL, both cutaneous relapses and development of extracutaneous disease are common, and the 5-year overall survival is decreased to 50%. A very small subset of PCLBCL (such as intravascular PCLBCL or anaplastic or plasmablastic PCLBCL) is categorized as "PCLBCL, other."[1]

Diagnosis and Evaluation

Evaluation of patients with suspected PCBCL should follow the basic protocol recommended by ISCL/USCLC/EORTC previously discussed.[13] In addition, a bone marrow biopsy is needed for PCBCL-LT and should be strongly considered in PCFCL (rate of bone marrow involvement may be as high as 11%). In other cases the need for bone marrow biopsy is left to the discretion of the treating physician. A further component to evaluation of PCBCL in European nations includes evaluation for *Borrelia burgdorferi* infection.[1,105] The *Borrelia* subspecies *Borrelia afzelii* that appears to be the causative organism is not found in the United States.[106]

Staging and Prognosis

PCBCLs should be staged in accordance with the ISCL/EORTC staging system for non-MF/SS cutaneous lymphomas (Table 83.6). A cutaneous B-cell lymphoma prognostic index (CBCL-PI) was developed by correlating outcome data from the Surveillance, Epidemiology, and End Results (SEER) database

with PCBCL histology and anatomic location (Table 83.7).[107] Four prognostic groups (IA, IB, II, III) were defined by the CBCL-PI based on specific combinations of histology and anatomic location. However, as described earlier, the histologic criteria in use during the years on which the CBCL-PI is based (1973 to 2001) were changed with the 2005 release of the WHO/EORTC consensus classification system,[1] and the CBCL-PI should be used with caution when modern histopathologic classification criteria are used.

In 2011, the International Extranodal Lymphoma Study Group (IELSG) released the CLIPi for indolent CBCL. Independent prognostic factors associated with progression-free survival included serum LDH, morphology (nodule vs. other), and number of distinct cutaneous sites of disease (greater than two). One point is scored for each factor, and patients are grouped into low risk (score 0), intermediate risk (score 1), and high risk (score 2 or 3) with associated 5-year progression-free survival rates of 91%, 64%, and 48%, respectively.[108] The clinical utility of this prognostic system in determining risk-adapted therapy remains unclear.

Treatment

No prospective randomized clinical trial data are available to help guide treatment decisions, but the ISCL/EORTC recently performed an extensive survey of the literature pertaining to treatment of the PCBCLs and published consensus recommendations.[109] The NCCN has also published treatment guidelines for PCBCLs.[110]

PCMZL and PCFCL

PCMZL and PCFCL are not expected to be associated with decreased survival relative to control populations (although PCFCL arising in the leg may have a worsened prognosis under the WHO/EORTC classification), and therefore, side effects of proposed treatments should be carefully considered. Treatment options include local superficial irradiation, surgical excision, intralesional IFN-α, local and systemic rituximab, antibiotics (where *B. burgdorferi* is endemic), and chemotherapy.

TABLE 83.7 CUTANEOUS B-CELL LYMPHOMA PROGNOSTIC INDEX

CBCL-PI Group[107]	Histology	Site	% 5-Year OS	% Relative 5-Year OS

IA	Any indolent	Any	81	94
IB	Diffuse large B cell	Favorable	72	96
II	Diffuse large B cell Immunoblastic diffuse large B cell	Unfavorable Favorable	48	60
III	Immunoblastic diffuse large B cell	Unfavorable	27	34

CBCL-PI, cutaneous B-cell lymphoma prognostic index; OS, overall survival.

Local Superficial Irradiation. In the ISCL/EORTC literature review, 132 patients with PCMZL treated with local superficial irradiation were identified, and a 99% CR rate was observed. Doses ranged from 30 to 45 Gy, and field margins ranged from 1 to 5 cm. Although cutaneous relapse of disease occurred in 46% of patients, extracutaneous progression occurred in only 2% of patients. For PCFCL, 460 patients treated with radiation were reviewed, and the CR rate was 99% with a 30% relapse rate. Doses ranged from 20 to 54 Gy and margins were 0.5 to 5+ cm. Current guidelines suggest that for definitive therapy, a dose of 24 to 30 Gy is sufficient, with treatment margins of 1 to 1.5 cm.[27] Recently, local superficial irradiation to 4 Gy in two fractions was shown to yield a 72% CR rate for PCMZL and PCFCL and is recommended as a palliative dose.[25,109]

Surgery. *Excision* is associated with a 99% CR rate and 43% cutaneous relapse rate in PCMZL and a 98% CR rate and 40% cutaneous relapse rate in PCFCL.[109]

IFN-*α*. Intralesional IFN-*α* yields a 100% CR rate and 25% local relapse rate for PCMZL and a 100% CR rate and 29% local relapse rate for PCFCL.[109]

Rituximab. Systemic rituximab (monoclonal antibody targeted against CD20) has proven effective as a treatment for non-Hodgkin lymphomas and has been applied to the treatment of PCBCL. In a review of five patients with PCMZL treated with systemic rituximab, the overall response rate was 60%, and in 10 patients with PCFCL treated with systemic rituximab, a 100% overall response rate and 80% CR rate was observed. Intralesional rituximab may also be effective, with a reported CR rate of 89% in nine patients with PCMZL, but with a high relapse rate of 62%. Twelve patients with PCFCL treated with intralesional rituximab had a CR rate of 83% with 40% relapse.[111] This is a useful modality for patients who have extensive skin involvement.

Chemotherapy. Single-agent treatment with chlorambucil was evaluated in 14 patients with PCMZL, and a CR rate of 64% with 33% relapse rate was observed. Multiagent chemotherapy with cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) was also evaluated in 33 patients with PCMZL, and an 85% CR rate with 57% relapse rate was observed. In 104 patients with PCFCL treated with CHOP or CHOP-like regimens, an 85% CR rate with 48% relapse rate was reported.[109]

ISCL/EORTC Recommendations. For patients who have only one or a few lesions clustered in one region, radiation (30 Gy or more) using a margin of 1 to 1.5 cm is highly effective. Patients presenting with a single small lesion may be treated with resection alone. Scattered lesions that cannot easily be encompassed in one or a few radiation fields may be carefully observed, with treatment reserved for only the most concerning or symptomatic sites. In the setting of diffuse disease, systemic rituximab should be considered. Of note, cutaneous relapses are common, and relapsed disease often responds to retreatment and does not predict for worsened overall survival rate.[109]

PCLBCL, Leg Type (PCBCL-LT)

PCLBCL-LT is a significantly more aggressive entity in comparison to PCMZL and PCFCL. The primary treatment options that are used in therapy for PCBCL-LT are radiation, rituximab, and multiagent chemotherapy.

Local Superficial Irradiation. The ISCL/EORTC literature review found 101 patients with PCLBCL-LT treated with radiation. In contrast to the more indolent lymphomas in which CR rates were close to 100%, the CR rate for PCLBCL-LT was lower at 88%. The rate of cutaneous relapse rate was high (58%), and even more concerning, 30% of patients were found to have extracutaneous progression of disease.

Rituximab. Systemic rituximab in PCLBCL-LT has been investigated (dose 375 mg/m^2 weekly for 4 to 8 weeks) and yielded a CR rate of 38%. Relapse rates are as yet unknown, and additional follow-up is necessary.[109]

Chemotherapy. Multiagent chemotherapy regimens have been tested in PCLBCL-LT, and in 32 patients treated with CHOP or CHOP-like regimens, an 81% CR rate has been observed. However, despite aggressive therapy, relapse rates remain high at 54%.[109]

ISCL/EORTC Recommendations. Based on the aggressive nature of PCLBCL-LT and its propensity to develop extracutaneous disease, recommended treatment in patients able to tolerate multiagent chemotherapy is R-CHOP, with the possible addition of local superficial radiation to distinct cutaneous lesions. In the subset of patients unable to tolerate a multiagent course of chemotherapy, systemic rituximab may be considered. Alternatively, an aggressive course of radiation to all cutaneous sites of disease may be considered, but relapse is expected.[109]

PRECURSOR HEMATOLOGIC NEOPLASMS

The third category of cutaneous lymphomas in the WHO/EORTC system is precursor hematologic neoplasms/immature hematologic malignancies. At present, this category primarily references CD4+/CD56+ hematodermic neoplasm (also referred to as blastic NK-cell lymphoma or blastic plasmacytoid dendritic cell neoplasm), which is characterized by development of red or violaceous cutaneous nodules. Biopsy reveals cutaneous infiltration of abnormal cells with an appearance reminiscent of lymphoblasts and myeloblasts. The origin of the tumor cells in CD4+/CD56+ hematodermic neoplasm is unclear. Immunohistochemistry indicates that the tumor cells lack CD3 and CD8 and express both CD4 and CD56. The expression of CD56 initially led investigators to believe these cells were of NK origin. However, the concomitant expression of CD4 and CD56 is unusual, and further exploration led to the identification of expression of CD123 and TCL1 in these tumor cells, which suggests a possible origin in plasmacytoid dendritic cells. Examination of TCR status in these cells indicates it remains in germline configuration, providing further support for the notion that these cells are not derived from a B- or T-cell lineage. CD4+/CD56+ hematodermic neoplasm is an aggressive malignancy, and it is common for patients to harbor nodal or systemic disease at diagnosis. Because of the propensity for systemic spread of disease, skin-directed therapies are usually unlikely to control disease and chemotherapy is often necessary. Although chemotherapy may induce remission of disease, the duration of remission is typically relatively brief and median survival is only 14 months.[1]

Summary

The primary cutaneous lymphomas are a diverse group of extranodal non-Hodgkin lymphomas, each with distinct biologic activity. A correct

histopathologic diagnosis is critical to the determination of appropriate management. Although significant advances in therapy have been made since the recognition of MF in 1806, numerous questions remain unanswered regarding the pathophysiology and optimal treatment of the cutaneous lymphomas. Advances in genomic profiling of the cutaneous lymphomas may yield greater insight into the molecular bases of these diseases and help identify better and more individualized therapies. Recent efforts to develop improved prognostic indices and uniform criteria for classification of disease and response to treatment should facilitate ongoing international collaborations. Because of the rarity of these diseases, large multi-institutional collaborative efforts are critical to the advancement of our understanding of the primary cutaneous lymphomas.

CHAPTER 84

Leukemia

Kenneth B. Roberts, Gottfried von Keudell, and Nikolai Podoltsev

INTRODUCTION

The leukemias are a group of neoplastic disorders of the hematopoietic system, characterized by aberrant or arrested differentiation. The role of radiotherapy (RT) in conventional curative treatment is largely to deliver central nervous system (CNS) treatment in combination with systemic therapy for patients with acute lymphocytic leukemia (ALL). Although the role of CNS prophylaxis has declined over the last 15 years because of toxicity concerns, it remains an important component of therapy for high-risk patients. Radiation oncologists must also be familiar with certain palliative situations unique to the leukemias as well as total body irradiation (TBI) (discussed elsewhere), as the latter is often part of a stem cell transplant program.

Childhood ALL can now be cured in 80% to 89% of cases, with initial remissions generally occurring in about 90%.[1–4] In adults, initial remission rates are generally equally high, but cure rates are only in the 30% to 45% range.[5] In contrast to the situation in pediatric ALL, pediatric acute myeloid leukemia (AML) generally fairs less well, with 60% cure rates, although this represents a marked improvement since the 1970s when cure rates were roughly 20%.[3] Adult AML cures are less frequent in the overall population, in large part a reflection that this disease principally afflicts older individuals. About 21,000 new cases are diagnosed per year in the United States with 10,000 patients dying from the disease.[2] Allogeneic stem cell transplantation has specifically targeted refractory/recurrent ALL and AML. Reduced-intensity transplants are being investigated to address the needs of high-risk or elderly patients with acute leukemia.

Chronic myelogenous leukemia (CML) and chronic lymphocytic leukemia (CLL) are primarily diseases of adults and have natural histories measured in years to decades. Both have the ability to transform to more aggressive diseases,

though CML, in particular, reliably progresses to a more acute disease or blast crisis in its terminal phase. Allogeneic stem cell transplantation is associated with a high cure rate for patients with CML if conducted early in the chronic phase of the disease. However, because of the widespread use of the ABL tyrosine kinase inhibitors (TKIs), the use of allogenic transplant for CML has declined dramatically over the past decade.[6]

ANATOMIC CONSIDERATIONS

The radiation oncologist must be knowledgeable about the anatomy of the CNS, particularly the meninges (dura mater, arachnoid, and pia mater) and subarachnoid space for the proper design of CNS-directed radiation treatments. The epidural space lies between periosteum and the dura, whereas the potential space between the dura and arachnoid is called the subdural space. The pia and arachnoid are often described as a combined membrane called the leptomeninges. Between the arachnoid and pia is the subarachnoid space, which is filled with cerebrospinal fluid (CSF). The pia hugs the surface of the brain extending into sulci, fissures, and the internal cavities or ventricles, whereas the bulk of the arachnoid follows along the dura except for the fine trabeculations and into some of the major fissures of the brain. Arachnoid sheathes both nerves and blood vessels penetrating the pia and exiting the CNS, creating relatively short segments of subarachnoid space, which is of particular anatomical importance in the vertebral column. In the design of the inferior aspect of craniospinal radiation fields, the subarachnoid space extends laterally to the spinal ganglia, which are located within the intervertebral foramina.[7,8] Thus, coverage of the entire sacroiliac joints in such spinal field design is excessive. The caudad extent of the subarachnoid space is variable within the sacrum.[9] Clinically, the end of the thecal sac is now routinely determined on magnetic resonance image scanning. Pathologically, CNS leukemia originates as a perivascular infiltrate along the subpial blood vessels. As this progresses, the leukemia infiltrates preferentially into the subarachnoid space as well as into the brain parenchyma.[10]

Base of skull anatomy is also of importance to the radiation oncologist in the design of lateral cranial fields. The middle cranial fossa and temporal lobe project over the sphenoid sinuses on lateral radiographs. The cribriform plate projects along the roof of the orbit along an imaginary line that connects to the inferior aspect of the frontal sinuses. Several radiologic–anatomic studies have

pointed out how the eye's lens in this "beam's eye view" is <1 cm away from the cribriform plate, having implications in field design. Insuring coverage of the entire subarachnoid space should supersede the concerns of radiation-induced cataracts as this is a readily manageable complication.[11,12] Moreover, because subarachnoid space extends as a sheath along the optic nerve, it is standard to include the posterior half of the eye globes within cranial radiation fields by using the anterolateral aspect of the bony orbit as an anatomic landmark, as it typically lies along a line that roughly bisects the eye[12] (Figs. 84.1 and 84.2).

FIGURE 84.1. Cranial irradiation field outlining treatment that encompasses the entire cranial subarachnoid space. The radiopaque markers outline the anterior aspect of the bony orbit so as to demarcate inclusion of the posterior aspect of the eye within the treatment fields.

To compensate for the blood–brain barrier, certain drugs are administered directly into the subarachnoid space either via lumbar puncture or via an intraventricular reservoir (e.g., an Ommaya reservoir). Intrathecal (IT) drugs distribute unevenly, however, throughout the subarachnoid space.[13,14] This is not surprising given the knowledge of brain anatomy and CSF circulation. CSF is mainly formed in the brain ventricles by the choroid plexuses, which are specialized capillary-rich tufted structures. This fluid then flows through the intraventricular foramina and the cerebral aqueduct of the midbrain into the fourth ventricle, from where it communicates with the rest of the subarachnoid space. CSF is resorbed principally in the dural sinuses via button-like projections called arachnoid villi. Thus, IT therapy theoretically undertreats the ventricular spaces and cerebral/cerebellar sulci as well as any gross disease extending into the brain substance. This concern has led to the concept of combining cranial RT with IT chemotherapy; the latter to cover the spinal subarachnoid space. Similarly, when craniospinal irradiation (CSI) is needed to treat a higher burden of CNS leukemia, IT therapy allows the spine to be treated to a lower dose than the brain.

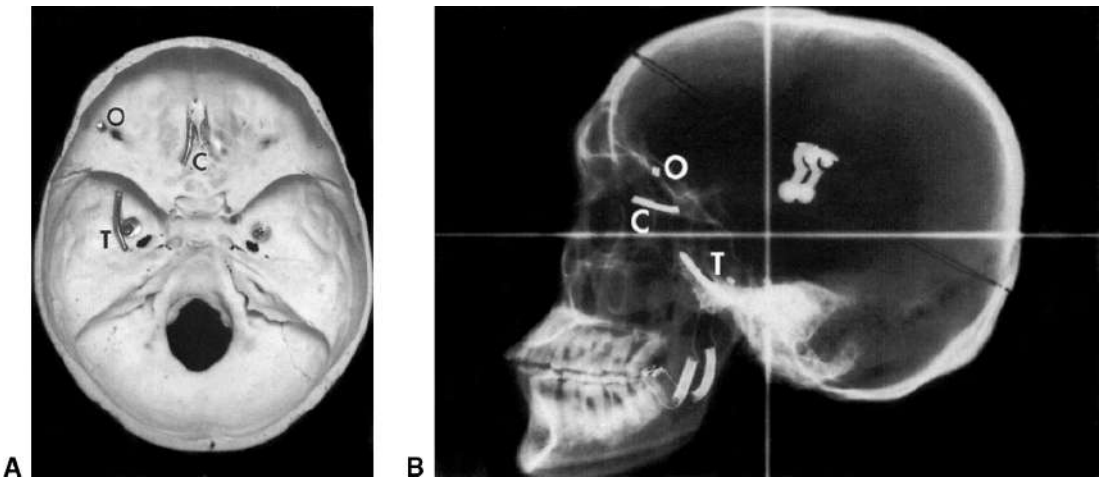

FIGURE 84.2. Skull views outlining anatomic limits of the base of skull for inclusion of the cranial subarachnoid space. **A:** Radiopaque markers have been placed at the cribriform plate (*C*), roof of the orbit (*O*), and the temporal fossa (*T*). **B:** Plain lateral radiograph shows the projection of the cribriform plate, orbital roof, and temporal fossa.

ACUTE LEUKEMIAS

Classification Systems, Pathology, and Risk Stratification

Acute leukemias have traditionally been classified using the French-American-

British (FAB) morphologic criteria. AML and its subtypes can most often be identified microscopically by the presence of Auer rods, staining for myeloperoxidase or monocyte-associated esterases, and other cytologic features of differentiation. Certain chromosome translocations are common to each AML subtype (Table 84.1). AML with minimal or no myeloid differentiation (M1 and M0 subtypes) can be confused with ALL but for flow cytometric identification of early myeloid antigens. The more differentiated AML subtypes M2-M6 are usually recognizable by morphology and cytochemistry.

TABLE 84.1 CORRELATION OF FRENCH-AMERICAN-BRITISH (FAB) CLASSIFICATION OF ACUTE MYELOGENOUS LEUKEMIA (AML) WITH COMMON CYTOGENETIC AND MOLECULAR ABNORMALITIES

FAB Type	Some Cytogenetic and Molecular Features	AML Cases (%)
M0, M1 (undifferentiated AML)	Trisomy 11, t(10;11)	31
M2 (acute myeloid leukemia)	t(8;21); RUNX1-RUNX1T1	25
M3 (acute promyelocytic leukemia)	t(15;17), t(11;17), t(5;17); PML/RAR*α*	28
M4Eo (acute myelomonocytic leukemia with eosinophilia)	inv(16); CBF*β*/MYH11	21
M5 (acute monocytic leukemia)	t(11;23), t(9;11)(p21.3;q23.3); MLLT3-KMT2A	15
M6 (acute erythroleukemia)	t(3;5)	4
M7 (acute megakaryocytic leukemia)	t(3;3), t(3;12), t(1;22)(p13.3;q13.3); RBM15-MKL1	1

The FAB assignment of subtypes was replaced by the World Health Organization (WHO) classification scheme for myeloid neoplasms.[15] The WHO classification creates four key subgroups: AML with recurrent genetic abnormalities (including t(8;21), inv(16), t(15;17), t(9;11) among others), AML with myelodysplasia-related changes, therapy-related myeloid neoplasms, and AML not otherwise specified. See Table 84.2. The new subgroups are meant to highlight meaningful biologic and genetic differences between disease entities with differing prognoses and clinical behavior. In addition, in the WHO scheme, the number of blasts in the blood or bone marrow required to confirm a diagnosis of AML is 20%, instead of the 30% specified by the older FAB criteria. The WHO classification has been recently updated in 2016, reflecting advances in molecular subtyping, which is beyond the scope of this chapter.[16]

TABLE 84.2 2016 WHO CLASSIFICATION OF AML

- AML with recurrent genetic abnormalities
  - t(8;21)(q22;q22); RUNX1-RUNX1T1
  - inv(16)(p13q22) or t(16;16)(p13q22); CBFβ-MYH11
  - t(15;17)Q22;Q12); PML/RARα
  - t(9;11)(p22;q23); MLLT3-KMT2A
  - AML with mutated NPM1
  - AML with mutated CEBPA
- AML with myelodysplasia-related changes
- AML, not otherwise specified

Adapted from Arber DA, Orazi A, Hasserjian R, et al. The 2016 revision to the World Health Organization classification of myeloid neoplasms and acute leukemia. *Blood* 2016;127:2391–2405.

The FAB classification for ALL specified three subtypes based on morphology, which is largely of historical interest. L1 is the predominant type in 85% of childhood ALL. It is characterized by small cells with scanty cytoplasm and inconspicuous nucleoli. L2 is common in ALL of adults and is identified morphologically by blasts that show prominent nucleoli, abundant cytoplasm, and more variability in size. L3 lymphoblasts are large cells with cytoplasmic basophilia and vacuolization, similar to Burkitt lymphoma cells. The common ALL antigen (CALLA, CD10) is expressed in about 85% of ALL cases. At least with childhood ALL, this FAB system has not proved to be terribly useful with high interobserver variability and a lack of correlation with the more prognostically important immunologic and genetic features for ALL.[17] In the WHO classification, most of these entities, with the exception of Burkitt's, fall under the category of precursor lymphoid neoplasms. These are subcategorized into B-cell lymphoblastic leukemia/lymphoma, not otherwise specified; B-cell leukemia/lymphoma with recurrent genetic abnormalities; and T-lymphoblastic leukemia/lymphoma.[16]

As may be apparent from the above discussion of the transition from the FAB to the WHO criteria for categorization, immunophenotyping and molecular markers have become very important in the classification of leukemia. Flow cytometry using specific monoclonal antibodies can be used to assay for a panel of antigens, often known as *cluster of differentiation (CD) molecules*, that define leukocyte maturation. For instance, CD19 and cytoplasmic CD79a define B-cell lineage, whereas cytoplasmic or surface CD3 defines T-cell lineage. Myeloid blasts are correlated with positivity for CD13, CD33, but cytoplasmic myeloperoxidase is required to definitively assign the cell to myeloid linage.

With other markers defining different degrees of differentiation and maturation, ALL is now conventionally divided into T-cell and B-cell lineage. B-cell leukemia has four distinct subclasses: early pre-B, pre-B, transitional pre-B, and the more mature B cell.

Cytogenetic or chromosomal abnormalities occur in up to 90% of ALL cases. Of these, roughly two-thirds are nonrandom, falling into distinct patterns. Specific cytogenetic abnormalities have important prognostic and therapeutic implications in ALL. Chromosomal translocations occur in approximately 15% of pediatric ALL, and a bit higher in adult cases. The oldest known is the t(9;22) *BCR/ABL* translocation that forms the Philadelphia chromosome. This translocation is associated with a higher risk of CNS involvement and overall poorer prognosis. Adult and childhood forms of ALL have distinctly different patterns of genetic abnormalities as well as immunophenotyping (see Table 84.3). This may partially explain the poorer prognosis in older patients. For example, the t(9;22) *BCR/ABL* translocation occurs in 4% of childhood ALL cases compared to about 25% in adults; moreover, this genetic lesion now represents an important therapeutic target with the development of TKIs and may be associated with improved outcomes.

The *TEL/AML1* fusion gene expression (cryptic t(12;21) translocation) is a common translocation, occurring in 22% of pediatric ALL patients, in which an in utero event juxtaposes the *RUNX1* gene on chromosome 21 with the *ETV6* gene on chromosome 12. The resulting chimeric protein impairs normal hematopoietic differentiation, increasing the self-renewal capacity of early progenitor cells. On balance, it is associated with a relatively better prognosis. Conversely, the MLL rearrangement tends to be found in infants and is associated with poor prognosis; it can arise from t(4;11), t(11;10), or t(9;11) translocations. About 6% of ALL patients have the t(1;19) translocation that creates the E2A-PBX1 fusion gene. Rarer genetic abnormalities include the t(4;11) translocation associated with African American children who have high WBC counts, the t(8;14) MYC defect in cases of mature B-cell ALL (2%), and t(11;14) associated with T-cell ALL with extramedullary involvement. One of the most recently identified genetic abnormalities is the IKAROS family zinc finger 1 (IKZF1) deletion found in 15% of precursor B-cell ALL cases. These are associated with older patients who have higher WBC count at diagnosis, and, as such, are also associated with a high-risk prognosis. IKZF1 deletions are also associated with higher chance of a BCR-ABL1 abnormality or Down syndrome.[18,19] CRLF2 overexpression and JAK mutations are also associated

with IKZF1 deletion and poorer prognosis. A CRLF2 abnormality has been found to independently confer worse prognosis, even in adult ALL[19–21] BCR-ABL1–negative patients with a gene expression profile similar to BCR-ABL1–positive patients have been referred to as Ph-like ALL. This occurs in 10% to 15% of pediatric ALL patients, increasing in frequency with age, and is also associated with a poor prognosis related to IKZF1 deletion/mutations. The leukemias in this subgroup have activated kinase signaling, with 50% containing CRLF2 genomic alterations and 25% concomitant JAK mutations. Many other cases of Ph-like ALL have analogous translocations involving ABL1, JAK2, PDGFRB, or EPOR. The resulting fusion proteins may prove to be therapeutic targets using existing TKIs or those under development.

TABLE 84.3 FREQUENCY AND DISEASE CONTROL ASSOCIATED WITH IMMUNOPHENOTYPES AND CYTOGENETIC ABNORMALITIES AND SURVIVAL IN ACUTE LYMPHOBLASTIC LEUKEMIA IN CHILDREN (AGES 1–18) VS. ADULTS (AGES 18 AND OLDER)

Pattern	Frequency (%)		5-Year Disease-Free Survival (%)	
	Children	Adults	Children	Adults
Pre-B cell	80–85	75–80	80	30–40
B cell	2	3–5	45–85	45–65
T cell	15	20–25	65–75	40–60
TEL/AML1 t(12;21)	20–25	1–3	90	Rare
MLL/AF4 t(4;11)	2	5–7	20	20
BCR/ABL t(9;22)	5	25–30	20–40	<10
Hyperdiploid	25	5	80–90	10–40
Normal karyotype	9–37	30	70–87	40

Abnormal DNA ploidy is extremely common, but two patterns seem to be clinically important. Hyperdiploidy with >51 chromosomes per cell (or DNA index >1.6) occurs in 25% of children with ALL. Although there is some association with favorable clinical factors (age >10 years and low presenting leukocyte counts), hyperdiploidy is an independent favorable factor; however, in adults with ALL, outcomes are poor even in presence of hyperdiploidy. In

childhood ALL, the most common trisomies involve chromosomes 4, 10, and 17 and are associated with a good prognosis. Conversely, hypodiploidy of fewer than 45 chromosomes conveys a more unfavorable outcome.

The aforementioned laboratory assessment and clinical disease features have led to distinct risk stratification categories, at least as far as childhood ALL is concerned. Clinical prognostic features of B-cell leukemias have been commonly used to place patients into risk groups. Using the National Cancer Institute's (NCI) risk classification scheme, standard risk includes patients (two-thirds of pediatric B-cell ALL patients) whose age at diagnosis is between 1 and 10 years as well as a presenting leukocyte count of <50,000/μL, in the absence of CNS involvement, was historically associated with an 80% 4-year disease-free survival (DFS).[22] High-risk patients—defined as a high white blood cell (WBC) count, age below 1 year or above 10 years, or CNS involvement at diagnosis—had a corresponding 65% 4-year DFS. T-cell phenotype occurs in 12% to 15% of pediatric ALL cases and was once thought to convey a relatively poorer prognosis. This prejudice has been due to numerous unfavorable clinical correlations, including older age, male sex, elevated WBC count, extensive extramedullary disease including mediastinal and peripheral adenopathy or hepatosplenomegaly, and a higher tendency for relapse in the CNS and testes in males.[23] Current clinical practice is for T-cell leukemias to be treated on different protocols than B-lineage ALL. Nevertheless, when one factors out unfavorable clinical features, the prognostic difference between T- and B-cell ALL is difficult to discern. In regard to B-cell ALL, current protocols assign patients to low, standard, and high risk. Low-risk patients are operationally defined by standard-risk features along with a rapid early response to induction chemotherapy.[24] Age is also an important prognostic factor. Apart from this, the intensity of the treatment program is of importance as shown by the fact that adolescents treated on pediatric leukemia regimens have had better outcomes than those treated on adult programs.[25]

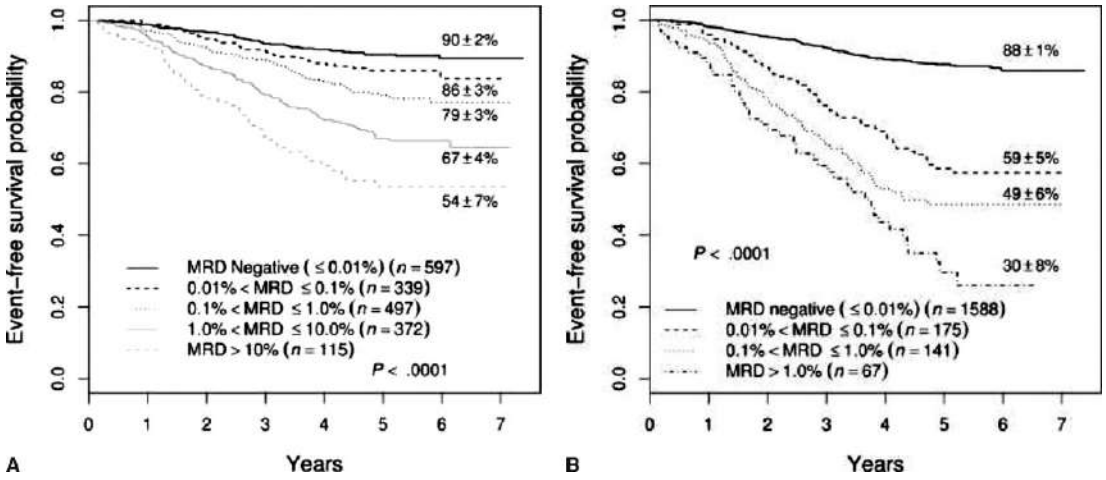

FIGURE 84.3. The prognostic importance of minimal residual disease (MRD) after induction chemotherapy for ALL. **A:** EFS of ALL patients as a function of level of day 8 PB MRD. **B:** EFS of ALL patients as a function of level of day 29 marrow MRD. (Republished with permission of American Society of Hematology from Borowitz MJ, Devidas M, Hunger SP, et al. Clinical significance of minimal residual disease in childhood acute lymphoblastic leukemia and its relationship to other prognostic factors: a Children's Oncology Group study. *Blood* 2008;111[12]:5477–5485; permission conveyed through Copyright Clearance Center, Inc.)

The response to induction chemotherapy has also been proven to be an extremely important prognostic category. In pediatric ALL, the concept of minimal residual disease (MRD) detected by flow cytometry or polymerase chain reaction (PCR) of postinduction peripheral blood or marrow aspirates has led to critical prognostic stratification. A contemporary analysis of MRD in a pediatric cooperative group trial showed that even up to 0.01% blasts from day 8 postinduction mononuclear peripheral blood cells conferred a poorer prognosis.[26] Moreover, day 29 and end of consolidation bone marrow MRD was able to further segregate unfavorable patient subgroups taking into account other prognostic factors such as *TEL/AML1*, trisomies 4 and 10, and NCI risk class. See Figure 84.3. From the assessment of MRD, the concept of risk-adapted therapy has allowed for improved outcomes with the intensification of therapy in those patients who continue to have detectable lymphoblasts after initial chemotherapy.

Assessment of CNS involvement at diagnosis in acute lymphoblastic leukemia (ALL) is critical for risk stratification, which is of course of particular importance to the radiation oncologist. Unfortunately, a traumatic lumbar puncture has been noted to be associated with a worse prognosis.[27] Regardless, CNS involvement has been unequivocally defined by a CSF leukocyte count of ≥5 WBC/μL along with either blast cells on cytospin or the presence of cranial

nerve palsy. By convention, this is now classified as CNS-3. CNS-1 is defined as no blast cells on CSF cytology, whereas CNS-2 is <5 WBC/μL with blast cells present. Clinical data are conflicting as to the prognostic importance of CNS-2, reflecting the fact that CNS involvement is not simply a distinction of being present or absent but that it has also been associated with improved control with more intensive systemic and IT therapies.[28,29] Patients with CNS-3 disease who have more intensive IT chemotherapy along with cranial radiation within the first year of therapy have similar event-free survival as CNS-2 patients. For patients in remission who undergo surveillance lumbar punctures, there is even controversy regarding the prognostic importance of finding low numbers of blast or atypical cells in the CSF.[30,31]

More recent Children's Oncology Group stratification of CNS involvement has added complexity, taking into account a correction formula for traumatic lumbar punctures (so-called Steinherz/Bleyer algorithm).[32] CNS-2 and CNS-3 are further subgrouped. Regardless, patients with CNS-3 disease are allocated to high-risk treatment protocols. See Table 84.4.

TABLE 84.4 ASSIGNMENT OF CNS STATUS AT DIAGNOSIS OF PEDIATRIC ALL

CNS-1	In cerebrospinal fluid (CSF), absence of blasts on cytospin preparation, regardless of the number of white blood cells (WBCs).
CNS-2	In CSF, presence of <5/μL WBCs and cytospin positive for blasts, or ≥5/μL WBCs but negative by Steinherz/Bleyer algorithm[b]
CNS-2a	<10/μL red blood cells (RBCs); <5/μL WBCs and cytospin positive for blasts
CNS-2b[a]	≥10/μL RBCs; <5/μL WBCs and cytospin positive for blasts
CNS-2c[a]	≥10/μL RBCs; ≥5/μL WBCs and cytospin positive for blasts but negative by Steinherz/Bleyer algorithm
CNS-3	In CSF, presence of ≥5/μL WBCs and cytospin positive for blasts and/or clinical signs of CNS leukemia:
CNS-3a	<10/μL RBCs; ≥5/μL WBCs and cytospin positive for blasts
CNS-3b[a]	≥10/μL RBCs; ≥5/μL WBCs and positive by Steinherz/Bleyer algorithm
CNS-3c	Clinical signs of CNS leukemia (such as facial nerve palsy, brain/eye involvement, or hypothalamic syndrome)

A patient with CSF WBC ≥5/μL blasts, whose CSF WBC/RBC is 2× greater than the blood WBC/RBC ratio, has CNS disease at diagnosis.

[a]CNS status that can be assigned after a TLP with blasts.

*b*The Steinherz/Bleyer algorithm provides a method of evaluating initial traumatic lumbar punctures: If the patient has leukemic cells in the peripheral blood and the lumbar puncture is traumatic and contains ≥5 WBC/μL and blasts, the following algorithm should be used to distinguish between CNS-2 and CNS-3 disease:
CSF WBC/CSF RBC >2× Blood WBC/Blood RBC.

AML patient risk stratification is based on cytogenetic and molecular characteristics of the underlying driver mutations of the disease. Table 84.5 is an authoritative risk stratification scheme from the European Leukemia Network, which classifies patients into favorable, intermediate, and adverse risk categories based on the current understanding of molecular and genetic prognostic factors. Presence of complex karyotype abnormalities, FLT3-ITD and TP53 mutations among others, may justify more aggressive treatment approach. In addition, presence of MRD after induction chemotherapy is associated with significant risk of relapse and may dictate need for allo SCT rather than chemotherapy consolidation.[33] Selecting treatment for older AML patients should take into consideration not only disease characteristics but also patient's characteristics like age, comorbidities, and performance status with induction chemotherapy reserved for fit patients and low-intensity regimens aimed at preserving quality of life for others.[34]

TABLE 84.5 2017 EUROPEAN LEUKEMIA NETWORK AML RISK STRATIFICATION BY GENETICS

Risk Group	Genetic Characteristics
Favorable	t(8;21)(q22;q22.1); RUNX1-RUNX1T1 inv(16)(p13/1;q22) or t(16;16)(p13.1;q22); CBFβ-MYH11 Mutated NPM1 with FLT3-ITD or with FLT3-ITD^{low} Biallelic mutated CEBPA
Intermediate	Mutated NPM1 and FLT3-ITD^{high} Wild-type NPMI without FLT3-ITD or with FLT3-ITD^{low} (without adverse-risk genetic lesions) t(9;11)(p21.3;q23.3); MLLT3-KMT2A Cytogenetic abnormalities not classified as favorable or adverse

Radiotherapeutic Emergencies

The radiation oncologist will be called on to assist with certain emergencies when the patient first presents with leukemia or at the time of relapse. Mediastinal adenopathy causing airway compression or spinal cord compression from epidural disease are clear indications for emergent RT. Generally, only one to three 1.5- to 2.0-Gy fractions are required while the diagnosis is being established, and systemic therapy is being initiated (Fig. 84.4). Glucocorticoids are an important adjunct to CNS RT but can produce rapid lysis of some lymphoblastic lymphomas/leukemias, which may hamper diagnostic evaluation. In the presence of cranial nerve palsies at diagnosis, some radiation oncologists recommend 10 to 15 Gy to the base of skull early in the treatment course to try and reverse the neurologic deficits.[35,36] Extreme leukocytosis with blast counts over 50,000 to 100,000/μL is a concern with myeloid leukemia, as leukostasis may occur, particularly in the vessels of the brain or lung. Lymphoid blasts are less adhesive to vessel walls, and blast counts of up to 400,000/μL or more are often well tolerated. In decades past, RT directed at the whole brain was employed using low doses on the order of 6 to 10 Gy in various fractionations. However, the role of RT in this setting has been questioned,[17,37,38] but may be considered when leukopheresis is contraindicated or unavailable. Nevertheless, one recent report suggests reconsideration of the role of cranial RT for leukostasis. Eighteen patients received WBRT in one to three fractions for a mean total dose of 5.63 Gy (range 2 to 9 Gy). Thirteen patients were treated to control neurologic symptoms rather than in a preventative manner resulting in 92% achieving prompt resolution of symptoms during RT or immediately thereafter. There was no toxicity above grade 2. Two (6%) patients developed an intracranial bleed following therapy from underlying leukostasis, whereas historically this leukostasis syndrome has been associated with a 20% acute mortality rate from stroke or heart failure.[39]

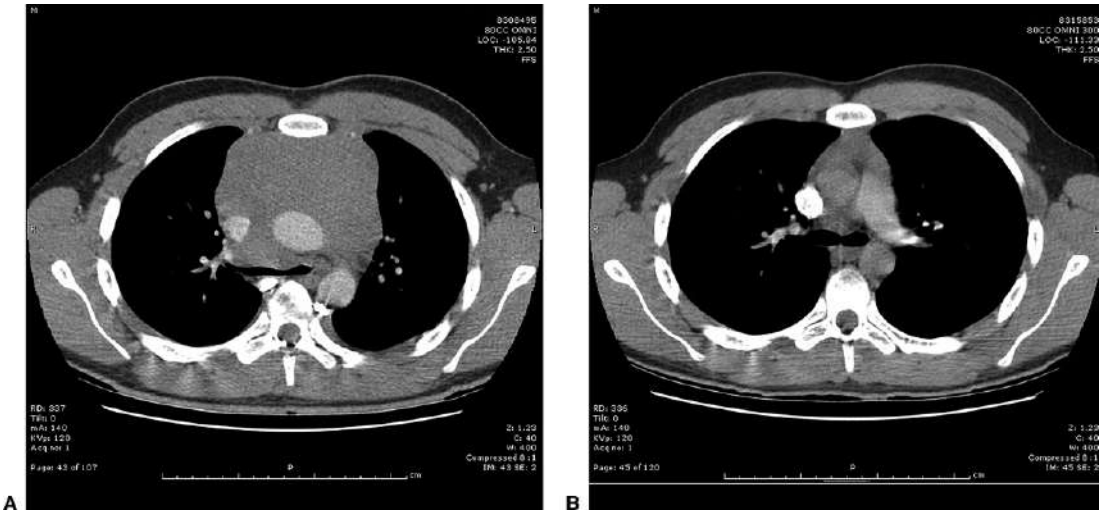

FIGURE 84.4. Computed tomography scans of chest before **(A)** and after **(B)** palliative radiotherapy (RT) for mediastinal mass associated with T-cell acute lymphocytic leukemia. A 16-year-old boy presented with dyspnea and chest pain. A chest x-ray showed a mediastinal mass, whereas blood counts revealed a lymphocytosis. Diagnosis was established by flow cytometry of blood. Initial treatment with steroids, doxorubicin, vincristine, and methotrexate failed to produce immediate response. Megavoltage RT with anterior and posterior opposed beams for 6 Gy in three fractions was administered, subsequently relieving acute symptoms and allowing for general anesthesia to take place without risk for complete airway obstruction in order for central line placement and lumbar puncture to be performed.

Treatment of Acute Myeloid Leukemias

A classical induction therapy for AML consists of an anthracycline on days 1 to 3 along with cytarabine (cytosine arabinoside, ara-C) for 7 days. Acute promyelocytic leukemia (M3 AML, APML) represents an exception to this rule. In many cases, the disseminated intravascular coagulation and associated PML-RAR fusion in APL are best managed with a combination of all-*trans* retinoic acid and arsenic trioxide, which promote differentiation and apoptosis of malignant promyelocytes.[40,41] Patients with high-risk APML defined by WBC > 10,000/μL are treated with the combination of differentiating agents and chemotherapy including anthracyclines.[42] For the remainder of the AML subtypes, daunorubicin and idarubicin are the anthracyclines most commonly used in induction chemotherapy regimens. Although a meta-analysis of multiple trials suggested that idarubicin has a higher complete response (CR) rate and survival over daunomycin,[43] more recent data from dose escalation trials using daunorubicin as part of the induction regimen suggest that when equivalently dosed, responses are similar.[44] Remission rates vary from 30% to 80% depending on patient age, karyotype, and subtype of AML.

Patients younger than age 60 have CR rates of 70% to 80%, whereas older

patients tend to have lower CR rates of 30% to 50%. Patients who develop secondary AML following chemotherapy for other cancers have CR rates in the 30% to 50% range. Some induction regimens in children have added other drugs such as etoposide. Adding other chemotherapy drugs to anthracycline and cytarabine was evaluated in many studies without convincing survival benefit for AML induction in adults.[45] A double-blind, placebo-controlled trial in 717 patients with previously untreated FLT3 mutation-positive (FLT3+) AML randomized patients to either placebo or midostaurin 50 mg orally twice daily on days 8 to 21 of each cycle of induction and consolidation chemotherapy followed by continuous daily midostaurin for up to 12 cycles. The trial demonstrated a statistically significant improvement in overall survival (OS) for patients receiving midostaurin compared with those on the placebo-containing arm (HR 0.77, $P = .016$).[46] The FDA approved midostaurin for the treatment of adult patients with newly diagnosed AML who are FLT3+ in combination with standard cytarabine and daunorubicin induction and cytarabine consolidation.

Adults older than 60 years of age with AML and intermediate or unfavorable cytogenetics who are not candidates for hematopoietic stem cell transplantation are generally considered suitable for treatment with low-intensity palliative therapies such as low dose subcutaneous cytarabine, azacitidine, or decitabine. Alternatively, such patients may be referred for clinical trials of novel agents.[34]

Once remission is achieved, the need for additional therapy has been well documented in large randomized trials. Current data suggest that optimal postremission consolidative therapy begins with high dose ara-C for up to four cycles.[47] Alternatively, additional cycles of anthracycline for 2 days along with conventional dose cytarabine for 5 days have been used in both younger and older individuals with AML. Lumping all types of AML together as one group, the roughly 10% to 20% of patients who then remain in remission for 3 years, have a high likelihood of being cured. High dose ara-C has considerable CNS toxicity in elderly patients and has also been avoided in pediatric protocols. Other drugs used for consolidative treatment or for second-line induction therapy include etoposide, 6-mercaptopurine, amsacrine, 5-azacytidine, and methotrexate (MTX), but no one regimen is clearly advantageous.

The role of CNS prophylaxis is not well defined for AML, particularly because CNS relapse rates are relatively infrequent (at roughly 5% to 10%). Some studies show no difference in relapse rates with cranial radiation. Nevertheless, many pediatric regimens employ IT drugs such as ara-C. Patients without neurologic symptoms who have a high WBC count (>40.000/μL) at

diagnosis, extramedullary involvement, high-risk APML, mixed phenotype acute leukemia, or monocytic variants of AML are believed to have a higher risk for CNS involvement, and screening CSF evaluation with prophylactic IT chemotherapy administration may be considered even after accomplishing remission. At least one study of childhood AML demonstrated a lower systemic relapse rate after cranial radiation.[48] This observation has been replicated in the Berlin-Frankfurt-Munster (BFM) group, which has studied the role of prophylactic cranial RT in childhood AML in a similar manner to their ALL studies described below. In combination with increasing intensity of induction therapy emphasizing anthracycline chemotherapy and cytarabine IT chemotherapy, cranial irradiation has helped to reduce the risk of CNS relapse. Results from study Childhood Acute Myelogenous Leukemia Study BFM-87 including nonrandomized patients showed an increased risk of CNS and/or bone marrow relapses in nonirradiated patients. Five-year DFS for patients who received cranial RT was 69% compared to 46% those not receiving RT. In later studies, there is evidence that 12 Gy resulted in the same relapse rate as 18 Gy.[49]

The radiation oncologist may be called on to treat myeloid or granulocytic sarcoma, which may predate a diagnosis of leukemia or be a harbinger of systemic relapse, and are typically associated with AML, but may also be seen with myeloproliferative disorders.[50–52] Also called a chloroma, these solid masses of leukemic infiltrates are responsive to modest doses of RT. The name chloroma derives from the fact that myeloid cells contain myeloperoxidase, which manifests a greenish color on gross inspection. These may occur in all varieties of extramedullary sites including periosteum, skin, soft tissues, gastrointestinal tract, the spine, and in epidural spaces or meninges.[53–56] Pathologic misclassifications are common, as this is a rare clinicopathologic disorder. Based on various case reports in the literature, symptomatic problems from chloromas may be readily relieved with doses of 10 to 24 Gy. The fractionation and total dose needs to take into consideration any normal tissue toxicities and the potential for future TBI should the patient be a potential candidate for an allotransplant. Recent reviews and commentary have suggested a prescription dose of 24 Gy in 12 fractions for most patients.[52,57] Although overall survival may be better than AML in many chloromas, long-term disease control requires systemic therapy used for AML.[50,58–60] Outcomes among patients with chloromas are defined by cytogenetic and molecular testing results, and selection of systemic treatment strategy should be similar to other AML patients.[61]

Treatment of Acute Lymphoblastic Leukemia

The four components of specific ALL therapy are (a) induction of remission, (b) intensification and/or consolidation, (c) maintenance therapy, and (d) CNS prophylaxis. In the 1960s, the problem of CNS recurrence was addressed with CNS radiation and IT chemotherapy. Subsequent improvements in ALL cure rates over the last 2 to 3 decades have resulted from improved risk stratification of patients with more effective, tailored multidrug regimens. As discussed in the following text, the late sequela of 24-Gy cranial irradiation was recognized in the 1980s and 1990s, leading to the elimination of cranial RT in favor of intermediate- or high dose MTX in all but high-risk patients or those with CNS-3 disease. Although not a standard worldwide, investigators at St. Jude Children's Research Hospital (SJCRH) have completely eliminated the use of upfront cranial RT in their protocols of pediatric ALL, accepting a small incidence of CNS relapse even in their high-risk patients.[62] In addition, with the improvements in systemic therapy, testicular relapse in males has become a rare event.[63] Testicular irradiation is rarely necessary except in the setting of testicular relapse or bone marrow transplantation.

Induction therapy for pediatric and young adult patients with ALL as a minimum typically includes a glucocorticoid, anthracycline, vincristine, and L-asparaginase. Other four or greater multidrug regimens have been used, all of which has resulted in initial remission rates of 95% to 99% in children and 75% to 90% in adults. Dexamethasone is now the preferred systemic steroid treatment as suggested in two clinical reports comparing it to prednisone, with dexamethasone reducing both CNS and systemic relapse in pediatric ALL.[64,65] This may be related to dexamethasone's better penetration into the CSF and longer half-life, providing enhanced protection against CNS relapse.[66]

Following induction and achieving CR, patients then receive intensification therapies that have been developed by cooperative groups in the United States and Europe.[67,68] This may consist of high doses of antimetabolites such as MTX, ara-C, or L-asparaginase. Additional anthracycline therapy is beneficial in high-risk patients.[69] It is believed that high dose MTX helps control CNS disease, which has allowed for less use of cranial radiation in some pediatric programs.

For high-risk ALL patients receiving anthracycline therapy, cardiomyopathy is a significant late side effect. American cooperative group investigators reported a randomized trial in patients with newly diagnosed T-cell acute lymphoblastic leukemia (T-ALL) who were planned to receive a threshold cumulative dose of doxorubicin of 360 mg/m^2 known to have increased cardiac

risks to randomly receive dexrazoxane, as a bolus infusion immediately before every dose of doxorubicin. Of 537 patients, the 5-year event-free survival did not differ between groups: 76.7% for the dexrazoxane group versus 76.0% for the doxorubicin-only group (P = .9). The frequencies of severe grade 3 or 4 hematologic toxicity, infection, CNS events, and toxic deaths were similar in both groups. A nonstatistically significant trend with a low incidence of secondary malignancies were seen in the dexrazoxane group. Cardiac function as assessed by mean left ventricular fractional shortening, wall thickness, and thickness-to-dimension ratio z scores were all significantly better in those patients receiving the investigational cardioprotectant. The investigators concluded that dexrazoxane was an effective cardioprotective that did not compromise antitumor efficacy nor increase the frequencies of toxicities. As such, they stated that there should be wider use of dexrazoxane should be considered for children and adolescents who have malignancies including ALL when at risk for late cardiac disease from anthracycline treatment.[70]

In high-risk pediatric ALL cases, there continues to be much progress in developing postinduction intensification phases of therapy. For instance, in a Dutch and Australian trial of 111 children with high-risk features or high MRD, patients received three novel intensive chemotherapy agents followed by allogeneic transplantation. Thirty of these patients were at high risk by MRD and had an improved 5-year EFS of 64%.[71] Following intensification therapy, patients undergo a phase of maintenance treatment. In all but mature B-cell ALL, maintenance therapy over 2 to 3 years with agents such as weekly low dose MTX and mercaptopurine appears to be quite important, albeit for unclear reasons. In high-risk patients, cooperative group studies have demonstrated a benefit to an additional “delayed” intensification after a period of maintenance therapy.[67,72]

For ALL in adults, particularly those with the Burkitt subtype, patients have experienced improved remission rates with multiagent induction regimens that include high dose MTX, cyclophosphamide, and sometimes ara-C. These drugs in combination with vincristine, steroids, L-asparaginase, and sometimes doxorubicin have been associated with 68% to 85% CR rates.

For relapsed ALL, a second induction generally consists of multiple drugs including vincristine, prednisone, L-asparaginase, an anthracycline with or without MTX, VP-16, or teniposide, and ara-C. If the CNS is involved, IT treatment is given along with RT.[73] If testicular relapse occurs, bilateral testicular irradiation is administered. When isolated CNS or testicular relapse

develops, systemic therapy is indicated along with local RT.[74]

If a second remission develops, as occurs in 70% to 90% of cases, subsequent treatment includes either allogeneic transplantation or consolidative chemotherapy.[74,75] There are no randomized trials to indicate which is better, but comparative analysis suggests that survival is improved with allogeneic transplantation, particularly in ALL patients who had brief initial remissions.[75,76]

For high-risk ALL patients (particularly in childhood) who would benefit from an allotransplant, availability of a donor frequently limits this option. A pool of unrelated donors is now available through the National Bone Marrow Tumor Registry, markedly improves the ability to provide this curative albeit high-risk therapy. An ongoing debate, however, has revolved around the theoretically increased risk of toxicity from the use of matched unrelated donors. A comparative study was untaken among 411 children with high-risk ALL, in the prospective multinational Berlin-Frankfurt-Muenster (BFM) study group trial: ALL-SCT-BFM 2003 (Allogeneic Stem Cell Transplantation in Children and Adolescents with Acute Lymphoblastic Leukemia) who underwent conditioning with total-body irradiation and etoposide. Depending on donor availability, grafts originated from HLA-genoidentical siblings or from HLA-matched unrelated donors who were identified and matched by high-resolution allelic typing and were compatible in at least 9 of 10 HLA loci. The investigators found that the 4-year event-free survival did not differ between patients with transplantations from unrelated or sibling donors (67% vs. 71%, $P = .41$), with cumulative incidences of nonrelapse mortality 10% and 3% ($P = .02$) and relapse rates of 22% and 24% ($P = .73$), respectively. Among recipients of transplantations from unrelated donors, no significant differences in event-free survival, overall survival, or nonrelapse mortality were observed between 9/10 and 10/10 matched grafts or between peripheral blood stem cells and bone marrow. The absence of chronic graft versus host disease had no effect on event-free survival. The only observed advantage for sibling related donors was that engraftment was faster after bone marrow transplantation and associated with fewer severe infections and pulmonary complications. Thus, among high-risk pediatric patients with ALL, allogeneic hematopoietic stem cell transplantation was not affected by donor type. Standardized myeloablative conditioning using TBI and etoposide produced a low incidence of treatment-related mortality and effective control of leukemia.[77]

In a Pediatric Oncology Group (POG) study of induction therapy comprising intensive asparaginase (weekly PEG-L-asparaginase or 12 doses of non

pegylated *Escherichia coli* [*E. coli*] asparaginase) with prednisone, vincristine, and doxorubicin for patients with first relapse, the second complete remission rate was 86% for those receiving PEG-L-asparaginase and 81% for those receiving *E. coli* asparaginase.[78]

CNS Prophylaxis of Acute Leukemia and the Role of Cranial Radiotherapy

Historically, as multiagent chemotherapy proved to be highly effective in producing remissions in childhood ALL, numerous investigators noted a significant increase in CNS relapses. The CNS was recognized as a sanctuary site, protected from chemotherapy by the blood–brain barrier. In addition, CNS recurrences invariably led to systemic recurrence suggesting that CNS disease was capable of reseeding the blood and marrow.

This observation led to a long series of CNS preventative therapy trials, which initially utilized CSI. For instance, studies V and VI from 1962 to 1967 at the SJCRH established that CSI for 24 Gy in 15 to 16 fractions reduced the isolated CNS relapse rate from 67% to 4%.[79,80] CSI doses of 12 Gy did not appear to be effective with the early chemotherapy regimens from this time.[81] Concerns that full spinal RT would be associated with more acute myelosuppression, late musculoskeletal hypoplasia, as well as the technical difficulties of CSI led SJCRH investigators to compare CSI with cranial radiation plus IT MTX in study VII.[82] Here, the two CNS preventative regimens were found to be equivalent with roughly an 8% risk of CNS relapse.

In SJCRH study VIII (1972 to 1975), all patients received 24-Gy cranial radiation plus IT MTX. Patients were randomized to one of four maintenance regimens: (a) weekly intravenous (IV) MTX begun during cranial radiation, (b) oral MTX and 6-mercaptopurine, (c) oral MTX, mercaptopurine, and cyclophosphamide, and (d) same three drugs plus ara-C.[83] The incidence of CNS relapse was 5.0%, 1.5%, 20%, and 11.4%, respectively. More troublesome, however, was the development in some patients of leukoencephalopathy, a disabling syndrome of lethargy, seizures, spasticity, paresis, and ataxia. The incidence of leukoencephalopathy in the four randomization groups was 55%, 0%, 7.1%, and 1.4%, respectively. Thus, standard maintenance with oral MTX and mercaptopurine following CNS treatment with cranial radiation along with IT MTX to treat the spinal subarachnoid space was found to have the lowest CNS relapse rate and the least toxicity. The major lesson learned was that IV MTX and cranial radiation in close temporal proximity should be avoided.

In the 1970s and 1980s, additional phase III trials further defined appropriate preventative CNS therapy for childhood ALL. The Children's Cancer Study Group (CCSG) trial 101 compared the following: (a) 24-Gy CSI plus extended field RT encompassing the liver, spleen, and gonads; (b) 24-Gy CSI alone; (c) 24-Gy cranial RT plus IT MTX; and (d) IT MTX alone. Overall, the different radiation regimens were comparable in preventing CNS relapse while statistically superior to IT chemotherapy alone.[84] This finding was further confirmed in a cross-study comparison[85] as well as a Cancer and Leukemia Group B trial.[63] The CCSG further compared cranial RT plus IT MTX with CSI in high-risk patients, defined by a WBC at diagnosis of >50,000/μL; cranial irradiation and IT MTX proved to be significantly superior with respect to both CNS and systemic relapse rates.

Further cooperative group trials have refined the efficacy of CNS-directed therapies within patient groups stratified by risk. Several trials have compared cranial RT with intermediate- or high dose IV MTX along with IT chemotherapy (some with the addition of IT hydrocortisone and ara-C to MTX known as "triple" IT therapy).[63,86,87] The essential findings have been that in patients with low- or standard-risk ALL (e.g., age 3 to 6 years and WBC count <10,000/μL) who are managed without cranial radiation by substituting IT MTX throughout induction, consolidation, and maintenance therapy, CNS relapse rates have remained at a low level of 5% or less.[88–90] Additionally, with triple IT chemotherapy, there was a trend toward fewer systemic failures as well as excellent CNS control when given throughout consolidation and maintenance therapy. This may be at the expense of increased neurotoxicity, however, when given in conjunction with intermediate dose IV MTX.[90]

Moreover, a meta-analysis of 65 randomized trials of pediatric ALL worldwide initiated prior to 1993 that evaluated the role cranial RT concluded that in the vast majority of patients, cranial RT may be avoided with the use of extended IT therapy.[91] IV MTX was particularly advantageous in reducing systemic relapse. One notable exception to the conclusions of aggregated trials of this meta-analysis was the CCG-105 trial of intermediate-risk ALL. In CCG-105, 1,388 patients (with a complex matrix of adverse risk factors defined by patient age, presenting WBC count, and FAB subtype) were randomly assigned to receive either IT MTX alone or cranial radiation for CNS treatment.[92] A secondary complex randomization scheme allocated patients to standard or intensive chemotherapy. Intensive chemotherapy included either more drugs for induction or the addition of a delayed intensification chemotherapy phase after

consolidative and CNS therapies. CNS recurrence rates were comparable in all groups at roughly 5% to 7% except in those patients receiving standard chemotherapy without cranial radiation, where the CNS recurrence was 20%. Thus, more intensive systemic therapy can lower CNS recurrence rates, abrogating any benefit to cranial irradiation. Finally, one interesting subanalysis of this systematic review of cranial RT for ALL looked at 809 patients across seven trials[93–97] that compared different doses of radiation (generally 18 to 21 Gy vs. 24 Gy). There were no differences in CNS or non-CNS relapse rates that could be discerned.

Regarding present-day use of prophylactic cranial RT, investigators have been focusing on patients who are at the highest risk for CNS relapse. At one extreme is the St. Jude's group that has become particularly concerned about the late effects of 24 Gy to the brain in terms of neurocognitive disabilities, hypothalamic/pituitary dysfunction, and secondary malignancies. With risk-adapted intensification of chemotherapy, Pui et al.[62] have reported favorable results with the complete elimination of cranial RT in all newly diagnosed ALL patients. In their St. Jude Total XV trial, 498 patients were treated without cranial RT yielding an 86.6% 5-year event-free survival, which was comparable to their prior studies that had included cranial RT. CNS-directed therapy used five cycles of high dose MTX including, as part of induction therapy, dexamethasone, and extended IT chemotherapy. High-risk ALL patients received up to 16 to 25 IT chemotherapy sessions, whereas low-risk patients received 13 to 18 doses of IT chemotherapy. Patients who were at increased risk of CNS relapse were those who had positive CSF cytology (CNS-2 or -3) or T-cell ALL. Moreover, a relatively high 7% of patients in first remission went on to undergo an allogeneic stem cell transplant correlating with high-risk features of MRD and adverse cytogenetic markers.

Elsewhere worldwide, the philosophy on the use of cranial RT in pediatric ALL has been to use it judiciously in high-risk patients while at the same time also reducing radiation doses to address the concerns about late effects, which includes learning disabilities and other cognitive defects, growth retardation, hypopituitarism, secondary malignancies, and the aforementioned leukoencephalopathy. The European BFM-ALL trials since 1990 have reduced the cranial radiation dose to 12 Gy with their risk-adapted intensification schemes, although those with CNS-3 disease received 24 Gy in their BFM-90 trial and 18 Gy in the more recent BFM-95 trial. Currently, the Children's Oncology Group (COG) has followed suit with a reduction in cranial radiation

doses in its current ALL trials.

High-risk B-cell ALL patients for whom cranial radiation is a consideration are defined by age and high presenting WBC counts per NCI criteria, by adverse cytogenetics (e.g., *bcr-abl*, MLL, and hypodiploidy), by MRD after induction chemotherapy, and by CNS-3 disease. Recent COG trials of high-risk bcr-abl–positive ALL patients, however, have now eliminated the routine use of cranial RT. Most T-cell ALL patients are at increased risk for CNS relapse because of accompanying risk factors and, therefore, continue to receive cranial irradiation. An analysis of T-cell ALL patients (generally with other poor-risk features) treated within several POG protocols suggested that omitting cranial radiation had an adverse impact on CNS relapse rates.[98] Specifically, the 3-year CNS relapse rate was 18% for those who did not receive RT compared to 7% who did. On the other hand, a European report looking at a subgroup of favorable T-cell ALL patients, generally those with young age and low WBCs, suggests that it may be safe to omit cranial radiation in this subgroup.[88] However, as most T-cell ALL patients present with high WBC counts, Conter et al.[88] published a relevant comparison of the AIEOP-91 trial with the BFM-90 trial in which similar backbone chemotherapy is used. The AIEOP-91 trial omits cranial RT albeit with more IT chemotherapy, leading to a significantly higher CNS relapse along with a 3-year event-free survival of 62% compared to 88% for the BFM-90 patients who received cranial RT. Multivariate analysis showed that age younger than 10 years and WBC >100,000 in particular defined a group of T-cell ALL patients who should receive cranial RT.

To reduce the toxicity of prophylactic cranial radiation, several investigations have explored a reduction in radiation dose. The use of 18 Gy in 9 or 10 fractions along with IT MTX yields comparable disease control rates as 24 Gy.[99] Although there were some initial reports of reduced cognitive dysfunction even with such a dose reduction,[100] this issue is by no means completely settled.[101–103] The Dana Farber Cancer Institute ALL Consortium has studied the role of hyperfractionated cranial radiation (0.9 Gy twice daily) compared to standard daily fractionated treatments (1.8 Gy daily) to 18 Gy in high-risk patients.[104,105] Results from Dana Farber ALL 87-04 show excellent CNS control rates with both the standard or hyperfractionated treatments. Late neurocognitive sequela has been similar in which systemic therapy emphasizes L-asparaginase and omits high dose MTX. A follow-up Dana Farber ALL trial 95-01 compared hyperfractionated 18 Gy cranial RT to extended IT chemotherapy without cranial RT. The interesting finding here is that

quantitative measurements of neurocognitive function were similar in both groups.[106] The German-Austrian-Swiss ALL-BFM ("Berlin-Frankfurt-Munich") Study Group has further reduced the radiation dose to 12 Gy, initially in a selected group of standard-risk pediatric patients.[89] With modern chemotherapy regimens as opposed to the older SJCRH experience, this further reduction in radiation dose was associated with excellent CNS control. Moreover, the ALL-BFM 90 protocol stopped using cranial RT in low- or standard-risk patients, but both the medium- and high-risk patients received 12-Gy prophylactic cranial radiation resulting in CNS recurrence rates well below 5%.[69] For the ALL-BFM 95 trial, cranial RT was deleted for the intermediate-risk B-cell ALL patients. This has resulted in a small increased risk for CNS relapse, which is considered clinically acceptable in order to avoid the late effects of such RT.[107] Specifically comparing intermediate-risk BFM 90 to BFM 95 patients, the isolated CNS relapse rate at 6 years is 0.5% versus 1.9%, $P < .01$. The 6-year "any-CNS" relapse rate was also statistically different at 2.2% versus 4.4%. Further follow-up and additional experience within the COG with this lower cranial radiation dose will be of interest in the years to come, hopefully seeing a reduction in late toxicity without compromising efficacy as cranial RT continues as used in a subset of high-risk pediatric ALL patients.

For adults with ALL, various protocols have used 24 Gy, whereas others employ 18 Gy.[101,102,108] Some programs such as Hyper-CVAD omit the use of cranial RT in the face of high dose MTX and ara-C, which effectively penetrate the blood–brain barrier.

Meningeal Leukemia at Diagnosis

At the time of diagnosis of ALL, approximately 3% to 5% of patients will present with clinically detectable CNS involvement (i.e., CNS-3 disease). Meningeal leukemia at diagnosis is typically managed as high-risk leukemia with cranial RT. The St. Jude investigators may disagree with the use of RT even here, but their results of the Total XV protocol included nine patients with CNS-3 disease whose 5-year event-free survival was only 43%.[62] These high-risk patients receive chemotherapy programs that include dose-intensive therapy with agents that penetrate the blood–brain barrier as well as IT therapy. Cranial radiation doses may vary from 18 to 25 Gy. Historically, CSI has been used, but modern practice has dispensed with the spine fields as the IT and systemic chemotherapy programs appear to be effective in assisting with CNS control. In children with ALL, meningeal involvement no longer carries a dire prognosis, as

5-year DFS rates approaching 70% are commonly seen.[109]

Within the older Children's Cancer Study Group (CCG) clinical trials for ALL, CSI has been consistently used in the management of CNS-3 disease. Until 1983, the cranial and spinal doses were 24 Gy and 12 Gy, respectively. Subsequent trials through 1989 utilized more intensive consolidation chemotherapy with a decrease in spinal radiation doses to 6 Gy. This allowed for a nonrandomized comparison of 6- and 12-Gy doses to the spine (in 2-Gy fractions). Interestingly, the patients who received a reduced spinal dose did just as well as those who received 12 Gy with less intensive chemotherapy. The 5-year event-free survival rate for patients with CNS-3 disease was 69%, compared to 67% for patients enrolled in all CCG ALL protocols in 1983 to 1989 who were without CNS-3 disease.[109]

Delay in RT up to 12 months has been found to be safe as long as intensive chemotherapy is being given first.[110,111] This avoids the marrow compromise that could potentially occur with early spine irradiation. In addition, with doses <16 Gy to the spine, myelosuppression has not been a major problem. Musculoskeletal hypoplasia would not be expected to be a significant problem for long-term survivors. The sequencing of RT *after* rather than *before* potentially neurotoxic drug therapy such as MTX may theoretically result in a lower incidence of cognitive dysfunction or encephalopathy. Some pediatric protocols will also tailor the dose to the brain based on patient age. For instance, the ALL-BFM 90 protocol, which utilizes cranial rather than CSI, avoids any RT for those younger than 1 year of age, 18 Gy for ages 1 to 2 years, and 24 Gy for older patients. In this large multicenter trial, 54 patients presented with CNS-3 disease and achieved a 48% 6-year event-free survival.[69] Arguably, this is inferior to protocols that use CSI, such as those reported by the CCG.[109] However, in the ALL-BFM 95, there were 64 patients with CNS-3 disease who had a 6-year event-free survival of 57.7% in which therapy included cranial radiation to 18 Gy without irradiation of the spine.

Some investigators in addition to those at SJCRH continue to try to avoid cranial RT in all cases including those with CNS-3 disease. The Dutch Childhood Oncology Group (DCOG) and the European Organization for Research and Treatment of Cancer (EORTC) have omitted cranial radiation by also using more high dose MTX during postinduction consolidation and by an increased frequency of IT chemotherapy. The SJCRH study also included higher cumulative doses of anthracycline than on Children's Oncology Group (COG) trials, and frequent vincristine/dexamethasone pulses and intensified dosing of L-

asparaginase, whereas the EORTC trials included multiple doses of high dose cytarabine, during postinduction treatment phases for CNS-3 patients. On the DCOG-9 trial, 21 CNS-3 patients treated without cranial radiation had a 5-year EFS of 67% ± 10%. On the EORTC trial, the 8-year EFS of 49 CNS-3 patients treated without cranial radiation was 68%. The cumulative incidence of isolated CNS relapse for those patients was 9.4%. This CNS-3 subgroup is relatively uncommon, and further studies will be required to see if CNS irradiation can be safely eliminated.[112,113]

Summary of Cranial RT for Initial ALL Management

In summary, cranial RT may be used to prevent CNS relapse of leukemia. From a historical perspective that considered the brain as a sanctuary site, cranial RT has been well documented to improve outcomes for selected patients with pediatric ALL. With concerns about late sequela and improvements in systemic therapy including agents that can better penetrate the blood–brain barrier, cranial RT is used much less frequently in the upfront management of ALL. Overall, only 15% to 20% of pediatric ALL patients who have high-risk features require cranial RT currently. In current practice, cranial radiation is employed selectively in high-risk ALL patients. Although the definition of high risk has been shifting, one needs to take into account the intensity and specifics of risk-adapted chemotherapy. Nevertheless, ALL patients who benefit from cranial RT include older age (e.g., older than 10 years of age, and probably increasing benefit at ages older than 13 years); T-cell phenotype, especially in older patients with high presenting WBC over 100,000; and risk groups CNS-2 or -3 by CSF findings. Additionally, among B-cell patients, those with MRD and adverse cytogenetics should be strongly considered for cranial RT. Moreover, a recent meta-analysis supports the concept that a relatively small cohort of high-risk pediatric ALL patients require cranial RT as part of initial CNS-directed therapy.[114] All adults with ALL may be considered to be at high risk for CNS relapse, but there are no standard recommendations on cranial RT. Patients with AML, except for specific subtypes such as monocytic variants, are not generally treated with prophylactic cranial radiation at the present as the risk for CNS relapse is <5%. Unless otherwise indicated, in a specific treatment protocol, the radiation prescription for prophylactic cranial radiation to prevent ALL relapse is 18 Gy in 9 or 10 fractions. When BFM-type chemotherapy programs are used, the radiation dose has been reduced to 12 Gy with favorable outcomes. The spinal region is specifically treated by IT chemotherapy rather than RT, although an open

question is whether there would be an incremental benefit to low radiation doses to the spine with meningeal leukemia at diagnosis.

The use of prophylactic cranial irradiation (PCI) in pediatric ALL is undergoing continued restriction and even abandonment because of concerns for limited efficacy and a historical body of evidence for neurocognitive, endocrine, and secondary tumor toxicities despite the recent trends in lower radiation doses for this indication. A group of international investigators performed a detailed meta-analysis of PCI use from 10 cooperative groups involving 16,623 patients age 1 to 18 years old with newly diagnosed ALL treated between 1996 and 2007. The proportion of patients eligible for PCI varied from 0% to 33% by trial, unrelated to eligibility for allogeneic stem cell transplantation in first complete remission. A meta-analysis using PCI as a dichotomous covariate compared event-free survival and cumulative incidence of isolated or any CNS relapse and isolated bone marrow relapse in high-risk subgroups of patients who either did or did not receive PCI. Results showed that only a small subgroup of patients with overt CNS disease at diagnosis had a plausible benefit from RT with a significantly lower risk of isolated CNS relapse of 4% with PCI compared to 17% who did not receive RT, $P = .02$; moreover, there was a trend toward lower risk of any CNS relapse (7% with PCI vs. 17% without, $P = .09$). These investigators, however, still questioned the role of PCI even in this or other high-risk groups of pediatric ALL receiving contemporary risk-adapted therapy as systemic relapse and death were equally high occurring in roughly one-third of patients regardless of RT usage.

The authors nicely summarized the current cooperative group use of PCI. In the current AIEOP-BFM ALL 2009 study, approximately 10% of patients receive PCI. In the current COG studies, prophylactic CRT is given only to the 2% to 3% of patients with CNS-3 status and approximately 10% of patients with T-ALL with high levels of MRD after 3 months of therapy. Bcr-abl mutations and other high-risk molecular markers are no longer an indication for PCI by itself. In the current DFCI Consortium study, approximately 20% of patients (all patients with T-ALL and patients with B-cell precursor ALL with CNS-3, high level of MRD at the end of remission induction, MLL rearrangement, or low hypodiploidy) receive PCI. But, in the upcoming DFCI study, only CNS-3 status will be used as a criterion for PCI for patients with B-cell ALL. In the current Cooperative Acute Lymphoblastic Leukemia (COALL) 08-09 study, PCI 12 Gy is given to approximately 6% of the patients. Only patients with CNS-3 status receive PCI in the current trial of the Japanese Pediatric Leukemia/Lymphoma

Study Group. Of note, several groups have completely omitted PCI including the Dutch group, the Nordic Society of Hematology and Oncology, the European Organisation for Research and Treatment of Cancer, the UK ALL group, and the St. Jude Children's Research Hospital.[115]

Therapeutic CNS Irradiation for Meningeal Relapse

With modern chemotherapy programs incorporating CNS-directed treatment, CNS relapse rates are typically <10%. As in overt CNS leukemia at diagnosis, RT has a central role. Formally, CNS relapse was thought to have a poor prognosis. Studies in the 1970s and 1980s describe disease control rates of 25% to 50%.[116–122] More recent trials, however, utilizing more intensive chemotherapy as well as RT, have reported ALL 5-year survivals of 50% to 70%.[111,123–126] Almost all trials have employed RT; the debate has been between cranial RT alone and CSI. Doses used have generally been approximately 24 Gy to the brain and 10 to 15 Gy to the spine. Most comparisons have not been randomized, but superior outcomes seem to be achieved with CSI.[69,111,123–126] One small phase III trial did show superiority for CSI compared to cranial RT.[123]

Although CNS relapse may ostensibly occur without over systemic disease, the latter is viewed as inevitable without additional systemic therapy. Therefore, intensive chemotherapy is an essential component of the treatment of meningeal relapse.[107,127]

Several prognostic factors have been found to be of importance in the setting of CNS relapse.[128–130] Patients who were originally deemed at diagnosis to be at low risk for CNS relapse by virtue of a low initial leukocyte count (<20,000/μL), who originally did not receive cranial irradiation, or whose CNS relapse occurred at a relatively long period after the original diagnosis have a better prognosis after CNS recurrence. An isolated CNS relapse has generally been more prognostically favorable compared to combined CNS and systemic relapse. After completing chemotherapy, those children with CNS relapse have better outcomes with longer disease-free intervals. For instance, experience within the POG with isolated CNS relapse of ALL in which RT used a cranial dose of 24 Gy and a spine dose of 15 Gy. The 4-year event-free survival was 71%. Those patients who presented with >18-month disease-free interval prior to CNS relapse had a 4-year event-free survival of 83% compared to 46% for those with shorter initial remission durations.[111] This has led subsequent POG and COG trials that omit RT to the spine if there is a long disease-free interval, but if the disease-free interval is <18 months, 24 Gy is given to the brain, whereas 15 Gy

is delivered to the spine. Whether the omission of spinal RT in this favorable subgroup is detrimental is unclear. However, high dose ara-C has generally been added to the management of CNS relapse of ALL. With this agent, Morra et al.[131] reported a favorable 63% CR rate. These concepts have been maintained with current COG trials for CNS relapse of ALL, but with intensification of systemic therapy, spinal RT has been proposed to be dropped even for short disease-free intervals, whereas the brain is treated to 18 Gy. As for adults with CNS leukemia, most of the published experience and commentary from medical oncologists has been opposed to the use of CSI mainly for fear of excessive myelosuppression.[101] Cranial irradiation is relatively standard, however. Quite possibly, the avoidance in treating the entire CNS is detrimental, although admittedly this is not a settled issue.

Selected high-risk patients with CNS relapse may be candidates for allogeneic transplants. TBI is often a component of the preparative regimen. One function of the TBI is to specifically treat the CNS burden of disease. Because doses on the order of 12 to 15 Gy are employed here, it makes sense to boost the head prior to TBI to bring total doses to the cranium to 18 to 25 Gy. Investigators at Stanford have evaluated the neurocognitive effects of this practice of boosting the CNS in conjunction with TBI. Forty-one pediatric patients with relapsed ALL undergoing TBI-based allogeneic transplants had the brain boosted to a total mean dose of 24 Gy. In 18 patients, the spine was also boost to a total cumulative dose of 18 Gy. Five-year DFS for all patients was 67% for this high-risk group. Patients with isolated CNS disease before transplant had a trend toward superior DFS (hazard ratio 3.64, P = .11, 5-year DFS 74%) compared with those with combined CNS and bone marrow disease (5-year DFS 59%). Neurocognitive testing revealed a mean post-SCT overall intelligence quotient of 103.7 at 4.4 years. Although relative deficiencies in processing speed and/or working memory were noted in 6 of 16 tested patients (38%), the pre- and posttransplant neurocognitive testing revealed no significant change in intelligence quotient. At a mean of 12.5 years after transplant, 11 of 13 long-term survivors (85%) had completed some college level coursework.[132]

Testicular Relapse

In boys with ALL, particularly those with T-cell subtype, testicular involvement was once a common problem. Overt testicular involvement by leukemia at diagnosis occurs in approximately 2% of males with ALL and is a particularly poor prognostic situation. Microscopic burden in the testes is estimated to be

higher at 5% to 15% based on biopsy data and the historic risk for testicular relapse. With modern chemotherapy, especially the use of intermediate- to high dose MTX, this is now rare. Similar to the experience with CNS relapse, there once was speculation as to whether the testes acted as a sanctuary site because of a physiologic blood–testes barrier. In 1980, a trial of prophylactic testicular irradiation significantly reduced the risk of testicular relapse but did not improve survival.[133] But modern risk-adapted chemotherapies as promulgated by St. Judes investigators no longer require testicular RT in the upfront management of patients presenting with testicular involvement as there is no reduction in relapses nor improvement in overall or event-free survival.[134]

In cases of testicular relapse, systemic and/or CNS relapse usually follows.[135] Both intensive systemic therapy and local RT are indicated. Doses <12 Gy are generally thought to be suboptimal, whereas doses of 24 to 26 Gy over 2.5 to 3.5 weeks are considered standard. Case reports of local recurrences despite adequate RT have led some to suggest higher doses. When only one testis is clinically involved, imaging or biopsy of the contralateral testes frequently reveals bilateral disease. Similarly, unilateral irradiation or orchiectomy as local management is felt to be associated with a significant risk of contralateral testicular relapse, justifying treatment directed at both testes for leukemia management, despite the expectation of infertility from RT. Data from CCG and POG studies suggest that local irradiation and intensive systemic therapy results in prolonged event-free survival in roughly 50% to 65% of patients.[74,136] Where allogeneic transplantation is indicated, TBI is often part of the conditioning regimen. One retrospective series from the Memorial Sloan-Kettering Cancer Center suggests that for TBI/cyclophosphamide preparative regimens, the risk of testicular relapse is significantly reduced with a local boost to the scrotum of 4 Gy to bring the total testicular dose to 16 to 20 Gy.[137] Regardless, there is not universal agreement about the need for a testicular boost in this setting.

Ocular Relapse

Historically, choroidal recurrence of leukemia was sometimes associated with inadequate coverage of the optic nerve and posterior globe with cranial RT. This has led to practice patterns in which the posterior eye is included in standard cranial fields. Even so, isolated relapse in the eye is rarely seen and may even occur in the anterior chamber. RT is often used as part of retrieval therapy analogous to relapse in the brain or testes. The best report of the incidence and management of this situation comes from the United Kingdom Medical Research

Council leukemia clinical trial experience.[138] Investigators found a 2.2% incidence of eye relapse in their leukemia XI and ALL97 trials between 1991 and 2001. There were 17 patients who had ocular leukemia as a first relapse, either in isolation or combined with relapse at another site, and three occurred as a poor prognosis second relapse event. Among the patients with ocular relapse as a first site of recurrence, 11 patients were long-term survivors with disease control who were treated with a full chemotherapy relapse protocol along with local RT. Disease tended to not be controlled when chemotherapy was of reduced intensity; again, a lesson that isolated leukemia recurrences is a harbinger of systemic relapse. From this limited experience and from other cooperative groups, there is a sense that posterior eye relapse should direct the RT volume to include not just the eye but the CNS comprehensively. Radiation doses to the eye ranged from 10 to 24 Gy, mostly using 24 Gy as a cumulative dose that might have also entailed TBI or cranial/craniospinal RT volumes with differential dosing. An isolated relapse in the anterior chamber is felt to have less risk for occult CNS involvement and may be managed with electron beam RT rather than photons just to the eye along with intensive chemotherapy.

THE CHRONIC LEUKEMIAS

Chronic Myelogenous Leukemia

CML is a chronic myeloproliferative disorder arising from clonal expansion of the primitive hematopoietic stem cell. It involves myeloid, erythroid, megakaryocytic, and sometimes lymphoid elements. It is the first neoplastic process to be characterized by a specific cytogenetic marker, the Philadelphia chromosome (Ph+), t(9;22) described in 1960.[139] This is detectable by cytogenetics in 90% to 95% of patients and by molecular analysis in most other patients.[140] This translocation results in a BCR-ABL1 fusion protein that has tyrosine kinase activity critical for leukemic transformation.

Clinically, the disease manifests with several phases: if untreated, an initial chronic indolent phase of 3 to 4 years will progress to an accelerated phase for about 6 months and finally will transform in to blast phase with a survival of 3 to 6 months. As the disease advances, the accelerated phase is characterized by increasing difficulty in controlling the peripheral WBC count, increasing splenomegaly, increasing blasts in the peripheral blood and bone marrow, and increasing basophilia and eosinophilia. The blast crisis resembles acute leukemia with ≥20% blasts in blood or bone marrow with symptoms such as bone pain,

sweats, fever, anorexia, or weight loss. Anemia, thrombocytopenia, and extramedullary disease involving bones, skin, CNS, and lymph nodes are common. In about 20% of cases, blasts are lymphoid by phenotype. Historically, prognostic factors for CML have included age, splenic size, platelet count, and percent of basophils in blood and marrow. Poor prognosis factors are age >60 years, spleen >l0 cm below the costal margin, blasts >3% in blood or marrow, basophilia >7% in blood or marrow, and platelets >700,000/μL.[141]

Therapy of CML

The first effective therapy for chronic leukemias was RT to the spleen and sometimes the liver, initiated in 1902 by Pusey[142] and assessed in 1924 by Minot et al.[143] Today, RT is primarily used in a palliative setting to relieve painful splenomegaly or other extramedullary sites when indicated. In some centers, TBI plays an important role in allogeneic transplantation.

There is a long history of treating CML in chronic phase with alkylating agents, hydroxyurea, cytarabine, and interferon alpha, which is beyond the scope of this chapter. Over the past decade, such therapies, as well as hematopoietic stem cell transplant, have largely been relegated to the salvage setting through the introduction of ABL TKIs effective in inducing and maintaining long-term remissions in CML without cumulative toxicities.[144,145] Imatinib is a relatively well-tolerated oral medication that has been shown to be effective in CML in both chronic and accelerated phases.[146,147] This agent has been a paradigm for molecularly targeted therapies and is now used as upfront therapy for CML. Second generation TKIs such as dasatinib and nilotinib may be used for resistance to imatinib or patients with poor prognostic features.[148] For those who do not respond adequately to the TKIs or who lose response, allogeneic transplantation remains an important option.[149,150] About 70% of good-risk patients achieve long-term DFS.[151] Allotransplantation and TBI are further discussed in Chapter 16.

Palliative RT may be of benefit in those patients with massive splenomegaly with responses seen with doses in the 10- to 20-Gy range or lower. The radiation oncologist is well advised to understand the extreme radiosensitivity of the malignant stem cells in CML and in other hematopoietic disorders causing splenomegaly with the admonition to use very low doses per fraction (25 to 100 cGy) once or twice a week with close monitoring of blood counts (see below).

Chronic Lymphocytic Leukemia

CLL is an indolent leukemia of B-cell origin and is characterized by the accumulation of clonal, functionally incompetent B lymphocytes. It is the most common leukemia in the western world, and the course of the disease demonstrates marked variability. While some patients live a normal life span, never require therapy, others progress rapidly despite treatment. The usual course is characterized by gradual progression from incidentally found lymphocytosis to lymphadenopathy, splenomegaly, to anemia, and thrombocytopenia because of progressive bone marrow involvement and/or autoimmune phenomena. Nonlymphoid organ involvement may occur with advanced stage of disease.

Occasionally, patients with CLL develop transformation to an aggressive large B-cell lymphoma referred to as *Richter syndrome*.[152] Its incidence ranges from 3% to 5% of CLL cases.[153] It may arise in the setting of active disease or during a remission. It is characterized by an abrupt onset of asymmetric adenopathy, splenomegaly, B symptoms, and elevated LDH. Other transformations include evolution to prolymphocytic leukemia with development of progressive refractory disease and a majority of prolymphocytes in the blood. Rarely, ALL or myeloma develop in the course of CLL.[154,155]

The clinical diagnosis is based upon the blood lymphocyte count, which must be at least $5 \times 10^3/\mu L$ in an adult. The malignant B cells have a distinct immunophenotype with expression of surface markers CD5, CD19, and CD23 in addition to immunoglobulin light chain restriction and dim CD20 positivity.[156,157] Healthy individuals may harbor monoclonal B cells of this phenotype and are classified as monoclonal B-cell lymphocytosis provided there are $<5 \times 10^3/\mu L$, and no other evidence of disease is present. Patients with lymphadenopathy or other tissue morphology and similar phenotype without leukemic involvement are diagnosed with small lymphocytic lymphoma. There have been many staging systems proposed, but the most widely used are those modified by Rai et al.[158] and Binet et al.,[159] the former used in the United States and the latter in Europe (see Table 84.6). Clinical stage is the most important predictor of survival in patients with CLL. Numerous other factors have been reported to have an impact on survival and include age, sex, lymphocyte doubling time, pattern of marrow involvement, β-2 microglobulin levels, and immunophenotype of malignant cells.[160] Cytogenetic and molecular abnormalities have more recently emerged as powerful predictors of outcome and may impact treatment decisions.[161] For example, deletion of chromosome 17p or p53 mutation confers both an inferior overall survival as well as

resistance to purine analog and alkylator-based therapy.

TABLE 84.6 CHRONIC LYMPHOCYTIC LEUKEMIA STAGING SYSTEMS

Staging System	Clinical Features	Median Survival (y)
Rai staging		
Low risk		>10
0	Lymphocytosis of blood and marrow	
Intermediate risk		7
I	Lymphadenopathy	
II	Splenomegaly	
High risk		2–4
III	Anemia, Hgb < 10 g/dL (unrelated to hemolysis)	
IV	Thrombocytopenia <100,000 platelets/μL	
Binet staging		
A	<3 areas of lymphadenopathy	12
B	≥3 involved nodal areas	7
C	Anemia and/or thrombocytopenia	2

Hgb, hemoglobin.

Asymptomatic early-stage patients are typically followed without therapy (“watch and wait” approach). About 20% of such patients will continue to have an indolent course. Of the remaining patients, the decision to intervene therapeutically is often challenging. The NCI has established guidelines for the initiation of treatment, which include constitutional symptoms (B symptoms) because of CLL, symptomatic lymphadenopathy and/or hepatosplenomegaly, anemia (hemoglobin <10 g/dL), thrombocytopenia (platelets <100,000/μL), and refractory autoimmune disease.[162] The absolute lymphocyte count should not be used as an indication for treatment, as symptoms associated with marked lymphocytosis because of leukocyte aggregation do not typically occur in patients with CLL.

For many years, the standard treatment for CLL included single-agent chlorambucil with or without prednisone.[163] The newer purine analogs, 2-deoxycoformycin, fludarabine, and 2-chloro-2′-deoxy-β-D-adenosine (cladribine or 2-CDA) have been tested in CLL and, of these, fludarabine has shown a high response rate in combination with the anti-CD20 antibody, rituximab.[164] In a phase III trial comparing fludarabine to chlorambucil, the CR rate with

chlorambucil was 4% and with fludarabine 20%.[165] Overall response rates were 37% with chlorambucil and 63% with fludarabine. The median survival was 66 months (fludarabine) versus 56 months. For these reasons, fludarabine is now accepted as a backbone of therapy for CLL. More recently, a combination of fludarabine, cyclophosphamide, and rituximab has resulted in a very high complete remission rate of 70% in patients with CLL, with a median time to progression of 80 months.[166] Moreover, when compared to fludarabine and cyclophosphamide, the addition of rituximab led to a survival benefit, which made this the regimen of choice in the upfront treatment of the young and fit.[167]

For patients who are older than 65 years, have comorbidities, and/or decreased renal function bendamustine plus rituximab has been used traditionally given the increased risk for adverse events including infectious complications.[168] This regimen has a relatively low toxicity mainly confined to a mild to moderate degree of reversible myelosuppression.[169]

Over the past few years, the treatment of CLL has been revolutionized with the advent of targeted therapies. Newer approaches to the treatment of CLL involve vaccines, cell cycle inhibitors, antiapoptotic agents, immunomodulatory agents, and monoclonal antibodies. Ibrutinib—a selective irreversible inhibitor of Bruton tyrosine kinase, part of the B-cell receptor signaling cascade—is the furthest developed and has been FDA approved for the upfront treatment of older patient with CLL based on the results of the RESONATE-2 trial.[170] This was an open-label, randomized phase 3 trial, which compared ibrutinib and chlorambucil, in previously untreated older patients with CLL or small lymphocytic lymphoma, and ibrutinib resulted in a higher overall response rate was 86% vs. 35%, $P < .001$, longer progression-free survival (median, not reached vs. 18.9 months), and overall survival with a relative risk of death that was 84% lower in the ibrutinib group than in the chlorambucil group (hazard ratio, 0.16; $P = .001$). Ibrutinib has also been FDA approved for patients with relapsed/refractory CLL and for the upfront treatment of patients with CLL harboring a deletion in the chromosome 17p or a deletion on p53 who have historically a poor response to traditional chemoimmunotherapy.[171,172]

Other novel agents include idelalisib, venetoclax, and ofatumumab, which are mentioned briefly, but a full discussion is beyond the scope of this review. Idelalisib is an oral inhibitor of phosphoinositide 3’-kinase (PI3K) delta, a pathway that is crucial for the maintenance and expansion of B cells.[173] In a phase III randomized, double-blind, placebo-controlled trial, patients with relapsed CLL receiving idelalisib versus those receiving placebo along with

Rituxan had improved rates of overall response (81% vs. 13%; odds ratio, 29.92; $P < .001$) and overall survival at 12 months (92% vs. 80%; hazard ratio for death, 0.28; $P = .02$).[174] Largely based on these results, the FDA approved idelalisib for the treatment of patients with relapsed CLL, in combination with rituximab, for whom rituximab alone would otherwise be considered appropriate therapy because of other comorbidities.

Venetoclax, a BH3 mimetic, specifically targets BCL2 and has been proven to have efficacy in relapsed CLL including with 17p deletion, and has a low toxicity profile except for a propensity to cause tumor lysis syndrome because of its high response rate.[175] Impressively it has led to an ORR of 79% with a 20% complete remission, which is highly unusual in this heavily pretreated patient population. Based on these results, it has been FDA approved for CLL patients with 17p deletion after at least 1 prior line of therapy. Finally, a new humanized anti-CD20 monoclonal antibody, ofatumumab, was evaluated in a phase III trial of relapsed CLL in complete or partial remission after second- or third-line treatment. Patients were randomly assigned to receive maintenance ofatumumab for up to 2 years versus observation. Ofatumumab maintenance resulted in superior estimated PFS (median 29 vs. 15 months), although this did not translate into an overall survival benefit.[176]

Allogeneic transplantation has been employed with increasing frequency in the past decade with the recognition of graft versus leukemia effects and the advent of reduced-intensity conditioning. Earlier studies of allografting showed promising results in young patients with regard to disease control at the expense of significant treatment-related toxicity.[177,178] Several groups have reported favorable disease control and survival in high-risk patients with reduced-intensity conditioning regimens that are fludarabine or low dose TBI based. Of note, patients with chromosome 17p deletion appear to respond as well to allografting as those without 17p deletion.[179,180] Indications for consideration of allografting have been proposed by the European Group for Blood and Marrow Transplantation and include early relapse following chemoimmunotherapy, resistance to fludarabine, chromosome 17p deletion, and Richter transformation.[180] It is not clear whether a survival advantage will occur with stem cell transplantation because there are no controlled trials.

RT was historically a very effective initial therapy for CLL. Prior to the plethora of modern chemotherapeutics, ultra-low dose TBI was used without stem cell support decades ago for CLL given its extraordinary radiosensitivity. This historical use of TBI used roughly 3 to 12 rad or 0.03 to 0.12 Gy/fraction

several times a week with doses titrated to response, but total doses in the range of 1 to 4 Gy.[181–184] But, RT is now relegated to a palliative role for CLL, for instance used in the management of painful splenomegaly or occasionally for cytopenias associated with splenomegaly when splenectomy is not an option. It is also indicated in instances of unresponsive disease to alleviate symptomatic adenopathy or nonlymphoid organ involvement. Remarkably low doses on the order of 4 Gy in 1 to 2 fractions can be effective for palliation as used with low-grade B-cell lymphomas, although fractionated doses up to 20 Gy are also reasonable for more definitive local control.[185–187]

IRRADIATION TECHNIQUES

Cranial Radiation

The volume of treatment must include the subarachnoid space within the cranial vault. The inferior margin has by convention extended to the bottom of either the first or second cervical vertebra and includes the whole vertebral body. This may facilitate matching of potential future treatment fields to the spine. Other field boundaries typically involve “flashing” over the scalp. With regard to blocking the anterior facial structures, attention must be given to the base of skull anatomy to adequately cover the cribriform plate and the middle cranial fossa. The cribriform plate is somewhat variable as a function of the age of the patient but is generally in line with the bottom of the frontal sinuses extending posteriorly for several centimeters. The middle cranial or temporal fossa projects on lateral radiographs over the sphenoid sinuses. Figure 84.2 shows plain radiographs of an adult skull with radiopaque markers at various anatomic landmarks. The posterior globe of the eye is typically included given concerns of leukemic relapse in the posterior retina near where there is subarachnoid space extending along the optic nerves. Radiopaque markers on the anterior aspect of the bony orbit are generally a good anatomic landmark that bifurcates the globe.

Figure 84.1 shows an example of lateral fields used to treat a patient with ALL. Head immobilization with Aquaplast or similar thermoplastic material facilitates a high degree of treatment position reproducibility. Accounting for setup variation and beam penumbra leads to field design that clearly must encroach on the eye. With forward gaze of the eyes, this would imply that the superior half of the lens is within the dose build-up region of the treatment fields. With the exception of very young children who cannot cooperate, voluntary rotation of the eye downward (“looking toward one’s toes”) would

theoretically reduce the risk of cataracts. Another important caveat in treatment technique to minimize dose to the anterior portion of the eyes is the alignment of the anterior beam edge divergence. Figure 84.5 depicts this concept of angling the gantry 3 to 5 degrees to achieve a parallel anterior beam margin behind the lens, bisecting the eye producing a relatively tight radiation dose gradient. The simple trigonometric equation to determine the proper gantry rotation is as follows:

$$\tan A = D/\mathrm{SAD}$$

where A is the desired rotation angle, D is the anteroposterior distance between the central axis (i.e., isocenter) and the projection of the anterior aspect of the bony orbit at midplane, and SAD is the source to axis (or isocenter) distance (which is generally 100 cm for most linear accelerator geometries). Because $\tan A \cong A$ (in radians) for small angles and the conversion factor for radians to degrees is approximately 57 (i.e., 180 degrees per π radians), this further simplifies to:

$$A = (D)(0.57) \text{ for a source to axis/isocenter distance of } 100\,\mathrm{cm}$$

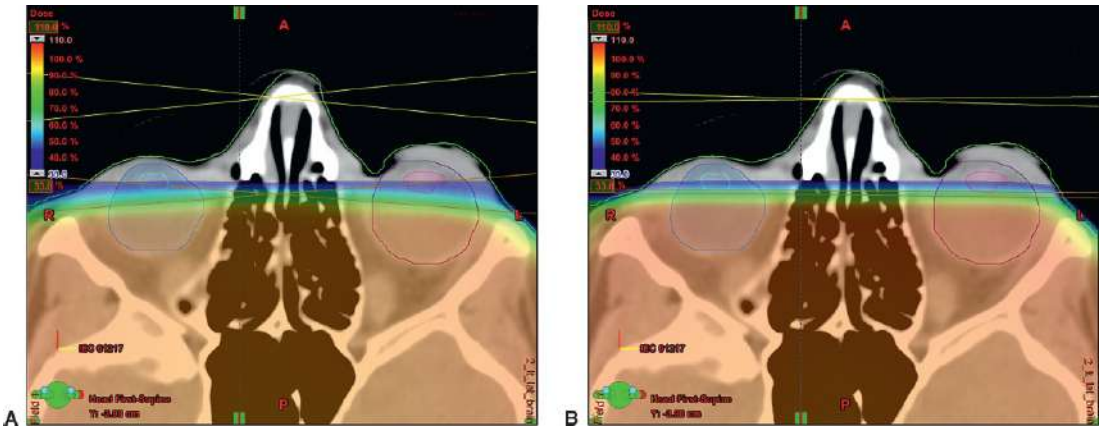

FIGURE 84.5. An 8-year-old boy with T-cell acute lymphoblastic leukemia, CNS-3 at diagnosis, requiring cranial RT to 18 Gy in 12 fractions after remission from systemic therapy. Alignment of anterior divergence of lateral cranial fields showing beam edge and color wash of radiation dose superimposed on axial CT scan at level of eyes. **A:** Parallel-opposed fields result in widened dose gradient within anterior aspect of eyes. **B:** Gantry angle of 3 to 5 degrees results in alignment of anterior margin beam divergence from lateral fields and tighter dose gradient.

Some radiation oncologists prefer to simply place the isocenter of the treatment beam just posterior to the lens so that the anterior eye is protected by a modified “half-beam block.” This is a fine technique for linear accelerators

equipped with independent primary collimators so that block trays are not excessively heavy. With the advent of CT simulators, alignment of beam divergence can be performed graphically without the need for trigonometric calculations. The standard radiation dose for prophylactic cranial radiation in pediatric ALL is 18 Gy in 9 to 10 fractions, but increasing use of 12 Gy in 8 fractions is based on evolving experience with selected patients being treated with BFM-type ALL programs. Although this is a reasonable dose for adults, some protocols still continue to utilize 24 Gy in 12 fractions. Photon energies >6 MV should not be used so that the dose build-up region at initial depths is superficial to the meninges.

Craniospinal Radiation and Therapeutic Cranial Radiation for CNS Leukemia

The techniques of cranial spinal radiation involve precise matching of beam divergence between a PA spine field and lateral parallel-opposed cranial fields. This topic is discussed in detail in the chapter on Central Nervous System Tumors in Children (see Chapter 88). It is recommended that there be minimal or no gap between the spine and cranial fields. The field junction may be shifted or "feathered" by 1 to 2 cm once or twice to avoid any excessive overlap of dose over the cervical spine. Some physicians prefer to place the beam isocenter at the inferior or caudad border of the initial craniocervical field so as to avoid the complexity of a couch rotation in the treatment setup. A gantry rotation to align the anterior beam divergence near the eye may still be performed. Other physicians place the isocenter near the eye to avoid divergence into the anterior globe, which can be done in conjunction with an appropriate couch rotation to match divergence with the posteroanterior spine field.

Maximum beam energy of 6 MV is recommended. Radiation doses for overt CNS leukemia are 18 to 30 Gy to the cranium in 1.5- to 1.8-Gy fractions. The authors recognize that it is increasingly rare that overt CNS leukemia for children or adults be treated with craniospinal fields, but there can be clinical circumstances where this may still be rationale. In such cases, along with the administration of IT chemotherapy, the spine may be treated to lower doses than the brain to total doses of 6 to 15 Gy depending on individual circumstances. Plans for possible TBI must be taken into account. This part of the preparative regimen for an allogeneic transplant can be conceptualized as being in part of CNS therapy.

Testicular Irradiation

For the management of leukemic infiltration of the testes, both gonads and the scrotum can be irradiated with either electrons or photons. With the patient in a "frog-leg" position and the penile shaft taped onto the abdomen, an anterior inferior oblique photon field works well. Attention to the cremaster reflex and potential ascent of the testes into the inguinal canal is important so as to avoid a geographic miss. For megavoltage photon beams, bolus may be required to avoid superficial underdosing. In young boys where the scrotum/testes thickness is under 2 cm, 250-kV orthovoltage x-rays may also be used. Alternatively, direct en face electron beams of appropriate energy work adequately. Though there are considerable dose inhomogeneities in treating such a curved surface with electrons, the relatively low doses employed in this setting translates into relatively low risks related to skin and subcutaneous soft tissue reactions. Radiation doses typically used are 24 to 26 Gy in 1.5- to 2.0-Gy fractions. When a testicular boost is given in conjunction with TBI for a hematopoietic stem cell transplant, the dose is either 4 Gy × 1 fraction or 2 Gy × 2 fractions.

Splenic Irradiation

Massive splenomegaly may be seen with CML, CLL, hairy cell leukemia, and splenic marginal zone lymphomas, where the spleen can extend into the pelvis. Significant splenomegaly may also occur with prolymphocytic leukemia, myeloproliferative disorders such as polycythemia vera or essential thrombocytosis, or myelofibrosis. One type of myelofibrosis called agnogenic myeloid metaplasia is characterized by progressive bone marrow failure, splenomegaly, and extramedullary hematopoiesis. It is therapeutically important to recognize which conditions of splenomegaly are due to extramedullary hematopoiesis rather than leukemic infiltration as whole-spleen RT with modest radiation doses can result in severe, long-lasting pancytopenia when the spleen is the primary hematopoiesis site.[188] Splenic hematopoiesis can also occur with late stages of CML, myeloproliferative disorders, and hairy cell leukemia. Extreme care is required to proceed slowly with RT in these circumstances.

Historically, splenic RT was commonly employed for palliation, but it is now uncommon, as more effective systemic treatments have been developed. Nevertheless, the radiation oncologist is called on to assist with the management of symptomatic splenomegaly from these hematologic disorders from time to time, often with excellent results.[189] Symptomatic problems include pain, early satiety, diaphragmatic irritation, and bleeding risk related to sequestration of

platelets. Leukemic infiltration of the spleen responds to relatively low doses of radiation.[190] Particularly in an elderly patient with other comorbidities, palliative splenic RT can offer significantly less risk than splenectomy.[191] Splenic irradiation has been reviewed by Weinmann et al.[192]

Anterior and posterior opposed portals for photon treatments are generally employed. In cases of leukemic infiltration, standard practice is to treat the whole spleen in 0.25- to 1.0-Gy fractions either daily or once to three times a week with doses titrated to response and hematologic tolerance.[193] As the spleen responds, one may progressively shrink the treatment fields accordingly. Generally, it is prudent to start treatment very conservatively. Blood counts may need to be monitored several times a week. Total radiation dose delivered is determined clinically by when palliation is achieved. Total doses are typically in the range of 4 to 10 Gy with usually no more than 20 Gy required. Occasionally, a large spleen that is extensively fibrotic will not response to RT. CLL and prolymphocytic leukemia are particularly radiosensitive, with occasional abscopal effects seen with splenic irradiation. One trial of CLL and splenomegaly successfully used 1.0 Gy a fraction once a week for an average of seven treatments yielding good palliation including complete normalization of blood counts in 44% of patients.[194]

In patients with extramedullary hematopoiesis, the potential for severe neutropenia or thrombocytopenia is very high with even modest radiation doses. Dose per fraction may need to be as low as 0.1 to 0.5 Gy treating several times a week to avoid severe and protracted myelosuppression. Another strategy in this situation is to treat only half of the spleen. For myelodysplastic conditions or extramedullary/intrasplenic hematopoiesis, total doses of 1 to 9 Gy are usually adequate.

With splenic irradiation, nausea is uncommon with these low dose fractions but can be readily managed with antiemetics if necessary. As there can be rapid cell lysis, allopurinol to prevent uric acid nephropathy is advised. Cumulative dose to the left kidney should be monitored, especially as retreatment in the future may be required, but it is rare for doses beyond 20 Gy to be required.

SEQUELAE OF THERAPY

Somnolence Syndrome

Approximately 1 month following cranial radiation, up to 40% to 50% of patients may develop lethargy, irritability, anorexia, and even fevers. This has

been termed somnolence syndrome. It has been associated with electroencephalographic abnormalities and CSF pleocytosis.[195,196] This syndrome is self-limited and typically reverses within 1 to 3 weeks. Glucocorticoids in acute management may be helpful. Two reports suggest that the incidence of this syndrome is reduced if patients receive steroids during cranial RT.[110,197]

Pituitary Dysfunction

Hypothalamic–pituitary irradiation can impact endocrine function in a dose- and age-dependant manner. For the doses used in leukemia management, growth hormone (GH) deficiency is the most common abnormality observed. Age younger than 5 years at the time of RT is associated with particular susceptibility to the development of GH deficiency. Higher radiation doses as well as younger age correlate with an increased incidence of GH deficiency and a shorter time period for its clinical manifestations.[198] It is more common after 24 Gy than 18 Gy.[199,200] Up to 22% of adult survivors of pediatric ALL who have received cranial RT may have diminished GH responses to provocative testing.[201] Precocious puberty has been reported with radiation doses to the hypothalamic–pituitary region as low as 18 Gy, although it seems to be more prevalent in females who receive doses of 24 Gy or higher.[202] Doses <35 to 40 Gy are rarely associated with other pituitary hormone deficiencies or abnormalities. Thus, patients receiving cranial RT for leukemia, particularly in childhood, require regular follow-up of their linear growth and sexual development. Abnormalities should then lead to appropriate endocrinologic evaluation so as to determine the need for therapy with either GH replacement or gonadotropin-releasing hormone agonists.

Cognitive Dysfunction

Intellectual and psychological impairments from the treatment of leukemia have received wide attention. Evidence that RT is to blame has been a major impetus in investigations aimed at lowering the dose delivered to the brain or eliminating it completely. Increasingly, however, there is evidence that chemotherapy may also be causing similar detriments. Objective measures of cognitive function and social functioning are inherently difficult. Nevertheless, a variety of assessment tools, intelligence quotients, or scales have been verified as useful measures of language, reasoning, and performance skills. Other descriptive measures of lowered school achievement have also been reported. Cognitive dysfunction is

thought to be the result of white matter injury causing deficits in the speed of information processing.[203] These effects are most pronounced in children younger than age 5 years and probably most pronounced in those younger than 3 years of age when the brain is still undergoing growth and development especially with myelination.

Some reports have suggested a gender difference in susceptibility to radiation injury, with females more likely than males to develop intellectual impairments, although this has not been consistently reported.[204,205] The Dana Farber group has suggested that the reduction in IQ seen in girls was the result of an interaction between high dose MTX and cranial radiation.[206] Moreover, an impairment in verbal memory observed in both boys and girls was independent of cranial radiation, suggesting toxicity from systemic therapy.[206]

A reduction in radiation dose from 24 to 18 Gy has not consistently reported to result in lower cognitive difficulties.[100,101,103] Further reduction to 12 Gy is under study. Overall, for these radiation doses, the cognitive deficits have been arguably small with average full-scale IQ measures decreasing by no more than 10%, whereas other studies fail to show measurable changes. Perhaps, a more important statistic is the proportion of patients with significant reductions, say >15 points in IQ scales; the SJCRH group has reported that up to 22% to 30% of children have such deficits after 18, 24 Gy, or no cranial RT.[205] One hypothesis is that a component of cognitive difficulties is related to chemotherapy rather than RT. Regardless, a recent report from the Dana Farber group suggests that in high-risk ALL patients receiving 18-Gy cranial radiation, neurocognitive function many years after therapy is not significantly different from that of the general population.[104] Importantly, this was a group of patients who experienced a favorable 5-year DFS of 75% with a 1% CNS relapse rate. The Dana Farber group has been investigating hyperfractionated cranial radiation for CNS prophylaxis (0.9 Gy twice daily vs. 1.8 Gy daily to a total dose of 18 Gy). There are no obvious differences between standard and hyperfractionated RT in terms of late neurotoxicity reported thus far, although there are numerous methodologic problems inherent in such a comparison.[104–106] An emerging experience suggests that stimulants such as methylphenidate may be of help in managing treatment-related cognitive problems, particularly some attentional or social deficits.[207]

Leukoencephalopathy

Some early prophylactic cranial radiation studies for childhood ALL showed a

significant incidence of profound encephalopathy occurring months after irradiation.[127,208] The highest incidence was seen when cranial radiation with doses as low as 24 Gy were combined with IV MTX. Leukoencephalopathy is thought to represent a demyelinating condition that may be initiated by endothelial damage and a subsequent cytokine cascade with ischemic microinfarcts.[209] Although concomitant IV MTX seems to be a significant synergistic factor, leukoencephalopathy has been observed at low incidence rates with RT alone at doses >30 to 35 Gy, with IT MTX, or in conjunction with other chemotherapy agents. High dose chemotherapy alone is becoming increasingly recognized as causing similar dementia-like syndromes. One should also remember that after cranial RT, the blood–brain barrier is thought to be more permeable, which may contribute to chemotherapy effects on cognitive function.[210] Regardless, the risk of leukoencephalopathy is decidedly rare after doses of <20 Gy.

Secondary Malignancies

One of the larger single institution series of pediatric ALL with extended follow-up of 2,169 patients from SJCRH treated between 1962 and 1998 reported that the cumulative incidence of secondary cancers was 4.2% and 10.9% at 15 and 30 years, respectively.[211] The incidence does not appear to plateau, although second malignancies occurring after 20 years tend to be lower-grade malignancies that include meningiomas and basal cell skin cancers. The Childhood Cancer Survivor Study (CCSG) has also documented an elevated risk for nonmelanoma skin cancers in pediatric ALL survivors, with a cumulative incidence of 10% at 30 years.[212] Cranial MRI surveillance imaging may also increase the detection of asymptomatic radiation-associated meningiomas, estimated to have an incidence of 15% at 20 years and which may sometimes be multifocal.[213] Other secondary cancers attributable to RT include gliomas, parotid gland tumors, thyroid cancers, and sarcomas (bone and soft tissue).[211,214–216] The types of secondary brain tumors from RT tend to be evenly split between meningiomas and high-grade gliomas.[211] In an earlier report from the CCSG of 9,720 patients treated for ALL, 43 secondary cancers were observed after a mean follow-up of 6 years.[216] Of these, 24 were CNS tumors in patients who had previously received 24-Gy cranial RT. All but one of these patients with CNS tumors had been younger than 5 years of age at diagnosis of their acute leukemia, suggesting an age-related susceptibility. Additional data from the CCSG suggest that the risk of gliomas and meningiomas both have a linear radiation dose–response

relationship.[216,217] The CCSG has now extended additional long-term follow-up of ALL patients in different treatment eras using various radiation dose prescriptions to more definitely observe that lower doses of cranial irradiation correlate with lower risk for meningiomas.[218] Age of exposure to radiation is also a significant determinant of meningioma risk as lower aged patients have higher risk. On multivariable modeling, there is an increase in hazard ratio of 1.12 per 5 Gy of cranial RT exposure. Although there is hope that a reduction in cranial radiation doses to as low as 12 Gy may reduce the incidence of secondary tumors, the German BFM group has observed in the long-term follow-up of their ALL-BFM 90 trial a 3.4% actuarial incidence of secondary brain tumors at 16 years of follow-up.[107] In comparison, for those children with ALL not receiving cranial RT, the incidence of subsequent brain tumors was 1.2% at 15 years.[214] In a review of 3,182 children treated by an allogeneic bone marrow transplant, 25 solid tumors were observed compared to an expected incidence of one case.[219] A majority of these cancers originated in the CNS or thyroid gland. Moreover, most of these patients had received TBI as part of their preparative regimen before transplant.

Testicular Effects from RT

Gonadal dysfunction is quite rare from cranial RT for leukemia management unless patients undergo retreatment that results in high cumulative doses. Direct effects from testicular irradiation, however, are very common. Doses as low as 1 Gy, even from scattered dose from adjacent external beam fields, will cause transient oligospermia or azoospermia. Higher doses, particularly those used in TBI or therapeutic testicular radiation, would be expected to cause permanent infertility. Leydig cell function, on the other hand, is more radioresistent.[220] Low serum testosterone levels or delayed puberty are unusual with doses <29 Gy to the testes. One report of 60 male survivors of ALL showed significant germ cell dysfunction as manifested by increased FSH levels and testicular atrophy in 55% of patients treated with testicular RT and in 17% treated with craniospinal RT. The incidence of Leydig cell dysfunction was very low.[220]

CHAPTER 85

Plasma Cell Myeloma and Plasmacytoma

David C. Hodgson, Joseph Mikhael, and Richard W. Tsang

EPIDEMIOLOGY AND ETIOLOGY

Plasma cell neoplasms account for 22% of all mature B-cell neoplasms in the Surveillance, Epidemiology, and End Results (SEER) program of the United States.[1] The majority of plasma cell neoplasms are multiple myeloma, with solitary plasmacytoma (SP) accounting for ≤6% of cases, and plasma cell leukemia occurring rarely. The incidence of multiple myeloma gradually increased in the 1970s through 2010s.[2] Data from the American Cancer Society indicate an incidence in the United States of 8 per 100,000 men per year and 5.2 per 100,000 women during the period 2009 to 2013.[3] For 2018, it is estimated that there will be 30,770 new cases and 12,770 deaths because of multiple myeloma in the United States.[3] The incidence exceeds that of Hodgkin lymphoma and is about one-third that of all malignant lymphomas. The incidence rises with advancing age, with a median age at diagnosis of 69 years,[2] and approximately 1% of cases are diagnosed in those younger than 45 years of age. Nonregistry studies usually report a lower median age ranging from 60 to 66 years.[4,5] There is a slight male predominance, and for black Americans, the incidence and mortality rates are approximately double that for whites. The 5-year relative survival rates have increased from 26% in 1975 to 30% in 1990 and almost 50% in the period 2007 to 2013.[2]

Little is known about the cause of multiple myeloma. There are studies reporting association with certain chemicals such as petroleum products.[6,7] It is now thought that all cases of myeloma are preceded by monoclonal gammopathy of unknown significance (MGUS).[8–10]

PATHOPHYSIOLOGY

Multiple myeloma arises from malignant transformation of a postgerminal center B cell. Although the full cascade of genetic abnormalities has yet to be defined, one of the earliest genetic events is the illegitimate switch recombination of partner oncogenes into the immunoglobulin heavy chain (IgH).[11] Other events may occur such as cytogenetic hyperploidy and up-regulation of cell cycle control genes. The result of these genetic abnormalities is the development and propagation of a clonal population of B cells within the bone marrow; this, however, is common and can be seen in up to 5% of the general population over the age of 70 (MGUS).[12] Most of these will not go on to develop myeloma, so there must be additional events to create the malignant phenotype of multiple myeloma. These secondary events may include mutations of kinase genes, chromosomal deletions, and up-regulation of enzymes such as c-myc.[11] Having sustained a secondary event, the malignant plasma cells begin to proliferate in the bone marrow microenvironment, producing monoclonal proteins and causing osteolytic bone disease. The slow accumulation of these malignant cells gradually results in the characteristic clinical features of myeloma: anemia, bone resorption, hypercalcemia, renal failure, and immunodeficiency. Established myeloma is sustained by a number of microenvironment features, including the bone marrow stroma itself and the cytokines interleukin-6, vascular endothelial growth factor (VEGF), and insulin-like growth factor-1.[11] The bone disease that arises in myeloma appears to be mediated in part by amplification of the RANK pathway and the inhibition of the Wnt signaling pathway.[11]

TABLE 85.1 THE SPECTRUM OF MYELOMA

	MGUS	Smoldering Multiple Myeloma	Multiple Myeloma[a]	Plasma Cell Leukemia
Clinical	No organ damage	No myeloma-defining events[b] or amyloidosis	One or more myeloma-defining events[b]	Organ damage, leukocytosis, high tumor burden, and high proliferation rate
Marrow disease/M-protein features	<10% clonal plasma cells	10%–60% clonal plasma cells and/or M-protein ≥30 g/L (or urinary M = protein ≥500 mg per 24 h)	≥10% clonal plasma cells or biopsy-proven plasmacytoma[a]	Plasma cells in peripheral blood ≥2 × 10^9/L or ≥20%. Immature plasma cells in bone marrow
Management	Monitor	Close follow-up	Chemotherapy	High-dose chemotherapy

Transformation rate	0.5%–1% per year	10% per year	—	—

[a]Multiple myeloma can be diagnosed when (a) clonal bone marrow plasma cells ≥10% or biopsy-proven bone or extramedullary plasmacytoma is present, plus (b) any one or more myeloma-defining events as outlined below.[b] Alternatively, without presence of myeloma-defining events, the presence of (a) with any one or more of the following biomarkers of malignancy also satisfies the diagnosis of multiple myeloma: clonal bone marrow plasma cell percentage ≥60%, involved:uninvolved serum light chain ratio ≥100, or >1 focal lesions on MRI (each focal lesion must be 5 mm or more in size).[13] This is also known as the SLiM (*S*ixty percent, *Li*ght chains, *M*RI) criteria.

[b]Myeloma-defining events: end-organ damage attributed to myeloma: hypercalcemia (calcium >2.75 mmol/L); renal insufficiency (creatinine >177 μmol/L or creatinine clearance <40 mL/min); anemia (hemoglobin <10 g/dL or >20 g/L below the lower limit of normal); and bone lesions (one or more osteolytic lesions on x-rays, CT, or PET scan).

MGUS, monoclonal gammopathy of unknown significance.

From Fernandez de Larrea C, Kyle RA, Durie BG, et al. Plasma cell leukemia: consensus statement on diagnostic requirements, response criteria and treatment recommendations by the International Myeloma Working Group. *Leukemia* 2013;27(4):780–791; Rajkumar SV, Dimopoulos MA, Palumbo A, et al. International Myeloma Working Group updated criteria for the diagnosis of multiple myeloma. *Lancet Oncol* 2014;15(12):e538–e548.

CLINICAL PRESENTATION

Multiple myeloma has a wide clinical spectrum, ranging from the preclinical condition of MGUS to the most aggressive form, plasma cell leukemia (Table 85.1). In all cases, a plasma cell clone exists, and the secretion of a monoclonal protein by these plasma cells, along with their interaction with the bone marrow environment, is the source of organ damage in patients with this illness.[11] These concepts have become particularly important, as the molecular mechanisms by which the disease progresses through these “stages” provide essential information that may help us to better understand the disease and its potential therapies.

Monoclonal Gammopathy of Unknown Significance

MGUS has traditionally been considered a benign or a premalignant condition, in which only a small proportion of patients will progress to multiple myeloma or related diseases (Table 85.1). Most are non-IgG MGUS, with 20% having light-chain immunoglobulin MGUS, and rarely IgM MGUS.[8] In MGUS, the monoclonal protein is <3 g/dL, and the bone marrow clonal plasma cells are <10% with no related organ damage. This condition is likely much more common than initially thought, as it has been documented in 3% of the

population and 5% in those over the age of 70 and 7.5% of those over the age of 85.[12] The risk of transformation to myeloma and related diseases (such as amyloidosis or Waldenstrom macroglobulinemia) has been estimated at 1% per year, based on a 30-year follow-up of 1,384 patients at the Mayo Clinic.[8]

Asymptomatic Multiple Myeloma (Smoldering Myeloma)

This category of myeloma represents an intermediate form of myeloma whereby patients meet serologic monoclonal protein levels ≥3 g/dL or urinary protein >500 mg per 24 hour and/or bone marrow clonal plasma cell infiltration of 10% to 60%[13] and absence of myeloma-defining events or amyloidosis (Table 85.1). These patients are not significantly anemic, do not have hypercalcemia or renal insufficiency, and do not have bony disease. Although the risk of transformation to multiple myeloma is much higher than in MGUS (20% per year), some patients' disease may remain asymptomatic without significant progression for many years. These patients generally do not require therapy but should be followed closely to monitor for progression.

Solitary Plasmacytomas

The median age at diagnosis of SP is 55 to 65 years, on average about 10 years younger than patients with multiple myeloma.[14–17] Males are affected predominately (male-to-female ratio 2:1).[14,15] A diagnosis of SP is made if all the following criteria are satisfied at presentation: a histologically confirmed single lesion with negative skeletal imaging outside the primary site, normal bone marrow biopsy (<10% monoclonal plasma cells), and no myeloma-related organ dysfunction.[13,18] A monoclonal protein is present in 30% to 75% of cases (particularly for an osseous presentation), and the level is usually minimally elevated (IgG < 3.5 g/dL, IgA < 2.0 g/dL, and urine monoclonal κ or λ < 1.0 g per 24 hours).[18–20]

The disease more commonly presents in bone (70%). Such cases are considered stage I multiple myeloma according to the original Durie Salmon staging system.[21] The most common location is the vertebra.[14,15] Patients with bone involvement often present with pain, neurologic compromise, and occasionally pathologic fracture. A lytic lesion is typical, with or without adjacent soft tissue mass. Less commonly, SP presents in an extramedullary site (20% to 30%), usually as a mass in the upper aerorespiratory passages, and produces local compressive symptoms.[14–16,22] The histologic diagnosis of extramedullary plasmacytoma (EMP) can be difficult, with the main differential

diagnosis being extranodal marginal zone lymphoma (mucosa-associated lymphoid tissue type), where there can be extensive infiltration by plasmacytoid cells.[23,24]

Multiple Myeloma

By definition, myeloma involves end-organ damage as myeloma-defining events, described by the mnemonic CRAB (*C*alcium elevation, *R*enal insufficiency, *A*nemia, and *B*one disease).[11,13] Recent modification added additional features when CRAB findings are absent, to include the SLiM criteria of 60% or more clonal plasma cells in bone marrow (*S*), light chains (*Li*) involved:uninvolved ratio >100, or MRI (*M*) detected number of bone lesions >1, measuring at least 5 mm in size for the diagnosis of multiple myeloma.[13] Bone pain and symptoms because of anemia, such as easy fatigability, are the most common.[5] Because of the myriad effects of the disease, other insidious symptoms can result from a combination of hypercalcemia, renal impairment, infection, neurologic compression, and occasionally, hyperviscosity. Bone disease manifesting as generalized osteopenia and multiple lytic bone lesions can frequently lead to pathologic fractures. In the vertebral column, this often results in a diminished height. Sclerotic lesions at presentation are rare.

Laboratory evaluation generally confirms anemia, high erythrocyte sedimentation rate, and a variable degree of granulocytopenia and thrombocytopenia. An abnormal monoclonal immunoglobulin (M protein) in the blood or urine is characteristic,[5,11] most commonly IgG or IgA. Biclonal disease is also recognized, and rarely, nonsecretory disease. In up to 10% of cases, only monoclonal light chains are detected. It is important to assess for hypercalcemia, renal dysfunction, and integrity of the skeleton because these complications require appropriate management. A constellation of polyneuropathy, organomegaly, endocrinopathy, M protein, and skin changes characterizes a rare plasma cell dyscrasia known as POEMS syndrome.[25,26]

Plasma Cell Leukemia

This is a very rare variant of multiple myeloma, where the proliferation of plasma cells is not confined to the bone marrow but may be detected in the peripheral blood (plasma cell count $\geq 2 \times 10^9$/L or ≥20%).[27] It carries a very poor prognosis, with median survival <1 year and shortest when occurring as secondary plasma cell leukemia.[27–29] There is currently no standard therapy for this condition, but patients are usually treated with high-dose, multiagent

chemotherapeutic regimens or with experimental therapies, followed by autologous stem cell transplant.[27]

TABLE 85.2 DIAGNOSTIC WORKUP FOR PLASMA CELL NEOPLASMS

General

History and physical examination

Complete blood count and blood smear, chemistry panel including calcium and creatinine

Standard Laboratory Tests

Bone marrow aspirate and trephine biopsy or biopsy of mass if solitary lesion (clonality, immunophenotype and cytogenetic studies (both conventional cytogenetics and fluorescence *in situ* hybridization), and plasma cell labeling index)

Serum β_2 microglobulin, albumin, C-reactive protein, and lactate dehydrogenase

M component measurement:

- Serum protein electrophoresis and immunofixation for quantification of immunoglobulins
- Urine protein electrophoresis
- Free light chain measurements if conventional M component is negative or equivocal (serum and urine)

Imaging Studies

Skeletal survey

Computed tomography and magnetic resonance imaging were indicated (e.g., to visualize soft tissue tumor, detailed assessment of local disease extent and bulk, assessing vertebral column osteopenia and compression fractures, and spinal cord compression)

Fluorine-18 fluorodeoxyglucose positron emission tomography or magnetic resonance imaging should be ordered to detect and quantify occult disease if present

TABLE 85.3 STAGING OF MULTIPLE MYELOMA (DURIE SALMON SYSTEM[21])

Clinical Stage	Durie and Salmon Staging System[21]
Stage I	All of the following: • Hemoglobin >10 g/dL • Serum calcium normal • Normal bone structure or solitary plasmacytoma only • Low M component (IgG < 5 g/dL, IgA < 3 g/dL, and urine light chains <4 g/24 h)[a]
Stage II	Fitting neither stage I nor stage III
Stage III	One or more of the following: • Hemoglobin <8.5 g/dL • Serum calcium >12 mg/dL • Advanced lytic bone lesions • High M component (IgG > 7 g/dL, IgA > 3 g/dL, and urine light chains >12 g/24 h)

Subclassified:	
A	Relatively normal renal function (serum creatinine <2 mg/dL)
B	Abnormal renal function (serum creatinine ≥2 mg/dL)

[a]For solitary plasmacytoma, current recommendations are IgG < 3.5 g/dL and IgA < 2 g/dL.

TABLE 85.4 STAGING OF MULTIPLE MYELOMA (THE INTERNATIONAL STAGING SYSTEM[4] AND THE REVISED INTERNATIONAL STAGING SYSTEM[36])

	International Staging System (ISS[4])	Median Survival
ISS Stage I	Serum β_2 microglobulin <3.5 mg/L and Serum albumin ≥35 g/L	62 mo
ISS Stage II	Neither I nor III i.e., β_2 microglobulin <3.5 mg/L, with albumin <35 g/L, or β_2 microglobulin 3.5–5.5 mg/L	44 mo
ISS Stage III	Serum β_2 microglobulin ≥5.5 mg/L	29 mo

	Revised International Staging System (R-ISS[36])	Median Survival
R-ISS Stage I	ISS stage I and standard risk chromosomal abnormalities[a] (by iFISH) and normal LDH	Not reached[b]
R-ISS Stage II	Neither R-ISS stage I nor III	83 mo
R-ISS Stage III	ISS stage III and either high-risk chromosomal abnormality[a] (by iFISH) or high LDH	43 mo

[a]High-risk chromosomal abnormalities are any one of Del(17p), translocation t(4;14), or translocation t(14;16).
[b]Median follow-up 46 months.
iFISH, interphase fluorescent *in situ* hybridization; LDH, lactate dehydrogenase.

DIAGNOSTIC WORKUP AND STAGING

The recommended tests for the diagnosis of plasma cell neoplasms are outlined in Table 85.2. The most important components relate to the measurement and quantification of the M protein, bone marrow examination with ancillary cytogenetic studies, serum β_2 microglobulin and albumin, and diagnostic imaging.[30] The M protein should be measured with serum protein electrophoresis. Quantification of the monoclonal Ig with immunofixation techniques is also acceptable and especially useful if the M component is at a low level. If no M protein is detectable, assays for free light chains should be performed in the serum and in the urine (Bence Jones proteinuria). The standard imaging is the skeletal survey, as radionuclide bone scan usually does not detect lytic disease and has limited value.[19] For localized areas of concern, both computed tomography (CT) and magnetic resonance imaging (MRI) can be useful. MRI is recommended to assess the extent of vertebral disease and the presence of spinal cord or nerve root compression,[31] and even if the solitary lesion is not located in the vertebra, MRI is a good screening tool to rule out additional lesions in the spine. With advances in diagnostic imaging, it is likely that "stage migration" has occurred.[32] It has been documented that some patients with presumed SP of bone will be upstaged following the detection of multiple vertebral lesions or bone marrow disease by MRI or by 18-fluorine (^{18}F) fluorodeoxyglucose positron emission tomography (FDG-PET).[33–35] PET scan is therefore a useful screening tool, as it examines the whole body in a single study and can be helpful for clarifying ambiguous CT or MRI abnormalities. The optimal role of PET in myeloma is yet to be determined but will likely evolve rapidly,[30] and it will likely be of most benefit in nonsecretory disease. The staging criteria for the historical Durie Salmon staging system are detailed in Table 85.3.[21] The newer revised International Myeloma Staging System (rISS) is simple, validated, and of importance particularly for present and future clinical trials (Table 85.4).[36] It incorporated important cytogenetic abnormalities (e.g., del(17p), t(4;14) and t(14;16)) into the staging system. Criteria for the diagnosis of MGUS and smoldering myeloma are also well established.[13]

PROGNOSTIC FACTORS

Solitary Plasmacytoma

With respect to local control, tumor bulk appears to be an important unfavorable factor. Tumors <5 cm achieved a high level of local control with 35 Gy, whereas those ≥5 cm had a local failure rate of 58% (7 of 12 patients, total dose range 25

to 50 Gy).[17] The importance of tumor bulk is also supported by other studies.[15,37–39]

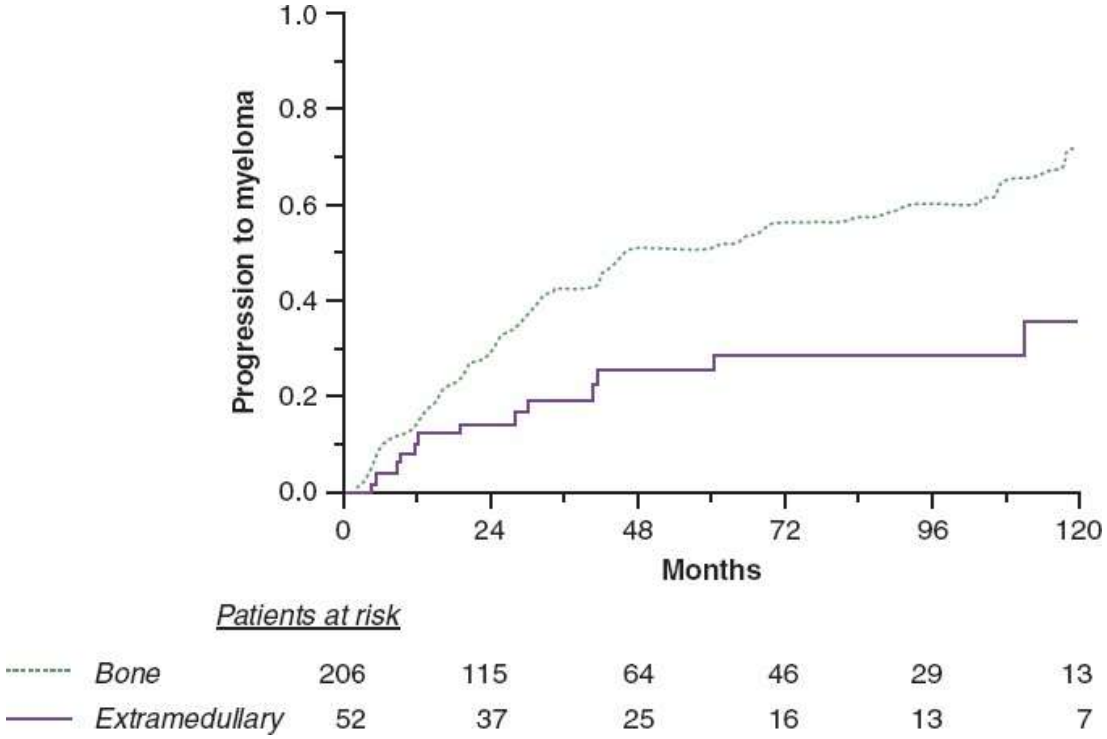

FIGURE 85.1. Probability of progression to multiple myeloma according to bone (*dotted line*) versus extramedullary (*solid line*) solitary plasmacytoma in 258 patients (P = .0009). (Reprinted from Ozsahin M, Tsang RW, Poortmans P, et al. Outcomes and patterns of failure in solitary plasmacytoma: a multicenter Rare Cancer Network study of 258 patients. *Int J Radiat Oncol Biol Phys* 2006;64[1]:210–217. Copyright © 2006 Elsevier. With permission.)

Age is a factor that affects the risk of progression to myeloma in some series[17,40–43] but not in others.[15,37–39,44,45] A bony presentation has been consistently demonstrated to have a significantly higher risk of subsequent development of myeloma with a 10-year rate of 76% compared with an extramedullary presentation where the 10-year rate was 36%[15] (Fig. 85.1). Subclinical bone disease, either detected as generalized osteopenia[46] or abnormal MRI scan of the spine,[31,47–49] predicts for rapid progression to symptomatic multiple myeloma. In the updated International Myeloma Working Group (IMWG) criteria for the diagnosis of multiple myeloma, MRI detection of more than one focal lesion in bone (of 5 mm or more in size) is recognized as multiple myeloma.[13] A suppression of the normal immunoglobulin classes has been shown to correlate with a higher risk of progressing to myeloma.[46,50] Where there was an elevation of M protein pretreatment, persistence of the M

protein following radiation therapy (RT) predicts for progression to myeloma.[20,51] Many of these factors reflect the presence of occult myeloma. Therefore, it is not surprising that generalized disease becomes manifest once the local disease is controlled. Pathologic factors have been examined in some studies, with the finding that anaplastic plasmacytomas (those with a higher histologic grade)[52] and those tumors expressing a high level of angiogenesis are associated with a poor outcome.[53] Anaplastic plasmacytomas share some common pathologic and clinical features with aggressive B-cell lymphomas (plasmablastic type) and can arise in the context of immunosuppression and Epstein-Barr virus infection.[54,55]

Multiple Myeloma

Analysis of over 1,000 patients evaluated at the Mayo Clinic revealed the following adverse prognostic risk factors: Eastern Cooperative Oncology Group performance status 3 or 4, serum albumin <3 g/dL, serum creatinine ≥2 mg/dL, platelet count <150,000/μL, age ≥70 years, β_2 microglobulin >4 mg/L, plasma cell labeling index ≥1%, serum calcium ≥11 mg/dL, hemoglobin <10 g/dL, and bone marrow plasma cell percentage ≥50%.[5] The ISS[4] and the revised ISS[36] have been validated to assist in prognostication. For the original ISS, over 10,000 patients were evaluated, and the three-stage system was developed based on two variables: serum albumin and β_2 microglobulin in the original ISS. In the revised ISS, cytogenetic abnormalities associated with a worse prognosis were also incorporated[36] (Table 85.4). These include del(17p), t(4;14), and t(14;16) detected with fluorescence *in situ* hybridization.

MANAGEMENT OF SOLITARY PLASMACYTOMA

RT is the standard treatment for SP. Surgery should be considered for structural instability of bone or rapidly progressive neurologic compromise such as spinal cord compression.[18] For patients treated with gross tumor excision, RT is still indicated because of a high likelihood of microscopic residual disease. Surgery alone without RT leads to an unacceptably high local recurrence rate.[15] A review of the literature for solitary bone plasmacytoma (Table 85.5) indicates a high local control rate with RT (79% to 95%), yet a modest overall survival rate of approximately 50% at 10 years. This is due to a high rate of progression to multiple myeloma in the bone plasmacytomas, a finding consistently reported from all series.[14,17,18,20,37,40–42,44,46,51,56,58] As shown in Table 85.5, over 60% of

patients with solitary bone tumor progressed to myeloma, at a median of 2 to 3 years after treatment. When actuarial methods were not used, the progression rate is slightly lower (crude rate ranges, 53% to 54%).[37,56] Therefore, SP of bone appears to be an early form of multiple myeloma. Studies have documented about 29% to 50% of patients with apparent SP will have multiple asymptomatic lesions detected in the spine on MRI.[30,31,47,49,59] If characteristic additional lesion(s) of 5 mm or more in size are detected, the patient satisfies the diagnostic criteria for multiple myeloma and should be treated as such.[13] With more routine use of MRI and/or FDG-PET as part of the diagnostic workup to rule out multiple myeloma, going forward there is likely stage migration with truly solitary patients remaining eligible for definitive RT alone as initial treatment strategy. One of the larger series of patients with SP treated prior to 2001 showed that the progression rate to myeloma following RT is more rapid in the first 3 years (~14% per year), compared to the subsequent 7 years (~3% to 4% per year), reaching a 10-year rate of 65%.[15] This suggested that subclinical myeloma existed in up to 40% of the patients at the time of initial RT. It is likely that sensitive imaging tests initially would identify these patients and alternate approaches such as chemotherapy with novel agents +/− RT being more appropriate.[60] The presence of low level M protein preradiation is extremely common and is not associated with a higher risk of progression to multiple myeloma. However, its persistence following radiation is highly predictive of subsequent systemic failure,[20,42,51,61] attesting to the importance of monitoring this as part of posttreatment follow-up. It has been observed that some patients recur with plasmacytoma(s) of bone or soft tissues, without bone marrow involvement.[37,40,62,63] This is infrequent, and the subsequent development of multiple myeloma is high, 75% in one series.[40]

The addition of adjuvant chemotherapy is theoretically attractive, both in enhancing local control and eradicating subclinical disease to prevent the development of myeloma. One randomized trial suggested a benefit with adjuvant melphalan and prednisone given for 3 years after RT.[64] With a median follow-up of 8.9 years, those treated with chemotherapy had a myeloma progression rate of 12%, whereas with RT alone, it was 54%. However, this was a small study, and the risk of diminishing stem cell reserve or inducing leukemia makes the prolonged use of alkylating agents an undesirable treatment option for most patients. The use of adjuvant novel agents, such as proteasome inhibitors (e.g., bortezomib) or immunomodulatory drugs (IMiDs, e.g., lenalidomide), is theoretically attractive, both in enhancing local control and eradicating

subclinical disease to prevent progression to myeloma. Pilot data indicate feasibility of combining novel agents with RT,[65,66] and this approach is under active investigation in the United Kingdom in a phase III clinical trial, examining the potential role of adding lenalidomide and dexamethasone to definitive RT (https://clinicaltrials.gov/ct2/show/record/NCT02544308).

In the management of EMP, although complete surgical excision may be curative for small lesions,[67] most patients with larger lesions or with tumor location not amenable to complete excision should receive local RT. Postoperative RT is indicated for incompletely excised lesions. In contrast to bone plasmacytoma, EMPs are frequently controlled with local radiation (Table 85.6), with a lower rate of progression to myeloma, ranging from 8% to 44%,[15,16,39,52,62,67,69–72,74] indicating a significant proportion of patients are cured of their disease. Although the 10-year survival varies widely in the reported literature (range, 31% to 90%), the two larger series report survival rates of 76% at 5 years[74] and 72% at 10 years.[15] The issue of dose will be discussed later.

Initial Treatment of Symptomatic Multiple Myeloma

Patients who have symptomatic multiple myeloma require treatment of the malignant plasma cell clone. Once the decision is made to treat, however, the first step is to determine candidacy for autologous stem cell transplantation (ASCT).[11] As this modality has become the standard of care for eligible patients, it is necessary to stratify patients initially so that the ability to collect stem cells is not compromised by induction therapy.[76]

Patients Eligible for Autologous Stem Cell Transplantation

In patients who are candidates for ASCT, various regimens can be used to induce response prior to stem cell collection. Historically, most regimens were steroid based, either with high-dose dexamethasone alone or with vincristine, Adriamycin (doxorubicin), and dexamethasone (VAD).[77,78] Newer agents that have been validated in the relapse setting are now being used as initial therapy with superior results, including bortezomib and lenalidomide. Both have been routinely adopted into initial treatment[79] or for relapsed disease.

[a]Crude rate.
[b]Multiple institutions.

Bortezomib

Bortezomib was the first proteasome inhibitor to be used in clinical trials and has demonstrated efficacy and safety in frontline therapy when used in combination. Indeed, response rates have dramatically improved when compared with VAD or dexamethasone alone. A randomized comparison of bortezomib plus dexamethasone (BD) versus VAD as induction therapy before ASCT showed that BD produced superior complete response or near-complete response: 14.8% versus 6.4%, at least very good partial response: 37.7% versus 15.1%, and overall response: 78.5% versus 62.8% than that of VAD. Median progression-free survival was 36.0 months (BD) versus 29.7 months (VAD; P = .064).[80] Even as a single agent, with dexamethasone or with doxorubicin, bortezomib has remarkable efficacy and safety in initial therapy.[81] It is often the preferred agent in patients with renal insufficiency and high-risk disease. Its greatest challenge, however, remains neuropathy, occurring in 13% to 15% of patients at ≥grade 3; this may be helped, however, with weekly use[82] or when given subcutaneously.[83]

Lenalidomide

Lenalidomide is an immunomodulatory drug derived from thalidomide that has also been shown to be effective, both as upfront therapy and in relapsed disease. It is most commonly used in combination with low-dose dexamethasone.[84] A phase III trial of lenalidomide with low-dose dexamethasone versus lenalidomide with high-dose dexamethasone found that despite a higher rate of complete or partial response with high-dose therapy, overall 1-year survival was 87% in the high-dose group versus 96% in the low-dose group (P = .0002), largely because of the significant toxicity of the former. As a result, the trial was stopped and patients on high-dose therapy were crossed over to low-dose therapy. Three-year overall survival rates now exceed 85%. This has resulted in the extensive use of this combination in upfront myeloma.[84]

Lenalidomide has also been used in combination with conventional chemotherapy and most recently with bortezomib.[79,85] This has resulted in even higher response rates and complete response rates of >50%. The combination of lenalidomide, bortezomib, and dexamethasone (RVD) gave a complete response/very good partial response rate of 77% and is adopted as a standard of care by many centers.[79]

Thalidomide

Early reports indicate that thalidomide and dexamethasone (TD) yields a response rate of 64% (similar to VAD), without compromising the ability to

collect stem cells, but with a rate of deep vein thrombosis of 12%.[86] The Medical Research Council Myeloma IX trial compared cyclophosphamide–thalidomide–dexamethasone (CTD) with cyclophosphamide–VAD as induction before ASCT. The complete response rate was 20.3% after CTD and 11.7% after cyclophosphamide–VAD,[87] lower than other regimens cited above.

In summary, preferred initial regimens include bortezomib- and/or lenalidomide-based combinations, whereas thalidomide or doxorubicin is very infrequently used in current practice.

Patients Not Eligible for Autologous Stem Cell Transplantation

In patients who will not be undergoing a transplant often because of a combination of advanced age, comorbidities, and unfit health status,[11,88] there are various options available for initial therapy. Historically, most transplant-ineligible patients received melphalan and prednisone (MP), which produced partial remissions in approximately 55% of patients, with the occasional complete response.[89] San Miguel et al.[90] reported the results of a randomized trial of 682 patients randomized to receive either nine 6-week cycles of MP or the same chemotherapy with bortezomib. The addition of bortezomib increased the proportion of patients achieving complete response (30% and 4%, $P < .001$) and improved median duration of response (19.9 vs. 13.1 months), time to progression (24.0 vs.16.6 months; $P < .001$), and the risk of death (hazard ratio 0.61 for the bortezomib group; $P = .008$).

The addition of thalidomide to melphalan and prednisone (MPT) also improves outcome compared with MP alone.[91,92] However, thromboses were more common with thalidomide with an incidence of 12% (vs. 2% in the MP group). The median progression-free survival was 21.8 months for MPT and 14.5 months for MP ($P = .004$).[92] A meta-analysis of MP versus MPT concluded that MPT increases response rates and overall survival but with increased toxicity such as thrombosis and somnolence.[93] In the FIRST randomized trial, lenalidomide and dexamethasone (LD) when used continuously (until disease progression) gave a better median PFS (25.5 months) when compared with MPT (median PFS 21.2 months, $P < .001$), and 4-year overall survival was also improved (LD regimen 59%, MPT regimen 51%, $P = .02$).[94] These results provide several options for the initial therapy of patients who will not proceed to ASCT, with preference for a lenalidomide-based regimen approach[94,95] and elimination of alkylator (melphalan) therapy altogether.[95] Geriatric assessment with a recognized scoring system is an important part of patient evaluation for

those over the age of 65 and with comorbidities or physical and/or cognitive impairment, as those who are frail tolerate treatment less well and have a poorer prognosis.[96]

Autologous Stem Cell Transplantation

ASCT has become the standard of care for eligible patients, as it has been demonstrated in multiple trials to improve the likelihood of complete response, prolong disease-free survival, and extend overall survival.[11,79,97,98] ASCT is still important even with highly effective induction therapy consisting of RVD regimen, as shown in a recently completed phase III trial of comparing RVD (eight cycles) with RVD (three cycles) followed by ASCT and then two further cycles of RVD.[79] Treatment-related mortality rates are now <2%, and often the transplant can be performed entirely as an outpatient. Melphalan 200 mg/m^2 is the most commonly used conditioning regimen, although it may be reduced in elderly patients or patients with renal insufficiency.

Tandem Transplantation

Tandem or double transplantation refers to a planned second ASCT after the patient has recovered from the first. A phase III trial in France evaluated tandem transplant versus single ASCT and demonstrated superior overall survival in the tandem group[99]; however, when further analyzed, the patients who benefited most from the second transplant were those who did not achieve a 90% reduction in their disease after the first ASCT. Therefore, it may be more prudent to consider tandem transplantation only in patients whose response to the first ASCT is suboptimal.

Allogeneic Stem Cell Transplantation

Myeloablative stem cell transplant is perhaps the only current potential cure for patients with myeloma, as the graft is not contaminated with tumor cells and may produce a profound graft versus myeloma effect.[100] However, its use is very limited because of the lack of donors, age restriction, high treatment-related mortality, and graft versus host disease. Reduced intensity nonmyeloablative allogeneic transplant following ASCT has also been investigated as a means of inducing a graft versus myeloma effect. In one study of 102 patients undergoing nonmyeloablative transplant, 5-year overall survival and progression-free survival were 64% and 36%, respectively, although the 5-year rate of nonmyeloma mortality was 18%.[101]

Maintenance Therapy

Much investigation of late has been directed at the use of maintenance therapy post-ASCT to prolong remission and survival. Two large randomized trials used maintenance lenalidomide versus placebo, with prolongation of progression-free survival by approximately 20 months.[102,103] Overall survival was similar in the European trial,[102] whereas the US trial showed a statistically improved survival with lenalidomide maintenance (3-year survival 85% vs. 77% with placebo).[103] The use of maintenance therapy post-ASCT is now considered the standard of care, with the use of lenalidomide for a duration of 1 year.[79]

Relapse after Autologous Stem Cell Transplantation

The general approach to myeloma is to provide sequential therapies to patients, knowing each will not be curative but will prolong the period of disease control. The goal is to convert the disease into a chronic illness. Whereas there used to be very limited treatment options, the armamentarium available has grown considerably over the past few years. This has contributed to a prolongation of the median survival of patients with myeloma. Patients will relapse after a median of 2 years after the first ASCT, and several options may be pursued for treatment (Table 85.7). The most commonly used agents are again the two key drugs in myeloma: bortezomib and lenalidomide. Both have been validated extensively in relapsed disease. Even with retreatment, these agents can confer prolonged progression-free and overall survival.

TABLE 85.7 TREATMENT OPTIONS FOR RELAPSED MULTIPLE MYELOMA

Conventional Therapy
Repeated courses of alkylator-based therapy (melphalan)
Cyclophosphamide (IV or PO) and steroids

Transplantation
Second autologous stem cell transplant

High-Dose Chemotherapy
DTPACE
High-dose cyclophosphamide

Novel Agents
Thalidomide
Proteasome inhibitors: bortezomib, carfilzomib
IMiDs: lenalidomide, pomalidomide
Monoclonal antibodies: elotuzumab, daratumumab
Immune check point drugs: pembrolizumab and others

Combination Conventional and Novel Agent
CyBorD (cyclophosphamide, bortezomib, dexamethasone)
CRD (cyclophosphamide, lenalidomide, dexamethasone)
Vel-Doxil (bortezomib, liposomal doxorubicin)

DTPACE, dexamethasone, thalidomide, cisplatin, doxorubicin, cyclophosphamide, and etoposide; IV, intravenous; PO, by mouth.

The most promising agents that are being added to this list are carfilzomib,[104] pomalidomide, elotuzumab, and daratumumab. Carfilzomib is an irreversible proteasome inhibitor with significant activity in relapsed myeloma. Pomalidomide is a novel IMiD, in the family of thalidomide and lenalidomide, that has also demonstrated efficacy in relapsed myeloma, even in patients refractory to both bortezomib and lenlidomide.[105,106] Elotuzumab and daratumumab are monoclonal antibodies targeting a glycoprotein SLAMF-7[107] and CD38,[108,109] respectively, both showing activity as single agents or in combination with lenalidomide and dexamethasone.

Supportive Care

A description of therapy of myeloma would not be complete without addressing the need to treat not only the disease itself but also the complications of this disease. Erythropoietic agents assist in the management of chemotherapy-induced anemia, leading to reduction of transfusions. Bisphosphonates are critical to the optimal therapy of bone disease and may even have an effect on overall survival in certain patients.[87,110]

Local RT for bony disease remains valuable in pain control and debulking disease. Patients often present with bony disease and anemia; both of these complications are treatable, allowing an improved quality of life. Newer surgical techniques such as vertebroplasty and kyphoplasty are also being used to improve back pain and spinal symptoms.[111]

RADIATION THERAPY OF MULTIPLE MYELOMA

Total Body Irradiation

Some high-dose chemotherapy protocols for multiple myeloma incorporate total body irradiation (TBI) into the conditioning regimen. Because of toxicity concerns (mucosal and hematologic) with TBI, many programs use chemotherapy alone, most commonly melphalan. A phase III French study (IFM [Intergroupe Francophone du Mye'lome] trial 9502) examined melphalan 200

mg/m^2 alone (M200) versus melphalan 140 mg/m^2 with TBI, 8 Gy in 4 fractions (M140/TBI),[112] and found that patients in the TBI-containing arm suffered more grade 3 or 4 mucosal toxicity, heavier transfusion requirement, and longer hospitalization stay. There was a higher toxic death rate in the M140/TBI arm (3.6% vs. 0% for the M200 arm). The event-free survival was no different between the two treatments, but the 45-month overall survival favored the M200 arm (M200: 65.8%; M140/TBI: 45.5%; P = .05). TBI is now rarely used in conditioning regimens for ASCT, unless it is part of a research clinical trial.

Hemibody Radiation

Diffuse bone pain involving wide areas of the skeleton can be effectively palliated by half-body radiation with single doses of 5 to 8 Gy,[113–115] although this is rarely used now. The bone marrow in the unirradiated half body serves as a stem cell reserve and will slowly repopulate the irradiated marrow after treatment. The dose for upper half body should not exceed 8 Gy because of lung tolerance.[116] The main toxicity is myelosuppression. The use of hemibody radiation must be carefully considered in patients heavily pretreated with chemotherapy. Growth factor support may be helpful, whereas transfusions of blood products should be given as needed. The sequential hemibody radiation technique has been used in phase II[117,118] and phase III trials as “systemic” treatment to control myeloma, in patients with or without skeletal pain. A phase III trial by the South West Oncology Group included newly diagnosed patients treated initially with chemotherapy, with complete responders randomized to sequential hemibody radiation (7.5 Gy in 5 fractions, upper hemibody, followed 6 weeks later by lower hemibody) or further chemotherapy.[119] Survival in this trial was significantly poorer with radiation compared with chemotherapy. At present, there is no standard role for sequential hemibody radiation as systemic treatment for myeloma outside of a clinical trial.

Local External Beam for Palliation

The most common use of RT in the management of plasma cell tumors is for palliative treatment of bony disease[113,120–124] and relief of compression of the spinal cord,[125–127] cranial nerves, or peripheral nerves. It has been estimated that approximately 40% of patients with multiple myeloma will require palliative radiation therapy for bone pain at some time during the course of their disease.[128] In practice, the actual proportion is lower than estimated, varying from 24% to 34%, leading investigators in Australia to suggest that this

potentially useful modality of treatment has been underutilized, even taking into account the beneficial effect of bisphosphonates, particularly for the elderly.[128] Palliative RT to the spine reduces the incidence of future vertebral fractures or the appearance of new lesions.[129] However, the role of RT in preventing impending pathologic fracture is unclear. In general, lesions at high risk for pathologic fracture should be referred for surgical stabilization, and RT can be administered after surgery for control of residual disease at the local site. Similarly, surgical intervention (decompression with or without stabilization) is indicated in patients who have structural compromise because of vertebral disease, for example, a bone fragment displaced into the spinal canal, and/or vertebral instability. Usually surgery is performed first, with radiation therapy considered in the postoperative period usually 4 to 6 weeks after surgery to allow for adequate healing.

When RT is given for pain because of disease involving a long bone, a local field suffices. It is unnecessary to treat the entire bone.[130] Doses of 10 to 20 Gy (in 5 to 10 fractions) are effective, although the pain relief is often partial.[131] Leigh et al.[121] found a symptomatic response rate of 97% (complete pain relief in 26% and partial relief in 71%) after an average dose of 25 Gy given to 306 sites in 101 patients. There was no dose–response relationship above 10 Gy. Recurrence of symptoms requiring further treatment was seen in 6% of sites after a median of 16 months. Similar results are also reported by Matuschek et al., with complete pain relief in 31% and partial relief in 54%, with median RT dose of 25 Gy.[124]

It is not clear if pain relief is better if RT is given concurrently with chemotherapy. A study by Adamietz et al.[120] reported complete pain relief in 80% of patients receiving RT with chemotherapy, compared with 40% among those receiving RT alone. In contrast, Leigh et al.[121] found no significant difference in pain relief when RT was given with or without concurrent chemotherapy. With the use of novel agent–based chemotherapy given concurrently with RT, Shin et al.[132] reported no increase in toxicity in 31 patients.

For spinal cord compression, motor improvement is expected in approximately 50% of irradiated patients. A multicenter study (not restricted to myeloma patients) suggested that a longer fractionated regimen (30 Gy in 10 fractions or higher) was associated with better neurologic recovery than 20 Gy in 5 fractions or a single 8 Gy,[133] although another recent prospective randomized trial showed that 20 Gy in 5 fractions was equivalent to 30 Gy in 10 fractions in

terms of 6-month functional outcome and local control.[134] With the availability of newer drugs, the advantage of radiation-sensitizing effects with drug–radiation combinations requires continued investigation, both in terms of enhancing local control[135] and possible toxicity. Bortezomib and spinal radiation given concurrently was reported to result in severe enteritis.[136,137] The use of bisphosphonates (e.g., pamidronate) has been shown to reduce skeletal complications and pain,[138] with a reduction of the use of RT from 50% to 34% in one study.[139]

Radioimmunotherapy Approaches

Bone-seeking radiopharmaceuticals targeting the bone marrow have been studied as an alternative to TBI. Typically, a β-emitting isotope is conjugated to a phosphonate complex, such as samarium-153-ethylene diamine tetramethylene phosphonate (^{153}Sm-EDTMP or Quadramet). The isotope also emits a γ-ray, permitting scanning to locate areas of uptake. This agent has been used for palliation of bone metastasis.[140] The feasibility of this approach in a small number of myeloma patients has been reported for stem cell transplantation.[141] Another bone-seeking pharmaceutical is holmium-166-DOTMP (^{166}Ho-1,4,7,10-tetraazacyclododecane-1,4,7,10-tetramethylene-phosphonic acid), with a higher energy β emission (maximum energy 1.85 MeV) than ^{153}Sm and a shorter $T_1/_2$ of 26.8 hours.[142] It also has a γ emission (81 KeV) suitable for imaging. With the ability to deliver much higher doses to the bone marrow than TBI, in the range of 30 to 60 Gy, yet sparing the dose-limiting normal tissues such as lung, mucosa, and kidneys, the concept of targeted radiation therapy is tantalizing. However, there remains a problem of heterogeneity of uptake in the skeleton, and the dosimetric variation may be even larger at a microscopic level because of the limited range of the β particle. Whether this approach will have a more favorable therapeutic ratio than standard conditioning regimens in the transplant setting awaits larger-scale phase II and phase III trials.

RADIATION THERAPY TECHNIQUES

Radical Radiation Therapy for Local Control of Solitary Plasmacytoma

Accurate evaluation of tumor extent is an important feature of radical RT for SP. MRI is useful to evaluate the extent of disease both within and beyond bone. This is particularly true for the paranasal sinuses, where inflammatory changes

may be difficult to distinguish from tumor on CT imaging. FDG-PET is also complimentary and if available can replace MRI for screening of occult systemic disease in the spine or elsewhere.

There are few data to support specific guidelines regarding RT treatment volumes. CT and MRI imaging should be used to determine gross tumor volumes. Clinical target volumes (CTV) should encompass probable routes of microscopic spread, recognizing that barriers to the extension of local disease will vary according to anatomic location, as will the morbidity of treating adjacent normal tissues (Fig. 85.2). For the spine, the historical practice of inclusion of two vertebral bodies above and below the grossly involved vertebra(e) should be abandoned. Three-dimensional planning should always be used (except for a small skin lesion that can be treated with superficial x-rays or high-energy electrons guided by clinical examination), and the "involved field" terminology is no longer preferred, rather the "involved site" concept should be adopted similar to the published guidelines for Hodgkin[143] and non-Hodgkin lymphomas.[144,145]

For RT of a lesion involving a long bone, although coverage of the entire involved bone has been recommended by some authors, a study of palliative RT to only the symptomatic area for multiple myeloma found that recurrence in the untreated portion of the involved bone was rare.[130] Similarly, no marginal recurrences were seen among 30 patients with SP treated with RT that encompassed only the tumor with a margin.[146] Prophylactic regional nodal coverage is not necessary in SP of bone as multiple studies have found a very low risk of regional nodal failure after involved site radiation without intentional coverage of adjacent nodes (i.e., 0% to 4%).[17,51,146] For EMP, nodal involvement at presentation is observed in 10% to 20%, and occasional nodal failure in the literature led to a common practice of extending the RT coverage to the draining lymph node region.[18] Some authors specifically recommend this practice if the primary disease involves a lymphatic structure (e.g., lymph nodes or Waldeyer ring).[18,38,62] However, this is controversial as some series reported a low incidence of regional nodal failure without routine prophylactic nodal irradiation,[39,42,52,63,71] leading to variation in practices between centers.[16] After reviewing their own series of 26 patients with EMP and contrasting the results with the literature, Strojan et al.[16] concluded that prophylactic nodal radiation is probably unnecessary. With the advent of more routine use of MRI and FDG-PET, elective nodal coverage likely has little or no benefit, unless the clinical scenario is persuasive such as a very bulky primary disease in proximity to the

drainage lymph node station.

In determining the CTV, using the GTV plus a margin of 1 to 3 cm is reasonable (depending on the site) respecting anatomic boundaries. A GTV to CTV expansion of 0.5 to 1 cm in the axial plane may be appropriate for covering potential microscopic extension in soft tissues, for example, in the head and neck area. However for a long bone site, for example the femur, the proximal and distant expansion should be increased to 2 to 3 cm. Planning target volumes (PTV) should account for day-to-day setup variation and will typically add 5 to 10 mm around CTV volumes depending on the immobilization technique employed (Fig. 85.2). Although parallel-opposed fields are commonly adequate to encompass disease without significant irradiation of normal tissues, CT-based planning and the use of conformal techniques, including intensity-modulated radiation therapy, should be employed when needed to treat the PTV adjacent to critical structures. This can be particularly important in extramedullary disease involving the paranasal sinuses, where avoidance of the optic structures and salivary glands is desirable.

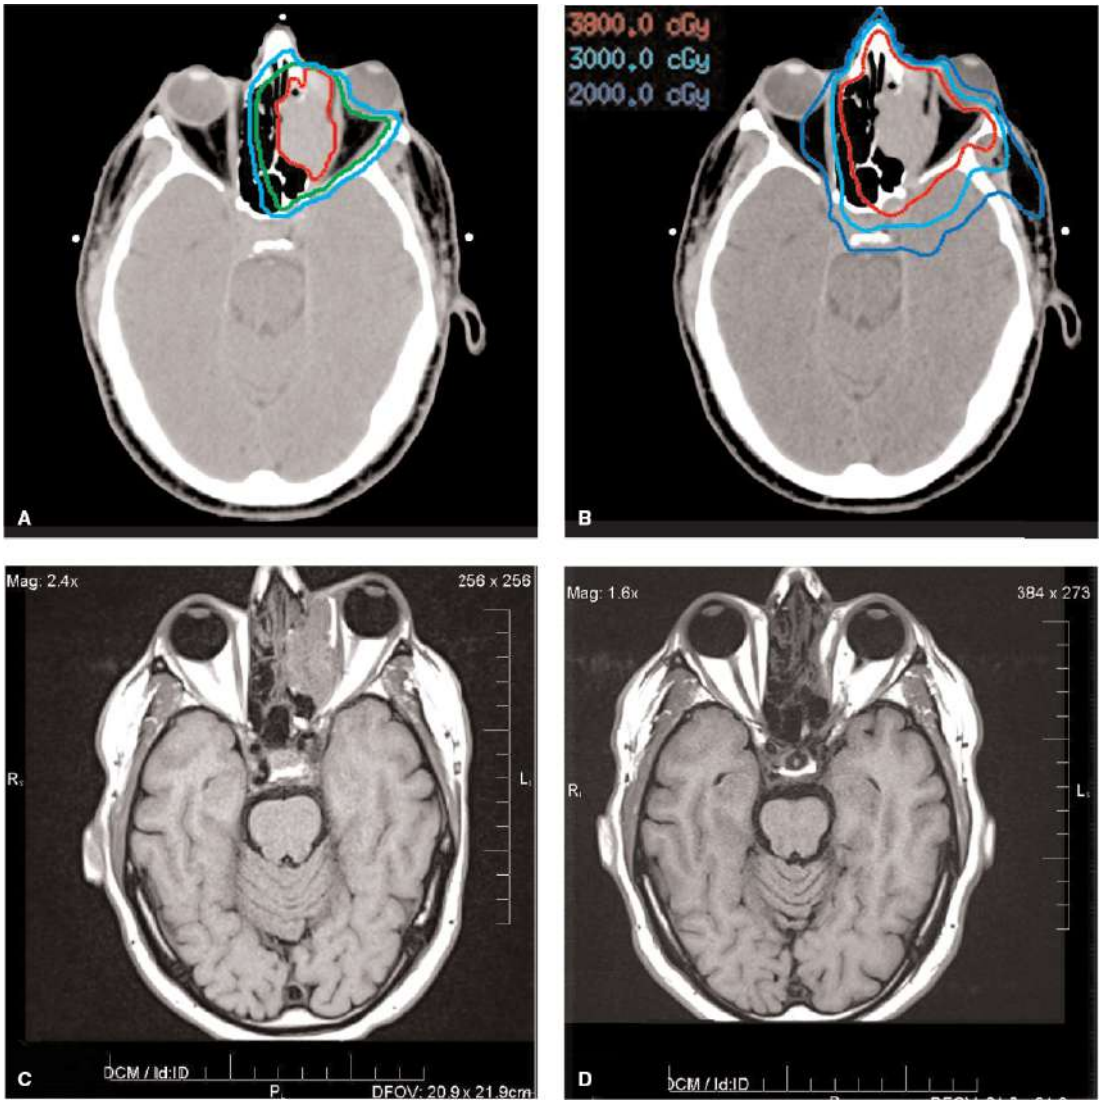

FIGURE 85.2. Radiation treatment plan for a solitary plasmacytoma of the left orbit **(A)**. The entire orbit was contoured as the clinical target volume and received 36 Gy; the gross tumor volume received a subsequent boost to a total of 40 Gy **(B)**. The initial mass on magnetic resonance imaging resolved 6 months after treatment **(C,D)**.

Radiation Therapy Dose

Studies evaluating RT dose–response in plasmacytoma have produced differing results. Most studies have found response rates >85% among patients treated with ≥35 Gy; some investigators have found better local control following doses ≥45 Gy,[22,56] whereas others have found no indication of improved outcome with higher doses.[15,146] Based on a dose–response analysis of 81 patients by Mendenhall et al.[147] reported in 1980, a minimum dose of 40 Gy was recommended, including osseous and extramedullary lesions. A total dose of 40 Gy and above resulted in a local failure rate of 6% versus 31% for lower doses.

Therefore, the usual practice is to administer a dose of 40 to 45 Gy or even higher for bulky tumors. However, in the largest of these studies (*n* = 258), there was no evidence of improved local control with RT doses ranging from 30 to 50 Gy, including a subset of patients with tumors >4 cm.[15] In fact, there was a worse local control rate for the group receiving total dose ≥50 Gy although not statistically significant.[15] It should be noted, however, that retrospective studies of dose–response are typically confounded by selection bias, as higher doses are prescribed to larger tumors with worse prognosis. Several studies have demonstrated durable local control in >85% of tumors <5 cm with 35 to 40 Gy, and there is little evidence that higher doses are necessary for small tumors, regardless of bone or EMP locations. In contrast, plasmacytomas >5 cm have worse local control,[15,17,39] and doses of 45 to 50 Gy are recommended in these bulkier tumors, which also tend to be EMPs. However, one should be aware that the quality of evidence supporting the use of higher RT doses is limited, and local failures are occasionally observed even after doses of 50 Gy or higher.[15,17,42]

Assessment of Response and Follow-Up

Reimaging is of greatest value in the response assessment of EMP. Repeat imaging, preferably with MRI and/or FDG-PET scan, should be done approximately 6 to 8 weeks following completion of treatment. It is rare to have symptoms suggestive of local progression that necessitate reimaging prior to this. It is common for a residual soft tissue abnormality to persist on follow-up imaging, and periodic reimaging may be required every 4 to 6 months until any residual mass disappears or remains stable on consecutive scans. It is generally not beneficial to continue to reimage a stable abnormality.

Bone destruction caused by tumor can produce persistent abnormalities on imaging following RT for painful bone metastases or isolated plasmacytoma of bone. Consequently, repeat imaging is of less value in establishing response in such cases.

With a high risk of recurrence of disease as multiple myeloma, the occurrence of new bone pain requires further investigations, including imaging as appropriate. Repeat measurement of the M protein often detects the onset of systemic disease prior to the development of symptoms and can be used as an indicator of disease burden.[20,148] Complete blood counts should be taken periodically to evaluate bone marrow function. A team of international investigators have developed recommendations for uniform response criteria for

assessing the treatment of multiple myeloma.[149]

The RT doses used for myeloma are rarely associated with significant delayed side effects. Treatment of significant volumes of the parotid or submandibular glands may result in prolonged xerostomia and should be avoided. As noted previously, TBI has been associated with significant toxicity and is not widely used. Evaluation of renal function should be undertaken prior to initiating RT, which may include the kidneys, and blood counts should be evaluated prior to treating a large volume of bone marrow in the spine or pelvis. Reirradiation of vertebral metastases is possible, but careful evaluation of all prior RT records is required to ensure that the tolerance of the spinal cord is not exceeded.

Bone aand Soft Tissue

CHAPTER 86

Osteosarcoma and Other Primary Tumors of Bone

Jaroslaw T. Hepel and Timothy J. Kinsella

Primary malignant tumors of bone are rare neoplasms accounting for <0.2% of all cancers. In 2010, an estimated 2,650 new cases and 1,460 related deaths were expected.[1] Osteosarcoma, chondrosarcoma, and Ewing sarcoma are the most common, comprising 35%, 30%, and 16% of cases, respectively. Other rare entities include malignant fibrous histiocytoma, fibrosarcoma, and chordoma. Ewing sarcoma is discussed in detail in Chapter 92. Osteosarcoma and the other malignant bone tumors will be discussed here.

OSTEOSARCOMA

Epidemiology

Osteosarcoma is a rare primary malignant tumor of bone, accounting for approximately 750 to 900 new cases in the United States annually. Despite its rarity, osteosarcoma is the fifth most common malignancy and the most common malignant bone tumor in children and adolescents.[2,3] It has a bimodal age distribution, with peak incidence in early adolescence and another smaller peak in adults older than 65 years of age.[4] In childhood, osteosarcoma typically occurs sporadically, whereas in adulthood, it is more commonly associated with sarcomatous degeneration of Paget disease or other benign bone lesions. There is a slight male predilection, with a ratio of 1.2:1.[2]

Pathogenesis and Risk Factors

The etiology of osteosarcoma is unknown, but there is a suggestion of a relationship with rapid bone growth. The peak incidence of osteosarcoma occurs during the adolescent growth spurt; this peak is earlier in girls corresponding to their earlier bone development. The most frequent sites of involvement

correspond to the areas of greatest increase in bone length—the metaphysis of the distal femur, proximal tibia, and proximal humerus. It has been suggested that an aberration in the natural process of bone growth leads to osteosarcoma, but the specific etiology has not been elucidated. Unlike other pediatric tumors, no characteristic translocation or genetic abnormality has been defined for osteosarcoma.

Several risk factors have been associated with osteosarcoma. Development of osteosarcoma after radiation therapy exposure in childhood has been reported. The mean latency period is generally >10 years.[5–7] Similarly, chemotherapy, especially alkylating agents, has been implicated with secondary osteosarcoma.[7] Benign bone lesions, particularly Paget disease, have also been associated with osteosarcoma. Paget disease of bone is a focal skeletal disorder characterized by accelerated bone turnover. Sarcomatous transformation is usually seen in long-standing Paget and occurs in only 0.7% to 1% of cases.[8] Other benign bone lesions have also been associated with risk of osteosarcoma, including chronic osteomyelitis, multiple hereditary exostoses, fibrous dysplasia, osteochondromas, enchondromas, sites of bone infarcts, and sites of metallic implants.[9] Several genetic conditions have been linked to an increase risk of osteosarcoma. Retinoblastoma is associated with an increased risk of secondary tumors, more than half of which are soft tissue sarcomas and osteosarcomas.[10] Li-Fraumeni syndrome is associated with a spectrum of malignancies, including breast, adrenocortical, brain, leukemia, and sarcomas, including osteosarcoma. Li-Fraumeni syndrome involves a germline inactivation of p53, a key cell cycle regulatory gene.[11] Rothmund-Thomson, Bloom, and Werner syndromes have also been associated with osteosarcoma.[12]

Clinical Presentation

Most patients present with localized pain in the affected bone. Pain is usually of several months duration and may wax and wane. There may be associated soft tissue swelling or a palpable mass. Some patients present with pathologic fracture. Osteosarcoma has a predilection for involvement of the metaphysis of long bones. The most common site of involvement is the knee (distal femur or proximal tibia), followed by the proximal humerus, mid and proximal femur, and then other bones.[13] Although most patients have micrometastatic disease at the time of presentation, only 10% to 20% of patients present with clinical evident macrometastases. The lung is the most common site of metastatic involvement, followed by bone.[14]

Diagnostic Evaluation

Plain x-ray of the affected bone classically demonstrates destruction of the normal trabecular bone with lytic and/or sclerotic lesions, osteoid formation under the periosteum (Codman triangle), and variable ossification of the associated soft tissue mass (Fig. 86.1). Magnetic resonance imaging (MRI) of the affected bone is essential to fully delineate the extent of the lesion, evaluate any soft tissue component, and evaluate for involvement of joint, nerves, and vasculature (Fig. 86.2). The entire affected bone should be imaged to evaluate for the presence of skip lesions. Skip metastases are well recognized in osteosarcoma but occur infrequently, with <5% incidence.[15,16] Systemic staging should include a computed tomography (CT) scan of the chest and radionuclide bone scan to evaluate for pulmonary and bone metastases, respectively. Positron emission tomography (PET) scan can be used as an alternative for systemic staging but may have less sensitivity than CT and bone scan.[17,18] PET scan has also been used to assess response to preoperative chemotherapy.[19]

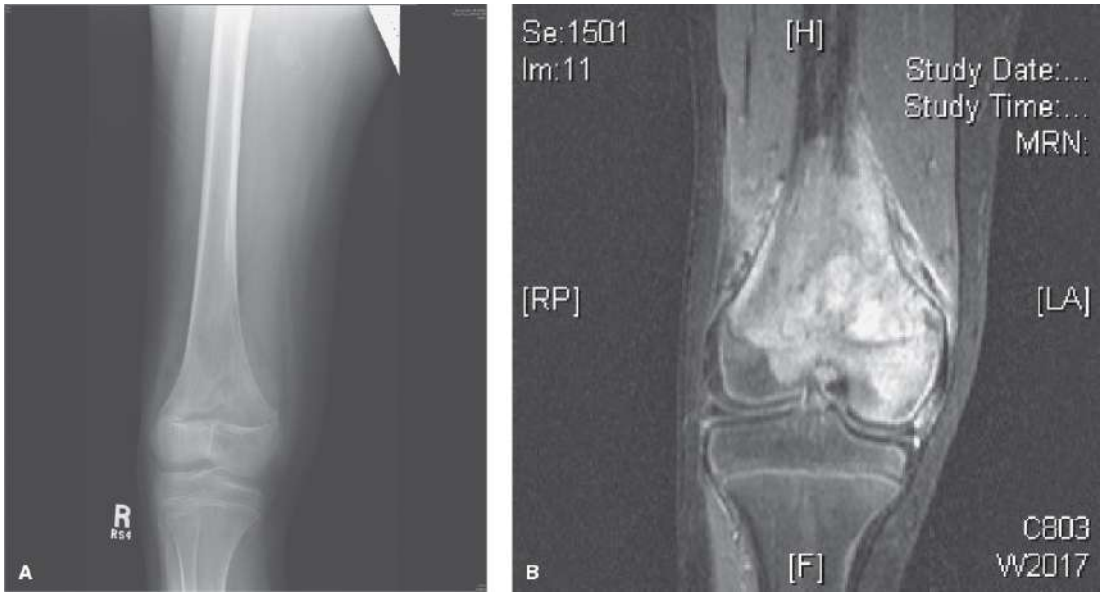

FIGURE 86.1. A: Plain radiograph of a distal femur osteosarcoma showing a lytic region and Codman triangle in the medial distal femur. **B:** Magnetic resonance image scan of the same lesion.

Biopsy of the tumor should be performed to confirm the diagnosis and to differentiate from other bone lesions. Similar to soft tissue sarcomas, the biopsy should be performed at a center with expertise in bone tumors and should be carried out by or in conjunction with the orthopedic surgeon who will be performing future definitive surgery in order to not jeopardize subsequent

treatment, particularly a limb-preserving procedure.

Staging Systems

There are two staging systems commonly used for osteosarcoma (Table 86.1). The Musculoskeletal Tumor Society (MSTS) staging system is a surgical staging system stratifying tumors by grade and subdividing by local extent.[20] The American Joint Committee on Cancer system is less often used.[21]

FIGURE 86.2. Plain radiograph of a sclerotic pelvic osteosarcoma.

Pathology

Osteosarcoma is characterized by the presence of malignant sarcomatous stroma with associated osteoid (immature bone) production.[22] Osteosarcoma is believed to arise from mesenchymal stem cells with the capacity to have fibrous tissue, cartilage, and bone differentiation. Thus, osteosarcoma shares many features with chondrosarcomas and fibrosarcomas. However, only osteosarcoma produces woven bone matrix, a key element for diagnosis.

TABLE 86.1 STAGING OF OSTEOSARCOMA

Stage	Grade	Site	Metastases
Enneking Staging System			
IA	Low	Intracompartmental	None
IB	Low	Extracompartmental	None
IIA	High	Intracompartmental	None
IIB	High	Extracompartmental	None
III	Any	Any	Present
Stage	Grade	Local extent (cm)	Metastases
AJCC Staging System[a]			
IA	Low	≤8	None
IB	Low	>8 or discontinuous	None
IIA	High	≤8	None
IIB	High	>8	None
III	High	Discontinuous	None
IVA	Any	Any	Pulmonary metastases
IVB	Any	Any	Other metastases

Osteosarcoma is classified into two main categories: conventional (intramedullary) and surface.[23] The conventional type accounts for 90% of osteosarcomas and is associated with the typical presentation in adolescence. The majority of conventional osteosarcomas are high-grade tumors. Conventional osteosarcoma is further subdivided into osteoblastic, chondroblastic, fibroblastic, and mixed subtypes. Other, less common histologic variants of conventional osteosarcoma include small cell, telangiectatic, malignant fibrous histiocytoma, and multifocal. Multifocal osteosarcoma typically carries a worse prognosis.

Surface osteosarcoma is subdivided into parosteal, periosteal, and high-grade surface.[24,25] Parosteal variant is considered to be a low-grade tumor with a low metastatic potential. Periosteal variant is intermediate in grade, with an intermediate rate of developing metastases, between parosteal and conventional osteosarcoma, about 20%. A rare variant, extraosseous osteosarcoma, arises in

soft tissues and is generally associated with prior radiation exposure.[26]

Treatment

Chemotherapy plays a critical role in the management of most patients with osteosarcoma. Although only 10% to 20% of patients present with overt metastatic disease, the vast majority of patients harbor subclinical metastatic disease at the time of presentation. Before effective chemotherapy, 80% to 90% of patients subsequently developed distant metastases and died of their disease despite achieving local disease control.[27] The typical treatment sequence for intermediate- and high-grade osteosarcoma is neoadjuvant chemotherapy, followed by surgery with a limb-sparing procedure if possible and then followed by further adjuvant chemotherapy. With this approach, 60% to 70% of patients without overt metastases at diagnosis are expected to be long-term survivors.[28] Those with isolated lung metastases have an overall survival of 35% to 40%, whereas those with more extensive metastatic disease at diagnosis have <20% likelihood of long-term survival. For the less common low-grade tumors such as parosteal osteosarcoma, treatment with surgery alone is appropriate because the risk of developing metastases is low. These patients have an 80% to 90% likelihood of long-term survival.[29]

Surgery

The mainstay of surgical management is the complete *en bloc* resection of tumor. The extent and functional implications of surgery have dramatically evolved over time, with an emphasis on more conservative, limb-sparing resections with maintenance of function rather than amputation. Neoadjuvant chemotherapy has played an important role in this evolution.

For extremity lesions, limb preservation is preferred and can be accomplished in the majority of cases. Retrospective studies have shown equivalent results of limb-sparing surgery and amputation as long as adequate margins can be achieved.[30–32] Contraindications to limb-sparing surgery include nerve or vascular encasement, presence of large, biopsy-related hematoma, and pathologic fracture. Some data suggest that pathologic fracture does not increase the risk of local recurrence after limb-sparing surgery as previously believed.[33,34] Reconstructive options include use of allografts, endoprostheses, and occasionally rotationplasty.

Axial tumors, although much less common, pose a particular challenge because achieving complete surgical resection can be difficult. As a result, these

lesions have a worse prognosis compared to extremity tumors. Pelvic tumors typically require a hemipelvectomy for *en bloc* resection. Some patients can undergo resection of the hemipelvis with preservation of the extremity (internal hemipelvectomy). This has a better functional outcome compared to an external hemipelvectomy, also referred to as a hindquarter amputation. Adjuvant radiation has been used to improve outcomes in patients with incomplete resections of pelvic tumors. Spinal tumors are also particularly difficult to resect with negative margins. Typically, an *en bloc* resection with vertebrectomy is performed, combined with mechanical stabilization. Postoperative radiation therapy can be used when negative margins cannot be obtained, particularly when there is microscopic dural involvement.

Chemotherapy

In the absence of chemotherapy, 80% to 90% of patients will subsequently develop distant metastases.[27] Chemotherapy thus plays an important role for all patients with intermediate- and high-grade tumors. Level I evidence for the benefit of chemotherapy was established by two randomized trials in the 1980s. Eilber et al.[35] reported on 59 patients with nonmetastatic osteosarcoma randomized to surgery followed by observation versus adjuvant chemotherapy. Disease-free survival at 2 years was 55% with chemotherapy and 20% with observation ($P < .01$). Overall survival was also superior at 2 years: 80% versus 48% with and without chemotherapy, respectively ($P < .01$). Link et al.[36] reported similar results in a group of 36 patients with nonmetastatic, high-grade osteosarcoma randomized to observation versus adjuvant chemotherapy after primary surgery. Disease-free survival at 2 years was 66% with chemotherapy and 17% with observation ($P < .001$).

The concept of neoadjuvant chemotherapy arose in conjunction with evolving surgical techniques striving for limb-preserving procedures and improved functional outcomes. This led to a randomized clinical trial by the Pediatric Oncology Group (POG).[37] POG 8651 randomized patients with nonmetastatic, high-grade osteosarcoma to neoadjuvant chemotherapy followed by surgery or surgery followed by the same chemotherapy. The 5-year relapse-free survival was not statistically different between the two groups (65% vs. 61%, respectively), nor was the rate of limb salvage (55% vs. 50%, respectively). Although this trial did not show improved outcomes with neoadjuvant chemotherapy, it did show equivalence and established a benchmark for comparison with future trials. Neoadjuvant chemotherapy is favored by most

centers, with the belief that the likelihood of limb-sparing surgery and, ultimately, functional outcome can be improved with this approach. Furthermore, the response to neoadjuvant chemotherapy has been shown to be prognostic.[38] This allows for the stratification of patients for more intensive postoperative treatment.

The optimal choice of chemotherapy and administration schedule remains a subject of active research. The Memorial Sloan Kettering Cancer Center T10 regimen is frequently used for nonprotocol patients and consists of high-dose methotrexate, doxorubicin, bleomycin, cyclophosphamide, and actinomycin D.[39] EURAMOS I (AOST 0331) was an international collaborative group trial sponsored by European and American Osteosarcoma Study Group, as well as by other groups, including the Children's Oncology Group.[40] This trial sought to better define optimal chemotherapy. Patients received preoperative and postoperative chemotherapy consisting of methotrexate, doxorubicin, and cisplatin (MAP). Those with a poor response to preoperative chemotherapy, defined as ≥10% residual viable tumor, were randomized to the addition of ifosfamide and etoposide (IE), whereas those with a good response to preoperative chemotherapy were randomized to the addition of interferon. A total of 2,260 patients were enrolled. Final results were unfortunately negative with neither ifosfamide and etoposide nor interferon showing improved event-free survival. For the poor response group, at 62 months median follow-up, 3-year event-free survival was 55% for MAP and 53% MAP + IE (P = .69).[41] For the good response group, at 44 months median follow-up, 3-year event-free survival was 74% for MAP and 77% MAP with interferon (P = .214).[42]

Radiation

Historically, radiation has been used for the treatment of osteosarcoma; however, high local failure rates with the use of radiation alone; improved surgical techniques, allowing for limb preservation; and effective use of chemotherapy limit the use of radiation therapy for osteosarcoma today. With a combined approach of chemotherapy and surgery with negative margins, local control rates of 90% to 98% have been reported.[30–32,43]

Patients who have tumor resection with inadequate or positive margins or who have unresectable tumors, however, have high rates of local recurrence. The Cooperative Osteosarcoma Study (COSS) Group performed a multivariate of 1,702 analysis patients found and that poor response to neoadjuvant chemotherapy and incomplete surgical resection predicted negatively for overall

survival.[38] Picci et al.[44] also reported that local recurrence was higher for limb-salvage surgery if wide, negative margins were not achieved. Furthermore, high recurrence rates have been reported in locations where complete surgery is usually not possible, including a recurrence rate of 70% in the pelvis, 68% in the spine, and 50% in the skull regions.[45–47] Radiation can potentially improve local control in these patients. Therefore, indications for integration of radiation therapy with other treatment modalities currently include incompletely resected tumors with positive margins and unresectable tumors or for palliation of symptoms.

Radiation Therapy Techniques

As with other sarcomas, proper patient position at the time of simulation and treatment is essential to achieve optimal tumor coverage and normal-tissue sparing. Customized immobilization devices may need to be constructed to achieve optimal positioning that is reproducible on a daily basis. Three-dimensional treatment planning with the aid of presurgical and postsurgical imaging is used to define gross tumor volumes and areas of subclinical disease. Typically, a 2-cm margin is used for axial tumors, which can be extended to 4 to 5 cm for extremity tumors. These margins can be restricted at natural tissue and fascial boundaries. The radiation technique used, either three-dimensional conformal or intensity-modulated radiation therapy, should be tailored to the individual patient. Dose to uninvolved organs should be minimized to prevent late organ dysfunction, as should the integral dose to minimize risk of secondary malignancy.

A prescription dose of 60 Gy in 2-Gy fractions is typically used for microscopically involved margins, whereas 66 Gy is used for macroscopic residual disease and 70 Gy is used for inoperable tumors. Chemotherapy should not be interrupted to deliver local radiation therapy. Radiation can be given concurrently but is usually delivered after chemotherapy because of increased acute toxicity with concurrent administration.

Intraoperative radiation therapy has been used to deliver dose directly to close or involved surgical margins.[48,49] Proton particle therapy has been used in an attempt to escalate radiation dose, particularly in unresectable tumors.[50,51] Radionuclide therapy with rhenium,[52] strontium,[53] and samarium[54] has been used for palliation of extensive bone metastases with good effects.

Results of Radiation Therapy

In the prechemotherapy era, Cade[55] pioneered a technique of radiotherapy with delayed amputation in patients who did not develop distant metastases. The primary tumor was controlled in some patients who refused amputation. However, the overall results were poor, with most patients dying of metastatic disease. The incorporation of chemotherapy with optimal surgery has resulted in significantly improved outcomes, obviating the need for radiation therapy for most patients. Dincbas et al.[56] evaluated the addition of preoperative radiation therapy to chemotherapy followed by limb-sparing surgery. They reported on a series of 46 patients, most of whom received 35 Gy in 10 fractions. Local control and overall survival rates at 5 years were 97.5% and 48.4%, respectively. Although the results were excellent, it is not clear whether preoperative radiation therapy improved outcomes, given that the rate of local control with chemotherapy followed by surgery in the absence of adjuvant radiation is high, as previously summarized.

For patients who have incomplete tumor resection or unresectable tumors, the risk of local recurrence/progression is high. These patients, therefore, can potentially benefit from radiation therapy. Machak et al.[57] reported on a series of 187 patients with nonmetastatic osteosarcoma treated with induction chemotherapy. Of these, 31 patients refused surgery and were treated with radiation to a mean dose of 60 Gy. Local control was related to response to induction chemotherapy. There were no local recurrences in 11 patients who had a good response to chemotherapy. However, local progression-free survival was 31% at 3 years and 0% at 5 years for nonresponders. Schwarz et al.[58] reported on an analysis of 100 patients treated with radiation therapy in the COSS registry. Local control and overall survival for the whole group were 30% and 36%, respectively, at 5 years. Local control was significantly better when surgery was combined with radiation compared to radiation alone: 48% versus 22%, respectively (P = .002). Local control was also higher for primary tumors compared with recurrent tumors: 40% versus 17%, respectively. Sole et al. reported on 72 patients treated with neoadjuvant chemotherapy, resection, and postoperative radiation therapy with a median follow-up of 174 months. Local control and disease-free survival and overall survival at 10 years were 82%, 58%, and 73%, respectively. R1 resection was predictive of worse local control.[59] DeLaney et al.[51] reported on the Massachusetts General Hospital (MGH) experience. Forty-one patients with osteosarcoma underwent radiation for close or positive margins or for unresectable disease. Anatomic sites included 17 skulls, 8 extremities, 8 spines, 7 pelves, and 1 trunk. Patients received a

median dose of 66 Gy (10 to 80 Gy), with about half of patients receiving a portion of their treatment with protons. The overall local control rate was 68% at 5 years. Local control was similar between patients who underwent a gross total resection or subtotal resection but was significantly better than for those who underwent biopsy only: 78% versus 78% versus 40% at 5 years, respectively ($P < .01$).

Overall, it appears that radiation is most effective when the tumor burden is small, with the best results achieved in patients who have a good response to chemotherapy or are able to undergo gross total or subtotal tumor resection. Total dose may also be an important factor. Gaitán-Yanguas[60] showed a dose–response relationship for osteosarcoma, with no lesions controlled at doses of ≤30 Gy and all lesions controlled at doses of >90 Gy. The best clinical results were reported in the MGH series.[51] A median dose of 66 Gy was used, and half of the patients received proton therapy as part of their treatment. The unique dose–depth properties of proton radiation therapy allows for dose escalation while maintaining normal-tissue sparing. This approach may explain the improved outcomes reported. However, this study did fail to show a dose–response relationship.

Whole-Lung Irradiation

Whole-lung irradiation has been shown to be beneficial in several other pediatric tumors with a propensity for lung metastases. This led to the rationale that this treatment may improve outcomes in osteosarcoma, which has a high propensity for metastases and for which the lung is the most common site of spread. Two initial small randomized trials in the prechemotherapy era showed a trend for improved disease-free and overall survival for whole-lung irradiation.[61,62] This led to the EORTC-20781/SIOP-03 phase III trial, which randomized 240 patients to three arms: chemotherapy, whole-lung irradiation, or both.[63] The whole-lung dose was 20 Gy. The 4-year disease-free survival and overall survival were 43% and 24%, respectively, with no difference between the arms. Therefore, with the recognition of the other advantages of systemic therapy, whole-lung irradiation has fallen out of favor.[64]

Surveillance and Sequelae of Treatment

Surveillance for recurrence should include imaging of the primary site with CT or MRI and chest imaging. Late complications are largely related to chemotherapy and surgical interventions. Limb functional outcomes are related

to location of tumor and type of resection and reconstruction performed. Complications related to radiation therapy include joint fibrosis with decreased range of motion, bone weakening and fracture, loss of allograft, and secondary malignancy.[51] Careful consideration of radiation technique and physical rehabilitative therapy is essential to minimizing late functional impairment.

CHONDROSARCOMA

Epidemiology

Chondrosarcoma is characterized by a neoplastic process with associated cartilage matrix production that is devoid of osteoid, a characteristic of osteosarcoma. It is the second most common primary bone tumor, accounting for approximately 30% of cases.[1] Chondrosarcoma may arise at any age but typically occurs in middle-aged and older adults.[65]

Pathogenesis and Risk Factors

The etiology of chondrosarcoma is not fully understood. It is usually sporadic but can also develop from malignant transformation of benign cartilaginous lesions—osteochondromas and enchondromas. Osteochondroma is a cartilage-capped bony projection arising on the external surface of bones. It is usually located on long bones, particularly around the knee. Multiple osteochondromas are associated with hereditary multiple exostoses, an autosomal dominant syndrome. Malignant transformation occurs in 5% of patients with either solitary or multiple osteochondromas.[66,67] Enchondroma is a benign cartilaginous tumor developing in the marrow cavity of bone. Multiple enchondromas, or enchondromatosis, are usually associated with congenital disorders such as Ollier disease or Maffucci syndrome. Malignant transformation of solitary enchondromas is extremely rare, but the risk with enchondromatosis is as high as 25% to 30%.[67,68]

Clinical Presentation and Diagnostic Evaluation

Patients typically present with localized pain in the affected bone with or without associated soft tissue swelling or a palpable mass. Plain radiograph is obtained for initial evaluation, but CT and MRI are essential to characterize the lesion(s) and determine the full extent of disease.

Tissue biopsy of the tumor is necessary to confirm the diagnosis and to differentiate it from other malignant bone tumors. Biopsy should be aimed at the

most aggressive portion as determined by imaging. This can help avoid biopsy of a portion of a benign precursor lesion. It also helps avoid less aggressive surgical approaches used for low-grade lesions if a high-grade component is present.[69]

The rate of metastatic disease for chondrosarcoma is very dependent on tumor grade. Low-grade lesions have a <10% risk of metastases, intermediate-grade lesions have a 10% to 50% risk, and high-grade lesion have a 50% to 70% risk.[70,71] The lungs are the main site of metastases. Staging evaluation thus should include a chest CT for intermediate- and high-grade lesions.

Staging Systems

As with osteosarcoma, both the MSTS staging system and the American Joint Committee on Cancer staging system can be used (Table 86.1). MSTS is used more often.[20,21]

Pathology

Chondrosarcoma pathologically is divided into conventional, which comprises 85% to 90% of cases, and other, uncommon variants. Conventional chondrosarcoma is further subdivided into central, peripheral, and periosteal.[72,73] Central chondrosarcoma is the most common type, accounting for 75% of all chondrosarcomas. Most are sporadic, but as many as 40% may arise for underlying enchondromas. Most commonly, the proximal femur, pelvis, and proximal humerus are involved.[74] Peripheral chondrosarcoma by definition arises from a pre-existing osteochondroma. The long bones, pelvis, and shoulder girdle are most commonly affected.[67] Periosteal chondrosarcoma arises from the surface of bone and is rare. It usually affects adults at a younger age, in their 20s and 30s, and tends to have a good prognosis.[75] Nonconventional chondrosarcoma variants include clear cell, dedifferentiated, myxoid, and mesenchymal. Clinical behavior of chondrosarcoma is highly dependent on histologic grade.[70,76,77]

Treatment

Histologic grade and tumor location are important determinates of treatment approach. Surgical excision is the primary treatment modality for chondrosarcoma. For low-grade tumors, which constitute the vast majority of chondrosarcomas, surgical resection alone is sufficient to achieve a high rate of disease control. For low-grade central tumors, intralesional excision or curettage is the preferred method of resection. This can be combined with local adjuvant

chemical treatment or cryotherapy. These approaches result in good local control rates and minimize the morbidity of more extensive surgical resection.[78–81] The best outcomes are obtained with small tumors located in the extremities. Larger tumors, tumors with intra-articular or soft tissue involvement, and axial or pelvic tumors have higher local recurrence rates with these more conservative treatments and are better treated with wide excision.[82,83] For the less common intermediate- and high-grade tumors, wide *en bloc* excision is the optimal surgical approach.[77] Radiation therapy is indicated for incompletely resected high-grade or locally recurrent tumors and tumors that are unresectable. Chemotherapy is generally not very effective for chondrosarcoma, especially for the most prevalent conventional type. There is no established adjuvant chemotherapy regimen for these patients. There is some suggestion that dedifferentiated and mesenchymal chondrosarcomas may potentially benefit from chemotherapy, but phase III randomized data are lacking in these rare tumors.[84–86]

Radiation

As with osteosarcoma, no level 1 evidence exists for radiation therapy in chondrosarcoma. Based on first principles and results of published case series, radiation therapy is indicated to improve on high local failure rates after incomplete resection of high-risk tumors. These indications include intermediate- to high-grade tumors, locally recurrent tumors, and tumors in locations where surgical resection is challenging or limited. Definitive radiation can also be used for unresectable tumors. Doses of 50 Gy preoperatively and 60 to 66 Gy postoperatively for close or positive margins are typically used. Doses of ≥70 Gy are needed for definitive treatment.

Results of Radiation Therapy

Although chondrosarcoma was traditionally considered to be a “radioresistant” tumor, modern series have shown good outcomes with radiation therapy. Goda et al.[87] presented the Princess Margaret Hospital experience of combined surgery and radiation therapy for high-risk extracranial chondrosarcoma. They reported on 60 patients with a median follow-up of 75 months and showed local control rates of 100%, 94%, and 42% for R0, R1, and R2 resected patients, respectively. Ten-year overall survival was 86%. Definitive radiation therapy has also been used for locations where complete surgical resection is difficult to achieve, that is, the spine and base of skull.[88–91] In these locations, *en bloc* resection is

generally not possible, and even piecemeal resection is often not complete. Proton radiation therapy has been used in this setting. The unique depth–dose properties of protons allows for dose escalation while sparing neighboring critical structures. A large series was reported from Massachusetts General Hospital consisting of 200 patients with base-of-skull chondrosarcoma treated using a combination of photon and proton radiation therapy.[92] With median dose of 72 Cobalt Gray Equivalent (CGE), they reported a 10-year local control rate of 98%. Similar local control rates have been reported by other institutions using various conformal radiation methods to achieve a high tumor dose, including protons, fractionated stereotactic photon, and carbon ions.[91,93–95] Tables 86.2 and 86.3 summarize the results of selected studies of radiation therapy for chondrosarcoma involving the base of skull and the spine, respectively.

Surveillance and Sequelae of Treatment

Functional assessment, rehabilitation, and physical therapy are important to minimize the long-term morbidity of surgery and/or radiation therapy. Surveillance for recurrence should include history and physical exam, CT or MRI imaging of the primary area, and chest imaging on a periodic basis. Follow-up should continue for a minimum of 10 years because late recurrences are more commonly observed with chondrosarcoma than with other sarcomas.[96]

CHORDOMA

Epidemiology

Chordoma is a rare, malignant neoplasm arising from the remnant of the primitive notochord. Chordoma accounts for 1% to 4% of primary bone tumors, with an annual incidence in the United States of 0.08 cases per 100,000.[97] Median age at presentation is 60 years, but base-of-skull location typically present at a younger age, usually in the third to fourth decade of life.

Pathogenesis

In normal embryologic development, the notochord regresses as the embryo matures. Remnants can be found anywhere along the tract of the notochord from the base of skull to the sacrum. The largest foci remain at the cranial and caudal ends. This corresponds well with the anatomic distribution of chordoma, with half arising in the sacrococcygeal region and one-third at the base of skull, typically the clivus.[97] The rest occur in the vertebral bodies of the spine.

Chordomas in other locations are exceedingly rare.[98]

Clinical Presentation and Diagnostic Evaluation

Chordomas are slow-growing but locally destructive tumors. They typically present with pain at the affected area that may be of long-standing duration. Neurologic symptoms based on location are frequent. Base-of-skull tumors can present with cranial nerve deficits, particularly cranial nerve 3 or 6 palsies (Fig. 86.3). Hydrocephalus and sensorimotor deficits can also occur. In the sacral region, sacral nerve roots can be affected, resulting in bowel or bladder dysfunction. Diagnostic evaluation includes CT and MRI to characterize the extent of the primary tumor and involvement or neighboring neural structures (Fig. 86.4). Biopsy should be performed to establish the pathologic diagnosis.

Chordomas have a low metastatic potential, but metastases may occur in as many as 10% to 40% of patients.[99–103] These typically occur late in the disease course and can involve lung, bone, liver, lymph nodes, or soft tissues. Metastatic deposits tend to be slow growing, and control of local disease progression remains the major therapeutic challenge in most patients.[103]

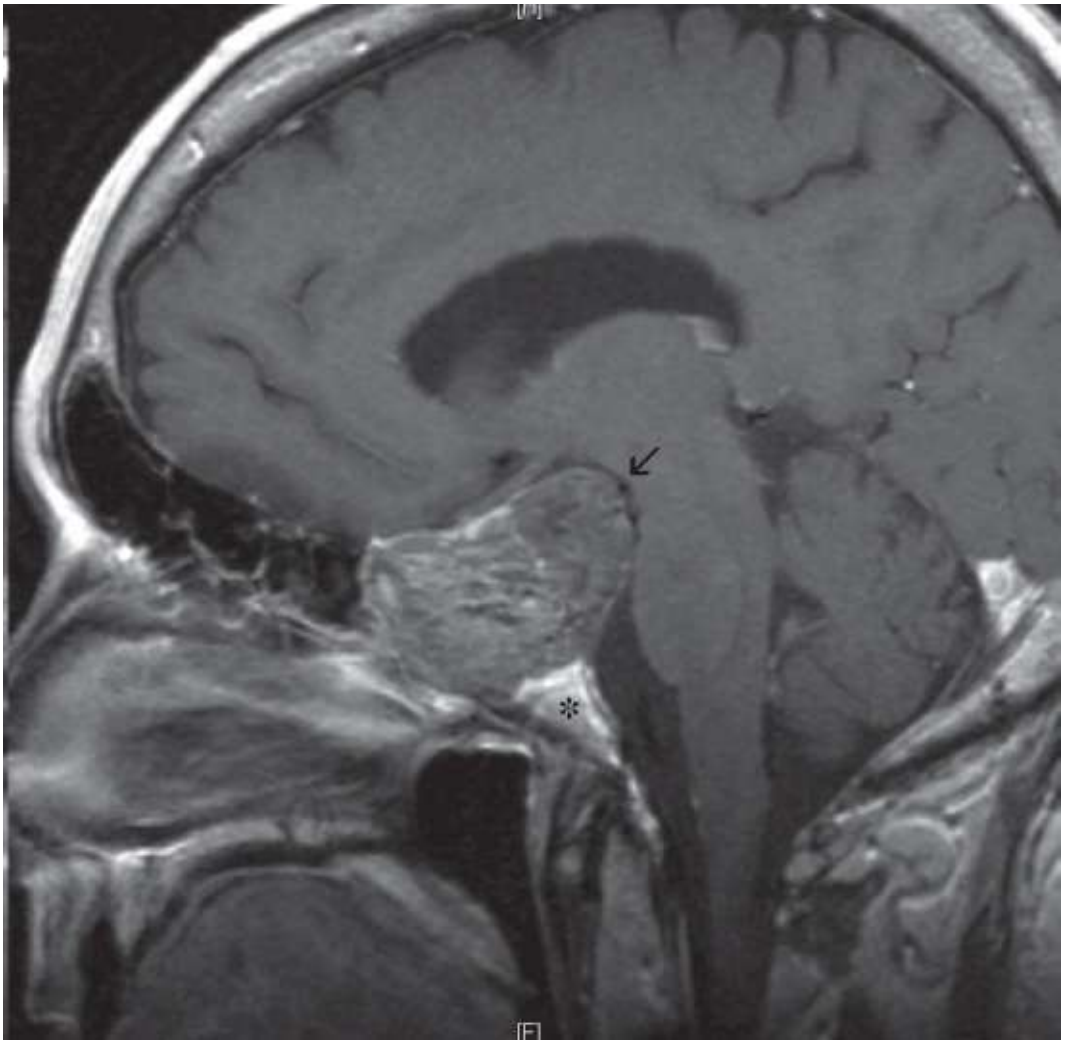

FIGURE 86.3. Base-of-skull chordoma. A 50-year-old patient who presented with several months of headaches and visual field deficits. T1-weighted, postgadolinium sagittal magnetic resonance imaging of the head depicts a chordoma (*arrow*) arising from the clivus (*asterisk*) with mass effect and posterior displacement of the brainstem.

Pathology

Chordomas are classified histologically into conventional (classic), chondroid, and dedifferentiated. The majority are conventional. Chondroid chordoma accounts for 5% to 15% and tends to have a better prognosis. Dedifferentiated chordoma account for <5% of chordomas but are more aggressive, faster growing, and more likely to metastasize.[104] Chordoma can be histologically difficult to differentiate from low-grade chondrosarcoma. The latter has a better prognosis, so the distinction is prognostically important. A careful pathologic review by a pathologist experienced in these tumors is recommended.[92]

Treatment

Although chordoma has the potential to metastasize, the dominant failure pattern is local recurrence, and this typically dictates morbidity and mortality for these patients. Salvage after local recurrence can achieve disease control for a period of time, but the ultimate outcomes tend to be poor. Thus, aggressive upfront treatment affords the best potential for cure. An analysis of the surveillance, epidemiology, and end results program of the National Cancer Institute consisting of 345 patients treated from 1974 to 2011 showed that 5-year overall survival of 78% to 80% was achieved with treatment using surgery +/− radiation therapy.[105]

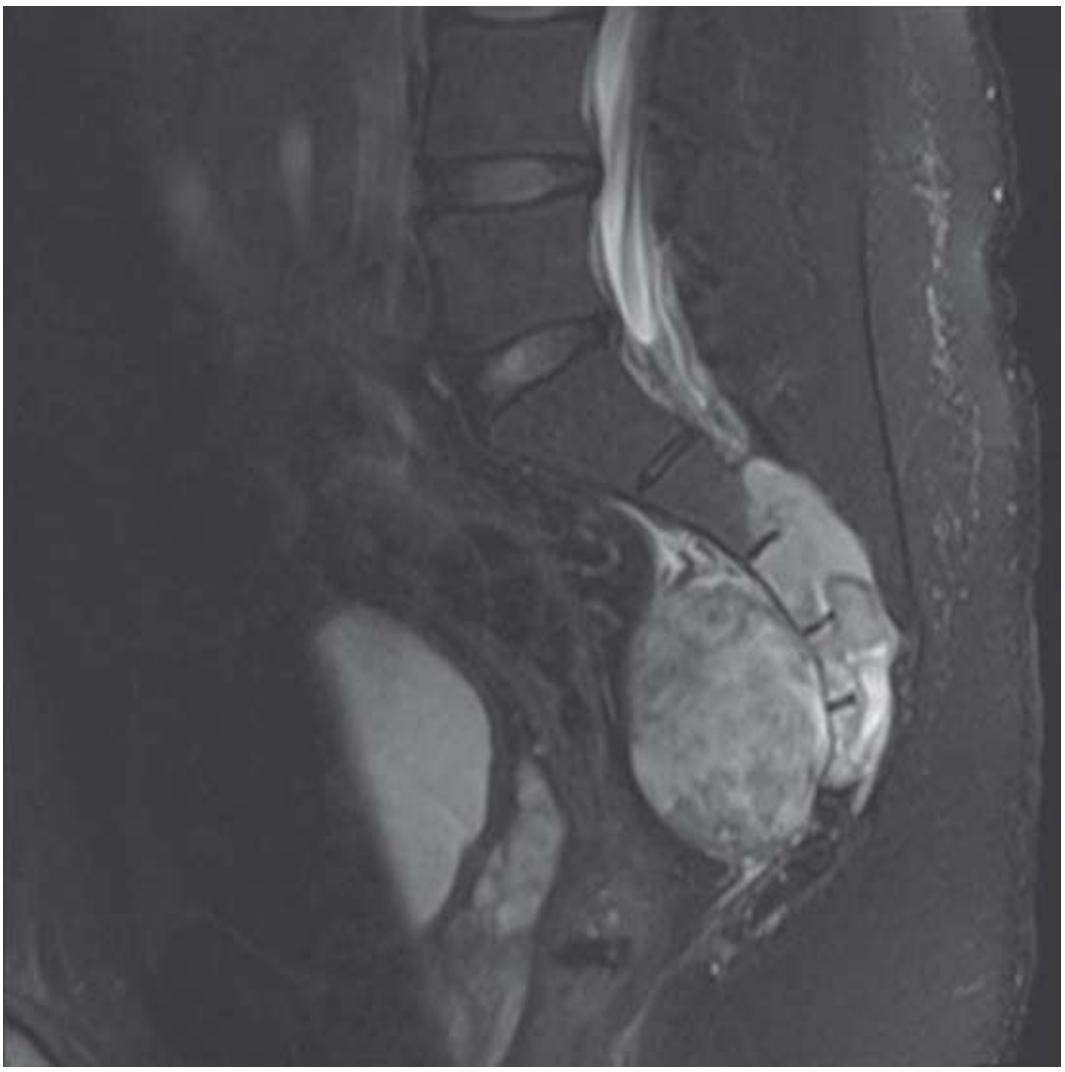

FIGURE 86.4. Sacral chordoma. A 45-year-old patient who presented with 1 year of low back pain radiating to the coccyx. T2-weighted sagittal magnetic resonance imaging of the pelvis depicts a 5-cm chordoma involving the inferior sacrum up to the level of S2.

Surgery has been the primary approach for these tumors. Complete *en bloc* resection with negative margins has been reported to achieve local control in 70% to 80% of patients.[106] However, when negative margins cannot be achieved, the failure rate is >70%.[106,107] Unfortunately, less than half of sacral tumors and even fewer base-of-skull tumors are amenable to complete resection. Aggressive surgery can also result in significant morbidity. Base-of-skull resection can result in cranial nerve deficits.[108] Resection of sacral chordomas can result in bowel and bladder dysfunction when S2 or S3 nerve roots are injured or sacrificed.[109,110]

Chordomas are considered relatively "radioresistant" tumors, and so doses of >66 Gy are required. These doses have traditionally been difficult to achieve with conventional external beam techniques, given the location of these tumors abutting sensitive neural structures. Given the advantages of the physical dose properties of the Bragg peak of charged particles, these tumors were treated early in the advent of this technology. Thus far, the best results in the treatment of chordomas have been achieved with a combination of surgery and high-dose proton radiation therapy. Local control rates of 54% to 90% have been reported.[91,93,111–114]

Chemotherapy has long been known to be inactive in chordoma, and thus, chemotherapy has not played a role in the definitive management of these patients. Recently, expression of platelet-derived growth factor and epidermal growth factor receptors on these tumors and antitumor activity of targeted therapies against these receptors have been described, renewing interest in systemic treatment.[115,116] Imatinib, cetuximab, and gefitinib have been used, but clinical experience is limited.[117,118]

Results of Radiation therapy

For base-of-skull chordomas, one of the largest experiences has been reported from Massachusetts General Hospital.[103] A crude local control of 69% was achieved in 204 patients treated using proton radiation therapy to a dose of 66.6 to 79.2 CGE. Reports of using heavier charged particle have shown similar outcomes.[119] With improvement in technology, dose escalation using conventional photons has also been achieved using intensity-modulated radiation therapy, fractionated stereotactic radiation therapy, and stereotactic radiosurgery techniques.[91,93,94,112,119,120] The outcomes with these approaches have been comparable to those reported for proton techniques. Table 86.2 summarizes the results of selected published studies for base-of-skull chordomas.

For sacral chordomas, the published literature is less robust but has shown similar results. DeLaney et al.[113] reported local control in 90% of 29 patients with sacral chordoma at a median follow-up of 4 years. Five-year actuarial local control was 100% for primary treatment versus 56% for salvage. There was no statistical difference based on extent of resection. Table 86.3 summarizes the results of published studies for spine sarcomas, including chordoma.

Sequelae of Radiation Therapy

Because of the high dose required for treatment of chordomas and the proximity of sensitive structures, late complications are not infrequent, and patients need to be followed and monitored closely. For base-of-skull chordoma, hypopituitarism, memory impairment, cranial nerve injury, sensory neural hearing loss, and central nervous system necrosis have been reported.[89,93,101] For sacral chordoma, sacral nerve root injury, erectile dysfunction, rectal bleeding, and sacral insufficiency factures have been reported.[113,121]

RARE MALIGNANT BONE TUMORS

Fibrosarcoma of bone is a very rare tumor, accounting for <5% of all primary bone tumors.[115] It is a malignant neoplasm of mesenchymal origin characterized by predominance of fibroblasts without tumor osteoid or cartilage production. It has a predilection for long bones and has a high metastatic potential. It is treated with complete surgical resection and often with adjuvant or neoadjuvant chemotherapy. Radiation therapy can be used for incompletely resected or unresectable tumors.

Malignant fibrous histiocytoma of bone also accounts for <5% of bone tumors.[122] It is characterized by a mixture of spindle-shaped fibroblastic cells in a storiform pattern and admixed with mononuclear cells with histiocytic morphology and anaplastic giant cells without tumor osteoid or cartilage production. The mainstay of treatment is complete surgical resection. Like osteosarcoma, it has a high rate of metastases. Malignant fibrous histiocytoma of bone is typically treated similarly to osteosarcoma and has been shown to benefit from chemotherapy.[123]

CHAPTER 87

Soft Tissue Sarcoma (Excluding Retroperitoneum)

Elizabeth H. Baldini

INCIDENCE

Soft tissue sarcomas (STS) constitute a heterogeneous group of rare malignancies that vary extensively by anatomic location, histology, and biologic behavior. They can occur at any anatomic site and may arise from many soft tissues including connective tissues, fat, muscle, vascular tissue, peripheral neural tissue, or visceral tissue. Annually, there are about 12,400 expected new cases of STS in the United States, and this accounts for approximately 0.7% of all new cancer diagnoses.[1] The median age at diagnosis for all STS is 65 years, but incidence varies by histologic subtype.[2] For example, embryonal rhabdomyosarcoma is common in children; synovial sarcoma occurs mostly in young adults; and undifferentiated pleomorphic sarcoma, liposarcoma, and leiomyosarcoma are seen mostly in older adults.

ETIOLOGY AND GENETICS

For the great majority of STS, there is no known etiology. A minority of cases can be attributed to environmental or genetic factors.[2] Associated environmental factors include radiation exposure; chemical exposures, such as vinyl chloride, dioxin, arsenical pesticides, and phenoxy herbicides; immunosuppression; lymphedema (Stewart-Treves syndrome); and viruses (human immunodeficiency virus, human herpesvirus type 8). Certain clinical syndromes are associated with a genetic predisposition for the development of sarcoma. A few examples include Li-Fraumeni syndrome and Werner syndrome, which are associated with the development of STS as well as other malignancies; neurofibromatosis type 1, which is associated with the development of malignant peripheral nerve sheath tumors; and familial adenomatous polyposis (Gardner syndrome), which is

associated with the development of abdominal desmoid tumors.

HISTOLOGIC CLASSIFICATION

The World Health Organization divides soft tissue tumors into four categories: benign; intermediate, locally aggressive (e.g., desmoid fibromatosis); intermediate, rarely metastasizing (e.g., plexiform fibrohistiocytic tumor); and malignant. There are more than 50 histologic subtypes of STS. The most common subtypes include undifferentiated pleomorphic sarcoma, liposarcoma, leiomyosarcoma, myxofibrosarcoma, synovial sarcoma, and malignant peripheral nerve sheath tumor. Together, these account for about 75% of STS cases.[2] Histologic diagnosis is determined largely by tumor cell morphology. Immunohistochemical staining helps refine the diagnosis in many cases, and, increasingly, several of the histologic subtypes have characteristic chromosome translocations and gene rearrangements. Some of these characteristic translocations include Ewing sarcoma, t(11,22); synovial sarcoma, t(X,18); myxoid liposarcoma, t(12,16); and clear cell sarcoma, t(12,22).[2] There are several grading systems. The two most widely used are the US National Cancer Institute (NCI) and the French Federation Nationale des Centres de Lutte Contre le Cancer (FNCLCC) grading systems, both of which employ a three-tiered system of low, intermediate, and high grade based on mitotic activity, necrosis, and differentiation.[3] The College of American Pathologists prefers the FNCLCC system as it is easier to use and more reproducible and may be a better predictor of prognosis.[4] Lastly, there are certain STS subtypes for which grading is not applicable.[2]

Given the rarity of STS as well as the numerous histologic subtypes, it is not surprising that diagnoses vary even among STS specialists. Several reports have examined concordance rates for histologic diagnosis or grade among pathologists. Agreement rates between nonspecialists and specialists range from 24% to 68%.[5–9] Even among sarcoma specialists, concordance rates can vary from 60% to 90%.[10,11] For this reason, it is very important to submit diagnostic slides for review by an experienced sarcoma pathologist prior to embarking on definitive treatment.

NATURAL HISTORY

STS can occur anywhere in the body. The most common site of presentation is

an extremity, specifically the thigh. The approximate distribution of STS sites at presentation is extremity, 60% (lower extremity, 45%, upper extremity, 15%); trunk, 15% to 20%; retroperitoneum, 10% to 15%; and head and neck, 9%.[12] Interestingly, certain histologic subtypes have predilections for specific sites. For example, angiosarcoma commonly occurs in the head and neck, desmoid tumors frequently occur in the abdomen associated with Gardner syndrome, and epithelioid carcinoma often involves the hand or forearm.[13–15]

In the classic reports by Simon and Enneking[16] and Enneking et al.,[17] the local behavior of STS is well described. STS tends to invade longitudinally along musculoaponeurotic planes. These tumors rarely transgress fascial boundaries or invade bone. As the sarcoma grows, it compresses surrounding normal tissue to form a pseudocapsule, which contains a compression zone and a reactive zone. The latter comprises edema, inflammatory cells, and tumor cells. Furthermore, Simon and Enneking[16] have shown that microscopic tumor cells perforate through and extend beyond the pseudocapsule.

Unlike most solid tumors, STS rarely spread to lymph nodes. Three series, each with more than 1,000 consecutive patients with STS, cited only 1.8% to 3.7% of lymph node involvement at the time of initial presentation.[18–20] However, there are a few histologic subtypes for which lymph node involvement is more common. Notable lymph node involvement rates have been demonstrated for Clear cell sarcoma (10% to 18%), cutaneous *A*ngiosarcoma (10% to 15%), *R*habdomyosarcoma (20% to 25%), and *E*pithelioid sarcoma (20% to 35%); these histologic subtypes can be remembered by the pneumonic "*CARE*."[15,19–23]

The American College of Surgeons Patterns of Care Study for adult STS showed 23% of patients had metastatic disease at presentation.[12] The single most frequent site of distant metastasis (34%) was the lung; bone, liver, and brain involvement were less common. Furthermore, as was the case for lymph node spread, certain histologic subtypes exhibit distinct patterns of recurrence. For example, myxoid liposarcoma has a predilection for spread to retroperitoneum, other extrapulmonary soft tissue sites, and bone. Among reported recurrences, about 50% occur in the retroperitoneum, 20% in other extrapulmonary soft tissue, and 15% to 17% in the bone.[24,25] For retroperitoneal STS, the most common site of recurrence is locally in the retroperitoneum.[26] These tumors also have a predilection for spread to the liver as well as the lung.[26] Epithelioid sarcoma can present with skip metastases involving discontiguous locations in a limb as well as lymph node involvement.[2,15,21] Lastly, myxofibrosarcoma

exhibits an infiltrative growth pattern and is associated with higher rates of positive resection margins and local recurrence (LR) compared to other STS histologic subtypes; conversely, the rate of distant recurrence to lung is lower than for other STS types.[2,27–30]

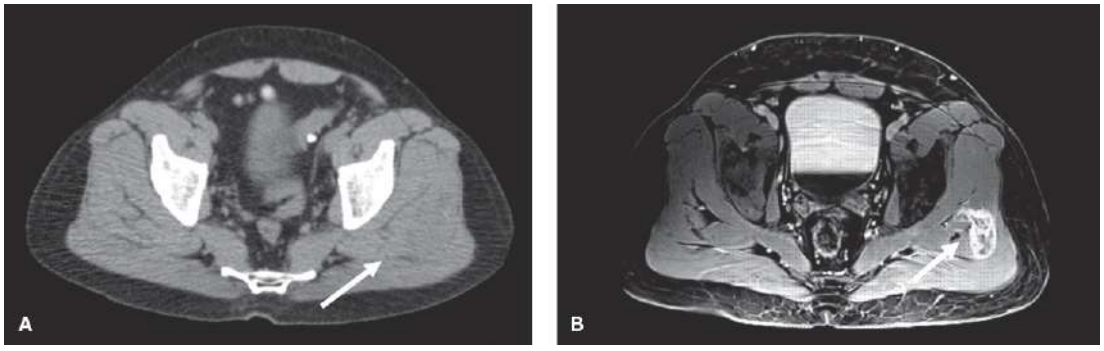

FIGURE 87.1. Comparison of computed tomography (CT) and magnetic resonance imaging (MRI) axial slices for a synovial sarcoma of the left gluteus medius muscle (denoted by *arrows*) in a 56-year-old man. **A:** The CT axial slice shows a vaguely defined soft tissue mass in the left gluteus medius muscle. **B:** The anatomic definition of the soft tissue sarcoma is seen much more clearly on the corresponding T1 postgadolinium axial slice of the MRI.

INITIAL EVALUATION

Most STS cases present as a painless mass. When taking a history, one should ask how long the mass has been present, if it has changed in size and at what rate, and if there are any associated local or systemic symptoms. It is also important to ask about potential risk factors for STS, including a history of radiation exposure or a family history of malignancies including STS. On physical examination, one should assess the mass for characteristics such as size, depth, fixation to underlying structures, the presence of overlying skin changes, and potential evidence of neurovascular compromise. On the general examination, one should also note if there are any stigmata of neurofibromatosis, such as neurofibromas or café au lait spots (as there is an association between neurofibromatosis type I and malignant peripheral nerve sheath tumors).[2]

Imaging workup should include evaluation of the primary site as well as sites of potential metastatic spread. For STS of the extremity, trunk, or head and neck, evaluation of the primary tumor with a magnetic resonance imaging (MRI) scan is generally preferred to computed tomography (CT) scanning.[31,32] The T1-weighted images of the MRI scan provide excellent definition of the anatomic relation between the tumor and adjacent structures. T2-weighted images

demonstrate the tumor and any associated edema. As peritumoral edema can contain malignant cells, it is important to identify this for both radiation and surgical planning.[33] Demas et al.[31] compared MRI and CT for STS lesions in the extremity and reported that for 23% of cases, the MRI scans showed tumor involvement in muscles that appeared normal on CT scan. On the other hand, a prospective study reported by Panicek et al. showed no significant difference between the two imaging modalities when performed for preoperative evaluation.[34] Nonetheless, most practitioners believe that MRI is superior to CT for evaluation of soft tissue tumors of the extremity, trunk, and head and neck. Figure 87.1 depicts a case of synovial sarcoma of the left gluteus medius muscle. The mass is difficult to discern on CT imaging (Fig. 87.1A) but very clearly delineated on MRI (Fig. 87.1B). Figure 87.2 is a second comparative example of CT and MRI and shows a leiomyosarcoma of the proximal anterior thigh. Although, the differences between the imaging modalities are not as pronounced as in Figure 87.1, the MRI again provides superior information compared to the CT scan. The MRI demonstrates probable arterial wall invasion, fascial enhancement of the vastus medialis muscle, and definition of tumor spiculations into the adjacent fat and along the biopsy tract. Chest CT scan is recommended to rule out pulmonary metastases for all cases except low-grade tumors or small (<5 cm) high-grade lesions, and even in these latter cases, it can be helpful to obtain a baseline chest CT at diagnosis. Currently, there is no clearly defined role for positron emission tomography (PET) as part of the diagnostic evaluation. However, PET scanning may have potential utility to help distinguish malignant peripheral nerve sheath tumors from benign neurofibromas in patients with neurofibromatosis.[35] Lastly, given that myxoid liposarcoma has a predilection for spread to bone and soft tissue, MRI of the spine and CT of the abdomen and pelvis are recommended as part of the initial evaluation for high-risk patients with this histologic subtype.[24,25,36]

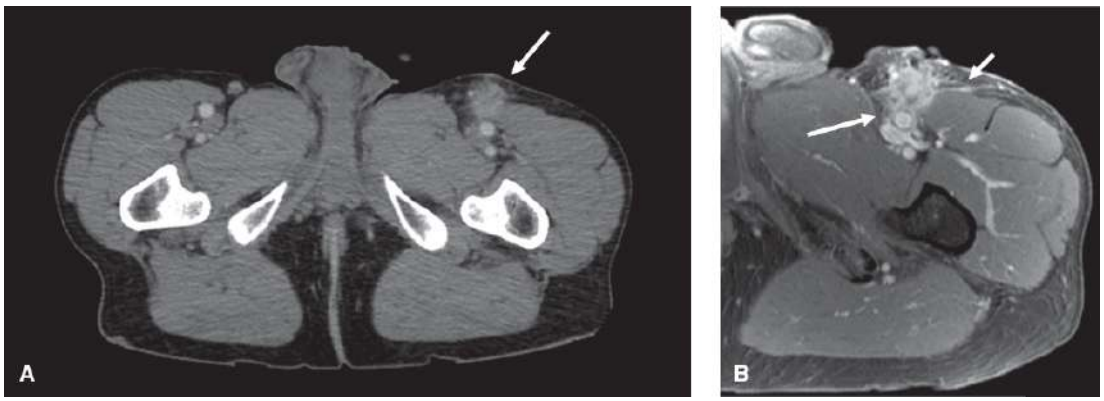

FIGURE 87.2. Comparison of computed tomography (CT) and magnetic resonance imaging (MRI) axial slices for a high-grade leiomyosarcoma of the proximal anterior thigh (denoted by *arrows*) in a 53-year-old man. **A:** The CT axial slice shows a soft tissue mass in the left anterior upper thigh anterior to the superficial femoral artery and vein. **B:** The T1 postgadolinium image of the MRI at the same level provides superior resolution compared to the CT. It shows a loss of fat plane between the mass and the superficial femoral artery suggestive of arterial invasion (*long arrow*), linear fascial enhancement overlying the vastus medialis muscle (*short arrow*), and tumor spiculations into adjacent subcutaneous fat and to the skin along the biopsy tract.

CT-guided core biopsy is the desired diagnostic approach as it is accurate, safe, and expeditious.[37] Incisional biopsy is accurate and acceptable, but it is more invasive than core biopsy. If utilized, incisional biopsies should be performed carefully with the subsequent definitive resection in mind.[38] Tumor cells can potentially seed an incision, thereby necessitating removal of skin incisions at the time of surgical resection. It is important that the biopsy approach does not transgress an uninvolved compartment or joint as this would create a situation where a much more radical resection would need to be performed. Consequences of inappropriately placed incisional biopsies can be significant and include the need to perform more complex operations, with the potential for subsequent loss of function, LR, and death.[38] Fine needle aspirate (FNA) can confirm malignancy for recurrent disease, but typically does not yield enough tissue to establish an initial diagnosis.

STAGING

In 2017, the American Joint Committee on Cancer (AJCC) published the eighth edition of the TNMG (tumor, node, metastasis, grade) staging system for STS.[36] There are several changes compared to the seventh edition including new separate staging systems for STS of (a) extremity and trunk, (b) retroperitoneum, (c) head and neck, and (d) visceral sites. For the extremity and trunk sites, grade, tumor size, and lymph node and distant organ involvement all remain elements of the staging system. There are now four T size categories rather than two: ≤5 cm, >5 to 10 cm, >10 to 15 cm, and >15 cm. Depth has been removed as a staging factor. Histologic subtype is still not included as a category. Lastly, there are new stage groupings including the movement of nodal involvement (N1) from stage III to stage IV. The 8th edition AJCC extremity and trunk STS stage groupings are shown in Table 87.1.

TABLE 87.1 AMERICAN JOINT COMMITTEE ON CANCER TNMG

STAGE GROUPINGS FOR EXTREMITY AND TRUNK SOFT TISSUE SARCOMA, 8TH EDITION					
Stage IA	G1,X	T1	N0	M0	Low Grade, Small
Stage IB	G1,X	T2-4	N0	M0	Low grade, large
Stage II	G2,3	T1	N0	M0	Moderate/high grade, small
Stage IIIA	G2,3	T2	N0	M0	Moderate/high grade, intermediate
Stage IIIB	G2,3	T3-4	N0	M0	Moderate/high grade, large
Stage IV	Any Grade	Any T	N1	M0	Nodal involvement
	Any Grade	Any T	Any N	M1	Metastatic

G, grade; GX, grade cannot be assessed; M0, no distant metastasis; M1, distant metastasis; NX, regional lymph nodes (LN) cannot be assessed; N0, no regional LN metastasis; N1, regional LN metastasis; T1, tumor ≤5 cm; T2, tumor >5 to 10 cm; T3, tumor >10 to 15 cm; T4, tumor >15 cm. PROGNOSTIC FACTORS FOR SURVIVAL AND LOCAL RECURRENCE

Many reports have evaluated patient and tumor characteristics to determine prognostic factors for disease-free survival (DFS) or overall survival (OS) and local recurrence (LR). The most powerful predictor for DFS and OS is the AJCC TNMG stage of the tumor. Survival rates are not yet available for the 8th edition, but 5-year DFS rates for AJCC seventh edition stages I, II, and III STS are 86%, 72%, and 52%, respectively.[39] The staging system incorporates most of the relevant prognostic variables. It is also valuable to consider predictive factors individually. The single most important individual prognostic factor for lower survival rates is high grade.[40–45] Five-year DFS rates range from 44% to 67% for high-grade tumors compared to 90% to 100% for low-grade tumors.[40–42] Other significant predictors for DFS include tumor size and site.[40,42–45] For a series of 1,091 patients from MD Anderson Cancer Center, 5-year OS rates were 85% for tumors ≤5 cm, 68% for tumors >5 to 15 cm, and 52% for tumors >15 cm.[44] Furthermore, patients with tumors located in the head and neck or retroperitoneum have lower survival rates than those with tumors located in the extremity or superficial trunk.[41,45,46] Histologic subtype is predictive of both OS and DFS in several reports.[40,43,44,46,47] Callegaro et al. developed two robust nomograms to predict OS and DFS for extremity STS and demonstrated adverse survivals for vascular tumors, leiomyosarcoma, synovial sarcoma and malignant peripheral nerve sheath tumor compared to all liposarcoma subtypes,

myxofibrosarcoma, and undifferentiated pleomorphic sarcoma.[43] It now appears that tumor depth (superficial or deep to fascia) is not a prognostic factor, and accordingly, depth has been removed from the staging system.[43,45,48] Older age at presentation, positive resection margins, bone or neurovascular invasion, gender, and race all show mixed results regarding their predictive value for DFS.[40–46] As stated earlier, lymph node involvement for STS is rare, but if present, it is an adverse prognostic factor.[18–20]

Consistently demonstrated significant predictors for LR include positive margins of resection, presentation with locally recurrent disease, older age, and head and neck or retroperitoneal location. Rates of LR for tumors resected with positive margins range from 28% to 56% compared to 0% to 20% for those with negative margins.[30,40,41,49–54] Patients who present with locally recurrent disease are at higher risk for subsequent LR (25% to 47%) than are those who present with primary disease (11% to 21%).[40,50] Age has been analyzed with varying cutoff values including >50 years, >64 years, and as a continuous variable. Repeatedly, older age has been associated with higher LR rates.[40,41,55]

MANAGEMENT AND OUTCOME FOR SOFT TISSUE SARCOMAS OF EXTREMITY AND TRUNK

Because of the rarity of STS and the numerous forms in which it can present with respect to tumor histology, site, and size, there are many nuances related to optimal management. Furthermore, delivery of treatment requires a multimodality team that includes experienced pathologists; radiologists; surgeons from the disciplines of surgical oncology, orthopedics, and reconstructive surgery; radiation oncologists; medical oncologists; nurses; physical therapists; and social workers. Treatment goals include complete eradication of tumor with optimal function preservation and minimal treatment-related toxicities. Execution of these goals is complex, and, for this reason, STS is best treated by an experienced team at a specialized sarcoma center. Reports from Sweden, the United Kingdom, the United States, and Canada have shown superior outcomes for STS treated at specialized centers.[56–60]

Surgery

In almost all cases, appropriate surgical resection is a prerequisite for curative treatment of STS. A range of surgical procedures has been employed for the treatment of STS with varying levels of success. These procedures include

marginal resection or excisional biopsy, wide resection, and radical resection or amputation. A marginal resection refers to simple removal of the tumor with its pseudocapsule. This is also often described as a “shell-out” or “whoops” procedure and is commonly performed when the diagnosis of STS is not suspected. LR rates after marginal resection range from 50% to 93%.[17,61,62] This is not surprising as it is known that microscopic tumor cells can extend beyond the pseudocapsule and up to several centimeters beyond palpable gross tumor.[16,33] Marginal resection is not an appropriate treatment.

At the other end of the spectrum is radical resection, which involves removal of all of the muscles and neurovascular structures within the compartment where the tumor resides or amputation. Reported LR rates after radical resection are much lower and range from 0% to 18%.[17,51,61,62] These LR rates are acceptable, but the cost of loss of limb (or loss of an entire compartment) is high. Amputation was a common procedure for STS of the extremities up to the 1970s.

The intermediate procedure is a wide resection. Wide resection is also described as conservative surgery (CS), limb-sparing surgery, or function-sparing surgery. It involves *en bloc* removal of tumor with a desired rim of normal tissue varying in width from about 1 cm to several centimeters depending on anatomic constraints. This procedure preserves good function (limb salvage) but as a treatment by itself is usually associated with moderately high LR rates, ranging from 25% to 60%.[17,61,62]

Wide resection/CS combined with pre- or postoperative radiation therapy (RT) is the current standard of care for most high-grade STS. Surgeons should attempt to attain negative margins at the time of definitive resection. As previously stated, the presence of positive margins is consistently associated with increased LR rates even when RT is used.[40,41,49–54,63] Because STS is so rare in comparison to benign soft tissue lesions, the initial procedure performed for an STS is often an unplanned excision (shell-out) with resulting positive margins. It is important to perform a definitive re-excision in these situations, if possible, as the likelihood of finding significant residual disease is on the order of 24% to 63%.[8,64–67] As part of the re-resection, incisions, biopsy tracts, drain sites, and any tissues contaminated by the first surgery need to be removed *en bloc* along with tumor-bed margins. Unfortunately, this often results in a greater scope of surgery and increased functional deficit than if an initial planned excision had been performed by an experienced oncologic surgeon.[38] Lastly, although the goal of resection is to attain negative margins, if this would require

debilitating surgery, such as resection of a nerve, vessel, or bone, a function-sparing approach with a planned positive margin is acceptable. These decisions are best handled by experienced sarcoma surgeons. Gerrand et al.[52] compared LR rates resulting from procedures with planned positive margins (abutting critical structures) to those of procedures with unplanned (unexpected) positive margins. They found a 4% LR rate for the former compared with a 32% to 38% LR rate for the latter.

Conservative Surgery and Radiation Therapy

Three sentinel randomized trials have been performed and have established RT combined with CS as the standard management for most (high-grade) STS of the extremities and trunk (Table 87.2). The first of these trials was conducted by Rosenberg et al.[51] at the NCI. Patients with high-grade STS of the extremity were randomized to amputation or to CS and postoperative external-beam RT (60 to 70 Gy). Patients in both treatment arms received postoperative doxorubicin, cyclophosphamide, and methotrexate; in the RT arm, chemotherapy was started 3 days prior to RT and continued concurrently with RT. LR rates were 0% (0 of 16) and 15% (4 of 27) for patients treated with amputation and with CS and RT, respectively (P = .06). There was no significant difference in survival rates. This trial was instrumental in setting a new standard for limb-sparing local management of STS. Amputations are now performed sparingly and in <15% of cases.[71,72]

TABLE 87.2 RANDOMIZED CONTROLLED TRIALS INCLUDING RADIATION THERAPY FOR SOFT TISSUE SARCOMAS OF THE EXTREMITIES AND TRUNK

Study	Treatment Arms	Local Recurrence	OS or DFS
Rosenberg[51] NCI 1982 N = 43 (Extremity)	Amputation vs. CS + EBRT (60–70 Gy) (both arms received doxorubicin, cyclophosphamide, methotrexate)	0% (0/16) 15% (4/27) P = .06	88% 83% P = .99 (5-year OS)
Pisters[63] MSKCC 1996 N = 164 (Extremity + trunk)	High grade (n = 119) CS vs. CS + BRT (42–45 Gy) Low grade (n = 45) CS vs. CS + BRT (42–45 Gy)	30% (19/63) 9% (5/56) P = .0025 26% (6/23) 36% (8/22) P = .49	All patients 81% 84% P = .65 (5-year DFS)

Yang[68] NCI 1998 *N* = 141 (Extremity)	High grade (*n* = 91) CS vs. CS + EBRT (63 Gy) (both arms received doxorubicin, cyclophosphamide) Low grade (*n* = 50) CS vs. CS + EBRT (63 Gy)	19% (9/47) 0% (0/44) *P* = .003 33% (8/24) 4% (1/26) *P* = .016	74% 75% *P* = .71 (10-year OS) 92% (22/24) 92% (24/26) (no. alive)
O'Sullivan[69,70] CSG 2004 *N* = 190 (Extremity)	Preop RT (50 Gy) + CS CS + postop RT (66 Gy)	7% 8% *P* = NS (5-year LR)	73% 67% *P* = .48 (5-year OS)

BRT, brachytherapy; CS, conservative (limb-sparing) surgery; CSG, Canadian Sarcoma Group; DFS, disease-free survival; EBRT, external-beam radiation therapy; MSKCC, Memorial Sloan-Kettering Cancer Center; NCI, National Cancer Institute; OS, overall survival; preop, preoperative; postop, postoperative.

The next question posed was whether adjuvant RT is necessary. Two hallmark trials randomized patients between CS alone and CS plus RT.[63,68] Both of these trials showed improved local control with the addition of RT. At the NCI, patients with high-grade STS of the extremity were randomized to treatment with CS and postoperative chemotherapy (doxorubicin and cyclophosphamide) with or without concurrent external beam RT (63 Gy). Patients with low-grade tumors were randomized to CS with or without postoperative external beam RT (63 Gy). LR rates for the high-grade tumors were 20% (9 of 44) for CS and chemotherapy compared to 0% (0 of 47) for CS, chemotherapy, and RT (*P* = .003). For the low-grade tumors, LR rates were 33% (8 of 24) for CS alone and 4% (1 of 26) for CS and RT (*P* = .016). There were no significant differences in survival rates between the two groups. An update of this trial confirmed the lack of survival difference with 20-year OS of 64% for CS alone and 71% for CS and RT (*P* = .22).[73] At Memorial Sloan-Kettering Cancer Center (MSKCC), patients with STS of the extremity and trunk were randomized to treatment with CS alone or CS plus adjuvant low dose rate brachytherapy (BRT).[63] BRT catheters were sewn into the tumor bed in a parallel array with 1-cm spacing between catheters and extension of catheters 1.5 to 2.0 cm beyond the tumor bed. Iridium-192 was loaded into the catheters, and a dose of 42 to 45 Gy was delivered over 4 to 6 days. LR rates for high-grade tumors were 30% (19 of 63) for CS alone compared with 9% (5 of 56) for CS plus BRT (*P* = .0025). No

difference in LR rates by treatment was seen for low-grade tumors; rates were 26% (6 of 23) and 36% (8 of 22) for patients treated with CS alone and CS plus BRT, respectively. As in the two prior trials, there were no significant differences in survival outcomes. Given that BRT did not improve local control for low-grade tumors in this trial, BRT is typically not recommended for low-grade STS. Furthermore, for high-grade tumors treated with BRT, LR rates are higher in the setting of positive margins.[74] Therefore, BRT as monotherapy is only recommended for high-grade tumors resected with negative margins.(In the setting of positive resection margins, a combination of external beam RT and BRT or external beam RT alone is preferred.) These two randomized trials have established the role for RT combined with CS for the management of high-grade (and, in select cases, low-grade) STS. In modern series, local control following CS and RT is excellent, with most reported LR rates being <15%.[50,54,69,75–78] It is important to note that the current treatment recommendation for most low-grade STS of the extremity and trunk is wide excision alone.[79,80] As long as negative margins are obtained, LR rates are expected to be well under 20%. Relative indications for RT in the setting of low-grade tumors include situations of positive resection margins, locally recurrent disease following initial wide excision, and tumor location that would not be amenable to subsequent salvage surgery.

Radiation Therapy

Positioning the Patient

The first step of RT planning is to determine the appropriate positioning of the patient. It is important for the patient to be comfortable to ensure setup reproducibility. The multiple beam angles employed with intensity-modulated RT (IMRT) techniques[81] enable more positioning options than would be the case for 3D-CRT techniques. In general, patients are placed in the supine position unless this places pressure on and deforms the tumor, in which case the prone position is used. Suitable positions for upper extremity lesions include supine with abduction of the arm away from the body with supination or pronation of the arm determined by the location of the tumor. Another good approach for upper extremity lesions is the “swimmer position,” whereby the patient is prone with the arm extended above the head (Fig. 87.3A). For treatment of a leg, the ipsilateral leg should be straight, and the contralateral leg separated to create a gap (Fig. 87.3B). If the target is in the proximal leg, the contralateral leg can be in a frog-leg position with support under the knee. For men with proximal

tumors, the genitalia should be pulled to the contralateral side (using mesh or other techniques). All men with treatment fields close to the genitalia should consider sperm banking if they wish to preserve fertility. Similarly, for cases with treatment fields close to the ovaries (e.g., tumors of proximal thigh, buttock, abdominal wall), woman interested in fertility preservation should be referred for reproductive counseling prior to starting RT. Tumors in the true anterior or posterior compartments of the leg are often the most challenging. Sometimes, the supine position with external rotation of the leg enables the use of predominantly obliquely oriented fields to achieve adequate target coverage and bone sparing. If this is not feasible, the decubitus position represents another option.

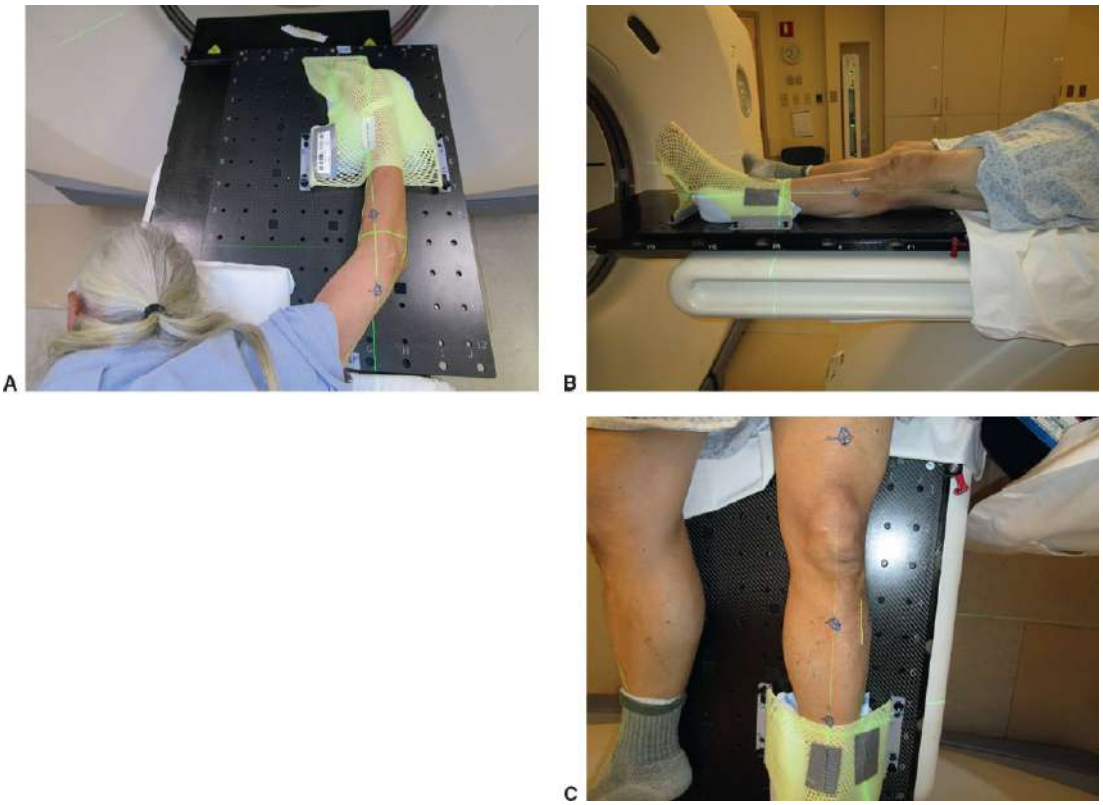

FIGURE 87.3. Examples of patient positions, immobilization, and tattoo placement for treatment of upper and lower extremity soft tissue sarcoma (STS). Patients are immobilized in custom casts that are indexed to the table top. **A:** The "swimmer position" is often an ideal position for treating STS of the hand, forearm, or distal upper arm. The hand is immobilized with a custom cast for all upper extremity tumors. Anterior tattoos are placed about 15 to 20 cm apart in the same sagittal plane. **B:** For treatment of a lower leg tumor, the patient is supine with the ipsilateral leg neutral and straight, and the contralateral leg is separated to create a gap. The foot is immobilized with a custom cast for all lower extremity tumors. Lateral tattoos are placed in the same axial plane as the anterior tattoos. **C:** Anterior view of the lower leg tumor showing placement of tattoos at isocenter and about 15 to 20 cm apart in the same

sagittal plane.

Once the position is determined, the patient must be immobilized in a reproducible fashion. A custom cast indexed to the table top is highly recommended for almost all scenarios; it is important to immobilize the foot with a custom mold for all lower extremity tumors and to immobilize the hand for all upper extremity tumors (Fig 87.3A and B). With respect to tattoo placement, a helpful protocol for extremities is to use 3 anterior tattoos and 3 lateral tattoos. The 3 anterior tattoos are placed about 15 to 20 cm apart in the same sagittal plane (Fig. 87.3A and C), and at each point, an additional lateral mark is placed in the same axial plane (Fig. 87.3B). The 6 tattoo points are all placed in a stable anatomical location for the primary purpose of reproducing the position of the entire length of the extremity, and the secondary purpose of creating a reference point for aligning the isocenter.

Target Volumes and Treatment Fields

Preoperative Radiation Therapy

Historically, treatment volumes for STS of the extremities and trunk were composed of large longitudinal margins of at least 5 cm and sometimes >10 cm with good success. Current standard of care target volumes for preoperative RT include gross tumor volume (GTV) defined as the gross tumor delineated by the T1 postgadolinium MRI. Fusion of the diagnostic MRI and planning CT for optimal target definition is strongly encouraged. Clinical target volume (CTV) is defined as the GTV plus 4-cm margins in the longitudinal directions and 1.5-cm margins radially.[82] These margins can be truncated if they extend beyond the compartment or beyond an intact fascial barrier, bone, or skin. Editing target volumes 5 mm beneath skin surface is recommended in most scenarios to attain superficial dose avoidance. (Planned skin resection should be confirmed with the surgeon in this setting.) Peritumoral edema on T2 MRI will often be included within the CTV as defined above. If the edema is more extensive and appears suspicious, the CTV can be enlarged to include it at the discretion of the radiation oncologist. Of note, more clarity is needed to determine in which situations peritumoral edema should be included in the CTV. One report showed the presence of sarcoma cells beyond the gross tumor in 10 of 15 patients. The location of the cells varied from 1 to 4 cm beyond the tumor but did not correlate with the location or extent of peritumoral edema on MRI.[33] It is reasonable to try to include the edema in the CTV, unless so doing would require a significant

increase in the treatment field. The planning target volume (PTV) is defined as the CTV plus 5 to 10 mm based on institution setup uncertainty. Figure 87.4 depicts MRI images and target volumes and for an STS of the right proximal medial thigh that was treated with preoperative IMRT.

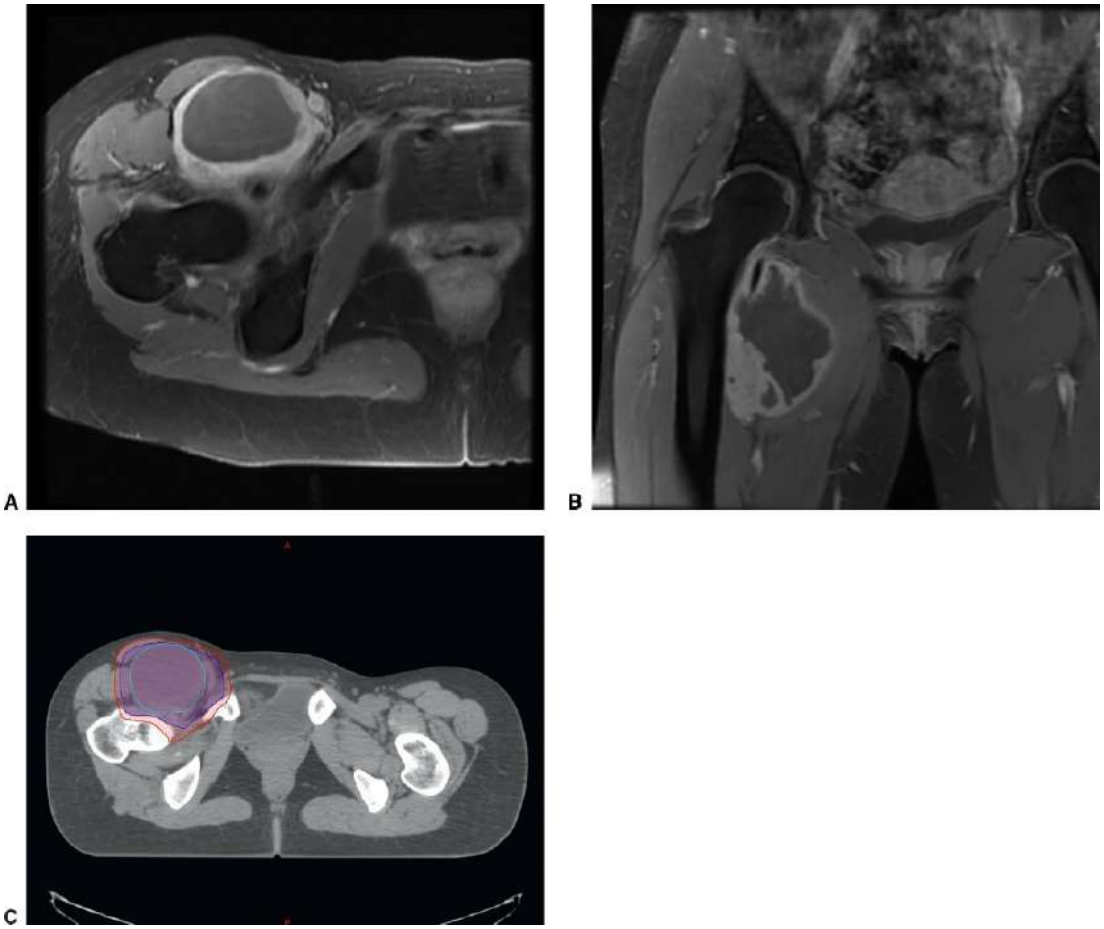

FIGURE 87.4. An unclassified pleomorphic high-grade sarcoma of the medial proximal right thigh in a 30-year-woman that was treated with preoperative IMRT (50 Gy). **A:** Axial T1 postgadolinium image of the magnetic resonance imaging (MRI) scan. **B:** Coronal T1 postgadolinium image of the MRI scan. **C:** Axial slice of the planning CT scan showing the gross tumor volume (GTV, *cyan*), clinical target volume (CTV, *purple*), and planning target volume (PTV, *red*).

Several series using treatment volumes similar to those described above have reported excellent local control rates on the order of 85% to 90%.[69,76–78,83] Furthermore, using these standard volumes, most LRs that occur are located within treatment fields rather than marginal to the fields.[76,77]

Postoperative Radiation Therapy

For postoperative treatment, the nomenclature for GTV and CTV is variably

described and partly a matter of semantics given that there is actually no “gross tumor.” It can be helpful to draw a GTV in the location where the gross tumor was preoperatively, as sometimes this volume is used for cone-down volumes. It is also helpful to contour the operative bed. The CTV should encompass all the tissues handled during the surgery including the incision and any drain sites. (Postoperative changes seen on MRI help define the operative bed.) An additional longitudinal margin of 4 cm and a radial margin of 1.5 cm is generally added to the operative bed to form the CTV.[82] The same principles apply as listed above in terms of using the T1 postgadolinium images for GTV definition, fusing the planning CT and MRI when possible, and editing the CTV to exclude bone, an intact fascial planes, skin, or extension beyond an uncontaminated compartment. The PTV is typically CTV plus 5 to 10 mm, per institutional standard for set-up uncertainty. A second course field reduction is typically used in the postoperative setting. CTV margins for the reduced field (cone down) are generally 2 cm from the initial GTV. These postoperative treatment field definitions are associated with excellent local control rates and are the current standard of care.[69,76,83]

The excellent local control rates resulting from the use of standard preoperative and postoperative treatment fields establish that these fields are adequately large, but they do not address the question of whether these field sizes could be reduced. As such, the necessity of such large treatment fields has been called into question. Initial development of these large fields predated the CT and MRI era, when imaging modalities to define STS were suboptimal. Moreover, the BRT experience at MSKCC produced excellent local control rates using treatment volumes that extended only 1.5 to 2 cm beyond the tumor bed.[63] Lastly, several single-institution series of treatment with surgery alone have been associated with very good local control rates ranging from 0% to 20% (see the Surgery Alone section).[84–89] Specifically, Baldini et al.[85] found no recurrences in 36 patients with resection margins ≥1 cm compared to an actuarial 10-year LR rate of 13% (4 of 38) for those with margins <1 cm. Based on these observations, it is reasonable to query whether treatment field sizes can be reduced. Two studies have addressed this question. The first study is RTOG-0630, a phase II study using image-guided RT (IGRT) and reduced fields for preoperative RT for extremity STS. For tumors that were grade 2 to 3 and ≥8 cm, the CTV was defined as GTV plus 3-cm longitudinal and 1.5-cm radial margins, and for tumors that were grade 1 or <8 cm, the CTV was defined as GTV plus 2 cm longitudinal and 1 cm radial margins. The CTV also included suspicious

edema on MRI T2 images. For a cohort of 79 patients, 2-year local control was 11% and all five LRs occurred within the treatment fields.[90] The authors conclude that because of the absence of marginal field recurrences, the reduced volumes were appropriate. These results are encouraging but require longer follow-up and external validation before widespread adoption of reduced volumes for preoperative RT is appropriate. The second trial is the VORTEX trial in which patients with extremity STS receiving postoperative RT were randomized to standard fields with GTV plus 5-cm longitudinal and 2-cm radial margins or to tailored fields of GTV plus 2 cm in all directions. Preliminary results presented in abstract form described a sample size of 216 patients, and 5-year local recurrence-free survival rates of 86% for standard fields and 84% for reduced fields (P = not significant).[91] Similar to the case above, these results are intriguing, but it is not appropriate to adopt reduced postoperative volumes based on early results of one study.

Brachytherapy

The CTV for BRT treatment as monotherapy should include the operative bed with a margin. The American Brachytherapy Society consensus statement describes an appropriate CTV as the surgical bed plus a 2-cm longitudinal margin and 1- to 2-cm lateral margin.[92] Similarly, the MSKCC randomized trial used margins of 1.5 to 2 cm beyond the tumor bed.[63] A more detailed description of BRT modalities, techniques, and indications is beyond the scope of this chapter. The American Brachytherapy Society consensus statement published in 2017 is a very good reference.[92]

Doses

The standard dose for preoperative external beam RT is 50 Gy delivered in 2-Gy fractions.[82] In the situation of positive margins, a postoperative external beam RT boost of 16 to 20 Gy (delivered in 1.8- to 2-Gy fractions) is sometimes delivered. The efficacy of this boost dose has not been proven and, as it may be associated with increased toxicity, its use has been called into question.[80,93,94] Other techniques to deliver an additional boost dose include BRT (both low dose rate and high dose rate) and intraoperative electron therapy. Because of variabilities in patient selection for these procedures, it is difficult to determine the relative benefit of the additional dose delivered by these modalities.[95–98] For postoperative external beam RT, treatment usually commences about 4 to 6 weeks following surgery and once the wound is fully healed. Recommended

total doses are 60 to 66 Gy (delivered in 1.8- or 2-Gy fractions) for the case of negative margins and 66 to 68 Gy for positive margins.[41,99,100] The first course of treatment is typically treated to a dose of 45 to 50 Gy and the balance of the dose is given in one reduced field. The standard dose for low dose rate (LDR) BRT is 45 Gy and for high dose-rate (HDR) BRT is 30 to 50 Gy in 2- to 4-Gy bid fractions.[63,92] For treatment combining external beam RT with BRT as a boost, doses are typically 45 to 50 Gy for external beam, 15 to 25 Gy for a LDR BRT boost, and 12 to 20 Gy (in 2- to 4-Gy bid fractions) for a HDR BRT boost, for a total of approximately 65 Gy.[92,95]

Principles of Treatment Planning

As for any other malignancy, the basic principles of RT planning are to achieve good coverage of the PTV with maximal sparing of adjacent normal structures. For extremity lesions, the important normal structures are the limb itself, soft tissues, bones, and joints. For proximal thigh lesions, the perineum and genitals are also relevant. For STS of the trunk, adjacent normal structures can include small bowel, kidneys, spinal cord, stomach, liver, heart, and lung. Basic tenets for treating the extremity are to “spare a strip” of the limb circumference (to prevent subsequent lymphedema and pain), to avoid treating the whole thickness of bone to high doses (to diminish risk of fracture), and to avoid treating an entire joint to high doses (to decrease joint stiffness). It is not always possible to preserve fertility (and in any borderline situation, one should offer sperm banking or fertility consultation). Every effort should be made to place the testicles as far out of the field as possible to avoid direct treatment and to minimize the contribution from internal scatter.

Specific dosing guidelines for structures of the extremity are as follows. Spare as much as possible of the limb circumference from receiving any dose, and at a minimum, spare a 1-cm thickness to receive <20 Gy. With 3D-conformal techniques, part of the limb can usually be excluded entirely from the treatment fields. With IMRT, in order to achieve more dose conformality, the trade-off is that the volume of tissue that receives a low dose is increased; for some of these cases, the entire circumference of the limb may receive some low dose. The acceptable low dose that can be delivered to the entire limb has not been well established and will most likely vary with factors such as the total dose delivered, total volume of tissue treated, and the location in the limb. However, as a guideline, it is helpful to contour a strip of limb circumference to use as an avoidance structure in order to keep part of the treated limb dose to a

minimum (<20 Gy). The whole-joint dose should be <40 to 45 Gy. Higher doses can be delivered to part of the joint if needed. Full-thickness bone irradiation should be avoided if possible, and the mean and maximum doses to the whole bone should also be kept to a minimum. Dickie et al.[101] performed a detailed analysis of dosimetric predictors for bone fracture using a matched pair analysis and found that radiation-related bone fractures were reduced if the following parameters were met: volume of bone receiving ≥40 Gy (V40) <64%, mean dose to bone <37 Gy, and maximum dose to bone <59 Gy. Normal-tissue complication probabilities for organs that may be affected by treatment of a truncal STS are listed in the Quantitative Analysis of Normal Tissue Effects in the Clinic document.[102] If RT treatment of a trunk lesion may potentially ablate ipsilateral kidney function, a renal scan should be performed to ensure adequate function of the contralateral kidney. Despite historical teaching to the contrary, tissue-equivalent bolus material is discouraged in the preoperative setting and infrequently necessary in the postoperative setting. In the preoperative setting, a paddle of skin is typically removed along with superficial tumor obviating the need for bolus; furthermore, increased surface dose appears to increase wound complication risk.[78,103] With respect to the postoperative setting, the BRT experience showed that failure to treat incision or drain sites was not associated with scar or drain site recurrences.[63]

Three-dimensional conformal RT (3D-CRT) and IMRT are both acceptable external beam treatment techniques, but IMRT has several advantages over 3D-CRT and is generally preferred. The principal dosimetric differences between these two techniques are that, compared with 3D-CRT, IMRT typically achieves comparable target coverage, improved conformality of the dose distribution around the target volume, and reduced volumes of high doses to normal tissues, but at the cost of greater volumes of low doses to normal tissues, and greater total body exposure due to increased monitor units.[104,105] Several studies show similarly excellent local control rates with IMRT compared to 3D-CRT.[69,78,83,90,103] Importantly, it also appears that IMRT is associated with a more favorable toxicity profile compared to 3D-CRT (see Chronic Radiation Therapy Toxicities). On the other hand, Hall[104] raised a caveat that IMRT may be associated with a higher rate of radiation-associated second cancers compared to 3D-CRT, resulting from the use of more monitor units with a greater total body exposure from leakage, and from a larger volume of normal tissue exposure to low doses of RT, resulting from the greater number of treatment fields. To date, there are no data suggesting higher second cancer rates dues to

IMRT. Weighing all the evidence, IMRT is the preferred technique for most extremity and trunk STS.

There continue to be exciting technologic advances for treatment, which include IMRT dose painting, IGRT, adaptive RT, particle-beam radiotherapy (protons, carbon ions), and stereotactic body RT (SBRT). *Dose painting* is an application of IMRT in which differential doses are delivered to different areas of the target volume simultaneously. An interesting concept is to use dose painting to deliver higher doses to areas of the tumor believed to be more radioresistant (such as hypoxic regions), areas that may contain a higher burden of disease, or high-risk areas of the tumor that may result in positive resection margins. This appealing technique is under investigation in the setting of retroperitoneal sarcoma.[106] *Image-guided radiation therapy* refers to serial imaging of patient setup prior to treatment so that appropriate positional adjustments can be made beforehand. Because of the increased certainty of treatment accuracy, in many cases, the added margins for "setup error" can be reduced, which allows for smaller treatment fields and potential dose escalation without undue normal tissue toxicity. For example, although spinal cord tolerance is 50 Gy, Hansen et al.[107] described the ability to treat paraspinal sarcomas to 59.4 Gy using IGRT with CT imaging to better assess patient position prior to treatment. IGRT and reduced treatment fields were also used in the phase II RTOG-0630 trial.[90] Another benefit of IGRT is that if imaging during a course of treatment demonstrates changes in patient anatomy (e.g., due to weight loss) or changes in tumor shape, a second radiation plan can be developed to adapt to these new data. This is referred to as *adaptive radiation therapy* and might be relevant for sarcomas that respond dramatically to radiation, such as myxoid liposarcoma.[108,109]

Particle beams such as protons and heavier ions (carbon ions) have more favorable physical and biologic characteristics than do photons, which make them appealing for clinical use. Specifically, because of the Bragg peak dose distribution property, treatment plans can be created with steep dose falloff at field borders.[110] This allows for ideal sparing of adjacent critical normal structures as well as opportunities for safe dose escalation. Proton-beam treatment for malignancies has been in use at a few centers for several decades. There are published data for treatment of chordomas and chondrosarcomas of the skull base as well as for paraspinal and sacral bone tumors. There have been no randomized studies comparing photons and protons for STS, but there are several single-institution reports for protons that show very good results. Local

control rates for skull-base chordomas treated with protons range from 46% to 90% and for skull-base chondrosarcomas range from 75% to 100%.[111–116] Carbon ions have been used for clinical treatment only since the 1990s. Schulz-Ertner et al.[117,118] reported a 74% 4-year local control rate for skull-base chordomas treated with carbon ions and a 90% local-control rate for skull-base chondrosarcomas. The group from Chiba, Japan, reported a 73% local-control rate for unresectable bone and STS and a 96% local-control rate for sacral chordomas.[119,120] These early results are impressive, but confirmatory long-term follow-up data are needed.

Stereotactic body radiation therapy is a technique that delivers highly focused photon radiation doses to extracranial lesions. The dose schedules are hypofractionated, with large ablative fraction sizes ranging from 6 to 30 Gy/fraction, typically for a course of 1 to 5 treatments. With respect to sarcoma, SBRT may have a role in the treatment of oligometastatic disease. Excellent local control rates, ranging from 73% to 96%, have been reported for treatment of metastases to the lung as well as other sites for a mix of tumors including sarcoma.[121–123] There are fewer data regarding the role of SBRT for definitive treatment of primary sarcomas, but there may be a role in select patients with tumors located in or adjacent to sensitive normal structures. For example, a study of SBRT for 14 patients with primary sarcoma of the spine reported local control for 5 of 7 patients treated with SBRT alone and for 5 of 7 patients treated with SBRT and surgery.[124] Figure 87.5 shows an MRI and dosimetry for a case of an unresectable leiomyosarcoma of the inferior vena cava that was treated with definitive SBRT at Brigham and Women’s Hospital.

IMRT with dose painting, adaptive RT, particle beams, and SBRT all show potential dosimetric and biologic advantages compared to conventional 3D-CRT photon treatment. Promising data are available for all of these approaches, but they are limited. There will likely be appropriate places for all of these technologies in the armamentarium for sarcoma treatment, but further careful study is needed to define the optimal role of each technology and to ensure that toxicities are acceptable.

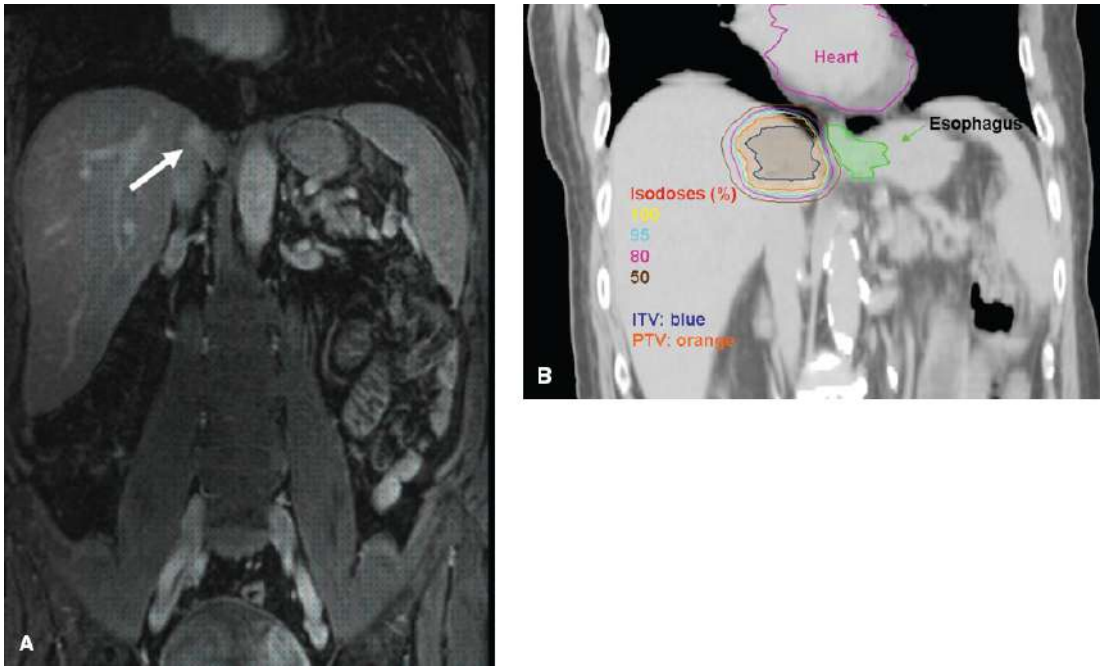

FIGURE 87.5. A 72-year-old man with a 1.8 × 1.8 cm unresectable leiomyosarcoma of the intrahepatic inferior vena cava in close proximity to the liver, esophagus, and heart that was treated with stereotactic body radiation therapy (SBRT) (60 Gy in 5 fractions). **A:** Coronal T1-weighted magnetic resonance image slice showing the tumor (denoted by the *arrow*). **B:** Coronal slice of the SBRT graphic plan showing the internal target volume (ITV, *blue*), planning target volume (PTV, *orange*), and covering isodose lines.

Radiation Therapy Toxicities

Acute Radiation Therapy Toxicities

Acute toxicities following RT treatment of the extremities include skin erythema and possible desquamation in high-dose areas, problems with wound healing, localized alopecia, and fatigue. Moist desquamation can be quite uncomfortable, but this heals typically quickly after completion of RT. Depending on tumor location, treatment of STS of the trunk can be associated with additional toxicities such as nausea, bowel irritability, or esophagitis.

The most significant of these acute sequelae is problems with wound healing. Several retrospective single-institution series have reported wound complication rates following preoperative RT of 25% to 46%.[78,125–128] Rates following postoperative RT are lower and range from 6% to 29%.[125,126] The most definitive data pertaining to wound complications are provided by the landmark randomized trial performed by the NCI Canada, in which the study endpoint was major wound complications within 120 days of surgery.[70] Major wound complications were defined as those requiring a second operation for wound repair or wound management requiring an invasive procedure, readmission, or

persistent deep packing for 120 days or longer. This trial randomized 190 patients to preoperative RT (50 Gy ± 16 to 20 Gy postoperative boost) or postoperative RT (66 to 70 Gy). With a median follow-up time of 3.3 years, the study met early stopping rules and closed. Wound complication rates were 35% for patients treated with preoperative RT compared to 17% for those treated with postoperative RT (P = .01). Further, lower extremity site and tumor size >10 cm were independent predictors for wound complications on multivariate analysis. Others have also found large tumor size and lower extremity site to be risk factors for wound complications.[78,126] Baldini et al.[78] have reviewed the experience at Brigham and Women's Hospital and Dana-Farber Cancer Institute for 103 patients with STS of the trunk or extremity treated with preoperative RT. On multivariate analysis, significant independent predictors for wound complications were tumor size >10 cm, tumor proximity to skin surface <3 mm, vascularized flap closure, and diabetes mellitus. In an attempt to decrease wound complications following preoperative RT, O'Sullivan et al.[103] conducted a phase II trial for 59 patients with lower extremity sarcoma. Together with the surgeon, the radiation oncologist contoured the area of the subsequent surgical flaps and designated it as an avoidance structure for IMRT planning. The resulting rate of wound complications was 30.5%, which was lower than but not statistically different from the 43% rate reported in the randomized trial. However, for patients with minimal (<1%) overlap of the flap and PTV, the wound complication rate was 14.3% compared to 39.5% for those with flap/PTV overlap (P = .04). The association of higher wound complications with higher flap doses is consistent with the findings in the Baldini report showing increased complications for tumors within 3 mm of the skin surface. Efforts continue to minimize postoperative wound complications.

Chronic Radiation Therapy Toxicities

The most significant chronic toxicities following RT to the extremities include edema, subcutaneous fibrosis, decreased muscle strength, decreased range of motion, pain, and, less commonly, bone fractures. Published rates of these toxicities vary, as series have different patient inclusion criteria (with respect to tumor site and treatment) and some report only moderate or severe complications, whereas others report any degree of complication. For series primarily composed of patients treated with 2-dimensional or 3D-CRT, reported rates for edema are 10% to 20%, for fibrosis they are 30% to 60%, and for bone fracture they are 0.04% to 7%.[101,129–135] Furthermore, several of these studies

correlated higher complication rates with higher doses and larger field sizes. Doses >60 or 63 Gy have been associated with higher rates of fibrosis, edema, bone fracture, pain, decreased muscle strength, and decreased range of motion.[101,129,130,132] Large RT field sizes have also been associated with more edema, fibrosis, and joint stiffness.[129,130] There have been no randomized trials comparing chronic toxicities for patients treated with 3D-CRT versus IMRT, but series composed primarily of patients treated with IMRT report lower chronic toxicities with rates for ≥ grade 2 edema of 5.3% to 11.1%, for fibrosis of 5.3% to 9.3%, and for joint stiffness of 3.5% to 5.6%.[83,90,103] Risk of bone fracture has been clearly correlated with bone doses, and IMRT enables better bone avoidance than 3D-CRT.

Radiation Timing: Preoperative Versus Postoperative

External beam RT can be delivered either prior to or following definitive resection. Reported local control rates with each approach are similar and range from 73% to 93% for preoperative RT and 72% to 92% for postoperative RT.[69,136–139] The randomized trial of preoperative versus postoperative RT conducted by the NCI Canada showed local control rates of 93% and 92% for the preoperative and postoperative groups, respectively.[69] Similarly, there is no clear difference in DFS or OS associated with either approach. The Canadian randomized trial initially showed improved survival for the preoperative RT treatment arm, but updated results showed no differences in any recurrence or survival outcomes.[69,70] One retrospective report that assessed 821 patients using the National Oncology Database showed improved DFS rates for patients treated with preoperative RT.[55] However, these results should be considered with caution given the retrospective nature of the report and associated potential selection biases.

Although the efficacy of these approaches seems to be similar, the toxicity profiles are clearly different. Preoperative RT is associated with a well-established increased risk of acute wound complications. Several retrospective reports have described wound complication rates on the order of 25% to 46%.[78,126,127] As described in detail above (see the Acute Radiation Therapy Toxicities section), the definitive data for wound complication rates come from the Canadian randomized trial in which the primary endpoint was wound complications. In that trial, wound complication rates were 35% for patients treated with preoperative RT compared to 17% for those treated with postoperative RT (P = .01).[70] Although wound complications adversely affected

functional outcome for patients in the early postoperative period (6 weeks after surgery), this toxicity was largely reversible, as evidenced by the fact that function was equivalent between the treatment arms 1 year after resection.

On the other hand, patients treated with postoperative RT have a higher rate of chronic and generally irreversible toxicities, which include subcutaneous fibrosis, joint stiffness, edema, and bone fractures. These late toxicities have been reported in retrospective series but, again, good data come from the Canadian randomized trial.[129,130,132,140] Davis et al.[130] reported that grade 2 or higher late toxicity rates were higher for the postoperative RT group than the preoperative group. Specifically, for the postoperative and preoperative groups, respectively, rates of grade 2+ complications were as follows: subcutaneous fibrosis, 48% versus 31.5%; joint stiffness, 23% versus 18%; and edema, 23% versus 15.5%. These differences were not statistically significant, but the study was not powered to detect these differences. Statistically significant associations were seen between larger field size and rates of fibrosis, joint stiffness, and edema. Additionally, in a retrospective series, Holt et al.[132] reported increased rates of bone fracture for patients treated postoperatively (60 to 66 Gy) compared to those treated preoperatively (50 Gy). The rates were 7% and 0.6%, respectively ($P = .007$).

It is helpful to summarize the relative advantages and disadvantages for preoperative versus postoperative RT. For preoperative RT, the advantages include the ability to treat with smaller RT fields and lower doses, both of which are associated with reduced permanent long-term toxicities. Lower RT doses are also associated with reduced treatment time, lower costs, and a hypothetical possibility of lower second-malignancy risks. Other potential advantages of preoperative RT include the ability to render unresectable or marginally resectable tumors resectable, the potential to prevent tumor seeding of the operative bed or systemic circulation, and an increased efficacy of RT from good oxygenation of tissues due to unperturbed tumor vasculature. Furthermore, in most cases, defining the tumor volume for RT planning is relatively straightforward given that it is *in situ*. The main disadvantage of preoperative RT is the higher risk of major wound complications and its concomitant increased morbidity and cost. However, most major wound complications are treatable, and therefore, this toxicity is generally considered reversible. Another disadvantage of preoperative RT is that the resected specimen is potentially less informative on pathology review because of the prior treatment.

Postoperative RT has the advantage that the complete tumor specimen is

available for pathology review for determination of histology and margin status. Another important advantage is the lower risk of major wound complications. The main disadvantages of postoperative RT are the necessity for larger treatment volumes and higher doses, which are associated with higher long-term toxicities such as subcutaneous fibrosis, joint stiffness, edema, pain, and bone fractures. For the most part, these toxicities are irreversible. In theory, the interrupted vasculature related to surgery may create a hypoxic environment, rendering RT less effective (this is a potential explanation for the need for higher doses compared to the preoperative setting). Lastly, determining an RT target definition is more complex in the postoperative setting, as it requires reconstruction of where the tumor resided as well as definition of the entire operative field.

In conclusion, pre- and postoperative RT are associated with equivalent efficacies but different toxicity profiles, the most salient of which are increased (reversible) wound complications for preoperative RT and increased (irreversible) long-term toxicities of fibrosis, edema, and joint stiffness for postoperative RT. The topic is controversial, but preoperative RT is generally the preferred approach for STS of the extremities or trunk. Even when a patient is at high risk of developing a wound complication, one could argue for preoperative RT, as most wound problems are highly treatable with eventual recovery of good function.

Surgery Alone

As stated previously, CS and RT is the standard treatment for high-grade STS of the extremity and trunk. However, there are also several reports that demonstrate excellent outcomes following treatment with surgery alone. It is important to acknowledge that these are all single-institution series, all but one are retrospective, and patients were highly selected for treatment. These factors render the results less generalizable, so caution is recommended when considering this approach. Nonetheless, crude and actuarial LR rates in these select studies range from 0% to 20% and most are 10% or lower.[84–89,141] What the appropriate selection criteria for this approach are remains unclear, but potential factors can be inferred by close analysis of these reports. Excellent local control appears to be associated with wide resection performed for tumors in a subcutaneous location. Rydholm et al.[86] described only four LRs (5%) among 73 subcutaneous tumors treated with wide excision. In addition, Gibbs et al.[88] reported no LRs among 35 patients with subcutaneous STS treated with

wide excision alone. Among these tumors, 47% were high grade and 32% were >5 cm. Pisters et al.[87] described a prospective series of patients with tumors <5 cm who had negative resection margins and were treated with surgery alone. The overall crude LR rate was 8%, and among the subcutaneous tumors, the rate was only 5%. Furthermore, surgical technique and margin status are important. In the series reported by Rydholm et al.,[84] a large proportion of the cases were resected without an initial biopsy and, thus, without the potential for tumor seeding of intervening tissues.

Several of the reports also describe a meticulous surgical approach to wide resection with removal of a cuff of normal tissue as well as intact fascia.[84,86,88] In the prospective trial of Pisters et al.,[87] negative resection margins were a required criterion for treatment by resection alone. The report by Baldini et al.[85] quantified surgical resection margins. In that series, 74 patients were treated with surgery alone and the overall 10-year actuarial LR rate was 7%. Interestingly, there were no recurrences seen for 36 patients with resection margins ≥1 cm compared to a 10-year actuarial LR rate of 13% (4 of 38) for those with margins <1 cm (P = .04).

Conversely, the authors of a retrospective study from the Institut Gustave Roussy also quantified margin status.[142] They reported a 10-year actuarial LR rate of 35% for patients treated with surgery alone who had resection margins ≥1 cm. Further, they found the addition of RT for patients with these characteristics was not associated with a significant local control benefit. As the LR rate in that series is high, it is difficult to draw meaningful conclusions except to reinforce the concept that treatment with surgery alone should be done with care.

Cahlon et al.[141] assessed 200 patients who were treated with surgery alone at MSKCC following re-resection showing no evidence of disease. Although the overall 5-year actuarial LR rate was only 9%, on multivariate analysis, age >50 and stage III disease were both predictors for higher LR rates. If both of these factors were present, the LR rate was 31%. The LR rates for low-grade tumors treated with surgery alone in these series were all very low and range from 0% to 5%.[84–88,143] In fact, the standard treatment recommendation for low-grade STS is wide resection alone. With this approach and negative margins, LR rates are typically <20%.[79] (Indications for adjuvant RT for low-grade tumors include positive resection margins, locally recurrent disease following initial treatment with surgery alone, or a tumor location that would not be amenable to subsequent salvage surgery.)

In sum, there is most certainly a subset of patients with STS of the extremity

and trunk for whom wide excision alone is appropriate treatment. The selection criteria for this strategy remain undefined but will perhaps include, but not be limited to, some of the following: subcutaneous tumors; tumors resected with wide negative margins >1 cm or an intact fascia; low-grade tumors; tumors representing primary presentation of disease (e.g., not locally recurrent); tumor locations amenable to limb-sparing salvage surgery for recurrence; and patient willingness to comply with appropriate follow-up. Before surgery alone can become standard of care for select patients with STS, the eligibility criteria need to be elucidated and tested in a prospective multi-institutional trial. Other than for low-grade tumors resected with negative margins, treatment with surgery alone should be employed cautiously.

Neoadjuvant, Concurrent, or Adjuvant Chemotherapy

Locally advanced (stage III) STS of the extremities and trunk has a significant risk of distant recurrence, and for this reason, the addition of systemic therapy to treatment algorithms is appealing. There is an established role for chemotherapy as part of the treatment for rhabdomyosarcoma and Ewing sarcoma.[144,145] For other histologies of adult STS, no clear role for chemotherapy has been defined, and this group is the subject of the discussion below. The two most standardly used drugs in the management of STS are doxorubicin and ifosfamide, with gemcitabine-based regimens increasingly used, particularly in patients with leiomyosarcoma.[146]

There are several potential benefits to a neoadjuvant chemotherapy approach. These include the potential to treat micrometastatic disease early in the treatment course; the potential to decrease the scope of the resection if sufficient response is achieved; the ability to ascertain the chemotherapy response or lack thereof for an individual patient, which could guide the use of additional (postoperative) chemotherapy; and enhanced drug delivery to the tumor with corresponding increased efficacy, given that the tumor vasculature has not been disrupted in the neoadjuvant setting. Few reports address the role of neoadjuvant chemotherapy for high-risk STS of the extremities and trunk. A prospective randomized phase II trial conducted by the European Organization for Research and Treatment of Cancer included 137 patients who were randomized to receive or not receive three cycles of doxorubicin and ifosfamide prior to resection with selective use of postoperative RT.[147] Unfortunately, the study was closed because of poor accrual and therefore lacks sufficient power for one to draw definitive conclusions. The results showed no statistically significant differences between

treatment arms for DFS or OS. Specifically, the 5-year DFS rate for the chemotherapy group was 56% compared with 52% for the observation group; the corresponding 5-year OS rates were 65% and 64%, respectively. Two other retrospective reports on the use of neoadjuvant chemotherapy showed mixed results.[148,149]

Similarly, informative data are scarce regarding the use of concurrent preoperative chemotherapy and radiotherapy. Several trials have shown that treatment with RT and concurrent doxorubicin, ifosfamide, gemcitabine, or temozolomide is both feasible and safe.[150–155] There are also two reports of an interdigitated chemotherapy and RT approach. The first was a pilot trial conducted at the Massachusetts General Hospital, which enrolled 48 patients. Treatment involved an interdigitated approach of chemotherapy (mesna, doxorubicin, ifosfamide, and dacarbazine) and 44 Gy given as a split course.[156] Results were very good and associated with improved survival compared with historical controls. The RTOG subsequently enrolled 66 patients in a phase II trial with a very similar treatment approach.[157] Efficacy was somewhat comparable to that of the pilot study, but toxicities were greater, with 5% treatment-related deaths and 83% grade 4 toxicities reported.

The most data available pertain to the use of chemotherapy in the adjuvant setting. A meta-analysis reported by the Sarcoma Meta-Analysis Collaboration (SMAC) included 1,568 patients treated in 14 randomized trials using adjuvant doxorubicin-based chemotherapy. It showed that chemotherapy was associated with statistically higher rates of LR-free survival and DFS at 10 years.[158] Ten-year LR-free survival rates were 81% and 75%, respectively, for the chemotherapy and observation groups (P = .02); the corresponding values for 10-year DFS were 55% and 45% (P = .001). For 10-year OS, there was no clear benefit, with rates of 54% for the chemotherapy group and 50% for the observation group (P = .12). However, exploratory analysis showed a significant 7% survival benefit for the subset of patients with STS of the extremities. Subsequent to this meta-analysis, several more randomized trials of adjuvant chemotherapy were performed using anthracycline or ifosfamide-based chemotherapy; many of these showed trends for survival benefits with chemotherapy, but none were statistically significant.[159–163] (One study from Italy initially reported a significant survival benefit due to chemotherapy at 4 years, but the survival benefit did not hold up with 7.5-year follow-up.)[159,160] SMAC updated their meta-analysis in 2008 with the inclusion of four additional trials (three adjuvant and one neoadjuvant).[147,159,161,162,164] The new analysis

included 18 randomized trials with 1,953 patients and reported statistically significant absolute reductions of 4% for LR and 9% for distant recurrence and an absolute improvement of 6% for survival attributable to chemotherapy.[164] However, the fact that this update did not include the largest negative trial renders the results less conclusive.[163] A subsequent randomized trial of 351 patients failed to show a benefit for five cycles of adjuvant doxorubicin and ifosfamide.[165] All of the above studies included a mix of STS histologic subtypes, which is probably not appropriate as we learn more about the varied biologic behaviors of individual STS entities. There are already reports showing encouraging response rates for certain histologies and specific cytotoxic agents such as eribulin for liposarcoma,[166] trabectedin for liposarcoma and leiomyosarcoma,[167] and gemcitabine and docetaxol for uterine leiomyosarcoma.[146] Going forward, trials should include centralized pathology review and stratification by histology.

In totality, although there are hints of efficacy for certain subgroups, the available data do not support the routine use of chemotherapy for locally advanced STS. However, for select high-risk patients with high-grade and large tumors (>8 to 10 cm), it is reasonable to address the pros and cons of neoadjuvant, concurrent or interdigitated, or adjuvant chemotherapy on an individual patient basis. As toxicity can be significant, concurrent approaches are best undertaken at experienced centers.

Isolated Limb Perfusion, Isolated Limb Infusion, and Chemotherapy with Regional Hyperthermia

Isolated limb perfusion (ILP) is a complicated technique that has been used in Europe for the treatment of locally advanced STS that would otherwise require amputation. This procedure involves isolating the arterial and venous circulation of the limb by connecting it to an extracorporeal circulation, where it is oxygenated and instilled with systemic agents, most commonly, melphalan and tumor necrosis factor. A tourniquet is applied to the limb to prevent leakage into the systemic circulation and the limb is often treated with hyperthermia as well. The treatment can have significant morbidity, but reported limb salvage success rates are quite high.[168–172] *Isolated limb infusion* (ILI) employs low-flow ILP without oxygenation and has been developed as a simpler alternative to ILP. Available data suggest comparable efficacy and less toxicity for ILI compared to ILP.[173,174] Lastly, chemotherapy with regional hyperthermia (delivered via an external electromagnetic field) is another approach for locally advanced disease.

A randomized trial of doxorubicin, ifosfamide, and etoposide, with or without regional hyperthermia delivered before and after local therapy, has shown superior DFS and progression-free survival rates for the regional hyperthermia group.[175] All of these techniques are complicated to deliver and associated with significant potential toxicities. However, they represent valuable potential alternatives to amputation in such settings as in transit metastases of epithelioid or clear cell sarcoma or extensive LRs after prior surgery and RT.

FUTURE DIRECTIONS

In summary, success rates for the treatment of stages I and II STS of the extremities and trunk are currently high, with local control rates of ≥85% and 5-year survival rates of 90% and 81%, respectively.[39] For these patients, we should continue to explore ways to reduce treatment-related morbidity related to surgery and RT. These strategies should include development of innovative techniques to reduce postoperative wound complications, efforts to reduce RT field sizes and to deliver more conformal therapy, and definition of patient subsets that can be effectively treated with surgery alone. For situations in which it is difficult to achieve local control, more aggressive local treatment is needed; this could include the use of RT dose escalation using IGRT, IMRT with dose painting, heavy particles, SBRT, or concurrent chemoradiation strategies. Lastly, patients with stage III disease have a high rate of distant relapse and death. For these patients, novel systemic therapies are needed. The discovery of the targeted agent imatinib mesylate for the treatment of gastrointestinal stromal tumors has been associated with great success, and similar discoveries for other histologies are anticipated.[176] As the field of STS continues to move forward, it is likely that treatment algorithms specific to various histologic subtypes will be developed.

ACKNOWLEDGMENT

I would like to acknowledge the editorial assistance of Susanna Hilfer and Mark Mackin.

Pediatric

CHAPTER 88

Central Nervous System Tumors in Children

Roger E. Taylor

INTRODUCTION

Central nervous system (CNS) tumors account for 20% to 25% of all malignancies that occur in childhood. According to the North American Association of Central Cancer Registries (NAACCR), the age-standardized incidence rate was 48.47 per million in the 0- to 19-year age group for the period 2004–2007.[1] The incidence was highest among children 1 to 4 years of age and lowest among 10- to 14-year-olds.

The etiology of pediatric CNS tumors remains largely unknown. Only 2% to 5% can be ascribed to a known genetic predisposition. Included in this category are those seen in patients with neurofibromatosis types 1 (NF-1) and 2 (NF-2), tuberous sclerosis, nevoid basal cell (Gorlin's) syndrome, familial adenomatous polyposis, and Li-Fraumeni syndrome. An even smaller percentage can be attributed to ionizing radiation used for diagnostic or therapeutic purposes. For the majority of patients, no predisposing factors can be identified.

The management of children with CNS tumors has changed substantially over the past three decades. Routine use of magnetic resonance imaging (MRI), and now frequently also functional imaging, and improved neuropathologic examination and molecular diagnostics have contributed to better characterization of the different tumor types. Improved neurosurgical techniques and perioperative care permit greater degrees of surgical resection even for tumors previously considered inoperable because of their location in eloquent areas of the brain. All of these, as well as improved radiotherapy techniques, newer chemotherapy agents and regimens, and national and international clinical trials, have contributed to improved outcomes for children and adolescents with CNS tumors. According to the NAACCR, 5-year survival has increased from

62.9% for patients diagnosed in 1980 to 1989 to 75.3% for those diagnosed in 2000 to 2006.[1]

RADIOTHERAPY FOR PEDIATRIC CNS TUMORS: GENERAL ISSUES

Radiotherapy is an essential component of treatment for many children with CNS tumors. However, survivors are at significant risk for the development of long-term sequelae,[2,3] many of which, while usually multifactorial, are in large part because of radiotherapy; many of the strategies used in the management of children with CNS tumors over the past three decades have been designed to reduce the risks associated with treatment. Recent developments in radiotherapy including improved targeting and new technologies and techniques for treatment, as well as new treatment modalities such as protons, all offer important opportunities for therapeutic gain that will be discussed below and in each section of this chapter.

Long-Term Effects of Radiotherapy

The quality of survival of children with brain tumors may be compromised by long-term sequelae. Although some patients (e.g., patients with NF-1) may be at particular risk and although some sequelae (e.g., neurologic deficits) are more often due to the tumor and/or surgery, it is clear that radiotherapy is directly, alone or modulated by other factors, responsible for many late effects. A review by Kortmann et al.[4] gives an excellent account of radiation-related sequelae in children treated for low-grade glioma including effects on brain parenchyma, neurologic deficits, neurocognitive and behavioral effects, endocrine dysfunction, vasculopathy, and the development of second tumors.

The neurocognitive sequelae of radiotherapy have become much better characterized over recent years. It is now known that myelinization and functional maturation of the CNS continue until well into adolescence and even into young adulthood. Through its effect on the microvasculature as well as on the oligodendrocyte precursor cells that produce myelin, radiotherapy causes disrupted neurogenesis and cortical atrophy. Patients fail to acquire new knowledge and skills at an age-appropriate rate and show a progressive decline in IQ over time.[5] The magnitude of the deficit depends most importantly on age at treatment, but many other host (e.g., NF-1 or not), tumor (e.g., location, hydrocephalus or not), and treatment factors (e.g., radiotherapy volume and

dose,[6–8] use of chemotherapy[9,10]) play a role. Moreover, the development of other deficits such as behavioral difficulties related to the location of the tumor and/or surgery or hearing impairment because of cisplatin may have a modulating effect. The end result for many patients is impaired school and social performance that deteriorates over time. There is increasing evidence that intervention using cognitive or behavioral therapy or pharmacotherapy and even exercise may be useful and that this should start soon after treatment for best results.[5,11,12]

Endocrine deficits are very common after radiotherapy.[13] Even though a substantial proportion of patients may have had deficits prior to radiotherapy because of the tumor or to surgery,[14,15] and even though there may be modulating factors such as chemotherapy that affect the frequency of deficits, radiotherapy is primarily responsible for the growth hormone deficiency that correlates with the dose of radiotherapy to the hypothalamic–pituitary axis[16–18] and the primary hypothyroidism seen after craniospinal radiotherapy. There may be direct and indirect effects on musculoskeletal development. Osteopenia is a rather common finding that may put patients, particularly those with residual neurologic deficits, at significant risk for fracture.

Radiotherapy has been implicated as well in the development of cardiovascular complications including cerebrovascular events and coronary heart disease.[15,19] Although again the etiology is likely multifactorial, it is important to be cognizant of the risks and to minimize the dose to vascular structures and the heart.

Strategies that have been used to avoid or minimize the long-term effects of treatment for pediatric brain tumors include the following:

- Avoidance of radiotherapy altogether (e.g., in patients with low-grade astrocytoma [LGA] for whom surgery alone may be a good option).
- Delay of radiotherapy for young children (i.e., those younger than age 3 to 8) by the use of chemotherapy.
- Use of daily anesthesia, improved immobilization techniques (e.g., rigid casts or a stereotactic frame), and/or daily pretreatment image verification, all of which allow the use of reduced safety margins.
- Use of image-based treatment planning using computed tomography (CT)–MRI or CT–MRI–functional imaging coregistration and better treatment planning and delivery techniques that result in greater sparing of normal brain and organs at risk.
- Use of new radiation modalities (particularly proton therapy that provides even

greater sparing of the surrounding normal brain and organs at risk). Over the last 5 to 10 years, there has been a significant increase in the proportion of children with CNS tumors treated by proton therapy.

- Use of reduced radiotherapy target volumes when it is shown safe to do so (e.g., tumor bed rather than whole posterior fossa for the boost in standard-risk medulloblastoma).
- Reduction of radiotherapy dose (e.g., in young patients with standard-risk medulloblastoma for whom in the North American studies the dose for craniospinal irradiation [CSI] has been reduced progressively from 35 to 36 Gy to 23.4 Gy and, in current studies, to 18 Gy for children younger than 8).
- Use of smaller fraction sizes where appropriate (e.g., 1.5 Gy/day for patients with radiosensitive tumors such as germinoma).
- Use of hyperfractionated radiotherapy (HFRT) (e.g., as in the current European studies for standard-risk medulloblastoma).

These will be discussed later in each relevant clinical situation.

Preparation for Radiotherapy

The planning and delivery of radiotherapy for children with CNS tumors are technically challenging and labor intensive for the entire interprofessional team. The expertise of specialist personnel such as pediatric nurses and play therapists can be pivotal in encouraging a young child to lie still for the making of an immobilization device, for radiotherapy planning procedures, and for treatment itself. For children younger than age 4 or 5 years, daily anesthesia will almost always be necessary, and this will require a skilled pediatric anesthetist because anesthesia will be administered in an environment without all of the support available in an operating room.

Radiotherapy Target Volumes and Treatment Techniques

Focal, Tumor, or Tumor Bed Radiotherapy

For most tumor types, target volume definition is best accomplished using CT simulation with CT–MRI image coregistration. For patients who have undergone cerebrospinal fluid (CSF) diversion or surgical resection or in whom tumor shrinkage has occurred with chemotherapy, it will be important to take into account any anatomic shifts that may have taken place. This will be more of an issue for tumors arising in some areas than others and often adds significantly to the time required for contouring. The clinical target volume (CTV) will be tumor type specific, whereas the planning target volume (PTV) will be technique specific, ranging from 1 to 5 mm depending on the type of immobilization

device used and whether daily pretreatment image verification is to be performed.

Modern radiotherapy treatment planning and delivery techniques make it easier to achieve conformity of the treated volume to the target and sparing of uninvolved normal structures than in the past. The choice of technique in an individual patient will require careful analysis of the dosimetry in the context of the available options. A review by Beltran et al.[20] provides an excellent example of the issues to be considered now when weighing alternatives.

Other options for focal treatment include brachytherapy and intracystic injection of radioactive colloids. These will be discussed in the context of the relevant clinical situation.

Whole-Ventricular Radiotherapy

Whole-ventricular irradiation is used most frequently in patients with CNS germ cell tumors. Because subependymal spread is common, the target volume logically would include the lateral, third, and fourth ventricles with a margin of 1 to 1.5 cm. If lateral opposed fields are used, the volume of brain spared will be small. Better sparing can be achieved using intensity-modulated image-guided radiotherapy[21–23] or more recently the use of proton therapy is advocated.

Craniospinal Radiotherapy

The CTV for craniospinal radiotherapy has an irregular shape that consists of the whole brain and spinal cord and their overlying meninges. In standard techniques, the lower borders of lateral whole-brain fields are matched to the cephalad border of a posterior spine field, usually with a moving junction between the brain and spine fields to minimize the risk of underdose or overdose in the cervical spinal cord. With conventional techniques, compensators may be needed to achieve dose homogeneity throughout the target volume.

Patient Positioning and Immobilization

Patients have traditionally received CSI in the prone position, but modern technology allows safe treatment in the supine position that in general is more comfortable and, if anesthesia is required, allows better control of the airway. In either case, immobilization is essential and involves the use of a head shell or full-body immobilization. Careful attention to positioning at the time of simulation is critical to minimize or even eliminate the risk of certain long-term effects. For example, using neck extension together with careful selection of the level for the junction of the brain and spine fields, it is possible to avoid

including the dentition in the exit from the superior aspect of the spinal field and thus damage to developing dentition. When modern techniques are employed, it is essential to apply the relevant dose constraints in order to avoid excessive or unnecessary dose to organs at risk (OARs).

Target Volume Definition

CT simulation is necessary to ensure adequate coverage of the CTV in the subfrontal region at the cribriform plate. Traditionally, blocks have been used in the lateral fields to shield not only the facial structures but also the lenses. However, in most children, it is impossible to adequately irradiate the cribriform plate and shield the lenses (Fig. 88.1), and adequate PTV coverage should take precedence.

CT simulation is also helpful in identifying the lateral aspect of CTV for the spine field that includes the extensions of the meninges along the nerve roots to the lateral aspects of the spinal ganglia (Fig. 88.2). The field will be narrower in the dorsal region to avoid unnecessary irradiation of the heart and lungs and wider in the lumbar region, although here it is important to avoid an excessively wide field that will result in unnecessary irradiation of the bone marrow and gonads. The lower limit of the CTV for the spine field should be determined using MRI. The lower border of the spinal CTV should include the lower border of the thecal sac, which can be as high as L5 or as low as S3. In the interest of both CTV coverage and normal tissue sparing, it is important that the lower border be individualized according to the MRI findings.

FIGURE 88.1. The use of computed tomography simulation is superior to conventional radiographs for determination of the clinical target volume for craniospinal irradiation and ensures coverage of the meninges in the subfrontal region. In most children, adequate coverage of the planning target volume precludes significant sparing of the lens.

TABLE 88.1 TECHNICAL CONSIDERATIONS FOR CRANIOSPINAL IRRADIATION

Problem	Possible Solutions
Target volume definition may be difficult using conventional simulation	Use CT simulation with CT-MRI coregistration
Prone position Uncomfortable Difficult to monitor airway	Supine position preferred
Field matching over cervical spine/risk of over- or underdosage	Angle brain fields Use half-beam block for brain fields

	Use couch rotation or match line wedge
Choice of extended SSD or second field for treatment of spinal axis	Two fields preferred
Inhomogeneity along spinal axis	Use compensator, MLC
Irradiation of normal tissues	
Mandible/teeth	Neck extension
Thyroid	Care with level of junction
Heart	Use lower junction
GI tract	Care with width of spine field
Gonads	Use protons, IMRT, electrons
	Use protons, IMRT, electrons
	Care with lower limit and width of spine field

CT, computed tomography; GI, gastrointestinal; IMRT, intensity-modulated radiation therapy; MLC, multileaf collimator; MRI, magnetic resonance imaging; SSD, source-to-surface distance.

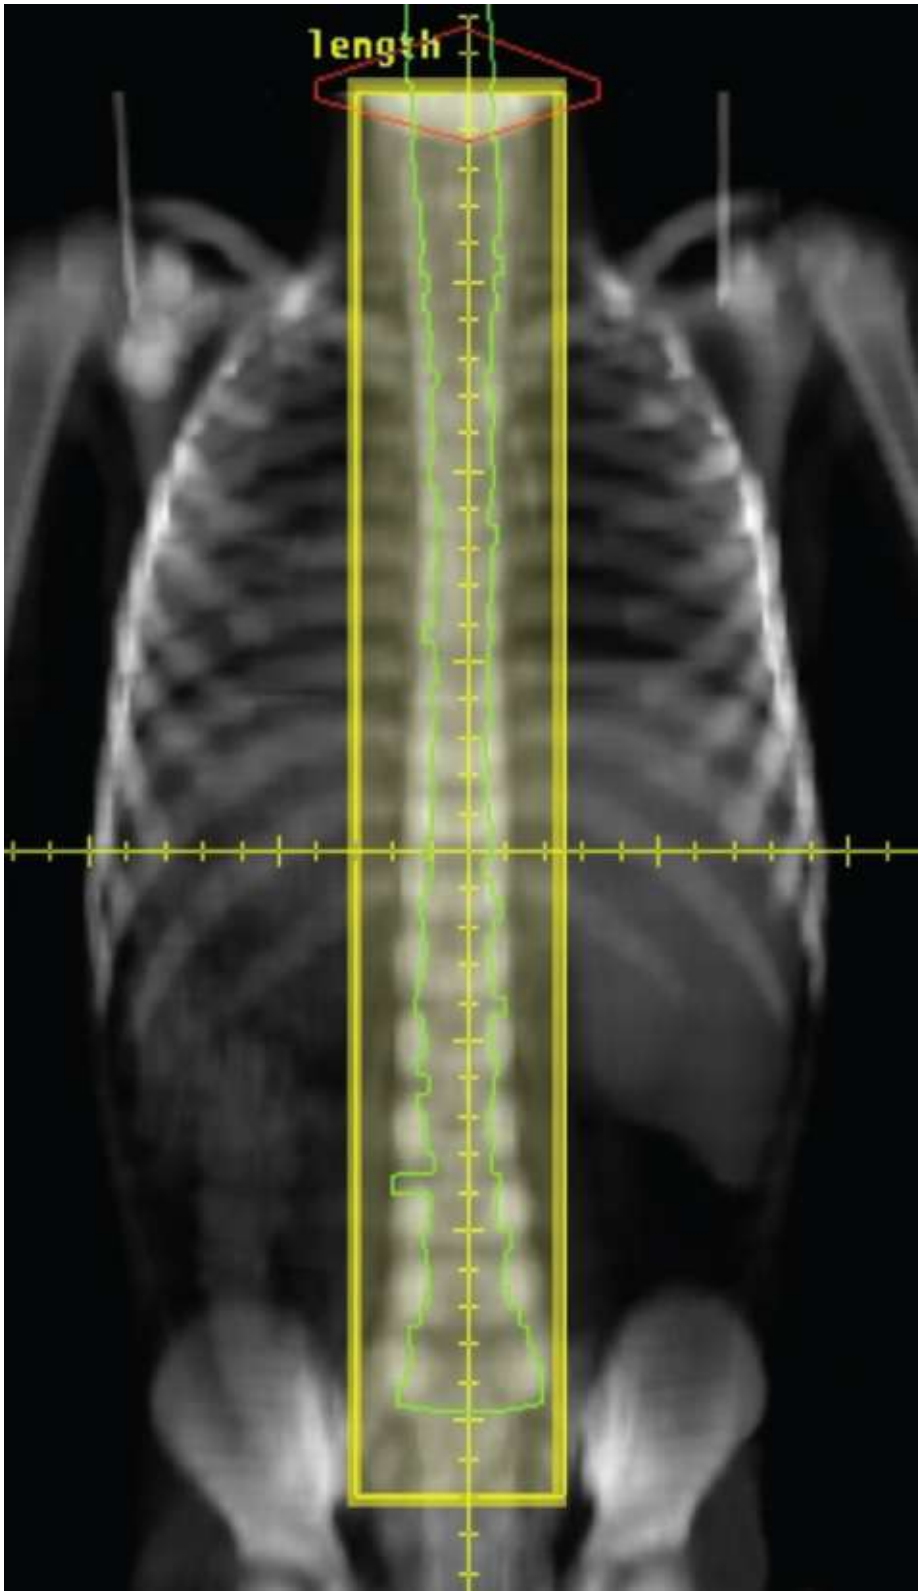

FIGURE 88.2. The use of computed tomography simulation with contouring of the cord and overlying meninges that extend laterally to the lateral aspect of the spinal ganglia results in a field width that is narrower than one based on bony anatomy. The addition of shielding further reduces the volume of normal tissues included in the

treated volume.

Treatment Planning and Delivery

There are many issues that need to be addressed in designing a CSI technique (Table 88.1). Many of the different solutions[24] add further complexity. Using modern tools for treatment planning and delivery, it is possible to greatly simplify the technique and substantially reduce planning and delivery times. One such technique is shown in Figure 88.3.[25] In general, photons in the 6- to 10-MV range provide satisfactory coverage of the PTV. A variation of dose along the spinal axis of >10% will require the use of dose compensation that can be achieved using multileaf collimation.

Electrons are used in some centers to treat the spinal axis and in fact may be of greater interest now than in the past because of improved dose calculation algorithms and even electron dose modulation techniques. However, at the same time, newer treatment planning and delivery methods such as intensity-modulated radiation therapy (IMRT) together with daily image verification allow for improved dosimetry with photons with clinically relevant dose reductions to structures anterior to the target volume such as the heart, gastrointestinal (GI) tract, and gonads.[26] The use of IMRT and smaller PTV margins raises new issues that are not as relevant as when lateral opposed fields were used, such as the need to ensure adequate coverage of all CSF extensions including those along the optic nerves and other cranial nerves (Fig. 88.4).

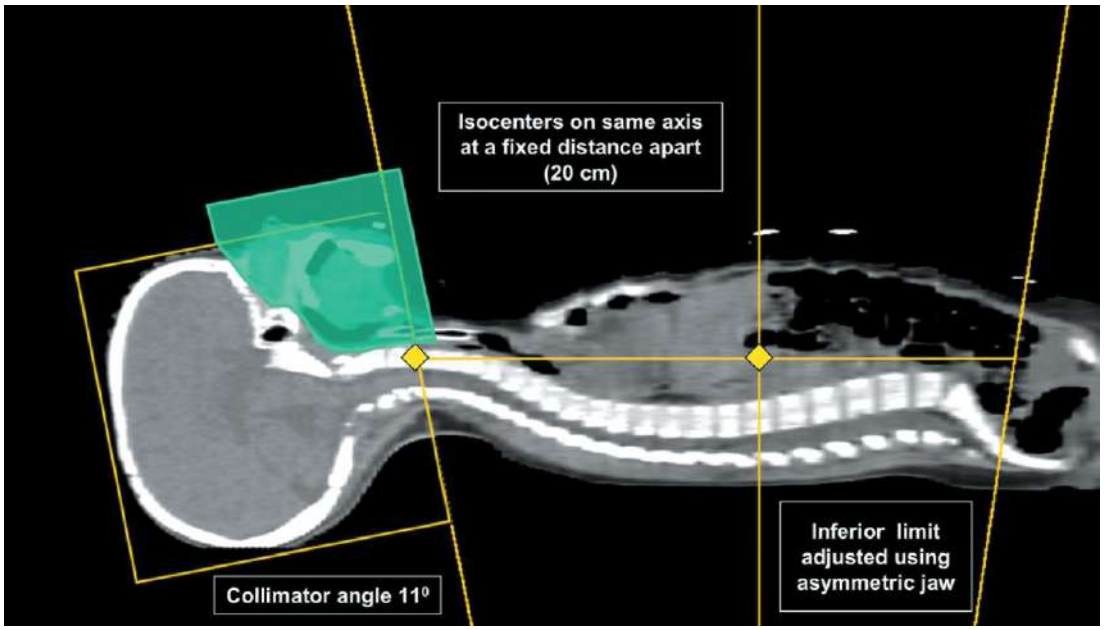

FIGURE 88.3. To cover the clinical target volume for craniospinal irradiation, lateral

opposed fields are used to treat the brain and a direct posterior field is used to cover the spinal axis. Magnetic resonance imaging is used to identify the caudal extent of the thecal sac. The field junction over the cervical cord should be at a level that avoids the inclusion of the teeth in the exit of the spinal field and usually is moved weekly ("feathered") to avoid over- or underdosage. The supine position is more comfortable for the patient and safer if sedation or anesthesia is required. In the technique shown, fixed field parameters are used, which greatly facilitates treatment planning and delivery. (Reprinted from Parker WA, Freeman CR. A simple technique for craniospinal radiotherapy in the supine position. *Radiother Oncol* 2006;78[2]:217–222. Copyright © 2005 Elsevier Ireland Ltd. With permission.)

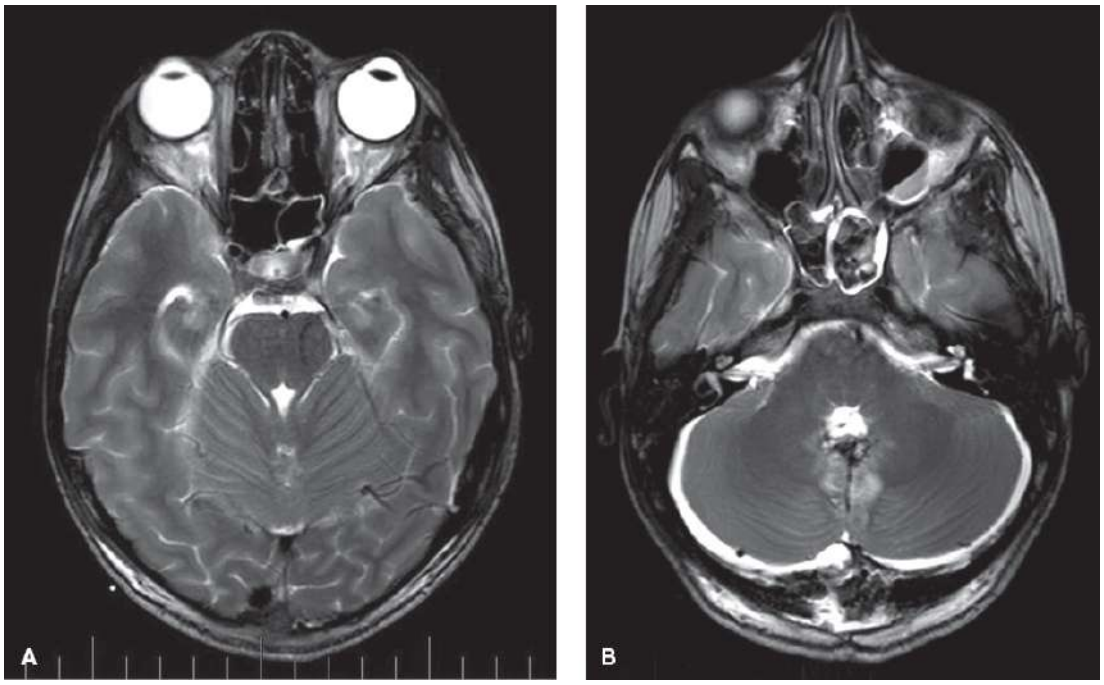

FIGURE 88.4. Postoperative axial T2-weighted magnetic resonance imaging for a patient receiving craniospinal irradiation (CSI) for medulloblastoma showing extension of cerebrospinal fluid along the optic nerves to the lamina cribrosa **(A)** and into the internal auditory canals **(B)**. Care is necessary to identify all such extensions when using intensity-modulated radiation therapy for CSI given that the margins are much tighter than when using conventional lateral opposed fields.

New Treatment Modalities for CSI

Protons provide a dose distribution for CSI that cannot be achieved by even the most sophisticated photon beam treatment planning, with significant reduction in low dose exposure outside the target volume.[27] There may be significant benefits from reduced irradiation of the heart and organs anterior to the spine. Currently, an increasing number of children requiring craniospinal radiotherapy are treated by proton therapy.[28]

Radiation Dose and Dose Fractionation Regimens

The conventional daily fraction size for the treatment of most pediatric CNS tumors is 1.8 Gy and the total dose typically on the order of 54 to 55.8 Gy. When treating a primary tumor of the spinal cord, it is conventional to use a lower total dose (e.g., 50.4 Gy). It is also usual to use lower doses for children younger than age 3 years to reduce the risk of neurocognitive deficits. When treating radiosensitive tumors such as intracranial germinoma, radiotherapy may be delivered using a lower dose per fraction (e.g., 1.5 Gy) and lower total doses of 30 to 45 Gy.

Many pediatric brain tumors exhibit a dose–response relationship for tumor control, and in some cases, local progression is not prevented by the use of a conventional "CNS tolerance" radiation dose. When the target contains only a small volume of normal brain tissue, dose escalation may be possible using newer treatment planning and delivery techniques. HFRT may be a useful strategy in situations where dose escalation cannot be achieved safely using conventional fractionation.

Follow-Up During and After Radiotherapy

An excellent review by Donahue[29] describes the acute reactions seen during treatment with radiotherapy and provides guidelines for their management. These days nausea and vomiting almost always can be prevented by the use of the 5HT-3 antagonists. Headache is not an expected side effect and should be investigated by physical examination for signs of raised intracranial pressure and by imaging as appropriate. Steroids, if used, usually can be tapered by the second or third week of treatment. Fatigue is a rather common symptom and is cumulative. The neurologic status of the patient, especially coordination and gait, may appear to worsen during the last weeks of treatment because of this. Children usually recover relatively quickly and often can get back to their usual routine quite soon after completion of treatment.

Predictable effects of treatment include hormonal deficits, especially primary hypothyroidism when CSI is delivered using photons and growth hormone deficit secondary to inclusion of the hypothalamic–pituitary axis. Patients should be monitored closely in follow-up and treatment instituted as appropriate. Many will also need regular follow-up in ophthalmology and audiology.

Extra pedagogic support may be necessary. Patients should have ready access to a neuropsychologist for evaluation of any special needs and in the longer term to vocational assessment and counseling.

RADIOTHERAPY FOR SPECIFIC TUMOR TYPES

The World Health Organization (WHO) classification of tumors of the nervous system that has recently been updated in 2016[30] is given in Table 88.2 and the distribution by tumor type and location in Fig. 88.5. The 2016 classification takes into account molecular characteristics of CNS tumors. There are important differences between tumors seen in childhood and those occurring in adults. In children, almost half of all tumors arise in the infratentorial compartment. Low-grade astrocytic tumors as a group account for approximately one-third to half of all CNS tumors, but medulloblastoma is the most common distinct entity. High-grade gliomas, which account for the majority of primary brain tumors seen in adults, are much less common in children.

TABLE 88.2 WORLD HEALTH ORGANIZATION CLASSIFICATION OF TUMORS OF THE CENTRAL NERVOUS SYSTEM

Diffuse Astrocytic and Oligodendroglial Tumors
Other Astrocytic Tumors
Ependymal Tumors
Other Gliomas
Choroid Plexus Tumors
Neuronal and Mixed Neuronal–Glial Tumors
Tumors of the Pineal Region
Embryonal TumorsTumors of the Cranial and Peripheral Nerves

This chapter will follow the order of the WHO classification. Although in the past tumors arising in infants and very young children were grouped together and all managed similarly with chemotherapy in order to delay or if possible avoid radiotherapy, they are now managed according to the specific tumor type and so will be discussed here in each relevant section.

ASTROCYTIC TUMORS

- Pilocytic astrocytoma (WHO grade I)
  - Pilomyxoid astrocytoma
- Subependymal giant cell astrocytoma
- Pleomorphic xanthoastrocytoma
- Diffuse astrocytoma (WHO grade II)
  - Fibrillary astrocytoma
  - Gemistocytic astrocytoma
  - Protoplasmic astrocytoma

- Anaplastic astrocytoma (WHO grade III)
- Glioblastoma multiforme (WHO grade IV)
  - Giant cell glioblastoma
  - Gliosarcoma
- Gliomatosis cerebri

These astrocytic tumors are heterogeneous with respect to clinical presentation (age, gender, location in the CNS, imaging findings) as well as to growth potential and rate of progression. Two entities, pleomorphic xanthoastrocytoma and subependymal giant cell astrocytoma, are rare tumors. Their clinical presentation and imaging findings are quite characteristic and surgery is usually curative. They will not be discussed further here.

Low-Grade Astrocytoma (WHO Grades I and II)

So-called benign or low-grade astrocytomas (LGAs) comprise a heterogeneous group of tumors with behavior patterns that are fairly typical according to location and pathologic type. In general, in children, they follow an indolent clinical course with overall survival rates at 10 and 15 years as high as 80% to 100%. LGAs can be grouped according to their anatomic location:

- Cerebellar astrocytomas (15% to 20% of all CNS tumors)
- Hemispheric astrocytomas (10% to 15% of all CNS tumors)
- Midline supratentorial tumors, including the corpus callosum, lateral and third ventricles, and hypothalamus and thalamus (10% to 15% of all CNS tumors)
- Optic pathway tumors (approximately 5% of all CNS tumors)
- Brainstem LGAs (brainstem tumors account for 10% to 15% of all CNS tumors; 20% to 30% of these are LGAs)
- LGAs of the spinal cord (spinal cord tumors account for 3% to 6% of all CNS tumors; approximately 60% of these are LGAs)

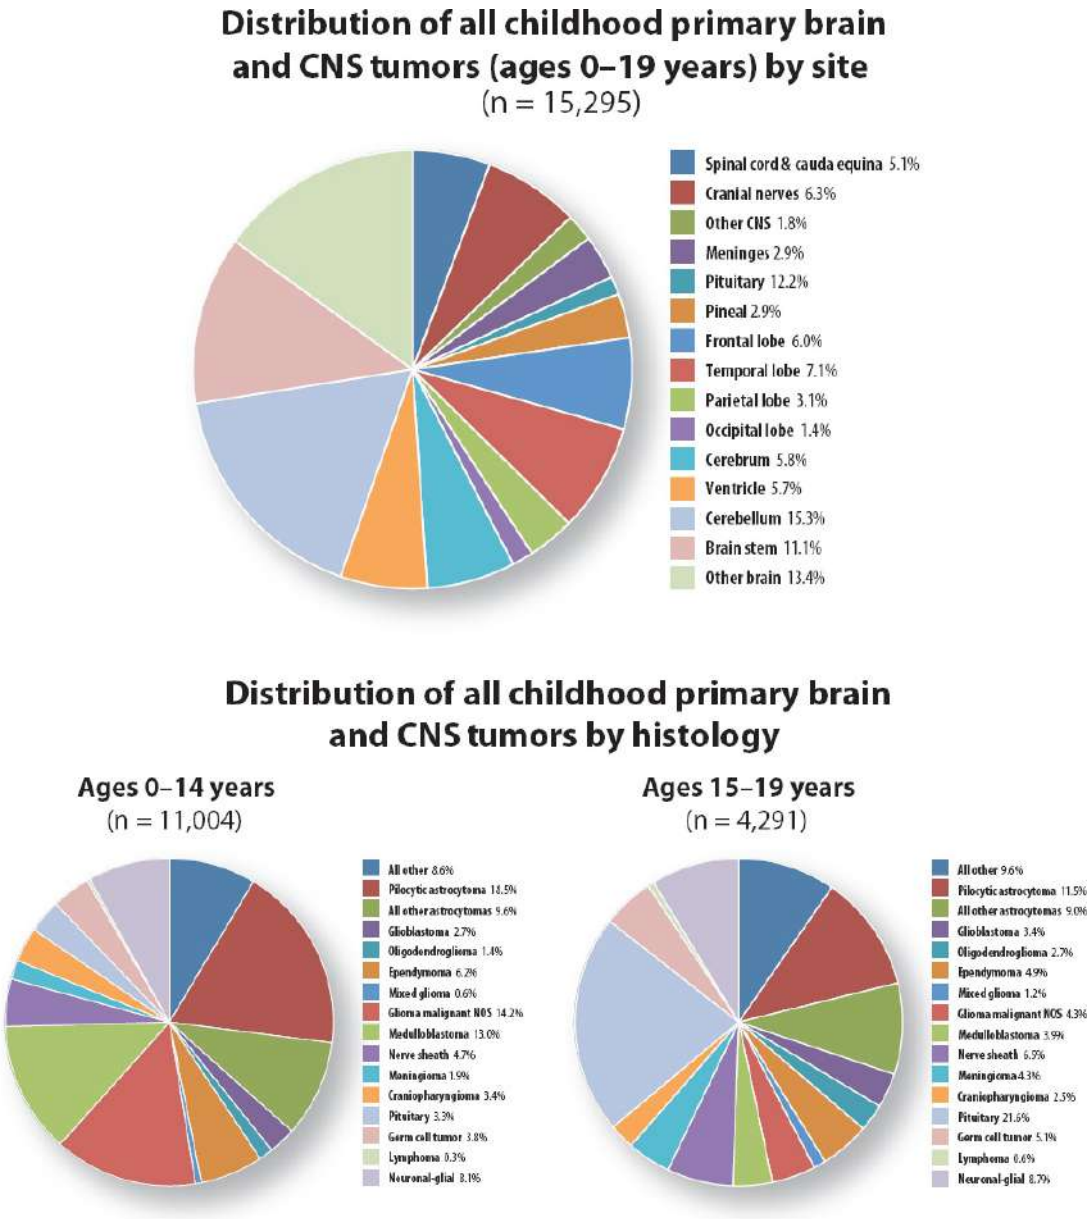

FIGURE 88.5. Distribution of central nervous system tumors by site **(A)** and histology **(B)** for the years 2004–2007. (Data from the Central Brain Tumor Registry of the United States [www.cbtrus.org].)

Pilocytic astrocytomas are the most common type in the pediatric age group, accounting for almost all of the LGAs at certain sites (e.g., the cerebellum and the anterior optic pathway). They account for a smaller proportion of LGAs arising in the deep midline structures and in the cerebral hemispheres. Macroscopically, pilocytic astrocytomas appear well circumscribed and frequently have an associated cystic component. Pilocytic astrocytomas are characterized histologically by a biphasic pattern with a varying proportion of

compacted bipolar cells with Rosenthal fibers and loose-textured multipolar cells with microcysts and granular bodies. Rare mitoses, occasional hyperchromatic nuclei, microvascular proliferation, and even infiltration of the meninges are compatible with a diagnosis of pilocytic astrocytoma and not a sign of malignancy. *KIAA1549-BRAF* fusions have been identified in 75% of patients with PA using an RT-PCR assay from FFPE tissue.[31] A variant, pilomyxoid astrocytoma, first described in infants and young children with chiasmatic/hypothalamic tumors, appears to be associated with more aggressive behavior that may include leptomeningeal seeding.[32]

Diffuse astrocytomas account for only approximately 10% to 15% of all LGAs in children but for a relatively higher proportion of those seen in infants and adolescents. Most intrinsic pontine tumors and a large proportion of astrocytomas arising in the cerebral hemispheres are diffuse astrocytomas. Diffuse astrocytomas grow by infiltration rather than destruction of anatomic structures and usually are not well circumscribed. Microscopically, they are composed of well-differentiated fibrillary or gemistocytic neoplastic astrocytes on a background of loosely structured, often microcystic, tumor matrix. Cellularity is moderately increased. The presence of nuclear atypia is a diagnostic criterion, but mitotic activity, necrosis, and microvascular proliferation are absent. The growth fraction as determined by Ki-67 and MIB-1 labeling indices is usually low. Diffuse astrocytomas may undergo malignant progression, although this is not common in the pediatric age group with the notable exception of tumors arising in the pons.

Patients with LGAs typically present with a long history of nonspecific and nonlocalizing symptoms. Symptoms and signs of raised intracranial pressure may be seen in patients with midline and cerebellar tumors. Patients with posterior fossa tumors may present with neck stiffness and a head tilt as a manifestation of raised intracranial pressure causing tonsillar herniation, altitudinal diplopia, or spinal accessory nerve irritation. Seizures are present in as many as three-quarters of patients with hemispheric lesions. Other symptoms relatively less frequent and usually of more recent onset relate to the location of the tumor. These may include, for example, focal motor deficits with hemispheric tumors, visual field deficits with tumors compressing or involving the optic pathway, neuroendocrine deficits with hypothalamic tumors, and the diencephalic syndrome (consisting of emaciation with loss of subcutaneous fat despite normal or increased appetite, alert appearance, increased vigor and euphoria, pallor without anemia, and nystagmoid movements of the eyes) in

young children with chiasmatic/hypothalamic tumors.

Neuroimaging findings are usually quite characteristic. Pilocytic astrocytomas are well circumscribed, often with a cystic component that may be large relative to the size of the solid component. There is usually little edema or mass effect. The solid component enhances brightly and uniformly with contrast material. Diffuse or fibrillary astrocytomas are usually not well seen on nonenhanced CT or MRI and usually show little enhancement with contrast material. T2-weighted or fluid-attenuated inversion recovery (FLAIR) MRI sequences usually best demonstrate the extent of disease.

Management of Low-Grade Astrocytomas: General Principles

Some children with LGAs may not require any tumor-specific treatment. These include, for example, patients with NF-1, as many as 15% of whom have optic pathway tumors.[33] NF-1 patients also may have astrocytic tumors in other parts of the CNS as well as hamartomatous lesions, typically in the brainstem. These lesions may be detected on routine imaging, but even tumors that are symptomatic may remain stable over long periods so that surveillance is appropriate initial management.[34–36] A number of clinical and imaging characteristics have been correlated with a more aggressive course, but even for these patients, active intervention will usually be undertaken only at time of progressive disease that is symptomatic.

Progression-free survival without treatment may also be very good for patients with tectal plate lesions who present with hydrocephalus without localizing brainstem signs. LGA in this region may be very indolent, showing either no progression (the majority) or only very slow progression over the course of many years following CSF diversion alone. The common characteristics of these very indolent tumors are their small size (<1.5 or 2 cm) and the fact that on imaging they are hypodense/hypointense and nonenhancing. Follow-up with MRI is essential to identify patients with progressive lesions as manifested by increasing size and/or enhancement with gadolinium. Treatment (usually radiotherapy but sometimes now surgery) at time of progression is associated with a high probability of long-term tumor control.

These special situations underscore the need for careful evaluation and individualization of management of patients with LGAs depending on the specific clinical situation and tumor type. If in doubt, a period of surveillance generally will be an acceptable initial approach, reserving nonsurgical treatment for symptomatic progression.

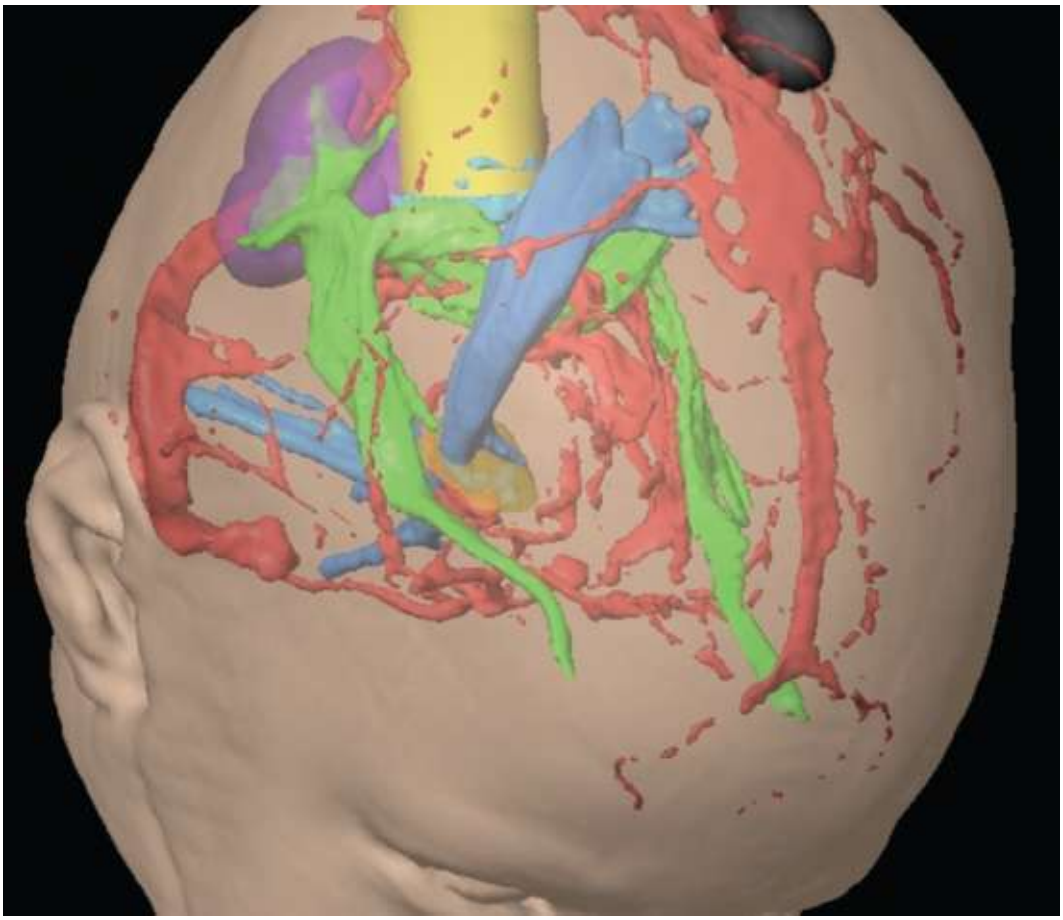

FIGURE 88.6. Surgical planning for a dysembryoplastic neuroepithelial tumor (*light blue*) in the right occipital lobe presenting with seizures. Functional magnetic resonance imaging data are used to identify the 1-degree visual cortex (*purple*). Fiber tracking identifies the optic radiations (*green*) and the corticospinal tract (*darker blue*). These data are then used to plan the trajectory (*yellow*). By identifying regions to be selectively avoided, similar information could be helpful in radiotherapy treatment planning.

Surgery is the mainstay of treatment for LGAs. Complete resection is more likely to be accomplished in patients with smaller tumors and those arising in noneloquent parts of the brain as well as in patients with the generally well-circumscribed pilocytic tumors. Modern surgical techniques that include, for example, computer-assisted resections (“neuronavigation”) aided by preoperative functional MRI, MR tractography, and intraoperative mapping of eloquent areas (Fig. 88.6) together with intraoperative MRI permit greater degrees of resection in larger proportions of patients, including many who in the past would have been considered to have inoperable lesions. Complete resection is now achieved in >80% of cerebral, cerebellar, and spinal cord tumors and about 50% of diencephalic tumors.

Children with LGAs who undergo complete resection fare very well, with long-term disease-free and overall survival rates of 80% to 100%.[37–42] In most series, results are better (close to 100%) for patients with pilocytic astrocytomas than for those with diffuse or fibrillary LGAs, although some have disputed this, showing equally satisfactory results for both. In either type, postoperative adjuvant therapy is not indicated.

For children who undergo less than complete resection, the progression-free survival rate after surgery alone is less satisfactory. In a joint Children's Cancer Group (CCG)–Pediatric Oncology Group (POG) study in which such patients were observed without adjuvant treatment, any residual tumor was associated with an inferior progression-free survival rate: the 8-year progression-free survival rate was 56% for patients with <1.5 cm^3 residual tumor and 45% for those with >1.5 cm^3. However, the majority of patients can be salvaged with a second surgical resection and/or radiotherapy. In the CCG–POG study, overall survival at 8 years was 95% and 90%, respectively.[43]

The role of postoperative radiotherapy following less than complete resection remains unclear. In most series, the use of radiotherapy in this situation results in improved disease-free survival without any benefit in terms of overall survival. Because only approximately half of all patients will develop progressive disease, the usual recommendation for a patient who is neurologically stable will be surveillance, with MRI performed at least every 6 months for the first 3 years, the period during which risk of progression is greatest.[44] A second surgical procedure would usually be considered at time of progression, and other treatment, either radiotherapy or chemotherapy, reserved for patients with progressive, inoperable disease (Fig. 88.7).

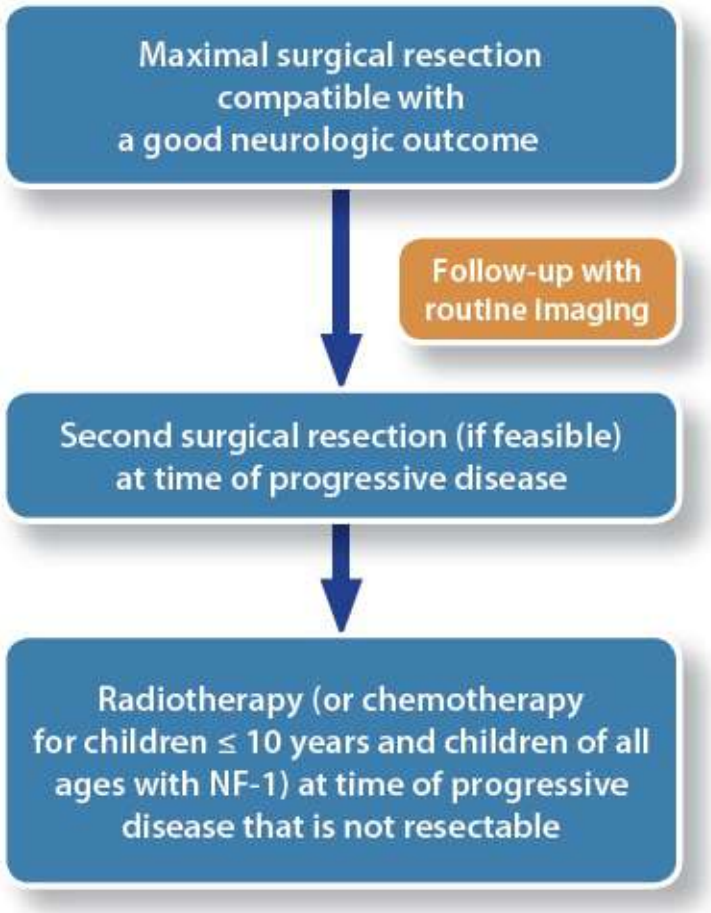

FIGURE 88.7. An algorithm for the management of patients with low-grade astrocytoma.

In the past, patients with deep midline and other tumors considered surgically inaccessible were treated with radiotherapy, often even without histologic confirmation of diagnosis. However, using modern neurosurgical techniques, it is feasible to resect surgically about half of these lesions (Fig. 88.8), and the overall strategy for these patients should now be as for patients with LGAs at other locations, albeit with the understanding that outcome is not as satisfactory. The 8-year progression-free and overall survival rates in the CCG–POG study for patients with midline chiasmatic tumors were 25% and 84%, respectively.[43]

When adjuvant therapy is indicated, the options include chemotherapy, particularly for infants and young children and for patients of all ages with NF-1 who are at greatest risk of developing neurocognitive, vasoocclusive, and neuroendocrine sequelae of treatment. The standard combination chemotherapy employed is based on a combination of carboplatin and vincristine. Complete responses to chemotherapy are not common, but overall response rates that

include stable disease range from 70% to 100% and the use of chemotherapy has been shown to permit delay of radiotherapy by 2 to as many as 4+ years.[45–48] The age limit below which chemotherapy should be used is controversial. There is a trend over time for chemotherapy to be employed as initial treatment for older children. It is likely that delaying radiotherapy for 2 to 3 years will be of benefit for a child younger than age 5 to 8. However, the benefit from a similar delay for an older child is less clear, particularly when any benefit may be offset by neurologic compromise from further tumor progression as well as the need for a larger radiotherapy target volume. Moreover, recent advances in radiotherapy practice that have the potential to reduce the risks of radiotherapy have led to a reassessment of the role of radiotherapy in LGAs and better acceptance of its earlier use even in very young children.

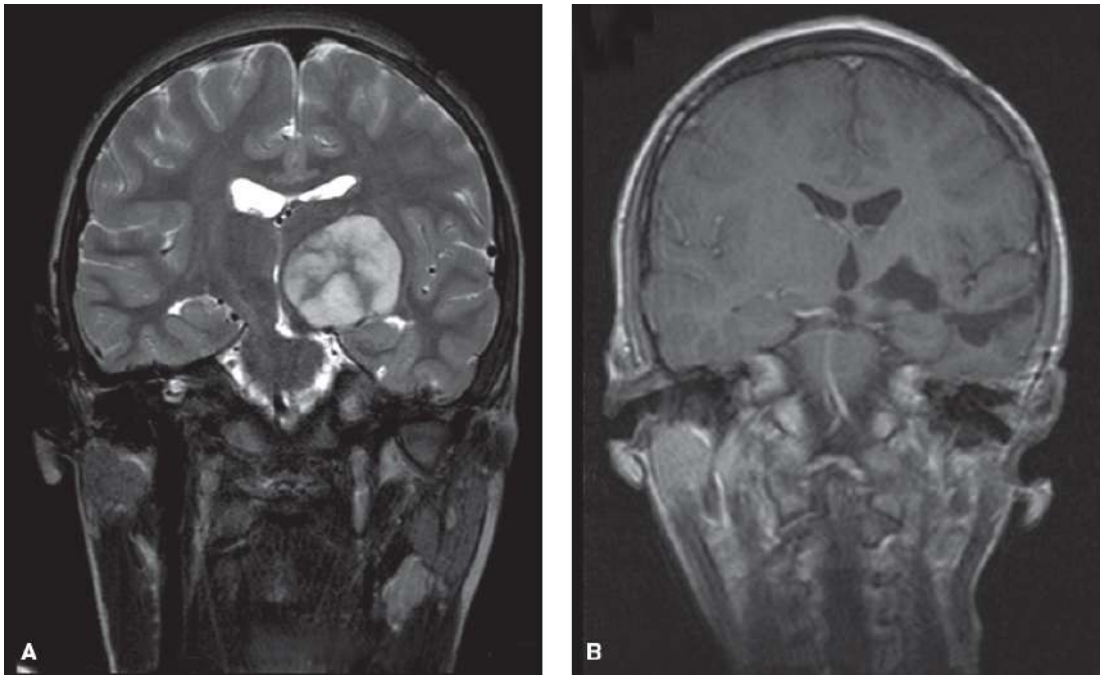

FIGURE 88.8. A 12-year-old boy referred to the radiation oncology department 3 years after diagnosis of a biopsy-proven JPA of the left thalamus at another institution. He had been deemed inoperable at diagnosis and had received chemotherapy first with vincristine and carboplatin and then with weekly vinblastine. **A:** At the time of referral, he was having more frequent choreoathetotic movements of his right hand and there was evidence of progressive disease on magnetic resonance imaging (MRI). **B:** He underwent complete resection without complications and has no evidence of residual disease on his most recent MRI. This was a far better approach than radiotherapy, avoiding the neurocognitive, endocrine, and vascular complications associated with radiotherapy for tumors in this region, and with a greater probability of long-term tumor control.

Radiotherapy in LGAs

Due largely to improvements in surgery and to a lesser extent to successful treatment of younger children with chemotherapy, there has been a substantial decrease in the use of radiotherapy over recent years. Currently, only approximately 10% of all children with LGAs receive radiotherapy.

Indications for Radiotherapy

- Radiotherapy is not indicated after complete resection.
- Radiotherapy may be indicated following incomplete resection in situations when tumor progression would compromise neurologic function (e.g., "threat to vision").
- The clearest indication for radiotherapy is in patients with progressive and/or symptomatic disease that is unresectable.

Radiotherapy Target Volume

The radiotherapy target volume (the gross tumor volume or GTV) consists of all disease seen on MRI performed just prior to treatment (Fig. 88.9). The resulting treatment volume usually will be considerably smaller than one based on preoperative imaging, which until recently would have constituted standard practice. Similarly, margins that were considered standard (and still are in adult practice) are unnecessary, particularly for the well-circumscribed pilocytic tumor for which a CTV margin of 1 cm[42] or even 0 cm (i.e., CTV = GTV)[49] around the GTV as seen on T1-weighted gadolinium-enhanced images has been shown to result in excellent local control. More generous margins of 1 to 1.5 cm around the GTV as seen on T2-weighted or FLAIR images may be more appropriate for the more infiltrative diffuse fibrillary tumors. Radiotherapy planning will also take into account OARs including the hippocampus. Future protocols will specify hippocampal dose constraints.

Radiotherapy Dose

Evidence for a dose–response correlation in LGAs in children is scant. Although the European and North American studies that randomized adult patients with LGAs between low dose (45 and 50.4 Gy, respectively) and high dose (59.4 and 64.8 Gy, respectively) radiotherapy failed to demonstrate any advantage for the higher dose, it may be unwise to extrapolate that in children doses of 45 to 50 Gy are as effective as the higher doses of 54 to 55 Gy that until now have constituted standard practice. There are biologic differences between LGAs in

children and in adults. As well, children who have progressed on chemotherapy may have tumors that are less sensitive. For now, the recommendation for children with LGAs would be a “standard” dose of 50 to 54 Gy depending on the age of the child and the location of the tumor and its relationship to critical normal structures such as the optic chiasm.

Radiotherapy Technique

External beam radiotherapy using a conventional dose-fractionation schedule should be considered the standard of care in LGAs and the technique to be used that which provides homogeneous irradiation of the CTV and best spares surrounding normal tissues. Increasingly proton therapy is being employed for the treatment of LGGs as a means of minimizing nontarget dose and hopefully late neurocognitive effects.

Other approaches that have been used in LGAs include radiosurgery using the gamma knife or linear accelerator–based techniques.[50] Although the use of a single fraction, typically of 10 to 20 Gy, to the periphery of the lesion or a small number of large fractions may not be optimal for diffuse or fibrillary LGAs with tumor cells embedded in rather than displacing normal brain, such treatment may be of interest for part or even all of the treatment for the less invasive pilocytic astrocytomas that are often small at time of progression.

Another option for treatment is brachytherapy, which has been used with some success particularly in European centers.[51–55] As for radiosurgery, the principal limitation with respect to the use of brachytherapy is the size of the target volume. Brachytherapy series necessarily select for smaller tumors, and there is no evidence that brachytherapy is a better treatment option than external beam radiotherapy. Radioactive solutions such as ^{32}P, ^{90}Y, ^{198}Au, and ^{186}Re may be useful in cystic LGAs, particularly for patients with recurrent disease after radiotherapy in whom symptoms not infrequently relate more to the cyst than to the solid component of tumor. Simple aspiration with or without placement of an internal shunt usually will alleviate symptoms for protracted periods, but in some cases, particularly those in which the cyst wall enhances and is felt to be biologically active, control of the cyst may be difficult, and the use of radioactive solutions could be considered. However, this is not a procedure without risks and care has to be taken to avoid leakage.

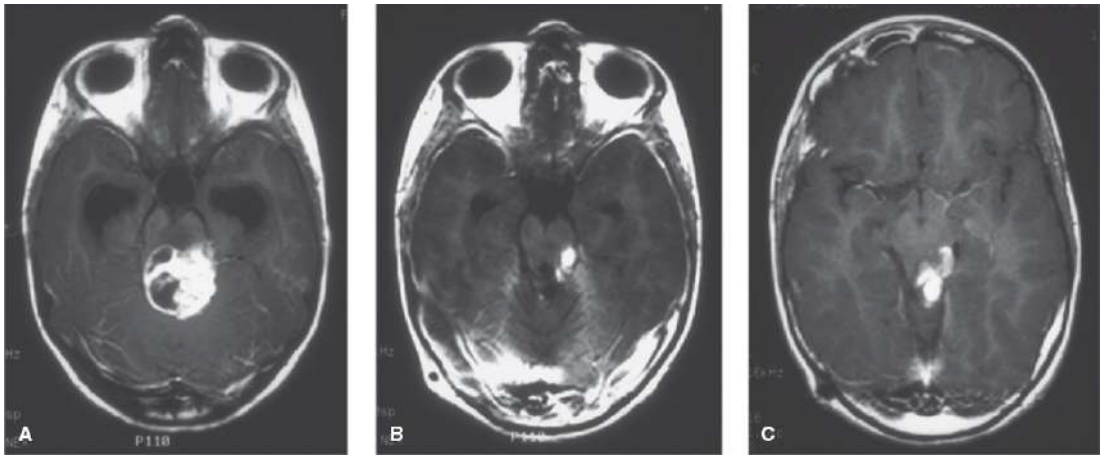

FIGURE 88.9. This patient underwent subtotal resection of a low-grade astrocytoma of the left cerebellar peduncle at age 8. **A:** Preoperative. **B:** Postoperative. **C:** Three years later, routine imaging showed evidence of progressive disease. The gross tumor volume for radiotherapy consists of the tumor as seen on magnetic resonance imaging at the time of treatment.

Follow-Up after Radiotherapy

Tumor regression after radiotherapy typically is slow and patients and their families need to be warned that the tumor may remain stable or sometimes even increase in size in the first months after completion of treatment. It is important not to assume that changes seen on MRI represent progressive disease. Close follow-up with early repeat imaging usually will be the best approach in this situation.

High-Grade Astrocytoma (WHO Grades III and IV)

Anaplastic astrocytoma (AA) is a diffusely infiltrating malignant astrocytoma characterized by nuclear atypia, increased cellularity, and significant proliferative activity. Glioblastoma multiforme (GBM) is the most malignant astrocytic tumor. Histopathologic features include nuclear atypia, cellular pleomorphism, mitotic activity, vascular thrombosis, microvascular proliferation, and necrosis. Both AA and GBM may develop from WHO grade II astrocytomas. However, with the exception of tumors that arise in the pons, they arise almost always in the pediatric age group *de novo* without evidence of a less malignant precursor lesion.

High-grade astrocytomas (HGAs) account for 5% of all CNS tumors in the pediatric age group. They are the most common tumor type in older adolescents. Two-thirds of HGAs are located in the cerebral hemispheres and the remainder approximately equally divided between the deep midline structures (thalamus and basal ganglia) and cerebellum. Patients with HGAs usually present with

symptoms of short duration that relate to the location of the lesion.

Surgery is an important component of treatment. Because most studies show a survival advantage for patients who have undergone complete resection,[56–60] maximal surgical resection compatible with a good neurologic outcome should be the goal for all patients and a second surgical procedure should be considered if there is significant residual tumor after the first. Postoperative radiotherapy always is indicated. Although leptomeningeal seeding is seen in a substantial minority (10% to 30%) of patients, the predominant failure pattern is local and the radiotherapy target volume is local, with a GTV that consists of the tumor bed and any residual enhancing or nonenhancing residual tumor plus any abnormality seen on T2-weighted MRI with a margin for the CTV of 1.5 cm. Because these are often large tumors and doses beyond tolerance levels for structures such as the optic chiasm are required, it is usual to consider a volume reduction at 50 to 54 Gy to a CTV that consists of the tumor bed and any residual tumor plus a reduced margin of 1 cm. The dose to the CTV should be at least 54 Gy given over 6 weeks, but a dose of 59 to 60 Gy is more usual if feasible. There is no evidence that higher doses delivered using radiosurgery or stereotactic boosts, boosts with brachytherapy, or HFRT result in improved outcome, but IMRT delivering accelerated treatment to a component of the target volume (such as the GTV) may be of interest, if only to decrease the overall treatment duration.

The role of chemotherapy remains to be defined. Although responses are seen to many different agents and regimens, results have often been difficult to interpret because of small patient numbers, inconsistent inclusion criteria with respect to pathology, and confounding variables such as tumor location and extent of surgical resection. The cooperative groups in North America and Europe are investigating a number of approaches that include newer chemotherapeutic and biologic agents, some of which have radiosensitizing properties. Whenever possible, patients should be treated on such protocols. Off study, it may be difficult to make a recommendation with respect to adjuvant chemotherapy, although the poor prognosis, particularly for patients with macroscopic residual disease following surgery, usually is given as an argument for the use of the “current best” regimen, most often now temozolomide as in adults. Recent trials have explored the role of bevacizumab in addition to temozolomide, and mature outcome data are awaited.

The prognosis for children with HGAs is poor, with a median time to progression of 10 to 11 months and an overall survival at 5 years of only

approximately 20%. Several factors correlate with outcome. Patients with lesions in the cerebral hemispheres fare better than those with tumors in other locations, apparently independent of extent of surgical resection. The prognosis for children with thalamic lesions appears to be particularly poor.[61] Age also may be an important factor. In contrast to most other tumor types, children younger than age 3 with HGAs fare better than older children, with overall survival at 3 to 5 years in the 33% to 50% range in the North American and United Kingdom Children's Cancer Study Group/International Paediatric Oncology Society (UKCCSG/SIOP) baby studies.[62–65] The prognosis may be even better for children younger than age 1.[66] Histologic grade (AA vs. GBM) has not been shown consistently to affect outcome, but p53 overexpression and a high MIB-1 labeling index appear to identify patients with a particularly adverse prognosis.[67]

Management of Astrocytic Tumors in Specific Locations

Optic Pathway Gliomas

Optic pathway gliomas collectively account for approximately 5% of all CNS tumors in the pediatric age group. These are tumors of young children: the peak age incidence is between 2 and 6 years and 75% of all patients are younger than 10. One-third of patients have NF-1. They may be divided into three clinicopathologic entities: tumors confined to the optic nerve(s), tumors of the optic chiasm with or without optic nerve involvement (collectively "anterior" tumors), and tumors that involve the hypothalamus or adjacent structures ("chiasmatic/hypothalamic" or "posterior" tumors). Management of patients with optic pathway gliomas is often said to be controversial but is really not when differences in behavior between the different tumor types and between patients with and without NF-1 are taken into consideration.

Optic nerve gliomas may involve one or both optic nerves. Bilateral involvement is pathognomonic of NF-1. In a substantial proportion of cases, the optic nerve tumors are incidental findings on routine imaging and patients may remain asymptomatic with nonprogressive lesions over long periods; even spontaneous regression is well documented. The frequency of progression is difficult to establish, ranging from lows of <10% among patients followed in NF-1 clinics to 40% to 50% in series reported by oncology centers. Even in patients with symptomatic tumors, the course can be quite variable: only 30% to 60% of such patients will develop progressive disease that requires treatment.[36,68] Thus, management of patients with optic nerve tumors will

usually consist initially of close follow-up with regular ophthalmologic examinations and MRI, with active intervention, usually chemotherapy, reserved for patients with clear evidence of progression that is symptomatic.[68–70]

Patients with unilateral optic nerve involvement may not have NF-1. They present most frequently with proptosis that may be relatively long-standing. Findings on examination may include optic atrophy and impaired visual acuity. On MRI, optic nerve tumors are usually relatively small and well circumscribed, with bright enhancement typical for pilocytic astrocytoma. Biopsy is not necessary to make a diagnosis. Treatment usually, although not always, will be necessary and the approach will depend on whether there is useful vision. If not, then surgical resection will be the treatment of choice. If useful vision is preserved, chemotherapy would be the preferred option for infants and very young children up to age 5 and for patients of all ages with NF-1. Radiotherapy could be considered for older children. Overall, the prognosis is very good. Visual acuity remains stable or improves in the majority of cases following chemotherapy or radiotherapy. Long-term tumor control approaches 100% with either modality.[71]

Chiasmatic gliomas are tumors that involve the optic chiasm and sometimes one or both optic nerves as well. Patients typically present with loss of visual acuity and temporal field defects. On imaging, the tumors are usually relatively small and well circumscribed and enhance uniformly and brightly with contrast material, suggestive of pilocytic histology. Biopsy is usually not necessary.

A period of surveillance is appropriate initial management, particularly for patients with NF-1. For patients without NF-1, especially those who present before age 5, there is a high probability of early progression and the majority of patients will require nonsurgical treatment within a few months following diagnosis. Surgery is rarely an option for tumors in this location. As for optic nerve tumors, chemotherapy usually will be the treatment of choice for infants and young children and for patients with NF-1. Radiotherapy is reserved for salvage after chemotherapy and for definitive treatment of older children without NF-1, providing a reasonable expectation that vision will not deteriorate further and a probability of long-term progression-free survival in the 60% to 90% range.[70,72–75] Overall survival for patients with chiasmatic tumors is in the 90% to 100% range.

Posterior, or chiasmatic/hypothalamic, gliomas account for approximately 70% of all optic pathway gliomas in children. They are typically rather large lesions that probably arise in the optic chiasm and extend to involve the

hypothalamus. They may extend posteriorly along the optic tracts as well. They often fill the third ventricle, eventually causing hydrocephalus. Early findings consist of nystagmus, impaired visual acuity, and visual field deficits; only later do patients present increasing head circumference and/or symptoms and signs of raised intracranial pressure.

Treatment consists of CSF diversion, if necessary, and surgical resection, particularly if tumor is growing exophytically into the basal cistern because this may provide rapid relief of symptoms. In most patients, however, resection will be incomplete. As for LGAs at other locations, a period of surveillance following surgery is reasonable, although most patients will require adjuvant therapy.[46,71] The treatment of choice for children younger than 5 and those with NF-1 usually will be chemotherapy. Progression-free survival at 3 to 5 years is rather low at 20% to at best 60%.[46–48,76] However, some patients will never need further treatment, and for those who do, the use of chemotherapy allows radiotherapy to be deferred by a median of 2 to 4+ years without jeopardizing overall survival.

The indications for radiotherapy are (a) progressive disease on chemotherapy for children younger than 10 and (b) progressive disease at diagnosis or after surgery for older patients. Radiotherapy in this situation, given to local fields to a dose of 45 to 50 Gy for younger children and of 50 to 54 Gy for those older than 5, results in local tumor control in 70% to 80% of cases.[46,71,75,77,78] Overall, however, outcomes are less satisfactory for this group of patients than for those with anterior tumors. Long-term survival is in the 50% to 80% range, and many patients will be left with significant neuroendocrine and neuropsychologic sequelae. Patients with NF-1 are particularly at risk. They may have subnormal IQ even without chemotherapy and/or radiotherapy.[79] They are also at greater risk for moyamoya syndrome, a progressive vasoocclusive process involving the circle of Willis. This may be seen without radiotherapy, but when radiotherapy is used in patients with NF-1, it is important to include MR angiography as part of the regular follow-up imaging protocol and intervene surgically if necessary to avoid a cerebrovascular accident.

Brainstem Gliomas

Tumors arising in the midbrain, pons, and medulla oblongata account for 10% to 15% of all CNS tumors in the pediatric age group. They are of several distinct types that can be broadly grouped as the more favorable low-grade focal, dorsal exophytic, and cervicomedullary tumors and the much more aggressive diffuse

intrinsic pontine tumors (DIPGs).[80–82]

Focal tumors by definition are tumors of limited size (<2 cm) that on MRI are well circumscribed, without evidence of infiltration, and without edema. They may be cystic, and, as with cystic tumors at other sites, the cystic component may be large relative to the solid, biologically active, component. Focal tumors may occur at any level in the brainstem but most frequently are seen in the midbrain and medulla. They usually present with a long history of localizing findings such as an isolated cranial nerve deficit and a contralateral hemiparesis. Signs and symptoms of raised intracranial pressure are uncommon except in patients with tumors arising in the tectal region that may cause aqueduct stenosis while still small.

The management depends on the location of the tumor in the brainstem and the specific imaging characteristics of the tumor. As noted previously, patients with nonenhancing focal tumors in the tectal region who present with only hydrocephalus may do well without any treatment other than CSF diversionary procedures, usually endoscopic third ventriculostomy. Active intervention, including biopsy, is reserved for patients with clinical and radiologic evidence of progressive tumor. This is important because surgery for tumors in this location is associated with a substantial risk of morbidity even with modern techniques.

Surgery is the treatment of choice for focal tumors at other locations that are surgically accessible (meaning that they extend either toward the surface of the brainstem laterally or at the floor of the fourth ventricle) and have imaging characteristics suggestive of low-grade histology. In this regard, uniform bright enhancement with contrast material, which correlates with pilocytic histology, and the absence of peritumoral hypodensity are of particular importance. In experienced hands, the risk of morbidity for well-selected patients is low and, as with completely or subtotally resected LGAs at other sites, results may be excellent with freedom from progression in a majority of cases.[83,84] Outcomes are less satisfactory for patients with bulky tumors and for patients with tumors in the medulla with lower cranial nerve deficits who are at risk of developing postoperative feeding and/or breathing difficulties.

There are several treatment options for patients with surgically inaccessible focal lesions. By extrapolation from series reporting results of treatment using conventional radiotherapy in brainstem tumors in which outcome correlates with location (pons vs. other), imaging appearance (tumor volume, density on CT, enhancement pattern), and histology (malignant vs. benign), it is reasonable to assume that 50% to 70% of focal lesions may be permanently controlled with

such treatment. Similar results have been obtained in small numbers of patients treated with HFRT and with interstitial irradiation using ^{125}I.[51,53,55] There is also some experience with the use of radiosurgery. However, standard treatment is as for LGAs at other locations, that is, external beam radiotherapy using a margin for the CTV of 0.5 cm, to a total dose on the order of 54 Gy given over 6 weeks. The risks of HFRT, radiosurgery, or stereotactic irradiation with large fraction sizes, or interstitial irradiation in inexperienced hands cannot be justified in the absence of any established superiority.

Dorsal exophytic tumors arise from the floor of the fourth ventricle. They are usually large, filling the fourth ventricle, but do not invade the brainstem to any significant extent. They present insidiously with failure to thrive in younger children and symptoms and signs of raised intracranial pressure in older patients. Cranial nerve deficits are seen in about half of the patients. On MRI, they are sharply delineated from surrounding structures. They are hypointense on T1-weighted images, are hyperintense on T2-weighted images, and enhance uniformly and brightly after gadolinium injection. Most are pilocytic astrocytomas.

Surgery is the treatment of choice for dorsal exophytic tumors. Intraoperative image guidance is essential to achieve a maximal degree of tumor resection. However, because there is usually no definite tumor–brainstem interface, even an optimal resection will leave a thin layer of tumor on the floor of the fourth ventricle. Nonetheless, the majority of children do well following surgery and routine postoperative adjuvant therapy is not indicated. Radiotherapy should be considered for the rare patient who is found to have a high-grade lesion or for patients with low-grade tumors who develop progressive disease in the early (<9 months) postoperative period. For patients whose tumors recur later, further surgery should be considered and radiotherapy reserved for those with inoperable disease. The radiotherapy volume and dose should be similar to those used for LGAs in other locations. The literature suggests that salvage is possible in the majority of cases, and overall, the prognosis for patients with dorsal exophytic tumors is excellent.[85–87]

Cervicomedullary tumors arise in the upper cervical cord and grow rostrally beyond the foramen magnum. Most are low-grade lesions whose axial growth is limited by the pyramidal decussations located ventrally at the junction of the cervical cord and medulla. At this point, the tumor grows posteriorly, causing a bulge in the dorsal aspect of the medulla, toward the fourth ventricle.[80] These tumors typically present with lower cranial nerve deficits, sleep apnea and

feeding difficulties in younger children, long tract signs, and sometimes torticollis. Hydrocephalus is unusual.

Surgery is the treatment of choice. Gross total resection may be achieved in 70% to 80% of cases and subtotal removal in most of the remainder. The probability of long-term tumor control after such treatment appears to be excellent for the typical low-grade lesion. There is, therefore, no indication for routine postoperative radiotherapy for these patients.

Diffuse intrinsic pontine tumors (DIPGs) account for 70% to 80% of all brainstem tumors. They arise in the pons and cause diffuse enlargement of the brainstem. Extension to the midbrain and medulla and/or exophytic growth is seen in at least two-thirds of cases. In contrast to the other types of brainstem tumors, the majority of DIPGs are fibrillary astrocytomas with a propensity for malignant change and a very poor prognosis.

DIPGs typically present with a short duration of symptoms consisting of multiple, bilateral, cranial nerve deficits (especially VI and VII) as well as long tract signs and ataxia. About 10% of patients have hydrocephalus at diagnosis. On CT, DIPGs are isodense or hypodense, with little enhancement after contrast injection, similar to diffuse fibrillary astrocytomas at other sites. They are best seen on T2-weighted or FLAIR MRI. The presence of ring enhancement is suggestive of high-grade histology.

Surgery has no role in the management of patients with DIPGs. Outside a clinical trial, even biopsy, a relatively nonmorbid procedure now, is considered unnecessary because in the context of a typical clinical presentation, the MRI findings are characteristic and histology does not influence treatment.[88,89] Treated with conventional radiotherapy, the majority (70% or more) of patients with DIPGs will improve clinically. However, the progression-free interval is short (median <6 months) and survival is poor, with a median survival of <1 year and survival rates at 2 years <20%.

So far all attempts to improve the outcome for children with DIPGs have proved futile. HFRT was tested in a series of phase I/II studies using doses ranging from 64.8 to 78 Gy. Time to progression and overall survival were not improved in comparison with conventional radiotherapy.[90,91] Moreover, at the higher doses of HFRT of 75.6 and 78 Gy, morbidity was considerable. This included steroid dependency, vascular events, and white matter changes outside the radiation field, as well as hearing loss, hormone deficiencies, and late-developing seizure disorders in the small number of long-term survivors.[90,92–94] Accelerated and hypofractionated radiotherapy regimens have also been tested in

single-institution studies using, respectively, a total dose of 50.4 Gy given in 28 twice-daily fractions of 1.8 Gy over 3 weeks[95] and 39 Gy in 13 daily fractions and 45 Gy in 15 daily fractions.[96,97] Progression-free and overall survival rates were similar to those seen in the HFRT studies. However there are potential benefits from the reduced duration of the radiotherapy course to help facilitate rehabilitation.

Alternative approaches that use chemotherapy in combination with radiotherapy also have been disappointing. None of the many single-agent and multiagent regimens that have been tested in this patient population have been shown to provide a survival advantage compared with radiotherapy alone. New agents and novel chemotherapy–radiotherapy combinations are under investigation by the pediatric cooperative groups in North America and Europe.

Currently, standard treatment for DIPGs consists of radiotherapy given to the GTV as usually best demonstrated on T2-weighted or FLAIR MRI with a margin for the CTV of 1 to 1.5 cm to a dose of 54 Gy given in 30 daily fractions over 6 weeks that because of the initial rapid progression of neurologic deficit treatment often needs to be started on a semiurgent basis. Because no unexpected toxicity was seen with the hypofractionated regimens, these in some cases could be considered an alternative to conventional radiotherapy that reduces the burden of treatment for the child and family.

Improvement in clinical status is usually evident as early as 2 to 3 weeks into treatment, and steroids, if used, usually can be discontinued at that point. This improvement is often impressive and well appreciated by the family, despite being of only short duration. Treatment at time of progression may include experimental chemotherapy regimens or supportive care or even retreatment with radiotherapy in selected cases.[98,99]

Astrocytoma of the Spinal Cord

Intramedullary spinal cord tumors account for 3% to 6% of all CNS tumors in the pediatric age group. About 60% are astrocytomas, the majority of which are LGAs; 30% are ependymomas; and the remainder are gangliogliomas and developmental tumors such as teratomas, lipomas, and dermoid and epidermoid cysts.

Patients typically present with pain and motor deficits, often of long duration. Rapid progression of symptoms and signs is suggestive of high-grade histology. On imaging, astrocytomas most often are seen to comprise a solid component and one or more cysts that may be intratumoral and/or extend rostrally and

caudally beyond the solid component. Most enhance heterogeneously with the use of contrast material. Ependymomas, in contrast, only rarely harbor intratumoral cysts (although they may have an associated syrinx) and usually enhance homogeneously.

The management of spinal cord tumors has changed over recent years.[100] In the past, patients typically were treated with biopsy followed by radiotherapy, and there is evidence to suggest that this is effective treatment in more than half of children with LGAs.[101] However, improvements in surgery and the routine use of surgical adjuncts such as ultrasonic aspiration and support systems such as intraoperative ultrasonography and sensory and more recently motor-evoked potential monitoring improve the safety and completeness of resection so that complete or subtotal resection is now possible in approximately 80% of children with pilocytic astrocytoma (the majority), especially those with a syrinx. Resection is more difficult and less likely to be complete in patients with grade II astrocytoma because of the more infiltrative nature of these tumors and the absence of a clear interface.[100] Because outcome following complete or subtotal resection for LGAs is very good, with long-term progression-free survival in the 70% to 90% range,[102–104] routine postoperative adjuvant therapy is not indicated. For children in whom complete or subtotal resection is not possible, the options will be as for patients with LGAs in other locations, that is, early second surgery if feasible, or close follow-up with second surgery and/or radiotherapy at the time of progression. As for LGAs in other locations, chemotherapy may be an alternative to radiotherapy for young children.[105,106] The benefit of surgical resection in HGAs is less clear and the more usual approach is biopsy followed by postoperative radiotherapy.[107]

The radiotherapy target volume for LGAs consists of the solid portion of the tumor (including intratumoral cysts) with a margin for the CTV of 1 to 1.5 cm. The usual dose is 50.4 Gy given in 28 daily fractions over approximately 6 weeks. The CTV should be larger for patients with HGAs for whom a margin beyond the entire lesion of at least 1.5 cm (or one vertebral body) would be more appropriate. The dose usually will be as for LGA because of the substantial risk of morbidity at higher doses but often chemotherapy will be given as well. Although older studies[101,102] and data from the Surveillance, Epidemiology, and End Results (SEER) registry[108] and from the German cooperative group[109] all suggest that 20% to 35% of children with high-grade gliomas will survive following such treatment, a recent study from St. Jude Children’s Research Hospital presents an even bleaker picture with a very high rate of both local

progression and leptomeningeal spread and no long-term survivors among patients with GBM.[107]

EPENDYMAL TUMORS

The following types are seen in children:

- Myxopapillary ependymoma (WHO grade I)
- Ependymoma (WHO grade II)
- Anaplastic ependymoma (WHO grade III)

Myxopapillary Ependymoma

Myxopapillary ependymomas are slowly growing lesions almost always located in the conus filum terminale region of the spinal cord. They are the most common spinal cord tumor in this location. They usually present with back pain. On imaging, myxopapillary ependymomas are well circumscribed and usually enhance brightly after contrast injection. Despite their low-grade histology, leptomeningeal spread is not uncommon even at diagnosis and all patients should have an MRI of the whole spine and brain as part of their initial workup.

Surgical resection is the treatment of choice. If the tumor is contained within the filum, complete resection may be possible after mobilization of the filum. Whether postoperative radiotherapy is necessary after complete resection is unclear. A significant proportion of tumors recur locally and/or with leptomeningeal metastases, but salvage with further surgery and/or with radiotherapy seems to be possible in most.[110–112] If the tumor is in continuity with the conus, resection is more difficult and more likely to result in significant sequelae so that there frequently will be residual tumor. If the tumor is not resected en bloc or if there is macroscopic residual tumor, the risk of recurrence is high. Postoperative radiotherapy in this situation results in improved local control.[103,113–115] The radiotherapy target volume is local (macroscopic disease plus a margin cephalad and caudad of 1.5 cm [or one vertebral body]) for the CTV and the dose, 50.4 Gy.[115] Patients with leptomeningeal seeding at diagnosis or at relapse after surgery alone should be treated with curative intent with CSI followed by a boost to the primary site with a reasonable expectation of long-term tumor control.[103,111,114,116]

Ependymoma

Ependymoma is the third most common CNS tumor in children. About half of

all cases arise in children younger than 5. Ependymoma can occur at any site in the ventricular system or in the spinal canal, but in children, approximately two-thirds arise in the ependymal lining of the fourth ventricle. Tumors in this location typically present with symptoms and signs of raised intracranial pressure. On imaging the tumor is usually large but relatively well circumscribed, with displacement rather than invasion of adjacent structures. Extension through the foramen magnum into the upper cervical region is not uncommon (Fig. 88.10). Tumors that arise in the supratentorial compartment, some of which arise outside the ventricular system, present with focal neurologic deficits. Intramedullary ependymomas, which account for approximately 30% of all spinal cord tumors arising in childhood, usually present initially with dysesthesia and sensory deficits because of their central location in the cord and only later with pain and motor deficits.

Spread of ependymoma is primarily local. However, 5% to 10% of patients have leptomeningeal seeding at diagnosis, and gadolinium-enhanced MRI of the whole CNS and CSF cytology are essential components of the workup for all patients.

Management of Ependymoma

The completeness of the surgical resection is the factor that has the greatest impact on the outcome of patients with ependymoma.[117–126] Currently, it is estimated that complete resection is achieved in 70% to 90% of supratentorial ependymomas and in a similar percentage of spinal ependymomas. Complete resection is less frequently possible in patients with infratentorial ependymomas. Most commonly, residual tumor is left behind on the floor of the fourth ventricle or laterally at the cerebellopontine angle where tumor protruding through the foramen of Luschka encircles lower cranial nerves and vessels. “Second-look” surgery may be considered, if feasible, either after the realignment of structures that takes place following resection of an initially bulky tumor in an often unstable young child or after chemotherapy.

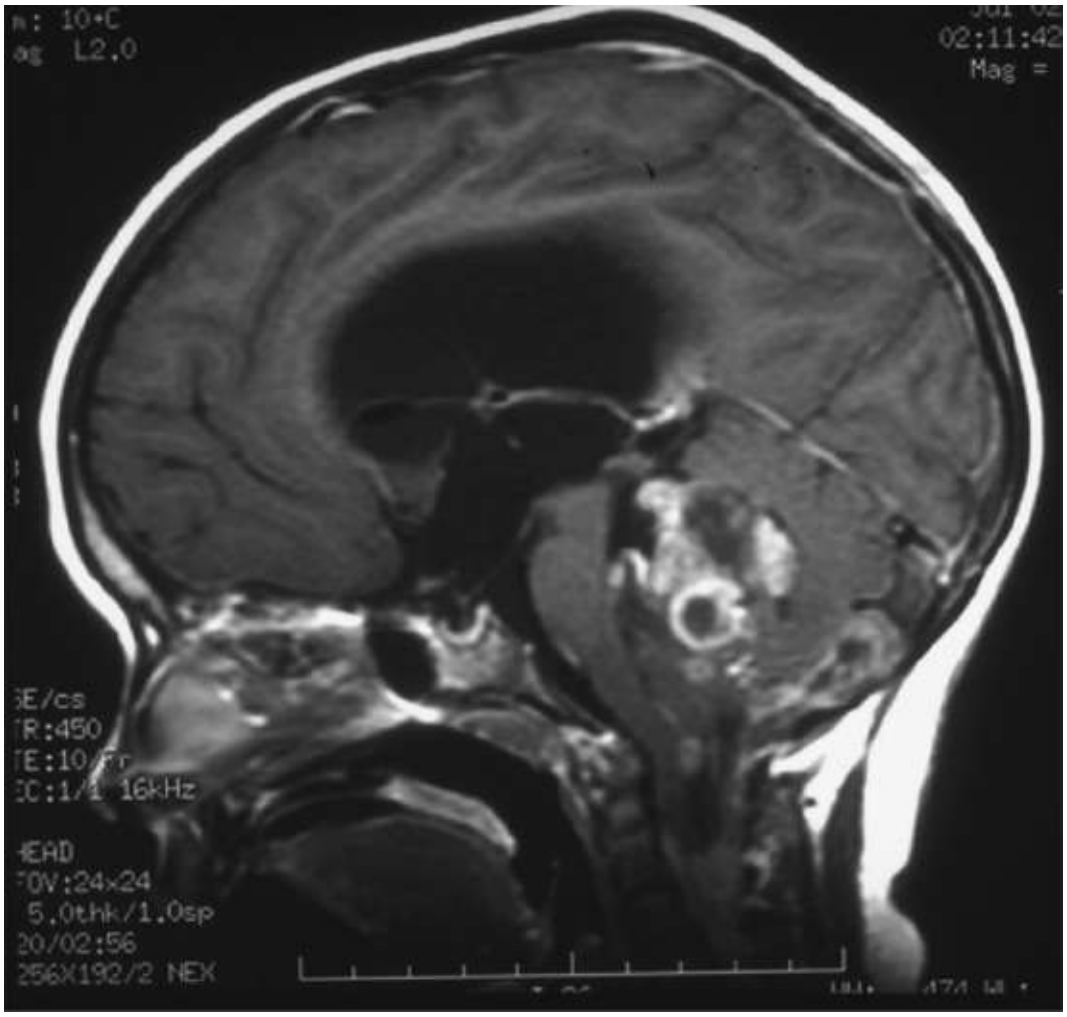

FIGURE 88.10. Typical appearance of an ependymoma that fills the fourth ventricle causing hydrocephalus and extends inferiorly below the foramen magnum over the dorsal aspect of the spinal cord to the level of C4.

Postoperative radiotherapy is the standard of care for all children with ependymoma. Some have questioned the need for such treatment for patients who have undergone complete resection.[123,127,128] However, a number of studies including studies in young children in which the goal was to delay or avoid altogether radiotherapy suggest that such a strategy results in worse disease-free and overall survival and in the long-term greater morbidity[124,129–132] and therefore can be considered acceptable only for (a) patients with ependymoma of the spinal cord who have undergone complete resection for whom disease-free survival in contemporary series approaches 100%[133–136] and (b) selected patients with supratentorial ependymoma, such as those with intraventricular tumors or with extraventricular tumors that are solid and located in noneloquent areas and can be resected with a wider margin.[128]

Radiotherapy Target Volume

Focal radiotherapy is the standard of care.[137,138] The GTV is a composite of the tumor bed, including any extension caudal to the foramen magnum and taking into account any anatomic shifts because of surgery plus any residual tumor. In the St. Jude prospective study of conformal radiotherapy that included both ependymoma and anaplastic ependymoma, the margin for the CTV was 1 cm.[126] In the subset of 107 patients in that study that received immediate postoperative radiotherapy, local control was excellent (cumulative incidence of local failure 7.8%) for patients who had undergone gross total resection, whereas patients who had undergone near-total or subtotal resection fared less well. All failures were reported to be within the 95% isodose. The current Children's Oncology Group (COG) study uses an even smaller margin for the CTV of 0.5 cm.

Radiotherapy Dose

There is evidence for a dose–response in ependymoma, with improved tumor control with doses >45 to 50 and even 54 Gy.[137] Although the lower doses may be the maximum possible for spinal ependymomas, the current standard is a dose of at least 54 Gy for children older than 18 months with infra- or supratentorial tumors. Moreover, because failure most often occurs at the site of macroscopic residual disease, even higher doses may be desirable and most would reduce the CTV at 54 Gy to respect the tolerance of the spinal cord and/or other structures and continue to a total dose of 59.4 Gy (Fig. 88.11).

HFRT has been explored in ependymoma as a strategy to more safely deliver these higher radiotherapy doses. Studies from the Children's Hospital of Philadelphia in which the majority of patients received HFRT to a mean dose of 70.7 Gy,[139] from the Italian pediatric oncology group that used a dose of 70.4 Gy,[140] and from the French pediatric oncology group that used a lower total dose of 60 Gy in 60 fractions[141] all reported HFRT to be feasible. However, in none of these studies was there any clear evidence of benefit, particularly in the context of improved surgery and modern radiotherapy.

The role of chemotherapy in ependymoma remains to be defined. There is some evidence of efficacy, but even in the more recent infant studies in which chemotherapy was used because of the desire to delay or even avoid altogether radiotherapy, more than half of the patients progressed on chemotherapy,[65,130,132,142,143] and in the COG baby study, prolonged use of chemotherapy and a delay to radiotherapy of more than 1 year were associated with a worse survival.[129] Consequently, most would now use radiotherapy for all

children older than 12 months following complete resection. In patients with residual disease, chemotherapy has been justified because of the poor prognosis. As well, it may facilitate complete resection of residual disease at second-look surgery, and current North American and European trials are testing chemotherapy in this setting. Furthermore, trials are also investigating the role of adjuvant chemotherapy following complete resection.

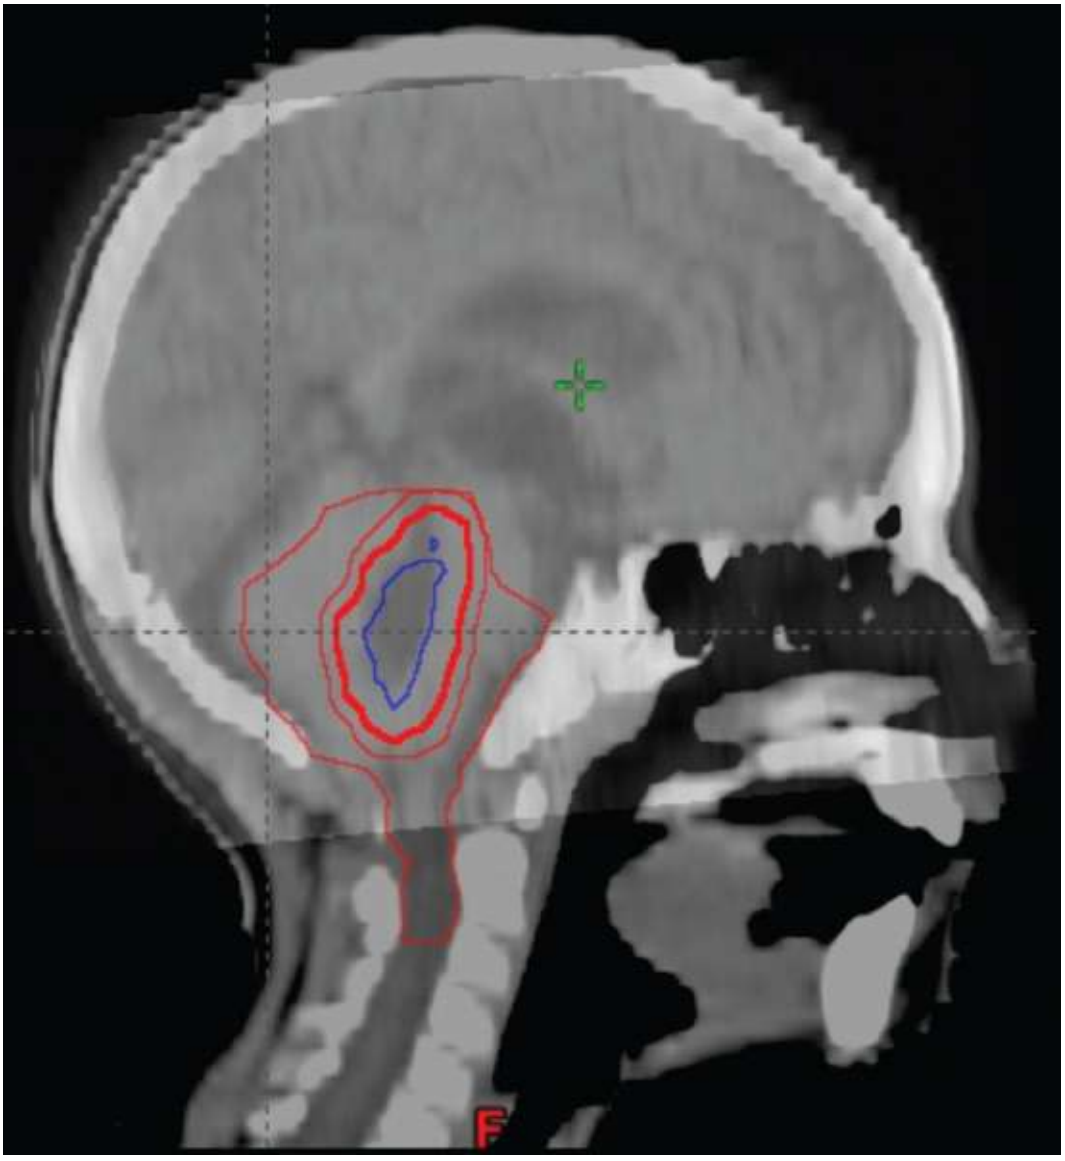

FIGURE 88.11. Care is necessary to ensure that the inferior extent of disease is included in the radiotherapy target volume. Volume reduction at 54 Gy is necessary to respect the tolerance of the spinal cord.

Reirradiation for Ependymoma

For patients who fail standard treatment with either local recurrence or, less

frequently, leptomeningeal dissemination, retreatment with radiotherapy is an option that may result in durable control in a proportion of patients.[144,145]

Anaplastic Ependymoma

By definition, an anaplastic ependymoma is a malignant glioma of ependymal differentiation that is characterized by high mitotic activity, often accompanied by microvascular proliferation and pseudopalisading necrosis. There are no histopathologic features that can reliably differentiate anaplastic ependymomas from the more slowly growing and more favorable ependymomas, which probably explains the controversy in the literature with respect to the prognostic significance of tumor grade. Proliferation markers may be more useful in this regard, but several groups also are investigating genetic and expression profiles based on preliminary data that suggest that a molecular classification system can be built that will prove useful for risk stratification.

Management of anaplastic ependymoma begins with maximum surgical resection consistent with a good neurologic outcome and a workup consisting of a gadolinium-enhanced MRI of the spinal axis and CSF cytology to rule out leptomeningeal seeding, which is only slightly more frequent than in ependymoma. Postoperatively all patients receive radiotherapy. As for ependymoma, the role of chemotherapy remains to be defined but may be an option in very young children to delay the use of radiotherapy.

CSI was previously the standard of care for anaplastic ependymoma, but several institutional studies, a careful retrospective review, and prospective studies by the POG all suggest that there is no survival advantage for CSI.[118,146–150] Thus, a target volume consisting of the tumor bed and any macroscopic residual disease with a margin for the CTV of 1 cm is used for patients with localized disease and only patients with leptomeningeal seeding at diagnosis receive CSI. As for ependymoma, the dose should be at least 54 to 55 Gy and, if feasible, 59 to 60 Gy.

In contemporary series, disease-free survival for patients with anaplastic ependymoma is typically still only in the 30% to 45% range at 3 to 5 years,[140,150] although results were better in the St. Jude series, with event-free survival at 7 years of 61.3% and overall survival, 71.8%.[126] This may be in part at least because of the high rate of gross total resection in that series because, as others have shown, the prognosis is better for patients in whom complete resection has been achieved than for those with residual disease.[149,150] Patients with leptomeningeal dissemination at diagnosis fare poorly despite intensive

treatment that includes CSI and chemotherapy.

CHOROID PLEXUS TUMORS

Choroid plexus tumors arise from the epithelium of the choroid plexus of the cerebral ventricles. They include:

- Choroid plexus papilloma (WHO grade I)
- Atypical choroid plexus papilloma (WHO grade II)
- Choroid plexus carcinoma (WHO grade III)

Choroid plexus tumors account for only 2% to 4% of all brain tumors that occur in children but as many as 10% to 20% of those seen in the first year of life. Choroid plexus papillomas (CPPs), which account for more than half of choroid plexus tumors in children, are composed of delicate fibrovascular connective tissue fronds covered by a single layer of uniform cuboidal columnar epithelial cells with round or oval basally situated monomorphic nuclei. Mitotic activity is low and increased mitotic activity in a CPP defines an atypical CPP. In contrast to both, choroid plexus carcinomas (CPCs) are solid tumors that tend to transgress the ventricular wall and invade the brain. Histologically, CPCs show frank evidence of malignancy including frequent mitoses (>5%/10 HPF), increased cellular density, nuclear pleomorphism, blurring of the papillary pattern with poorly structured sheets of tumor cells, and necrotic areas.

In children, most choroid plexus tumors arise in the lateral ventricles causing obstruction to CSF flow. Infants commonly present with increasing head circumference and older children with symptoms and signs of raised intracranial pressure. On neuroimaging, choroid plexus tumors are usually hyperdense, contrast-enhancing masses. Even papillomas seed into the CSF space and workup for both benign and malignant lesions should include a gadolinium-enhanced MRI of the spinal axis and CSF cytology.

Management of Choroid Plexus Tumors

Surgery is the treatment of choice for CPPs both for the primary lesion and for metastatic deposits, if feasible. Complete resection is achieved in a high percentage of cases now and outcome in this situation is excellent. Less than 10% of tumors recur and overall survival is close to 100%.[151–154] The role of radiotherapy following incomplete resection is unclear, but because not all patients will progress, follow-up without adjuvant treatment would be the usual strategy, with consideration of further surgery, if feasible, and/or radiotherapy

only at the time of progression.

Results are less satisfactory for patients with CPCs. Surgery is an important component of treatment but often difficult. Blood loss may be considerable and staged procedures may be necessary to obtain maximal resection. In most series, results are better for patients who have undergone complete resection[151,155–164] and the need for adjuvant therapy in this situation is not clearly established. In one series of pooled data, survival was significantly better when radiotherapy had been given postoperatively despite a probable bias toward the use of radiotherapy in patients considered to have more unfavorable disease.[158,161] Others have reported excellent results following complete resection, in some cases with chemotherapy but without radiotherapy.[155,156,159,160] In contrast, patients who have residual disease fare very poorly. Postoperative radiotherapy appears to be useful,[164] but the desire to avoid radiotherapy in infants and very young children may mean that chemotherapy is used instead despite less convincing evidence of efficacy. When both are used, radiotherapy is usually delivered early (following two cycles of chemotherapy) with the exception of infants and very young children in whom radiotherapy is delayed until age 3 years. Genetic and genomic analyses may in the future help guide therapy. A substantial percentage of patients with CPCs have TP53 mutations, and patients without such mutations are reported to have a more favorable prognosis and be successfully treated without radiotherapy.[165]

The radiotherapy target volume is also controversial. CSI was traditionally used in patients with CPCs, and a recent literature review showed that the use of CSI was associated with improved progression-free survival as compared with radiotherapy to the whole brain or tumor bed only.[164] Importantly, more than half of all failures occurred outside the treatment field. This is problematic given the young age of the patients, and a pragmatic approach in which local fields are used for patients with CPPs with postoperative residual (including metastatic sites) as well as for patients with atypical CPPs or CPCs without evidence of leptomeningeal seeding and only patients with atypical CPPs or CPCs with leptomeningeal seeding receive CSI would seem reasonable for now.

NEURONAL AND MIXED NEURONAL-GLIAL TUMORS

These are uncommon tumors that are characterized by the presence of both neuronal and glial elements in variable amounts. They include entities such as desmoplastic infantile astrocytoma and dysembryoplastic neuroepithelial tumor.

Most will be cured by surgery, but radiotherapy may be indicated in two tumor types:

- Ganglioglioma and anaplastic ganglioglioma
- Central neurocytoma

Ganglioglioma and Anaplastic Ganglioglioma

Gangliogliomas are well-differentiated slowly growing tumors composed of mature ganglion cells in combination with neoplastic glial cells (WHO grade I or II). Tumors in which the glial component shows anaplastic features (WHO grade III) are called anaplastic gangliogliomas.

Although these tumors can arise anywhere within the CNS, most in children arise in the temporal region and typically present with seizures. Surgery is the treatment of choice. When resection is complete, the probability of long-term tumor control in patients with ganglioglioma is excellent.[166–168] The indications for radiotherapy are as for patients with LGAs, that is, for patients with progressive or recurrent disease that is not resectable, and the radiotherapy target volume and dose likewise. The significance of a high proliferation index or of the presence of anaplasia in patients with ganglioglioma is controversial. Although it seems clear that the risk of recurrence is higher in patients with these features,[166,167,169] the indications for postoperative radiotherapy remain undefined except for patients with anaplastic gangliogliomas who have undergone less than complete resection in whom the use of radiotherapy has been shown to result in improved progression-free survival.[168,170]

Central Neurocytoma

This is a neoplasm composed of uniform round cells with neuronal differentiation that arises in the lateral or third ventricles, typically the former, that is seen predominantly in adolescents and young adults. Patients usually present with symptoms and signs of raised intracranial pressure. Surgery is the treatment of choice, and when complete resection is achieved, long-term tumor control is excellent without adjuvant treatment.[171] Patients in whom complete resection cannot be achieved as well as those with tumors with atypical histology or a high mitotic rate fare less well,[171,172] and postoperative radiotherapy should be considered in these situations. Although a dose of 50 Gy appears adequate for patients with typical neurocytomas,[173] there is evidence of improved tumor control at doses of at least 54 Gy in patients with atypical neurocytoma.[174]

PINEAL PARENCHYMAL TUMORS

Pineal region tumors account for 2% to 8% of intracranial tumors in children. Approximately half are germ cell tumors, one-fourth to one-third are pineal parenchymal tumors, and most of the remainder are astrocytic tumors. Pineal parenchymal tumors are derived from pineocytoma, which are cells with photosensory and neuroendocrine functions, or their embryonal precursors. According to the WHO classification, the following entities can be distinguished:

- Pineocytoma (WHO grade I)
- Pineal parenchymal tumor of intermediate differentiation
- Pineoblastoma (WHO grade IV)

Pineocytoma

Pineocytoma is a slow-growing tumor composed of small uniform mature cells resembling pineocytes, with occasional large pineocytomatous rosettes, that accounts for approximately half of pineal parenchymal tumors and in childhood most commonly occurs in the teenage years. Patients typically present with symptoms and signs of raised intracranial pressure. Some will have symptoms of upper mesencephalic tegmental dysfunction (Parinaud syndrome), consisting of limitation of upward gaze, lid retraction, retraction nystagmus, and pupils that react more poorly to light than to accommodation. On MRI, pineocytomas are usually spherical, well-circumscribed masses, hypointense on T1- and hyperintense on T2-weighted images, with homogeneous contrast enhancement. Leptomeningeal spread has been described in pineocytoma,[175] but it is probable that the explanation for this lies in sampling error. With better imaging and more extensive surgery with more complete histologic evaluation of the tumor, it seems that leptomeningeal spread can be considered to be an uncommon event.[176]

Treatment consists of surgical resection via an occipital transtentorial or an infratentorial supracerebellar approach using modern operative adjuncts such as functional MRI and MR tractography in relation to the location of the primary visual cortex and deep MR venography. If complete or subtotal resection is accomplished, progression-free survival is in the 90% to 100% range.[177,178] Patients who undergo lesser degrees of resection or only biopsy fare less well and, although some have questioned its usefulness based on the results of a systematic review,[178] postoperative radiotherapy usually is recommended.[179]

The target volume is local, consisting of macroscopic residual disease with a margin for the CTV of 1 cm, and the dose, 50 to 55 Gy over 6 weeks.

Pineal Parenchymal Tumor of Intermediate Differentiation

Pineal parenchymal tumors of intermediate differentiation are composed of diffuse sheets or large lobules of uniform cells with mild to moderate nuclear atypia and low to moderate mitotic activity. They are rare tumors, accounting for only 10% of pineal parenchymal tumors, and optimal management remains to be defined. In one series, three patients treated with surgery alone survived free of disease.[177] At the other extreme, another group considers these to be tumors "with seeding potential" and recommends postoperative treatment with CSI as for pineoblastoma.[176]

Pineoblastoma

Pineoblastoma is a highly malignant tumor composed of patternless sheets of densely packed small cells with round to irregular nuclei and scant cytoplasm.

Pineoblastomas most frequently affect infants and very young children, who typically present with an enlarged head circumference or symptoms and signs of short duration of raised intracranial pressure. On MRI, pineoblastomas are usually multilobulated and often enhance heterogeneously, with areas of necrosis and/or hemorrhage. Infiltration of surrounding structures is common. Leptomeningeal spread is seen in as many as 50% of patients at diagnosis.

Surgery for lesions in the pineal region is difficult and complete resection is often not possible. Postoperatively, children older than 3 are treated with CSI and chemotherapy, as for high-risk medulloblastoma and supratentorial PNETs (see later). Five-year survival in this age group is in the 50% to 70% range.[176,180,181] However, infants treated with chemotherapy without radiotherapy fare extremely poorly: in prospective studies of the POG and CCG, all tumors recurred within the first 11 months (POG) and 1.2 years (CCG) and all patients died of disease.[182,183] Thus, more aggressive treatment that includes chemotherapy dose intensification is necessary. Patients with familial bilateral retinoblastoma with pineoblastoma ("trilateral retinoblastoma") also have an extremely poor prognosis, most dying within a year following diagnosis.

EMBRYONAL TUMORS

Embryonal tumors as a group are the second most common type of CNS tumor in the pediatric age group. They include medulloblastoma (MB) and atypical

teratoid rhabdoid tumor (ATRT):

- Medulloblastoma

I. Medulloblastoma, WNT-activated
II. Medulloblastoma, SHH-activated, TP53 mutant
III. Medulloblastoma, SHH-activated, TP53 wild type
IV. Medulloblastoma, non-WNT/non-SHH, group 3
V. Medulloblastoma, non-WNT/non-SHH, group 4

These medulloblastoma subgroups refer to the use of conventional histopathologic features together with molecular biologic parameters in classification. Conventional histologic varieties are also recognized and are associated with particular clinical characteristics. Desmoplastic MB is associated with a better prognosis, particularly in very young children. Anaplastic and large cell MBs (A/LC MBs) appear to be adverse prognostic factors.

Medulloblastoma

Medulloblastoma accounts for 15% to 20% of all CNS tumors in children with a median age at presentation of 6 years. It is a malignant invasive embryonal tumor of the cerebellum with predominantly neuronal differentiation and an inherent tendency to metastasize via CSF pathways.

It is accepted that medulloblastomas are defined according to four subgroups based on a combination of histopathology and molecular biology.

The WNT subgroup is associated with a very good prognosis with long-term survival in excess of 90%. The majority of WNT subgroup MBs have classic histology, and a particular feature is that these tumors demonstrate beta-catenin nucleopositivity, *CTNNB1* gene mutations, and monosomy-6. Rarely, the WNT subgroup may include large-cell/anaplastic cases. WNT MB can arise at all ages but is infrequent in infants. Although overall MB is more common in males, the male to female (M:F) ratio for the WNT subgroup is approximately 1:1. Germline mutations of the WNT pathway inhibitor APC predispose to Turcot syndrome, which includes a predisposition to MB.

The SHH MB subgroups include *TP53* mutant and *TP53* wild-type subgroups. They are named after the sonic hedgehog signaling pathway, which is considered to drive tumor initiation in the majority of cases. The age incidence of SHH subgroups of MB is bimodal and is frequent in both infants aged <3 years and adults. The M:F ratio is approximately 1:1. The majority of nodular/desmoplastic MBs are included within the SHH subgroup. However,

around 50% of SHH subgroup MB have other histologic subtypes, including classical and large-cell/anaplastic varieties. The prognosis for SHH appears to be similar to group 4 (see below) and intermediate between WNT and group 3. Individuals with germ-line mutations of the SHH receptor PTCH have Gorlin syndrome, which for several decades has been recognized as carrying a predisposition to the development of MB. Preliminary clinical trials are being designed to target the SHH pathway to improve outcome for this subgroup.

Group 3 MB represents the subgroup of MB with the poorest prognosis. The majority of MBs in group 3 are classical MB and include the majority of large cell/anaplastic tumors. They are more frequent in males than females. They arise in infants and older children, but only rarely in adults and frequently present with metastases. Group 3 MB is typically characterized by high-level amplification of the *MYC* proto-oncogene, and almost all cases exhibit aberrant *MYC* expression.

Patients with group 4 MB have an intermediate to good prognosis similar to patients with SHH tumors. They include classical and large cell/anaplastic histologies and account for approximately 30% to 40% of cases. This subgroup represents the archetypal MB, exemplified by a 7-year-old boy with a classical histology MB who has an isochromosome 17q. The M:F ratio is approximately 3:1. The molecular pathogenesis of group 4 MB is not currently clear.

Improvements in the understanding of the molecular mechanisms of MB tumorigenesis are emerging as important factors in clinical trial design leading to a tailored approach for different histologic and molecular biologic subtypes. Collaborative clinical trial groups are developing studies that will investigate prospectively the stratification of therapy according to pathologic, biologic, as well as the more traditional clinical parameters. In particular, clinical studies are beginning to involve a cautious lowering of the treatment intensity for patients with WNT MB and maintaining intensity for those in group 3. This approach requires a timely and well-coordinated approach to tumor sample collection and analysis of biologic parameters prior to treatment decisions.[184]

In most cases of MB, the tumor arises in the cerebellar vermis and projects into the fourth ventricle. Patients typically present with symptoms and signs of raised intracranial pressure (i.e., headache and morning vomiting). On MRI, medulloblastomas appear as solid masses that enhance usually fairly homogeneously with contrast material (Fig. 88.12). The frequency of leptomeningeal seeding at diagnosis is approximately 30% to 35%, and investigation at diagnosis must include a gadolinium-enhanced MRI of the spinal

axis and CSF cytology. The former should be obtained whenever possible preoperatively or else at least 2 weeks postoperatively because of the artifactual changes that may be seen in the early postoperative period. CSF cytology, which should be obtained by lumbar puncture, usually cannot be obtained safely preoperatively because of the presence of raised intracranial pressure and more commonly is obtained at least 2 weeks postoperatively to avoid false positives that may be seen in the early postoperative period. Medulloblastoma is one of the few CNS tumors to spread outside the CNS (to lymph nodes, bone), but this is a very uncommon event at diagnosis, and other studies such as a bone scan or bone marrow aspiration or biopsy are not justified as a routine.

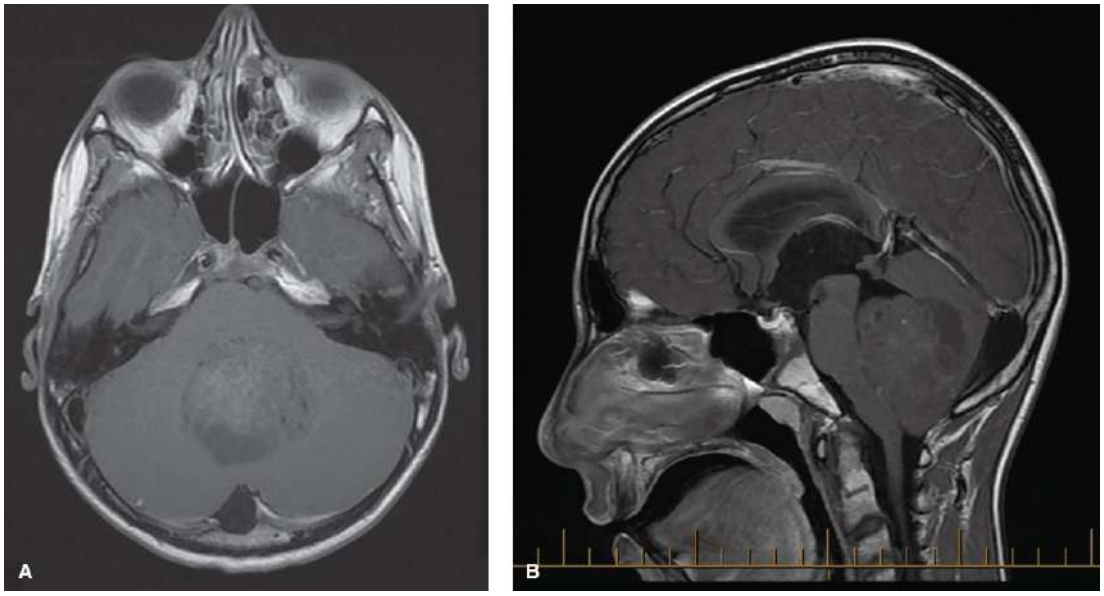

FIGURE 88.12. T1 axial **(A)** and T1 gadolinium-enhanced sagittal **(B)** magnetic resonance images of a medulloblastoma in an 11-year-old boy. Note the typical midline location of the tumor that is causing ventricular outlet obstruction with dilatation of the third and lateral ventricles.

In addition to molecular biologic parameters, conventional factors that correlate with outcome include age at diagnosis, the presence or absence of leptomeningeal spread at diagnosis, and the completeness of the surgical resection. Patients are allocated to one of two overall risk categories: standard and high risk. Those who have undergone complete or subtotal resection with $<1.5\ cm^2$ of residual tumor on postoperative MRI performed within 48 to 72 hours of surgery, and no evidence of CSF dissemination (M0) are considered to have standard-risk disease, whereas patients who have larger-volume residual tumor and those with evidence of CSF dissemination at diagnosis are

characterized as high risk. With contemporary neurosurgical techniques, complete or near-total resection is accomplished in approximately 80% of cases. Overall, approximately two-thirds of patients will be standard risk and one-third will be high risk.

Management of Standard-Risk Medulloblastoma

Until the 1990s, the standard of care for patients older than 3 years with standard-risk disease consisted of postoperative radiotherapy to the craniospinal axis to a dose of 35 to 36 Gy followed by a boost to the whole posterior fossa to a total dose of 54 to 55.8 Gy. In multi-institution studies, such treatment results in long-term event-free survival in 60% to 65% of patients.[10,185,186] Sequelae of treatment include hormonal deficits, decreased bone growth, and neurocognitive deficits that correlate with the age of the child and the radiation dose.[7]

Several treatment strategies designed to reduce the morbidity associated with the use of radiotherapy have been tested. An attempt by the French Cooperative Group (SFOP) to reduce the radiotherapy target volume to avoid supratentorial radiation produced disastrous results,[187] and CSI remains the standard of care. The use of reduced-dose CSI (23.4 Gy) alone (without chemotherapy) in the North American intergroup study (CCG-923/POG#8631) resulted in a significantly increased risk of isolated neuraxis failure and an event-free survival at 5 and 8 years of only 52%.[186] HFRT may be a more promising strategy. In an SFOP pilot study that tested HFRT to a CSI dose of 36 Gy without chemotherapy, early toxicity was reduced and progression-free survival at 3 years was 81%.[188] The results of the European SIOP PNET-4 study in which patients were randomized to HFRT or conventional radiotherapy are pending.

An alternative strategy consists of reduced-dose CSI followed by a boost to the posterior fossa to a total dose of 55.8 Gy in combination with systemic chemotherapy. Progression-free survival was 79% at 5 years in a CCG pilot study that used CSI to a dose of 23.4 Gy in combination with weekly vincristine followed by adjuvant systemic chemotherapy consisting of vincristine 1.5 mg/m^2, CCNU 75 mg/m^2, and cisplatin 75 mg/m^2.[189] In the joint CCG/POG phase III randomized study (A9961) that followed, this regimen was compared to a regimen in which the CCNU was replaced by cyclophosphamide. Event-free survival at 4 years was approximately 85% in both arms,[190] and such an approach is now considered to be the standard of care for children with standard-risk medulloblastoma in North America. The recently presented COG ACNS 0331 trial evaluated the safety of an even lower dose of CSI (18 Gy) in children

aged 3 to 8 years and of a reduced-volume posterior fossa boost in children of all ages.

This compared a boost to the whole posterior fossa with a tumor/surgical bed plus margin boost. Preliminary results have recently been reported.[190a] There was no significant difference in EFS for patients treated with a tumor/surgical bed plus margin boost compared with those treated with a whole posterior fossa boost. However, patients treated with 18 Gy CSRT had a reduced 5-year EFS of 71.4% compared with 82.1% for those treated with 23.4 Gy. Currently, the standard of care for children with standard-risk MB is with CSRT 23.4 Gy with a boost to the tumor bed to a total dose of 54.0 Gy, followed by eight cycles of chemotherapy with vincristine, CCNU, and cisplatin.

In the latest generation of trials in medulloblastoma such as the recently opened European PNET-trial, risk stratification is based on biologic parameters in addition to clinical and pathologic features. Patients with anaplastic large-cell histology are no longer included in the standard-risk group given their poorer outcome. Furthermore, evidence suggests that WNT medulloblastoma with β-catenin nucleopositivity is associated with a better prognosis and MYC gene amplification with a worse one, opening up the possibility of reduced-intensity radiotherapy and chemotherapy for patients with WNT medulloblastoma and the evaluation of additional treatment intensity for patients with less favorable prognosis.[191]

Management of High-Risk Medulloblastoma

Patients with residual disease >1.5 cm^2 and/or those with leptomeningeal seeding are considered to have high-risk disease. This is the group of patients in which the use of chemotherapy was shown in the prospective randomized phase III studies conducted in the 1970s to result in significant improvement in disease-free survival. Research since then has largely focused on the chemotherapy regimens, including changes in scheduling in relation to radiotherapy and in doses and routes of delivery of chemotherapy. Some have used higher-dose CSI or altered radiotherapy fractionation schedules. An overview of studies performed by the North American and European cooperative groups up until the early 2000s is given in Freeman et al.[192]

It is important to note that the definition of risk factors has evolved considerably over the past two decades, making comparison of published data quite problematic. Better postoperative imaging and more complete staging as well as identification of unfavorable pathologic features (e.g., large cell and

anaplastic histology) have led to transfer of patients from the standard-risk to the high-risk category, which may partly explain the improving results for both standard-risk and high-risk disease. The category of high-risk disease is heterogeneous and includes more favorable subsets such as patients with postoperative residual disease without leptomeningeal spread, and even those with M1 (cytology-positive) disease, for whom it may be appropriate to consider a treatment approach different from that for patients with M2/3 disease with nodular seeding. For example, for patients with residual disease, M0, it would be logical to consider using a boost to residual disease in the posterior fossa to a dose higher than the standard 55.8 Gy. Management of patients with M1 disease remains controversial, but the weight of evidence suggests that they should be treated similarly to those with M2/3 disease.[193] Results for patients with M2/3 disease remain quite poor, although an impressive 81% 4-year overall survival was reported for patients treated on a COG pilot study using carboplatin daily during radiotherapy as a radiosensitizer. This forms the backbone of the current COG study for high-risk medulloblastoma, whereas the standard of care in many centers in Europe is now a hyperfractionated accelerated radiotherapy (HART) regimen given in combination with pre- and postradiotherapy chemotherapy.[194]

Management of Medulloblastoma in Infants

Medulloblastoma accounts for 20% to 40% of all CNS tumors in infants. Although up to half of infants have more favorable histologic types (desmoplastic/nodular or medulloblastoma with extensive nodularity), the prognosis overall is worse than in older children. The explanation for this is likely multifactorial. In addition to biology, the rate of complete resection is lower in this age group, and the frequency of leptomeningeal seeding at diagnosis is higher (as much as 50%), but also, many patients do not receive optimal treatment.[195] Because of the significant risks with respect to neurocognitive function associated with the use of radiotherapy in infants and very young children, chemotherapy has been used in an attempt to either delay or avoid radiotherapy altogether. Infants with M0 disease who have undergone total resection may do well with chemotherapy alone, with a 5-year overall survival of 69% in the first POG infant study[196] and of 93% in the German study,[197] although it is noteworthy that treatment in the latter included intraventricular methotrexate for which there are also concerns about the risk of neurocognitive sequelae. In other studies results were less satisfactory, in some because of the need for aggressive salvage regimens that were associated with

significant long-term sequelae.[198] In fact, with the possible exception of very young children with desmoplastic/nodular medulloblastoma without residual disease, evidence suggests that radiotherapy is an important component of treatment,[64] and because recurrences are generally early (6 to 12 months) and local,[64,196,199] the recently completed North American study used early radiotherapy to a limited treatment volume consisting of the tumor bed plus an anatomically confined margin for the CTV of 1 cm for patients without leptomeningeal seeding. Infants with M2/3 disease generally are treated with intensive chemotherapy regimens. Although patients with desmoplastic/nodular histology may do quite well, with an overall survival at 5 years of 52.9% in the UKCCSG/SIOP baby study, for example,[65] the prognosis for those with other subtypes is much less satisfactory. Despite this, the goal of treatment generally will still be to avoid radiotherapy (especially CSI) and the decision to use it highly individualized based on the clinical situation and the wishes of the parents.

Radiotherapy for Medulloblastoma

CSI is the standard of care, and careful attention to coverage of the entire target volume that includes the meninges overlying the brain and spine including extensions along nerve roots is critical. In the SFOP M-7 protocol, 50% of relapses could be correlated with targeting deviations. In the subsequent studies (MSFOP-93 and MSFOP-98), the relapse rate was 17% in patients who had inadequate coverage of only one part of the CTV (a typical example being the cribriform plate), 28% for patients who had inadequate coverage at two sites, and 67% for patients who had inadequate coverage at three or more sites.[200,201] In an SFOP pilot study that tested reduced-dose CSI for standard-risk disease, overall survival at 5 years was significantly worse for patients with inadequate coverage at two or more sites as compared with no or only one major deviation (54.4% vs. 79.3%).[202]

CSI is followed by a boost to the tumor bed or posterior fossa. Previously, the entire posterior fossa had been treated to a total dose of 54 to 55.8 Gy. Using conformal treatment techniques, it is possible to reduce the dose to the cochlea, which is important in children who will also be receiving cisplatin-based chemotherapy. Better sparing of the cochlea,[203] pituitary and hypothalamus, and the temporal lobes can be achieved using a reduced target volume for the boost (Fig. 88.13). Fukunaga-Johnson et al.[204] found a low risk of isolated failure outside the tumor bed in the posterior fossa in a cohort of 114 patients, and data

from several other centers as well as an SFOP pilot study that used a conformal boost limited to the tumor bed similarly support such an approach.[188,205–208] The optimal CTV for a reduced-volume posterior fossa boost remains to be defined, although an anatomically confined expansion of 1.5 cm around the GTV (any macroscopic residual tumor and the surgical bed) until recently has been regarded as reasonable and this was the margin employed in the COG ACNS 0331 trial.

Based on outcomes from this trial, the standard of care for the boost is tumor bed irradiation.

Delay to radiotherapy may be associated with poorer outcomes, and CSI should ideally start within 28 to 40 days following surgical resection. There is also evidence that it is important to deliver radiotherapy in a timely fashion, avoiding unnecessary gaps in treatment resulting from machine servicing, holidays, and the like. In the SIOP PNET-3 study event-free and overall survival were significantly worse when the duration of treatment exceeded 50 days as compared with the results for children treated as planned over 45 to 47 days.[209] When CSI has to be interrupted, for example, because of hematologic toxicity, treatment should continue to the posterior fossa boost volume while waiting for the blood counts to recover. Granulocyte colony-stimulating factor may be used to hasten recovery of the counts.

Supratentorial Primitive Neuroectodermal Tumor

Recent molecular analysis of case series has established that the group of tumors previously referred to as supratentorial primitive neuroectodermal tumor (stPNET) are now more correctly allocated to various different histologic groups, including other embryonal tumors such as ATRT (see below) or sometimes those of astrocytic lineage. This has led to confusion over how best to manage these patients.

Traditionally, the conventional usual approach for a child older than 3 with a stPNET without leptomeningeal spread consisted of maximal surgical resection followed by postoperative radiotherapy (CSI followed by a boost) and chemotherapy. Experimental regimens such as high dose chemotherapy with stem cell rescue are used in infants and young children and in patients with M+ disease. In view of current knowledge, patients who would previously have been diagnosed as having stPNET require multidisciplinary discussion including detailed expert review of pathology to determine optimum management of the individual case.

Atypical Teratoid/Rhabdoid Tumor

Atypical teratoid/rhabdoid tumor (ATRT) is a highly malignant embryonal tumor seen in very young children with a peak incidence in the birth to 2-year age group, at which age in one population-based study ATRT was as common as PNET and medulloblastoma.[210] Composed of rhabdoid cells with or without fields resembling a classical PNET, ATRT is diagnosed on the basis of the characteristic molecular findings, namely, deletion and/or mutation of the INI1 locus on chromosome 22. ATRT can arise at any location within the CNS, including the spine. Leptomeningeal seeding is seen at diagnosis in a quarter to a third of patients.

Since recognition of ATRT as a separate entity with a high frequency of early relapse and a very poor prognosis, patients have been treated with increasingly intensive chemotherapy regimens. Radiotherapy appears to be an important component of treatment.[211–217] In a series of 37 patients treated at St. Jude, early use of radiotherapy and the use of CSI were found to be associated with improved outcomes,[215] and it has been suggested that the worse survival reported for children younger than age 3 may be due in part to the less frequent use of radiotherapy and, when used, to the use of local radiotherapy rather than CSI in this age group. However, in a recent update limited to patients who received age- and risk-stratified radiotherapy, delay to radiotherapy was found to be the important factor.[218] In the current COG study, the treatment plan calls for early radiotherapy (after completion of two cycles of induction chemotherapy), although in practice, the use and timing of radiotherapy depend on the age of the child, the location (infra- or supratentorial), and the extent of disease at diagnosis (M0 or M+). Thus, children younger than 6 months at completion of chemotherapy with an infratentorial tumor and those younger than 12 months with a supratentorial tumor receive radiotherapy later, upon completion of both induction and consolidation chemotherapy. The radiotherapy target volume is local (tumor bed and any macroscopic residual disease plus a margin for the CTV of 1 cm) for children with localized disease and CSI followed by a boost for those with leptomeningeal spread. Doses are age dependent for both local radiotherapy and CSI (50.4 vs. 54 Gy and 23.4 vs. 36 Gy for children younger and older than 3 years, respectively). In Europe, patients with nonmetastatic ATRT receive doxorubicin-based chemotherapy and local radiotherapy to a dose of 54 Gy, whereas those with metastatic disease receive CSI. An ATRT registry (EURHAB) has been established to collect multi-institutional and multinational data on patient management and outcome.

Axial images of an intensity-modulated radiation therapy/image-guide radiation therapy plan for a whole posterior fossa **(A)** and a reduced-volume posterior fossa boost **(B)** for a patient with medulloblastoma. **C:** Dose–volume histograms show significant sparing of organs at risk with the reduced-volume boost.

Embryonal Tumors with Multilayer Rosette

In 2000, Eberhart et al.[218a] described a variant of StPNET, the embryonal tumor with abundant neuropil and true rosettes (ETANTR) as a tumor exhibiting prominent ependymoblastic rosettes, neuronal differentiation, and a neuropil background. This tumor was predominantly recognized in young children and was associated with a very poor prognosis. More recently, in 2014, it has been

recognized that there is a group of tumors that are distinct from other embryonal tumors and are referred to as embryonal tumors with multilayer rosettes (ETMRs). ETMR is now recognized as containing the three histologic variants ETANTR, ependymoblastoma, and medulloepithelioma.[219] These newly recognized tumors are yet to have a universally accepted mode of management.

GERM CELL TUMORS

Germ cell tumors of the CNS constitute a group of rare tumors that are morphologic homologs of germinal neoplasms arising in the gonads and at other extragonadal sites. They include the following entities although in many cases more than one tumor type is present:

- Germinoma
- Embryonal carcinoma
- Yolk-sac tumor (endodermal sinus tumor)
- Choriocarcinoma
- Teratoma
  - Mature
  - Immature
  - Teratoma with malignant transformation
- Mixed germ cell tumor

A teratoma is a tumor composed of an admixture of different tissue types representative of ectoderm, endoderm, and mesoderm. A mature teratoma is composed exclusively of fully differentiated tissues, sometimes arranged in such a manner as to resemble normal tissue relationships. Mitoses are absent or rare. An immature teratoma is composed of incompletely differentiated tissues resembling those of the fetus. Mitoses typically are present.

In the West, CNS germ cell tumors are relatively rare, accounting for 3% to 5% of all CNS tumors in the pediatric age group. They are more common in Asia, where they account for as many as 15% to 18% of all CNS tumors occurring in childhood. The peak age incidence is 10 to 12 years. Boys are affected more frequently than girls, with a ratio of approximately 3:1. CNS germ cell tumors arise from primordial germ cells in structures about the third ventricle, with the region of the pineal gland being the most common site of origin followed by the suprasellar region. Nongerminomatous germ cell tumors (NGGCTs) are the most common tumor type in the former area and germinomas in the latter.

The presenting symptoms and signs depend on the tumor type and the location of the tumor. Tumors in the pineal region cause obstruction to CSF flow at the aqueduct of Sylvius resulting in hydrocephalus, and most patients with tumors in this region present with a relatively short history with symptoms and signs of raised intracranial pressure. Another characteristic presentation of tumors in this region is Parinaud syndrome as a result of dorsal midbrain compression. In contrast, patients with tumors in the suprasellar region usually present with a longer history initially of neuroendocrine deficits, especially diabetes insipidus, growth failure, and precocious puberty, and only later of visual field deficits and, later still, of symptoms and signs of raised intracranial pressure. On imaging, most germ cell tumors appear as solid masses. Teratomas are more heterogeneous with cysts, areas of calcification, and sometimes fat, whereas choriocarcinomas often contain areas of hemorrhage. Bi- or multifocal disease around the third ventricle is seen in approximately 10% of patients with germinomas. Gadolinium-enhanced MRI of the spinal axis is an essential part of the workup to exclude leptomeningeal dissemination, which is found at diagnosis in approximately 10% of patients with germinomas and 10% to 15% of patients with NGGCTs. Measurement of serum and CSF tumor markers is another essential part of the initial workup. Modest elevation of β-human chorionic gonadotropin (β-hCG) (<100 IU/mL) may be seen with pure germinomas that may contain syncytiotrophoblastic cells. Higher levels of β-hCG are more suggestive of a choriocarcinoma. An elevated α-fetoprotein (α-FP) is diagnostic of a yolk-sac tumor.

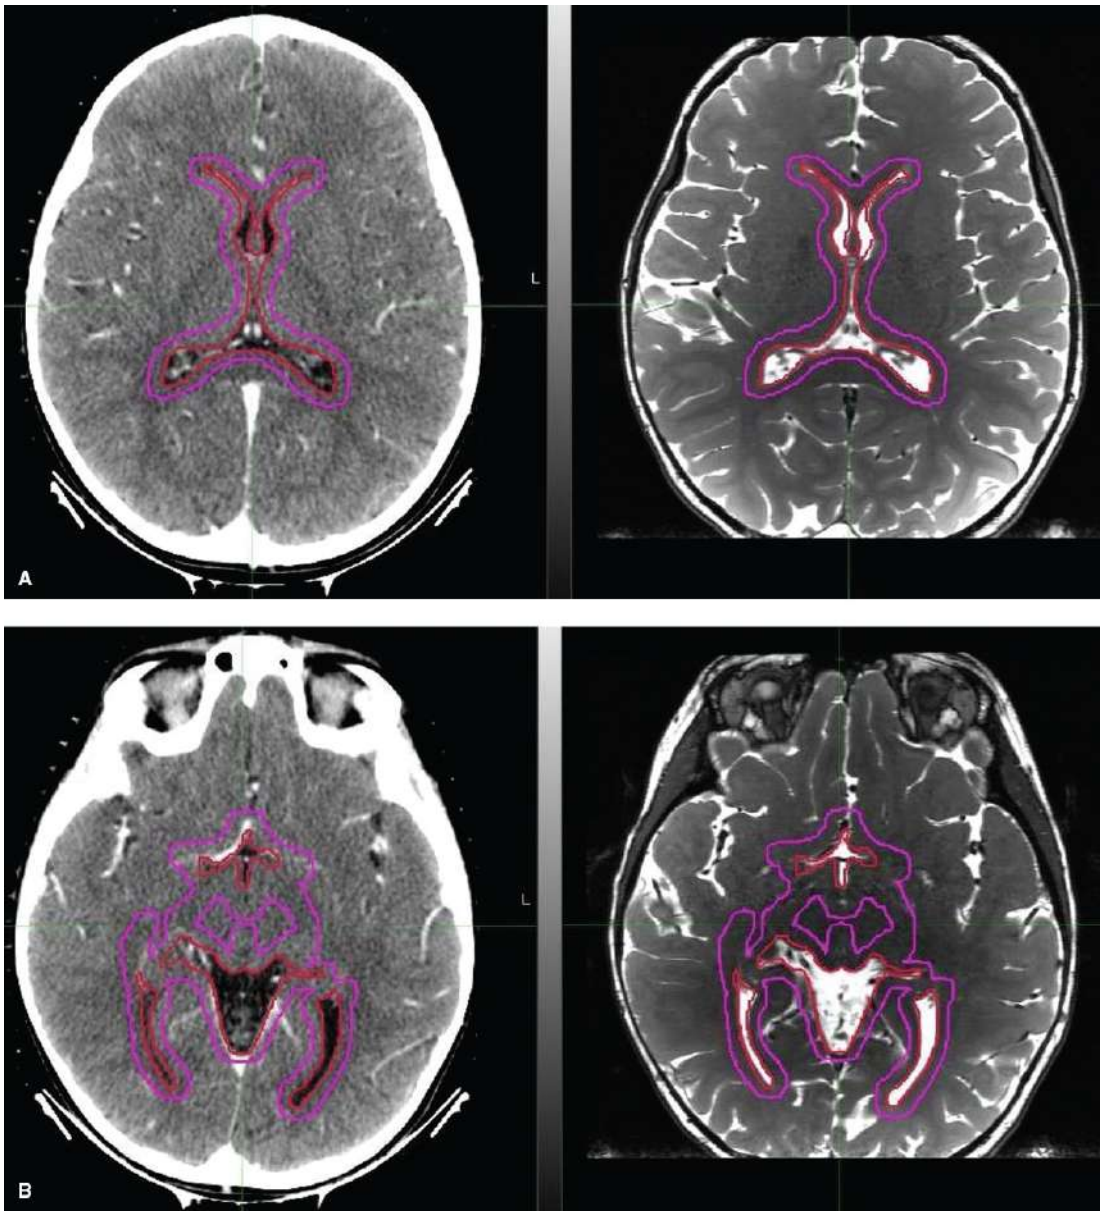
In the past, many lesions arising in or about the third ventricle were treated without histologic confirmation of diagnosis. This is no longer considered acceptable practice because the differential diagnosis includes many disparate entities (such as Langerhans cell histiocytosis, astrocytoma, and ependymoma), and all patients should undergo biopsy unless CSF and/or serum markers confirm the presence of an NGGCT (elevated α-FP and/or β-hCG > 100 IU/mL) or unless a histologic diagnosis is made by other means (e.g., CSF cytology). For tumors in the pineal region with hydrocephalus, the usual surgical approach is an endoscopic third ventriculostomy, which allows access to the lesion for biopsy purposes. Intraventricular lesions have to be biopsied with care because hemorrhage, which is not infrequent, may be difficult to manage endoscopically. A stereotactic approach is also possible, but this may be quite challenging because of the proximity of deep cerebral veins and, moreover, may be suboptimal for diagnosis because of the potential for sampling error.

Occasionally, complete resection will be possible; this would be a reasonable strategy for patients with NGGCTs if it can be accomplished without major morbidity because it would ensure complete characterization of the pathology and may even obviate the need for further therapy.

Germinoma

In the past, standard treatment for patients with germinoma, whether localized or disseminated, was radiotherapy alone. Results of treatment using CSI followed by a boost to the primary site are excellent, with long-term disease-free survival rates of 100% in some series.[220–224] For patients with unifocal disease without leptomeningeal spread, radiotherapy alone to limited volumes, that is, whole brain[225,226] or whole ventricle,[220,222,227] results in a high probability of local control and a low (0% to 5%) risk of failure in the spinal axis. Experience with local radiotherapy (tumor plus a margin) alone generally has been less satisfactory,[225–229] although some have reported excellent results.[230] To reduce the risk of morbidity associated with radiotherapy, chemotherapy has been considered another option, either alone or in combination with reduced-volume and/or reduced-dose radiotherapy. Several studies have shown clearly that the former, that is, the use of chemotherapy alone, is not acceptable: only 40% to 50% of patients remain disease free, and although salvage using further chemotherapy together with radiotherapy is possible in most cases and overall survival is high, this is achieved at the cost of considerable toxicity.[231–234]

In contrast, a combined approach using platinum-based chemotherapy followed by reduced-volume, reduced-dose radiotherapy is an attractive option that results in disease-free survival rates in the 90% to 96% range.[232,235–237] The optimal radiotherapy target volume using such an approach remains to be defined. Local failures were seen in 10 of 60 patients treated in the SFOP TGM-TC-90 study with chemotherapy followed by local radiotherapy[238] and with even greater frequency in some single-institution studies, which, although with a patient population with a median age in adolescence, included adult patients.[229,239] Local failure appears to be less frequent after whole ventricular radiotherapy[239] and this is becoming generally accepted as the appropriate volume in this context (Fig. 88.14), but prospective data are lacking for now.



A
B

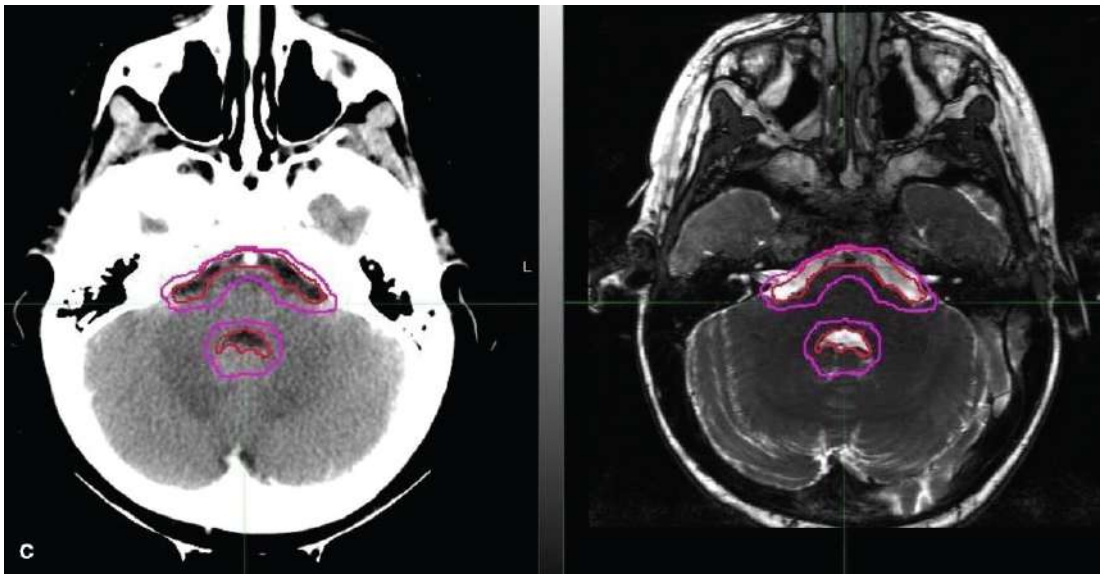


FIGURE 88.14. Target volume definition for whole ventricular irradiation as per the guidelines for the current Children's Oncology Group study for central nervous system germ cell tumors. Planning computed tomography and T2-weighted magnetic resonance images at the level of lateral ventricles **(A)**, hypothalamus and pineal cistern **(B)**, and fourth ventricle and prepontine cistern **(C)**. Note that this volume needs to be expanded to include the primary tumor and any other sites of involvement. Whether the suprasellar, basal, and prepontine cisterns need to be included is controversial for now. Better sparing of nontarget tissues will be achieved with the use of a four-field technique or intensity-modulated radiation therapy than with lateral opposed fields. (Courtesy of Dr. Shannon MacDonald.)

For patients with leptomeningeal spread at diagnosis, radiotherapy alone using CSI with boosts to macroscopic disease is certainly an option, although in North America and Europe, chemotherapy followed by CSI followed by a boost to all sites of involvement would now be the more usual approach. Management of patients with bi- or multifocal midline tumors is controversial. In the past, these patients were treated as having disseminated disease, but at least some, that is, those with bifocal disease by imaging or by inference (e.g., in a patient with a pineal region primary who has diabetes insipidus), are now more usually treated with chemotherapy and whole ventricular radiotherapy.

There is less controversy now with regard to the radiotherapy dose and dose-fractionation schedule for germinoma. Results are excellent with a CSI dose as low as 21 Gy even in patients with leptomeningeal spread. The total dose to the primary site has typically been 40 to 45 Gy but probably can be safely reduced to 30 Gy or even to 24 Gy[232,237] in patients treated with a combined chemotherapy–radiotherapy regimen who have had a complete response to chemotherapy. Finally, because germinoma is a very radiosensitive tumor, a

fraction size of 1.5 Gy can be used, which, in theory, further reduces the risk of injury to normal structures.

Nongerminomatous Germ Cell Tumors

For NGGCTs, the diagnosis can be made in as many as one-third of all patients on the basis of imaging findings (location and appearance) plus tumor markers. NGGCTs are of several different histopathologic types that carry different prognoses (Table 88.3). Patients with mature teratomas without any associated malignant elements can be managed with surgery alone, whereas those with mature teratoma with germinomatous elements will be treated as germinomas. All other patients with intermediate- and poor-prognosis tumor types[240] require more aggressive treatment. The results of treatment using radiotherapy alone are very poor, with overall survival in the 10% to 30% range. Results are better with chemotherapy alone, although 40% to 60% of patients relapse following chemotherapy and will be subjected to aggressive salvage regimens.[231,241,242] A multimodality approach that includes both chemotherapy and radiotherapy appears to be associated with the best outcome. Event-free survival was 81% in the German/Italian pilot study that led to the most recent SIOP CNS GCT study.[243] The current standard of care therefore consists of platinum-based chemotherapy followed by radiotherapy.

TABLE 88.3 CLASSIFICATION OF NONGERMINOMATOUS GERM CELL TUMORS

Good Prognosis
Mature teratoma
Intermediate Prognosis
Immature teratoma
Mixed germ cell tumors consisting of germinoma with either mature or immature teratoma
Poor Prognosis
Teratoma with malignant transformation
Embryonal carcinoma
Yolk sac tumor
Choriocarcinoma
Mixed germ cell tumors including a component of embryonal carcinoma, yolk sac tumor, choriocarcinoma, or teratoma with malignant transformation

Adapted from Sawamura Y, Ikeda J, Shirato H, et al. Germ cell tumours of the central nervous system: treatment consideration based on 111 cases and their long-term clinical outcomes. *Eur J Cancer* 1998;34(1):104–110. Copyright © 1997 Elsevier. With permission.

There is controversy with respect to the radiotherapy target volume for NGGCT. Although good results have been reported by some groups using chemotherapy followed by local radiotherapy,[179] others show a high rate of failure outside the primary site.[242,244–248] Thus, as for germinoma, a whole-ventricle volume may be a better option for more favorable patients (e.g., the intermediate-risk group, α-FP < 1,000 ng/mL), whereas CSI would be used for those with less favorable or disseminated disease. The usual dose to the whole ventricle volume or CSI is 30 to 36 Gy and to the primary site, 54 Gy.

Patients who have less than a complete response to chemotherapy fare poorly. Second-look surgery may be useful to both exclude the possibility that the residual imaging abnormality represents mature teratoma and/or resect residual viable tumor. This would be followed by CSI and more intensive chemotherapy such as high dose chemotherapy with stem cell rescue.

TUMORS OF THE SELLAR REGION

Tumors arising in the sellar region in children include the following:

- Craniopharyngioma
  - Adamantinomatous
  - Papillary
- Pituitary adenomas

Craniopharyngioma

By definition, craniopharyngiomas are benign partly cystic epithelial tumors that arise in the sellar region from remnants of Rathke pouch. In children, almost all are of the adamantinomatous type. They account for approximately 5% of intracranial tumors in the pediatric age group with a peak incidence between the ages of 5 and 14 years.

In the majority of patients, craniopharyngiomas have both suprasellar and intrasellar components. Children typically present with neuroendocrine deficits, especially diabetes insipidus and growth failure. Visual field deficits often go unnoticed initially. Cognitive and behavioral changes are not uncommon. Compression of or tumor growth within the third ventricle may lead to hydrocephalus and symptoms and signs of raised intracranial pressure. On neuroimaging, the findings are very typical, with solid and cystic areas in varying proportions. Calcification is seen in the majority of cases. The solid portion(s) and the cyst capsule usually enhance with the use of contrast material.

Treatment of craniopharyngiomas, although long considered a controversial issue,[249] in practice depends on the characteristics of the tumor and the availability of the surgical expertise required. The argument for surgical resection is based on single-institution (mostly specialist center) reports of long-term tumor control after complete resection as confirmed on postoperative imaging in 85% to 100% of patients.[250] However, in a three-nation prospective study event-free survival at 3 years was only 64%.[251] Moreover, although visual deficits, if present, improve after surgery in the majority of cases, new neuroendocrine deficits are very common and hypothalamic damage is a major concern particularly in patients with tumors that have grown retro-chiasmatically into the floor of the third ventricle.[252–254] Devastating sequelae that include rage, aggressivity, and hyperphagia permanently compromise the quality of life of the patient and his or her family. The transsphenoidal approach that has been used more frequently in recent years, even in younger children and even in patients with tumors with a supradiaphragmatic component, is associated with fewer complications. In general, therefore, tumors that are smaller and/or subdiaphragmatic in location and without hypothalamic involvement would be managed surgically. Patients who have residual tumor following surgery are at high risk for progressive disease within the first 2 to 3 years following surgery,[251,255–258] mandating close follow-up with MRI performed at 3-month intervals during that time period. Patients at greater risk for complications secondary to surgery would be managed with biopsy, cyst decompression, if necessary, and radiotherapy.[259–264]

FIGURE 88.15. A: Craniospinal radiotherapy for young adult with conventional photon radiotherapy—exit from spinal field delivers low to intermediate dose to structures anterior to spine. **B:** Craniospinal radiotherapy for young adult with proton therapy—no exit dose beyond Bragg peak avoiding dose to structures anterior to spine. (Figure courtesy of Dr. D. Indelicato, University of Florida, Jacksonville.)

Radiotherapy may, therefore, be given as the sole therapy after biopsy, after incomplete surgery, or at time of progression/recurrence after surgery, and the

heterogeneity of tumor types and situations means that one of several approaches may be used. For example, a lesion with a small solid component and a simple cyst may be well treated with intracavitary injection of liquid radioactive material. Most contemporary experience is with β emitters such as ^{32}P and ^{90}Y delivering a high dose (i.e., 200 Gy) to the cyst wall. Intracavitary injection of radioactive material is not always easy.[265] Sometimes, the cyst fluid is very thick in consistency and there may be little or no communication between multiple cysts. It is essential to use contrast material to ensure that the catheter is well placed in the cavity and that there is no leakage of material outside the cyst before injecting radioactive material. This could be combined with radiosurgery or fractionated stereotactic irradiation to the associated solid component, although it may be reasonable to do so only later and only if there is evidence of progressive disease. Special care is needed if, as is usually the case, the tumor is in close proximity to the optic chiasm or optic nerves.[266] Tumor control rates using this approach are good for carefully selected patients.[267] However, conventionally fractionated external beam radiotherapy may be a better option for all except very small tumors, with a lower risk of morbidity.[249,268]

The target volume for external beam radiotherapy consists of the entire lesion (i.e., both the solid and cystic components) as demonstrated on MRI performed just prior to treatment. Although some have used a margin for the CTV of 1 cm,[269] a smaller margin of 0.5 cm or even 0 cm (i.e., CTV = GTV) can be justified on the basis of excellent tumor control using such margins.[270–272] A dose of 54 to 55 Gy given in 30 daily fractions over 6 weeks appears to be necessary to achieve a high probability of tumor control. Cyst enlargement during treatment or within the first 2 to 3 months after completion of radiotherapy is not uncommon. Early recognition and appropriate management consisting usually of cyst decompression is essential to avoid further neurologic compromise or even death.[273] The long-term prognosis is good, with event-free survival of 80% to 100% in most series.[251,269,272,274,275]

There is increasing interest in the use of proton therapy to reduce nontarget dose, which would be predicted to minimize late neurocognitive effects (Fig. 88.15).

Pituitary Adenomas

Pituitary adenomas are rare in childhood. Almost all cases arise in adolescence. Most are functioning adenomas that present with endocrine dysfunction, most often menstrual irregularities and galactorrhea in girls and delayed puberty in

boys. They may be quite large, with extrasellar extension, and appear to be more invasive than those seen in adults.[276–278] Visual loss, when present, may be more severe and more likely to be associated with optic atrophy.[277]

Management will, in general, parallel that for adult patients. Prolactin- and growth hormone–secreting adenomas are managed medically as in adults. When surgery is necessary, a transsphenoidal approach using neuronavigation appears to be feasible and safe in children, even in those with poor pneumatization of the sphenoid sinus.[276,278] Radiotherapy is indicated if surgical resection is not possible or if hormone levels remain elevated following surgery. Highly conformal treatment with a margin for the CTV of 0.5 cm beyond macroscopic disease is appropriate in most cases, the technique used being that which optimally spares adjacent critical structures including major vessels. The usual dose, as in adults, will be 45 Gy over 5 weeks. Close follow-up by an endocrinologist is essential to ensure appropriate management of hormone deficits.

CHAPTER 89

Wilms Tumor

John A. Kalapurakal

INTRODUCTION

Wilms tumor (WT, nephroblastoma) is a highly curable childhood neoplasm. The prognosis of children with WT has improved considerably from a very high mortality rate at the beginning of the 20th century to the current cure rate of >90%.[1] The management of WT is a paradigm for successful interdisciplinary treatment of solid tumors of childhood to maximize cure rates and minimize treatment-related complications.

EPIDEMIOLOGY

WT is the most common malignant renal tumor of childhood. It occurs with an annual incidence of 7 cases per million children <15 years of age. Approximately 500 new cases are diagnosed each year in North America. The peak incidence is between 3 and 4 years of age. WT may arise as sporadic or hereditary tumors or in the setting of specific genetic disorders.[2] Most WTs are solitary lesions, multifocal within a single kidney in 12% and bilateral in 7%.[3] The clinical syndromes associated with WT include WAGR syndrome (*WT*, *A*niridia, *G*enitourinary malformations, mental *R*etardation), Denys-Drash syndrome (pseudohermaphroditism, mesangial sclerosis, renal failure, and WT), and overgrowth syndromes like Beckwith-Wiedemann syndrome (somatic gigantism, omphalocele, macroglossia, genitourinary abnormalities, ear creases, hypoglycemia, hemihypertrophy, and a predisposition to WT and other malignancies) and Simpson-Golabi-Behmel syndrome.[4,5]

BIOLOGY

Among the various genetic changes implicated in the development of WT, the most widely studied involves *WT1*, which is a tumor suppressor gene at

chromosome 11p13 that was isolated from a child with WAGR syndrome.[6] *WT1* is likely to play a specific role in glomerular and gonadal development.[7] *WT1* can also act as a dominant negative oncogene resulting in abnormal cell growth such as in Denys-Drash syndrome.[8] Germ-line *WT1* mutations are observed in approximately 82% of WT patients who have genitourinary anomalies or renal failure. The frequency of *WT1* mutations in sporadic and familial WT is much lower at approximately 20% and approximately 4%, respectively.[9] Beckwith-Wiedemann syndrome maps to chromosome 11p15.5; this locus is also referred to as *WT2*.[10]

Patients with loss of heterozygosity (LOH) at 16q and 1p have higher relapse and mortality rates.[11] The National Wilms Tumor Study-5 (NWTS-5) prospectively evaluated the prognostic significance of LOH on 16q and 1p. When the effects of LOH for both 1p and 16q were considered jointly, the RR for relapse in stage I and II FH diseases was 2.9 (P = .001) and for stage III and IV FH diseases was 2.4 (P = .01). The RR for death for patients with stage I and II FH diseases with LOH for both regions was 4.3 (P = .01) and for stages III and IV was 2.7 (P = .04). Based on these results, it was proposed that in future WT trials, the therapy for children with LOH at both 1p and 16q be augmented by the addition of doxorubicin to regimen EE4A (discussed below) for early-stage (stages I and II) tumors and cyclophosphamide/etoposide to regimen DD4A (discussed below) for advanced-stage tumors (stages III and IV).[12]

A novel WT suppressor gene on the X chromosome, *WTX*, was recently discovered. This gene is inactivated in approximately one-third of sporadic WT cases.[13] Anaplastic tumors have shown changes on 17p consistent with *TP53* deletion and specific genomic loss or underexpression on 4q and 14q and focal gain of *MYCN*.[14] Rhabdoid tumors are characterized by the genetic loss of the *SMARCB1/hSNF5/INI-1* gene located at chromosome 22q11. Global gene expression studies have shown that loss of *SMARCB1* results in repression of neural crest development and loss of cyclin-dependent kinase inhibition.[15] In children with very low-risk WT treated with just surgery alone, the presence of *WT1* mutation and 11p15 loss has been prospectively validated to be an important predictor of relapse. These biomarkers may be used to stratify patients to receive reduced chemotherapy in the future.[16] Recent gene expression studies have shown that VLRWT is composed of at least two biologically distinct clusters of tumors. Cluster 1 is composed of epithelial differentiated tubular histology tumors without nephrogenic rests and lack of LOH for 1p, 16q, and 11p. These tumors have a unique gene expression profile consistent with renal

developmental arrest following mesenchymal to epithelial transition. None of these tumors relapsed. Cluster 2 is composed of mixed histology tumors with nephrogenic rests and a heterogenous gene expression pattern including down-regulation of WT1. WT1 mutation and 11p15LOH were significant predictors of relapse in VLRWTs. Prospective validation of these novel biomarkers will enable refinement of the current arbitrary definition of VLRWT based on age and tumor weight.[17,18]

Another recent COG study demonstrated that gain of 1q is a promising biomarker for patients with favorable histology WT. In a report of 1,114 patients on NWTS-5, 317 (28%) patients displayed 1q gain. The 8-year EFS with and without 1q gain was 77% and 90%, respectively ($P < .001$). The 8-year overall survival (OS) with and without 1q gain was 88% and 96%, respectively ($P < .001$). 1q gain was associated with a higher relative risk of relapse (2.4, $P < .001$).[19] Similar results were obtained by the SIOP WT2001 study after preoperative chemotherapy and nephrectomy. Among 586 patients, 28% had 1q gain. The 5-year EFS was 75% and 88% ($P < .001$), and OS was 88% and 94% ($P = 0.01$), with and without 1 q gain, respectively. Other molecular aberrations associated with poorer outcomes included *MYCN* gain and *TP53* loss.[20]

PATHOLOGIC CLASSIFICATION

Although histopathologists had attempted to relate appearance to prognosis, no generally acceptable classification was available until the report of Beckwith and Palmer[21] from the National Wilms Tumor Study-1 (NWTS-1). The NWTS classifies all tumors as having either FH or unfavorable histology (UH). The UH tumors include anaplastic tumors, clear cell sarcoma, and rhabdoid tumor of the kidney. Of 1,465 patients randomly assigned on NWTS-3, 163 (11.1%) had UH.[22] WTs are usually sharply demarcated, spherical masses with a “pushing” border and a surrounding distinct intrarenal pseudocapsule. Histologically, WT reflects the development of the normal kidney, consisting of three components, blastemal, epithelial (tubules), and stromal elements, in varying proportions.[21] The proportion of the different components has prognostic significance.[23] Nephrogenic rests consist of embryonal nephroblastic tissue and are found in 35% of kidneys with unilateral WT and in nearly 100% of kidneys with bilateral WT (BWT).[24] Nephrogenic rests may be intralobar or perilobar based on their location within the kidney.[25] Most nephrogenic rests undergo spontaneous regression and only a small proportion (1% to 5%) transform into WT.[26] The

histologic feature of greatest clinical significance in WT is anaplasia.[27] Anaplasia may be focal (FA) or diffuse (DA). The definitions of FA and DA have been revised to reflect the distribution of anaplastic cells in the tumor rather than their quantitative density. These revised definitions are of prognostic significance. The 4-year survival rates for patients with stage II, III, and IV FA were 90%, 100%, and 100%, compared with 55%, 45%, and 4%, respectively, for patients with similar stage DA WT.[28]

Clear cell sarcoma of the kidney (CCSK) and malignant rhabdoid tumor of kidney (RTK) are no longer considered true WT, but they have been included in NWTS protocols.[21] CCSK has a propensity to metastasize to bone, and a skeletal survey and bone scan should be performed. RTK is the most lethal renal neoplasm in children. Primitive neuroepithelial tumors of the cerebellum or pineal region may be seen in 10% to 15% of patients with RTK.[29]

CLINICAL PRESENTATION

The classic presentation for WT is that of a healthy child in whom abdominal swelling is discovered by the child's mother or by a physician during a routine physical examination. A smooth, firm, nontender mass on one side of the abdomen is felt. Gross hematuria occurs in as many as 25% of these cases.[30] The child may be hypertensive or have nonspecific symptoms such as malaise or fever.[31] Only rarely does a patient present with symptomatic metastases.

DIAGNOSTIC WORKUP

The differential diagnosis of WT includes other malignant childhood lesions of the kidney, neuroblastoma, and benign conditions such as hydronephrosis, polycystic disease, and splenomegaly in left-sided tumors. Plain films of the abdomen may demonstrate calcifications, which occur in 60% to 70% of neuroblastomas but in only 5% to 10% of WT. Excretory urography (intravenous pyelography) was once the mainstay of imaging in WT and now has largely been replaced by ultrasonography and computed tomography (CT) scanning. Ultrasonography is very useful because it is readily available and is cost-effective.[32] A specific advantage of ultrasonography is its ability to assess vessels for flow and tumor thrombus with duplex and color Doppler.[33] Routine use of Doppler sonography after abdominal CT scans was not found to be useful in detecting cavoatrial thrombus in a Children's Oncology Group (COG) study.[34]

Abdominal CT scans can demonstrate gross extrarenal spread, lymph node involvement, liver metastases, and the status of the opposite kidney (Fig. 89.1).[35] Magnetic resonance imaging (MRI) has several advantages over CT scans, especially in identifying renal origin and vascular extension of the tumor.[36] CT and MRI are useful in the detection and follow-up of patients with nephrogenic rests.[37] Clinical and imaging impressions do not, however, obviate the need for inspection at laparotomy.[38] Plain chest radiography and chest CT are also essential because asymptomatic pulmonary metastases are common.[39] A complete blood cell count and urinalysis should be performed. Patients with WT can be anemic from hematuria. Serum blood urea nitrogen and creatinine levels and liver function tests are routine. If neuroblastoma is not ruled out, a test for urinary catecholamines should be performed. Table 89.1 outlines the pretreatment investigations recommended by the COG.

FIGURE 89.1. Computed tomography scan of a 4-year-old girl with a large right-sided Wilms tumor measuring 10.5 × 8.4 × 13.5 cm. The left kidney did not show any lesions. At laparotomy, the tumor was found to invade the diaphragm. She underwent a right radical nephrectomy. Surgical margins of resection were positive and she had metastases in the para-aortic lymph nodes. The tumor was classified as stage III favorable histology and received 10.8 Gy to the right flank and chemotherapy with vincristine, dactinomycin, and doxorubicin.

NATURAL HISTORY

The disease is often localized at diagnosis, as evidenced by the fact that surgery and radiation therapy (RT) are curative in almost 50% of cases.[40] The first signs of local tumor spread beyond the pseudocapsule are invasion into the renal sinus or the intrarenal blood and lymphatic vessels. Spread throughout the peritoneal cavity may also occur, especially if there has been preoperative rupture or the disease has been spilled at surgery.[41,42] The most common sites of metastases of WT are in the lungs, lymph nodes, and liver. Among patients with stage IV disease, lungs were the only metastatic site in approximately 80% and 15% had liver metastases.[43] The NWTS-2 study demonstrated the prognostic importance of lymph node involvement. The 2-year relapse-free survival (RFS) with and without lymph node involvement was 54% and 82%, respectively.[41]

TABLE 89.1 PRETREATMENT WORKUP

History	Record preexisting conditions, family history of cancer, or congenital defects
Physical examination	Blood pressure, weight, height, presence of abdominal masses, congenital anomalies particularly genitourinary, hemihypertrophy, and aniridia
Laboratory	Hemoglobin, white cell, and differential counts, platelets, urinalysis, serum blood urea nitrogen, creatinine, protein, alanine, and aspartate aminotransferases, alkaline phosphatase, bilirubin
Radiology	CT or MRI scan of the abdomen and pelvis, abdominal ultrasonography, chest CT scan, chest x-ray Bone scan and MRI of the brain (CCSK, RTK, and renal cell carcinoma)

CT, computed tomography; CCSK, clear cell sarcoma of the kidney; MRI, magnetic resonance imaging; RTK, rhabdoid tumor of the kidney.

TABLE 89.2 CHILDREN'S ONCOLOGY GROUP STAGING OF WILMS TUMOR, RHABDOID TUMOR, AND CLEAR CELL SARCOMA OF THE KIDNEY

Stage I: Tumor limited to the kidney, completely resected. The renal capsule is intact. The tumor was not ruptured or biopsied prior to removal. The vessels of the renal sinus are not involved. There is no evidence of tumor at or beyond the margins of resection. *Note*: For a tumor to qualify for certain therapeutic protocols as stage I, regional lymph nodes must be examined microscopically

Stage II: The tumor is completely resected and there is no evidence of tumor at or beyond the margins of resection. The tumor extends beyond the kidney, as is evidenced by any one of the following criteria[a]:

- There is regional extension of the tumor (i.e., penetration of the renal capsule or extensive invasion of the soft tissue of the renal sinus)
- Blood vessels within the nephrectomy specimen outside the renal parenchyma, including those of the renal sinus, contain tumor

Stage III: Residual nonhematogenous tumor present following surgery and confined to the abdomen. Any one of the following may occur:

- Lymph nodes within the abdomen or pelvis are involved by tumor (lymph node involvement in the thorax or other extra-abdominal sites is a criterion for stage IV)
- The tumor has penetrated through the peritoneal surface
- Tumor implants are found on the peritoneal surface
- Gross or microscopic tumor remains postoperatively (e.g., tumor cells are found at the margin of surgical resection on microscopic examination)
- The tumor is not completely resectable because of local infiltration into vital structures
- Tumor spillage occurring either before or during surgery
- The tumor was biopsied (whether Tru-Cut, open, or fine needle aspiration) before removal
- Tumor is removed in more than one piece (e.g., tumor cells are found in a separately excised adrenal gland; a tumor thrombus within the renal vein is removed separately from the nephrectomy specimen)

Stage IV: Hematogenous metastases (i.e., lung, liver, bone, brain) or lymph node metastases outside the abdominal–pelvic region are present (the presence of tumor within the adrenal gland is not interpreted as metastasis and staging depend on all other staging parameters present)

Stage V: Bilateral renal involvement by tumor is present at diagnosis. An attempt should be made to stage each side according to the criteria here on the basis of the extent of disease

[a]Rupture or spillage confined to the flank, including biopsy of the tumor, is no longer included in stage II and is now included in stage III.

STAGING

Tumor staging is performed after examining the radiologic, operative, and histopathologic findings.[42,43] In NWTS-1 and NWTS-2, a tumor grouping system was used for staging and treatment stratification. After analyzing the prognostic significance of several clinical–pathologic factors in NWTS-1 and NWTS-2, a new staging system was adopted in NWTS-3. The presence of lymph node involvement was upstaged to stage III instead of group II, and local tumor spill was downstaged from group III to stage II.[42] In NWTS-5, the most significant change was the distinction between stages I and II. The criteria for stage I were revised to accommodate an important subset of WT that is being managed by nephrectomy alone. Before NWTS-5, the distinction between stages I and II in the renal sinus was established by the hilar plane, which was an imaginary plane connecting the most medial aspects of the upper and lower poles of the kidney. This criterion was difficult to apply because of tumor distortion, and thus, the hilar plane criterion has been replaced with renal sinus vascular or lymphatic invasion. This definition includes not only the involvement of vessels within the hilar soft tissue but also the vessels located in the radial extensions of the renal sinus into the renal parenchyma.[44,45] The COG staging guidelines for WT are shown in Table 89.2. The major change from

NWTS-5 is that children with tumor spillage are upstaged from stage II to stage III because of the higher risk for relapse with two-drug chemotherapy alone.[46] The COG risk group classification for treatment assignment in the new generation of WT protocols is shown in Table 89.3. In addition to tumor stage, this classification will also consider the patient's age, tumor weight, presence or absence of LOH at 1p and 16q, and response to chemotherapy in children with FH tumors and lung metastases.

GENERAL MANAGEMENT

The diagnosis of WT is usually made before surgery and confirmed at surgery. A transverse transabdominal, transperitoneal incision is recommended for adequate exposure and thorough abdominal exploration.[47] The surgeon must excise all tumors without spillage, if possible. Lymph node sampling from the para-aortic, celiac, and iliac areas must be performed. The use of titanium clips to identify residual tumor and margins of resection is also recommended. Routine exploration of the contralateral kidney was mandated in the past, but it is no longer recommended because of better imaging of the contralateral kidney with CT and MRI scans.

The chemotherapy and RT regimens for WT in the COG protocols are outlined in Tables 89.4 and 89.5.

RADIATION THERAPY TECHNIQUES

RT guidelines used for primary and recurrent WT in the COG protocols are shown in Table 89.5.

TABLE 89.3 CHILDREN'S ONCOLOGY GROUP RISK GROUP CLASSIFICATION FOR FAVORABLE HISTOLOGY WILMS TUMORS

Age	Tumor Weight	Stage	LOH	Rapid Response	Risk Group	COG Study	Treatment
<2 y	<550 g	I	Any	N/A	Very low	AREN0532	Surgery only
Any	≥550 g	I	None	N/A	Low	AREN0532	EE4A
≥2 y	Any	I	None	N/A	Low	AREN0532	EE4A
Any	Any	II	None	N/A	Low	AREN0532	EE4A
≥2 y	Any	I	Yes	N/A	Standard	AREN0532	DD4A
Any	≥550 g	I	Yes	N/A	Standard	AREN0532	DD4A

Any	Any	II	Yes	N/A	Standard	AREN0532	DD4A
Any	Any	III	None	Any	Standard	AREN0532	DD4A
Any	Any	III	Yes	Any	Higher	AREN0533	M
Any	Any	IV	Yes	Any	Higher	AREN0533	M
Any	Any	IV	None	Yes	Standard	AREN0533	DD4A
Any	Any	IV	None	No	Higher	AREN0533	M

DD4A (V [vincristine] A [dactinomycin], D [doxorubicin]); EE4A (VA); LOH, loss of heterozygosity at both 1p and 16q; M (VAD/Cy [cyclophosphamide], E [etoposide]); N/A, not applicable.

TABLE 89.4 OUTLINE OF CHILDREN'S ONCOLOGY GROUP RENAL TUMOR STUDY

Tumor Risk Classification	Multimodality Treatment
Very Low-Risk FH Wilms Tumor	
<2 y, stage I, tumor weight <550 g	Nephrectomy without adjuvant therapy, if node sampling and central pathology review have been performed
Low-Risk FH Wilms Tumor	
≥2 y, stage I, tumor weight ≥550 g, stage II without LOH	Nephrectomy, no RT, regimen EE4A
Standard-Risk FH Wilms Tumor	
Stage I and II with LOH	Nephrectomy, no RT, regimen DD4A
Stage III without LOH	Nephrectomy, RT, regimen DD4A
Stage IV FH: rapid responders of lung metastases at week 6 with regimen DD4A, without LOH	Nephrectomy, RT, regimen DD4A; no WLI
Higher-Risk FH Wilms Tumor	
Stage III with LOH	Nephrectomy, RT, regimen M
Stage IV slow responders (lung) and nonpulmonary metastases, with LOH	Nephrectomy, RT, regimen M, WLI and RT to metastases
High-Risk UH Renal Tumors	
Stage I–IV focal anaplasia	Nephrectomy, RT, regimen DD4A
Stage I diffuse anaplasia	Nephrectomy, RT, regimen DD4A
Stage I–III CCSK	Nephrectomy, RT, regimen I
Stage II–IV diffuse anaplasia	Nephrectomy, RT, regimen UH1, RT to all metastatic sites
Stage IV CCSK	Nephrectomy, RT, regimen UH1, RT to all metastatic sites
Stage I–IV RTK	Nephrectomy, RT, regimen UH1, RT to all metastatic sites

CCSK, clear cell sarcoma of the kidney; FH, favorable histology; LOH, loss of heterozygosity at 1p and 16q; regimen DD4A (V [vincristine], A [dactinomycin], D [doxorubicin]); regimen EE4A (VA); regimen M (VAD/Cy [cyclophosphamide], E [etoposide]); RT, flank or abdominal irradiation;

RTK, rhabdoid tumor of the kidney; regimen I (alternating VDCy/CyE); regimen UH1 (alternating VDCy/CyC [carboplatin] E); UH, unfavorable histology; WLI, whole-lung irradiation.

TABLE 89.5 CHILDREN'S ONCOLOGY GROUP RENAL TUMOR PROTOCOL RADIATION THERAPY GUIDELINES

Abdominal Tumor Stage and Histology	RT Dose/RT Field[a]
Stage I and II FH Wilms tumor	None
Stage III FH, stage I–III focal anaplasia	10.8 Gy to the flank[b]
Stage I–II DA, stage I–III CCSK[c]	10.8 Gy to the flank[b]
Stage III DA, stage I–III RTK	19.8 Gy flank[b] RT, infants ≤12 months 10.8 Gy
Recurrent abdominal Wilms tumor	12.6–18 Gy (<12 months)[b]
	21.6 Gy (older children, previous RT ≤ 10.8 Gy)
	Boost dose of 9 Gy to gross residual tumor
Lung metastases (favorable histology)	12 Gy WLI in 8 fractions[d]
Lung metastases (unfavorable histology)	12 Gy WLI in 8 fractions
Brain metastases	30.6 Gy whole brain in 17 fractions
	21.6 Gy whole brain + 10.8 Gy IMRT or stereotactic boost
Liver metastases	19.8 Gy whole liver in 11 fractions
Bone metastases	25.2 Gy to the lesion plus 3-cm margin
Unresected lymph node metastases	19.8 Gy

[a]Timing of RT (RT delay): RT should begin as close to the beginning of chemotherapy as possible, preferably by day 9 (surgery is day 0), but no later than day 14, unless medically contraindicated or when there is a delay in central pathology review.
[b]Whole-abdomen irradiation (WAI) is indicated when there is diffuse tumor spillage, preoperative or intraperitoneal tumor rupture, peritoneal tumor seeding, or hemorrhagic or cytology positive ascites. When WAI dose is >10 Gy, renal shielding is required to limit the dose to the remaining kidney to <14.4 Gy. Gross residual disease after surgery should receive a boost of 10 Gy. WAI dose is not to exceed 10 Gy in infants ≤12 months.
[c]COG protocol (AREN0321) is studying the possibility of eliminating RT in children with stage I CCSK tumors who have lymph node sampling and central pathology review.
[d]COG protocol (AREN0533) is studying the possibility of eliminating WLI in children with lung metastases who are rapid responders (complete response of lung metastasis after three-drug chemotherapy on central review of computed tomography [CT] scans at week 6). Tumor size, number of lesions, and CT or x-ray detectability are not considered indications for WLI in FH tumors.
CCSK, clear cell sarcoma of the kidney; DA, diffuse anaplasia; FH, favorable histology; IMRT, intensity-modulated RT; RT, radiation therapy; RTK, rhabdoid tumor of the kidney; WLI, whole-lung irradiation.

Timing of Radiation Therapy

The NWTS has shown that although RT does not need to be given immediately

after surgery,[40] a delay of ≥10 days after surgery was associated with a significantly higher abdominal relapse rate, particularly among patients with UH tumors.[48–51] Because the pathologist cannot always rule out UH quickly, all patients with WT should be scheduled to start RT no later than day 9, the day of surgery being day 0. Although most patients may not be irradiated, it is easier to cancel than to make arrangements to start RT for a small child on short notice. The influence of RT delay on abdominal tumor recurrence in patients with FH tumors treated on NWTS-3 and NWTS-4 has been reported. The mean RT delay was 10.9 days. Although univariate and multivariate analysis did not reveal RT delay of ≥10 days to adversely influence flank and abdominal recurrence, it is important to note that in 59% of children, the RT delay ranged from 8 to 12 days.[52] For the COG protocols, it is recommended that RT be given preferably by day 9 but no later than day 14 after surgery.

Radiation Therapy Dose

In NWTS-1 and NWTS-2, RT dosages to the operative bed were given according to the age of the patient; however, no significant dose–response association was detected.[49,51] In NWTS-3, there was a randomization for patients with FH tumors that resulted in elimination of RT for stage II FH and a reduction of dose to 10 Gy for stage III patients.[50] NWTS-3 and NWTS-4 data showed no RT dose response for CCSK and anaplastic tumors.[53] Therefore, it was decided to treat all abdominal disease with 10 Gy. In the COG protocols, the dose is 10 Gy for most indications except for stage III DA and stage I to III RTK, where a higher dose of 19.8 Gy is recommended (Table 89.5).[54,55]

Radiation Therapy Volume

Parallel-opposed fields using 4- or 6-MV photons are preferred. The flank RT field is determined by the CT or MRI scan performed at diagnosis before any chemotherapy is administered. The planning target volume is the tumor bed (outline of the kidney and associated tumor on the initial CT or MRI) with a 1-cm margin. The medial border must cross the midline to include the entire width of the vertebrae so as to minimize growth disturbances. An example of a flank RT portal is shown in Figure 89.2.[48] When whole-abdomen RT is administered, the femoral heads and acetabulum must be shielded (Fig. 89.3). Whole-lung irradiation (WLI) portals are shown in Figure 89.4. If the lungs and either the flank or whole abdomen have to be treated simultaneously, it is preferable to include them in one treatment portal.

Intensity-Modulated Radiation Therapy for Lung and Liver Irradiation

A multiinstitutional prospective clinical trial was conducted to determine the feasibility of cardiac-sparing lung intensity-modulated radiation therapy (IMRT). All centers were credentialed. The IMRT PTV was the 4-D minIP total lung volume plus 1cm. All target volumes, cardiac contours, and treatment plans were centrally reviewed (QARC) for preapproval prior to treatment. 20 patients were accrued. The majority had pediatric sarcomas or WTs. Lung IMRT was feasible in all patients. Median RT dose was 15 Gy (12 to 15 Gy). Pretreatment review resulted in target contour changes in 7, replanning in 3, and minor dose deviations in 2 patients. There were no major deviations. The mean cardiac (whole heart, ventricles, atria, coronary arteries, myocardium) volume doses were significantly lower after IMRT compared to AP–PA techniques. The 4-D lung volumes were significantly larger than 3-D volumes (<0.0001), and thus, standard AP–PA RT would have significantly underdosed 4-D lung volumes (P = 0.008). IMRT was well tolerated. No patient had radiation pneumonitis, pulmonary consolidation, or fibrosis after a minimum 2-year follow-up. The 2- and 3-year OS and lung metastasis progression-free survival were 90% and 90% and 65% and 52%, respectively. This trial demonstrated the feasibility, dosimetric advantages, safety, and efficacy of lung IMRT with chemotherapy.[56,57] The dosimetric advantages of whole-liver IMRT compared to AP–PA techniques have also been published.[58] In future WT protocols, IMRT targeting 4-D lung and liver volumes with QARC central review will be utilized for stage IV patients with lung and liver metastases.

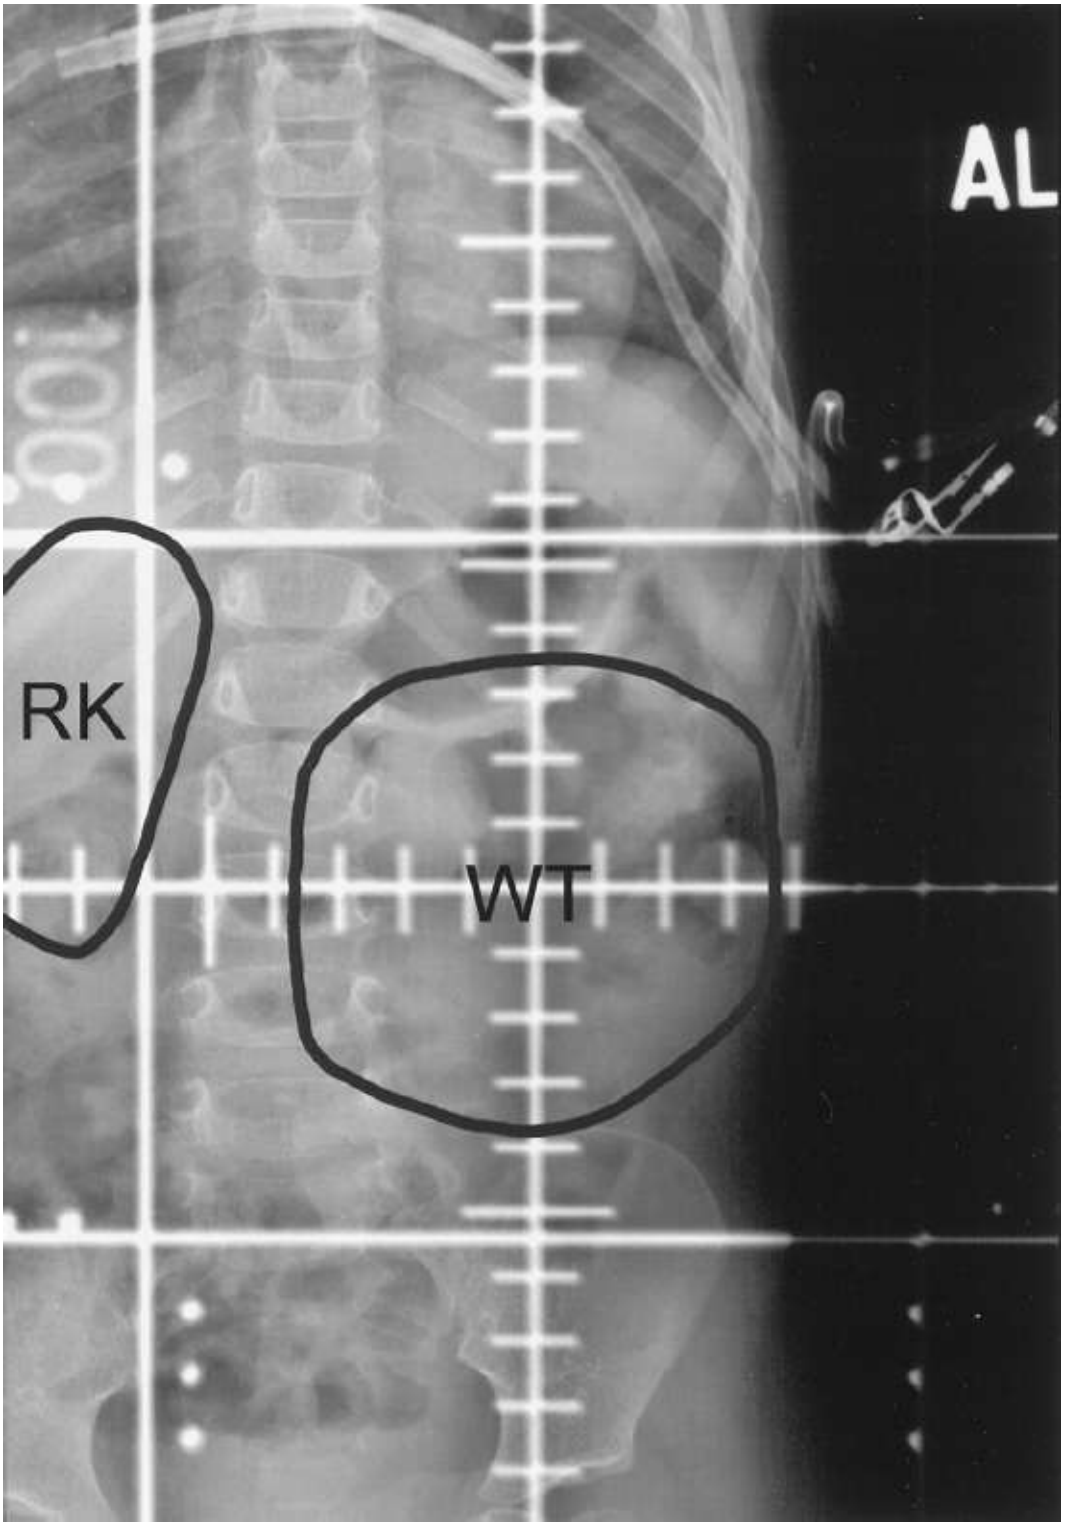

FIGURE 89.2. Anteroposterior flank irradiation portal in a 2-year-old child with a left-sided stage III favorable histology Wilms tumor (WT), showing inclusion of the entire width of the vertebral body in the irradiated volume. The outline of the right kidney (RK) and the WT from the preoperative computed tomography scan is shown.

SUMMARY OF CLINICAL TRIALS

No tumor has been studied by clinical trials as thoroughly and effectively as WT. The NWTS has been active in North America since 1969. There have also been successful studies run by the International Society of Pediatric Oncology (SIOP). The long-term results of NWTS-3 and NWTS-4 are shown in Table 89.6.

First National Wilms Tumor Study (1969–1974)

NWTS-1 showed that postoperative RT was not necessary for children younger than 2 years of age with group I tumors and that combined dactinomycin and vincristine for irradiated patients with group II and III tumors was better than therapy with either agent alone. The RFS with and without RT among patients with group I tumors younger than 2 years of age was 90% and 88%, respectively.[48]

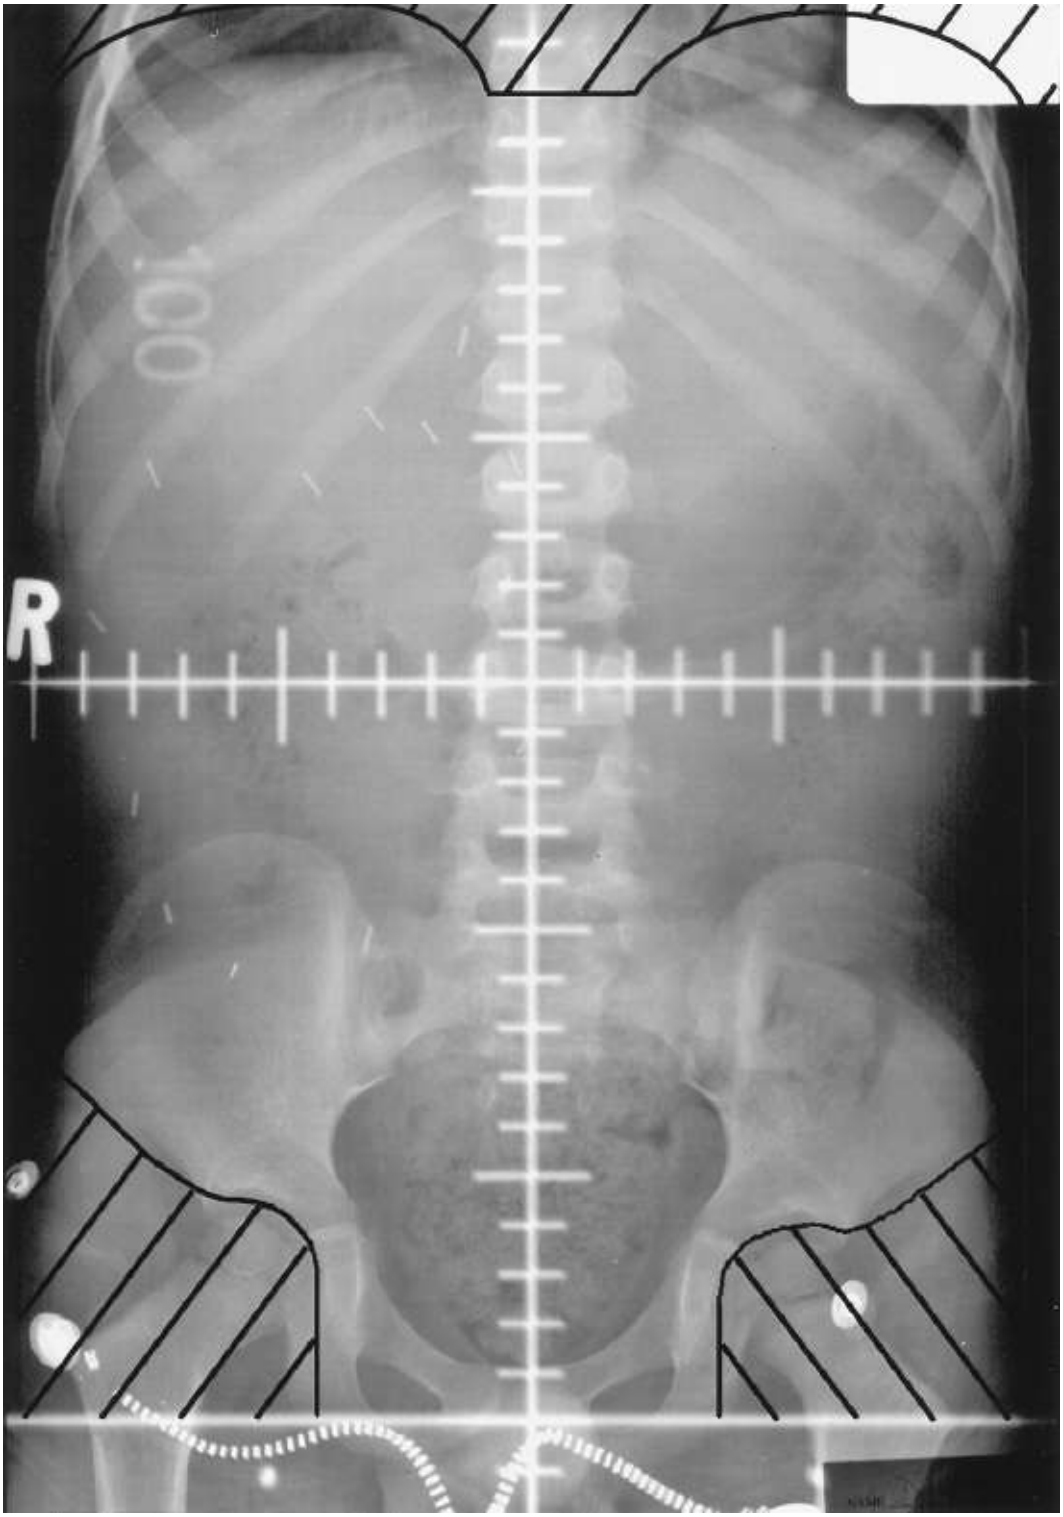

FIGURE 89.3. Anteroposterior whole-abdomen irradiation portal in a patient with stage III Wilms tumor and diffuse peritoneal tumor spillage. The upper margin of the abdominal field must include the diaphragm. The acetabulum and femoral head should be excluded from the irradiated volume to decrease the probability of slipped femoral capital epiphysis. The pants zipper can be seen low on the hips. In general, it is advisable to remove the trousers completely to ensure a reproducible setup.

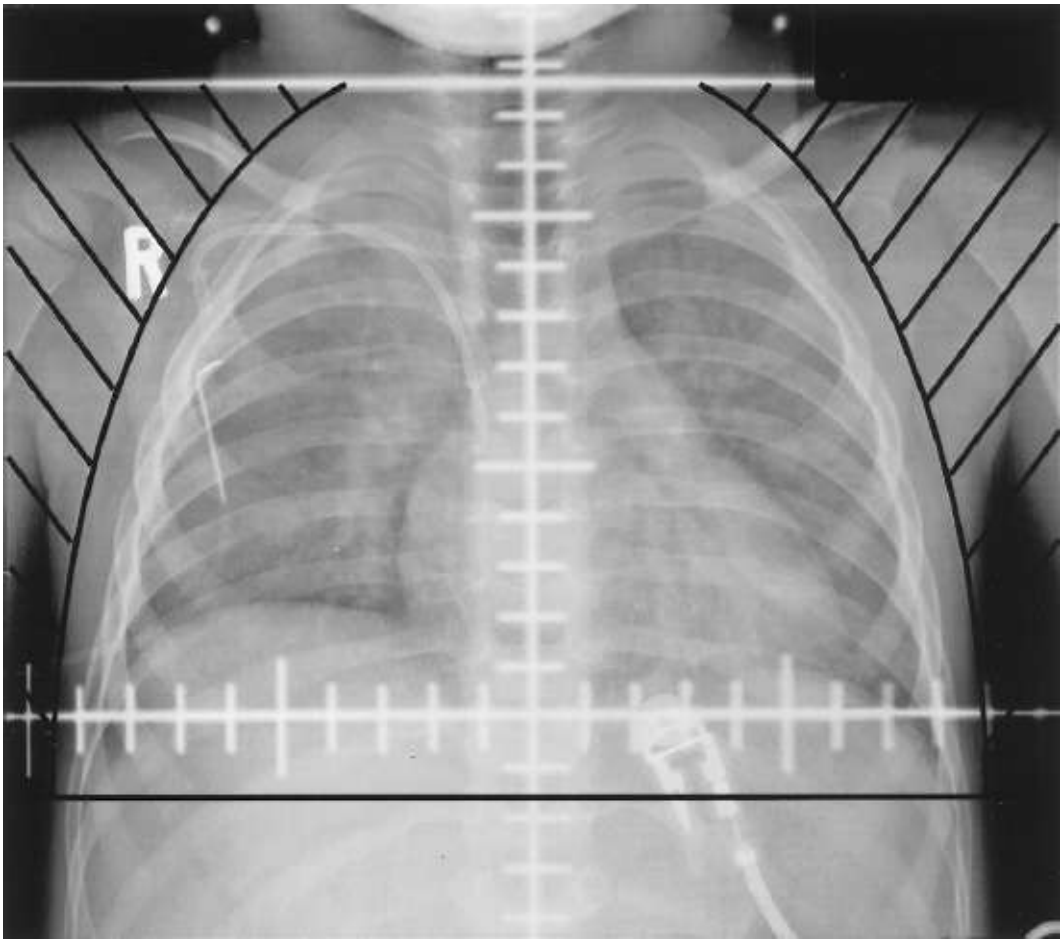

FIGURE 89.4. Anteroposterior whole-lung irradiation portal in a patient with stage IV favorable histology Wilms tumor. The axial, coronal, and sagittal chest computed tomography simulation scans should be carefully reviewed to ascertain inclusion of the anterior and posterior costophrenic angles at the inferior edge of the treatment volume with a 1-cm margin.

TABLE 89.6 Long-Term Results of National Wilms Tumor Studies 3 and 4[a]

Category	Number of Patients	10-Year RFS (%)	10-Year OS (%)
Stage I FH	1,582	91.4	96.6
Stage II FH	1,006	85.5	93.4
Stage III FH	1,038	84.2	89.5
Stage IV FH	592	75.2	80.7
Stage V FH	344	65.1	77.9
All FH	4,562	84.4	90.8
Clear cell sarcoma	170	67.1	77.1
Stage II–III anaplasia	128	43.0	49.2
Stage IV anaplasia	55	18.2	18.2

Rhabdoid tumor	88	27.3	28.4

[a]National Wilms Tumor Study unpublished data.
FH, favorable histology; OS, overall survival; RFS, relapse-free survival.

Second National Wilms Tumor Study (1974–1979)

NWTS-2 showed that in patients with group I tumors, there was no survival difference between 6 months and 15 months of dactinomycin plus vincristine. Patients with group II to IV tumors had a superior 2-year RFS of 77% with doxorubicin, dactinomycin, and vincristine compared with 63% with dactinomycin and vincristine alone.[41]

Third National Wilms Tumor Study (1979–1985)

The overall objective of NWTS-3 was to reduce therapy for low-risk patients (stage I to III FH) and to intensify treatment by adding a fourth drug, cyclophosphamide, for stage IV tumors with FH and all UH tumors. The results of this study demonstrated that RT and doxorubicin could be eliminated in children with stage II FH tumors. Patients with stage III FH tumors who received doxorubicin or 20 Gy had fewer abdominal relapses than those receiving 10 Gy without doxorubicin.[50] The addition of cyclophosphamide in high-risk patients did not improve outcomes.[53]

Fourth National Wilms Tumor Study (1986–1994)

By the conclusion of NWTS-3, it was clear that the treatment of WT had been refined for the majority of patients; 62% of patients with WT have stage I or II FH disease and therefore require neither flank RT nor the potentially cardiotoxic doxorubicin. NWTS-4 was designed with cost containment in mind. The results proved that the survival was similar among patients who received standard course (5 days) or single-dose, pulse-intensive (PI) dactinomycin chemotherapy. Further, PI therapy was associated with less hematologic toxicity and marked reduction of treatment costs.[59,60]

Fifth National Wilms Tumor Study (1995–2001)

One of the major goals of the NWTS-5 trial was to prospectively analyze the prognostic significance of LOH at chromosomes 1p and 16q. These results have been discussed elsewhere.[12] Patients with stage I FH and anaplastic histology and stage II FH tumors were treated with 18 weeks of dactinomycin and vincristine without RT. Stage I FH tumors in children younger than 24 months of age and with tumor weight <550 g were treated with surgery alone. Stage III and

IV FH and stage II to IV focal anaplastic tumors were treated with 24 weeks of dactinomycin, vincristine, doxorubicin, and irradiation. Stage II to IV diffuse anaplastic tumors and stage I to IV CCSK were treated with cyclophosphamide, vincristine, doxorubicin, and etoposide along with irradiation. Stage I to IV RTK was treated with carboplatin, etoposide, cyclophosphamide, and irradiation. The RT guidelines in NWTS-5 were similar to those used in NWTS-4 except for anaplastic tumors, where a dose of 10.8 Gy to the flank and abdomen was recommended compared to an age-adjusted schedule used in NWTS-1 to NWTS-4.

Children's Oncology Group Studies (2002–)

The COG renal tumor committee is the successor of the NWTS. The COG staging and risk group classification for treatment assignment in the new generation of WT protocols are shown in Tables 89.2 and 89.3. This classification will, in addition to tumor stage, also consider the patient's age, tumor weight, presence or absence of LOH at 1p and 16q, and response to chemotherapy in children with FH tumors and lung metastases. The main objectives of the first generation of COG protocols are listed below. The COG chemotherapy regimens and RT guidelines are outlined in Tables 89.4 and 89.5, respectively.

AREN0321

This was a study for children with high-risk renal tumors. This study was designed to determine whether a regimen (UH 1, 2) of cyclophosphamide/carboplatin/etoposide alternating with vincristine/doxorubicin/cyclophosphamide improves the survival of patients with DA and RTK. This study would also determine whether the excellent event-free survival in stage I CCSK can be maintained without the use of abdominal RT. Preliminary results: A higher than expected severe toxicity rate was encountered in these young children with UH tumors after treatment with these intensive multimodality treatment regimens. Despite reductions in chemotherapy dosages and large-field RT doses in young infants, severe toxicities continued to be observed and thus the study was permanently closed in 2013. In a report of AREN0321, a total of 24 patients with stage IV DA tumors were enrolled on the phase 2 window with vincristine and irinotecan. The partial response rate was 79% indicating that this regimen has high response rate in patients with diffuse anaplasia.[61] Among 66 stage II to IV DA tumors, 4-year EFS and OS were 75%

and 76%, respectively. Four-year EFS for stage II, III, and IV diseases were 86%, 85%, and 54%, respectively. These results were superior to NWTS-5, where after vincristine, doxorubicin, cyclophosphamide, and etoposide, plus radiotherapy (XRT) (regimen I), the 4-year EFS for stage II to IV DA tumors was 58% (COG unpublished data).

AREN0532

This was a study for children with very low- and standard-risk FH WT. The main objectives were (a) to demonstrate that very low-risk patients treated by nephrectomy and observation alone will have a 4-year RFS of ≥85% and OS of ≥95%; (b) to document continued excellent outcome for patients with stage III WT without LOH of 1p and 16q treated with vincristine, dactinomycin, doxorubicin, and RT (regimen DD4A); and (c) to improve the current 4-year RFS for patients with stage I and II WT with LOH of 1p and 16q by adding doxorubicin but not RT to the standard dactinomycin and vincristine regimen. Preliminary results: A total of 116 children with very low-risk WTs were treated with nephrectomy alone on this study, and their 4-year event-free and OS rates were 90% and 100%, respectively. Tumor 11p15 methylation status was highly predictive of relapse.[62] Among patients with stage I/II tumors with LOH at 1p and 16q, the 4-year event-free survival after augmentation of therapy with DD4A was 84% compared to 75% with regimen EE4A.[63]

AREN0533

This was a study for higher-risk FH WT. The main objectives were (a) to demonstrate that patients with stage IV tumors with pulmonary metastases only, who have complete resolution of the pulmonary lesions after 6 weeks of regimen DD4A chemotherapy (rapid complete responders), would have a 4-year RFS of 85% with additional chemotherapy (regimen DD4A) and without WLI; (b) to demonstrate that stage IV patients who do not have resolution of pulmonary metastases by week 6 (slow incomplete responders) would have a 4-year RFS of 85% with the addition of cyclophosphamide and etoposide to a modified regimen DD4A (regimen M) and WLI; and (c) to improve the 4-year RFS to 75% for patients with stage III or IV FH WT with LOH of chromosomes 1p and 16q. Preliminary results: Among patients with stage III/IV tumors with LOH at 1p and 16q, the 4-year event-free survival after augmentation of therapy with regimen M was 92% compared to 66% with regimen DD4A.[64] Among 296 patients with lung metastasis, 105 (39%) had a complete response at week 6.

Their 4-year event-free and OS rates were 78% and 95%, respectively, without WLI. Although these results were inferior to the event-free survival of 85% with WLI and DD4A, the difference was not statistically significant.[65] Among patients who had a slow incomplete response (SIR) at week 6, the augmentation of therapy with regimen M and WLI resulted in a 3-year event-free and OS of 88% and 92%, respectively. These outcomes were significantly superior to the estimated event-free survival of 75% with regimen DD4A and WLI.[66]

AREN0534

This was a study for patients with bilateral, multicentric, or bilaterally predisposed unilateral WT. The main objectives were (a) to improve 4-year RFS to 73% for patients with BWT; (b) to prevent complete removal of at least one kidney in 50% of patients with BWT by using prenephrectomy three-drug chemotherapy induction with vincristine, dactinomycin, and doxorubicin; and (c) to have 75% of children with BWT undergo definitive surgical treatment by 12 weeks after initiation of chemotherapy. Preliminary results: Two hundred and forty-nine patients were enrolled on this study, 88% were younger than 48 months, and 20% had a genetic syndrome. The 4-year RFS and OS were 81% and 94%, respectively. A total of 143 (74%) patients completed prenephrectomy chemotherapy and 60% had complete removal of at least one kidney. Among BWT patients, 84% had definitive surgical treatment by 12 weeks after initiation of chemotherapy. Surgical approaches included unilateral total nephrectomy with contralateral partial nephrectomy (48%), bilateral partial nephrectomy (35%), unilateral total nephrectomy (10.5%), unilateral partial nephrectomy (4%), and bilateral total nephrectomies (2.5%) (COG unpublished data).

Outcomes of Children with Wilms Tumor

Lung Metastases

Patients with stage IV FH with lung metastases had a 4-year survival of 80% on NWTS-3, whereas survival for those with stage IV UH was 55%.[22,43,53] In a United Kingdom Children's Cancer Study Group (UKCCSG) trial, patients with stage IV FH were spared WLI if they had complete resolution of pulmonary metastases after chemotherapy. The 6-year RFS and OS were 50% and 65%, respectively.[67] These results appear to be somewhat worse than the 4-year survival rate of 82% on NWTS-3 and 75% in the second UKCCSG Wilms tumor study because of the greater use of WLI.[22,68] In children with FH tumors enrolled in NWTS-3 and NWTS-4 who had negative chest radiographs and CT

scans positive for pulmonary metastases, the 4-year RFS with and without WLI was similar at 89% and 80%, respectively.[69] In a report from NWTS-4 and NWTS-5, among children with lung metastases detected only by CT scans, the 5-year RFS after three drugs with or without WLI was significantly higher than those receiving two drugs (80% vs. 56%). There was no difference seen in 5-year OS between the three-drug and two-drug subsets (87% vs. 86%). There were no significant differences in RFS (82% vs. 72%) or OS (91% vs. 83%) based on whether these patients did or did not receive WLI. This report concluded that in patients with CT-only lung lesions, the addition of doxorubicin may improve RFS but not OS, and there was no added benefit from WLI.[70] In COG protocol AREN0533, chemotherapy response at week 6 was be used to determine whether WLI is delivered or not. Patients with FH tumors and lung metastasis who achieved a complete radiologic response to three-drug chemotherapy at week 6 did not receive WLI; all others received WLI. All patients with UH WT and lung metastases received WLI, regardless of response to chemotherapy (Tables 89.4 and 89.5).

Liver Metastases

Patients with liver metastasis undergo hepatic RT if the metastatic lesions are not completely resected at the time of initial diagnosis before any chemotherapy is delivered. Whole-liver RT is given for diffuse disease, with supplementary boosts to gross disease as indicated. When possible, however, more limited RT fields are used if the disease is more localized in the liver. In a report from NWTS-4 and NWTS-5, the RFS for patients with FH WT and liver metastases was 76%, and this was similar to the RFS in patients with lung metastases (76%), liver and lung metastases (70%), and metastases to other sites (64%).[71]

Bilateral Wilms Tumor

The goals of treatment in BWT are to maximize cure rates and to preserve functional renal parenchyma; thus, the role of radical nephrectomy and RT has been restricted. Initial surgical resections should be performed only if more than two-thirds of each kidney can be preserved.[72] The initial surgery should confirm histologic diagnosis, assess extent of disease in the kidney, and perform a lymph node biopsy. Systemic chemotherapy is then delivered, after which second-look surgery is done in order to perform tumor resection with maximal preservation of renal function. Unpublished 10-year data from the NWTS-3 and NWTS-4 showed that BWT patients, compared with those who have stage I to IV

unilateral FH tumors, had lower RFS (65% and 86%) and OS (78% and 92%). In NWTS-4, the 8-year RFS and OS were 74% and 89%, respectively, for FH and 40% and 45%, respectively, for UH BWT. The incidence of end-stage renal disease was 12% among stage V patients.[73] In NWTS-5, BWT patients had a 4-year RFS and OS of only 61% and 80%, respectively. The factors that might have contributed to these poor outcomes were understaging or undertreatment, delay in definitive surgical resection, and increased incidence of anaplasia.[74,75] The current COG protocol (AREN0534) recommends earlier biopsies or resection of nonresponsive tumors so that ineffective therapies for patients with DA could be avoided. This study will intensify chemotherapy upfront (three drugs), require second-look surgery at 6 weeks and definitive surgery at 12 weeks, and recommend chemotherapy based on histologic response after definitive surgery. RT is indicated for stage III FH tumors, stage I to III UH tumors, or when chemotherapy and several surgeries do not result in complete tumor resection with negative margins. Unlike in unilateral WT, the performance of a tumor biopsy or the use of chemotherapy before definitive surgery is not an indication for flank RT in BWT.

Effect of Tumor Spillage on Outcome in Patients with Stage II and III Diseases

Operative tumor spillage was identified in 24% of patients in NWTS-3 and NWTS-4, and 22% of the spills were classified as diffuse.[46,76,77] An analysis was undertaken to determine the influence of RT and chemotherapy on abdominal tumor recurrence caused by spilled cells in abdominal stage II and III FH WT. The odds ratio for the risk of recurrence relative to no RT was 0.35 for 10 Gy (P = .01) and 0.08 for 20 Gy (P = .01). Thus, RT (10 or 20 Gy) significantly reduced abdominal tumor recurrence rates following tumor spillage. After adjusting for RT, the effect of doxorubicin on tumor recurrence was not significant. For stage II patients (NWTS-4), the 8-year RFS and OS with and without spillage were 74% and 85% (P = .02) and 90% and 94% (P = .4), respectively. The higher relapse rate among stage II children with spillage was the reason for upstaging patients with tumor spillage to stage III in the new COG staging system (Table 89.2). These patients will now receive three drugs and flank RT.[46]

Nephrectomy Only for Patients with Stage I Favorable Histology Wilms Tumor

In NWTS-5, a single-arm study was conducted to evaluate the efficacy of nephrectomy alone in children younger than 24 months of age with small (<550 g) stage I FH WT. A total of 75 children were enrolled and the 2-year RFS and OS were 87% and 100%, respectively. This study was ended because of stringent stopping rules.[78] In a recent update, the 5-year RFS and OS for these children treated with just surgery alone were 85% and 98%, respectively. These outcomes were similar after treatment with surgery and two-drug chemotherapy (regimen EE4A).[79]

Wilms Tumor with Peritoneal Implants

The outcome of 57 patients with FH WT and peritoneal implants at the time of nephrectomy in NWTS-4 and NWTS-5 was analyzed. All children received multimodality therapy with three-drug chemotherapy and RT. Forty-seven patients (82%) received whole-abdominal RT to a dose of 10.5 Gy. The overall abdominal and systemic tumor control rates were 97% and 93%, respectively. The detection of peritoneal implants was not associated with inferior survival. The 5-year RFS with and without peritoneal implants was 90% and 83%, respectively.[80]

Clear Cell Sarcoma

In the NWTS-1 through NWTS-4 experience for 351 patients with CCSK, the OS rate was 69%. Multivariate analysis revealed four independent prognostic factors for survival: treatment with doxorubicin, tumor stage, age at diagnosis, and tumor necrosis.[81] In NWTS-4, there was no significant difference among those patients initially randomized to PI or standard chemotherapy with vincristine, dactinomycin, and doxorubicin. The 8-year RFS and OS were 72% and 87% for PI and 70% and 84% for standard chemotherapy, respectively. The second randomization to short-duration and long-duration chemotherapy also did not show any significant difference in survival between the two arms. The survival in NWTS-4 was significantly superior to that of NWTS-3 (83% vs. 67%). The PI chemotherapy administration of dactinomycin and doxorubicin in NWTS-4 was presumed to be one of the reasons for the improvement in outcomes.[82]

Rhabdoid Tumor of the Kidney

A total of 142 children with RTK were enrolled in the NWTS-1 through NWTS-5 trials. The OS at 4 years was 23%. The survival rate for children with stage I or II tumors (42%) was significantly higher than for those with stage II or III

tumors (16%; $P = .014$). The survival rate in infants <6 months of age was 9% compared with 41% in children >2 years of age ($P < .001$). Children who received a higher dose of RT (>25 Gy) had a significantly better outcome. However, the dose of RT was not an independent predictor of survival.[55]

Anaplastic Wilms Tumor

In NWTS-5, among 2,596 patients who were enrolled, 281 (11%) had anaplastic WT. The 4-year RFS and OS for patients with stage I anaplasia treated with vincristine and dactinomycin without RT were 70% and 83%, respectively. The 4-year RFS for anaplastic tumor patients who underwent immediate nephrectomy and regimen I chemotherapy was 83%, 65%, and 33% for stage II, III, and IV tumors, respectively. The 4-year RFS and OS for stage V tumors were 44% and 55%, respectively. Based on these results, the therapy for stage I, III, IV, and V tumors was augmented in the new COG protocols (Tables 89.4 and 89.5).[54]

Recurrent Wilms Tumor

Children with relapsed FH WT have a variable prognosis depending on the site of relapse, the time from initial diagnosis to relapse, and their previous therapy. The favorable prognostic factors include no previous treatment with doxorubicin, relapse more than 12 months after diagnosis, and intra-abdominal relapse in a patient not previously treated with abdominal RT.[83] In NWTS-5 relapse protocol, patients who relapsed after initial treatment with vincristine and dactinomycin only without RT were treated on stratum “B” with regimen “I” chemotherapy, surgery, and RT. The 4-year RFS and OS were 71% and 81% for all patients, 68% and 81% for those who relapsed in the lung only, and 78% and 83% for those who relapsed in the operative bed with or without lung metastasis.[84] Patients who relapsed after treatment with vincristine, dactinomycin, doxorubicin, and RT were treated on stratum “C” of NWTS-5 protocol, with alternating courses of drug pairs, cyclophosphamide/etoposide and carboplatin/etoposide, surgery, and RT. The 4-year RFS and OS were 42% and 48% for all patients and 49% and 53% for those who relapsed in the lung only.[85] The COG protocol (Table 89.5) recommends postoperative RT for all children with abdominal relapse because these tumors are generally large and infiltrative and surgical resection with negative margins is unlikely.

Wilms Tumor in Older Patients

WT is rarely seen in patients ≥16 years of age. Their survival is similar to that of

children and they should be treated similarly.[86,87]

International Society of Pediatric Oncology Trials

The International Society of Pediatric Oncology (SIOP) studies have primarily used preoperative therapy. The goals of administering preoperative therapy are to facilitate surgical removal of the tumor without rupture, to allow for early treatment of micrometastases, and to stratify patients for postoperative therapy based on pathologic tumor response at the time of surgery. The first SIOP trial found that preoperative RT reduced the incidence of tumor spillage but did not increase survival.[88] SIOP-5, reported in 1983, showed that preoperative chemotherapy with vincristine and dactinomycin was as effective as preoperative RT plus dactinomycin in preventing tumor rupture.[89] In SIOP-6, patients with stage I disease were randomly assigned to either 17 or 38 weeks of vincristine and dactinomycin and showed no difference in survival. Among patients with stage II disease and negative lymph nodes (SIOP staging is not identical to NWTS staging) who were randomly assigned to not receive RT, there was a higher recurrence rate.[90] In SIOP-9, there was a randomization of the duration of prenephrectomy therapy with vincristine and dactinomycin (4 weeks vs. 8 weeks). No advantage was noted for 8 weeks of therapy. Among patients with stage II disease with negative lymph nodes, the rate of abdominal relapse was reduced to 7% by the addition of epirubicin.[91] SIOP 93-01 further stratified treatment according to the pathologic response to preoperative chemotherapy. The recommended dose of RT in SIOP-9 and SIOP 93-01 was 15 Gy in patients with low- and intermediate-risk stage III disease and 30 Gy in high-risk patients.[92] SIOP 93-01 showed that the amount of postoperative chemotherapy of stage I patients with either intermediate-risk histology or anaplasia could be reduced to four doses of vincristine and one course of dactinomycin with 5-year RFS and OS rates of 87% and 95%, respectively.[93] Among 1,090 patients in SIOP 93-01, 5% had tumor progression during preoperative chemotherapy. These tumors were generally smaller at diagnosis, more often stage III after surgery, and associated with higher-grade histology. They had significantly poorer event-free and OS compared to those who responded to chemotherapy.[94] A pathologic review of stage II tumors in SIOP 93-01 revealed that there was a significantly higher survival among patients who were stage II because of nonviable tumor in the renal sinus or perirenal fat compared to those with viable tumor in these sites (100% vs. 91%). It was proposed that the definition of stage II be revised.[95] In a report from SIOP WT2001 trial, after preoperative

chemotherapy (VA) and surgery, patients with stage II to III intermediate-risk tumors were randomized to receive AVD (actinomycin D, vincristine, doxorubicin) versus AV without doxorubicin. Stage III patients received 14.4-Gy flank RT and 10-Gy boost to positive lymph nodes or macroscopic residual tumor. The 2-year EFS was 93% and 88%; and 5-year OS was 97% and 96%, respectively, with no statistical significant difference between these two regimens. They concluded that doxorubicin was not required for these patients.[96] In another WT2001 report for blastemal-type WTs after VA chemotherapy and surgery, stage I patients received AVD for 26 weeks, and stage II to III patients received etoposide, carboplatin, doxorubicin, and cyclophosphamide for 26 weeks. Local RT was recommended only for stage III patients. The 5-year EFS and OS were for 80% and 88%, respectively, in WT2001 compared to 67% (P = 0.006) and 84% (P = 0.4), respectively, in SIOP 93-01 trials.[97]

United Kingdom Children's Cancer Study Group

The first UKCCSG Wilms tumor study (UKW1) showed that vincristine could be used alone in patients with stage I FH disease. Among patients with lung metastases, the 6-year survival rate of 65% was significantly worse than the 4-year survival rate of 82% on NWTS-3, probably because of the inclusion of routine WLI in the NWTS.[67] In the second UKCCSG WT study (UKW2), stage I FH patients had similar survival rates as NWTS stage I patients after 10 weekly doses of vincristine. The 4-year survival rate in patients with stage IV disease was higher than in UKW1, at 75%, probably because of the greater use of WLI. The flank RT doses used for stage III FH and UH tumors are 20 and 30 Gy, respectively.[68] The UKW3 trial conducted a randomized comparison of a primary nephrectomy followed by adjuvant therapy based on surgical stage (NWTS approach) and a preoperative chemotherapy followed by nephrectomy and adjuvant therapy (SIOP approach). The 4-year RFS and OS were equivalent in the primary nephrectomy arm (80% and 85%) and in the preoperative chemotherapy arm (79% and 95%), respectively. The UKCCSG has now joined the current SIOP clinical study.[98]

LATE EFFECTS OF TREATMENT

The study of late effects is of paramount importance to prevent survivors of childhood cancer from becoming chronically sick adults.

Scoliosis

A series from Washington University showed a high incidence of scoliosis in 54% of patients who were treated with a median dose of 30 Gy. However, there was minimal functional disability.[99] In another report, the incidence of scoliosis after 10 to 12 Gy, 12.1 to 23.9 Gy, and 24 to 40 Gy was 8%, 46%, and 63%, respectively.[100] Thus, at present, with the use of megavoltage x-rays, lower doses, and coverage of the entire width of the vertebra, the incidence of scoliosis should be low.

Congestive Heart Failure

The cumulative frequency of congestive heart failure among patients on NWTS-1 through NWTS-4 was 4.4% at 20 years among patients treated initially with doxorubicin and 17.4% among patients treated with doxorubicin for their first or subsequent relapse. The factors that were significantly associated with the incidence of heart failure were female sex, cumulative doxorubicin dose, WLI, and left abdominal RT.[101]

Pregnancy Outcome in Wilms Tumor Survivors

The NWTS Long-Term Follow-Up Study analyzed pregnancy outcomes among WT survivors. Malposition of the fetus and premature labor were significantly more frequent among previously irradiated women. The offspring of female patients who received flank RT were more likely to be of low birth weight (<2,500 g), to be premature (<36 weeks of gestation), and to have congenital malformations. A flank RT dose response was identified with higher complication rates at doses >25 Gy. A number of radiation-induced side effects involving the spine, uterus, and ovaries may all have been responsible.[102–104] The pregnancy outcomes in survivors who received abdominal RT on NWTS protocols were also analyzed. Fertility could be preserved in children with upper abdominal RT that did not include the pelvis. In rare instances, fertility could be preserved after whole-abdominal RT to 10.5 Gy. However, higher doses to the abdomen and pelvis resulted in miscarriages and fetal deaths.[105]

END-STAGE RENAL DISEASE

The 20-year cumulative incidence of end-stage renal disease among WT survivors after unilateral nephrectomy on NWTS protocols was 74% for children with Denys-Drash syndrome, 36% for children with WAGR syndrome, 7% for children with genitourinary anomalies, and 0.6% for patients with none of these conditions. The importance of long-term screening for high-risk children to

facilitate early detection and treatment of impaired renal function was emphasized.[106]

Second Malignant Neoplasm

Among NWTS patients, the 15-year cumulative risk of second malignant neoplasm (SMN) was 1.6%. The risk of developing a lymphoma or leukemia was 0.4% at 8 years, after which no cases occurred. However, the risk of developing a solid tumor continued to rise sharply with time. Approximately 73% of solid tumors arose within a previous RT field. Higher doses of abdominal RT, doxorubicin use, and treatment for relapse were the significant factors correlated with the development of second tumors.[107] In another NWTS report, the standardized mortality ratio was 24.3 within 5 years of diagnosis, 12.6 for the next 5 years, and >3.0 thereafter. The main cause of mortality within the first 5 years was the original disease (91%). However, beyond 5 years, the two important causes of mortality were the original disease (40%) and late effects of treatment (39%). The three common treatment-related late effects that contributed to mortality were SMNs, congestive heart failure, and end-stage renal disease. The risk of death, particularly from treatment-related late effects, remained elevated even 20 years after diagnosis.[108] Similar results have been shown recently by the Childhood Cancer Survivor Study after a follow-up of 25 years.[109] In the British Cancer Survivor Study, the cumulative incidence of a second primary neoplasm at 30, 40, and 50 years of age was 2%, 7%, and 12%, respectively.[110] In another NWTS report, female survivors who received WLI had nearly a 15% risk of developing invasive breast cancer by age 40 years. This report highlighted the need for reevaluating current COG guidelines that recommend breast cancer screening only for those who received >20 Gy to the chest.[111]

FUTURE DIRECTIONS

The first generation of WT protocols conducted by the COG has been completed and detailed analyses are underway. Study proposals for the second generation of COG protocols are presently being considered. All of these proposals are aimed at further refining the treatment of low-risk patients to decrease treatment-related toxicity and intensify treatment of high-risk tumors to improve outcomes. The following are some of the proposals under consideration by COG and others: to include tumor molecular signatures (1q gain, LOH 1p and 16q, LOH11p15) as

part of the COG risk stratification system to further refine treatment, to use cardiac-sparing IMRT in children receiving WLI to reduce cardiac toxicity,[56,57] to use IMRT to reduce renal toxicity in children receiving whole-liver irradiation,[58] to reevaluate the necessity of irradiating all children who receive chemotherapy before nephrectomy, to reevaluate the current recommendation for using whole-abdomen RT in children with localized preoperative tumor rupture limited to the flank without any ascites or peritoneal implants, to add new biologic agents to the currently used chemotherapy regimens in children with diffuse anaplastic WT and rhabdoid tumors, to intensify therapy for children with FH WT and lymph node metastases who have a higher risk of tumor relapse, to evaluate the role of proton therapy for WT; to determine the value of surgical resection or focal RT boost doses to residual lung lesions after WLI, and to explore the role of intraoperative RT in selected cases of unilateral, bilateral, and recurrent WT. The biologic sample banks of COG will continue to be a valuable source of tissue for studies aimed at identifying new biologic markers that may be of prognostic significance.

CHAPTER 90

Neuroblastoma

Arnold C. Paulino and Anita Mahajan

INTRODUCTION

Neuroblastoma is an enigmatic malignant neoplasm. In its early stages, it can be readily cured with surgery or, in some circumstances, can even spontaneously regress or mature to a benign ganglioneuroma. In the more common advanced stages, the disease can be fatal. The unique biology of neuroblastoma has attracted the interest of many researchers and is one of the first malignancies in which molecular biologic assays have influenced treatment and prognosis.

EPIDEMIOLOGY

Neuroblastoma is the most common extracranial tumor of childhood. Approximately 90% of cases occur in children <10 years old. The median age at diagnosis is 18 months. The relatively good prognosis of infants diagnosed with early-stage neuroblastoma prompted the initiation of infant-screening studies.[1]

Screening of infants for neuroblastoma has been studied systematically in large clinical trials conducted in Japan, North America, and Europe.[2–5] Excretion of catecholamine metabolites in the urine of children with neuroblastoma has served as the basis of these screening tests. Urine samples were collected and dried on filter paper and returned to screening centers to be tested qualitatively for vanillylmandelic acid (VMA) levels or quantitatively for VMA and homovanillic acid (HVA) measured by high-performance liquid chromatography and normalized to urinary creatinine levels. Children with elevated levels of these metabolites subsequently were referred for further diagnostic evaluation. The incidences of the diagnosis and death rates from neuroblastoma in the screened populations were compared to control populations in the same country or continent. The study populations generally were chosen because of access to an existing screening infrastructure that could readily be adapted to

neuroblastoma. The Japanese study screened children at 6 months of age. The Quebec study screened children at 3 weeks and 6 months of age. The German study tested children at their first year's birthday.

The results and conclusions of these three large screening trials on three continents are remarkably similar. In Japan, 1,142,519 children were screened using a qualitative test, and another 550,331 were screened with the quantitative test; they all were compared to 713,025 children in a control population. The incidence rates per 100,000 were 1.12 in the control group compared to 5.69 in the qualitative group and 17.81 in the quantitative group. Despite this increased incidence in the screened group, the neuroblastoma mortality rates were unchanged by the screening.[5] In Germany, 1,475,773 children were screened between 1994 and 1999. Screening detected neuroblastoma in 149 children, 3 of whom died. Despite the screening at 12 months, another 55 children subsequently developed neuroblastoma, 14 of whom died. Compared to the control group, the incidence of stage 4 neuroblastoma was similar. The death rate from neuroblastoma was unaffected by the screening.[3] In Quebec, a total of 425,838 children were enrolled in the neuroblastoma screening trial (89% of births during a 5-year study period from 1989 to 1994). The standardized incidence ratios of neuroblastoma death in the Quebec cohort were nearly identical to those in control groups in Ontario, Minnesota, Florida, and the Greater Delaware Valley.[4] In summary, each of these trials demonstrates that screening does not affect the mortality rate of neuroblastoma. Furthermore, the overdiagnosis of clinically insignificant disease may lead to significant financial, emotional, and physical burdens on the children and their families when one considers that this tumor has high frequency of spontaneous regression in infancy. The mass screening programs have led to the diagnosis of biologically favorable and clinically insignificant tumors.[6,7]

NATURAL HISTORY

Neuroblastoma, along with ganglioneuroma and ganglioneuroblastoma, may arise from any site in the sympathetic nervous system. The most common sites of origin are the adrenal medulla (30% to 40%) and paraspinal ganglia in the abdomen or pelvis (25%). Thoracic (15%) and head and neck primary tumors (5%) are slightly more common in infants than in older children. More than 70% of patients have metastatic disease at presentation. The most frequent metastatic sites are lymph nodes, bone, bone marrow, skin (or subcutaneous tissues), and

liver.[8] The lung and central nervous system are rare sites of involvement.
